VOLUME I

Béla G. Lipták

EDITOR-IN-CHIEF

ISA–The Instrumentation, Systems, and Automation Society

CRC PRESS
Boca Raton London New York Washington, D.C.

This reference text is published in cooperation with ISA Press, the publishing division of ISA—Instrumentation, Systems, and Automation Society. ISA is an international, nonprofit, technical organization that fosters advancement in the theory, design, manufacture, and use of sensors, instruments, computers, and systems for measurement and control in a wide variety of applications. For more information, visit www.isa.org or call (919) 549-8411.

Library of Congress Cataloging-in-Publication Data

Instrument engineers' handbook / Béla G. Lipták, editor-in-chief.
p. cm.
Rev. ed. of: Instrument engineers' handbook. Process measurement and analysis. c1995 and Instrument engineers' handbook. Process control. c1995.
Includes bibliographical references and index.
Contents: v. 1. Process measurement and analysis.
ISBN 0-8493-1083-0 (v. 1)
1. Process control—Handbooks, manuals, etc. 2. Measuring instruments—Handbooks, manuals, etc. I. Lipták, Béla G. II. Instrument engineers' handbook. Process measurement and analysis.

TS156.8 .I56 2003

Dedicated to you, my colleagues, the instrument and process control engineers. I hope that by applying the knowledge found on these pages you will make our industries more efficient, safer, and cleaner, and thereby will not only contribute to a happier future for all mankind but will also advance the recognition and respectability of our profession.

CONTRIBUTORS

The names of the authors of each edition are given at the beginning of each section. Here, all the contributors of all editions of this volume are listed in alphabetical order, showing their academic degrees, titles, and **positions they held at the time of making their contributions**. The authors who have participated in the preparation in this fourth edition of the *Instrument Engineers' Handbook (IEH)* are noted by an asterisk (*) in front of their names, but, because they built on the work of the authors of the previous editions, all authors are listed.

*BUD ADLER	BSEE; Life Member ISA; Director, Business Development, Moore Industries-International, Inc.
ROSS C. AHLSTROM, JR.	BSCh and Math, Executive Vice President, Mentech Inc.
ARTHUR ALSTON	BS, PE, Senior Research Engineer, Chevron Research Co.
MARTIN ANKLIN	PhD, Research Scientist, Endress + Hauser, Switzerland
*RAYMOND ANNINO	PhD, retired Professor and Researcher, formerly with The Foxboro Co.
CATHY APPLE	BSChE, Project Engineer, Micro Motion Inc.
*JAMES B. ARANT	BSChE, PE retired Senior Consultant, formerly with E.I. du Pont de Nemours Co.
*TIBOR BAAN	BME, CEO of Aalborg Instrument and Controls Inc.
ALLAN T. BACON, JR.	BACh, Staff Engineer, Environmental Technologies Group
*STEVEN BAIN	BscEE, PEng, Canada
WENDALL M. BARROWS	Senior Applications Coordinator, Union Carbide Corp.
JAN BARTH	EE, MS, Manager, Industrial Instrument Users Association, The Netherlands
*ERNEST H. BAUGHMAN	PhD, Assistant Professor, University of La Verne, California
JONAS BERGE	Engineer, Smar, Singapore
A. C. BLAKE	EE, Manager, Industrial Instrument Div., Cambridge Instrument Co.
CHRISTOPHER P. BLAKELEY	BSChE, Marketing Manager, Water Treatment, Honeywell Inc.

***L JOSEPH BOLLYKY**	PhD, PE, President, Bollyky Associates
R. V. BOYD, JR.	BSEE, MSEE, PE, Engineering Supervisor, Saudi Aramco
***WALT BOYES**	Principal, Marketing Practice Consultants
AUGUST BRODGESELL	BSEE, President, CRB Systems Inc.
JAMES E. BROWN	BSME, PE, Manager of Engineering, Union Carbide Corp.
THOMAS M. CARDIS	MSCh, Laboratory Manager, ABB Process Analytics
***BOYCE CARSELLA, JR.**	BA, Senior Product Manager, Magnetrol International
THOMAS J. CLAGGETT	BSEE, Application Specialist, Honeywell, Inc.
WILSON A. CLAYTON	BSChE, MSME, Chief Engineer, Hy-Cal Engineering
GERALD L. COMBS	PhDCh, Research Chemist, Applied Automation/Hartmann & Braun
VINCENT B. CORTINA	BSChE, MSIM, Business Manager, EG&G Co.
GILES M. CRABTREE	BSEE, PE, Principal Engineer, GIMACA Engineering
H. L. DANEMAN	BChE, PE, Principal, LabPlan
JOHN L. DANIEWICZ	BSEE, MA, Product Manager, TN Technologies Inc.
***RONALD H. DIECK**	BS, MS, FISA, President, Ron Dieck Associates, Inc.
LOUIS D. DINAPOLI	BSEE, MSEE, Director, Flowmeter Marketing and Technology, BIF Products of Leeds & Northrup Co.
WOLFGANG DRAHM	PhD, Research Scientist, Endress + Hauser, Germany
***WATSON P. DURDEN**	AS, Senior Engineer, Westin Engineering
***MICHAEL PAUL DZIEWATKOSKI**	PhD, Applications Manager, Metter-Toledo Ingold
***SUZANNE MARIE EDVI**	IIT, Senior Instrument Specialist, Bantrel Inc., Canada
ALBERT D. EHRENFRIED	MS in Instrumentation, President, Metritape Inc.
***HALIT EREN**	ME, MBA, PhD, Senior Lecturer, Cutin University, Australia
***GEORG F. ERK**	BSME, MSChE, PE, Consultant
JOSEF FEHRENBACH	Dipl. Ing., VEGA Grieshaber GmbH & Co., Germany
KENNETH S. FLETCHER	PhD, Technical Group Leader, Analytical Measurements, The Foxboro Co.
ALBERT P. FOUNDOS	BSChE, MBA, President, Fluid Data Inc.
WALTER F. GERDES	BSEE, PE, Technical Specialist, The Dow Chemical Co.

***PEDRO M. B. SILVA GIRÃO**	PhD, Professor, Instituto Superior Técnico, Lisbon, Portugal
***IAN H. GIBSON**	BSc, Dip. App. Chem., Dip. Chem. Eng, Dip. Inst. Tech., Principal Technical Specialist, Process Control Systems, Fluor, Australia
***RICHARD A. GILBERT**	BA, MS, PhD, Professor of Chemical Engineering, University of Florida
ANTHONY C. GILBY	PhD, Research Coordinator, The Foxboro Co.
PAUL M. GLATTSTEIN	BSEE, Senior Electrical Engineer, Crawford & Russell Inc.
JOHN D. GOODRICH, JR.	BSME, Engineering Supervisor, Bechtel Corp.
ROBERT J. GORDON	PhD, Environmental Division Manager, Global Geochemistry Corp.
DAVID M. GRAY	BSChE, Senior Application Specialist, Leeds & Northrup, a Unit of General Signal
***JAMES R. GRAY**	BSCh, MBA, Applications Manager, Rosemount Analytical
BHISHAM P. GUPTA	BSME, MSME, PhD, PE, Specialist Supervisor, Saudi Aramco
JOHN T. HALL	BS, Senior Technical Editor, Instrument & Control Systems
CHARLES E. HAMILTON	BSChE, Senior Environmental Specialist, The Dow Chemical Co.
JOHN N. HARMAN III	BSCh, MSCh, PE, Senior Project Engineer, Beckman Instruments
***HASHEM M. HASHEMIAN**	MSNE, President, Analysis and Measurement Services Corp.
ROBERT A. HERRICK	BSChE, PE, Consulting Engineer
HEROLD I. HERTANU	MSEE, PE, Senior Vice President, Advanced Engineering Concepts Inc.
CONRAD H. HOEPPNER	BSEE, MSEE, Consultant, Simmons Precision Products Inc.
MICHAEL F. HORDESKI	BSEE, MSEE, PE, Control System Consultant, Siltran Digital
JOEL O. HOUGEN	PhDChE, PE, Consultant, Professor Emeritus, University of Texas
WALTER D. HOULE	BSEE, President, Automation Management International
WILFRED H. HOWE	BSEE, MBA, PE, Chief Engineer, The Foxboro Co.
DAVID L. HOYLE	BSChE, System Design Engineer, The Foxboro Co.
JAY S. JACOBSON	PhD, Plant Physiologist, Boyce Thomson Institute for Plant Research
RAJSHREE R. JAIN	BSChE, Applications Engineer, Capital Controls Co.
ROBERT F. JAKUBIK	BSChE, Manager, Process Control Applications, Digital Applications Inc.
***JAMES E. JAMISON**	BSc-ChE, PE, Technical Director, Instrumentation and Process Control Systems, VECO (Canada) Ltd.

***JOHN M. JARVIS**	PhD, Manager of Gas Products Engineering, Detector Electronics
HERBERT H. JONES	BS, Principal Applications Engineer, Beckman Instruments Inc.
RICHARD K. KAMINSKI	BA, Senior Instrument Designer, Dravo Engineers and Constructors
DAVID S. KAYSER	BSEE, Senior Instrument Engineer, Texas City Refining Inc.
THOMAS J. KEHOE	BSChE, PE, Manager, Technical Services, Beckman Instruments Inc.
TAMÁS KEMÉNY	ME, EE, PhD, Secretary General, IMEKO International Measurement Confederation, Hungary
CHANG H. KIM	BSChE, Manager, Technical Services, ARCO Chemical Co.
JOHN G. KOCAK, JR.	BA, Consultant
JOHN G. KOPP	BSME, PE, Senior Product Marketing Manager, Fischer & Porter Co.
JOSEF KOZÁK	PhD, Aeronautical Research and Test Institute, Czech Republic
***CULLEN G. LANGFORD**	BSME, PE, ISA Fellow, Consultant, Cullen G. Langford Inc.
GEORGE R. LEAVITT	BSME, PE, Consultant
***MARIA T. LEE-ALVAREZ**	PhD, Physical Science Teacher, Cincinnati Public School District
***DAVID LEWKO**	Senior Analyzer Specialist, Bantrel Co.
TRUMAN S. LIGHT	BSCh, MSCh, PhDCh, Consultant
***BÉLA G. LIPTÁK**	MME, PE, ISA Fellow, Consultant, inducted into Control Process Automation Hall of Fame in 2001
DAVID H. F. LIU	BSc, MS, PhD, Principal Scientist, J. T. Baker Inc.
***ANDREW J. LIVINGSTON**	BS, MBA, Nuclear Product Manager, Ohmart Vega
HARRY E. LOCKERY	BSEE, MSEE, PE, President, Hottinger-Baldwin Measurements Inc.
DAVID J. LOMAS	Marketing Support Executive, Kent Process Control Ltd.
ORVAL P. LOVETT, JR.	BSCE, Consulting Engineer, Instruments and Control Systems, I. E. du Pont de Nemours Co.
JIRÍ LUKAS	MSC, Scientific Worker, Aeronautical Research and Test Institute of Czech Republic
***JULES J. MAGDA**	PhD, ChE, Associate Professor, Dept. of Chemical and Fuels Engineering, University of Utah
DAVID C. MAIR	BCE, PE, Manager, Sales Services, Wallace & Tiernan Div. of Pennwalt Corp.
***RAMASAMY MANOHARAN**	PhD, Manager of Sensor Technology, Rosemount Analytical Inc.

FRED D. MARTIN	BS, Analyzer Consultant, Fluid Data, Amscor
THOMAS A. MAYER	BSE, MSE, PE, Senior Development/Research Engineer, PPG Industries
GERALD F. McGOWAN	BSEE, MSEE, Vice President of Engineering, Lear Siegler Inc.
GREGORY K. McMILLAN	BSEPhys, MSEE, Fellow, Monsanto Chemical Co.
*DEAN MILLER	BSME, MBA, Manager of Pressure Relief and Tooling Engineering, Fike Corp.
HUGH A. MILLS	ME, President, Macran Products
CHARLES F. MOORE	BSChE, MSChE, PhDChE, Professor of Chemical Engineering, University of Tennessee
*LEONARD W. MOORE	PE, President and CEO of Moore Industries International Inc.
*GERHARD MURER	Dipl. Eng., Manager of Anton Paar GmbH, Austria
THOMAS J. MYRON, JR.	BSChE, Senior Systems Design Engineer, The Foxboro Co.
*JAMES A. NAY	PE, BSME, Consultant, Retired
S. NISHI	DSc. Research Scientist, National Chemical Laboratory for Industry, Japan
ROBERT NUSSBAUM	BSEE, Senior Instrument Engineer, Crawford & Russell Inc.
*DAVID S. NYCE	BSEE, MBA, Director of Technology at MTS Systems Corp.
RICHARD T. OLIVER	BSChE, MSChE, PhDChE, Senior Design Engineer, The Foxboro Co.
WILLIAM H. PARTH	BS, MS, Senior Instrument Specialist, The Dow Chemical Co.
*SIMON J. PATE	B. Eng., Director of Projects & Systems, Detector Electronics Corp.
*ALMONT V. PAWLOWSKI	BSEE, CSST, PE, Research Associate at Louisiana State University
KENNETH A. PERROTTA	BSCh, Vice President of Technology, Balston Inc.
KURT O. PLACHE	BSChE, PE, Vice-President Marketing, Micro-Motion Inc.
GEORGE PLATT	BSChE, PE, Staff Engineer, Bechtel Power Corp.
DANIEL E. PODKULSKI	BSChE, Senior Instrument Engineer, Chevron Research & Technology
MICHAL PTÁCNÍK	PhD, Aeronautical Research and Test Institute, Czech Republic
DIETER RALL	BSME, MSME, PE, General Manager, Trans-Met Engineering Inc.
M. RAZAQ	PhD, Senior Scientist, Teledyne Analytical Instrument Co.
*MORTON W. REED	PE, PhD, Consultant
JAMES B. RISHEL	BSME, President, Corporate Equipment

HOWARD C. ROBERTS	BAEE, PE, Consultant
***JACK C. RODGERS**	PE, Vice President of Nuclear Business at Ohmart/VEGA
***JOHN B. ROEDE**	ME, Senior Application Consultant, AMETEK-Drexelbrook
***ALBERTO ROHR**	EE, Dr. Eng., Consultant, Vedano al Lambro (MI), Italy
LEWIS B. ROOF	BS, MS, Senior Measurement Engineer, Applied Automation Inc.
GREGORY J. RORECH	BSChE, PE, Principal Engineer, Geraghty & Miller Inc.
STEPHAN RUDBÄCH	MSc, President, Matematica AB, Sweden
***ROBERT S. SALTZMAN**	BS, Eng. Phys., Principal of Bob Saltzman Associates
***GARY C. SANDERS**	BSEE, MT, FICMT, Director of Engineering Tyco Valves & Controls — Penberthy
ERIC J. SCHAFFER	BSEE, MSEE, Project Engineer, MST Systems Corp.
***NARESH K. SETHI**	BS, PhD, Technical Team Leader, BP South, Houston, Texas
***ROBERT E. SHERMAN**	BSCh, MSCh, MSBA
DONALD J. SIBBETT	PhD, Vice President, Geomet Inc.
ROBERT SIEV	BSChE, MBA, CE, Engineering Specialist, Bechtel Corp.
MIKHAIL SKLIAR	PhD ChE, Associate Professor, Dept. of Chemical and Fuels Engineering, University of Utah
***KENNETH C. SLONEKER**	BSME, V.P., Laboratory Director, Electronic Development Laboratories Inc.
RALPH G. SMITH	BS, MS, PhD, Professor, University of Michigan
***ROBERT J. SMITH II**	BSEET, Plant Engineer at Rock-Tenn Co.
JOAN B. STODDARD	PhD, President, Stoddard Productivity Systems Inc.
RICHARD STRAUSS	BSChE, MSChE, Consultant
EUGENE L. SZONNTAGH	MSChE, PhD, PE, Consultant
***JAMES F. TATERA**	BS, MBA, Senior Process Analysis Consultant, Tatera Associates Inc.
EDWARD TELLER	PhD, Professor-at-Large, University of California
AMOS TURK	PhD, Professor of Chemistry, City University of New York
***ALAN H. ULLMAN**	BS (Chemistry), PhD, Senior Scientist at The Procter & Gamble Co.
***IAN VERHAPPEN**	BscEnv, BScCh, PE, Engineering Associate at Syncrude Canada Ltd.
MICHAEL VUJICIC	PE, Director, Industrial Products, Optech Inc.

WILLIAM H. WAGNER	BSChE, PE, Staff Engineer at Union Carbide Corp.
***MICHAEL H. WALLER B**	ME, SM, ME, Professor at Miami University
WILLEM M. WALRAVEN	ME, M&CE, Head of Evaluation Department Netherlands Organization for Applied Research
NORMAN S. WANER	BSME, MSME, ME, PE, Manager of Training and Development, Bechtel Corp.
JOHN V. WELCH	BSME, MBA, Market Specialist at MKS Instruments Inc.
ALAN L. WERTHEIMER	PhD, Principal Scientist, Leeds & Northrup Co.
GEORGE P. WHITTLE	BSChE, MSChE, PhDChE, PE, Associate Professor, University of Alabama
THEODORE J. WILLIAMS	BS, MSChE, MSEE, PhD, PE, Professor of Engineering, Director of Purdue Laboratory for Applied Industrial Control
ROBERT W. WORRALL	BA, PE, Principal Instrument Engineer, Catalytic Inc.
IRVING G. YOUNG	BS, MS, PhD, Chemist, Advanced Technology Staff, Honeywell Inc.
***JESSE L. YODER**	PhD, President, Flow Research

INTRODUCTION

Ours is a very young profession: when the first edition of the *Instrument Engineers' Handbook (IEH)* came out, Marks' *Mechanical Engineers' Handbook* was in its fifth edition, and Perry's *Chemical Engineers' Handbook* was in its sixth! Now, as we are starting to work on the fourth edition of the *IEH*, we are already in a new millenium. But while our profession is young, we are also unique and special.

After all, no other engineering profession can claim what we can! No other engineering profession can offer to increase the GDP by $50 billion without building a single new plant, and to do that while *increasing* safety and *reducing* pollution. We can do that! We can achieve that goal solely through the optimization of our existing industries. We can increase productivity without using a single pound of additional raw material, without needing a single additional BTU.

THIS FOURTH EDITION

During the nearly four decades of its existence, the *IEH* has become the most widely used reference source of the instrumentation and control (I&C) engineering profession. During this same period, the tools of our I&C profession have changed as control systems were transformed from the early mechanical and pneumatic ones to today's electronic and digital implementations.

During this period, even the name of our profession has changed. Today, some call it *automation*, while others refer to it by a variety of other names, including *instrumentation*, *process control*, *I&C*, and *computer automation*. Yet, while we have not been able to agree even on the name of our profession, our experience and our knowledge of control principles has penetrated all the fields of modern science and technology. I hope that the three volumes of the *IEH* have played a major role in spreading this knowledge and understanding.

In 1968, this handbook started out as a three-volume reference set, and, in that respect, no change has occurred. The first volume deals with measurement, the second with control, and the third with digital networks and software systems.

CONTENTS OF THE *IEH* VOLUMES

In this, the first volume, a chapter is devoted to each major measured variable, and a subchapter (section) is devoted to each different method of making that measurement. Some measurements are relatively simple as, for example, the detection of level; therefore, that chapter has only 21 sections. Others, such as analysis, are more varied, and that chapter has 66 sections.

The individual sections (subchapters) begin with a *flowsheet symbol* and a *feature summary.* This summary provides quick access to specific information on the available sizes, costs, suppliers, ranges, and inaccuracies of the devices covered in that section.

This fourth edition updates the information content of the previously published sections, incorporates the new developments of the last decade by the addition of new sections, and broadens the horizons of the work from an American to a global perspective.

In this first volume, *Process Measurement and Analysis*, the emphasis is on measurement hardware, including the detection of flow, level, temperature, pressure, density, viscosity, weight, composition, and safety sensors.

The second volume of this set, *Process Control*, covers control hardware, including transmitters, controllers, control valves, and displays, and it provides in-depth coverage to the theory of control and explains how the unit processes of pumping, distillation, chemical reaction, heat transfer, and many others are controlled.

The third volume is devoted to *Process Software and Digital Networks*. In combination, the three volumes cover all the topics used by process control or instrument engineers.

READERS OF THE *IEH*

Experienced process control engineers are likely to use this reference set either to obtain quick access to specific information or to guide them in making selections. Less experienced engineers and students of instrument engineering are likely to use this reference work as a textbook. A student might use it to learn about the tools of our profession.

To fulfill the expectations of both the experienced and the beginning engineer, the handbook has been structured to be flexible. On one hand, it contains all the basic information that a student needs, but it also covers the most recent advances and provides quick and easy access to both types of information. Quick access to specific topics and information is provided both by the *feature summary* at the beginning of each section and by an extensive index at the end of each volume.

BIRD'S EYE VIEWS: ORIENTATION TABLES

Another goal of this reference set is to assist the reader in selecting the best sensors for particular applications. To achieve this goal, each chapter begins with a section that provides an application- and selection-oriented overview along with an *orientation table*.

The orientation tables list all the sensors that are discussed in the chapters and summarize the features and capabilities of each. If the reader is using this handbook to select a sensor for a particular application, the orientation table allows the narrowing of the choices to a few designs.

After the options have been reduced, the reader might turn to the corresponding sections and, based on the information in the *feature summaries* at the front of each section, decide if the costs, inaccuracies, and other characteristics meet the requirements of the application. If so, the reader might focus in on the likely candidate and read all the information in the selected section.

NEW NEEDS AND EXPECTATIONS

As I was editing this reference set for the fourth time, I could not help but note the nature of both the new solutions and the new needs of the process control industry.

The new solutions become obvious as you review the contents of the 400 to 500 sections of the 25 or so chapters of this set of handbooks. The new needs are not so obvious. The new needs are the consequences of the evolution of new hardware, new software, and the completely new technologies that have evolved. These needs become obvious only if one is immersed in the topic to the depth and for the duration that I have been. It might speed technological progress if some of these needs are mentioned here.

INTERNATIONAL STANDARDIZATION

In earlier decades, it took some time and effort to agree on the 3 to 15 PSIG (0.2 to 1.0 bar) signal pressure range for the standard pneumatic or on the 4 to 20 mA DC standard analog electronic signal range. Yet, when these signal ranges were finally agreed upon, everybody benefited from having a standard signal.

Similarly, the time is ripe for adopting a worldwide standard for *a single digital communication protocol*. The time is ripe for an internationally accepted digital protocol that could link all the digital "black boxes" and could also act as the "translator" for those that were not designed to "speak the same language." In so doing, the valuable engineering energies that today are being spent to figure out ways for black boxes to communicate could be applied to more valuable tasks, such as increasing the productivity and safety of our processing industries. Optimization can make our industries competitive once again and contribute not to the export of jobs but to the creation of jobs at home.

MEANINGFUL PERFORMANCE STANDARDS

It is also time to rein in the commercial interests and to impose uniform expectations so that all sales literature will provide performance data in the same form. In today's sales literature, the performance-related terms such as *inaccuracy* and *rangeability* are rarely defined properly.

Such terms as "inaccuracy" are frequently misstated as "accuracy," and sometimes the error percentages are given without stating whether they are based on full-scale or actual readings. It is also time for professional societies and testing laboratories to make their findings widely available so that test results can be used to compare the products of different manufacturers.

It is also desirable to have the manufacturers always state not only the inaccuracy of their products but also the rangeability over which that inaccuracy statement is valid. Similarly, it would be desirable if *rangeability* were defined as the ratio between those (maximum and minimum) readings for which the inaccuracy statement is valid.

It would also be desirable to base the inaccuracy statements on the performance of at least 95% of the sensors tested and to include in the inaccuracy statement not only linearity, hysteresis, and repeatability, but also the effects of drift, ambient temperature, overrange, supply voltage, humidity, radio frequency interference (RFI), and vibration.

BETTER VALVES

The performance capabilities of final control elements should also be more uniformly agreed upon and more reliably stated. This is particularly true for the characteristics, gains, and rangeabilities of control valves. For example, a valve should be called linear *only* if its gain (Gv) equals the maximum flow through the valve (Fmax) divided by the valve stroke in percentage (100%).

Valve manufacturers should publish the stroking range (minimum and maximum percentages of valve openings) within which the gain of a linear valve is still Fmax/100%.

Valve rangeability should be defined as the ratio of these minimum and maximum valve openings. Other valve characteristics should also be defined by globally accepted standards in this same manner.

"SMARTER" SENSORS AND ANALYZERS

In the case of transmitters, the overall performance is largely defined by the internal reference used in the sensor. In many cases, there is a need for multiple-range and multiple-reference units. For example, pressure transmitters should have both atmospheric and vacuum references and should have sufficient intelligence to switch automatically from one to the other reference on the basis of their own measurement. Similarly, d/p flow transmitters should have multiple spans and should have the intelligence to automatically switch their spans to match the actual flow as it changes.

The addition of "intelligence" could also increase the amount of information gained from such simple detectors as pitot tubes. If, for example, in addition to detecting the difference between static and velocity pressures, the pitot tube were also able to measure the Reynolds number, it would be able to approximate the shape of the velocity profile. An "intelligent pitot-tube" of such capability could increase the accuracy of volumetric flow measurements.

IMPROVED ON-LINE ANALYZERS

In the area of continuous on-line analysis, further development is needed to extend the capabilities of probe-type analyzers. The needs include the changing of probe shapes to achieve self-cleaning or using "flat tips" to facilitate cleaning. The availability of automatic probe cleaners should also be improved, and their visibility should be increased by the use of sight flow indicators.

An even greater challenge is to lower the unit costs of fiber-optic probes through multiplexing and by sharing the cost of their electronics among several probes. Another important goal for the analyzer industry is to produce devices that are self-calibrating, self-diagnosing, and modular in design. To reduce the overall cost of analyzer maintenance, defective modules should identify themselves and should be easily replaceable.

EFFICIENCY AND PRODUCTIVITY CONTROLLERS

In the area of control, what is most needed is to move from the uncoordinated single loops to optimizing, multivariable envelope, and matrix algorithms. When using such multivariable envelopes, the individual levels, pressures, and temperatures become only constraints, while the overall multivariable envelope is dedicated to maximizing the efficiency or productivity of the controlled process.

In this sense, most of today's digital controls are still only "empty boxes." New software packages are needed to "educate" and to give "personality" to them. Software is needed that, when loaded, will transform a general-purpose unit controller into an advanced and optimized control system serving the particular process, whether it is a chemical reactor, a distillation tower, a compressor, or any other unit operation.

This transformation in the building blocks of control systems would also make the manufacturing of digital control hardware more economical, because all "empty boxes" could be very similar.

UNIT OPERATION CONTROLLERS

The use of such multipurpose hardware could also provide more flexibility to the user, because a unit controller that was controlling a dryer, for example, could be switched to control an evaporator or a pumping station just by loading a different software package into it. Once the particular software package was loaded, the unit controller would require customization only, which could be done in a menu-driven question-and-answer format.

During the customization phase, the user would answer questions on piping configuration, equipment sizes, material or heat balances, and the like. Such customization software packages would automatically configure and tune the individual loops and would make the required relative gain calculations to minimize interaction between loops. It will probably take a couple decades to reach these goals, but to get there, it is necessary to set our sights on these goals now.

COMMON SENSE RECOMMENDATIONS

While talking about such sophisticated concepts as optimized multivariable control, it is very important to keep our feet on the ground, keep in mind that the best process control engineer is still Murphy, and remember that, in a real plant, even Murphy can turn out to be an optimist. For that reason, I list the following common sense, practical advice, and recommendations:

- Before one can control a process, one must fully understand it.
- Being progressive is good, but being a guinea pig is not.
- If an outdated control strategy is implemented, the performance of even the latest digital hardware will be outdated.
- Increased safety is gained through the use of multiple sensors, configured through voting systems or median selectors.
- If an instrument is worth installing, it should also be worth calibrating and maintaining.

- Constancy is the enemy of efficiency; as the load and feed compositions float, the process variables should also be allowed to change with them.
- Control loops can be stabilized by replacing their single set points with control gaps.
- Annunciators do not correct emergencies, they just report problems that the designer did not know how to handle and therefore decided to drop into the laps of the operators. The smaller the annunciator, the better the control system design.
- A good process control engineer will tell the user what he needs to know and not what he wants to hear. The right time for business lunches is not before receiving the purchase order, but after the plant has started up and is running.

HISTORY OF THE HANDBOOK

The birth of this handbook was connected to my own work. In 1962, at the age of 26, I became the chief instrument engineer at Crawford & Russell, an engineering design firm specializing in the building of plastics plants. C&R was growing, and my department had to grow with it. Still, at the age of 26, I did not dare to hire experienced people, because I did not believe that I could lead and supervise older engineers.

But the department had to grow, so I hired fresh graduates from the best engineering colleges in the country. I picked the smartest graduates, and I obtained permission from C&R's president, Sam Russell, to spend every Friday afternoon teaching them. In a few years, not only did my department have some outstanding process control engineers, C&R also saved a lot on their salaries.

By the time I reached 30, I felt secure enough to stop disguising my youth. I shaved off my beard and threw away my thick-rimmed, phony eyeglasses. I no longer felt that I had to look older, but my Friday's notes remained—they still stood in a two-foot high pile on the corner of my desk.

"DOES YOUR PROFESSION HAVE A HANDBOOK?"

In the mid-1960s, an old-fashioned Dutch gentleman named Nick Groonevelt visited my office and asked, "What is that pile of notes?" When I told him, he asked: "Does your profession have a handbook?"

"If it did, would I be teaching from these notes?" I answered with my own question. (Actually, I was wrong in giving that answer, because Behar's *Handbook of Measurement and Control* was already available, but I did not know about it.)

"So, let me publish your notes, and then instrument engineers will have a handbook!" Nick proposed, and in 1968 the first edition of the *Instrument Engineers' Handbook (IEH)* was published.

In 1968, the Soviet tanks (which I fought in 1956) were besieging Prague, so I decided to dedicate the three volumes of the *IEH* to the Hungarian and Czech freedom fighters. A fellow Hungarian-American, Edward Teller, wrote the preface to the first edition, and Frank Ryan, the editor of *ISA Journal*, wrote the introduction.

My coauthors included such names as Hans Baumann, Stu Jackson, Orval Lovett, Charles Mamzic, Howard Roberts, Greg Shinskey, and Ted Williams. It was an honor to work with such a team. In 1973, because of the publication of the first edition of the *IEH*, I was elected the youngest ISA fellow ever.

LATER EDITIONS

By the end of the 1970s, the world of process control had changed. Pneumatics were on the way out, and new approaches, such as distributed control systems (DCS) and on-line analyzers, proliferated. It was time to revise the handbook. By 1975, I also had to run my own consulting office, so I could not devote my full attention to updating the handbook.

Therefore, I hired Kriszta Venczel to do most of the work, and she did her best by inserting metric units and the like. We got some excellent new contributions, from Ed Farmer, Tom Kehoe, Thomas Myron, Richard Oliver, Phillip Schnelle, Mauro Togneri, and Theodore Williams. The second edition was published in 1982. It was well received, but I knew that it would have been better if I had devoted more time to it.

By the mid-1990s, the handbook was ready for another updating edition. By that time, the process control market was becoming globalized, "smart" instruments had evolved, and such hardware inventions as fiber-optic probes and throttling solenoid valves proliferated. Therefore, I stopped teaching at Yale and cut back on consulting to make time to edit the third edition.

By the second half of the 1990s, the first two volumes of the third edition, one on measurement and the other on control, were published. At that time, I realized that a third volume was also needed to cover all of the evolving digital software packages, communication networks, buses, and optimization packages. Therefore, it took the last decade of the twentieth century to publish the three volumes of the third edition.

THE FOURTH EDITION

Work on the fourth edition of the *IEH* started in the new millenium, and this first volume on measurement and analysis is the result of this effort. I do hope that, in three to five years, you might hold all three updated *IEH* volumes in your hands. Now that the fourth edition of the *Measurement and Analysis* volume has been published, I am starting work on the second volume, which is devoted to *process control*.

This second volume will cover control hardware, including transmitters, controllers, control valves, and displays, and it provides in-depth coverage of both control theory and how the unit processes of pumping, distillation, chemical reaction, heat transfer, and many others are controlled and optimized. My main goal is to expand this last area by both increasing the list of unit operations that we cover and, more importantly, by giving much more emphasis to optimization.

WHY DON'T YOU PITCH IN?

I would like to ask you to help me locate the best experts on all five continents for each important unit operation in our processing industries. If you have spent a lifetime learning and understanding the unique personality of a process and have figured out how to maximize its efficiency, don't keep that knowledge to yourself—share it with us.

If you or one of your colleagues would like to participate as a coauthor, please send me an e-mail, and I will send you the table of contents (TOC) of the control volume. If the topic of your interest is not in the TOC, we can add it; if it is, I will consider your offer to update the material that has already appeared in the third edition.

Please understand that I am not looking for people with writing skills, I am looking for engineers with knowledge and experience! This is not to say that I will reject college professors; naturally, I will not, although I might delete some of their differential equations and bring them down from the frequency domain back into the time domain. Similarly, I will consider the contributions of professional consultants if they do not view the *IEH* as a forum for self-promotion. I will also consider manufacturers as coauthors if they are able to be balanced and are willing to give credit where credit is due, even if it means crediting their competition.

But my favorite coauthor is the plant engineer who is short on words but long on experience. I do not mind getting answers such as, "I don't know if this is conductivity or ultrasonics, all I know is that it works!" The *IEH* is written by users and for users, and it is not about fancy packaging—it is about content. So don't worry about your writing skills, I can help with that. Please help make the fourth edition of the *IEH* one we can be proud of. Please drop me an e-mail if you want to pitch in.

We know that there is no greater resource than the combined knowledge and professional dedication of a well educated new generation. We live in an age in which technology can make a difference in overcoming the social and environmental ills on this planet. We live in an age in which an inexhaustible and nonpolluting energy technology must be developed. It is hoped that this handbook will make a contribution toward these goals and that, in addition, it will improve the professional standing of instrument and process control engineers around the world.

Béla Lipták
Stamford, Connecticutt

DEFINITIONS

ABSOLUTE (DYNAMIC) VISCOSITY (μ)	Constant of proportionality between applied stress and resulting shear velocity (Newton's hypothesis).
ABSORBANCE (A)	Ratio of radiant energy absorbed by a body to the corresponding absorption of a blackbody at the same temperature. Absorbance equals emittance on bodies whose temperature is not changing. (A = 1 − R − T, where R is the reflectance and T is the transmittance.)
ABSORPTION	The taking in of a fluid to fill the cavities in a solid.
ACCUMULATION	The pressure increase over the maximum allowable working pressure of a tank or vessel during discharge through the pressure relief valve. It is given either in percentage of the maximum allowable working pressure or in pressure units such as bars or pounds per square inch.
ADMITTANCE (A)	The reciprocal of the impedance of a circuit. Admittance of an AC circuit is analogous to the conductance of a DC circuit. Expressed in units of Seimens.
ADSORPTION	The adhesion of a fluid in extremely thin layers to the surfaces of a solid.
ALPHA CURVE	The relationship between the resistance change of an RTD vs. temperature. In the European alpha curves, the alpha value is 0.00385 Ω/°C; in the American curves, it is 0.00392 Ω/°C.
AMPACITY	The current (amperes) a conducting system can support without exceeding the temperature rating assigned to its configuration and application.
AMPEROMETRIC TITRATION	Titration in which the end point is determined by measuring the current (amperage) that passes through the solution at a constant voltage.
AMPEROMETRY	The process of performing an amperometric titration. The current flow is monitored as a function of time between working and auxiliary electrodes while the voltage difference between them is held constant; in other designs, the current is monitored as a function of the amount of reagent added to bring about titration of an analyte to the stoichiometrically defined end point. Also called constant *potential voltametry.*
APPARENT VISCOSITY	Viscosity of a non-Newtonian fluid under given conditions. Same as consistency.
ATTENUATION	Loss of communication signal strength.
BACKPLANE	Physical connection between individual components and the data and power distribution buses inside a chassis.
BACKPRESSURE	Pressure on the discharge side of a pressure relief valve. This pressure is the sum of the superimposed and the built-up backpressures. The superimposed backpressure is the pressure that exists in the discharge piping of the relief valve when the valve is closed.
BALANCED SAFETY RELIEF VALVE	A safety relief valve with the bonnet vented to atmosphere. The effect of backpressure on the performance characteristics of the valve (set pressure, blow-down, and capacity) is much less than on the conventional valve. The balanced safety relief valve is made in three designs: (1) with a balancing piston, (2) with a balancing bellows, and (3) with a balancing bellows and an auxiliary balancing piston.
BALLING DEGREES	Unit of specific gravity used in the brewing and sugar industries.
BALUN (BALANCED/ UNBALANCED)	A device used for matching characteristics between a balanced and an unbalanced medium.
BANDPASS FILTER	An optical or detector filter that permits the passage of a narrow band of the

	total spectrum. It excludes or is opaque to all other wavelengths.
BANDWIDTH	Data-carrying capacity; the range of frequencies available for signals. The term is also used to describe the rated throughput capacity of a given network medium or protocol.
BARKOMETER DEGREES	Unit of specific gravity used in the tanning industry.
BASEBAND	A communication technique whereby only one carrier frequency is used to send one signal at a time. Ethernet is an example of a baseband network; also called *narrowband*; contrast with *broadband*.
BAUMÉ DEGREES	A unit of specific gravity used in the acid and syrup industries.
BLACKBODY	The perfect absorber of all radiant energy that strikes it. The blackbody is also a perfect emitter. Therefore, both its absorbance (A) and emissivity (E) are unity. The blackbody radiates energy in predictable spectral distributions and intensities that are a function of the blackbody's absolute temperature (Figure 4.11a). A blackbody can be configured as shown in Figure 4.11b.
BLOWDOWN (BLOWBACK)	The difference between the set pressure and the reseating (closing) pressure of a pressure relief valve, expressed in percent of the set pressure, bars, or pounds per square inch.
BOLOMETER	Thermal detector which changes its electrical resistance as a function of the radiant energy striking it.
BONDING	The practice of creating safe, high-capacity, reliable electrical connectivity between associated metallic parts, machines, and other conductive equipment.
BRIGHTNESS PYROMETER	This device uses the radiant energy on each side of a fixed wavelength of the spectrum. This band is quite narrow and usually centered at 0.65 μm in the orange-red area of the visible spectrum.
BRITISH THERMAL UNIT (BTU)	The amount of heat required to raise the temperature of 1 lb of water by 1°F at or near 60°F.
BRIX DEGREE	A specific gravity unit used in the sugar industry.
BROADBAND	A communication technique that multiplexes multiple independent signals simultaneously, using several distinct carriers. A common term in the telecommunications industry to describe any channel having a bandwidth greater than a voice-grade channel (4 kHz). Also called *wideband*. Contrast with *baseband*.
BTU "DRY"	This is the heating value that is expressed on a "dry basis." The common assumption is that pipeline gas contains 7 lb (or less) of water vapor per million standard cubic feet.
BTU "SATURATED"	This is the heating value that is expressed on the basis of the gas being saturated with water vapors. This state is defined as the condition when the gas contains the maximum amount of water vapors without condensation, when it is at base pressure and 60°F.
BUILT-UP BACKPRESSURE	Variable backpressure that develops as a result of flow through the pressure relief valve after it opens. This is an increase in pressure in the relief valve's outlet line caused by the pressure drop through the discharge headers.
BURNING	Burning is when the flame does not spread or diffuse but remains at an interface where fuel and oxidant are supplied in proper proportions.
CAPACITANCE (C)	The amount of charge, in coulombs, stored in a system necessary to raise the potential difference across it by 1 V, represented in the SI unit *farad*.
CAPACITOR DEVICE	This device consists of two conductors electrically isolated by an insulator. The conductors are called *plates*, and the insulator is referred to as the *dielectric*. The larger the capacitor, the smaller its impedance and the more AC current will flow through it.
CHARACTERISTIC IMPEDANCE	The impedance obtained from the output terminals of a transmission line that appears to be infinitely long, when there are no standing waves on the line and the ratio of voltage to current is the same for each point of the line (nominal impedance of a waveguide).
CHATTER	Rapid, abnormal reciprocating variations in lift during which the disc contacts the seat.
CHRONOPOTENTIOMETRY	Process in which the potential difference between a metallic measuring electrode and a reference electrode is monitored as a function of time. At the measuring electrode, an oxidation or reduction of a solution species takes place.
CLOSING PRESSURE (RESEAT PRESSURE)	The pressure, measured at the valve inlet, at which the valve closes, flow is substantially shut off, and there is no measurable lift.

COAX	Jargon meaning *coaxial cable*, consisting of a center wire surrounded by low-K insulation, surrounded by a second, shield conductor. It has the characteristic of low capacitance and inductance to facilitate transmission of high-frequency current.
COLD DIFFERENTIAL TEST PRESSURE (CDTP)	The pressure at which the PRV is adjusted to open during testing. The CDTP setting includes the corrections required to consider the expected service temperature and backpressure.
COMBUSTION AIR REQUIREMENT INDEX (CARI)	This dimensionless number indicates the amount of air required (stoichiometrically) to support the combustion of a fuel gas. Mathematically, the combustion air requirement index is defined by the equation below: $\text{CARI} = \dfrac{\text{air/fuel ratio}}{\sqrt{\text{s.g.}}}$
CONDUCTANCE (G)	The reciprocal of resistance in units of Siemens (S, formerly *mhos*).
CONDUCTIVITY (g)	The reciprocal of resistivity. All solids and liquids have some degree of conductivity. For the purpose of this section, any material above 1 μS/cm will be considered to be conductive (including most metals and water containing any ions).
CONSISTENCY	Resistance of a substance to deformation. It is the same as viscosity for a Newtonian fluid and the same as apparent viscosity for a non-Newtonian fluid.
CONSTANT BACKPRESSURE	Backpressure that does not change under any condition of operation, whether the pressure relief valve is closed or open.
CONVENTIONAL SAFETY RELIEF VALVE	A safety relief valve with the bonnet vented either to atmosphere or internally to the discharge side of the valve. The performance characteristics (set pressure, blowdown, and capacity) are directly affected by changes of the backpressure on the valve.
COULOMETRY	Process of monitoring analyte concentration by detecting the total amount of electrical charge passed between two electrodes that are held at constant potential or when constant current flow passes between them.
CPVC	Chlorinated polyvinyl chloride, a low-cost, reasonably inert polymer, used in the construction of some noninsertion sensors. It is easily solvent welded. The maximum temperature range is up to about 225°F.
CRYSTALLOGRAPHY	How atoms are arranged in an object; the direct relationship between these arrangements and material properties (conductivity, electrical properties, strength, etc.).
CURIE (CI)	A unit of radiation source size corresponding to 37 billion disintegrations per second.
DATA SERVERS	A standard interface to provide data exchange between field devices and data clients.
DEAD BAND	The range through which an input can be varied without causing a change in the output.
DEFLAGRATION OR EXPLOSION	A process in which a flame front advances through a gaseous mixture at subsonic speeds.
DEIONIZED	Refers to water of extremely high purity, with few ions to carry current. If exposed to air for any significant period, it will have a conductivity of about 5 μS/cm because of dissolved CO_2.
DEMULTIPLEXING	Separation of multiple input streams that were multiplexed into a common physical signal back into multiple output streams.
DESIGN PRESSURE	This pressure is equal to or less than the maximum allowable working pressure. It is used to define the upper limit of the normal operating pressure range.
DETONATION	A process in which the advancement of a flame front occurs at supersonic speeds.
DEVICE DESCRIPTION	A clear, unambiguous, structured text description that allows full utilization/operation of a field device by a host/master without any prior knowledge of the field device.
DEW POINT	Saturation temperature of a gas–water vapor mixture.
DIELECTRIC	An electrical insulator (includes metal oxides, plastics, and hydrocarbons).
DIELECTRIC COMPENSATION	A scheme by which changes in insulating liquid composition or temperature can be prevented from causing any output error. Requires a second sensor and homogeneous liquid. A dielectric is a material that is an electrical insulator or in which an electric field can be sustained with a minimum of dissipation of power.
DIELECTRIC CONSTANT	A unit expressing the relative charge storage capability of various insulators. Full vacuum is defined as 1.0, and all gases are indistinguishable for practical

	purposes. TFE has a dielectric constant of 2.0, cold water about 80. There are no related units, because this is the ratio of absolute dielectric constant to that of vacuum. The dielectric values of selected materials are given in Tables 3.3q and 3.14a.
DIODE	A two-terminal electronic (usually semiconductor) device that permits current flow predominantly in only one direction.
DISCONTINUITY	An abrupt change in the shape (or impedance) of a waveguide (creating a reflection of energy).
DUST-IGNITION-PROOF	Enclosed in a manner to exclude ignitable amounts of dust or amounts that might affect performance. Enclosed so that arcs, sparks, and heat otherwise generated or liberated inside of the enclosure will not cause ignition of exterior accumulations or atmospheric suspensions of dust.
EFFECTIVE COEFFICIENT OF DISCHARGE	This is a coefficient used to calculate the minimum required discharge area of the PRV.
ELECTROCHEMICAL PROCESS	The changes in voltage or current flow that occur between two electrodes in a solution (electrolyte) over time. The oxidation or reduction of the analyte provides data related to concentration.
ELECTROLYTIC PROBE	A probe that is similar to a galvanic probe, except that a potential is applied across the electrodes, and the electrodes are not consumed. Dissolved oxygen detection is a primary application of this type of probe.
ELECTROMAGNETIC WAVE (ENERGY)	A disturbance that propagates outward from any electric charge that oscillates or is accelerated; far from the charge, it consists of vibrating electric and magnetic fields that move at the speed of light and are at right angles to each other and to the direction of motion.
ELECTRON MICROSCOPE	Electron microscopes are scientific instruments that use a beam of highly energetic electrons to examine objects on a very fine scale.
EMISSIVITY OR EMITTANCE (E)	The emissivity of an object is the ratio of radiant energy emitted by that object divided by the radiant energy that a blackbody would emit at that same temperature. If the emittance is the same at all wavelengths, the object is called a *gray body*. Some industrial materials change their emissivity with temperature and sometimes with other variables. Emissivity always equals absorption, and it also equals 1 minus the sum of reflectance and transmittance (E = A = 1 − T − R).
EQUIVALENT TIME SAMPLING (ETS)	A process that captures high-speed electromagnetic events in real time (nanoseconds) and reconstructs them into an equivalent time (milliseconds), which allows easier measurement with present electronic circuitry.
ETHERNET	A baseband local area network specification developed by Xerox Corporation, Intel, and Digital Equipment Corp. to interconnect computer equipment using coaxial cable and transceivers.
EXPLOSION-PROOF	All equipment is contained within enclosures strong enough to withstand internal explosions without damage, and tight enough to confine the resulting hot gases so that they will not ignite the external atmosphere. This is the traditional method and is applicable to all sizes and types of equipment.
FARAD (F)	A unit of capacitance. Because this is a very large unit, a unit equal to one trillionth of a farad (called a *picofarad, pF*) is commonly used in RF circuits.
FEP	Fluorinated ethylene propylene, a fluorocarbon that is extremely chemically inert, melts at a reasonable temperature, and can be plastic-welded fairly easily. It is difficult to bond with adhesives. The maximum temperature range is limited to the 300°F (150°C) area.
FIELDBUS	An all-digital, two-way, multidrop communication system for instruments and other plant automation equipment.
FIREWALL	A router or access server designated as a buffer between any public networks and a private network.
FLASH POINT	The lowest temperature at which a flammable liquid gives off enough vapors to form a flammable or ignitable mixture with air near the surface of the liquid or within the container used. Many hazardous liquids have flash points at or below room temperatures. They are normally covered by a layer of flammable vapors that will ignite in the presence of a source of ignition.
FLUIDITY	Reciprocal of absolute viscosity; unit in the cgs system is the rhe, which equals 1/poise.
FLUTTER	Rapid, abnormal reciprocating variations in lift during which the disc does not contact the seat.

FUEL CELLS	Cells that convert the chemical energy of fuel and oxygen into electrical energy while the electrode and the electrolyte remain unaltered. Fuel is converted at the anode into hydrogen ions, which travel through the electrolyte to the cathode, and electrons, which travel through an external circuit to the cathode. If oxygen is present at the cathode, it is reduced by these electrons, and the hydrogen and oxygen ions eventually react to form water.
GALVANIC PROBE	A probe for which no external voltage is applied across electrodes; current flows as the cell is depolarized when diffusion of the analyte occurs. Electrodes are consumed during this operation and require periodic replacement.
GRAY BODY	This is an object having an emittance of less than unity, but this emittance is constant at all wavelengths (over that part of the spectrum where the measurement takes place). This means that gray-body radiation curves are identical to the ones shown in Figure 4.11a, except that they are dropped down on the radiated power density scale.
GROSS CALORIFIC VALUE	The heat value of energy per unit volume at standard conditions, expressed in terms of British thermal units per standard cubic feet (Btu/SCF) or as kilocalories per cubic Newton meters (Kcal/N·m^3) or other equivalent units.
GROUND	A conducting connection, whether intentional or accidental, between an electrical circuit or equipment and the Earth, or to some conducting body that serves in place of Earth. (See NFPA 70–100.)
GROUND FAULT PROTECTOR	A device used to open ungrounded conductors when high currents, especially those resulting from line-to-ground fault currents, are encountered.
GUARD	The “electronic guard” (called a *shield* in some RF level literature) consists of a concentric metallic element with an applied voltage that is identical to the voltage on the conductor that it is “guarding.” This negates the capacitance between the guarded conductor and the outside world.
GUIDED WAVE RADAR (GWR)	A contact radar technology for which time domain reflectometry (TDR) has been developed into an industrial-level measurement system in which a probe immersed in the medium acts as the waveguide.
HAGEN-POISEUILLE LAW	Defines the behavior of viscous liquid flow through a capillary.
HOME RUN WIRING	Wire between the cabinet where the Fieldbus host or centralized control system resides and the first field junction box or device.
HUB (SHARED)	Multiport repeater joining segments into a network.
HYGROMETER	An apparatus that measures humidity.
HYGROSCOPIC MATERIAL	A material with a great affinity for moisture.
IMPEDANCE	Maximum voltage divided by maximum current in an alternating current circuit. Impedance is composed of resistive, inductive, and capacitive components. As in DC circuits, the quantity of voltage divided by current is expressed in ohms (Ω).
INFRARED	The portion of the spectrum whose wavelength is longer than that of red light. Only the portion between 0.7 and 20 μm gives usable energy for radiation detectors.
INTERFACE	(1) Shared boundary; for example, the physical connection between two systems or two devices. (2) Generally, the point of interconnection of two components, and the means by which they must exchange signals according to some hardware or software protocol.
INTEROPERABILITY	A marketing term with a blurred meaning. One possible definition is the ability for like devices from different manufacturers to work together in a system and be substituted one for another without loss of functionality at the host level (HART).
INTRINSIC SAFETY	Available energy is limited under all conditions to levels too low to ignite the hazardous atmosphere. This method is useful only for low-power equipment such as instrumentation, communication, and remote control circuits.
KINEMATIC VISCOSITY (υ)	Dynamic viscosity/density = $\upsilon = \mu/\rho$.
LAMBDA	The desired closed-loop time constant, often set to equal the loop lag time.
LATENCY	Latency measures the worst-case maximum time between the start of a transaction and the completion of that transaction.
LIFT	The rise of the disc in a pressure-relief valve.
LINE DRIVER	Inexpensive amplifier and signal converter that conditions digital signals to ensure reliable transmissions over

	extended distances without the use of modems.
LOWER EXPLOSIVE LIMIT (LEL)	The lowest concentration of gas or vapor in air at which, once ignition occurs, the gas or vapor will continue to burn after the source of ignition has been removed.
LOWPASS FILTERS	Filters that are used to remove high-frequency interference or noise from low-frequency signals.
MANCHESTER	A digital signaling technique that contains a signal transition at the center of every bit cell.
MANUFACTURING RANGE	A range around the specified burst pressure within which the marked or rated burst pressure must fall. Manufacturing range is not used in ISO standards.
MAXIMUM ALLOWABLE OPERATING PRESSURE (MAOP)	The maximum pressure expected during normal operation.
MAXIMUM ALLOWABLE WORKING PRESSURE (MAWP)	This is the maximum pressure allowed for continuous operation. As defined in the construction codes (ASME B31.3) for unfired pressure vessels, it equals the design pressure for the same design temperature. The maximum allowable working pressure depends on the type of material, its thickness, and the service conditions set as the basis for design. The vessel may not be operated above this pressure or its equivalent at any metal temperature other than that used in its design; consequently, for that metal temperature, it is the highest pressure at which the primary pressure relief valve can be set to open.
MECHANICAL EMISSIVITY ENHANCEMENT	Mechanically increasing the emissivity of a surface to near-blackbody conditions (using multiple reflection).
MICRON	Equals 001 mm, 10,000 angstroms (Å). A unit used to measure wavelengths of radiant energy.
MODEM	Modulator-demodulator; a device that converts digital and analog signals. At the source, a modem converts digital signals to a form suitable for transmission over analog communication facilities. At the destination, the analog signals are returned to their digital form. Modems allow data to be transmitted over voice-grade telephone lines.
MORPHOLOGY	The shape and size of the particles making up the object; the direct relationship between these structures and their material properties (ductility, strength, reactivity, etc.).
MULTIPLEXING	A scheme that allows multiple logical signals to be transmitted simultaneously across a single physical channel. Compare with *demultiplexing*.
NARROWBAND PYROMETER	A radiation pyrometer that is sensitive to only a narrow segment of wavelengths within the total radiation spectrum. Optical pyrometers are among the devices in this category.
NET CALORIFIC VALUE	The measurement of the actual available energy per unit volume at standard conditions, which is always less than the gross calorific value by an amount equal to the latent heat of vaporization of the water formed during combustion.
NETWORK	All of the media, connectors, and associated communication elements by which a communication system operates.
NEWTON	The internationally accepted unit of force, defined as the force required to accelerate 1 kg by 1 m/sec^2. It equals 0.2248 pound-force or about 4 oz.
NONFRAGMENTING DISC	A rupture disc design that, when burst, does not eject fragments that could interfere with the operation of downstream equipment (i.e., relief valves).
NONINCENDIARY	Equipment that, in normal operation, does not constitute a source of ignition; i.e., surface temperature shall not exceed ignition temperature of the specified gas to which it may be exposed, and there are no sliding or make-and-break contacts operating at energy levels capable of causing ignition. Used for all types of equipment in Division 2 locations. Relies on the improbability of an ignition-capable fault condition occurring simultaneously with an escape of hazardous gas.
OIL IMMERSION	Concept in which equipment is submerged in oil to a depth sufficient to quench any sparks that may be produced. This technique is commonly used for switchgears, but it is not utilized in connection with instruments.
OPERATING PRESSURE	The operating pressure of a vessel is the pressure, in pounds per square inch gauge (PSIG), to which the vessel is usually subjected in service. A processing vessel is usually designed for a maximum allowable working pressure, in PSIG, that will provide a suitable

	margin above the operating pressure to prevent any undesirable operation of the relief device. It is suggested that this margin be approximately 10% or 25 PSI (173 kPa), whichever is greater. Such a margin will be adequate to prevent the undesirable opening and operation of the pressure relief valve caused by minor fluctuations in the operating pressure.
OPERATING PRESSURE MARGIN	The margin between the maximum operating pressure and the set pressure of the PRV.
OPERATING PRESSURE RATIO	The ratio of the maximum operating pressure to the set pressure of the PRV.
OPERATING RATIO OF A RUPTURE DISC	(1) The ratio of the maximum operating pressure to the marked burst pressure expressed as a percentage (common U.S. definition). (2) The ratio of the maximum operating pressure to the minimum of the performance tolerance expressed as a percentage (common ISO definition).
OPTICAL PYROMETER	Also called *brightness pyrometer*, it uses a narrow band of radiation within the visible range (0.4 to 0.7 μm) to measure temperature by color matching and other techniques.
OVERPRESSURE	The pressure increase over the set pressure of the primary relief device. When the set pressure is the same as the maximum allowable operating pressure (MAOP), the accumulation is the same as the overpressure. Pressure increase over the set pressure of the primary relieving device is overpressure. We may observe from this definition that, when the set pressure of the first (primary) safety or relief valve is less than the maximum allowable working pressure of the vessel, the overpressure may be greater than 10% of set pressure.
PARTIAL PRESSURE	In a mixture of gases, the partial pressure of one component is the pressure of that component if it alone occupied the entire volume at the temperature of the mixture.
PASCAL-SECOND (PA · S)	Internationally accepted unit of absolute (dynamic) viscosity. One Pa·s = 1 Newton-sec/m^2 = 10 poise = 1000 centipoise.
PDVF (POLYVINYLIDENE FLUORIDE)	This fluorocarbon has substantially lower temperature limits than the others (250°F or 120°C) and is less inert chemically. It is dissolved by the ketones (acetone, MEK, MIBK) and attacked by benzene and high concentrations of sulfuric acid. The most insidious enemy is caustic, which causes brittleness and cracking. It has much better toughness and abrasion resistance than the other fluorocarbons, as well as unique electrical properties ($K = 8$).
PE (POLYETHYLENE)	A low-temperature insulation that is compatible with a wide range of corrosives but is attacked by most petroleum products. Generally limited to situations where fluorocarbons and chlorocarbons are not allowed, such as the tobacco and nuclear power industries. Maximum allowable temperature is in the 180°F (80°C) area.
PEEK (POLYETHER ETHERKETONE)	A high-temperature, injection-molded polymer that is chemically quite inert. This material has wide chemical application. Temperature capability is high at 450 to 500°F (225 to 260°C). Avoid any liquids with “phenol” in their names. Adhesive bonding to the molded parts would be difficult.
PFA (PERFLUOROALKOXY)	A fluorocarbon that is quite inert chemically, melts at a fairly high temperature, and is easily plastic welded. It can be used up to 550°F (290°C) but, as a probe insulation, it is generally limited to 350°F (175°C) because of bonding limitations with the metal rod.
PHASE DIFFERENCE SENSOR (PDS)	A contact radar technology; unlike TDR-based systems, which measure using subnanosecond time intervals, PDS derives level information from the changes in phase angle.
PHOTODETECTOR	A device that measures thermal radiation by producing an output through release of electrical changes within its body. They are small flakes of crystalline materials, such as CdS or InSb, that respond to different portions of the spectrum, consequently showing great selectivity in the wavelengths at which they operate.
PIXEL (“PICTURE ELEMENT”)	A dot that represents the smallest graphic unit of display in a digital image, used in machine vision and camera technology.
PLENUM	Air distribution ducting, chamber, or compartment.
POISE (μ)	Unit of dynamic or absolute viscosity (dyne-sec/cm^2).
POISEUILLE (PI)	Suggested name for the new international standard unit of viscosity, the pascal-second.
POLAROGRAPHY	Process for monitoring the diffusion current flow between working and auxiliary

	electrodes as a function of applied voltage as it is systematically varied. The concentration of analyte allows for the flow of the diffusion current, which is linearly dependent on the analyte concentration. Polarography can be applied using direct current, pulsed direct current, and alternating current voltage excitation waveforms. Dissolved oxygen determination is an example of an application for which polarography is used.
POTENTIOMETRY	When no current is passing between electrodes. Examples: ORP, pH, selective-ion electrodes. The electromotive force or potential difference (at zero current) is monitored between the measuring and reference electrodes.
POTTING	Refers to the use of a potting compound to completely surround all live parts, thereby excluding the hazardous atmosphere; has been proposed as a method of protection. There is no known usage except in combination with other means.
PP (POLYPROPYLENE)	Similar to PE. Used for low cost and where fluorocarbons and chlorocarbons are excluded. Maximum temperature is in the area of 200°F.
PRESSURE-RELIEVING DEVICE	The broadest category in the area of pressure-relief devices; includes rupture discs and pressure relief valves of both the simple spring-loaded types and certain pilot-operated types.
PRESSURE RELIEF VALVE (PRV)	A generic term that can refer to relief valves, safety valves, and pilot-operated valves. The purpose of a PRV is to automatically open and to relieve the excess system pressure by sending the process gases or fluids to a safe location when its pressure setting is reached.
PRIMARY STANDARD	A measuring instrument calibrated at a national standard laboratory such as NIST and used to calibrate other sensors.
PROOF	A unit of specific gravity used in the alcohol industry.
PROTOCOL	Formal description of a set of rules and conventions that govern how devices on a network exchange information.
(P)TFE (TETRAFLUOROETHYLENE)	The oldest, highest-temperature, and most inert fluorocarbon probe insulation. Extremely difficult to adhesive bond, it is usable up to 550°F (290°C) but, on probes, its temperature limit is determined by the type of bonding to the probe rod (300, 450, or 550°F). This is the most common probe insulation in the industry. Because it never melts (it disintegrates, producing HF at >600°F), it is difficult to fabricate, is impossible to plastic weld, and exhibits a high degree of microporosity. Can be destroyed by butadiene and styrene monomer. (The "P" in (P) TFE stands for polymerized.)
PURGING, PRESSURIZATION, VENTILATION	This refers to the maintenance of a slight positive pressure of air or inert gas within an enclosure so that the hazardous atmosphere cannot enter. Relatively recent in general application, it is applicable to any size or type of equipment.
QUEVENNE DEGREE	A specific gravity unit used in expressing the fat content of milk.
RACEWAY	A general term for enclosed channels, conduit, and tubing designed for holding wires and cables.
RADAR (RADIO DETECTION AND RANGING)	A system using beamed and reflected radio frequency energy for detecting and locating objects, measuring distance or altitude, navigating, homing, bombing, and other purposes; in detecting and ranging, the time interval between transmission of the energy and reception of the reflected energy establishes the range of an object in the beam's path.
RADIO FREQUENCY (RF)	A frequency that is higher than sonic but less than infrared. The low end of the RF range is 20 kHz, and its high end is around 100,000 MHz.
RADIO FREQUENCY INTERFERENCE (RFI)	A phenomenon in which electromagnetic waves from a source interfere with the performance of another electrical device.
RATED RELIEVING CAPACITY	The maximum relieving capacity of the PRV. This information is normally provided on the nameplate of the PRV. The rated relieving capacity of the PRV exceeds the required relieving capacity and is the basis for sizing the vent header system.
RATIO PYROMETER	See two-color pyrometer.
REACTANCE (X)	The portion of the impedance of a circuit that is caused by capacitance, inductance, or both. Expressed in ohms.
REAR MOUNT	A technique for making long inactive sections by mounting the probe on the end of a pipe, with its coax cable running through the pipe to the top of the tank. The coax must survive the process temperature, so it is often of high-temperature construction.
REFLECTANCE OR REFLECTIVITY (R)	The percentage of the total radiation falling on a body that is directly reflected without entry. Reflectance is

	zero for a blackbody and nearly 100% for a highly polished surface. ($R = 1 - A - T$, where A is the absorbance and T is the transmissivity.)
RELATIVE HUMIDITY	The ratio of the mole fraction of moisture in a gas mixture to the mole fraction of moisture in a saturated mixture at the same temperature and pressure. Alternatively, the ratio of the amount of moisture in a gas mixture to the amount of moisture in a saturated mixture at equal volume, temperature, and pressure.
RELATIVE VISCOSITY	Ratio of absolute viscosity of a fluid at any temperature to that of water at 20°C (68°F). Because water at this temperature has a μ of 1.002 cP, the relative viscosity of a fluid equals approximately its absolute viscosity in cP. Because the density of water is 1, the kinematic viscosity of water equals 1.002 cSt at 20°C.
RELIEF VALVE	An automatic pressure-relieving device actuated by the static pressure upstream of the valve, which opens in proportion to the increase in pressure over the operating pressure. It is used primarily for liquid service.
RELIEVING PRESSURE	The sum of opening pressure plus overpressure. It is the pressure, measured at a valve's inlet, at which the relieving capacity is determined.
REOPENING PRESSURE	The opening pressure when the pressure is raised as soon as practicable after the valve has reseated or closed from a previous discharge.
RESISTIVE COMPONENT	AC current can be separated into two components; the portion that is *in phase* with the excitation voltage is the resistive component.
RESISTIVITY (ρ)	The property of a conductive material that determines how much resistance a unit cube will produce. Expressed in units of ohm-centimeters ($\Omega\cdot$cm).
RICHTER DEGREES	A unit of specific gravity used in the alcohol industry.
ROENTGEN (R)	A unit for expressing the strength of a radiation field. In a 1-R radiation field, 2.08 billion pairs of ions are produced in 1 cm^2 of air.
ROENTGEN EQUIVALENT MAN (REM)	A unit of allowable radiation dosage, corresponding to the amount of radiation received when exposed to 1 R over any period of time.
ROOT VALVE	The first valve off the process.
RUPTURE TOLERANCE OF A RUPTURE DISC	The tolerance range on either side of the marked or rated burst pressure within which the rupture disc is expected to burst. Rupture tolerance may also be represented as a minimum–maximum pressure range. Also referred to as performance tolerance in ISO standards.
SAFETY RELIEF VALVE	An automatic pressure-actuated relieving device suitable for use as either a safety or relief valve.
SAFETY VALVE	An automatic pressure-relieving device actuated by the static pressure upstream of the valve and characterized by rapid and full opening or pop action. It can be used for steam, gas, or vapor service.
SAND FILLING	All potential sources of ignition are buried in a granular solid, such as sand. The sand acts partly to keep the hazardous atmosphere away from the sources of ignition and partly as an arc quencher and flame arrester. It is used in Europe for heavy equipment; it is not used in instruments.
SATURATION	A condition in which RF current from a probe to ground is determined solely by the impedance of the probe insulation. Increased conductivity in the saturating medium, even to infinity, will not cause a noticeable change in that current or in the transmitter output.
SATURATION PRESSURE	The pressure of a fluid when condensation (or vaporization) takes place at a given temperature. (The temperature is the saturation temperature.)
SATURATED SOLUTION	A solution that has reached the limit of solubility.
SAYBOLT FUROL SECOND (SFS)	A time unit referring to the Saybolt viscometer with a Furol capillary, which is larger than a universal capillary.
SAYBOLT UNIVERSAL SECOND (SUS)	A time unit referring to the Saybolt viscometer.
SAYBOLT VISCOMETER (UNIVERSAL, FUROL)	Measures time for given volume of fluid to flow through standard orifice; units are seconds.
SEALING	Excluding the atmosphere from potential sources of ignition by sealing such sources in airtight containers. This method is used for components such as relays, not for complete instruments.
SEAL-OFF PRESSURE	The pressure, measured at the valve inlet after closing, at which no further liquid, steam, or gas is detected at the downstream side of the seat.
SEGMENT	The section of a network that is terminated in its characteristic impedance. Segments are linked by repeaters to form a complete network.

SERVICE	Term used by NFPA-70 (NEC) to demarcate the point at which utility electrical codes published by IEEE (NESC) take over. Includes conductors and equipment that deliver electricity from utilities.
SET PRESSURE (OPENING PRESSURE)	The pressure at which a relief valve is set to open. It is the pressure, measured at the valve inlet of the PRV, at which there is a measurable lift or at which discharge becomes continuous as determined by seeing, feeling, or hearing. In the pop-type safety valve, it is the pressure at which the valve moves more in the opening direction as compared to corresponding movements at higher or lower pressures. A safety valve or a safety relief valve is not considered to be open when it is simmering at a pressure just below the popping point, even though the simmering may be audible.
SHEAR VISCOMETER	Viscometer that measures viscosity of a non-Newtonian fluid at several different shear rates. Viscosity is extrapolated to zero shear rate by connecting the measured points and extending the curve to zero shear rate.
SIKES DEGREE	A unit of specific gravity used in the alcohol industry.
SIMMER (WARN)	The condition just prior to opening at which a spring-loaded relief valve is at the point of having zero or negative forces holding the valve closed. Under these conditions, as soon as the valve disc attempts to rise, the spring constant develops enough force to close the valve again.
SMART FIELD DEVICE	A smart field device is a microprocessor-based process transmitter or actuator that supports two-way communications with a host, digitizes the transducer signals, and digitally corrects its process variable values to improve system performance. The value of a smart field device lies in the quality of data it provides.
SPECIFIC HUMIDITY	The ratio of the mass of water vapor to the mass of dry gas in a given volume.
SPECIFIC VISCOSITY	Ratio of absolute viscosity of a fluid to that of a standard fluid, usually water, both at the same temperature.
SPECTRAL EMISSIVITY	The ratio of emittance at a specific wavelength or very narrow band to that of a blackbody at the same temperature.
START-TO-LEAK PRESSURE	The pressure at the valve inlet at which the relieved fluid is first detected on the downstream side of the seat before normal relieving action takes place.
STICTION	Combination of sticking and slipping when stroking a control valve.
STOKE	Unit of kinematic viscosity, υ (cm^2/sec).
STRESS	Force/area (F/A).
SUBCHANNEL	In broadband terminology, a frequency-based subdivision creating a separate communication channel.
SUPERIMPOSED BACKPRESSURE	Variable backpressure that is present in the discharge header before the pressure relief valve starts to open. It can be constant or variable, depending on the status of the other PRVs in the system.
SWITCHED HUB	A multiport bridge joining networks into a larger network.
TEFLON®, TFE, FEP, AND PFA	Most people interchange the name Teflon with TFE. This is *completely* incorrect but understandable. TFE was the first fluorocarbon polymer to carry the trade name “Teflon” at E.I. DuPont. Dupont chose to use the Teflon trade name for a whole *family* of fluorocarbon resins, so FEP and PFA made by Dupont are also called Teflon. To complicate the matter, other companies now manufacture TFE, FEP, and PFA, which legally cannot be called Teflon, because that name applies only to DuPont-made polymers.
THERMOPILE	A device that measures thermal radiation by absorption to become hotter than its surroundings. It is a number of small thermocouples arranged like the spokes of a wheel with the hot junction at the hub. The thermocouples are connected in series, and the output is based on the difference between the hot and cold junctions.
TRALLES DEGREE	A unit of specific gravity used in the alcohol industry.
THROUGHPUT	The maximum number of transactions per second that can be communicated by the system.
TIME DOMAIN REFLECTOMETER (TDR)	An instrument that measures the electrical characteristics of wideband transmission systems, subassemblies, components, and lines by feeding in a voltage step and displaying the superimposed reflected signals on an oscilloscope equipped with a suitable time-base sweep.
TIMEOUT	An event that occurs when one network device expects to hear from another network device within a specified period of time but does not. The resulting timeout

	usually results in a retransmission of information or the dissolving of the session between the two devices.
TOPOLOGY	(1) Physical arrangement of network nodes and media within an enterprise networking structure. (2) The surface features of an object—"how it looks" or its texture; a direct relation between these features and the material's properties (hardness, reflectivity, etc.).
TOTAL EMISSIVITY	The ratio of the integrated value of all spectral emittance to that of a blackbody.
TRANSISTOR	A three-terminal, solid state electronic device made of silicon, gallium arsenide, or germanium and used for amplification and switching in circuits.
TRANSMITTANCE OR TRANSMISSIVITY (T)	The percentage of the total radiant energy falling on a body that passes directly through it without being absorbed. Transmittance is zero for a blackbody and nearly 100 percent for a material such as glass in the visible spectrum region. ($T = 1 - A - R$, where A is the absorbance and R is the reflectance.)
TWADDELL DEGREE	A unit of specific gravity used in the sugar, tanning, and acid industries.
TWO-COLOR PYROMETER	A device that measures temperature as a function of the radiation ratio emitted around two narrow wavelength bands. Also called a *ratio pyrometer.*
UPPER EXPLOSIVE LIMIT (UEL)	The highest concentration of gas or vapor in air in which a flame will continue to burn after the source of ignition has been removed.
VARACTOR	A voltage-sensitive capacitor.
VARIABLE BACKPRESSURE	Backpressure that varies as a result of changes in operation of one or more pressure-relief valves connected into a common discharge header.
VELOCITY GRADIENT (SHEAR)	Rate for change of liquid velocity across the stream—V/L for linear velocity profile, dV/dL for nonlinear velocity profile. Units are V–L = ft/sec/ft = sec^{-1}.
VELOCITY HEAD	The velocity head is calculated as $v^2/2\,g$, where v is the flowing velocity, and g is the gravitational acceleration (9.819 m/s^2 or 32.215 ft/s^2 at 60° latitude).
WAVEGUIDE	A device that constrains or guides the propagation of electromagnetic waves along a path defined by the physical construction of the waveguide; includes ducts, a pair of parallel wires, and coaxial cable.
WIDEBAND (TOTAL) PYROMETER	A radiation thermometer that measures the total power density emitted by the material of interest over a wide range of wavelengths.
WOBBE INDEX	AGA 4A defines the Wobbe index as a numerical value that is calculated by dividing the square root of the relative density (a key flow orifice parameter) into the heat content (or BTU per standard cubic foot) of the gas. Mathematically, the Wobbe index is defined by the equation below: $\mathrm{WI} = \mathrm{CV}/\sqrt{\mathrm{SQ}}$ where: WI = the Wobbe index CV = the calorific value SG = the specific gravity

ABBREVIATIONS, NOMENCLATURE, ACRONYMS, AND SYMBOLS

2D	two-dimensional
3D	three-dimensional

A

a	acceleration
A	(1) area; (2) ampere, symbol for basic SI unit of electric current; (3) admittance
Å	angstrom (= 10^{-10} m)
AA	atomic absorption
AAS	atomic absorption spectrometer
abs	absolute (e.g., value)
AC	alternating current
ACFM	actual cubic feet per minute; volumetric flow at actual conditions in cubic feet per minute (= 28.32 alpm)
ACL	asynchronous connectionless
ACMH	actual cubic meters per hour
ACMM	actual cubic meters per minute
ACS	analyzer control system
ACSL	advanced continuous simulation language
A/D	analog to digital, also analog-to-digital converter
AD	actuation depth
ADC	analog-to-digital converter
ADIS	approved for draft international standard circulation
A&E	alarm and event
AES	atomic emission spectrometer
AF, a-f	audio frequency
AFD	adjustable frequency drive
AGA3	American Gas Association Report No. 3
ai	Adobe Illustrator®
AI	analog input
a(k)	white noise
ALARA	as low as reasonably achievable
ALARP	as low as reasonably practicable
alpm	actual liters per minute
alt	altitude
AM	amplitude modulated or actual measurement
amp	ampere; also A
AMPS	advanced mobile phone system
AMS	asset management solutions or analyzer maintenance solutions
AO	analog output
AOTF	acousto-optical tunable filters
AP	access point
APC	automatic process control
APDU	application (layer) protocol data unit
API	application programming interface or absolute performance index
°API	API degrees of liquid density
APM	application pulse modulation
AR	autoregressive
ARA	alarm response analysis
ARIMA	autoregressive integrated moving average
ARP	address resolution protocol
ASCII	American Standard Code for Information Interchange
AS-i	actuator sensor interface
ASIC	application-specific integrated circuit
ASK	amplitude shift keying
asym	asymmetrical; not symmetrical
ATG	automatic tank gauging
atm	atmosphere (= 14.7 psi)
ATP	adenosine triphosphate
ATR	attenuated total reflectance
AUI	attachment unit interface
aux	auxiliary
AWG	American wire gauge

B

b	dead time
°Ba	balling degrees of liquid density
bar	(1) barometer; (2) unit of atmospheric pressure measurement (= 100 kPa)
barg	bar gauge
bbl	barrels (= 0.1589 m^3)
BCD	binary coded decimal
BCS	batch control system

°Bé	Baumé degrees of liquid density
BFO	beat frequency oscillator
BFW	boiler feedwater
bhp	brake horsepower (= 746 W)
°Bk	Barkometer degrees of liquid density
blk	black (wiring code color for AC “hot” conductor)
BMS	burner management system
BOD	biochemical oxygen demand
bp, b.p.	boiling point
BPCS	basic process control system
BPS, b/sec	bits per second
BPSK	binary phase shift keying
Bq	becquerel, symbol for derived SI unit of radioactivity, joules per kilogram, J/kg
°Br	Brix degrees of liquid density
Btu	British thermal unit (= 1054 J)
BWG	Birmingham wire gauge
B2B	business to business

C

c	(1) velocity of light in vacuum (3 × 10^8 m/s); (2) centi, prefix meaning 0.01
C	coulombs, symbol for discharge coefficient, capacitance
°C	Celsius degrees of temperature
ca.	*circa* (about, approximately)
CAC	channel access code
CAD	computer aided design
Cal	calorie (gram = 4.184 J); also g-cal
CAN	control area network or control and automation network
CARI	combustion air requirement index
CATV	community antenna television (cable)
cc	cubic centimeter (= 10^{-6} m^3)
CCD	charge-coupled device
CCF	common cause failure or combination capacity factor
Ccm	cubic centimeter per minute
CCR	central control room
Ccs	constant current source
CCS	computer control system or constant current source
CCTV	closed circuit television
CCW	counterclockwise
CD	dangerous coverage factor
cd	candela, symbol for basic SI unit of luminous intensity
CD	compact disk or collision detector
CDDP	cellular digital data packet
CDF	cumulative distribution function
CDMA	code division multiple access
CDPD	cellular digital packet data
CDT	color detection tube
CDTP	cold differential test pressure
CEMS	continuous emissions monitoring system
CENP	combustion engineering nuclear power
CE	Conformité Européne (European Conformity), applicable to electrical safety
CFA	Continuous flow analyzer
CFM, cfm, ft^3/min	cubic feet per minute (28.32 lpm)
CFR	Code of Federal Regulations
CF/yr	cubic foot per year
Ci	curie (= 3.7 × 1010 Bq)
CI	cast iron
CIM	computer integrated manufacturing
CIP	computer aided production or control and information protocol (an application layer protocol supported by DeviceNet, ControlNet, and Ethernet/IP)
CJ	cold junction
CIP	clean in place
CL1	electrically hazardous, Class 1, Division 1, Groups C or D
CLD	chemiluminescence detector
CLP	closed-loop potential factor
cm	centimeter (= 0.01 m)
CM	condition monitoring or communication (interface) module
CMF	Coriolis mass flowmeter
CMMS	computerized maintenance management system
CMPC	constrained multivariable predictive control
cmph, m^3/h	cubic meter per hour
CNI	ControlNet International
CO	controller output or carbon monoxide
CO_2	carbon dioxide
CO_2D	carbon dioxide demand
COD	chemical oxygen demand
COF	coefficient of haze
COM	component object model
COTS	commercial off-the-shelf
cpm	cycles per minute; counts per minute
Co	cobalt
cos	cosine (trigonometric function)
cp, c.p.	(1) candle power, (2) circular pitch, (3) center of pressure (cp and ctp sometimes are used for centipoise)
cps	(1) cycles per second (hertz, Hz); (2) counts per second; (3) centipoise (= 0.001 Pa·S)
CPS	computerized procedure system
CPU	central processing unit
CPVC	chlorinated polyvinyl chloride
CR	corrosion rate
CRC	cyclical redundancy check or cyclic redundancy code. (An error detection coding technique based on modulo-2 division. Sometimes misused to refer to a block check sequence type of error detection coding.)
CRDS	cavity ring-down spectroscopy

CRLF	carriage return-line feed
CRT	cathode ray tube
Cs	cesium
CS	carbon steel
CSL	car seal lock
CSMA/CD	carrier sense, multiple access with collision detection
CSO	car seal open
CSS	central supervisory station
cSt	centistoke
CSTR	continuous-stirred tank reactor
CT	cooling tower or the product of C for disinfectant concentration and T for time of contact in minutes
CTDMA	concurrent time domain multiple access
CTMP	chemi-thermo-mechanical pulp
CVAAS	cold vapor atomic absorption spectroscopy
CVF	circular variable filters
cvs	comma-separated variables
CW	clockwise

D

d	(1) derivative, (2) differential as in dx/dt, (3) deci, prefix meaning 0.1, (4) depth, (5) day
D	diameter; also dia and ϕ or derivative time of a controller
DA	data access
D/A	digital-to-analog
DAC	device access code
DACU	data acquisition and control unit
DAE	differential algebraic equation
DAMPS	digital advanced mobile phone system
dB	decibels
DBB	double-block and bleed
DBPSK	differential binary phase shift keying
DC	diagnostic coverage
DC, dc	direct current
DCE	data communications equipment
DCOM	distributed COM
DCS	distributed control system
DD	data definition or dangerous component failure is detected in leg or a device description written using DDL
D/DBP	disinfectants/disinfection byproducts
DDC	direct digital control
DDE	dynamic data exchange
DDL	device description language (an object-oriented data-modeling language currently supported by PROFIBUS, FF, and HART)
deg	degree; also ° ($\pi/180$ rad)
DES	data encryption standard
DFIR	diffused infrared
DFR	digital fiber-optic refractometer
DFT	digital Fourier transform
DH	data highway
DI	discrete (digital) input
dia	diameter; also, D and ϕ
DIAC	dedicated inquiry access code
DIR	diffused infrared
DIS	draft international standard
DIX	Digital-Intel-Xerox (DIX is the original specification that created the *de facto* Ethernet standard. IEEE 802.3 came later, after Ethernet was established.)
d(k)	unmeasured disturbance
D(k)	measured disturbance
DLE	data link escape
DLL	dynamic link library
DMA	dynamic mechanical analyzer
DMM	digital multimeter
DN	diameter normal, the internal diameter of a pipe in rounded millimeters
DO	dissolved oxygen or discrete (digital) output
DOAS	differential optical absorption spectroscopy
d/p cell	differential pressure transmitter (a Foxboro trademark)
DPD	*N*,*N*-diethyl-*p*-phenylenediamine
DPDT	double-pole double-throw (switch)
dpi	dots per inch
DQPSK	differential quadrature phase shift keying
DSL	digital subscriber line
DSP	digital signal processing
DSR	direct screen reference
DSSS	direct sequence spread spectrum
DT	dead time (second or minutes)
DTC	digital temperature compensation
DTE	data terminal equipment
DTGS	deuterated tryglycine sulfate
DTM	device type manager (An active-X component for configuring an industrial network component. A DTM “plugs into” an FDT.)
DU	dangerous component failure occurred in leg, but undetected
DVM	digital voltmeter

E

e	(1) error, (2) base of natural (Naperian) logarithm, (3) exponential function; also exp (–*x*) as in e^{-x}
E	(1) electric potential in volts, (2) scientific notation as in $1.5E - 03 = 1.5 \times 10^{-3}$
E{.}	expected value operator
EAI	enterprise application integration
EAM	enterprise asset management
EBCDIC	extended binary code for information interchange
EBR	electronic batch records
ECD	electron capture detector
ECKO	eddy-current killed oscillator
ECN	effective carbon number

ECTFE	ethylene chloro-tetra-fluoro-ethylene (Halar)
EDS	electronic data sheet (DeviceNet)
EDTA	ethylenediaminetetraacetic acid
EDXRF	energy dispersive x-ray fluorescence
E/E/PE	electrical/electronic/programmable electronic
E/E/PES	electrical/electronic/programmable electronic system
EFD	engineering flow diagram
e.g.	*exempli gratia* (for example)
EHC	electrohydraulic control
EHM	equipment health management
e(k)	feedback error
E.L.	elastic limit
Emf, EMF	(1) electromotive force (volts), (2) electromotive potential (volts)
EMI	electromagnetic interference
EMI/RFI	electromagnetic interference/radio frequency interference
em(k)	process/model error
EN	European standard
EPA	enhanced performance architecture, Environmental Protection Agency
EPC	engineering-procurement-construction (firm or industry)
EPCM	engineering, procurement, and construction management (companies)
EPDM	ethylene propylene diene terpolymer
EPS	electronic pressure scanner, Encapsulated PostScript file or emergency power supply
EQ, eq	equation
ERM	enterprise resource manufacturing
ERP	enterprise resource planning, effective radiated power
ERW	electric-resistance welded
ESD	emergency shutdown (system), electrostatic discharge
ESN	electronic serial number
ETFE	ethylene-tetrafluoroethylene copolymer (Tefzel®)
ETS	equivalent time sampling
Exp	exponential function as in exp (– at) = e^{-at}; also e

F

F	frequency (also freq.)
F	farad, symbol for derived SI unit of capacitance, ampere-second per volt, A·s/V
°F	degrees Fahrenheit [t°C = (t°F − 32)/1.8]
FAT	factory acceptance testing
FBAP	function block application process (FF)
FBD	function block diagram
FBG	fiber bragg grating
FC	flow controllers
FCC	fluid catalytic cracking unit
FCOR	filtering and correlation (method)
FCS	frame check sequence
FDE	fault disconnection electronics
FDL	fieldbus data link
FDMA	frequency division multiple access
FDS	flame-detection system
FDT	field device tool (a Windows®-based Microsoft framework for engineering and configuration tools)
FE	final elements
FEED	front end engineering and design
FEGT	furnace exit gas temperature
FEP	fluorinated ethylene propylene
FES	fixed end system
FF-HSE	Foundation Fieldbus, high-speed Ethernet
FFT	fast Fourier transform
FH	frequency hopping
Fhp	fractional horsepower (e.g., 1/4-hp motor)
FHSS	frequency hopped spread spectrum
FI	flow indicator
FIA	flow injection analyzer
FIC	flow indicator controller
FID	flame ionization detector
FIE	flame ionization element
FIFO	first-in, first-out
Fig.	figure
FISCO	fieldbus Intrinsic Safety COncept
fl.	fluid
fl. oz.	fluid ounce (= 29.57 cc)
FM	frequency modulated
FMCW	frequency modulated carrier wave
FMEA	failure mode and effects analysis
FMEDA	failure modes, effects and diagnostic analysis
FMS	fieldbus message specification or fieldbus messaging services/system
FO	fiber optic or fail open
FOP	fiber-optic probe
FOV	field of view
fp, f.p.	freezing point
FPC	fine particle content
FPD	flame photometric detector
FPM, fpm, ft/min	feet per minute (= 0.3048 m/m)
fps, ft/s	feet per second (= 0.3048 m/s)
FRC	flow recording controller
FRM	frequency response method
FS, fs	full scale
FSC	fail safe controller
FSD	full scale deflection
FSK	frequency shift keying
FT	Fourier transform
FTA	fault tree analysis
FTIR	Fourier transform infrared
FTNIR	Fourier near infrared
FTP	file transfer protocol
FTS	fault-tolerant system
FTU	formazin turbidity unit

G

g	acceleration resulting from gravity (= 9.806 m/s^2) or conductivity
G	giga, prefix meaning 10^9, or process gain or conductance
gal	gallon (= 3.785 liters)
GB	gigabyte, 1,000,000,000 bytes
GbE	gigabit Ethernet
gbps, GBPS	gigabits per second
G_c	feedback controller transfer function
GC	gas chromatograph
g-cal	gramcalorie, see also cal
G_d	unmeasured disturbance transfer function
GD	measured disturbance transfer function
GD	approximate feedforward transfer function model
GEOS	geosynchronous Earth orbit satellite
G_{ff}	feedforward controller transfer function
GFC	gas filter correlation
GHz	gigahertz
GIAC	general inquiry access code
GLR	gas-to-liquid ratio
G-M	Geiger-Mueller tube, for radiation monitoring
G_m	model transfer function
GMR	giant magneto resistive
GPH, gph, gal/h	gallons per hour (= 3.785 lph)
G_p	process transfer function
GPM, gpm, gal/min	gallons per minute (= 3.785 lpm)
GPS	global positioning satellite, global positioning system
g	gram
grn	green (wiring code color for grounded conductor)
GSC	gas-solid chromatography
GSD	Profibus version of an electronic data sheet
GUI	graphical user interface
GWR	guided wave radar
Gy	gray, symbol for derived SI unit of absorbed dose, joules per kilogram, J/kg

H

h	(1) height, (2) hour
H	(1) humidity expressed as pounds of moisture per pound of dry air; (2) henry, symbol of derived SI unit of inductance, volt-second per ampere, V·s/A
H1	field-level fieldbus; also refers to the 31.25 kbps intrinsically safe SP-50, IEC61158–2 physical layer
HAD	historical data access
H&RA	hazard and risk analysis
HART	highway addressable remote transducer
HAZOP	HAZard and OPerability studies
HC	horizontal cross-connect
HCN	hydrogen cyanide
HEC	header error check
HF	hydrogen fluoride or hydrofluoric acid
HFE	human factors engineering
HFT	hardware fault tolerance
hhv	higher heating value
HIPS	high-integrity protection systems
HIPPS	high-integrity pressure protection system
HIST	host interface system test
HMI	human-machine interface
HMSD	hexamethyldisiloxane
hor.	horizontal
HP, hp	horsepower (U.S. equivalent is 746 W)
HPLC	high-pressure (or high-precision) liquid chromatography
HSE	high-speed Ethernet (host-level fieldbus)
HSI	human system interface
HTG	hydrostatic tank gauging
HTML	hypertext markup language
HTTP	hypertext transfer protocol
HVAC	heating, ventilation, and air conditioning
H/W	hardware
HWD	height, width, depth
Hz	hertz, symbol for derived SI unit of frequency, one cycle per second (l/s)

I

I	integral time of a controller in units of time/repeat
IA	instrument air
IAC	inquiry access code
IAE	integral of absolute error
I&C	instrumentation and control or information and control
I&E	instrument and electrical
IAQ	indoor air quality
ibidem	in the same place
IC	integrated circuit, intermediate cross-connect, or inorganic carbon
ICA	independent computing architecture
ICCMS	inadequate core cooling monitoring system
ICMP	internet control message protocol
ICP	inductively coupled plasma
ID	inside diameter
i.e.	*id est* (that is)
IEH	*Instrument Engineers' Handbook*
IETF	Internet engineering task force
IIS	Internet information server
IL	instruction list
ILD	instrument loop diagrams
IMC	internal model control
iMEMS	integrated microelectromechanical system
in.	inch (= 25.4 mm)

InGaAs	iridium gallium arsenide
in-lb	inch-pound (= 0.113 N × m)
I/O	input/output
I-P	current-to-pressure conversion
IP	Internet protocol or ionization potential
IPA	isopropyl alcohol
IPL	independent protection layer
IPTS	international practical temperature scale
IR	infrared
IS	intermediate system
ISAB	ionic strength adjustment buffer
ISE	integral of squared error or ion selective electrode
ISFET	ion-selective field-effect transistor
ISM	industrial, scientific, medical
ISP	Internet service provider or interoperable system provider
IT	information technology (as in IT manager or IT department)
ITAE	integral of absolute error multiplied by time
ITSE	integral of squared error multiplied by time
ITT	intelligent temperature transmitters
JTU	Jackson turbidity unit
IXC	interexchange carrier

J

J	joule, symbol for derived SI unit of energy, heat or work, Newton-meter, N·m
JIT	just-in-time (manufacturing)

K

k	kilo, prefix meaning 1000
K	coefficient, also dielectric constant
K	Kelvin, symbol for SI unit of temperature or process gain (dimensionless), not used with degree symbol
kbs, kbps, kb/sec	kilobits per second
kBps, kB/sec	kilobytes per second
k-cal	kilogram-calories (= 4184 J)
kg	kilogram symbol for basic SI unit of mass
kg-m	kilogram-meter (torque, = 7.233 foot-pounds)
KHP	potassium acid phthalate
kip	1000 pounds (= 453.6 kg)
km	kilometers
KOH	potassium hydroxide
K_p	proportional gain of a PID controller
kPa	kilopascal
kVA	kilovolt-amperes
kW	kilowatts
KWD	kilowatt demand
kWh	kilowatt-hours (= 3.6×10^6J)

L

l	liter (= 0.001 m^3 = 0.2642 gal), also L
L	(1) length, (2) inductance, expressed in henrys
L2F	laser two-focus anemometer
Lab	CIE functions for lightness, red/green, blue/yellow
LAN	local area network
LAS	link active scheduler (FF)
lat	latitude
lb	pound (= 0.4535 kg)
LC	level controller or liquid chromatography
LCD	liquid crystal display
Lch	CIE functions for lightness, chroma, hue
LCM	life cycle management
LCSR	loop current step response
LD	ladder diaphragm
LDA	laser Doppler anemometer
LDP	large display panel
LEC	local exchange carrier or lower explosive limit
LED	light-emitting diode
LEL	lower explosive limit
LEOS	low Earth orbit satellites
LF	linear feet
LGR	liquid-to-gas ratio
LI	level indicator
LIC	level indicator controller
LIDAR	laser induced doppler absorption radar or light detection and ranging
lim	limit
lin	linear
liq	liquid
LLC	logical link control
lm	lumen, symbol for derived SI unit of luminous flux, candela-steradian, cd·sr
ln	Naperian (natural) logarithm to base e
LNG	liquefied natural gas
LO	lock open
LOC	limiting oxygen concentration
log, $\log_{10}$	logarithm to base 10; common logarithm
LOI	local operation interface
long.	longitude
LOPA	layers of protection analysis
LOS	line of sight
LP or LPG	liquefied petroleum or propane gas
LPC	large particle content
LPG	liquefied petroleum gas
lph	liters per hour (0.2642 gph)
lpm	liters per minute (0.2642 gpm)
LPR	linear polarization resistance
LQG	linear quadratic Gaussian
LRC	longitudinal redundancy check or level recording controller
LRL	lower range limit
LRV	lower range value

LTI	linear time-invariant
LVDT	linear variable differential transformer
LVN	limiting viscosity number
lx	lux, symbol for derived SI unit of illuminance, lumen per square meter, lm/m^2

M

m	(1) meter, symbol for basic SI unit of length, (2) milli, prefix meaning 10^{-3}, (3) minute (temporal) (also min)
M	(1) 1000 (in commerce only), (2) mach number, (3) molecular weight; mole; (4) mega, prefix meaning 10^6
mA	milliampere (= 0.001 A)
MAC	medium access control
MACID	medium access control identifier
MAE	minimum absolute error
MAOP	maximum allowable operating pressure
MAP	manufacturing automation (access) protocol
MAU	media access unit
MAWP	maximum allowable working pressure
max.	maximum
Mb	megabit, 1,000,000 bits
MB	megabyte, 1,000,000 bytes
Mbps, Mb/sec	megabits per second
MBps, MB/sec	megabytes per second
MC	main cross-connect
mCi, mC	millicuries (= 0.001 Ci)
m.c.p.	mean candle power
MCR	main control panel
MCT	mercury cadmium telluride
MDBS	mobile data base station
MDIS	mobile data intermediate system
m/e	mass-to-energy ratio
med.	medium or median
MEDS	medium Earth orbit satellite
MEMS	microelectromechanical system
m.e.p.	mean effective pressure
MES	manufacturing execution system or mobile end station
MeV	mega-electron volt
MFD	mechanical flow diagram
MFE	magnetic flux exclusion
mfg	manufacturer or manufacturing
mg	milligrams (= 0.001 g)
mho	outdated unit of conductance, replaced by siemens (S)
mi	mile (= 1.609 km)
MI	melt index
MIB	management information base
micro	prefix meaning 10^{-9}; also μ (mu); sometimes (incorrectly) u, as in ug to mean μg [both meaning microgram (= 10^{-9} kg)]
micron	micrometer (= 10^{-6} m) (term now considered obsolete)
MIE	minimum ignition energy
MIMO	multiple-input, multiple-output
MIMOSA	machinery information management open system alliance
min.	(1) minute (temporal), also m, (2) minimum, (3) mobile identification number
MIR	multiple internal reflection
MIS	management information system
ml	milliliter (= 0.001 l = 1 cc)
MLR	multiple linear regression
mm	millimeter (= 0.001 m) or millimicron (= 10^{-9} m)
mmf	magnetomotive force in amperes
MMI	man-machine interface
mmpy	millimeters per year
MMS	machine monitoring system or manufacturing message specification
MOC	management of change
MODEM	modulator/demodulator
MON	motor octane number
MOS	metal oxide semiconductor
MOSFET	metallic oxide semiconductor field-effect transistor
mol	mole, symbol for basic SI unit for amount of substance
mol.	molecule
MOON	M out of N voting system
mp, m.p.	melting point
MPa	megapascal (10^6 Pa)
MPC	model predictive control
MPFM	multiphase flowmeter
mph, MPH, mi/h	mile per hour (1.609 km/h)
mps, m/s	meters per second
MPS	manufacturing periodic/aperiodic services
mpy	mills per year
mR	milliroentgen (= 0.001 R)
mrd	millirad (= 0.001 rd)
mrem	milliroentgen-equivalent-man
MRP	material requirement planning or manufacturing resource planning
ms, msec	millisecond (= 0.001 s)
MS	mass spectrometer, Microsoft®
MSA	metropolitan statistical areas
MSB	most significant bit
MSD	most significant digit
MSDS	material safety data sheet
MT	measurement test
MTBE	methyl tertiary butyl ether
MTBF	mean time between failures
MTSO	mobile telephone switching office
MTTF	mean time to failure
MTTFD	mean time to fail dangerously
MTTFS	mean time to spurious failure
MTTR	mean time to repair
MTU	master terminal unit

MVC	minimum variance controller
MW	megawatt (= 10^6 W)
MWC	municipal waste combustors
MWD	molecular weight distribution

N

N	Newton, symbol for derived SI unit of force, kilogram-meter per second squared, $kg \cdot m/s^2$
n	(1) nano, prefix meaning 10^{-6}, (2) refractive index
N_0	Avogadro's number (= 6.023×10^{23} mol^{-1})
N-16	nitrogen-16
NAAQS	national ambient air quality standards
NAP	network access port/point
NAT	network address translation
NB	nominal bore, internal diameter of a pipe in inches
NC, N/C	normally closed (switch contact)
NC	numeric controller
NDIR	nondispersive infrared
NDM	normal disconnect mode
NDT	nondestructive testing
NEC	National Electrical Code
NESC	National Electrical Safety Code
NEXT	near-end crosstalk
NIC	network interface card
NIP	normal incident pyrheliometer
NIR	near infrared
nm	nanometer (10^{-9} m)
NMR	nuclear magnetic resonance
NO, N/O	normally open (switch contact)
NPS	nominal pipe size, the internal diameter of a pipe in inches
NRM	normal response mode
NRZ	non-return to zero (refers to a digital signaling technique)
NS	nominal pipe size, the internal diameter of a pipe in inches
NTC	negative temperature coefficient
NTP	network time protocol or normal temperature and pressure corresponding to 1 atm absolute (14.7 psia) and 0°C (32°F)
NTSC	National Television Standards Code
NTU	nephalometric turbidity unit
NUT	network update time

O

OCD	orifice-capillary detector
OD	outside diameter or oxygen demand
ODBC	open database connectivity or communication
OES	optical emission spectrometer
oft, OFT	optical fiber thermometry
ohm	unit of electrical resistance; also Ω (omega)
OJT	on-the-job training
OLE	object linking and embedding
OLE_DB	object linking and embedding data base
OMMS	optical micrometer for micromachine
ON	octane number
OPC	object link embedding (OLE) for process control
OP-FRIR	open path Fourier-transform infrared
OP-HC	open-path hydrocarbon
OP-TDLAS	open-path tunable diode-laser absorption spectroscopy
OP-UV	open-path ultraviolet
or	orange (typical wiring code color)
ORP	oxidation-reduction potential
OS	operator station or operating system
OSFP	open shortest path first
OSI	open system interconnect (model)
OSI/RM	open system interconnect/reference model
OT	operator terminal or open tubular
OTDR	optical time domain
oz	ounce (= 0.0283 kg)

P

P&ID	piping and instrumentation diagram
p	(1) pressure; (2) pico, prefix meaning 10^{-12} (3) variable for resistivity
Pa	pascal, symbol for derived SI unit of stress and pressure, Newtons per square meter, N/m^2
PA	plant air
PAC	path average concentration
PAL	phase alternating line
PAN	personal area network
P&ID	piping (process) and instrumentation diagram (drawing)
Pas, Pa·s	pascal-second, a viscosity unit
PAS	process automation system (successor to DCS)
PB	proportional band of a controller in percent (100%/controller gain)
PC	personal computer (usually Microsoft Windows®-based) or pressure controller
PCA	principal component analysis
PCCS	personal computer control system
PCDD	polychlorinated dibenzo-*p*-dioxine
PCDF	polychlorinated dibenzo furans
PCR	principal component regression
PCS	process control system or personal communication services
pct	percent; also%
PCTFE	polychlorotrifluoroethylene
PCV	pressure control valve
PD	positive displacement or proportional and derivative
PDA	personal digital assistant or photodiode array
PDD	pulsed discharge detector

PDF	probability density function, probability of failure or portable document file
PDS	phase difference sensor
PDU	protocol data unit
PDVF	polyvinylidene fluoride
PE	polyethylene
PED	pressure equipment directive
PEEK	poly ether ether ketone
PEL	permissible exposure level
PES	programmable electronic system
PFA	per-fluoro-alkoxy copolymer
PFC	procedure functional chart
PFD	process flow diagram
PdM	predictive maintenance
pF	picofarad (= 10^{-12} F)
PF, p.f.	power factor
PFA	perfluoralkoxy (a form of Teflon)
PFD	process flow diagram
PFD	probability of failure on demand
PFDavg	average probability of failure on demand
PFPD	pulsed flame photometric detector
PGNAA	prompt gamma neutron activation analysis
PGC	process gas chromatograph
pH	acidity or alkalinity index (logarithm of hydrogen ion concentration)
PHA	process hazard analysis
pi, pl	Poiseuille, a viscosity unit
PI	proportional and integral, or pressure indicator
P/I	pneumatic to current (conversion)
PIC	pressure indicating controller or path integrated concentration
PID	proportional, integral, and derivative (control modes in a classic controller), or photoionization detector
PI-MDC	path integrated minimum detectable concentration
PIMS	process information management system
PIP	process industry practices
PIR	precision infrared radiometer
PLC	programmable logic controller
PLS	physical layer signaling or partial least squares
PM	photomultiplier
PMA	physical medium attachment
PMBC	process model based control
PMD	photomultiplier detector
PMF	probability mass function
PMMC	permanent magnet moving coil
PMT	photomultiplier tube or photometer tube
POPRV	pilot-operated pressure relief valve
PP	polypropylene
ppb, PPB	parts per billion
ppm, PPM	parts per million
PPP	point-to-point protocol
ppt	parts per trillion
PRC	pressure recording controller
PRD	pressure relief device
precip	precipitate or precipitated
PRV	pressure relief valve
PS	power supply (module)
PSAT	pre-startup acceptance test
PSD	power spectral density or photosensitive device
PSG	phosphosilicate glass
PSI	pre-startup inspection
psi, PSI, lb/in^2	pounds per square inch (= 6.894 kPa)
PSIA, psia	absolute pressure in pounds per square inch
PSID, psid	differential pressure in pounds per square inch
PSIG, psig	above atmospheric (gauge) pressure in pounds per square inch
PSK	phase shift keying
PSM	process safety management
PSSR	re-startup safety review
PSTN	public switched telephone network
PSU	post-startup
PSV	pressure safety valve
pt	point, part, or pint (= 0.4732 liter)
PTB	Physikalisch-Technische Bundesanstalt
PTC	positive temperature coefficient
PTFE	polytetrafluoroethylene (conventional Teflon)
PUVF	pulsed ultraviolet fluorescence
PV	process variable (measurement) or the HART primary variable
PVC	polyvinyl chloride
PVDF	polyvinylidene fluoride
PVLO	process variable low (reading or measurement)
PVHI	process variable high (reading or measurement)
PWM	pulse width modulation
PWR	pressurized water reactor
PZT	lead-zirconate-titanate ceramic

Q

q	(1) rate of flow, (2) electric charge in coulombs, C
q^{-1}	backward shift operator
Q	quantity of heat in joules, J, or electric charge
°Q	Quevenne degrees of liquid density
QA	quality assurance
QAM	quadrature amplitude modulation
QCM	quartz crystal microbalance
QPSK	quadrature phase shift keying
qt	quart (0.9463 l)
QV	quaternary variable

R

r	radius; also rad
r^2	multiple regression coefficient

R	(1) resistance, electrical, in ohms, (2) resistance, thermal, meter-Kelvin per watt, m·K/W, (3) gas constant (= 8.317 × 107 erg·mol^{-1},$°\text{C}^{-1}$), (4) roentgen, symbol for accepted unit of exposure to X and gamma radiation (= 2.58 × 10^{-4} C/kg)
Ra	radium
rad	(1) radius, also r, (2) radian, symbol for SI unit of plane angle measurement or symbol for accepted SI unit of absorbed radiation dose (= 0.01 Gy)
RADAR	radio detection and ranging
RAID	redundant array of inexpensive disks
RAM	random access memory
R&D	research and development
RASCI	responsible for, approves, supports, consults, informed
RCU	remote control unit
RDP	remote desktop protocol
rem	roentgen equivalent man (measure of absorbed radiation dose by living tissue)
rev	revolution, cycle
Re	Reynolds number
Re_D	Reynolds number corresponding to a particular pipe diameter
RF, rf	radio frequency
RFC	request for comment (an Internet protocol specification)
RFF	remote fiber fluorimetry
RFI	radio frequency interference
RFQ	request for quote
RGA	residual gas analyzer
RGB	red, green, blue
RGM	reactive gaseous mercury
RH	relative humidity
RI	refractive index
RIP	routing information protocol
r(k)	set point
RMS, rms	root mean square (square root of the mean of the square) or rotary mirror sleeves
ROI	return on investment
ROM	read-only memory
RON	research octane number
RPC	remote procedure call (RFC1831)
RPM, rpm, r/min	revolutions per minute
RVP	Reid vapor pressure
rps, r/sec	revolutions per second
RRF	risk reduction factor
RRT	relative response time (the time required to remove most of the disturbance)
RS	recommended standard
RSA	rural service areas
RSS	root sum squared
RTD	resistance temperature detector
RTO	real-time optimization or operation
RTOS	real-time operating system
RTR	remote transmission request
RTS	ready (or request) to send
RTS/CTS	request to send/clear to send
RTU	remote terminal unit
RUDS	reflectance units of dirt shade
RV	relief valve
RWS	remote workstation

S

s	second (also sec), symbol for basic SI unit of time; also Laplace variable
S	siemens (siemens/cm), symbol for unit of conductance, amperes per volt, A/V
s^2y	sample variance of output y
SAP	service access point
sat.	saturated
SAT	site acceptance test or supervisory audio tone
SAW	surface acoustic wave
SC	system codes
SCADA	supervisory control and data acquisition
SCCM	standard cubic centimeter per minute
SCD	streaming current detector
SCFH	standard cubic feet per hour
SCCM	standard cubic centimeter per minute
SCD	sulfur chemilumenesce detector
SCE	saturated calomel electrode
SCFH	standard cubic feet per hour
SCFM	standard cubic feet per minute (air flow at 1.0 atm and 70°F)
SCM	station class mark
SCMM	standard cubic meters per minute
SCO	synchronous connection oriented
SCOT	support coated open tubular (column)
SCR	silicon-controlled rectifier
SCS	sample control system
SD	component in leg has failed safe and failure has been detected
SDIU	Scanivalve digital interface unit
SDN	send data with no acknowledgement
SDS	smart distributed system
SEA	spokesman election algorithm
sec	second, also s
SER	sequence of event recorder
SFC	sequential function chart
SFD	system flow diagram or start of frame delimiter
SFF	safe failure fraction
SFI	sight flow indicator
SFR	spurious failure rate
S.G.	specific gravity, also sp. gr.
SHE	standard hydrogen electrode
SHS	sample handling system
SID	system identification digit (number)
SIF	safety instrumented function
SIG	special interest group

SIL	safety integrity level
sin	sine, trigonometric function
SIS	safety instrumented system
SISO	single-input single output
SG, SpG	specific gravity; also sp. gr.
SIL	safety integrity level
SIS	safety instrumented system
SKU	stock keeping units
SLAMS	state and local air monitoring stations
SLC	safety life cycle
slph	standard liters per hour
slpm	standard liters per minute
SMR	specialized mobile radio
SMTP	simple mail transfer (management) protocol
S/N	signal-to-noise (ratio)
SNG	synthetic natural gas
SNMP	simple network management protocol
SNR	signal-to-noise ratio
SOAP	simple object access protocol (an Internet protocol that provides a reliable stream-oriented connection for data transfer)
SOE	sequence of events
SONAR	sound navigation and ranging
SOP	standard operating procedure
SP	set point
SPC	statistical process control
SPDT	single-pole, double-pole throw (switch)
SPL	sound pressure level or sound power level
SPRT	standard platinum resistance thermometer
SPST	single-pole, single-throw (switch)
sq	square, squared
SQC	statistical quality control
SQL	structured (or standard) query language
Sr	steradian, symbol for SI unit of solid angle measurement
SRD	send and request data with reply
SRS	safety requirements specification
SRV	safety relief valve
SS	stainless steel
SSL	secure socket layers
SSU	Saybolt seconds universal
std.	standard
ST	structural text
STEL	short-term exposure limit
STEP	standard for the exchange of product model data
STP	shielded twisted pair, or standard temperature and pressure, corresponding to 70°F (21.1°C) and 14.7 psia (1 atm abs)
STR	spurious trip rates
SU	security unit or component in leg has failed safe and failure has not been detected
SUS	Seybold universal seconds
SV	secondary variable or safety valve
S/W	software

T

T	(1) ton (metric = 1000 kg), (2) time, (3) thickness
T	(1) temperature, (2) tera, prefix meaning 10^{-12}, (3) period (= 1/Hz, in seconds), (4) tesla, symbol for derived SI unit of magnetic flux density, webers per square meter, Wb/m^2
$T^1/_2$	half life
tan	tangent, trigonometric function
TAS	thallium arsenic selenide
tau, τ	process time constant (seconds)
TBM	tertiary butyl mercaptan
t/c	thermal coefficient of linear expansion
TC	thermocouple, temperature controller, or total carbon
TCD	thermal conductivity detector
TCP	transmission control protocol
TCP/IP	transmission control protocol/internet protocol
TCV	temperature control valve
td	process dead time (seconds)
T_d	derivative time (in seconds) of a PID controller
TDLAS	tunable diode laser absorption spectroscopy
TDM	time division multiplexing
TDMA	time division multiple access
TDR	time domain reflectometry
T/E	thermoelectric
TEM	transmission electron microscope
TG	thermogravimetry
Ti	integral time (in seconds) of a PID controller
TI	time interval between proof tests (test interval), temperature indicator
TIC	temperature indicating controller or total inorganic carbon
TIFF	tagged image file format
TISAB	total ionic strength adjustment buffer
TLV	threshold limit value
TMP	thermomechanical pulp
TMR	triple modular redundancy
TN	total nitrogen
TOC	total organic carbon
TOD	total oxygen demand
TOF	time of flight
TQM	total quality management
TOP	technical and office protocol
TR	temperature recorder
T/R	transmit/receive
TRC	temperature recording controller
T.S.	tensile strength
TTFM	transit time flow measurement
TTP	through the probe
TV	tertiary variable

°Tw	Twaddell degrees of liquid density
TWA	time weighed average

U

u	prefix = 10^{-6}, used incorrectly when the Greek letter μ is not available
UART	universal asynchronous receiver transmitter
UBET	unbiased estimation
UCMM	unconnected message manager
UDP	user/universal data protocol (an Internet protocol with low overhead but no guarantee that communication was successful)
UEL	upper explosive limit
$u_{fb}(k)$	feedback controller output
UFD	utility flow diagram
$u_{ff}(k)$	feedforward controller output
UHF	ultra-high frequency
UHSDS	ultra-high-speed deluge system
u(k)	controller output
UML	universal modeling language
UPS	uninterruptible power supply
UPV	unfired pressure vessel
URL	upper range limit
URV	upper range value
USB	universal serial bus
UTP	unshielded twisted pair
UTS	ultimate tensile stress
UUP	unshielded untwisted pair
UV	ultraviolet
UV-VIS-NIR	ultraviolet-visible-near infrared

V

v	velocity
V	volt, symbol for derived SI units of voltage, electric potential difference and electromotive force, watts per ampere, W/A
Vac	voltage, alternating current
V&V	verification and validation
VBA	Visual Basic for Applications
VDF	vacuum fluorescent display
VDT	video display tube
VDU	video display unit
vert.	vertical
VFD	variable frequency drive
VFIR	very fast infrared
VHF	very high frequency
VIS	visible
V-L	vapor-liquid (ratio)
VLF	very low frequency
V/M	voltmeter
VME	Virsa Module Europa (IEEE 1014–1987)
VMS	vibration monitoring system
VOC	volatile organic compounds
VR	virtual reality
VRML	virtual reality modeling language
vs.	versus

W

w	(1) width, (2) mass flow rate
W	(1) watt, symbol for derived SI unit of power, joules per second, J/s, (2) weight (also wt)
w.	water
WAN	wide area network
Wb	weber, symbol for derived SI unit of magnetic flux, volt-seconds, V·s
WCOT	wall coated open tubular (column)
WDXRF	wavelength dispersion x-ray fluorescence
WG	standard (British) wire gauge
wh	white (wiring code color for AC neutral conductor)
WI	Wobbe index
WLAN	wireless local area network
WPAN	wireless personal area network
WS	workstation
wt	weight, also W

X

X	reactance in ohms
XML	extensible markup language
x-ray	electromagnetic radiation with a wavelength <100 Å
XRF	x-ray fluorescence
XYZ	tristimulus functions

Y

Y	expansion factor
y(k)	process output
yd	yard (= 0.914 m)
yr	year

Z

Z	(1) atomic number (proton number), (2) electrical impedance (complex), expressed in ohms
ZEB	zero energy band

SOCIETIES AND ORGANIZATIONS

AATCC	American Association of Textile Chemists and Colorists
ACC	American Chemistry Council
ACGIH	American Conference of Governmental Industrial Hygenists
ACS	American Chemical Society
AGA	American Gas Association
AIA	Automatic Imaging Association
AIChE	American Institute of Chemical Engineers
AMTEX	American Textile Partnership
ANSI	American National Standards Institute
AOCS	American Oil Chemists Society
APHA	American Public Health Association
API	American Petroleum Institute
ARI	Air Conditioning and Refrigeration Institute
ASA	American Standards Association
ASCE	American Society of Civil Engineers
ASME	American Society of Mechanical Engineers
ASRE	American Society of Refrigeration Engineers
ASTM	American Society for Testing and Materials, or ASTM International
AWWA	American Water Works Association
BSI	British Standards Institution
CARB	California Air Resources Board
CCITT	Consultative Committee for International Telegraphy and Telephony
CENELEC	European Committee for Electrotechnical Standardization
CIE	Commission International del'Eclairage
CII	Construction Industry Institute
CIL	Canadian Industries Limited
CPAC	Center for Process Analytical Chemistry
CSA	Canadian Standards Association
DARPA	Defense Advanced Research Projects Agency
DIERS	Design Institute for Emergency Relief Systems
DIN	Deutsche Institut fuer Normung
DOD	Department of Defense (United States)
DOE	Department of Energy
DOT	Department of Transportation
EIA	Electronic Industries Association
EIA/TIA	Electrical Industries Alliance/Telecommunications Industries Alliance
EPA	Environmental Protection Agency
EPRI	Electric Power Research Institute
EXERA	Association des Exploitants d'Equipements de Mesure, de Régulation et d'Automatisme, an instrument user's association based in France
FCI	Fluid Control Institute
FDA	Food and Drug Administration
FF	Fieldbus Foundation
FIA	Fire Insurance Association
FM	Factory Mutual
FMRC	Factory Mutual Research Corporation
FPA	Fire Protection Association
FSEC	Florida Solar Energy Center
GERG	Groupe Europeen de Recherches GaziSres (European Gas Research Group), Brussels
GRI	Gas Research Institute
HCF	HART Communication Foundation
IAEI	International Association of Electrical Inspectors
ICE	Institute of Civil Engineers
ICEA	Insulated Cable Engineer's Association
IEC	International Electrotechnical Commission
IEEE	Institute of Electrical and Electronic Engineers
IETF	Internet Engineering Task Force
IGT	Institute of Gas Technology
IPTS	International Practical Temperature Scale
IrDA or IRDA	Infrared Data Association
ISA	Instrumentation, Systems, and Automation Society
ISO	International Standards Organization
ISSeP	International Soros Science Education Program
ISTM	International Society for Testing and Materials

ITA	Instrumentation Testing Association
JBF	Japan Batch Forum
JPL	Jet Propulsion Laboratory
KEPRI	Korean Electric Power Research Institute
LCIE	Laboratoire Central des Industries Electriques
LPGA	National LP-Gas Association
MCA	Manufacturing Chemists' Association
NAMUR	Normen-Arbeitsgemeinschaft für Meß-und Regulungstechnik in der Chemischen Industry (German standardization association for process control)
NASA	National Aeronautics and Space Administration
NBFU	National Board of Fire Underwriters
NBS	National Bureau of Standards
NEMA	National Electrical (Equipment) Manufacturers Association
NEPSI	National Supervision and Inspection Center for Explosion Protection and Safety Instrumentation
NFPA	National Fire Protection Association
NIOSH	National Institute of Occupational Safety and Health
NIST	National Institute of Standards and Technology
NRC	Nuclear Regulatory Commission
NSC	National Safety Council
NSPE	National Society of Professional Engineers
OSHA	Occupational Safety and Health Administration
OTS	Office of Technical Services
SAE	Society of Automotive Engineers
SAMA	Scientific Apparatus Manufacturers Association
SIREP	An international instrument user's association based in the United Kingdom
TAPPI	Technical Association of the Pulp and Paper Industry
TIA	Telecommunications Industries Alliance
UL	Underwriters Laboratories, Inc.
USASI	USA Standard Institute
USNRC	U.S. Nuclear Regulatory Commission
WBF	World Batch Forum
WEF	Water Environment Federation
WIB	An international instrument user's association based in the Netherlands

NOTES

1. Whenever the abbreviated form of a unit might lead to confusion, it should not be used, and the term should be written out in full.
2. The values of SI equivalents were rounded to three decimal places.
3. The words "meter" and "liter" are used with their accepted English spelling instead of those in European standards (i.e., metre and litre).

G. PLATT (1982) **B. G. LIPTÁK** (1995) **J. E. JAMISON, A. ROHR** (2003)

The purpose of this section is to help the reader establish a uniform means of depicting and identifying all classes of instruments, instrumentation systems, and functions used for measurement, monitoring, and control. It is done by presenting a designation system of graphic symbols and identification codes.

It must be noted that a significant part of this section has been extracted from the revision work of the ISA** SP5.1 subcommittee, and much of it has been based on draft working documents being utilized at the time of this writing, documents with which one of the authors has been actively involved. Other portions of this section, dealing with certain symbols, graphics, and practical tips, are based on the authors' experience in industry and are not part of the SP5.1 subcommittee's proposed forthcoming revision.

> *A disclaimer to any future ISA standards documents is hereby stated: The reader is cautioned that the draft ISA document that provided much of the information in this section has not been approved as of the time of this writing. It cannot be presumed to reflect the position of ISA or any other committee, society, or group*. The intent is to pass along to the reader the best and latest thinking on this subject at this point in time, although many items are contentious and are ultimately subject to change in the continuously evolving fields of digital control systems and digital data buses.

Another view of flowsheet and piping and instrument diagram (P&ID) symbols and diagrams covered in this section is in terms of practical aspects and practices used by instrumentation and control practitioners in the engineering, procurement, and construction (EPC) industry.

SCOPE**

General

The procedural needs of various users are different, and these differences are recognized, when they are consistent with the objectives of this standard, by providing alternative symbol and identification methods.

A limited number of examples are provided later that illustrate (with the emphasis on digital systems/loops) how to accomplish the following:

a) Design an identification system and construct an identification number
b) Use graphic symbols to construct the following:
    1) Schematic diagrams of instrument devices and functions in monitoring and control loops
    2) Schematic and ladder diagrams of electrical circuits
c) Add information and simplify diagrams

Examples of symbol applications are generally shown as applied in the oil and chemical processing industries as in the original version of this standard, but the principles shown are applicable to most other industries.

Specific applications are to be addressed in greater detail and will be forthcoming in the planned S5.1 (now ANSI/ISA-5.01.01) series of Technical Reports dedicated to the various processing, generating, and manufacturing industries. These will include processes such as continuous and batch chemical, oil, and metal refining, pulp and paper, water and waste treatment, power generation and distribution, and discrete parts manufacturing.

Application to Industries

The proposed revised ISA S5.1 (now ANSI/ISA-5.01.01) standard will be suitable for use in the above-mentioned process industries and in discrete parts manufacturing where the use of control system schematic and functional diagramming is required to describe the relationship with processing equipment and the functionality of measurement and control equipment.

Certain fields, such as astronomy, navigation, and medicine, use very specialized instruments that are different from conventional industrial process instruments. No specific effort was made to have the ISA standard meet the requirements of those fields. However, it is expected that, in certain areas such as control functional diagrams, they will prove applicable for such specialized fields.

**Formerly called the Instrument Society of America.

Application to Work Activities

The proposed revised ISA S5.1 (now ANSI/ISA-5.01.01) standard will be suitable for use whenever reference to measurement and control instrumentation, control device functions, or software applications functions is required for the purposes of symbolization and identification. Such references may be required for the following uses as well as others:

a) Design sketches
b) Teaching examples
c) Technical papers, literature, and discussions
d) Instrumentation system diagrams, loop diagrams, logic diagrams, and functional diagrams
e) Functional descriptions
f) Conceptual drawings: process flow diagrams (PFDs) and utility flow diagrams (UFDs)
g) Construction drawings: engineering flow diagrams (EFDs), mechanical flow diagrams (MFDs), piping and instrument diagrams (P&IDs), and system flow diagrams (SFDs)
h) Specifications, purchase orders, manifests, and other lists
i) Identification and tag numbering of instruments and control functions
j) Installation, operating, and maintenance instructions, drawings, and records

The standard is intended to provide sufficient information to enable anyone with a reasonable amount of process and instrumentation knowledge to understand the methods of measurement and process control.

It is not necessary to possess the detailed knowledge of a specialist in instrumentation and control systems to understand the standard.

Application to Classes of Instrumentation and to Instrument Functions

The symbolism and identification methods provided in the standard are applicable to all classes and types of measurement and control instruments and functions.

The methods can be used for, but are not limited to, describing and identifying the following:

a) Discrete (individual) instruments and their functions
b) Shared display and control functions
c) Distributed control functions
d) Computer control functions
e) Programmable logic controller display and control functions
f) Application software display and control functions

Extent of Loop and Functional Identification

The ISA S5.1 standard (now ANSI/ISA-5.01.01) provides identification codes and methods for the alphanumeric identification of monitoring and controlling loops, instruments, and functions. The user is free to apply additional identification by serial, equipment, unit, area, or plant number or any other additional means required for the unique identification of a loop, instrument, or function.

A unique function identification number shall identify each instrument, its inherent functions, and each configurable function that requires or allows a user-assigned, unique microprocessor or computer address required by a loop.

Extent of Symbolization

The standard provides symbol sets for the graphic depiction of limited or total functionality for instruments and other devices, entire monitor/control loops, or control circuits. The amount of detail to be shown by the use of symbols depends on the purpose and audience for which the document is being prepared.

A sufficient number of symbols should be used to show the functionality of the instrumentation and control loop being depicted. However, it is not considered necessary to provide a symbol for each instrument device and each function within a loop.

Additional construction, fabrication, installation, and operation details of an instrument are better described in a suitable specification, data sheet, drawing, sketch, or other document intended for individuals who require such details.

Inclusion of the New S5.1 Standard (now ANSI/ISA-5.01.01) in User/Owner Documents

This is a new concept in ISA standards at this point in time. Mandatory use of the standard is required by users/owners based on the following statements.

When the latest issue of the standard is included in user/owner's engineering and/or design guidelines or standards by reference and

a) "Without exception," then the standard in its entirety shall be mandatory.
b) "With exceptions," then the parts of the standard:
    1) "Excepted to" shall be fully described and detailed.
    2) "Not excepted to" shall be mandatory.

When a previous issue of the standard is included by reference with or without exception in user/owner's engineering and design guidelines or standards, that standard in part or in its entirety shall be mandatory until such time as the user/owner's guidelines or standards are revised. When the new issue is used as a guide in the preparation of user/owner's guidelines or standards, symbols and letter and symbol meanings different from those in the standard shall be fully described and detailed.

Symbols and the meanings of letters and symbols from previous issues of the S5.1 standard (now ANSI/ISA-5.01.01) that are different from those contained in this new issue may continue to be used, provided that they are fully described and detailed.

DEFINITIONS RELATED TO FLOWCHART DIAGRAM SYMBOLOGY

See statement of permission on page 4.

General

For the purpose of understanding the ISA S5.1 standard (now ANSI/ISA-5.01.01), the following definitions and terminology apply. For a more complete treatment, see ISA-S51.1 and the ISA-S75 series of standards. Terms italicized within a definition are also defined in this clause.

Definitions Related to Flowsheet Symbology

Accessible A feature of a discrete device function or feature of an interactive shared system function or feature that can be used or seen by an operator for the purpose of performing control operations, such as setpoint changes, auto-manual transfer, or on–off operations.

Alarm An indicating instrument that provides a visible and/or audible indication if and when the value (or rate of change value) of a measured or initiating variable is out of limits, has changed from a safe to an unsafe condition, and/or has changed from a normal to an abnormal operating state or condition.

a) Actuation may be by binary switch or function or analog transmitter or function.
b) Indication may be by annunciator panel, flashing light, printer, buzzer, bell, horn, siren, and/or shared graphic display systems.

Analog A signal or device that has no discrete positions or states and changes value as its input changes value. When used in its simplest form, as in “analog signal” as opposed to “binary signal,” the term denotes a continuously varying quantity.

Application software Software specific to a user application that is configurable and in general contains logic sequences, permissive and limit expressions, control algorithms, and other code required to control the appropriate input, output, calculations, and decisions. See also *software*.

Assignable A system feature permitting channeling or directing of a signal from one device to another without the need for changes in wiring either by means of patching, switching, or via keyboard commands to the system.

Auto-manual station A manual loading station or control station that also provides switching between manual and automatic control modes of a control loop. See also *manual loading station*.

Balloon An alternative term for the circular symbol used to denote and identify the purpose of an instrument or function that may contain a tag number. See preferred term, *bubble.*

Behind the panel A location that, in a broad sense, means “not normally accessible to an operator,” such as the rear of an instrument or control panel, an enclosed instrument rack or cabinet, or an instrument rack room within an area that contains a panel.

Binary A signal or device that has only two discrete positions/states and, when used in its simplest form, as in “binary signal” as opposed to “analog signal,” the term denotes an “on–off” or “high–low” state.

Board A freestanding structure consisting of one or more sections, cubicles, or consoles that has groups of discrete (individual) instruments mounted on it, houses the operator–process interface, and is chosen to have a unique designation. See *panel*.

Bubble The preferred term for the circular symbol used to denote and identify the purpose of an instrument or function that may contain a tag number. See alternative term, *balloon.*

Communication link A wire, cable, or transmitter network or bus system that connects dedicated microprocessor-based and computer-based systems so that they share a common database and communicate according to a rigid protocol in a hierarchical and/or peer-to-peer relationship. See also *data link*.

a) Wires or cables may be of twisted pair, coaxial, telephone, or fiber optic construction.
b) Transmitters may be radio, telephone, and/or microwave devices.

Computer control system A system in which all control action takes place within a control computer, such as a mainframe computer or minicomputer, which may be single or redundant.

Computing device Preferred term for a device that performs one or more calculations or logic operations, or both, and transmits one or more resultant output signals. See also *computing relay.*

Computing function A hardware or software function that performs one or more calculations or logic operations, or both, and transmits one or more resultant output signals.

Computing relay Alternative term for a device that performs one or more calculations or logic operations, or both, and transmits one or more resultant output signals. See also *computing device.*

Configurable A term for devices or systems whose functional or communication characteristics can be selected or rearranged through setting of program switches, application software, fill-in-the-blank forms, pull-down menus, entered values or text, or other methods other than rewiring as a means of altering the configuration.

Controller A device having an output that varies to regulate a controlled variable in a specified manner that may be a self-contained analog or digital instrument or may be the equivalent of such an instrument in a shared-control system.

a) An automatic controller varies its output automatically in response to a direct or indirect input of a measured process variable.
b) A manual controller, or manual loading station, varies its output in response to a manual adjustment; it is not dependent on a measured process variable.
c) A controller may be an integral element of other functional elements of a control loop.

Control station A manual loading station that also provides switching between manual and automatic control modes of a control loop. See also *auto-manual station*.
a) The operator interface of a distributed control system may be referred to as a *control station*.

Control valve A device, other than a common, hand-actuated process block valve or self-actuated check valve, that directly manipulates the flow of one or more fluid process streams.
a) The designation "hand control valve" shall be limited to hand-actuated valves that, when used for process throttling, require identification as an instrument or control device.

Converter A device that receives information as one form of an instrument signal and transmits an output signal as another form, such as a current to pneumatic signal converter.
a) An instrument that changes a sensor's output to a standard signal is properly designated as a transmitter and not a converter. Typically, a temperature element (TE) connects to a transmitter (TT) and not to a converter (TY).
b) A converter is sometimes referred to as a *transducer,* a completely general term not recommended for signal conversion.

Data link A wire, cable, or transmitter network or bus system that connects field located devices with dedicated microprocessors so that they share a common database and communicate according to a rigid protocol in a hierarchical or peer-to-peer relationship to other such devices and/or compatible microprocessor-based systems. See also *communication link*.
a) Wire or cable may be of twisted-pair, coaxial, telephone, or fiber optic construction.
b) Transmitters may be radio, telephone, or microwave devices.

Detector A device that is used to detect the presence of something, such as flammable or toxic gases or discrete parts. See also *primary element* and *sensor*.

Device A piece of instrument hardware that is designed to perform a specific action or function, such as a controller, indicator, transmitter, annunciator, or control valve.

Digital A signal or device that generates or uses binary digit signals to represent continuous values or discrete states.

Discrete A term used to describe the following:
a) Signals that have any number of noncontinuous distinct or defined states or positions. Binary signals are a subset. See *binary*.
b) Instruments or devices that have separate or individual entities, such as a single-case controller or recorder.

Distributed control system Instrumentation, input/output devices, control devices, and operator interface devices that, in addition to executing stated control and indication functions, permits transmission of control, measurement, and operating information to and from single- or multiple-user specifiable locations, connected by single or multiple communication links.

Field instrument An instrument that is not mounted on a panel or console or in a control room but commonly in the vicinity of its primary element or final control element. See *local instrument*.

Final control element A device, such as a control valve, that directly controls the value of the manipulated variable of a control loop.

Function The purpose of, or the action performed by, a device or application software.

Identification The sequence of letters or digits, or both, used to designate an individual instrument, function, or loop.

Instrument A device used for direct or indirect measurement, monitoring, or control of a variable.
a) Includes primary elements, indicators, controllers, final control elements, computing devices, and electrical devices such as annunciators, switches, and pushbuttons.
b) Does not apply to an instrument's internal components or parts, such as receiver bellows or resistors.

Instrumentation A collection of instruments or functions or their application for the purpose of measuring, monitoring, controlling, or any combination of these.

Local instrument An instrument that is not mounted on a panel or console or in a control room but commonly is in the vicinity of its primary element or final control element. See *field instrument.*

Local panel A panel that is not a central or main panel and is commonly located in the vicinity of plant subsystems or subareas (sometimes called a *local instrument panel*).
a) The term *local panel instrument* should not be confused with *local instrument* or *local instrument panel*.

Loop A combination of two or more instruments or control functions arranged so that signals pass from one to another for the purpose of measurement indication or control of a process variable.

Manual loading station A device or function that has a manually adjustable output and may also have indicators, lights, and/or other functions that are used to actuate or modulate one or more devices. It does not provide switching between auto-manual modes of a control loop.

Measurement The determination of the existence or magnitude of a process variable.

Monitor A general term for an instrument or instrument system used to measure or sense the status or magnitude of one or more variables for the purpose of deriving useful information. This sometimes means an analyzer, indicator, or alarm.

Monitor light A light that indicates which of a number of normal (but not abnormal) conditions of a system or device exists. See also *pilot light.*

Multifunction devices Devices (controllers) that receive one or more input signals and send out two or more output signals or perform two or more functions. See *multipoint* and *multivariable devices*.

Multipoint devices Indicators or recorders that may be single or multivariable type and that receive input signals from two or more primary elements or transmitters. See *multifunction devices* and *multivariable devices*.

Multivariable devices Devices (indicators, recorders, or controllers) that receive two or more input signals and send one output signal. See *multifunction* and *multipoint devices*.

Panel A freestanding or built-in structure, consisting of one or more sections, cubicles, consoles, or desks, in which groups of instrument hardware are mounted. It could house the operator–process interface and is given a unique designation.

Panel-mounted An instrument or other device that is mounted in a panel or console and is accessible for an operator's normal use.

a) A function that is normally accessible to an operator in a shared-display system is the equivalent of a discrete panel-mounted device.

Pilot light A light that indicates which of a number of normal conditions of a system or device exists. It is not an alarm light that indicates an abnormal condition. See also *monitor light.*

Primary element An external or internal instrument, or a system element, that quantitatively converts the measured variable into a form suitable for measurement. See also *detector* and *sensor*:

a) An orifice plate is an external primary element.
b) The sensing portion of a transmitter is an internal primary element.

Process Any operation or sequence of operations involving a change of energy, state, composition, dimension, or other properties that may be defined with respect to zero or some other defined initial value.

Process variable Any measurable property of a process. Used in this standard to apply to all variables other than instrument signals between devices in a loop.

Program A repeatable sequence of actions that defines the state of outputs as a fixed relationship to the state of inputs.

Programmable logic controller A controller, usually with multiple inputs and outputs, that contains an alterable program that is

a) Typically used to control binary and/or discrete logic or sequencing functions.
b) Also used to provide continuous control functions.

Relay A device whose function is to pass on information in an unchanged form or in some modified form; often used to mean the preferred term, *computing device.*

a) *Relay* is a term applied specifically to an electric, pneumatic, or hydraulic switching device that is actuated by a signal, and to functions performed by a relay.

Scan To sample or multiplex, in a predetermined manner, each of a number of variables periodically and/or intermittently.

a) A scanning or multiplexing device is often used to ascertain the state or value of a group of variables and may be associated with other functions such as recording and alarming.

Sensor A separate or integral part, or function, of a loop or an instrument that first senses the value of a process variable. It assumes a corresponding predetermined and intelligible state and/or generates an output signal indicative of or proportional to the process variable. See also *detector* and *primary element*.

Setpoint An input variable that sets the desired value of the controlled variable manually, automatically, or by means of a program in the same units as the controlled variable.

Shared control A feature of a control device or function that contains a number of preprogrammed algorithms that are user retrievable, configurable, and connectable. It allows user-defined control strategies or functions to be implemented and is often used to describe the control features of a distributed control system.

a) Control of multiple process variables can be implemented by sharing the capabilities of a single device of this kind.

Shared display The operator interface device (such as video, light emitting diode, liquid crystal, or other display unit) used to display process control information from a number of sources at the command of the operator. It is often used to describe the visual features of a distributed control system.

Software The programs, codes, procedures, algorithms, patterns, rules, and associated documentation required for the operation or maintenance of a microprocessor- or computer-based system. See also *application software*.

Software link The interconnection of system components via communications networks or functions via software or keyboard instruction.

Supervisory setpoint control system The generation of setpoint or other control information by a computer control system for use by shared control, shared display, or other regulatory control devices.

Switch A device that connects, disconnects, selects, or transfers one or more circuits and is not designated as a controller, relay, or control valve. As a verb, the term is also applied to a function performed by a switch.

Test point A process connection to which no instrument is permanently connected; it is intended for the temporary or intermittent connection of an instrument.

Transducer A general term for a device, which can be a primary element, transmitter, relay, converter, or other device, that receives information in the form of one or more physical quantities, modifies the information or its form if required, and produces a resultant output signal.

Transmitter A device that senses a process variable through the medium of a sensor or measuring element and has an output whose steady-state value varies only as a predetermined function of the process variable. The sensor can be an integral part, as in a direct connected pressure transmitter, or a separate part, as in a thermocouple-actuated temperature transmitter.

IDENTIFICATION SYSTEM GUIDELINES

See statement of permission on page 4.

General

This subsection establishes an identification system for instrument loop devices and functions. It is logical, unique, and consistent in application with a minimum of exceptions, special uses, and requirements. The identification system is used to identify instrumentation in text, sketches, and drawings when used with graphic symbols as described in the subsection titled “Graphic Symbol System Guidelines.”

The identification system provides methods for identifying instrumentation required to monitor, control, and operate a processing plant, unit operation, boiler, machine, or any other system that requires measurement, indication, control, modulation, and/or switching of variables.

Primary instrumentation, hardware and software devices, and functions that measure, monitor, control, and calculate, and application software functions that require or allow user-assigned identities, shall be assigned both loop and functional identification.

Secondary instrumentation, such as hardware devices that measure and monitor, as well as level glasses, pressure gauges, and thermometers, shall be assigned only a functional identification.

Loop and functional identification shall be assigned in accordance with the guidelines in the standard or with modified guidelines based on the standard, established by the user or owner of the plant, unit, or facility in which the instrumentation is to be installed.

A unique loop identification number shall be assigned to identify each monitoring and control loop. A unique instrument identification/tag number based on the loop identification number shall be assigned for each monitoring or control loop to identify each of the following:

a) Hardware device and integral functions
b) Application software functions that require or allow a user-assigned unique microprocessor or computer address

A monitor or control loop consists of some or all of the following (as indicated):

a) Measurement of the process variable (monitor and control):
    1) Measuring element device, such as an orifice plate or thermocouple
    2) Measurement transmitter, with an integral measuring element, such as a pressure transmitter or without an integral measuring element, such as a temperature transmitter and thermocouple
b) Conditioning of the measurement or input signal (monitor and control):
    1) Calculating devices
    2) Calculating functions
    3) Safety barriers
c) Monitoring of the process variable (monitor):
    1) Indicating or recording device
    2) Application software display function
d) Controlling of the process variable (control):
    1) Indicating or recording control device
    2) Application software control function
e) Conditioning of the controller or output signal (control):
    1) Calculating devices
    2) Calculating functions
f) Modulation of the manipulated variable (control):
    1) Control valve modulation or on–off action
    2) Manipulation of another control loop setpoint
    3) Limiting another control loop output signal

Secondary instrumentation shall be assigned instrument identification/tag numbers or other forms of identification in accordance with the guidelines established in the ISA standard or with modified guidelines based on the standard established by the user/owner of the plant, unit, or facility in which the instrumentation is to be installed.

Examples of instrument identification systems will be found in a future series of S5.1 (now ANSI/ISA-5.01.01) Technical Reports.

Instrument Index

Loop identification numbers and instrument identification/tag numbers shall be recorded in an instrument index (either manually generated or computerized instrument database), which shall be maintained for the life of the facility for the recording and control of all documents and records pertaining to the loops and their instrumentation and functions.

An instrument index shall contain references to all instrumentation data required by owner or government regulatory agency management-of-change requirements. It should contain, as a minimum, for each loop:

a) Loop identification number
b) Service description
c) Instrument identification/tag numbers
d) Piping and instrument (P&ID) drawing numbers
e) Instrument data sheet numbers
f) Location plan numbers
g) Installation detail drawing numbers

Guideline Modifications

These guidelines may be modified to suit the requirements of the following:

a) Existing user-designed identification and numbering schemes that are not included in this standard
b) Computer databases used for record keeping
c) Microprocessor-based monitoring or control systems

When modified guidelines are adopted, they shall be fully described and detailed in the user/owner's engineering or design standards.

Multipoint, Multivariable, and Multifunction Devices

Input and output devices and functions that are components of a multipoint device shall have tag suffixes that delineate between the different components.

Multivariable devices that receive two or more input signals, transmit one output signal, and have been assigned measured/initiating variable multivariable [U], shall have the following indicators:

a) Each different input shall be assigned its own loop identification number, and each output indicating, recording, switching, alarming, or other device and function that is actuated solely by a single variable, shall be assigned an instrument/tag number that identifies it as part of these loops.
b) Each indicating, recording, switching, alarming, or other device or function that is actuated by more than one of the multivariables shall be assigned an instrument/tag number that identifies it as part of the multivariable loop.

Multifunction devices that receive two or more input signals, send out two or more output signals, or perform two or more functions may be assigned readout/passive or output/active function multifunction [U] and shall have a loop number assigned according to the measured/initiating variable.

Loops that perform two or more functions from a single measured/initiating variable may have the following:

a) Each function assigned a unique instrument/tag number and shown on diagrams as multiple tangent bubbles for the integral functions and multiple individual bubbles for the nonintegral functions.
b) One readout/passive and/or output/active function designated by succeeding letter [U], for the integral functions and multiple individual bubbles for the nonintegral functions, and, if necessary, a note or comment defining the integral functions.

Graphic symbol examples of these loops are given later in this section.

System Identification

Instrumentation is often assembled into systems for various reasons including ease of purchase, ease of application, compatibility, and so on. These systems may need to be identified on drawings and in text.

Some of the more common instrumentation systems and the system codes for identifying them are the following:

ACS = Analyzer control system
BMS = Burner management system
CCS = Computer control system
CEMS = Continuous emissions monitoring system
DCS = Distributed control system
FDS = Flame detection system
MMS = Machine monitoring system
PCCS = Personal computer control system
PLC = Programmable logic controller
SIS = Safety instrumented system
VMS = Vibration monitoring system

Suffixes may be added to the instrumentation system codes [SC] when required as follows:

a) [SC] 1, [SC] 2, and so forth, when more than one system is used in a complex
b) [SC]-M, [SC]-L, when main and local systems are used in a unit
c) [SC]-[unit identifier]

Loop Identification Number

A loop identification number is a unique combination of letters and numbers that is assigned to each monitoring and control loop in a facility to identify the process or machine variable that is being measured for monitoring or control (see Table 1.1a).

TABLE 1.1a
Typical Loop Identification Number

Measured/Initiating Variable

10	-	P	-	*01	A	Loop identification number
10						Optional loop number prefix
	-					Optional punctuation
		P				Measured/initiating variable
			-			Optional punctuation
				*01		Loop number
					A	Optional loop number suffix

First Letters

10	-	P	D	-	*01	A	Loop identification number
10							Optional loop number prefix
	-						Optional punctuation
		P	D				First letters
		P					Measured/initiating variable
			D				Variable modifier
				-			Optional punctuation
					*01		Loop number
						A	Optional loop number suffix

See statement of permission on page 4.

TABLE 1.1b
Typical Instrument Identification/Tag Number

10	-	P	D	A	L	-	*01	A	-	A	-	1	Loop identification number
10													Optional loop number prefix
	-												Optional punctuation
		P					*01	A					Loop number, measured variable
		P	D				*01	A					Loop number, first letters
						-							Optional punctuation
							*01						Loop number
								A					Optional loop number suffix
		P	D	A	L								Functional identification letters
		P	D										First letters
		P											Measured/initiating variable
			D										Variable modifier
				A	L								Succeeding letters
				A									Function identifier
					L								Function modifier
									-				Optional punctuation
										A			Tag number suffix
											-		Optional punctuation
												1	Tag number suffix

See statement of permission on page 4.

Loop identification numbers are assigned as follows:

a) Numerals in parallel, serial, or parallel/serial sequences
b) Letters or letter combinations selected from Table 1.1c, Identification Letters (column 1, Measured/Initiating Variables and column 2, Variable Modifiers)

Loop identification number numerals shall be assigned to loop variables letters according to one of the following sequencing methods:

a) Parallel: duplicated numerical sequences for each loop variable letter or letter combination
b) Serial: the same numerical sequence regardless of loop variable letter or letter combination
c) Parallel/serial: parallel sequences for selected loop variable letters or letter combinations and a serial sequence for the remainder

Loop number numerical sequences are normally three or more digits, -*01, -*001, -*0001, and so on, where

a) -* can be any digit from 0 to 9
b) Coded digits are related to drawing numbers or equipment numbers
c) *00, *000, *0000, and so on are not used

Gaps may be left in any sequence to allow for the addition of future loops. (See Tables 1.1c through 1.1f for various combinations of allowable instrumentation identification/tag numbers.)

IDENTIFICATION LETTER TABLES

See statement of permission on page 4.

General

This clause provides in tabular form the alphabetic building blocks of the Instrument and Function Identification System in a concise, easily referenced manner.

Table 1.1c, Identification Letters, defines and explains the individual letter designators to be used as loop and functional identifiers in accordance with the guidelines of the subsection titled “Identification System Guidelines.”

The letters in Table 1.1c shall have the mandatory meanings as given in the table except as follows:

TABLE 1.1c

Identification Letters (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

	First Letters (1)		*Succeeding Letters (15)*		
	Column 1 *Measured/Initiating Variable*	*Column 2* *Variable Modifier*	*Column 3* *Readout/Passive Function*	*Column 4* *Output/Active Function*	*Column 5* *Function Modifier*
A	Analysis		Alarm		
B	Burner, combustion		User's choice	User's choice	User's Choice
C	User's choice			Control	Close
D	User's choice	Differential, deviation			Deviation
E	Voltage		Sensor, primary element		
F	Flow, flow rate	Ratio			
G	User's choice		Glass, gauge, viewing device		
H	Hand				High
I	Current		Indicate		
J	Power		Scan		
K	Time, schedule	Time rate of change		Control station	
L	Level		Light		Low
M	User's choice				Middle, intermediate
N	User's choice		User's choice	User's choice	User's Choice
O	User's choice		Orifice, restriction		Open
P	Pressure		Point (test connection)		
Q	Quantity	Integrate, totalize	Integrate, totalize		
R	Radiation		Record		
S	Speed, frequency	Safety		Switch	
T	Temperature			Transmit	
U	Multivariable		Multifunction	Multifunction	
V	Vibration, mechanical analysis			Valve, damper, louver	
W	Weight, force		Well		
X	Unclassified	X-axis	Unclassified	Unclassified	Unclassified
Y	Event, state, presence	Y-axis		Auxiliary devices	
Z	Position, dimension	Z-axis		Driver, actuator, unclassified final control element	

See statement of permission on page 4.

a) The user shall assign a variable name to the user's choice letters in column 1 and a function name to the user's choice letters in columns 3 through 5 when such letters are used.
b) The user may assign meanings to the blanks in columns 2 through 5 if needed.

Table 1.1d, Allowable Loop Identification Letter Schemes, provides the allowable loop identification letters and combinations according to the loop identification number construction schemes.

The letters and combinations shall have the mandatory meanings as given in the table except as follows:

a) The user shall assign a variable name to the user's choice letters in the "First Letter" column.

Tables 1.1e and 1.1f, Allowable Function Identification Letter Combinations, provide allowable combinations of function identifying letters.

The letter combinations shall have the meanings given in the table, except as follows:

a) The user shall assign a variable and/or function to user's choice letters if used.
b) The user may assign a meaning to blanks if needed.
c) Cells marked N/A are combinations that shall not be allowed.

TABLE 1.1d
Allowable Loop Identification Letter Schemes

See statement of permission on page 4.

N/A = not allowed.

Note (1): Alarm combinations are given with Function Modifiers for deviation from set point and absolute values. Adding [H] or [L] forms low–low and high–high alarm Functional Identifications.

Note (2): Readout/Passive Function [G] (glass, gauge) is shown for local direct connected devices, such as flow sight glasses, level glasses, pressure gauges, and thermometers, and also for weigh scales and position indicators. These devices provide a simple view of a process condition. The Readout/Passive Function [I] (indicate) may continue to be used in facilities where it is currently used.

See statement of permission on page 4.

N/A = not allowed.

Note (3): The combinations in the [IC] and [RC] columns indicate the order to be followed in forming the Functional Identification of a controller device or function that also provides indication or recording.

Note (4): The combinations in the [C] column do not have operator visible indication of measured variable, set point, or output signal, when used with discrete hardware single case instruments.

Note (5): The combinations in the [C] column may also be used for a controller function configured in a shared or distributed control system.

Note (6): The combinations in the [CV] column indicate the order to be followed in forming the Functional Identification for self-actuated control valves.

GRAPHIC SYMBOL SYSTEM GUIDELINES

See statement of permission on page 4.

General

The future revised ISA Standard S5.1 (now ANSI/ISA-5.01.01) establishes a graphic symbol system and functional identification for depicting instrument loop devices and functions, application software functions, and the interconnections between them that is logical, unique, and consistent in application with a minimum of exceptions, special uses, and requirements.

The graphic symbol system shall be used to depict instrumentation in text and in sketches and drawings. When used with identification letters and numbers as described in the subsection titled "Identification System Guidelines," it shall identify the functionality of each device and function shown.

The graphic symbol system provides methods for schematic loop diagramming, functional diagramming (see Section 1.2), and electrical schematic diagramming of any process or system that requires measurement, indication, control, modulation, or switching of variables.

Table 1.1g, Instrument Line Symbols, contains lines used to represent process connections and the measurement and control signals that connect instruments and functions to the process and to each other.

Tables 1.1h through 1.1k depict circles, squares, diamonds, hexagons, and lines used to represent the majority of hardware and software instruments and functions as follows:

Table 1.1h, Discrete (Individual) Devices and/or Functions, represents discrete hardware instruments and/or functions that are implemented in nonmicroprocessor-based systems similar or equal to single-case transmitters, controllers, indicators, or recorders.

Table 1.1i, Shared Continuous Devices and/or Functions, represents shared and/or distributed software analog instruments and/or functions that are implemented in microprocessor-based systems similar or equal to distributed control or programmable logic control systems.

Table 1.1j, Shared On–Off Devices and/or Functions, represents shared and/or distributed on–off software instruments and/or functions that are implemented in microprocessor-based control systems similar or equal to a distributed control or programmable logic control systems.

Table 1.1k, Computer Devices and/or Functions, represents shared and/or distributed on–off software instruments and/or functions that are implemented in a computer-based control system.

Figures 1.1l and 1.1m illustrate some practical but not standardized P&ID symbology for a fieldbus system (DeviceNet).

Table 1.1n, Primary Elements—Flow, describes various geometric shapes that represent primary measurement elements, such as orifice plates and thermocouples, that are located in the process piping.

Tables 1.1o through 1.1r, Final Control Elements, consist of various geometric shapes that represent final control elements, such as control valves and their actuators, that are located in the process piping:

Table 1.1o–Control Valve Bodies
Table 1.1p–Control Valve Actuators
Table 1.1q–Self-Actuated Devices (includes such self-actuated elements as pressure control valves and pressure relief valves)
Table 1.1r–Failure Position Indicators for Control Valves (indicates the position which the valve takes when/if the actuating power fails)

Table 1.1s, Electrical Schematic Symbols, represents electrical circuit elements.

Specific industrial application examples of the graphic symbol system will be found in a future series of S5.1 (now ANSI/ISA-5.01.01) Technical Reports. Sketches that are not all inclusive of acceptable methods of depicting instrumentation are included in the following text to illustrate the intent of the standard. However, the individual symbols and their meanings are to be mandatory in the future, imminent standard.

Guideline Modifications

These guidelines may be modified to suit the requirements of existing user-designed graphic symbols that are not included in this standard. When modified symbols are adopted, they shall be fully described and detailed in the user/owner's engineering or design standards.

Instrument Line Symbols

In Table 1.1g, symbols represent the following:

a) Instrument and device connections at process measurement points
b) Connections to instrument power supplies
c) Signals between measurement and control instruments and functions

Lines shall be

a) Fine in relation to process equipment and piping lines
b) As short as possible and consistent with clarity

Measurement and Control Devices and/or Function Symbols

See Table 1.1h, Discrete (Individual) Devices and/or Functions, in which symbols represent discrete devices that perform continuous and/or on–off functions that do not share control or display functions for the following:

TABLE 1.1g

Instrument Line Symbols (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol*	*Application*
01		Instrument impulse line from process Instrument impulse line from equipment Analyzer sample line from process Functional instrument diagram signal lines
02		Heat (cool) traced instrument impulse line from process Heat (cool) traced instrument impulse line from equipment Heat (cool) traced analyzer sample line from process Type of tracing may be indicated as ET = electrical, RT = refrigerated, ST = steam, etc.
03		Generic instrument impulse line connected to process line Generic instrument impulse line connected to equipment
04		Heat (cool) traced generic instrument impulse line connected to process line Heat (cool) traced generic instrument impulse line connected to equipment Process line or equipment may or may not be traced
05		Heat (cool) traced instrument connected to process impulse line Instrument impulse line may or may not be traced
06		Flanged instrument connection to process line Flanged instrument connection to equipment
07		Threaded instrument connection to process line Threaded instrument connection to equipment
08		Socket welded instrument connection to process line Socket welded instrument connection to equipment
09		Welded instrument connection to process line Welded instrument connection to equipment *Practical industry tip:* Use symbol for both seal weld on threaded connection as well as butt weld on larger sizes
10		Instrument air supply Indicate supply pressure as required: AS-60 psig, AS-400 kPa, etc. IA (instrument air) or PA (plant air) may be used for AS Use as required
11		Instrument electric power supply Indicate voltage and type as required, e.g., ES-24 VDC, ES-120 VAC, etc. Use as required *Practical industry tip:* Add note if it is coming from UPS
12		Undefined signal Use for PFDs Use for discussions or diagrams where type of signal, pneumatic or electronic, is not of concern
13		Pneumatic signal
14		Electric signal Electronic signal Functional instrument diagram signal lines
15		Hydraulic signal
16		Filled thermal element capillary tube
17		Guided electromagnetic signal Fiber optic cable Guided sonic signal
18		Unguided electromagnetic signal Unguided sonic signal Alternate radio communication link (see symbol 22)

TABLE 1.1g Continued

Instrument Line Symbols (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol*	*Application*
19		Communication link or system bus, between devices and functions of a microprocessor-based system *Industry tip:* Use this for traditional DCS main data highway systems. System internal software link
20		Shared communication link or bus (not system bus) between two or more independent microprocessor-based systems Shared data link from/between field located microprocessor-based devices and/or functions *Industry tip:* Use for fieldbus field devices
21		Dedicated communications link or bus (not system bus) between two or more independent microprocessor-based systems Dedicated data link from a field located microprocessor-based device and/or function
22		Dedicated radio communications link (not system bus) between radio transmitting and receiving devices and/or systems Unguided radio signal Alternate unguided electromagnetic signal (see symbol 18)
23		Mechanical link or connection
24		Signal connector Drawing-to-drawing signal connector Internal signal connector used to avoid long signal lines
25		Signal connector Internal signal connector used to avoid long signal lines Drawing-to-drawing signal connector

See statement of permission on page 4.

TABLE 1.1h

Discrete (Individual) Devices and/or Functions (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol*	*Location and Accessibility*
01		Field or locally mounted Not panel or cabinet mounted Normally accessible to an operator
02		Central or main control room Front of main panel mounted Normally accessible to an operator
03		Central or main control room Rear of main panel mounted Not normally accessible to an operator
04		Secondary or local control room Field or local control panel Front of secondary or local panel mounted Normally accessible to an operator
05		Secondary or local control room Field or local control panel Rear of secondary or local panel or cabinet mounted Not normally accessible to an operator
06		Signal processor identifier located in upper right or left quadrant of symbols above Signal processor identifier attached to symbols where affected signals are connected

See statement of permission on page 4.

a) Measurement (transmitters, primary elements)
b) Indication (indicators, annunciators)
c) Control (controllers, control valves, switches, solenoids)

Limited operator accessibility (setpoint changes, control mode transfers, etc.) and unlimited engineer or technician accessibility through location and enclosure methods are shown.

Table 1.1i covers analog, digital, and/or discrete shared control devices and/or functions for continuous control, indication, calculation, and so forth that are microprocessor based and configurable. They communicate with each other and share control or display functions in applications such as distributed control and programmable logic systems.

Limited operator accessibility (setpoint changes, control mode transfers, and so forth) and unlimited engineer accessibility is through local or wide area communications networks, keyboards, and video displays as shown.

Table 1.1j deals with analog, digital, and discrete control devices and functions for on–off or binary control, indication, calculation, and so forth that are microprocessor based and configurable. They communicate with each other and share control or display in distributed control and programmable logic systems.

Limited operator accessibility (setpoint changes, control mode transfers, and so on) and unlimited engineer accessibility is through local or wide area communications networks, keyboards, and video displays as shown.

The devices and functions in Table 1.1k include process plant computer-implemented regulatory and/or advanced control analog/digital/discrete (individual) control and indication functions that are mainframe computer or minicomputer based.

TABLE 1.1i

Shared Continuous Devices and/or Functions (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol*	*Location and Accessibility*
01		Dedicated single function device Field or locally mounted Not panel or cabinet mounted Normally accessible to an operator at device
02		Central or main console Visible on video display Normally accessible to an operator at console
03		Central or main console Not visible on video display Not normally accessible to an operator at console
04		Secondary or local console Field or local control panel Visible on video display Normally accessible to an operator at console
05		Secondary or local console Field or local control panel Not visible on video display Not normally accessible to an operator at console
06		Mathematical function located in upper right or left quadrant of symbols above Mathematical function attached to symbols where affected signals are connected

See statement of permission on page 4.

Limited operator accessibility (setpoint changes, control mode transfers, etc.), and unlimited engineer accessibility is through local or wide area communications networks, keyboards, and video displays as shown.

Fieldbus P&ID Examples: DeviceNet Figures 1.1l and 1.1m show the practical methods used by one EPCM company in establishing a P&ID detail and markup for a low-voltage motor control plus a VFD motor control implemented with DeviceNet as the fieldbus. It should be pointed out that these figures do not completely conform to the ISA S5.1 (now ANSI/ISA-5.01.01) proposed standard and are a compromise born of necessity.

In Table 1.1n, symbols are pictorial representations of primary flow elements that generate a measurement or signal equal to, or a signal proportional to, a fluid flow rate or total flow.

In Table 1.1o, valve body symbols, when combined with valve actuator symbols, shall be used to represent control valves and solenoid valves as follows:

Symbols 01 through 05 may be used as generic symbols to represent control and solenoid valve bodies.

The remaining symbols may be used when it is desired to more clearly indicate a specific valve body type.

TABLE 1.1j

Shared on–off devices and/or Functions (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol*	*Location and Accessibility*
01		Field or locally mounted Not panel or cabinet mounted Normally accessible to an operator at device
02		Central or main console Visible on video display Normally accessible to an operator at console
03		Central or main console Not visible on video display Not normally accessible to an operator at console
04		Secondary or local console Field or local control panel Visible on video display Accessible to an operator at console
05		Secondary or local console Field or local control panel Not visible on video display Not normally accessible to an operator at console
06		Mathematical function located in upper right or left quadrant of symbols above Mathematical function attached to symbols where affected signals are connected

See statement of permission on page 4.

TABLE 1.1k

Computer Devices and/or Functions (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol*	*Location and Accessibility*
01		Undefined location Undefined visibility Undefined accessibility
02		Central or main computer Visible on video display Normally accessible to an operator at console or computer terminal
03		Central or main computer Not visible on video display Not normally accessible to an operator at console or computer terminal
04		Secondary or local computer Visible on video display Normally accessible to an operator at console or computer terminal
05		Secondary or local computer Not visible on video display Not normally accessible to an operator at console or computer terminal

See statement of permission on page 4.

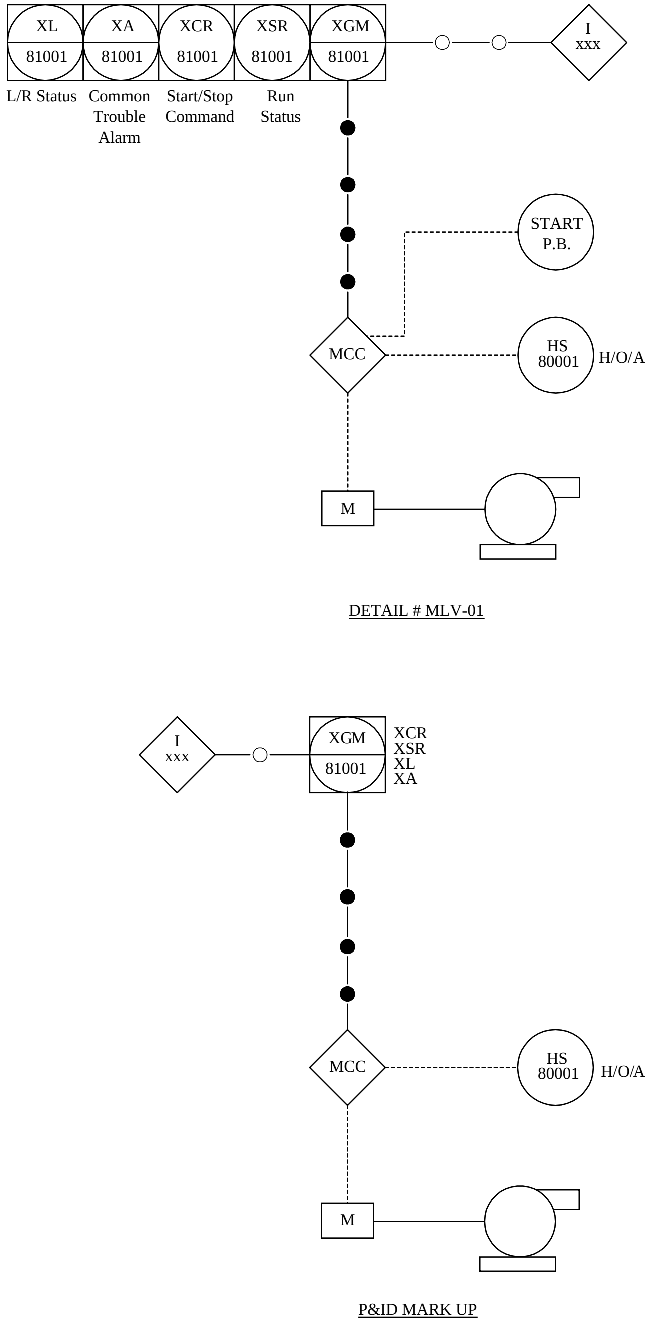

FIG. 1.1l
Low voltage motor control on DeviceNet (detail and P&ID mark up).

In Table 1.1s, contacts shall be shown in shelf condition. Rising switch actuator will cause contacts to switch.

Multipoint, Multifunction, and Multivariable Devices and Loops

Multipoint devices are indicators or recorders that may be single or multivariable and receive input signals from two or more primary elements or transmitters.

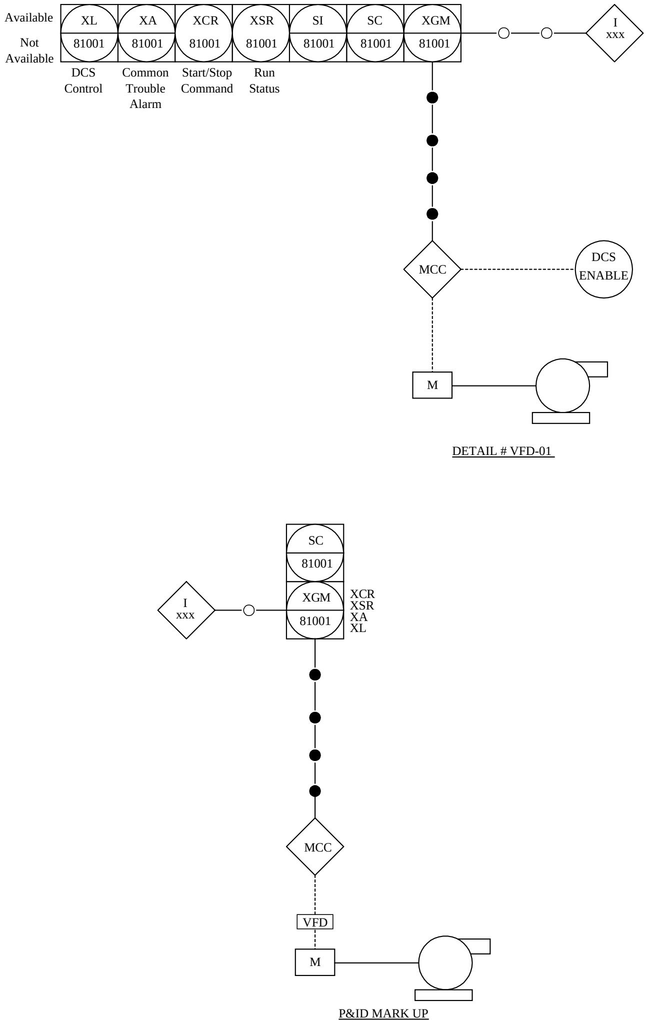

FIG. 1.1m
VFD motor control on DeviceNet (detail and P&ID mark up).

Multivariable devices are indicators, recorders, and controllers that receive input signals from two or more primary elements or transmitters and control one manipulated variable.

Multifunction devices are controllers or switches that receive input signals from two or more primary elements or transmitters and control two or more manipulated variables.

Single variable or multivariable multipoint indicators and recorders for two or three points shall be drawn with bubbles either

a) Tangent to each other in the same order, left to right, as the pen or pointer assignments:

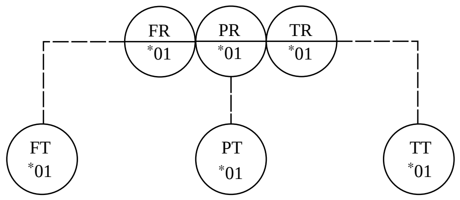

TABLE 1.1n

Primary Elements—Flow (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	Symbol	Description
01		Generic flow element
02		Standard orifice plate Restriction orifice
03		Orifice plate in quick change fitting
04		Generic venturi tube, flow nozzle, or flow tube Notation required if used for more than one type
05		Venturi tube
06		Flow nozzle
07		Flow tube
08		Standard pitot tube
09		Averaging pitot tube
10		Turbine flowmeter Propeller flowmeter
11		Vortex shedding flowmeter
12		Target flowmeter
13		Magnetic flowmeter
14		Positive displacement flowmeter
15		Cone meter Annular orifice meter
16		Wedge meter
17		Coriolis flowmeter
18		Sonic flowmeter Ultrasonic flowmeter
19		Variable area flowmeter
20		Open channel weir plate
21		Open channel flume
22		Flow straightening vanes Flow conditioning element

See statement of permission on page 4.

TABLE 1.1o

Final Control Elements—Control Valve Bodies (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	Symbol	Description
01		Generic two-way valve Straight globe control valve Two-way solenoid valve Gate valve
02		Generic two-way angle valve Angle globe control valve Angle solenoid valve
03		Generic three-way valve Three-way globe control valve Three-way solenoid valve Arrow indicates air failure or de-energized flow path
04		Generic four-way valve Four-way plug or ball control valve Four-way four ported on–off valve Arrows indicate air failure or de-energized flow paths
05		Four-way five ported on–off valve Arrows indicate air failure or de-energized flow paths
06		Butterfly valve
07		Two-way globe valve
08		Ball valve
09		Plug valve
10		Eccentric rotary disc valve
11		Diaphragm valve
12		Pinch valve
13		Generic damper Generic louver
14		Parallel blade damper Parallel blade louver
15		Opposed blade damper Opposed blade louver

See statement of permission on page 4.

TABLE 1.1p
Final Control Elements—Control Valve Actuators (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol*	*Description*
01		Generic actuator Spring-opposed diaphragm linear actuator
02		Spring-diaphragm actuator with positioner
03		Pressure-balanced diaphragm linear actuator
04		Generic piston actuator May be linear or rotary
05		Piston actuator, single-acting, spring-opposed, with positioner
06		Piston actuator, double-acting, with positioner
07		Rotary motor-operated actuator May be electric, pneumatic, or hydraulic
08		Automatic reset solenoid actuator Nonlatching solenoid actuator Dual solenoids may be used
09		Manual or remote reset solenoid actuator Latching solenoid actuator
10		Manual and remote-reset solenoid actuator Latching solenoid actuator
11		Manual actuator Hand actuator
12		Spring-, weight-, or pilot-actuated relief or safety actuator
13		Actuator with side-mounted handwheel
14		Actuator with top-mounted handwheel
15		Electrohydraulic actuator May be linear or rotary action

See statement of permission on page 4.

TABLE 1.1q
Final Control Elements—Self-Actuated Devices (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol*	*Description*
01		Automatic flow regulator XXX = FCV w/o indicator XXX = FICV w/integral indicator
02		Variable area flowmeter with a manual regulating valve
03		Constant flow regulator Manual setpoint variable area flowmeter
04		Flow sight glass Type shall be noted if more than one type used
05		Generic flow restriction Single stage orifice plate as shown Note required for multistage or capillary tube types
06		Restriction orifice hole drilled in valve plug Tag number may be omitted if valve is otherwise identified
07		Level regulator Ball float and mechanical linkage
08		Backpressure regulator Internal pressure tap
09		Backpressure regulator External pressure tap
10		Pressure-reducing regulator Internal pressure tap
11		Pressure-reducing regulator External pressure tap
12		Differential-pressure regulator External pressure taps
13		Differential-pressure regulator Internal pressure taps
14		Pressure-reducing regulator w/integral outlet pressure relief and pressure gauge
15		Generic pressure safety valve Pressure relief valve
16		Generic vacuum safety valve Vacuum relief valve
17		Generic pressure and vacuum relief valve Tank pressure and vacuum relief valve

TABLE 1.1q Continued

Final Control Elements—Self-Actuated Devices (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	Symbol	Description
18		Pressure safety element Pressure rupture disk Pressure relief
19		Pressure safety element Vacuum rupture disk Vacuum relief
20		Temperature regulator Filled thermal system
21		Thermal safety element Fusible plug or disk
22		Generic moisture trap Steam trap Note required for other trap types
23		Moisture trap with equalizing line

See statement of permission on page 4.

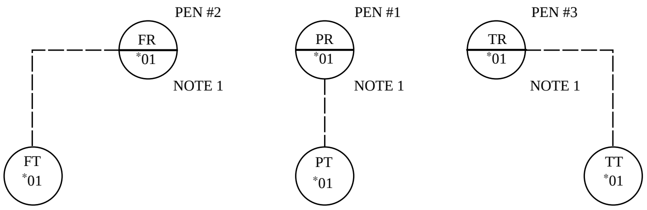
TABLE 1.1r

Final Control Elements—Control Valve Air Failure Position Indication (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	Method 1	Method 2	Definition
01			Fail to open position
02			Fail to closed position
03			Fail locked in last position
04			Fail at last position Drift open
05			Fail at last position Drift closed

See statement of permission on page 4.

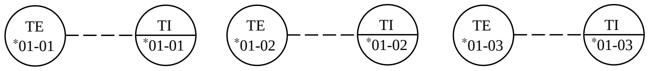
b) Separate from each other, with pen or pointer number indicated preferably in upper right or left quadrant and a note defining instrument or device indicated in preferably lower right or left quadrant:



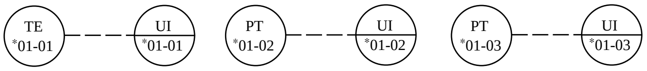
Note 1. Indicated pen in 3-pen Recoder

Multipoint indicators and recorders for four or more points may be drawn with bubbles separate from each other, with point number indicated by adding a suffix to the tag numbers as follows:

a) Single variable:



b) Multivariable:



Multivariable controllers may be drawn with bubbles for each measured variable input and for the output to the final control element; measured variable indicators may be:

a) Shown:

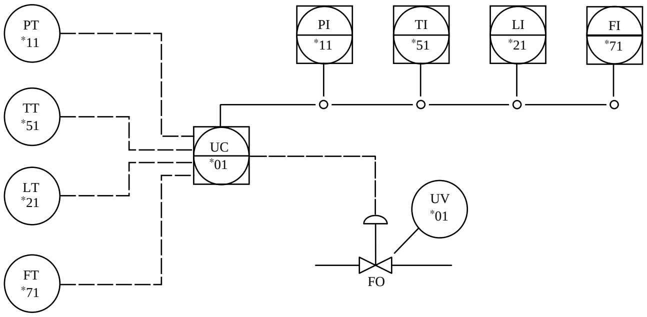


TABLE 1.1s

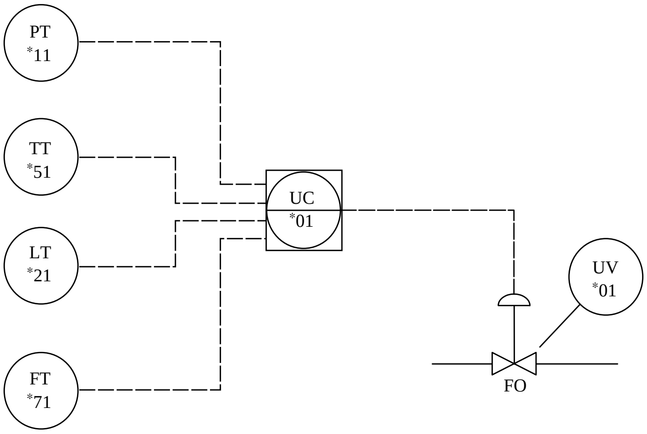
Electrical Schematic Symbols (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

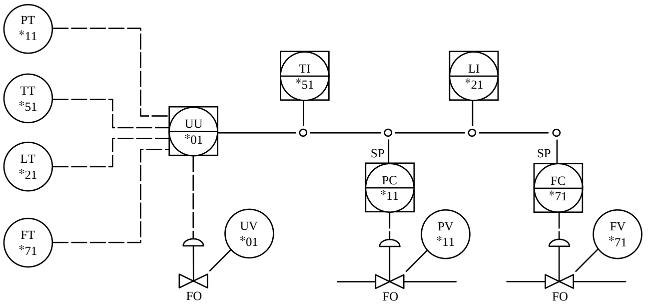
No.	*Symbol*	*Description*
01		Normally open, single-circuit pushbutton switch contact Single-pole, normally open (SPNO) pushbutton switch contact Combine with symbols 06 or 07 to form toggle or rotary-actuated switches
02		Normally closed, single-circuit pushbutton switch contact Single-pole, normally closed (SPNC) pushbutton switch contact Combine with symbols 06 or 07 to form toggle or rotary-actuated switches
03		Normally open, double-circuit pushbutton switch contact Double-pole, normally open (DPNO) pushbutton switch contact Combine with symbols 06 or 07 to form toggle or rotary-actuated switches
04		Normally closed/normally open double-circuit pushbutton switch contact Double-pole, normally open/closed (DPNO/NC) pushbutton switch contact Combine with symbols 06 or 07 to form toggle or rotary-actuated switches
05		Two-position toggle or rotary-maintained position pushbutton switch actuator Combine with symbols 01 through 05 to form single-pole, double-throw (SPDT) or multipole double-throw (DPDT, TPDT, etc.) switches
06		Three-position toggle or rotary-maintained position pushbutton switch actuator Combine with symbols 01 through 05 to form single-pole, triple-throw (SPTT) or multipole, triple-throw (DPTT, TPTT, etc.) switches
07		Single-pole, single-throw (SPST) normally open toggle switch Form A switch contact
08		Single-pole, single-throw (SPST) normally closed toggle switch Form B switch contact
09		Single-pole, double-throw (SPDT) normally closed/normally open toggle switch Form C switch contact
10		Pressure switch actuator
11		Differential-pressure switch actuator
12		Liquid level switch actuator
13		Temperature switch actuator
14		Flow switch actuator
15		Foot switch actuator
16		Relay coil
17		Normally open relay contact
18		Normally closed relay contact
19		Connection convention A: Left = not connected Right = connected
20		Connection convention B: Left = not connected Right = connected

b) Assumed:

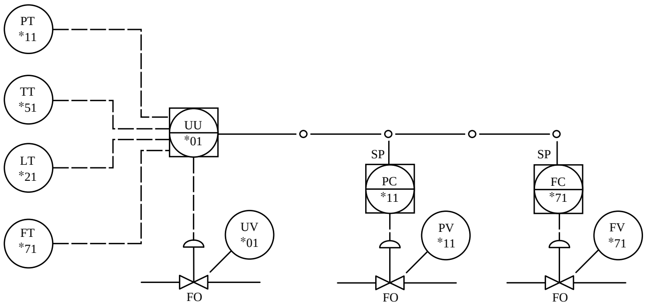


Multifunction controllers shall be drawn with bubbles for each measured variable input and output to final control elements; measured variable indicators may be:

a) Shown:



b) Assumed:



Fieldbus Devices, Loops, and Networks

Comments and Exceptions (Including Non-ISA Industrial Practice) Instrument and control systems staff working at engineering, procurement, and construction management (EPCM) companies had to improvise on P&ID symbols for fieldbus devices, loops, segments, and networks throughout the late 1990s and early 2000s. This has been the case while waiting for the draft standard work outlined in this section to be discussed and approved as the latest revision to ISA S5.1 (now ANSI/ISA-5.01.01). (For specific details on fieldbus technologies, please refer to later chapters and sections in this volume.)

Certain techniques and shortcuts used by several EPCM companies, and how they have handled fieldbus symbology, will be mentioned in this subsection. A few companies have generated their P&IDs using the proposed Instrument Line Symbol no. 20 (Table 1.1g) as the shared data links or Foundation™ fieldbus (FF) segments between field located microprocessor-based devices as well as FF host systems. In this way, it is implicit that the devices connected by that symbol are fieldbus devices and do not need any further symbology or identification on the P&IDs. This symbol also has been used for other fieldbuses such as PROFIBUS PA, PROFIBUS DP, AS-i Bus, and DeviceNet (see Figures 1.1l and 1.1m).

Another symbol used by the EPCM companies for fieldbus has been the Instrument Line Symbol no. 19 (Table 1.1g), which is the current existing symbol (ANSI/ISA S5.1-1984[1992]) and normally the one used for data links and DCS data highways. This has been done occasionally when the EPCM company's client/owner had specific, custom P&ID symbology standards and was reluctant to change a worldwide standard to a new symbol such as no. 20. Once again, any field devices such as transmitters and control valves that are connected together by Symbol no. 19 are now known to be fieldbus-type devices. The disadvantage is that the P&IDs must be studied carefully to determine real communication link, DCS data highway, system bus, or internal software link applications from the fieldbus applications.

Another EPCM company used the conventional analog electronic signal (Symbol no. 14 in Table 1.1g) at the urging of its client but added the suffix "FB" to each fieldbus device bubble on the P&IDs. Once again, this was not a standardized approach, and it led to ambiguity and misunderstanding. It is highly recommended that the proposed draft revision Instrument Line Symbol no. 20 (which we hope will be approved by the time this volume is released) be used for all types of fieldbus segments and networks.

P&IDs: Practical Aspects and Practices in the EPC Industry

Piping and instrument diagrams (P&IDs) are the basic documents describing a plant from mechanical and control point of view. They are sometimes called mechanical flow diagrams (MFDs) by some EPC and operating companies. Process flowsheets/diagrams (PFDs) are used and generated by process design engineering in the very early stage of the front-end engineering phase and do not normally include ISA symbols except in the most elementary fashion. However, they are the starting point for P&ID development.

The P&ID life cycle extends through the feasibility study, project estimate, detailed engineering phase, construction phase, precommissioning, commissioning, and, finally, to exploitation of the plant. According to which phase the project is in, the P&IDs show different level of details to suit various needs.

1) During the feasibility study, not all equipment and lines are shown; only the major ones appear, such as used to follow the path of authorizations, obtain of financing, and so on. At this stage, only major equipment is sized, such as to show environmental impact, and effluent systems are studied to comply with the information requested by various environmental authorities. Only major lines are shown, without sizing information. Very few instruments and control loops are shown, and then only in the most simplified manner.
2) During the project estimate, all equipment is shown, but without auxiliary services such as cooling water to machinery. The lines are sized, and their material and rating are shown. All control loops are shown, or at least all transmitters, local instruments, and control valves. All motor-operated valves and safety valves are shown and are sized if possible. Small-bore/diameter piping (<2 in) is not shown unless it is made of an exotic material.
3) Within the detailed engineering phase, the P&IDs are issued several times, incorporating information as it becomes available from vendors or as derived from calculations and finalization of choices. Normally, there are about three or four issues before the issue for construction. At that time, the P&IDs shall show all equipment and all lines including services to machinery, drains, and vents (as far as piping is concerned) and all instruments, control loops, and valves (as far as instrumentation is concerned).

Each line shall be sized, classified, and numbered, meaning that each line is identified with nominal diameter, piping class (which defines the material), rating (unless the piping class covers only one rating), corrosion allowance, and winterization. The control valves shall be shown with their true nominal diameter and flange rating along with block and bypass valves, handwheel, action on air failure, and possibly the pressure drop. If the valve is the angle type, the inlet and outlet shall be shown correctly. The transmitters shall be shown singularly, duplicated, or triplicated, with their pressure taps. If level bridles are used, they shall be shown with correct valving. The flow measurements shall show the correct type of primary element. Magnetic flowmeters that are required to run full should show the indication "low point."

If some devices (such as desuperheaters) require special precautions, such precautions shall be shown to prevent wrong piping design (e.g., minimum unobstructed straight length = X feet). The safety valves shall be shown with size and rating of input and output connections plus the set pressure. All vents, drains, silencers, and so on shall be shown. If many vents use common silencers, this shall be clearly indicated by means of drafting or notes. The control loops shall be shown in complete form. However, in the power industry, some boiler manufacturers show the transmitters (since they are supplied by them) and the control loops in several different documents (vendor package drawings) to be delivered to the DCS supplier or the EPC company responsible for DCS design. To prevent multiple repeats of the same information, some typical sketches should be prepared covering, for instance, the indications and commands related to an on–off motor-operated valve, an inching motor-operated valve, high-voltage motors, low-voltage motors, on–off pneumatic valves, and so forth. The typical sketches shall be numbered and referred to nearby each device on the P&ID to which it applies.

Although the P&ID symbols are normally in accordance with ISA standards, it is recommended that a P&ID symbol key sheet be prepared with a summary of all equipment and instrument symbols used to prevent any misunderstanding. The reader is referred to the previous subsection, "Inclusion of the New S5.1 Standard (now ANSI/ISA-5.01.01) in User/Owner Documents."

The tag numbering of the instruments shall be in accordance with ISA guidelines, standards, and recommended practices previously covered in this section, and all components of a loop shall have the same distinctive number so as to simplify maintenance and understanding of the process. In the case in which an instrument or loop is cancelled, its tag number shall not be used again to prevent the possibility of keeping the old process data that is no longer correct. The tag/loop cancellations must be carefully noted and retained in the instrument index, and especially in the computerized instrument database (IDB) that generates the index. For the same reason, if an instrument or a loop is moved to a different tapping point, it should be renamed—although this depends on different company standards/policies on this subject. In some cases, two pieces of equipment are used (e.g., two pumps, one spare to the other), which are named with the suffix A/B. Their relevant instruments are often tagged with the tag number suffixed with A/B. To avoid misinterpretations when two or three instruments are used in a redundant/voting configuration, it is suggested to attach suffixes to them using the letters X, Y, and Z.

Even though the P&IDs are not representative of the layout of the plant, it is recommended that the equipment be shown as it is to appear; e.g., a horizontal vessel shall be shown as horizontal and not vertical, and a boiler feed water pump with intermediate MP draft should be shown with the nozzles in correct sequence. A distillation column with different sections should be represented not as a constant one but to be roughly representative of the true situation. It is noted that the P&IDs are to be suitable for a take-off of the valves, reducers, branches, and instruments, but not for the take-off of piping and elbows.

The P&IDs depicting utility distribution or fire detection/fighting instead follow the plant plot plan and include some instruments as well.

It is important that all instruments appear on the P&ID and that none is overlooked. If some instruments are supplied as an integral part of a machine (e.g., resistance temperature detectors in electric motor windings and vibration probes in a compressor or turbine), it is advisable that the manufacturer's P&ID be numbered with the same system as the project P&IDs, and always from the viewpoint of taking care of all signals that will be connected to a PLC or DCS. In fact, most EPC companies supply the proper compatible tags and loop numbers from the IDB to the vendor after the first vendor document/drawing review and subsequent return to the vendor.

During construction and precommissioning, the P&IDs are used to keep track of the installed piping and instruments. At the precommissioning stage, they are used to verify that the plant has been built according to the P&IDs issued for construction. This is called the *check against P&IDs*. Any discrepancy found during this check shall be resolved and the plant modified or, if acceptable, the P&IDs shall be marked up to prepare the "as-built" issue.

During commissioning, some modifications could be necessary to overcome operational problems that could arise. These modifications could involve additional drains and vents, control strategy changes, and so forth and need to be recorded on the P&IDs to be introduced in the "as-built" issue.

During the life cycle of the plant, the P&IDs can be modified because of different products required, different feedstock, or additional treatment systems. This is even more evident in batch processes that can be modified to obtain different products. Sometimes, it is a concern that the revamping or debottlenecking of the original plant could be so extensive that the original P&IDs need to be redrawn. In this case, it is possible that starting from existing P&IDs could cause the introduction of several errors because they have not been updated.

The P&IDs have also a commercial impact on a project in that a payment is tied to their first issue. In defining the commercial aspects, one should determine to what extent the first issue of the P&IDs shall be complete so as to avoid conflicts between the owner and the supplier. A possible request could be as follows:

- All lines sized, classified, and numbered
- All instruments tagged
- All set values of safety valves shown

To go even farther, the size of control valves could be shown.

The P&IDs are the first step in ensuring the safety of maintenance personnel, which today is based on widely used outsourcing. For example, people should immediately be warned about the risks involved in the case of piping that has a high rating, is made with an exotic material, has high corrosion allowance, has a thick insulation, or belongs to a system with high set values for the safety valves.

1.2 Functional Diagrams and Function Symbols*

J. E. JAMISON (2003)

The purpose of this section is to help the reader establish a uniform means of depicting and identifying mainly digital-based application software functions used for measurement, monitoring, and control. It is done by presenting a designation system including graphic symbols and identification codes as well as functional diagramming techniques that were formerly known as the Scientific Apparatus Manufacturers' Association (SAMA) system.

It must be noted that a significant part of this section has been extracted from the revision work of the ISA SP5.1 subcommittee, and much of it has been based on draft working documents being utilized at the time of this writing, documents with which one of the authors has been actively involved. Other portions of this section are based on the author's experience in the industry and are not any part of the SP5.1 subcommittee proposed forthcoming revision.

> *A disclaimer to any future ISA standards documents is hereby stated: The reader is cautioned that the draft ISA document that provided much of the information in this section has not been approved as of the time of this writing. It cannot be presumed to reflect the position of ISA or any other committee, society, or group.*

The intent is to pass along to the reader the best and latest thinking on this subject at this point in time.

ISA FUNCTIONAL DIAGRAMMING (EX-SAMA)*

Instrument and Control Systems Functional Diagramming

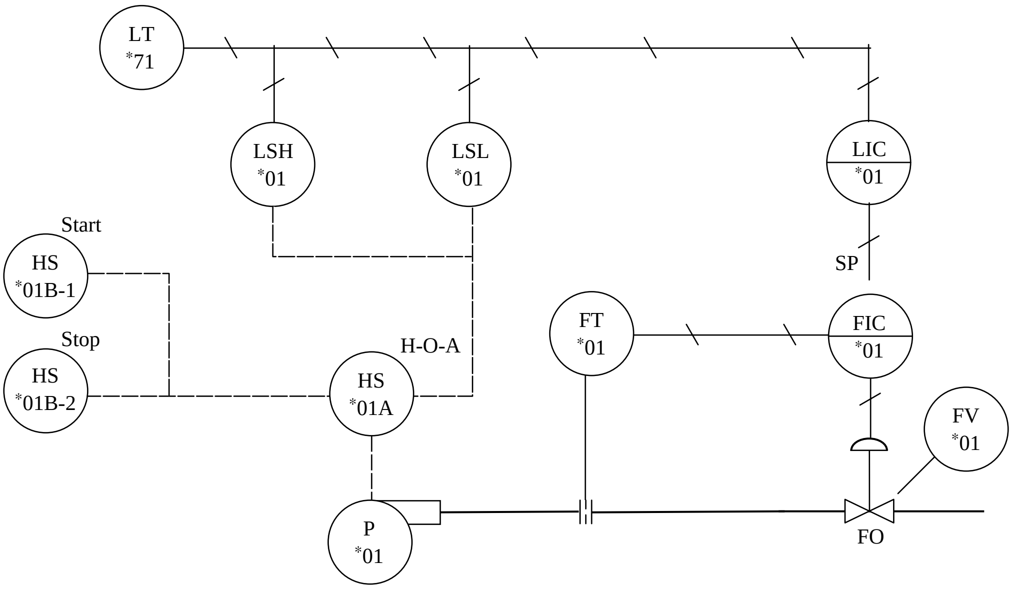
Symbol tables are given for use in preparing instrument and control loop functional diagrams, which are not normally shown on process flow diagrams (PFDs) and piping and instrument diagrams (P&IDs). They are used to depict monitoring and control loops in functional instrument diagrams, functional logic diagrams, application software diagrams, sketches, and text. They shall be prepared from the following:

a) Instrument line symbols
b) Instrument functional diagramming symbols
c) Mathematical function block symbols

Equivalent P&ID Loop, Functional Instrument and Electrical Diagrams

See statement of permission in the footnote below.

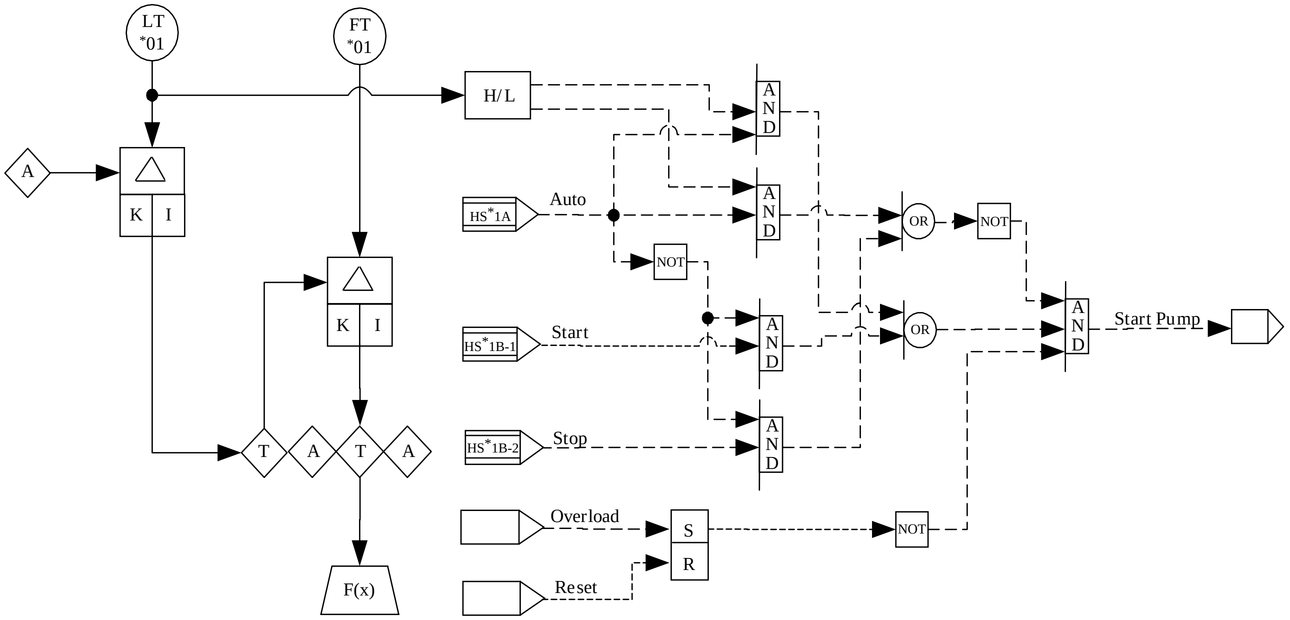
a) P&ID loop schematic:



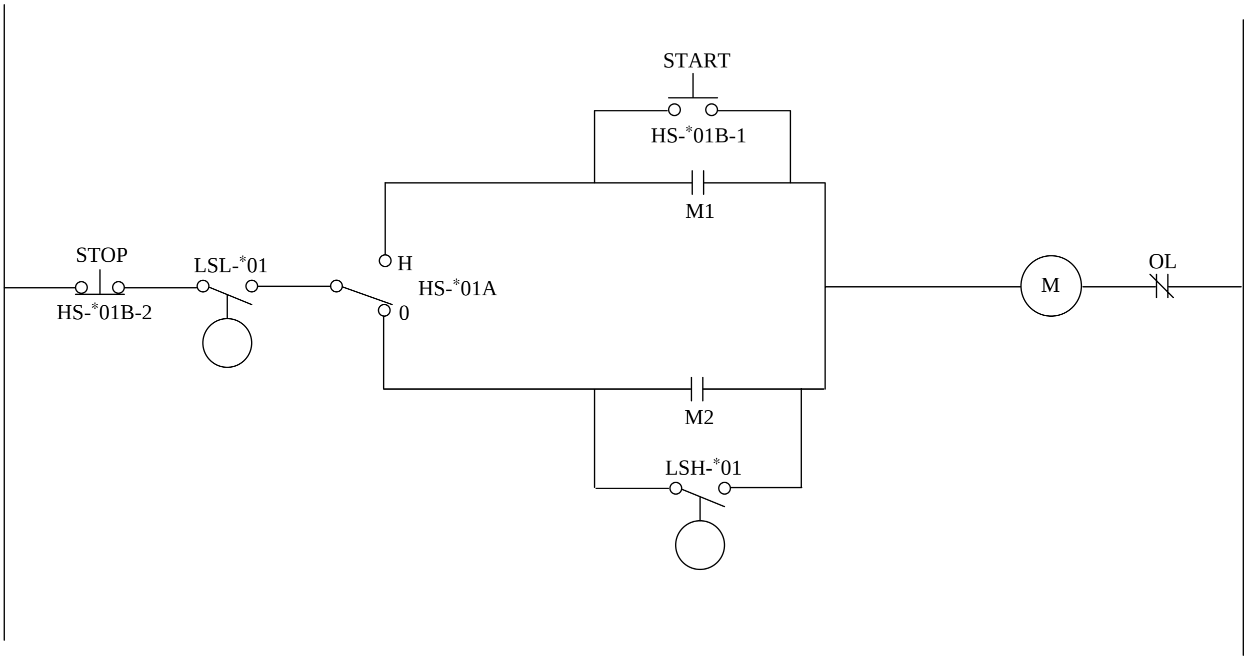
---

* Used with permission of the Instrumentation, Systems and Automation Society.

b) Functional instrument diagram:



c) Electrical schematic diagram:



Note: There is no equivalent electrical schematic for the process control instrumentation.

Functional Diagramming Symbol Tables*

The symbols used in Table 1.2a are not normally used on P&IDs but are used to diagram control systems at the hardware and function level for configuration and other purposes.

The symbols in Table 1.2b are never used in P&IDs and are used to help document and diagram logic control designs and narratives. The present standard ISA S5.2 (ANSI/ISA-S5.2–1976 [R1992]) is now being revised and rolled into the new ANSI/ISA-5.01.01 standard as proposed in the current (as of this writing) Draft 4. Symbols, truth tables, definitions, and graphs used in this section are in accordance with Draft 4 and are very different from S5.2. They are given here to illustrate the latest thinking in this area, including expanded

*The symbols have been extracted by ISA, with permission, from Scientific Apparatus Manufacturers' Association SAMA Standard PMC 22.1–1981, Functional Diagramming of Instrument and Control Systems, which is no longer supported by SAMA.

TABLE 1.2a

Functional Diagramming Symbols—Instrument and Mathematical Functions (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol*	*Description*
01		Measuring device Input device Readout device Output device Symbols from Tables 1.1h through 1.1k may be used
02		Automatic controller Single-mode controller Discrete device driver Insert function symbols, as required to define controller algorithm, from Table 1.2c Use for vertical diagramming
03		Automatic controller Two-mode controller Insert function symbols, as required to define controller algorithm, from Table 1.2c Use for vertical diagramming
04		Automatic controller Three-mode controller Insert function symbols, as required to define controller algorithm, from Table 1.2c Use for vertical diagramming
05		Automatic signal processor Insert function symbol from Table 1.2c Use for vertical diagramming
06		Automatic controller Two-mode controller Insert function symbols, as required to define controller algorithm, from Table 1.2c Use for horizontal diagramming
07		Automatic controller Two-mode controller Insert function symbols, as required to define controller algorithm, from Table 1.2c Use for horizontal diagramming
08		Automatic signal processor Insert function symbol from Table 1.2c Use for horizontal diagramming May be rotated 90°
09		Final control element Control valve Insert function symbol identifier from Table 1.2c (no. 14)
10		Final control element with positioner Control valve with positioner Insert function symbol identifier from Table 1.2c (no.14)
11		Manual signal processor (*) = A, adjustable signal generator (*) = T, signal transfer
12		Manual auto station

See statement of permission on page 31.

timing functions. Application information and examples on the use of the binary symbols are given in Section 1.12, Binary Logic Diagrams, and they use the current standard ANSI/ISA-S5.2–1976 (R1992).

Binary logic switching and memory functions are used in analog or sequential control schemes. In truth tables and graphs, logic one (1) is *true* and logic zero (0) is *false*.

TABLE 1.2b

Instrument and Control System Functional Diagramming Symbols—Binary Logic, Memory, and Time Functions (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No. *Symbol/Truth Table* *Definition/Graph*

01

	A	B	C	x	O
1	0	0	0	0	0
2	1	0	0	0	0
3	0	1	0	0	0
4	0	0	1	0	0

TABLE 1.2c
Mathematical Function Block Symbols (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol/Function*	*Equation/Graph*	*Definition*
01	Σ Summation	$M = X_1 + X_2 \dots + X_n$ 	Output equals the algebraic sum of inputs.
02	Σ/n Average	$M = X_1 + X_2 \dots + X_n/n$ 	Output equals the algebraic sum of the inputs divided by number of inputs.
03	Δ Difference	$M = X_1 - X_2$ 	Output equals the difference between two inputs.
04	X Multiplication	$M = X_1 X_2$ 	Output equals the product of the two inputs.
05	÷ Division	$M = X_1 / X_2$ 	Output equals the quotient of the two inputs.
06	X^2 Square	$M = X^2$ 	Output is equal to the square of the input.
07	X^n Exponential	$M = X^n$ 	Output is equal to the *n*th power of the input.

(Continued)

TABLE 1.2c Continued

Mathematical Function Block Symbols (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol/Function*	*Equation/Graph*	*Definition*
08	√ Square Root	 $M = \sqrt{X}$	Output is equal to the square root of the input.
09	$\sqrt[n]{\ }$ *n*th Root	 $M = \sqrt[n]{X}$	Output is equal to the *n*th root of the input.
10	K or P Proportional	 $M = KX$	Output is proportional to the input. Replace “K” with “1:1” for volume boosters. Replace “K” with “2:1”, ‘3:1”, etc. for integer gains.
11	-K or -P Reverse Proportional	 $M = -KX$	Output is inversely proportional to the input.
12	∫ or I Integral	 $M = (1/T_I) \int X\,dt$	Output varies with the magnitude and time duration of the input. Output is proportional to the time integral of the input. T_I, the integral time constant.
13	d/dt or D Derivative	 $M = T_D\,(dX/dt)$	Output is proportional to the time rate of change of the input. T_D, derivative time constant.
14	*ƒ*(X) Unspecified Function	 $M = f(X)$	Output is a nonlinear or unspecified function of the input. Function is defined in note or other text.

TABLE 1.2c Continued

Mathematical Function Block Symbols (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol/Function*	*Equation/Graph*	*Definition*
15	$f(\mathrm{t})$ Time Function	$M = Xf(t)$ 	Output equals a nonlinear or unspecified time function times the input. Output is a nonlinear or unspecified time function.
16	$>$ High Select	$M = X_1$ for $X_1 \geq X_2$, $M = X_2$ for $X_1 \leq X_2$ 	Output equals greater of two or more inputs.
17	$<$ Low Select	$M = X_1$ for $X_1 \leq X_2$, $M = X_2$ for $X_1 \geq X_2$ 	Output equals lesser of two or more inputs.
18	$\ngtr$ High Limit	$M = X_1$ for $X_1 \leq H$, $M = X_2$ for $X_1 \geq H$ 	Output equals the lower of the input or high limit values.
19	$\nless$ Low Limit	$M = X_1$ for $X_1 \geq L$, $M = X_2$ for $X_1 \leq L$ 	Output equals the higher of the input or low limit values.
20	V̶ Velocity Limiter	$dM/dt = dX/dt$ $(dX/dt \leq H, M = X)$ $dM/dt = H$ $(dX/dt \geq H, M \neq X)$ 	Output equals input as long as the input rate of change does not exceed the limit value that establishes the output rate of change until the output again equals the input.

(Continued)

TABLE 1.2c Continued

Mathematical Function Block Symbols (proposed for the next revision of ISA S5.1 [now ANSI/ISA-5.01.01] at the time of this writing)

No.	*Symbol/Function*	*Equation/Graph*	*Definition*
21	+ Positive Bias	$M = X + b$ 	Output is equal to input plus an arbitrary value.
22	– Negative Bias	$M = X - b$ 	Output is equal to input minus an arbitrary value.
25	*/* Conversion	I = P, P = I, etc. 	Output signal type is different from that of input signal. * is equal to: E – voltage, A – analog I – current, B – binary P – pneumatic, D – digital R – resistance, H – hydraulic O – electromagnetic, sonic
26	*H High Signal Monitor	(State 1) $M = 0 @ X < H$ (State 2) $M = 1 @ X \geq H$ 	Output state is dependent on the value of the input. Output changes state when the input is equal to or higher than an arbitrary high limit.
27	*L Low Signal Monitor	(State 1) $M = 0 @ X \leq H$ (State 2) $M = 1 @ X > H$ 	Output state is dependent on the value of the input. Output changes state when the input is equal to or lower than an arbitrary low limit.

TABLE 1.2c Continued

No.	*Symbol/Function*	*Equation/Graph*	*Definition*
28	$*$HL High/Low Signal Monitor	(State 1) $M = 1$ @ $X \le L$ (State 2) $M = 0$ @ $L < X < H$ (State 3) $M = 1$ @ $X \ge H$ 	Output states are dependent on value of input. Output changes state when input is equal to or lower than an arbitrary low limit or equal to or higher than an arbitrary high limit.
29	T Transfer	(State 1) $M = X_1$ (State 2) $M = X_2$ 	Output equals input that is selected by transfer. Transfer is actuated by external signal.

See statement of permission on page 31.

1.3 Instrument Terminology and Performance*

B. G. LIPTÁK (1982, 1995, 2003)

This section was reprinted with format change only from the work titled "Process Instrumentation Terminology (ANSI/ISA-51.1-1979, Reaffirmed 26 May 1995)" with the permission of The Instrumentation, Systems and Automation Society. This permission is gratefully acknowledged. When using the definitions in this document, please indicate, "This definition is from ANSI/ISA-51.1–1979 (R1993), Process Instrumentation Terminology. Copyright © 1993, ISA—The Instrumentation, Systems and Automation Society." For information, visit www.isa.org.

The purpose of this standard is to establish uniform terminology in the field of process instrumentation. The generalized test procedures described in the section titled "Test Procedures" are intended only to illustrate and clarify accuracy-related terms. It is not intended that they describe specific and detailed test procedures.

This process instrumentation terminology standard is intended to include many specialized terms used in the industrial process industries to describe the use, performance, operating influences, hardware, and product qualification of the instrumentation and instrument systems used for measurement, control, or both. Many terms and definitions relate to performance tests and environmental influences (operating conditions) as further explained in the "Introductory Notes" section. Basically, this document is a guideline to promote vendor/user understanding when referring to product specifications, performance, and operating conditions. Process industries include chemical, petroleum, power generation, air conditioning, metallurgical, food, textile, paper, and numerous other industries.

The terms of this standard are suitable for use by people involved in all activities related to process instrumentation, including research, design, manufacture, sales, installation, test, use, and maintenance.

The standard consists of terms selected primarily from Scientific Apparatus Makers Association (SAMA) Standard PMC20.1 and American National Standards Institute (ANSI) Standard C85.1. Additional terms have been selected from other recognized standards. Selected terms and definitions have not been modified unless there was a sufficiently valid reason for doing so. New terms have been added and defined where necessary.

This standard is primarily intended to cover the field of analog measurement and control concepts and makes no effort to develop terminology in the field of digital measurement and control.

INTRODUCTORY NOTES

Defined terms, where used as a part of other definitions, are set in italics to provide a ready cross-reference. In defining certain performance terms, the context in which they are used has been considered. It is fitting, therefore, that the philosophy of performance evaluation on which these terms are based be explained.

Ideally, instruments should be designed for realistic operating conditions (those they are likely to meet in service), and they should be evaluated under the same conditions. Unfortunately, it is not practical to evaluate performance under all possible combinations of operating conditions. A test procedure must be used that is practical under laboratory conditions and, at the same time, will make available, with a reasonable amount of effort, sufficient data on which a judgement of field performance can be made.

The method of evaluation envisioned is that of checking significant performance characteristics such as accuracy rating, dead band, and hysteresis under a set of reference operating conditions, these having a narrow range of tolerances.

Reference performance is, therefore, to be evaluated and stated in terms of reference operating conditions. Generally, reference performance under reference operating conditions represents the "best" performance that can be expected under ideal conditions.

The effect of change in an individual operating condition, such as ambient temperature, atmospheric pressure, relative humidity, line voltage, and frequency, will be determined individually throughout a range defined as "normal operating conditions." Logically, these can be expected to occur above and below the values of reference operating conditions during field operation.

While this approach does not duplicate all actual conditions, where many operating variables may vary simultaneously in random fashion, it does develop data from which

---

* Used with permission of the Instrumentation, Systems and Automation Society.

performance may be inferred from any given set of operating conditions.

The effect of changes in an individual operating condition, all other operating conditions being held within the reference range, is herein called *operating influence*. There may be an operating influence corresponding to a change in each operating condition. In some cases, the effect may be negligible; in others, it may have significant magnitude.

Tabulations of operating influences will usually denote the performance quality level of a given design. Comparisons of reference performance and operating influences for instruments of a given design, or for different designs, will show clearly their relative merits and probable performance under actual operating conditions.

Operating Conditions vs. Performance

Operating Conditions	*Performance*
Reference (narrowband)	Reference (Region within which accuracy statements apply unless indicated otherwise.)
Normal (wideband)	Conditional (Region within which the influence of environment on performance is stated.)
Operative Limits (extreme band)	Indefinite (Region within which influences are not stated and beyond which damage may occur.)

SOURCES AND REFERENCES

In the preparation of this standard of terminology, many standards and publications sponsored by technical organizations such as the American Society of Mechanical Engineers (ASME), the Institute of Electrical and Electronics Engineers (IEEE), and ISA (formerly called the Instrument Society of America) were studied by the committee, in addition to those listed as principal source documents. These are listed as references.

Existing terms and definitions have been used wherever they were considered suitable. In many cases, terms have been extracted from source documents with verbatim definitions. In such cases, permission to quote from the respective source document has been obtained from the organization concerned, as indicated below. Terms defined verbatim are followed by the reference number in parentheses. For example, (4) after a defined term indicates that this term is quoted verbatim from ANSI C85.1, “Terminology for Automatic Control.”

In other cases, definitions have been modified in varying degrees to conform with current practice in process instrumentation. These have been noted in parentheses as “Ref.” followed by the reference number. For example, (Ref. 8) indicates that this term is a modified definition of the referenced term in SAMA-PMC 20.1–1973, “Process Measurement and Control Terminology.”

An omission or alteration of a note following a definition is not considered to be a modification of the definition and is not identified by the abbreviation “Ref.”

Principal source documents used from the many reviewed are as follows:

1) American National Standard C39.4–1966, “Specifications for Automatic Null-Balancing Electrical Measuring Instruments,” published by the American National Standards Institute, Inc., copyright 1966 by ANSI.
2) American National Standard C42.100–1972, “Dictionary of Electrical and Electronics Engineers, Inc., copyright 1972 by IEEE.
3) American National Standard C85.1–1963, “Terminology for Automatic Control,” published by the American Society of Mechanical Engineers, copyright 1963 by ASME.
4) SAMA Standard PMC20.1–1973, “Process Measurement and Control Terminology,” published by Scientific Apparatus Makers Association, Process Measurement and Control Section, Inc., copyright 1973 by SAMA-PMC.

Copies of the American National Standards referred to above may be purchased from the American National Standards Institute, 1430 Broadway, New York, NY 10018. Copies of the SAMA Standard may be purchased from Process Measurement and Control Section, Inc., SAMA, 1101 16th Street N.W., Washington, DC 20036.

DEFINITION OF TERMS

*Accuracy**. In process instrumentation, degree of *conformity* of an indicated value to a recognized accepted standard value, or ideal value. (Ref. 4, Ref. 8)

Accuracy, measured. The maximum positive and negative *deviation* observed in testing a *device* under specified conditions and by a specified procedure. See Figure 1.3a. *Note 1:* It is usually measured as an inaccuracy and expressed as accuracy. *Note 2:* It is typically expressed in terms of the measured variable, percent of span, percent of upper range value, percent of scale length, or percent of actual output reading. See section titled “Test Procedures.”

Accuracy rating. In process instrumentation, a number or quantity that defines a limit that *errors* will not exceed when a *device* is used under specified *operating conditions*. See Figure 1.3a. *Note 1:* When operating conditions are not specified, *reference operating conditions* shall be assumed. *Note 2:* As a performance specification, *accuracy* (or reference accuracy)

---

* Throughout this handbook, the term *inaccuracy* has been used instead of *accuracy*, because the term relates to the error in a measurement. In the following paragraphs, the *accuracy* term is used, because this section is being quoted from an ISA standard and not because the author agrees with its use.

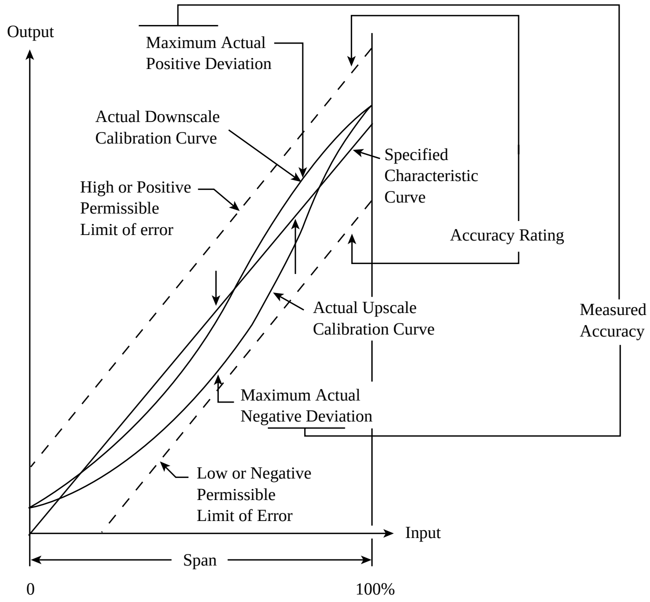

FIG. 1.3a
Accuracy.

shall be assumed to mean accuracy rating of the *device* when used at *reference operating conditions. Note 3:* Accuracy rating includes the combined effects of *conformity*, *hysteresis*, *dead band*, and *repeatability* errors. The units being used are to be stated explicitly. It is preferred that a ± sign precede the number or quantity. The absence of a sign indicates a + and a − sign.

Accuracy rating can be expressed in a number of forms. The following five examples are typical:

(a) Accuracy rating expressed in terms of the *measured variable*. Typical expression: The accuracy rating is ±1°C, or ±2°F.
(b) Accuracy rating expressed in percent of *span*. Typical expression: The accuracy rating is ±0.5% of span. (This percentage is calculated using scale units such as degrees Fahrenheit, psig, and so forth.)
(c) Accuracy rating expressed in percent of the upper range value. Typical expression: The accuracy rating is ±0.5% of upper range value. (This percentage is calculated using scale units such as kPa, degrees Fahrenheit, and so forth.)
(d) Accuracy rating expressed in percent of scale length. Typical expression: The accuracy rating is ±0.5% of scale length.
(e) Accuracy rating expressed in percent of actual output reading. Typical expression: The accuracy rating is ±1% of actual output reading.

Accuracy, reference. See *accuracy rating.*

Actuating error signal. See *signal, actuating error.*

Adaptive control. See *control, adaptive*.

Adjustment, span. Means provided in an instrument to change the slope of the input–output curve. See *span shift*.

Adjustment, zero. Means provided in an instrument to produce a parallel shift of the input–output curve. See *zero shift*.

Air conditioned area. See *area, air conditioned.*

Air consumption. The maximum rate at which air is consumed by a *device* within its operating *range* during *steady-state signal conditions. Note:* It is usually expressed in cubic feet per minute (ft^3/min) or cubic meters per hour (m^3/h) at a standard (or normal) specified temperature and pressure. (8)

Ambient pressure. See *pressure, ambient*.

Ambient temperature. See *temperature, ambient*.

Amplifier. A *device* that enables an *input signal* to control power from a source independent of the *signal* and thus be capable of delivering an output that bears some relationship to, and is generally greater than, the *input signal*. (3)

Analog signal. See *signal, analog*.

Area, air conditioned. A location in which temperature at a nominal value is maintained constant within narrow tolerance at some point in a specified band of typical comfortable room temperature. Humidity is maintained within a narrow specified band. *Note:* Air conditioned areas are provided with clean air circulation and are typically used for instrumentation, such as computers or other equipment requiring a closely controlled environment. (Ref. 18)

Area, control room. A location with heat and/or cooling facilities. Conditions are maintained within specified limits. Provisions for automatically maintaining constant temperature and humidity may or may not be provided. *Note:* Control room areas are commonly provided for operation of those parts of a *control system* for which operator surveillance on a continuing basis is required. (18)

Area, environmental. A basic qualified location in a plant with specified environmental conditions dependent on severity. *Note:* Environmental areas include *air conditioned areas; control room areas,* heated and/or cooled; *sheltered areas (process* facilities); and *outdoor areas* (remote field sites). See specific definitions.

Area, outdoor. A location in which equipment is exposed to outdoor ambient conditions, including temperature, humidity, direct sunshine, wind, and precipitation. (Ref. 18)

Area, sheltered. An industrial *process* location, area, storage, or transportation facility, with protection against direct exposure to the elements, such as direct sunlight, rain or other precipitation, or full wind pressure. Minimum and maximum temperatures and humidity may be the same as outdoors. Condensation can occur. Ventilation, if any, is by natural means. *Note:* Typical areas are shelters for operating instruments, unheated warehouses for storage, and enclosed trucks for transportation. (18)

Attenuation. (1) A decrease in *signal* magnitude between two points or between two frequencies. (2) The reciprocal of *gain. Note:* It may be expressed as a dimensionless ratio, scalar ratio, or in decibels as 20 times the log$_{10}$ of that ratio. (Ref. 4)

Auctioneering device. See *signal selector.*

Automatic control system. See *control system, automatic.*

Automatic/manual station. A *device* that enables an operator to select an automatic *signal* or a manual *signal* as the input to a controlling element. The automatic *signal* is normally the output of a *controller*, while the manual *signal* is the output of a manually operated *device.*

Backlash. In process instrumentation, a relative movement between interacting mechanical parts, resulting from looseness when motion is reversed. (Ref. 4)

Bode diagram. In process instrumentation, a plot of log gain (magnitude ratio) and phase angle values on a log frequency base for a *transfer function.* See Figure 1.3b. (8, Ref. 4)

Break point. The junction of the extension of two confluent straight line segments of a plotted curve. *Note:* In the asymptotic approximation of a log-gain vs. log-frequency relation in a Bode diagram, the value of the abscissa is called the *corner frequency.* See Figure 1.3b. (4, 8)

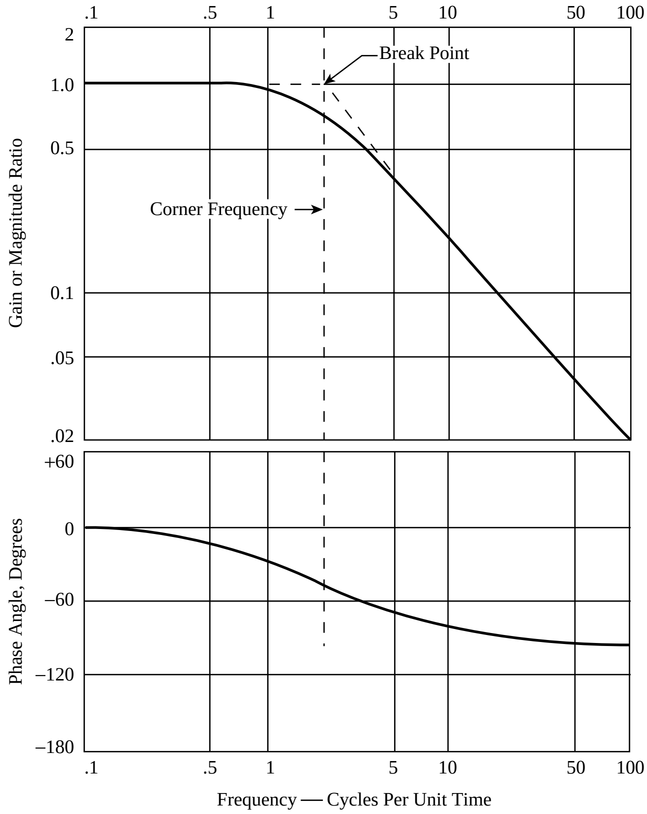

FIG. 1.3b
Typical Bode diagram.

Calibrate. To ascertain outputs of a *device* corresponding to a series of values of a quantity that the *device* is to measure, receive, or transmit. Data so obtained are used to:

1. Determine the locations at which scale graduations are to be placed
2. Adjust the output, to bring it to the desired value, within a specified tolerance
3. Ascertain the *error* by comparing the *device* output reading against a standard (Ref. 3)

Calibration curve. A graphical representation of the *calibration report.* (Ref. 11) For example, see Figure 1.3ff.

Calibration cycle. The application of known values of the *measured variable* and the recording of corresponding values of *output* readings, over the *range* of the instrument, in ascending and descending directions. (Ref. 11)

Calibration report. A table or graph of the measured relationship of an instrument as compared, over its *range,* against a standard. (Ref. 8) For example, see Table 1.3gg.

Calibration traceability. The relationship of the calibration of an instrument through a step-by-step process to an instrument or group of instruments calibrated and certified by a national standardizing laboratory. (Ref. 11)

Cascade control. See *control, cascade.*

Characteristic curve. A graph (curve) that shows the ideal values at *steady state,* or an output variable of a system as a function of an input variable, the other input variables being maintained at specified constant values. *Note:* When the other input variables are treated as *parameters,* a set of characteristic curves is obtained. (Ref. 17)

Closed loop. See *loop, closed.*

Closed-loop gain. See *gain, closed-loop.*

Coefficient, temperature/pressure/etc. See *operating influence.*

Cold junction. See *reference junction.*

Common-mode interference. See *interference, common-mode.*

Common-mode rejection. The ability of a circuit to discriminate against a *common-mode voltage. Note:* It may be expressed as a dimensionless ratio, a scalar ratio, or in decibels as 20 times the log$_{10}$ of that ratio.

Common-mode voltage. See *voltage, common-mode.*

Compensation. In process instrumentation, provision of a special construction, a supplemental device or circuit, or special materials to counteract sources of error due to variations in specified operating conditions. (Ref. 11)

Compensator. A device that converts a signal into some function that, either alone or in combination with other signals, directs the final controlling element to reduce deviations in the directly controlled variable. See Figures 1.3j and 1.3k for application of "setpoint compensator" and "load compensator."

Compliance. The reciprocal of stiffness.

Computing instrument. See *instrument, computing.*

Conformity (of a curve). The closeness to which the curve approximates a specified one (e.g., logarithmic, parabolic, cubic, and so on). *Note 1:* It is usually measured in terms of nonconformity and expressed as conformity, e.g., the maximum deviation between an average curve and a specified curve. The average curve is determined after making two or more full-range traverses in each direction. The value of conformity is referred to the output unless otherwise stated. See *linearity. Note 2:* As a performance specification, conformity should be expressed as independent conformity, terminal-based conformity, or zero-based conformity. When expressed simply as conformity, it is assumed to be independent conformity. (8, Ref. 4)

Conformity, independent. The maximum deviation of the calibration curve (average of upscale and downscale readings) from a specified characteristic curve positioned so as to minimize the maximum deviation. See Figure 1.3c. (8)

Conformity, terminal-based. The maximum deviation of the calibration curve (average of upscale and downscale readings) from a specified characteristic curve positioned so as to coincide with the actual characteristic curve at upper and lower range values. See Figure 1.3d. (8)

Conformity, zero-based. The maximum deviation of the calibration curve (average of upscale and downscale readings) from a specified characteristic curve positioned so as to coincide with the actual characteristic curve at the lower range value. See Figure 1.3e. (Ref. 8)

Contact, operating conditions, normal. See *operating conditions, normal.*

Control action. Of a controller or of a controlling system, the nature of the change of the output effected by the input. *Note:* The output may be a signal or a value of a manipulated variable. The input may be the control loop feedback signal when the setpoint is constant, an actuating error signal, or the output of another controller. (Ref. 4, Ref. 8)

Control action, derivative (rate) (d). Control action in which the output is proportional to the rate of change of the input. (8, Ref. 4)

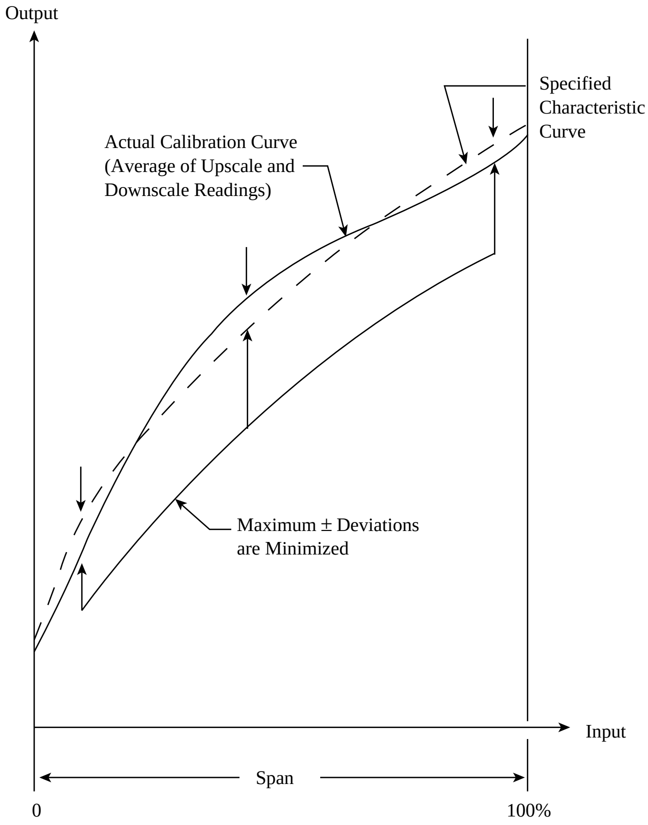

FIG. 1.3c
Independent conformity.

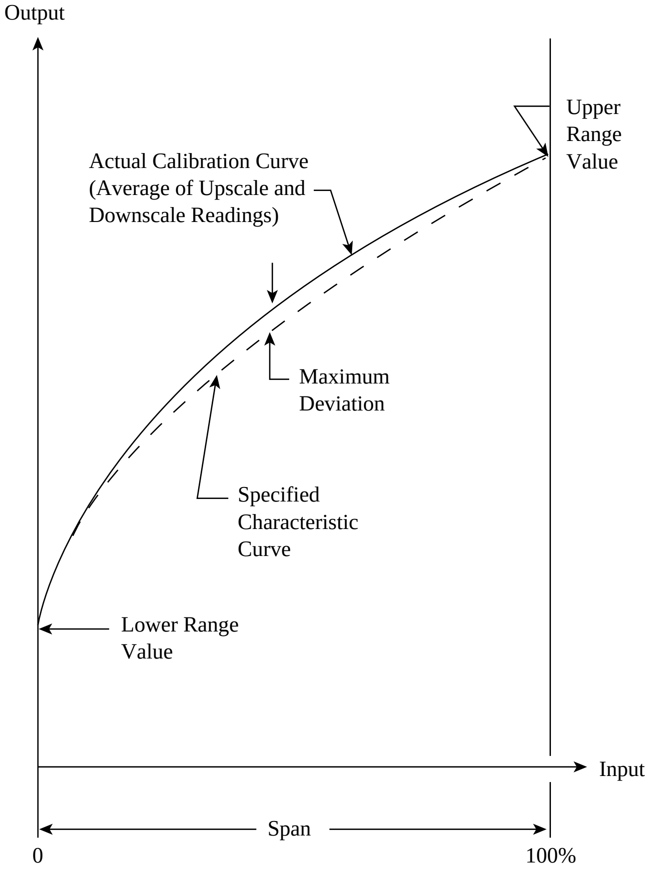

FIG. 1.3d
Terminal-based conformity.

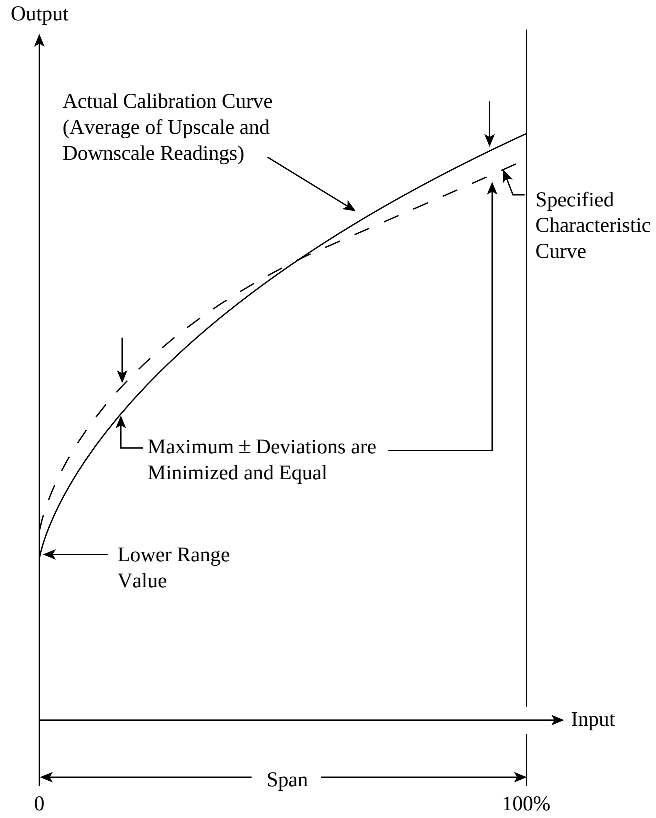

FIG. 1.3e
Zero-based conformity.

Control action, floating. Control action in which the rate of change of the output variable is a predetermined function of the input variable. *Note:* The rate of change may have one absolute value, several absolute values, or any value between two predetermined values. (Ref. 17, "floating action")

Control action, integral (reset) (i). Control action in which the output is proportional to the time integral of the input; i.e., the rate of change of output is proportional to the input. See Figure 1.3f. *Note:* In the practical embodiment of integral control action, the relation between output and input, neglecting high-frequency terms, is given by

$$\frac{Y}{X} = \pm\frac{I/s}{bI/s+1}, \quad \text{where } 0 \leqq b \ll 1 \tag{1.3(1)}$$

and

b = reciprocal of *static gain*
$1/2\pi$ = *gain crossover frequency* in hertz
s = complex variable
X = input transform
Y = output transform
I = *integral action rate* (4, 8)

See note under *control action*.

Control action, proportional (p). Control action in which there is a continuous linear relation between the output and the input. *Note:* This condition applies when both the output and input are within their normal operating *ranges* and when operation is at a frequency below a limiting value. (4, 8) See note under *control action.*

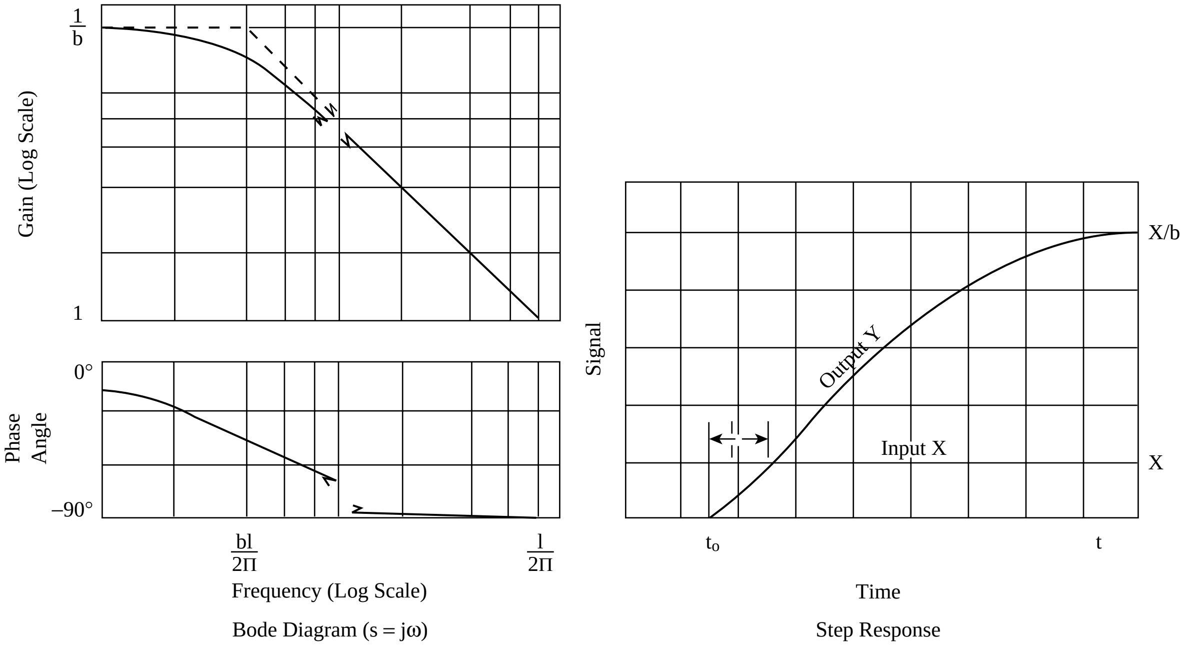

FIG. 1.3f
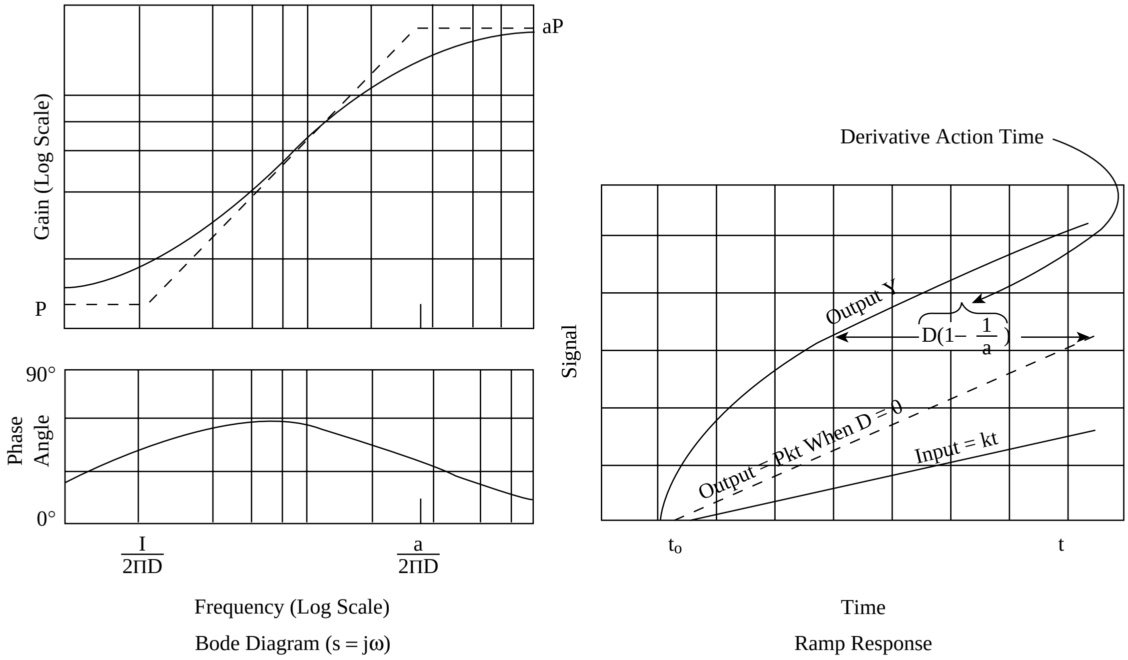
Integral control action.



Frequency (Log Scale)
Bode Diagram (s = jω)

Time
Ramp Response

FIG. 1.3g
Proportional plus derivative control action.

Control action, proportional plus derivative (rate) (pd). Control action in which the output is proportional to a linear combination of the input and the time rate of change of the input. See Figure 1.3g. *Note:* In the practical embodiment of proportional plus derivative control action, the relationship between output and input, neglecting high frequency terms, is

$$\frac{Y}{X} = \pm P\frac{1+sD}{1+sD/a}, \quad \text{where } a > 1 \qquad \textbf{1.3(2)}$$

a = *derivative action gain*
D = *derivative action time constant*
P = *proportional gain*
s = complex variable
X = input transform
Y = output transform (4, 8)

See note under *control action.*

Control action, proportional plus integral (reset) (pi). Control action in which the output is proportional to a linear combination of the input and the time integral of the input. See Figure 1.3h. *Note:* In the practical embodiment of proportional plus integral control action, the relationship between output and input, neglecting high-frequency terms, is

$$\frac{Y}{X} = \pm P\frac{I/s+1}{bI/s+1}, \quad \text{where } 0 \leqq b \ll 1 \qquad \textbf{1.3(3)}$$

and

b = *proportional gain/static gain*
I = *integral action rate*
P = *proportional gain*
s = complex variable
X = input transform
Y = output transform (4, 8)

See note under *control action.*

Control action, proportional plus integral (reset) plus derivative (rate) (pid). Control action in which the output is proportional to a linear combination of the input, the time integral of input, and the time rate of change of input. See Figure 1.3i. *Note:* In the practical embodiment of proportional plus integral plus derivative control action, the relationship of output to input, neglecting high-frequency terms, is

$$\frac{Y}{X} = \pm P\frac{I/s+1+Ds}{bI/s+1+Ds/a}, \quad \text{where } a > 1.0 \leqq b \ll 1 \qquad \textbf{1.3(4)}$$

and

a = *derivative action gain*
b = *proportional gain/static gain*
D = *derivative action time constant*
I = *integral action rate*
P = *proportional gain*
s = complex variable
X = input transform
Y = output transform (4, 8)

See note under *control action.*

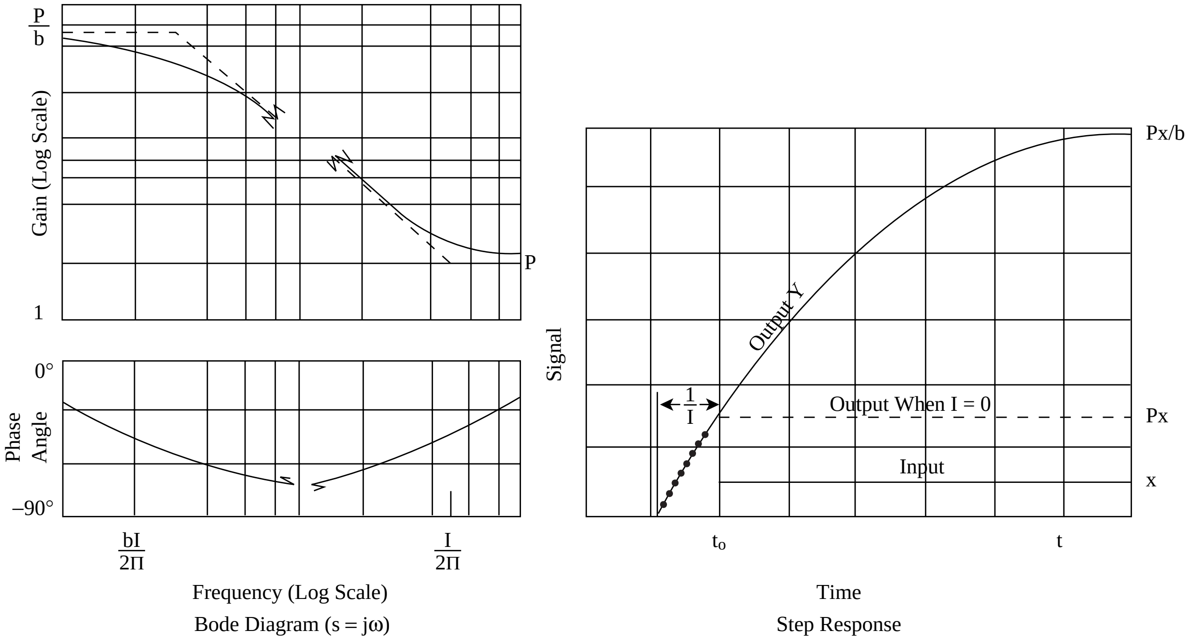


FIG. 1.3h
Proportional plus integral control action.

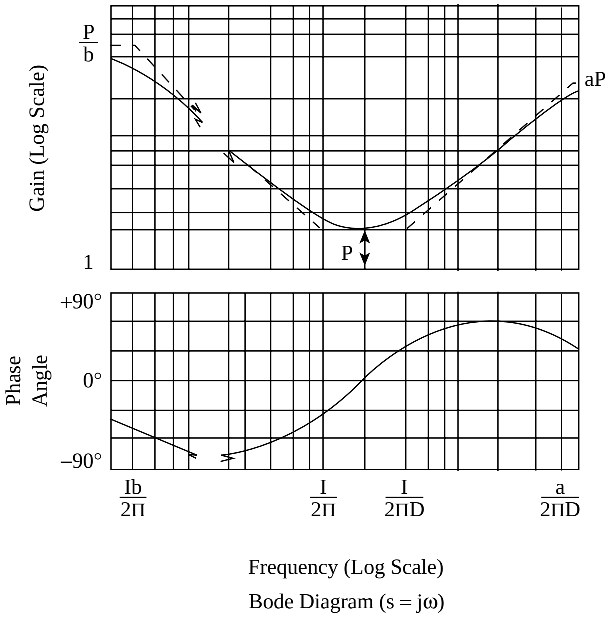

FIG. 1.3i
Proportional plus integral plus derivative control action.

Control, adaptive. Control in which automatic means are used to change the type or influence (or both) of control *parameters* in such a way as to improve the performance of the *control system.* (8, Ref. 4, “control system, adaptive”)

Control, cascade. Control in which the output of one *controller* is the *setpoint* for another *controller.* (Ref. 8, “control action, cascade”)

Control center. An equipment structure, or group of structures, from which a *process* is measured, controlled, and/or monitored. (Ref. 12)

Control, differential gap. Control in which the output of a *controller* remains at a maximum or minimum value until the controlled variable crosses a band or gap, causing the output to reverse. The controlled variable must then cross the gap in the opposite direction before the output is restored to its original condition.

Control, direct digital. Control performed by a digital *device* that establishes the *signal* to the *final controlling element. Note:* Examples of possible digital (D) and analog (A) combinations for this definition are (Ref. 8, “control action, direct digital”) as follows:

	Feedback Elements	*Controller*	*Final Controlling Element*
1.	D	D	D
2.	A	D	D
3.	A	D	A
4.	D	D	A

Control, feedback. Control in which a *measured variable* is compared to its *desired value* to produce an *actuating error signal* that is acted upon in such a way as to reduce the magnitude of the *error.* (Ref. 8, “control action, feedback”)

Control, feedforward. Control in which information concerning one or more conditions that can disturb the conrolled variable is converted, outside of any feedback loop, into corrective action to minimize *deviations* of the controlled variable. *Note:* The use of feedforward control does not change system stability, because it is not part of the feedback loop, which determines the stability characteristics. See Figures 1.3j and 1.3k. (Ref. 8, "control action, feedforward")

Control, high limiting. Control in which the output *signal* is prevented from exceeding a predetermined high limiting value. (Ref. 8 "control action, high limiting")

Controlled system. See *system, controlled*.

Controller. A *device* that operates automatically to regulate a controlled variable. *Note:* This term is adequate for the *process* industries in which the word "controller" always means "automatic controller." In some industries, "automatic" may not be implied,

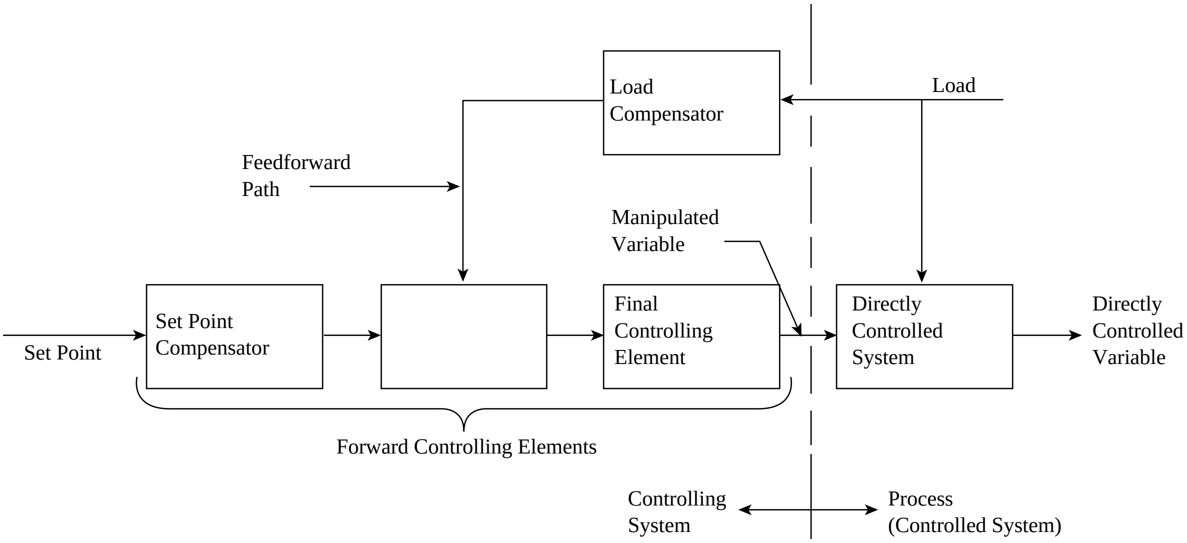

FIG. 1.3j
Feedforward control without feedback.

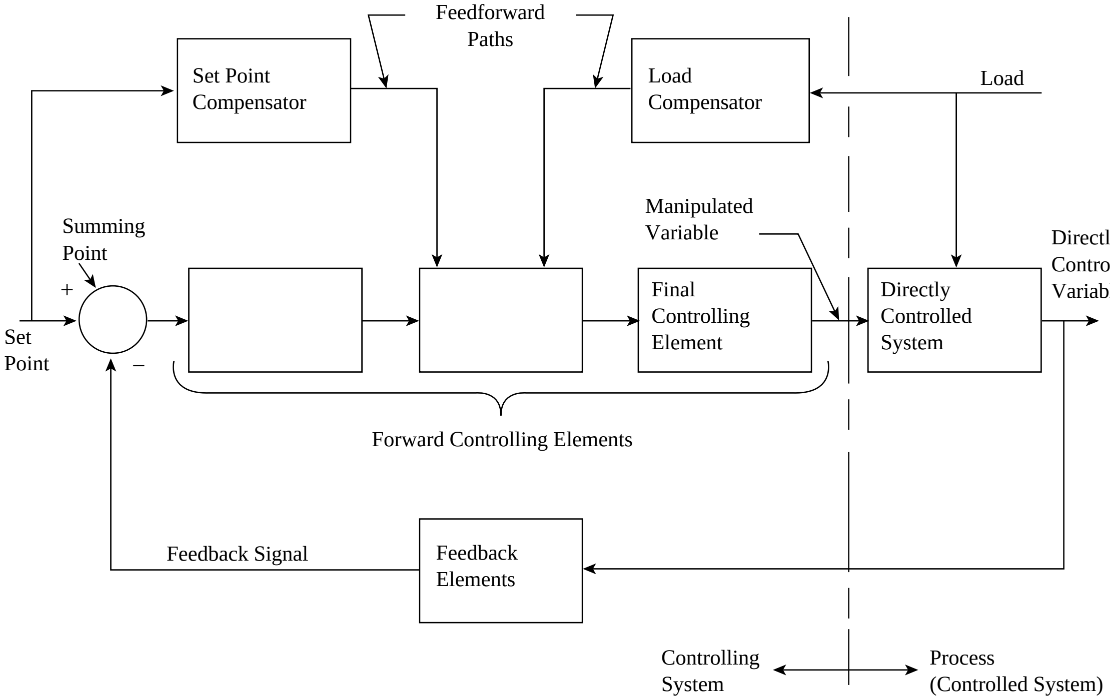

FIG. 1.3k
Feedforward control with feedback.

and the term "automatic controller" is preferred. (8, Ref. 4, "automatic controller")

Controller, derivative (d). A *controller* that produces *derivative control action* only.

Controller, direct acting. A *controller* in which the value of the *output signal* increases as the value of the input (*measured variable)* increases. See *controller, reverse acting.* (Ref. 8)

Controller, floating. A *controller* in which the rate of change of the output is a continuous (or at least a piecewise continuous) function of the *actuating error signal. Note:* The output of the *controller* may remain at any value in its operating *range* when the *actuating error signal* is zero and constant. Hence, the output is said to *float*. When the *controller* has *integral control action* only, the mode of control has been called *proportional speed floating*. The use of the term *integral control action* is recommended as a replacement for "proportional speed floating control." (8)

Controller, integral (reset) (i). A controller that produces *integral control action* only. *Note:* It may also be referred to as "controller, proportional speed floating." (8)

Controller, multiple-speed floating. A *floating controller* in which the output may change at two or more rates, each corresponding to a definite range of values of the *actuating error signal.* (8, Ref. 4, "control system, multiple-speed floating")

Controller, multiposition. A *controller* having two or more discrete values of output. See Figure 1.3l. (8)

Controller, on–off. A *two-position controller* of which one of the two discrete values is zero. See Figures 1.3n and 1.3o. (Ref. 8)

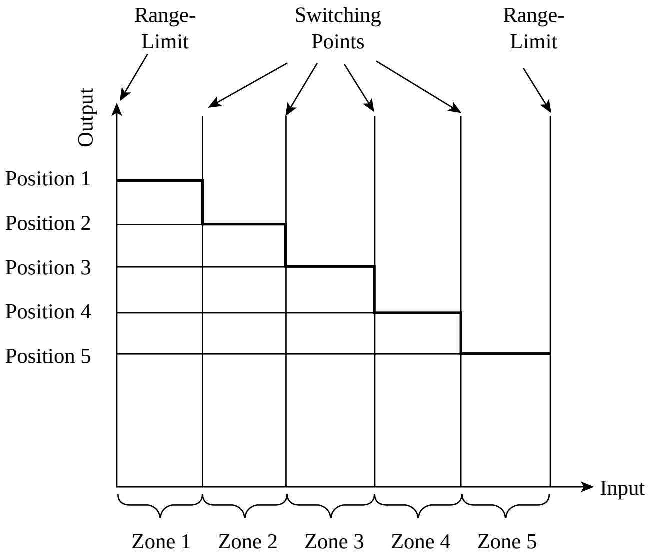

FIG. 1.3l
Multi-position controller.

Controller, program. A *controller* that automatically holds or changes *setpoint* to follow a prescribed program for a *process.*

Controller, proportional (p). A *controller* that produces *proportional control action* only. (8)

Controller, proportional plus derivative (rate) (pd). A *controller* that produces *proportional plus derivative (rate) control action.* (8)

Controller, proportional plus integral (reset) (pi). A *controller* that produces *proportional plus integral (reset) control action.* (8)

Controller, proportional plus integral (reset) plus derivative (rate) (pid). A *controller* that produces *proportional plus integral (reset) plus derivative (rate) control action.* (8)

Controller, proportional speed floating. See *controller, integral (reset) (I).* (8)

Controller, ratio. A *controller* that maintains a predetermined ratio between two variables. (Ref. 4, "control system, ratio," Ref. 8)

Controller, reverse acting. A *controller* in which the value of the *output signal* decreases as the value of the input *(measured variable)* increases. See *controller, direct acting.* (Ref. 8)

Controller, sampling. A *controller* using intermittently observed values of a *signal* such as the *setpoint* signal, the *actuating error signal*, or the *signal* representing the controlled variable to effect *control action.* (8, Ref. 4, "control system, sampling")

Controller, self-operated (regulator). A *controller* in which all the energy to operate the *final controlling element* is derived from the *controlled system.* (Ref. 4, Ref. 8)

Controller, single-speed floating. A floating controller in which the output changes at a fixed rate, increasing or decreasing depending on the sign of the *actuating error signal.* See *controller, floating. Note:* A neutral zone of values of the *actuating error signal* in which no action occurs may be used. (Ref. 4, "control system, single speed floating." Ref. 8)

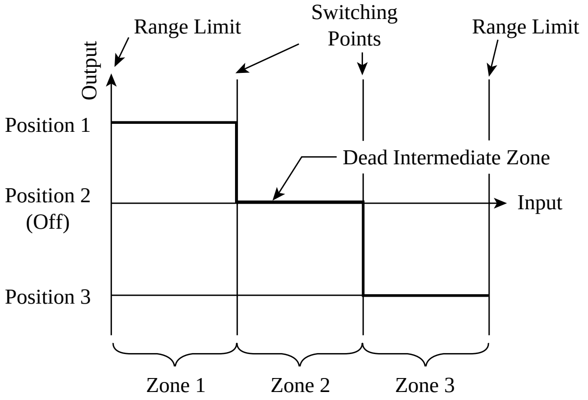
Controller, three-position. A *multiposition controller* having three discrete values of output. See Figure 1.3m. *Note:* This is commonly achieved by selectively energizing a multiplicity of circuits (outputs) to establish three discrete positions of the *final controlling element.* (Ref. 8)

Controller, time schedule. A *controller* in which the *setpoint* or the *reference-input signal* automatically adheres to a predetermined time schedule. (8. Ref. 4)

Controller, two position. A *multiposition controller* having two discrete values of output. (Also called a switch.) See Figures 1.3n and 1.3o. (8)

Controlling system. See *system, controlling.*

Control, low limiting. Control in which output *signal* is prevented from decreasing beyond a predetermined



Dead Intermediate Zone

low limiting value. (Ref. 8, “control action, low limiting”)

Control mode. A specific type of *control action* such as *proportional*, *integral*, or *derivative*. (8)

Control, optimizing. Control that automatically seeks and maintains the most advantageous value of a specified variable rather than maintaining it at one set value. (Ref. 4, “control action, optimizing”)

Control room area. See *area, control room.*

Control, shared time. Control in which one *controller* divides its computation or control time among several control loops rather than by acting on all loops simultaneously. (Ref. 4, “control action, shared time”)

Control, supervisory. Control in which the control loops operate independently subject to intermittent corrective action, e.g., *setpoint* changes from an external source. (Ref. 4,“control action supervisory”)

Control system. A system in which deliberate guidance or manipulation is used to achieve a prescribed value of a variable. See Figure 1.3p. *Note:* It is subdivided into a *controlling system* and a *controlled system*. (4, 8)

Control system, automatic. A *control system* that operates without human intervention. (4) See also *control system.*

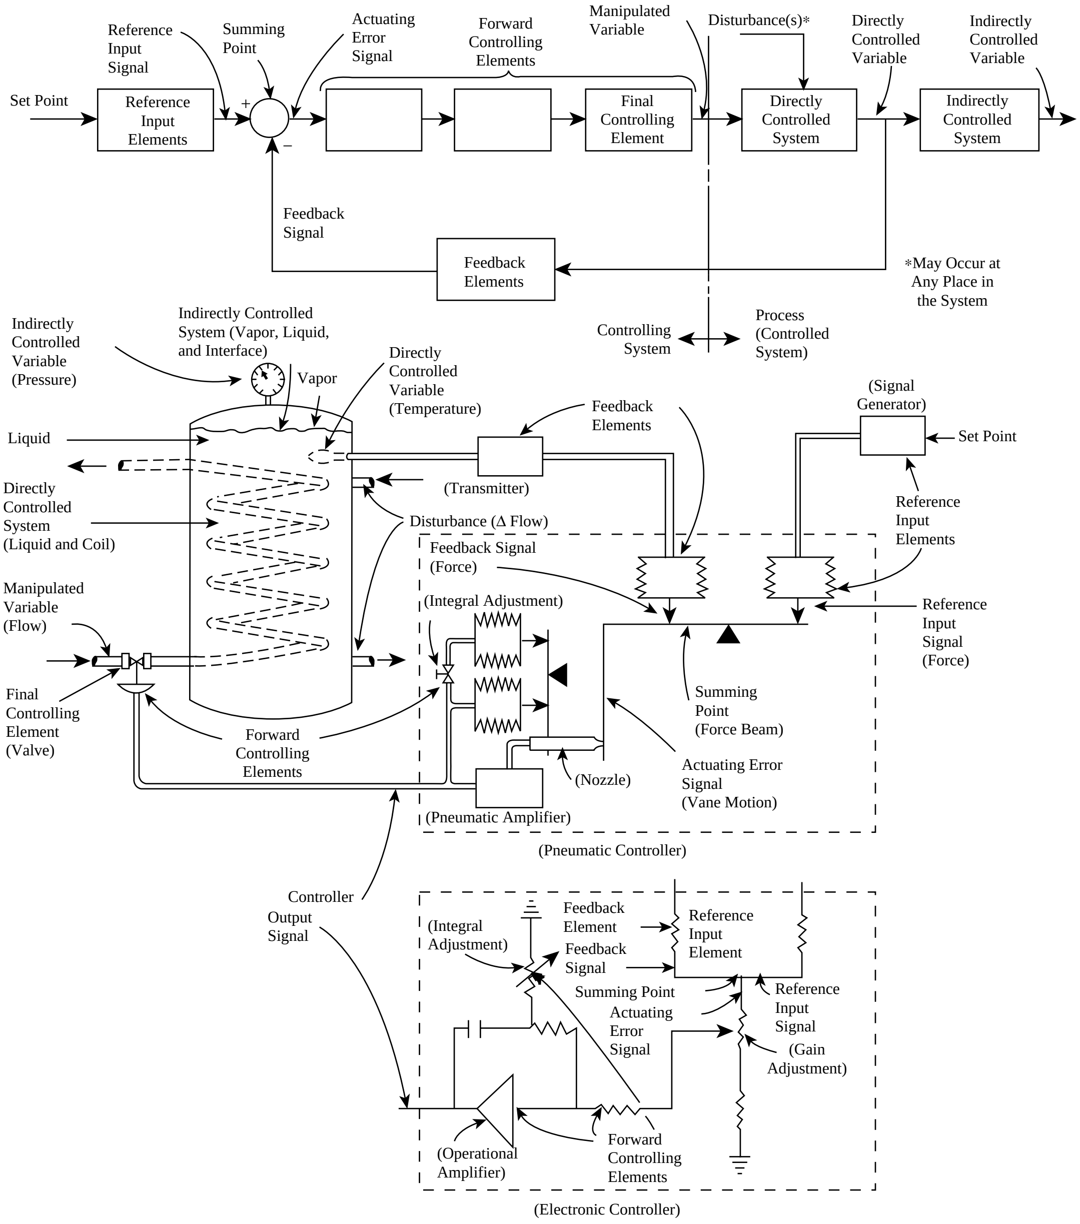

FIG. 1.3p
Control system diagrams.

Control system, multi-element (multivariable). A *control system* utilizing *input signals* derived from two or more *process* variables for the purpose of jointly affecting the action of the *control system. Note 1:* Examples are *input signals* representing pressure and temperature, or speed and flow, or other conditions. (Ref. 8) *Note 2:* A term used primarily in the power industry.

Control system, noninteracting. A *control system* with multiple inputs and outputs in which any given input–output pair is operating independently of any other input–output pair.

Control, time proportioning. Control in which the output *signal* consists of periodic pulses whose duration is varied to relate, in some prescribed manner, the time average of the output to the *actuating error signal.* (Ref. 4, “controller, time proportioning”)

Control valve. A *final controlling element,* through which a fluid passes, which adjusts the size of flow passage as directed by a *signal* from a *controller* to modify the rate of flow of the fluid. (Ref. 17, “value”)

Control, velocity limiting. Control in which the rate of change of a specified variable is prevented from exceeding a predetermined limit. (Ref. 8, “control action, velocity limiting”)

Corner frequency. In the asymptotic form of *Bode diagram*, that frequency indicated by a *break point*, i.e., the junction of two confluent straight lines asymptotic to the log *gain* curve. (4)

Correction. In process instrumentation, the algebraic difference between the *ideal value* and the indication of the *measured signal.* It is the quantity that, added algebraically to the indication, gives the *ideal value.*

$$\text{(correction = ideal value − indication).} \qquad \textbf{1.3(5)}$$

See *error.* (Ref. 4, Ref. 8) *Note:* A positive correction denotes that the indication of the instrument is less than the *ideal value.*

Correction time. See *time, settling.*

Cycling life. The specified minimum number of full-scale excursions or specified partial *range* excursions over which a *device* will operate as specified without changing its performance beyond specified tolerances. (Ref. 11)

Damped frequency. See *frequency, damped.*

Damping. (1) (noun) The progressive reduction or suppression of oscillation in a *device* or system. (2) (adjective) Pertaining to or productive of damping. *Note 1:* The response to an abrupt stimulus is said to be “critically damped” when the *time response* is as fast as possible without overshoot, “underdamped” when overshoot occurs, or “overdamped” when response is slower than critical. *Note 2:* Viscous damping uses the viscosity of fluids (liquids or gases) to effect damping. *Note 3:* Magnetic damping uses the current induced in electrical conductors by changes in magnetic flux to effect damping. (Ref. 4, Ref. 8, Ref. 11)

Damping factor. For the free oscillation of a second-order *linear system,* a measure of *damping,* expressed (without sign) as the quotient of the greater by the lesser of a pair of consecutive swings of the output (in opposite directions) about an ultimate *steady-state* value. See Figure 1.3q. (8, Ref. 4)

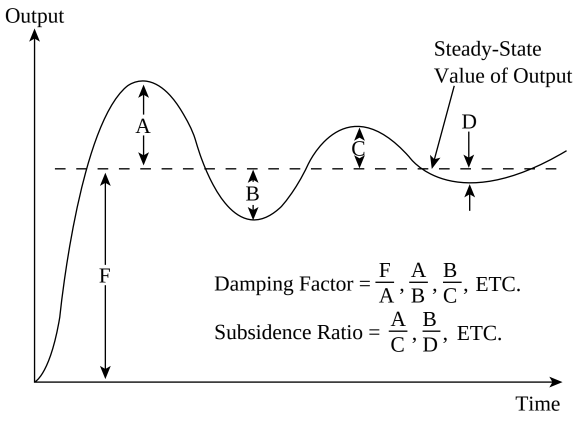

FIG. 1.3q
Underdamped response of system with second-order lag.

Damping ratio. For a *linear system* of the second order described by the differential equation

$$\frac{d^2x}{dt^2} + 2\zeta\omega_0\frac{dx}{dt} + \omega_0^2 = 0 \qquad \textbf{1.3(6)}$$

The damping ratio is the value of the factor ζ. *Note:* ω_0 is called the angular *resonance* frequency of the system. (17)

Damping, relative. For an underdamped system, a number expressing the quotient of the actual *damping* of a second-order *linear system* or *element* by its critical *damping. Note:* For any system whose transfer function includes a quadratic factor $s^2 + 2\zeta\omega_n s + \omega_n^2$, relative damping is the value of ζ, since $\zeta = 1$ for critical damping. Such a factor has a root $-\sigma + j\omega$ in the complex s-plane, from which $\zeta = \sigma/\omega_n = \sigma/(0^2 + \omega^2)^{1/2}$.

D controller. See *controller, derivative (D).*

Dead band. In process instrumentation, the range through which an input signal may reverse direction without initiating observable change in output signal. (See Figure 1.3r. Ref. 8) *Note 1:* There are separate and distinct input–output relationships for increasing and decreasing signals as shown in Figure 1.3r(b). *Note 2:* Dead band produces phase lag between input and output. *Note 3:* Dead band is usually expressed in percent of *span.* (Ref. 4, Ref. 8) See *zone, dead* and *test procedure.*

Dead time. See *time, dead.*

Dead zone. See *zone, dead.*

Delay. The interval of time between a changing *signal* and its repetition for some specified duration at a downstream point of the *signal* path; the value L in the transform factor $\exp(-Ls)$. See *time, dead.* (4)

Derivative action gain. See *gain, derivative action (rate gain).*

Derivative action time. See *time, derivative action.*

Derivative action time constant. See *time constant, derivative action.*

Derivative control. See *control action, derivative (D).*

Derivative control action. See *control action, derivative.*

Derivative controller. See *controller, derivative.*

Design pressure. See *pressure, design.*

Desired value. See *value, desired.*

Detector. See *transducer.* (11)

Deviation. Any departure from a *desired value* or expected value or pattern. (4, 8)

Deviation, steady-state. The *system deviation* after *transients* have expired. (4, 8) See also *offset.*

Deviation, system. The instantaneous value of the *directly controlled variable* minus the *setpoint.* (8, Ref. 4) See also *signal, actuating error.*

Deviation, transient. The instantaneous value of the *directly controlled variable* minus its *steady-state* value. (Ref. 4)

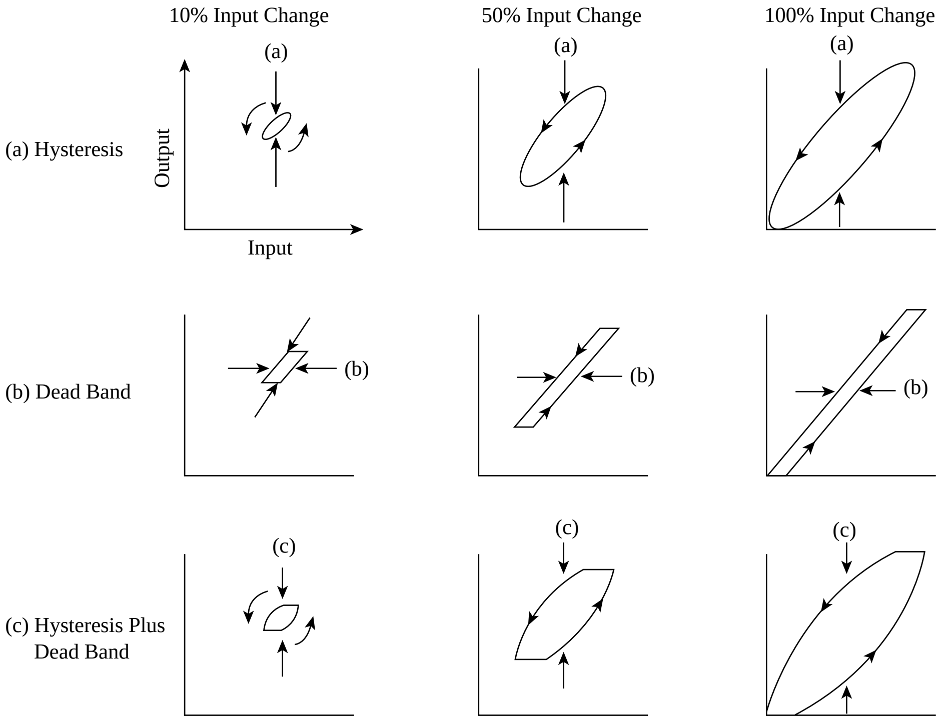

FIG. 1.3r
Hysteresis and dead band.

Device. An apparatus for performing a prescribed function. (8)

Differential gap control. See *control, differential gap.*

Differential-mode interference. See *interference, normal-mode.* (2, 8)

Digital signal. See *signal, digital.*

Direct acting controller. See *controller, direct acting.*

Direct digital control. See *control, direct digital.*

Directly controlled system. See *system, directly controlled.*

Directly controlled variable. See *variable, directly controlled.*

Distance/velocity lag. A delay attributable to the transport of material or to the finite rate of propagation of a *signal.* (Ref. 4, Ref. 17)

Disturbance. An undesired change that takes place in a *process* and that tends to affect adversely the value of a controlled variable. (8, Ref. 4)

Dither. A useful oscillation of small magnitude, introduced to overcome the effect of friction, *hysteresis,* or recorder pen clogging. See also *hunting.* (Ref. 4)

Drift. An undesired change in output over a period of time, the change being unrelated to the input, environment, or load. (4)

Drift, point. The change in output over a specified period of time for a constant input under specified *reference operating conditions. Note:* Point drift is frequently determined at more than one input, as, for example, at 0, 50, and 100% of *range.* Thus, any *drift* of zero or *span* may be calculated. Typical expression of drift: The *drift* at mid-scale for *ambient temperature* (70 ± 2°F) for a period of 48 h was within 0.1% of output *span.* (8) See *test procedure.*

Droop. See *offset.*

Dynamic gain. See *gain, dynamic.*

Dynamic response. See *response, dynamic.*

Electromagnetic interference. See *interference, electromagnetic.*

Electrostatic field interference. See *interference, electromagnetic.*

Element. A component of a device or system. (8)

Element, final controlling. The *forward controlling element* that directly changes the value of the *manipulated variable.* (8, Ref. 4, “controlling element, final”)

Element, primary. The system *element* that quantitatively converts the *measured variable* energy into a form suitable for measurement. *Note:* For *transmitters* not used with external primary elements, the sensing portion is the primary element. (Ref. 2, “detecting means,” Ref. 8)

Element, reference-input. The portion of the *controlling system* that changes the *reference-input signal* in response to the *setpoint.* See Figure 1.3p. (8, Ref. 4)

Element, sensing. The *element* directly responsive to the value of the *measured variable. Note:* It may include the case protecting the sensitive portion. (Ref. 8)

Elements, feedback. Those *elements* in the *controlling system* that act to change the *feedback signal* in response to the *directly controlled variable.* See Figure 1.3p. (Ref. 4, Ref. 8)

Elements, forward controlling. Those *elements* in the *controlling system* that act to change a variable in response to the *actuating error signal.* See Figure 1.3p. (Ref. 4, Ref. 8)

Elevated range. See *range, suppressed-zero.* (4, Ref. 1, "Range, suppressed-zero")

Elevated span. See *range, suppressed-zero.*

Elevated-zero range. See *range, elevated-zero.*

Elevation. See range, *suppressed-zero.*

Environmental area. See *area, environmental.*

Environmental influence. See *operating influence.*

Error. In process instrumentation, the algebraic difference between the indication and the *ideal value* of the *measured signal.* It is the quantity that, algebraically subtracted from the indication, gives the *ideal value*. *Note:* A positive error denotes that the indication of the instrument is greater than the *ideal value.* See *correction.* (Ref. 2, Ref. 8)

$$\text{error} = \text{indication} - \textit{ideal value} \qquad \textbf{1.3(7)}$$

Error curve. See *calibration curve*.

Error, environmental. *Error* caused by a change in a specified *operating condition* from *reference operating condition.* See *operating influence.* (Ref. 8, "operating influence")

Error, frictional. *Error* of a *device* due to the resistance to motion presented by contacting surfaces.

Error, hysteresis. See *hysteresis*.

Error, hysteretic. See *hysteresis*.

Error, inclination. The change in output caused solely by an inclination of the *device* from its normal operating position. (Ref. 1, "influence, position")

Error, mounting strain. *Error* resulting from mechanical deformation of an instrument caused by mounting the instrument and making all connections.
See also *error, inclination.*

Error, position. The change in output resulting from mounting or setting an instrument in a position different from the position at which it was *calibrated*. See also *error, inclination.*

Error signal. See *signal, error.*

Error, span. The difference between the actual *span* and the ideal *span*. *Note:* It is usually expressed as a percentage of ideal *span*. (8)

Error, systematic. An *error* that, in the course of a number of measurements made under the same conditions of the same value of a given quantity, either remains constant in absolute value and sign or varies according to a definite law when the conditions change.

Error, zero. In process instrumentation, the *error* of a *device* operating under specified conditions of use, when the input is at the *lower range value*. (Ref. 8) *Note:* It is usually expressed as percent of ideal *span*.

Excitation. The external supply applied to a *device* for its proper operation. *Note:* It is usually expressed as a range of supply values. See also *excitation, maximum*. (Ref. 11)

Excitation, maximum. The maximum value of excitation *parameter* that can be applied to a *device* at rated *operating conditions* without causing damage or performance degradation beyond specified tolerances. (Ref. 11)

Feedback control. See *control, feedback*.

Feedback elements. See *elements, feedback*.

Feedback loop. See *loop, closed (feedback loop).*

Feedback signal. See *signal, feedback*.

Feedforward control. See *control, feedforward*.

Final controlling element. See *element, final controlling*.

Floating control action. See *control action, floating*.

Floating controller. See *controller, floating*.

Flowmeter. A *device* that measures the rate of flow or quantity of a moving fluid in an open or closed conduit. It usually consists of both a primary and a secondary device. *Note:* It is acceptable, in practice, to further identify the flowmeter by its applied theory (such as differential pressure, velocity, area, force, and so forth) or by its applied technology (such as orifice, turbine, vorex, ultrasonic, and so on). Examples include turbine flowmeter, magnetic flowmeter, and the fluidic pressure flowmeter.

Flowmeter primary device. The *device* mounted internally or externally to the fluid conduit that produces a signal with a defined relationship to the fluid flow in accordance with known physical laws relating the interaction of the fluid to the presence of the primary *device*. *Note:* The primary device may consist of one or more *elements* required to produce the primary device *signal*.

Flowmeter secondary device. The *device* that responds to the *signal* from the primary *device* and converts it to a display or to an output signal that can be translated relative to flow rate or quantity. *Note:* The secondary *device* may consist of one or more *elements* as needed to translate the primary device *signal* into standardized or nonstandardized display or transmitted units.

Forward controlling elements. See *elements, forward controlling*.

Frequency, damped. The apparent frequency of a damped oscillatory *time response* of a system resulting from a nonoscillatory stimulus. (4)

Frequency, gain crossover. (1) On a *Bode diagram* if the *transfer function* of an *element* or system, the frequency at which the *gain* becomes unity and its decibel value zero. (2) Of *integral control action*, the frequency at which the *gain* becomes unity. See Figure 1.3f. (4)

Frequency, phase crossover. Of a *loop transfer function*, the frequency at which the phase angle reaches ±180°. (Ref. 4)

Frequency response characteristic. In process instrumentations, the frequency-dependent relation, in both amplitude and phase, between *steady-state* sinusoidal inputs and the resulting fundamental sinusoidal outputs. *Note:* Frequency response is commonly plotted on a *Bode diagram*. See Figure 1.3b. (8, Ref. 4, "frequency-response characteristics")

Frequency, undamped (frequency, natural). (1) Of a second-order *linear system* without damping, the frequency of free oscillation in radians or cycles per unit of time. (2) Of any system whose *transfer function* contains the quadratic factor $s^2 + 2z\omega_n s + \omega_n^2$ the value ω_n, where

s = complex variable
z = constant
ω_n = natural frequency in radians per second

(3) Of a *closed-loop control system* or *controlled system,* a frequency at which continuous oscillation (*hunting*) can occur without periodic stimuli. *Note:* In *linear systems,* the undamped frequency is the phase crossover frequency. With *proportional control action* only, the undamped frequency of a *linear system* may be obtained, in most cases, by raising the *proportional* gain until continuous oscillation occurs. (Ref. 4, Ref. 8)

Frictional error. See *error, frictional*.

Gain, closed loop. In process instrumentation, the *gain* of a *closed loop* system, expressed as the ratio of the output change to the input change at a specified frequency. (8, Ref. 4)

Gain, crossover frequency. See *frequency, gain crossover.*

Gain, derivative action (rate gain). The ratio of maximum *gain* resulting from *proportional plus derivative control action* to the *gain* due to *proportional control action* alone. See Figures 1.3g and 1.3i. (4, 8)

Gain, dynamic. The magnitude ratio of the *steady-state* amplitude of the *output signal* from an *element* or system to the amplitude of the *input signal* to that *element* or system, for a sinusoidal *signal.* (8)

Gain, loop. In process instrumentation, the ratio of the absolute magnitude of the change in the *feedback signal* to the change in its corresponding *error signal* at a specified frequency. *Note:* The *gain* of the loop *elements* is frequently measured by opening the loop, with appropriate termination. The *gain* so measured is often called the "open loop gain." (8, Ref. 5)

Gain (magnitude ratio). For a *linear system* or *element,* the ratio of the magnitude (amplitude) of a *steady-state* sinusoidal output relative to the causal input; the length of a phasor from the origin to a point of the transfer locus in a complex plane. *Note:* The quantity may be separated into two factors: (1) a proportional amplification, often denoted K, which is frequency independent and associated with a dimensioned scale factor relating to the units of input and output; (2) a dimensionless factor, often denoted $G(j\omega)$, which is frequency dependent. Frequency, conditions of operation, and conditions of measurement must be specified. A *loop gain characteristic* is a plot of log gain vs. log frequency. In nonlinear systems, gains are often amplitude-dependent. (4, 8)

Gain, open loop. See *gain, loop.*

Gain, proportional. The ratio of the change in output due to *proportional control action* to the change in input. See *proportional band*. (4, 8)

Illustration: $Y = \pm PX$

where

P = proportional gain
X = input transform
Y = output transform

Gain, static (zero-frequency gain). If *gain* of an *element*, or *loop gain* of a system, the value approached as a limit as frequency approaches zero. *Note:* Its value is the ratio of change of *steady-state* output to a step change in input, provided the output does not saturate. (4, Ref. 8)

Gain, zero frequency. See *gain, static (zero-frequency gain).*

Hardware. Physical equipment directly involved in performing industrial *process* measuring and controlling functions.

Hazardous (classified) location. See *location, hazardous (classified)*.

High limiting control. See *control, high limiting*.

Hunting. An undesirable oscillation of appreciable magnitude, prolonged after external stimuli disappear. *Note:* In a *linear system,* hunting is evidence of operation at or near the stability limit; nonlinearities may cause hunting of well-defined amplitude and frequency. See also *dither.* (4)

Hysteresis. That property of an *element* evidenced by the dependence of the value of the output, for a given excursion of the input, on the history of prior excursions and the direction of the current traverse. *Note 1:* It is usually determined by subtracting the value of the *dead band* from the maximum measured separation between upscale going and downscale going indications of the *measured variable* (during a full *range* traverse, unless otherwise specified) after *transients* have decayed. This measurement is sometimes called "hysteresis error" or "hysteretic error." See Figure 1.3r. *Note 2:* Some reversal of output may be expected for any small reversal of input; this distinguishes hysteresis from *dead band*. See *test procedure*.

I controller. See *controller, integral (reset) (I).*

Idealized system. See *system, idealized*.

Ideal value. See *value, ideal*.

Impedance, input. Impedance presented by a *device* to the source. (3, 8)

Impedance, load. Impedance presented to the output of a *device* by the load. (8, Ref. 3)

Impedance, output. Impedance presented by a *device* to the load. (8, Ref. 3)

Impedance, source. Impedance presented to the input of a *device* by the source. (8, Ref. 3)

Inclination error. See *error, inclination*.

Independent conformity. See *conformity, independent*.

Independent linearity. See *linearity, independent*.

Indicating instrument. See *instrument, indicating*.

Indicator travel. The length of the path described by the indicating means or the tip of the pointer in moving from one end of the scale to the other. *Note 1:* The path may be an arc or a straight line. *Note 2:* In the case of knife-edge pointers and others extending beyond the scale division marks, the pointer shall be considered as ending at the outer end of the shortest scale division marks. (2, 8)

Indirectly controlled system. See *system, indirectly controlled*.

Indirectly controlled variable. See *variable, indirectly controlled*.

Inherent regulation. See *self-regulation*.

Input impedance. See *impedance, input*.

Input signal. See *signal, input*.

Instrumentation. A collection of instruments or their application for the purpose of observation, measurement, or control.

Instrument, computing. A *device* in which the output is related to the input or inputs by a mathematical function such as addition, averaging, division, integration, lead/lag, signal limiting, squaring, square root extraction, or subtraction.

Instrument, indicating. A *measuring instrument* in which only the present value of the *measured variable* is visually indicated. (Ref. 8)

Instrument, measuring. A *device* for ascertaining the magnitude of a quantity or condition presented to it. (Ref. 8)

Instrument, recording. A *measuring instrument* in which the values of the *measured variable* are recorded. *Note:* The record may be either analog or digital and may or may not be visually indicated. (Ref. 8)

Insulation resistance. The resistance measured between specified insulated portions of a *device* when a specified direct current voltage is applied, at *reference operating conditions* unless otherwise stated. *Note:* The objective is to determine whether the leakage current would be excessive under *operating conditions*. (Ref. 11)

Insulation voltage breakdown. The voltage at which a disruptive discharge takes place through or over the surface of the insulation. (3)

Integral action limiter. A *device* that limits the value of the *output signal* due to *integral control action* to a predetermined value. (8)

Integral action rate (reset rate). (1) Of *proportional plus integral* or *proportional plus integral plus derivative control action devices;* for a step input, the ratio of the initial rate of change of output due to *integral control action* to the change in *steady-state* output due to *proportional control action. Note: Integral action rate is often expressed as the number of repeats per minute, because it is equal to the number of times per minute that the proportional response to a step input is repeated by the initial integral response*.

(2) Of integral control action devices; for a step input, the ratio of the initial rate of change of output to the input change. (8, Ref. 4)

Integral action time constant. See *time constant, integral action*.

Integral control action. See *control action, integral*.

Integral controller. See *controller, integral (reset)*.

Interference, common-mode. A form of interference that appears between measuring circuit terminals and ground. (3, 8)

Interference, differential-mode. See *interference, normal-mode*.

Interference, electromagnetic. Any spurious effect produced in the circuits or *elements* of a *device* by external electromagnetic fields. *Note:* A special case of interference from radio transmitters is known as “radio frequency interference (RFI).”

Interference, electrostatic field. See *interference, electromagnetic*.

Interference, longitudinal. See *interference, common-mode*.

Interference, magnetic field. See *interference, electromagnetic*.

Interference, normal-mode. A form of interference that appears between measuring circuit terminals. (2, 8)

Interference, transverse. See *interference, normal-mode*.

Intermediate zone. See *zone, intermediate*.

Intrinsically safe equipment and wiring. Equipment and wiring that are incapable of releasing sufficient electrical or thermal energy under normal or abnormal conditions to cause ignition of a specific hazardous atmospheric mixture in its most easily ignited concentration. (14)

Laplace transform, unilateral. Of a function $f(t)$, the quantity obtained by performing the operation

$$F(s) = \int_{\sigma}^{\infty} F(t)e^{-st}dt \tag{1.3(8)}$$

where

$F(s)$ = function of s
s = complex variable, $\sigma + j\omega$
$f(t)$ = function of t
t = time, seconds
σ = real part of the complex variable s
$j = \sqrt{-1}$
ω = angular velocity, radians per second (8, Ref. 4)

Leak pressure. See *pressure, leak*.

Linear system. See *system, linear*.

Linearity. The closeness to which a curve approximates a straight line. *Note 1:* It is usually measured as a nonlinearity and expressed as linearity; e.g., a maximum *deviation* between an average curve and a straight line. The average curve is determined after making two or more full *range* traverses in each direction. The value of linearity is referred to the output unless otherwise stated. *Note 2:* As a performance specification, linearity should be expressed as *independent linearity, terminal based linearity,* or *zero-based linearity.* When expressed simply as linearity, it is assumed to be *independent linearity.* See *conformity.* (8, Ref. 4, "Linearity of signal")

Linearity, independent. The maximum *deviation* of the *calibration curve* (average of upscale and downscale readings) from a straight line positioned so as to minimize the maximum *deviation*. See Figure 1.3s. See *test procedure*. (Ref. 8)

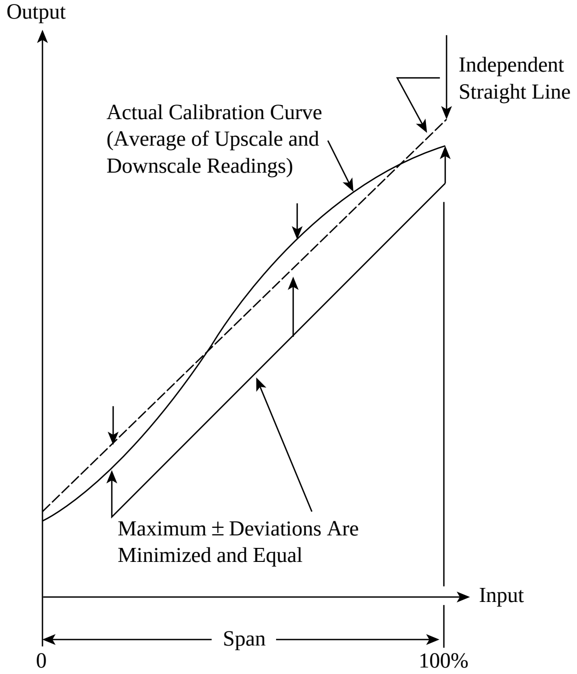

FIG. 1.3s
Independent linearity.

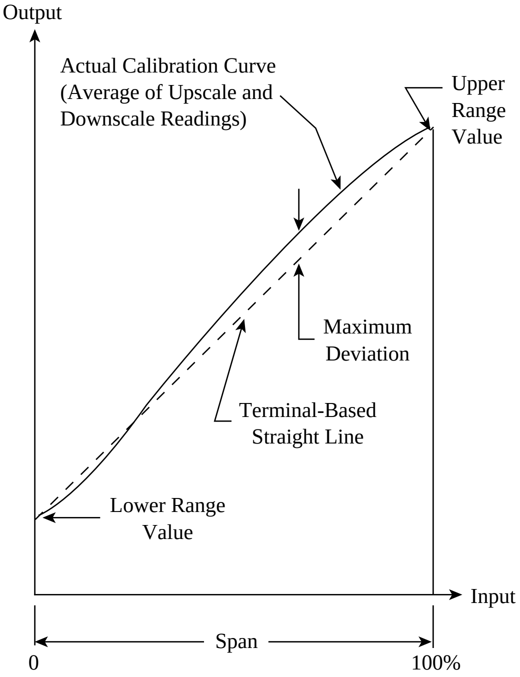

FIG. 1.3t
Terminal-based linearity.

Linearity, terminal-based. The maximum *deviation* of the *calibration curve* (average of upscale and downscale readings) from a straight line coinciding with the *calibration curve* at the *upper* and *lower range values*. See Figure 1.3t. See *test procedure.* (Ref. 8)

Linearity, zero-based. The maximum *deviation* of the *calibration curve* (average of upscale and downscale readings) from a straight line positioned so as to coincide with the *calibration curve* at the *lower range value* and to minimize the maximum *deviation*. See Figure 1.3u. See *test procedure*. (Ref. 8)

Live zone. See *zone, live*.

Load impedance. See *impedance, load*.

Load regulation. The change in output (usually speed or voltage) from no-load to full-load (or other specified load limits) conditions. See *offset*. *Note:* It may be expressed as the percentage ratio of the change from no-load to full-load conditions divided by the no-load value. (8)

Location, hazardous (classified). That portion of a plant where flammable or combustible liquids, vapors, gases, or dusts may be present in the air in quantities sufficient to produce explosive or ignitable mixtures. (Ref. 9)

Longitudinal interference. See *interference, common-mode*.

Loop, closed (feedback loop). A *signal* path that includes a forward path, a *feedback* path, and a *summing point*, and forms a closed circuit. (4, 8)

Loop, feedback. See *loop, closed (feedback loop)*. (4, 8)

Loop gain. See *gain, loop*.

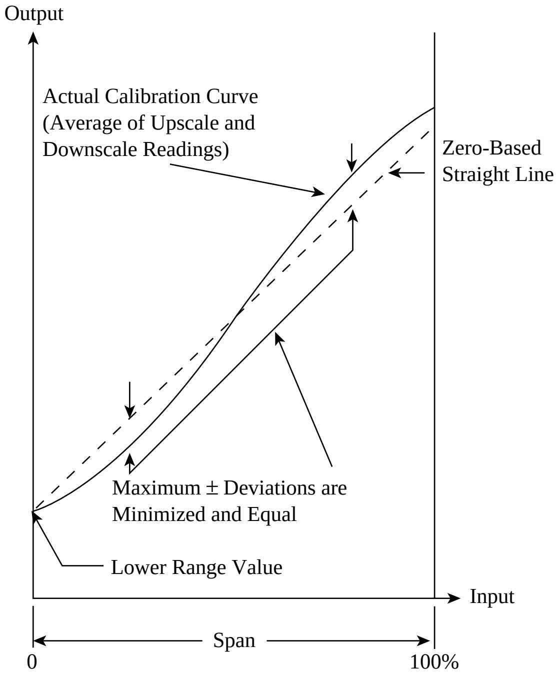

FIG. 1.3u
Zero-based linearity.

Loop gain characteristics. In process control, of a *closed loop*, *the characteristic curve* of the ratio of the change in the *return signal* to the change in the corresponding *error signal* for all real frequencies. (8)

Loop, open. A *signal* path without *feedback*. (4, 8)

Loop transfer function. Of a *closed loop*, the *transfer function* obtained by taking the ratio of the *Laplace transform* of the *return signal* to the *Laplace transform* of its corresponding *error signal*. (4, 8)

Lower range limit. See *range limit, lower.*

Lower range value. See *range value, lower.*

Low limiting control. See *control, low limiting.*

Magnetic field interference. See *interference, electromagnetic*.

Magnitude ratio. See *gain (magnitude ratio).*

Manipulated variable. See *variable, manipulated*.

Maximum excitation. See *excitation, maximum.*

Maximum working pressure. See *pressure, maximum working (MWP)*.

Measurand. See *variable, measured.*

Measured accuracy. See *accuracy, measured.*

Measured signal. See *signal, measured.*

Measured value. See *value, measured.*

Measured variable. See *variable, measured.*

Measuring instrument. See *instrument, measuring*.

Mechanical shock. The momentary application of an acceleration force to a device. *Note:* It is usually expressed in units of acceleration of gravity (g). (Ref. 8)

Modulation. The process, or result of the process, whereby some characteristic of one wave is varied in accordance with some characteristic of another wave. (4, 8)

Module. An assembly of interconnected components that constitutes an identifiable *device*, instrument, or piece of equipment. A module can be disconnected, removed as a unit, and replaced with a spare. It has definable performance characteristics that permit it to be tested as a unit. *Note:* A module could be a card or other subassembly of a larger *device*, provided it meets the requirements of this definition.

Mounting position. The position of a *device* relative to physical surroundings. (8)

Mounting strain error. See *error, mounting strain.*

Multi-element control system. See *control system, multi-element (multivariable).*

Multiposition controller. See *controller, multiposition.*

Multispeed floating controller. See *controller, multiple-speed floating.*

Multivariable control system. See *control system, multi-element (multivariable).*

Natural frequency. See *frequency, undamped.*

Neutral zone. See *zone, neutral*.

Noise. An unwanted component of a signal or variable. *Note:* It may be expressed in units of the output or in percentage of output span. See *interference, electromagnetic*. (Ref. 4, Ref. 8)

Nonincendive equipment. Equipment that, in its *normal operating condition*, would not ignite a specific hazardous atmosphere in its most easily ignited concentration. *Note:* The electrical circuits may include sliding or make-and-break contacts releasing insufficient energy to cause ignition. Wiring that, under normal conditions, cannot release sufficient energy to ignite a specific hazardous atmospheric mixture by opening, shorting, or grounding shall be permitted using any of the methods suitable for wiring in ordinary locations.

Noninteracting control system. See *control system, noninteracting*.

Normal-mode interference. See *interference, normal-mode.*

Normal-mode rejection. The ability of a circuit to discriminate against a *normal-mode voltage. Note:* It may be expressed as a dimensionless ratio, a scalar ratio, or in decibels as 20 times the $\log_{10}$ of that ratio.

Normal-mode voltage. See *voltage, normal-mode*.

Normal operating conditions. See *operating conditions, normal*.

Offset. The steady-state deviation when the setpoint is fixed. See also *deviation, steady-state. Note:* The offset resulting from a no-load to a full-load change (or other specified limits) is often called “droop” or “*load regulation*.” See *load regulation*. (8, Ref. 4)

On–off controller. See *controller, on–off.*

Operating conditions. Conditions to which a *device* is subjected, not including the variable measured by the *device.* Examples of *operating conditions* include *ambient pressure, ambient temperature,* electromagnetic fields, gravitational force, inclination, power supply variation (voltage, frequency, harmonics), radiation, *shock,* and *vibration.* Both static and dynamic variations in these conditions should be considered. (Ref. 2, Ref. 8)

Operating conditions, normal. The range of *operating conditions* within which a *device* is designed to operate and for which *operating influences* are stated. See Figure 1.3v. *Note:* In case of normally open or normally closed switches, the *normal* position is the unactuated position.

Operating conditions, reference. The range of *operating conditions* of a *device* within which *operating influences* are negligible. See Figure 1.3v. *Note 1:* The range is usually narrow. *Note 2:* They are the conditions under which reference is stated and the base from which the values of *operating influences* are determined. (8)

Operating influence. The change in a performance characteristic caused by a change in a specified *operating condition* from *reference operating condition,* all other conditions being held within the limits of *reference operating conditions. Note:* The specified *operating conditions* are usually the limits of the *normal operating conditions.*

Operating influence may be stated in either of two ways:

1. As the total change in performance characteristics from *reference operating condition* to another specified *operating condition.* Example: Voltage influence on *accuracy* may be expressed as 2% of *span* based on a change in voltage from reference value of 120 V to value of 130 V.

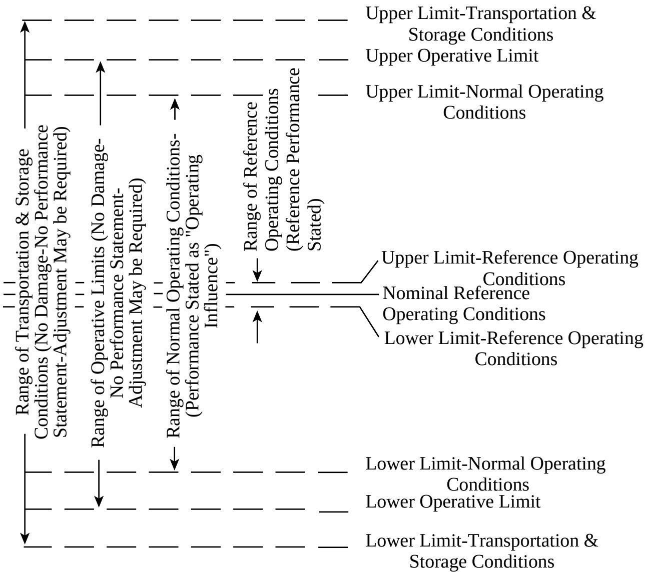

FIG. 1.3v
Diagram of operating conditions.

2. As a coefficient expressing the change in a performance characteristic corresponding to unit change of the *operating condition,* from *reference operating condition* to another specified *operating condition.* Example: Voltage influence on *accuracy* may be expressed as

$$\frac{2\% \text{ of span}}{130\text{ V} - 120\text{ V}} = 0.2\% \text{ of span per vol} \qquad \mathbf{1.3(9)}$$

Note: If the relationship between operating influence and change in *operating condition* is linear, one coefficient will suffice. If it is nonlinear, it may be desirable to state more than one coefficient such as 0.05% per volt from 120 to 125 V, and 0.15% from 125 to 130 V. (8, Ref. 2)

Operating pressure. See *pressure, operating.*

Operative limits. The range of *operating conditions* to which a *device* may be subjected without permanent impairment of operating characteristics. See Figure 1.3v. *Note 1:* In general, performance characteristics are not stated for the region between the limits of *normal operating conditions* and the operative limits. *Note 2:* Upon returning with the limits of *normal operating conditions,* a *device* may require adjustments to restore normal performance. (Ref. 2, "design limits," Ref. 8)

Optimizing control. See *control, optimizing.*

Outdoor area. See *area, outdoor.*

Output impedance. See *impedance, output.*

Output signal. See *signal, output.*

Overdamped. See *damping.*

Overrange. In process instrumentation, of a system or *element,* any excess value of the *input signal* above its *upper range value* or below its *lower range value.* (8, Ref. 4)

Overrange limit. The maximum input that can be applied to a *device* without causing damage or permanent change in performance.

Overshoot. See *transient overshoot.*

Parameter. A quantity or property that is treated as a constant but sometimes may vary or be adjusted. (6)

P controller. See *controller, proportional.*

PD controller. See *controller, proportional plus derivative.*

Pen travel. The length of the path described by the pen in moving from one end of the chart scale to the other. The path may be an arc or a straight line. (8)

Phase crossover frequency. See *frequency, phase crossover.*

Phase shift. (1) Of a *transfer function,* a change of phase angle with test frequency, as between points on a loop phase characteristic. (2) Of a *signal,* a change of phase angle with transmission. (4)

PI controller. See *controller, proportional plus integral.*

PID controller. See *controller, proportional plus integral plus derivative.*

Pneumatic delivery capability. The rate at which a pneumatic *device* can deliver air (or gas) relative to a specified output pressure change. *Note:* It is usually determined, at a specified level of input *signal*, by measuring the output flow rate for a specified change in output pressure. The results are expressed in cubic feet per minute (ft^3/min) or cubic meters per hour (m^3/h), corrected to standard (normal) conditions of pressure and temperature.

Pneumatic exhaust capability. The rate at which a pneumatic *device* can exhaust air (or gas) relative to a specified output pressure change. *Note:* It is usually determined, at a specified level of input *signal*, by measuring the output flow rate for a specified change in output pressure. The results are expressed in cubic feet per minute (ft^3/min) or cubic meters per hour (m^3/h), corrected to standard (normal) conditions of pressure and temperature.

Point drift. See *drift, point.*

Position. Of a *multiposition controller,* a discrete value of the *output signal.* See Figure 1.3l.

Position error. See *error, position.*

Power consumption, electrical. The maximum power used by a *device* within its operating *range* during *steady-state signal* condition. *Note 1:* For a power factor other than unity, power consumption shall be stated as maximum volt-amperes used under the above-stated condition. *Note 2:* For a *device* operating outside of its operating *range*, the maximum power might exceed what is experienced within the operating *range.* (Ref. 8, "Power consumption")

Power factor. The ratio of total watts to the total root-mean-square (rms) volt-amperes.

$$F_p = \frac{\Sigma \text{ watts per phase}}{\Sigma \text{ rms volt-amperes per phase}} = \frac{\text{active power}}{\text{apparent power}} \qquad \textbf{1.3(10)}$$

Note: If the voltages have the same waveform as the corresponding currents, power factor becomes the same as phasor power factor. If the voltages and currents are sinusoidal and for polyphase circuits, from symmetrical sets, $F_p = \cos(\alpha - \beta)$. (3)

Pressure, ambient. The pressure of the medium surrounding a *device.*

Pressure, design. The pressure used in the design of a vessel or *device* for the purpose of determining the minimum permissible thickness or physical characteristics of the parts for a given *maximum working pressure (MWP)* at a given temperature.

Pressure, leak. The pressure at which some discernible leakage first occurs in a *device.*

Pressure, maximum working (MWP). The maximum total pressure permissible in a *device* under any circumstances during operation, at a specified temperature. It is the highest pressure to which it will be subjected in the *process.* It is a designed safe limit for regular use. *Note:* MWP can be arrived at by two methods: (1) designed, by adequate design analysis, with a safety factor and (2) tested, by rupture testing of typical samples. See *pressure, design.*

Pressure, operating. The actual pressure at which a *device* operates under normal conditions. This pressure may be positive or negative with respect to atmospheric pressure.

Pressure, process. The pressure at a specified point in the *process* medium. (Ref. 8)

Pressure, rupture. The pressure, determined by test, at which a *device* will burst. *Note:* This is an alternative to the design procedure for establishing *maximum working pressure* (MWP). The rupture pressure test consists of causing the *device* to burst.

Pressure, static. The *steady-state* pressure applied to a *device;* in the case of a differential-pressure *device,* the *process pressure* applied equally to both connections.

Pressure, supply. The pressure at the supply port of a *device.* (8)

Pressure, surge. Operating pressure plus the increment above *operating pressure* to which a *device* may be subjected for a very short time during pump starts, valve closings, and so on.

Primary element. See *element, primary.*

Process. Physical or chemical change of matter or conversion of energy; e.g., change in pressure, temperature, speed, electrical potential, and so on.

Process control. The regulation or manipulation of variables influencing the conduct of a *process* so as to obtain a product of desired quality and quantity in an efficient manner.

Process measurement. The acquisition of information that establishes the magnitude of *process* quantities.

Process pressure. See *pressure, process.*

Process temperature. See *temperature, process.*

Program controller. See *controller, program.*

Proportional band. The change in input required to produce a full *range* change in output due to *proportional control action. Note 1:* It is reciprocally related to proportional gain. *Note 2:* It may be stated in input units or as a percentage of the input span (usually the indicated or recorded input span). The preferred term is "proportional gain." See *gain, proportional.* (8)

Proportional control action. See *control action, proportional.*

Proportional controller. See *controller, proportional.*

Proportional gain. See *gain, proportional.*

Proportional plus derivative control action. See *control action, proportional plus derivative.*

Proportional plus derivative controller. See *controller, proportional plus derivative.*

Proportional plus integral control action. See *controller, proportional plus integral.*

Proportional plus integral controller. See *controller, proportional plus integral.*

Proportional plus integral plus derivative control action. See *control action, proportional plus integral plus derivative.*

Proportional plus integral plus derivative controller. See *controller, proportional plus integral plus derivative.*

Proportional plus rate control action. See *controller, proportional plus derivative.*

Proportional plus rate controller. See *controller, proportional plus derivative.*

Proportional plus reset control action. See *control action, proportional plus integral plus derivative.*

Proportional plus reset controller. See *controller, proportional plus integral plus derivative.*

Proportional speed floating controller. See *controller, integral.*

Ramp response. See *response, ramp.*

Ramp response time. See *time, ramp response.*

Range. The region between the limits within which a quantity is measured, received, or transmitted, expressed by stating the *lower* and *upper range values. Note 1:* For example, (a) 0 to 150°F, (b) –20 to +200°F, and (b) 20 to 150°C. *Note 2:* Unless otherwise modified, input *range* is implied. *Note 3:* The following compound terms are used with suitable modifications in the units: *measured variable range, measured signal range,* indicating scale range, chart scale range, and so on. See Tables 1.3w and 1.3x. *Note 4:* For multirange *devices,* this definition applies to the particular range that the *device* is set to measure. (3, 8)

Range, elevated-zero. A *range* in which the zero value of the *measured variable, measured signal,* or other quantity is greater than the *lower range value.* See Table 1.3w. *Note 1:* The zero may be between the lower and upper range values, at the upper range value, or above the upper range value. *Note 2:* Terms *suppression, suppressed range,* or *suppressed span* are frequently used to express the condition in which the zero of the *measured variable* is greater than the *lower range value.* The term "elevated-zero range" is preferred. (Ref. 8)

Range limit, lower. The lowest value of the *measured variable* that a *device* can be adjusted to measure. *Note:* The following compound terms are used with suitable modifications to the units: *measured variable* lower range limit, *measured signal* lower range limit, and so on. See Tables 1.3w and 1.3x. (Ref. 8)

Range limit, upper. The highest value of the *measured variable* that a *device* can be adjusted to measure. *Note:* The following compound terms are used with suitable modifications to the units: *measured variable* upper range limit, *measured signal* upper range limit, and so on. See Tables 1.3w and 1.3x. (Ref. 8)

Range, suppressed-zero. A *range* in which the zero value of the *measured variable* is less than the *lower range value.* (Zero does not appear on the scale.) See Table 1.3w. *Note 1:* For example: 20 to 100. *Note 2:* Terms *elevation, elevated range,* or *elevated span* are frequently used to express the condition in which the zero of the *measured variable* is less than the *lower range value.* The term "suppressed-zero range" is preferred. (Ref. 2, Ref. 8)

Range value, lower. The lowest value of the *measured variable* that a *device* is adjusted to measure. *Note:* Several compound terms are used with suitable modifications to the units, including *measured variable* lower range value, *measured signal* lower range value, and others. See Tables 1.3w and 1.3x. (Ref. 8)

Range value, upper. The highest value of the *measured variable* that a *device* is adjusted to measure. *Note:* Several compound terms are used with suitable modifications to the units, including *measured variable* upper range value, *measured signal* upper range value, and others. See Tables 1.3w and 1.3x. (Ref. 8)

Rate. See *control action, derivative.*

TABLE 1.3w
Illustrations of the Use of Range and Span Terminology

Typical Ranges	*Name*	*Range*	*Lower Range Value*	*Upper Range Value*	*Span*	*Supplementary Data*
0 +100	—	0 to 100	0	+100	100	—
20 +100	Suppressed zero range	20 to 100	20	+100	80	Suppression Ratio = 0.25
–25 0 +100	Elevated zero range	–25 to +100	–25	+100	125	—
–100 0	Elevated zero range	–100 to 0	–100	0	100	—
–100 –20	Elevated zero range	–100 to –20	–100	–20	80	—

TABLE 1.3x
USA Domestic Units: Illustrations of the Use of the Terms "Measured Variable" and "Measured Signal"

Typical Ranges	*Type of Range*	*Range*	*Lower Range Value*	*Upper Range Value*	*Span*
(1) Thermocouple 0 2000°F Type K T/C	Measured variable	0 to 2000°F	0°F	2000°F	2000°F
–0.68 +44.91 mV	Measured signal	–0.68 to +44.91 mV	–0.68 mV	+44.91 mV	45.59 mV
0 20 ×100 = °F	Scale and/or chart	0 to 2000°F	0°F	2000°F	2000°F
(2) Flowmeter 0 10 000 lb/h	Measured variable	0 to 10 000 lb/h	0 lb/h	10 000 lb/h	10 000 lb/h
0 100 in H_2O	Measured signal	0 to 100 in H_2O	0 in H_2O	100 in H_2O	100 in H_2O
0 10 ×1000 = lb/h	Scale and/or chart	0 to 10 000 lb/h	0 lb/h	10 000 lb/h	10 000 lb/h
(3) Tachometer 0 500 rpm	Measured variable	0 to 500 rpm	0 rpm	500 rpm	500 rpm
0 5 V	Measured signal	0 to 5 V	0 V	5 V	5 V
0 80 ft/s	Scale and/or chart	0 to 80 ft/s	0 ft/s	80 ft/s	80 ft/s

Rate control action. See *control action, derivative.*

Rate gain. See *gain, derivative action.*

Ratio controller. See *controller, ratio.*

Recording instrument. See *instrument, recording.*

Reference accuracy. See *accuracy rating.*

Reference-input element. See *element, reference-input.*

Reference-input signal. See *signal, reference-input.*

Reference junction. The thermocouple junction that is at a known or reference temperature. *Note:* The reference junction is physically the point at which the thermocouple or thermocouple extension wires are connected to a *device* or where the thermocouple is connected to a pair of lead wires, usually copper. (Ref. 7)

Reference junction compensation. A means of counteracting the effect of temperature variations of the *reference junction* when allowed to vary within specified limits.

Reference operating conditions. See *operating conditions, reference.*

Reference performance. Performance attained under *reference operating conditions. Note:* Performance includes such things as accuracy, dead band, hysteresis, linearity, repeatability, etc. (8)

Regulator. See *controller, self-operated (regulator).*

Relative damping. See *damping, relative.*

Reliability. The probability that a *device* will perform its objective adequately, for the period of time specified, under the *operating conditions* specified. (Ref. 4)

Repeatability. The closeness of agreement among a number of consecutive measurements of the output for the same value of the input under the same *operating conditions*, approaching from the same direction, for full *range* traverses. See Figure 1.3y. *Note:* It is usually measured as nonrepeatability and expressed as *repeatability* in percent of *span.* It does not include *hysteresis.* See *test procedure.* (8, Ref. 2)

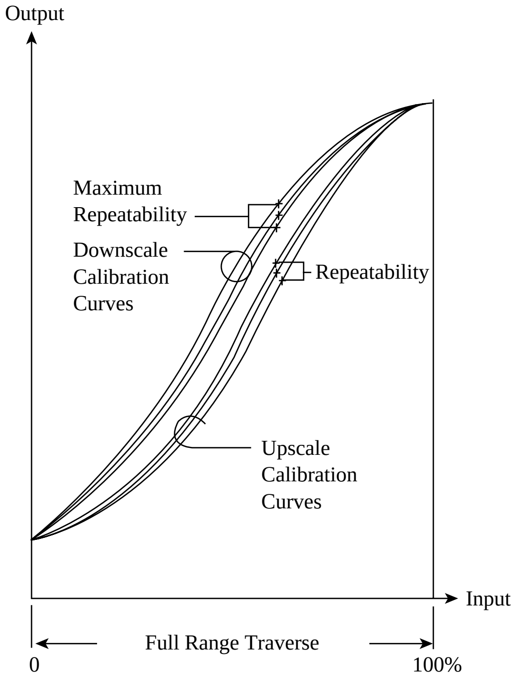

FIG. 1.3y
Repeatability.

Reproducibility. In process instrumentation, the closeness of agreement among repeated measurements of the output for the same value of input made under the same *operating conditions* over a period of time, approaching from both directions. *Note 1:* It is usually measured as nonreproducibility and expressed as reproducibility in percent of *span* for a specified time period. Normally, this implies a long period of time, but, under certain conditions, the period may be a short time during which *drift* may not be included. *Note 2:* Reproducibility includes hysteresis, dead band, drift, and repeatability. *Note 3:* Between repeated measurements, the input may vary over the *range* and *operating conditions* may vary within *normal operating conditions*. See *test procedures*. (8)

Reset control action. See *control action, integral (reset)*.

Reset rate. See *integral action rate*.

Resolution. The least interval between two adjacent discrete details that can be used to distinguish one from the other. (4)

Resonance. Of a system or element, a condition evidenced by large oscillatory amplitude, which results when a small amplitude of periodic input has a frequency approaching one of the natural frequencies of the driven system. (4, 8)

Response, dynamic. The behavior of the output of a *device* as a function of the input, both with respect to time. (8, Ref. 2)

Response, ramp. The total (transient plus *steady-state*) *time response* resulting from a sudden increase in the rate of change from zero to some finite value of the input stimulus. (Ref. 4, “response, ramp-forced”)

Response, step. The total (*transient* plus *steady-state*) *time response* resulting from a sudden change from one constant level of input to another. (4, “response, stepforced”)

Response, time. An output expressed as a function of time, resulting from the application of a specified input under specified *operating conditions*. See Figure 1.3z. (4, 8)

Return signal. See *signal, return*.

Reverse action controller. See *controller, reverse acting*.

Rise time. See *time, rise*.

rms value. See *value, rms*.

Rupture pressure. See *pressure, rupture*.

Sampling controller. See *controller, sampling*.

Sampling period. The time interval between observations in a periodic sampling control system. (4, 8)

Scale factor. The factor by which the number of scale divisions indicated or recorded by an instrument should be multiplied to compute the value of the measured variable. (Ref. 8) *Note:* Deflection factor is a more general term than scale factor in that the instrument response may be expressed alternatively in units other than scale divisions. (Ref. 3)

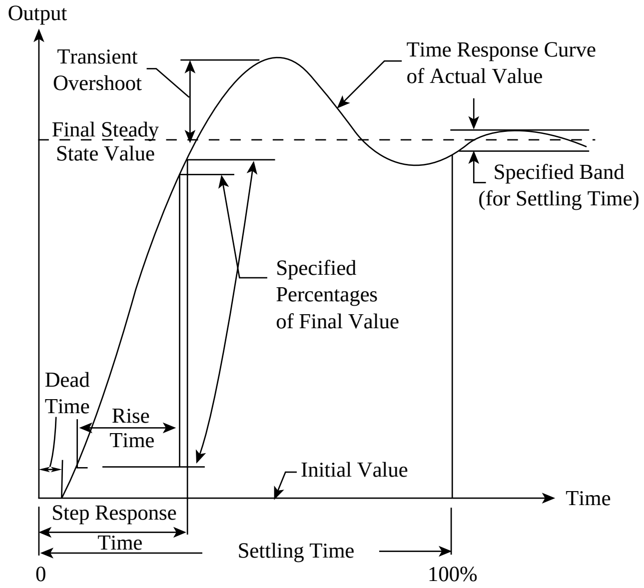

FIG. 1.3z
Typical time response of a system to a step increase of input.

Self-heating. Internal heating resulting from electrical energy dissipated with a device. (Ref. 11)

Self-operated controller. See *controller, self-operated (regulator)*.

Self-regulation (inherent regulation). The property of a process or machine that permits attainment of equilibrium, after a disturbance, without the intervention of a controller. (4)

Sensing element. See *element, sensing*.

Sensing element elevation. The difference in elevation between the sensing element and the instrument. *Note:* The elevation is considered positive when the sensing element is above the instrument. (8)

Sensitivity. The ratio of the change in output magnitude to the change of the input that causes it after the steady-state has been reached. *Note 1:* It is expressed as a ratio with the units of measurement of the two quantities stated. (The ratio is constant over the range of a linear device. For a nonlinear device, the applicable input level must be stated.) *Note 2:* Sensitivity has frequently been used to denote the dead band. However, its usage in this sense is deprecated, since it is not in accordance with accepted standard definitions of the term. (8, Ref. 4)

Sensor. See *transducer*. (11)

Servomechanism. An automatic feedback control device in which the controlled variable is mechanical position or any of its time derivatives. (Ref. 4)

Setpoint. An input variable that sets the desired value of the controlled variable. *Note 1:* The input variable may be manually set, automatically set, or programmed. *Note 2:* It is expressed in the same units as the controlled variable. (8, Ref. 4, “command”)

Settling time. See *time, settling.*

Shared time control. See *control, shared time.*

Sheltered area. See *area, sheltered.*

Signal. In process control, a physical variable, one or more *parameters* of which carry information about another variable (which the signal represents). (17)

Signal, actuating error. In process instrumentation, the *reference-input signal* minus the *feedback signal.* See Figure 1.3p. See also *deviation, system.* (8, Ref. 4, "signal, actuating")

Signal amplitude sequencing (split ranging). Action in which two or more *signals* are generated or two or more *final controlling elements* are actuated by an *input signal,* each one responding consecutively, with or without overlap, to the magnitude of that *input signal.* See Figure 1.3aa. (8)

Signal, analog. A *signal* representing a variable that may be continuously observed and continuously represented.

Signal converter. See *signal transducer.*

Signal, digital. Representation of information by a set of discrete values in accordance with a prescribed law. These values are represented by numbers.

Signal, error. In a *closed loop*, the *signal* resulting from subtracting a particular *return signal* from its corresponding *input signal.* See also *signal, actuating error.* (4, 8)

Signal, feedback. In process instrumentation, the *return signal* that results from a measurement of the *directly controlled variable.* See Figure 1.3p. (8. Ref. 4)

Signal, feedforward. See *control, feedforward.*

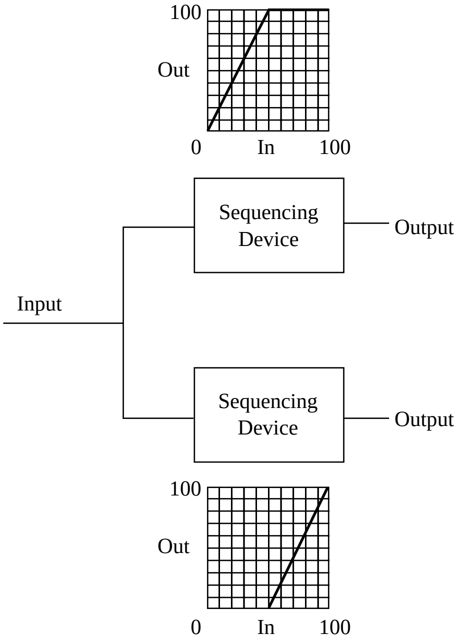

FIG. 1.3aa

Signal amplitude sequencing.

Signal, input. A *signal* applied to a *device, element,* or system. (8, Ref. 4)

Signal, measured. The electrical, mechanical, pneumatic, or other variable applied to the input of a *device.* It is the analog of the *measured variable* produced by a *transducer* (when such is used).

Example 1: In a thermocouple thermometer, the measured signal is an electromotive force (emf), which is the electrical analog of the temperature applied to the thermocouple.

Example 2: In a *flowmeter,* the measured signal may be a differential pressure, which is the analog of the rate of flow through the orifice.

Example 3: In an electric tachometer system, the measured signal may be a voltage, which is the electrical analog of the speed of rotation of the part coupled to the tachometer generator.

See *variable, measured.* (8, Ref. 2)

Signal, output. A *signal* delivered by a *device, element,* or system. (8, Ref. 4)

Signal, reference-input. One external to a control loop, serving as the standard of comparison for the *directly controlled variable.* See Figure 1.3p. (4, 8)

Signal, return. In a *closed loop,* the *signal* resulting from a particular *input signal* and transmitted by the loop and to be subtracted from the *input signal.* See also *signal, feedback.* (4, 8)

Signal selector. A *device* that automatically selects either the highest or lowest *input signal* from among two or more *input signals. Note:* This device is sometimes referred to as a "signal auctioneer." (Ref. 8, "auctioneering device")

Signal-to-noise ratio. Ratio of *signal* amplitude to *noise* amplitude. *Note:* For sinusoidal and non-sinusoidal *signals,* amplitude may be peak or rms and should be so specified. (Ref. 8)

Signal transducer (signal converter). A transducer that converts one standardized transmission *signal* to another. (Ref. 8)

Single-speed floating controller. See *controller, single-speed floating.*

Source impedance. See *impedance, source.*

Span. The algebraic difference between the upper and lower range values. *Note 1:* For example, (a) *range* 0 to 150°F, *span* 150°F, (b) *range* –20 to 200°F, *span* 220°F, and (c) *range* 20 to 150°C, *span* 130°C. *Note 2:* The following compound terms are used with suitable modifications to the units, e.g., *measured variable span,* and *measured signal span. Note 3:* For multirange *devices,* this definition applies to the particular *range* that the *device* is set to measure. See Tables 1.3w and 1.3x. (8, Ref. 3)

Span adjustment. See *adjustment, span.*

Span error. See *error, span.*

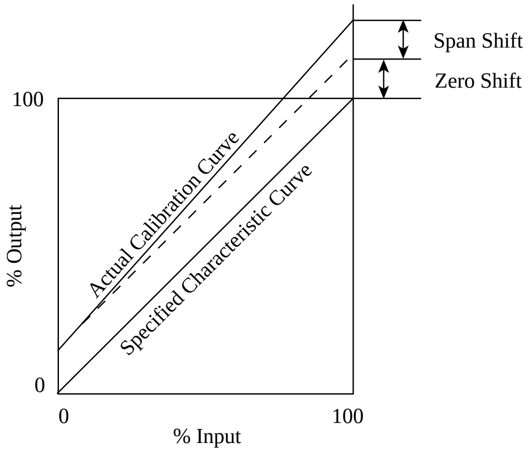

FIG. 1.3bb
Shift, span, and zero.

Span shift. Any change in slope of the input–output curve. See Figure 1.3bb.

Split ranging. See *signal amplitude sequencing (split ranging)*.

Static friction. See *stiction.*

Static gain. See *gain, static.*

Static pressure. See *pressure, static.*

Steady state. A characteristic of a condition, such as value, rate, periodicity, or amplitude, exhibiting only negligible change over an arbitrarily long period of time. *Note:* It may describe a condition in which some characteristics are static and others are dynamic. (8, Ref. 4)

Steady-state deviation. See *deviation, steady-state.*

Step response. See *response, step.*

Step response time. See *time, step response.*

Stiction (static friction). Resistance to the start of motion, usually measured as the difference between the driving values required to overcome static friction upscale and downscale. (4)

Stiffness. In process control, the ratio of change of force (or torque) to the resulting change in deflection of a spring-like *element. Note:* Stiffness is the opposite of compliance.

Subsidence. See *damping*, also *subsidence ratio.*

Subsidence ratio. In process instrumentation, the ratio of the peak amplitudes of two successive oscillations of the same sign, the numerator representing the first oscillation in time. See Figure 1.3q. (Ref. 16)

Summing point. Any point at which *signals* are added algebraically. See Figure 1.3p. (4, 8)

Supervisory control. See *control, supervisory.*

Supply pressure. See *pressure, supply.*

Suppressed range. See *range, elevated-zero.*

Suppressed span. See *range, elevated-zero.*

Suppressed-zero range. See *range, suppressed-zero.*

Suppression. See *range, elevated-zero.*

Suppression ratio (of a suppressed zero range). The ratio of the lower range value to the span. *Note:* For example: *range* 20 to 100, suppression ratio = 20/80 = 0.25. See Table 1.3w. (8, Ref. 2)

Surge pressure. See *pressure, surge.*

Switching point. A point in the input *span* of a *multiposition controller* at which the *output signal* changes from one *position* to another. See Figure 1.3l. (8)

Systematic error. See *error, systematic.*

System, control. See *control system.*

System, controlled. The collective functions performed in and by the equipment in which the variable(s) is (are) to be controlled. *Note:* Equipment as embodied in this definition should be understood not to include any automatic control equipment. (Ref. 8, “process”)

System, controlling. (1) Of a *feedback control system*, the portion that compares functions of a *directly controlled variable* and a *setpoint* and adjusts a *manipulated variable* as a function of the difference. It includes the *reference-input elements*; *summing point*; *forward* and *final controlling elements*; and *feedback elements* (including *sensing element*). (2) Of a *control system* without *feedback*, the portion that manipulates the *controlled system*. (Ref. 4, Ref. 8)

System deviation. See *deviation, system.*

System, directly controlled. The body, *process*, or machine directly guided or restrained by the *final controlling element* to achieve a prescribed value of the *directly controlled variable.* (4, 8)

System, idealized. An imaginary system whose ultimately controlled variable has a stipulated relationship to a specified *setpoint. Note:* It is a basis for performance standards. (8, Ref. 4)

System, indirectly controlled. The portion of the *controlled system* in which the *indirectly controlled variable* is changed in response to changes in the *directly controlled variable.* See Figure 1.3p. (Ref. 4, Ref. 8)

System, linear. One of which the *time response* to several simultaneous inputs is the sum of their independent *time responses. Note:* It is represented by a linear differential equation and has a *transfer function*, which is constant for any value of input within a specified *range.* A system not meeting these conditions is described as “nonlinear.” (Ref. 4)

Tapping. See *dither.*

Temperature, ambient. The temperature of the medium surrounding a *device. Note 1:* For *devices* that do not generate heat, this temperature is the same as the temperature of the medium at the point of *device* location when the *device* is not present. *Note 2:* For *devices* that do generate heat, this temperature is the temperature of the medium surrounding the *device* when it is present and dissipating heat. *Note 3:* Allowable ambient temperature limits are based on the assumption that the *device* in question is not exposed to significant radiant energy sources. (8)

Temperature, process. The temperature of the *process* medium at the *sensing element.* (8)

Terminal-based conformity. See *conformity, terminal-based.*

Terminal-based linearity. See *linearity, terminal-based.*

Terminal shock. An abrupt temperature change applied to a device. (8)

Three-position controller. See *controller, three-position.*

Time constant. In process instrumentation, the value T in an exponential response term $A \exp(-t/T)$ or in one of the transform factors

$$1 + sT,\ 1 + j\omega T,\ 1/(1 + sT),\ 1/(1 + j\omega T) \qquad \mathbf{1.3(11)}$$

where

s = complex variable
t = time, seconds
T = time constant
$j = \sqrt{-1}$
ω = angular velocity, radians per second

Note: For the output of a first-order system forced by a step or an impulse, T is the time required to complete 63.2% of the total rise or decay; at any instant during the process, T is the quotient of the instantaneous rate of change divided into the change still to be completed. In higher-order systems, there is a time constant for each of the first-order components of the process. In a *Bode diagram,* break points occur at $\omega = 1/T$. (Ref. 4, Ref. 8)

Time constant, derivative action. Of *proportional plus derivative control action,* a *parameter* the value of which is equal to $1/2\pi f_d$ where f_d is the frequency (in hertz) on a *Bode diagram* of the lowest frequency gain corner resulting from *derivative control action.* (4, 8)

Time constant, integral action. (1) Of *proportional plus integral control action,* a *parameter* whose value is equal to $1/2\pi f_i$ where f_i is the frequency (in hertz) on a *Bode diagram* of the highest frequency gain corner resulting from *integral control action.* (2) It is the reciprocal of *integral action rate. Note:* The use of integral action rate is preferred. (8, Ref. 4)

Time, correction. See *time, settling.*

Time, dead. The interval of time between initiation of an input change or stimulus and the start of the resulting observable response. See Figure 1.3z. (Ref. 4, Ref. 8)

Time, derivative action. In *proportional plus derivative control action,* for a unit ramp *signal* input, the advance in time of the *output signal* (after *transients* have subsided) caused by *derivative control action,* as compared to the *output signal* due to *proportional control action* only. (Ref. 5, Ref. 8)

Time proportioning control. See *control, time proportioning.*

Time, ramp response. The time interval by which an output lags an input when both are varying at a constant rate. (4, Ref. 3, "response time, ramp-forced")

Time response. See *response, time.*

Time, rise. The time required for the output of a system (other than a first-order one) to change from a small specified percentage (often 5 or 10) of the *steady-state* increment to a large specified percentage (often 90 to 95), either before or in the absence of overshoot. See Figure 1.3z. *Note:* If the term is unqualified, response to a unit step stimulus is understood; otherwise, the pattern and magnitude of the stimulus should be specified. (Ref. 4, Ref. 8)

Time schedule controller. See *controller, time schedule.*

Time, setting. The time required, following the initiation of a specified stimulus to a system, for the output to enter and remain within a specified narrow band centered on its *steady-state* value. See Figure 1.3z. *Note:* The stimulus may be a step impulse, ramp, parabola, or sinusoid. For a step or impulse, the band is often specified as ±2%. For nonlinear behavior, both magnitude and pattern of the stimulus should be specified. (8, Ref. 4)

Time, step response. Of a system or an *element,* the time required for an output to change from an initial value to a large specified percentage of the final *steady-state* value either before or in the absence of overshoot, as a result of a step change to the input. See Figure 1.3z. *Note:* Usually stated for 90, 95, or 99% change. See *time constant* for use of 63.2% value. (Ref. 4, "time response," Ref. 8)

Transducer. An *element* or *device* that receives information in the form of one quantity and converts it to information in the form of the same or another quantity. *Note:* This is a general term and definition and, as used here, applies to specific classes of *devices* such as *primary element, signal transducer,* and *transmitter.* See *primary element, signal transducer,* and *transmitter.* (Ref. 4, Ref. 8)

Transfer function. A mathematical, graphical, or tabular statement of the influence that a system or *element* has on a *signal* or action compared at input and at output terminals. (4, 8)

Transient. In process instrumentation, the behavior of a variable during transition between two *steady states.* (17)

Transient deviation. See *deviation, transient.*

Transient overshoot. The maximum excursion beyond the final *steady-state* value of output as the result of an input change. (Ref. 8)

Transient overvoltage. A momentary excursion in voltage occurring in a *signal* or supply line of a *device* that exceeds the maximum rated conditions specified for that *device.*

Transmitter. A *transducer* that responds to a *measured variable* by means of a *sensing element* and converts it to a standardized transmission *signal* that is a function only of the *measured variable.* (Ref. 8)

Transportation and storage conditions. The conditions to which a *device* may be subjected between the time of construction and the time of installation. Also included are the conditions that may exist during shutdown. See Figure 1.3v. *Note:* No permanent physical damage or impairment of operating characteristics shall take place under these conditions, but minor adjustments may be needed to restore performance to normal. (8)

Transverse interference. See *interference, normal-mode.*

Two-position controller. See *controller, two-position.*

Ultimately controlled variable. See *variable, ultimately controlled.*

Undamped frequency. See *frequency, undamped.*

Underdamped. See *damping.*

Upper range limit. See *range limit, upper.*

Upper range value. See *range value, upper.*

Value, desired. In process instrumentation, the value of the *controlled variable* wanted or chosen. *Note:* The desired value equals the *ideal value* in an *idealized system.* (8)

Value, ideal. In process instrumentation, the value of the indication, output, or *ultimately controlled variable* of an idealized *device* or system. *Note:* It is assumed that an ideal value can always be defined even though it may be impossible to achieve. (8)

Value, measured. The numerical quantity resulting, at the instant under consideration, from the information obtained by a measuring *device.* (Ref. 16)

Value, rms (root-mean-square value). The square root of the average of the squares of the instantaneous values. *Note:*

$$\text{rms value} = \left[\frac{1}{T}\int_{t_o}^{t_o+T} x^2 dt\right]^{1/2} \qquad \textbf{1.3(12)}$$

where

x is the instantaneous value
t_o is any value of time
T is the observation period (4)

Variable, directly controlled. In a control loop, the variable whose value is sensed to originate a *feedback signal.* (4, 8)

Variable, indirectly controlled. A variable that does not originate a *feedback signal* but is related to and influenced by the *directly controlled variable.* (4, 8)

Variable, manipulated. A quantity or condition that is varied as a function of the *actuating error signal* so as to change the value of the *directly controlled variable.* (4, 8)

Variable, measured. A quantity, property, or condition that is measured. *Note 1:* It is sometimes referred to as the measurand. *Note 2:* Common measured variables are temperature, pressure, rate of flow, thickness, speed, and others. (Ref. 8)

Variable, ultimately controlled. The variable whose control is the end purpose of the *automatic control system.*

Velocity limit. A limit that the rate of change of a specified variable may not exceed. (Ref. 8)

Velocity limiting control. See *control, velocity limiting.*

Vibration. A periodic motion or oscillation of an *element, device,* or system. *Note 1:* Vibration is caused by any excitation that displaces some or all of a particular mass from its position of equilibrium. The resulting vibration is the attempt of the forces, acting on and within the mass, to equalize. *Note 2:* The amplitude and duration of any vibration is dependent on the period and amplitude of the excitation and is limited by the amount of *damping* present.

Voltage, common-mode. A voltage of the same polarity on both sides of a differential input relative to ground. See Figure 1.3cc.

Voltage, normal-mode. A voltage induced across the input terminals of a *device.* See Figure 1.3dd.

Warm-up period. The time required after energizing a *device* before its rated performance characteristics apply. (8)

Zero adjustment. See *adjustment, zero.*

Zero-based conformity. See *conformity, zero-based.*

Zero-based linearity. See *linearity, zero-based.*

Zero-elevation. For an *elevated-zero range,* the amount by which the *measured variable* zero exceeds the

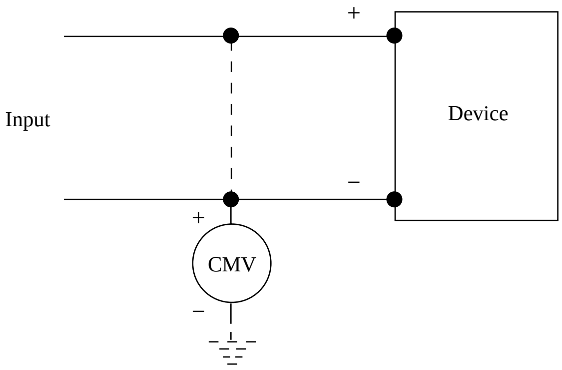

FIG. 1.3cc
Common mode voltage.

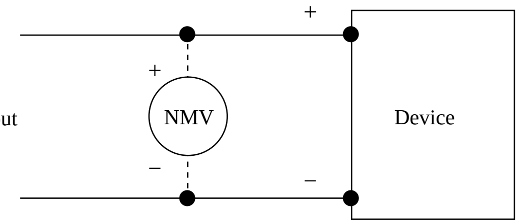

FIG. 1.3dd
Normal mode voltage.

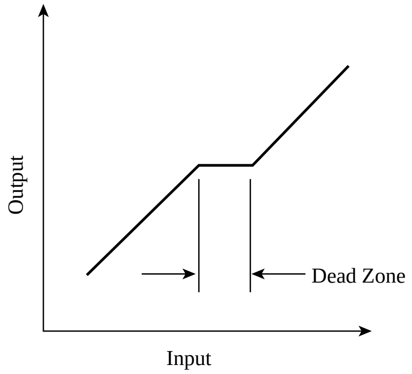

Fig. 1.3ee
Dead zone.

lower range value. It may be expressed either in units of *measured variable* or in percent of *span.* (8)

Zero error. See *error, zero.*

Zero frequency gain. See *gain, zero frequency.*

Zero shift. Any parallel shift of the input–output curve. See Figure 1.3bb.

Zero suppression. For a *suppressed-zero range,* the amount by which *measured variable* zero falls below the *lower range value.* It may be expressed either in units of the *measured variable* or in percent of *span.* (8)

Zone. On a *multiposition controller,* the *range* of input values between selected switching points or any *switching point* and range limit. See Figure 1.3l. (8)

Zone, dead. (1) For a *multiposition controller,* a *zone* of input in which no value of the output exists. It is usually intentional and adjustable. See Figure 1.3m. (Ref. 8) (2) A predetermined range of input through which the output remains unchanged, irrespective of the direction of change of the *input signal.* See Figure 1.3ee. The notes apply to definition (2) only. *Note 1:* There is but one input-output relationship, as shown in Figure 1.3ee. *Note 2:* Dead zone produces no phase lag between input and output.

Zone, intermediate. Any *zone* not bounded by a range limit. (8)

Zone, live. A *zone* in which a value of the output exists. (8)

Zone, neutral. A predetermined *range* of input values in which the previously existing output value is not changed. See Figure 1.3o. (Ref. 4)

TEST PROCEDURES

The purpose of the test procedures, as described herein, is to illustrate and clarify accuracy-related terms. It is intended only that the procedures indicate a generalized method of test. The test procedures that follow are for the following terms:

accuracy, measured
dead band
drift, point
hysteresis
linearity, independent
linearity, terminal-based
linearity, zero-based
repeatability
reproducibility

Tests described are for determination of static, not dynamic, performance characteristics. When relating performance characteristics such as values of *accuracy* to values of other terms such as *linearity, hysteresis, dead band,* and *repeatability,* equivalent units must be used.

The *accuracy rating* of reference measuring means as related to the characteristics being tested shall, preferably, be no greater than one-tenth the tolerance allowed on the test device, but in any case not greater than one-third the allowed tolerance.

Example: dead band
Test device, allowed dead band 0.2%
Measuring *device,* preferred *dead band* 0.02%
Measuring *device,* allowed *dead band* 0.06%

When the *accuracy rating* of the reference measuring means is one-tenth or less than that of the *device* under test, the *accuracy rating* of the reference measuring means may be ignored. When the *accuracy rating* of the reference measuring means is one-third or less but greater than one-tenth that of the *device* under test, the *accuracy rating* of the reference measuring means shall be taken into account.

The *device* under test and the associated test equipment shall be allowed to stabilize under *steady-state operating conditions.* All testing shall be done under these conditions. The *operating conditions* that would influence the test shall be observed and recorded. If the performance characteristic being determined requires *reference operating conditions,* the conditions of test shall be maintained at *reference operating conditions.*

The number of test points to determine the desired performance characteristic of a *device* should be distributed over the *range.* They should include points at or near (within 10%) the *lower* and *upper range values.* There should not be less than five points, and preferably more. The number and location of these test points should be consistent with the degree of exactness desired and the characteristics being evaluated.

Before recording observations, the *device* under test shall be exercised by a number of full range traverses in each direction.

At each point being observed, the input shall be held steady until the *device* under test becomes stabilized at its apparent final value.

Tapping or vibrating the *device* under test is not allowed unless the performance characteristic under study requires such action.

Calibration Cycle

Maintain test conditions and precondition the test device as indicated above in the introduction. Observe and record output values for each desired input value for one full-range traverse in each direction starting near the mid-range value. The final input must be approached from the same direction as the initial input. Apply the input in such a way as to not overshoot each input value.

Calibration Curve

For the purpose of the following test procedures, the *calibration curve* will be prepared as a "deviation plot." Determine the difference between each observed output value and its corresponding ideal output value. This difference is the *deviation* and may be expressed as a percent of ideal output *span*. The *deviation* is plotted vs. input or ideal output. Figure 1.3ff illustrates percent *deviation* plotted vs. percent input. A positive *deviation* denotes that the observed output value is greater than the ideal output value.

Test Procedures

Accuracy, measured. Measured accuracy may be determined from the *deviation* values (Table 1.3gg) of a number of calibration cycles. It is the greatest positive and negative *deviation* of the recorded values (from both an upscale and a downscale output traverse) from the reference or zero *deviation* line. *Measured accuracy* may be expressed as a plus and minus percentage of ideal output *span*. Example: The *measured accuracy* is +0.26% to −0.32% of output *span*.

Dead band. Maintain test conditions and precondition the test *device* as indicated in the introduction and proceed as follows:

1. Slowly vary (increase or decrease) the input to the *device* being tested until a detectable output change is observed.
2. Observe the input value.
3. Slowly vary the input in the opposite direction (decrease or increase) until a detectable output change is observed.
4. Observe the input value.

The increment through which the *input signal* is varied (difference between steps 2 and 4) is the *dead band*. It is determined from a number of cycles (steps 1 through 4). The maximum value is reported. The *dead band* should be determined at a number of points to make certain that the maximum *dead band* has been observed. *Dead band* may be expressed as a percent of input *span*.

Example: The dead band is 0.10% of input span.

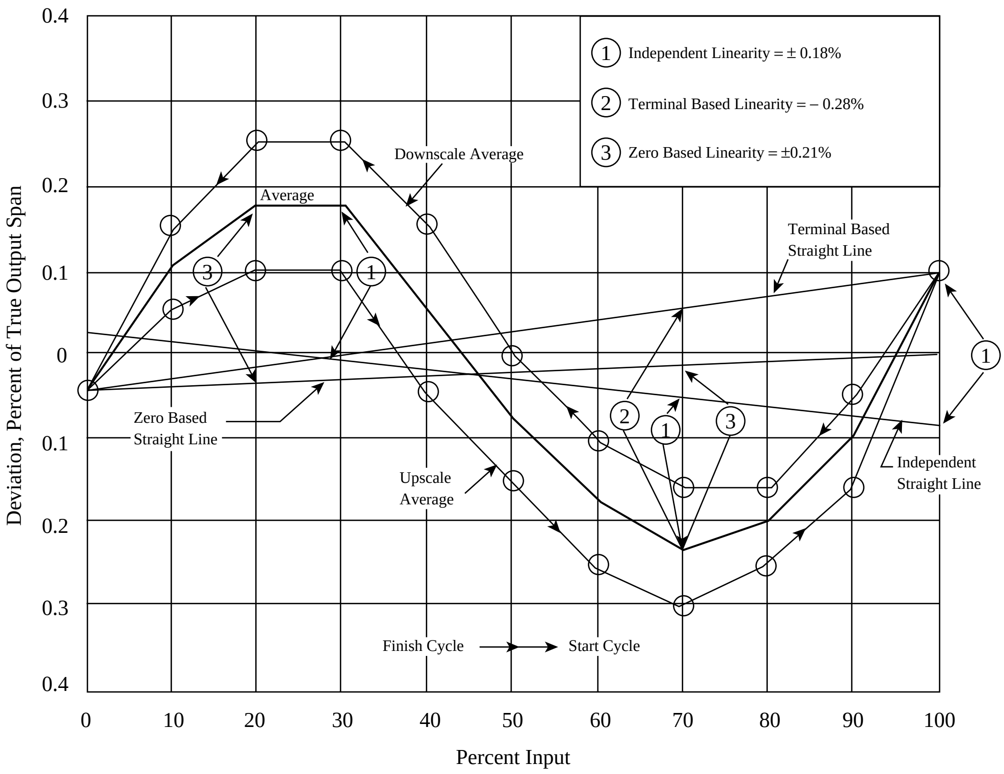

FIG. 1.3ff
Calibration curve (of data from Table 1.3gg).

TABLE 1.3gg
Calibration Report (see Fig. 1.3ff)

Input	ERROR										
	Up Actual	Down Actual	Up Actual	Down Actual	Up Actual	Down Actual	Up Actual	Up Average	Down Average	Up Average	Average Error
%	%	%	%	%	%	%	%	%	%	%	%
0		–0.04		–0.05		–0.06			–0.05		–0.05
10		+0.14	+0.04	+0.15	+0.05	+0.16	+0.06		+0.15	+0.05	+0.10
20		+0.23	+0.08	+0.26	+0.09	+0.26	+0.13		+0.25	+0.10	+0.175
30		+0.24	+0.09	+0.25	+0.10	+0.26	+0.11		+0.25	+0.10	+0.175
40		+0.13	–0.07	+0.15	–0.04	+0.17	–0.04		+0.15	–0.05	+0.05
50	–0.18	–0.02	–0.16	+0.01	–0.13	+0.01	–0.13	–0.15	0	–0.15	–0.075
60	–0.27	–0.12	–0.25	–0.10	–0.23	–0.08		–0.25	–0.10		–0.175
70	–0.32	–0.17	–0.30	–0.16	–0.28	–0.12		–0.30	–0.15		–0.225
80	–0.27	–0.17	–0.26	–0.15	–0.22	–0.13		–0.25	–0.15		–0.20
90	–0.16	–0.06	–0.15	–0.05	–0.14	–0.04		–0.15	–0.05		–0.10
100	+0.09		+0.11		+0.10			+0.10			+0.10

Measured Accuracy = +0.26%
–0.32%
Hysteresis plus Dead Band = +0.22%
Repeatability = 0.05%

Note: Accuracy of reference measuring means was not considered in the determination of the average error.

Drift, point. Maintain test conditions and precondition the test device as indicated in the introduction and proceed as follows:

1. Adjust the input to the desired value without overshoot and record the output value. *Note:* The test *device* should be permitted to warm up (if required) before recording the initial output value.
2. Maintain a fixed *input signal* and fixed *operating conditions* for the duration of the test.
3. At the end of the specified time interval, observe and record the output value.

In evaluating the results of this test, it is presumed that the *dead band* is either negligible or of such a nature that it will not affect the value of *drift.*

Point drift is the maximum change in recorded output value observed during the test period. It is expressed as a percentage of ideal output *span* for a specified time period. Example: The point drift is 0.1% of output span for a 24-h test.

Hysteresis. Hysteresis results from the inelastic quality of an *element* or *device.* Its effect is combined with the effect of *dead band.* The sum of the two effects may be determined directly from the *deviation* values (Table 1.3gg) of a number of test cycles and is the maximum difference between corresponding upscale and downscale outputs for any single test cycle. *Hysteresis* then is determined by subtracting the value of *dead band* from the corresponding value of *hysteresis* plus *dead band* for a given input. The maximum difference is reported. The difference may be expressed as a percentage of ideal output *span.* Example: The hysteresis is 0.12% of output span.

Linearity, independent. Independent linearity may be determined directly from the *calibration* curve (Figure 1.3ff) using the following procedure:

1. Plot a *deviation* curve, which is the average of the corresponding upscale and downscale output readings.
2. Draw a straight line through the average *deviation* curve so as to minimize the maximum *deviation.* It is not necessary that the straight line be horizontal or pass through the end points of the average *deviation* curve.

Independent linearity is the maximum *deviation* between the average *deviation* curve and the straight line. It is determined from the *deviation* plots of a number of calibration cycles. It is measured in terms of independent nonlinearity as a plus or minus percentage of ideal output *span.* Example: The ideal *independent linearity* is ±0.18% of output *span. Note:* The average *deviation* curve is based on the average of corresponding upscale and downscale readings. This permits observation of *independent linearity* independent of *dead band* or *hysteresis.* This concept assumes that, if no *hysteresis* or *dead band* were present, the *deviation* curve would be a single line midway between upscale and downscale curves.

Linearity, terminal-based. Terminal-based linearity may be determined directly from the *calibration curve* (Figure 1.3ff) using the following procedure:

1. Plot a *deviation* curve, which is the average of corresponding upscale and downscale output readings.
2. Draw a straight line such that it coincides with the average *deviation* curve at the *upper range value* and the *lower range value.*

Terminal-based linearity is the maximum *deviation* between the average *deviation* curve and the straight line. It is determined from the *deviation* plots of a number of calibration cycles. It is measured in terms of terminal-based nonlinearity as a plus or minus percentage of ideal output *span*. Example: The *terminal-based linearity* is 0.28% of output *span. Note:* The average deviation curve is based on the average of corresponding upscale and downscale readings. This permits observation of terminal-based linearity independent of dead band or hysteresis. This concept assumes that, if no hysteresis or dead band were present, the deviation curve would be a single line midway between upscale and downscale readings.

Linearity, zero-based. Zero-based linearity may be determined directly from the calibration curve (Figure 1.3ff) using the following procedure:

1. Plot a *deviation* curve, which is the average of corresponding upscale and downscale output readings.
2. Draw a straight line such that it coincides with the average *deviation* curve at the *lower range value* (zero) and minimizes the maximum deviation.

Zero-based linearity is the maximum *deviation* between the average *deviation* curve and the straight line. It is determined from the *deviation* plots of a number of calibration cycles. It is measured in terms of zero-based linearity as a plus or minus percentage of the ideal output *span*. Example: The *zero-based linearity* is ±0.21% of output *span. Note:* The average *deviation* curve is based on the average of corresponding upscale and downscale readings. This permits observation of *zero-based linearity* independent of *dead band* or *hysteresis*. This concept assumes that, if no *hysteresis* or *dead band* were present, the *deviation* curve would be a single line midway between upscale and downscale readings.

Repeatability. Repeatability may be determined directly from the *deviation* values (Table 1.3gg) of a number of calibration cycles. It is the closeness of agreement among a number of consecutive measurements of the output for the same value of input approached from the same direction. Fixed *operation conditions* must be maintained.

Observe the maximum difference in percentage *deviation* for all values of output considering upscale and downscale curves separately. The maximum value from either upscale or downscale curve is reported.

Repeatability is the maximum difference in percentage *deviation* observed above and is expressed as a percent of output *span.* Example: The *repeatability* is 0.05% of output *span.*

Reproducibility.

1. Perform a number of calibration cycles as described under “Calibration Cycle.”
2. Prepare a calibration curve based on the maximum difference between all upscale and downscale readings for each input observed. The *deviation* values are determined from the number of calibration cycles performed for step 1 above. See section titled “Calibration Curve.”
3. Maintain the test device in its regular operating condition, energized and with an *input signal* applied.
4. At the end of the specified time, repeat steps 1 and 2.

The test *operating conditions* may vary over the time interval between measurements if they stay within the *normal operating conditions* of the test *device.* Tests under step 4 above must be performed under the same *operating conditions* that existed for the initial tests.

Reproducibility is the maximum difference between recorded output values (both upscale and downscale) for a given input value. Considering all input values observed, the maximum difference is reported. The difference is expressed as a percentage of output *span* per specified time interval. Example: The *reproducibility* is 0.2% of output *span* for a 30-day test.

1.4 System Accuracy*

B. G. LIPTÁK (1982, 1995, 2003)

DEFINITIONS OF TERMS

Accuracy (Webster). Freedom from error or the absence of error. Syn. precision, correctness, exactness. (In this sense, the term is a qualitative, not quantitative, concept.)

Accuracy (ISA). In process instrumentation, degree of conformity of an indicated value to a recognized accepted standard value, or ideal value.

Accuracy, measured (ISA). The maximum positive and negative deviation observed in testing a device under specified conditions and by a specified procedure.

Accuracy of measurement (NIST). Closeness of the agreement between the result of a measurement and the value of the measurand…. Because accuracy is a quantitative concept, one should not use it quantitatively or associate numbers with it. (NIST also advises that neither *precision* nor *inaccuracy* should be used in place of *accuracy*.)

Error (ISA). In process instrumentation, the algebraic difference between the indication and the ideal value of the measured signal. It is the quantity that, algebraically subtracted from the indication, gives the ideal value.

Range (ISA). The region between the limits within which a quantity is measured, received, or transmitted, expressed by stating the lower and upper range values.

Rangeability (recommended by IEH). Rangeability of a sensor is the measurement range over which the error statement, in the units of a percentage of actual reading, is guaranteed.

Repeatability (ISA). The closeness of agreement among a number of consecutive measurements of the output for the same value of the input under the same operating conditions, approaching from the same direction, for full-range traverses.

Repeatability (NIST). Closeness of agreement between the results of successive measurements of the same measurand carried out under the same conditions of measurement…. Repeatability may be expressed quantitatively in terms of the dispersion characteristics of the results.

Reproducibility (ISA). In process instrumentation, the closeness of agreement among repeated measurements of the output for the same value of input made under the same operating conditions over a period of time, approaching from both directions.

Reproducibility (NIST). Closeness of agreement between the results of measurements of the same measurand carried out under changed conditions of measurement.

Uncertainty (Webster). A feeling of unsureness about something.

Uncertainty (IEH Section 1.5). Measurement uncertainty is expressed to a confidence level of 95%, and it is the limit to which an error may extend.

Language, Terminology, and Reality

The guide titled *International Vocabulary of Basic and General Terms in Metrology* (commonly referred to as *VIM*) was published by ISO in the name of seven organizations and contains the VIM definitions of 24 terms relevant to measurement and accuracy. So, from a theoretical point of view, we do have standards and internationally agreed upon definitions.

But the reality in the average industrial plant is different, and this *Instrument Engineers' Handbook* is written for the average instrumentation and control (I&C) engineer in those plants. Therefore, when we quantify an error herein, which one should expect when making a measurement with a particular instrument, we will not (yet) use terms such as *uncertainty* but will try to stay on familiar grounds. On the other hand, we will try to take a step in the right direction by improving the clarity of our language.

When an instrument is specified to have ±1% accuracy, people do not expect it to have 99% error! The intended meaning of that statement is ±1% inaccuracy or a ±1% error relative to some reference standard. It is important to emphasize the role of a reference standard in all measurements, as we humans are incapable of measuring anything in the absolute. All we can do is compare an unknown quantity to a known one and determine which is larger or smaller and by how much. The presence of a reference also means that a measurement can be in error not only because the sensor is inaccurate but also because the reference has drifted or was inaccurate to start with.

CLARIFYING THE "ACCURACY" STATEMENT

In a volume dealing with process measurement, no subject is more deserving of in-depth evaluation than the error that is inherent in all measurement. Good control is possible only if the controlled variable is precisely measured. Yet the term *accuracy* (or, more precisely, *inaccuracy* or *uncertainty*) itself is poorly defined, frequently misunderstood, and often used as a sales gimmick. Consequently, use of this term cries out for international standardization and, as was noted above, ISO has already prepared such standards. The need for clarity of language and standardization exists for the following reasons:

1. When the error or inaccuracy of an instrument is stated to be ±1%, one would assume that this statement refers to the actual measurement—the actual reading. One would assume that, if this particular instrument happens to read 100, the true value of that measurement must fall between 99 and 101, but this frequently is not the case. Some manufacturers express their error statements (inaccuracy percentages) on the basis of "percent of actual span," while others might base it on "percent of full scale," "percent of range," or "percent of upper range value," and so on. This inconsistency is undesirable, because it is confusing. It would be better if all measurement error statements always referred to the *actual measurement.*
2. To make error statements expressed as percentages of the actual measurement truly meaningful, the statement should also specify the measurement range over which the statement holds true. This would be a simple matter if all manufacturers agreed to define *rangeability* as the *measurement range over which their error statement (as a percentage of actual reading units) is guaranteed*. This approach would allow all sensor inaccuracies to be stated on the same basis and therefore would eliminate the confusion. If all detector inaccuracies were stated as "*x*% of actual reading throughout the range of *y*," users could be "comparing apples with apples" when comparing bids, and the room for "creative specmanship" would at least be reduced.
3. Further confusion occurs because different manufacturers include different factors in their error statements. Most suppliers include only linearity, rangeability, and hysteresis errors in their total error statement; they list the error contributions caused by drift, temperature effects, overrange, power supply, humidity, RFI, and vibration separately. Actually, some manufacturers claim an apparent increase in accuracy not by improving precision but by considering fewer and fewer effects in the total error statement. Naturally, to reverse this trend, international agreement is needed with regard to the amount of variation (in ambient temperature, power supply, and others) that the manufacturer's error statements must include.

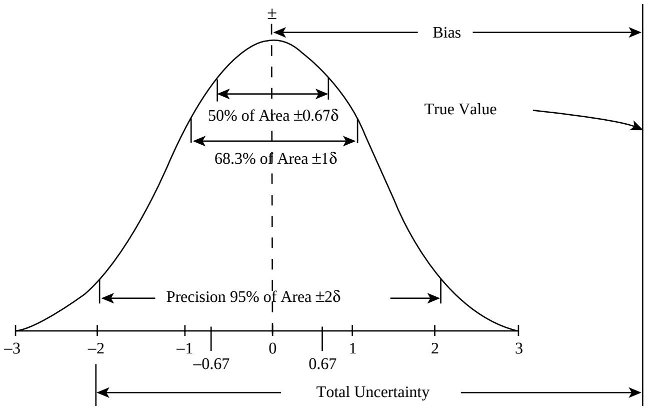

FIG. 1.4a
In any measurement, the total uncertainty (total error) is the sum of the sensor's random error (precision) and its systematic error (bias).

4. Yet another source of confusion is the fact that, when the error of 100 sensors is tested, the results fall onto a "bell curve" (Figure 1.4a). It would be desirable to reach international agreement so that all error statements would always be based on the performance of at least 95% of the units tested. In addition, an error statement should always state if it is based on self-evaluation performed by the supplier or on an evaluation by an independent testing laboratory and, in the latter case, if the test report is available for review.

If the above four recommendations were universally accepted, the subject of sensor error and inaccuracy would be much less confusing. While this is not likely to occur soon, a better understanding of the factors that cause the present state of confusion should be helpful, because it can speed the development of universal standards for sensor error and performance.

TERMINOLOGY OF INACCURACY AND REPEATABILITY

The purpose of all measurement is to obtain the true value of the quantity being measured, and error is thought of as the difference between the measured and the true quantity. Because it is impossible to measure a value without some uncertainty, it is equally impossible to know the exact size of the error. What is possible is to state the limits within which the true value of a measurement will fall.

The accuracy-related terminology used in the process control industry can be illustrated by an example of target shooting (Figure 1.4b). The spread of the nine shots fired into the upper right-hand corner of the target in a tight pattern represents the random error of the shooter. Looking at the penetration of the bullets, one can say that his shooting is repeatable and precise, but precision alone does not guarantee accuracy; it is only the measure of the ability of the shooter, which is called *random error.*

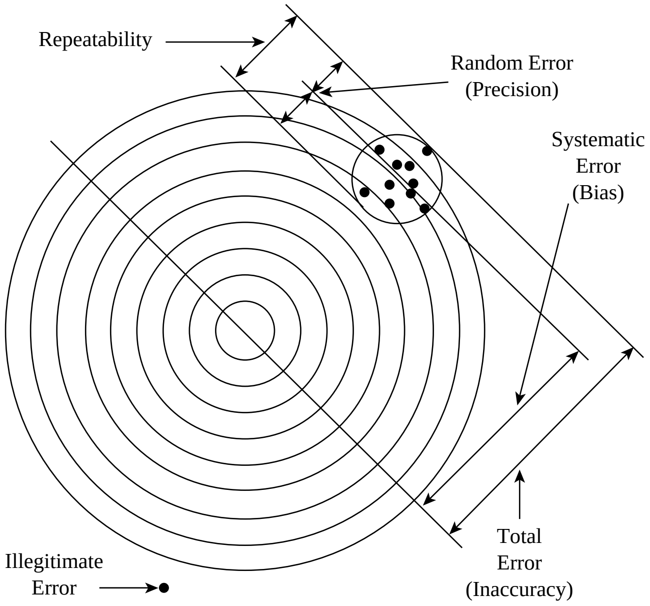

FIG. 1.4b
Accuracy terminology.

The distance between the mean impact of the nine bullets and the bull's-eye of the target is the *systematic error.* This error (caused by the wind or by the faulty adjustments of the sights) is repeatable and can be eliminated (in case of sensors, by calibration or by rezeroing; in case of the shooter, by waiting until the wind stops or by readjusting the sights). This error is not related to the shooter's inability to duplicate his shots. Systematic error is also referred to as *bias*, which is the systematic displacement of the measured value from the true one. It can be reduced by recalibrating the sensor against a reference standard, such as a calibrated (standard) thermal element, a known composition analytical sample, or dead weights.

The shot in the lower left-hand corner of the target is an illegitimate error, which is caused by blunders and can be totally eliminated.

The total error in a measurement can thus be defined as *the sum of the random error and the systematic error or bias.* If the purpose of an installation is to maintain the process conditions at previously experienced levels, and there is no interest in their true values, then the goal is to reduce the random error, without paying much attention to the remaining bias. In many industrial installations, such a repeatable (but inaccurate) measurement is sufficient.

Conversely, if the interest is in determining the true value of the measurement, because the installation serves such absolute purposes as accounting or quality control, the repeatable measurement is insufficient, and attention must be concentrated on absolute (total) accuracy. This can be obtained only through the reduction of both the random and the systematic errors, which is usually achieved by recalibration.

THE ACCURACY STATEMENT

The accuracy of a product category (sensors, transmitters, and so on) is established on the basis of testing large numbers of these products. For the more important sensors, the accuracy statements[1] should also include information on testing. An example of such a statement is quoted below from a National Bureau of Standards Calibration Certificate for a turbine flowmeter:

> *The results given are the arithmetic mean of ten separate observations, taken in groups of five successive runs on two different days. The reported values have an estimated overall uncertainty of ±0.13%, based on a standard error of ±0.01% and an allowance of ±0.1% for possible systematic error.*

Figure 1.4a illustrates the results of such a test. In that test, the precision (half of repeatability) of 68% of the devices tested has been found to be ±1% of the true value, while, for 95% of the devices, it fell within ±2%, and, for all 100% of the devices, it amounted to ±3%. The total error (total uncertainty) is the sum of precision plus bias, which is the systematic error of the bell curve itself. Because the bias can be reduced by calibration and rezeroing, but the precision (or repeatability) cannot, it would be desirable if manufacturers identified both of these values. Manufacturers should also state if the basis of this data is 68, 95, or 100% of the devices tested. To allow the I&C profession to mature, manufacturers should eliminate "specmanship" from their sales literature, so that users can "compare apples with apples" when making a selection.

FLOW MEASUREMENT EXAMPLE

Figure 1.4c illustrates three flow sensors installed in series in the same process pipe, with each measurement signal being totalized. All three flow sensors are sized for the same full range of 100 GPM (380 l/min) flow rate. The goal of this example is to illustrate how the total system error is determined at the flow rates of 20 GPM (76 l/min) and 80 GPM (304 l/min) in two different cases. In Case 1, the basic assumption is that the component errors are additive. In Case 2, the assumption is that the total system error will be the error of the least precise component in the system. Errors introduced by counter-totalizers, which is usually one count, will be neglected.

For the purposes of the example of Figure 1.4c, the magnetic flowmeter, transmitters, and integrators will all have ±0.5% full-scale (FS) error. The orifice plate will be assumed to have an inaccuracy of ±0.5% of rate and the error of the turbine flowmeter will be assumed to have an inaccuracy of ±0.25%. (The orientation table in Chapter 2 [Table 2.1b] provides complete data for all flow sensors, including their performance characteristics.)

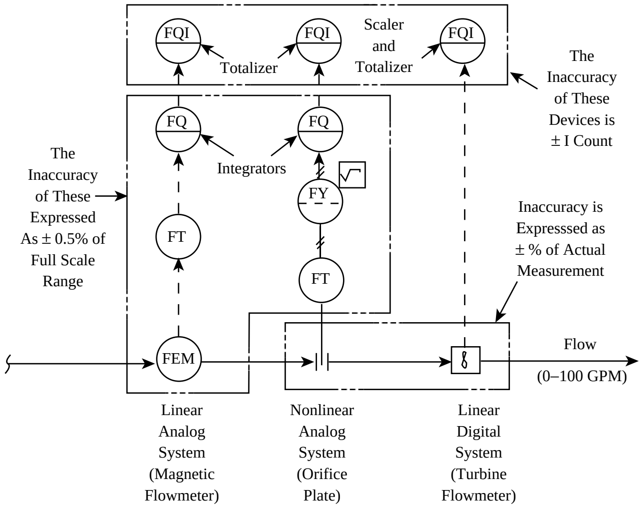

FIG. 1.4c
Errors of the components of three different flow totalization loops.

In the more detailed discussion that follows, it will be shown that the overall system error can be much greater than the component errors. It will be shown that, at 20% of full-scale flow, the error of a turbine flowmeter will be around 0.25% of actual flow, the error of a magnetic flowmeter might range from 3% to 9% of actual flow, and the measurement error of an orifice-based measurement error will range from 5 to 12% of actual rate.

The ±0.5% maximum inaccuracy (some based on actual readings, others on full-scale readings) was selected to reflect the typical installations in the existing plants. Today, when "smart" transmitters and improved sensors are available, one can select more accurate system components, some with maximum errors of ±0.1% of actual span. Here, we will assume that the maximum error of any of the system components is ±0.5% and, based on that assumption, we will determine the resulting total system error. The performance of analog and digital, linear and nonlinear devices will be discussed separately.

Analog and Linear Devices—Traditional Magnetic Flowmeters

The performance of a linear analog flow sensor, such as a magnetic flowmeter, is shown in Figure 1.4d. The line marked "actual" represents the relationship between the actual flow and the output signal generated by the flow sensor. Figure 1.4e illustrates this error as a percentage of full scale (FS), with the error limits being ±0.5% FS.

In Figure 1.4f, the same ±0.5% FS sensor performance is illustrated, but against a vertical coordinate that is a percentage of actual flow units (instead of full scale). The specific detector performance is likely to be better at most points of its range than what these error limits would imply. The main message is that, for sensor with percent-FS performance, the measurement error increases as the flow rate drops, as shown in Figure 1.4g.

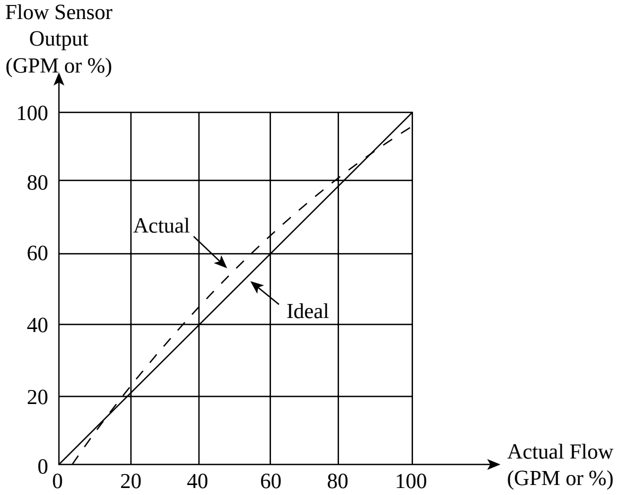

FIG. 1.4d
Performance of a linear analog flow sensor, such as a magnetic flowmeter.

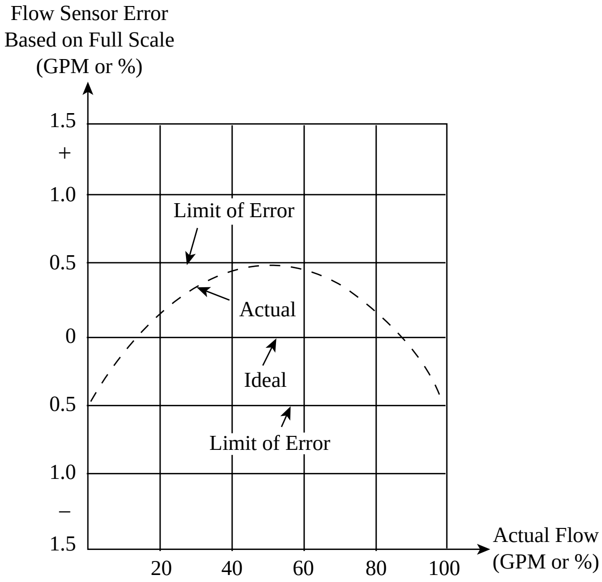

FIG. 1.4e
Error plot for a percentage of full-scale flow sensor.

It should be noted that the performance described here is representative of the older designs of magnetic flowmeters, which continuously maintained their magnetic fields. In the newer designs, the field is cycled on and off, and the sensor can be automatically rezeroed, so the measurement error can be reduced. Therefore, the inaccuracy of these newer magnetic flowmeters can approach ±0.5% of actual flow.

Analog, Nonlinear—Orifice Plates

The orifice plate itself is rather accurate and is a percent-of-actual-flow sensor, having an error limit of ±0.5% of actual flow rate, as shown in Figure 1.4h.

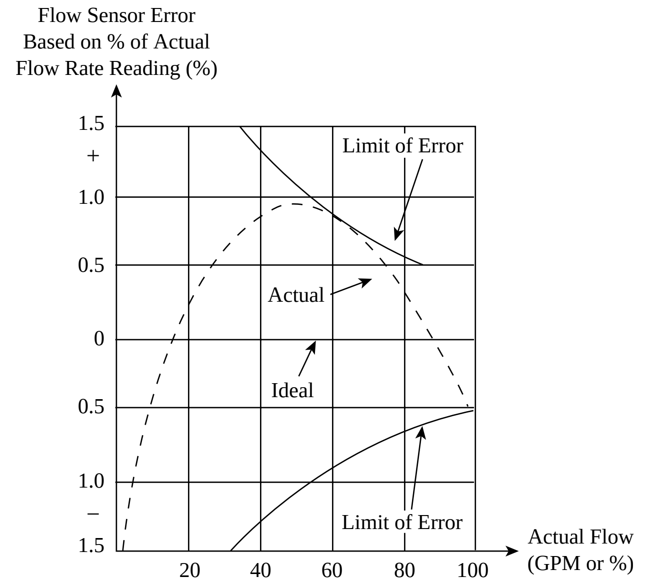

FIG. 1.4f
The error of a linear flow sensor shown in units of percentage of full-scale flow.

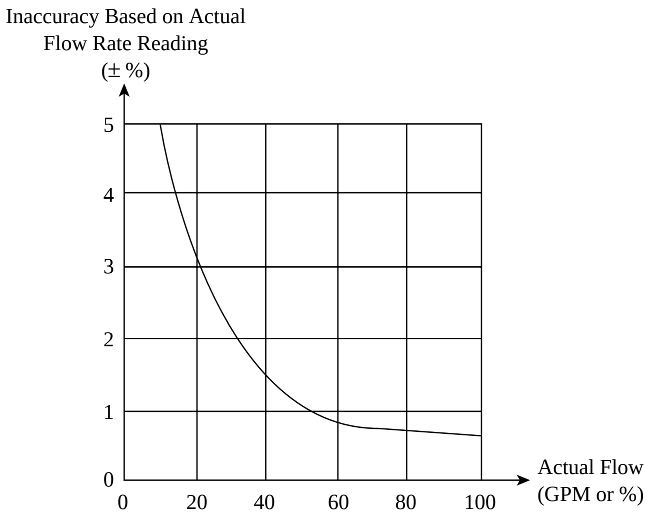

FIG. 1.4g
The error of a linear flow sensor shown in units of percentage of actual flow.

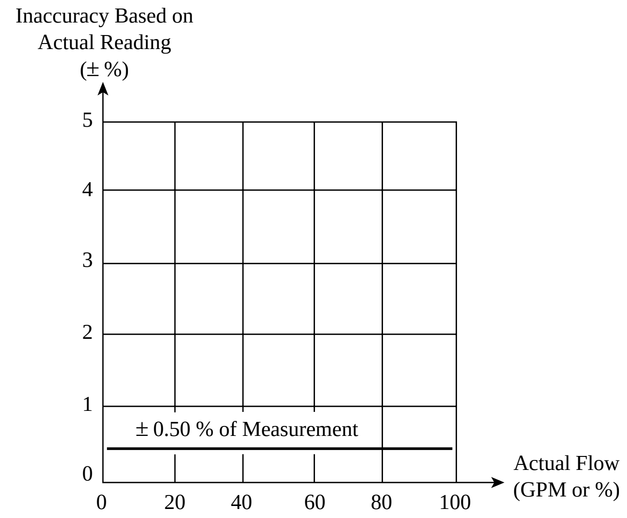

FIG. 1.4h
The error contribution of the orifice plate alone.

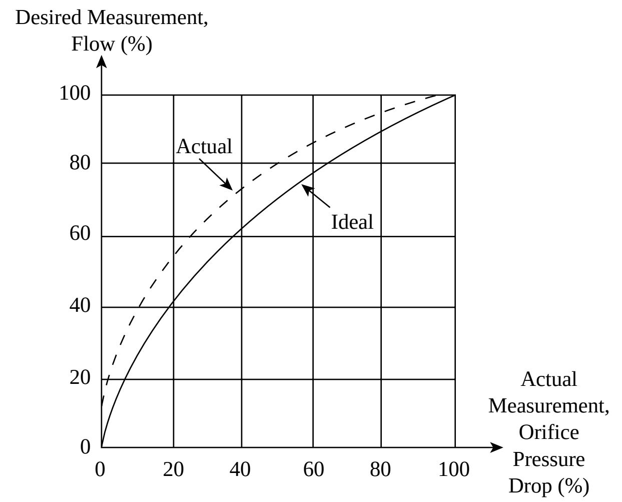

FIG. 1.4i
Performance of an orifice type nonlinear analog flow sensor.

The pressure drop through an orifice relates to the square of the flowing velocity or volumetric flow rate through the orifice plate. Figure 1.4i illustrates both, i.e., this ideal nonlinear (square root) relationship and the actual performance of a specific differential-pressure (d/p) cell used in an orifice type, nonlinear flow sensor.

To the error contribution of the orifice plate shown in Figure 1.4h (±0.5% of actual flow rate), one must add the error of the differential-pressure transmitter shown in Figure 1.4i (±0.5% FS). In addition, when the square root must be extracted before the signal can be integrated (Figure 1.4c), the error contribution (the *gain effect*) of this extraction must also be recognized. Figure 1.4j illustrates that this extraction of the square root improves the accuracy at the higher flow rates but degrades it as the flow rate is reduced.

Digital Linear—Turbine Flowmeter

The calibration of a turbine meter in terms of the K factor, given in units of pulses per gallon, is rather similar to the calibration curve of an orifice plate (Figure 1.4k). The inaccuracy of a turbine meter is also in units of percentage of the actual flow and is rather constant over a fairly wide range of flows. Turbine flowmeter inaccuracy can be improved by reducing the rangeability requirement of the unit (Figure 1.4l).

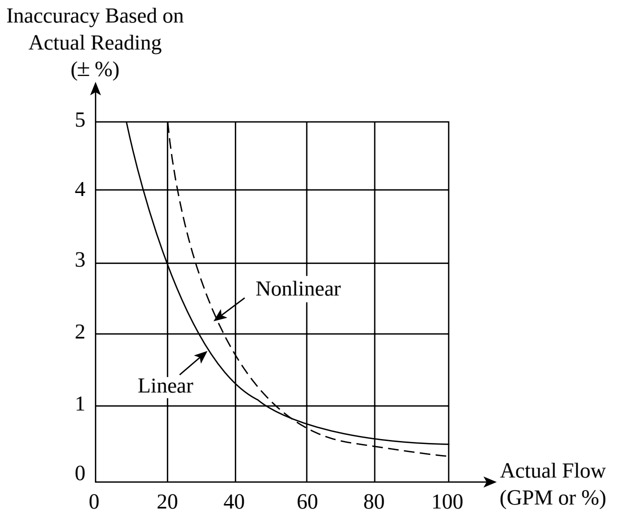

FIG. 1.4j
Comparing the inaccuracies of linear and a nonlinear flowmeter.

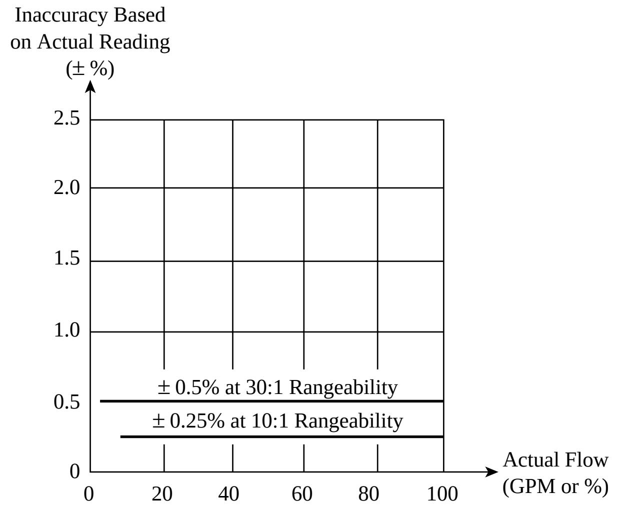

FIG. 1.4l
Turbine flowmeter inaccuracy as a function of rangeability.

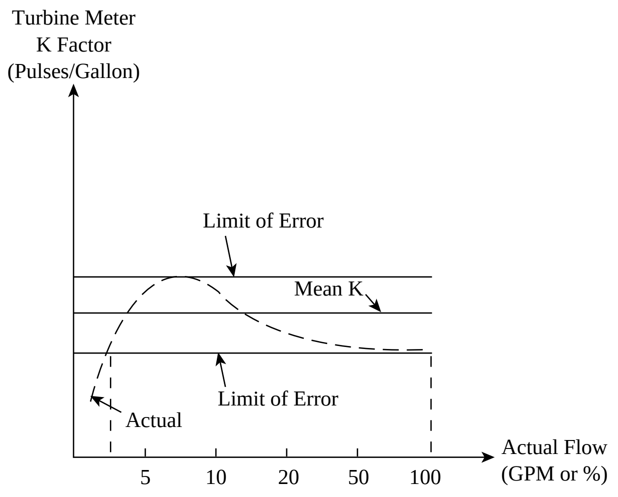

FIG. 1.4k
Turbine flowmeter calibration curve.

TABLE 1.4m
System Inaccuracy (Total Loop Error) in Units of Percentage of Actual Readings

Assumption Used to Estimate Accumulated System Inaccuracy	*Basis 1*		*Basis 2*	
	Operating Flow Rate (GPM)			
Type of flow detection loop	*20*	*80*	*20*	*80*
Analog, linear (magnetic flowmeter)	±9.0%	±1.5%	±3.0%	±0.5%
Analog, nonlinear (orifice flowmeter)	±12.0%	±2.0%	±5.0%	±0.5%
Digital, linear (turbine flowmeter)	±0.25%	±0.25%	±0.25%	±0.25%

Combined System Accuracy

Having reviewed the inaccuracies of the three flow sensors and the various loop components shown in Figure 1.4c, the next step is to evaluate the resulting total loop errors. There is no proven basis for determining the accumulative effect of component inaccuracies, and only an actual system calibration can reliably establish the total loop inaccuracy.

Still, we have learned the following from experience. We know that, the fewer the number of components in an analog measurement loop, the better the loop's performance. In digital systems, no additional error seems to be introduced by the addition of functional modules.

It has also been reported that the averaging of the outputs of several sensors that are detecting the same process variable will reduce the measurement error. These reports suggest that the error is reduced by the square root of the number of sensors in parallel. So, if two sensor outputs (each having a 1% error) are averaged, the error will be reduced to $1/\sqrt{2} = 0.7\%$ (and with three outputs, to 0.58%, with four outputs, to 0.5%, and so on).

Without actual system calibration, the evaluation of the overall loop accuracy must be based on some assumptions. Table 1.4m summarizes the system inaccuracies for the three loops in Figure 1.4c at 20 and 80% of flow rate and by evaluating the accumulated effect of component inaccuracies on the basis of one of two assumptions:

Basis 1 — Here, it is assumed that the inaccuracy of each component is additive, and therefore the total loop inaccuracy is the sum of component inaccuracies (a very conservative basis).

Basis 2 — Here, the assumption is that the system inaccuracy is the same as the inaccuracy of the least accurate component and therefore other inaccuracies can be neglected (a very optimistic assumption).

If Basis 1 is accepted for evaluating the total system error, an orifice-type installation operating at 20% of full-scale flow will have an error of ±12% of the reading, although the inaccuracy of any component in the loop does not exceed ±0.5% FS.

The data in Table 1.4m is based on the performance of conventional d/p transmitters and on conventional magnetic flowmeters. With the newer, pulsed DC magnetic flowmeters, the error can be reduced to ±0.5% of actual flow over a 10:1 range. Similarly, if the intelligent, multiple-range d/p cells are used, orifice measurement error can be reduced to ±1% of actual flow over a 10:1 range.[2] To achieve this level of performance, it is necessary to automatically switch the d/p cell span from its "high" to its "low" setting, based on the actual flow measurement.

If the conventional magnetic flowmeters and d/p cells are considered, and if they are evaluated on a basis that is slightly more conservative than Basis 2 but less conservative than Basis 1, the resulting loop errors are as shown in Figure 1.4n.

From the data in Table 1.4m and Figure 1.4n, it can be concluded that neither error nor inaccuracy is by any means a clearly defined single number and that the required rangeability of the measurement has a substantial impact on performance. Therefore, a meaningful accuracy statement should answer the following questions: (1) What portion of the total error is the precision (random error) of the sensor? (2) Is the sensor error based on full scale (FS) or on actual reading (AR)? (3) Over what range of measurement values is the error statement applicable?

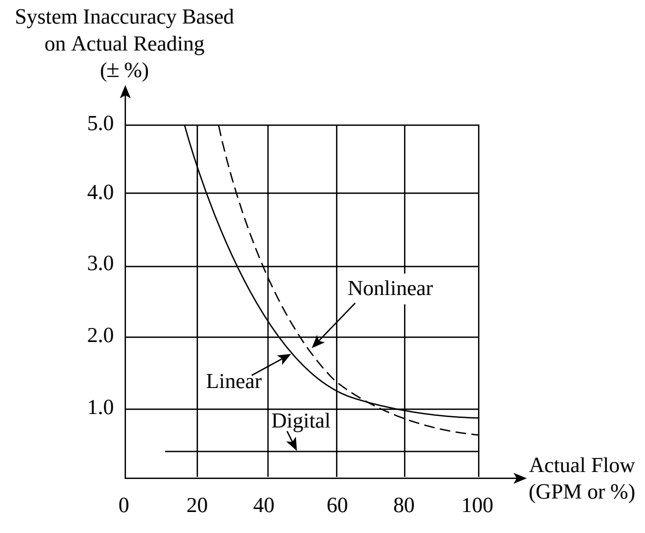

FIG. 1.4n

Total loop inaccuracies as a function of sensor type and flow rate, calculated on the basis of equation 1.4(1), where the total loop error is obtained by taking the square root of the sum of the component errors squared. (Accuracy in simple flow measurement. TI-1-30a. The Foxboro Company.)

TEMPERATURE AND PRESSURE EFFECTS

If a sensor such as a d/p cell has been tested at temperatures and pressures that differ from the operating temperature and pressure, this will affect the total error. The total error includes the d/p cell error (E), which is determined under atmospheric ambient conditions. Therefore, E reflects the linearity, repeatability, and hysteresis errors of the sensor.

For the purposes of this example, it is assumed that E = ±0.2% of actual span. Other factors that affect the total error include the zero (T_z) and span shifts (T_s) that might occur as a result of temperature variations. For a temperature variation of 100°F (55°C), T_z is assumed to be ±0.5% of maximum range, while T_s is assumed to be ±0.5% of actual reading.

The effect of changes in static pressure on the zero and span are noted by P_z and P_s. They are evaluated as the consequence of the physical distortion caused by 2000 psig (138 bars) of operating pressure. For the purposes of this example, it will be assumed that $P_z = \pm 0.25\%$ of maximum range, and $P_s = \pm 0.5\%$ of actual reading.

For the purposes of this example, assume a d/p cell with a maximum range of 0 to 750 in (0 to 19 m) H_2O and an actual span of 0 to 100 in (0 to 2.54 m) H_2O. It is further assumed that the actual operating temperature of the d/p cell is within 50°F (18°C) of the temperature at which the unit was calibrated and that the actual operating pressure is 1000 psig (69 bars). When the process measurement is 100 in. (2.54 m) H_2O, the above assumptions will result in the following error components:

$E = \pm 0.2\%$

$T_z = 0.5\ (750\text{ in.}/100\text{ in.})\ (50°\text{F}/100°\text{F}) = \pm 1.875\%$

$T_s = 0.5\ (50°\text{F}/100°\text{F}) = \pm 0.25\%$

$P_z = 0.25\ (1000\text{ psig}/2000\text{ psig})\ (750\text{ in.}/100\text{ in.}) = \pm 0.9375\%$

$P_s = 0.5\ (1000\text{ psig}/2000\text{ psig}) = \pm 0.25\%$

If we calculate the total error (E_t) as being the square root of the sum of the square of the individual errors, the result is:

$$E_t = \sqrt{(0.2^2 + 1.875^2 + 0.25^2 + 0.9375^2 + 0.25^2)} = \pm 2.13\%$$

1.4(1)

From the above example, one might note that the largest contributions to the total error are the zero shifts caused by the pressure and temperature differences between the calibration and the operating conditions. These errors can be reduced by selecting a d/p cell with a maximum range that is closer to the actual reading. One might also note that the total error (E_t) would have been even higher if the actual measurement did not correspond to 100% of the actual span (100 in H_2O), but only some fraction of it.

It should also be noted that the above E_t value is not the total measurement error of the loop but only the error contribution of the d/p cell. Finally, one should note that one advantage of the “smart” transmitters is their ability to reduce the pressure and temperature effects on the span and zero. Therefore, if E is ±0.1% in an intelligent transmitter, the total error E_t can be kept within about ±0.3%.

REPEATABILITY VS. TOTAL ERROR

Based on the information presented above, the following qualitative conclusions can be drawn:

1. Inaccuracy is likely to be improved by reducing the number of components in a measurement loop.
2. Inaccuracy statements are meaningful only when given in combination with rangeability. The wider the rangeability required (expected load variations), the more inaccurate the measurement is likely to be. Furthermore, the rangeability effect on digital systems is the least; it increases when linear analog system are used, and it is the highest in case of nonlinear analog systems.
3. On nonaccounting systems, the interest is focused on repeatability (random error) and not on total inaccuracy. The repeatability of most measurement loops is several-fold better than their total error.
4. Instrumentation worth installing is usually also worth calibrating. In this regard, several points should be made: (a) The accuracy of a multicomponent system is unknown unless it is calibrated as a system. (b) The calibration equipment used must be at least three times more accurate than the system being calibrated. (c) Periodic recalibration is a prerequisite to good control.
5. Instrumentation worth installing should also be worth keeping in good condition. The performance of all sensors is affected by corrosion, plugging, coating, and process property variations. Therefore, scheduled maintenance is required to guarantee reliable operation.

In summary, (a) inaccuracy should be stated as a function of rangeability, (b) multicomponent systems require system calibration, and (c) maintaining good performance requires periodic recalibration and scheduled maintenance.

1.5 Uncertainty Calculations

R. H. DIECK (2003)

The purpose of this section is to outline the fundamental methods of measurement uncertainty analysis for use as an objective estimator of data quality. These methods apply to all test, evaluation, and process data secured by a measurement instrument or system. Some examples are given to clarify the application of the principles presented.

UNCERTAINTY AND ERROR

Measurements are made so that the resulting data may be used for decision-making. In fact, the most fundamental definition of "good" data is "data that are applicable, or useful, for drawing conclusions or making decisions." Because of this, no test or evaluation data should be presented or used without including its measurement uncertainty. It is a properly evaluated measurement uncertainty that provides the information needed to properly assess the usefulness of data. For data to be useful, it is necessary that their measurement errors be small in comparison to the changes or effect under evaluation. The actual measurement error is unknown and unknowable. Measurement uncertainty estimates its limits with some confidence.

Therefore, *measurement uncertainty* may be defined as the limits to which a specific error or system error may extend with some confidence. The most commonly used confidence in uncertainty analysis is 95%, but other confidences may be employed where appropriate. In this section, all examples will be at 95% confidence.

Error is most often defined as the difference between the measured value of one data point and the true value of the measurand. That is:

$$E = (\mathit{measured}) - (\mathit{true}) \qquad \mathbf{1.5(1)}$$

where

E = measurement error
measured = value obtained by a measurement
true = true value of the measurand

It is possible to estimate only the expected limits to an error at some confidence. The most common method for estimating those limits is to use the *normal distribution*.[1]

For an infinite population ($N = \infty$), the standard deviation, σ, would be used to estimate the expected limits of a particular error with some confidence. That is, the average, plus or minus 2σ divided by the square root of the number of data points, would contain the true average, μ, 95% of the time.

However, in test measurements, one typically cannot sample the entire population and must make do with a sample of data points. The sample standard deviation, S_X, is then used to estimate σ_X. For a large data set (defined as having 30 or more degrees of freedom[1]) $\pm 2S_X$ divided by the square root of the number of data point e reported average contains the true average, μ, 95% of the time. That S_X divided by the square root of the number of data points in the reported average, M, is called the *standard deviation* of the average (sometimes also called the *random uncertainty*) and is written as

$$S_{\bar{X}} = \sqrt{\frac{\sum_{i=1}^{N}(X_i - \bar{X})^2}{N-1}} \Bigg/ \sqrt{M} = S_X/\sqrt{M} \qquad \mathbf{1.5(2)}$$

where

$S_{\bar{X}}$ = standard deviation of the average; the sample standard deviation of the data divided by the square root of M
S_X = sample standard deviation
$\bar{X}$ = sample average, that is,

$$\bar{X} = \sum_{i=1}^{M}(X_i/N) \qquad \mathbf{1.5(3)}$$

X_i = ith data point used to calculate the sample standard deviation and the average
N = number of data points used to calculate the sample standard deviation
$(N - 1)$ = degrees of freedom of S_X and $S_{\bar{X}}$
M = the number of data points in the reported average test result

Note in Equation 1.5(3) that, usually, $N = M$. This is not a requirement, however. N does not necessarily equal M. It is possible to obtain S_X from historical data with many degrees of freedom ($(N - 1)$ greater than 30) and to take only M data points in a specific test. The test result, or average, would therefore be based on M measurements, and the standard deviation of the average could still be calculated with Equation 1.5(3). In that case, there would be two averages. One average would be from the historical data used to calculate the sample standard deviation, and the other would be the average test result for *M* measurements.

In summary, the error for any particular error source is unknown and unknowable. To use data for decisions, it is necessary to estimate the limits to which a particular error may extend with some confidence. This estimate is called the *uncertainty.* Many are familiar with the term *accuracy.* However, *accuracy* is sometimes ambiguous. For example, if an experimenter needed an instrument with twice the accuracy of ±1%, would that be ±0.5% or ±2%? For this reason, this section will use the term *uncertainty* throughout to describe the quality of test data.

CLASSIFYING ERROR SOURCES AND THEIR UNCERTAINTIES

When estimating the limits of errors, their sources may be grouped into classifications to ease their understanding. The most common error source and uncertainty classifications now utilized are the International Standards Organization (ISO)[2] classifications and the United States/American Society of Mechanical Engineers (US/ASME)[3] classifications. The first groups error sources and their uncertainties by a type designation depending on whether there are data available to calculate the sample standard. The second classification groups errors and their uncertainties by their effects on the experiment or test data. That is, the US/ASME classification groups error sources and uncertainties by *random* and *systematic* types with subscripts used to denote whether there are data to calculate a standard deviation. For this reason, the US/ASME, or engineering, classification system groups usually are more useful and recommended for engineering applications.

The ISO Classification of Errors and Uncertainties

The ISO error and uncertainty classification system is not recommended in this section. However, the total uncertainty it yields is in complete agreement with the recommended classification system, the engineering classification system. In this system, errors and uncertainties are classified as Type A if there are data to calculate a sample standard deviation and Type B if there are not.[2]

The impact of multiple sources of error is estimated by root-sum-squaring their corresponding uncertainties. The equations follow.

ISO Type A Uncertainties and Errors For Type A, where data exist for the calculation of a standard deviation,

$$U_A = \left[\sum_{i=1}^{N_A}\left(\theta_i U_{A_i}\right)^2\right]^{1/2} \tag{1.5(4)}$$

where

U_{A_i} = standard deviation (based on data) of the average for uncertainty source *i* of Type A each with its own degrees of freedom (U_A is in units of the test or measurement result. It is an $S_{\overline{X}}$).
N_A = number of parameters of Type A uncertainty
θ_i = sensitivity (or influence coefficient) of the test or measurement result, *R,* to the *i*th Type A uncertainty

The uncertainty of each error source is in units of that source. When multiplied by the sensitivity for that source, it is converted to that uncertainty in result units. The effects of several error sources may be estimated by root-sum-squaring their uncertainties, as they are now all in the same units. The sensitivities, θ_i, are obtained for a measurement result, *R*, which is a function of several parameters, P_i. The equations follow.

R = the measurement result where
$R = f(P_1, P_2, P_3 \ldots P_N)$
P = a measurement parameter used to calculate the result, *R*

$$\theta_i = \frac{\partial R}{\partial P_i}$$

Obtaining the θ_i is often called error propagation or uncertainty propagation.

ISO Type B Uncertainties and Errors For Type B, where there are no data to calculate a standard deviation,

$$U_B = \left[\sum_{i=1}^{N_B}\left(\theta_i U_{B_i}\right)^2\right]^{1/2} \tag{1.5(5)}$$

where

U_{B_i} = standard deviation of the average for uncertainty source *i* of Type B. (U_B is in units of the test or measurement result, *R*. It is an $S_{\overline{X}}$. This standard deviation of the average is an estimate and not based on data.)
N_B = number of parameters with a Type B uncertainty
θ_i = sensitivity of the test or measurement result to the *i*th Type B uncertainty *R*

For these uncertainties, it is assumed that the U_{B_i} represent one standard deviation of the average for one uncertainty source with an assumed normal distribution of errors. Here, the degrees of freedom associated with this standard deviation (also standard deviation of the average) is assumed to be infinity.

Note that θ_i, the sensitivity of the test or measurement result to the *i*th Type B uncertainty, is actually the change in the result, *R*, that would result from a change of the size of the Type B uncertainty in the *i*th input parameter used to calculate that result.

The degrees of freedom from both the U_{A_i} and the U_{B_i} are needed to compute the degrees of freedom of the combined total uncertainty. The degrees of freedom for this total uncertainty are needed to select a proper Student's *t* for the confidence of interest, usually 95%. Those degrees of freedom are calculated with the Welch–Satterthwaite approximation. The general formula for degrees of freedom[4] is

$$df_R = \nu_R = \frac{\left[\sum_{i=1}^{N}\left(S_{\bar{X}_i}\right)^2\right]^2}{\left[\sum_{i=1}^{N}\frac{\left(S_{\bar{X}_i}\right)^4}{(\nu_i)}\right]} \qquad \textbf{1.5(6)}$$

where

$df_R = \nu_R$ = degrees of freedom for the result

ν_i = the degrees of freedom of the *i*th standard deviation of the average

For the ISO model, Equation 1.5(6) becomes

$$df_{R,ISO} = \nu_{R,ISO} = \frac{\left[\sum_{i=1}^{N_A}\left(\theta_i U_{A_i}\right)^2 + \sum_{i=1}^{N_B}\left(\theta_i U_{B_i}\right)^2\right]^2}{\left[\sum_{i=1}^{N_A}\frac{\left(\theta_i U_{A_i}\right)^4}{(\nu_i)} + \sum_{i=1}^{N_B}\frac{\left(\theta_i U_{B_i}\right)^4}{(\nu_i)}\right]} \qquad \textbf{1.5(7)}$$

The degrees of freedom calculated with Equation 1.5(7) is often a fraction. The *U.S. National Standard on Test Uncertainty*[5] recommends that this be truncated to the next lower whole number to be conservative.

In computing a total uncertainty, the uncertainties noted by Equations 1.5(5) and 1.5(6) are combined. For the ISO model,[3] this is calculated as

$$U_{R,ISO} = \pm t_{95}\left[(U_A)^2 + (U_B)^2\right]^{1/2} \qquad \textbf{1.5(8)}$$

where t_{95} = Student's *t* for ν_R degrees of freedom

Student's *t* may be obtained from Table 1.5a.

Note that alternative confidences are permissible; 95% is recommended by the ASME,[5] but 99% or 99.7% (or any other confidence) is obtained by choosing the appropriate Student's *t*. However, 95% confidence is recommended for uncertainty analysis.[5]

TABLE 1.5a

Student's t Statistic for 95% Confidence, t_{95}, Degrees of Freedom, ν. This is Frequently Written as $t_{95,\nu}$

ν	t_{95}	ν	t_{95}	ν	t_{95}
1	12.706	11	2.201	21	2.080
2	4.303	12	2.179	22	2.074
3	3.182	13	2.160	23	2.069
4	2.776	14	2.145	24	2.064
5	2.571	15	2.131	25	2.060
6	2.447	16	2.120	26	2.056
7	2.365	17	2.110	27	2.052
8	2.306	18	2.101	28	2.048
9	2.262	19	2.093	29	2.045
10	2.228	20	2.086	≥30	2.000

In all of the above, the errors were assumed to be independent. Independent sources of error are those for which an error in a measurement in one source cannot be used to predict the magnitude or direction of an error from the other, independent, error source. Nonindependent error sources are related. That is, if it were possible to know the error in a measurement from one source, one could calculate or predict an error magnitude and direction from the other nonindependent error source. These are sometimes called *dependent error sources.* Their degree of dependence may be estimated with the linear correlation coefficient. If there are some nonindependent errors, whether Type A or Type B, Equation 1.5(8) becomes[6]

$$U_{R,ISO} = t_{95}\left\{\sum_{T=A}^{B}\sum_{i=1}^{N_{i,T}}\left[(\theta_i U_{i,T})^2 + \sum_{j=1}^{N_{j,T}}\theta_i\theta_j U_{(i,T),(j,T)}(1-\delta_{i,j})\right]\right\}^{1/2} \qquad \textbf{1.5(9)}$$

where

$U_{i,T}$ = *i*th elemental uncertainty of Type T (can be Type A or B)

$U_{R,ISO}$ = total uncertainty of the measurement or test result

θ_i = sensitivity of the test or measurement result to the *i*th Type T uncertainty

θ_j = sensitivity of the test or measurement result to the *j*th Type T uncertainty

$U_{(i,T),(j,T)}$ = covariance of $U_{i,T}$ on $U_{j,T}$

$$= \sum_{l=1}^{K} U_{i,T}(l)U_{j,T}(l) \qquad \textbf{1.5(10)}$$

= sum of the products of the elemental systematic uncertainties that arise from a common source (*l*)

l = an index or counter for common uncertainty sources

K = number of common source pairs of uncertainties

$\delta_{i,j}$ = Kronecker delta ($\delta_{i,j} = 1$ if $i = j$, and $\delta_{i,j} = 0$ otherwise[6])

This ISO equation will yield the same total uncertainty as the engineering equation, but the ISO classification does not provide insight into how to improve an experiment's or test's uncertainty—that is, whether to possibly take more data because the random uncertainties are too high or calibrate better because the systematic uncertainties are too large. The engineering classification presented next is therefore the recommended approach.

Engineering Classification of Errors and Uncertainties

The engineering classification recognizes that experiments and tests have two major types: systematic and random. Their corresponding estimates of the limits of those errors are the systematic uncertainties and random uncertainties, respectively.

Random Errors and Uncertainties The general expression for random uncertainty is the $(1\,S_{\overline{X}})$ standard deviation of the average[9]

$$S_{\overline{X},R} = \left[\sum_{T=A}^{B}\sum_{i=1}^{N_{i,T}}\left(\theta_i S_{\overline{X}_{i,T}}\right)^2\right]^{1/2} = \left[\sum_{T=A}^{B}\sum_{i=1}^{N_{i,T}}\left(\theta_i S_{X_{i,T}} \Big/ \sqrt{M_{i,T}}\right)^2\right] \qquad \textbf{1.5(11)}$$

where

$S_{X_{i,T}}$ = sample standard deviation of the *i*th random error source of Type T

$S_{\overline{X}_{i,T}}$ = random uncertainty (standard deviation of the average) of the *i*th parameter random error source of Type T

$S_{\overline{X},R}$ = random uncertainty of the measurement or test result

$N_{i,T}$ = total number of random uncertainties, Types A and B, combined

$M_{i,T}$ = number of data points averaged for the *i*th error source, Type A or B

Note that $S_{\overline{X},R}$ is in units of the test or measurement result as a result of the use of the sensitivities, θ_i. Here, the elemental random uncertainties have been root-sum-squared with due consideration for their sensitivities, or influence coefficients. Since these are all random uncertainties, there is, by definition, no correlation in their corresponding error data, so these can always be treated as independent uncertainty sources.

Systematic Errors and Uncertainties The systematic uncertainty of the result, B_R, is the root-sum-square of the elemental systematic uncertainties with due consideration for those that are correlated.[6] The general equation is

$$B_R = \left\{\sum_{T=A}^{B}\sum_{i=1}^{N_T}\left[(\theta_i B_{i,T})^2 + \sum_{j=1}^{N_T}\theta_i\theta_j B_{(i,T),(j,T)}(1-\delta_{i,j})\right]\right\}^{1/2} \qquad \textbf{1.5(12)}$$

where

$B_{i,T}$ = *i*th parameter elemental systematic uncertainty of Type T

B_R = systematic uncertainty of the measurement or test result

N = total number of systematic uncertainties

θ_i = sensitivity of the test or measurement result to the *i*th systematic uncertainty

θ_j = sensitivity of the test or measurement result to the *j*th systematic uncertainty

$B_{(i,T),(j,T)}$ = covariance of B_i on B_j

$$= \sum_{l=1}^{M} B_{i,T}(l)B_{j,T}(l) \qquad \textbf{1.5(13)}$$

= sum of the products of the elemental systematic uncertainties that arise from a common source (l)

l = an index or counter for common uncertainty sources

$\delta_{i,j}$ = Kronecker delta ($\delta_{i,j} = 1$ if $i = j$, and $\delta_{i,j} = 0$ otherwise[6])

Here, each $B_{i,T}$ and $B_{j,T}$ are estimated as $2S_{\overline{X}}$ for an assumed normal distribution of errors at 95% confidence with infinite degrees of freedom. If there are less than an infinite number of degrees of freedom, the appendix of Reference 5 details that analysis.

The random uncertainty, Equation 1.5(11), and the systematic uncertainty, Equation 1.5(12), must be combined to obtain a total uncertainty,

$$U_{R,ENG} = t_{95}\left[(B_R/2)^2 + (S_{\overline{X},R})^2\right]^{1/2} \qquad \textbf{1.5(14)}$$

Note that B_R is in units of the test or measurement result, as was $S_{\overline{X},R_i}$.

The degrees of freedom will need to be determined for the engineering system total uncertainty. It is done with the Welch–Satterthwaite approximation, the general form of which is Equation 1.5(10). The specific formulation here is

$$df_R = \nu_R = \frac{\left\{\sum_{T=A}^{B}\left[\sum_{i=1}^{N_{S_{\overline{X}_i,T}}}\left(S_{\overline{X}_i,T}\right)^2 + \sum_{j-1}^{N_{B_i,T}}\left(\frac{\theta_j B_{j,T}}{2}\right)^2\right]\right\}}{\left\{\sum_{T=A}^{B}\left[\sum_{i=1}^{N_{S_{\overline{X}_i,T}}}\frac{\left(S_{\overline{X}_i,T}\right)^4}{\nu_{i,T}} + \sum_{j-1}^{N_{B_i,T}}\frac{\left(\theta_j B_{j,T}\big/2\right)^4}{\nu_j}\right]\right\}} \qquad \textbf{1.5(15)}$$

where

$N_{S_{\overline{X}_{i,T}}}$ = number of random uncertainties of Type T

$N_{Bj,T}$ = number of systematic uncertainties of Type T

$\nu_{i,T}$ = degrees of freedom for the *i*th uncertainty of Type T

$\nu_{\varphi,T}$ = infinity for all systematic uncertainties

TOTAL UNCERTAINTY

ISO Total Uncertainty

The ISO total uncertainty, which ISO refers to as the *expanded uncertainty*, for independent uncertainty sources (the most common) is [from Equation 1.5(8)]

$$U_{ISO} = \pm K\left[(U_A)^2 + (U_B)^2\right]^{1/2} \qquad \mathbf{1.5(16)}$$

The ISO uncertainty with some non-independent uncertainty sources is [from Equation 1.5(9)]

$$U_{R,ISO} = \pm\left\{\sum_{T=A}^{B}\sum_{i=1}^{N_{i,T}}\left[(\theta_i U_{i,T})^2 + \sum_{j=1}^{N_{j,T}}\theta_i\theta_j U_{(t,T),(j,T)}(1-\delta_{i,j})\right]\right\}^{1/2} \qquad \mathbf{1.5(17)}$$

Engineering Total Uncertainty

The engineering equation for total uncertainty for independent uncertainty sources (the most common) is [from Equation 1.5(14)]

$$U_{R,ENG} = \pm t_{95}\left[(B_R/2)^2 + (S_{\bar{X},R})^2\right]^{1/2} \qquad \mathbf{1.5(18)}$$

Here, just the first term of Equation 1.5(17) is needed, as all the systematic uncertainty sources are independent.

The engineering equation for uncertainty for nonindependent uncertainty sources (those with correlated systematic uncertainties) is also Equation 1.5(18), but it is necessary to also to use the full expression for B_R [Equation 1.5(12)]

$$B_R = \left\{\sum_{T=A}^{B}\sum_{i=1}^{N_T}\left[(\theta_i B_{i,T})^2 + \sum_{j=1}^{N_T}\theta_i\theta_j B_{(i,T),(j,T)}(1-\delta_{i,j})\right]\right\}^{1/2} \qquad \mathbf{1.5(19)}$$

The number of degrees of freedom needed to define Student's *t* for Equations 1.5(16) through 1.5(19) is calculated with the Welch–Satterthwaite approximation, Equation 1.5(7) for the ISO system and Equation 1.5(15) for the engineering system.

It usually may be assumed that the degrees of freedom equal 30 or higher. In these cases, the equations for uncertainty simplify further by setting t_{95} equal to 2.000. This approach is recommended for a first-time user of uncertainty analysis procedures, as it is a fast way to get to an approximation of the measurement uncertainty.

CALCULATION EXAMPLE

In the following calculation example, all the uncertainties are independent, and are all in the units of the test result, temperature. More detailed examples are given in many of the references cited. Their review may be needed to assure a more comprehensive understanding of uncertainty analysis. Of particular importance is the concept of uncertainty propagation. This is needed when the uncertainties are for parameters that contribute to a calculated result.

It has been shown[7] that there is often little difference among the uncertainties calculated with the different models. The data from Table 1.5b[8] will be used to calculate measurement uncertainty with these two models. This data are all in temperature units, so the influence coefficients, or sensitivities, are all unity.

Note the use of subscripts "A" and "B" to denote where data exist to calculate a standard deviation. Also note that, in this example, all errors (and therefore uncertainties) are independent and that all degrees of freedom for the systematic uncertainties are infinity except for the reference junction, whose degrees of freedom are 12. Also note that B_R is calculated as

$$B_R = 2\left[\left(\frac{0.06}{2}\right)^2 + \left(\frac{0.07}{2.18}\right)^2 + \left(\frac{0.1}{2}\right)^2\right]^{1/2} = 0.13 \qquad \mathbf{1.5(20)}$$

TABLE 1.5b
Test Measurement Uncertainties, F

Defined Measurement Process	*Systematic Uncertainty, B_i*	*Degrees of Freedom for B_i*	*Standard Deviation, $S_{X,i}$*	*Number of Data Points, N_i*	*Random Uncertainty, $S_{\bar{X},i}$*	*Degrees of Freedom for $S_{\bar{X},i}$*
Calibration of thermocouple	0.06_A	∞	0.3_A	10	0.095_A	9
Reference junction	0.07_B	12	0.1_A	5	0.045_A	4
Data acquisition	0.10_A	∞	0.6_A	12	0.73_A	11
RSS	$B_R = 0.13$	N/A	N/A	N/A	$S_{\bar{X},R} = 0.20$	N/A

Notice that the 0.07 is not divided by *t* but by its appropriate Student's *t* for 12 degrees of freedom. The use of "2" for Student's *t* is only appropriate for all degrees of freedom of 30 or more.[5]

Each uncertainty model will now be used to derive a measurement uncertainty.

ISO Uncertainty Calculation Example

For the U_{ISO} model we have, from Equation 1.5(13), the following expressions:

$$U_A = \left[(0.095)^2 + (0.045)^2 + (0.173)^2 + \left(\frac{0.07}{2.18}\right)^2\right]^{1/2} = 0.21 \qquad \textbf{1.5(21)}$$

$$U_B = \left[\left(\frac{0.06}{2}\right)^2 + \left(\frac{0.10}{2}\right)^2\right]^{1/2} = 0.058 \qquad \textbf{1.5(22)}$$

$$U_{R,ISO} = \pm K[(U_A)^2 + (U_B)^2]^{1/2} = \pm K[(0.21)^2 + (0.058)^2]^{1/2} \qquad \textbf{1.5(23)}$$

Here, remember that the 0.21 is the root sum square of the 1 $S_{\overline{X}}$ Type A uncertainties in Table 1.5b, and 0.058 is that for the 1 $S_{\overline{X}}$ Type B uncertainties. Also note that, in most cases, the Type B uncertainties have infinite degrees of freedom and represent an equivalent 2 $S_{\overline{X}}$. That is why they are divided by 2 to get an equivalent 1 $S_{\overline{X}}$. Where there are less than 30 degrees of freedom, one needs to divide by the appropriate Student's *t* that gave the 95% confidence interval. For the reference junction systematic uncertainty above, that was 2.18.

If *K* is taken as Student's t_{95}, the degrees of freedom must first be calculated. Remember that all the systematic components of Type B have infinite degrees of freedom except for the 0.07, which has 12 degrees of freedom. Also, all the B_i in Table 1.5a represent an equivalent 2 $S_{\overline{X}}$ except for 0.07, which represents 2.18 $S_{\overline{X}}$, as its degrees of freedom are 12 and not infinity. To use their data here, divide all of them except the 0.07 by 2, and divide the 0.07 by 2.18; they all now represent 1 $S_{\overline{X}}$ as do the random components. All Type A uncertainties, whether systematic or random in Table 1.5a, have degrees of freedom as noted in the table. The degrees of freedom for U_{ISO} is then

$$df_R = \nu_R$$

$$= \frac{[(0.095)^2 + (0.045)^2 + (0.173)^2 + (0.06/2)^2 + (0.07/2.18)^2 + (0.10/2)^2]^2}{\left[\frac{(0.095)^4}{9} + \frac{(0.045)^4}{4} + \frac{(0.173)^4}{11} + \frac{(0.06/2)^4}{\infty} + \frac{(0.07/2(0.07/2.18)^4)^4}{12} + \frac{(0.10/2)^4}{\infty}\right]}$$

$$= 22.51 \approx 22 \qquad \textbf{1.5(24)}$$

t_{95} is therefore 2.07. $U_{R,ISO}$ is then

$$U_{R,ISO} = \pm 2.07[(0.21)^2 + (0.058)^2]^{1/2} = 0.45 \text{ for 95\% confidence} \qquad \textbf{1.5(25)}$$

Engineering Uncertainty Calculation Example

For the engineering System, $U_{R,ENG}$, model [Equation 1.5(18)], we have the following expression:

$$U_{R,ENG} = \pm t_{95}[(0.13/2)^2 + (0.20)^2]^{1/2} \qquad \textbf{1.5(26)}$$

Here, the (0.13/2) is the $B_R/2$, and the 0.20 is (as before) the random component. To obtain the proper t_{95}, the degrees of freedom need to be calculated just as in Equation 1.5(24). There, the degrees of freedom were 22, and $t_{95} = 2.07$. $U_{R,ENG}$ is then

$$U_{R,ENG} = \pm 2.07[(0.13/2)^2 + (0.20)^2]^{1/2} = 0.44 \text{ for 95\% confidence.} \qquad \textbf{1.5(27)}$$

This is essentially identical to $U_{R,ISO}$ [Equation 1.5(25)] within round-off errors and degrees of freedom approximations, as predicted.

SUMMARY

Although these formulae for uncertainty calculations will not handle every situation, they will provide a useful estimate of test or measurement uncertainty in most cases. For a more detailed treatment or specific applications of these principles, consult the references and bibliography.

1.6 Configuring Intelligent Devices

J. BERGE (2003)

DESIGN FEATURE RECOMMENDATIONS

- Use permanently connected communications infrastructure.
- For the HART® Field Communications Protocol, use a handheld with large, user-friendly screen.
- Use device configuration templates.
- Use a fieldbus tool that requires no proprietary files from the host manufacturer.
- Be mindful of revisions when configuring fieldbus devices.

COSTS

A HART handheld, such as Smar International's HPC301, costs approximately U.S. $1000.

A FOUNDATION™ fieldbus host, such as the SYSTEM302, starts at U.S. $4000.

INTRODUCTION

Intelligent devices include "smart" instruments that have both an analog 4- to 20-mA signal with simultaneous digital communication, such as HART (Volume 3, Section 4.11), and fieldbus devices that are completely digital, such as FOUNDATION fieldbus (Volume 3, Section 4.12). Intelligence in these devices, along with networking and the right tools, can also be put to good use to improve maintenance practices.

Both FOUNDATION fieldbus and HART protocols are specifically designed for the configuration of field instruments and are therefore the most commonly used in the process industries. They both have special parameters for the specific purpose of device configuration, and both use the concept of device description (DD) files to inform a host device how to communicate these parameters with the device. This is a unique characteristic of these protocols that makes them highly suitable for instrumentation and control.

In the HART protocol, device parameter configuration is based on commands for reading and writing. There are three classes of commands: universal, common-practice, and specific. All HART devices support the universal commands, and most also support several common-practice commands. Together, the universal and common-practice commands cover most functions needed in a device. This enables a host to perform most device functions without access to the DD. Essentially, all devices also have a number of specific commands to access unique functionality. Either a DD or a special driver is required to communicate the special commands.

For FOUNDATION fieldbus device configuration parameters are arranged in a resource block and in transducer blocks. There are also function blocks, but these are used for control strategy building rather than device configuration. This distinction makes it easy to draw the line between device and strategy configuration. The block parameters are accessed using sophisticated communication services. A host needs to be loaded with the DD to be able to communicate with a device. In addition, to allow configuration of the device off-line, in advance, the capabilities file (CF) is required.

Range setting is perhaps the most important setting of a device based on a 4- to 20-mA signal such as used by a HART instrument. *Range* sets the scale for the 4- to 20-mA signal. Because FOUNDATION fieldbus devices communicate in floating-point mode and engineering units, there usually is no need to set a range. Calibration shall not be confused with range setting, since they are in fact different operations. For example, for a *transmitter* range setting means configuring the measured values at which the output shall be 4 and 20 mA, respectively. Calibration, on the other hand, means adjusting the reading from the sensor to match the correct value from a standard (Section 1.8). Range setting does not correct the sensor reading; it only affects the output scale.

To calibrate a transmitter, you must always apply a known input. Therefore, calibration cannot be done remotely. The expression *remote calibration* is often used erroneously to mean *remote range setting.* Some confusion exists in the marketplace as to what calibration is. This is a legacy from the era of analog devices in which calibration and range setting was done at the same time using the same set of potentiometers. For the HART protocol, calibration is usually called *trim* to distinguish it from range setting. FOUNDATION fieldbus avoids this confusion by calling range setting *scaling*. Still it is quite common in HART devices to change the range instead of calibrating the device when the sensor reading is wrong. The result is a correct 4- to 20-mA output, but any digital reading in the display or host will be wrong, which may lead to confusion.

CONFIGURATION TOOLS

FOUNDATION fieldbus devices are permanently connected via a network to a host in a convenient central location. HART devices, on the other hand, normally operate only using 4 to 20 mA, and a hand-held HART communicator is connected and communicates only when required. A FOUNDATION fieldbus host is therefore predominantly a stationary desktop computer, whereas a HART communicator is usually a portable device. However, portable interfaces for laptops exist for both HART and FOUNDATION fieldbus operation.

The handheld can be connected at any convenient point along the 4- to 20-mA wire as long as it is on the instrument side of the stipulated resistor (see Figure 1.6a). This connection is often done at the device itself, giving on-line access to information, configuration, remote monitoring, calibration and range setting, diagnostics, and maintenance.

The handheld can be either a dedicated text-based HART device or a HART interface for an organizer with a graphical user interface (GUI). Rapid development in the area of personal organizers has brought about tools that incorporate displays larger than three inches across and are capable of sophisticated graphics with a Windows-like appearance. They are also are very fast (see Figure 1.6b).

Fieldbus instruments are connected on the H1 field-level nework that ties in with a linking device on the HSE host-level network where the host computers with the configuration tool is (Figure 1.6c). This is a permanent connection where the network used for control, monitoring, and operation is also used for configuration and diagnostics, etc.

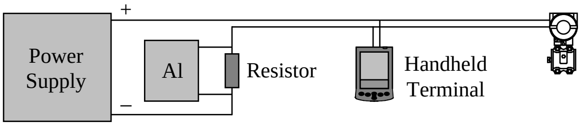

FIG. 1.6a

FIG. 1.6b
HART pocket Configurator. (Courtesy of Smar International.)

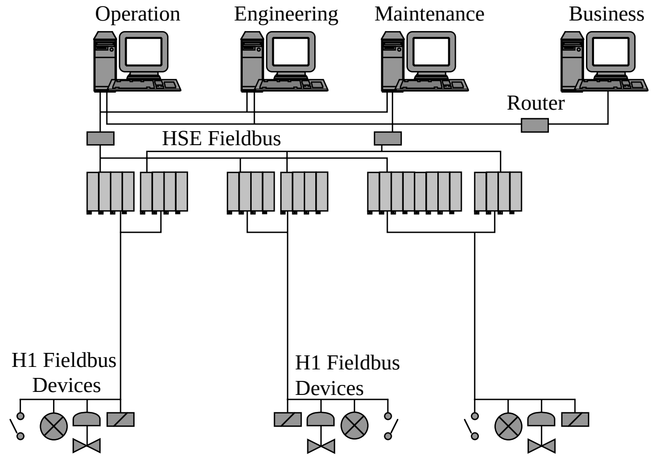

FIG. 1.6c
FOUNDATION™ fieldbus system architecture.

FIG. 1.6d
FOUNDATION™ fieldbus linking device. (Courtesy of Smar International.)

Linking device is typically one of many functions integrated in a single device. Usually the same device is responsible for powering the field instruments, etc. A linking device typically has several H1 ports and can be connected in a redundant scheme for high availability (Figure 1.6d).

For FOUNDATION fieldbus interoperability with the host is achieved through DD. By installing the device support files for a device, the host computer has the information required to communicate with the device and to allow the user to prepare a configuration in advance, even without being connected to the device. The files usually can be obtained from the manufacturer's site on the Internet. To guarantee interoperability, an open host uses only standard files to support any device. However, some tools may require proprietary files for each device to work, in which case a short list of approved devices applies.

DEVICE CONFIGURATION

HART devices are typically configured on line only, using a handheld unit communicating directly with the device. However, some handhelds also support off-line configuration for later download.

Although HART transmitters can operate in a purely digital mode, the 4- to 20-mA output is almost always used to deliver the process variable to the central controller. Setting the range of the transmitter is therefore required. The primary variable output settings are the most important part of the configuration. The lower range value (LRV) is the measured value at which the transmitter output will be 4 mA, and the upper range value (URV) is the input value at which the output will be 20 mA; i.e., 0 and 100% of range, respectively. Although LRV and URV are the proper terms, most call them *zero* and *span* instead. But span is really the difference between the URV and the LRV. The engineering unit can also be selected.

Range setting can be accomplished from the handheld by simply keying in the desired range values, regardless of input. This can even be done remotely and stored as an off-line configuration. Another method is to apply an input and (by pressing a button on the handheld or on the transmitter itself) informing the device that the applied input is to be the LRV or URV, thus setting the range (see Figure 1.6e). The latter method is often used for pressure transmitters that are installed with impulse lines that add hydrostatic pressure. Pressing the button elevates or suppresses the zero, ensuring that the output is 4 mA when appropriate. If the transmitter has a noninteractive zero and span, the URV will be pushed by the equivalent amount, leaving the span unaffected. For example, if the range of a pressure transmitter in a level application starts off as 0 to 5.48 kPa, and applied rerange is done with 1.86 kPa input, the new range becomes 1.86 to 7.34 kPa. However, when a rerange is applied for the URV, this does not affect the zero; i.e., the span is changed instead.

The damping is a first-order lag filter time constant.

The transfer function is used to select linear or square root extraction for differential-pressure flowmeters, and possibly for other options such as a freely configurable lookup table or square root of third or fifth power for open-channel flow measurements. Square root extraction is often done in the central control system, but it is in fact better to do it in the transmitter, as this results in less A/D and D/A conversion error.

Fail-safe mode can be set as upscale or downscale as per the NAMUR NE-43 standard. *Downscale* means that the output current will be set to 3.6 mA in case the internal diagnostics detect a fault. *Upscale* means the output will be set to 21 mA. Ideally, the receiving controller should have an input module that can interpret the failure signal and use this to shut down the control loop.

It is also possible to review the write protection status of the device—if the device has been write protected using a jumper or other solution.

When performing range setting or calibration, the user needs to know the sensor limits and is therefore usually prompted with this information, which typically can be reviewed at any time (see Figure 1.6f). HART device information includes lower range limit (LRL), upper range limit (URL), and the minimum span. The minimum span is the smallest permitted absolute difference between the URL and LRL for the sensor.

Many configuration options are device specific in HART devices. For example, for a temperature transmitter, the sensor type and wiring has to be configured (see Figure 1.6g). For a valve positioner, the actuator type has to be configured.

In most FOUNDATION system installations, the device configuration is created off-line for all devices in advance and downloaded after installation. Moreover, the device configuration is typically accomplished with the network and control

FIG. 1.6h
Pay attention to revisions when creating device configurations.

strategy configuration, all in the same tool. Thus, when configuring devices in a FOUNDATION system, the first step is to create the devices on the networks and give the devices a physical device tag (PD_TAG). Fieldbus devices are developing very rapidly. New versions are constantly being released, and many users already have several versions around the plant and in the store, this on top of a variety of brands of the same kind of device. When inserting new devices, it is important to specify the revisions to be used (see Figure 1.6h). Usually, the latest revision is the default. There is a risk that you will accidentally download a device configuration to the wrong model or wrong version device. A good tool prevents this and thus avoids the many headaches that could result.

Fieldbus devices do not require any range, because all values are communicated as floating-point values in engineering units. Ranges are typically used only in PID function blocks, or possibly in AI function blocks, to cater for conversions in inferred measurements, such as converting differential pressure to flow within specified ranges. That is, scaling is done as part of the control strategy configuration, not as part of the device configuration.

Every fieldbus device, H1 as well as HSE, needs to have one resource block. Really, the only parameter that must be configured is the mode. The MODE_BLK parameter *target* shall be set to automatic.

A fieldbus transducer block is required, in conjunction with every sensor and actuator, to act as an interface between the device and the control strategy. By parameterizing the transducer blocks, the device can be set up for the proper sensor or actuator type, such as HART devices. Similarly the transducer block also contains information about sensor limits. Indeed, there is a transducer scale range indication in the transducer block, but it is essentially a reflection of a setting done in the associated I/O function block. The MODE_BLK parameter target shall be set to automatic.

IDENTIFICATION

Information for identifying the device is very helpful during commissioning and maintenance. During the commissioning stage, it is useful for further assurance that connection has been made to the correct device. During maintenance, it is helpful for retrieving serial numbers, special instructions, important dates, and model numbers. The user can configure some of these parameters to be pertinent to the application. These parameters do not affect the operation of the device.

In addition to the sensor information such as range limits, HART device data such as sensor serial number, final assembly number, message, device tag, descriptor, date, manufacturer, device type, software and hardware revisions, and circuit board serial number are provided. For HART devices, the tag can use up to eight characters. The descriptor and message are 16 and 32 characters in length and can be configured as annotations describing the application and remind technicians of special precautions when servicing a device (see Figure 1.6i).

The date has no specific purpose but may be used to store when calibration or maintenance was last performed or is scheduled. Manufacturer, model, and version information can also be accessed (see Figure 1.6j).

HART devices such as pressure transmitters usually provide additional information about the materials of construction for the parts wetted by the process, e.g., the sensor isolating diaphragm, O-ring, flange and remote seal parts, and so on.

The resource block found in any FOUNDATION fieldbus device contains, among other things, identification information for the device. The tag descriptor parameter may be used to describe the application of the device. Manufacturer, model, and version information can also be accessed (see Figure 1.6k).

Fieldbus devices such as pressure transmitters usually provide additional information about the materials of construction for the parts wetted by the process, e.g., the sensor isolating diaphragm, O-ring, flange and remote seal parts, and so on (see Figure 1.6l).

If any changes are ever made to the device parts, it is important to update this information.

CALIBRATION

When the sensor reading differs from the actual applied input, the sensor has to be calibrated. The correct reading is entered from the maintenance tool, and the device then performs the necessary adjustment. A special case of sensor calibration is zeroing, which by definition is done with a zero value applied. This is accomplished, for example, by venting in the case of a pressure transmitter; hence, no value has to be entered (see Figure 1.6.m).

Nonzero calibration is usually done with a precision source applied. Calibration is usually done in two points, known as the low and high calibration points, respectively. For most transmitters, calibration of these two points is noninteractive. There is a limit to how close the two calibration points can be, and the distance is referred to as the *minimum span.* Output converters also need to be calibrated. This is usually done by first forcing an output at one end of the scale and then comparing the actual output against a standard. The actual reading is entered into the device that makes the necessary correction. Control valve positioners usually calibrate their position-sensing sensor themselves by automatically stroking the valve over its entire travel.

Since HART devices rely on 4 to 20 mA, this current loop can also be calibrated. However, it is rarely done because, being totally electronic, this part of the device rarely experiences any drift at all. For a HART transmitter, this means that a fixed output current is generated. The technician checks the current against a standard and keys it into a device that makes the necessary correction (see Figure 1.6n). For HART output devices, a signal is injected, and the device is informed of the true current.

Sensor or actuation calibration for FOUNDATION fieldbus devices is done from the associated transducer block. The standard transducer block also includes several parameters for storing information about the last calibration. This includes two parameters for keeping the values of the two calibration points. This is useful when determining if a device has been calibrated at points that are suitable for the operating range. Additional information that can be stored includes calibration date, location, the method used, and who performed the calibration. It is good practice to update this information at each calibration and to display it along with useful sensor limit information (Figure 1.6o).

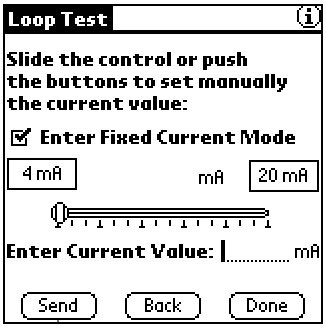
FIG. 1.6p
Monitoring of dynamic transmitter variables from a HART tool.

MONITORING

Configuration tools for HART and Foundation fieldbus systems are generally designed in different ways, not only in terms of the way they look, but also the way they work. In HART tools, menus are usually arranged according to the function performed, whereas device configuration in fieldbus tools is arranged according to the resource and transducer blocks. Thus, in a HART device, there generally is a screen on which the transmitter variables can be monitored on line (see Figure 1.6p).

SIMULATION

At the time of commissioning, it is common to check that all indicators, recorders, and computer screens show the correct values, that alarm trips are working properly, and so on. This is particularly important for HART devices, because there is a chance that the range set in the device does not match that set in the central controller, and any difference would result in operational problems. To verify that all ranges are consistent, it is helpful to use the simulation function found in HART and fieldbus devices.



Slide the control or push the buttons to set manually the current value:

☑ Enter Fixed Current Mode

4 mA mA 20 mA

Enter Current Value: ______ mA

☑ Configuration Changed
☐ Field Device Malfunction

FIG. 1.6r
Basic HART diagnostics.

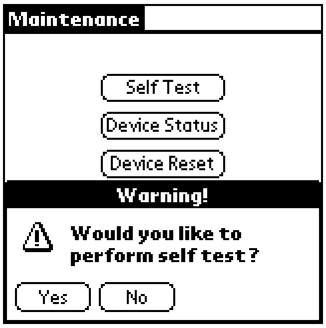
When performing simulation in a HART transmitter, the output current is manipulated independently of the applied input (see Figure 1.6q). Generally, the handheld allows the current to be set slightly above and below the 4- to 20-mA range to simulate fault conditions.

Simulation is primarily used to test the control strategy. Therefore, simulation for Foundation fieldbus devices is done from the input and output function blocks.

DIAGNOSTICS

Many device diagnostics can be performed from a configuration tool, but only if communication is established. If there is no functional communication, troubleshooting has to rely on traditional means. When it comes to diagnostics, one of the major differences in the application of HART and Foundation fieldbus becomes most evident. While fieldbus devices are constantly communicating, making it possible to monitor device conditions continuously and instantly detect faults, communication with HART devices is typically carried out to confirm a problem only after the failure has already been detected. Although applications with continuous HART communications do exist, they are rare. To fully benefit from intelligence in field devices, the engineering tool should continuously communicate with the instruments.

Generic diagnostic information is communicated in every exchanged HART message, giving the device the opportunity to inform the user of any failure. Such error message includes general malfunction, exceeded limits, and a message that more detailed status report is available (see Figure 1.6r).



Would you like to perform self test?

FIG. 1.6s
Advanced diagnostic self-test.

For some devices, a more thorough diagnostic self-test routine can be invoked (see Figure 1.6s).

Every FOUNDATION block, including function blocks, contains a block error parameter with some basic condition for the block itself, including configuration errors, I/O or memory failure, and others. In addition, the block mode parameter is useful for spotting problems, which often results in the actual mode being different from the target mode. Yet another good source of diagnostic information is the status associated with the function block inputs and outputs, and also with some of the parameters contained in transducer blocks and function blocks (see Figure 1.6t).

FIG. 1.6t
Abnormal status and actual mode are useful for tracing problems.

Diagnostic information for sensors and actuators is kept in their respective transducer blocks. The primary source for this information is the transducer error parameter that displays a single error at the time. Transducer blocks are always customized and typically contain extensive manufacturer-specific parameters related to diagnostics.

1.7 Instrument Installation

I. H. GIBSON (2003)

COST

- On the order of 40 to 50% of the capital cost of the equipment—extremely variable.
- A full set of PIP Process Control Practices documents cost U.S. $6500 in 2002.

For process measurements to achieve the targets of safety, accuracy, reliability, and economy, more than measuring equipment is involved. The entire system—from the process fluid characteristics, the ambient conditions, legal and regulatory requirements, and operations/maintenance requirements—must be coordinated to ensure that the equipment can be installed, calibrated, operated, recalibrated, maintained, and, if necessary, rebuilt or replaced while meeting the above primary criteria.

This section attempts to provide guidance to persons who are unfamiliar with current industrial practice; it does not attempt to cover all industries and all measurements. Specifically, it cannot cover the multitude of legal and regulatory requirements mandated by bodies such as the Occupational Safety and Health Administration (OSHA).

INSTALLATION DOCUMENTATION

The primary installation document is commonly called the *instrument index* (see Figure 1.7a). This tabulates all the tagged physical devices and commonly also includes tagged software devices. Each of the physical devices is then referenced to the associated installation drawings, such as the physical location plans, installation details (mechanical support, piping and wiring), cable ladder and conduit routing diagrams, and the connection diagrams. The instrument index is usually one of many documents from a large database, which also keeps track of calculations, specifications, and procurement documents and may also interface with a three-dimensional CAD model of the plant.

In a plant being designed with three-dimensional modeling, many of the dimensional drawings that otherwise would have been made previously are generated on demand by selection from the model. This enhances the quality of the design by flagging and eliminating clashes between equipment, piping and electrical/instrumentation space requirements and permits virtual walk-through reviews for operations and maintenance personnel.

Physical vs. Schematic Documents

The physical or scalar documents are the location plans (often sectional plans), cable/conduit routing plans, and the room layout drawings. These are based on the mechanical or piping layouts, commonly with the instrument information available as an overlay. The instrument tapping locations will be defined on the vessels and piping, and the final location for the various instruments becomes a matter for negotiation between the various groups to balance the requirements for operability with accessibility for maintenance. Traditionally, the instrument installation details have been essentially schematic, being used largely for material take-off. But with the growing use of three-dimensional CAD techniques, there is a tendency to produce approximately scale models for the common details to ensure that access requirements are addressed. Connection diagrams (electronic, electrical, pneumatic, hydraulic, and process) are purely schematic. These are now largely automated, with a minimal amount of input data being fed to a database loaded with connection rules for the various types of equipment.

SAFETY IN DESIGN

The instrument connections to the process are commonly the least mechanically secure components in the system. Consider the relative strength of a 1/2NS (DN15) Sch. 160 pipe as used by the piping designer to the usual 0.5-inch (12.7-mm) OD seamless 316L tube with 0.049-inch (1.24-mm) wall used for equivalent duty by the instrument designer. Yet this material has in fact an adequate strength for most applications within the range of Class 600 piping, provided that it is adequately protected and supported. Supported not only when the equipment is in service, but when any components are removed for maintenance. Many installations can be found with long runs of tube run to an absent transmitter, with the tube supported at best by a rope or wire. Not only are long tubing runs a significant source of measurement error, the lack of support is inherently hazardous. Modern installation details will anchor the tubing runs by supporting the instrument manifold, which remains in place if the transmitter is removed, and minimize any hazard from the temptation to use tubing runs as a hand (or foot) support.

The first valve off the process (known as the “root valve”) has traditionally been the province of the piping designer. More recently, the selection of this valve has become a joint

responsibility, with ‘process-rated’ instrument valves being available which give ‘double-block and bleed’ (DBB) capability in the envelope of a 1NS (DN40) blind flange (Figures 1.7b and c). The ability to close couple a transmitter to the line in this manner can reduce potential leak points and weight significantly for offshore installations at similar cost to older designs.

The point of DBB deserves comment. For a technician to work on a transmitter or gauge, the process must be securely isolated. If the process fluid is flammable or at high or low temperature any chance of a leak should be obviated. DBB provides this by providing two isolation valves between the technician and the process, with the space between vented to a safe place. The definition of where DBB is required is normally part of the operating company’s standards, but Class 600 (and higher) piping should always be covered by it. Toxic materials call for more stringent techniques, with tubed vents and designed-in decontamination methods.

Pipe and Tube Material

Current minimum design practice is to use a stainless steel meeting both 316 and 316L for tubing and fittings for both pneumatic and process connections. The pneumatic tubing may be 0.25 inch (6.35 mm) or 0.375 inch (9.53 mm) OD, while process connections are usually 0.375 or 0.5 inch (9.53 or 12.7 mm). The wall thickness of pneumatic tube is commonly 0.035 inch, while process tubing is a minimum of 0.048 inch, with heavier (0.064 inch) used for pressures above about 1000 psi (6800 kPa). This is the heaviest wall tube that can conveniently be bent and fitted off without using hydraulic benders and setters.

Plants using metric standards may use either metric or inch series tube but mixing the two in the same plant should be avoided, as accidents can be caused by mismatching. 12 mm OD tube will fit in a half-inch compression fitting but will rapidly disassemble itself under test. Always use seamless drawn tube for compression fitting installations, as electric-resistance-welded (ERW) tube has a small flat on the outside that makes for difficulty in achieving a leaktight connection.

316 stainless is a good general-purpose material, but it is prone to chloride attack at temperatures above 140°F (60°C).

This can be significant both internally and externally—tropical marine installations can easily achieve such temperature in sunlight. Monel™ (cupronickel) and duplex stainless are both widely used in such locations; duplex offers higher tensile strength and pressure rating. Ensure that the tube wall thickness chosen meets the most stringent pressure and temperature combination likely to be found.

If possible, avoid using or having tube with identical diameter but different wall thicknesses and materials in the same plant, even at the expense of using more costly material, because the probability of getting under-rated material installed during maintenance or modification is severely increased. If it is necessary, ensure that the installations with higher-grade material are permanently flagged on drawings and in the field (Table 1.7d).

Electrical Installations in Potentially Explosive Locations

While the practices for piping/tubing installations are similar around the world, there is a split between North American and European practices (commonly described as NEC v. IEC practices) in wiring methods. Fortunately this divide is now closing, as IEC design practices are becoming accepted in parallel with NEC in North America, though there are still a few standards where features mandated by IEC are prohibited by NEC. The best advice is to determine the statutory and regulatory rules for the site, and try to avoid any violation of them. 'Try' may be the operative word in many cases, where considerable negotiating might be required with the regulatory inspectors if 'state-of-the-art' equipment is required, and the approval certification is not quite ready for your site.

Physical Support

The traditional support for field instruments is 2NS (DN50) pipe. Most non-inline field instruments are provided with mounting brackets designed to attach to vertical or horizontal pipe, and also to flat plate. Traditionally, these supports have been fabricated from carbon steel pipe and plate and been hot-dip galvanized after fabrication. Some design details endeavour to weld zinc plated material, but this practice is difficult in achieving good welds and the 'zinc fume' from the welding is toxic. Therefore, one should generally avoid the use of zinc coatings. Also, there have been a number of

significant failures of stainless and high alloy piping when minor fires melted the zinc from galvanized walkways, etc. If molten zinc comes in contact with an austenitic alloy, it penetrates its grain structure within seconds and the strength of the alloy vanishes. To protect from this effect and to avoid corrosion, a number of sites are now using stainless steel “strut” supports.

PROCESS INDUSTRIES PRACTICES

A consortium of the major petroleum, chemical, and related manufacturers, together with major engineer-constructors have joined to form the Process Industry Practices (PIP) division of the Construction Industry Institute, an organization associated with The University of Texas at Austin. The PIP offices are located to 3925 West Braker Lane (R4500), Austin, TX 78759.

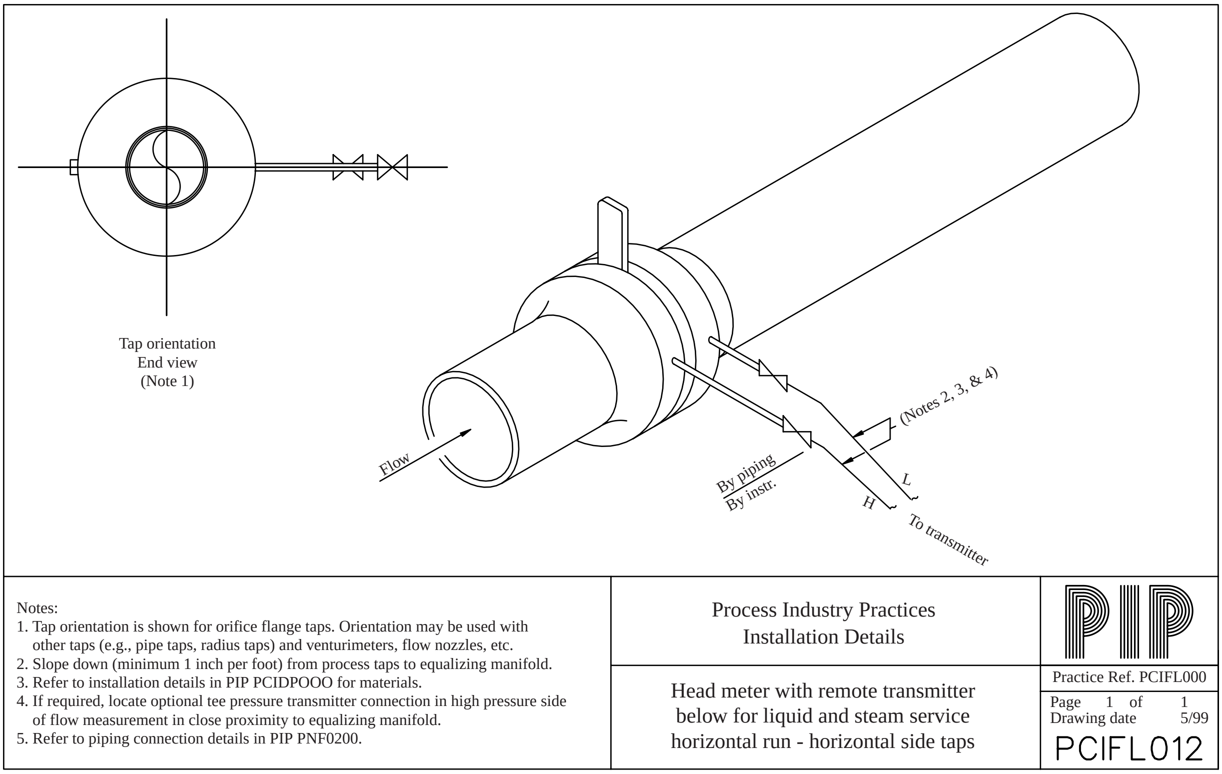
PIP (website *http://www.pip.org*) has generated a wide-ranging series of standard practices in a variety of engineering fields. Among the 20 Practices for Process Control are some 9 sets covering instrument installation. These are available to members of the consortium and subscribers for their direct use, and can be purchased by other organizations Figures 1.7e, f, and g).

In an effort to minimize the cost of process industry facilities, these Practices have been prepared from the technical requirements in the existing standards of major industrial users, contractors, or standards organisations. By harmonising these technical requirements into a single set of Practices, administrative, application, and engineering costs to both the purchaser and the manufacturer should be reduced. While these Practices are expected to incorporate the majority of requirements of most users, individual applications may involve requirements that will be appended to and take precedence over individual Practices. Determinations concerning fitness for purpose and particular matters or application of the Practice to particular project or engineering situations should not be made solely on information contained in these materials.

The tabulation of PIP installation documents (Table 1.7h) is not exhaustive, and they are frequently edited and extended.

Bibliography

Process Industry Practices (see Table 1.7h) issued by Process Industry Practices, 3925 West Braker Lane (R4500), Austin, TX 78759, USA.



Notes:
1. Tap orientation is shown for orifice flange taps. Orientation may be used with other taps (e.g., pipe taps, radius taps) and venturimeters, flow nozzles, etc.
2. Slope down (minimum 1 inch per foot) from process taps to equalizing manifold.
3. Refer to installation details in PIP PCIDPOOO for materials.
4. If required, locate optional tee pressure transmitter connection in high pressure side of flow measurement in close proximity to equalizing manifold.
5. Refer to piping connection details in PIP PNF0200.

1.8 Instrument Calibration

H. M. HASHEMIAN (2003)

INTRODUCTION

The performance of a process instrument such as a temperature or pressure sensor normally depends on its accuracy and response time. *Accuracy* is a qualitative term that describes how well the instrument may measure the process parameter (see Section 1.4 for an in-depth discussion), and *response time* specifies the speed by which the instrument can detect any significant change in the value of a process parameter. Accuracy and response time are largely independent and are therefore identified through separate procedures.

The accuracy of a process instrument is established through its calibration, and the response time is determined by exposing the instrument to a dynamic input and measuring its response time from the transient output. Response time is discussed in more detail in Section 1.9. Calibration is done by providing the instrument with a number of known and stable inputs to ensure that the output accurately represents the input.

Two terms are important in instrument calibration. These terms are *zero* and *span*, as illustrated in Figure 1.8a. In this figure, the calibration of a linear transmitter is approximated with a straight line, represented by the equation $y = mx + b$, where y is the output, x is the input, m is the slope of the line, and b is the intercept. The calibration of an instrument may change due to a change in zero, a change in span, or a change in both zero and span. A change in zero is also referred to as a *bias error, DC offset*, or *zero shift*. A zero shift results in a change in instrument reading (either positive or negative) at all points along its range (Figure 1.8b). A zero shift can result from several causes, such as a change in ambient temperature affecting the calibration. For example, if an instrument is calibrated at room temperature and used at a different temperature, its output may include a bias error (or zero shift) due to the temperature difference.

The change in span is also referred to as a *gain error* or span shift. A span shift means an increase or a decrease in the slope of the instrument output line for the same input (see Figure 1.8c). Typically, calibration errors involving span shift alone are less common than calibration errors due to both zero and span shifts. In Figure 1.8c, both cases are shown: span shift without zero shift and span shift with zero shift. In pressure transmitters, about 40% of the calibration changes are caused by zero shift, about 30% by span shift, and only about 20% by span shift alone.[1] As for the remaining 10%, the calibration changes are due to other effects, such as nonlinearity.

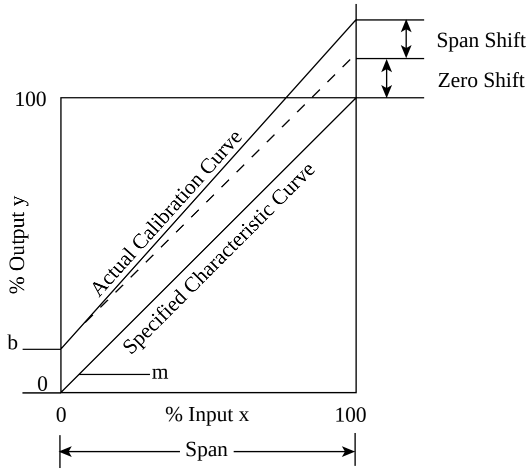

FIG. 1.8a
Illustration of zero and span. b = zero elevation; m = gain of a linear transmitter; span = the change in input (x) as it travels from 0–100%; range = the change in output (y) corresponding to 0–100% span; output @ input = 0 is called lower range value; output @ input = 100% is called upper range value.

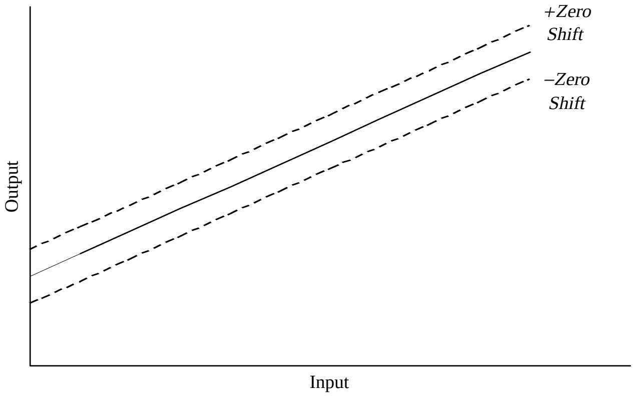

FIG. 1.8b
Illustration of a zero shift in an instrument calibration.

Calibration of Pressure Sensors

Calibration of pressure sensors (including both absolute and differential-pressure sensors) involves using a constant pressure source such as a deadweight tester (see Figure 1.8d). With a deadweight tester, constant pressure is produced for the sensor while the sensor output is monitored and adjusted

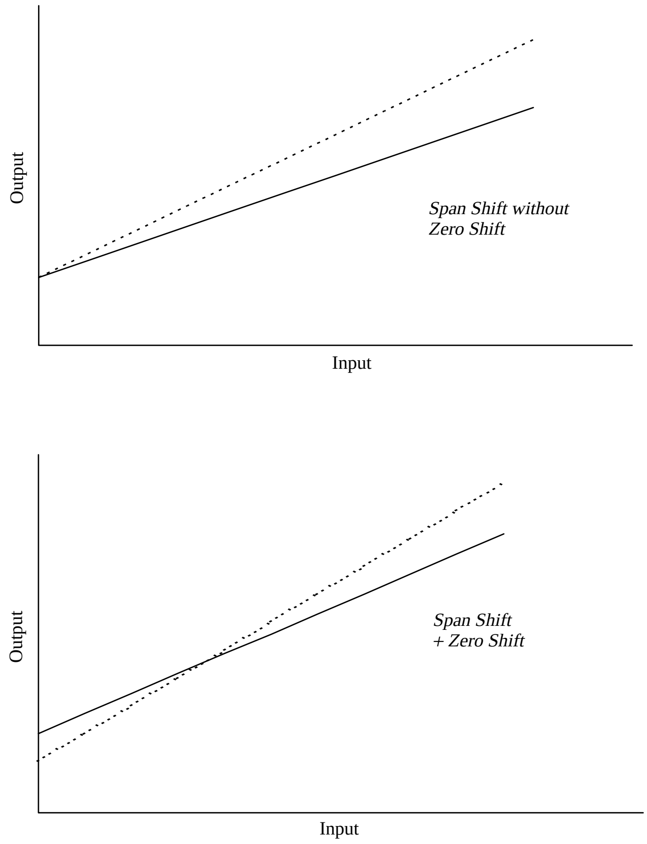

FIG. 1.8c
Illustration of span shifts.

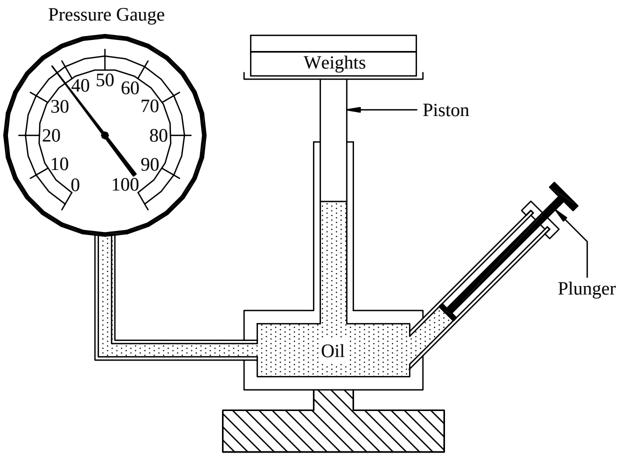

FIG. 1.8d
Schematic of a typical deadweight tester.

to make the electrical output proportional to the applied pressure. For example, a pressure sensor may be calibrated to produce an output in the range of 4 to 20 mA for pressure inputs covering the whole span of the sensor (0 to 100%). For most pressure sensors, with no pressure applied, the transmitter output is adjusted to produce a 4-mA signal. Next, a pressure that corresponds to 100% of the span is applied by the deadweight tester, and the sensor output is adjusted to 20 mA. These adjustments to the output are made by setting two potentiometers provided in the pressure sensor. These adjustment devices are referred to as the *zero* and *span* potentiometers. The next step in the calibration of a pressure transmitter is to apply known pressures between 0 and 100% of span to verify the linearity of the transmitter and to make any necessary adjustments to obtain accurate mA outputs for all inputs.

The zero and span adjustments of a pressure sensor interact, meaning that changing one will cause the other to change, and vice versa. Thus, in calibrating a pressure sensor, the zero and span are often both adjusted to produce the most accurate output that can be achieved for each input pressure. Because of the nonlinearities in some pressure sensors, the input/output relationships cannot be exactly matched, no matter how well the span and zero adjustments are tuned together. For that reason, in most pressure sensors, a linearity adjustment is also provided (in addition to the zero and span potentiometers) to help achieve the best agreement between the input pressure and the output current.

In lieu of a deadweight tester, one can also use a stable pressure source and a precision pressure gauge as the input. Precision pressure gauges are available in a variety of ranges from a number of manufacturers (see Section 5.11). Highly accurate digital pressure indicators can also be used for calibration. As will be seen later, automated pressure sensor calibration equipment is also available that uses digital technology to offer both accuracy and convenience.

As-Found and As-Left Data

The calibration of an instrument can change with time. Therefore, instruments are recalibrated periodically. The periodic calibration procedure typically involves two steps: (1) determine if calibration is needed, and (2) calibrate if needed. In the first step, known input signals (e.g., 0, 25, 50, 75, and 100% of span) are applied to the instrument, and its output is recorded on a data sheet. The data thus generated is referred to as the *as-found* calibration data (see Table 1.8e). If the as-found data show that the instrument's calibration is still acceptable, no calibration is needed. Otherwise, the instrument is

TABLE 1.8e
Example of an Instrument Calibration Data

Input Signal (% of Span)	*Desired Output (mA)*	*As-Found Data (mA)*	*As-Left Data (mA)*
0	4.00	3.93	3.99
25	8.00	8.03	8.01
50	12.00	11.92	12.04
75	16.00	16.09	15.96
100	20.00	20.12	19.97

calibrated by systematically applying a series of input signals and making zero and span adjustments as necessary to bring the sensor within acceptance limits or criteria. The input/output data after this calibration is referred to as the *as-left* data, and the difference between the as-found and as-left data is often termed the *calibration drift* or *calibration shift.*

The acceptance criterion for calibration is normally established by the user, based on the accuracy requirements for the instrument and/or on the manufacturer's specification. Typically, manufacturers state the inaccuracy (the error or uncertainty) of an instrument in terms of a percentage of span throughout the range of the instrument. For example, pressure sensor errors can be as low as about 0.05% of span in high-precision sensors or as high as about 1% of span in sensors for general applications.

The high-precision performance can only be obtained if the sensor is properly calibrated, because overall accuracy depends as much on the quality of the calibration process as it does on the ability of the sensor to provide a particular accuracy. Reliable calibration requires the availability of trained personnel, written procedures, and accurate calibration equipment. Obviously, the accuracy of the calibration equipment must be much better than the equipment being calibrated, and the calibration personnel must understand the calibration process and exercise care in performing the calibration task, reading the calibration data, and documenting the results. If an instrument is not properly calibrated, it will not produce accurate and reliable measurements, even if the quality of the instrument itself is high.

Hysteresis

Hysteresis is a phenomenon that causes an instrument's output to vary, depending on the direction of the applied input signals, i.e., whether it is increasing or decreasing (see Figures 1.3b and 1.8f). To account for hysteresis, instruments are sometimes calibrated using both increasing and decreasing input signals, and the results are averaged. For example, a pressure sensor may be calibrated using input signals in this sequence: 0, 25, 50, 75, 100, 75, 50, 25, and 0% of span.

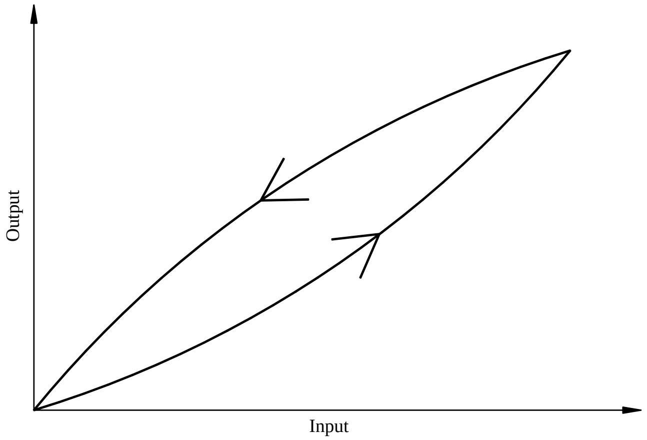

FIG. 1.8f
Illustration of hysteresis.

Normally, a manufacturer's specification of an instrument's accuracy is arrived at considering hysteresis, linearity, repeatability, and other factors that can affect the instrument's input/output relationship (see Section 1.3 for the definitions of these terms).

Calibration Traceability

To be valid and acceptable, all calibrations should be traceable to a national standard or to a known physical phenomenon. In the United States, equipment calibrations are expected to be traceable to the National Institute of Standards and Technology (NIST), in Gaithersburg, MD. Each country has its own standard calibration laboratory for a variety of parameters such as pressure, temperature, voltage, resistance, weight, time, and so on. The national standards laboratories are normally charged with calibration of primary standards. A primary standard is an instrument that is calibrated at the national standard laboratory like the NIST and used to calibrate other equipment. For example, the primary standard for calibration of resistance temperature detectors (RTDs) is a precision RTD that is referred to as a *standard platinum resistance thermometer* or *SPRT.* Each RTD calibration laboratory has one or more SPRTs that are sent to NIST periodically to be calibrated.

To be calibrated by a national standard laboratory such as NIST, a primary standard must be in good working condition and meet certain requirements. Otherwise, NIST may not calibrate it. National standards laboratories are charged with helping to maintain primary standards and therefore do not calibrate common-purpose equipment, nor do they repair equipment that is not in good working order.

To protect the primary standard equipment, a secondary standard (also called *transfer standard*) may be used. In this case, the primary standard is used to calibrate the secondary standard, which is then used for calibration of other instruments. The advantage of this approach is that it preserves the integrity as well as the accuracy of the primary standard by minimizing its handling and use. The disadvantage is that, every time an instrument is calibrated, the accuracy that can be claimed is below the accuracy of the standard that is used in its calibration. Therefore, in going from a primary standard to a secondary standard, a loss of accuracy results.

A common rule is that an instrument shall be calibrated using a standard that is at least four times more accurate than the instrument being calibrated. This requirement is sometimes difficult to meet, as instruments have become so accurate in recent years that one may not find a standard that can be four times more accurate.

Linearity and Damping Adjustments

As was mentioned before, in addition to zero and span, some instruments also have a linearity adjustment that is used to produce the most linear input/output relationship throughout the span. A damping adjustment is also available in some instruments. This adjustment does not affect the calibration of an instrument, but it affects its response time. The purpose of the damping adjustment is to reduce the noise in the output signal of the instrument when the process is very noisy. This is accomplished by increasing the damping, which slows the dynamic response of the instrument so that it is not sensitive to high-frequency or noisy inputs.

Automated Calibration Equipment

Recent advancements in electronics and computer technologies have resulted in the development of a variety of automated test equipment and computer-aided calibrations. For example, Figure 1.8g illustrates the components of an automated pressure sensor calibration system. It consists of a programmable pressure source that is controlled by a computer and produces known pressure inputs that are applied to the sensor being calibrated. The output of the sensor is recorded by the same computer and produces the record of the *as-found* data. The sensor is calibrated using both increasing and decreasing input signals as shown in Figure 1.8h, and a hysteresis curve is also produced. Next, the software compares the as-found data against the acceptance criteria and automatically determines if the sensor needs to be recalibrated. If so, the system provides the necessary input signals to the sensor under calibration and holds the input value constant until zero and span adjustments are made manually. After the calibration, the software produces a report and stores the calibration data for trending, incipient failure detection, and other purposes.

Calibration of Temperature Sensors

Temperature sensors such as RTDs and thermocouples are calibrated using a constant-temperature bath and a standard thermometer. The type of calibration bath used depends on the temperature range, the accuracy requirements, and the application of the sensor. For example, for the calibration of primary and secondary temperature standards, melting- or freezing-point cells are used. These cells are made of such material as tin, zinc, silver, and gold whose melting or freezing temperatures are set by nature and are accurately known. These cells are referred to as *intrinsic standards*. These *fixed-point cells* are expensive, difficult to maintain, and normally are used only in standard laboratories.

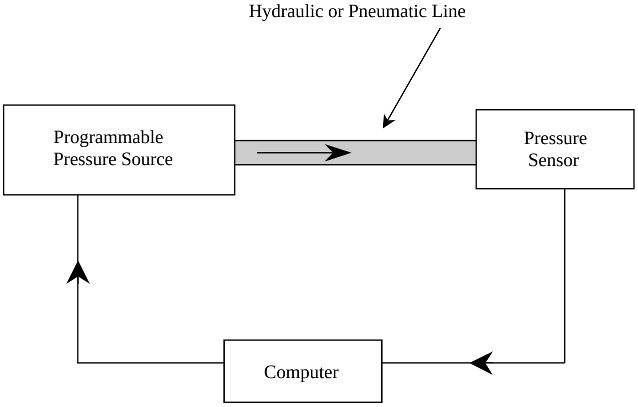

FIG. 1.8g
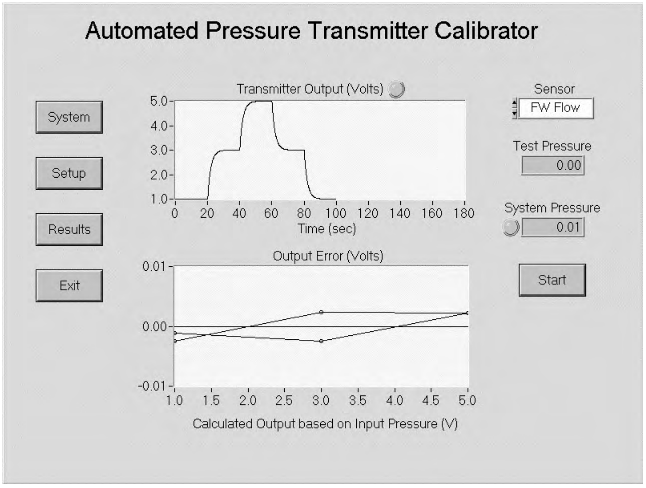
Principle of an automated pressure sensor calibration system.



Automated Pressure Transmitter Calibrator

Sensor: FW Flow
Test Pressure: 0.00
System Pressure: 0.01

FIG. 1.8h
Calibration results from automated calibration.

For the calibration of average temperature sensors, the fixed-point cells are seldom used. The more likely choice for a reference cell is an ice bath, an oil bath, or an electric furnace-controlled bath. As shown in Figure 1.8i, the sensor to be calibrated is installed in a temperature bath along with a standard reference sensor. The reference sensor is used to measure the bath temperature. A data table is then made of the bath temperature vs. the output of the sensor being calibrated. This procedure is repeated for a number of widely spaced temperatures covering the temperature range of the sensor.

Each pair of measurements is referred to as a *calibration point.* The number of calibration points depends on the type of sensor and the temperature range. For RTDs, three calibration points may be sufficient, whereas thermocouples normally require a larger number. This is because the temperature vs. resistance relationship of RTDs is quadratic, but the thermocouple output relates to temperature by a higher-order polynomial. The calibration data is then fit to an interpolation equation, and the constants of the equation are identified and used to produce a calibration table for the sensor. The calibration table should not be extrapolated much beyond the calibration end points. A good rule of thumb is to extrapolate the calibration table above the highest calibration point or below the lowest calibration point by no more than 20%.[2]

Automated equipment is often used in the calibration of temperature sensors. These systems automatically control and change the bath temperature, record the reading of both the reference sensor and the sensor(s) being calibrated, fit the

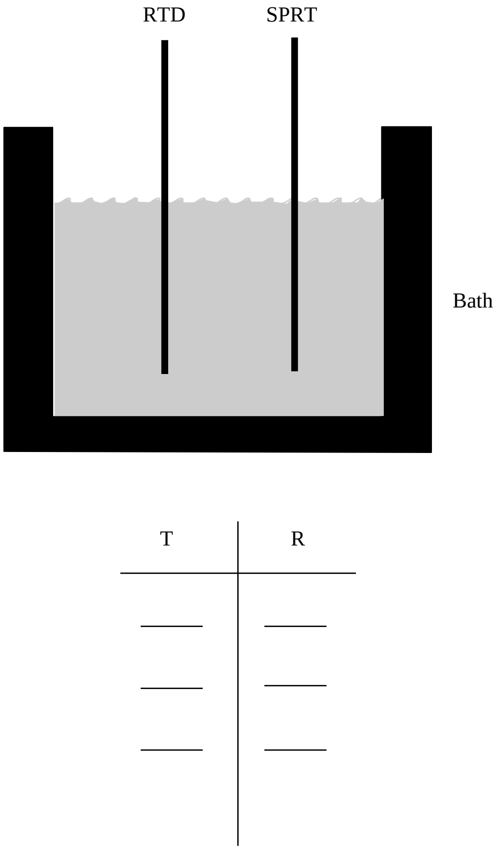


FIG. 1.8i
Temperature sensor calibration setup.

calibration data to interpolation equations, and print both a calibration table and a report or certification of the results. Using such a system, a number of sensors can be calibrated simultaneously with excellent repeatability and consistency.

Calibration Intervals

Instruments are traditionally calibrated once a year, or more often, depending on the accuracy requirements. However, due to the great advances in electronics in recent years, it has been determined that annual calibrations may not be needed for high-quality instruments, especially if an on-line monitoring system is implemented to verify their performance. This is described in detail in Section 1.9.

To determine the right calibration interval for an instrument, two pieces of information are required: (1) the accuracy requirement for the sensor and (2) the instrument drift rate. For example, if a pressure transmitter drift rate is 0.25% of span per year, and the accuracy requirement is 0.50% of span, then biannual calibrations may be sufficient. The problem is that the drift rates of most instruments are usually not known. Research has shown that instruments such as temperature and pressure sensors do not drift unidirectionally upward or downward so as to provide an opportunity to calculate an objective drift rate. Rather, these and most other instruments drift randomly within a certain band. Typically, the band is the largest at the beginning of the life cycle of the instrument, then it narrows and remains stable for a long period before it widens again as the instrument ages.

Calibration of Smart Instruments

Smart instruments such as smart pressure sensors often can be calibrated remotely and without the need for manual zero or span adjustment at the sensor location. The zero is adjusted by adding or subtracting a bias signal at the output of the sensor as necessary to offset the zero shift. The span is adjusted by changing the gain of the sensor output as necessary to make up for changes in sensor span.

The main advantage of the remote calibration of smart instruments is time conservation. For example, to calibrate a conventional pressure sensor, its cover must be removed to access the zero and span potentiometers. This can be a difficult and time-consuming task when the pressure sensor is installed in a harsh industrial environment.

Assessment of Accuracy

The accuracy of an instrument is determined from its calibration accuracy, environmental effects on calibration, and instrument drift rate. Right after calibration, the accuracy of an instrument is derived from the accuracy of the calibration standard and the calibration process. Next, the effects of the environment on the calibration must be determined. For example, the calibration of a pressure sensor is often changed by variations in the ambient temperature. In the case of differential-pressure sensors, changes in the static pressure of the process can also change the calibration. The manufacturer can usually provide data on temperature and static pressure effects on accuracy. The errors caused by these effects must be combined with the calibration errors to arrive at the total error of the installed sensor.

Next, the instrument drift must be accounted for in determining the total error. Usually, the drift error is added to the sum of calibration error and the errors due to the environmental effects so as to calculate the total error. The inaccuracy of the sensor is then stated based on this total error. A common formula for determining the total error is

$$\begin{aligned}\text{Total error} &= \text{Root sum squared (RSS) of random errors}\\ &\quad + \text{Sum of bias errors}\end{aligned} \qquad \textbf{1.8(1)}$$

Typically, the total error may be a number like 0.35% of span, of range, or of the actual indicated value, depending on the type of sensor used. This number, although an indication of the total error, is referred to as the *inaccuracy* or *uncertainty* of the instrument.

Calibration and Range Setting

Calibration and range setting are the same in case of analog transmitters. As for intelligent devices, calibration and range setting are different. For example, for smart (HART) transmitters, calibration is called *trim* to distinguish it from range.

For fieldbus devices, ranging is called *scale* to distinguish it from calibration. Ranging is accomplished by selecting input values at which the outputs are 4 mA and 20 mA, while calibration is performed to correct the sensor reading when it is inaccurate.

For example, if a differential-pressure sensor has a lower range limit (LRL) of −200 inches of water and an upper range limit (URL) of +200 inches of water, and if one wants to use it to measure a differential pressure in the range of 0 to 100 inches of water, then both the LRV and the URV settings must be changed. This adjustment would “range” (increase) the lower range value (LRV) to equal 0 and lower the upper range value (URV) to be 100 inches of water. Note that this is ranging and not calibration. Calibration is when at zero differential pressure the transmitter reading is found to be 1 inch of water and it is corrected to read 0 inches of water.

1.9 Response Time and Drift Testing

H. M. HASHEMIAN (2003)

Off-line calibration of the zero and span of measurement was the topic of the previous section. In this section, the on-line methods of response time determination and calibration verification will be described for sensors that have already been installed in operating processes. As in Section 1.8, the discussion here will also focus on temperature and pressure sensors.

FUNDAMENTALS OF RESPONSE TIME TESTING

The response time of an instrument is measured by applying a dynamic input to it and recording the resulting output. The recording is then analyzed to measure the response time of the instrument. The type of analysis is a function of both the type of instrument under test and on the type of dynamic input applied, which can be a step, a ramp, a sine wave, or even just random noise.

The terminology used in connection with time response to a step change was defined in Figure 1.3z. The time constant (T) of a first-order system was defined as the time required for the output to complete 63.2% of the total rise (or decay) resulting from a step change in the input. Figures 1.9a and 1.9b show the responses of instruments to both step changes and ramps in their inputs and identify the time constant (T) and response times (τ) of these instruments.

As shown in Figure 1.9a, the time constant of an instrument that responds as a first-order system equals its response time and it is determined by measuring, after a step change in the input, the time it takes for the output to reach 63.2% of its final value. The response of a first-order system is mathematically described by a first-order differential equation,

$$c(t) = K(1 - e^{-t/\tau}) \qquad \textbf{1.9(1)}$$

where

c = output

t = time

K = gain

τ = time constant of the instrument

The 63.2% mentioned earlier is obtained from this equation by calculating the output when the time equaling the time constant ($t = \tau$) has passed.

$$c(\tau) = K(1 - e^{-1}) = 0.632\ K \qquad \textbf{1.9(2)}$$

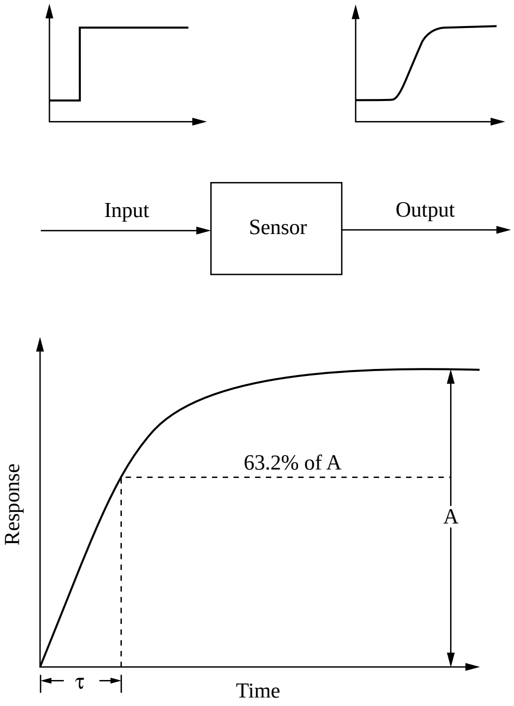

FIG. 1.9a
Illustration of step response and calculation of time constant.

Although most instruments are not first-order systems, their response time is often determined as if they were, and as if their response time were synonymous with their time constant. However, if the system is of higher than first order, there is a time constant for each first-order component in the system. In spite of this, in the field, the definition of the first-order time constant is often also used in connection with higher-order systems.

The ramp response time is the time interval by which the output lags the input when both are changing at a constant rate. For a ramp input, the response time (τ) is defined as the delay shown in Figure 1.9b. This is also referred to as *ramp time delay* and can be measured after the initial transient, when the output response has become parallel with the input ramp signal. For a first-order system, the ramp time delay, response time, and time constant are synonymous. The ramp time delay can be mathematically described as

$$c(t) = C(t - \tau) \qquad \textbf{1.9(3)}$$

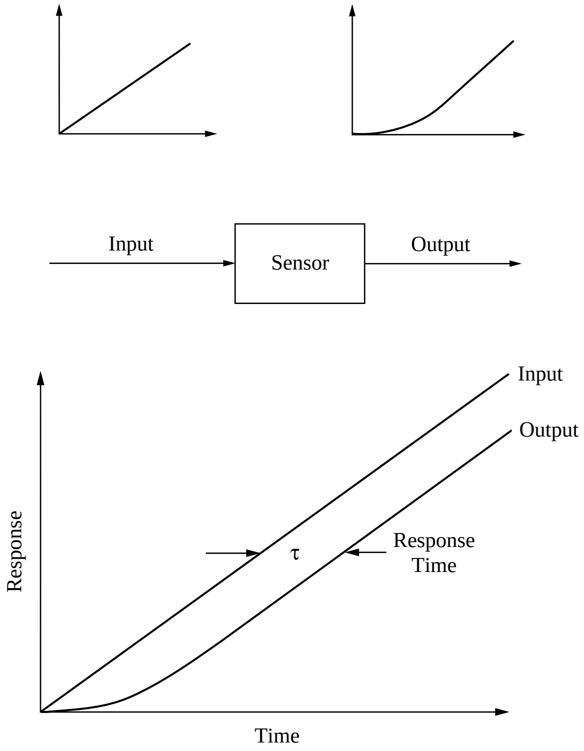

FIG. 1.9b
Illustration of ramp response and calculation of ramp time delay.

where C is the ramp rate of the input signal. The derivations of Equations 1.9(1) through 1.9(3) and the topic of Laplace transformation is covered in the second volume of the *Instrument Engineers' Handbook* and also in Reference 1.

LABORATORY TESTING

The response time of temperature sensors is measured by using a step input, whereas the response time of pressure sensors is usually detected by using ramp input signals. This is because obtaining a step change in temperature is easier and more repeatable than obtaining a step change in pressure. Ramp inputs are also preferred for the testing of pressure sensors, because a step input can cause oscillation of the pressure transmitter output, which may complicate the measurement.

Testing of Temperature Sensors

Figure 1.9c illustrates the equipment used in determining the response time of a temperature sensor. This experiment is called the *plunge test.* At the beginning of the test, the sensor is held by a hydraulic plunger, and its output is connected to a recorder. The heated sensor is then plunged into a tank of water at near-ambient temperature. This step change in temperature determines the type of transient in its output, as was illustrated in Figure 1.9a. To identify the response time of the temperature sensor, the time corresponding to 63.2% of the full response is measured.

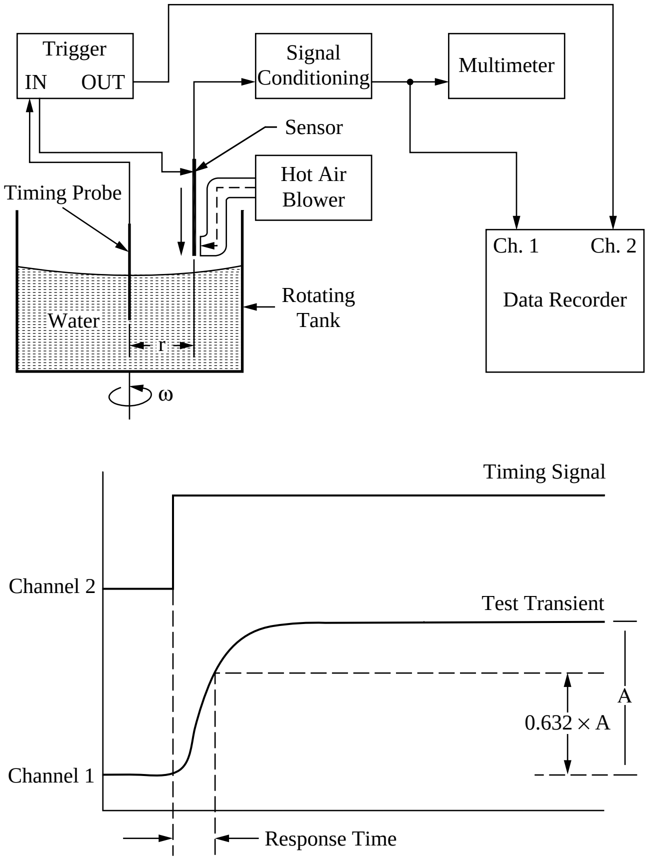

FIG. 1.9c
Plunge test setup.

Because the response time of a temperature sensor is a function of the type, flow rate, and temperature of the media in which the test is performed, the American Society for Testing and Material (ASTM) has developed Standard E644 (Reference 2), which specifies a standard plunge test. This document specifies that a plunge test should be performed in water that is at near room temperature and is flowing at a velocity of 3 ft/sec (1 m/sec). A plunge test can therefore be performed by heating the sensor and then plunging it into a rotating tank that contains water at room temperature. By controlling the speed and the radial position of the sensor, the desired water velocity can be obtained for the plunge test.

There can be other ways for performing the plunge test. For example, the sensor can be at room temperature and plunged into warm water. Although the actual temperatures have an effect on response time, this effect is usually small; therefore, the response time is not significantly different if the water is at a few degrees above or below room temperature.

Testing of Pressure Sensors

The response time of pressure sensors is usually determined by using hydraulic ramp generators, which produce the ramp test input signals. A photograph of a hydraulic ramp generator is provided in Figure 1.9d. This equipment consists of two pressure bottles, one bottle filled with gas or air and the other

FIG. 1.9d
Photograph of pressure ramp generator for response time testing of pressure sensors.

with water, as shown in Figure 1.9e. In the outlet from the gas bottle, an on–off and a throttling valve is provided. The setting of the adjustable valve determines the flow rate of the gas into the water bottle. Therefore, the desired ramp pressure rate can be generated by adjusting the throttling valve.

The water pressure is detected simultaneously by two sensors, a high-speed reference sensor and the sensor under test, as shown in Figure 1.9f. The outputs of the two sensors are recorded on a two-pen recorder, and the time difference (delay) between the two outputs is measured as the response time of the sensor being tested. This delay time measurement is taken after the pressure in the water bottle has reached a predetermined setpoint or after the input and output curves have become parallel.

The pressure setpoint is based on the requirements of the process where the sensor is going to be used. For example, if a full process shutdown is initiated, and if the pressure exceeds a certain upper limit, then this pressure is likely to be used as the setpoint pressure at which the response time of the pressure sensor is measured. When testing differential-pressure sensors (serving the measurement of level or flow), the setpoint pressure can be selected to correspond to the low level or flow alarm setpoint of the process. In such cases, a decreasing ramp input signal is used during the response time test and the setpoint that initiates the test reading corresponds to the low d/p pressure setting at which the alarm or shutdown is triggered in the process.

These response time measurements can be important to overall process safety if the instrument delay time is significant relative to the total time available to take corrective action after the process pressure has exceeded safe limits.

IN SITU RESPONSE TIME TESTING

The laboratory testing methods described earlier are useful for testing of sensors if they can be removed from the process and brought to a laboratory for testing, but this is often not the case. For testing installed sensors, a number of new techniques have been developed as described below. They are referred to as *in situ*, on-line, or in-place testing techniques.

To measure the in-service response time of a temperature sensor, *in situ* testing is mandatory. This is because the response time of a temperature sensor always is a function of the particular process temperature, process pressure, and process flow rate. The most critical effect is process flow rate, followed by the effect of process temperature and then pressure. The reason why the response time is affected by the process pressure and flow rate is because they affect the heat transfer of the film of the temperature-sensing surface of the detector. In contrast, the process temperature affects not only the heat transfer of the film but also the properties of the sensor internals and sensor geometry.

Consequently, it is not normally possible to accurately predict or model the effect of process temperature on the response time of temperature sensors; predicting the effects

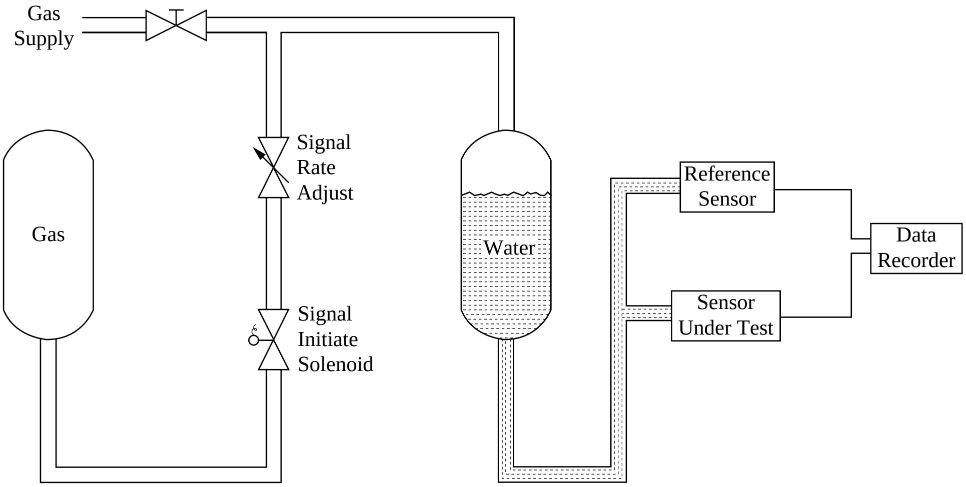

FIG. 1.9e
Simplified diagram of pressure ramp generator.

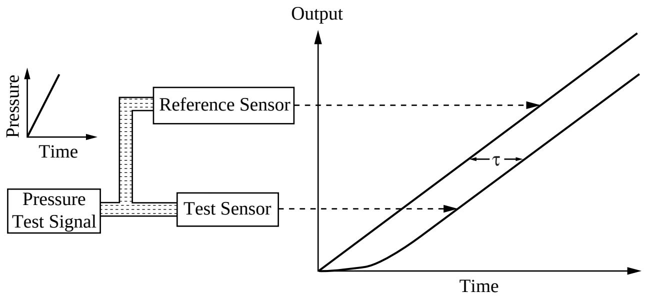

FIG. 1.9f
Ramp test setup.

of process pressure and flow rate are easier. This is because we know that, as the process pressure or flow rate increases, the heat transfer coefficient on the sensor surface also increases and causes a decrease in the response time, and vice versa. In contrast, an increase in process temperature can cause either an increase, or a decrease in the response time of a sensor. This is because, on the one hand, an increase in process temperature can result in an increase in the heat transfer coefficient, which reduces sensor response time. On the other hand, an increase in process temperature can also expand or contract the various air gaps in the internals of the temperature sensor, causing dimensional changes or altering material properties, which can increase or decrease the response times of the various sensors.

In the case of pressure sensors, the response time is normally not changed by variations in process conditions. Thus, for pressure sensors, the choice of *in situ* response time testing is based on considering the convenience of *in situ* testing and less on the basis of the accuracy of the test results. Therefore, one can measure the response time of an installed pressure sensor without removing it from the process by taking the ramp test generator (Figure 1.9d) to the installed sensor (if this can be done efficiently and safely). In fact, this operation is often tedious, time consuming, and expensive, especially in hazardous locations or in processes such as exist in nuclear power plants. Still, if one can afford it, using an *in situ* technique to measure the response time of a pressure sensor is preferred.

Testing of Temperature Sensors

The *in situ* response time testing of temperature sensors is referred to as the *loop current step response (LCSR)* test. LCSR is performed by electrically heating the temperature sensor by sending electric current through the sensor extension leads. This causes the temperature of the sensor to rise above the ambient temperature. Depending on the sensor involved, the amount of current and the amount of temperature rise used in the LCSR test can be adjusted. When testing resistance temperature detectors (RTDs), the use of 30 to 50 mA of DC current is normally sufficient. This amount of current raises the internal temperature of the RTD sensor by about 5 to 10°C (8 to 18°F) above the ambient temperature, depending on the RTD and the process fluid surrounding it.

For thermocouples, a higher current (e.g., 500 mA) is typically required. This is because the electrical resistance of a thermocouple is distributed along the length of the thermocouple leads, but the resistance of an RTD is concentrated at the tip of the sensing element. In the case of thermocouples, the LCSR current heats the entire length of the thermocouple wire, not only the measuring junction. Because, in testing thermocouples, we are interested only in heat transfer at the measuring junction, it is preferred to heat up the thermocouple first and measure its output only after the heating current has been turned off. Also, for LCSR testing of thermocouples, AC current is used instead of DC to avoid Peltier heating or cooling, which can occur at the thermocouple junction if DC current is used. The direction of the DC current determines whether the measuring junction is cooled or heated.

Testing RTDs As shown in Figure 1.9g, a Wheatstone bridge is used in the LCSR testing of RTDs. The RTD is connected to one arm of the bridge, and the bridge is balanced while the electrical current in the circuit is low (switch is open). Under these conditions, the bridge output is recorded, and the current is then switched to high (switch closed) to produce the bridge output for the LCSR test shown in Figure 1.9h. In preparing for the LCSR test, the power supply is adjusted to provide a low current within the range of 1 to 2 mA and a high current in the range of 30 to 50 mA. The actual values depend on the RTD and on the environment in which the RTD is operating. In addition, the amplifier gain is adjusted to give an output in the range of 5 to 10 V for the bridge.

Figure 1.9i shows a typical LCSR transient for a 200-Ω RTD that was tested with about 40 mA of current in an operating power plant. In some plants, because of process

temperature fluctuations, the LCSR transient is not as smooth as shown in Figure 1.9i. In such cases, the LCSR test is repeated several times on the same RTD, and the results are averaged to obtain a smooth LCSR transient as in Figure 1.9i. The LCSR test duration is typically 30 sec for RTDs mounted in fast-response thermowells and tested in flowing water. The LCSR test duration, when the sensor is detecting the temperature of liquids, typically ranges from 20 to 60 sec but is much longer for air or gas applications.

Testing Thermocouples The LCSR test equipment for thermocouples includes an AC power supply and circuitry shown in the schematic in Figure 1.9j. The test is performed by first applying the AC current for a few seconds while the thermocouple is heated above the ambient temperature. After that, the current flow is terminated, and the thermocouple is connected to a millivolt meter to record its temperature as it cools down to the ambient temperature (Figure 1.9k). The millivolt output records a transient representing the cooling of the thermocouple junction alone. The rate of cooling is a function of the dynamic response of the thermocouple.

Figure 1.9l shows an LCSR transient of a thermocouple that was tested in flowing air. As in the case of RTDs, LCSR transients for thermocouples can also be noisy as a result of fluctuations in process temperature and other factors. To overcome noise, the LCSR test can be repeated a few times, and the resulting transients can be averaged to produce smooth

LCSR results. In the case of thermocouples, extraneous high-frequency noise superimposed on the LCSR transient can be removed by electronic or digital filtering.

Analysis of LCSR Test Results The raw data from the LCSR test cannot be interpreted easily into a response time reading. This is because the test data is the result of step change in temperature inside the sensor, whereas the response time of interest should be based on a step change in temperature outside the sensor. Fortunately, the heat from inside the sensor to the ambient fluid is transferred through the same materials as the heat that is transferred from the process fluid to the sensor (Figure 1.9m). Therefore, the sensor response due to internal temperature step (LCSR test) and external temperature step (plunge test) are related if the heat transfer is unidirectional (radial) and the heat capacity of the sensing element is insignificant. These two conditions are usually satisfied for industrial temperature sensors. Nevertheless, to prove that the LCSR test is valid for an RTD or a thermocouple, laboratory tests using both plunge and LCSR methods should be performed on each sensor design to ensure that the two tests produce the same results.

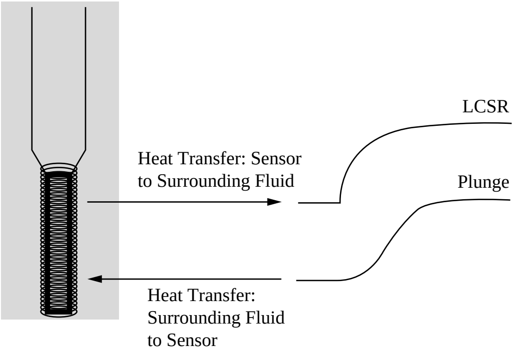

FIG. 1.9m
Heat transfer process in plunge and LCSR tests.

Because, for most sensors, the heat transfer path during LCSR and plunge tests is usually the same, one can use LCSR test data to estimate the sensor response of a plunge test where the step change in temperature occurs outside the sensor. The equivalence between the two tests has been shown mathematically (theoretically) as well as in numerous laboratory tests (see References 3 through 5). Therefore, it can be concluded that the test results gained from internal heating of a sensor (LCSR) can be analyzed to yield the response time of a sensor to a step change in temperature that occurred in the medium outside the sensor.

One can mathematically prove the similarities between the transient outputs, which are generated by the same temperature sensor, when evaluated by the plunge and the LCSR tests. For the plunge test, the sensor output response $T(t)$ to a step change in the temperature of the surrounding fluid is given by

$$T(t) = A_0 + A_1 e^{-t/\tau_1} + A_2 e^{-t/\tau} + \cdots \qquad \textbf{1.9(4)}$$

Each of the three (or more) elements in Equation 1.9(4) is referred to as a mode, while the terms τ_1 and τ_2 are called the *modal time constants*, and the terms $(A_0, A_1, A_2, \ldots)$ are called the *modal coefficients*. For the LCSR test, the sensor output response $T'(t)$ to a step change in the temperature inside the sensor is given by

$$T'(t) = B_0 + B_1 e^{-t/\tau_1} + B_2 e^{-t/\tau_2} + \cdots \qquad \textbf{1.9(5)}$$

Note that the exponential terms in the above two equations are identical; only their modal coefficients are different. The response time (τ) of a temperature sensor is defined by Equation

1.9(5), and it is therefore independent of the modal coefficients, although it does depend on the modal time constants.

$$\tau = \tau_1\left[1 - ln\left(1 - \frac{\tau_2}{\tau_1}\right) - ln\left(1 - \frac{\tau_3}{\tau_1}\right)\ldots\right] \qquad \textbf{1.9(6)}$$

The other terms in the equation are the natural logarithm, *ln*, and the response time (τ) of the sensor. Therefore, one might list the steps required in the LCSR test to obtain the response time of a temperature sensor as follows:

1. Perform the LCSR test and generate the raw data.
2. Fit the LCSR data to Equation 1.9(5) and identify the modal time constants (τ_1, $\tau_2,\ldots$).
3. Use the results of Step 2 in Equation 1.9(6) to obtain the sensor response time.

The above procedure has been successfully used for determining the response times of both RTDs and thermocouples, both in laboratory and *in situ* applications. As a result, it has been demonstrated that the LCSR test can determine the response time of a temperature sensor within about 10% of the conclusions of a plunge test if both were performed under the same conditions.

Applications of LCSR Testing Nuclear industry applications of the LCSR test include the response time determination of reactor coolant temperature sensors. The LCSR technique has been approved by the U.S. Nuclear Regulatory Commission (NRC) for *in situ* measurement of the response time of RTDs in nuclear power plants.[6] The LCSR test has also been used in aerospace applications to correct transient temperature data and in solid rocket motors to determine the quality of the bonding of thermocouples with the solid materials such as the nozzle liners.[7]

In addition to response time measurements, the LCSR test has been used for sensor diagnostics such as

1. The *in situ* determination of discontinuities or nonhomogeneities in thermocouples.[8] In this case, the purpose of running the LCSR test on the thermocouple is to check if the resulting LCSR signal is normal. This test is especially useful if a reference set of baseline LCSR data is available, representing the test results on normal thermocouples so that gross nonhomogeneities can be easily noted.
2. Determining if “strap-on” RTDs are properly bonded to pipes or tubes. In case of the Space Shuttle main engine,[7] in an experiment, the LCSR test was used to verify the quality of “strap-on” RTD bonding within the fuel lines. In this application, the RTD-based temperature measurement is used to detect fuel leakages.
3. Verifying the bonding of strain gauges to solid surfaces. Figure 1.9n illustrates how the transients resulting from LCSR tests change as a function of the strength of RTD bonding to the pipe. Therefore, the LCSR test can determine the degree of bonding between the solid surface and RTDs or strain gauges (Figure 1.9o).

determines the response times for each RTD. The system can send the data to a printer and print a table of RTD response times. A response time test transient display of a thermocouple is illustrated in Figure 1.9q.

In Situ Testing of Pressure Sensors

The response time of installed pressure sensors can be measured remotely while the plant is in operation. This technique is called *noise analysis* and is based on the monitoring of the normally present fluctuations of the pressure transmitter output signals. In Figure 1.9r, such an output signal is shown at a steady state that corresponds to the normal process pressure. This steady-state value is referred to as the DC reading. When magnified, it displays some small fluctuations. This magnified signal is called the noise or the AC component of the signal.

Analyzing of Noise Data The noise is produced by two sources. The first source is the fluctuation of the process pressure caused by turbulence, random heat transfer, vibration, and other effects. Second, there is electrical noise superimposed on the pressure transmitter output signal. Fortunately, these two phenomena occur at widely different frequencies and thus can be separated by filtering. This is necessary, because only the process pressure fluctuations are of interest.

Figure 1.9s illustrates how the noise can be extracted from a raw signal that includes both the DC and the AC components. The first step to remove the DC component is by adding a negative bias or by *highpass* electronic filtering. Next, the signal is amplified and passed through a lowpass filter, which removes the extraneous noise and provides for *anti-aliasing*. Next, the signal is sent through an analog-to-digital (A/D) converter and subsequently to a data acquisition computer. The computer samples the data and stores it for analysis.

The raw noise data from a pressure transmitter (Figure 1.9t) represents the natural process pressure fluctuations and includes the information required to determine the response time of the pressure sensor that generated the steady-state (DC) signal. The raw noise data is a small portion of a noise record, which is normally about 30 to 60 min.

For noise data analysis, the two techniques available are the frequency-domain analysis and the time-domain analysis. The first uses the power spectral density (PSD) technique involving fast Fourier transform (FFT). The PSD is obtained by bandpass filtering the raw signal in a narrow frequency band and calculating the variance of the result. This variance is divided by the width of the frequency band, and the results are plotted as a function of the center frequency of the band pass. This procedure is repeated from the lowest to the highest expected frequencies of the raw signal to obtain the PSD. In Figure 1.9u, the frequency spectrum of the noise signal from a pressure transmitter in an operating power plant is shown against PSD. If the pressure transmitter is a first-order system, its response time can be determined on the basis of measuring the break frequency of the PSD as shown in Figure 1.9v.

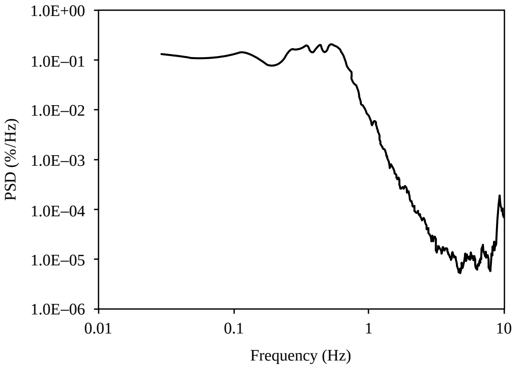

FIG. 1.9u
Pressure sensor PSD.

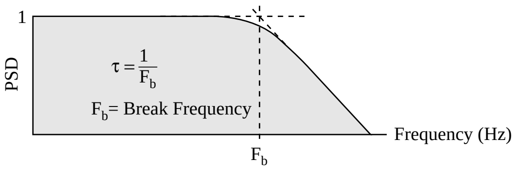

FIG. 1.9v
First-order system PSD.

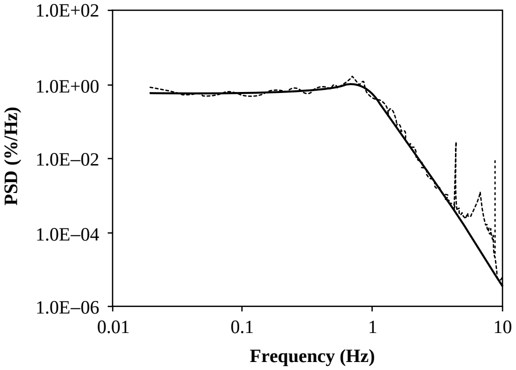

FIG. 1.9w
Flow sensor PSD and its model fit.

However, pressure sensors are not necessarily first order, and PSD plots for actual process signals are not smooth enough to allow the accurate measurement of the break frequency. In addition, PSDs often also contain resonance and other disturbances that further complicate the response-time analysis. Therefore, both experience and a validated dynamic model of the sensor are needed to obtain the sensor response time by analyzing a PSD plot. The model, which usually is a frequency-domain equation, is fit to the PSD to yield the model parameters, which are then used to calculate the response time of the pressure sensor. A PSD for a flow sensor in an operating power plant and its model fit are shown in Figure 1.9w.

Autoregressive (AR) modeling is used for noise data analysis in the time domain. An AR model is a time series equation to which the noise data is fit and the model parameters are calculated. These parameters are then used to calculate the response time of the sensor.[9] Time-domain analysis is generally simpler to code in a computer and therefore is preferred for automated analysis. However, in time-domain analysis, it is often difficult to remove noise data components that are unrelated to the sensor response time. For example, if the noise data contains very low-frequency process fluctuations, the AR model will take them into account. In such a case, it gives an erroneously large response time value. In contrast, in frequency-domain analysis, it is easier to ignore low-frequency process fluctuations and to fit the PSD to that portion of the data that most accurately represents the sensor.

Commercial, off-the-shelf equipment is available for both the frequency-domain and the time-domain analysis of noise data. A number of companies provide spectrum analyzers (also called FFT analyzers), which take the raw noise data from the output of a sensor and provide the necessary conditioning and filtering to analyze it and calculate the sensor response time. However, because of resonance and other influences, simple FFT analysis does not always yield the correct response time reading. This is not a shortcoming of the FFT equipment but a consequence of the inherent nature of the input signal with which they must work.

ON-LINE VERIFICATION OF CALIBRATION

The calibration of installed instruments such as industrial pressure sensors involves (1) the decision whether calibration is needed at all and (2) the actual calibration, when necessary. The first step can be automated by implementing an on-line drift monitoring system. This system samples the steady-state output of operating process instruments and, if it is found to have drifted, it calls for it to be calibrated. Conversely, if there is no (or very little) drift, the instrument is not calibrated at all (or calibrated less frequently). The accuracy requirements of the sensor involved determines the amount of allowable drift.

Drift Evaluation Using Multiple Sensors

In drift evaluations, it is necessary to distinguish the drift that occurs in the process from instrument drift before a reference limit of "allowable drift" can be defined. For example, if redundant sensors are used to measure the same process parameter, their average reading can be assumed to closely represent the process and used as the reference. This is done by first sampling and storing the normal operating outputs of the redundant instruments and then averaging these readings for each instant of time. These average values are then subtracted from the corresponding individual readings of the redundant instruments to identify the deviation of each from the average.

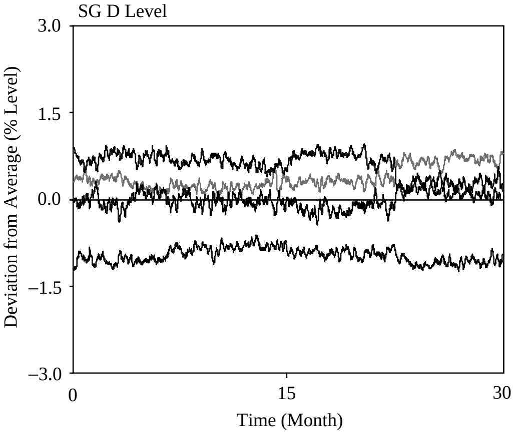

FIG. 1.9x
On-line monitoring data for steam generator level transmitters.

In Figure 1.9x, the results of on-line monitoring of four steam-generator level transmitters in a nuclear power plant are shown. The difference between the average of the four transmitters and the individual readings are shown on the *y* axis as a function of time in months. The data are shown for a period of about 30 months of operation, and the four signals show no significant drift during this period. Consequently, one can conclude that the calibration of these transmitters did not change and, therefore, they do not need to be recalibrated. If it is suspected that all four transmitters are drifting in an identical manner (drifting together in one direction), the data for deviation from the average would not reveal the drift. Therefore, to rule out any systematic or common drift, one of the four transmitters can be recalibrated.

Empirical Models, Neural Networks Another approach for detecting systematic drift is to obtain an independent estimate of the monitored process and track that estimate along with the indication of the redundant sensors. Both empirical and physical modeling techniques are used to estimate systematic drift. They each monitor various related process variables and, based on their values, evaluate the drift in the monitored parameter. For example, in a process involving the boiling of water (without superheating of the steam), temperature and pressure are related. Thus, if temperature is measured, the corresponding saturated steam pressure can be easily determined, tracked, and compared with the measured pressure as a reference to identify systematic drift. The use of this method of drift detection does not require the use of multiple sensors, and individual sensors can also be tracked and their calibration drift evaluated on line.

The relationship between most process variables is much more complex than the temperature–pressure relationship of saturated steam. Therefore, most process parameters cannot be evaluated from measurement of another variable. In addition, an in-depth knowledge of the process is needed to provide even an estimate of a parameter on the basis of physical models. Therefore, for the verification of on-line calibration, empirical models are often preferred. Such empirical models use empirical equations, neural networks, pattern recognition, and sometimes a combination of these, including fuzzy logic for data clustering, are used to generate the model's output(s) based on its multiple inputs.[10–14]

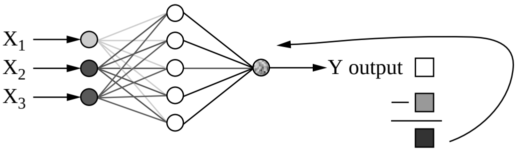

FIG. 1.9y
Illustration of training of a neural network.

Before using the empirical model, it is first trained under a variety of operating conditions. As shown in Figure 1.9y, if the output parameter (y) is to be estimated on the basis of measuring the input parameters x_1, x_2, and x_3, then, during the training period, weighting factors are applied to the input variables. These factors are gradually adjusted until the difference between measured output and the output of the neural network is minimized. Such training can continue while the neural network learns the relationship between the three inputs and the single output, or while additional input and output signals are provided to minimize the error in the empirical model. Training of the model is completed when the measured output is nearly identical to the estimate generated by the neural network. Once the training is completed, the output of the model can be used for drift evaluation or control purposes.

An on-line calibration monitoring system might use a combination of averaging of redundant signals (averaging can be both straight and weighted), empirical modeling, physical modeling, and calibrated reference sensor(s) in a configuration similar to the one shown in Figure 1.9z. In such a system, the raw data is first screened by a data-qualification algorithm and then analyzed to provide an estimate of the process parameter being monitored. In the case of averaging analysis, a consistency algorithm is used to make sure that a reasonable agreement exists among the redundant signals and that unreasonable readings are either excluded or weighted less that the others before the signals are averaged. Such systems as the one illustrated in Figure 9.1z can be considered for both power plants and chemical industry applications for the on-line verification of the calibration requirements of process sensors.

The data for on-line monitoring can be obtained from the plant computer or from a dedicated data acquisition system. Figure 1.9aa illustrates a data acquisition system used in a power plant for on-line calibration monitoring purposes. The computer applies the on-line calibration algorithms and, based on the sampled data from a variety of process instruments, provides such information as plots of deviation for each instrument from a process estimate and a listing of instruments that have drifted. The data acquisition system

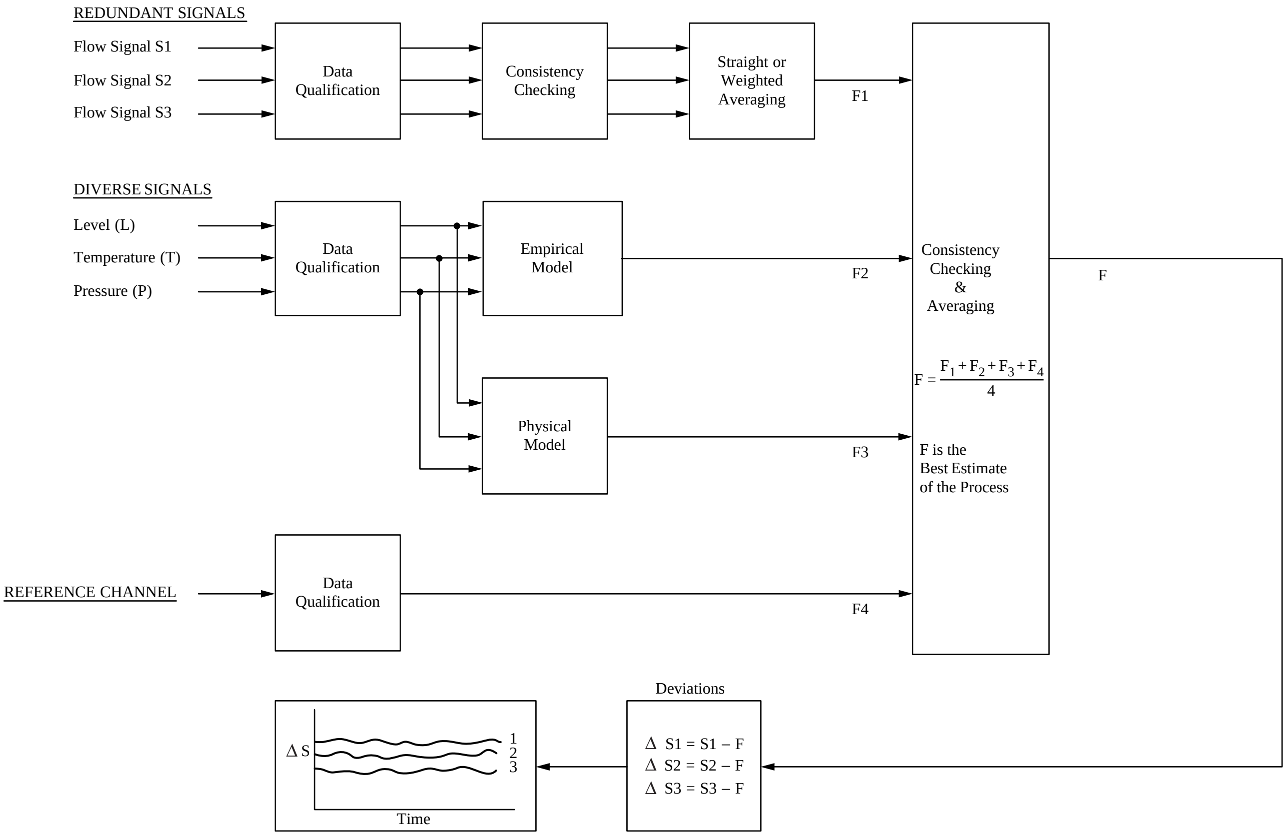

FIG. 1.9z
Conceptual design of an on-line monitoring system.

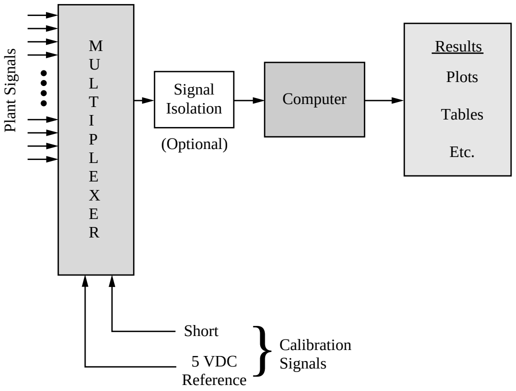

FIG. 1.9aa
Dedicated system.

includes its own calibration signals so that test equipment drift can be isolated from the drift that occurs in process instruments. If on-line monitoring data is already available in the plant computer, it can be stored or analyzed to provide calibration verification results.

On-line calibration monitoring identifies calibration problems at the monitored point (i.e., the process operating conditions). As such, the above approach may be labeled as a one-point calibration check. To verify the calibration of instruments over their entire range, on-line monitoring data shall also be collected during plant startup and shutdown episodes. With data from these episodes, the instrument calibration can be verified for a wide range.

According to research data on pressure transmitters in nuclear power plants,[14] about 70% of the time, the one-point calibration monitoring can reveal calibration problems throughout the instrument range. This is because the drift in pressure transmitters is usually due to a zero shift, which does affect the entire operating range of the transmitter.

1.10 Redundant and Voting Systems

T. J. WILLIAMS, E. J. SCHAFFER (1982) **T. J. WILLIAMS** (1995) **A. ROHR** (2003)

INTRODUCTION

Reliability in process control computing can be defined as the correct operation of a system up to a time $t = T$, given that it was operating correctly at the starting time $t = 0$.[1] However, correct operation can have many meanings, depending on the requirements previously established for the system. A common attitude today is that single or multiple failures can be accepted as long as the system does not go down or the desired operation is not interrupted or disturbed. Reliability is therefore a goal to be expected of a system and is set by the users.

To obtain a certain measure of reliability, the term *fault-tolerant computing* can be used. It may be defined as "the ability to execute specified algorithms correctly regardless of hardware errors and program errors."[2] Since different computers in different applications have widely different requirements for reliability, availability, recovery time, data protection, and maintainability, an opportunity exists for the use of many different fault-tolerant techniques.[3]

The understanding of fault tolerance can be helped by first understanding faults. A fault can be defined as "the deviation of one or more logic variables in the computer hardware from their design-specified values."[1] A logic value for a digital computer is either a zero or a one. A fault is the appearance of an incorrect value such as a logic gate "stuck on zero" or "stuck on one." The fault causes an "error" if it, in turn, produces an incorrect operation of the previously correctly functioning logic elements. Therefore, the term *fault* is restricted to the actual hardware that fails.

Faults can be classified in several ways. Their most important characteristic is a function of their duration. They can be either permanent (solid or "hard") or transient (intermittent or "soft"). Permanent faults are caused by solid failures of components.[4] They are easier to diagnose but usually require the use of more drastic correction techniques than do transient faults. Transient faults cause 80 to 90% of faults in most systems.[5] Transient faults, or intermittents, can be defined as random failures that prevent the proper operation of a unit for only a short period of time—not long enough to be tested and diagnosed as a permanent failure. Often, transient faults become permanent with further deterioration of the equipment. Then, permanent fault-tolerant techniques must be used for system recovery.

The goal of system reliability or of fault-tolerant computing therefore is to either prevent or be able to recover from faults and continue correct system operation. This also includes immunity to software faults induced into the system. To achieve a high reliability, it is essential that component reliability be as high as possible. "As the complexity of computer systems increase, almost any level of guaranteed reliability of individual elements becomes insufficient to provide a satisfactory probability of successful task completion."[6] Therefore, successful fault-tolerant computers must use a judicious selection of protective redundancy to help meet the reliability requirements. The three redundancy techniques are as follows:

1. Hardware redundancy
2. Software redundancy
3. Time redundancy

These three techniques cover all methods of fault tolerance. *Hardware redundancy* can be defined as any circuitry in the system that is not necessary for normal computer operation should no faults occur. *Software redundancy*, similarly, is additional program instructions present solely to handle faults. Any retrial of instructions is known as *time redundancy.*

Hardware Redundancy

Hardware redundancy can be described as the set of all hardware components that need to be introduced into the system to provide fault tolerance with respect to operational faults.[1] These components would be superfluous should no faults occur, and their removal would not diminish the computing power of the system in the absence of faults.

In achieving hardware fault tolerance, it is clear that one should use the most reliable components available.[7] However, increasing component reliability has only a small impact on increasing system reliability. Therefore, it is "more important to be able to recover from failures than to prevent them."[8] Redundant techniques allow recovery and are thus very important in achieving fault-tolerant systems. The techniques used in achieving hardware redundancy can be divided into two categories: static (or masking) redundancy and dynamic redundancy.

Static techniques are effective in handling both transient and permanent failures. Masking is virtually instantaneous and automatic. It can be defined as any computer error correction method that is transparent to the user and often to the software. Redundant components serve to mask the effect of hardware failures of other components.

Many different techniques of static redundancy can be applied. The simplest or lowest level of complexity is by a massive replication of the individual components of the system.[1] For example, four diodes connected as two parallel pairs that are themselves connected in series will not fail if any one diode fails "open" or "short." Logical gates in similar quadded arrangements[9,10] can also guard against single faults, and even some multiple faults, for largely replicated systems.

More sophisticated systems use replication at higher levels of complexity to mask failures. Instead of using a mere massive replication of components configured in fault-tolerant arrangements, identical nonredundant computer sections or modules can be replicated and their outputs voted upon. Examples are triple modular redundancy (TMR) and more massive modular redundancy (NMR), where N can stand for any odd number of modules.

In addition to component replication, coding can be used to mask faults as well as to detect them. With the use of some codes, data that has been garbled (i.e., bits changed due to hardware errors) can sometimes be recovered instantaneously with the use of redundant hardware. Dynamic recovery methods are, however, better able to handle many of these faults.

Higher levels of fault tolerance can be achieved more easily through dynamic redundancy and implemented through the dual actions of fault detection and recovery. This often requires software help in conjunction with hardware redundancy. Many of these methods are extensions of static techniques.

Massive redundancy in components can often be better utilized when controlled dynamically. Redundant modules, or spares, can have a better fault tolerance when they are left unpowered until needed, since they will not degrade while awaiting use. This technique, standby redundancy,[11] often uses dynamic voting techniques to achieve a high degree of fault tolerance. This union of the two methods is referred to as *hybrid redundancy.*[12] Additional hardware is needed for the detection and switching out of faulty modules and the switching in of good spares within the system by this technique.

Error detecting and error correcting codes[13] can be used to dynamically achieve fault tolerance in a computing system. Coding refers to the addition of extra bits to and the rearranging of the bits of a binary word that contains information. The strategy of coding is to add a minimum number of check bits, the additional bits, to the message in such a way that a given degree of error detection or correction is achieved.[4] Error detection and correction is accomplished by comparing the new word, hopefully unchanged after transmission, storage, or processing, with a set of allowable configurations of bits. Discrepancies discovered in this manner signal the existence of a fault, which sometimes be corrected if enough of the original information remains intact.

This means that the original binary word can be reconstructed with some such codes if a set number of bits in the coded word have not changed. Encoding and decoding words with the use of redundant hardware can be very effective in detecting errors. Through hardware or software algorithms, incorrect data can also often be reconstructed. Otherwise, the detected errors can be handled by module replacement and software recovery actions. The actions taken depend on the extent of the fault and of the recovery mechanisms available to the computing system.

Software Redundancy

Software redundancy refers to all additional software installed in a system that would not be needed for a fault-free computer. Software redundancy plays a major role in most fault-tolerant computers. Even computers that recover from failures mainly by hardware means use software to control their recovery and decision-making processes. The level of software used depends on the recovery system design. The recovery design depends on the type of error or malfunction that is expected. Different schemes have been found to be more appropriate for the handling of different errors. Some can be accomplished most efficiently solely by hardware means. Others need only software, but most use a mixture of the two.

For a functional system, i.e., one without hardware design faults, errors can be classified into two varieties: (1) software design errors and (2) hardware malfunctions.

The first category can be corrected mainly by means of software. It is extremely difficult for hardware to be designed to correct for programmers' errors. The software methods, though, are often used to correct hardware faults—especially transient ones. The reduction and correction of software design errors can be accomplished through the techniques outlined below.

Computers may be designed to detect several software errors.[14,15] Examples include the use of illegal instructions (i.e., instructions that do not exist), the use of privileged instructions when the system has not been authorized to process them, and address violations. This latter refers to reading or writing into locations beyond usable memory. These limits can often be set physically on the hardware. Computers capable of detecting these errors allow the programmer to handle the errors by causing interrupts. The interrupts route the program to specific locations in memory. The programmer, knowing these locations, can then add his own code to branch to his specific subroutines, which can handle each error in a specified manner.

Software recovery from software errors can be accomplished via several methods. As mentioned before, parallel programming, in which alternative methods are used to determine a correct solution, can be used when an incorrect solution can be identified. Some less sophisticated systems print out diagnostics so that the user can correct the program off line from the machine. This should only be a last resort for a fault-tolerant machine. Nevertheless, a computer should always keep a log of all errors incurred, memory size permitting.

Preventive measures used with software methods refer mainly to the use of redundant storage. Hardware failures often result in a garbling or a loss of data or instructions that are read from memory. If hardware techniques such as coding cannot recover the correct bit pattern, those words will become permanently lost. Therefore, it is important to at least duplicate all necessary program and data storage so that it can be retrieved if one copy is destroyed. In addition, special measures should be taken so that critical programs such as error recovery programs are placed in nonvolatile storage, i.e., read-only memory. Critical data as well should be placed in nondestructive readout memories. An example of such a memory is a plated-wire memory.

The second task of the software in fault tolerance is to detect and diagnose errors. Software error-detection techniques for software errors often can be used to detect transient hardware faults. This is important, since "a relatively large number of malfunctions are intermittent in nature rather than solid failures."[9] Time-redundant processes, i.e., repeated trials, shall be used for their recovery.

Software detection techniques do not localize the sources of the errors. Therefore, diagnostic test programs are frequently implemented to locate the module or modules responsible. These programs often test the extent of the faults at the time of failure or perform periodic tests to determine malfunctions before they manifest themselves as errors during program execution. Almost every computer system uses some form of diagnostic routines to locate faults. In a fault-tolerant system, the system itself initiates these tests and interprets their results, as opposed to the outside insertion of test programs by operators in other systems.

Fault-Tolerant Computer System Design

The design of a fault-tolerant industrial computer system should be different from that of a similar system for a spaceborne computer system. Maintenance is available in an industrial environment to replace any modules that may have failed. In addition, the system may be much larger, and a hierarchy of many computers of different sizes may be necessary to handle the various operations.[16] Therefore, a fault-tolerant communication network may be required as well.

Future advancements must also be considered when studying the design of fault-tolerant systems. Throw-away processors on a chip are no longer a myth, and the manufacture of equivalent inexpensive mass memory is probably already here as well.[6] Valid future designs must incorporate provisions for these advances and allow for larger replacement modules for quicker and simpler fault location and maintenance.

The ways in which faults manifest themselves have not changed. They may be summarized as the following:[17]

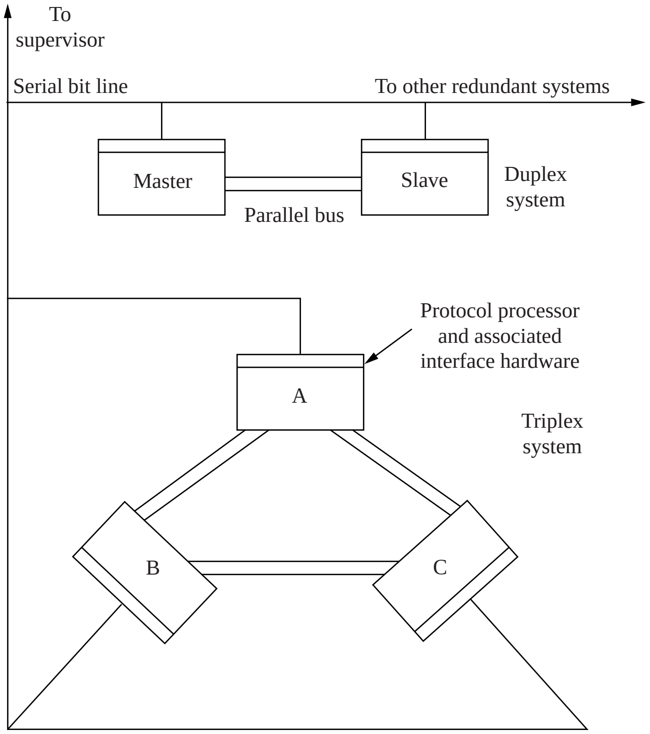

FIG. 1.10a
Comparison of duplex and triplex redundancy systems.

1. Intramodule data errors
2. Intermodule data transfer errors
3. Address errors
4. Control signal errors
5. Power failure
6. Timing failure
7. Reconfiguration faults

The two main designs considered here are that of a duplex system with two identical computers operating in parallel and that of a triplex system (see Figure 1.10a). The triplex system has three computers operating synchronously. In addition to those error detecting and correcting capabilities already built into the computers, fault-tolerant features will be present in software for both systems. The duplex system will feature a comparison of data for fault detection with rollback and recovery to handle transient errors. The triplex system will incorporate a software voting scheme with memory reload to recover from transient failures. This removes the overhead of rollback. Each duplicated system of computers will communicate internally via a parallel data bus that will allow high-speed communication, plus a parallel control bus that will initiate interrupts to handle any faults within the system. All computer elements will communicate with higher level systems via a full-duplex synchronous serial bit bus, a bus that will permit simultaneous message transfer in both directions, through the protocol microprocessor. With these components, a fully reliable system should be realized.

FIELD INSTRUMENT REDUNDANCY AND VOTING

The above concepts apply not only to process computers but also to basic process control systems (BPCSs) and safety instrumented systems (SISs), where they also improve performance, availability, and reliability. In the case of field instruments and final control elements, they mainly guarantee continuity of operation and increase uptime, whereas, in SIS systems, they minimize nuisance or spurious interventions and alarms.

The techniques used in BPCS and SIS systems are similar and have initially been developed for the inherently more demanding SIS applications. For SIS systems, the need of international regulations has been recognized (ANSI/ISA-84.01-1996,[18] IEC 61508-1998/2000,[19] and IEC 61511,[20] in draft version) while, for non-safety related control loops, this is left to good engineering practice. Therefore, the discussion of redundancy and voting techniques, as applied to the field instruments of BPCS systems, will be based on the SIS standards as guidelines. The BPCS goal is to improve control loop availability such that the trigger point for the intervention of the associated SIS system is unlikely ever to be reached. Thereby, redundancy in BPCS also improves safety. This is because increased availability reduces the number of shutdowns, which tend to shorten the life of the plant due to the resulting thermal and other stresses.

One of the main objectives of measurement and control specialists is to improve the availability and accuracy of measurements. To achieve that goal and to minimize systematic uncertainty while increasing reliability, correct specification, instrument selection, and installation are essential.

Assuming that the transmitters have been properly specified, selected, and installed, one can further improve total performance by measuring the same variable with more than one sensor. Depending on the importance of the measurement, redundancy can involve two or more detectors measuring the same process variable. When three or more sensors are used, one can select the "majority view" by voting. With this approach, one would select m measurements out of the total n number of signals so, that $m > n/2$. In industrial practice, n is normally 3 so that m is 2.

The redundant and voting techniques have been standardized in various SIS-related documents, including ANSI/ISA-84.01, IEC 61508, and IEC 61511. The SIS systems usually evaluate on–off signals or threshold limits of analog signals whereas, in process control, redundancy and voting is obtained by the evaluation of multiple analog signals. The main difference between BPCS and SIS systems is that SIS is a "dormant" system, but continuously self-checking, and it is called upon to operate only in an emergency. In addition, the SIS is fail safe; i.e., if it fails, it brings the plant to a safe status. SIS malfunctioning is inferred from diagnostic programs and not from plant conditions, because the plant cannot be shut down or brought to unsafe conditions just to test the SIS system. All international regulations follow this approach.

In contrast to SIS systems, the BPCS control loops are always active and, if they malfunction, they actuate alarms, which the operator immediately notices. The consequence is that the SIS-based definitions developed in IEC 61508, to some extent, can also be used as guidelines for control loops that require high uptime and whose unavailability would, within a short time, drive the plant to conditions requiring plant shutdown.

IEC 61508 Part 6 gives the definition of the various architectures most commonly used in the safety instrumented systems. They apply for use with one, two, or three elements and their various combinations. The elements that are used in a single or multiple configuration can be either transmitters or final control elements, but they are mainly for transmitters, and only very rarely for control valves, because of the substantial difference in costs. The control system, such as a DCS system, is usually configured with multiple controllers and redundant other system components (e.g., system bus, I/O bus, HMI). IEC 61508 considers and gives definitions to the configurations described below.

Single-Transmitter Configuration (Figure 1.10b)

1oo1 A single transmitter is used, as in many control loops. These loops consist of an analog transmitter and an analog controller (pneumatic or electronic). This configuration is the most prone to overall malfunctioning. Errors and failures can be caused by a sticking control valve or transmitter or by an out of range signal (up or down scale). In these loops,

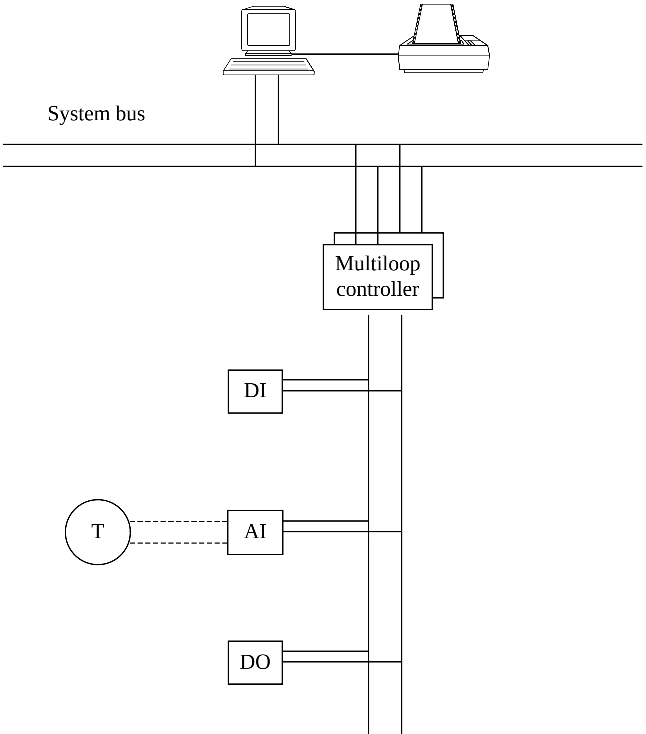

FIG. 1.10b
1oo1/1oo1D transmitter input.

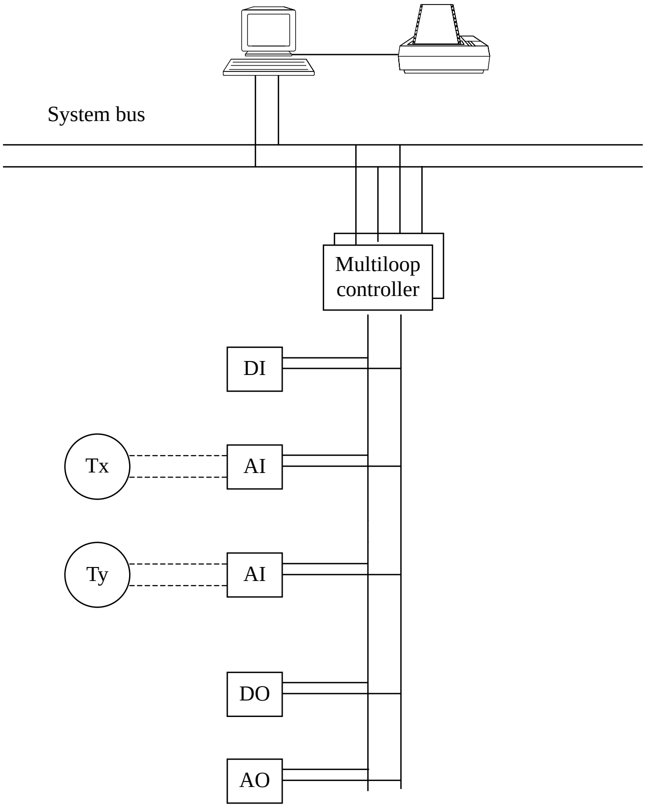

FIG. 1.10c
2oo2D transmitter input.

diagnostic protection is very limited. Remember, in the past, the burn-out feature of thermocouples was almost the only diagnostic function implemented in the mV/psi converters or mV/mA transducers.

1oo1D A single transmitter is used, with diagnostic coverage integral to the transmitter (e.g., self-validating transmitters[21,22]) and/or external in the control system.

Two-Transmitter Configuration (Figure 1.10c)

1oo2 Two transmitters in parallel are used; the failure of one determines the loss of control. In principle, this definition cannot be borrowed from IEC 61508.

1oo2D Two transmitters in parallel are used, with diagnostic coverage mainly residing in the control system. The type of diagnostic functions will be covered afterward.

2oo2 Two transmitters in parallel are used. The loss of control should be determined by the failure of both. In principle, this definition cannot be borrowed from IEC 61508.

Three-Transmitter Configuration (Figure 1.10d)

2oo3 Three transmitters in parallel are used. The concurrent value indicated by two of them is assumed as correct and representative of the process conditions. Concurrency means that they differ by no more than X%.

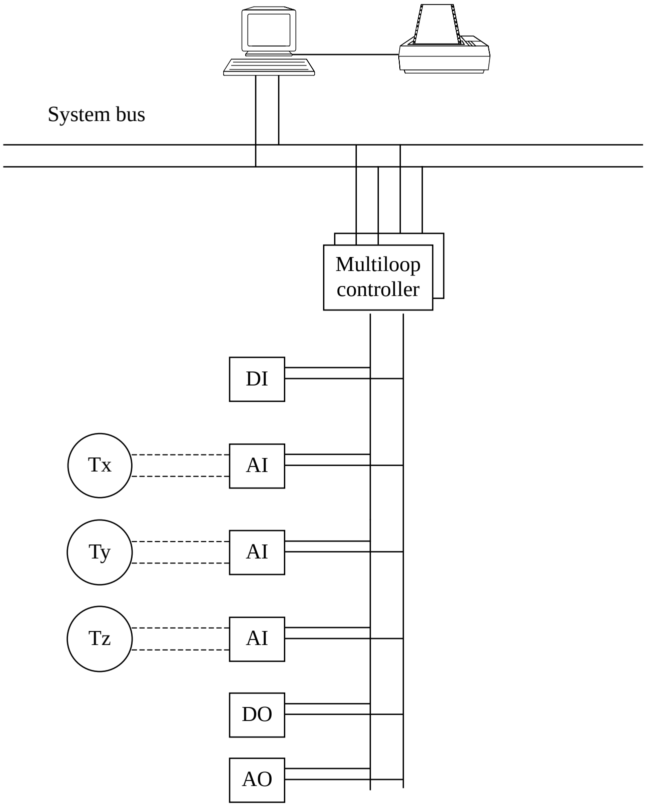

FIG. 1.10d
2oo3 transmitter input.

Diagnostic Coverage

The diagnostic coverage in the BPCS is much less than in the SIS, for reasons outlined previously, and is provided mainly in and by the DCS, which has the capability of comparing the signals received from the transmitters and determining whether they are within the imposed limits so as to consider them to be concurrent. If an inconsistency is detected, the DCS is capable of signaling the abnormal situation and to maintain control, at least in some instances, without operator intervention.

1oo1D The diagnostic coverage can be partly integral to the transmitter and/or external in the control system (rate of change alarms, overrange alarms detecting the individual fault). In a broader sense, in addition, the material balance (data reconciliation) performed in the DCS can contribute to detect a failure in the flow transmitters or their unreliable reading.

1oo2D The signal from each transmitter is checked to verify if it is within the validity limits (i.e., 4-20 mA). If a transmitter is outside the validity range, its signal

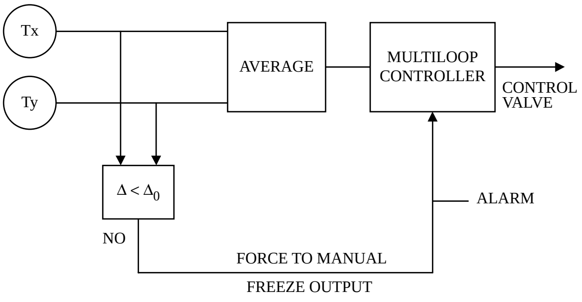

FIG. 1.10e
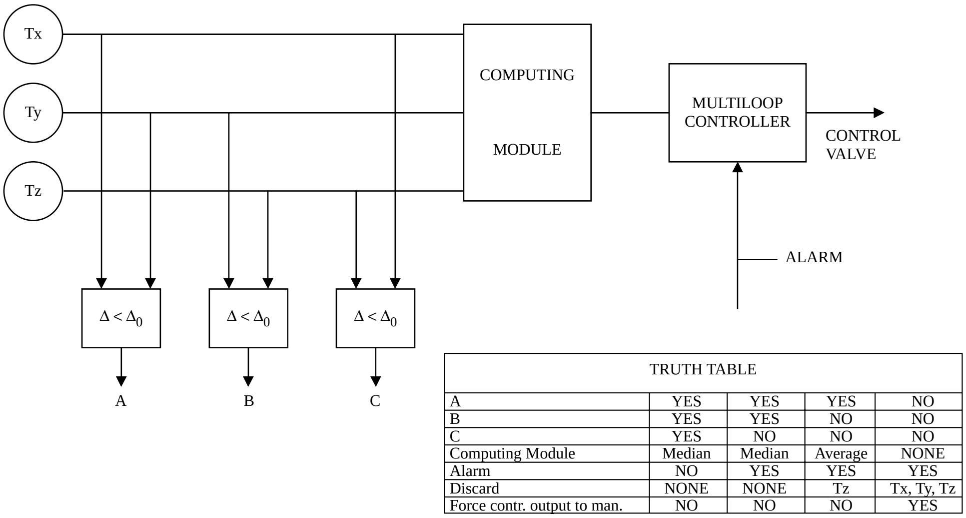
1oo2D signal conditioning.

is discarded, the controller receives the value from the other transmitter and an alarm is issued to warn the operator about the malfunctioning. If both transmitters are within validity limits, the difference among their signals is calculated. In case the difference is within a preset value (in the range of few percent), the average value is assumed as good and used for the control function (Figure 1.10e).

The acceptable discrepancy between the two transmitters depends on the measurement conditions; for instance, the acceptable discrepancy in the level measurement in a steam drum is larger than in the case of a pressure measurement. As an indication, for two level transmitters installed at different ends of the steam drum, 5% discrepancy is acceptable. However, for pressure measurement, 2% should not be exceeded. Normally, in the process industry, it is not necessary to select a very small discrepancy (such as twice the declared accuracy) between the transmitted values, because the difference could be the result of many causes other than a transmitter failure or the need for recalibration (the main reason could be the installation). Sometimes, a common percentage discrepancy value is chosen and used for all measures, because experience has shown that it is unlikely that a transmitter fails to a value close to the correct one.

When the discrepancy is beyond the preset value, but both signals are within validity limits, it is not possible to determine which one is invalid. In this case, an alarm is produced, and the controller is automatically forced to manual, with output frozen at the last valid value. The operator then has the responsibility to discard one of the two transmitters and use the other as the input to the controller, then switch to auto again.

2oo3 The signal from each transmitter is checked to verify whether it is within the validity limits (i.e., 4 to 20 mA). If a transmitter is outside the validity range, its signal is discarded as invalid, and the remaining two are used as if they were in 1oo2D configuration. If no invalid signal is detected, then the discrepancy between the values is calculated. Supposing the three signals are X, Y, and Z, the differences X – Y, Y – Z, and Z – X are calculated. If each of them is within the preset limits, the median value is taken as good and used as process variable by the controller. If one difference exceeds the preset limit, an alarm is issued to the operator, and the median value is used as process variable for the controller. If two differences exceed the preset limit, the value of the transmitter involved in both the excessive differences is discarded, an alarm is issued to the operator, and the average value of the remaining two is used as process value. If all three differences exceed the preset limit, this means that at least two transmitters are not reliable. In this case, the controller is automatically forced to manual, with output equal to last valid value (Figure 1.10f).



TRUTH TABLE

A	YES	YES	YES	NO
B	YES	YES	NO	NO
C	YES	NO	NO	NO
Computing Module	Median	Median	Average	NONE
Alarm	NO	YES	YES	YES
Discard	NONE	NONE	Tz	Tx, Ty, Tz
Force contr. output to man.	NO	NO	NO	YES

FIG. 1.10f
2oo3 signal conditioning.

> The operator has the responsibility to select one of the three transmitters as the good one, use it as input to the controller, and switch to auto again. There are some possible variations in the algorithms used for the selection of the valid signals and the discarding of the unreliable ones, and they depend on the available control blocks of the involved DCS.

Engineering Redundant Measures

When redundant measures are performed, attention shall be given to avoid common-mode failures. A possible common-mode cause of inaccuracy in flow measurement is the primary flow element, which can be erroneously calculated, wrongly installed, or show wear after extended operation. This situation is not easily corrected but can be detected by material balance and/or maintenance (i.e., by checking the size of the orifice or throat and the sharpness of the orifice edge).

Starting from the tapping point on the process, the most usual common-mode failures are examined. Two or three pressure transmitters connected to the same valved branch on a pipe or vessel are prone to common-mode failure, because the closing or clogging of the root valve puts all transmitters out of service. Such an installation is therefore to be avoided.

The same multicore cable containing the 4 to 20 mA signals of redundant transmitters is a possible cause of common-mode failure because, if it is cut, all the signals are lost at the same time. Therefore, the signals should be contained in different cables, and the cables themselves should be routed on different cable racks.

The same input card receiving the signals from redundant transmitters is a possible cause of common-mode failure because, even if only a single channel (even different from the ones under consideration) of the input card fails and the card is then replaced, all the transmitter inputs are lost simultaneously. It is appropriate to connect the redundant transmitters to different input cards.

If the multiloop controller in the DCS is not redundant (or fault tolerant), the input cards connected to the redundant transmitters should belong to different multiloop controllers to avoid common-mode faults. It is, however, highly preferable to use redundant multiloop controllers (rather than two independent nonredundant multiloop controllers) because of the increased traffic in the system bus and of a loop failure consequent to the system bus failure.

Because all the transmitters are powered from the DCS, redundant power supplies to the DCS modules should be provided, coming from different sources.

For an exhaustive evaluation of failure modes, Tables B.5.1 and B.5.2 of ANSI/ISA-84.01-1996 provide a useful guideline, even though they cover the SIS.

These simple examples clearly indicate that it is not sufficient to duplicate or triplicate the transmitters and that, to obtain the best possible results, the complete engineering of the system shall be carried out correctly. However, it is necessary to evaluate properly to what extent it is necessary to avoid common-mode failures as a factor of the criticality of the application. If, for instance, all the cables are installed on the same tray, distributing the redundant transmitters in different cables does not improve the situation; it would be unusual for only one cable to break while the others remain in operation.

Complex Control Loops

In the power generation industry, two or three transmitters in redundant or voting configuration are commonly used for all control loops. As the boiler control requires complex loops, a question to be answered is to what extent can it be justified that the transmitters be duplicated or triplicated.

Consider the steam drum level control, and suppose that duplicated measurements are the contractual requirement. Of course, the level transmitters, the relevant steam and water flow transmitters, are duplicated to allow for a fully redundant three-element control. What about the pressure transmitter used to compensate the level measurement for density? If the boiler is operating at constant pressure, a single transmitter should be sufficient. If it fails, the last valid value could be frozen and used, obviously sending an alarm to the operator. If the boiler is operating in sliding pressure, then it must also duplicate the pressure transmitter.

Consider the steam flow compensation for pressure and temperature. If the flow transmitter is duplicated, the pressure and temperature transmitters do not always require duplication; if these variables are allowed to vary only slightly and the measure is not used for custody transfer, it should be sufficient to freeze the last valid value for compensation, with a warning to the operator. But, again, if the boiler is operating in sliding pressure mode or could possibly have a variable steam temperature, then the transmitters should be duplicated.

Notwithstanding these considerations, if a plant is supplied as a turnkey operation, the specifications uniformly will call for redundancy without closely examining the real need for duplication or triplication of the transmitters.

Final Control Elements

In very rare instances, the final control elements can be duplicated, as when the erosive/corrosive or sticking characteristics of the fluid could cause unacceptable downtime. It should be noted that the need for duplicating the valves is more stringent if the valves are more sophisticated and therefore more expensive, so justifying this duplication is often difficult. The price of a critical valve can be 10 to 20 times the price of a transmitter (and on occasion, even more).

If duplicated, the control valves are not operating in parallel, but one is in “cold standby,” so the analogy with redundant transmitters is not accurate.

The possible configurations of the final control elements are as listed below:

1oo1 A single control valve is used, as in all typical control loops. This configuration covers the majority of the applications, being the simplest; however, a valve malfunction (e.g., sticking) could be detected, with some time delay, as a drift in process variables caused by the incorrect positioning of the trim.

1oo1D A single valve is used, with some diagnostic coverage integral with the electropneumatic positioner. This is a check of the valve's actual position against the required one and verification that the dynamic response of the valve has not changed over time. This function is made possible by smart positioners that generate a position signal that is transferred to the control system as a feedback on valve behavior. The DCS compares the requested position with the actual one and gives an alarm if the discrepancy becomes excessive or does not tend to zero in a reasonable time. The value of the discrepancy being alarmed is somewhat higher than between two transmitters and is considered acceptable if it is about 5 to 7%, provided that this offset tends to zero in time.

For on–off control valves, the diagnostic function can occasionally command the valve to move from the current condition shortly and slightly, performing only a partial travel, to determine whether the trim is stuck and to prevent it from sticking. The result is monitored, and any malfunctioning sets off an alarm. This partial movement, however, shall be compatible with the process characteristics.

1oo2D Two valves in cold standby are used, with diagnostic coverage mainly residing in the DCS. The diagnostic helps to determine if and when the switching from the main valve to the spare one must be performed. To avoid encountering a faulty spare valve, it is necessary to exercise it regularly so as to achieve an awareness of and confidence about its operability.

If the problem is associated with erosion or corrosion, the Cv of the valve increases at low lift. However, if the flow remains within the operational values, it is not easy to detect a problem. Only when the valve is almost closed and the passing flow creates process upsets can the erosion/corrosion situation be detected, unless a correlation between flow and valve opening can be established and logged over time.

An example of a different application that always involves redundancy of the final control element is stroke control of the dosing pumps. In boiler applications, the chemical dosing pumps are normally redundant and in cold standby because of the criticality of the application, while the accuracy is not a major requirement (in some cases, the stroke adjustment is manual). If the stroke is controlled from the DCS, it is important that both pumps be controlled, but control redundancy is not essential. The solution can be a simple analog output feeding, in series, both of the I/P converters whose pneumatic output adjusts the pump stroke. The output to the stopped pump has no effect. If one I/P converter fails in short circuit, the signal through the other keeps flowing correctly. It is sufficient that the pump in operation is the one controlled by the healthy I/P converter, and so the plant will have no problems. To prevent the stroke from going to zero if one I/P converter fails open, it is sufficient to install a zener diode on the terminals of each I/P converter to guarantee the signal flow continuity (Figure 1.10g). In this way, if all the equipment is healthy, the 4 to 20 mA signal does not flow through the zener diodes. However, if a converter fails open, the current flows through the parallel diode without any deleterious effect.

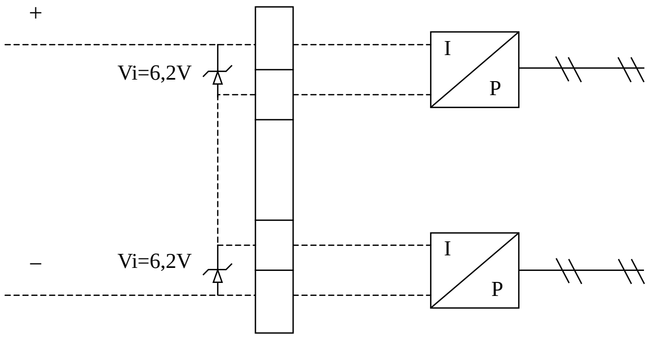


FIG. 1.10g
Single output to two I/P converters.

Availability Considerations

Availability can be defined as "the probability that a system is operating at time *t*."[23] For control loops, the availability is the major parameter in that high availability means continuity of operation. If a single component (e.g., a transmitter) is used, its failure means that the control loop is no longer operable in an automatic mode until the component has been repaired or replaced. This can require several hours and could involve a plant shutdown, which requires additional time for restarting and consequent loss of production.

By duplicating the transmitter, the failure probability is doubled, but the measure becomes almost immediately available (in terms of minutes), and the probability that the second transmitter will fail during the few hours needed to replace/repair the failed one is really close to zero. With the technique explained above, the duration of unavailability corresponds to the time needed for the operator to select the transmitter he trusts most and assign it as the process variable to the controller.

By triplicating the transmitters, the failure probability is tripled, but even the short period of unavailability of the measure is eliminated. The control system is able to automatically calculate, from the set of available measurements, the one that best represents the process.

Of course, these qualitative statements are true only if the maintenance activity is immediate and the faulty equipment is repaired/substituted within the shift or the day. The triple transmitters are less sensitive to the faulty operation of one (or even two) units, because it is possible for the operator to select the remaining healthy transmitter and use it as the process variable of the control loop.

These qualitative considerations can be studied quantitatively with statistical methods based on the fact that failures are random variables. Further information is available in the specialized literature.[23,24]

1.11 Instrument Evaluation

J. BARTH, W. M. WALRAVEN (1995) **ROBERT J. SMITH II** (2003)

Instrumentation evaluations are difficult to accomplish in the field. Independent evaluations by users and associations prove to be the best sources for determining whether a particular instrument will work in a given application. Manufacturers' specifications can provide many details about the instrument, but comparing apples to apples is sometimes difficult.

Instrumentation undergoes rapid changes every year. The pressure on manufacturers to implement techniques that are novel in theory proves to be a challenge. The development cycle is furious, resulting in instruments that do not meet users' expectations. This results in:

1. Delays in design/engineering, construction, and start-up
2. Increased cost for commissioning
3. Decreased performance of the plant's process or adverse consequences on personnel, plant, or the environment

End users cannot assume these risks in today's market. Although the supplier usually corrects problems with the instruments, the cost of any resulting damage is still paid by the end user.

Independent evaluation has become difficult for users whose time constrains do not allow them to perform tests that verify certain design criteria of a particular instrument. When it was found that cooperative evaluations could substantially reduce the costs and workloads for the individual users, internationally orientated instrument users' associations were founded.

EVALUATION RESULTS

Statistics show the potential problems one might expect from an instrument (see Table 1.11a). Improvements have increased over the years. This implies that evaluation results have provided manufacturers with feedback that benefits the user. The types of instruments evaluated are shown in Figure 1.11b. It is desirable for a manufacturer to have a good quality management system, based on internationally accepted standards, such as those of International Standards Organization (ISO),

TABLE 1.11a
Instrumentation Evaluation Results (Numbers Represent Percentages of Population)

	1963–77	*1980–82*	*1984–88*	*1995–99*
Defective on arrival	25	18	7	18
Defective during testing	17	35	17	18
Outside manufacturer's own specifications	27	48	33	49
Variations in output in excess of 0.5%	N/A	N/A	29	N/A
Sensitive to external influences that cannot be expressed in percentages	N/A	N/A	68	N/A
Unanticipated effects	N/A	N/A	39	N/A
Inadequate documentation	54	47	25	86
Modified after evaluation	29	35	44	27
Population (number of reports issued)	710	193	750	105

Data provided by Evaluation International.

to ensure that its instruments all have the same characteristics. Independent firms regularly audit these systems. It has been found, however, that even the most reputable auditors sometimes lack the instrumentation know-how needed to perform an effective audit. This weakness can be remedied by the participation of an instrument engineer on the audit team.

ORGANIZATION

The International Instrument Users' Association (WIB) is a nonprofit organization located in The Hague, the Netherlands. It has more then 50 members worldwide. Its working language is English. An executive elected by and from the members is responsible for the association's general policy and finances, while a full-time professional staff handles day-to-day business.

The association's funds are provided by the annual membership fees, which are determined at the General Members Meeting. After the deduction of a share for organizational costs, each member has a say in determining the evaluations upon which the balance is spent.

The evaluation work is always contracted out to independent, internationally renowned laboratories such as the Netherlands Organisation for Applied Scientific Research (TNO), Sira Certification Service, NEL Laboratories, Laboratoire Central des Industries Electriques (LCIE), The KEMA group, and so on. The interested members and the manufacturer base the work on a mutually acceptable test program. After completion of the evaluation, all findings are reported along with any observations from the manufacturer. The reports contain an objective comparison with the manufacturer's specifications and do not provide a rating of *good* or *not recommended*. Applications and requirements vary so widely that only the individual user can decide whether the instrument is suitable for a particular application. Similar user associations exist in the United Kingdom (e.g., SIREP International Instrument Users Association) and France (Association des Exploitants d'Equipements de Mesure, de Régulation et d'Automatisme, EXERA). A Liaison Agreement was concluded in 1982 to ensure similarity in reporting and a free exchange of reports and other information. The three associations together have approximately 100 members, covering many multinationals in markets varying from oil, chemical, steel, food, and beer to utilities such as the electricity, gas, water, and nuclear industries.

EVALUATION METHODOLOGY

Evaluations of instruments and systems aim at confirming the claims made by manufacturers' specifications. Where these are lacking, user requirements or relevant IEC/ISO evaluation standards may be used. The methodology in use in the evaluation laboratories of TNO, Netherlands, provides guidance to the engineers involved in the evaluation. An evaluation is an iterative process in which the evaluator needs the involvement of user and manufacturer for setting up the evaluation objectives and techniques. Evaluation is becoming increasingly complex because of the introduction of sophisticated electronics and software-based data processing, measurement, and communication techniques.

Evaluation requires an analysis of four main aspects of the device being tested, as follows:

1. System configuration in terms of functional and physical modules
2. Functions relevant for the user
3. Properties relevant to the quality of the functions
4. External environmental and operating conditions that affect performance

The first three items can be interrelated with the last one in a multidimensional matrix that has the structure shown in Table 1.11c. Each field represents a test. In actual practice, not all possible tests will be performed. The choices by the parties involved (user, manufacturer, evaluator) may depend on priorities of the intended application, cost and time constraints, and knowledge of system performance based on other applications. The completed matrix then forms the unambiguous agreement on the evaluation program, which still has to be supplemented by a description of the tests.

SYSTEM CONFIGURATION

The description of a system to be evaluated is based on the functional models of Figure 1.11d and the physical mode of Figure 1.11e.

In the functional model the following modules are distinguished:

- The input module converting the physical quantities (analog and/or digital) to be measured into signals suitable for further processing.

Functional system model.

- The data processing module that processes the various input signals (measurements, human inputs, and foreign system inputs) through a library of algorithms and programs for self-monitoring and maintaining integrity, security, and data storage. It sends the processed data to the various output facilities.
- The output module providing signals suitable for steering final control elements such as valves or motors.
- The communication module that provides a digital communication between the various elements or units of a system or with foreign systems. This does not apply to single, stand-alone instruments.
- The user interface module providing means for manual control and access to relevant data including data presentation (measurements in real time or historic trends and system status).
- The power supply module providing properly conditioned power to the system modules.
- The enclosure providing environmental protection. It may consist of a simple housing, but it can also provide temperature control and vibration protection through active dampers.

The physical model of Figure 1.11e shows the physical elements (subsystem, units, and so on) that can be identified in a system and are its building blocks. Specific system configurations for specific applications can be built that utilize the various physical elements in any required amount within

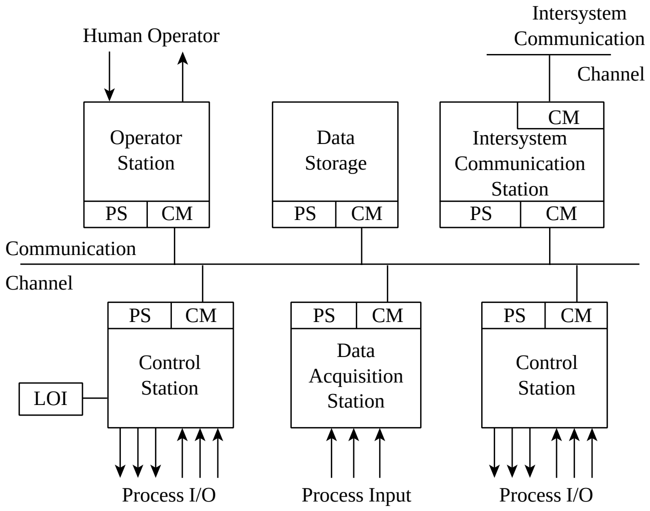

FIG. 1.11e
Physical system model: CM = communication interface module; PS = power supply module; LOI = local operation interface module.

the overall limitations of a system. Each physical element may be equipped with all or some of the basic functional modules described above.

The modules and elements of systems from different manufacturers may differ considerably in size and capabilities. The subdivision of instruments and systems into elements and modules is only relevant and practical when they can be treated and tested as separate entities and when it provides relevant information.

SYSTEM FUNCTIONS

A system function is defined as the intended relationship between a dependent variable (output) and one or more independent variables (inputs) of a system of a system element (subsystem, unit, and so forth). System functions are distinguished at the following three different hierarchical levels:

1. Management (strategic) level, dealing mainly with functions related to efficiency aspects.
2. Process measurement and control (operations) level, dealing with functions for measuring, controlling, and supervising the energy and material flows in a process or the product quality.
3. Support level, consisting of auxiliary functions at the operations level (accessible to the user) and compensation functions provided for counteracting environmental influences (not accessible to the user).

The functions of interest to system users are grouped together as follows:

- Process I/O functions (measurement, actuation)
- Data processing functions (reporting, alarming, data storage, optimization, real-time clock)
- Control functions (continuous, batch, logic, and sequential control)
- Communications functions
- Human I/O functions
- Auxiliary functions (configuration, self-diagnostics, supply, environmental protection)

PROPERTIES

System properties are grouped into the following categories: functionality, accuracy, dependability, operability, safety, and non-task-related. Each category deals with a specific set of system performance aspects.

Functionality is the extent to which a system is provided with an inherent basic hardware and software structure with which specific functional structures can be formed to control processes. Functionality comprises system capacity (number and size of elements, network structure, software size and structure), flexibility, configurability, compatibility, robustness, and so on.

Accuracy is the closeness of agreement between the theoretical function concepts and their material-bound (imperfect) realization. Accuracy comprises conformity errors, hysteresis, repeatability, and resolution. Accuracy is a property specially related to functions for measuring, controlling, processing, observing, and manipulating quantities such as pressure, temperature, density, current, and functions for calculation and communication. In systems, the routes that data follow through the functional modules affect the accuracy of data. Measurement data obtained at one module may appear with different accuracy at a local or a remote operator interface. Accuracy can be quantified either in absolute values such as V, mA, bar, or percent of full scale, or in relative values such as scale factor or percent of reading.

Dependability is the extent to which the system can be relied upon to exclusively and correctly perform the tasks and duties delegated to it. Dependability comprises availability, reliability, maintainability, integrity, and security. Some of the dependability aspects are probabilistic, while others are deterministic in nature. Dependability is strongly affected by adding redundancy to a system.

Operability is the degree to which a system is provided with the means for observing and manipulating the operation of a process. It also includes the ability to observe and manipulate the operation of a system. Operability depends on the tools and procedures for giving commands and calling up and representing process data and on the speed of response for executing commands and providing data to the demanding recipient. The term *speed of response* is related to transmission of information from:

- Process (measurement)-to-process (actuator), as in a control loop
- One system element to another system element
- Process or system element to the user (operator) and vice versa

Safety is the extent to which a system is provided with facilities that exclude hazards to persons, plant equipment, and the environment. Safety depends on the exclusion of and protection against electrical shocks, exceptionally high temperatures, radiation, emission of dangerous or poisonous gases, explosion and implosion, and fire. The safety aspects are in general subject to tight, well-defined rules for approval.

Non-task-related properties are not related to the above groups, and they include documentation, training, system identification, physical dimensions, weight power consumption, and so forth.

TEST CONDITIONS

Proper system operation will be affected by external environmental conditions at the application area and the demands for plant operation. Along with the application boundaries specified by the manufacturer, they provide the data for definition of the test conditions. Based on the main links between a system and the environment and demands, the test conditions are divided into the following domains:

- Process
- Utility
- Foreign systems
- Environment
- System tasks
- User
- System

Each of these domains is described below.

The process domain considers disturbances that enter a system via the I/O connections to the process, such as common- and series-mode signals, line break, earthing, conducted RFI, load effects, and so on. At the sensors and actuators, a system is in direct contact with the product, providing information concerning specific conditions of the product, such as temperature, pressure, pH, density, and corrosiveness.

The utility domain considers mainly electrical disturbances entering the system via power supply lines, such as voltage and frequency variations and interruptions, high-frequency noise, and transient overvoltages.

The foreign systems domain considers mainly electrical disturbances entering the system via the links with foreign systems, such as common-mode noise, transient overvoltage signals, short circuits, and open circuits on bus cables.

The environment domain considers a large range of disturbances, such as ambient temperature and humidity, corrosive media, dust, radiation (heat, UV, RFI), vibration, and so forth.

The system tasks domain considers disturbances imposed on a system by the various control and data acquisition tasks under normal and critical conditions (high alarm rates, periodic reporting, and so on), overload conditions (too many tasks at too high a speed), and demand from foreign systems.

The user domain considers disturbances caused by incorrect or unauthorized actions of operators and maintenance personnel.

The system (hardware) domain considers disturbances imposed on a system by the appearance of component failures in the system hardware.

EVALUATION TECHNIQUES

From the larger variety of evaluation techniques available, some techniques developed for the evaluation of microprocessor-based systems have been selected as examples for description herein.

Dependability is challenged by conditions in the hardware domain such as:

- Loss of the supply signals on printed circuit boards due to fuse burnout
- Loss of operation of units, subsystems, or their redundant parts
- Component failures and rupture of bus cables
- Incorrect connections of cables by maintenance personnel
- Incorrect exchange of printed circuit boards

In these failed or erroneous situations, the following points are raised to reveal the different dependability aspects of the system:

- Failure detection and reporting performed correctly by the self-diagnostics (integrity)
- Correct continuation of operation through redundant units (availability)
- Security against failure propagation to other units (integrity)
- The possibility of hot-swapping parts

The speed of response as an aspect of operability is defined and measured under arbitrarily agreed-upon reference conditions. For a system under test, these conditions comprise the hardware modules involved, the implemented functions and tasks, and the load under steady conditions.

Then the system is stressed in the task domain and investigated for delays in data transfer loss of information, or operation. These conditions may be

- A change of the internal load of a subsystem by changing cycle times or number of active function blocks
- Increase of the external demand by means of the introduction of large amounts of alarms or requests
- Changing the allocation of functions and tasks between subsystems mutually or between subsystems/ peripherals

1.12 Binary Logic Diagrams*

G. PLATT (1970, 1982) **R. A. GILBERT** (1995, 2003)

Diagrams are key components of a process documentation portfolio. The complexity of a modern production process has increased the process engineer's use and reliance on symbolic representations of a process and its unit operations. This section reviews diagram symbols and their role in binary logic diagrams. The complete description of a production process demands the use of several types of descriptive diagrams. The three important drawings that make up a specific process documentation package are the process function diagram (a site-specific binary logic diagram), the process flow sheet (a piping and instrument diagram [P&ID]), and a hardware diagram (a detailed equipment wiring diagram).

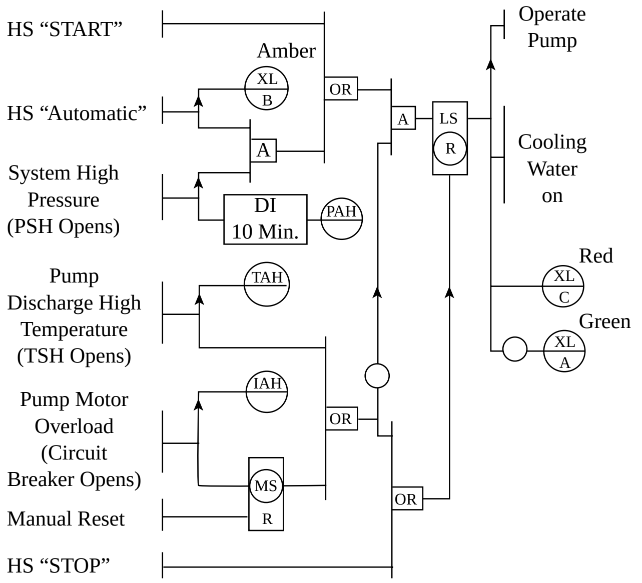

FIG. 1.12a
Logic diagram for standby vacuum pump with cooling water on and water valve (UV) open (see Table 1.12g).

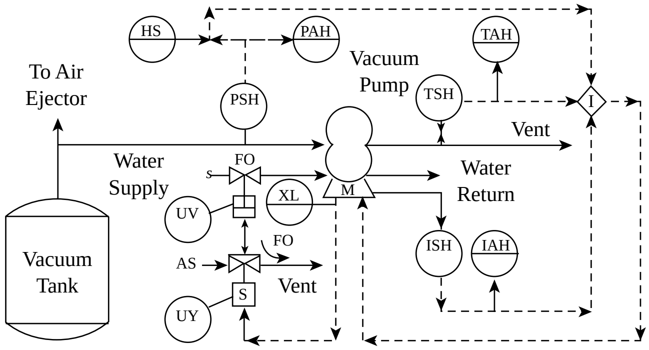

FIG. 1.12b
Control system for standby vacuum pump.

LOGIC DIAGRAMS

Consider a section of a chemical vapor deposition process that includes only a backup vacuum roughing pump. The process function diagram, Figure 1.12a, along with its accompanying process flow sheet, Figure 1.12b, are expected to provide all of the information required to understand the control scheme and general operation of this process subsystem. For the example illustrated, the process flow sheet indicates the equipment and instrumentation associated with the operation of the backup vacuum pump. However, a P&ID has its limitations. For example, this P&ID indicates that the vacuum pump is water-cooled but does not provide any plumbing details. In addition, the diagram makes little or no attempt to indicate the specific details of the reactor's backup vacuum control scheme. In fact, key control components, start and stop pushbuttons for example, are commonly omitted in P&IDs.

The role of the process function diagram and the binary logic diagram is to illustrate the overall control flow of the process. The diagram is a combination of logic and instrumentation symbols that reflects the overall control strategy. It also includes the details for the successful operation of the specified process equipment. For the example under consideration, the binary logic diagram indicates the operation requirements for the auxiliary vacuum pump. Note that the symbol for this pump doesn't even appear in the diagram; however, its operational characteristics with respect to the cooling water system are clearly indicated. In addition, the diagram does not provide for the reader or require the reader to possess knowledge of the complex and specialized circuit information associated with the assembly of the instrumentation presented. Its function is to provide an informed view

---

* Permission by the ISA to abstract from its standard, ANSI/ISA S5.2 Binary Logic Diagrams for Process Operators, is gratefully acknowledged.

of the process to operating personnel, maintenance workers, process engineers, and others who need to appreciate the expected behavior of the specified process equipment.

LOGIC SYMBOLS

Although the symbols selected to represent the logic operations associated with a control scheme are arbitrary, the choice of logic operations is universally consistent. All process function diagrams describe a process control scheme as a sequence and/or combination of the AND, the OR, the NOT, the NAND, and the NOR logic operations. Table 1.12c summarizes the ANSI/ISA standard symbols that describe these operations. The additional symbols in the table illustrate other commonly represented logic functions.

It is important to recognize that binary logic diagrams are "living" documents. Because they illustrate a process control procedure, binary logic diagrams also reflect any updates in process control strategy as well as the personalities of the process personnel who create and maintain the documents. As a result, it is likely that a selected (i.e., standard) set of diagram symbols will be modified within a company's various plant locations across the country, and completely different symbol sets may be adopted by different process industries.

Table 1.12d summarizes another common set of logic symbols. These symbols are often used in the description of digital electronic circuit operation. As a result, they are particularly popular with process technical personnel with computer science or electrical engineering backgrounds. Although this and other varieties of logic symbolism for binary logic diagrams exist, once the diagram reader's attention is focused on the logic operations represented, the significance and meaning of even unfamiliar symbols becomes apparent.

PREPARATION OF LOGIC DIAGRAMS

The number of logic operations involved dictates the arrangement of the symbols on a binary logic diagram. There are no specific rules as to symbol placement. Most process function diagrams depict the flow of information from top to bottom and left to right. Lines interconnect the logic symbols, and arrowheads might be added to lines where the input to output directions are not clear.

A summary of possible final control element operating states is often added to the diagram when the control action is not the result of one of two specific alternative states. For example, if the control action involves a control valve, it is not sufficient to indicate that the valve is not closed. This could mean that the valve is completely open or that the valve is in some position between almost closed and wide open. Since logic diagrams should be interpreted as literally as possible, in this example, the reader would accept that the diagram indicates that the valve was not closed but make no assumptions as to its degree of openness.

By contrast, if a logic diagram indicates that the result of the logic operations is the control of a constant-speed pump, it is sufficient to indicate the pump's state as either operating or not operating, i.e., the logic one or logic zero state. In this case, it would be the reader's responsibility to recognize that any variation in pump throttling was not the result of the control signal to the pump but rather due to the action of a separate signal to its accompanying valve. The two possible pump logic signals are responsible only for starting or stopping the transfer of energy to the pump. Any planned adjustment in the fluid flow rate is not the result of the logic one or logic zero binary signals delivered to the pump.

The binary logic diagram may have additional inputs to its logic symbols that do not represent actual process variables. For example, a process operation may be affected by loss of a component power supply. This would be especially true if the process equipment involved had electronic memory elements, and that memory was vital to the specific operation under consideration. Thus, the power failure might adversely affect the performance of one part of the process but not shut down its operation or directly influence the operation of other elements of the process. To take such situations into account, it would be necessary to consider the effect of that power loss on the logic of that component's operation and indicate what the new control action might be. In such cases, power or loss of power should be entered as a logic input to the diagram. The diagram should then indicate the expected sequence of events as if the power signal were just an additional binary process input to the entire process.

The indication of time delays and other time functions is common in binary logic diagrams. It is recommended for clarity that a single time function symbol be used to represent each single time function in the diagram. The use of one symbol to represent a sequence of unusual or complex time functions in immediate succession is often confusing to the reader. Even the correct use of NOT operations combined with a time function is confusing and often leads to the diagram reader reaching the opposite conclusion intended from these symbol combinations.

It is quite common for the binary logic diagram for a process to require more than one page of drawings. When the diagram has more than one page, each sheet should be clearly labeled with the plant location, the process identification, the last update to the diagram, and which page out of the total this sheet happens to be. For example, each sheet of an 11-page logic diagram might be labeled:

> "Cheese Curd Vacuum Packing Process"
> Tug Hill Packing Plant

The fifth sheet for this process diagram would have the additional information:

> "Auxiliary Vacuum Pump Control"
> Last Update: March 15, 2003
> Sheet 5 of 11

TABLE 1.12c
Binary Logic Diagram Symbols

<table>
<tr><th><i>Function</i></th><th><i>Symbol</i></th><th><i>Definition and Truth Table</i></th><th><i>Example</i></th></tr>
<tr><td>INPUT</td><td>(Input statement) ⊢
Statement may be preceded by instrument balloon with tag number.</td><td>Input for logic value or sequence of values.</td><td>Start chemical injection by pushbutton.
Start injection manually ⊢</td></tr>

Basic Method
This uses the following specific symbols:
<table>
<tr><th>Symbol</th><th>Meaning</th></tr>
<tr><td>DI</td><td>Delay Initiation of output. The continuous existence of input *A* for a specified time causes output *B* to become active when the time expires. *B* becomes passive when *A* becomes passive.</td></tr>
<tr><td>DT</td><td>Delay Termination of output. When input *A* is active, output *B* becomes active. When *A* becomes passive for the specified time, Output *B* will become passive (terminate) as well.</td></tr>
<tr><td>PO</td><td>Pulse Output. If Input *A* becomes active and then immediately passive, output *B* is active for specified time.</td></tr>
</table>
</td><td>
If a Pressure Alarm High is active (in alarm) for 4 sec, the auxiliary vacuum pump is engaged. The pump shuts down when the PAH becomes passive.

When the auxiliary vacuum pump is active (running), the water jacket pump is also engaged. When the auxiliary vacuum pump is shut down, the water jacket pump remains on for 5 min before it shuts down. If vacuum pump is started before 5 min is up, water jacket pump stays on.
If vessel purge fails even momentarily, operate evacuation pump for 3 min and then stop the pump.
</td></tr>
</table>

In addition to this detailed labeling of each sheet of the diagram, care must be taken to identify lines that come from or go to other sheets of the drawing. There are no standards for accomplishing this, but one good practice is to repeat the label on a line that leaves one sheet as that line begins again on another sheet. Another popular approach to the task is to identify each sheet entrance and exit line with its source and destination. Numbering all exit lines from one sheet from top to bottom and then identifying each line that enters a new sheet in the same manner is the usual approach. With this numbering system in hand, each line entering or leaving a sheet can be identified with its source and destination address.

For example, suppose a diagram line that leaves sheet 5 of a binary logic diagram was labeled 5–7/8–3. This label would identify that logic signal as exit signal 7 from sheet 5 and indicate that it was going to enter sheet 8 as the third external input from the top of the page. To complete the redundancy for this numbering system, 8–3/5–7 would be the label on the third external input line from the top of sheet 8. This tag would confirm that the signal in question indeed was the third external sheet source input signal for sheet 8 and that this particular signal was also the seventh off-the-sheet output from sheet 5. Letters and numbers are often interlaced in this identification scheme, but the source, destination, and redundancy aspects of the system are always maintained.

In summary, the creation of a binary logic diagram requires specific knowledge of how the process is controlled. In addition, this type of process function diagram must be clearly

TABLE 1.12d
An Alternate Set of Logic Symbols

Function	*Symbol*	*Definition*
AND		If PSH and TSH are both at logic 1, then output to pump alarm is at logic 1
OR		If either PSH or TSH is at logic 1, then output to pump alarm is at logic 1
AND		If PSH and TSH are both at logic 1, then output to pump alarm is at logic 0
OR		If either PSH or TSH is at logic 1, then output to pump alarm is at logic 0
Mixed		If PSH is at logic 0 or TSH is at logic 1, then output to pump alarm is at logic 0

Note: When logic 1 is assigned to the high physical signal value, the output of an AND device is active when it is at logic 1.

TABLE 1.12e
Intermediate Position Labels

Device State	*Definition*
Open position	Device 100% open
Not open position	Device less than 100% open (may or may not be closed)
Not closed position	Device more than 0% open
Closed position	Device that is 0% open
Intermediate position	Device at specific position (greater than 0% but less than 100% open)
Not-at-intermediate position	Device at position above or below the specified intermediate position (0% or 100% open)

labeled and religiously updated. Below are several common-sense guidelines that will help develop a good diagram:

1. Develop the logic diagram in such a way that it presents results in a positive logic format. For example, if the result of the logic operation is to completely open a valve, it should be so stated and not be stated as being "not closed."
2. Use a specific separate label to indicate conditions of final control elements that have more than two responses to binary signals. Table 1.12e defines labels for devices that have open, closed, and intermediate positions.
3. Label each input and output of each set of logic operations on every sheet of the diagram.
4. Label each external input or output for each sheet of the diagram so that its source and destination are clearly understood.
5. Adopt a standard set of logic symbols and instrument labels (see Section 1.1), and resist the temptation to modify your logic symbols for the "special situation" that inevitably develops. If the situation cannot be initially explained with relatively simple combinations of AND, OR, NOT, NAND, and NOR symbols, think about it some more until it can be done that way.
6. Avoid using ladder diagrams or ladder diagram logic symbolism. These types of icons are useful when installing or troubleshooting the control scheme but are only routinely used and understood by a small percentage of the technical personnel who need to know about the process.

These useful rules of thumb all follow from one "golden rule."

> *If the binary logic diagram does not clearly, easily, and unambiguously indicate what is going on in the process, then the diagram is of marginal value and should be reworked until it does.*

Following this rule will increase the chances of having the diagram match what it is intended to say with what it actually says.

DIAGRAM INTERPRETATION

Even if authors follow the "golden rule" when creating logic diagrams, interpreting logic diagrams is not always an easy assignment. Consider the example process presented in this section. Its process function diagram, Figure 1.12a, describes the operation of a standby vacuum pump system for a process that needs to maintain a specified pressure in the vacuum tank illustrated in Figure 1.12b. Information about the panel instrumentation indicated in Figure 1.12b is provided in Table 1.12f. Complete details about the other instrumentation symbols used in Figure 1.12b are available in Section 1.1.

The logic diagram shown in Figure 1.12a indicates that the backup pump control is based on the binary value from seven independent process input signals. By contrast, a close inspection of the diagram reveals the existence of only one independent output signal. This example's high ratio of input to output signals is typical of most binary logic diagrams, indicates the reason why logic diagrams might be difficult to interpret, and suggests that a good way to analyze the entire diagram is to study it from right to left.

TABLE 1.12f
Control Panel Instrumentation

Panel Symbol	*Instrument Function*
HS	Manual control switch for pump operation. Three momentary-contacts for Start, Automatic, and Stop actions.
PAH	Alarm if vacuum fails. Alarm sounds 10 min after backup vacuum pump start request.
TAH	Temperature alarm if pump discharge temperature rises above normal operating value.
XL-A	Green pilot lamp when bright indicates pump motor circuit breaker is not closed, i.e., pump cannot operate.
XL-B	Amber pilot lamp when bright indicates pump is ready for automatic start.
XL-C	Red pilot lamp when bright indicates pump motor circuit breaker is closed, i.e., the pump can operate.

Note: XL-C is not connected to a pump motor feedback signal. It cannot confirm that motor is on.

As stated above, the condition of all four output logic signals in Figure 1.12a (i.e., the red and green pilot lamps, the cooling water control value, and the pump operation signal) depends on the logic state of a single output. This is represented as the logic output from the "memory lost on loss of power" memory operation of the LS flip-flop located on the upper far right side of the diagram. The logic one signal on this output will cause the pump to be engaged, the cold-water control valve to open, and the red closed motor circuit-breaker light to glow. The logic signal inversion represented by the circle symbol between the flip-flop output and the green not-closed motor circuit-breaker light (XL/A) assures that the green light is not glowing when the flip-flop output is at logic one.

It should be clear at this point in the analysis of Figure 1.12a that the input signals to the LS flip-flop are the key to understanding the operation of the backup vacuum pump. The diagram indicates that this flip-flop is controlled by two input logic signals: a signal that comes from an AND operation (the "pump run" AND) and a signal that comes from an OR operation (the "pump reset" OR). It is also clear, but not necessarily appreciated by the reader, which of these two input signals is more important.

The output of the "pump reset" OR device goes to the reset terminal of the memory lost on loss of power to the flip-flop. If this OR output is at logic one, the flip-flop's output resets to logic zero. This logic signal forces the pump to shut down, the cold water control valve to close, and the red panel indicator (XL/C) to go off.

The circle around the letter R in the memory lost on loss of power flip-flop symbol indicates that a logic one output from the "pump reset" OR will initiate the flip-flop reset action even if the output of the "pump run" AND device is at logic one. Since the HS "STOP" signal is directly connected to one of the inputs of the "pump reset" OR, placing the hand switch in the HS "STOP" position allows the pump to receive the logic zero reset signal from the LS flip-flop and stop running.

Although not directly connected to the "pump reset" OR, activation of either the PUMP MOTOR OVERLOAD CIRCUIT BREAKER or the PUMP DISCHARGE HIGH TEMPERATURE (TSH) alarm produces logic signals that generate the same control action as the HS "STOP" input. These two control signals feed to an OR that is connected to the other input of the "pump reset" OR. Therefore, a logic one output signal from this OR produces the same response in the "pump reset" OR as a logic one signal from the HS "STOP".

The "memory maintain on loss of power" flip-flop is located in the lower left portion of Figure 1.12a. It is arranged so that, if both its inputs are activated simultaneously, the PUMP MOTOR OVERLOAD CIRCUIT BREAKER signal overrides the MANUAL RESET signal. In other words, the pump cannot start again until the pump motor overload has been cleared. Once that pump motor circuit problem no longer exists, a logic one MANUAL RESET signal will produce a logic zero on the memory-maintain flip-flop. If the TSH sensor is not in alarm (i.e., at logic zero) or the HS "STOP" is not engaged (i.e., at logic zero), then the logic zero output from the flip-flop is passed directly to the reset input of the memory lost on loss of power flip-flop. Although, at this point, the flip-flop's output still remains at logic zero, and the pump remains off, the pump will engage the next time the "pump run" conditions are satisfied.

"Pump run" operating scenarios are determined by the output of an AND operation. This "pump run" AND is the other input connected to the "memory lost on loss of power" flip-flop. If the output of the "pump run" AND is at logic one, the pump will be turned on. The only constraint on this logic

TABLE 1.12g
Control Valve Operating Sequence

Current Vacuum Pump Status	*Motor Circuit Breaker Auxiliary Contacts*	*Solenoid Valve (UY) Coil*	*Control Valve (UV)*		
			Actuator	*Port*	*Water*
Off	Closed	Energized	Pressurized	Closed	Off
On	Open	De-energized	Vented	Open	On

one "pump run" signal is if the reset input to the memory-loss flip-flop is already at logic one. Under that condition, the "pump run" signal will not override the reset, and the pump will not start.

There are two inputs to the "pump run" AND operation. The HS "START," HS "AUTOMATIC," and SYSTEM HIGH PRESSURE (PSH) process signals identified in the upper left corner of Figure 1.12a all eventually feed their logic signals to one of these inputs. Basically, the pump will engage if the hand switch is in the HS "START" position or if it is in the HS "AUTOMATIC" position and the PSH is in alarm, i.e., at logic one. An operator panel alarm function is also provided when PSH goes into alarm. If the pressure alert is not corrected within 10 min (i.e., the backup vacuum pump has not returned the vacuum tank to an acceptable vacuum condition), a panel alarm, PAH, will be activated.

The other input to the "pump run" AND is a gate signal from the TSH and PUMP MOTOR OVERLOAD CIRCUIT BREAKER logic section of the diagram. This gate signal is at logic one only when the pump is not in a temperature or overload circuit alarm condition. If either such alarm condition exists, the gate input to the "pump run" AND would be at logic zero and the pump would not run even if the reset input to the "memory loss on lost power" flip-flop were at logic zero.

ACTIVE AND PASSIVE LOGIC

The example process provided in this section is adequate to illustrate the important aspects of drawing and reading a process diagram. This specific logic diagram is typical with respect to elements in the diagram but not in the number of these elements. To read diagrams that have many more components and interactions among them, it is convenient to initially identify the input and out logic signals as active or passive and then further classify the logic device inputs and outputs as active high or active low. For the example presented in Figure 1.12a, the vacuum pump is active when a logic one signal is presented to that pump. By contrast, the XLA indicator is active when the logic zero signal is presented to it. Thus, the vacuum pump input terminal is identified as an active high input while the XLA indicator input terminal is an active low input. When the vacuum pump is not running, the signal to the pump is the passive logic signal; when the XLA indicator is on, the signal to that device is the active signal. Thus, the entire logic diagram can be initially reviewed by first establishing what the active and passive signals are for each device represented in the diagram and then determining if the input and output terminals for each device are identified as active high or active low terminals.

For this standby vacuum pump example, the AND device that accepts signals directly from the HS "automatic" and PSH field elements has two active high inputs and one active high output. The AND device that controls the LS flip-flop has an active high input, an active low input, and an active high output. The three OR devices each have two active high inputs and one active high output. The efficiency of this identification scheme is appreciated once it is realized that the output of an AND logic device is active only when all its inputs are active, while the output of an OR device is active when any of its inputs are active. Thus, it becomes clear very quickly that the OR device in the lower part of the diagram that deals directly with high-temperature and motor-overload situations can prevent the HS "automatic" input from activating the standby vacuum pump. It also becomes clear that, when the output of that OR device is active, the LS flip-flop is reset, and the vacuum pump would stop if running. In other words, the vacuum pump becomes passive.

FINAL CAUTION

Now that the function diagram in Figure 1.12a has been reviewed, a few concluding remarks are in order. A complete understanding of a process requires all three types of diagrams in the process documentation package. For the example sited, no attention was focused on the hardware diagram. In fact, assumptions were made to facilitate the explanation of Figure 1.12a. For example, Figure 1.12a does not indicate how the green not-closed motor circuit-breaker light (XL/A) is wired. If it uses a pull-up resistor type wiring scheme, then the light is off when the motor is running. However, if XL/A is wired directly to its source, then the inverted logic one from the memory lost on loss of power LS flip-flop will allow the XL/A light to glow. If this were the situation, many binary logic diagram authors would draw a line over the XL/A symbol to indicate that the green not-closed motor circuit-breaker light had an active low input. This would indicate that the light would glow when it detected the low logic signal. Always check the wiring diagram to determine the active/passive signals for all sensors and final control elements included in a binary logic diagram.

The biggest danger when reading a binary logic diagram is projecting what "should" be there instead of reading the diagram as it is written. There are often different views as to how to implement the specific details for a process control strategy. The example process discussed in this section is no exception to that observation. Constructive criticism about a control scheme is an important aspect of improving the control of a process. However, it is important to distinguish between not liking the logic presented in a logic diagram and mentally refusing to read the logic as it is presented in the diagram. The responsibility of binary logic diagram creators is to produce unambiguous diagrams that explain the process's current control logic. The responsibility of binary logic diagram readers is to interpret the diagram without altering its mental image with personal bias about the control scheme described. Once the creator and reader of a logic diagram agree as to what the diagram says, then it is time to discuss the merits of the current control scheme and consider any reader-suggested alterations.

2.1 Application and Selection

D. J. LOMAS (1982) **B. G. LIPTÁK** (1995, 2003)

No industrial measurement is more important than the accurate detection of the flow rates of gases, liquids, and solids. In this section, an overview is given of the availability and characteristics of some of the most widely used flow sensors. In addition, emphasis is given to the latest developments, such as the polyphase (oil/water/gas) and the wide-rangeability dual-rotor turbine flowmeters. General guidelines are provided about selecting the best flow sensor for a particular application.

GETTING ORIENTED

Table 2.1a provides information on conversion factors among flow measurement units, whereas Table 2.1b summarizes the features and capabilities of more than 20 flow sensor families. The variety of choices that an application engineer faces is even greater, because nearly every flowmeter category can be further subdivided into a variety of distinctly different subcategories. For example, the positive-displacement type of flow sensors include rotary piston, oval gear, sliding vane, and reciprocating piston designs. If these subvariants are also counted, the number of flow sensors available for consideration is even higher.

The selection process should consist of at least two steps. First, identify the meters that are technically capable of performing the required measurement and are available in the required size and materials of construction. Once such a list has been developed, proceed to consider cost, delivery, performance, and other factors to arrive at the best selection.

When considering a particular application, we might use a yellow marker on a copy of Table 2.1b to highlight the nature of the process fluid, the purpose of the measurement, and the displays or transmission signals required. By this process, we are likely to eliminate from consideration about half of the flow sensors listed in the table.

TABLE 2.1a
Conversion of Volume or Flow Units

gallons of water	pounds of water	8.3453
gallons/min	cu. ft/sec	2.228×10^{-3}
gallons/min	liters/sec	0.06308

After this first pass, concentrate on the performance requirements, such as the maximum error that can be tolerated (defined either as a percentage of actual reading or full scale) and the required metering range. Based on the error limits and range requirements, we can next determine the rangeability required for the particular application (the ratio of maximum and minimum flow limits within which the

pounds	tons (short)	0.0005

specified error limit must not be exceeded) and identify the flow sensor categories that can provide such rangeability.

After considering such key criteria as rangeability, it is appropriate to prepare a list of other requirements that might relate to installation, operation, or maintenance and, by referring to Tables 2.1b through 2.1e, check their availability. Usually, by the end of this process, the choice will have been narrowed to two or three designs.

Having narrowed the choices, the application engineer is advised to turn the pages of this handbook to the sections in which the selected flowmeter designs are discussed. At the beginning of each of these sections, a “feature summary” is provided, containing data on the limits on operating pressure and temperature, sizes, construction materials, costs, and other factors. The final selection is usually made by choosing the least expensive flow sensor that possesses all the features and characteristics needed for the application.

Special Requirements

To consider such special features as reverse flow, pulsating flow, response time, and so on, it is necessary to study the individual meter specifications in detail. Sometimes it is also necessary to obtain unpublished test data from the manufacturers.

Although the steps we have described will eliminate the technically unsuitable meters, it does not necessarily follow that a meter will always be found that is perfectly suited for a given application. For example, electromagnetic flowmeters are available for operating at pressures as high as 1500 PSIG (10.3×106 N/m^2). They are also available for flow rates as high as 500,000 GPM (31.5 m^3/sec), but they are not available to detect a flow rate of 500,000 GPM at 1500 PSIG.

The list of technically suitable meters will get shorter as the complexity of the application increases. For an application in which the flow of a highly corrosive and nonconductive sludge is to be measured, the list of acceptable sensors might consist of a single meter design (the cross-correlation type discussed later in this section). In contrast, on a straightforward clean-water application, the list will consist of most of the flow detectors listed in the orientation table (Table 2.1b).

In such cases, the engineer should narrow the choice by concentrating on the reasons for measuring the flow. We should ask if high accuracy is the most important or if the emphasis should be on long-term repeatability, low installed cost, or ease of maintenance. It should also be realized that certain flow detectors, such as those for the measurement of two-phase flow, are still in the developmental stage and are not readily available.[1–4]

In the following paragraphs, the features, characteristics, and limitations of some of the more widely used flow sensor categories will be briefly discussed. After that discussion, the important considerations of cost, accuracy, Reynolds number, safety, and installation requirements will be covered.

DIFFERENTIAL PRESSURE

The detection of pressure drop across a restriction is undoubtedly the most widely used method of industrial flow measurement. The pressure decrease that results from a flowing stream passing through a restriction is proportional to the flow rate and to fluid density. Therefore, if the density is constant (or if it is measured and we correct for its variations), the pressure drop can be interpreted into a reading of flow. This relationship is described by the following formula:

$$Q(\text{flow}) = K(\text{constant})\sqrt{\frac{h(\text{differential head})}{d(\text{fluid density})}} \qquad \textbf{2.1(1)}$$

Differential-pressure (d/p) meters have the advantage of being the most familiar meter type. They are widely used to measure the flow of both gases and liquids, including viscous and corrosive fluids. Their advantages include the lack of moving parts and a suitability for practically all flow rates in a wide variety of pipes and tubes.

All differential-pressure meters exhibit a square-law relationship between the generated head and flow rate, which severely limits their rangeability (typically 3:1, with 4:1 being the maximum). Another disadvantage of d/p type flowmeters is that, in addition to the sensor element, several other components are needed to make a measurement. These include not only the readout or transmitter but also a three-valve manifold and fittings to attach the readout or transmitter

to the sensor. As a result, the installation is time consuming and, as a result of the many tube or pipe joints, it requires relatively high maintenance to eliminate leakage.

Reynolds Number

If the Reynolds number (Re) and flow rate are both constant, the output signal of a head-type flowmeter will also be constant. However, if the Re changes, that will also change the meter reading, even at constant flow. Therefore, it is recommended to calculate the Reynolds numbers at both maximum and minimum flows and check whether the corresponding change in flow coefficients is within the acceptable error. If it is not, a different type of sensor must be selected, such as the quadrant-edged orifice for low-Reynolds-number applications or a flowmeter type that is insensitive to Reynolds variations, such as the magnetic meter.

Figure 2.1f depicts the relationship between the pipeline Reynolds number and the discharge coefficients of various head-type flow elements. The Reynolds number can be calculated by the following equation:

$$\mathrm{Re} = \frac{3.160 G_f Q_f}{D\mu} \tag{2.1(2)}$$

where

G_f = process fluid specific gravity (at 60°F, or 15.5°C)
Q_f = liquid flow in GPM
D = pipe inside diameter (in inches)
μ = viscosity of the process fluid (in centipoise)

As shown by Figure 2.1f, the orifice plate discharge coefficient is constant within ±0.5% over a Reynolds number range of 2×10^4 to 10^6. The discharge coefficient being constant guarantees that no measurement errors will be caused by Reynolds number variations within this range. On the other hand, if, at minimum flow, the Reynolds number would drop below 20,000, that would cause a substantial increase in the discharge coefficient of the meter and a corresponding error

in the measurement. Therefore, it is advisable to limit the use of orifice plates to applications where the Reynolds number stays above 20,000 throughout the flow range.

Energy Costs

In larger pipes or ducts, the yearly energy operating cost of d/p-type flowmeters can exceed the purchase price of the meter. The permanent pressure loss through a flowmeter is usually expressed in units of velocity heads. The velocity head is calculated as $v^2/2g$, where v is the flowing velocity and g is the gravitational acceleration (9.819 m/sec^2 or 32.215 ft/sec^2 at 60° latitude).

Therefore, the velocity head at, say, a flowing velocity of 10 ft/sec is calculated (in the English units) as $10^2/64.4 = 1.55$ ft of the flowing fluid. If the flowing velocity is 3 m/sec, the velocity head is calculated (in the metric units) as $32/19.64 = 0.46$ m of the flowing fluid. The velocity head is converted into pressure drop by multiplying it with the specific gravity of the flowing fluid. As shown in Table 2.1g, the different flowmeter designs require different pressure drops for their operation.

One can calculate the yearly operating cost of any flow measurement installation by using the following formula:

$$\$/\text{yr} = C(\$/\text{KWH})(OT)(dP)(F)(SpG)/(\%) \qquad \textbf{2.1(3)}$$

where

C = a correction factor for the units used ($C = 1.65$ if the flow is in GPM and the pressure loss is in feet)
$/KWH = unit cost of electricity in the area
OT = operating time of the meter (1.0 if operated continuously)
dP = pressure loss in velocity heads in the particular meter (units are feet or meters)
F = flow rate (units are in GPM or m^3/sec)
SpG = specific gravity of the flowing fluid (water = 1.0)
% = efficiency of the pump (or compressor) expressed as a fraction (70% = 0.7)

Example Let us calculate the yearly cost of operation if an orifice sized for 100-in. H_2O pressure drop ($dP = 8.333$ ft =

TABLE 2.1g
Velocity Head Requirements of the Different Flowmeter Designs

Flowmeter Type	*Permanent Pressure Loss (in Velocity Heads)*
Orifice plates	Over 4
Vortex shedding	Approximately 2
Positive displacement	1 to 1.5
Turbine flowmeter	0.5 to 1.5
Flow tubes	Under 0.5

3.6 PSID) in a 16-in. schedule 40 steel pipe is measuring the flow of 5000 GPM of water flow. The meter is operating continuously ($OT = 1.0$), the cost of electricity is \$0.1/kWh, and the pump efficiency is 60% (% = 0.6).

$$\begin{aligned}\$/\text{yr} &= 1.65(0.1)\,(1.0)\,(8.333)\,(5000)\,(1.0)/0.6\\ &= \$11{,}457 \text{ per year}\end{aligned} \qquad \mathbf{2.1(4)}$$

If the cost of electricity is \$0.1/kWh and the pumping efficiency is 60%, the operating cost of any continuous pressure drop in any water pumping system can be calculated as

$$\$/\text{yr} = 0.635\,(\text{GPM})\,(\text{PSID}) \qquad \mathbf{2.1(5)}$$

Therefore, when selecting a flowmeter, we should consider not only the purchase and installation costs but also the operating cost during the life of the flowmeter. As was shown above, a major component of the operating cost of flowmeters is their pumping (or compressor operating) energy costs.

In the following paragraphs, the main advantages and disadvantages of the large family of d/p measurement-based flow sensors (Figure 2.1h), this most widely used flowmeter category will be discussed. The discussion here will be limited to the highlights of sensor features. For an in-depth discussion of their features and characteristics, the reader should turn to the appropriate section in this chapter that is devoted to the particular design.

Orifice Plates

Orifice plates are the simplest and least expensive flow element within the d/p-type sensors. The total installed cost is relatively independent of pipe diameter, because the cost of the piping manifold and the differential-pressure readout or transmitter are unaffected by pipe size and are relatively constant. Consequently, the orifice-type installations are relatively expensive in smaller pipe sizes and rather economical in pipe sizes over 6 in. (150 mm).

Orifices can be used in a wide range of applications, because these plates are available in a variety of materials and in many designs, such as concentric, segmental, or eccentric. Another advantage is that the orifice plate can be badly worn or damaged, yet it will still provide a reasonably repeatable output, albeit significantly inaccurate. Another very convenient feature of the orifice-type installation is the ability to service or replace the readout or transmitter without the need to remove the orifice or to interrupt the process flow.

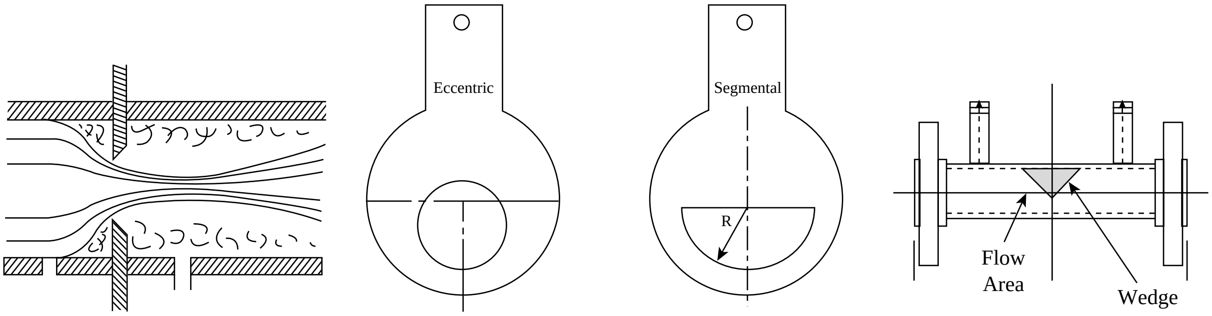
The main disadvantages are the low accuracy[5] (Figure 2.1i) and low rangeability of standard orifices, although substantial improvements been reported (error under 1% of actual flow over a 10:1 range) when intelligent and multirange d/p cells are used. Other disadvantages of orifice-type installations include the high irrecoverable pressure loss (40 to 80% of the generated head) and the deterioration in both measurement accuracy and in long-term repeatability as the edge wears or as deposits build up. High maintenance is another disadvantage in installations where manifold leakage or pressure tap plugging are likely.

Orifice-type flow measurement has been modified, and new, special-purpose devices have been introduced to meet particular process requirements. One such unique design is the annular orifice used to measure the hot and dirty gases in the steel industry. Here, the process flow passes through an annular opening between the pipe and a disk-shaped, concentrically located plate, and the pressure difference is detected between the upstream and downstream faces of that disk. This design is shown in the section on target meters.

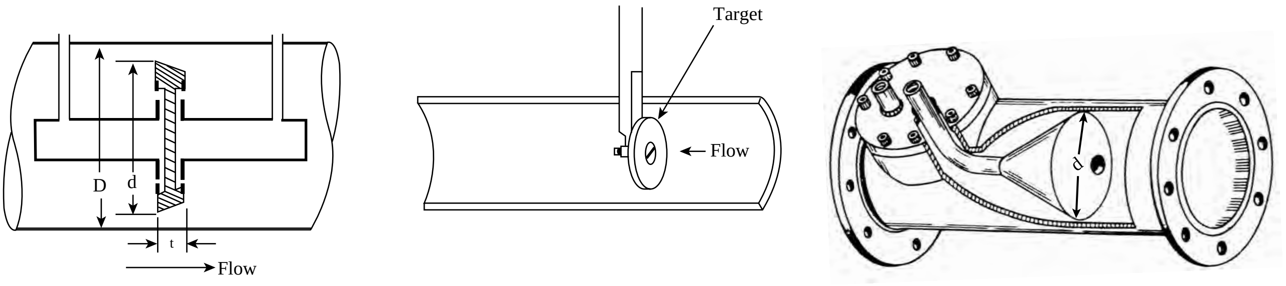
For paper pulp or slurry flow detection, the segmental and eccentric orifices (Section 2.15), venturi cones (Section 2.28) and the segmental wedge elements (Section 2.21) have been developed. The venturi cone is shaped as a restriction in the center of the flow path, forcing the flowing stream into an annular space between the cone and the pipe. The segmental wedge element restricts the flow passage, because the top of the pipe is indented. These sensors are all used on dirty fluids or fluids at higher temperatures.

Venturi Tubes and Nozzles

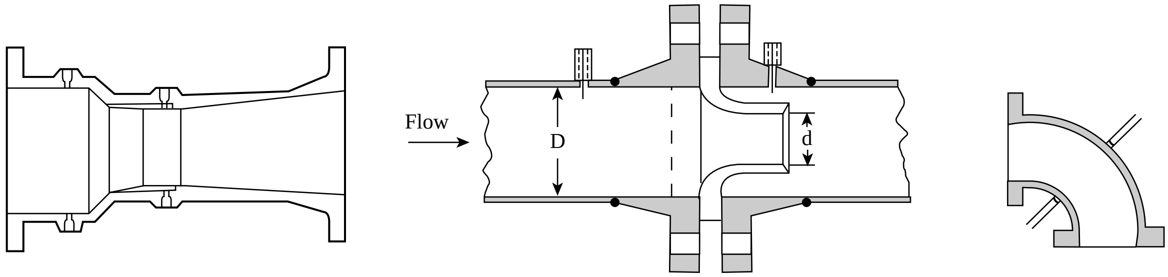
The shapes of these tubes and nozzles have been obtained with the goal of minimizing the pressure drop across them. These tubes are often installed to reduce the size of (and therefore capital expenditures on) pumping equipment and to save on pumping energy costs. In contrast with the sharp-edged



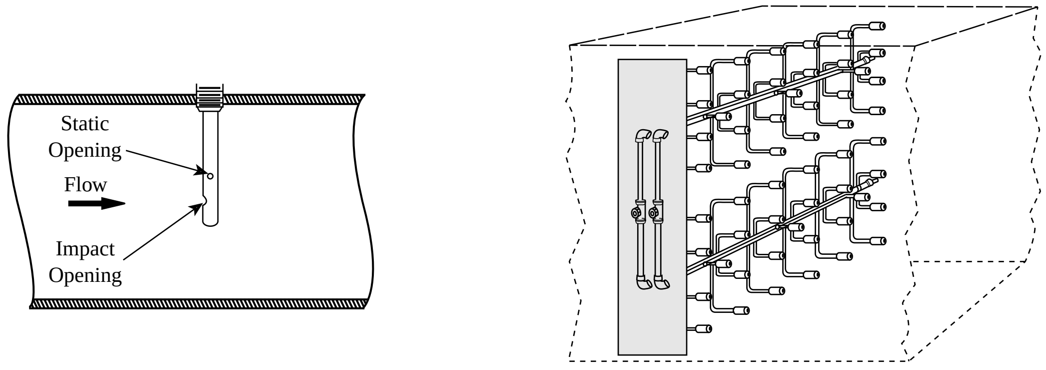
a) Sharp-edged, eccentric, segmental orifice and wedge designs



b) Annular, target and V-cone designs



c) Venturi tube, flow nozzle and elbow tap designs



d) Conventional and area-averaging pitot tube designs

FIG. 2.1h
Pressure difference producing flowmeter designs.

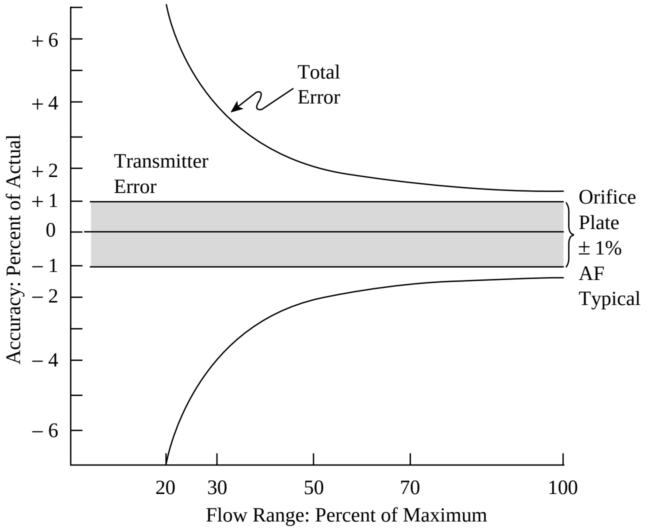


FIG. 2.1i
Total error of an orifice type flow measurement, using a ±1/2% full-scale d/p cell, is shown as a function of actual flow.

orifice, these tubes and nozzles are resistant to abrasion and can also be used to measure the flow of dirty fluids and slurries. They are, however, considerably larger, heavier, and more expensive than the orifice plate. Their installation is also more difficult.

Flow nozzles represent a transition between orifices and flow tubes. They are less expensive, but they produce more head loss than do the flow tubes.

Sonic Venturi Meters

A flowmeter with very high rangeability can be obtained when the venturi tubes are inserted into a multiport digital control valve (illustrated in Figure 2.1j) in which the area of each port is twice the size of the next smaller one. The on/off ports are opened through binary manipulation and, therefore, the meter rangeability is a function of the number of ports used. With 8 ports, the rangeability is 255:1; with 10, it is 1023:1; with 12 it is 4095:1; and so on. The digital control valve is converted into a flowmeter by inserting a sonic velocity venturi into each of the ports. A sonic velocity venturi element passes a known and constant flow rate when the flow velocity at its throat reaches sonic velocity. Therefore, this flowmeter requires that the meter pressure drop continuously exceed 40% of the absolute upstream pressure to guarantee the continuous presence of sonic velocity of the throat of the venturi tubes. Because of the inherent requirement for this high pressure drop, this meter is ideal for applications in which it is desirable to lower pressure as well as to measure the flow.

The accuracy of the sonic venturi is 1/2 to 1% of actual flow throughout the meter range. With the addition of inlet gas pressure, temperature, and/or density sensors, it can be converted for mass flow measurement. The sonic venturi can also meter the flow of liquids. This flowmeter is available in sizes from 1 to 8 in. (25 to 200 mm). Units have been built for up to 10,000 PSIG (69 MPa) pressure services and for temperatures from cryogenic to 1200°F (650°C).

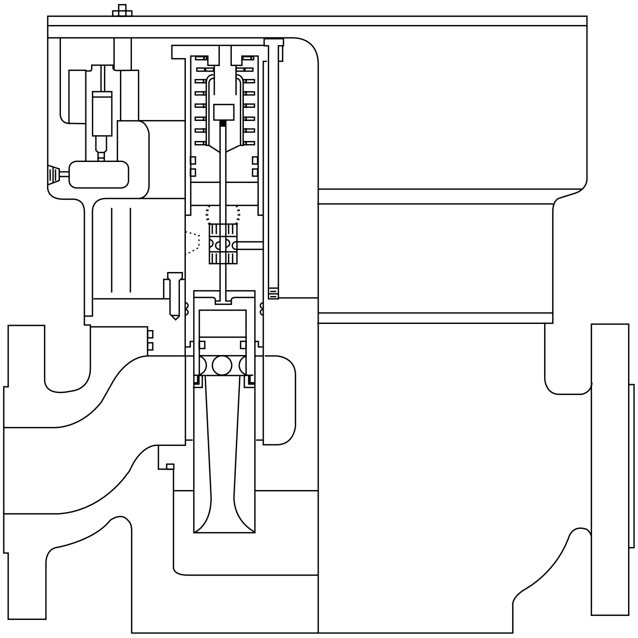

FIG. 2.1j
Sonic venturi digital flowmeter featuring extremely wide rangeability.

Pitot Tubes

A pitot tube is a small, open-ended tube, that is inserted into the process pipe with its open end facing into the flow. The differential between the total pressure on this open impact port and the static pipeline pressure is measured as an indication of flow. For the measurement of large flows, the pitot-tube-type sensors provide a very low-cost measuring system with negligible pressure loss. They are also convenient for temporary measurements and for traversing pipes and ducts to obtain their velocity profiles. Their principal limitation is that they measure the flowing velocity at only one point and therefore, even after calibration, they will be in error every time the velocity profile changes. Therefore, they are used only when low-accuracy volumetric readings are acceptable, such as in HVAC applications. They are also subject to plugging and therefore require substantial maintenance.

To reduce the effect of velocity profile changes and thereby improve the measurement accuracy, multiple-opening pitot tubes and area-averaging pitot traverse stations have also been developed.

Elbow Taps

Elbow taps measure the flow rate by detecting the differential pressure between taps located on the inner and outer radii of an elbow. In larger pipes, this results in a very low-cost installation, because pipe size does not affect cost. This is a crude, inaccurate measurement, requiring high flow velocities and long upstream, straight pipe lengths.

Target (or Impact) Meters

In a target flowmeter, a target or impact plate is inserted into the flowing stream, and the resulting impact force is detected electronically or pneumatically as an indication of flow. The target meter installations are more expensive than orifices but because (in case of the target design) there are no pressure taps to plug, they are better suited for applications in which the process fluid is "sticky" or contains suspended solids. The other advantage is that they have no moving parts. Their accuracy and rangeability (3:1) are low, but they can be reranged.

ELECTROMAGNETIC METERS

Magnetic flowmeters operate in accordance with Faraday's law, because these meters measure the velocity of electrically conductive liquids as they cut the magnetic fields that are maintained across these metering tubes. The main advantages of magnetic flowmeters include their completely unobstructed bore and their lack of moving parts. Because of these features, they introduce no pressure loss and experience no wear and tear on their components. Other advantages include their chemical compatibility with virtually all liquids; indifference to viscosity, pressure, temperature, and density variations; ability to provide linear analog outputs and to measure bidirectional flows; availability in a wide range of sizes; and ease and speed of reranging on site.

Their major limitation is that they can be used only on electrically conducive fluids. (This requirement eliminates their use on all gases and on most hydrocarbon fluids.) Another disadvantage is their high purchase price and the cost of maintaining the magnetic field. To locate the flow tube in an explosion-proof area, the converter and power supply must be remotely located, and intrinsic safety barriers must be installed between them and the tube.

Electromagnetic flowmeters are often recommended for applications involving corrosive aqueous liquids and slurries. In their more recent designs, the magnetic flowmeter probes are provided with electrode cleaners, and the magnetic field is cycled so as to conserve electric energy and to allow automatic rezeroing, which guarantees better accuracy. The use of ceramic flowtubes has reduced their costs while eliminating electrode leakage, because the sintered electrodes cannot leak. The addition of intelligence through digital chips has allowed double-range operation, increased turndown, guaranteed the detection of empty pipes, and reduced the measurement error to within 0.5% of actual flow over a 10:1 range.

TURBINE METERS

In turbine meters, a digital output is generated, which is linear with the process flow, as the speed of rotation of the turbine is measured. Turbine meters can be used in both liquids and gases, and they are suitable for the measurement of both very low and very high flow rates, as insertion designs. The liquid turbine meter is one of the most accurate meters available for low- to medium-viscosity products. Rangeability of single turbine meters is around 10:1, for dual-turbine meters, it exceeds 100:1. Turbine meters can be used under practically any pressure and for applications involving extremely high and low temperatures. They are easy to install and, relative to the pipe diameter, are also small in size and weight. The meter provides a very fast response speed and is suitable for hygienic applications.

Their principal limitations include high cost, incompatibility with viscous or dirty liquids, and the potential for being damaged by over-speeding if slugs of gas or vapor are sent through the liquid meter. The installation of upstream filters is often recommended, in spite of the fact that it increases both the pressure drop and the maintenance requirement of the installation.

Turbine meters are widely used when high-accuracy measurements are required in applications involving product sales. They are also used when high accuracy is required in blending, on test rig duty, and in general measurement. Variations on the basic turbine flowmeter design include nonelectric (fiber optic) detectors; turbine probes; bearingless "hover-flow" designs; and various paddlewheel, impeller, and shunt-flow designs. The impeller and paddle-flow designs cost less but also provide less accuracy than traditional turbine flowmeters.

VORTEX METERS

While fishing in Transylvania, Theodore von Kármán noticed that, downstream of the rocks, the distance between the shed vortices was constant, regardless of flow velocity. From that observation evolved the three types of vortex meters: the vortex shedding, the vortex precession, and the fluidic oscillation versions. All three types detect fluid oscillation. They have no moving components and can measure the flow of gas, steam, or liquid. Their advantages include good accuracy and repeatability, high rangeability, low maintenance, and the ability to provide either frequency or linear analog outputs.

Vortex flowmeters cannot be used to measure the flow of viscous or dirty process fluids. These flowmeters are also limited to sizes under 12 in. (300 mm), because the frequency of fluid oscillation drops off as the line size increases. The other limitation is that vortices do not form at Reynolds numbers below 10,000; therefore, this meter cannot be used in low-Reynolds-number applications.

Vortex shedding meters can be general-purpose, economically competitive alternatives to the orifice plate, and they are also used in many more demanding applications because of their superior accuracy and rangeability.

VARIABLE-AREA METERS

Variable-area meters are widely used for applications in which small flow rates are to be measured or where local indication is required. They are also common in purge meter installations, test rigs, and general industry. Variable-area meters are available in both glass and metal tube construction.

In the glass tube design, the position of the float can be visually observed as an indication of flow rate.

The main advantage of the glass tube design is its self-contained nature, which eliminates the need for power supplies. Other advantages include their low cost, low pressure loss, direct flow indication, and the ability to detect very low flow rates of both gases or liquids, including viscous fluids.

The limitations of all variable-area meters include the need for vertical mounting and that they are available only in smaller sizes. The disadvantages of the glass tube design also include its low accuracy, the limited availability of transmitters, and the design's relatively low pressure ratings.

The metallic tube units are readily available as transmitters and can be obtained in larger sizes, with higher pressure ratings. They provide good rangeability (5:1) and a linear output, but they, too, are limited to use with clean fluids and must be mounted vertically.

A wide variety of the types of designs exist in which gravity has been replaced by spring loading. In these units, an increase in flow results in a compression or deflection of a spring, and this motion is used to operate the display. These units can be mounted in any position, including horizontally, as flow-through pipeline devices.

POSITIVE-DISPLACEMENT METERS

Positive-displacement (PD) meters are often used when accurate quantities need to be delivered, either for reasons of recipe formulation in batch processes or for accounting purposes during sales. The PD meters trap a fixed volume of fluid and transfer it from the inlet to the outlet side of the meter. The number of such calibrated "packages" of fluid is counted as a measure of volumetric flow. Design variations include the rotary piston, oval gear, sliding vane, and reciprocating piston types.

Liquid PD meters offer good accuracy and rangeability (>10:1) and are particularly suited to measure the flow of high-viscosity fluids. These meters provide local readouts and do not require a power supply. When operated as a transmitter, the PD meter's output signal is linear with flow.

The PD meter applications are limited to clean fluids, because their operation depends on close meshing surfaces. Another disadvantage of PD meters is that they require regular recalibration and maintenance, particularly when used to measure the flow of nonlubricating liquids. Another disadvantage is that they are bulky and heavy. Their installed cost is high because, in addition to block and bypass valves, they also require filters and air releases for proper operation.

ULTRASONIC METERS

Ultrasonic meters are ideally suited to measure the flow of very corrosive liquids. They are available in two forms: Doppler and transit-time version.

In case of the Doppler meters, an ultrasonic pulse is beamed into the pipe and is reflected by inclusions such as air or dirt. The Doppler meter is frequently used in a "clamp-on" design, which can be attached to the outside of existing pipelines. It detects the flowing velocity only in a small area where the sonic beam enters the flowing stream. Therefore, if that velocity is not representative of the full cross section of the pipe, the measurement accuracy will be poor. Its main advantage is its low cost, which does not increase with pipe size. Its main limitation is that it is not suitable for the measurement of clean fluids or clean gases.

The transit-time type ultrasonic flowmeters are often found in water treatment and chemical plant applications. Here, single or multiple ultrasonic beams are sent at an acute angle across the flowing stream, first in the same direction as the flow and then in the opposite direction. Flow rate is detected as the difference in transit times. This type of ultrasonic meter is considerably more expensive than the Doppler version, but it offers better accuracy. Unlike the Doppler meter, it is usable only on relatively clean fluid applications. Its advantages include that it introduces no restriction or obstruction to flow, so its pressure drop is low. One limitation is that its performance is a function of the piping configuration, and it requires fairly substantial upstream, straight runs (about 15 pipe diameters).

METERING PUMPS

Metering pumps serve the purposes of both pumping and metering. They usually are used to accurately charge relatively small quantities of clean fluids. Their two basic design variations are the plunger and diaphragm versions. The plunger pump provides better accuracy, whereas the diaphragm type is preferred for dangerous or contaminated fluid services. Their advantages include that they are self-contained, easy to install, and generally provide good accuracy. Metering pump performance is a function of both the process fluid (which must be clean and contain no bubbles) and the process conditions (which must be constant in pressure and viscosity to keep the leakage flow constant). Other disadvantages include their high cost, the need for periodic recalibration, and the requirement for such accessory equipment as filters and air-releases.

MASS FLOWMETERS

The measurement of mass flow can be obtained as the product of volumetric flow and density or as a direct measurement of the mass flow of the flowing process gas, liquid, or solids.

The mass flow of homogeneous gases is most frequently measured by thermal flowmeters. The main advantage of these detectors is their good accuracy and very high rangeability. The main disadvantage is their sensitivity to specific heat variations in the process fluid due to composition or temperature changes. If not compensated for, these changes will register as changes in mass flow. Thermal devices, such as the hot wire anemometers and thermal flow switches, can also detect volumetric flow rates and the flow velocities of process streams.

The mass flow of liquids and gases can be directly detected by angular-momentum devices or indirectly through the measurement of volumetric flow and density. These traditional methods have, in recent years, been overshadowed by the Coriolis mass flowmeter. These units detect the twisting of an oscillating, usually stainless steel, flow tube. This twist is a function of the mass flow through the tube. Coriolis meters can operate at process flow velocities from 0.2 to 20 ft/sec (0.061 to 6.1 m/sec) and therefore can provide a rangeability of 100:1. Their accuracy is also high (0.2% of actual flow), their pressure and temperature ratings are acceptable, and, in addition to the mass flow output signal, they can be provided with additional outputs for signaling alarm conditions or detecting the process fluid's density.

Some limitations include their relatively small sizes (up to 6 in. [150 mm]), their vibration sensitivity, and the inability to handle high-temperature process fluids (over 400°F [205°C]). The Coriolis-based mass flowmeters are very popular in the measurement of fuel flows and reactor feed flows, and in other measurements where the mass rather than the volume of the process flow is of interest.

At low flow rates, the Wheatstone-type mass flowmeter can measure flow within an error of ±0.5% of actual flow over a 100:1 range.

The mass flow of solids in gravity flow installations can be detected by impact flowmeters, which are relatively low-accuracy devices. Better accuracy and rangeability are provided by belt-type gravimetric feeders, which measure both the speed and loading of the moving belt. In addition, the loss in weight-type systems can also measure the mass flow of liquids or solids by differentiating the load cell signal from tank weighing systems. The rate at which the total weight is dropping is the mass flow out of the tank. These systems do not provide high precision and are recommended for the measurement of hard-to-handle process flows, because they do not make physical contact with the process stream.

Cross-correlation flowmeters are available for the measurement of mass flow of solids in pneumatic conveying systems or for volumetric flow measurements. The cross-correlation flowmeter uses statistical means to average the time it takes for particles in a fluid to travel a known distance. The meter can be noninvasive and is suitable for the measurement of the flow of solids and two-phase flows, including heavy slurries and very corrosive and difficult liquid-flow measurement applications. Their disadvantages include high cost, a fairly high minimum requirement on the operating Reynolds number, and poor accuracy.

LOW-FLOW APPLICATIONS

The measurement and control of low flow rates is a requirement in such applications as purging, in bioreactors, in leak testing, and in controlling the reference gas flow in chromatographs or in plasma emission spectrometers.

The most traditional and least expensive low-flow sensor is the variable area flowmeter, which is frequently made out of a transparent acrylic material. It has a high rangeability (10:1) and requires little pressure drop. Due to its relatively low accuracy, it is most often used in purge and leak-detection applications.

A much more accurate low flow detector and controller in gas metering applications is the sonic flow nozzle. This nozzle accurately maintains constant flow as long as sonic velocity is maintained, which is guaranteed by keeping the inlet pressure at about 50% over the outlet pressure. The disadvantages of the sonic nozzle include its high cost and high pressure drop. Another disadvantage is the difficulty in modulating the flow rate.

In laminar flow elements, the pressure drop and flow are in a linear relationship. The laminar flow element can be used in combination with either a differential-pressure or a thermal type of flow detector. These flowmeters provide better rangeability at about the same cost as sonic nozzles. They have a 100:1 rangeability, and control capability is readily available. Another advantage of thermal flowmeters over sonic nozzles is their inherent capability to detect mass flow. Thermal flowmeters also can directly detect low-mass flows without any laminar elements. In that case, they are installed directly into the pipeline as either thermal flowmeters or anemometers.

SPECIFYING THE KEY REQUIREMENTS

Inaccuracy

The accuracy of a flow detector is one of its most important features. One should not specify accuracy in such vague terms as "best possible" or "better than one-quarter percent" because (1) these statements are not explicit and (2) if taken at face value, they could severely limit the meter choice and result in unnecessarily high costs. Therefore, the metering accuracy should be specified precisely and at a realistic value.

In some instances—for example, in case of repetitive batch dispensing—absolute accuracy is of no critical consequence, provided that the long-term reading of the meter is stable and repeatable. In such applications, absolute accuracy is less important than long-term repeatability. In other applications, where absolute accuracy is important, one should clearly specify the flow range over which the specified error limit applies. If the error limit is given as a percentage, it should be clearly stated whether it is based on full scale (%FS) or on actual reading (%AR). It is also important to distinguish the accuracy requirements for the meter from the expected installed performance, which can be affected by variations in the properties of the flowing stream, piping configurations, and other factors.

The comments made about accuracy in Section 1.5 (Chapter 1) are also applicable to flow sensors. As stated there, one should always define the flow range over which the accuracy statement applies. As illustrated in Figure 2.1k, in case of %FS sensors, the absolute error increases as the flow rate drops.

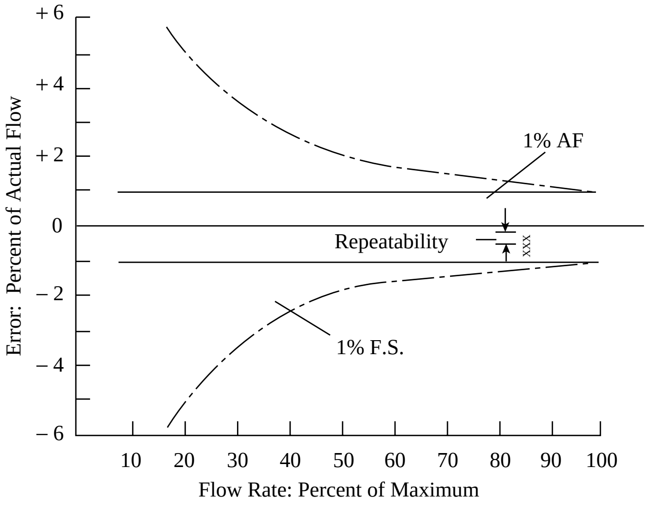

FIG. 2.1k
Comparison of 1% F.S. inaccuracy with 1% of flow inaccuracy.

Therefore, in a properly prepared specification, the accuracy requirement should state both the required flow range and the allowable error. Such a specification might read “1% AF from 10 to 100% flow” or “0.5% FS from 5% to 100% flow.”

If a flow detector is nonlinear, that nonlinearity must be corrected for; otherwise, it will degrade the measurement accuracy. Linearity is the extent to which the relationship between the flow and the meter output approaches a straight-line relationship. The linearity of a flow sensor is often different during factory calibration as compared with under the installed conditions in the field.

The vendor’s published data on meter performance is generally based on ideal installation and operating conditions. Therefore, although the meter is capable of achieving that performance level, there is no guarantee that it will realize it under actual operating conditions. For example, insufficient upstream straight piping can result in substantial swirling, which will cause a deterioration in the linearity of the meter and will therefore shift the calibration constant of the meter. Consequently, the manufacturer’s installation recommendations should be followed carefully, or, if this is not possible, the likely deterioration in performance should be evaluated and determined to be acceptable before making the installation.

Changes in fluid characteristics can also alter the meter’s performance. Figure 2.1l for example, illustrates the effects of viscosity variations between 0.3 and 25 CTP on the performance of two of the most accurate flow detector types, the turbine meter and the positive-displacement meter. In case of the turbine meter, an increase in viscosity lowers the measurement accuracy; in case of the PD meter, it improves the performance, and it is the reduction in viscosity that causes a deterioration in the performance. For any application, the acceptability of the consequences of the expected operating conditions should be verified in advance.

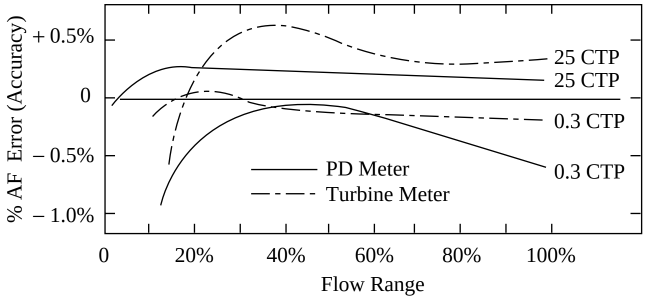

FIG. 2.1l
Differing effects of viscosity variation on a turbine meter and a positive displacement meter (CTP = centiPoises).

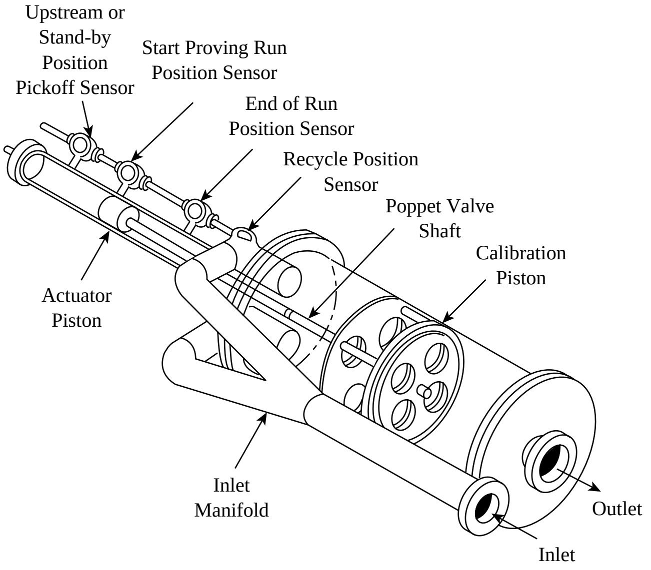

FIG. 2.1m
Inline ballistic flow prover. (Courtesy of Brooks Instrument Div. of Emerson Electric.)

Wear, drift, and expected shifts in calibration should also be investigated, and the corresponding maintenance costs evaluated, when considering alternative meter options. In critical applications, one might consider the installation of automatic on-stream recalibration equipment. Figure 2.1m illustrates an in-line ballistic prover that can recalibrate a flow detector without requiring an interruption of the process flow.

Safety

Safely is one of the most important considerations in the selection of any industrial equipment. In case of flow detection, all meter components must be certified as suitable for the applicable electrical area classification for the location at which they will operate. Meeting such requirements may be achieved by installing purely mechanical or pneumatic devices or, more commonly, by selecting intrinsically safe, flameproof, or explosion-proof devices.

Other safety aspects (often overlooked) are the safety of the selected materials of construction and the possible safety consequences of leakage. Fluids such as oxygen or liquid chlorine can cause explosions, because they react with certain materials. If the heat of such reactions cannot be removed, and especially if the resulting pressure is confined, violent explosions can result. Therefore, various organic and inorganic substances, including ordinary lubricants such as oil, grease, and wax, can cause explosions in the presence of oxygen or chlorine. It is therefore essential that any flowmeter operating in such services be thoroughly cleaned and degreased.

The choice of the materials of construction is also critical for applications involving high concentrations of oxygen. The use of steels, for example, presents an explosion hazard, which increases with a rise in the velocity and pressure of the flowing oxygen. The maximum allowable velocity and pressure in such applications depends on the cleanliness and surface finish of the working components. Therefore, clean steel with high surface finish can be used at higher pressures and flow rates than can regular steel. Yet, the best protection is to select such alternative materials as phosphor bronze, gun metal, brass, beryllium, copper, and so forth.

To protect the operators, it is essential that leakage of noxious or dangerous fluids be eliminated or kept to an absolute minimum. The addition of every joint increases the probability of leakage. Therefore, the presence of manifolds, pressure taps, and fragile components all add to the probability of leakage. Therefore, when metering dangerous or noxious materials, nonpenetrating flowmeter designs are preferred.

Installation

Installation requirements vary dramatically among the various meter types and can be the deciding factors in meter selection. The most demanding applications are ones in which the process flow cannot be stopped and the measurement point cannot be bypassed. In such applications, the selection choice is limited to clamp-on meters, such as the ultrasonic Doppler or the cross-correlation design, and to the hot-tap insertion meters, such as the various probe designs.

Even if block and bypass valves can be installed around the meter, the installation requirements still affect both cost and plant acceptability. One critical consideration is the availability of the requisite straight upstream and downstream pipe lengths. If they are not available, it is necessary to derate the performance of the meter or to consider an alternative design such as an electromagnetic sensor, which requires only the equivalent of 5 pipe diameters in straight upstream piping.

Specific application requirements affect different meters in different ways. For example, if an electric power supply is not available at the measurement point, this eliminates the electromagnetic flowmeter from consideration. If a vertical pipe section cannot be provided, one cannot consider the variable area meter. A positive-displacement meter requires a strainer, often an air release, and so on. Even if the meter installation requirements can be met, their effect on the overall system cost must still be considered and quantified, because the selection should consider the total cost, which should include installation, operation, and maintenance expenses.

Cost

Cost is a critical factor in the selection of any equipment. To arrive at a “reasoned” decision, one should not evaluate the purchase price only. Other factors, such as operating costs, maintenance, spare parts inventory, the effect of downtime, and many others, should all be considered if a reasoned decision is to be reached. Hardware costs, in general, should always be balanced against the potential benefits of increased plant efficiency or product quality. These benefits are usually by-products of increased sensor accuracy, repeatability, and rangeability, which all tend to increase metering costs.

When evaluating the various flowmeter choices, the cost comparison should be based on the total system cost and not merely the flowmeter price. Not only should such costs as the expenses for providing separate converters or transmitters be included, we should also consider the cost of ancillary items such as straight upstream and downstream piping, flow conditioning and filtering equipment, electric power supplies, and so on. The cost of installation also varies with local labor rates and can be a significant factor in the meter selection process.

Operating costs are also an important consideration. Operating costs are affected by the amount of routine service required and by the level of maintenance personnel needed. These costs also increase if special tools such as flow simulator equipment are required and are not already available.

In addition to the preceding, we should consider the versatility of the selected meter. We should determine whether the secondary units required for the particular device can also be used on other meters. We should check whether the meter can be used in other applications and determine the ease with which it can be reranged. Spare parts requirements should also be reviewed to establish both the value of the required inventory and whether the spares will be interchangeable with other meter sizes and models. And we should also consider the estimated total life of the meter (which tends to be shorter if there are moving components) and review the coverage of the guarantee provided for the meter.

The pressure loss through the meter is also part of its total operating cost. If we are comparing an orifice plate and a low-loss flow tube, the initial cost of the orifice plate is much lower; however, because of the head loss, its total cost can be higher. As was discussed earlier, pumping cost is a function of flow rate, electricity costs, pumping efficiency, and pressure loss. Consequently, the higher the pressure drop across the flow sensor, the higher will be the pumping costs throughout the life of the installation.

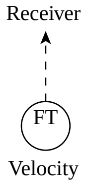
2.2 Anemometers

D. S. KAYSER (1982) **J. KOZÁK** (1995) **B. G. LIPTÁK** (2003)



Flow Sheet Symbol

Types	A. Pitot B. Mechanical B1. Vane B2. Cup B3. Propeller or turbine C. Thermal D. Doppler D1. Acoustic or ultrasonic D2. Laser
Applications and Designs	Hand-held air velocity sensors are used in HVAC applications; transmitting anemometers are utilized in industry and as wind speed monitors
Airflow Velocity Ranges, Given in Feet per Minute (ft/min)	(1 ft/min = 0.3048 mpm = 0.0183 km/h = 0.0114 mph = 0.0167 ft/sec = 0.005 m/sec = 101.2 knots) A. 0 to 300, 0 to 1250, 0 to 2500, 0 to 5000, and 0 to 10,000 are standard ranges; total capability is 25 to 30,000 B1. 300 to 3000 is standard; can cover 30 to 12,000 B2. 0 to 15,000 B3. 0 to 13,000 C. 20 to 500, 50 to 1000, 100 to 2000, and 0 to 6000 are standard ranges; stack flow probes can go up to 18,000 D1. 0 to 7000 D2. 0 to 60,000 or up to supersonic
Wind Measurement Heights	A, B, and C. Detect wind velocities at the elevation of the tower height D1. Measures wind velocity in strata of 150 ft (50 m) thickness from 200 to 2000 ft (60 to 600 m) and sometimes up to 5000 ft (1500 m)
Inaccuracy	A. 2 to 3% of full scale B1. From 1% of reading to 2% of full scale C. 2% of full scale D1. 1% of full scale
Costs	Hand-held pitot, thermal, and mechanical anemometers range from \$500 to \$2500. Sensor probes alone cost about \$300 to \$500; combined units reading air velocity, humidity, and temperature are available from \$800 to \$3000. A vane-type probe with a 4- to 20-mA DC transmitter with a 1.5% full-scale error is about \$2500. Thermal stack flow probes for wet and dirty gas applications cost about \$5000. Doppler acoustic sounders for remote sounding of wind profiles range in cost from \$15,000 to \$90,000; average cost is about \$50,000. Laser Doppler units range from \$25,000 to \$45,000.

Anemometers are used to measure air and gas flows in a variety of applications, including such tasks as the balancing of HVAC systems using hand-held air velocity meters. They are also used in stacks to measure the velocity of wet and dirty gases and in wind detection applications to obtain three-dimensional wind velocity profiles using Doppler-type sensors. Anemometer designs include pitot, mechanical (vane, cup, propeller, turbine), thermal, and Doppler types. Pitot tubes and thermal flowmeters are discussed later in this chapter. This section concentrates on the mechanical and Doppler-type anemometers.

MECHANICAL ANEMOMETERS

Figure 2.2a illustrates the vane design. Airflow causes the vanes to rotate with an angular velocity that is proportional to the wind speed. When a portable unit is required, or when the local readout is satisfactory, vane velocity is sent to a local indicator through a gear-and-spring assembly. When remote readouts are required, a magnetic or capacitive coupling is used to generate a transmission signal.

Figure 2.2b shows a three-cup anemometer, which is insensitive to wind direction. In one design, the shaft drives a direct current (DC) tachometer, which generates an output voltage that is proportional to the wind speed. This signal can be used as the input to a remote mounted indicator or recorder. The impeller design shown in Figure 2.2c is also provided with a shaft-driven tachometer. Because the tail of this impeller design always points the impellers into the wind, this instrument can detect both wind speed and wind direction.

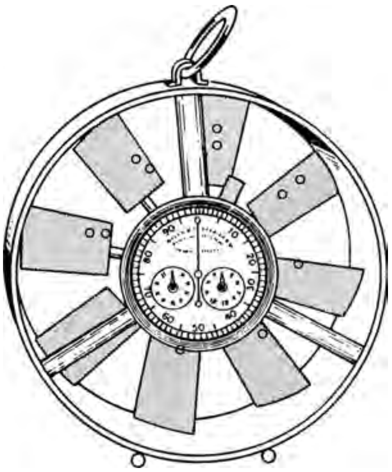

FIG. 2.2a
Vane anemometer with local readout.

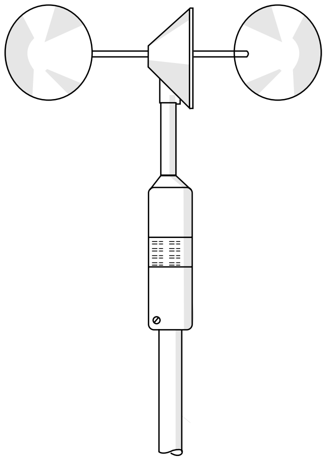

FIG. 2.2b
Three-cup anemometer.

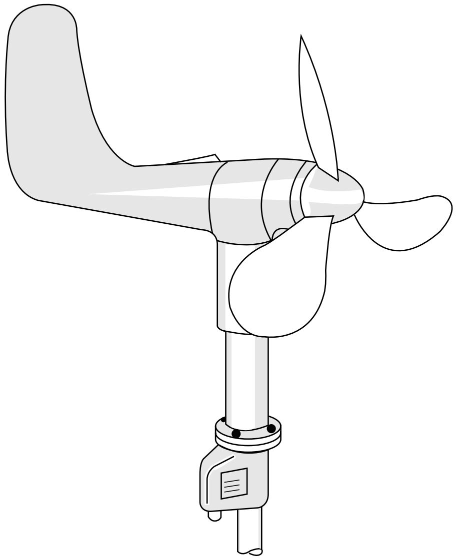

FIG. 2.2c
Impeller anemometer.

The response speed of an anemometer is expressed in terms of the *length of wind* that has to pass through the meter before the velocity sensor response amounts to 63% of a step change in velocity. This is known as the *distance constant* and is generally expressed in feet. A typical distance constant for commercially available units is 6 ft (1.8 m).

THERMAL ANEMOMETERS

The thermal flowmeters are discussed in some detail later in this chapter and therefore are only briefly mentioned here. The hot-wire anemometer (Figure 2.2d) operates as a heated thermopile that is cooled at a rate that is proportional to the air (or gas) velocity at the probe tip. It is available in ranges of 100 to 2000, 50 to 1000, and 20 to 500 ft/min (0.5 to 10.0, 0.25 to 5.0, and 0.1 to 2.5 m/sec, respectively).

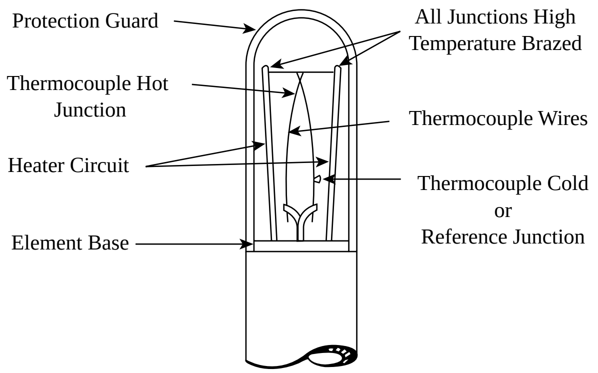

FIG. 2.2d
Hot-wire anemometer.

DOPPLER ANEMOMETERS

When sound or light is beamed into the atmosphere, any nonhomogenities in the air will reflect these beams. The resulting Doppler shift in the returning frequencies can be interpreted as an indication of wind velocity. The acoustic Doppler devices are more often used than the laser types. They are particularly useful in air pollution monitoring applications.

When laser-based Doppler anemometers are used, the intensity of the light scattered by the reflecting particles in the air is a function of their refractive index and the size (up to 5 microns). At particle sizes under 5 microns, it is safe to assume that the particle velocity is the same as that of the air (gas or liquid). Often, the naturally present particles (especially in water) will guarantee satisfactory performance, but, to obtain "perfect" measurements, seeding is recommended.

The operation of laser Doppler anemometers (LDAs) utilizes the Doppler effect or Doppler shift of frequency (color), which occurs as light is dispersed from the surface of moving particles. This shift in the frequency (color) of the light source (laser beam) is proportional to the velocity of the dispersing particles. Relative to the frequency of the light, this frequency shift is very small (from 1 kHz up to 0.1 MHz), and thus it cannot be directly measured.

Therefore, an arrangement using the interference between the original and the refracted lights is used. This configuration is called the differential mode of the LDA. Figure 2.2e illustrates this principle, where beams from the laser source intersect each other in the measurement zone. In this zone, a set of interference plates are formed. When particles pass through these plates, they generate optical signals with flash frequencies equaling the Doppler frequency. This signal is then scanned by the photomultiplier and analyzed. The signal

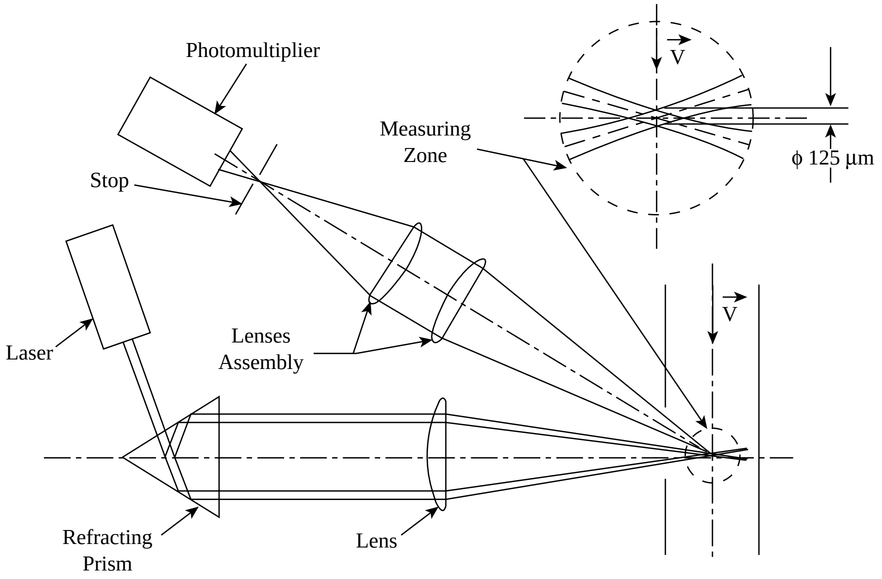

FIG. 2.2e
Operation of the laser Doppler anemometer.

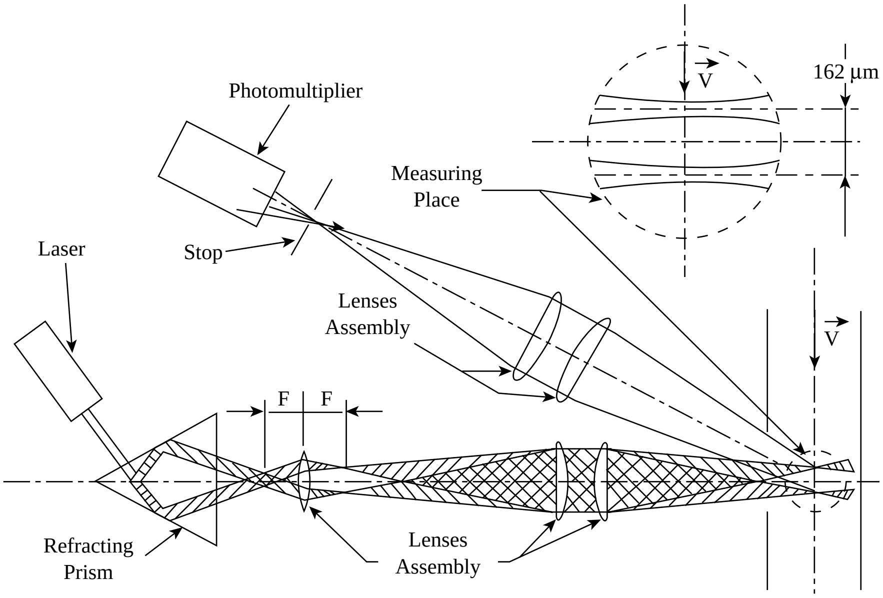

FIG. 2.2f
Operation of the laser two-focus anemometer.

has high frequency, several cycles, variable amplitude, and background noise.

In addition to the anemometers using the laser Doppler principle, there also are laser anemometers utilizing two-focus and transmit time principles. The laser two-focus anemometer (L2F) measures the time needed for particles to pass between the known distance between two focused beams (Figure 2.2f). The signal consists of two pulses and is scanned by a photomultiplier. The processing is provided by an autocorrelator. The disadvantage of this method is that the probability is small that the particles will pass through both beams. On the other hand, the resulting measurement signal is stronger and has less background noise.

Both types of noncontact Doppler measurements are suitable for nearly all hydrodynamic and aerodynamic velocity measurement applications.

CONCLUSION

For noncontacting velocity measurements, only the Doppler-type sensors can be considered. When locating other anemometers, the structures on which they are mounted are likely to disturb the airflow. A rectangular building will disturb airflow up to an elevation of about twice its height above grade, six times its height leeward, and twice its height in the windward direction.

In process industry installations, it is always a good idea to have wind direction indicators so the operators will always know which is the safe direction for escape in the event of a spill. Under such emergency circumstances, the knowledge of wind speed is of considerably less importance.

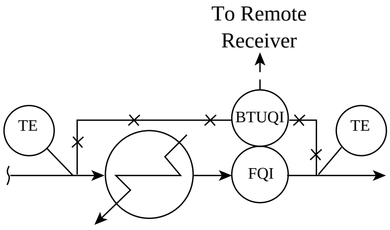
2.3 BTU Flowmeters for Heat Exchangers

B. G. LIPTÁK (1982, 1995, 2003)



Flow Sheet Symbol

BTU Flowmeter Types	A. All mechanical design B. Electronic BTU computer
Approximate Cost	A. About 50% more than the cost of the positive-displacement flowmeter; in smaller sizes and standard materials, usually less than \$5000. B. The sum of the costs of a flow transmitter, a temperature-difference transmitter, multiplier, and display. The package cost varies with line size, materials of construction, transmitter accuracy, and type of display; it is likely to reach or exceed \$10,000.
Inaccuracy	A. ±2 to 5% of full scale B. ±0.5% of full scale
Minimum ΔT	A. 5°F (2.8°C) B. 1°F (0.56°C)
Partial List of Suppliers	ABB Water Meters Inc., which bought Kent Meters Inc. (www.jerman.com/abbmeter.html) (A) Tyco Valves & Controls LP, which bought Hersey Measurement Co. (www.tycovalves.com) (A) Type "B" units can be configured by multiplying the output signal of any digital or analog flow transmitter with that of a temperature difference transmitter.

BTU flowmeters play a critical role in monitoring the energy flows and increasing energy efficiency in industry. The first step toward an energy-efficient plant design is a reliable energy audit throughout the plant. Such overall heat balance around the plant can be prepared only if the individual loads are accurately and separately measured.[1] This is illustrated in Figure 2.3a.

In the figure, the efficiency of the boiler is measured by the ratio of the total energy flows at points 1 and 2. This is usually done intermittently, by totalizing the fuel and steam flows over some period of time. The total energy input into the boiler is obtained by multiplying the total fuel consumed over that period with its heating value. The total useful energy output obtained from the boiler is obtained by multiplying the totalized steam flow by the difference between the enthalpy of the steam and the enthalpy of the feedwater. The ratio of these energy in and outputs is the boiler's actual efficiency.

Similarly, the coefficient of performance of the chiller shown in Figure 2.3a is measured by the ratio of the energy flows at points 10 and 11. Similarly, the efficiency of the

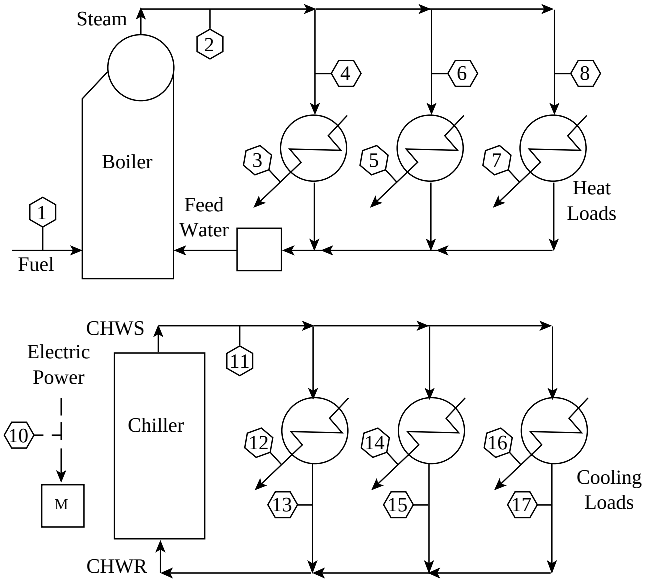


FIG. 2.3a
Plant-wide energy audit.

individual heat exchangers is also detected by measuring the energy flows on both the utility and the process sides of the exchanger, such as at points 3 and 4 or points 12 and 13 in Figure 2.3a.

The efficiency of the overall utility distribution system is determined by comparing the sum of the individual loads with the total supply at the source, such as comparing the energy flow at point 1 with the sum of energy flows 3, 5, and 7 or comparing 10 with the sum of 13, 15, and 17. The difference between the two represents the losses that occur as a result of phenomena such as insufficient thermal insulation of the pipe lines, leaking steam traps, and others.

When various techniques are considered for the optimization of the unit operations in a plant, it is recommended to empirically measure the energy consumption both before and after the optimization of the process. Without such reliable data, no accurate cost–benefit analysis can be made. The payback period for the installation is determined by dividing the optimization costs with the measured yearly energy saving.

For measuring most of the energy flows in Figure 2.3a, BTU flowmeters are required. These BTU computing units are available in both mechanical and electronic designs.

MECHANICAL BTU METERS

In mechanical BTU meters, flow is detected by positive-displacement or propeller-type sensors, and the volumetric flow rate is mechanically transmitted through gear trains. The temperature difference between the cold and hot sides of the exchanger is sensed by filled thermal bulbs, which are connected to a bourdon spring as illustrated in Figure 2.3b. Dual cam rollers are used in the computing mechanism so as to produce digital displays in both units of total BTUs and total flow.

The advantages of this design include its simplicity, low cost, and the fact that it does not require an external power supply. In centralized control systems, transmitting attachments can also be provided where remote readouts are needed.

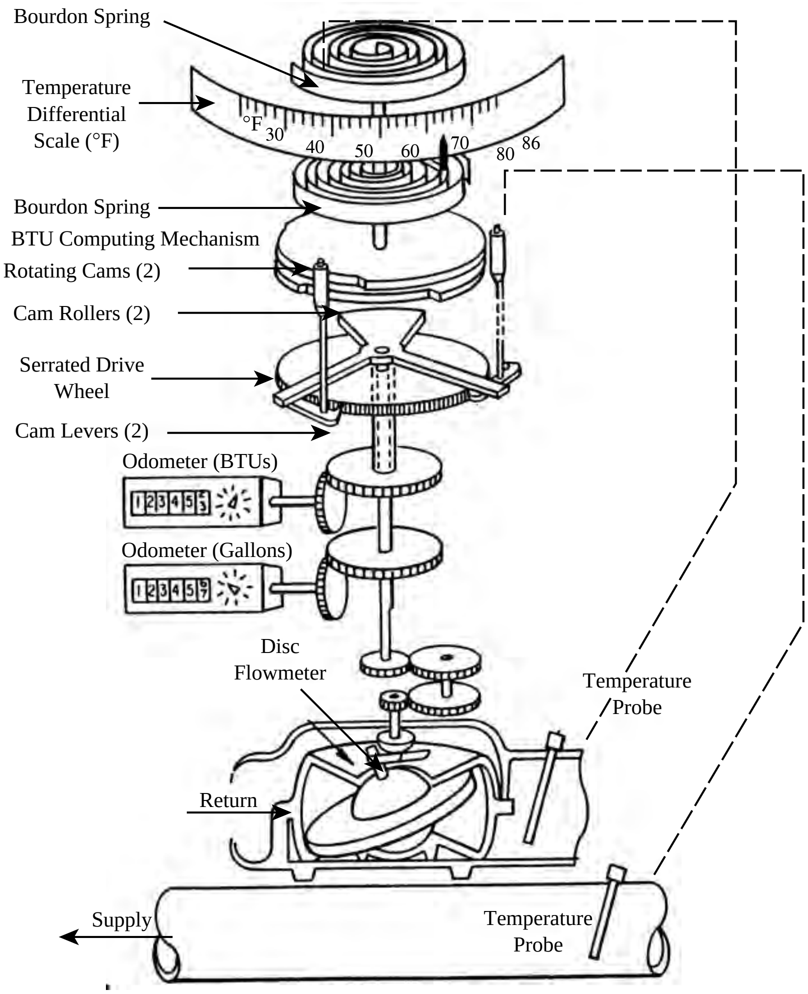

FIG. 2.3b
Mechanical BTU meter.

The limitations of this design include its relatively low accuracy, which is about ±2% of full scale, if the temperature difference exceeds 15°F (8.3°C). As the temperature difference decreases, this error rises and it becomes unacceptable at around 5°F (3°C). Therefore, these units are not recommended for use in applications where the temperature difference is under 5°F (3°C).

The typical applications for the mechanical BTU meters are in the heating, ventilating, and air conditioning (HVAC) industry and in heat exchanger efficiency monitoring.

ELECTRONIC BTU METERS

In electronic BTU computer packages, the flow sensor is usually a high-accuracy turbine flowmeter. The two temperatures or the temperature difference are usually detected by RTD-type temperature transmitters. Both the flow and temperature sensors are accurate devices, and they do provide high repeatability and wide turndown.

Therefore, the main advantage of electronic BTU computers is their superior accuracy. Their total error usually does not exceed ±0.5% of full scale.

As illustrated in Figure 2.3c, the BTU computer digitally displays the accumulated total ton-hours of refrigeration. In addition, analog electronic retransmission signals are also provided to facilitate the remote displays of flow rate, BTU rate, and temperature difference.

While these units are more expensive than mechanical BTU meters, the increase in cost can frequently be justified if the installation is larger or highly critical, or if accuracy is a prime concern.

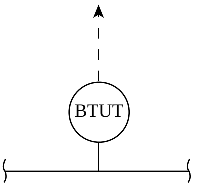
2.4 BTU Flowmeters for Gaseous Fuels

A. P. FOUNDOS (1982) **B. G. LIPTÁK** (1995, 2003)



Flow Sheet Symbol

Sensors Required	Conventional head-type flowmeter, calorimeter, or wobble index detector plus pressure and temperature measurements
Process Fluids	Gaseous fuels
Applications	Combustion processes are optimized by measuring and controlling fuel gas flow on the basis of the heat flow (BTU/h) requirement of the process
BTU Flow Range	From 100 BTU/min to very large heat flow rates; limited only by pipe sizes
Inaccuracy	±1.0 to ±2.0% of full scale, depending on the accuracy of the head type flowmeter used
Costs	Refer to Section 8.8 for the costs of the different types of calorimeters. The cost of a general-purpose wobble index detector is $10,000 to $12,000. Explosion-proof designs cost $5000 to $6000 more. For flow, temperature, and pressure transmitter costs, refer to Chapters 2, 4, and 5.
Partial List of Suppliers	ABB Process Automation—Analytical Div. (www.abb.com/us) The Foxboro Co. (www.foxboro.com) Honeywell Industrial Control (www.honeywell.com/acs/cp) ICS (www.icsadvent.com) Thermo Onix Process Analyzers (formerly Fluid Data/Amscor) (www.thermoonix.com).

The heat flow rate provided by the burning of a fuel gas can be measured by detecting its mass flow rate and multiplying it by its heating value, which can be detected by wobble index sensors or calorimeters (discussed in Section 8.8). The burning of waste gases from a variety of process sources (Table 2.4a) and the accurate control of regular fuel gases made it necessary to measure their heat flows on line and continuously.

In the past, only the volumetric flow of the fuel gas was measured, and the heating value and the specific gravity of the gas were assumed to be constants. This approach is not acceptable for applications involving the burning of waste gases, because both their composition and heating values are variable.

In the past, in hazardous areas, the heating value of fuel gases could not be continuously measured, so specific gravity measurements were used to estimate their heating value and to control the combustion process. Today, continuous and explosion-proof calorimeters are available (Section 8.8) for the measurement of the heating value of any fuel gas. These optimized combustion controls are automatically adjusted for variations in either the specific gravity or the heating value of the fuel gas.

MEASURING HEAT FLOW BY WOBBLE INDEX

The heat flow rate (Q) of a gaseous fuel is calculated as the product of its volumetric flow rate at standard conditions (V_0) and of its calorific value (CV) or composition.

$$Q = V_0 \times CV = \mathrm{SCF/hr} \times \mathrm{BTU/SCF} = \mathrm{BTU/hr} \qquad \textbf{2.4(1)}$$

Variations in composition affect both the heating value of the fuel gas and the pressure drop produced when the gas passes through an orifice plate. The volumetric flow through an orifice plate (V_0) can be expressed as the product of a constant (K) and the square root of the ratio $\Delta P/SG$. Therefore, the heat flow rate Q can be expressed as

$$Q = K\sqrt{\Delta P/SG} \times CV \qquad \textbf{2.4(2)}$$

where ΔP is the pressure differential across an orifice plate and SG is the specific gravity of the flowing fuel gas.

Rearranging that relationship for orifice pressure drop gives the following for $\sqrt{\Delta P}$:

$$\sqrt{\Delta P} = K \times V_0 \times \sqrt{SG} \qquad \textbf{2.4(3)}$$

*Heavier hydrocarbons and traces of compounds including sulfurs.

The wobble index (*WI*) measures the ratio between the net calorific value (*CV*) and the square root of specific gravity (*SG*):

$$WI = CV/\sqrt{SG} \qquad \textbf{2.4(4)}$$

The advantage of detecting the wobble index is that it eliminates the need for separately measuring the specific gravity, because, as shown in Equation 2.4(5), the product of wobble index and orifice pressure drop [the product of Equations 2.4(3) and 2.4(4)] results in a value ($K \times Q$), which is directly related to the heat flow rate (Q), without requiring a separate measurement of SG.

$$WI \times \sqrt{\Delta P} = \left(CV/\sqrt{SG}\right) \times \left(K \times V_0 \times \sqrt{SG}\right)$$
$$= CV \times K \times V_0 = K \times Q \qquad \textbf{2.4(5)}$$

Because wobble index can be measured continuously in hazardous areas, this approach provides an on-line method of detecting heat flow rate.

THE BTU FLOWMETER LOOP

For gas fuels, the BTU flowmeter consists of a calorimeter (see Section 8.8) and an orifice type flow element. When the transmitted signals of these sensors are properly scaled, they can be multiplied to satisfy Equation 2.4(5) and the output of the multiplier (Figure 2.4b) represents the rate of heat flow in BTU/h units.

APPLICATIONS

In all combustion control processes, the calculation described in Figure 2.4b can provide a measurement signal that corresponds to the BTU flow rate. An optimized control system will ration the combustion air to this BTU flow rate in a feedforward configuration while responding to the firing rate demand signal of the process load in a feedback manner, as depicted in Figure 2.4c. This firing demand feedback signal to the setpoint of FIC-1 will throttle the fuel gas control value

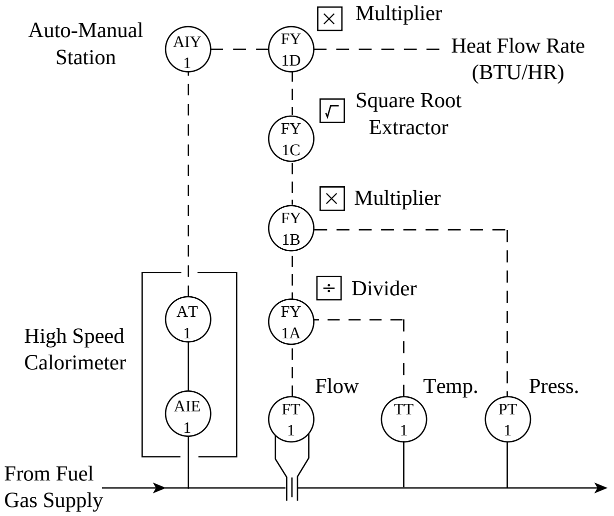

FIG. 2.4b
Heat flow rate detection loop.

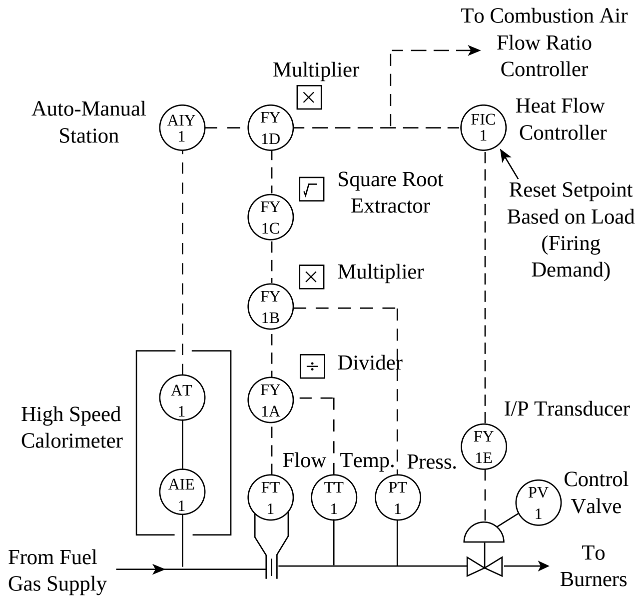

FIG. 2.4c
Combustion control system with heat flow controller.

(PV-1) until it delivers the BTU flow rate required. In conventional systems, only the volumetric flow rate of the fuel gas is maintained.

The configuration shown in Figure 2.4c is commonly used when combustion systems are optimized or plants are updated. This control system makes the control of multiple fuel boilers and furnaces much easier, because, by fixing the BTU flow rate of the gaseous fuel, it becomes feasible to modulate the liquid fuel(s) as a function of the excess air in the flue gas.

Another common application of BTU flow metering is the blending of an enriching or diluting gas into the fuels so as to control the BTU of the blend at a constant value. This constant BTU fuel gas can then be distributed throughout the plant to the various boilers, heaters, and gas-fired processes. In this case, the fuel gas BTU controller (AIC-1) becomes the cascade master of the makeup or diluent flow controller (FIC-1). Such a flow schematic of a typical blending control loop is shown in Figure 2.4d.

CONCLUSION

Using proven, available technology, a BTU flow rate loop can provide the control signal needed in such applications. In most combustion processes, the basic elements of such a control loop are an orifice flowmeter and a heating value detector that is fast enough to provide good response speed to process load variations.

Measuring the BTU flow rate provides a direct and accurate method of controlling and optimizing combustion processes.

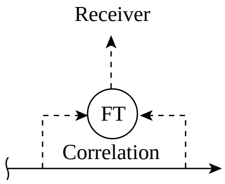
2.5 Cross-Correlation Flow Metering

B. G. LIPTÁK (1982, 1995) **H. M. HASHEMIAN** (2003)



Flow Sheet Symbol

Current Applications	Pumped paper pulp, pneumatically conveyed coal dust, cement, grain, plastic granules, chalk, water flow in nuclear and industrial plants, and animal foodstuffs
Sizes	Practically unlimited
Cost	A 4-in 150 # mass flowmeter with epoxy-resin-lined, enameled steel pipe costs $6000. If the sensor costs are not considered, the electronic detector alone is around $2000. Nuclear power plant flow metering installations range from $25,000 to $50,000.
Partial List of Suppliers	Analysis and Measurement Services Corp. (www.ams-corp.com) Endress+Hauser Inc. (www.us.endress.com) Kajaani Electronics Ltd. (Finland)

The oldest and simplest methods of flow measurement are the various tagging techniques. Here, a portion of the flowstream is tagged at some upstream point, and the flow rate is determined as a measurement of transit time. Variations of this technique include particle tracking, pulse tracking, and dye or chemical tracing, including radioactive types. The advantages of tagging techniques include the ability to measure the velocity of only one component in a multicomponent flowstream without requiring calibration or pipeline penetration. For example, electromagnetic tagging of gas-entrained particles allows for the determination of their speed through the detection of their time of passage between two points that are a fixed distance from each other.

Flow metering based on correlation techniques[1,2] is similar in concept to the tagging or tracing techniques, because it also detects transit time. As illustrated in Figure 2.5a, any measurable process variable that is noisy (displays localized variations in its value) can be used to build a correlation flowmeter. The only requirement is that the noise pattern must persist long enough to be seen by both detectors *A* and *B* as the flowing stream travels down the pipe. Flow velocity is obtained by dividing the distance (between the identical pair of detectors) by the transit time. In recent years, the required electronic computing hardware, with fast pattern recognition capability, has become available. Consequently, it is feasible to build on-line flowmeters using this technique.[3]

The following process variables display persistent enough noise patterns (or local fluctuations) that correlation flowmeters can be built by using an identical pair of these sensors:

Density
Pressure
Temperature
Ultrasonics
Gamma radiation
Capacitive density
Conductivity

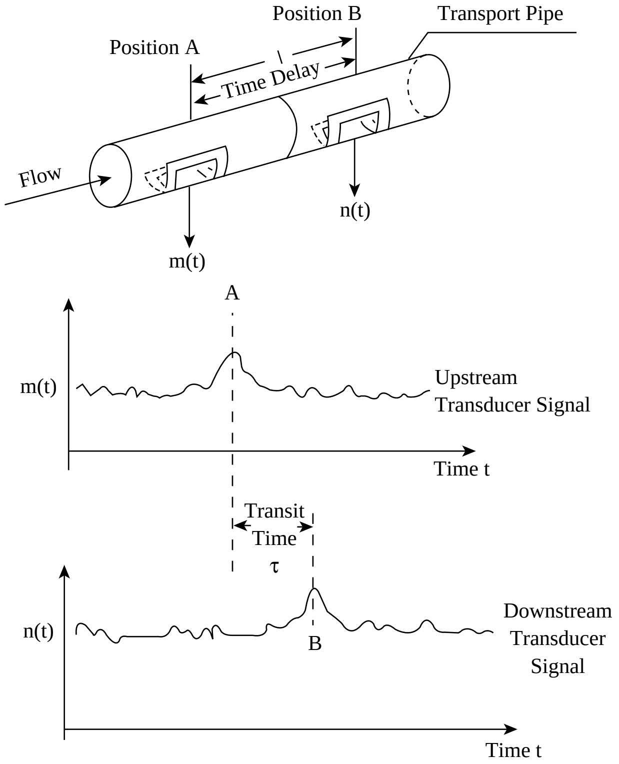


FIG. 2.5a
Cross-correlation flow metering.

Several of the above process variables (such as temperature,[4,5] gamma radiation, and capacitive density[6]) have been investigated as potential sensors for correlation flowmeters. One instrument has been developed that uses the principle of ultrasonic cross-correlation to measure heavy-water flow.[3] Others are available for paper pulp applications using photometric sensors and for solids flow measurement utilizing capacitance detectors (Figure 2.23v). For cross-correlation flowmeters applied in solids flow applications, refer to Section 2.23.

When fully developed, correlation flow metering can extend the ability to measure flow not only into the most hostile process environments but also into areas of multiphase flow and into three-dimensional flow vectoring.

NUCLEAR POWER PLANT APPLICATIONS

Most process variables fluctuate, so the outputs of most process sensors undergo variations in their output. These variations can also be exploited to obtain cross-correlation flow sensors. More specifically, process sensors that normally measure temperature, pressure, radiation, or other process variables can also be used to determine the velocity of fluid flow. This can be done passively by recording the sensor output for a period of time and extracting the fluctuating component of the output (called the AC signal). If a pair of sensors are installed in the same pipe at a known distance from each other, flow velocity can be obtained by cross-correlating the two AC signals from these two sensors. Once the fluid flow velocity is determined, the volumetric or mass flow rate can be calculated on the basis of the physical dimensions of the process piping and the properties of the fluid.

Determining the Transit Time

The principle of cross-correlation flow measurement is illustrated in Figure 2.5b, where a pipe is shown with two sensors installed some distance apart. Also shown in Figure 2.5b are the AC outputs of these two sensors. The output of one sensor is represented by $x(t)$, and the output of the other sensor is represented by $y(t)$. These output signals may be cross-correlated to identify the *transit time* between the two sensors. The transit time is the time required for the process fluid to travel between the two sensors. To obtain the fluid flow velocity, the transit time has to be divided by the distance between the two sensors.

To cross-correlate the outputs of two sensors, first the two output signals are multiplied by each other, after which the second signal is slowly shifted, a little bit at a time, toward the first signal until the two signals are superimposed. The averaged product of the two signals is then plotted as a function of the time shift. This plot will normally peak at a time that is equal to the transit time, as illustrated in Figure 2.5c.

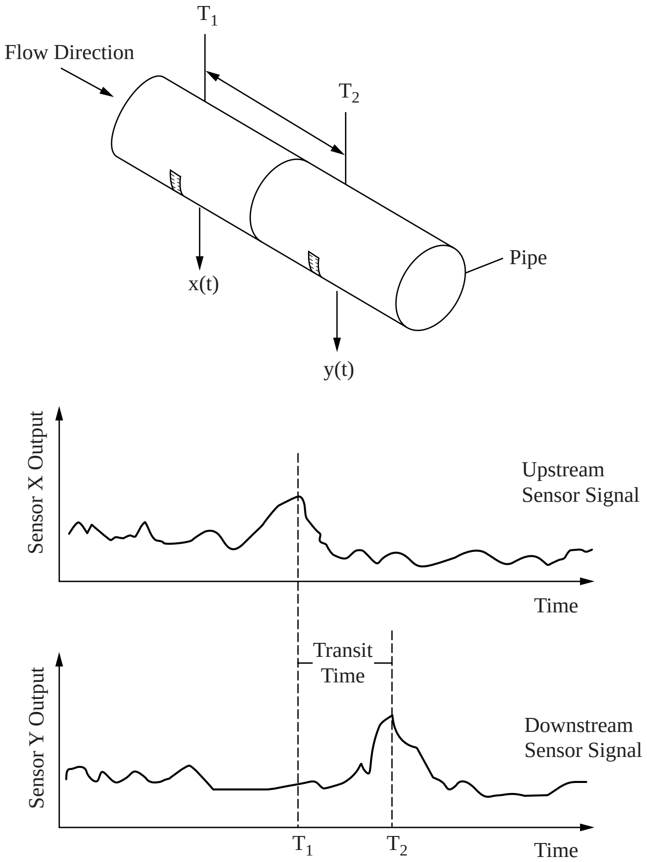

FIG. 2.5b
Illustration of principle of cross-correlation flow monitoring.

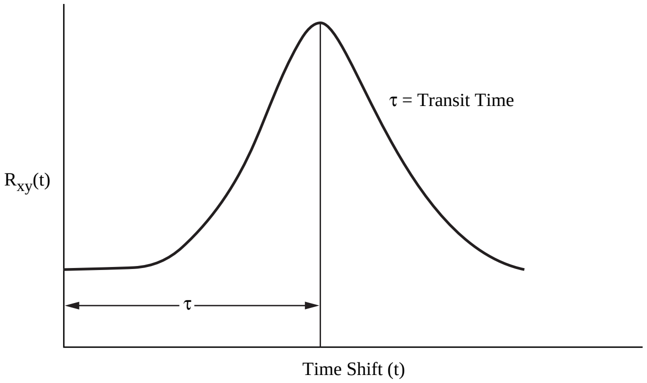

FIG. 2.5c
Cross-correlation plot and illustration of transit time.

The cross-correlation function (R_{xy}) for the signals $x(t)$ and $y(t)$ is given by the following equation:

$$R_{xy}(t) = \int x(z)y(t+z)dz \qquad \textbf{2.5(1)}$$

In this equation, t is the time interval that one signal is shifted toward the other, and z is the integration variable.

The cross-correlation function, R_{xy}, will normally have values between +1.0 and −1.0, provided that x and y are constructed from mean-removed raw signals divided by their standard deviations. Values close to +1.0 indicate a good direct correlation between two signals, and values close to −1.0 indicate a good inverse correlation. Conversely, when there is little or no correlation between the two signals, the value of R_{xy}, will approach zero.

The transit time can also be obtained from plotting the phase between the two signals as a function of frequency. For this, the slope of the phase as a function of frequency is used to calculate the transit time as follows:

$$2\pi\Delta F\tau = \Delta\phi$$

$$\tau = \frac{\Delta\phi}{2\pi\Delta F} = \frac{\text{slope (Degrees/Hz)}}{\text{360 (Degrees)}} \qquad \textbf{2.5(2)}$$

where

τ = transit time (sec)
$\Delta\varphi$ = change in FFT phase (degrees)
ΔF = frequency band of highest coherence (Hz or sec^{-1}) over which $\Delta\phi$ occurs
2π (radians) = 360°

To eliminate the effects of process variations that are not related to flow, the slope is calculated over the region of the phase spectrum where the two signals are most coherent. Figure 2.5d shows a phase vs. frequency plot and the calculation of the transit time. As shown by Equation 2.5(2) and Figure 2.5d, the transit time is calculated by dividing the slope of the phase plot by 360°.

Reliability and Accuracy

The reliability of cross-correlation flow metering is improved if

1. The response times of the two sensors are similar and fast compared to the spectrum of the process and the transit time that must be resolved.
2. The correlation between the data does not occur at or after the break frequency of the sensor and/or the data acquisition system.
3. The information being correlated can be resolved from the effects of other process perturbations and noise.

In theory, any two sensors can be used to provide signals for cross-correlation flow measurements as long as the two sensors can register a process parameter that affects the output of both sensors. For example, signals from two temperature sensors (thermocouples, RTDs, and so forth) or two pressure sensors can be cross-correlated to determine fluid flow rate. Figure 2.5e shows a phase plot for two RTDs. This information was generated in a laboratory test loop where cross-correlation flow equipment and techniques were developed and validated. The plot shows the experimental data as well as the least-squares fit to the data. The least-squares fit provides the slope of the line that is then divided by 360° to obtain the transit time. Based on these laboratory experiments, it has been determined that the error in cross-correlation-based flow measurement is less than 3%.

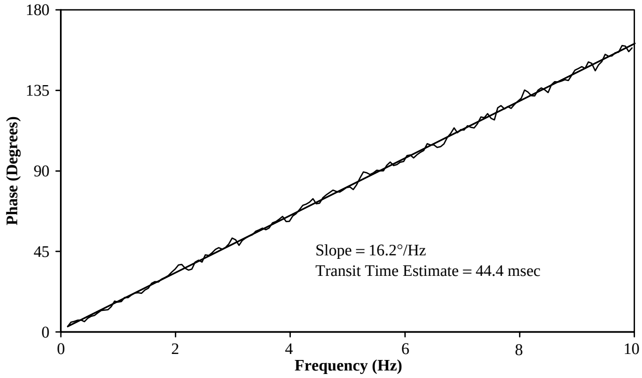

FIG. 2.5d
Phase plot and calculation of transit time.

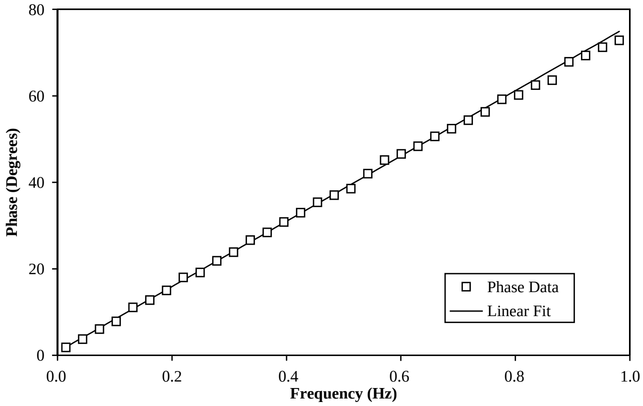

FIG. 2.5e
Cross-correlation phase plot for a pair of RTDs.

Even dissimilar sensors, such as a temperature and a pressure detector, can be used for cross-correlation flow measurement if the temperature and pressure measurements are related.

Nuclear Power Applications

The cross-correlation technique of flow metering has been used successfully in nuclear power plants by using the thermal hydraulic fluctuations within the reactor coolant system, which are detectable by temperature, pressure, and radiation sensors. For example, the signals from temperature and neutron detectors have been cross-correlated to monitor the

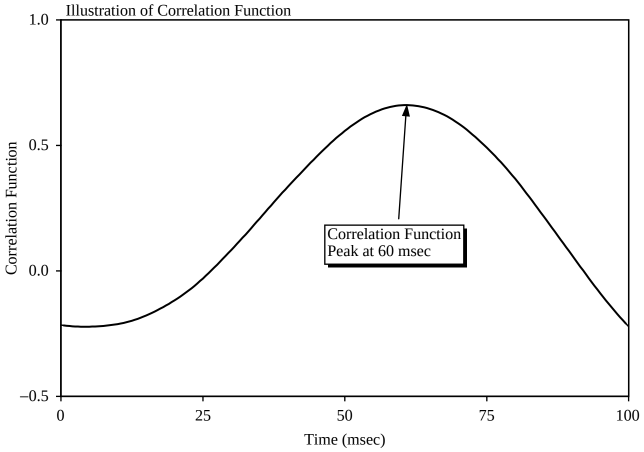

FIG. 2.5f
Plot of correlation function for a pair of signals from a thermocouple and a neutron detector.

flow through the core. Figure 2.5f shows a cross-correlation plot for a thermocouple that is installed on top of the reactor core inside a pressurized water reactor (PWR) and a neutron detector located outside the reactor at a lower elevation than the thermocouple. This method is not normally used for flow measurements in nuclear power plants. Rather, it is used for monitoring flow rate changes and for detecting flow blockages within the reactor coolant system.

A more direct means of flow measurements in PWR plants is to cross-correlate the signals from a pair of nitrogen 16 (N-16) radiation detectors that are installed on the reactor coolant pipes. The N-16 detectors measure the gamma radiation produced in the reactor water by the neutron bombardment of oxygen-16. When oxygen-16 is bombarded by fast neutrons, an unstable isotope of nitrogen is produced, which is N-16. It decays rapidly while emitting gamma radiation. Even though it decays rapidly, N-16 activity lasts long enough to measure the gamma radiation as the water circulates in the reactor coolant loop. This method of flow measurement is often referred to as *transit-time flow measurement (TTFM)*. Figure 2.5g shows two raw data records for a pair of N-16 detectors in a PWR plant.

Data accumulated for a period of only one second is shown, although data can be collected for periods of 1 or 2 h if high measurement accuracy is desired. If the purpose of the measurement is only to detect sudden flow changes or blockages, then shorter data recording periods are adequate.

The TTFM System

The TTFM system (Figure 2.5h) includes a signal conditioning circuit shown in Figure 2.5h. This circuitry is used to extract the AC signals that are cross-correlated for flow measurement. The raw signal typically contains a DC component on which the AC signal of interest is superimposed.

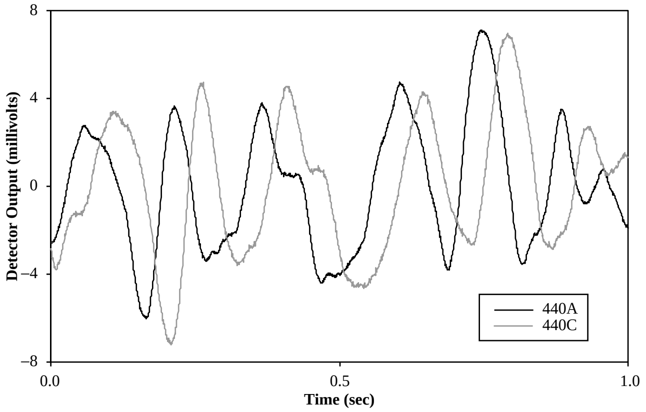

FIG. 2.5g
Examples of raw data for a pair of sensors used for cross-correlation flow measurements.

FIG. 2.5h
Photograph of TTFM system. (Courtesy of Analysis and Measurement Services Corp. [AMS].)

As shown in Figure 2.5i, the DC component of each signal is removed by a highpass filter or by a bias that is added to or subtracted from the signal. The remaining component (the AC signal) is then amplified and sent through a lowpass filter to remove the extraneous noise and to provide for anti-aliasing. A computer with a built-in analog-to-digital converter (A/D) then samples the signals and performs the cross-correlation to identify the transit time and calculate the flow. Typically, the cross-correlation analysis is performed in both the time domain, using the cross-correlation plot, and in the frequency domain, using the phase plot, and the results are averaged to provide the fluid flow velocity.

The TTFM software not only collects the data, it performs data qualification and statistical analysis to ensure that the signals are suitable for analysis, the sensors have comparable response times, and the cross-correlated AC signals have the required statistical and spectral properties. Figure 2.5j shows a block diagram of the entire TTFM system.

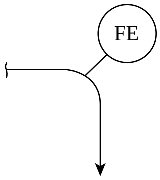
2.6 Elbow Taps



W. H. HOWE (1969) **B. G. LIPTÁK** (1982, 1995) **I. H. GIBSON** (2003)

Design Pressure	Limited by piping design class only
Operating Temperature Range	–330 to +1100°F (–200 to +600°C)
Fluids	Liquids, vapors, or gases
Differential Pressure	0- to 10-in water column (0 to 2.5 kPa)
Sizes	0.5 to 20 in (12 to 500 mm)
Inaccuracy	±2 to ±10% FS
Cost	Approximately $1000 plus value of elbow and measuring device (usually a differential-pressure transmitter)
Partial List of Suppliers	Normally fabricated on site

Flow measurement using elbow taps depends on the detection of the differential pressure developed by centrifugal force as the direction of fluid flow changes in a pipe elbow. Taps are located on the inner and outer radii in the plane of the elbow. The pressure taps are located at either 45° or 22.5° from the inlet face of the elbow (Figure 2.6a).

A SIMPLE FLOWMETER

Elbow taps are easy to implement, because most piping configurations already contain elbows in which taps can be located. This guarantees an economical installation and results in no added pressure loss. The measurement introduces no obstructions in the line. Accumulation of extraneous material in the differential-pressure connections can plug the elbow taps. Therefore, they should be purged if the process fluid is not clean.

As is the case with other head-type primary flow measurement devices, the differential pressure developed by a given flow is precisely repeatable. However, the flow coefficient of an elbow tap calculated from the physical dimensions of the pipe is generally considered reliable to only ±5 to ±10%. This is quite satisfactory for many flow control applications where repeatability is the primary consideration. If absolute accuracy is desired, a more precise flowmeter should be used, or the elbow tap readings should be calibrated, preferably in place and using the working fluid. Not enough data exist to establish precise correction factors for effects of upstream disturbances, viscosity, and roughness in pipe and elbow surfaces, and no published standards are available.

Elbow taps develop relatively low differential pressures. For this reason, they cannot be used for measurement of low-velocity streams. Typically, water flowing at an average velocity of 5 ft/sec (1.5 m/sec), roughly 200 GPM in a 4-in. pipe (45 m^3/h in a 100-mm pipe) through a “short-radius” elbow with a centerline radius equal to the pipe diameter develops about 10 in. of water differential pressure (2.5 kPa). This is approximately the minimum full scale value recommended for reliable measurement. Taps in long radius pipe or tube bends do not develop sufficient differential pressure for good flow measurement at low flow velocities.

In comparison with an elbow installation, an orifice will generate a head (1.4 to 2.2) $(1-\beta^4)/\beta^4$ higher at the same flow rate. For example, for $\beta = 0.65$, the orifice head developed will be approximately 6.5 times that of a short-radius elbow.

LOCATION AND SIZE OF TAPS

The upstream piping is a factor in the installation of elbow taps. It is recommended to provide at least 25 pipe diameters of straight pipe upstream and 10 diameters downstream. The tap holes should be perpendicular to the surface of the elbow and slightly rounded at the pipe surface, with no burrs

Note: short-radius 45-degree elbows are not standard
design

FIG. 2.6a
Alternate tap locations in elbow flowmeter designs.

or protrusions. Jig setting the tap connections using a rod across the elbow to ensure a common axis is recommended.

Tap hole diameter should not exceed 0.125 of the pipe diameter. Elbows may be flanged with the elbow diameter equal to the pipe diameter or, more commonly, welded. With a welded installation, it is preferable to make the upstream weld first, because this permits access to clean up the more critical upstream joint.

An elbow of smaller diameter than the pipe, with a reducer between pipe and elbow, has the advantage of higher differential for a given flow. Threaded elbows with the flow section larger than the pipe develop less differential pressure and thereby increase the error.

The flow coefficient of a pipe elbow can be reliably determined only if the inside surface of the elbow is smooth. The elbow should be precisely aligned with the pipe, making sure that no gaskets or weld metal are protruding into the flowing stream either at the inlet or outlet of the elbow.

When selecting an existing elbow for flow measurement purposes, it is preferable to pick one that is located between two horizontal pipe sections. This will guarantee that the pressure taps will be horizontal, and material will not accumulate in them. If the elbow were located between a horizontal and a vertical pipe section, the pressure tap on the inner radius would slope upward, and the one on the outer radius would slope downward.

As the differential-pressure instrument is piped to these taps, this piping will not be self-draining. The high and low points in the connecting piping will tend to trap either the vapors on liquid services or the liquid condensate on vapor services. As the total pressure differential to be measured is already low, this interference can make the installation unsatisfactory.

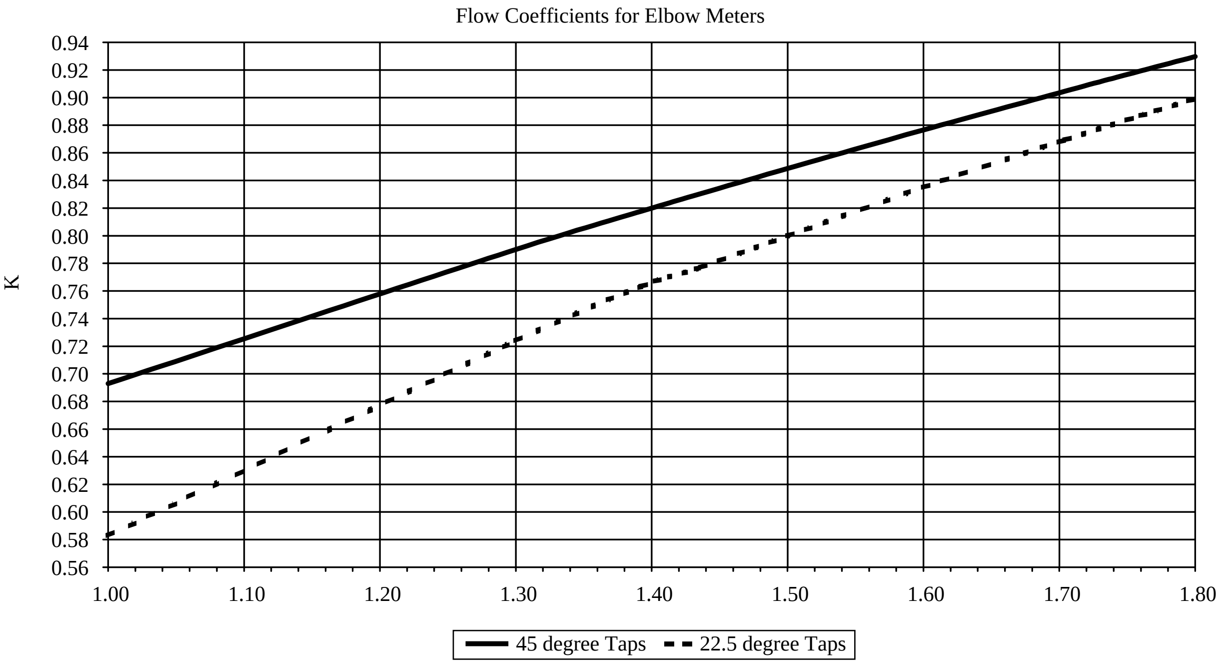

FIG. 2.6b
Elbow flowmeter flow coefficients.

Some tests suggest that the 22.5° tap locations provide more stable and reliable readings and are less affected by upstream pipe configuration. They also give 7 to 15% higher differential than the 45° values. Spink[5] gives a set of correlated experimental data for both 45° and 22.5° measurements. The 22.5° data in Figure 2.6b is adapted from this information.

For 45° tap orientation, the flow coefficient (K) is given by Murdock[1,2] as

$$K = \sqrt{\frac{r_b}{2D}} + \frac{6.5\sqrt{\frac{r_b}{2D}}}{\sqrt{\mathrm{Re}_D}} = \sqrt{\frac{r_b}{2D}} * \left(1 + \frac{6.5}{\sqrt{\mathrm{Re}_D}}\right) \pm 4\% \qquad \mathbf{2.6(1)}$$

using consistent units, where the pipe Reynolds number (Re_D) is greater than 10^4 and $r_b/D > 1.25$. Note that, for short-radius elbows, this ratio is 1.0, and hence outside the limit, r_b, is the centerline radius of the elbow, and D is the actual bore of the elbow, measured in four planes and averaged.

The second term is 6.5% at the minimum Reynolds number of 10^4 and negligible above 10^6. Later work by Murdock[3] suggests a slightly lower value,

$$K = 0.98\sqrt{\frac{r_b}{2D}} \pm 6\% \text{ for Reynolds number above } 10^5 \qquad \mathbf{2.6(2)}$$

Units

Symbols used are consistent with ISO 5167.

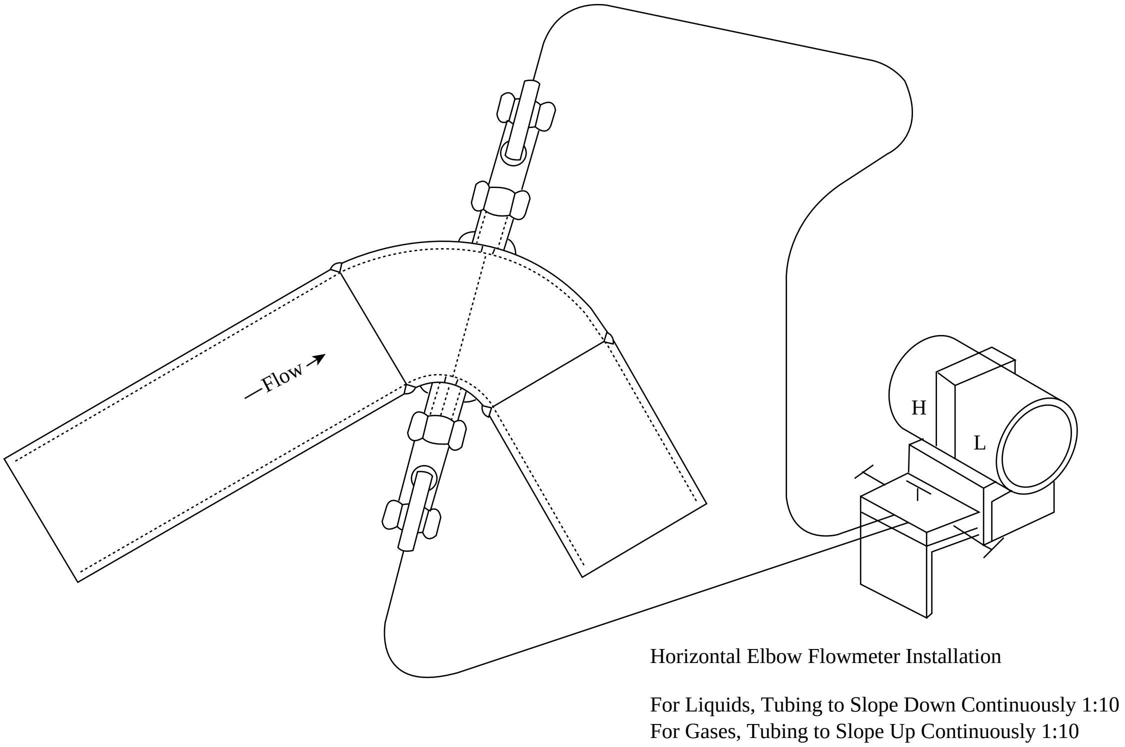
C	Discharge coefficient in orifice equations
D	Pipe diameter (at plane of elbow tappings)
K	Discharge coefficient term for elbow
p_{f1}	Absolute pressure upstream of elbow
p_{lp}	Absolute pressure at inner tapping of elbow
p_{hp}	Absolute pressure at outer tapping of elbow
q_m	Mass flow rate
r_b	Radius of curvature of elbow at centerline
Re_D	Reynolds number referred to D
ε	Expansion factor (in U.S. standards, Y)
ρ	Density
$_1$(subscript 1)	Upstream conditions

The factor K replaces the term $C/\sqrt{1-\beta^4}$, and D replaces d in the standard orifice equations (see Section 2.15).

$$q_m = \frac{C}{\sqrt{1-\beta^4}}\varepsilon_1 \frac{\pi}{4} d^2 \sqrt{2\Delta p \rho_1} \quad \text{to give}$$

$$q_m = K\varepsilon_1 \frac{\pi}{4} D^2 \sqrt{2(p_{hp} - p_{lp})\rho_1} \qquad \mathbf{2.6(3)}$$

For gas flow, the gas expansion factor has not been heavily studied; a single set of data on air suggests $\varepsilon = 1 + 1.3((p_{hp} - p_{lp})/p_{f_1})^2$ where the pressure measurements are in consistent units.



Horizontal Elbow Flowmeter Installation

For Liquids, Tubing to Slope Down Continuously 1:10
For Gases, Tubing to Slope Up Continuously 1:10

FIG. 2.6c
Horizontal elbow flowmeter installation.

The pressure differential term is so small that $\varepsilon = 1$ is within the normal limits of error in many cases. The coefficient values for 22.5° taps are quoted by Spink.

For an elbow tap installation, complete with d/p transmitter and three-valve manifold, refer to Figure 2.6c.

OTHER d/p-PRODUCING ELEMENTS

In addition to elbow taps, the differential pressure produced by centrifugal forces can also be converted into flow readings by other configurations. These include the Winter-Kennedy taps installed in the scroll case of hydraulic turbines. Another design is the full-circle loop with taps located at the midpoint of the loop. It is claimed that this design provides high accuracy and minimum sensitivity to upstream piping configuration.

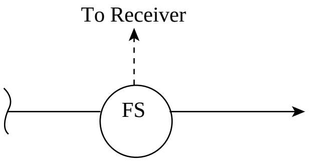
2.7 Flow Switches

B. G. LIPTÁK (1982, 1995) **W. H. BOYES** (2003)



Types of Designs

A. Bypass or differential-pressure
B. Capacitance or RF inductance
C. Hot wire anemometer
D. Paddle, vane, or rotor
E. Thermal
F. Ultrasonic (including Doppler)
G. Valve body
H. Variable area or piston
I. Microwave
J. Surface charge

Types of Services

0. Liquids (flow or no-flow)
1. Liquids (adjustable high- or low-flow)
2. Gases, vapors (adjustable high- or low-flow)
3. Solids (flow/no-flow, some adjustable)

Costs

Small oil, air, and water switches (types A and D) can be obtained for $50 to $150; paddle-type flow switches for air ducts cost $150, and for water service through 1-in (25-mm) NPT fitting and stainless-steel construction, $375; types B, E, and H units range from $150 to $800 in small sizes and standard materials; types C and F start at approximately $500 and range to over $1000; solids flow switch types I and J cost around $1000; Type G in 1-in (25-mm) size and bronze construction is $120, in stainless steel $400; a 2-in (50-mm) unit in these materials is $300 and $600, respectively.

Flow switches are used to determine if the flow rate is above or below a certain value. This value (the setpoint) can be fixed or adjustable. When the setpoint is reached, the response can be the actuation of an electric or pneumatic circuit. When the flow switch is actuated, it will stay in that condition until the flow rate moves back from the setpoint by some amount. This difference between the *setpoint* and the *reactivation point* is called the switch *differential*. The differential can be fixed or adjustable. If the differential is small, the switch is likely to cycle its control circuit as the flow fluctuates around its setpoint.

In certain applications, a manual reset feature is desirable. This will guarantee that, once the switch is actuated, it will not be allowed to return to its preactuation state until manually reset by the operator. This feature is designed to require the operator to review and eliminate the cause of the abnormal flow condition before resetting the switch.

All instruments that can measure flow can also be used as flow switches. On the other hand, if only a flow switch is required for a particular application, the installation of indicating or transmitting devices cannot be economically justified. Therefore, in this section, only the direct flow switches will be discussed. Indirect devices, such as differential-pressure switches piped around orifice plates and receiving switches connected to the output signals of transmitters, are not covered.

DESIGN VARIATIONS

The least expensive and therefore the most widely used are the various paddle-type devices. At "no flow," the paddle hangs loosely in the pipe in which it is installed. As flow is initiated, the paddle begins to swing upward in the direction of the flow stream. This deflection of the paddle is translated into mechanical motion by one of several techniques, including a pivoting cam, a flexure type, or a bellows assembly. The mechanical motion causes the switch to open or close. If a mercury switch is used, the mechanical motion drives a magnetic sleeve into the field of a permanent magnet that trips the switch. A hermetically sealed switch will be directly actuated by the permanent magnet as it moves up or down according to the paddle movement. If a microswitch is used, the translated motion will cause direct switch actuation.

The range and actuation point of paddle switches can be changed and adjusted by changing the length of the paddle. For any given pipe size, the actuation flow rate decreases as the paddle length increases.

Paddle-type flow switches are sensitive to pipeline turbulence, pipeline vibration, and installation configuration. For these reasons, it is advisable to provide them with the equivalent of a 10-pipe-diameter straight upstream run, to use dampers if pipe vibration or pulsating flow is expected, and to readjust their settings if they are to be mounted in vertical upward flow lines. The conventional paddle-type designs are incapable of distinguishing low flow velocities from no-flow conditions. Therefore, if lower flows are to be detected, the folding circular paddle should be used (Figure 2.7a), which permits the full diameter paddle to fold back upon itself to minimize pressure drop.

In smaller pipelines where it is desired to provide local flow indication, the variable-area-type flow switches can be considered in addition to the flow switch action. If the vertical upward flow configuration of the rotameter design is not convenient from a piping layout point of view, the circular swinging vane design, illustrated in Figure 2.7b, can be considered. In existing systems, the clamp-on-type ultrasonic liquid flow switch can be a convenient solution, because it does not require process shutdown or pipe penetration. If the purpose of the flow switch is to protect pumps from running dry, the wafer-type capacitance insert unit is a good choice (Figure 2.7f).

Flow switch reliability is increased by the elimination of moving parts so that pipe vibrations or fluid flow pulses will

not cause erroneous switch actuation. One of the most popular solid-state designs is the thermal flow switch. All heat-actuated flow switches sense the movement or stoppage of the process stream by detecting the cooling effect (temperature change) on one or more probes. They are available both in the flow-through and in the probe configuration. One design consists of a heater probe and two sensor probes connected in a Wheatstone bridge. When the flow stops, an imbalance in the bridge circuit occurs, as illustrated in Figure 2.7c. The main advantage of this design is its ability to detect very low flow velocities (Table 2.7d). Its main limitation is that it cannot respond instantaneously to flow changes. Depending on switch adjustments and on type of process fluid, the speed of response will vary from 2 sec to 2 min.

The valve body-type flow switches are built into a pipe fitting that resembles the body of a single seated globe valve. A flow disk is allowed to move in a vertical direction within what is normally considered the valve seat. A magnetic sleeve is mounted above the flow disk and, as the disk is lifted upward due to initiation of flow, a mercury switch is actuated by the movement of the magnetic sleeve into the field of the externally mounted permanent magnet.

A bypass-type switch (Figure 2.7e) has an externally adjustable vane that creates a differential pressure in the flow stream. This differential pressure forces a proportional flow through the tubing that bypasses the vane. A piston retained by a spring is in the bypass tubing and will move laterally as flow increases or decreases; the piston's movement actuates a switch. Bypass flow switches can be used for fairly low flow rates, and their ability to be externally adjusted is a very desirable feature.

Capacitance-type ring sensors can detect the absence or presence of liquids or slurries, which usually relates to flow/no-flow conditions. This can prevent pumps from running dry or cavitating. The ring sensor (Figure 2.7f) is a capacitance switch that fits between two flat-faced flanges in standard pipe sizes between 2 and 8 in. (50 and 200 mm). When the ring sensor contains air (no-flow condition), it detects a dielectric constant of 1. When flow starts, it detects the dielectric constant of the flowing fluid, which is greater than 1, which causes a corresponding increase in radio frequency (in the megahertz range) current flow. The circuitry detects this current flow and operates the switch accordingly. An adjustable time delay of 0 to 20 sec is provided to protect from premature shutdowns. The construction materials are usually PVC and steel, with the electronics housed in explosion-proof or water-tight aluminum or thermoplastic housing. The operating temperature range for the standard ring sensor is 0 to 212°F (–18 to 100°C).

SOLIDS FLOW SWITCHES

In pneumatically conveyed or gravity-flow-type solids handling systems, it is important to quickly detect blockages or other abnormal conditions, such as feed loss, bin bridging, cyclone overflow, or the rupture of baghouse filters. The flows of certain powders (such as flyash, cement, or alumina) are particularly difficult to detect. Level sensors; tilt switches; and capacitance, radiation, sonic, and optical devices have been used in the past to detect abnormal flow conditions. In addition to these, one can also measure the flow rate of these solids' flows by the following techniques.

One solids flow switch, the "Triboflow," collects, on its probe surface, the static charges of the solid particles passing over its surface. The resulting current is related to the flow rate of solids. These probes are sensitive enough to detect flow increases as small as what results from baghouse rupture. These probe-type solids flow switches are inexpensive and can be installed in hazardous areas.

Microwave switches detect the flow of solids by detecting motion or the absence of it. In the microwave-type motion detector, the transducer emits a 24-GHz signal into the flowing solid stream and analyzes the reflected frequency (Doppler effect) to determine the speed of the object that reflected it. The sensitivity of the solids flow switch is adjustable, so it might be used to detect flow/no-flow or trip at a velocity as low as 6 in./min (15 cm/min) when the pipe is full or at a velocity of one particle every 5 sec in a free-falling gravity flow system. Units are available in aluminum or stainless steel. They can be connected to a pipe by a coupling or flange (see Figures 2.7g and 2.23w), or they can view through windows or nonmetallic walls without any openings. The units are intrinsically safe and can be used at working pressures up to 15 PSIG (1 bar). The switch can also observe motion at a distance of several feet from the detector and can tolerate 0.5 in of nonconductive coating buildup or 0.1 in of conductive coating buildup.

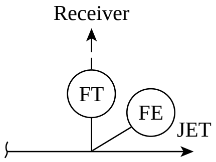
2.8 Jet Deflection Flow Detectors

D. S. KAYSER (1982) **B. G. LIPTÁK** (1995, 2003)



Flow Sheet Symbol

Maximum Process Pressure	10 PSIG (0.7 bar)
Design Temperature	450°F (232°C) standard and up to 1200°F (650°C) special
Standard Materials	Type 316 stainless steel
Connection and Insertion	Standard connection is 3 in. flanged; insertion depth is adjustable from 0 to 60 in. (0 to 1.5 m).
Air (Nitrogen) Requirement Pressure	10 to 90 PSIG (0.7 to 6.2 bar) over process pressure
Flow	2.5 and 5.0 SCFM (71 to 142 l/min)
Velocity Ranges	0 to 50 ft/sec and 0 to 85 ft/sec (0 to 15 m/sec and 0 to 26 m/sec)
Output Differential Range	0 to 80 in H_2O and 0 to 130 in H_2O (0 to 20 kPa and 0 to 32 kPa)
Inaccuracy	±2% of full scale (if sensor is inserted to average velocity point in the duct)
Rangeability	20:1
Cost	About $2500 to $5000; varies with accessories
Partial List of Suppliers	Fluidynamic Devices Ltd. United Scientific/Monitor Labs (formerly Lear Siegler Measurement Controls Corporation)

OPERATING PRINCIPLE

Volumetric flow rate in a pipe or duct can be inferred from a measurement of gas velocity, and one of the methods to measure this velocity is jet deflection detection. The operation of this sensor requires the blowing of air (or some other gas that is compatible with the process) through a nozzle, which forms a jet as shown in Figure 2.8a. The jet is centered between the two receiver ports when there is no flow in the process pipe or duct. In that case, the differential pressure between the two ports is zero. As a process flow is initiated, the jet is deflected, and the amount of this deflection will be related to the velocity of the flowing process stream. Figure 2.8a shows how the pressure profile of the jet shifts as the velocity of the process stream increases.

The deflection of the jet will cause an increase in the pressure at the downstream port and a decrease at the upstream port. The geometry of the ports is so designed that, over the useful

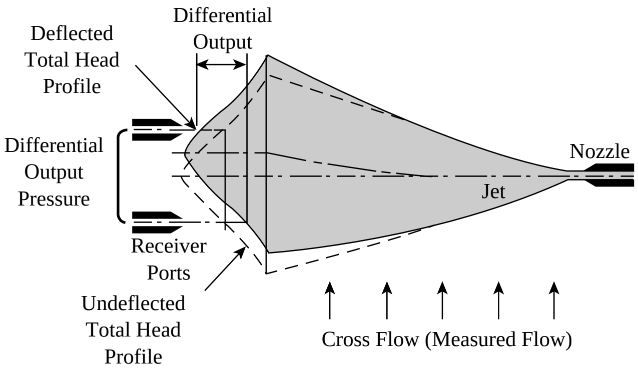


FIG. 2.8a
Pressure profile generated by a jet deflection-type flow detector.

range of the element, the change in differential pressure is linearly proportional to the velocity of the process stream. The actual value of this pressure differential is a function of the product of the process velocity and the square root of the gas density. If the density is constant, the pressure drop varies linearly with gas velocity. If the particulate concentration in the process fluid (flue or stack gases) is separately measured, this reading will yield the mass emission rate of particulate materials.

In some respects, this flowmeter is similar to the conventional pitot tube. Similarities include the negligible pressure drop created, the high speed of response, and the retractable design, which can be used for wet tapping or to measure flow profiles by traversing the cross section of the pipe or duct. On the other hand, the jet-deflection sensor has features that are superior to those of conventional pitot sensors.

These advantages include the existence of a continuous back-purge and of the auxiliary cleaning jets, which keep the receiver ports clean. Another advantage is that the element is heated to a temperature above the dew point, so condensation is avoided. In addition, the output signal is not only linear but is also much stronger than that of a conventional pitot element. At a supply pressure of 50 PSIG (345 kPa), the output differential-pressure signal generated about 1.5 in of water column per each ft/sec (0.3 m/sec), which is about 100 times what is generated by a pitot tube.

The relationship between process gas velocity and flow rate is

$$Q = 60VA \qquad \textbf{2.8(1)}$$

where

Q = flow rate, in actual cubic feet per minute (ACFM)
V = velocity, feet per second (ft/sec)
A = pipe or duct cross-sectional area, square feet (ft^2)

In case of laminar flow in a circular duct, the profile is parabolic with the maximum velocity at the center and zero velocity at the walls. In this case, the maximum velocity is twice the average; therefore, the reading taken at the center of the duct will be twice the average for the laminar flow case. In turbulent flow in a circular duct, the average velocity point is located at approximately 25% of the radius as measured from the duct wall. The accurate determination of average velocity in rectangular ducts is more complicated, and no simple rules of thumb can be given. The point velocity, in general, is inaccurate, because the velocity profile is not uniform.

In many actual installations, the point of average velocity will not be located at the predicted insertion depth because of disturbances introduced by the upstream piping configuration. For proper operation, the upstream piping should be straight for at least 20 pipe diameters to allow for the disturbances to smooth out. When this upstream straight run requirement cannot be met, an average velocity point can sometimes be found by traversing the duct and making a number of measurements at a number of points across the cross section.

A traverse should always be made on rectangular ducts, if accurate measurement is required. Traversing rectangular ducts is time consuming because of the need for traversing in two or more planes. In addition, the average velocity points can shift as flow rates vary in both the rectangular or circular ducts.

HOT-TAPPING

Probe-type instruments, such as the jet deflection type element or the pilot tube, can be installed so that they can be removed for inspection without shutting down the process. Figure 2.8b shows the detail of such a *hot-tapping* installation, which makes it possible to remove the probe while the pipe is under pressure. To remove the sensor, first the gland nut is loosened sufficiently to allow the withdrawal of the shaft of the element until it is outside of the gate valve and in the “outside chamber.” The valve is then closed, the outside chamber is vented, and the gland nut is removed to allow the safe removal of the element.

Normally, the jet deflection element is installed in piping that is under low pressure or vacuum; thus, the risk of having the element blow out during removal is slight. Nonetheless, it is recommended to install stop rods or safely chains so as to completely eliminate the possibility of injury caused by a blowout.

The step-by-step hot-tapping procedure is shown in Figure 2.8c. The first step is to weld a flanged nozzle to the pipe that is to be tapped. As the second step, a flanged gate valve is attached to the weld neck flange. The third step is to bolt a hot-tapping drill to the downstream side of the gate valve. After the gate valve is opened, the hot-tapping machine drills through the wall of the process pipe. Rigid safety procedures must be enforced during hot-tapping operations, particularly if the process is flammable or hazardous. Hot-tapping can be performed only if the piping specification does

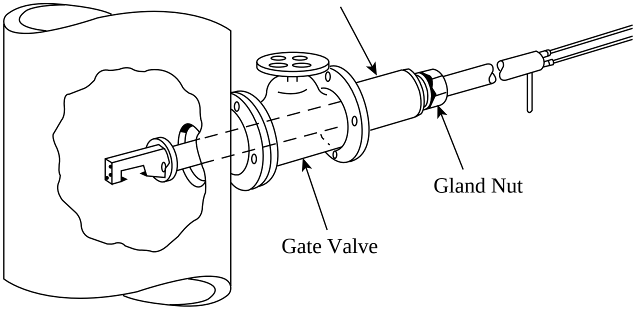

FIG. 2.8b
Hot-tap installation allows for the removal of the flow element, while the pipe or duct is under pressure.

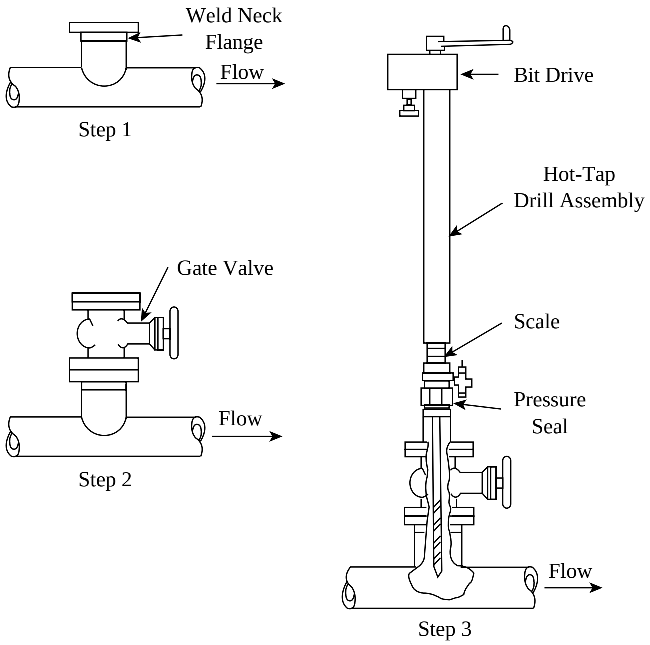

FIG. 2.8c
Hot-tapping procedure.

not require that welds be stress relieved and if there is flow in the pipe so that the heat of welding and drilling is removed.

The pressure seal on a hot-tap machine is similar in its design to that of a control valve packing box and it allows the tapping of pipes under relatively high pressures. A hand-operated drilling assembly is shown in the figure, but units are also available with pneumatic or electric drives. A scale is provided on the machine, showing the depth to which the operator has drilled into the pipe. After the drilling is done, the bit is retracted, the valve is closed, and the hot-tap machine is removed. The tap is now ready to accept the gland nut and outside chamber, which is provided with the flow element as shown in Figure 2.8b.

CONCLUSION

Jet deflection flow detectors can be considered for flow measurement in low-pressure, circular, or rectangular ducts. They can be periodically purged or flushed and can be removed for inspection and cleaning. They are suitable for dirty, abrasive, corrosive, and plugging services. Their accuracy of ±2% of full scale is usually acceptable for making flow measurements around flare headers, stacks, and air ducts. It should be remembered that the actual installed accuracy is dependent on one’s ability to insert the element to a depth at which the velocity is the average of the velocity profile across the duct.

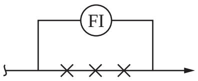
2.9 Laminar Flowmeters



Flow Sheet Symbol

R. SIEV (1969) **B. G. LIPTÁK** (1995) **J. B. ARANT** (1982, 2003)

Design Pressure	Up to 5000 PSIG (34 MPa)
Design Temperature	Up to 300°F (150°C) normally, but can be higher with special designs
Material of Construction	Stainless steel, aluminum, or any alloy available in small bore tubing
Fluids	Liquids and gases
Flow Range	0.0001 to 2000 scfm for gases (3 cm^3/min to 57 m^3/min) 0.0003 to 10 GPM for liquids (1 cm^3/min to 38 l/min)
Inaccuracy	0.5% to 1% of actual flow for commercial gas flow elements, if calibrated
Flow Turndown	10:1 minimum
Flow Characteristic	Linear to approximately linear
Costs	A 1/2-in. (13 mm) stainless-steel laminar flow element costs $700, a 2-in. (50 mm) unit costs $1500, and a 16-in. (300 mm) all-stainless unit costs $11,000. The differential-pressure readout devices are additional to the above element costs.

Laminar flowmeters fill a special need in flow measurement where the requirements might include low to extremely low flow rates, linear calibration and low noise, the ability to measure high-viscosity liquids, or steady low-flow repeatability and control accuracy. Laminar flowmeters are intended for very low flow rates where other types of meters are either marginal in performance or cannot be used at all. Laminar flowmeters can be constructed by various methods, but the most common is with capillary tubes. Hence, the terms *laminar flowmeter* and *capillary flowmeter* are virtually synonymous. Proprietary commercial units use other matrix shapes and are intended for use with gases (Figure 2.9a). Where gas is metered, it is preferable to use calibrated commercial units instead of undertaking the design of a laminar flowmeter.

The flowmeter consists of the laminar flow element and a differential-pressure measuring instrument. While the flow is theoretically linear with pressure drop, in practice, some nonlinearities are often encountered. In most cases, these are of little consequence.

The theory for laminar flowmeters is based on the Hagen–Poiseuille Law for laminar flow and the Reynolds number as a means of defining the type of flow. Both are required to investigate and design a laminar flow element. More detailed explanations and discussions of theory can be found in any standard textbook on fluid mechanics.

THEORY

Fluid flow in pipes and tubes is characterized by a nondimensional number called the Reynolds number (Re). Up to approximately Re 2000, the flow is called laminar, viscous, or streamline. Above 10,000, the flow is called fully developed

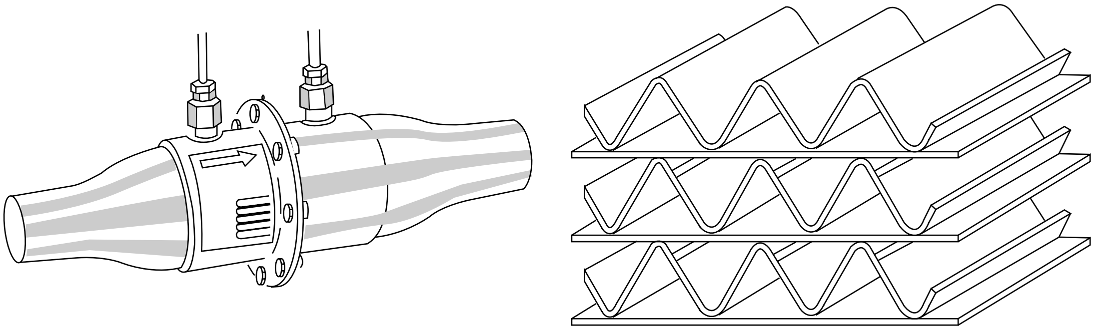

FIG. 2.9a
The laminar flowmeter and its matrix element with miniature triangular duct passage with under 0.1-mm effective diameters. (Courtesy of Meriam Instrument Div. of Scott Fetzer Co.)

turbulent. The region between 2000 and 10,000, where the flow is shifting from laminar to turbulent, is not clearly defined but is called transitional. Generally, laminar flow elements are restricted to numbers under 2000 and, most commonly, well below 1200. Certain methods will enable a capillary element to be used satisfactorily up to Re 15,000 with a modest sacrifice in error and linearity.

Reynolds number is defined by the following equations:

For liquid flow,

$$\mathrm{Re} = \frac{50.7\rho Q}{D\mu} \quad \text{or} \quad \mathrm{Re} = \frac{6.32W}{D\mu} \qquad \mathbf{2.9(1)}$$

where

Re = Reynolds number
ρ = density (lb/ft^3) at flowing temperature
Q = flow rate (gal/min)
D = internal tube diameter (in.)
μ = viscosity of flowing temperature (centipoise)
W = flow rate (lb/h)

For gas flow,

$$\mathrm{Re} = \frac{6.32\rho Q}{D\mu} \quad \text{or} \quad \mathrm{Re} = \frac{6.32W}{D\mu} \qquad \mathbf{2.9(2)}$$

where

ρ = density at standard conditions (lb/ft^3)
Q = flow rate (scfh)
Other units = as defined for liquid

For the laminar flowmeter shown in Figure 2.9a, the Reynolds number is limited to a range of 150 to 300 and is calculated as

$$\mathrm{Re} = 228(SG)(P)(\Delta P)/m\mu \qquad \mathbf{2.9(3)}$$

where

SG = specific gravity relative to air (Table 2.9b)
P = flowing gas pressure in inches of mercury absolute
ΔP = differential pressure in inches of water
$m\mu$ = viscosity of the flowing gas in micropoise (Table 2.9b)

TABLE 2.9b
Gas Properties under the Standard Conditions of 29.92 in of Mercury and 70°F (760 mm of Mercury and 21°C)

Gas	*Density (lb/ft^3)*	*μ Viscosity, Micropoise*	*Specific Gravity*
Air	0.0749	181.87	1.000
Argon	0.1034	225.95	1.380
Helium	0.0103	193.9	0.138
Hydrogen	0.0052	88.41	0.0695
Nitrogen	0.0725	175.85	0.968
Oxygen	0.0828	203.47	1.105
Carbon dioxide	0.1143	146.87	1.526

Hagen–Poiseuille Law

Once the tube inside diameter required to give laminar flow according to the Reynolds number calculation has been defined, the length of the capillary has to be determined to design the laminar flowmeter system. These equations are as follows.

For liquid flow,

$$L = 1.5876 \times 10^3 \, \frac{\Delta P D^4}{\mu Q} \qquad \mathbf{2.9(4)}$$

or

$$L = \frac{\Delta P D^4 \rho}{7.86 \times 10^5 \mu W} \qquad \mathbf{2.9(5)}$$

where

L = length of tube (in.)
ΔP = differential pressure drop (in water)
D = tube internal diameter (in.)
μ = viscosity at flowing temperature (centipoise)
ρ = density at flowing temperature (lbm/ft^3)
Q = flow rate (gal/min)
W = flow rate (lbm/h)

Equation 2.9(5) can also be used for calculating a gas flow capillary element if the value of ΔP is no greater than 10% of the inlet pressure. Otherwise, changes in gas density, specific volume, and flow velocity cause too many complications in the calculations. While the calculation is in weight units, this can be easily converted to any desired scale units.

Design Parameters

There are a number of guidelines for successful design of a laminar flowmeter.

1. The differential pressure drop can range from 5 to 800 in. of water (1.24 to 200 kPa).
2. $(L/D)/\text{Re}$ should be a minimum of 0.3; for best linearity, a value of 0.6 or greater is preferable. Large L/D ratios and/or lower Reynolds numbers contribute to accuracy. For example, the entrance effect for laminar flow is negligible if $(L/D)/\text{Re} > 0.3$ and $\text{Re} < 500$.
3. The area of the flow conduit preceding the capillary should be a minimum of 20 times the capillary area.
4. The differential-pressure instrument's pressure connections should be located 100 to 200 capillary diameters from the capillary ends.
5. A filter capable of removing particles 0.1 in. (2.54 mm) or larger than the capillary internal radius should be installed upstream of the system.
6. The metering system should be sloped up for liquids to permit gas venting and sloped down for gases to permit liquid draining.
7. Examination of the Hagen-Poiseuille equation shows that viscosity is a primary variable; changes in viscosity can result in large flow measurement errors. With a known fluid or composition, the only thing that affects viscosity is temperature. For this reason, the temperature must be known and held essentially constant. This can be done by immersing the metering system and measuring capillary in a constant temperature bath as shown in Figure 2.9c. If the flow is measured in weight units such as pounds per hour, then fluid density must be known. Fluid density also varies with temperature, but controlling the temperature to fix viscosity will also fix density. With some fluids, cooling may be required instead of heating, but the overall principle is the same.

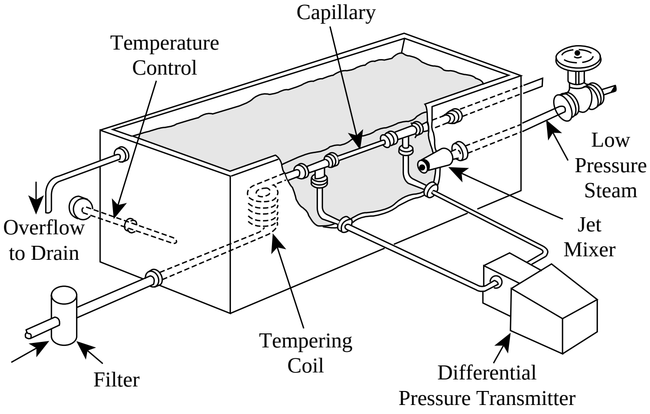

FIG. 2.9c
Typical capillary with constant temperature bath.

Design Calculations for Liquid Service

Based on the flow rate and the viscosity of the fluid, select a tube internal diameter that will result in a Reynolds number within the laminar range and preferably less than 1200. Calculate the length of tubing required using the selected tube diameter to ensure that it is a reasonable length and that it meets the $(L/D)/\text{Re}$ criteria. By working back and forth between the various equations, the system can be tailored to meet almost any design criteria. For example, let us assume that it is desired to design a capillary flowmeter to measure a small liquid catalyst stream, and the basic data for the catalyst flow is as follows:

Maximum flow capacity: 50 lbm/h
Viscosity: 20 cP at 100°F
Density: 53.8 lbm/ft^3
Desired instrument ΔP: 100 in of water

Small-diameter, standard stainless-steel tubing is readily available and should be used. To design as linear and accurate a flowmeter as possible, a tube bore that provides a large $(L/D)/\text{Re}$ is desirable. To minimize plugging problems and to enable the use of a filter that won't clog easily, start by looking at a 3/16 × 0.032-in. wall thickness tubing with a nominal internal diameter of 0.1235 in. From Equation 2.9(1),

$$\text{Re} = \frac{6.32W}{D\mu} = \frac{6.32\times 50}{0.1235\times 20} = 128 \qquad \textbf{2.9(6)}$$

This is well into the laminar range, so the length of the flow element can be calculated to determine if it will make a reasonable design. From Equation 2.9(5),

$$L = \frac{\Delta P D^4 \rho}{7.86\times 10^{-5}\mu W} = \frac{100\times 0.1235^4\times 53.8}{7.86\times 10^{-5}\times 20\times 50} = 15.7\,\text{in.} \qquad \textbf{2.9(7)}$$

$$(L/D)\,\text{Re} = (15.7/0.1235)/128 = 0.993 \qquad \textbf{2.9(8)}$$

This is an easy length to work with in fabricating a meter element and a constant temperature bath, and it looks like a reasonable design based on the criteria.

ERROR SOURCES

Changes in viscosity and density can result in flow measurement errors. Viscosity changes in liquid as a result of temperature can be substantial, while density changes are more moderate. With gases, the reverse is usually true, with temperature having more influence on density and less on viscosity. The need for careful control of the operating temperature to minimize these effects must be emphasized.

From Equations 2.9(4) and 2.9(5), it can be seen that internal diameter of the tube is very important, because it is multiplied to the fourth power. While high-quality tubing will be very close to published specifications, manufacturing tolerances will result in variations from these dimensions, both laterally and longitudinally. If the actual effective internal diameter of the capillary tube differs by 1% from the value used in the calculation for a given ΔP, an error of about 4% will result. Therefore, the laminar flowmeter should be calibrated on a known fluid before use, and appropriate design adjustments should be made as necessary.

To measure the true capillary differential pressure drop according to the Poiseuille equation, it would be necessary to put the pressure taps into the capillary at the calculated L dimension. This is impractical because of the small tubing. A pressure tap must be perfectly flush with the inside of the tube and must be clean with no burrs or other projections into the tube. Otherwise, considerable differential-pressure measurement error will result. Using practical methods of constructing a capillary flowmeter, there are three additional sources of pressure drop in addition to the capillary loss. These are all additive and will give a greater indicated pressure drop than the capillary flow alone. These three sources of error are inlet loss, exit loss, and capillary entrance loss. These losses also contribute to nonlinearity.

There is very little loss from the entrance fitting into the capillary tube if laminar flow conditions exist. But if the piping cavity ahead of the capillary is extremely large relative to the capillary (approximating a reservoir) and the fluid velocity is thus extremely low (approaching zero), there can be an inlet effect and pressure loss.[1] This is a result of the sudden contraction from the large reservoir to the small tube bore, forming a bell-mouth shape approach flow. This loss can be expressed as

$$\Delta P_i = \frac{2.8 \times 10^{-7} W^2}{D^4 \rho} \qquad \textbf{2.9(9)}$$

This equation is derived from Bernoulli's equation for flow out of a reservoir.

When the fluid exits the capillary, the flow path enlarges. If the piping is similar to that described under inlet loss, the loss can be calculated by

$$\Delta P_e = \frac{5.6 \times 10^{-7} W^2}{D^4 \rho} \qquad \textbf{2.9(10)}$$

Entrance loss occurs in addition to the normal capillary pressure drop in the initial fluid path distance or, to state it in another way, for a short distance the pressure drop is higher than that predicted by the Poiseuille Equation.[2,3] The additional loss is due to the work expended in the formation of the parabolic velocity distribution profile characteristic of laminar flow. It can be expressed in terms of an equivalent length of capillary, L_{eq}, added to that calculated by the Poiseuille equation. Refer to Figure 2.9d for determining the L_{eq}.

The following equation can be used for the pressure drop:

$$\Delta P_{en} = \frac{1.96 \times 10^{-7} W^2}{D^4 \rho} \qquad \textbf{2.9(11)}$$

Table 2.9e can be used as a quick guide for judging the design factors that will minimize overall entrance effects. For the conditions given in the table, the error involved will be less than 1%. In general, the effect of all of the above errors will be minimized if the Reynolds number is low, the laminar flow element is long, and the pressure drop is high. The overall

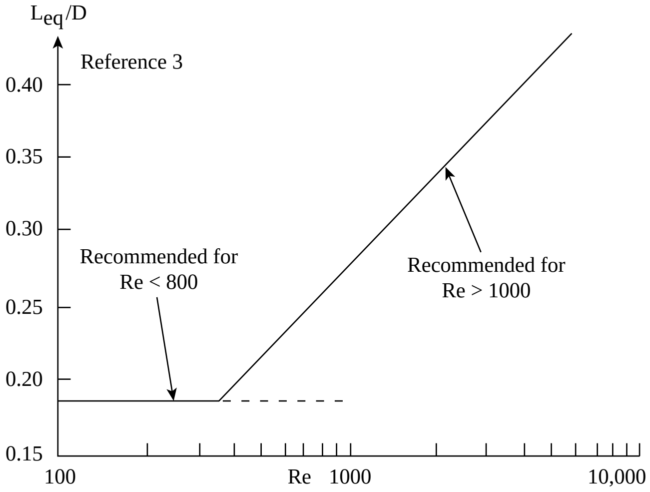

FIG. 2.9d
Equivalent length of capillary (L_{eq}).

TABLE 2.9e
L/D Ratio to Minimize Entrance Effect

Re	10	50	100	500	1000	2000
L/D>	15	75	150	750	1500	3000

error can be calculated by this equation as

$$\text{Percent error} = \frac{\Delta P_i + \Delta P_e + \Delta P_{en} \times 100}{\Delta P} = \frac{0.367W \times 100}{\mu L} \qquad \textbf{2.9(12)}$$

RANGE EXTENSION TECHNIQUES

Two techniques are used to expand the range capability of laminar flow elements. One is to use a number of capillary tubes in parallel. The other is to use a tight helical coil capillary. The choice of technique depends on such factors as desired flow rate, nonlinearity requirements, Reynolds number, capillary length, and system space design limitations.

If the amount of flow desired is greater than can be conveniently handled by a single capillary, the flow can be split into many smaller units as necessary.[4] Units with matrix elements (Figure 2.9a) or with more than 900 individual capillary tubes have been built and used successfully. The mechanical construction of multiparallel capillaries can be a problem. Tube packing voids may not affect meter operation but add considerable difficulty to calculating the meter range. Normally, it is best to eliminate the voids by filling the spaces with solder, braze material, or plastic resin; the filler material chosen will depend on fluid compatibility and operating conditions. Overall, it is a tricky mechanical design.

Coiling a length of straight capillary results in a flow phenomenon called the *Dean effect*. When a fluid flows through a curved pipe or coil, a secondary circulation of fluid, known as a double eddy, takes place at right angles to the main direction of flow. This circulation accounts for the fact that the pressure drop in curved pipe is greater than in a corresponding length of straight pipe. The Dean effect stabilizes laminar flow and raises the Reynolds number at which turbulent flow starts. It has been established that this will allow properly designed coiled capillaries to be operated up to a Reynolds number of 15,000.[5] The Reynolds number at which laminar flow can be sustained for various coil curvature ratios is called the *critical Reynolds number.* It is a function of the internal diameter of the tube and the coil tightness or diameter. Table 2.9f gives the approximate critical Reynolds number at which laminar flow can be sustained for various coil curvature ratios.

In this table, D is the tube inside diameter, and Dc is the mean coil diameter, centerline to centerline. From a practical viewpoint, the ratio of $D/Dc = 1/9$ is equivalent to the maximum allowable critical Reynolds number of 15,000 and can be used as a safe design in most cases.

The pressure drop of laminar flow through coils can be expressed in terms of an equivalent length, L_e, of straight pipe of the same diameter and shape which will have the same friction loss as the curved pipe. The ratio of the equivalent to actual coil length, L_e/L is a function of the Dean number, or $\mathrm{Re}(D_C/D)^{1/2}$, as shown in Figure 2.9g. This curve is accurate to about ±5%.

TABLE 2.9f
Critical Reynolds Number vs. Coil Curvature Ratio

Coil Curvature Ratio (Dc/D)	*Critical Reynolds Number* $(\mathrm{Re})_c$
Straight Pipe	2100

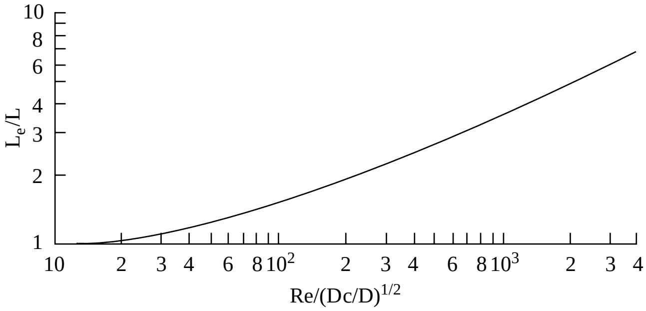

FIG. 2.9g
Equivalent lengths for curved pipe.

The equation for calculating the length of a coiled capillary required to meet a specific metering design is expressed by

$$L = \frac{\Delta P D^4 \rho}{7.86 \times 10^{-5} \mu W C} \qquad \textbf{2.9(13)}$$

where C = the coil factor correction.

The coil factor correction is a function of the term $\mathrm{Re}(D/D_C)^{1/2}$. Refer to Figure 2.9h for C vs. $\mathrm{Re}(D/D_C)^{1/2}$ or to Figure 2.9i for C versus Re for various D/Dc ratios. In very small capillaries, the coil diameter can be the nominal value, since exact centerline measurement is insignificant.

In laminar flow, the friction factor is a function of Reynolds number only and is independent of surface roughness.

The friction factor can be expressed as

$$f = 16/\mathrm{Re} \qquad \textbf{2.9(14)}$$

Therefore, the Fanning equation 2.8(15) can be used as an alternate means of calculating the capillary element as shown by

$$L = \frac{2\Delta P g_c D}{4 f \rho V^2} \qquad \textbf{2.9(15)}$$

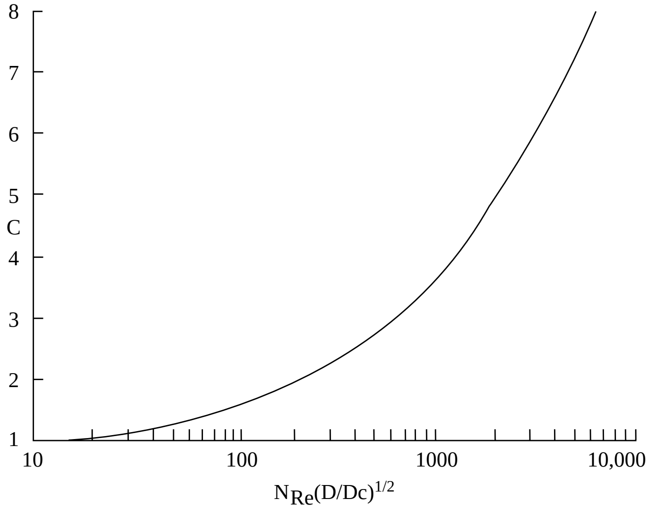

FIG. 2.9h

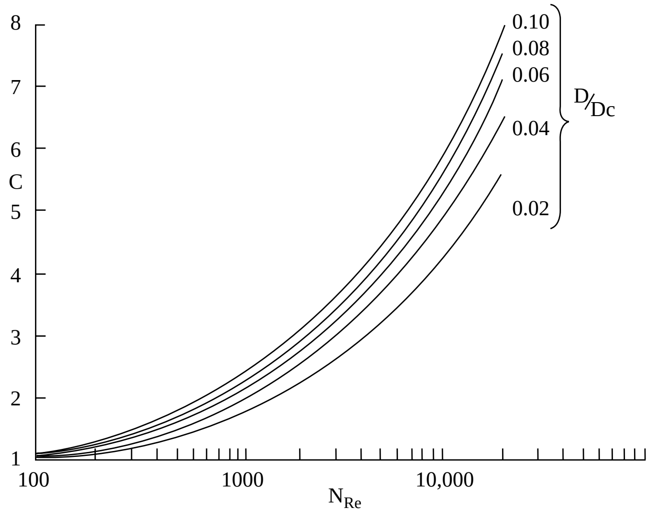

FIG. 2.9i
Correction factors for coiled capillary flowmeters (data adapted from reference 5).

where

L = capillary length (ft)
ΔP = pressure drop (lbf/ft^2)
g_c = gravity constant 32.17 (ft/sec^2)
D = capillary internal diameter (ft)
ρ = fluid density (lbm/ft)
V = fluid velocity (ft/sec)

COMMERCIALLY AVAILABLE UNITS

In the past decade, the use of laminar flowmeters has greatly expanded, and the number of suppliers has also increased. Their applications range from the testing of internal combustion equipment to semi-conductor manufacturing, leak testing, and fan or blower calibration. Standard units are available in several materials, including stainless steel. They can be provided with a variety of connections and in sizes ranging from 0.25 to 16 in. (6 to 400 mm).

In terms of airflow capability, these units range from 5 cc/min to approximately 65 cubic meters/min (2285 SCFM). Pressure differentials generated by the laminar flow elements are usually under 20 in. of water (510 mm of water). The recommended installation practice is to provide 10 to 15 diameters of straight pipe upstream of the flow element. Installation of a filter is also recommended at the meter inlet. In engine testing, a backfire trap is also desirable to prevent carbon deposits on the matrix element.

The measurement error is usually between 0.5 and 1% of actual flow within a 10:1 range. However, this performance is a function of both the quality of calibration of the system and of the precision of the d/p detector.

CONCLUSION

Laminar flowmeters are highly useful in measuring low flow rates of liquids and gases. Design of the elements is based on the use of the Reynolds number and Poiseuille's law. Design for most units is relatively simple, but fabrication of a complete unit and system can be complex. Simple capillary units can be fabricated by the user, but most require manufacturers' skills and design knowledge.

It is highly recommended that the final system be calibrated with the same type of fluid as the fluid upon which the sensor will operate, such as air or nitrogen for gas services and water for liquid services. After such calibration, the conversion is easily made to the actual fluid. The critical consideration is to calibrate the unit under conditions that will approximate the actual in-service Reynolds number of the application. Some sources of calibration services, other than the manufacturers, are the National Institute of Standards and Technology (NIST), Edison ESI, and the Colorado Engineering Experiment Station, Inc. (CEESI).

Magnetic
Flow Sheet Symbol

Design Pressure	Varies with pipe size; for a 4-in. (100-mm) unit, the maximum is 285 PSIG (20 bars); special units are available with pressure ratings up to 2500 PSIG (172 bars)
Design Temperature	Up to 250°F (120°C) with Teflon® liners and up to 360°F (180°C) with ceramic liners
Materials of Construction	Liners: ceramics, fiberglass, neoprene, polyurethane, rubber, Teflon, vitreous enamel Kynar Electrodes: platinum, Alloy 20®, Hasselloy C, stainless steel, tantalum, titanium, tungsten carbide, Monel®, nickel, platinum-alumina ceramic
Type of Flow Detected	Volumetric flow of conductive liquids, including slurries and corrosive or abrasive materials
Minimum Conductivity Required	The majority of designs require 1 to 5 μS/cm. Some probe types require more. Special designs can operate at 0.05 or 0.1 μS/cm.
Flow Ranges	From 0.01 to 100,000 GPM (0.04 to 378.000 l/min)
Size Ranges	From 0.1 to 96 in. (2.5 mm to 2.4 m) in diameter
Velocity Ranges	0–0.3 to 0–30 ft/sec (0–0.1 to 0–10 m/sec)
Power Consumption	20 W with DC excitation, 30 W for a 2-in. (50-mm) AC and 0.3 kW for a 30-in. (760-mm) AC unit.
Input Signals	Voltage signal from detector proportional to flow rate; digital input 20 to 30 VDC for range switching, totalizer control, zero adjustment
Output Signal	4 to 20 mA DC, digital outputs for pulse outputs, multirange selection, high and low limits, empty pipe alarm, preset count, and converter failure outputs
Communication Output	Digital signal is superimposed on 4- to 20-mA; current signal conforms with HART protocol
LCD Display	Two-line, line, or dot matrix
Surge Protection	Arresters are installed in the power supply and current signal output circuits
Error (Inaccuracy)	±1% of actual flow with pulsed DC units within a range of up to 10:1 if flow velocity exceeds 0.5 ft/sec (0.15 m/sec); ±1% to ±2% full scale with AC excitation
Cost	The least expensive designs are the probe versions that cost about $1500. A 1-in. (25-mm) ceramic tube unit can be obtained for under $2000. A 1-in. (25-mm) metallic wafer unit can be obtained for under $3000. An 8-in. (200-mm) flanged meter that has a Teflon liner and stainless electrodes and is provided with 4- to 20-mA DC output, grounding ring, and calibrator will cost about $8000. The scanning magmeter probe used in open-channel flow scanning costs about $10,000.

Unlike many other types of flowmeters, magnetic flowmeters offer true noninvasive measurements. They can be constructed easily to the extent that existing pipes in a process can be configured to act as a meter by simply adding two external electrodes and a pair of suitable magnets. They measure both forward and reverse flows. They are insensitive to viscosity, density, and other flow disturbances. Electromagnetic flowmeters are linear devices that are applicable to a wide range of measurements, and they can respond rapidly to changes in the flow. In the recent years, technological refinements have resulted in more economical, accurate, and smaller instruments.

As in the case of many electrical devices, the underlying principle of the magnetic-type flowmeters is Faraday's law of electromagnetic induction. Faraday's law states that, when a conductor moves through a magnetic field of a given strength, a voltage is produced in the conductor that is dependent on the relative velocities between the conductor and the field. This concept is used in electric generators. Faraday foresaw the practical application of this principle to the flow measurements, since many liquids are electrical conductors to some extent. Faraday went farther and attempted to measure the flow velocity of the Thames River. The attempt failed because his instrumentation was not sensitive enough. However, about 150 years later, we successfully can build magnetic flowmeters based on Faraday's law.

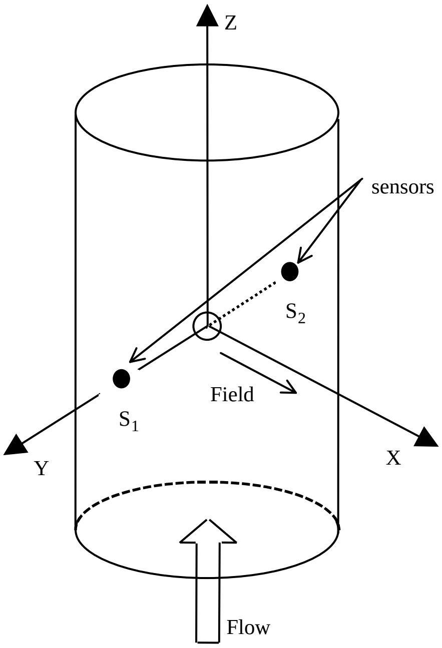

FIG. 2.10a
Operational principle of electromagnetic flowmeters: Faraday's Law states that a voltage is induced in a conductor moving in a magnetic field. In electromagnetic flowmeters, the direction of movement of conductor, the magnetic field and the induced emf are perpendicular to each other in X, Y and Z axes. Sensors S_1 and S_2 experience a virtual conductor due to liquid in the pipe.

THEORY

Faraday's law states that, if a conductor of length l (m) is moving with a velocity v (m/sec) perpendicular to a magnetic field of flux density B (Tesla), a voltage e will be induced across the ends of the conductor. The value of the voltage may be expressed by

$$e = Blv \qquad \textbf{2.10(1)}$$

Figure 2.10a shows how Faraday's law is applied in the electromagnetic flowmeter. The magnetic field, the direction of the movement of the conductor, and the induced emf are all perpendicular to each other. The liquid is the conductor that has a length, D, equivalent to the inside diameter of the flowmeter. The liquid conductor moves with an average velocity V through the magnetic field of strength B. From Equation 2.11(1), the induced voltage e is

$$e = BDV/C \qquad \textbf{2.10(2)}$$

where C is a constant to take care of the proper units.

Figure 2.10b illustrates the principles of operation of electromagnetic flowmeters in detail. When the pair of magnetic coils are energized, a magnetic field is generated in a plane that is mutually perpendicular to the axis of the liquid conductor and the plane of the electrodes. The velocity of the liquid is along the longitudinal axis of the flowmeter body; therefore, the voltage induced within the liquid is mutually perpendicular to both the velocity of the liquid and the magnetic field. The liquid can be considered as an infinite number of conductors moving through the magnetic field, with each element contributing to the voltage generated. An increase in flow rate of the liquid conductors moving through the field will result in an increase in the instantaneous value of the voltage generated. Also, each of the individual "generators" is contributing to the instantaneously generated voltage. Whether the profile is essentially square (characteristic of a turbulent velocity profile), parabolic (characteristic of a laminar velocity profile), or distorted (characteristic of poor upstream piping), the magnetic flowmeter averages the voltage contribution across the metering cross section. The sum of the instantaneous voltages generated is therefore representative of the average liquid velocity, because each increment of liquid velocity within the plane of the electrode develops a voltage proportional to its local velocity. The signal voltage generated is equal to the average velocity almost regardless of the flow profile.

Once the magnetic field is regarded to be constant, and the diameter of the pipe is fixed, the magnitude of the induced voltage will be proportional only to the velocity of the liquid [Equation 2.10(2)]. If the ends of the conductor, in this case the sensors, are connected to an external circuit, the induced voltage causes a current, i, to flow that can be processed suitably as a measure of the flow rate. The resistance of the

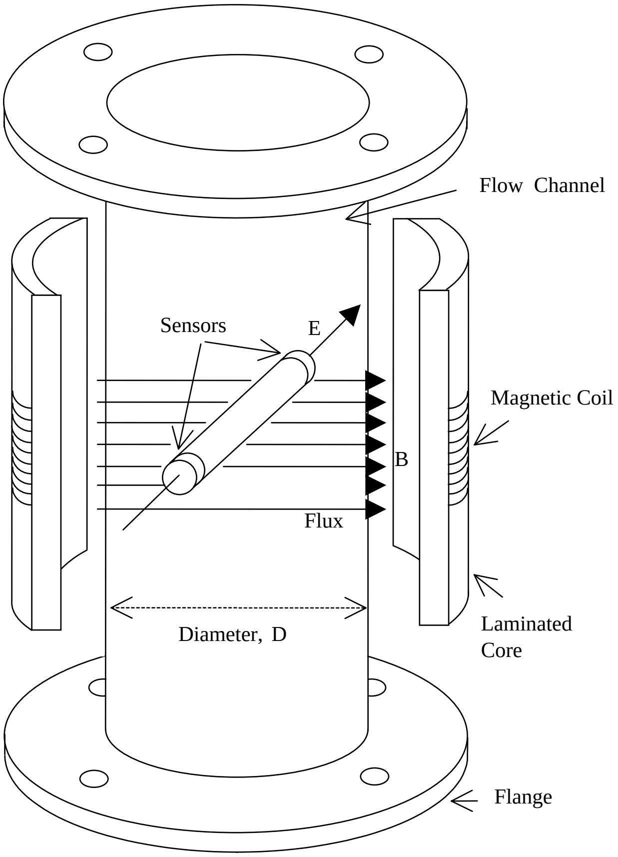

FIG. 2.10b
Construction of practical flowmeters: External electromagnets create a homogeneous magnetic field that passes through the pipe and the liquid inside. Sensors are located 90 deg to the magnetic field and the direction of the flow. Sensors are insulated from the pipe walls. Flanges are provided for fixing the flowmeter to external pipes. Usually, manufacturers supply information about the minimum lengths of the straight portions of external pipes.

moving conductor may be represented by R to give the terminal voltage v_T of the moving conductor as $v_T = e - iR$.

Often, magnetic flowmeters are configured to detect the volumetric flow rate by sensing the linear velocity of the liquid. The relationship between the volume of liquid Q (l/sec) and the velocity may be expressed as

$$Q = Av \qquad \textbf{2.10(3)}$$

Writing the area, A (m^2), of the pipe as

$$A = \pi D^2/4 \qquad \textbf{2.10(4)}$$

gives the induced voltage as a function of the flow rate; that is,

$$e = 4BQ/\pi D \qquad \textbf{2.10(5)}$$

This equation indicates that, in a carefully designed flowmeter, if all other parameters are kept constant, the induced voltage is linearly proportional only to the mean value of the liquid flow. Nevertheless, a main difficulty in electromagnetic flowmeters is that the amplitude of the induced voltage may be very small relative to extraneous voltages and noise. The noise sources include the following:

- Stray voltage in the process liquid
- Capacitive coupling between signal and power circuits
- Capacitive coupling in connection leads
- Electromechanical emf induced in the electrodes and the process fluid
- Inductive coupling of the magnets within the flowmeter

Advantages

1. The magnetic flowmeter is totally obstructionless and has no moving parts. Pressure loss of the flowmeter is no greater than that of the same length of pipe. Pumping costs are thereby minimized.
2. Electric power requirements can be low, particularly with the pulsed DC-types. Electric power requirements as low as 15 or 20 W are not uncommon.
3. The meters are suitable for most acids, bases, waters, and aqueous solutions, because the lining materials selected are not only good electrical insulators but also are corrosion resistant. Only a small amount of electrode metal is required, and stainless steel, Alloy 20®, the Hastelloys®, nickel, Monel®, titanium, tantalum, tungsten carbide, and even platinum are all available.
4. The meters are widely used for slurry services not only because they are obstructionless but also because some of the liners, such as polyurethane, neoprene, and rubber, have good abrasion or erosion resistance.
5. Magmeters are capable of handling extremely low flows. Their minimum size is less than 0.125 in. (3.175 mm) inside diameter. The meters are also suitable for very high-volume flow rates with sizes as large as 10 ft (3.04 m) offered.
6. The meters can be used as bidirectional meters.

Limitations

The meters have the following specific application limitations:

1. The meters work only with conductive fluids. Pure substances, hydrocarbons, and gases cannot be measured. Most acids, bases, water, and aqueous solutions can be measured.
2. The conventional meters are relatively heavy, especially in larger sizes. Ceramic and probe-type units are lighter.
3. Electrical installation care is essential.
4. The price of magnetic flowmeters ranges from moderate to expensive. Their corrosion resistance, abrasion resistance, and accurate performance over wide turndown ratios can justify the cost. Ceramic and probe-type units are less expensive.

5. To periodically check the zero on AC-type magnetic flowmeters, block valves are required on either side to bring the flow to zero and keep the meter full. Cycled DC-units do not have this requirement.
6. An important limitation in electromagnetic flowmeters may be the effect of magnetohydrodynamics, which is especially prominent in fluids with magnetic properties. Hydrodynamics refers to the ability of magnetic field to modify the flow pattern. In some applications, the velocity perturbation due to magnetohydrodynamic effect may be serious enough to influence the accuracy of operations (e.g., in the case of liquid sodium and its solutions).

TYPES OF MAGNETIC FLOWMETERS

There are many different types of electromagnetic flowmeters, all based on Faraday's law of induction, such as the AC, DC, dual-excited, and permanent magnet types. This section concentrates on most commonly used flowmeters: the AC, the DC and the dual-excited types. Classification due to usage is briefly explained in the subsection titled "Other Types."

Modern magnetic flowmeters are also classified as

- Conventional flowmeters
- Smart magnetic flowmeters
- Multivariable magnetic flowmeters

Conventional flowmeters have normally have a 4- to 20-mA output. But these magnetic flowmeters are gradually being phased out because of their limited communication capabilities.

Smart magnetic flowmeters are microprocessor-based devices, and they are capable of communicating digitally with other equipment, such as computers. The communication protocols include HART, FOUNDATION™ fieldbus (FF), Profibus (PB), and serial and parallel communications. Integration of microprocessors give them additional features such as self-diagnostic and self-calibration capabilities. Table 2.10c illustrates communication features of some selected magnetic flowmeters.

Multivariable magnetic flowmeters are capable of measuring more than one process variable. For example, by measuring pressure and temperature, it is possible to calculate

density of the flowing materials. From the density, mass flow can be determined.

AC Magnetic Flowmeters

In many commercial magnetic flowmeters, an alternating current of 50 or 60 Hz creates the magnetic field in coils to induce voltage in the flowing liquid. The signals generated are dependent on the velocity of liquid and flowmeter dimensions. Generally, they resemble low-level AC signals, being in the high microvolt to low millivolt ranges. A typical value of the induced emf in an AC flowmeter fixed on a 50 mm internal diameter pipe carrying 500 l/min is observed to be about 2.5 mV.

The AC excitations may be in different forms, but generally they can be categorized into two families: those using on–off excitation and those using plus–minus excitation. In either case, the principle is to take a measurement of the induced voltage when the coils are not energized and to take a second measurement when the coils are energized and the magnetic field has stabilized. Figure 2.10d shows some of the types of excitation offered by various manufacturers.

AC flowmeters operating 50, 60, or 400 Hz are readily available. In general, AC flowmeters can operate from 10 Hz to 5000 Hz. High frequencies are preferred in determining the instantaneous behavior of transients and pulsating flows. Nevertheless, in applications where extremely good conducting fluids and liquid metals are used, the frequency must be kept low to avoid skin effect. On the other hand, if the fluid is a poor conductor, the frequency must not be so high that dielectric relaxation is not instantaneous.

AC magnetic flowmeters reduce the polarization effects at the electrodes, and they are less affected by the flow profiles of the liquid in the pipe. They allow the use of high-Z_{in} amplifiers with low drift and highpass filters to eliminate slow and spurious voltage drifts emanating mainly from thermocouple and galvanic actions. These flowmeters find many diverse applications, including measurement of blood flow in living specimens. Miniaturized sensors allow measurements on pipes and vessels as small as 2 mm dia. In these applications, the excitation frequencies are higher than industrial types—200 to 1000 Hz.

A major disadvantage of an AC flowmeter is that the powerful AC field induces spurious AC signals in the measurement circuits. This requires periodic adjustment of zero output at zero-velocity conditions, which is more frequent than in DC counterparts. Also, in some harsh industrial applications, currents in the magnetic field may vary due to voltage fluctuations and frequency variations in the power lines. The effect of fluctuations in the magnetic field may be minimized by the use of a reference voltage proportional to the strength of the magnetic field to compensate for these variations. To avoid the effects of noise and fluctuations, special cabling and calibration practices recommended by the manufacturers must be used to ensure accurate operations. Usually, the use of two conduits is required—one for signals and one for power. The cable lengths also should be set to specific levels to minimize noise and sensitivity problems.

DC Magnetic Flowmeters

Unlike AC magnetic flowmeters, direct current or pulsed magnetic flowmeters excite the flowing liquid with a magnetic field operating at 3 to 8 Hz. In all of the pulsed DC approaches, the concept is to take a measurement when the coils are excited and store (hold) that information, then take a second measurement of the induced voltage when the coils are not excited (Figure 2.10d). As the current to the magnet is turned on, a DC voltage is induced at the electrodes. When the current in the magnetic coils is turned off, the signal represents only the noise. The signals observed at the electrodes represent the sum of the induced voltage and the noise, as illustrated in Figure 2.10e. Subtracting the measurement of the flowmeter when no current flows through the magnet from the measurement when current flows through the magnet effectively cancels out the effect of noise.

When the magnetic field coils are energized by a normal direct current, several problems occur, such as polarization and electrochemical and electromechanical effects. Polarization is the formation of a layer of gas around the measured electrodes. Some of these problems may be overcome by

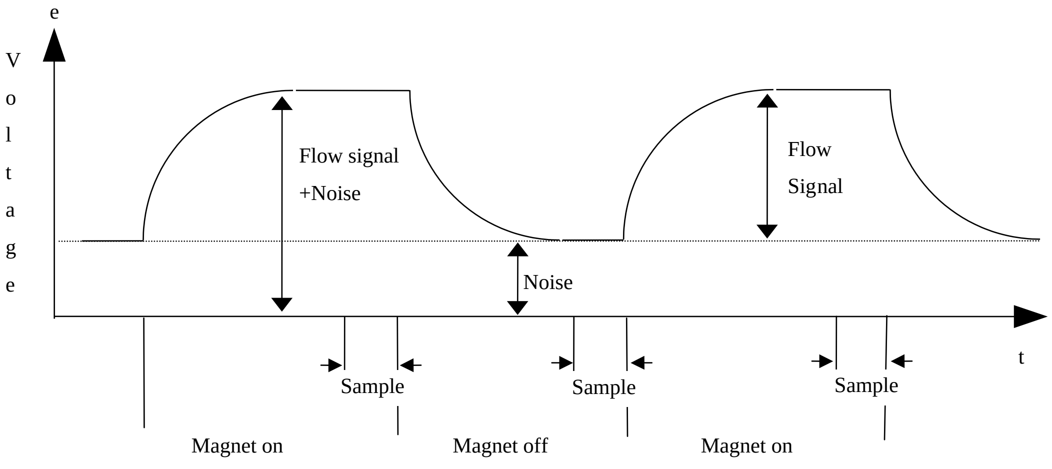

FIG. 2.10e
Signal development of pulsed DC-type magnetic flowmeter with half-wave excitation. As shown, the magnetic field is generated by a square wave which, in function, turns the magnet "on" and "off" in equal increments. When "on," the associated signal converter measures and stores the signal which is a composite of flow plus a variable (non-flow-related) residual voltage. During the "off" period, the converter measures the variable (non-flow-related) residual signal only. Since no field excitation is present, no flow signal will be generated. The converter then subtracts the stored residual signal from the flow developed-plus residual signal, resulting in the display of a pure flow signal.

energizing the field coils at higher frequencies. However, higher frequencies generate transformer action in the signal leads and in the fluid path. Therefore, the coils are excited by DC pulses at low repetition rates to eliminate the transformer action. In some flowmeters, by appropriate sampling and digital signal processing techniques, the zero errors and the noise can be rejected easily.

The pulsed DC-type systems establish zero during each on–off cycle. This occurs several times every second. Because zero is known, the end result is that pulsed DC systems are potential percent-of-rate systems. The AC-type systems must be periodically rezeroed by stopping flow and maintaining a full pipe so as to zero out any voltage present at that time.

The zero compensation inherent in the DC magnetic flowmeters eliminates the necessity of zero adjustment. This allows the extraction of flow signals regardless of zero shifts due to spurious noise or electrode coating. Unlike AC flowmeters, larger insulating electrode coating can be tolerated that may shift the effective conductivity significantly without affecting performance. As effective conductivity remains sufficiently high, a DC flowmeter will operate satisfactorily. Therefore, DC flowmeters are less susceptible to drifts, electrode coatings, and changes in the process conditions as compared with conventional AC flowmeters.

As a result of the slow, pulsed nature of their operations, DC magnetic flowmeters do not have good response times. However, so long as there are not rapid variations in the flow patterns, zero to full-scale response times of a few seconds do not create problems in most applications. Power requirements are also much less, because the magnet is energized only part of the time. This gives power savings of up to 75%.

If the DC current to the magnet is constant, the proportional magnetic field may be kept steady. Therefore, the amplitudes of the DC voltages generated at the electrodes will be linearly proportional to the flow. However, in practice, the current to the magnet varies slightly due to line voltage and frequency variations. As in the case of AC flowmeters, voltage and frequency variations may require the use of a reference voltage. Because the effect of noise can be eliminated more easily; the cabling requirements are not as stringent.

As mentioned before, polarization may be a problem in DC-type flowmeters. To avoid electrolytic polarization of the electrodes, bipolar pulsed DC flowmeters are available. Also, modification of the DC flowmeters has led to the development of miniature DC magnetic flowmeters that use wafer technology for a limited range of applications. The wafer design reduces weight and power requirements.

Dual-Frequency Excitation

Changing the method of excitation from line frequency (AC) to low frequency (DC) provided dramatic improvements in both the accuracy and the zero stability of magnetic flowmeters. Yet it did not represent the summit in technological advancements. A limitation of low-frequency (DC) designs is their relatively low response speed (0.2 to 2 sec) and their sensitivity to measurement noise caused by slurries or low-conductivity fluids.

The idea behind dual-frequency excitation is to apply both methods and thereby benefit from the advantages of both: the zero stability of low-frequency excitation and the good noise rejection and high-speed of response of high-frequency excitation. This is achieved by exciting the magnetic field coils by a current with such a compound wave, as illustrated in Figure 2.10f. One component is a low-frequency waveform, much below 60 Hz, which guarantees good

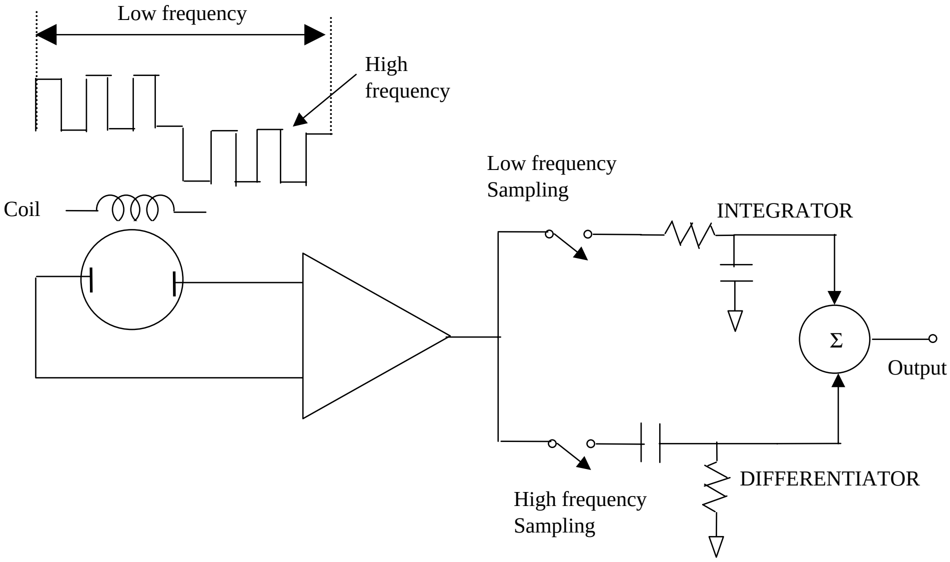

FIG. 2.10f
Dual-frequency excitation design combines the advantages of both systems.

zero stability. The output generated by the low-frequency signal is integrated via a long time constant to provide a smooth and stable flow signal.

The high-frequency component is superimposed on the low-frequency signal to provide immunity to noise caused by low conductivity, viscosity, slurries, and electrochemical reactions. The output generated by the high-frequency component is sampled at a high frequency and is processed in a differentiating circuit having the same time constant as the integrating circuit. By adding the two signals, the result is an output that is free of "slurry" noise and has good zero stability plus good response speed.

Other Types

Classification of magnetic flowmeters varies from one manufacturer to the next. A typical classification involves several types: wafer, flange, partially filled, micro-fractional, large-size, and sanitary. There are variations in the size of detectors and other features made suitable for a specific application. For example, micro-fractional detectors are designed to measure small amounts of fluids containing substances such as chemicals. The wetted materials are made from corrosion-resistant ceramic and platinum. They are lightweight, palm-size detectors suitable for use in 2.5-mm pipes. In contrast, in large-size types, the coils are arranged to measure uneven flows, and the flowmeters are made with improved noise suppression. The size can be as large as 3000 mm (120 in.).

CONSTRUCTION OF MAGNETIC FLOWMETERS

Figure 2.10g is a cutaway view showing how the principle of electromagnetic induction is employed in a practical flowmeter. The basic element of the flowmeter is a section of nonconducting pipe such as glass-reinforced polyester or a nonmagnetic pipe section lined with an appropriate electrical conductor such as Teflon, Kynar, fiberglass, vitreous enamel, rubber, neoprene, or polyurethane, among others. On alternate sides of the pipe section are magnet coils that produce the magnetic field perpendicular to the flow of liquid through the pipe. Mounted in the pipe, but insulated from it and in contact with the liquid, is a pair of electrodes that are located at right angles both to the magnetic field and the axis of the pipe.

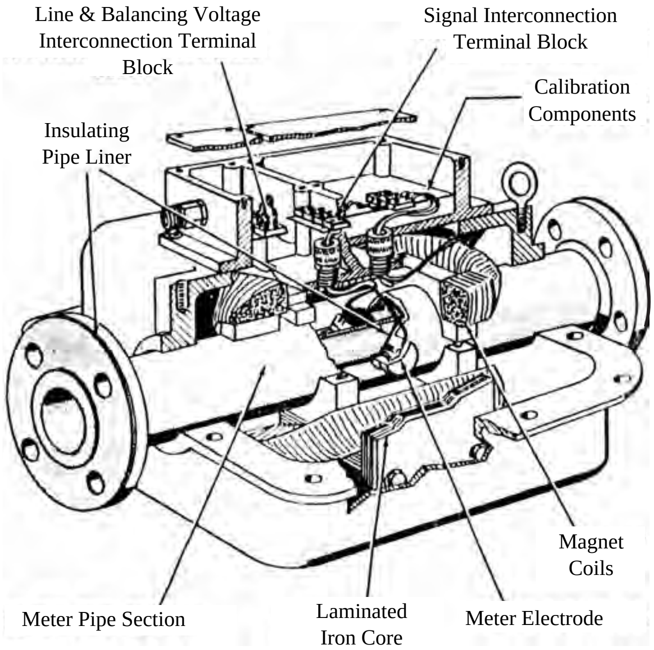

FIG. 2.10g
Cutaway view of the magnetic flowmeter.

As the liquid passes through the pipe section, it also passes through the magnetic field set up by the magnet coils, inducing a voltage in the liquid; the amplitude of the voltage is directly proportional to the liquid velocity. This voltage is conducted by the electrodes to a separate converter that, in effect, is a precision voltmeter (electrometer) capable of accurately measuring the voltage generated and converting that voltage to the desired control signals. These may be equivalent electronic analog signals, typically 4 to 20 mA DC, or a frequency or scaled pulse output.

Most electromagnetic flowmeters are built with flanged end fittings, although the insert types are also common. Designs are available with sanitary-type fittings. In large pipe sizes, Dresser-type and Victaulic-type end connections are also widely used. Some electromagnetic flowmeters are made from replaceable flow tubes whereby the field coils are located external to the tubes. In these flowmeters, the flanges are located far apart so as to reduce their adverse effects on the accuracy of measurements; hence, they are relatively large in dimension. In others, the field coils are located closer to the flow tube or even totally integrated. In this case, the flanges could be located closer to the magnets and the electrodes, thus giving relatively smaller dimensions. On the other hand, the miniature and electrodeless magnetic flowmeters are so compact in size that face-to-face dimensions are short enough to allow them to be installed between two flanges.

The pipe between the electromagnets of a flowmeter must be made from nonmagnetic materials to allow the field to penetrate the fluid without any distortion. Therefore, the flow tubes are usually constructed of stainless steel or plastic. The use of steel is a better option, since it adds strength to the construction. Flanges are protected with appropriate liners, and they do not make contact with the process fluid.

The electrodes for the magnetic flowmeters must be selected such that they will not be coated with insulating deposits of the process liquid during long periods of operations. The electrodes are placed at positions where maximum potential differences occur. They are electrically isolated from the pipe walls by nonconductive liners to prevent short-circuiting of electrode signals. The liner also serves as protection to the flow tube to eliminate galvanic action and possible corrosion due to metal contacts. Electrodes are held in place by holders that also provide sealing. In some flowmeters, electrodes are cleaned continuously or periodically by ultrasonic or electrical means. Ultrasonics are specified for AC- and DC-type magnetic flowmeters when frequent severe insulating coating is expected on the electrodes that might cause the flowmeter to cease to operate in an anticipated manner.

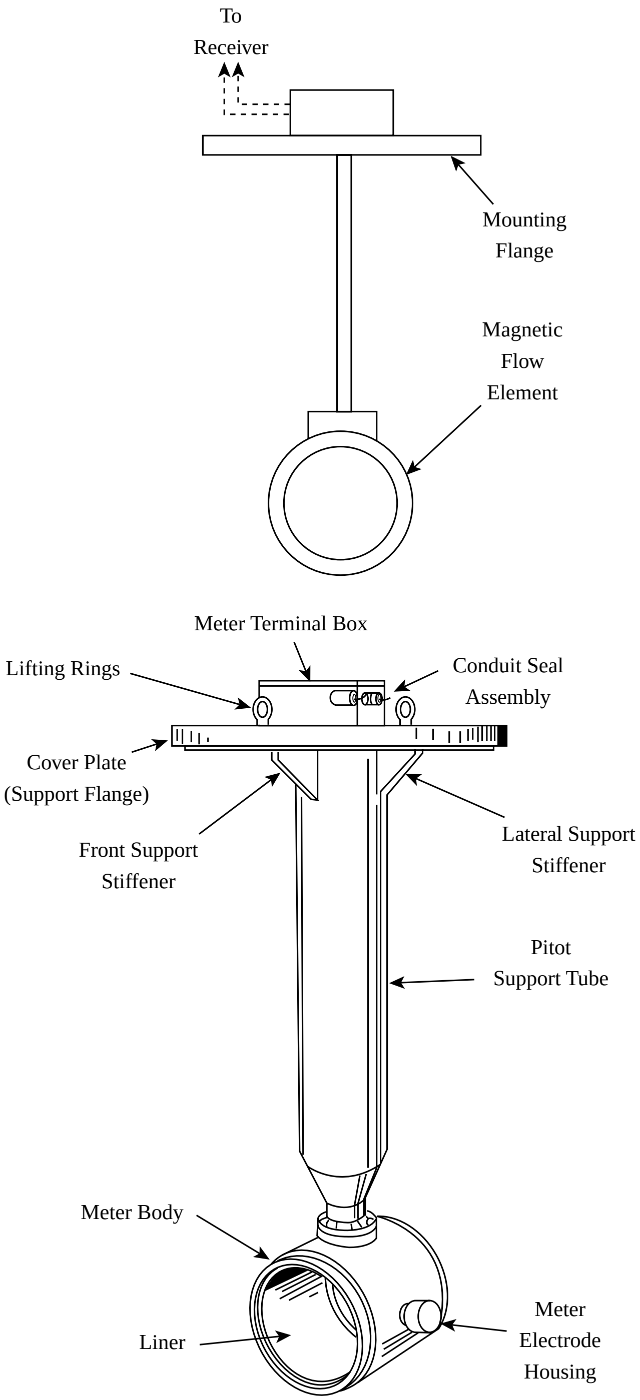

FIG. 2.10h
Pitot-type magnetic flowmeter.

Versions of magnetic flowmeters are available for periodic accidental submergence and for continuous submergence in water at depths of up to 30 ft (9 m). An outgrowth of the continuous submergence design is a sampling type (pitot). The pitot-type magnetic flowmeter samples the flow velocity in large rectangular, circular, or irregularly shaped pipes or conduits. A typical design is shown in Figure 2.10h. A small magnetic flowmeter is suspended in the flow stream. The magnet coils are completely encapsulated in the liner material, allowing submersion in the liquid to be measured. The short length of the meter body and the streamlined configuration are designed to minimize the difference between the flow velocity through the meter and the velocity of the liquid passing around the meter. The velocity measurement

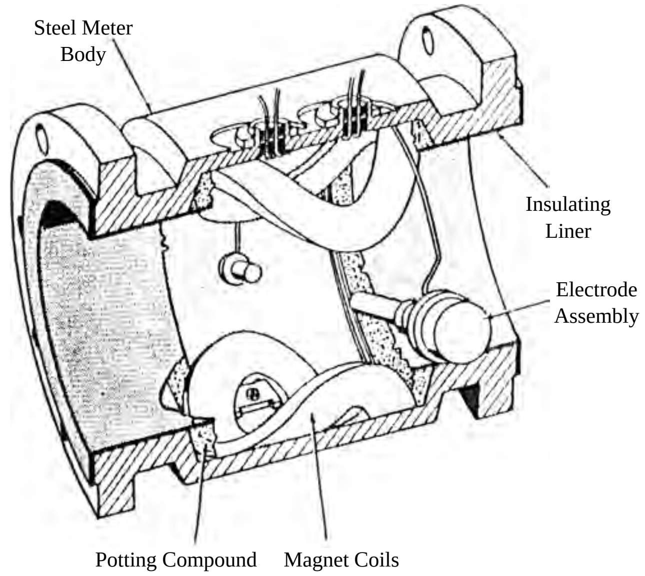

FIG. 2.10i
The short-form magnetic flowmeter.

of the liquid through the meter is assumed to be representative of the pipe velocity. Repeatability of the system is typically 0.25 to 0.5% of full scale. As with any sampling-type flowmeter, the information from the flowmeter is representative only of the flow through the flowmeter. It is the user's responsibility to relate that "sampled" velocity to the average velocity in the pipe, which reflects the total volumetric flow rate. When applying any sampling-type flowmeter, including the pitot-type magnetic flowmeter, substantial errors can occur in applications where the velocity profile can change due to changes in Reynolds number or due to the effects of upstream piping configuration.

Most manufacturers construct their flowmeters with coils external to the meter pipe section. Some designs place the coils within the flowmeter body, which is made from carbon steel to provide the return path for the magnetic filed as in Figure 2.10i. In this design, the meters can be shorter, have reduced weight, and offer lower power consumption. The lowest power consumption is a feature of the pulsed DC design, because its coils are energized only part of the time. An additional saving with pulsed DC types is that the power factor approaches 1.

Ceramic Liners

The use of ceramic liners represents a major improvement in the design of magnetic flowmeters, because they cost less to manufacture and also provide a better meter. Ceramic materials such as Al_2O_3 are ideal liner materials, because their casting is inexpensive, they are electrically nonconductive, and they are abrasion- and wear-resistant. In contrast with plastic liners, they can be used on abrasive slurry services (pipelining of minerals or coal), and their inner surfaces can be scraped with wire brushes to remove hardened coatings. Ceramic units are also preferred for sanitary applications because they do not provide any cavities in which bacteria can accumulate and grow. Ceramic meters can also handle higher temperatures (360°F, 180°C) than Teflon-lined ones (250°F, 120°C). Magnetic flowmeters are velocity sensors and, to convert velocity into volumetric flow rate, the pipe cross section has to be constant. Therefore, the ceramic liners have the added advantage of expanding and contracting less with changes in temperature than do metals or plastics. Ceramic liners are also preferred by the nuclear industry because they are not affected by radiation, whereas plastics are destroyed by it.

The design of the ceramic insert-type magnetic flowmeter also eliminates the possibility of leakage around the electrodes. This perfect seal is produced by allowing a droplet of liquid platinum to sinter through the ceramic wall of the liner. Through this process, the ceramic particles and the platinum fuse into a unified whole, providing not only a perfect seal but also a permanent, rugged, and corrosion-resistant electrode. This electrode cannot move, separate, or leak.

For the reasons listed above, the ceramic insert-type magnetic flowmeter is an improvement. However, it also has some limitations. One of its limitations has to do with its brittle nature. Ceramic materials are strong in compression but should not be exposed to pipe forces that cause tension or bending. Another possible way to crack the ceramic lining is by sudden cooling. Therefore, these elements should not be exposed to downward step changes in temperature that exceed 90°F (32°C). Another limitation of the Al_2O_3 ceramic liner is that it cannot be used with oxidizing acid or hot, concentrated caustic applications (over 120°F, 50°C).

Probe-Type Units

The probe-type magnetic flowmeter is an "inside out" design in the sense that the excitation coil is on the inside of the probe, as shown in Figure 2.10j. As the process fluid passes through the magnetic field generated by the excitation coil inside the probe, a voltage is detected by the electrodes that are embedded in the probe. The main advantage of this design is its low cost, which is not affected by pipe size, and its retractable nature, which makes it suitable for wet-tap installations. The probe-type magmeter is also suited for the measurement of flow velocities in partially full pipes or in detecting the currents in open waters. When water flow is not constrained by a pipe, flow velocity has to be expressed as a three-dimensional vector. By inserting three magmeter probes parallel with the three axes, one can detect that vector.

The main disadvantage of the magmeter probe is that it detects the flow velocity in only a small segment of the cross-sectional area of the larger pipe. Therefore, if the flowing velocity in that location is not representative of the rest of the cross section, a substantial error can result.

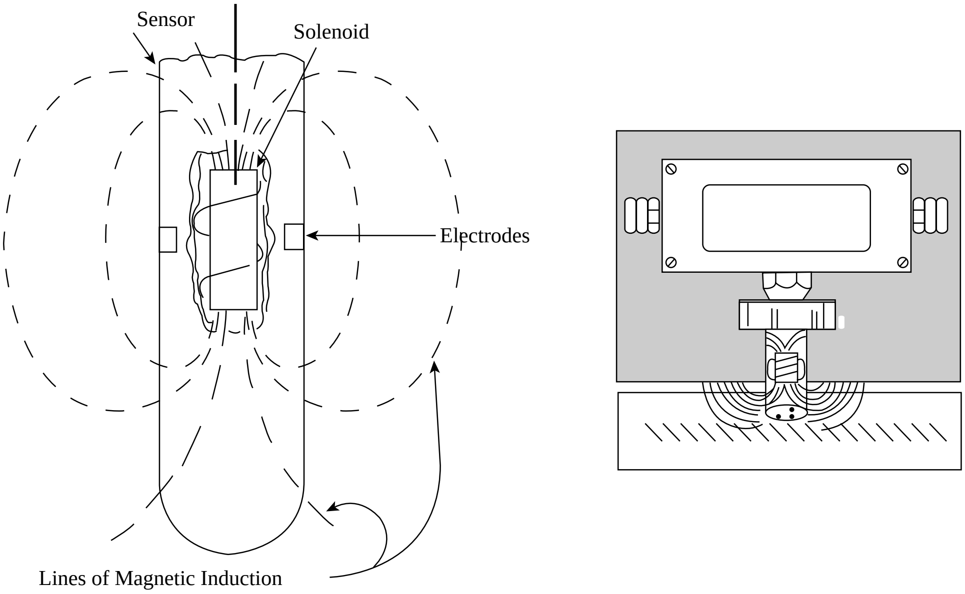

FIG. 2.10j
The probe-type magnetic flowmeter.

TABLE 2.10k
Sizes and Capacities of Commonly Used Electromagnetic Flowmeters

			Flow Rate (m^3/h)			*Standard Flow Range*	
Meter Size (mm)	*Dimensions (mm)*	*Weight (kg)*	*0.3 m/s*	*1.0 m/s*	*10 m/s*	*m^3/h*	*m/s*
15	70 × 180 × 50	3	0.191	0.636	6.360	2	3.125
25	80 × 170 × 65	3	0.530	1.770	17.67	6	3.400
40	100 × 240 × 85	6.5	1.357	4.525	45.25	15	3.315
50	110 × 260 × 100	7	2.120	7.067	70.67	25	3.540
80	110 × 280 × 125	8	5.428	18.10	180.9	60	3.315
100	120 × 315 × 160	10	8.482	28.30	282.7	100	3.540
150	230 × 390 × 215	22	19.10	63.61	636.1	200	3.125
200	300 × 440 × 270	36	33.90	113.1	1131.0	300	2.655

APPLICATIONS OF MAGNETIC FLOWMETERS

In the applications of magnetic flowmeters, a number of considerations must be taken into account, including the following:

- Cost, simplicity, precision, and reproducibility
- Metallurgical aspects
- Velocity profiles and upstream disturbances

During the selection of electromagnetic flowmeters, the size of the required flowmeter, the process characteristics and existing structure, and the velocity constraints should be evaluated carefully to secure accurate performance over the expected range. Table 2.10k illustrates the typical sizes and capacities of most commonly available flowmeters. The full-scale velocity of the flowmeter is typically 0.3 to 10 m/sec. Some flowmeters can measure lower velocities, with somewhat poorer accuracy. Generally, employment of electromagnetic flowmeters over a velocity of 5 m/sec should be considered carefully, since erosion of the pipe and the damage to liners can be significant. In all applications, determining the size of the flowmeter is a matter of selecting the one that can handle the liquid velocities. The anticipated liquid velocity must be within the linear range of the device. The capacities of various sizes of flowmeters are given in Figure 2.10l as a typical guide for selection.

Magnetic flowmeters are the first to be considered for very corrosive applications and for applications involving measurement of abrasive and/or erosive slurries. They are widely used in pulp and paper stock measurement and other non-Newtonian applications. They can be used for very low flow rates; pipe inside diameters as small as 0.1 in. (2.5 mm) are offered that can handle flow ranges as low as 0.01 to 0.1 GPM (0.038 to 0.38 l/min). Magnetic flowmeters are also available in pipe sizes up to 120 in. (3 m).

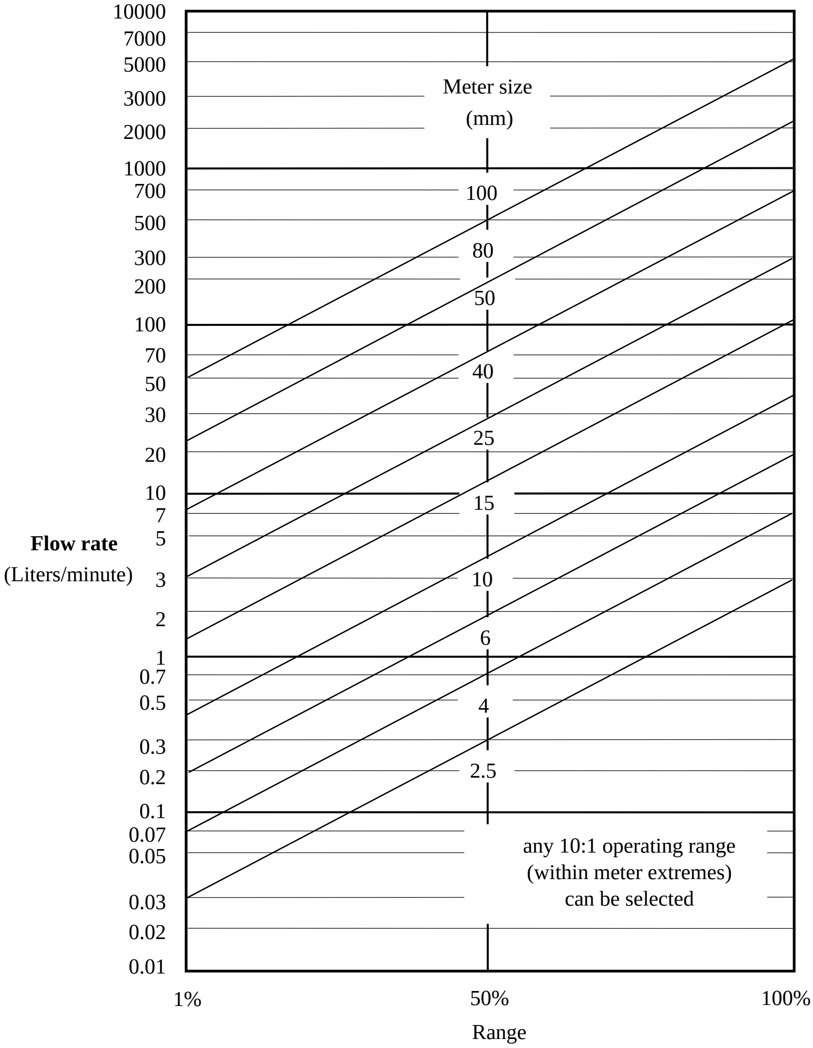

FIG. 2.10l

Selection of flowmeters: In the selection of a suitable flowmeter for a particular application care must be exercised for handling the anticipated liquid velocities. The velocity of liquid must be within the linear range of the device. For example, a flowmeter with 100 mm internal diameter can handle flows between 50 L/min to 4000 L/min. An optimum operation will be achieved at flow-rate of 500 L/min.

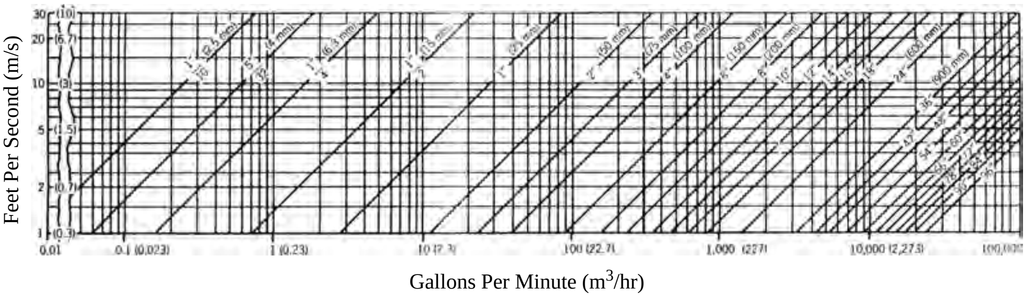

FIG. 2.10m

Magnetic flowmeter capacity nomograph.

Figure 2.10m is a nomograph for magnetic flowmeter capacities. Magnetic flowmeters have an excellent operating range of at least 100:1. For AC types, typical inaccuracy is ±1% of full scale. To improve performance, range is usually divided into two portions and automatically switched between the two. Pulsed DC-types have typical inaccuracy of ±1% of rate applicable to a 10:1 range or ±0.5% of rate over a 2:1 or 5:1 range, and at flow rates below 10% of maximum it is on the order of ±0.1% of full scale. The converter can be set for 20 mA output at any flow between 10 and 100% of meter capacity and still have at least a 10:1 operating range. This ability to field set or reset the meter for the actual operating conditions provides optimal performance.

Most processes employ circular piping that adds simplicity in the construction of the system. The flowmeters connected to circular pipes give relatively better results as compared to rectangular or square-shaped pipes, and velocity profiles of the liquid are not affected by the asymmetry. However, in circular pipes, the fringing of the magnetic field may be significant, making it necessary to employ empirical calibrations.

Upstream and downstream straight piping requirements may vary from one flowmeter to another, depending on the manufacturer's specifications. As a rule of thumb, the straight portion of the pipe should be at least 5D/2D from the electrodes and 5D/5D from the face of the flowmeter in upstream and downstream directions, respectively. For a good accuracy, the recommendations of manufacturers for piping requirements should be carefully observed. In some magnetic flowmeters, coils are used in such a way that the magnetic field is distributed in the coil to minimize the piping effect.

Magnetic flowmeters are often used to measure explosive fluids in hazardous environments. In these applications, explosion-proof housings are absolutely essential. The construction and specifications of such housings are regulated by authorities such as the European Committee for Electrotechnical Standardization (CENELEC). Usually, integral or remote electronics are offered for mounting flexibility and reliability. In many instruments, the electronic circuitry is separated from field wiring terminations by a dual-compartment housing and an integral backlit LCD design that provides an easy operator interface.

Accuracy and Calibration

The power consumption of a conventional (high-frequency AC excited) 2-in. (50-mm) flowmeter is about 30 W. For a 30-in. (76-cm) flowmeter, it is about 300 W. Low-frequency DC excitation has reduced the power consumption of some magnetic flowmeters to 20 W, regardless of meter size. The accuracy of conventional magnetic flowmeter is usually expressed as a function of full scale, typically 0.5 to 1% FS. However, DC flowmeters have a well-defined zero due to an automatic zeroing system; therefore, they have percentage rate of accuracy better than AC types (typically 0.5 to 2%).

Magnetic flowmeters do not require continuous maintenance other than periodic calibrations. Nevertheless, electrode coating, damage to the liners, and electronic failures may occur. Any modifications and repairs must be treated carefully because, when installed again, some accuracy may be lost. After each modification or repair, recalibration may be necessary.

Calibration of electromagnetic flowmeters is achieved with a magnetic flowmeter calibrator or by electronic means. The magnetic flowmeter calibrators are precision instruments that inject simulated output signals of the primary flowmeter into the transmitter. Effectively, this signal is used to check correct operation of electronic components and make adjustments to the electronic circuits. Alternatively, calibrations can also be made by injecting suitable test signals to discrete electronic components. In some cases, empirical calibrations must be performed at zero flow while the flowmeter is filled with the stationary process liquid.

Zero adjustment of AC magnetic flowmeters requires compensation for noise. If the zero adjustment is performed with a fluid other than process fluid, serious errors may result because of possible differences in conductivities. Similarly, if the electrodes are coated with an insulating substance, the effective conductivity of the electrodes may be altered, causing a calibration shift. If the coating changes with time, the flowmeter may continually require calibration for repeatable readings.

Errors in Magnetic Flowmeters

Operation of a magnetic flowmeter is generally limited by factors such as liner characteristics, pressure ratings of flanges, and temperatures of the process fluids. The maximum temperature limit is largely dependent on the liner material selection and usually is set to around 120°C. For example, the ceramic liners can withstand high temperatures but are subject to cracking subjected to sudden temperature changes in the process fluid.

For accurate measurements, magnetic flowmeters must be kept full of liquid at all times. If the liquid does not contact the electrodes, no measurements can be taken. Figure 2.10n illustrates this point. If the measurements are made in flows other than vertical, the electrodes should be located in horizontal directions to eliminate the possible adverse effect of the air bubbles, given that air bubbles tend to concentrate on the top of the liquid.

Often, the magnetic flowmeter liners are damaged by the presence of debris and solids in the process liquid. Also, the use of incompatible liquid with the liners, wear due to abrasion, and excess temperature during installations and removals can contribute to the damage of liners. The corrosion in the electrodes

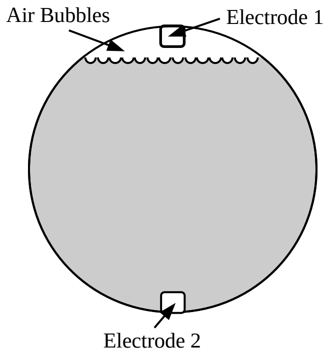

FIG. 2.10n
The pipes of electromagnetic flowmeters must be full of liquid at all times for accurate measurements. If the liquid does not make full contact with electrodes the high impedance prevents the current flow hence measurements cannot be taken. Also, If the pipe is not full, even if contact is maintained between the liquid and electrodes, the empty portions of the pipe will lead to miscalculated flow rates.

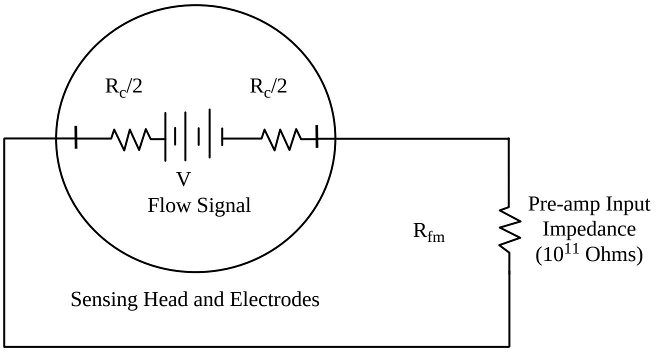

FIG. 2.10o
Increased flowmeter impedance (R_{fm}) reduces coating error.

may also be a contributing factor for the damage. In some cases, magnetic flowmeters may be repaired on site if severe damage occurs; in others, they must be shipped to the manufacturer for repairs. Usually, manufacturers supply spare parts for electrodes, liners, flow tubes, and electronic components.

Grease and other nonconductive electrode coatings introduce an error in the measurement, because the voltage generated by the conductive fluid is measured by the magmeter electronics as a voltage drop across its input impedance R_{fm} as in Figure 2.10o. When there is an electrically resistant coating on the electrodes, some of the voltage generated by the conductive liquid drops across the coating, and less of it remains to be detected by the input impedance. The resulting error percentage can be calculated as follows:

$$E = 100R_c/(R_{fm} + R_e) \qquad \textbf{2.10(6)}$$

Coating resistance (R_c) can reach 10^7, and if the input impedance (R_{fm}) in similar, substantial errors will result. In some newer designs, the input impedance of the flowmeter has been increased to $R_{fm} = 10^{11}$. Even at a coating impedance of $R_c = 10^7$, this limits the coating error to 0.01%. With such high-impedance electronics, the need for electrode cleaning is minimized or eliminated.

The meter's electrodes must remain in electrical contact with the fluid being measured and should always be installed in the horizontal plane. In applications where a buildup or coating of the inside wall of the flowmeter occurs, periodic "flushing" or cleaning is recommended. Coatings can have conductivities that are the same, lower, or higher than the liquid. These effects are significantly different. Where the conductivity of the coating is essentially the same as that of the liquid, there is no effect on the accuracy of the measurement except for the effect of a reduced cross-sectional area. This can be viewed as a specific profile condition, and the meter will average the velocity to give the correct value for the particular flow rate. Fortunately, this is the most common coating condition. If the conductivity of the coating is significantly lower than that of the liquid being measured, the electrically insulating coating can disable the meter. If periodic cleaning is not possible, mechanical, ultrasonic, thermal, and other electrode cleaning techniques can be applied. Manufacturers also offer specifically shaped protruding electrodes to take advantage of the self-cleaning effect of the flow at the electrode. If the conductivity is higher than that of the process fluid, no corrective measure is needed.

EFFECTS OF ELECTRICAL CONDUCTIVITY OF FLUID

For electromagnetic flowmeters to operate accurately, the process liquid must have minimum conductivity of about 1 to 5 μS/cm. Most common applications involve liquids whose conductivity is greater than 5 μS/cm. Nevertheless, for accurate operations, the requirement for the minimum conductivity of liquid can be affected by length of leads from sensors to transmitter electronics. For example, the resistance between electrodes may be approximated by $R = 1/\delta d$, where δ is the fluid conductivity and d is the electrode diameter. For tap water, $\delta = 200$ μS/cm, for gasoline $\delta = 0.01$ μS/cm, and for alcohol 0.2 μS/cm. A typical electrode with a 0.74-cm diameter in contact with tap water results in a resistance of 6756 Ω.

Application of magnetic flowmeters can be realized only with conductive liquids such as acids, bases, slurries, foods, dyes, polymer emulsions, and suitable mixtures that have conductivities greater than the minimum conductivity requirements. Generally, magnetic flowmeters are not suitable for liquids containing organic materials and hydrocarbons. As a rule of thumb, magnetic flowmeters can be applied if the process liquids constitute a minimum of about 10% conductive liquid in the mixture.

Most liquids or slurries are adequate electrical conductors to be measured by electromagnetic flowmeters. If the liquid conductivity is equal to 20 μS/cm or greater, most of the conventional magnetic flowmeters can be used. Special designs are available to measure the flow of liquids with threshold conductivities as low as 0.1 μS/cm. Some typical electrical conductivities are as shown in the following table.

Liquid (at 25°C except where noted)	*Conductivity, μS/cm*
Acetic acid (up to 70% by weight)	250 or greater
Ammonium nitrate (up to 50% by weight)	360,000 or greater
Molasses (at 50°C)	5000
Ethyl alcohol	0.0013
Formic acid (all concentrations)	280 or greater
Glycol	0.3
Hydrochloric acid (up to 40% by weight)	400,000 or greater
Kerosene	0.017
Magnesium sulfate (up to 25% by weight)	26,000 or greater
Corn syrup	16
Phenol	0.017
Phosphoric acid (up to 87% by weight)	50,000 or greater
Sodium hydroxide (up to 50% by weight)	40,000 or greater
Sulfuric acid (up to 99.4% by weight)	8500 or greater
Vodka (100 proof)	4
Water (potable)	70

The effect of conductivity changes above the threshold conductivity may be minimal, but the effect of liquid operating temperature on the threshold conductivity should be considered. Most liquids have a positive temperature coefficient of conductivity. Liquids that are marginal at one temperature can become nonconductive enough at a lower temperature to impair metering accuracy. At a higher temperature, the same liquid may be metered with good results. There are a few liquids that have a negative temperature coefficient; these should be carefully checked for their minimum conductivity before applying magnetic flowmeters.

Magnetic flowmeters are not affected by viscosity or consistency (referring to Newtonian and non-Newtonian fluids, respectively). The changes in flow profile resulting from changes in Reynolds numbers, or from upstream piping, do not greatly affect the performance of magnetic flowmeters. The voltage generated is a summation of the incremental voltages across the entire area between the electrodes, resulting in a measure of the average fluid velocity. Nevertheless, it is recommended to install the meter with 5 diameters of straight pipe before it and 3 diameters of straight pipe following it.

INSTALLATION

The signal detected by magnetic flowmeter electrodes is in the high microvolt to low millivolt range. Proper electrical installation and grounding is mandatory. Individual manufacturer's recommendations for installation are the result of extensive experience and should be scrupulously followed, as illustrated in Figure 2.10p.

Alternating-current-type magnetic flowmeters occasionally shift their no-flow indication after some operating time, requiring a zero reset. One of the most important installation considerations with electromagnetic flowmeters is a proper *bonding* of the flowmeter to the adjacent piping to minimize zero shifts. The intent of this bonding, or *jumpering*, is to prevent stray currents from passing through the flowmeter near the electrodes. Magnetic flowmeters are lined with an electrically insulating material; generally, this lining covers the flange face of the meter, making the meter an electrical discontinuity in the system. The flange bolts should not be used for bonding, given that rust, corrosion, paint, and other insulating materials can create an insulating barrier between the bolts and the flanges. Manufacturers supply, and insist on, the installation of copper braid jumpers from the meter flange to the pipe flange at either end of the flowmeter. The jumpers provide a continuous path for the stray currents, which guarantees a more stable zero. It is also essential to install a ground strap to a grounded piece of structural steel, a grounding rod, or a conductive cold water pipe.

We can eliminate the above-described installation process, which involves labor-intensive drilling, tapping, and strapping of adjacent pipe flanges in metallic pipes or the installation of expensive grounding rings in lined or nonconductive pipes, if the magmeter is provided with built-in grounding electrodes. When installing the flowmeter, the grounding electrode must always be at the bottom and must be connected to the third-wire ground of the power input.

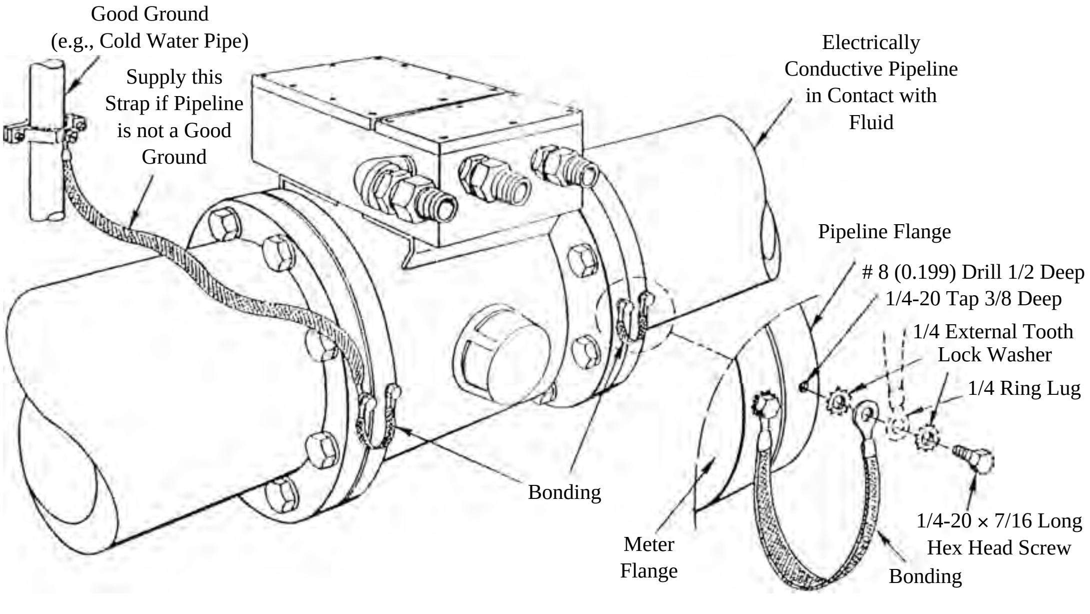

FIG. 2.10p
Typical bonding and grounding procedure. A good grounding is absolutely essential to isolate noise and high common mode potential. If the pipe is conductive and makes contact with the liquid the flowmeter should be grounded to the pipe. If the pipe is made from nonconductive materials, the ground rings should be installed to maintain contact with the process liquid. Improper grounding results in excessive common mode voltages that can severely limit the accuracy and damage the processing electronics.

The conservative installation of magnetic flowmeters requires 3 to 5 diameters of straight pipe, the same size as the flowmeter, to be installed upstream from the meter, plus 2 or 3 diameters downstream. Meters can be installed in horizontal pipelines, vertical pipelines, or sloping lines. It is essential to keep the electrodes in the horizontal plane to ensure uninterrupted contact with the liquid or slurry being metered. In gravity-feed systems, the meter must be kept continually full; therefore, the meter should be installed in a "low point" in horizontal lines or, preferably, in a vertical upflow line.

SIGNAL CONSIDERATIONS AND DEMODULATION TECHNIQUES

Each magnetic flowmeter requires electronics to convert the electrode output into a standardized analog or digital signal. The electronics can be mounted locally, directly on the flowmeter, or remotely. Integral mounting simplifies the installation, reduces cost, and eliminates the noise and other problems associated with the transmission of a low-level signal over a relatively long distance. The advantages of remote mounting include the reduced headroom requirement for the meter, accessibility, operator convenience, and the distancing of the sensitive electronics from the high-temperature or otherwise undesirable environment of the flowmeter. If shielded, twisted wires are used, the electronics can be 200 ft (67 m) from the meter.

The housings of the electronics can be designed for indoor or outdoor use and for general-purpose or hazardous environments. The converters can serve several flowmeters simultaneously and provide for interfacing with computers. The displays can provide flow rate or total flow indication. "Smart" magmeters provide the added features of self-diagnostic and detection of coil/converter/metering tube failure or of empty pipe, as well as switching, alarming, flow integration, and preset batching functions. They can also detect pipe blockage; signal erroneous settings; or change the range, engineering units, damping times (63% response time settable from 0.1 to 100 sec), or even the flow direction of metering.

Magnetic flowmeters are essentially four-wire devices that require an external power source for operations. Particularly in AC magnetic flowmeters, the high-voltage power cables and low-voltage signal cables must run separately, preferably in different conduits. In contrast, for DC magnetic flowmeters, the power and signal cables can be run in one conduit. This is because, in DC-type magnetic flowmeters, the voltage and the frequency of excitation of the electromagnets are much lower. Some manufacturers supply special cables along with their flowmeters.

Despite beliefs to the contrary, magnetic flowmeters demonstrate a certain degree of sensitivity to flow profiles. Another important aspect is the effect of turbulence. Unfortunately, there is very little information available on the behavior of turbulent flows when they are in transverse magnetic fields. Figure 2.10q shows an example of flow profile in which the velocity profile perturbed. The fluid is being retarded near the center of the channel and accelerated at the top and bottom near the electrodes.

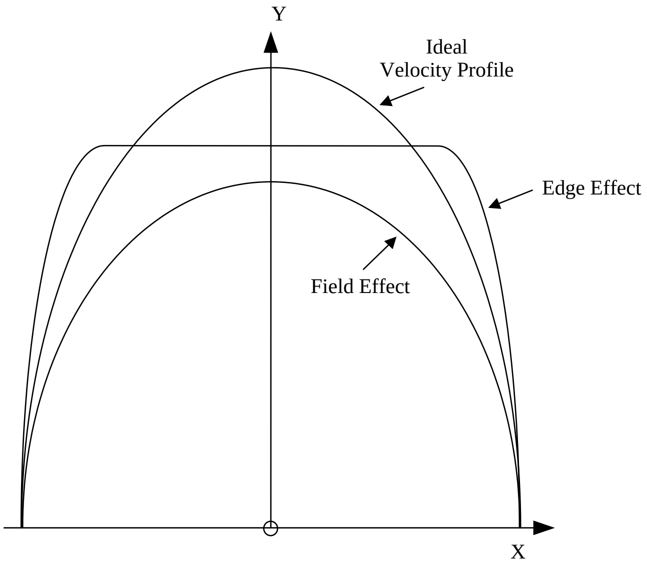

FIG. 2.10q
Flow profiles in the pipes. Magnetic flowmeters demonstrate a certain degree of sensitivity to flow profiles. The ideal velocity profile may be distorted due to edge effects and also field effects known as magneto-hydrodynamics. In some applications the velocity perturbation due to magneto-hydrodynamic effect may be serious enough to severely influence the accuracy of operations.

In AC flowmeters, the electrode signals may be amplified much more readily as compared with their DC counterparts. That is why AC flowmeters have been used successfully to measure very low flow rates as well as the flow of very weakly conducting fluids. Nevertheless, AC flowmeters tend to be more complicated, bulky, and expensive, and they require electromagnets with laminated yokes along with stabilized power supplies. In some magnetic flowmeters, it is feasible to obtain sufficiently large flow signal outputs without the use of yoke by means of producing magnetic fields by naked coils. In this case, the transformer action to the connecting leads may be reduced considerably.

One of the main drawbacks of AC-type flowmeters is that it is difficult to separate the signals caused by transformer action from the useful signals. The separation of the two signals is achieved by exploiting the fact that the flow-dependant signal and the transformer signal are in quadrature. That is, the useful signal is proportional to the field strength, and the transformer action is proportional to the time derivative of the field strength. The total voltage vT can be expressed as

$$v_T = v_F + v_t = V_F \sin(\omega t) + V_t \cos(\omega t) \qquad \textbf{2.10(7)}$$

where v_F is the induced voltage due to liquid flow, and v_t is the voltage due to transformer action on wires, and so on.

Phase-sensitive demodulation techniques can be employed to eliminate the transformer action voltage. The coil magnetizing current, $i_m = I_m \sin(\omega t)$ is sensed and multiplied with the total voltage v_T giving

$$v_T\, i_m = [V_F \sin(\omega t) + V_t \cos(\omega t)]\, I_m \sin(\omega t) \qquad \textbf{2.10(8)}$$

Integration of Equation 2.11(8) over one period between 0 and 2π eliminates the transformer voltage, yielding only the voltage that is proportional to the flow.

$$V_f = V_F I_m \pi \qquad \textbf{2.10(9)}$$

where V_f is the voltage after integration. This voltage is proportional to the induced voltage modified by constants I_m and π.

In reality, this situation can be much more complicated because of phase shift due to eddy currents in nearby solids and conductors. Other reasons for complexity may be the result of harmonics because of nonlinearities such as hysteresis, or caused by capacitive pickup.

Particularly in AC flowmeters, if the flowmeter is not grounded carefully relative to the potential of the fluid in the pipe, then the flowmeter electrodes may be exposed to excessive common-mode voltages that can severely limit the accuracy. In some cases, excessive ground potential can damage the electronics, because the least-resistance path to the ground for any stray voltage in the liquid would be via the electrodes.

Some commercial magnetic flowmeters have been developed that can operate on sawtooth or square waveforms. Standardized magnetic flowmeters and calibration data still do not exist, and manufacturers use their own particular design of flow channels, electromagnets, coils, and signal processors. Most manufacturers provide their own calibration data.

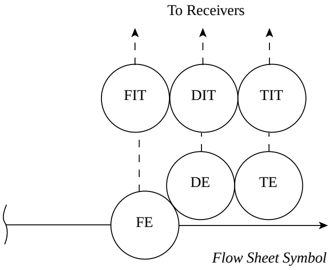
2.11 Mass Flowmeters, Coriolis

CATHY APPLE (1995) **MARTIN ANKLIN,**
WOLFGANG DRAHM (2003)



Flow Sheet Symbol

Measured Variables	Mass flow, volume flow, density and temperature
Sizes	1/25 to 10 in. (1 to 250 mm)
Flow Range	0 to 63,000 lb/min (0 to 28,300 kg/min)
Fluids	Liquids, slurries, gases (compressed, low-pressure, etc.), liquefied gases; not gas-liquid mixtures
Output Signal	Linear frequency, analog, digital (HART, Profibus, FOUNDATION™ fieldbus, Modbus, scaled-pulse, display, alarm outputs, manufacturer-specified protocols)
Operating Pressure	Depends on tube size and flange rating: 1400 PSIG (100 bar) typical standard rating; 5000 PSIG (345 bars) typical high-pressure rating
Pressure Drop	Function of flow, viscosity, and design, varying from very low (<0.1 PSIG, 10 mbar) to moderately high (22 PSIG approximately 1.5 bar)
Operating Temperature	Depends on design: –60 to 400°F (–50 to 200°C) typical standard; 32 to 800°F (0 to 426°C) high-temperature, special versions also used for cryogenic applications
Materials of Construction	Stainless steel, Hastelloy®, titanium; special materials as tantalum, zirconium and others are available
Inaccuracy	±0.1% of rate ± (zero offset/mass flow rate) × 100% Zero offset depends on size and design of the flowmeter; for a 1-in. (25-mm) meter with a typical maximum flow rate of 650 lb/min (18,000 kg/h), the zero offset is typically 0.04 lb/min (0.9 kg/h), which is below 0.01% of the maximum flow value. Typical: 0.15% within the range of 10:1 of full-scale flow rate (FS) and 1% within the range of 100:1 of FS
Repeatability	Typical: 0.075% within the range of 10:1 of FS and 0.5% within the range of 100:1 of FS
Rangeability	Up to 100:1
Cost	Depends on size and design: 1/25 in. (1 mm), $5000; typical 1-in. (25-mm) meter, $7000; 6-in. (150-mm), $27,500

In recent decades, there has been a great deal of interest in Coriolis mass flowmeters (CMFs). The market for CMFs grew dramatically in the late 1980s and the 1990s. Today, CMFs are widely accepted in many industrial fields, and their performance has improved steadily. One of the advantages of CMFs is that they measure the true mass flow directly, whereas other types measure only volumetric flow. The high accuracy and rangeability of CMFs is another reason for their fast growth and acceptance in industry. The commercially available units show a broad variety of designs, such as single-tube, dual-tube, bent-tube, and straight-tube. Since CMFs are available that incorporate different tube materials (e.g., stainless steel, Hastelloy®, titanium, zirconium, tantalum, and lined tubes), they can be used for all kinds of liquids or gases. CMFs are most common in the food and beverage, chemical and pharmaceutical, and, increasingly, oil and gas industries.

MEASURING PRINCIPLE AND THEORY

Principle

Coriolis mass flowmeters have the proven ability to record the total mass flow to better than 0.1% for water at moderate velocities. Each Coriolis instrument gets its own calibration factor that depends only on the geometrical data and material properties of the tube. Thus, the calibration factor is independent of fluid properties. The measuring principle of CMF is Coriolis force, which appears in rotating and oscillating (vibrating) systems. Such a vibrating system is shown in Figure 2.11a for a straight tube. The tube is excited by an external force $\vec{F}_E$. The excitation frequency is kept at the natural frequency of the tube, which minimizes the energy needed for vibration. The general expression for the Coriolis force is $\vec{F}_C = 2 \cdot m \cdot \vec{v} \times \vec{\omega}$, where $\vec{q} = m \cdot \vec{v}$ is mass flow and

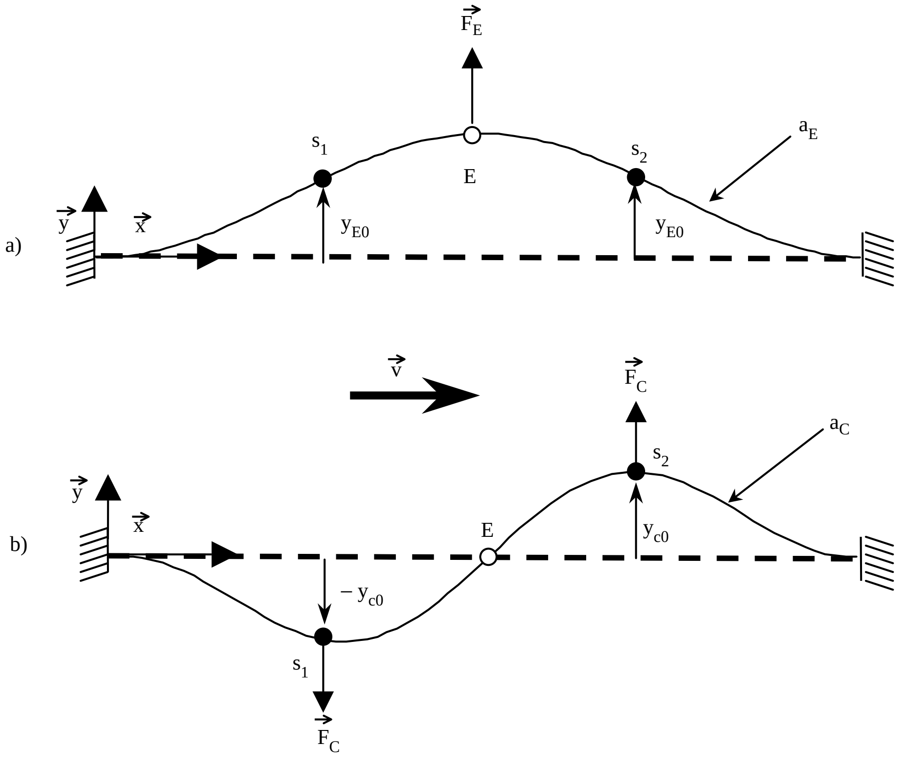

FIG. 2.11a
Panel a) describes the movement of a straight tube conveying a fluid, which is oscillating at the excitation frequency. The oscillation is maintained with the excitation force F_E at location E. The measuring signal is detected with the two sensors S_1 and S_2. When the fluid begins to flow, the Coriolis force F_C induces an oscillation as shown in panel b). The final lateral displacement is the superposition of both oscillations.

$\vec{\omega}$ is the rotation vector. When fluid is not flowing within a vibrating tube, the Coriolis force is zero $(\vec{F}_C = 0)$. When fluid begins to flow, the Coriolis force is no longer zero $(\vec{F}_C \neq 0)$, and the shape of the tube is illustrated by superimposing Figure 2.11a, panel (a) and panel (b). At the inlet section, the Coriolis force tends to decelerate the movement of the oscillating tube, whereas, for the outlet section, the Coriolis force tends to accelerate the movement. In the middle of the tube, the Coriolis force is always zero, since either $\vec{\omega}$ is zero for straight tubes or $\vec{q}$ is parallel with $\vec{\omega}$ for curved tubes, bringing the product $\vec{q} \times \vec{\omega}$ to zero. As soon as the fluid begins to flow, the Coriolis force induces a phase shift along the tube. This phase shift is proportional to the mass flow. The mass flow can then be determined by measuring the phase shift between two sensor positions, S_1 and S_2. Since the oscillation is kept at the natural frequency of the system, the frequency changes with changing density of the fluid in the tube; i.e., the natural frequency increases with decreasing density. Therefore, by knowing the actual frequency of the system, the density of the fluid can be calculated directly. Another direct measurement, in addition to mass flow and density, is the fluid temperature, which is measured by the CMF.

Theory

In the literature, there are different approaches to describe the dynamics of vibrating tube conveying a fluid or a gas (see, for example, Païdousses and Li[1] or Raszillier and Durst)[2]. The general problem is very complex, and an analytical solution can only be obtained for a simple system with an ideal tube conveying an incompressible and nonviscous fluid. For more complex systems, solutions can be found only through approximations or using finite element methods. In this section, we derive an analytical solution to determine mass flow in a simplified system. However, by solving this simple model, we gain insight into the major physical effects of CMF.

We consider a straight tube conveying a fluid. We first look at the first *eigenmode** of this system, which is shown in Figure 2.11a, panel (a). The tube is fixed at both ends, and the velocity $\vec{v}$ of the fluid shall be zero. The movement of the sensors S_1 and S_2 is described by the differential equation,

$$M_E \cdot \ddot{y}_E + K_E y_E = F_E \qquad \textbf{2.11(1)}$$

where

y_E = lateral excitation displacement at the sensor
F_E = excitation force
M_E = effective mass
K_E = the stiffness of the tube for the excitation mode
$\ddot{y} = \dfrac{d^2y}{dt^2}$

We are looking for solutions with $y_E(t) = \hat{y}_E \sin(\omega t)$ and $F_E(t) = \hat{F}_E \cdot \sin(\omega t)$. The eigenfrequencies of this system are found by setting the excitation force $F_E(t)$ to zero. Inserting the trial function for $y_E(t)$ in Equation 2.11(1), we get the frequency of the first eigenmode,

$$\omega_E = \omega_E(\rho_{\text{Fluid}}) = \sqrt{\frac{K_E}{M_E}} \qquad \textbf{2.11(2)}$$

Aside from the tube properties, ω_E depends only on fluid density. Therefore, using Equation 2.11(2), the fluid density can directly be determined by measuring the frequency of the eigenmode. Now, we include the excitation force $F_E(t)$ to determine the lateral displacement at the sensors. Solving Equation 2.11(1) with trial functions $y_E(t)$ and $F_E(t)$ and Equation 2.11(2), we get

$$\hat{y}_E = \frac{\hat{F}_E}{K_E \cdot \left(1 - \dfrac{\omega^2}{\omega_E^2}\right)} \qquad \textbf{2.11(3)}$$

For commercially available instruments the amplitude for $\hat{y}_E$ varies between 10 μm and 1 mm, and the frequency, $f_E = \omega_E/2\pi$, typically ranges from 80 Hz to 1100 Hz. Equation 2.11(3) also shows that the excitation force $\hat{F}_E$ is at a minimum when the driving frequency, ω, is similar to the frequency of the eigenmode, ω_E. In a real system, damping will prevent the lateral movement from becoming infinite even if ω equals ω_E. When the fluid begins to flow, the second mode is induced by the Coriolis force as shown in Figure 2.11a, panel (b). For the Coriolis mode, the differential equation is

$$M_C \cdot \ddot{y}_C + K_C y_C = F_C \qquad \textbf{2.11(4)}$$

where y_C is the lateral Coriolis displacement of the tube at S_1 and S_2, F_C is the Coriolis force, M_C is the effective mass, and K_C represents the stiffness of the tube for the Coriolis mode. The trial function for the lateral displacement of the Coriolis mode is $y_C(t) = \hat{y}_C \cdot \cos(\omega t)$, and the function for the Coriolis force is $F_C(t) = \hat{F}_C \cdot \cos(\omega t)$. Using the same procedure as above, we get the frequency of the Coriolis mode $\omega_C = \sqrt{K_C/M_C}$, which is typically 2.7 times higher than ω_E. The lateral displacement at the sensors becomes

$$\hat{y}_C = \frac{\hat{F}_C}{K_C \cdot \left(1 - \dfrac{\omega_E^2}{\omega_C^2}\right)} \qquad \textbf{2.11(5)}$$

The Coriolis force F_C is calculated by integration along the tube

$$F_C = \int_0^{L/2} \dot{m} \cdot \dot{y}_E \cdot a'_E(x) \cdot a_C(x) \cdot dx$$
$$F_C = \dot{m} \cdot C_{EC} \cdot \dot{y}_E \qquad \textbf{2.11(6)}$$

---

* Resonance frequency or the first resonance frequency.

where C_{EC} is a coupling factor between the excitation and the Coriolis mode, $\dot{m}$ is the mass flow, L is the length of the tube, $a'_E = (da_E)/(dx)$ is the derivative of the normalized excitation mode shape, $\dot{y}_E \cdot a'$ is the local rotation velocity, and a_C is the normalized Coriolis mode shape shown in Figure 2.11a, panel (b). If we define $\mathrm{v}_E = \dot{y}_E$ and with $\hat{\mathrm{v}}_E = \hat{y}_E \cdot \omega$, we get $\dot{y}_E = \hat{y}_E \cdot \omega \cdot \cos(\omega t) = \hat{\mathrm{v}}_E \cdot \cos(\omega t)$. Thus, Equation 2.11(6) becomes $\hat{F}_C = \dot{m} \cdot C_{EC} \cdot \hat{\mathrm{v}}_E$, and the lateral displacement of the sensors, Equation 2.11(5), becomes

$$\hat{y}_C = \frac{\dot{m} \cdot C_{EC} \cdot \hat{\mathrm{v}}_E}{K_C \cdot \left(1 - \dfrac{\omega_E^2}{\omega_C^2}\right)} \qquad \textbf{2.11(7)}$$

As described before, the final lateral displacement of S_1 and S_2 is the superposition of excitation mode and Coriolis mode. As seen in Figure 2.11a, the total lateral displacement of S_1 is $y_{S1} = y_E - y_C$, and for S_2 it is $y_{S2} = y_E + y_C$. The time difference $\Delta\tau$ between the two sensors becomes

$$\Delta\tau = \frac{\Delta\varphi}{\omega_E} \approx \frac{2 \cdot \hat{y}_C}{\omega_E \cdot \hat{y}_E} = \frac{2 \cdot \hat{y}_C}{\hat{\mathrm{v}}_E} = \frac{2}{\omega_E} \cdot \frac{\overline{(y_{S2} - y_{S1})}}{\overline{(y_{S2} + y_{S1})}} \qquad \textbf{2.11(8)}$$

where $\Delta\tau$ is the time lag and $\Delta\varphi$ is the phase shift between the two sensors. Now, we can determine the mass flow by inserting Equation 2.11(7) into 2.11(8), producing $\dot{m} = \frac{K_C \cdot (1 - \omega_E^2 / \omega_C^2)}{2 \cdot C_{EC}} \cdot \Delta\tau$, where the expression $\frac{K_C \cdot (1 - \omega_E^2 / \omega_C^2)}{2 \cdot C_{EC}}$ is a constant value C. Thus, by knowing $\Delta\tau$, the mass flow of a CMF can be determined through the simple equation

$$\dot{m} = C \cdot \Delta\tau \qquad \textbf{2.11(9)}$$

where the constant C does not depend on fluid properties. For commercially available CMFs, this constant is determined for each unit through calibration. Although we have derived the formula to determine the mass flow of this system, the model does not include effects such as axial pressure, in-line pressure, temperature, pulsation, compressibility, and so on. As mentioned before, analytical calculations including such effects are very cumbersome and can be achieved only as approximations. The experimentally found influences of these effects on mass flow measurements will be described below.

DESIGN OF CMF

Figure 2.11b shows the tube assembly of a CMF. Generally, it consists of two components: the flow tube assembly and the electronics. Typically, two electrodynamic pickups generate electrical signals containing the flow information. The signal processing unit implemented in the electronics calculates the flow from these signals, which are very small in amplitude. The flow is split into two tubes as shown in Figure 2.11b. Sensors are mounted at the inlet and outlet section of the tubes, measuring the phase difference between these two points. The tubes are forced into oscillation by the driver, which is mounted between the two tubes. Thus, the tubes are automatically driven in counterphase, which is the preferred type of motion. To vibrate the flow tubes, all commercially available CMFs use a magnet and a coil as the driving mechanism. Typically, the coil is mounted on one tube, and the magnet is mounted on the opposite tube. To protect the measuring system from any external disturbances, the tubes are fixed into a rigid carrier housing, which is strong

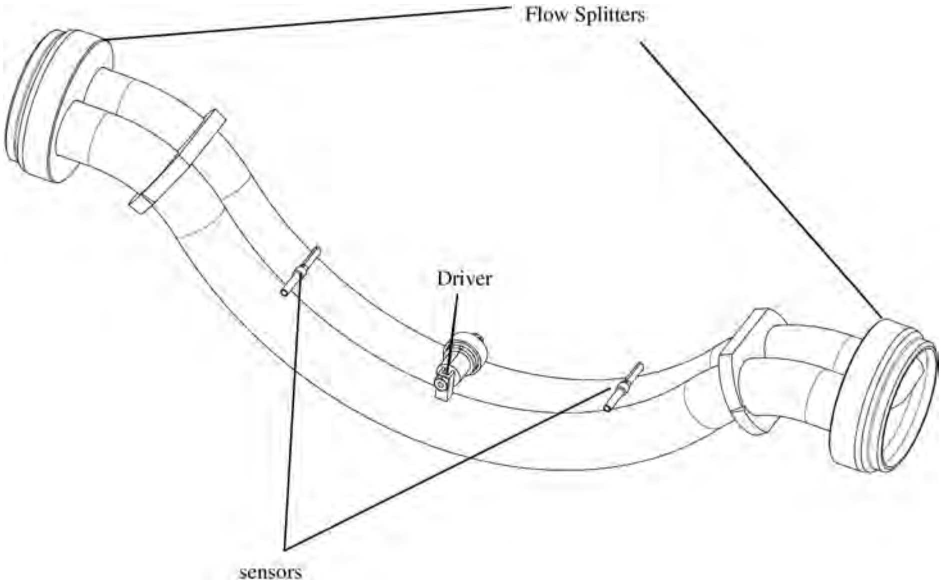

FIG. 2.11b
Tube assembly of a typical Coriolis flowmeter.

enough to isolate the system from the environment. This carrier housing is not shown in Figure 2.11b.

The tubes are vibrated at their natural frequency. As shown before, this frequency requires the least amount of energy to excite the system. Even large meters can be vibrated with only a few milliamps of excitation current. The natural frequency depends mainly on the mass of the system and the elastic properties of the measuring tubes. The total mass of the system includes the mass of the tube itself, the mass of the fluid within the tube, and the mass of any attached items such as driver and sensors. Therefore, since the material properties remain constant, a change in natural frequency directly indicates a change in the density of the fluid. As described before, this change in frequency can be used to determine the density of the fluid.

Balancing Systems for CMF

CMF are among the most accurate flowmeters on the market. This accuracy is achieved over a wide measuring range, which is required because, for example, liquids with high viscosities do not reach high velocities and have low total mass flow. A high turndown from maximum flow is also needed for gas flow measurements because, even at high pressure and at high velocity, the total mass flow rate for gas is small in comparison to mass flow rate of fluids. The accuracy for lower flow rates is limited by the zero-point errors. An error of 0.005% of full scale due to zero-point instability is typical.

In the previous section on “Theory,” it is shown that mass flow induces very small displacements along the measuring tube. These displacements have to be measured accurately, even though the instruments are often mounted in a harsh process environment. A key parameter to achieve a precise and stable CMF reading is the decoupling of the internal measuring system from any environmental and external disturbances. If CMFs are not decoupled to near perfection, the oscillations from the measuring tube will be transmitted to the connected process piping, which in turn begins to vibrate as well. Vibrating process piping can then cause the CMF to be excited by undefined vibrations. Depending on the magnitude and the strength of such external excitations, this can lead to a disturbed reading of the CMF. Therefore, it is an important requirement of a CMF to be a balanced system, in which oscillations of the measuring tube are well defined within the meter and are not transmitted to flanges and process piping. This requirement is also a general rule to ensure a good zero-point stability.

Dual-Tube Meters

Designs with dual tubes offer the best performance for the decoupling of the measuring system from the process environment. Similar to a tuning fork, the two tubes vibrate in counterphase. While the oscillation is maintained, the forces at the fixation points of the two tubes are identical in absolute value but in counterphase directions. Ideally, this results in zero force acting on the flanges. The perfect symmetry of the two tubes is unaffected by changes in fluid density, temperature, pressure, viscosity, and so on.

The sensors shown in Figure 2.11b can be mounted between the two tubes and do not have to be supported by the housing. This results in maximum common-mode rejection and maximum suppression of externally induced vibrations. The mounting of the driver and sensors must be done in such a way that the overall mass balance of the tubes is maintained.

If the flow is not split completely symmetrically into the two measuring tubes, no additional error will occur, because the flow signal, which is due the Coriolis forces, is composed of the displacements of each tube separately and therefore is independent of the exact flow distribution. Thus, a well-defined flow profile is not a requirement for the design of a CMF. This also indicates that no special precautions are needed for installations near devices that may generate flow turbulences.

The majority of the commercially available CMFs use a double-tube design, because this offers the best performance with regard to accuracy and insensitivity to external disturbances. However, the dual-tube design requires flow splitters, which are not recommended for applications with fluids that are prone to plugging. Such fluids are often used in the food processing industry, where single-tube meters are required.

Single-Tube Meters

Generally, there are two different designs of single-tube flowmeters. In the first design, the tubes are bent to form a double loop. This design behaves similarly to the dual-tube flowmeter with the difference that the tubes are in series rather than parallel. Such single-tube flowmeters offer the same advantages as dual-tube meters, and they do not have the disadvantage of employing flow splitters. However, with this design, the tube length increases dramatically, which results in increased pressure loss. Furthermore, easy drainage of the instrument is impossible with this design. The second single-tube flowmeter design contains a straight, or fairly straight, single tube. From the customer’s point of view, these designs are preferred, since they offer the best cleanability and the most prudent fluid handling. A challenge is to find a balancing mechanism for such flowmeters that allows accurate measurements for various process conditions and changing fluid densities. Nevertheless, straight (or fairly straight) single-tube CMFs are available that offer comparable performance to that of dual-tube flowmeters.

Tube Geometries

A variety of tube designs are currently available, a small selection of which is shown in Figure 2.11c. Most designs aim to magnify the effect of the Coriolis force by the geometrical form of the tubes. The larger the Coriolis effect

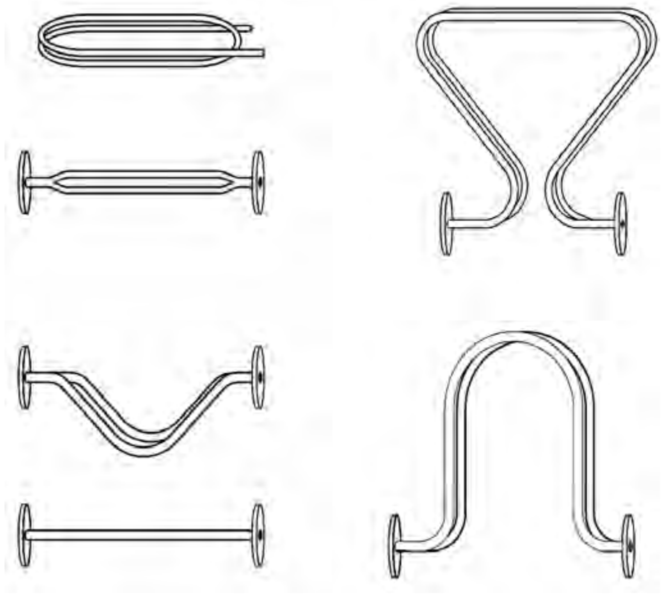

FIG. 2.11c
Selection of geometries of various Coriolis flowmeters.

becomes, the larger the time or phase difference between the flow sensors becomes, and the easier it is to determine the mass flow. Such magnifying geometrical forms often result in large tube loops that take up much space and have no advantage in zero-point stability, because external disturbances are also magnified. Thus, the signal-to-noise ratio remains the same. As electronics have become more and more efficient, the need for such geometrical magnification of the Coriolis effect has disappeared. Therefore, the large loops can be replaced by compact tube designs that require little space. An example of such a compact design is shown in Figure 2.11b. In addition, the compact design shortens the tube length, which results in higher oscillation frequencies of about 300 to 1100 Hz. Higher oscillation frequencies have the advantage of a better decoupling performance from pipeline vibrations and external disturbances, which are predominantly in the range of about 50 to 180 Hz.

For the dual-tube design, symmetry is the key factor, so a pair of tubes are chosen that are nearly identical in terms of mechanics. The two tubes have to be assembled in such a way that tube symmetry is not altered. Therefore, the production of these tube assemblies needs to be done very accurately, with a good understanding of the production process itself.

The main reason for using bent tubes is the thermal expansion of the measuring tube. While the fluid temperature may change by several hundred degrees Celsius, the temperature of the supporting structure changes much less, due to thermal transport, convection, and radiation. This can lead to large temperature differences between measuring tube and housing, which increase the axial forces of the tube. For a straight-tube CMF, the axial forces are largest and mainly depend on the expansion coefficient of the tube material. To prevent the tube from damage, the axial force must stay below a certain value, which depends on the material of the tube. By choosing a material with a low expansion coefficient, the axial forces can be kept below the critical value, even for straight tube CMF. Unfortunately, the rather high expansion coefficient of stainless steel, which is the most common material for measuring tubes, allows only a very restricted temperature range for a straight-tube design. Therefore, stainless steel tubes need to have a curved shape to reduce the maximum stress, since the tube can expand into the curve. All commercially available CMFs with straight tubes use titanium or zirconium for the measuring tubes, since these materials offer a small temperature expansion coefficient. With these materials, even great temperature differences between the measuring tube and the housing result in only small additional axial stress. Moreover, titanium offers higher stress limits than stainless steel. CMFs with single straight tubes are available for use up to 150°C.

With regard to corrosion, erosion, and pressure rating, the wall thickness of the measuring tubes should be as thick as possible. However, the sensitivity of the instrument to flow-induced Coriolis forces decreases with increasing wall thickness. Therefore, tube dimensions have to be optimized for several considerations, including the overall pressure loss. For a 1.5-in. (DN 40) dual-tube design, a typical size of the measuring tube is 1 in. (25 mm) inside diameter with a wall thickness of 1/16 in. (1.5 mm).

Flowmeters are commercially available with stainless steel, Hastelloy®, titanium, zirconium, and tantalum as tube material. Exotic materials such as glass or Tefzel®-lined tubes are also available for special purposes.

Sensors

As shown in Figure 2.11b, two motion sensors are needed to measure the displacement of the tube at the inlet and outlet sections. The phase difference or time lag between the two sensor signals is a measure of the mass flow. The sensor could be of any type that can represent the motion of the flow tubes, measuring position, velocity, or acceleration. At present, the most commonly used device is the electrodynamic sensor, in which a coil is mounted on one tube and a magnet on the other tube. The relative motion between the tubes induces a voltage in the coil, representing the differential velocity of the tubes. Electrodynamic sensors have the advantages of offering very good phase accuracy and high reliability.

Temperature Sensors

As described previously, mechanical properties change with temperature. This leads to axial stress and also changes the Young's modulus. An increase in temperature decreases the stiffness of the tube by lowering the Young's modulus. To compensate for the influence of thermal effects on CMF readings, each flowmeter needs to be equipped with at least one sensor to measure fluid temperature. Furthermore, because a temperature difference between the measuring tube and the housing results in an axial force, a second temperature sensor is needed to adjust the reading of the flowmeter for this effect. Instead of a second temperature sensor, the axial stress can also be detected by a strain gauge attached to the measuring tube.

Temperature sensors have uses beyond merely accounting for thermal effects. Because they measure the temperature of the fluid, temperature information is used as the third direct process signal of a CMF, in addition to mass flow and density.

Security

The oscillation amplitude of a CMF is very small (typically, 100 μm). Stress in the measuring tubes is limited to ensure reliable operation of the meter for many years and to protect the meter from damage due to tube oscillation.

The whole vibration system, including driver and sensors, is fixed in a solid housing, typically constructed of stainless steel. This housing can act as a secondary containment. The more compact the CMF, the smaller the housing can be and, possibly, the higher the pressure rating of the secondary containment. Housings with pressure ratings up to 1500 psi (100 bar) are available.

Because they employ a small excitation current, intrinsically safe CMF versions are available for use in hazardous areas. The electronics must be tested for electromagnetic compatibility (EMC), fulfilling general EMC requirements according to applicable guidelines.

Electronics

The drive circuit initiated the tube oscillation and maintains the oscillation at a certain amplitude. This circuit needs to be built to provide a fast response to changing fluid properties. Air bubbles, for example, cause a sudden increase in excitation power. This information has to be supplied to the driver quickly so as to keep the amplitude of the oscillation constant. The driver circuit also controls the excitation frequency.

The sensor signals are very small sinusoidal signals, which have to be amplified to make them processible in the succeeding signal processing stages of the electronics. These amplifiers need to have a very broad bandwidth to prevent the mass flow signal from containing additional zero-point errors.

The electronics can be mounted on the flowmeter directly, forming one compact flowmeter unit, or the flowmeter can be interfaced to the electronic via a cable. This permits the electronics to be located remotely from the sensor. The remote assembly may be necessary for high-temperature meters, or it may be convenient if the sensor is installed in a place that is not easily accessible.

Signal Processing

The sinusoidal signals from the two sensors are compared to determine either the time difference or phase shift between the two signals. The mass flow rate is calculated directly by multiplying the time difference or the phase shift with the calibration constant of the flowmeter. Furthermore, thermal effects on the mass flow and density reading have to be included as well. This is commonly done with a microprocessor. However, analog circuitry can also be used. Today, much analog circuitry is being replaced by digital signal processors, which offer powerful mathematical functions to allow, for example, filtering of the flow signals. With digital processing, the response time of a CMF becomes faster, and the reproducibility of the flow reading improves. Thus, with digital signal processors, CMFs become capable of controlling formidable applications such as rapid batching, where fast response and high accuracy are critical.

Communication/Output

The primary output from a CMF is mass flow. However, most electronic designs are also capable of providing temperature, density, and volumetric flow data. Furthermore, totalizers provide mass or volume totals.

Most electronics are equipped with configurable alarm outputs. Sophisticated relay functions are available whereby the CMF directly controls a valve in a batching process.

Many digital output protocols are supported (e.g., Profibus, FOUNDATION™ fieldbus, HART, Modbus, scaled pulse, and others), allowing a choice of communication solutions. However, current (4- to 20-mA) and frequency outputs for mass flow are still the preferred and most common output signal formats.

TECHNICAL DATA

Measuring Accuracy/Range

Figure 2.11d shows the excellent measuring accuracy and the large rangeability of CMF. During the 12-h test run, the zero point and the calibration factor remain stable and are well within the specification of the instrument. Note that the reading remains accurate even at low flow rates, even below 1/100 of the maximum flow rate specified for the CMF.

Pressure Drop

The pressure drop depends on tube design and mainly depends on the length of the tube and its inner diameter. For the pressure drop of CMF with dual tubes, the design of the flow splitter is also important. The lowest pressure drop occurs with single straight-tube flowmeters, where the inner diameter of the measuring tube is identical to that of the connected process pipe. Typical pressure drops at the maximum flow speeds specified by manufacturers are 7 to 20 PSIG (0.5 to 1.5 bar) referred to water. For the measurements shown in Figure 2.11d, the pressure drop at 80 in./sec (2 m/s) is only 0.4 PSIG (30 mbar).

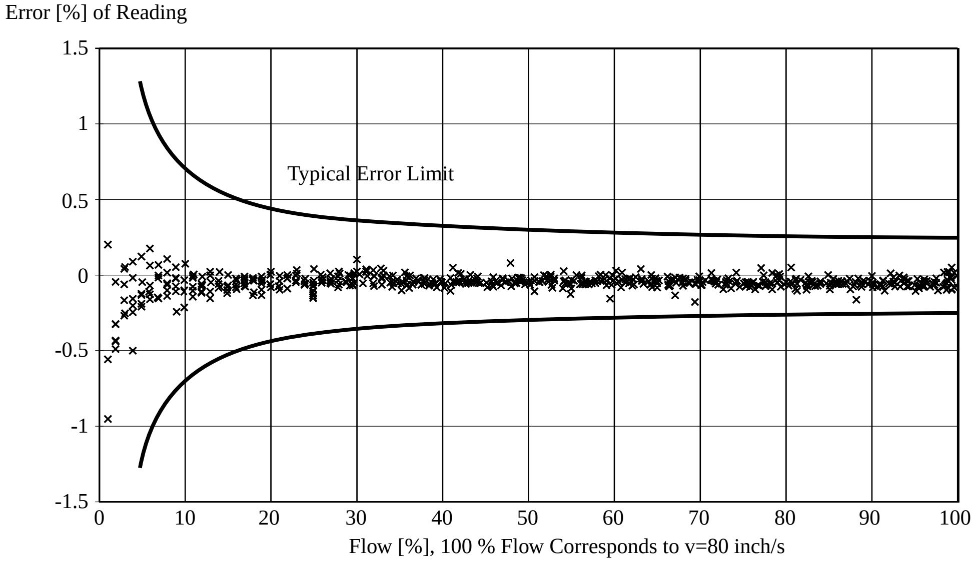

FIG. 2.11d
This figure shows the measuring uncertainty for a 1” (DN25) Coriolis flowmeter. The maximum flow speed is 80 in./s (2 m/s), which is 20% of the maximum specified flow speed of the flowmeter. The curves show the specified error limits.

Influences on the CMF Reading

While improving the accuracy of CMFs during the past decade, many effects, mostly secondary, can be identified that influence the performance of a CMF. These effects can be roughly separated into two groups.

1. Effects such as changing fluid temperature, for which CMF can directly account
2. Effects like external vibration, for which CMF cannot directly account

The latter effects are minimized by either the design layout or, if that is not possible, by special installation or correction instructions. In this section, we will briefly describe different effects.

Temperature As mentioned previously, changing fluid and housing temperatures will affect the elastic properties of the CMF and thus influence the mass flow and density readings. We can account for this effect directly by measuring the fluid and housing temperatures separately. On the other hand, temperature changes can also influence the zero offset and the performance of the electronic components to some degree. The drift in electronic components will usually lead to changes in the zero offset of the flowmeter. Both influences can be minimized by using a special design that does not require any further corrections or installation instructions.

In-Line Pressure With changing in-line pressure, the tube becomes slightly deformed, which influences the stiffness of the layout and thus can affect the reading of the CMF. With special designs, this effect can be minimized.

Mounting Pipe stress is introduced not only by in-line pressure and temperature, as described before, but also by different mounting conditions. These conditions may cause compression, tension, or shear forces to be applied to the flowmeter, which may affect the zero offset of the CMF. The influence of these effects has been greatly reduced during the last decade so that, today, a zero-point calibration is needed only for special applications as described below.

Vibration In most applications CMFs are exposed to some external vibrations. Such vibrations can occur as a result of the pumping system or nearby vibrating devices, or they may be flow induced as observed in pipeline systems. External vibrations typically occur at 50 to 180 Hz. As mentioned previously, CMFs are designed such that the effect of external influences is minimized. Therefore, external vibration plays a minor role and generally has no effect on the accuracy of the CMF reading. However, if the external vibration is close to the working frequency of the CMF, measurement errors will occur. It has been shown that pulsation is critical not only at the working frequency (f_E) of the CMF but also at frequencies $f = f_C - f_E$, where f_C is the Coriolis frequency.[3] Therefore, CMFs with high working frequencies are much less sensitive to pulsation and external vibrations than others. This is because both f_E and the difference $f_C - f_E$ are high; i.e., above roughly 200 Hz. For severely vibrating applications, where the low working frequency of the CMF might become critical, the influence of the external vibration can be greatly reduced by using flexible piping and vibration-isolating pipe supports.

Humidity Because CMFs are typically enclosed in sealed cases that are completely isolated from atmospheric conditions, external humidity has only a minor influence. Also, the flowmeter electronics are commonly enclosed in a housing that provides protection against external humidity. However, in CMFs with inadequate case seals or damaged housings, extremely humid environments can create condensation on the flow detector coils, which may lead to corrosion and component failure.

Fluid Velocity It is well known that the velocity of the fluid can slightly influence the accuracy of the CMF reading.[1] This is a minor effect, which is below the specified accuracy of most CMFs and does not necessarily require any correction. Nevertheless, given that the velocity of the fluid is known, a CMF can directly account for this effect.

Gas Measurements Only in recent years has it been shown that the compressibility of gas can affect the accuracy of the CMF reading.[4] Although this effect can be neglected for most fluids, it becomes relevant for gases in which the speed of sound is diminished. Knowledge about this effect allows us to correct the reading of CMF.

Two-Component Flow A CMF may be suitable for homogeneous two-phase (solid/liquid) flows and for heterogeneous flows. Such applications include many food processes, sand in water, pulverized coal in nitrogen, water in oil, and many others. To measure two-phase fluids, single-tube meters may be preferable.

Corrosion, Erosion Corrosion and erosion diminish the wall thickness and therefore change the stiffness of the tube, which can lead to faulty CMF readings. Since CMFs are available with different tube materials, corrosion can significantly be reduced by choosing the appropriate material for each application. To reduce erosion caused by highly abrasive media, it is necessary to keep the flow velocity low. Erosion also depends on the design of CMF and is smallest in straight, single tubes.

Reynolds Number Although the accuracy of a CMF generally does not depend on the flow profile, the sensitivity changes slightly from laminar flow to eddy flow. Knowledge of the Reynolds number allows us to determine the state of the flow regime and thus to account for it directly.

Installation

Some general recommendations for installations are applicable to all CMFs. The measuring tubes should remain full of the process fluid. Mixtures of gas and liquid should be avoided. For gas measurements, the tubes should be filled with gas only, with no fluid droplets present.

The preferred installation orientation is vertical, with an upward flow direction. With this orientation, entrained solids can sink downward, and gases can escape upward, when the medium is not flowing. This also allows the measuring tubes to be completely drained and protects them from solid build up.

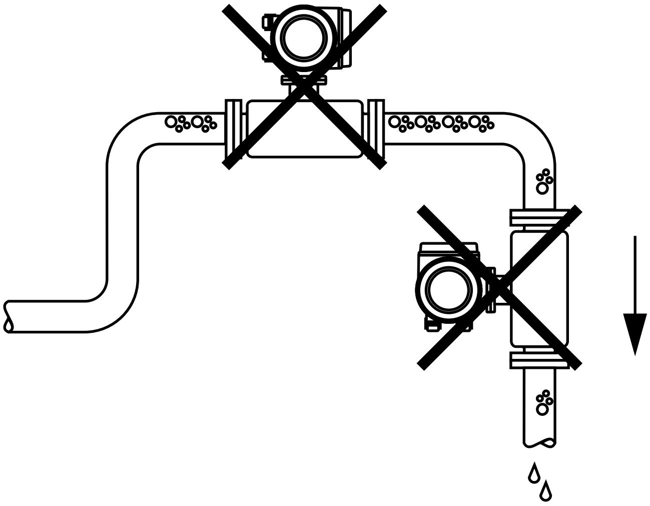

FIG. 2.11e
Not recommended mounting location of a CMF.

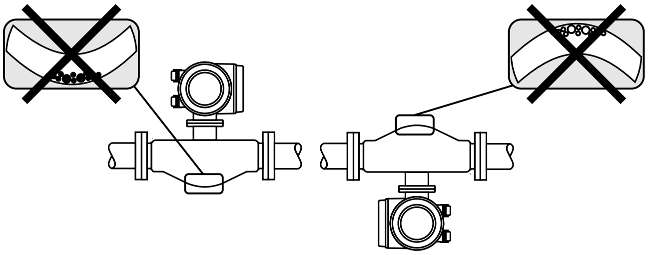

FIG. 2.11f
Orientation of CMF with curved tubes; the orientation shown in the left panel is not suitable for fluids with solids content; the orientation shown in the right panel is not suitable for outgassing fluids.

When measuring liquids, the CMF should not be installed at the highest point of the system, because gas may accumulate in the flowmeter as shown in Figure 2.11e. Installation in a vertical pipeline directly upstream of a free pipe outlet should also be avoided.

With curved tubes, the CMF orientation should be adapted to type of fluid used. Figure 2.11f illustrates problems with outgassing fluids and with fluids containing solid particles.

Mechanical Installation Modern CMFs offer good balance in the vibration system and therefore have no specific installation requirements. The CMF can be installed easily in a pipeline. When heavy CMFs are used, mechanical support of the pipeline has to be considered. Pipeline supports should not be attached directly to the sensor, and the CMF should not be used to support process piping directly.

TABLE 2.11g
Examples of Common Coriolis Flowmeter Applications

Food and Beverage	*Chemical and Petrochemical*		*Petroleum Products*
Beer, soda	Adhesives	Hydrogen peroxide	Asphalt
Chocolate	Alcohol	Latex	Bunker C
Fruit juice	Ammonia	Nitric acid	Crude oil
Honey	Catalysts	Phosgene	Diesel fuel
Ice cream	Caustic	Phosphoric acid	Fuel oil
Margarine	Cyclohexane	Polyol	Gasoline
Milk	Ethylene	Propylene	Hydraulic oil
Molasses	Formaldehyde	Resins	Jet fuel
Peanut butter	Freon®	Solvents	Kerosene
Pet food	Glycerine	Styrene	Lube oil blending
Tomato paste	Glycol	Sulfuric acid	Oil/water emulsion
Animal, vegetable fat	Hydrochloric acid	Toluene	Tar
Pharmaceutical	*Pulp and Paper*	*Other*	
Alcohols	Antifoaming agents	Compressed gases: nitrogen, helium, carbon dioxide, CNG	
IV bag filling	Black liquor		
Palm oil	Cellulose slurry	Dyes	
Perfume	Paper pulp	Ink	
Pill coatings	Red liquor	Liquefied gases: carbon dioxide, LPG, LNG	
Soap	Titanium dioxide	Magnetic tape coating	
Sodium methylate		Paint	
Talcum powder		Photographic emulsion	
Vitamins		Wax	
		Filling airbags (automobile industry)	

Zero-Point Adjustment (Static/Dynamic) After factory calibration of a CMF, the calibration factor and the zero point are stored in the electronics. CMFs that have good balance, and thus are decoupled from connected piping, are not affected by the installation into the process piping. As a result, the zero point will not change, and no special zero-point adjustment is necessary. Practical experience has shown that a zero-point calibration is required only in special cases; for example, to achieve the highest measuring accuracy possible in the presence of very slow flow rates or in the case of extreme process conditions such as very high fluid temperatures.

Zero-point calibration is carried out using completely filled measuring tubes with no mass flow. During the zero-point adjustment, care has to be taken that no gas or solids are present in the measuring tube. Keeping the in-line pressure high during the zero-point calibration reduces the risk of gas formation in the CMF and thus increases the accuracy of the zero-point calibration.

APPLICATIONS

CMFs are currently used in many areas, including chemical, petroleum, petrochemical, pharmaceutical, food and beverage, and pulp and paper industries. Because of their versatility, CMFs are used for process control, batching, inventory, precision filling of containers, custody transfer, and other applications. An overview of some of them is presented in Table 2.11g. CMFs are suitable for many applications, because they can be very compact and do not have any upstream or downstream piping restrictions. An example of a compact application is shown in Figure 2.11h. The photo shows a

FIG. 2.11h

single-tube CMF Promass I from Endress+Hauser Flowtec AG. Note that inlet and outlet parts are bent at a 90° angle and that the available room is very limited.

ADVANTAGES OF CMFs

1. One of most important advantages of CMFs is that mass flow is measured directly. This can be performed with high accuracy, typically with 0.1% error. High accuracy is also maintained over wide ranges of temperatures (typically from –50 to +200°C) and in-line pressures. Furthermore, CMFs are extremely linear over their entire flow range.
2. CMF rangeability is extremely high. Measurements can still be performed at low flow rates, 100 times lower than the maximum flow rate specified.
3. In addition to direct measurement of mass flow, temperature and density are measured directly. Knowledge about density allows us to convert mass flow data into volume flow data.
4. The measuring principle is independent of the flow profile of the fluid or gas. Therefore, no flow conditioner or special upstream or downstream pieces are required. A CMF can also be used with a pulsating flow.
5. The accuracy of a CMF is independent of fluid properties such as viscosity or density. Therefore, a CMF can measure all kinds of fluids, including Newtonian and non-Newtonian fluids, slurries, and gases.
6. CMFs do not have any moving parts that wear out and require replacement. This reduces the need for and the cost of maintenance.
7. Single-tube CMFs do not have internal obstructions that could be damaged or plugged.
8. CMFs are designed to measure forward and reverse flows with high accuracy.
9. Because CMFs are available based on different construction materials, they can be used for many different applications, including corrosive fluids.
10. The design of CMFs allow them to operate with low power requirements.

LIMITATIONS OF CMFs

1. CMF prices are rather high as compared to other measuring device types. However, to measure mass flow with a volumetric meter, it is often necessary to install an in-line densitometer, which brings the cost up to roughly the equivalent of a CMF alone.
2. There are no CMFs available for medium temperatures above 800°F (426°C).
3. CMFs cannot be used for liquids with any significant gas content. This effect can be reduced by increasing the in-line pressure.
4. CMFs are not available for large pipelines; the largest CMF has a maximum flow rate of 63,000 lb/min (28,300 kg/min) using flanges with 10-in. (25-cm) diameters. To measure higher flow rates, two or more CMFs must be mounted in parallel.
5. CMFs are not suitable for gas applications with low in-line pressure, since low-pressure gases have low densities. To generate enough mass flow to provide a sufficient Coriolis signal, the velocity of the gas must be quite high. This may lead to a large pressure drop across the meter.

Flow Sheet Symbol

Types	A. Flow computers using inputs from volumetric flow sensors and densitometers, or pressure/temperature transmitters B. Doppler ultrasonic or magnetic flowmeter and radiation-type densitometer combinations C. Angular momentum and other similar principles D. Linear hydraulic Wheatstone-type
Applications	Gas, liquid, solids
Design Pressures and Temperatures	Magmeter/radiation units available up to 255 PSIG (17.5 bars) and 300°F (150°C)
Pipe Sizes Available	A. Unlimited B. 2 to 36 in. (50 mm to 0.9 m) C. Small diameters only—aero turbine fuel applications D. Under 1 in. (25 mm), for very low flows only
Errors (Inaccuracy)	Varies with the designs, generally approximately ±1% of full scale
Costs	A. Flow computers without the sensors can cost approximately $600 minimum; $700 to $4000 normally, depending on options, features, remote communications capabilities, and so on B. A 6-in. (150-mm) magmeter/radiation combination costs about $13,000 C. Costs vary substantially with size and materials of construction D. Price starts at about $2000 minimum; normally $7000 to $13,000, depending on model, options, and range required

A knowledge of mass flow rates is necessary in combustion fuel control, reactor recipe formulations, and many other applications, including the mining and dredging, food, pulp and paper, pharmaceuticals, and chemical industries. The various weighing systems, solids flowmeters, and the more frequently used liquid/gas mass flowmeters (such as Coriolis and thermal types) are discussed in Sections 2.11 and 2.13. In this section, some of the other mass flow detection methods are covered.

RADIATION-TYPE MASS FLOWMETERS

One of the earliest methods of mass flow determination was to install two separate sensors—one to measure the volumetric flow and the other to detect the density of the flowing stream—and then to use the two transmitter signals as inputs into a mass flow computing module. This approach was feasible, but it required coordination between the products of different suppliers and corrections for such process variables as temperature, pressure, viscosity, particle size, and velocity profile changes. The introduction of density/mass flow systems has made it easier to use this technique. The key working component in these combinational designs is the multiple-input transmitter (Figure 2.12a), which, in addition to a radiation-type density input, accepts a flow measurement signal from any volumetric flowmeter. Based on these two inputs, the microprocessor-based transmitter generates an output signal that relates to mass flow.

A further improvement occurred in the design of these density/mass flow systems in which the density and volumetric flow sensors were combined in a single package (Figure 2.12b). These units are composed of a either a Doppler ultrasonic flowmeter or a magnetic flowmeter and a gamma-radiation-based densitometer, all in a single unit including a microcomputer. These mass flow units do not require compensation for changes in process variables and are installed as a single, obstructionless mass flow sensor. Its features and materials of construction are similar to those of a magnetic or ultrasonic flowmeter except that it is bulkier and more expensive because it incorporates a radiation-type densitometer. If the flow sensor is a magnetic flowmeter, the unit is also limited to use on process fluids having at least 3.0 μS/cm conductivity.

Combination mass flow system.

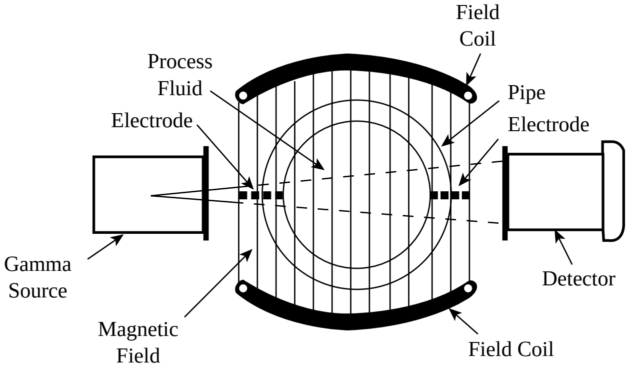

FIG. 2.12b
Mass flowmeter combining a magnetic flowmeter and a radiation-type densitometer in a single unit.

ANGULAR MOMENTUM-TYPE MASS FLOWMETERS

The principle of angular momentum can best be described by referring to Newton's second law of angular motion and the definition of angular momentum, using the following notation:

H = angular momentum (lbf-ft-sec)
I = moment of inertia (lbf-ft^2)
ω = angular velocity (rad/sec)
α = angular acceleration (rad/sec^2)
Y = torque (ft-lbf)
r = radius of gyration (ft)
m = mass (slugs)
t = time (sec)

Newton's second law of angular motion states that

$$Y = I\alpha \qquad \mathbf{2.12(1)}$$

and defines that

$$H = I\omega \qquad \mathbf{2.12(2)}$$

But because, by definition,

$$I = mr^2 \qquad \mathbf{2.12(3)}$$

Equation 2.12(1) becomes

$$Y = mr^2\alpha \qquad \mathbf{2.12(4)}$$

and Equation 2.12(2) becomes

$$H = mr^2\omega \qquad \mathbf{2.12(5)}$$

Because

$$\alpha = \frac{\omega}{t} \qquad \mathbf{2.12(6)}$$

Equation 2.12(4) becomes

$$Y = \frac{m}{t}r^2\omega \qquad \mathbf{2.12(7)}$$

Solving for mass flow rate, $\frac{m}{t}$, (lbm/sec), we get

$$\frac{m}{t} = \frac{Y}{r^2\omega} \tag{2.12(8)}$$

Also, dividing both sides of Equation 2.12(5) by t,

$$\frac{H}{t} = \frac{m}{t} r^2\omega \tag{2.12(9)}$$

Because torque is expressed in terms of force, the right-hand side of Equation 2.12(8) must be multiplied by g (32.2 ft/sec^2 or 9.8 m/sec^2) to obtain a dimensionally correct equation. Therefore, since r^2 is a constant for any given system, the mass flow of fluid can be determined if an angular momentum is introduced into the fluid stream and measurements are made of the torque produced by this angular momentum and of the fluid's angular velocity.

Impeller-Turbine Flowmeter

The impeller-turbine-type mass flowmeter uses two rotating elements in the fluid stream, an impeller and a turbine (see Figure 2.12c). Both elements contain channels through which the fluid flows. The impeller is driven at a constant speed by a synchronous motor through a magnetic coupling and imparts an angular velocity to the fluid as it flows through the meter. The turbine located downstream of the impeller removes all angular momentum from the fluid and thus receives a torque proportional to the angular momentum. This turbine is restrained by a spring that deflects through an angle that is proportional to the torque exerted upon it by the fluid, thus giving a measure of mass flow.

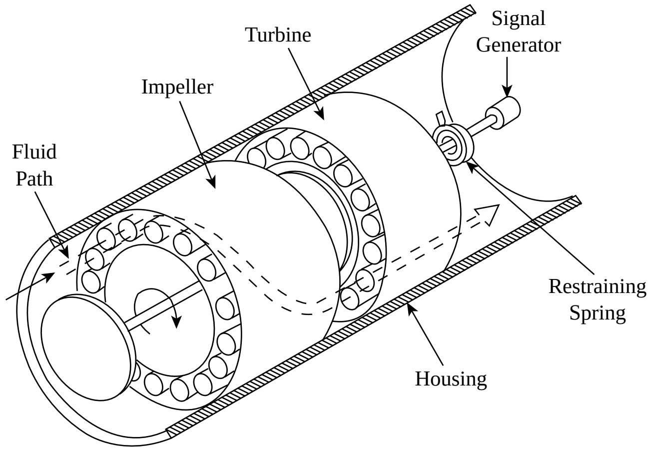

FIG. 2.12c
Impeller-turbine mass flowmeter. (Illustration reproduced by permission of the General Electric Co.)

Constant Torque-Hysteresis Clutch

Another angular-momentum type mass flowmeter eliminates the necessity of making a torque measurement after imparting a constant torque to the fluid stream. The relationship between mass flow and torque is

$$\frac{m}{t} = \frac{Y}{r^2\omega} \tag{2.12(10)}$$

Therefore, if Y is held at a constant value, and since r^2 is a physical constant of any given system,

$$\frac{m}{t} = \frac{k}{\omega} \tag{2.12(11)}$$

This relationship is used in designing a mass flowmeter as follows:

1. A synchronous motor is placed in the center of the flowmeter assembly.
2. This motor is magnetically coupled to an impeller that is located within the flowing process stream.
3. The magnetic coupling between the motor and the impeller is provided by means of a hysteresis clutch that transmits a constant torque from the motor to the impeller.

Thus, a measurement of the rotational speed of the impeller is inversely proportional to the mass flow rate.

Twin-Turbine Flowmeter

Another angular-momentum-type device is the twin-turbine mass flowmeter. New developments in this technology are also discussed in Section 2.25, which covers turbine flowmeters.

In this instrument, two turbines are mounted on a common shaft (see Figure 2.12d). They are connected with a calibrated torsion member. A reluctance-type pickup coil is

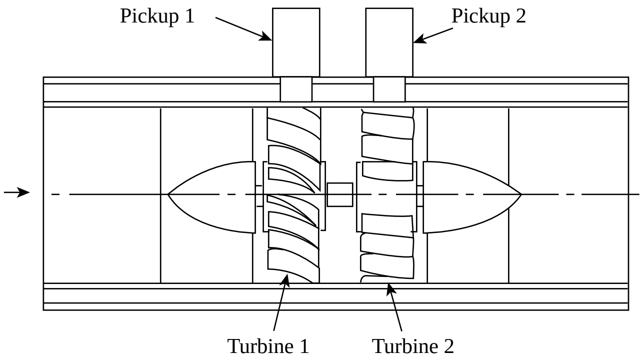

FIG. 2.12d
Twin-turbine mass flowmeter.

mounted over each turbine, and a strong magnet is located in each turbine within the twin-turbine assembly.

Each turbine is designed with a different blade angle; therefore, there is a tendency for the turbines to turn at different angular velocities. However, because the motion of the turbines is restricted by the coupling torsion member, the entire assembly rotates in unison at some average velocity, and an angular phase shift is developed between the two turbines. This angle is a direct function of the angular momentum of the fluid. As previously shown, angular momentum can be measured by torque, and angular momentum is a function of mass flow. In the twin-turbine assembly, the turbines are not restrained by a spring, but the torsion member that holds them together is twisted. This torsion member has a well established torsion-spring rate (ft-lbf/rad). Therefore, the angle developed between the two turbines is a direct function of the twist or torque exerted by the system.

This angle is measured by a unique method. As each turbine magnet passes its own pickup coil, the coil generates a pulse. The pulse from the upstream turbine is used to open a so-called electronic gate, while the pulse from the downstream turbine closes this gate. An oscillator is placed in the electronic circuit, and the oscillations are counted while the gate is opened. The number of oscillations is thus a function of the angle between the two turbines. Knowledge of the angle gives the value of torque, which, in turn, is proportional to mass flow rate.

Coriolis

Coriolis mass flowmeters are discussed in detail in Section 2.11 and are mentioned here only for the purpose of completeness. The classic Coriolis-type mass flowmeter (see Figure 2.12e) consists of a centrifugal-pump impeller wheel and a vaned sensing wheel that acts as a turbine wheel to extract the angular momentum imparted to the fluid by the impeller. The sensing (or turbine) wheel is contained in the same housing as the impeller and is attached to the latter by a strain gauge; the combination is driven at a known constant speed. The power applied to the impeller is merely that required to overcome the frictional drag of the system.

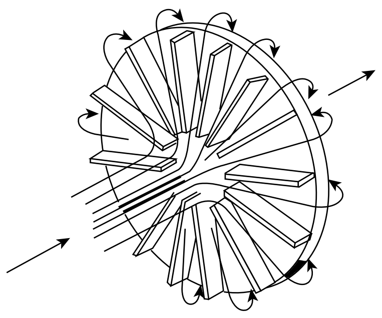

FIG. 2.12e
Classical Coriolis mass flowmeter.

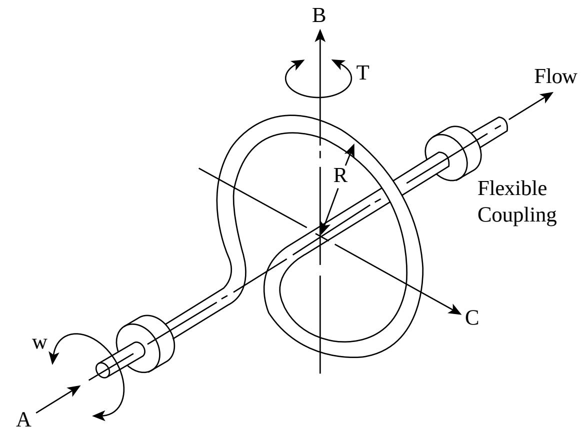

FIG. 2.12f
Gyroscopic mass flowmeter.

The torque measured is that required to impart to the fluid stream a Coriolis acceleration, given by the expression

$$Y = \omega\left(R_2^2 - R_1^2\right)\frac{m}{t} \qquad 2.12(12)$$

where R_2 and R_1 = outer and inner radii (ft).

Comprehensive analysis and laboratory testing of this type of flowmeter are described in Reference 1.

Gyroscopic

Another angular momentum mass flowmeter (Figure 2.12f) operates on the principle of a gyroscope. It consists of a pipe shaped in the form of a circle or a square. A motor introduces an oscillating vibration at a constant angular velocity ω about the A axis. When the fluid passes through the loop, a precession-type moment is produced about the B axis and is measured by the deflection of a sensing element. This deflection can be shown to be directly proportional to mass flow.

The gyroscopic mass flowmeter can handle slurries in the medium pressure and temperature ranges, but its industrial use is very limited as a result of its high cost and inability to handle high flow rates. The gyroscopic and basic Coriolis flowmeters described earlier were generally not successful in the mass-flow-measurement market. A newer combination of the two principles has resulted in the highly successful Coriolis mass flowmeter described in the previous section.

LINEAR MASS FLOWMETERS

The linear mass flowmeter is, in principle, a hydraulic equivalent of the electrical Wheatstone bridge. Four matched orifices make up the bridge, and an integral constant flow recirculating pump establishes the internal reference flow. Sensing imbalance generated by external flow through the meter, the hydraulic bridge produces an output of differential pressure that is both linear and proportional to the true mass liquid flow.

This flowmeter has a wide rangeability and is unaffected by changes in process temperature, density, and viscosity. It is a fast-responding flowmeter that can detect very low flows at very low pressure drops. This meter is widely used in the automotive industry and wherever engines and fuel systems are checked, such as in the manufacturing of fuel injectors.

INDIRECT MASS FLOWMETERS

As is shown in Figure 2.12a, mass flow can also be obtained as the product of volumetric flow and density. In the case of measuring the mass flow of steam, one can also measure its volumetric flow and multiply it by density, which is obtained indirectly from the measurements of steam pressure and temperature. This technique is commonly used in the monitoring of steam distribution and determining steam losses caused by leakage, poor insulation, and so on.

Calculating the Mass Flow of Steam

Water at atmospheric pressure boils at 212°F. The boiling temperature of water is affected by pressure and, as the pressure drops, the boiling point decreases; as it rises, the boiling point increases. This pressure-temperature relationship is as follows:

Pressure	*Boiling Point, °F (°C)*
14.696 psia	212 (100)
50 psia	281 (138)
100 psia	328 (164)
200 psia	382 (194)
400 psia	445 (229)
800 psia	518 (270)

The boiling temperature of water at any given pressure is called the *saturation temperature*, and the steam produced at these temperatures is referred to as *saturated steam*. If the steam temperature is increased over the saturation temperature, it is referred to as *superheated steam*, and the temperature difference between the saturation and the actual temperature is referred to as *degrees of superheat*. So, for example, if 100 psia steam is at 428°F, it has 100° of superheat.

Steam Density and Accounting

If the steam temperature and pressure are known, the internal energy, which is called *enthalpy*, is also known, as provided by the steam tables in the appendix of this handbook. From the steam tables, it is seen that the density of steam is also a function of only its temperature and pressure. Therefore, by measuring the temperature and pressure of steam, its density can be calculated, and if the volumetric flow of the steam is known, its mass flow can be calculated as the product of the two.

TABLE 2.12g
Plant Steam Balances

Boiler Output	*Volumetric Plant Consumption*	*Mass Plant Consumption*
20,000 lb/h (67,340 ft^3/h)	Weaving: 13,841 ft^3/h	4000 lb/h
	Spinning: 14,286 ft^3/h	4000 lb/h
	Finishing: 14,706 ft^3/h	4000 lb/h
	Services: 30,534 ft^3/h	8000 lb/h
Total: 20,000 lb/h (67,340 ft^3/h)	Total: 77,367 ft^3/h	Total: 20,000 lb/h

The energy content of steam is a function of its enthalpy. When steam is purchased for heating or to drive turbines, it is usually paid for on the basis of enthalpy. Therefore, by measuring the pressure, temperature, and volumetric flow of steam, one can calculate the mass flow or heat flow of steam.

The heat content of the steam drops, and some of the steam is also lost, as it travels from the boiler to the various users. This is the result of

- Insufficient thermal insulation of pipes
- Leaking joints on valves, pipes and other equipment
- Long line lengths

Example*

The steam distribution example given in Table 2.12g and Figure 2.12h is that of a textile factory. From Table 2.12g, one can observe that, when measured by volumetric flowmeters only (which disregard the effects of the drop in steam pressure as it travels through the distribution pipe lines), the total steam consumption appeared to be 9% greater than the volumetric flow of the steam as it left the boiler. On the other hand, if the measurements at the individual users are corrected for the drops in the pressure and temperatures at the users (and if no steam loss occurs due to leakage or condensation), this error can be eliminated through mass flow calculation.

Such calculations have the additional advantage of being able to provide the plant operator with information not only on mass flow but also on heat flow or total consumption of both mass and heat. In addition, such monitoring packages can keep records of pressure, temperature, specific volume, and enthalpy variations.

CONCLUSION

The most successful mass flowmeters have been described in the previous section (Section 2.11), but the devices covered in this section also have their applications. For example, the integrated ultrasonic or magnetic flowmeter/radiation densitometer package is the best solution for mass flow measurement of large slurry streams, in size ranges of 12 in.

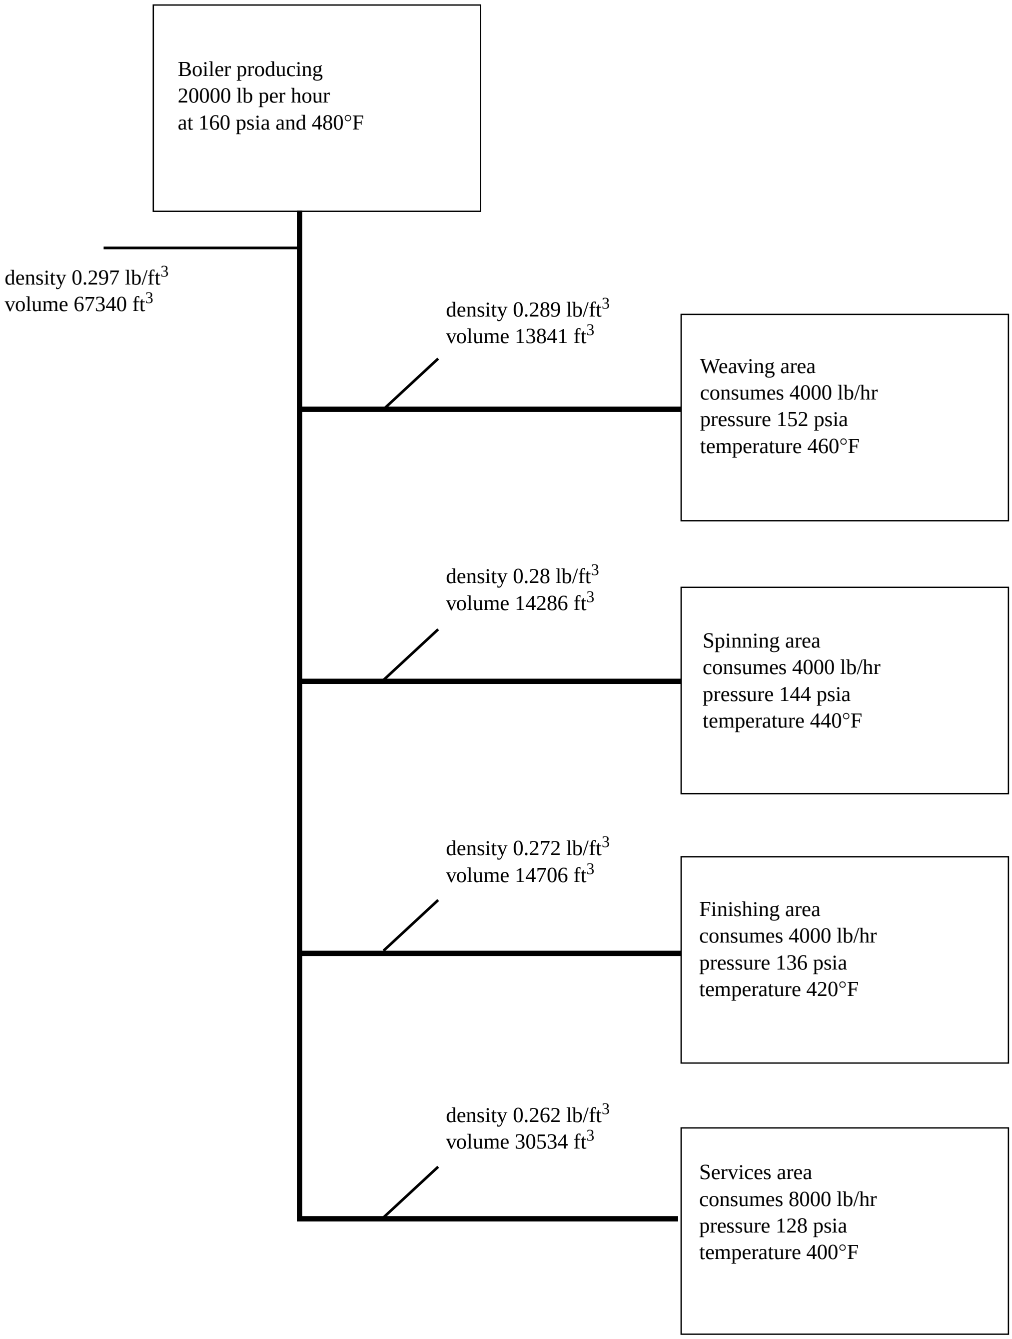

FIG. 2.12h
Plant steam balance example.

(300 mm) and above. Also, the flow computer approach sees many practical applications in many industries.

Accurate mass flow detection frequently can increase the efficiency of processes or allow for optimization, which results in energy or fuel conservation in combustion systems.

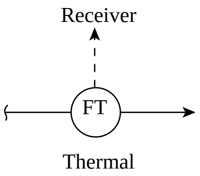
2.13 Mass Flowmeters—Thermal

R. SIEV (1969, 1982) **B. G. LIPTÁK** (1995) **T. J. BAAN** (2003)



Flow Sheet Symbol

Types	A. Heat transfer-type mass flowmeters B. Thermal mass flowmeters employing externally heated capillary bypass sensor tubes and main conduits with laminar flow elements C. Heated-element-type mass flowmeters (note: Thermal flow switches are discussed in Section 2.7)
Check Cross Design Temperature	A. Up to 350°F (176°C), higher with special designs B. Some limited to 105°F (40°C) operation; others up to 300°F (150°C) C. Standard units up to 140°F (60°C), special ones up to 930°F (500°C)
Design Pressure	A. Up to 1200 PSIG (83 bars), higher with special designs B. Up to 1000 PSIG (69 bars) C. Low-pressure designs up to 15 PSIG (1 bar); others up to 1000 PSIG (69 bars) in smaller sizes
Pressure Drop	A. Usually, only a few inches of water B. Up to 45 PSIG (3 bars) C. Same as A
Process Fluids	A. Air, gas, liquids, and slurries B. Gases, some very low flow rate liquid devices C. Gases and liquids
Flow Range	A. From 0.5 sccm to 40,000 lbm/h (10,000 kg/h) B. Flow control units from 0 to 10 sccm to 0 to 35 scfm (0 to 1000 slm); special units up to 0 to 500 scfm (0 to 14 scmm) C. From 0 to 50 sccm to 0 to 2500 scfm (0 to 70 scmm)
Error (Inaccuracy)	±1% to ±2% of full scale, some better
Rangeability	10:1 to 100:1
Materials of Construction	Stainless steel, glass, Teflon™, Monel®, and so on
Cost	A type "B" thermal mass-flowmeter costs $500 and up, mass flow controller for low gas flows costs about $700 and up; purged probes for stack velocity measurement cost about $4500 each

Thermal flowmeters can be divided into the following two categories:

1. Flowmeters that measure the rise in temperature of the fluid after a known amount of heat has been added to it. They can be called *heat transfer flowmeters.*
2. Flowmeters that measure the effect of the flowing fluid on a hot body. These instruments are sometimes called *hot-wire probes* or *heated-thermopile flowmeters.*

Both types of flowmeters can be used to measure flow rates in terms of mass, which is a very desirable measurement, especially on gas service.

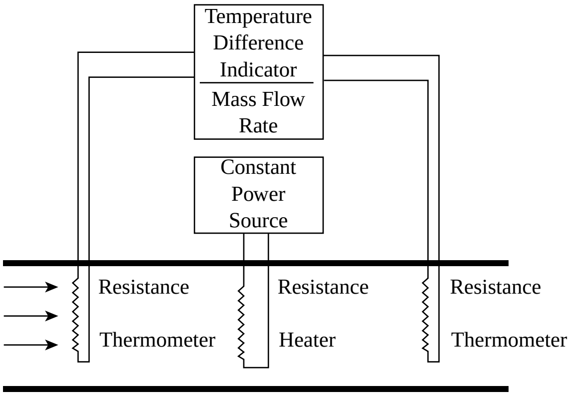

FIG. 2.13a
Heat transfer flowmeter.

HEAT TRANSFER FLOWMETERS

The operation of the heat transfer flowmeter is based on

$$Q = Wc_p(T_2 - T_1) \qquad \text{2.13(1)}$$

where

Q = heat transferred (BTU/h or Cal/h)
W = mass flow rate of fluid (lbm/h or kgm/h)
c_p = specific heat of fluid (BTU/lbm °F or cal/kgm °C)
T_1 = temperature of the fluid before heat is transferred to it (°F or °C)
T_2 = temperature of the fluid after heat has been transferred to it (°F or °C)

Solving for W, we get

$$W = \frac{Q}{C_p(T_2 - T_1)} \qquad \text{2.13(2)}$$

A simple flowmeter based on this equation is shown schematically in Figure 2.13a. Heat is added to the fluid stream with an electric immersion heater. The power to the heater equals the heat transferred to the fluid (Q) and is measured using a wattmeter. T_1 and T_2 are thermocouples or resistance thermometers. Since we know the fluid, we also know the value of its specific heat. Thus, by measuring Q, T_1, and T_2, the flow rate (W) can be calculated. T_1 and T_2 do not have to be separately detected; they can be connected to each other so that the temperature difference ($T_1 - T_2$) is measured directly.

A flowmeter of this type of construction has many limitations. The temperature sensors and the heater must protrude into the fluid stream. Thus, these components (particularly the heater) are easily damaged by corrosion and erosion. Furthermore, the integrity of the piping is sacrificed by the protrusions into the fluid stream, increasing the danger of leakage.

To overcome these problems, the heater and the upstream and downstream temperature sensors can be mounted outside of the piping (see Figure 2.13b). In this type of construction, the heat transfer mechanism becomes more complicated, and the relationship between mass flow and temperature difference becomes nonlinear. Figure 2.13c illustrates this nonlinear shift in ΔT in a heated-tube-type flowmeter, where the asymmetricity of the temperature distribution increases with flow.

To understand the operating principle of this flowmeter, we must review the effects of fluid mechanics and heat transfer. When a fluid flows in a pipe (turbulent or laminar), a thin

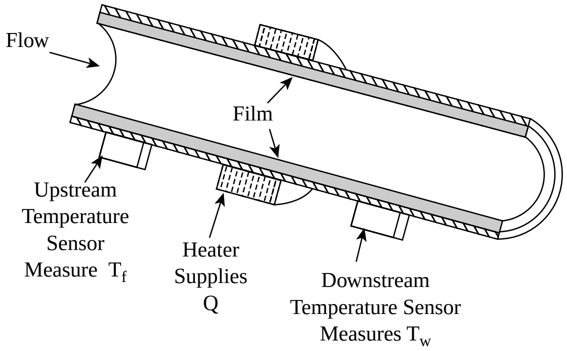

FIG. 2.13b
Thermal flowmeter with external elements and heater.

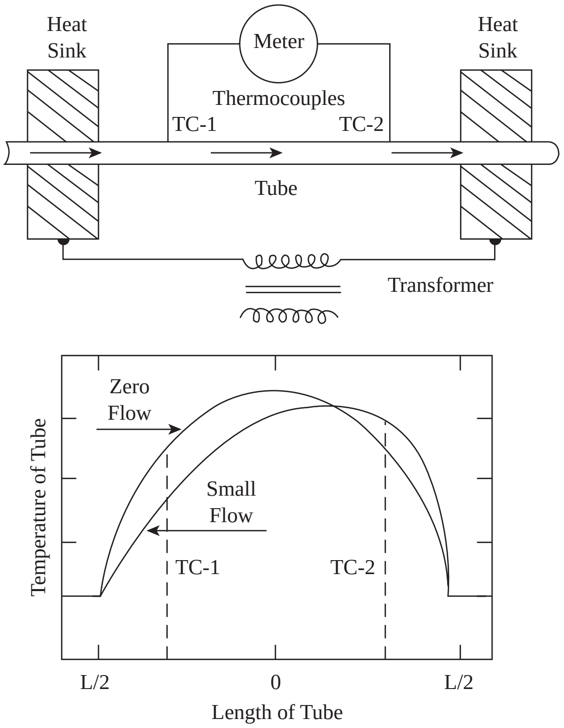

FIG. 2.13c
Heated-tube-type mass flowmeter.

layer (film) exists between the main body of the fluid and the pipe wall. When heat is passing through the pipe wall to the fluid, this layer resists the flow of heat. If the heater is sufficiently insulated, and if the piping material is a good heat conductor, the heat transfer from the heater to the fluid can be expressed as

$$Q = hA(T_{\text{wall}} - T_{\text{fluid}}) \qquad \textbf{2.13(3)}$$

where

h = film heat transfer coefficient [BTU/(hr × ft^2 × °F)]
A = area of pipe through which heat is passing (ft^2)
T_{wall} = temperature of wall (°F)
T_{fluid} = temperature of fluid (°F)

The film heat transfer coefficient, h, can be defined in terms of fluid properties and tube dimensions for both laminar and turbulent flow.[1]

$$h_{\text{turbulent}} = \frac{0.023K^{0.6}c_{\text{p}}^{0.4}W^{0.8}}{D^{1.8}\mu_1^{0.4}} \qquad \textbf{2.13(4)}$$

$$h_{\text{turbulent}} = \frac{1.75K^{0.67}c_p^{0.33}W^{0.33}}{DL^{0.33}} \qquad \textbf{2.13(5)}$$

where

K = thermal conductivity of the fluid [BTU/(hr × ft × °F)]
c_p = specific heat of the fluid [BTU/(lbm × °F)]
D = pipe diameter (ft)
L = heated length (ft)
μ_1 = absolute viscosity of the fluid (lbf/h-ft^2)
W = flow rate (lbm/h)

Using the turbulent flow condition as an example, and solving Equations 2.13(3) for h and 2.13(4) for W,

$$h = \frac{Q}{A(T_{\text{wall}} - T_{\text{fluid}})} \qquad \textbf{2.13(6)}$$

$$W^{0.8} = \frac{hD^{1.8}\mu_1^{0.4}}{0.023K^{0.6}c_p^{0.4}} \qquad \textbf{2.13(7)}$$

Substituting Equation 2.13(6) into 2.13(7),

$$W^{0.8} = \frac{QD^{1.8}\mu_1^{0.4}}{0.024K^{0.6}c_p^{0.4}A(T_{\text{wall}} - T_{\text{fluid}})} \qquad \textbf{2.13(8)}$$

Therefore, the mass flow (W) will vary with $T_{\text{wall}} - T_{\text{fluid}}$ if the fluid properties (μ, K, and c_p) and the meter design parameters (Q, D, and A) are all held constant. Letting all these constants = X,

$$W^{0.8} = \frac{X}{T_{\text{wall}} - T_{\text{fluid}}} \qquad \textbf{2.13(9)}$$

The downstream temperature sensor is located near the heater so that it measures T_{wall}. The upstream temperature sensor is located where the wall and fluid temperatures are in equilibrium. Thus, flow rate is obtained by measuring ΔT if the geometry of the flowmeter, the thermal conductivity, the thermal capacity and viscosity of the fluid, and the heater power are constant. This type of flowmeter can also be operated by keeping the ΔT constant and measuring the required power to the heater.

When building and/or using a flowmeter based on heat transfer principles, an instrument engineer must tread with caution. One must be sure that the values that have been assumed to be constants are truly so. One must also understand that relationships such as those given in Equations 2.13(4) and 2.13(5) are limited to a range of Reynolds numbers, L/D ratios, and so on. Finally, it is highly recommended that this type of instrument be calibrated, either by the manufacturer or by the user, under conditions that as nearly as possible duplicate its actual application.

These types of flowmeters are best suited for the measurement of homogeneous gases and are not recommended for applications in which the process fluid composition or moisture content is variable. For these flowmeters to be useful in a system, both the thermal conductivity and the specific heat of the process fluid must be constant.

Bypass-Type Designs

To facilitate measurement and control of larger flow rates, heat transfer-type flowmeters with bypass designs have been introduced (Figure 2.13d). Bypass thermal mass flowmeters are comprised of a capillary sensor tube connected to the main flow conduit as a shunt line. Sensor tubes with wall thicknesses as low as 0.002 in. (0.051 mm), usually with inside diameters of under 0.125 in. (3 mm), are fitted with three precision windings externally. The one in the middle is used to transfer heat through the thin wall to the fluid stream inside; the other two are upstream and downstream of the heater, serving to monitor temperature differences. The temperature gradient is due to fluid flow carrying heat from upstream to downstream in the sensor tube.

Measurements are taken by Wheatstone bridge configurations. The main flow conduit includes a laminar flow element to ensure laminar flow and also to act as a restriction forcing a portion of the flow into the sensor tube. Two conduits, if connected in a bypass pattern maintaining laminar flow, will sustain a constant ratio of their flow rates. When zero-flow conditions exist, the temperature differential between upstream and downstream sections is zero. Under flow conditions, fluids carry heat from upstream toward downstream sections of the sensor tube, and the change in resistance is directly proportional to the temperature, and thus, to the mass molecular flow of the gas medium. As the flow through the sensor tube is a function of the temperature gradient, the mass flowmeter can be calibrated to express the total rate of flow in suitable engineering units.

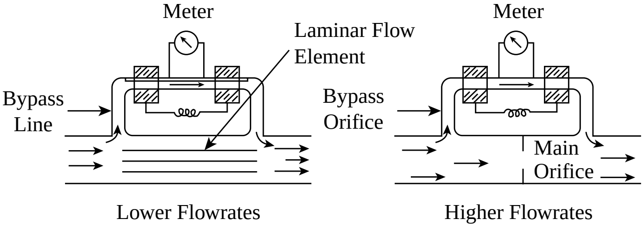

FIG. 2.13d
Bypass-type thermal mass flowmeters.

The smaller the diameter of the sensor tube, the faster the response, although, at the same time, the danger of impediment-related failure increases. There are two kinds of sensor tubes: straight and U-shaped. The advantage of U-shaped tubes is the more compact "footprint" of the mass flowmeter and controller, whereas straight tube designs facilitate stress-free conditions and the possibility of cleaning of the sensor tubes. Shunting sensor tubes ensure laminar flow over the full operating range of the meter. Additionally, small size is advantageous in minimizing the electric power requirement and also in increasing their speed of response, but it requires the use of upstream filters to protect against obstructions. Some units require up to 45 PSIG (3 bars) pressure drop to develop laminar flow conditions.

Traditional analog thermal mass flowmeters and controllers are increasingly being replaced by digital devices with advanced capabilities including user-accessible programming, totalizing, multiple primary calibrations, built-in correction factor libraries, RS-485 interface to permit up to 256 thermal mass flow devices to be controlled from a single PC, and other features. Communication protocols are available in HART, Profibus, and other configurations.

Mass flow controllers consist of flow measurement modules and automatic control valves assembled into compact closed-loop devices (Figure 2.13e). The cost of these units is very competitive. Therefore, if it is sufficient to control the flow of small gas streams to within ±1% of full scale, these units represent a good selection. Flow is most frequently controlled by variable-stroke electromagnetic valves. Thermal expansion valves are also available. Such valves are operated without seals and therefore without friction or wear.

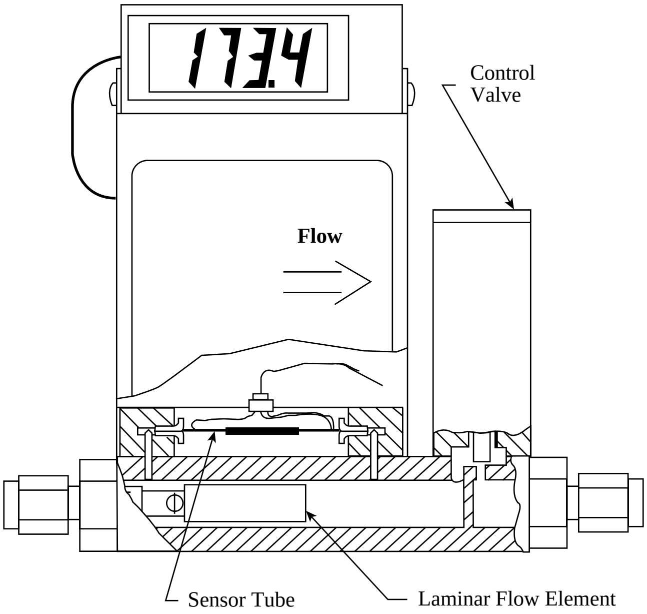

FIG. 2.13e
Bypass-type thermal mass flow controller with readout. (Courtesy AALBORG Instruments & Controls Inc.)

The stem of a thermal expansion valve is heated by the controller, and the expanding stem moves the valve plug into the seat, thereby closing the valve. Due to the type of valve actuator used, it takes 5 to 30 sec to bring the flow to setpoint. Mass flow controllers with flow capacities above 100 sL/min use linear step motor actuated mechanical valves. Proportionating electromagnetic valves have the fastest response, typically facilitating 800 ms time constants, or bringing setpoint-controlled flow rates to within ±2% of full-scale values over 20 to 100% of flow range within 2 sec. Linear step motor valves will typically reach set point values of ±2% of FS within 5 sec over the entire flow range of the meter.

Process applications should be evaluated from the point of view of fast time constants, which sometimes may be accompanied by undesirable overshoot and undershoot attributes vs. slower operations with "soft landings." This is a crucial factor in semiconductor manufacturing processes, where an overshoot condition may destroy a whole batch of expensive silicon wafers.

HOT-WIRE PROBES

In this design, two thermocouples (A and B) are connected in series to form a thermopile. A schematic of this type of flowmeter is shown in Figure 2.13f. This thermopile is heated by passing an alternating current through it. A third thermocouple (C) is placed in the direct current output circuit of the thermopile. Alternating current does not pass through this thermocouple, and it is therefore not electrically heated. This assembly is inserted into the process fluid (usually gas) stream. The gas cools the heated thermopile by convection. Because the AC input power to the thermopile is held constant, the thermopile will attain an equilibrium temperature and produce an emf that is a function of the gas temperature, velocity, density, specific heat, and thermal conductivity. The third, unheated thermocouple (C) generates an emf that is proportional to the gas temperature. This cancels the effect of the ambient gas temperature on the output signal of the heated thermopile. A and B are the heated thermocouples; C is the unheated one.

The output signal (voltage) of this instrument is given by the equation derived by King.[2]

$$e = \frac{C}{2(\pi K c_p \rho d v)^{1/2} + K} \qquad \textbf{2.13(10)}$$

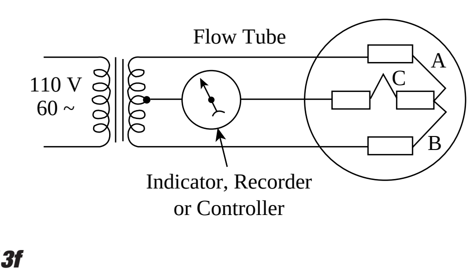

FIG. 2.13f
Hot wire flow-sensing probe.

where
e = voltage generated
C = instrument constant
K = thermal conductivity of fluid (BTU/h-ft-°F)
c_p = specific heat of fluid (BTU/lbm-°F)
d = diameter of heated thermocouple wire (ft)
v = velocity of fluid (ft/h)
ρ = density of the fluid (lbm/ft^3)

Once the instrument has been calibrated for a certain gas, a change in the gas temperature will have little effect on the gas properties and thus on the output signal. For example, the properties of air, over a wide range of temperatures, are as follows:

Temp. (°F)	*K (BTU/h-ft-°F)*	*c_p (BTU/lbm°F)*	*ρ (lbm/ft^3)*	*$(Kc_p\rho)^{1/2}$*
70	0.0150	0.243	0.0753	0.0165
500	0.0246	0.245	0.0416	0.0159
1000	0.0359	0.263	0.0274	0.0161

Because K (in the denominator) is very small, and because the term $(Kc_p\rho)^{1/2}$ remains constant over a wide range of temperatures, this type of instrument can be used to measure the mass flow rate of gases.

The hot-wire-type sensors are also used as air velocity sensors. These devices are called *anemometers*. A major limitation of the hot-wire-type mass flowmeters is similar to the limitations of all pitot-type flowmeters, namely that they do not detect the mass flow across the full cross section of the pipe—only at the sensor. Therefore, if the sensor is installed in a nonrepresentative location across the velocity profile, the resulting reading will be in error. The more recent developments in the design of this type of flowmeter include a more rugged mass flow sensor element, an integral (usually 10-diameter-long) pipe section to ensure smooth velocity profiles, and a conditioning nozzle that eliminates boundary layer effects and concentrates the flow onto the sensor (Figure 2.13g). These sensors can also be provided with

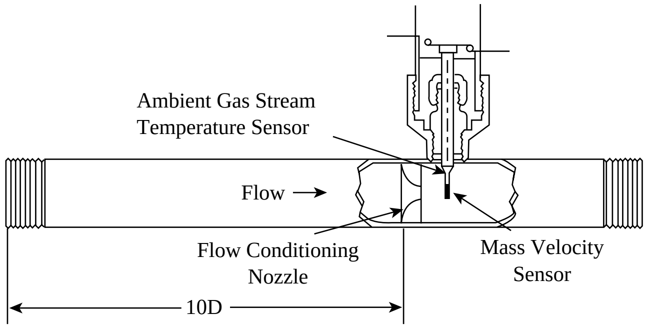

FIG. 2.13g
Complete mass flow sensor assembly. (Courtesy Kurz Instruments Inc.)

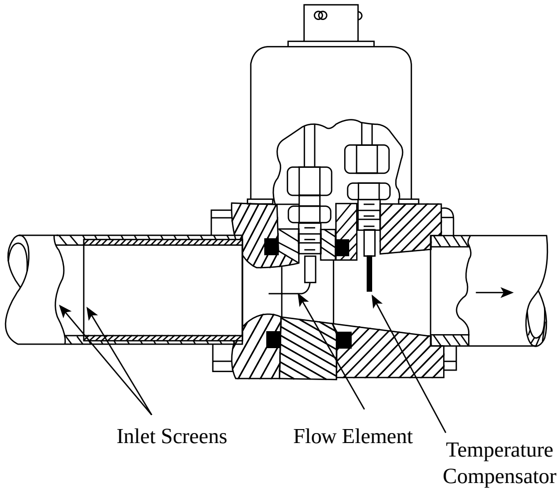

FIG. 2.13h
Venturi-type thermal mass flowmeter. (Courtesy TSI Inc.)

controllers and control valves to result in a complete flow control loop.

Other designs place the heated mass flow sensor at the throat of a venturi and add a screen upstream to make the flow profile more uniform (Figure 2.13h). These units are offered for both liquid and gas service. Other designs are of the insertion-probe type. Their flow ranges are a function only of the size of the pipe into which they are inserted, whereas their performance is similarly influenced by the correctness of the insertion depth (as are all pitot tubes).

CALIBRATING THERMAL MASS FLOW DEVICES

(See also Chapter 1, Section 1.4, "System Accuracy," and Section 1.8, "Instrument Calibration.")

Gas Flowmeter Calibrations

Gas calibrations are generally performed at standard conditions (STP) of $P = 101325$ Pa and $T = 20°$. Calibrating small gas flow rates of up to 20 slpm is most accurately accomplished using "mercury ring" piston prover calibrators. A calibrator of this type consists of a cylindrical glass tube, mounted vertically, and a plastic piston installed inside. The piston is free to move in the glass tube. There is a groove around the piston's circumference filled with mercury, sealing it in a virtually friction-free manner against the inside diameter of the glass tube.

Gas enters under the piston and is trapped by a valve, buoying the piston upward inside the tube. The edge of the piston registers a referenced zero and continues to travel up in the glass tube until it reaches the appropriate flow capacity. Timing the travel of the piston determines unit flow rates at each calibration point. The calibrator is corrected for temperature and pressure and compensated for the weight of the piston and friction in the line.

This method is demonstrated to offer a maximum uncertainty of ±0.25% of reading. Typically, National Institute of Standards and Technology (NIST) and equivalent international traceability standards require an uncertainty percentage ratio of 4 to 1; thus, an NIST traceable uncertainty of no better than ±1% may be claimed by a calibrating laboratory using such methods.

Calibrating larger flow rates of up to 5000 slpm (175 scfm) is facilitated by bell provers. The bell prover consists of a concentric inner and an outer cylindrical tank. The annular area between the concentric cylinders is filled with water or oil. An inverted bell is placed over the inner tank with its wall floating in the oil or water in the annular area between the two cylinders. During calibration at each reference point of the meter, gases are trapped under the bell. The rectilinear travel of the bell corresponds to sample volumes in timed intervals and is automatically recorded. Movement of the bell is usually detected by photoencoders or other sensing devices. Bells are precision balanced to maintain constant pressure and compensate for buoyancy throughout the collection stroke, and move freely, as gases are collected.

When more relaxed requirements of accuracy are acceptable, "transfer standards" will suffice. This means that a device, for example a mass flowmeter calibrated by a primary method, is used to calibrate flow instrumentation. As an example, a transfer standard calibrated for an uncertainty of ±1% may permit ±4% of traceable results.

Recalibration periods of mass flowmeters are based on industry standards. For example, in pharmaceutical processes, a period of six months is common. In industrial applications, depending on the industry, periods of six months to one year are recommended. When periodic recalibrations are performed, "as found" readings are recorded as well.

Liquid Calibrations

More recently, manufacturers developed bypass-type mass flowmeters and controllers for liquid microflow capacities. This requires calibration of microliter order of magnitude capacities of water. Ultra low liquid flow calibration is done by timed collection and weighing of water directly in a receptacle of a suitable pharmaceutical balance. Care should be taken to eliminate errors due to evaporation during sampling.

Small water flowmeters of up to 20 ml/min capacities are calibrated volumetrically. At steady state, flow water is delivered into an NIST-traceable, certified volumetric buret while timing appropriate volumetric segments. For meters with flow rates of a few liters per minute, an NIST-traceable, certified graduated cylinder is used.

Larger flow rates of liquids are calibrated at a steady-state flow of water by employing metering pumps into weighing tanks. Flows of up to 38 cmpm (10,000 gal/min) are accomplished through pipes with diameters of up to 16 in.

Collections of samples are timed, computing average flow through the meter, typically using ten or more points between 10 and 100% of capacity.

Proportioning Pump with Automatic and Manual Stroke Control
Flow Sheet Symbol

Types	A. Peristaltic (including progressive cavity) B. Piston or plunger types (provided with packing glands) C. Diaphragm or glandless types (mechanical, hydraulic, double-diaphragm, and pulsator designs)
Capacity	A. 0.0005 ccm to 20 GPM (90 l/min) B. 0.001 GPH to 280 GPM (0.005 lph to 1250 l/min) C. Mechanical diaphragms, from 0.01 to 50 GPH (0.05 to 3.7 l/min); mechanical bellows, from 0.01 to 250 GPH (0.05 to 18 l/min); others, from 0.01 to 800 GPH (0.05 lph to 60 l/min); pulsator pumps, from 30 to 1800 GPH (2 to 130 l/min); air-operated double diaphragm pumps, 0.0 to 275 GPM (1041 l/min)
Error (Inaccuracy)	A. ±0.1 to ±0.5% of full scale over a 10:1 range B. and C. ±0.25 to ±1% of full scale over a 10:1 range; can be as good as ±0.1% full scale at 100% stroke and tends to drop as stroke is reduced
Maximum Discharge Pressure:	A. 50 PSIG (3.5 bars) B. 50,000 PSIG (3450 bars) C. Mechanical bellows, up to 75 PSIG (5 bars); mechanical diaphragm, up to 300 PSIG (21.1 bars); hydraulic Teflon® diaphragm, 1500 PSIG (104 bars); pulsator pumps, up to 5000 PSIG (345 bars); hydraulic metallic diaphragms, up to 40,000 PSIG (2750 bars)
Maximum Operating Temperature	A. –70 to 600°F (–57 to 315°C) B. Jacketed designs, up to about 500°F (260°C) C. Units containing hydraulic fluids can handle from –95 to 360°F (–71 to 182°C), Teflon® and Viton® diaphragms are limited to 300°F (150°C), and neoprene and Buna N are limited to 200°F (92°C); the metal bellow and the remote head designs can operate from cryogenic to 1600°F (870°C)
Materials of Construction	A. Neoprene, Tygon, Viton®, silicone B. Cast iron, steel, stainless steel, Hastelloy® C, Alloy 20®, Carpenter 20, Monel®, nickel, titanium, glass, ceramics, PTFE, Teflon, PVC, Kel-F®, PVDF, PFA, Penton, polyethylene, and other plastics C. Polyethylene, Teflon, PVC, Kel-F®, Penton, steel, stainless steel, Carpenter 20, Monel®, Hastelloy® B & C
Cost	A. \$200 to \$800 B. \$1000 to \$6000 C. \$1000 to \$12,000, depending on type and service configuration

A metering pump is a positive-displacement pump providing a predictable and accurate rate of process fluid flow. Normally, the application design, specification, and use of pumps are the concern of mechanical engineers and machinery designers. Metering pumps, however, are sometimes used to actually measure or control flow rate, and in many cases they are the final control elements in an instrumentation loop. Therefore, the instrument engineer should be familiar with their operation and application.

Some controlled-volume pumps (as metering pumps are sometimes called) are designed to meet the needs of just one particular application, such as adding sodium hypochlorite to a swimming pool or providing chemical reagents to a chromatograph. Thus, each industry has its own particular types of metering pumps that could be classified by their applications. A better way of classifying metering pumps, however, is to distinguish them by their design. Any positive-displacement pump, due to its volumetric mode of fluid transfer, can be used as a metering pump. In practice, however, only those positive-displacement pumps that have no, or only very little, internal and/or external leakage can provide the precision and accuracy that are normally required of a metering pump.

The three basic metering pump designs are the peristaltic, piston, and diaphragm types. They are all positive-displacement devices used for the precise charging of corrosive, radioactive, toxic, flammable, or otherwise difficult fluids such as slurries, melts, liquefied gases, or liquid metals. They are used either in a controlled-volume metering mode or in a mixing-proportioning mode. The piston or plunger designs are provided with a packing gland, while the diaphragm or bellows designs are also referred to as glandless. The pulsator pump is a special variety of the glandless design. The actuators can adjust either the speed or the stroke, and the controls used for stroke adjustment include micrometers, positioners, and reversing motors with slide-wire feedback.

PERISTALTIC PUMPS

Peristaltic action is similar to the operation of the intestines and other hollow, muscular structures in which the successive contraction of the muscular fibers of their walls forces their content forward. In the peristaltic pump, the fluid is moved forward by progressively squeezing a flexible container from the entrance to discharge. This container is usually a tube that can be made out of any material that possesses sufficient resiliency to allow it to recover to its original shape immediately after compression. A variety of methods are employed for squeezing the tube (or container) to produce flow, including

1. Rollers that are connected to a rotating body squeeze the tubing against a circular housing (see Figure 2.14a)
2. Rollers that are driven by a chain drive squeeze tubes against a flat plate

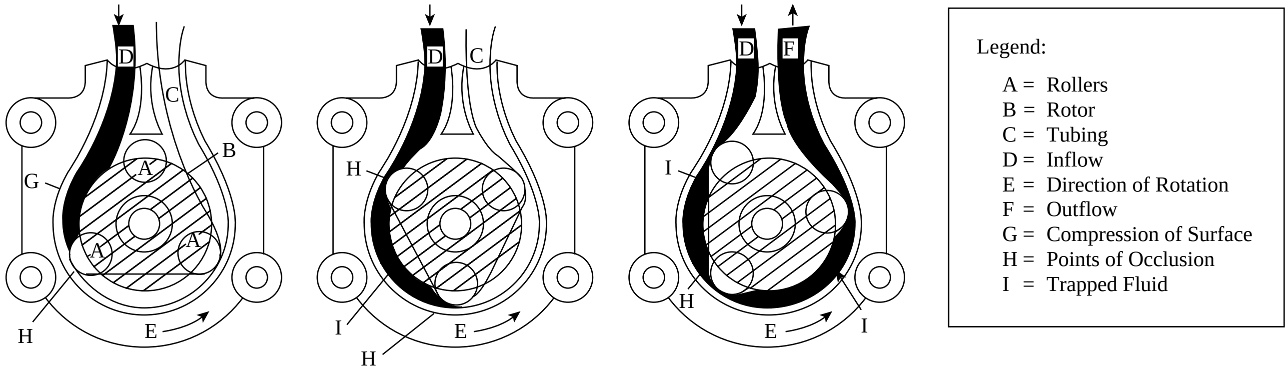

FIG. 2.14a
The three-roller design prevents backflow and eliminates the need for check valves. (Masterflex® is a registered trademark of Cole-Parmer Instrument Co.)

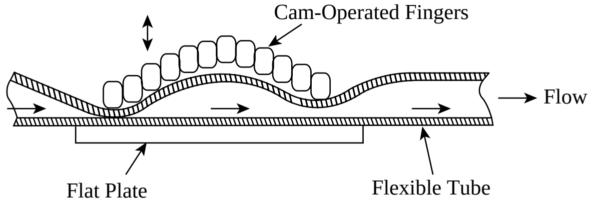

FIG. 2.14b
Peristaltic pump with cam-operated fingers.

3. Cam-operated fingers successively squeeze the tubing against a flat surface (see Figure 2.14b)
4. A rotating wobbling cam squeezes a tube against a flat plate

The plastic hose or tubing provides an external, tight, sanitary, and easily cleanable and replaceable container. It must be remembered that the tube is the only component of the pump that comes into contact with the fluid. A plastic material usually can be found that is suitable for even the most corrosive and abrasive application. However, the use of plastic tubing also places severe limits on the capability of the peristaltic pump. These pumps can furnish only low flow rates and low-pressure heads.

The peristaltic pump has found particularly large acceptance in medical and biochemical fields where high accuracy, low flow rates, inherent enclosure of the fluid, and sterilization are prime requirements. The flow rate of the peristaltic pump can be adjusted by changing the speed of the squeezing mechanism. Commonly, 50/60-Hz, 100/110-V electrical motors provide power to these pumps. Air-operated and electrical explosion-proof motors are also available.

Another peristaltic pump employs a plastic liner separating a rotating cam from the pumped fluid. This allows the use of a cam-type positive-displacement pump for metering service but prevents any external leakage. Higher pressures and flow rates can be obtained from this pump, but the advantages of the flexible tubing are lost.

Recently, some manufacturers of a specialized type of peristaltic pump, the progressive cavity pump, have been providing versions that are optimized for metering pump use. These pumps are useful in pumping highly viscous fluids such as adhesives, sludge, and slurries such as chocolate, tomato paste, and similar highly viscous liquids.

PISTON PUMPS

The piston pump employs a piston or plunger that moves with a reciprocating motion within a chamber. A fixed volume of liquid is delivered with each stroke. The flow rate is a function of piston diameter, chamber length, and piston speed. Check valves located at the pump inlets and outlets are required to prevent backflow. A schematic of a typical piston pump is shown in Figure 2.14c. The piston produces pressure in only one direction; therefore, the flow produced by plunger pumps (as piston pumps are sometimes called) is pulsating. If the

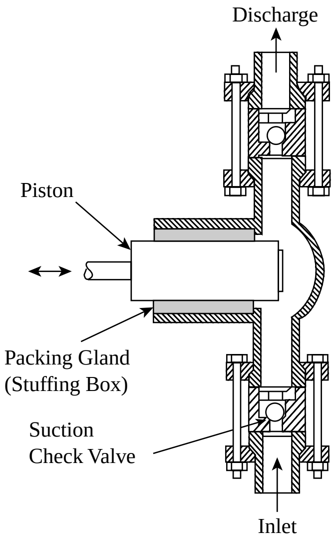

FIG. 2.14c
Piston pump schematic.

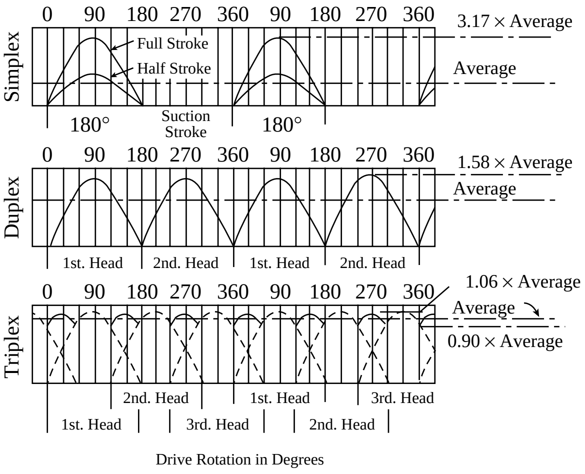

FIG. 2.14d
Multiple pistons tend to dampen pressure fluctuations.

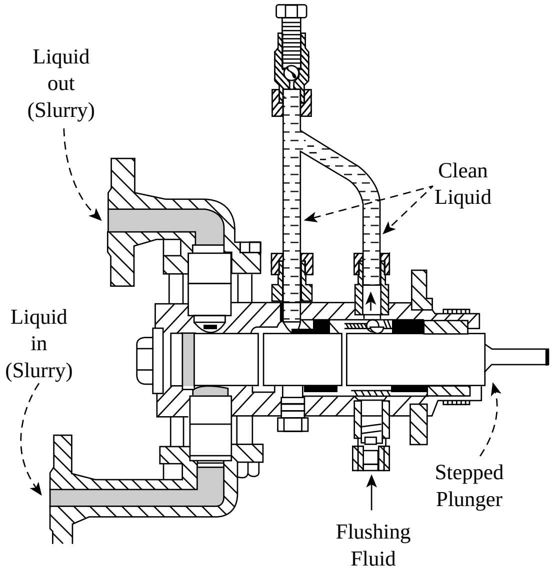

FIG. 2.14e
Flushing fluid keeps the packing free of solids on slurry services.[1]

pulsating flow characteristics are undesirable, a damping reservoir (accumulator) should be installed in the discharge line of the pump. Another method available to reduce pulsation is to use a pump that employs more than one chamber/piston combination in parallel. Pumps having as many as four chambers (cylinders) are commercially available. These multiple-piston pumps are called *duplex pumps* if they have two pistons, *triplex* if they have three, and so on (see Figure 2.14d).

The construction materials of a piston pump's components must be selected with care, because its housing, piston, piston packing, valve body, and valve seat all come into intimate contact with the process fluid.

The displacement of the pump is the area of the plunger multiplied by the stroke length. This is not the volume that is actually delivered, because some of the fluid slips back into the cylinder while the check valves are closing. Worn valves and fluid compressibility at high discharge pressures further reduce the volumetric efficiency (usually around 95%) of plunger pumps. Check valve leakage can be reduced by installing two check valves in series at both the pump suction and discharge. Volumetric efficiency should not be taken as metering accuracy, because leakage is repeatable and can be zeroed out by calibration. Therefore, in properly maintained and calibrated metering pumps, the measurement error will be much less than the leakage.

The plunger packing must be carefully selected not only to minimize leakage and wear but also for lubrication, cooling, sterilization, and flushing. This pump design can deliver both high flow rates and high discharge pressures. The smaller the plunger diameter, the greater the possible discharge pressure.

When metering abrasive slurries such as kaolin, diatomaceous earth, and metal-based catalysts, it is necessary to introduce a clean flushing fluid. This flushing fluid flows from the piston–cylinder cavity into the process fluid (Figure 2.14e), thereby keeping the piston and its packing clean during both the suction and discharge strokes. This flushing action prevents the slurry from reaching the plunger packing. The metering action can still take place, because the mix proportion between the slurry and the flushing liquid is kept constant.

DIAPHRAGM PUMPS

The diaphragm or membrane pump uses a flexible member to transmit a pulsating force to the pumped fluid without allowing external leakage such as what might occur past the piston pump's packing. Like the piston pump, inlet and exit check valves are used to direct the flow. The diaphragm may be soft, made of Teflon®, neoprene, or a similar material, or it can be hard and made of metal. The diaphragm may be moved directly by a piston as in a reciprocating piston pump (see Figure 2.14f). This type, which may also employ a

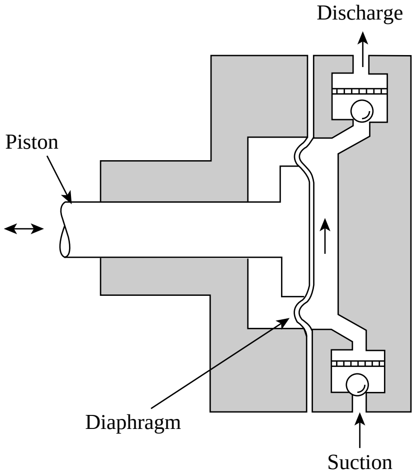

FIG. 2.14f
Direct-driven diaphragm pump.

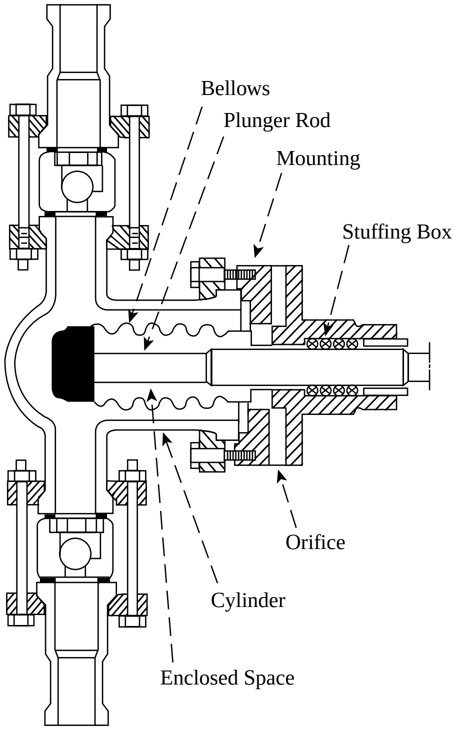

FIG. 2.14g
For extreme temperature applications the bellows-type, direct, mechanically actuated metering pump is a good choice.[1]

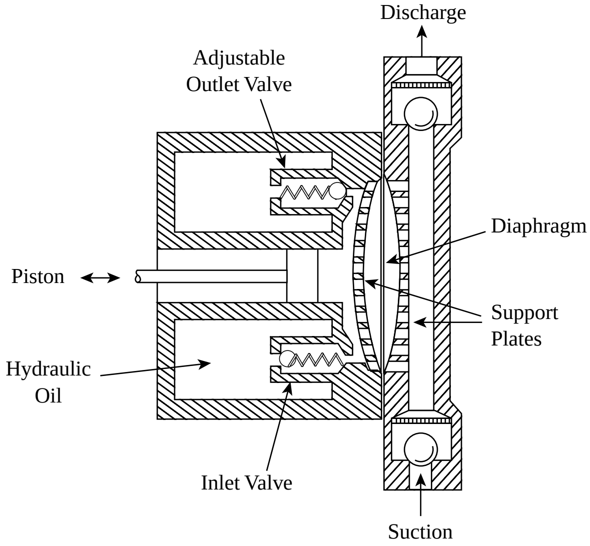

FIG. 2.14h
Oil-driven diaphragm pump.

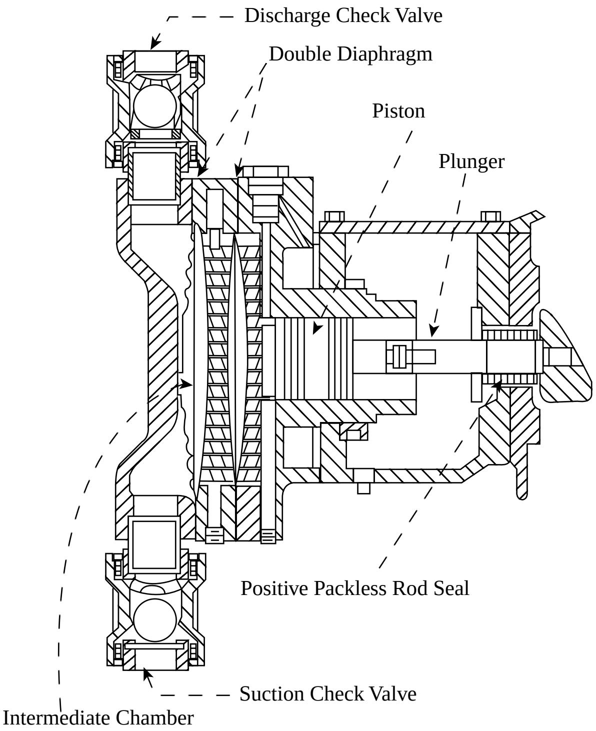

FIG. 2.14i
Double diaphragm design provides improved seal.

bellows instead of a diaphragm (Figure 2.14g), generally has a pressure limitation of about 125 PSIG (8.5 bars).

The glandless metering pumps can handle toxic, corrosive, radioactive, high-purity, odorous, volatile, and abrasive materials. The direct-actuated diaphragm designs are the least expensive and are suited for low-pressure, low-flow-rate services. The mechanically actuated bellows design can deliver more flow and is well suited for vacuum or extreme temperature services. For higher temperatures and corrosion resistance, metal bellows are used.

Hydraulic-Actuated Metering Pumps

In these designs, the forces delivered by hydraulic oil that is pumped by a reciprocating piston pump replace the direct mechanical forces on the diaphragm. The other side of the diaphragm is exposed to the process fluid (Figure 2.14h); therefore, the diaphragm is inherently balanced, being exposed to equal pressures on both of its sides. The support plates serve to keep the diaphragm deflections well within the endurance limits of the diaphragm material. This guarantees long useful life.

Metallic diaphragms can be damaged by dirt particles, and plastic diaphragms cannot handle high pressures and temperatures. Where a reliable seal is essential (for example, for pharmaceutical or liquid chlorine services), the double-diaphragm design is recommended (Figure 2.14i). In these designs, the diaphragm rupture can be visually observed if a sight glass is installed in the intermediate chamber, which is filled with a liquid of a preselected pH reference color. If the process-side diaphragm is damaged, the leakage of process fluid into the intermediate chamber changes the pH and thereby changes the color of the intermediate fluid. The materials exposed to the pumped fluid—diaphragm, housing, and valves—must be carefully selected for the application.

As with the piston pump, the flow is pulsating but may be smoothed by multiple diaphragms and/or by the use of a

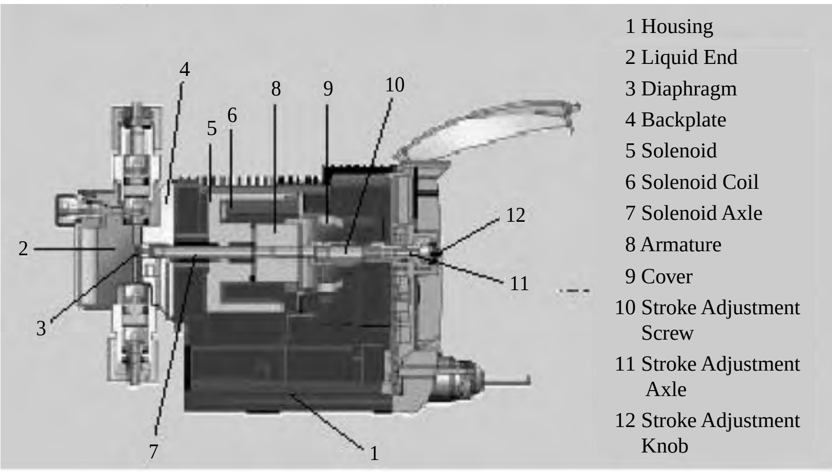

FIG. 2.14j
Solenoid-driven diaphragm pump is one of the most commonly used types for most metering pump applications. (Courtesy of Prominent Fluid Controls Co.)

damping reservoir. Check valve leakage provides the same problem for the diaphragm pump as it did for the piston pump.

The slave fluid's pulsation rate is varied by adjusting the piston pump's stroke length, altering the eccentricity of the crank or changing the duration of the stroke by diverting a portion of each stroke to idle motion by mechanical or hydraulic means. Because slave hydraulic fluid leakage does not affect the metered rate of flow, many variations of the standard reciprocating piston pump can be used.

When it is desired to keep the metering pump away from hot processes, a remote head design is frequently used in which the check valve assembly remains in the process pipe while the diaphragm and pump are located at some distance away. The connecting pipe is filled with a column of the process fluid, and a temperature gradient through this column of liquid isolates the diaphragm and its hydraulic fluid from the hot process.

Solenoid-Driven Metering Pumps

Since the early 1970s, by far the most common forms of metering pump have been the peristaltic and the solenoid-driven-diaphragm metering pumps. The diaphragm metering pump described previously is fitted with a shaft that extends behind the pump head to a mechanical stop, which is adjustable to control the stroke length (Figure 2.14j). This shaft passes through the coil of a solenoid. The solenoid is actuated based on either a timer or an external input, and each actuation of the solenoid produces one pulse of the diaphragm. These pumps are widely used in industrial water treatment, chemical feed systems, and municipal and utility water treatment. They can be either manual, with the stroke and stroke length controlled at the pump, or they can be proportioning, based on an input signal from a controller. They have the same mechanical constraints as hydraulically driven diaphragm metering pumps.

Pulsator-Head Pumps

These pumps can be valuable when very difficult fluids are being metered, such as boiling sulfuric acid, pyrophoric fluids, fluorinated hydrocarbons, and slurries suspended in Freon®. In this design, hydraulic oil is pumped through the hollow cavity of the pulsator support into two hermetically sealed diaphragms called *pulsators*. As the pulsator elements expand, they displace the process fluid from the pressure chamber. When the hydraulic oil is exhausted from the pulsator, fresh process fluid is drawn into the pressure chamber through the suction port (Figure 2.14k). Although the illustration shows only one pulsator, two normally are used to smooth out the flow. The alternate expansion and contraction of the pulsators causes the pumping action. The inner pulsator is usually Buna N, and the outer one is selected to match the fluid being pumped.

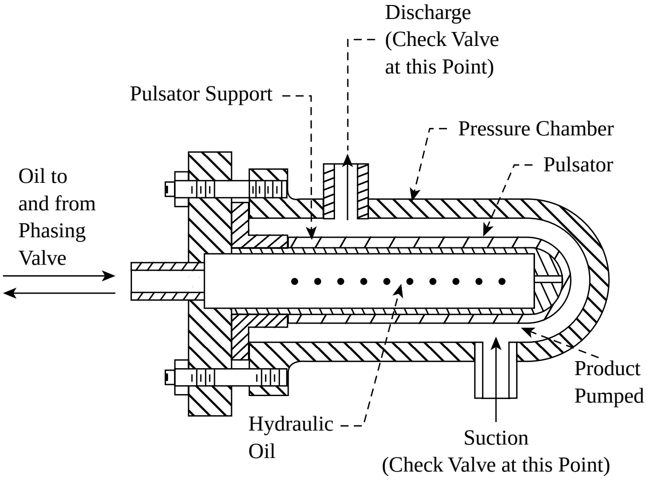

FIG. 2.14k
The pulsator-type metering pump.[1]

The pulsator pump produces a substantially pulsation-free, infinitely adjustable flow rate, which is set by the variable-volume oil pump. In hazardous areas, the hydraulic fluid can be pumped from a remote location, thereby removing all electrical components from the process area. The pump can be easily sterilized, because only the outside of the pulsator is exposed to contamination. Consequently, the pump can be cleaned by removing just the pressure chamber.

PROPORTIONING PUMPS

Proportioning pumps are used when several process streams need to be mixed in some preset proportion. These can be continuous mixing processes or batch processes in which the ingredients are simultaneously fed. In digital batch blending, it is the cycle time and the pump size that set the number of pump strokes or pulses per batch. For example, if the cycle time is 30 min and the amount to be charged is 60 gal, a pump capacity of 2 GPM is required. If this pump operates at a speed of 60 strokes per minute, then 1800 strokes or pulses would represent the 60 gal of batch charge. The pump pulse transmitter transmits the pulses and, when the 1800 count is reached, the batch controller stops the pump.

The proportioning of several process streams can be achieved in many different ways, depending on the hardware used. One possible solution is to operate several metering pumps in parallel. When using piston or diaphragm pumps, it is also possible to place multiple heads on the same drives, which will also achieve the same proportioning goal. On idle motion pumps, the proportioning adjustments can be achieved by varying the stroke duration.

The peristaltic pumps are natural proportioning devices. One can lay as many as 23 tubes of various sizes on a flat plate, and the finger or chain-driven rollers of the peristaltic pump will squeeze all tubes simultaneously and at the same speed. In this configuration, the tube sizes set the ratios between flows, whereas the total pumping rate for the mix is set by the motor speed.

All proportioning and digital batch-blending controls use modern, computer-compatible, microprocessor-based controls.

CONTROLLERS

Pulse-Input Type

Most modern metering pumps have on-board controllers that accept pulses generated by external controllers or sensors. These inputs are usually either a two-wire switch closure (such as a reed switch or SPST relay) or a powered, three-wire switch closure for a transistor switch input such as a Hall effect sensor or a Wiegand sensor. Many pumps can take the pulse input directly from a flow sensor, such as a paddle wheel or a pulse-contact head water meter, and scale it internally and use the raw sensor signal to proportionally control the stroke rate of the pump. A manual stroke length adjustment in the most commonly used solenoid-driven diaphragm metering pumps still performs dosage control in most cases.

Analog-Input Type

Some modern metering pumps are equipped with on-board signal conditioners to accept an incoming analog signal (4- to 20-mA DC, 1 to 5 VDC, and others) and convert that signal to an internal scaled pulse to operate the metering pump.

Start/Stop Type

In some industries, particularly industrial water treatment and boiler control, manual start/stop metering pumps are regularly used. External controllers are usually supplied that turn AC power to these pumps on and off for varying lengths of time, depending on an external signal from either a flow sensor or a pH, conductivity, or oxidation-reduction-potential (ORP) controller. The pump then becomes a proportioning feeder.

CONCLUSION

Each metering pump discussed has its particular application. Piston pumps are used to deliver high pressures. They require check valves and produce pulsating flows that can be damped. Diaphragm pumps are utilized in the medium-pressure range. The membrane serves as a moving partition between the mechanical or hydraulic drive and the process fluid. Rotary and pulsator pumps furnish pulsation-free high flow rates and are suitable for high-viscosity service. The accuracy of rotary pumps is a function of the clearances between the rubbing surfaces. This generally results in low precision, so rotary pumps are not considered to be metering devices. Peristaltic pumps are very accurate; they can handle extremely small flows, are self-priming, and require no seals or check valves.

If one is responsible for the operation and maintenance of a metering pump, one must be aware that a pump differs in many aspects from other flowmeters. For example, the pump motor must be lubricated periodically, and the pump must not be operated without liquid in it. The inlet piping must be designed to prevent cavitation. Running a pump dry or cavitating it will cause damage.

A metering pump should be calibrated, not only before it is first used but also periodically during its operation. The calibration should duplicate fluid properties, suction and discharge pressures, and inlet and outlet piping configuration.

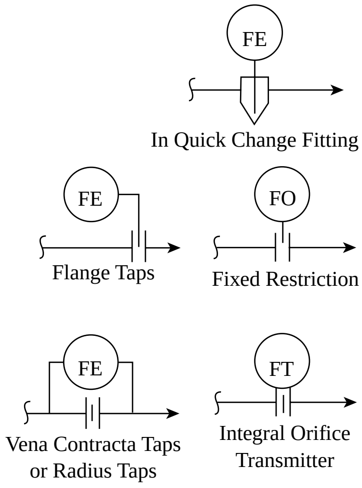
J. B. ARANT (1982, 2003)



Flow Sheet Symbol

Design Pressure	For plates, limited by readout device only; integral orifice transmitter to 1500 PSIG (10.3 MPa)
Design Temperature	This is a function of associated readout system, only when the differential-pressure unit must operate at the elevated temperature. For integral orifice transmitter, the standard range is –20 to 250°F (–29 to 121°C).
Sizes	Maximum size is pipe size
Fluids	Liquids, vapors, and gases
Flow Range	From a few cubic centimeters per minute using integral orifice transmitters to any maximum flow, limited only by pipe size
Materials of Construction	There is no limitation on plate materials. Integral orifice transmitter wetted parts can be obtained in steel, stainless steel, Monel®, nickel, and Hastelloy®.
Inaccuracy	The orifice plate; if the bore diameter is correctly calculated, prepared, and installed, the orifice can be accurate to ±0.25 to ±0.5% of actual flow. When a properly calibrated conventional d/p cell is used to detect the orifice differential, it will add ±0.1 to ±0.3% of full-scale error. The error contribution of properly calibrated “smart” d/p cells is only 0.1% of actual span.
Smart d/p Cells	Inaccuracy of ±0.1%, rangeability of 40:1, built-in PID algorithm
Rangeability	If one defines rangeability as the flow range within which the combined flow measurement error does not exceed ±1% of actual flow, then the rangeability of conventional orifice installations is about 3:1 maximum. When using intelligent transmitters with automatic switching capability between the “high” and the “low” span, the rangeability can approach 10:1.
Cost	A plate only is \$100 to \$300, depending on size and materials. For steel orifice flanges from 2 to 12 in. (50 to 300 mm), the cost ranges from \$250 to \$1200. For flanged meter runs in the same size range, the cost ranges from \$500 to \$3500. The cost of electronic or pneumatic integral orifice transmitters is between \$1500 and \$2500. The cost of d/p transmitters ranges from \$1000 to \$2500, depending on type and “intelligence.”

HEAD-TYPE FLOWMETERS

Head-type flowmeters compose a class of devices for fluid flow measurement including orifice plates, venturi tubes, weirs, flumes, and many others. They change the velocity or direction of the flow, creating a measurable differential pressure or “pressure head” in the fluid.

Head metering is one of the most ancient of flow detection techniques. There is evidence that the Egyptians used weirs for measurement of irrigation water in the days of the Pharaohs and that the Romans used orifices to meter water to households in Caesar’s time. In the 18th century, Bernoulli established basic relationship between pressure head and velocity head, and Venturi published on the flowtube bearing his name. However, it was not until 1887 that Clemens Herschel developed the commercial venturi tube. Work on the conventional orifice plate for gas flow measurement was commenced by Weymouth in the United States in 1903. Recent developments include improved primary elements, refinement of data, more accurate and versatile test and calibrating equipment, better differential-pressure sensors, and many others.

Theory of Head Meters

Head-type flow measurement derives from Bernoulli’s theorem, which states that, in a flowing stream, the sum of the pressure head, the velocity head, and the elevation head at one point is equal to their sum at another point in the direction of flow plus the loss due to friction between the two points. Velocity head is defined as the vertical distance through which a liquid would fall to attain a given velocity. Pressure head is the vertical distance that a column of the flowing liquid would rise in an open-ended tube as a result of the static pressure.

This principle is applied to flow measurement by altering the velocity of the flowing stream in a predetermined manner, usually by a change in the cross-sectional area of the stream. Typically, the velocity at the throat of an orifice is increased relative to the velocity in the pipe. There is a corresponding increase in velocity head. Neglecting friction and change of elevation head, there is an equal decrease in pressure head (Figure 2.15a). This difference between the pressure in the pipe just upstream of the restriction and the pressure at the throat is measured. Velocity is determined from the ratio of

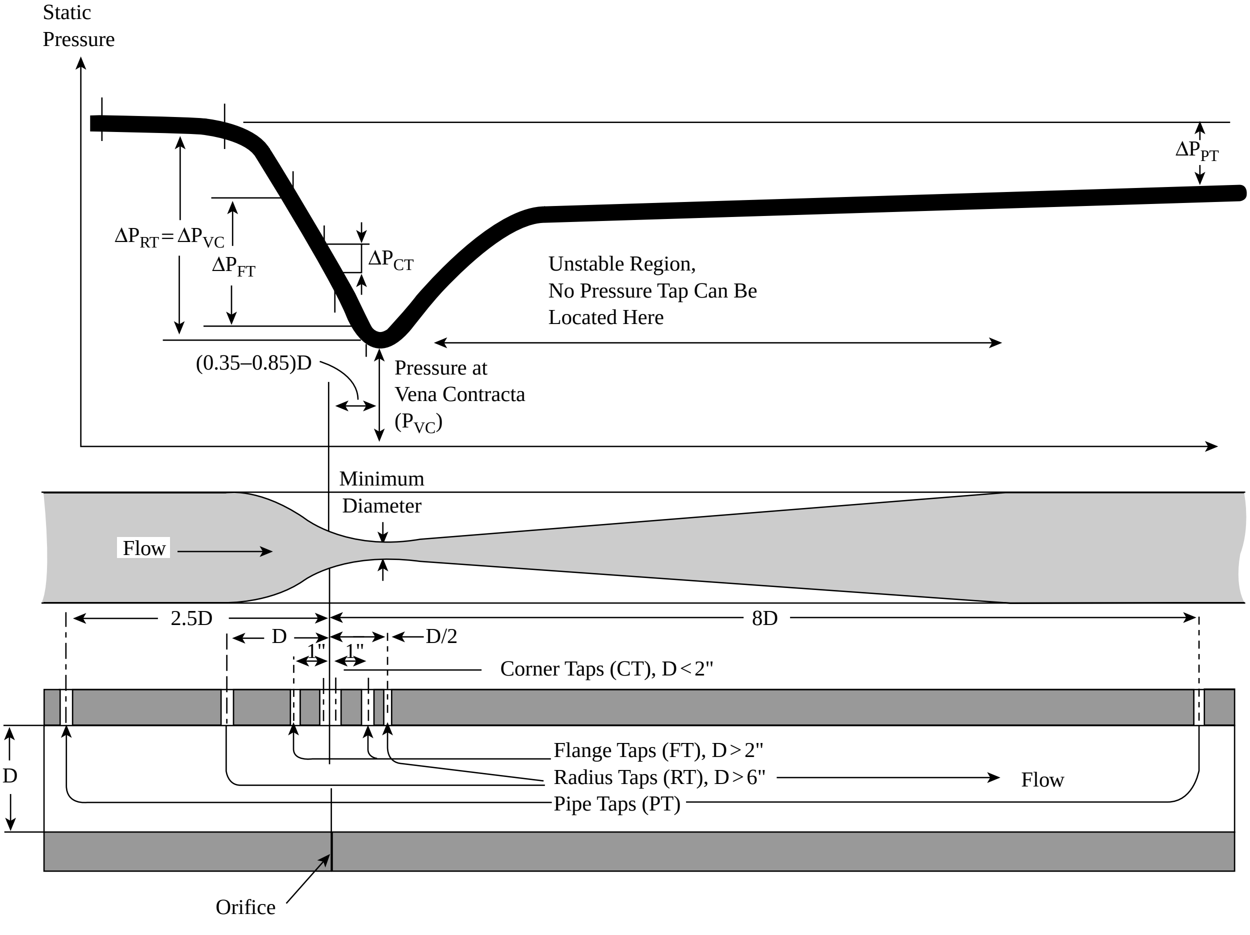

FIG. 2.15a
Pressure profile through an orifice plate and the different methods of detecting the pressure drop.

the cross-sectional areas of pipe and flow nozzle, and the difference of velocity heads given by differential-pressure measurements. Flow rate derives from velocity and area. The basic equations are as follows:

$$V = k\sqrt{\frac{h}{\rho}} \qquad \textbf{2.15(1)}$$

$$Q = kA\sqrt{\frac{h}{\rho}} \qquad \textbf{2.15(2)}$$

$$W = kA\sqrt{h\rho} \qquad \textbf{2.15(3)}$$

where

V = velocity
Q = volume flow rate
W = mass flow rate
A = cross-sectional area of the pipe
h = differential pressure between points of measurement
ρ = the density of the flowing fluid
k = a constant that includes ratio of cross-sectional area of pipe to cross-sectional area of nozzle or other restriction, units of measurement, correction factors, and so on, depending on the specific type of head meter

For a more complete derivation of the basic flow equations, based on considerations of energy balance and hydrodynamic properties, consult References 1, 2, and 3.

Head Meter Characteristics

Two fundamental characteristics of head-type flow measurements are apparent from the basic equations. First is the square root relationship between flow rate and differential pressure. Second, the density of the flowing fluid must be taken into account both for volume and for mass flow measurements.

The Square Root Relationship This relationship has two important consequences. Both are primarily concerned with readout. The primary sensor (orifice, venturi tube, or other device) develops a head or differential pressure. A simple linear readout of this differential pressure expands the high end of the scale and compresses the low end in terms of flow. Fifty percent of full flow rate produces 25% of full differential pressure. At this point, a flow change of 1% of full flow results in a differential pressure change of 1% of full differential. At 10% flow, the total differential pressure is only 1%, and a change of 1% of full scale flow (10% relative change) results in only 0.2% full scale change in differential pressure. Both accuracy and readability suffer. Readability can be improved by a transducer that extracts the square root of the differential pressure to give a signal linear with flow rate. However, errors in the more complex square root transducer tend to decrease overall accuracy.

For a large proportion of industrial processes, which seldom operate below 30% capacity, a device with pointer or pen motion that is linear with differential pressure is generally adequate. Readout directly in flow can be provided by a square root scale. Where maximum accuracy is important, it is generally recommended that the maximum-to-minimum flow ratio shall not exceed 3:1, or at the most 3.5:1, for any single head-type flowmeter. The high repeatability of modern differential-pressure transducers permits a considerably wider range for flow control where constancy and repeatability of low rate are the primary concern. However, where flow variations approach 10:1, the use of two primary flow units of different capacities, two differential-pressure sensors with different ranges, or both is generally recommended. It should be emphasized that the primary head meter devices produce a differential pressure that corresponds accurately to flow over a wide range. Difficulty arises in the accurate measurement of the corresponding extremely wide range of differential pressure; for example, a 20:1 flow variation results in a 400:1 variation in differential pressure.

The second problem with the square root relationship is that some computations require linear input signals. This is the case when flow rates are integrated or when two or more flow rates are added or subtracted. This is not necessarily true for multiplication and division; specifically, flow ratio measurement and control do not require linear input signals. A given flow ratio will develop a corresponding differential pressure ratio over the full range of the measured flows.

Density of the Flowing Fluid Fluid density is involved in the determination of either mass flow rate or volume flow rate. In other words, head-type meters *do not* read out directly in either mass or volume flow (weirs and flumes are an exception, as discussed in Section 2.31). The fact that density appears as a square root gives head-type metering an actual advantage, particularly in applications where measurement of mass flow is required. Due to this square root relationship, any error that may exist in the value of the density used to compute mass flow is substantially reduced; a 1% error in the value of the fluid density results in a 0.5% error in calculated mass flow. This is particularly important in gas flow measurement, where the density may vary over a considerable range and where operating density is not easily determined with high accuracy.

β (Beta) Ratio Most head meters depend on a restriction in the flow path to produce a change in velocity. For the usual circular pipe and circular restriction, the β ratio is the ratio between the diameter of the restriction and the inside diameter of the pipe. The ratio between the velocity in the pipe and the velocity at the restriction is equal to the ratio of areas or β^2. For noncircular configurations, β is defined as the square root of the ratio of area of the restriction to area of the pipe or conduit.

Reynolds Number

The basic equations of flow assume that the velocity of flow is uniform across a given cross section. In practice, flow velocity at any cross section approaches zero in the boundary layer adjacent to the pipe wall and varies across the diameter. This flow velocity profile has a significant effect on the relationship between flow velocity and pressure difference developed in a head meter. In 1883, Sir Osborne Reynolds, an English scientist, presented a paper before the Royal Society proposing a single, dimensionless ratio (now known as Reynolds number) as a criterion to describe this phenomenon. This number, Re, is expressed as

$$R_e = \frac{VD\rho}{\mu} \qquad \textbf{2.15(4)}$$

where

V = velocity
D = diameter
ρ = density
μ = absolute viscosity

Reynolds number expresses the ratio of inertial forces to viscous forces. At a very low Reynolds number, viscous forces predominate, and inertial forces have little effect. Pressure difference approaches direct proportionality to average flow velocity and to viscosity. At high Reynolds numbers, inertial forces predominate, and viscous drag effects become negligible.

At low Reynolds numbers, flow is laminar and may be regarded as a group of concentric shells; each shell reacts in a viscous shear manner on adjacent shells, and the velocity profile across a diameter is substantially parabolic. At high Reynolds numbers, flow is turbulent, with eddies forming between the boundary layer and the body of the flowing fluid and propagating through the stream pattern. A very complex, random pattern of velocities develops in all directions. This turbulent mixing action tends to produce a uniform average axial velocity across the stream. The change from the laminar flow pattern to the turbulent flow pattern is gradual, with no distinct transition point. For Reynolds numbers above 10,000, flow is definitely turbulent. The coefficients of discharge of the various head-type flowmeters changes with Reynolds number (Figure 2.15b).

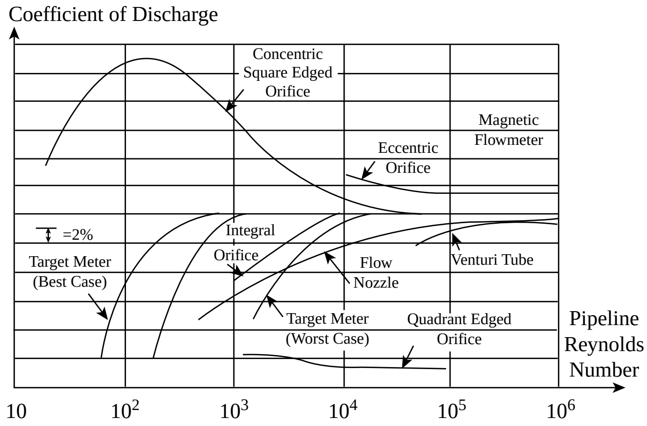

FIG. 2.15b
Discharge coefficients as a function of sensor type and Reynolds number.

The value for k in the basic flow equations includes a Reynolds number factor. References 1 and 2 provide tables and graphs for Reynolds number factor. For head meters, this single factor is sufficient to establish compensation in coefficient for changes in ratio of inertial to frictional forces and for the corresponding changes in flow velocity profile; a gas flow with the same Reynolds number as a liquid flow has the same Reynolds number factor.

Compressible Fluid Flow

Density in the basic equations is assumed to be constant upstream and downstream from the primary device. For gas or vapor flow, the differential pressure developed results in a corresponding change in density between upstream and downstream pressure measurement points. For accurate calculations of gas flow, this is corrected by an *expansion factor* that has been empirically determined. Values are given in References 1 and 2. When practical, the full-scale differential pressure should be less than 0.04 times normal minimum static pressure (differential pressure, stated in inches of water, should be less than static pressure stated in PSIA). Under these conditions, the expansion factor is quite small.

Choice of Differential-Pressure Range

The most common differential-pressure range for orifices, venturi tubes, and flow nozzles is 0 to 100 in. of water (0 to 25 kPa) for full-scale flow. This range is high enough to minimize errors due to liquid density differences in the connecting lines to the differential-pressure sensor or in seal chambers, condensing chambers, and so on, caused by temperature differences. Most differential-pressure-responsive devices develop their maximum accuracy in or near this range, and the maximum pressure loss—3.5 PSI (24 kPa)—is not serious in most applications. (As shown in Figure 2.27f, the pressure loss in an orifice is about 65% when a β ratio of 0.75 is used.) The 100-in. range permits a 2:1 flow rate change in either direction to accommodate changes in operating conditions. Most differential-pressure sensors can be modified to cover the range from 25 to 400 in. of water (6.2 to 99.4 kPa) or more, either by a simple adjustment or by a relatively minor structural change. Applications in which the pressure loss up to 3.5 PSI is expensive or is not available can be handled either by selection of a lower differential-pressure range or by the use of a venturi tube or other primary element with high-pressure recovery. Some high-velocity flows will develop more than 100 in. of differential pressure with the maximum acceptable ratio of primary element effective diameter to pipe diameter. For these applications, a higher differential pressure is indicated. Finally, for low-static-pressure (less than 100 PSIA) gas or vapor, a lower differential pressure is recommended to minimize the expansion factor.

Pulsating Flow and Flow "Noise"

Short-period (1 sec and less) variation in differential pressure developed from a head-type flowmeter primary element arises from two distinct sources. First, reciprocating pumps, compressors, and the like may cause a periodic fluctuation in the rate of flow. Second, the random velocities inherent in turbulent flow cause variations in differential pressure even with a constant flow rate. Both have similar results and are often mistaken for each other. However, their characteristics and the procedures used to cope with them are distinct.

Pulsating Flow The so-called pulsating flow from reciprocating pumps, compressors, and so on may significantly affect the differential pressure developed by a head-type meter. For example, if the amplitude of instantaneous differential-pressure fluctuation is 24% of the average differential pressure, an error of ±1% can be expected under normal operation conditions. For the pulsation amplitudes of 24, 48, and 98% values, the corresponding errors of ±1, ±4, and ±16% can be expected. The Joint ASME-AGA Committee on Pulsation reported that the ratio between errors varies roughly as the square of the ratio between differential-pressure fluctuations.

For liquid flow, there is indication that the average of the square root of the instantaneous differential pressure (essentially average of instantaneous flow signal) results in a lower error than the measurement of the average instantaneous differential pressure. However, for gas flow, extensive investigation has failed to develop any usable relationship between pulsation and deviation from coefficient beyond the estimate of maximum error.[4]

Operation at higher differential pressures is generally advantageous for pulsating flow. The only other valid approach to improve the accuracy of pulsating gas flow measurement is the location of the meter at a point where pulsation is minimized.

Flow "Noise" Turbulent flow generates a complex pattern of random velocities. This results in a corresponding variation or "noise" in the differential pressure developed at the pressure connections to the primary element. The amplitude of the noise may be as much as 10% of the average differential pressure with a constant flow rate. This noise effect is a complex hydrodynamic phenomenon and is not fully understood. It is augmented by flow disturbances from valves, fittings, and so on both upstream and downstream from the flowmeter primary element and, apparently, by characteristics of the primary element itself.

Tests based on average flow rate as accurately determined by static weight/time techniques (compared to accurate measurement of differential pressure including continuous, precise averaging of noise) indicate that the noise, when precisely averaged, introduces negligible (less than 0.1%) measurement error when the average flow is substantially constant (change of average flow rate is not more than 1% per second).[5] It should be noted that average differential pressure, not average flow (average of the square root of differential pressure), is measured, because the noise is developed by the random, not the average, flow.

Errors in the determination of true differential-pressure average will result in corresponding errors in flow measurement. For normal use, one form or another of "damping" in devices responsive to differential pressure is adequate. Where accuracy is a major concern, there must be no elements in the system that will develop a bias rather than a true average when subjected to the complex noise pattern of differential pressure.

Differential-pressure noise can be reduced by the use of two or more pressure-sensing taps connected in parallel for both high and low differential-pressure connections. This provides major noise reduction. Only minor improvement results from additional taps. Piezometer rings formed of multiple connections are frequently used with venturi tubes but seldom with orifices or flow nozzles.

THE ORIFICE METER

The orifice meter is the most common head-type flow measuring device. An orifice plate is inserted in the line, and the differential pressure across it is measured (Figure 2.15a). This section is concerned with the primary device (the orifice plate, its mounting, and the differential-pressure connections). Devices for the measurement of the differential pressure are covered in Chapters 3 and 5.

The orifice in general, and the conventional thin, concentric, sharp-edged orifice plate in particular, have important advantages that include being inexpensive manufacture to very close tolerances and easy to install and replace. Orifice measurement of liquids, gases, and vapors under a wide range of conditions enjoys a high degree of confidence based on a great deal of accurate test work.

The standard orifice plate itself is a circular disk; usually stainless steel, from 0.12 to 0.5 in. (3.175 to 12.70 mm) thick, depending on size and flow velocity, with a hole (orifice) in the middle and a tab projecting out to one side and used as a data plate (Figure 2.15c). The thickness requirement of the orifice plate is a function of line size, flowing temperature, and differential pressure across the plate. Some helpful guidelines are as follows.

By Size
  2 to 12 in. (50 to 304 mm), 0.13 in. (3.175 mm) thick
  14 in. (355 mm) and larger, 0.25 in. (6.35 mm) thick
By Temperature ≥600°F (316°C)
  2 to 8 in. (50 to 203 mm), 0.13 in. (3.175 mm) thick
  10 in. (254 mm) and larger, 0.25 in. (6.35 mm) thick

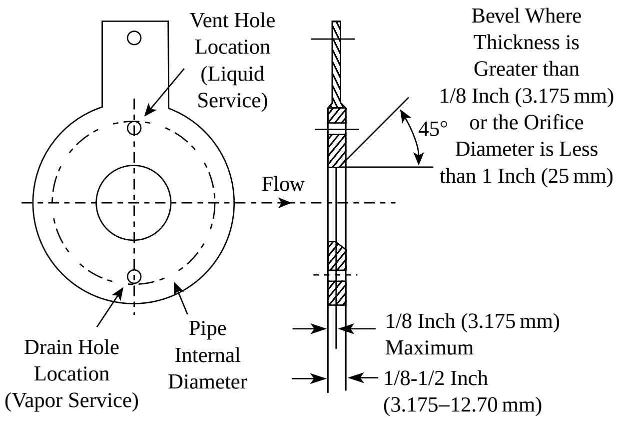

FIG. 2.15c
Concentric orifice plate.

Flow through the Orifice Plate

The orifice plate inserted in the line causes an increase in flow velocity and a corresponding decrease in pressure. The flow pattern shows an effective decrease in cross section beyond the orifice plate, with a maximum velocity and minimum pressure at the vena contracta (Figure 2.15a). This location may be from 0.35 to 0.85 pipe diameters downstream from the orifice plate, depending on β ratio and Reynolds number.

This flow pattern and the sharp leading edge of the orifice plate (Figure 2.15d) that produces it are of major importance. The sharp edge results in an almost pure line contact between the plate and the effective flow, with negligible fluid-to-metal friction drag at this boundary. Any nicks, burrs, or rounding of the sharp edge can result in surprisingly large measurement errors.

When the usual practice of measuring the differential pressure at a location close to the orifice plate is followed, friction effects between fluid and pipe wall upstream and downstream from the orifice are minimized so that pipe roughness has minimum effect. Fluid viscosity, as reflected in Reynolds number, does have a considerable influence, particularly at low Reynolds numbers. Because the formation of the vena contracta is an inertial effect, a decrease in the ratio of inertial to frictional forces (decrease in Reynolds number) and the corresponding change in the flow profile result in less constriction of flow at the vena contracta and an increase of the flow coefficient. In general, the sharp edge orifice plate should not be used at pipe Reynolds numbers under 2000 to 10,000 or more (Table 2.1e). The minimum recommended Reynolds number will vary from 10,000 to 15,000 for 2-in. (50-mm) through 4-in. (102-mm) pipe sizes for β ratios up to 0.5, and from 20,000 to 45,000 for higher β ratios. The Reynolds number requirement will increase with pipe size and β ratio and may range up to 200,000 for pipes 14 in. (355 mm) and larger. Maximum Reynolds numbers may be 10^6 through 4-in. (102-mm) pipe and 10^7 for larger sizes.

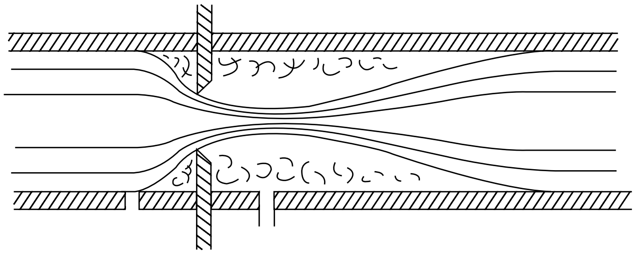

FIG. 2.15d
Flow pattern with orifice plate.

Location of Pressure Taps

For liquid flow measurement, gas or vapor accumulations in the connections between the pipe and the differential-pressure measuring device must be prevented. Pressure taps are generally located in the horizontal plane of the centerline of horizontal pipe runs. The differential-pressure measuring device is either mounted close-coupled to the pressure taps or connected through downward sloping connecting pipe of sufficient diameter to allow gas bubbles to flow up and back into the line. For gas, similar precautions to prevent accumulation of liquid are required. Taps may be installed in the top of the line, with upward sloping connections, or the differential-pressure measuring device may be close-coupled to taps in the side of the line (Figure 2.15e). For steam and similar vapors that are condensable at ambient temperatures, condensing chambers or their equivalent are generally used, usually with down-sloping connections from the side of the pipe to the measuring device. There are five common locations for the differential-pressure taps: flange taps, vena contracta taps, radius taps, full-flow or pipe taps, and corner taps.

In the United States, flange taps (Figures 2.15e and 2.15f) are predominantly used for pipe sizes 2 in. (50 mm) and larger. The manufacturer of the orifice flange set drills the taps so

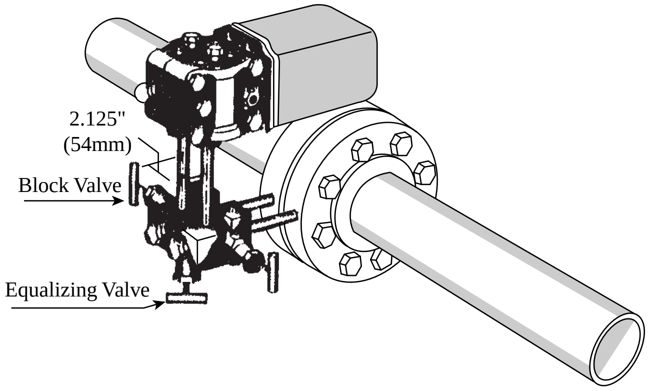

FIG. 2.15e
Measurement of gas flow with differential pressure transmitter and three-valve manifold.[3]

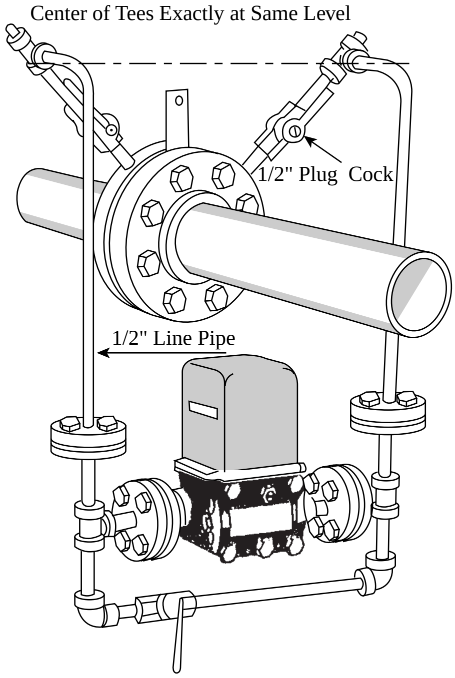

FIG 2.15f
Steam flow measurement using standard manifold.[3]

that the centerlines are 1 in. (25 mm) from the orifice plate surface. This location also facilities inspection and cleanup of burrs, weld metal, and so on that may result from installation of a particular type of flange. Flange taps are not recommended below 2 in. (50 mm) pipe size and cannot be used below 1.5 in. (37.5 mm) pipe size, since the vena contracta may be closer than 1 in. (25 mm) from the orifice plate. Flow for a distance of several pipe diameters beyond the vena contracta tends to be unstable and is not suitable for differential-pressure measurement (Figure 2.15a).

Vena contracta taps use an upstream tap located one pipe diameter upstream of the orifice plate and a downstream tap located at the point of minimum pressure. Theoretically, this is the optimal location. However, the location of the vena contracta varies with the orifice-to-pipe diameter ratio and is thus subject to error if the orifice plate is changed. A tap location too far downstream in the unstable area may result in inconsistent measurement. For moderate and small pipe, the location of the vena contracta is likely to lie at the edge of or under the flange. It is not considered good piping practice to use the hub of the flange to make a pressure tap. For this reason, vena contracta taps are normally limited to pipe sizes 6 in. (152 mm) or larger, depending on the flange rating and dimensions.

Radius taps are similar to vena contracta taps except that the downstream tap is located at one-half pipe diameter (one radius) from the orifice plate. This practically assures that the tap will not be in the unstable region, regardless of orifice diameter. Radius taps today are generally considered superior to the vena contracta tap, because they simplify the pressure tap location dimensions and do not vary with changes in orifice β ratio. The same pipe size limitations apply as to the vena contracta tap.

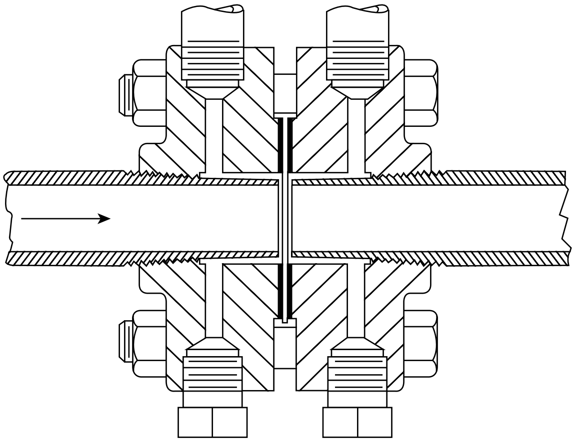

FIG 2.15g
Corner tap installation.

Pipe taps are located 2.5 pipe diameters upstream and 8 diameters downstream from the orifice plate. Because of the distance from the orifice, exact location is not critical, but the effects of pipe roughness, dimensional inconsistencies, and so on are more severe. Uncertainty of measurement is perhaps 50% greater with pipe taps than with taps close to the orifice plate. These taps are normally used only where it is necessary to install an orifice meter in an existing pipeline and radius or where vena contracta taps cannot be used.

Corner taps (Figure 2.15g) are similar in many respects to flange taps, except that the pressure is measured at the "corner" between the orifice plate and the pipe wall. Corner taps are very common for all pipe sizes in Europe, where relatively small clearances exist in all pipe sizes. The relatively small clearances of the passages constitute possible sources of trouble. Also, some tests have indicated inconsistencies with high β ratio installations, attributed to a region of flow instability at the upstream face of the orifice. For this situation, an upstream tap one pipe diameter upstream of the orifice plate has been used. Corner taps are used in the United States primarily for pipe diameters of less than 2 in. (50 mm).

ECCENTRIC AND SEGMENTAL ORIFICE PLATES

The use of eccentric and segmental orifices is recommended where horizontal meter runs are required and the fluids contain extraneous matter to a degree that the concentric orifice would plug up. It is preferable to use concentric orifices in a vertical meter tube if at all possible. Flow coefficient data is limited for these orifices, and they are likely to be less accurate. In the absence of specific data, concentric orifice data may be applied as long as accuracy is of no major concern.

The eccentric orifice plate, Figure 2.15h, is like the concentric plate except for the offset hole. The segmental orifice

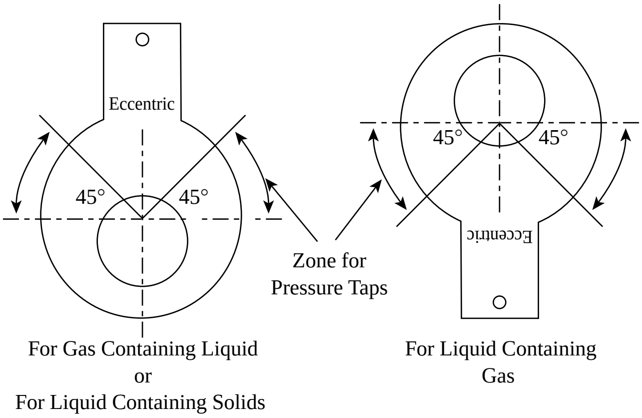

FIG. 2.15h
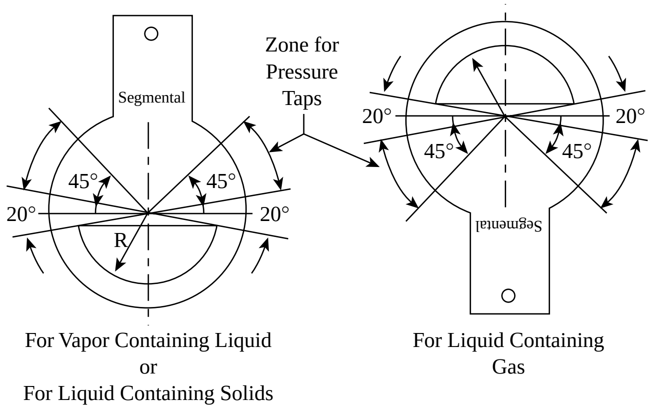
Eccentric orifice plate.



Pressure taps must always be located in solid area of plate and centerline of tap not nearer than 20° from intersection point of chord and arc.

FIG. 2.15i
Segmental orifice plate.

plate, Figure 2.15i, has a hole that is a segment of a circle. Both types of plates may have the hole bored tangent to the inside wall of the pipe or more commonly tangent to a concentric circle with a diameter no smaller than 98% of the pipe internal diameter. The segmental plate is parallel to the pipe wall. Care must be taken so that no portion of the flange or gasket interferes with the hole on either type plate. The equivalent β for a segmental orifice may be expressed as $\beta = \sqrt{a/A}$, where a is the area of the hole segment, and A is the internal pipe area.

In general, the minimum line size for these plates is 4 in. (102 mm). However, the eccentric plate can be made in smaller sizes as long as the hole size does not require beveling. Maximum line sizes are unlimited and contingent only on calculation data availability. Beta ratio limits are limited to between 0.3 and 0.8. Lower Reynolds number limit is 2000D (D in inches) but not less than 10,000. For compressible fluids, $\Delta P/P_1 \leq 0.30$, where ΔP and P_1 are in the same units.

Flange taps are recommended for both types of orifices, but vena contracta taps can be used in larger pipe sizes. The taps for the eccentric orifice should be located in the quadrants directly opposite the hole. The taps for the segmental orifice should always be in line with the maximum dam height. The straight edge of the dam may be beveled if necessary using the same criteria as for a square edge orifice. To avoid confusion after installation, the tabs on these plates should be clearly stamped “eccentric” or “segmental.”

QUADRANT EDGE AND CONICAL ENTRANCE ORIFICE PLATES

The use of quadrant edge and conical entrance orifice plates is limited to lower pipe Reynolds numbers where flow coefficients for sharp-edged orifice plates are highly variable, in the range of 500 to 10,000. With these special plates, the stability of the flow coefficient increases by a factor of 10. The minimum allowable Reynolds number is a function of β ratio, and the allowable β ratio ranges are limited. Refer to Table 2.15j for β ratio range and minimum allowable Reynolds number. The maximum allowable pipe Reynolds number ranges from 500,000 × (β – 0.1) for quadrant edge to 200,000 × (β) for the conical entrance plate. The conical entrance also has a minimum $D \geq 0.25$ in. (6.35 mm). For compressible fluids, $\Delta P/P_1 \leq 0.25$ where ΔP and P_1 are in the same units

Flange pressure taps are preferred for the quadrant edge, but corner and radius taps can also be used with the same flow coefficients. For the conical entrance units, reliable data

is available for corner taps only. A typical quadrant edge plate is shown in Figure 2.15k, and a typical conical entrance orifice plate is shown in Figure 2.15l. These plates are thicker and heavier than the normal sharp-edge type. Because of the critical dimensions and shape, the quadrant edge is difficult to manufacture; it is recommended that it be purchased from skilled commercial fabricators. The conical entrance is much easier to make and could be made by any qualified machine shop. While these special orifice forms are very useful for lower Reynolds numbers, it is recommended that, for a pipe Re > 100,000, the standard sharp-edge orifice be used. To avoid confusion after installation, the tabs on these plates should be clearly stamped "quadrant" or "conical."

An application summary of the different orifice plates is given in Table 2.15m. For dirty gas service, the annular orifice plate (Figure 2.24a) can also be considered.

TABLE 2.15m
Selecting the Right Orifice Plate for a Particular Application

Orifice Type	*Appropriate Process Fluid*	*Reynolds Number Range*	*Normal Pipe Sizes, in. (mm)*
Concentric, square edge	Clean gas and liquid	Over 2000	0.5 to 60 (13 to 1500)
Concentric, quadrant, or conical edge	Viscous clean liquid	200 to 10,000	1 to 6 (25 to 150)
Eccentric or segmental square edge	Dirty gas or liquid	Over 10,000	4 to 14 (100 to 350)

THE INTEGRAL ORIFICE

Miniature flow restrictors provide a convenient primary element for the measurement of small fluid flows. They combine a plate with a small hole to restrict flow, its mounting and connections, and a differential-pressure sensor—usually a pneumatic or electronic transmitter. Units of this type are often referred to as *integral orifice* flowmeters. Interchangeable flow restrictors are available to cover a wide range of flows. A common minimum standard size is a 0.020-in. (0.5-mm) throat diameter, which will measure water flow down to 0.0013 GPM (5 cm^3/min) or airflow at atmospheric pressure down to 0.0048 SCFH (135 cm^3/min) (Figure 2.15n).

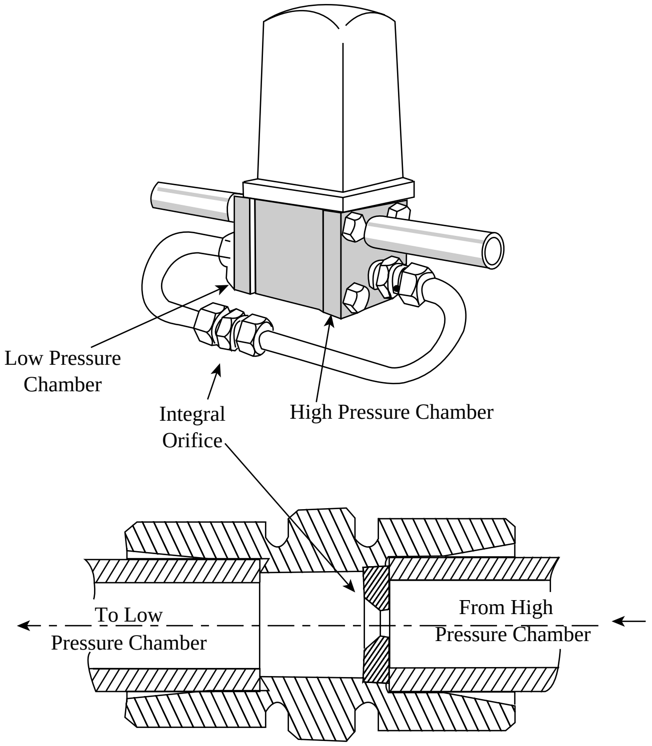

FIG. 2.15n
Typical integral orifice meter.

Miniature flow restrictors are used in laboratory-scale processes and pilot plants, to measure additives to major flow streams, and for other small flow measurements. Clean fluid is required, particularly for the smaller sizes, not only to avoid plugging of the small orifice opening but because a buildup of even a very thin layer on the surface of the element will cause an error.

There is little published data on the performance of these small restrictors. These are proprietary products with performance data provided by the supplier. Where accuracy is important, direct flow calibration is recommended. Water flow calibration, using tap water, a soap watch, and a glass graduate (or a pail and scale) to measure total flow, is readily carried out in the instrument shop or laboratory. For viscous liquids, calibration with the working fluid is preferable, because viscosity has a substantial effect on most units. Calibration across the working range is recommended, given that precise conformity to the square law may not exist. Some suppliers are prepared to provide calibrated units for an added fee.

INSTALLATION

The orifice is usually mounted between a pair of flanges. Care should be exercised when installing the orifice plate to be sure that the gaskets are trimmed and installed such that they do not protrude across the face of the orifice plate beyond the inside pipe wall (Figure 2.15o). A variety of special devices are commercially available for mounting orifice plates, including units that allow the orifice plate to be inserted and removed from a flowline without interrupting the flow (Figure 2.15p). Such manually operated or motorized orifice fittings can also be used to change the

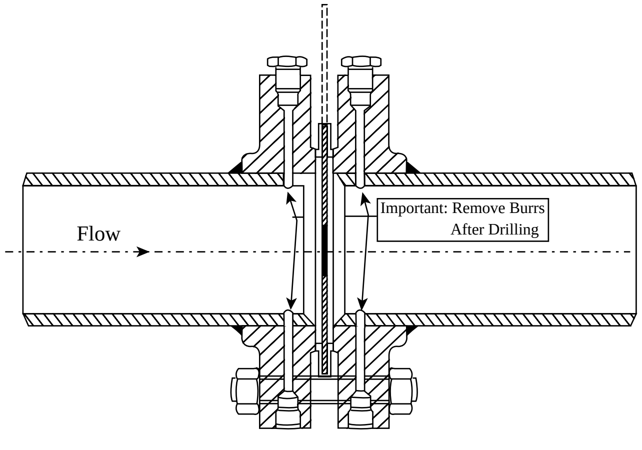

FIG. 2.15o
Prefabricated meter run with inside surface of the pipe machined for smoothness after welding for a distance of two diameters from each flange face. The mean pipe ID is averaged from four measurements made at different points. They must not differ by more than 0.3%.[3]

flow range by sliding a different orifice opening into the flowing stream.

To avoid errors resulting from disturbance of the flow pattern due to valves, fittings, and so forth, a straight run of smooth pipe before and after the orifice is recommended. Required length depends on β ratio (ratio of the diameter of the orifice to inside diameter of the pipe) and the severity of the flow disturbance.

For example, an upstream distance to the orifice plate of 45 pipe diameters with 0.75 β ratio is the minimum recommendation for a throttling valve. For a single elbow at the same β, the minimum distance would be only 17 pipe diameters. Figure 2.15q gives minimum values for a variety of upstream disturbances. Upstream lengths greater than the minimum are recommended. A downstream pipe run of five pipe diameters from the orifice plate is recommended in all cases. This straight run should not be interrupted by thermowells or other devices inserted into the pipe.

Where it is not practical to install the orifice in a straight run of the desired length, the use of a straightening vane to eliminate swirls or vortices is recommended. Straightening vanes are manufactured in various configurations (Figure 2.15r) and are available from commercial meter tube fabricators. They should be installed so that there are at least two pipe diameters between the disturbance source and vane entry and at least six pipe diameters from the vane exit to the upstream high pressure tap of the orifice.

The installation of the pressure taps is important. Burrs and protrusions at the tap entry point must be removed. (Figure 2.15o). The tap hole should enter the line at a right angle to the inside pipe wall and should be slightly beveled. Considerable error can result from protrusions that react with the flow and generate spurious differential pressure. Careful installation is particularly important when full-flow taps are located in areas of full pipe velocity and in positions that are difficult to inspect.

LIMITATIONS

Certain limitations exist in the application of the concentric, sharp-edged orifice.

1. The concentric orifice plate is not recommended for slurries and dirty fluids, where solids may accumulate near the orifice plate (Table 2.15m).
2. The sharp-edged orifice plate is not recommended for strongly erosive or corrosive fluids, which tend to round over the sharp edge. Orifice plates made of materials that resist erosion or corrosion are used for conditions that are not too severe.
3. For flows at less than 10,000 Reynolds number (determined in the pipe), the correction factor for Reynolds number may introduce problems in determining the total flow when the flow rate varies considerably (Figure 2.15b). The quadrant-edged orifice plate is recommended for this application in preference to the sharp-edged plate (Table 2.15m).
4. For liquids with entrained gas or vapor, a “vent hole” in the plate can be used for horizontal meter runs to prevent accumulation of gas ahead of the orifice plate (Figure 2.15c). If the diameter of the vent hole is less than 10% of the orifice diameter, then the flow is less than 1% of the total flow. If this error cannot be tolerated, appropriate correction can be made to the orifice calculation. On dirty service, vent or drain holes are considered to be of little value, because they are subject to plugging; they are not recommended.
5. In a similar fashion, a drain or weep hole can be provided for gas with entrained liquid. However, it is recommended that meters for liquid with entrained gas or gas with entrained liquid services be installed vertically. Normally, the flow direction would be upward for liquids and downward for gases. For severe entrainment situations, eccentric or segmental orifice plates should be used.
6. The basic flow equations are based on flow velocities well below sonic. Orifice measurement is also used for flows approaching sonic velocity but requires a different theoretical and computational approach.
7. For concentric orifice plates, it is recommended that the β ratio be limited to a range of 0.2 to 0.65 for best accuracy. In exceptional cases, this can be extended to a range of 0.15 to 0.75.
8. For large flows, the pressure loss through an orifice can result in significant cost in terms of power requirements (see Section 2.1). Venturi tubes with relatively large pressure recovery substantially decrease the pressure loss. Lo-Loss Tubes, Dall Tubes, Foster Flow Tubes, and similar proprietary primary elements develop 95% or better pressure recovery. The pressure loss is less than 5% of differential pressure (see Figure 2.29f). Elbow taps involve no added pressure loss (see Section 2.6). Pitot tube elements introduce negligible loss. Orifice plates can be sized for full-scale differential pressure ranging from 5 in. (127 mm) of water to several hundred inches of water. Most commonly the range is from 20 to 200 in. (508 to 5080 mm) of water. The pressure recovery ratio of an orifice (except for pipe taps) can be estimated by $(1 - \beta^2)$.
9. For compressible fluids, $\Delta P/P_1$ should be ≤ 0.25 where ΔP and P_1 are in the same units. This will minimize the errors and corrections required for density changes in flow through the orifice.
10. The use of vent and drain holes is discouraged, if in order to keep them from plugging, they would need to be large enough to adversely affect accuracy.

ORIFICE BORE CALCULATIONS

Accurate flow calibration, traceable to recognized standards and using the working fluid under service conditions, is difficult and expensive. For large gas flows, it is nearly impossible and is rarely done. A major advantage of orifice metering is the ease with which flow can be accurately determined from a few simple, readily available measurements. In particular, for the concentric, sharp-edged orifice, measurement confidence is supported by a large body of experience and precise, painstaking tests.

Precise flow calculations are quite complex, although the calculation methods and equations have been well standardized. These calculation methods are thoroughly covered in the references at the end of this section. Most, if not all, of the calculations have been automated using readily available computer software for both volumetric and mass flow calculations.

The Old Approach

Before the proliferation of computers, approximate calculations were used, giving only moderate accuracy. These are illustrated below more for historical perspective than as a recommended technique. Figure 2.15s illustrates how orifice bore diameters were approximated, and Table 2.15t lists the maximum air, water, and steam flow capacities for both flange and pipe tap installations at various pressure drops. When using Figure 2.15s, the following equations were used to determine the orifice bore.

For liquid flow,

$$Z = \frac{5.663\ ER\sqrt{hG_f}}{GPM\ G_t} \qquad \mathbf{2.15(5)}$$

For steam,*

$$Z = \frac{358.9\ ERY}{lbm/hr}\sqrt{\frac{h}{V}} \qquad \mathbf{2.15(6)}$$

For gas,*

$$Z = \frac{7727\ ERY}{SCFH}\sqrt{\frac{hP_f}{GT_f}} \qquad \mathbf{2.15(7)}$$

---

* For steam and gas, h expressed in inches H_2O should be equal to or less than P_f expressed in PSIA units.

where

E = area factor, determined from curve C on Figure 2.15s
R = pipe constant, determined from table on Figure 2.15s
G = specific gravity of gas (air = 1.0)
G_f = specific gravity of liquid at operating temperature
G_t = specific gravity of liquid at 60°F (15.6°C)
h = pressure differential across orifice in inches H_2O
Y = compressibility factor, determined from curve B in Figure 2.15s
V = specific volume (ft^3/lbm), determined from steam tables provided in the Appendix
T_f = flowing temperature expressed in °R (°F +460)
P_f = flowing pressure in PSIA
X = pressure loss ratio defined as $h/2P_f$

A useful simplified form of the mass flow equation [Equation 2.15(3)] is

$$W = 359\ Cd^2\sqrt{\frac{h\rho}{1-\beta^4}} \qquad \textbf{2.15(8)}$$

where

W = mass flow in lb/h
d = orifice diameter in inches
h = differential pressure in inches of water; water density assumed to be 62.32 lb/ft^3, corresponding to 68°F (20°C)
ρ = operating density in lb/ft^3
β = ratio of orifice diameter to pipe diameter in pure number
C = coefficient of discharge in pure number

This is a modification of the basic equation for mass flow [Equation 2.15(3)] substituting the 359 $Cd^2\sqrt{1-\beta^4}$ for kA. The constant 359 includes a factor for the chosen units of measurement. The coefficient of discharge is involved with the flow pattern established by the orifice, including the vena contracta and its relation to the differential-pressure measurement taps. An average value of $C = 0.607$ can be used for flange and other close-up taps, which gives working equation

$$W = 218d^2\sqrt{\frac{h\rho}{1-\beta^4}} \qquad \textbf{2.15(9)}$$

For full flow taps, $C = 0.715$, and the equation becomes

$$W = 275d^2\sqrt{\frac{h\rho}{1-\beta^4}} \qquad \textbf{2.15(10)}$$

These working equations can be used for approximate calculations of the flow of liquids, vapors, and gases through any type of sharp-edged orifice. When using orifices for measurement in weight units, errors in determination of ρ must be considered. (Refer to Chapter 6 for density measurement and sensors.) Accurate determination of density under flowing conditions is difficult, particularly for gases and vapors. In some cases, even liquids are subject to density changes with both temperature *and* pressure (for example, pure water in high-pressure boiler feedwater measurement).

For W, d, h, and ρ given in dimensions other than those stated, simple conversion factors apply. Transfer of ρ in Equations 2.15(8) through 2.15(10) from the numerator to denominator will give volume flow in actual cubic feet per hour at flowing conditions [see Equations 2.15(2) and 2.15(3)].

Beta ratio, and hence orifice diameter, can be calculated from a transposed form of the mass flow Equation 2.15(8).

ORIFICE ACCURACY

If the purpose of flow measurement is not absolute accuracy but only repeatable performance, then the accuracy in calculating the bore diameter is not critical, and approximate calculations will suffice. On the other hand, if the measurement is going to be the basis for the sale of, for example, valuable fluids or of large quantities of natural gas transported in high-pressure gas lines, absolute accuracy is essential, and precision in the bore calculations is critical.

Some engineers believe that, instead of individually sizing each orifice plate, bore diameters should be standardized.[6] This approach would make it practical to keep spare orifices on hand in all standard sizes. This approach seems reasonable, because the introduction of the microprocessor-based DCS systems means it is no longer important to have round figures for the full-scale flow ranges. If this approach to orifice sizing were adopted, the orifice bore diameters and d/p cell ranges would be standardized, round values, and the corresponding maximum flow would be an uneven number that corresponds to them.

If orifice bore diameters are selected from standardized sizes, the actual bore diameter required can be calculated, as is normally done, and the next size from the standard sizes (available in 0.125-in. diameter increments) can be selected. The use of this approach is practical and, although it results in an "oddball" full flow value, that is no problem for our computing equipment.

In the past, to increase flow rangeability, the natural gas pipeline transport stations used a number of parallel runs (Figure 2.15u). In these systems, the flow rangeability of the individual orifices was minimized by opening up another parallel path if the flow exceeded about 90% of full-scale flow (of the active paths) or by closing down a path when the flow in the active paths dropped to a selected low limit, such as 80%. By so limiting the rangeability, metering accuracy was kept high, but at the substantial investment of adding piping, metering hardware, and logic controls for the opening and closing of runs.

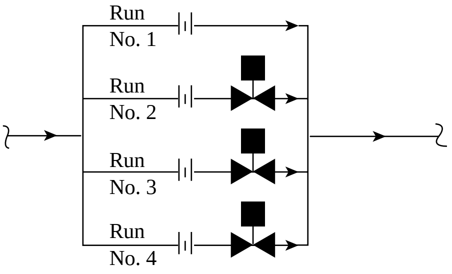

FIG. 2.15u
Metering accuracy can be maximized by keeping the flow through the active runs between 80% and 90% of full scale.[8]

Another, less expensive, choice was to use two (or more) transmitters, one for high (10 to 100%) pressure drop and the other for low (1 to 10%), and to switch their outputs depending on the actual flow. This doubled the transmitter hardware cost and added some logic expense at the receiver, but it increased the rangeability of orifice flowmeters to about 10:1.

As smart d/p transmitters with 0.1% of span error became available, another relatively inexpensive option became obtainable: the dual-span transmitter. Some smart d/p transmitters are currently available with 0.1% of span accuracy, and their spans can be automatically switched by the DCS system, based on the value of measurement.[7] Therefore, a 100:1 pressure differential range (10:1 flow range) can be obtained by automatically switching between a high (10 to 100%) and a low (1 to 10%) pressure differential span. As the transmitter accuracy at both the high and low flow condition is *0.1% of the actual span*, the overall result can be a 1% of actual flow accuracy over a 10:1 flow range.

Where the ultimate in accuracy is required, actual flow calibration of the meter run (the orifice, assembled with the upstream and downstream pipe, including straightening vanes, if any) is recommended. Facilities are available for very accurate weighed water calibrations, in lines up to 24 in. (61 cm) diameter and larger, and with a wide range of Reynolds numbers. For orifice meters, highly reliable data exists for accurate transfer of coefficient values for liquid, vapor, and gas measurement.

Flow Sheet Symbol

Types	A. Standard, single-ported B. Multiple-opening, averaging C. Area averaging for ducts
Applications	Liquids, gases, and steam
Operating Pressure	Permanently installed carbon or stainless-steel units can operate at up to 1400 PSIG (97 bars) at 100°F (38°C) or 800 PSIG (55 bars) at approximately 700°F (371°C); pressure rating of retractable units is function of the ratings of the isolating value
Operating Temperature	For permanent installations, up to 750°F (399°C) in steel and up to 850°F (454°C) in stainless-steel construction
Flow Ranges	Can be used in pipes or ducts in sizes 2 in. (50 mm) or larger; no upper limit
Materials of Construction	Brass, steel, stainless steel
Minimum Reynolds Number	In the range of 20,000 to 50,000
Rangeability	Usually limited to 3:1
Straight-Run Requirements	Twenty-five to 30 pipe diameters upstream and 5 downstream are required if the pitot sensor is located downstream of a valve or of two elbows in different planes; if straightening vanes are provided, this requirement is reduced to 10 pipe diameters upstream and 5 downstream
Inaccuracy	For standard industrial units: 0.5 to 5% of full scale. Industrial pitot venturies must be individually calibrated to obtain 1% of range performance. Full-traversing pitot venturies under laboratory conditions meeting the National Bureau of Standards can limit the error to 0.5% of actual flow. Inaccuracies of individually calibrated multiple-opening averaging pitot tubes, when Reynolds numbers exceed 50,000, are 2% of range. The errors of area-averaging duct units are claimed to be between 0.5 and 2% of span. The errors listed above do not include that of the d/p cell, which is additional.
Costs	The cost of the pitot tube itself in case of a 1-in. dia. averaging tube in stainless-steel materials is $800 if fixed and $1500 if retractable for hot-tap installation. Hastelloy® units for smokestack applications can cost $2000 or more. A local pitot indicator cost $500; a d/p transmitter suited for pitot applications costs about $1,500. Calibration costs are additional and can amount to $1000/tube.

For the measurement of the velocities of fluids, in 1732, Henri de Pitot invented the pitot tube. Pitot tubes detect the flowing velocity at a single point (standard), at several points that lead into an averaging probe (multiported), or at many points across the cross section of a pipe or duct (area-averaging). Their advantages are low cost, low permanent pressure loss, and the capability of inserting the probe-type sensors into the process pipes while the system is under pressure (wet- or hot-tapping). The disadvantages of pitot tube-type sensors are low accuracy, low rangeability, and the limitation of being suitable only for clean liquid, gas, or vapor service unless purged.

THEORY OF OPERATION

The impact pressure on a body, which is immersed in a moving fluid is the sum of the static pressure and the dynamic pressure. Thus,

$$P_t = P + P_v \tag{2.16(1)}$$

where

P_t = total pressure, which can be sensed by a fixed probe when the fluid at the sensing point is in an isentropic state (constant entropy)
P = static pressure of the fluid whether in motion or at rest
P_v = dynamic pressure caused by the kinetic energy of the fluid as a continuum

With respect to the energy relation at the isentropic stagnation point of an ideal probe,

$$\int_P^{P_t} \frac{dp}{\rho} = \int_o^{v_p} \frac{v_p\,dv}{g_c} \tag{2.16(2)}$$

where

v_p = approach velocity at the probe location
ρ = fluid density
g_c = a constant

For a liquid of constant density, integration yields, at a point,

$$(P_t - P) = P_v = \frac{Pv_p^2}{2g_c} \tag{2.16(3)}$$

For a compressible perfect gas for which $\frac{p}{\rho\gamma}$ remains constant during an isentropic change, a similar relation emerges.

$$(P_t - P) = P_v = \rho\frac{(\gamma-1)}{\gamma}\frac{v_p^2}{2g_c} \tag{2.16(4)}$$

where γ = ratio of specific heats.

Assuming isentropic stagnation at the sensing point of the probe,

$$\int_P^{P_t} \frac{dp}{\rho} = \int_o^{v_p} \frac{V_p d^V}{g_c} \tag{2.16(5)}$$

where, using English units,

V_p = velocity of approach, ft/s
P = pressure, lbf/ft^2
ρ = fluid density, lbm/ft^3
$g_c = 32.2\,\frac{\text{lbm}}{\text{lbf}}\frac{\text{ft}}{\text{s}^2}$

If density is constant, integration yields

$$(P_t - P) = P_v = \frac{p\left(V_p^2\right)}{2g_c} \tag{2.16(6)}$$

For a compressible perfect gas, the ratio $\frac{P}{\rho\gamma}$ remains constant during an isentropic change, and a similar relation is obtained.

$$(P_t - P) = P_v = \frac{(\gamma-1)}{\gamma}\frac{\rho\left(V_p^2\right)}{g_c} \tag{2.16(7)}$$

where γ is the ratio of specific heats.

To compute the fluid velocity at a particular point, it is necessary to measure the values of both the static pressure

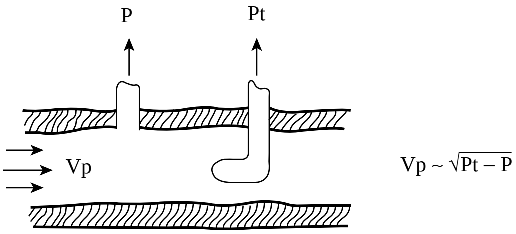

FIG. 2.16a
The velocity at a point (in the turbulent flow range) is related to the square root of the pressure difference between total and static pressures.

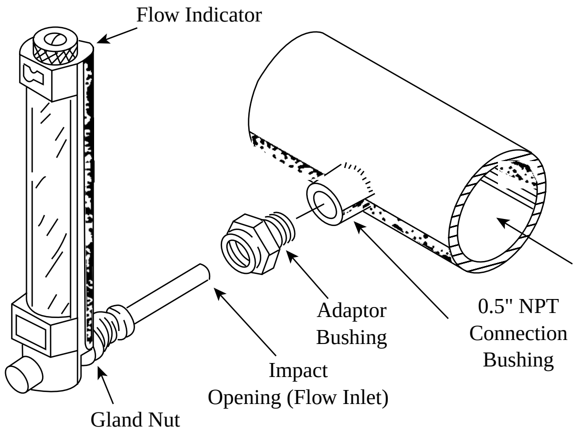

FIG. 2.16b

(P) and the total pressure (P_t) at that point (Figure 2.16a), whence

$$V_P = C\frac{(P_t - P)^{0.5}}{\rho} \qquad \textbf{2.16(8)}$$

where C = a dimensional constant.

PRESSURE DIFFERENTIAL PRODUCED

One of the problems with pitot tubes is that they do not generate strong output signals. The d/p cells available are discussed in Chapter 5, under “Pressure Measurement.” The minimum span of a “smart” d/p cell is 0 to 2 in. of H_2O (0 to 0.5 kPa). These smart d/p cell units are accurate up to 0.1% of actual span. For narrower differentials, down to 0 to 0.1 in. H_2O (0 to 25 Pa), the membrane-type d/p cells can be used.

In addition to using d/p cells, one can also install elastic element or manometer-type readout devices, variable-area flowmeters (Figure 2.16b), or thermal flowmeters (Figure 2.16c) as pitot tube detectors. The thermal detector gives the highest rangeability, but it can be used only if the pitot tube is purged.

STATIC PRESSURE MEASUREMENT

In process fluids flowing through pipes or ducts, the static pressure is commonly measured in one of three ways: (1) through taps in the wall, (2) by static probes inserted into the fluid stream, or (3) by small apertures located on an aerodynamic body immersed in the flowing fluid.

The data of Shaw[1] (presented by Benedict[2]) show that errors in the measurement of static pressure are minimal for velocities up to 200 ft/s (60 m/s) if the wall tap dimensions conform to those in Figure 2.16d, where the tap diameter (d) is 0.0635 in., the sensing tube ID ≅ 2d, and the tap length-to-diameter ratio (l/d) is 1.5 < l/d < 6.

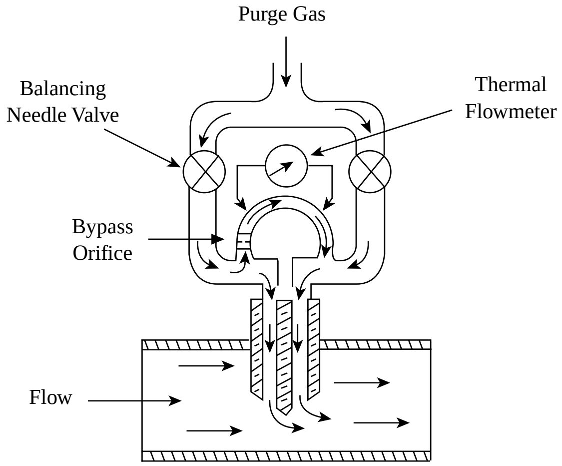

FIG. 2.16c
Pitot-tube rangeability can be increased by replacing the d/p cell detector with a thermal flowmeter.

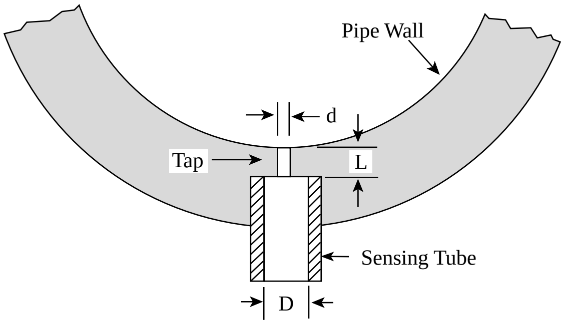

FIG. 2.16d
Wall tap for static pressure measurement.

Static pressure errors also depend on fluid viscosity, fluid velocity, and whether the fluid is compressible. Shaw[1] states that, for incompressible fluids flowing in a circular conduit with a pipe Reynolds number of 2×10^5, an error of about 1% of the mean dynamic pressure may occur using a wall tap with a diameter 1/10th that of the pipe. Rayle[3] mentions that a tap diameter of 0.03 in. (0.75 mm) with a conical countersink 0.015 in. (0.34 mm) deep will ensure nearly true static pressure sensing.

Static pressure may also be sensed through a tube inserted into the moving fluid. One configuration is shown in Figure 2.16e.

Other static probe designs are also described in the literature.[2] The aerodynamic probe is a bluff body inserted into the flowing fluid with appropriately located holes on its surface through which pressure signals are obtained. The probe is oriented so that the sensed pressure is a measure of the static pressure. Two configurations taken from Benedict,[2] the cylinder and the wedge, are shown in Figure 2.16f. The probes are rotated until the pressure sensed from each hole is the same or, alternatively, the two taps may be manifolded to obtain an averaged pressure.

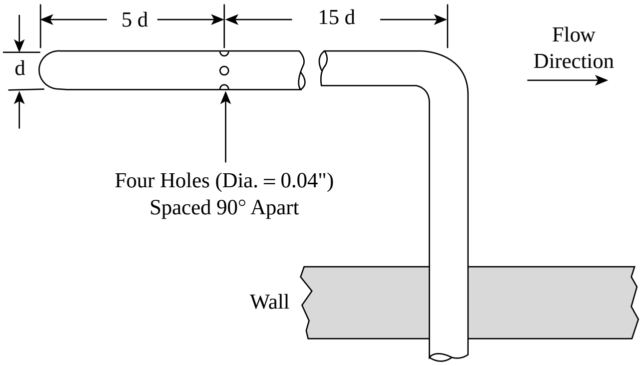

FIG. 2.16e

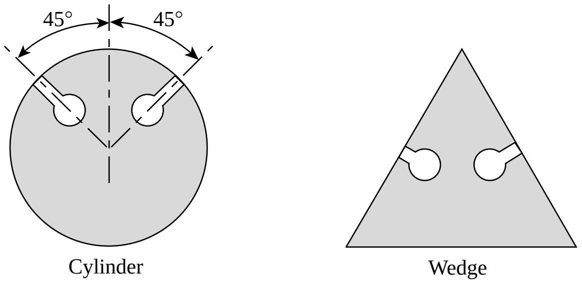

FIG. 2.16f
Two shapes of aerodynamic probes used to sense static pressure.

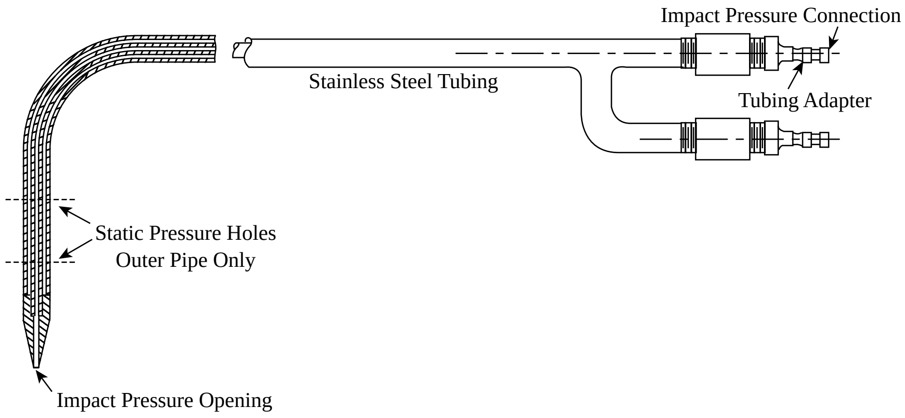

FIG. 2.16g
Typical pitot tube.

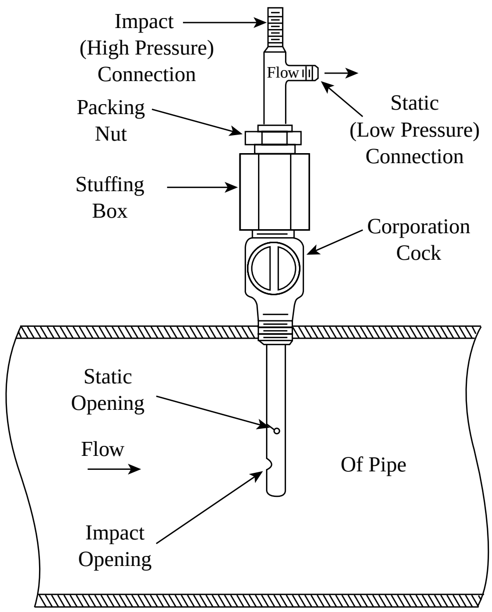

FIG. 2.16h
Schematic of an industrial device for sensing static and dynamic pressures in a flowing fluid.

The total pressure develops at the point where the flow is isentropically stagnated, which is assumed to occur at the tip of a pitot tube or at a specific point on a bluff body immersed in the stream. Figure 2.16g illustrates a typical pitot tube, also showing the taps for sensing static pressure. Another variation is shown in Figure 2.16h.

SINGLE-PORTED PITOT TUBE

Pitot tubes are sensitive to flow direction and must be carefully aligned to face into the flow. This can be difficult if the flow direction is caused to vary by changes in turbulence. The pitot tube is made less sensitive to flow direction if the impact aperture has an internal bevel of about 15° extending about 1.5 diameters into the tube. The characteristics of various designs and orientations are discussed in Benedict.[2] Figure 2.16i illustrates the typical performance of a pitot tube.

Pitot venturi and double-venturi elements have been developed to amplify the pressure signals generated by the in-stream velocity sensors, as shown in Figures 2.16j and 2.16k. These elements are intended to remain in a fixed position, so their measurements must be converted to flow rate through calibration, which accounts for the properties of

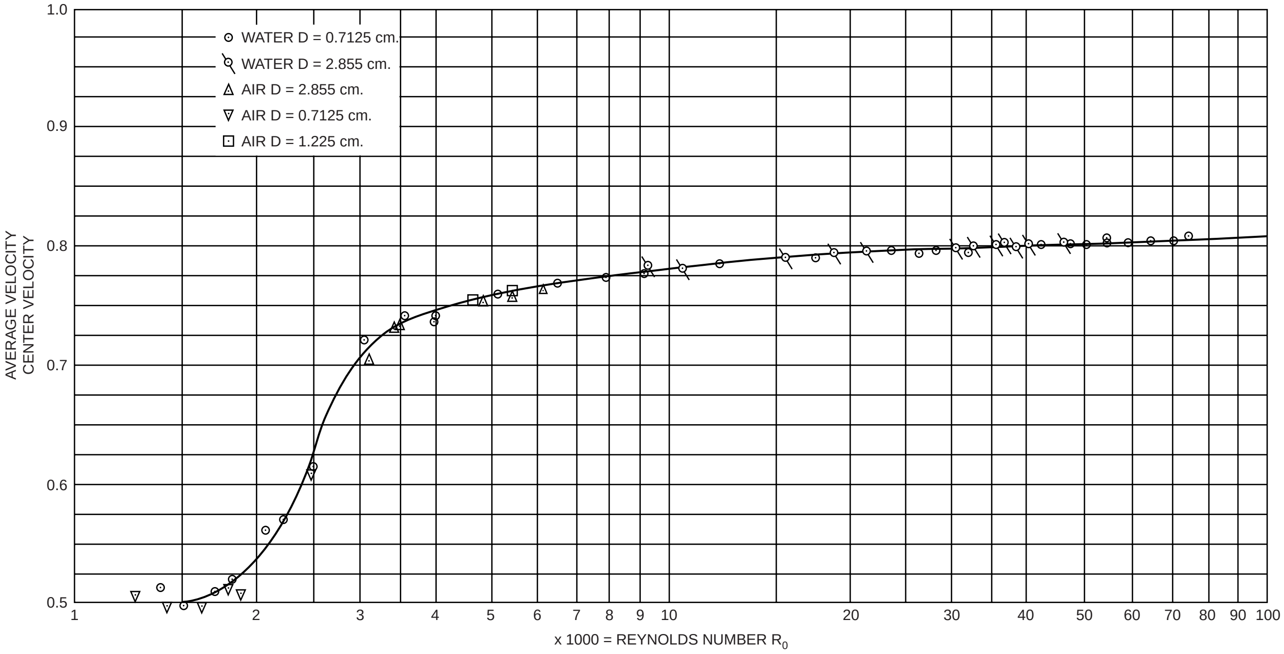

FIG. 2.16i
Center to average velocity ratios in straight and smooth pipes.[7]

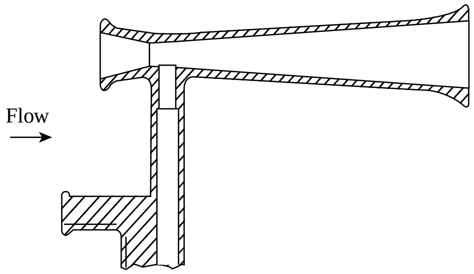

FIG. 2.16j

the fluid and the velocity profile (e.g., Reynolds number). To obtain a stable velocity profile, it is recommended that a smooth, straight section of pipe, of a length equaling at least 10 to 15 pipe diameters, be provided both upstream and downstream of the probe.

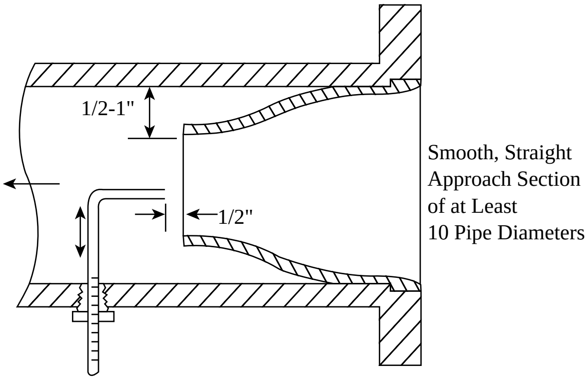

FIG. 2.16l
Reduction nozzle used to expedite velocity traverses.

To determine the average velocity in a pipe, it is necessary to traverse it with a pitot tube. For circular pipes, such an average is obtained from measurements of $(P_t - P)$ on each side of the cross section at the following locations, expressed in percentage of the diameter measured from the center:

$$\left(\sqrt{\frac{2n-1}{N}}\right)\times 100\%, \quad \left(n=1,2,3K\,\frac{N}{2}\right) \qquad \textbf{2.16(9)}$$

where N is the number of measurements per traverse. Two measurements normal to each other are recommended.

To improve the measurements made near the walls of pipes that are more than 6 in. (150 mm) in diameter, a reduction nozzle is inserted into the pipeline (Figure 2.16l).

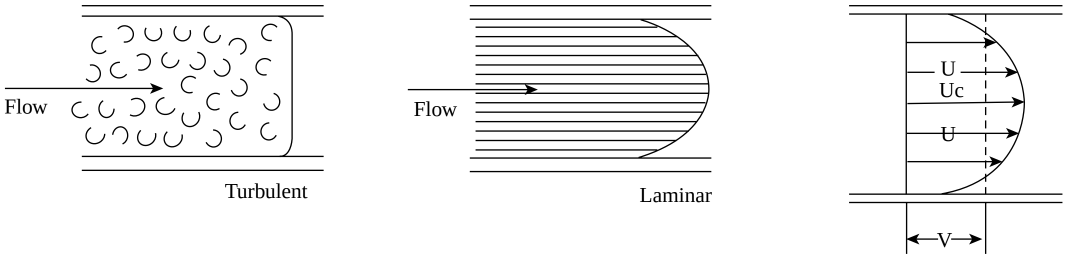

FIG. 2.16m
The velocity profile becomes flatter as the Reynolds number rises (the flow becomes more turbulent), and the task of the pitot-type flow sensor is to find the insertion depth corresponding to the average velocity (V).

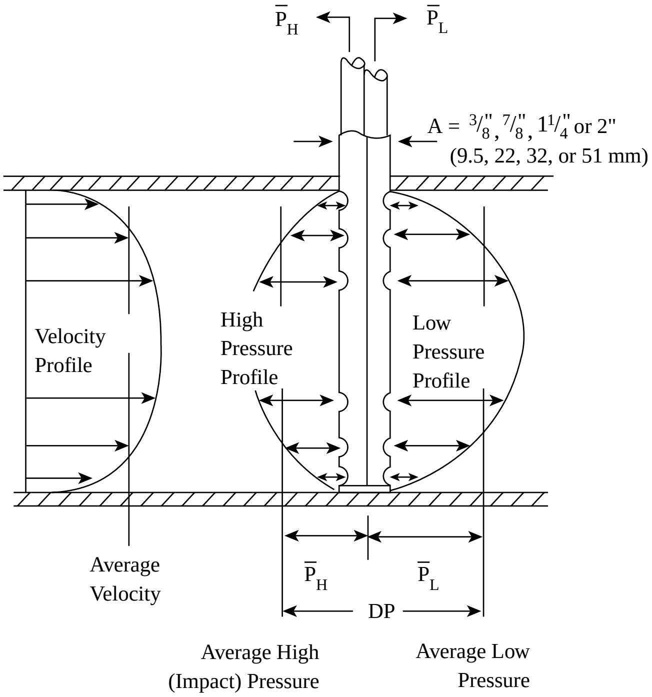

FIG. 2.16n
The design of a particular averaging pitot tube. (Courtesy of Dietrich Standard.)

Calibration of Pitot Tubes

In high-precision laboratory tests, the pitot tube is traversed across the cross-section of the pipe, thereby establishing the velocity profile that exists in the pipe. In industrial applications, the pitot tube is fixed and measures the flow velocity only at one point on the velocity profile (Figure 2.16m). If the velocity (U) measured by this fixed pitot tube is not the average velocity (V), a substantial error will result. This error cannot be easily eliminated because, even if the pitot tube insertion is carefully set to measure the average velocity V under one set of flow conditions, it will still be incorrect as soon as the flow velocity changes. At Reynolds numbers under 1000 (in the fully laminar region), the ratio between the average velocity and the center velocity is 0.5 ($V/U_c = 0.5$ in Figure 2.16m). In fully developed turbulent flow ($Re = 50,000$ or more), this same ratio is about 0.81($V/U_c = 0.8$).

Unfortunately, the velocity profile is affected not only by the Reynolds number but also by the pipe surface roughness and by upstream valves, elbows, and other fittings. To reform the velocity profile, it is recommended to provide a straight pipe length of about 25 pipe diameters between the upstream disturbances and the pitot element.

If the data for calculating the Reynolds number is available, and if the pitot tube is installed in a pipe with smooth inner surface, it should be possible to design a microprocessor-based *smart pitot tube* that measures only the center velocity (U_c) and, based on that reading, accurately calculates the flow under all flow conditions.

The National Bureau of Standards calibrates pitot tubes by mounting them on a carriage, which is drawn through stagnant air at a known velocity. Smoke is introduced into the room to verify that the air is stagnant—that there is no turbulence. Such tests have shown that pitot tubes with coefficients very close to unity can be designed. Devices such as pitot-venturies or double venturies can provide flow rate measurements with less than 1% error, but only after extensive *in situ* calibration for each installation.

MULTIPLE-OPENING PITOT TUBES

One approach in attempting to overcome the inherent limitation of the pitot tube—that of being a point velocity sensor—was to measure the velocities at several points and average these readings. It was argued that, by averaging the velocities measured at four fixed points, for example (see Figure 2.16n), changes in the velocity profile will be detected, and therefore the reading of a multiple-opening pitot tube will be more accurate than that of single-point sensors.

The manufacturers of averaging pitot tubes usually claim that the flow coefficient (K) will stay within 2% between the Reynolds numbers of 50,000 and 1,000,000. This is probably so, but it might not be attributable to averaging action but rather to the fact that, in this highly turbulent region, the velocity profile is flat and changes very little.

Critics of this device argue that it offers little improvement over the single-opening pitot tube, because it is ineffective at Reynolds numbers below 50,000. This means that it is not applicable for the measurement of a large portion of industrial liquid flows. The other argument made by critics is that the averaging pitot tube openings are too large and, consequently, these devices are not true averaging chambers; rather, the sensed pressure is dominated by the pressure at the nearest port. For these reasons, further testing by independent laboratories is still needed.

The reason for making the ports of the averaging pitot tubes so large is to prevent plugging. Some manufacturers of area-averaging pitot tubes do overcome this limitation by purging, because the small port openings are kept clean by the purge gas, and these units can act as true averaging chambers. Naturally, they can be used only on processes in which the introduction of a purge media is acceptable.

One advantage of the averaging pitot tubes that both its manufacturers and its critics agree on is their ability to be installed into operating, pressurized pipelines. This hot-tapping capability, and the ability to remove the sensor without requiring a shutdown, are important advantages of all probe-type instruments (Figure 2.16o).

In calculating the pressure differential produced by an averaging pitot tube, one might use the equations listed in Table 2.16p. For the metric equivalents of the units used in this table, refer to the Appendix. The flow coefficient (*K*) of the pitot tube varies with its design. The *K* values of the averaging pitot tube shown in Figure 2.16n are listed in Table 2.16q. The distance “A” used in Table 2.16q is also defined in Figure 2.16n.

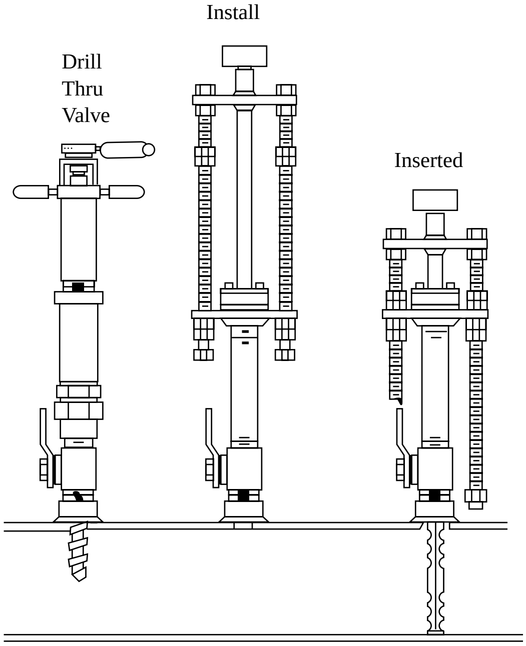

FIG. 2.16o
The hot-tap installation of an averaging pitot tube involves the same steps, which are required in installing all “retractable” probe-type instruments. (Courtesy of Dietrich Standard.)

AREA-AVERAGING PITOT STATIONS

Area-averaging pitot stations have been designed for the measurement of large flows of low-pressure gases. Measurements include the flow rate of combustion air to boilers, airflow to dryers, and air movement in HVAC systems. These units are available with circular or rectangular cross sections (Figures 2.16r and 2.16s) and can be mounted in the suction or discharge of fans or in any other large pipes or ducts. These stations are designed so that one total pressure detection port and one static pressure sensing port are located in each unit area of the cross section of the duct, and they each are

TABLE 2.16p

connected to their own manifold. The manifolds act as averaging chambers, and they are also purged to protect the sensing ports from plugging.

The straight-run requirement of these units is reduced by the addition of a hexagon-cell-type flow straightener and a flow nozzle in front of the area-averaging flow sensor. This nozzle also serves to amplify the differential pressure produced by the unit (Figure 2.16s). According to the manufacturer, this design (Figure 2.16s) reduces the straight-run requirement of most installations to a range of 0 and 10 diameters. The longest straight run (10 diameters) is recommended when the flow meter is installed downstream of a butterfly valve or a damper.

Because these area-averaging pitot stations generate very small pressure differentials, special d/p cells are required to detect these minute signals. One such detector is the membrane-type design (Fig. 2.16t), which can have a span as small as 0 to 0.01 in. H_2O (to 2.5 Pa). When such extremely small pressure differentials are detected, the pressure drop in the tubing between the d/p cell and the pitot station must

be minimized. This is achieved by making the connecting tubes short and large in diameter. The pressure differential generated by the flow element shown in Figure 2.16s can be calculated by using the equations in Table 2.16u. For the equivalent SI units for use in these equations, refer to the Appendix.

SPECIAL PITOT TUBES FOR PULSATING FLOW

The mean velocity measurements of unsteady flows, if made by conventional pitot tubes, are usually inaccurate.[4] In such measurements, one can expect errors in the range of 5 to 30% of mean total pressure. This measurement can be improved by using specially designed probes when the application involves unsteady or pulsating flows.

Figure 2.16v shows a design provided with a low-capacity capillary probe filled with silicon oil. The oil serves to transmit the process pressure to the d/p transducer. This type of probe was developed and is used by Deutsche Forschungs– und Versuchsanstalt für Luft und Raumfahrt in Germany.[5]

Figure 2.16w shows another example of a probe designed to measure unsteady flow. This probe was developed in the Aeronautical Research and Test Institute in Czechoslovakia.[6] The main design challenge in this design is to equalize the resistances in the input and output openings of the probe. Also, to protect against resonance during measurement, the natural frequency of the probe must be carefully tuned.

TABLE 2.16u
*Calculation of Pressure Differentials Generated By Area Averaging Pitot Stations**

Equations for Differential Pressure Calculation	*Terms Used*
$DP = \left(\frac{\text{ACFM}}{\text{Area}}\right)^2 \times \frac{\text{DENS}}{(1096.845)^2}$	Area = Cross-sectional area of duct section in ft^2
	ACFM = Actual cubic feet per minute
	DP = Differential pressure in inches w.c.
$DP = \left(\frac{\text{SCFM}}{4000.7 \times \text{Area}}\right)^2$	M = Mass flow in pounds per hour
	SCFM = Standard cubic feet per minute
$DP = (V)^2 \times \frac{\text{DENS}}{(1096.845)^2}$	V = Velocity in feet per minute
	PABS = Absolute pressure in PSIA

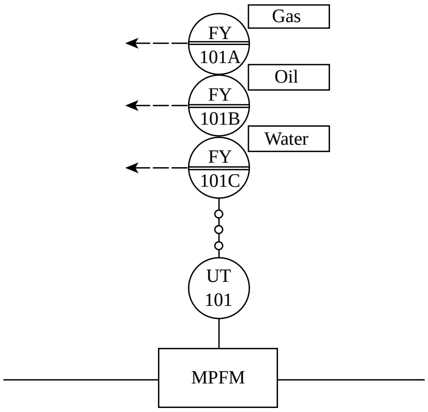
2.17 Polyphase (Oil/Water/Gas) Flowmeters

I. H. GIBSON (2003)



Flow Sheet Symbol

Design Pressure	Limited by piping design class
Operating Temperature Range	Limited by piping design class, 30 to 270°F (0 to 130°C)
Fluids	Mixtures of liquids, vapors, or gases; typically oil, water, and gas
Cost	Extremely variable, depending on line size, pressure rating, and installation requirements, starting at about $100,000 Subsea equipment commonly twice the price of surface-design units of comparable capacity
Accuracy	Five to 10%, depending on relative proportions of phases
Partial List of Suppliers	3-Phase Measurements AS (VenturiX, PhaseTester) (www.framoeng.no) Agar Corp. (www.agarcorp.com) Aker-Kvaerner (DUET) (www.kvaerner.com/kop) FlowSys AS (Topflow) FMC Technologies (www.fmctechnologies.com) Framo Engineering AS, Schlumberger (www.framoeng.no) Jiskoot Autocontrol (Mixmeter) (www.jiskoot.com) McCrometer (www.mccrometer.com) Petroleum Software Ltd. (ESMER) (www.petroleumsoftware.co.uk) Roxar AS (Fluenta, MFI) (www.roxar.com) Solartron ISA (Dualstream) (www.solartronisa.com)

Whereas most flow measurements are carefully designed to operate in single phase (gas, vapor, liquid), there are many circumstances in which the ability to distinguish the components of a liquid/vapor/gas mixture (or, indeed, multiple immiscible liquids, vapor, and gas) in the presence of solids is highly desirable.

In the production of oil/gas from unpumped petroleum wells, the flow from several thousand meters underground to the surface brings up water (commonly saline), inert gases such as carbon dioxide and nitrogen, water-saturated hydrocarbon gas (methane, ethane), hydrocarbon condensates (propane, butane, and so on), and higher hydrocarbons.

The liquids and gases do not normally travel at the same velocity, as the liquids are being dragged to the surface by the expanding gas flow. A wide variety of flow regimes are possible, depending on the mixture of phases and the geometry. A production facility may have tens of wells, and individual wells in a facility may have different mixes of ownership. This leads a requirement to be able to determine the flow of the economically interesting components from each well as accurately as possible.

The traditional method has been to use a small *test separator* that will separate the gas and the oil and water phases from a single well by gravity while production from the rest of the facility is flowing to production separators. The test separator is fitted with a full array of level and pressure controls and flowmeters (turbine, positive-displacement, orifice, and others) to enable a steady-state operation to be achieved. Commonly, the test separator is operated at a pressure slightly above the production separator to allow the streams from the test separator to be mixed with the flows out of the production separator. This requires a large amount of room and a complex valving system to enable each well to be tested separately. As pressures are commonly 1000 to 4500 PSI (7000 to 30,000 kPa) or higher, and the temperature is 150 to 270°F (65 to 130°C) at the surface, the test separator is not an inexpensive device. Individual well tests rarely can be scheduled more frequently than monthly as a result of the time taken to stabilize operation at a set of operating conditions. Even with the best of intentions, test separator measurements are notorious for inaccuracies, because quite small amounts of vapor disengaging in the liquid meters can induce errors in the 5 to 10% region.

For offshore platforms, where the cost of test separator equipment can exceed on-shore costs by many times (and especially for subsea operations, where operators cannot easily access equipment), the potential savings from an on-line method of measurement have driven the development of a variety of devices over the past 15 years. These employ a wide variety of operating principles, some of which are outlined below.

The techniques used differ depending on the ratio of liquid to gas (known as LGR or the inverse, GLR). The extreme end of the LGR (say <10% by mass) is classified as *wet gas.*

WET-GAS METERING

The standard approach for wet-gas metering treats the fluid as a gas. This uses differential-pressure devices (venturi or orifice) or vortex or ultrasonic meters. Turbine meters are unsatisfactory because even small quantities of high-velocity liquid can damage the meter. The venturi has a considerable advantage over the orifice in that it does not dam liquid behind the device, altering the flow profile. The McCrometer V-cone™ meters (Section 2.28) are also suitable for this service and have also been used for flow conditioners.

Normal ISO 5167 flow conditioners are *not* recommended for wet-gas service; not only can they dam liquids, they can induce hydrocarbon hydrate formation.

Where practical, insulation of the metering run is recommended. In some environments, trace heating may be indicated to prevent hydrate formation in the tapping connections.

Pressure tappings should be short and inclined vertically upward to avoid trapping condensate in the connections and to avoid hydrate formation.

Process gas chromatographs are not recommended for wet-gas services unless the liquid content is below 0.1%.

Venturi Meters

The venturi (Section 2.29) is much more rugged than the orifice in wet-gas service and allows for higher differential-pressure operation. With modern transmitters, turndown up to 10:1 is possible and may be necessary, given that wet-gas behavior is far more variable than that of a pure gas.

Design is generally in accordance with ISO 5761–1, although recent work by Reader-Harris et al[1] has shown that the ISO coefficients are not as well defined as claimed. The coefficients are quite sensitive to minor machining variations and, at high Reynolds number operation, the flow may break away from the throat. The coefficient can also be sensitive to the diameter-to-length ratio of the tappings; use of the "triple-T" piezometer connections advocated by ISO 5167 is impractical for wet-gas service, because the downward-facing tappings would fill with liquid.

A downstream tapping after the full pressure recovery is achieved is recommended to allow the calculation of liquid content and temperature correction to upstream conditions.

Algorithms for Wet-Gas Measurement

Differential devices used on wet-gas service will generally *overestimate* the dry-gas flow rate, and various algorithms have been developed to compensate. The Chisholm and Murdock[2] correlations were developed for orifice plates; the de Leeuw correlation has been developed for venturi meters and is an extension of the Chisholm equations.

In addition to the dry-gas flow rate, it is normally required to determine the liquid flow rate, and particularly the condensate flow rate. All three correlations (de Leeuw, Chisholm, Murdock) are based on the Lockhart–Martinelli parameter, which is a function of both liquid flow rate and density. The liquid flow rate can be determined by

- Routing the flow to a test separator
- The use of tracer techniques
- Sampling

or a combination of these. Since these are all spot-test techniques, modification to the Lockhart–Martinelli equation can be made to work in terms of the dry-gas mass fraction, which is relatively constant, provided the wetness of the gas is constant. None of these techniques is easily useful in subsea conditions, and adaptations have been made to apply dual measurements in series with devices of different geometry that allow the Lockhart–Martinelli relationship to be solved for equal values of liquid/gas. These still require considerable input of process data derived from composition.

Theory of Operation of Wet-Gas Metering

It has long been known that a gas stream carrying a well-dispersed liquid content through a differential flow element (orifice, nozzle, venturi, or V-cone) will develop a higher differential than that due to the corresponding gas flow. If the properties of the gas and liquid are known, it is possible to calculate the relative content of liquid in the gas.

The following development has been adapted from the UK DTI Oil and Gas Division's Guidance Notes for

Petroleum Measurement under the Petroleum (Production) Regulations.[2]

de Leeuw Wet-Gas Venturi Correlation

de Leeuw[3] has shown that the real gas mass flow rate can be derived from the following equations (all equations are based on SI units):

$$Q_{\text{real gas}} = \frac{Q_{\text{uncorrected gas}}}{\sqrt{(1 + CX + X^2)}} \qquad \textbf{2.17(1)}$$

where $Q_{\text{uncorrected gas}}$ = uncorrected gas mass flow rate as indicated by the venturi meter using the following equation:

$$Q_{\text{uncorrected gas}} = C_{\text{gas}} \varepsilon \pi d^2 \frac{\sqrt{(2\rho_{\text{gas}} \Delta P)}}{4\sqrt{1-\beta^4}} \qquad \textbf{2.17(2)}$$

where

C_{gas} = discharge coefficient of the venturi flowmeter in dry gas as determined through calibration
ε = expansibility of gas in venturi as defined by ISO 5167-1
d = throat diameter of the venturi flowmeter (corrected for temperature)
ρ_{gas} = gas density at upstream conditions
ΔP = raw differential pressure as measured by the transmitter
β = ratio of d to D, the pipe diameter

and X is the *Lockhart–Martinelli* parameter, which is derived as follows:

$$X = \frac{Q_{\text{liquid}}}{Q_{\text{real gas}}} * \sqrt{\frac{\rho_{\text{liquid}}}{\rho_{\text{gas}}}} \qquad \textbf{2.17(3)}$$

where

Q_{liquid} = combined liquid flow rate through the venturi flowmeter
ρ_{liquid} = combined liquid density

The coefficient C is given by the following equation:

$$C = \left(\frac{\rho_{\text{liquid}}}{\rho_{\text{gas}}}\right)^n + \left(\frac{\rho_{\text{gas}}}{\rho_{\text{liquid}}}\right)^n \qquad \textbf{2.17(4)}$$

where the exponent n is given by

$$n = 0.606(1 - e^{-0.746 Fr_g}) \quad \text{for } Fr_g \geq 1.5 \qquad \textbf{2.17(5)}$$

$$n = 0.41 \quad \text{for } 0.5 \leq Fr_g \leq 1.5 \qquad \textbf{2.17(6)}$$

and Fr_g is the gas Froude number given by

$$Fr_g = \left[\frac{V_{\text{gas}}}{\sqrt{(gD)}}\right] * \left[\frac{\sqrt{\rho_{\text{gas}}}}{\sqrt{(\rho_{\text{liquid}} - \rho_{\text{gas}})}}\right] \qquad \textbf{2.17(7)}$$

where

V_{gas} = superficial gas pipe velocity
g = local acceleration due to gravity

V_{gas} can be derived using an iterative method and "seeding" a velocity based on the uncorrected mass flow rate. The first pass equation is

$$V_{\text{gas}} = \frac{4 * Q_{\text{uncorrected gas}}}{\rho_{\text{gas}} \pi D^2} \qquad \textbf{2.17(8)}$$

For further iterations $Q_{\text{uncorrected gas}}$ is replaced by consecutive $Q_{\text{real gas}}$ values until the equation converges to a solution.

Liquid Mass Flow Rate Correction Algorithm

The resultant liquid mass flow rates can be derived from the following equations:

$$Q_{\text{total}} = Q_{\text{real gas}} + Q_{\text{liquid}} \qquad \textbf{2.17(9)}$$

Condensate mass flow rate

$$Q_{\text{condensate}} = Q_{\text{total}} * \zeta_{\text{condensate}} \qquad \textbf{2.17(10)}$$

Water mass flow rate

$$Q_{\text{water}} = Q_{\text{total}} * \zeta_{\text{water}} \qquad \textbf{2.17(11)}$$

Methanol (or glycol) mass flow rate

$$Q_{\text{methanol}} = Q_{\text{total}} * \zeta_{\text{methanol}} \qquad \textbf{2.17(12)}$$

where

$\zeta_{\text{condensate}}$ = condensate mass fraction
ζ_{water} = water mass fraction
ζ_{methanol} = methanol mass fraction

In turn,

$$\zeta_{\text{condensate}} = X * \psi_{\text{condensate}} \qquad \textbf{2.17(13)}$$

$$\zeta_{\text{water}} = X * \psi_{\text{water}} \qquad \textbf{2.17(14)}$$

$$\zeta_{\text{methanol}} = X * \psi_{\text{methanol}} \qquad \textbf{2.17(15)}$$

where

$\psi_{\text{condensate}}$ = condensate-to-gas mass fraction
ψ_{water} = water-to-gas mass fraction
ψ_{methanol} = methanol-to-gas mass fraction (methanol injection is commonly used to suppress hydrocarbon hydrate formation)

Liquid Density Calculation Algorithm

The liquid density can be calculated as follows:

$$\rho_{\text{liquid}} = \frac{\psi_{\text{liquid}}}{\left(\left(\frac{\psi_{\text{condensate}}}{\rho_{\text{condensate}}}\right)+\left(\frac{\psi_{\text{water}}}{\rho_{\text{water}}}\right)+\left(\frac{\psi_{\text{methanol}}}{\rho_{\text{methanol}}}\right)\right)} \qquad \mathbf{2.17(16)}$$

where

ψ_{liquid} = total liquid to gas mass ratio
ρ_{liquid} = density of liquid
$\rho_{\text{condensate}}$ = density of hydrocarbon condensate
ρ_{water} = density of water
ρ_{methanol} = density of methanol
$\rho_{\text{condensate}}$ = is derived from the condensate base density and corrected for temperature and pressure (Ctl and Cpl)

Corrections from the standard API MPMS11.2.1M may be applied. However, for improved accuracy, it is recommended that samples of the condensate be obtained and analyzed to derive specific correction factors. The values of K_0 and K_1 for crude oil (613.9723 and 0, respectively) are not ideal for condensate, and the alternatives from the standards referred to above may be no better.

Water and methanol densities can be derived as follows:

$$t = (t_m + 273.15) * \left(\frac{P_3}{P_1}\right) K_3 - 273.15 \qquad \mathbf{2.17(17)}$$

where

t = temperature at the inlet of the venturi
A, B, C = water constants (e.g., –0.0001732, –0.1307, 1040)
D, E, F = methanol constants (e.g., 0.0000713, –0.3344, 540)

The correct values of these methanol and water constants may vary due to salinity or product type. It is therefore advisable to have the liquids analyzed to determine appropriate values.

Upstream Temperature Correction and Pressure Recovery

The correction for downstream measured temperature to upstream temperature (in degrees centigrade) at the inlet is given by

$$t = (t_m + 273.15) * \left(\frac{P_3}{P_1}\right) K_3 - 273.15 \qquad \mathbf{2.17(18)}$$

where

t_m = measured temperature
P_3 = fully recovered downstream pressure
P_1 = pressure measured at the upstream tapping
K_3 = downstream to upstream temperature correction exponent

P_3 can be measured using a third pressure tapping or calculated (in bar) from the following empirical equation from Miller:[4]

$$P_3 = P_1 - 10^{-3} * \Delta\omega \qquad \mathbf{2.17(19)}$$

where

$$\Delta\omega = (A\beta^2 + B\beta + C) * \Delta P \qquad \mathbf{2.17(20)}$$

and the constants A, B, and C, for venturies with 7 and 15° exit cone angles, are as follows:

7° cone angle	$A = 0.38$	$B = 0.42$	$C = 0.218$
15° cone angle	$A = 0.59$	$B = 0.86$	$C = 0.436$

Gas Mass Fraction Estimation Using Tracer Techniques

The gas mass fraction can be estimated as follows:

1. Perform the tracer flow technique to determine condensate and water flow rates and mass ratios. This uses concentrated oil-soluble and water-soluble fluorescent chemicals, injected upstream and partially recovered by sampling downstream of the flowmeter.
2. Analyze the condensate to determine base density.
3. Sample the gas to determine gas density.
4. Record the total uncorrected gas flow from venturi during the tracer flow technique.
5. Determine the dry "first pass" gas mass fraction and liquid-to-gas ratio based on the recorded uncorrected gas flow and tracer flow results (corrections for methanol injection after completion of tracer technique may be required).
6. *Seed* values from the last stage into the wet-gas venturi flow calculation to determine a "first pass" corrected gas flow rate.
7. *Re-seed* this value into the calculation, correcting gas mass ratio and liquid-to-gas ratio.
8. Iterate the process until the corrected gas flow rate converges.

Solartron-ISA Dualstream II™ Theory

The Solartron-ISA Dualstream™ II, originally developed by British Gas, extends the theory noted above by fitting two dissimilar pressure differential devices in series. These have differing Lockhart–Martinelli characteristics, and the

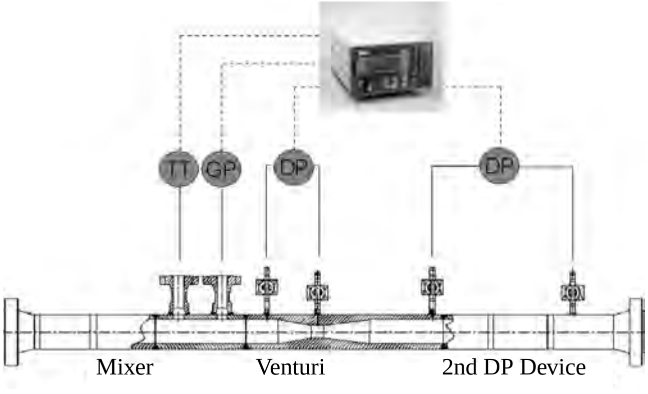


FIG. 2.17a
Solartron—ISA Dualstream II™ wet gas flowmeter.

combination can determine changes in the gas-to-liquid ratio. The venturi will generate an indicated flow rate. This can be corrected to generate a "true" gas flow rate using the equations in previous sections.

The second "DP device" will generate a second indicated flow rate. This flow rate can be corrected to give a "true" gas flow rate using similar relations.

A simultaneous equation can be formed from these flow rates:

$$Q_g = \frac{Q_{gi\,(\text{venturi})}}{1+M_{(\text{venturi})}\dfrac{(1-x)}{x}\dfrac{C_g}{C_l}\varepsilon_g\sqrt{\dfrac{\rho_g}{\rho_l}}} = \frac{Q_{gi\,(\text{2nd Dp})}}{1+M_{(\text{2nd Dp})}\dfrac{(1-x)}{x}\dfrac{C_g}{C_l}\varepsilon_g\sqrt{\dfrac{\rho_g}{\rho_l}}} \qquad \textbf{2.17(21)}$$

$$x = \frac{\sqrt{\dfrac{\rho_g}{\rho_l}}\left(\dfrac{Q_{gi\,(\text{2nd Dp})}}{Q_{gi\,(\text{venturi})}}M_{(\text{venturi})} - M_{(\text{2nd Dp})}\right)}{\left(1-M_{(\text{2nd Dp})}\sqrt{\dfrac{\rho_g}{\rho_l}}\right) - \dfrac{Q_{gi\,(\text{2nd Dp})}}{Q_{gi\,(\text{venturi})}}\left(1-M_{(\text{venturi})}\sqrt{\dfrac{\rho_g}{\rho_l}}\right)} \qquad \textbf{2.17(22)}$$

This enables a continuous estimation of the liquid-to-gas ratio without the necessity for tracer measurements, and it is particularly useful sub-sea, where tracer measurements are impractical with current technology.

MULTIPHASE FLOWMETERS

The various true multiphase flowmeters can be effective from straight liquid through to 95 or 97% gas. Some meters, such as the Agar MPFM400 and Jiskoot, attain the extreme gas end by using an in-line separator to send the wet gas through a wet-gas meter and the remaining gas, with oil and water, through a separate multiphase flowmeter section. No standards exist as yet to assist engineers in designing multiphase metering systems, and there are wide variations in the methods used to define *accuracy* and performance. When considering a manufacturer's performance and accuracy statements, it is essential to understand the implications of accuracies quoted in different ways. There are three common ways in which multiphase meter accuracies are presented:

1. Percent phase volume flow rate
2. Percent total multiphase flow rate
3. Percent gas and liquid flow rate plus absolute uncertainty of water cut in liquid phase

Method 1 is favored by metrologists and clearly represents performance as stated. This method may not be the most practical for extreme cases of phase fractionation.

Methods 2 and 3, whereas quoting relatively small numbers on the order of 5 to 10% for gas/liquid phase uncertainties and 2 or 3% for percentage water cut, may nevertheless exhibit very large individual phase errors of 100% or more, depending on the absolute value of the percentage water.

The first requirement for a mixed liquid phase is to distinguish hydrocarbon from water. If the liquid phase is oil-continuous, typically water less than 40% liquid hydrocarbon, then dielectric constant measurement at microwave frequencies can determine the water fraction. The dielectric constant of dry hydrocarbon is in the order of 2 to 4, depending on composition, while water is 82, giving a sensitive means of measurement.

For higher water content, the measuring element will short out in a water-continuous phase, but density measurement can distinguish water from oil. This requires stream-specific characterization, as the composition and density of the liquid is pressure and temperature dependent.

The next requirement is to distinguish the flow of liquid from the flow of gas in a system where the two will try to separate and travel at different velocities. Flow conditioning in these systems is commonly provided by a horizontal branch-in, vertical-out tee, which acts as a mixer. Cross-correlation flowmeters (see Section 2.5) used by some suppliers apply nuclear techniques to measure the density of the stream twice, a short vertical distance apart, and correlate the fluctuations in density with time; others use electrical characteristics in a similar manner.

As it is difficult to distinguish the differing velocities of liquid and gas, it is common to measure the velocity of one phase and use flow-modeling techniques to estimate the velocity of the other phase.

Most of the techniques are limited by the liquid/gas ratio (LGR). Lean gas streams, with less than 5% liquid, are difficult to measure given that the density of the gas stream can be comparable with that of the liquid phase; at 3000 PSI (21,000 kPa), the gas phase can be on the order of 200 kg/m^3 with the liquid phase perhaps 600 kg/m.^{3} So, a change from 5% liquid to 4% liquid is a 20% variation in liquid, but it will

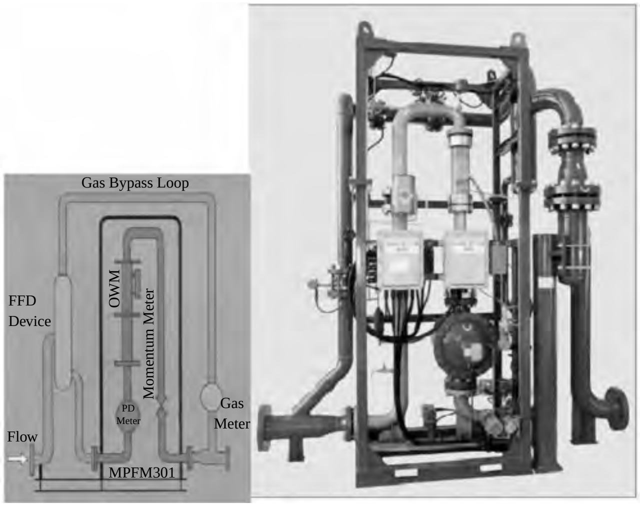

FIG. 2.17b
Agar MPFM 400 high void fraction meter.

only change the density by less than 2%. To avoid this, one supplier (AGAR) uses a centrifugal separator to separate much of the gas from a remaining three-phase mixture, measure this separately, and then mixes it back after the other stream has been measured. Removing 80% of the gas enables the multiphase meter section to be much smaller and more sensitive to the valuable liquid hydrocarbon. The true volumetric flow of the multiphase mixture is measured by a positive-displacement Oval™ gear meter, and venturi techniques and microwave water content distinguish the different phases.

The orientation of a multiphase flowmeter can strongly influence the multiphase flow regime. In systems with medium to high gas content and low velocity, vertical upflow can find the gas phase unable to continuously sweep the liquid phase forward, and the liquid may recycle backward, leading to metering errors and to slug flow. This offers a significant low-end constraint on flow through devices of fixed geometry, which will differ between devices of similar size.

Horizontal-flow installations can show internal segregation, with gas, oil, and water layers traveling at different velocities. Again, maintaining a high velocity helps to mix the phases, but the upstream piping layout may contribute to slugging, which the meter system can do little to correct.

Measurement in multiphase flow is notable by widely varying conditions under nominally constant flow. In slug flow, the liquid fraction can vary between almost zero in the region after a liquid slug to almost 100% inside the slug. Significant fluctuations will also be present in annular and churn flow patterns.

The pressure drop of a liquid slug passing through a venturi meter can be five times higher than the average pressure drop for the flow; the minimum pressure drop in the same flow, corresponding to the *film* region, can be 20% of the average. Therefore, a venturi meter would experience pressure drop varying by 25:1 at a nominally steady multiphase production condition. This is one reason for the

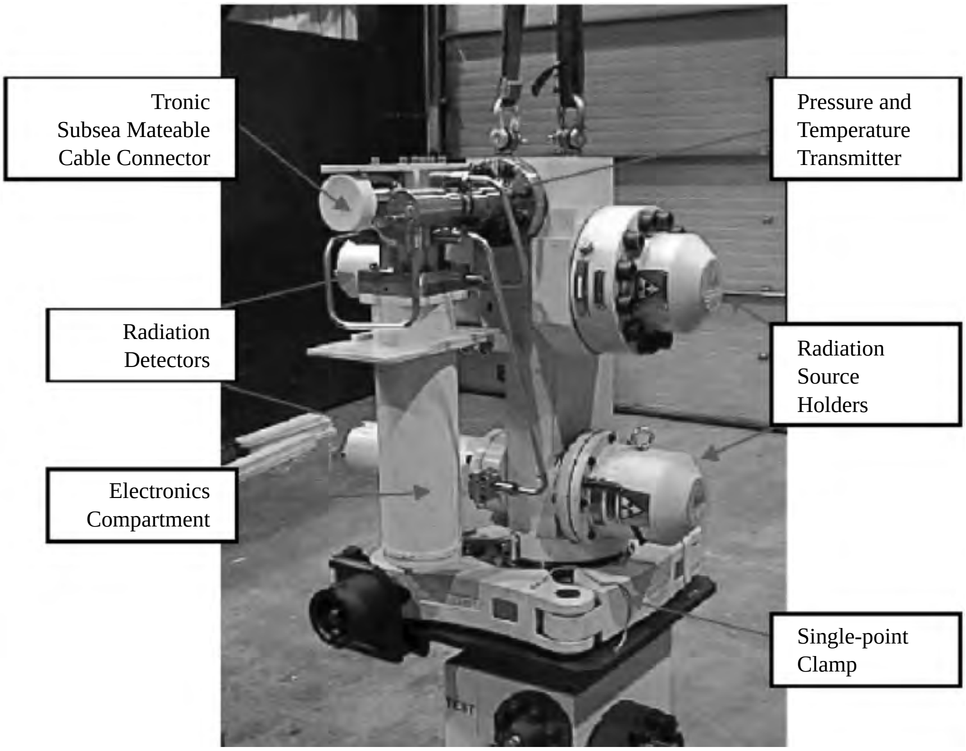

FIG. 2.17c
Aker-Kvaerner "DUET" subsea multiphase flowmeter.

FIG. 2.17d
Aker-Kvaerner "DUET" subsea multiphase flowmeter sectional drawing.

attraction of correlation flowmetering techniques, which do not experience such extremes yet require (and see) appreciable fluctuations in physical properties in the short term.

To reduce the uncertainty associated with measurement of a parameter that fluctuates over such a wide range, many samples are required over a relatively long measuring period.

When a multiphase meter is located at the receiving end of a pipeline, the resulting measurement is influenced by the flow into the line (which may be combined from several wells); the flow patterns developing along the line; the elevation changes along the line, which can trap liquid at low points; the outlet pressure changes; and other fluctuations. As can be imagined, the flow out of such a pipeline varies considerably, and the measuring equipment must be specified to cover the full range of the variation, usually based on inadequate data.

2.18 Positive-Displacement Gas Flowmeters

Flow Sheet Symbol

R. SIEV (1969) **G. M. CRABTREE** (1982, 1995) **JESSE YODER** (2003)

Type of Design	A. Positive-displacement B. High-precision
Design Pressures	Low-pressure designs available from 5 to 100 PSIG (0.34 to 6.9 bars); high-pressure units available up to 1440 PSIG (100 bars)
Design Temperatures	Standard units can be used from –30 to 140°F (–34 to 60°C)
Materials of Construction	Aluminum, steel, plastics, and synthetic elastomers
Inaccuracy	A. 0.5 to 1% of registration B. 0.5% of actual flow over 50:1 range
Costs	A household gas meter for 250 SCFH (7 SCMH) capacity costs about $150. A 50,000 SCFH (1416 SCMH) capacity, diaphragm-type, displacement-type flowmeter in cast aluminum for natural gas service costs about $5000. For natural gas service a 70,000 SCFH (1983 SCMH) rotary positive-displacement meter in cast aluminum costs about $3000.

Positive-displacement gas meters measure by internally passing isolated volumes of gas that successively fill and empty compartments with a fixed quantity of gas. The filling-and-emptying process is controlled by suitable valving and is translated into rotary motion to operate a calibrated register or index that indicates the total volume of gas passed through the meter.

The liquid sealed drum meter is the oldest commercial positive-displacement gas meter (see Figure 2.18a). Developed in the early 1800s, it was used for many years during the gaslight era. This type of meter is still available today and remains one of the most accurate of the displacement-type meters. Applications of the liquid sealed drum meter today

include laboratory work, appliance testing, pilot plant measurements, and as a calibration standard for other meter types.

Some of the inherent difficulties with the liquid sealed meter, such as changes in liquid level and freezing, were overcome in the 1840s with the development of the diaphragm-type positive-displacement meter. Thomas Glover is credited with inventing the first two-diaphragm, sliding-vane meters in 1843, in England. The early meters were constructed with sheepskin diaphragms and sheet metal enclosures. Today, meters are made of cast aluminum with synthetic rubber-on-cloth diaphragms. The principle of operation, however, has remained the same for almost 150 years. However, many material, product design, manufacturing, and calibration changes have occurred during that time.

THE DIAPHRAGM METER

The operating principle of the four-chamber diaphragm meter is illustrated in Figure 2.18b. The measurement section consists of four chambers formed by the volumes between the diaphragms and the center partition and between the diaphragms and the meter casing. Differential pressure across the diaphragms extends one diaphragm and contracts the other, alternately filling and emptying the four compartments. The control for the process is through the "D" slide valves that are synchronized with the diaphragm motion and timed to produce a smooth flow of gas by means of a crank mechanism. The crank and valve mechanism is designed and adjusted with no *top-dead-center* to prevent the meter from stalling. The rotating crank mechanism is connected through suitable gearing to the index, which registers the total volume passed by the meter.

The rating of small diaphragm meters is usually specified in cubic feet per hour (0.03 m^3/h) of 0.6 specific gravity gas that results in a pressure drop of 0.5-in. water column (0.13 kPa). Larger meters are often rated for flow at 2 in. water column (0.5 kPa) differential.

Since most meters are sold to gas utility companies that sell natural gas with a specific gravity of approximately 0.6, it may be necessary to determine the flow rating of a diaphragm for other gases. This is accomplished by the following equation:

$$Q_n = Q_c\sqrt{\frac{(SG)_c}{(SG)_n}} \qquad \textbf{2.18(1)}$$

where

Q_n = new flow rating (ft^3/h)*
Q_c = meter rating (ft^3/h)
$(SG)_c$ = specific gravity for which meter is rated (usually 0.6)
$(SG)_n$ = specific gravity of new gas

The inaccuracy of diaphragm positive-displacement meters is typically ±1% of registration over a range in excess of 200:1. This accuracy is maintained over many years of service. Deterioration of meter accuracy is rare unless unusual conditions of dirt, wear, or moisture in the gas are present.

ROTARY METERS

Rotary meters have one or more rotating parts that implement their measurement operation. Meter design enables them to operate at higher rates of speed than diaphragm meters. For this reason, they can meter higher gas volumes than diaphragm meters. In many cases, rotary meters have built-in temperature compensation to avoid measurement errors based on temperature variations.

---

* For SI units, refer to Appendix.

There are three types of rotary positive-displacement meters in use today for gas flow measurement:

- Lobed impeller
- Sliding vane
- Rotating vane

The Lobed Impeller

The lobed-impeller meter (described in Section 2.19, “Positive-Displacement Liquid Meters and Provers”) is used for high-volume measurement up to 100,000 ft^3/h (up to 3000 m^3/h). This meter has a housing upon which two figure-eight impellers are mounted. The rotation is caused by a pressure differential that is set up across the meter. In this meter, the close clearance of moving parts requires the use of upstream filters to prevent deterioration of accuracy performance. Typically, the inaccuracy of lobed-impeller meters is ±1% over a 10:1 flow range at pressure drops of approximately 0.1 PSI (0.7 kPa).

Sliding-Vane Meters

A sliding-vane meter has four radial vanes in a single rotating drum that is eccentrically mounted. The rotation of the drum is caused by differential pressure against the vanes. When the drum revolves a single time, four volumes of gas are passed. The meter counts the number of revolutions to provide a readout of total volume.

Rotating-Vane Meters

The rotating-vane meter, as illustrated in Figure 2.18c, is an improvement on the lobed-impeller meter. Here, four compartments formed by the vanes rotate in the same direction as a rotating gate. The fixed volumes of gas are swept through the meter by the vanes, which are passed from inlet side to outlet side through the gate. Gears synchronize the motion of the vanes and gate. Typical inaccuracy for the rotating vane meter is ±1% over a 25:1 range at pressure drops of 0.05 in. of water column (0.013 kPa).

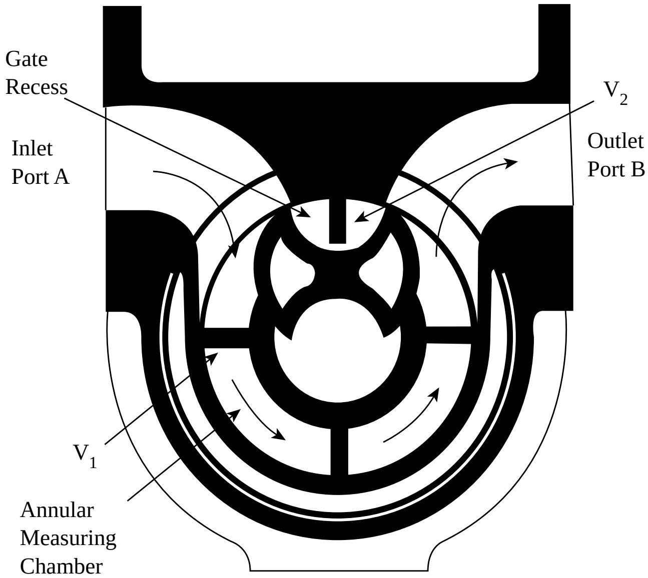

FIG. 2.18c
The rotating-vane meter.

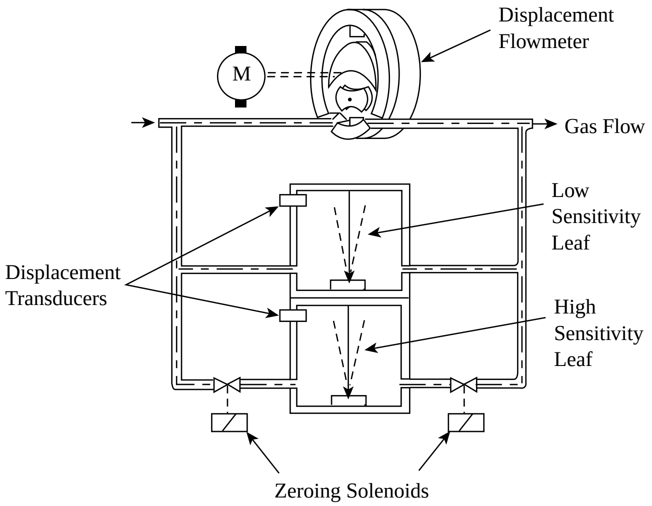

FIG. 2.18d
High-precision displacement flowmeter for gas service. (Courtesy of Pierburg Instruments.)

HIGH-PRECISION GAS FLOWMETER

For the high-precision measurement of airflows in engine test rigs, positive-displacement flowmeters are used. High precision and high rangeability are achieved by eliminating the pressure drop and thereby eliminating the slip or leakage flows. This is achieved by providing a motor drive for the displacement element and using it to introduce only as much driving energy as is needed to keep the pressures at the inlet and outlet of the meter equal (Figure 2.18d). This flowmeter uses high-sensitivity leaves to detect the pressure differential and displacement transducers to detect the deflection of the leaves. The flowmeter is also provided with automatic rezeroing capability through periodic solenoid isolation of the high-sensitivity leaves.

This flowmeter is claimed to provide a reading with only a 0.25% error over a 50:1 range and a 0.5% error over a 100:1 range. The meter is designed for ambient operating temperatures and 30 PSIG (2 bars) operating pressures. The different models of this flowmeter can detect air or gas flows from 0.3 to 1500 ACFM (0.6 to 2500 ACMH).

APPLICATION NOTES

All displacement gas meters can be used to measure any clean, dry gas that is compatible with the meters’ construction materials and flow and pressure ratings. Dirt and moisture are the worst enemies of good meter performance; inlet filtering should be used when indicated. Since all gases change

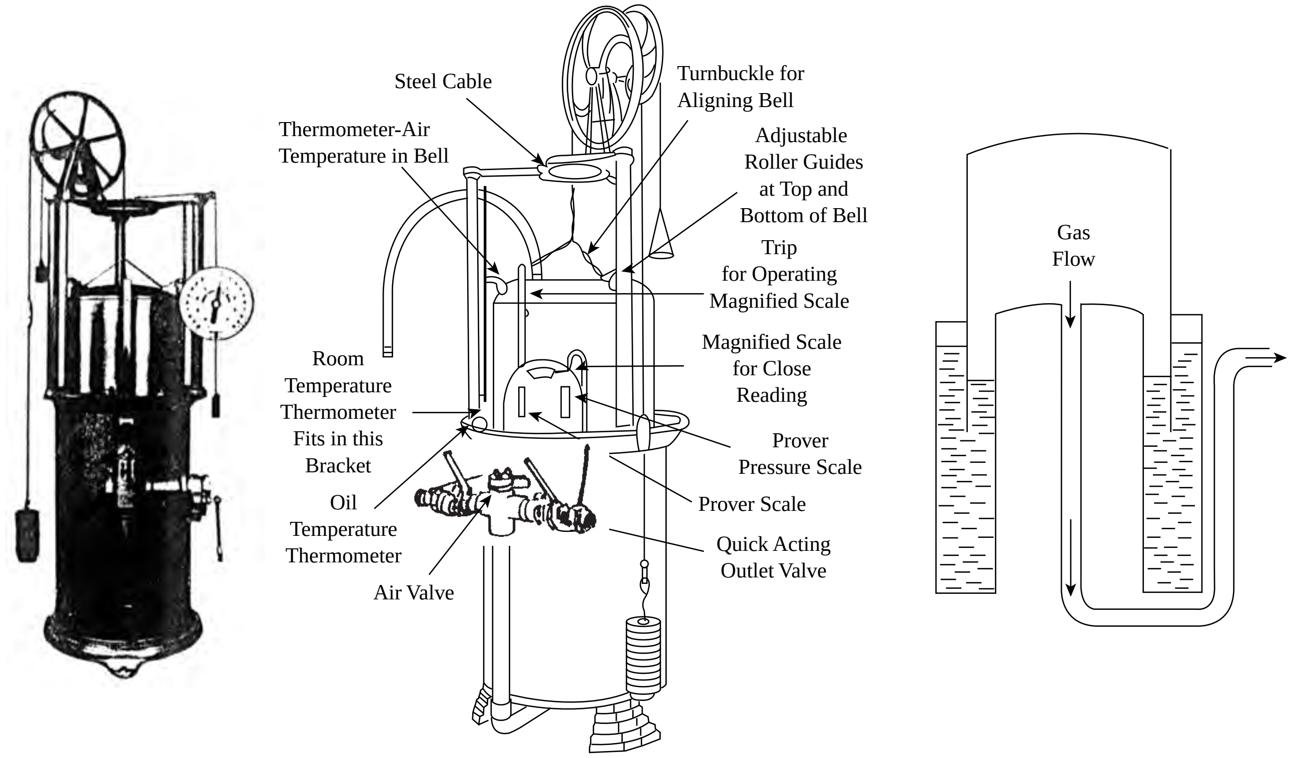

FIG. 2.18e
The construction of a meter prover.

volume with pressure and temperature changes, these sources of possible error should be controlled or compensated. The national standard cubic foot of fuel gas is at 14.73 PSIA and 60°F; significant deviation from these values should be accounted for in measuring standard gas volumes. At elevated pressures and lower temperatures, a deviation from the ideal gas laws occurs, requiring the application of a compressibility factor to the measured volumes.

TESTING AND CALIBRATION

The testing (or *proving,* as it is called in the gas utility industry) of gas meters is usually done using a special type of gasometer referred to as a *prover.* The construction of a meter prover is shown in Figure 2.18e. An accurately calibrated “bell” of cylindrical shape is sealed over a tank by a suitable liquid. The lowering of the bell discharges a known volume of air through the meter under test to compare the volumes indicated. Meter provers are typically supplied to discharge volumes of 2, 5, and 10 ft^3 (0.06, 0.15, and 0.3 m^3), and larger provers of several hundred cubic foot capacity are in use by meter manufacturers and gas utility companies. The volumetric inaccuracy of meter provers is on the order of ±0.1% as determined by physical measurement and comparison with more accurate volumetric standards.

Other standards used to calibrate gas meters are calibrated orifices and critical flow nozzles. These devices compare rates of flow rather than fixed volumes and typically have inaccuracy ratings from ±0.15 to ± 0.5%.

ADVANTAGES

The chief advantages of positive-displacement flowmeters for gas applications are their high accuracy and wide rangeability. The chief disadvantages of these meters are maintenance costs and the fact that wear can degrade their performance.

Flow Sheet Symbol

R. SIEV (1969) **J. B. STODDARD** (1995) **B. G. LIPTÁK** (1982, 2003)

Types of Designs	A. Impeller, propeller, turbine B. Nutating disc C. Oval gear, C-1 if toothless D. Piston E. Rotating vane F. Viscous helix G. High-precision, specialized, low-flow, and so on H. Prover
Design Pressure	To 3000 PSIG (21 MPa)
Design Temperature	From –450°F (–268°C) to 560°F (293°C)
Strainer Required	Yes
Materials of Construction	Bronze, cast iron, aluminum, steel, stainless steel, Monel®, Hastelloy®, and plastics
Size Range	0.25 to 16 in. (6 to 406 mm)
Flow Range	From 0.01 GPH to 20,000 GPM (0.04 l/h to 75 m^3/m)
Rangeability	From 3:1 to >100:1 (for specialized designs), 10:1 about average
Inaccuracy	Ranges from ±0.1 to ±2% of actual flow; typical average error ±1/2% of actual flow, dropping as size increases
Cost	A 1 in. (25 mm) bronze disk-type water meter with 2 to 3% error costs about $750. Plastic-piston meters for laboratory applications in 1- and 2-in. (25- and 50-mm) sizes are $600 and $1200. A 1-in. (25-mm) toothless oval meter for high-viscosity service in type 316 SS is $2500. A 1-in. (25-mm) oval flowmeter for LPG service with ductile iron housing complete and valve, vapor eliminator, and register with printer, about $3000. A 2-in. (50-mm) piston meter, in steel construction, having 0.5% error and provided with register, preset valve, and ticket printer costs about $5000 to $6000. A 6-in. (150-mm) flanged, bi-rotor meter for fuel oil service with ductile iron preset valve, impulse contactor, large dial register, and ticket printer costs about $12,000 to $15,000. Prover costs range from $50,000 to $300,000 depending on size, materials of construction, and control accessories.

Positive-displacement meters split the flow of liquids into separate known volumes, the size of which are based on the physical dimensions of the meter. The meters act as counters or totalizers of the number of these volumes as they pass through. These mechanical meters have one or more moving parts in contact with the flow stream and physically separate the fluid into increments. Energy to drive the moving parts is extracted from the flowing stream itself, resulting in a pressure loss through the meter. The error of these meters depends on the clearances between the moving and stationary parts. The smaller the clearance and the longer the length of the leakage path, the better the precision of the meter. For this reason, meter accuracy tends to increase with larger meter sizes.

OVERVIEW

Positive-displacement meters for liquids are among the most widely used volumetric flow sensors for batch-size measurement applications and when fluid is bought and sold on a contract basis. A wide variety of meters, covering a broad spectrum of requirements, are available. Their good accuracy, wide rangeability, and ready availability warrant their consideration when selecting a volumetric meter.

These flowmeters are especially useful when the fluid to be measured is free of any entrained solids. A typical example is the measurement of water delivered to homes, factories, office buildings, and so forth. On the other hand, some designs are well suited for viscous liquid applications.

Wear on parts, with the resulting change in clearance dimensions, introduces the major source of error over the service life of the meter. Leakage error increases with dropping process fluid viscosity but remains relatively constant with time. In larger meters, temperature variations and the resulting change in fluid density and viscosity must also be taken into consideration.

Positive-displacement meters provide good accuracy (±0.25% of flow) and high rangeability (15:1). They are repeatable to ±0.05% of flow. Some designs are suited for high- or variable-viscosity services (up to or even exceeding 100 cSt). They require no power supplies for their operation (only for remote transmission) and are available with a wide variety of readout devices. Their performance is virtually unaffected by upstream piping configuration. Positive-displacement meters are excellent for batch processes, mixing, and blending applications.

These meters are simple and easy to maintain by regular maintenance personnel using standard tools. No specially trained crews or special calibration instruments are needed. On the other hand, because of the close tolerances of the moving parts, they are subject to wear and maintenance, and recalibration is required at frequent intervals. On corrosive services, this may result in high costs.

Positive-displacement meters require relatively expensive precision-machined parts to achieve the small clearances that guarantee their high accuracy. From this it follows that the liquids metered must be clean, because wear can rapidly destroy precision. Contaminant particle size must be kept below 100 microns, and most of these meters are not adaptable to the metering of slurries. Positive-displacement flowmeters are expensive in larger sizes or in special materials. They can be damaged by overspeeding and can require high pressure drops. In general, they are not suited for dirty, nonlubricating, or abrasive services.

ROTATING LOBE AND IMPELLER (TYPE A)

In this type of meter, two lobed impellers rotate in opposite directions within the housing (Figure 2.19a). They are geared together to maintain a fixed relative position, so a fixed volume of liquid is displaced by each revolution. A register is geared to one of the impellers. These meters are normally built for 2- to 24-in. (50- to 610-mm) pipe sizes, and their capacities (upper limits of their ranges) range from 8 to 17,500 GPM (30.4 to 66,500 l/min).

The advantages of this design include good repeatability (0.015%) at high flows, the availability of a range of materials of construction, and high operating pressures (1200 PSIG or 8300 kPa) and temperatures (400°F or 205°C).

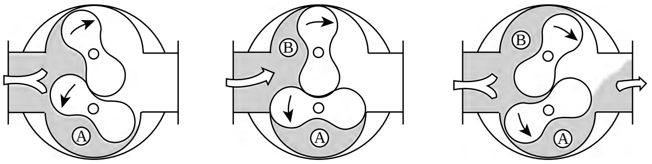

FIG. 2.19a
Rotating lobe meter.

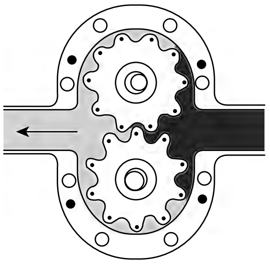

FIG. 2.19b
Rotating impeller flowmeter. (Courtesy of Flowdata Inc.)

The disadvantages include loss of accuracy at low flows because of the large size, heavy weight, and high cost.

The rotating impeller design is illustrated in Figure 2.19b. It has only two moving parts: the two impellers, which are made out of wear-, abrasion-, and corrosion-resistant thermoplastics. Operation is based on a proximity switch sensing the passage of magnets that are implanted in the impeller lobes and transmitting the resultant pulses to a counter. Units are available from 0.125- to 4-in. (3- to 100-mm) sizes with up to 3000 PSIG (21 MPa) pressure and 0 to 400°F (205°C) temperature ratings. The design is suited for high-viscosity operation, and the claimed precision and rangeabilities are also high.

NUTATING DISK (TYPE B)

The nutating disk meter is used extensively for residential water service. The moving assembly, which separates the fluid into volume increments, consists of an assembly of a radially slotted disk with an integral ball bearing and an axial pin (see Figure 2.19c). This part fits into and divides the metering chamber into four volumes—two above the disk on the inlet side and two below the disk on the outlet side. As the liquid flows through the meter, the pressure drop from inlet to outlet causes the disk to wobble, or *nutate*. For each cycle, the meter displaces a volume of liquid equal to the volume of the metering chamber minus the volume of the disk assembly. The end of an axial pin, which moves in a circular motion, drives a cam that is connected to a gear train and to a totalizing register. This flowmeter measures the liquids with an error range of about ±1 to 2% of actual flow. It is built only for smaller pipe sizes. Its temperature range is from –300 to 250°F (–150 to 120°C), and its maximum working pressure rating is 150 PSIG (1034 kPa). On cold water service, the capacity ranges are approximately as follows:

Size	*Capacity*
0.5 in. (13 mm)	2 to 20 GPM (7.5 to 75 l/min)
1 in. (25 mm)	5 to 50 GPM (19 to 190 l/min)
1.5 in. (38 mm)	10 to 100 GPM (38 to 380 l/min)
2 in. (51 mm)	16 to 160 GPM (61 to 610 l/min)

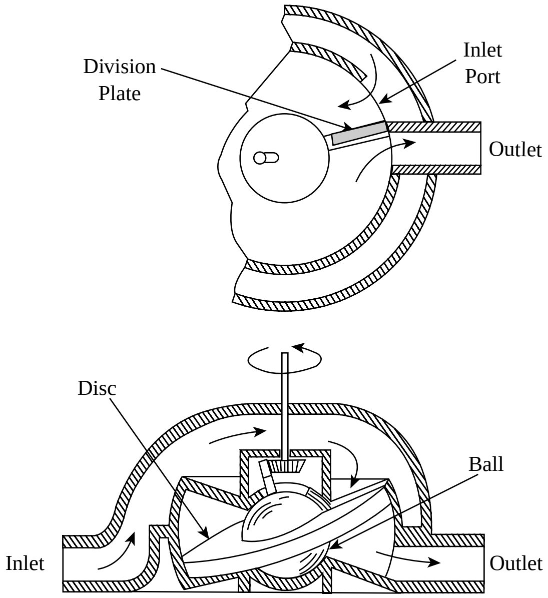

FIG. 2.19c
Nutating disk meter.

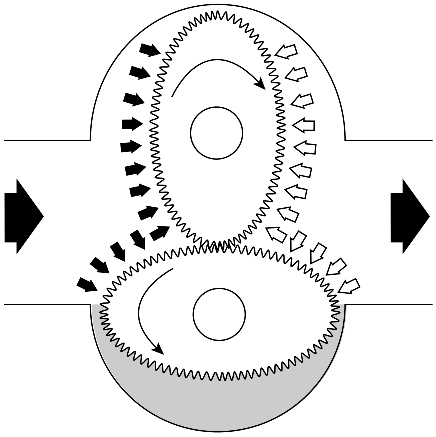

FIG. 2.19d
Oval-gear flowmeter. (Courtesy of Brooks Instrument.)

OVAL-GEAR FLOWMETERS (TYPE C)

A special variety of the rotating-lobe flowmeter is made using oval-geared metering elements. In this design, shown in Figure 2.19d, a precise volume of liquid is captured by a crescent-shaped gap, which is formed between the housing and the gear. This volume is then carried to the outlet, and this movement causes the gears to rotate an output shaft through which the register operates.

In new condition, when the slippage between the oval gears and the housing is small, and when both the flow rate and viscosity are high (>1 GPM and >10 cP, respectively), these flowmeters can operate at errors as low as 0.1% of actual flow. At lower flow rates, the relative proportion of the "slip" leakage increases, and so accuracy drops to about 0.5% of actual flow. Viscosity variations will also affect the slip flow. If a meter was calibrated using water, a fluid with a viscosity of 1 cps, it will have a 1.2% high error if the viscosity rises to 100 cps.

These flowmeters are available in sizes from 0.25 to 16 in. (6 to 406 mm). When the viscosity of the process fluid is between 1.5 and 10 cps, they can handle flow ranges from 0.05 to 0.5 up to 250 to 5000 GPM (from 0.2 to 2 up to 950 to 19,000 l/min). They are available in a wide range of construction materials, including brass, carbon steel, type 316 stainless steel, and Alloy 20®. Operating pressure ratings are available up to 1450 PSIG (10 MPa) and operating temperatures up to 560°F (293°C).

The servo version of this meter has been introduced to completely eliminate slip leakage in smaller sizes (0.2 to 40 GPH or 0.8 to 150 l/h). In this design, the servomotor drives the oval-gear elements at a speed that eliminates the pressure drop across the meter and keeps the outlet pressure the same as the inlet. This eliminates the motivating force, which causes the slip flow and therefore increases accuracy at low flows or under variable viscosity conditions.

A smooth, toothless oval gear design is also available in 1-in. (25-mm) size with screwed connections. It can handle viscosities up to 100 cSt and is rated for 3000 PSIG (21 MPa) and 450°F (232°C). Its linear range is 2 to 25 GPM (7.5 to 94 l/min). If it is used with a nonlinear Hall-effect pickup, its range is claimed to increase to 0.02 to 25 GPM (0.075 to 94 l/min). The meter is made of type 316 stainless steel, its inaccuracy is within its linear range is 0.25% of actual flow, and it is provided with accessories for remote readouts, both analog and digital.

PISTON DESIGNS (TYPE D)

Reciprocating Piston

The oldest of the positive-displacement meters, this meter is available in many forms, including multi-piston meters, double-acting piston meters, rotary valves, and horizontal slide valves. Figure 2.19e shows the schematic of a reciprocating piston meter. Here, a crank arm is operated by the reciprocating motion of the pistons, and this motion drives the register. These meters are widely used in the petroleum industry and can reach the precision of ±0.2% of actual flow.

Another version of this meter is shown in Figure 2.19f. In this design, the liquid enters the cylinder on the left, forcing the piston down by lever action of the control plate. As a result, the piston on the right is forced up, discharging the liquid first into the inner portion of the valve, then down through the center of the meter and out through the meter discharge outlet.

Oscillating Piston

The moving portion of the oscillating piston meter consists of a slotted cylinder that oscillates about a dividing bridge that separates the inlet port from the outlet port. Spokes connect this cylinder to a pin located on the axis of the cylinder. As the cylinder oscillates about the bridge (Figure 2.19g) the pin makes one rotation per cycle. This rotation is transmitted to the gear train and registers either directly or magnetically through a diaphragm. This meter, in addition to being in common usage for the measurement of domestic water has the capability of handling clean viscous and/or corrosive liquids. This type of flowmeter is normally used in smaller pipelines (2 in./50 mm or below) to measure low flow rates.

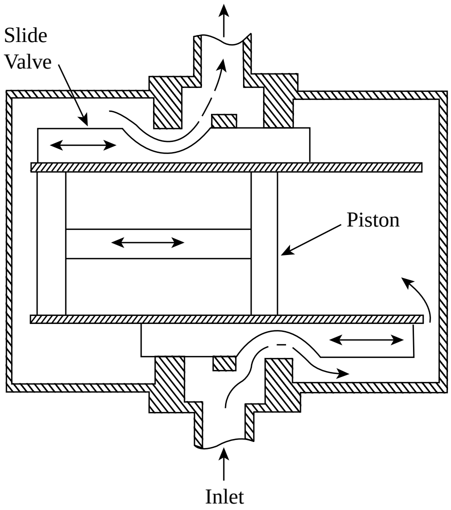

FIG. 2.19e
Reciprocating piston meter.

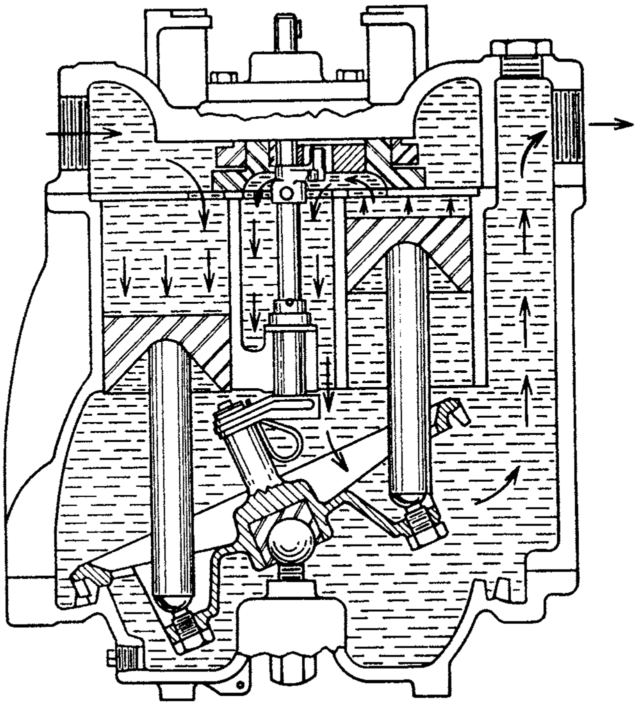

FIG. 2.19f
Cutaway of reciprocating piston meter with two opposing pistons.

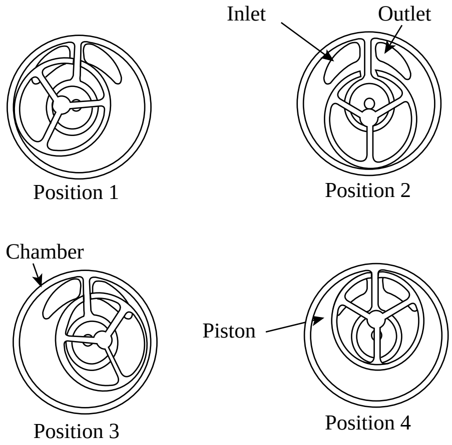

FIG. 2.19g
Oscillating piston meter.

Measurement errors are in the range of ±1% of actual flow. Metering accuracies are increased by reducing the clearance spaces to 0.002 in. (5 microns). Such small clearances do necessitate pre-filtering the entering fluid in order to remove larger particulars. The cases are usually made of cast iron, bronze, or steel, while the chamber and piston materials are usually made of bronze, aluminum, and Ni-Resist. Iron and bronze meters are good for up to 150 PSIG (1034 kPa) and 200°F (93°C), while steel meters can be used up to 400 PSIG (2760 kPa) and 300°F (149°C).

ROTATING VANE (TYPE E)

This flowmeter has spring-loaded vanes that seal increments of liquid between the eccentrically mounted rotor and the casing (Figure 2.19h) and transport it from the inlet to the outlet, where it is discharged as a result of the decreasing volume. This type of meter is widely used in the petroleum industry and is used for such varied services as gasoline and crude oil metering, with ranges from a few gallons per minute of low-viscosity clean liquids to 17,500 GPM (66.1 m^3/m, or 25,000 bbl/h) of viscous particle-laden crude oils. Precisions of ±0.1% of actual flow are normal, and ±0.05% has been achieved in the larger meters.

This instrument is built from a variety of materials and can be used at temperatures and pressures up to 350°F (177°C) and 1000 PSIG (6.9 MPa).

Another rotary design is illustrated in Figure 2.19i. Here, an abutment rotor operates in timed relation with two displacement rotors and at half their speed.

VISCOUS HELIX (TYPE F)

The helix flow transducer (Figure 2.19j) is a positive-displacement device utilizing two uniquely nested, radically pitched helical rotors as the measuring elements. Close machining tolerances ensure minimal slippage and thus high accuracy. The design of the sealing surfaces provides a ratio of longitudinal to lateral sealing to minimize pressure drop, especially with high-viscosity liquids.

The large inlet size of the progressive cavity allows for the passage of gels, fines, agglomerates, and even undissolved

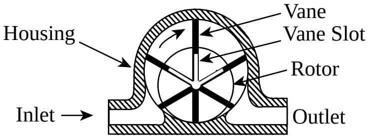

FIG. 2.19h
Rotating-vane meter.

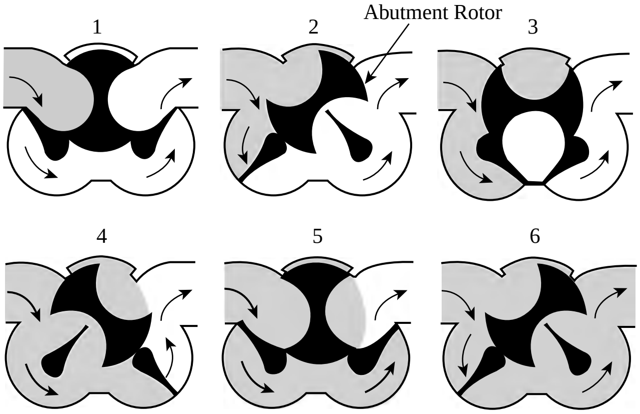

FIG. 2.19i

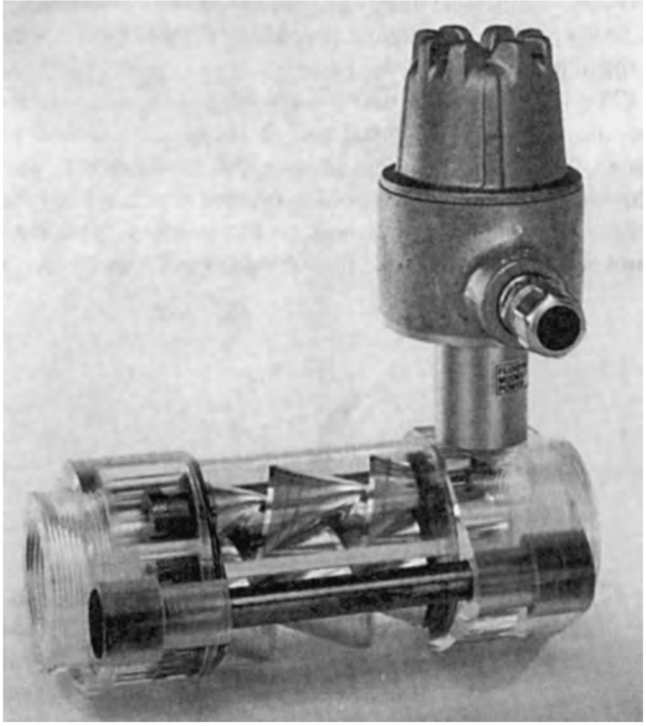

FIG. 2.19j
Viscous helix flowmeter. (Courtesy of Fluidyne Instrumentation.)

or hydraulically conveyed solids. The meter can measure flow rates from 0.5 to >4000 GPM (2 to 15,000 l/min). This flow sensor is available in sizes from 1.5 in. to 10 in. (38 to 250 mm) and can operate at temperatures up to 600°F (315°C) and at pressures up to 3000 PSIG (21 MPa). It is a high-pressure-drop device requiring a minimum of 10 PSID (69 kPa) for its operation at full flow. Its turndown can reach 100:1, and its metering error is claimed to be under 0.5% of actual flow.

Available design variations include versions that are heated to maintain line temperatures for metering melted solids or polymers. Also available are units in sanitary construction. This meter is suited for high-viscosity (over 1000 cps) and for slurry services. The straight-through design with no pockets is also available to simplify cleaning. It is recommended that the process fluids be filtered by mesh size 30 filters before they enter this flowmeter.

HIGH-PRECISION AND SPECIALIZED (TYPE G)

For the high-precision measurement of fuel and alcohol flows in engine and carburetor test rigs and other applications, specialized positive-displacement flowmeters are often used. Their high precision and high rangeability are achieved by eliminating the pressure drop and thereby eliminating the slip or leakage flows. This is achieved by providing a motor drive for the displacement element and using it to introduce as much pumping energy as is needed to equalize the pressures at the inlet and outlet of the meter (Figure 2.19k). This flowmeter uses a high-sensitivity piston to detect the pressure differential and utilizes photoelectric sensors to detect the position of the piston. The flowmeter is also provided with a variable-speed controller, which adjusts the drive speed whenever the pressure differential is other than zero. Because the response time of the system is less than 0.5 sec, the flowmeter is able to follow most dynamic flow transients or can be used on short-duration tests.

This flowmeter is claimed to provide a reading with only 0.25% error over a 50:1 range and a 0.5% error over a 100:1 range. The meter is designed for ambient operating temperatures and for up to 150 PSIG (10 bars) operating pressures.

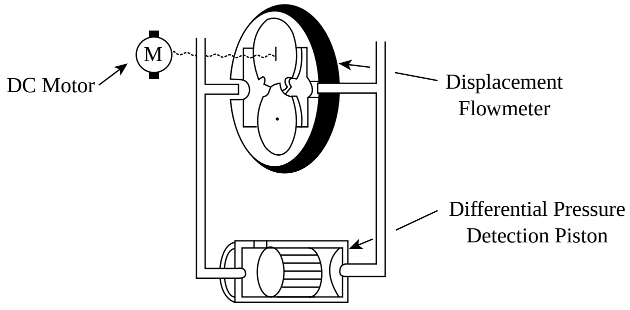

FIG. 2.19k
High-precision positive displacement flowmeter. (Courtesy of PLU, Pierburg GmbH.)

The different models of this flowmeter can detect diesel, gasoline, and alcohol flows from 0.04 to 40 GPH (0.15 to 150 l/h). Because vapor lock is a common problem in fuel flow metering, the unit is provided with a vapor separator.

PROVERS (TYPE H)

All flowmeters that consist of moving and stationary parts that rub against each other (such as positive-displacement and turbine type flowmeters) require periodic recalibration. This is necessary because the clearance space and the slip or clearance flow through that space increase with wear. Recalibration can be done by removing the flowmeter from the pipeline and sending it to a calibration laboratory, or it can be done in line. The flow provers that allow for inline recalibration without interruption of the process flow are described below.

As shown in Figure 2.19l, provers consist of a smooth-walled, precalibrated displacement chamber and a barrier piston within it. Usually, a follower rod is attached to the back side of the piston, which is connected to position sensors. The calibrated flow rate is obtained by dividing the volume of the prover with the time it takes to displace its volume. This calibrated flow rate is then compared to the reading of the flowmeter being calibrated.

To minimize the disturbance to the process flow, inline ballistic flow provers have been developed. In these units (Figure 2.19l), the piston is constructed so that it will not disrupt the flow in the line. Therefore, the prover can be permanently installed in an operating pipeline, upstream or downstream of the flowmeter being calibrated. The poppet valve within the piston assembly allows for the piston to be withdrawn to the start position after a calibration run while the process flow continues undisturbed. Both portable (Figure 2.19m) and permanently installed provers are available, and the calibration can be manual or automatic.

The repeatability of provers is around 0.02% of the actual flow if the seals are tight. It is recommended to periodically check the seals by closing a tight shutoff valve downstream of the prover and applying nitrogen pressure to the upstream

face of the piston. If this results in any movement of the piston, the seals need maintenance. Provers are available for up to 3000 PSIG (21 MPa) operating pressure and 165°F (74°C) operating temperature; they can detect flow rates from 0.001 GPM (0.004 l/min) to 20,000 GPM (75,000 l/min). The calibrated displacement volume of provers can range from a fraction of a gallon to several hundred gallons. Large provers can fit on truck beds or trailers (Figure 2.19m).

ACCESSORIES AND INTELLIGENT ELECTRONICS

Standard accessories for positive-displacement include strainers; air release assemblies, which remove all the vapors from the flow stream before it enters the meter; automatic batch shutoff valves, which provide two-stage closure for full and dribble flow operation; temperature compensators; manual and/or automatic ticket printers; and pulse generators for remote indication, totalization, and other forms of data monitoring and/or control. In addition to the totalizer-type digital readout registers, flow rate indication can also be provided. Impulse contactors are also available to actuate predetermining counters or to serve as electrical interlocks that actuate flow ratio systems, pumps, valves, solenoids, alarms, printers, sampling devices, and so on. Pneumatic pulse generators are still available and sometime used in explosion-proof areas for interfacing with pneumatic batch controllers.

The intelligent positive-displacement meters are usually provided with magnetic or Hall-effect-type pickup and frequency outputs from solid-state pulse transmitters. The frequency outputs can be sent to central computers or DCS/PLC systems over the data highways and can also be converted to 0- to 10-VDC or 4- to 20-mA analog signals.

In household utility applications, there is substantial economic justification for substituting a telemetering system, operated either on the telephone lines or by radio, replacing the current system (human meter readers). It is also feasible to combine the readings of electric, water, and gas meters of a household into a single transmitter and to transmit that information to the appropriate utilities without the need for a meter reader to visit the home or apartment. The economic advantages of this type of metering is not only in labor savings but also in the speed and frequency at which the data can be obtained and used for billing or other purposes.

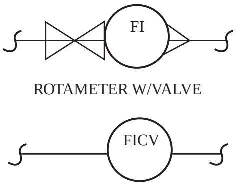
2.20 Purge Flow Regulators

E. L. SZONNTAGH (1995) **B. G. LIPTÁK** (2003)



Flow Sheet Symbol

Applications	Purge flow regulators serve the regulation of low flow rates of air, gas, or liquids. They are most often used in air bubblers or in purging electrical housings (in explosion-proof areas) and in purging optical windows of smokestack analyzers. Water and liquid purge meters are most often applied to protect process connections from plugging.
Purge Fluids	Air, nitrogen, and liquids
Operating Pressure	Up to 450 PSIG (3 MPa)
Operating Temperature	For glass tube, up to 200°F (93°C)
Ranges	Range is from a minimum of 0.01 cm^3/min for liquids and from 0.5 cm^3/min for gases. A 0.25-in. (6-mm) glass tube rotameter can handle 0.05 to 0.5 GPM (0.2 to 2 l/min) of water or 0.2 to 2 SCFM (0.3 to 3 cmph) of air.
Inaccuracy	Generally, 2 to 5% of range (laboratory units are more accurate)
Costs	A 150-mm glass-tube unit with 0.125-in. (3-mm) threaded connection, in type 316 stainless steel, and a 16-turn high-precision valve will cost about $300; the same with an aluminum frame and a standard valve is about $125. Adding a differential-pressure regulator of brass or aluminum construction costs about an additional $150 (in stainless steel, about $500). For highly corrosive services, all-Teflon®, all-PTFE, all-PFA, and all-CTFA units are available that, when provided with valves, cost from $500 with 0.25-in. (6-mm) to $1500 with 0.75-in. (19-mm) connections.

Purge flows are low flow rates of either gases or liquids. They serve to protect pressure taps from plugging or being contacted by hot or corrosive process fluids. Inert gas purging can also serve to protect electrical devices from becoming ignition sources by maintaining a positive pressure of incombustible gases inside their housings. In the case of analyzers, purging protects the cleanliness of the optics.

DETECTION OF LOW FLOWS

The low flow rates of purge media can be detected by a variety of devices. They include capillaries, miniature orifices, metering pump, positive-displacement, thermal, and variable-area-type flow sensors. Most of these devices are detailed in other sections of this chapter. Capillary flow elements (Section 2.9) are ideal for the measurement of low flow rates. They can also be combined with thermal flowmeters to provide flow regulators with higher precision and higher rangeability—but also higher cost (Section 2.13). Integral orifices (Section 2.15) can also be used in both gas and liquid flow measurement, whereas positive-displacement meters and metering pumps are most often used to detect the flows of liquids (Sections 2.14 and 2.19). In addition, the second volume of the *Instruments Engineers' Handbook* ("Process Control") includes a section that describes self-contained flow regulators.

Only one purge flow regulator design is not covered in other parts of this three-volume handbook: the rotameter-type purge meter. This is the least expensive and most widely used purge meter design, and it is described in this section.

PURGE ROTAMETERS

Purge flowmeters are widely used devices and are probably the most widely used form of the variable-area flowmeter, the rotameter. These meters are inexpensive and are intended for the measurement and control of low flow rates. Most purge meters are used on inert gas or water services at low flow rates, where measurement accuracy is not critical. These units are reasonably repeatable, which is all that is required in many purge applications where, as long as a low flow rate is maintained, it is not critical to know how much it is. The flow rates through the purge meters are adjusted by needle-type throttling valves as shown in Figure 2.20a.

The metering needle valves are usually multiple-turn units provided with long stems. The opening around their needle-shaped plugs is very small and can approach capillary dimensions. Figure 2.20b shows a high-precision needle valve provided with a vernier-type scale that allows a more accurate setting of the valve opening. The dual scale increases the precision and reproducibility of setting by subdividing the smallest reading of the first scale onto the second. The flow rate through these devices is a function of the opening in the valve, the pressure differential across that opening, and both the density and the viscosity of the purge media. Table 2.20c provides information on the density and viscosity of a number of purge gases.

When the purge flowmeter is combined with a differential-pressure regulator (Figure 2.20d), it becomes a self-contained flow controller. The purge flow is fixed by adjusting springs 1 and 2 for a particular pressure difference, usually in the range of about 60 to 80 in. (150 to 200 cm) of water. This constant pressure drop ($P_2 - P_o$) is than maintained across

the flow control valve (V). The configuration in Figure 2.20d maintains the outlet pressure (P_o) constant by compensating for any variation in the inlet pressure P_i by changing the regulator valve opening.

Other purge flowmeter designs are also available that work in a reverse configuration by keeping the inlet pressure P_i constant and allowing the outlet P_o to vary. In these designs, the constant pressure drop across the valve (V) is maintained to equal ($P_i - P_2$) instead of ($P_2 - P_o$) being kept constant. The gas flows through purge flow controllers are usually adjustable in a range of 0.2 to 2 SCFH (6 to 60 slph). The error or inaccuracy is usually 5% of full scale over a range of 10:1. The standard pressure and temperature ratings are 150 to 300 PSIG (1 to 2 MPa) and 212 to 572°F (100 to 300°C).

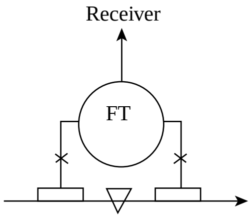
2.21 Segmental Wedge Flowmeter

B. G. LIPTÁK (1995, 2003)



Flow Sheet Symbol

Applications	Clean, viscous (down to Rd no. = 500) solids containing fluids, gas, and steam
Sizes	0.5- to 24-in. (12- to 610-mm) diameter pipes
Designs	In the smaller sizes (0.5 to 1.5 in.), the wedge can be integral; for larger pipes, remote seal wedges are used with calibrated elements
Wedge Opening Height (H)	From 0.2 to 0.7 of pipe inside diameter
Pressure Drops	25 to 200 in. H_2O (6.2 to 49.8 kPa)
Materials of Construction	Carbon, type 316 SS, Hastelloy®, Monel® wetted parts; special wedge materials like tungsten carbide are also available. Sealing gasket can be silicate ceramic filled TFE. Chemical tee gasket up to 645°F (340°C) can be graphite.
Design Pressure	300 to 1500 PSIG (20.7 to 103 bars) with remote seals, up to 3000 PSIG (21,000 kPa) in 1-in. size and below
Design Temperature	In sizes 1.5 in. and below, 300°F (148.9°C); higher temperature designs are available from –40 to 700°F (–40 to 370°C) but have been used in higher-temperature processes up to 850°F (454°C).
Inaccuracy	Error, if uncalibrated, is 5% of actual flow. When the elements are individually calibrated, the error drops to 0.5 to 0.75% of actual flow; to this one should add the d/p cell error contribution of about 0.25% of full scale. The total error over a 3:1 flow range is usually not more than 2% of actual flow
Cost	A 3-in. (75-mm) calibrated stainless-steel element with two stainless chemical tees and with an electronic d/p transmitter provided, and provided with remote seals, is about $4000.
Partial List of Suppliers	ABB Automation Instrumentation Division (www.abb.com/us/instrumentation)

The shape of the flow opening of a segmental wedge flowmeter is similar to that of a segmental orifice except that the obstruction to flow is less abrupt (more gradual). Also, the sloping entrance somewhat resembles the shape of the various flow tubes.

The wedge flowmeter was primarily designed for slurry applications. Its main advantage is its ability to operate at Reynolds numbers as low as 500 to 1000.[1] This is in contrast with sharp-edged orifices, venturies, and flow nozzles, where the square root relationship between flow and pressure drop requires a Reynolds number well above 10,000 (see Figure 2.1f). For this reason, wedge flowmeters can measure low-velocity and viscous fluid flows. In this regard, the wedge flowmeter capability is similar to that of the conical or quadrant edge orifices.

For pipe diameter sizes under 2 in. (50 mm), the segmental wedge flow element is made by cutting a V-notch into the pipe and accurately welding a solid wedge in place. In sizes over 2 in., the wedge is fabricated from two flat plates that are welded together before insertion into the spoolpiece (Figure 2.21a). On clean services, regular pressure taps are used and located equidistant from the wedge (Figure 2.21a). On viscous or dirty services, or on applications where the process fluid contains solids in suspension, "chemical tees" are installed upstream and downstream of the wedge flow element (Figure 2.21b).

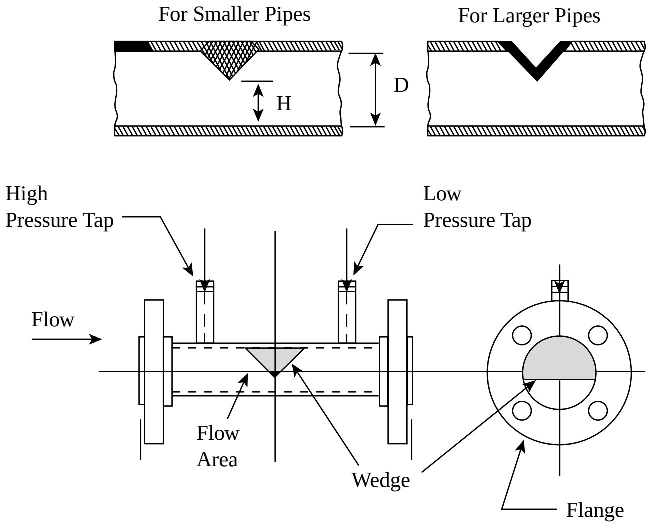


FIG. 2.21a
The segmental flowmeter designed for clean fluid service.[1,2]

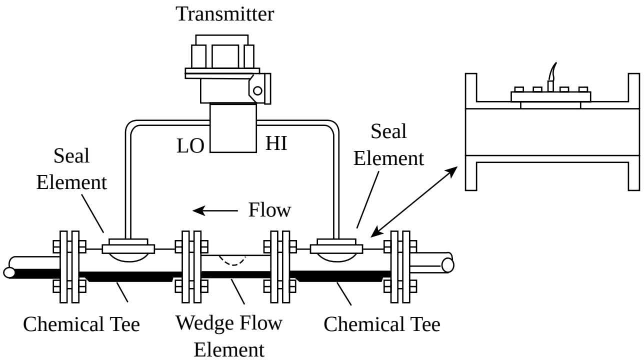

FIG. 2.21b
Segmental wedge flowmeter designed for corrosive or slurry service.[1]

	0.4	475.0	671.0	824.0	1060.0	1165.0	1340.0
	0.5	659.0	930.0	1140.0	1470.0	1610.0	1860.0

*The units in the table can be converted as follows: 1.0 in. H_2O = 249 Pa, 1.0 GPM = 3.785 lpm, 1.0 inch = 25.4 mm.

†The H/D values shown above represent ratios between segmental opening height and the pipe diameter (Fig. 2.21a).

On these tees, chemical seal elements are installed flush with the pipe, eliminating pockets and making the installation self-cleaning. The seals are usually made of corrosion-resistant materials and are also suited for high-temperature services. Some applications have been reported in which the operating conditions reached 3000 PSIG (210 bars) and 850°F (454°C).[2]

The segmental wedge flowmeters are usually calibrated on water. The pressure drop detected by d/p transmitter is interpreted on the basis of these calibration curves. The measurement error is a function of the precision of the calibration and some users report performance on slurry service within 2.5 and 3.5% of actual flow.[2] The flow capacities of these sensors are listed in Table 2.21c.

Based on the above, one might conclude that the segmental wedge flowmeter fills the need for corrosion-resistant slurry flowmeters that are capable of operating at high process pressures and temperatures, but only if the accuracy and rangeability requirements for the measurement are not high.

Sight flow indicators (SFIs, a.k.a. flow glasses) provide a window into a pipe when visual inspection of a process fluid is necessary. Figure 2.22a shows five standard designs.

DESIGN VARIATIONS

The plain design is used to observe physical characteristics of the process fluid; it is not meant to provide full pipe flow indication. Four types of indicating devices are incorporated when flow indication is desired. A metallic flapper design is used in transparent or slightly opaque liquids, and a lightweight polymer/glass flapper is for low-flow gaseous service. Flow direction must be vertically upward or horizontal. Some indication of relative flow velocity can be made by observing the angular position of the flapper; some manufacturers place decals on the window that approximate flow quantity (based on impact force × area) (Figure 2.22b). Bidirectional flappers are hinged in the center of the SFI body

(Figure 2.22c) for horizontal use only. The drip-tube design is used for intermittent or extremely slow flows such as distillation; flow direction should be vertically downward or horizontal. The rotator (a.k.a., propeller, paddle, or paddlewheel, usually made of white virgin PTFE) is used with dark or opaque process fluids. The rotator is placed close to the window, and its motion is easily detected. Flow through the rotator design may be in any orientation. Very high flow rates will rapidly destroy a rotator, so it is advisable to oversize the SFI (to reduce flow velocity) or use a different indicator if high flow rates are likely. Caged balls provide an indicator that is more sensitive to low flow than the flapper and will withstand high flow velocities that would destroy a rotator. All indication devices have a minimum flow velocity for first indication. The rotator-style indicator creates relatively high pressure drops (almost an order of magnitude greater than other indicators) due to internal flow redirection required for operation (Figure 2.22d).

Figure 2.22e shows the cross section of a typical flanged sight flow indicator. The assembly consists of the body, glasses, sealing and cushion gaskets, covers, and bolting. It is similar in many respects to the transparent level gauge discussed in Chapter 3. Soda-lime glass (like window panes) should be considered only for nonsevere applications. Standard industrial glass is borosilicate, rated to 500°F (260°C) for flow glass applications. It has good resistance to mechanical and thermal shock. For higher temperatures, special glass must be specified such as aluminosilicate, up to 800°F (425°C); fused silica or quartz allows ratings in excess of 1000°F (535°C). Tempered glass is not recommended for fluorine, hydrofluoric acid, or phosphoric anhydride service, because corrosion causes uneven stresses and eventual failure. Annealed glass is a better choice, because it signals the approach of failure by turning cloudy. To reduce point compression stress on the glass, a design is available that forms glass inside a metallic compression ring. Bolting stresses are applied to the metallic ring, not to the glass. For steam service, mica shields help protect the glass from corrosion; for fluoride/phosphoric or caustic service, consider PCTFE shields. Polymer-coated glass is also available. Polycarbonate (PC) can be used instead of glass. Acrylic (PMMA) may be used if high impact strength and abuse resistance is required, but acrylic scratches easily.

Polymer bodies are available for low pressure, near ambient temperature applications. SFI bodies may be obtained in almost any castable alloy. Metallic bodies can be lined with a variety of polymers enabling a properly specified SFI to be used in almost any corrosive service. Use caution when specifying a lining if the SFI is used in vacuum service; not all lining materials are adherent. The non-wetted bolting and covers are normally steel but may be obtained in different materials depending on anti-corrosion and temperature requirements.

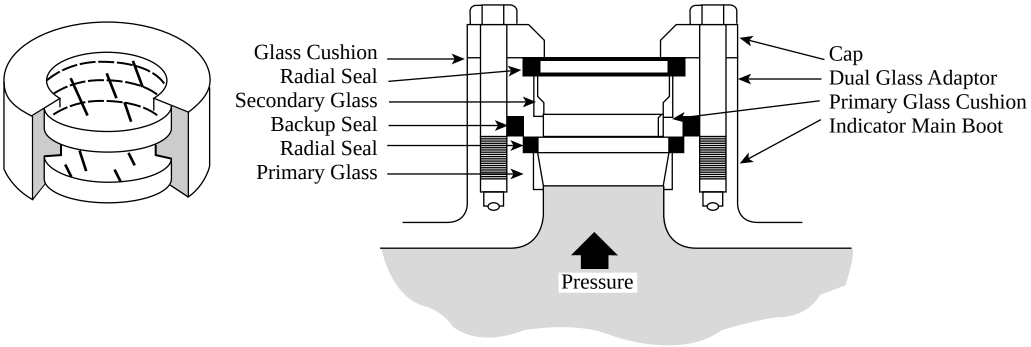

FIG. 2.22f
Cross-section of a dual window assembly. (Courtesy of Dover Corp., OPW Div.)

DUAL-WINDOW AND FULL-VIEW DESIGNS

Figure 2.22f shows the cross section of a dual-window assembly. This assembly improves the safety of an SFI in two ways. In high-temperature service, the thermal gradient across each glass is reduced, and the outer glass protects the inner glass from thermal shock caused by splashes of cold water, e.g., slant rain or snow. If the outer or inner glass breaks, there is a chance that the remaining glass may contain the process until the assembly can be repaired. Dual-window SFIs may be ordered with third-party safety approvals. To further enhance safety due to abuse or vandalism, or if the process fluid is hazardous or toxic, protective sheaths are recommended on either standard or dual-window SFIs.

In smaller pipe sizes, pressure ratings are available up to 3000 PSIG (20.6 MPa). Gasketing may be any available type except those that would cause pressure risers on the glass (e.g., graphite with tanged stainless-steel inserts). Final SFI pressure and temperature ratings may depend on the gasketing material selection. Special designs are available that can be used in sanitary services such as food/pharmaceutical processing. Available accessories include safety jackets, illuminators, insulation blankets, and spray nozzles/rings and wiper blades for cleaning the glass in place.

Most SFI bodies are designed for the inclusion of instrumentation taps, e.g., thermowells. Several types of process analyzers require plain flow glass so the operator can see the probe or other sensing element in the process. Instrumentation using visible, IR, or UV light has been adapted to SFIs using attenuation or backscatter to noninvasively monitor chemical processes. Elbow-style SFIs, both 45 and 90° (Figure 2.22g), have tapping bands available to allow use as elbow differential-pressure flowmeters.

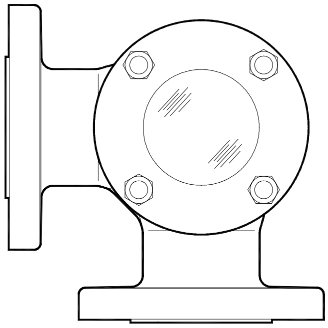

FIG. 2.22g
90° elbow sight flow indicator.

Standard SFI bodies are made with a cross-sectional area expansion from piping bore to accommodate full-bore-size vision. If minimum flow profile distortion is desired, full view SFIs (Figure 2.22h) are designed to maintain piping bore diameter. These are essentially constructed of a spoolpiece with tubular glass either radially or end compression sealed forming the body. They are available plain (360° viewing) or in an armored version for breakage protection, but the armoring reduces visibility. These are normally used for vertically upward flow and are available flanged or threaded.

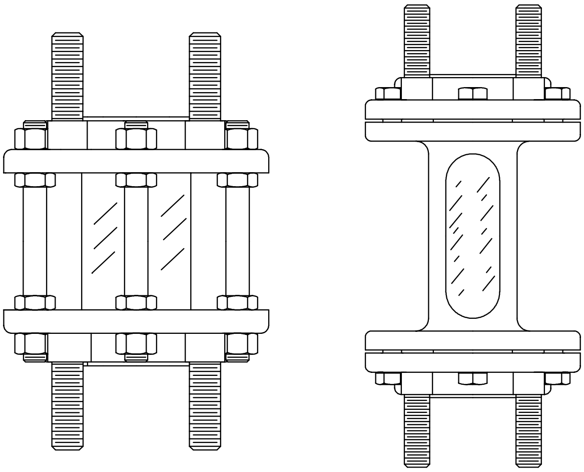

FIG. 2.22h
Flanged full view and armored full view SFI.

A variation of the standard SFI called a sight window (Figure 2.22i) is one window face of an SFI with either flanged or threaded connections designed to fit a piping tee or coupling.

CONCLUSION

Sight flow indicators offer an inexpensive means of viewing process material inside a pipe to detect flow or to note process characteristics such as color, turbidity, or other properties that might indicate process deterioration or equipment malfunction. SFIs are also used in secondary services such as condensate pot installations.

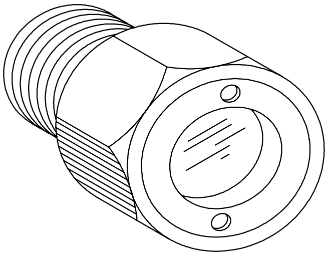

FIG. 2.22i
Threaded sight window.

Nonetheless, SFI use is limited to primary industrial process areas, because it is difficult to estimate flow rate through a flow glass, and a hazard is created if the glass breaks. They are more commonly used in utility services associated with industrial processing.

Many types of solids flowmeters are currently available. The majority depend on some method of weighing, but others utilize a variety of other phenomena ranging from various forms of radiation to impact force determination, and from dependence on electrical properties to centrifugal force. The conditions and properties of the flowing solids have a major impact on the type of flowmeter required. For example, the flow rate of coal can be measured by microwave detectors or belt feeders. This choice is a function of the coal being pulverized and whether it is pneumatically conveyed.

Before undertaking a discussion of solids flowmeters, we will discuss associated process equipment such as solids storage devices and the feeders that bring the solids from the storage vessel. Because keeping solids in motion and preventing arching and rat-holing in the supply bins are serious problems, the description of feeders will be preceded by the topic of feeder accessories.

SOLIDS HANDLING EQUIPMENT

The bin, the feeder, and the solids flowmeter should be designed in an integrated manner, taking into account the characteristics (density, particle size, moisture content, temperature, or hazardous properties) of the solids. For example, the bed depth on a belt must be less than the height of the skirts (to avoid spillage), but it must be at least three times the maximum lump size to guarantee stable solids flow. Coarse materials (+60 mesh) or wet ores are likely to bridge or rat-hole in the bin (Figure 2.23a) and require vibrators and special feeders.

Similarly, aerated, dry, and fine solids (–200 mesh) are likely to either free-flow or be compacted and thereby plug the standard rotary vane or screw feeders. Changing the pitch or inserting additional flights can alleviate flushing. Vibrators usually also help, although in some cases they might worsen the situation by packing the solids. In general, the addition of high-amplitude and low-frequency vibrators or air pads and the use of mass flow bins (steep walls at 10 to 30° from the vertical) tend to improve material flow.

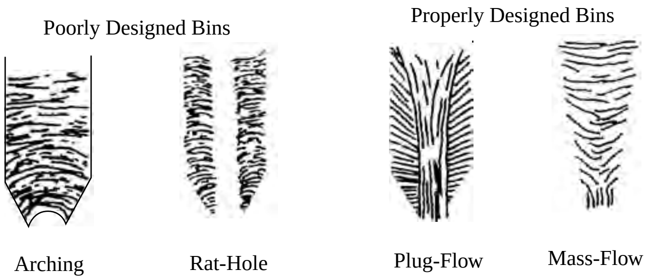

FIG. 2.23a
Good bin design is a critical requirement for a successful solids metering installation.

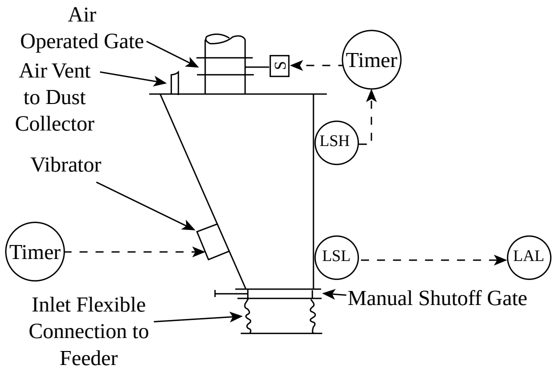

FIG. 2.23b
Deaerating surge hopper.

Hoppers and Accessories

A surge hopper, when located between the storage hopper and feeder inlet, provides a means of deaerating the solids. This guarantees that the solids can be fed, using a gate-controlled belt feeder, without causing flooding. The solid feed into the surge hopper is controlled by bin level switches (LSL and LSH in Figure 2.23b), which maintain the solids level within an acceptable zone by on–off control of the hopper supply gate valve. The hopper inlet device may be a rotary vane feeder, screw conveyor, or a knife gate with suitable actuator.

If the required feed rate is constant or nearly so, the bin switches are located so as to provide a hopper capacity that is equivalent to about 2 min retention time when operating at the design feed rate. In cases in which the material may compact in the hopper and interrupt the supply to the feeders, excess retention time is undesirable. If the feed rate is varied, an adjustable timer is incorporated in the level control circuit to adjust the time setting for keeping the hopper feed valve closed. This timer is started by the upper bin level switch (LSH), which simultaneously closes the bin supply valve when the material contacts the probe. This condition is maintained until the timer runs out and reopens the supply valve, which than stays open until the high-level detector is once again reached.

In this arrangement, the low-level switch (LSL in Figure 2.23b) serves only as a low-level alarm, which is used to shut down the feeder. Such shutdown is usually desirable to prevent loss of the plug of material ahead of the belt feeder. If the solids easily aerate, the loss of a plug of deaerated material can cause production delays, because a new supply of deaerated material has to be obtained first. Some materials will deaerate in the surge hopper without the need for vibration. Other materials require that the hoppers be furnished with electric or pneumatic vibrators. The required frequency and duration of vibration varies with solids characteristics and the vibrators therefore are provided with the means for adjusting these variables.

All manufacturers recommend that a feeder or meter be isolated from sources of vibration, and some include shock mounts with each machine. Inlet and discharge flexible connections to isolate the equipment from vibration and pipe strain in the material inlet and outlet ducting are also recommended.

Material Characteristics A number of common materials, of which sulfur is an example, will compact unless kept in almost continuous motion. Others will compact even while in motion if placed under the pressure of a relatively low head of material. In these applications, it is necessary to use small surge hoppers and use level switches that keep the head of material on the feeder belt low. The retention time of these small hoppers is on the order of a few seconds, and external vibration is not used.

The discharge flow pattern of a belt feeder varies with belt speed and material characteristics. A granular free-flowing material such as sugar will flow smoothly off the belt even at low belt speeds. Other materials having a high angle of repose coupled with a tendency to compact will drop off the end of the belt in lumps, especially at low belt speeds. This results in erratic feed rates and in short-term blend errors when part of multifeeder systems. The discharge flow pattern can be markedly improved by equipping the feeder with a material distributor. This device consists of a blade located across the full width of the belt at the discharge end of the feeder and vibrated by an electric or pneumatic vibrator. The blade is located so that it almost touches the belt and the material is directed across it. This vibration causes the solids to be spread out into a ribbon and to smoothly stream off the belt.

Unlike liquids, which exhibit predictable flow behavior, solids flow characteristics are extremely difficult to evaluate on any basis other than an actual trial. For this reason, most manufacturers maintain a test and demonstration facility in which samples of a potential customer's solids samples can be fed by various test feeders equipped with various volumetric feed sections. Recognizing that a wealth of experience with commonly used materials can very often permit a feed section recommendation without the need for testing, it also should be noted that even a minor change in the properties of a material can drastically change its feeding characteristics. These changes might be in particle size or particle shape but can also be caused by the entrainment of air, which occurred during pneumatic conveying prior to the solids entry into the feeder, or by the addition of an additive to the preblended solids.

Many installations involve feeding directly into processes that may be under low pressure or that may discharge corrosive vapors back through the feeder discharge ducting. If pressures are very low, the feeder can be purged with inert gas, or a rotary valve can be installed in the ducting. The rotary valve body should be vented to remove process vapors from the valve pockets before they reach the inlet or feeder discharge side of the valve. If the valve is not vented, blowback resulting from the release of pressure in the rotor pockets can cause discharge flow pattern disturbances and, in extreme cases, affect the feeder weigh section. The valve is vented into a dust or vapor collecting system via a vent port in the side of the valve rotor housing.

Taking Samples Feeder manufacturers base their performance guarantees on taking a timed sample, weighing it, and comparing the result with the setpoint of the feeder. This requires some means of sampling, which are available either as sample trays, which are inserted into the feeder discharge stream for a predetermined period and then weighed, or as flap valves, which temporarily divert the discharge stream from the process duct into a sampling container. The flap-type valve is generally preferred, because the tray-type sampler is suitable only for low feed rates. Sampling normally involves the taking of 10 consecutive 1-min samples and comparing the average sample weight to the setpoint. Another advantage of the flap-type sampler is that it is faster acting, and the sample weights obtained are thus more accurate.

Each feeder or meter is usually supplied with a test weight or drag chain, which may be used to check the calibration of the device without actually running material. The weight is usually selected to match the full scale of the weight-sensing mechanism. Such test weight is also useful in aligning the control setpoints in multifeeder master–slave systems prior to running any material. In such systems, the test weight can be applied to the master feeder, and the resultant output signal can be sent to the ratio station setpoints of the slave feeders.

Feeder Designs

A gravimetric feeder consists of a weight-rate measuring mechanism coupled with a volumetric feed rate control device. The vertical gate volumetric regulator, which is perhaps the most popular, is not suitable if the solids have large particle size, are fibrous, are irregularly shaped, or tend to flow like a fluid because of fine particle size. Because of this wide variation of solids properties, a variety of feeders have been designed as described in the following paragraphs.

Vertical-Gate The vertical-gate gravimetric feeder is available in a variety of sizes to produce typical material ribbon widths of 2 to 18 in. (50 to 457 mm) and to regulate up to 6 in. (152 mm) of material depth on the weigh belt. Gate actuators may be electromechanical or pneumatic, or they may use computer-controlled electric servomotors or stepping motors. Manually adjustable gates are also available. The vertical gate has a typical depth control range of 10:1 and is generally suitable for materials that are not fluidized and that have a particle size not larger than about 0.125 in. (3.175 mm). Larger particles will not flow smoothly under the lip of the gate, thus resulting in an irregular belt load. This may require excessive damping of the belt load transmitter output, which will have an undesirable effect on both control accuracy and sensitivity. In addition to producing undesirable control characteristics, rangeability will be decreased as particle size increases. As a rule of thumb, the minimum gate opening should be approximately three times the maximum particle size for solids having irregularly shaped particles of random size. This 3:1 ratio may be reduced somewhat if the material is homogeneous and particles do not tend to interlock and tumble while in motion (typically, if particle shape approaches that of a sphere).

Rotary-Vane Figure 2.23c shows a rotary-vane feeder, which can be provided with a variable-speed drive and conventional or computer controls. Such a feeder is used as the volumetric feed section in instances in which the material is aerated or has a low bulk density. Rotary feeders are not recommended for handling solids with large particle sizes or if the solids are sensitive to abrasion by the feeding device. In solids-blending applications, it is possible to operate several feeders in parallel or in cascade from the same setpoint.

Similarly to the vertical gate feeder, the rotary-vane feeder is not suitable either for handling fibrous or stringy materials, because sticky or hygroscopic materials tend to clog the pockets of the rotor. The sizing of pocket shape and depth is based on the required volumetric flow rates and material characteristics. Volumetric capacity is regulated by rotor speed, but if the speed is too high, rotor pockets won’t completely fill as they pass under the inlet opening, and volumetric output may decrease if rotor speed exceeds the optimum. Therefore, care must be taken in determining a maximum practical rotor speed.

The rotary-vane feeders therefore have limitations when used on applications involving free-flowing powders or materials having small particle size but, unlike the vertical gate, they can handle low-density or aerated materials. The rotary feeder should be separately mounted from the gravimetric meter and should be interconnected by means of a flexible connection to prevent transmittal of vibration from the rotary feeder to the weight-sensing meachanism. Figure 2.23c also shows a manually positioned leveling gate, which is located ahead of the weighing section. This device levels the irregular feed pattern created by a rotary feeder and produces a more consistent feed to both the weighing section and eventually to the process. The shutoff gate at the feeder inlet serves the isolation of the feeder from the material supply during inspections or servicing.

Screw Feeders The feeder element in this device is a screw whose rotary motion delivers a fixed volume of material per revolution (Figure 2.23d). The screw is located at the bottom of a hopper so that its inlet is always flooded with solids. Screws grooved in one direction discharge material at one end only. Screws grooved in opposite directions from the middle deliver material at both ends. Rotation of the screw

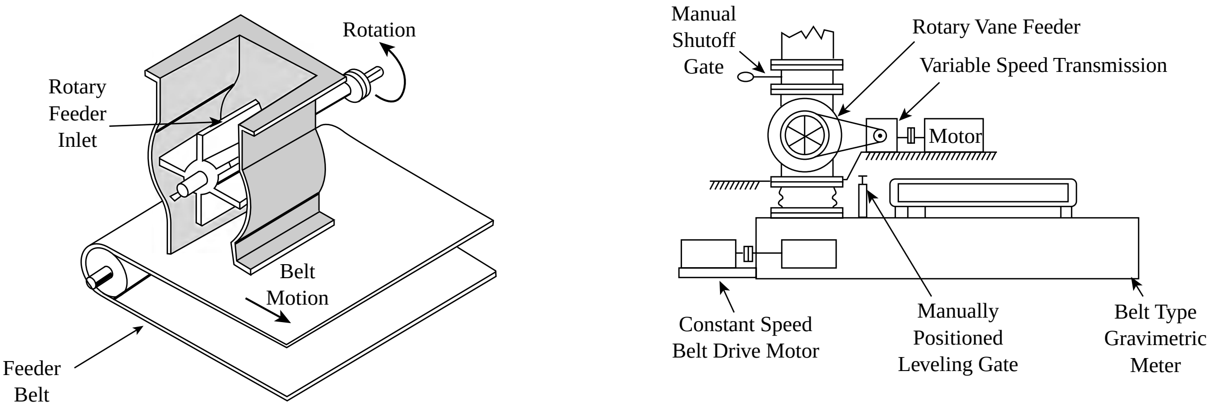

FIG. 2.23c
Gravimetric feeding system utilizing a rotary vane volumetric feeder controlled by a belt-type gravimetric meter.

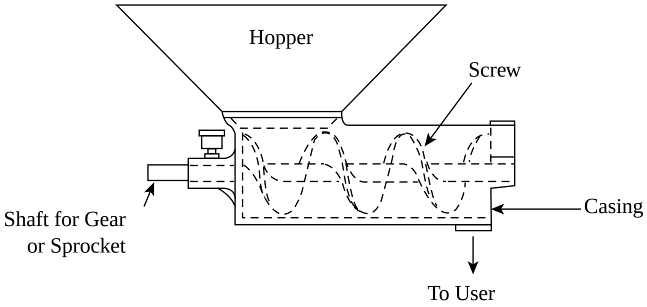

FIG. 2.23d
Screw feeder.

can discharge material into receiving vessel(s), at one or both ends of the screw.

A variable-speed screw feeder can feed control low-density or aerated materials. The screw section can be made as long as is necessary to prevent the material from flooding through it. Screw feeders have also been successfully used on fibrous solids and on powdered materials, which tend to cake. The major advantage of the screw feeder, compared to a rotary vane feeder, is that custom-built screw feeders can be provided with extremely large inlet openings to facilitate the entry of fibers and coarse lumps into the conveying screw.

When the solids have a tendency to cake or clog the screw, the double-ended version of the screw feeder can be oscillated laterally. This oscillation imparts lateral forces that assist in moving the solids through the unit by alternately moving the material first toward one end and then the other.

To assure an accurate feed, the hopper on the inlet side of the feeder must be designed to provide a uniform supply of material to the feed screw. Vibrators can be added to the hopper to keep the solids agitated and to prevent caking and bridging.

Feeder drives are usually electric motors. If the drive is a constant-speed unit, the feed rate is adjustable over a 20:1 range by means of a mechanical clutch that varies the on–off operating time per cycle. In this case, if the feed rate is set at 75%, the screw feeder will be operating 75% of the time or 75% of a clutch revolution. The addition of an analog or digitally controlled variable-speed drive can extend the rangeability of the unit to 200:1.

Vibratory Feeders Vibratory feeders are used in gravimetric feeding systems to handle solids with particles that are too large to be handled by screw, rotary-vane, or vertical-gate feeders, or in operations where the physical characteristics of the solid particles would be adversely affected by passage through these volumetric feeding devices. The discharge flow pattern of a vibrating feeder is extremely smooth and thus is ideal for continuous weighing in solids flow metering applications.

The vibratory feeder (Figure 2.23e) consists of a feed chute (which may be an open pan or closed tube) that is moved back and forth by the oscillating armature of an electromagnetic driver. The flow rate of the solids can be controlled by adjusting the current input into the electromagnetic driver of the feeder.

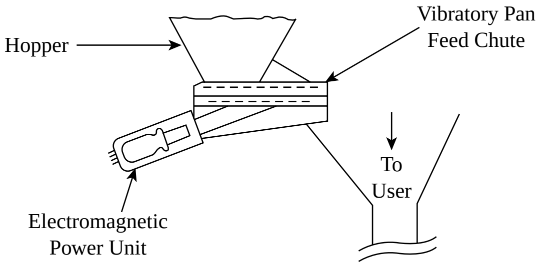

FIG. 2.23e
Vibratory feeder.

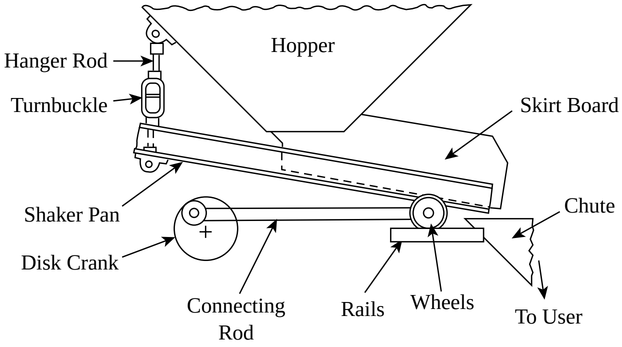

FIG. 2.23f
Shaker feeder.

This input controls the pull of the electromagnet and the length of its stroke. Vibratory feeders are well suited for remote computer control in integrated material-handling systems.

The vibratory feed chute can be jacketed for heating or cooling, and the tubular chutes can be made dust tight by flexible connections at both ends. The vibratory feeders can resist flooding (liquid-like flow) and are available for capacity ranges from ounces to tons per hour.

Shaker Feeders The shaker feeder (Figure 2.23f) consists of a shaker pan beneath a hopper. The back end of the shaker pan is supported by hanger rods. The front end is carried on wheels and is moved by a crank. As the pan oscillates, the material is moved forward and dropped into the feed chute.

In most units, the number shaking strokes is kept constant while the length of the stroke is varied. The angle of inclination of the shaker varies from about 8° for freely flowing solids to about 20° for sticky materials. If arching is expected in the hopper, special agitator plates are installed in the hopper to break up the arches. The shaker feeder is rugged and self-cleaning, and it can handle most types of solids regardless of particle size or condition.

Roll Feeder Roll feeders are low-capacity devices used for handling dry granules and powders (Figure 2.23g). The feeder consists of a feed hopper, two feed rolls, and a drive unit. Guide vanes in the hopper distribute the material and provide agitation by oscillation. The feed rolls form the material into

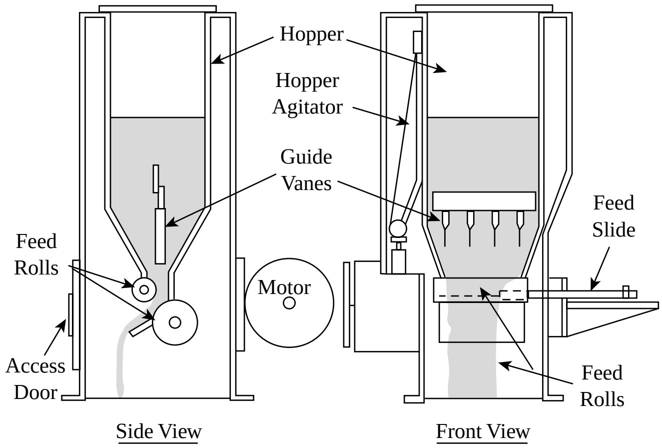

FIG. 2.23g
Roll feeder.

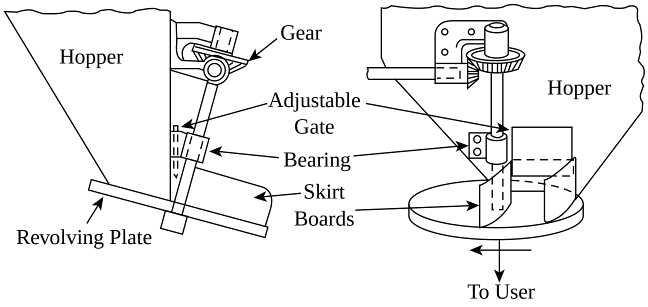

FIG. 2.23h
Revolving plate feeder.

a uniform ribbon, and the feed rate is controlled either by means of a slide that varies the width of the ribbon or by means of a variable-speed drive. The rangeability is typically 6:1 when using the feed slide and 10:1 when variable-speed drives are used. For materials that tend to cake or bridge in the hopper, agitators can be provided to maintain the material in a free-flowing state.

Revolving-Plate Feeders Revolving-plate feeders (Figure 2.23h) consist of a rotating disk or table (usually horizontal), which is located beneath the hopper outlet. The table is rotated and, as it rotates, fresh material is drawn from the hopper while the solids that the feeder discharges are scraped off by skirt boards. The feed rate is controlled by adjusting the height of the gate or positioning the skirt board.

Revolving-plate feeders handle both coarse and fine materials. Sticky materials are also handled satisfactorily, because the skirt boards are able to push them into the chute. This type of unit cannot handle materials that tend to flood. A variation of the revolving plate feeder utilizes rotating fingers to draw feed material from the bin. Revolving-plate feeders can also be equipped with arch-breaker agitators in the conical throat section of the hopper.

GRAVIMETRIC FEEDERS

Belt feeders are compact factory-assembled devices that use belts to transport the material across a weight-sensing mechanism. In the case of solids flowmeters, the flow of solids is uncontrolled, and the load on the constant speed belt is measured as an indication of the solids flow rate. The flow rate of solids on a simple gravimetric feeder can be regulated by a vertical or rotary gate, screw, or other volumetric control device. More accurate control methods are based on varying the belt speed or adjusting both the belt speed and the belt loading. (Although this volume of the *Instrument Engineers' Handbook* is devoted only to measurement, in connection with gravimetric belt feeders, it is also necessary to touch upon the topics of regulation and control, which will be discussed in much more detail in the second volume.)

Early Belt Feeder Designs

Figure 2.23i illustrates the forerunner of most modern belt feeders. It consists of a constant-speed belt coupled to a gate that modulates the solids flow rate so that the belt load is balanced by an adjustable poise weight. This feeder is unique in its simplicity but is inferior to the more modern designs for the following reasons:

1. The entire feeder is weighed rather than only a portion of the belt. Consequently, the ratio of live load to tare weight is low. In addition, the mechanical friction in the pivots results in a low sensitivity in the belt load-detection system.
2. This is a proportional-only controller, because the opening of the gate control element is proportional to the belt load error. Much as a float-operated level-control valve cannot maintain the level at setpoint if valve supply pressure or tank draw-off vary, this feeder cannot maintain the solids flow rate if the bulk density of the solids changes.

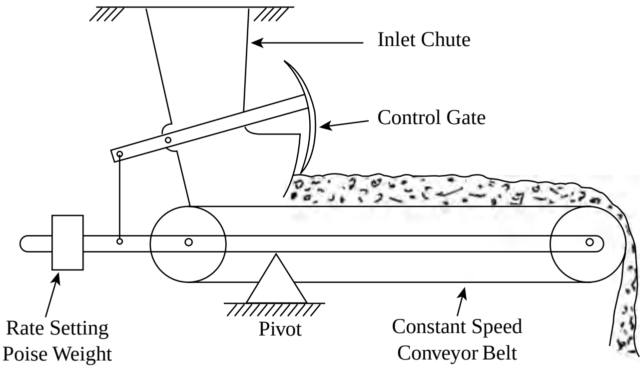

FIG. 2.23i
Early belt-type mechanical gravimetric feeder.

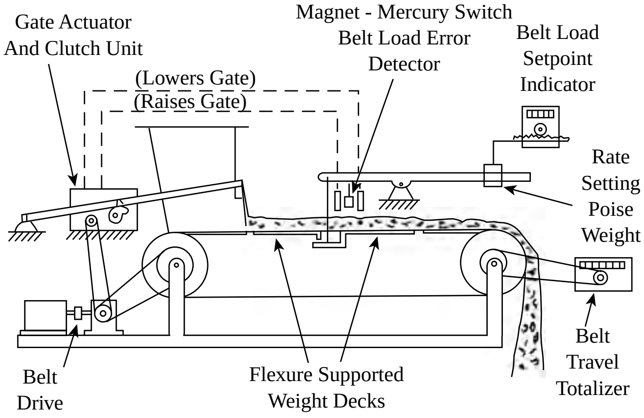

FIG. 2.23j
Belt-type electromechanical gravimetric feeder.

Figure 2.23j illustrates another early electromechanical gravimetric feeder design. Here, the belt load is balanced by a poise weight on a mechanical beam, which also carries a magnet. If the beam is not balanced, the magnet energizes one or the other of two clutches via a pair of mercury switches, which are energized by the magnet. These clutches actuate and establish the direction of travel of the gate-positioning mechanism. The gate modulates the belt loading to keep it constant and matched with the belt load set by the poise weight on the balance beam.

This feeder will maintain the belt loading regardless of changes in material density and subject only to the volumetric control limits of the gate. In this design, the belt load setpoint can be indicated by a mechanical counter that is geared to the beam poise weight drive. A second counter can be geared to the belt drive, which can give the total length of belt travel. The total weight of solids fed can thus be calculated by multiplying the readings of the two counters.

In more up-to-date versions of this design, remote setpoint and the measurement signals are provided, along with automatic shutdown, after the desired total weight of material has been fed. Gate position-actuated adjustable limit switches can be provided to activate alarms that can indicate either the stoppage of the supply of solids to the feeder or the overtravel of the control gate resulting from abnormally low material density.

Feed Rate Control

The feed rate of all belt-type gravimetric feeders is a function of the belt speed and the unit loading of the belt. If belt speed is expressed in feet per minute and belt loading in pounds of solids per foot of belt, the solids flow is obtained as

$$\text{Flow rate} = (\text{Belt speed})\ (\text{Belt loading}) = \text{1bm/min} \qquad \textbf{2.23(1)}$$

In the case of the constant-speed belt feeders previously discussed, the flow rate of solids is directly proportional to belt loading. Another method of flow rate adjustment is to vary the belt speed while maintaining the belt loading constant. The third option is to vary both the belt speed and the belt loading, in which case the flow rate is obtained as in Equation 2.23(1).

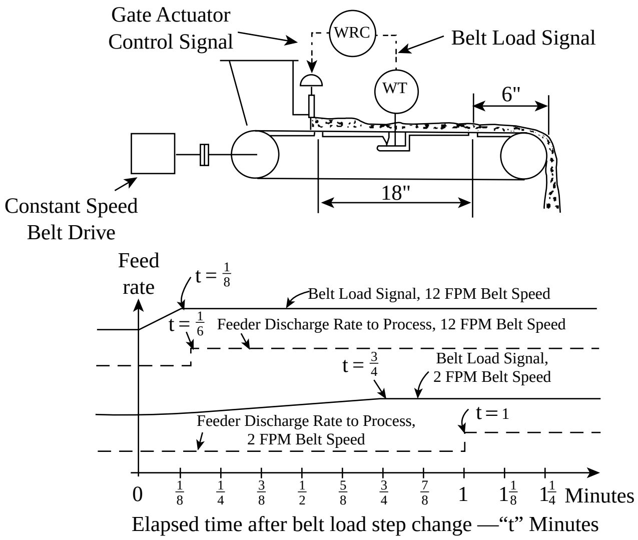

FIG. 2.23k
Open loop response to a step change in belt loading.

Belt Load Control of Constant-Speed Belts A standard constant-speed belt feeder, provided with a pneumatic gate actuator, is shown in Figure 2.23k. The length of the weighing section and the distance from the end of weighing section to the end of belt are approximately the same as those in an actual feeder. The response shown in Figure 2.23k is not precisely depicted, because it assumes instantaneous gate response and does not consider the controller lags, but these effects are minor in comparison to the effect of the belt transportation lag, which is the major source of concern in using constant-speed belt feeders.

The uppermost curve shows the response of the belt load signal to a step change in belt loading if the belt is moving at a speed of 12 ft/min. The dashed line below represents the instantaneous feeder discharge rate at the end of the feeder belt. This is the solids flow rate that the process downstream of the feeder receives. By reviewing the top line, one can conclude that some effect of the stem change in belt loading is sensed almost immediately after the step change, because the control gate is located at the upstream edge of the weighing section. At the 12-ft/min belt speed, the full length of the weighing section will be covered by the new level of solids in 18/144 = 1/8 min after the step change. Yet, at that time, the feeder is still discharging at the rate, that existed prior to the step change, and an additional 1/24 min is required to transport the material to the end of the belt—a distance of 6 in.

If the belt speed is 2 ft/min, the corresponding feeder response will be as described by the lower pair of curves in

Figure 2.23k. In this case, it will take a full minute before the downstream process starts receiving the new solids flow rate after a step change in belt loading is made. Such response times might be tolerable by some single-feeder processes, but not all.

Belt Speeds and Blending In continuous blending operations, the instantaneous blend ratio must be continuously maintained, so acceptability of constant-speed feeders is more limited. We can conclude from the data in Figure 2.23k that, if two feeders having belt speeds of 12 ft/min and 2 ft/min were controlled from a common belt loading signal, and a step change occurred in that signal, the result would be a temporary upset in the actual blend ratio. This upset would start 10 sec after the change in the belt loading setpoint and would persist for a period of 50 sec, at which time the original blend ratio would be restored.

Therefore, blend ratios that are obtained from two or more constant-speed gate feeders cannot be maintained unless the belt speeds of all feeders are identical. This is a serious limitation, because, in blending application, it is rarely possible to size a number of feeders that are delivering different solids flow rates so that they all have the same belt speed. If the solids flow characteristics permit it, one can increase the belt speed by decreasing the width of the material ribbon on the belt, but this does not satisfactorily solve the problem in most applications.

The blend ratio upsets can be reduced if the feeders are cascaded in a master–slave relationship wherein the step change in the belt load is first applied to the master feeder's gate actuator, and its belt load signal is used to control the gate actuator of the slave feeder. One should always select the slow speed feeder as the master, because slaving the low-speed feeder to the high-speed one will only increase the duration of the upset in blend ratio. Computer studies indicate that the upsets in blend ratio will be minimized if the belt speed of the slave feeder is 1.5 times that of the master.

Belt Speed Selection Guidelines

1. In single-feeder applications, optimal response is obtained by selecting the maximum possible belt speed commensurate with the characteristics of the material being fed and with the belt load limits established by the feeder manufacturer.
2. In continuous blending applications involving two or more feeders of identical speed, the upsets in blend ratio caused by step changes in loading will be minimized if the feeders are controlled in parallel from a common loading-rate signal.
3. In continuous blending applications, where the constant-speed belt feeders have different speeds, the upset in blend ratio can be minimized by arranging the individual feeders in a cascaded (master–slave) configuration and selecting the lowest-speed feeder as the master. The upsets in blend ratio will be minimized if the speed of the slave is 1.5 times that of the master.

Varying the Belt Speed The main advantage of belt speed control over belt load control is that the solids flow to the process changes almost simultaneously with a change in belt speed setpoint. The use of speed control in multifeeder blending applications eliminates the blend ratio error that was caused by the differential transport lag, typical of constant-speed feeders. In variable speed blending systems, a common speed signal is applied in parallel to manipulate the speeds of all feeders, increasing or decreasing the total throughput of the blended solids.

The ratio of any ingredient in the total blended product can be modified by changing either the belt load or the belt speed of the corresponding feeder. The latter method is preferred if the ratio has to be changed while the system is operating, because the changing of belt loading during operation will cause a temporary blend error due to the transport lag between the control gate and the process. If a continuous integrator is used, it will accurately register the total solids flow, no matter if the blend ratio was manipulated by changes in belt loading or in belt speed.

Limitations of Belt Speed Control While the manipulation of the belt speed guarantees fast response to setpoint changes and eliminates the transport response error in blending, it also has some disadvantages.

1. One disadvantage relative to constant-speed feeders is that the variable-speed design does not provide feed rate readout. Therefore, the feed rate must be calculated by multiplying the belt speed times the belt loading.
2. In multifeeder blending systems every change in the blend ratio requires a change in the belt loading or in the speed ratio setpoint to one or more of the feeders. This, in turn, will change the total throughput to the process unless a master speed adjustment is made to compensate.

To overcome the above limitations, it is necessary to measure both the belt speed and the belt loading and, based on these two measurements, calculate the total solids flow rate, which then can be compared to a single setpoint representing the required feed rate. Figure 2.23l illustrates such a control configuration.

In the older, pneumatic version of this control system, the belt speed rangeability was 10:1. In the electronic version, where silicon-controlled rectifier (SCR) drives are utilized, the rangeability of speed variation is at least 20:1. In Figure 2.23l, the feeder is equipped with a fixed gate. This is acceptable in all applications where the material density is constant enough that the adjustment rangeability of the belt speed drive can accommodate all variations in both density and gravimetric feed rate. If the density variation is substantial, or if the feeder is to be used on a variety of materials having different bulk densities, the rangeability of belt speed adjustment might be insufficient. In such cases, a secondary or slave control loop is added to manipulate belt loading.

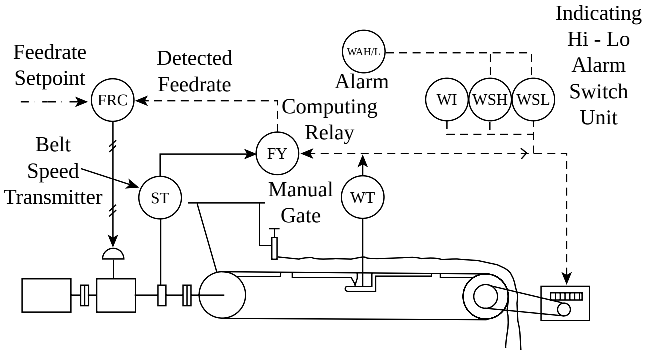

FIG. 2.23l

Speed-controlled belt feeder with both set-point and measurement in feed rate units.

Precision of Weighing Weighing accuracy is the highest if the belt loading is maximized. This, in turn, will maximize the live load to dead load ratio. Gravimetric belt feeders are sized to handle the maximum required solids feed rate when the belt drive is operating at near maximum speed and the belt loading is at about 90% of maximum, based on the minimum expected material density.

To allow accurate setting of the manual gate position, a belt load indicator is desirable. To remind the operator that the manual gate opening needs to be readjusted because of changes in solids density, belt loading alarms are recommended. Such high and low alarm switches (LSH, LSL), as shown in Figure 2.23l, can simultaneously actuate audible alarms and initiate computer printouts.

Nuclear Belt Loading Detectors Belt loading can also be measured by detecting the radiation absorption of a discrete length of material. In all other respects, the nuclear belt scales are similar to gravimetric belt scales except that the load cells are replaced by nuclear densitometers. These devices have been used successfully not only on belt feeders but also on screw, drag chain, and vibrating feeders. The radiation source can be cesium 137, cobalt 60, or americium 241. The radiation source is usually placed above the belt and is supported on either side by a C- or A-frame (Figure 2.23m). In this configuration, the radiation detector is located below the belt and receives a radiation intensity that is inversely proportional to the mass of solids on the conveyor.

Nuclear belt scales are suited for such hard-to-handle services as hot, abrasive, dusty, and corrosive materials. If the moisture content, bulk density, and particle size of the solids are all constant, they can measure the belt loading within an error limit of 0.5% of full scale when the belt load is high (70 to 100% of full scale). On the other hand, if dissimilar solids are intermixed and measured by the same scale, the differences in radiation absorption characteristics can result in substantial errors. For nuclear belt scales, the minimum required belt loading is about 2.5 lb/ft^2 (12 kg/m^2), and these units are not recommended for belt runs that are shorter than 10 min or for belt loadings that are below 10% of full scale.

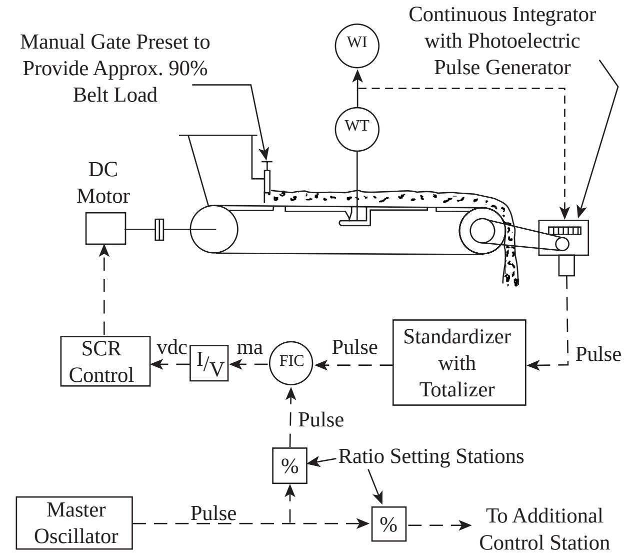

FIG. 2.23n

Belt-type gravimetric feeder with digital controls.

Digital Control The continuous integrator at the bottom right of Figure 2.23l totalizes the quantity of solids delivered by multiplying belt travel times belt loading. The instantaneous rate of integration is the rate of feeding the solids. Therefore, if the continuous integrator was provided with a feed rate transmitter, the belt speed transmitter (ST) and feed rate relay (FY) in Figure 2.23l could be eliminated, and the feed rate signal from the integrator could be sent directly to the feed rate controller (FRC). Figure 2.23n describes this arrangement, which has been developed for use in commercial digital control systems.

The digital control system is theoretically without error, because the pulses generated by the master oscillator in Figure 2.23n must be matched by those derived from the pulses generated by the integrator transmitter on the feeder. Laboratory evaluations and field tests have shown that the feeding precision based on weighed samples vs. total integrator pulses is better than 0.5% of feed rate over a 10:1 feed rate range.

Digitally controlled gravimetric feeders are utilized in situations involving a number of materials that must be blended in a wide variety of frequently changed formulations. High accuracy, high speed, ease of formula change, and centralized control characterize the digital control system. Although the cost of the feeder and its associated digital control is perhaps 50% higher than the cost of a feeder with conventional analog controls, digital control is widely used in continuous blending systems, particularly in the food industry.

Digital systems are superior to analog ones, because each pulse represents a specific increment of weight. Therefore, a pulse rate of 100 pulses per minute, for example, with a pulse value of 2 lb, signals a solids flow of 200 lb/min. The pulses are totalized on both the measurement and the setpoint side, so errors due to temporary starvation or overcharge, common in analog systems, cannot occur in digital ones. Another advantage of the digital system is the flexibility of the microprocessor, which can easily and quickly be reprogrammed, for example, for operating like a mass flowmeter or being part of a blending system.

The microprocessors also provide the capability for automatic recalibration and retention, for future reference, of the corrections that were applied at each test. The microprocessor-operated units are also capable of functioning in several modes, such as in start-up, predetermined fixed flow, or flow-ratio modes. They can have a variety of ratio or cascade configurations, logic interlocks, input and output signals (BCD, serial, analog), displays, printers, and memory units. They can receive their setpoints from other systems and also can receive stop/start signals as a function of other operations in the plant. They can operate as PID loops with dead time compensation utilizing such algorithms as "sample" and "hold," and, finally, they can operate as batching units with remote resets.

Batch vs. Continuous Charging Digital control systems are available in two basic arrangements: one for batching systems, the other for continuous feeding systems. In the batching version, the master oscillator in conjunction with a timer delivers a total number of pulses that are proportional to the desired total weight of solids. The pulse frequency is adjusted to vary the duration of the batch preparation period. The pulses are applied as the setpoint to the feed rate controllers (FIC in Figure 2.23n) via ratio setting stations for ingredient ratio. The feed rate measurement pulses are generated by the photoelectric pulse generator, which is driven by the feeder integrator. These pulses are sent to the feed rate controller after being scaled and standardized.

The controller compares the setpoint and measurement pulse frequencies and adjusts the feed rates as required by varying belt drive speed. In the batch controller version, a memory feature is also included so that the feeder continues running until it has generated the total number of pulses that equal the total pulses received as the setpoint by the feed rate controller from its ratio station. In a multifeeder batching system, this feature may result in feeders shutting down at different times, but the batch blend ratio will be correct.

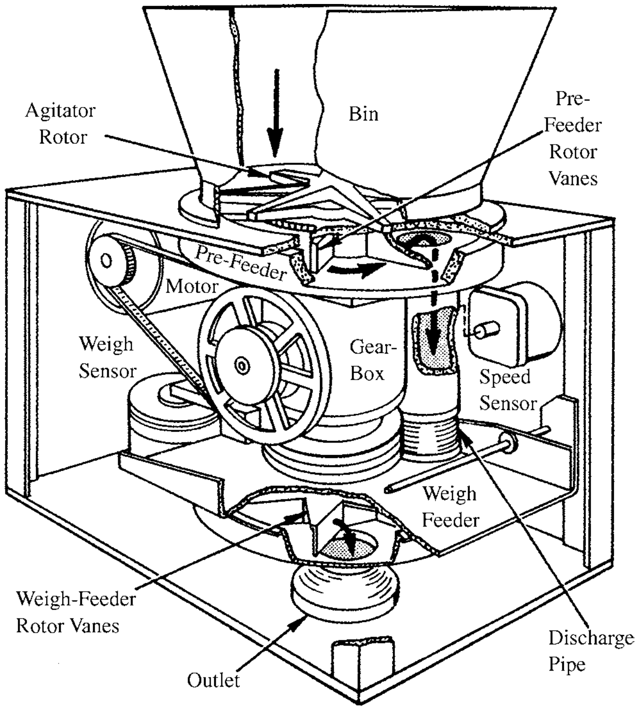

FIG. 2.23o
Vertical gravimetric feeder.

In continuous systems, another version of controller is used. It includes a pacing feature, which paces down all the feed rates if the feed rate of one feeder drops. Therefore, if the controller cannot correct a decrease in feed rate of one feeder, the corresponding controller will "gate" the output of the master oscillator and thus will pace down the feed rates of the other feeders to maintain blend ratio. When the faulty feeder corrects or is corrected, all feeders are automatically returned to normal control, and the master oscillator continues to set the feed rate. If the faulty condition persists for some predetermined period, an alarm is activated.

Vertical Gravimetric Feeders

A vertical gravimetric feeder is illustrated in Figure 2.23o. An agitator rotor within the supply bin guarantees a "live" bin bottom. The process material enters through a hole in the top cover of the pre-feeder and is swept through a 180° rotational travel by the rotor vanes until it is dropped into the discharge pipe. The solids are weighed along with the rotary weight feeder as it transports the solids to the outlet.

The advantages of this feeder include its convenient inlet–outlet configuration; its sealed, dust-tight design; and its self-contained nature wherein all associated control instruments are also furnished. After calibration, ±0.5% of full scale performance can be expected if a 5:1 rangeability is sufficient. At a 20:1 rangeability, the error, if the unit is calibrated, is ±1% of full scale.

The main disadvantages of this design are that the unit has a limited capacity and can only handle dry and free-flowing powders with particle diameters under 0.1 in. (2.5 mm). Large foreign objects cannot be tolerated in the process material, nor can damp or sticky solids that might cake or refuse to flow freely.

LOSS-IN-WEIGHT FLOWMETERS

One continuous loss-in-weight feeder design is illustrated in Figure 2.23p. In this system, the weight of the solids in the hopper is counterbalanced by a poise weight, which travels on the scale beam and is retracted at a constant rate. The controller modulates the speed of the rotary feeder so as to maintain the rate of retraction of the poise weight constant. The balance of the beam is maintained by increasing the rate of solids discharge if the weight of solids in the hopper exceeds that of the poise weight or decreasing the rate if it does not. Instead of a rotary feeder, the modulated control device can be a rotary screw feeder or a vibratory feeder.

The loss-in-weight systems are suitable for handling liquids and slurries as well as solids, because the weight-sensing section of the system is a tank or silo rather than a horizontal belt surface, which is open on all sides. Manufacturers of such units claim that if the delivery time period is short, their feeder gives better precision than other continuous feeders, because in their case the weight is measured ahead of the solids discharge device. Therefore, if an error in flow rate exists, it is corrected before the material leaves the feeder and enters the process.

Continuous Operation

In this configuration, the supply hopper or tank is suspended off one or more load cells. Tension cells are preferred to minimize the errors caused by nonsymmetrical loading. The controller detects the weight sensed by the load cell(s) and subtracts it from its setpoint, which is generated by a programmer. In other words, the programmer generates a signal corresponding to a fixed reduction rate of the total weight in the hopper, and this signal becomes the setpoint. The difference between the weight of material in the hopper and the programmed setpoint weight is continually sensed, and the flow rate of the material exiting from the hopper is regulated to keep them in balance.

The hopper must be periodically refilled, and this filling cycle must be initiated before the hopper is completely empty. Consequently, a “heel” always remains in the hopper and serves to minimize the shock on the load cells at the beginning of the filling cycle. The filling operation is controlled by a differential gap controller and a material supply valve, gate, or feeder (not shown in Figure 2.23p). When the weight of material in the hopper drops to the preset “heel” weight, the differential gap controller starts the filling cycle and at the same time either “locks” the discharge flow regulating device in its last position or closes it. When hopper weight reaches a high limit (corresponding to the filled condition), the differential gap controller stops the filling cycle and restarts the feeding cycle by returning control of the discharge regulator to the loss-in-weight control system. During the filling cycle, the feeding system is operating on a volumetric rather than on a gravimetric basis; hence, filling is accomplished as rapidly as possible. It is desirable to design these system such that the refill cycle is a small portion of the total cycle time.

Equipment

Hermetically sealed load cells are used that withstand not only dust and corrosion but are also compensated for temperature and barometric pressure changes. To withstand shock loading, the load cells should also be designed to withstand overloads of 150% of rating or more. If strain-gauge-type load cells are used, their power supplies should not only be closely regulated, but they should also be compensated for supply voltage variations. For loss-in-weight applications, tension-type cells are preferred, because the compression-type strain gauge load cells are sensitive to side load forces, which can be generated either by thermal expansion of the structure or by nonsymmetrical hopper loading.

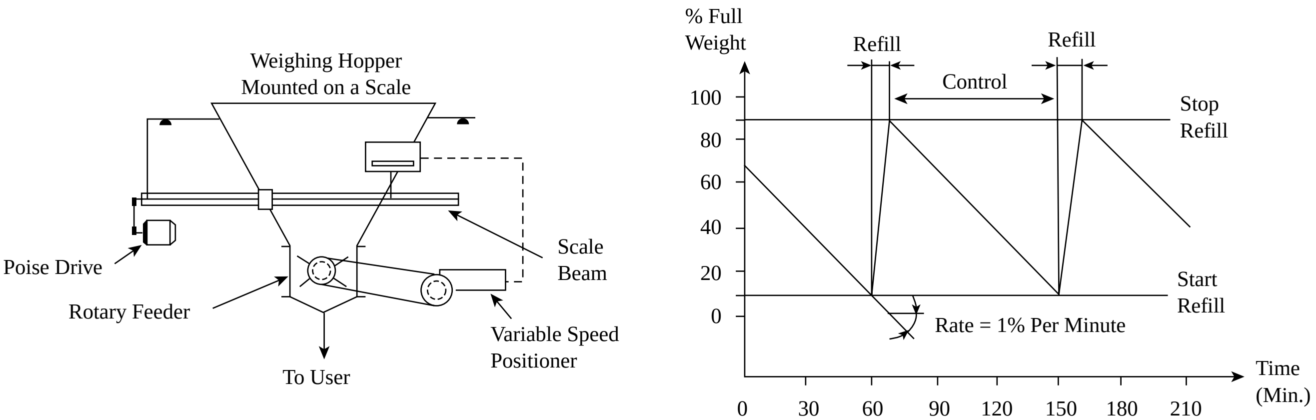

FIG. 2.23p
Continuous loss-in-weight feeder.

The weigh hoppers are often supplied by the user rather than by the supplier of the loss-in-weight feeding system. Their design criteria should not only include capacity and structural strength considerations but should also aim for minimum weight, because the tare weight should be minimized for maximum weighing sensitivity.

The material discharge regulator can be a control valve if the material is a liquid or slurry. Solids can be controlled by a rotary vane, belt, or vibrating feeders or by positioned knife gate valves. The choice is based on the required feed rate and on the physical characteristics of the process material.

System Sizing

In designing a loss-in-weight feeder system, the most important component is the hopper or tank. On the one hand, the hopper should be as large as possible, because the larger the hopper, the longer will be the running cycle and less frequent the filling cycle. On the other hand, for a particular feed rate (loss-in-weight rate), the system accuracy will decrease as the weight of the hopper and its contents increases. Therefore, a compromise is needed between these conflicting considerations.

It is recommended that the hopper be sized to hold the equivalent of about 15 min of discharge or approximately 15 times the maximum pounds-per-minute flow rate. The "heel" should equal 1/3 of the total hopper capacity, and the size of a charge during a refill cycle should be set to 2/3 of the total hopper capacity. The refill cycle should be completed in about 1 min or in less than 10% of the total cycle time.

CONCLUSION

The loss-in-weight feeders are not truly continuous weight rate control systems, because the gravimetric rate control is interrupted during the refill cycle. As a consequence, high accuracy totalization of the charge is not possible, although counters are available to indicate the number of times the hopper has been refilled.

The loss-in-weight systems are not used to feed easy-to-handle, free-flowing materials, because the belt-type gravimetric feeders are less expensive and suited for those applications. Loss-in-weight systems are usually considered for hard-to-handle liquid and slurry services. When no flowmeter or metering pump is available to detect or control the flow of a highly viscous, nonconductive, corrosive, or abrasive liquid, it is then that they are considered, and many highly satisfactory applications have been reported.

DUAL-CHAMBER GRAVIMETRIC FEEDER

The feeder illustrated in Figure 2.23q consists of two independently weighed hoppers. While the solids are being discharged from weigh hopper A, hopper B is being filled by the feed of fresh solids. When chamber B has filled up to its target weight (while the weight of hopper A is tared off), the feed is switched to hopper A, and hopper B is weighed prior to its contents being discharged into the process. Once chamber B has been weighed, its contents are discharged into the

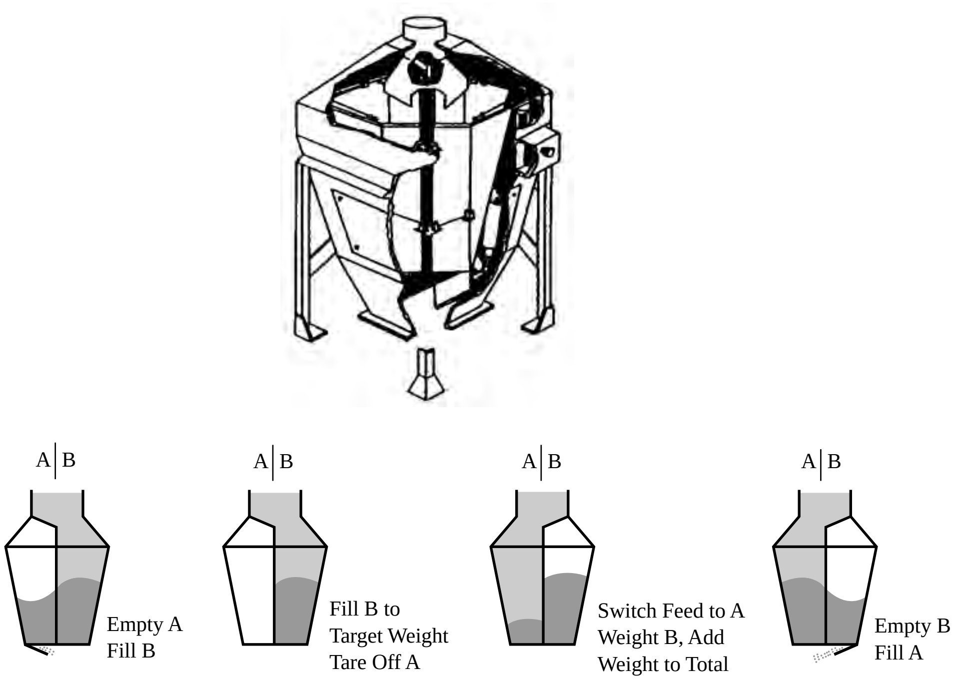

FIG. 2.23q
Dual-chamber gravimetric feeder. (Courtesy of Technicon Industrial Systems.)

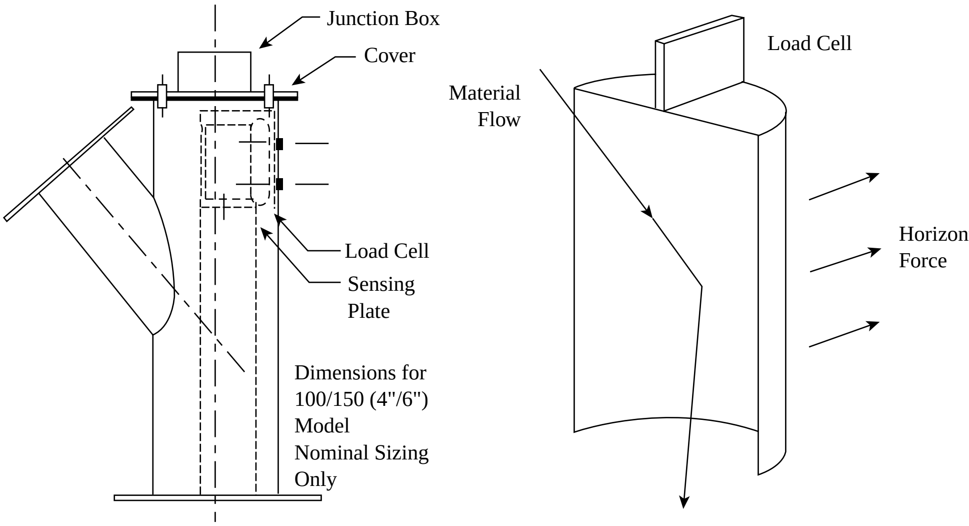

FIG. 2.23r
Cylindrical impulse flow element. (Courtesy of Milltronics Inc.)

process. After each discharge, the corresponding weight is added to the total weight that has previously been discharged.

The weighing cycle shown in Figure 2.23q is computer controlled. The only moving parts of the system are the diverter at the top and the two discharge gates at the bottom of the chambers. Because the hoppers are relatively small, their contents can be weighted accurately. The measurement error is usually about 0.5% of actual flow. Because the chambers are filled and emptied on a cycle period of around a minute, the discharged solids flow appears to be almost continuous. Where space is limited, the small size and vertical flow pattern of the equipment can also be of advantage.

This dual-chamber gravimetric feeder is suited for the measurement of free-flowing bulk solids and can be utilized as a continuous solids flowmeters or as batch recipe executors.

DYNAMIC SOLIDS FLOWMETERS

Whereas the previously discussed devices measure the flow rate while the solids are stationary on a belt or in a hopper, the devices described here measure the flow of falling or moving solid streams. These units detect either the forces needed to initiate the dynamic state by accelerating the solids or the forces resulting from the impact of the falling solids.

Impulse-Type Solids Flowmeter

When a stream of solids strikes a plate or a cylindrical surface at an angle, the resulting horizontal force component relates to its mass flow rate. The flowmeter illustrated in Figure 2.23r operates on the basis of this principle. The meter housing is manufactured from steel or stainless steel, and the sensing plate is made out of stainless steel. The units can handle free-flowing powers or granular and pelletized solid materials of up to 0.5 in. particle size.

The manufacturer claims both a very high sensitivity and wide rangeability (100:1). The smallest capacity unit is claimed to have a range of 300 to 30,000 lb/h (130 to 13,000 kg/h), and the largest unit can handle flows up to 650,000 lb/h (300,000 kg/h). The standard units can be operated at 140°F (60°C) temperature, but special units are available for operation at up to 450°F (232°C). Metering precision is claimed to be 1% of full scale. (If full scale is defined as the maximum flow the unit can handle, then at maximum turn-down, a unit with 100:1 rangeability will experience 100% error.) Microprocessor-based computer controls are available to integrate this flowmeter into batching or other automated material handling systems.

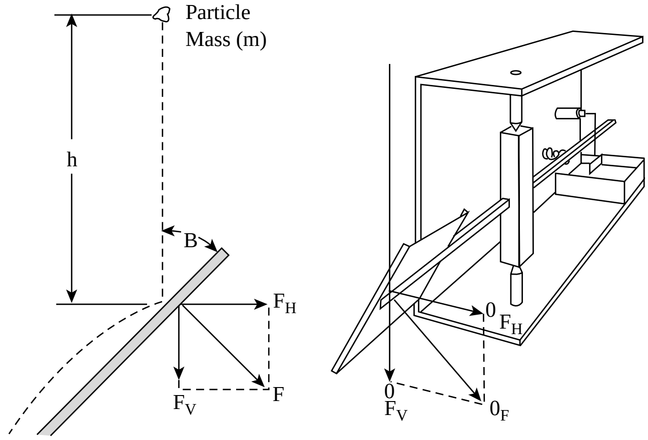
The principles of impulse and momentum detection have been used in liquid flowmeters such as the target, drag-body, and angular momentum designs. Their operation is based on Newton's second law of motion and on the conservation of momentum. These principles have also been successfully applied to solids flow measurement.

Figure 2.23s illustrates a design in which solid particles fall by gravity on a calibrated spring-loaded plate, the displacement of which is a function of the mass flow rate of the solids. A position transmitter is used to continuously detect the force caused by the falling particles.

Both of these solids flow transmitters (Figures 2.23r and 2.23s) can be used in continuous weighing applications. They can also be used in flow monitoring and control applications for batch or continuous services. Almost all types of solids can be measured by impulse-type flowmeters, including sugar, salts, cement, and ores.

Accelerator-Type Flowmeter

In this design, the solids stream enters the "accelerator" section of the meter by gravity (Figure 2.23t). The accelerator is driven at constant speed and, as the entering solids are



The horizontal component of the impact force on the plate is directly proportional to the flow rate of material over the plate

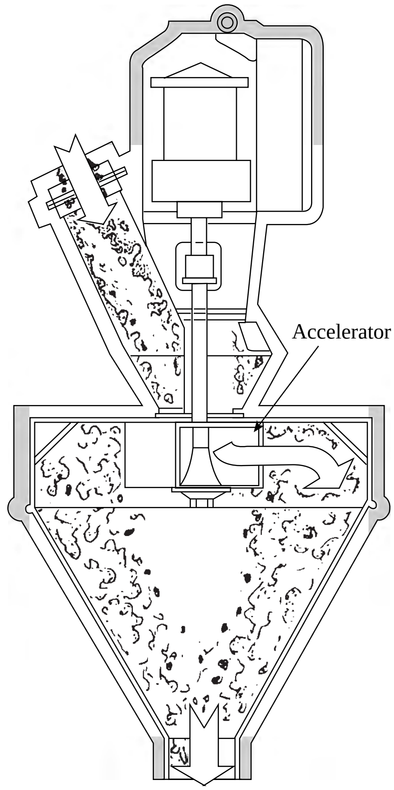

FIG. 2.23t
Accelerator-type solids flowmeter.

accelerated, they create a corresponding torque on the motor. Variations in this torque are detected by a torque transducer and amplified so that the transmission signal becomes directly proportional to the mass flow rate of solids.

The unit is designed for use on a wide range of materials, including powders, granules, pellets, and irregular solids as well as liquid slurries. The measurement rangeability of this flowmeter is fairly high (25:1), but so is the measurement error (around 2% FS).

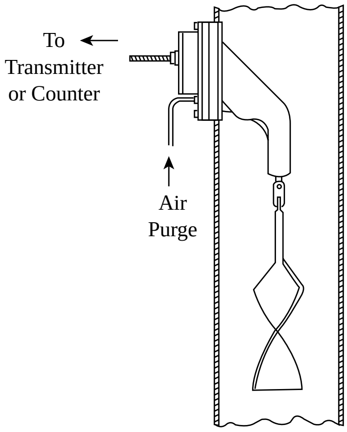

FIG. 2.23u
Volumetric solids flow detector.

Volumetric Flowmeters

The designs of volumetric solids flowmeters include the positive-displacement screw impellers, but if reasonable accuracy is desired, they should only be used to measure uniform-size solids such as lead shot. The operation of this type of instrument is similar to that of the turbine- or propeller-type liquid flowmeters except that a helical vane is used instead of the turbine.

As the flow of the falling granular material rotates the vane, a flexible cable transmits the rate of rotation to a counting mechanism mounted outside of the pipe or duct (see Figure 2.23u). This counting device can be a mechanical counter mounted directly onto the piping, or it can be a transmitter for remote monitoring and/or control. In this design, the transmitter output is determined by the position of a slotted cam. The cam is positioned by the balance between two rotations: the rotary motion produced by a synchronous motor and the rotary motion of the flexible cable.

The vane element is installed in the vertical position, and its bearing surfaces are protected by an air purge. To obtain acceptably accurate flow measurement, the instrument must be calibrated using the same process material, which it will measure after final installation. The measurement error of this flowmeter is around 3% of full scale, and its rangeability is about 10:1.

CROSS-CORRELATION SOLIDS FLOWMETERING

The concept of cross-correlation is based on tagging, which is the oldest of all flowmetering techniques. It consists of injecting some particles, a dye, a chemical, a radioactive material, or a pulse of any other form and measuring the time it takes for such a tag to travel a known distance. Cross-correlation flowmeters also detect the time of transit but, instead of tagging the process

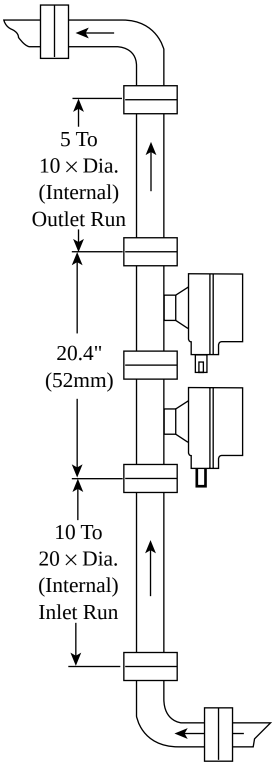

FIG. 2.23v
Solids flowmeter of the cross-correlation type. (Courtesy of Endress+Hauser Inc.)

fluid, they look at a noisy process variable and detect the time of travel of the recognizable noise pattern. If the noise pattern exists long enough to pass both detectors, computers are fast enough to recognize and interpret the readings.

The general subject of cross-correlation flowmetering is covered in more detail in Section 2.5. Here, we concentrate only on solids flow detection. A variety of sensors have been evaluated for this application, including gamma radiation, ultrasonic, and photometric designs. Figure 2.23v shows a solids flow detector that employs capacitance sensors. While further development is needed before reliable performance data can be reported, this metering technique does have potential, because it is not limited by hostile environments or by the characteristics of the solids being metered.

SOLIDS FLOW SWITCHES

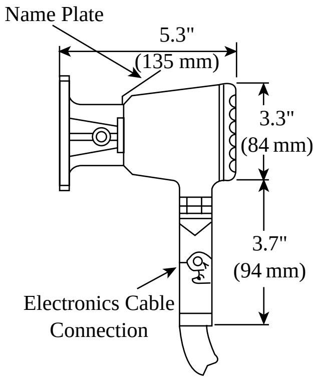

FIG. 2.23w
Microwave solids flow switch. (Courtesy of Endress+Hauser Inc.)

Solids flow switches are used to detect abnormal flow conditions that result from either a flow or a no-flow condition. These can include detection of plugging or blockages, loss of feed, bridging in bins, overflowing of cyclones, rupture of bag filters, and the like. These switches should be both inexpensive and sensitive, because the amount of flow resulting from, for example, a bag rupture is not substantial. One solids flow switch (the *Triboflow*) that can detect such flows consists of a probe that collects the static charges of solid particles passing over its surface.

Microwave flowmeters of the continuous type are used to measure the flow of pulverized solids such as coal. Microwave switches detect the flow of solids by detecting only the motion or the absence of it. In a microwave motion detector, the transducer emits a 24-GHz signal into the flowing solid stream and analyzes the reflected frequency (Doppler effect) to determine the speed of the moving object that reflected it. The switch sensitivity is adjustable, so it may be used to trip at a velocity as low as 6 in./min (15 cm/min) when the pipe is full or at a velocity of one particle every 5 sec in a free-falling, gravity flow system. Units are available in aluminum or stainless steel. They can be connected to a pipe by a coupling or flange (Figure 2.23w) or can look through windows or nonmetallic walls without any openings. The units are intrinsically safe and can be used at working pressures up to 15 PSIG (1 bar). The switch can also observe motion at a distance of several feet from the detector and can tolerate the buildup of 0.5 in. of nonconductive coating or 0.1 in. of conductive coating.

MASS FLOW MEASUREMENT OF PULVERIZED COAL

To obtain the mass flow of pulverized coal being transported to a burner, one needs to know both the concentration (in mass density) and the velocity of the coal in the burner pipe. The main advantage of the technique described below is that it does not require *in situ* calibration, the use of isokinetic sampling, or rota-probing.

Detecting Mass Concentration

The concentration of the pulverized coal is measured using low-power, low-frequency microwaves, with each burner's pipe functioning as its own unique waveguide. Since the coal flow in all pipes served by the same mill has the same fuel source, variables such as moisture content, fineness, coal type, and so on are the same for all pipes. Therefore, the only

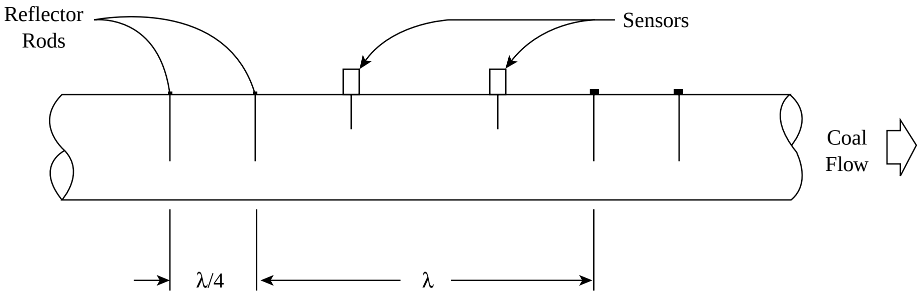

FIG. 2.23x
Standard Sensor and Rod Arrangement. (Courtesy of Air Monitor.)

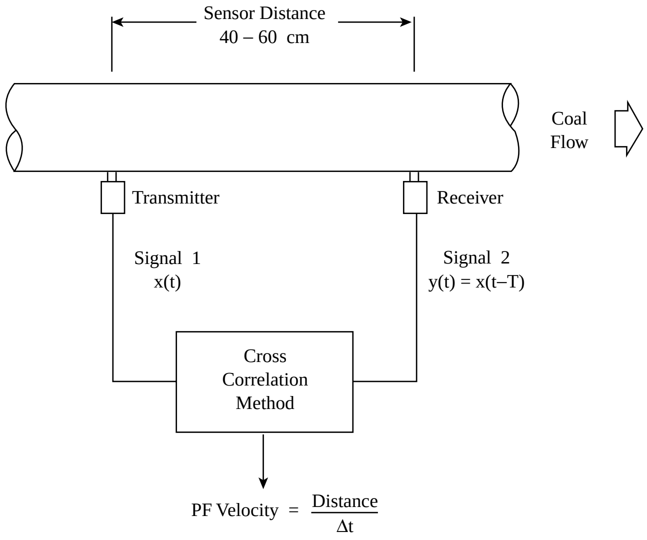

FIG. 2.23y
Cross-correlation configuration. (Courtesy of Air Monitor.)

pipe-to-pipe variable is the dielectric load, i.e., the concentration of the pulverized fuel in the section of pipe being measured. Starting with the measured microwave transmission characteristic of each empty pipe, variations in the dielectric load caused by changing coal concentration produce corresponding shifts in measurement frequency, resulting in quantifiable values that are reported as the absolute coal density in each pipe.

The concentration measurement is performed by two sensors aligned parallel with the longitudinal axis of the pipe; one functions as the microwave transmitter, and the other operates as the receiver, as shown in Figure 2.23x. Located upstream and downstream from the sensors are pairs of reflector rods—abrasion resistant, electrically conductive rods that prevent the microwave signal from leaving the measurement area and then being reflected back in the form of microwave noise.

Measuring the Coal Velocity

The velocity of the pulverized coal is measured by the cross-correlation method, which is conceptually depicted in Figure 2.23y. The same two sensors used for the measurement of coal concentration have a known separation distance. Stochastic signals created on the pair of sensors by the charged coal particles are nearly identical but are shifted by the time the pulverized coal needs to get from one sensor to the other. As the distance between the sensors is fixed, the velocity of the pulverized coal in the pipe can be accurately calculated.

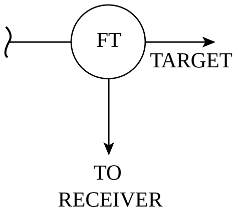
2.24 Target Meters

W. H. HOWE (1966, 1982) **B. G. LIPTÁK** (1995)
W. H. BOYES (2003)



Flow Sheet Symbol

Design Pressure	Up to 3000 PSIG (20.70 MPa) with strain-gauge type
Design Temperature	Up to 300°F (150°C) through 600°F (315°C) with strain-gauge type; special units up to 1200°F (649°C)
Sizes	0.5 to 8 in. (12.5 to 203 mm) with standard and up to 48 in. (1.2 m) pipes with the probe design
Fluids	Liquids, gases, and steam; also handles two-phase flows
Flow Range	From 1 GPM (3.785 l/min), 1 SCFM (28 l/min), 3 lb/h (1 kg/h) to practically any value using the probe design
Inaccuracy	±0.5% of full scale for standard and to ±5% of full scale for probe type
Materials of Construction	Usually carbon or stainless steel; PVC targets and internals available
Cost	$1500 to $10,000 as a function of size, design, and materials of construction
List of Suppliers	Aaliant Division of Venture Measurement (www.venturemeas.com) J.W. Sweet Co.

Material buildup in front of orifice plates can cause both measurement errors and plugging when the process stream is a liquid slurry or a gas carrying wet solids. The annular orifice and the target flowmeter were introduced to solve this problem by providing an annular opening for the solids to pass through. This design is no longer marketed, and the only type of target flowmeter sold today is the drag-body-type target meter.

The drag-body target flowmeter (Figure 2.24a) detects the impact forces produced by the flowing fluid by means of strain-gauge circuitry. This unit is available in standard configurations (Figure 2.24b) and is also available in retractable probe designs (Figure 2.24c), which are used in larger pipe sizes in which it is desirable to withdraw the sensor periodically for cleaning without opening the process line.

The target meter is applied in a number of fields for measurement of liquids, vapors, and gases. It allows unimpeded flow of condensates and extraneous material along the bottom of a pipe while allowing unimpeded flow of gas or vapor along the top of the pipe. It has given consistent, dependable service on "difficult" measurements such as hot, tarry, sediment-bearing fuels to a pipe still where no other head-type meter has proved successful. There are no differential-pressure connections to "freeze." This is useful in steam flow measurement in exposed locations and for liquids that congeal at ambient temperature in pressure connections. Units are available for service up to 700°F (371°C), which is useful in steam service up to 200 PSIG (14 bars) pressure.

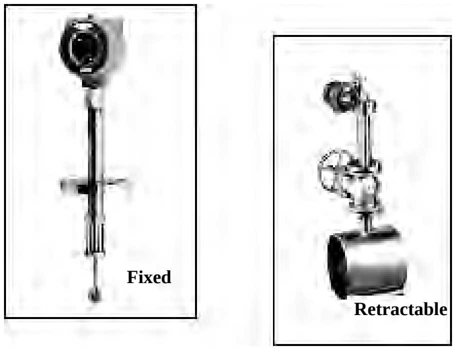

FIG. 2.24c
The insertion target flowmeter.

DRAG-BODY DESIGN

Drag-body targets are empirically derived, and a wide variety of sizes and shapes are available, according to the suppliers. Combined with wide-range force measurement transducers, a wide selection of full-scale flow rates is provided.

The manufacturers provide calibration data. The flow range through a particular-size meter can be varied by changing the target size and by replacing or readjusting the transducer.

Repeatability of output is good. Calibration accuracy includes not only the uncertainty of the primary element but also the characteristics of the transducer and the precision of the transducer adjustment. As is the case with some other proprietary devices, test data is unavailable for determination of flow coefficients from physical dimensions for different process fluids and operating conditions. On the other hand, target meters with accurate water flow calibration over almost any range of Reynolds numbers can be obtained. Transfer characteristics to other fluids based on Reynolds number are reliable. Because the transducer and the primary element are calibrated as a unit, overall accuracy of calibrated target meters is better than that of orifice-type systems.

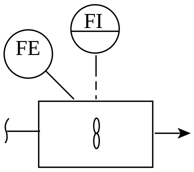
2.25 Turbine and Other Rotary Element Flowmeters



Flow Sheet Symbol

J. G. KOPP (1969) **D. J. LOMAS** (1982) **B. G. LIPTÁK** (1995)
J. B. ARANT (2003)

Types	A. Turbine flowmeters A-1. Single-Rotor A-2. Dual-Rotor B. Propeller, impeller, and shunt-flow types C. Insert, probe, or paddlewheel designs
Services	Relatively clean liquids, gases, and vapors (some units for gas service are also covered in Section 2.2)
Sizes	A-1. 3/16 to 24 in. (5 to 610 mm) in flow-through designs A-2. 0.25 to 12 in. (6.12 to 294 mm) in flow-through designs B. Impeller designs available from 3 to 72 in. (75 mm to 1.8 m) C. Paddlewheel units available for up to 12 in. (305 mm) pipes; insertion turbine probes not limited by pipe size, can also be used in open channels
Outputs	Generally, linear frequency outputs are provided, but 4- to 20-mA DC can also be obtained through conversion
Operating Pressure	A-1. 1500 PSIG (10.3 MPa) in standard and 5000 PSIG (34.5 MPa) in special designs A-2. ANSI 150 PSIG (1.03 MPa) up to ANSI 1500 PSIG (10.3 MPa) B. Impeller designs usually designed for 150 PSIG (1 MPa) C. Plastic paddlewheel units operable up to 200 PSIG (1.4 MPa) at ambient temperatures
Pressure Drops	A. Usually, one velocity head or about 3 to 5 PSIG (20 to 35 kPa) B. Usually less than 1 PSID (7 kPa) for the impeller types C. Negligible
Operating Temperature	A-1. –58 to 300°F (–50 to 150°C) in standard and –328 to 840°F (–200 to 450°C) in extended pickup designs A-2. –440 to 840°F (–268 to 450°C) B. Up to 160°F (71°C) for the impeller design C. The plastic paddlewheel units operable at up to 220°F (105°C) if operating pressure is <25 PSIG (<172 kPa)
Materials of Construction	A. Normally, stainless-steel housing and rotor with tungsten carbide sleeve bearings are used, but Hastelloy® C or other housing materials and ceramic or PTFE bearings are also available B. The impeller-type unit is provided with a plastic impeller and with aluminum, epoxy-coated carbon steel, or stainless-steel housing C. The plastic paddlewheel units are made of polypropylene, PVDF, Ryton™, and metallic parts
Error or Inaccuracy	A-1. Linearity is 0.25% of actual flow for turbine meters larger than 3/4 in. (19 mm) and 0.5% for smaller units. The repeatability (after calibration) is 0.02% of

	actual flow. This performance assumes constant viscosity (within 0.3 and 3 cP) and density, proper installation including flow straighteners, a 10- to 15-diameter straight pipe run, and the use of a DC power supply and a preamplifier located at the meter. A-2. 0.1 to 1% of actual flow with linearity and repeatability between 0.01 and 0.05%. Viscosity, density, velocity effects, and upstream straight run requirements are similar to A-1. B. Shunt flowmeters are accurate within 2% of actual flow over a range of 10:1. The impeller-type units are also claimed to have a 2% of actual flow accuracy if operated at velocities exceeding 1 ft/sec (0.3 m/sec) C. Linearity is 1% relative to actual velocity at point of insertion. Accuracy similar to pitot tubes, or 2 to 5%.
Rangeability	A-1. 10:1 unless limited by use of line-size units or by high process fluid viscosity A-2. 10:1 to 500:1 for liquids and up to 1000:1 for gas flows B. 10:1 for the shunt flow design C. The optical designs provide flow rangeabilities in excess of 20:1
Cost	A-1. A turbine flowmeter with a preamp (but without readout electronics) and with 150-lb carbon steel flanges can be estimated as follows (1 in. = 25.4 mm): 0.5 to 1.5 in., $2200; 2 to 3 in., $2800; 4 in., $3500; 6 in., $5000; 8 in., $8000; 10 in., $12,000; 12 in., $16,000; 16 in., $28,000; 18 in., $32,000; 20 in., $50,000; 24 in., $75,000. Electronic readout devices might include auxiliary, explosion-proof power supply, $1200; remote register drive, $3500; frequency-to-analog converter with digital display, $1200; locally mounted, explosion-proof totalizer/flow indicator, $1200. Accessories include flow straighteners, strainers, batch control units, and two-stage shutoff valves. A-2. Generally, 10 to 50% over A-1 C. The flow element of the plastic paddlewheel units for sizes between 0.5 and 12 in. (13 to 305 mm) costs between $250 and $500. Flow elements can be provided with analog indicators ($350), digital readouts ($500), recorders ($850), or batch totalizers ($600).

---

* *Note:* Most popular are units from Brooks, Daniel, Smith, Hoffer, and Badger.

Turbine meters are available for liquid, gas, and very low flow rates in both full-bore and insertion designs. The most widely used type is the full-bore meter for liquid service.

LIQUID TURBINE METERS

A turbine meter consists of a multibladed rotor suspended in the fluid stream on a free-running bearing (see Figure 2.25a). The axis of rotation of the rotor is perpendicular to the flow direction, and the rotor blades sweep out nearly to the full bore of the meter. The fluid impinging on the rotor blades causes the rotor to revolve. Within the linear flow range of the meter, the angular speed of rotation is directly proportional to the volumetric flow rate. The speed of rotation is monitored by an electromagnetic pickup coil, which is fitted to the outside of the meter housing. Two types of pickup coil are primarily used: reluctance and inductance. Both operate on the principle of a magnetic field moving through a coil.

In the reluctance pickup coil system, the permanent magnet is the coil. The field produced is concentrated to a small point by the cone (see Figure 2.25b). The turbine rotor blades are made of a paramagnetic material, i.e., a material that is attracted by a magnet. As a blade approaches the cone point, its magnetic properties deflect the magnetic field. This deflection causes a voltage to be generated in the coil. As the blade passes under the cone point, the voltage decays, only to be built back up in the opposite polarity as the departing blade deflects the magnetic field in the opposite direction. Thus, each blade produces a separate and distinct voltage pulse as it passes the cone. Because each blade sweeps a discrete volume of fluid, each electrical impulse represents the same discrete volume of fluid.

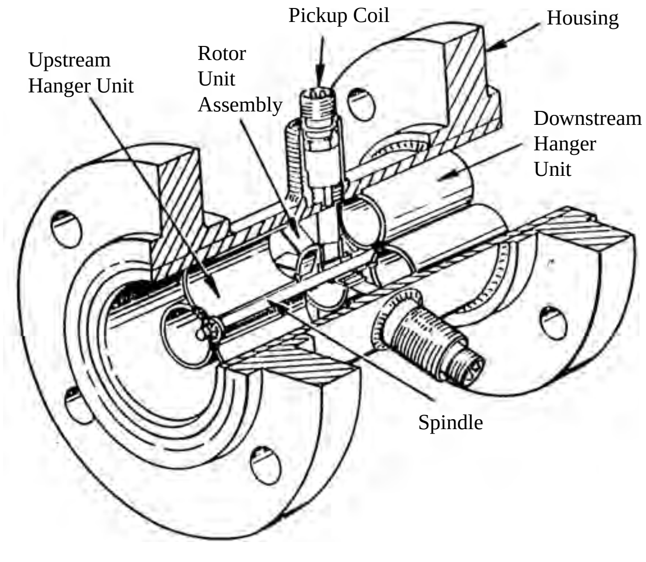

FIG. 2.25a
Cutaway view of a typical turbine meter.

With the inductance pickup coil system (see Figure 2.25b), the permanent magnet is embedded in the rotor. As the magnet rotates past the pickup coil position, it generates a voltage pulse for every complete revolution of the rotor.

The typical operating temperature range for standard pickup coils is −58 to 300°F (−50 to 150°C). Specially modified

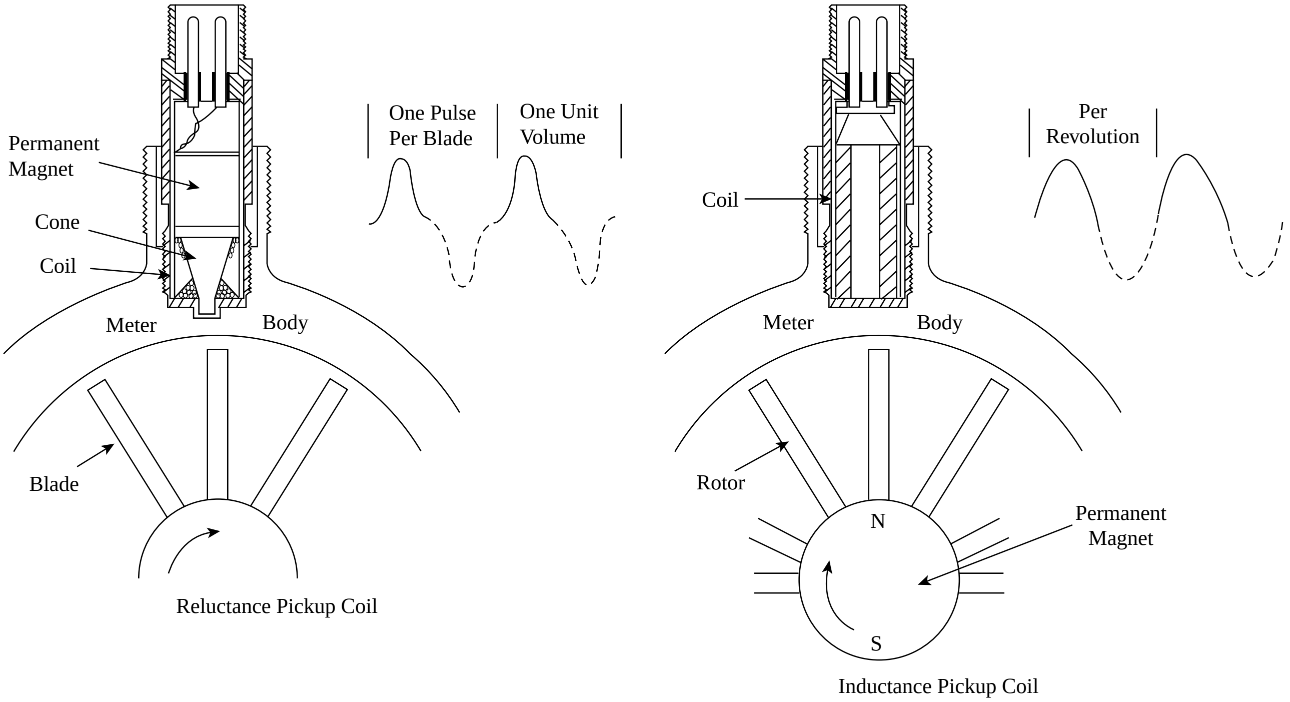

FIG. 2.25b
Alternative signal generation systems.

pickup coils are available, however, to cover operation at temperatures ranging from –328 to 840°F (–200 to 450°C). If the meter is located in a hazardous area, the pickup coil can be mounted in a flameproof or explosion-proof conduit box or, alternatively, an intrinsically safe pickup coil can be used in conjunction with zener barrier to provide an inherently safe system.

Electronic Display Units

The output signal from the turbine meter is a continuous sine-wave voltage pulse train with each pulse representing a small, discrete volume of fluid. Associated electronic units display total volumetric flow or flow rate and perform preset batching, control, automatic temperature correction, and other functions.

Most turbine meter systems incorporate a totalizer unit with a factorizing and scaling function. The pulse output from the turbine meter is not in direct engineering units. For example, each pulse might represent 0.001231 gal. The factorizer is set to this value, and the incoming pulses are multiplied by 0.001231. The display presented is then in gallons.

Alternatively, the totalizer can be a preset batch unit for automatically dispensing predetermined quantities of liquid. The required value is preset, and the totalizer then counts down to zero and provides an output (that is, contact closure) to operate a valve and terminate the batch. To provide better system repeatability and avoid hydraulic shock, the preset batch unit can be fitted with an advance warning contact, or it can incorporate a ramp function. In the former case, an output is provided, typically 2 to 5% before batch completion. This output partially closes the valve and the batch is “topped off” at a low flow rate up to the final preset quantity. The latter system includes a ramp function in the preset batch unit, providing an analog output signal at the start of the batch to open the valve at a predetermined rate. As the batch nears completion, the valve is progressively closed down to a low flow rate. The final valve closure signal is then given at the preset batch size.

Turbine meters volume flow at actual operating conditions. Consequently, if high accuracy is required, and the fluid temperature is subject to variation, automatic temperature correction is necessary. This involves measuring the liquid temperature with a platinum resistance thermometer and providing an analog control signal proportional to temperature. The temperature/volume relationship for the metered liquid is built into the automatic temperature correction (ATC) unit. Depending on the measured temperature, the ATC unit modifies the totalizer volume reading in accordance with the preset temperature coefficient of the liquid to give volume readout at the required reference temperature.

To safeguard against interference or lost pulses during signal transmission, a pulse comparator is often used on high-accuracy systems. This involves using two pickup coils (A and B) and taking two separate signal leads to the electronics. The pulse comparator unit monitors the two signals for integrity. If any pulses are lost or picked up on either line, the correct pulse sequence (A, B, A, B, A, B, and so on) will be interrupted. Any such false pulses are logged and the associated totalizer reading corrected accordingly.

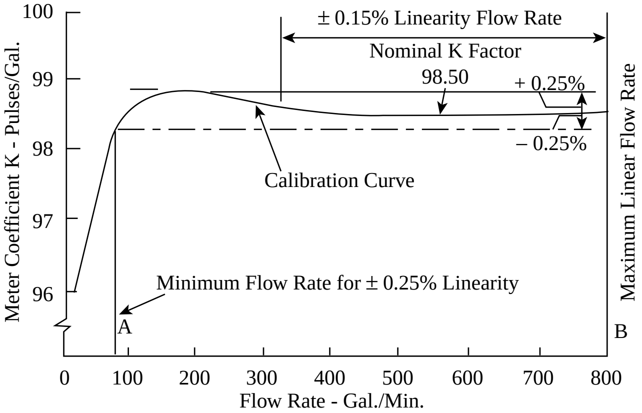

FIG. 2.25c
Typical calibration curve for a turbine meter.

Most turbine meter systems require flow rate indication or an analog control signal. These options can generally be provided from the basic totalizer unit.

Linearity and Repeatability

The nominal K factor (the number of pulses per unit volume) is primarily determined by the size and type of turbine meter. In practice, the actual K factor varies slightly between apparently identical meters due to manufacturing tolerances. Consequently, it is essential to calibrate each meter to establish its own specific K factor. A typical turbine meter calibration is shown in Figure 2.25c.

The graph is a plot of K factor against flow rate. It will be noted that, over the flow range A to B GPM, the K factor is a constant within the linearity tolerance band. The linearity tolerance band is typically ±0.25% of point over a 10:1 flow range for meters 0.75 in. (20 mm) and larger and ±0.5% of point over a 5:1 or 8:1 flow range on meters smaller than 0.75 in. (20 mm). It is important to note that the linearity is specified as “of point” or “of actual reading” and is not “of full-scale deflection.”

The calibration in Figure 2.25c has a typical turbine meter hump in the low flow region (the lower 30% of the flow range). If this region is avoided, the turbine meter linearity can be improved to ±0.15% on the larger meters and ±0.25% on the smaller meters.

The repeatability of the turbine meter is typically ±0.02% of point at any flow rate within the linear range of the meter.

Viscosity and Density Effects

The principal fluid parameter that affects a turbine meter is viscosity. High viscosities change the nominal K factor and cause the calibration curve to fall away at a higher minimum flow rate (see Figure 2.25d). This causes a deterioration in the

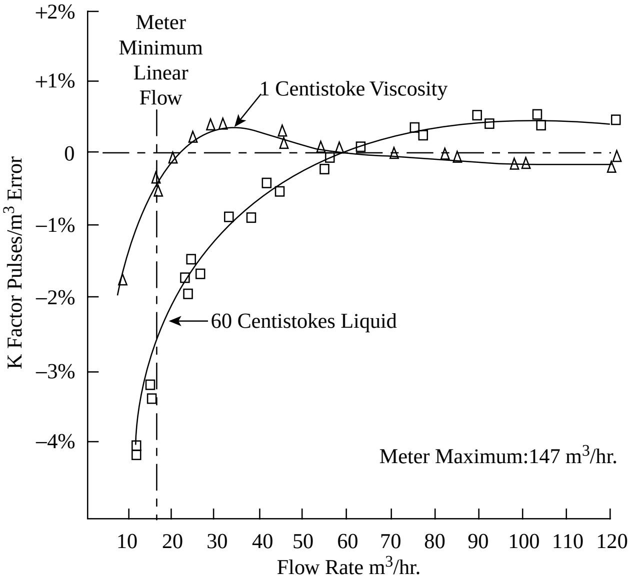

FIG. 2.25d

Calibration curves illustrating the effect of high viscosity on meter performance.

linearity tolerance over the full flow range or, alternatively, a shorter usable flow range at the standard linearity tolerance.

The effect of viscosity cannot be easily quantified, because it depends on the size and type of turbine meter. In general, larger meters are less affected by viscosity than are smaller sizes. This does not imply that an oversize meter should be used on a viscous application. In fact, quite the reverse is true. On a high-viscosity application, it is advisable to size the meter so that its maximum permitted flow rate is as close as possible to the application flow rate. Thus, by tending to undersize the meter, the nonlinear portion of the calibration is avoided, and the best possible flow range is achieved.

The above comments about viscosity are applicable to the linearity of the meter. Turbine meter repeatability will not be affected in this way, and the standard repeatability tolerance will still be maintained at high viscosities. Consequently, a turbine meter can be used for such duties as on–off control on very viscous products. The control points can be determined impartially, and the meter will then repeat these readings even though its calibration may be completely nonlinear. To achieve reliable repeatability, the operating conditions must be constant.

Density has a small effect on the turbine meter's performance. On low-density liquids, the meter's minimum flow rate is increased as a result of the lower driving torque, but the change in density has a minimal effect on the meter's calibration.

Meter Sizing

Turbine meters are sized by volumetric flow rate. Each meter size has a specified minimum and maximum linear flow figure, and the meter normally should not be used outside these values. Typical flow capacities for a range of turbine meters from 0.75 in. (19 mm) to 20 in. (508 mm) are shown in Table 2.25e.

TABLE 2.25e

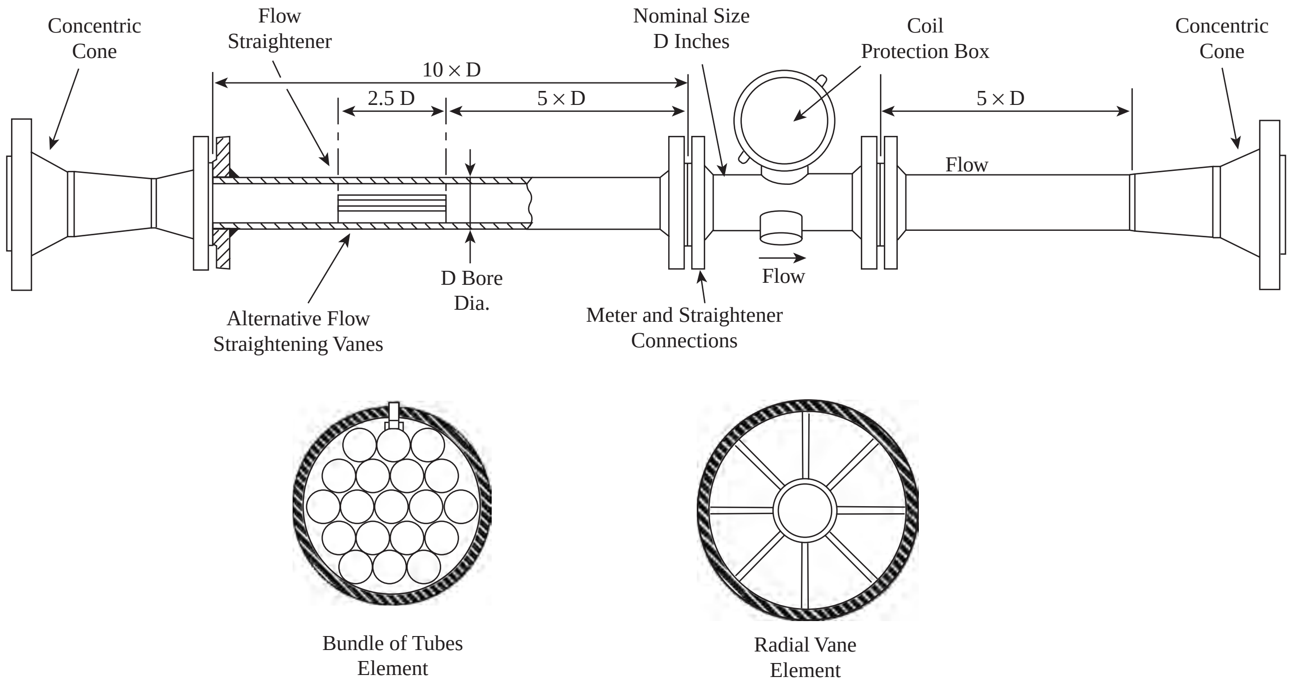
Typical Flow Capacity for a Range of Turbine Meters

Nominal Diameter		*Minimum Linear Flow*		*Maximum Linear Flow*	
Inches	*mm*	*GPM*	*m³/h*	*GPM*	*m³/h*
0.75	20	2.5	0.68	25	6.8
1	25	3.3	0.90	50	13.6
1.5	40	7.2	1.96	108	29.5
2	50	20	5.45	160	43.6
3	75	60	16.3	400	109
4	100	180	27.2	1000	272
6	150	250	68.1	2000	545
8	200	415	113	4150	1130
10	250	715	195	6400	1750
12	300	1025	280	9160	2500
14	350	1210	330	10,800	2950
16	400	1830	500	14,650	4000
18	450	2310	630	18,500	5050
20	500	2930	800	24,000	6540

When sizing the meter, it is recommended that the maximum flow rate of the application should fall at approximately 70 to 80% of the maximum flow rate of the meter. This results in a good flow rangeability (about 8:1), and yet there is still approximately 25% spare capacity to allow for future expansion in production or increased metering requirements. Exceptions to this rule of thumb are applications that demand maximum rangeability, high-viscosity applications that demand maximum rangeability, and high-viscosity applications.

To achieve optimal performance and flow range, most turbine meters are designed for a maximum velocity of 30 ft/s (9.14 m/s). This velocity is higher than the velocities that exist in typical process pipelines, which are typically 7 to 10 ft/s (2.13 to 3.05 m/s). Consequently, if the turbine meter is the same size as the pipeline, the meter flow range will be limited to approximately 2:1 or 3:1. Hence, it is important to size the turbine flowmeter on the basis of volumetric flow rate and not on the basis of pipe diameter. If the turbine meter is sized on volumetric flow rate, it will end up to be smaller than the pipe size. This is a perfectly acceptable and normal practice if the meter is installed with the appropriate upstream and downstream straight pipe lengths and cone-type reducers (see Figure 2.25f).

Another aspect that must be considered when sizing the meter is available line pressure. Turbine meters have a typical pressure loss of 3 to 5 PSIG (20.7 to 34.5 kPa) at maximum meter flow rate. The pressure loss reduces with the square of flow rate. Consequently, if the meter is operating at 50% of maximum capacity, the pressure loss is 25% of that at maximum flow rate.



Bundle of Tubes Element

Radial Vane Element

FIG. 2.25f
Recommended turbine meter installation pipework.

A typical pressure distribution through a turbine meter is shown in Figure 2.25g. As will be noted, the minimum pressure point occurs in the region of the rotor, with a substantial pressure recovery occurring immediately thereafter. It is essential to provide sufficient line pressure to prevent liquid cavitation or gassing in the rotor region. To ensure that cavitation does not occur, the downstream line pressure must be at least twice the net meter pressure loss plus 1.25 times the vapor pressure of the flowing fluid at its maximum operating temperature. When the backpressure on the meter is insufficient to meet this requirement, either the backpressure should be increased, or a larger meter operating in a lower region of its flow range (with a resultant lower pressure loss) should be considered. The meter flow range will be reduced by this approach.

If cavitation occurs, it will cause an error in the meter output, and the meter will read high. If severe cavitation is present, it will destroy some of the metallic parts and will cause serious overspeeding of the rotor, resulting in possible mechanical damage to the rotor and bearing.

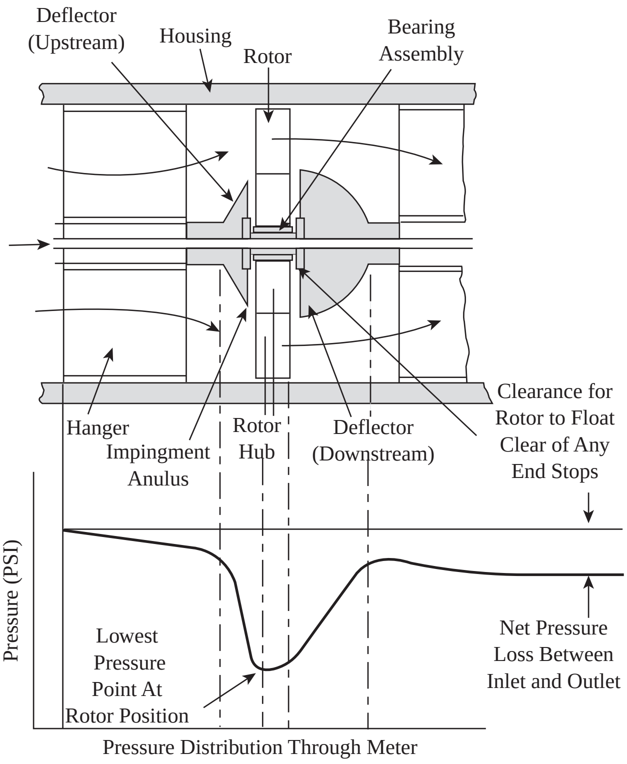


FIG. 2.25g
Typical pressure distribution through a turbine meter.

Pelton Wheel Meters

It is not practical to make turbine meters for very low flow rates below 0.25 GPM (1.58×10^{-5} m^3/s). Pelton wheel meters have been developed for these very low flow rates. The meter has a small orifice that projects the liquid onto a small Pelton wheel. The velocity of rotation is then measured electromagnetically, and a frequency output signal produced. By varying the diameter of the orifice, a range of flow rates can be covered from 0.001 GPM through to 2 GPM (6.3×10^{-8} to 1.26×10^{4} m^3/s). Flow range varies with meter type but is generally between 10 and 20:1. The meters offer good repeatability (±0.1%) but are generally nonlinear and have a high pressure loss, typically 15 to 20 PSIG (103 to 138 kPa). Typical applications for this type of device are metering internal combustion engine fuel flows in test rigs and additive dosing.

Meter Characteristics and Features

The wetted materials of a turbine meter are generally stainless steel throughout except for the bearing. The most widely used bearings at present are tungsten carbide or ceramic sleeve bearings, which offer exceptional reliability and immunity to wear. These materials provide good corrosion resistance capability on a wide range of process liquids (Figure 2.25h). Where these materials are not suitable, other, more expensive possibilities, such as Hastelloy® C with PTFE bearings, are feasible. On clean liquids, some meter designs use ball race bearings to achieve greater rangeability.

Turbine flowmeters have also been manufactured without bearings (Figure 2.25i). In this design, the hydraulic forces of the flowing fluid kept the dual turbine in a suspended, "hovering" state. This meter is no longer being manufactured but is mentioned here because of the interesting concept behind its operation.

In very small sizes (under 1 in. or 25 mm), a single turbine can also be rotated without having any physical contact to the meter body. In the design shown in Figure 2.25j, the process fluid enters as a tangential jet and spins and stabilizes the turbine as it exits through the center of the rotor. The speed of rotation is detected optically by a photodetector. In the 8 cm^3/m to the 8 GPM (330 l/min) flow range, up to 30:1 rangeability is claimed.

Turbine meters are suitable for extremes of temperature. When appropriate pickup coils and bearings are selected, turbine meters can operate at temperatures varying from –328°F (–200°C) to 840°F (450°C). The turbine meter housing is a very good pressure vessel, because there are no tappings or protrusions into the meter bore. Consequently, most small

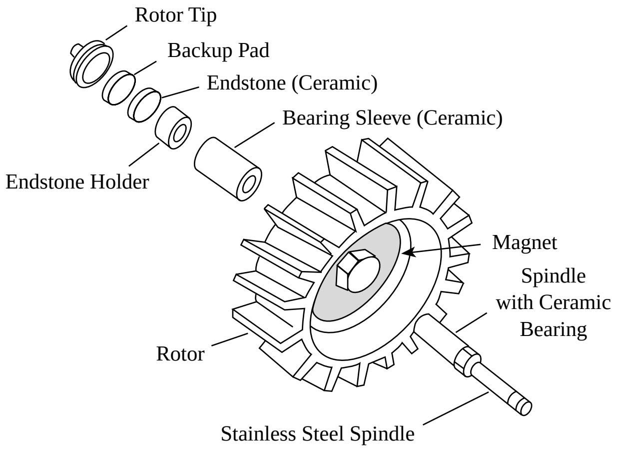

FIG. 2.25h

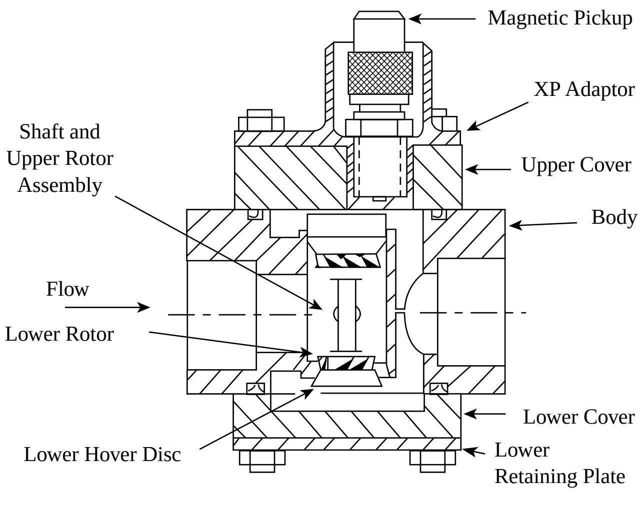

FIG. 2.25i
Bearingless turbine flowmeter. (Discontinued.)

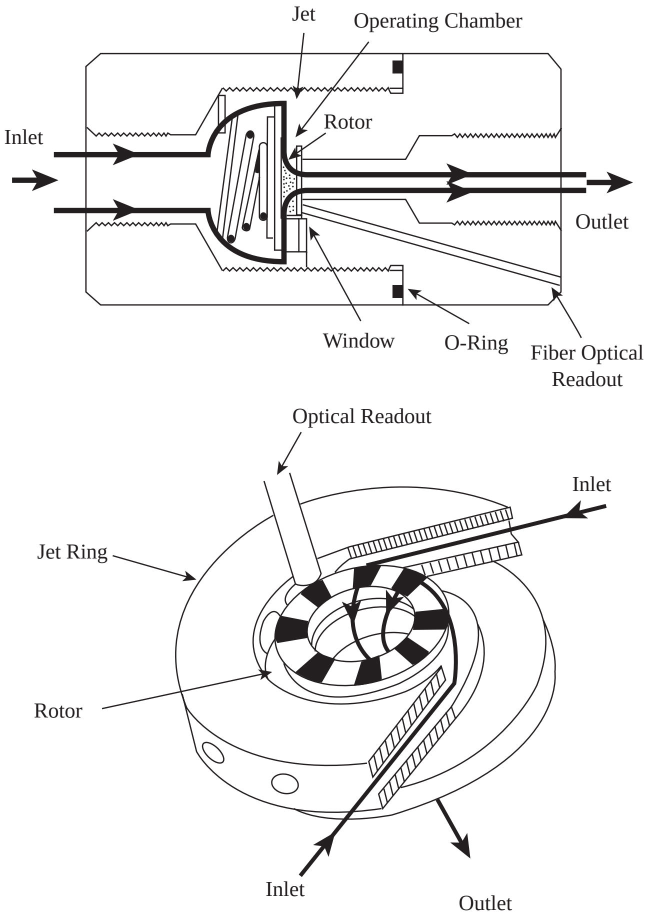

FIG. 2.25j
Unsupported single rotor with optical readout. (Courtesy of Miniflow Systems Inc.)

turbine meters are suitable for operating pressures up to 5000 PSIG (34.5 MPa), subject to the pressure limitation on the flanges or other end connections.

Another significant feature of the turbine meter is that it has a high throughput for a given size and is small in size and weight relative to the pipeline. Consequently, turbine meters can handle large-volume flow rates with a minimal requirement for space without needing special mounting stands or pads. Other features of the turbine meter include fast response time, suitability for hygienic applications, linear digital output, ease of maintenance, and simple installation.

The main limitations of the turbine flowmeter include high cost; limitation to clean and nonviscous services; the error caused by viscosity and density changes; the requirement for filtration and for 15 to 20 diameters of straight upstream pipe; the need for periodic recalibration (at operating conditions) and maintenance because the moving components are subject to wear; the potential problems of gassing, cavitation, and overspeeding; the need for relatively high backpressure; and the need for secondary components in providing a readout.

Due to its excellent performance characteristics, the turbine meter is widely used for high-accuracy royalty and custody transfer of crude oil, refined hydrocarbons, and other valuable liquids. Turbine meters are used throughout the petrochemical industry for many other applications, such as process control metering, blending, and pipeline leak detection. Turbine meters are also used in other industries for a broad range of applications, flow rates, and duties. More specialized applications include measurement of cryogenic liquids (liquid oxygen and nitrogen), high-pressure water injection to oil wells, aircraft fuel metering, test rig duty, and road tanker filling. Some of these applications require modified or special meters (for example, aircraft meters are made from aluminum alloy to save weight), but fundamentally the same meter is used in all cases.

Mechanical Installation

The turbine meter's high accuracy can be easily negated by a substandard installation. Upstream disturbances such as bends, valves, or filters may cause swirl and/or a nonuniform velocity profile, which, in turn, affects both the linearity of the meter and the nominal K factor. The errors may be positive or negative, depending on the direction of the swirl. If there is sufficient straight pipe between the disturbance source and the meter, the fluid shear or internal friction between the liquid and the pipe wall will condition the flow to an acceptable degree. The length of straight pipe required depends on the upstream disturbance and, in some instances, may have to be as long as 50 times the nominal meter diameter.

To avoid excessively long straight lengths of pipe, an internal flow-straightening element is generally used if good accuracy is required. The flow-straightening element may be a bundle of thin-wall tubes or a series of radial vanes inserted longitudinally in the upstream section of the straight pipe. The location of the vane is important; the recommended position is shown in Figure 2.25f. When a flow-straightening element is used, the upstream straight pipe requirement is reduced to 10 times the nominal meter diameter. The required downstream length is 5 times nominal meter diameter. Nevertheless, it is good practice to avoid installing the meter downstream of any severe source of disturbance, such as regulating control valves, whenever possible.

TABLE 2.25k
Typical Strainer Recommendations for Turbine Meter Installations

	Recommended Strainer			
Turbine Meter Size (Inches)	*U.S. Sieve No.*	*Wire Size (Inches)*	*Meshes/ Linear Inch*	*Opening (Inches)*
½ and smaller	120	0.0034	120.48	0.0049
¾ to 1 ½	45	0.0087	44.44	0.0138
2 and larger	18	0.0189	17.16	0.0394

If the meter is smaller in diameter than the process piping, 15° inclined angle concentric cones should be fitted at either end of the metering piping as shown in Figure 2.25f. Care should be taken with the internal alignment of all flange joints in the metering section; no gaskets should protrude into the fluid path.

To avoid mechanical damage to the turbine meter and to ensure optimal life, a suitable mesh strainer should be fitted upstream of the meter. The recommended mesh size depends on the size and type of turbine meter, but typical guidelines are given in Table 2.25k. Close attention should be paid to any application in which there are fibrous particles in the fluid. Contaminants of this type are frequently not removed by the strainer; the fibrous strands tend to wrap around the rotor and bearing, causing the rotor to slow down and the calibration to change.

Electrical Installation

The output frequency from a typical turbine meter pickup coil varies in frequency and amplitude with flow range. At low flows, the signal may be as small as 20 mV peak to peak. Consequently, if the turbine meter and electronic readout equipment are not from the same manufacturer, care must be taken to ensure that the two units are compatible with regard to pulse shape (sinewave or squarewave), signal frequency, and pulse amplitude and width.

Careful attention should also be given to the cable routing between the turbine meter and the electronics. Areas of electrical noise should be avoided, cable lengths should be kept as short as possible, impedance matching should be verified, and the appropriate shielded cable should be used. When long transmission distances are involved or the area is electrically noisy, a preamplifier should be fitted to the meter (see Figure 2.25l).

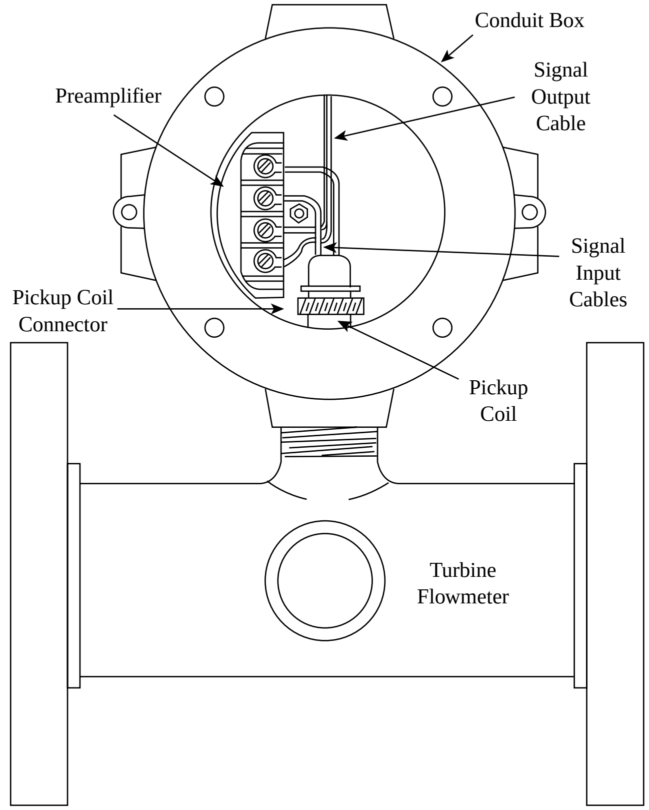

FIG. 2.25l
Complete turbine flowmeter assembly showing pickup coil and preamplifier.

The preamplifier output signal amplitude is independent of flow rate and is typically a 12-V squarewave signal. This high-level signal can be transmitted for great distances, typically 15,000 ft (4572 m) and is far more immune to electrical interference than an unamplified pickup signal. The limitations of a preamplifier include increased cost and the necessity for a DC power supply at the meter. In some designs, an additional cable is required (a three-wire system as opposed to a two-wire system), and the ambient temperature is typically limited to 212°F (100°C).

GAS TURBINE METERS

The operating principle of the gas turbine meter is the same as already described for the liquid turbine meter. The major difference is that, as a result of the much lower density of the gas, the available fluid driving torque is greatly reduced. Consequently, gas turbine meters feature various design changes to enable the meter to operate at higher fluid velocities and to compensate for the lower driving torque. The principal changes are the use of larger hub diameters to give a smaller ratio of rotor annular area to pipe area (see Figure 2.25m), lightweight rotors, increased number of blades, modified blade angle, and alternative bearings. Some designs feature local mechanical volume flow indication and employ reduction gears in the rotor driving external gears via a magnetic coupling.

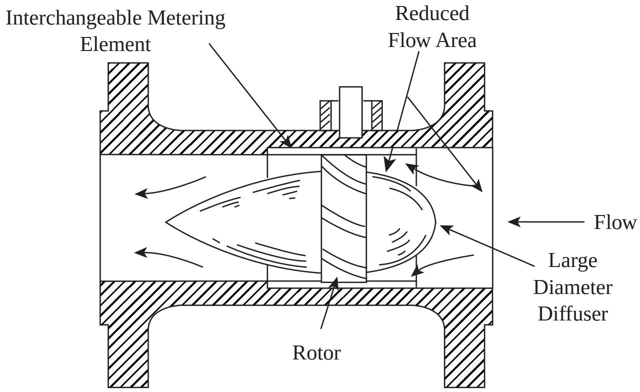

FIG. 2.25m
Typical gas turbine meter showing low ratio rotor annular-to-pipe area.

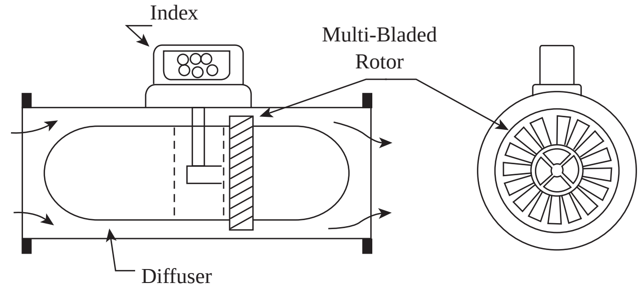

FIG. 2.25n
The axial flow gas turbine meter.

Gas turbine meters find application in fuel and other gas measurement applications because of their simplicity and wide rangeability. Figure 2.25n shows the principle of the axial flow gas turbine meter. A flow diffuser increases the flowing gas velocity and directs it to a multibladed rotor mounted in precision bearings. The calibrated index is driven by the rotor through suitable gearing. Gas turbine meters are available in sizes from 2 to 12 in. pipe diameter (50 to 305 mm) and flow ratings up to 150,000 ft^3/h (4500 m^3/h). A desirable characteristic of gas turbine meters is their increase in rangeability at elevated operating gas pressures. Rangeabilities in excess of 100:1 are attainable in large meters operating at 1400 PSIG (9.7 MPa).

As a result of the lower driving torque of the gas, it is essential to keep bearing frictional resistance to a minimum. The liquid turbine meter journal bearing is usually replaced by a ball race bearing. Any change in the bearing frictional resistance will result in a change in the meter calibration. Meters are frequently used in dust-laden gases, and the ball races are frequently of the sealed, self-lubricated type. Some designs, however, use gas bearings.

It is essential to calibrate the gas turbine meter initially, preferably under simulator operating conditions, to establish

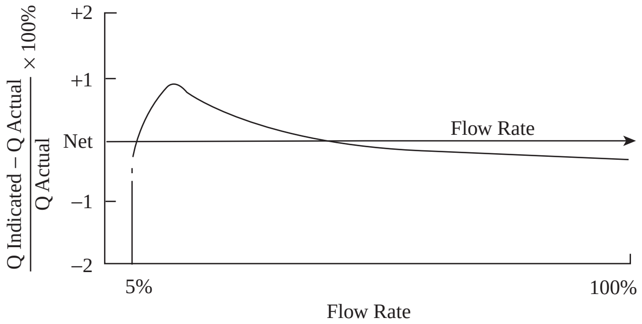

FIG. 2.25o
Typical gas turbine flowmeter calibration.

its own specific K factor. A typical calibration curve is shown in Figure 2.25o. Linearity is normally ±1% of actual flow over a flow range of 20:1. Gas turbine meters have specific minimum and maximum volumetric flow rate values, and it is essential to select the meter on the basis of these volumetric flow rates and not on the basis of the pipe size. The meter must be sized on the basis of actual volume flow and on the basis of standard reference units.

The turbine meter output frequency is proportional to the volumetric flow rate at the actual operating pressure and temperature. Pressure and temperature correction are required to convert the meter output into volume flow at reference conditions. If readout in mass units is required, either pressure and temperature correction can be used (although it does not compensate for variations in the composition of the gas) or the meter reading can be multiplied by a density gauge reading to give true mass flow.

In any compensation system, the volume and pressure or density should be measured at the same flow rate. The gas turbine meter has a typical pressure loss of one velocity head $[0.5(\rho V^2/g)]$ and a similar pressure distribution as that of the liquid turbine meter shown in Figure 2.25g. Consequently, if the pressure or density measurement is not taken at the rotor, a slight correction factor may be necessary to relate the measured value back to that pertaining at the rotor position.

Gas turbine meters are less sensitive to damage by grit and dust particles than are other positive-displacement meters. Gas turbine meters can also operate at higher pressures and have a high flow-rate capacity for a given meter size. In addition, if the meter fails, the gas flow is not obstructed, ensuring continuity of flow. Typical upstream pipe requirements are 20 times the nominal meter diameter.

Because of possible variations in the meter-bearing characteristics, calibration checks should be made at regular intervals if optimal performance is to be achieved.

TWIN-ROTOR TURBINE METERS

The single-rotor design of the turbine meters dates back to the early 1950s, when the United States aerospace industries began to use such meters extensively. At that time, they were not widely used in the process industries, because they were limited to clean services and considered somewhat fragile and therefore not always reliable. Even today, the twin- or dual-rotor turbine meter design is not well known outside the aerospace industry. The *twin-turbine* design uses two identical turbines. The *dual-turbine* design uses two turbines of different designs. The three suppliers listed in the feature summary at the beginning of this section offer three different design variations and also differing capabilities and operation.

History

By the late 1950s and early 1960s, the single-rotor turbine meters, which were used for their high accuracy and repeatability in aerospace fueling applications, were often overspun by flashing cryogenic fuels, resulting in bearing failure, and sometimes even in the loss of the turbine rotor. Such rotor losses could lead to engine failures if the turbine rotor enters the engines. This was clearly unacceptable.

Therefore, a design was needed, which in addition to extremely high accuracy over very wide flow ranges would also offer ruggedness, decrease bearing wear and improve reliability and calibration longevity. The solution was the twin rotor design, which is provided with a housing designed for 3000 PSIG (208 bar) working pressure. The actual operating pressure can be less, because it is limited by the pressure ratings of the end fittings. Special versions have been used in applications up to 40,000 PSIG (2777 bar). The meter can be used from cryogenic liquid hydrogen temperatures up to temperatures greater than 750°F (400°C). The flow sensor body and all major components are manufactured from stainless steel.

Thus, the two-rotor turbine meter was developed primarily to help overcome bearing wear and overspeeding and to provide wider flow turndown or rangeability. These same attributes are also useful in process industry applications. The twin-rotor turbine meters are capable of limiting the error to 0.1% of actual flow and providing a precision of 0.01% of reading. Their turndown can be 200:1 up to 500:1 on volumetric liquid flow applications and up to 1000:1 on gas or vapor mass flow applications.

Twin-Rotor Design

The twin-rotor design dates back to 1959, when it was used only for aerospace and military applications. In the 1970s, some major chemical companies had also started to use them for leak detection and pipeline accounting. This design withstands the flashing of fuel propellants, launch vibration, and shock while providing high-precision signal conditioning electronics. Applications included physiological measurements by NASA, where it was used to monitor astronaut breathing and urine flow during space missions. Military applications included their installation on jet engine test stands and on interservice flow transfer applications under U.S. Navy/NBS auspices. The QDI meter (as it is referred

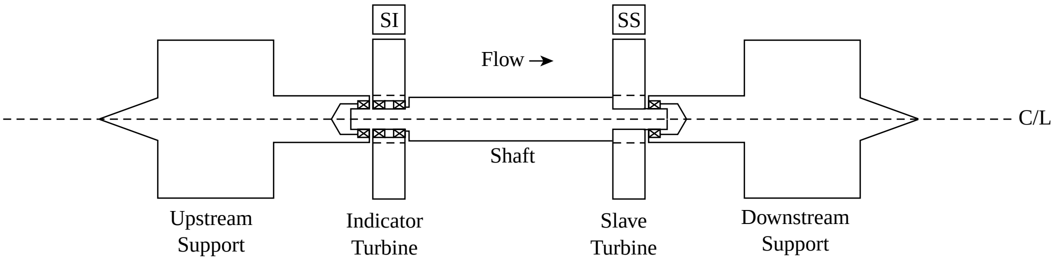

FIG. 2.25p
Twin turbine flowmeter initially designed for aerospace applications to provide long life, high rangeability, and accuracy. (Courtesy of Quantum Dynamics Inc.)

to, using the abbreviation of the manufacturer's name) is also used in flowmeter "prover" applications to check the calibration and accuracy of other flowmeters.

The QDI twin-turbine meter (Figure 2.25p) utilizes two identical turbines mounted on a single shaft, as follows:

- The downstream *slave* turbine is rigidly affixed to the sensor shaft, which rotates within the flow sensor on precision ball bearings. The bearings may use either stainless-steel alloy balls or specialty ceramic balls. Thus, the flow drives the "slave" turbine along with the flow sensor shaft.
- The upstream *indicator* turbine corotates on the driven shaft in the same direction as the shaft motion, thus minimizing the relative velocity between the indicator turbine and the driven shaft. This provides high rangeability while low angular velocities with respect to the shaft protect the indicator turbine bearings and provide improved dynamic response. Since the total angular velocity of the indicator turbine is distributed over the indicator turbine bearings and the corotating shaft bearings, the high rangeabilities can be achieved without deleterious bearing wear. Actual liquid volumetric flow rates are extremely repeatable over 200:1 turndowns or more where the linear correlation coefficients exceed 0.999999, whereby 1.0 indicates absolute perfect linearity. In compressible gaseous flow measurement applications, the mass flow rate turndown exceeds 1000:1.

The downstream turbine is referred to as the *slave* turbine, which performs the primary work of driving the shaft upon which the upstream *indicator* turbine bearings ride. Hence, this minimizes the latter's bearing RPM and friction and significantly improves rangeability, dynamic response, and bearing longevity.

Applications and Features The QDI twin-turbine meter uses an integral upstream flow profile control device to create a relatively flat flow profile, even in the low laminar flow regime. The use of integral upstream flow profiler allows for the use of a slim central shaft and long turbine blades. This contrasts with single-blade turbine meters, which utilize a large central body to accelerate the flow past the short turbine blades having high blade angles. Thus, the aerospace twin-turbine design also has a lower pressure drop. This is important in aerospace and cryogenic applications where high pressure drops could cause flashing.

The patented zero-drag RF pickups on both the indicator and slave turbines provide a powerful, high-reliability diagnostic tool, because redundant flow measurement is provided. In addition, bearing wear or contamination can be detected as changes in the relative velocity between the indicator and slave turbines. Since the slave turbine/shaft bearings experience the greatest prolonged rotation, they will begin to show wear long before the indicator turbine does. An advantage over single-turbine designs is that, in this design, even after bearing wear is thus detected, the indicator turbine will continue to provide accurate flow for some extended time period, thus allowing scheduled maintenance of the twin turbine flow sensor.

The slim central shaft of the twin-turbine design allows larger flow volumes to pass through the flow sensor without causing high pressure drops. The QDI flow sensor is used to measure flows at high velocities, such as in natural gas fired power plant, where the gas velocity reaches mach 0.3. In applications where measurement rangeability was previously obtained by using several orifice plates installed in parallel runs (Figure 2.15u), the QDI sensor can provide considerable cost savings by eliminating multiple meters and associated pipes and valves.

This flow sensor can also be used to measure bidirectional flows, with flow direction determined by quadrature. This capability, along with high dynamic response, was used to monitor astronauts' respiratory patterns. More recently, this capability has been used for detecting in–out flow in commercial gas storage applications such as in large holders or in underground storage caverns such as salt domes.

In the case of cryogenic liquid fuel loading systems, the same meter can handle liquid, gas, and two-phase flows. More recently, it has been successfully applied to high-accuracy petroleum and petrochemical custody transfer systems, power plant combustion control, pipeline leak detection based on mass balance principles, batch charging, and metrology applications involving high-value liquid or gas products such as ethylene, propylene, and so on.

The mechanical/electronic reliability of the standard unit, as calculated per military specifications, yields an MTBF of 2.5×10^5 t (28 yr). Using space-grade components yields an MTBF of 6.14×10^5 h (70 yr).

DUAL-TURBINE DESIGNS

Dual-turbine meters differ from twin-turbine designs in that they use two turbines of different blade angles and configurations, each rotating on its own bearing systems on its own shafts. These designs are more susceptible to bearing damage due to overspeeding than are the twin-turbine units, and care must be taken not to subject such flow sensors to excessive flow velocities.

Dual Turbines Rotating in the Same Direction

In the 1960s, Rockwell International was studying the problems of wear and the associated loss of accuracy in turbine meters, and the company also came up with idea of using a dual-rotor turbine system to reduce the effects of bearing friction and wear. As a result, Rockwell designed its dual-turbine sensor (Figure 2.25q) primarily for clean gas services such as natural gas, and it provides adequate service life for its intended end use in the gas pipeline and distribution industries. (Rockwell subsequently sold off this dual-rotor design to Invensys Energy Metering, located in DuBois, PA.)

The size of this meter ranges from 4 in. (100 mm) to 12 in. (300 mm). Its materials of construction are normally aluminum or carbon steel. The aluminum model is rated for a maximum working pressure of 175 PSIG (12.15 bar), whereas the steel model is rated from ANSI 150 (275 PSIG or 19 bar) to ANSI 600 (1440 PSIG or 100 bar). Temperature ratings for the meters are –20 to +165°F (–29 to +74°C), but a special low-temperature steel model is also available that can be used down to –40°F (–40°C).

The rotor bearings in this meter design require lubrication. This can be done manually or at specified time or volume intervals by an automatic, meter-mounted system. Mechanically, this meter is rather complex, but the needed maintenance can be done in line if the process flow is shut down or bypassed. Precalibrated measuring assemblies can be provided for quick change-out needs. The meter is fitted with a flow conditioning inlet nose cone that reduces the straight upstream pipe length required, but damage to this nose cone can result in significant calibration errors.

Operation This dual-turbine meter uses two turbines that are located close together and rotating on two independent shafts. The upstream turbine has a high blade angle, and the downstream turbine has a very low blade angle. Since the upstream turbine blade angle is much higher than that of the downstream one, the latter will rotate at a slower angular velocity. The flow rate is measured as the difference in the speed of the two rotors. In theory, when the bearings begin to wear, the upstream turbine will spin slower, changing the fluid exit angle and causing the downstream indicator turbine to adjust its speed by an equal amount. This is claimed to adjust away bearing wear and also provide bearing diagnostics, but the validity of this claim depends on the assumption that the wear and contamination is the same on both sets of bearings.

This flow sensor has a very large central hub, which also contains the sensor's mechanical index gearing. The large hub accelerates the flow through a narrow annulus, which results in a somewhat high pressure drop. Since both the upstream and the downstream turbines rotate on a single set of bearings, the meter should not be subjected to excessive flow rates, given that this might damage the bearings. Also, this meter should not be used where slugs of condensate flow may occur, since this also will cause damage.

The inaccuracy of the meter is claimed to be ±1.0% of actual flow over the entire operating range, and the normal linearity of ±1.0% can be improved to ±0.5% if high-pressure calibration is used. The repeatability is better than 0.05%, and reproducibility is better than ±0.1%. While the above-described performance is not much superior to single-rotor conventional turbine meters on natural gas applications, this meter is more immune to positive or negative swirl, pulsation, jetting, and contamination. This meter is also autocorrecting.

Dual Turbine with Counter-Opposed Rotation

The dual-rotor turbine meter from Exact Flow is relatively new (Figure 2.25r); the company's meters date back to about 1995. It is similar to the QDI meter (Figure 2.25p) in some ways, but there are marked differences as well. These contribute to performance improvements (such as high turndowns) but also to limitations (such as being limited to liquid service only), because its bearings are susceptible to damage by overspeeding.

In this design, the two turbines have counter-opposed blade angles and rotate on a single shaft. The swirl from the upstream turbine thus impinges on the downstream one at near right angles, causing the downstream turbine to rotate faster and in the opposite direction (unlike the corotation of the QDI twin turbine). This approach improves metering rangeability by forcing the downstream indicator turbine to spin at higher RPM at low flow rates, but it can also make the bearings more vulnerable.

This dual turbine also utilizes a large central hub that constricts the flow into a narrow annulus, thus accelerating the flow past the downstream indicator turbine and promoting the onset of the turbulent flow regime in the narrow annulus. The disadvantage of this increased velocity is the corresponding increases in the pressure drop across the flow sensor.

Because each turbine is mounted on its own set of bearings, as is the case with single-rotor meters, care must be taken not to subject this meter to excessive velocities or to flashing liquid flows, because such conditions will likely result in excessive bearing wear or failure. This design is not

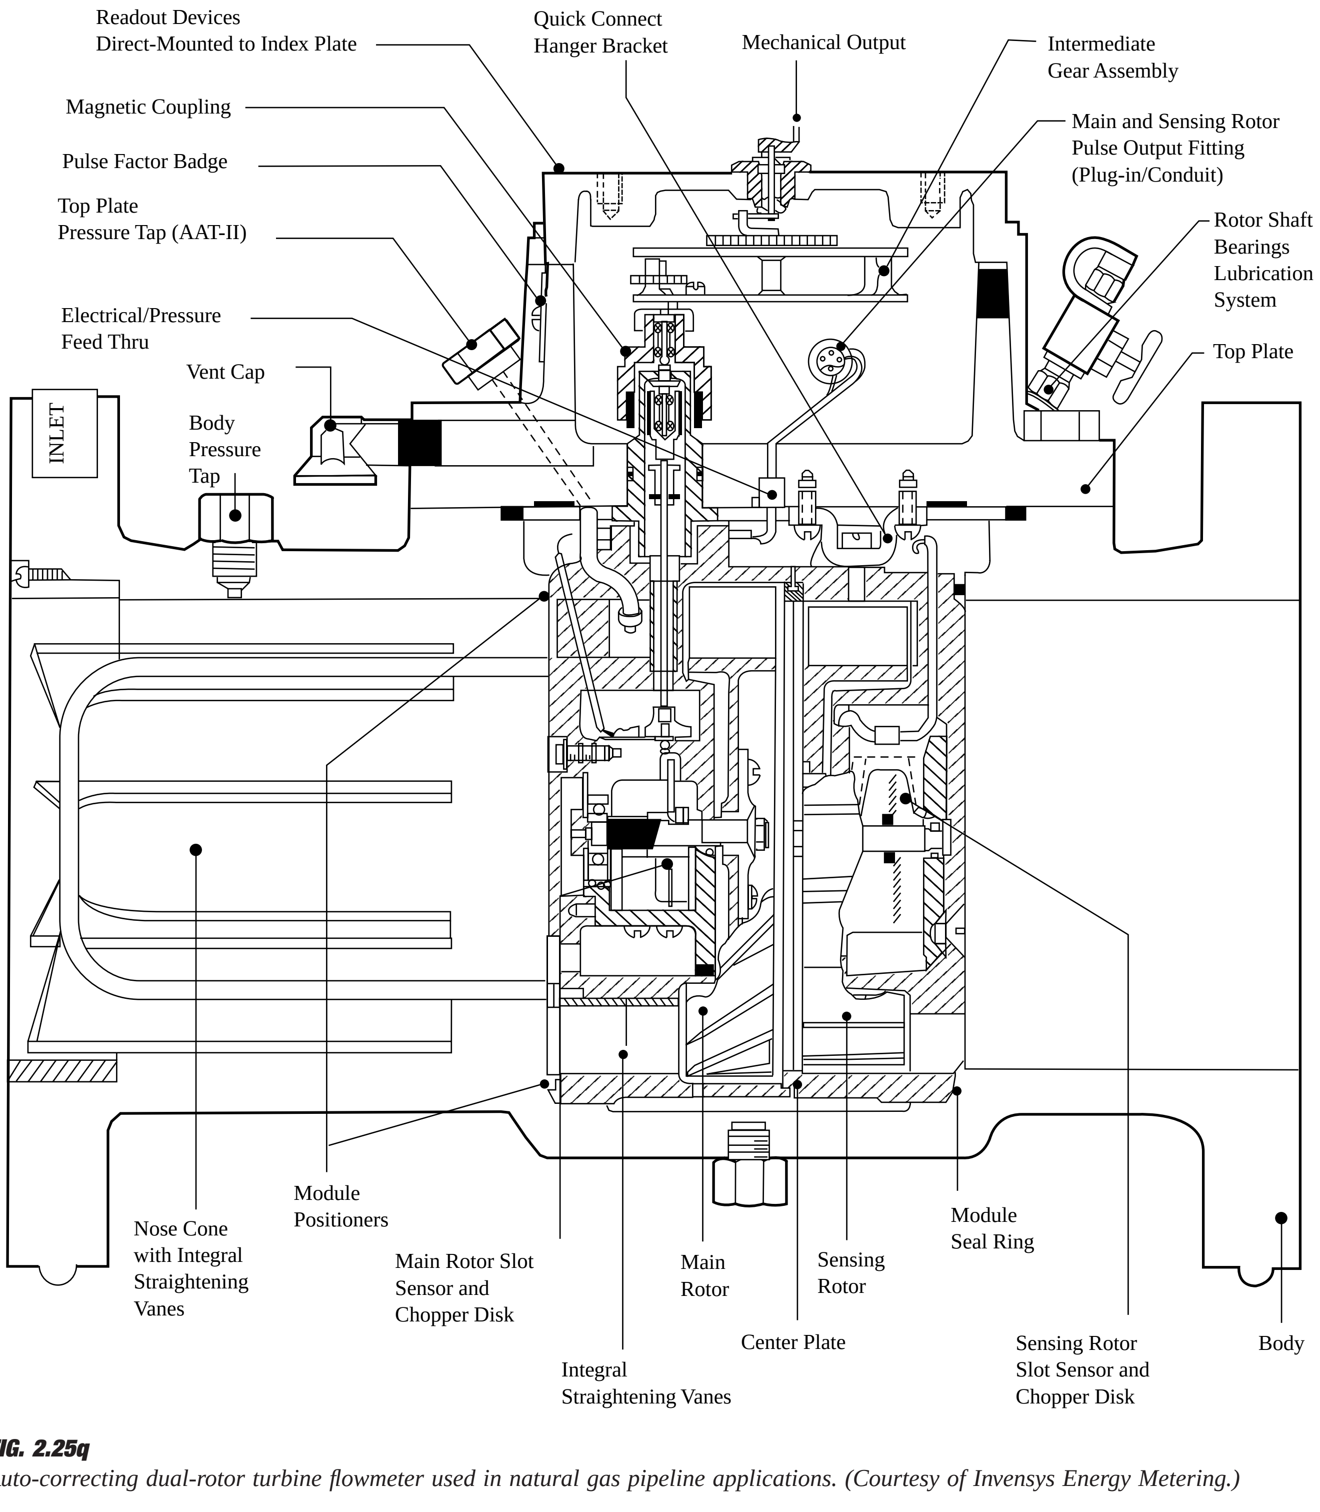

FIG. 2.25q
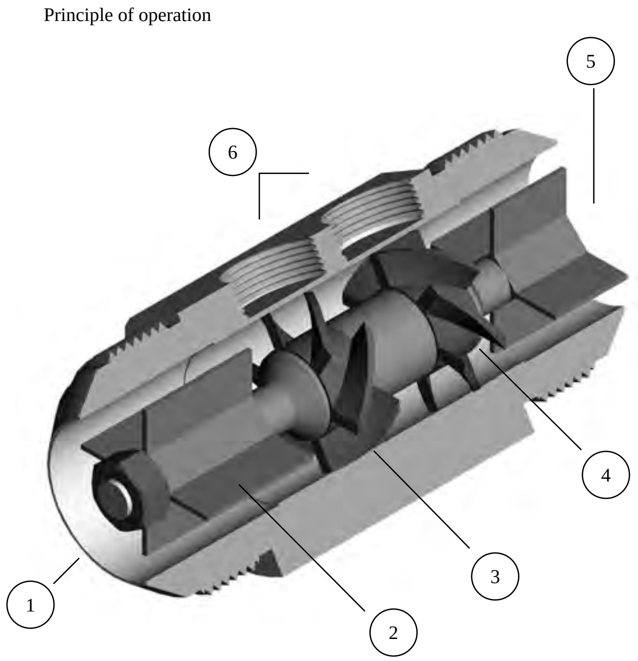
Auto-correcting dual-rotor turbine flowmeter used in natural gas pipeline applications. (Courtesy of Invensys Energy Metering.)

immune to overspeeding damage, and the bearing wear is also worse than with the QDI design. Both turbines in this dual-turbine flow sensor can be instrumented in the same manner as in the QDI twin-turbine sensor to provide bearing diagnostics.

Standard sizes range from 0.5 in. (12 mm) to 4 in. (100 mm), but special units up to 12 in. (295 mm) can be obtained. Essentially all ANSI pressure ratings are available, and the available operating temperatures range from −40°F (−40°C) to 450°F (232°C). Claimed calibration inaccuracy is ±0.1% of actual flow, and linearity is ±0.15 to 0.20% of rate with a typical repeatability of ±0.02%. Turndown ratio can range from 300:1 to 700:1 and, if reduced accuracy is acceptable, can reach up to 1000:1.



① Unconditioned flow enters flowmeter.

② Straightening vanes smooth the flow as it enters the first rotor.

③ Flow transfers momentum to the first rotor making it spin counterclockwise. Flow then exits rotor with a clockwise spin.

④ Flow enters second rotor with a nearly perpendicular angle of attack thereby transferring additional momentum to the second rotor. This additional momentum results in greatly extended turndown.

⑤ Flow exits flowmeter.

⑥ A pick-up transmits the rotor frequency signal to remote instrumentation. Optional dual pick-ups transmit signals from both rotors - the sum of which is a constant for any given flowrate. This provides powerful diagnostics and swirl insensitivity. In addition, the dual rotor effect increases the turndown ratio by 10 times that of a standard single rotor turbine meter.

FIG. 2.25r
Dual-turbine flowmeter, provided with dual pick-ups and with counter-opposed turbine rotation. (Courtesy of Exact Flow Corp.)

This dual-turbine flow sensor is primarily for nonflashing liquid flow applications and is not recommended for use on two-phase flow streams. The track record of this flowmeter, as compared to the QDI, is relatively limited, given that only a moderate number of existing field applications are now in operation. Yet, because of the inherent advantages of increased reliability and rangeability resulting from having two rotors (over single-rotor designs), the numbers of both QDI and Exact Flow installations are likely to rise in the coming years.

Comparing the Three Two-Turbine Designs

QDI is the only supplier that markets only complete flow measurement systems, which include all electronics and algorithms, rather than just turbine meters. This is because their system employs proprietary designs and algorithms. They do not sell just the turbine meters—only complete and totally integrated systems. Thus, the total responsibility for the system, including documentation and warranties, comes from them. This can be a big plus. QDI is also the only turbine meter design that is qualified as a continuous U.S. Defense Logistics Agency “certified quality vendor” and by the U.S. Navy as a “quality/lowest cost of ownership” equipment contractor.

IMPELLER AND SHUNT FLOWMETERS

Another flowmeter widely used in steam and gas flowmetering and totalizing applications is the shunt flowmeter illustrated in Figure 2.25s. It consists of an orifice plate in the main flow line and a self-operating rotor assembly in the bypass.

As gas flows through the meter body, a portion of flow is diverted to drive the fan shaft assembly, which is rotating on a jewel bearing. A second set of blades on the fan shaft, rotating in damping fluid, acts as a damper or governor. Rotational speed of the shaft is proportional to the rate of flow at all rates within the normal range of the meter.

These flowmeters are available in sizes of 2 in. (50 mm) and larger. Their inaccuracy is around ±2% of the actual flow, and their rangeability is about 10:1.

Impeller- and propeller-type flowmeters are widely used in wastewater and irrigation application where large flows and line sizes (up to 48 in. or 11.2 m) are required and cost is more important than accuracy. Accuracy is claimed to be 2% of reading. As illustrated in Figure 2.25t, in this meter, a corrosion-resistant plastic impeller is connected to a flexible and self-lubricating cable, which through a magnetic coupling drives an external mechanical register without requiring gears for its operation. The register is sealed from the process and requires no external power for operating a six-digit totalizer and a flow rate indicator. Easy access and removal of the complete flowmeter is provided through a cover plate. Straightening vanes are provided to improve the flow profile. The materials of construction can be aluminum, epoxy-coated carbon steel, plastic, or stainless steel.

INSERTION-TYPE FLOWMETERS

Both the liquid and gas turbine meters described above are full-bore metering devices; all flow passes through the meter. Their cost increases proportionately with pipe diameter. The insertion

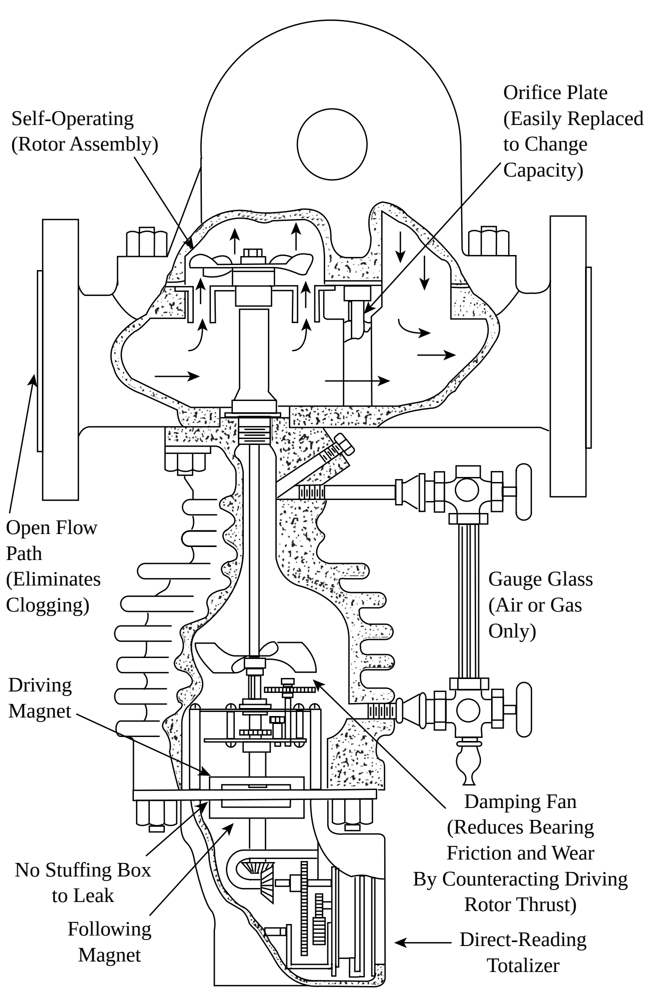


FIG. 2.15s
Shunt flowmeter.

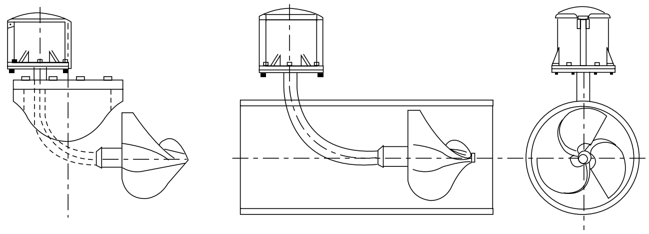

FIG. 2.25t
Impeller flowmeters are available in the paddle or the flow-through design. (Courtesy of McCrometer.)

turbine meter is a set of small turbine meter internals mounted on a probe in a large diameter pipe (see Figure 2.25u). The meter operating principles are the same as described previously except that the meter measures the fluid velocity only at a single point on the cross-sectional area of the pipe and does not "see" all the fluid. Total volumetric flow rate for the pipeline can then be inferred if certain assumptions are made about the velocity at measurement point. The velocity distribution

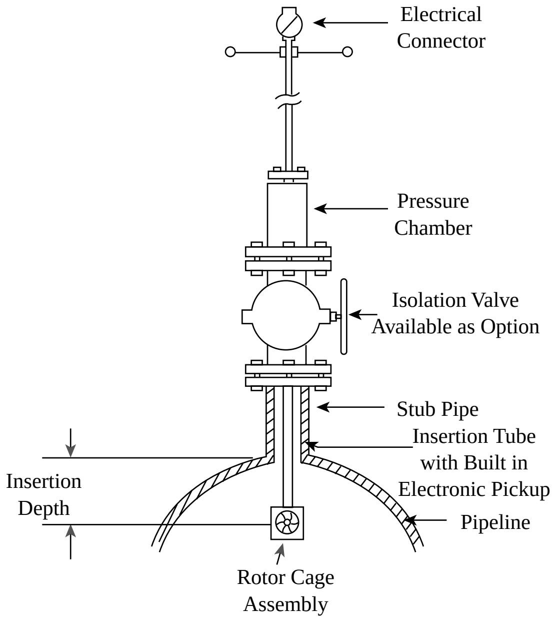

FIG. 2.25u
Insertion turbine flowmeter installed in large-diameter pipe.

can either be established by "profiling" the line (that is, taking a series of measurements across the pipeline and establishing the fluid velocity profile) or by establishing the optimal compromise insertion depth for a range of pipe diameters.

The insertion meter cannot be as accurate as a full-bore meter, since it is measuring velocity only at one point on the cross-sectional area. It does, however, provide a very low-cost metering system for large-diameter gas or liquid pipelines where accuracy is not important.

Insertion meters can be hot-tapped into existing pipelines through a valving system without shutting down the pipeline. A flanged riser, complete with valve, is welded to the pipeline. A hot-tap device is coupled to the valve, the valve is opened, and the pipe is penetrated. The hot-tap unit is withdrawn, and the valve is closed. The insertion meter is then installed, the valve is opened, and the meter is screwed in to the appropriate depth.

Insertion meters can be used on pipelines above 4 in. (102 mm) and, due to the small cross-sectional area relative to the pipe area, their pressure loss is very low. Typical linearity and repeatability figures are ±1% and ±0.25%, respectively. These are point velocity readings; in overall volumetric accuracy terms, the effects of changes in velocity profile must also be considered.

Optical Flow Sensors

A specialized version of the insertion-type turbine flowmeter is the optical photoflow sensor. The flow transducer consists of a probe supporting a low-mass rotating element that interrupts a light ray traveling from a light source to a photo transistor. The result is a pulse train that is converted into a volumetric flow representation.

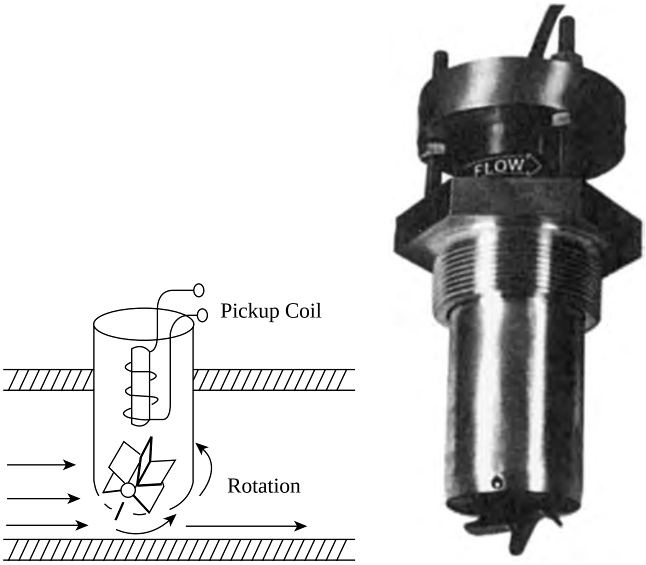

FIG. 2.25v
Paddlewheel flowmeter. (Courtesy of Data Industrial Corp.)

This flow transducer provides flow ranges as high as 100:1, bidirectional measurement without additional calibration, and extremely low pressure drop. The transmitter has only one moving part, the flow-sensing element. The bearing for the element is not located directly in the flow stream, enabling the transducer to handle severe flow conditions such as heavy surging and pulsating flows.

The installation requirements include the need for ten or more diameters of upstream straight run and the need to eliminate rotary valves (such as butterflies) at the ends of the measuring run.

Paddlewheel Flowmeters

One of the least expensive ways of measuring liquid flow in larger pipes (up to 12 in. or 305 mm) is to use one of the paddlewheel-type probes illustrated in Figure 2.25v. The rotation of the paddlewheel can be directed magnetically or optically, and the different manufacturers offer these probe units in both plastic and metallic materials. Accuracies, pressure ratings, and temperature ratings are low, but rangeability is reasonable, as these units are responsive to velocities as low as 1 ft/s (0.3 m/s) and can handle just about any maximum velocity. The fixed-insertion-length designs tend to be less accurate than the adjustable ones, as they cannot be moved as velocity profiles change. Some manufacturers claim these units to be usable on slurry service, but this is likely to require frequent cleaning.

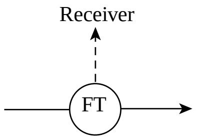
B. G. LIPTÁK (1995) **J. YODER** (2003)



Ultrasonic
Flow Sheet Symbol

Types	A. Transmission (contrapropagating transit time) B. Reflection (Doppler frequency shift or multipulse time shift) C. Open-channel (Note: A and B can be either “wetted” or “clamp-on.” Type A is more often wetted, type B is more often clamp-on. Clamp-on designs cannot be used as easily on concrete or lined metal pipe as on ordinary metal pipe. Type C is usually noncontacting.)
Applications	A. Clean liquids with little or no solids or bubbles; gases B. Slurries with solids (0.2 to 60% concentration, depending on particle size), liquids that are aerated or contain bubbles, gases with sound-reflecting particles, single-phase turbulent clean liquid C. Open-channel flow measurement based on upstream level in front of flumes or weirs
Flow Velocity Range	A. Normal is 1 to 50 ft/s (0.3 to 15 m/s); maximum reported is 0.1 to 100 ft/s (0.03 to 30 m/s). B. Minimum velocity for solids to stay in suspension is about 2.5 ft/s (0.75 m/s); bubbles require 6 ft/s (1.8 m/s). Otherwise, 0.2 to 60 ft/s (0.06 to 18 m/s) would be usable. C. Limits are unavailable in the literature.
Process Temperature	A and B. −300 to 500°F (−184 to 260°C); higher or lower with special sound-transmitting wedges
Design Pressure	A. Up to 3000 PSIG (207 bars) for wetted; unlimited for clamp-on B. Unlimited for clamp-on C. Usually atmospheric
Materials of Construction	A. Spools or transducer probes: steel, stainless steel, or alloys B. Usually clamp-on C. Noncontacting
Sizes	A. 0.125 to 120 in. (3 mm to 3 m) diameter B. 0.5 to 72 in. (13 mm to 1.8 m) diameter C. Not applicable
Straight Pipe Required	A and B. 10 to 20 diameters upstream, 5 downstream; very disturbed profiles require even longer straight runs or flow straighteners C. See requirements for weirs of flumes
Inaccuracy	A. From 1% of actual flow to 2% of full scale. Error can be reduced by careful determination of pipe ID and by increasing number of paths B and C. 2 to 5% of full scale
Costs	A. Spool designs in steel, not including options or special features and of the single-path design: $5000 for 4 in. (100 mm), $8000 for 10 in. (250 mm), $14,000 for 24 in.

(600 mm). Clamp-on design: \$3000 regardless of size, and \$1000 per acoustic coupling with thermal expansion chamber.

B. Clamp-on design, not including options or special features, is about \$3000, independent of pipe size; acoustic coupling is additional.

C. \$2200

Ultrasonic flowmeters were first introduced in Japan, in 1963, by Tokyo Keiki (now Tokyo). In 1972, Controlotron became the first U.S. manufacturer to introduce them in the United States. During the 1970s and early 1980s, the process control industry had high expectations for these devices. It was anticipated that they could be used for all types of process fluids (transit-time designs for clean fluids and Doppler reflection types for dirty, slurry-type streams); they could be installed without requiring a process shutdown (clamp-on types); their prices would be unaffected by pipe size and therefore would be economical for larger pipes; and they would not generate any pressure drop and would provide wide rangeability in both directions. These expectations generally did not come true until very recently.

The image of ultrasonic flowmeters was rather tarnished for decades because the complexity of the measurement produced was not initially realized. Factors that affect the measurement include the influence of the pipe, the flow profile, and the many practical obstacles and environment interferences that can occur. For the clamp-on designs, it turned out to be difficult to maintain a good acoustic coupling that would not fail from thermal expansion or drying out of the couplant (at higher temperatures for prolonged periods) and would not short-circuit by "ringing around the pipe." These problems have now been solved, or at least well defined.

For wetted designs, failure contributions included the effect of changes in velocity profiles (Figure 2.26a), the effect of variations in the refractive index, upstream piping configurations,

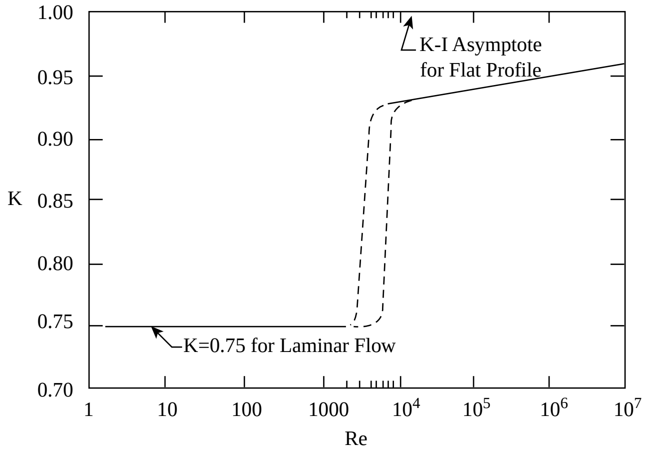

FIG. 2.26a
The ultrasonic flowmeters operate by averaging the velocity profile. This profile is flat at high Reynolds numbers and elongated at low Reynolds numbers. Consequently, the meter factor (K) also varies with Re, and it is rather unpredictable in the transition zone between laminar and turbulent regions.[1]

---

* Note: Most popular are units from GE Panametrics, Daniel-Emerson, Siemens-Milltronics, Controlotron, Endress+Hauser, Krohne, Thermo Polysonics, and ADS Environmental Service.

† Clamp-on design available.

making the acoustic path long enough in smaller sizes, overcoming the effects of turbulence, ambient conditions, and fluid property changes, including the change in the velocity of sound with temperature. These problems also have been solved or at least better identified.

TRANSIT-TIME FLOWMETERS

As the name implies, these devices measure flow by measuring the time taken for an ultrasonic energy pulse to traverse a pipe section, both with and against the flow of the liquid within the pipe. Figure 2.26b is a diagram of a representative transit-time flowmeter.

The time (t_{AB}) for the ultrasonic energy to go from transducer A to transducer B is given by the expression

$$t_{AB} = L/(C + V \cdot \cos\theta) \qquad \textbf{2.26(1)}$$

The time (t_{BA}) to go from B to A is given by

$$t_{BA} = L/(C - V \cdot \cos\theta) \qquad \textbf{2.26(2)}$$

where

C = speed of sound in the fluid
L = acoustic path length in the fluid
θ = angle of the path with respect to the pipe axis

By combining terms and simplifying it can be shown that, for $V << C$,

$$\Delta t = t_{BA} - t_{AB} = 2 \cdot L \cdot V \cdot \cos\theta / C \qquad \textbf{2.26(3)}$$

It can also be shown that:

$$V = L \cdot \Delta t / 2 \cdot \cos\theta \cdot t_A^2 = K \cdot \Delta t / t_A^2 \qquad \textbf{2.26(4)}$$

where t_A is the average transit time between the transducers.

Since the cross-sectional area of the pipe section or *spoolpiece* is known, the product of area and velocity will yield volumetric flow rate.

Frequency-Difference Type

In sing-around flowmeters, the reciprocals of transit times are used. This leads to a frequency difference (Δf) that is proportional to the flow velocity V or to the mach number V/C. The difference in frequencies is related to the velocity as follows:

$$V = \Delta f \cdot L/2 \cdot \cos\theta \qquad \textbf{2.26(5)}$$

The multipulse time-shift reflection method uses one or more pulses and times them to determine the change in range per second to an ensemble of scatterers. The change in range per unit time yields the velocity of scatterers.

Flowmeter Construction

The flowmeter usually consists of an electronics housing, transducers, and a pipe section. Several options are available as to the construction of the transducers and pipe section. Some designs allow removal of the transducers without interrupting process flow. A spoolpiece with integral transducers is one of the most common types of construction and is shown in Figure 2.26b. The manufacturer mounts the transducers to a flanged pipe section (spoolpiece). Usually, the manufacturer calibrates the unit to meet the customer's specifications. The spoolpiece thus becomes an integral part of the hydraulic system, so it is not easily retrofitted into an existing system.

Clamp-on transducers can be mounted outside an existing pipe, as shown in Figure 2.26c. The manufacturer can calibrate this type of system only if the customer provides detailed information on pipe diameter, pipe wall thickness, process fluid, percent of solids concentration, process temperature, variations in process temperature, and so forth. This type of flowmeter is easily retrofitted onto an existing system, given that no pipe section need be installed.

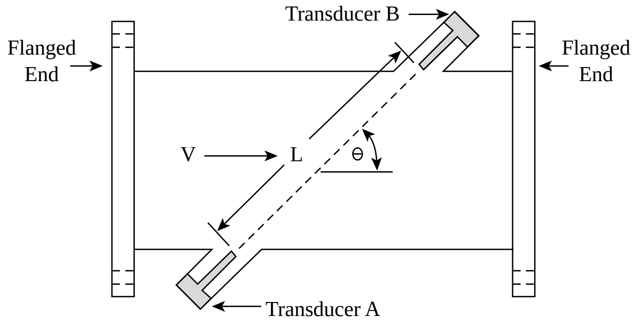

FIG. 2.26b
Transit-time flowmeter.

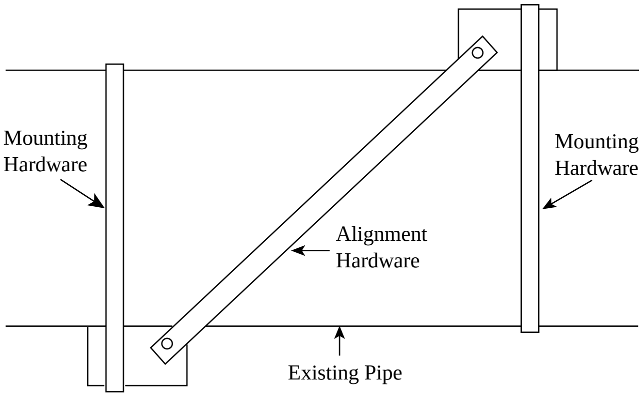

FIG. 2.26c
External transducers.

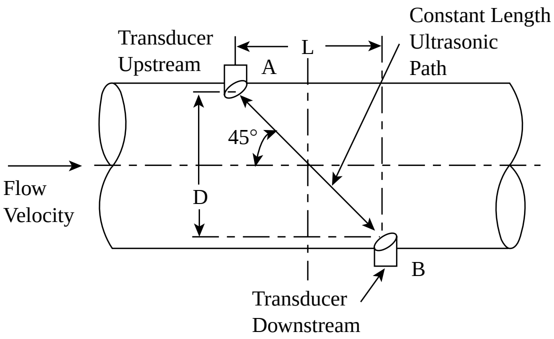

FIG. 2.26d
Wetted transducers communicate over a path that is fixed and independent of fluid speed, unless sound speed is nonuniform. (Courtesy of Panametrics Inc.)

Some manufacturers provide wetted transducers and mounting hardware that the user installs into an existing pipe. The user drills holes into the existing pipe and attaches the transducer mounting hardware by welding or other suitable means. The transducers are then mounted and aligned. Usually, the user may calibrate this type of unit after measurements of transducer angle and spacing and pipe diameter are made.

In case of “wetted” transducers, it is important to keep the distance that the ultrasonic pulse travels constant. The best way to achieve this is to keep the transmitting and reflecting surfaces perpendicular to each other (Figure 2.26d). This eliminates the effect of changes in the angle of refraction that can result from changes in process temperature or composition. Particularly in smaller pipes, the travel distance of the ultrasonic pulse might not be sufficient to produce accurate flow signals. Figure 2.26e shows how such distances can be increased.

In the early clamp-on designs, one of the difficulties was establishing an acoustically efficient sound-conductive path between the transducer and the process fluid inside the pipe. In the case of clamp-on designs, the transmitting and reflecting surfaces are the inside surfaces of the pipe. Potential errors caused by “ringing around the pipe” (pulse blockage by a molecular layer of air between the pipe and its lining, or variations in travel distance due to changes in the angle of refraction) are more difficult to solve with clamp-on units than with wetted ones. The acoustic coupling between the transducer and the pipe can be improved (Figure 2.26f) by eliminating the possibility of dry-out and by allowing for thermal expansion and contraction. Unfortunately, such couplings are relatively expensive and require periodic refilling of the fluid.

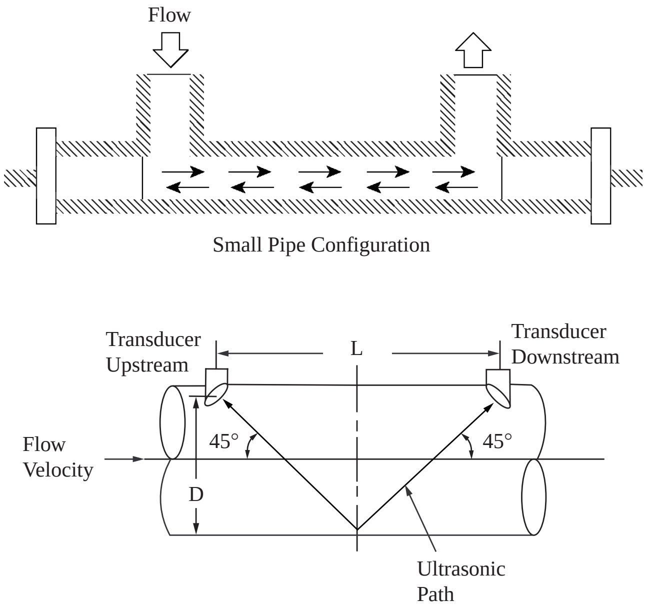

FIG. 2.26e
In smaller pipelines the time difference can be amplified by locating the transducers at the ends of a straight pipe section or by “bouncing” the ultrasonic pulse (one or more times) as shown on the right. (Courtesy of GE Panametrics Inc.)

Application and Performance

As with most flowmeters, the spoolpiece or pipe section must always be full to ensure proper operation and volumetric flow indication. Most manufacturers will specify the minimum distance from valves, tees, elbows, pumps, and so on that will ensure accurate flowmeter performance. Typically, 10 to 20 diameters upstream and 5 diameters downstream are required. The flowmeter relies on an ultrasonic signal traversing across the pipe; therefore, the liquid must be relatively free of solids and air bubbles. Bubbles in the flowstream generally cause more attenuation of the acoustic signals than do solids and therefore can be tolerated less. The flowmeter can tolerate a larger percentage of solids than bubbles.

Depending on the process fluid, proper transducer materials and protection must be chosen to prevent transducer damage due to chemical action. Process temperature limitations must also be considered for proper flowmeter application.

Accuracy is usually specified as a percent of rate. Typically, for a single-path flowmeter, it is approximately 1 to 2% of rate, depending on design, velocity, pipe size, and process. This accuracy can be expected only with calibrated flowmeters and only within the range of their calibration. Repeatability is usually specified as a percent of rate, typically about 0.5%, depending on velocity range and calibration.

To improve performance and accuracy for larger pipe sizes, some suppliers offer flowmeters with two, four, or more pairs of transducers arranged to interrogate multiple acoustic paths. The cost of such units is higher than that of a single-path flowmeter. The inaccuracy of multipath flowmeters can reach or exceed 0.5% of actual reading within a narrower range if the flow velocity exceeds 1 ft/s (0.3 m/s). Multipath flowmeters are widely used for custody transfer of natural gas. The ultrasonic market for measuring natural gas flow is the fastest-growing segment of the flowmeter market.

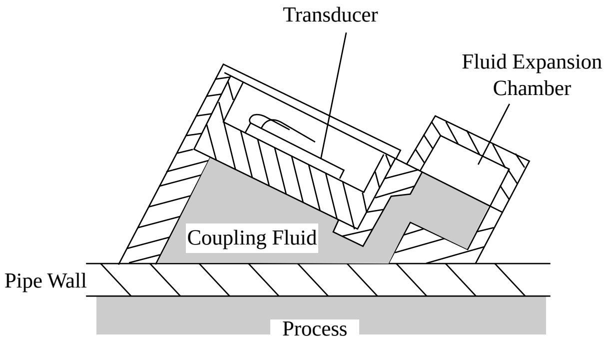

FIG. 2.26f
Liquid-filled ultrasonic coupling assembly.

DOPPLER FLOWMETERS

In 1842, Christian Doppler discovered that the wavelength of sound received by a stationary observer from a source that is moving toward the observer appears to be shorter, and the wavelength received when the source is moving away from the observer appears to be longer. The transmitter of a Doppler flowmeter projects an ultrasonic beam at a frequency of about 0.5 MHz into the flowing stream and detects the reflected frequency, which is shifted in proportion to stream velocity. The difference between transmitted and reflected velocities is called the "beat frequency," and its value relates to the velocity of the reflecting surfaces (solid particles and gas bubbles) in the process stream.

As shown in Figure 2.26g, an ultrasonic wave is projected at an angle through the pipe wall into the liquid by a transmitting crystal in a transducer mounted outside the pipe. Part of the energy is reflected by bubbles or particles in the liquid and is returned through the pipe wall to a receiving crystal. If the reflectors are traveling at the fluid velocity, the frequency of the reflected wave is shifted according to the Doppler principle in proportion to the flow velocity.

Combining Snell's law and the classical Doppler equation, the flow velocity can be determined as follows if $V << C$:

$$V = \Delta f \cdot C_t/(2 \cdot f_o \cdot \cos\theta) = \Delta f \cdot K \qquad \textbf{2.26(6)}$$

Where Δf is the difference between transmitted and received frequency, f_o is the frequency of transmission, θ is the angle of the transmitter and receiver crystal with respect to the pipe axis, and C_t is the velocity of sound in the transducer. As shown in Equation 2.26(6), velocity is a linear function of Δf. Since the inside diameter of the pipe is known, volumetric flow rate can be measured using Equation 2.26(7).

$$\text{GPM} = 2.45 \cdot V \cdot (ID)^2 \qquad \textbf{2.26(7)}$$

The single-transducer design is a popular one. Both the transmitter and received crystal are contained in a single transducer assembly that mounts on the outside of the pipe. The manufacturer thus controls alignment of the crystals. This approach is shown in Figure 2.26g.

In one form of the dual-transducer design, the transmitter crystal and the receiver crystal are mounted separately, on opposite sides of the outside of the pipe. Alignment is maintained by a mounting assembly that maintains the relative positions of the transducer as shown in Figure 2.26h.

When the process stream contains large amounts of solids (is sonically highly attenuative)—and bearing in mind that the velocity of the solid particles near the wall is likely to be less than the average, and recognizing that particles near the wall would dominate the readings in a single-transducer installation (causing large errors)—it is recommended that the two-transducer approach (supplemented by range gating) be used. With this approach, the reflected ultrasonic radiation is received from a more representative portion or portions of the flow stream.

Each manufacturer provides instructions on how to mount the transducer or transducers to the pipe. The acoustic

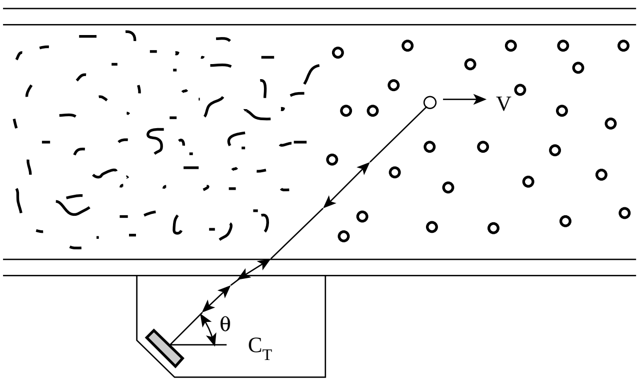

FIG. 2.26g
Doppler flowmeter principle of operation.

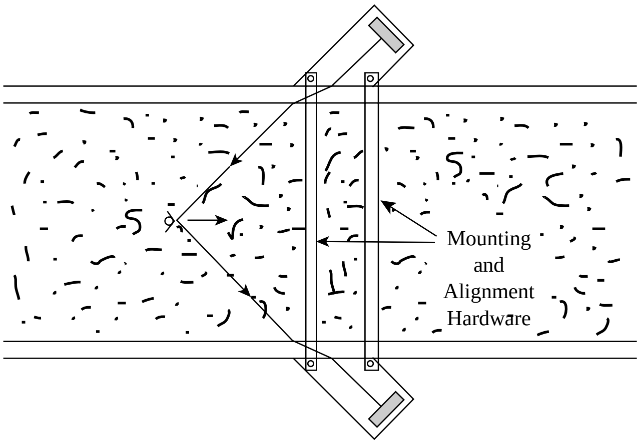

FIG. 2.26h
Two-transducer approach.

coupling to the pipe and the relative alignment of the transducers must be maintained in spite of pipe temperature changes and vibration so as to obtain acceptable performance.

Application and Performance

As with transit-time flowmeters, to properly indicate volumetric flow, the pipe must always be full. A Doppler unit will, however, indicate velocity in a partially full pipe as long as the transducer is mounted below the liquid level in the pipe.

The minimum straight pipe distance required from valves, elbow, tees, pumps, and so on is typically 10 to 20 diameters upstream and 5 diameters downstream for relatively clean fluids. This requirement can increase with process solids concentration or solids composition.

A Doppler flowmeter relies on reflectors in the flow stream to reflect the ultrasonic energy. There is a lower limit for the concentration and size of solids or bubbles in the liquid that will give reliable, accurate operation. The flow also must be fast enough to keep the solids or bubbles in suspension, typically at 6 ft/s (1.8 m/s) minimum for solids and 2.5 ft/s (0.75 m/s) for small bubbles, according to one manufacturer.

In the past few years, some manufacturers have introduced flowmeters that operate at frequencies of 1 MHz or higher. The claim for these high-frequency units is that they will operate on virtually clean liquids, because reflections will occur off the swirls and eddys in the flow stream. While this might be so, a high-frequency unit generally will not be suitable if the concentration of bubbles or particles exceeds 0.05%, because the penetration depth of the higher-frequency energy is much lower. Thus, for proper operation, a high-frequency Doppler flowmeter is limited to low-concentration applications.

On horizontal pipes, the best place to locate the transducer around the circumference should be determined on the basis of empirical testing and application experience.

The Doppler flowmeters will operate independent of pipe material if the pipe is sonically conductive. Such pipes as concrete, clay, and very porous cast iron absorb the ultrasonic energy and are not suited for Doppler-typed flowmetering. Similarly, the lining in lined pipes is not bonded well enough to allow the use of this type of clamp-on flowmeter, because even just a molecular layer of air is enough to block the transmission of the ultrasonic radiation.

The maximum operating temperatures of some ultrasonic flow transducers is about 212°F (100°C). The inaccuracy or error of the Doppler-type flowmeter is about 3% of full scale or span. The error does vary with flow velocity, pipe size, and flowmeter calibration. The error will also increase as the open flow area in the pipe changes either due to material buildup on the inside of the pipe or because the inside diameter was incorrectly measured in the first place. Repeatability is usually about 1% of full scale or full span.

DISPLAYS, RECEIVERS, AND INTELLIGENT UNITS

The electronics can be mounted either integrally with the ultrasonic flowmeter or remotely connected by cable. Remote location can be the choice for high-temperature services, although thermally isolating waveguides (Figure 2.26i) are also available. Routinely available transmitters can provide 4- to 20-mA DC analog, voltage, pulse train, or digital outputs, while the displays can provide both analog and digital indication in addition to totalization and alarming functions.

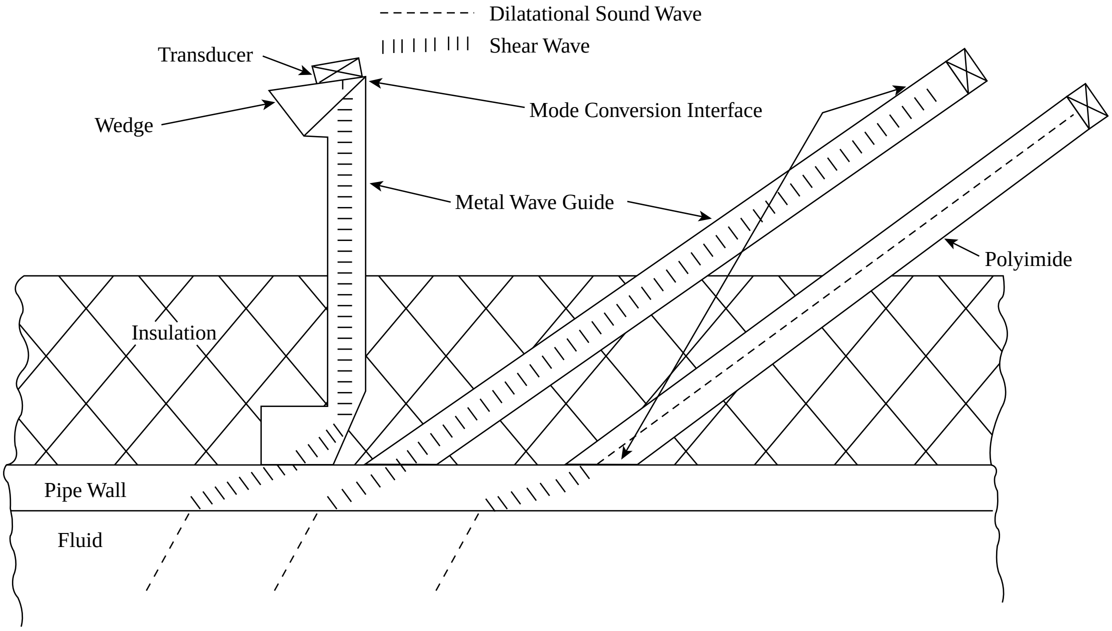

FIG. 2.26i
Three forms of thermally isolating waveguides.[2]

"Intelligent" flowmeters are capable of bidirectional flow measurement and of distinguishing true reflector movement from stationary particle or bubble vibration under no-flow conditions. One of the most promising tasks for smart ultrasonic flowmeters is to automatically evaluate the presence or absence of reflector particles or bubbles and to automatically switch from the transit-time to the Doppler reflection mode of operation and back. If and when this capability is fully developed, this "all-purpose" ultrasonic flowmeter (TransFlection®) will be able to measure the flow of both clean and dirty fluids. This capability, in combination with reduction in the unit costs, would make the ultrasonic flowmeter industry highly competitive.

ADVANTAGES OF ULTRASONIC FLOWMETERS

Ultrasonic flowmeters are members of the class of new-technology meters. Other members of this class are Coriolis, magnetic, vortex, and multivariable differential-pressure units. Ultrasonic flowmeters have some important advantages over other new-technology meters as well as over traditional-technology meters.

Ultrasonic meters have an advantage over Coriolis meters in that they do well in large-size pipes. Over 90% of Coriolis meters sold are for 2-in. pipes or smaller. Size is actually an advantage for ultrasonic meters, because there is more room for the ultrasonic beam to travel.

As compared to magnetic flowmeters, ultrasonic meters have the advantage that they can measure nonconductive fluids. Ultrasonic meters are widely used to measure liquids and gases, and they are beginning to be used for steam. Magnetic flowmeters, by contrast, are not used on gases or steams.

Ultrasonic meters measure fluids at a low flow rate better than do vortex meters. Vortex meters require a minimum Reynolds number and, therefore, a minimum velocity that might not be available at low flow rates. This is because, for a vortex meter to work effectively, the fluid has to be flowing fast enough to generate regular vortices.

As compared to traditional-technology meters such as differential-pressure (d/p) meters, ultrasonic flow detectors have the advantage of being less intrusive. The intrusiveness of d/p meters varies with the type of primary element. Clamp-on ultrasonic meters are completely nonintrusive, whereas spoolpiece meters are slightly intrusive. Insertion ultrasonic meters are somewhat more intrusive than the spoolpiece variety.

Ultrasonic flowmeters have significant advantages over turbine and positive-displacement meters. They are far less intrusive than either. Unlike both of these traditional-technology meters, ultrasonic meters do not have moving parts that are subject to wear. A great deal of competition is evolving between ultrasonic and turbine meters in their use for custody transfer of natural gas.

RECENT DEVELOPMENTS

Several important developments have occurred in this field in the past ten years. One of the most remarkable is the increased use of ultrasonic flowmeters for custody transfer of natural gas. This began in 1995, in Europe, when Groupe Europeen de Recherches GaziSres (GERG) approved the use of multipath ultrasonic flowmeters for custody transfer of natural gas. The movement picked up steam in the United States, in 1998, when the American Gas Association (AGA) followed suit with its own approval, using independent criteria. Both approvals helped generate very rapid growth in the ultrasonic flowmeter market, and this growth continues today.

Instromet and Daniel dominate the ultrasonic flowmeter market for measuring natural gas, although FMC Energy Systems has also introduced a flowmeter for this application. Apart from the somewhat specialized area of natural gas, Panametrics and Controlotron are the top suppliers. However, Krohne is rapidly gaining ground. Thermo-Polysonics is the top supplier of Doppler flowmeters.

More than 50 ultrasonic flowmeters are available from suppliers worldwide. With so many suppliers in a fast-growth market (see Table 2.26j), consolidation seems very likely. One would expect that this consolidation will be led by the major process control equipment suppliers.

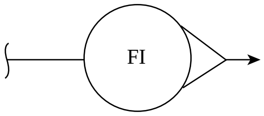
2.27 Variable-Area, Gap, and Vane Flowmeters



Flow Sheet Symbol

J. G. KOPP (1969,1982) **B. G. LIPTÁK** (1995) **T. J. BAAN** (2003)

Types	A. Rotameter (float in tapered tube) B. Orifice/rotameter combination C. Open-channel variable gate D. Spring-and-vane or piston
Standard Design Pressure	A. 350 PSIG (2.4 MPa) average maximum for glass metering tubes, depending on size Up to 720 PSIG (5 MPa) for metal tubes, special designs to 6000 PSIG (41 MPa)
Standard Design Temperature	A. Up to 400°F (204°C) for glass tubes and up to 1000°F (538°C) for some models of metal tube meters
End Connections	Female pipe thread or flanged
Fluids	Liquids, gases, and vapors
Flow Range	A. 0.01 cm^3/min to 4000 GPM (920 m^3/h) of liquid, 0.3 cm^3/min to 1300 SCFM (2210 m^3/h) of gas
Inaccuracy	A. Laboratory rotameters can be accurate to ±0.5% of actual flow; most industrial rotameters will perform within ±1 to ±2% of full scale over a 10:1 range, dual float rotameters can detect flow over a 20:1 range, and purge or bypass meters ±5 to ±10% of full range. B and D. ±2 to ±10% of full range C. ±7.5% of actual flow
Materials of Construction	A. Tube: Borosilicate glass, stainless steel, Hastelloy®, Monel®, Alloy 20®, PFA, Acrylic, Polysulfone, and polycarbonate. Float: *Conventional type*—brass, stainless steel, Hastelloy®, Monel®, Alloy 20®, nickel, titanium, or tantalum, and special plastic floats. Ball type—glass, stainless steel, tungsten carbide, sapphire, or tantalum. End Fittings: aluminum, brass, stainless steel, PTFE, or alloys for corrosive fluids. Packing: The generally available elastomers are used and O-rings of commercially available materials; Teflon® is also available.
Cost	A $\frac{1}{4}$-in. (6-mm) glass tube purge meter starts at \$75. A $\frac{1}{4}$-in. stainless-steel meter is about \$300. Transmitting rotameters in $\frac{1}{2}$-in. (13-mm) size and with 2.5% error start at about \$1200 whereas, with 0.5% of rate accuracy, their costs are over \$2500. A 4-in. (100-mm) transmitting rotameter with ±2.5% FS error is \$3000; a 3-in. (75-mm) standard bypass rotameter is about \$750, and a 3-in. stainless-steel tube standard rotameter is about \$2500. A 3-in. tapered-plug variable-area meter in aluminum construction is about \$1200, and the same unit in spring-and-vane design is around \$800.

The variable-area flowmeter is also a head-type flow sensor, but it does not measure the pressure drop across a fixed orifice; instead, the pressure drop is held relatively constant, and the orifice area is varied to match the flow (Figure 2.27a). In gravity-type variable-area flowmeters, increasing flow lifts the float, piston, or vane, and it is the weight of these flow elements that has to be balanced by the kinetic energy of the flowing stream. These units can operate only in a vertical position. When the lifting of the float, piston, or vane is resisted by a spring instead of gravity, the meter can be installed in any position and can be configured as a pipeline spool piece. This advantage of piping convenience has to be weighed against the fact that a spring in the process stream can be a maintenance problem and may not yield as constant a force as does gravity.

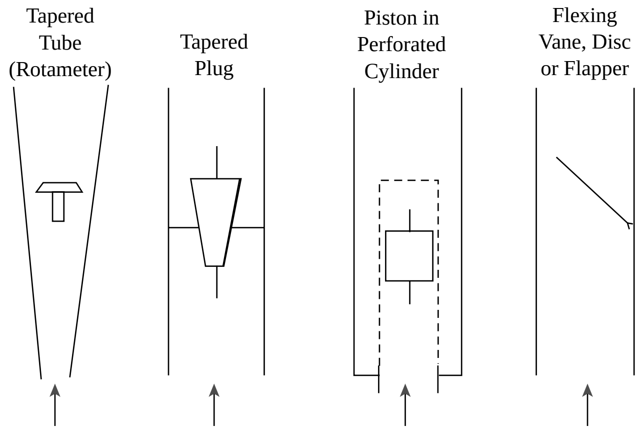

FIG. 2.27a
The area open to flow is changed by the flow itself in a variable-area flowmeter. Either gravity or spring action can be used to return the float or vane as flow drops.

All variable-area flowmeters can be provided with direct local indicators. In addition, most of them can also be furnished with pneumatic, electronic, digital, or fiber optic transmission or with microprocessors for intelligent and convenient operation. A few of the designs can also be used as self-controlled flowmeters or purge meters. In the discussion below, the different variable-area flowmeters will all be discussed, starting with the tapered tube (rotameter) designs.

ROTAMETERS

Rotameters are popular choices for low-flow measurement because of their low cost, simplicity, low pressure drop, relatively wide rangeability, and linear output. They are limited in that they can be installed only vertically, they can be used only on clean fluids, and, if glass tubes are used, they can present a safety hazard (and dirt buildup on the glass tube can limit visibility). Glass tubes are also limited in terms of their maximum pressure and temperature ratings. Their safe working pressure drops as the tube diameter increases. For a ¼-in. (6-mm) diameter tube, it is 450 PSIG (3 MPa), whereas, for a 4-in. (100-mm) diameter tube, it is only 40 PSIG (275 kPa). Because the stainless-steel float expands more with temperature than does the glass tube, the operating temperature is limited to 200°F (93°C) for a ¼-in. (6-mm) diameter tube, and this limit drops to 120°F (49°C) for a 4-in. (100-mm) diameter tube. The flow capacity of glass tube rotameters is also limited. A ¼-in. (6-mm) diameter tube will pass 0.05 to 0.5 GPM (0.19 to 1.9 l/min) water or 0.18 to 1.8 SCFM (0.3 to 3 cmph) of air. For a 3-in. (75-mm) diameter unit, the maximum water flow range is 60 to 120 GMP (225 to 450 l/min), and the maximum airflow is 200 to 500 SCFM (350 to 900 cmph). (For a detailed discussion of purge rotameters, refer to Section 2.20.)

The rotameter is a variable-area-type flowmeter. It consists of a tapered metering tube and a float that is free to move up and down within the tube. The metering tube is mounted vertically with the small end at the bottom. The fluid to be measured enters at the bottom of the tube, passes upward around the float, and flows out at the top. Figure 2.27b is a representation of a rotameter.

When there is no flow through the rotameter, the float rests at the bottom of the metering tube where the maximum diameter of the float is approximately the same as the bore of the tube. When fluid enters the metering tube, the buoyant effect of the fluid lightens the float, but it has a greater density than the fluid, and the buoyant effect is not sufficient to raise it. There is a small annular opening between the float and the tube. The pressure drop across the float increases and raises the float to increase the area between the float and tube until the upward hydraulic forces acting on it are balanced by its weight minus the buoyant force. The metering float is “floating” in the fluid stream. The float moves up and down in the tube in proportion to the fluid flow rate and the annular area between the float and the tube. It reaches a stable position in the tube when the forces are in equilibrium. With upward movement of the float toward the larger end of the tapered tube, the annular opening between the tube and the float increases. As the area increases, the pressure differential across the float decreases. The float will assume a position, in dynamic equilibrium, when the pressure differential across the float plus the buoyancy effect balances the weight of the float. Any further increase in flow rate causes the float to rise higher in the tube; a decrease in flow causes the float to drop to a lower position. Every float position corresponds to one particular flow rate, and no other, for a fluid of a given density and viscosity. It is merely necessary to provide a reading or calibration scale on the tube, and flow rate can be determined by direct observation of the position of the float in the metering tube.

Frequently, glass metering tubes are installed in metallic frames with thick, clear front shields to protect the operator from accidental spillages or leaks. There are also acrylic, polycarbonate, polysulfone, or other plastic flowmeters for lower-cost applications.

Metal metering tubes are used where glass is not satisfactory. In this case, the float position must be indirectly determined by either magnetic or electrical techniques. The use of indirect float position sensors also provides functions other than direct visual indication. Rotameters are available that transmit pneumatic, electronic, or time-pulse signals or provide recording, totalizing, or control functions. For highly corrosive applications, PTFE flowmeters with translucent PFA metering tubes are available. These meters are designed with PTFE seals and O-rings excluding elastomeric materials. Figure 2.27c illustrates a typical PTFE-PFA flowmeter.

PTFE-PFA rotameter for highly corrosive fluids. (Courtesy of AALBORG Instruments.)

Sizing

To size a rotameter, it is customary to convert the actual flow to *standard flow.* For liquid flows, it is necessary to calculate the GPM (l/min or l/hr) water equivalent. For gases, it is necessary to determine the SCFM (l/min or l/hr) air equivalent. Capacity tables are based on these standard flows of GPM or cm^3/min of water and SCFM or cm^3/min of air at standard conditions. The tables also are based on using stainless-steel floats.

The equations necessary to calculate the water or air equivalent are provided below.

Liquids

Volume Rate

$$\text{GPM Water Equivalent} = \frac{(\text{GPM})(\rho)(2.65)}{\sqrt{(\rho_f - \rho)\rho}} \qquad \textbf{2.27(1)}$$

Weight Rate

$$\text{GPM Water Equivalent} = \frac{(\text{lbm/min})(0.318)}{\sqrt{(\rho_f - \rho)\rho}} \qquad \textbf{2.27(2)}$$

Base or Contract Volume Rate

$$\text{GPM Water Equivalent} = \frac{(\text{GPM}_b)(\rho_b)(2.65)}{\sqrt{(\rho_f - \rho)\rho}} \qquad \textbf{2.27(3)}$$

Gases or Vapors

Standard Volume Rate

$$\text{SCFM Air Equivalent} = \frac{(\text{SCFM})(\rho_{g\,std})(10.34)}{\sqrt{\rho_r(\rho_{g\,act})}} \qquad \textbf{2.27(4)}$$

Weight Rate

$$\text{SCFM Air Equivalent} = \frac{(\text{lbm/min})(10.34)}{\sqrt{\rho_r(\rho_{g\,act})}} \qquad \textbf{2.27(5)}$$

Operating or Actual Volume Rate

$$\text{SCFM Air Equivalent} = \frac{(\text{ACFM})(\rho_{g\,act})(10.34)}{\sqrt{\rho_r(\rho_{g\,act})}} \qquad \textbf{2.27(6)}$$

where

GPM = maximum flow of liquid at metering condition in units of gallons per minute
GPM_b = maximum flow of liquid at base or contract condition in units of gallons per minute
lbm/min = maximum flow of fluid at metering condition in units of pounds per minute
SCFM = maximum flow of gas referred to a base or standard condition in units of cubic feet per minute
ACFM = maximum flow of gas at operating conditions in units of cubic feet per minute
ρ = density of flowing liquid at metering conditions in units of grams per cubic centimeter
ρ_b = density of flowing liquid at base or contract conditions in units of grams per cubic centimeter
ρ_f = density of float in units of grams per cubic centimeter
$\rho_{g\,std}$ = density of gas at 14.7 PSIA and 70°F or 14.4 PSIA and 60°F in units of pounds per cubic foot
$\rho_{g\,act}$ = density of gas at metering conditions in units of pounds per cubic foot

To facilitate these computations, manufacturers offer slide rules or nomographs specifically designed for rotameter sizing.

Rotameter Characteristics

A very wide range of liquids can be handled by the rotameter. A wide choice of tube, float, end fitting, and packing or O-ring materials are available for the particular service being considered. Even liquid metals such as mercury and liquid lead can be metered. Because these metals are denser than the stainless-steel float, they are metered by an inverted rotameter. In this case, the flow is from top to bottom. When the meter is full of the liquid metal but there is no flow, the stainless-steel float is buoyed up by the heavier liquid and rests at the inlet, which is at the top. When there is flow, the flow forces the float down against the net buoyant force, and the float takes a position related to the flow rate.

The rotameter is an inexpensive flowmeter for gas flow measurement. The pressure drop across the meter is essentially constant over the full 10:1 operating range. Pressure drop is low, generally less than 1 PSI (6.89 kPa). Special designs are available for even lower pressure drops.

The position of the float in the metering tube varies in a linear relationship with flow rate. This is true over ranges up to 10:1. Percent of maximum, universal millimeter, and direct reading scales are used. Direct reading scales are convenient; however, they are valid only for the fluid for which they were designed and only at a unique set of pressure and temperature conditions. Universal millimeter scales are used in conjunction with separate calibration charts relating the elevations of the float to flow rates. The advantage of universal scales is the capability of a single flowmeter to be used for different fluids at various pressure and temperature conditions. Rotameters can directly measure flows as high as 4000 GPM (920 1/h). Even higher flow rates can be economically handled using

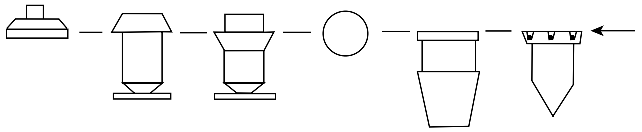

FIG. 2.27d
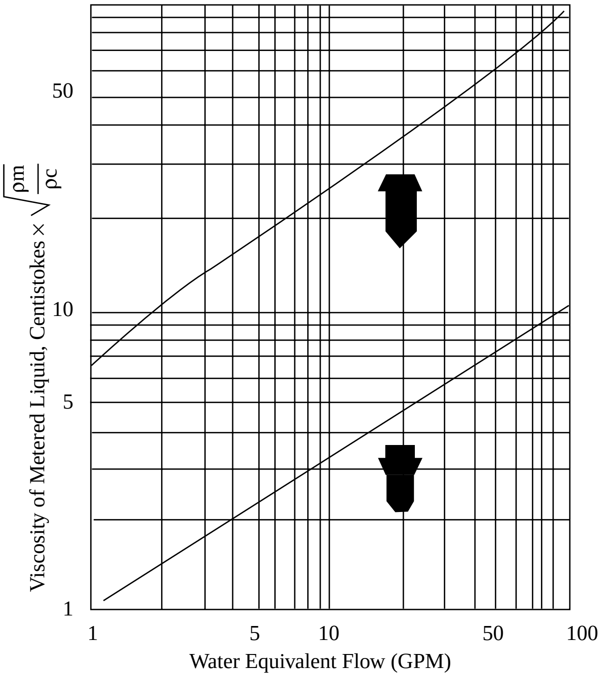
Variation in the shape of rotameter floats. The float on the right is provided with slots, which caused the early floats to rotate (for stabilizing and centering purposes); hence the name "rotameter."



ρm = Density of Metered Liquid
ρc = Density of Calibrating Liquid (Water)

FIG. 2.27e
Viscosity limits of rotameters depend on float shape. (Courtesy of Brooks Instrument Div. of Rosemount.)

the bypass-type rotameter. The capacity of the rotameter can be changed by changing the float. Various float configurations are available for higher capacities and generally permit a 2:1 change in capacity (Figure 2.27d). By using the same housing but changing both the metering tube and the float, a gross change in capacity is possible. These changes can be required by both a change in flow rate and a change in fluid density. For small flows in which spherical floats are employed, a downturn of better than 20:1 is achieved when two floats of different densities are installed in the same flow tube. The flow capacity of a rotameter is increased when floats have guide rods to permit the use of metering tubes with larger conical tapers.

The rotameter tends to be self-cleaning. The velocity of the flow past the float and the freedom of the float to move vertically enable the meter to clean itself of some buildup of foreign material. Liquids with fibrous materials are exceptions and should not be metered with rotameters. Generally, the size of particle, type of particle (whether fibrous or particulate), and the abrasiveness of the particle determine the suitability of the rotameter for a given service. Also, the percentage of solids by weight or by volume and the density of the solids influence the selection of the rotameter for this service.

Rotameters are relatively insensitive to viscosity variations. In the very small rotameters with ball floats, this is not the case, and the meters do respond to Reynolds number changes, which makes them sensitive to changes in both viscosity and density. However, the larger rotameters are less sensitive (Figure 2.27e). The viscosity immunity threshold can be as high as 100 cps (1 Pa · s). Meters can be operated above the viscosity limit; however, for these conditions, the meter is calibrated for discrete viscosity conditions that are to be encountered, and correction curves are furnished to adjust the indicated flow to the actual flow for the given viscosity.

The rotameter can also be used to approximate mass flow rate, given that the float responds to changes in fluid density. For a fixed volumetric flow rate, the float position in the metering tube will change with changing fluid density. The effect of fluid density changes on float position is a function of the relative densities of the float and the fluid. The closer the float density approaches the fluid density, the greater the effect of a given fluid density, and the greater the effect of a given fluid density change. It has been derived that, if the float density is twice the fluid density, the compensation for fluid density change is exact, and the rotameter is a mass flowmeter. However, fluid density normally varies and, because the float density is not adjustable to follow the fluid density changes, a compromise is made. The mean fluid density is used to establish the float density. A 10% fluid density change from the reference causes only a 0.5% inaccuracy in mass flow measurement. The mass rotameter can be used only for low-viscosity fluids such as raw sugar juice, gasoline, jet fuels, and other light hydrocarbons.

Although the vast majority of rotameters operate at errors of 2 to 10% of full scale, some are available with percent-of-rate performance. Logarithmic scale meters are designed to give the same percent-of-rate accuracy at all scale positions over the 10:1 range of the meter. Accuracy statements of 0.5% of rate and 1% of rate are available. The high-accuracy type rotameter finds greatest application in laboratory testing, development, and production, where best accuracy is mandatory.

The meter is not affected by upstream piping effects. The meter can be installed with practically any configuration of piping before the meter entrance. For vacuum applications, a valve should be installed at the outlet of the rotameter to permit virtually atmospheric conditions at the inlet and inside the metering tube. This configuration will help preserve the validity of STP calibrations.

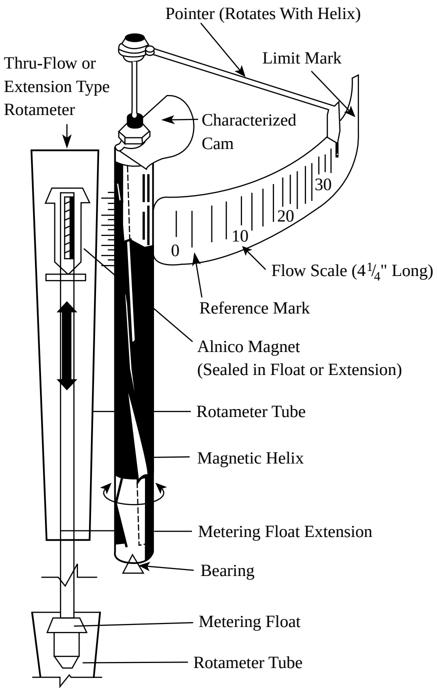


FIG. 2.27f
Magnetic coupling operates external indicator or transmitter across stainless-steel rotameter tube.

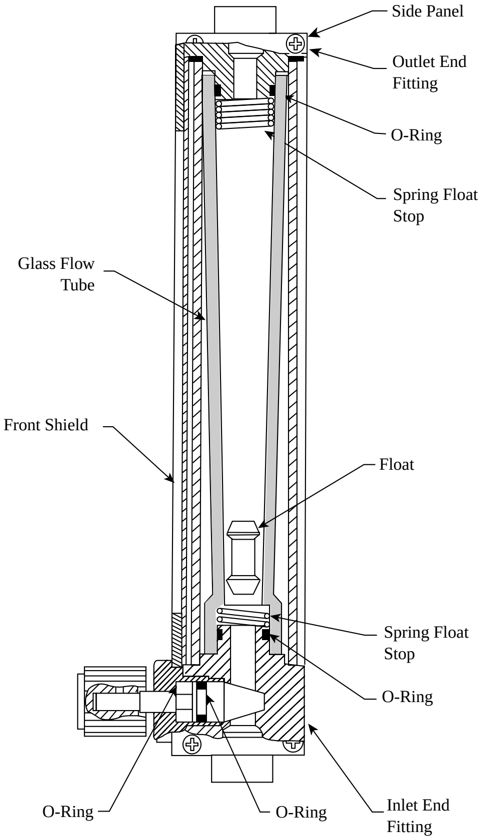

FIG. 2.27g
Typical tapered glass tube rotameter. (Courtesy of AALBORG Instruments.)

The rotameter is a highly developed flowmeter. The meters are available with an extremely broad selection of alarms, indicators, transmitters (Figure 2.27f), totalizers, controllers, and recorders. A choice of totalizers, controllers, recorders, indicators, and alarms are available locally at the flowmeter. Practically any combination of system requirements can be handled by the accessories and instruments associated with rotameters.

Rotameter Types

Figure 2.27g shows a cross-sectional view of a representative general-purpose rotameter. The meter is almost always used for flow indication only. A wide choice of materials are available for the float, packing, O-rings, and end fittings to handle the widest selection of fluids. The only fluids that cannot be handled are those that attack the glass metering tube. The meters also are limited to the pressure and temperature extremes of the glass metering tube, and by safety considerations. The accuracy of these rotameters is usually ±1 to ±2% of full scale.

Metal tube meters are used when the general-purpose meters cannot be applied. They can be used for hot (above 100°F or 38°C) and strong alkalies (above 20% concentration), fluorine, hydrofluoric acid, hot water (above 200°F or 93°C), steam, slurries, or molten metals where glass cannot be used. This classification of meters is used where the operating temperature and pressure exceed the ratings of the glass tube or, generally, where transmission of electronic or pneumatic signals is needed. A typical metal tube meter is shown in Figure 2.27h.

Bypass and Pitot Rotameters

The cost of a rotameter installation can be reduced if, instead of a full pipe-size rotameter, an orifice or pitot tube is used in the main pipeline to develop a pressure drop. This, in turn, causes a related small flow that can be directed through an inexpensive bypass rotameter. Such units are illustrated in Figures 2.27i and 2.27j. The pitot-type can be used in pipe sizes of 1.5 in (38 mm) and larger, whereas the orifice bypass assemblies are available from 0.375 to 20 in. (1 to 51 cm) pipe diameters. In some designs, the bypass rotameter is provided with a range orifice that is sized to lift the rotameter float to the maximum position when the flow in the main line is at maximum. The flow measurement is linear over a 10:1 range and is accurate to about 2% of full scale with the orifice and to 5 to 10% of full scale with the pitot design. These units are usually designed for clean process streams such as water and air and are provided with easily accessible filters for periodic cleaning. The bypass rotameters are also available with isolation valves to allow for their removal and maintenance while the process is in operation.

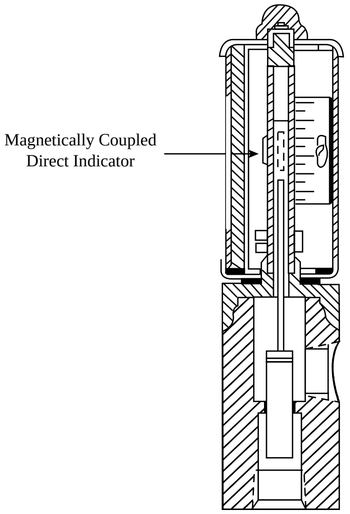

FIG. 2.27k
Tapered-plug variable-area flowmeter. (Courtesy of Brooks Instrument Div. of Rosemount.)

TAPERED PLUG AND PISTON METERS

Tapered-plug variable-area flowmeters are made with metallic meter bodies and are used on higher-pressure applications where errors of 5 to 10% full scale can be tolerated. They can be gravity operated (Figure 2.27k) or spring loaded (Figure 2.27l) and can handle pressures exceeding 1000 PSIG (70 bars). Their sizes range from ¼ to 4 in. (6 to 100 mm), and their body materials include brass, aluminum, steel, stainless steel, and PVC. The gravity-operated units must be installed vertically, whereas the spring-loaded ones can also be horizontal. One common application is to detect the flow rate of high-pressure oil.

One type of variable-area flowmeter operates a piston in a perforated cylinder (see Figure 2.27m). This instrument is less expensive than a regular rotameter. It has been designed for clean liquid flows at rates up to 120 GPM (450 l/min) or gas flows up to 700 SCFM (20 SCMM) with pressures up to 100 PSIG (7 bars) and temperatures up to 400°F (205°C).

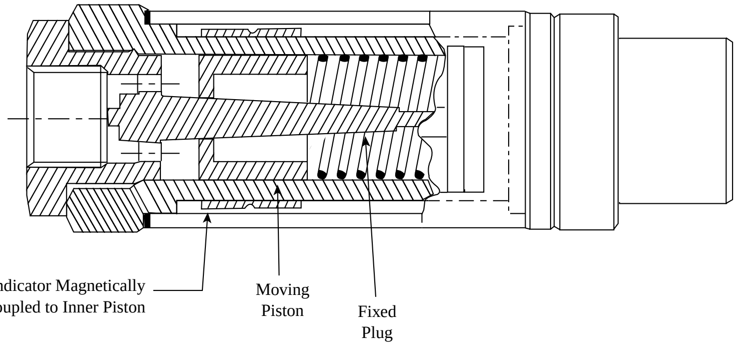

FIG. 2.27l
Tapered plug and spring-loaded piston. (Courtesy of Headland Div. of Racine Federated Inc.)

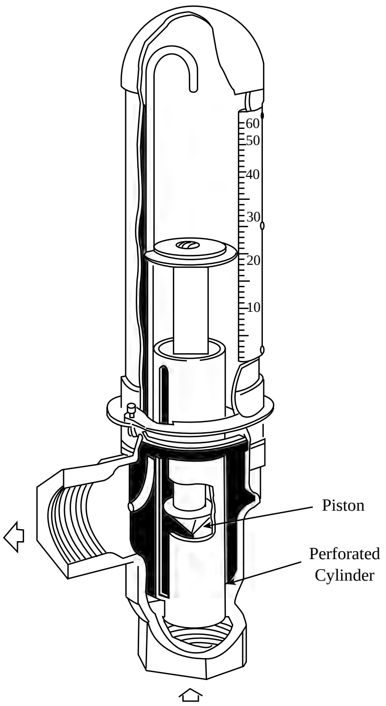

FIG. 2.27m
Piston in perforated cylinder variable-area flowmeter.

GATES AND VANES

A family of variable-area flowmeters operates by the flowing stream lifting hinged gates or forcing spring-loaded vanes to open. The variable gate is a mix of a variable-area and a flume-type flowmeter. It is used to measure wastewater or other liquids in open channels or in partially filled pipes. The meter can be inserted into 6- or 8-in. (150- or 200-mm) diameter pipes. A stainless-steel ring holds it in place, and an inflatable bladder seals the insert so that all the flow will pass through the gate opening. The pivoted gate opening is pneumatically controlled and is measured along with the upstream level to arrive at the actual flow. The same 8-in. (200-mm) insert can measure the flow from 0.25 to 500 GPM (1 to 1900 l/min).

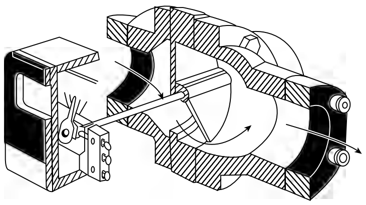

FIG. 2.27n
Rotary vane-type variable-area meter. (Courtesy of Universal Flow Monitors Inc.)

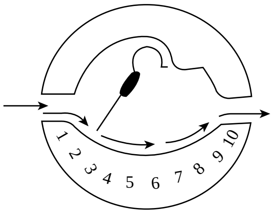

FIG. 2.27o
Magnetically coupled vane. (Courtesy of ERDCO Engineering Corp.)

Reasonable accuracy is obtained over this nearly 2000:1 flow range. Up to 10 GPM (38 l/min), the maximum error is 0.75 GPM (2.8 l/min); at higher flows, it is claimed to be 7.5% of actual reading. The meter is provided with data storage, printer, and local or remote monitoring capability.

One vane-type variable-area flowmeter resembles a butterfly valve (Figure 2.27n). The changing flow through the orifice area forces the spring-loaded vane to rotate. A shaft attached to the vane operates a pointer giving local flow rate indication. The measurement error is 2 to 5% of full scale. The meter can be used on oil, water, air, and other services and is available in $\frac{1}{4}$- to 4-in. (6- to 100-mm) sizes and in most standard materials. This variable-area flowmeter is frequently used as an indicating flow switch for safety interlock purposes.

Another vane-type variable-area flowmeter is illustrated in Figure 2.27o. This unit can also measure the flow rates of liquids, gases, and steam and is available in sizes from $\frac{1}{2}$ to 12 in. (12 to 300 mm). The flow indicator is magnetically coupled to the vane, and the indication is claimed to be accurate within 2% of full scale over a 10:1 range. The flow direction through the meter can be left-to-right, right-to-left, or vertical. Operating pressures are limited to 200 PSIG (1.4 MPa). Operating temperatures are limited to 250°F (120°C) in standard and to 400°F (205°C) in units with Viton® O-rings. The housing can be aluminum, brass, copper/nickel, or stainless steel. A limitation or a possible source of error to be considered for this type of a variable area meter is posed by nearby strong electromagnetic fields that could interfere with the magnetic coupling of the indicator.

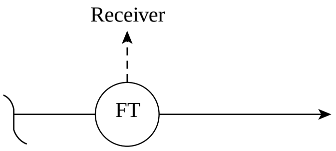
2.28 V-Cone Flowmeter

B. G. LIPTÁK (1995) **W. H. BOYES, JR.** (2003)



Flow Sheet Symbol

Applications	Liquids, gases, and steam
Sizes	From 0.5 to 72 in. (12 mm to 1.8 m) in V-cone From 0.5 to 6 in. (12 mm to 150 mm) in wafer-cone
Materials of Construction	V-cone: All type 316 stainless-steel or PVC construction with cone made out of stainless steel, PVC, or Teflon®-coated aluminum Wafer-cone: machinable in any material according to the supplier
Design Pressure	150 to 600 PSIG (10.3 to 41.4 bars) with flanged connections; higher with threaded connections
Design Temperature	From cryogenic to 700°F (371°C)
Pressure Differential	The low-range d/p cell can have a 0- to 2-in. (51-mm) H_2O range, and the high-range cell can have 0- to 30-in. (762-mm) H_2O range. If even higher rangeability is needed, a third 0- to 250-in. (6.35-m) H_2O d/p cell can be added.
Reynolds Numbers	Square root relationship is maintained down to Re = 8000.
Inaccuracy	This is a function of the calibration and accuracy of d/p cell used. With two transmitters, a 0.25% error of actual span used can be expected.
Rangeability	Over 10:1 if two transmitters are used, one for high the other for low pressure drop
Straight Pipe Run Requirements	Supplier recommends 1 to 3 diameters upstream and 1 diameter downstream.
Beta Ratios	From 0.45 to 0.85 in either version
Cost	A 0.5-in. (12-mm) flow element costs \$500. A high-quality d/p transmitter costs approximately \$1200.
Partial List of Suppliers	McCrometer (www.mccrometer.com)

In a venturi-cone (V-cone) meter, a cone is positioned in the center of a metering tube (Figure 2.28a). This cone reduces the cross-sectional area available for the process flow and, much like an orifice restriction, generates a low-pressure region downstream of the flow element. The square root of the difference between the low pressure downstream and the upstream pressure is related to the flow through the meter.

THEORY OF OPERATION

The flow or pressure drop through the V-cone meter can be calculated on liquid service using the following equations:

$$Q = 29.808 \times \frac{\beta^2 \times D^2}{\sqrt{1-\beta^4}} \times \sqrt{\Delta P} \qquad \textbf{2.28(1)}$$

$$\Delta P = \frac{Q^2 \times (1-\beta^4)}{888.517 \times \beta^4 \times D^4} \qquad \textbf{2.28(2)}$$

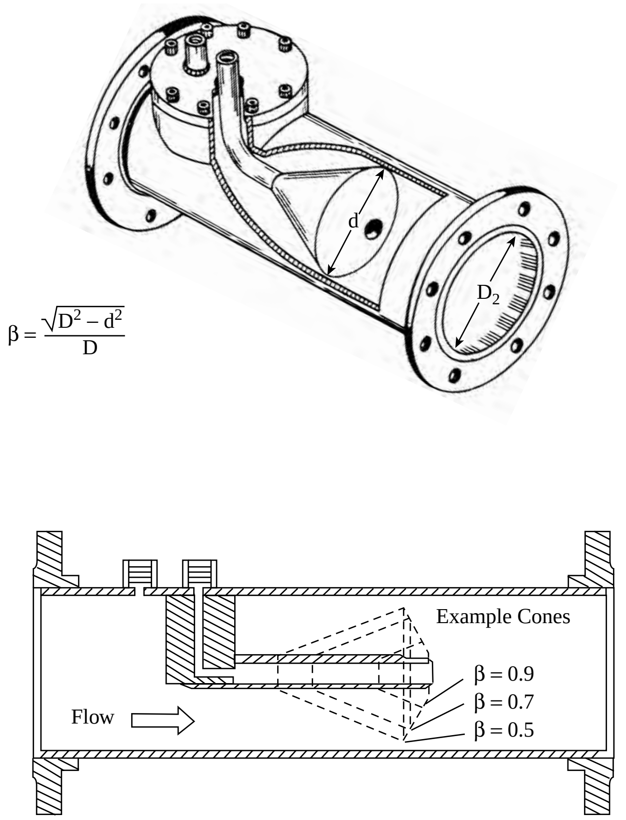


FIG. 2.28a
The V-Cone flowmeter requires less upstream straight pipe and maintains the square root relationship between flow and pressure drop at lower Reynolds numbers than does an orifice plate. (Courtesy of McCrometer Div. of Danaher Corporation.)

where

Q = water flow in GPM
D = inside diameter of the process pipe in inches
d = outside diameter of the cone in inches
ΔP = pressure drop at full flow in PSID
β = beta ratio defined as $\sqrt{D^2 - d^2/D}$

The main difference between an orifice plate and a V-cone element is that, at lower Reynolds numbers (where the velocity profile is no longer flat, as in the highly turbulent region, but starts to take on the shape of an elongated parabola, with the maximum velocity in the center of the pipe), the cone element tends to flatten the velocity profile. This is caused by the cone, which interacts with most of the flowing stream and tends to slow the flow velocity in the center while increasing it near the wall. This flow conditioning effect results in a velocity profile that is more uniform across the pipe and therefore closer to the fully developed turbulent behavior than it would be otherwise.

OPERATING FEATURES

According to the supplier, this flattening of the velocity profile results in a true square-root relationship down to a Reynolds number of 8000. Below that, the transitional and later laminar flow behavior does develop, gradually changing the square root relationship into a linear one. As with all other d/p flow elements, the V-cone is also usable in the transitional or laminar regions, but the interpretation of the pressure drop developed becomes more complex than just taking the square root. It requires the use of an accurately developed calibration curve, which can be read by the operator or can be placed into the computer's memory.

The manufacturer of the V-cone flowmeter claims very high (30:1) rangeabilities and similarly high accuracies (0.5% of actual flow), presumably over such ranges. These claims are excessive. On the other hand, we can agree that 0.1% of actual span d/p cells are available. If we use two of them (a high and a low span), we can obtain a combined range of a 100:1 in terms of pressure drop, which corresponds to 10:1 in terms of flow, and the accuracy over that range can be 1% of actual flow. Two points should be made in this connection. One is that such performance assumes that the flow element is accurately calibrated over the complete flow range. The other is that this performance can be obtained from all properly calibrated d/p flow elements, not just from the V-cone.

In addition to maintaining turbulent conditions at lower Reynolds numbers, the V-cone has the added advantage over the sharp-edged orifice of requiring less maintenance, because the flow is directly away from the cone edge. Therefore, the edge is not likely to wear. Because of the cone geometry, it also provides a sweeping action that eliminates stagnant areas and prevents gas accumulation or solids entrapment that can occur in front of sharp-edged orifices. The straight-pipe run requirements suggested by the manufacturer are substantially below those required by orifices: two diameters upstream and five downstream. This is because the cone reshapes the incoming nonuniform velocity profiles and thereby reduces the effect of upstream disturbances.

The V-cone flowmeter should be installed horizontally so that the two pressure taps are at the same elevation. This guarantees that the d/p cell will see zero pressure differential when there is no flow. If the unit is installed at a slope or vertically, it is necessary to zero out the hydrostatic head difference between taps. Any transmitting or indicating device can detect the differential pressure generated by the flow element. The manufacturer can also supply such devices, including "smart registers," that are capable of totalization and digital or analog retransmission.

A modification of the V-cone design is the wafer-cone (Figure 2.28b), which, according to the manufacturer, can be made from any material.

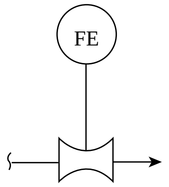
2.29 Venturi Tubes, Flow Tubes, and Flow Nozzles



Flow Sheet Symbol

W. H. Howe (1969) **L. D. Dinapoli** (1995) **J. B. Arant** (1982, 2003)

Design Types	A. Venturi tubes B. Flow tubes C. Flow nozzles
Design Pressure	Usually limited only by transmitter, readout device or by pipe pressure ratings
Design Temperature	Limited only by readout device, if operation is at very low or high temperature
Sizes	A. 1 in. (25 mm) up to 120 in. (3000 mm) B. 4 in. (100 mm) up to 48 in. (1200 mm) C. 1 in. (25 mm) up to 60 in. (1500 mm)
Fluids	Liquids, gases, and steam
Flow Range	Limited only by minimum and maximum beta (β) ratio and available pipe size range
Inaccuracy	Values given are for flow elements only; d/p cell and readout errors are additional A. ±0.75% of rate uncalibrated to ±0.25% of rate calibrated in a flow laboratory B. May range from ±0.5 to ±3% of rate depending on the particular design and variations in fluid operating conditions C. ±1% of rate uncalibrated to ±0.25% calibrated
Materials of Construction	Virtually unlimited. Cast venturi tubes are usually cast iron, but fabricated venturi tubes can be made from carbon steel, stainless steel, most available alloys, and fiberglass plastic composites. Flow nozzles are commonly made from alloy steel and stainless steel.
Pressure Recovery	Ninety percent of the pressure loss is recovered by a low-loss venturi when the beta (β) ratio is 0.3, whereas an orifice plate recovers only 12%. (The corresponding energy savings in a 24-in. [600-mm] waterline is about 20 HP.)
Reynolds Numbers	Venturi and flow tube discharge coefficients are constant at Re > 100,000. Flow nozzles are used at high pipeline velocities (100 ft/s or 30.5 m/s), usually corresponding to Re > 5 million. Critical flow venturi nozzles operate under choked conditions at sonic velocity.
Costs	Flow nozzles are less expensive than venturi or flow tubes, but cost more than orifices. ASME gas flow nozzles in aluminum for 3- to 8-in. (75- to 200-mm) lines cost from \$300 to \$1000. Epoxy-fiberglass nozzles for 12- to 32-in. (300- to 812-mm) lines cost from \$1000 to \$3000. The relative costs of Herschel venturies and flow tubes in different sizes and materials are given below:

	6-in. Stainless Steel	*8-in. Cast Iron*	*12-in. Steel*
Herschel venturi	\$9000	\$6000	\$6500
Flow tube	\$4000	\$2500	\$3200

Venturi tubes, flow nozzles, and flow tubes, like all differential pressure producers, are based on Bernoulli's theorem. General performance and calculations are similar to those for orifice plates. In these devices, however, there is continuous contact between the fluid flow and the surface of the primary device, in contrast to the pure line contact between the orifice plate edge and main flow. The surface finish of the devices can have some effect on the meter coefficient, although the venturi tube has a relatively constant coefficient, seldom varying more than a fraction of 1%. Modern precision manufacturing techniques allow much greater accuracy of the coefficient for venturi tubes and flow nozzles computed from dimensions, and the coefficients are only moderately less reliable than those for orifice plates. The C (meter coefficient) values for venturi tubes and flow nozzles have been well established by years of test data and are tabulated in sources such as the handbook called *Fluid Meters—Their Theory and Application.*[1] In general, this is not true of the proprietary flow tubes, and flow calibration is required to establish the actual meter coefficient. Meter coefficients for venturi tubes and flow nozzles are approximately 0.98 to 0.99 and for orifice plates average about 0.62. Therefore, almost 60% (98/62) more flow can be obtained through these elements for the same differential pressure.

THE CLASSIC VENTURI

The venturi tube, as designed by Clemens Herschel in 1887 and described in Reference 1, is shown in Figure 2.29a. It consists of

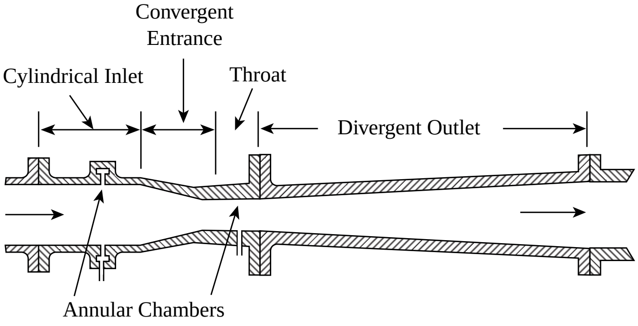

FIG. 2.29a
Classic Herschel venturi with annular pressure chambers.[1]

- A cylindrical inlet section equal to the pipe diameter
- A converging conical section in which the cross-sectional area decreases, causing the velocity to increase with a corresponding increase in the velocity head and a decrease in the pressure head
- A cylindrical throat section where the velocity is constant so the decreased pressure head can be measured
- A diverging recovery cone where the velocity decreases and almost all of the original pressure head is recovered

The unrecovered pressure head is commonly called *head loss.*

The classic venturi is always manufactured with a cast-iron body and a bronze or stainless-steel throat section. At the midpoint of the throat, six to eight pressure taps connect the throat to an annular chamber so that the throat pressure is averaged. The cross-sectional area of the chamber is 1.5 times the cross-sectional area of the taps. Because there is no movement of fluid in the annular chamber, the pressure sensed is strictly static pressure. Usually, four taps from the external surface of the venturi into the annular chamber are made. These are offset from the internal pressure taps. Throat pressure is measured through these taps. This flow meter is limited to use on clean, noncorrosive liquids and gases, because it is impossible to clean out or flush out the pressure taps if they clog up with dirt or debris. The flow coefficient for the classic venturi is 0.984, with an uncertainty tolerance of ±0.75%.

SHORT-FORM VENTURIES

In the 1950s, in an effort to reduce costs and laying length, manufacturers developed the second-generation, or *short-form*, venturi shown in Figure 2.29b. There were two major differences in this design. The internal annular chamber was replaced by a single pressure tap or, in some cases, an external pressure averaging chamber, and the recovery cone angle was increased from 7 to 21°. The short-form venturi can be manufactured from cast iron or welded from a variety of materials as compatible with a given application. The flow coefficient for the short-form venturi is 0.985, with an uncertainty tolerance of ±1.5%.

The pressure taps are located one-quarter to one-half pipe diameter upstream of the inlet cone and at the middle of the throat section. A piezometer ring is sometimes used for differential pressure measurement. This consists of several holes in the plane of the tap locations. Each set of holes is connected in an annulus ring to give an average pressure. Venturies with piezometer connections are unsuitable for use with purge systems used for slurries and dirty fluids, because the purging fluid tends to short circuit to the nearest tap holes. Piezometer connections are normally used only on very large tubes or where the most accurate average pressure is desired to compensate for variations in the hydraulic profile of the flowing fluid. Therefore, when it is necessary to meter dirty fluids and use piezometer taps, sealed sensors that mount flush with the pipe and throat inside wall should be used. These sensors function as independent measuring devices at each tap connection, yet they function together to read differential pressure only while automatically compensating for static pressure changes within the pipe. Single-pressure-tap venturies can be purged in the normal manner when used with dirty fluids. Because the venturi tube has no sudden changes in contour, no sharp corners, and no projections or stagnant areas, it is often used to measure slurries and dirty fluids that tend to build up on or clog other primary devices.

Venturies are built in several forms. These include the standard long-form or classic venturi (Figure 2.29a), a modified short form where the outlet cone is shortened (Figure 2.29b), an eccentric form (Figure 2.29c) to handle mixed phases or to minimize buildup of heavy materials, and a rectangular form (Figure 2.29d) used in ductwork. If a rectangular venturi is substantially square, it is customary to converge–diverge all four sides with angles the same as for the circular form. Where duct width differs from height, the short sides are kept parallel, with the long sides converging–diverging. A converging angle of 21° and a diverging angle of 15° give satisfactory operation. Throat length should be equal to minimum throat height or width, whichever is smaller. Tap locations are the same as for the circular form.

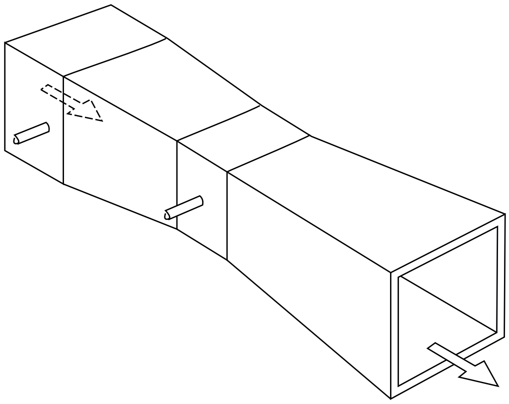

FIG. 2.29d
Rectangular venturi tube.

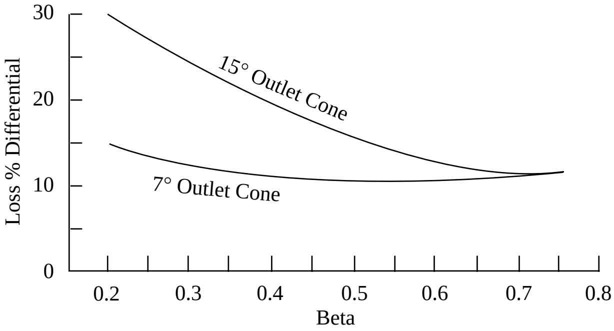

FIG. 2.29e
Venturi pressure loss.

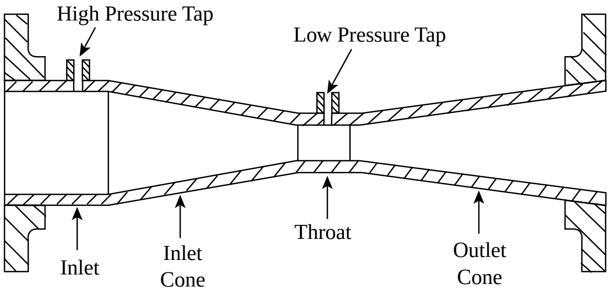

FIG. 2.29b
Short-form venturi tube.

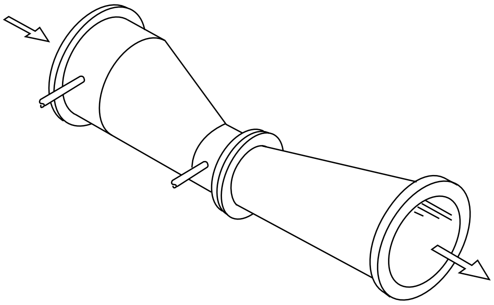

FIG. 2.29c
Eccentric venturi tube.

The angle of convergence, which may range from 19 to 23°, is the classical value established by Herschel in 1887. This angle is not particularly critical, and 21 ± 1° is commonly used. The recovery cone provides pressure recovery with its smooth flow transition. The classic long cone form is 7.5° ± 0.5° on the divergence, but up to 15° is allowed, and the sharper angle allows the short-form version to be fabricated. The 15° outlet cone sacrifices a modest amount of pressure recovery (Figure 2.29e). The venturi pressure loss of 10 to 25% is the lowest of the standard primary head measurement elements. The long-cone form develops up to 89% pressure recovery at 0.75β ratio, decreasing to 86% at 0.25β ratio. The short-cone form develops up to 85% recovery at 0.75β, decreasing to 75% at 0.25β ratio. As an example of the power savings to be obtained in an energy-short era, an added pressure recovery of 50 in. (1270 mm) H_2O differential pressure can represent a 10-HP savings in a 24-in. (610-mm) water line flowing at a velocity of 6 ft/s (1.829 m/s). For a comparison of various head-meter elements from the pressure recovery point of view, see Figure 2.29f.

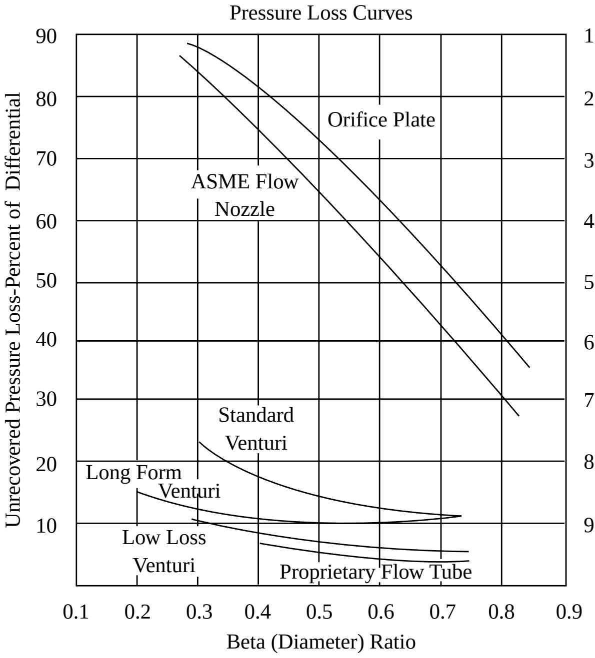

FIG. 2.29f
Pressure loss curves.

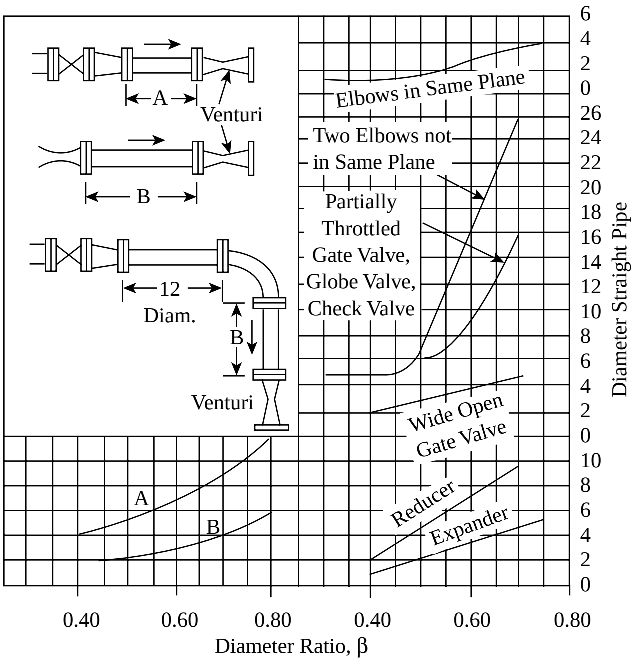

FIG. 2.29g
Venturi piping requirement.

Installation

A venturi tube may be installed in any position to suit the requirements of the application and piping. The only limitation is that, with liquids, the venturi is always full. In most cases, the valved pressure taps will follow the same installation guidelines as for orifice plates.

Upstream piping should be as long as needed to provide a proper velocity profile (Figure 2.29g). However, in most installations, shorter upstream piping is required than for orifices, nozzles, or pitot tubes, because the venturi hydraulic shape itself provides some flow conditioning. Often, the combined length of a venturi and its upstream piping is less than the overall amount of piping required for an orifice or nozzle. Figure 2.29h shows typical upstream pipe diameters required for various elements at 0.7β ratio and one elbow upstream. Straightening vanes can be used upstream to reduce the inlet pipe length.

In *Fluid Meters*,[1] the ASME recommends the use of tubular straightening vanes (19 tubes and 2 diameters long) upstream of the venturi to reduce the inlet pipe length. The vane installation should have a minimum of 2 diameters upstream and 2 diameters downstream before entering the venturi.

There is no limitation on piping configuration downstream of the venturi except that a valve should be no closer than two diameters. Valves on other devices that protrude into the flow stream should not be mounted upstream of the venturi, if possible.

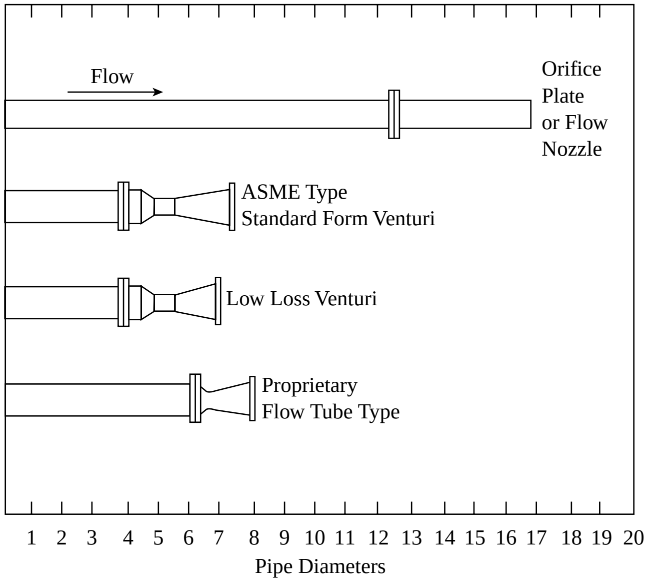

FIG. 2.29h
Typical installation piping comparison.

Flow Calculations

The American Society of Mechanical Engineers Fluid Research Committee has adopted a general coefficient of discharge of 0.984 for the classic rough-cast entrance cone venturi tube from 4 in. (100 mm) through 32 in. (813 mm) and for β ratios between 0.3 and 0.75. For tubes with machined entrance cones, the general coefficient is 0.995. The Reynolds number must be 200,000 or greater. Approximate flow rates can be calculated from a working equation,

$$W = 353d^2\sqrt{\frac{h\rho}{1-\beta^4}} \qquad \textbf{2.29(1)}$$

and, for approximate venturi tube design,

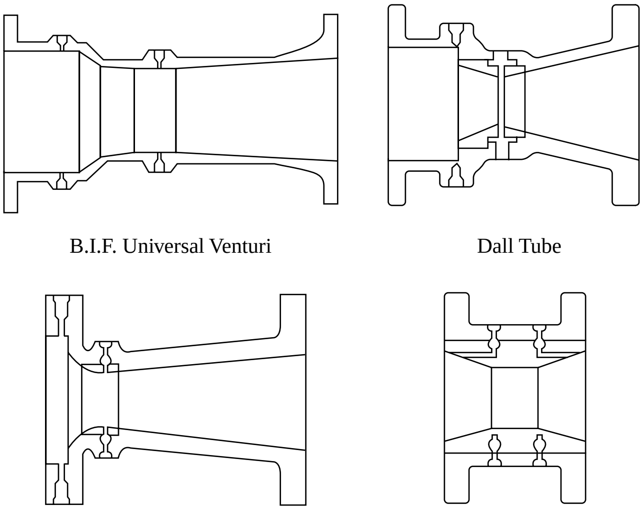
$$\beta = \frac{1}{\sqrt[4]{\dfrac{1+125{,}000 h\rho D^4}{W^2}}} \qquad \textbf{2.29(2)}$$

For Reynolds numbers between 50,000 and 200,000, substitute 344 for 353. Below 50,000, reliable data are not available. It should be noted that, it contrast to an orifice, a decrease in Reynolds number results in a decrease of flow corresponding to a given differential pressure. Other correction factors, such as temperature coefficient of expansion, gas expansion factor, and so on, are similar to those for orifices and flow nozzles.

FLOW TUBES

There are several proprietary primary-head-type devices that have a higher ratio of pressure developed to pressure lost than a venturi tube (Figure 2.29i). They are all considerably more compact than the classical venturi tube, with its long recovery cone, although the short-from venturi can come close to some types of these tubes.

These designs are available in cast iron, can be welded from various materials, and in some cases can have insert-type units in fiberglass-reinforced plastic or metal. The flow coefficient ranges from 0.9797 for an all-static-tap “near venturi” design to 0.75 for an all-corner-tap “flow tube” design. All of these proprietary units are available in the United States except the Dall tube, which was developed in England. All of these tubes vary in contour used, tap locations, and differential pressure and pressure loss for a given flow. All have a laying length less than 4 diameters long. The shortest are the corner tap designs, with lengths equaling 2 to 2.5 diameters.



B.I.F. Universal Venturi

Dall Tube

Badger Lo-Loss Flow Tube

Gentile or Bethlehem Flow Tube

FIG. 2.29i
Proprietary flow tubes.

A *flow tube* is broadly defined by the ASME as any differential-pressure-producing primary whose design differs from the classic venturi. Flow tubes fall into three main classes, depending on the hydraulic position of the inlet and throat pressure tap. Type 1 has static pressure taps at both the inlet and outlet, Type 2 has a corner tap in the inlet and a static tap in the throat, and Type 3 has a corner tap at both the inlet and outlet.

The classic venturi had static pressure taps that provided a section in which the velocity is not changing direction and is parallel to the pipe wall. A corner tap senses pressure in a section where the velocity is changing direction and is not parallel to the pipe wall. Figure 2.29i shows examples of several flow tubes.

Type 3 flow tubes can be useful in larger sizes because of their shorter lay length, but they may also require longer upstream pipe runs for proper performance. They can be subject to coefficient change due to variations in Reynolds number, line size, and beta ratio; manufacturers can provide data on these effects.

The B.I.F. Universal Venturi is the product (Type 1) that most closely approaches the Herschel design classic venturi. The inlet cone has two *vena contracta* angles that condition the fluid as it enters the throat. This is claimed to reduce the sensitivity to upstream piping configuration and give higher accuracy. Also claimed are a stable coefficient (0.9797) that is unaffected by internal surface roughness, lower Reynolds number application (90,000), low head loss (4 to 18%), and extensive documentation including expansion factors.

Whereas flow tubes can be useful in larger sizes because of their shorter lay length, they may also require longer upstream pipe runs than the venturi for proper performance and thus lose any real advantage. They can be subject to coefficient change with viscosity and Reynolds number; manufacturers can provide data on these effects. None has the smooth contour and resistance to clogging of the venturi meter; however, some are claimed to operate satisfactorily on wastewater and sewage flow measurement.

In general, these devices are available in 4-in. (100-mm) and larger sizes up to 48 in. (1219 mm). There is little justification for their use in small-flow, small-pipe applications. In the larger sizes, their installed cost may be less than that of the venturi tube. Accuracy depends basically on the manufacturer’s calibration data. Derivation of the flow coefficient by extrapolation from theory and tests on smaller sizes is much less direct than in the simple structure of the venturi tube; actual flow calibration, particularly in sizes above 24 in. (610 mm), can be difficult and expensive. Although these devices generally have a better pressure recovery than the venturi (expressed as a percentage of the differential), most flow tubes have a lower coefficient of discharge (less efficient). As a result, there is often very little difference in the actual head loss.

In selecting a primary flow element, the possible advantages of slightly lower pressure loss and shorter laying length of the flow tubes should be carefully weighed against the metering accuracy and established flow data available on the Herschel-form venturi. The ASME recommends that, if a proprietary flow tube is used, it should be calibrated with the piping section in which it is to be used and over the full range of flows to which it will be subjected. The only possible exception to this is the Universal Venturi, and it must be carefully evaluated. The background of extensive tests under a wide range of conditions that support orifice meters does not exist for these proprietary devices.

FLOW NOZZLES

There are two types of flow nozzles. The 1932 ISA nozzle is a European design that has not seen use in the United States. A special variation known as a *venturi nozzle* is a hybrid combination of a 1932 ISA nozzle inlet profile combined with the divergent cone of a venturi tube. The common nozzle used in the United States is the so-called *long-radius* or ASME flow nozzle. This nozzle comes in two versions, known as *low-beta-ratio* and *high-beta-ratio* designs. This flow nozzle, shown in Figure 2.29j, is a metering primary whose shape consists of a quarter ellipse convergence section and a cylindrical throat section. In the United States, the nozzle generally used is the long-radius ASME flow nozzle. The ASME Fluid Meters Research Committee has investigated various configurations and has developed the geometry for these nozzles based on the required beta ratio for the application. High-beta nozzles are recommended for diameter ratios between 0.45 and 0.80. Low-beta nozzles are recommended for diameter ratios between 0.20 and 0.50. For beta values between 0.25 and 0.5, either design may be used.

The difference between the two nozzles is basically a flattening of the ellipse in the high-beta-ratio version. The power test code, PTC-6, requires that the low-beta-ratio version be used in their test section for turbine acceptance.

Both types of nozzles may be either welded in the pipeline or provided with a holding ring for mounting between flanges. The latter design, shown in Figure 2.29k, is preferred when frequent inspection of the nozzle is required.

Nozzles may be manufactured from any material that can be machined; typically, they are fabricated from aluminum, fiberglass, stainless steel, or chrome-moly steel. Modern manufacturing methods and fluid contact surface finishes on the order of 6 to 10 μin result in more predictable nozzle coefficients and highly repeatable data. The standard surface finish is 16 RMS. Flow nozzle inaccuracy of ±1% is standard with ±0.25% flow calibrated. The standard coefficient, as published in Reference 1, is 0.9962 with correction factors for beta ratio and throat Reynolds number. ASME gives an uncertainty of ±–2% for nozzles having a beta ratio between 0.2 and 0.8 and throat Reynolds numbers between 1×10^5 and 2.5×10^6.

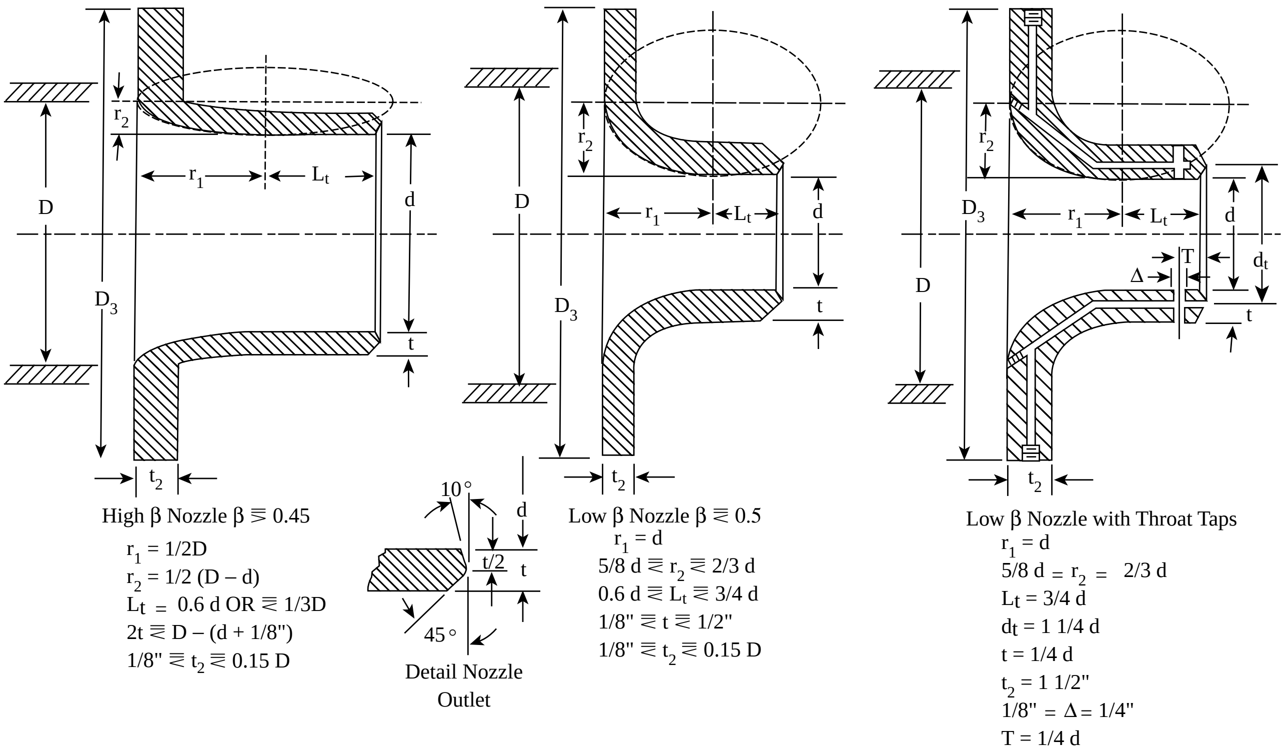


FIG. 2.29j
ASME nozzle construction.

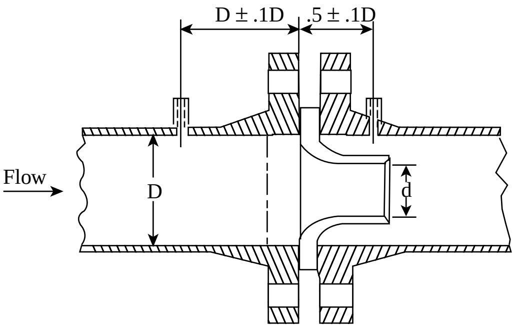

FIG. 2.29k
Typical nozzle installation.

Most ASME nozzles are calibrated as meter sections 20 pipe diameters long. As with venturi tubes, the uncertainty of calibrated units depends on the uncertainty of the hydraulic laboratory. Generally, one could expect ±0.25% uncertainty on the calibration.

The outlet or discharge side of the nozzle is normally beveled and is one of the more critical points of manufacture. Where the 10° back angle meets the throat bore, the edge must be sharp. Particular care must be taken to avoid taper and out-of-roundness of the throat.

Flow nozzles are made in various configurations. The most common is the flange type (Figure 2.29k), but others are the holding-ring type, the weld-in type, and the throat-tap type. Differential pressure measurement taps are commonly located one pipe diameter upstream and one-half pipe diameter downstream from the inlet face (U.S. practice), except for the throat-tap type, which has a special downstream construction. The PTC-6 nozzle uses throat taps to sense the low pressure and standard pipe wall taps for the high pressure.

Application Considerations

Tap installation precautions are the same as for orifice plates. The preferred installation position for flow nozzles is horizontal, but they can be installed in any position. However, a vertical downflow position is preferred for wet steam or for gases and liquids with suspended solids. In general, upstream and downstream piping requirements are similar to those required for orifices. Because of the width, nozzles installed between flanges are difficult to remove. Common practice is to provide a flange in the downstream piping to allow the nozzle to be removed as part of a spool section for inspection at regular intervals. Sometimes, inspection openings are placed just upstream of the nozzle so that frequent inspections can be made without removing the nozzle from service.

Flow nozzles are particularly suited for measurement of steam flow and other high-velocity fluids, fluids with some solids, wet gases, and similar materials. Because the exact contour is not critical, the flow nozzle can be expected to retain good calibration for a long time under erosion or other hostile conditions. Because of its streamlined contour, it tends to sweep solids or moisture through the throat and is far superior to orifice plates in these services. Because tap geometry and contour is critical to maintaining calibration, it is not recommended to use flow nozzles on slurries or dirty fluids.

A flow nozzle will pass about 60% more flow than an orifice plate of the same diameter and differential pressure. It also has the advantage of operating acceptably over a wide beta ratio range of 0.2 to 0.8. For the same flow and differential pressure, the flow nozzle has a similar but slightly lower pressure loss than an orifice plate. This becomes apparent when it is recognized that the area of the throat and the velocity in the throat of a flow nozzle must be approximately the same as the area of flow and velocity at the *vena contracta* following an orifice so as to develop the same differential pressure from the same flow. The slightly lower pressure loss of the flow nozzle is due to its streamlined entrance.

On the other hand, because the ASME flow nozzle does not utilize a recovery cone, the permanent head loss can still be as much as 40% of the differential pressure (Figure 2.29f). In an effort to reduce these losses, particularly in applications for PTC-6 testing of turbines, a recovery cone may be added. In this design, the permanent head losses can be substantially reduced. The actual amount of reduction should be determined through testing.

Although nozzles should be used at Reynolds numbers of 50,000 or above, data are available for Re down to 6000, so it is possible to use nozzles with more viscous fluids. Still, work published by the ASME Fluid Research Committee suggests that the most stable flow coefficients are seen at *throat Reynolds number* of 1×10^6. For throat Reynolds numbers below 1×10^5, the shift in flow coefficient can be as high as 6%.

Flow nozzles have very high coefficients of discharge, typically 0.99 or greater. Using a typical value of 0.993, approximate flow rates can be calculated from a working equation,

$$W = 358d^2\sqrt{\frac{h\rho}{1-\beta^4}} \qquad \mathbf{2.29(3)}$$

and, for approximate flow nozzle design,

$$\beta = \frac{1}{\sqrt[4]{1+\dfrac{128,000h\rho D^4}{W^2}}} \qquad \mathbf{2.29(4)}$$

CRITICAL-VELOCITY VENTURI NOZZLES

One of the most accurate ways to measure gas flow is to cause “choked” flow (sonic velocity flow) through a venturi nozzle. Critical-velocity venturi nozzles are also used as secondary flow standards in calibrating other flowmeters. The nozzle can be the ASME long-radius, elliptical inlet, wall-tap nozzle; the ISA 1932 nozzle; or the ASME throat-tap nozzle used in steam turbine testing.

One of the highest rangeability and most accurate gas flowmeters has been devised by combining the sonic venturi nozzles with the digital control valve (Figure 2.1j).

ACCURACY

Operation and calibration of venturi tubes over a period of many years has resulted in extensive documentation. As a result, most manufacturers will guarantee a standard design inaccuracy of ±0.75% of actual flow. This can be reduced to ±0.25% by calibration at a recognized hydraulics laboratory. Modern manufacturing techniques have led to predictable discharge coefficients and a repeatability of ±0.2% for venturi tubes of the same size and design.

For very small (<4 in. or 100 mm) and very large (>32 in. or 813 mm) venturi tubes, and for very high (>2,000,000) or very low (<150,000) Reynolds numbers, flow calculations for venturi tubes have about a 50% greater uncertainty than a corresponding sharp-edged orifice plate. However, fluid flow calibration, particularly when made under conditions closely approximating service values, can provide a coefficient with practically the same accuracy as that of the calibration facilities.

The error contribution of the d/p-generating flow sensor is defined as the uncertainty tolerance of the flow coefficient. The inaccuracy values can range from as low as 0.25% of rate for calibrated units to 1.5% of rate for uncalibrated welded units and can be expected to hold true only for a limited range of Reynolds numbers (see Figure 2.1f) and beta ratios.

The overall performance of the total flow measurement system therefore will be the sum of the transmitter and sensor errors. This sum will hold true only over the flow range between the maximum flow and the flow rate corresponding to the minimum Reynolds number for which the sensor error is still guaranteed. This minimum Reynolds number for venturies and flow tubes is around 100,000, and for flow nozzles it is over 1,000,000. Consequently, the rangeability of these devices, if defined in terms of actual flow error, can be rather low.

DIFFERENTIAL PRESSURE MEASUREMENT

The differential pressure generated by these primary devices (venturi, flow tubes, and flow nozzles) can be measured by manometers, gauges, and electronic pressure transmitters. The accuracy of analog electronic transmitters varies from ±0.1 to ±0.5% of calibrated span. When square-root circuitry is added, there is usually a ±0.05% increase in the error. Microprocessor-based (“smart”) transmitters have an inherent accuracy of ±0.1% of calibrated span or less, regardless of whether the square-root function is used.

Overall accuracy of the entire flowmeter system is a function of the transmitter and other instruments in the loop. The most common method for determining accuracy is to root mean square (RMS) the errors to calculate the total error. Let’s look at an example with only the primary device and an electronic transmitter. Recognize that transmitter accuracy is specified as a percent of calibrated span. Thus, at 25% of span, the error will be four times the error at full scale. The venturi, flow tube, and flow nozzle accuracy is specified as a percent of rate. Thus, the sensor accuracy is the same throughout its usable range.

Assume the venturi and the electronic transmitter are both set up such that there is a 100-in. H_2O differential pressure at full scale flow. Assume that the venturi has an accuracy of 0.75% of rate, and the transmitter has an accuracy of 0.25% of calibrated span. At full-scale flow, the total RMS uncertainty will be $\sqrt{(.75)^2+(.25)^2} = 0.79\%$. At 50% flow, the total RMS uncertainty will be $\sqrt{(.75)^2+(.50)^2} =$ 0.90%. At 25% of flow, the total RMS uncertainty will be $\sqrt{(.75)^2+(.50)^2}$ = 1.25%. At 10% flow, the total RMS uncertainty will be $\sqrt{(.75)^2+(2.5)^2} = 2.61\%$. Therefore, the transmitter can contribute significantly to the total error of the system when used over a wide range, even though the primary device maintains its accuracy over that range.

Some manufacturers of smart transmitters have routines that reduce the full-scale value of the transmitter as the differential pressure signal from the primary decreases so as to increase the total accuracy. This requires that the transmitter communicate digitally to the receiver so the reduced full scale and the measured differential pressure can be transmitted to the receiver. The total error in a flow measurement is the sum of two errors: that of the sensor and that of the transmitting or readout device. The error contribution of the best d/p transmitters is about 0.1% of span. To cover a flow range of 10:1, d/p range of 100:1 needs to be covered, which requires either an extremely wide-range d/p cell or, more likely, two d/p transmitters (a high-span and a low-span one). If such a dual-transmitter configuration is used, and if the transmitters are switched as needed, the actual error contribution of the transmitter can be limited to 1% of actual flow.

CONCLUSION

The main limitation of venturi tubes is cost, both of the tube itself and often of the piping layout required for the length necessary in the larger sizes. However, the energy-cost savings attributable to venturi tubes’ higher pressure recovery and reduced pressure loss usually justifies their use in larger pipes.

Another limitation is the relatively high minimum Reynolds number required to maintain accuracy. For venturies and flow tubes, this minimum is around 100,000, whereas, for flow nozzles, it is greater than 1,000,000. Naturally, correction data are available for Reynolds numbers below these limits, but measurement performance will suffer.

Cavitation can also be a problem. At the high flow velocities (corresponding to the required high Reynolds numbers) at the *vena contracta*, the static pressure will be low. When it drops below the vapor pressure of the flowing fluid, cavitation occurs. This, if present, will destroy the throat section of the tube, as no material can stand up to cavitation. The possible ways to eliminate cavitation include relocating the meter to a point in the process where the pressure is higher and the temperature is lower, reducing the pressure drop across the sensor, and replacing the sensor with one that has less pressure recovery.

As a result of their construction, venturies, flow tubes, and flow nozzles are relatively difficult to inspect. This problem can be solved by providing an inspection port on the outlet cone near the throat section. This can be an important factor when metering dirty (erosive) gases, slurries, or corrosive fluids. On dirty services where the pressure ports are likely to plug, the pressure taps on the flow tube can be filled with chemical seals having stainless-steel diaphragms that are installed flush with the tube interior (Figure 2.29l).

The main advantages of these sensors include their relatively high accuracy, good rangeability (on high Reynolds number applications), and energy-conserving high-pressure recovery. For these reasons, in higher-velocity flows and in larger pipelines (and ducts), the venturies are still favored by many users in spite of their high costs. Their hydraulic shape also contributes to greater dimensional reliability and therefore to better flow-coefficient stability than that of the orifice-type sensors, which depend on the sharp edge of the orifice for their flow coefficient.

The accuracy of a flow sensor is defined as the uncertainty tolerance of the flow coefficient. Accuracy can be improved by calibration. Table 2.29m gives some accuracy data in percentage of actual flow as reported by various manufacturers. These values are likely to hold true only for the stated ranges of beta ratios and Reynolds numbers, and they do not include the added error of the readout device or d/p transmitter.

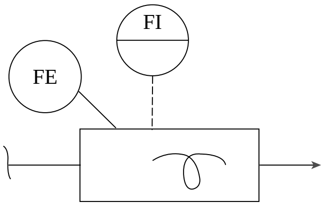
2.30 Vortex and Fluidic Flowmeters

J. G. KOPP (1969) **D. J. LOMAS** (1982) **B. G. LIPTÁK** (1995)
W. H. BOYES (2003)



Flow Sheet Symbol

Types	A. Vortex B. Fluidic-shedding Coanda effect C. Vortex precession (Swirlmeter™)
Services	A. Gas, steam, reasonably clean liquids B. Gas, reasonably clean liquids C. Gas, steam, reasonably clean liquids
Size Ranges Available	A. 0.5 to 12 in. (13 to 300 mm), also probes B. 0.5 to 4 in. (13 to 100 mm); up to 12 in. (300 mm) in bypass versions C. 0.5 to 12 in. (13 to 300 mm)
Detectable Flows	A. Water, 2 to 10,000 GPM (8 l/min to 40 m^3/hr); air, 3 to 12,000 SCFM (0.3 to 1100 SCMM); steam (D&S at 150 PSIG [10.4 bars]), 25 to 250,000 lbm/hr (11 to 113,600 kg/hr) B. Water, 0.033 to 1000 GPM (0.125 to 4000 l/min); fluids, to 80 cSt C. Water, 2 to 10,000 GPM (8 l/min to 40 m^3/hr); air, 3 to 12,000 SCFM (0.3 to 1100 SCMM); steam (D&S at 150 PSIG [10.4 bars]), 25 to 250,000 l/hr (11 to 113,600 kg/hr)
Flow Velocity Range	A and C. Liquids, 1 to 33 ft/s (0.3 to 10 m/s) Gas and steam, 20 to 262 ft/s (6 to 80 m/s)
Minimum Reynolds Numbers	A. Below Re of 8000 to 10,000, meters do not function at all; for best performance, Re should exceed 20,000 in sizes under 4 in. (100 mm) and exceed 40,000 in sizes above 4 in. B. Re = 3000; some models claim Re = 400 at specified inaccuracy, with reading down to Re = 75. C. Same as A.
Output Signals	A, B, C linear pulses or analog
Design Pressure	A. 2000 PSIG (138 bars) B. 600 PSIG (41 bars) below 2 in. (50 mm); 150 PSIG (10.3 bars) above 2 in. C. 2000 PSIG (138 bars)
Design Temperature	A. –330 to 750°F (–201 to 400°C) B. 0 to 250°F (–18 to 120°C) C. –330 to 750°F (–201 to 400°C)
Materials of Construction	A. Mostly stainless steel, some in plastic B. Cast bronze, plastic, stainless, and some specialty metals C. Mostly stainless steel, specialty alloys available
Rangeability	A. Reynolds number at maximum flow divided by minimum Re of 20,000 or more B. Reynolds number at maximum flow divided by minimum Re of 3000 (400 for some models) C. Reynolds number at maximum flow divided by minimum Re of 20,000 or more

Inaccuracy	A. 0.5 to 1% of rate for liquids, 1 to 1.5% of rate for gases and steam with pulse outputs; for analog outputs, add 0.1% of full scale B. 1 to 2% of actual flow for liquids, 1% of rate for gases claimed C. 0.5 to 1% of rate for liquids, 1 to 1.5% of rate for gases and steam with pulse outputs; for analog outputs, add 0.1% of full scale
Cost	A. Plastic and probe units cost between $250 and $1500; stainless steel units in small sizes cost about $2500; insertion types cost about $3000 B. Small versions for domestic water or heat metering cost between $50 and $125; larger versions including bypass meters cost between $300 and $1500 C. Stainless-steel units in small sizes cost about $2500, specialty materials are extra

This section is devoted mainly to the vortex-shedding flowmeter and its variations, including the earlier designs of vortex-precession (swirl) meters and the recent combination designs of vortex bypass elements around orifices. Included in this category of devices are oscillating fluidic flowmeters using the Coanda effect.

THE VORTEX SHEDDING PHENOMENON

It was Tódor von Kármán who discovered that, when an obstruction (a nonstreamlined object) is placed in the path of a flowing stream, the fluid is unable to remain attached to the object on its downstream sides and will alternately separate (shed) from one side and then the other. The slow-moving fluid in the boundary layer on the bluff body becomes detached on the downstream side and rolls into eddies and vortices (Figure 2.30a). Von Kármán also noticed that the distance between the shed vortices *is constant*, regardless of flow velocity. Stated in terms of a flag fluttering in the wind, what von Kármán discovered is that the intervals between vortices (1) (or the wavelength of fluttering) is *constant* and is only a function of the diameter of the flag pole (d). Therefore, the faster the wind, the faster the vortices are formed, and the faster the flag flutters as a consequence—*but without changing its wavelength.*

Later, Strouhal determined that, as long as the Reynolds number of the flowing stream is between 20,000 and 7,000,000, the ratio between the shedder width (d) and the vortex interval (1) is 0.17. This number is called the *Strouhal number.*

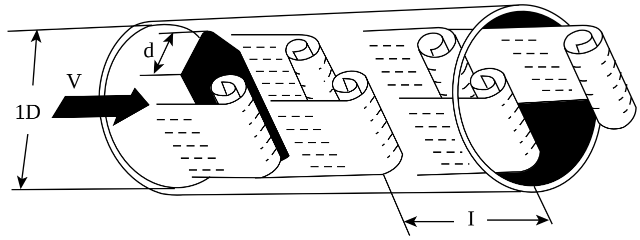

FIG. 2.30a
The distance between the Kármán vortices (l) is only a function of the width of the obstruction (d), and therefore the number of vortices per unit of time gives flow velocity (V).

Therefore, if one knows the vortex shedder width (d) and has a detector that is sensitive enough to count the vortices and determine the vortex frequency (f), one can measure the flowing velocity of any substances as

$$\text{flow velocity} = (f \times d)/(0.17) = kfd \qquad \textbf{2.30(1)}$$

In building a flowmeter based on Kármán's principle, the manufacturer usually selects an obstruction width (d) that is one-quarter of the pipe diameter (ID). As long as the obstruction is not eroded or coated, as long as the pipe Reynolds number is high enough to produce vortices, and as long as the detector is sensitive enough to detect these vortices (for gases such as hydrogen, the forces produced by the vortices are very small), the result is a flowmeter that is sensitive to flow velocity and insensitive to the nature of the flowing media (liquid, gas, steam), the density, the viscosity, the temperature, the pressure, and any other properties.

THE DETECTOR

As a vortex is shed from one side of the bluff body, the fluid velocity on that side increases, and the pressure decreases. On the opposite side, the velocity decreases, and the pressure increases, thus causing a net pressure change across the bluff body. The entire effect is then reversed as the next vortex is shed from the opposite side. Consequently, the velocity and pressure distribution adjacent to the bluff body change at the same frequency as the vortex shedding frequency changes.

Various detectors can be used to measure one of the following:

1. The oscillating flow across the face of the bluff body
2. The oscillating pressure difference across the sides of the bluff body
3. A flow through a passage drilled through the bluff body
4. The oscillating flow or pressure at the rear of the bluff body
5. The presence of free vortices in the downstream to the bluff body

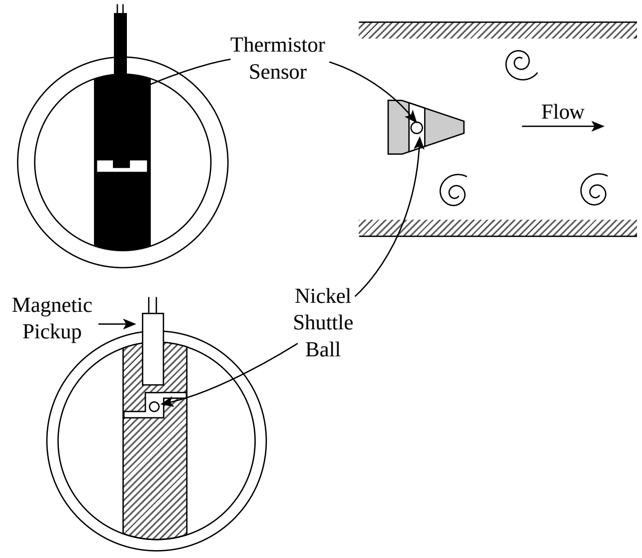

FIG. 2.30b
Shuttle-ball and shuttle-flow-type early vortex flowmeter detectors.

A flow-sensitive detector can be either a heated thermistor element or a spherical magnetic shuttle (with the movement of the shuttle measured inductively). Detectors that are sensitive to pressure use metal diaphragms or vanes. Pressure exerted on diaphragms can be converted into a variable capacitance or a variable strain on a piezoresistive, piezoelectric, or inductive sensor. Pressure exerted on vanes can similarly be converted into an electrical signal through any of the aforementioned sensors. Alternatively, the velocity components in the free vortices downstream of the bluff body can be used to modulate an ultrasonic beam diametrically traversing the meter housing. Depending on the characteristics of the sensing system, the flowmeter will be suitable for liquid, gas, or both.

The earliest detector designs were highly sensitive to plugging and required frequent maintenance (Figure 2.30b). These devices were later replaced by units that could not plug and were of solid-state design (Figure 2.30c). The majority of these designs are still marketed and are well received by users who are not concerned about quick and convenient access to, and replacement of, the detector or about the reliability and sensitivity of heat transfer or ultrasonic detectors. Still, the trend seems to be toward detectors that are modular, inexpensive, and interchangeable so they can be quickly replaced when necessary. Several vortex flowmeter detectors on today's market can be replaced easily (Figure 2.30d). In this design, the detector is a liquid-filled, double-faced diaphragm capsule with a piezoelectric crystal in the center that detects the vortex-produced pressure changes as they are transmitted through the filling liquid.

Other design modifications aim at compensating for background noise by using two detectors, one of which is exposed to vortex forces and the other is not, and using their difference as the measurement signal (Figure 2.30e). Other design

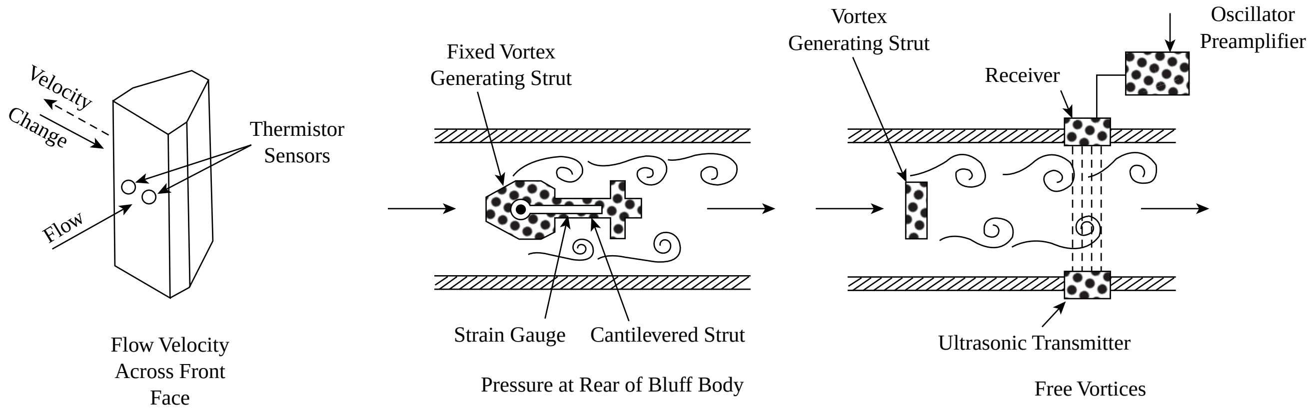

FIG. 2.30c

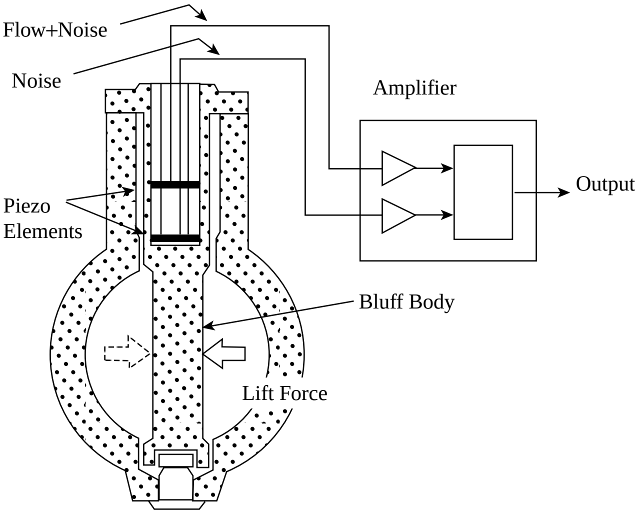

FIG. 2.30e
Dual detector serves noise compensation. (Courtesy of Johnson Yokogawa Corp. of America.)

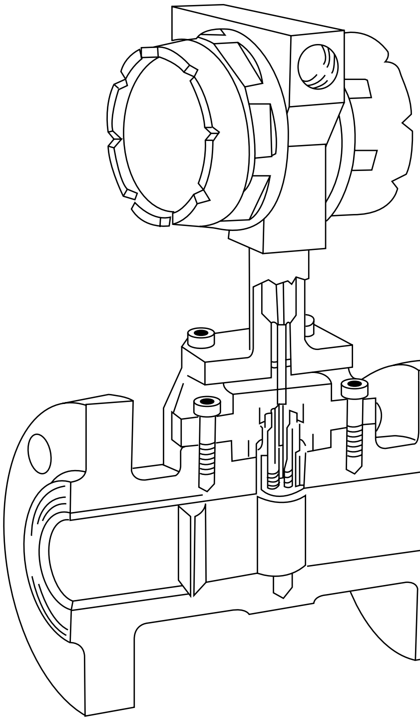

FIG. 2.30f
Separating the rugged obstruction and the detector allows the detector to be much more sensitive to the pressure waves. The increases in the forces detected allows for the use of more rugged (less sensitive and therefore less fragile) sensors. (Courtesy of EMC Co.)

modifications aim at amplifying the signal generated by low-energy vortices, such as by low-density gases. One approach is to use two detector elements (capacitance or piezoelectric) and measure the difference between their signals. This tends to amplify the detector output because, as the vortices emerge on alternate sides of the flow element, the two detectors sense the forces acting on the two different sides of the element. Still another method of amplifying the vortex forces is by physically separating the vortex shedding element and the vortex force detector (Figure 2.30f). If the vortex forces are

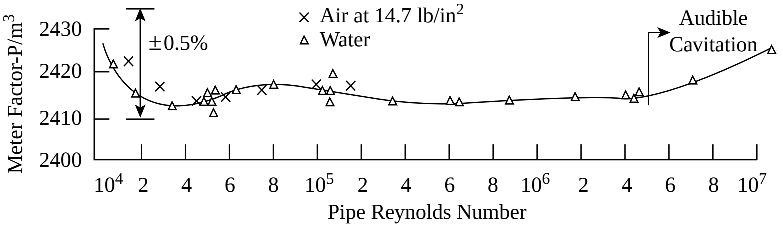

FIG. 2.30g
Typical calibration curves for a 3 in. (76 mm) vortex meter showing the close correlation between water and atmospheric air calibrations.

amplified, the force detectors can be made less sensitive and therefore more rugged and reliable.

The types of detectors in use as of this writing are listed below:

- mechanical
- thermal
- ultrasonic
- strain gauge
- capacitance
- piezoelectric

It would seem that the piezoelectric designs (particularly their dual or differential versions) dominate the market, but other designs claim superior performance under certain operating conditions. The manufacturers of the capacitance design, for example, claim superior immunity to pipe vibration effects.

The fundamental meter output is a frequency signal in all cases, which can be fed directly into digital electronic units for totalization and/or preset batching, into computers, or into data loggers. The frequency signal also can be converted into a conventional 4- to 20-mA DC analog signal for flow rate indication, recording, and control purposes. Most meters are available in either a standard form or in a design to satisfy Division 1 explosion-proof area requirements.

Features

The vortex-shedding meter provides a linear digital (or analog) output signal *without* the use of separate transmitters or converters, simplifying equipment installation. Meter accuracy is good over a potentially wide flow range, although this range depends on operating conditions. The shedding frequency is a function of the dimensions of the bluff body and, being a natural phenomenon, ensures good long-term stability of calibration and repeatability of better than ±0.15% of rate. There is no drift, because this is a frequency system.

The meter does not have any moving or wearing components, which provides improved reliability and reduced maintenance. Maintenance is further reduced by the fact that there are no valves or manifolds to cause leakage problems. The absence of manifolds and valves results in a particularly safe installation, an important consideration when the process fluid is hazardous or toxic.

If the sensor utilized is sufficiently sensitive, the same vortex-shedding meter can be used on both gas and liquid. In addition, the calibration of the meter is virtually independent of the operating conditions (viscosity, density, pressure, temperature, and so on) whether the meter is being used on gas or liquid (see Figure 2.30g).

The vortex-shedding meter also offers a low installed cost, particularly in pipe sizes below 6 in. (152 mm) diameter, which compares competitively with the installed cost of an orifice plate and differential pressure transmitter.

The limitations include meter size range. Meters below 0.5 in. (12 mm) diameter are not practical, and meters above 12 in. (30.0 mm) have limited application as a result of their high cost (compared to an orifice system) and their limited output pulse resolution. The number of pulses generated per unit volume decreases on a cube law with increasing pipe diameter. Consequently, a 24-in. (610-mm) diameter vortex-shedding meter with a typical blockage ratio of 0.3 would have a full-scale frequency output of only approximately 5 Hz at 10 ft/s (3 m/s) fluid velocity.

Selection and Sizing

As the first step in the selection process, the operating conditions (process fluid temperature, ambient temperature, line pressure, and so on) should be compared with the meter specification. The meter wetted materials (including bonding agents) and sensors should then be checked for compatibility with the process fluid with regard to both chemical attack and safety. With oxygen, for example, nonferrous materials should be used because of the reactive nature of oxygen. Applications in which there are large concentrations of solids, two-phase flow, or pulsating flow should be avoided or approached with extreme caution. The meter minimum and maximum flow rates for the given application should then be established. (See Figures 2.30h and 2.30i, and Table 2.30j.)

A typical performance curve for a vortex-shedding flowmeter is shown in Figure 2.30g. The meter minimum flow rate is established by a Reynolds number of 10,000 to 10,500, the fluid density, and a minimum acceptable shedding frequency for the electronics. The maximum flow rate is governed by the meter pressure loss (typically, two velocity heads), the onset of cavitation with liquids, and sonic velocity flow (choking) with gases. Consequently, the flow range for

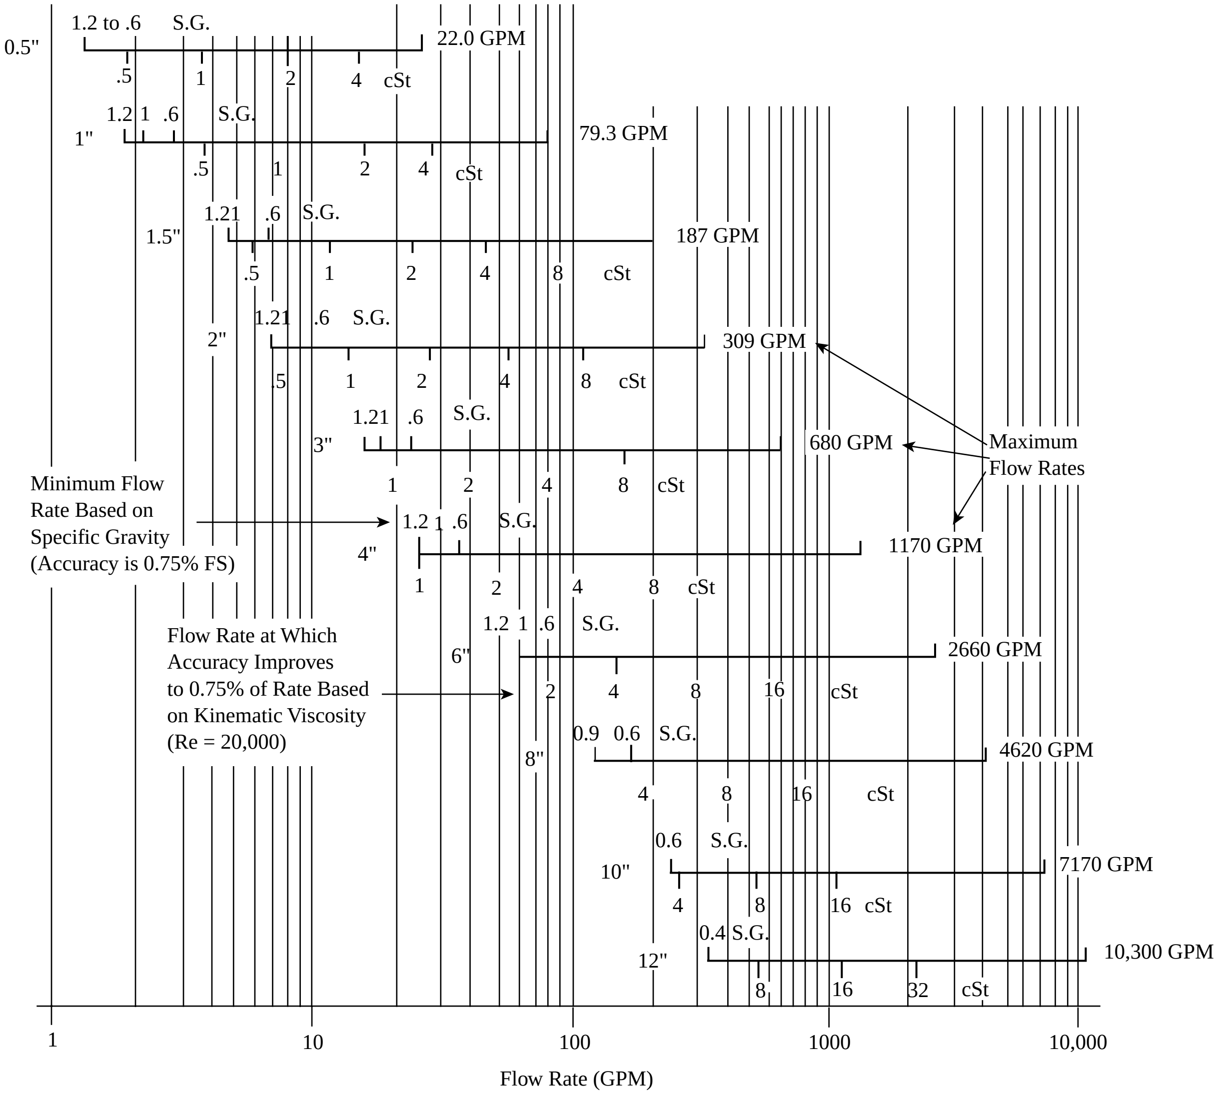

FIG. 2.30h

Sizing chart for liquid flow measurement. Note that minimum flows are limited by both specific gravity (water SG = 1) and viscosity limitations. (To convert to metric units use: 1 in. = 25.4 mm, 1 GPM = 3.78 lpm). (Courtesy of Endress+Hauser Inc.)

any application depends totally on the operating fluid viscosity, density, and vapor pressure, and the application's maximum flow rate and line pressure. On low-viscosity products such as water, gasoline, and liquid ammonia, and with an application maximum velocity of 15 ft/s (4.6 m/s), vortex-shedding meters can have a rangeability of about 20:1 with a pressure loss of approximately 4 PSIG (27.4 kPa).

The meter's good (*of-rate*) accuracy and digital linear output signal make its application over wide flow ranges a practical proposition. The rangeability declines proportionally with increases in viscosity, decreases in density, and reductions in the maximum flow velocity of the process. Vortex-shedding meters are therefore *unsuitable* for use on high-viscosity liquids.

For liquid applications, it is necessary to verify that sufficient line pressure exists to prevent cavitation in the vortex meter. The maximum pressure drop in a vortex-shedding meter is in the region of the bluff body, and there is a considerable pressure recovery by the meter outlet. Upstream line pressure requirements vary from one meter design to another, but a typical minimum acceptable upstream pressure requirement (to protect against cavitation) is given by the expression,

Upstream pressure ≥ 1.3(vapor pressure + 2.5 × net pressure loss across the meter)

Cavitation conditions must be avoided at all costs, as no material can stand up to the damage caused by cavitation. One might approximate the minimum upstream pressure required to avoid cavitation (P_{min}) on the basis of the maximum velocity expected in the pipeline (V_{max}) as follows:

$$P_{min} = (1.3)P_v + (2.5)V_{max}{}^{2}/g \qquad \textbf{2.30(2)}$$

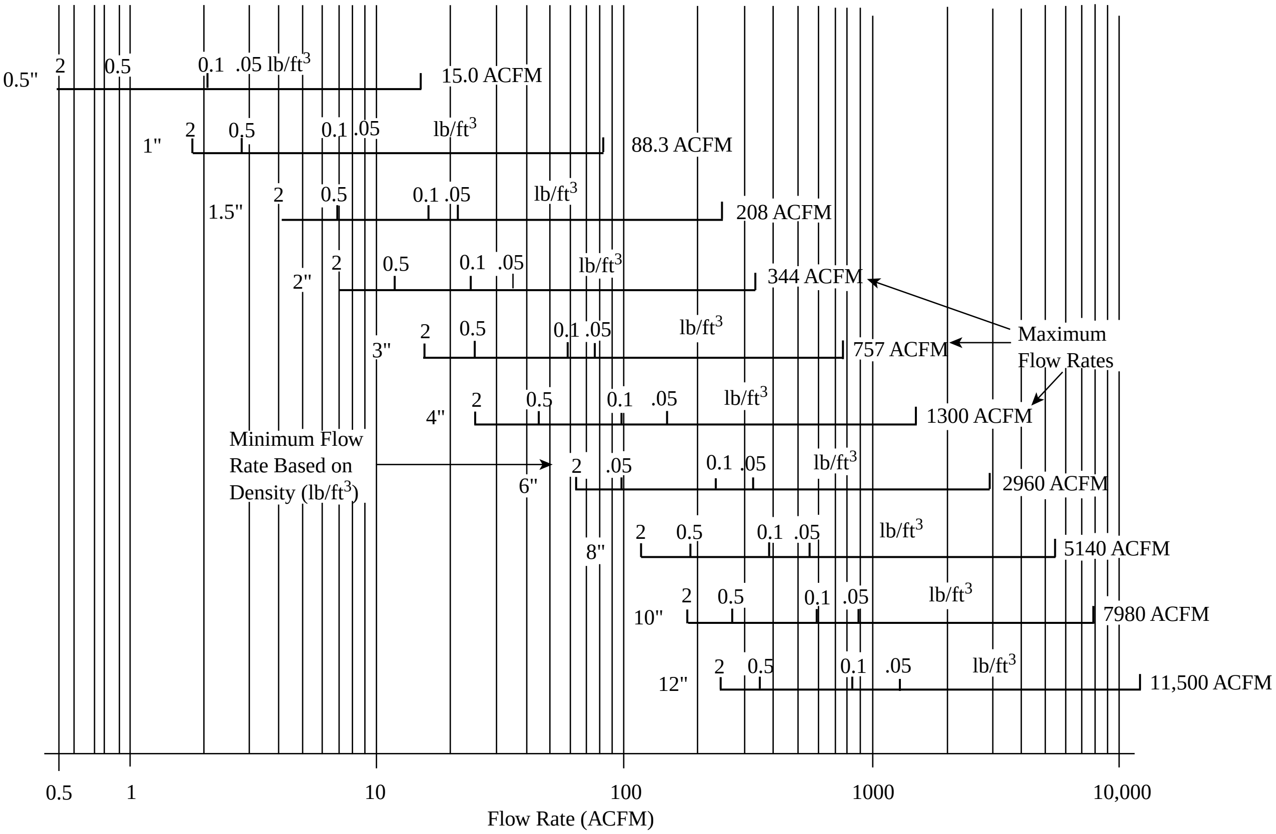

FIG. 2.30i

Sizing chart for gas and vapor flow detection: For extremely dense gases, the maximum flow may be less than shown. Gases with extremely low densities (e.g., hydrogen, helium) may not be measurable. Note that minimum flows are a function of flowing density. To convert to metric units use: 1 in. = 25.4 mm, 1 ACFM = 0.02832 ACMM, and 1 lb/ft^3 *= 16 kg/m*^{3}*. (Courtesy of Endress+Hauser Inc.)*

where

P_{min} = minimum required upstream pressure in feet of liquid head

P_v = vapor pressure of the flowing liquid at maximum operating temperature in feet of liquid head

V_{max} = maximum anticipated flowing velocity in feet per second

g = gravitational acceleration constant of 32.2 having the units square feet per second

Vortex-shedding flowmeters cannot survive cavitation, but they can survive episodes of *flashing* (i.e., when some of the incoming liquid stream is permanently vaporized in the flowmeter). If the liquid *gases*, the vortex-shedding flowmeter will not be mechanically damaged (although the meter output will be seriously in error).

Installation Requirements

Vortex-shedding meters require a fully developed flow profile. The length of upstream pipework necessary to ensure satisfactory approach conditions depends on the specific design of meter, the type of upstream disturbance present, and the level of accuracy required. Typical upstream and downstream pipework requirements for a variety of disturbances are given in Figure 2.30k.

Where there is a severe upstream disturbance, the resulting long, straight lengths of pipe can be reduced by fitting a radial vane or bundle-of-tubes flow-straightening element in the upstream pipework. Wherever possible, however, the meter should be installed upstream of any severe source of disturbance such as regulating control valves. The downstream straight pipe requirement is five times nominal meter diameter. The meter can be installed in any attitude (horizontal or vertical), but it is not suitable for reverse flowmetering.

Other instrument connections (pressure, temperature) all should be located downstream of the flowmeter and more than five diameters away from it. The flowmeter should be the same size as (or smaller than) the pipeline, but never larger. The unit can be insulated for cryogenic or high-temperature services and can be provided with extension bonnets. It should be installed in self-draining low points in the piping or in vertical upward flows to keep the meter flooded and to avoid air bubbles and standing liquid pools. Block and bypass valves should be provided if the meter is

to be serviced while the process is in operation. There should be no excessive pipe vibration in the area where the meter is installed, and gaskets should not protrude into the pipeline.

VORTEX-PRECESSION (SWIRL) METERS

A predecessor of the vortex-shedding meter, the vortex-precession meter or Swirlmeter™, is currently manufactured by a single vendor and sold in combination with that vendor's vortex-shedding product line, sharing common sensors, electronics, and programming features.

Construction of a typical vortex-precession (swirl) meter and the operating principles are illustrated in Figure 2.30l. The fixed, swirl-inducing helical vanes at the entrance to the meter introduce a spinning or swirling motion to the fluid. After the exit of the swirl vanes, the bore of the meter contracts progressively, causing the fluid to accelerate, but with the axis of rotation still on the centerline of the meter. The swirling fluid then enters an enlarged section in the meter housing, which causes the axis of fluid rotation to change from a straight to a helical path. The resulting spiraling vortex is known as *vortex precession.* The frequency of precession is proportional to velocity and, hence, volumetric flow rate above a given Reynolds number.

The velocity of fluid in the vortex is higher than that of the surrounding fluid. Consequently, as each vortex passes the sensor, there is a change in the local fluid velocity. The frequency at which the velocity changes occur is proportional to volumetric flow rate and can be detected by piezoelectric or thermistor sensors. Currently, the only vortex-precession meter in manufacture uses piezoelectric sensors.

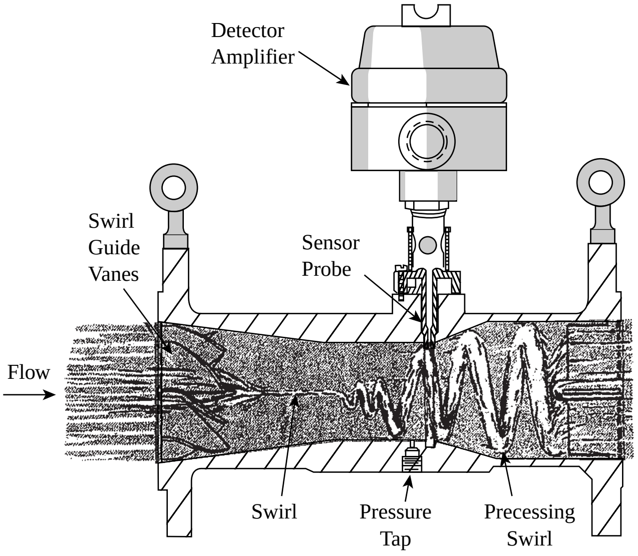

FIG. 2.30l
Construction of a typical vortex-precession (swirl) meter.

A flow straightener is fitted at the meter outlet to isolate the meter from downstream piping effects that might otherwise impair the development of the precessing vortex.

The internal components of the swirl meter required a significant amount of complex machining; thus, it is more expensive than some other meter types.

The swirl meter operates in most of the same applications as the vortex-shedding flowmeter but has the advantage that, since flow conditioning is done at the inlet and outlet of the meter body, virtually no upstream or downstream straight run is required for optimal installation. The sole supplier currently furnishes the swirl meter and the vortex-shedding meter in interchangeable "kits."

FLUIDIC (COANDA EFFECT) METERS

In fluidic meters, fluid entering the meter is entrained into a turbulent jet from its surroundings, causing a reduction in pressure. The internal geometry of the meter body causes the jet to be deflected from its central position and initially attach itself to one of the side walls. The jet curvature is sustained by the pressure differential across the jet. If a sufficient volume of fluid is then introduced into the control port on that side, it will cause the jet to switch to the opposite side wall. This is known as a *Coanda effect*. The jet can be made to oscillate by one of two methods. The simplest method is a relaxation oscillator. In this system, the two ports are connected. Fluid is sucked from the high-pressure side to the low-pressure side causing the jet to switch to the other wall. The jet thus continues to oscillate as the fluid is sucked alternately from one side to the other.

The more commonly used system is the feedback oscillator (see Figure 2.30m). The deflected jet causes a low-pressure area at the control port. At the upstream feedback passage, the pressure is higher due to a combination of the jet expansion and the stagnation pressure. Thus, a small portion of the main stream of fluid is diverted through the feedback passage to the control port. The feedback flow intersects the main flow and diverts it to the opposite side wall. The whole feedback operation is then repeated, resulting in a continuous, self-induced oscillation of the flow between the side walls of the meter body. The frequency of oscillation is linearly related to the volumetric flow rate above a minimum Reynolds number. As the main flow oscillates between the side walls, the flow in the feedback passages oscillates between zero and a maximum value. This frequency is detected by means of a sensor (either a thermistor or magnetic inductive pickup), providing a frequency output signal.

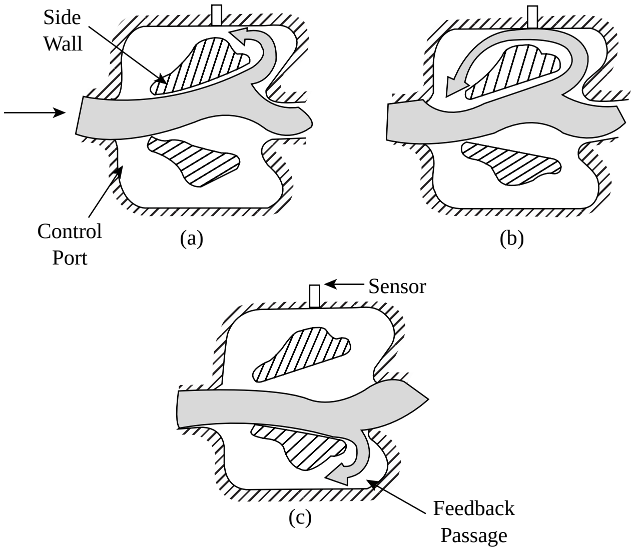

FIG. 2.30m
Diagram of the mode of operation of a feedback oscillator.

Characteristics

The principal features include a lack of moving components, fixed calibration based on the geometry of the housing, linear digital or analog output, and good rangeability. One advantage over vortex meters is that fluidic meters can operate down to a Reynolds number of 3000. The maximum flow range (dependent on size and viscosity) is 30:1. The complex housing shape largely dictates the operating pressure and maximum practical pipe diameter. In practice, a 4-in. (100-mm) diameter unit is the largest commercially available, and the operating pressure in this diameter is typically limited to 150 PSIG (1.03 MPa). Some vendors provide larger diameters up to 12 in. (300 mm) by using a bypass flow tube design. In this design, a flow restriction is placed in the tube, forcing fluid through the fluidic flowmeter mounted on top of the flow tube.

Although theoretically suitable for gaseous applications, fluidic meters have been used almost exclusively in liquid applications. Recent experimentation by several manufacturers has produced fluidic flowmeters that appear to be able to meet AGA certification requirements for household gas meters, and one manufacturer has placed a fluidic-principle gas meter in distribution for industrial and commercial natural gas metering applications.

A special, separate converter is required for the meter, which, in some instances, can incorporate a pneumatic output. As shown in Figure 2.30n, the meter factor in pulses per volume of flow passed remains within 1%, and therefore the measurement error remains well within 2% of actual flow between the Reynolds numbers of 3000 and 100,000.

CONCLUSION

The advantages of vortex-shedding flowmeters include their suitability for liquid, gas, and steam service; independence from viscosity, density, pressure, and temperature effects; low installed cost in smaller sizes; good accuracy and linearity without requiring calibration; wide rangeability; low maintenance using simple, easily accessible and interchangeable spare parts; simple installation; and direct pulse output capability.

In terms of disadvantages, they are not suitable for services that are dirty, abrasive, viscous, or mixed-flow (gas with liquid droplets, liquid with vapor bubbles), or that have low Reynolds numbers (below 20,000); the available choices in materials of construction are limited; the pulse resolution (number of pulses per gallon or liter) drops off in larger sizes; the pressure drop is high (two velocity heads); and substantial straight runs are required both upstream and downstream.

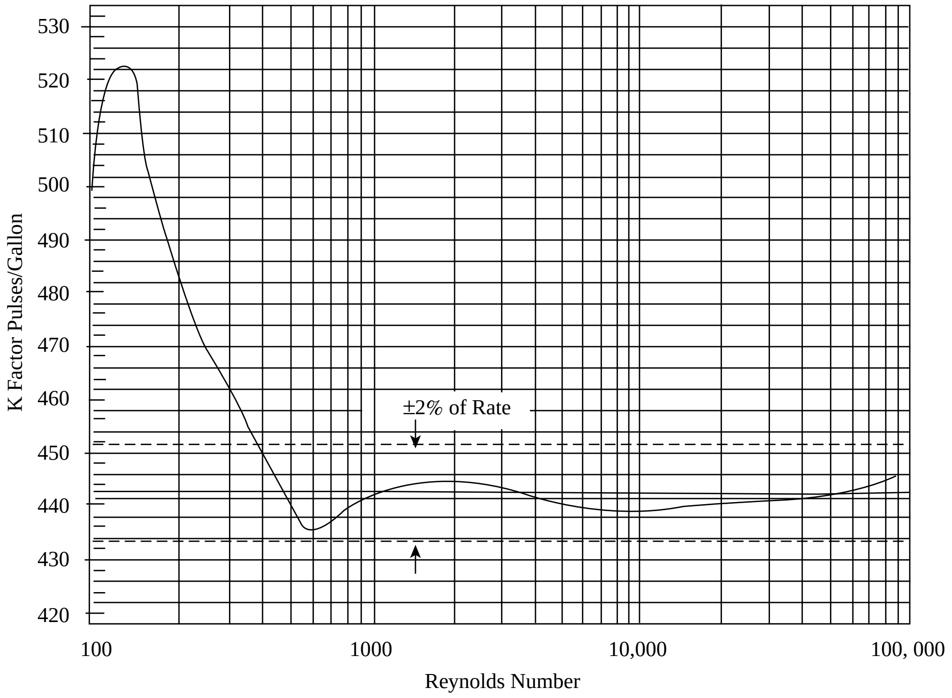

FIG. 2.30n
The meter factors of a 1-in. (25.4-mm) fluidic flowmeter stay accurate at lower values of Reynolds numbers than they do for vortex-shedding flowmeters. (Courtesy of Mycrosensor Inc.)

Flow Sheet Symbol

Types	Open-channel flow can be measured by detecting level in front of primaries. Bubblers, capacitance, float, hydrostatic, and ultrasonic devices are used as level sensors. Open-channel flows can also be measured without primaries by calculating flow from depth and velocity using ultrasonic and magnetic sensors.
Operating Conditions	Atmospheric
Applications	Waste or irrigation water flows in open channels
Flow Range	From 1 GPM (3.78 l/m), no upper limit
Rangeability	Most devices provide 75:1; V-notch weirs can reach up to 500:1
Inaccuracy	Laboratory devices: 2 to 3% of full scale Field installations: 5 to 10% of full scale
Costs	Primaries used in pipe inserts cost less than \$1000. A 6-in. (150-mm) Parshall flume costs about \$1500, and a 48-in. (1.22-m) one costs about \$5000. Primaries for irrigation applications are usually field-fabricated. Manual depth sensors can be obtained for \$300; local bubbler or float indicators for \$750 to \$1500; and programmable, transmitting, capacitance, *ultrasonic*, or bubbler units from \$2000 to \$3000. Open-channel flowmeters calculating flow (based on depth and velocity) range from \$5000 to over \$10,000.

WEIRS

Weirs are apertures in the top of a dam, across a channel through which flows the liquid to be measured (Figure 2.31a). The aperture may be rectangular (Figure 2.31b), trapezoidal (Figure 2.31c), or V-notch (Figure 2.31d). The special case of a trapezoidal weir with side slopes of 1:4 (Figure 2.31c) is known as a *Cippoletti weir*; this form leads to a simplified flow calculation. V-notch weirs generally have a notch angle from 30 to 90°, depending on required flow capacity.

The head is measured as the difference in level of the pool at an adequate distance upstream from the weir as compared to the horizontal crest of a rectangular or trapezoidal weir, or the bottom point of the V of a V-notch weir. Heads less than 0.1 ft (30 mm) for minimum measured flow or more than 1.0 ft (300-mm) for maximum flow are generally to be avoided, although a 1.25-ft (380-mm) head can be tolerated under favorable conditions. These limits are easily met by practical design, given that a 30° V-notch will measure a minimum flow of 1 GPM (3.8 l/m), whereas the maximum value for a rectangular or trapezoidal weir is limited only by practical crest length.

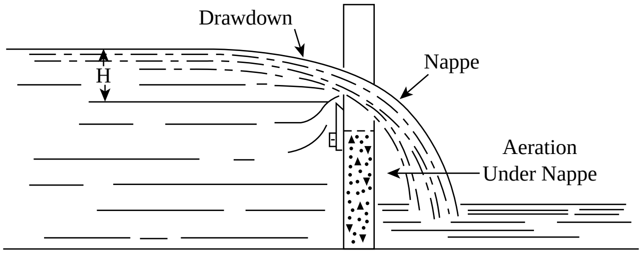

FIG. 2.31a
Flow over a weir.

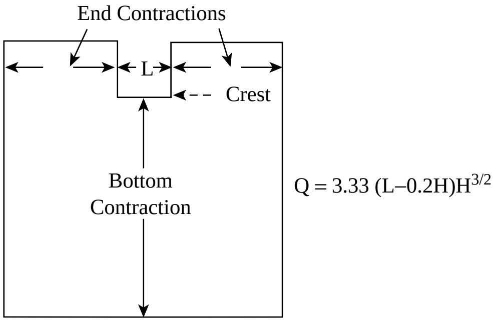

FIG. 2.31b
Rectangular weir.

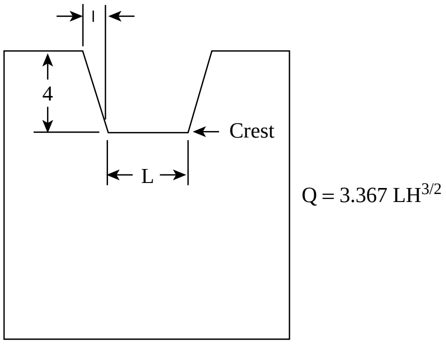

FIG. 2.31c
Cippoletti (trapezoidal) weir.

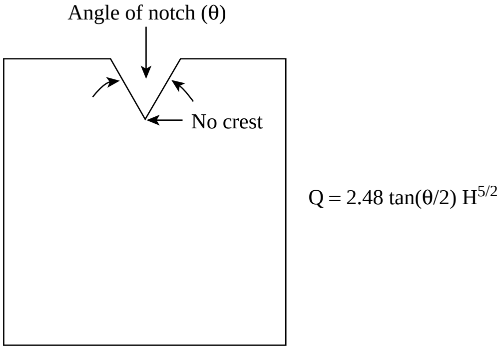

FIG. 2.31d
V-notch weir.

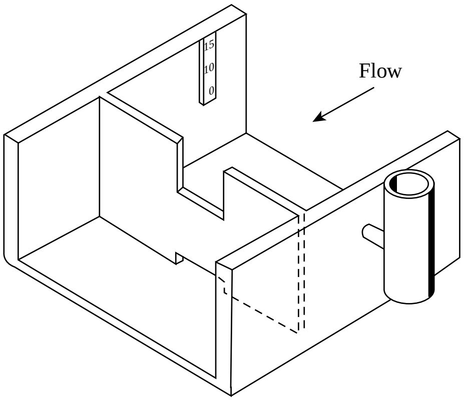

FIG. 2.31e
Weir box.

V-notch weirs are used for smaller flows. A 30° V-notch weir has a practically constant coefficient from 3.0 to 300 GPM (11.4 to 1140 l/min) with flow proportional to the five-halves power of the head. Coefficient increases roughly 2% for flow down to 1 GPM (3.8 l/min) and changes relatively little for flow up to 500 GPM (1893 l/min). For notch angle up to 90°, flow varies as the tangent of half the notch angle. Notch angle exceeding 90° is not recommended.

Rectangular or Cippoletti weirs are used for larger flows. A rectangular weir with a crest 2 ft (0.6 m) long develops a head of about 0.2 ft (60 mm) for 250 GPM (946 l/min) and 1.0 ft (305 mm) for 2700 GPM (10,221 l/min). For this weir, flow is directly proportional to crest length and to the three-halves power of the head.

The weir plate may be located in a dam in a natural channel or in a weir box (Figure 2.31e). The stilling basin ahead of the weir should be large enough so that the upstream velocity does not exceed 0.33 ft/sec (0.01 m/sec). Width and depth immediately ahead of the weir should be sufficient so that the wall effect of the bottom and sides of the channel has negligible effect on the pattern of flow through the notch. It is important that the flow break clear from the sharp edge of the notch with an air pocket maintained immediately beyond and below the weir plate. The channel downstream from the weir must be sufficiently wide and deep so that, at maximum flow, there is ample clearance between flow through the notch to downstream liquid level so that this air pocket is maintained (Figure 2.31a). The upstream edge of the weir should be sharp and straight. It is usual practice to bevel the downstream edge of the weir at 45° to about a 1/32-in. (0.8-mm) edge. For rectangular and Cippoletti weirs, the crest must be carefully leveled.

Accuracy of the relation between flow and head (level) to ±2% is attainable, based on the dimensions of the primary device. Reference 1 gives full data on installation and operation of weirs.

The following equations establish the relationships between flow and measured head, provided that the installation and operation of the weir are as recommended in this section and also in the cited references.

For a V-notch weir

$$Q = 2.48\ \tan \frac{1}{2}\theta H^{2.5} \qquad \textbf{2.31(1)}$$

For a rectangular weir

$$Q = 3.33(L - 0.2H)H^{1.5} \qquad \textbf{2.31(2)}$$

For a Cippoletti weir

$$Q = 3.367\ LH^{1.5} \qquad \textbf{2.31(3)}$$

where

Q = rate of flow in cubic feet per second
θ = V-notch angle in degrees
H = head* in feet of following liquid
L = crest length in feet

For conditions other than exactly as recommended, see references for correction factors.

THE PARSHALL FLUME

Developed by R.L. Parshall at the Colorado Experiment Station of the Colorado Agricultural College, in cooperation with the Division of Irrigation of the U.S. Department of Agriculture,[2] this device is a special type of venturi flume (Figure 2.31f). The loss of head is about one-quarter of that for a weir of equal capacity. Compared to weirs, approach velocity effects are practically eliminated so that a large upstream stilling basin is not required. The relatively high velocities in the system tend to flush away deposits of silt and other solids that might accumulate and alter measurement. There are no sharp edges, no pockets, and few critical dimensions; also, the device can be locally fabricated from available materials. Calibration data based on physical dimensions are available from 3 in. (76 mm) throat width with minimum range of 0.03 second-feet (13 GPM or 49 l/m) up to 50 ft (15.2 m) throat width with maximum capacity of 3300 second-feet (1,485,000 GPM/5,619,900 l/m). Flow is approximately proportional to the three-halves power of level with flow capacity of a single unit covering a range of 35:1 or more, depending on size.

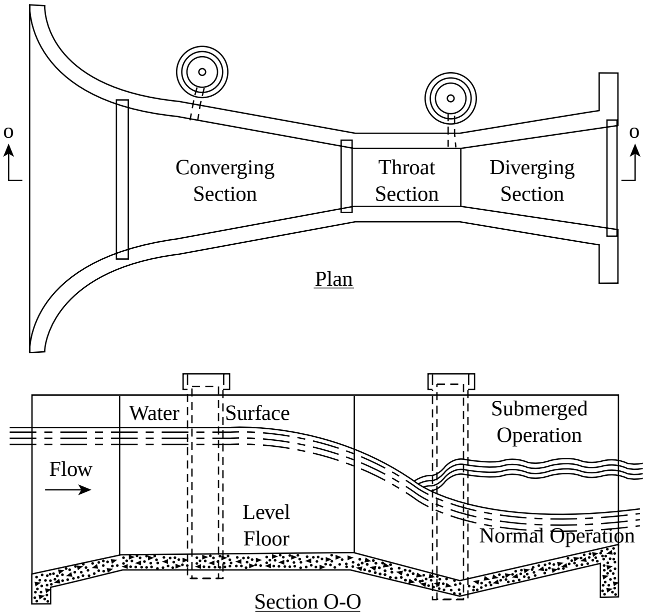

FIG. 2.31f
Parshall flume.

Extreme accuracy is not claimed for flow measurement using this device; however, measurement is very dependable with minimal maintenance and good repeatability. Accuracy is adequate for most applications to irrigation, waste, and sewage flows.

Downstream level has minimal effect on the measurement as long as the level near the downstream end of the throat does not exceed 70% of the level measured near the upstream end of the converging section (Figure 2.31f). (Both levels are referred to the floor section of the flume.) For flumes less than 1 ft (305 mm) wide, the ratio of levels is 60% maximum. This is the preferred and more usual mode of operation. It provides best accuracy. Only one measurement of level is required, with flow computed directly from this upstream level measurement; direct, continuous readout of flow rate is readily provided.

Where operating conditions (available head, maximum flow rate, weir size, and so on) result in a throat level greater than 70% of upstream level, so-called *submersion* results. Measurement can be obtained with a downstream level as great as 95% of upstream level. However, this requires a correction factor based on both upstream level and downstream level in the flow computation, accuracy suffers, and special equipment is usually required for direct readout of flow.

The simplified equations based on a single measurement at the upstream location are as follows:

---

* Head is measured between the level in the stilling pond and the crest of a rectangular or Cippoletti weir, or the bottom of the V of a V-notch weir.

TABLE 2.31h

†Courtesy of ABB Inc.

For $L = 0.25$ ft,

$$Q = 3.97\ LH^{1.547} \tag{2.31(4)}$$

For $L = 0.5$ ft,

$$Q = 4.12\ LH^{1.58} \tag{2.31(5)}$$

For $L = 0.75$ ft,

$$Q = 4.10\ LH^{1.53} \tag{2.31(6)}$$

For $L = 1$ to 8 ft,

$$Q = 4.0\ LH(1.522L)^{0.026} \tag{2.31(7)}$$

For $L = >8$ ft,

$$Q = (2.5 + 3.69\ L)H^{1.6} \tag{2.31(8)}$$

where

L = width of throat section in feet
Q = volume flow rate in cubic feet per second
H = head in feet*

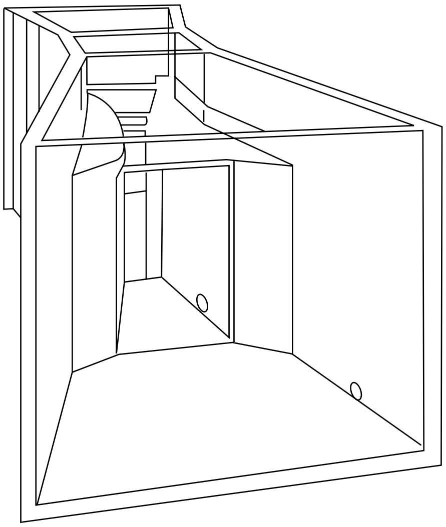

FIG. 2.31g
Dual-range Parshall flume. (Courtesy of ABB - Fischer & Porter Co.)

Parshall flumes are available in plastic construction. One variation of the plastic units is the nested, dual-range configuration in which two flumes are nested inside each other. This configuration is used in installations where the start-up conditions are substantially lower than the final operating flow rates (Figure 2.31g). With these units, the flow initially passes through the inner flume; then, when the flow exceeds its capacity, the inner flume is removed while the outer flume remains in place permanently. Dimensions of fiberglass-reinforced resin Parshall flumes are given in Table 2.31h.

THE PALMER BOWLUS FLUME

Palmer-Bowlus flumes provide the advantages of rounded bottoms and relatively small size. Compared with other flumes, this makes for easier installation in pipe inverts, ends, and sewer manholes. They also have a smaller head change vs.

---

* H (head) is measured at a designated point in the upstream converging section, referred to the level floor of this section.

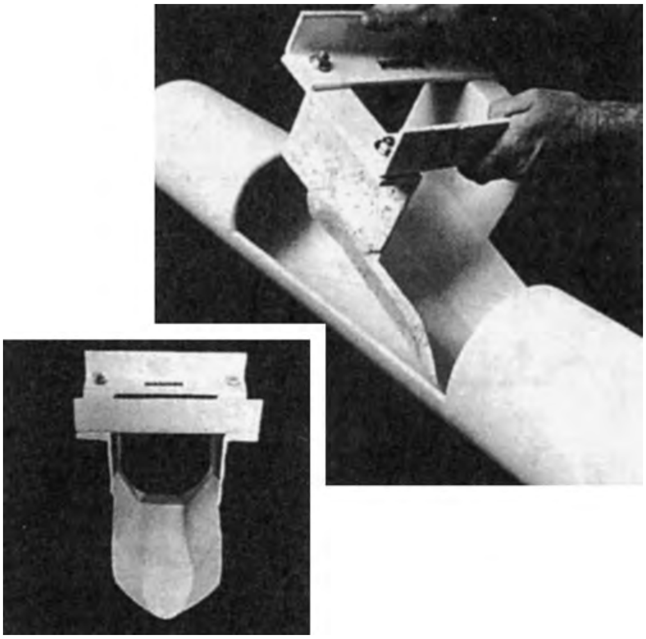

FIG. 2.31i
Flume insert elements. (Courtesy of Manning Environmental Corp.)

flow, and their dimensions are scalable to throat width, which makes rating of off-size flumes possible. A disadvantage is that the throat is raised; therefore, the possibility exists for upstream silt deposition at low flows. Reference 3 provides data on this.

These flumes are available for installation in existing round pipe using the type of insert shown in Figure 2.31i.

THE KENNISON NOZZLE, PARABOLIC FLUME, AND LEOPOLD LAGCO FLUME

These are typical proprietary products that were designed primarily for end-of-pipe flow measurement of waste, sewage, and the like, where the liquid flow to be measured emerges from a cylindrical pipe or conduit that usually is not completely full of liquid. All are designed to flush solids through the device without accumulations and to allow accessibility for inspection and cleaning if necessary.

These devices develop heads that are a function of flow rate. In the Kennison nozzle, head is almost linear with flow above 10% of maximum flow rate. Accuracy is stated as 2% in this range. For the parabolic flume and the Leopold Lagco flume, flow varies approximately as the three-halves power of head.

These devices are available in medium to large sizes. Details as to structure, application, and characteristics are available from the manufacturers.

DETECTORS FOR OPEN-CHANNEL SENSORS

The level rise generated by flumes or weirs can be measured by nearly any of the level detectors described in Chapter 3, including such simple devices as the air or nitrogen bubblers (Section 3.2).

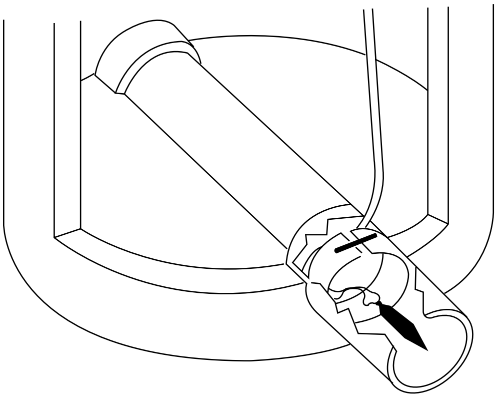

FIG. 2.31j
Volumetric flow computer measures depth and velocity in open channel and does not require a primary device. (Courtesy of Montedoro-Whitney Corp.)

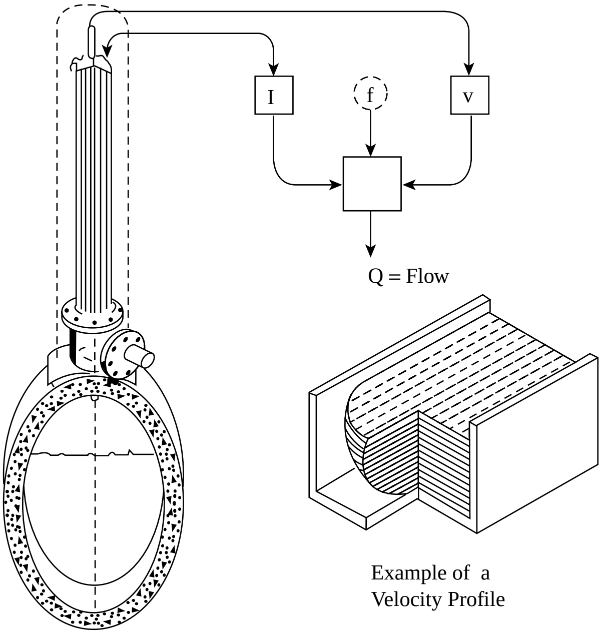

FIG. 2.31k
Robot-operated magnetic flow meter probe sensor is used to compute channel flow. (Courtesy of MSR Magmeter Mfg. Ltd.)

It is also possible to detect the flow in open channels without the use of flumes, weirs, or any other primary devices. One such design computes flow in round pipes or open channels by ultrasonically measuring the depth, calculating the flowing cross-sectional area on that basis, and multiplying the area by the velocity to obtain volumetric flow (Figure 2.31j).

Another open-channel flowmeter that does not need a primary element uses a robot-operated magnetic flowmeter probe to scan the velocity profile in the open channel (Figure 2.31k). In this design, the computer algorithm calculates and separately adds up the flow segments through each slice of the velocity profile as the velocity sensor moves down to the bottom of the channel.

INTRODUCTION

There are dozens of variations on the 22 technologies presented in this chapter. Each one has a slight advantage in terms of some of the infinite combinations of range, tank shape, process materials, available power, pressure and temperature, and accuracy requirements. The purpose of this section is to assist the reader in narrowing the choices and focusing on the most appropriate technologies for a particular application. In selecting the level instrument, we should determine which factors are desirable and which are not. In practice, this is seldom carried out, and, frankly, there is a great tendency to reach for a d/p transmitter, if not a displacer, and live with whatever performance it produces. This is the cliché solution and, like so many clichés, it is, if not the wrong answer, often not the best.

If a level instrument depends on motion (such as float, paddle, slip-tube, and tape types), if it has dead-ended cavities that might plug (such as some diaphragms, differential-pressure types, and sight gauges), if it will not operate properly when coated (such as some capacitance, conductivity, displacer, float, optical, and thermal types), or if a flow of a purge medium is required for its operation (bubbler type), it will be less reliable (more likely to require maintenance) than otherwise. Therefore, from a maintenance point of view, level sensors that do not make physical contact with the process material might be preferable. These include proximity capacitance, radar, laser, sonic and ultrasonic types, and sensors that can be located outside the tank, such as time-domain reflectometry (TDR) and microwave for fiberglass tanks, nuclear gauges and load cells (the last of these is discussed in Chapter 7). To assist the reader in selecting the right level instrument for a particular application, please refer to Orientation Tables 3.1a and 3.1b.

To use these tables, the particular service is first defined. The service is divided into three liquid categories and that of solids. The nature of the process material determines the applicable subdivision. With the service defined, the reader can scan down the selected column to find a letter indication (E = excellent; L = only particular models, geometries, or fluids work well; F = fair; or NA = not applicable) of the suitability for a particular technology. The ratings are based on such factors as inaccuracy, reliability, and ease of maintenance, but they do not take hardware cost into account. Therefore, an instrument that is rated “excellent” for a particular service may not be the cheapest selection. It is an unfortunate fact of today’s economic life that nearly every capital budget is divorced from the maintenance budget for the equipment purchased. The cost of downtime caused by a cheap, misapplied level switch generally is not factored into the project purchasing decision. Another table, provided to give general guidance on level sensor selection, is Table 3.1c.

Certain factors, listed below, must be known to make an intelligent choice, regardless of who makes it.

- Maximum and minimum temperature (real, not “design”)
- Maximum and minimum pressure (real, not “design”)
- Tank geometry, including nozzle dimensions
- Process chemicals (no trade names); remember cleaning solutions
- Tank construction materials
- Agitation horsepower and RPM
- Moisture range of granular solids
- Which phase is on top for interface measurements

When the possible selections have been narrowed down to a few, the reader may refer to the corresponding sections of this chapter. In the front of each section, there is a summary of basic features, such as inaccuracy, range, materials of construction, pressure and temperature ratings, and instrument price range (any required mounting, plumbing items, and labor cost can change the picture significantly). A brief inspection of the summary can determine whether the instrument meets the general requirements of the application under consideration. If so, additional information may be obtained from the text in the section. If some of the characteristics are unacceptable, the reader should return to the “Orientation Tables” for an alternative.

PERFORMANCE

There are no level transmitters or switches that can precisely specify accuracy or reliability outside of the context of the particular application. Nearly every manufacturer publishes an *accuracy* specification, which this volume refers to as *inaccuracy* and which, hopefully, everyone recognizes as *error*.

Source: I&CS/Endress+Hauser, Inc.
1 = Good; 2 = Fair; 3 = Poor or Not Applicable.

This is a statement of maximum error that is usually obtained by measuring something other than level. With d/p transmitters, the “other” is usually air pressure. With capacitance, it is a high-precision capacitance box. With sonic and radar instruments, it is a handy wall. With displacers, it is precision weights. These results should be considered to be *laboratory inaccuracy*, which relates to the least possible error. It is achievable only in perfect applications, where the critical parameters are invariable.

The real-world variables that can multiply the inaccuracy include

- Density variation for any of the density-sensing instruments
- Variations in the speed of sound resulting from the composition in the “air space” for sonic instruments
- Insulating coatings that change the speed of light for TDR instruments
- Conductive coatings on capacitance probes
- Any kind of coating for optical instruments
- Condensation on the antennas of radar instruments

The disingenuous use of lab error by manufacturers is no less appropriate than user specifications that call for unrealistic and unusable error limits. An example of specifiers run amok would be “0.25% inaccuracy on a 6-ft (1800-mm) interface” application, where the interface cannot be defined within 6 in. (150 mm). Certainly, in custody transfer measurements of storage tanks, extreme precision is required. How realistic though, is a 0.125-in. (3-mm) measurement of the top surface when water accumulation of several inches is ignored at the bottom of the tank?

When accuracy is critical, it should be quoted by the supplier, in the context of the application, just as we specify model number, price, and delivery. Of course, this puts the onus on the purchaser to fully define the application (beyond the limits of an “ISA spec sheet”). It also requires that the description include all chemicals (no trade names), including those for cleaning, purging, and so forth. It should also include the functional reason for making the measurement (e.g., “control pump-out between X and Y feet,” “material scheduling,” “operator information,” “feed-forward to dryer control”) rather than descriptions such as “to PLC.”

RELIABILITY

It is popular to confuse *mean time between failures (MTBF)* for the electronic circuits with the expected trouble-free life of the total instrument. Because we are dealing with primary instruments, the effects of temperature extremes and cycling, and stress due to agitation, are more significant factors in the expected trouble-free life. The characteristics of the process materials (such as coating, foaming, density variation, and crystallization) can produce major errors in days or even hours. Although many instruments, properly installed, can perform untouched for 20 years, any instrument can fail at any time. When instrument failure could cause more than irritation, backups should be mandatory. In such cases, the need for backups, such as independent level switches, cannot be overstated.

The best way to detect the level of all hard-to-handle substances is by avoiding physical contact with them. This can be very challenging when those substances are highly agitated, flung through the air space (dust), or produce weak reflections.

OPERATING PRINCIPLES

The following provides a brief review of the various technologies, grouped by sensing characteristics.

Density/Weight

Air bubblers measure the pressure required to force a constant flow of gas down and out the bottom of a tube that is immersed in the process. This is proportional to the length of the submerged tube times the specific gravity of the process liquid.

Differential-pressure (d/p) transmitters measure differential pressure between the bottom of a tank and some higher point, usually the top. Output is the product of level and specific gravity, which equates to weight only in straight-sided tanks.

Diaphragm (continuous) transmitters are essentially the same as d/p units used on a vented tank, except that they often go into the process liquid. On short spans, the atmospheric reference becomes critical to a submerged sensor.

Displacer transmitters measure buoyant force on the displacer body. The level signal is the length of the displacer body covered by a liquid times the specific gravity of the liquid.

Load cells (See Chapter 7) weigh the entire vessel, so translation to level depends on straight sides and the density of the process material.

Manometers traditionally use a heavier liquid than the process one to produce a short, vertical presentation that represents the process level times its specific gravity. A less obvious manometer effect occurs in standpipes and sight glasses, when temperature differential or changing process composition produces a density differential between the pipe and the tank contents. (No moving parts are employed.)

Radiation (nuclear) transmitters use a multitude of geometric configurations to shoot gamma rays through the process to a detector. The level signal depends on how much gamma is impeded by the process material, and that is a function of density. An often-neglected aspect of this technology is the cost of radioactive source disposal. (No touch is possible, no moving parts are employed.)

Thermal dispersion technologies depend on heat transferred by the process liquid, which is proportional to density and also depends on chemical composition. (No moving parts are employed.)

Conductivity/Dielectric

Capacitance/RF transmitters. These measure RF current flowing from a probe, usually but not necessarily probe-to-ground. Various means of examining and manipulating the RF signal provide a wide spectrum of performance in a variety of applications. This approach is most accurate on conducting process media. (No moving parts are employed.)

Conductance (continuous >2 MHz), sometimes referred to as *antenna loading*. This technique requires an insulated probe and significant distance to ground. It measures the eddy current loss in the area surrounding the probe, which is directly proportional to the volume (level within the electric field) of liquid and also the conductance of the liquid. (No moving parts are employed.)

Conductance (point-DC or low-frequency). When conductive material touches any part of the bare metal probe, it signals HIGH. Above an initial threshold, any conductance value works. Oil coating or disruption of the path to ground (such as a plastic-coated tank) defeats the instrument. (No moving parts are employed.)

Microwave switches. These devices sense the difference in dielectric between gas (1.0) and the process material, generally >2.0. Generally, there is a sender on one side of the vessel and a receiver on the other. (No moving parts are employed.)

Radar. Various types of antennas are used to generate an electromagnetic pulse or wave (moving at the speed of light), which is reflected by an abrupt change in dielectric constant. Numerous electronic schemes are used to determine the distance that the reflection represents. (No touching, no moving parts are employed.)

TDR (time domain reflectometry). In this case, the instrument sends an electromagnetic wave or pulse (at the speed of light) down a probe, and the pulse is reflected by the process. It is possible to sense more than one reflection point, allowing the measurement of total level and interface with a single instrument. As with radar, various techniques are used to determine what distance the reflections represent. (No moving parts are employed.)

Mechanical Contact

Diaphragm (point). This is primarily a sensor for granular solids. Movement of the diaphragm, caused by process granulars (S.G. >0.5) pressing on it, closes a mechanical switch. A more sensitive version employs an electrically excited, vibrating diaphragm that is damped by the presence of process solids. The resulting electrical change is used to switch a relay.

Dip stick. This is the world's oldest level measurement technology. It can involve the use of a stick or a tape, with or without a sensitive paste, to determine the level of a specific liquid. It is highly labor intensive.

Floats (cable connection). The mechanics of cable retraction and hang-up due to various causes are the biggest problem. When the equipment is new, it provides excellent accuracy in storage applications.

Floats (inductively coupled). Inductive sensing of float location eliminates the cable mechanics, but float hang-up is still a problem in some applications. Accuracy in storage applications is excellent.

Floats (magnet/reed relay). The switches employed require no power. Floats can hang up or sink, but there is no problem with mechanical connections. The resolution of transmitters is limited by number of reed switches per foot.

Floats (magnetostrictive pulse sensing). This is much like the inductive float position sensing, except the permanent magnet in the float produces the reflection of a magnetostrictive pulse in a physically isolated, ferromagnetic tape.

Paddlewheel (point). A rotating paddle in a dusty atmosphere has an inherent failure mechanism. It can be used only in granular solids. The presence of material stops the paddle's motion, causing a change in motor current and relay closure.

Plumb bobs (yo-yos). Dust buildup on the cable, dust in the bearings, and potential for trapping the plumb bob under incoming solids have made this long-time standard obsolete. It is used only for granulars.

Resistance tape. This is an accurate but delicate sensor for liquid storage tanks. The mechanical force from the measured liquid shorts out the submerged segment of the top-to-bottom precision resistor. Changes in density have a minor effect.

Sonic/ultrasonic. Most of these switches use a sonic path across a gap of selected width. The presence of gas bubbles or solid particles in the gap can interfere with their operation. The transmitters are quite accurate but require a consistent speed of sound in the "air" space, freedom from spurious echoes, and a process material that produces a strong sonic reflection. Condensation and dust buildup on the transducer are problematic. The transmitter won't work in vacuum. Frequencies are selected for the application, not the range of human hearing. All these instruments are “sonic,” but not all are “ultrasonic.” (No continuous touch is involved, and no moving parts are employed.)

Vibration (point). Using a fork or a single vibrating rod, these devices are now available for solids or liquids. They operate on a modification of the vibration character, switching a relay when submerged in the process material. Coating and packing materials can be a problem. They tend to be delicate because of the sensitivity required.

Optical

Lasers. Lasers constitute the best way to measure coal in silos. They are not susceptible to spurious reflections as are radar and sonic devices. They require a clear optical path and reflectance rather than transmittance from the process material. (No continuous touch is involved, and no moving parts are employed.)

Optical (photocell) switches. Generally, these are quite limited by coating and temperature. An optical switch has the virtue of isolation from the process material but requires that the isolating medium be optically and process compatible. (No continuous touch is involved, and no moving parts are employed.)

Level (sight) gauges. A sight gauge is a simple mechanism with complex limitations. Liquids that coat obscure the actual level. The level indication most trusted by operators (“seeing is believing”). A temperature differential between the tank and glass, a classic boiler glass problem, causes incorrect indication. (No moving parts are employed.)

TANK ACCESS

Existing tanks often present a challenge to placing the measuring instrument in the correct location to perform properly. Glass-lined and coded pressure vessels provide no possibility of adding or enlarging any penetrations. If an external standpipe proves to be troublesome as a result of plugging or thermal differential, the level instrument needs direct access to the tank. The simplest possibility is to place a spare nozzle of sufficient diameter and short length on top of the tank. Failing that, there is always a chance of “teeing” into the vent pipe or pressure relief line. If there is a manway on top of the tank, the cover can be removed and a nozzle welded on in the shop. There are ways to sneak a continuous sensor into a tank from a side nozzle, but this usually entails a bit of plumbing ingenuity and customarily reduces the maximum height that can be measured. Obviously, a d/p transmitter can be mounted on a tank bottom nozzle, but it could also accept an RF probe mounted upside down. Most switch technologies have provision for vertical or horizontal entry. The refining and fuel storage industries are competent to “hot-tap” a tank while the level is above the new nozzle. This approach definitely requires a sensor that can be inserted through a block valve under pressure.

For new tanks, regardless of the level transmitter selected, a wise precaution is to add a spare 8-in. (200-mm)* and a spare 2-in. (50-mm) nozzle to the top of the tank. If there is a problem in the measurement, or whenever the process is modified, this will allow the installation of nearly any level transmitter. The smaller nozzle allows for the addition of an overfill switch. The nozzle length should be as short as possible (4 to 6 in. or 100 to 150 mm) as compatible with required bolting space.

APPLICATIONS

Level measurement applications can be broadly grouped in terms of service as *atmospheric vessels* and *pressurized vessels*. With the exception of liquefied gases, accounting-grade measurements are made in atmospheric vessels. These are a quantum leap in precision from the *process control* or *material scheduling* class of measurement.

Atmospheric Vessels

Liquid level detection in atmospheric vessels rarely presents a serious problem. The most common problems are caused by high temperature or heavy agitation. Instrumentation generally can be selected and installed so that it is removable for inspection or repair without draining the vessel. With few exceptions, a level indicator located at eye level, combined with the available digital communication technologies, eliminates the necessity for the operator or instrument technician to climb the vessel. Most of the transmitters (with the exception of d/p types) are available as top-mounted designs, eliminating the possibility of a spill if the instrument or nozzle corrodes or ruptures. Most vented-to-atmosphere vessels can be manually gauged. It is always comforting to know that such a simple procedure as manual gauging is available to calibrate or verify an instrument output. Various float types can be used in low-volume storage tanks, underground tanks, transport tankers, and other applications outside of the processing area.

Solids level measurement also is generally done in atmospheric tanks, but, in this case, the specifier has fewer available level detecting devices and less installation flexibility. Devices that are suitable for point level detection of solids include the capacitance/RF, diaphragm, rotating paddle, radiation, vibration, microwave, and optical types. Some level switches must be located at the actuation level; this can lead to accessibility problems. Except for the radiation-type device, it also means that a new connection must be provided

---

* Or 4-in. (100-mm) in horizontal cylinders.

if the actuation point is raised or lowered. Paddle, vibration, and RF sensors can be extended at least 10 ft (3 m) from the top, and RF allows the switching point to be adjusted electrically. Solids that behave unpredictably can cause serious measurement problems. If the solid is not free flowing, sensing should be limited to an area beyond the expected wall buildup. If it can bridge or rat-hole, particular care must be taken in the location and installation of the level switch.

Continuous level measurement of solids can be made by yo-yo (automatic plumb-bob), laser, nuclear, RF, TDR, radar, and sonic instruments. The yo-yo was formerly most popular, but its problems with its moving parts in dusty bins have spurred the use of stationary devices. These designs are generally top mounted, but all can be equipped with ground-level or remote readouts. Density variation and angle of repose are inherent in the granular solids. Both can cause inaccuracy of the level measurement, which is a substantial multiple of the instrument's laboratory error specification. As with the switches, good performance requires that the solids be free flowing. These measurements will all be suitable for *material scheduling* functions. If an *inventory* grade measurement is required (definitely a weight measurement), load cells are used. Load cells are covered in Chapter 7.

Pressurized Vessels

Point level detection of liquids in a pressurized vessel can be made using one of ten types of level sensors. For clean services in industrial processing plants, preference has traditionally been given to the externally mounted displacer switch. This unit is rugged and reliable, it has above-average resistance to vibration, and its actuation point can be easily changed over a limited range. There are a number of cases in which microwave, sonic, capacitance, and float switches are considered if they are installed so that they can be removed for repair without venting the vessel to the atmosphere. Conductivity switches are used in water services to 700°F (370°C) and 3000 PSIG (21 MPa). Optical and thermal dispersion switches have no moving parts, are inexpensive, and are used on clean services.

Continuous liquid level detection in pressurized vessels is subdivided into clean and hard-to-handle processes. For clean services requiring local indication only, the traditional choice is the armored sight gauge. Even when a transmitted signal is required, many users specify that transmitters be backed up with a sight gauge for use in calibration and to allow that the process can run manually if the transmitter is out of service. Nevertheless, the need for a sight gauge should be carefully evaluated, as it can be a weak point (personnel hazard) in high-pressure processes and can become plugged in sludge and slurry services. In hazardous services, magnetic-float level gauges can be used.

Preferences for clean service transmitters vary from industry to industry. Petroleum refiners have traditionally preferred the externally mounted displacer transmitter but have recently discovered that much related maintenance and rebuilding can be avoided by using electronic sensing. The existing rugged "cages" can be retrofitted with lower-maintenance instruments. Strength is important in the petroleum industry, because a break at the instrument connection could cause a hydrocarbon spill above the autoignition temperature. The low-side (vapor-phase) connection of these cages does not require a chemical seal. This reduces maintenance requirements and eliminates possible inaccuracies that a d/p transmitter might produce. Most refinery processes are compatible with carbon or alloy steel materials, which are readily available in all sensor designs.

In other chemical processing industries, first consideration usually goes to the d/p transmitter when a level signal is required. It is reliable and accurate (provided that specific gravity is constant), and many modifications are available for unique services. The major problem with the d/p transmitter, when used for level measurement on pressurized vessels, is in handling the low-pressure tap. If the low side of the d/p cell can be connected directly to the vapor space of the vessel, the problem is eliminated, but this is rarely the case. Normally, the low-pressure leg must be filled with a seal oil or with the process material. If a seal oil is used, the oil must be compatible with the process. If the leg is filled with the process material, the process fill must not boil away at high ambient temperatures. In either case, ambient temperature variations will change the density of the fill, which can cause inaccuracies in the level reading. The liquid seal also requires frequent inspection. Low-pressure-side repeaters and chemical seals are also available, but although they eliminate the seal problem, they introduce inaccuracies of their own and increase the purchase cost. Despite this, d/p cells are successfully used in a wide range of applications and can be considered whenever the span to be measured is greater than 60 in. (1.5 m). Other devices, such as capacitance/RF, nuclear, sonic, radar, and TDR technologies, are in use for level measurement in pressurized vessels, especially where level indication must be independent of density.

Accounting Grade (Tank Gauging)

Accounting-grade measurements are made in both atmospheric and pressurized vessels. The need for accuracy in accounting-grade installations can be demonstrated as follows. A typical 750,000-barrel American Petroleum Institute (API) storage tank has a diameter of 345 ft (105 m), and it takes some 8000 gallons (30 m^3) to raise the level 1 in. (25 mm). A level measurement error of 1 in. (25 mm) would therefore indicate that 8000 gallons (30 m^3) have been gained or lost. In the case of hydrocarbon storage tanks, the accumulation of water at the bottom must be factored into the measurement, or errors equivalent to several inches of product could result. This is no small matter, particularly if the level measurement is used as a basis for custody transfer of the product. Substantial effort has been put into the development of storage

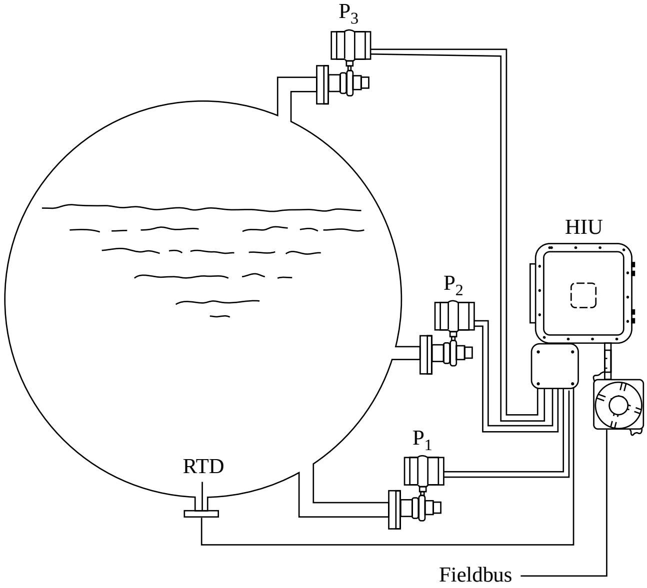

FIG. 3.1d
A Hydrostatic Tank Gauge applied to a pressurized, spherical tank. (Courtesy of The Foxboro Co.)

tank gauging systems that have good reliability, high accuracy, and high resolution. These efforts have been relatively successful, and the user can be confident of obtaining satisfactory results if adequate attention is given to installation details. Every bit as critical as the instruments installed is an accurate, up-to-date *strapping table.* Because tanks settle and sag over time, it should be updated after the first two years of service. Tanks that are 20 years old often use a strapping table that was created before they saw the first batch of product.

The use of differential-pressure transmitters (Figure 3.1d) for hydrostatic tank gauging (HTG) is one of the popular methods to make these high-accuracy measurements. Pressure 1 minus pressure 2 ($P_1 - P_2$) divided by the distance between them produces the density information. The pressure P_1 is divided by the density to obtain the level. The level is entered into the strapping table for the particular tank to obtain the volume of liquid. In the case of nonvented tanks, P_3 is subtracted from P_1 before making the division by density. Although it is often neglected, the water level beneath the organic should be entered into the strapping table, and the resulting volume subtracted to obtain net product volume.

Radar is another favored technology for obtaining the 0.125-in. (3-mm) accuracy usually required for these applications. In that method, the actual level is measured directly and entered into the strapping table to obtain volume. This may appear to be a more straightforward approach, but measuring to this accuracy from the top of a tall tank has other mechanical considerations such as roof deflection and thermal tank expansion. The float and servo-operated plumb bob that were formerly the top-mounted standards are being replaced by these newer technologies. For custody transfer, dip tapes are still probably the most common measurement. The manual approach has the advantage of measuring the water under organic products at relatively minor additional cost. In this case, the inaccuracy risk is the very real possibility of human error, either in the measurement itself or in the volume abstracted from the strapping table.

Sludge and Slurries

A number of level-switch designs are suited for hard-to-handle service in pressurized vessels. In making a selection, one would first decide if a penetrating design is acceptable (Figure 3.1e). The use of such a level switch usually implies that the tank will have to be depressurized, or sometimes even drained, when maintenance is required. If penetration is not allowed, then only nuclear, clamp-on sonic, or microwave (for fiberglass or plastic tanks) devices can be considered.

When a level transmitter is selected for a hard-to-handle service, the radiation type or the load cell might seem to be obvious choices, but licensing and regulatory requirements in the case of radiation, and high costs of both, tend to make them choices of last resort. The installation cost of load-cell systems can be reduced by locating the strain gauge elements directly on the existing steel supports (Figure 3.1f). There are, of course, applications in which almost nothing can be used other than such expensive devices as the nuclear-type level gauge. One example of such an application is the bed level in a fluidized-bed type of combustion process. If the accuracy of purging taps is insufficient, there is little choice but to use radiation gauges.

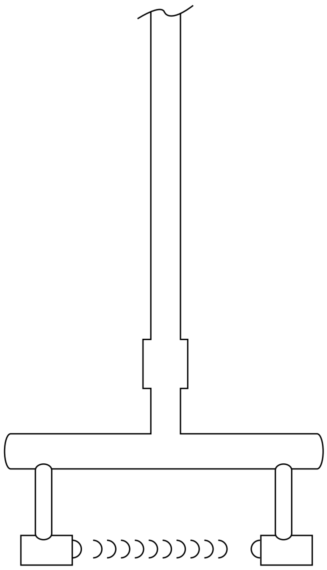

FIG. 3.1e

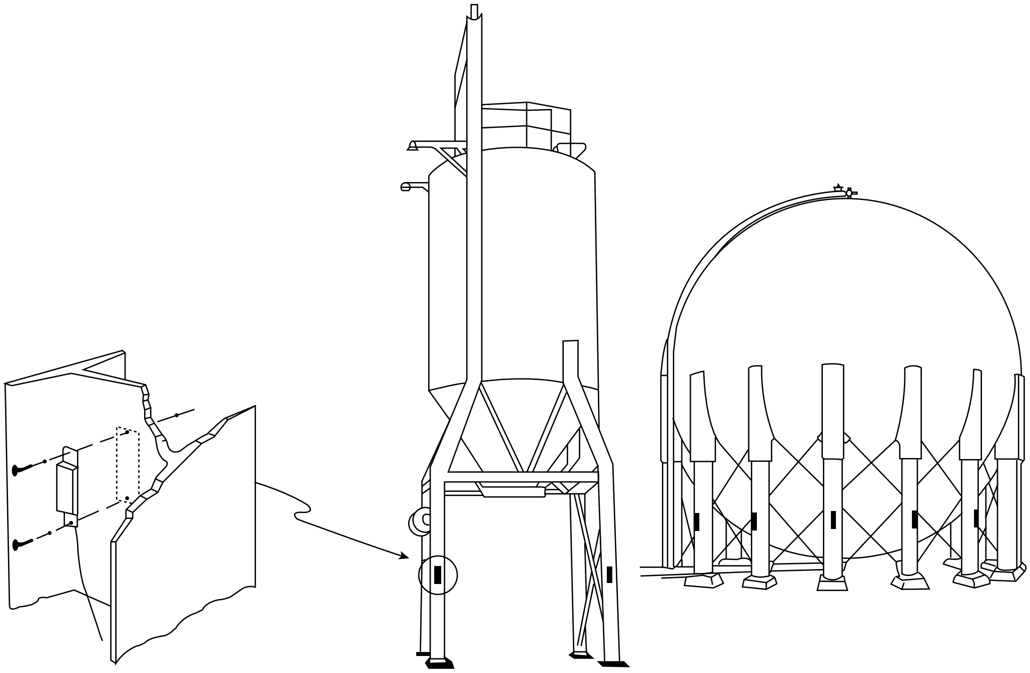

FIG. 3.1f
Steel support-mounted strain gauges (see Chapter 7) can be calibrated by measuring the output when the tank is empty, and again when it is full. (Courtesy of Kistler-Morse.)

On slurry and sludge services, d/p units are most likely to exhibit large errors due to density variation. The required extended-diaphragm type of differential pressure transmitter eliminates the dead-ended cavity in the nozzle where materials could accumulate and brings the sensing diaphragm flush with the inside surface of the tank. The sensing diaphragm can be coated with TFE to minimize the likelihood of material buildup. One of the best methods of keeping the low-pressure side of the d/p transmitter clean is to insert another extended diaphragm device in the upper nozzle. This can be a pressure repeater (Figure 3.1g), which is capable of repeating either vacuums or pressures if it is within the range of the available vacuum and instrument air supplies. Outside of these pressures, extended-diaphragm types of chemical seals can be used (Figure 3.1h) if they are properly compensated for ambient temperature variations and sun exposure. Other level transmitters that should be considered for hard-to-handle services include the capacitance/RF, laser, radar, sonic, and TDR types. Foaming and surface disturbances due to agitation tend to interfere with the performance of radar, laser, and sonic units. Capacitance probes and TDR probes stand a better chance of operation in these services. They can withstand some coating or can be provided with probe cleaning or washing attachments. Radar transmitters perform accurately and reliably on paper pulp and other applications that coat and clog.

Foaming, Boiling, and Agitation

In unit operations such as strippers, the goal is to maximize the rate at which the solvents are boiled off against the constraint of foaming. In other processes, the goal is to maintain

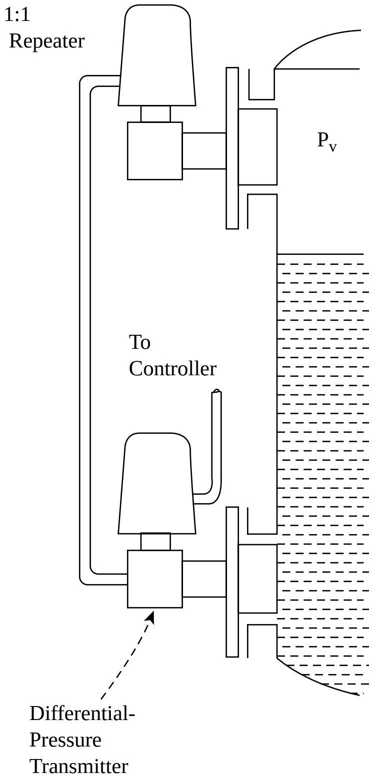

FIG. 3.1g
The clean and cold air output of the repeater duplicates pressure (P_v) of the vapor phase.

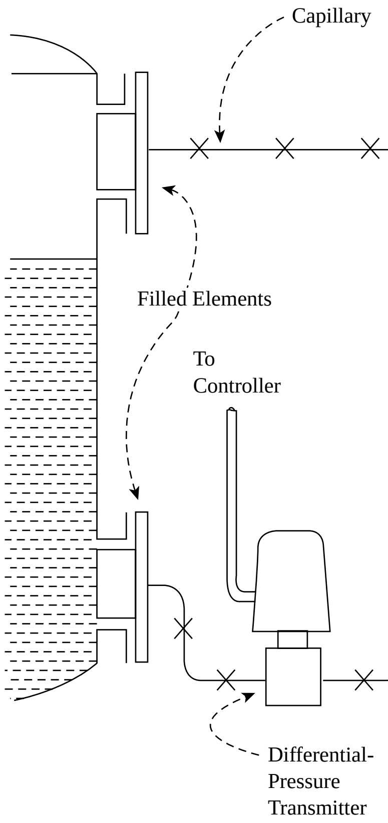

FIG. 3.1h
Chemical seals with temperature compensation and extended diaphragm protect a d/p transmitter from plugging and chemical attack.

a controlled and constant thickness of foam. In these types of processes, one must detect both the liquid–foam interface and the foam level. The detection of the liquid level below the foam is the easier of the two level-measurement tasks, because the density of the foam tends to be negligible relative to the liquid. A d/p transmitter installation (Figure 3.1h) will measure the hydrostatic weight of the foam, disregarding most of its height. Different industries tend to use different sensors for measuring the foam–liquid interface. In Kraft processing, for example, radiation detectors are used to detect that interface in the digester vessel. RF (capacitance) and TDR transmitters and conductance and RF switches make excellent foam level measurements as long as the foam is conductive (in fact, only very specialized RF switches can differentiate between conductive foam and liquid).

The continuous measurement of insulating foam level is more difficult and, for that reason, some people will circumvent its measurement by detecting some other process parameter that is related to foaming. These indirect variables can be the vapor flow rate generated by the stripper, the heat input into the stripper, or just historical data on previous batches of similar size and composition. If direct foam level measurement is desired, it is easier to provide a point sensor than a continuous detector. Horizontal RF switches generally operate successfully if density is sufficient to produce a dielectric constant in the foam that is greater than 1.1 (vacuum and gases are 1.0). In the case of heavier foams, vibrating or tuning fork switches and beta radiation gauges have been used; in some cases, optical or thermal switches have also been successful.

Boiling will change the hydrostatic weight of the liquid column in the tank due to variable vapor fraction. As the rate of boiling rises, the relative volume of bubbles will also increase, and therefore the density will drop. Density rises as the rate of boiling is reduced. Density also varies with level as bubbles expand on the way up. Therefore, the measurement of hydrostatic head alone can determine neither the level nor the mass of liquid in the tank. This problem is common when measuring the water in nuclear, boiling-water reactors (BWRs) or in the feedwater drums of boilers. High-temperature capacitance/RF transmitters can do the feedwater job, but the fluorocarbon insulation is not applicable to nuclear reactors. A standpipe with a series of 10 to 20 horizontal conductance sensors is very common in these applications. If only level indication is required, then the refraction-type level gauge is sufficient, given that it shows only the interface between water and steam. These “external” strategies require the temperature to be equal with the tank to be useful.

Some agitators prevent the use of probe-type devices, because they leave no room for them, and they also challenge the use of sonic and radar transmitters unless programmed to ignore the agitator blades and sense the rough surface. Glass-lined reactors are a classic enemy of probes, as they usually have heavy agitation, and the lining prevents support or anchoring. A probe, broken due to fatigue, can cause very expensive damage in these vessels. Radar transmitters with “tank mapping” software are quite suitable as long as the dielectric constant is greater than 2 (most common). Agitation usually does not affect the performance of the displacer and d/p-cell-type level sensors, which are external to the tank. They can measure level in the special case, where the specific gravity is constant. Of the two, the d/p cell is preferred, because it is looking at the liquid inside the tank and not in an external chamber, where its temperature and therefore its density can be different. Of course, the primary reason for heavy agitation is to keep unlike components mixed, which implies variable specific gravity.

Interface Measurement

When detecting the interface between two liquids, we can base the measurement on the difference of densities (0.8:1.1 is a typical ratio), electrical conductivity (1:1000 is common), thermal conductivity, opacity, or sonic transmittance of the two fluids. Figure 3.1i illustrates the difference in typical separator response between the conductivity sensors and the density sensors. One should base the measurement on whatever process property gives the largest stem change between the upper and the lower fluid. If, instead of a clean interface,

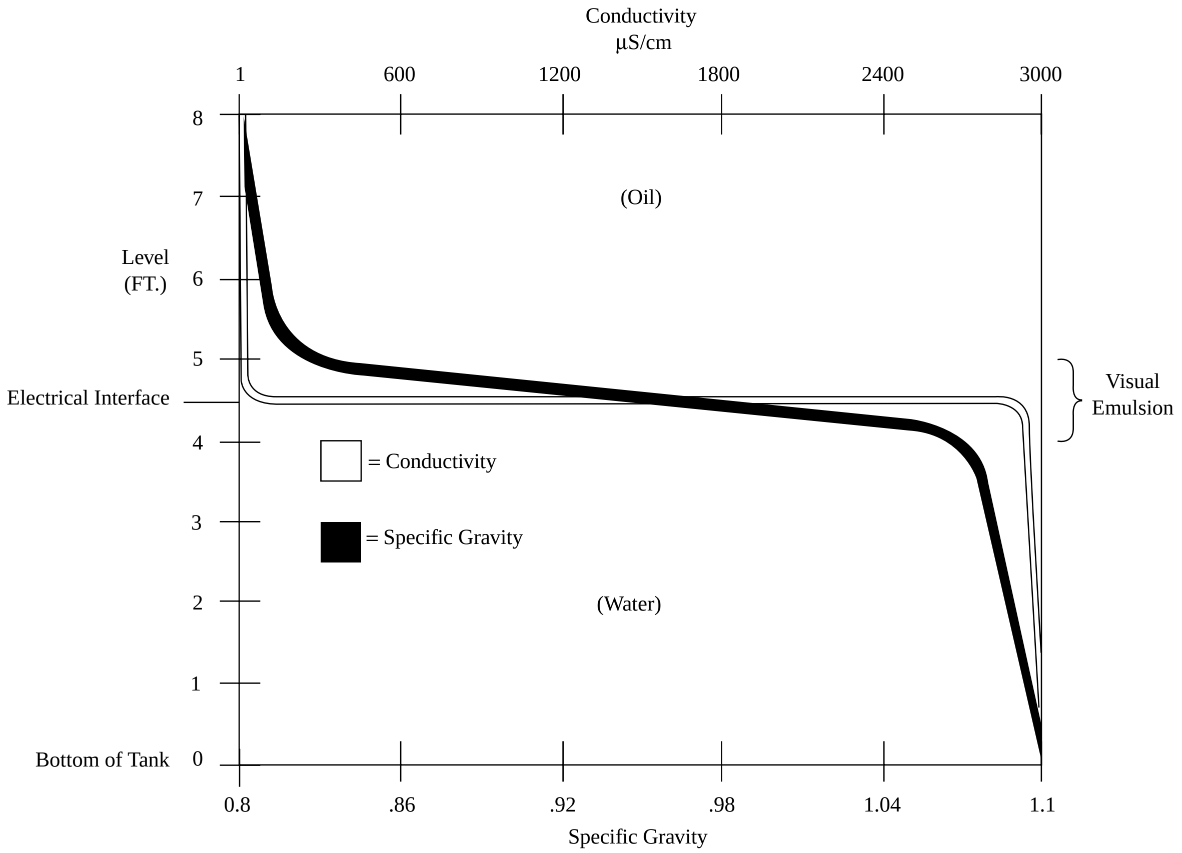

FIG. 3.1i

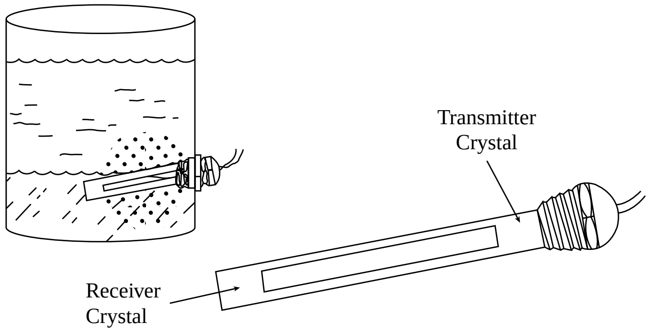

FIG. 3.1j
Sonic interface level switch. (Courtesy of Thermo MeasureTech.)

there is a *rag layer* (an emulsion of the two fluids) between the two fluids, the interface instrument cannot change that fact (it cannot eliminate the rag layer). If the separator and its control system are properly designed, the emulsion can be kept out of both separated products.

Interface-level switches are usually of the optical (Figure 3.1e), capacitance, displacer, conductivity, thermal, microwave, or radiation designs. The unique sonic switch described in Figure 3.1j utilizes a gap-type probe that is installed at a 10° angle from the horizontal. At one end of the gap is the ultrasonic source, and at the other is the receiver. The instrument depends on the acoustic impedance mismatch between the upper and lower phases. When the interface is in the gap, it will attenuate the energy of the sonic pulse before it is received at the detector. This switch is used in detecting the interface between water and oil or other hydrocarbons. Of course, this is no way to control the interface, because, once outside, it could be above or below the gap. It is suitable as a backup to an interface control system.

D/P transmitters can continuously detect the interface between two liquids, but, if their density differential is small, it produces only a small pressure differential. Changes in density typically produce 5 to 10 times the error on an interface calibration that they do on a single-liquid calibration. A major limitation is that the range of interface movement must cause a change that is as great as the minimum d/p span. If the difference in conductivity is at least 100:1, such as in case of the dehydrating of crude oil, continuous capacitance or TDR probes make excellent interface transmitters. Interface between two insulating liquids (a rare situation) can be accomplished with TDR but is unreliable using capacitance. Sonic transducers lowered into the brine layer of oil or liquefied gas storage caverns (Figure 3.1k) can measure the interface

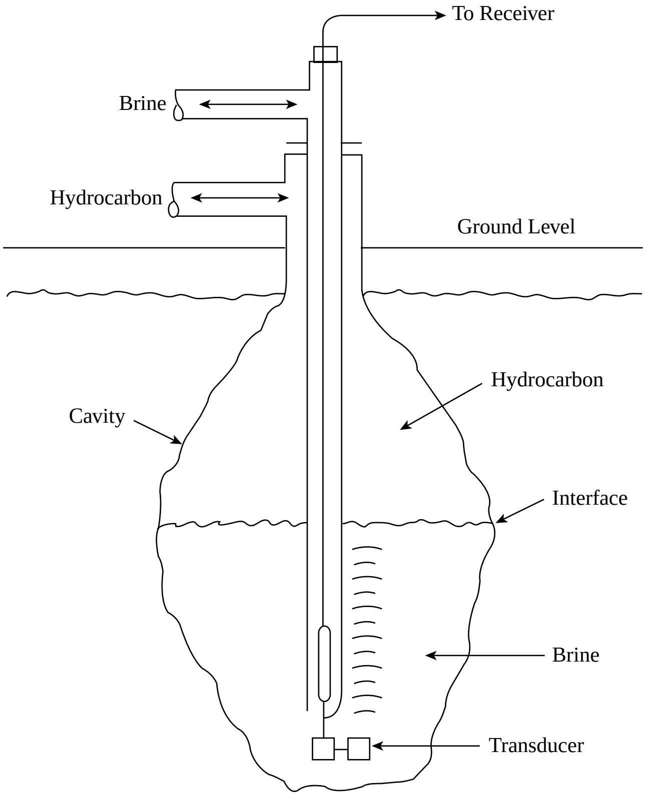

FIG. 3.1k
A unique, bottom-up, sonic interface measurement.

between brine and hydrocarbon by shooting up from the bottom.

On clean services, float and displacer-type sensors can also be used as interface-level detectors. For the float-type units, the trick is to select a float density that is heavier than the light layer but lighter than the heavy layer. With displacer-type sensors, it is necessary to keep the displacer flooded with the upper connection of the chamber in the light liquid phase and the lower connection in the heavy liquid phase. By so doing, the displacer becomes a differential density sensor and, therefore, the smaller the difference between the densities of the fluids, and the shorter the interface range, the smaller the force differential produced. To produce more force, it is necessary to increase the displacer diameter. The density of the displacer must be heavier than the density of the heavy phase.

In specialized cases, such as the continuous detection of the interface between the ash and the coal layers in fluidized bed combustion chambers, the best choice is to use the nuclear radiation sensors.

Liquid/solid interface measurements are extremely demanding, and the only general successes have been achieved with nuclear or sonic sensing. The sonic sensor must always be submerged, because a gas phase will either disrupt the measurement entirely or appear to be the solid. In special noncoating cases, optical sensors have worked without frequent cleaning.

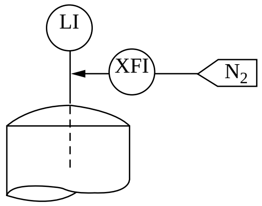
3.2 Bubblers

D. S. KAYSER (1982) **B. G. LIPTÁK** (1969, 1995)
C. G. LANGFORD (2003)



Flow Sheet Symbol

Application	Level, interface, and density; open or closed, pressurized tanks and vessels
Operating Pressure	Limited only by the pressure of the available purge gas supply
Operating Temperature	As required; limited only by materials in contact with the process; has been used on such high-temperature processes as coal gasification
Materials	Limited only by the availability of exposed pipe materials
Costs	\$200 for the simplest local indicator installation, can reach \$5000 for installations requiring special materials and remote transmission
Inaccuracy	Function of error in the readout and other parts used, ±0.05% to ±2.0% of full scale
Range	Unlimited as long as purge gas supply pressure exceeds that of the process
Partial List of Suppliers	Bubbler-type level detector packages can be assembled from components described in other sections, such as variable area flowmeters described in Section 2.27, various types of pressure sensing and display devices described in Chapter 5
Prepackaged bubbler assemblies are also available from	Aalborg Instruments & Controls (www.aalborg.com) ABB Fischer & Porter (www.abb.com) Blue-White Industries (www.bluwhite.com) Brooks Instrument Div. of Emerson (www.emersonprocess.com) Dwyer Instruments Inc. INTRODUCTION

Many industrial accidents are caused by incomplete or inaccurate level information. Bubblers serve to solve that problem in an inexpensive and reasonably reliable manner. The operation of an air bubbler is similar to blowing air into a glass of water with a straw. The more water is in the glass, the harder one needs to blow. Bubbler-type level sensors have been in use for as long as compressed air has. If the air pressure entering the dip pipe is greater than the hydrostatic head of the process fluid in the tank, the air will bubble out at the bottom of the pipe.

Figure 3.2a illustrates an air bubbler installation for an open (atmospheric) tank with various purge controls. The transmission line should be sloped toward the tank so that, if the purge is lost and process vapors enter the transmission tube, the condensate will drain back into the vessel. If the readout device must be below tank level, a condensate trap can be installed as shown by the dotted line.

The purge supply pressure should be at least 10 PSI (69 kPa) higher than the highest hydrostatic pressure to be gauged. The purge flow rate is kept small and relatively constant at about 1 SCFH (500 cm^3/min), so there will be no significant pressure drop in the dip tube. Usually, the purge

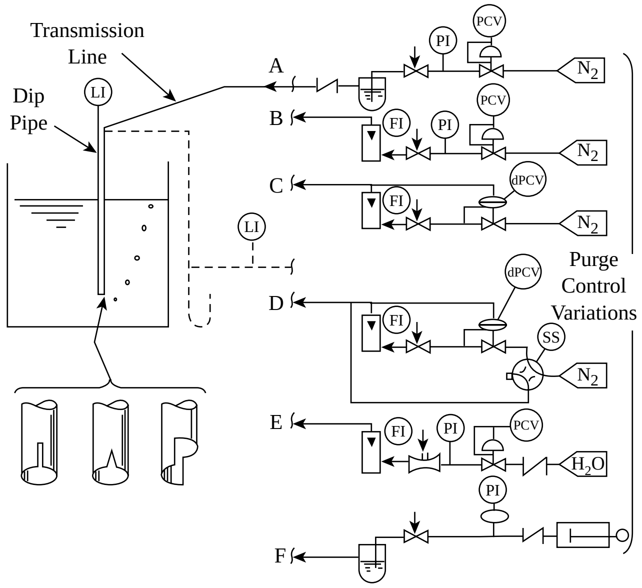

FIG. 3.2a
Variations of air bubblers for atmospheric tanks.

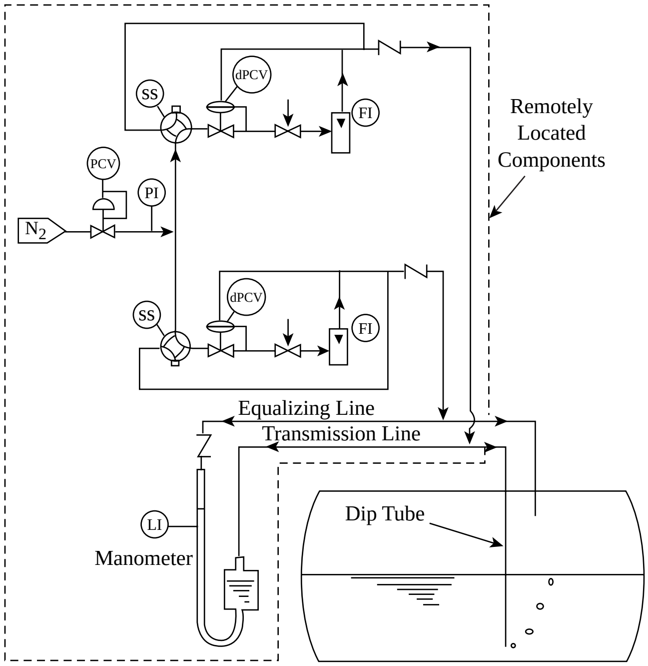

FIG. 3.2b
Air bubbler installation for pressurized tanks.

media is air or inert gas, although liquids can also be used. Several methods of gas purge controls are shown in Figure 3.2a to illustrate some of the installation considerations. In most traditional installations such as system A, nitrogen supply pressure is regulated to a value corresponding to a pressure that is higher than the hydrostatic head when the tank is full. The purge flow rate is adjusted by a needle valve and is sent through a sight feed bubbler, which allows visual inspection of the actual flow. This system allows for detection of levels up to 10 ft (3 m).

If higher levels are to be detected, system B, which uses a rotameter instead of a sight feed bubbler, can be considered, because a rotameter can withstand higher pressures. In systems A and B, as the liquid level varies, the downstream pressure also will vary, thereby causing variations in the purge flow rate.

Since the purge pressure at the readout device is the sum of hydrostatic head and the dynamic pressure drop in the dip tube, variations in purge flow will cause errors. To correct this condition, a differential-pressure control valve can be installed across the fixed restriction of the needle valve as shown in system C. This will cause the purge flow to be uniform regardless of the liquid head.

If the process material can build up or plug the dip tube, either as a result of loss of purge gas or because of the nature of the fluid, an aerator selector switch may be installed as shown on system D to allow for periodic blowing out of the transmission line. System E can be considered in remote locations where gas purge media is not available and a bubbler is desired instead of a liquid purge for level detection. Here, water is jetted across a gap while air is aspirated into the stream and compressed. The air–water mixture enters the dip tube, where the small amount of water runs down the inside of the bubbler tube while the pressure of the escaping air is detected as a measure of level. Such a setup would be in service only when the operator wanted to make a level reading, so the water would not flow into the vessel continuously. System F shows a more common approach for remote bubbler installations where a small hand pump is used to compress the purge air.

For tanks that operate under pressure or vacuum, the installation of a bubbler indicator becomes slightly more complex, because the liquid level measurement is a function of the difference between two bubbler pressures. Because of the differential measurement involved, the readout device can be a manometer or other type of differential-pressure detector. Figure 3.2b shows one of these installations. All of the previously discussed variations apply to both pressure and vacuum installations.

GENERAL

The bubbler detects the hydrostatic pressure in a vessel and displays it in a more convenient location. The pressure of an inert gas is used to transport the level information to this more convenient location. Bubbler-type level detection has been in use since compressed air became available. As illustrated in Figure 3.2c, after the air fills the dip pipe, its pressure inside the dip tube will equal the hydrostatic head of the process fluid outside the dip tube, and the excess air that is introduced will bubble out at the bottom of the tube.

If the tank is not open to the atmosphere, a second pressure tap is required to provide a reference pressure from the vapor space. The dip tube can enter from the top or side of

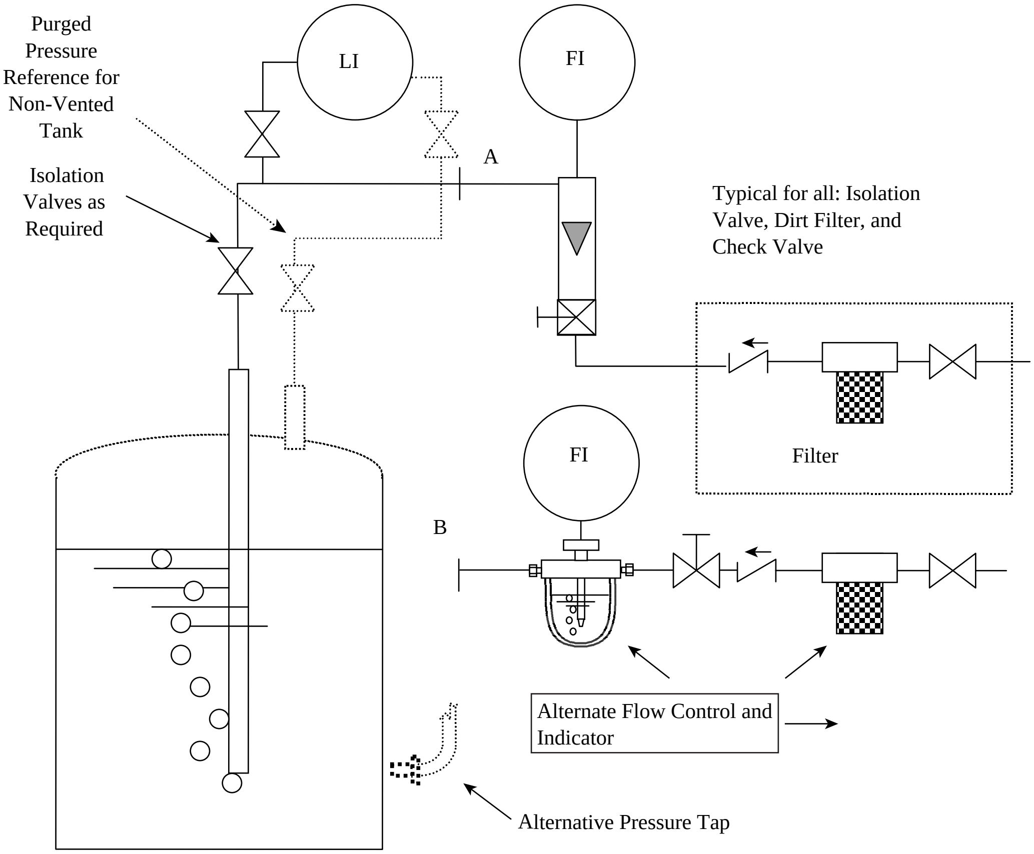

FIG. 3.2c
Bubbler-type level local indicator system.

the tank as long as it extends below the minimum level that is to be detected. As shown in Figure 3.2a, various combinations of valves, check valves, needle valves, and flow indicators may be required for various applications.

Of the bubbler design options, the *blow-back dip tube* is the simplest and usually the least expensive. Here, piping or tubing is provided to bring the purge gas pressure to the level display or transmitter. The bubbler, because of its simplicity, is inexpensive and robust while being easy to maintain or adopt to changing process conditions. The display portion of the system is not wetted by the process fluid and is in a convenient location. Calibration and replacement of the level readout or transmitting devices is also safe and convenient if, before service, the isolating valves (Figure 3.2c) are fully closed, and the standard safety precautions (see Chapter 7) are observed.

If a short dip tube is inserted horizontally in the side of the tank, the dip tube will be easier to access and support. Figure 3.2d illustrates that a tap can be provided for cleaning (*rodding out*) the accumulated deposits. In this design any plugging or dirt accumulation can be mechanically removed by inserting a rod into the dip tube. If it is desired to clean out the dip tube while the process is in operation (or if the tank is full or pressurized), packing glands are provided, and a “captive rod” is permanently installed to allow clearing the dip tube at any time.

Replaceable dip tubes, with or without packing glands, have also been used on the more difficult applications. Other options, such as dual or self-washing purges, will also be discussed later in this section. In addition, jacketed dip tubes are also available and have been successfully used in applications in which condensation or freezing is a concern (Figure 3.2e).

One of the advantages of the bubbler-type level measurement is that their readings are not affected (or affected only very slightly) by foam and by variations in pressure or composition of the vapor space above the liquid. These changes, particularly foaming, can interfere with many other types of level detectors, as was shown in Table 3.1b. On the other hand, process phenomena that change the density of the liquid (bubble formation, boiling) will result in “understating” the level, because a drop in density reduces the hydrostatic head.

Purge Gas

Air and nitrogen are the most commonly used purge gases. Other gases can also be used if, for some reason (such as their available maximum pressure being insufficient), these cannot be used. The measurement itself is as reliable as the availability of the purge gas supply. The flowing gas also

Side entering dip pipe (tube) installations.

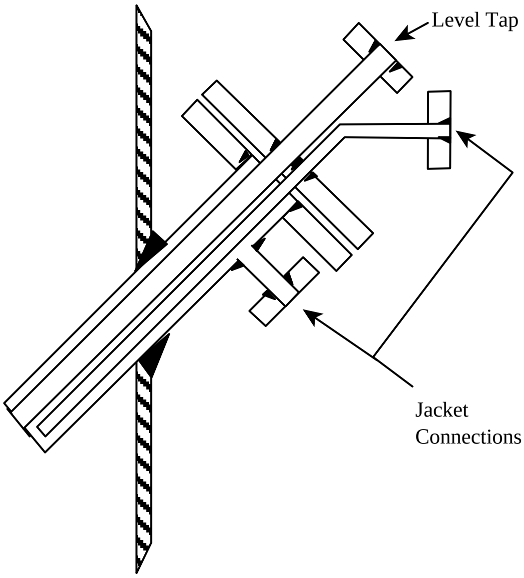

FIG. 3.2e
Jacketed dip pipe (tube) installation.

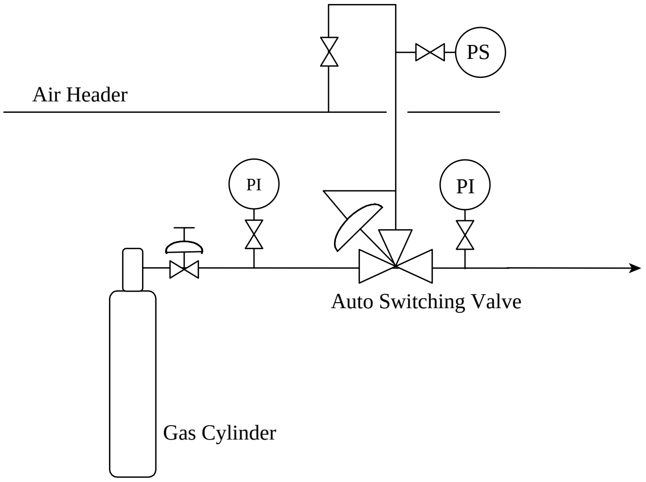

FIG. 3.2f
Purge gas supply system with automatic backup.

serves to keep the inside of the dip tube dry and clean. Proper functioning requires that the purge air or gas pressure be higher than the maximum process pressure plus the maximum friction drop anticipated within the dip tube. Reliability is improved with increasing supply pressures.

Some bubbler-type level packages include an air pump to generate the purge pressure and use a manometer to indicate the level. The danger here is that any loss of air due to air leakage or pump failure will result in a false low-level indication. Therefore, it is more reliable to supply the bubblers from the central air supply of the plant.

For critical applications, bottled gas, typically nitrogen, is used as a backup for the air supply. Pressure-operated pneumatic valves can provide automatic switching of the gas supply without electrical connections (Figure 3.2f). A low-pressure detector switch can also be used and in that case; its contact not only can switch to the backup gas supply, it can also initiate and alarm so that plant operators will be aware of the loss of air.

SIZING CALCULATIONS

The bubbler is fundamentally a mass or weight detector, because the pressure it senses is a function of both the liquid height and density. Therefore, the pressure of the purge gas reflects level only if the liquid density (composition and phase) is constant.

Bubbler applications include level control, inventory management, custody transfer, overflow protection, flow rate smoothing, and pump suction protection. For inventory control or for accounting purposes, the information desired is not the volume but the mass of the liquid. Chemical reactions are also based on mass, and even fuels that are sold to end users by volume (gasoline, fuel oil, natural gas) are often sold commercially by mass. As discussed in Section 3.18, they are sold by "standard" volume, and this apparent volume is corrected for density (or temperature) difference from the standard.

A narrow-range dip tube mounted near the top of a tank can provide accurate overflow protection because, over that small range, the density correction is insignificant.

Mass and Level

Level is inferred from the pressure (H) measured by the bubbler. Equation 3.2(1) shows how this hydrostatic head is calculated.

$$H = (h)(\rho)(G/G_c) \qquad \textbf{3.2(1)}$$

where

H = hydrostatic head
h = vertical depth
ρ = average fluid density over depth
G = local gravity
G_c = units conversion factor, not required with SI units

The total mass of liquid in the tank is obtained by Equation 3.2(2).

$$M = (H)(A) \qquad \textbf{3.2(2)}$$

where

H = hydrostatic head
A = cross-sectional area of vessel

The mass calculations must be corrected for any variations in cross-sectional area over the range of interest. The oil industry uses the term *strapping* to refer to the process of calibrating a tank. Internal devices, construction tolerances, and even the deformation of a large storage tank with level variations affect the accuracy of any level gauge. Actual test data is required for reliable measurement accuracy.

The prudent user will not calibrate the level measurement to 100% of the tank height but will allow for errors and for changes in density. If a tank is calibrated for 100% of full tank level for a heavy liquid of, say, specific gravity of 1.2, it will overflow if used on water with a specific gravity of 1.0. If the liquid cannot freely overflow, the hydrostatic pressure will build up inside the vessel and create a lifting force on the top while pushing the walls out. As a result, the side-to-bottom joints might fail.

The Hydrostatic Tank Gauge (HTG)

Density can be measured by detecting the pressure difference from two dip tubes immersed in the liquid, with their bottom ends vertically separated by a fixed distance "*h*" in Figure 3.2g. Where needed, a third pressure, the vapor-space pressure above the liquid, is also measured and can be used to determine the density of the liquid. If both level and density are known, one can determine the mass in the tank. All three values (volume, mass, and density) can be reported for different uses. Improved accuracy in pressure transmitters has made it possible to install hydrostatic tank gauges (HTG), which are illustrated in Figure 3.6e.

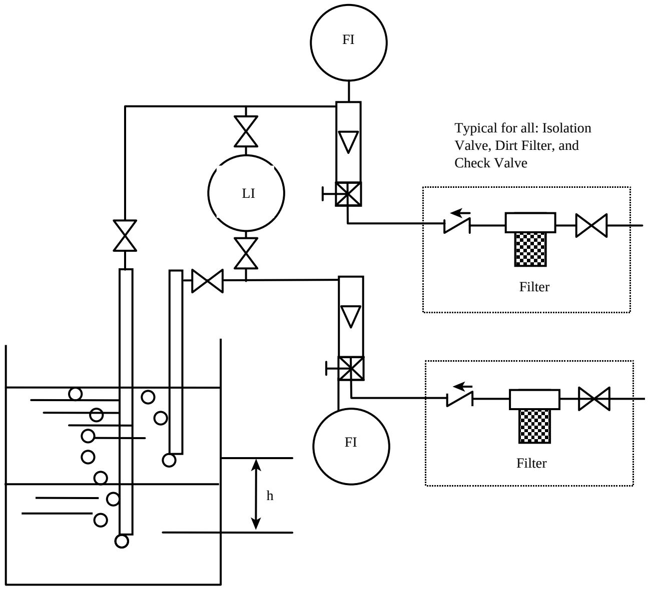

FIG. 3.2g
The measurement of density by bubblers.

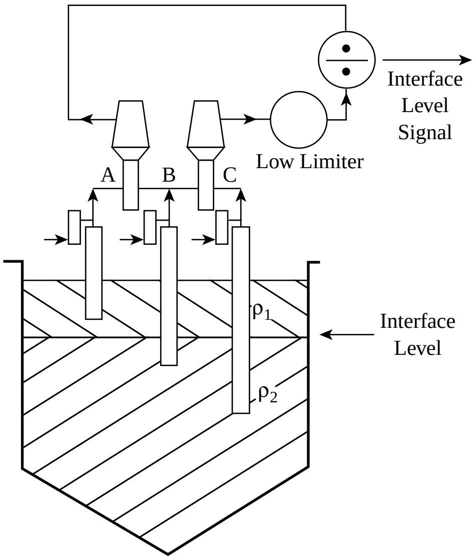

FIG. 3.2h
Density compensated interface detection with bubbler tubes.

If there are two immiscible (nonmixing) liquids, then the height of the interface above the more dense liquid may be inferred by the HTG. Note that the difference in pressures in the two tubes may be small and require a very accurate detector and a large suppression of zero. Note also that the interface measurement is affected by changes in density, which can be caused by changes in composition or density.

Density

As shown in Figure 3.6e, the differential pressure can also be a measure of density. Figure 3.2h shows how bubblers can also be used to correct the level for variations in density or to measure interface or other hydrostatic-head-related variables.

Calibration

The bubbler differential pressure can be calibrated in inches or millimeters of level or in regular pressure units, but it is absolutely vital to have good records of the units used and of all the conversion factors. For high precision at very high operating pressures, it might also be necessary to correct for the weight of the highly compressed gas column in the bubbler. Another factor to consider is the thermal expansion and contraction of the vessel and the dip tube caused by atmospheric or process temperature variations. In addition, pressure changes and gravity forces caused by level variations should be considered.

FLOW RATE AND PLUGGING CONSIDERATIONS

Minimum Purge Flow Rate

For accurate level signals and to keep the inside of the dip tube dry, it is necessary to provide a sufficient mass flow rate of purge gas to keep the dip tube full, even during a high rate of level or vessel pressure increase. These required rates can be calculated by first calculating the total volume of the tank corresponding to each inch of level change and, after that, determining the corresponding mass of air in this volume. The difference in this mass divided by the time for the pressure or level to change is the average mass flow rate required. A typical conservative value commonly used for atmospheric tank level detection is 0.5 SCFH, or 50% of full range on a 0 to 1 SCFH range rotameter.

Maximum Purge Flow Rate

The tubing must be large enough to keep the pressure drop between the air or gas supply regulator and the end of the dip tube at a negligible value. Most users specify a minimum of 3/8-in. (10-mm) OD tubing and, preferably, 1/2-in. (12-mm) OD tubing or piping should be used. To test the maximum flow limit of a bubbler installation, make a small change in purge flow rate and observe the effect. The level readout should not change as a result.

Most problems with excessive pressure drops are caused by damaged or deformed tubing or to partially closed valves. Sometimes, when excessive leakage from the system is noticed, maintenance technicians will respond by increasing the airflow sufficiently to keep the level detector in operation. The resulting problem is that the level signal then will vary not only with level but also with the purge flow rate. On high-vacuum processes, the low density, and therefore high specific volume of the purge gas, will cause high gas velocities and will also increase the probability of leakage.

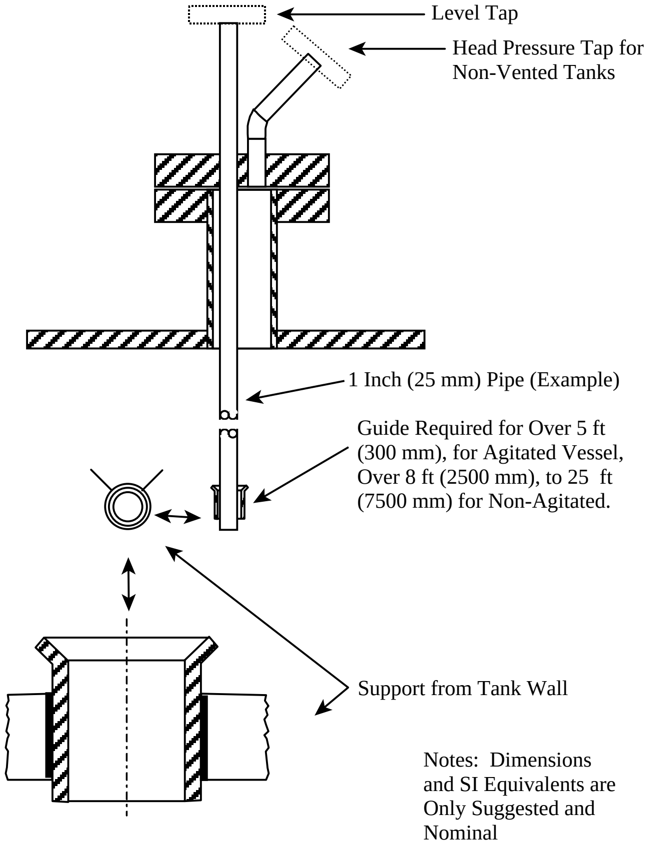
Dip Tube Diameter Selection

Dip tube sizing is determined both by the pressure drop through it, but mostly by the required mechanical strength of the system. Up to a length of 8 ft in un-agitated tanks (or 5 ft in agitated ones), the size of the dip tube should typically be 1 in. diameter, Schedule 40 pipe. Longer dip tubes must be supported (Figure 3.2i). In case of even longer dip tubes in agitated tanks, in addition to the guide support, a 2-in. (51-mm) pipe sheath is added as shown in Figure 3.2j.

Upsets and Plugging

The most common complaint about dip tubes is plugging, whereby the purge flow is lost or is inadequate. Under these conditions, the process liquids may rise up inside the dip tube and coat the walls. Over time, the coating will accumulate and restrict the flow of the purge gas. The beginning of plugging can be detected by slightly changing the purge flow rate and observing whether a change in level follows.

The probability of plugging in saturated salt solution services increases as the area of the tip of the dip tube is reduced. To unplug the dip pipe, we can apply “rodding out”



Notes: Dimensions and SI Equivalents are Only Suggested and Nominal

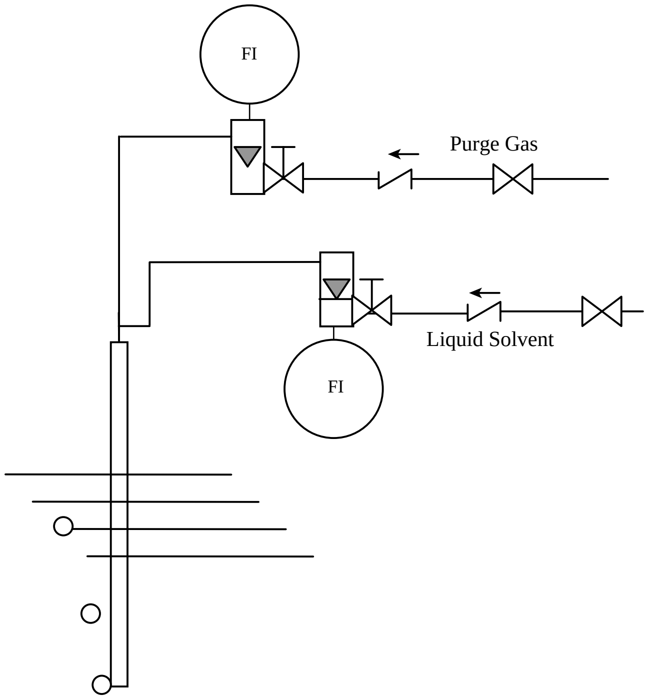

FIG. 3.2k
Alternate liquid purge can clean bubbler dip tubes.

using a twist drill that has been welded to a rod so that the end can be drilled clear. Special bubbler system designs can be used when the process liquid is a saturated salt solution and the salts are deposited inside the dip tube as the purge gas dries the solution. In saturated salt solution service, one can use water or a solvent to dissolve the deposits (Figure 3.2k). In viscous fluid services, solvents are used at flow rates of about 1 GPH to keep the dip tube clean. The solvent purge flow rate should be enough to maintain high humidity within the dip tube and to wash out any salts or solids.

When measuring the level of caustic, a common practice is to add a secondary purge of low-pressure steam, which is introduced very close to the point at which the dip tube enters the tank. The steam flow is restricted by an orifice union, typically bored for 0.125 in. (3 mm).

The theoretical design conditions in a plant can drastically differ from real-life and upset conditions. The prudent design engineer understands that, at one time or another, every instrument will be exposed to the pressure at which the system relief valve is set to open. On the other hand, the minimum pressure for a closed system is full vacuum. One should also consider the plant's safety in terms of the quality and availability of experienced personnel if, for example, the upset occurs at 3 A.M. on a weekend.

When a plant upset or system overhaul occurs, process equipment designed to operate at a high vacuum will be exposed to positive pressures as attempts are made to unplug piping or valves. As high-temperature processes are shut down, they might suddenly develop high vacuums, because their vapors cool and condense. Pumps, blowers, and other equipment are all cycled on and off because of stuck check valves or other system components. A power outage can also cause a loss of control and, on top of all that, human beings are not fully predictable, either. Some people, under an upset condition, will react with great confidence and do exactly the wrong thing.

INSTALLATION DETAILS

There are two fundamentally different approaches to the installation of bubblers, as illustrated in Figures 3.2l and 3.2m. Figure 3.2l illustrates a transmitter mounted on the top of the tank and therefore has a shorter purged tubing run. This makes the system less prone to plugging but also results in a less convenient access for maintenance. In Figure 3.2m, where the transmitter is mounted at ground level, the purged tubing runs are longer and more prone to plug, but access is more convenient.

The ground-mounted installation is usually provided with drip legs that, during upsets, can capture any liquid that might leave the tank. The drip legs can thereby protect the transmitter. In either case, the most important consideration is to maintain the adequate and reliable flow of purge gas. As was shown in Figure 3.2a, it is also advisable to prevent the blocking of the flow of purge gas when the dip pipe rests on the bottom of the tank. A simple solution is to cut the end at about a 45° angle to prevent blocking. On the other hand, this author has

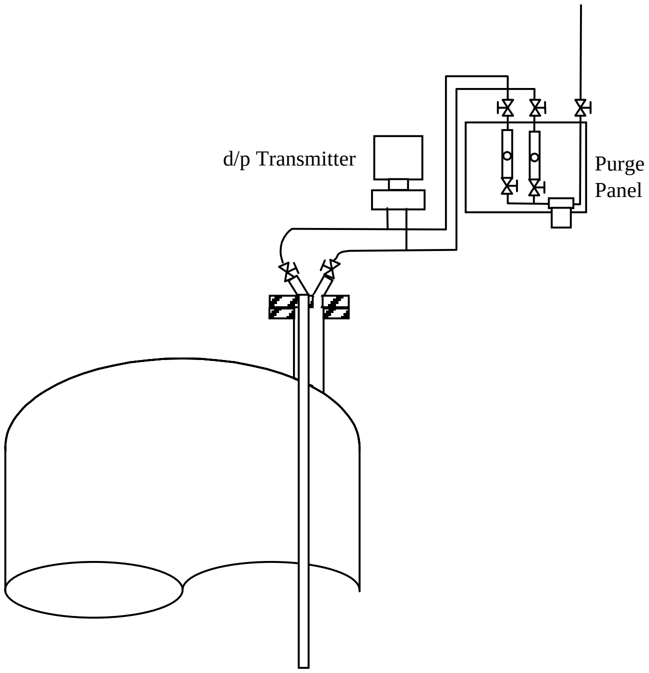

FIG. 3.2l
D/P transmitter mounted on the top of a tank.

not found that V-notches cut in the end of the tube will reduce the size of the bubbles or damp the small bump in pressure as each bubble escapes. This writer also believes that maintaining the purge flow rate at a constant value is not essential.

Pressure and/or Flow Regulators

Figure 3.2a shows a pressure regulator, but it is not necessarily true that a purge gas pressure regulator is necessary to stabilize the purge flow rate; some designs use only a flow rate regulator. For a properly designed system, the flow velocity in the tubing must be low enough that any reasonable change in flow will have practically no effect on the gas pressure at the tip of the dip pipe. If pressure changes with purge rate, then something is wrong with the installation, and the problem should be addressed.

The most likely cause is that the flow rate is restricted at the wrong place. It is apparent to this writer that reducing the purge gas pressure is not the preferred practice, because it increases the probability of the loss of purge flow. This can lead to plugging or to measurement errors.

The standard air supply regulator has a built-in overpressure vent to protect pneumatic instruments. However, in bubbler service, this vent allows the process to back into the dip tube if the process pressure exceeds the setpoint of the overpressure vent. Therefore, the "nonbleed" regulators should be used on bubbler installations, which will not vent and will therefore make the full air supply pressure available as the flow is reduced to nearly zero. Nonbleed regulators are available but are not always used, because of concern that they might be accidentally installed on other pneumatic instruments as instrument air supply regulators.

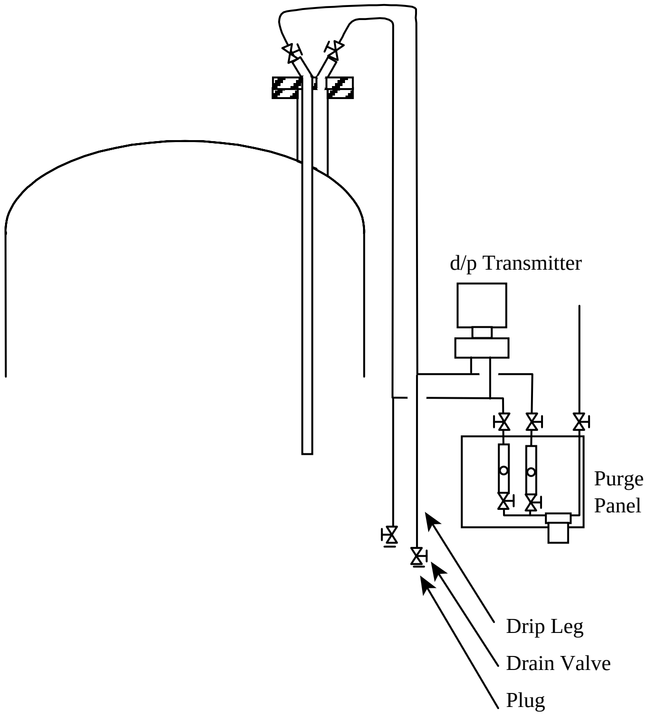

FIG. 3.2m
Ground-level mounted d/p transmitter installation.

The purge gas supply pressure is commonly far higher than the pressure in the dip tube, and the pressure drop across the flow-restricting needle valve is large. This results in a nearly constant purge flow rate, even if the pressure of the air supply or in the dip tube changes. Yet, the full supply pressure remains available if needed. This is similar to the constant-current concept used in some electronic circuits.

The only remaining reason for having a pressure regulator is to protect the pressure indicator, but, if there is no pressure regulator, no gauge is needed. A modern d/p-cell type of pressure transmitter will withstand the full instrument air supply pressure without damage. For the above reasons, it is this writer's view that the traditional installations shown in Figures 3.2a and 3.2b can be simplified by eliminating the pressure regulators and by making sure that all instruments and tubing components will withstand the maximum possible supply pressure.

DIAPHRAGM-TYPE DIP TUBE

For some applications where the normal dip tube is not acceptable, the "dry" dip tube or plug-proof dip tube is used, as described in connection with Figure 3.5d in Section 3.5. All that has been related here about purge supplies and sensors also applies to these installations except that a barrier is provided to prevent process liquids from backing up into the dip tube.

The diaphragm is not perfectly flexible and does offer same resistance, so a small offset will exist in the resulting signal pressure. There is a choice of diaphragm sizes, and the larger diaphragms will have smaller offsets, whereas the smaller diaphragms are less likely to fail.

SAMPLE CALCULATIONS

Level Detector Calibration Example

If one is to calibrate the range of the level detector (r) in inches of water column ("WC) for a 25-ft-high tank containing a liquid of 0.85 specific gravity (SG), which corresponds to 62.4 lb/ft^3 or 999.8 kg/m^3, and it was decided that the tank will be considered full at 80% of tank level.

$$\text{Range } (r) = 25 \times 12 \times 0.8 \times 0.85 = 204 \text{ "}WC \text{ (5182 mm } WC) \tag{3.2(3)}$$

If the same level detector range is to read in units of PSI,

$$\text{Range } (r) = (25 \times 0.8 \times 0.85 \times 62.4)/144 = 7.36 \text{ PSI} \tag{3.2(4)}$$

If a tank contains oil (SG = 0.8) and water (SG = 1.0) and we want to detect the movement of the interface in inches of WC over a range of 10 in.,

$$\text{Range } (r) = (1.0 - 0.8)\, 10 = 2.0 \text{ "}WC \text{ (50.8 mm } WC) \tag{3.2(5)}$$

Density Detector Calibration Example

If one is to detect the average density of a 10" layer of liquid in a tank by measuring the differential pressure across that layer, which can contain any mixture of oil (SG = 0.8, density = 49.92 lbm/ft^3) and water (SG = 1.0, density = 62.4 lbm/ft^3), the d/p cell range is:

$$\text{Range } (r) = 10\,(1.0 - 0.8) = 2 \text{ "}WC = 50.8 \text{ mm } WC$$
$$= 49.92 - 62.4 \text{ lbm/ft}^3 \tag{3.2(6)}$$

CONCLUSION

The bubbler remains a valuable tool in level measurement due to its low cost, simplicity, and flexibility. It is also valuable as an inexpensive and easily installed backup overflow protector. For some specialized measurements, such as interface detection between oil and water, the capacitance gauge is more popular because of its higher sensitivity and better performance.

When designing a difficult level-measurement system, a prudent design engineer might do well to specify spare nozzles for installing a bubbler as a backup on a vessel if more modern level sensors could fail to work properly. Successful bubbler applications include polymers, tars, salts, and other difficult fluids. Failures resulting from dirt and plugging can be simpler to live with using a bubbler than with floats or other devices that have moving parts. The advantages of the HTG system (Figure 3.6e) can also be realized with the dip-tube type of bubbler detectors.

There has been some environmental concern that, with a bubbler, the purge gas that enters the tank also has to be removed, but these purges are a very small portion of the total gas and vapor flow that must be removed anyway. For example, in the case of large storage tanks, the gas displaced during each cycle of emptying and filling is usually more than the volume of the gas used for purging at 1 SCFH for a week.

The main advantage of air bubbler systems is their simplicity and the ease with which the readout device can be relocated to just about any convenient location. For remote tank farms where compressed air is not available, one of the simplest methods of level detection is to use a small hand pump and a gauge. Bubblers are widely used in the wastewater and food industries and in some bulk storage applications, but they have lost some of their earlier popularity in the processing industries, where the trend seems to be favoring nonflowing, solid-state electronic devices.

Flow Sheet Symbol

Service	Point level control (using contact and proximity sensors) and continuous level transmission for liquids, granular solids, and liquid–liquid interface
Design Pressure	Routinely to 1000 PSI (7 MPa), others to 5000 PSI (35 MPa), specialized applications to 20,000 PSI (140 MPa)
Design Temperature	500°F (260°C) maximum with insulated sensors; 1000°F (540°C) bare metal, sealed to 200 PSI (30 kPa); 2000°F (1100°C) bare metal at atmospheric pressure
Excitation	Less than 10 V @ 10 kHz to 1 MHz
Wetted Materials	Type 316 SS and TFE for common models, with options for CPVC, FEP, PE, PEEK, PFA, PP, PVDF, urethane, Hastelloy®, Inconel®, Monel®, nickel, titanium
Span	2 to 3 in. (50 to 75 mm) of insulating liquid to 1000 ft. (300 m) for immersion probes and 0.1 in. (2.5 mm) to 10 in. (250 mm) with proximity sensors
Inaccuracy	Horizontal, less than the diameter of the probe rod Vertical, less than 0.1 in. (2.5 mm) for bare single points in conducting material, roughly 1% of maximum active length for *all* insulated probes in conducting or interface service, 3% in insulating liquids (or 0.5% with dielectric compensation), roughly 5% for granular insulating solids with constant density and composition, and 2 to 5% for conducting granular solids
Dead Band	Unmeasurable with analog instruments and horizontal probes; dependent on A/D resolution with digital continuous instruments; small and application dependent on vertical single points, but optional dead band adjustment is available
Temperature Coefficient	Extremely variable depending on (a) probe insulation and degree of probe-to-sheath bonding in conducting materials, and (b) composition and density variation in insulating liquids
Damping and Time Delay	Adjustable time delay of 0 to 30 sec is included on most single-point controls; adjustable time constants up to 30 sec are available on most analog transmitters, and digital instruments offer zero to several minutes
Cost	$200 to $800 for single-point controls; $500 to 1500 for two-wire level transmitters; all with type 316 SS and TFE wetted parts; increased cost with exotic metals, hermetic seals, flange mounting, longer insertion length, digital output, dielectric compensation, extended press and temp, and longer inactives

INTRODUCTION

Characteristic of probe-type sensors, the RF probes operate by applying a constant voltage to a metallic rod and monitoring the current that flows. This current is proportional to the admittance or capacitance (if conductivity is absent) from the metallic rod to a second electrode. Because the tank wall is the most convenient second electrode, most instruments monitor current to ground (which is usually connected through the probe mounting). The obvious difference between conductance and RF probes is the frequency of that constant voltage. Whereas conductance types use DC or low-frequency AC, the RF items usually operate in the range of 0.1 to 1.0 MHz (although special applications can operate at 15 kHz or even lower frequencies). RF probes are connected to their associated electronic units with coaxial cable except when the electronics are integrally mounted on the head of the probe.

The classic shortcoming of capacitance probes is false HI level indications caused by conductive coatings that connect the above-level sensing element to ground (or the actual process level). Since 1970, solutions to this problem have existed in all but the heaviest, high-conductance process situations. In the case of single-point level switches, the answer is electrogeometric. In the continuous level transmitters, the approach is purely electrical.

Because of the solid, no-moving-parts construction, there is very little to deteriorate or fail once an RF probe is installed. Compatibility with process liquids is the most obvious obstacle to a satisfactory life span. This is no problem with common, well-documented reagents at temperatures below 150°F (65°C). At higher temperatures, the increased chemical activity and accelerated permeation experienced by polymers can produce unexpected results. Abrasion of metals and insulators is another cause of shortened life that must be anticipated. Baffles to protect the sensor from high-velocity solids, combined with judicious location, can minimize this danger.

Probe failure in heavily agitated tanks can be avoided by attention to structural considerations. In the case of rigid probes, the most likely cause of breakage is fatigue failure caused by eddies rapidly pushing the probe in one direction and then in the opposite. A support, with an insulated bushing, near the tip of the probe greatly reduces the possibility of such a failure. Flexible cable types can wrap around an agitator and fail in minutes if not adequately anchored to the tank structure. If they are anchored without removing slack, they can whip back and forth, causing insulation failure and eventual breakage. Intermediate supports are possible in highly agitated service using insulated bushings. Beware of thick, conductive coatings that can cause substantial errors at each support point. These “shortcuts” to ground can defeat the electrical coating rejection in the worst cases. Correct structural design is the responsibility of the system designer, not the probe supplier. Most suppliers can give rules of thumb for their probes and provide structural details of the construction. It may require a consultant who is skilled in fluid dynamics and mechanics to arrive at a sure configuration in a highly agitated vessel.

Process instruments that depend on electrical characteristics of the process material are at a disadvantage, given that the electrical character is of little interest to most instrument users. Fortunately, exact values of conductivity (g) are never required, and *changes* in relative dielectric constant (K) are more important than the precise value. In most cases, classification as *conducting* or *insulating* goes a long way toward successful application. Within the conducting category, it is sufficient to know that, except for completely deionized water, aqueous solutions *will* be conductive. On the insulating side, it is generally sufficient to understand that most liquids will have a K of 2 or greater. The main exceptions are liquids that would be gases at room temperature (with the notable except for ammonia, for which $K > 15$) and atmospheric pressure. Not only do these fluids tend to have K less than 2, they tend to have much higher temperature coefficients of K than insulators that are normally liquids.

This section is divided into single-point and continuous transmitter categories to reduce confusion. The RF sensors are somewhat unique in that single-point switches have a substantial *performance* advantage over the continuous type in terms of accuracy, temperature capability, coating rejection, self-checking, and reliability. It seems that, in many cases, the transmitters are thought to be the superior approach to control, and they obviously are necessary to obtain a proportional band. In many cases, strategically placed single-point units are a superior route to precise and reliable process control. Considering that *any* instrument can fail on occasion, single-point probes provide highly reliable backup, with self-test capability, and are superior to any transmitter.

TYPES OF PROBES

The most basic probe configuration is a metal rod. The rod is insulated from a metal mounting element that connects it to the process vessel via threads into a half coupling or a flange that mates with one on a tank nozzle. The insulated junction of rod and mounting includes whatever seal is required between the process and outside world. The next step in complexity includes an insulating coating on the rod, (Figure 3.3a) that isolates it chemically as well as electrically from the process. Insulated probes should have the insulation securely bonded to the metal rod over the entire range of service temperature. This bonding ensures that process pressure changes will not compress air space and change the calibration. Bonding is also important to minimize permeation, which is present to some slight degree with *all* polymers. The addition of a tight-fitting metal tube over part of the insulation, welded to the mounting element (Figure 3.3b), will make the covered section of the probe "inactive," because it will always see the same impedance to ground, regardless of the process material on the outside. A more sophisticated way to "inactivate" a section of the probe is to use the widely known *electronic guard* principal. A tight-fitting metal tube, insulated both from the rod and the mounting element (Figure 3.3c), with a voltage identical to that on the rod, will not only deactivate that section of the probe but will also negate the rod to mounting capacitance. These are sometimes referred to as *three-terminal* probes, because there is now a rod connection, a ground connection, and a guard (sometimes called a *shield*) connection, as opposed to the *two-terminal* rod and ground style connections. An additional variation is the probe that carries its own intrinsic ground reference. This can be a larger concentric tube welded to the mounting element (Figure 3.3d), with bleed holes at the top to avoid compressing gas as the liquid rises in a closed chamber. Perforated tubes, insulated and bare ground rods, as well as structural cages (Figure 3.3e) are also available for various conditions of agitation, temperature, and chemical compatibility. The sensors, which use a ground wire wrapped in a helix directly on the probe insulation, are unstable, unreliable, and facilitate coating.

A three-terminal probe, with a plate welded on for greater capacitance (Figure 3.3f), makes an excellent proximity sensor. The field from the guard can even be used to direct or focus the field from the sensing element and determine the region of sensitivity. In proximity measurements, the

capacitance change (proportional to sensor area) is typically very small but stable, because it is effectively looking at the air capacitance between sensor and process material. Even minute capacitance changes due to temperature or stress in the mounting area could be catastrophic with an unguarded probe. The distance between the probe and process material should be as short as feasible. The capacitance produced is inversely proportional to this distance. This means that beyond 10 in. (250 mm), the capacitance change becomes extremely hard to detect. The error produced by splashing and condensation buildup on the plate is fairly benign—never more than the actual coating thickness, and usually less. Spans of 2 or 3 picofarads (pF) have been used successfully. Such small ranges are the result of level change in shallow pans, with limited space for proximity plates.

The electronic guard principle can be employed in an infinite variety of geometries. A typical example is the flat plate probe (Figure 3.3g), which mounts flush with the tank wall. This is very effective in reducing abrasion, eliminating bending of low-level sensors under heavy mechanical loads, and eliminating sparks from static discharge. The monitored current flows from the center plate, and the guard surrounds

it, interrupting a path to ground through any coating on the face of the probe.

For the ultimate in seal reliability and hermeticity, plastic welding offers unique benefits. By plastic welding a polymer flange facing to the probe insulation (Figure 3.3h), a high-pressure seal is formed (and has been used to 5000 PSI [35 MPa] with the correct flange rating), with the normal process seal acting as a backup. This type of weld is not possible using TFE, which does not melt, but most other polymers are candidates. It also precludes the use of thin probe insulation. The flange facing should be used as the only gasket, because it must be pinched between the flange faces. Only raised face flanges provide the correct sealing, so RTJ and flat-faced flanges are not applicable.

MOUNTING AND TANK ENTRY

One of the most frustrating barriers to good RF probe application is inadequate or misplaced tank access on existing tanks. Often, adding a nozzle or even a half-coupling is impossible, because the tank is pressure coded, requires arduous inerting, or cannot be taken out of service. One very simple-minded and geometrically demanding approach is to use a bent probe inserted through a side entry so as to get its active area to the desired measurement location. A flange mounting is usually mandatory to avoid “screwing,” which would cause the bent probe to rotate inside the tank like an airplane propeller. Its angular location, once the thread is tightened, would also be a question. If a suitable nozzle is available, it must be short enough to get the bend in the probe “around the corner” before it binds. If the measuring leg of the probe is relatively long, it must not hit the opposite wall of the vessel before the bend allows it to pivot. Another drawback to the bent probe is the requirement that any insulation be flexible enough to tolerate the bending process without tearing or splitting. This limits the selection to soft, thick insulation and therefore relatively low capacitance (60 to 100 pF/ft).

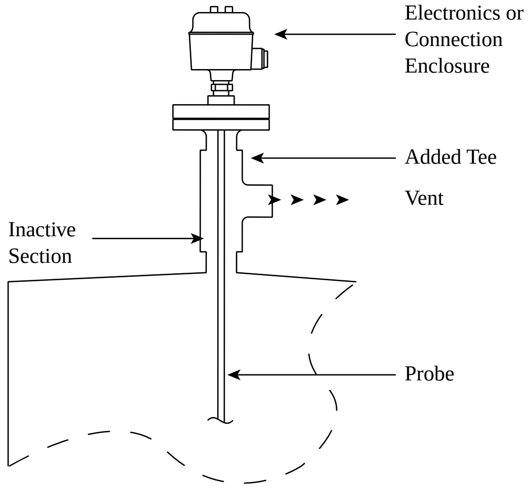

FIG. 3.3i
Vent pipe serving dual function for tank access.

Many strategies allow us to avoid the bent-probe trap by using a little bit of imagination. Every tank or bin should have a vent or pressure relief pipe. It is usually possible to tee that pipe so that the vent or relief goes off to the side and a probe has straight access into the process (Figure 3.3i). This does not affect the pressure code of the vessel, since it is external plumbing. Other ways to avoid the “pretzel probe” include the following:

- Angle mount a straight probe from the side.
- Install the probe from the bottom up.
- Use a grounded inactive section to get through various impediments.
- “Dog-leg” a pressure gauge to give the probe a straight shot.
- Cut a hole in the building’s roof or ceiling in lieu of headroom.

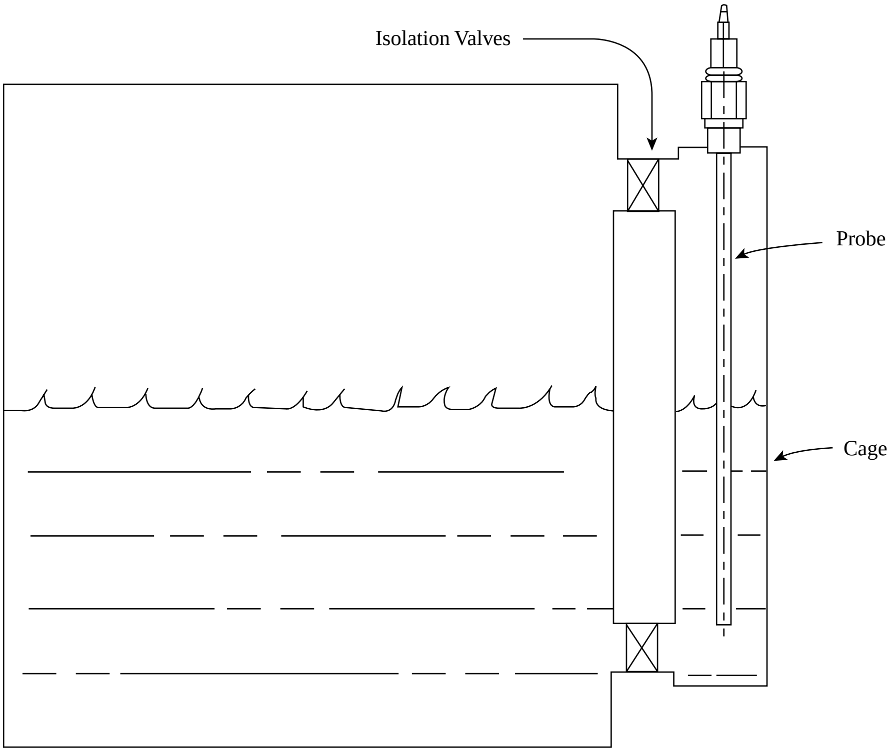

FIG. 3.3j
Side arm (cage) mounting, when there's no other way. (Courtesy of Robertshaw Controls Co.)

- Use "rear mount" piping to plumb through a dust collector or a side of the tank.
- Add a stand pipe (sidearm) parallel to the tank (Figure 3.3j).
- Tee into a fill pipe (this needs detailed application analysis).

Ingenuity will always trump bent probes for performance, cost, and efficiency.

ELECTRONIC UNITS

Electronic units for single-point instruments are available in line-powered configurations for 24 VDC; 120 V, 50 to 60 Hz AC; and 230 V, 50 to 60 Hz AC. They also can be obtained with "universal power" capability that allows them to use any of these plus 130 VDC. The output from these units is generally a set of double-pole, double-throw relay contacts. Some of the DC-powered instruments use an NPN or PNP output transistor to effect the switching. There are also two-wire, loop-powered versions that offer intrinsic safety and automatic self-checking. The signal from these instruments is a high or low current within the 4- to 20-mA range. Various types of automatic calibration are available for these instruments, but they all encounter certain conditions that prevent them from being calibrated properly under every possible condition. Regardless, the calibration of single-point instruments is hardly rocket science.

Level transmitters are primarily loop powered, although line-powered items are available from some suppliers. The traditional analog 4- to 20-mA instruments have been giving way to those with microprocessors on board. Most of the digital instruments are capable of communication using one of the HART, Honeywell, or fieldbus protocols. This allows interrogation and modification of the instrument by means of a digital communicator. One of the most popular features of these instruments is their ability to calibrate on any two points in the range. It is possible to enter the correct output (in milliamps or level units) at an existing low level and enter a high point days later. The instrument locks the input/output curve into those two points. The signal from the instrument is either analog 4- to 20-mA or digital. The digital mode allows more than one transmitter to use a single loop. The limited power available at the transmitter, combined with the multitude of calculations being executed, causes digital instruments to be considerably slower than the analog ones. Response times of 3 to 4 sec are possible, whereas analog instruments are capable of responses within 100 to 300 ms. For small tanks with high fill and drain rates, the digital instruments might not be an option.

A hybrid instrument is the "multipoint" control. It is essentially an analog instrument with internal, adjustable pick-offs and multiple relay outputs. It is useful for sump control where several pumps might be involved, but the absence of an analog output makes calibration lengthy. Each pick-off must be adjusted with the level at the desired point on the probe. This type of instrument is specified for HI, HI-HI, and HI-HI-HI points at times. This doesn't make much sense, because one failure kills the whole operation.

SINGLE-POINT SWITCHES

The typical capacitance switch employs a vertical or horizontal probe, either polymer insulated or bare metal, projecting some distance into the process vessel with the center rod insulated from the mounting (Figure 3.3k). With any gas or vacuum ($K = 1.0$) on the probe, there will be a minute RF current flowing from the center rod to the metallic tank wall. When a liquid or granular solid covers the center rod, the current from there to ground will increase. This change in current is detected by the electronic unit, which switches the output. When the process material drops below the probe, the RF current decreases and, hopefully, returns to its previous low-level state. If the process material is thick and conductive, any coating remaining on the insulator between probe and mounting will maintain a higher RF current level and can cause the switch to continue signaling a high level.

The answer to false high-level indications is based on the classic *electronic guard* principle. By interposing a third metallic element (shield) with an identical RF voltage between the center rod and the mounting (Figure 3.3c), no current can flow from center rod to mounting. The shield element supplies whatever RF current the coating demands, but this current is not included in the measurement. "Length is strength" in capacitance probes. Longer active lengths translate to more substantial capacitance changes in insulating processes, and longer interelement insulators allow the instrument to reject higher conductance coatings. This means using horizontal probes for switch points close to the bottom and top of a tank rather than a vertical 2 or 3 in. (50 or 75 mm).

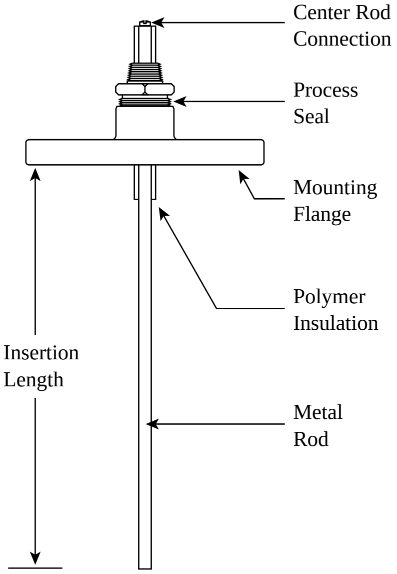

FIG. 3.3k
Bare metal, two-terminal probe.

Conducting Process Materials

Conducting materials (aqueous, metals, and most forms of carbon) carry the ground potential of the tank walls right to the probe. If bare metal, the probe will signal "high level" the instant it contacts the process. If it is insulated, the switching point will depend on the capacitance setting of the instrument. With a vertical, insulated probe, it is possible to adjust the level at which the switching takes place by varying the capacitance setting of the instrument. A horizontal probe of either type allows no level adjustment other than by relocating the mounting.

Coating is a serious consideration in all conducting materials, and the guard-type construction is usually required. With bare metallic probes mounted vertically, the plain capacitance probe will do as long as the process never reaches the mounting area and no crystallization or heavy condensation occurs. When using the guarded probes, the guard should be long enough to project well into the vessel, beyond nozzles and potential wall buildup.

Insulating Process Materials

The insulating materials (oils, solvents, resins) are subtler in their effect on the switching circuit. A horizontal probe produces a sharp capacitance change over the thickness of the center rod. Any portion that is in a nozzle should be inactive, either with the guard or a grounded inactive. With a vertical probe, capacitance increases gradually as more of the active length is covered. The switching point is adjustable even if the probe is bare metal. Good practice requires that the probe be at least 2 in. (50 mm) into the process material at the desired switching point. Attempting to get switching at the tip of the probe will lead to unreliable performance, because the slightest change in probe mounting or electronics can cause a constant high-level signal.

Dielectric constant (K) is relative to the absolute dielectric of a vacuum (K of gases barely differs). This means that the capacitance (and the proportional RF current) in air will be doubled in gasoline ($K = 2$). It will be multiplied by 20 in ethanol ($K = 20$). It will only be raised by 60% in liquid carbon dioxide ($K = 1.6$). Insulating coatings are a very minor problem. Just avoid bridging to a grounded part.

Plastic, Concrete, or Fiberglass Tanks and Lined Metal

The absence of metallic contact for a ground reference is seldom a problem using single-point RF probes in conducting process media. The probe will indicate high level whenever it touches the process. Unlike metallic tanks (or those with metal pipes, pumps, or grounding rods), it must be tuned to a value less than the capacitance-to-ground value of the tank. Most tanks have at least 10 pF to ground, which is a perfectly adequate level for a reliable measurement. Probes with a guard element should not be mounted horizontally in ungrounded tanks with conductive contents. The guard can drive the entire process at the same voltage as the center rod, hence there is no current flow and no high-level signal.

In the case of an insulating medium in a fiberglass tank, even metal pipes offer little help to the miniscule capacitances. The only sure answer is a vertically mounted probe with its own metal ground rods or concentric tube. This is also a good precaution against RFI from walkie-talkies and other sources, which can cause false high-level signals.

Metal tanks that are rubber or plastic lined and steel-reinforced concrete vessels, on the other hand, represent excellent RF grounds. The capacitance from process to metal structure is very high as compared with the capacitance produced by an insulating medium. This makes it look like a short circuit to the RF current. It is excellent for conducting media, too, but it still requires the avoidance of horizontal probes with driven guards. Underground concrete or fiberglass tanks (except in desert conditions) present a similar ground configuration.

Concrete structures of cinder block with no vertical steel reinforcing bars are completely ungrounded and perform exactly the same as fiberglass tanks.

Interface

Electrical sensing is the premier method of detecting the interface between an insulating and a conducting process medium. The typical margin between the conductivity of organic and aqueous phases is greater than 1000:1. The measurement is completely independent of temperature and density variation. Probes may be mounted vertically or horizontally. Vertical probes should be inactive down to about 6 in. above the desired interface control point. This can be accomplished by use of the electronic guard, a grounded inactive, or a short probe mounted from the rear (*rear mount*) on the end of a suitable pipe. The instrument will indicate high level as soon as conductive material contacts the tip of the bare probe. In the case of heavy oil separators, it may be desirable to use a probe with sharp edges machined into the tip (Figure 3.3l). This will ensure good contact between water and steel in spite of oil coating. An interface detector with bare metal rod should be tuned to the maximum capacitance level of which it is capable.

Horizontal probes should be bare metal with relatively long insulators between probe and mounting (ground). Typical proportions, to maximize the margin between insulating and conducting phases, would be 12 in. (300 mm) overall length with a 10-in. (250-mm) long insulator. The use of sharp edges machined on the tip of the probe is also advantageous in this orientation. This is one situation in which the electrical guard is of no advantage (coatings are usually insulating rather than conducting) and can actually be a drawback if the guard drives the entire conducting phase at the same potential as the probe. This phenomenon is usually a product of insufficient grounding, but it has been observed in metal tanks.

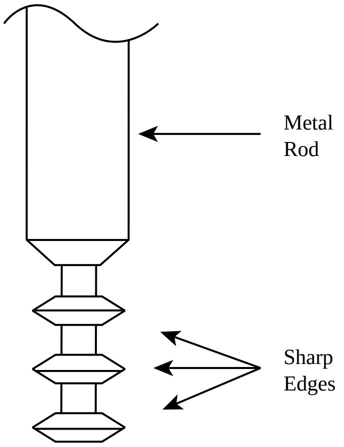

FIG. 3.3l
Oil shedding tip for interface with viscous organic phase.

GRANULAR SOLIDS

The best approach for establishing the high level in large silos is usually via a flexible cable probe with a long, thin weight at the bottom. It can be mounted close to the fill point (Figure 3.3m) and negate most of the angle of repose that side-mounted sensors encounter. The flexible aspect allows it to swing out of the way when struck by incoming solids. The actual switching should take place on the weight that will be least vulnerable to abrasion. In insulating materials, at least 6 in. of weight should be covered at the desired switching point. Conducting materials, of course, will switch as soon as they touch the tip of the probe. Incoming material will not cause false high-level indication as long as it is in free fall. This is because there is a very small air capacitor between each grain and all the others. All this series air capacitance means that any deviation from normal air capacitance is a negligible quantity. If the incoming material is compressed (especially conducting materials), it *is* possible that it could cause a trip, so the probe should be located accordingly. Rigid probes, located near the fill, are suitable for smaller bins and lighter duty.

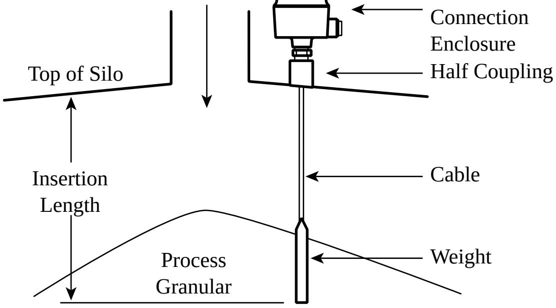

FIG. 3.3m
High-level probe for heavy granulars in large silos.

Horizontal probes mounted in the bin wall should be of the "guarded" variety to avoid false high-level alarms—especially for low-level service. The primary concern is bending or abrasion, which becomes more acute as the depth and density of the material increases. Short, fat probes have much better lifespan, and it is possible to use a flat-plate probe (Figure 3.3g) mounted flush with the wall for optimal life.

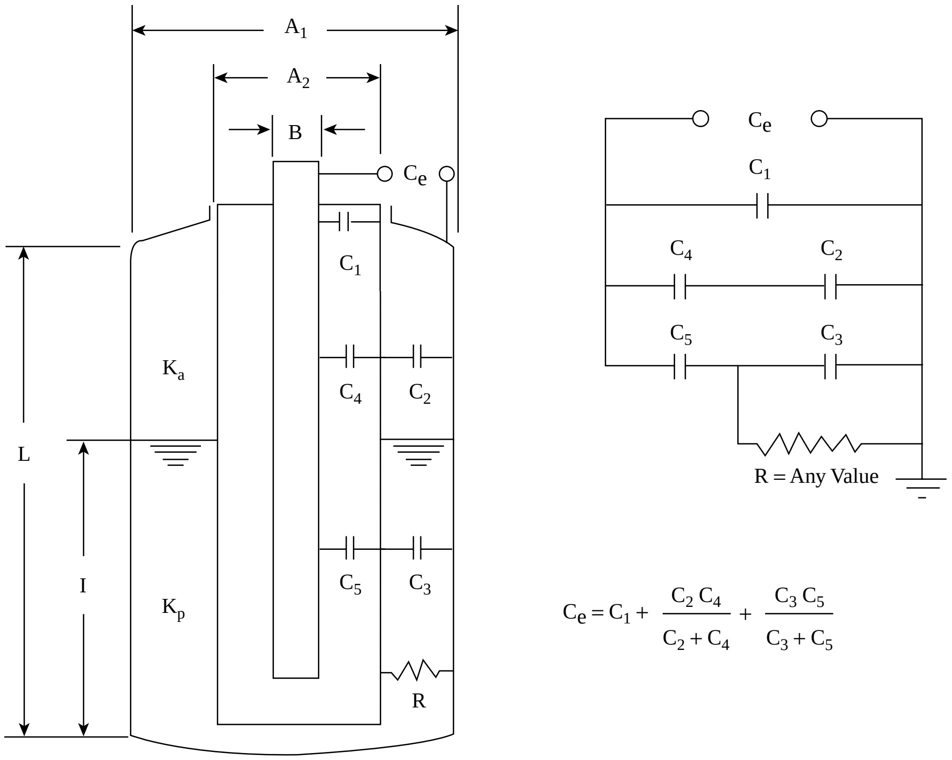
CONTINUOUS TRANSMITTERS

Probes are most commonly mounted vertically from the top of the tank. Angle mounting through the side of a tank is possible, as is mounting up from the bottom. When tank penetrations are at a premium, it is often possible to "tee" into a vent or drain line for probe mounting. There are even cases in which probes have been successfully "teed" into fill nozzles, but this requires considerable application analysis to predict the effect of incoming material. The insertion length of the probe should not extend beyond the desired measuring range by more than 5%. An active probe that is not producing signal can still produce errors.

Conducting Liquids

The main concept required to understand this class of applications is called *saturation*. Assume that an insulated probe is immersed in deionized water with minimal conductivity (Figure 3.3n). The addition of drops of hydrochloric acid to the vessel will gradually increase the conductivity. The output will also rise as more RF current flows from probe to ground. Eventually, the conductivity will be high enough that the resistance (R) from probe to tank wall is negligible compared to the capacitive impedance of the probe insulation (C_5). Further increases in conductivity will make no observable difference in the RF current and, therefore, the output (i.e., the RF current has reached its *saturation point*). This is the concept that makes the RF transmitter an instrument rather than a lab curiosity. A probe that is not saturated will have a calibration that is a function of two variables (conductivity and level), just as a d/p transmitter calibration is a function of density and level. It is possible to adjust the threshold of saturation by adjusting insulation thickness (hence capacitance) and excitation frequency. Raising the impedance of the insulation lowers the threshold, and vice versa. Saturation thresholds from 0.1 to 1000 μS/cm can be accomplished. A reasonable question might be, "Why not just use the 0.1 μS/cm threshold at all times?" The answer is "coating rejection."

The higher impedance that correlates with a low saturation threshold is less able to ignore high-conductivity coatings. In fact, a large mismatch may allow the coating to saturate the probe so that the output reflects the actual level plus coating length. In general, the path to best conducting coating rejection lies in the highest probe capacitance and excitation frequency that will allow saturation by the process material



$$C_e = C_1 + \frac{C_2\,C_4}{C_2 + C_4} + \frac{C_3\,C_5}{C_3 + C_5}$$

FIG. 3.3n
Electrical representation of an insulated probe in conductive liquid. (Courtesy of The Foxboro Co.)

being measured. A special case for coating rejection is one in which the process liquid is conductive but can dry on the probe, forming an impervious, insulating coating. An example is latex paint. The liquid is quite conductive, but the dried paint adds to the insulation thickness of the probe, decreasing its capacitance and changing the calibration. The solution is to use a thick (low-capacitance) probe insulation so that thin additions will have negligible effect on calibration. By using the highest possible frequency, conductive coating rejection will also be maximized, and the resulting accuracy will be the best possible compromise.

Complex impedance (or its inverse, *admittance*) measurement allows the electronic unit to measure two variables: the capacitive component of RF current and the resistive component of RF current. The actual liquid level that saturates the probe produces a pure capacitive current. The conductive coating, because it is relatively thin, has a much higher resistance than the bulk liquid, so it will produce both capacitive and resistive phase current. By subtracting the resistive component from the capacitive, the effect of conductive coating on the output will be decreased. In fact, once the coating is longer than a nominal value, the two RF current phases equate, and the effect of coating is precisely zero. Maximum coating error occurs when the coating length is relatively short and its resistance therefore is low. The maximum error is a fixed, predictable number of inches for a given probe capacitance, excitation frequency, coating thickness, and conductivity. This means that percent inaccuracy due to coating will be greater on short ranges than on long ones. In other words, *length is strength*.

Insulating Liquids

Probes for measuring insulating liquids should generally include their own parallel ground reference to guarantee a uniform distance to ground through the process liquid. Linearity, sensitivity, and immunity to RFI are enhanced by a concentric ground tube (Figure 3.3d) or other construction. In some cases, it is efficacious to use a metallic tank wall, baffle, or ladder to furnish the required parallel ground reference. This is frequently the case in pharmaceutical or beverage applications where a concentric tube interferes with any clean-in-place function. It is also common in tall tanks that require flexible cable sensors and with slurries, which can accumulate solids and plug the ground reference.

Changes in dielectric constant will cause a change in calibration. If composition is constant, temperature will be the only concern for variation of K. Because K is proportional to the number of molecules between probe and ground, output (as with a d/p transmitter) will be proportional to density and, hence, the weight of process material. For cases in which constant composition and a reasonably narrow temperature range are not possible, a transmitter with dielectric compensation is available. By using such an instrument, it is possible to obtain a level signal that is independent of dielectric, and even conductivity, when tanks are not dedicated. This technology demands two conditions:

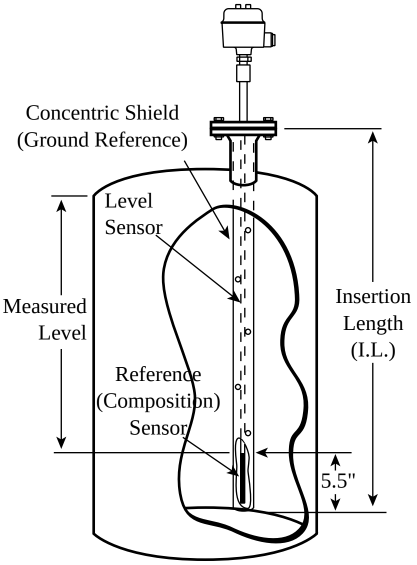


FIG. 3.3o
A probe with a second element for dielectric compensation. (Courtesy of AMETEK-Drexelbrook.)

1. A short inactive section at the bottom of the probe, approximately 6 in. (150 mm)
2. Homogeneity of the process liquid (no stratification)

The compensation is accomplished by making two independent measurements. The first measurement is made with a short sensor (composition probe) below the tip of the level probe (Figure 3.3o). This segment is assumed always to be covered by the process liquid. Its capacitance is proportional to the electrical character of the process material. The second measurement uses the level probe. Its output is proportional to the level times the electrical character of the process fluid. By dividing the output of the level probe by the output of the composition probe, the transmitter output becomes independent of the electrical properties. Please note that conductive coatings can cause large inaccuracies in these particular transmitters. Even so, conducting liquids that do not coat will be measured with accuracy equal to the insulating ones. For the sake of utility, both probe segments are usually provided, coaxially, in the same assembly. It is also possible to use two completely separate probes, with the composition probe mounted horizontally below the tip of the level probe. Inaccuracy can be limited to 0.5% over a wide range of electrical values and a wide temperature range.

Continuous Liquid–Liquid Interface

Two elements are key to successful interface level measurement: immunity to total level variation and maximum margin between the signal contribution of the organic and aqueous phases. Making the probe inactive down to a point that *always* will be covered by liquid can negate variation in total level. Of course, *packed* vessels and separators on overflow do not exhibit the problem. The primary item to minimize the signal from organics is to maximize the distance to ground. Low *K* is another positive item. The only practical way it can be varied is by better separation to exclude the high *K* aqueous content. Concentric ground references, small-diameter stilling wells, and external standpipes, by bringing the ground closer, make the measurement more sensitive to changes in the organic phase. The ideal mounting is in the center of the tank, with no metal nearby.

Maximizing the aqueous contribution means using a probe insulation with the highest feasible capacitance. A good margin would be one in which the aqueous contributes 300 pF/ft and the organic 8 pF/ft. Regardless, many very satisfactory separators in the heavy oil fields operate with an 80- to 30-pF/ft margin. The limitations on maximum probe capacitance include fragility (thinner coatings have higher capacitance), temperature (TFE and PFA have the lowest *K* of common polymers and highest temperature capability), and chemical compatibility (again, the low-*K* insulators are most inert chemically).

The question of an intermediate emulsion or *rag layer* adds a bit of confusion to the measurement. Users often desire a measurement at the bottom of the rag, but that area is generally very close to the aqueous in conductivity. The point sensed by the continuous probe is always that at which the emulsion reverses from organic continuous (aqueous drops in organic matrix) to aqueous continuous (organic drops surrounded by aqueous liquid). In liquids with distinctly different colors, users often believe that the instrument is not functioning correctly. The visual interface typically does not coincide with the electrical interface except in the rare case of perfect separation. This means that sight glasses are useless for calibration of interface transmitters. Sample taps are more valuable, but only if the electrical conductivity of the sample, rather than color and viscosity, is observed.

Users often lose sight of the fact that the instruments *cannot* separate the components. The first criterion for accurate interface control is good separation. This may entail more or better emulsion-breaking chemicals, longer residence time (less throughput), higher temperature, or additional mechanical or electrical aid to coalescence. The idea that certain instruments can produce lower organic in the aqueous stream, less water in the organic stream, *and* raise throughput is total baloney. In many cases, separators are run above the design throughput, so something needs to be done to accelerate separation if product quality is to be maintained. For best results, the probe should be located as far from the inlet as possible, where the best separation will have occurred.

The most frequent use of interface transmitters is in horizontal separators, where the total level is usually maintained by overflow, and the interface is maintained by controlling the aqueous dump valve. A whole other class of application has been largely ignored because of the difficulty in getting the probe to the interface area. That application, sometimes called *water bottoms*, measures the water level beneath organic products (usually fuels) in large storage tanks. Typically, this involves measuring a few inches of water at the bottom of 40-ft (15-m) or taller tanks. Dropping a short probe, attached by a cable or pipe, down from the top of the tank is pretty straightforward unless the tank has a floating roof. The most successful floating-roof applications have used a 45° hot-tapped nozzle near the bottom of the tank. Because the tank is seldom empty, it generally requires a probe to be inserted through a sliding seal under pressure.

Granular Solids

The most common problem in granular measurements is caused by moisture variation in insulating materials, which represent the majority of granular solids. Since water has a nominal $K = 80$, and the typical solids are in the $K = 2$ area, small variations in water content can produce large percentage changes in $K - 1.0$ and, hence, the slope of the input/output curve. If the particular granular produces a similar change in conductivity, subtracting the resistive phase of RF current from the capacitive component can compensate moisture variation over a particular range of water content. The same instrument that provides electronic coating rejection, for example, compensates grains of wheat, corn, and rice. These whole grains produce capacitive and conductive RF current components that are affected equally by moisture variation in the 8 to 20% water range. By subtracting the resistive component from the capacitive, the effect of these changes is eliminated.

At the opposite end of the moisture spectrum, very dry (<0.1% H_2O) insulators produce high-voltage static discharge when conveyed into silos. The probe appears to be a ground element to these highly charged materials, and substantial voltages can be coupled into the electronic unit, where semiconductors are easily destroyed. It is necessary to protect the electronics by shorting these voltages to ground before they reach transistors and microcircuits. The protection elements should be capable of handling peak short-term current of at least 10 A, and a 100-A capability is sometimes required.

Probes will require a parallel ground reference, just as in insulating liquids. A surrounding intrinsic ground reference is obviously not an option in granulars. The straight-sided bin or silo wall is the best choice. This precludes accurate measurement in cone bottoms, which hopefully represent a very small percentage of bin capacity. Rigid probe rods are usually limited to about 10 ft. Flexible cable sensors have been used up to 200 ft in length. To avoid probe movement, which can change the capacitance and hence the calibration, flexible probes with a weight should be mounted directly above the dump location so that material flow will tend to keep them in position. If the probe can't be located there, it will need to be anchored to the silo floor or some other structural element. The mounting location should be so strong and stiff that force on the probe is insufficient to deform the tank roof. Do not expect vendors to predict what force will be produced, as they have neither sufficient application details nor expertise.

Conducting granulars are relatively few and far between. This is unfortunate, because they can be measured more accurately and with less trouble than the more numerous insulating materials. Because the ground is carried right to the probe insulation, weighted probes are not sensitive to the distance to the tank walls and can be allowed to wander without a noticeable change in calibration. Conversely, the probe will read every inch of conductive material in contact with it. Since granulars are notable for angle of repose, these probes should be located at the point of minimum angle-of-repose error.

Glossary

Admittance (A). The reciprocal of the impedance of a circuit. Admittance of an AC circuit is analogous to the conductance of a DC circuit. Expressed in units of siemens (S).

Capacitance (C). The property of an electrical insulator that permits the storage of energy through electric displacement when opposite surfaces are held at different voltages. This is the property that allows AC current to appear to flow through an insulator. Expressed in units of farads.

Capacitive component. AC current can be separated into two components; current with a phase relation to the excitation voltage of +90° is called the *capacitive component.*

Capacitor. A device consisting of two conductors electrically isolated by an insulator. The conductors are called *plates,* and the insulator is referred to as the *dielectric*. The larger the capacitor, the smaller its impedance and the more AC current will flow through it.

Coax. Jargon meaning *coaxial cable*, which consists of a center wire surrounded by low-*K* insulation, surrounded by a second shield conductor. It has the characteristics of low capacitance and inductance for transmission of high-frequency current.

Conductance (G). The reciprocal of resistance. Expressed in units of siemens (formerly called *mhos*).

Conductivity (g). The reciprocal of resistivity. All solids and liquids have some degree of conductivity. For the purpose of this section, any material above 1 μS/cm will be considered to be conductive (for example, most metals, water with any ions present, coke, carbon black, soaking-wet insulators, and aqueous-external emulsions). Expressed in units of siemens/cm.

CPVC. Chlorinated polyvinyl chloride, a low-cost, reasonably inert polymer used for some noninsertion sensors. It is easily solvent welded. Its maximum temperature range is about 225°F.

Deionized. Refers to water of extremely high purity, with few ions to carry current. If exposed to air for any significant period, it will have a conductivity of about 5 μS/cm because of dissolved CO_2.

Dielectric. An electrical insulator (includes metal oxides, plastics, and hydrocarbons).

Dielectric compensation. A scheme by which changes in insulating liquid composition or temperature can be prevented from causing any output error. It requires a second sensor and homogeneous liquid.

Dielectric constant (K). A unit expressing the relative charge storage capability of various insulators (see Table 3.3p). Full vacuum is defined as 1.0, and all gases are indistinguishable for practical purposes. TFE has a dielectric constant of 2.0, cold water about 80. This is expressed in unitless numbers, because this is the ratio of absolute dielectric constant to that of vacuum.

Farad (F). A unit of capacitance. Because this is a very large unit, a unit equal to one trillionth of a farad (the picofarad, pF) is commonly used in RF circuits.

FEP. Fluorinated ethylene propylene, a fluorocarbon that is extremely chemically inert. It melts at a reasonable temperature and can be plastic welded fairly easily. It is difficult to bond with adhesives. Maximum temperature range is limited to the 300°F (150°C) area.

Guard. The *electronic guard* (called a *shield* in some RF-level literature) consists of a concentric metallic element with an applied voltage that is identical to the voltage on the conductor it is "guarding." This negates the capacitance between the guarded conductor and the outside world.

Impedance (Z). The opposition to the flow of alternating current. Impedance in AC circuits is analogous to resistance in DC circuits. Expressed in units of ohms (Ω).

PE. Polyethylene, a low-temperature insulation that is compatible with a wide range of corrosives but is attacked by most petroleum products. Generally limited to situations in which fluoro- and chlorocarbons are not allowed, such as the tobacco and nuclear power industries. Maximum allowable temperature is in the 180°F (80°C) area.

PEEK. Polyether ether ketone, a high-temperature, injection molded polymer that is chemically quite inert. This material has wide chemical application. Temperature capability is high at 450 to 500°F (225 to 260°C). Avoid any liquids with "phenol" in their names. Adhesive bonding to the molded parts would be difficult.

PFA. Perfluoroalkoxy, a fluorocarbon that is quite inert chemically, melts at a fairly high temperature, and is easily plastic welded. It can be used up to 550°F (290°C) but, as a probe insulation, it is generally limited to 350°F (175°C) because of bonding limitations with the metal rod.

TABLE 3.3p

Table of Nominal Dielectric Constants for Some Common Materials

Solids			
	Dielectric Constant		*Dielectric Constant*
Acetic acid	4.1	Phenol	4.3
Asbestos	4.8	Polyethylene	4.5
Asphalt	2.7	Polypropylene	1.5
Bakelite	5.0	Porcelain	5.7
Calcium carbonate	9.1	Quartz	4.3
Cellulose	3.9	Rubber (hard)	3.0
Ferrous oxide	14.2	Sand	3.5
Glass	3.7	Sulfur	3.4
Lead oxide	25.9	Sugar	3.0
Magnesium oxide	9.7	Urea	3.5
Naphthalene	2.5	Zinc sulfide	8.2
Nylon	45.0	Teflon®	2.0
Paper	2.0		

Liquids					
	Temp. °F/°C	*Dielectric Constant*		*Temp. °F/°C*	*Dielectric Constant*
Acetone	71/22	21.4	Heptane	68/20	1.9
Ammonia	–27/–33	22.4	Hexane	68/20	1.9
Ailine	32/0	7.8	Hydrogen chloride	82/28	4.6
Benzene	68/20	2.3	Iodine	224/107	118.0
Benzil	202/94	13.0	Kerosene	70/21	1.8
Bromine	68/20	3.1	Methanol	77/25	33.6
Butane	30/–1	1.4	Methyl alcohol	68/20	33.1
Carbon tetrachloride	68/20	2.2	Methyl ether	78/26	5.0
Castor oil	60/16	4.7	Mineral oil	80/27	2.1
Chlorine	32/0	2.0	Naphthalene	68/20	2.5
Chloroform	32/0	5.5	Octane	68/20	2.0
Cumene	68/20	2.4	Pentane	68/20	1.8
Cyclohexane	68/20	2.0	Phenol	118/47	9.9
Dimethylheptane	68/20	1.9	Phosgene	32/0	4.7
Dimethylpentane	68/20	1.9	Propane	32/0	1.6
Dowtherm®	70/21	3.3	Pyridine	68/20	12.5
Ethanol	77/25	24.3	Styrene	77/25	2.4
Ethyl acetate	68/20	6.4	Sulfur	752/400	3.4
Ethyl benzene	68/20	2.5	Toluene	68/20	2.4
Ethylene chloride	68/20	10.5	Urethane	74/23	3.2
Ethyl ether	68/20	4.3	Vinyl ether	68/20	3.9
Ethyl benzene	76/24	3.0	Water	68/20	80.0
Formic acid	60/16	58.5	Water	32/0	88.0
Freon 12	70/21	2.4	Water	212/100	48.0
Glycol	68/20	41.2	Xylene	68/20	2.4

PP. Polypropylene, similar to PE. Used for low cost and where fluoro- and chlorocarbons are excluded. Maximum temperature is in the area of 200°F.

PVDF. Polyvinylidene fluoride. This fluorocarbon has substantially lower temperature limits than the others (250°F or 120°C) and is less inert chemically. It is dissolved by the ketones (acetone, MEK, MIBK) and attacked by benzene and high concentrations of sulfuric acid. The most insidious enemy is caustic, which causes brittleness and cracking. It has much better toughness and abrasion resistance than the other fluorocarbons as well as unique electrical properties ($K = 8$).

Radio frequency (RF). A frequency that is higher than sonic but less than infrared. The low end of the RF range is 20 kHz, and its high end is around 100,000 MHz.

Radio frequency interference (RFI). A phenomenon in which electromagnetic waves from one source interfere with the performance of another electrical device.

Reactance (X). That part of the impedance of a circuit that is caused by either capacitance, inductance, or both. Expressed in units of ohms (Ω).

Rear mount. A technique for making long inactive sections by mounting the probe on the end of a pipe, with its coax cable running through the pipe to the top of the tank. The coax must survive the process temperature, so it is often of high-temperature construction.

Resistance (R). The opposition offered by an electrical conductor to the flow of direct electric current. Expressed in units of ohms (Ω).

Resistive component. AC current can be separated into two components. The portion that is in phase with the excitation voltage is called the resistive component.

Resistivity (ρ). This is the property of a conductive material that determines how much resistance a unit cube will produce. Expressed in units of ohm-centimeters (Ω-cm).

Saturation. A condition in which probe-to-ground RF current is determined solely by the impedance of the probe insulation. Increased conductivity in the saturating medium, even to infinity, will not cause a noticeable change in that current or in the transmitter output.

*(P)TFE.** Tetrafluoroethylene (the *P* stands for *polymerized*, which is understood). The oldest, highest temperature, and most inert fluorocarbon probe insulation. Extremely difficult to adhesive bond, it is usable up to 550°F (290°C). On probes, its temperature limit is determined by the type of bonding to the probe rod (300, 450, or 550°F). This is the most common probe insulation in the industry. Because it never melts (but disintegrates, producing HF, at >600°F), it is difficult to fabricate, impossible to plastic weld, and exhibits a high degree of microporosity. Can be destroyed by butadiene and styrene monomer.

TECHNOLOGY

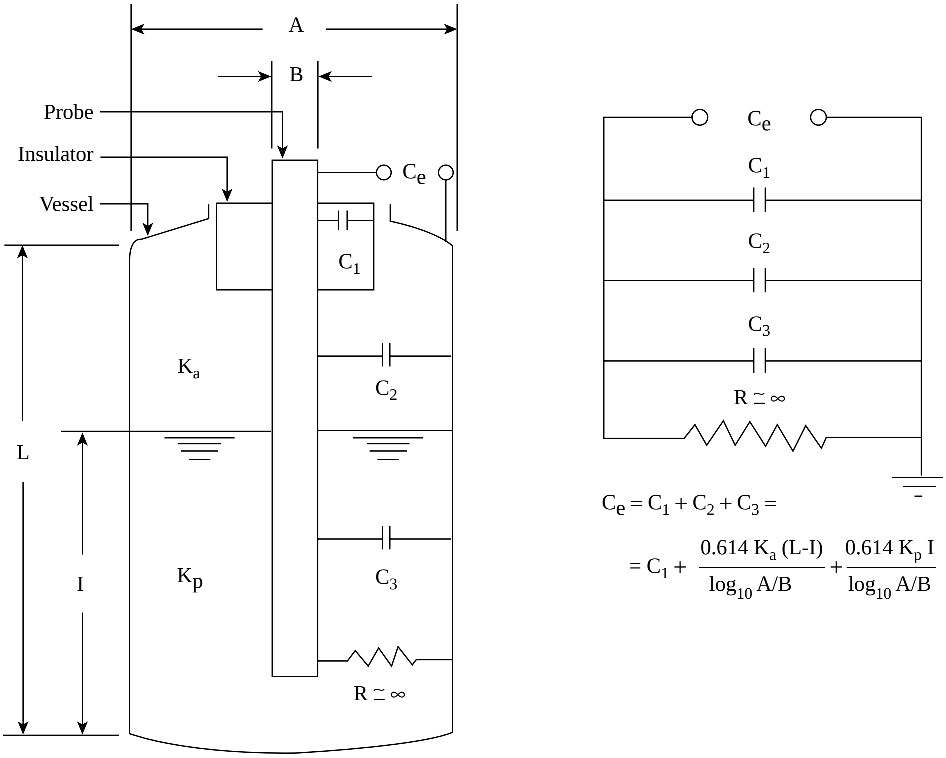
The purpose of this section is to help the more technically inclined to understand just what is happening in a particular application. It is not necessary to personally make good use of this information. Your friendly vendor will be glad to take the necessary steps to ensure a good result with the instruments you purchase.

Analysis of RF probe circuits requires little more than a knowledge of AC circuits. The simplest situation is the bare probe mounted in the center of a vertical, cylindrical tank (Figure 3.3q). The expression for C_2 and C_3 is the formula for a concentric capacitor and can also be used to calculate the capacitance of probe insulation. (To do so, use $K = 2$ for TFE, PFA, FEP, PE, and PP. Use $K = 8$ for PVDF.) The length units are inches, and the diameters can be any units as long as both are the same. A good approximation of C_1 is 20 pF. For rough estimates of air capacitance in tanks that are not cylindrical and/or not concentric, 0.35 pF/in. is a good rule of thumb. If the probe is within 1 ft of the wall, it will be higher. A probe in the center of the tank is least sensitive to position. Capacitance increases as the distance to ground is reduced. In the center of the tank, motion toward one wall increases the distance to the opposite wall, so the capacitance is nearly constant. Close to the wall, the capacitance increases rapidly with any reduction in the distance. The capacitance produced by any insulating liquid will be its K times the air capacitance.

The insulated probe complicates the calculation because of the nonlinear combination of series capacitors (Figure 3.3n). The equation shown is correct for insulating liquids. For conducting liquids (assuming saturation), the third term is reduced to C_5, because the low resistance represents a short circuit to ground. In the case of a liquid–liquid interface, the organic phase would substitute for the air space shown. The K of the organic phase must be measured based on an upper phase sample at operating temperature. The amount of aqueous phase held in the organic will be a function of temperature as well as throughput. Table 3.3p is a list of nominal dielectric constants, which can be used to make rough estimates of what capacitance will result from a particular probe geometry.

---

* Most people interchange the name Teflon® with TFE. This is *completely* incorrect but understandable. TFE was the first fluorocarbon polymer to carry the trade name Teflon at E. I. DuPont. Dupont chose to use the Teflon trade name for a whole *family* of fluorocarbon resins, so FEP and PFA made by Dupont are also called Teflon. To complicate the matter, other companies now manufacture TFE, FEP, and PFA, which legally cannot be Teflon, since that name applies only to DuPont-made polymers.



$$C_e = C_1 + C_2 + C_3 = C_1 + \frac{0.614\, K_a\, (L\text{-}I)}{\log_{10} A/B} + \frac{0.614\, K_p\, I}{\log_{10} A/B}$$

CONCLUSION

Early capacitance probes had the advantages of simplicity, relatively low cost, corrosion resistance, and a lack of moving parts. In addition, the proximity design required no contact with the process fluid. On the other hand, these early capacitance probe designs were subject to errors resulting from changes in the dielectric constant of insulating process fluids, to errors resulting from the tank geometry and fiberglass construction, and to conductive coating buildup on the probes. In the newer designs, these problems have been largely solved by increasing the operating frequency, incorporating a phase detector component in the electronic circuits, and modifying the design of the sensors and their guards. These improvements have made the capacitance/RF admittance type probes a powerful means of level detection. The only types of measurements that are still excluded with these instruments are interfaces between two conductive liquids or the liquid–solid interface. A major maintenance problem is water in the head assembly that results from incorrect conduit routing and venting. The head may be potted with two-component RTV to eliminate this problem.

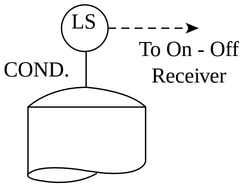
3.4 Conductivity and Field-Effect Level Switches

D. S. KAYSER (1982) **B. G. LIPTÁK** (1969, 1995, 2003)



Flow Sheet Symbol

Applications	Point detection or differential detection of level of conductive liquids or slurries having dielectric constants of 20 or above. For electric switches, the maximum fluid resistivity is 20,000 Ω/cm; electronic types can work on even more resistive fluids. Field-effect probes are used on both solids and liquids, and they can be conductive or nonconductive.
Design Pressure	Up to 3000 PSIG (21 MPa) for conductivity probes, 100 PSIG (6.9 bars, or 0.69 MPa) for field conductivity probes
Design Temperatures	Operating ranges for conductivity-type level switches are from −15°F (–26°C) to 140°F (60°C) for units with integral electronics and from −15°F (–26°C) to 1880°F (982°C) for units with remote electronics. Field-effect probes can operate at up to 212°F (100°C).
Materials of Construction	Conductivity probes are made out of type 316 stainless steel, Hastelloy®, titanium, or Carpenter 20 rods with Teflon®, Kynar, or PVC sleeves. Housings are usually made of corrosion-resistant plastic or aluminum for NEMA 4 and 12 service. The field effect probes are available with a Ryton™ probe with aluminum housing.
Probe Lengths	Conductivity probes with 0.25 in. (6 mm) solid rods are available in lengths up to 6 ft (1.8 m); 1/16-in. (2-mm) stainless-steel cables can be obtained in lengths up to 100 ft (30 m). The length of field-effect probes is 8 in. (200 mm).
Sensitivity	Adjustable from 0 to 50,000 Ω for conductivity probes
Inaccuracy	0.125 in. (3 mm)
Cost	From $100 to $500. The typical price of an industrial conductivity switch is about $300.

Conductance is the inverse of resistance ($G = 1/R$). The conductivity of a substance is defined as the conductance (G) of cylindrical column of that substance, which is 1.0 cm long and 1.0 cm^2 in area. The units of conductivity are in siemens per centimeter (S/cm) or in mhos (siemens and mhos are different terms for the same unit). The ability of a liquid to conduct electricity is a function of the number of charged ions in that solution. Deionized pure water has very high resistance, but liquids such as sewage water, sea water, and city water are quite conductive. In fact, the conductivity of most liquids is much higher than that of air. Therefore, if an electrical circuit is closed by the substance surrounding the tip of a probe, the resulting current flow will be much higher when the probe is submerged in the liquid that when it is the air space above it. Conductivity-type level switches discriminate between air and liquid by that method.

CONDUCTIVITY-TYPE LEVEL SWITCH

The process fluid itself closes an electric circuit when the air–liquid interface rises to contact the level probe (Figure 3.4a). The dual-tip probe of this design eliminates the need for grounded metallic tanks and can be used to detect both levels and interfaces between conductive and nonconductive liquids. The current flow is at the microampere level, which removes the hazards of shock and sparking. The sensitivity of the switch is adjusted to match the conductivity of the process liquid.

In grounded metallic tanks, the level probes are usually installed vertically. If the liquid in the tank is agitated or is turbulent for other reasons, it is desirable to employ two electrodes in detecting a single level point (Figure 3.4b). The small vertical distance between the two probes provides a dead band or neutral zone, which protects against cycling in case of splashing inside the tank. A 0- to 20-sec time delay is also available serving the same purpose.

Figure 3.4c illustrates a conductivity level probe installed in a grounded tank. One electrode is shown above the liquid level on the left side of the sketch. The circuit on the left, therefore, is open, no current is flowing through the relay coil, and the load contact is open. When the liquid level rises, as shown on the right side of the sketch, a conductive path between the electrode and the grounded tank is established,

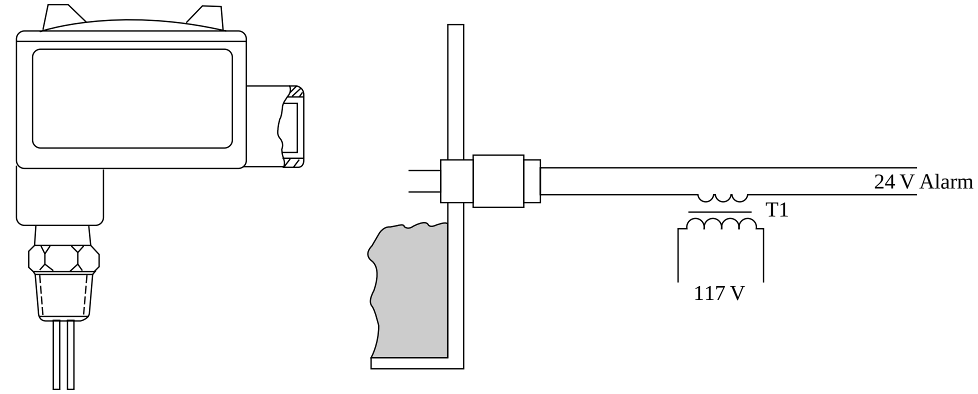

FIG. 3.4a

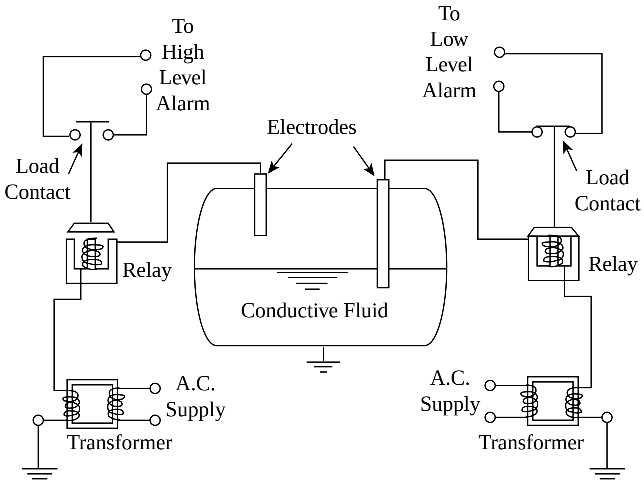

FIG. 3.4c
Single-point conductivity switch.

closing the circuit through the relay coil. Energizing the relay closes the load contact, which, in turn, can operate pumps, solenoid valves, and other processing equipment. In this system, the liquid in the tank acts as a switch in the relay circuit. Although electromechanical relays are shown in the figure, these days, the solid-state relays are more commonly used. If the tank is fabricated of fiberglass or other insulating material, the switching circuit is configured between the sensing probe and a reference probe (Figures 3.4a and 3.4b).

Pump Alternator Circuit

Because these switches are available in a variety of configurations, they can be used for the on–off control of one piece of equipment or for the staged control of several pieces of equipment. When two pumps are installed in the same on–off service, it is desirable to automatically alternate the pumps so that they will wear evenly and so that "hot starting" of pump motors is reduced. Figure 3.4d shows how one level switch with two conductivity probes can be used in conjunction with an electromechanical alternator to cycle the pumps.

As level rises, the LSL contact of probe 1 will close, because this contact is operated by the lower probe. The control relay CR remains de-energized with its contact CR-2 closed and contacts CR-1 and CR-3 open. When the level rises to a higher level, the LSH contact of probe 2 closes, thereby energizing CR, which, in turn, closes contacts CR-1 and CR-3 and opens CR-2. The relay CR will remain energized after the level drops below and the LSH contact opens, because CR-1 is still closed. With CR energized, CR-3 is closed, and the circuits that are connected to contact A of the position switch and to contact 1 of the sequence switch are energized. The circuit connected to contact A starts the alternator switch motor, which, in turn, moves the position switch to contact B. This de-energizes the switch motor, because the CR-2 contact is held open by CR, which is energized. The circuit through contact 1 of the sequence switch energizes M1, which is the starter coil for the motor associated with the pump 1, and the first pump starts.

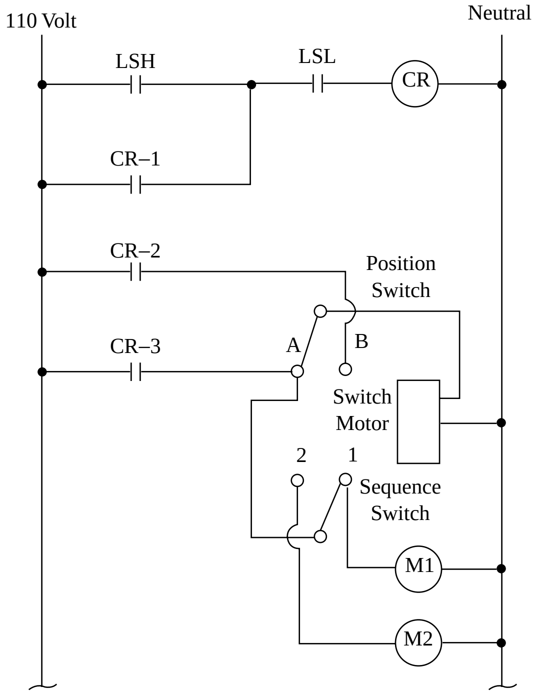

FIG. 3.4d
Pump down alternator circuit. M1 = first pump; M2 = second pump.

When the level falls below the level of the LSL probe tip, relay CR is de-energized, which opens contacts CR-1 and CR-3 and opens CR-2. Dropping out CR-3 stops the motor (M1) associated with the first pump. The closing of CR-2 energizes the switch motor, which steps to move the sequence switch to contact 2 and moves the position switch back to contact A. As a consequence, on a subsequent rise in level, M2 will be energized, and the second pump will start. This is the most basic of the pump-down alternator circuits. A similar circuit can be designed for pump-up applications, and a wide variety of additional control requirements can be met if the numbers of probes and relays are increased.

Advantages and Limitations

The advantages of the conductivity switch include low cost, simple design, and elimination of moving parts in contact with the process material. Conductivity-type level switches can also be used to detect the level of moist bulk solids. The three-probe-element design can also provide differential level control.

The disadvantages include the possibility of sparking when the liquid level is close to the tip of the probe. Such phenomena are eliminated in the solid-state designs, which are rated for intrinsic safe operations. The conductivity switch is also limited to conductive (below 108 Ω resistivity) and noncoating process applications. One should also consider the possible harmful side effects of electrolytic corrosion of the electrode. Electrolysis can be reduced, but not eliminated, by using AC currents.

Conductivity switches are rarely used in chemical processing services. However, they are routinely used in the food, paper, and wastewater industries and in other water-level applications, including those on steam drums operated at up to 3000 PSIG (21 MPa). Specialized applications also include the measurement of the level of molten glass, which is a conductor at elevated temperatures.

FIELD-EFFECT LEVEL SWITCHES

As illustrated in Figure 3.4e, the field-effect probe creates a field between a metallic cap cast into a Ryton probe and the metal in the tank or in the probe gland and probe housing. When a conductive or nonconductive liquid, slurry, or solid material (with electrical characteristics different from that of air) breaks the field lines, the high-frequency current increases, and the relay trips. The probe should be installed horizontally

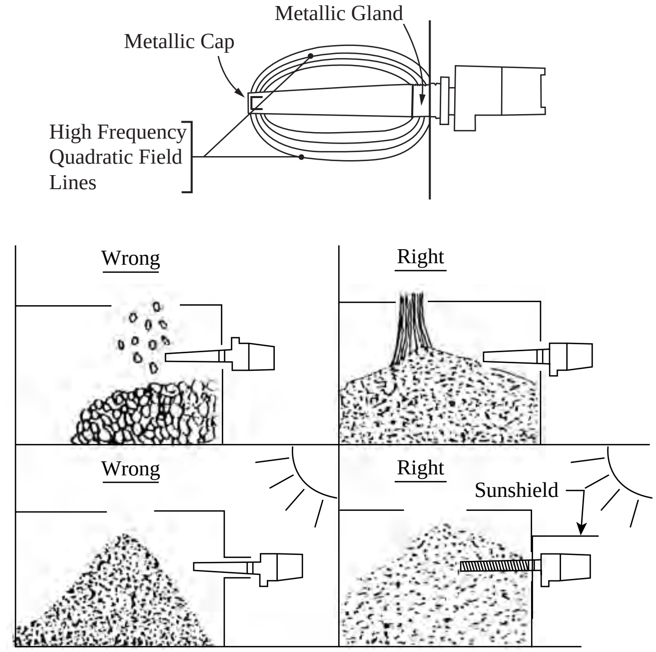

FIG. 3.4e
The field effect level switch and its installation. (Courtesy of Endress+ Hauser Inc.)

(as shown in Figure 3.4e), with a small downward angle, if installed on slurry services.

The Ryton probe material is unaffected by solvents if the operating temperature is under 212°F (100°C). The probe is 8 in. (200 mm) long and requires a 1.5-in. NPT tank connection. As illustrated in Figure 3.4e, it is advisable to protect the probe form the impact of the flowing solids and to protect the electronics from direct sunshine.

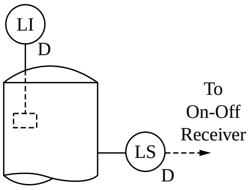
3.5 Diaphragm Level Detectors

D. S. KAYSER (1982) **B. G. LIPTÁK** (1969, 1995)
J. B. ROEDE (2003)



Flow Sheet Symbol

Service	Level transmitter in water wells, open tanks with immersed sensor; tank-mounted diaphragm pressure transmitter and repeaters; level switch for solids in bins and silos
Design Pressure	Switches, atmospheric; transmitters, submersible to 500 PSI (3.5 MPa); others to 5000 PSI (35 MPa)
Temperature	–40°F (–40°C) to 180°F (80°C) typical
Wetted Materials	Switches: aluminum, SS, neoprene, and various polymers. Submersibles: SS, TFE, neoprene, Buna-N, and polyethylene. Tank mounted: type 316 SS, Hastelloy®, Inconel®, and Monel®.
Ranges	Single point for solids; up to 700 ft of water for the transmitters
Inaccuracy	Single points are repeatable to about 1 in. (25 mm) on solids; transmitters are accurate to 0.5 to 1.0%, based on pressure. Level inaccuracy depends on the specific gravity of the liquid.
Cost	Switches, \$150 to \$500; submersibles, \$350 to \$600; tank mounted, \$1000 to \$2500

All diaphragm detectors operate on the simple principle of detecting the force exerted by the process material against the diaphragm. The designs discussed below include diaphragm switches for liquid and solid services and diaphragm devices for continuous liquid level detection and transmission in tanks or wells.

DIAPHRAGM SWITCHES FOR SOLIDS

For solid service, diaphragm switches can be selected from a number of design variations. Devices with mercury switches can be used with materials having a bulk density of more than 30 lb/ft^3 (48 kg/m^3), whereas units with microswitches are used for lower-density services. Some of the most sensitive diaphragm switches will actuate with as little as 6 oz (171 g) of force on the diaphragm. The differential of a single diaphragm can be as high as 8 in. (200 mm), meaning that the switch will close its circuit when the solids rise to the top of the diaphragm and will open the circuit when they drop 8 in. The lower the solid density, the larger the diaphragm area required. Units are available with 4- to 10-in. (100- to 250-mm) diameter diaphragms. As illustrated in Figure 3.5a, there are three ways to install these detectors. They can be suspended on a support pipe to provide for quick adjustment of the switch position, they can be mounted on the inside wall of thick-walled silos, or, as is most commonly done, they can be externally mounted on thin-walled bins and silos. The mounting location should always be selected to guarantee the free flow of solids to and from the diaphragm area.

As shown in Figure 3.5a, diaphragm-type switches for solids can serve several purposes. Switch 1 protects against overfilling, switch 2 signals low supply level, and switch 3 indicates choke-up in the screw conveyor. Diaphragm 4 detects overfeeding the elevator boot, and diaphragm 5 detects plugging of the elevator discharge spout. Diaphragm switches 6 and 7, in the storage silo, will signal extreme level conditions. Switch 6 can interlock the material feed and shut it down when the storage silo is full.

In newer designs, the diaphragm itself is vibrated by built-in piezoelectric elements and, when the solids level rises up to the diaphragm, the resulting load on the diaphragm decreases the amplitude of vibration. This change in amplitude is used to trigger the level switch. This solids level switch (Figure 3.5b) is smaller, lighter, and more sensitive than the earlier designs, and its stainless-steel diaphragm (in an ABS resin body) is more rugged than the rubber diaphragms of the direct pressure-sensing units. The vibration

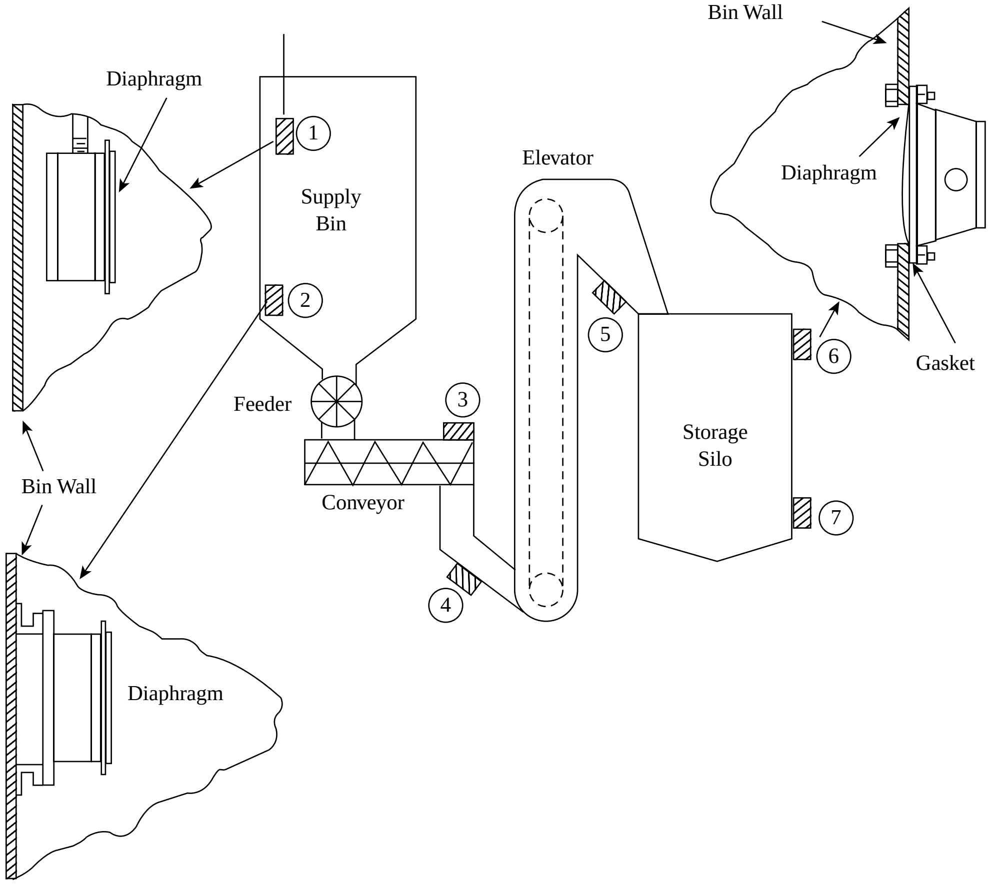

FIG. 3.5a
Use of diaphragm switches in solid services.

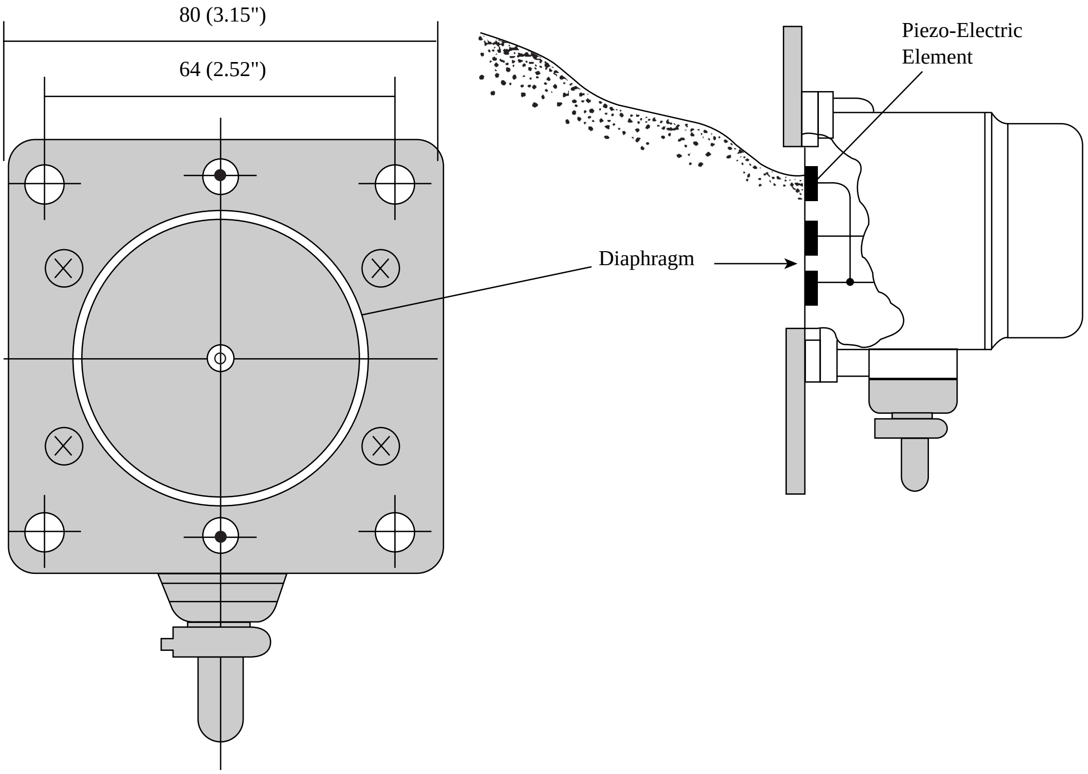

FIG. 3.5b
Vibrating diaphragm-type solids level switch. (Courtesy of Scientific Technologies Inc.)

of the diaphragm at 200 to 400 Hz reduces the probability of material sticking to the diaphragm and it also increases its sensitivity. The switch will actuate when it is 50% covered by materials with specific gravities exceeding 0.5, such as flour (0.48 to 0.55), polyethylene pellets (0.56), rice (0.58), PVC pellets (0.76), or wheat (0.77). On lighter materials, such as instant coffee (0.22) and copier toner (0.49), the diaphragm will actuate when it is 80% covered. To eliminate cycling, a 1- to 3-sec time delay is provided.

DIAPHRAGM SWITCHES FOR LIQUIDS

Figure 3.5c shows how diaphragm switches can be used to detect liquid level by sensing the pressure of a captive air column in a riser pipe beneath the diaphragm. An 8-in. (203-mm) head of liquid above the inlet of the riser pipe generally compresses the air sufficiently for switch actuation. The unit can handle a maximum of 60 ft (18 m) of liquid. The diaphragm is in contact with the captive air but not with the process. The liquid rises in the dip pipe enough to compress the enclosed mass of gas to match the level-caused pressure outside the dip pipe minus the liquid rise inside the dip tube. Physical dimensions are important. Sensitivity increases as the wetted portion of the dip tube increases and decreases in proportion to the enclosed air volume. These units can be used only on atmospheric tanks and should be considered only for applications where low cost is desired and accuracy is not a critical consideration.

DIAPHRAGM-TYPE LEVEL SENSORS AND REPEATERS

Figure 3.5d illustrates two versions of the continuous level detector, both limited to atmospheric tanks and to applications where low cost is more important than quality or accuracy of measurement. The diaphragm box unit, shown on the left side of the sketch, is similar in operation to the previously discussed riser pipe diaphragm switches except that the diaphragm isolates the captive air from the process fluid. The unit consists of an air-filled diaphragm box connected to a pressure detector via capillary tubing. Correct function depends on a large volume displacement by the diaphragm, with negligible spring constant. As the level rises above the slack diaphragm, the liquid head pressure compresses the captive air spring. The air pressure in the capillary tubing is sensed by a pressure element and displayed as an indication of level.

A one-to-one pressure repeater is illustrated on the right side of Figure 3.5d. With this unit submerged in the vessel, the static head of the liquid exerts an upward force on the diaphragm that increases as the level rises. The air supply pressure on the other side of the diaphragm opposes the upward force. The force caused by the rising level moves the diaphragm toward a bleed orifice, thus restricting its flow to atmosphere and causing the air pressure to build up until it equals the static head pressure. When the forces on the two sides of the diaphragm are equal, the unit is in equilibrium. The speed of response of the unit is changed by an adjustable restriction that, if opened, will increase sensitivity by allowing

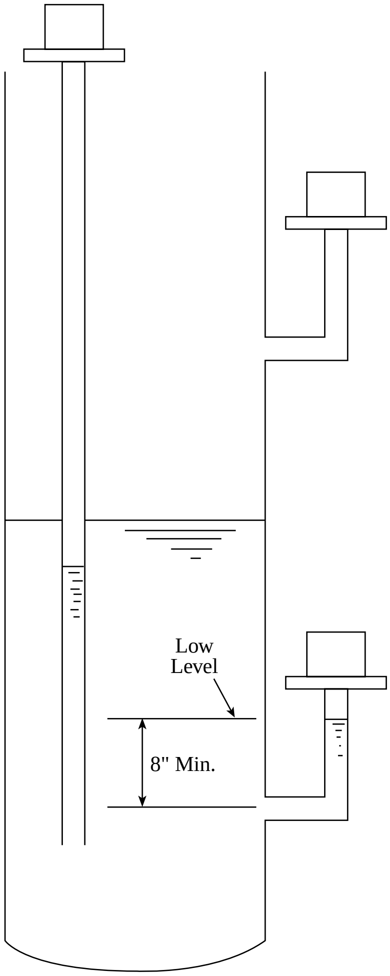

FIG. 3.5c
Diaphragm switches in liquid service.

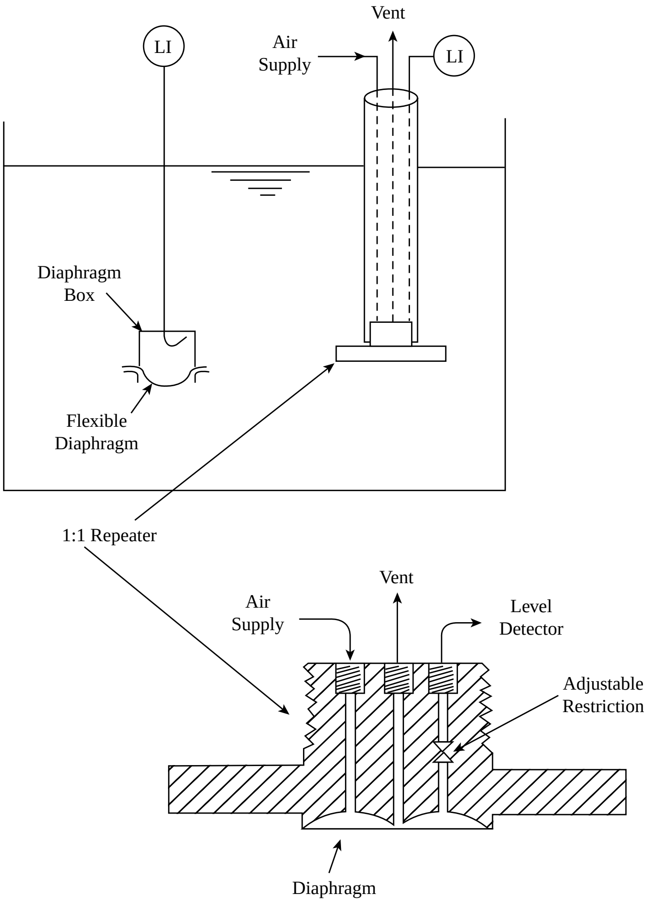

FIG. 3.5d

more air to flow onto the diaphragm. Air supply to the unit should be regulated at a pressure of 3 to 5 PSIG (0.2 to 0.3 bar) in excess of the maximum hydraulic head to be repeated.

The pressure repeater can be submerged, as shown in Figure 3.5d, or mounted on a nozzle near the bottom of an atmospheric tank (Figure 3.5e). These flange-mounted units are available with stainless-steel diaphragms and steel or stainless-steel bodies. They can operate with up to 160 PSIG (11 bars) air supply and can repeat hydrostatic pressures up to within 5 PSI (0.35 bars) of the air supply pressure. The air consumption of these repeaters is under 0.2 scfm (5.7 slpm). Other repeater designs, such as the extended diaphragm version, are discussed in the following section (Section 3.6), because they are used to complement differential pressure transmitters in level-measurement applications.

ELECTRONIC DIAPHRAGM LEVEL SENSORS

Most diaphragm-type pressure detectors and pressure transmitters can also be used to detect level by measuring the weight of a column of liquid in an atmospheric tank. In the unit shown in Figure 3.5f, the pressure applied to the diaphragm is transferred to a fill fluid that also fills the inner cavities. A straight-axis, twisted Bourdon tube is cantilevered from the process side to convert pressure of the fill fluid to proportional, rotary motion at its free end. A rotary variable differential transformer (RVDT) detects the rotation and converts it to an electrical signal. This particular sensor is available with ranges from 0 to 100 in. (0 to 2.5 m) of water column up to 0 to 300 PSIG (0 to 20.7 bars) and has a 150% overpressure protection over its range. Other means of transduction include strain gauges bonded directly to the diaphragm, silicon diaphragms with the strain gauges etched and diffused into the side away from the process, and capacitive sensing of the diaphragm by an internal parallel plate.

Diaphragm-type electronic pressure transmitters are available in all stainless-steel sanitary designs and are used in the food industry. They are available with 0–20 to 0–100 ft (0–6 to 0–30 m) ranges and with 4- to 20-mA DC output signals, and they are suited for process temperatures between 25 and 225°F (–4 and 107°C). They can provide level measurement accuracies (assuming constant specific gravity) of 0.5% of full-scale reading.

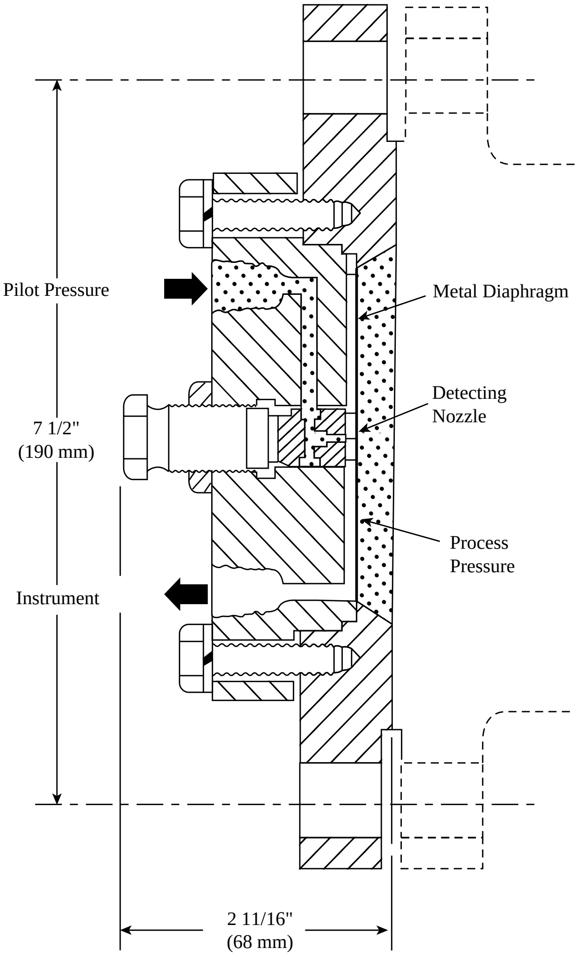

FIG. 3.5e
Pressure repeater for mounting on 4-in. (200-mm) tank nozzles. (Courtesy of Siemens Energy and Automation.)

Diaphragm-type electronic transmitters can also be submersed to detect levels in wells or in open water bodies. They are available with ranges up to 700 ft (213 m) and can be connected by cable to their readout instruments. Accessories generally supplied for these lake and well installations include digital readouts with a variety of packaging types, battery/solar cell power packs, power supplies for various line power voltages, multiple high- and low-level current relays, and optional analog (4- to 20-mA DC) or digital (RS-232, HART, Honeywell protocols) outputs.

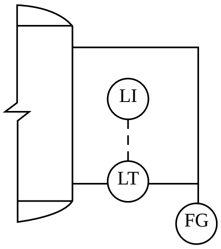
3.6 Differential Pressure Level Detectors

B. G. LIPTÁK (1969) **D. S. KAYSER** (1982) **J. A. NAY** (1995, 2003)



Flow Sheet Symbol

Design Pressure	To 10,000 PSIG (69 MPa)
Design Temperature	To 350°F (175°C) for differential-pressure (d/p) cell and to 1200°F (650°C) for filled systems; others to 200°F (93°C); standard electronics generally limited to 140°F (60°C)
Range	Differential-pressure cells and indicators are available with full-scale ranges as low as 0 to 5 in. (0 to 12 cm) H_2O. The higher ranges are limited only by physical tank size, since d/p cells are available with ranges over 433 ft H_2O (7 MPa or 134 m H_2O).
Inaccuracy	±0.5% to 2% of full scale for indicators and switches. For d/p transmitters, the basic error is from ±0.1% to 0.5% of the actual span. Added to this are the temperature and pressure effects on the span and zero. In case of "intelligent" transmitters, the pressure and temperature correction is automatic, and the overall error is ±0.1% to 0.2% of span with analog outputs and may approach ±0.01% with digital outputs.
Materials of Construction	Plastics, brass, steel, stainless steel, Monel®, and special alloys for the wetted parts. Enclosures and housings are available in aluminum, steel, stainless steel, and fiberglass composites, with aluminum and fiberglass being most readily available.
Cost	$200 to $1500 for transmitters in standard construction; $50 to $500 for local indicators. Add $400 to $1000 each for extended diaphragms and up to $1000 for "smart" features such as communications and digital calibration, although many "smart" features may be included in the base price. "Expert" tank systems cost approximately $1500 for each basic transmitter plus $3500 to $4500 each for one or more interface units and $1500 to $4000 for software plus a hand-held communicator and/or permanent connection to an in-house network. Some "expert" functions may be incorporated in an in-house network.
Partial List of Suppliers	See also Sections 5.6 and 5.7. Any d/p cell may be installed and connected to measure level if it has the appropriate accuracy and rangeability. Similarly, for vented tanks, any suitable gauge pressure device may be adapted to measure level. ABB Instrumentation Inc. For a general treatment of differential pressure devices, refer to Section 5.6. For a discussion of electronic pressure and differential pressure instruments, refer to Section 5.7.

Liquid level can be measured (inferred) by measuring a differential pressure (d/p) caused by the weight of the fluid column in a vessel balanced against a reference. For vessels at atmospheric pressure, the high side of the instrument is connected to the bottom of the vessel, and the low side (reference) is vented to the atmosphere. This method of level measurement is often referred to as *hydrostatic tank gauging*

(HTG), especially in the bulk liquid industries. For pressurized vessels, the reference side must also be connected to the vessel so that both sides of the instrument equally sense the static pressure changes within the vessel and their differential responds only to the d/p caused by fluid head. The reference can be a column of fluid of fixed height such as a liquid-filled reference leg outside the tank or, as in the case of a bubbler system, a gas-filled reference leg, usually inside the tank. The key requirement is that the reference leg provide (or represent) a constant, known, hydrostatic head. An increase in the tank level from empty (0% level) to full (100% level) can result in a readout of 0 to 100% d/p (direct acting) or in a readout of 100 to 0% d/p (reverse acting). To obtain an accurate measurement using d/p cells, the densities of the process liquid and of the reference leg must be known and either be constant or continuously considered.

SENSING DIFFERENTIAL PRESSURE

Differential pressure can be detected by sensing two pressures separately and taking the difference to obtain liquid level. In practice, however, it is generally desirable to use a single pressure-difference sensor so that the static pressure levels are balanced before any measurement errors are introduced. The importance of this consideration can be visualized, for example, on a 0- to 100-in. (0- to 2.5-m) water column (WC) measurement where the expected accuracy is ±0.5 in. (±13 mm) WC. It would be virtually impossible to approach this accuracy if the measurements were made at a static pressure of 1000 PSIG (7 MPa) using two independent sensors. Since 1000 PSI (7 MPa) is equivalent to about 28,000 in. (714,000 mm) WC, the required accuracy of each measurement would be ±0.25 in./28,000 in., or 0.0009% (7 mm/714,000 mm). Nevertheless, several highly accurate HTGs do use two or more transmitters for gauging tanks at atmospheric pressures (Figure 3.6e). For instance, a third transmitter located a fixed distance above the bottom transmitter can be used to sense, in real time, the difference in pressure caused by the density of the fluid. Its sensing line to the tank must always be submerged and full to ensure accurate readings. However, when the tank is being initially filled or completely emptied, a temperature measurement in the fluid may be used to calculate an estimate of density or to help extrapolate from earlier density measurement records.

Extended Diaphragms

The d/p cell can be modified for use on viscous, slurry, or other plugging applications. Figure 3.6a shows two such designs: the extended and the flat diaphragm d/p cell transmitters. Their principles of operation are the same as those of the conventional d/p cells, except that the high-pressure side of the diaphragm capsule is exposed and extended to be in direct contact with the process. The extended diaphragm version is designed to bolt directly to the vessel nozzle; the protrusion can be sized to fill the space in the nozzle, placing the diaphragm flush with or slightly inside of the vessel wall. This design completely eliminates dead-ended cavities and is used especially on materials that can freeze at high temperatures or that can deteriorate or discolor if pocketed. This design cannot be serviced without depressurizing and draining the vessel.

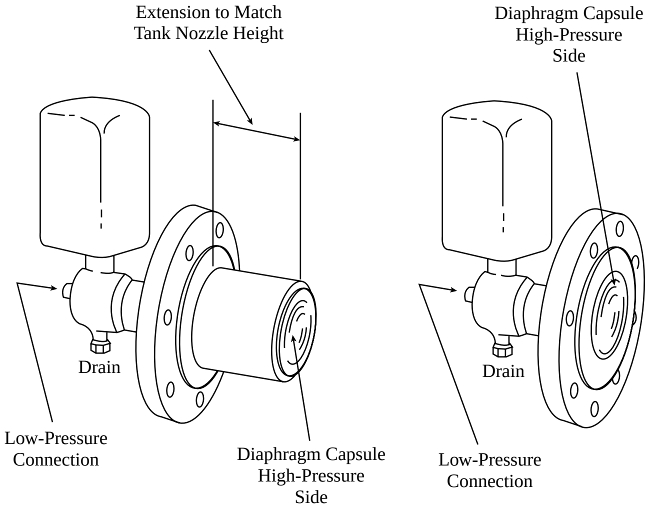

FIG. 3.6a
Extended diaphragm d/p cell (left); flat diaphragm d/p cell.

The flat diaphragm design is normally installed by bolting it directly to a block valve on the vessel nozzle. A full-size gate or ball valve can allow for service without draining or depressurizing the tank. Because the connection is large, typically 3 in. (76 mm), the process is less apt to bridge or plug the sensing connection. Flat diaphragm cells can also be furnished with a solvent flush or steam-out connection. Both the flat and the extended designs are available with ranges up to 850 in. (2160 mm) with an accuracy of ±0.5% of span. The flat units can withstand 550 PSIG (3.8 MPa) operating pressures when the process is at 350°F (175°C). The maximum process temperature rating for the extended design is 750°F (400°C). Changes in process or ambient temperatures can cause zero shifts, as is the case with many similarly designed instruments. To minimize this effect, the d/p cell should be zeroed at the normal operating temperature, and the exposed body of the transmitter should be insulated. Alternatively, temperature at the connection or within the transmitter may be measured and continuously accounted for in the computation of level.

Some suppliers offer the extended and flat diaphragms with Teflon®, Viton®, or other plastic coating. This coating is intended as a slippery surface to minimize material buildup on the diaphragm. Do not rely on the plastic coatings for corrosion protection unless the supplier states specifically that the coating is so designed. As a general rule, engineers should not rely on coatings for corrosion protection of wetted parts of most process instruments, because, if the coating is nicked during installation, that protection is destroyed.

Chemical Seals

Transmitters may also be provided with liquid-filled extension elements (chemical seals). The units shown in Figure 3.6a are used on atmospheric tanks or on pressurized tanks if the low-side connection can be kept clean or sealed. The designs shown in Figures 3.6b and 3.6c are used on pressurized vessels where plugging or corrosion can occur on both the high- and the low-pressure sides. The chemical seal designs are available in a broad range of materials including such metals as tantalum and zirconium. Vessel connection considerations apply to both the high and the low side. As can be seen from Figure 3.6c, the process material contacts both the diaphragm and the process side of the flange.

The instrument side of the diaphragm is filled with an oil or other suitable fluid (sometimes including water) and is connected by capillary to the high and low sides of the d/p cell. The differential pressure capabilities of these systems depend on the d/p cell selected. The accuracy of the system will always be worse than the accuracy of the d/p cell itself.

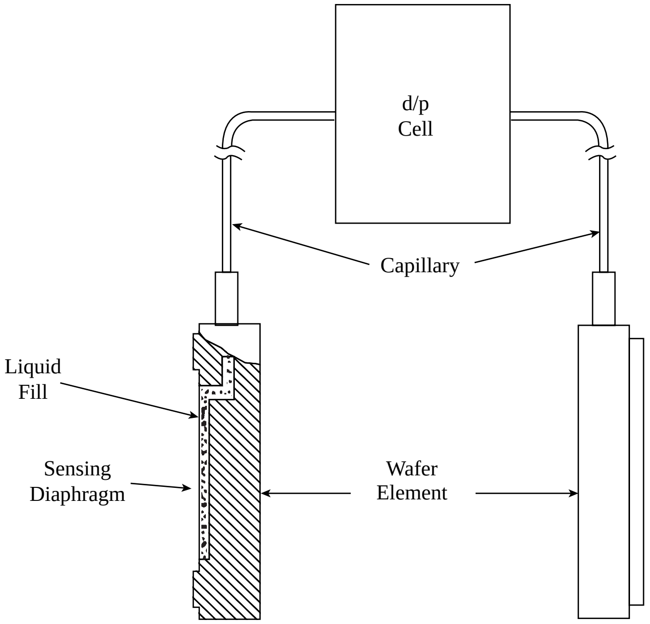

FIG. 3.6b
d/p cell with wafer elements.

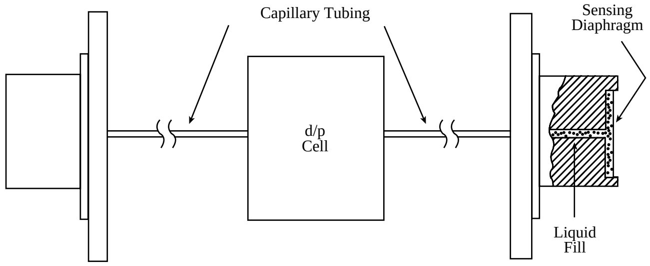

FIG. 3.6c
d/p cell with extended chemical seal elements.

The spring constant of the diaphragms at the chemical seals and the elasticity of the fill fluid will introduce some error, not all of which can be fully compensated. This error becomes more pronounced at very small differential pressure ranges and at high static pressures. A larger and less predictable error can result from the temperature-sensitive nature of the seal and capillary system. Temperature differences between the low and high sides will cause differing amounts of thermal expansion; this will be sensed by the d/p cell as a differential pressure and interpreted as a level change. Because the unequal amounts of expansion can be caused by the process temperatures or by changes in the ambient conditions, it is not always possible to zero-out this error.

The pressure and temperature ratings for these filled systems depend on seal design and filling liquid. Seals are readily available that are rated to 1500 PSIG (10 MPa). The fill material is normally a silicone oil that is good to 450°F (232°C). Other fill materials raise temperature ratings to 1200°F (650°C), allowing chemical seal designs to be considered for high-temperature applications. The volume of fluid in the seal, capillary, and d/p cell housing may be significant. Process, environmental, or health sensitivity to accidental leakage of the fill fluid may restrict choices. Distilled water has been successfully used as a fill fluid in some cases.

INTELLIGENT D/P CELLS AND TANK EXPERT SYSTEMS

The microprocessor has extended the applications of electronic differential-pressure transmitters. The detection is still accomplished by use of the elastic element (diaphragm or bellows), although the actual elastic element may be very small. The elastic element may actually have some of the electronic and microprocessor circuits attached to, embedded in, or otherwise incorporated directly. The microprocessor can convert the analog readings of deflection to a linearized, high-resolution digital signal compensated for temperature effects. Transmitter stability is thus improved, and the time between physical calibrations is often extended to more than a year.

"Smart" level transmitters can convert the level readings of spherical or cylindrical tanks into actual volume percentage readings (Figure 3.6d). Intelligent transmitters have also been

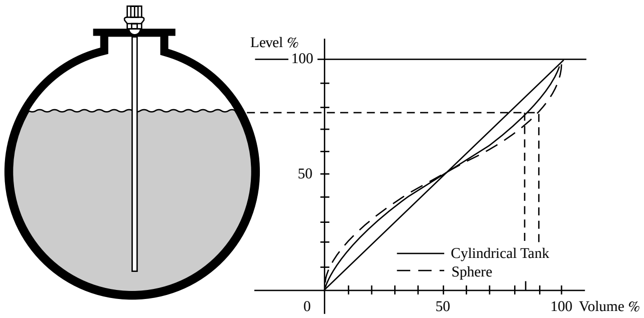

FIG. 3.6d
Intelligent transmitters can automatically convert level readings into volume.

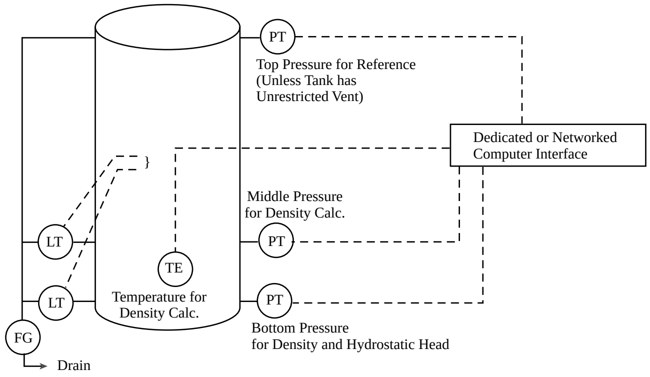

FIG. 3.6e
Multiple transmitters to provide level, mass, volume, and density data.

combined into tank expert packages that, in addition to level, can also calculate mass, density, and volume based on the measurements from three or more d/p cells and one temperature transmitter as shown in Figure 3.6e. Outputs are available through digital RS485 and RS232 connections and may be networked digitally for multiple remote access to the data. Most manufacturers offer optional digital communication with the transmitter through the output signal wires coincident with the analog output signal. Wireless Ethernet local area networking per IEEE-802b and other wireless technologies is also available. Calibration, range and zero setting, elevation, suppression, and linearization may all be accomplished remotely, although periodic physical calibration to a known NIST traceable standard is still recommended for the most accurate results.

In Figure 3.6e, the "TOP" pressure transmitter can be eliminated if the tank is completely vented without any possible vent restrictions. Simple problems, such as a bird's nest in a vent pipe, may cause unexpected and possibly undetected errors. This is a particular concern under transient conditions where the restricted vent does not allow enough flow to keep up with filling or draining operations. If the top transmitter is eliminated, it may be prudent to install a very low-pressure detector to alert operators of unexpected pressure or vacuum conditions. A better solution would be to use differential-pressure level transmitters (LTs) for the middle and bottom locations as shown on the left in Figure 3.6e. In this case, they should share a common dry reference leg.

The bottom and middle transmitters, whether pressure or differential pressure, must be placed a known vertical distance apart. Because horizontal distance does not matter, on large tanks, it would facilitate maintenance if each were placed within reach of stairways, ladders, or platforms existing at the appropriate levels. Density is determined by the difference in readings between the middle and bottom transmitters. For instance, if the transmitters were placed 50 in. (125 mm) apart, and if the tank contains distilled water at 68°F (20°C), the bottom transmitter should read exactly 50 in. (125 mm) of water more than the middle transmitter. If the tank contained an oil with a specific gravity of 0.75, then the difference in readings would be 37.5 in. (93.75 mm) of water. Anything that changes the density, including bulk temperature changes and chemical composition changes, will be reflected in the difference in readings between the middle and bottom transmitters. Thus, the density can always be calculated.

A temperature reading may be useful as a diverse measurement to verifying expected density or to assist in estimating or extrapolating density as the tank is initially filled or as it is emptied below the middle transmitter.

PRESSURE REPEATERS

When detecting the level in pressurized vessels, the vapor space pressure must be connected to the low side of the d/p cell to serve as a reference. On hard-to-handle materials, a one-to-one pressure repeater may be used to provide this reference and simultaneously isolate the d/p cell from the process. Repeaters develop an air output pressure equal to the vapor-space pressure. They are inexpensive, but their accuracy is limited. The error in the repeated output pressure increases as the repeated pressure rises. At a pressure level of 40 PSIG (0.27 MPa), the error is 2 in. (51 mm) H_2O; at a pressure level of 400 PSIG (2.7 MPa), the error is 20 in. (508 mm) H_2O. Obviously, errors of this magnitude are not acceptable for most process level measurements. Repeaters have generally fallen into disuse in favor of high-accuracy digital transmitters made from the same materials.

DRY, MOTION BALANCE DEVICES

These differential pressure detectors are also referred to as *bellows meters*, because they depend on liquid-filled, double-opposed bellows. Bellows meters are most useful where local indication or recording is required and where compressed air and electric power are not available as energy sources. They can be very sensitive to low differential pressures because of the large area and slack resistance to motion that can be built in.

Figure 3.6f illustrates the high- and low-pressure chambers, the range spring, and the drive assembly (a bell crank of sorts) to transfer bellows motion to the readout pointer. The bellows in both chambers and the passage between them are liquid filled. When the unit is installed, the pressure in the high-pressure chamber compresses the bellows so that the liquid flows from it into the low-side bellows. When the low-pressure (or range) bellows expands, it exerts a force against the range spring, which determines the span of the instrument. The linear motion of the range bellows moves the drive lever, mechanically transmitting a rotary motion through the sealed torque tube assembly to the indicator. The output motion from the torque tube assembly is limited to a few degrees of angular rotation. This is sufficient for most

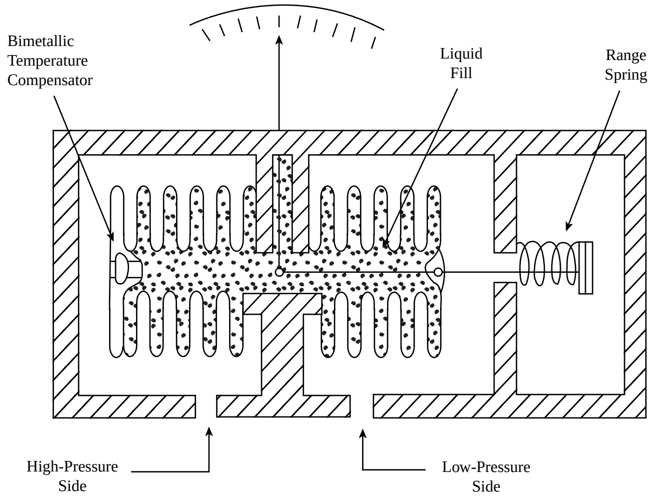

FIG. 3.6f
Motion detector d/p indicator.

mechanically driven local indicators or recorders and well within the capabilities of modern electronic motion sensors.

If the secondary device imposes a considerable load on the torque tube assembly, however, the accuracy and sensitivity of the unit can be destroyed. For sustained accuracy, bellows meters depend on the repeatability of their mechanical systems, which have proven to be linear within 0.5% to 1% of full range, and down to 0.2% or less when the range can be limited to a small portion of the total available motion. A temperature compensator built into the bellows assembly compensates for the changing volume of the fill liquid resulting from ambient temperature variations. Bellows meters are provided with overrange protection. The operation of one of the protection mechanisms is as follows: The bellows move in proportion to the differential pressure applied across them and in proportion to the spring rate of the bellows plus the resisting springs. When the bellows have moved over their calibrated travel, a valve mounted on the center stem seals against its seat, thereby trapping the fill liquid in the bellows. Because the liquid is essentially incompressible, the bellows are fully supported and will not rupture, regardless of the pressure applied. This overrange protection is furnished in both directions, protecting both bellows. Another design of overrange protectors involves the use of liquid-filled bellows with a number of diaphragm discs and spacer rings between them. As the bellows are subjected to overrange pressures, the diaphragms nest, and the metallic spacer rings form a solid stop, thereby fully protecting the bellows from rupture.

Bellows meters can detect full-range pressure differentials at least as low as 20 in. (508 mm) WC and as high as 400 PSIG (2.7 MPa). Measurement of low differentials is limited by the small forces available to actuate the motion detector mechanism. For very high differentials, the limitation is the mechanical strength of the bellows. Standard units are available with steel or stainless-steel housings and stainless-steel or beryllium copper bellows. For corrosive applications, other materials can be obtained or special, high-displacement-volume chemical seals can be used. Static pressure ratings up to 10,000 PSIG (69 MPa) are available as standard; operating temperature is limited to 200°F (93°C).

LIQUID MANOMETERS

These instruments are discussed in detail in Section 5.9. Their design variations include the U-tube, the well, and the float-type manometers. The float designs can provide remote readouts, whereas regular manometers can serve as the readout indicators for bubbler-type level sensors. Where the use of glass is not allowed, digital manometers using magnetic coupling between a float inside a stainless-steel U-tube manometer, and an outside electronic transmitting mechanism can be used.

Glass-tube manometers are available with ranges up to 120 in. (3.05 m), which is sufficient for many level applications. The magnetically coupled float manometers are available for high-pressure services, up to 6000 PSIG (41 MPa), and can measure up to 1000 in. (25 m) of water column.

Because of the fragile nature of glass, the toxicity of mercury, and the chemical interaction between the manometer filling fluids and the process, manometers are not widely used on process level measurement applications and are mostly restricted in their use to occasional utility services.

LEVEL APPLICATIONS OF D/P CELLS

The applications of pressure differential detectors as components in level-measurement loops will be covered in the following paragraphs. The requirements of atmospheric and pressurized tanks and the features of level loops on clean and hard-to-handle process fluids will be discussed separately. Figure 3.6g shows the symbols used for the

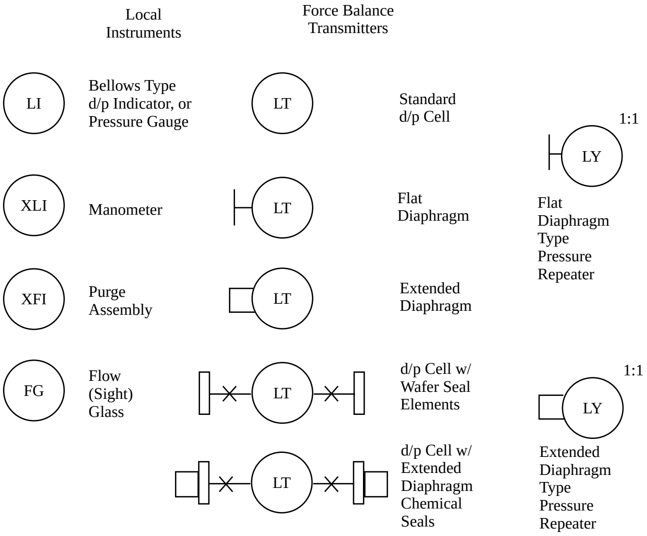

FIG. 3.6g
Symbols for d/p level loops.

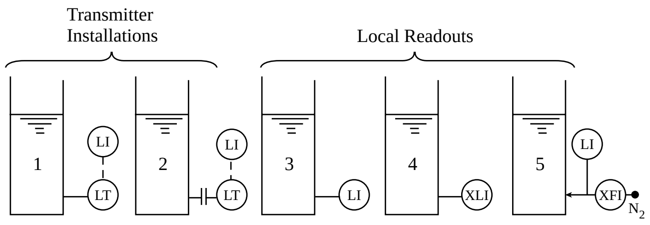

FIG. 3.6h

Detection of clean liquid levels in atmospheric tanks by d/p instruments.

various loop components. In the discussion that follows, the air-bubbler-type d/p cell installations will not be included, as these are covered in Section 3.2.

Clean Liquids in Atmospheric Tanks

Unpressurized vessels containing clean liquids are the least demanding as far as level measurement is concerned, because the two most common sources of difficulties (vapor pressure compensation and plugging) are not present. Figure 3.6h shows five tanks equipped with five different types of level devices. The first two are for remote readout, and the others are for local readout. On tank 1, a standard d/p transmitter with screwed connections is shown with its low-pressure side open to the atmosphere. This installation can be made by using a pressure transmitter instead of a d/p transmitter. The pneumatic receiver gauge is normally calibrated for 0 to 100% level. The flat diaphragm-type d/p transmitter is shown on tank 2. Compared to the standard d/p cell, the flat diaphragm-type transmitter is simpler to install, and it is nozzle mounted, requiring no other means of support. It also can be less expensive, because only the diaphragm and the retaining ring are in contact with the process. As a result, only these parts must be made of corrosion-resistant materials whereas, in the standard d/p cell, the entire body is exposed to the process fluids. A flat diaphragm-type pressure repeater can also be used in place of the d/p transmitter, in which case the receiver gauge will sense the actual hydraulic head instead of a 3 to 15 PSIG (21 to 103 kPa) transmitted signal. Tank 3 shows a motion balance local d/p indicator with the low-pressure side vented to atmosphere. The same measurement can be made by using a standard pressure gauge. The level in tank 4 is detected by a manometer. Although this is one of the most accurate and economical devices to use for local readout, the consequences of mechanical damage and proper selection of the filling liquid must be considered. The installation on tank 5 is basically an air bubbler system, which is detailed in Section 3.2. Not shown is a system (usually portable) wherein a miniaturized electronic transmitter is actually lowered, by a cable containing its wiring, into an atmospheric tank and down through the liquid until it reaches the bottom. The operator can tell that it is on the bottom when the level indication stops increasing. This is particularly useful for occasional tank gauging and for measuring the level in wells.

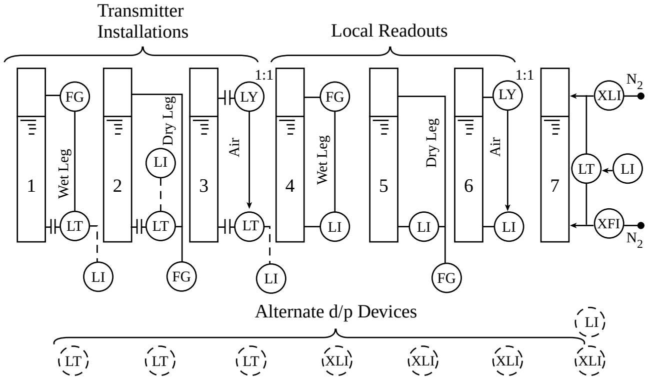

FIG. 3.6i

Measurement of clean liquid levels in pressurized tanks by d/p instruments.

Clean Liquids in Pressurized Tanks

When the level in a pressurized vessel is to be established by hydraulic head measurement, the instrument has to be compensated for the vapor pressure in the tank. This is done by exposing the low-pressure side of the d/p cell to these vapor pressures. Compensation can be achieved by various means. Figure 3.6i shows seven variations of this installation. Tank 1 illustrates a wet-leg application in which the compensating leg is prefilled with a chemically inert liquid that will not freeze or vaporize under operating temperature conditions. The wet-leg installations are used when the process vapors would otherwise condense into the compensating leg, thereby exposing the low-pressure side of the d/p cell to unpredictable hydraulic heads, or when the transmitter must be sealed from corrosive vapors. The prefilled wet leg creates a constant pressure on the low-pressure side of the transmitter. The leg is filled through a seal pot to provide excess capacity.

It is desirable to make this seal pot out of a sight flow indicator so that the level of the filling liquid is visible to the operator. The d/p cell can be either the standard or the flat diaphragm design. On tank 2, the same d/p transmitter is installed in a dry-leg system. This is acceptable when the process vapors are not corrosive and condensation at ambient temperatures is not expected. For such applications, a condensate pot is installed below the d/p cell, and it also should incorporate a sight flow indicator so that the operator can visually determine if it is time to drain out any accumulation of condensate. Tank 3 illustrates the use of a flat diaphragm pressure repeater for vapor pressure compensation. The problems associated with range depressor adjustments, corrosion, and condensate accumulation are eliminated by the use of repeaters, but they do add to the total error of the installation. On tanks 4, 5, and 6, the same basic installations (wet-leg, dry-leg, and repeater) are shown in connection with local bellows indicators. Manometers can also be considered in place of the motion balance d/p indicators if mechanical damage, chemical inertness of the filling fluid, and its compatibility with the operating temperatures are previously established. One concern with

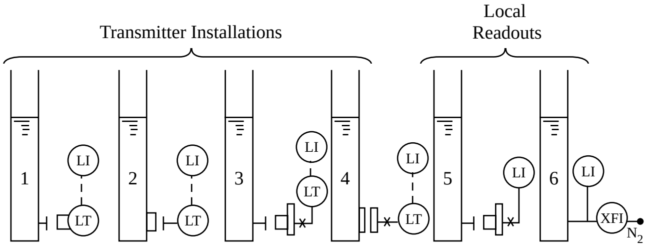

FIG. 3.6j
Sensing of hard-to-handle liquid levels in atmospheric tanks by d/p devices.

the dry-leg installation shown in tank 5 is the possibility that, if the vapors in the tank condense, or if the tank is flooded, process liquids will fill the dry leg. This is unsafe because, under these conditions, the d/p cell will signal a low level or an empty tank condition. The installation of a float trap can lower (but not eliminate) this risk by draining the dry leg if the liquid buildup is slow. Tank 7 illustrates a bubbler system with either transmitting or local indicating d/p devices. The advantages, limitations, and drawbacks of such installations have been pointed out in Section 3.2.

Hard-to-Handle Fluids in Atmospheric Tanks

Level measurement is more difficult when the process fluid is highly viscous, is likely to freeze, contains solids that can settle out, or can gel or polymerize in dead-ended cavities. Figure 3.6j shows six installations that may be considered for these conditions. On tank 1, an extended diaphragm-type force balance transmitter is shown. The diaphragm motion is limited to a few thousandths of an inch, and the nozzle cavity is completely filled by the diaphragm extension. The extended diaphragm transmitter is a good candidate for level measurement of hard-to-handle liquids, provided that the vessel can be drained when the transmitter needs service. Tank 2 is provided with a flat diaphragm transmitter mounted on a pad. The nozzle cavity is reduced but not eliminated. Tank 3 is furnished with liquid-filled chemical seals such as the one shown in Figure 3.6c. This unit will perform as well as the extended diaphragm d/p cell but, because of the liquid-filled capillary system, it is subject to errors caused by temperature variations. A wafer-type, liquid-filled element such as the one illustrated in Figure 3.6b is shown on tank 4. This sensing method combines the disadvantages of 2 and 3; the dead-ended cavity is not eliminated, and it is subject to temperature errors. However, it can be used on extremely hot processes. On tank 5, the element is the same extended chemical seal as on tank 3, but the readout is a local pressure gauge. An air bubbler is shown on tank 6.

Hard-to-Handle Fluids in Pressurized Tanks

When the process material in the vessel is hard to handle, it is frequently the case that the vapor space also contains materials such as foam that can build up and plug the sensing line of the compensating leg. Figure 3.6k shows six methods for dealing with these applications. Tank 1 shows an extended d/p transmitter in the liquid region and an extended repeater in the vapor space. The use of these devices eliminates all possible plugging problems, because the sensing diaphragms are flush with the inside of the vessel wall. This detecting system will function properly on all except the most difficult crystallizer applications, where the inside wall of the tank might be coated with a layer of crystals.

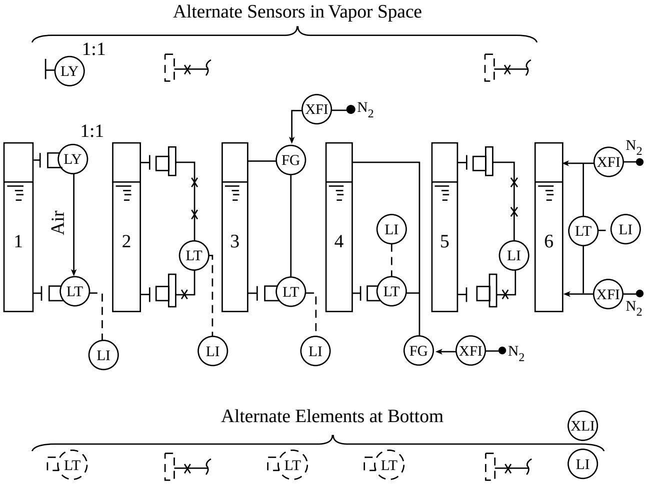

FIG. 3.6k
Detection of hard-to-handle liquid levels in pressurized tanks by d/p instruments.

The extended chemical seals shown on tank 2 will provide an installation similar to that on tank 1 and will perform similarly if temperature differences between the wafers or ambient temperature variations do not cause inaccuracies. Tanks 3 and 4 are equipped with extended d/p transmitters, but a purge flow prevents the process vapors from entering the compensating legs. The purge medium can be either liquid or gas and can be applied to both dry- and wet-leg installations. Such systems require additional maintenance and range depressor adjustments, and corrosion or condensate accumulation can cause calibration or reliability problems. Tank 5 shows a local indicator equipped with extended chemical seals. This device is subject to temperature effects and requires large displacement seals to match the displacement of the d/p indicator. For tanks 1 through 5, flat diaphragm elements can also be considered, but it should be realized that they do not completely eliminate the dead-ended nozzle cavities in which material can accumulate. Such designs should be considered only where it is essential to have an isolating valve between the tank and the level device so that it will not have to be drained prior to removal of the instrument. The bubbler system is illustrated on tank 6; either liquids or gases can be used as the purge media.

The extended diaphragm transmitter/repeater installation is attractive for pressure vessels containing hard-to-handle materials if isolation valves are not required. Purged installations are also acceptable if the availability of a purge media and maintenance are both reliable and if the process can tolerate accumulation of the purge flow.

SPECIAL INSTALLATIONS

One variation that can be considered is to install the d/p cell in a "reverse" arrangement wherein the high-pressure side is connected to the wet leg. Naturally, this can be done only with nonextended units such as the ones used on tanks 1 and 4 in Figure 3.6i. If this is done, these transmitters will detect the maximum d/p when the tank is empty and the minimum d/p when it is full.

On hard-to-handle processes where extended diaphragms are used, a "reverse-acting" d/p cell can be used when one or both sides are protected by chemical seals (such as in tanks 2 and 5 in Figure 3.6k) and the d/p is located near the bottom of the tank. In these cases, the high-pressure side of the d/p cell can be connected to the chemical seal element at the top of the tank. In that case, the maximum reading of the d/p cell occurs when the tank is empty.

Boiling Applications

Reverse-acting differential pressure level transmitters can be used on boiler or steam drum level applications (Figure 3.6l) where the wet leg is the high-pressure side of the process. When the process fluid condenses into a liquid at ambient temperatures, a wet-leg configuration can be obtained by allowing the condensate to accumulate in the wet leg rather than mechanically filling the wet leg with a slow drip. This can be achieved by installing an uninsulated condensate pot that remains at ambient temperature. Excess condensation from this pot drains back into the tank and therefore maintains a constant height of the reference wet leg.

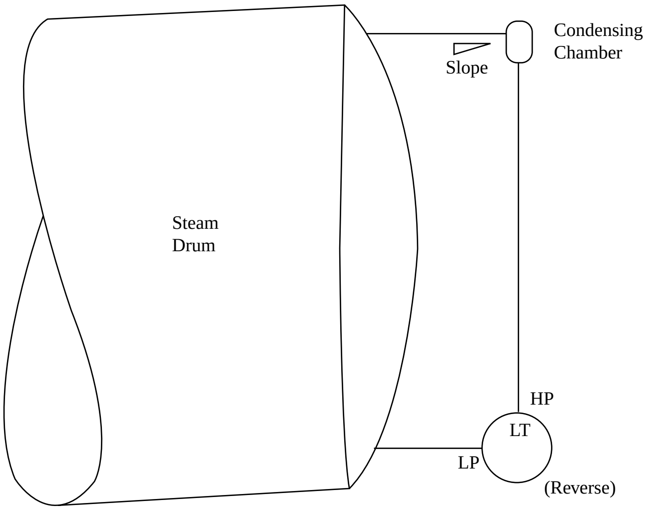

FIG. 3.6l
Level measurement in steam drums or on other boiling liquid applications.

One should understand that the output signal of such a d/p cell relates *not to the level inside the steam drum* but to the mass of water inside. If the condensate in the wet leg is cold, the wet-leg density will be substantially greater than that of the boiling fluid inside the drum. In addition, the density inside the drum will be a variable; density will drop as a result of the swelling effect when the steaming rate rises, and it will rise when the steaming rate drops. A level control system that adds colder feedwater to a steaming drum may result in bubble collapse such that the actual level decreases even further. The exact position of the *top surface* of the boiling fluid may never be determined. A large *void fraction* will result in a higher surface position without necessarily changing the differential pressure. A "full" tank or drum will not produce zero differential pressure under those conditions. Therefore, the d/p cell output can be converted into a true level reading only if the density and void fraction of the boiling fluid are separately accounted for using other available parameters, such as steaming rate, bulk fluid temperature, and/or discharge pressure (equivalent to temperature for saturated conditions). These are *very* important considerations when determining safety system setpoints. The shrinkage that may be caused by cold feedwater or a sudden reduction in steaming rate must be accounted for to avoid uncovering hot tubes. The swell that may be caused by an increasing demand transient must be accounted for to avoid liquid carryover. Nevertheless, differential pressure remains a popular method of measuring and controlling level in boiling vessels. Many safe and effective installations exist throughout industry, including many on nuclear and fossil-fueled boilers and steam generators in the power industry.

Cryogenic Applications

A similar situation exists when the process liquid is very cold, except that major bulk boiling rarely takes place within the vessel itself. The tank may be located inside high-thermal insulation, called a *cold box*. More often, it is located in a double-walled high-vacuum dewar tank (Figure 3.6m). These applications also involve boiling, but here the liquid nitrogen or other liquefied gas will, by design, boil primarily in external piping or heat exchangers. For sensing lines, this increase in temperature occurs as the liquid-filled pipe is approaching the wall of the cold box or nears the penetration point of the dewar. At some point in the sensing line, the liquid boils, causing a liquid–gas interface. From that point on, the sensing line is filled with vapor. To provide a stable and noise-free level signal, the installation should be such that the boiling will occur at a stable, well-defined point in the sensing line. Boiling should occur in a large-diameter, low-slope section of the sensing line as it approaches the penetration of the vessel outer wall. The line diameter should be large (1 in. or 25 mm), because the interface between the liquid and vapor can be turbulent during consumption transients. This low-slope section should approach the wall of the cold area so that the temperature will be high enough to guarantee

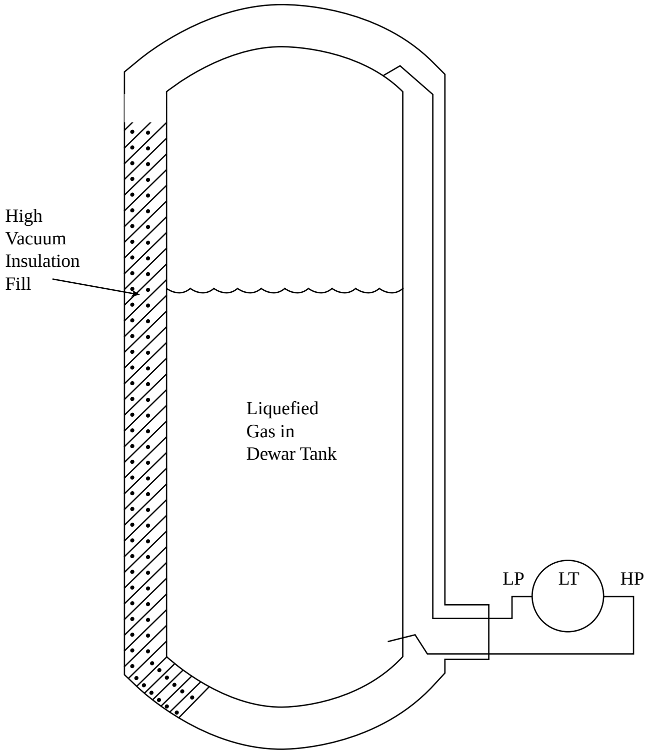

FIG. 3.6m
Cryogenic level measurement in vacuum-insulated tank.

that the process liquid is in the vapor form under all process and ambient conditions. To account for transient conditions that may temporarily move the interface point, a “dry” loop is often provided in the warmer portion of the sensing line so as to catch and quickly evaporate any temporary liquid carryover.

For most cryogenic level measurements, the density of gas in vertical sections of the sensing lines can safely be ignored. However, for argon (a very heavy gas), the effect should at least be calculated at limiting conditions to ensure that the weight will not exceed the desired accuracy of the measurement.

Normal Ambient Temperature Bi-phase Applications

Differential pressure may also be used for level measurement on large tanks containing gases such as refrigerants or propane under pressure, where a liquid–gas interface exists at normal ambient temperature. In these cases, a dry reference leg is suggested. A few watts of heat tracing along the dry reference leg will ensure that it remains a degree or two above ambient temperature (thus slightly superheated above saturation temperature) to avoid condensation of the gas. Care must be taken during fast filling operations to ensure that major condensation does not collect temporarily in the reference leg as a result of increasing pressure in the tank. Provision of a drip leg with a sight glass at the bottom of the reference leg is suggested.

TABLE 3.6n
D/P Cell Capsule Capabilities

	Low Range	*Medium Range*	*High Range*
Minimum span - in. H_2O	0–2	0–25	0–30 PSID
- kPa	0–0.5	0–6.2	0–210
Maximum span - in. H_2O	0–150	0–1000	0–3000 PSID
- kPa	0–37.5	0–250	0–207 bars
Maximum zero suppression	(maximum span) minus (calibrated span)		
Maximum zero elevation	Minimum span		

SPAN, ELEVATION, AND DEPRESSION

All d/p cells can be provided with zero, span, elevation, and depression adjustments, either mechanical or electronic. Table 3.6n shows some typical d/p cell ranges and the available elevation and suppression setting adjustments for each. Whenever the d/p is at an elevation other than the connecting nozzle on an atmospheric tank, the zero of the d/p cell needs to be elevated or depressed. It is important to realize that two zero reference points exist. One is the level in the tank that is considered to be zero (lower range value) when the tank is near empty. The other zero reference point is the point at which the d/p cell experiences a zero differential (zero value of the measured variable). The terms *elevation* and *depression* as used in this discussion refer to the zero experienced by the d/p cell (Figure 3.6o). This figure uses mechanical spring adjustments to physically illustrate the relationships. Equivalent electronic adjustments are available. In both cases, the overall available span must be wide enough to encompass the required adjustments. The tension in the elevation spring can be set to cancel out any initial pressure exerted on the high side of the diaphragm capsule. Similarly, the depression spring can be adjusted to compensate for initial forces on the low-pressure side of the d/p cell. The amount of depression setting is limited to the full range of the capsule, whereas the sum of elevation setting and span cannot exceed the full range of the cell. These settings are normally adjusted in the factory if sufficient data are furnished to the manufacturers. If the setting is changed in the field, it will affect the span of the transmitter.

Figure 3.6p shows a dry-leg d/p cell installation with the desired minimum and maximum liquid levels noted. The output of the transmitter will be zero when the level is at the minimum and 100% when it is at the predetermined maximum. The span (range) of the cell will be product of liquid density and the distance between minimum and maximum levels desired (X). The elevation spring will be set for the product of density times distance between the minimum level desired and the cell datum (Y). A reference leg is also shown on this sketch, which is convenient for checking the transmitter. Checking is done by temporarily isolating the cell from the tank and filling the reference leg with a known

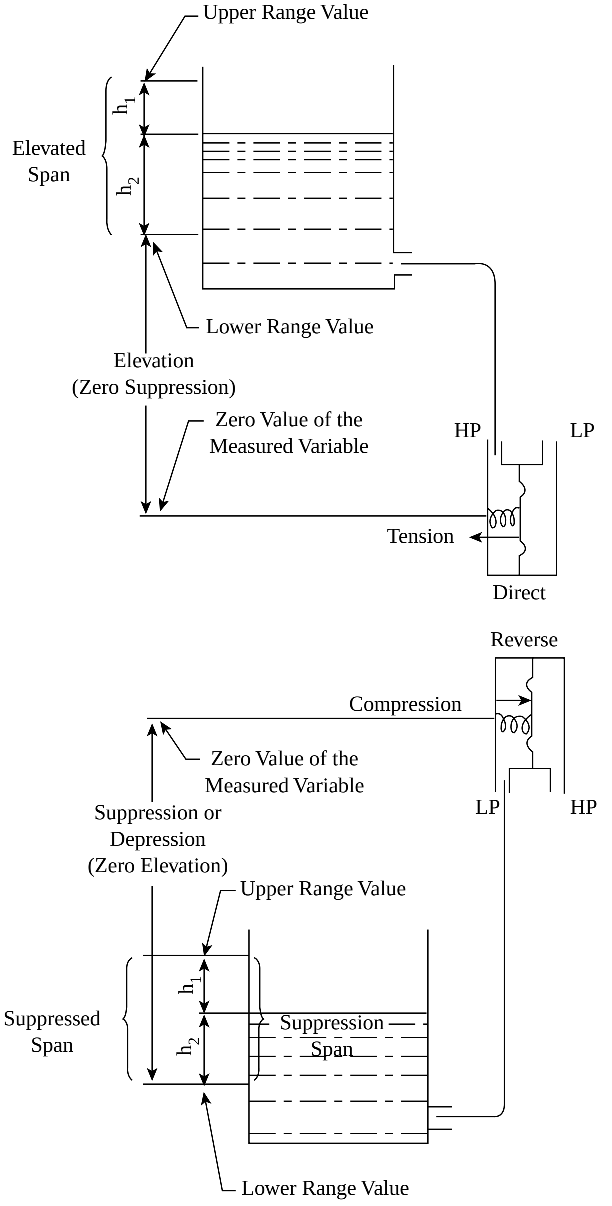

FIG. 3.6o
Illustration of elevation and depression in connection with d/p-type level measurement on atmospheric tanks.

gravity fluid. Once this figure is obtained, the repeatability of the unit can be checked periodically.

Figure 3.6q shows a wet-leg installation. Span is determined the same way as before ($X \times SG_1$). Range depression is calculated as the difference between the hydraulic head in the wet leg (ZSG_2) and the range elevation (YSG_1) desired. The difference between process and filling fluid densities must be selected such that the depression does not exceed the limit given in Table 3.6n. For example, if the desired minimum level is at the cell datum line ($Y = 0$), the difference between maximum and calibrated span is 200 in. (5 m) of water column, and the height of the wet leg is 100 in. (2.5 m), then the density of the filling liquid cannot be more than 2. The actual span setting of the cell can be anywhere below the full range.

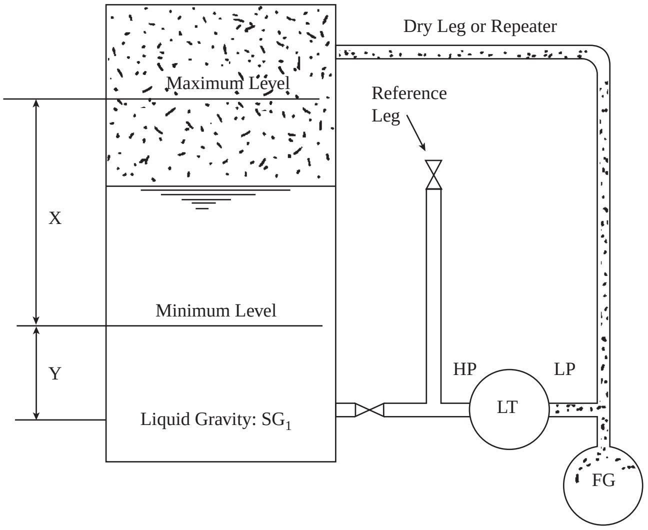

FIG. 3.6p
Illustration for range elevation; span = $X(SG_1)$ and elevation = $Y(SG_1)$.

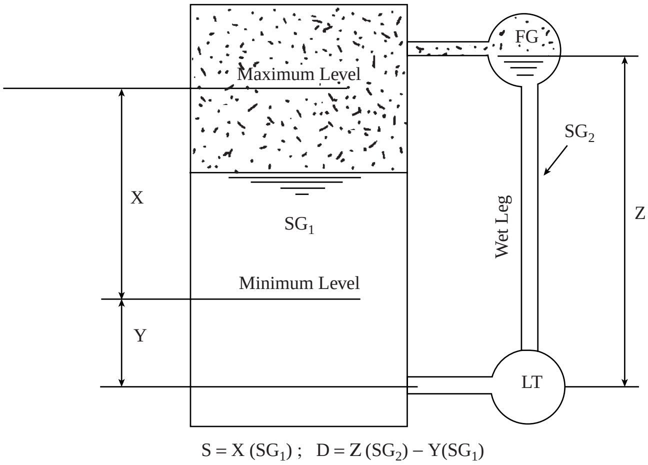

FIG. 3.6q
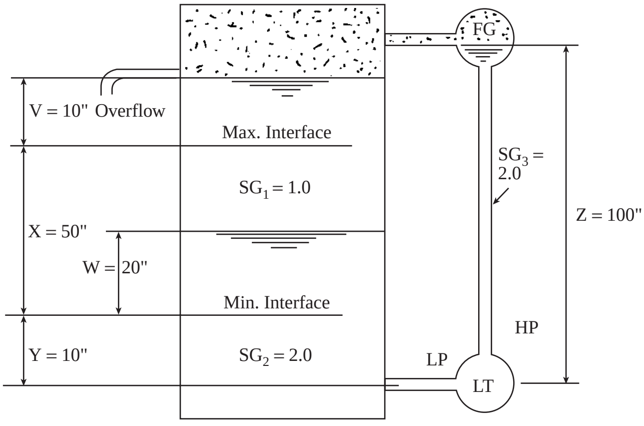
Illustration for range depression.

INTERFACE DETECTION

Figure 3.6r shows the settings for a liquid–liquid interface application. The span for this cell is the product of the density difference of the two liquids ($SG_2 - SG_1$) and the distance between the maximum and minimum interface levels (X). The range depression is the difference between the hydraulic head of the filling fluid ($Z \times SG_3$) and the sum of the range elevation ($Y \times SG_2$) plus the light liquid head over the range of minimum interface to overflow level ($[X + V] \times SG_1$). No depression is required if the minimum interface is at the cell datum, the height of the wet leg is the same as the maximum total level, and the filling fluid density (SG_3) is the same as the light liquid (SG_1). If the minimum interface is at the cell datum and a dry-leg system is used, then, instead of depression, the cell must



$$S = X(SG_2 - SG_1);\ \ D = Z(SG_3) - [Y(SG_2) + (X + V)SG_1]$$

FIG. 3.6r
Span and depression settings for interface detection.

be elevated by the hydraulic head of the light liquid over the range of cell datum to overflow level ($X + V \times SG_1$).

The following calculations, which are based on the data shown in Figure 3.6r, will serve as examples.

$$\text{Wet leg hydraulic head} = Z(SG_3) = 200 \text{ in. } H_2O \qquad \textbf{3.6(1)}$$

$$\text{Process side hydraulic head at minimum interface} = (V + X)SG_1 + Y(SG_2) = 80 \text{ in. } H_2O \qquad \textbf{3.6(2)}$$

$$\text{Process side hydraulic head at maximum interface} = V(SG_1) + (X + Y)SG_2 = 130 \text{ in. } H_2O \qquad \textbf{3.6(3)}$$

$$\text{Transmitter span} = X(SG_1 - SG_2) = 50 \text{ in. } H_2O \qquad \textbf{3.6(4)}$$

$$\text{Range depression} = Z(SG_3) - [Y(SG_2) + (X + V)SG_1] = 120 \text{ in. } H_2O \qquad \textbf{3.6(5)}$$

To determine the correct output signal from the transmitter at any known interface level, the proper result is simply the percentage of the transmitter span represented by the known level. If *W* is the known level, then 20 in. represents 40% of the 50-in. span. For a 3- to 15-PSI output, this will be 40% of 12 (= 4.8) plus 3 PSI for the "live zero," giving a final answer of 7.8 PSIG. Similarly, for a 4- to 20-mA output, the result will be 40% of 16 (= 6.4) plus 4 mA for the "live zero," to give a final answer of 10.4 mA.

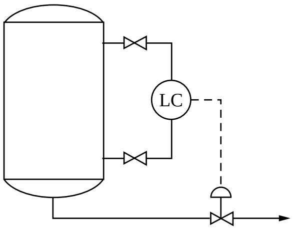
3.7 Displacer Level Devices

D. S. KAYSER (1982) **B. G. LIPTÁK** (1969, 1995)
C. G. LANGFORD (2003)



Flow Sheet Symbol

Design Pressure	Set by the flange rating of the chamber or by the maximum working pressure of the displacer, usually up to 100 PSIG (7 bars, 0.7 MPa) for the flexible disc and up to 600 PSIG (41 bars, 4.1 MPa) for the diaphragm-sealed designs. The flexible shaft unit can operate up to 1000 PSIG (69 bars, 6.9 MPa); torque-tube designs are available up to 2500 PSIG (170 bars, 17 MPa); magnetically coupled units can be used up to 6100 PSIG (410 bars, 41 MPa). Verify ratings with the manufacturer.
Design Temperature	Generally in the range of –50 to 451°F (–45 to 230°C). Inconel® torque tubes can operate from –350 to 850°F (–212 to 454°C). For electronic transmitters, the temperature of the topworks must be kept below 180°F (82°C). If the process temperature is above 500°F (260°C) or below 0°F (–18°C), thermal insulation barriers or torque-tube extensions are usually recommended.
Materials of Construction	Displacers are available in type 316 stainless steel, Monel®, polypropylene, or solid Teflon®. The hanger cable assemblies can be obtained in type 316 stainless steel, Monel®, and Hastelloy® C. The cage (chamber) is usually carbon or stainless steel.
Inaccuracy	Varies widely with application and the instrument, typically 0.5% of full scale.
Range	Standard displacers are available in lengths of 14 to 60 in. (0.35 to 1.5 m). The range of special units can go up to 60 ft (18 m).
Cost	Displacer-type switches cost from $200 to $500, and a 32-in. (0.81-m) electronic transmitter costs about $2500; add $500 to $700 for an external steel chamber.

INTRODUCTION

Archimedes' (c. 290 to 212 BC) principle states that a body wholly or partially immersed in a fluid is buoyed up by a force equal to the weight of the fluid displaced. A level or a density instrument is sensitive to the apparent weight of an immersed displacer. If the cross-sectional area of the displacer and the density of the liquid are constant, then a unit change in level will result in a reproducible unit change in the apparent weight of the displacer. The simplest level device of this type involves a displacer that is heavier than the process liquid and is suspended from a spring scale. When the liquid level is below the displacer, the scale shows the full weight of the displacer. As the level rises, the apparent weight of the displacer decreases, thereby yielding a linear and proportional relationship between spring tension and level. The spring scale can be calibrated as desired.

This simple device is limited to applications in open tanks. In practical industrial service, the basic problem is to seal the process from the spring scale or other force-detecting mechanism. This seal has to be frictionless and useful over a wide range of pressures, temperatures, and corrosion conditions. The variations in the design of this seal provide the basis to distinguish the types of displacement detectors that are in use and are discussed below. They are the magnetically coupled switch, the torque tube, the diaphragm and force bar, the spring balance, the flexible disc, and the flexible shaft design. Each of these units operates on Archimedes' principle but is different as far as its seals are concerned. All of them can be used to detect a liquid–vapor interface, a liquid–liquid interface, and, if the level is constant, the changes in density as well. The flexible disc unit is available as a pneumatic transmitter, and the flexible shaft unit is available as a high-gain pneumatic controller or as a switch. The other designs are available with integral pneumatic or electronic transmitters or controllers.

DISPLACER SWITCH

The major difference between a float level switch and a displacer level switch is that a float moves with the surface, whereas a displacer is partially or totally immersed and moves very little with process changes. Switching arrangements and installation considerations are similar for the displacer and float switches. Float-type switches are covered in the next section, and the discussion here will be limited to the design features of the displacer switch. Figure 3.7a shows a displacer mounted on a flexible cable attached to a support spring. When the tank is empty, the spring must support the full weight of the displacer. As the level rises, and the displacer becomes immersed in the liquid, the downward force on the support spring is reduced, and a small stem movement occurs to activate the switch.

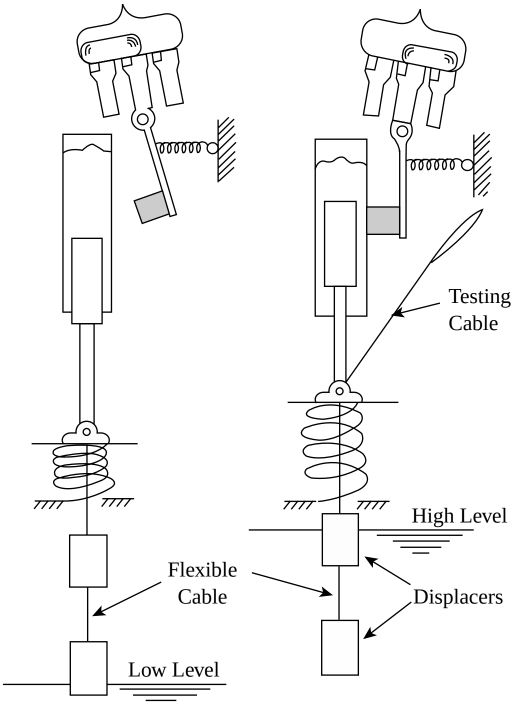

FIG. 3.7a
Displacement level switches.

Figure 3.7a also illustrates how the displacer level switch systems might be tested when installed in open tanks and sumps, or on floating roofs. The technician or operator can attach a testing cable as shown on the right side of Figure 3.7a. Once the cable is attached, lifting on the cable simulates a high-level condition, changing the state of the switch to prove the operation of the switch and probably the wiring.

In the next section, the operation of different switching contacts and the designs of the different float chambers are described. Although this information is provided for float-type switches, it is also applicable for displacer-type units. When deciding between float-type and displacer-type level switches, the following advantages can be noted for the latter:

1. The maximum differential between high and low settings can be as much as 50 ft (15 m).
2. Level settings are adjusted by moving the displacer(s) to a new elevation on the cable.
3. Moderate surface turbulence is less apt to cause switch chatter, because the cable is in tension.
4. Within broad ranges, fluid density has no effect on the displacer sizing diameter, making units interchangeable between services of varying density simply by changing the support spring.
5. The displacer switch is less apt to cause spurious trips in vibrating services, because the cable is always in tension. This is an important consideration for automatic shutdown systems such as may be used at compressor suction drums.

The displacer switch is available in many configurations to achieve the desired functionality. Some have multiple switches and can be used for multiple control functions. For example, a single unit can be used to sequence two pumps by actuating both pumps at high level, one at mid level, and neither at low level. The one disadvantage of most implementations of this style of displacer switch is that the support spring is exposed to the process. This limits the switch to applications that are reasonably clean, nonfreezing, and not corrosive to the available spring materials. One way to eliminate the need for a spring is to install the displacer horizontally and connect it to a microswitch through a flexible shaft seal (Figure 3.7b).

TORQUE-TUBE DISPLACERS

The torque tube shown in Figure 3.7c uses a tube in torsion to provide the spring function. The hollow torsion tube supports the displacer, which is always heavier than the process fluid, and also provides a frictionless pressure seal. This makes it

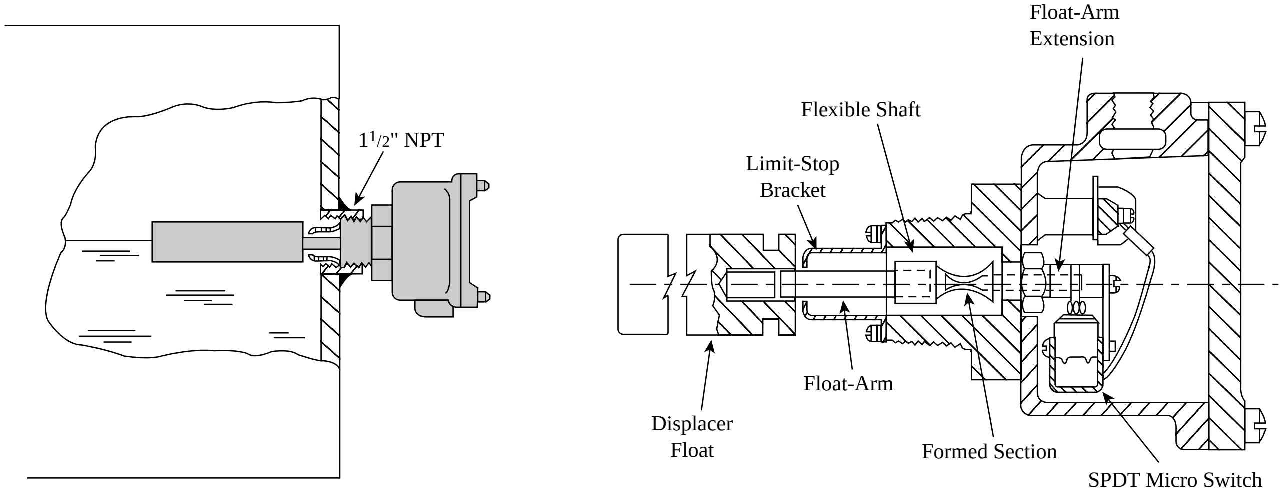

FIG. 3.7b
Side-mounted displacer switch. (Courtesy of Siemens Moore Energy & Automation.)

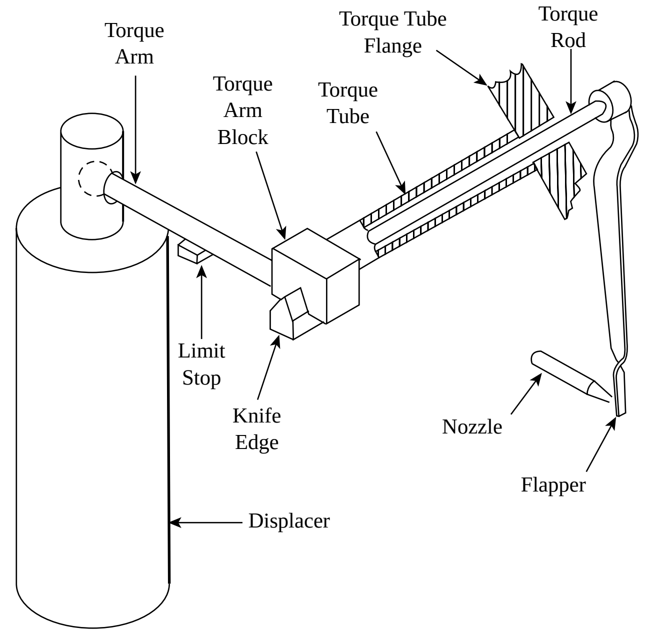

FIG. 3.7c
Torque tube displacer level detector.

possible to transfer the changes in the apparent weight of the displacer through the wall of the pressure vessel into a measuring device. Figure 3.7c is a schematic presentation of the displacer and torque tube. The displacers are typically cylindrical and can be furnished in a wide selection of plastic and alloy materials. Although any length displacer up to 60 ft (18 m) can be obtained, the most common lengths cataloged are 14, 32, 48, and 60 in. (0.3, 0.8, 1.2, and 1.5 m). The volume of a standard displacer is 100 in.^{3} (1638 cm^3), and the diameter is reduced as the length increases.

The torque arm connects the displacer to the torque tube and absorbs any lateral forces. Friction is minimized by use of a knife-edge bearing support. A limit stop prevents accidental overstressing of the torque tube by limiting the downward motion of the torque arm. The angular displacement of the torque tube and torque arm are the same at the knife edge end of the tube. At the flange end, the tube is anchored in place and does not rotate, but the torque rod is free to rotate the same amount as it did at the knife edge. The angular displacement, which amounts to about 5° or 6°, is linearly proportional to the apparent weight of the displacer and thus to the level or density. With the pressure sealing problem solved, it is a simple matter to convert the angular displacement to a usable electronic or pneumatic analog signal. The standard torque-tube material is Inconel®, but the torque tube is also available in stainless steel, Hastelloy®, Monel®, nickel, or Durimet. Note that the mechanical design requires the technician to be knowledgeable and careful in doing maintenance or repairs.

Sizing of Displacers

The technique given below for determining the desirable displacer diameter is applicable for all types of buoyant-force detectors, not just the torque-tube design. The displacer diameter sets the weight change of the displacer per level increment. The torque tube is designed to twist a fixed amount for each increment of buoyancy change. Therefore, in selecting the displacer diameter, the torque-tube characteristics, the density of the process fluid, and the level span must be considered. For purposes of this discussion, it will be assumed that the motion of the torque rod will be used to operate a proportional band controller. *Proportional band (PB)* refers to the response sensitivity of the controller, and it determines the percentage change in output signal in response to a 1% change in the level. A 100% apparent proportional band setting means that the level in the tank has to cover the displacer completely to generate a full output signal, and that the level has to drop to the bottom of the displacer to generate the minimum output. A controller set to a PB of 100% can be used as a transmitter if the process fluid is water. At 50% apparent proportional band, a level variation of 50% of the displacer length produces minimum to maximum output, and, at 25% setting, a level variation of 25% will generate the minimum to maximum output.

The term *apparent* proportional band is necessary to distinguish the *actual* band setting on the instrument based on water density at standard temperature from the resulting *apparent* band related to the density of the process fluid being measured. Figure 3.7d shows the relationship between the two terms as a function of process liquid density. It can be seen from Figure 3.7d that, if the band setting on the instrument is 50%, the output of the controller will change 50% of the level change with a liquid gravity of 1. It will change 100% with a gravity of 0.5, and, with a specific gravity of 0.1, the output will equal 10 times the level change. The process fluid density thus affects the apparent gain of the controller in an inverse linear fashion.

Because the weight change per unit level change generated by the displacer is balanced by the torsion spring constant, the characteristics of the torque tube must be considered. The range of a standard torque tube matches the buoyant force generated by a 100 in.^{3} (1638 cm^3) displacer in water for a band setting of 100%. This is equivalent to a force range of 0 to 3.6 lb$_f$ (0 to 1.6 kg$_f$). Table 3.7e below lists the force ranges of standard and thin-wall torque tubes for one design at various proportional band settings. The thin-wall tube requires one-half as much force for full range operation as the standard-wall tube. Review the technical literature for the actual device used to confirm the actual numerical constants to use. The calculations here are only examples.

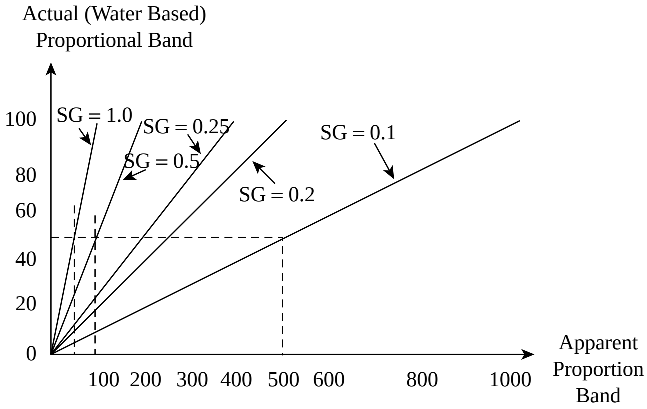

FIG. 3.7d
Relationship between apparent and actual proportional band.

TABLE 3.7e
Force Ranges of Standard and Thin-Walled Torque Tubes

Actual PB Setting (percent)	*Force Range for Std.-Wall lbf (Kgf)*	*Force Range for Thin-Wall lbf (Kgf)*
100	0–3.60 (0–1.6)	0–1.8 (0–0.8)
50	0–1.80 (0–0.8)	0–0.720 (0–0.32)
20	0–0.72 (0–0.32)	0–0.36 (0–0.16)
10	0–0.36 (0–0.16)	0–0.18 (0–08)

Interface Measurement

In most liquid level measurement applications, the specific gravity of the liquid is 0.5 (or greater), and it generates sufficient force on the torque tube for a full range of output signals, even with the use of a standard volume displacer, unless a very narrow proportional band is required. This may not be true for liquid–liquid interface applications. Difference in buoyant forces is generated only by the density difference between the two fluids, and the displacer must be completely submerged for meaningful readings. Therefore, available forces are smaller, and the sizing of displacers for liquid–liquid interface is more difficult and requires more attention.

On interface applications, it is advisable to select a displacer diameter to result in a 100% apparent proportional band when the actual band setting is 20%. This leaves additional adjustment capability to the operator who, if required, can reduce the actual band to 10% (the minimum recommended) to achieve a reduction in apparent band to 50%. An example will illustrate this.

Assume an installation in which the specific gravity of the light fluid is 0.98 and of the heavy fluid is 1.02, and the required displacer is 32 in. (812 mm) long. Furthermore, it is desired to generate full controller output over a level interface change of 16 in. (406 mm). To select a displacer diameter suitable for these requirements, it is necessary to calculate the displacer volume that will generate the force range required by a thin-wall tube when the level variation is 16 in. (406 mm). A thin-wall tube at an actual band of 20% requires a full-range force of 0.36 lb$_f$ (0.16 kg$_f$). The calculation of displacer volume to generate this force is as follows:

Volume for 16 in. length

$$= (\text{torque tube force})/(\Delta SG)(\text{wt. of 1 in.}^3\ \text{H}_2\text{O})$$

$$= 0.36/(0.004)(0.036) = 250\ \text{in.}^3 \qquad \textbf{3.7(1)}$$

$$\text{Diameter} = ((4V)/(\pi L))^{1/2} = [((4)(250))/((\pi)(16))]^{1/2} = 4.5\ \text{in.} \qquad \textbf{3.7(2)}$$

If it is required to broaden the actual proportional hand to 40%, full controller output will result from a 32-in. (812-mm) change in the interface. If the band is narrowed to 10%, full controller output will correspond to a level change of 8 in. (203 mm). If a standard-wall torque tube had been selected for the above example, the diameter of the tube would have worked out to about 6.5 in. The sizing method

Side-mounted displacer. (Courtesy of Siemens Moore Energy & Automation.)

given can be used for all displacer applications including density detection. Standard displacer diameters are 3, 4, and 6 in. (76, 102, and 152 mm), but special sizes and designs are also available (Figure 3.7f). Carefully review the engineering specifications or check with the manufacturer for the details that apply to the specific instrument being considered.

In a large vessel, the interface may have a very slow but substantial wave motion if the difference between densities is small. The gravity forces are small, and the fluids have little friction to damp out any fluid motion. If no sight port is located so as to make this motion visible, the operator will have the impression that the signal or the control is cycling.

Rag Layer

Another cause of measurement doubt and confusion is the common situation of a *rag layer* of material, lighter than the heavy layer and heavier than the light layer, that will accumulate between the two desired layers. If there is no mechanism or procedure to remove this material, it will become ever deeper until it suddenly appears in the upper layer outlet. In continuous processes, even tiny amounts of undesired materials will always accumulate wherever conditions make this possible.

Features and Installation

Torque-tube level devices can be mounted internally or externally to the vessel. Internal displacers are used where it is possible to drain the tank for level detector maintenance. If the displacer is to be internally mounted, it is good practice to install it inside of a stilling well, which may be fabricated from a piece of pipe. To avoid errors, the standpipe must have a number of vertical slots or holes along its length to permit a free but restrained flow of liquids, and it should have a stop bar across the bottom to prevent the displacer from falling to the bottom of the vessel if it becomes disconnected from the torque tube.

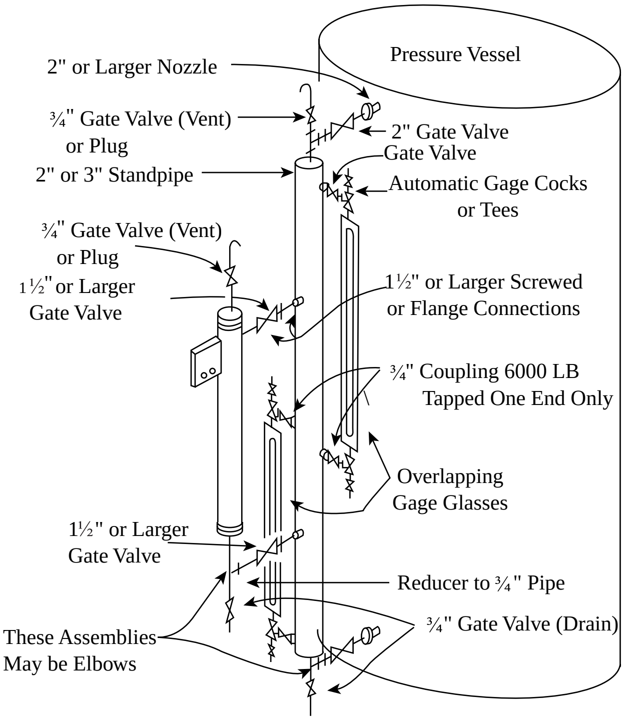

FIG. 3.7g
The installation of an external cage displacer on a standpipe with two level gauge sections. (Courtesy of the American Petroleum Institute, API RP 550.)

For installations in which the vessel cannot be opened and drained to perform maintenance on the displacer, it may be installed in a level chamber mounted outside of the tank and isolated from the process by means of lockable valves. Local safety rules must be observed. A single barrier between vessel and the environment may require special precautions.

It has been typical practice to install a level gauge to approximately match the span of the displacer to provide visual observation of the level. Figure 3.7g shows the installation of a displacer transmitter and level gauge mounted on a standpipe or level chamber. Note that the two units have independent isolation and drain valves. Some users prefer to eliminate the installation of breakable sight glasses for environmental and safety reasons.

When an external chamber is used, it may be necessary to heat-trace and insulate the level chamber for freeze or fire protection. The density measurement is for the liquid in the chamber and may not represent the vessel contents density if the level chamber temperature is not the same as the vessel bulk temperature. For liquid–liquid interface applications, the standpipe must have three connections to the vessel: one in the heavy liquid layer, one in the light liquid layer, and one in the vapor space that vents back into the vessel.

Special torque-tube and displacer designs are available for operating pressures up to 2500 PSIG (17 MPa). For high-temperature installations, the torque-tube material may be the limiting factor. The spring characteristics of the tube will change at sufficiently high temperatures. Low temperatures have little effect on the spring characteristics of the tube. For torque-tube materials, Inconel® is suitable for temperatures between –350 and 850°F (–212 and 454°C). All other materials are limited to 500°F (260°C) except bronze, which is rated at 300°F (150°C). Torque-tube extensions will provide substantial thermal isolation for the instrument case. Installation details will also affect the instrument temperature. When the process is at a temperature above 500°F (260°C), finned extensions are recommended; when it is below 0°F (–18°C), plain extensions may be used. The extensions should not be insulated. Additional thermal insulation or thermal radiation barriers can be used to protect the indicating and transmitting portions of the instrument. Note that pneumatic transmitters may have a higher allowable temperature than the electronic version. Jacketed displacer chambers are available for hard-to-handle services if field-applied tracing is judged to be inadequate. The process connections on external chamber displacers are normally 1.5 or 2 in. (38 or 51 mm) and often flanged, so they may be used in mildly dirty services. Consider *blowdown* or drain valves where appropriate and permissible. It is preferred not to use external chambers if there is a likelihood of plugging because of solids accumulation.

The torque-tube displacer can be furnished with pneumatic or electronic transmitters or with local control. Controllers are available with gain, integral, and/or derivative control action. An output gauge should be installed on the transmitter signal to indicate level and for troubleshooting. It may also be good practice to install an independent level gauge. The torque tube and displacer design has an excellent field record for accuracy and reliability. Over time, accumulated noncondensable and solids may compromise accuracy, and some verification of proper performance is desirable. The torque-tube seal is virtually trouble-free if properly specified to meet the process requirements. In processes in which level setpoint changes are infrequent, or where speed of response is a concern, displacer units are often used as local level controllers, even if a sophisticated control system is used. The units may also be furnished with transmitter/controller combinations, allowing the advantage of local control with remote process indication.

SPRING-BALANCE DISPLACER

This instrument is similar to the torque-tube unit except that the spring function of the torque tube is replaced by a conventional range spring, and the isolation of the process from the instrument is by means of a magnetic coupling. As illustrated in Figure 3.7h, the displacer is suspended in the liquid by means of an extension range spring. As the level in the vessel rises or falls, the buoyancy force on the displacer changes, causing the spring to extend and contract. A magnetic attracting ball attached to the displacer rod rises and falls in response to the displacer movement. The movement is about 1 in. (25 mm) full range. The ball is centered within the enclosing tube, and its movement is nearly frictionless. A follower mechanism moves with the magnetic ball for indication and signal transmission.

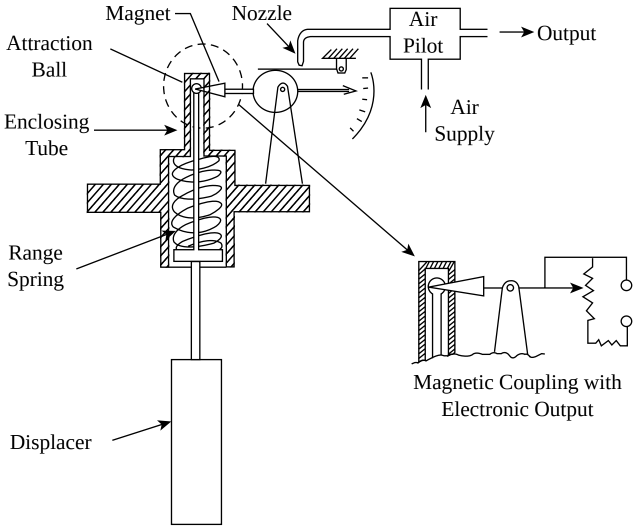

FIG. 3.7h
The old spring balance, magnetically coupled displacer.

Other design features and accessories are similar to the ones discussed in the section on torque-tube design. The spring-balanced displacers are also available with corrosion-resistant wetted parts and are suitable for operating temperatures between –250°F (–157°C) and 600°F (316°C). Because the interior-to-exterior motion is magnetically coupled, units with very high pressure ratings to 6000 PSIG (41 MPa) are available. The merits and disadvantages of the spring-balanced design are similar to those of the torque-tube units, except that the movement of the displacer is greater, and the range spring is exposed to the process. Greater movement almost always causes faster wear at pivot points. The range spring exposure creates difficulty in installations where vapor space condensation, polymerization, or crystallization is expected, because material buildup on the spring will interfere with proper operation. Inert gas purging of the spring chamber has been used to prevent the process vapors from entering the chamber, but the large flow rates required make this solution impractical.

FORCE-BALANCE DISPLACER

The basic mechanism of the classic differential-pressure transmitters illustrated in the previous section can be adapted to produce another family of displacer level devices. Figure 3.7i shows the force-balance type of top-mounted design. Level variations in the vessel cause a proportional change in buoyant

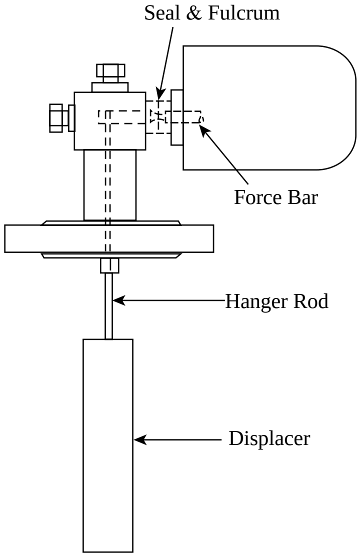

FIG. 3.7i
Force balance, diaphragm sealed displacement level transmitter. (Courtesy of The Foxboro Co.)

force of the displacer, reducing the apparent weight on the force bar as the level increases. In the side-mounted version, the process is sealed by a diaphragm, which also serves as the fulcrum of the force bar. The buoyant force is transmitted to the balancing rod, which pivots on the range wheel. An increase in level causes a minute movement that, it turn, is detected by the transmitter, which in the past generated a pneumatic signal. Today, the signal is electronic, in the form of either an analog signal or digital data communicated over the bus or network of the plant.

This instrument is available with the displacer mounted either inside the vessel or in an external chamber. The latter is used where maintenance must be performed while the tank is under pressure. The limitations of this device are similar to those of the torque-tube design, but the diaphragm seal is not as rugged as the torque tube, and the operating pressure is limited to 600 PSIG (4.1 MPa) with operating temperatures to 400°F (204°C). A variety of materials are available to meet requirements of corrosive services (see Table 3.7j).

The displacer sizing procedure for density, interface, or level detection follows the same basic method outlined for the torque-tube units, except that the buoyant force range involved is different. The buoyant force span for one standard unit is 2.90 lb_f (1.29 kg_f) or more; for the narrow design, it is 1.45 lb_f (0.65 kg_f) or more. The formula to calculate tile buoyant force is:

$$F = (0.36)(SG)(V)(Lw)/L \qquad \textbf{3.7(3)}$$

where

F = buoyant force in pounds
SG = specific gravity difference
V = displacer volume in cubic inches
Lw = working length of displacer in inches
L = total length of displacer in inches

This instrument is available for mounting either inside the vessel or in an external chamber. The latter is used where maintenance must be performed while the tank is under pressure. The limitations of this device are similar to those of the torque-tube design but, in addition, the diaphragm seal is not as rugged as the torque tube, limiting operating pressures to 600 PSIG (4.1 MPa) and operating temperatures to 400°F (204°C).

FLEXIBLE DISC DISPLACER

In case of the flexible disc design, as rising liquid level reduces the apparent weight of the displacer, a force balance mechanism detects this change in weight while maintaining equilibrium. The output signal is directly related to the level in the vessel. Span adjustments are made by changing the total length of the float arm.

The float arm is supported by the flexible disc. As a result of the force-balance principle of operation, all components maintain their predetermined position with essentially no movement. This protects the flexible disc from fatigue due to bending. The weight of the displacer and float arm is carried by the flexible disc, and the static pressure in the vessel acts upon the thrust pivots. Limit stops keep the float arm motion within the elastic limits of the disc when the vessel is empty.

This design has the same limitations as the other displacer units but has a narrower range of application, because the flexible disc seal limits its use to 100 PSIG (0.7 MPa) operating pressure. At higher pressures, the unit becomes inaccurate, and an increase in error of ±1% of full scale can be expected per 100 PSIG of process pressure. The flexible disc is normally made of stainless steel, but it is also available in Monel® and nickel. The displacer can be made of a wide variety of materials. The performance of this unit is generally inferior to the other designs covered in this section.

FLEXIBLE-SHAFT CONTROLLERS

This unit moves too much to be simply classified as a displacer and too little to be simply a float device. But the limited float motion makes it more nearly a displacer, so it is considered as such here. As with the other displacer designs, the flexible-shaft unit detects the buoyant force of the float with practically no motion involved approximately 1/32 in. (0.8 mm) travel. As shown in Figure 3.7k, the shaft is tubular, with a flattened center section that moves easily in the vertical direction but resists horizontal motion. In the pneumatic-controller version, the extension tongue transmits the float motion to an air pilot.

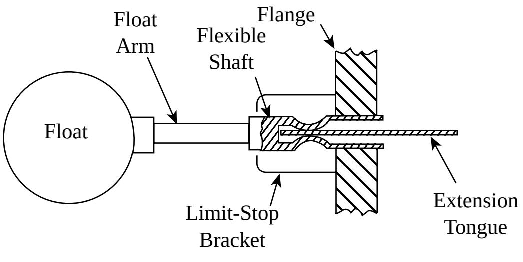

FIG. 3.7k
Flexible shaft level controller. (Courtesy of Siemens Moore Energy and Automation.)

An increase in level moves the tongue, gradually closing the vent of the pilot and increasing the output signal to the control valve. By turning the mounting flange 180°, the control pilot action can be reversed so that an increase in level will be accompanied by a decrease in the signal to the valve. The unit can also be provided as an on–off switch with either pneumatic or electric output.

As with other displacer designs, this device can be used to control interface or fluid density, but it is very limited in adjustment flexibility as compared to the torque-tube design. The flexible shaft unit has a narrow and fixed proportional band without integral action. The ball float has a throttling range of approximately 0.5 in. (12.7 mm), depending on arm length. This high sensitivity limits application in many services. The flexible shaft level controller can be furnished with pressure ratings to 1000 PSIG (0.9 MPa) and temperature ratings to 700°F (371°C). Construction materials include stainless steel, nickel, Monel®, Hastelloy®, and others. The flexible shaft design is generally used in services where near on–off control action is desired. Cost is less than for the torque-tube devices.

CONCLUSION

The external-cage-type displacement level transmitters and controllers are very popular in power plants and chemical processes. Applications include close control of level in high-temperature and high-pressure vessels and where the process cannot be shut down for instrument replacement or maintenance. They have lost some ground to electronic level sensors, partly because they are limited to use on clean fluids, because dirt and material buildup on the displacer cannot be tolerated, and partly as a result of cost considerations. They are not confused by foam, vapors, and changes in vapor density of the devices used, the torque-tube type continuous units up to 60 in. (1.5 m) and the displacement-type switches are the most popular.

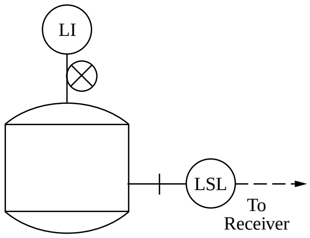
C. G. LANGFORD (2003)



Flow Sheet Symbol

Types	Switches and transmitters can be mechanically or magnetically coupled and may have single- or multiple-point sensors. Indicators include the tape board gauge.
Design Pressures	Level switch units used in vending-machine type applications are usually limited to 100 PSIG (6.9 bars, 0.69 MPa), while magnetically coupled float level indicators can operate up to 1000 PSIG (70 bars, 7 MPa), and special designs can go up to 2000 PSIG (140 bars, 14 MPa).
Design Temperatures	Standard level switch units used in vending machine-type applications are usually suited for –40 to 225°F (–40 to 117°C); special designs are available for 500°F (260°C) and higher.
Float Materials	Brass, copper, stainless steel, Monel®, Hastelloy®, polysulfone, polypropylene, and other plastics
Costs	Vending-machine-quality level switches can be obtained for about \$50; the cost of a type 316 stainless-steel industrial float switch ranges from \$150 to \$500, depending on the type of mounting and area classification. A tape-board-type level indicator costs about \$500, and a continuous float level transmitter costs from \$2000 to \$5000.
Inaccuracy	The repeatability of actuation is about 1 in. (25 mm) for level switches and for guide-tube and float-type level indicators. The error in most level transmitters is about 1% of full scale. Consult the manufacturer for guidance if higher precision is required.

In addition to this section, other sections in this handbook discuss float-type devices. These include the displacer-type level devices discussed in Section 3.7, the magnetic level gauge covered in Section 3.10, and the various tape level devices discussed in Section 3.18. In addition, the float level control valves, which are covered in Volume 2 of this handbook, also utilize floats for their operation. In addition, floats are combined with capacitance and ultrasonic level detectors.

INTRODUCTION

The immersion of a theoretically perfect float would have a perfectly constant immersion depth. The immersion of real floats is not perfectly constant because of the work they have to do to move the mechanical components of the instrument.

The level devices discussed in this section can be functionally grouped into point-sensing level switches and continuous or proportional level devices such as level indicators, controllers, or transmitters. They can be directly connected or can include isolation or seal devices; if they have seals, one can also group them according to the method of sealing used. The older ball-float gauges depended on stuffing boxes for sealing. The newer designs use magnetic coupling or other, more reliable means to separate the pressurized process from the readout.

The float in float level switches and indicators follows the liquid level or the interface level between liquids of differing specific gravities. The commonly understood difference between the float and the displacer is that floats are allowed to move if level or density changes, whereas the displacers do not move—or move very little. This means that the float devices follow the changes in level more closely, while the displacer follows the changes in density more accurately.

Standard floats for top mounting are spherical or cylindrical; they are spherical or oblong for side-mounted designs. Spherical floats are available from 3 to 7 in. (76 to 178 mm) in diameter. The smaller-diameter floats are used in higher-density materials, and the larger ones are used in liquid–liquid interface detection applications and for measuring the level of lower-density materials. Another reason for using larger floats is to provide additional force for operating the associated instrument.

FLOAT LEVEL SWITCHES

Figure 3.8a illustrates a simple device that can be used for level indication or switch actuating in atmospheric tanks or sumps. The ball float has a rod connected to it, and the rod motion is used either to indicate level on a gauge board or to trip any combination of high- and low-level switches for alarm or automatic starting and stopping of lift pumps. For some pump applications, the float and rod may be furnished with the pump and can be factory assembled by the pump manufacturer.

Figure 3.8b illustrates the operation of the magnetically coupled and spring-loaded float switch. The magnet and switch are assembled on a swinging arm that rotates on a pivot. As the liquid level rises, the float rises with it and lifts the attractor. When the attractor reaches its high position, it pulls in the magnet on the swing arm against the nonmagnetic enclosing tube, thus tilting the mercury switch to the right. The spring is selected so as to provide snap-action switching. When the switch tilts, the middle-to-left leg circuit is broken, and the middle-to-right leg circuit is closed.

The magnetic coupling across the enclosing tube isolates the process liquid from the switching elements of the instrument. The swing-arm design can also be arranged to operate one or more dry contact switches. When two switches are

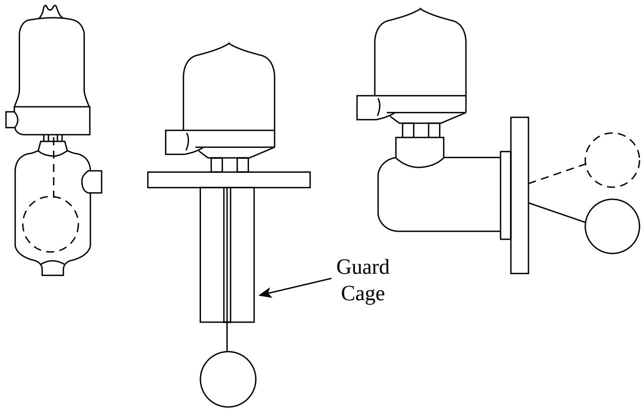

FIG. 3.8c
Float switches mounted inside external chamber or on the top or side nozzles of tanks.

employed, they can be spaced approximately 1 to 3 in. (25 to 76 mm) apart. One disadvantage is that making changes to the setpoint or the span of this and other float-operated switch designs can be complicated and time consuming.

Figure 3.8c shows some of the external top- and side-mounted float switch designs. The switch operating point is the vessel nozzle elevation. These direct-connected installations usually require that the vessel be depressurized and drained for maintenance. If this would cause a plant shutdown or interfere with normal operations, an external cage (chamber) design can be used. The external chamber can be isolated from the vessel by shutoff valves, which make maintenance possible without draining the vessel—if local safety practices permit.

If ambient temperatures can cause the process fluid to freeze or gel, the external chamber should be heat traced.

Another type of single-point magnetically coupled float switch is illustrated in Figure 3.8d. As the process level rises, the float rises with it, and the float magnet pivots down, which attracts the switch magnet. As it moves up, it changes the state of the electric or pneumatic switch. This design is available with a plastic boot that covers the float magnet and

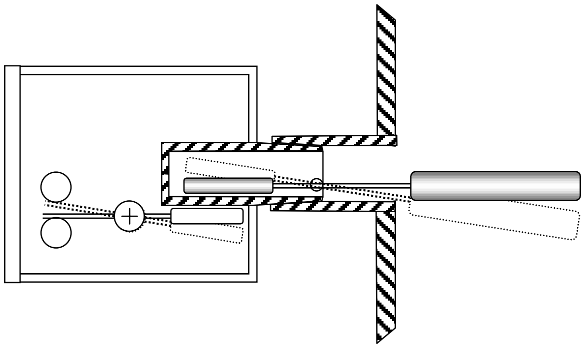

FIG. 3.8d
Magnetically coupled float level switch.

the float pivot point to prevent the buildup of solids or caking at the pivot. If the boot is used, it lowers the pressure and temperature ratings of the switch. The previous discussion on direct versus external cage mounting also applies to this switch design.

Reed-Switch Designs

Some of the earlier reed-switch-based level switches consisted of several moving parts, which contributed to their potential for maintenance problems caused by corrosion and plugging. Figure 3.8e illustrates one such design, containing a spring-opposed shuttle-and-cam mechanism. Here, the level lifts the float, which in turn rotates a cam counterclockwise, thereby moving the permanent magnet into close proximity with the reed switch. As a result, the switch changes its electrical state.

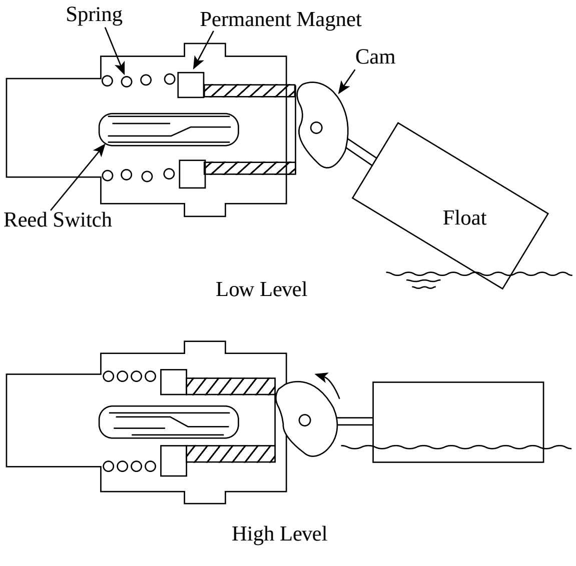

FIG. 3.8e
Magnetically coupled level switch, which is triggered by a float-operated cam.

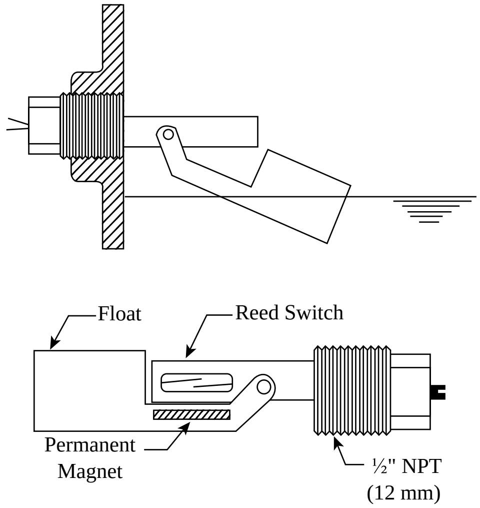

FIG. 3.8f
Reed switch-type level sensor which is operated by a plastic float. (Courtesy of Thomas Products Ltd.)

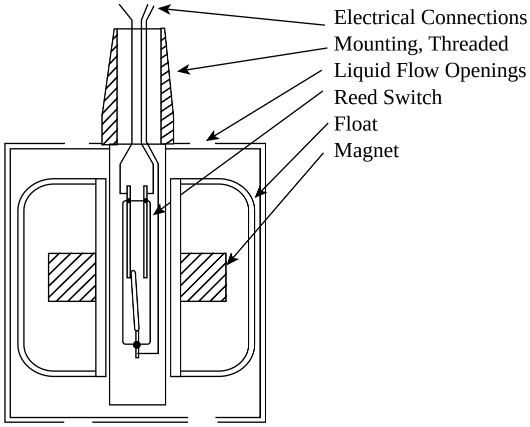

FIG. 3.8g
Reed switch-type level float.

The main concerns with most such designs are ruggedness, simplicity, and the ability to overcome the resistance of dirt or material buildup that resists float motion. For these reasons, the more successful designs tend to have only one moving component and a relatively large float on a relatively long float arm to maximize the angular momentum generated.

An inexpensive float switch used in vending machine applications is illustrated in Figure 3.8f. This unit is available in polypropylene and in polysulfone materials and can be used from –40 to 225°F (–40 to 107°C) and up to 150 PSIG (10.3 bars, 1.03 MPa) operating pressures.

In another all-plastic level switch, also used in vending machines, the float and reed switch assembly is contained within a housing chamber that is inserted vertically into the process (Figure 3.8g). The process fluid enters this chamber and lifts the float (which contains the magnet) until it actuates the hermetically sealed reed switch within the stem.

It is always wise to inquire into the electrical ratings of a reed switch. Devices that are mounted in the field with long cable runs (possibly in a cable tray) may be exposed to induced currents and high voltages resulting from electrical storms. In such cases, voltage surge protection is needed, because such voltage surges can destroy small switches.

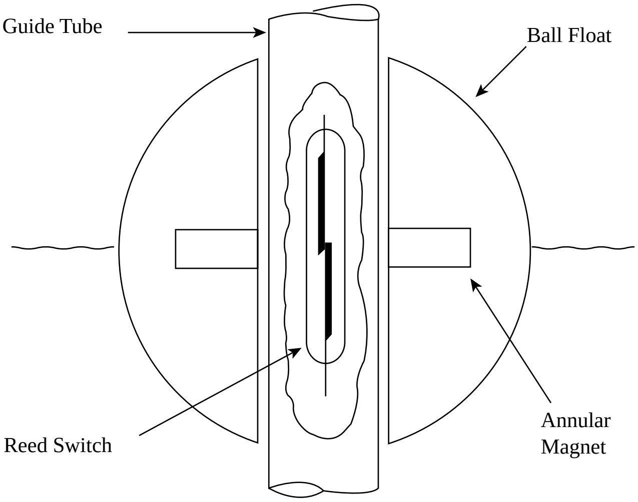

FIG. 3.8h
Ball float-operated and magnetically coupled reed switch.

Float and Guide Tube Designs

The float and guide tube design shown in Figure 3.8h is also a magnetically coupled float switch. In its simplest configuration, a reed switch is positioned inside a sealed, nonmagnetic guide tube at the point where the rising or falling liquid level is to actuate the switch. The float, which contains an annular magnet, rises or falls with the liquid level while it is guided by the tube. In the design shown in Figure 3.8h, the switch is normally open and closes when the float reaches the elevation of the switch.

The switch closure can be used to sound an alarm or to initiate logic functions such as starting a pump. The switch will reopen when the float falls, or if it rises and the switch cannot detect whether it was closed by a falling or a rising float. As a solution for answering this question, a mechanical stop can be placed on the guide tube to prevent the float from rising above the elevation of the switch. With the stop installed, the switch will stay closed whenever the level is at or above the switch elevation and will open only when the process level falls. Several mechanically stopped floats can be placed along the same tube to provide multiple switching at different levels.

Figure 3.8i shows this configuration. Two floats and two switches are used to control a sump pump, which is started on high level and stopped on low. When the level in the sump is below the elevation of the *level switch low* (LSL), both LSL and *level switch high* (LSH) are open, and the relay coil R is de-energized. When the level rises above LSL, it closes that switch. If it continues to rise, when it also closes LSH, relay coil R is energized, and the relay contacts R1 and R2 are both closed.

Contact R1 is a "hold-in" contact around LSH, whereas the R2 closure starts the pump motor. When the liquid level

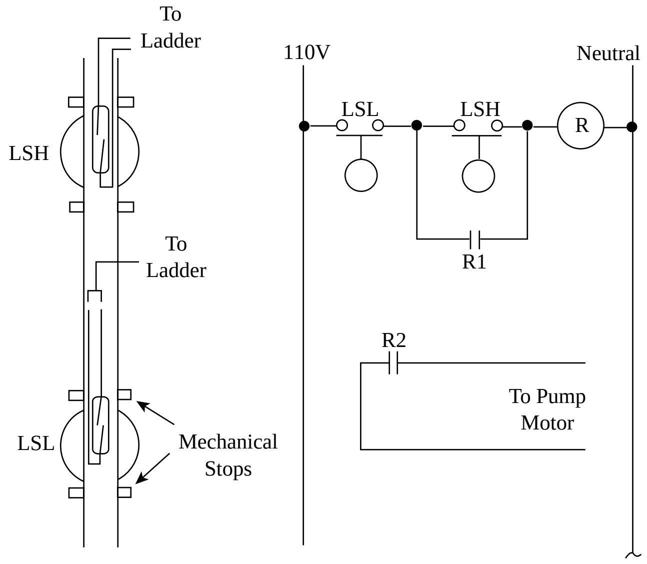

FIG. 3.8i
Pump-down control system for operating a single pump.

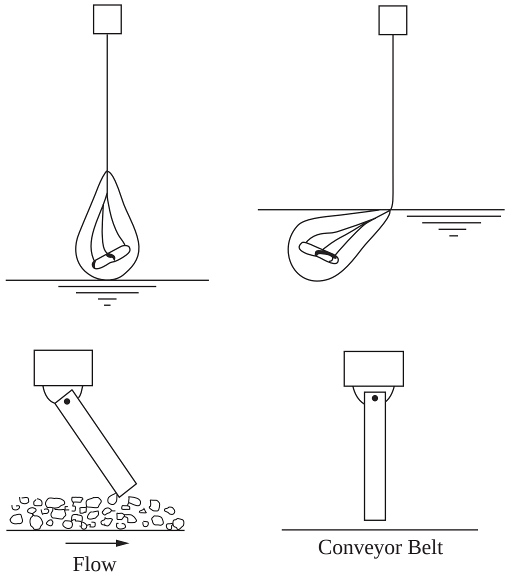

FIG. 3.8j
Tilt switches for liquid (top) and solids service (bottom).

drops below LSH, it will open, but the pump will remain energized, because the still-closed R1 keeps relay R energized. When the level falls below LSL, the opening of that switch will de-energize the relay coil, which in turn sets both R1 and R2 to open. At this point, the pump shuts down, and the system is at the initially described state. By adding more floats and switches to the assembly, more complex control schemes can be devised.

Tilt Switches

Figure 3.8j illustrates two commercially available tilt switch designs: the upper one for liquid and the lower one for solids services. In the liquid level detector switch, a mercury switch is enclosed in a plastic casing and is freely suspended from a cable at the desired level. When the liquid reaches the plastic casing, it tilts it, causing the switch to close (or open) an electric circuit, which in turn actuates a warning device or starts a pump. This device is used in sumps and ponds and is limited to atmospheric pressure and ambient temperature applications. If it is installed outdoors above grade, it should be sheltered by a windscreen.

The second tilt switch design, shown in the lower half of the figure, is used primarily to detect the presence or absence of solids on a conveyor belt. As long as there is material on the conveyor belt, the switch is tilted up. If the feed to the belt is lost, the switch rotates to its vertical position, and the switch contacts change state, thereby enabling alarm actuation, belt shutdown, or other automated actions to be initiated. Other designs are available that use a steel ball. As it changes position, the ball also operates a switch as the housing is tilted. This design is available for corrosive or pressurized services.

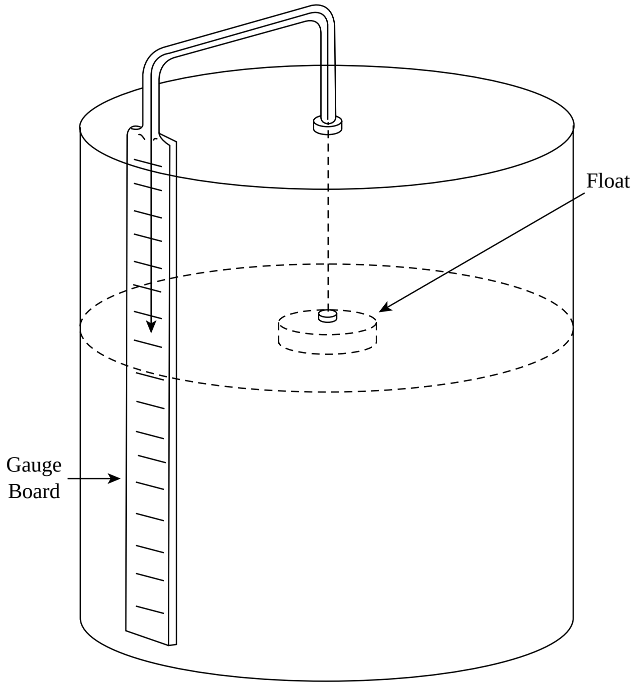

FIG. 3.8k
Tape gauge operated by float and provided with a gauge board for level indication.

Float-Operated Continuous Indicators

The simplest and most direct method of float level measurement is illustrated in Figure 3.8k. The unit shown is basically a tape gauge (detailed in Section 3.18). A tape is connected to a float at one end and to a counterweight at the other, thereby keeping the tape under constant tension. The float moves the counterweight up and down in front of a direct reading gauge board, thereby indicating the level in the tank. The installation shown is typically used on water storage tanks, although it can be used in any processes that are left open to the atmosphere. Float and tape materials are selected to suit corrosion requirements. The instrument range is a function of tape length used, which can be up to 100 ft (30 m). For float devices used in closed tanks, refer to Section 3.18.

Pressurized Tank Applications

When float-operated devices are used on pressurized tanks, they require a seal between the process and the indicator. In most cases, the float motion is transferred to the indicator by magnetic coupling, but other designs also exist.

Where no external power source is available, the float level indicator shown in Figure 3.8l can be used to obtain remote indication.

When the level of the tank rises, the float moves up, and the float arm rotates around the float arm pivot, thus pulling the push rod down. This, in turn, operates the stroke lever. The stroke lever turns on its pivot, which is sealed inside the bellows. This motion is carried by linkage to the *tank side bellows* (A and B). As bellows A is compressed, some of its filling liquid is transferred into receiver bellows C. At the same time, as bellows B is expanded, it draws some of the filling liquid from receiver bellows D. The net result of this action of the differential bellows is to change the position of a remote level indicator, which requires no power supply.

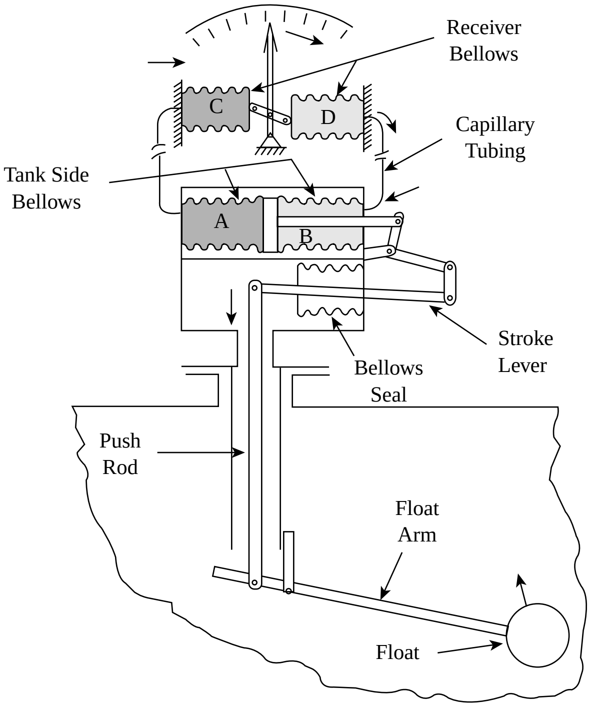

FIG. 3.8l
Float gauge provided with liquid-filled bellows and capillary tubing for remote level indication.

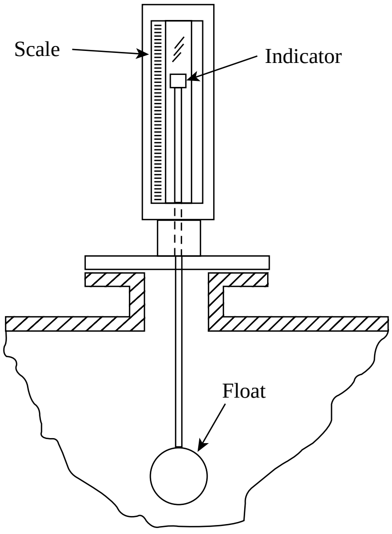

FIG. 3.8m
Rotameter indicator adopted as a means of displaying level.

These liquid-filled float gauges are available with temperature compensation to eliminate the effect of ambient temperature variations on the measurement. For installations in which the process vapors are not corrosive to copper and the operating pressure is below 15 PSIG (0.1 MPa), the bellows seal shown in the sketch can be eliminated. If the seal is used, it allows the unit to be exposed to 200 PSIG (1.4 MPa) operating pressures while isolating the process vapors from most of the working parts. The bellows seal and other parts that are wetted by the process can be made out of stainless steel, Monel® aluminum, synthetic rubber, or other materials. The capillary tubing between tank side and receiver bellows can be up to 250 ft (76 m) in length.

Figure 3.8m shows another simple level indicator. The float can be placed directly in the tank or mounted in an external chamber that is provided with isolating valves. The maximum level range of the device shown, which uses a standard variable-area flowmeter indicator, is 15 in. (381 mm). This limits its use to narrow-span applications. Another variation, used on home heating oil tanks, is designed with both a pivoted and a rotating arm to allow use of the short indicator scale.

Materials of construction are either steel or stainless steel, with glass indicating tubes used on nonhazardous, low-pressure services only. In other installations, metal tubes are used with magnetic coupling to drive the scale indicator. This design can be used for operating pressures to 1200 PSIG (8 MPa) and temperatures to 800°F (427°C). The rotameter design can be used for local indication and can be equipped with high and low alarm switches and electronic or pneumatic transmitters.

Magnetically Coupled Indicators

Continuous level indication can be obtained by placing many closely spaced switches inside a guide tube and detecting which ones are being held closed by the magnet as it is lifted with the ball float (Figure 3.8n). In this design, a voltage divider

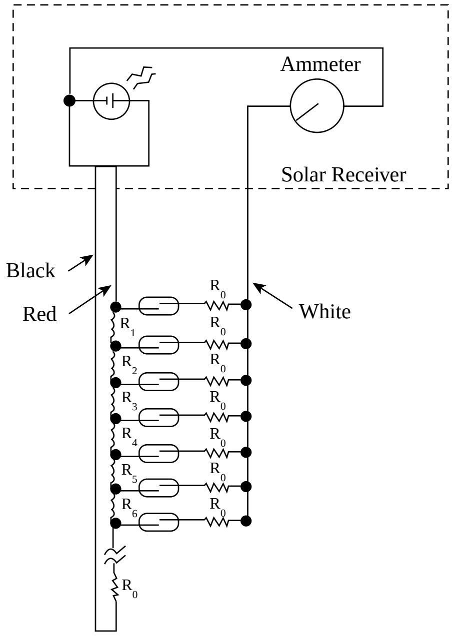

FIG. 3.8n
Magnetically coupled level indicator, which detects the status of float operated switches inside a guide tube.

network is configured by connecting resistors R1, R2,…, Rn in series across the power supply. Since the resistors have equal value, the voltage drop across each one will be equal. If the magnet in the ball float closes the third switch from the top, for example, the voltage between R2 and R3 will be impressed on R0, causing a very small current to flow through the ammeter. As the level continues to fall and closes the fourth switch, R4 is inserted into the circuit, and the voltage to R0 will be reduced.

The ammeter scale may display the level in percentage or in engineering units. Resistor R0 is specified at a high value so that current flow through the meter is small in comparison with that in the divider. The switches can be placed with a minimum spacing down to 0.25 in. (6 mm), which is the resolution for this type of indicator. As can be expected, replacement of faulty switches is difficult, so the guide tube normally includes spare (redundant) switches installed at each point. Maximum length available for this design is 10 ft (3 m) if the assembly is furnished with the metal guide tube. However, it is possible to obtain a flexible, plastic-jacketed assembly that can be furnished in longer coils. The plastic jacketed assemblies are field installed into stainless steel or other nonmagnetic guide tubes. Solar-powered versions of this design are also available.

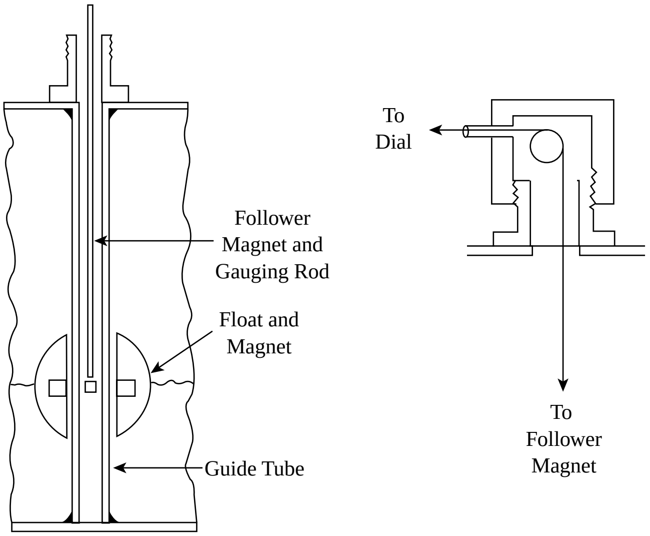

FIG. 3.8o
Level display can be at ground level, if float operates a magnetic follower inside a guide tube.

Figure 3.8o shows how the magnetically coupled float and guide tube design can be used for manual gauging or to operate a direct-reading dial. The sketch to the left shows the same magnet-carrying float and guide tube as described earlier. But here, instead of switch closures, the magnet is used to reposition a gauging rod. As the level moves the float up, the rod projects farther out of the tank, thus indicating the rising level. When the gauge is not in use, the rod can be pushed down to the bottom of the well, and the opening can be capped. This feature makes the gauge attractive for use on transportation tankers.

Given the right geometry, this system can also be installed from the bottom so that the reading can be made from under the tank. As shown on the right side of the sketch in Figure 3.8o, this design is also available with a direct-reading tape-driven indicator. This unit eliminates the need for the operator to climb on top of the tank. The major drawback of this design is that, if the pipe that contains the tape is ruptured, a spill can result unless some other form of spill protection is provided.

Another magnetically coupled float design is shown in Figure 3.8p. This gauge has been installed on a fair number of stationary and mobile liquefied petroleum gas and anhydrous ammonia tanks. The vertical motion of the float is converted

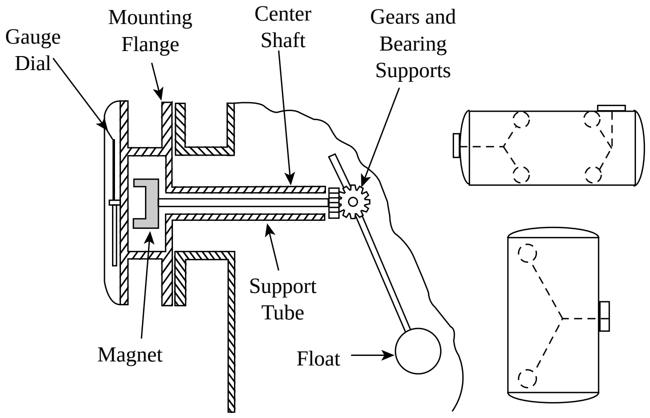

FIG. 3.8p
Magnetically coupled float-type level indicator.

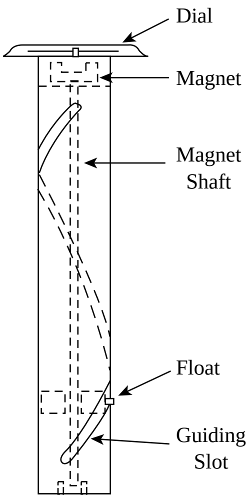

FIG. 3.8q
Magnetically coupled float gauge with float inside a slotted guide tube.

to rotary motion by the use of gears and pivots. The center shaft, in turn, positions a permanent magnet behind the dial pointer. There are no shaft connections or holes for any purpose through the gauge head, because it is the magnetic coupling that positions the pointer. This magnetic coupling guarantees a leakproof installation and is applicable up to an operating pressure of 1000 PSIG (6.9 MPa).

The readout dial can be calibrated for horizontal, vertical, and spherical tanks and, for good readout visibility, the dial diameter can be up to 8 in. (203 mm). Figure 3.8p also illustrates some of the options for locating the dial on the side or top of tanks. The standard material of construction for the wetted parts is stainless steel. As with most float-operated indicator designs, remote-readout configurations are also available.

The common automobile gasoline tank gauge is simply a float on an arm. This arm turns a variable resistor, and the change in resistance changes the current that flows through the meter on the dashboard.

Figure 3.8q illustrates a level indicator utilizing a slotted tube combined with a magnetically coupled float level indicator. This design can be considered for installations where the shape or the internals of the vessel prevent the use of the rotary-type float gauge. As the float rises, enclosed in a tube that has a guide slot, its angular position is determined by the slot. The rotation of the float turns the shaft of the magnet and the magnet repositions the pointer on the dial, which indicates the level. This device is used primarily on liquid transporters. It has a limited pressure rating and cannot be used in corrosive services.

DENSITY MEASUREMENT

Hydrometers are discussed in detail in Section 6.3 but, also being float operated, they are mentioned here. In a hydrometer (Figure 6.3a), a calibrated float with a small-diameter upper section is placed in the process fluid and sinks to a level where the buoyancy and its weight are in balance. One version is calibrated to detect the composition of automobile radiator cooling liquid. Another version is calibrated to measure the state of charge of a lead-acid battery. Others can be calibrated for the specific gravity ranges of various liquids and mixtures.

CONCLUSION

Float-operated devices are widely used in utility services and as alarm switches. In some applications, the size of the float may limit its use; in other designs, the associated support and guide tubes cannot be accommodated. Other limitations include that the immersed magnets will accumulate pipe scale and other ferrous metal particles from the process. These buildups will eventually interfere with the proper operation of such switches.

In all areas of instrumentation, it is safe to assume that trash, dirt, and solids will always accumulate in unwanted places. Many of the float-operated designs have moving parts exposed to the process and therefore should not be used in dirty or plugging services. The ball float switch designs are relatively inexpensive and reasonably reliable. For these reasons, they are used (selectively) in industrial processes and routinely in a wide array of applications outside of the industrial area.

Applications of float level instruments include the protection of pumps and compressors by detecting the presence or the absence of liquids in pipes and vessels. Pneumatically operated level switches avoid the problems associated with the availability of electrical power or the issues of electrical hazards. Independent level alarm and interlock switches are used to back up other level measurements for overflow protection and other safety purposes. The large number of float level device suppliers is an indication of the wide variety of available designs, and the user is advised to search for the most current sources and designs.

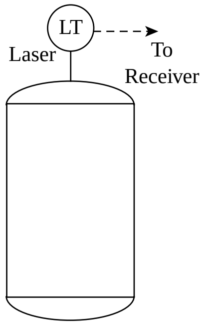
3.9 Laser Level Sensors

J. FEHRENBACH (1995) **M. VUJICIC** (2003)



Flow Sheet Symbol

Applications	Granular solids, nontransparent liquids, slurries, and molten metals
Design Pressure	Unlimited; transmitter outside of tank
Design Temperature	Ambient at transmitter –40 to +50°C (–40 to 122°F) standard; up to 150°C (302°F) with cooling options; process temperatures up to 1500°C (2732°F)
Materials of Construction	Aluminum, alloys, or plastic enclosures
Inaccuracy	±5 mm (±0.2 in)
Range	0.2 to 250 m (0.5 to 800 ft)
Price	$4000 to $6000 USD
Suppliers	K-Tek Corp. (www.ktekcorp.com) Optech Inc. (www.optech.on.ca) Thermo MeasureTech (www.thermomt.com)

BACKGROUND

In recent years, laser-based level sensors have become accepted in industrial process control as a means of obtaining reliable noncontact level measurements in difficult applications. Process conditions or installation methods often preclude the use of more conventional noncontact gauges such as ultrasonic, radar, and nuclear devices, creating both a technical and economic advantage for laser technology.

Three types of laser technology are commonly used in the process control market today: pulsed, continuous-wave (frequency-modulated), and triangulation. It is important to be aware of the fundamental operating differences between the technologies and the suitability of each for specific types of applications.

Pulsed Laser Sensors (Time of Flight)

Pulsed technology is time of flight based; it measures the time for individual laser pulses to travel from the transmitter of the instrument to the target (where the beam is reflected) and back to the receiver of the instrument. The distance is then calculated using the time and the speed of light outlined by the formula,

$$D = (C \times T)/2 \qquad \mathbf{3.9(1)}$$

where
D = distance to the target (m)
C = speed of light (3×10^8 m/sec)
T = time of flight of laser pulse (sec)

In general, pulsed lasers are used for most industrial level-monitoring applications because they offer better range and penetration characteristics (through dust and steam) without sacrificing accuracy and repeatability. Pulsed laser level sensors have improved greatly over the past few years with respect to dust penetration and pulse discrimination, allowing them to be used effectively in severe solids and vapor applications that were precluded in the past. Higher-quality pulsed laser sensors allow the user to select the return

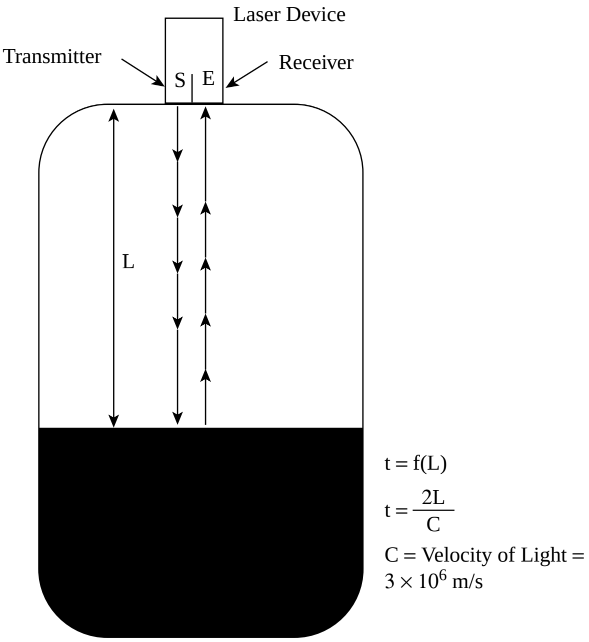


FIG. 3.9a
Level can be detected by measuring the time of reflection. Light travels at a speed of about 0.3 m per nanosecond (10^{-9} sec).

pulse of interest (first or last) so as to optimize performance in solids applications (see Figure 3.9a).

Frequency-Modulated (Continuous-Wave) Sensors

Continuous-wave laser technology directs a continuous laser beam at the target. When it hits the target, this beam is phase shifted and subsequently returned to the receiver. The outgoing and incoming beams are compared to determine the degree of phase shift and the distance is calculated on the basis of frequency, wavelength, and phase shift.

Continuous-wave lasers are better suited for short-range, extremely high-accuracy, clean-air applications usually found in laboratory-type settings. In terms of industrial applications, they are suitable for more benign applications, such as positioning, and are not usually used for level monitoring.

Triangulation Measurement Sensor

Triangulation measurement is done at an angle, with a sharply focused laser beam directed toward an object. The luminous spot on the target surface is optically projected to a CCD device, which maps out the intensity distribution of the reflected light. The electronics determine the illuminated CCD zone and the angle to the luminous spot. Because the angle change is reduced with increasing range, the accuracy also drops, making this type of measurement suitable only for a relatively short range. Primary applications for this type of measurement are object positioning and robotics. Because of these limitations, this method is not used for industrial level sensing (see Figure 3.9b).

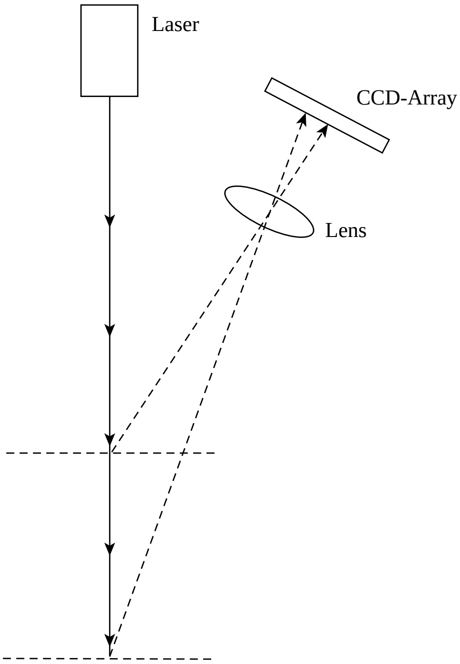

FIG. 3.9b
Triangular laser measurement is used in cameras and in robotics.

PULSED-LASER LEVEL SENSOR

Installation

Pulsed-laser level gauges have many inherent properties that help overcome the limitations of other gauges and allow them to be the alternative of choice for many applications.

First and foremost, the laser level gauge is a nonintrusive instrument that provides a flexible mounting arrangement. Process vessel flanges can be closed off with the use of a process-rated sightglass (from vacuum rated vessels to 600 class), and the laser level gauge is mounted external to the process. The laser can effectively fire through a quality sightglass to the target with no interruptions to the production process for commissioning, adjustment, or troubleshooting. The fact that the process and gauge do not come in contact makes this approach ideal for applications such as corrosives and acids that would damage an ultrasonic antenna or a radar horn (Figure 3.9c).

Common practice is to use spray rings or air curtains to help keep the sightglass or sensor window clean to optimize performance when warranted by application conditions. Clean air or process-compatible gas or fluid can be continuously or intermittently injected to keep the glass surfaces clean and laser beam transmittance losses to a minimum. Higher-quality laser sensors can provide a return signal-intensity output that can be used to control the cleaning process or for general troubleshooting and optimization.

Vapor-Space Effects

Different gases and varying pressures and temperatures in the vapor space required for passage of the laser pulse do

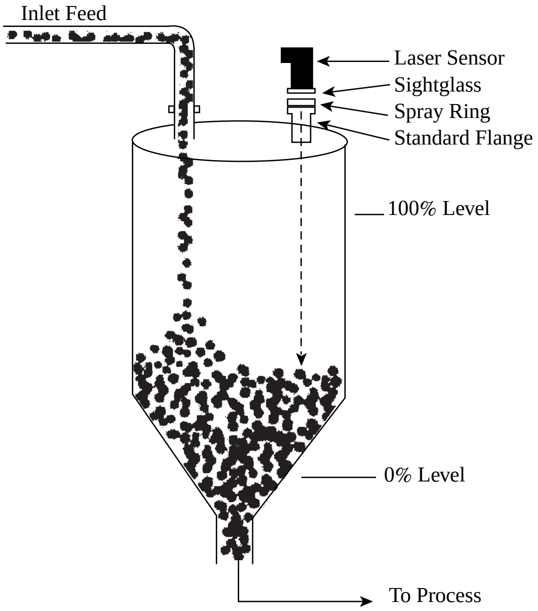

FIG. 3.9c
Installation of the laser level transmitter.

affect the speed of light and thus the level reading. The relationship is defined by

$$\text{Light velocity in a gas/vapor } (C) = C_o/N \qquad \textbf{3.9(2)}$$

where
C_o = light velocity in a vacuum (3×10^8 m/sec)
N = index of refraction for gas/vapor

Fortunately, the change in the index of refraction is minute, so the effect is negligible for industrial sensing applications, and no adjustment is needed for the laser sensor. It is therefore effective for a variety of applications. Table 3.9d shows values for the index of refraction (N) for some common gases/vapors. The laser is ideal for vacuum applications because, unlike ultrasonic sensors, the laser does not need a medium for propagation.

The laser beam itself, produced by a laser diode, is a very narrowly focused beam with minimal divergence (typically 0.3°). This narrow beam is ideal for applications where geometry is tricky, such as tall, narrow silos and vessels with baffles/agitators or support beams acting as obstructions. The fact that the beam is narrow means that a particular spot can be identified as the target, and no baseline echoes or elaborate subroutines are needed to eliminate obstructions as part of the calibration and commissioning procedure.

Types of Targets and Angle of Repose

Laser level gauges use extremely short wavelengths of the electromagnetic spectrum. Combined with the narrow beam, this makes them very accurate, even at oblique angles to the target. This translates into the ability to measure to solid targets with varying angles of repose consistently and reliably. Regardless of cone-up or cone-down conditions, the laser will provide accurate measurements to the specific point of contact without the reflection and beam bounce inherent in both ultrasonic and radar gauges. This unique property also makes installation and commissioning much easier and more flexible, as off-center and side mountings become possible.

One of the most flexible and useful properties of the laser is its ability to measure to a variety of different types of materials. Both solids and liquids can be effectively monitored with no adjustments required for target temperature, material dielectric, density, or other physical properties. Lasers have been used effectively for materials ranging from cryogenic temperatures to molten metals, with equally positive results.

Laser Eye Safety

In the United States, laser eye safety is regulated by the Food and Drug Administration (FDA). In Europe, it is regulated by the IEC. Both organizations have standards that govern eye safety (CFR1040 and IEC-60825) and these are generally accepted worldwide. The organizations are in the process of harmonizing their standards. Instrument engineers should try to specify and use Class 1 or 2 eye-safe lasers, if possible, to prevent inadvertent exposure to potentially dangerous laser sources. Additionally, engineers should ensure that the specified laser instruments indicate compliance with FDA and/or IEC guidelines for labeling, safety, manufacturing requirements, and power regulation. Class 1 and 2 laser level sensors can be used freely in industrial applications and require no specific registration or training requirements.

Laser Power and Ignition Safety

Investigations have shown that a particle or surface heated by radiation from a laser can ignite flammable gas or vapors through localized temperature increases or plasma formation. Industrial agency approvals (CE, CSA, FM, UL, and so on) require that laser manufacturers prove that their lasers are powered at below the minimum ignition energy (MIE) of common materials to eliminate ignition hazard. When specifying laser level sensors, engineers should ensure that the instruments have an agency rating for hazardous locations and/or the CE mark. These markings will indicate compliance with industrial requirements and minimize any potential problems in service. Consulting with the laser manufacturer for nonstandard applications is recommended.

SUMMARY

As laser technology develops, there exists a huge potential for laser level gauges to capture more of the noncontact level-monitoring market. In North America, there is now an annual shift away from contact gauges to noncontact gauges of 1 to 3%. This shift is the result of the development of better and newer technologies that continue to optimize processes from both a technical and economic standpoint. With their inherent advantages, laser level gauges are particularly well positioned to benefit greatly from this market shift and become even more common as a multipurpose industrial device.

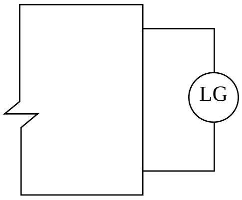
3.10 Level Gauges, Including Magnetic

D. S. KAYSER (1982) **B. G. LIPTÁK** (1969, 1995) **D. S. NYCE** (2003)



Flow Sheet Symbol

Types	(A) tubular, (B) circular or bull's-eye, (C) transparent, (D) reflex, (E) magnetic, (F) magnetostrictive transducer, and (G) gauge glass.
Design Pressure	Maximum pressures for tubular glass gauges range from 1 to 20 bars (0.1 to 2.0 MPa), but caution is needed for applications above 1 bar; circular gauges, 200 bars, with bull's-eye units up to 690 bars; transparent flat glass gauges, 200 bars; reflex gauges, 250 bars; armored gauges, 400 bars; and magnetic level gauges, 300 bars. Maximum operating pressure depends on maximum temperature. (Note: 1 bar = 0.1 MPa = 14.5 PSI.)
Design Temperature	Maximum operating temperature for tubular glass gauges is 80 to 200°C (176 to 400°F); circular gauges, 250°C (480°F); transparent flat glass gauges, 300°C (570°F); reflex gauges, 300°C (570°F); armored gauges, 350°C (660°F). Magnetic level gauges can handle process temperatures ranging from −196 to 400°C (−320 to 750°F). For all types with gauge glass, maximum operating temperature depends on maximum pressure and gauge length.
Materials of Construction	Transparent elements are of prestressed borosilicate glass, aluminosilicate glass, or quartz; other components may be carbon steel, stainless steel, K-monel®, Hastelloy®C®, PVDF (Kynar®), PTFE (Teflon®), PVC, and others for special applications.
Range	Tubular glass gauges are usually limited to 1 m maximum indicated length. The length per section for a flat glass transparent gauge (multiple sections can be arranged for a larger combined length) ranges from 100 to 500 mm; reflex, 100 to 500 mm; armored gauge, 250 to 500 mm; magnetic, 250 mm to 3 m.
Inaccuracy	Gauge error is usually a factor of the resolution of graduations on the scale, if provided. The readability can be degraded by foaming, boiling, and other effects that alter density or reduce visibility. The resolution of magnetic flag indicators is controlled by the spacing of the individual flags, typically about 6 mm. Magnetic gauges fitted with magnetostrictive sensor-based indicators can resolve the float position to 0.1 mm or less.
Cost	Excluding pipe stands, fittings, accessories, and so on, the cost per 300 mm (≈1 ft) of various gauge types is as follows: tubular glass gauge, \$100; transparent glass gauge, \$400; reflex, \$300; armored, \$450; magnetic, \$1500. A circular (welding pad) gauge costs about \$100 to \$500.

INTRODUCTION

Many types of devices are called level gauges, including various transducers, sensors, transmitters, and indicators. The detection methods depend on properties such as head pressure, differential head pressure, conductivity, and capacitance, and they employ optical, microwave, RF, radiation, magnetostriction, ultrasonic, and other principles. This section of the handbook, however, deals with liquid level gauges that operate by connecting a measuring chamber in parallel to the vessel being monitored so as to directly indicate the level visually or by the use of a magnetic indicator or transducer. The configurations of glass-type gauges comprise tubular glass, flat glass-transparent (circular and long-form), reflex, armored, and magnetic gauges. The level in the gauge follows the level in the vessel, as illustrated in Figure 3.10a.

The process level is directly visible in a glass gauge. Conversely, in a magnetic level gauge, the measuring chamber can be opaque and is typically constructed fully of metal. A float within the measuring chamber of a magnetic gauge floats on the liquid and incorporates a permanent magnet. The float magnet drives an indicator or transducer through magnetic coupling as shown in Figure 3.10b. Local indication from the magnetic level gauge can be implemented through the use of a magnetic follower, magnet operated flags, or with magnetic switches or a magnetostrictive transducer.

Level gauges are often used in process vessels as well as storage vessels. In level gauges providing direct visual indication, the accuracy is limited by the readability of the meniscus of the liquid in the indicating area of the gauge. The readability can be reduced when monitoring foaming, boiling, or inhomogeneous liquids. On visible glass lengths in excess of ≈300 mm, multiple gauge covers are stacked along the length of the measuring chamber. If a single chamber is used with multiple covers as described, there are small spaces over which the view of the level is blocked by the top and bottom edges of the individual gauge covers. In magnetic gauges with a magnetostrictive transducer,

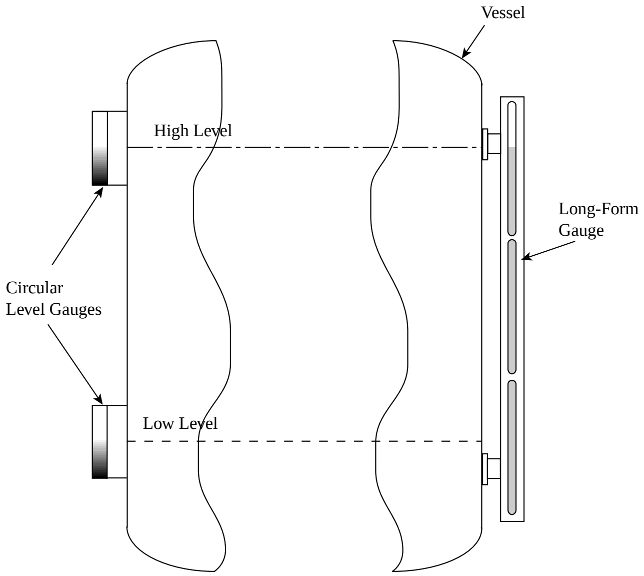

FIG. 3.10a
A level gauge (on right) is mounted in parallel to the vessel, extending over the range of level to be indicated. A circular gauge is mounted at the level of interest (left).

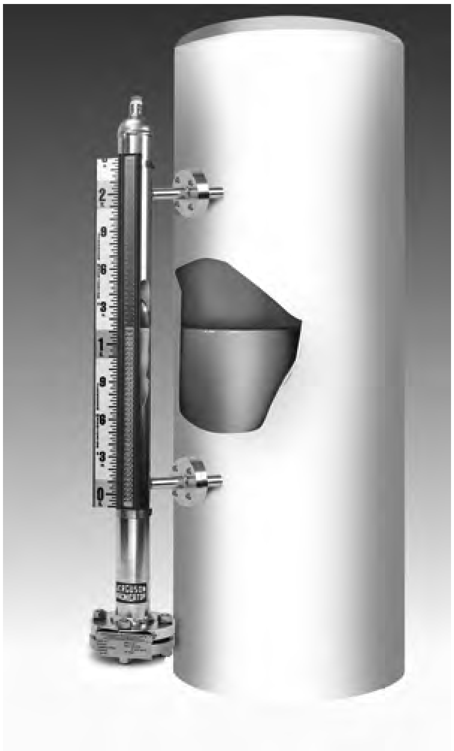

FIG. 3.10b
A magnetic gauge is shown mounted to a process vessel. A float within the measuring chamber floats on the liquid. A magnet within the float operates the magnetic flags to indicate the level. (With permission from Clarke-Reliance.)

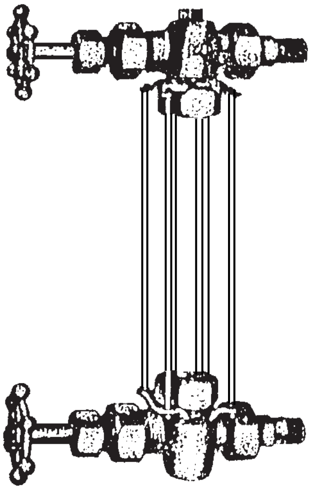

FIG. 3.10c
The traditional tubular glass level gauge is not recommended for most industrial applications.

improved accuracy is possible because of the high resolution that can be provided by a magnetostrictive transducer, and continuous indication is available through the entire range.

TUBULAR GLASS GAUGE

A simple tubular glass gauge (Figure 3.10c) comprises a transparent glass tube, seals, end blocks, and guard rods to protect the glass. It is positioned parallel to the vessel along the elevation over which the level is to be indicated and mounted with suitable fittings to retain the pressure as well as to seal the ends of the sight tube. This construction, however, is not well suited for use with dangerous process fluids.

An important consideration in gauge selection is that of maintaining the safety of personnel and associated equipment. The difficulty is evident when the process vessel, storage tank, pipeline, and so on are used with high-temperature, high-pressure, corrosive, or other dangerous fluids or steam. If a sight glass tube sustains a fracture of the glass or a leak at the seals, the dangerous fluid can escape and create the potential for a hazardous condition. The single tube design is not recommended for use with toxic materials, pressures above 1 bar (0.1 MPa or 14.5 PSIG), or temperatures above 100°C. Some tubular glass gauge designs have extra protection against breakage, an improvement on the simple guard rods of standard designs.

The protection elements may include an outer tube that contains the fluid if the inner tube is fractured, sheet metal protectors, and a wire glass protector surrounding the gauge glass. Even considering these improvements, it is recommended that flat glass, reflex, armored, and magnetic gauges be specified when the process includes hazardous materials, high temperatures, or high pressures.

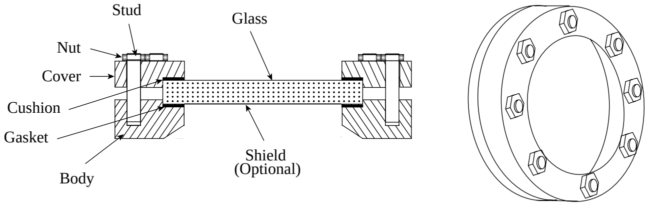

FIG. 3.10d
Construction of a circular gauge. Cutaway view (left) and side view (right).

CIRCULAR TRANSPARENT GAUGE

Circular level gauges (some small versions are also called *bull's-eye gauges*) are mounted next to the monitored vessel at the elevation of interest for level indication, as shown in Figure 3.10a. The circular gauge has a limited range and is used when the level variation that must be indicated is small. This type of gauge is typically constructed as shown in Figure 3.10d. The body, glass, and gasket are wetted by the process. A shield can be added to protect the glass from the process fluid if required.

Since circular gauges are used to indicate liquid level over a relatively short range, two or more can be used to show high and low levels, and other gauges can be used at selected locations in between. They can also be used to show fluid in motion and fluid color or contamination.

TRANSPARENT GAUGE (LONG FORM)

When monitoring levels over a wider range than is practical with a circular gauge, a long-form flat glass transparent gauge can be used. Typically, if a flat glass gauge is not specified as being circular, it is assumed to be long-form, and the term *long-form* is not added. The construction of a transparent gauge is shown in Figure 3.10e. The measuring chamber retains the fluid and accepts the glass and covers, which are secured with bolts. One or more vision slots are machined into the chamber to allow viewing of the level. Tie bars are areas that may be left (i.e., not machined out) in the vision slot so as to provide higher strength. Gasket material is compressed between the chamber and the glass to prevent direct contact and to provide a seal. Cushions are placed between the glass and the covers to prevent direct glass-to-metal contact. The chamber, glass, and gaskets are wetted by the process. Shields can be optionally installed to protect the glass from the process fluid and/or from the ambient environment (e.g., windblown sand).

The gauge is called *transparent* because there are glass panels both in front of and behind the measuring chamber, with respect to the observer who is reading the gauge. Accordingly, the liquid level indication is illuminated by light coming from behind. This configuration is useful to allow

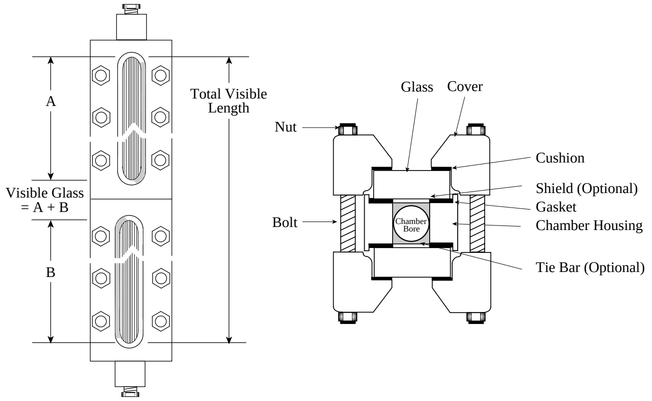

FIG. 3.10e
Transparent level gauge construction, front view (left), and cutaway view (right). The front view shows two covers attached to one chamber, and shows the distinction between visible length and visible glass.

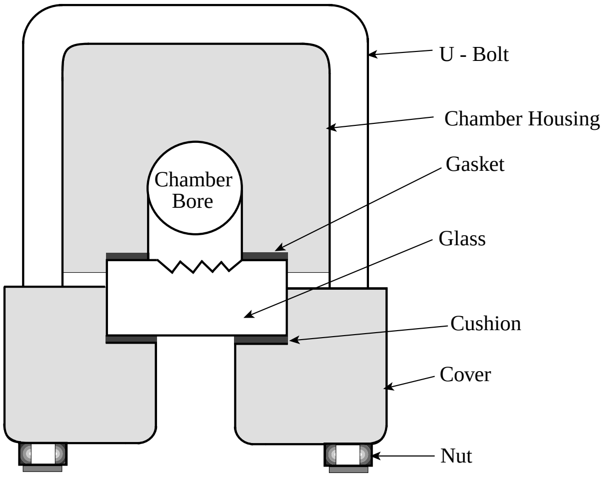

FIG. 3.10f
Construction of a reflex glass level gauge.

visual inspection of the liquid for color and presence of particles, for example, in addition to indicating the level. One drawback is that it requires the availability of some light from behind. Lighting panels (called *illuminators*) are available for providing this illumination when it is not available from the ambient lighting. Because of the process fluid viewing capability, transparent gauges can be used in applications that require the indication of the interface between two liquids.

As indicated in Figure 3.10e, the *total visible length* is the distance between the uppermost and lowermost possible reading positions. There may be some unreadable areas included, resulting from tie bars and top and bottom edges of covers. The *visible glass* is the sum of the lengths of unobstructed glass available for viewing.

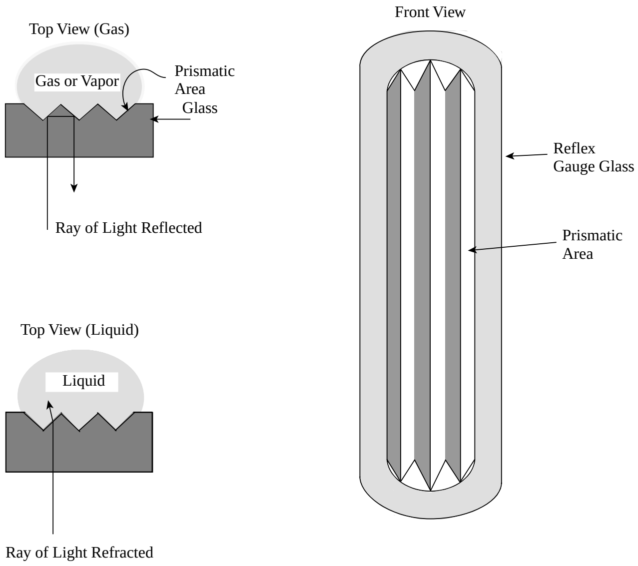

FIG. 3.10g
Light is directed back toward the observer in the gas or vapor space above the liquid in a reflex gauge (top, left). Where liquid touches the glass (bottom, left), light is not reflected. The figure on the right shows a gauge glass with grooves forming the prismatic area.

REFLEX GAUGE

Greater visibility of the transition between the liquid level and the gas or vapor above it is provided by the reflex-type glass gauge. The construction, shown in Figure 3.10f, incorporates a glass element in front of the measuring chamber housing, but not behind it. Illumination is only from the front, and level visibility is aided through the use of grooves in the glass where it contacts the liquid being monitored.

The gauge glass is smooth on the outside (the side toward the observer). The grooved surface is called the *prismatic* area. The face of each groove is at a right angle to the faces of adjacent grooves. When the prismatic area *is not in contact* with a liquid, the groove faces reflect the incoming light. The light is reflected due to the large difference in the index of refraction between the glass and the gas or vapor above the liquid. The incoming light strikes one groove face, is reflected across to the adjacent groove face, and then is reflected back to the observer in front of the gauge (see Figure 3.10g).

When the prismatic area *is in contact* with a liquid, there is little difference in the index of refraction between the glass and the liquid, so the light passes through the prismatic area at a slight angle (it is refracted) without being reflected back toward the observer. The combination of these two effects provides an improved visibility of the liquid and an increase in the distance over which the level indication can be viewed.

When viewing a transparent or semi-transparent liquid in a reflex gauge, the liquid will appear black or dark because the light is not reflected back to the viewer from the prism area. The column above the liquid will appear silvery, because the light is reflected back from the glass-to-gas interface at the prism area (e.g., there will be a dark column below the indicated level and a silvery column above the indicated level). An opaque liquid will show its color in the liquid column area (e.g., milk will show a white column below the indicated level, with a silvery column above the indicated level). Because of the reflection of light back to the viewer, reflex gauges are well suited to viewing with a flashlight in low-light areas.

Because of the front illumination and the prismatic glass, reflex gauges are recommended for use only with clean, clear, process fluids and when there is no liquid–liquid interface to be viewed. Because of its irregular shape, shields cannot be installed against the prismatic glass, so corrosive fluid service is limited to those with little or no effect on the glass.

Armored Gauges

Since a gauge of standard construction provides for clamping of the glass between the cover and the measuring chamber, the edges of the glass may be exposed. In an armored gauge, a lip is formed into the cover, and it wraps around and covers the sides of the gauge glass. So, between the chamber and the cover, the edge of the gauge glass is completely covered. The purpose is to protect the glass from possible damage resulting from, for example, accidental impact from a wrench. The front of the cover is also made thick enough to prevent contact with the glass if the same wrench were to hit the front of the cover.

Armored gauges are also often made for extreme duty (e.g., vibration, high temperature, or high pressure). They utilize thicker glass and measuring chamber walls and higher-performance gaskets, and they may have shorter spans of visible glass separated by tie bars in the measuring chamber. They are often used in pressure vessels and where no electrical power is available to operate electronic level indicators. Many manufacturers supply only armored-style gauges.

Gauge Glass Materials

Borosilicate glass is the most common type of gauge glass. It has good chemical resistance up to about 300°C. In addition, transparent shields can be mounted between the glass and the process fluid to protect the glass from corrosive media in transparent level gauges (e.g., the shields can be made of mica or PCTFE).

Borosilicate glass is usually tempered to improve its resistance to thermal shock. The tempering process comprises the heating of the glass to the glassy transition point, followed by rapid cooling. This is done during manufacture of the glass to induce mechanical compressive stress in the outer layer, resulting in an increase in the ultimate tensile strength (UTS). The tensile strength is increased, because the compressive stresses must be offset by tensile stresses before cracks can propagate (cracking is required before breakage of the material).

Aluminosilicate glass has a lower coefficient of linear thermal expansion (also called t/c) than borosilicate glass, but it can be used at higher process temperatures of up to 425°C. While borosilicate glass has a t/c of 4.5×10^{-6}/°C, aluminosilicate glass has a coefficient of only 2.0×10^{-6}/°C. For comparison, the t/c of carbon steel is 23×10^{-6}/°C, and type 316 stainless steel (SS) is 17×10^{-6}/°C.

Quartz glass has the highest temperature rating (up to 530°C) and also has the lowest t/c (0.5×10^{-6}/°C). It can be used in transparent gauges but is not available in reflex gauges, because it would be difficult to form the grooves. The materials of construction other than quartz determine the maximum operating temperature of a quartz gauge assembly. Extremely flat gasket and cushion seating surfaces are required when using quartz glass to avoid bending and torsional or point stress. Belleville® spring washers are used to control the clamping forces between the glass and its seating area.

Fused natural quartz is made by melting naturally occurring crystalline silica. Synthetic fused quartz (or synthetically fused silica) is made by melting man-made silicon dioxide.

Design Features

It is typical for all glass level gauges to have a reduction in pressure rating as the temperature increases. Manufacturers list representative charts for general guidance in selecting the type of construction and components to meet the application requirements. Once the complete gauge model has been specified, including chamber model, glass type, shields, and so forth, it is important to verify with the manufacturer the resulting temperature vs. pressure curve for that particular configuration.

Transparent and reflex gauges are normally limited to a maximum single-gauge length of up to 1.5 m. If a greater total visible length is required, multiple gauges will have to be installed. Overlapping is suggested to allow viewing of levels that would otherwise be blocked by the top and bottom edges of the covers.

To reduce problems from boiling or foaming process fluids, a larger-diameter measuring chamber (approximately 50 mm) can be used as shown in the top row of gauge cross sections illustrated in Figure 3.10h.

In cryogenic service, the view of the level in standard glass gauges may be blocked by ice accumulation. A nonfrosting lens can be added that consists of a T-shaped plastic lens held against the glass by the cover and extending out in front of the glass. The plastic lens has a relatively low thermal conductivity and is not as cold on the front viewing surface as the face of the gauge glass, which reduces frosting.

Heating or cooling of the gauge may be required to keep it at approximately the same temperature as the process fluid in the vessel. The appropriate device may be added externally or mounted in the bore of the chamber.

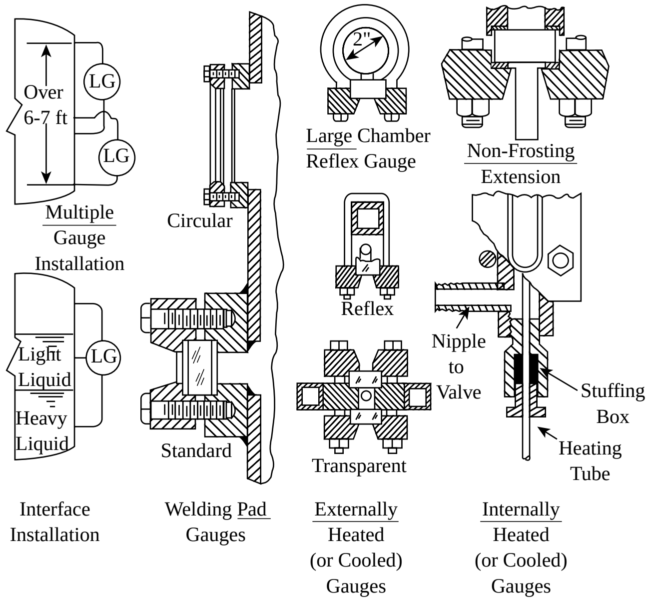

FIG. 3.10h
Special level gauge designs and cross sections.

GAUGING INACCURACIES

Gauge error usually depends on the resolution of graduations on the scale, if provided. Readability can be degraded by foaming, boiling, and other effects that alter density or reduce visibility. The indicated level can be affected by a difference between the temperature of the gauge and the vessel. If the gauge is cooler than the vessel, the liquid within the gauge may be more dense and therefore indicate low. This can be eliminated by using a heater on the gauge and controlling the gauge temperature to match the vessel temperature. Conversely, the gauge temperature can be reduced, if needed, by adding a cooler in a similar manner. Gauge heating/cooling configurations are shown in Figure 3.10h.

In a gauge with a magnetic follower, some error is due to the strong magnetic attraction required between the float magnet and the follower magnet, which induces friction on the walls between them. The resolution of magnetic flag indicators is controlled by the spacing of the individual indicator flags, typically about 6 mm. Magnetostrictive transducer-based indicators can resolve the float position to 0.1 mm or less and do not have a detectable magnetic attraction between the transducer and the float magnet.

Foaming or boiling can show false high readings because of an apparent lower specific gravity (SG) of the fluid in the gauge compared to the fluid in the vessel (if the vessel fluid has less foaming or boiling). This can be reduced by using a gauge with a larger chamber diameter, as was shown in Figure 3.10h.

Internal condensation can cause readings to become blurred. To prevent this, a heater can be added inside or outside the chamber.

ACCESSORIES

Gauge support brackets are used with long gauges, where the distance between supports is about 1.5 m or longer, to reduce the load placed on nipples and valves. Steel brackets are welded directly to the measuring chamber and then bolted to a support plate on the vessel. On a reflex gauge, the bracket can be welded to the back of the chamber (between sections to avoid interference with cover bolts). On a transparent gauge, suitable welding locations include the right or left side of the chamber, between sections. The brackets are normally welded on at the factory according to customer specifications.

Valves and fittings are also needed, of course, for the installation of level gauges. Fittings can be any of several types, including spherical union, flanged, socket weld, solid shank, or NPT union. Spherical unions allow correction of misalignment but may be difficult to seal if they are connected more than once.

Valves are normally factory assembled to the gauge. The fitting of unions to the vessel side of the gauge valve will facilitate the initial connection of the gauge. The gauge can be removed without depressurizing the vessel if valves are included on both the gauge and vessel sides of the unions. Gauge valves are normally supplied with ball checks to minimize venting to the atmosphere in case of breakage of a section of the gauge.

Teflon coating is a common requirement in the chemical processing industry. The Teflon can be applied by electrostatic spray or by wet spray. It often includes a base coat of PTFE followed by a top coat of PFA, with a minimum total thickness of 0.25 mm. Maximum service temperatures are up to 230°C. The user should specify whether the Teflon coating is required only for the wetted parts or for the complete gauge.

An illuminator can be used with transparent gauges to increase visibility in lower-light areas. A lamp is used with a diffuser to illuminate the entire visible glass area. Explosion-proof versions are available for use in hazardous areas.

Scales can be engraved or etched in the desired units and are attached to the gauge cover. If the installed scale does not accurately indicate the actual level in the vessel, a calibration can be undertaken. The calibration data can be used to derive a conversion factor between the indicated reading and the actual vessel volume.

APPLICATION-SPECIFIC REQUIREMENTS

Low-temperature applications require specific attention to gauge materials. Some materials, particularly ferritic steels, change from their normally tough property to a more brittle behavior with a decrease in temperature. The transition temperatures and toughness vary with different materials. When materials are used under conditions in which brittle behavior may occur, there is a potential that minor internal flaws, which would not present a problem if the material were sufficiently tough, may propagate to failure (see ASTM A352 supplements[1] for more information).

Boiler and steam/water gauges must be reliable to ensure the safety of personnel and equipment. High pressures and temperatures require attention to the specification and application of all parts and materials of the gauge, valves, and fittings. Saturated steam tables should be consulted to ensure that the operating pressure and temperature for the application are within the range shown in the tables provided by the gauge manufacturer. Standard glass level gauges may not be suitable for use with steam. Check with the manufacturer of the gauge to find out which models are specifically suited for use with steam at the vessel design pressure/temperature ranges. Shields (usually mica) should be used to protect against etching of the glass (the etching is also called *frosting*, but this is different from frosting due to accumulation of ice in cryogenic systems). Transparent gauges are used because shields cannot be applied to the prismatic surface of reflex glass. For more information on boiler equipment installation requirements, consult the ASME Boiler and Pressure Vessel Code, as well as codes that are specific to the locality in which the equipment will be installed.

Hydrofluoric acid applications require special materials to prevent attack of the gauge glass by the acid. Hydrogen fluoride (HF) is an extremely corrosive gas that becomes hydrofluoric acid in solution with water. Like many acids, it vigorously attacks most metals but also attacks glass and other silica-containing materials. Some fluorinated polymers are designed to protect against hydrofluoric acid, including PCTFE (Kel-F®), ETFE (Tefzel®), and PECTFE (Halar®). Metals used with HF can be Hastelloy®C up to 90°C or K-Monel®.

INSTALLATION

The level gauge(s) should be installed so that the full operating range can be observed, including levels found during warm-up and cool-down, and as indicated by switches, displacers, and so on. For multiple gauges, overlap their elevations so the complete range of levels can be seen without the view being blocked by the top and bottom edges of the covers. As shown in Figure 3.10i, this can be done by installing single section gauges on a standpipe. Using a standpipe also can reduce the number of vessel connections and increase the flexibility in the mounting and positioning of the gauges.

To obtain the lowest error when viewing a liquid–liquid interface, add a central connection to the vessel in the area of the lighter liquid phase, in addition to the top and bottom connections. This will prevent errors due to an excessive column height of the light phase when the top level of the light phase is below the upper connection (bottom-left area of Figure 3.10h).

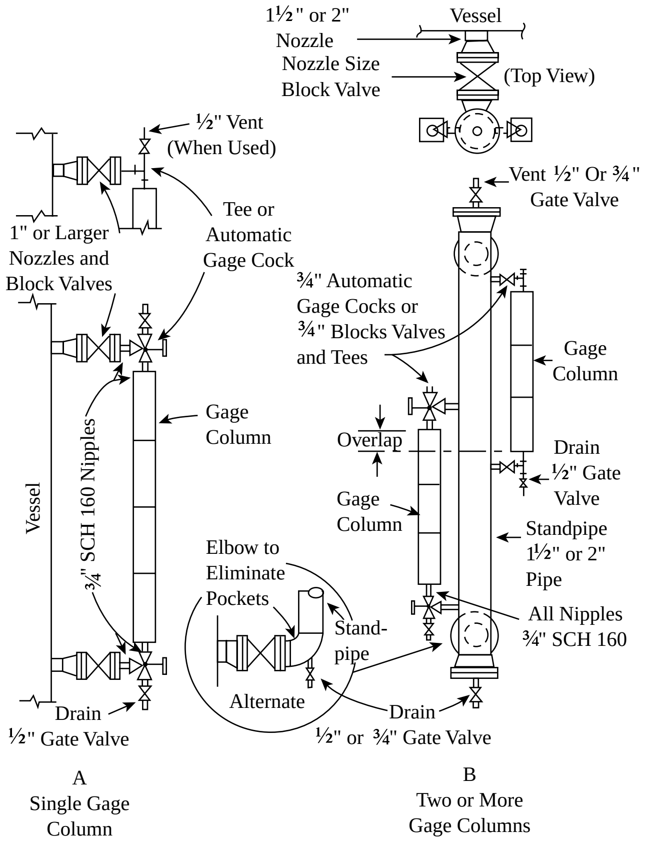

FIG. 3.10i
A gauge column (left) may incorporate several gauge glass and covers on one chamber. A standpipe (right) allows more flexibility.

An expansion loop can be added to gauges that will operate over a wide temperature range to allow for differences in the coefficient of thermal expansion between the gauge and the vessel (see Figure 3.10j). An expansion loop is also particularly useful in cases where the gauge can be valved off and allowed to cool, while the vessel is still hot.

MAGNETIC LEVEL GAUGES

Because the magnetic level gauge does not require direct viewing of the level (i.e., there is no need for glass), the measuring chamber can be opaque, and welded metal construction is normally used. This substantially widens the operating temperature range and increases the ruggedness as compared to chambers using gauge glass. The wide temperature range is possible, because the measuring chamber can have approximately the same coefficient of thermal expansion as the vessel, and there is no glass (which would have a lower t/c) to interface with the metal chamber.

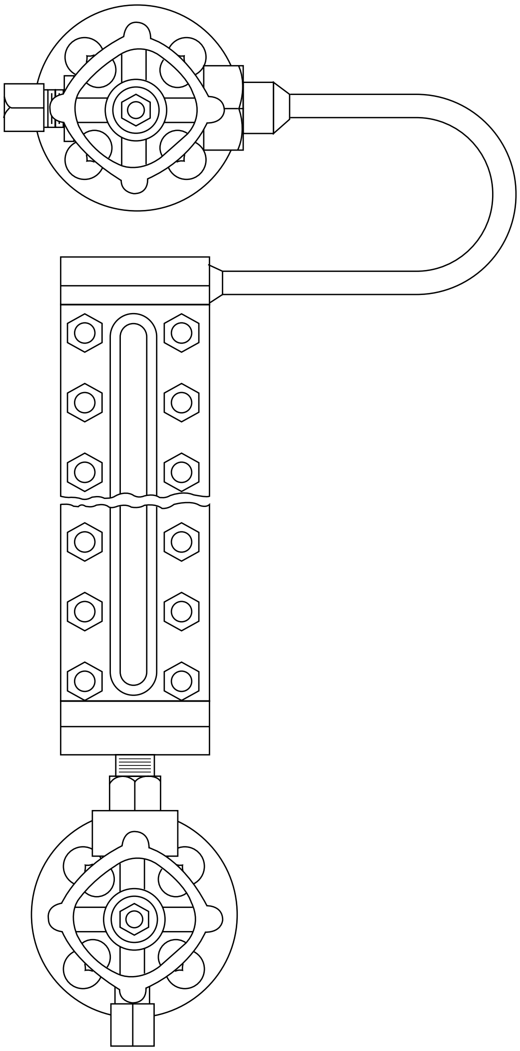

FIG. 3.10j
Installing an expansion loop improves reliability over a wide temperature range.

To allow the magnetic system to operate properly, the chamber metal must be of a nonmagnetic type—usually an austenitic stainless steel such as AISI 316 SS.

Because the float in the chamber of a magnetic gauge incorporates a permanent magnet, any reliable method of detecting the location of a magnetic field can be used to show the location of the float and, thus, the level. Three common methods of indicating the float position are the magnetic follower, magnet-operated flags, and magnetostrictive linear position transducers (also called *magnetostrictive transducers*).

Magnetically operated reed switches may require maintenance and lack the long-term reliability needed for many industrial applications. Therefore, they are not presented here.

One limitation in magnetic gauges is that the float must have a comparatively thick wall to operate at higher pressures. Due to the related weight, it is more difficult to measure process fluids of low SG (e.g., less than 0.45) when the pressure is high (e.g., over 200 bars/20 MPa).

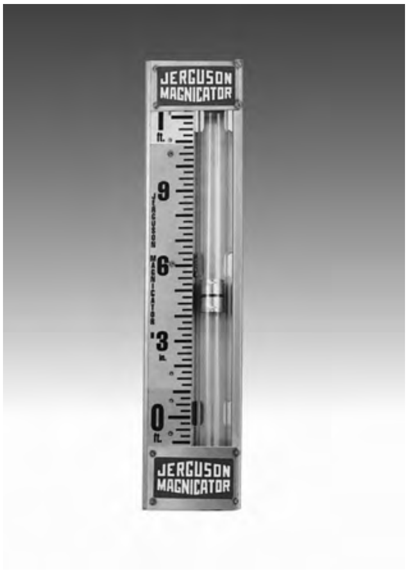

FIG. 3.10k
This magnetic follower can be mounted alongside the measuring chamber of a magnetic level gauge to indicate the float position. (With permission from Clarke-Reliance.)

Magnetic Followers and Indicators

Magnetic followers and magnetic flag indicators are mounted alongside the measuring chamber of a magnetic gauge. A magnetic follower is shown in Figure 3.10k. A magnetic flag indicator was shown in Figure 3.10b. A permanent magnet inside of the float (within the measuring chamber) lines up with the follower or adjacent flag as the float slides up or down the measuring chamber. In the case of the follower, the position of the follower is read against a scale. Friction of the follower against the adjacent wall is substantial because of the magnetic attraction between the magnet in the follower and the magnet in the float. This causes an additional limitation on resolution, which is observable as a discontinuous motion of the follower in response to level changes.

With magnet-operated flags, the magnet in each flag causes it to flip one way as the float passes while moving upward and flip the other way as the float passes while moving downward. The flags can be colored red and white, for example, to show a red line from the bottom of the indicator up to the indicated level and a white line above that. Red, orange, and yellow are often used, because they are highly visible. Fluorescent colors are good, because they are more easily read when using a flashlight.

Some limitations include an occasional flag flipping the wrong way and coarse resolution of ≈6 mm. An incorrect flag position is sometimes caused by the float bobbing up and down or by rapid movement of the level. The flag position can be corrected by passing a magnet along it externally. If the actual float position is in question, it can be found by using a compass and watching the needle movement.

The resolution of the flag indicators is limited by the spacing of the magnetic flags and somewhat by the friction of the float against the measuring chamber wall resulting from the attraction between the magnets in the flags and the magnet in the float.

Magnetostrictive Transducers

Magnetostrictive transducers and associated indicators represent an improvement in the state of the art in level gauges. They can increase the effectiveness of installed magnetic gauges having followers or flags, or they can stand alone in new installations for accurate level gauging without the associated limitations of using glass gauges. The original loop-powered magnetostrictive transducer was invented and developed in 1990 by the author.[2] Magnetostrictive transducers are now available from several manufacturers.

A magnetostrictive transducer is a linear device that can detect the location of a magnetic field (provided by the position magnet) that moves along in parallel to the sensing probe of the transducer (see Figure 3.10l). When used with a magnetic level gauge, the magnet within the float acts as the position magnet. A magnetostrictive transducer can be added to a follower or flag-type gauge, but it exhibits the highest performance when used with a simple nonmagnetic metal tube (such as type 316 stainless steel) that contains a float/magnet assembly.

The primary component inside of a magnetostrictive transducer is called the *waveguide* (see Figure 3.10m). When a current pulse (called the *interrogation pulse*) is applied to the waveguide circuit, a torsional force is induced into the waveguide at the location of the position magnet. This phenomenon is called the *Wiedemann effect.* Also, a timer circuit is initiated when the interrogation pulse is applied.

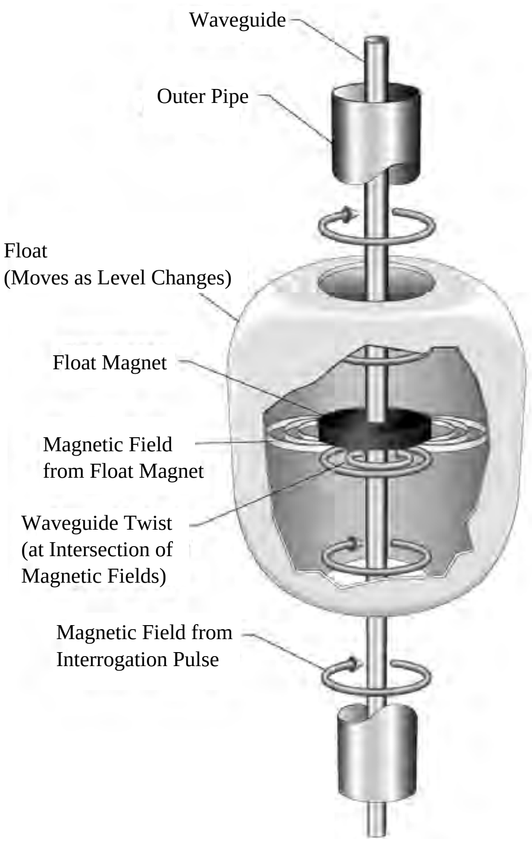

FIG. 3.10m
A torsional strain wave (waveguide twist) travels along the waveguide of a magnetostrictive transducer. The wave starts at the location of the float magnet, and its travel time to one end of the waveguide is measured.

The torsional force causes formation of a strain wave that travels at the "speed of sound" in the waveguide material (≈2850 m/sec). When the strain wave arrives at the pickup, it is detected, and the timer is stopped. The elapsed time measured by the timer indicates the location of the position magnet. The time is converted into the desired output signal, usually 4 to 20 mA or a digital communication protocol.

Because the diameter of the waveguide is small (less than 0.5 mm), there is no detectable attraction between it and the magnet within the float, and hence there is no float friction due to magnetic attraction against the chamber wall. This is one reason why the resolution and accuracy can be better than indicated by a follower or flag indicator. The other reason is that a magnetostrictive transducer can resolve as small a position difference as a few microns, but indication resolution is limited by the float system to about 0.1 mm.

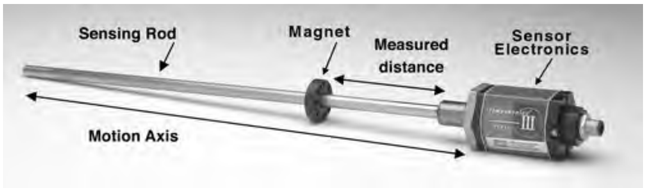

FIG. 3.10l
A magnetostrictive transducer measures the location of a magnet, called the position magnet. (Courtesy MTS Systems Corporation.)

Figure 3.10n shows the application of a magnetostrictive transducer to a magnetic level gauge. The transducer output can be indicated locally or remotely, on a stand-alone indicator, or as an input to a computer or data acquisition system or other device.

REMOTE READING GAUGES

Several schemes for remote reading gauges have been employed for high-pressure and high-temperature applications of up to 3000 PSIG (20 MPa) and 371°C. Remote reading gauges are often needed to meet the requirements of steam boiler codes. Differential pressure, conductivity probe, and circular gauge glass configurations have been used in the past. However, since the mid-1990s, the remote reading capability of a magnetic gauge with magnetostrictive transducer has become a preferred method to consider when power is available for operation of the transducer.

FIG. 3.10n
A magnetostrictive transducer is shown mounted to the right side of a magnetic level gauge with a flag indicator. (With permission from Clarke-Reliance.)

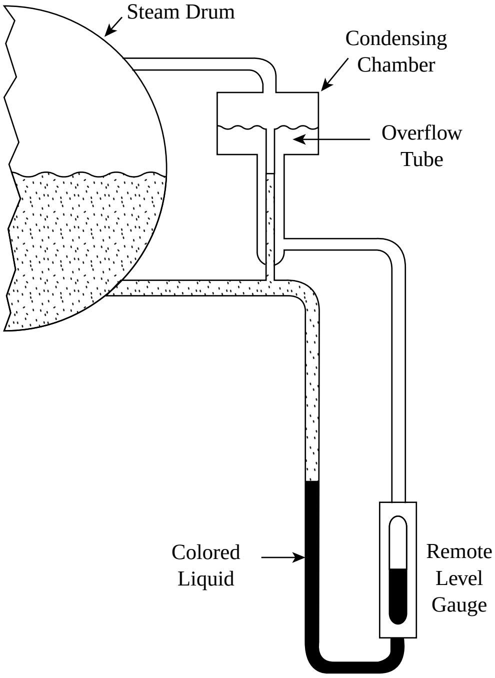

FIG. 3.10o
A differential pressure type of remote reading level gauge is useful when there is no power available.

Differential Pressure

A *differential-pressure* remote reading gauge is shown in Figure 3.10o. The maximum level is fixed by the elevation of the overflow tube in the condensing chamber. The actual level is obtained by measuring the difference in hydraulic head between the level in the chamber and the level in the overflow tube, the latter being equal to the level in the steam drum. The legs are connected to a manometer assembly filled with a colored liquid that is insoluble in water. A transparent gauge is used as a portion of the manometer and located so that the colored liquid in the gauge will rise as the level in the steam drum rises. For accurate level indication, it is important to keep both legs of the system at the same temperature. Also, when specifying this type of gauge, it is important to specify the pressure of the steam drum, because the water in the steam drum may contain bubbles of steam and thus have a significantly lower specific gravity than that in the gauge. This arrangement is useful in applications where power is not available.

Conductivity

A *conductivity probe* configuration was sometimes used in boiler systems and composed of a metal chamber with a series of conductivity probes. As the water rose in the chamber, successive probes energized their associated switches and relays. This arrangement had the safety advantage of not requiring a gauge glass, but its complexity was a disadvantage, and its long-term reliability was not as high as that of magnetostrictive transducers now available. It also required power for operation of the conductivity switches, relays, and indicator lights. The electrodes of the conductivity probes were subject to corrosion and routine replacement, and resolution was limited by the spacing of the conductivity sensing electrodes. This method is not recommended for new installations.

Circular Gauges

Circular gauges and closed-circuit television monitoring have also been used for remote indication; but again, the complexity, coarse resolution, and long-term reliability have no advantage over the currently preferred magnetic gauge with magnetostrictive transducer for remote reading. These methods also required power for operation of the light sources and video monitor.

Magnetostrictive Transducers

Magnetostrictive transducers used with magnetic gauges now constitute a preferred method of remote indication in applications where power is available for operation of the transmitter (see Figure 3.10n). The measuring chamber is normally a metal tube containing a float that rides on the liquid level so that the center of the float is even with the level. If there is a liquid–liquid interface, a float can be weighted to sink through the lighter liquid and float so that its center is at the interface level. It is also possible to use two floats, the first one riding at a liquid–liquid interface (indicating the level of the heavier phase) and the second one floating on and indicating the level of the lighter phase.

Although power must be provided to operate the magnetostrictive transducer, the advantages of this arrangement over other remote indicator types include increased safety (because no gauge glass is needed), a lack of parts that need recalibration or replacement, and obtainable resolution of better than 1 mm. A wide range of electronic remote indicators are available. The electronic output signal can be directly read by current-loop-compatible indicators and other equipment or fed to data acquisition systems or computers.

CONCLUSION

The various types of glass level gauges provide a means to view the liquid level as well as the color and possible contamination of the liquid. For accurate level indication, foaming and boiling must be minimized. The process fluid in the gauge should be at the same temperature (and density) as that in the vessel. Tubular glass gauges are not recommended for hazardous applications such as toxic liquids, high temperature, and high pressure. Magnetic level gauges can provide a higher safety margin when direct viewing of the liquid is not required. Magnetic level gauges with magnetostrictive transmitters yield the lowest errors, where power is available, at a higher cost. They also provide easy means for remote indication and communication interface to data acquisition systems and computers.

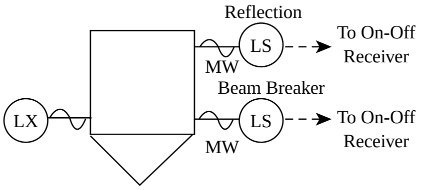
3.11 Microwave Level Switches

J. L. DANIEWICZ (1995) **W. H. BOYES** (2003)



Flow Sheet Symbol

Applications	Microwave level switches can be used on liquids and small-particle-size solids if they are noncoating and have a dielectric greater than 10; they are suited for interface as well. The reflection switch is also suited for interface. The reflection switch is suited for denser material; the beam breaker switch is not limited by density or particle size, but it is limited by vessel diameter.
Design Pressure	Up to 400 PSIG (275 kPa) for reflection type; depends on vessel window for beam-breaker type
Design Temperature	Up to 400°F (200°C) for reflection type; depends on vessel window for beam-breaker type (up to 600°F [300°C])
Wetted Materials of Construction	TFE, polyphenylene sulfide, or ceramic as standard for reflection type; firebrick, plastic, unleaded glass, quartz, or mica window for beam-breaker type
Range	Immediate proximity for reflection type; up to 100 ft (30 m) horizontal transmission in air for beam-breaker type
Inaccuracy	0.125 in. (3 mm) for reflection type; ±0.25 to 0.5 in. (6 to 13 mm) for beam-breaker type
Cost	$400 to $1200 for beam-breaker type (cost may vary according to cost of transmission window and material)
Partial List of Suppliers	Reflection type: WADECO Ltd. (www.wadeco.co.jp) Beam-breaker type: Delavan Process Instrumentation Div. of L & J Technologies (www.landj.com) (X-band) STI (www.sti.com) (K-band) Insatech (www.insatech.com) WADECO Ltd. (www.wadeco.co.jp)

This section discusses the use of side-mounted microwave level switches that are used in hard-to-handle solid, liquid–solids interface, and liquid–liquid interface applications. Top-mounted microwave detectors that use the radar technique for continuous level measurement on liquid applications are covered in Section 3.13. Microwave level switches were briefly popular in the early 1990s as a replacement for RF switches and gamma nuclear point level switches. However, due to instability and erratic operation, most manufacturers have ceased making them. There is no current U.S.-based manufacturer of reflection-type microwave point level switches, but the information is included for historical purposes. Typically, the beam-breaker switches are used in solids applications, although they can be used in liquids.

Microwave level detectors use electromagnetic radio waves, typically in either the microwave X-band, around 10 GHz, or the microwave K-band, around 24 GHz. Because these are short-range measurements, emissions are at very low power levels ranging from 0.6 to 32 mW/in.^{2} (0.1 to 5 mW/cm^2). At these energy levels, health, safety, licensing, and product contamination concerns are minimal, and only solid-state diodes (instead of tubes) are needed to generate and detect the microwaves.

Microwaves do not pass through metal walls, but they do pass through fiberglass or plastic tank walls and through windows of plastic, ceramic, or glass that are installed in metal vessel walls. As long as the window material has a relatively low dielectric constant (e.g., less than 4.0), and as long as its thickness is close to an *even multiple* of a half wavelength, attenuation is minimal. (Wavelength can be calculated by dividing the wavelength in a vacuum by the square root of the window material's dielectric constant.)

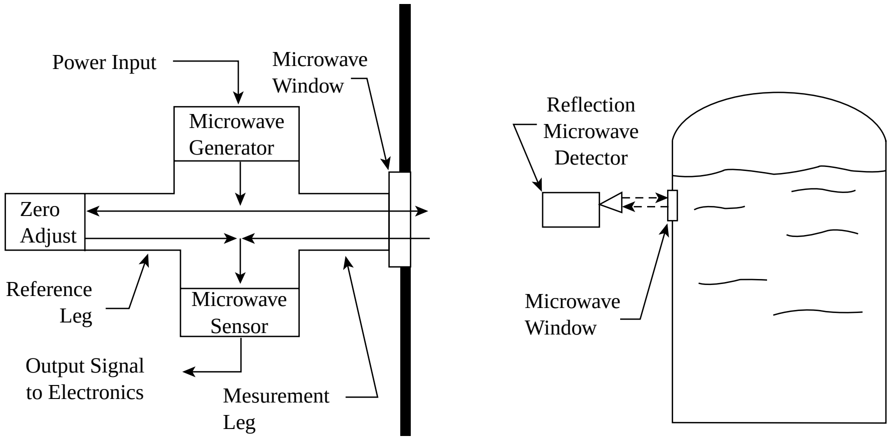


FIG. 3.11a
Reflection detector with balanced bridge (patented).

This permits the use of thick windows to withstand heavy abrasion on solids service and to isolate the sensor from hazardous and toxic liquids on high-pressure service.

Another advantage of the microwave technique is that the presence of dust, mist, or nonmetallic foam has negligible effect. The dielectric constant of these compositions is essentially the same air; therefore, their beam reflection and transmission characteristics are similar to those of free space. They appear to be somewhat product and installation sensitive, however, so it is recommended that the engineer be mindful of that fact when specifying one of these switches.

REFLECTION SWITCHES

There is currently only one manufacturer of this type of switch. Several manufacturers use this technique, but it is used for flow/no-flow sensing instead of level sensing. The sensors are quite similar, however, and the information is furnished for completeness.

This type of detector, shown in Fig. 3.11a, uses changes in the amplitude and/or phase of the reflected signal to determine material presence. Reflection is proportional to the dielectric constant of the material immediately next to the process window, as shown in Fig. 3.11b. Air, other gases, and foam have a low dielectric constant and return little or no signal. Materials with high dielectric constants, such as water, tend to return almost the entire signal.

One type of reflection detector, shown in Fig. 3.11a, compares the return signal to a reference signal in a balanced bridge circuit to provide additional sensitivity. This helps the detector to recognize low-dielectric materials such as plastic pellets (dielectric of 1.1), and it is useful for liquid–liquid interface and liquid–solid interface detection on materials that have a little as 0.1 difference in dielectric constant.

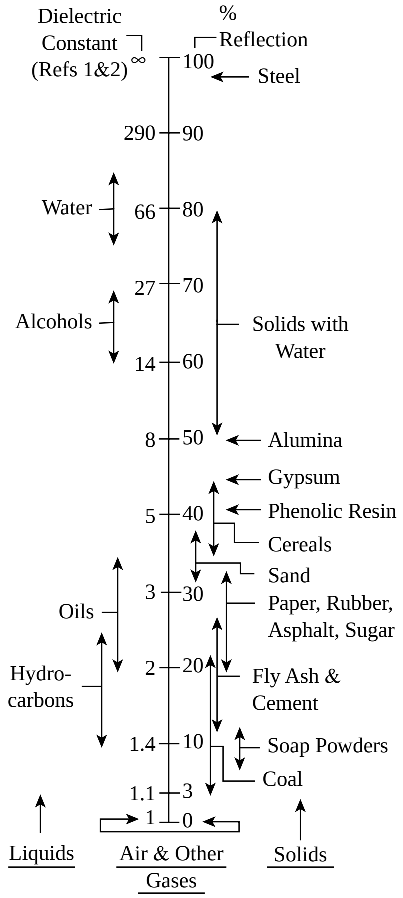

FIG. 3.11b
Microwave reflection characteristics.

On solid applications, the reflection technique is limited to detecting particles with diameters less than 0.25 in. (6 mm) for an X-band detector and to 0.1 in. (2.5 mm) for a K-band detector. Above this size, the particles begin to scatter the

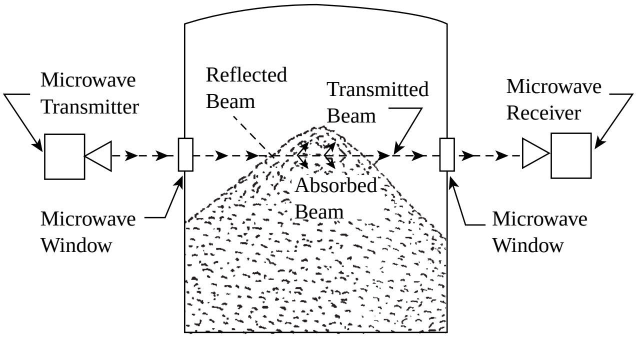

FIG. 3.11c
Beam-breaker detector.

beam and reduce the amount of signal that is reflected directly back to the detector.

BEAM-BREAKER SWITCH

This type of a detector sends a beam across the measurement zone, as shown in Fig. 3.11c. When air or vapor is in this zone, a strong signal is received at the detector. When process material breaks the beam path, it reduces the signal received at the detector as a result of signal reflection and beam absorption in the material caused by molecular and ionic resonances.

Beam-breaker detectors are very small antennas, so the beam's included angle is fairly wide: about 26° for K-band and 50° for X-band. Thus, alignment is not critical. Although signal amplitude falls off rapidly in proportion to the square of the distance, separation distance can still be up to 100 ft (30 m), which is considerably greater than with ultrasonic or nuclear approaches.

On solids services, the detector will not provide repeatable performance if it is expected to detect the top of the solids pile in the tank. Its switching action will be repeatable when the transmitter and receiver are both covered by solids at the time of switching.

COATING EFFECTS

Microwave devices can tolerate more coating than ultrasonic or laser units but less than radiation-type level switches. The amount of coating that microwave switches can tolerate is a function of their frequency band (K or X) and of the nature of the coating (conductive or nonconductive). The maximum coating thickness that can be tolerated is given in Table 3.11d.

TABLE 3.11d
Maximum Coating That Can Be Tolerated by Microwave-Type Level Switches

Microwave Frequency Band	*Maximum Coating Thickness*	
	Conductive Coating (e.g., water-based)	*Nonconductive Coating (e.g., hydrocarbon-based)*
X	.125 in. (.3 cm)	1 in. (2.5 cm)
K	.06 in. (.16 cm)	.5 in (1.25 cm)

CONCLUSION

Because of their expense, both types of level switches should be considered primarily for the more difficult applications or where a nonintrusive measurement provides major advantages. The beam-breaker type is the more expensive, as it requires two devices to be installed along with separate windows on metal vessels. However, because it can detect large solid particles, and because windows can be selected that are both thick and abrasion resistant, the beam-breaker technique is useful for detecting large and abrasive materials such as coal, minerals, wood chips, and vegetable pulp. It is also useful for detecting very light materials such as dry sawdust and powdered materials in fluidized beds, especially with the K-band design, which is more easily attenuated. Microwave level switches can be useful on granular solids and powders such as limestone, carbon black, and pelletized materials. In such applications, they have advantages in terms of abrasion and coating resistance as well as having no mechanical parts in the vessel that can be broken or pulled off. They should also be considered on difficult-to-handle liquids that are viscous, toxic, or hazardous because the detector is isolated from the vessel contents. The reflection-type microwave switch is also sensitive to liquid–liquid and liquid–solid interfaces.

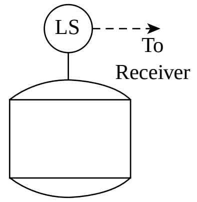
3.12 Optical Level Devices

D. S. KAYSER (1982) **B. G. LIPTÁK** (1995, 2003)



Flow Sheet Symbol

Types	Visible or infrared (IR) light reflection. Noncontacting type, usually for solids. Laser type (discussed in Section 3.9) is used for solids and molten glass. Light transmission designs are usually for sludge level, while light refraction is for clean liquid level services. Fiber optic probes of various designs for many applications are discussed in Section 8.23.
Applications	Point sensor probes for liquid, sludge, or solids (some continuous detectors also available)
Design Pressure	Up to 150 PSIG (10.3 bars) with polypropylene, polysulfone, PVDF, or Teflon®, and up to 500 PSIG (35 bars) with stainless-steel probes
Design Temperature	Between 150 and 200°F (66 to 93°C) with plastic probes and up to 260°F (126°C) with stainless-steel probes
Materials of Construction	Quartz reflectors with Viton® A or Rulon® seals, mounted in polypropylene, polysulfone, Teflon®, polyvinyl fluoride, phenolic, aluminum, or stainless-steel probes
Housings	Can be integral with the probe or remote. Explosion-proof enclosures and intrinsically safe probes are both available. With remote electronics, the fiber optic cable can be from 50 to 250 ft (15 to 76 m) long.
Dimensions	Refraction probe lengths vary from 1 to 24 in. (25 to 600 mm), and the probe diameter is usually 0.5 to 1 in. (12 to 25 mm).
Costs	Light-refraction level switches cost from $150 to $500. Portable sludge level detectors cost $1000. A continuous transmitter for detecting sludge depth or sludge interface costs $4000 and up.

The operation of optical level detectors can be based on the reflection, transmission, or refraction of conventional, laser, or IR light. Because laser level sensors have already been discussed in Section 3.9, and fiber optic systems will be dealt with in more detail in Chapter 8, we will concentrate here on sensors that operate with visible and IR light.

LIGHT REFLECTION

Reflected visible or infrared light beams can detect the level of liquids or solids, as illustrated in Figure 3.12a. A beam of light is aimed at the surface of the liquid or solids and is reflected back to a light-sensitive transistor, which is located in the same holder as the light source.

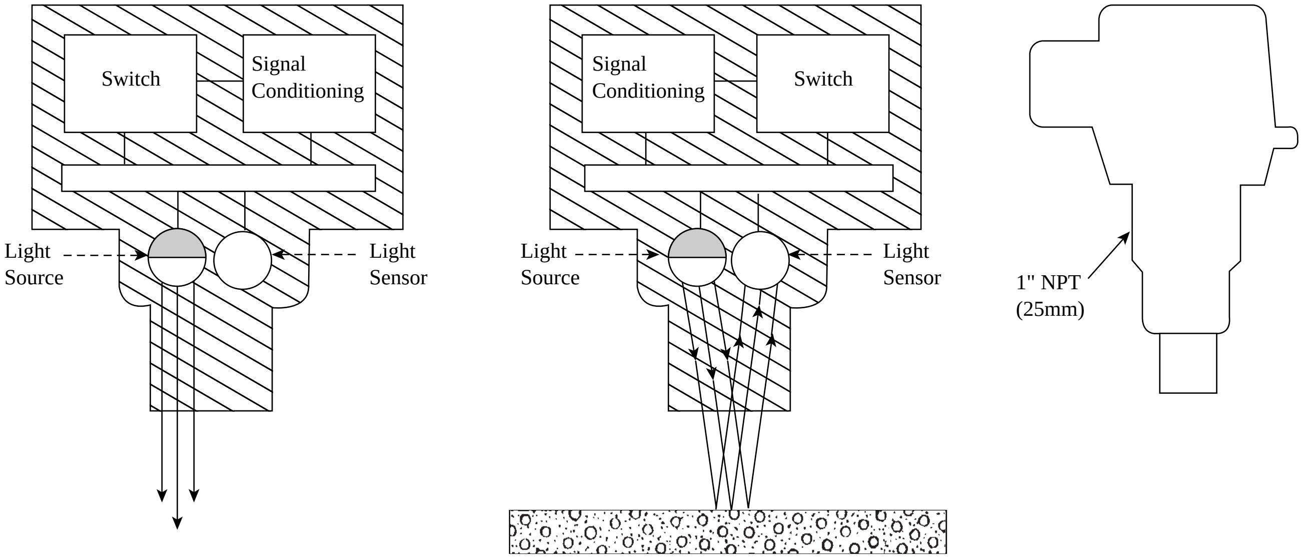

FIG. 3.12a
Noncontacting optical level sensor. (Courtesy of Bindicator, Inc.)

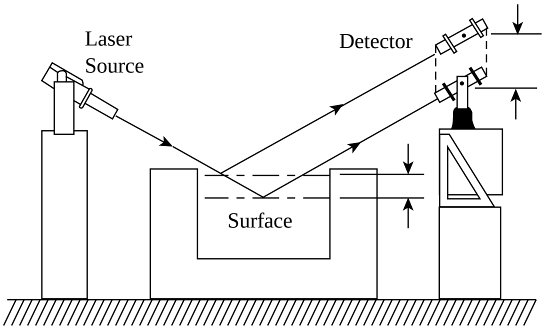

FIG. 3.12b
A laser beam reflected from the fluid surface is tracked by a servo-controller detector.[1]

As a point sensor (switch) on reflective, opaque liquids (such as milk) or on solids services, the transistor sensitivity can be adjusted to detect distances from 0.25 in. (6.3 mm) to 12 in. (300 mm). The sensor can be provided with several light-sensitive detectors to permit multipoint switch actuation. The allowable operating temperature range is from –40 to 150°F (–40 to 66°C). Because of its noncontacting design, the switch is suitable for use on corrosive, sticking, and coating process. The operation of the switch is adversely affected by changes in the reflectivity of the process.

The reflection of laser light (see Figure 3.9a) is used in some specialized applications. The measurement of the thickness of molten glass is illustrated in Figure 3.12b. Here, a laser source is mounted on one side of the process at an angle of between 15 and 60° from horizontal. The detector is mounted on the other side of the process and at the same angle as the source. As surface level changes, the reflected beam is displaced as shown in the figure. The detector is arranged so that this displacement can be measured, and the control unit is calibrated to convert the displacement to an analog signal proportional to level. It can also be furnished with alarm or interlock contacts.

For this unit to work properly, the surface of the process level must be clean and reflective. The span is limited to approximately 0.5 in. (12.5 mm). This noncontacting instrument can be used, for example, to monitor the thickness of molten glass as it is formed into sheets.

LIGHT TRANSMISSION

When light is passing through a fixed distance in a fluid, the intensity of light received at the detector can be used to measure the concentration of solids in the liquid. This same principle can also be used to measure sludge level or the interface between sludge and supernatant. The level sensor can be a point-sensing switch (Figure 3.12c) or a continuous sludge depth detector.

In one design, the sensor and its electronics are portable, and the sensor is attached to a 30-ft (9-m) cable with which

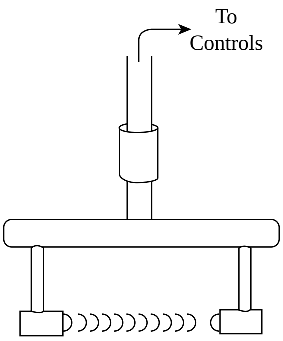

FIG. 3.12c
Optical sludge level detector.

the operator lowers the sensor into the clarifier until the interface is detected between the low solids supernatant and the high solids settled sludge. Wetted-parts materials are available in nickel plated naval brass. The error in such measurement, assuming that the cable is marked and read correctly, is 1 in. (25 mm).

In clarifiers, digesters, or air flotation thickeners, traveling scrapers are often provided at the bottom of the tank. In such installations, the sludge depth or the sludge-supernatant interface can be detected by pivoted probes that are provided with an optical gap. Inside that gap, pairs of IR light sources and detectors are stacked vertically on 3-in. (19-mm) centers. Figure 3.12d illustrates an installation with 64 such LED and detector pairs.

LIGHT REFRACTION

Infrared or visible light refracts when sent into a liquid through a submersed prism. Figure 3.12e illustrates a simple and inexpensive use of that principle for level detection. In this design, a light beam is directed along a cylindrical translucent rod that has a 45° bevel at its base. When no liquid is present at the tip, the beam is reflected back to a light-sensitive transistor. As the level rises and covers the tip of the probe, the index of refraction increases, and light escapes into the liquid. This reduces the amount of light received by the transistor and triggers the switching action. The unit is small, lightweight, and available in plastic, brass, aluminum, or stainless-steel construction. It is capable of detecting such small changes in level as 1/16 in. (1.6 mm).

The probe has a pressure rating of 100 PSIG (0.69 MPa) and can operate at temperatures between 15 and 250°F (–90 and 121°C). The switch cannot be used in caking or coating liquids. Another limitation is the false level indication that can result if drops of liquid remain of the probe after the liquid level has dropped down. In that case, the switch will continue to indicate a high level. Therefore, the use of this switch is limited to clean, noncoating services.

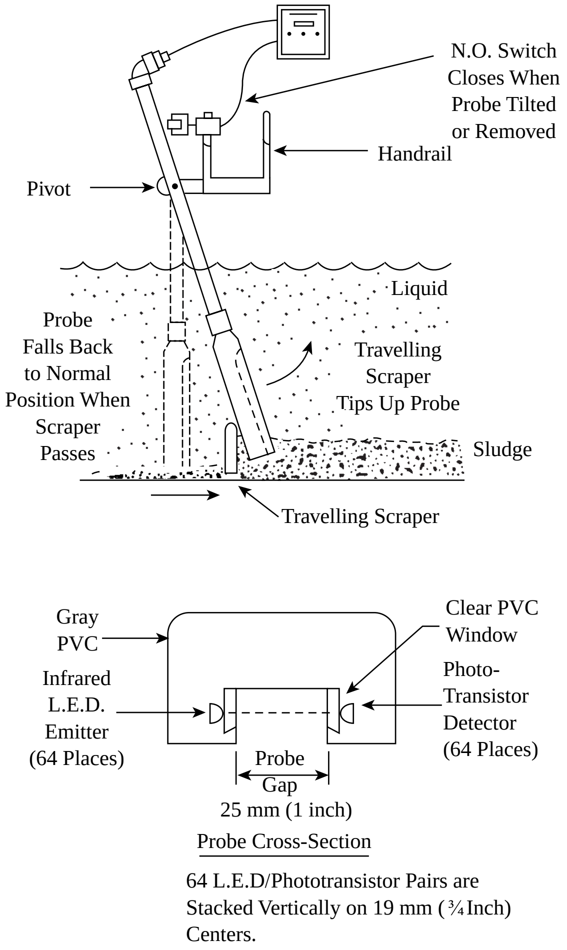

FIG. 3.12d
Optical sludge level detector for wastewater treatment processes. (Courtesy of Markland Specialty Engineering Ltd.)

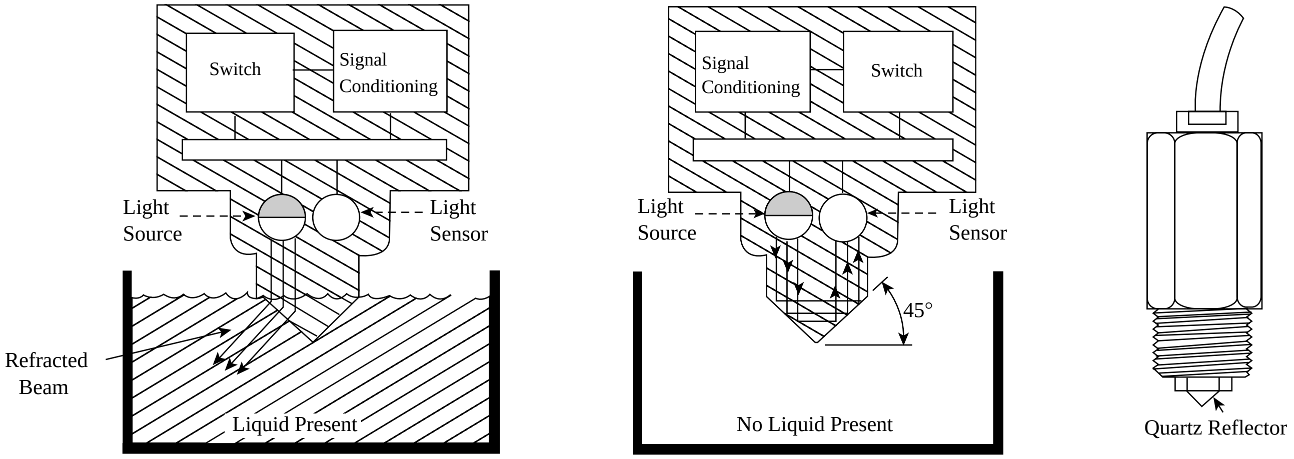

FIG. 3.12e
Light-refraction-type level switch. (Courtesy of Bindicator Inc.)

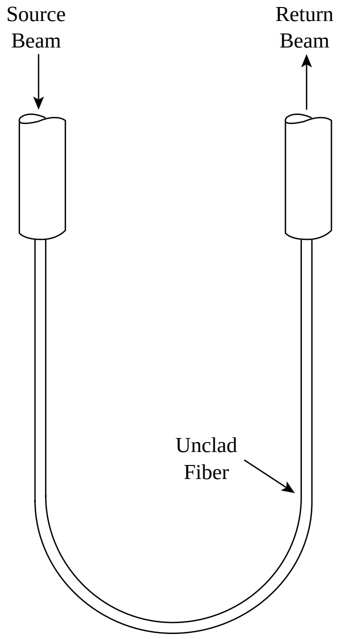

FIG. 3.12f
Level detection using fiber optics.

Figure 3.12f shows how optical fibers can be used for liquid level detection. A light beam travels in the illustrated fiber and, as long as no process fluid contacts the fiber, the return beam will have the same intensity as the source beam. As the level rises, and liquid covers some of the fiber, the index of refraction increases, allowing some of the light to escape into the liquid. This reduces the strength of the return beam.

CONCLUSION

The refraction-type optical level switches are not used in severe services, because of their pressure and temperature limitations, and because they are not suited for fouling and caking services. The reflection-type designs are used as noncontacting sensors in processes in which the vapor space is clear and the operating pressures are low. Their laser versions can provide high precision on narrow-span applications. The light-transmission-type optical level sensors have been used successfully in the wastewater treatment industry, both as level switches and as level transmitters.

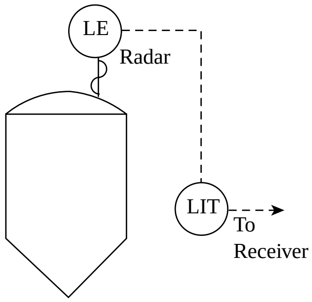
3.13 Radar, Noncontacting Level Sensors

J. L. DANIEWICZ (1995) **W. H. BOYES** (2003)



Flow Sheet Symbol

Instrument Types	Frequency modulated carrier wave (FMCW); pulse
Applications	Noncontact measurement of liquids in tanks. The two basic types are tank farm gauges for inventory control or custody transfer and for process control in tanks and reactors. Interference can be caused by agitators and other metallic surfaces, thick foam, window coatings or condensation, and splashing during filling. Some solids applications depend on instrument type and frequency.
Antenna Designs	Parabolic reflectors, horns, extended horns, internal horns with process seals, dielectric rods
Design Pressure	Up to 1200 PSIG (800 kPa) for suspended antennas, to 300 PSIG (200 kPa) for isolated antennas
Design Temperature	Up to 450°F (230°C) for standard designs, higher temperatures to 750°F (400°C)
Wetted Materials of Construction	For suspended antennas, type 316 stainless steel, aluminum, or Hastelloy® with TFL seal; for isolated antennas, a wide choice of plastics; for dielectric rods, generally TFE
Range	Up to 650 ft (200 m) for large antenna sizes of 8, 12, or 18 in. (20, 30, or 45 cm) in diameter; up to 50 ft (15 m) for small antenna sizes of 2, 3, 4, or 6 in. (5, 8, 10, or 15 cm) in diameter when used in free space, and up to 120 ft (35 cm) when used in a stilling well
Inaccuracy	±0.04 to ±0.125 in. (±1 to ±3 mm) for tank farm gauges, from ±1 in. (±25 mm) to ±0.5% of full scale for process-control transmitters
Tolerated Coating	Up to 1 in. (2.5 cm) if the buildup is a nonconductive oil, tar, or wax; up to 0.125 in. (0.3 cm) if the buildup is conductive and water based
Tolerated Turbulence	Up to 3 ft (1 m) waves. FMCW sensors handle turbulence better than pulse sensors do.
Tolerated Foam	Up to 5 to 6 ft (1.5 to 2.0 m) if nonconductive; up to 6 to 12 in. (15 to 30 cm), depending on density, if conductive; negligible source of error
Mist or Spray Effects	Minimal effect for a light mist; full falling curtain of spray will block the beam. If the full spray is horizontal as a result of throwing action from a partially uncovered agitator blade or from a side fill, it will be reported as the level.
Cost	$3500 to $5000 for tank farm gauges, $1500 to $2500 for process-control transmitters

Radar level transmitters and gauges use electromagnetic waves, typically in the microwave K- and X-bands (≈ 6 to 28 GHz), to make a continuous liquid level measurement. Most applications have been on liquid service, although several companies report small to moderate success on solids and powders.

Emissions are at low power levels, typically less than 0.1 mW/in.^{2} (0.015 mW/cm^2), because industrial level measurement typically requires less than a 100-ft (30-m) range, which is a short range for a radar technique. At these energy levels, there are no special health, safety, licensing, or product contamination considerations; only solid-state transistors or diodes (rather than tubes) are needed to generate and detect the microwaves. Radar level instruments are generally line powered, although at least one company now claims a loop-powered instrument.

The radar sensor is mounted at the top of the vessel and is aimed down, perpendicular to the liquid surface. This causes the signal that is reflected from the surface to return directly to the sensor. Figure 3.13a shows two types of sensor mountings available for FMCW gauges, whereas Figure 3.13b shows the various types of sensor mountings for pulse systems.

FIG. 3.13b
Pulse radar transmitters. (Courtesy of Endress+Hauser Inc.)

FIG. 3.13a
FMCW radar transmitters. (Courtesy of Thermo MeasureTech Inc.)

PRINCIPLES OF OPERATION

Two basic principles of operation exist for continuous level radar transmitters and gauges. Most tank-farm gauges and some process gauges are operated on the frequency modulated carrier wave (FMCW) principle. Other gauges and transmitters, particularly the lowest-cost units, are operated on the pulse principle.

Both principles are fundamentally based on the *time of flight* from the sensor to the level surface to be measured. In the FMCW method, this time of flight is tracked on a carrier wave; in the pulse method, it is the *echo return*. The latter is analogous to the air sonar principle under which most ultrasonic level sensors operate except that the pulse method operates between 6 and 28 GHz instead of at ultrasonic acoustic frequencies.

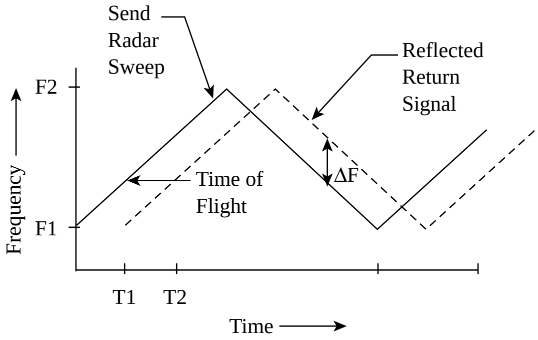

FIG. 3.13c
Radar frequency sweep.

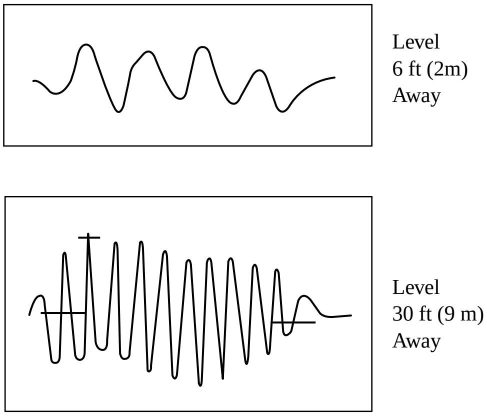

FIG. 3.13d
FM return signal.

FMCW

The time of flight of the reflected signal is measured by controlling the sensor oscillator so that it sends out a linear frequency sweep at a fixed bandwidth and sweep time, as shown in Figure 3.13c. The radar detector is exposed simultaneously to both the send radar “sweep” and to the reflected return signal, which is an “older part” of the radar sweep. The detector output is a frequency signal that equals the difference between the “send” and the “older” signals. This difference in frequency is directly proportional to the time of flight and thus to the distance between the sensor and the liquid level. The result is a frequency-modulated (FM) signal that varies between 0 and more than 200 Hz as the distance varies between 0 and 200 ft (60 m). See Figure 3.13d for oscilloscope views of this signal for different distances. An advantage of this technique is that the process variable information is in the frequency domain instead of the amplitude-modulated (AM) or time difference domain, which allows more accurate signal conversion. This is the same advantage that FM radio has over AM radio. Most tank noise sources are in the amplitude domain, so FM signal processing can ignore them, because accuracy is not affected.

PULSE

The sensor transmits a pulse of microwave energy and receives a return signal from the material level surface. The transit time of the signal is calculated and used to determine the distance to the level surface. This calculation can then be used to determine the level of the material itself.

The amount of return signal received depends on the specific reflective properties of the material level surface as well as signal loss from foam, agitation, and other interferences. Reflectivity can be determined by examining the conductivity and dielectric constant of the material. Generally, conductive products such as water and other water-based liquids (acids, strong bases, and so on) can be measured, regardless of dielectric constant. Nonconductive materials have reflectivity based on the dielectric constant exclusively. Materials with low dielectric constants absorb microwaves and provide much lower reflected signal strength than do materials with high dielectric constants.

To make an accurate distance measurement using time-of-flight calculations, the velocity of wave travel must be constant or it must be measured. The velocity of radar wave transmission is equal to the speed of light divided by the square root of the medium’s dielectric constant. Fortunately, the dielectric constants of different gases at different pressures and temperatures vary only slightly from that of air and from that of a total vacuum, so measurement errors due to changing tank conditions are very small. Radar waves are similar to laser signals and very different from ultrasonic waves in this regard. Table 3.13e provides a comparison of radar velocity and ultrasonic velocity under varying gas compositions and temperatures. In ultrasonic gauges, the errors caused by velocity changes can be reduced by wet calibration, by temperature compensation, or by compensation using reference targets. The target in this case should be located near the top of the tank, where the vapor space is uniform and no concentration

TABLE 3.13e
The Velocity of Sound and of Microwaves (Radar) Do Not Change the Same Amount as a Function of the Substance Through Which They Travel

*From References 1 and 2.
= From Reference 1.

gradients exist (as they do near the liquid surface). The presence of nonmetallic foams, mists, and dust in the wave path will have little effect on a microwave's velocity, because the dielectric constant of these media differ little from that of air.

Typically, the minimum dielectric constant for FMCW radar instruments is approximately 2. The minimum dielectric constant for pulse radar instruments is approximately 5. One of the significant application issues for radar continuous level measurement in low-dielectric materials is the fact that, at low levels, the reflectivity of the material being measured may be less than the reflectivity of the vessel bottom or sidewall in the case of a non-straight-sidewall vessel. This means that, when the level is close to zero, the return signal from the vessel bottom may be stronger than the return signal from the material level itself. *Live zeroes* and metallic targets have been used to overcome this application difficulty.

ACCURACY AND RESOLUTION FACTORS

FMCW radar level gauges are the primary tank farm radar devices because of the inherent accuracy in their design. The most accurate units also have the most precise oscillators, and there is a direct correlation between oscillator precision and cost of the component. This essentially means that there is a direct correlation between the highest-accuracy gauges and the most expensive gauges. Pulse transmitters are generally not suitable for tank-farm inventory and custody transfer applications because of the difficulty of producing a highly accurate level measurement with this type of radar transmitter. Pulse transmitters are extremely effective in process tank and reactor level measurements, however, where the limitations on accuracy are less critical and where the smaller antenna designs are essential. In addition, pulse-type transmitters are usually less expensive than FMCW transmitters.

APPLICATION CONSIDERATIONS

Since the early 1990s, radar level transmitters and gauges have become more reliable and have become a mature instrument technology. In use, they have replaced many applications previously handled by ultrasonics and by gamma nuclear continuous level systems. Radar gauges are not a panacea, however. Interferences exist. Although the existence of changing vapor and foam in a vessel has less effect on a radar gauge than on an ultrasonic level sensor, the combination of foam and low-dielectric material can cause the radar gauge to read erroneously or to provide an insufficient signal strength on the return signal for the measurement to be made at all. In glass-lined reactors, tuning problems may exist because of the tendency of the glass lining to act as a waveguide. In other reactors, the tank nozzle acts as a waveguide, and special mounting fixtures or antennas may be necessary to deal with nozzles that are not exactly perpendicular to the tank bottom. The existence of agitators and other internal structures must also be taken into account, because they can produce spurious echo effects. Radar provides an excellent alternative to bubblers, ultrasonics, and gamma nuclear in applications of medium difficulty such as fuming acids, asphalt, LNG, tars, and other heavy hydrocarbons and many other tank-farm and process reactor vessel levels.

Flow Sheet Symbol

Applications	Liquids and solids with dielectric greater than 1.4 (lower with special techniques)
Supply Voltage	Line (24 to 240 VAC) or loop (24 VDC, two-wire)
Design Pressure	Full vacuum to 5000 PSIG (–1 to 345 bar)
Design Temperature	–230 to +750°F (–150 to +400°C)
Materials of Construction	Metals, 316SS, Hastelloy® C, Monel®; plastics, Teflon®, Halar®, Tefzel®
Range	2 to 200 ft (0.67 to 60 m)
Dielectric range	1.4 to 100
Sensor Pull Strength	11,000 lb (4330 kg)
Inaccuracy	Liquids, 0.1 in. (3 mm) or 0.1%, whichever is greater Solids, 1.0 in. (25 mm)
Tolerated Coating	Low-dielectric coating (E < 10); inaccuracy increases with increase in coating dielectric, thickness, and length
Tolerated Foam	Low-dielectric foam (E < 10); inaccuracy increases with increase in foam dielectric, density, and thickness
Tolerated Mist or Spray Effects	High (little effect)
Tolerated Turbulence	Measurement, high (little effect); mechanical, may need probe secured when severe
Area Classification	Nonincendive, intrinsically safe, and explosion-proof
Cost	$750 to $3500

DEFINITION OF TERMS

Characteristic impedance. The impedance that, when connected to the output terminals of a uniform transmission line of arbitrary length, makes the line appear to be infinitely long. A uniform line so terminated will have no standing waves on the line, and the ratio of voltage to current will be the same at any point on the line (nominal impedance of the waveguide).[1]

Dielectric. A material that is an electrical insulator or in which an electric field can be sustained with a minimum of dissipation of power.[1]

Dielectric constant. A material characteristic expressed as the capacitance between two plates when the intervening space is filled with a given insulating material, divided by the capacitance of the same plate arrangement when the space is filled with air or is evacuated.[2] The dielectric values of selected materials are given in Table 3.14a.

Discontinuity. An abrupt change in the shape (or impedance) of a waveguide (creating a reflection of energy).[1]

Electromagnetic wave (energy). A disturbance that propagates outward from any electrical charge that oscillates or is accelerated; at a great distance from the charge, it consists of vibrating electric and magnetic fields that move at the speed of light and are at right angles to each other and to the direction of motion.[1]

Equivalent time sampling (ETS). The process that captures high-speed electromagnetic events in real time (nanoseconds) and reconstructs them into an equivalent time (milliseconds) that allows easier measurement with contemporary electronic circuitry.

Guided wave radar (GWR). A contact radar technology in which time domain reflectometry (TDR) has been developed into an industrial level measurement system; a probe immersed in the medium acts as the waveguide.

Phase difference sensor (PDS). A contact radar technology; unlike TDR-based systems, which measure using subnanosecond time intervals, PDS derives level information from the changes in phase angle.

Radar. Radio detection and ranging; a system using beamed and reflected radio-frequency energy for detecting and locating objects, measuring distance or altitude, navigating, homing, bombing, and other purposes. In detecting and ranging, the time interval between transmission of the energy and reception of the reflected energy establishes the range of an object in the beam's path.[1]

Time domain reflectometry (TDR). A process in which an instrument (a time domain reflectometer, also abbreviated *TDR*) measures the electrical characteristics of wideband transmission systems, subassemblies, components, and lines by feeding in a voltage step and displaying the superimposed reflected signals on an oscilloscope equipped with a suitable time-base sweep.[1]

Waveguide. A device that constrains or guides the propagation of electromagnetic waves along a path defined by the physical construction of the waveguide; for example, ducts, a pair of parallel wires, or a coaxial cable.[1]

TABLE 3.14a
Dielectric Constant (ε) Values of Selected Media

Media	*Dielectric @°F (°C)*

Water, DI	15 @70 (20)
Water, tap	80 @80 (27) 48 @212 (100)

INTRODUCTION

Modern contact radar level transmitters owe much of their existence to time domain reflectometry. Although new to the industrial level market, TDR technology has been used for decades. It has been employed for finding breaks in underground cables and the in-wall installations of large buildings. Companies such as Hewlett-Packard, Agilent, and Tektronics supply TDR generators that are optimized for this use. Recent breakthroughs have made this technology less costly and allowed it to consume much less power. Cost-effective loop-powered (24-VDC) transmitters are now available in the industrial market. Two basic types of contact radar level measurement need to be discussed: guided wave radar (GWR) and the phase difference sensor (PDS).

THEORY OF OPERATION

Guided Wave Radar

The fundamentals of GWR come directly from time domain reflectometry, a pulse-sampling technique that characterizes the distributed electrical properties of transmission lines. TDR instruments launch low-amplitude, high-frequency pulses onto a transmission line, cable, or waveguide under test and then sequentially sample the reflected signal amplitudes. Typically, the reflected pulse amplitudes are displayed on a calibrated time scale. In this way, cable impedance changes and discontinuities can be spatially located and assessed.

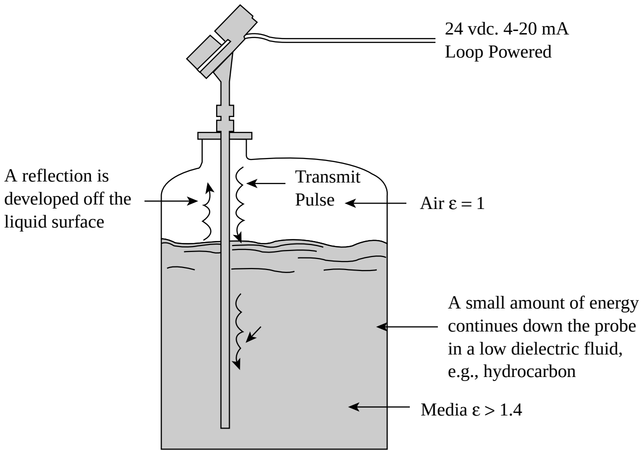

FIG. 3.14b
Fundamentals of guided wave radar level measurement.

In guided wave radar, the waveguide becomes a probe immersed in the liquid (or dry, bulk medium). The characteristic impedance, ε, of the probe (in air, $\varepsilon = 1$) decreases when a liquid (or dry media) of a higher dielectric displaces the air. The electromagnetic pulses transmitted down the waveguide are reflected at this point of discontinuity, and the reflections are measured by high-speed circuitry in the transmitter head; in this manner, the level is established. The fundamentals of guided wave radar level measurement are illustrated in Figure 3.14b.

For typical process media, the dielectric can range from 1.4 to 100. The higher the dielectric constant, the stronger the reflected signal. An oscilloscope trace of guided wave radar showing fiducial (baseline reflection) and strong reflection received from water (a high-dielectric medium) is shown in Figure 3.14c. The oscilloscope trace in Figure 3.14c shows the extremely large reflection created by the high-dielectric water ($\varepsilon = 80$ at 70°F). The small fiducial, or baseline reflection, is the zero point for the GWR measurement. A typical fiducial is ≈200 mV. The large negative level pulse is developed by the reduction in impedance in the waveguide from the presence of the high-dielectric water. The higher the dielectric of the medium, the higher the amplitude of the reflection it creates. In this oscilloscope trace, the high dielectric ($\varepsilon = 80$) water is approximately 2000 mV.

Figure 3.14d shows the same oscilloscope trace with a low-dielectric reflection (≈750 mV) added for comparison. The lower-dielectric medium creates a reflected pulse with decreased amplitude; however, the reflection still exists at the same point in time (position) as the pulse with larger amplitude. Variation in the dielectric of the medium, although important to the creation of a good reflection, is not critical to accurate measurement.

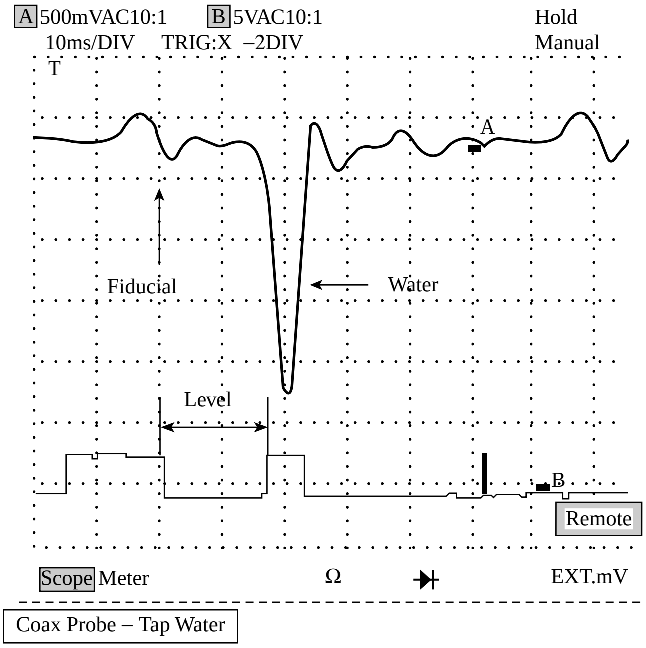

FIG. 3.14c
Oscilloscope trace of guided wave radar showing fiducial (baseline reflection) and strong reflection received from water (high dielectric medium).

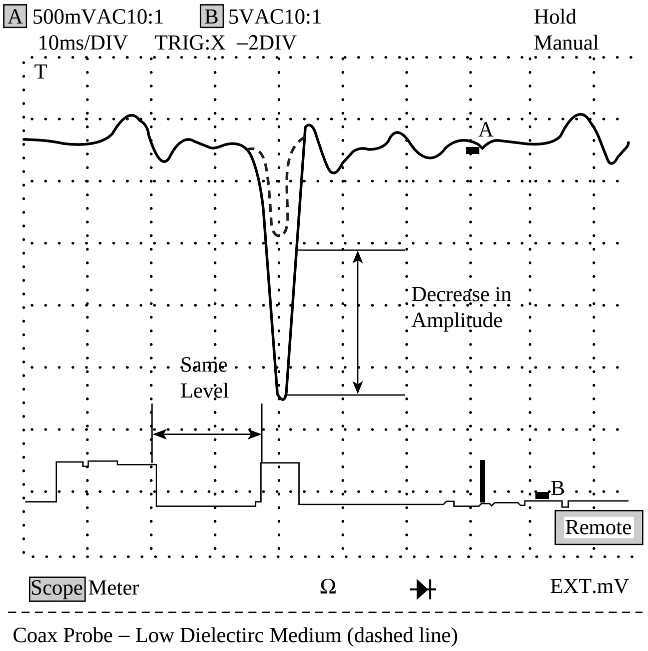

FIG. 3.14d
Oscillоscope trace showing reflection amplitude decreasing dielectric constant of liquid yet its position in time (space) remains constant.

Theoretically, error can be introduced by variations in the speed of propagation related to vapor space dielectric. The high-frequency electromagnetic pulses travel at the speed of light. The speed of light (c) in a vacuum ($\varepsilon = 1$) travels at 186,000 mi/sec or 3×10^8 m/sec. This is calculated as

$$c / \sqrt{\varepsilon} \tag{3.14(1)}$$

where
c = speed of light
ε = dielectric constant of vapor space

As Equation 3.14(1) shows, as long as the pulses travel in a vapor space with ε close to 1.00, no significant variation in the speed of propagation is expected. In practice, this is not a consideration for contact radar.

Phase Difference Sensors

Phase difference sensors are similar to time domain reflectometers (TDRs), except the detection circuit operates in the phase domain rather than the time domain. A high-frequency (f) signal travels through parallel conductors at a fixed velocity (V_0) until it is partially reflected by the stored material interface, where the sensor impedance changes abruptly. The dielectric constant of the vapor space remains nearly unity, even if dust, vapor, condensate, or foam is present. Therefore, the signal injected into the sensor travels down to the material interface and back at a constant velocity V_0. Because of the travel distance of 2(l), there will be a phase difference (β) between the input and the reflected signals, as shown in Figure 3.14e.

Contact Radar Systems

The contact radar system is composed of two basic components: an electronic transmitter and probe (waveguide). Careful choice of the probe is particularly important for the successful application of contact radar.

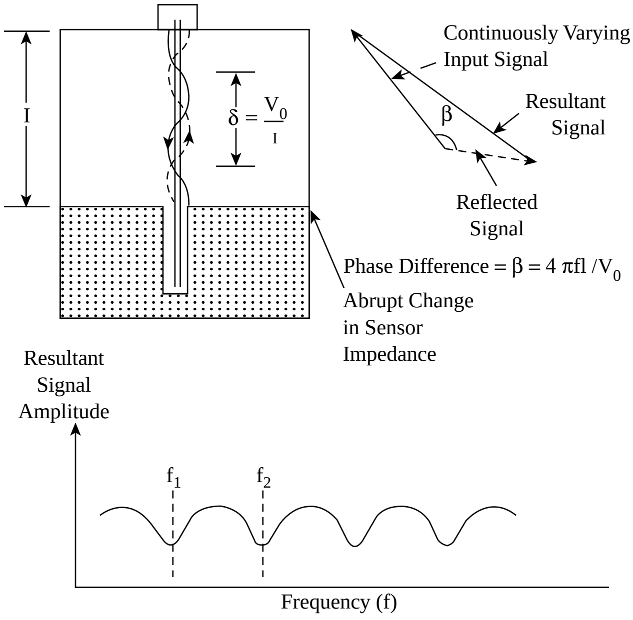

FIG. 3.14e
Frequency (phase) difference measurement used to measure the levels in silos. (Courtesy of Bindicator/Venture.)

Electronics Contact radar circuitry is accurate and responsive. The most modern devices (particularly guided wave equipment) are inexpensive and operate at low power levels (loop powered). Systems benefit from the confluence of two key issues.

1. There have been significant advancements in high-speed, microwave circuits, including the use of equivalent time sampling (ETS). ETS captures the high-speed electromagnetic pulses in real time (nanoseconds) and reconstructs them in equivalent time (milliseconds), allowing the use of slower, less-complex circuitry.
2. The probe, or waveguide, provides a conductive path for the highly efficient transfer of energy to the medium surface and back. Signal processing needs no duty cycling to conserve energy, and there are no false-target reflections to ignore (eliminating a source of complex signal processing required in through-air transit time devices—for example, radar and ultrasonic). This efficient propagation of energy allows reliable measurement of extremely low-dielectric (>1.4) media.

The measurement stability described previously has two key ramifications.

1. A constant speed of light (electromagnetic energy) allows factory calibration; no field calibration is needed—only simple configuration (no level movement is necessary).
2. Accuracy is unaffected by dielectric changes in the medium.

Probe (Waveguide) Three basic probe configurations are utilized today: coaxial, twin-element, and single-element. Coaxial probes (waveguides) are the most efficient, providing efficiency similar to that of the standard 75-Ω coaxial cable used for video and data. The twin element is less efficient; it is analogous to the twin-lead antenna cable used before the implementation of coaxial cable. (It is the configuration of choice with phase difference sensors.) The single-element probe is the least efficient but most forgiving in applications in which the media will coat the probe. Figure 3.14f shows

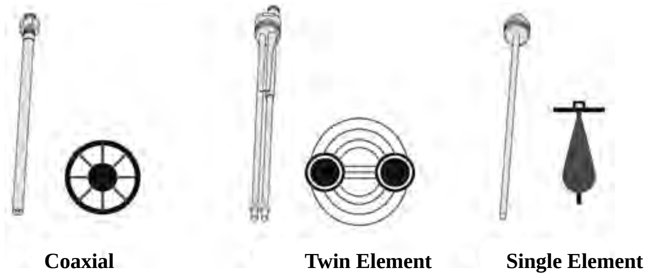

FIG. 3.14f
Fundamental probe (waveguide) configurations and energy fields.

the three fundamental probe configurations with their respective energy fields.

PROBE SELECTION AND APPLICATION

Choosing the proper probe (waveguide) is the most important aspect of applying contact radar. The following are the key issues to consider.

Temperature/pressure. The most fundamental process parameters to be considered are temperature and pressure. Because the market offers contact radar sensors rated from –235 to +750°F (–150 to +400°C), and full vacuum to 5000 PSIG (345 bar), there are few process applications that cannot be accommodated.

Dielectric sensitivity. Coaxial probes are the best choice in applications of low dielectric ($\varepsilon < 2.0$) given their propagation efficiency; butane ($\varepsilon = 1.4$) and propane ($\varepsilon = 1.6$) have been measured very successfully. It is important to note that the dielectric of most media has a tendency to change inversely over temperature; as temperature increases, dielectric decreases. It is useful to understand the dielectric of a medium at the specific temperature of the process. Due to the inverse relationship, higher temperatures are more problematic.

Mounting/obstructions/proximity effects. Mounting can be an issue to varying degrees. A coaxial probe suffers from no proximity effects, whereas a single-element probe is the most sensitive and must be applied carefully.

Length. GWR is a contact technology requiring the probe length to be at least as long as the span. This can become an issue for long probes. Shipping costs increase as probe lengths increase. Physically installing a 20-ft (6-m) rigid probe takes some thought; headroom is a key concern.

Material compatibility. Probes are constructed of various combinations of metal, plastic (insulator), and, often, O-rings. Type 316 SS is the most common metal, with Hastelloy® and Monel® common options. Various types of Teflon® (TFE, FEP, PFA) are used as an insulator more than any other plastic. Halar® (ECTFE) and Tefzel® (ETFE) are also used. A common process seal utilizes an O-ring as part of the design and must be considered as a wetted part. The most common O-ring materials are Viton®, EPDM, and Neoprene®. Kalrez®, although more expensive, is specified as an option because of its superior chemical compatibility.

Coating/clogging/buildup/bridging. Being based on contact technology, guided wave and phase difference sensors can suffer error caused by various degrees of coating. Error is related to three key elements: dielectric, coating thickness, and coated length. Low-dielectric media cause little error, whereas higher-dielectric media (e.g., water-based substances) can be problematic. The worst error is caused by a thick, high-dielectric coating that runs the length of the probe before the measurement takes place.

Viscosity. Thin media (<500 cP) can be used with all probes, including coaxial. Single- or twin-element probes should be considered when viscosity exceeds 500 cP.

Turbulence. Turbulence has two effects on GWR, electrical and mechanical. Electrically, turbulence does little to scatter the signal, so it is very effective in these applications. Because there is a probe in the medium, mechanical issues must be considered. Occasionally, it is necessary to secure the probe to prevent failure.

Pull strength. When measuring bulk solid materials (e.g., grains, pellets, and aggregate), the force exerted by the medium on the probe (*pull force*) must be considered; bulk density is the most important parameter. Probes are available with >10,000 lb (4000 kg) of pull strength.

Overfill. Measuring to the very top of a vessel can be problematic for any transit-time device (radar, ultrasonic). Ambiguous readings or nonmonotonic measurement can be experienced. Care must be taken when encountering this application. Contact radar devices exist that measure into an overfill or “flooded” condition (cage/chamber installations).

Hazardous area/Div. 2 implementation. All modern transmitters carry explosion-proof, intrinsically safe and nonincendive (National Electrical Code Division 2, or *Div. 2*, hazardous area) approvals. GWR is a technology that must inject a small amount of energy into the vessel to accomplish its measurement. For this reason, it is important in CLI/Div. 2 applications to consider what is inside the vessel as well as outside. If the medium to be measured is flammable, an intrinsically safe probe circuit must be used. In a Div. 2 area, this may require the use of a transmitter that is rated explosion proof.

INTERFACE MEASUREMENT

In industrial level measurement, *interface* is defined as the point between two immiscible liquids. Contact radar has the ability to measure both the upper and lower liquids if the following conditions are met:

- The upper liquid is a low-dielectric medium ($\varepsilon < 10$)
- The lower liquid is a higher-dielectric medium ($\Delta\varepsilon > 10$)
- The interface is clean and distinct, with no emulsion layer

A small reflection will be generated by the upper (low-dielectric) medium while most of the energy continues down the probe. A larger reflection is generated by the lower (high-dielectric) medium. The key is to accurately compensate for the change in pulse propagation velocity while it is traveling through the upper medium, which has a dielectric that differs from that of the vapor space. Emulsion layers are problematic because, by definition, there is not a distinct difference between two media but, rather, a gradual change from one to another. For this reason, detectable pulses are not generated.

CONCLUSION

There is no ideal level measurement technology. In a perfect world, all measurement would be noncontact and even noninvasive. Noncontact radar comes close, but it also has some weaknesses that contact radar overcomes. The new radar technologies, both contact and noncontact, form a team in effective level measurement for many process applications.

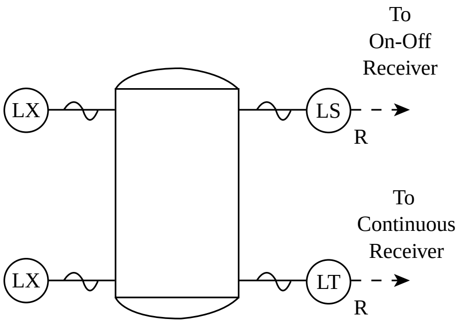
3.15 Radiation Level Sensors

B. G. LIPTÁK (1969) **D. S. KAYSER** (1982)
A. J. LIVINGSTON (1995) **J. C. RODGERS** (2003)



Flow Sheet Symbol

Applications	Noncontact and nonintrusive level measurement of liquids and solids
Temperature	External detectors are suitable for –40 to 160°F (–40 to 70°C) ambient conditions. Units can be provided with heaters for lower ambient temperatures and with air/water cooling for higher ambient temperatures. Traversing backscatter units can operate at up to 250°F (121°C).
Radiation Sources	Cobalt 60 (5.3 years of half-life), cesium 137 (30 years of half-life), americum 241 (455 years of half-life), and radium 226 (1602 years of half-life). Cesium is used most often, because it decays more slowly; cobalt is selected when the tank walls are thick. Point sources are affected by product density variations, but strip sources are not.
Radiation Exposure	One roentgen is received during one hour spent within one meter of a one-curie (1-Ci) radiation source. A subject receives a dose of one rem (roentgen equivalent man) when exposed to one roentgen in any time period. General public allowable limits are 2 mrem/hr and 100 mrem/year. The dose for an occupational worker is 5 rems/year.
Source Sizes	In external types, usually a few hundred mCi or less; in dry-well-type backscatter units, usually 10 mCi. A curie is generated by 1 g of radium, 0.88 mg of cobalt, or 11.5 mg of cesium. One Ci equals 3.7 × 10^{10} disintegrations/sec or 3.7 × 10^{10} becquerels (Bq, SI units).
Inaccuracy	For alarm switches, 0.25 in. (6 mm) error can be expected. Errors in continuous units range from 0.125 in. (3 mm) to 1% of span.
Ranges	External units have ranges from 1 in. (25 mm) to 23 ft (7 m) for single stationary units, higher for multiple units, and up to 50 ft (15 m) for motorized units. Traversing backscatter units mounted in dry wells can detect up to a range of 150 ft (45 m).
Costs	Assuming a 10-ft (3-m) diameter vessel with 0.25 in. (6 mm) wall thickness and 1.0-in. (25-mm) insulation, the following costs can be expected: on–off alarm, $2240; continuous level transmitter $8000 and up; gamma backscatter-type level switch $9000 to $15,000; neutron backscatter-type level switch, $16,000 to $35,000; continuous (scanning) backscatter units for up to 150 ft (50 m), $60,000.
Partial List of Suppliers	Barton Instrument Systems LLC (www.barton-instruments.com) Berthold Industrial Systems (www.berthold.com.au) Endress+Hauser Inc. (www.endress.com) Flow-Tech Inc. Radiation at different frequencies can be used for level measurement. Included are ultrasonic, radar (or microwave), laser (infrared light), neutron, and gamma forms of radiation. These different radiation forms are also of different strengths in terms of what materials they can penetrate. Some require nozzles on the tank (most ultrasonic and radar designs), and others need windows (laser) or nonmetallic tanks (microwave). Nuclear radiation can pass through metallic walls. The weaker, less penetrating the signal, the more likely is it to be used in the echo, reflection, or backscatter mode. Gamma radiation is sufficiently penetrating to pass through tank contents, although radiation gauges are also used in the backscatter mode, as discussed below.

RADIATION PHENOMENON

Atoms with the same chemical behavior but with a different number of neutrons are called *isotopes*. Many elements have one or more naturally occurring stable isotopes. For example, the stable isotopes of oxygen are as follows:

Stable Isotopes	*No. of Protons*	*No. of Neutrons*	*Percent Abundance*
^{16}O	8	8	99.76
^{17}O	8	9	0.04
^{18}O	8	10	0.20

Most elements also have unstable (radioactive) isotopes. Oxygen's radioactive isotopes are ^{15}O and ^{19}O, which have 7 and 11 neutrons, respectively. The unstable isotopes disintegrate to form elements or stable isotopes. Most of the elements that are heavier than lead are also unstable and disintegrate to form lighter elements. Radioactive disintegration is accompanied by the emission of three different kinds of rays. Alpha (α) radiation consists of positively charged particles having two neutrons and two protons. Beta (β) radiation consists of electrons. Gamma (γ) radiation consists of electromagnetic waves that are comparable to X-rays. The relative penetrating powers of the three kinds of radiation are approximately in the range of 1, 100, and 10,000 for the alpha, beta, and gamma rays, respectively. The penetrating power of alpha rays is less than 8 in. (203 mm) of atmospheric pressure air. Alpha radiation cannot penetrate the skin. Beta radiation can penetrate approximately 0.25 in. of aluminum. Alpha and beta rays carry an electrical charge and can be deflected by an electric or magnetic field. Because gamma rays have great penetrating power and cannot be deflected, gamma radiation sources are chosen for use in level-detecting equipment.

Source Materials

The two most commonly used gamma sources are the radioactive isotopes Co 60 (cobalt) and Cs 137 (cesium). Co 60 is produced by bombarding the stable isotope Co 59 with neutrons. When Co 60 decays, it emits beta and gamma radiation to form the stable element Ni 60 (nickel). In similar fashion, when Cs 137 decays, it emits beta and gamma radiation to form the stable element Ba 137 (barium). The Co 60 isotope decays at two different energy levels, 1.173 million electron volts (MeV) and 1.332 MeV, while Cs 137 decays at 0.662 MeV. Cs 137 is one of many fission products of uranium and is obtained when spent fuel rods from nuclear power plants are reprocessed. There are two important points to note about the gamma decay phenomenon. One is that the decay produces electromagnetic energy, which cannot induce other materials to become radioactive. This means that gamma sources can be used around such materials as food and food-grade packaging materials. The second point is that the source loses strength as it decays. The rate of decay is expressed as half-life, the period of time during which the source loses half of its strength. Co 60 has a half-life of 5.3 years; it will decay approximately 12.3% per year. The figures for Cs 137 are 30 years and 2.3% per year. For point or continuous level measurement, source decay does not affect accuracy, but the initial source size should be fashioned so that the installation has a reasonably long useful life. Typically, the gauge electronics compensate for the decay of the source. In rare instances, the isotope Ra 226 (radium) can be used. This material has a half-life of 1602 years and therefore has no appreciable loss of strength over the life of the installation.

Units and Attenuation of Radiation

The units used to quantify the activity of any radioactive material are the curie (Ci) and the becquerel (Bq). One gram of Ra 226 has 3.7×10^{10} disintegrations per second. This rate of activity is defined as 1 Ci or 3.7×10^{10} Bq, whether it is produced by Ra or some other source. For most level detection applications, source strengths of 100 millicuries (mCi) or less are satisfactory. The unit of radiation exposure is the roentgen (r), which is defined as the quantity of radiation that will produce ionization equal to one electrostatic unit of charge in one cubic centimeter of dry air under standard conditions. A 1-Ci source will produce a dose of 1 r at a receiver placed 1 m (3 ft) away from the source for 1 h. The dose rate unit is the roentgen/hour (r/hr), a measure of the photons reaching the receiver at a defined distance. Radiation is attenuated when it penetrates liquids or solids, and the rate of attenuation is a function of the density of the material. The higher the density, the more attenuation the shielding material will provide. The following shows how various thicknesses of different materials will provide different levels of attenuation. The various thickness values illustrate the half-value layer concept. Each of the listed thicknesses of each material represent the thickness needed to attenuate or reduce the radiation field by one-half. As can be seen, various isotopes, due to their decaying energy value, have different half-value layer thicknesses.

Material	*Cs-137*	*Co-60*
Dirt/wood	6 in.	8.5 in.
Water/plastic	3.75 in.	7.5 in.
Steel	0.5 in.	1 in.
Lead	0.25 in.	0.5 in.

For example, a 0.5-in. (13-mm) steel plate will reduce radiation from a Cs 137 source by half. An additional plate will cause another 50% reduction, so the overall reduction caused by a 1-in. (25-mm) plate is 0.5 × 0.5 = 0.25.

As would be expected, the amount of radioactive material required to produce 1 Ci of activity depends on the material. One Ci is generated by 1 g of Ra 226, by 0.88 mg of Co 60 or by 11.5 mg of Cs 137.

The dose rate also will vary. Assuming a 1-mCi source and a receiver 32 in. (812 mm) away, the dose rates will be 1.3 milliroentgens per hour (mr/hr) for Ra 226, 2.0 mr/hr for Co 60, and 0.60 mr/hr for Cs 137. Radiation field intensity in air can be calculated from the following equation:

$$D = 1000\frac{K\text{mCi}}{d^2} \qquad \textbf{3.15(1)}$$

where

D = intensity, mr/hr
mCi = size of source in millicuries
d = distance of source in inches
K = a constant, 1.3 for Ra 226, 0.6 for Cs 137, and 2.0 for Co 60

SOURCE SIZING

In actual installations, radiation must penetrate substances in addition to air, and it is of interest to determine the radiation field intensity after the gamma rays have passed through the vessel walls and process material. The previous equation may be used for this purpose. Figure 3.15a shows a typical installation, and the information below will show how the radiation intensity at the receiver is determined and what levels of operator exposure to radiation may be expected. It will be assumed that the minimum radiation field intensity at the detector should be 2.0 mr/hr when the vessel is empty and that the field should be reduced at least 50% as the vessel is filled. The liquid in the vessel has a specific gravity of 1.0. The calculation is based on the use of a 100 mCi source of Cs 137. With no vessel at all, field intensity at the detector would be

$$D = 1000\frac{K\text{mCi}}{d^2} = \frac{0.6 \times 100}{84^2} = 8.50 \text{ mr/hr} \qquad \textbf{3.15(2)}$$

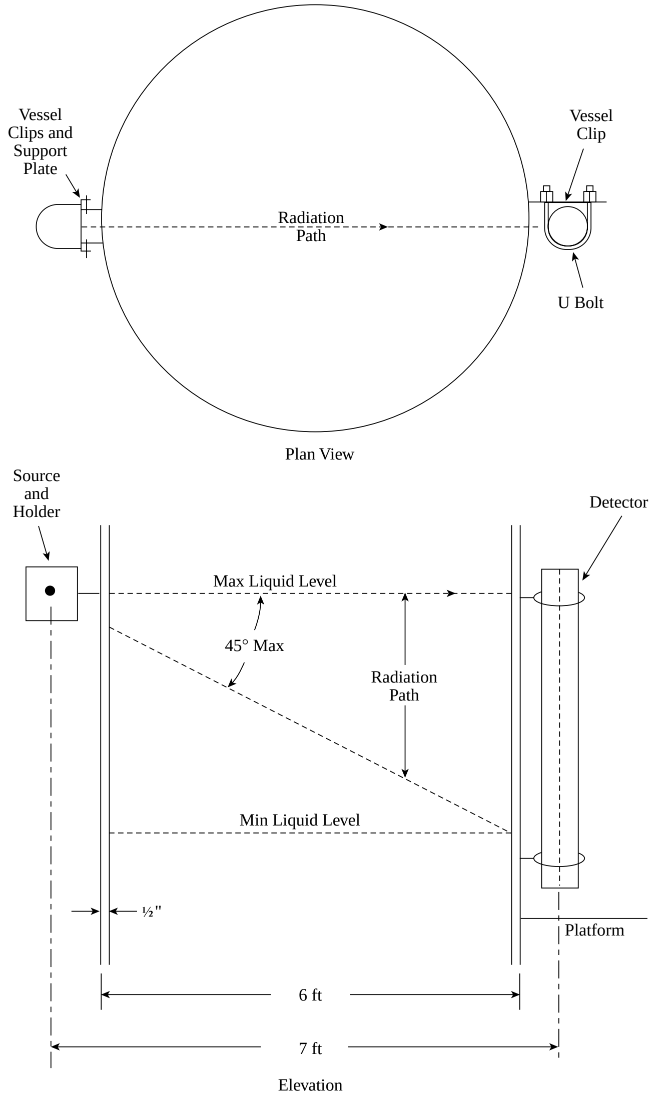

FIG. 3.15a
Radiation instrument installation.

With the empty vessel in place, the attenuation through the two 0.5-in. steel walls will be 0.50 × 0.50 = 0.25 (see Figure 3.15a), and the resultant field intensity at the detector is 8.50 × 0.25 = 2.125 mr/hr. When the tank is full, the radiation will have to penetrate 72 in. (1.8 m) of material having a specific gravity of 1 (water). From the previous information, approximately 4 in. of water will reduce the radiation field by 50% (half-value layer). In this example, we would need only approximately 4 in. of water to reduce the radiation field to meet the 50% radiation field reduction requirement. This example will have 72 in. divided by 3.75 in./half-value layer = 19.2 half-value layers between the source and the detector with the vessel full, creating effectively no radiation at the detector.

During the empty condition and with the source providing radiation to the detector of approximately 2.125 mr/hr, the radiation field can be calculated for personnel exposures at any distance from the detector by the inverse square law formula as follows:

$$R2 = R1(d1/d2)^2 \qquad \textbf{3.15(3)}$$

$R2$ = radiation field at any distance $d2$ from the source
$R1$ = radiation field at a known distance $d1$ from the source

Doubling the distance from the detector will decrease the radiation field by four times.

Normally, Cesium 137 sources are used over Cobalt 60 sources because of the longer half-life of the cesium isotope. In some instances, such as very thick vessel walls, Co 60, with its higher decaying energy, can offer a solution where CS 137 cannot.

The minimum radiation field intensity required at the detector for good performance depends on several variables, including type of detector technology, sizing practice of the manufacturer, acceptable useful life of the gauge, and radiation safety considerations. For proper sizing, the application information listing all materials between the source and detector, their densities, and their thicknesses must be provided to the manufacturer. This would include insulation, thermal jackets outside or inside the vessel, internal structural supports, diffusers, and agitator blades or shafts. All attenuating materials in the path of the radiation beam must be accounted for to make a proper measurement.

SAFETY CONSIDERATIONS

A gamma source radiates electromagnetic energy in all directions, just as a glowing ember radiates heat in all directions. Short-term exposure to high-intensity gamma radiation or long-term accumulative exposure to lower-intensity radiation is known to be hazardous. The degree of hazard, particularly to long-term low-intensity exposure, is a somewhat subjective determination. Therefore, if an error is made, it should be made on the safe side.

Radiation sources are formed into ceramic pellets that are placed in a double-walled stainless-steel capsule (double encapsulation). The capsule is contained in a source holder that is constructed so as to allow a radiation beam to escape through a very narrow window (collimation) while it is blocked by shielding in all other directions. For the window, a shutter is provided that can be closed and locked when the source is being shipped or when it is out of service. Source shielding is thick enough to reduce the field intensity 1 ft (305 mm) from the source to 5 mr/hr or less. As was mentioned earlier, the disintegrations that produce gamma rays will also produce beta emissions. Because of their low penetrating power, beta rays cannot escape the stainless-steel capsule that encloses the source.

Source holders are designed for a range of source sizes. For example, one holder may be used for sources in the range of 10 to 30 mCi, whereas the next-heavier holder, which provides more shielding, may be used for sources in the range of 31 to 90 mCi. Obviously, if the source being used is at the low end of the range, the field intensity outside of the holder will be less and will approach the maximum 5 mr/hr limit when the source being used is at the top of the range.

Source holders are typically constructed of a steel or stainless-steel outer surface, with lead as the shielding material surrounding the stainless-steel capsule. Some manufacturers offer a fire-proof design in which the source holder is a casting of iron material. Since lead has a melting point of approximately 620°F, during a fire, the lead shielding from the source holder could be lost. The use of iron as shielding material raises the melting point to approximately 1400°F, which is the temperature rating of the source capsule.

Allowable Radiation Exposures

In the United States, rules governing safe exposure limits to radioactive materials have been established by the Nuclear Regulatory Commission (NRC). These rules are incorporated in the Occupational Health and Safety Act. Exposure to external radiation is referred to in units of *rem* (roentgen + equivalent + man). A rem is a measure of the dose to body tissue in terms of its estimated biological effect relative to a dose of 1 r of X-ray. A person receives the dose of 1 rem when exposed to 1 r of radiation in any time period. As illustrated in Figure 3.15b, a person should not receive more than 250 rems over an entire lifetime. The rate at which this exposure is accumulated is also important. It is desirable to keep the yearly dose below 5 rems, and it should definitely not exceed 12 rems per year or 3 rems per quarter. In most industrial processing applications, it is possible to keep operator exposure far below these levels.

For each industrial installation, it is essential to estimate the dosage received by personnel working in the vicinity of

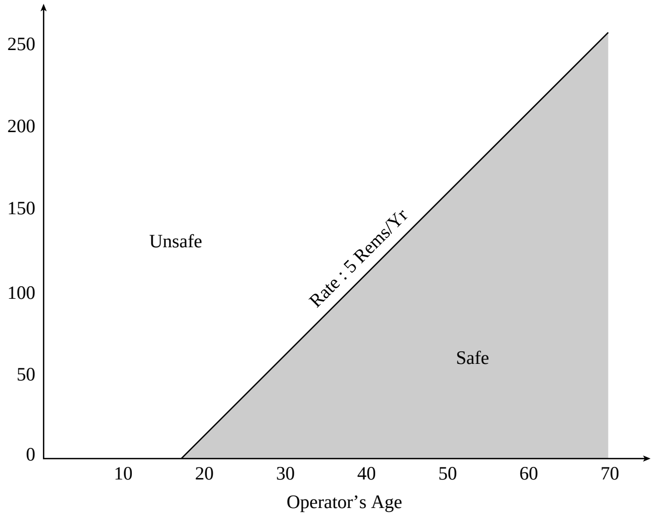

FIG. 3.15b
Radiation exposure as a function of time and safety.

the source, using both the assumed occupancy and the proximity to the source, on a "worst-case" basis. Returning to the installation shown in Figure 3.15a, it is assumed that the occupancy is 25 h per week and that the operator is within 12 in. (305 mm) of the tank during this period; the worst case would be if the operator were working next to the source. Assuming that the holder just meets the requirements for 5 mr/hr at 1 ft, operator exposure would be 5 × 25 = 125 mr per week, or approximately 6.25 rem per 50-week year. This exposure would exceed set limits.

The second-worst case would be if the operator were working by the detector when the tank was empty. Here, the field intensity would be approximately 2 mr/hr, and the operator's weekly and yearly exposure would be 50 mrem and 2.5 rem, respectively. (The second-worst case condition is cited to illustrate the point that the source shutter should always be closed when the tank is empty. The ultimate in bad practice is to allow a maintenance worker into the tank when the source shutter is open. Special interlock systems are available to prevent this.)

After making the worst-case calculations, the design engineer should determine what can be done to reduce operator exposure. By implementing the tools of time, distance, shielding, and planning, the design engineer can create a gauge installation that will minimize an operator's exposure to radiation. These tools are the essential elements of a principle called ALARA, which stands for "as low as reasonably achievable." By minimizing time around the radiation field, positioning the gauge installation away from traffic areas or using of shielding, and implementing lock-out/tag-out procedures, radiation exposure to personnel can be kept to very low levels.

Nuclear Regulatory Commission

The use of radioactive sources for industrial gauging systems is under the jurisdiction of the Nuclear Regulatory Commission (NRC). The gauges are required to be licensed for use. In many states, the NRC has granted permission for individual state regulatory bodies (*agreement states*) to be the primary contact for the licensing and regulating of the use of radioactive isotopes. The regulations for use, licensing requirements, identification of agreement states, and responsible contacts for emergency notification or basic contacts can be obtained from the NRC web site at www.nrc.gov. The United States is divided into several regions, and the appropriate contact information for each regional office is provided.

When submitting a license application to the NRC or an agreement state for use of a radioactive isotope for industrial gauging, the following information is required:

- Isotope used and source size
- Manufacturer and model number of both the instrument and the source holder
- Description of installation (see Figure 3.15c)
- Maximum occupancy of area
- Responsible individual to contact

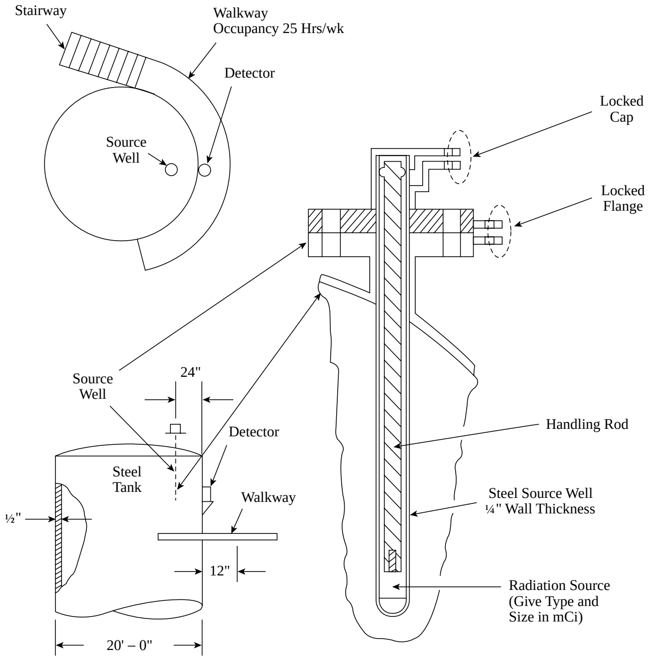

FIG. 3.15c
Typical radiation instrument installation.

Depending on the number of radioactive isotopes that will be used at the facility, the licensing process can range from a relatively simple to a more complicated program that incorporates training, detailed procedures for lock-out/tag-out, and other safety measures. In all cases, the end-user is responsible for maintaining documentation and the ongoing testing that is occasionally required to meet the NRC requirements for possession and use of radioactive isotopes.

DETECTORS

A number of gamma radiation detectors are available, but the three commonly used in conjunction with level detection are the Geiger–Mueller (G–M) tube, the gas ionization chamber, and the continuous level scintillator.

Geiger–Mueller Tube

The G–M tube has a wire element anode in the center of a cylindrical cathode. The cathode tube is filled with inert gas and sealed. A bias voltage of up to 700 V is applied across the anode and the cathode. Incident gamma radiation ionizes the inert gas so that there is an electrical breakdown between the anode and cathode. The frequency of the breakdown is related to the intensity of the gamma radiation; therefore, field strength can be determined by counting the pulses produced over a given time interval.

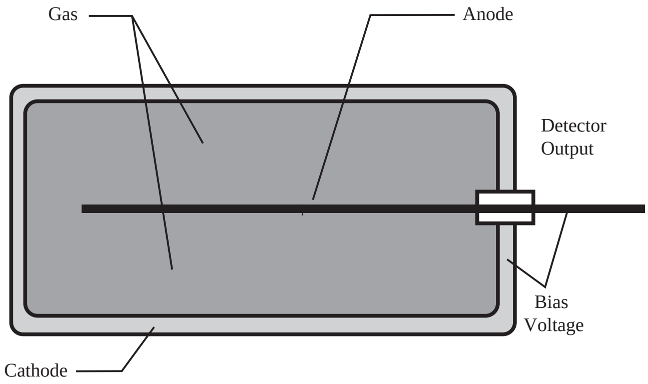

FIG. 3.15d
Gas ionization chamber.

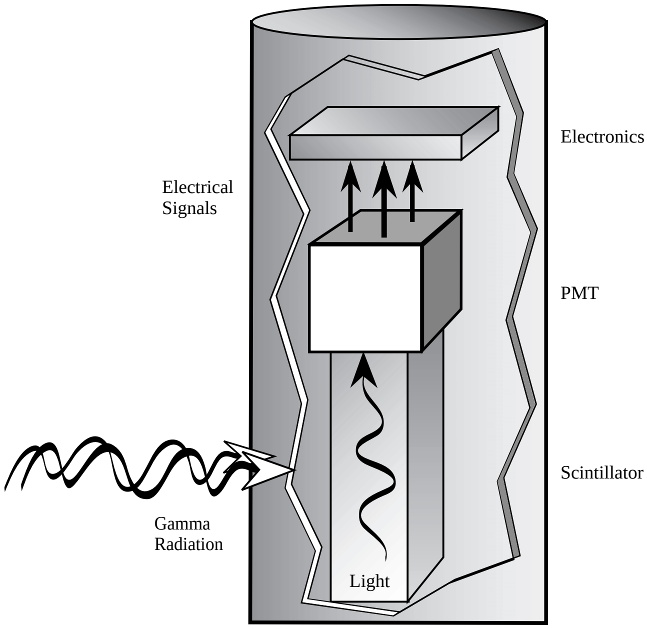

FIG. 3.15e
Scintillator technology.

Gas Ionization Chamber

The ionization chamber is likewise filled with inert gas and sealed, but, rather than applying a breakdown voltage, a smaller voltage in the range of 6 to 100 V is applied across the chamber from end to end (Figure 3.15d). The exact bias voltage varies among manufacturers and is related to optimal performance of that particular chamber design. When the chamber is exposed to gamma radiation, ionization occurs, and a continuous current in the microampere range is caused to flow. This current is proportional to field intensity.

Scintillation

The third gamma radiation detector technology is scintillation (Figure 3.15e). This technology is more sensitive to the same given field of radiation as compared to the G–M tube or the ion chamber. With this technology, a crystal, either specially treated plastic or sodium iodide, replaces the tube of inert gas. The crystal, when exposed to gamma radiation, will create photons of light within the crystal structure. The number of photons created will increase as the radiation field increases. A photomultiplier tube senses the photons of light from the crystal and converts the light to an electrical signal in proportion to the amount of light present.

FIG. 3.15f
Flexible scintillation detector.

LEVEL SWITCH APPLICATIONS

The G–M tube is most commonly used for level switch designs (point detection). The switch detector is arranged so that it sees the full field intensity (tank empty), or it sees little or no field (tank full). Both ion chamber and scintillation detectors are used for continuous level detection. Ionization chambers are made in continuous lengths up to 20 ft (6 m). As shown in Figure 3.15f, the newer flexible scintillation detectors are made in lengths of up to 23 ft (7 m). Geiger–Mueller tubes are furnished in 6-in. (152-mm) and 12-in. (305-mm) lengths and can be stacked to form a continuous detector. The stacked G–M tubes are less expensive than an equivalent length of ionization chamber. However, the G–M tubes are more subject to drift, their performance can deteriorate with time, and they generally require more radiation. A more serious drawback to the use of the G–M tubes is that an exposed (above the liquid level) element can fail altogether. If this happens, it will appear to the receiver that the failed section is covered by the liquid. In a five-section assembly, this would cause a reading that is 20% too high.

Typical level switch installations are shown in Figure 3.15g. The most common is shown at the left, where the source and detector are at the same elevation, and the G–M tube detector is horizontally mounted. In this case, the differential between on–off relay action is 0.25 in. (6.3 mm), meaning that a 0.25-in. (6.3-mm) rise in liquid level is sufficient to block the source beam and change the state of the switch. If a wider differential is desired, the detector is mounted at an angle to the horizontal. For a maximum differential in this installation,

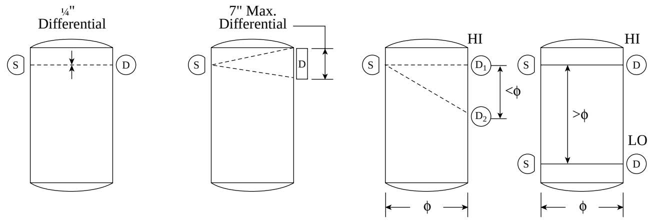

FIG. 3.15g
On–off radiation switch installations.

the sensor is mounted vertically, producing a differential of 7 in. (178 mm). For even wider differentials, two detectors can be used with a single source. In this case, the maximum differential between high and low level settings can equal the tank diameter when using a 45° source beam collimator. Differentials greater than the tank diameter require two separate sets of sources and detectors.

In high-level applications, the G–M tube and switch assembly is normally above the liquid level and therefore exposed to full field intensity. Pulses from the G–M are taken to a trigger circuit that, in turn, continuously resets a time-out relay much like the time-out relay used in a computer watchdog circuit. When rising level blocks the radiation beam, the relay is no longer reset, and the switch changes state; for fail-safe operation, the switch would open. The switch circuitry is arranged so that the switch will open on failure of the G–M tube or failure of any of the switch components, and therefore the entire installation may be judged fail-safe. Low-level switching applications are a different matter. In this case, the G–M tube or switch component failure would not be detected, because exposure of the tube to the beam on falling level would not actuate the switch. Where fail-safe design for falling-level applications is required, a test circuit can be installed in the G–M tube and switch assembly to test the switch when the level is high. There are several ways to do this, but, in general, a small source is installed in the detector and used continuously or intermittently to test the integrity of the tube and switching circuitry.

CONTINUOUS LEVEL MEASUREMENT

Two methods exist for making continuous level measurements using fixed sources and detectors. One method, using a strip source and strip detector, is illustrated in Figure 3.15h. The second, shown in Figure 3.15i, uses a point source and a strip detector. As shown, the strip source radiates a long, narrow, uniform beam in the direction of the detector. As the level rises a small increment, a corresponding small increment of the detector is screened off. This incremental response is uniform and linear over the entire span, and therefore the signal produced is linear with level change over the entire span, except for small nonlinear end effects near 0 and 100% of span. Moreover, this installation, unlike the point switch installation, is not sensitive to variations in the

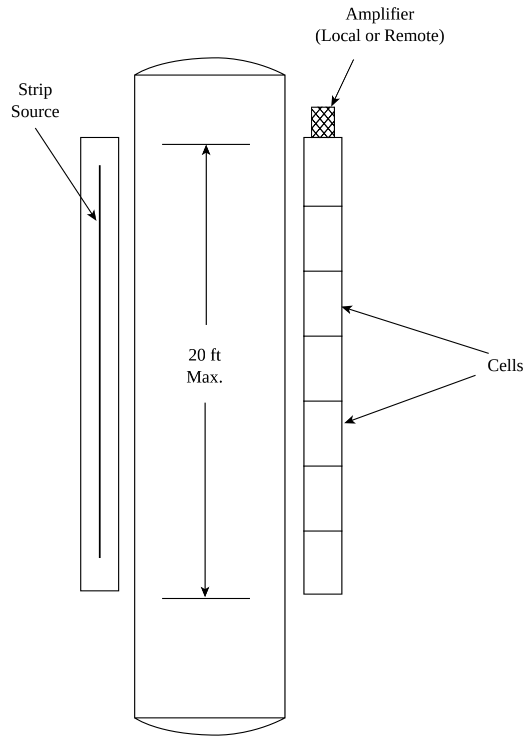

FIG. 3.15h
Continuous level detection by use of strip source and electronic cell receivers.

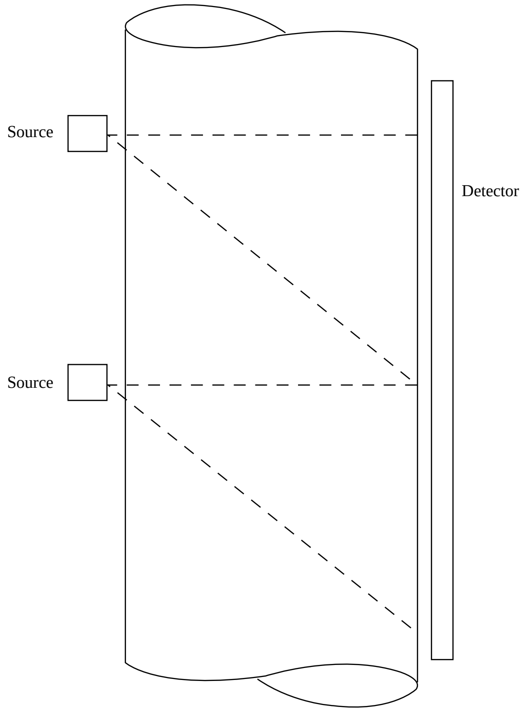

FIG. 3.15i
Level detection using two sources and one detector.

specific gravity of the material in the vessel. For example, if the specific gravity of the material varied from 0.40 to 0.70, the source would be sized for 0.40 specific gravity material; material of higher gravity would cause higher attenuation, and this would not affect the performance of the detector.

The point source and strip detector installation also works as a very small incremental on–off device insofar as a small level rise blocks off the radiation beam of a corresponding increment of the detector. The incremental changes in level do not produce a uniform change in the coverage of the detector; consequently, this installation produces a nonlinear signal with level change. Not only does the thickness of the material change as the level changes, but the geometry of the fixed portion of the system—the vessel walls, wall-to-detector distances, and the free space—also changes as the level changes. The nonlinearity of this system can be rectified by correcting the detector output electronically by implementing a linearizer curve.

Narrow Vessels or Interface

For narrow vessels with long measurement spans implementing the point source and strip detector arrangement, it will be necessary to use multiple sources with a single detector, or multiple sources with multiple strip detectors. If the source holder utilizes a 45° collimator where the radiation coming out of the source holder is broadcast from 0 to 45° down from the top of the measurement (see Figure 3.15i), the maximum measurement span from one source is approximately equal to the diameter of the vessel. The second source is located so that the radiation from the first source slightly overlaps with the second source. For the best accuracy, it is important to implement a linearizer curve in the electronics to correct for the changing radiation fields across the measurement span.

Radiation gauges can be arranged to detect, either at a point or continuously, solids levels and liquid–liquid interfaces. The accuracy of these installations depends on source size, detector sensitivity, material gravities, and vessel geometry. Sometimes, a system may be needed to continuously monitor a liquid–liquid interface or a liquid or solid level over a long, vertical, straight side. In these cases, strip source or multiple source and strip detectors would be expensive. Figure 3.15j shows how a point source and point detector may be motor driven over a wide span to detect levels of the above type. The motor drive may be set up to continuously hunt the level (that is, undershoot and overshoot), or it may be set up to look for the level on operator demand, as might be required for an inventory. The exact location of the level is determined by the sprocket-driven position sensor.

INSTALLATION NOTES

Source holders are furnished with a mounting flange on the window side of the holder (Figure 3.15a). Most older detectors are supplied inside a piece of steel pipe that is capped on both ends. The preferred method of installing this equipment is to bolt it to clips that have been welded to the outside surface of the vessel. Figure 3.15a illustrates how this is done. Newer, lightweight detector designs require a simple support system. The installation can be arranged so that the elevation of both the detector and the source can be changed easily.

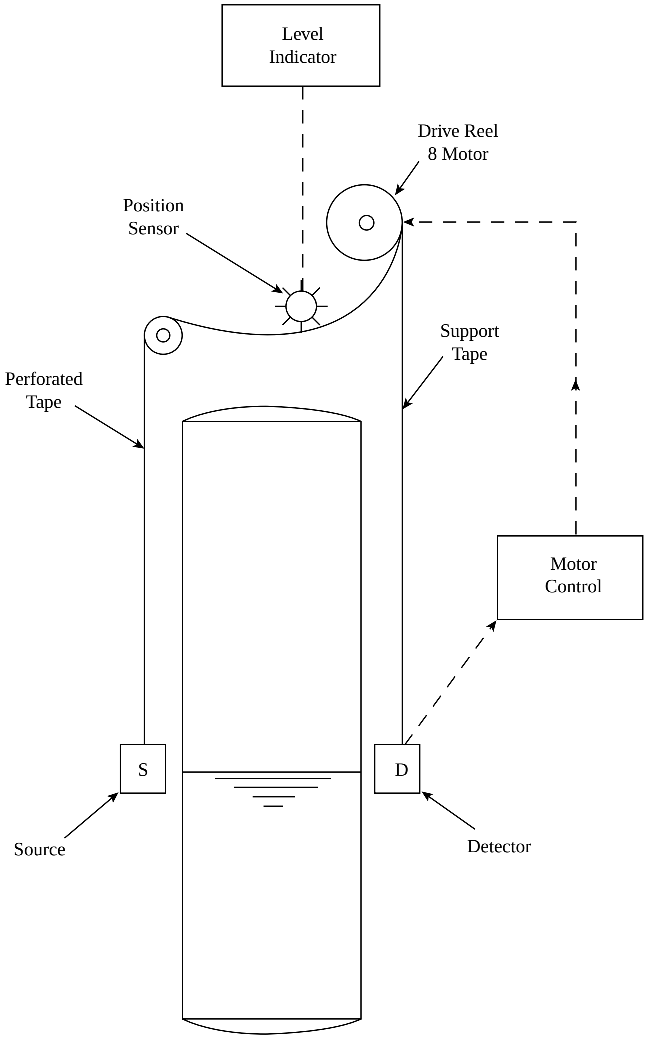

FIG. 3.15j
Continuous high accuracy radiation detector system for accounting installations.

The system shown calls for the beam to pass through the center of the vessel. This is unnecessary and would be undesirable in some cases. If the vessel has a center-mounted agitator, fill nozzle, or other internal obstruction, the source and detector should be located so that the beam radiates across a chord where there are no obstructions. A chord may also be selected on large-diameter vessels to reduce source size (Figure 3.15k). The cable run to the detector should be made in such a way that condensate from the conduit system will not flood the detector.

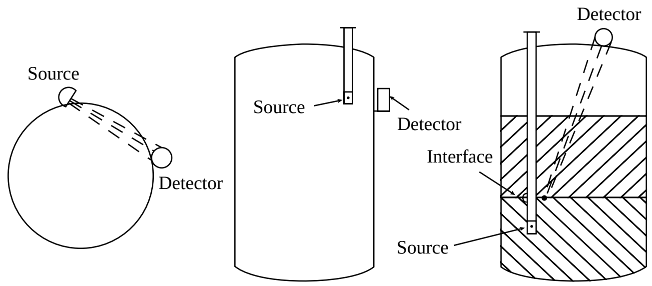

FIG. 3.15k
Relative locations of radiation sources and detectors.

Calibration Considerations

The technique for calibrating radiation level detectors is very important. The gauge should be calibrated after all vessel construction is completed, including the mounting of external insulation. For optimal accuracy, all attenuating materials such as insulation, heating/cooling jackets, internal baskets, internal support structures, and so on need to be in place before calibration is performed.

Radiation detectors do not work on the absolute amount of radiation from the source; rather, the detectors interpret the change in radiation from the 0 level position to the 100% level position. With the source holder open and the vessel empty, the detector's 0 level condition is determined. Optimally, the vessel is then filled to the position to the 100% full level, and the detector interprets the full vessel. Many times, the vessel cannot be filled, so technicians will simply close the source holder shutter to represent the blockage of radiation to the detector, simulating a 100% full condition. Unless the upper measurement range accuracy is needed, this generally is acceptable.

To determine the actual level in the vessel at any given time when using radiation gauges, the technician can use a portable survey meter and run the meter up along the side of the vessel. The top of the level in the vessel will be at the point at which a substantial increase in radiation intensity is detected. Below that level, most of the radiation will be blocked by the process fluid.

BACKSCATTER DESIGNS

Radiation does not always travel in a straight line. In any stream of radiation, there is a certain percentage of the stream that will strike some of the atoms of the material in its path so that part of the radiation stream will bounce back or *backscatter.* The percentage of the radiation that backscatters depends on how much material is in the path and how dense that material is. This method of detection has the advantage that both the source and the detector are on the same side of the vessel. However, one must make sure that there is enough shielding between the source and the detector so that only the radiation backscattered by the process material will be seen by the detector.

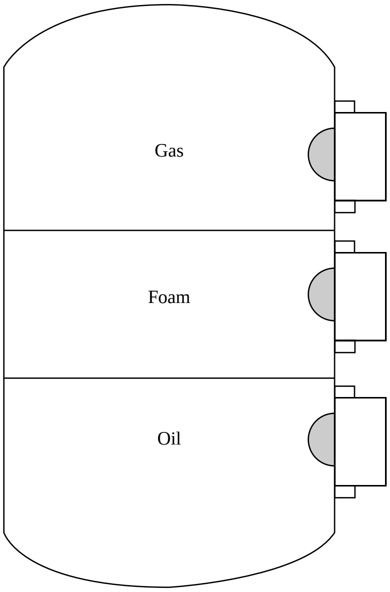

FIG. 3.15l
Neutron backscatter-type level or interface level switch has a repeatability of about 1 in. (25.4 mm).

The exception to this is the neutron backscatter gauge. This type of source emits fast neutrons that become slow neutrons after they have passed through or been backscattered by the process material. The neutron detector only "sees" slow neutrons; therefore, the source and the detector can be placed side by side without any interference (Figure 3.15l). The disadvantages of neutron systems are their high costs ($15,000 to $35,000 per point) and the fact that this investment pays for only a single point sensing level switch.

When gamma radiation is used in a backscattered radiation sensor, a shield between the source and the detector is essential. These units are less expensive than the neutron backscatter switches but are also more limited in their capabilities. They cannot penetrate vessel walls that are thicker than 0.5 in. (12 mm) and must be mounted right next to the wall to minimize backscattering from the wall. This requirement makes it impossible to place thermal insulation between the wall and the source or the detector; therefore, these units are limited to cold tank applications.

Traversing Designs and Density Measurement

To provide continuous level detection based on backscattered radiation, it is necessary to move the source/detector assembly up and down the vessel. In earlier tank-farm level gauges, this was achieved by the operator manually moving a backscatter source/detector assembly up and down on the outside wall of the tank. Automatic traversing is achieved by installing a 2- to 4-in. (50- to 100-mm) dry well inside the tank and by mounting the source/detector assembly inside this well in the form of a traversing plumb-bob. This assembly is connected by a signal cable to the electronics, which are on

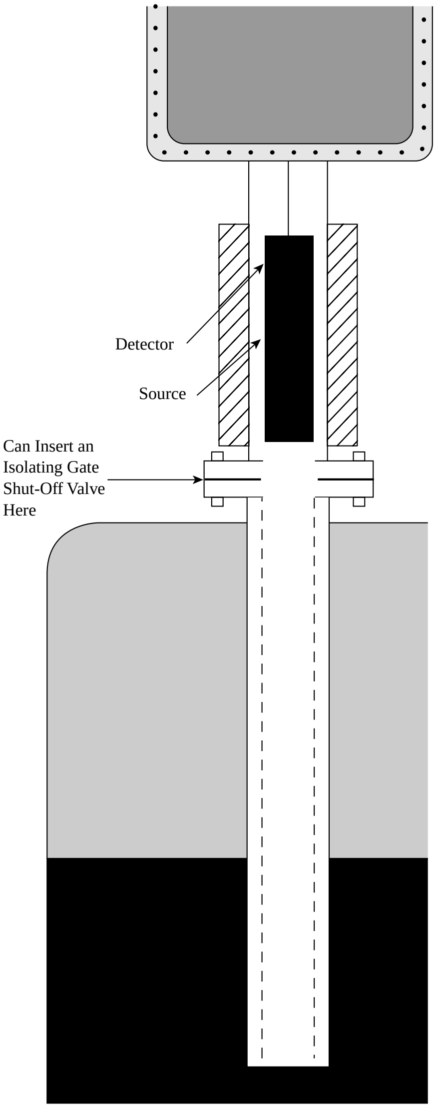

FIG. 3.15m

Traversing radiation backscatter detector can monitor total and interface levels in addition to drawing a specific gravity profile. (Courtesy of Ohmart/Vega Corp.)

the top of the tank. This cable also serves to lift and lower the assembly under the control of a stepping motor (Figure 3.15m). Such a well-type installation tends to amplify the measurement signal, because the backscattered radiation is received from all around the pipe rather than from a single direction.

This increased sensitivity allows the backscatter gauge to detect not only the level but also the density of the tank contents. Because of its density-sensing capability, the traversing backscatter detectors are well suited for interface measurement between two or more layers. If the output of the transmitter is sent to a DCS-based CRT, it can display the location of the different liquid layers, the thickness of the "rag" layers between them, and the density within each layer. Presently, the traversing backscatter units are limited to approximately 120°F (49°C) applications. Another variation of this design is a two-dry-well arrangement in which one well contains the source and the other well the detector. Both the source and detector are scanned up and down in their respective wells to make a transmission measurement of the process between the wells.

The required source size (10 mCi to 50 mCi) is much less than for external source units, because the radiation is received from all directions, and because there is no tank wall to look through. The inner surface of the dry well must be clean and smooth, and the pipe itself must be straight to protect against capsule hangup. These units can detect level ranges up to 150 ft (45 m) and are unaffected by tank diameter or wall thickness.

ELECTRONICS

The detector electronics can be integrally or remotely mounted. In the past, remote-mounted electronics were common. The detector output was a frequency or voltage signal that ran via wire to the remote-mounted electronics, which were generally mounted in the control room or rack room. Mounting the electronics in such a location normally eliminated the need and cost of hazardous qualified enclosures. The electronics received the detector output and provided, normally, a 4- to 20-mA DC output.
