In connection with the tank, one must describe the tank supports, the pipe connections, agitation, if any, the tank location, including seismic classifications and wind conditions, the required load cell materials, and protection (wash-down) required. The process data should state the weighing range and the temperature conditions. The instrumentation data should specify the maximum allowable error for the complete system, the type and location of the transmitter and/or display devices and the electrical area classifications in those locations. In addition, the supplier should be advised of the communication protocols and electrical interface requirements, including the digital networks and fieldbuses used in the plant (see Table 7.24d.) The International Electrotechnical Commission (IEC) has adopted DeviceNet as an international standard within their networking standard IEC 62026.

In addition to digital communications, the weighing system packages can also be provided with various software packages that allow engineers and operators to configure, calibrate, and provide documentation for their systems.

TABLE 7.24c
Weighing System Specification Form

Vessel Related Information
The tank is supported on how many points?
Is the vessel suspended or supported on legs/gussets?
Are piping connections flexed?
Is the vessel located in or outdoors? If outdoors, what is the design basis for maximum wind velocity (MPH)?
What is the area seismic classification? (None or Zone 0, 1, 2, 3, or 4)
Is vessel agitated? (Give type, HP, location)
Is weigh tank in a wash-down area?
Are stainless steel load cells required?
Process Data
What is the empty (dead) weight of the tank?
What is the full (live) product weight of the tank?
What is the product being weighed?
What is the minimum, normal operating, and maximum ambient temperature?
What is the minimum, normal, and maximum process temperature?
Will conduction cause load cell temperatures to exceed 130°F? Should thermal pads be used?
Instrument and Control Data
What is the system accuracy requirement in % FS or other units? Is the system to be installed and/or calibrated?
Should the weight transmitter be blind or indicating? Should the transmitter be provided with set-point control capability?
Is the transmitter located at the vessel or in the control room? What is the distance between load cells and transmitter?
What is the vessel and what is the transmitter hazardous area classification? (General Purpose, Class 1, 2, or 3, Div. 1 or 2, Group A, B, C, D, E, F, or G. Can also use NEMA Classification 1 to 13.)
What will the weigh transmitter be connected to? (PC, PLC, DCS, Other)
If analog signal is required, is it to be 0–20 mA, 4–20 mA, or 0–10 VDC?
What are the electrical interface requirements? (None, RS-485, RS-422, RS-232, or other)
What are the communication protocol requirements? (ASCII, Modbus RTU, Modbus Plus, DeviceNet, others)
Is a network/gateway controller desirable?
Is remote indicator required?

[a] Number of nodes that can be physically connected per segment: in some cases the number of logical addressable nodes can far exceed this number.

[b] Practical guideline for control networks: the more nodes there are, the longer the refresh time of the system.

Weighing vs. Metering

Hopper, tank, or reactor weighing are the most widely used application of scales. Hopper scales range up to 75,000 lb (35,000 kg), while tank scales can range up to 150,000 lb (70,000 kg). Batch formulation is usually under microprocessor (distributed control system or programmable logic controller) control, where a number of ingredient hoppers, collecting bins or weigh tanks, feeders and discharge devices, and conveyors are automatically sequenced through the operation.

The recipe ingredients are fed into the same weight hopper one at a time or into different weight hoppers simultaneously. The charging of the ingredient is done in two stages: first at full flow, and near the target weight at dribble flow. At the end of each ingredient charge, an automatic tolerance check is made and, if the precision is acceptable, the individual ingredient or the completed formulation is discharged. A printout is provided for each batch giving the batch number, the desired recipe formulation, the actual total batch weight, the actual individual ingredient weights, the hopper residual (heel) after dumping, and the destination. As part of the batch control package, a computer remote terminal is usually provided, which continuously displays the batch status.

A large number of weighing installations are used in connection with batch charging of various chemicals to meet the requirements of a particular recipe. Because the use of weight scales necessitates the purchase of weight tanks and pumps, the cost of such installations can only be fairly evaluated by considering the price of all related equipment and building space. If a comparison is made on this basis with flow-metering hardware that requires no additional equipment or support design, the relative costs of weighing versus metering techniques will be placed in a more realistic perspective.

In general, the weighing method is favored in all cases where the batch media is hard to handle, such as in solids, slurries, and very high viscosity or very hot fluids. Elsewhere, the choice might be made on the basis of installed cost (which favors metering), accuracy (which favors weighing), and other relevant considerations.

Bulk Weighing

When large quantities are being weighed (bulk weighing), it can be advantageous to incrementally weigh the total quantity in a bulk weigher. Such systems are used on grain elevators, where weighing accuracy is increased and weigh hopper costs are reduced by weighing the contents of, say, a 100-t hopper car in 10 or 20 increments, instead of all at once (Figure 7.24e). The sequence of operation is such that during filling, the gate between bins A and B opens and charges the weight hopper to a preset draft weight. At this point, the gate between A and B closes and the gross weight of B is recorded as a positive weight. After that, the gate between B and C opens and stays open until B is empty. The empty weight of B (including the heel left in the hopper) is recorded as a negative weight and the cycle is repeated.

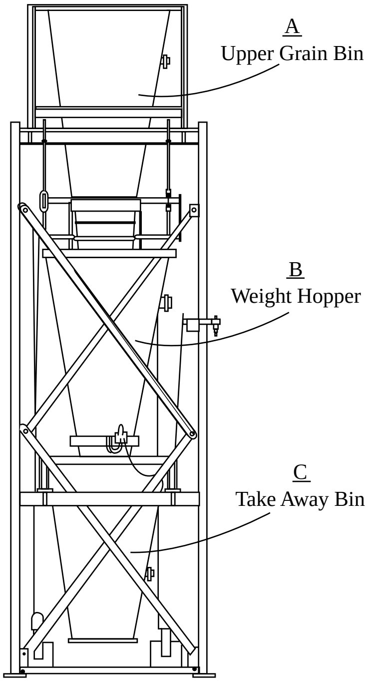

FIG. 7.24e
Bulk weighing system used to measure large weights in applications such as in grain elevators. (Courtesy of Cardinal Scale Mfg. Co.)

Weighing installations in the petrochemical industry can also include microprocessor-controlled drum filling scales. At the end of filling, these scales automatically print the drum number, its weight, the identification of the contents, and the time and date.

Weighing Platforms

In many industries, portable bench scales (sometimes with wheels for moving) are used. Their capacities range from 25 lb (10 kg) up to 2500 lb (1000 kg), and their corresponding platform sizes range from 16 × 16 in. (0.4 × 0.4 m) up to 36 × 36 in. (0.91 × 0.91 m). Floor scales are also widely used. In these permanent installations, a 12 in. (0.3 m) deep frame is incorporated into the floor structure, so that the weighing platform is flush with the floor. The removable center plate provides maintenance access to the working components. These units range in size from 500 to 10,000 lb (200 to 5000 kg).

A less expensive installation uses a deck scale; it requires no pit, but instead rests right on the floor. This results in a need to lift the weight up because the weighing platform is above the floor. To minimize this inconvenience, deck scales that are portable and low-profile (2 to 3 in., or 5 to 8 cm, above the floor) have been marketed. These units are available with up to 20,000 lb (10,000 kg) ranges and with 6 × 8 ft (2 × 2.5 m) platforms.

Weighing Platform Transducers Weighing platform transducers are now the basic sensing elements in medium capacity, low height, semiportable platform scales. Available in

capacities from 500 to 14,000 lb (225 to 6300 kg), one can be located almost anywhere within the process area without the need for pits and attendant preparation costs. Typical units, depending on capacity, are from 2 to 35 ft^2 (0.19 to 3.3 m^2) in platform area and 1.5 to 6 in. (37.5 to 152 mm) in overall height (Table 7.24f).

Beam-type transducers are placed in each corner of the weighing platform (Figure 7.24g). A steel cable or alternative flexible arrangements suspend the active weighing platform from the end of the transducer. The flexible connection allows the transducer to operate in its normal deflection mode, capitalizing on its inherently high accuracy. The flexible connections also render the entire structure less susceptible to uneven foundation conditions.

In addition to low height, high accuracy, and relative insensitivity to foundation unevenness, the units are semiportable.

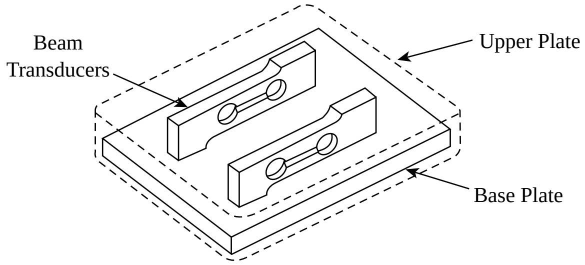

FIG. 7.24h
Low-capacity beam platform.

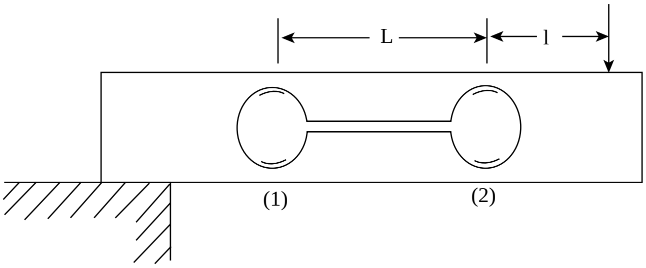

FIG. 7.24i
Load position desensitization.

Beam-Type Platforms Smaller, lower capacity beam-type platforms available in the range of 10 to 250 lb (4.5 to 114 kg) use two beam-type sensing elements (Figure 7.24h). Features and characteristics are similar to those of platforms already described. One significant difference relates to the use of only two beam-type sensing elements. In this configuration, the reduction of corner loading sensitivity or load placement errors must be approached differently. It is no longer a matter of simply dividing the load among four linear transducers, but rather involves a reduction of the effect of changing load position on two transducers.

A changing load position results in a different bending moment applied to the beam-type transducers (Figure 7.24i). However, as discussed in connection with beam-type transducers, the strain gauges are applied and wired in a way such that the beam-type element is insensitive to load position or bending moment.

This concept can be explained as follows. Strain gauges at location 1 sense the bending moment there (M_1). Gauges at position 2 sense the bending moment at that position (M_2). The strain gauge bridge is arranged so that the output is proportional to the difference $M_1 - M_2$, and this may be expressed by the relationship:

$$M_1 - M_2 = F(L + l) - F(l) \qquad \textbf{7.24(1)}$$

$$M_1 - M_2 = FL \qquad \textbf{7.24(2)}$$

Hence, the output of the beam-type transducer is proportional to the applied force and the distance between the strain gauge locations (L). It is insensitive to the placement of the load (l). This relationship is theoretically correct, assuming perfect strain gauge location and zero machining tolerances. Since this relationship seldom exists, electrical “tuning”

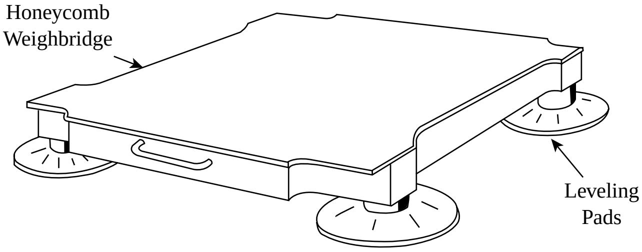

FIG. 7.24j
Portable platform scale.

TABLE 7.24k
Performance Characteristics of Portable Platform Scales

Rated capacity	50,000 lbs (22,500 kg)

Temperature effect on zero	0.1%/100°F (38°C)
Temperature effect on output	0.15%/100°F (38°C)

methods tailor the sensitivities at locations 1 and 2 to give virtually perfect moment rejection.

The lower capacity platform configurations are available in capacities of 10 to 250 lb (45 to 114 kg) with roughly 15 × 18 in. (381 × 457 mm) weighing area and height of about 3.5 in. (88 mm).

Portable Platform Scales Another portable platform scale (Figure 7.24j) is composed of a honeycomb weigh-bridge and four load cells, one at each corner. Adjustable leveling pads level the platform. Each pad includes a swivel joint for accommodating sloping surfaces. An entire structure weighs less than 140 lb (63 kg).

The units are available with ramps and spacers for use with various vehicle wheel configurations. They are being used in portable aircraft and vehicle weighing (Table 7.24k).

Truck, Monorail, and Railway Scales

Truck Scales When weights of transported materials are to be measured, monorail, truck, and railway scales are used. Monorail scales range from 1000 to 10,000 lb (450 to 4500 kg). Truck scales are available for both static and in-motion weighing. The electronic truck scales provide fast printouts and self-diagnostic features. Typical truck scales range from 10 to 100 t and can be provided with platforms up to 12 × 100 ft (3.6 × 30 m).

Railway track scales are also available for static or in-motion weighing and can include self-balancing and self-checking features. They are available with up to 200-t ranges and with up to 50 × 150 ft (16 × 50 m) platforms. When railroad cars are loaded by floating chutes, the positioning of the trucks and the opening and closing of the chutes can be fully automated.

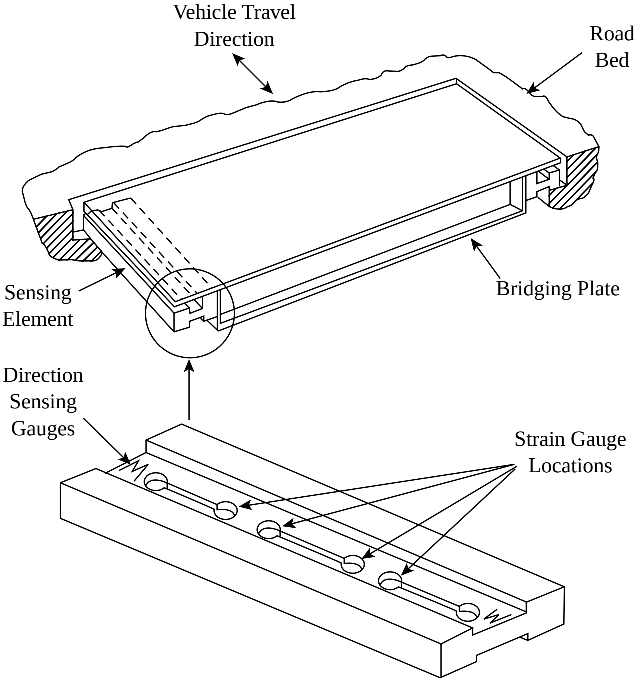

FIG. 7.24l
Treadle scale.

Treadle Scales In the past, scales for weighing vehicle axles on highways at toll booth locations utilized individual load cells, weigh-bridges, and mechanical stabilization hardware, all of which required expensive pits and additional installation. An integrated treadle scale now eliminates some of these requirements and provides a self-contained unit that can be lowered into place in a shallow pit.

Conceptually, the treadle scale (Figure 7.24l) consists of two strain gauge sensing elements located at opposite ends of the bridging plate. The sensing elements measure shear forces by virtue of the sensing element configuration and gauge location. Strain gauges at each of the reduced sensing sections sense the principal tensile and compressive strains due to the applied shear forces.

Additional strain gauges on the leading and trailing ends of the sensing elements are connected in a bridge configuration, providing direction sensing information for the associated instrumentation. Invalid vehicle entries are thereby detected (Table 7.24m).

Two units are generally installed end on end across a lane, spanning a distance of 10 ft (3 m). Total capacity for the pair is 36,000 lb (16,300 kg). Currently, the units are used to sense overweight vehicles for subsequent weighing by law enforcement scales. Another use is axle weight measurement for toll assessment by weight classification.

Monorail Weighing Transducer Another beam-type weighing transducer is being used in monorail conveyor systems such as those in meat processing plants. Conventional monorail weighing systems support the live rail by load cell and

Weight	200 lbs (90 kg)

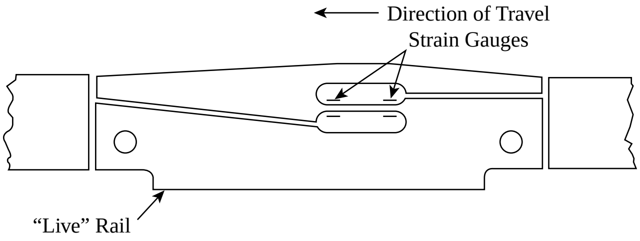

FIG. 7.24n
Monorail weighing transducer.

flexure assemblies. The new monorail transducer replaces the live rail and is self-supporting.

A typical unit is shown in Figure 7.24n. Strain gauges at the designed location sense bending strains as the load traverses the transducer. The gauges interconnected in a bridge arrangement supply a constant output independent of load position on the transducer. The sloping arrangement on the upper edge of the transducer decouples the moving carrier from the pusher mechanism during the sensing period. That means on the downward slope the carrier rolls free, eliminating contact with the pusher mechanism.

This simplified transducer not only provides greater measuring accuracy, but also eliminates a second load cell and associated flexure and mounting arrangements. This reduces the overall cost.

When cranes are used to transport material, weighing can take place during transportation. Load cells with ranges from 1000 to 100,000 lb (450 to 45,000 kg) can be incorporated into the hook assembly to achieve this (Figure 7.24o).

TYPES OF WEIGHING SYSTEMS

Mechanical Lever Scales

Mechanical lever systems are available for such applications as motor truck scales, railroad track scales, hopper scales, tank scales, platform scales, crane scales, dynamometer scales, and many other specialized types and applications.

They utilize the principles of the lever and involve countless combinations of load support arrangements. Although portable models are available in the lower capacities, most installations are permanent in nature and usually require some preparation of the installation area.

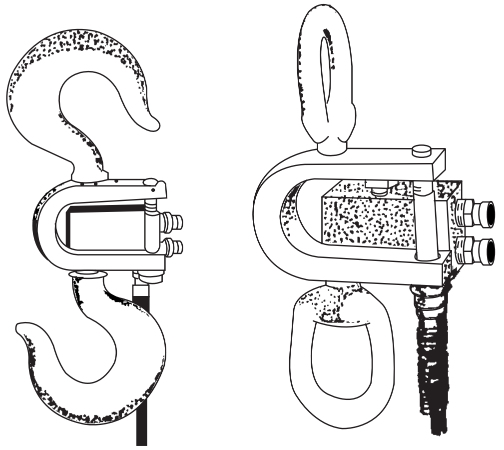

FIG. 7.24o
Load cells can be attached to cranes to measure the size of the load or to protect from overloading. (Courtesy of W.C. Dillon and Co.)

Mechanical level scales have reached a high degree of perfection through many years of development by hundreds of individuals and manufacturers. One of their advantages is their simplicity, which allows them to be used even in those parts of the world where sophisticated maintenance service is not available.

Because of their accuracy and reliability when well maintained, the performance of mechanical level scales has been the basis for laws and standards established in connection with weights and measures for the regulation of commerce on a local, national, and international level.

Spring-Balance Scales

Perhaps the simplest of all methods of weighing, the spring-balance scale consists basically of a calibrated spring and some means of reading deflection or elongation of the spring under load. This rudimentary principle can be very accurate when properly applied in correct design, with presently available high-grade constant temperature modulus alloys. Although spring-balance scales are dependent on relatively large deflection of the weighed load, and are best suited for relatively light loads, they represent a most economical approach to accurate weighing.

Load Cell Weighing

Weight sensors such as load cells are discussed in detail in Section 7.25. Although load cells have been available in one form or another for over 50 years, the use of load cells as weighing devices has become widespread only in the last few decades. Load cells have proven their accuracy and reliability for many types of installations that previoulsy had proven most difficult.

Load cell weighing systems have several outstanding advantages:

1. They are relatively easy to install
2. They have fast response and short settling time
3. They are not subject to wear
4. They permit remote location of the readout module
5. They yield an analog weight signal that is either directly compatible with, or easily converted to, standard control instrumentation

FACTORS INFLUENCING PERFORMANCE

Some of the common factors affecting weighing system performance are:

1. Temperature
2. Vibration
3. Ambient conditions
4. Maintenance
5. Installation
6. Calibration

Temperature Effects

In general, most scales or weighing systems are designed to operate under normal atmospheric temperature conditions. Operating personnel are usually present, at least part time. The average operating limits are 20 to 120°F (–6.7 to 48.9°C). Operations outside these limits are commonplace; wintertime operation of platform scales with the scale indicator head located in a heated control room is one example. This example also infers operation at different temperature levels on a single piece of equipment.

All modern weighing systems are compensated for operation over varying temperatures. Performance and accuracy guarantees are usually given for operation at 70 ± 50°F (21 ± 28°C). For operation outside these limits, temperature correction curves are available from most manufacturers.

Mechanical Lever Scales A mechanical lever scale system is largely self-compensating when subject to gradual temperature changes. In a lever ratio relationship, it can be readily seen that although the overall length of a lever may change due to expansion, the relative position of the fulcrum point with respect to the reaction points does not change and the lever ratio remains constant.

However, under conditions of nonuniform temperature on a lever system, errors in reading or balance will be introduced. The types of direct reading scale errors due to temperature shift may be divided into zero shift or span shift.

Zero shift causes a constant error over the complete weight range. Span shift error is variable over the weight range. In modern weighing packages, both can be automatically detected and corrected. Zero error or unbalance may also be checked from time to time by direct observation. All standard systems are equipped with zeroing adjustment, which can be manipulated as required.

In the case of span errors resulting from temperature change, there is a more serious problem. It is substantially impossible for an operator to compensate for such errors unless temperature correction factors or temperature correction curves are available. The use of such factors or charts involves careful determination of temperature. Naturally, it is desirable that the weighing package be provided with automatic self-compensation, avoiding all temperature errors.

Load Cell Weighing Systems The effect of temperature on load cell weighing systems is quite different from that on mechanical scales. The elimination of levers and mechanical linkages precludes errors (or compensations) arising from these members. The individual load cells must be designed for minimum effect of temperature and contain compensating devices or networks that will assure performance within specification.

Electronic Load Cells All types of load cells contain some form of load supporting member and an associated electrical component designed to detect precisely deflection of the support member under load. Deflection may be in the order of 0.001 to 0.010 in. (0.025 to 0.25 mm) or more. The electrical signal may take the form of changing current, voltage, or resistance.

The most popular electronic load cell is the strain gauge type, which changes its electrical resistance in direct proportion to the weight or force applied. Load cells involving one or more bonded, or unbonded strain gauges (semiconductor or thin-film sensors) also contain appropriate compensation networks. These networks not only correct for changing electrical characteristics due to temperature variation, but also, in most instances, for modulus changes in the support member and for other temperature related errors.

Hydraulic Load Cells Hydraulic load cells are subject to zero and span errors when subjected to varying temperature. Temperature compensation must be provided to prevent errors in output signals.

Pneumatic Load Cells Pneumatic load cells considered here are of the force-balance type. They are relatively free of temperature-related errors, provided proper care has been given to the choice of diaphragm material. It is of fundamental importance that the operating medium, whether compressed air or other gas, shall be sufficiently dry to prevent condensation of water vapor and freezing at temperatures below 32°F (0°C).

Errors Caused by Vibration

Vibration and dynamic disturbances may seriously affect weighing system performance. Accuracy, stability of reading, and frequency of maintenance are factors that may be affected. Vibration can be caused by either external effects or by internal causes (e.g., impact loading).

In the case of external sources, relocation of the scale may be possible. One should select locations where the foundation is stiff and stable and where sources of vibration, such as compressors, punch presses, etc., are not present. Where foundation stability is known to be poor, one should consider methods of improving stability, such as erecting additional bracing columns, gussets, or concrete work. Consideration can also be given to the use of suitable vibration absorption or insulation material, such as Fabreeka.

Vibration caused by internal disturbances, such as those caused by loading methods, or by agitation of tank content etc., may also cause serious problems. Design consideration should be given to the loading method on all weighing systems in order to eliminate or minimize impact or shock loading. Baffle plates are frequently helpful in reducing surging and gyration of fluid contents in weighing vessels.

Most weighing systems are provided with adjustable vibration dampers. These should be maintained in good working order and adjusted for optimum scale performance under the operating conditions.

Errors Caused by Ambient Conditions

Weighing system installation frequently has to be made in areas where the equipment may be continuously or intermittently exposed to high or low temperatures, wet or humid atmosphere, corrosive or abrasive contaminants, etc. In such areas, steps should be taken to afford as much protection as possible to the weighing system. Foundation pits should always be provided with adequate drainage that will allow quick runoff and thorough drainage of the pit. Attention should also be directed to the possibility of accidental backflooding through the drain in the event of flooding in other areas.

Standard methods of protection, such as corrosive-resistant paint, electroplating, etc., may be employed. It is often practical to specify that materials and alloys unaffected by the anticipated corrosive materials be used in the manufacture of the equipment.

When conditions are particularly severe, it may be desirable to provide a small atmosphere-controlled area to house the readout instruments for the weighing system. Prefabricated structures are available for this purpose.

Maintenance Requirements

Proper and timely maintenance is most important in the operation of any weighing system. Reference should be made to manufacturer's suggested practices, and adjustments in this program should be made to accommodate special conditions.

The weighing process is frequently the basis of control for manufacturing or chemical processes. It is very important that calibration checks be made from time to time to assure accurate performance.

Where the weighing system is used for commercial purposes (i.e., buying or selling of goods or merchandise), it is the legal responsibility of the seller to maintain the accuracy and performance of the weighing equipment in conformance with local laws on weights and measures.

Installation Requirements

The main goal is to eliminate all external forces, such as wind or pipe strain effects or other causes from superimposing a force component on the weight tank, that would appear as a change in weight. These goals are achieved by stabilizing the vessel and by providing flexible joints in the connected piping.

Vessel Stabilization Stabilizing devices are mechanical elements designed to secure a weigh vessel to the structure. This allows free movement in a vertical plane and restrains lateral movements, thereby maintaining an initial alignment throughout service life. The following effects may destabilize a vessel mounted on load cells:

1. Fluid sloshing
2. Violent chemical reactions
3. Thrust and impact forces due to mass flow entering or leaving the vessel
4. Vibration of live bottoms
5. Agitators
6. Thermal expansion of attached piping
7. Structural support vibration and/or deflection
8. Wind
9. Seismic events

Stabilizing devices are also required for most weigh applications using load cells to guarantee safety and accuracy. If tank or pipe motion causes a pipe or vessel rupture, the result can be dangerous when hazardous material are being weighed. Vessel vibration, movement, or oscillation can apply side loads on load cells, causing readout errors.

Stabilizing Devices Two types of stabilizing devices have emerged to prevent the lateral movement of vessels: stay rods and safety check rods.

Stay rods are mechanical elements installed securely between a gusset on the vessel support bracket and a rigid floor bracket. Vessel translocation and rotation is restricted, while radial thermal expansion is relatively free. Installation and sizing of stay rods in a perfect horizontal plane must ensure a linear response to vertical movement. Figures 7.24p and 7.24q show typical installation of stay rods on vertical and horizontal vessels.

Safety check rods are backup elements whose function is to prevent gross vessel tipping or wobbling (Figure 7.24p).

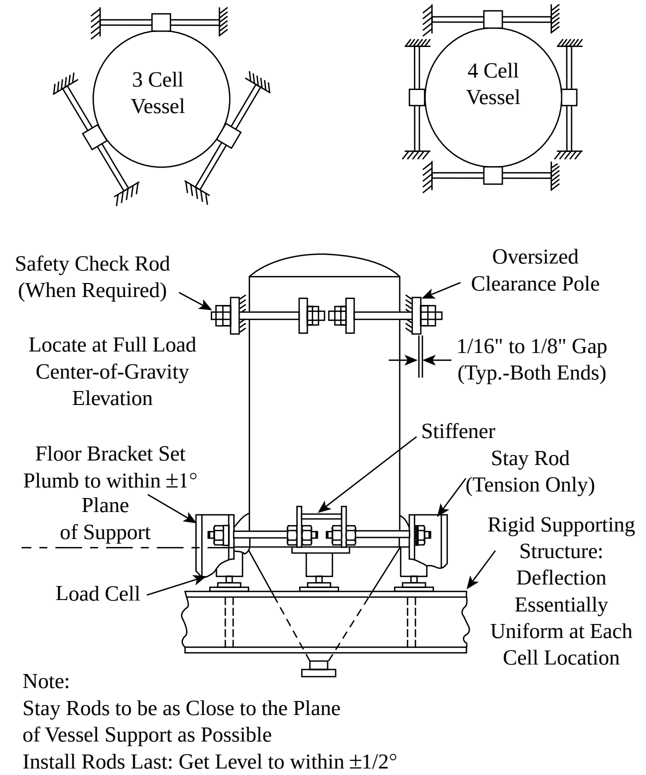

FIG. 7.24p
Typical staying arrangement.

Stay and check rod sizing and arrangements vary from application to application. The design criteria define the total acceptable vertical force generated by the deflection of all stabilizing devices expressed in percent of total load. A limit is established for the total rod elongation, minimizing significant side-loading of load cell and attached piping. The mechanical arrangement of stay and check rods to obtain optimal equilibrium depends on the center of gravity of the fully loaded vessel in relation to the staying plane.

The stay rods should not introduce any vertical force components. This is best achieved by making them completely flexible in the vertical direction. If guy ropes or rods with dual ball joints are used, it is unlikely that the weigh tank will be partially hanging on the stay rods instead of transferring all its weight to the load cells (Figure 7.24r).

Piping Connections Weigh vessels are generally connected to pipes through which materials are introduced and extracted. Any pipe directly attached to the vessel becomes an active part of the weigh system; any relative motion between the vessel and a particular pipe will generate vertical and horizontal reaction forces on the weigh vessel. The total vertical force V generated by the deflection of all piping connected to a weigh vessel should not exceed a percentage of maximum live load, proportional to the required system accuracy A in Equation 7.24(3):

$$V \le (30A)L \tag{7.24(3)}$$

where

V = total vertical force
A = system accuracy (percent)
L = maximum live load

Types of Vertical Forces There are three types of vertical forces generated due to piping:

1. Differential motion between the pipe connecting point on the vessel and the first pipe support
2. Thermal expansion of the vertical run between the points mentioned above

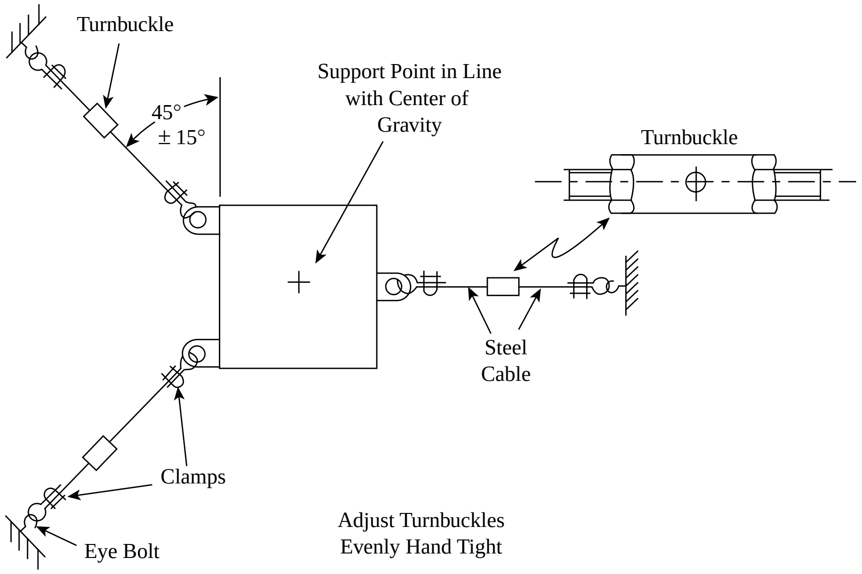

FIG. 7.24q
Staying method for suspended hoppers.

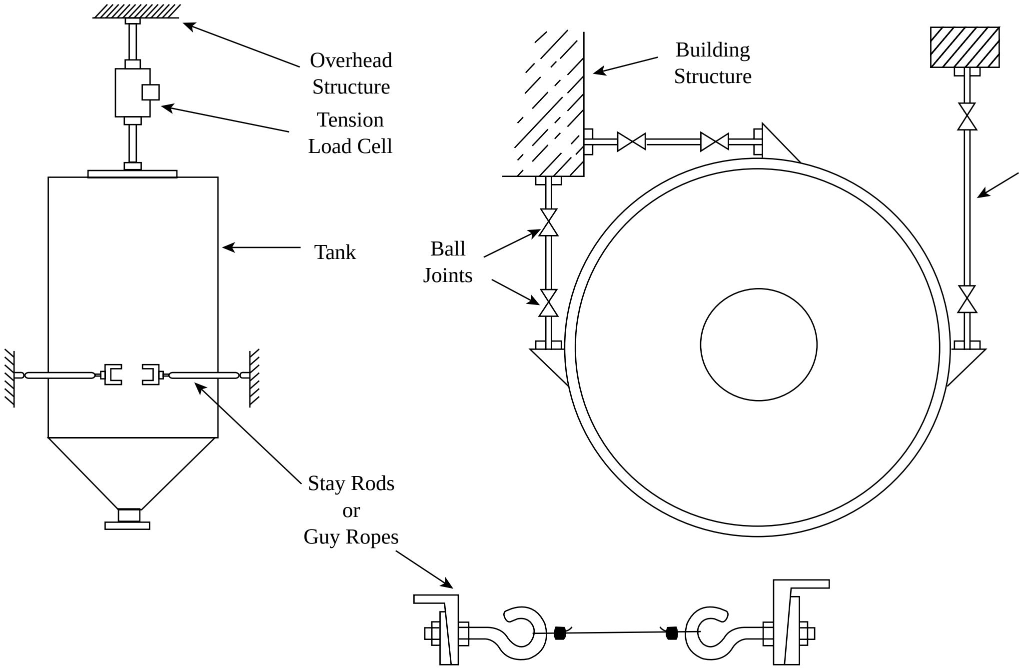

FIG. 7.24r
Three stay rods or guy ropes can protect against both clockwise and counterclockwise rotation.

3. Forces generated that tend to lift or push down the vessel as pressure varies in vertical pipes connected to the tank

In order to minimize the vertical forces associated with piping, it is recommended to mount all first pipe supports to the vessel support structure using only horizontal runs between the vessel and the first piping supports. The closest pipe support to the weigh vessel is the first support. The total vertical piping force represents the sum of individual vertical piping reactions, generated as described above. The total vertical deflection, which must be evaluated for each pipe run, is expressed in the following formula:

$$\delta V = \delta_S + \delta t_v + \delta t_p + \delta_a \qquad \textbf{7.24(4)}$$

where

δV = vertical deflection
δ_s = vessel support deflection
δt_v = vessel thermal expansion to point of pipe attachment
δt_p = pipe thermal expansion in vertical runs
δ_a = deflection of first pipe support or anchorage

Deflection tending to increase the vessel weight is given a positive sign; deflection tending to decrease the vessel weight is given a negative sign. The vertical reactions developed in one straight span of pipe in response to differential vertical motion between fixed end points are calculated by the following formula:

$$P_i = K_i\, \delta V_i \qquad \textbf{7.24(5)}$$

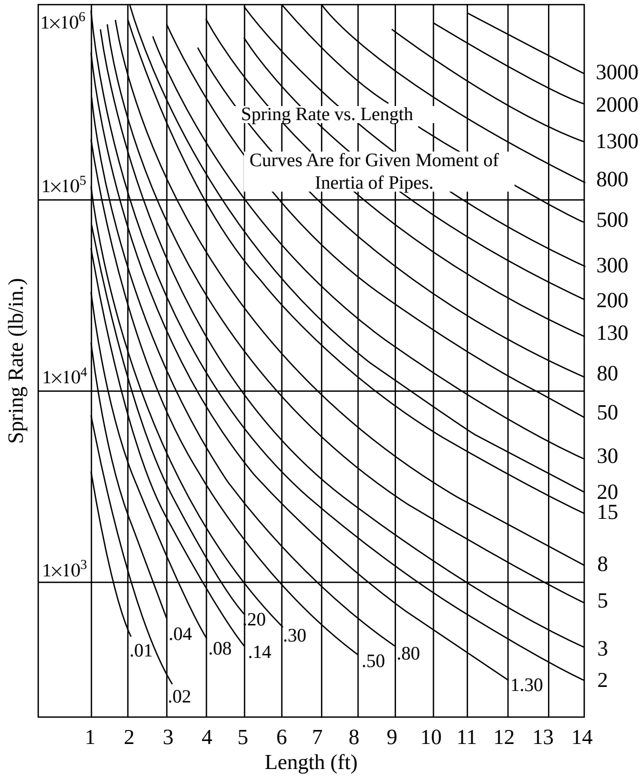

FIG. 7.24s
Pipe spring rates versus length for various moments of inertia of pipes.

where

P_i = sum of piping vertical reaction forces
K_i = spring rate or pipe stiffness
δV_i = sum of vertical deflections

The piping flexibility must verify the following criterion in order to achieve the required system accuracy for a given live load:

$$V = \left|\sum P_i\right| = \left|\sum K_i \, \delta V_i\right| \leq (30\,A)\,L \qquad \textbf{7.24(6)}$$

where

V = total vertical force
P_i = vertical reaction force exerted by span pipe i
K_i = spring rate of span pipe i
δV_i = vertical deflection of span pipe *i*
A = system accuracy (percent)
L = maximum live load
i = n where n is the number of pipes connected to the weigh vessel. The span of pipe is assumed to be the portion of piping between the vessel connection and the first support

Spring Rates of Pipes The spring rate K for any pipe is derived from the bending formula, taking into account the moment of inertia for the pipe section under consideration. Figure 7.24s shows pipe spring rates versus length for various moments of inertia of pipes. Figure 7.24t shows spring rate versus length for schedule 40 steel pipe. If the resultant

vertical force exceeds the live load criterion for a required accuracy, design solutions are required to increase the piping flexibility. There are three practical ways available:

1. Reduce the pipe spring rate by choosing a different pipe schedule.
2. Introduce flexible devices whenever possible. Limitations are usually related to design pressure, temperature, and material of construction.
3. Increase the length of horizontal runs between the vessel connection and the first support. Table 7.24u presents calculated force reactions for several pipe runs and flexible devices.

Flexible Connections

When the goal is to maximize the precision of weighing, it is desirable to install all piping and electrical conduit connections in the horizontal plane. Whenever the design pressures and temperatures allow it, flexible joints should be installed in the horizontal pipes connected to the tank. For best performance, two horizontal flexible couplings can be installed in series. Flexible joints are available in metallic constriction or with Teflon liners. The flexible joints illustrated in Figure 7.24v are available in 1 to 14 in. (25 to 610 mm) sizes with pressure ratings in excess of 100 PSIG (7 bars) in all sizes and at temperatures up to 400°F (205°C).

Calibration

Most weighing systems are factory calibrated, but it is advisable to recalibrate them after installation and also periodically after start-up. The method to be used greatly depends on not only the type of weighing system involved, but also on the desired level of accuracy and on the sophistication of the available plant personnel. One summary of a list of calibration options is given in Table 7.24w. Most suppliers offer both recalibration services and also advice on calibration methods and procedures. Calibration is also discussed in the next section, which deals with weight sensors.

Flow Sheet Symbols

Types:

- A. Mechanical (lever, spring)
    - A1. Laboratory
    - A2. Industrial
- B. Hydraulic load cells
- C. Pneumatic load cells
- D. Electronic load cells
    - D1. Strain gauge
    - D2. Piezoelectric
    - D3. Piezoresistive (semiconductor)
    - D4. Capacitance
    - D5. Inductive
    - D6. Reluctance
    - D7. Magnetostrictive
    - D8. Nuclear
- E. Feeders (screw, belt, gravimetric, nuclear, and loss-in-weight; see Section 2.23)

Operating Temperature Ranges:

A1. Ambient
A2. –10 to 135°F (–23 to 57°C)
B, C. 0 to 125°F (–18 to 52°C)
D. Normally from –4 to 160°F (–20 to 70°C); special units are available for –4 to 450°F (–20 to 230°C)

Ranges:

A1. From 0–3 g to 0–150 kg
A2. From 0–1 to 0–1,000,000 lbm (0–0.5 to 450,000 kg)
B. 100 to 1,000,000 lbm (45 to 450,000 kg)
C. 10 to 10,000 lbm (4.5 to 4500 kg)
D. From 0–1 to 0–12 million lbm (0–5 to 0–4.5 million kg)

Inaccuracy:

A1. Readability of a 0- to 3-g range can be as low as 0.1 μg; for a 0- to 150-kg range, the readability is 50 g.
A2. From ±0.01 to ±0.1% of full scale

B, C. From ±0.1% to ±1% of full scale
D. 0.03 to 0.25% of full scale

Costs:

A1. The cost of laboratory balances is a function of their precision. Units with 0.1% readability can be obtained for $100 to $300; with 0.01% readability, for $500 to $1000; and with 0.001% readability or better, for $1000 to $4000. Microprocessor-based balances with microgram readability can cost up to $10,000.
A2. Highly variable with application but usually in excess of $5000.
B, C. From $750 to $1500 per load cell or totalizer; $500 to $1000 per high-precision pressure gauge readout. Costs for electronic pressure transmitters range from $1000 to $2000.
D. Load washers, low-profile load cells, and compression load buttons cost from $500 to $1200; universal load cells for higher loads cost $2000 to $3500; remote display costs range from $500 for a standard indicating transducer to $2500 for an 8-channel unit. A strain gauge telemetry transmitter with FM output costs $1800. A complete batch weighing control system, depending on its complexity, will cost from $10,000 to about $25,000. A nuclear continuous weigh scale costs about $10,000.
E. Feeders (screw, belt, gravimetric, nuclear, and loss-in-weight; see Section 2.23)

Electronic Load Cells

Overload Limitations: Up to 125% of rating including shock, impact, or static loading

Nonrepeatability: Generally from 0.01 to 1%

Nonlinearity: Generally from 0.03 to 2%

Hysteresis: Generally from 0.02 to 2%

Output Signals: 2 to 3 mV per volt of excitation. Excitation voltage is usually around 10 V.

Mechanical Configurations: Canister (longitudinal tension or compression stress); cantilever (bending stress); shear

Design Materials: For high capacities, the load (spring) elements are usually steel alloys, while for low capacities, aluminum alloys are used. The strain sensing grid can be constantan, Karma, Isoelastic, or platinum tungsten. The strain gauge backings include polyamides, epoxies, or reinforced epoxies. The bonding adhesive is often cyanoacrylate.

(The most popular suppliers are Mettler-Toledo, Thermo BLH, Weight-Tronix, Kistler-Morse, and Rice Lake in that order.)

INTRODUCTION

The more general aspects of weighing were discussed in the previous section (7.24), while the subjects of rate-of-weight measurement and gravimetric feeders were covered in Section 2.23. This section is devoted to the discussion of the detectors used in the measurement of stationary weights, whether in the laboratory or in general industry. The types of sensors discussed include the mechanical lever scales and the hydraulic, pneumatic, or electronic load cells. Naturally, because of their popularity, more space is devoted to electronic load cells than the others, and within that group, the emphasis is placed on the most popular design—the strain gauge type load cell.

The section begins with a general discussion of load cell selection and installation. This is followed by the description of the individual designs and ends with a fairly extensive bibliography of recommended reading material for readers who need more in-depth or more application oriented information.

The use of mechanical, hydraulic, and pneumatic weight sensors is declining in most areas except in the laboratory, where high-precision mechanical balances are still widely used. However, even in the case of these devices, electronic sensors are often used to operate digital displays or to provide memory and computer compatibility. In industrial application, mechanical platforms or truck scales are often combined with electronic load cells to operate remote displays or to provide computer compatibility.

The description of mechanical, hydraulic, and pneumatic designs are followed by the discussion of electronic load cells—their design variations, features, accessories, and the more recent advances that have occurred in their designs. The discussion begins with the topic of strain gauge-type load cells. The reader should be aware that strain-gauge-type sensors, circuits, and electronics have already been discussed in other sections of this volume (Sections 5.7, 7.19, and 7.21). For this reason, some of the points that were already made will not be repeated here.

LOAD CELL SELECTION

Concepts and selection procedures for weigh systems based on load cells are focused on accuracy and repeatability of measurements of relatively large loads within a variety of constraints imposed by shape and vessel sizes, structural and mechanical arrangements, materials to be weighed, and environmental conditions. Here we present some established criteria for load cell selection—design concepts used in load cell installation. For an analysis of the impact of piping arrangements, mechanical equipment, and structural deformation on total weigh system performance, refer to Section 7.24.

To obtain the best performance in designing a load cell based weighing system, consideration must be given both to the selection of the load cells (Table 7.25a) and to the choice

TABLE 7.25a
Load Cell Performance Comparison

Type of Load Cell	*Weight Range*	*Inaccuracy (FS)*	*Applications*	*Advantages*	*Disadvantages*
Mechanical Cells					
Hydraulic	Up to 10,000,000 lb	0.25%	Tanks, bins, and hoppers; hazardous areas	Takes high impacts; insensitive to temperature	Expensive, complex
Pneumatic	Wide	High	Food industry; hazardous areas	Intrinsically safe; contains no fluids	Slow response; requires clean, dry air
Strain Gauge Cells					
Bending beam	10–5,000 lb	0.03%	Tanks; platform scales	Low cost, simple construction	Strain gages are exposed, require protection
Shear beam	10–5,000 lb	0.03%	Tanks, platform scales, off-center loads	High side load rejection, better sealing and protection	
Canister	to 500,000 lb	0.05%	Truck, tank, track, hopper scales	Handles load movements	No horizontal load protection
Ring and pancake	5–500,000 lb		Tanks, bins, scales	All stainless steel	No load movement allowed
Button and washer	0–50,000 lb 0–200 lb typ.	1%	Small scales	Small, inexpensive	Loads must be centered; no load movement permitted
Other Types					
Helical	0–40,000 lb	0.2%	Platform, forklift, wheel load, automotive seat weight	Handles off-axis loads, overloads, shocks	
Fiber optic		0.1%	Electrical transmission cables; stud or bolt mounts	Immune to RFI/EMI and high temps; intrinsically safe	
Piezoresistive		0.03%		Extremely sensitive; high signal output level	High cost; nonlinear output

of load cell installation assemblies. A correctly designed weighing system must have the following characteristics:

1. Low deflection (typically 0.005 to 0.008 in., or 0.125 to 0.2 mm): permitting process piping to be attached to the weighed vessel
2. Excellent repeatability: ±0.002% of full scale, or better, within a prescribed temperature range
3. Accuracy: Ranges from 1 to better than 0.05% of full scale

Selection Factors

The following factors should be considered when selecting load cells.

Mode of Loading: Tension or Compression This choice is determined by the type and capacity of the vessel and by structural and mechanical design criteria. It is proven by experience that tension support for very large tanks or hoppers is more difficult to design and is more costly than a

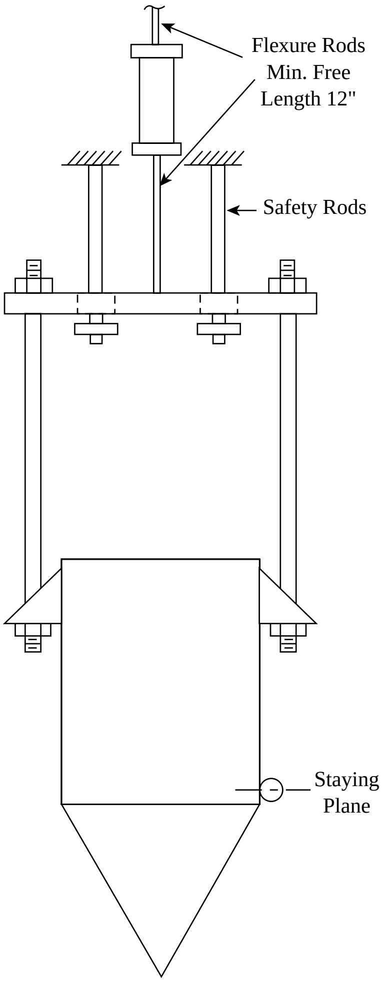

FIG. 7.25b
Suspended tank installation detail, load cell in tension (electric cell only).

compression support. In addition, tension load cells with female threads on both ends and the need for eyes and rods require greater vertical clearances. A single load cell (Figure 7.25b) supporting a small tank in tension is stable and less expensive than a multiple compression support. A weight of maximum 20,000 lb (9000 kg) load usually limits the tension mounting applicability.

Ambient Temperature The compression load cell assembly will require low friction expansion assemblies in order to accommodate differential thermal expansion or contraction between vessel and supporting structure. The tension load cell assembly does not require additional accessories for expansion compensation. The adjustment of flexure rods, which are part of the standard tension mounting assembly, will compensate for differential thermal expansion between vessel and structure.

Lateral Restraints Lateral restraints on vessel movements are frequently required when a compression assembly is chosen. In a tension assembly, lateral restraints are not required for vented vessels, which store, for instance, dry, nonhazardous materials, since a hanging mass is inherently stable.

Structure Vibrations Tension assemblies are more sensitive to vibration because of reduced structural stiffness and dampening capability caused by tension linkages. The compression assemblies' sensitivity to vibration is a function of the stiffness of the structure and vessel supports.

Number of Load Cells

The number of load cells required is determined by the plane view geometry of the supported structure—hopper, tank, or silo. The main considerations include cost and accuracy. Cost can obviously be reduced by lowering the number of load cells used. On the other hand, if a load cell is not placed under each point of support, the total load is not being measured; therefore, if the load distribution is not symmetrical between points of support, the reading will be in error. Three points fully define a plane, so the ideal number of supports for uniform load distribution is three.

Positioning can have an effect on number of cells required; for example, a vertical circular tank might require three cells (Figure 7.25c), while the same tank in a horizontal position might require four cells (Figure 7.25d). Considerations must

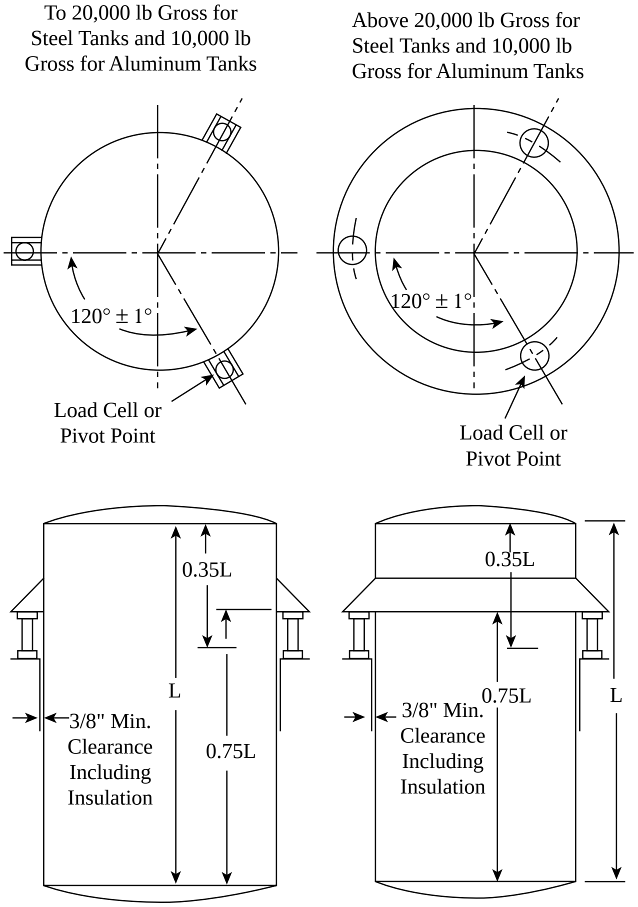

FIG. 7.25c
Load cell locations for vertical vessels.

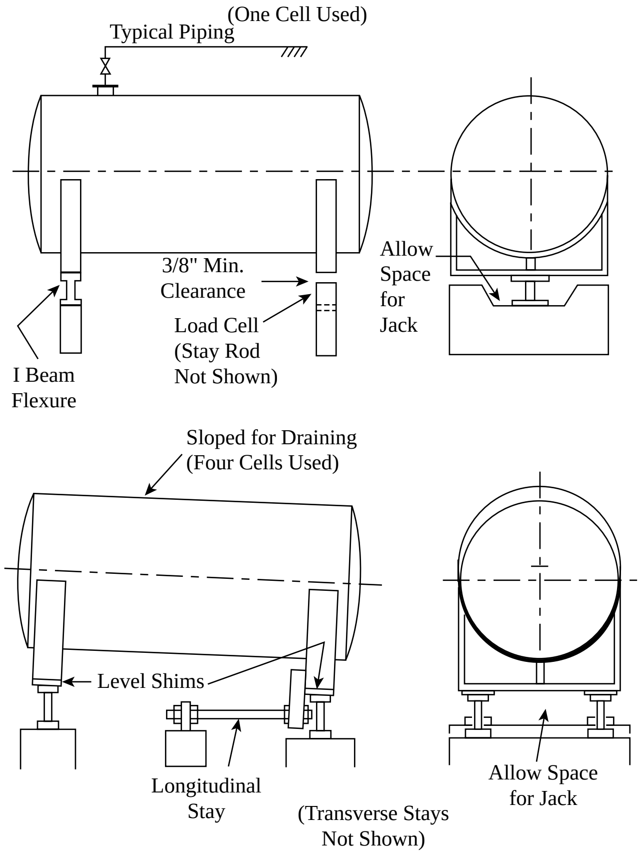

FIG. 7.25d
Load cell and stay locations for horizontal tanks.

also be given to the strength and rigidity of the weigh-bridge structure. Horizontal dimensions in excess of 25 ft (7.5 m) may increase the number of load cells needed. Related to the number of load cells required are two additional factors: capacity and degree of precision required.

When a load is supported from more than one point, pivots or flexures can replace some of the cells, depending on the symmetry of the load, at the expense of overall accuracy expected. Vertical vessels with supports above the center of gravity may use three cells instead of one cell and two pivots. Three cells give more accuracy but cost more. Instead of four cells, a horizontal vessel can use a flexure and two cells or a flexure and one cell. The use of a flexure reduces the staying requirements but with some loss of accuracy.

Capacity and Type

The minimum load cell capacity can be calculated with the following formula:

$$C = 1.25\,K\,\frac{W_T + W_N}{N} \qquad \textbf{7.25(1)}$$

where

C = minimum load cell capacity
1.25 = allowance factor for low tare estimates and unequal load distribution on the load cells as installed
W_T = tare weight of the empty vessel
W_N = net weight of projected vessel content (live load)
N = number of load cells
K = dynamic factor ($K = 1.25$ for certain dynamic loads, otherwise $K = 1$)

When calculating the tare weight of the empty vessel, one must include any additional equipment attached to the vessel, such as agitators, valves, and filters, that contributes to the weight that the empty vessel (including its accessories) will exert on the load cells.

Examples of anticipated dynamic loads are vessels with crane buckets and vessels with horizontal agitators. Assuming for these cases $K = 1.25$, one can provide an extra capacity for sizing, resulting in a higher capacity load cell selection. A higher capacity load cell will perform better under repeated impact loads or high cycle fatigue.

Load Cell Types A selection must be made between hydraulic and electric load cells. Hydraulic load cells can be considered for large vessels when the required accuracy is low (within 0.25 to 1%). Hydraulic load cells are rugged and require low maintenance, and their cost is reasonable. On outdoor installations where temperature changes are drastic, heated enclosures are necessary. Electric load cells are more expensive, but are the most accurate and trouble-free. Inaccuracy is as low as 0.1% and can be even lower depending on mounting, staying, and piping factors.

Classes of Load Cells Manufacturers offer the following classes of load cells: general purpose, precision, high-temperature environment, corrosive environment, and rugged design.

General-purpose load cells may be used in any service (tension or compression) whenever weigh system accuracy required is not better than 1%. Precision load cells are specified in systems where accuracy is expected to be 0.1% or better. Specially designed load cells using adequate materials of construction are utilized in a high temperature environment (maximum 450°F, or 232°C). Precision and high-temperature load cells have temperature compensation accessories that make the operation unaffected by temperature variations within the compensation range (15 to 115°F, or –10 to 46°C, for general purpose and precision, and 15 to 425°F, or –10 to 218°C, for high-temperature design).

Load cells can be protected with a special coating in order to prevent deterioration due to the presence of corrosive chemicals. Rugged load cells are offered whenever mechanical shocks may affect their performance.

LOAD CELL INSTALLATION

Load cells measure all vertical forces acting upon the vessel. Forces other than the weight of the vessel and contents must be kept small, elastic, and repeatable so that their effect can be removed by field calibration.

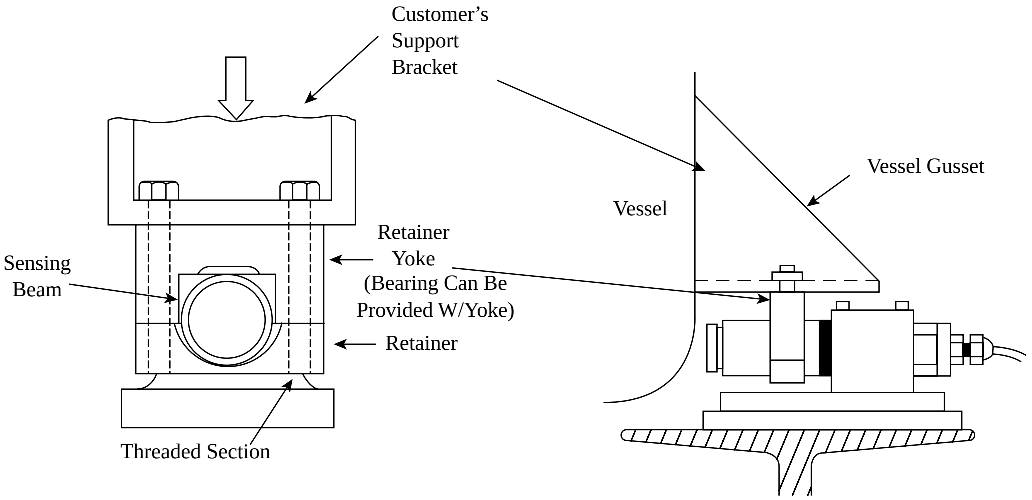

FIG. 7.25e
The cantilever-type load cell requires less restraining of the weighed tank.

The general rules for load cell and vessel arrangements are:

1. The vessel structure in the area of the load cell mounting must be rigid.
2. The supporting structure or foundation, depending upon the loading mode (tension or compression), must be rigid. If more than one vessel is to be supported on the same structure, the structure must be designed with sufficient rigidity to prevent interaction errors caused by large deflections.
3. On multiple load cell arrangements, the load cells must be positioned and should be installed so that after the vessel is fully loaded each cell will carry not more than 120% of rated capacity.
4. Optimal vessel stability requires flexibility in the vertical plane and rigidity in the horizontal plane.

Some load cell designs can tolerate more horizontal movement; these designs require less restraining of the vessel movement than others. In general, it can be said that the cantilever beam-type load cell requires less restraining. The cantilever load cell is illustrated in Figure 7.25e. It is connected to the weighed vessel through the retainer yoke, which encircles the sensing beam of the cantilever load cell. Therefore, when this type of load cell is used, the weigh tank is securely held in place and often does not require additional restraining.

If the weigh tank is expected to undergo thermal expansion, bearings can be provided with the retainer yoke to accommodate the movements caused by thermal expansion. Naturally, in case of outdoor installation of tall vessels where heavy winds can create extreme forces, restraining is still necessary.

The canister type of load cell is illustrated in Figure 7.25f. When this type of load cell is used, the weigh tank must always be stabilized (restrained). Most of the discussion that follows assumes the use of canister-type load cells.

Load Cell Adapter

As already noted, many load cell based weighing installations involve large differential expansions that can impose severe horizontal forces on the installed load cells. Also, in vehicle scales, large horizontal forces can be applied owing to deceleration and acceleration forces associated with bringing the vehicle on and off the scale. The load cell adapter described here virtually eliminates such forces.

Primarily a mechanical arrangement, the active weighing platform is suspended from the top of the load cell by three suspension links (Figure 7.25g), and an upper plate and adapter ring contact the load cell at the desired loading point. The upper plate carries the three links by link pins projecting radially from the upper plate. Hanging on the opposite end of the links is the lower plate that includes three additional link pins for engaging the lower end of the links.

The lower plate is connected to the active weighing platform, thereby transmitting the weight through the links and upper plate to the top of the load cell. The load cell is supported by a base plate, that rests on the foundation or ground structure. The base plate also serves to absorb heavy side loads when the horizontal deflection of the weigh-bridge exceeds the clearances provided between the base plate and the cutout portion of the lower plate. The height of the adapter assembly can be adjusted by a center screw, enabling the equal distribution of total load among the several load cells in a given installation.

The structure provides a highly flexible load cell adapter assembly, which transmits virtually no side loads to the load cell caused by differential expansion of the weighing structure relative to the ground structure. The side loads that are transmitted to the load cell are from weigh-bridge deflections, imposing angular loads on the load cell. These are minimized by appropriate structural design of the weigh-bridge.

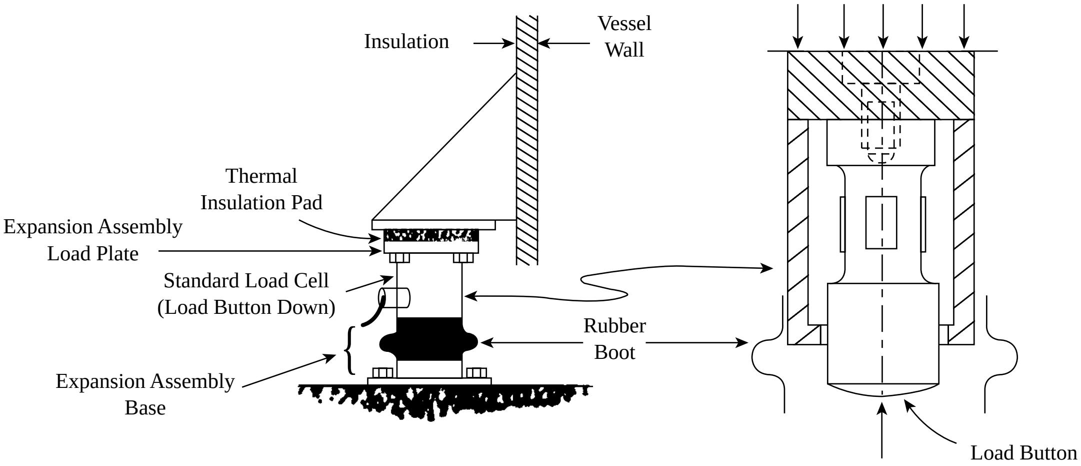

FIG. 7.25f
Weigh tanks with canister-type load cells always require restraining.

Rocker assembly.

Rocker Assembly

Another load cell adapter used in the past in weighing systems was the rocker assembly (Figure 7.25h). An adapter is added to the bottom of the load cell, which in effect provides a convex loading surface on both the bottom and top of the unit. The load cell and adapter are located in place by a stabilizer plate. Load is introduced to the load cell through the upper bearing block and transmitted through the load cell and the lower bearing block to the mounting plate. The stabilizer plate allows partial rotation of the load cell, while at the same time restricting excessive lateral motion.

Differential expansion between the structure being weighed and the foundation causes slight rotation of the load cell, reducing the magnitude of the horizontal forces, which would have been present in the absence of the rocker assembly. The load cell is thus protected from the adverse effects of large lateral forces caused by differential expansion in multiple cell weighing systems. While found in existing installations, the spring-loaded stabilizing plate has not been a successful solution and is seldom used on new installations.

Vessel Expansion

Temperature variations can cause the vessel or the supporting structure to contract or expand. Under these circumstances, load cells are subjected to horizontal loads resulting in weighing errors. Whenever the mode of loading is compression, one can minimize the expansion/contraction effect by adapting the following solutions.

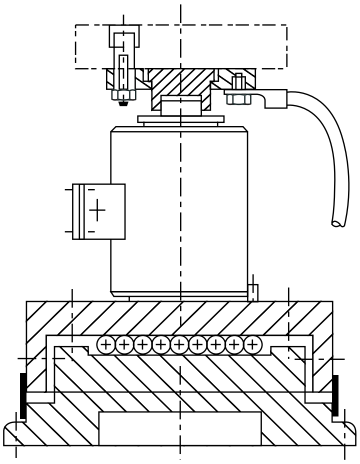

FIG. 7.25i
Vessel movement due to thermal expansion can be accommodated when a self-aligning strut bearing is provided above the load cell, with a multiple ball bearing below.[1]

I-Beam Flexure I-Beam flexures are short lengths of standard I-Beams used to provide flexible support for weigh vessels. I-Beam flexures bend through very small angles about their web and allow slight motion perpendicular to the web. The flexures mounted as supports can accommodate lateral movement up to 0.010 in. (0.25 mm). I-Beam flexures are utilized in weigh systems where load cells sense only a portion of the tank weight (Figure 7.25d). This arrangement is commonly used for weighing liquids where an accuracy of 0.5% or less is acceptable.

Expansion Assemblies These assemblies are, in principle, sliding bearing units that have a low coefficient of friction and can move laterally within ±3/8 in. (9.5 mm). Figure 7.25i illustrates a self-aligning strut bearing installation that is well suited for minimizing the effect of vessel movement due to thermal expansion.

Load cells used outdoors in areas subjected to large temperature variation should be provided with expansion assemblies. In cases where the mode of loading is tension, flexure rods are used (Figure 7.25b). Flexure rods link the load cell with the structure in a tension weighing arrangement; the flexure rod had tensile strength of approximately 90,000 PSI (621 MPa) and can accommodate deflection of ±3/32 in. (2.3 mm).

MECHANICAL LEVER SCALES

All mechanical lever scales employ lever systems that balance the weight of the unknown (gravity pull) against a known (calibrated) lever and mass: it is, in fact, a balancing of one moment against another. It is customary to adjust the lever system so that the pull from the unknown will fall within a convenient range—usually 25 to 50 lb (11 to 23 kg).

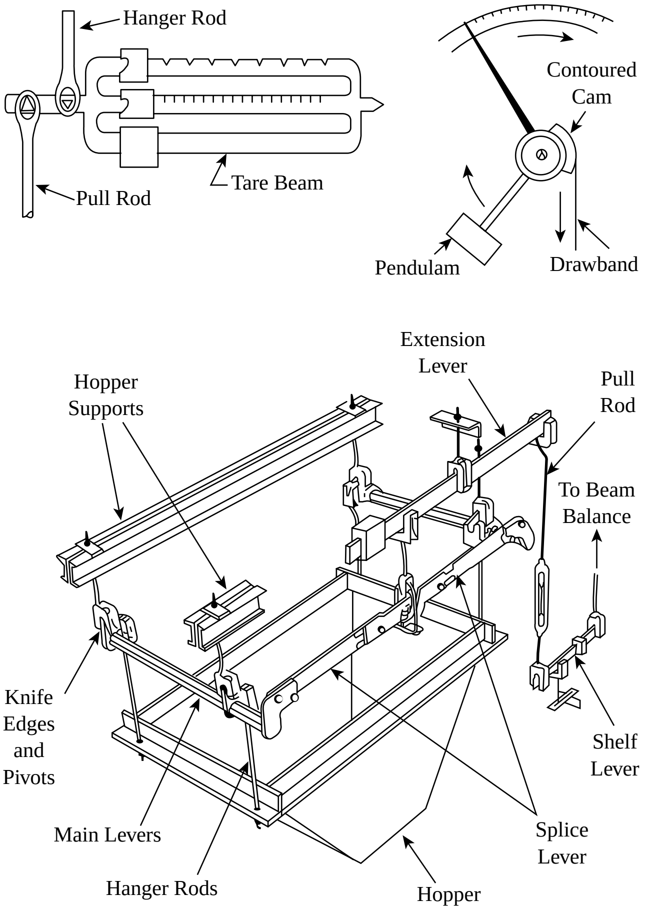

FIG. 7.25j
Typical counterbalancing devices, and typical mechanical lever scale installation.

The unknown mass includes the mass of the bin, hopper, or platform holding the material to be weighed. A tare device cancels out these weights by balancing them. In Figure 7.25j, the hopper, hopper supports, gathering levers, hanger rods, and the pull rod leading to the counterbalancing means, or balance device, are shown for a typical industrial scale. In the same figure, two widely used balancing devices—the tare beam and the pendulum—are also shown.

Balancing Devices

The most often used mechanical scales transmit the load by levers. For the different moving connections, such as the fulcrum, knife-edge bearings were traditionally used. More recently these have been replaced by V-grooves to receive the knife-edge or by ball bearings or plate-fulcrum elements. The mechanical balance can be established by moving poises on a weigh-beam, by helical springs, or by the rotation of pendulums. In the latter designs, oil-filled cylindrical dashpots are included to dampen the oscillation.

The tear beam (top left in Figure 7.25j) is usually an array of three smooth bars, each marked off linearly, and each carrying a poise. One beam is for balancing out tare weight;

TABLE 7.25k
Types of Mechanical Scales Used in Industry and Their Typical Ranges

Type	*Typical Capacity* lbm/kg
Even-arm scale	5/2.26
Bench dial scale	200/90
Platform scale	1500/680
Floor scale	6000/2720
Overhead scale	12,000/5443
Suspended hopper scale	25,000/11,345
Truck scale	100,000/45,400
Railroad track scale	400,000/181,800

it may not be calibrated. Another is for balancing out hundreds (or perhaps thousands) of pounds; it carries a rather heavy poise. The third is calibrated to balance out tens and units, and its poise is one-tenth the weight of the hundreds poise. The total moment exerted by the beam is the sum of the three. Balance is indicated by the position of the free end of the beam, usually guided within a trig loop.

The pendulum (often a double pendulum for greater stability and accuracy) employs a heavy mass swinging around a horizontal pivot (top right of Figure 7.25j); the moment is proportional to the displacement of the mass in a horizontal direction. This displacement is indicated on a circular scale. Linear calibration is provided by the use of a contoured cam and a draw-band. Tare corrections are made with a tare beam.

Scale Ranges

A few of the most widely used types of industrial scales, and their typical ranges are listed in Table 7.25k.

Applications

Mechanical lever scales are used in virtually every phase of industry, in development and in scales. The greatest scope for their application is probably in the weighing of stationery objects or quantities of material. Such scales may have almost any capacity, and can accommodate loads of almost any material. Overhead track scales, motor truck scales, and railroad track scales are all forms of mechanical lever scales.

Great many moving-body scales are also used. Vehicles in motion (trucks, railroad cars, etc.) can be weighed on mechanical lever scales if their velocity is low—usually less than 5 mi/h (8 km/h). Such scales usually employ pendulum counterbalances, indicating on a dial for easy reading.

Gravimetric Feeders Granular materials are conveniently weighed on conveyor-belt scales. A short section of conveyor belt is built into the scale mechanism, with tare adjustment to balance the scale with the belt empty; the balancing device then indicates the weight of the material on the belt.

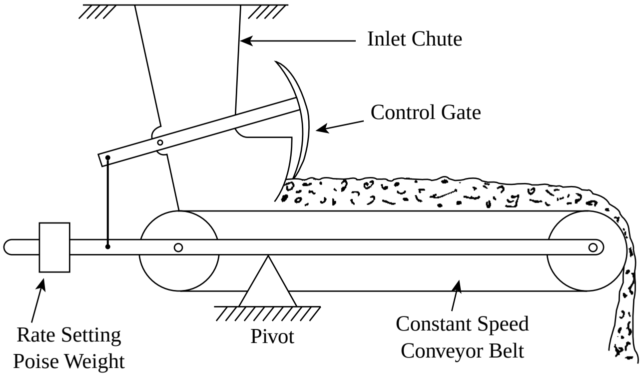

FIG. 7.25l
Early design of a belt-type gravimetric feeder.

An extension of this is the integrating weighing device. The belt is driven at a known speed; the total amount of material delivered is readily computed from the duration of the operation and the average weight of material on the belt. Accuracy is improved if the amount of material on the belt is kept uniform and constant.

Granular material can be conveniently supplied at a known rate by a conveyor-belt scale. The feed rate to the belt is controlled by the balance device; the load on the belt is thus kept constant (Figure 7.25l). Under such conditions, the feed rate can be manipulated by adjusting the speed of the belt.

Batch Additives Many industrial processes require the weighing of batches of material individually; others require the weighing of a series of materials for later mixing or other treatment. Batches of constant size are readily weighed into a hopper, using beam scales, with the position of the beam indicating when the feed should be stopped.

A series of quantities of materials can be weighed into the same hopper; this is most readily done with a dial-type scale (although a series of balance beams, dropped into position in succession, can also be used). The dial pointer positions for each added material are made to actuate gates to stop the flow of each material when the required weight is reached. Pointer positions are detected by various means: photoelectric pickups, reed switches, etc. Similar devices are used to sense balance-beam position.

Output Signals While many scales provide only a visual indication of balance, many electrical output devices are available. The simplest of these are cutoff devices, which indicate only when a desired weight (or each one of a series of weights) has been reached. There are also transducers that are attached to dial-scale pointers; these provide a continuous electrical output that can be fed into computer controls to perform sophisticated functions.

Advantages and Limitations

Mechanical lever scales are notable for long-time accuracy, with proper maintenance; they are also quite resistant to most environmental conditions. They are available in an extremely wide range of capacities and forms; they are available in sizes ranging from quite small to a railroad-track scale more than 100 ft (30 m) long. They can readily be made a working part of other industrial devices; in fact, most industrial scales are so used.

Their principal limitation is in speed of response. The mass and inertia of the lever system does not permit weighing speeds as great as strain-gauge load cells, which can be used to weigh vehicles moving at high speeds. The normal output of a mechanical lever scale is a visual signal, not readily coupled into other systems, but may be handled quite easily.

HYDRAULIC LOAD CELLS

All hydraulic load cells function on the principle of a force counterbalance. Weight imposed upon the load cell causes a change in internal fluid pressure. A wide variety of pressure detecting devices is employed to translate pressure into an analog signal proportional to weight. The most popular readout device is a precision bourdon tube.

For practical application, hydraulic load cells must function without leakage, they must be relatively free of internal friction, and, most desirably, they must be linear and precise in operation.

One approach to the above criteria has been through the use of a close fitting piston and cylinder, using an ordinary O-ring as a means of preventing leakage past the piston. While such devices will function rather satisfactorily under some conditions, one must guard against frictional losses due to the rubbing of the O-ring.

The Rolling Diaphragm Design

With the introduction of the so-called rolling diaphragm, a new and very successful design of hydraulic load cell appeared. This is illustrated in Figure 7.25m. Here we note that the hydraulic fluid is confined within the diaphragm chamber by means of the clamped seal between the cylinder wall and base plate. The piston or load-bearing member is guided within the cylinder by two sets of ball guide rings. Thus, the piston is substantially limited to one degree of freedom (i.e., parallel to its major axis). The effective acting area of the piston equals the area of a circle whose diameter is the mean diameter of the diaphragm convolution. It has been found that this area is very constant over a wide range of piston displacements. Thus, the requirement of linearity and precise performance is satisfied. One limiting factor on this design is the ability of the elastomer diaphragm to withstand pressure. Materials available limit the maximum internal pressure to 800 to 1000 PSIG (5.5 to 6.9 MPa). One can increase the size (area) of the load cell to overcome this pressure constraint, but the diaphragm molding techniques tend to limit size.

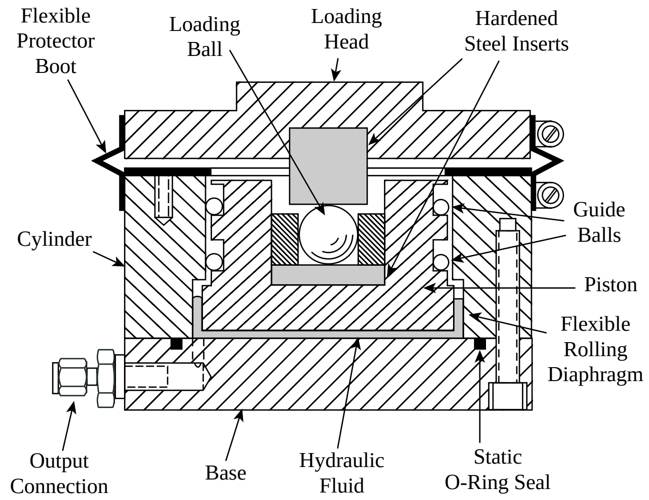

FIG. 7.25m
Cross section of the rolling diaphragm hydraulic load cell.

Performance Performance of the rolling diaphragm type of hydraulic load cell is acceptable for most process weighing applications. One may except measurement inaccuracies of ±0.25% of full scale or better on properly installed systems.

An outstanding feature of the rolling diaphragm type hydraulic load cell is its relative insensitivity to the amount of hydraulic filling. Thus, in making connections to gauges or other readout equipment, high-pressure hoses rather than rigid tubing may be permitted where desirable.

It is also easy to visualize that because of the relative insensitivity to filling, changes in hydraulic fluid volume due to ambient temperature variations have little effect on load cell performance. The system tends to be quite stable under varying temperature conditions provided that other factors, such as diaphragm stiffness variations, do not affect its performance.

All Metal Design

A more complex design, eliminating the flexible (elastomeric) diaphragm, is shown in Figure 7.25n. This design

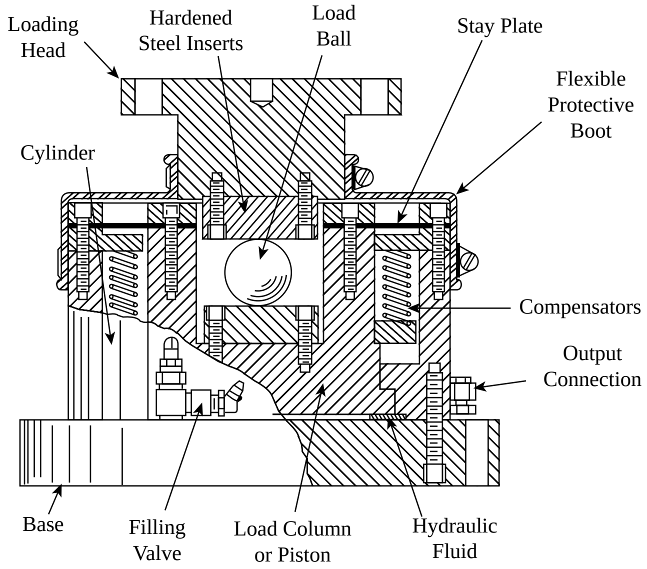

FIG. 7.25n
Cross section of the all metal hydraulic load cell.

is characterized by all metal construction, using a very limited quantity of hydraulic fluid. One outstanding feature of this design is its ability to accept extremely heavy unit loads. Successful hydraulic load cells with individual capacities of 10,000,000 lbm (4,500,000 kg) have been constructed.

By eliminating all bearings, pivots, and knife-edges, hydraulic load cells offer high sustained accuracy. Displacement under capacity load, although dependent on connected auxiliary instrumentation, can usually be limited to 0.005 to 0.010 in. (0.125 to 0.25 mm). The natural frequency of hydraulic load cells is high, and on dynamic load applications, resonance is rarely, if ever, encountered. The viscous damping characteristics of the hydraulic medium tend to yield stable weight signals even under dynamic disturbances.

Hydraulic load cells are self-contained and require no outside power for operation. They are inherently explosion proof and are available for both tension and compression force measurement. The hydraulic load cells illustrated in Figures 7.25m and 7.25n are applicable to tank, bin, and hopper weighing. In both types, the supported load is borne by a top member, or head plate, which in turn rests upon a ball or rolling member.

The rolling member is supported by the load sensitive piston or column. Any tendency of the load head to move in a horizontal plane, as under the influence of an expanding or contracting vessel, is accommodated by a corresponding rolling action of the ball. The load cell is protected from heavy side forces that would tend to interfere with its free vertical displacement under varying load conditions.

Hydraulic Totalizers

In using hydraulic load cells for process weighing applications, a special problem arises when the vessel is supported on more than one load cell. In order to obtain the total weight of the supported body, the output of the support points must be added. If the load cells are simply interconnected, and an average pressure is obtained, the danger of grounding of one point may occur, especially under conditions of nonuniform support loading.

This problem is solved through the use of a hydraulic totalizer, as shown in Figure 7.25o. Here, the output of each load cell is conducted to individual modules, which are, in effect, small pistons and cylinders. The output forces of the piston/cylinder combinations are collected on an output module, usually of larger acting area than the input modules. Provided this can be accomplished without serious internal losses, one pressure signal proportional to the several inputs may be developed.

Units totalizing two, three, and four inputs have been constructed with totalizing inaccuracy of ±0.1% of full scale. However, due to temperature sensitivity and other nonlinear effects, hydraulic totalizing inaccuracy in the order of ±0.25 to ±0.50% of full scale is more commonly encountered.

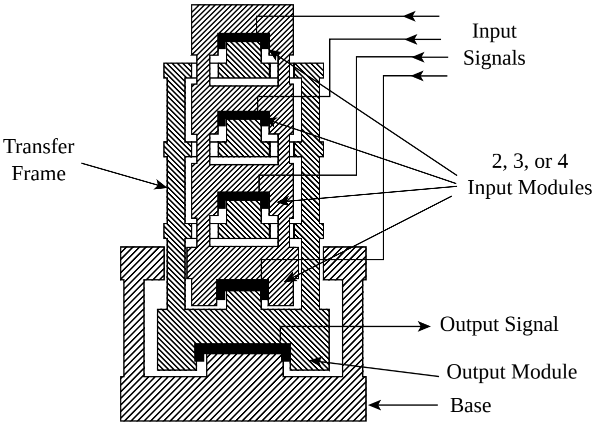

FIG. 7.25o
The hydraulic totalizer.

Electronic Totalizers Hydraulic load cells used in multiples may also be totalized by transducing the hydraulic pressure output into proportional DC voltage or current. Commercial transducers of high quality are available for this purpose. This method has the added capability of very long transmission without loss of accuracy.

Other Features

Hydraulic load cells are particularly well adapted for high impact loading applications and will withstand high overloads (300 to 400% in some instances), without loss of accuracy or zero shift.

Well-designed hydraulic load cells do include some means of temperature compensation for both span and zero effect. Nevertheless, most manufacturers specify standard operating limits of 0 to 120°F (–18 to 49°C) as a basis for the performance guarantees. Operation outside these normal limits will necessitate the reference to temperature correction charts and graphs available from all suppliers.

Hydraulic load cells have found other applications in the force measurement and weighing field. The high natural frequency, low deflection, and fast response rate make this device well adaptable to web tension control, dynamometer torque measurement, jet engine and rocket thrust measurement, and other similar highly dynamic installations.

PNEUMATIC LOAD CELLS

Pneumatic load cells have been successfully applied in process weighing. The units that are still available are all force-balance designs and function with high accuracy. Most pneumatic weighing systems are offered with tare balancing chambers, which enhance their overall performance.

The pneumatic output signal from the load cell may be read locally or transmitted by metal or plastic tubing to a remote point. The local readout of weight is usually by precision bourdon tube gauges, while for remote readouts, outputs can be transduced into electronic or digital forms.

Pneumatic weighing systems have several advantages. They are inherently explosion-proof; are quite insensitive to temperature variation; and in the event of rupture or leakage, they contain no contaminating fluid medium (e.g., hydraulic fluid). This feature is of particular interest to the food and drug industry.

For successful operation, pneumatic load cells and associated weighing equipment must have a carefully regulated source of clean, dry air. Although systems have been operated for short periods on inert gases such as dry nitrogen, such operation would be too expensive and impractical for process applications. Therefore, when installing a pneumatic weighing system, in addition to the system components themselves, attention must be directed to the air supply for the system. A typical requirement is 10 SCFM (283 lpm) of dry air (–40°F [–40°C] dew point) per load cell.

Figure 7.25p illustrates the cross section of a pneumatic load cell. The natural frequency of pneumatic load cells is quite low, but under certain conditions of dynamic loading, resonance may occur. This problem has been largely overcome by incorporating stabilizing or dampener chambers (Figure 7.25p).

Pneumatic weighing systems have relatively slow rates of response when the load changes incrementally. Their deflection is also low, because of their force-balance principle of operation, usually from 0.003 to 0.005 in. (0.075 to 0.125 mm).

ELECTRONIC LOAD CELLS

A variety of electronic load cells will be discussed here, including their design variations, features, accessories, and more recent advances. The more advanced, microprocessor based designs have been programmed to automatically recognize and correct errors caused by external influences, such as wind or loads moving on the scale base while weighing is in progress.

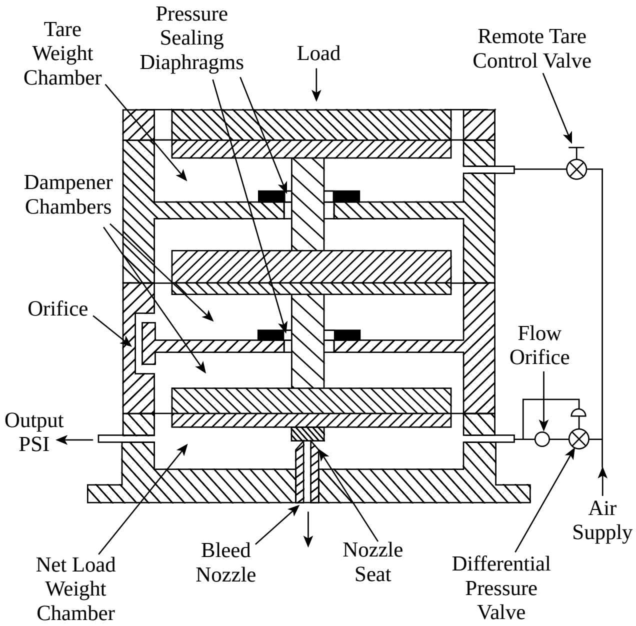

FIG. 7.25p
Pneumatic load cell cross section.

The discussion of electronic load cells starts with the strain-gauge type sensors. These detectors, their circuits, and electronics have already been discussed in Sections 5.7, 7.19, and 7.21, so the reader is also referred to those sections.

STRAIN-GAUGE-TYPE LOAD CELLS

One of the first uses of the bonded resistance wire strain gauge following its discovery in the early 1940s was in the development of an accurate and reliable load cell or force transducer. The strain gauge and its applications have been one of the most intensely researched fields in recent technological history. As a result of this work, there is a wide variety of accurate, stable, and reliable strain gauge load cells available for nearly all applications.

Strain gauge load cells represent the most practical means of weighing. One of the largest uses is in retailing, but other uses include postal and shipping scales, crane scales, laboratory scales, onboard weighing for trucks, and agricultural and petrochemical applications. Strain gauge applications include thrust measurement on rocket and jet engine test stands, launching pads, and also wind tunnels and other branches of aeronautical research.

Operating Principle

If a wire is bonded to a spring element in such a manner that its cross section varies as the spring element is strained, it is possible to establish a relationship between the electrical resistance of the wire and the force causing the deformation of the spring element. Strain gauge load cells are designed to permit controlled elastic deformation of the spring element.

In Figure 7.25q, a column is loaded in the direction of the *Z*-axis. Bonded to the four sides of the column are grids

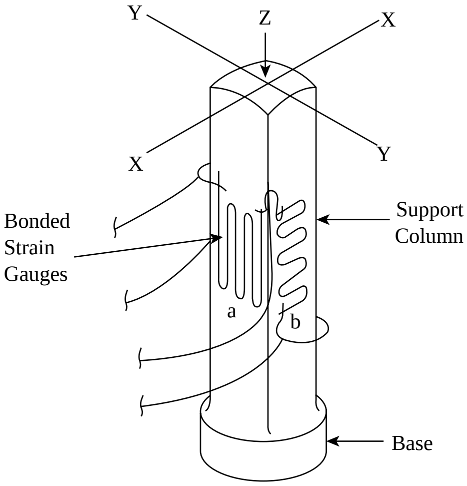

FIG. 7.25q
Column spring element used in a canister-type load cell.

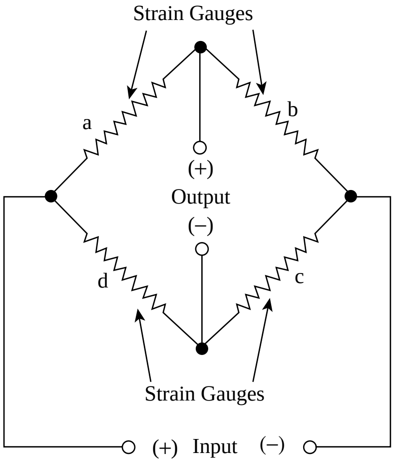

FIG. 7.25r
Wheatstone bridge for strain guage load cells.

of fine wire, a, b, c, and d. As load increases, gauges a and c tend to decrease in length, and their resistance decreases. Gauges b and d, mounted perpendicular to *Z*, are placed in tension by the column tending to decrease in cross section (Poisson effect), and their resistance will increase.

The four gauges are connected into a Wheatstone bridge circuit as shown in Figure 7.25r. By having gauges b and d strain opposite to a and c, the bridge unbalance due to load variations is amplified and output voltage is greater than if b an d were strained in the same manner as a and c.

In the 1950s, metallic foil bonded strain gauges were introduced and quickly supplanted wire gauges in most forms of strain gauge load cells. Using foil instead of wire improved heat dissipation, reduced creep effects, and allowed much greater design freedom in adapting gauge shapes and sizes to complex transducer geometry. For a discussion of the more recent diffused semiconductor and thin-film designs refer to Sections 5.7 and 7.21.

Design Variations

The most critical mechanical component in any load cell is the spring element. Broadly stated, the function of the spring element is to serve as the reaction for the applied load, and, in doing so, to focus the effect of the load into an isolated, preferably uniform, strain field where strain gauges can be placed for load measurement. Load cell spring elements can be divided into three types: bending, shear, and direct stress. Each will be described below.

Bending or Cantilever Elements The simplest beam configuration for a bending transducer is the basic cantilever beam (Figure 7.25s). In configuration A, pairs of longitudinally aligned strain gauges are mounted on the upper and lower surface, near the root of the beam. For certain types of applications, the characteristics of the straight cantilever beam can be improved upon by designs that induce multiple bending in the beam element. A rather simple and popular way of accomplishing this in commercial load cells is shown in configuration B, often referred to as the binocular design.

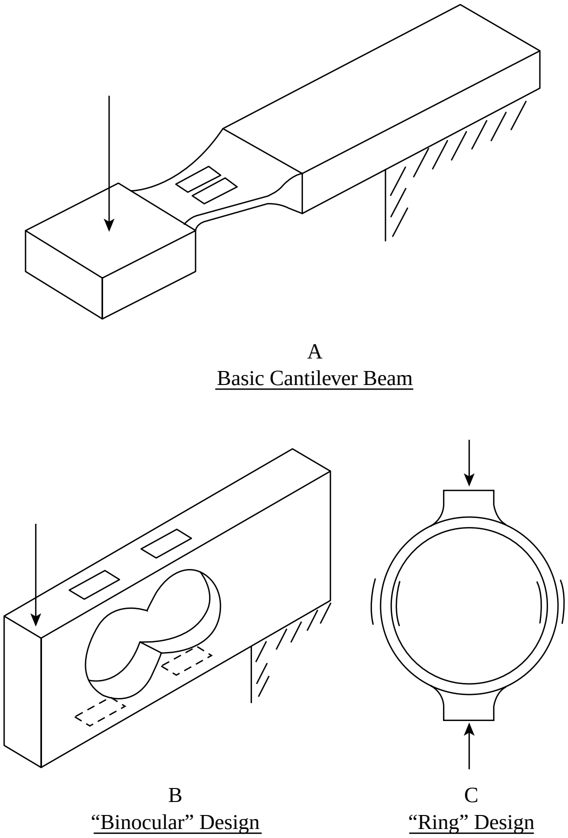

FIG. 7.25s
Load cell elements designed to detect bending.

Another type of bending spring element, which ranks with the beam designs in terms of the number and variety of its implementations, is the ring. The ring design is shown in configuration C in Figure 7.25s.

Figure 7.25t shows some of these elements incorporated into canister-type (A, B, and D) or cantilever-type (C) load cell installations. As was explained in connection with Equations 7.24(1) and 7.24(2), this type of load cell is insensitive to changes in the location of the point of loading. Therefore, it can tolerate some amounts of tank movement due to thermal expansion or other causes. The cantilever beam design is also insensitive to torsional loads. This insensitivity can permit the use of simplified installations and less staying or restraining of the weigh tanks.

Beam-Type Load Cells The beam-type design consists of a slotted bending beam construction (Figure 7.25u). Strain gauges at the locations shown are arranged in a Wheatstone bridge configuration, so that the output of the sensing element is independent of the position of the applied load. Electrical compensation of the bridge circuitry can reduce the load position sensitivity to virtually zero. As will be observed, this is a very important feature.

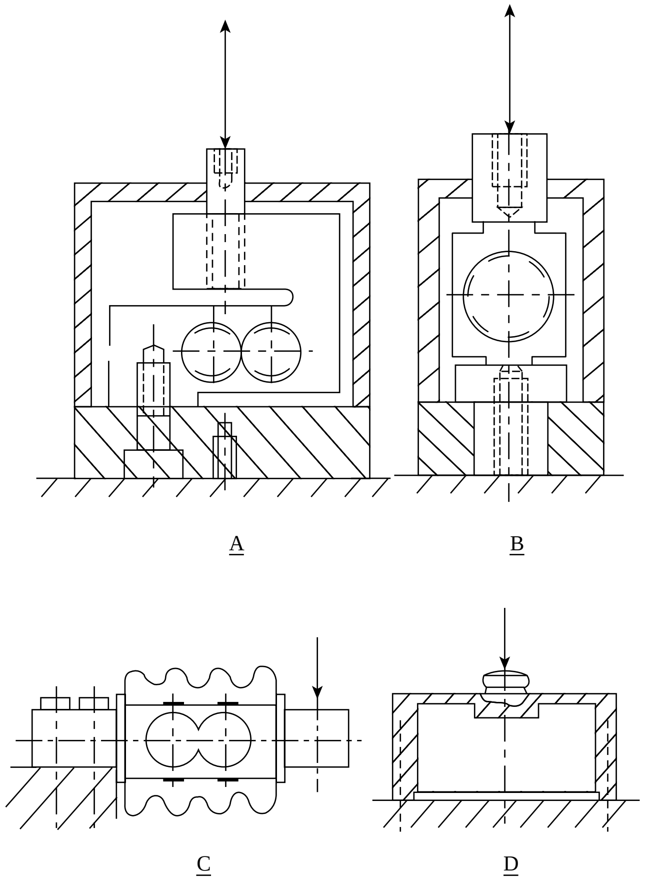

FIG. 7.25t
Canister (A, B, D) and cantilever (C) load cells with strain gauge elements that detect bending.

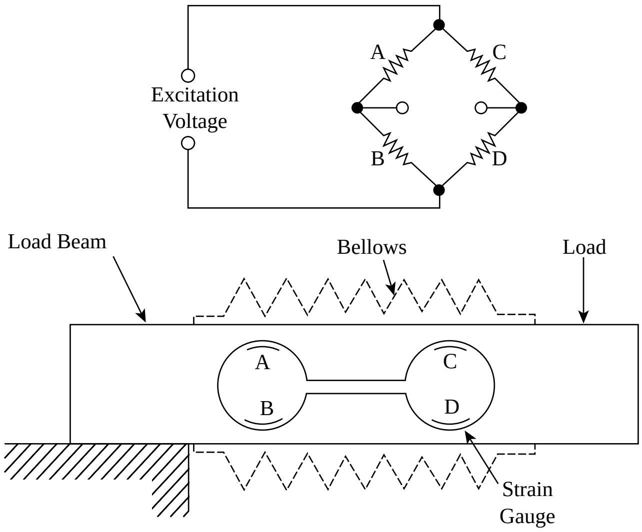

FIG. 7.25u
Beam-type strain gauge transducer.

TABLE 7.25v
Performance of Beam-Type Strain Gauge Transducer

Rated capacity range	10 to 5000 lbs (4.5 to 2270 kg)
Output	2 mv/v
Terminal linearity	±0.03%
Hysteresis	0.015%
Creep (30 min)	0.02%
Temperature effect on zero	0.15%/100°F (38°C)
Temperature effect on output	0.08%/100°F (38°C)

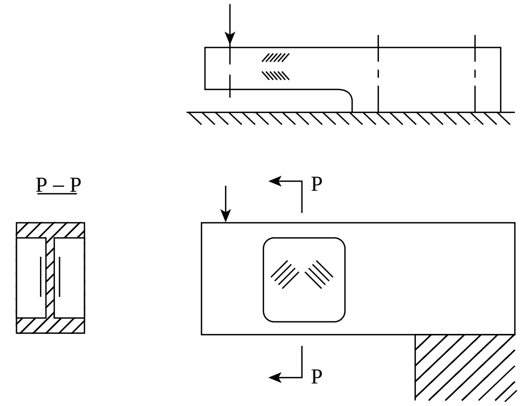

FIG. 7.25w
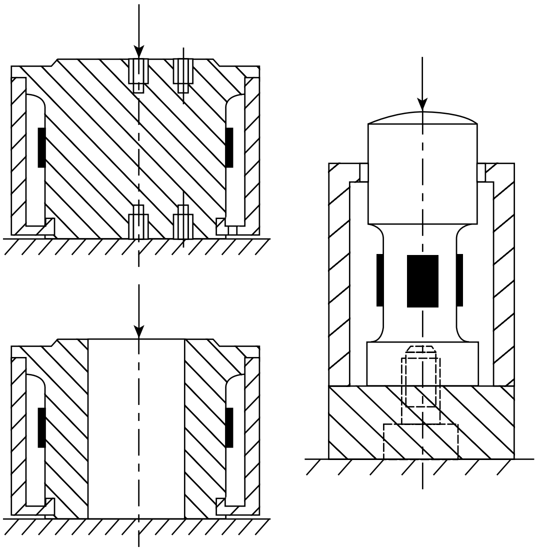
Shear-type load cell element installed in a cantilever configuration.

Protection from environment effects is by a simple bellows arrangement, making the conventional diaphragm and cylindrical casing unnecessary. Strain gauge location and beam design make the installation insensitive to variations in the location of the loading point or to end loading and torsional loads. This simplified load sensing configuration provides inherent linearity as well as very low creep and very high repeatability. Typical performance features are summarized in Table 7.25v.

Shear Elements The operating principle of the shear-web spring element is illustrated in Figure 7.25w. At section P–P of the beam, a recess has been machined in each side, leaving a relatively thin web in the center. Pairs of strain gauges, with their grid lines oriented along the principal axes, are installed on both sides of the web. Shear-web spring elements are not limited, of course, to cantilever beam configurations; a variety of other designs can also be found in commercial load cells.

Direct Stress or Column-Type Elements The history of the column load cell dates back to the earliest strain gauge transducers. The column spring element consists of one or more cylindrical members of the general form shown in Figure 7.25q. The spring element is intended for axial loading. It typically has a minimum of four strain gauges, two in the longitudinal direction and two oriented transversely to sense the Poisson strain. Column spring elements take on a wide variety of forms in designers' attempts to optimize the load cell in terms of both production and performance considerations. The column cross



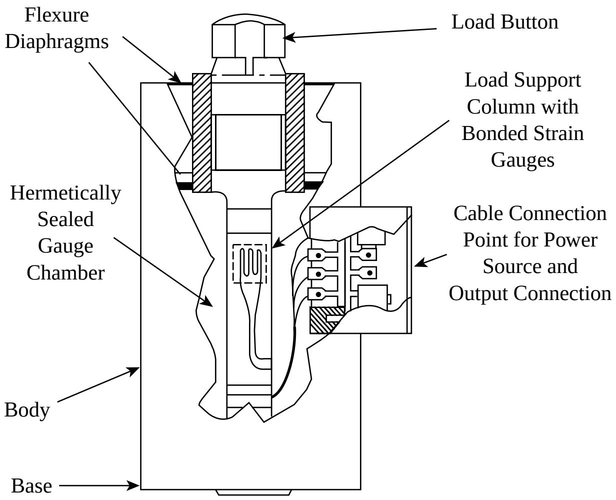


FIG. 7.25x
Canister-type load cells with coloumn-type direct-stress elements.[1]

section may be square, for example, instead of circular, or it may be circular with flats machined on four sides to facilitate strain gauge installation (Figure 7.25x).

Transducer Design

Selection of the transducer spring material deserves careful attention. Linear-elastic load response, with minimal hysteresis, is one of the most desirable mechanical properties for a spring material. Among thermal properties, thermal conductivity is important. From a manufacturing perspective, it is important that the transducer material be easily machined and must harden without distortion.

The modulus of elasticity of the material is important in determining the dimensions of the spring element with respect to load rating. While steel alloys make excellent materials for high-capacity spring elements, they are often unsatisfactory for low-capacity units. In the latter case, to achieve suitable strain levels in reasonably thick and easy-to-machine sections, it is generally necessary to use low-modulus materials such as aluminum alloys.

Practical transducer design considerations dictate that the strain gauge be mounted in the area of highest strain. For most load-cell designs, a good general rule of thumb is that the strain under the gauge grid should not vary by more than 10 to 15% from the absolute maximum. Usually gauge lengths are in the range from 0.060 to 0.125 in. (1.5 to 3.2 mm).

Strain Gauge Backings and Bonding Three broad types of strain gauge backings are commonly used in transducers. These are: polymides, epoxies, and reinforced epoxies. For the strain-sensing grids, four alloy types are commonly used: constantan, Karma, Isoelastic, and platinum-tungsten. Since not all backing alloy combinations are mutually compatible, the strain gauge catalog must be consulted for actual selection.

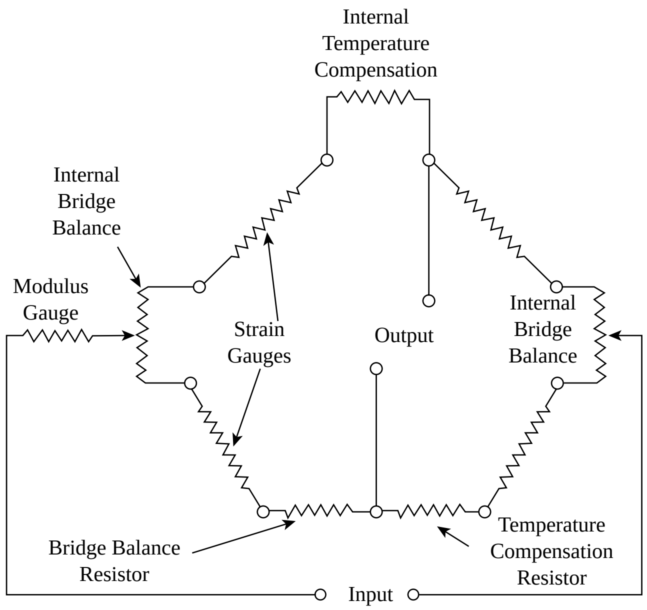

FIG. 7.25y
Strain gauge circuit schematic.

No single manufacturing step in transducer production has more influence on the performance and longevity of a transducer than does strain gauge bonding. Paramount to this process is the selection of the appropriate adhesive. The epoxies form the largest class of adhesives used for strain gauge bonding. Cyanoacrylate adhesive is used in simple load cells where high accuracy is not required.

Strain Gauge Circuits

As illustrated in Figure 7.25y, modern strain gauge transducers commonly employ four strain gauge grids electrically connected to form a Wheatstone bridge measuring circuit. All strain gauge load cells are compensated for the effects of temperature on zero shift and span. This is accomplished by making the strain wires out of temperature insensitive alloys and introducing suitable compensating resistors into the bridge network.

A typical strain gauge circuit is shown diagrammatically in Figure 7.25y. The output signal of a strain gauge is relatively small and is a function of the excitation. A common value is 2 to 3 mV per volt of excitation. The excitation voltage (AC or DC) is usually in the range of 5 to 20 V, with values in the order of 12 V recommended for average installations.

Performance of Strain Gauge Load Cells

As a result of increasing experience and a widening background of empirical knowledge, it is practical to consider the use of strain gauge load cells on installations requiring inaccuracies from ±0.03 to ±0.25% of full scale.

Temperature compensation systems for span and zero shift are now an intrinsic part of all high quality strain gauge load cells. Nevertheless, for operation outside normal temperature limits, generally −4 to 160°F (−20 to 70°C), the use of correction factors is needed. One might also provide means of controlling temperatures around the load cells by auxiliary means.

Strain gauge load cells should be protected from angular or nonaxial loads. Any force other than normal or axial will tend to cause bending of the support column or columns. Inasmuch as a strain gauge cannot discriminate between bending and axial loads, errors in output can result. Where strain gauge load cells are installed under tanks, bins, or hoppers that are subject to excessive bending, expansion, or contraction, special mounting equipment is available to help isolate the load cell from undesirable external side forces (Figures 7.25f, 7.25g, 7.25h, and 7.25i). In extreme cases, specially designed mounting pedestals may be required.

Strain gauge load cells are designed for operation within specific capacity ratings. Excessive overloads may result in loss of accuracy or failure. In general, the load cells should not be subjected to more than 125% of their rated capacity. This includes impact or shock loading, as well as static loading.

OTHER LOAD CELL DESIGNS

For the sake of completeness, a large variety of load cell designs are described in the following paragraphs. The capacitance-type load cells are not covered here, because their principle of operation has already been described in connection with Figure 5.7i. Similarly, the piezoelectric dynamometer load cells are not discussed here either, as they have already been discussed in Figure 7.21b. Some of the load cell designs that are discussed in the following paragraphs are only addressed to make the coverage of the topic complete (inductive, reluctance, magnetostricitve), but they are not widely used.

Semiconductor Strain Gauge

The scientists at Bell Laboratories discovered the piezoresistive characteristics of germanium and silicon semiconductor materials in the mid-1950s. It was discovered that the terminal resistance of these devices is highly sensitive to applied stress or strain. In fact, their gauge factors (unit change in resistance divided by unit strain) are more than fifty times those of their metallic wire or foil strain gauge counterparts.

While possessing very high strain sensitivity relative to that of metallic strain gauges, they also exhibit substantial nonlinearity, and temperature effects on strain sensitivity and terminal resistance are also relatively high. The latter characteristics have somewhat limited their application. Nevertheless, semiconductor strain gauges are used in force measuring devices in which high output signal level and low system cost are the primary objectives.

Semiconductor strain gauges in load cell configurations provide units with rated output capabilities of 1.0 V at 15 V bridge excitation. As a result of the high signal level, semiconductor units are used in simple weighing systems with simple regulated power supplies and direct meter readouts. Sometimes an amplifier is interposed between the transducer and the meter display.

Typical performance characteristics of semiconductor load cells are listed in Table 7.25z along with the load cells' metallic strain gauge counterparts.

The moderately high cost of semiconductor load cells and the dramatic cost reductions in linear integrated circuitry have limited the use of the semiconductor load cell in low cost weighing systems. In other words, the cost of linear amplification required to raise metallic strain gauge load cell signals to the levels offered by their semiconductor counterparts is now less than the additional cost for semiconductor load cells.

Nuclear Radiation Sensors

This form of weight sensing is generally applied to in-motion weighing of bulk materials. It utilizes a radioactive source of gamma rays that are directed through a certain section of the moving material. The material absorbs some of the gamma

TABLE 7.25z
Performance Characteristics of Semiconductor and Strain-Gauge-Type Load Cell

Performance Characteristic	*Semiconductors Load Cell*	*Metallic Strain Gauge Load Cell*
Output (at 15 v)	1.0 V	30 mV
Terminal linearity	0.25%	0.05%
Hysteresis	0.02%	0.02%
Temperature effect on zero balance	±0.25%/100°F (38°C)	±0.15%/100°F
Temperature effect on output	±0.5%/100°F	±0.08%/100°F
Selling price index	1.3	1.0

rays and allows others to pass through. The amount of radiation transmitted through the bulk material depends on the amount of material on the conveyor.

A radiation sensor converts the transmitted radiation to an electronic signal, which bears a known relationship to the amount of material on the weighing section of the conveyor (Figure 7.25aa).

The nuclear radiation form of weight sensing is applicable when the weight sensor should not contact the material or the conveying devices. Certain shortcomings of conventional belt scales can be avoided with this technique.

Inductive Sensing

Inductive weight sensors use the change in inductance of a solenoid coil with changing position of an iron core. Two forms of the inductive sensing principle are illustrated in Figure 7.25bb. If iron core in configuration #1 moves to the right, the inductance of coil B increases and the inductance of coil A is reduced. Arranging the two coils in a Wheatstone bridge with resistors completing the bridge network provides a means for developing a voltage signal proportional to the core position.

Configuration #2 utilizes three solenoid coils. Coils C and D are wound in opposite directions and surround an iron core, whereas coil E is placed between the two coils and is excited by an external AC voltage source. When the iron core is centrally located, voltages induced into the secondary coils (C and D) are equal and opposite, and no voltage appears across the output terminals (F and G). If the iron core is moved to the right, the voltage coupled into coil D is greater than that coupled into coil C, and a voltage is developed at the output terminals.

If the core were moved in the opposite direction by the same amount, a similar voltage of opposite phase would be developed. Other embodiments of inductive sensors are in current use. Those discussed here are for illustrative purposes only.

Inductive sensors furnish relatively high output signal levels and efficient null stability. Since their inertial masses are greater than strain gauge sensors, they are more subject to vibration.

Variable Reluctance Sensing

This design is similar to the inductive sensing method. The difference is that here the inductance of one or more coils is changed by altering the reluctance of a very small air gap. This technique is illustrated in Figure 7.25cc. Solenoid coils A and B are mounted on a structure of ferromagnetic material, and a U-shaped armature completes the magnetic circuit through air gaps 1, 2, and 3. Motion of the coil assembly to the right decreases air gap 2 while air gap 1 is increased. Air gap 3 remains constant during the translation of the coil assembly.

As a result of horizontal translation, the inductance of coil B increases while that of coil A drops. Incorporating the two coils in a Wheatstone bridge similar to that utilized in

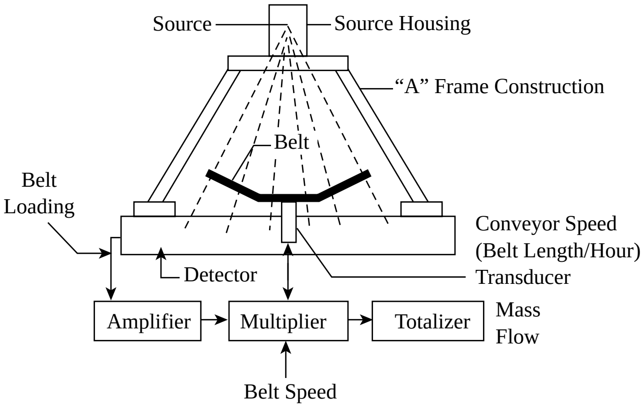

FIG. 7.25aa
Nuclear belt scale. (Courtesy of Thermo MeasureTech/Kay-Ray.)

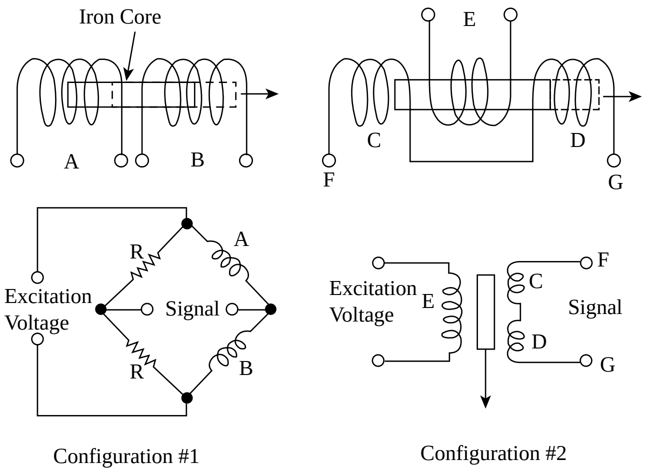

FIG. 7.25bb
Inductive sensing techniques.

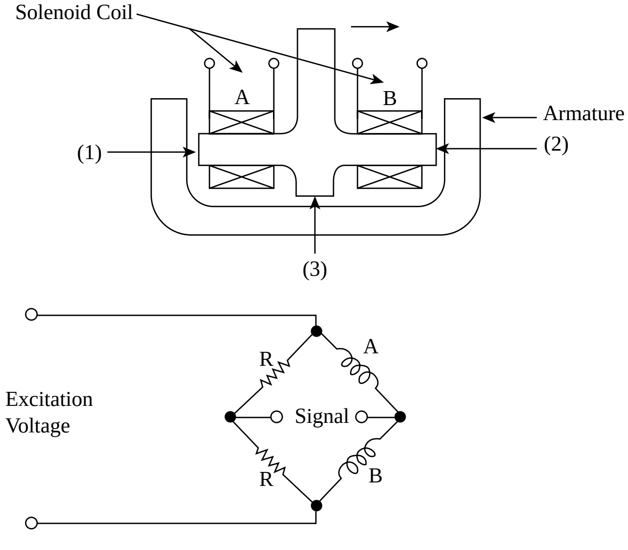

FIG. 7.25cc
Variable reluctance sensing technique.

the inductive sensing principle permits development of a voltage proportional to the translation of the coil assembly.

The variable reluctance sensing principle also offers a relatively high output voltage and efficient null stability with the higher vibration sensitivity due to the relatively high inertial masses of the mechanical structure.

Inductive and Reluctance Load Cells

Inductive and reluctance load cells incorporate the two basic sensing principles in the same way (i.e., the motion of a ferromagnetic core [inductive] or a coil assembly [reluctance] is converted to a voltage signal directly proportional to the displacement).

Various force sensing elements convert the applied force (weight) to a displacement to which the sensing element is coupled (Figure 7.25dd).

These transducers furnish relatively high output signal levels and moderate to high accuracy. They also cover a broad range of measuring capacities (Table 7.25ee).

Magnetostrictive Sensing

Based on the Villari effect, this technique utilizes the change in permeability of ferromagnetic materials with applied stress. A stack of laminations forms a load-bearing column (Figure 7.25ff), and primary and secondary transformer windings are wound on the column through holes oriented as shown. Coil A is excited with an AC voltage and coil B provides the signal voltage. In the unstressed condition, the permeability of the material is uniform throughout the structure. Since the coils are oriented at 90 degrees with respect to each other, little or no coupling exists between coil A and coil B. Hence, no output signal is developed.

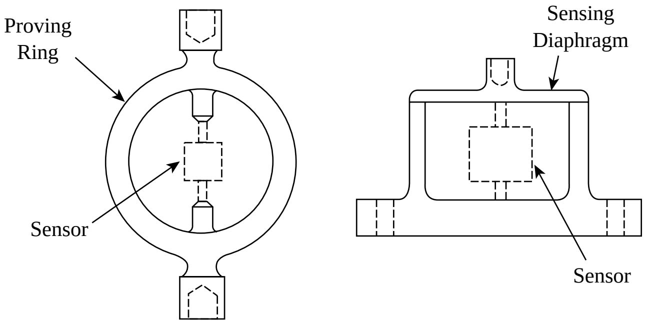

FIG. 7.25dd
Inductive and reluctance load cells.

TABLE 7.25ee
Performance Characteristics for Inductive or Reluctance Load Cells

Capacity range	0.01 to 100,000 lbs (0.0045 to 45,000 kg)
Rated output range	5 to 200 mV/V
Linearity range	0.1 to 0.5%
Repeatability	0.05%
Temperature effect on zero	1%/100°F (38°C)
Temperature effect on output	1%/100°F (38°C)

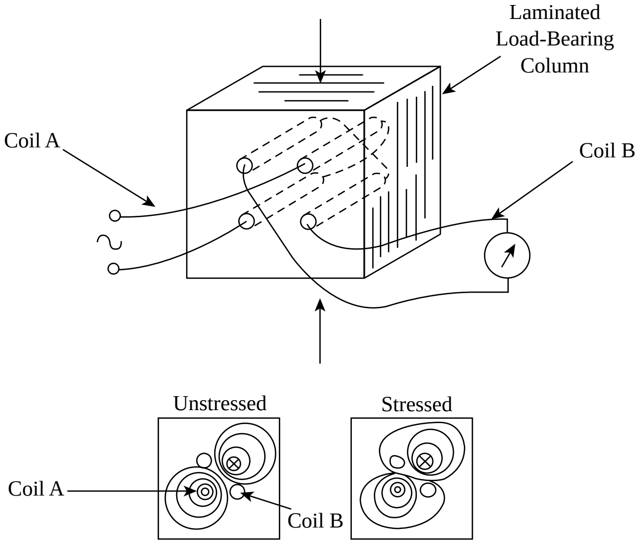

FIG. 7.25ff
Magnetostrictive sensing principle.

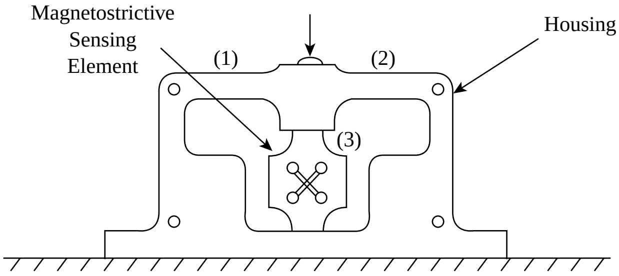

FIG. 7.25gg
Magnetostrictive load cell.

When the column is loaded, the induced stresses cause the permeability of the column to be nonuniform, resulting in corresponding distortions in the flux pattern within the magnetic material. Magnetic coupling now exists between the two coils and a voltage is induced in the signal coil, providing an output signal proportional to the applied load.

The magnetostrictive principle produces relatively high output signal levels and offers extreme ruggedness in load cells incorporating this sensing principle.

Magnetostrictive Load Cells Magnetostrictive sensing load cells (pressductors) are finding use in industrial applications in which large output signals and ruggedness are desirable. Several typical configurations are shown in Figures 7.25gg and 7.25hh.

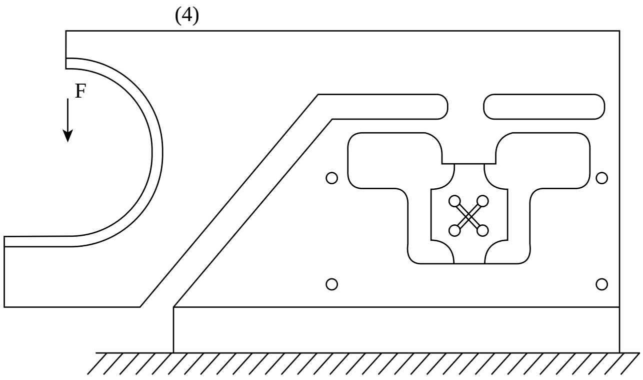

FIG. 7.25hh
Magnetostrictive load cell.

The first configuration is for applications in which there are no bearing surfaces on the devices being weighed; in the presence of lateral loads, the pressductor is very sensitive unless adequately protected. The vertical load (Figure 7.25gg) is transmitted through the flexures (1 and 2) to the sensing element (3). The same flexures also transmit lateral forces to ground in a way so that the pressductor sensing unit is subjected to only a small portion of the adverse lateral loads.

The second embodiment (Figure 7.25hh), designed for weighing during coiling operations, uses a similar construction with an additional overhanging member (4) that supports the coiler shaft, and continuous weighing during coiling operations is provided. All units are adequately protected with watertight covers to accommodate applications in industrial environments.

New pressductor designs provide weighing inaccuracies of 0.1% of rated capacity. Output signal levels range from 1 to 20 VDC, with source impedance ranging from 0.5 to 25 Ω. Overload ratings as high as fifteen times the rated load are supplied. Although usable for weighing, the pressductor has greater applicability in the steel industry for the measurement of roll-forces in rolling mills and strip-tension in strip mills.

LINEARIZATION OF LOAD CELLS

Column-type strain gauge load cells in capacities above 10,000 lb (4500 kg) heretofore have suffered from a characteristic nonlinearity of about 0.15% of rated capacity. The inherent nonlinearity of these devices results from electrical bridge nonlinearity caused by the fact that all strain gauges are not subjected to equal strain. Additional nonlinearity also results from the column area change with increasing load. The characteristic column-type load cell nonlinearity is parabolic and lends itself to almost perfect compensation by utilizing a semiconductor strain gauge compensating element.

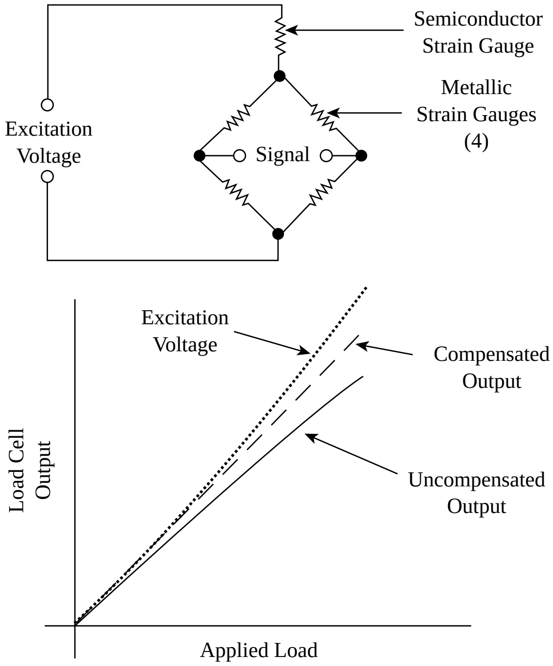

FIG. 7.25ii
Linearization of column load cells.

Figure 7.25ii shows a semiconductor strain gauge incorporated in series with the excitation terminals of the load cell bridge circuitry. From the curve of output voltage vs. applied load, an uncompensated column-type load cell exhibits a drooping concave downward characteristic when loaded in compression. The linearizing strain gauge senses column strain induced by the applied compressive load and, due to its piezoresistive characteristics, its terminal resistance decreases with increasing load. The decreasing resistance with load causes the net excitation voltage applied to the bridge circuitry to increase with increasing load (dotted line), which compensates for the drooping characteristic of the uncompensated load cell and results in improved linearity (interrupted line). Adjusting the terminal resistance of the linearizing strain gauge almost exactly compensates for the inherent parabolic drooping characteristic, and terminal linearity of better than 0.02% of rated load can be provided.

Linearity of this magnitude not only eliminates external linearization within the instrumentation, but also reduces errors in multiple load cell weighing systems in which unequal distribution of total load between the individual load cells may be substantial. Unequal loading on nonlinear load cells can cause serious system errors, even in systems in which load cell nonlinearity compensation is included in the display instrumentation.

LOAD CELL HOUSINGS AND SAFETY

The standards governing the sealing of load cells are usually based on sealing against water only; they are not useful in connection with chemical protection. The typical water-sealing test is performed by submerging the load cell for

0.5 h in 3 ft (l m) of water. The hydrostatic head of the water is usually less than the water pressure that can occur during wash-down procedures.

Load cells for explosive atmospheres are specially designed and tested. For Europe, the regulations are dictated by the European Committee for Electro-technical Standardization (CENELEC). (For electrical safety practices in the United States, see Section 7.2.) The best protection can be achieved by using a flameproof enclosure. This protection is called d and is marked as EEx-d. With this type of protection, the load cells can be directly connected to the instrument in the safe area.

Another solution is to place Zener barriers between the instrument and the load cells. This is called intrinsic safety i and is marked as EEx-i. However, it should be noted that the load cells and the indicator are temperature-compensated devices and the Zener barriers have a serious temperature effect. The instrument must be compensated for temperature errors.

The classification system used to identify situations where the presence of electrical equipment could create an explosion hazard is differently determined in various countries. In the United States, Factory Mutual is the recognized leader in certifying equipment for hazardous environments. A hazard can be caused by the equipment's generating enough heat to reach the ignition temperature of ambient gases (or dusts) or by generating an arc due to shorting or to opening an electrical connection.

Intrinsic Safety

Ultra-low power displays are marketed by some weighing system manufacturers like Fairbanks Scales. This instrument is intrinsically safe for every class, division, and group of the classification discussed above. It has fiber-optic digital outputs, 1 to 4 set points, and 4 to 20 mA analog output for weighing and for process control applications. It needs no explosion-proof enclosures, and its 1.25 in. (30 mm) large liquid crystal displays are easy to read. Both the platform and the indicator can be placed in the same hazardous area. The battery, which powers the unit, lasts up to 6 months before recharging is required.

SPECIAL APPLICATION

High Temperature Load Cells

As load cell weighing was applied to the metal processing industry, the need for devices to withstand high environmental temperatures became pressing. In recent years, organic and inorganic bonded strain gauge backing and installation materials have become available and can withstand higher temperatures than conventional units. Bonded strain gauges with organic backings are now available for continuous operation at temperatures as high as 500°F (260°C).

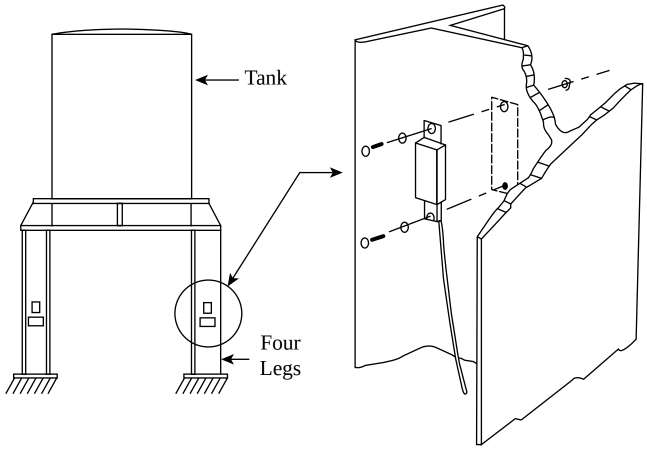

FIG. 7.25jj
Direct gauging of tank supports. (Courtesy of Kistler-Morse Corp.)

On special applications, high temperature strain sensing wire alloys have been installed with inorganic bonding materials, such as ceramic cements and flame spray techniques, where molten aluminum oxide is sprayed on the sensing element and on the strain sensing grid to hold the latter firmly in place. These installations allow short-term operation at temperatures of 1000°F (538°C), but with some degradation in performance.

Weighing of Tank Legs

In some installations, load cells cannot be used at all. This can be because the structures are already fabricated and erected, and their support by load cells would require extensive field modification.

One solution to the weighing of these structures is installing strain gauges directly on the supporting legs. In such installations, the legs become the sensing elements to which the strain gauges are applied in full bridge configurations.

In a typical installation (Figure 7.25jj), a pair of gauges is applied longitudinally, sensing the compressive stresses in the tank legs. Another pair is applied in the transverse direction, sensing the tensile strains due to the Poisson effect. The four gauges are connected in a Wheatstone bridge arrangement and leads are brought out from each leg to a summing box and from there to the readout instrumentation. The installation is thoroughly protected with waterproofing materials.

Usually, the strains established in the supporting legs are very low and it is difficult to achieve perfect waterproofing permanently. As a result, the accuracy of such a weighing system tends to be relatively poor—3 to 5% of rated capacity.

DEVELOPING NEW SENSORS

In the area of new sensor developments, fiber optic load cells are gaining attention because of their immunity to electromagnetic and radio frequency interference (EMI/RFI), suitability for use at elevated temperatures, and intrinsically safe nature. Work continues on the development of optical load sensors.

Two techniques are showing particular promise: measuring the micro-bending loss effect of single-mode optical fiber and measuring forces using the Fiber Bragg Grating effect. Optical sensors based on both technologies are undergoing field trials in Hokkaido, Japan, where they are being used to measure snow loads on electrical transmission lines.

A few fiber optic load sensors are commercially available. One fiber optic strain gage can be installed by drilling a 0.5 mm diameter hole into a stud or bolt, and then inserting the strain gage into it. Such a sensor is completely insensitive to off-axis and torsion loads.

The development of micro-machined silicon load cells is also underway. At the Universiteit Twente in The Netherlands, work is progressing on a packaged monolithic load cell using micro-machining techniques, and it is possible that silicon load cells will dominate the weighing industry in the future.

New Load Cells

Load cell technology is advanced by improved accuracy, reduced sensitivity to interferences, increasing life through better sealing, better calibration, reduced costs through high volume production and calibration, and the use of built-in microprocessors. An illustration of a newer load cell is given in Figure 7.25kk. This bending ring load cell is only 3 in. in diameter and 1 in. tall (75 × 26 mm) for a load of 1.3 tons and 3.75 × 1.4 in. (95 × 35 mm) for a 13-ton load application.

Load cells of this type with foil strain gauges are produced for retail shop scales having a resolution up to 6000 graduations over their ranges. The foil gauges can be used down to 5 lbm (2 kg) and with bridge resistance values over 2 kΩ. With smaller loads, a force shunt occurs which increases the errors due to creep.

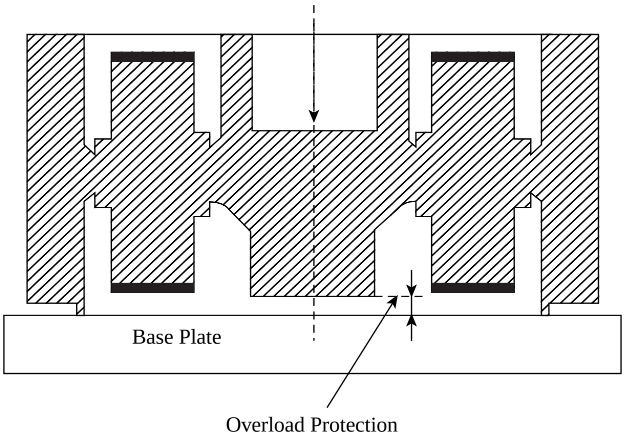

FIG. 7.25kk
Cross-sectional view of a bending-ring-type load cell.[2]

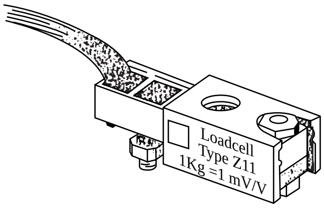

FIG. 7.25ll
Thin-film strain gauge for small loads of 1 to 10 lbm (0.5 to 5 kg) and providing 5000 graduations.[3]

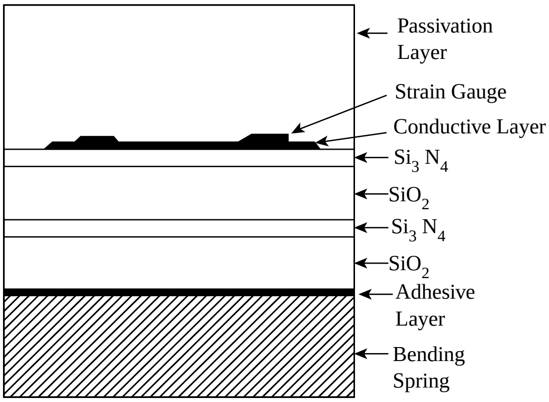

FIG. 7.25mm
The layer-by-layer construction of a thin-film strain gauge element.

Thin-Film Strain Gauges Load cells using thin-film strain gauges are available with nominal loads from 1 to 10 lbm (0.5 to 5 kg) and with a bridge resistance of 4 kΩ.[3] These provide the measuring stability of load cells without hermetic metallic encapsulation of the strain gauge. Stability is tested for a period of 50 days with daily temperature cycles ranging from 77 to 131°F (25 to 55°C) under saturated conditions, which cause occasional condensation. The sensitivity of such a load cell having 5000 graduations may vary by up to 0.02%, and its zero signal may vary by up to 10% (Figure 7.25ll).

In the new thin-film load cell, CrSi thin-film technology is used. Stability and moisture resistance are provided by a patented insulation layer between the spring body and the strain gauge elements that consists of a fourfold sandwich of SiO_2 and Si_3N_4. SiO_2 supplies the necessary insulation against electronic current flows. Si_3N_4 prevents ion migration into the strain gauges that could otherwise happen due to the electric field generated by the bridge excitation (Figure 7.25mm).

Another problem in thin-film technology is the material of the spring element in the load cell. This is because the thin film has no creep at all, and the strain gauge cannot compensate for the creep of the spring material. For this reason, the spring material is the rather expensive FeNi alloy. Due to the cost of FeNi, the spring is rather small (3 mm thick).

Thin-film load cells have low power consumption, small size, and meet the following calibration requirements:

Weight Range	*Graduations (Divisions)*
4 to 10 lbm (2 to 5 kg)	3000
2 to 4 lbm (1 to 2 kg)	2000
1 to 2 lbm (0.5 to 1 kg)	1500

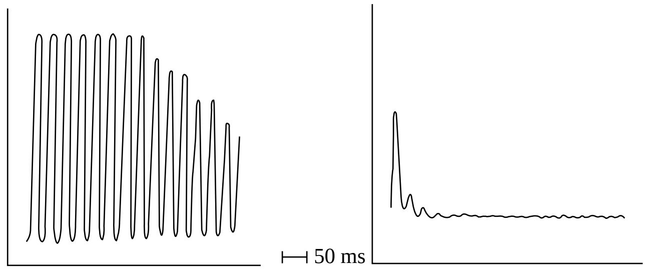

FIG. 7.25nn
Load-cell output signals: without damping (left) and with hydraulic damping provided in the load cell (right).

Hydraulically Damped Load Cells Another new load-cell combines a mechanical damping system with adjustable mechanical tare compensation. The single-point load cells are provided with a damping plate immersed in high-viscosity silicone oil and provide a stabilized signal within 150 ms (Figure 7.25nn). On applications involving bins or conveyors, preloads of up to 20 lbm (10 kg) can be tared out with the help of a built-in adjustable spring. Thus smaller-range load cells with higher output signals can be used for the same application.

The hydraulically damped load cells are available with 6 to 10 lbm (3 to 5 kg) ranges with a combined error of less than 0.02% full scale. They are particularly advantageous in multi-head, computerized packaging scales. Overload protection is effective up to 1000%.

Microprocessors and Networks

There are many load cell designs that are provided with built-in microprocessors. Some are able to withstand the adverse weather conditions in outdoor sites. Others contain a microprocessor that has been programmed to automatically recognize and correct errors caused by external influences or by the movement of the loads on the scale base while weighing is in progress. The capacity of some of these intelligent weight bridges can be 500 tons.[4]

Interfacing with Programmable Logic Controllers Advanced weighing modules[15] can exchange weighing information on a digital bus or network, using 32 read and write registers, or work as a stand alone device (Modbus Plus, Modbus TCP/IP, Interbus, I/O bus supported).

They can interface with up to 8 load cells to give one weighing measure. Such modules usually have 4 inputs (tare, reset tare, zero, print) and two high speed outputs (1 ms resolution). Such advanced weighing modules bring the data to the programmable logic controllers. Therefore, it becomes global in the sense that the user has access to the weighing system from all the different devices on the plant's network.

The Role of the Personal Computers The output signals of the load cells must be compatible with computerized data processing systems and/or with personal computers (PCs). The software tasks include in-motion and multi-head scale weighing and the intergration of these systems into plant-wide bus systems.

An example of newer digital load cell electronics is the signal by Hottinger Baldwin Messtechnik.[5] In this unit the electronic circuit is on a small board and it forms a link between the strain gauges and the serial RS-232 interface of a PC. It supplies the bridge with DC power and digitizes the output over the full measurement range. Gate-array technology is applied in the analog-to-digital (A/D) converter, utilizing a method of conversion that offers a resolution of 16 bits, coupled with a speed of 150 measurements per second.

Following the A/D conversion, the signal conditioning is implemented by a mask-programmed microprocessor that carries out the zero-point balancing and auto-calibration, scales the transducer signal, filters, forms mean values, and tares the system. The digital filter can provide suppression of noise or unwanted parts of the signal. Various filter cutoff frequencies are selectable. When averaging consecutive measurements, the measurement rate can be changed in steps.

There is also a trend to use PCs as weighing system components, because of their low cost and flexibility. One consideration in the use of PC is the operator accessibility of software functions and data security against manipulations.[6]

Verified Weighing with PCs Figure 7.25oo illustrates a method of verified weighing through the use of personal computers. In this system, the hardware and software for the handling of the verified data are collected in an external PC card that communicates through an optional slot with the PC. This is called the security unit (SU)—a data channel that transfers measurement and print data among the PC, printer, and verified receiver.[7]

The video displays the verified data (with the highest priority) as a window into the existing picture on the PC monitor. As is shown on the block diagram, the output of the enhanced graphics adapter video card is directly connected to the video input of the SU. Therefore, a window for the display of weight data is generated into the normal display without an access possibility of the PC.

Networks and Buses As one integrates weighing systems into plant-wide process control systems, it becomes an important requirement to easily connect single sensors and actuators into networks. Bus systems for high-capacity data transmission have been primarily developed for computer communication, and the demand for networking of passive field instruments started only recently.[13] For a listing of the various fieldbus protocols and their attributes, refer to Table 7.24d in the previous section.

In Europe, the process field bus Profibus has been around for a while, and Sensorbus has also gained some ground. ISIbus has been offered to the international standardization bodies based on a rugged and environmentally resistant connection method—the inductive coupling. Its ability to combine high data rates and power transfer to field devices operating

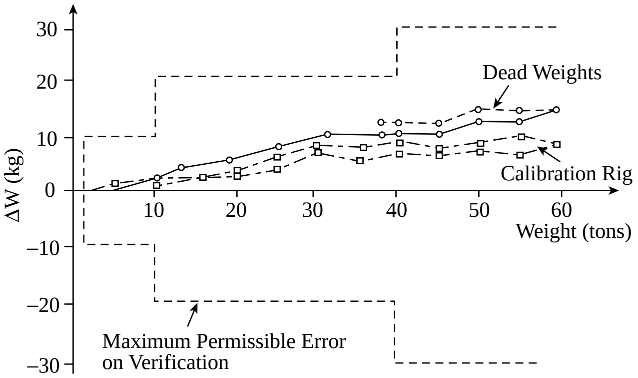

FIG. 7.25qq
The relative performance of a weigh-bridge when calibrated against deadweights and when calibrated against master load cells.

in hazardous areas makes ISIbus a useful contribution to the field bus concept.[14]

CALIBRATION AND TESTING

Calibration and testing of large weigh-bridges is usually done by deadweights, and it is an expensive, time-consuming, and sometimes even dangerous process. To calibrate a 60 or 100-ton road weigh-bridge or 200-ton railway weigh-bridge, considerable amounts of standard weights must be transported to the location and placed on the bridge.

The idea of the application of master load cells instead of standard weights is not new, but until recently, their stability and accuracy were not satisfactory. The accuracy of the master cell must be at least 3 times better than that of the weighing cell. The master load cell approach[8] offers 10 times higher resolution even when calibrating a 6-load-cell weigh-bridge with 3000 divisions.

In terms of the number of steps, this corresponds to 10 × 3000 × 6 = 180,000 steps. In the system illustrated in Figure 7.25oo, the force is generated by a DC servomotor instead of by hydraulic systems, which have been found to be unstable.

The procedure for calibration can involve incremental loading, where at each step in load the two output signals (weigh-bridge and master load cell) are compared, or it can be continuous. If continuous calibration is used, both sensors are triggered at certain load levels and the instantaneous readings are compared. Figure 7.25qq shows the results of the calibration of a 60-ton 6-load-cell weigh-bridge using deadweights and also using the test rig.

Aircraft Weighing The weighing of aircraft is a specialized application and serves the function of loading controls, deicing, etc.[9] The weighing is done either by jacking and leveling the aircraft at three points or by using mobile weighing platforms. Still air environment is essential (even the blower heaters must be turned off) and an enclosed hangar is necessary.

The center of gravity of the airplane is obtained from weighing and is used to evenly distribute the passenger/cargo/fuel loads in the aircraft to ensure that the balance is within specified

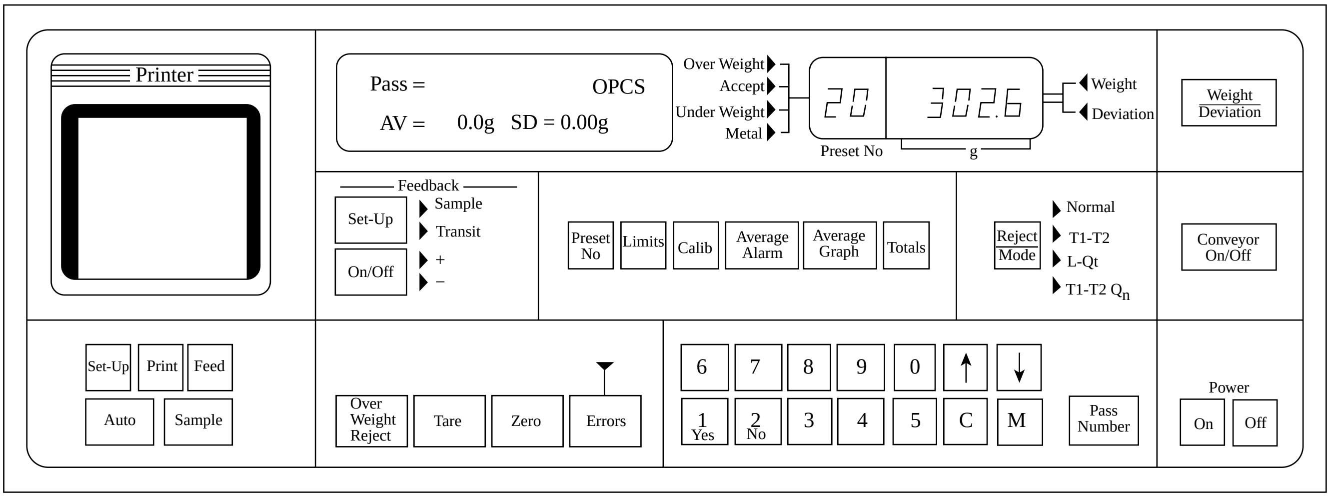

FIG. 7.25rr
The faceplate of a check-weigher controller.[12]

limits. For this purpose, the GEC Brainweigh microcomputer can be used, as it memorizes the geometry of most popular aircraft types and thereby provides quick and reliable measurements.[10]

Packaging Industry The packaging industry uses some of the most sophisticated scales. Net weighing scale technology has progressed substantially in recent years.

A new concept is the combination weighing system, which offers high packaging speeds. The system consists of a series of weighing heads with computer control. The Yamato Dataweigh design[11] with 16 heads is able to produce 160 packs per minute with weighing precision of 2000 graduations per scale range.

The command console with a 16 bit microprocessor provides all necessary controls and monitors the operation. System connection is via optical fiber cables which guarantees noise-free operation. Information or commands are entered by touching the appropriately labeled rectangles on the light emitting diode touch screen. Menu-driven software makes it easy to call up operational, monitoring, or diagnostic displays.

In-line check-weighers can provide more than weight control. As the packages travel across the weigh cell platform, they are transported on flying belts, chains, or ultra light ribbons. These systems can attain product speeds of 400 to 500 units per minute. In addition to rejecting out-of-spec packages, their most important feature is the feedback, which controls the filling machine for automatic optimal adjustment of fill. The modern check-weighers inform line operators of almost everything they want to know about the product and its statistical weight, record, and trend.

The face plate of modern Yamato check-weigher is shown in Figure 7.25rr. Four reject modes and programmed, including the T1-T2-Qn modes in full compliance with International Electrotechnical Commission (IEC) legislation. The built-in bar graph indicator provides instant information on product weight deviation from the target. The stated accuracy is maintained up to a rate of 300 packs per minute.[12]

INTRODUCTION

Modern process control requires current information on the state (composition, temperature, pressure, flow rate, etc.) of the material being produced. Modern distributed control systems linked to various control elements (valves, pumps, etc.) require data much more often than the manual control systems of years gone by. While grab samples taken to a modern laboratory will be the gold standard for quality control purposes, the effort and time it takes to get a sample, transport it to the lab, and wait for the result can add significantly to the costs of the process in process output, energy, etc. For many industries, the solution is to move the analysis directly to the process.

This need for more and better analyzers does not mean that their application is, or ever will be, a simple, routine task. For an analyzer system to fulfill its expectations, careful planning and evaluation must precede its purchase, and the users must realize that if an expensive analyzer is worth purchasing, it must also be worth calibrating and maintaining. The operator's acceptance, which depends largely on training and familiarization, is also crucial. New self-diagnosing and self-calibrating analyzers are a major contribution to improved operator acceptance, but people issues are still more important and should not be discounted.

In this section, a process for the selection of an analyzer is presented. The many issues that must be considered are covered, as is an overview of kinds of analyzers. The latter material should be viewed only as introductory. Detailed discussion of the different instruments is covered elsewhere in this volume and in the references.

The most important aspect of an analyzer application is a clear understanding of why the analyzer is needed, what information is needed, and what will be done with the information. Put another way, the analyzer problem must be clearly defined and understood. Too many analyzer applications have failed because the needed measurement was not the one installed in the process.

In general, the instrument engineer (analyzer engineer, process analytical chemist, etc.) is asked by a process control engineer to install an analyzer in a process. It is the analyzer engineer's duty to his company to push back and insure that the application is needed and clearly understood. Merely doing what is asked, in many cases, will lead to unnecessary or even failed installations.

The Selection Process

The process to follow in selecting the appropriate analyzer for an application involves eight steps:

1. Problem definition
2. Information gathering (to understand the problem fully)
3. Analyzer selection (making sure to consider and balance these criteria)
   Specificity
   Accuracy and precision
   Calibration
   Analysis frequency
   Kind of analyzer
4. Sampling
5. Analyzer location
6. Handling of the data
7. Maintenance issues
8. Total cost: hardware, installation, maintenance, etc.

It is not uncommon to cycle back from one step to another, as more information is needed to assure that the proper decisions are made. Installing the wrong kind of analyzer or putting it in the wrong place will not solve the problem, and instead of saving money or improving quality, money and effort will be wasted.

PROBLEM DEFINITION

Defining the problem begins with understanding how the measurement will be used. Is it for closed-loop process control or for information purposes? Is the measurement really needed “on-line,” or could 80% of the benefits be obtained for 20% of the cost and effort by making the measurement “at-line” in the control room? What is the benefit of the measurement? How will the cost be justified? Is this to reduce staffing by moving the measurement from the lab to the pipe? Is it a yield-improvement project? Answers to these questions begin to clarify the needed timescale for the measurement. In addition, it is important to understand the process to be monitored. What is the response time of the process? Obviously, if the process takes 60 min to respond to a temperature change (e.g., distillation column), analyzer requirements are quite different from those of a process that responds in 6 sec. These issues are important and referred to throughout this chapter.

Before continuing our discussion of problem definition, it is helpful to define some commonly used terms. In analytical chemistry, we usually define measurements as laboratory, at-line, on-line, and in-line. In addition, measurements can be invasive or noninvasive. Process analytical chemistry encompasses all of these, except laboratory measurements.

An *at-line* measurement is generally a manual measurement, instrumental or chemical, performed near the process, generally in or adjoining the control room. The method may be identical to the laboratory method, but normally it is simpler and faster. The at-line approach is ideal when the resulting information is used to control slow response processes, or for quality control, or when true real-time measurements are prohibitively expensive, compared to the benefit. An example of an at-line measurement might be a caliper measurement of a paper product or a multiphase titration of a surfactant. In both cases, production samples are manually taken to the measurement station and tested. A typical frequency for an at-line measurement might be hourly.

On-line measurements are those installed on the process such that a sample or slipstream is brought to the measurement device, frequently with sample conditioning. In general, this method is used when data are needed very frequently and the measurement approach is not conducive to in-line use. The slipstream approach is needed when the measurement instrument requires sample conditioning, such as filtration. This will be discussed in more detail later. Process gas chromatographs are examples of instruments that normally use the on-line method and require sample conditioning to allow proper sampling of the small volumes needed for injection. (Of course, chromatographs do not normally provide rapid or continuous data output.)

In-line measurements are those in which a probe is inserted directly into the process. No sample conditioning is required. Common examples include pH and other electrode measurements. In a gray zone between the on-line and in-line categories, we find approaches in which the instrument is able to look into the process through a window (for example, a spectroscopic measurement) or directly on a moving web or conveyor belt. These are real-time approaches, but not on a slipstream and not really in-line either.

An *invasive* measurement is one that in some way penetrates or changes the process. Any in-line approach would be considered invasive, as would an on-line approach that modified the process flow with a slipstream. A near-infrared (NIR) photometer positioned above a web would be *noninvasive* since it does not enter or change the process or material. Similarly, a clamp-on ultrasonic flow or density meter is noninvasive.

When an adequate discussion of the measurement need has occurred, we can assume that the problem has been defined sufficiently, at least in terms of the kind of process measurement needed and how it will be used. It may be necessary to return to this subject and refine the problem definition further, based on additional information that will be gathered in the next steps.

INFORMATION GATHERING

Reasons for installing process analyzers include the improvement of safety, as well as of product quality; reduction of by-products, decrease in analysis time, tightening of specifications, and monitoring of contaminants, toxicants, or pollutants.

Additional requirements and characteristics of the measurement must be understood, including the needed frequency of analysis, sample availability, cost, and safety considerations.

Many analyzer experts find filling out a form to be helpful in gathering data on needs and desires (Table 8.1a). In selecting an analysis system, one must ask whether the need for the measurement justifies the cost. If the answer is yes, the study progresses until several possible types of analyzers are identified, at which time the question of cost is again raised, and some of the more expansive analyzers may be eliminated from further consideration. After the complete system has been defined, the estimated costs can be compared with the expected benefits and a decision reached.

With the basic problem defined, the process analytical chemist must now understand the measurement approach to be selected. This requires an understanding of the current approach, if any, including whether such a measurement is made in the plant laboratory. Frequently this information gathering step involves discussions with research and development analytical chemists, plant quality control laboratory personnel, and library research. In general, for any needed measurement, there will be several different possible approaches (methods) that could be taken. While gathering information, the process analytical chemist or instrument engineer should be open-minded to the methods, while carefully evaluating each one in light of the specific problem at hand. If the results of the measurement will be compared to the laboratory's results, it becomes crucial to understand any differences between the methods. Where possible, similar methods should be used. However, lab methods are not typically suitable to the process, so other approaches will probably be needed. The critical question to be answered during this information gathering phase is, "What is the measurement handle I can employ for the process measurement?" In other words, "What attribute of the analyte would be easiest to 'grab' (measure) in the process environment?" For example, if the project request is for an oxygen measurement, the engineer will have learned that it is gaseous oxygen, not dissolved oxygen, that is needed, and must now determine how to make the measurement, keeping in mind the process conditions. There are several common oxygen measurement approaches, each of which uses a different "handle" or attribute of the oxygen molecule. Depending on the process conditions, other components of the matrix, etc., the chemist could select a paramagnetic oxygen analyzer, which makes use of the fact that elemental oxygen is one of the few gases attracted to a magnet, or an electrochemical cell device, which makes use of oxygen's electroactivity. After the appropriate candidate process method has been selected, the chemist must address these issues: How will the method be calibrated? Will it be compared to the lab results? Does it

measure the same thing(s)? Of course, the most important question is, “Will this measurement method provide the information needed by the process engineer or customer?”

Frequently, while gathering information, one must return to problem definition and seek clarification. This is an iterative process. It is not uncommon for the problem definition to change as you learn more about the possible measurement approaches and share these learnings with your customer. Finally, you feel you have enough clarity regarding the problem and can move forward to the technique or analyzer selection step in the process.

TECHNIQUE OR ANALYZER SELECTION

The most important factors that must be weighed by the instrument engineer are discussed in the remainder of this chapter and in the chapters that follow. Unfortunately, no single analyzer combines all the desirable features of providing on-stream, specific, continuous, unattended high-sensitivity readings without drift, noise, or need for a sampling system. Therefore, the selection is always a compromise, which is likely to give satisfactory results only if it is preceded by careful evaluation.

If the problem has been defined as one requiring the measurement of one material in the presence of another, it is necessary first to look for the handle or unique property of the material to be measured. Usually, a first step in determining the suitable methods of analysis is to investigate laboratory methods used to determine the desired property. As previously noted, a meeting with laboratory personnel is a good first step. Industry methods are another good starting point. For example, the American Society for Testing Materials (ASTM) has established certain test methods for the determination of various properties and materials. Their methods are widely available in book form and on the web.[1] Other organizations such as the American Oil Chemists Society (AOCS) and the Technical Association of the Pulp and Paper Industry (TAPPI) have also published compendia of analytical methods.[2,3] Suppliers of the material to be analyzed are possible sources of information for methods of analysis, as are suppliers of on-line analyzers.

Once prospective methods of analysis have been selected, the search for appropriate hardware begins. Ordinarily, details of the desired measurement are given to the potential analyzer suppliers, and estimates of performance are obtained. The analysis system can often be purchased on a guaranteed-performance basis. For proprietary installations, the user himself must determine how the general analyzer specifications apply for the particular application, and since the user is buying hardware only, the supplier will guarantee only the quality of materials and workmanship. Alternatively, once a single supplier has been selected, a confidentiality agreement can be signed allowing information sharing by both parties—a true partnership to assure a successful installation.

When comparing different analysis approaches, the following criteria are critical.

Specificity (Selectivity)

Specificity is the characteristic of responding only to the property or component of interest. The specificity of the analyzer will not exceed that of the analysis. Specificity is often a function of the range to be measured, the sample background, and the process conditions (solid, liquid, or gas; pressure and temperature). The more selective a measurement is, the less we need be concerned with interferences from other constituents of the sample matrix. Obtaining a high degree of selectivity frequently means compromising other analytical attributes. For example, a gas chromatographic separation with baseline resolution of the analyte of interest may require a longer analysis time than is desired or allowable.

Accuracy and Precision

Frequently, absolute accuracy of a process measurement cannot be established owing to the lack of a suitable calibration standard or the inability to draw an unchanged sample from the process and analyze it by an “official” laboratory method. For this reason, other terms, such as repeatability, take on added importance. Often, the terms do not have industry-wide significance, so the definition should be agreed upon with each supplier. (Note: With proper calibration, an analyzer will be “accurate.”)

In general, in process measurement, precision or repeatability is more important than accuracy. Since the measurement is being made continuously or repeatedly, we are much more interested in changes in a value than whether that value is “absolutely correct” or accurate. Changes in the process are what we are trying to measure and understand (and control).

For the purpose of this discussion, *precision* is defined as the ability of an analyzer to produce the same output each time the sample contains the same quantity of component or property being measured. The terms *stability*, *reliability*, and *reproducibility* are sometimes used synonymously with *repeatability*. However, *reliability* is also used to describe the instrument’s “up time” and should not be used as a synonym for precision. Lack of repeatability may be caused by the analyzer, the sampling system, or the effects of temperature, power supply, composition, pressure, and flow rate. Poor precision or low repeatability can come in two forms: short term and long term. Short term may mean the measurement system has lots of randomness (noise). Such random noise degrades the utility of any given reading, but may be tolerable since many data points are collected. Long-term drift can be a more significant problem requiring frequent instrument recalibration or adjustment. Repeatability and inaccuracy are normally expressed either as a percentage of the full measurement range or as a percentage of the actual reading.

When discussing specifications for an analyzer, especially with prospective vendors, be very careful to define all technical terms and understand exactly what the literature or the sales engineer means by terms such as accuracy, drift, precision, etc. If there is any doubt, ask for a clarifying example with actual numbers, such as, “The refractometer is stable to ±1% of the actual reading over 14 days, without any adjustments. That is, it will read 1.102 ± 0.1 for 2 weeks, if the temperature changes no more than ±5°C.” Sales literature is notorious for specifications that are unclear and frequently misleading.

Calibration

The ability to calibrate an analyzer properly usually depends on the availability of a reliable reference sample, or the ability to perform reliable laboratory analysis on the actual sample that is entering the analyzer. Never lose sight of these inherent difficulties (challenges) in calibration: 1) Samples can change after removal from the process and hence are different when they reach the lab. 2) Highly variable process streams, in which the lag time between the process measurement point and the sampling valve cause the sample drawn from the stream and the sample measured in the process to be different. (In some cases, the sample itself may be inhomogeneous, which further complicates comparison measurements.) 3) The two measurement methods may not be measuring the identical analyte. For example, a near-infrared moisture analyzer may be calibrated against a loss-on-drying lab method, but these are not identical, and there may be a bias between them caused by other volatile constituents of the sample.

Interferences with the analysis can be caused by physical or chemical effects that cause a deviation in the analyzer output. If the effect of the interfering substance remains constant, a compensation factor can usually be applied in the calibration procedure. During checkout of the installed system, one should verify the effect of interference by calibrating the analyzer for each suspected substance.

When interferences cannot be predetermined, it may be both necessary and practical to send known samples to prospective suppliers for evaluation. In any case, known and suspected interferences and their concentrations should be made known to prospective suppliers when requesting quotations.

Both the method of calibration and the accuracy of the calibration procedure must be established before one purchases a process analyzer.

Analysis Frequency

As discussed in the Problem Definition section, one should first determine whether continuous analysis, automatic-repetitive batch sampling, or an occasional spot check is required. The information from the analyzer and the rate of the dynamic changes in the sample are the main factors to be considered.

The need for process control suggests either a continuous analyzer or an analyzer with a continuous output signal, because a continuous analyzer provides a better chance for the system to reach and maintain equilibrium with the sample. Also, the mechanical design of a continuous analyzer ordinarily is less complicated than that of a discontinuous system. However, the discontinuous analyzer may be more attractive if automatic zero checks are frequently needed, if reagents are blended with the sample, or if the sample is corrosive. Some analyzers, for example, chromatographs, are inherently discontinuous.

The rate at which the measured variable changes in the process is an important factor in determining the frequency of discontinuous analyses. If the sample has to be withdrawn and transported to the analyzer, the time lag factor must also be considered. If several different samples are to share the analyzer (e.g., stream switching), additional time allowances are required.

Kinds of Analyzers

Analytical techniques suitable for process measurement may be organized into several arbitrary categories. No one approach is inherently superior to another, although for a specific project, the constraints covered previously will narrow the choice.

Separation Techniques

Separation techniques literally involve the separation of different components in the sample with appropriate detection. Gas chromatography, which dates to the 1950s, is probably the most widely used technique in process analysis, with the possible exception of pH.

In all chromatographic techniques, a small portion of the sample stream is injected into a flowing carrier fluid that passes through a column in which it contacts a separation medium prior to reaching a detector. In gas chromatography, the sample is vaporized, if it is a liquid, and carried with helium or nitrogen (most commonly) through the column. The column may be a tube packed with adsorbent media or a thin capillary column coated with an appropriate phase to cause a separation. If the sample was a gas to begin with, it is carried through the column without the need for vaporization. Depending on the analytes to be separated, one chooses the appropriate length of column and coating or packing material. Many different separation materials are available. Similarly, many different gas chromatography detectors exist to provide specificity or broad detectabilty. For fixed gases, the thermal conductivity detector (TCD) is mandatory; for organic compounds, either the TCD or the flame ionization detector (FID) is acceptable, but the FID is more sensitive. Added sensitivity (lower detection limits) comes at a price: the FID needs additional gases and extra safety precautions. Later chapters will address these subjects in more detail. In liquid chromatography, the sample is injected into a flowing stream of solvent (mobile phase), separated, and detected. Common detectors include the refractive index (RI) detector, which monitors the eluting mobile phase for RI changes; absorbance detectors, which monitor the spectral absorbance of the mobile phase at one or more wavelength, commonly in the ultraviolet (UV) or visible (Vis) areas of the spectrum; and the electrochemical detector, which monitors an electrochemical property such as conductance of the mobile phase.

Other chromatographic techniques that are available for process measurement include ion chromatography, which can measure either the anions or cations of a stream; gel permeation chromatography, which measures the molecular weight distribution, typically of polymer samples; and supercritical fluid chromatography, which operates in the pressure and temperature regime where a carrier fluid, such as carbon dioxide, is neither liquid nor vapor.

The disadvantages of the chromatographic techniques are the length of time many of the separations take, the fact that these are not continuous techniques (samples are injected only after the previous run is complete and the system has stabilized), aging of the columns, consumption of gases or solvents, and maintenance of the frequently complex and costly sampling systems. In fact, the cost of the chromatograph itself can be less than half of the total installation cost and, if the expense of maintenance is also included, the fraction of the instrument's cost is reduced even further. Some reports indicate that for every successful chromatograph installation in the chemical industry, one has failed and been abandoned. For this reason, some engineers favor simple inexpensive chromatographs, monitoring one component in a single sample to increase reliability. Proponents maintain that an overburdened chromatograph is more a liability than an asset, and that even

TABLE 8.1b
Absorption/Emission of Electromagnetic Energy Useful for Measurements

Type of Radiation	*Wavelength Range*	*Characteristic Process Probed*
Gamma-rays	$<10^{-12}$ m	Nuclear transitions
X-rays	1 nm–1 pm	Inner-shell electron transitions in atoms
UV	400 nm–1 nm	n, π (valence) electron transitions in molecules
Vis	750 nm–400 nm	n, π (valence) electron transitions in molecules
NIR	2.5 μm–750 nm	Molecular vibrations
IR	25 μm–2.5 μm	Molecular vibrations
Microwaves	1 mm–25 μm	Rotations in molecules
Radio waves	>1 mm	Rotations in molecules, electron spin flips[a]

[a] NMR uses a magnetic field to split the energy levels and the Rf energy to probe the spin state.

when it is operating, the volume of information generated is more likely to swamp than to assist the operator. Therefore, their target is to achieve a degree of standardization and simplicity similar to that found in flow or temperature detectors. It is reported that these simple chromatographs can accommodate the majority of present applications.

New developments in the simplification of sampling systems may reduce their cost and complexity while increasing reliability. Recent developments in the field of sampling systems using a small, industry standard platform of modular components show much potential.[4–8] Recent research in the use of chemometrics to extract information from poorly resolved peaks may provide advantages in analysis time by allowing faster run times. Parallel columns of different separation power combined with chemometrics will provide additional benefits. Chemometrics can help address the issue of swamping the operator with information.

Other Separation Techniques

Developments in nonchromatographic separation techniques, such as capillary electrophoresis, in which an applied electric potential is used to drive the separation of charged species, are occurring rapidly. The combination or merger of chromatography and flow injection analysis (FIA) is also on the horizon.

Spectroscopic or Radiant Energy Techniques

This family of sensors uses the interaction of electromagnetic radiation with matter. Most commonly, the technique operates on either absorption or reflection principles, but fluorescence and scattering are also used.

If radiation at different wavelengths is passed through a process material, the amount of absorption may be an indicator of sample identity or composition. The output of such an analyzer is related to the absorption of the light in a linear way, as shown in Beer's law (more correctly, the Lambert–Beer law) of radiation absorption. (Transmission is logarithmic with respect to light transmission, but linear with absorption and concentration.)

$$A = abc = \log \frac{I_0}{I} \qquad \textbf{8.1(1)}$$

where
A = absorbance
a = molar absorption or extinction coefficient (a constant for any given compound and wavelength)
b = sample path length
c = absorber (sample) concentration
I_0 = incident radiation
I = radiation leaving sample

The region of the spectrum used for the measurement varies with the kind of compound and information desired (Table 8.1b). In addition, the instrument itself will be quite different in specific components since the properties of the light vary. Instruments to make these measurements can vary from single-wavelength photometers to grating instruments to multiplex designs, depending on the spectral region and the needs of the measurement.

Ultraviolet and Visible

These regions of the spectrum are similar and are generally grouped together. In fact, most laboratory instruments for this region include both. The energy of this region corresponds to electronic transitions in compounds. In the UV, compounds with double bonds, such as those in Table 8.1c, are commonly measured. Other functional groups with π electrons are also excellent absorbers (Table 8.1d). Vis absorbers are compounds that are colored to the human eye. Obviously, dyes, inks, etc. are readily measured in the visible portion of the spectrum. One major thing to watch out for is that compounds that absorb in this region may be such strong absorbers that a short path length is needed to get a good response, and only very low concentrations can be measured. Reducing the path length may help, but too small a path length in a typical process stream will act as a filter and cause the measurement to fail.

- Sulfuric acid
- Toluene
- Trichlorobenzene
- Xylene (*ortho*, *meta*, and *para*)

Fluorescence

When radiation of one wavelength is absorbed by a molecule with the appropriate molecular structure, it can be remitted at a higher wavelength (lower energy). This process, called fluorescence, is an extremely useful measurement technique, provided that the analyte has the appropriate structure. Molecules with many double bonds, especially conjugated double bonds, will fluoresce. Many biomolecules, including some vitamins, proteins, cofactors, and the like, fluoresce, allowing the technique to be used in fermentation and other bioprocessing. Crude oil also contains fluorescent molecules; low levels of oil on water are frequently detected using fluorescence. Table 8.1e provides a list of some fluorescent compounds along with their excitation and fluorescence (emission) wavelengths maxima.

Infrared and Near-Infrared

Infrared (IR) instruments were one of the first analyzers to be moved from the laboratory to the pipeline, and the technology is available for use with gas, liquid, or solid samples. In the absorption mode of operation on liquid samples, the path length has to be very short, though not as short as in the UV. Noncontacting backscatter designs readily measure moisture in solids (e.g., conveyor belts of flour) or composition with fiber-optic probes (FOPs) in liquids. The probe version of the IR analyzer eliminates the need for a sampling system and can be used in both liquid and gas phase processes. NIR is widely used for moisture measurement. Probably every paper machine in the world has an IR or NIR analyzer to

Absorption Bands of Some Raman and Infrared-Absorbing Chromophores

Chromophore (Functional Group)	*Region* (cm^{-1})	*Intensity*	
		Raman	*Infrared*
CC aliphatic chains	250–400	Strong	Weak
S—S	430–550	Strong	Weak
Si—O—Si	450–550	Strong	Weak
C—Cl	550–800	Strong	Strong
C—O—C	800–970	Medium	Weak
O—O	845–900	Strong	Weak
C—O—C asymmetric	1060–1150	Weak	Strong
CH_3	1380	Medium	Strong
CH_2, CH_3 asymmetric	1400–1470	Medium	Medium
N═N aromatic	1410–1440	Medium	—
C═C	1500–1900	Strong	Weak
C═N	1610–1680	Strong	Medium
H_2O	1640	Weak	Strong
C═O	1680–1820	Medium	Strong
C≡C	2100–2250	Strong	Weak
C≡N	2220–2255	Medium	Strong
C—H	2800–3000	Strong	Strong
O—H	3100–3650	Weak	Strong

Note: Intensities and wave number ranges are approximate and may vary with exact compounds.

measure and control drying. NIR instruments can be filter photometers or spectral instruments using gratings, interferometers, or acousto-optic tunable filters (AOTFs) to select the wavelengths needed for the measurement. Table 8.1f and Figure 8.1g give some absorption wavelengths for various organic functional groups in the IR and NIR regions.

Raman

In recent years, the Raman spectrometer has moved from the laboratory to the process floor. This has been driven by the combination of improved lasers, fiber optics, and compact spectrometer designs. Raman spectroscopy is complementary to IR and provides similar functional group information. Raman spectroscopy obtains its information from the scattering of light from molecules. It is amenable to direct, noninvasive sampling of solids and liquids. Water and glass are weak Raman scatters, providing the opportunity to investigate samples in aqueous media and through glass site windows, or a glass container, or via FOPs. Reports of Raman being used to monitor polymerization reactions and distillation processes are among the growing number of published applications. Use of NIR laser diodes has reduced the problem of background fluorescence. Table 8.1f compares some molecular absorption bands in the IR and Raman.

Microwave and Radio Frequency

Microwave and radio frequency (Rf) analyzers operate in both the absorption and reflection modes. Their most common

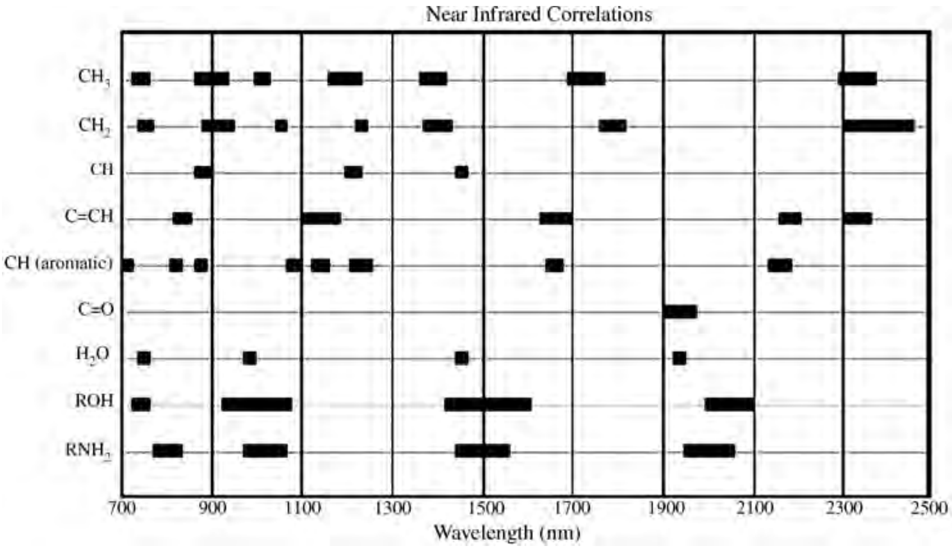

FIG. 8.1g
Absorption bands of some NIR-absorbing chromophores.

application is in the measurement of moisture in solids—without requiring physical contact with the sample. In these wavelength regions, dielectric properties are probed by the radiation; hence water, with its high dielectric constant (~78), compared to many common organic compounds (<5), is readily determined (e.g., moisture in wood). The technique is also used for binary solutions. Compared to the previously described spectral regions, this is a relative newcomer to process measurement. Tables of dielectric constants may be found in References 9 and 10.

Refractometry

The RI is a unique property of a chemical compound, based on the fact that light travels at different speeds in different media, and as such can be used for composition determination in binary systems and for various nonspecific concentration measurements, e.g., dissolved solids, black liquor, and Brix (sugar). Snell's law expresses the relationship between RI, the angle of incidence (α), and the angle of refraction (β) as light of a given wavelength passes through the interface between two materials.

$$\mathrm{RI} = \frac{\sin\alpha}{\sin\beta} \qquad \textbf{8.1(2)}$$

Most refractometers use visible light, but at least one uses a diode source that emits just beyond the red. Differential refractometers utilize this relationship by keeping α constant; therefore, a measurement of β expresses RI. At a critical value of α, the light is totally reflected; the measurement of this angle can also be related to RI as follows:

$$\alpha_{\text{critical}} = \text{arc sin}\left(\frac{\text{variable sample RI}}{\text{fixed prism RI}}\right) \qquad \textbf{8.1(3)}$$

Although less sensitive, this latter technique (critical angle refractometry) requires no sampling system and, therefore, is preferred for on-stream applications. In fact, it has practically replaced the differential refractometer in all but the most demanding applications. It should be noted, though, that the critical angle refractometer only measures the RI of that portion of the sample that is in direct contact with the crystal. If even a thin coating develops on the surface, the readings will be useless. A variety of cleaning systems may be used if this is a problem. Turbulent flow has proven useful in minimizing fouling. (For a listing of refractive indexes, see Table 8.1h.)

Turbidity and Particle Size

As with refractometers, turbidity sensors also work with light, but make use of light scattering to measure the suspended solids in the liquid. Depending on the concentration of the particles, turbidity can be measured at 90°, 180°, or complete backscatter. (Technically, turbidity is the term applied to the straight-through approach, and nephelometry is used for the scattering measurement.) In addition to scattered light, some light may be absorbed by the liquid. Since there is a particle size dependence to light scatter, instruments are also available that use scattering to measure particle size distribution. Turbidity instruments are quite commonly used to monitor filtering systems, centrifuges, etc., for breakthrough, whereas the more expensive particle size instruments find use monitoring crystallization and polymerization processes.

Nuclear Techniques

A variety of techniques utilizing x-rays and other radiation sources are used in process measurements. X-ray fluorescence (XRF) is widely used to determine metal concentrations in slurries and to measure silicon coatings on paper. (XRF works

TABLE 8.1h

Note: All data based on 68°F (20°C).

by exciting an inner-shell electron of an element, causing an x-ray to be emitted. The energy (wavelength) of the emitted x-ray is indicative of the element, and the number of x-rays is proportional to concentration. The excitation radiation can come from an x-ray tube or a radioactive source.)

The absorption or backscatter of neutron or gamma radiation can also be correlated to composition in some systems. Neutrons have been used to measure the moisture content of solids in processes in which hydrogen is present only in the free water and is not bonded to the other molecules (or is relatively constant in the nonwater part of the matrix). For example, the moisture of wood chips in pulping has been determined by this technique. Gamma rays, which are extremely energetic, are absorbed nonspecifically, and their attenuation can be used as a measure of density. Since gamma rays can penetrate metallic walls, they can give composition data for binary systems without contacting the process stream. These techniques are also used extensively as a noninvasive way to measure tank or pipe level, density within a pipe, and the like.

ELECTROCHEMICAL SENSORS

Several kinds of measurements make direct use of electricity in the measurement. These are potentiometric, wherein an electric potential is measured and the solution remains unchanged; conductive, in which a minute current is measured, but the system is essentially unchanged; and amperometric, in which a chemical reaction occurs during the course of the measurement.

The basic principle of their operation for a system in which a reactant, R, goes to a product, P, is the Nernst equation:

$$\mathrm{E} = \mathrm{E}^0 - \frac{\mathrm{RT}}{\mathrm{nF}} \ln \frac{C_P^0}{C_R^0} \qquad \mathbf{8.1(4)}$$

where

E = applied potential
E^0 = standard potential for the system (the chemistry of the reaction being measured)
R = the molar gas constant
T = the absolute temperature (°K)
n = the number of electrons involved in the reaction
F = Faraday constant
C_P^0 = the concentration of product at the electrode surface
C_R^0 = the concentration of reactant at the electrode surface

Potentiometric

The family of analytical sensors that detect the electrical potential generated in response to the presence of dissolved, ionized solids in a solution include pH, oxidation–reduction potential (ORP), and ion-selective electrodes (ISEs) or probes. In potentiometric analysis, the potential difference between two electrodes (reference and measurement) is determined. As these two electrodes must be electrically connected, another potential, the junction potential, is also inherent to the measurement. (In fact, most of the problems of process pH measurement occur because of fouling of the junction.)

For these measurements, the Nernst equation can be rewritten to:

$$\mathrm{E}_{\mathrm{cell}} = \mathrm{K} + \frac{\mathrm{RT}}{z_i\mathrm{F}} \ln\left(a_i + k_{ij} a_j^{\left(\frac{z_i}{z_j}\right)}\right) + \mathrm{E}_{\mathrm{LJ}} \qquad \mathbf{8.1(5)}$$

where

$\mathrm{E}_{\mathrm{cell}}$ = the measured potential
K = is a constant for the measurement system (electrode, etc.)
R = the molar gas constant
T = the absolute temperature (°K)
F = Faraday constant
a_i = the activity of the analyte ion, i
a_j = the activity of an interfering ion, j
k_{ij} = selectivity coefficient
z_i and z_j = the charges of ions i and j, respectively
E_{LJ} = the liquid junction potential

It can be further simplified in *dilute* solutions (where activity and concentration are approximately equal) to

$$E_{cell} = K + \frac{0.0592 \log c}{n} \qquad \textbf{8.1(6)}$$

where

c = the concentration of analyte
n = charge of the analyte ion
0.0592 = the combination of the RT/F at 25°C

ORP sensors are available in probe designs to detect the ratio of reducing agent to oxidizing agent—an important parameter in effluent treatment controls, for example.

ISEs are also based on the Nernst law. If total ionized solids (conductivity) are constant, a correlation can be drawn between the activity of a specific ion and its concentration in the process stream. The ideal reference electrode produces a constant potential that is independent of the composition of the solution. A perfect measuring electrode gives a 59-mV change in potential for each tenfold change in the *activity* of a monovalent ion. It is important to emphasize that it is the *activity* of free ions that the electrodes respond to and *not* the concentration. It is important to understand that according to the Nernst equation, concentration, c, can be determined by the measurement of activity (activity = γc, where γ is the activity coefficient of the ion) *only if* the other variables of the equation are *constant*. To achieve this involves scrupulous design; occasionally, it also requires sample preparation. Frequently, in real-world applications, calibration of the electrode in the matrix, over a limited analyte range, can be used to minimize concerns over activity–concentration discrepancies.

Unless the interferences to which ion-selective measurements are subject can be recognized and eliminated in the potential installations, misapplications are likely. The available ISEs are listed in Table 8.1i, where they are also grouped by the type of membrane utilized. Coating or material buildup on the membranes calls for the same degree of maintenance as required for pH electrodes.

pH sensors are ISEs, sensitive to the activity of hydrogen ions in the process stream, and as such, reflect the acidity or alkalinity of the sample. pH is one of the most commonly made measurements in industry. On the surface, it appears to be easy to measure pH, since all that is needed is the insertion of the probe into the process, but in practice, it is not so simple. Probes may become fouled on the sensing surface; most are made of glass and quite fragile; concentrated solutions, or ones that are not aqueous, stretch the definition of pH (which is for dilute aqueous solutions), and high purity water (e.g., boilers)

TABLE 8.1i
Ion-Selective Electrodes: Types and Applications

Ion	*Type of Electrode*	*Lower Detectable Limit (ppm)*	*Principal Interferences*
Bromide	Solid state	0.4	CN^-, I^-, S^-
Cadmium	Solid state	0.01	Ag^+, Hg^{++}, Cu^{++}, Fe^{++}, Pb^{++}
Calcium	Liquid–ion exchange	0.4	Zn^{++}, Fe^{++}, Pb^{++}, Cu^{++}, Ni^{++}, Sr^{++}, Mg^{++}, Ba^{++}

Redox	Solid state	Varies	All redox systems
Silver	Solid state	0.01	Hg^{++}
Sodium	Solid state	0.02	Ag^+, H^+, Li^+, K^+
Sulfide	Solid state	0.003	
Thiocyanate	Solid state	0.6	I^-, $S_2O_3^-$, Br^-, CI^-, NH_3
Water hardness	Liquid–ion exchange	0.001	Zn^{++}, Fe^{++}, Cu^{++}, Ni^{++}, Ba^{++}, Sr^{++}

requires specially designed probes, if it is to work at all. Recent improvements in electronics have reduced drift, instability, and transmission distance limitations. Combination electrodes (measurement and reference), gel fill *solutions*, and the development of various electrode-cleaning devices, such as air and water jets, and mechanical and ultrasonic cleaners have reduced many of the problems. New nonglass electrodes based on ion-sensitive field effect transistors (ISFETs) have opened up new applications where glass has been problematic (e.g., food and beverage processes). Automation of the removal, cleaning, and reinsertion of pH probes is now available "off-the-shelf" for those applications that require nearly continuous pH measurement and cannot tolerate downtime for maintenance. Nevertheless, despite all this activity, pH remains a difficult measurement for which installation of standby spare sensors and scheduled periodic maintenance are likely to be necessary.

Conductive

Conductivity sensors measure a solution's ability to conduct electricity, which is a function of all dissolved ionized solids in the solution. Two basic kinds of conductance measurement instrument are available: direct contact and inductive. The direct device makes direct, electrical contact with the process solution with two (or sometimes four) electrodes and measures the flow of electricity from one electrode to the other. Any fouling of the probes, which affects electric contact, requires cleaning of the probes. The inductive type is less sensitive to fouling because it does not make electrical contact with the process fluid. Toroidal (donut shapes are common) probes use several electric coils to probe the electric properties of the fluid. The probe is coated with an inert material such as a fluorocarbon. Another design builds the inductive probe directly into a pipe spool piece. Inductive conductance probes are widely used to measure the concentration of strong acid and base solutions. Plots of conductivity vs. concentration of various electrolytes are used to determine if an application is suitable for these devices. Conductance data for various compounds are available in various chemical handbooks and an excellent compilation from a vendor.[9–11]

Amperometric

Amperometric, also known as galvanic and polarographic, cells induce a reaction in the sample by applying a high enough voltage. The resulting current is measured and is proportional to the concentration of the species reacting. The electrolyte and electrodes are separated from the process stream by a membrane, a feature that eliminates the need for a sample system and can perform well *if* the membrane is kept clean. (Of course, the analyte molecules must diffuse through the membrane into the electrolyte to the electrodes if there is to be a reaction and resulting signal.) In the world of process measurements, such instruments are commonly used to measure oxygen, including both dissolved oxygen in liquids and vapor phase oxygen in gas samples. Membrane-separated amperometric sensors are also used for other gases, such as CO, H_2S, and Cl_2. Sensors using this concept are also being developed for bioanalytes such as glucose, where a specific enzyme is part of the measurement system.

Chemical Techniques

In-process measurement using wet chemical methods can be performed in two different ways: batch, or discontinuous and continuous.

Process autotitrators draw a sample from the process at a regular interval and deliver the sample to a titration vessel. Once in the vessel, the sample may be diluted or prepared in other ways for a titration, very similar to a titration performed in the lab. An autoburet delivers the titrant until an end point is sensed. The titration cell is then drained and rinsed, and a new sample is drawn. Cycle times depend on the chemistry, but are typically 5 to 15 min. The end point may be determined potentiometrically, conductimetrically, or photometrically. Methods to measure acid value (number) are common examples.

In continuously flowing wet chemistry methods, a very small sample is injected into a flowing stream that can be a solvent or a reagent. (In some applications, a small portion of the process stream is the carrier and reagent is injected into it.) Additional reagent(s) can be added, as can heat, mixing, time to allow a reaction, etc., until the reacted sample reaches a detector. Detectors are most commonly photometers, but flow-through pH and other electrochemical detectors are also available. The flowing system can be continuous (flow injection analysis), bubble segmented (as in autoanalyzers), or a variant of FIA, sequential injection, in which a rotary valve takes the place of much of the tubing.[12]

Miscellaneous Techniques

Quartz Crystal Microbalances Certain crystals are known to generate an electric signal when they are deformed; conversely, these crystals can be caused to move when a voltage is applied. These phenomena are known as the piezoelectric effect, and it has been used to create sensors. The former effect has been used to detect pressure, acceleration, temperature, force, and thickness; the latter effect has been applied to measure various analytes, including moisture, in gases. The frequency of crystal oscillation is affected by the mass of material on the crystal, so that a crystal coated with an absorbent material will vibrate differently when the coating absorbs more or less analyte. If the specificity of the coating is high, a sensitive and specific analytical sensor can be developed. Surface acoustic wave (SAW) sensors, in which the speed of sound transmission through the coating is affected by the absorbed analyte, can be even more sensitive.

Mass Spectrometry Previously only available for gas streams, mass spectrometry (MS) is becoming available for liquids as well. Various approaches to the method are used, but all require a gaseous sample (vaporized, if necessary) that is injected into a vacuum and ionized (usually by an electron beam). The ionized sample molecules and the charged fragments of their decomposition are then sorted and measured by their mass-to-charge ratio. This last process can be accomplished by the time of flight of the ions down an evacuated tube, their trajectory through a magnetic field, or selection by an electrostatic field. Detection is by electron multipliers or other devices. The most common application of process MS is in gas plants, where many gases can be detected simultaneously, or multiple streams can be examined sequentially.

Nuclear Magnetic Resonance Nuclear magnetic resonance (NMR) is an excellent technique for compositional information. In the laboratory, it is widely used to identify unknown materials. Its use in process analysis is a relatively recent occurrence. NMR makes use of a fundamental property of all matter—its nuclear structure. (Despite the fears of the public, NMR is not a technique involving radiation. If an application is contemplated using NMR, this will need to be explained to plant personnel.) NMR probes the molecules by applying both a magnetic and Rf field. Depending on the instrument, this can yield a simple number or a relatively high resolution spectrum. NMR can only measure nuclei of atoms with a magnetic moment (caused by an odd number of neutrons or protons). Therefore, the technique can only be used to measure species containing ^{1}H, ^{13}C, ^{14}N, ^{19}F, and ^{31}P. From a practical standpoint, process instruments have not yet been built that are sensitive enough to be used with anything other than proton NMR. Low-resolution (wide-band or pulsed) NMR units are useful for the measurement of free (unbound) proton-rich compounds such as water or oil.

Analyte-Specific Techniques

Many analytes have unique characteristics that have led to instruments designed specifically for their measurement. Water[13] and oxygen stand out as examples.

Water The measurement of water in the gas phase (humidity) is one of the most common. There may be more patents for humidity sensors than any other measurement. With so many different approaches for the measurement, selection of the appropriate one for a given application is both complicated and critical.

In the liquid or solid phase, moisture measurement can also be made with a wide variety of techniques. Already mentioned in this chapter were IR and NIR, microwave and Rf, and neutron techniques. In addition, there are techniques based on capacitance, impedance, and electrical resistance.

Several chapters of this book are devoted to water measurement in more detail.

Oxygen Oxygen is an important and unique analyte in industry. It is measured as the element in both gas and liquid samples. In the gas phase, it is important for breathing (environmental sensing), combustion control, and chemical stability. As mentioned previously, oxygen is paramagnetic and can be measured using this property. Such instruments operate best in relatively clean, noncondensing environments with oxygen levels from ~0.5% to ambient levels. Oxygen can also be measured electrochemically, and several varieties of instruments are available using different electrochemical techniques. High-temperature catalytic instruments are most commonly used in combustion control applications where the gas stream is already hot and the oxygen level is low. Fuel cell (amperometric) devices are also available. They require periodic replacement of the fuel cell, as it is a consumable part of the measurement.

Oxygen dissolved in water (and other liquids) can also be measured with an electrochemical probe. The oxygen diffuses through a membrane to the active electrode.

One of the parameters of interest in pollution control is the oxygen demand of the effluent. This is a measure of the organic load in the system, which will potentially use oxygen as it is consumed by microorganisms (biological oxygen demand (BOD)) or reacts chemically (chemical oxygen demand (COD)). Laboratory measurement of BOD takes several days of incubation and requires the sample to be inoculated with the appropriate organisms. Instruments are available that can reduce this time. Total organic carbon (TOC) analyzers give a close correlation to COD. Several different approaches are taken by the commercially available instruments. However, in all cases, the sample stream is first digested, and then the carbon dioxide formed from this combustion step is measured. The digestion may be strictly chemical or UV light induced (with catalyst). The resulting CO_2 is measured either directly by infrared photometry or by the change in conductivity of water into which the CO_2 is dissolved. The entire cycle is completed in a few minutes.

SAMPLING

Perhaps the most critical aspect of any analyzer installation is the sampling mechanism. The data an instrument generates can be no better than the sample it has been presented for analysis. Sampling is such an important area that entire books have been published on that subject alone.[14–16] In this volume, there are several chapters on sampling.

In the discussion above, mention has been made of analyzers, such as chromatographs, that require the sample to be withdrawn from the process and delivered to the instrument. For such instruments, there is no option, but for many of the spectroscopic and electrochemical analyzers, the option of using directly inserted probes is available.

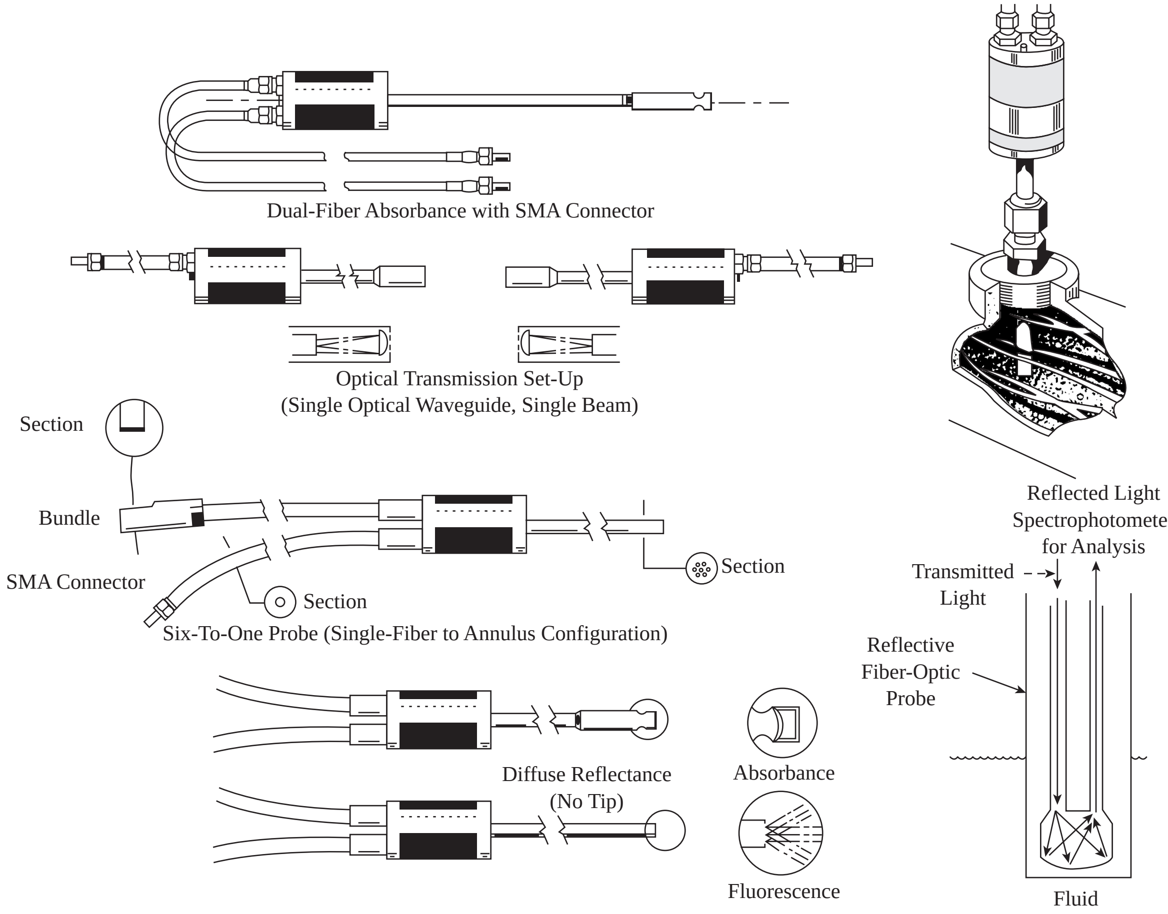

FIG. 8.1j
Fiber-optic probes can provide data on absorbance, diffuse reflectance, fluorescence, and scattering. (Courtesy of Guided Wave, Inc., http://www.guided-wave.com.)

Probe-type analyzers have been used for a long time to measure pH, conductivity, selective ion, dissolved oxygen, relative humidity, residual chlorine, oxidation–reduction potential, differential vapor pressure, corrosion, and many other variables. Improvements in quality and cost of fiber-optic probes have made them widely available for in-line measurement.

Fiber-optic probes use waveguides made of glass or quartz or other more esoteric material to deliver and return the process-modified light from the probe to the instrument located some distance away, frequently in a control room (Figure 8.1j). FOPs can acquire data on spectral absorbance, diffuse reflectance, fluorescence, or scattering, and several FOPs can be multiplexed to the same computer-controlled analyzer. Performing spectroscopic measurements over FOPs first became popular with near-infrared instruments, but their use in the UV-Vis and IR regions has grown as well.

Insertion probe critical angle refractometers are available. RI units are also available with fiber-optic sensing and transmission (Figure 8.1k). They claim the same advantages of all FOP instruments—minimal consumption of space on the pipe and ease of access to hard-to-reach locations—and they are unaffected by electromagnetic interference, dust, humidity, or hazardous environments. Measurements can be transmitted over large distances, up to 1 km (0.625 mi).

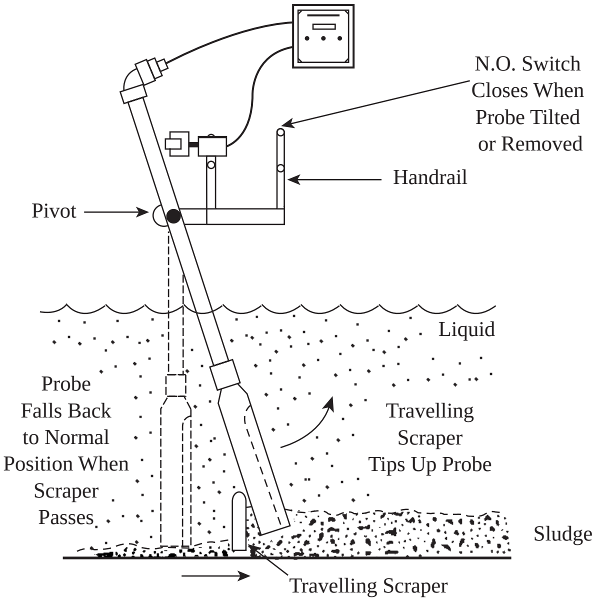

FIG. 8.1l
Probe-type sensors are used to detect the location and density of sludge and slurry layers in clarifiers. (Courtesy of Markland Specialty Engineering, Ltd., http://www.sludgecontrols.com.)

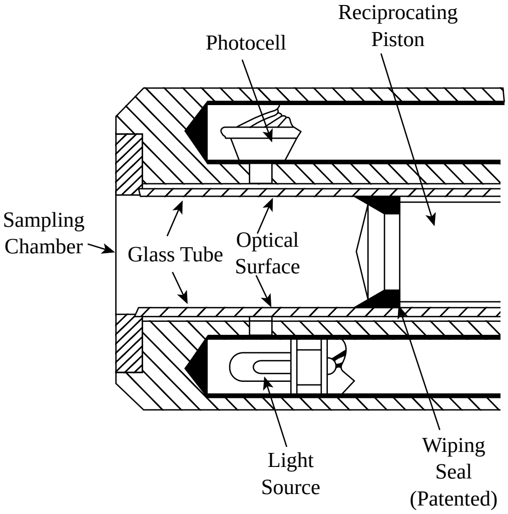

FIG. 8.1m
Probe-type self-cleaning suspended solids detector. (Courtesy of Monitek Technologies, Inc., a Metrisa Company, http://www.monitek.com.)

Probe-type sensors have also been developed for sludge and slurry measurement applications. These include the detection of sludge levels, interfaces, and densities in clarifiers and digesters (Figure 8.1l).

Figure 8.1m illustrates a mechanically self-cleaning probe design used to measure the suspended solids concentration in biological sludge. In this design, a motor-driven reciprocating piston located within a glass tube is stroked once every 15 sec. This action serves to refresh the sample while at the same time eliminating deposits and wiping the optical surfaces clean of dirt or slime. The result is a low-maintenance installation that provides reliable measurements of suspended solids concentration.

In-line, probe-type analyzers are also used in stack gas composition measurement. Some of the microprocessor-based designs also provide self-calibration for both zero and span. In addition, they can provide automatic cleaning and drying to accommodate wet-scrubber applications, in which it is necessary to periodically force hot and pressurized instrument air into the probe cavity to thoroughly dry the diffuser. The measurement is made by analyzing the measurement beam as it is returned by the retroreflector within the probe's gas measurement cavity (Figure 8.1n). These probe-type stack gas analyzers can operate in locations with high water vapor and particulate loadings and at temperatures up to 800°F (427°C).

A relatively new development in the area of in-stack analyzers is the introduction of acousto-optic tunable filters. Their main advantage is speed and the elimination of maintenance-prone mechanical elements such as filter wheels, moving gas cells and mirrors, diffraction gratings, and mechanical light choppers. The AOTF acts as an electronically controllable narrow-band filter that can be tuned to any desired frequency in milliseconds. As shown in Figure 8.1o, the resulting beam at the selected wavelength is directed across the stack and can simultaneously measure the concentrations of CO, CO_2, C_2H_6, CH_4, NO, NO_2, H_2O, etc. This is achieved by the computer selecting the frequencies required for the measurement of the concentration of each component and the AOTF being tuned to each of the selected frequencies one at a time, but at a high speed. This results in a “scanning” spectrometer without moving parts.

Probe Cleaners

While probe-type in-line analyzers can eliminate the transportation lag and sample deterioration problems associated with on-line analysis, they are not without problems of their own, the largest of which is fouling. Various mechanisms are available to clean the probe automatically. It is recommended that when a probe cleaner is used, it be placed inside a sight glass so that the operator can continuously observe the performance of the cleaner (Figure 8.1p). Wide varieties of probe-cleaning devices are available on the market. Their features and capabilities for various types of coatings, and a list of their suppliers are given in Table 8.1q. Probe cleaners for pH and other electrodes have been available for many years.

If there is no sampling system, the integrity of the sample is automatically guaranteed, and preference should be given to sensors that penetrate the process pipe with a retractable, cleanable probe. Probe sensors, either solid or membrane, require periodic cleaning, which can be done manually, by withdrawing the probe through an isolating valve so that the

Many or most vendors of electrodes can provide self-cleaning or auto-cleaning capability for their systems. Many operate on a timer, cleaning the electrode periodically. Some can automatically extract a probe from the process, clean, and even recalibrate before reinserting it into the line. For example, pH, ORP, and ISE probe vendors GLI (Great Lakes, http://www.gliint.com) and Foxboro (http://www.foxboro.com/index.htm) have a variety of systems to clean electrodes, including ultrasonic, brushes, and Teflon balls.

process is not opened when the electrode is cleaned, or automatically. Automatic probe-cleaning devices may be pressurized liquid or gas jets, or thermal, mechanical, or ultrasonic cleaning and scraping devices.

ANALYZER LOCATION

The location of the analyzer can be critical to the success of the installation. If the instrument is to be installed at some distance from the process, the lines bringing the sample to the instrument must be considered. Many questions will need to be answered. For example, what is the lag time to reach the instrument? Do the lines need heat tracing? Will the sample be returned to the process?

Ambient conditions for the analyzer must be considered. Should the instrument or several instruments be housed in an analyzer house or shelter? Instruments require power and other utilities that must be included in the planning. Access to the instrument for maintenance, local readout or display of the measured value, or of diagnostic information should be considered. Quality of the electrical power can be critical, as many microprocessors in analyzers can be reset or damaged by voltage spikes.

If a sampling system is used, variation in pressure in vents and drains, and oil or moisture, or both, in air lines can wreak havoc on the system. The temperature and humidity of the atmosphere surrounding the analyzer may also contribute to unreliable performance.

Fire and explosion are the major safety hazards of analyzer installations (See Table 8.1r). The safety of analyzer houses is also a consideration. (See Sidebar 8.1s by Georg Erk.) The inability of most laboratory instruments to meet electrical requirements limits their use in on-line applications. Often, however, purging an analyzer that is not explosion-proof allows it to be used in hazardous areas. Samples or stored reagents containing toxic, flammable, or noxious substances are also safety hazards. This can be a major issue when considering liquid chromatography analyzers, for example.

TABLE 8.1r
Electrical Area Classifications

Flammable Gas Class I	*Combustible Dust Class II*	*Ignitable Fibers Class III*
Group A: acetylene	Group E: metal dust, aluminum, magnesium, etc.	No groups listed
Group B: hydrogen or manufactured gas	Group F: carbon black, coal or coke dust	
Group C: ethyl-ether, ethylene, cyclopropane	Group G: flour, starch, grain dust	
Group D: gasoline, hexane, naphtha, benzene, propane, butane, alcohol, acetone, benzol, lacquer solvent, natural gas		
Division 1 Division 2	***Division 1 Division 2***	***Division 1 Division 2***

Class I Flammable Gases	
Division 1 Locations	*Division 2 Locations*
Locations in which:	Locations in which:
(1) Hazardous concentrations exist continuously, intermittently, or periodically under normal operating conditions.	(1) Gases are handled, processed, or used, but will normally be confined to closed containers or systems from which they can escape only in accidental rupture or abnormal operation of equipment.
(2) Gases exist frequently because of repair, maintenance, operations, or leakage.	(2) Gases are normally prevented by positive ventilation, but might become hazardous through failure of ventilating equipment.
(3) Breakdown or faulty operation might release gases that might cause simultaneous failure of electrical equipment.	(3) Adjacent to Class I, Division I locations in which gases might occasionally be communicated.

HANDLING THE DATA

Another issue that must be considered during the analyzer selection process regards the data. How will the valuable data your instrument and sampling system have generated be transferred from the analyzer to the people and control system computer that can make use of it? What kind of output is there? Will there be a local display?

For years, most analyzers provided only an analog output of current (most common, and typically 4 to 20 mA) or voltage. In recent years, this has changed so that more and more analyzers provide a digital output, as well as, or instead of, the analog output. In the case of the analog output, analyzers generally need to be calibrated in two ways. First, as already mentioned, calibration standards (knowns or samples that are independently measured by the lab) are determined and used to set the instrument, frequently just a zero and span setting. The second calibration is more of an adjustment. The output of the analog signal must be set. In other words, the low and high output must be made to read correctly. Frequently this must also be matched to the input on the control system. For example, an NIR calibrated to read percent moisture of wheat flour from 0 to 25% might have its 4 to 20 mA output set so that 4 mA equals 10% moisture and 20 mA equals 25%, thus providing higher resolution for the output.

Newer-style analyzers provide digital outputs. These may be a relatively simple ASCII output using an RS232 connection or Ethernet, TCPIP, etc. If an analyzer provides a single piece of information, such as moisture, the issue is quite different from another analyzer that measures a process stream and transmits the concentrations of five different constituents, e.g., a gas chromatograph measuring three alkanes, two alkenes, and several aromatic compounds.

Even more complex is the question of chemometric models that are used by some spectral techniques (IR, NIR, for example) and are beginning to be used in chromatography as well.

When selecting the analyzer for an installation, the data handling must be considered. What inputs are available on the control system? Will chemometric calculations be done on the analyzer system or a separate computer system or by the control system? What kind of cable is needed for the data transmission, and over what distance can it be used without degrading the signal? How does that affect installation cost?

MAINTENANCE

Analyzer hardware is likely to receive better care if it is accessible and housed in pleasant surroundings, such as in air-conditioned buildings. Spare parts and special testing components should be ordered at the same time as the system to avoid future delays; the availability and most effective use of qualified maintenance personnel are also factors of major importance.

Analyzers already used in the plant are helpful in determining maintenance and spare parts requirements. Major subassemblies not stocked as spare parts can also be interchanged and can help to obviate waiting for parts for the duplicated system. Standardizing on one model of a particular analyzer within a site will reduce training and spare parts costs.

COST

For the approximate cost ranges of the various analyzer categories, refer to Table 8.1t, and for more accurate costs of the various analyzers, refer to the feature summaries at the beginning of each section in this chapter. The cost elements of an analyzer installation include the following:

Engineering study
Analyzer
Recorder or other display hardware
Sample system
Startup and checkout in the laboratory

Sidebar 8.1s

Safety of Analyzer Houses (by Georg Erk)

With major input from the U.S. National Delegation and under its leadership, the International Technical Commission issued the document "Safety of Analyser Houses," IEC 61285 Ed. 1.0.b: 1994.

This document discusses all aspects of the safety of analyzer houses. It is recommended that the reader obtain the full document for detailed information, specifications, and documentation for the design and installation of analyzer houses and their components. It is available from:

Customer Service
American National Standards Institute
25 West 43rd Street
New York, NY 19936
Telephone: 212 642-4980
Fax: 212 302-1286

www.ansi.org and their Information Handling Service—Global Engineering Documents
Hard copy: U.S. $96
Electronic: U.S. $89

The major concepts of this international standard are:

Analyzers and analyzer sampling system require varying degrees of protection. In some cases, the instrument itself may require additional protection, such as an analyzer case, analyzer cabinet, a shelter, or a house. The selection of the housing may be determined by the minimal protection requirement.

The highest cost installation is the house, but it is generally justified when regular attention is needed and a high service factor is expected. For installation in extreme conditions, the house may need a natural or a forced ventilation system.

The electrical area classification for the location of the house should be in accordance with IEC 60079-10.

If toxic materials are introduced into the house, the ventilation system must ensure that the occupational exposure limit (OEL) is not exceeded under normal or any likely fault condition.

Safety monitoring and alarm systems can vary considerably from simple alarms direct from the analyzer to announce, for example, purge failure; to interactive systems taking inputs from gas detectors, fire detectors, and ventilation monitors; to initiate alarms, automatic shutdowns, extinguisher release, and interlocks on ventilation systems control.

Types of failure in the system that require monitoring, alarming, or shutdown systems are ventilation failures, flammable gas or vapor detection, toxic gas detection, oxygen deficiency detection, fire detection and protection, and purge failure.

Alarms generated and displayed may be local audible and visual systems, but in most cases, they will also require transmittal to the plant operator and into the central control room.

On a more general note, IEC Technical Report IEC/TR 61831: 1999, "On-Line Analyzer Systems: Guide to Design and Installation," an 84-page document, defines many more items for consideration when dealing with design, installation, and documentation of analyzer systems. The first edition of this document was printed in July 1999 and may be available directly from IEC as follows:

SUMMARY

In an analyzer project, there are many different options and choices to be made. The skilled analyzer engineer or chemist must make many decisions and, in general, none of them are right or wrong; as in most of life, compromise is the order of the day. We must balance the cost, complexity, maintainability, etc., against the value of the measurement data to the process and make our choices. Tables 8.1t to 8.1v provide some summary and comparison information that may help clarify the different techniques and which one might be best for a given analyzer project. Table 8.1t compares key attributes (cost, complexity, type of sample, etc.) for many of the techniques covered in this section. Table 8.1u provides analyzer suggestions for some commonly measured analytes. Finally, Table 8.1v provides suggestions for analysis techniques for some common analyzer applications. All three tables should be taken (and used) with

TABLE 8.1t

Summary of Some Attributes of Major Analyzer Approaches

Use this table as a basic guide. It provides you with a starting point, to help you think about the analyte's measurable attribute. Usually, several methods will be applicable to any given analyte, depending on concentration, matrix, etc.

Technique	*Cost*	*Complexity*	*Calibration*	*Sample Phase*	*Sampling System*	*Selectivity*	*Mode*	*Range*
Gas chromatography	2, 3	2, 3	1	1, 2	3	1	1a, 3	1, 2, 3
Liquid chromatography	3	3	1	2	3	1	1a, 3	1, 2, 3
IC	3	3	1	2	3	1	1a, 3	1, 2, 3
UV-Vis								
Filters (1–2 wavelengths)	1	1	1	1, 2	1	1, 2, 3	1a, 2	1, 2, 3
Full spectrum	2, 3	1	2, 3	1, 2, 3	1	1, 2, 3	1a, 2	1, 2, 3
Fluorescence (filter)	2	1	2	2, 3	1	1, 2	1a	1, 2
NIR								
Filters (2–6 wavelengths)	2	1	2	2, 3	1, 2	2	1a, 2	2, 3
Full spectrum	3	2, 3	3	2, 3	1, 2	2	1a, 1b, 2	2, 3
IR								
Filters (2–6 wavelengths)	2	1	2	1, 2, 3	1, 2	1, 2	1a, 1b, 2	2, 3
Full spectrum	3	2, 3	3	1, 2	1, 2	1, 2	1a, 1b, 2	2, 3
Raman, with fiber optics	3	2, 3	2, 3	2	2	2	1b, 2	2, 3
Microwave/Rf	2, 3	2	2	2, 3	2	3	1a, 1b, 2	2, 3
RI	1, 2	1	1	2	1	3	1b, 3	2, 3
Turbidity	1, 2	2	1	2	1	3	1b, 2	2, 3
Particle size	3	2	1	1, 2, 3	1, 2	3	1b, 2, 3	N/A
XRF	3	3	1	2, 3	1, 2	1	1a, 1b, 2	2, 3
Potentiometric (pH/ISE/ORP)	1	1	1	2	1, 2	1, 2	1b, 2	1, 2, 3
Conductance	1	1	1	2	1	3	1a, 1b, 2	2, 3
Amperometric (fuel cell, galvanic/polarographic)	1	1	1	1, 2	1	1, 2	1b, 2	1a, 2, 3
Autotitration	2, 3	2	2	2	2	2	3	1, 2, 3
FIA	3	3	2	2	2	2	2, 3	1, 2, 3
MS	3	2	2	1	2	1	2	1, 2, 3
NMR	3	3	2	2	2	2	3	3

Explanation of Codes:

Attribute	*Code 1*	*Code 2*	*Code 3*
Cost	<$5000	$5000–20,000	>$20,000
Complexity	Low	Moderate	High
Calibration	2 points (or does not need)	Several points	Chemometrics
Sample Phase	Gas	Liquid	Solid
Sampling System	None	Simple	Complex
Selectivity	Specific	Varies with system	Nonspecific
Mode	Noninvasive (a); invasive (b)	Continuous	Intermittent
Range	Trace (<0.1%)	0.1–5%	>5%

Note: N/A = not applicable. As with all generalizations, these comparisons should be taken as a guide. Different installation schemes, different analytes, etc., can dramatically change costs, complexity, and the other attributes in the above table. The addition of fiber optics to any of the optical techniques will provide increased accessibility to the process from remote locations and eliminate the need for a sampling system, but the cost of the fiber, especially in the mid-infrared region, is considerable.

TABLE 8.1u
Analyzer Selection Guide for Some Common Analytes

The analyzers suggested here make use of the main measurement attributes of each analyte, so that, for example, a UV analyzer is suggested for nitrobenzene, a strong UV absorber. Most organic compounds can be measured using gas or liquid chromatography, so those techniques are not noted for every analyte in the table. Many additional factors will affect the final analyzer choice, especially concentration and matrix. See the text.

Acetaldehyde	9	Furfural	9
Acetic anhydride	9	Hazardous gases	1
Acetone	9	Hexane	3
Acrylonitrile	9	Hydrazine, ppb	17
Aldehydes	3, 9	Hydrogen chloride	1, 6
Alkyl chloride	1	Hydrogen cyanide	1
Aluminum	6	Hydrogen fluoride	1
Amines, ppm	17	Methane	3
Ammonia	1, 3, 5, 6, 11	Methyl bromide	1
Aniline	9	Methyl chloride	1
Argon	11, 14, 15	Methylene chloride	1, 3
Bromine	9	Nitrogen compounds (e.g., NH_3, NO_3^-, NO_2, amines)	6
Butadiene	9, 10	Nitrogen peroxide	9
Butane	2, 7, 8	Nitrous fumes	1
Caffeine	4, 9	Potassium dichromate	9
Carbon disulfide	1, 9	Propylene dichloride	1
Chlorine	1, 5, 6, 9, 12	Proteins	6, 9
Chlorine, residual	1, 5, 6	Residual chlorine	1, 5, 6
Chlorine, ppm	1	Sulfuric acid	2, 5, 6, 19
Chlorobenzene	1	Tetraethyl lead, ppb	17
Chloroform	1	Trichloroethylene	1, 3
Color	9	Trichloroethylene, ppm	17
Cyclohexane	6, 10	Ketones	9
Diolefin vapors	9	Methanol	3
Ethane	3	Nitrobenzene	9
Ethyl bromide	1	Nitrogen dioxide, ppm	14, 15
Ethyl chloride	1	Nitrous oxide	3
Ethylene bromide, ppm	17	Oxygen	1, 6, 11, 13, 16
Ethylene chloride, ppm	17	Propane	3, 14, 15
Ethylene glycol	10	Pyridine	9, 14, 15
Ethylene in %	3, 14, 15	Silicon	18
Ethylene oxide	3, 11	Sulfur dioxide	1, 3, 6, 9, 11
Freon	3, 11	Tetrachloroethylene, ppm	17
		Vinyl chloride	1, 3

Code numbers used:

1. Electrochemical (polarographic, amperometric, fuel cell, etc.)
2. Conductance
3. IR
4. NIR
5. pH, ORP, ISE
6. Wet chemistry (FIA, autotitration, etc.)
7. Electrolytic hygrometer
8. Capacitance
9. UV-Vis
10. Refractometers
11. Thermal conductivity
12. Phototape
13. Zirconium oxide
14. Mass spectrometer
15. Chromatography (gas or liquid)
16. Paramagnetic
17. Flame ionization
18. XRF
19. Density
20. Miscellaneous analyte-specific techniques

TABLE 8.1v
Analyzer Selection Guide for Some Common Applications

Use this table as a basic guide. It provides you with a starting point, to help you think about the analyte's measurable attribute. Usually, several methods will be applicable to any given analyte, depending on concentration, matrix, etc.

Acidity (of aqueous solutions)	5, 6	Ethylene in C_1–C_8, H_2, CO_2	15
Acids in water	2, 5, 6, 10,19	Ethylene oxide in methane, ethane, propane	14, 15
Alcohol in water	10, 19	Fluoride in water	5, 6
Alkalinity of water	6	Freon moisture content	7, 20
Ammonium ions in water	5, 6	Glycerine and salts in water	10, 19
Aromatics in vapors or in water	9	Green, white, or black liquor concentration	10
Benzene in ethanol or cyclohexane	9, 10	Hardness (total) in water	6
Benzene in raffinate or in ethyl alcohol	9	Helium in oxygen, nitrogen	11
Benzene moisture content	4, 8	Helium moisture content	7, 20
Benzotriazole in water, ppm	9	Hexane moisture content	7, 20
Brine concentration	2, 10, 19	Hexavalent chromium	6
Bromide ions in water	5	Humidity (air)	7, 20
Butadiene in butanes and butylenes	9, 15	Hydrazine in water	6
Butadiene in styrene	10, 15	Hydrocarbon in H_2S, CO_2, air	1, 14, 15
Cadmium ions in water	5, 6	Hydrocarbon vapors in ambient air	17, 11
Caffeine in coffee	4	Hydrogen impurities (in O_2, N_2, CO, H_2O)	14, 15
Caffeine in water or ethylaetate or CH_2Cl_2	9	Hydrogen in chlorine	9, 11
Calcium ions in water	5, 6	Hydrogen in nitrogen, oxygen, inert gases	11, 15
Carbon dioxide in carbonated beverages	3	Hydrogen sulfide in air	1, 9, 12
Carbon dioxide in gases	1, 3, 6	Hydrogen sulfide in hydrocarbon liquids	6
Carbon dioxide moisture content	7, 20	Hydrogen sulfide in natural gas or in stack gas	1, 9
Carbon monoxide in gases	1, 3	Iodide ions in water	5, 6
Carbon monoxide moisture content	7, 20	Iron (total) in water	6
Carbon tetrachloride in air	1	Isobutane in C_5, n-C_6, i-C_7 hydrocarbons	15
Catsup and tomato paste (solids content)	10, 19	Isobutane in *n*-butane (liquid)	10
Caustic concentration	2, 6, 10, 19	Isoprene in solvents	9
Chemical oxidation demand	6	Jams, jellies, juices for sugar content (Brix)	10
Chloride ion in aqueous solution	5, 6	Kerosene moisture content	4, 8
Chlorine in air	1, 11	Lead ions in water	5, 6
Chlorine in ethylene dichloride	9	Methane in other gases	3, 11, 14, 15
Chlorine, ppm, in off-gas or phosgene	9	Methane moisture content	4, 7, 20
Chromium in water (hexavalent or total)	6	Methanol in water	10, 19
Citrus juice (Brix, sugar concentration)	10, 19	Natural gas moisture content	3, 7, 8, 20
Combustibles in air	17	Neon moisture content	3, 7, 20
Copper in water	5, 6	Nitrate and nitrite in water	6
Cyanide in water	5, 6	Nitric acid in water	2, 5, 6, 10
Cyclohexane in *n*-hexane/methylcyclopentane	10	Nitric oxide in air	1
Divalent ions in water	5, 6	Nitrogen (NH_3, NO_3^-, NO_2^-, total, etc.) in water	6
Divinyl acetylene in acrylonitrile	9	Nitrogen in argon	14, 15
Ethane moisture content	7, 20	Nitrogen moisture content	3, 7, 20
Ethanol in benzene or in water	10, 19	Octane rating of gasoline	4
Ethyl chloride moisture content	7, 20	Oil (triglyceride) in milk and other foods	4
Ethylene glycol in water	10, 19	Oil in liquid Freon	3, 4

TABLE 8.1v Continued

Analyzer Selection Guide for Some Common Applications

Oil in wax	10, 19	Starch in water	10, 19
Ortho- and *meta*-xylene in *para*-xylene	10, 14, 20	Steam in air	3, 20
Ortho-phosphate in water	6	Styrene in ethyl benzene	10, 20
Oxygen (dissolved) in water	1	Sucrose in water	3, 6, 10, 19
Oxygen in argon, hydrogen	11, 13, 14, 15, 16	Sugars in water, syrups	3, 6, 10, 19
Oxygen in ethylene	11, 13, 14, 15, 16	Sulfate and sulfite in water	6
Oxygen in stack gases	13, 16	Sulfur dioxide in stack gas	3, 9
Oxygen moisture content	3, 7, 20	Sulfur dioxide moisture content	3, 7, 20
Ozone in air	9	Sulfuric acid in water	5, 6, 10, 19
Paper moisture	3, 4, 20	Tetranitromethane in air	3
Phenol in water	6, 9	TiO_2 in paint or paper	18
Phosgene in air	1, 9, 12	Toluene in hydrocarbons	9
Phosphoric acid concentration in water	5, 6, 10, 19	*Trans*-unsaturation of vegetable oils, detergents	3, 4
Phosphorus (total or *o*-phosphate) in water	6	Vinyl acetate in polymer vapor	3
Polymer–solvent mixtures	10, 19	Water (moisture) in liquids	3, 4, 20
Potassium dichromate in water	5, 6, 9	Water (moisture) in solids	4, 8, 20
Potassium ions in water	5, 6	Water (moisture, humidity) in gases	3, 7, 20
Propane moisture content	3, 7, 8, 20	Water hardness	5, 6
Propylene glycol in water	3, 10, 19	Water in liquid SO_2	3, 4
Propylene moisture content	3, 7, 8, 20	Water in methylene chloride liquid	3, 4
Silicates in water and in seawater	6	Water in organic liquids	3, 4
Silicon in paper	18	Water vapor in air	3, 7, 20
Sodium carbonate in water	2, 3, 5, 6	Wax in oil	10, 20
Sodium chloride in water	2, 10, 19	Wine, ethanol	10, 19
Sodium hydroxide in water	2, 4, 5, 6, 19	Xylenes in hydrocarbon	9
Sodium ions in water	5		

Code numbers used:

1. Electrochemical (polarographic, amperometric, fuel cell, etc.)
2. Conductance
3. IR
4. NIR
5. pH, ORP, ISE
6. Wet chemistry (FIA, autotitration, etc.)
7. Electrolytic hygrometer
8. Capacitance
9. UV-Vis
10. Refractometers
11. Thermal conductivity
12. Phototape
13. Zirconium oxide
14. Mass spectrometer
15. Chromatography (gas or liquid)
16. Paramagnetic
17. Flame ionization
18. XRF
19. Density
20. Miscellaneous analyte-specific techniques

Note: Careful study of this table will show some apparent inconsistencies, but also some patterns. The inconsistencies are not real; they occur when several techniques are listed because the concentration and details of the application are missing. For example, the concentration vs. conductance curve for sulfuric acid increases with concentration and then rolls over and decreases. The use of conductance is fine in some ranges, but not in others. An example of one of the patterns that emerge from the table is the apparent similar utility of three inferential methods of analysis: conductance, refractive index, and density. As the concentration of some analytes increases, the conductivity, refractive index, and density all change, providing three relatively simple measurements to consider.

the proverbial grain of salt. Analyzers are constantly changing; developments in electronics, sensing transducers, and all aspects of measurement science improve almost daily. In addition, very few applications are exactly the same. Therefore, use these tables as a starting point, and carefully evaluate all the criteria discussed in this section and the rest of this volume.

INTRODUCTION

This section starts with a discussion of the general considerations that the designer needs to evaluate before starting the actual hardware selection for a sampling system. Next, the various sample system components are described. The section is concluded by a detailed evaluation of the various sampling applications, considering gas, liquid, solids, stack, reactor, slurry, trace, and other types of process samples.

Sampling is also discussed in the first section of this chapter and under the individual analyzer categories. The subject of sampling stack particulate concentration is separately discussed in Section 8.3.

GENERAL CONSIDERATIONS

The sampling system is an integral and key part of an analyzer system and should be designed to obtain a representative sample; transport the sample to the analyzer; condition the sample; accomplish sample stream switching, if necessary; provide facilities for return and disposal of the sample; and provide not only calibration facilities, but also preventive maintenance features, and alarm functions for on-line reliability and operator alerts.

If a sample has to be brought to an analyzer, a sample transportation delay and a potential for interference with the integrity of the sample will be introduced. If the measured composition is to be controlled, the transportation lag can seriously deteriorate the closed-loop control stability of the system.

Even more serious is the potential for interference with the integrity of the sample, due to the effects of filtration, condensation, leakage, evaporation, and so on, because these operations can not only delay, but also change information that is to be measured: the composition of the process fluid.

Consequently, the best solution is to eliminate all sampling systems and place the analyzer directly into the process. The “in-pipe” analyzer designs are becoming more and more available. Particularly well suited for this design are the various radiant energy and probe-type sensors.

Feasibility Evaluation

Sample systems are rarely duplicated, and thus each system must be *debugged* as a new entity. In deciding the design of a sampling system, the following questions should be raised:

1. Will the sample be adversely affected by sample transport and conditioning?
2. From what stage in the process will the sample be taken?
3. How can the sample be transported to the analyzer?
4. Is the sample a solid, liquid, gas, or mixture?
5. In what phase must the sample be for analysis?
6. Must the sample be altered (filtered)?
7. Is sufficient sample available?
8. What will be the time lag introduced by transporting the sample?
9. Where is the excess sample returned?
10. Will the analyzer be shared by one or more samples?

These considerations are applicable both to the continuously flowing sample systems and to the less frequently used grab samples. Grab sampling is limited by variations in cleanliness of the sample containers, changes in the method of collecting the sample, delays in transporting the sample, and deviations in withdrawing the sample from the sample container.

The piped-in sample system usually includes the hardware for calibrating the analysis system. It also provides a tap for obtaining samples for laboratory testing. Sample conditioning systems are usually costly to maintain.

The installation price for the sampling system frequently exceeds the cost of the analyzer, but its importance overrides this economic consideration because a second-class analyzer can still furnish usable data if it operates with an efficient sample system, whereas a poor sample invalidates the entire measurement.

Therefore, the most important criterion is to keep the samples representative, both in time (short sample lines guarantee minimum transportation delays) and in composition. Whenever possible, the sample should not be tampered with because the steps of sample preparation (drying, vaporizing, condensing, filtering, and diluting) always degrade the sample.

Sample Data Requirements

A comprehensive listing of the characteristics of each sample stream, including any abnormal conditions, should be prepared before an analyzer sample system is designed. Data are usually available from process conditions and laboratory analysis in existing plants and from design data for new plants. Table 8.2a is a form to be used in summarizing the characteristics of a sample.

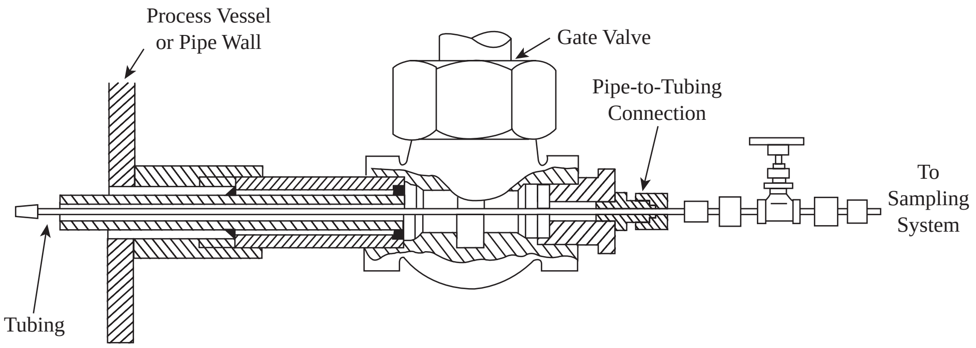

FIG. 8.2b
Sample probe assembly with process shutoff value.

Sample Takeoff Point

Sample conditioning begins with the location of a suitable sample takeoff point. To obtain a representative sample, the takeoff is usually located at the side of a process line, especially in the case of liquid samples where there is the possibility of vapor on the top of a horizontal line and dirt or solids on the bottom of the line. For sampling vapors, the connection may be located in the side or top of the process line, but in both cases with due consideration to accessibility for maintenance.

Ideally, the sample at the appropriately selected takeoff point will require little or no conditioning; however, it is good practice to install a sampling probe (Figure 8.2b) for most applications as a precautionary measure to prevent particulates from entering the sample transport system. Sampling processes that are still reacting chemically or pyrolysis gases may require reaction quenching, or fractionation, at the sample takeoff. This is done by cooling or back-flushing with an inert gas or liquid to keep the sample takeoff clean and reliably active (Figure 8.2c), while drawing off a reproducible sample for analysis.

With the advent of *in situ* analyzer detectors, the sample takeoff becomes the point of analysis and, for locating *in situ* analyzers, the above considerations must be carefully evaluated.

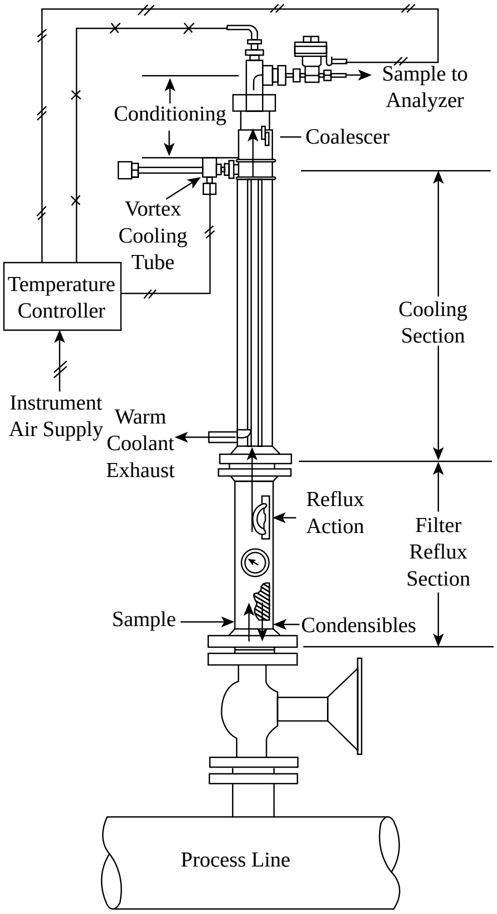

FIG. 8.2c
Pyrolysis gas sample fractionation and conditioning unit.

Sample Transport

A representative sample extract from a process line must be continuously conditioned while in transport to avoid compromising the sample integrity. Thus, provision must be made to heat or cool the line as necessary for the specific condition. The sample is normally transported in one of three ways (Figure 8.2d).

Single-line transport is the most direct approach and is used when the sample line volume is small in relation to the analyzer sample consumption so that the transport time lag is reasonably short. It is usually used when the analyzer is field-mounted close to the sample point and sample exhaust facilities are available.

Bypass-stream transport is a commonly used method for maintaining a high sample transport velocity that provides minimum transportation lag. This method is used when samples are vaporized at the tap and no facilities exist for returning the vapor to the process, or in similar situations. Consideration must be given to the fact that the sample bypass must be piped to a drain or vent. This procedure may have a negative impact on the environment, despite the fact that the cost of the sample being disposed of may economically justify a sample recovery system.

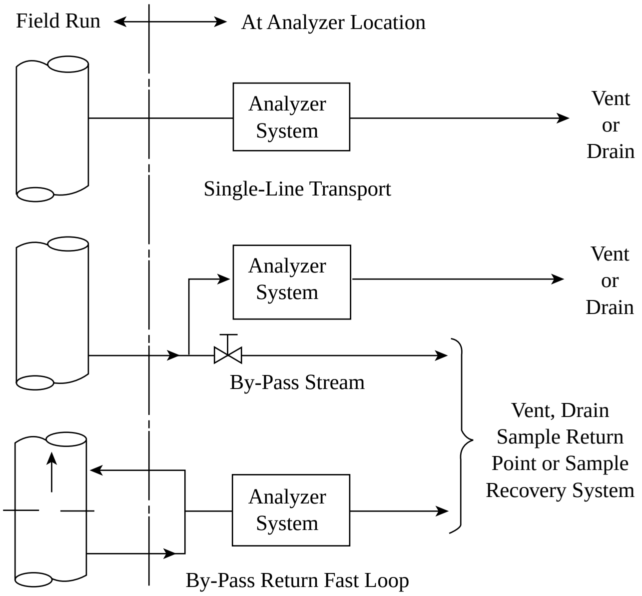

FIG. 8.2d
Sample transport methods.

Bypass-return fast loop is the most commonly used transport loop for an analyzer mounted away from the sample takeoff point. By circulating a continuous high velocity across a device, to create a differential pressure, and drawing off a bypass stream to the analyzer, a fast loop is obtained, which is adjustable with no waste in the product. In most cases, such devices as pumps, control valves, and process equipment exist in the process for this purpose. Otherwise, it may be necessary to install an orifice in the process line or a circulating sample pump. With a circulation sample pump, care must be taken to prevent cavitation by locating the pump close to the sample takeoff.

Transport Lag

After selecting the appropriate sample transport method for each analyzer system, a calculation of the sample time lag should be made, using conventional flow equations based on the following:

1. Available differential pressures.
2. Total length of the fast loop from the sample takeoff point to the analyzer location and back to the sample return point. Any restrictions on this loop should be excluded from available differential pressures.
3. Line sizes used.
4. Viscosity of the sample.

Table 8.2e should be used as an aid in establishing volumes and pressure drops for some typical tubing and pipe used in sample systems.

TABLE 8.2e
Dimensions and Volumes of Tubing and Pipe Used in Sample Systems

	Nominal Volume per Diameter, in.	Inner Diameter, in.	Internal Area

	$^3/_4$	0.8268	0.5363	106.6800

Sample Disposal

Sample disposal is a critical area, both from the economic point of view that would preserve any quantity of sample not used and from the environmental side that would prevent the emission of most hydrocarbons into the air.

When there is an economic justification for saving the sample, for example, liquids in boiling point and viscometer analyzers, a sample collection and return systems must be furnished to collect the sample at atmospheric pressures and pump it back at high pressure into the process. For gases with no sample return point, the sample can be pressurized back into the process, or as is most frequently done, the sample can be vented into the flare system. However, except in rare cases, venting is done directly into the atmosphere. When this is not possible, extreme caution should be taken to control the back-pressure when venting the sample into a flare or other collection system with varying pressures.

Ambient Considerations

Sample systems condition a sample suitable for introduction into an analyzer while maintaining the integrity of the sample. As has been emphasized throughout this section, once a sample is conditioned, it must be preserved in the conditioned state; therefore, provisions for heating, or in some cases cooling, the sample lines and system must be furnished for the integrity of the sample. Thus, the entire system must be protected from varying ambient temperatures, which could condense or flash the sample.

Furthermore, as a general rule, the sample should be located in enclosures that provide limited access to unauthorized personnel and also protect the equipment from any corrosive environment. It is accepted practice that systems be completely preassembled and tested in conjunction with analyzers prior to installation in the field.

Test and Calibration

The reliability of each analyzer is measured by its ability to check the analyzer calibration as recommended by the manufacturer. Therefore, each system must include provisions for testing and calibration. As is shown in Figure 8.2f, a means of isolating the inlet is needed in order to allow a calibration sample to be introduced manually or automatically.

Also necessary is a suitable calibration manifold with gas or liquid to furnish a reliable calibration sample to the analyzer.

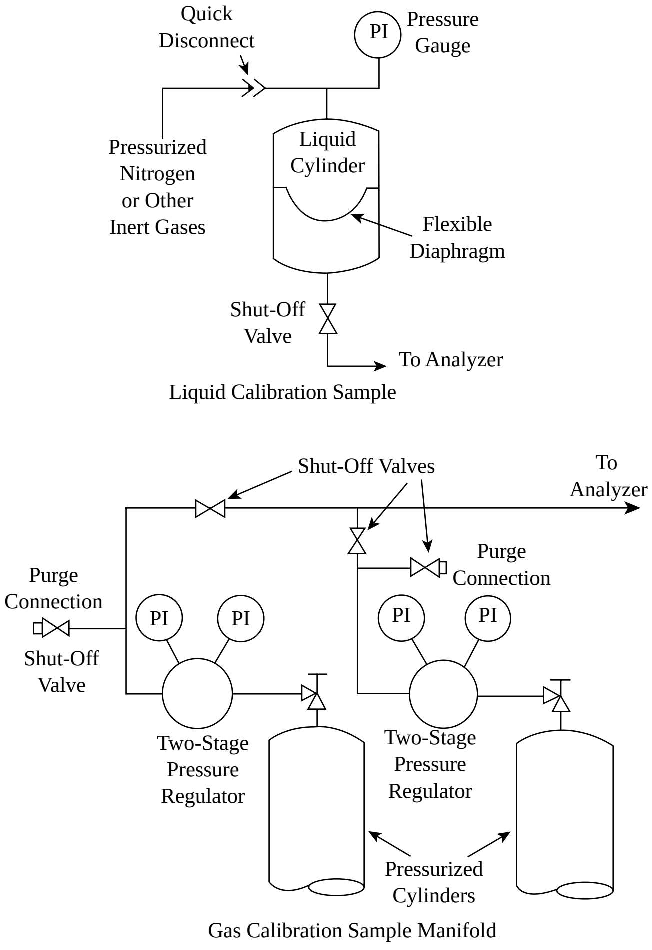

FIG. 8.2f
Calibration provisions for liquid.

Storage of the test sample may be a consideration, especially for unstable liquids or gases with low dew points. Treatment of the containers is very important for trace analysis samples. In all cases, the calibration provisions must be incorporated into the systems and a sample provided that is compatible with the desired stream composition and suitable for analysis by the analyzer used for the system. It is desirable, but not essential, that the calibration sample be introduced automatically from a remote location so that the instrument can be periodically checked; however, in most systems the introduction of the sample is done by manual switching at the analyzer.

COMPONENTS OF SAMPLING SYSTEMS

A number of devices are discussed here that are components of analyzer sampling systems. These devices include gas and liquid filters, bypass filters, liquid homogenizers, liquid grab sample collectors, chemical reactor sampling systems, and solids samplers. Later, under Applications, the various sampling probe packages and single-stream and multistream process sampling systems are described.

The more components there are in a sampling system, the less reliable it is likely to be. The mean time between failure and maintenance needs of the overall system will improve as the number of pumps, ejectors, regulating valves, coolers, heaters, filters, coalescers, dryers, knockout traps, manifolds, timers, and other components that comprise the system are reduced.

Selecting the System Components

Sampling systems require certain components, which are commercially available. One source is the analyzer's manufacturer, who through the years has developed systems compatible with its analyzer, such as filter coalescers, condensers, and washing and treating systems.

A second source is the analyzer systems vendor, who had designed special components, such as kinetic separators, filter probes, and the like, for use with analyzers for applications in rather hard service.

A third source is the specialty vendor, who has developed unique sampling components, such as pyrolysis gas sample conditioners; permeation devices for water removal systems; high-efficiency, self-cleaning filters; and so on. It is desirable to check whether specialty items are available before trying to design new components. Most of the specialty components have taken years of field testing to develop and modify for successful application.

When a large number of analyzers are used, the components selected must be of the same type and manufacture for interchangeability and stocking of spare parts. Documenting a sample system with complete flow schematics, part identification, and manufacturing of various components is an essential part of being able to properly start up a system and maintain it successfully over a long period.

The successful design of sample systems requires careful analysis of the physical and chemical conditions of the stream, as well as serious consideration of the ambient and transport conditions, to ensure integrity of the sample. Therefore, care should be taken in evaluating the above considerations with respect to a given stream and in applying the correct analyzer to provide the desired measurement.

Sample system design is based on experience, and whenever possible, previous experience should be given prime consideration in the selection and application of components. A successful sample system normally results in a successful analyzer system. Therefore, no effort must be spared in proper sample systems design, which requires a careful selection of the system components. These are discussed below, starting with filters.

Filter Designs

Most analyzer sampling systems will include a filter with at least one wire mesh strainer (100 mesh or finer) to remove larger particles that might cause plugging. Available filter materials include cellulose, which should only be considered in applications where it does not absorb components of interest. Sintered metallic filters can remove particles as fine as 2 microns; cellulose filters can remove down to 3 microns; and ceramic or porous metallic elements can trap particles of 13 microns or larger. When the solids content is high, two filters can be installed in parallel, with isolation valves on each. Motorized self-cleaning filters are also available for such services.

Separating Liquids from Gases Glass microfiber filter tubes efficiently separate suspended liquids from gases. The filter tubes capture the fine droplets suspended in the gas and cause the droplets to run together to form large drops within the depth of the filter tube. The large droplets are then forced by the gas flow to the downstream surface of the filter tube, from which the liquid drains by gravity. This process is called coalescing.[1]

The coalesced liquid drains from the tubes at the same rate as liquid droplets enter the tubes. Therefore, the tubes have an unlimited life when coalescing liquids from relatively clean gases. The filters operate at their initial retention efficiency even when wet with liquid. The flow direction is inside to outside to permit the liquid to drip from the outside of the filter to the housing drain (Figure 8.2g).

The filter tube grade should be selected for maximum liquid drainage rate, rather than maximum filtration efficiency rating, because a liquid drainage rate decreases with increasing filtration efficiency rating. If liquid is carried into the filter in slugs rather than dispersed as droplets in the gas, a filter that is properly sized for steady-state conditions can be flooded and permit liquid carryover. If slugging of liquid is expected, a filter with a relatively large bowl should be selected to provide adequate liquid-holding capacity, and provisions

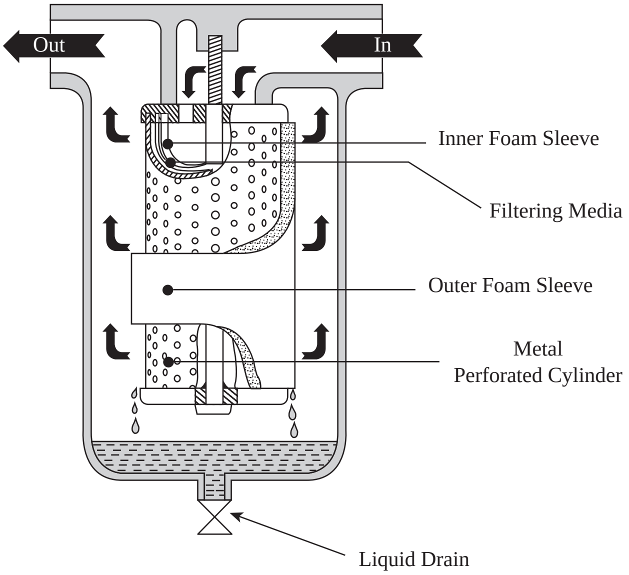

FIG. 8.2g
Coalescing gas filter serves to remove liquid entrainment. (Courtesy of Parker Filtration, formerly Balston Inc.)

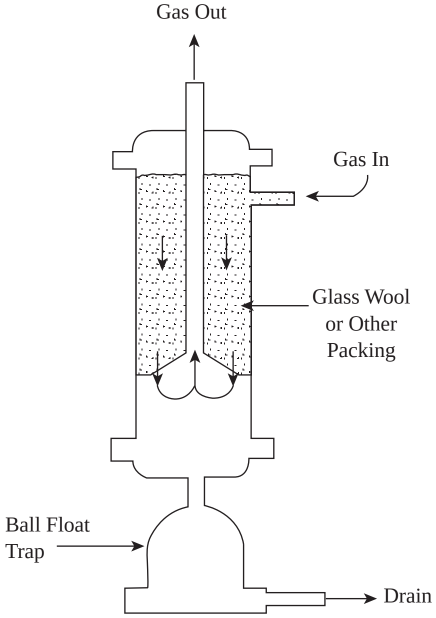

FIG. 8.2h
Entrained liquid separator with ball float trap.[2]

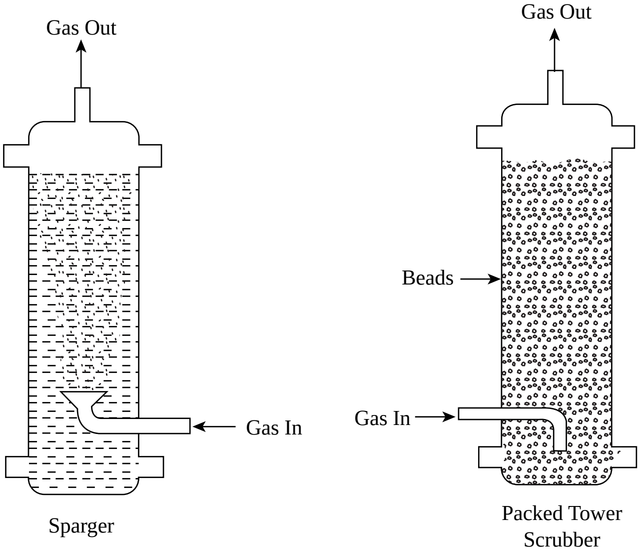

FIG. 8.2i
Removal of corrosive gases or of condensable vapors.[2]

should be made to drain the liquid automatically from the bowl of the housing as it accumulates.

An automatic float drain can be used if the pressure is in the 10- to 400-psig (28 bars) range. Above 400 psig, which is the upper limit for commercially available float drains (Figure 8.2h), the possibilities are 1) a constant bleed drain, 2) a valve with an automatic timed actuator, or 3) an external reservoir with manual valves. The external reservoir can be constructed of pipe or tubing with sufficient volume to hold all the liquid that is expected to be collected during any period of unattended operation. To drain liquid while the filter is operating at pressure or vacuum conditions, the reservoir inlet valve is closed and the outlet valve is opened.

If the filter is under vacuum, the external reservoir is a practical method of collecting coalesced liquid for periodic manual draining. Alternatively, if an external vacuum source is available, such as an aspirator, the liquid may be drained continuously from the housing drain port.

Spargers, Packed Towers, and Strippers In some analyzer applications it is necessary to remove corrosive gases or condensable vapors from the sample. This removal can be done by bubbling the sample stream through a liquid solution.

In the case of a sparger (Figure 8.2i), the gas enters below the scrubbing medium through a sintered disc, which breaks it into small bubbles. This increases the liquid–gas contact surface area and thereby provides improved scrubbing efficiency. At the same time, the small bubbles also increase the tendency for foaming and liquid carryover, and therefore the sample flow velocities should be kept low.

Packed towers (Figure 8.2i) can also be used as scrubbers. In these designs the gas sample bubbles up through a nonreactive packing of beads that are wetted by a liquid solution. Foaming and liquid carryover are problems in packed towers, as in a sparger.

When the impurities in the process gas stream are both solids and liquids, such as in particulate matter and mist—carryover problems in chlorine plants—the fiber mist eliminator[3] (Figure 8.2j) should be considered. The liquid particles form a film on the fiber surface, and the drag of the gas moves this film and the dissolved solids radially, while gravity causes them to move downward, resulting in a self-cleaning action.

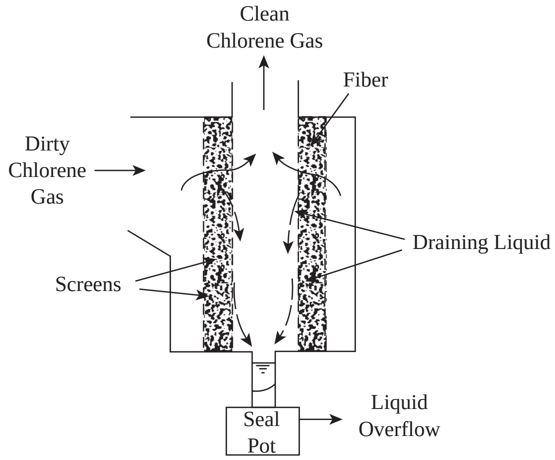

FIG. 8.2j
Fiber mist eliminator.

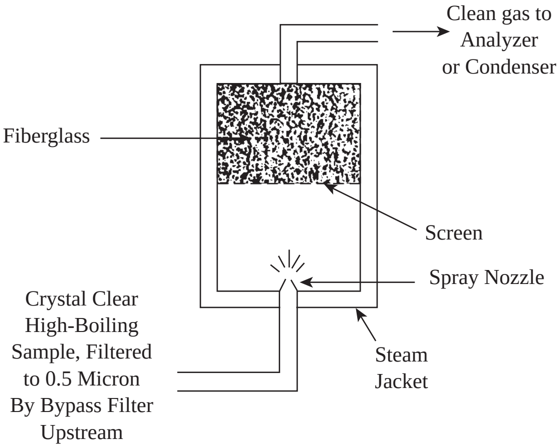

FIG. 8.2k
When dissolved inorganic solids or polymer-forming compounds are present, stripping the liquid sample may be the answer.

Dissolved solids or polymer-forming compounds in a process stream would leave a residue and eventually plug the liquid sample valve. The logical solution is to force the residue formation to take place in a controlled area, such as in the fiberglass filter of the spray-stripping chamber shown in Figure 8.2k.

If polymers represent a substantial portion of the process stream, the need for filter replacements becomes excessive and therefore impractical. A better technique is to vaporize the unreacted monomers through pressure reduction while keeping the polymers in a molten state through heating. This technique (Figure 8.2l) not only discharges polymers continuously, but also provides a usable vapor sample.

When it is necessary to clean the windows on the various photometers operating on gas samples, a warm air purge can be used, keeping the window compartment isolated from the sample.

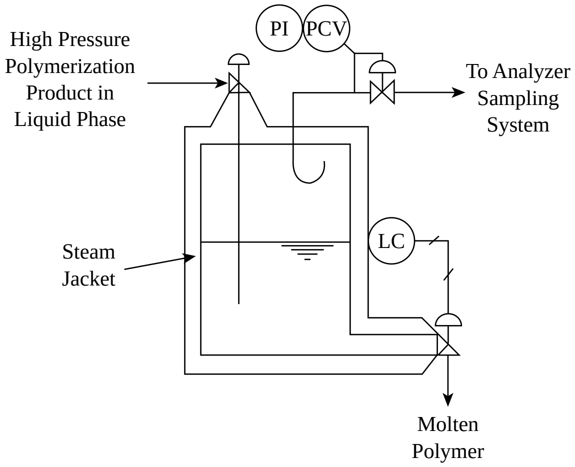

FIG. 8.2l
Flash chamber makes the analysis of unreacted monomers possible.

Separating Two Liquid Phases Theoretically, glass microfiber filter tubes can separate suspended droplets of a liquid that are immiscible in another liquid using the same process by which they separate droplets of liquid from a gas. The liquid droplets suspended in the continuous liquid phase are trapped on the fibers and run together to form large drops, which are then forced through the filter to the downstream surface. The large drops separate from the continuous liquid phase by gravity difference, settling if heavier than the continuous phase and rising if lighter. The coalescing action of glass microfiber filters is effective with aqueous droplets suspended in oil or other hydrocarbons, and also with oil-in-water suspensions.

In practice, however, liquid–liquid separations are much more difficult to achieve than are liquid–gas separations. The specific gravity difference between two liquids is always less than that between a liquid and a gas and, therefore, a longer phase separation time is needed. Either the filter housing must be oversized or the flow rate greatly reduced to avoid carryover of the coalesced phase.

As a rule of thumb, flow rate for liquid–liquid separation should be no more than one fifth the flow rate for solid–liquid separation. Even at low flow rates, if the specific gravity difference between the two liquids is less than 0.1 U (for example, if an oil suspended in water has a specific gravity between 0.9 and 1.1), the separation time for the coalesced phase may be too long to be practical. In that case, if there is only a small quantity of suspended liquid, the filter tube can be used until saturated with suspended liquid and then changed.

Another practical problem with liquid–liquid separation is that small quantities of impurities can act as surface-active agents and interfere with the coalescing action. For this reason, it is not possible to predict accurately the performance of a liquid–liquid coalescing filter, and each system must be tested on-site. Testing can be started with 25-micron filter tubes and with inside-out flows at very low flow rates. If the

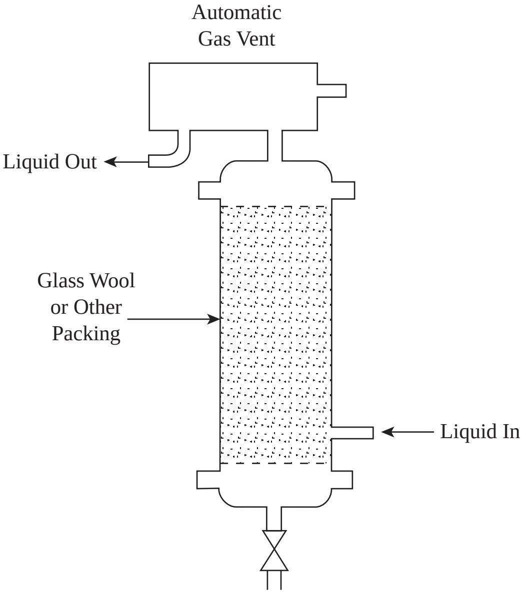

FIG. 8.2m
Entrained gas separator.[2]

suspended liquid is lighter than the continuous phase, the housing should be oriented so that the drain port is up.

Removing Gas Bubbles from Liquids Glass microfiber filter tubes readily remove suspended gas bubbles from liquid, eliminating the need for deaeration tanks, baffles, or other separation devices. Flow direction through the filter is outside to inside, and the separated gas bubbles rise to the top of the housing and are vented through the drain port. If slipstream sampling is used, the separated bubbles are swept out of the housing with the bypassed liquid. Filter tubes rated at 25 microns are a good choice for gas bubble separation.

Columns with glass wool packing can also be used to remove entrained bubbles (Figure 8.2m). Here the gas bubbles collect and agglomerate on the packing and form large bubbles. These bubbles break away and rise to the top, where they are separated from the liquid and vented.

Slipstream and Bypass Filters In order to minimize the transportation lag, a relatively large slipstream is usually taken from the process and brought near the analyzer. As the actual sample flow to the analyzer is small, only a small portion of this slipstream is sent to the analyzer; the bulk is returned to the process (Figure 8.2n). This arrangement permits the main volume of the filter to be swept continuously by the high-flow-rate system, thus minimizing lag time; at the same time, only the low-flow stream to the analyzer is filtered, thus maximizing filter life.

A slipstream filter requires that its inlet-to-outlet ports be located at opposite ends of the filter element to allow the high flow rate of the bypassed material to sweep the surface of the filter element. A third port connecting the low-flow-rate lines to the analyzer allows filtered samples to be withdrawn from the filter reservoir.

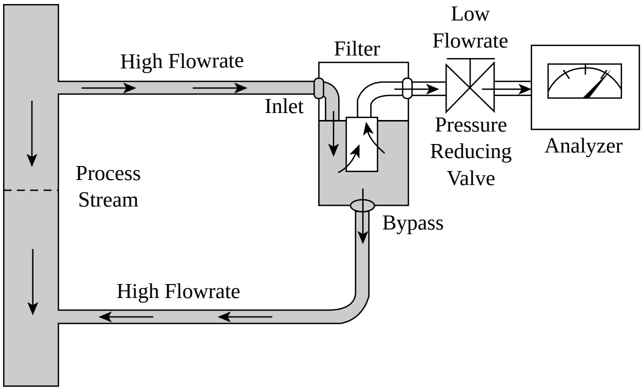

FIG. 8.2n
Slipstream or bypass filtration.

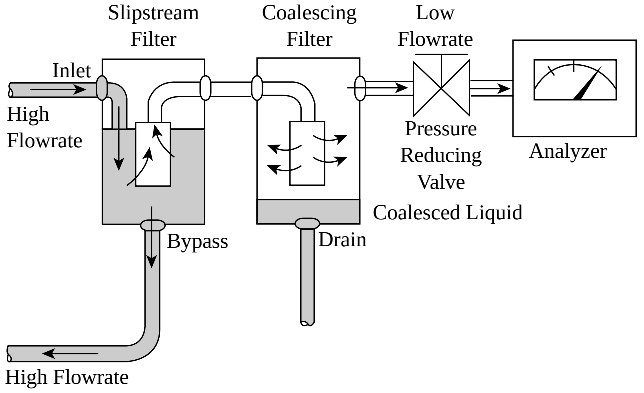

FIG. 8.2o
Slipstream plus coalescing filtration.

If bubble removal from a liquid is a requirement, this function may be combined with slipstream filtration, since the recommended flow direction for bubble removal is outside to inside, and the separated bubbles will be swept out of the housing by the bypass stream. In this case, the liquid feed should enter at the bottom of the housing and the bypass liquid should exit at the top of the housing.

A special problem arises in slipstream sampling if the filter is to coalesce and continuously drain suspended liquid from a gas stream or to coalesce liquid droplets from a liquid stream. The coalescing filter requires two outlet ports, one for the dry gas and one for the liquid drain. To combine coalescing and slipstream filtration, a filter housing would need four ports—two for inlet and bypass and two for filtered gas and coalesced liquid—which is not a practical design.

Therefore, slipstreaming plus coalescing requires two stages of filtration (Figure 8.2o). The second (coalescing) stage must be located in the sample line into the analyzer and should be as small as possible to minimize lag time. If the quantity of suspended liquid is not large, a miniature inline disposable filter unit may be used as a trap for the suspended liquid, to be replaced when saturated.

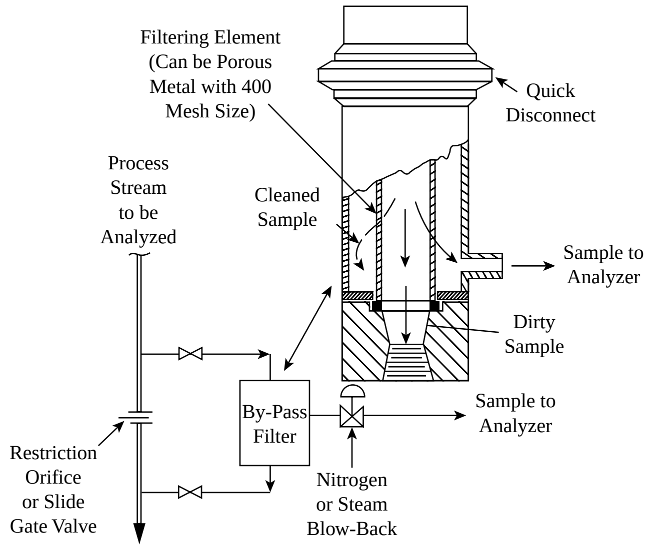

FIG. 8.2p
Self-cleaning bypass filter and its installation.

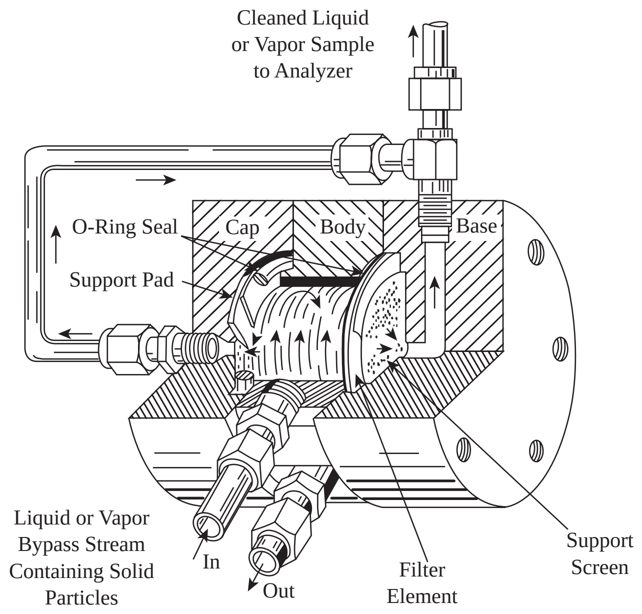

FIG. 8.2q
Bypass filter with its cleaning action amplified by the swirling of the tangentially entering sample.

Self-Cleaning and Rotary Disc Filters If the material to be removed is dust, the self-cleaning bypass filter (Figure 8.2p) with automatic blow-back constitutes a potential solution. In some instances, cyclone separators should be considered. In the latter device (Figure 8.2q), the process stream enters tangentially to provide a swirling action, and the cleaned sample is taken near the center. Transportation lag can be kept to less than 1 min, and the unit is applicable to both gas and liquid samples. This type of centrifuge can also separate streams by gravity into their aqueous and organic constituents.

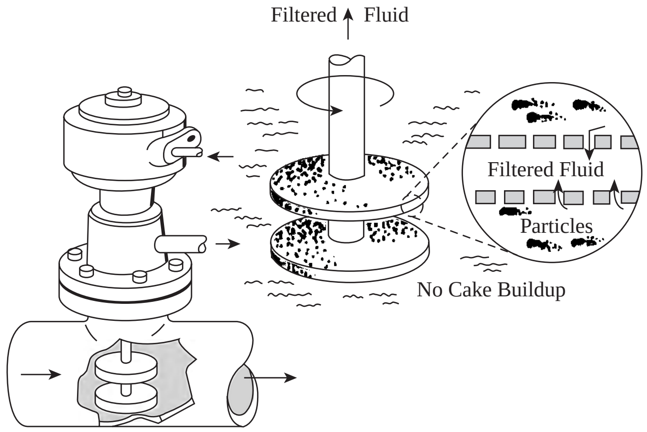

FIG. 8.2r
Rotary disc filter.

Another good filter design is the rotary disc filter (Figure 8.2r). Here the filtered liquid enters through the small pores in the self-cleaning disc surfaces. The sample liquid is drawn by the sample pump through the hollow shaft and is transported to the analyzer.

For the removal of small amounts of polymer dust in vapor samples, there are melt filters with removable, heated metallic surfaces that melt and collect the polymer dust from the sample.

Liquid analyzer sample streams usually have a high solids content. In addition, the analyzers are often located in remote areas of the plant and are infrequently serviced. Therefore, the sample filter system must have a long life between filter tube changes even when solid loading is high. The recommendation for this type of application is a two-stage filter system, a 75-micron prefilter followed by a 25-micron final filter. The filters should be oversized as much as possible without causing excessive lag time. Plastic filter housings are usually a good choice.

Keeping Probes Clean

Figure 8.1p illustrates one of the probe cleaner designs, and Table 8.1q lists the features and capabilities of a number of probe cleaners. There is yet another approach to keeping probes clean, which grew out of the mining industry, where gypsum buildup on pH and oxidation–reduction potential (ORP) probes was blinding these sensors.

The Filterate Master (Figure 8.2s) consists of a filter cup at the tip of a 2-in.-(50-mm)-diameter standpipe, which is inserted into the process. The pH or other electrode is inside this cup, which is made out of porous sintered stainless steel. A pump housed outside the process draws a vacuum inside the cup, thereby drawing in the filtrate of the process fluid. The excess filtrate can be continuously returned by the pump, while the filtered-out solids accumulate on the outside surface of the filter cup.

Operating experience shows that solids can build up to over an inch (25 mm) thickness without blocking the filtrate flow. The timer is set to periodically reverse the filtrate pump.

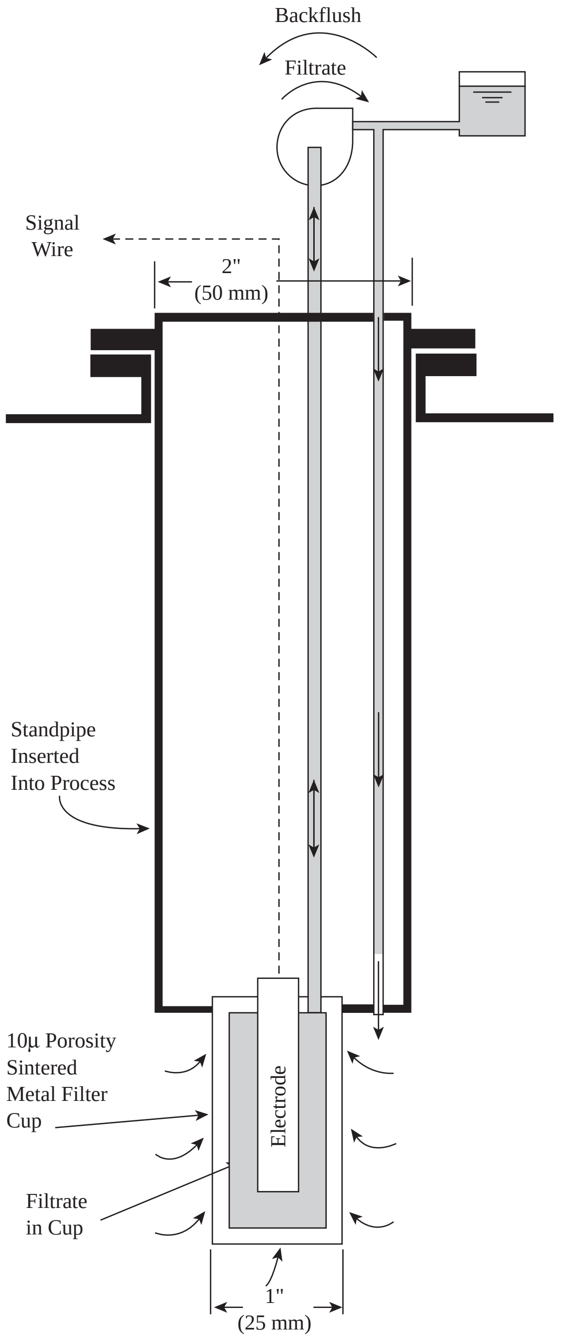

FIG. 8.2s
Electrode is protected from material buildup by back-flushed porous filter cup. (Courtesy of TBI-Bailey Controls.)

When the flow direction is reversed, the filtrate flows back into the filter cup and out through the porous filter. During back-flush, the buildup is quickly removed and another filtering cycle is initiated automatically.

Homogenizers

A frequent problem of sampling systems is plugging. There are two ways to eliminate it. The older, more traditional approach is filtering. Unfortunately, as the filters remove materials that might otherwise plug the system, they also remove process constituents and make the sample less representative.

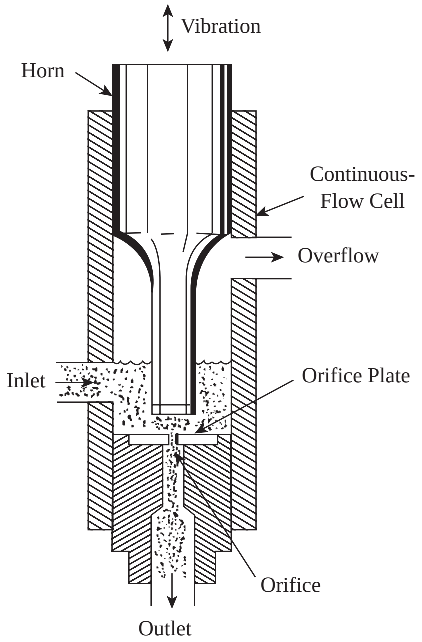

FIG. 8.2t
Ultrasonic homogenizer. (Courtesy of Cole-Parmer Instrument Co.)

The newer approach is to eliminate the potential for plugging by reducing the size of solid particles (homogenization) while maintaining the integrity of the sample. Thus, when a pulverizer is used to replace the filter, the sample becomes representative.

Homogenizers serve to disperse, disintegrate, and reduce the particle size of solids and thereby reduce agglomerates and liquefy the sample. Homogenizers can be mechanical, using rotor-stator-type disintegrator heads. In this design, the rotor acts as a centrifugal pump, which is recirculating the slurry while the shear, impact collision, and cavitation at the disintegrator head provide homogenization.

In ultrasonic homogenizers, high-frequency mechanical vibration is introduced into the probe (horn), which creates pressure waves as it vibrates in front of an orifice (Figure 8.2t). As the horn moves away, it creates large numbers of microscopic bubbles (cavities), and when it moves forward, these bubbles implode, producing powerful shearing action and agitation due to cavitation.

Such homogenizers are available with continuous-flow cells for flow rates up to 4 g/h (16 l/h) and can homogenize liquids to less than 0.1-micron particles sizes. The flow cell is made of stainless steel and can operate at sample pressures of up to 100 psig (7 bars).

Sample Conditioning

The extracted sample begins conditioning at the takeoff point, continues through the transport, and finishes conditioning at the analyzer location prior to entering the analyzer (Figure 8.2u).

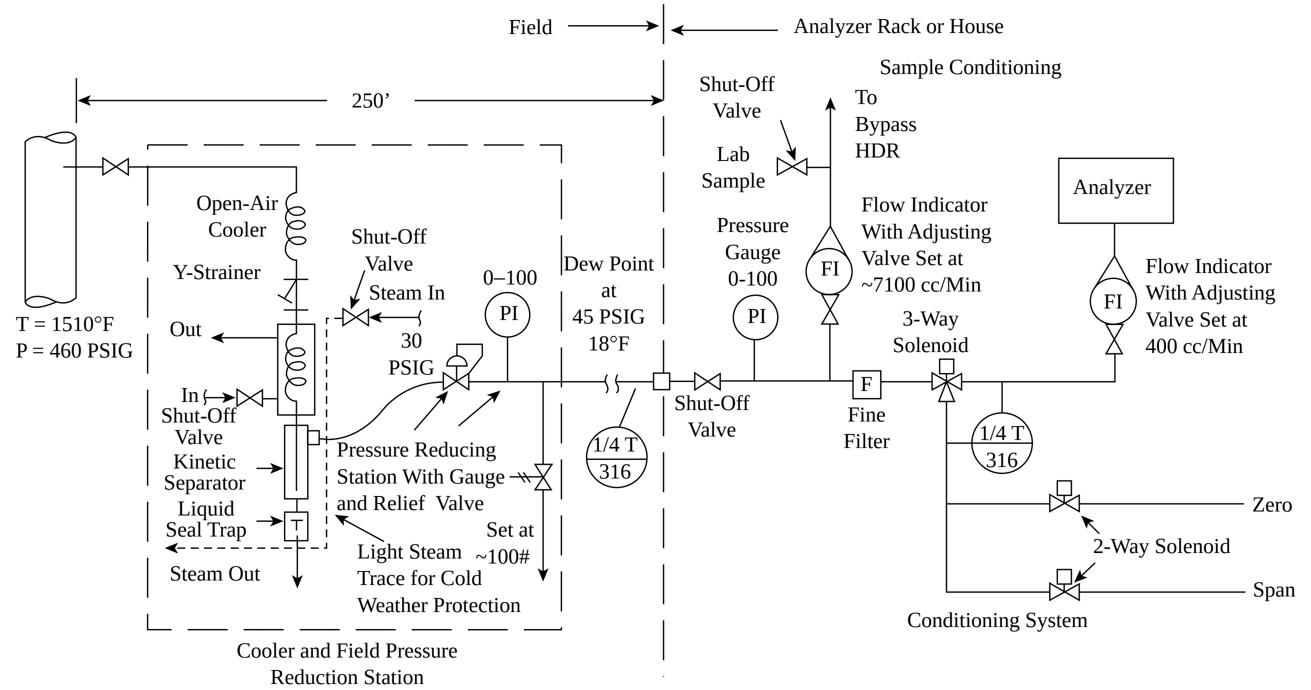

FIG. 8.2u

Typical sample conditioning system with remote preconditioning unit.

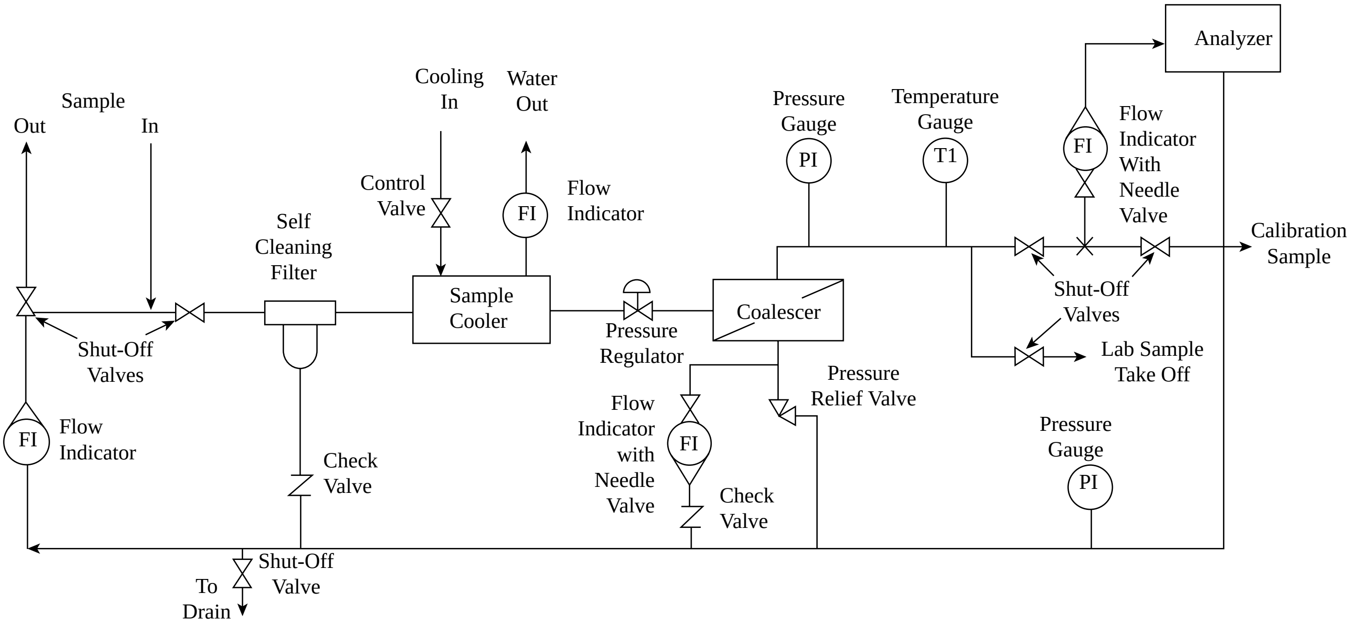

FIG. 8.2v

Typical liquid product sample system for refinery applications.

All samples require some form of conditioning to make them suitable for the analyzer and to assure reliable on-stream operation. The conditioning is done at the appropriate location in the sample system loop in order to maintain the integrity of the sample (Figure 8.2v).

Sample washing is usually limited to dirty, particle-laden streams whose composition will not be affected by the solubility of the components in the liquid used to wash the sample. The conditions of flow, temperatures, and pressures must be controlled to maintain a relatively constant predetermined relationship of the composition. When washing, care must be taken to keep the sample in the vapor phase by providing heated transport lines or by making provisions for final moisture removal as the analyzer may require.

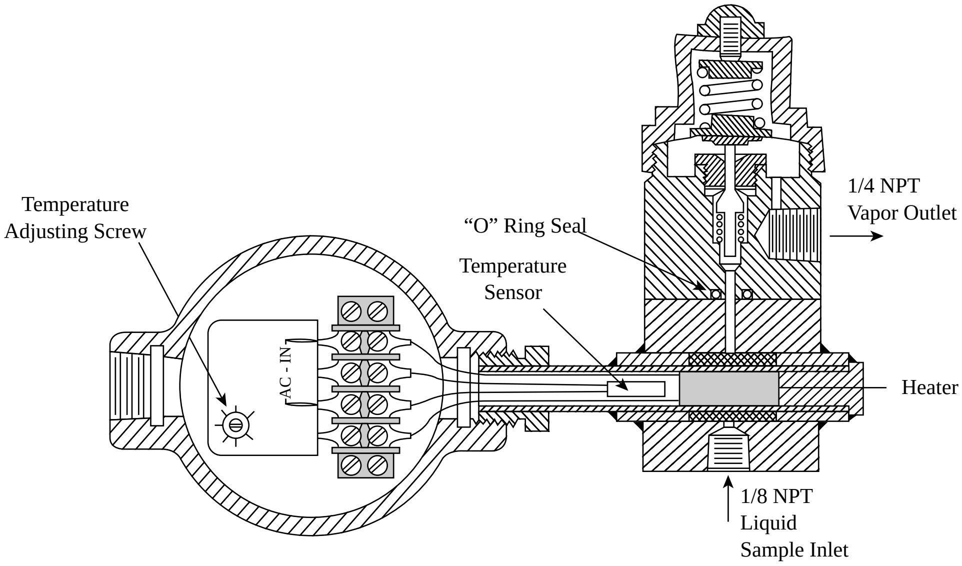

FIG. 8.2w
Vaporizing regulator assembly (electrically heated).

Vaporizing Samples Vaporizing is frequently necessary for equilibrium liquids or when the analyzer requires it. The vaporization is usually done by a vaporizer regulator (Figure 8.2w). In such a regulator the sample is vaporized simply by pressure reduction across a capillary or, more often, by using a heater as well. Care must be exercised to avoid partial vaporization and fractionation by selecting a suitably heated vaporizing regulator to accommodate the sample.

Entrainment Removal The removal of entrainment from liquid or gas samples normally starts with locating a sample tap and providing a sample probe at the takeoff point. Filtration is normally used for both gases and liquids, because it removes both liquid and particulate entrainment from gases and particulate matter from liquids.

For gases requiring further conditioning of heavy loading, cyclone filters can be used if the sample has adequate velocity. For liquids, coalescers are frequently used to remove both undesirable gases and liquids by gravity. The removal of free water from a hydrocarbon stream is usually accomplished by passing the liquid through a hydrophilic element, causing the water droplets to accumulate on the element. The hydrocarbon stream is then passed through a hydrophobic element that rejects the water, removing it from the bottom with a hydrocarbon bypass stream.

Another method of removing moisture from a stream uses a selective permeation device with a drying medium that creates differential pressures to drive the water through the permeable materials, thus removing it from the flowing stream (Figure 8.2x).

Selection of Component Materials Adsorption of the sample components of interest on the walls or surface with which the sample comes in contact will affect the analysis, especially for measurements in the parts per million (ppm) range. Therefore, proper selection of materials and conditioning is essential for establishing an equilibrium that will make analysis reliable.

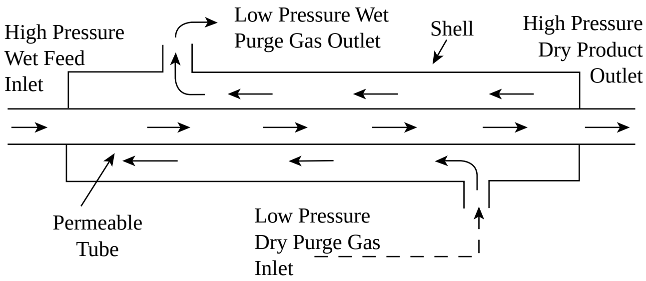

FIG. 8.2x
Permeable tube sample dryer.

Specifically, water vapor samples reach equilibrium more rapidly in stainless steel lines than in copper or plastic tubing. Diffusion is another consideration. Samples system design should assure that gases do not permeate the walls of the sample system. This is especially important in high-pressure systems and ppm analysis. Another problem with diffusion is leakage, which can change the sample composition because gas molecules will flow in both directions of the leak and can significantly affect ppm analysis. This is best illustrated by the fact that in an oxygen ppm analyzer system, the slightest leak will create a full-scale reading on the instrument even though the leak is from a high-pressure sample to atmospheric pressure.

Some sample streams may contain corrosive gases or water vapor that influence the accuracy of the measurements or potentially damage the analyzer. Removal of such undesirable matter or components can be accomplished by passing the sample through a packed bed of soil chemicals or desiccant. Further, a liquid treating agent may be applied with provisions that gas streams be broken up into small bubbles to assure proper contact between the liquid and gas phases. Care should be taken in such systems to avoid alteration of the sample and to condition the sample to a desired and reproducible form for analysis.

APPLICATIONS

Here a brief discussion will follow of the various sample probe and sampling system package designs that are used for gas, liquid, and solids sampling. The discussion will also cover the more special cases of stack, reactor, condensate, trace component, and multiple-stream sampling systems.

Gas Sampling Probes

When taking gas samples, the goal is to obtain representative samples with minimum time lag, using short, small-volume sampling lines. Whenever possible, it is preferred to draw dry and clean samples in order to minimize the need for filters, dryers, knockout traps, or steam tracing.

The sample tap should be located on the side of the pipeline to minimize liquid or dirt entrainment, and the sample should be taken from the center of the pipe. If it is necessary to periodically remove the probe for cleaning or to perform a sampling traverse, it is desirable that the probe be inserted through a packing gland and block valve, as shown in Figure 8.2y.

The volume of the sampling system should be kept to a minimum, while the velocities through the sample lines should be high to protect against the settling of entrained liquids or particulates that can cause plugging. Sample line tubing can be small as 1/8 in. (3 mm) in diameter, and sample flow velocities should be between 5 and 10 ft/sec (1.5 to 3 m/sec). When the sample is taken from a combustion zone or other *dirty* processes, a filter is usually provided at the tip of the sample probe, and a high-pressure filter blow-back line is provided for periodic filter cleaning (Figure 8.2z).

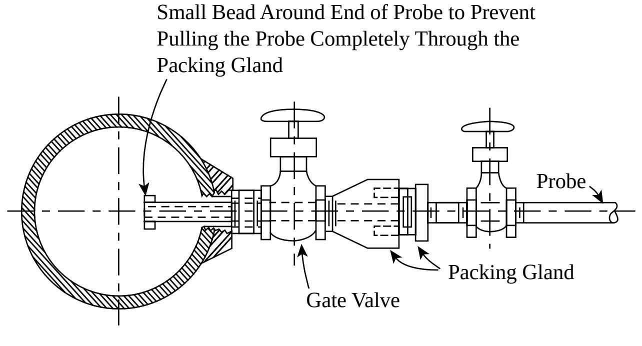

FIG. 8.2y
Gas sampling probe should be inserted from the side of the pipe to near the center of the pipe.[2]

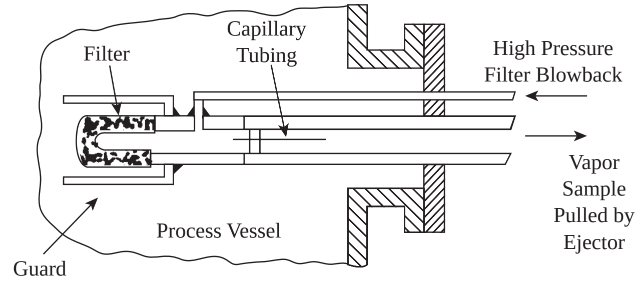

FIG. 8.2z
Gas sampling probes used on combustion processes are usually provided with probe-tip filters and blow-back lines for filter cleaning.

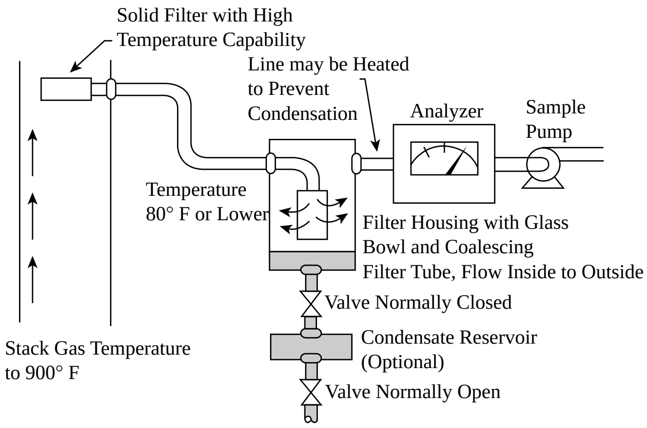

FIG. 8.2aa
Stack gas sampling.

Stack Gas Sampling

When sampling hot, wet stack gas, a filter capable of withstanding the gas temperature should be installed in the stack at the tip of the sample line to prevent solids from entering the gas sample line. After the sample is cooled, a coalescing filter is used to remove suspended liquids before the sample goes to the analyzer (Figure 8.2aa).

The sample flow direction is from inside to outside. Filter housings with Pyrex glass bowls are often used in this application to permit visual check of the liquid level in the filter housing. Since there is often a considerable amount of liquid present in the sample, steps must be taken to drain the housing to ensure that liquid does not build up and carry downstream to the analyzer.

The liquid coalescing filter should be located as close to the analyzer as possible to minimize the chance of condensation between the filter and the analyzer. Additional precautions that can be taken to avoid downstream condensation are to cool the sample below ambient temperature upstream of the coalescing filter and to heat the line gently between the filter and the analyzer.

Automatic Stack Sampling In these sampling packages, a microprocessor directs the automatic sampling method, which can be selected to follow U.S. Environmental Protection

Agency (EPA) Methods 1 to 6, 8, 17, and 23 or international methods specified by VDI, BS, or ISO. The microprocessor stores all measurements, reviews and diagnoses all inputs, controls the required parameters, calculates isokinetic conditions, and either reports the results in a printed form or transfers them to a floppy disc.

Besides the controller, such a package usually consists of a probe, a filter (hot) box, a cold box, a flexible sample line, glassware, a node box, and a monorail system. The probe is usually 3, 5, 7, or 10 ft (0.9, 1.5, 2.1, or 3 m) and made of stainless steel with a glass liner. Most probes are jacket heated and are provided with both a liner thermocouple and a stack temperature thermocouple.

The measured variables include the temperatures of the stack, probe liner, filter box, condenser outlet, and the dry gas meter. The pressures are detected by an absolute and a differential pressure transducer and are used to measure the pressure of the stack gas, the barometric pressure, and the velocity pressure of the stack gas. The normal capacity of the vacuum pump that draws the sample is 0.75 CFM (21 l/min), and the dry gas meter has an operating range of 0.1 to 1.5 CFM (2.8 to 42 l/min).

The node box provides the interface between the filter box and the cold box by measuring the temperatures in both. It measures and stores the temperature, pressure, and velocity in the stack. The monorail eliminates the need for bulky supports.

Automatic Liquid Samplers

Automatic liquid samplers collect intermittent samples from pressurized pipelines and deposit them in sample containers. The sample can be collected on a time-proportional or on a flow-proportional basis. Figure 8.2bb illustrates a sampler that withdraws a predetermined volume of sample every time the actuator piston is stroked. In the time-proportional mode, this sampling frequency is constant, while in the flow-proportional mode, this unit would vary the sampling frequency as a function of flow.

In some automatic liquid samplers, the sampling frequency is adjusted by pneumatic pulse relays or by electronic controls (Figure 8.2cc). Pulse duration is usually adjustable from 0.25 sec to 1 min, while pulse frequency can be adjusted from a few seconds to up to an hour. The intermittent in-line sampler illustrated in Figure 8.2cc can take samples at pressure up to 1500 psig (105 bars).

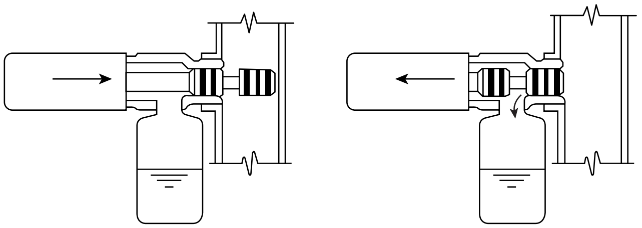

FIG. 8.2bb
Intermittent collection of samples. (Courtesy of Bristol Equipment Co.)

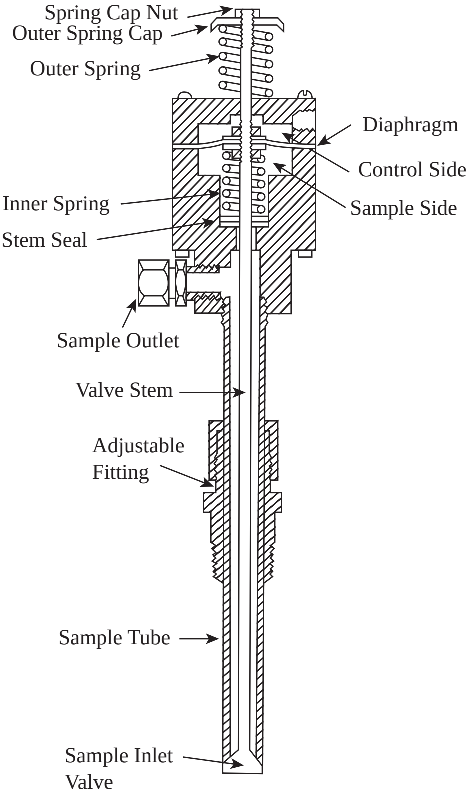

FIG. 8.2cc
Adjustable automatic load sampler.

Sampling of High-Pressure Condensate In high-pressure boiler systems, measurements of condensate conductivity, specific ion concentration, and feed-water additive concentrations are often required. In a continuous sampling system, the high-pressure steam or condensate is cooled below 100°F (38°C) and then reduced to near atmosphere pressure for metering to the analyzers. Filtration is required upstream of the pressure-reducing valves to prevent pitting to the valve seats by suspended particles and to eliminate variations in flow rate to the analyzers.

A stainless steel filter housing with the appropriate pressure rating and 25-micron filter tube is recommended. Since the analyzer system is often located some distance from the sampling point, slipstream filtration is usually required. Figure 8.2dd shows a sampling system in operation at a steam generation facility.

Chemical Reactor Samplers When samples are taken from chemical reactors by opening manholes, the operators can be exposed to dangerous fumes while the product can be degraded or cause explosions. To eliminate these problems, reactor sampling systems have been designed that allow the safe taking of samples.

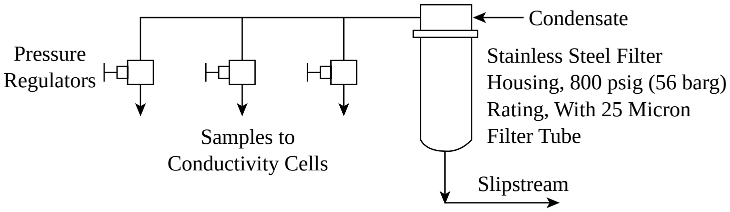

FIG. 8.2dd
High-pressure stream sampling.

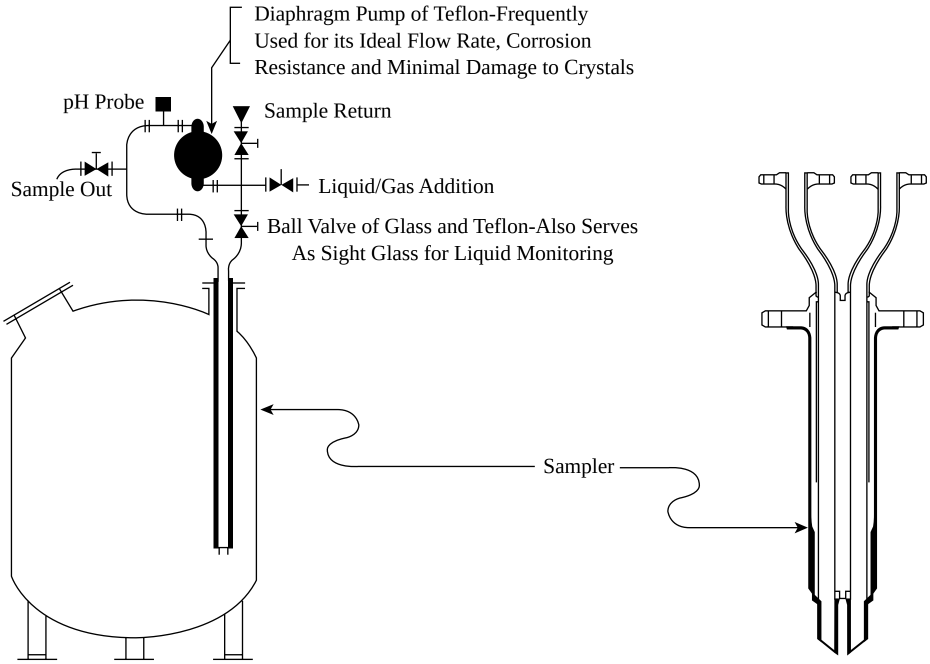

FIG. 8.2ee
Continuous or intermittent sampling of chemical reactor.[4]

The design illustrated in Figure 8.2ee requires only one nozzle (3 in. or 75 mm) and utilizes a Teflon-coated sampler assembly that can be used up to 150 psig (10.5 bars) and 350°F (177°C). For continuous sampling applications, such as for closed-loop pH control, a Teflon diaphragm pump is used to continuously return the analyzed sample.

Duckbill Samplers This sampler should be considered when liquid or sludge samples are to be collected at remote locations, from below the level in tanks, sewers, channels, sumps, lakes, or rivers.[5] As shown in Figure 8.2ff, this device has no moving mechanical components, only a rubber (EPT, Buna-N, or Viton) bucket-shaped Duckbill®, which is inside a housing made of polyvinyl chloride (PVC), aluminum, or stainless steel. This rubber insert closes around fibers or particulate matter without jamming. It is operated by compressed air.

The sample enters by gravity through the bottom connected Duckbill inside the sampling chamber, which is installed below the process liquid (or sludge) level and traps some air at the top of the chamber as it fills with the process fluid. When a sample is required, compressed air is introduced, which closes the Duckbill inlet and discharges the sample from the bottom of the chamber. When a new sample is to be drawn into the sample chamber, the compressed air is vented and a new fill cycle is initiated.

An automatic controller is provided on which the user can adjust the frequency at which samples are to be taken into a composite sample collection bottle.

Solids Sampling

When solids in bins or silos need to be sampled, one of the various solids feeders (described in Section 2.23) can be considered. When solids are to be sampled while flowing by gravity or while pneumatically conveyed under the pressure, the choice of sampling devices becomes more limited. The screw-type solids sampler can be used on these applications

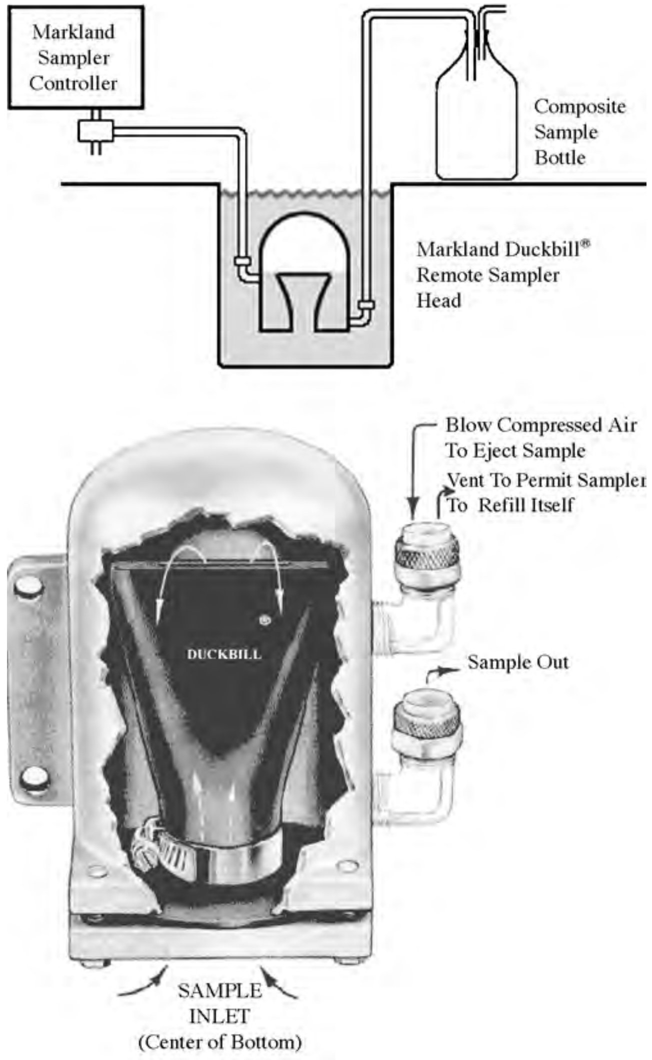

FIG. 8.2ff
Duckbill sampler. (Courtesy of Markland Specialty Engineering Ltd., www.sludgecontrols.com)

(Figure 8.2ff), but it is limited in the amount of pressure or vacuum it can seal against, and it does not provide an intermixed, representative sample. Screw samplers also introduce large transportation lags and cannot easily return the sample into the process.

An improved sampler design is described in Figure 8.2gg. This sampler can be sealed against small pressures or vacuums. It is operated by two actuators. During the sample collection phase, both actuators are extended into the process line. When a representative sample has been collected, it is withdrawn and simultaneously intermixed by pulling back actuator 1. As the analyzer is right above the withdrawn sample, the composition can be measured as soon as the sample has been taken. After analysis, actuator 1 is once again extended to return the old sample into the process. When it is time to take a new sample, actuator 2 is also extended and another sample is collected.

Sampling Difficult Processes

An analyzer system enhances process control by providing specific measurement of physical or compositional data of a process or ambient condition. With the advent of computer technology, the need for such analysis has increased substantially to provide on-line data that the computers use to optimize process control. Some of these advances have also improved the handling of such difficult tasks as sampling for trace component analysis or sampling multiple streams.

Trace Analysis Sampling Trace analysis sampling systems necessitate more stringent requirements than normal analyzer sample systems because of contamination, adsorption, and desorption (Figure 8.2hh). Care should be taken in the selection of construction materials and proper applications of design criteria to avoid alteration of the sample. The following is a list of recommended practices for such systems:

1. Stainless steel seamless tubing is the preferred material because it provides inertness, smooth surfaces, and low porosity.
2. All components should be thoroughly cleaned of oil, gas, or other contaminating materials.
3. Dense fluorocarbons or other soft inert materials may be used as diaphragms as required.

4. Tubing sizes are critical, especially where low flows are used, because they limit the amount of increase in the adsorption–desorption phenomenon. A rule of thumb is to use the smallest possible tubing to achieve maximum flow to accommodate the sample loop design.
5. Packless shutoff valves with a diaphragm or bellows seals should be used; however, due to their high cost, serious consideration must be given to this area, and conventional valves are suitable for most applications.
6. Filtration of the sample in ppm analysis can create significant problems unless the filter is totally inert. Therefore, stainless steel filters using a high flow rate or dense fluorocarbon inert materials are recommended for such applications.
7. Conditioning of the lines and system to accommodate the ambient temperature requirements for preventing condensation of components of interest in the sample must be considered; if necessary, heat tracing of the lines must be furnished.
8. When it is necessary to provide an aid for transporting the sample from its sample point to the sample system through the analyzer, as is frequently done in ambient monitoring systems, a sample pump, ejector, or aspirator is necessary. In such cases, the pump must be a diaphragm. If practical, an ejector to pressurize the sample or an aspirator to aspirate it through the measuring device can be used. Both are more desirable than a sample pump.

Multistream Switching Multistream switching is usually used when it is practical to analyze several streams using one analyzer. However, because this system is more complex than single-stream sample conditioning, the following considerations should be reviewed to determine if multistreaming is feasible:

1. The potential problem of cross-contamination among multiple streams
2. The importance of each analysis and frequency of analysis
3. The loss of information from more than one analysis in case of analyzer failure
4. The cost of an additional analyzer vs. the cost of multistreaming
5. Maintenance requirements

After reviewing the above, one can decide if multistreaming is feasible and whether it should be manual or automatic. Whether manual or automatic, multistreaming requires good-quality valves for stream switching.

A typical multistream sampling system is shown in Figure 8.2ii. A common and important requirement in all such systems is that a continuous bypass be provided for each sampling point to avoid dead-end sample lines. The sample system should be laid out in such a manner that contamination between streams is avoided. This is best accomplished by arranging the solenoid valve in a double-block double-bleed configuration, which is rather expensive.

More often, a three-way solenoid valve is used for each stream, with the venting port always at low pressures to create a relief in case of a leak. To prevent contamination, dead

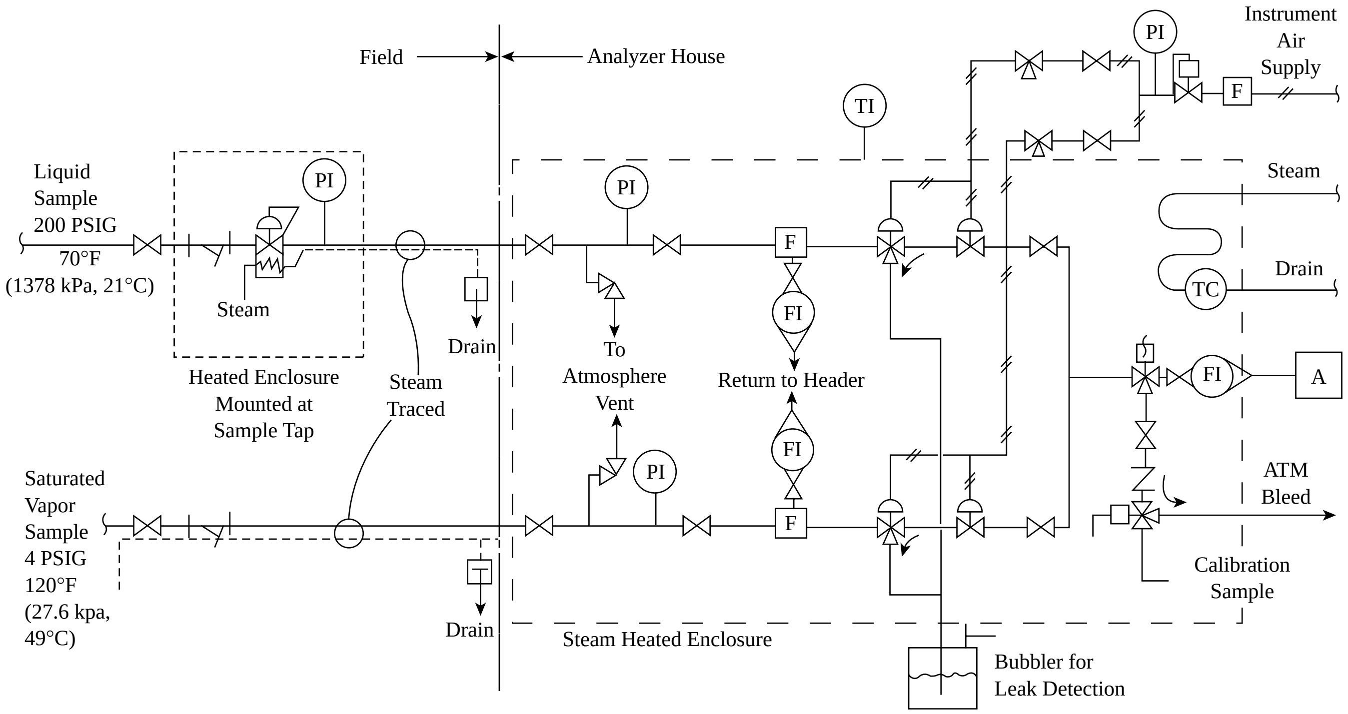

FIG. 8.2ii
Two-stream sampling system for trace analysis with a double-block, double-bleed configuration.

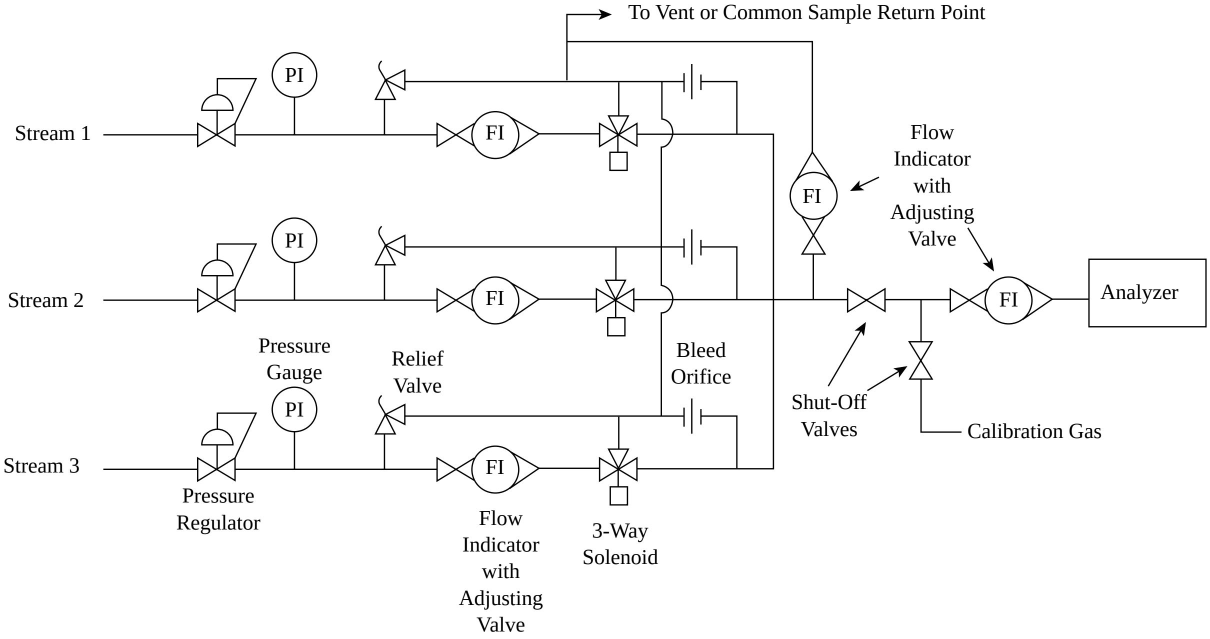

FIG. 8.2jj
Typical multistream automatic sampling system.

volume of the sample system should be considered, as well as equalization of the pressures upstream of the three-way valves. The problem is more severe in ppm sampling systems because of the adsorption–desorption effects, and careful consideration should be given to the design criteria described above.

INTRODUCTION

Stack gas sampling has already been discussed in the previous section in connection with Figure 8.2aa. In this section the emphasis will be on particulate sampling, and in that connection, the topics of traverse point locations and pitot tube designs will be emphasized.

THE EPA PARTICULATE SAMPLING SYSTEM

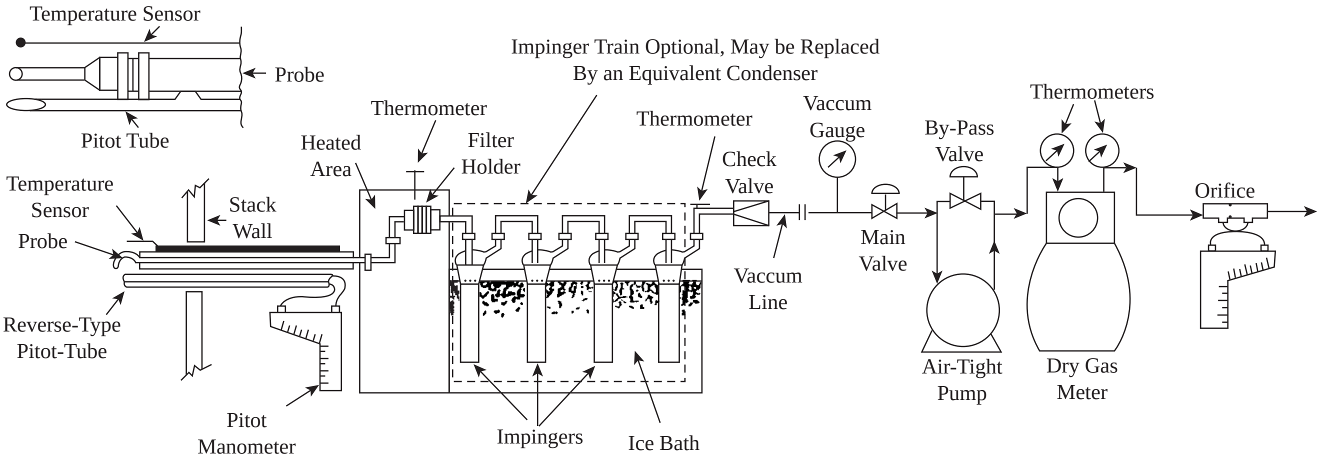
A complete Environmental Protection Agency (EPA) particulate sampling system (Reference Method 5)[1–8] is comprised of four major subsystems:

1. A pitot tube probe or *pitobe* assembly for temperature and velocity measurements and for sampling
2. A two-module sampling unit that consists of a separate heated compartment with provision for a filter assembly, and a separate ice-bath compartment for the impinger train and bubblers
3. An operating–control unit with a vacuum pump and a standard dry gas meter
4. An integrated, modular umbilical cord that connects the sample unit and pitobe to the control unit

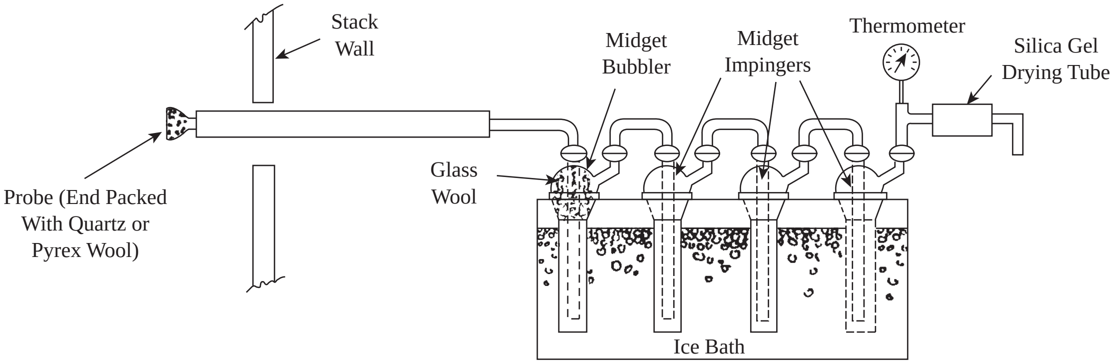
Figure 8.3a is a schematic of an EPA particulate sampling train (Method 5). As shown in the figure, the system can be readily adapted for sampling sulfur dioxide (SO_2), sulfur trioxide (SO_3), and sulfuric acid (H_2SO_4) mist (Method 8).[1,2]

Microprocessor-Controlled Stack Sampling

In these sampling packages, a microprocessor directs the automatic sampling method, which can be selected to follow



EPA Particulate Sampling Train (Method 5)
(Federal Register, Vol. 36, Nos. 234 and 247)



Sampling Case for SO_2, SO_3, and H_2SO_4 MIST (Method 8)

FIG. 8.3a

U.S. EPA Method 5 or other international methods specified by Verein Deutscher Ingenieure (VDI), British Standards Institution (BSI), or International Standards Organization (ISO). The microprocessor stores all measurements, reviews and diagnoses all inputs, controls the required parameters, calculates isokinetic conditions, and either reports the results in a printed form or transfers them to a floppy disk.

Besides the controller, such a package usually consists of a probe, a filter (hot) box, a cold box, a flexible sample line, glassware, a node box, and a monorail system. The probe is usually 3, 5, 7, or 10 ft (0.9, 1.5, 2.1, or 3 m) and made of stainless steel with a glass liner. Most probes are jacket heated and are provided with both a liner thermocouple and a stack temperature thermocouple.

This section will give a detailed description of each of the four subsystems: the pitot assembly, the heated and ice-bath compartments, and the control unit.

The Pitot Tube Assembly

The procurement of representative samples of particulates suspended in gas streams demands that the velocity at the entrance to the sampling probe be precisely equal to the stream velocity at that point. This is accomplished *by regulating the rate of sample withdrawal* so that the static pressure within the probe is equal to the static pressure in the fluid stream at the point of sampling.

A pitot tube of special design is used for such purposes with means for measuring the pertinent pressures. The pressure difference can be maintained at zero by automatically controlling the sample draw-off rate. Figure 8.3b shows a pitot tube manometer assembly for measuring stack gas velocity.

The Type S (Stauscheibe, or reverse) pitot tube consists of two opposing openings: one made to face upstream and the other downstream during the measurement. The pressure difference detected between the impact pressure (measured against the gas flow) and the static pressure is related to the stack velocity.

Type S Pitot and the Sampling Probe Figure 8.3c illustrates the construction of the Type S pitot tube. The external tubing diameter is normally between $\frac{3}{16}$ and $\frac{3}{8}$ in. (4.8 and 9.5 mm). As can be seen, there is an equal distance from the base of each leg of the tube to its respective face-opening planes.

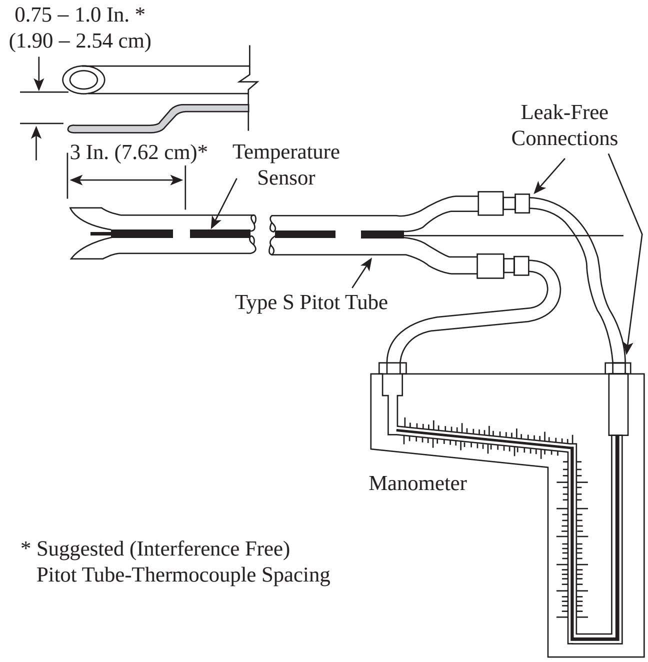

FIG. 8.3.b
Type S pitot tube manometer assembly.

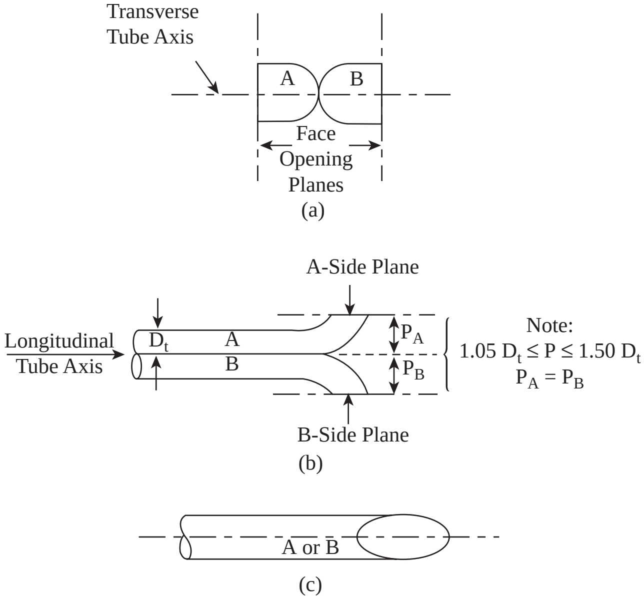

FIG. 8.3c
Properly constructed Type S pitot tube. (a) End view: face-opening planes perpendicular to transverse axis. (b) Top view: face-opening planes parallel to longitudinal axis. (c) Side view: both legs of equal length and center lines coincident, when viewed from both sides; baseline coefficient values of 0.84 may be assigned to pitot tubes constructed this way.

This distance (P_A and P_B) is between 1.05 and 1.50 times the external tube diameter. The face openings of the pitot tube should be aligned as shown.

Figure 8.3d shows the pitot tube in combination with the sampling probe. The relative placement of these components eliminates the major aerodynamic interference effects. The probe nozzle is of the bottom-hook or elbow design. It is made of seamless 316 stainless steel or glass with a sharp, tapered leading edge. The angle of taper should be less than 30°, and the taper should be on the outside to preserve a constant internal diameter (ID).

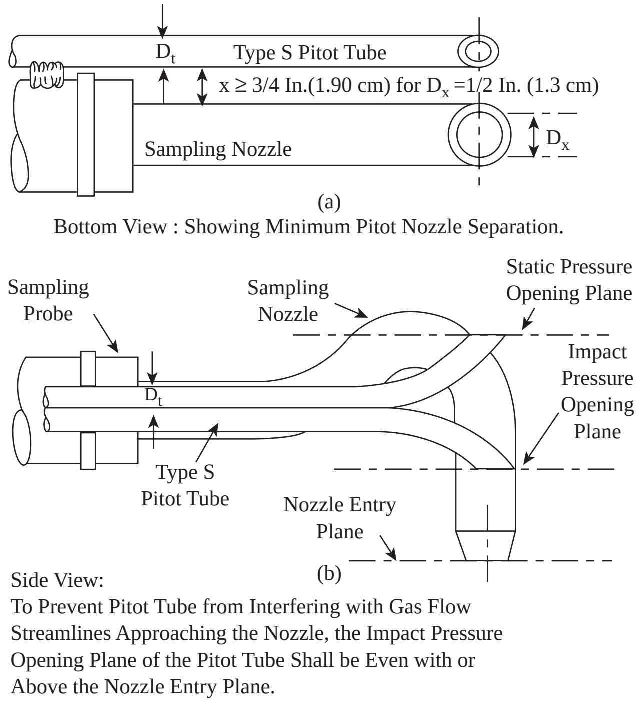

FIG. 8.3d
Proper pitot tube with sampling probe nozzle configuration to prevent aerodynamic interference. (a) Bottom view: minimum pitot nozzle separation. (b) Side view: to prevent pitot tube from interfering with gas flow streamlines approaching the nozzle, the impact pressure-opening plane of the pitot tube shall be even with or above the nozzle entry plane.

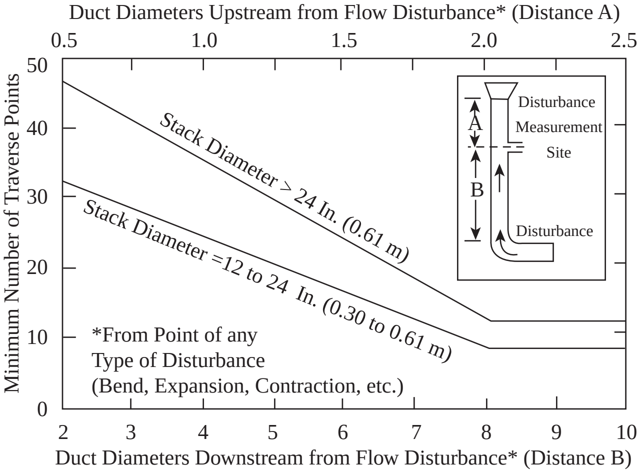

FIG. 8.3e
Minimum number of traverse points for particulate traverses.

For probe lining of either borosilicate or quartz glass, probe liners are used for stack temperatures up to approximately 900°F (482°C); quartz liners are used for temperatures between 900 and 1650°F (482 and 899°C). Although borosilicate or quartz glass probe linings are generally recommended, 316 stainless steel, Incoloy, or other corrosion-resistant metal may also be used.

Selecting the Sampling Point The specific points of stack sampling are selected to ensure that the samples collected are representative of the material being discharged or controlled. These points are determined after examination of the process of the sources of emissions and their variation with time.

In general, the sampling point should be located at a distance equal to at least eight stack or duct diameters downstream and two diameters upstream from any source of flow disturbance, such as expansion, bend, contraction, valve, fitting, or visible flame. (Note: This eight and two criterion is adopted to ensure the presence of stable, fully developed flow patterns at the test section.) For rectangular stacks, the equivalent diameter is calculated from the following equation:

$$\text{Equivalent diameter} = 2(\text{length} \times \text{width})/(\text{length} + \text{width}) \qquad \textbf{8.3(1)}$$

Traversing Point Locations Next, provisions must be made to traverse the stack. The number of traverse points is 12. If the eight and two diameter criterion is not met, the required number of traverse points depends on the sampling point distance from the nearest upstream and downstream disturbances. This number may be determined by using Figure 8.3e.

The cross-sectional layout and location of traverse points are as follows:

1. For circular stacks, the traverse points should be located on two perpendicular diameters, as shown in Figure 8.3f and Table 8.3g.
2. For rectangular stacks, the cross section is divided into as many equal rectangular areas as traverse points, such that the ratio of the length to width of the elemental area is between 1 and 2. The traverse points are to be located at the center of at least nine and preferably more equal areas, as shown in Figure 8.3f.

Pitot Tube Calculation Form The velocity head at various traverse points is measured using the pitot tube assembly shown in Figure 8.3b. The gas samples are collected at a rate proportional to the stack gas velocity and analyzed for carbon monoxide (CO), carbon dioxide (CO_2), and oxygen (O_2).

The pitot tube is calibrated by measuring the velocity head at some point in the flowing gas stream with both the Type S pitot tube and a standard pitot tube with a known coefficient. Other data also needed for calculation of the volumetric flow are stack temperature, stack and barometric pressures, and wet-bulb and dry-bulb temperatures of the gas sample at each traverse.

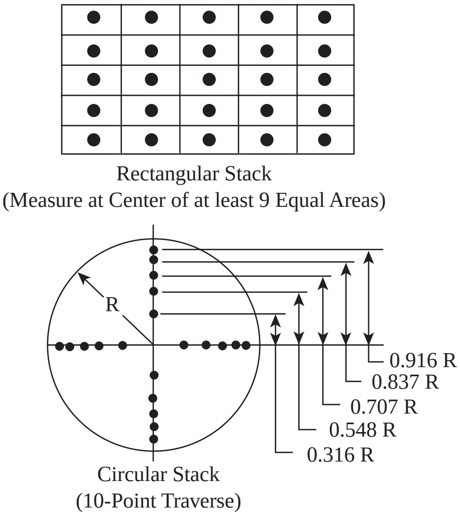

FIG. 8.3f
Traverse point locations for velocity measurement or for multipoint sampling.

Table8.3h gives the equations for converting pitot tube readings into velocity and mass flow, and a typical data sheet for stack flow measurements.[3]

Sampling Velocity for Particle Collection Based on the range of velocity heads, a probe with a properly sized nozzle is selected to maintain isokinetic sampling of particulate matter. As shown in Figure 8.3i, a converging stream will be developed at the nozzle face if the sampling velocity is too high. Under this subisokinetic sampling condition, an excessive amount of lighter particles enters the probe.

Because of the inertia effect, the heavier particles, especially those in the range of 3 microns or greater, travel around the edge of the nozzle and are not collected. The result is a sample indicating an excessively high concentration of lighter particles, and the weight of the solid sample is in error on the low side. Conversely, portions of the gas stream approaching at a higher velocity are deflected if the sampling velocity is below that of the flowing gas stream.

Under this superisokinetic sampling condition, the lighter particles follow the deflected stream and are not collected, while the heavier particles, because of their inertia, continue into the probe. The result is a sampling indicating high concentration of heavier particles, and the weight of solid sample is in error on the high side.

Isokinetic Sampling Isokinetic sampling requires the precise adjustment of the sampling rate with the aid of the pitot tube manometer readings and nomographs such as APTD-0576.[9] If the pressure drop across the filter in the sampling unit becomes too high, making isokinetic sampling difficult to maintain, the filter may be replaced in the midst of a sample run.

To measure the concentration of particulate matter, the sampling time for each run should be at least 60 min, and the minimum volumetric rate of sampling should be 30 dry scfm (51 m^3/h).[4]

TABLE 8.3g
Location of Traverse Points in Circular Stacks[a]

[a] Percent of stack diameter from inside wall to traverse point.

Heated Compartment (Hot Box)

As shown in Figure 8.3a, the probe is connected to the heated compartment that contains the filter holder and other particulate-collecting devices, such as cyclone and flask. The filter holder is made of borosilicate glass, with a frit filter support and a silicone rubber gasket.

The compartment is insulated and equipped with a heating system capable of maintaining a temperature around the filter holder during sampling at 248 ± 25°F (120 ± 14°C), or such other temperature as specified by the EPA. The thermometer should measure temperature to within 5.4°F (3°C). The compartment should be provided with a circulating fan to minimize thermal gradients.

Ice-Bath Compartment (Cold Box)

The ice-bath compartment contains a number of impingers and bubblers. The system for determining stack gas moisture content consists of four impingers connected in series, as shown in Figure 8.3a. The first, third, and fourth impingers are of the Greenburg–Smith design. To reduce the pressure drop, the tips are removed and replaced with a 0.5-in. (12.5-mm) ID glass tube extending to 0.5 in. (12.5 mm) from the bottom of the flask.

The second impinger is of the Greenburg–Smith design with a standard tip. During sampling for particulates, the first and second impingers are filled with 100 ml (3.4 oz) of distilled and deionized water. The third impinger is left dry to separate entrained water. The last impinger is filled with 200 to 300 g (7 to 10.5 oz) of precisely weighed silica gel (6 to 16 mesh) that has been dried at 350°F (177°C) for 2 h to completely remove any remaining water.

A thermometer capable of measuring temperature to within 2°F (1.1°C) is placed at the outlet of the last impinger for monitoring purposes. Crushed ice should be added during the run to maintain the temperature of the gas, leaving the last impinger at 60°F (16°C) or less.

Control Unit

As shown in Figure 8.3a, the control unit consists of the system's vacuum pump, valves, switches, thermometers, and totalizing dry gas meter. This system is connected by a vacuum line to the last Greenburg–Smith impinger. The pump intake vacuum is monitored with a vacuum gauge just after the quick disconnect.

A bypass valve parallel with the vacuum pump provides fine control and permits recirculation of gases at a low sampling rate so that the pump motor is not overloaded. Downstream from the pump and bypass valve are thermometers, a dry gas meter, and calibrated orifice and inclined/vertical manometers.

The calibrated orifice and inclined manometer indicate the instantaneous sampling rate. The totalizing dry gas meter gives an integrated gas volume. The average of the two temperatures on each side of the dry gas meter gives the temperature at which the sample is collected. The addition of atmospheric pressure to orifice pressure gives meter pressure.

Automatic Sampling Trains In the automatic sampling train (AST) packages (Figure 8.3j), a microprocessor stores all measurements, reviews and diagnoses all inputs, controls the required parameters, calculates isokinetic conditions, and

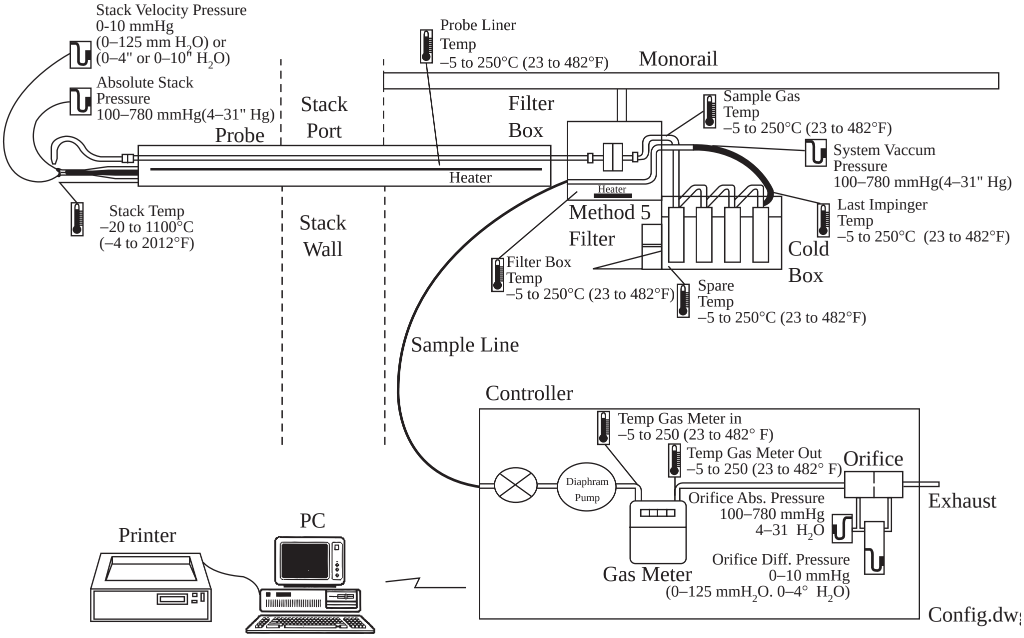

Fig. 8.3k

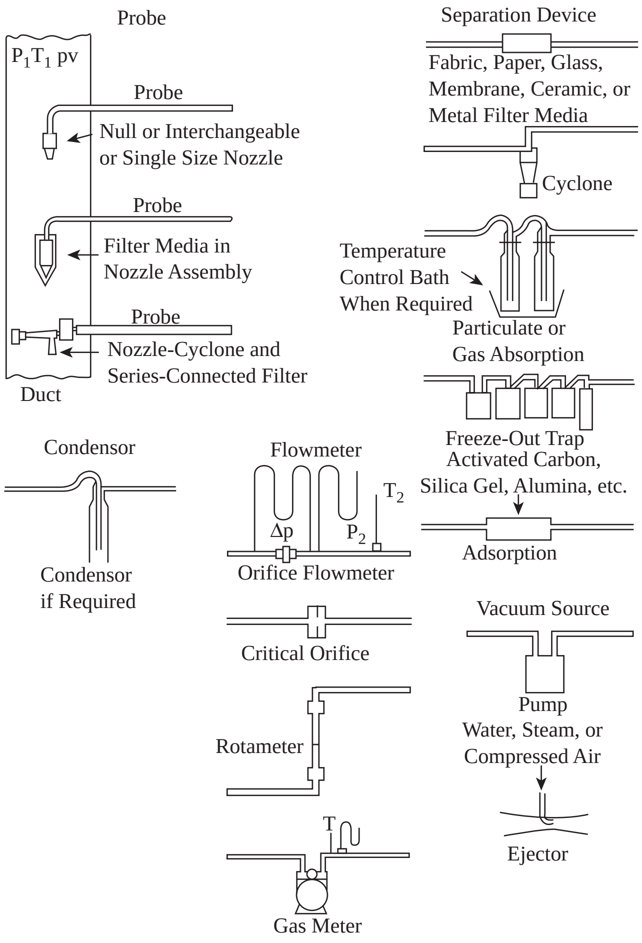

FIG. 8.3l

Components of common sampling systems.

either reports the results in a printed form or transfers them to a floppy disk.

The measured variables include the temperatures of the stack, probe liner, filter box, condenser outlet, and dry gas meter (Figure 8.3k). The pressures are detected by an absolute and a differential pressure transducer and are used to measure the pressure of the stack gas, the barometric pressure, and the velocity pressure of the stack gas. The normal capacity of the vacuum pump that draws the sample is 0.75 cfm (21 l/min), and the dry gas meter has an operating range of 0.1 to 1.5 cfm (2.8 to 42 l/min).

The node box provides the interface between the filter box and the cold box by measuring the temperatures in both. It measures and stores the temperature, pressure, and velocity in the stack. The monorail eliminates the need for bulky supports.

Precise measurements require that the thermometers be capable of measuring the temperature to within 5.4°F (3°C); the dry gas meter is inaccurate to within 2% of the volume; the barometer is inaccurate within 0.25 mmHg (torr) (0.035 kPa); and the manometer is inaccurate within 0.25 mmHg (torr) (0.035 kPa).

The umbilical cord is an integrated multiconductor assembly containing both pneumatic and electrical conductors. It connects the two-module sampling unit to the control unit, as well as the pitot tube stack velocity signals to the manometers or differential pressure gauges.

SAMPLING FOR GASES AND VAPORS

Some commonly used components in stack-sampling systems are illustrated in Figure 8.3l. If ball-and-socket joints and compression fittings are used, any arrangement of components is readily set up for field use. The stack sampling components are selected on the basis of the source to be sampled, the substances involved, and the data needed.

A summary of sampling procedure outlines was developed by industrial hygienists[10] for specific substances. The procedural outlines serve as a starting point in assembling a stack sampling system, after consideration has been given to the complications that might arise because of the presence of interfering substances in the gas samples. Other recommended sampling procedures that form gases and vapors are given in Reference 11.

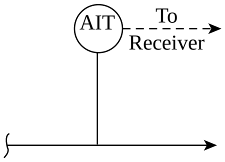
8.4 Analyzers Operating on Electrochemical Principles



Flow Sheet Symbol

R. GILBERT (1982) **J. N. HARMAN III** (1995) **B. G. LIPTÁK** (2003)

Design Variations:	Amperometric, coulometric, galvanometric, polarographic, and potentiometric principles
Sections Discussing Specific Applications:	8.10—carbon monoxide, 8.11—chlorine, 8.17—conductivity, 8.24—fluoride, 8.26—hydrogen sulfide, 8.28—ion-selective electrodes, 8.33—moisture in gas, 8.41—ORP probes, 8.42—oxygen, 8.44 and 8.45—ozone, 8.48—pH, 8.56—sulfur oxide, 8.59—toxic gases
Inaccuracy:	Generally 1% of full scale with absolute error values down to under 1.0 parts per billion (ppb)
Costs:	Amperometric or polarographic residual chlorine transmitters cost about $8000, with the yearly cost of chemicals for the amperometric units adding another $3000 (somewhat less for polarographic). An electrochemical gas diffusion detector for hydrogen sulfide costs $2500. Potentiometric probes for pH, oxidation–reduction potential, and ion-selective measurements cost about $500, with associated transmitter about $2500. Electrochemical probes for nitrogen oxide detection in stacks cost $7000. The electrolytic dissolved oxygen probe and transmitter cost $3500. Costs for amperometric gas and dissolved ozone detector range from $4000 to $8000. An electrochemical membrane diffusion system to automatically monitor toxic gas concentration in 16 locations costs from $12,000 to $20,000. For more detailed cost information, refer to the sections in this chapter where the specific analyzers are discussed.

INTRODUCTION

The purpose of this section is to give an overall perspective of the many electrochemical analyzers used in the processing industries. These instruments will be discussed in more detail in later sections of this chapter. Electrochemical analyzers measure composition or concentration by detecting the changes in voltage or current that occur between two electrodes in a solution (electrolyte) over time, because of the oxidation or reduction of that solution.

In galvanic and polarographic analyzers (such as CO, O_2, and toxic gas sensors discussed in Sections 8.10, 8.42, and 8.59), the electrolyte is usually a gel. The gel is separated from the process stream by a membrane and the electrochemical reaction in this electrolyte either occurs spontaneously or is caused by a polarizing voltage.

In potentiometric analyzers (such as Cl, conductivity, ion-selective, oxidation–reduction potential (ORP), and pH probes discussed in Sections 8.11, 8.17, 8.28, 8.39, and 8.48), an electrical potential is detected, which is generated in response to the presence of dissolved ionized solids. The ORP probe detects the ratio of oxidizing to reducing agent. Conductivity sensors measure the solution's ability to conduct electricity, which depends on the concentration of dissolved ionized solids.

In amperometric analyzers (such as Cl, Fl, HS, moisture in gas, O_3, and toxic gases covered in Sections 8.11, 8.24, 8.26, 8.33, 8.44, 8.45, and 8.59) if a strong oxidizing agent is present, the polarization of the measuring electrode is depolarized and a current flow is generated, which is proportional to the concentration of the oxidizing agent.

In coulometric analyzers (such as CO, oxygen in gas, and SO sensors discussed in Sections 8.10, 8.42, and 8.56), the measured gas diffuses through the potassium hydroxide electrolyte to the cathode of the electrochemical cell, where it is reduced to hydroxyl ions. As an external voltage causes these ions to migrate to the anode, the resulting cell current is a measure of concentration.

VOLTAMETRIC ANALYSIS

Voltametric analyzers monitor the current, voltage, or charge that results from a specific oxidation–reduction reaction of the component of interest. During an oxidation–reduction reaction, one or more electrons are transferred from one atom or molecule to another.

This section presents a brief review of voltametry, including a discussion of the concepts and properties of electrochemical probes, potentiometry, amperometry, polarography, and coulometry. The distinctions among voltametric methods are summarized in Table 8.4a. This table lists the common voltametric methods of analysis and their usual applications.

TABLE 8.4a
Summary of Voltametric Methods

Method	*Measured[†] Variables*	*On-Line Instrument*	*Determinations[a]*
Potentiometry	V	Yes	pH Anions (F^-, $S^=$, Cl^-) Cations (NH_4^+, Ca^{++}, Mg^{++})
Polarography	i, v	Yes	Pesticides Mercaptans Thiosulfates Chlorinated organics Toxic heavy metals
Stripping	i, v	No	Heavy metals Selenides Halogens Thioamides Trace metals
Amperometry	i, t, c	Yes	Sulfates Halides Phenols Aromatic amines Olefins
Controlled potential coulometry	$\int$ i(t)	Yes	Precious metals Alloys Dissolved oxygen
Differential pulse polarography	i, v	No	Aromatic hydrocarbons Aromatic amines Phenol Ammonium salts Carboxylic anhydrides N-nitrosamines

Note: i = current; v = applied potential; c = concentration; i(t) = current as function of time.
[a] Partial list.

Current, Voltage, and Time

Successful application of voltametry for monitoring and controlling process streams requires an understanding of the significant voltametric variables. The fundamental requirements for voltametry instrumentation are two electrodes, provisions for a current and voltage supply, and monitors for the respective voltage and current responses as a function of time. The characteristic response curves indicate the nature of the electrochemical analysis occurring in the solution between the electrodes. Figure 8.4b illustrates a surface that relates the three variables (current, voltage, and time), which are of interest in an electrochemical analysis.

The exact shape of a particular response curve in Figure 8.4b depends on the mass transport phenomena associated with the movement of the component of interest (analyte) to the working electrode. (The working electrode is the electrode in which the electrochemical process of interest occurs, while the reference electrode is passive. The usual working electrode is made from a metal, such as mercury, platinum, palladium, or gold.) Analyte diffusion to the working electrode is the usual transport mechanism required if the analytical expressions for the curves of Figure 8.4b are to be obtained. The control of diffusional mass transport is important for chronopotentiometry, amperometry, and polarography.

The electrochemical surface presented in Figure 8.4b is generated from the following equation:[1]

$$E = (E° + (RT/nF)\ \ln(f_o/f_r(D_r/D_o)^{1/2}) + (RT/nF)\ \ln[K - it^{1/2})/it^{1/2})] \qquad \textbf{8.4(1)}$$

Equation 8.4(1) expresses the potential (E) of the working electrode in terms of E°, the standard thermodynamic potential; R, the gas constant; T, the absolute temperature; F, Faraday's constant; n, the number of electrons transferred for the specified oxidation–reduction reaction; f, the activities of oxidized and reduced analyte forms; i, the current; and K, a constant dependent upon particular analysis parameters other than voltage, current, or time.

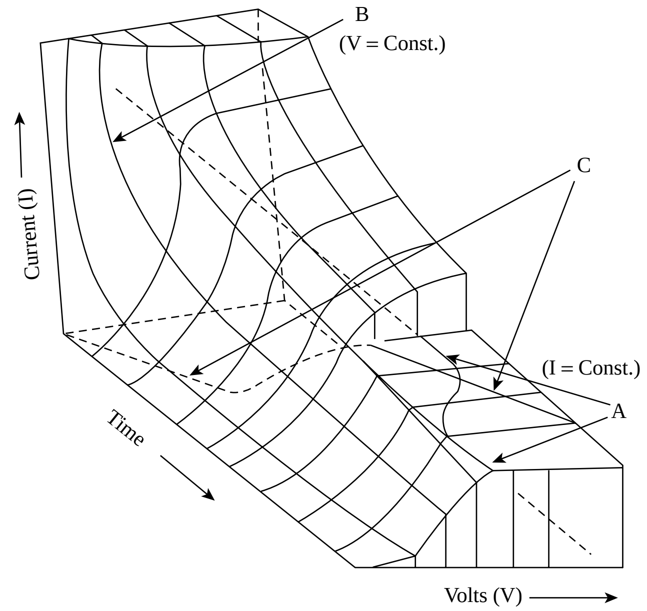

FIG. 8.4b
Response surface for voltametry, showing curve A, the process of chronopotentiometry; curve B, amperometry; and curve C, the polarographic process.

Potentiometry

During a potentiometric analysis, such as in ORP, pH, or ion-selective measurements, no current is passing between electrodes. The potential difference (at zero current) is monitored between the measuring and reference electrodes. At the measuring electrode, an oxidation or reduction of a solution species is taking place. Such an analysis is called chronopotentiometry when the potential difference between a metallic measuring electrode and a reference electrode is monitored as a function of time.

Potentiometry may be done with a bare metal electron-conducting electrode and a reference electrode, in which case the technique responds to the oxidation–reduction couples present in the test solution. If a potentiometric determination is conducted using an ion-selective electrode and a reference electrode, one may determine solution species over a wide dynamic concentration range with good selectivity, and there is no need for oxidation–reduction couples in the solution. Examples of ion-selective electrodes are glass electrodes for pH (Figure 8.4c) and sodium ion determination; solid-state electrodes for fluoride, chloride, and sulfide determination; and liquid ion exchange electrodes for the determination of calcium, magnesium, and nitrate ions.

If a constant current is supplied to the electrodes, the progress of the electrochemical reaction is observed by monitoring the change in potential as a function of reaction time. This procedure is labeled chronopotentiometry, and a response curve would be similar to curve A in Figure 8.4b.

If the electrochemical process occurs at a constant potential, the reaction response is monitored as a changing current as a function of time. This type of analysis is called constant potential voltametry, or amperometry. A typical response curve is labeled B in Figure 8.4b.

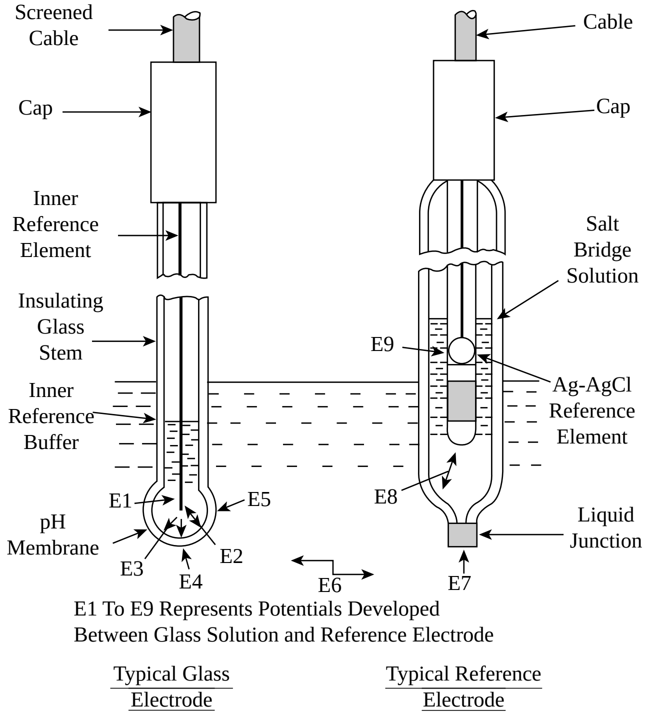

FIG. 8.4c
pH electrodes.

Finally, monitoring reaction current as a function of applied potential is called polarography, and a typical polarographic curve is represented by C, which is a diagonal cut through the response surface, in Figure 8.4b.

Galvanic and Electrolytic Probes

A probe is galvanic when no external voltage is applied across the electrodes. In that case, the current flows as the cell is depolarized as diffusion of the analyte occurs. Electrodes are consumed during this operation and require periodic replacement. An electrolytic probe is similar to a galvanic one, except that a potential is applied across the electrodes and the electrodes are not consumed. Dissolved oxygen detection is a primary application of this type of probe.

Electrochemical probes are electrochemical cells that have been designed to respond to the presence of a particular analyte. Similar to electrochemical cells, electrochemical probes can be classified as either galvanic or electrolytic. Electrolytic probes require an external potential to be applied across the electrodes; galvanic probes do not. Both types of probes require a pair of electrodes, usually metallic, which are immersed in an electrolyte so that current passes through the electrodes as the desired oxidation or reduction occurs at the surface of the working electrode.

The difference between an electrolytic and a galvanic probe is whether or not a potential from an external source is

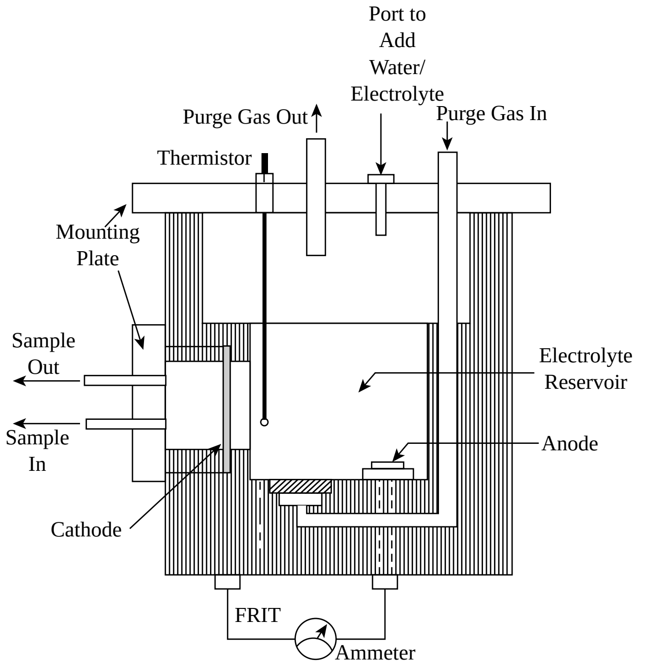

FIG. 8.4d
Galvanic oxygen detector cell. (Courtesy of Teledyne Analytical Instruments.)

applied across the electrodes. Galvanic probes are constructed in such a manner that the presence of the analyte depolarizes the cell and allows a flow of electrons in the cell (Figure 8.4d). Because the electrochemical reaction occurs spontaneously, no external potential need be applied across the electrodes. However, galvanic probes have a major disadvantage in that the electrodes are consumed as the reaction continues. This limitation restricts their usefulness to monitoring situations in which periodic replacement of spent probes is acceptable.

Electrolytic probes are principally used as monitoring devices for dissolved oxygen in aqueous and nonaqueous media. Unlike with the galvanic probe, here a potential is applied from an external source across the electrodes. The choice of potentials is controlled by the analyte to be determined. The current from the probe is obtained at constant potential as a function of time, location of the probe within the process, or the process state.

Membrane-Covered Probes To reduce the chemical interference from the process, a diffusion-limiting membrane can be placed over both electrodes. These membranes are permeable to the component of interest and are filled with the appropriate electrolyte. The thin analyte-permeable membrane separates the cell components and the electrolyte from the solution to be analyzed (Figure 8.4e).

A deficiency of this technique is the dependence of the membrane permeability on the process temperature. This is usually corrected by measuring the process temperature and adjusting the gain of the analyzer unit to compensate for the permeability effects. Another problem is the interferences caused by dissolved gases other than oxygen, which permeate the membrane and cause interferences as they are oxidized or reduced at the working electrode. Fouling or coating of the probe necessitates frequent cleaning, although the equilibrium-dissolved oxygen sensor greatly reduces the fouling problems and also allows use in almost stagnant flows with very small face velocity at the probe.

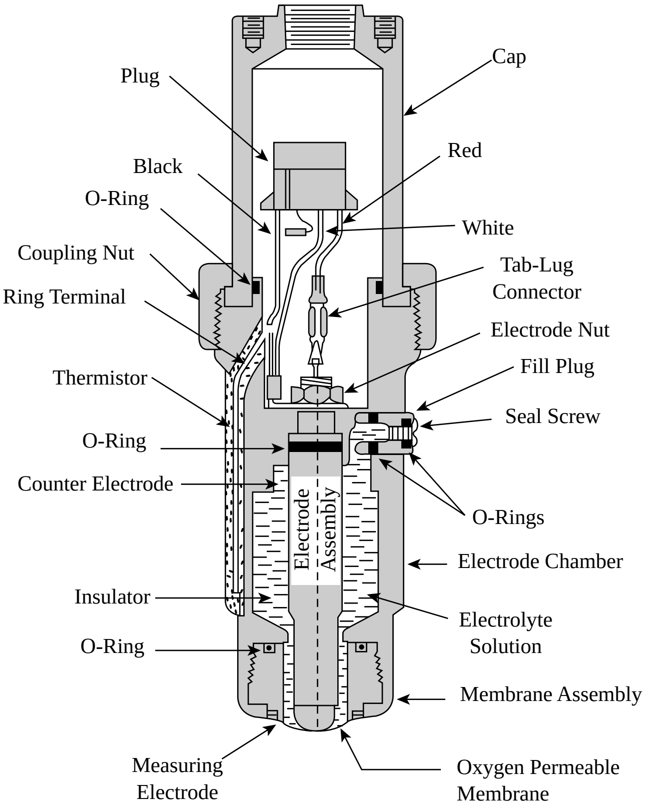

FIG. 8.4e
An oxygen-permeable membrane protects the working components of a galvanic dissolved oxygen probe. (Courtesy of ABB Inc., formerly Fischer & Porter.)

Figure 8.4f shows a nominal configuration for an electrolytic probe. The probe consists of an inner and outer element. The inner element contains the cathode and anode with wires leading to the power supply and current-monitoring circuit. The anode is positioned in a way that isolates the cathode from the anode. The outer element fits over the inner element and provides a space for the electrolyte. The membrane is mounted on the outside of this outer element and secured with an O-ring.

Sensors are available in disposable, nonrechargeable configurations, as well as in rechargeable configurations, in which access is provided to allow electrolyte change, electrode cleaning, and membrane replacement.

Amperometry

Amperometric titration is when the end point is determined by measuring the current (amperage) that passes through the solution at a constant voltage. Amperometry is the process

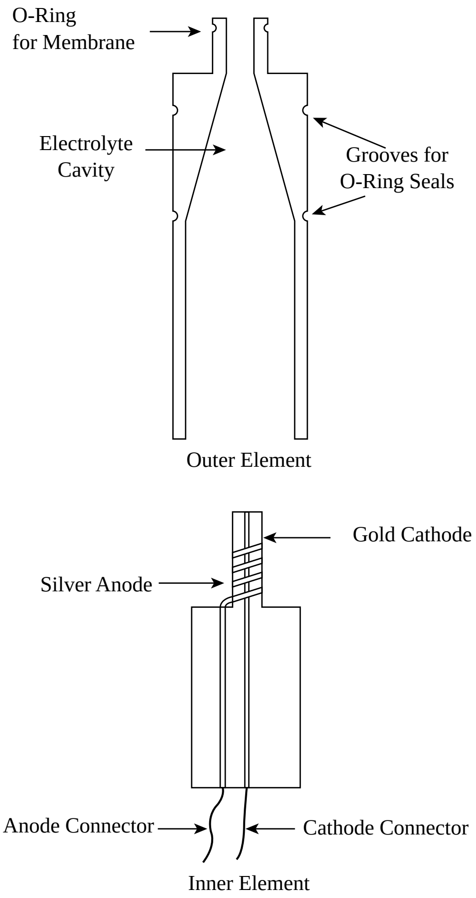

FIG. 8.4f
Configuration of an electrolytic probe. The inner element contains the anode and cathode, while the outer element isolates the electrolyte from the sample.

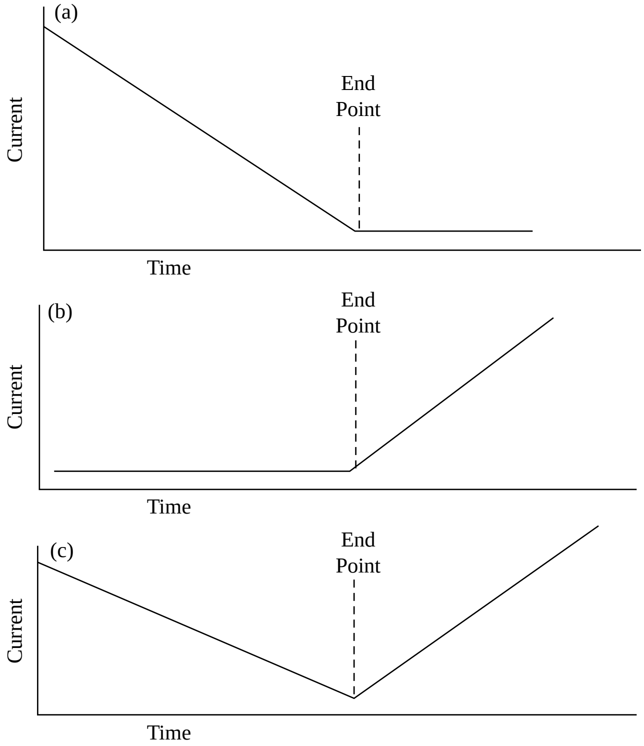

FIG. 8.4g
Response curves for polarographic cell system, showing curve A, when analyte reacts at electrode; curve B, when reagent reacts at electrode; and curve C, when analyte and reagent react at electrode.

of performing an amperometric titration. During such titration, the current flow is monitored as a function of time between working and auxiliary electrodes while the voltage difference between them is held constant. Alternatively, the current can also be monitored as a function of the amount of reagent added to bring the titration of an analyte to the (stoichiometrically defined) end point. This is also called constant potential voltametry.

In amperometry, the titrating reagent is coulometrically generated and the current that passes through a polarographic cell (containing either a solid or dropping mercury electrode at the appropriate oxidation or reduction potential) is measured as a function of reagent volume or time. Three types of response curves can be expected (Figure 8.4g).

Curve (a) is the result of the analyte reacting at the electrode, while the reagent does not. This curve indicates that the diffusion current is detected as long as the analyte remains. Once the reagent removes all the analyte, the current stops. This dead-stop end-point technique is often used for amperometric determinations of dissolved oxygen.

In curve (b), the analyte is not reduced at the working electrode, but the reagent is. In this situation, there is no current flow until the analyte is completely destroyed and the reagent is allowed to react at the electrode surface.

Finally, curve (c) indicates the response when both analyte and reagent are electroactive. The increase after the equivalence point indicates that the current is the result of excess reagent reacting at the electrode surface.

Solid Electrodes If the polarographic cell is replaced by a two-solid electrode system with a small applied potential (0.1 to 0.2 V), the response curves of interest are determined by a number of reversible reactions occurring in the cell at the voltage level impressed across the cell.

The set of reversible half-reactions of interest are symbolized as

$$R_r \ f \ R_o + e^- \qquad \textbf{8.4(2)}$$

and

$$A_o + e^- \ f \ A_r \qquad \textbf{8.4(3)}$$

where A_o and R_o are the oxidized forms, and A_r and R_r are the reduced forms of the analyte and reagent, respectively. The fundamental concept of interest is the fact that the applied potential will support current flow only when both forms represented in Equation 8.4(2) or Equation 8.4(3) are present in the test solution. Figure 8.4h represents the possible response curves that illustrate this concept.

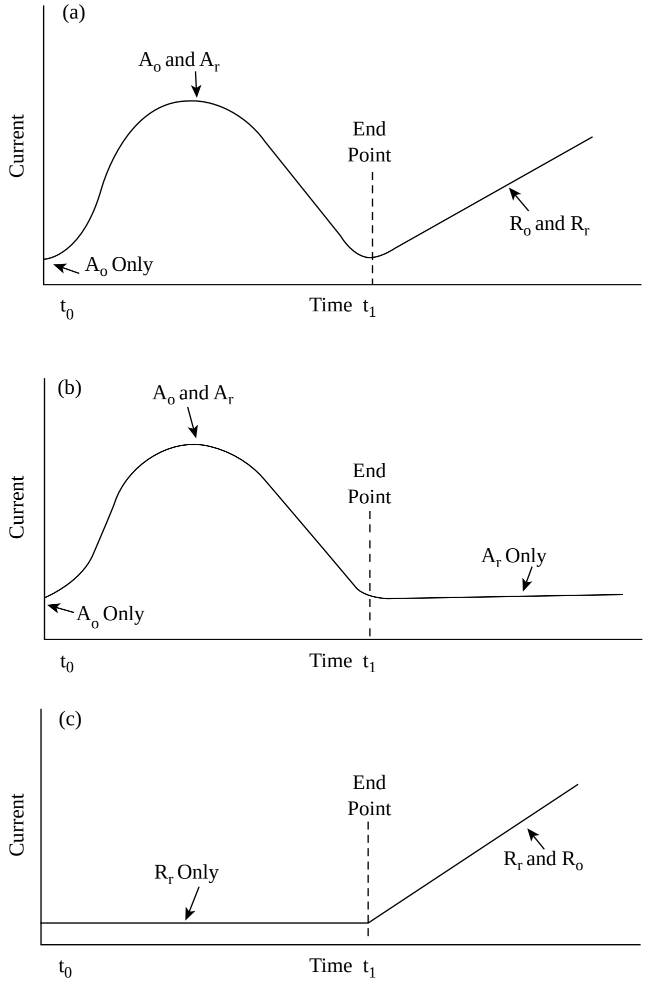

FIG. 8.4h
Response curves for two-solid electrode system, showing curve A, when analyte and reagent are reversible; curve B, when only the analyte is reversible; and curve C, when only the reagent is reversible.

In curve (a) of Figure 8.4h, the absence of current at t_o is due to the lack of A_r. For values of t so that $t_o < t < t_1$, the current response is the result of varying concentrations of A_o and A_r as R_r is added. At $t = t_1$, the current returns to zero because of the absence of A_o and R_r. Finally, for $t > t_1$, the continuous addition of R_r, coupled with the R_o present from the redox reaction with A_o, results in a continuously increasing current flow.

Curve (b) indicates the response when only the analyte reaction is reversible. The curve from $t_o < t \leq t_1$ is identical to the same portion of curve (a) for the same reasons. However, for $t > t_1$, no current is detected because the reagent half-reaction is irreversible.

Curve (c) shows the results when the analyte reaction is irreversible but the reagent half-reaction is reversible. Current is not detected until R_r remains in the solution. This case is often called a dead-start titration because the current does not begin until all the analyte has been removed. Figure 8.4i illustrates the design of another membrane-type amperometric sensor.

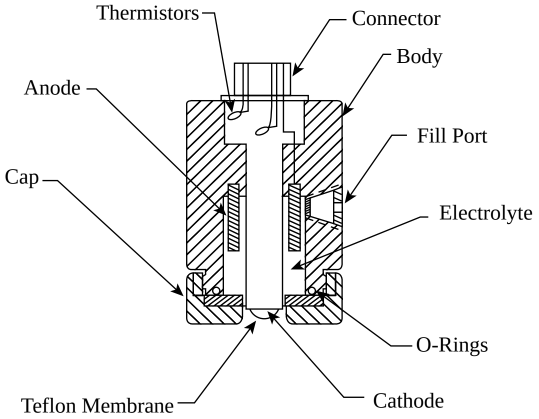

FIG. 8.4i
Membrane-type amperometric probe.

Polarography

Polarography is a process for monitoring the diffusion current flow between working and auxiliary electrodes as a function of applied voltage as it is varied systematically. The diffusion current that results is linearly dependent on the concentration of the analyte. Polarography can be applied using direct current, pulsed direct current, or alternating current (AC) voltage excitation waveforms. Dissolved oxygen determination is an example of an application for which polarography is used (Figure 8.4e).

Nobel Prize winner Jaroslav Heyrovsky developed direct current polarography in 1922. Polarography is performed by measuring the current flow, which is a function of the systematically varied electrode potential. Different types of polarographies can be performed as a function of the voltage variation patterns, voltage sweep rates, and the choice of working electrode materials.

Figure 8.4j shows a typical polarographic response curve.

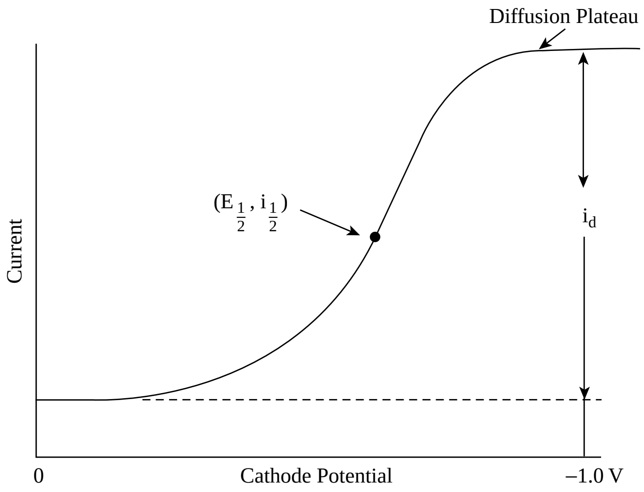

FIG. 8.4j
Polarogram showing typical current vs. cathode potential response. The diffusion current, i_d; the half-wave potential, $E_{1/2}$; and the half-wave current, $i_{1/2}$, are all illustrated.

For this curve, the K term in Equation 8.4(1) is defined as

$$K = nFC°(7/3D_o)^{1/2} \qquad \textbf{8.4(4)}$$

and

$$(nF/KT)(E - E° - \ln(f_o/f_r(D_o/D_r)^{1/2}) = \ln(i_d - i/i) \qquad \textbf{8.4(5)}$$

where i_d is the diffusion current. The curve shows an S-shaped current response as the potential at the cathode, the working electrode where analyte reduction occurs, becomes more negative. Current limited by diffusion occurs at cathodic potentials beyond the potential required to initiate reduction. Thus, i_d is sufficient to reduce the diffusion-supplied analyte concentration to zero.

The significance of this is that the diffusion rate is controlled by the concentration gradient established between the concentration at the surface of the working electrode, which is held to zero as a result of the electrode reaction, and the concentration existing in the bulk of the solution. The current observed for the Faradic process of interest is directly proportional to the concentration of the desired analyte.

Subsequently, this technique was modified by changing the voltage excitation waveform to alternating current (AC polarography) or to pulsed direct current (pulse polarography or differential pulse polarography); these modifications resulted in increased sensitivity and better discrimination for the detection of the desired analyte in a background matrix of interferences.

Advantages One of the valuable aspects of a polarographic determination is that the potential observed at the point $i_{1/2} = i_d/2$ is unique to the analyte in the solution matrix. This occurs because the potential at $i_{1/2}$ is independent of the reactant concentrations but directly related to the standard potential for the analyte half-reaction. This inflection point potential is defined as the half-wave potential, $E_{1/2}$, and is a common parameter for qualitative identification of electroactive components in a solution.

When the reaction is fast and reversible and the diffusion coefficients of the oxidized and reduced forms of the analyte are virtually identical, $E_{1/2}$ becomes E°. Another value of polarography is that the diffusion current is linearly related to the concentration of the analyte.

Coulometry

Coulometry is the process of monitoring analyte concentration by detecting the total amount of electrical charge passed between two electrodes that are held at a constant potential or when constant current flow passes between them. Because the coulomb provides a direct connection through Faraday's law between reaction current and analyte concentration during a redox process, coulometry offers a direct method of determining analyte concentration.

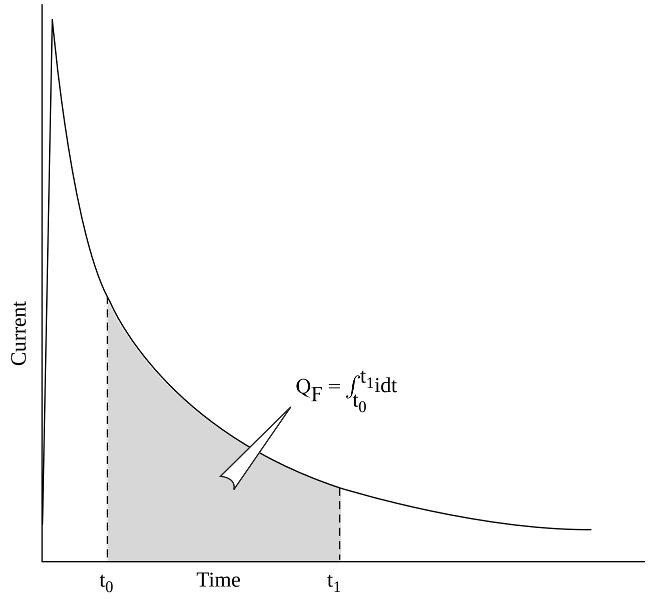

FIG. 8.4k
Response curve for controlled potential coulometry, showing the relationship among current, i; time, t; and coulombs, Q_F, in the Faradic portion of the curve.

Two types of coulometry are possible: constant current and controlled potential. Constant current coulometry depends on analyte oxidation–reduction to support the specified current flow. When the supply of material is insufficient to carry this current, the electrode potential drifts until another reaction begins. The result of this process is a potential time relationship similar to the results obtained in chronopotentiometry, and the amount of charge passed is simply the product of the constant current and electrolysis time.

Controlled Potential Coulometry By contrast, controlled potential coulometry is conducted by maintaining a constant electrode potential while a current flow is measured. The number of coulombs is determined by integration of the reaction current as a function of electrolysis time. Figure 8.4k illustrates the current–time relationship for controlled potential coulometry.

The choice of integration time is important because the current is the sum of the Faradic component and a capacitative component. As a result of this dual contribution, current integration is not started until the capacitative-charging contribution is minimal.

CONCLUSIONS

Although instruments are available for all types of voltametric analysis, currently only the potentiometric, polarographic, amperometric, and coulometric designs are available as online process analyzers. This is likely to change.

Limitations

The limitations of this category of sensors are mostly related to the membranes. One major problem with the thin permeable membranes is the fact that the electrode response to the analyte is directly dependent on the condition of the membrane. Once the potential has been applied across the electrodes and the concentration depletion wave has reached the inner membrane wall, the amount of analyte that reaches the electrode depends on the diffusion of the analyte through the membrane. This situation is usually acceptable because the membrane condition is stable. The membrane itself is also subject to failure, and the surface of the membrane is exposed to the process fluid, which can alter its permeability to the analyte. These conditions make the long-term reliable use of electrolytic probes problematical, because they require constant maintenance and recalibration.

Amperometric end points pose another problem. To date, provisions for the various end points possible are not available, and care must be taken when determining analysis end points. Finally, instrumentation for coulometric methods requires that the working electrode be physically separated from the auxiliary electrode so that the reaction products do not migrate to the opposite electrode. Sintered glass discs are used to restrict the migration of reaction products between the electrodes, but they permit electrical conduction through the cell. Table 8.4a provides a summary of voltametric methods and applications.

Advances

Significant advances have been made by the introduction of equilibrium-state voltametric probes. These have the advantage of analyte sensitivities that are relatively independent of membrane coating and consume so little of the analyte as a result of the measurement process that they are able to work in processes where the sample flow rate past the face of the sensor is small.

INTRODUCTION

This section covers the monitoring of ambient air quality. Air sampling is discussed, but the same subject is also covered in more detail in Section 8.2. Particulate and opacity monitoring are not covered here, as those topics are discussed in a later section in this chapter.

This section starts with a general discussion of air quality monitoring systems and continues with a description of air quality detecting sensors, automatic monitoring packages, and microprocessor-based portable ambient air analyzers. The section is concluded with a discussion of ambient air sampling for both gases and particulate matter.

AIR QUALITY MONITORING SYSTEMS

There are many options for the types of air quality information that can be collected, and the cost of air quality monitoring systems can vary by orders of magnitude. Only with a thorough understanding of the decisions that must be made based on the information received from the air quality monitoring system can an appropriate selection be made. Regardless of the type of instruments used to measure air quality, the data are only as good as they are representative of the sampling site selected. See Table 8.5a for a list of air quality and meteorological parameters and their measurement ranges, accuracy, and method of analysis.

TABLE 8.5a
Ambient Air Monitoring and Meteorological Measurement Parameters

Compound	*Range*	*Accuracy*	*Technique Employed*
Oxides of nitrogen	0–20 ppm	0.5 ppb	Chemiluminescence or DOAS open path
Sulfur dioxide	0–20 ppm	0.5 ppb	Fluorescence dual-channel ratiometric phase detection or DOAS open path
Ozone	0–20 ppm	0.5 ppb	Ultraviolet photometrics or DOAS open path
Carbon monoxide	0–200 ppm	50 ppb	Gas filter correlation or DOAS open path
Carbon dioxide	0–100%	50 ppb	Gas filter correlation or DOAS open path
Benzene, toluene, xylene	0–5 ppm	0.5 ppb	Gas chromatography or DOAS open path
Nonmethane hydrocarbons	0–1000 ppm	0.01 ppm	FID or DOAS open path
Methane	0–1000 ppm	0.01 ppm	FID or DOAS open path
Particulates (PM10, TSP, PM2.5)	0–5 g/m^3	0.1 $\mu g/m^3$	Tapered element oscillating microbalance
Carbon particulates	0–5 g/m^3	0.25 $\mu g/m^3$	Thermal CO_2 method
Local visual distance	0–16 km	±10%	Nephelometer
Wind speed	0–70 m/sec	0.22 m/sec	Anemometer
Wind direction	0–540°	±3°	Airfoil vane
Ambient temperature	–50 to 100°C	±0.1°C	Solid state thermistor
Relative humidity	0–100%	±2%	Thin film capacitor
Barometric pressure	800–1200 mbar	±1.3 mbar	Solid state transducer
Precipitation	NA	0.1 mm	Net radiometer
Solar radiation	250–2800 nm	9 mV/kWm^2	Pyranometer
Net radiation	250–60000 nm	8 mV/kWm^2	Net radiometer

Note: NA = not applicable; FID = flame ionization detector.

Source: Courtesy of Ecotech.

The simplest air quality monitors are static sensors, which are exposed for a given length of time and are later analyzed in the laboratory. In some cases, these devices provided all the information required. More commonly, a system of automatic instruments measuring several different air quality parameters will be used. With more than a few instruments, the signals from these instruments can be retained on magnetic tape rather than on recorder charts.

The most common errors in the design of air quality monitoring systems are poor site location and the acquisition of more data than necessary to accomplish the purpose of the installation.

Purpose of Monitoring

The principle purpose of air quality monitoring is frequently the acquisition of data for comparison to regulated standards. In the U.S., standards have been promulgated by the federal government[1] and by many of the states. Where possible, these standards have been based on the physiological effect of the air pollutant in question, so that human health is protected. The averaging time over which various concentration standards must be maintained is different for each pollutant. Tables 8.5b and 8.5c are tabulations of the ambient air quality standards promulgated by the federal government.

Impact of Single Sources

Some air quality monitoring systems are operated to determine the impact of a single source or a concentrated group of sources of emission on the surrounding area. In this case, it is important to determine the background level, the maximum ground-level concentration in the area, and the geographical extent of the air pollutant impact of the source. When the source is isolated, such as a single industrial plant in a rural area, the design is straightforward. Utilizing meteorological records, which are normally available from nearby airports or from government meteorological reporting stations, a wind rose can be prepared to estimate the direction of principal drift of the air pollutant from the source.

Dispersion calculations can be performed to estimate the location of the expected point of maximum ground-level concentration. As a rule of thumb, with stacks between about 50 and 350 ft tall, this point of maximum concentration will be approximately 10 stack heights downwind. The air quality monitoring system should include at least one sensor at the point of expected maximum ground-level concentration. Additional sensors should be placed not less than 100 stack heights upwind (prevailing) to provide a background reading, and at least two or three sensors should be placed between 100 and 200 stack heights downwind to determine the extent

TABLE 8.5b
Primary Air Quality Standards[a]

Pollutant	*Long-Term Concentration Level($\mu g/m^3$)*	*Short-Term Concentration Level*[b] *($\mu g/m^3$)*
Particulate matter	75—annual geometric mean	260—maximum 24-h concentration
Sulfur oxides (SO_2)	80 (0.03 ppm)—annual arithmetic mean	365 (0.14 ppm)—maximum 24-h concentration
Carbon monoxide	—	10,000 (9 ppm)—maximum 8-h concentration or 40,000 (35 ppm)—maximum 1-h concentration
Photochemical oxidants	—	160 (0.08 ppm)—maximum 1-h concentration
Hydrocarbons	—	160 (0.24 ppm)—maximum 3-h concentration (6–9 A.M.)
Nitrogen dioxide	100 (0.05 ppm)—mean arithmetic mean	

[a] Levels of air quality that are deemed necessary, with an adequate margin of safety, to protect the public health.
[b] Stated concentration not to be exceeded more than once per year.

TABLE 8.5c
Secondary Air Quality Standards[a]

Pollutant	*Long-Term Concentration Level($\mu g/m^3$)*	*Short-Term Concentration Level*[b] *($\mu g/m^3$)*
Particulate	60—annual geometric mean	150—maximum 24-h concentration
Sulfur dioxide	60 (0.02 ppm)—annual arithmetic mean	260 (0.1 ppm)—maximum 24-h concentration
Carbon monoxide	—	10,000 (9 ppm)—maximum 8-h concentration or 40,000 (35 ppm)—maximum 1-h concentration
Photochemical oxidants	—	160 (0.08 ppm)—maximum 1-h concentration
Hydrocarbons	—	160 (0.24 ppm)—maximum 3-h concentration (6–9 A.M.)
Nitrogen dioxide	100 (0.05 ppm)—maximum arithmetic mean	—

[a] Levels of air quality that are deemed adequate to protect the public welfare from any known or anticipated adverse effects.
[b] Stated concentration not to be exceeded more than once per year.

of the travel of the pollutants from the source in question. If adequate resources are available, sampling at the intersection points of a rectilinear grid with its center at the source in question is advisable.

With such a system for an isolated source, adequate data can be obtained in 1 year to determine the impact of the sources on the air quality of the area. There are very few instances where less than 1 year of data collection will provide adequate information because of the variability in climatic conditions on an annual basis. If a study of this type is performed to determine the effect on air quality of process changes, it may be necessary to continue the study for 2 to 5 years to develop information that is statistically reliable.

Some air quality monitoring is designed for the specific purpose of investigating complaints concerning an unidentified source. This usually happens in urban situations for odor complaints. In these cases, a triangulation technique is used. By the use of this technique, human observers over a period of days can correlate the location of the observed odor and the direction of the wind. Plotting on a map can pinpoint the offending source in most cases. While this is not an air pollution monitoring system in an instrumental sense, it is a useful tool in certain situations.

Research Needs The research needs of air pollution call for a completely different approach to air quality monitoring. Here, the purpose is to define some known variable or combination of variables. This can be either a new atmospheric phenomenon or the evaluation of a new air pollution sensor. In the former case, the most important consideration is the proper operation of the instrument used. In the latter case, the most important factor is the availability of a reference determination against which the results of the new instruments can be compared.

Monitoring in Urban Areas

Urban situations are the areas of major interest in air pollution in the U.S., since most of the population lives in urban areas. The most sophisticated and expensive air quality monitoring systems in the U.S. are those of large cities (and one or two of the largest states) where data collection and analysis are centralized at a single location through the use of telemetry. On-line computer facilities provide data reduction.

Three philosophies can be utilized in the design of an urban air quality monitoring system: 1) using location of sensors on a uniform area basis (rectilinear grid); 2) installing location of sensors in areas where pollutant concentrations are expected to be high; and 3) installing location sensors in proportion to population distribution. The operation of these systems is nearly identical, but the interpretation of the results can be radically different.

The most easily designed systems are those where the sensors are located uniformly on a geographical basis according to a rectilinear grid. Adequate coverage of an urban area frequently requires at least 100 sensors, so this concept is usually applied only with static or manual methods of air quality monitoring.

The location of air quality sensors at points of maximum concentration indicates the highest levels of air pollutants that are encountered throughout the area. Typically, this will include the central business district and the industrial areas on the periphery of the community. Data of this type are extremely useful when interpreted in the context of total system design. One or two sensors are usually placed in clean or background locations, so the average concentration of air pollutants over the entire area can be estimated. The basis of this philosophy is that if the concentrations in the dirtiest areas are below the air quality standards, there will certainly be no problem in the cleaner areas.

The design of air quality monitoring systems based on population distribution calls for the placement of air quality sensors in the most populous areas. While this may not include all the high-pollutant-concentration areas in the urban region, it generally encompasses the central business district and is a measure of the levels of air pollutants to which the bulk of the population is exposed. The average concentrations from a sampling network of this type are an adequate description from a public health standpoint. However, this system design may miss some localized high-concentration areas.

Agreement on the purpose of air quality monitoring must be reached between the system designer and those responsible for interpreting the data before the system is designed.

Sampling Site Selection

Once the initial layout has been developed for an air quality monitoring system, specific sampling sites must be located as close as practical to the ideal locations. The major considerations are the lack of obstruction from local interference and the adequacy of the site to represent the air mass of interest, accessibility, and security.

Local interference can cause major disruptions to air quality sensor sites. A sampler inlet placed at a sheltered interior corner of a building is most undesirable because of poor air motion. Tall buildings or trees immediately adjacent to the sampling site can also invalidate most readings.

The selection of sampling sites in urban areas is complicated by the canyon effect of streets and by the high density of pollutants, both gaseous and particulate, immediately at street level. In order to be representative of the air mass to be sampled, the purpose of the study must again be reviewed. If the data are to be collected for the determination of area-wide pollutant averages, it may be best to locate the sampler inlet in a city park, vacant lot, or other completely open area. If this is not possible, the sampler inlet could be at the roof level of a one- or two-story building so that street-level effects could be minimized. On the other hand, if the physiological impact of the air pollutants is a prime consideration, the samplers should be at or near the breathing level of the people exposed. As a rule of thumb, an elevation of 3 to 6 m aboveground is suggested as optimum.

Sampling site location can be different for the same pollutant depending upon the purpose of the sampling. Carbon monoxide sampling is an example. The federally promulgated air quality standards for carbon monoxide include both an 8- and 1-h concentration limit. Maximum 1-h concentrations are likely to be found in a high-traffic-density center-city location. It is unlikely that people would ordinarily be exposed to these concentrations for 8-h periods. When sampling for comparison with the 1-h standard, the sensor should be located within about 20 ft of a major traffic intersection. When sampling for comparison with the 8-h standard, the sensor should be located near a major thoroughfare in either the center-city area or the suburban area, with the sample less than about 50 ft from the intersection.

The purpose for two different locations of sampling sites is to be consistent with the physiological effects noted from carbon monoxide exposure and with the living pattern of the bulk of the population. If only one site can be selected, the location described for the 8-h averaging time is preferred.

When the sampling instruments are located inside a building and an air sample is to be drawn in from the outside, it is frequently advantageous to utilize a sampling pipe with a small blower to bring outside air to the instrument inlets. This improves sampler line response time. An air velocity of approximately 700 ft/min in the pipe is a good choice to balance the problems of gravitational and inertial deposition of particular matter, where particulates are to be sampled.

The sampling site should be accessible to the operation and maintenance personnel. Since most air pollution monitoring sites are unattended much of the time, sample site security is a very important consideration; the risk of vandalism is high in many areas.

Static Methods of Air Monitoring

Minimum capital cost is attained when static sensors are used to monitor air quality. While averaging times are in terms of weeks and sensitivity is frequently low, there are many cases where static monitors provide the most information for the amount of investment. They should not be rejected out of

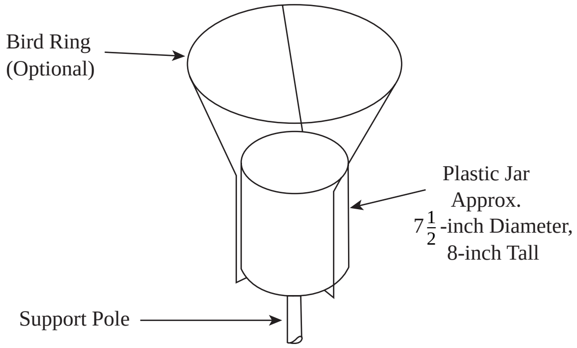

FIG. 8.5d
Dust-fall jar.

hand, but should be considered as useful adjuncts to more sophisticated systems.

Dust-Fall Jars The simplest of all air quality monitoring devices is the dust-fall jar (Figure 8.5d). This device measures the fallout rate of coarse particulate matter, generally above about 10 microns in size. Dust-fall and odor are two of the major reasons for citizen complaints concerning air pollution. Dust-fall is offensive because it builds up on porches, automobiles, and such, and it is highly visible and gritty to walk upon.

Dust-fall seldom carries for distances in excess of $\frac{1}{2}$ mi because these large particles are subject to strong gravitational effects. For this reason, dust-fall stations must be more closely spaced than other air pollution sensors, if detailed study of an area is desired.

Dust measurements conducted in large cities in the U.S. in the 1920s and 1930s commonly indicated dust-fall rates in hundreds of tons per square mile per month. These levels would be considered excessive today, as evidenced by the dust-fall standards of 25 to 30 tons/mi^2/month promulgated by many of the states. While the measurement of low or moderate values of dust-fall does not indicate freedom from air pollution problems, measured dust-fall values in excess of 50 to 100 tons/mi^2/month in an area are a sure indication of the existence of excessive air pollution.

The large size of the particulate matter found in dust-fall jars makes it amenable to chemical analysis or to physical analysis by such techniques as microscopy. These analyses can be useful to identify specific sources.

Lead Peroxide Candles For many years, lead peroxide candles had been used in measuring the concentration of sulfur dioxide. These devices are known as candles because they are a mixture of lead peroxide paste spread on a porcelain cylinder that is about the size and shape of a candle. They are normally exposed to the ambient air in the location of interest for 1 month. Sulfur gases in the air react with lead peroxide to form lead sulfate. Sulfate is analyzed according to standard laboratory procedures to give an indication of the atmospheric levels of sulfur gases during the period of exposure.

The laboratory procedure can be simplified by a modification of this technique, which uses a fiber filter cemented to the inside of a plastic petri dish (a flat-bottom dish with shallow walls, used for biological cultures). The filter in the dish is saturated with an aqueous mixture of lead peroxide and a gel (commonly gum tragacanth) and is allowed to dry. These dishes, or plates, are exposed to the ambient air in an inverted position for 1 to 4 weeks.

Lead peroxide estimation of sulfur dioxide suffers from inherent weakness. All sulfur gases, including reduced sulfur, react with lead peroxide to form lead sulfate. More importantly, the reactivity of lead peroxide is dependent upon its particle size distribution. For this reason, the results from different investigators are not directly comparable. Nevertheless, a network of lead peroxide plates over an area provides a good indication of the relative exposure to sulfur gases during the particular exposure period. This is useful for determining the geographical extent of sulfur pollution.

Other Static Methods The use of a fiber filter cemented to a petri dish has been modified by the use of sodium carbonate rather than lead peroxide for the measurement of sulfur gases. This method also shows some success in indicating the relative concentration of other gases, including nitrogen oxides and chlorides. Relative levels of gaseous fluoride air pollution have been measured using larger filters, e.g., 3 in. in diameter, dipped in sodium carbonate, and placed in shelters to protect them from the rain. With all these static methods, the accuracy is extremely low and the data cannot be converted directly into ambient air concentrations. They do, however, provide a low-cost indicator of relative levels of pollution in a given area.

The corrosive nature of the atmosphere has been evaluated, using standardized steel exposure plates for extended periods to measure the corrosion rate. This provides a gross indication of the corrosive nature of the atmosphere. As with other static samplers, the results are not directly related to the concentration of air pollutants.

Laboratory Analyses

Manual analyses for air quality measurements are those that require the simple to first be collected and then analyzed in the laboratory. Manual instruments provide no automatic indication of pollution levels.

The manual air sampling instrument, which is in widest use, is the high-volume sampler shown in Figure 8.5e. With this method, ambient air is drawn through a preweighed filter at a rate of approximately 50 ACFM for 24 h. The filter is then removed from the sampler, returned to the laboratory, and weighed. The gain in weight, in combination with the measured air volume through the sampler, allows for the calculation of particulate mass concentration, expressed in micrograms per cubic meter.

Reference methods for nearly all gaseous air pollutants involve the use of a wet sampling train in which air is drawn

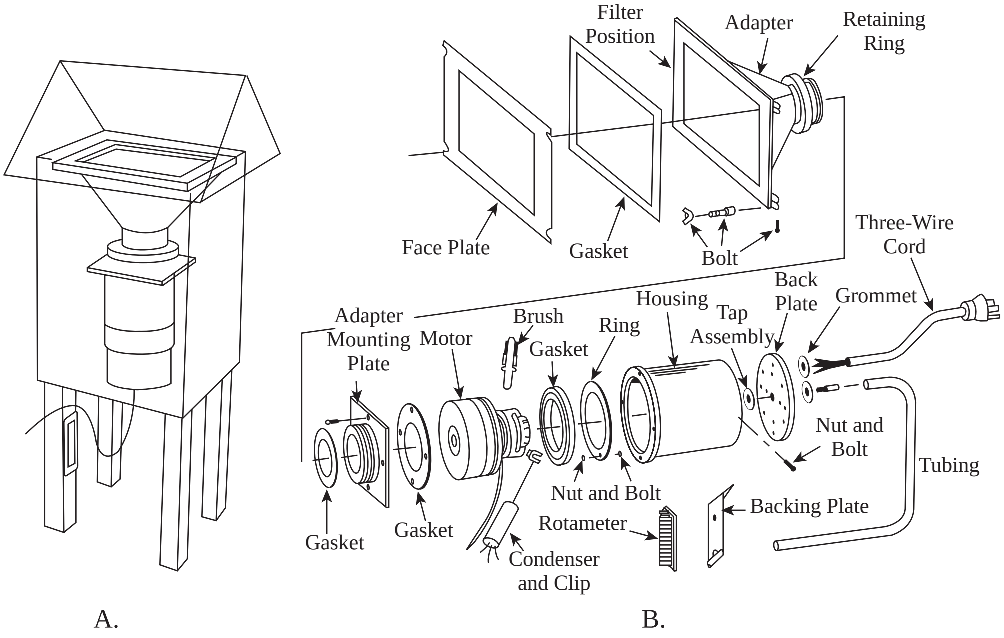

FIG. 8.5e

The high-volume air sampler. (A) Illustrates the assembled sampler and its shelter. (B) Shows the components of a typical high-volume air sampler.

through a collecting medium for some period of time. The exposed collecting medium is then returned to the laboratory for chemical analysis. Sampling trains have been developed that allow the sampling of five or more gases simultaneously in separate bubblers. There are also sequential samplers, which automatically divert the airflow from one bubbler to another at preset time intervals.

These methods of sampling can be accomplished with a modest initial investment, but the manpower required to distribute and pick up the samples and to analyze them in the laboratory raises the total cost to a point where automated systems may be more economical for long-term studies.

AUTOMATIC MONITORING

As the need for accurate data that can be statistically reduced in a convenient manner becomes more the rule than the exception, automated sampling systems become more and more desirable. The elements of an automated system include the airflow handling system, the sensors, the data transmission storage and display apparatus, and the data processing facility. The overall system is no more valuable than the weakest link of this chain.

Sensors

Some of the sensor categories used have been listed in Table 8.5a. The detectors that are available to measure the various individual air pollutants are discussed in other sections of this chapter.

The reliability of the output from an air quality sensor is dependent upon its inherent accuracy, sensitivity, zero drift, and calibration. The inherent accuracy and sensitivity are a function of the design of the instrument and of the principle upon which it operates. Zero drift can be either an electronic phenomenon or an indication of difficulties with the instrument. In those instruments using an optical path, lenses can become dirty. In wet chemical analyzers, the flow rates of reagents can vary, causing a change in both the zero and the span (range) of the instrument. Because of these potential problems, every instrument should have routine field calibration at an interval determined in field practice to be reasonable for the sensor.

The calibration of an air quality sensor is frequently accomplished using either a standard gas mixture or a prepared, diluted gas mixture using permeation tubes. In some cases, the airstream entering the sensor is concurrently sampled by a reference wet chemical technique.

The operator of air quality sensors should always have an adequate supply of spare parts and tools so that downtime can be held to a minimum. Operator training should, at a minimum, include instruction to recognize the symptoms of equipment malfunction and vocabulary to describe the symptoms to the individual responsible for instrument repair. Ideally, each operator would receive a short training session from the instrument manufacturer or someone trained in the use and maintenance of the instrument, so that he or she can make repairs on-site. Since this is seldom possible in actual practice, the recognition of symptoms of malfunction becomes increasingly important.

Data Transmission

The output signal from a continuous monitor used in an air quality monitoring system is typically the input to a strip-chart recorder, magnetic tape data storage, or an on-line data transmission bus or highway system. If the output of the air quality transmitter is in analog form, it is suitable for direct input to a strip-chart recorder, but it has to be converted into a digital signal before it can be sent over a data highway. In the case of sensors with a logarithmic output, it may be desirable to first convert this signal into a linear form.

Many of the first automated air quality monitoring systems in the U.S. experienced major difficulties with their data transmission systems. In some cases, this was caused by attempts to overextend the lower range of the sensors, which resulted in an unfavorable signal-to-noise ratio. In other cases, the matching of sensor signal output to the data transmission system was poor. With developments of the new data highway protocols, these early difficulties have been overcome.

Continuous detectors tend to increase the complexity of the air quality monitoring systems, but data from the continuous monitors can be stored on magnetic tape for later processing and statistical reduction. In case of an on-line system, this can be done instantaneously. When decisions with substantial community impact must be made within a very short time, this real-time capability is likely to be necessary.

Data Processing

The concentration of many air pollutants has been found to follow a lognormal rather than a normal distribution. In a lognormal distribution, a plot of the logarithm of the measured value more closely approximates the bell-shaped Gaussian distribution curve than does a plot of the numerical data. Suspended particulate concentrations are a prime example of this type of distribution.

When this is the case, the geometric mean is the statistical parameter that best describes the population of data. The arithmetic mean is of limited value because it is dominated by a few occurrences of high values. The geometric mean, in combination with the geometric standard deviation, is a complete description of a frequency distribution for a lognormally distributed pollutant.

Averaging Times The averaging time over which the sample results are reported is a consideration in the processing and interpretation of air quality data. For sulfur dioxide, air quality standards have been promulgated by various agencies based on annual, monthly, weekly, 24-h, 3-h, and 1-h arithmetic average concentrations.

The output of a continuous analyzer can be averaged over nearly any discrete time interval. In order to reduce the computation time, the time interval over which the continuous analyzer output is averaged to obtain a discrete input for the calculations must be considered. If a 1-h average concentration is the shortest time interval of value in interpreting the study results, it is not economical to use a 1- or 2-min averaging time for inputs to the computation program.

Displays Caution must be exercised in using strip-chart recorders for the acquisition of air quality data. The experience of many organizations, both governmental and industrial, is that the reduction of data from strip charts is a tedious chore at best. Many organizations have decided that they did not really need all that data in the first place, once they find a large backlog of unreduced strip charts. Two cautions are suggested by this experience. First, if you do not plan to use the data, do not collect it. Second, be aware of the advantages of magnetic tape data storage followed by computer processing.

The visual display of air quality data has considerable appeal to many nontechnical personnel. Long columns of numbers can be deceptive if only one or two important trends are to be shown. The use of bar charts or graphs is frequently advantageous, even though they do not show the complete history of the air quality over the time span of interest.

Audits

Periodic performance audits are required to validate the accuracy of the air monitoring system. The Code of Federal Regulations (CFR) requires that performance audits be conducted at least once a year for criteria pollutant analyzers operated at State and Local Air Monitoring Stations (SLAMS). The U.S. Environmental Protection Agency (EPA) recommends that each analyzer be disconnected from the monitoring station manifold and be individually connected to the audit, from which it will receive the audit gas of known concentration.

The audit gas concentrations are usually generated in a van, using a gas calibrator to dilute multiblend gases with zero air. Each state approaches air pollution monitoring differently. The California Air Resources Board (CARB), for example, has been conducting through-the-probe performance audits of continuous ambient air analyzers since 1981. CARB has the responsibility of overseeing the implementation of the California Clean Air Act and the Federal Clean Air Act in California.

Automatic Analyzers

The automatic sampling train (AST) packages have been described in Section 8.3. They can automate any of the U.S. EPA Methods or international methods specified by VDI, BS, or ISO. In these packages the microprocessor stores all measurements, diagnoses all inputs, controls the manipulated variables, calculates isokinetic conditions, and reports the results in either a printed form or over the data bus.

Infrared Spectrometers Microprocessor-controlled spectrometers are also available to measure the concentrations of a variety of gases and vapors in ambient air. These units can be portable or permanently installed and can serve compliance with environmental and occupational safety regulations. In the infrared spectrometer design, the ambient air is drawn into the test cell by an integral air pump, operating at a flow rate of 0.88 ACFM (25 l/min).

The microprocessor selects the appropriate wavelengths for the components of interest, and the filter wheel in the analyzer allows the selected wavelengths to pass through the ambient air sample in the cell. The microprocessor automatically adjusts the path length through the cell to give the required sensitivity. Because of the folded path length design, the path length can be increased to 20 m (60 ft), and the resulting measurement sensitivity can be better than 1 ppm in many cases.

As shown in Table 8.5f, practically all organic and also some of the inorganic vapors and gases can be monitored by these infrared spectrometers. The advantage of the microprocessor-based operation is that the monitor is precalibrated for the analysis of over 100 Occupational Safety and Health Administration (OSHA)-cited compounds. The memory capacity of the microprocessor is sufficient to accommodate another 10 user-selected and user-calibrated gases.

Analysis time is minimized because the microprocessor automatically sets the measurement wavelengths and parameters for any of the compounds in its memory. A general scan for contaminant in the atmosphere takes about 5 min, while the analysis of a specific compound can be completed in just a few minutes. The portable units are battery operated for 4 h of continuous operation and are approved for use in hazardous areas.

Handheld Indoor Air Quality Monitors Battery-operated, handheld indoor air quality (IAQ) monitors are available for monitoring the air quality in schools, offices, meeting rooms, and greenhouses, and to service heating, ventilation, and air conditioning (HVAC) systems. These units monitor and record the temperature (range: 0 to 50°C = 32 to 122°F), relative humidity (range: 0 to 100%), and the concentration of different selected gases. Plug-in sensors are available for gases, such as CO_2, with a range of 0 to 10,000 ppm.

Dual-beam infrared radiation is used for making the measurement. The sample flow is drawn by diffusion or is maintained at 100 to 300 ml/m. Sample rates are adjustable from 10 sec to one per day, and data loggers are also available with capacities for up to 50,000 samples.

SAMPLING OF AMBIENT AIR

The sampling of process gases and vapors has been discussed in Section 8.2, and some of that discussion is also applicable to ambient air monitoring. Yet ambient air sampling is sufficiently different to justify a separate discussion in addition to what has already been said.

All substances in the ambient air exist as either particulate matter or gases and vapors. In general, the distinction is easily made; gases and vapors consist of substances dispersed as molecules in the atmosphere, while particulate matter consists of aggregates of molecules sufficiently large that they are said to behave like particles. Particulate matter (or particulates) are filterable, may be precipitated, and, in still air, may be expected to settle out. By contrast, gases and vapors do not behave in this fashion and are homogeneously mixed with the air molecules.

A substance such as carbon monoxide may exist only as a gas; an inorganic compound like iron oxide may exist only as a particle. Many substances may exist as either particles or vapors, however; additionally, substances that are gases can also be attached by some means to the particulate matter in the air. If sampling is to be intelligently conducted, prior knowledge of the physical state in which a substance exists must be available or else a judgment must be made. Particulate matter, opacity, dust, and smoke analyzers are discussed in a separate section in this chapter. They do not usually collect gases or vapors; hence, an incorrect selection of sampling method may lead to erroneous results. Fortunately, a considerable body of experience has evolved concerning the more common pollutants, and it is not difficult in most cases to select a sampling method reasonably suitable for the substances of interest.

General Air Sampling Problems

Certain general observations relative to sampling ambient air must be recognized. For example, the quantity of a given substance contained in a volume of air is likely to be extremely small, and it will necessitate a sample of sufficient size for the analytical method employed to be adequate. Even air, which is heavily polluted, is not likely to contain more than a few milligrams per cubic meter of most contaminants and, more frequently, the amount present will best be measured in micrograms, or even nanograms, per cubic meter.

Consider, for example, the air quality standard for particulates, which is 75 g/m^3. A cubic meter of air, or 35.3 ft^3, is a relatively large volume for many sampling devices, and a considerable sampling period may be required to draw such a quantity of air through the sampler. If atmospheric mercury analyses are to be attempted, then it must be realized that background levels are likely to be as low as several nanograms per cubic meter and, in general, most substances tend to be of concern at quite low levels in the ambient air.

In addition to problems arising from the low concentrations of substances being sampled, other problems include those caused by the reactivity of the substances, changes after collection, and necessitating special measures to minimize such changes.

Whenever something is removed from a volume of air by sampling procedures, some alteration of the substance of interest may taken place and analysis may be less informative than desired, or may even be misleading. Therefore, it would be ideal to perform analyses of the unchanged atmosphere if possible, using direct-reading devices, which could give accurate information concerning the chemical and physical states of contaminants as well as concentration information. Such instruments do exist for some substances, and many more are being developed, but conventional air sampling methods are still used in many instances and doubtlessly will continue to be required for some time to come.

Vinyl chloride	0–10		

Sampling for Gases and Vapors

The simplest method of collecting a sample of air for subsequent analysis is to fill a bottle or other rigid container with it or, more conveniently, to use a bag made of suitable material. Although it may be relatively easy to sample by this method, the sample size is distinctly limited, and it may not be possible to collect a sufficiently large sample to permit subsequent analysis. Bottles larger than several liters in capacity are awkward to transport, and while bags of any size are conveniently transported when empty, they may be difficult to deal with when inflated. Nevertheless, it may prove more convenient to collect a number of samples in small bags than to take more complex sampling apparatus to a number of sampling sites. If it is possible to analyze for the contaminant of interest by means of gas chromatographic procedures, or by gas phase infrared spectroscopy, for example, then samples as small as a liter or less may be adequate and can be quickly and easily collected by bags.

There are several methods of filling rigid containers such as a bottle. One is to evacuate the bottle beforehand and then fill it at the sampling site by drawing air into the bottle and sealing it again (Figure 8.5g). Alternatively, a bottle may be filled with water, which is then allowed to drain and fill with the air. A third method consists of passing a sufficient amount of air through the bottle by using a pumping device until the original air is completely displaced by the air being sampled.

Plastic bags are frequently filled by means of a simple, hand-operated squeeze bulb with values on each end (Figure 8.5g) and then connected to a piece of tubing attached to the sampling inlet of the bag. In most cases, this procedure is satisfactory, but care should be taken to avoid contamination of the sampled air by the sampling bulb or possible losses of the constituent on the walls of the sampling bulb. To avoid problems of this kind, it is possible to place the bag in a rigid container such as a box and then withdraw air from the box so that a negative pressure is created, which results in air being drawn into the bag.

Bag materials must be selected with care, for some will permit losses of contaminants by diffusion through the walls, and others to the air being sampled. A number of polymers have been studied, and several have been found to be suitable for air sampling purposes. Materials suitable for use as sampling bags include Mylar, Saran, Scotchpak (a laminate of polyethylene, aluminum foil, and Teflon), and Teflon.

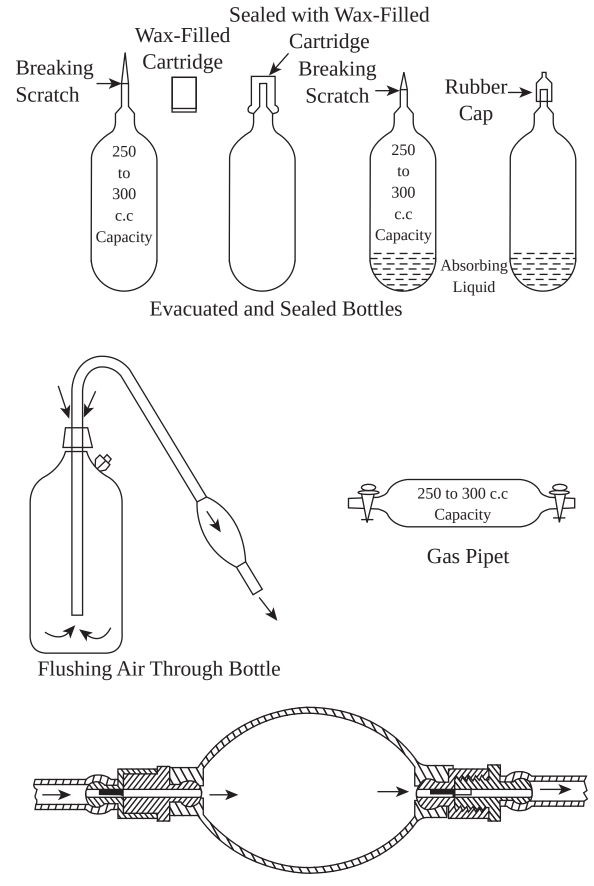

FIG. 8.5g
Devices for obtaining grab samples.

Even though the bag may be made of relatively inert materials, it is always possible that gas phase chemical reactions will occur, so that after a period of time the contents of the bag may not be identical in composition with the air originally sampled. Thus, a reactive gas like sulfur dioxide or nitric oxide can be expected to gradually oxidize, depending upon the storage temperature. It is generally advisable to perform analyses as soon as possible after collecting the samples. Losses by adsorption or diffusion will also tend to be greater with the passage of time and will occur to some extent even though the best available bag materials have been used.

The use of small bags may permit the collection of samples to be analyzed for a relatively stable gas such as carbon

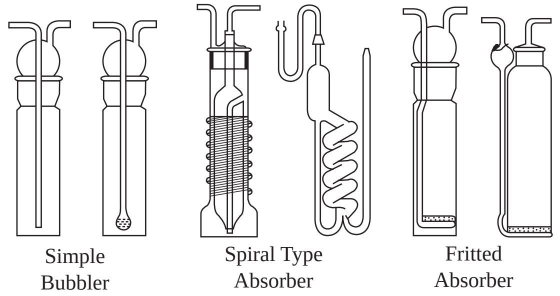

FIG. 8.5h
Gas-absorbing vessels.

monoxide at a number of locations throughout a community of interest, thus permitting routine air quality measurements that might otherwise be inordinately expensive.

Absorption The gases or vapors of interest can also be absorbed in a suitable sampling medium. Ordinarily, this medium is a liquid of some kind, but absorption may also take place in solid absorbents or upon supporting materials such as filter papers, which are impregnated with suitable absorbents. Carbon dioxide, for example, may be absorbed in a granular bed of alkaline material, and sulfur dioxide is frequently measured by absorption of reactive chemicals placed on a cloth or ceramic support.

A number of gases are also detected by passing them through filter papers or glass tubes containing reactive chemicals, with the immediate production of a color change, which can be evaluated by eye to give a measure of the concentration of the substance of interest.

Liquid Absorption Most commonly, however, gases and vapors are absorbed by passing them through a liquid in which they are soluble, or which contains reactive chemicals that will combine with the substance being sampled. Many different absorption vessels have been designed, ranging from simple bubblers made by inserting a piece of tubing beneath the surface of a liquid to rather complex gas-washing devices that are designed to increase the length of time that the air and liquid are in contact with each other (Figure 8.5h).

Impingers Probably the most widely used contacting device is the impinger, which is available in several sizes and configurations. An impinger consists of an entrance tube terminating in a small orifice, causing the velocity of the air passing through the orifice to greatly increase. When this jet of air strikes a plate or the bottom of the sampling vessel, an intense impingement or bubbling action occurs, which results in much more efficient absorption of gases from the airstream than would take place if the air was simply bubbled through at low velocity.

The two impingement devices most frequently used are the standard impinger and the midget impinger (Figure 8.5i). They are designed to operate best at airflow rates of 1 and 0.1 ft^3/min, or 28.3 and 2.8 l/min, respectively. Using such devices for sampling periods of 10 or 30 min will result in the passage of a substantial amount of air through the devices, thus permitting low concentrations of trace substances to be determined with improved sensitivity and accuracy. Many relatively insoluble gases, such as nitrogen dioxide, are not quantitatively removed by passage through an impinger containing the usual sampling solutions.

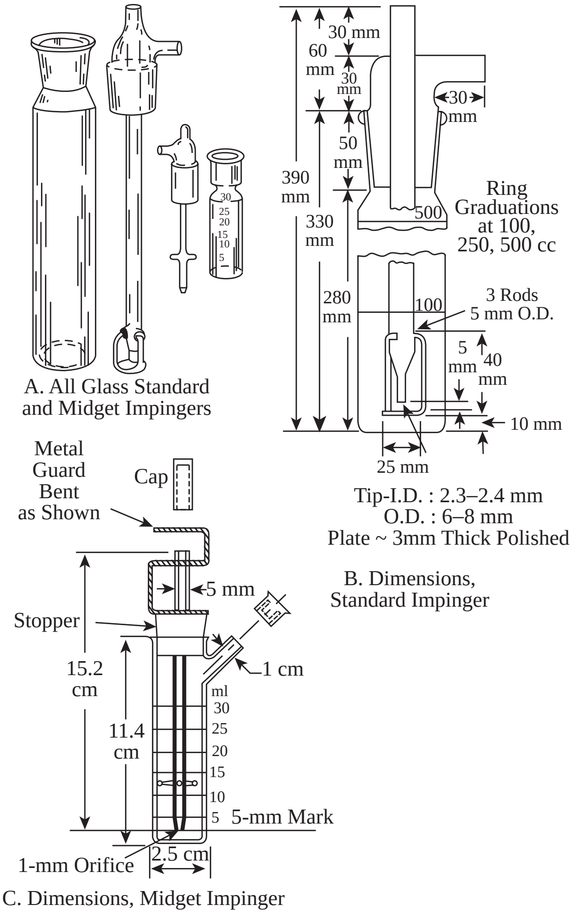

FIG. 8.5i
Standard and midget impingers.

Fritted Absorber The most useful sampling devices for absorbing trace gases from air are those in which a gas dispersion tube made of fritted or sintered glass, ceramic, or other materials is immersed in a suitable vessel containing the absorption liquid (Figure 8.5h). This device causes the gas stream to be broken into thousands of small bubbles, thus promoting contact between the gas and the liquid with resulting high collection efficiencies in most cases.

In general, fritted absorbers are more widely applicable to sampling gases and vapors than are impingers and, in addition, are not as dependent upon flow rates as are impingers. They are standard items available from scientific supply houses and come in various sizes suitable for many sampling tasks. It is often advisable to prefilter the air prior to sampling with a fritted absorber in order to prevent the gradual accumulation of dirt within the pores of the frit.

The use of solid absorbents is not widely practiced in ambient air sampling because the quantity of absorbed gases is usually determined by gravimetric means. With the exception of carbon dioxide, relatively few gases of interest in the atmosphere lend themselves to this type of analysis.

Adsorption Adsorption, by contrast with absorption, consists of the retention of gaseous substances by solid adsorbents that, in most cases, do not chemically combine with the gases. Instead, the gases or vapors are held by adsorptive forces and may subsequently be removed unchanged. Any solid substance will adsorb a small amount of most gases, but to be useful as an adsorbent, a substance must have a large surface area and be able to concentrate a substantial amount of gas in a small volume of adsorbent.

Most widely used for this purpose are activated carbon or charcoal and activated silica gel. A small quantity of either adsorbent placed in a U-tube or other container through which air is passed will quantitatively remove many vapors and gases from a large volume of air and may subsequently be taken to the laboratory where desorption will remove the collected substance for analysis. Desorption is commonly achieved by heating the adsorbent and collecting the effluent gases or by eluting the collected substance with a suitable organic liquid.

In the case of most organic vapors, subsequent analysis by gas chromatographic, infrared, or ultraviolet spectroscopic means is usually most convenient. For some purposes, either silica gel or activated carbon may be used. In other instances, the use of silica gel is undesirable because it also adsorbs water vapor, and a relatively short sampling period in humid air can result in saturation of the silica gel before sufficient contaminant is adsorbed. Charcoal does not adsorb water and hence may be used in humid environments and may be sampled for days or even weeks if the concentration of contaminant is low.

The ease of sampling by using adsorbents is offset somewhat by the difficulty of quantitatively desorbing the samples for analysis. When literature data are not available to assist in predicting the behavior of a new substance, it is advisable to perform tests in the laboratory to determine both the collection efficiency and the success of desorption procedures after sample collection.

Freeze-Out Sampling Vapors or gases, which are condensable at low temperature, may be removed from the sampled airstream by passage through a vessel that is immersed in a refrigerating liquid. Table 8.5j lists liquids that are commonly used for this purpose, and usually it is desirable to form a sampling train in which two or three coolant liquids progressively lower the air temperature in its passage through the system. All freeze-out systems are hampered somewhat by the accumulation of ice resulting from water vapor and may eventually become plugged with ice.

TABLE 8.5j
Coolant Solutions for Freeze-Out Sampling

Coolant	*Temperature (°C)*
Ice water	0
Ice and salt (NaCl)	–21
Dry ice and acetone	–78.5
Liquid air	–147
Liquid oxygen	–183
Liquid nitrogen	–196

Flow rates through a freeze-out train are necessarily limited also; in order for the air to be cooled to the required degree, a sufficient residence time in the system must be provided. For these reasons, and because of the general inconvenience of assembling freeze-out sampling trains, they are not generally used for routine sampling purposes unless no other approach is feasible. However, freeze-out sampling is an excellent means of collecting substances for research studies, inasmuch as the low temperatures tend to arrest further chemical changes and ensure that the material being analyzed will remain in the sampling container ready for analysis after warming. Analysis is most frequently conducted by means of gas chromatographic, infrared, or ultraviolet spectrophotometry, or by mass spectrometric means.

Sampling of Particulates

Particulate matter is most conveniently removed from air by passage through a filter (Figure 8.5e). Before filtration is used to obtain a sample, however, consideration should be given to the purpose for which the sample is being taken. Many filters collect particulates efficiently, but thereafter it may be impossible to remover the collected matter except by chemical treatment. If the samples were initially collected for the purpose of examining the particles and measuring their size, or noting morphological characteristics, then many filters are not suitable because the particles are imbedded in the fibrous web of the filter and cannot readily be viewed or removed.

If the sample is collected for the purpose of performing a chemical analysis, then it is important that the filter itself does not contain significant quantities of the substance for which analysis is required. If the purpose of sampling is to collect a sufficient amount of particulate matter to permit weighing, then it is necessary to select a filter that can be weighed. This can be a problem, because many filtration materials are hygroscopic and change weight appreciably in response to changes in the relative humidity.

Filters may be made of many substances and, in fact, almost any solid substance could probably be made into a filter. In practice, however, fibrous substances, such as cellulose or paper, fabrics, asbestos, and a number of plastics or polymerized materials, are generally used. The most readily available filters are those made of cellulose or paper used in chemical laboratories for filtering liquids. Such filter papers come in a variety of sizes and range in efficiency from rather loose filters, which remove only the larger particles, to paper, which will remove very fine particles with high efficiency. All filters display similar behavior, and ordinarily a high collection efficiency is accompanied by increased resistance to airflow.

Air Filters Certain kinds of filtration media are more suited to air sampling than most paper or fibrous filters. Of these, membrane filters are of greatest utility. The commercially available membrane filters combine extremely high collection efficiencies with relatively low resistance to flow. Such filters are not made up of a fibrous mat, but instead are usually composed of gels of cellulose esters or other polymeric substances in such fashion that a smooth surface of predictable characteristics is formed.

Such filters contain many small holes, or pores, and may be made to exacting specifications in this regard so that their performance characteristics may be predicted. In addition, the filters are usually of high chemical purity and are well suited to trace metal analyses. Some of the membrane filters can also be rendered transparent and thus permit direct observation of collected particles with a microscope. Alternatively, the filters can be dissolved in an organic solvent, and the particles may be isolated and studied. Most membrane filters are not greatly affected by relative humidity changes and may be weighed before and after use to obtain reliable gravimetric data.

Fiberglass Filters Another kind of filter that is widely used in sampling ambient air is the fiberglass filter. These filters are originally made of glass fibers in an organic binder; subsequently, the organic binder may be removed by firing, leaving a web of glass, which is very efficient in collecting fine particles from the air. The principal advantage of using this type of filter is its relatively low resistance to airflow and its virtually unchanging weight regardless of relative humidity.

The filters are not well suited to particle size studies, however; additionally, they are not chemically pure, and care must be taken to be certain that a substance for which analysis is to be made will not be contributed in unknown quantities by the filter itself. In the U.S., most of the data relating to suspended particulate matter in our cities have been obtained on filters made of fiberglass and used in conjunction with a sampling device referred to as a high-volume sampler (Figure 8.5e).

Many other kinds of filters are available, but most sampling needs are well met by membrane or fiberglass filters. Extensive data concerning the types of filters available and their performance characteristics will be found in the bibliography cited at the end of this section.

Impingement and Impaction The impingers previously described in relation to sampling gases and vapors (Figure 8.5i) may also be used for the collection of particles and, in fact, they were originally developed for that purpose. However, in ambient air sampling they are not used, inasmuch as the efficiency of collection tends to be low and unpredictable for the fine particles that may be present in ambient air. The relatively low sampling rates also make them less attractive than filters for general air sampling, but instances do arise when impingers can be satisfactorily used. When they are used, it is important that the correct sampling rates be maintained, for the collection efficiency of impingers for particles may vary drastically when flow rates are other than optimal.

Impactors Of more widespread use in ambient air sampling are devices known as impactors, in which air is passed through small holes or orifices and made to impinge or impact against a solid surface. When such devices are constructed so that the air passing through one stage is subsequently directed onto another stage containing smaller holes, the resulting device is known as a cascade impactor and has the capability of separating particles according to their sizes. Various commercial devices are available.

Figure 8.5k portrays one that is widely used and consists of several layers of perforated plates through which the air must pass. Each plate contains a constant number of holes, but the hole size is progressively decreased so that the same volume of air passing through each stage will impinge at an increased velocity. The result is that coarse particles are deposited on the first stage and successively finer particles are removed at each subsequent stage. While the particle size fractions obtained by such instruments are not very accurate, they do perform predictably when the characteristics of the aerosol being sampled are known.

In use, a cascade impactor is assembled after scrupulously cleaning each stage and applying a sticky substance

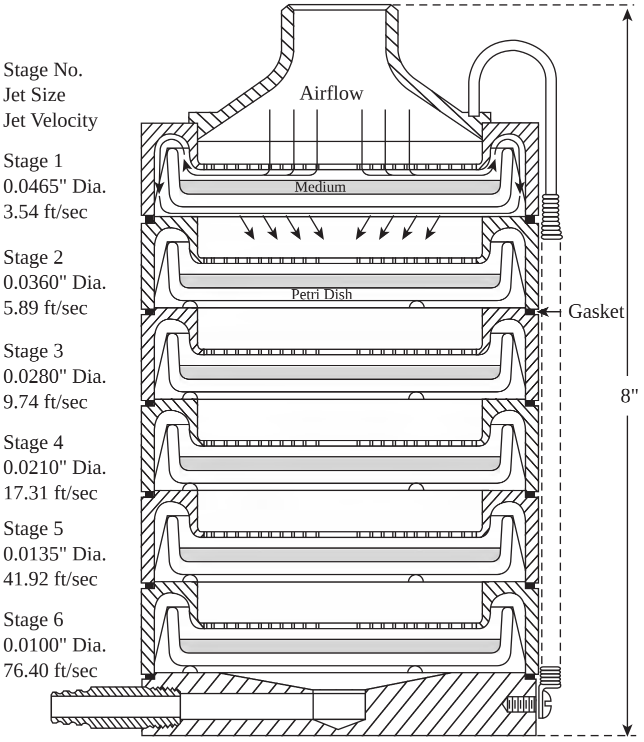

FIG. 8.5k
Cascade impactor (Andersen sampler).

or a removable surface on which the particles are to be deposited. After a suitably long period of sampling, during which time the volume of air is metered, the stages may be removed and the total weight of each fraction determined, as well as the fractions' chemical composition. Such information may be more useful than a single weight or chemical analysis of the total suspended particulate matter without regard to its particle size.

Electrostatic Precipitation Particulate matter can be quantitatively removed from air by means of instruments known as electrostatic precipitators. They operate on the same principle as the devices used to remove particulate matter from stack gases prior to discharging into the atmosphere. There are several commercially available electrostatic precipitators that may be used for air sampling. They operate on the same general principle that passing the air between charged surfaces imparts a charge to the solid particles in the air. Therefore, these particles can be collected on an oppositely charged surface or plate.

In one of the more widely used commercial devices (Figure 8.5l), a high-voltage discharge is made to occur along a central wire; the collecting electrode is a metallic cylinder that is placed around the central wire, while the air to be sampled is passing through the tube. An intense corona discharge takes place on the central wire; the particles entering the tube are charged and are promptly swept to the walls of the tube where they remain firmly attached.

By this means, it is possible to collect a sample for subsequent weighing or chemical analysis. It is also possible to examine the particles and study their particle size and shape, and the intense electrical forces may produce aggregates of particles that are different than those that existed in the sampled air.

Electrostatic precipitators are not as widely used as filters for ambient air sampling, because they are generally less convenient and tend to be heavy due to the power pack necessary to generate the required high voltage. Nevertheless, when available, they are excellent instruments for obtaining samples for subsequent analysis, and samples at relatively high flow rates and very low resistance.

Thermal Precipitators Whenever a strong temperature gradient exists between two adjacent surfaces, there will be a tendency for particles to be deposited on the colder of these surfaces. Collection of aerosols by this means is termed thermal precipitation and, in practice, several such commercial devices are available.

Because thermal forces are so weak, it is necessary to have a rather large temperature difference maintained in a small area.

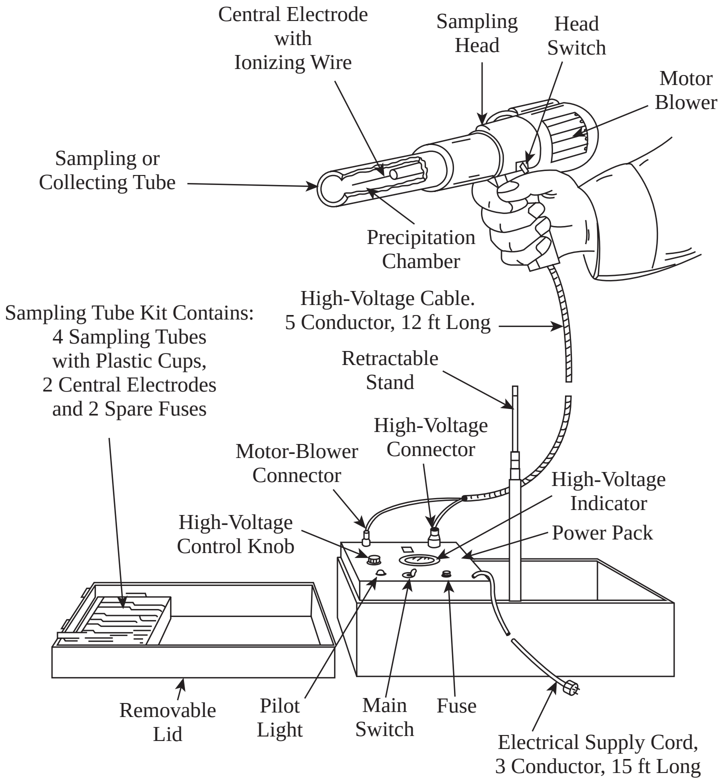

FIG. 8.5l
Electrostatic precipitator. (Courtesy of MSA Instrument Div.)

Additionally, the rate of airflow between the two surfaces must be low in order not to destroy the temperature gradient and to permit particles to be deposited before moving out of the collection area. As a result of these requirements, most devices use a heated wire as the source of the temperature differential and deposit a narrow ribbon of particles on the cold surface. Airflows are very small, being on the order of 10 to 25 ml/min. At such low rates, the amount of material collected will normally be insufficient for chemical analysis or weight determinations, but will be ample for examination by optical or electron microscopy.

Collection for particle size studies is, in fact, the principal use for thermal precipitation units, and they are well suited to collecting samples for such investigations. Because the collecting forces are gentle, it is generally believed that the particles are deposited unchanged. The microscopic examination gives information that can be translated into data concerning the number of particles and their morphological characteristics. It is convenient also to use a small grid suitable for insertion into an electron microscope as the collecting surface, thus making it unnecessary to perform additional manipulations of the sample prior to examination by electron microscopy.

8.6 Biometers

I. G. YOUNG (1974, 1982) **B. G. LIPTÁK** (1995, 2003)

Method of Detection:	Photometric measurement of light emitted by chemical reaction
Sample Pressure:	Atmospheric
Sample Temperature:	Ambient
Sample Type:	Grab sample
Materials of Construction:	Glass
Range:	10^{-7} to 10^{-2} μg of ATP per 10-ml sample of bacterial extract. Sensitively to 10^{-7} μg per 10-μl sample. It can be calibrated for number of bacteria per microgram of ATP.
Response:	Laboratory method: minutes after starting reaction
Cost:	About $10,000
Supplier:	Asay Design Inc. (www.assaydesign.com) Bio-Tek Instruments (www.biotek.com) Innovative Imaging Inc. (www.innovative-imaging.com) Sigma-Aldrich (www.sigmaaldrich.com) SP Industries Inc. (www.wilmad-labglass.com)

INTRODUCTION

The key wastewater-related measurements, which detect the concentration of the discharged waste stream in terms of its oxygen demand, are discussed in Section 8.7. The sensors discussed in this section measure the biological population and the biological oxidative activity by detecting the amount of adenosine triphosphate (ATP) and the changes in its concentration.

ATP ANALYSIS

In a detailed study of the control parameters for the activated sludge process, measurements of great interest are biochemical oxygen demand (BOD) and chemical oxygen demand (COD). BOD and COD reduction, biological population density, and biological oxidative activity are important indicators of this process.

It has been found that the amount of ATP is proportional to the viable biomass in a sample. It has also been found that changes in ATP concentration measure the oxidative capability of the biomass.[1] Thus, it is of great interest to measure the ATP content of samples in the activated sludge process as well as in rivers, lakes, and other receiving waters.

Sensitive methods for ATP analysis have been developed based on the observation that the luminescent reaction in fireflies is absolutely dependent on the presence of ATP. The *in vitro* light-yielding reactions are given in Equations 8.6(1) and 8.6(2):

$$LH_2 + E + ATP \overset{[Mg2^{+}]}{\rightleftharpoons} E - LH_2 - AMP + PP \qquad \mathbf{8.6(1)}$$

$$E - LH_2 - AMP + O_2 \rightarrow E + PRODUCT + CO_2 + AMP + Hv \qquad \mathbf{8.6(2)}$$

where

LH_2 = luciferin
E = luciferase enzyme
$E - LH_2 - AMP$ = enzyme–luciferin–adenosine monophosphate complex
PP = pyrophosphate

It is seen that the yield of light quanta (Hv) is in proportion to the amount of ATP present in the sample.

LUMINESCENCE BIOMETER

ATP assay procedures have been developed based on the reactions just described. Briefly, the procedure involves rapid killing of the live bacterial cells and immediate extraction of ATP into aqueous solution. The latter is then treated with firefly lantern extract, and the light emission of the resultant solution is measured with a photometer. The firefly lantern extract and the ATP required for calibration are commercially available.

A manually operated instrument is available for the ATP measurement. It is supplied with all the required reagents. A tablet containing buffer and magnesium sulfate is dissolved in water, after which a homogeneous powder of luciferin and luciferase is added. The sample is filtered through a coarse filter to remove solid matter, and the latter is discarded. The filtrate is passed through a bacterial filter to catch all the living bacteria. The bacteria on the filter are treated with butanol, which ruptures the cell walls and releases the ATP.

The filtrate is made up to volume with water, and a microliter aliquot is added to the prepared reagent already in a cuvette. The cuvette is then placed in the instrument for reading of its light emission. The light flash is automatically converted to ATP or microorganism concentration per milliliter, depending on how the instrument is calibrated.

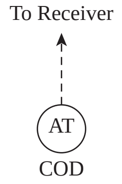
8.7 Biological Oxygen Demand, Chemical Oxygen Demand, and Total Oxygen Demand



Flow Sheet Symbol

I. G. YOUNG (1974, 1982) **B. G. LIPTÁK** (1995) **J. F. TATERA** (2003)

Types of Measurements:	A. Biological oxygen demand (BOD) B. Chemical oxygen demand (COD) C. Total oxygen demand (TOD)
Sampling Technique:	Depending on the application, composite flow-averaged or time-averaged samples are often automatically collected for manual introduction to an instrument, in addition to traditional instantaneous grab samples. Continuous-flow automatic sampling is common for instruments that are in continuous operation for process monitoring and control.
Sample Pressure:	Typically collected at near atmospheric pressure
Sample Temperature:	Collected at process or ambient conditions
Suspended Solids:	Varies with the application and instrument. Many applications are interested in the oxygen demand/impact of both the liquid and solids in the sample stream.
Materials of Construction:	Glass, quartz, Teflon, polyethylene, Tygon, polyvinyl chloride (PVC), stainless steel, ceramic
Ranges:	A. 0.1 to 1500 mg/l is typical and higher with dilution B. 5 to 1500 mg/l is typical and higher with dilution or some methods C. 0 to 60,000 ppm
Inaccuracy:	A. 3 to 20% B. 2 to 10% C. 2 to 5%
Response:	A. 3 min to 5 days B. 2 to 15 min C. 3 to 10 min
Costs:	A. $500 to $20,000 B. $8,000 to $20,000 C. $5,000 to $20,000

INTRODUCTION

A significant portion of the total damage caused by the discharging of wastewater into lakes or rivers is because many of these discharges deplete the oxygen content of the lake or river and the resulting impact that this depletion has on the lake's or river's ecosystem. This oxygen-depleting potential is usually expressed and quantified by biological oxygen demand (BOD), chemical oxygen demand (COD), or total oxygen demand (TOD) measurements. These instruments measure the amount of oxygen that a liter of wastewater is expected to take from the receiving waters as its pollutants are degraded by oxygen-consuming (aerobic) bacteria.

BOD analyzers utilize bacteria to oxidize the pollutants. In COD analyzers, the oxygen demand is usually measured through chemical oxidation and catalytic combustion techniques. TOD analyzers typically oxidize the sample in a catalyzed thermal combustion process and detect both the organic and inorganic impurities in a sample.

This section describes the various BOD, COD, and TOD analyzers. The main distinction between the various designs is in the speed at which the measurement is obtained and in the correlation of the resulting readings with manometric BOD tests. Other measurements that are often used for similar applications and correlated to these measurements include total carbon (TC), total inorganic carbon (TIC), and total organic carbon (TOC) analyzers; they are described in Section 8.58.

OXYGEN DEMAND

The oxygen demand of a sample of water is the amount of elemental oxygen required to react with biodegradable material that is dissolved and suspended in the sample. This amount is expressed as milligrams of oxygen per liter of sample. When a population of bacteria causes the oxidation reaction in a population of bacteria, the oxygen required is called the biological oxygen demand.

When the oxidation is carried out with a chemical oxidizing reagent such as potassium dichromate, the oxygen equivalent is called the chemical oxygen demand. In a sample of water, oxidation can also be caused by heating of the sample in a furnace in the presence of a catalyst and oxygen. This is called total oxygen demand. If the heating in a furnace occurs in the presence of carbon dioxide, the result is called total carbon dioxide demand (TCO_2D).

The BOD test is perhaps the most important oxygen demand measurement for the analysis of effluents and receiving waters (streams, lakes, and rivers). Basically, the BOD test measures the amount of oxygen used by microorganisms that feed on organic pollutants in the water under aerobic conditions. In this test, a bacterial culture is added to the sample under well-defined conditions and oxygen utilization is measured.

Although test procedures are carefully defined,[1,2] it is difficult to obtain highly reproducible results, and the procedure is subject to the influence of many variables, particularly when the wastewater contains a variety of complex materials. Some of the factors that contribute to variations in BOD results are discussed below.

The Seed

The seed is the bacterial culture that affects the oxidation of materials in the sample. If the biological seed is not acclimated to the particular wastewater, erroneous results are frequently obtained. Because different bacterial cultures are used in BOD measurements at different locations, it is not surprising that the results may be inconsistent. Also, recall the intent of the measurement. If the intent is to monitor plant feeds to help control the waste treatment operation, bacteria from the plant waste treatment process may be most useful, as it is probably acclimated to the plant's typical composition. If the intent is to predict the impact on receiving waters, a more random population may better predict this.

pH

The BOD results are also greatly affected by the pH of the sample, especially if it is lower than 6.5 or higher than 8.3. Not only is oxidation of the material itself pH dependent, but so is that of the bacterial activity. In order to achieve uniform conditions, the sample should be buffered to a pH of about 7.

Temperature

Although the standard test condition calls for a temperature of 20°C (68°F), field tests often require operation at other temperatures and, consequently, the results tend to vary unless temperature corrections are applied (Figure 8.7a).

Toxicity

Toxic materials in the sample, although they may be oxidizable or biodegradable, frequently have a biotoxic or biostatic effect on the biological seed. The presence of toxic materials of this type is indicated by an increase in the BOD value as a specific sample is diluted for the BOD test. Consistent values may be obtained either by removing the toxic materials from the sample or by developing a seed that is compatible with the toxic materials in the sample.

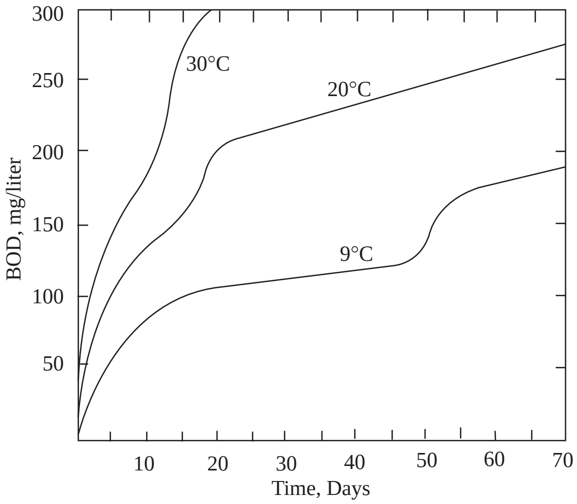

FIG. 8.7a

Progress of BOD at 9, 20, and 30°C (48, 68, and 86°F).[3] The break in each curve corresponds to the onset of nitrification.

Incubation Time

The usual standard lab test incubation time is 5 days, although the time required for stabilization (complete biochemical degradation of materials in the water) may take as long as 20 or 30 days. The 5-day results may occur at a flat part of the oxygen demand vs. time curve, or they may occur at a steeply rising portion. Thus, depending on the type of seed and the type of oxidizable material, divergent results can be expected for this reason alone (Figure 8.7a).

On-line and more rapid BOD-based testing (like fast BOD and respirometry) typically reduce this time factor into the range of minute to hours. To accomplish this, they avoid long-term equilibrium requirements and usually optimize sample size to bacteria population and other relevant factors to give them a faster analysis with reasonable repeatability.

Nitrification

In the usual course of the BOD test, the oxygen consumption rises steeply at the beginning of the test owing to attack on carbohydrate materials. Another sharp increase in oxygen utilization occurs sometime during the 10th to 15th day in those samples containing nitrogenous materials (Figure 8.7a). Stated another way, the rate constant for attack on nitrogenous materials is much lower than that for attack on carbonaceous materials, and the demand due to nitrification is not appreciable until most of the carbonaceous material has been destroyed.[3,4]

In view of difficulties and variability of the classic BOD determination, a rapid procedure that minimizes or eliminates these problems has been sought for many years. Although other procedures are used, the BOD continues to remain the universal standard method, supported by the force of tradition and the weight of legal authority in many jurisdictions.

Thus, those who are concerned with estimating the oxygen depletion load of effluent waters must be thoroughly acquainted with the BOD test and prepared to support other methods by suitable correlation to BOD results. Therefore, although oxygen demand may be measured in a number of ways, the 5-day BOD result is what is meant by oxygen demand in most cases.

BIOLOGICAL OXYGEN DEMAND

Five-Day BOD Procedure

If the BOD of a sample of water at 20°C (68°F) is measured as a function of time, a curve such as the one in Figure 8.7a is obtained. For the first 10 to 15 days, the curve is approximately exponential, but at about the 15th day a sharp increase is noted, which then falls off to a steady BOD rate.

Because of the length of time and because the curve does not flatten, a standard test period of 5 days has been adopted universally for the BOD procedure. This is a laboratory procedure requiring some skill and training to obtain concordant results. The procedure is described in greater detail in the literature;[1,2] only a brief description is given here.

A measured portion of the sample to be analyzed is mixed with seeded dilution water so that after 5 days of incubation, the dissolved oxygen (DO) in the mixture is still sufficient for biological oxidation of materials in the sample. Of course, this cannot be known beforehand; consequently, a number of dilutions are run simultaneously for an unknown sample, or experience is used as a guide for well-defined samples.

The seeded dilution water contains phosphate buffer (including ammonium chloride), magnesium sulfate, calcium chloride, and ferric chloride, as well as a portion of seeding material. The former group of inorganic materials is frequently referred to as nutrients. The latter group is a suspension of bacteria in water, usually supernatant liquor from a domestic sewage plant.

Seeds may also be prepared from soil, developed from cultures in the laboratory, or obtained from receiving water 2 to 5 mi downstream of the discharge. The DO content of the mixture is determined at the start of the test and again after 5 days of incubation at 20°C in a special BOD bottle.

DO Determination and Standards The DO may be determined by the Winkler titration method[1] or instrumentally with a DO membrane electrode. The difference in DO after 5 days is used to calculate the BOD of the original sample. Corrections must be applied for immediate oxygen demand (that due to inorganic reducing materials) and for the oxygen required by the bacteria themselves for sustaining life (endogenous metabolism). A blank sample is run to assist with this.

There is no standard against which the accuracy of the BOD test can be measured. The precision of the method is also difficult to ascertain because of the many variables. However, the single-operator precision of the method has been tested using a standard glucose–glutamic acid solution.

Using eight different types of seed materials, the single-operator precision was 11 mg/l at a level of 223 mg/l, or about 5%. It must be recognized that these results were obtained with highly skilled personnel under well-controlled laboratory conditions.

Instrumentation A semiautomatic instrument has been designed to measure the BOD of as many as 11 samples. The samples have to be manually placed on the instrument turntable and the controls manually set. Means are provided for automatic re-aeration of those samples in which the DO has fallen to low values.

Measurements of the DO are made on a preset time schedule by the polarographic DO sensor. The capability of automatic re-aeration when the DO is low eliminates the need for dilution, leading to improved precision in the BOD results. The instrument consists of a measuring unit (DO probe, aerator, water-sealing mechanism, unplugging mechanism, sample bottle, and turntable) and a control unit, by which all of the operations are programmed. The measuring

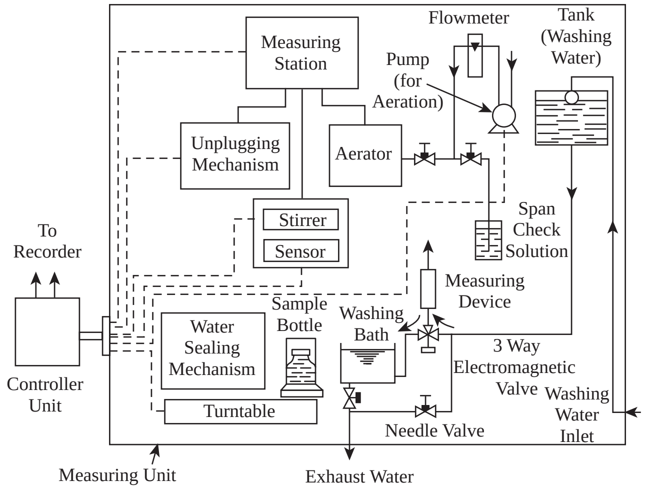

FIG. 8.7b
Semiautomatic BOD instrument.

unit is housed in a chamber maintained at 20°C. Means for storing DO data on each sample are supplied, and the BOD is calculated from the DO values as already described. Figure 8.7b illustrates this instrument.

Extended BOD Test

As reflected in Figure 8.7a, continuation of the BOD test beyond 5 days shows a continuing oxygen demand, with a sharp increase in BOD rate at the 10th day owing to nitrification. The latter process involves biological attack on nitrogenous organic material accompanied by an increase in BOD rate. The oxygen demand continues at a uniform rate for an extended time.

Knowledge of oxygen utilization of a polluted water supply is important because 1) it is a measure of the pollution load, relative to oxygen utilization by other life in the water; 2) it is a means for predicting progress of aerobic decomposition and the amount of self-purification taking place; and 3) it is a measure of the oxygen demand load removal efficiency by different treatment processes.

As a means for treatment plant control and setting the legal standards for wastewater effluents, the extended test is not used. However, it must be remembered that the 5-day BOD does not represent the TOD load of a receiving water. The dynamics of oxygen removal and replenishment in receiving water is discussed in the literature.[3]

Manometric BOD Test

In the standard dilution method that was previously described, all the oxygen required must already be inside the BOD bottle, since it is sealed in a gas-tight manner at the initiation of the incubation period, and care is taken to prevent access of air into the sample. In the manometric procedure,[5] the seeded sample is confined in a closed system that includes an appreciable amount of air.

As the oxygen in the water is depleted, it is replenished by the gas phase. A potassium hydroxide (KOH) absorber within the system removes any gaseous carbon dioxide generated by bacterial action. The oxygen removed from the air phase results in a drop in pressure that is removed with a manometer. This fall is then related to the BOD of the sample.

Thus, in the manometric method, the DO of the water remains at a moderately high level, close to saturation (9 mg/l at 20°C), whereas in the standard BOD, the DO falls continuously during the 5-day incubation period to values near 1 mg/l. Despite this marked difference in conditions of DO during incubation, results in close agreement are obtained on many samples by the two different procedures.

An apparatus is commercially available in which the BODs of five samples can be determined simultaneously by the manometric method. A measured sample of the sewage or wastewater is placed in one of the bottles of the apparatus, and the bottle is connected to a closed-end mercury manometer (Figure 8.7c). Above the water sample a quantity of air is trapped. As bacteria in the sample utilize oxygen, it is replenished by oxygen from the air. The removal of oxygen from the air results in a lowering of the air pressure.

The fall in pressure is read on the mercury manometer directly in BOD units, assuming that the original air contained 21% oxygen. The preceding description assumes a sample that is already seeded. Of course, the method can be modified for those samples that require the addition of a bacterial culture. The procedure is carried out manually in the laboratory. In addition to the manipulations already described, it requires reading of the manometer by the laboratory technician.

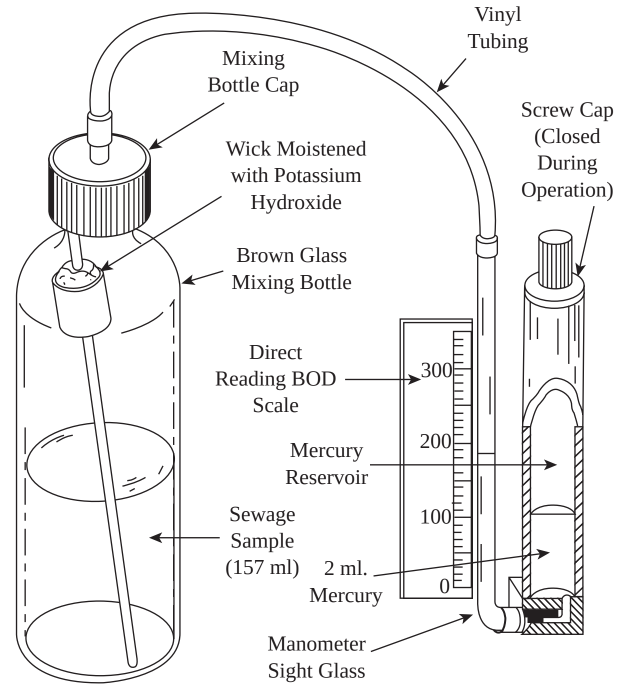

FIG. 8.7c
Manometric BOD apparatus.

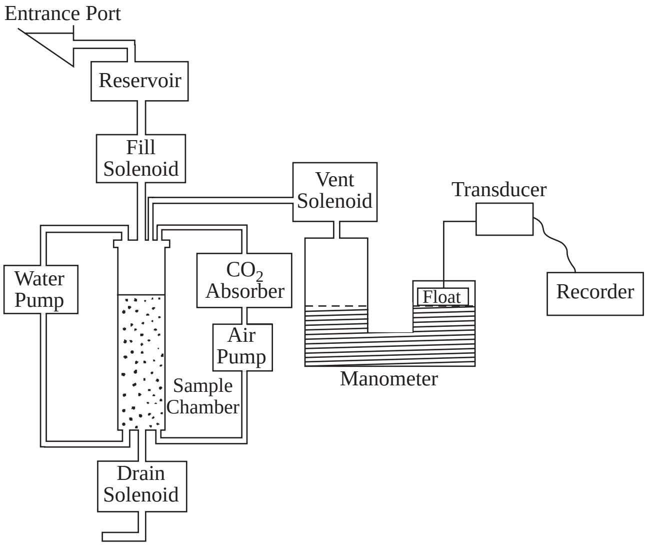

FIG. 8.7d
BOD determination by automatic respirometer.

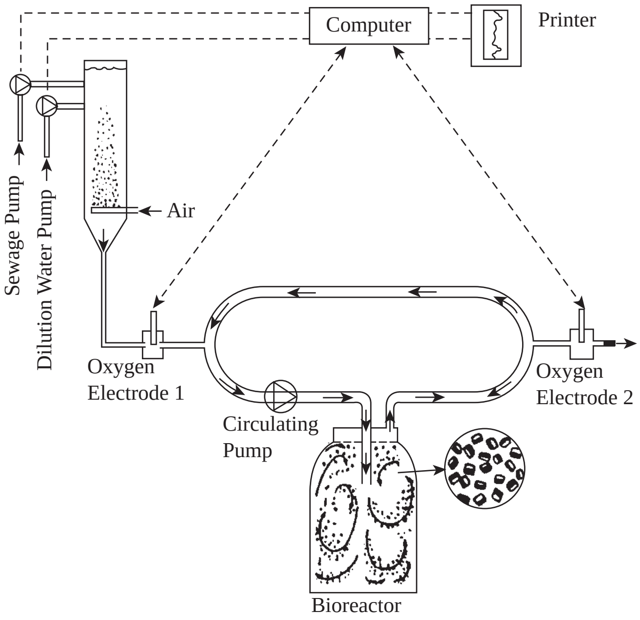

FIG. 8.7e
BOD assessment is obtained in a few minutes in a continuously circulated bioreactor where the oxygen take-up of the organisms controls dilution.[8]

Automatic Recording The manometric method also lends itself to automatic recording of the course of oxygen utilization, since it is possible to monitor the pressure continuously. This has been accomplished in an automatic respirometer[6] now commercially available (Figure 8.7d).

The sample, from 1 to 4 l, is introduced into a closed system containing air. Countercurrent circulation of both air and water insures equilibrium between dissolved and gaseous oxygen. A carbon dioxide scrubber is provided in the gas-circulation line. A recording manometer detects the utilization of oxygen as the test is run for several hours. Published data indicate a correlation between the respirometer BOD and the standard BOD.[7] Both laboratory and automated on-line versions of this instrument are available.

It must be recognized that BOD is inherently a time-consuming process and ill-suited to the requirements of process monitoring or control. The shortest period mentioned for the automatic respirometer is 2 h, often too long for an effective control instrument. However, it is an excellent device for longer-term laboratory and process studies, since it can be made to simulate the activated sludge process.

Useful fast BOD and respirometric measurements have been reduced to times under an hour and have been useful in the control of several waste treatment operations, though they are more often utilized in a monitoring role.

BOD Assessment in Minutes

When determining the BOD concentration in groundwaters, it might be acceptable to wait 5 days for the results, but in the control and operation of sewage treatment plants, it is not. The hold-up capacity of industrial and municipal wastewater treatment facilities and the desire for closed-loop control necessitates the use of a much faster sensor. One such analyzer is described in Figure 8.7e.

In this design a bioreactor is filled with a large number of plastic rings, the interior of which are protected against mechanical abrasions and thereby provide a growth surface for organisms. A circulation pump serves to quickly distribute the sewage in the bioreactor and to keep the plastic rings in continuous motion.

The sewage concentration (nutrient level) in the reactor is maintained at a constant low value, which results in an oxygen demand of about 3 mg/l. This oxygen demand is measured and maintained constant by detecting the decrease in oxygen concentration at the points where the diluted sewage enters and leaves the reactor. The dissolved oxygen concentration at electrode 2 is kept at a constant value below that at electrode 1. If this difference drops, the sewage concentration is increased; if this difference rises, the concentration is reduced.

The sewage concentration (the nutrient concentration) in the bioreactor is adjusted by a computer. It varies the mixing ratio of sewage and dilution water. The total flow from the sewage and dilution water pumps is always 1 l/min, and it is the ratio of the two streams that is modulated. Therefore, this pumping ratio is an indication of the BOD concentration of the sewage sample.

Correlation between this fast BOD measurement and the 5-day BOD obtained through conventional methods has been acceptable.[8] Fouling of the piping was found to be minimal, and weekly recalibration of the oxygen electrodes was found to be satisfactory.

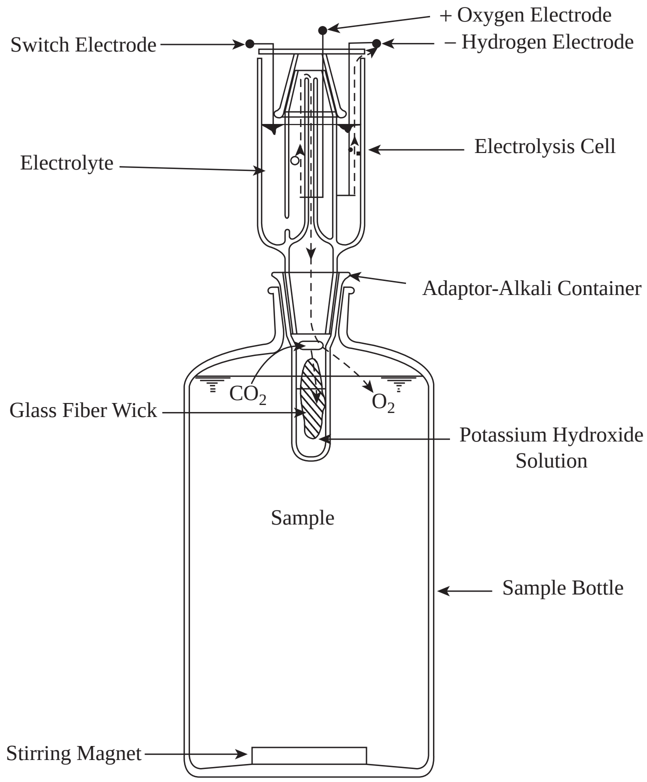

FIG. 8.7f
Electrolysis system for measuring BOD.

Electrolysis System for BOD

Electrolysis of water can supply oxygen to a closed system[9,10] as incubation proceeds (Figure 8.7f). At constant current, the time during which electrolysis generates the oxygen to keep the system pressure constant is a direct measure of the oxygen demand (by Faraday's law).

An instrument based on this principle permits the running of six samples simultaneously, and its readout gives BOD directly, in milligrams per liter for each sample. After starting the test run, operator attention is not required.

CHEMICAL OXYGEN DEMAND

Standard Dichromate COD Procedure

This laboratory method requires skill and training[1,2] similar to that required for the BOD test. A sample is heated to its boiling point with known amounts of sulfuric acid and potassium dichromate. Loss of water is minimized by use of a reflux condenser. After 2 h, the solution is cooled, and the amount of dichromate that reacted with oxidizable material in the water sample is determined by titrating the excess potassium dichromate with ferrous sulfate, using ferrous 1,10-phenanthraline (ferroin) as the indicator. The dichromate consumed is calculated as to oxygen equivalent for the sample and reported as milligrams of oxygen per liter of sample.

Interpretations of COD values are difficult, since this method of oxidation is markedly different from the BOD method. Although ultimate BOD values can be expected to agree with COD values, a number of factors may prevent this concordance. Among these, we may mention the following:

1. Many organic materials are oxidizable by dichromate but not biochemically oxidizable, and vice versa. For example, pyridine, benzene, and ammonia are not attacked by the dichromate procedure.
2. A number of inorganic substances such as sulfide, sulfites, thiosulfates, nitrites, and ferrous iron are oxidized by dichromate, creating an inorganic COD that is misleading when estimating the organic content of wastewater. Although the factor of seed acclimation will give erroneously low results on the BOD tests, COD results are not dependent on acclimation.
3. Chlorides interfere with the COD analysis, and their effect must be minimized in order to obtain consistent results. The standard procedure provides for only a limited amount of chlorides in the sample. Despite these limitations, the dichromate COD has been useful in control of wastewater effluents from plants concerned with caustic and chlorine, dyeing and textiles, organic and inorganic chemicals, paper, paints, plating, plastics, steel, aluminum, and ammonia. This is usually accomplished by diluting the sample to achieve a lower chloride concentration and interference. This can be a problem for low COD concentration samples, as the dilution may dilute the COD concentration below the detection level or to levels at which accuracy and repeatability are poor.

COD Detector

The term COD usually refers to the laboratory dichromate oxidation procedure, although it has also been applied to other procedures that differ greatly from the dichromate method but which do involve chemical reaction. These methods have been embodied in instruments both for manual operation in the laboratory and for automatic operation on-line. They have the distinct advantage of reducing analysis time from days (5-day BOD) and hours (dichromate, respirometer) to minutes.

Automatic On-Line Designs

Figure 8.7g illustrates an on-line analyzer available with COD ranges from 0 to 5000 ppm and with measurement cycle times that are adjustable from 10 min to 5 h. The sample flow can be continuous at rates up to 0.25 GPM (1.0 lpm) and can contain solid particles up to 100 microns in size. The automatic COD analyzer periodically takes a 5 cc sample from the flowing process stream and injects it into the reflux

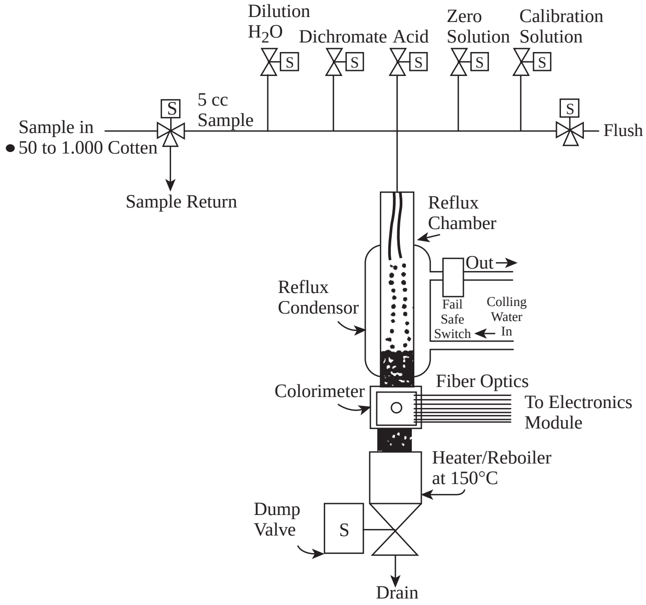

FIG. 8.7g

Automatic COD analyzer using dichromate reagent and fiber-optic colorimeter detector and providing features of adjustable reflux time and autocalibration. (Courtesy of Ionics Inc.)

chamber after mixing it together with dilution water (if any) and with two reagents: dichromate solution and sulfuric acid.

The reagents also contain an oxidation catalyst (silver sulfate) and a chemical that complexes chlorides in the solution (mercuric sulfate). The mixture is boiled at 302°F (150°C) by the heater, and the vapors are recondensed by the cooling water in the reflux condenser. The solution is refluxed for a preset time, during which the dichromate ions are reduced to trivalent chromic ions, as the oxygen-demanding organics are oxidized in the sample. The chromic ions give the solution a green color.

The COD concentration is measured by detecting the amount of dichromate converted to chromic ions by measuring the intensity of the green color through a fiber-optic detector. The microprocessor-controlled package is available with automatic zeroing, calibration, and flushing features. Analyzers utilizing this or other COD wet chemical reaction schemes are generally categorized as flow injection analyzers (FIAs) or continuous-flow analyzers (CFAs), and some of the manufacturers of these types of analyzers do not advertise them as COD analyzers. To them, COD is just one application of their FIA or CFA capability.

In one instrument, a 20-μl water sample is manually injected into a carbon dioxide carrier stream and swept through a platinum catalyst combustion furnace. In that furnace, the pollutants are oxidized to carbon monoxide and water, and the water is removed from the stream by a drying tube, after which the reaction products receive a second platinum catalytic treatment.

A nondispersive infrared (NDIR) detector is used to measure the concentration of carbon monoxide, and a calibration chart is utilized to convert the readings into COD. An analysis can be completed in 2 min. This instrument is available commercially for manual operation (Figure 8.7h). Data obtained on domestic sewage[11] indicate excellent correlation between this method (frequently called CO_2D) and the standard COD.

Some other approaches to COD monitoring include methods that utilize ozone and OH–radicals as the oxidizing agents. One ozone-based scheme enriches dilution water with ozone and measures the dissolved ozone concentration of the dilution water and the residual dissolved ozone concentration downstream of the reaction chamber. It then calculates a COD value based on the difference in the two measurements and the ratios of dilution water and sample being delivered to the reaction chamber.

It has a response time of 3 min. Another OH–radical approach produces OH–radicals on an electrode, by an electrical current. These OH–radicals are extremely strong oxidizing agents. An electrochemical measurement signal based on the OH–radicals being converted and measured as OH–ions results in a 30-sec analysis with a range of 1 to 100,000 ppm that is said to correlate to the dichromate standard method.

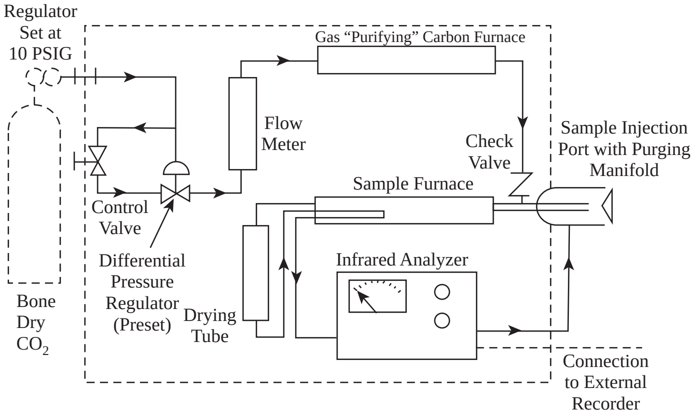

FIG. 8.7h

COD detection employing combustion in a carbon dioxide carrier and an NDIR sensor.

One thing to remember is that all of these techniques are based on a chemical oxidation reaction and that all reactions can experience interferences. The nice thing about having several options is that you can pick the one that is most suited to your sample matrix.

TOTAL OXYGEN DEMAND

The TOD method is based on the quantitative measurement of the amount of oxygen used to burn the impurities in a liquid sample. Thus it is a direct measure of the oxygen demand of the sample. Measurement is by continuous analysis[12,13] of the concentration of oxygen in a combustion process gas effluent (Figure 8.7i).

The oxidizable components in a liquid sample introduced into the combustion tube are converted to their stable oxides by a reaction that disturbs the oxygen equilibrium in the carrier gas stream. The momentary depletion in the oxygen concentration in the carrier gas is detected by an oxygen detector and recorded as a negative oxygen peak. The TOD for the sample is obtained by comparing the recorded peak height or area to the peak sizes of the standard TOD calibration solutions, e.g., potassium acid phthalate (KHP).

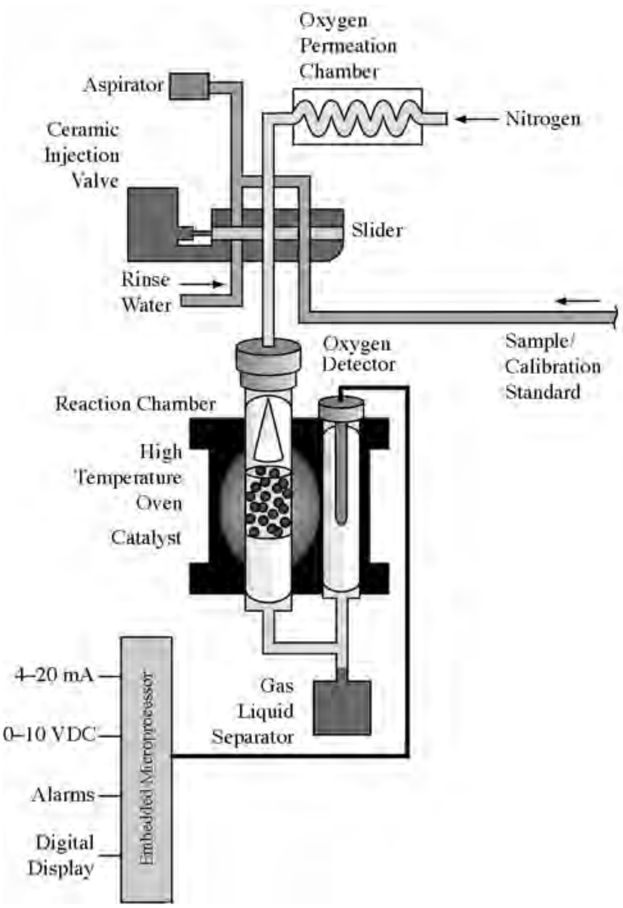

FIG. 8.7i
Basic components of an on-line TOD analyzer. (Courtesy of Ionics Inc.)

Prepurified nitrogen from a cylinder passes through a fixed length of tube permeable to oxygen (usually silicone) into the combustion chamber packed with a solid catalyst, the gas scrubber, and then the oxygen detector. The baseline oxygen concentration is obtained as the nitrogen passes through the temperature-controlled permeation tube and can be varied to accommodate different TOD ranges by changing the nitrogen flow rate and the length of permeation tubing.

The combustion chamber is a length of Victor tubing, quartz tube, ceramic tube, or other metal tube that contains a platinum catalyst and is mounted in an electric furnace and held at a temperature of 900°C (1672°F). The aqueous sample is injected into this chamber, and the combustible components are oxidized.

Sample Valves

Two basic types of injection valves are in use today, the sliding plate and the rotary sampling valve. Manual injection can be accomplished though a silicone rubber septum, if desired.

Figure 8.7j shows the main features of the sliding plate valve. Upon a signal from a cycle timer, the air actuator temporarily moves the valve to its “sample fill” position. At the same time, an air-operated actuator moves a 20-μl sample through the valve into the combustion tube. A stream of oxygen-enriched nitrogen carrier gas moves the slug of sample into the combustion tube.

Traditionally, sliding plate valves were manufactured from a variety of metals (stainless steel, Hastelloy, Monel, and others), but ceramic sliding plate sampling valves have been developed to provide reduced maintenance for this harsh application.

The rotary sample valve is mainly used for on-stream TOD analyzers. Figure 8.7k shows the cross section of the

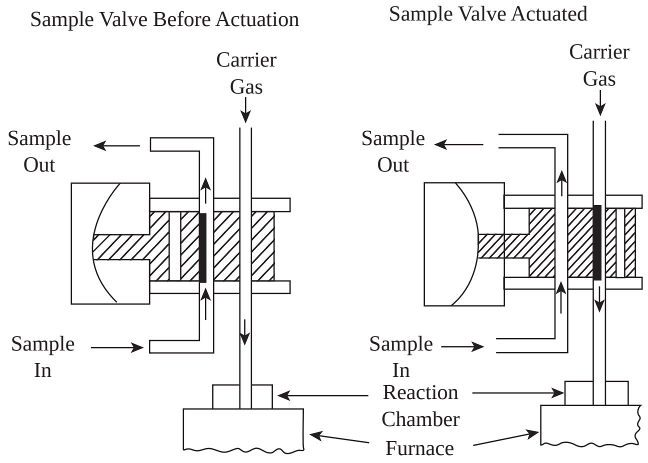

FIG. 8.7j
Automatic sliding plate liquid sample injection value.

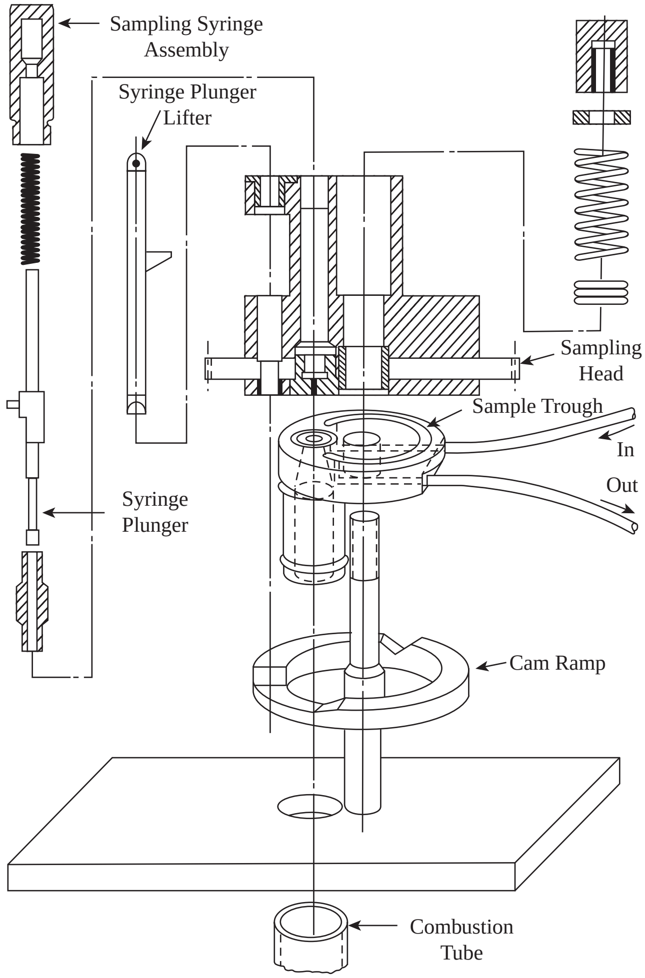

FIG. 8.7k
Rotary sample valve.

valve, in which a motor continuously rotates a sampling head, which contains a built-in sampling syringe. For part of the time, the tip of the syringe is over a trough that contains the flowing sample. Two or more cam ramps along the rotational path cause the syringe plunger to rise and fall, thus rinsing the sample chamber. Just before the syringe reaches the combustion tube, it picks up a 20-μl sample. As it rotates over the combustion tube, it discharges the sample.

Oxygen Detector

One type of TOD oxygen sensor is a platinum–lead fuel cell that generates a current in proportion to the oxygen content of the carrier gas passing through it. Before entering the cell, the gas is scrubbed in a potassium hydroxide solution, both to remove acid gases and other harmful combustion products and to humidify the gas.

The oxygen cell and the scrubber are located in a temperature-controlled compartment. The fuel cell output is monitored and zeroed to provide a constant baseline. The output peaks are linearly proportionate to the reduced concentration of oxygen in the carrier gas as a result of the sample's TOD.

Another type of TOD oxygen detector is a yttrium-doped zirconium oxide ceramic tube that has been coated on both sides with a porous layer of platinum. It is maintained at an elevated temperature and also provides an output that represents the reduction in oxygen concentration in the carrier gas that is a result of the sample's TOD.

A more complete discussion of this detector technology can be found in Section 8.42 ("Oxygen in Gases") under "High-Temperature Zirconium Fuel Cells."

Calibration

Analysis is by comparison of peak heights or areas to a standard calibration curve. To prepare this curve, known TOD concentrations of a primary standard (KHP) are prepared in distilled and deionized water. Standard solutions are stable for several weeks at room temperature. Water solutions of other pure organic compounds can also be used as standards.

Several analyses can be made at each calibration concentration, and the resulting data are recorded as parts per million (ppm) TOD vs. peak height or area. Older instruments utilize a recorder, and within the normal instrument range, the plot is a straight line. Consequently, a single-concentration calibration of the recorder chart in milligrams per liter TOD can be made.

Newer instruments are microprocessor controlled, and the microprocessor stores the calibration results and outputs a result directly as ppm TOD.

Interferences

Nitrate salts and sulfuric acid will normally decompose under sample combustion conditions as follows:

$$2\text{NaNO}_3 \xrightarrow[\text{Pt}]{900^\circ\text{C}} \text{Na}_2\text{O} + 1\tfrac{1}{2}\text{O}_2 + 2\text{NO} \qquad \textbf{8.7(1)}$$

$$\text{H}_2\text{SO}_4 \xrightarrow[\text{Pt}]{900^\circ\text{C}} \text{H}_2\text{O} + \text{SO}_2 + \tfrac{1}{2}\text{O}_2 \qquad \textbf{8.7(2)}$$

This oxygen release results in a proportionate reduction in the TOD reading. The interference from sulfuric acid can be overcome by neutralizing it with sodium hydroxide. Dissolved oxygen in the aqueous sample also becomes an unknown source of oxygen to the combustion reaction and lowers the TOD readings. But unless special precautions are taken, the standard solutions are also at or near saturation, thus automatically minimizing this potential interference. If absolute TOD levels are required, the oxygen equivalent of the interference should be added to the TOD reading.

Oxygen-saturated or air-saturated samples with very low TOD values pose a special problem, which can be circumvented by spiking the sample with a known concentration of a standard solution. The actual TOD will then be the analysis value minus the spiking concentration.

Heavy-metal ions give long-term interferences, usually by eventual reduction of the catalyst efficiency. Replacement of the combustion tube and a thorough cleaning of the catalyst

TABLE 8.7l
Application Suggestions for TOD Analyzers

Application	*Purpose*
Waste treatment plant influent	Determines loading of plant
Primary, secondary, and plant effluents	Determines efficiency of treatment and TOD load on the receiving waterway
Enforcement programs	Determines pollution levels
Industrial process control	Determines process efficiency and leaks by continuous monitoring
Research and development	Evaluates waste treatment processes
Stream surveillance	Monitors fresh, estuarine, and marine water quality
Municipal or industrial water treatment plants	Monitors quality of influent water prior to treatment
Boiler feed and high-purity water monitoring	Measures TOD with great sensitivity

is the only remedy. Materials like silanes or siloxanes also combust in the reactor and exhibit a positive TOD, but can leave a residue of silica in the reactor that can coat and desensitize the catalyst.

The catalyst and the reactor components can be coated when the sample is vaporized and combusted in a fashion that leaves some solids behind in the reactor. The total matrix of the sample should be evaluated before committing to a technique, not just the components being measured.

Applications

Table 8.7l lists typical applications for the TOD analyzer. Instruments equipped with the rotary or sliding plate sampling valve lend themselves nicely to multistream analysis, since no carryover of the previous sample is present. If the streams have varying levels of TODs, each stream must be diluted to the basic range of the analyzer by appropriate automatic dilution techniques. On the laboratory analyzers, it is best to sample deionized water when the instrument is in a standby condition.

CORRELATION BETWEEN MEASUREMENT TECHNIQUES

Many regulatory agencies recognize as the basis for oxygen-depleting pollution control only the BOD or COD (preferably BOD) measurements of pollution load. The reason for this is that they are concerned with the oxygen-consuming pollution load on receiving waters, which is related to lowering of the DO due to bacterial activity.

Thus, if the other methods described are to be used to satisfy legal requirements of the oxygen-consuming pollution load in effluents or to measure BOD removal, it is necessary that a correlation be established between the other methods and BOD.

In order to summarize the features of various methods, it is assumed that the BOD is the standard reference method. The salient features of this method are: 1) a measurement of property (the BOD) of the sample, i.e., the amount of oxygen required for bacterial oxidation of bacterial food in the water; 2) dependence of the oxygen demand on the nature of the food as well as on its quantity; and 3) dependence of the oxygen demand on the nature and amount of the bacteria.

Variations in Oxygen Demand

Variations in oxygen demand due to variations in the amount (pounds per gallon) of food in the wastewater are expected; we are less able to deal with variations in oxygen demand when the amount of food is constant but changes occur in its BOD requirements. The same observations apply to the bacterial seed. Thus, variation in oxygen demand due to variation in the number of bacteria or their activity, as well as those due to the changes in the nature of their foodstuffs, leads to a systematic or bias error in BOD measurements, which cannot be predicted or corrected for.

The standard reference method is therefore inherently variable—one subject to analytical error. Researchers in an interlaboratory comparative study[14] employing a synthetic waste found standard deviations around the mean of ±20% for BOD and ±10% for COD.

BOD and COD Correlation

Another extensive study[15] concluded the following: 1) A reliable statistical correlation between BOD and COD of a wastewater and its corresponding TOC or TOD can frequently be achieved, particularly when the organic strength is high and the diversity in dissolved organic constituents is low. 2) The relationship is best described by a least squares regression with the degree of fit expressed by the correlation coefficient—this applies to the characterization of individual chemical-processing and oil-refining wastewaters, not to all types of samples across the board. 3) The observed correspondence of COD-TOD was better than that of COD-BOD for the wastewaters. It was difficult to correlate BOD with TOD, particularly when the wastewater contained low concentrations of complex organic materials. 4) The BOD-COD or BOD-TOC ratios of an untreated wastewater are indicative of the biological treatment possible with the particular wastewater. As these ratios increased, higher treatment efficiencies by biological methods in terms of organic removal were noted.

BOD and Other Methods Several papers have indicated high correlation between BOD and other methods. This can be achieved when the nature of the pollutant is constant and only its amount changes. For complex and varying mixtures, it is difficult or impossible to obtain good correlations.

An interesting example is given in the work of Nelson et al.,[16] who discuss a pyrolytic method combined with flame ionization detector (FID) (Section 8.12) detection. Values from the new method agreed with BOD values within ±15%

for BOD values greater than 100 ppm on raw sewage and primary effluent.

However, discrepancies of several hundred percent were found when the BOD was 20 ppm or less. These poor results can be attributed to marked variation in biodegradability of carbonaceous products in the secondary effluent, compared with products before treatment, as well as to the very small amount of total material left.

The ability to truly correlate one measurement to another requires more than measurements that are measuring often-related properties. Correlation can also be highly dependent on the matrix of the sample being measured. Different measurement techniques often respond differently to different backgrounds and to different interferences.

For example, techniques like FID and ultraviolet (UV) absorption (Section 8.61) are being sold to make correlated COD measurements. Obviously, they are not measuring the ability to oxidize the sample. What they are measuring is a generalized organic content of a sample and trying to predict what a COD value of that sample would be, assuming the determined organic content represents it. While this is possible for some very well characterized samples, this approach often fails to adequately handle surprises (process upsets or changes that result in significant sample matrix changes).

Many types of analyzers can measure various components that contribute to the BOD, COD, or TOD loading of a sample and, under the right circumstances, they can be reliably correlated to an appropriate BOD, COD, or TOD result. Many of these analyzers offer advantages like continuous or faster analysis and lower purchase, operating, and maintenance costs.

The key to instrument selection in this case is to insure that you have selected one that is appropriate for your process, sample, and measurement requirements. If in doubt, usually the safest path is to go with an instrument that is compatible with your sample and most directly measures the property of interest.

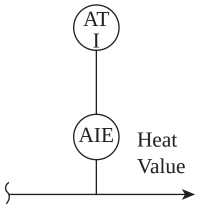
8.8 Calorimeters

P. FOUNDOS (1982) **G. LIPTÁK** (1995) **D. LEWKO** (2003)



Flow Sheet Symbol

Type of Designs:

A. Direct measurement by burning of fuel gas
B. Inferential by calculation from composition and physical analysis, including chromatography (Section 8.12), mass spectrometry (Section 8.29), etc.
C. Special designs such as reaction calorimeters of Mettler-Toledo, designs for the measurement of partial molar heat capacities of biopolymers by CSC, and total absorption calorimeters made by Opal

Applications:

1. Custody transfer
2. Process monitoring and control
3. Blending and mixing of fuel gases
4. Gas and liquefied natural gas (LNG) processing
5. Compliance recording

Operation:

a. Continuous
b. Cyclic
c. Portable

Performance:

(1) Controlled environment
(2) Varying ambient
(3) High speed of response
(4) Inaccuracy ±0.5% of full scale or better
(5) Inaccuracy ±1.0% of full scale or better
(6) Inaccuracy ±2.0% of full scale or better

Area Classification:

(a) General purpose
(b) Explosion-proof

Cost:

Under \$10,000 [A, 2/3, a, (3)/(5)/(6)]
\$10,000 to \$15,000 [A, 2, a, (3)/(5)/(6), (b)]
\$15,000 to \$30,000 [A/B, 2/3, a/b, (1)/(2)/(4), (a)/(b)]

INTRODUCTION

This section does not discuss the special calorimeter designs such as reaction calorimeters (Mettler-Toledo), designs for the measurement of partial molar heat capacities of biopolymers (CSC), or total absorption calorimeters (Opal), but only directs the reader to the web pages of their respective suppliers.

Inferential calorimeters, which determine the heat content by calculation from composition and physical analysis, including chromatography (Section 8.12) and mass spectrometry

(Section 8.29), are not covered in detail either, because they are discussed in the above-noted sections.

Calorimeters are analyzers that measure the heat value or energy content of gaseous fuels. There are two broad categories of this type of instrument: those that can be considered true calorimeters, because they are actually burning the gas and directly measuring its heating value, and inferential calorimeters, which analyze the composition of the gas or measure a physical parameter to determine the heating value.

TERMINOLOGY

Basic terms and definitions used in gas calorimetry are given here and may also be found in the references listed at the end of this section. A summary of the measurement calibration techniques is outlined in Table 8.8a.

British Thermal Unit

A British thermal unit (BTU) is the amount of heat required to raise the temperature of 1 lb of water by 1°F at or near 60°F.

BTU Dry

This is the heating value that is expressed on a dry basis. The common assumption is that pipeline gas contains 7 lb (or less) of water vapor per million standard cubic feet (SCF).

BTU Saturated

This is the heating value that is expressed on the basis that the gas is saturated with water vapors. This state is defined as the condition when the gas contains the maximum amount of water vapors without condensation, when it is at base pressure and 60°F.

Combustion Air Requirement Index

The combustion air requirement index (CARI), a dimensionless number, indicates the amount of air required (stoichiometrically) to support the combustion of a fuel gas. Mathematically, the CARI is defined by Equation 8.8(1):

$$\text{CARI} = \frac{\text{Air/Fuel Ratio}}{\sqrt{\text{s.g.}}} \qquad \textbf{8.8(1)}$$

Gross Calorific Value

This is the heat value of energy per unit volume at standard conditions, expressed in terms of BTU per SCF, kilocalorie per cubic Newton meters (Kcal/N.m^3), or other equivalent units.

Net Calorific Value

This the measurement of the actual available energy per unit volume at standard conditions, which is always less than the gross calorific value by an amount equal to the latent heat of vaporization of the water formed during combustion.

Wobbe Index

American Gas Association (AGA) 4A defines the Wobbe Index as a numerical value that is calculated by dividing the square root of the relative density (a key flow orifice parameter) into the heat content (or BTU/SCF) of the gas. Mathematically, the Wobbe Index is defined by Equation 8.8(2):

$$\text{Wobbe index} = \frac{\text{calorific value}}{\sqrt{\text{specific gravity}}} \qquad \textbf{8.8(2)}$$

The Wobbe Index accounts for composition variations in terms of their effect on the heat value and specific gravity, which affect the flow rate through an orifice. In essence, the Wobbe Index is a measurement of the available potential heat, and it can be used in conjunction with the gas flow measurement to produce a measurement of heat flow rate (see Section 2.5).

In the following paragraphs, some basic terms and gas calorimeter design variations are described. The American Society for Testing Materials (ASTM) Standards listed in the references serve to compliment this information.

UNITS, ACCURACY, AND OUTPUT SIGNALS

When calorimeters are used for custody transfer of natural gas, the unit of measurement is often the BTU. The Natural Gas Policy Act of 1978 (15USC 3311, Supplement 1981) established the BTU as the basic measurement of natural gas for pricing purposes, supplanting the traditional volume bases measurement. As a result, the market demand for custody transfer type calorimeters increased markedly. In Europe and in other countries where the metric system is used, natural gas calorimeters are calibrated in mega-Joule units.

The response time can be a critical consideration in selecting the right analyzer for closed-loop control applications. On the other hand, for custody transfer applications, one should maximize accuracy even at the expense of response time, while improved response time even at the expense of accuracy is justified in some critical process control applications.

The analog output of the analyzer may represent the gross calorific value (sometimes referred to as upper heating value or gross heating value), the net calorific value (sometimes referred to as lower heating value or net heating value), or the Wobbe Index.

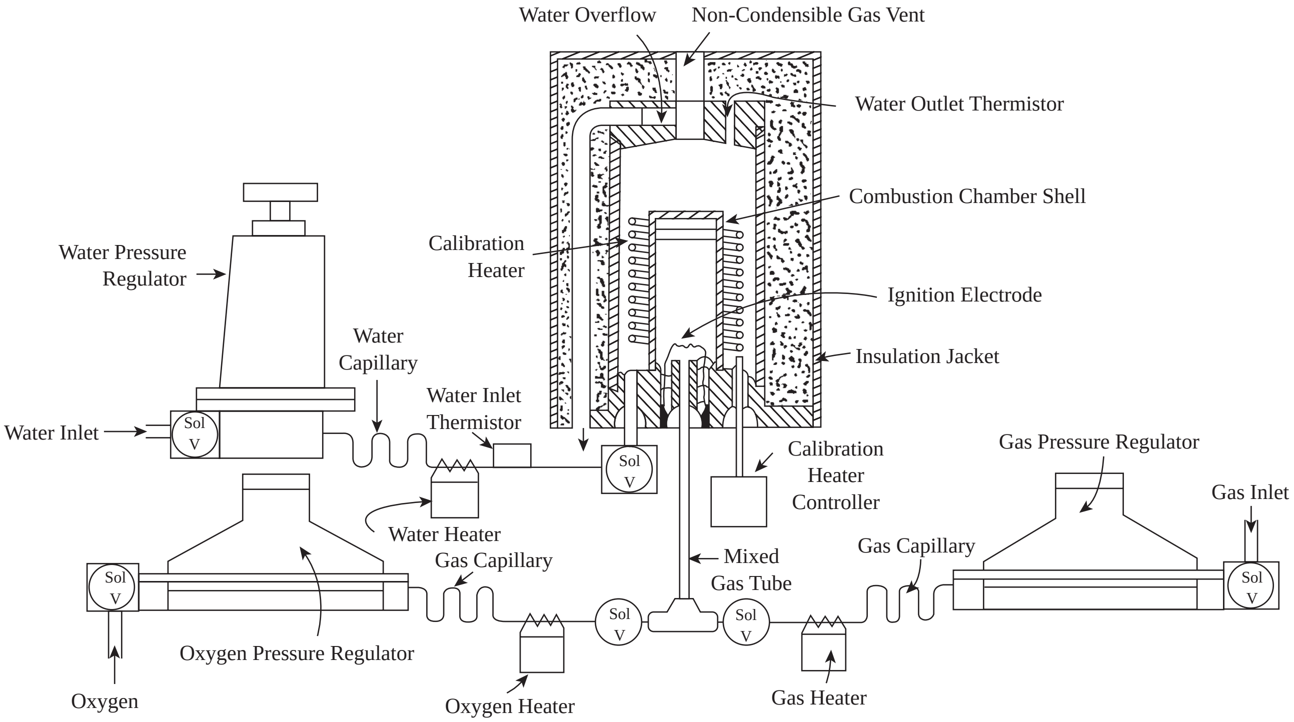

FIG. 8.8b
Water-temperature-rise-type calorimeter provided with electric heater for direct calibration.[1]

DESIGN VARIATIONS

In the following paragraphs, a brief description is given of the various gas calorimeter designs that are used to detect the heating value of gaseous fuels and waste gases.

Water-Temperature-Rise Calorimeter

One variation of this design is illustrated in Figure 8.8b. Here a constant (capillary-controlled) flow rate of the gas is mixed with a constant flow rate of oxygen (or air) and is burned. The resulting heat of combustion is removed by a constant flow rate of water. Both the flow rates and the temperatures of the entering streams are controlled at a constant value.

Thermistors measure the temperature of the water entering and leaving. The temperature difference or temperature rise is therefore a direct measure of the heating value of the burned gas. This calorimeter can be compensated for the variations in barometric pressure and can therefore measure the gross calorific value of fuel or waste gases.

Figure 8.8b also shows a calibration heater. During the calibration cycle this electrical resistance heater is turned on while the gas flow is off. Thereby a known accurately determined amount of heat is introduced and the corresponding temperature rise on the water side is measured. When the temperature rise is the same as it was when gas was being burned, the amount of electric heat introduced matches the heating value of the gas. This type of calibration can be made at any time and for any reading of the calorimeter.

Air-Temperature-Rise Calorimeter

The measurement is accomplished by continuously transferring all the combustion heat of a metered quantity of gas to a metered quantity of air (see Figure 8.8c). The temperature rise of the air is measured and is related directly to gross calorific value of the gas. The unit can be modified so that the heat-absorbing air is not separated from the products of combustion, thus resulting in a more accurate measurement of the net calorific value.

Airflow Calorimeter

In this design the variations in the heat released by the continuous burning of the fuel gas are offset by a continuous, varying airflow that maintains the temperature of the products of combustion constant (see Figure 8.8d). Thus, the airflow is correlated to the heat value of gas or to the Wobbe Index. With the addition of a constant-volume gas-metering pump, and compensating for specific gravity variations, the instrument can be calibrated for the net calorific value.

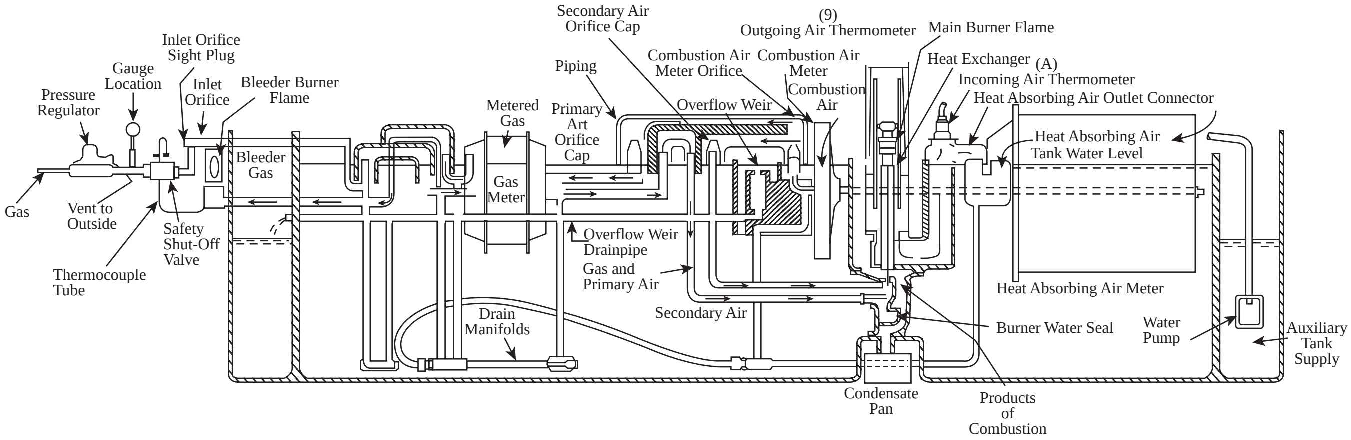

FIG. 8.8c
Air ΔT calorimeter.

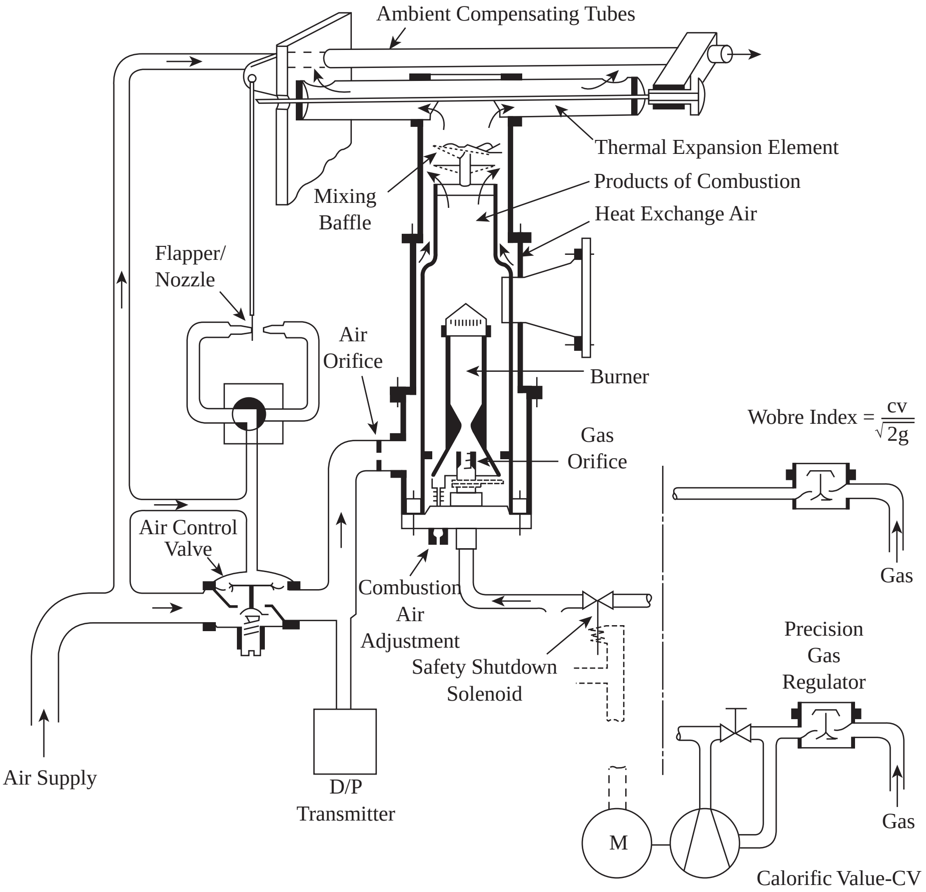

FIG. 8.8d
Airflow calorimeter.

Residual Oxygen Calorimeter

In this design, a continuous gas sample is mixed with dry air at a precisely maintained ratio. The ratio is dependent on the BTU range of the gas to be measured. The fuel–air mixture is oxidized in a combustion furnace, and the oxygen concentration in the spent sample is measured using a zirconia oxide cell. With the addition of a precision specific gravity cell, the analyzer can be calibrated to provide a measurement corresponding to the calorific value of the gas.

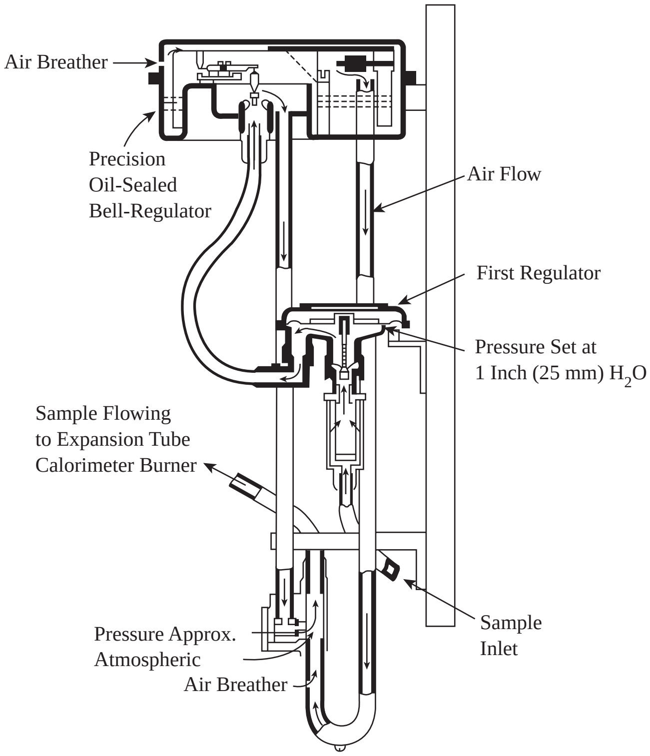

FIG. 8.8e
Precision regulator used for expansion tube-type calorimeter. (Courtesy of Cosa Instrument Corp.)

Chromatographic Calorimeter

A conventional chromatograph can also be used to analyze gas composition (see Section 8.12), and a microprocessor can be used to calculate the heating value and specific gravity of the gas from empirical data held in memory by the microprocessor. This information can be used to calibrate for the gross or net calorific value of the Wobbe Index.

Expansion Tube Calorimeter

In this design, the gas sample is delivered through a precision regulator system (Figure 8.8e), which is independent of specific gravity and atmospheric pressure. The gas is burned at the base of a differential expansion tube unit that responds to the temperature of the products of combustion and excess air. The differential signal is calibrated as the net calorific value. Modification of the regulator to respond to specific gravity changes allows calibration to the Wobbe Index.

Adiabatic Flame Temperature

The gross calorific value of fuel gas is proportionate to the ratio of air to a fuel that maximizes the adiabatic flame temperature of the mixture. Therefore, in this design, flows are controlled and two burners are used to obtain the mathematical derivative of the flame temperature composition that allows calibration for gross calorific value.

Thermopile Calorimeter

The thermopile calorimeter measures the temperature of the hot products of combustion mixed with a constant volume of air supplied by a fan. The sample to the burner is provided with an orifice bypass, which is needed for specific gravity compensation; thus, the resulting measurement is in terms of net calorific value. To measure the Wobbe Index, the bleed is blocked and the sample goes through the burner.

APPLICATIONS

There are five general areas of application:

1. *Custody transfer:* Sale or purchase of fuel gas with accuracy being the primary consideration.
2. *Process monitoring and control:* To effect on-line manual or automatic control of process or efficient burning of the gas by using heat value measurement as one of the measured variables. Such applications include feed-forward control of fuel gas-fired heaters or boilers, stove-firing control, vaporizer control, and synthetic natural gas (SNG) reactor control. In these applications, measurement of heat value is important as a process measurement for efficient control of energy consumption, or to limit the flow of heat to an energy-sensitive process. This application requires high speed of responses as well as reliability to achieve effective control.
3. *Blending and mixing of fuel gas:* To obtain a uniform quality gas or to utilize waste or by-product gases by blending them into the main fuel gas. Blending is often used to achieve a desired ratio of streams such as propane/air or blast furnace gas/coke oven gas. However, when by-product or waste gases are to be injected into a stream and they vary significantly in quantity, monitoring of the mixture is necessary to make proper use of the fuel. Speed of response and reliability are essential.
4. *Processing of gas and liquefied natural gas (LNG) operations:* LNG must be vaporized and conditioned for efficient consumption. Coke oven and blast furnace gases are the main fuels used by the steel industry, and refinery gas is a major by-product that is used in petroleum refining. All these fuel gases are produced in specific processing operations that require monitoring and conditioning for efficient use.
5. *Compliance recording:* For government-regulated energy transfer by pipeline and utility distributors to the consumers. Accuracy and traceability are essential criteria.

SAMPLE CONDITIONING

The requirements for the sample conditioning system are dependent on the limitations of the selected analyzer and the minimum, normal, and maximum limits of the process stream being monitored. In many industrial applications, fuel gases are generated as by-products of other processes, and these "off-gases" can be extremely dirty and require sample conditioning. In some cases, special consideration must be given to the dew point of the off-gas when designing the sample conditioning system. Refer to Sections 8.2 and 8.3 for sample system options and design features.

CONCLUSION

Gaseous fuel energy is a costly commodity that is being consumed with much more care and efficiency than in the past. The key to its efficient consumption is measuring the available heat of the fuel gas. There are several calorimeters available for reliable on-line measurement of gas heating values. For closed-loop control applications, the designs that provide a speed of response of less than a minute (Table 8.8a) are preferred.

In addition, there are several manufacturers that offer calorimeters specifically for custody transfer applications. These analyzers offer improved accuracy at the expense of response time (Table 8.8a).

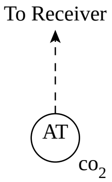
8.9 Carbon Dioxide

R. A. HERRICK (1974, 1982) **B. G. LIPTÁK** (1995, 2003)



Flow Sheet Symbol

Types of Sensors:	a) Nondispersive infrared (NDIR); see Table 8.9a for IR analyzer designs and applications b) Gas filter correlation (GFC) c) Orsat
Sample Pressure:	Up to 15 PSIG (104 kPa), but atmospheric or near atmospheric is normal
Sample Temperature:	Up to approximately 120°F (49°C) not a consideration when freeze-out trap is used
Sample Flow Rate:	Generally less than 0.5 acfm (2.35×10^{-4} m^3/sec); typically 1 to 2 l/min
Inaccuracy:	a) Can be as high as ±0.2 ppm; typically ±1% to ±2% of full-scale range b) 1% to 2% of full scale, including drift c) Laboratory procedure
Ranges:	a) 0 to 2000 ppm, 0 to 3000 ppm, 0 to 5000 ppm, 0 to 1%, 0 to 2%, 0 to 5%, 0 to 10%, 0 to 20%, and 0 to 100% (see Table 8.9b for overall capability) b) 0 to 5 ppm, 0 to 10 ppm, 0 to 20 ppm, 0 to 50 ppm, 0 to 100 ppm, 0 to 500 ppm, 0 to 1000 ppm, 0 to 2000 ppm (low detectable limit is 0.1 ppm)
Response:	a) Determined by cell volume and sampling rate; typically less than 30 sec b) 90 sec with 30-sec signal averaging time
Costs:	Portable, battery-operated, diffusion type monitor with two alarm settings, digital display, and 4- to 20-mA output is $1500; permanently installed, explosion-proof NDIR analyzer with recorder is about $10,000.

INTRODUCTION

The measurement of carbon dioxide in the ambient air is the primary concern of geophysicists, rather than of the air pollution control engineer. The precise measurement of the carbon dioxide content of the atmosphere is of significant concern in determining long-term changes in the composition of the atmosphere. The measurement techniques used by geophysicists are highly precise compared to the techniques used for air quality- or air pollution-related measurements.

Air quality-related measurements can be used to monitor the return air quality from occupied spaces and, based on those measurements, to modulate the rate at which fresh air is being introduced. In air pollution-related applications, carbon dioxide is hardly ever measured in the ambient air. It is usually measured at emission points since some combustion equipment regulations are stated in terms of allowable pollutant discharges corrected to 50% excess air.

AMBIENT AIR MEASUREMENT

The precise knowledge of the carbon dioxide concentration in the atmosphere is necessary. An increase in global carbon dioxide concentration of only 1% (or about 3 ppm) has significant consequences on the weather. The instruments used to measure atmospheric carbon dioxide concentrations must, of necessity, be highly precise, such as the gas filter correlation (GFC) units discussed later.

Nondispersive Infrared Type

These instruments are discussed in detail in Section 8.27. Since the absorption bands of water and carbon dioxide somewhat overlap, a freeze-out trap (–80°C or –112°F) is often used in the sample preparation system to remove the water prior to the measurement.

TABLE 8.9a
IR Analyzer Applications Summary

			Organic Vapors				
Analyzer	*Carbon Monoxide*	*Carbon Dioxide*	*Simple Molecules*	*Complex Molecules*	*Organic Liquids*	*Solids (Reflection)*	*Comments*
NDIR	✓	✓	✓				Single-component analysis: ethylene, CO, acetylene, methane, etc.
Mid-IR filter	✓	✓	✓	✓	✓		Single-component analysis: same as above, including ammonia, vinyl chloride, carbon tetrachloride, methyl ethyl ketone, ethylene dichloride, etc.
Near-IR filter					✓	✓	Single-component analysis: ethylene dichloride, water, phenol, methyl alcohol, etc.; moisture in solids
Correlation spectrometer	✓						Stack analysis, single-component gas analysis
Multiple-filter near-IR							Multiple components for cereal, meat, and paper analysis
Multiple-filter mid-IR	✓	✓	✓	✓	✓		Automotive exhaust analysis (CO, CO_2, –CH); multiple components for mike analysis, multiple components of gases using a programmable circular variable filter

TABLE 8.9b
Typical Applications for NDIR Analyzers

Gas	*Minimum Range (ppm)*	*Maximum Range (%)*
Ammonia (NH_3)	0–300	0–10
Butane (C_4H_{10})	0–300	0–100
Carbon dioxide (CO_2)	0–10	0–100
Carbon monoxide (CO)	0–50	0–100
Ethane (C_2H_6)	0–20,000	0–10
Ethylene (C_2H_4)	0–500	0–100
Hexane (C_6H_{14})	0–200	0–5
Methane (CH_4)	0–2000	0–100
Nitrogen oxide (NO)	0–500	0–10
Propane (C_3H_8)	0–300	0–100
Sulfur dioxide (SO_2)	0–500	0–30
Water vapor (H_2O)	0–3000	0–5

When using prepared calibration standard mixtures of carbon dioxide in nitrogen, an inaccuracy of ±0.2 ppm is attainable. At normal atmospheric CO_2 concentration levels of approximately 314 ppm, this error is equivalent to ±0.06%.

Nondispersive infrared (NDIR) type CO_2 monitors for heating, ventilation, and air conditioning (HVAC) and industrial applications are available in both portable and permanently installed designs. The portable units are usually battery operated, and their ambient sample is received by a combination of diffusion and convection effects in the sensor head, without any pumps or filtering. These units are usually provided with digital displays, one or two alarm settings, and analog or digital output signals.

The more expensive, permanently installed or wall-mounted NDIR units often include data loggers, which can store about 1000 readings along with their times and dates. Some of these units can also detect other gases, such as CO, H_2S, or O_2.

Gas Filter Correlation Type

When very accurate low-level measurements are needed, or when background gases that have the potential to interfere with the measurement are present, GFC is used. In these designs, the measuring and reference filters are replaced by gas-filled cuvettes. The reference cuvette is filled with CO_2 and the measuring cuvette usually with nitrogen.

In addition to being unaffected by the presence of background gases, both the accuracy and the response time of these instruments are better than those using filters. If DFC is used in combination with single-beam, dual-wavelength technology, it is virtually immune to obstruction of the optics. This, in turn, prevents drift and thereby reduces the frequency at which recalibration is needed.

SOURCE MEASUREMENT

Measurement of the carbon dioxide, carbon monoxide, and oxygen concentration of flue gases from boilers has been done for many years (see Figure 8.3k). These measurements allow precise setting of boiler operating variables for maximum fuel economy.

Before the use of the infrared analyzer became accepted practice, mechanical instruments were used to continuously determine the carbon dioxide content of flue gases. Their operation was based on the reduction in gas volume resulting from the absorption of carbon dioxide in a strong alkaline solution. This is the principle of the Orsat analyzer, still used as the standard method for manual determination of combustion gas composition.

For air pollution testing purposes, the carbon dioxide content of the flue gas is determined only during the few hours of the test. The usual procedure is to slowly withdraw a low-volume integrated sample into a plastic bag over the duration of the test. The bag sample is then analyzed manually using an Orsat analyzer or instrumentally using a NDIR analyzer.

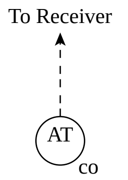
8.10 Carbon Monoxide

R. J. GORDON (1974, 1982) **B. G. LIPTÁK** (1995, 2003)



Flow Sheet Symbol

Detector Types:	A. Nondispersive infrared (NDIR); see Table 8.9a for IR analyzer designs and applications B. Mercury vapor C. Gas chromatography D. Electrochemical fuel cell E. Catalytic oxidation F. Others, from color change badges, dosimeter tubes, and radon canisters to mass spectrometers, are discussed in Section 8.60.
Reference Method:	Infrared
Application:	For ambient air monitoring, electrochemical sensors are used most often; for detecting stack gas concentration, infrared sensors are used most often.
Ranges:	A. From 0 to 1, 0 to 5, 0 to 10, 0 to 20, 0 to 50, and 0 to 100 ppm for ambient and 0 to 200, 0 to 500, 0 to 1000, 0 to 2000, 0 to 5000, and 0 to 10,000 ppm for other applications, including stack gas. (See Table 8.9b for overall range capability.) B. 0 to 50 ppm C. 0 to 200 ppm D. 0–50 to 0–500 ppm or more E. 0 to 500 ppm
Sensitivity:	Generally 1 ppm; chromatographs can provide 0.1 ppm and mercury vapor analyzers 0.05 ppm
Response Times:	Infrared units are usually adjustable down to a few seconds, while electrochemical sensors require 30 to 60 sec.
Inaccuracy:	For NDIR sensors, ±1% of full scale for up to 1000 ppm and ±2 to 3% of full scale for higher ranges. For infrared stack gas analyzers, 2 to 4% of reading can be expected, while for electrochemical ambient monitors, 1 to 3% of full scale is usual.
Costs:	Pocket-size, battery-operated personal toxic gas monitor—\$400 to \$700; continuous industrial electrochemical or infrared monitor/alarm/transmitter—\$400 to \$2000; portable, battery-operated flue gas analyzer—\$2000 to \$5000; mercury vapor analyzer—\$7500; NDIR with recorder included—about \$10,000; gas chromatograph (see Section 8.12)—\$25,000 and up

INTRODUCTION

Carbon monoxide (CO) is a toxic gas and, as such, it is monitored in the ambient air for personal safety reasons. The threshold limit value (TLV) adopted by the American Conference of Governmental Industrial Hygienists for CO is 50 ppm. In industrial applications, lower limits are often used for alarm set points. Electrochemical and catalytic sensors are used in personal toxic gas monitors.

Carbon monoxide is also an indicator of incomplete combustion and, therefore, it is measured to optimize boilers and other combustion processes (see Figure 8.3k). For these applications, the most frequently used analyzer is the nondispersive infrared (NDIR) sensor (Section 8.27).

In the chemical processing industries, when higher sensitivity (0.1 ppm) measurements of carbon monoxide are required, mercury vapor and gas chromatographic analyzers (Section 8.12) are also used. Each of these techniques will be briefly described in the discussion that follows.

CALIBRATION TECHNIQUES

Ambient carbon monoxide analyzers (Table 8.10a) are calibrated with gas mixtures of known concentrations. Such mixtures may be prepared by volumetric dilution of pure carbon monoxide with nitrogen or helium, which are free of carbon monoxide. If the volumes used in dilution are accurately known, the concentration may be calculated.

A known small volume of pure carbon monoxide is placed in an evacuated tank of known volume, and the tank is then filled with the dilutor gas. The pressures of the carbon monoxide volume and the final mixture must be known (or else known to be equal). Smaller samples may be prepared in plastic bags by injecting pure carbon monoxide from a gas syringe into a stream of dilutor gas metered accurately into the bag with a flow device such as a wet test meter.

Because cylinder nitrogen commonly has small amounts of carbon monoxide present in it, it must not be assumed to be pure without verification. Pure helium is reliably free of carbon monoxide. A useful procedure is to zero the detector using helium. After that, one can measure the CO content of the available cylinder nitrogen and can make the required correction. This permits using the less expensive nitrogen for most calibrations.

A reference gas mixture whose carbon monoxide content is not accurately known can also be analyzed gravimetrically or volumetrically by various methods, but these techniques are usually less convenient and often require large amounts of gas.

TABLE 8.10a
Atmospheric Carbon Monoxide Analyzers

Detection Method	*Range, ppm*	*Sensitivity, ppm*	*Advantages*	*Disadvantages*
NDIR	0–25, 50, 100	0.5–1	U.S. reference method, accurate, stable, dry gases	Sensitive, water, and CO_2 interferences (correctable), zero gas problems
Mercury vapor (hot HgO + CO releasing Hg vapor)	0–50	0.05	Sturdy, accurate, dry gases, high sensitivity	Interferences by water and other gases
Gas chromatography (reduction of CO to CH_4, flame ionization detection)	0–200	0.1	Accurate, high sensitivity, also read CH_4, dry gases	Complex and expensive

NONDISPERSIVE INFRARED ANALYZERS

NDIR analysis[1] is the reference method for the U.S. National Air Quality Standard for carbon monoxide and is discussed in detail in Section 8.27. It allows continuous analysis, because carbon monoxide absorbs the infrared radiation at a wavelength of 4.6 microns. Because infrared absorption is a nonlinear measurement, it is necessary for the analyzer to accurately linearize its output signal.

A schematic diagram of a typical NDIR analyzer is shown in Figure 8.10b. Infrared radiation from a hot filament is chopped to pass alternately through sample and reference cells, to be absorbed in the detector cell divided by a pressure-sensitive diaphragm. If the sample contains carbon monoxide, it will absorb part of the radiation, causing that half of the detector to exert less pressure on the diaphragm, whose distortion is converted to an electrical signal for rectification and amplification.

Sample airflow is continuous at or sometimes above atmospheric pressure. The cell is commonly 0.5 m long. The measuring range usually extends from a minimum of 0.5 to 1 ppm up to a full-scale range of 25 to 100 ppm. Response times are in the range of less than 1 to 5 min. Although the NDIR response is nonlinear, it is assumed to be linear over the limited calibration range in use. Some instruments correct for nonlinearity in the output amplifier. These analyzers can be operated by nontechnical personnel.

Interferences

Carbon dioxide and water vapor in the sample interfere with the measurement. Filter cells filled with these gases, or optical filters when placed in front of the cells, can minimize effects of normal atmospheric levels of these interfering gases. The control of water vapor interference by its removal with desiccants (e.g., silica gel) or by a refrigerator condenser is preferable in many cases, even at the cost of some increase in response time.

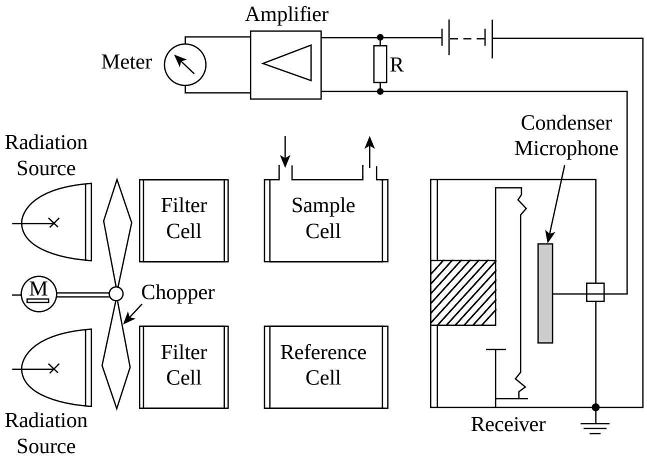

FIG. 8.10b
NDIR carbon monoxide analyzer.

Gas Filter Correlation

When very accurate low-level measurements are needed, or when background gases that have the potential to interfere with the measurement are present, gas filter correlation (GFC) is used (Figure 8.10c). In these designs the measuring and reference filters are replaced by gas-filled cuvettes. The reference cuvette is filled with CO and the measuring cuvette usually with nitrogen.

In addition to being unaffected by the presence of background gases, both the accuracy and the response time of these instruments are better than those using filters. If DFC is used in combination with single-beam, dual-wavelength technology, it is virtually immune to obstruction of the optics. This in turn prevents drift and thereby reduces the frequency at which recalibration is needed.

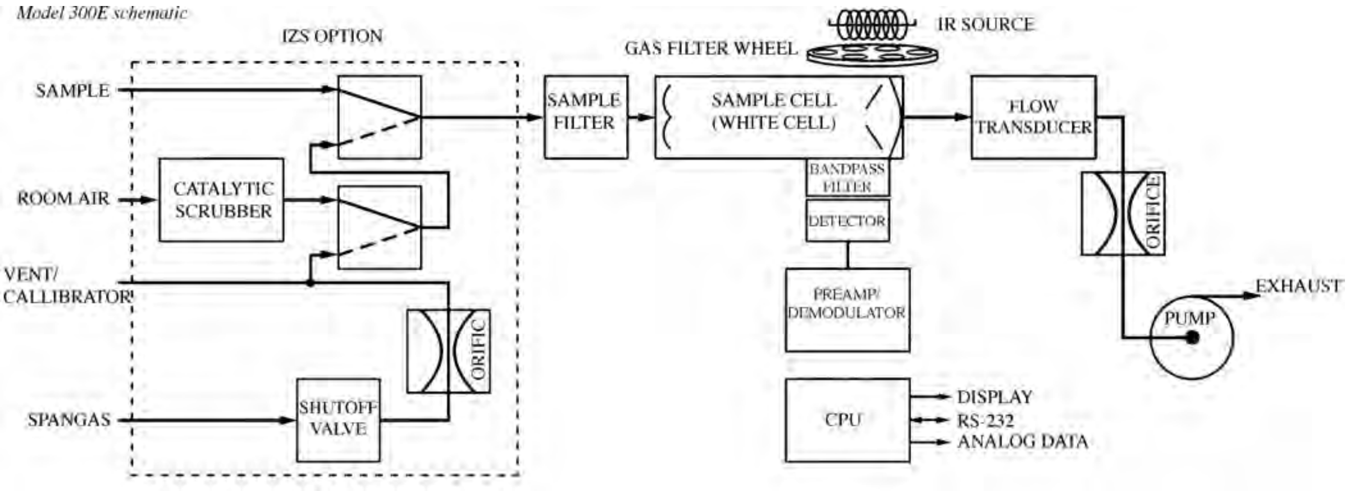

FIG. 8.10c
GFC-type carbon monoxide analyzer. (Courtesy of Teledyne Technologies Co.)

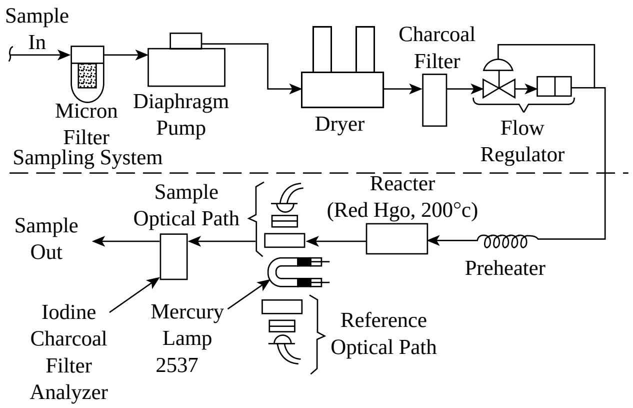

FIG. 8.10d
Mercury vapor carbon monoxide analyzer.

MERCURY VAPOR ANALYZER

Carbon monoxide is oxidized by hot mercuric oxide[2] as follows:

$$\mathrm{CO} + \mathrm{HgO(s)} \xrightarrow{(210^\circ)} \mathrm{CO_2} + \mathrm{Hg(g)} \tag{8.10(1)}$$

The mercury vapor released may be measured photometrically. An analyzer based on this principle (Figure 8.10d) can be operated continuously. It has higher sensitivity than does the NDIR type, but it also suffers from some interference. Detection levels go down to 0.025 ppm, and changes of a tenth of that can be observed. Oxygenated hydrocarbons, olefins, and hydrogen interfere with the measurement, but all are normally at much lower concentrations in air than carbon monoxide. Water also interferes and should be removed by a dryer. This instrument has found particular use in nonurban measurements where carbon monoxide levels are low.

GAS CHROMATOGRAPH

Gas chromatographs are discussed in detail in Section 8.12. Figure 8.10e illustrates an automated gas chromatograph[3] that is the heart of a high-precision and specificity system measuring methane and carbon monoxide (Figure 8.10e).

A precolumn prevents carbon dioxide, water, and hydrocarbons other than methane from reaching the molecular sieve separation column. After separation, a catalytic nickel reactor converts carbon monoxide to methane, which is detected by flame ionization. The system permits determination of both methane and carbon monoxide about once every 5 min. The output is linear for both components and can be read from 0.1 to 200 ppm. The instrument is relatively complex and expensive, however, and requires technically trained operators.

ELECTROCHEMICAL ANALYZER

A galvanic cell for continuous carbon monoxide analysis[1] is based on the reaction of carbon monoxide with iodine pentoxide:

$$5\,\mathrm{CO} + \mathrm{I_2O_5} \xrightarrow{(150^\circ\mathrm{C})} 5\,\mathrm{CO_2} + \mathrm{I_2} \tag{8.10(2)}$$

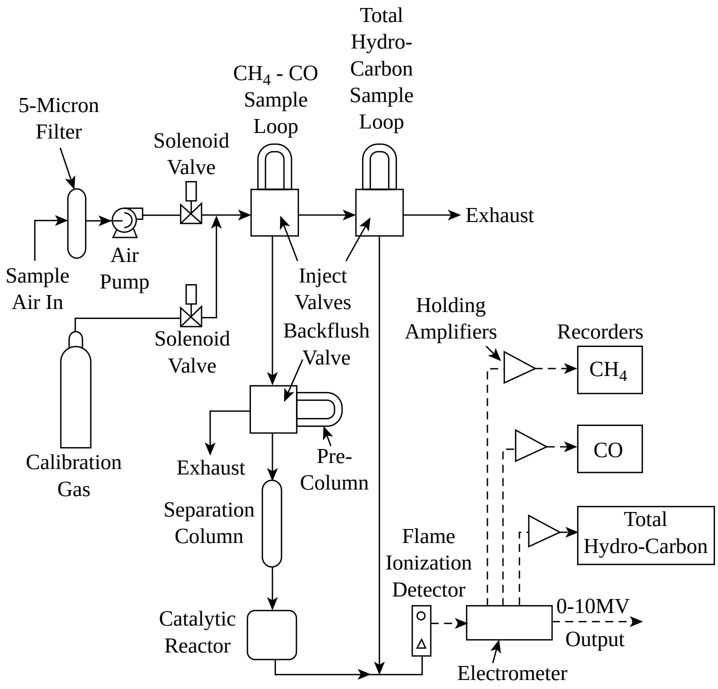

FIG. 8.10e
Methane and carbon monoxide analyzer.

The iodine liberated is absorbed by an electrolyte and reaches the cathode of a galvanic cell where it is reduced. The resulting current is measured by a galvanometer. Interference by mercaptan, hydrogen sulfide, hydrogen, olefins, and acetylene may be minimized by sampling through an absorption tube of mercuric sulfate on silica gel. Water vapor interference can be eliminated by the use of a drying column.

The same reaction is used in a coulometric method with a modified Hersch-type cell. The iodine is passed into the cell, and the current flow is measured by an electrometer. The interference possibilities are the same as those for the galvanic analyzer.

The minimum detectable concentration is 1 ppm with good precision if flow rates and temperature are controlled. Careful column preparation is required, and the response time is relatively slow.

Portable Monitors

For purposes of personal protection, battery-operated portable units are available. These units are usually provided with one or two alarm set points and with memory for some thousands of data points, together with their times and dates. Table 8.10f lists the ranges, resolutions, and alarm set points for a number of toxic gases, including carbon monoxide.

These pocket-size, battery-operated, portable electrochemical detectors are usually provided with digital displays and audible alarms. They can be configured for one or more monitoring channels. Figure 8.10g illustrates a unit with four individual channels of detection.

TABLE 8.10f
Typical Range, Sensitivity, and Alarm Set Points of Portable Personal Protection Monitors

Gas	Range	Resolution	Alarm Set Points (low/high)
O_2	0–30%	0.1%	19.5/23.5%
CO	0–500 ppm	1 ppm	35/200 ppm
H_2S	0–100 ppm	1 ppm	10/20 ppm
SO_2	0–20 ppm	1 ppm	2/10 ppm
NO	0–250 ppm	1 ppm	25/50 ppm
NO_2	0–20 ppm	0.1 ppm	1/10 ppm
NH_3	0–50 ppm	1 ppm	25/50 ppm
PH_3	0–5 ppm	0.1 ppm	1/2 ppm
Cl_2	0–10 ppm	0.1 ppm	0.5/5 ppm
HCN	0–100 ppm	1 ppm	4.7/50 ppm

Typical pocket-size portable electrochemical detector configured for four individual channels of detection. (Courtesy of Sensidyne Inc.)

CATALYTIC ANALYSIS

The catalyst Hopcalite will oxidize carbon monoxide to carbon dioxide.[1] The resultant temperature rise may be recorded continuously as a measure of carbon monoxide concentration. The catalyst temperature and residence time must be controlled to avoid interference by hydrocarbons. The method is not suitable for most air monitoring applications because of low sensitivity.

SPOT SAMPLING OF AMBIENT AIR

When only intermittent analyses are required, it is convenient to collect samples in the field for later analysis in the laboratory. Rigid glass bulbs or stainless steel tanks may be evacuated and then simply opened briefly to collect the air sample. Plastic bags may be filled by means of a small air pump.

The samples may be analyzed later by various means, including use of a continuous analyzer at some other location. The samples may be analyzed in a central laboratory by an infrared spectrophotometer with a long-path gas cell or by suitable gas chromatographic apparatus.

Some colorimetric methods are also available for carbon monoxide analysis, although in general, their sensitivity and precision are low for atmospheric work. An NBS colorimetric indicating gel, if freshly prepared, will limit errors to 5 to 10%, with detectability down to 0.1 ppm. The technique is simple but time-consuming and tedious, with interference by oxidizing and reducing gases.

CONCLUSIONS

As discussed in more detail in Section 8.59, for simple and less accurate measurements of short-term carbon monoxide levels, gel tubes can be used. For continuous and higher precision measurements, nondispersive infrared analysis is the most common.

If it is necessary to also measure methane, the combination gas chromatograph with carbon monoxide analyzer is worthy of consideration, but this is an expensive choice. The mercury vapor analyzer is suitable where the carbon monoxide levels are low.

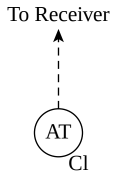
8.11 Chlorine

G. P. WHITTLE (1974, 1982) **B. G. LIPTÁK** (1995, 2003)



Flow Sheet Symbol

Methods of Detection:	A. Colorimetric: visual (A1), spectrophotometric (A2) B. Amperometric (B1), polarographic (B2) C. Iodometric (For a detailed discussion of wet chemistry analyzers and autotitrators, refer to Section 8.66.)
Sampling:	All three methods can be used both on grab samples and as automatic continuous analyzers.
Sample Pressure:	Generally atmospheric or near atmospheric. For continuous analyzer, water pressure is reduced to atmospheric.
Sample Temperature:	All methods are generally limited to the range of 32 to 120°F (0 to 49°C), with method B employing automatic temperature compensation within this range. Method A may or may not require precise temperature control, depending on the reagents employed.
Sample Size of Flow Rate:	In method A1, grab samples as small as 5 ml are sufficient. For method A2, flow rates of 10 to 75 ml/min are generally specified. In method B1, flow rates of 100 to 750 ml/min are required. B2 design probes are available for *in situ* installations without sampling.
Materials of Construction:	Enclosures for units are available in fiberglass, styrene, urethane-painted steel, vinyl-covered aluminum, and other corrosion-resistant construction, suitable for modular or control panel installation. Wetted parts are constructed of polyvinyl chloride (PVC), Teflon, Lucite, polyethylene, or glass. In method B, gold or platinum measuring and copper reference electrodes generally are employed.
Readout:	All designs have indicating meters or transmitted output signals for remote display, recording, and control. High–low alarm actuation or chlorinator controls are also available.
Specificity:	Methods A and B determine either free or total residual chlorine; method C measures total residual chlorine.
Interferences:	For method A, interfering substances may include other oxidants, e.g., manganese, nitrite, and chlorine dioxide, as well as turbidity and color. In method B, nitrogen trichloride and chlorine dioxide may interfere with free chlorine determinations.
Inaccuracy:	Generally ±2 to 5% of full scale for ranges up to 20 ppm
Ranges:	For method A, available ranges include 0 to 1 ppm free chlorine, and 0 to 3 ppm, 0 to 5 ppm, and 0 to 10 ppm total chlorine. For method B, 0 to 0.1, 0 to 1, 0 to 2, 0 to 5, 0 to 10, and 0 to 20 ppm or higher are available. The three-electrode units can measure chlorine residuals from the parts per billion (ppb) range to as high as 60 mg/l. For method C, the measurement range is from 0.001 to 10 mg/l.
Response to Chlorine Concentration Change:	Three minutes or more for method A2, generally less than 10 sec for method B (continuous analyzer)

Cost: Visual test kits are available from $25 to $100. A portable amperometric titrator costs about $1800. A free chlorine electrode in acrylic flow cell and with residual chlorine controller is about $2000. A corrosion-resistant amperometric transmitter system with probe cleaner costs about $8000, with the yearly cost of chemicals and maintenance amounting to $3000 or more. The purchase cost of polarographic transmitters is similar, but the cost of chemicals is much less. Chlorine in gas samples can be detected by UV analysis or by gas chromatography; both are discussed in later sections in this chapter.

INTRODUCTION

The concentration of chlorine is of interest in both liquid and gas samples. The discussion in this section concentrates on the measurement of total or free residual chlorine in water, which can be measured by colorimetric, amperometric, polarographic, or iodometric analyzers. The measurement of chlorine concentration in gas samples is not discussed here, except to note that ultraviolet (UV) analyzers (Section 8.61) and chromatographs (Section 8.12) with thermal conductivity or flame ionization detectors are most often used to make this measurement.

Chlorine gas-leak detector alarms are also available. These units pull a sample of an airstream through an electrochemical cell, which produces a current. This current is proportional to the chlorine concentration in the air sample. These units are capable of detecting concentrations as low as 0.5 ppm by volume.

RESIDUAL CHLORINE ANALYZERS

Chlorine does not exist as Cl_2 in water. Therefore, the amount of free available chlorine is defined as the amount of chlorine that exists in the form of HOCl. Total available chlorine, on the other hand, is defined as the chlorine that exists in any of the following forms: HOCl, NH_2Cl, NCl_3, or $NHCl_3$. The combined available (residual) chlorine is obtained as the difference between total and free chlorine.

Standard laboratory methods for determining aqueous chlorine concentrations involve iodometry, in which free iodine liberated from potassium iodide is titrated with sodium thiosulfate, using starch as an indicator. All active forms of chlorine will liberate free iodine, and therefore, the iodometric methods of analysis are limited to the determination of total active chlorine. For an automatic total residual chlorine analyzer with a 4-20 mADC logarithmic output, refer to Figure 8.11a.

Other titrimetric procedures employing indicators other than starch have also been developed for the determination and differentiation of the active chlorine forms. The amperometric titration method is based on polarographic principles and allows determination of the various forms of active chlorine.

Various colorimetric procedures are available in which a colorless indicator is oxidized to a colored product, the color intensity of which is proportional to the chlorine concentration. Many of the colorimetric procedures allow the determination of the various forms of chlorine. Colorimetric procedures are adaptable to field determination by the use of kits containing the necessary reagents, color standards for visual estimation, and portable, battery-operated colorimeters. The amperometric titration and colorimetric methods have also been adapted to automated continuous analyzers.

FIG. 8.11a
Iodometric total residual chlorine analyzer with a range of 0.001 to 10 mg/l and a 4- to 20-mADC logarithmic output. (Courtesy of Thermo Orion/Orion Research Inc.)

COLORIMETRIC ANALYZERS

In the Environmental Protection Agency (EPA) recommended DPD 330.5 method of chlorine analysis, a chemical reaction causes the intensity of the color of magenta to change in proportion to the concentration of chlorine. In the automatic analyzer, the color intensity of the sample is measured twice: once before reagents are added, for automatic zeroing and to compensate for any turbidity or natural color in the sample; and again after addition of the reagents and stirring of the sample. The second measured wavelength, around 510 nm, is compared with the reference. The chlorine concentration is calculated on the basis of the difference between the two readings.

Figure 8.11b illustrates the basic components of a chlorine colorimetric analyzer. The water sample is introduced into a head regulator where the sample flow rate is regulated by an overflow arrangement and a capillary delivery tube. The sample is passed into a channel and is mixed with the colorimetric reagent metered through another capillary tube from a storage container. The treated sample flows over a sample heater, if required, and into the sample cell, which fills and overflows at a predetermined frequency.

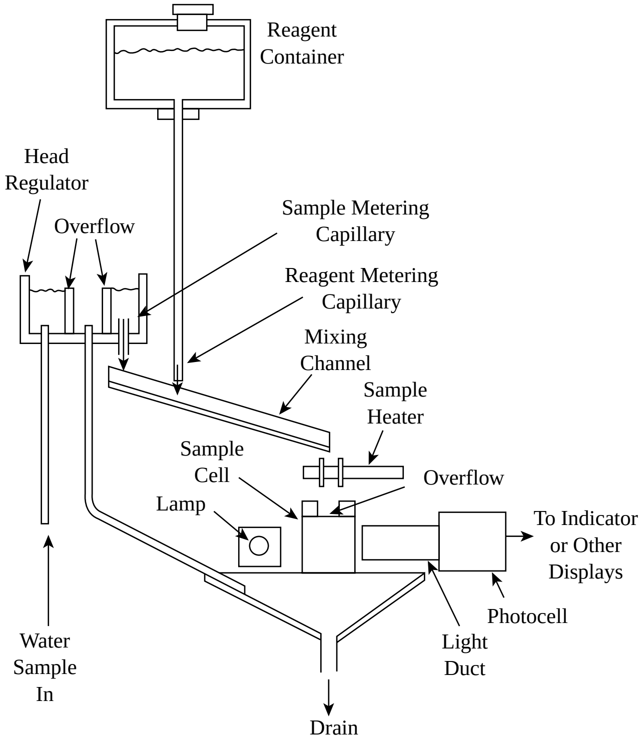

FIG. 8.11b
Chlorine colorimetric analyzer.

If chlorine is present in the water, a characteristic color develops with an intensity in proportion to the amount of chlorine present. A filtered photocell develops an output signal, which is in proportion to the reduction in intensity of the transmitted light through the sample. Periodic standardization of the analyzer is required and is done by adjustment of the indicator to read 0 ppm chlorine on an untreated water sample and to read on the extreme upper end of the scale when the photocell is completely shielded.

Automatic Colorimetric Analyzer Features

Automatic free or total chlorine analyzers can control in the on–off mode by stopping and starting a feed pump and sounding alarms, or can provide throttling control by modulating the pumping rate of the chlorine feed pump. The output signals can be to computers or printers through an RS232 interface, or can be analog selected from among the choices of 0 to 10 mV, 0 to 100 mV, 0 to 1 V, and 4 to 20 mA. The measurement range is usually 0 to 5 mg/l with a 0.01 resolution, but other ranges from 0–1 to 0–10 mg/l are also available.

These analyzers can perform an analysis every 2.5 min and use about 500 ml of reagents and color indicators per month. Therefore, monthly refilling is necessary. The flow cell should be cleaned at the same time the reagents are refilled. Although requiring about a monthly 1 h of maintenance, these are relatively inexpensive and stable analyzers that are insensitive to sample pH variations or other interferences.

AMPEROMETRIC ANALYZERS

In amperometric analyzers, the composition of the electrodes is so selective that the polarization of the measuring electrode prevents a current flow when no strong oxidizing agent is present in the sample. On the other hand, when a strong oxidizing agent such as chlorine is present, the electrodes are depolarized and a current flow is generated.

This current is proportional to the amount of chlorine residual in the sample. Because pH affects the dissociation constants, the water samples are usually conditioned with a buffer solution. Similarly, because of sensitivity to temperature variations, temperature compensation is provided.

Types of Amperometric Analyzers

Amperometric analyzers are used in three basic forms: as titrators, as free residual chlorine analyzers, and as total residual chlorine analyzers. The amperometric titrator determines the end point of a 200-ml sample in a manually filled sample jar by using a portable, battery-operated instrument.

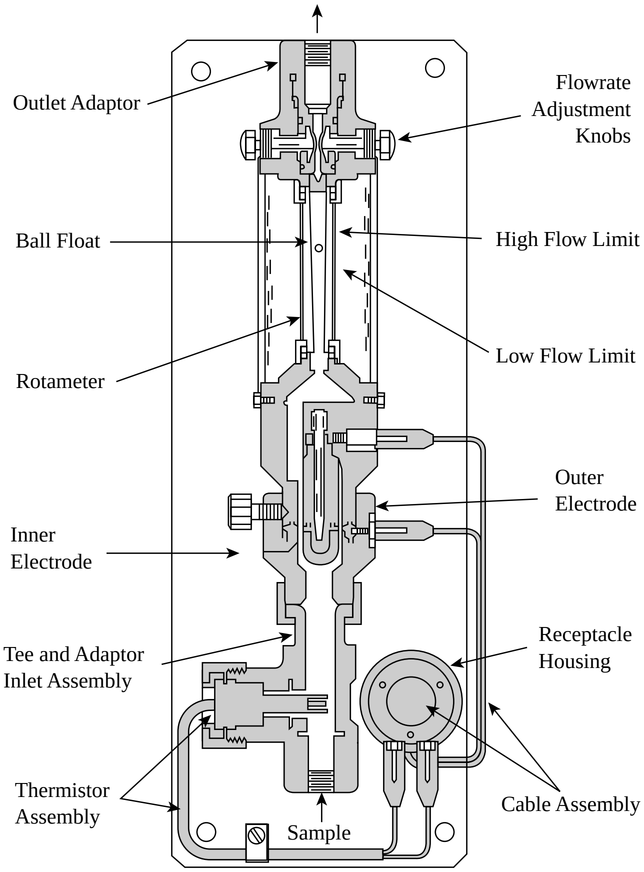

FIG. 8.11c
Measurement cell of a free residual chlorine analyzer.

During titration for free residual chlorine, a buffer solution maintains the sample pH at neutrality and a titrant (phenylarsene oxide) is added until no more current is produced by the electrode cell. This is considered the end point, and the amount of titrant used is an indication of free residual clorine in the sample.

When total residual chlorine is measured, the titration process is similar, but the buffer is at a pH of 4 and potassium iodide is also added to the sample.

Free Residual Chlorine Analysis

For free residual chlorine analysis, the sample pH is held between 5 and 9. Simple flow-through units are available that do not require the use of buffers or reagents (Figure 8.11c). These analyzers are temperature compensated and operate in a range of 0 to 2 ppm of free chlorine, with an inaccuracy of about 0.1 ppm.

Figure 8.11d shows the components of a typical amperometric analyzer, which does require buffers or reagents. The water sample is delivered to a diaphragm-type regulator for flow rate control. If required for pH control, a metered amount of buffer solution is also pumped to the regulator and is mixed with the sample prior to its reaching the cell block.

In the cell block, contact is made between the electrodes and the sample, and a direct current is generated in proportion to the chlorine in the sample. The cell block usually contains

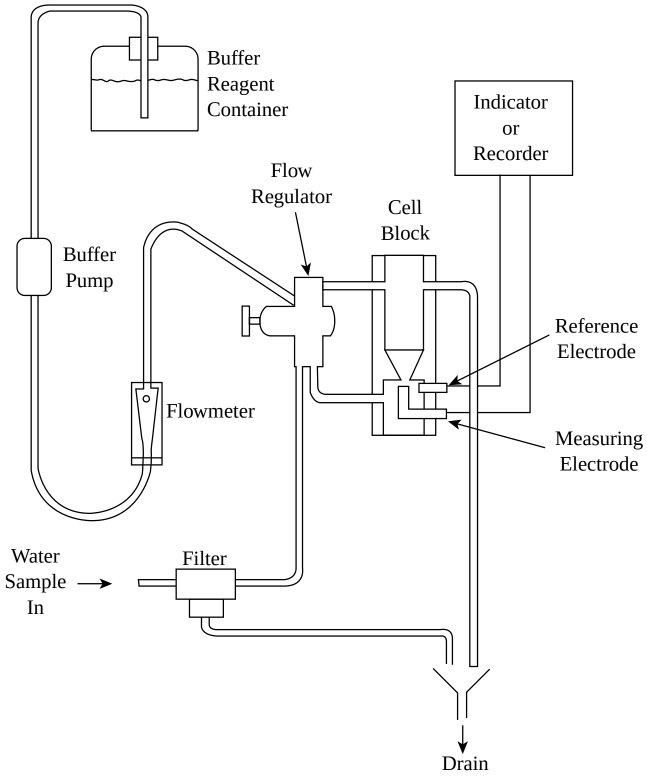

FIG. 8.11d
Chlorine amperometric analyzer.

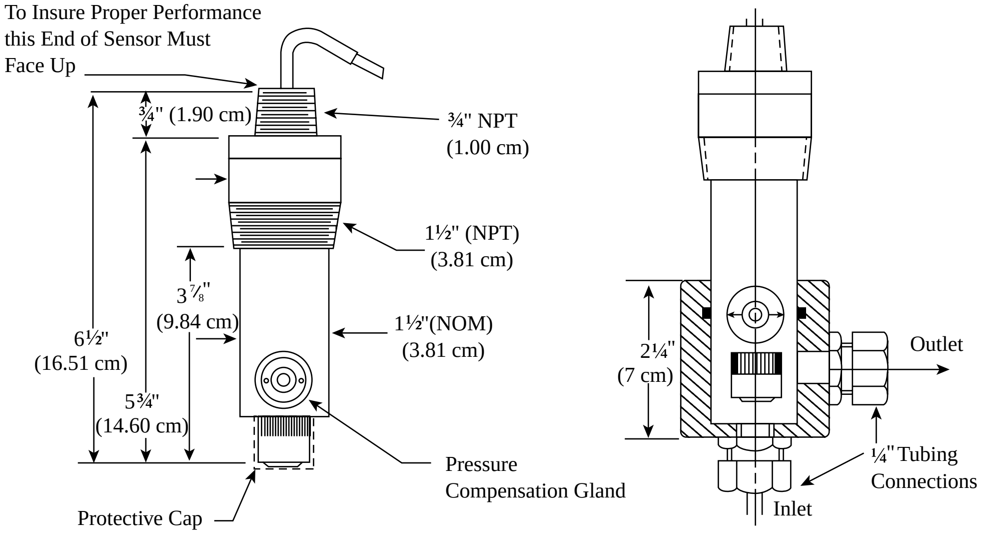

FIG. 8.11e
Amperometric chlorine probe for in-line or sample bypass-type installation. (Courtesy of Rosemount Analytical Inc.)

grit, which cleans the electrodes by means of sample velocity agitation. Periodic calibration is required through a separate determination of chlorine and is usually performed on a laboratory amperometric titrator using a standardized phenylarsine oxide solution.

Membrane Probes

Microprocessor-based chlorine analyzers are available with built-in diagnostics and simulator features. They can automatically detect chlorine and temperature and can also be equipped with a pH detector probe.

The amperometric probe consists of a gas-permeable membrane, a gold cathode, and a silver anode (Figure 8.11e). The probe is filled with a salt electrolyte. As chlorine penetrates the membrane, it is reduced at the gold cathode, which causes a current to flow that is proportional to the chlorine concentration in the water.

The main advantages of the immersion probe designs include the elimination of the sampling system and the elimination of the continuous need for chemical reagents and buffers. The elimination of sample pumps and other sampling system components not only lowers costs and maintenance, but also reduces transportation lag, which makes the installation better suited for closed-loop operation.

The elimination of the need for the continuous feed of chemicals reduces the yearly operating cost by thousands of dollars. The maintenance that is still needed is usually limited to replacing the membrane and refilling the probe with fresh electrolyte once every 2 months.

The membrane probe is shown in Figures 8.11e and 8.11f. It can be provided with an *in situ* nutating sensor or with paddle-oscillation-type cleaner agitators to provide the required apparent sample velocity at the membrane. The probe can be inserted in pipes at pressures of up to 150 PSIG (10.6 bars) or can be handrail mounted (Figure 8.11f) in open tanks, with the local chlorine transmitter mounted on or above the handrail.

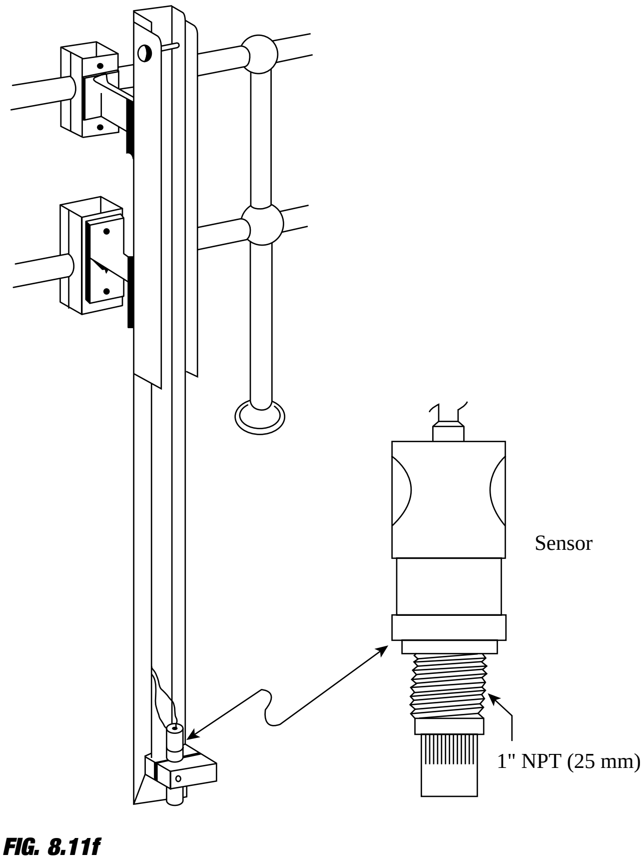

FIG. 8.11f
Immersion probe-type polarographic chlorine detector. (Courtesy of Rosemount Analytical Inc.)

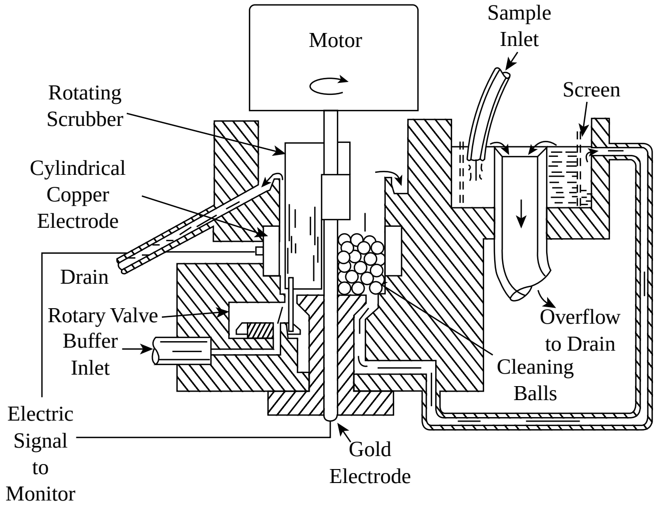

FIG. 8.11g
Electrode cleaner used in chlorine or ozone analyzers.

Buffers and Reagents

The main disadvantage of some amperometric chlorine analyzers is the need for the periodic replacement of substantial quantities of buffering and reagent chemicals.

When measuring free residual chlorine, the buffer maintains a pH of 7 and the reagent that is added to the buffer is usually potassium bromide. When measuring total residual chlorine, the butter maintains the pH at around 4 and the reagent added to the buffer is usually potassium iodide. Other chemicals that are sometimes used to adjust the pH include acetic acid and sodium hydroxide.

The cost of these chemicals can reach several thousand dollars per year, and the scheduled replenishment of these materials also adds to the maintenance cost of operating the plant.

Electrode Cleaners

Keeping the chlorine electrodes clean also requires attention. In some designs, the measuring electrode rotates at 1550 rpm to maintain ideal electrolysis conditions (relative velocity) between the sample and the electrode surface. In other designs, the space between electrodes contains plastic pellets, which are continuously agitated by the swirling water or by a rotating scrubber (Figure 8.11g).

CONCLUSIONS

Colorimetric and amperometric analyzers may be obtained with diverse accessories serving various functions, including alarm actuation and external control. Automatic temperature compensation is also available for the amperometric analyzer. The three-electrode amperometric designs do not require zero calibration and are capable of detecting chlorine residuals as low as 1 μg/l (1 ppb).

The relative merits of the continuous colorimetric and amperometric analyzers are listed in Table 8.11h.

TABLE 8.11h
Relative Merits of Colorimetric and Amperometric Analyzers

Consideration	*Colorimetric*	*Amperometric*
Type of sample	Better suited for clarified natural or treated waters than for highly turbid or colored waters and wastewaters	Turbidity and color generally not a problem; applicable to both treated water and wastewater
Interference	Intefering ions should be absent; oxidized manganese compounds produce serious interference	Copper and silver ions may interfere by plating out on electrodes
Sample temperature	Temperature control may or may not be required, depending on reagent employed	Manual or automatic temperature compensation required
Speed of response	Generally 3 min or more required to detect a change in chlorine concentration	Chlorine concentration change detected in 10 sec or less
Calibration	Analyzer precalibrated; periodic standardization requires only simple manipulations	Periodic calibration required by separate analytical technique
Reagents required	External reagent solution required	External buffer may be required for varying sample pH
Maintenance stability	Cell staining may require periodic cleaning	Electrodes may require periodic cleaning
Stability	Drift compensated for by relatively simple standardization step	Drift not a problem when electrodes are kept clean
Initial cost	Generally less expensive	Generally more expensive

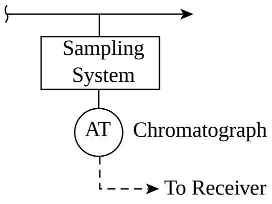
8.12 Chromatographs: Gas

RAYMOND ANNINO (1995, 2003)



Flow Sheet Symbol

Type of Sample:	Vapor or vaporizable liquid
Sample Pressure:	0 to 100 PSIG (1 to 7 bar)
Ambient Temperature:	–4 to 122°F (–20 to 50°C); however, a sheltered environment is recommended.
Analysis Zone:	140 to 356°F (60 to 180°C) provided that the desired oven temperature is at least 18°F (10°C) above ambient (stable oven temperature ±0.1°F (±0.05°C) at steady ambient ±1°F (±0.5°C) for –4 to 122°F (–20 to 50°C) ambient change)
Contacting Material:	Stainless steel or surface-deactivated steel for trace analysis of reactive compounds, Teflon
Auxiliary Utilities:	Instrument air-dry, oil-free, available at 50 PSIG min (3.5 bar) and 2 to 3 scfm (1 to 1.5 sl/sec); carrier gas, zero air, and hydrogen for FID; possible steam tracing or electrical heating for sample lines
Cycle Time:	2 to 20 min, depending on application and packed or capillary column operation
Special Features:	Accepts other inputs (e.g., flow rate and density in the calculation of output, e.g., BTU/h); built-in diagnostics with local and remote indication; multicomponent readout; stand-alone or networked; communication link (fieldbus or Ethernet directly to the plant or local LAN and local control system); local and remote operator interface; single- or multistream analysis
Location:	Class 1, Groups B, C, and D, Division 1 hazardous areas
Analyzer Cost:	Basic analyzer, $35,000 to $45,000 (depending on number purchased)
Installed Cost:	$45,000 to $125,000 (depending on type, number, and application)
Suppliers:	ABB Process Analytics (www.abb.com/analytical) Applied Instrument Technologies (www.orbital-ait.com) Daniel Industries (www.danielind.com) Fluid Data/Thermo Onix (www.fluid-data.com) HNU Process Analyzers (www.hnu.com) Questar Baseline Industries (www.baselineindustries.com) Rosemont/Emerson (www.processanalytic.com) Siemens Applied Automation (www.sea.siemens.com) SRA Instruments (www.sra-instruments.com) Wasson-ECE Instrumentation (www.wasson-ece.com) YEW Yokagawa (www.yokorawa.co.jp) Among these suppliers, about 65% of the market is shared by ABB and Siemens AA. About 30% of the market is shared by AIT (supplying the Foxboro 931D), Thermo Onix, Daniel Industries, Rosemont, and Yokagawa.

INTRODUCTION

Gas chromatography (GC) is a method for separating the components of a sample that contains a mixture of volatile compounds. The separations are made in order to determine the quantity of each of the sample components of interest. It has become one of the most often used procedures in analytical chemistry for separation and analysis. The reasons for its popularity can be traced to its ease of use for the separation of complex mixtures, its high sensitivity, and the small sample required for the analysis.

In the elution form of GC, the sample mixture to be separated is vaporized and injected into a flowing stream of carrier gas (the *mobile* phase) that carries it into a column containing a so-called *stationary* phase. The stationary phase is a high-boiling nonvolatile liquid that is suspended on an inert solid with a large surface area or coated in a thin film on the walls of a small-bore tube (capillary, or *wall-coated open tubular* (WCOT) column). The support-coated solid can be packed into a fairly large-bore column (packed column) or attached to the wall of a small-bore capillary (*support-coated open tubular* (SCOT) column). Similarly, a solid stationary phase (such as silica gel, alumina, or charcoal) can be packed into a column or suspended on the walls of a small-bore tube.

Separations occur because the sample components have different solubilities in the *liquid* stationary phase or different adsorbtivities on a *solid* stationary phase. Therefore, each sample component is retarded a different amount by the stationary phase and is carried down the column by the mobile phase at a different rate. Provided that a stationary phase has been selected that maximizes the solubility or absorbtivity differences, complete separation will occur with each sample component emerging from the column at a different time. A detector that responds to some property difference between the carrier gas and the sample components is placed at the end of the column. It yields a signal that, when recorded as a function of time, produces the familiar chromatogram such as that shown in Figure 8.12a. The observed peak separation (resolution, R) is a function of the above-mentioned solubility or adsorbtivity differences and the efficiency of the column, that is, its ability to produce narrow peaks. The efficiency (hetp) of a GC column is expressed as height equivalent to a theoretical plate (N). The smaller the hetp, the more efficient the column (that is, there are more theoretical plates per unit length of column).

The resolution of peaks 5 and 6 in Figure 8.12a at retention times of t_{R5} and t_{R6} is calculated from the chromatogram as follows:

$$R = \frac{2(t_{R6} - t_{R5})}{w_5 + w} \qquad \textbf{8.12 (1)}$$

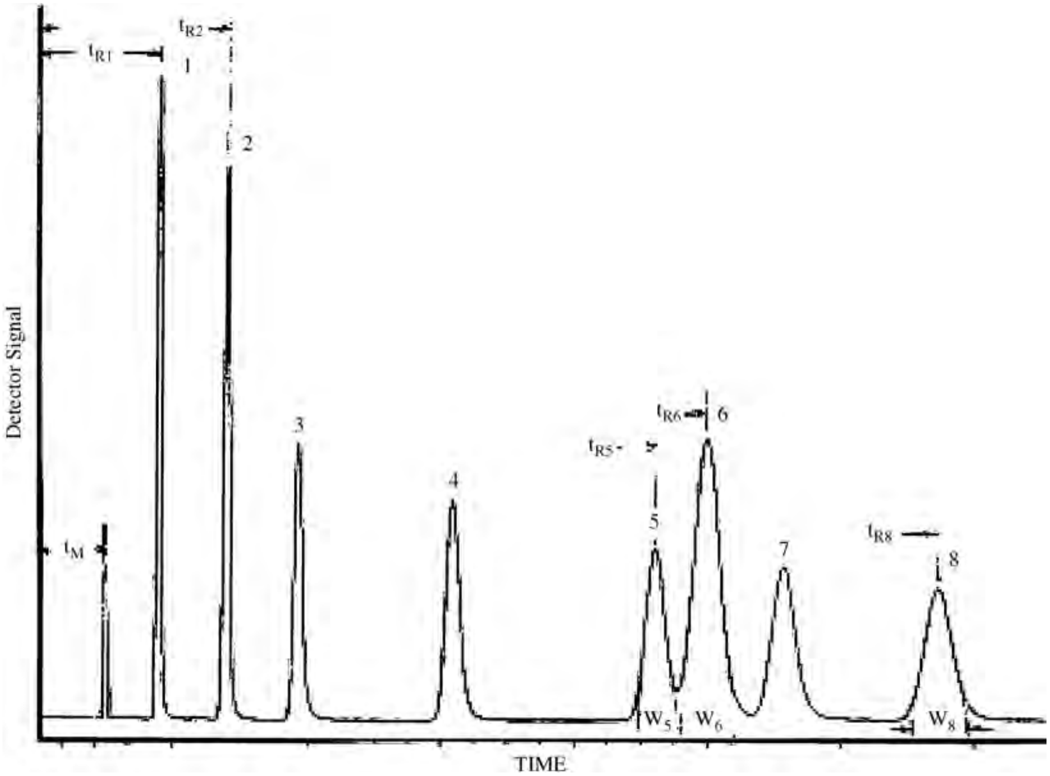


FIG. 8.12a

A typical packed column chromatogram showing fully and partially resolved peaks. Retention time of an unretained sample component (such as air) measured from the time of injection = t_M*. Retention time of sample components 1 to 8 =* t_{R1} *to* t_{R8}*. The resolution of peaks 5 and 6 = 1.1. The number of theoretical plates calculated using peak 8 = 4158.*

where w_5 and w_6 are the respective peak widths measured at the base of the peak. In this case, the resolution of the two peaks is 1.1. Two compounds of equal concentration are baseline resolved at a resolution of 1.5.

The theoretical plate as calculated from a peak (number 8 in Figure 8.12a) using Equation 8.12(2) is found to be 4158 and was obtained using a *packed column*.

$$N = 16\frac{t_{R8}^2}{w_8^2} \tag{8.12(2)}$$

and the efficiency of a column of length, L, is

$$\text{hetp} = \frac{N}{L} \tag{8.12(3)}$$

The time required for each component to emerge is called the *retention time*, t_R, and the magnitude of the detector signal (peak height or peak area) is related to the amount of the compound present in the injected sample. If these individual retention times and detector responses are made to remain constant (by adequate control of carrier gas flow rate, column temperature, amount of stationary phase, and detector variables), the process can be automated so that the instrument will provide this information quite precisely and cyclically on a repetitive basis.

BASIC CHROMATOGRAPHIC INSTRUMENTATION

The basic instrumentation necessary to accomplish the above-described chromatography is extremely simple (see Figure 8.12b).

It consists of a supply of carrier gas (commonly helium, hydrogen, or nitrogen) with appropriate pressure regulation, a sample introduction device (described later on) to inject a fixed volume of sample into the carrier gas stream, a column containing the stationary phase, and a detector. Since the degree of solubility of the sample components in the stationary phase is temperature dependent (and thus so will be the retention times), a precisely regulated temperature environment must be provided for the column. In some cases, to minimize the analysis time for samples that contain a wide boiling range of compounds, the temperature of the oven is varied linearly with time. This procedure is called *temperature-programmed chromatography.*

Although they employ the same principles, the process gas chromatograph (PGC) is quite a different instrument than its laboratory counterpart. These differences appear as the result of a number of factors, not the least of which include:

- The need for continuous, reliable operation of the unit
- The need for the cycle time of the analysis to be shorter than the time required for the process control system to achieve proper control action
- The nature of the environment in which the PGC is placed
- The diverse user attitudes regarding maintenance, and their capability regarding the operation of the unit
- The necessity to interface with modern-day computer-controlled systems

Thus, a premium is placed on simple, reliable design to ensure a low mean failure rate, but straightforward, rapid repair when required, and the strategic placement of appropriate sensors to aid in diagnosing problems and to provide alarms with regard to the operation of the unit.

To summarize, the PGC has the following distinguishing attributes:

- Located in the plant as close as possible to the sample point to minimize sample transport time
- Dedicated to monitor one or more components in one or more process streams
- Designed for continuous, unattended operation
- Designed for operation in hazardous environments
- Designed to withstand exposure to weather, humidity, dust, and corrosive atmospheres
- Contains integral hardware and software to allow communication with the process control system as well as remote maintenance stations

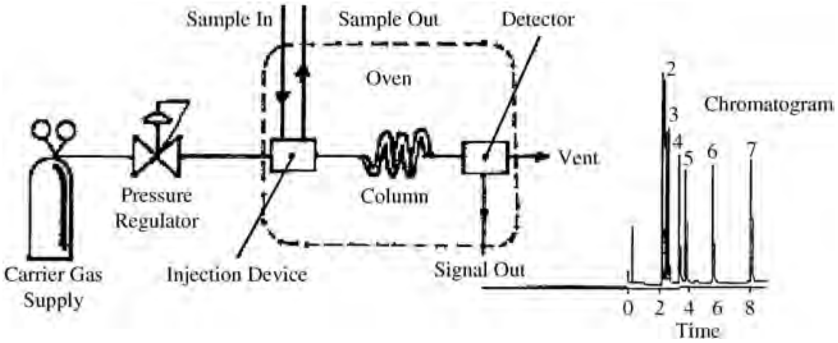

FIG. 8.12b
Basic elements of a chromatograph.

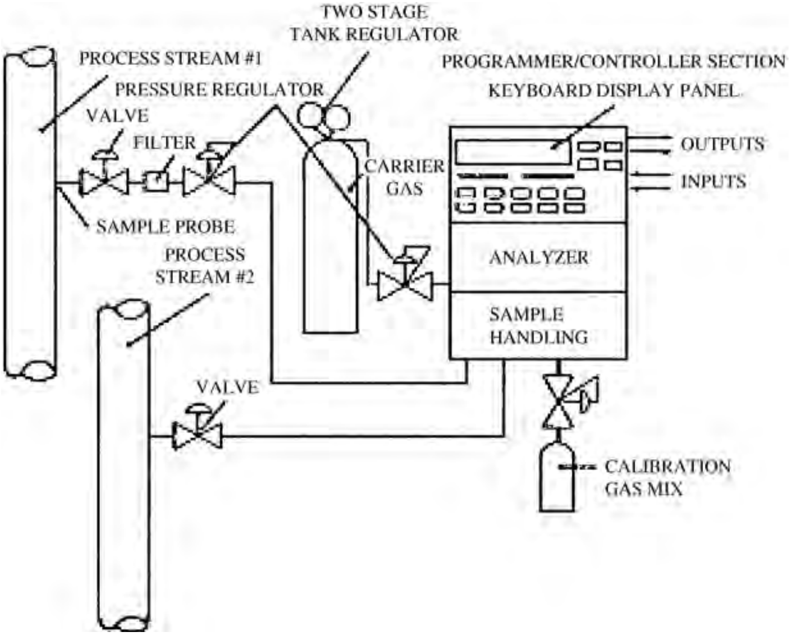

FIG. 8.12c
Basic elements of a multistream process gas chromatographic system.

- Contains alarms and diagnostic aids to continuously monitor the health of the instrument and aid in diagnosing problems

A process gas chromatographic system (as shown in Figure 8.12c) consists of both the PGC and a sample handling system (SHS). They will be discussed separately in the following sections.

COMPONENTS OF A PROCESS GAS CHROMATOGRAPH

The architecture of a PGC can be broken into two principal parts: the *analyzer*, containing the hardware that makes up the basic chromatograph; and the *programmable controller*, containing the electronics for the control and operation of the chromatograph plus a communication package. What follows is a detailed discussion of these various parts and specifications of the PGC.

The traditionally designed unit, such as illustrated in Figure 8.12d, is fairly large (typically 40" × 26" × 18" in. HWD) and is mounted in a protected analyzer enclosure. An alternative so-called transmitter design, focused on a narrow market such as natural gas analysis in custody transfer applications,[1] has been available for some time. However, the development of a full-featured transmitter to compete with the more traditional design in a variety of applications has a checkered history. A totally pneumatic PGC transmitter[2] was introduced in the mid-1970s and was on the market until 1989. More recently, a detailed transmitter design appeared in the literature[3] but was never commercialized, and in the

FIG. 8.12d
Typical PGC for mounting in an analyzer shelter. This unit can be obtained as shown with a single large oven or, with this space divided to provide two separate ovens each with its own thermostat. (Photo courtesy of Siemens Applied Automation.)

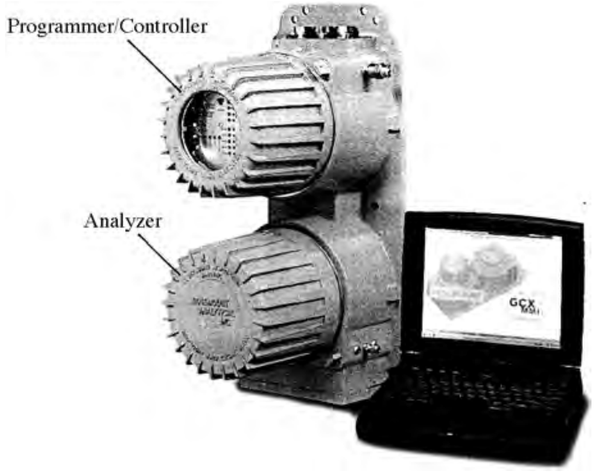

FIG. 8.12e
A "transmitter" designed PGC; Dimensions 28" × 12" × 15" HWD. The analyzer and programmer/controller are mounted separately in their own explosion proof enclosure (similar to the old dP cell hats). The ubiquitous notebook PC is shown as the remote analyzer maintenance station. (Courtesy of Rosemont Analytical Inc.)

mid-1990s a unit was introduced to the U.S. market (designated as the SGC 3000[4]) that has since disappeared but may be offered in Japan and Europe. Finally, in the late 1990s a transmitter design (illustrated in Figure 8.12e) was marketed that is still current and appears to be quite successful. All of the functions that will be discussed in the following text also pertain to this latter design.

The advantages of the transmitter are that it can be mounted close to the sample point (thereby decreasing sample transport time and thus cycle time) and it does not require an analyzer shelter (thus decreasing installed cost). The overall size of the transmitter and its sample handling hardware is much smaller than the shelter-mounted units for ease of field mounting. In previous designs, the oven space necessary to mount the complex valve and column arrangements was sacrificed along with its ability to handle many applications. This severely limited the market for such a design and may account for its rather limited success over the years. However, the newer design appears to be much more flexible, offering parallel chromatography, complex column valving options, many detector options, and a full communication package. In addition, efforts have been made to design the units for easy maintenance. In the absence of a complex sample-handling package, however, the transmitter, with its simple modular sample handling unit close-coupled to it, is basically a single- or, at most, a dual-process stream analyzer. However, to accommodate users who wish to spread the cost of the analyzer by using it for the analysis of several streams, the transmitter equipped with an external sample-handling package can handle up to 16 streams. The only advantage left for this design then is the decreased cost due to the elimination of the analyzer shack required for the traditional PGC.

Analyzer

The analyzer section contains all of the basic elements of the chromatograph, namely, columns, sample and column-switching valves, and detectors, all enclosed in a precisely thermostated oven. In some designs, the associated pneumatic components are also placed in the oven, and in others they are not. Which option is elected depends on the quality of the components and robustness of the software to tolerate retention time changes that may occur when pressure and flow controllers experience a varying temperature environment. The oven may be designed for isothermal and temperature programming operation.

As mentioned previously, temperature programming is a procedure for decreasing the analysis time for a sample consisting of compounds of widely divergent boiling points and polarity. The temperature of the column is usually maintained at some initial value for a fixed period of time while the low boilers elute from the column, and is then raised in a linear fashion (at a suitable rate) during the remainder of the cycle so as to ensure the separation of the remaining sample components in a much shorter period of time than if the analysis had been run isothermally. The oven then must be cooled rapidly to exactly the same starting temperature and programmed at the same rate if one is to obtain reproducible retention times for the various sample constituents—clearly not a trivial design problem, especially if the unit is to be certified for use in Division 1 areas.

Oven

For economy and design simplicity, a single isothermal temperature zone is most frequently used. However, units with two separated temperature zones are now available. This provides the application engineer with tremendous flexibility, since parallel chromatography can be run on the same sample at the same or different temperatures with columns containing the same or different stationary phases. In this manner, the solution to difficult applications can be considerably simplified and the cycle time shortened.

Although isothermal oven operation is usually the choice, temperature-programmed units are offered to extend GC applications to other *volatility measurements* such as *simulated distillation*, *Reid vapor pressure*, etc.

The majority of PGCs utilize air-bath ovens for both isothermal and temperature-programmed applications. In this design, each of the analyzer elements, such as the oven heater and detectors, is built to be explosion-proof for mounting in a basically non-explosion-proof air-bath enclosure. A continuous flow of instrument air (at 3 to 4 scfm) is passed through a heater (see Figure 8.12f) and the oven, and then vented inside or outside the analyzer shelter. The temperature of the oven is usually in the range of 50 to 225°C (±0.1°C), but may be limited by the area safety classification regarding the permitted surface temperature (the T rating). The T rating may also limit heat-up rates.

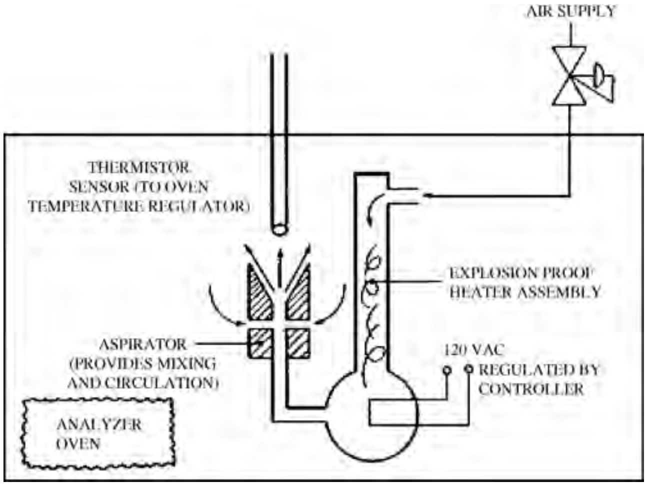

FIG. 8.12f
Basic elements of an explosion-proof isothermal air bath oven heater assembly.

Also available for the analyzer shelter-mounted units is an airless heat-sink oven of about the same size as the air-bath units. The heating elements in this oven are not exposed, but cast into the oven walls, providing conductive and convective heat transfer with heat-up rates not much slower for the same oven volume than that of the air-bath variety. Also, higher temperatures can be achieved with this design within a given area T rating than with the air-bath oven. The advantages of such a design are that operational costs are decreased because:

- It does not require instrument air for its operation.
- Power consumption is less than half that of the air-bath unit since only conductive heat loss must be compensated, while with the air-bath design, new ambient air must be heated continuously.

In addition, with this design the explosion-proof detectors can be mounted outside the oven (similar to laboratory GC design), providing much more working space within the oven (see Figure 8.12g).

The second and oldest design that has evolved through the years is achieved by placing all the elements of the analyzer in an explosion-proof enclosure. This design also does not require purge air for the oven. Historically, this has lead to a very heavy and unwieldy package, but now, using the smaller, modern engineered analyzer and electronic components, compact units such as the PGC transmitter are available. Field maintenance of the analyzer portion of these instruments consists of replacement of the total oven–GC assembly (see Figure 8.12h for details of the transmitter construction). Similarly, as with modern traditional design, the electronics package has been modularized to allow quick replacement of electronic components.

Valves

Valves are used for the injection of sample and as column switches in the various column configurations that may be required in the application. The most popular of these are the

FIG. 8.12g
One half of a dual airless oven assembly showing the placement of the explosion-proof detector outside of the oven. Space for the explosion-proof heater assembly is not required in an airless oven and an application using "valveless" column switching has further reduced the oven space needed for the application. (Photo courtesy of Siemens Applied Automation.)

rotary, sliding plate, diaphragm mechanical, and no-moving-part valves, and the so-called *valveless* or *Deans switch*.[5]

The sample valve is designed to deliver a fixed volume of sample to the head of the column. For very small samples (less than a microliter), the sample volume is defined internally by a slot machined into the movable member of the valve (sliding plate or rotor), and for larger volumes, by an external loop made from a length of deactivated tubing attached to the valve.

In the past, the smaller volumes were used to inject a liquid volume of sample (which was rapidly vaporized in the carrier gas). However, with the increasing popularity of capillary columns (which require much smaller samples than their packed column analogs), these valves are being used for the injection of gaseous samples. In any case, because liquid samples pose particular problems with regard to sample valve reliability, sample handling, and safety, liquid sample injection is best avoided by vaporizing the sample before presenting it to the sample valve.

Rotary Valve The most popular rotary valve (especially for capillary chromatography) contains a conical rotor with machined grooves interconnecting the outer ports that are drilled into the outer body. Two positions of the rotor define different flow paths, as shown in Figure 8.12i.

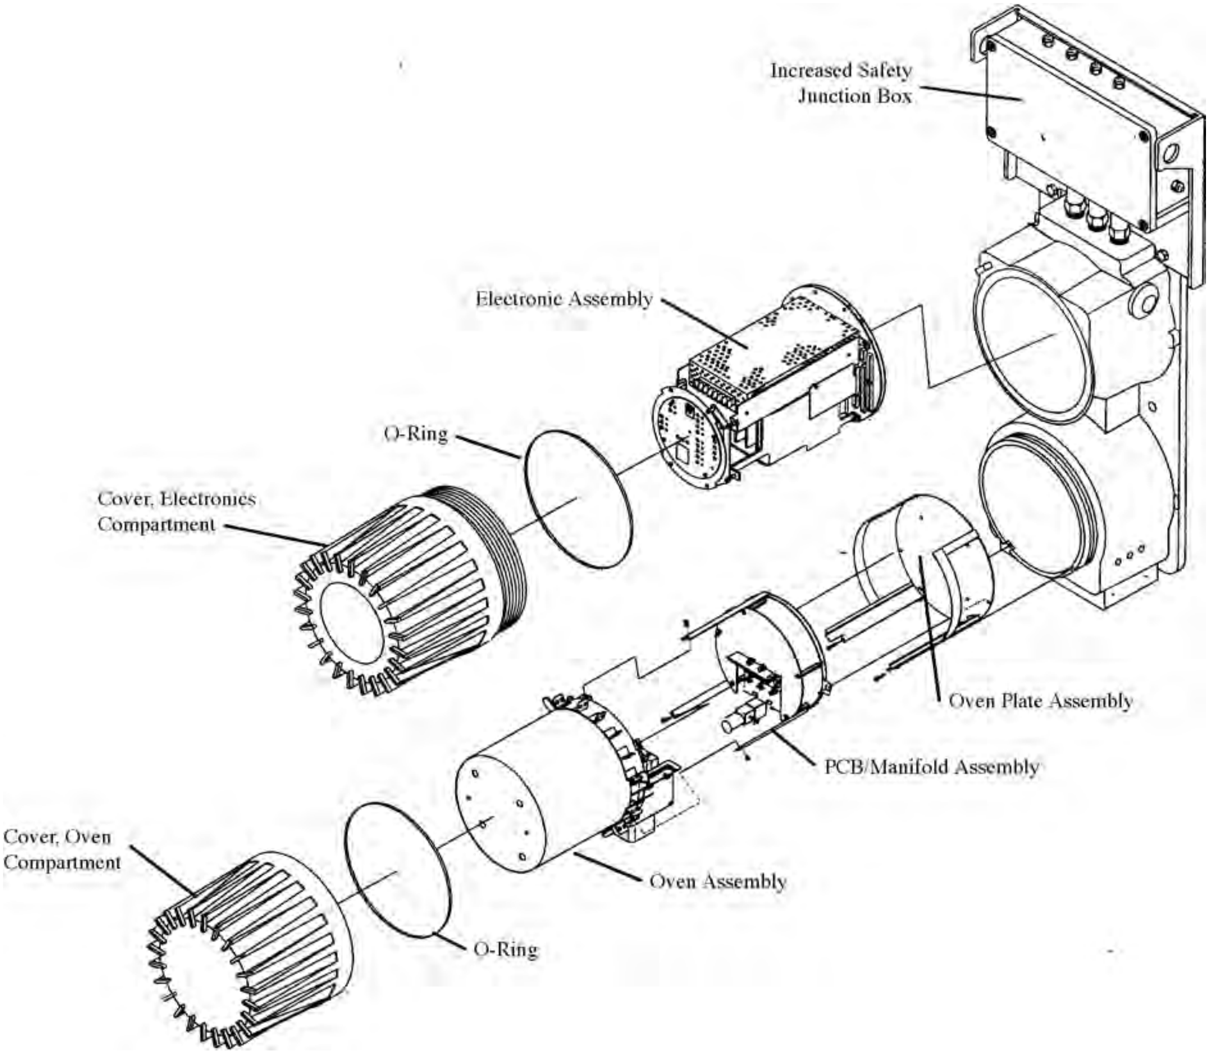

FIG. 8.12h
An exploded view of the "transmitter" illustrates the modular construction of the unit. Rapid field maintenance of the analyzer is met by replacement of the total oven assembly which includes columns, detectors, valves, actuators, heaters, temperature sensors, and electronic pressure/flow controller components. In the electronics section, the printed circuit board assemblies are "euro-card" slide rail mounted and may be removed/replaced without the use of tools. (Courtesy of Rosemont Analytical Inc.)

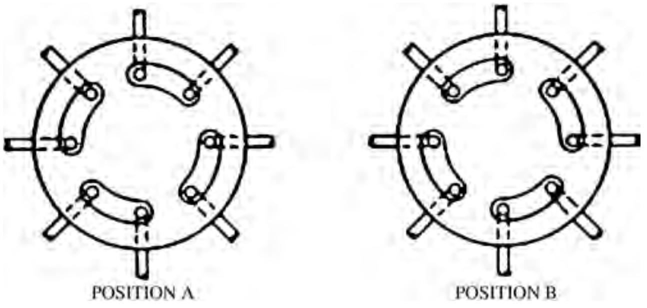

FIG. 8.12i
Rotary valve.

The rotor faces are of filled Teflon or similar polymer that provides chemical resistance as well as sealing and lubricity. The valve body is made of stainless steel, or other corrosion-resistant alloy, with highly polished conical faces to form a mating seal with the rotor. The rotor is held against the stator by a factory-calibrated threaded cap that applies the correct force. An exploded view of a manually operated version of such a valve is shown in Figure 8.12j.

The PGC version of this valve is actuated either by a compressed air operator or by an electrically driven solenoid. Although these valves meet the stringent demands for capillary chromatography, there are disadvantages in that they require regular maintenance, since the rotors wear and must be replaced after about 200,000 cycles. In addition, they require a much more complicated driver since the simple linear motion commonly available must be converted to a rotary one.

Sliding Plate The sliding plate valve comes in both linear and rotary versions, the former being the most popular by virtue of the simple operator required for lateral rather than rotary movement of the slider.

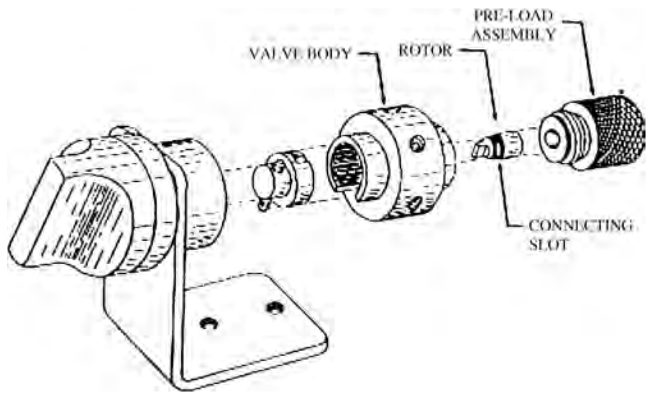

FIG. 8.12j
Exploded view of a manually actuated rotary valve. (Courtesy of Valco Instrument Co. Inc.)

In a manner similar to that of the rotary valve, the switching is done by a plate with channels machined in its face that is switched over holes that are drilled into the valve body. Again, the slide is made of filled Teflon or similar polymer, for the reasons outlined above. The slider is moved between its two positions either by a diaphragm operator mechanically linked to it (with compressed air, released by an external solenoid, supplying the necessary force) or directly with a solenoid whose shaft is linked to it.

Diaphragm The diaphragm valve comes in 10-, 6-, and 4-port versions and operates on a different principle than the sliding plate or rotary valves. The flow of gases between adjacent ports arranged in a circular pattern in a machined and polished metal surface is controlled by a Teflon diaphragm. Two versions of the diaphragm valve are available. In one, the force is applied to the diaphragm by a series of plungers that are in turn moved by two pneumatically actuated pistons. This is illustrated in Figure 8.12k for a six-port sample valve. The other version uses pressure-on-diaphragm activation with no moving parts. Both versions are highly reliable (1-million-cycle rating for the piston-operated one, and 16 million for the no-moving-part variety).

Although the sample valve example shown in Figure 8.12k utilizes an external sample loop, these valves are also available with small internal-volume loops.

Columns

Packed columns are still the most commonly used in most PGC applications. However, open tubular (OT) capillary column solutions are making inroads in many cases. WCOT columns are often preferred because they are more efficient than packed columns, and thus it is possible to simplify the column configuration necessary to achieve the desired separations. In addition, they often allow for faster analysis cycles. There is a downside, however, to using capillary columns in PGC applications in that many of the older designed PGCs will not adequately support them. Also, because of the ease of plugging the small-diameter columns and connecting plumbing, sample handling to produce extremely clean samples is of paramount importance. Very small sample volumes must be injected to maintain the efficiency of the WCOT columns. Thus, special sample valves and additional hardware to split the sample delivered from the sample valve are necessary. Also, detectors designed with small internal volumes are necessary, as well as critical attention to plumbing details, to avoid unswept volumes that degrade chromatographic peaks by creating long tails on the trailing edges. In addition, in some cases, the small sample volumes may lead to inadequate detectability by some detectors.

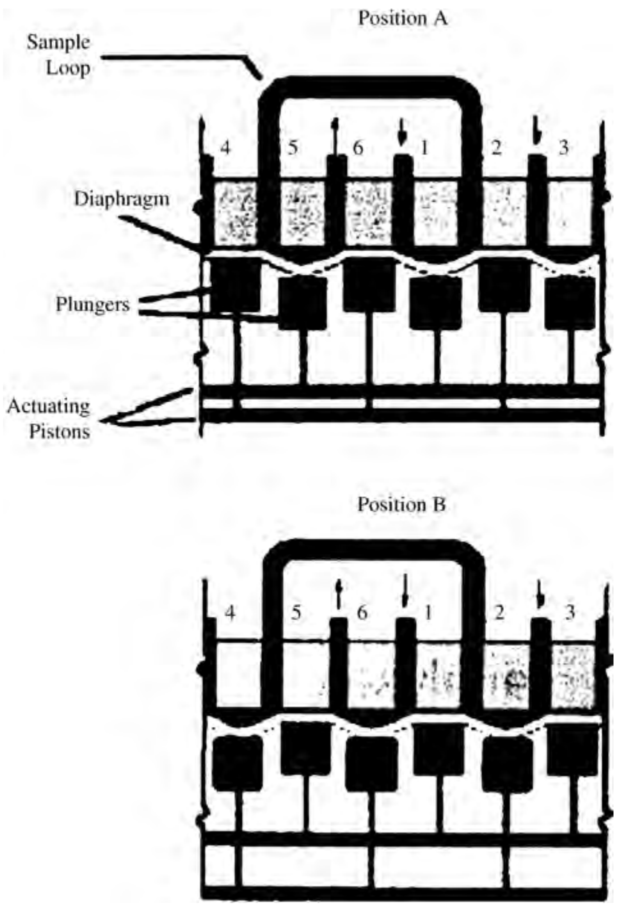

FIG. 8.12k

In Position A, the sample loop is being filled with sample. In Position B, sample is swept from the loop by carrier gas. (Courtesy of Valco Instrument Co. Inc.)

Packed Columns Packed columns in 1/8-in.-outer diameter (o.d.) (0.079-in., 2-mm-inner diameter (i.d.)) stainless steel tubing are in widest use, although the smaller-diameter 1/16-in.-o.d. (0.039-in., 1-mm-i.d.) micropacked (smaller-diameter particles) are increasingly being used. Occasionally, the larger 3/16-in.-o.d. columns are used in special application. The length of these columns will vary with the difficulty

TABLE 8.12l
Popular Stationary Phases

Stationary Phase	*Comments*
OV-101™ (100% methyl silicone) useful from 0 to 330°C	Most frequently used GC phase. Low polarity, separates homologous series of compounds according to their boiling points.
OV-17™ (50% phenyl–50% methyl silicone) useful from 50–250°C	Moderately polar silicone phase.
OV-25™ (75% phenyl–25% methyl silicone)	Highly polar silicone phase. Selective for aromatics over aliphatic hydrocarbons.
OV-225™ (25% cyanopropyl–25% phenyl–50% methyl silicone useful from 0–250°C	Increased polarity over OV-25. Increased retention of aromatics over aliphatics, alcohols over ethers, ketones over primary alcohols.
Carbowax 20M (polyethylene glycol, mol. wt 15,000–20,000) useful from 60–225°C	Generally useful polar phase.

in making the separations. Longer columns produce more plates and thus have more separating power. However, the maximum column length is ultimately determined by the pneumatic equipment. Large pressure drops are avoided by keeping column lengths to less than 12 ft. The stationary phase is coated on support particles (sieved to 80 to 100 or 100 to 120 mesh) of Chromosorb™ (a diatomaceous earth product that has the large surface area needed to make efficient columns). Some popular stationary phases and the separations for which they are used are listed in Table 8.12l.

Additionally, it has been suggested in the literature that most separations can be accomplished by using mixtures of a polar and nonpolar phase in the proper proportions.[6,7] Indeed, computer-aided series-connected capillary column design procedures have been published that produce column systems optimized for the analysis restraints (such as analysis time and detectability) that are operative for that particular application.[8]

Active solid supports such as alumina, activated charcoals, and silica gels have been used in the past for the separation of fixed gases and light hydrocarbons. However, their use is now avoided if possible because their activity is difficult to stabilize, leading to changes in retention time and separating power. Similarly, molecular sieves (synthetic alkali metal aluminosilicates) once used primarily for the separation of hydrogen, oxygen, nitrogen, methane, and carbon monoxide must be protected from carbon dioxide (by using a trapping column ahead of it) and from other hydrocarbon gases that are adsorbed and deactivate the column. Many of the applications that once used these solid phases can now be performed with synthetic porous polymer phases such as Porapaks™ and HaySep™.

WCOT (Capillary) Columns In the past, capillary columns were avoided because of their fragility (they were made of glass since metal capillaries had active surfaces that produced less efficient columns due to tailing peaks) and also the stationary phase tended to bleed off over a period of time. However, these problems are no longer present because of two technological breakthroughs. The fragility problem has been solved by coating the outside of the fused silica capillary with a polyamide (similar to the coating used for optical fibers), which turns it into a tough, bendable capillary tube.[9] In addition, the stationary phase stability problem has been eliminated by performing the appropriate chemistry on the stationary phase after it is coated on the walls of the capillary tubing to produce partial cross-linking of the phase to itself and to the silica surface.[10,11] Columns of this type are classified as having *stabilized stationary phases* and are readily available from all GC column vendors.

Although capillaries of 0.25-mm i.d. are commonly used in laboratory GCs, it is much more common to see the so-called megabores (0.32- to 0.50-mm i.d.) used in PGC applications as a direct replacement to the packed column. Minimum hardware modifications are necessary on older PGCs to accommodate these larger capillary columns. They provide comparable or better efficiency than their packed column analogs and, in many cases, better separations, since longer columns can be used (because of their high permeability).

The characteristics of the various columns used in process GC are summarized in Table 8.12m.

COLUMN AND VALVE CONFIGURATIONS

One of the most severe restraints operative in PGC applications is that of timely analysis cycle time. Since the cycle time includes the sample transport time as well as analysis time, this restraint has implications from both a chromatographic and a sample handling point of view. The latter concern will be discussed later on in this text. The solution to analysis time has historically been to use multiple columns in various configurations. Multiple columns and column-switching systems serve several important functions, namely:

- Housekeeping: To ensure that all components are removed from the columns during each analysis cycle. The method commonly used to achieve this objective is called backflushing.
- Discard unmeasured components: In many process control applications, a rapid analysis of only one or two components is required, not the total analysis. Both backflushing and heart-cutting are used.
- Simplify the separation problem: A single column that will separate all of the measured sample components within the desired cycle time may be difficult to find. However, it may be possible to optimize separate columns for different portions of the analysis and then combine them in such a fashion to achieve the

TABLE 8.12m
Characteristics of Columns Used in PGCs

Type mls/min	*Length, m*	*o.d. mm*	*i.d. mm*	*Flow*
Packed				
Conventional	0.1–5	3.18 (1/8")	2	10–50
Micropacked	0.02–1	1.59 (1/16")	1	1–10
Capillary	1–100	0.4–0.8 (1/64–1/32)	0.1–0.5	0.5–10

Type	*Advantages*	*Disadvantages*
Conventional	Ease of fabrication Large Sample capacity affords High detectability Relatively inexpensive	Large carrier gas consumption Modest efficiency
Micropacked	Lower gas consumption Higher effiency Faster analysis	Higher head pressure reqd. Lower sample capacity Difficult to fabricate
Capillary	Lower gas consumption Higher effiency Fast analysis Best separating power	Lowest sample capacity Reduced detectability Expensive

desired analysis. This simplifies the application problem. Trap-and-store methods, as well as parallel and series columns, are frequently used for this purpose.

While the solutions to some applications may have changed with the advent of more instrumentation that can support capillary, temperature-programmed, and parallel chromatography, many remain that can only be solved with the use of the various column configurations discussed below. While there are literally hundreds of possible column configurations, they are all built from a few basic ones.

Hardware

Six- and 10-port valves are often used in multicolumn chromatography. However, an alternative switching procedure, the so-called valveless or Deans[5] switching, is used extensively in process GC, particularly in Europe. Basically, this valve depends on applying a pressure differential to change the flow pattern of carrier gas. The columns are connected in series by a T, the center connection of which is connected to a second source of carrier gas through a solenoid located outside the heated oven. The solenoid controls the supply of carrier gas to the tee to shift the flow pattern (see Figure 8.12n). The main hardware advantages of this arrangement are that solenoids that satisfy the lower temperature specification are much easier to find; it is a less expensive solution to the problem, since a solenoid and a tee are less expensive than a high-temperature rated chromatographic grade-switching valve; and, finally, the assembly takes up much less oven space than a conventional rotary or diaphragm valve.

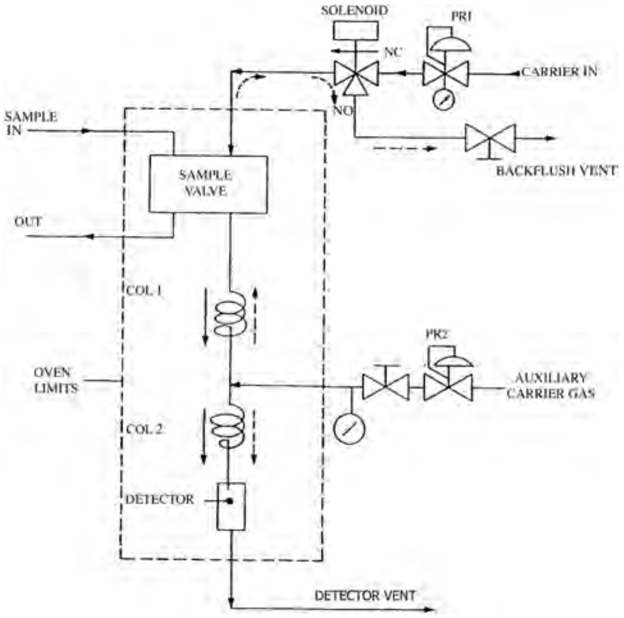

FIG. 8.12n
Backflush to vent configuration using a Deans switch. Column 1 is backflushed to vent in the "fail-safe" unenergized position of the solenoid. The auxilary regulator, PR2, supplies carrier gas to both columns in its backflush mode. Except for the sample valve, there are no moving parts within the heated analyzer oven. (From Annino, R. and Villalobos, R., Process Gas Chromatography: Fundamentals and Applications, Research Triangle Park, NC: ISA, copyright 1992 ISA. Used with permission. All rights reserved.)

Sample Injection The primary function of the sample inject valve is to place a sharply defined fixed volume of sample into the carrier gas stream so that it can be carried into the column for separation into its individual components. The sample volume is defined by an external length of tubing connecting two of the valve ports, as shown in Figure 8.12k,

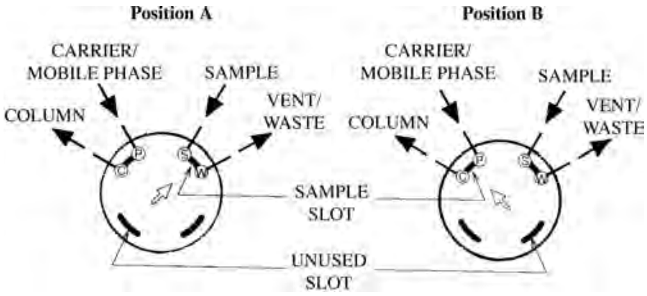

FIG. 8.12o
Rotary valve with internal sample loop for the injection of small volume liquid or vaporized sample.

or internally by a groove machined into one of the valve faces (see Figure 8.12o for an internal sample loop in a rotary valve). The latter configuration is used for small-volume gaseous or liquid injections.

In the case of some liquid samples, a special valve is used that is designed to have two distinct temperature zones: 1) a cool zone near ambient through which the sample circulates, and 2) an internally heated vaporizing zone where the liquid sample is injected into the carrier gas stream, vaporized, and carried into the column. This type of sample valve is called a vaporizing liquid sample valve. An important feature of this design is that the circulating liquid sample does not contact the heated zone. Hence, it can be used for samples that will not tolerate heat, for example:

- Samples that tend to polymerize (such as styrene)
- Samples with a high vapor pressure such that heating them to the temperature of the column would increase their vapor pressure above the line pressure and result in partial vaporization (flashing) of the sample.

The internally heated vaporizing valve is also used if local or company safety codes prohibit the introduction of flammable liquids into the heated analyzer zone.

Capillary columns require much smaller injection volumes than do packed columns. For gas samples, the appropriate volumes (0.5 to 10 ml) can be obtained using the external or internal sample loop. Acceptable liquid sample volumes for capillary chromatography, however, are a thousand times smaller than this and are obtained by adding a splitter between the sample inject valve and the column. The splitter is essentially a Y specially designed so as not to produce any discrimination of the vaporized sample according to some function of composition; that is, it provides only a volume split of the sample. Since one leg of the Y may be operating at 200 to 500 times the column flow rate, it potentially constitutes an increased operating cost for the instrument. For this reason, it is normally dead-ended, except when injecting sample.

Backflush The column configuration most frequently used in process GC is the backflush precut to vent. Both this and the sample inject operation are shown combined in the 10-port valve configuration shown in Figure 8.12p, using a rotary valve, and in Figure 8.12n, using a Deans switch. The backflush procedure performs the all-important housekeeping function of removing all unmeasured heavy components or those that may degrade the analytical column (such as water) from the column system each cycle. The system consists of at least two columns: a precut (or stripper) column, C1, and an analysis column, C2. The precut column is backflushed shortly after the sample is injected, thus allowing only the components that are to be measured to enter the analytical column.

Typically, the precut column is approximately one third the length of the analytical column. This allows sufficient time for all components to backflush during the time necessary to chromatograph the rest of the sample on the analytical column.

Another version of backflush, called backflush to detector, is illustrated in Figure 8.12q. It is used when it is desired to have a measure of the "heavies" that are backflushed.

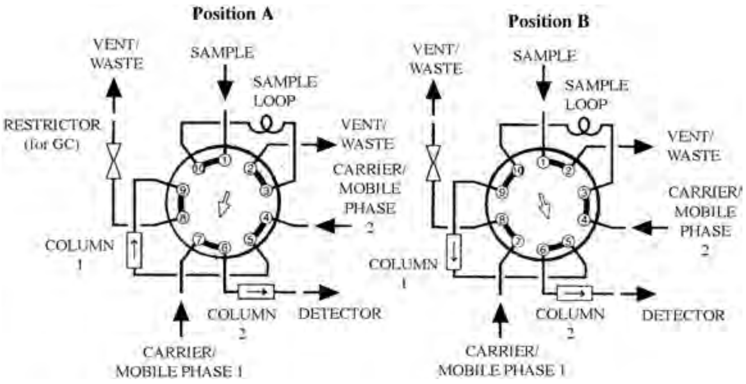

FIG. 8.12p
A 10-port rotary valve with an external sample loop configured in Position B for the injection of sample into column 1 and column 2 and, in Position A, for backflush to vent of the sample components trapped on column 1 while the rest of the sample is separated on column 2 and the sample loop is refilled with fresh sample. (Courtesy of Valco Instrument Co. Inc.)

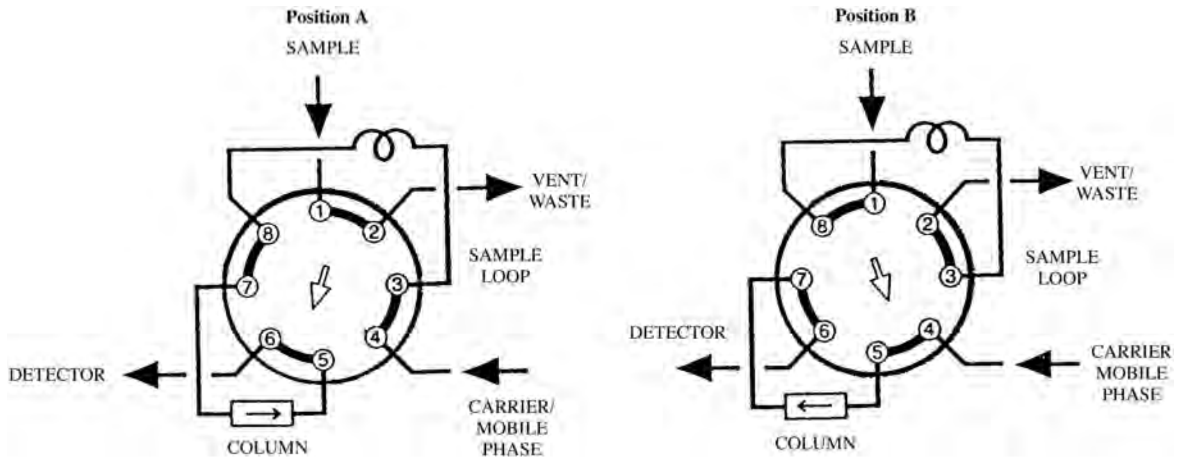

FIG. 8.12q
Backflush to measure configuration: an 8-port rotary valve is configured so that the backflushed components can be flushed through the detector and measured as a group. (Courtesy of Valco Instrument Co. Inc.)

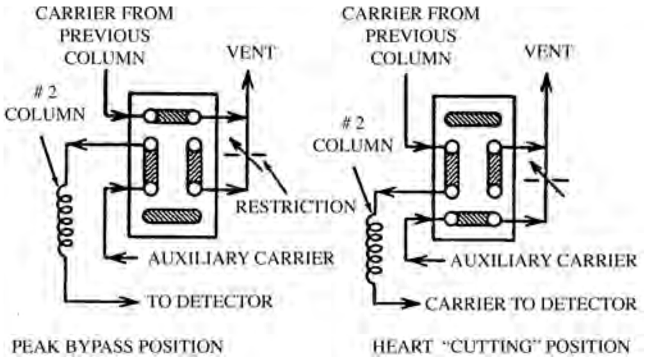

FIG. 8.12r
Heart-cut configuration: a six-port plate valve is configured so as to divert a large portion of a major component in order to simplify the separation of a small concentration of a sample component riding on its tail.

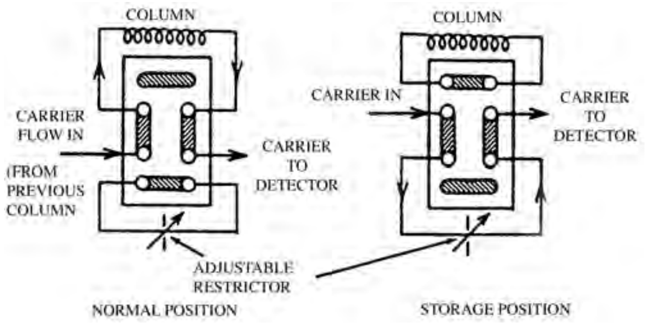

FIG. 8.12s
A six-port plate valve configured so that a group of early eluting sample components pass into a storage column which is then isolated from carrier gas flow (the group of components remain stationary on the column except for a samll amount of longitudinal diffusion) and stored until the rest of the sample is separated and measured by the detector. When the valve is again switched, the components on the storage column are developed and measured by the detector.

Heart-cutting Heart-cutting is one of the most useful column configurations. It is frequently used for the analysis of trace components that elute immediately after a large concentration of another sample component that interferes with its determination (for example, trace amounts of acetylene in ethylene). The design consists of two columns, a heart-cut column and an analysis column, as shown in Figure 8.12r, using a six-port sliding-plate valve. In the normal position of the heart-cut valve, the effluent of the heart-cut column is diverted to vent. When the component of interest is about to elute, the heart-cut valve diverts it into the analysis column and then returns to its venting position. A heart-cut of only the compound of interest and a narrow band or "tail" from the major component are thus introduced into the analysis column. This operation may be repeated for each component of interest, although it is usually not practical to measure more than three heart-cut components per analysis.

The trap-and-store configuration consists of two analytical columns arranged in series through a column-switching valve, as shown in Figure 8.12s. The switching valve is used to direct the effluent from column 1 into column 2 or through a bypass restrictor to the detector for measurement. In a manner similar to that used in heart-cutting, two or more components that are not separated on column 1 are diverted to column 2, as shown in Figure 8.12s, *normal position*. In the other *storage position* of the valve, carrier gas is not available for this leg. Column 2 is thus isolated, and the diverted compounds are stored while the rest of the sample is developed in column 1 and passed on through the restrictor to the detector for measurement. The trapped compounds are then passed to the detector for measurement.

DETECTORS

Of the many detectors that have been proposed for use in PGC over the years, two emerge as the most popular and have been applied to a far-ranging number of applications. They are the

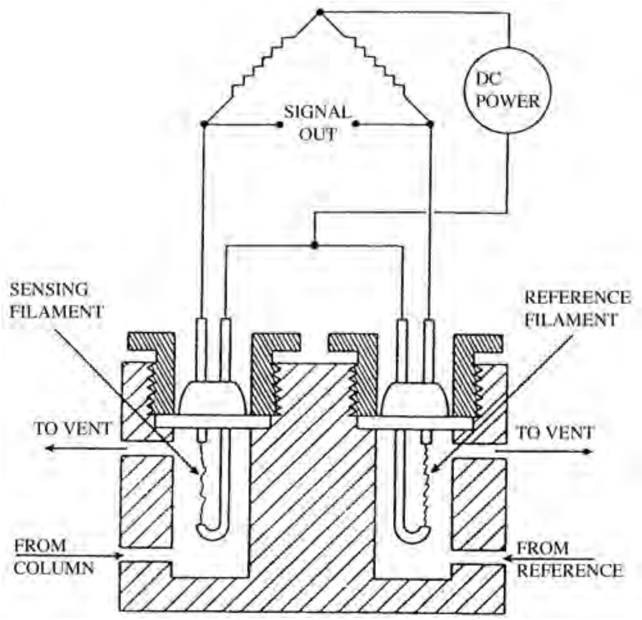

FIG. 8.12t
Single sensing filament, single reference filament, flow-through TCD with replaceable elements shown in a classical Wheatstone bridge circuit. In a properly designed TCD block assembly, the inclusion of reference filaments imparts greater stability to the signal by balancing out small temperature variations in the cell block.

thermal conductivity detector (TCD) and the flame ionization detector (FID). Their popularity stems from their basic simplicity and ruggedness coupled with their acceptable sensitivity for most applications. There are other detectors used in PGC applications (such as the flame photometric and other ionization detector), but only under special circumstances.

Thermal Conductivity Detector

The TCD is a concentration-responsive detector of moderate sensitivity (MDQ = 10^{-9} g) and dynamic range (10^5).[*] It is a reliable, simple, easy-to-maintain, and relatively inexpensive detector with a universal response. The unit shown in Figure 8.12t is of classical design and consists of a cavity in a metal block with a filament (made of a metal with a large resistance/temperature coefficient such as tungsten or an alloy such as tungsten-rhenium) suspended in the carrier gas flow stream. In support of capillary chromatography, the newer detector designs strive to minimize detector cavity volume. The filament is heated electrically and reaches some equilibrium temperature (and corresponding resistance) based on the power supplied to it and the thermal conductance of the gas passing over it, and the temperature of the cavity wall. The cavity wall temperature is maintained constant by the oven environment, and the carrier gas is selected for its large thermal conductivity (helium or hydrogen), compared to the components of the sample. Thus, as sample components– carrier gas mixtures enter the detector, the consequent thermal conductance change experienced by the filament environment leads to a change in the equilibrium temperature and resistance of the filament.

Traditionally, the filament is made to be one arm of a Wheatstone bridge that is supplied with a constant voltage. The change in null voltage experienced by the bridge when the filament changes resistance is recorded as the chromatographic signal. Modern TCD electronics, however, favor constant-current (Figure 8.12u) or constant-resistance designs (Figure 8.12v) for faster response and also for filament protection in the presence of large sample concentrations and cessation of carrier gas flow.

---

[*] MDQ is the minimum amount of solute that will produce a detector signal twice the peak-to-peak noise of the detector. The dynamic range of the detector is the range of concentration of the test solute over which a change in concentration results in a measurable change in detector signal.

Alternatively, the filaments can be replaced with thermistors (sintered mixtures of manganese, cobalt, and nickel oxides along with trace elements). They are mounted in the form of a bead on platinum wire leads and coated with glass to make them inert. Thermistors have a very large negative temperature coefficient, making them very sensitive sensors. However, they have a limited temperature range and their sensitivity decreases with increasing temperatures Thus, they are most useful in low-temperature applications. Also, their use is commonly restricted to helium carrier gas as the glass covering becomes embrittled and cracks when hydrogen is used.

TABLE 8.12x
FID Effective Carbon Number (ECN)

Atom	*Type*	*ECN*
Carbon	Aliphatic	1.0
Carbon	Aromatic	1.0
Carbon	Olefin	0.95
Carbon	Acetelenic	1.30
Oxygen	Ether	–1.00
Oxygen	Primary Alcohol	–0.60

Flame Ionization Detector

Even though the use of a FID involves increased operating cost and increased analyzer complexity, its very large dynamic range (10^7), high sensitivity (0.015 coulombs/g C), low detection limits (10^{-12} gC/sec), and vanishing small dead volume (10^{-2} μl) have made it probably one of the most popular GC detectors in use today. With optimized operating parameters, it is possible to determine as low as 20 pg, or about 5 ppb, of a sample.

The FID consists of an oxygen-rich hydrogen flame that burns organic molecules, producing ionized fragments. These ions are subjected to an electrical field produced by impressing a potential (usually 150 to 300 V) across a jet and the collecting electrode (the jet is usually made negative, and the collector positive).

The essential components of a FID are shown schematically in Figure 8.12w. The hydrogen fuel is mixed with the column effluent and then fed to the jet. An outer sheath of air supports the flame. In some designs, the flame points downward. This ensures removal of water from the flame vicinity together with any solid particles that may be present. The presence of either of these substances will contribute to the background noise of the system and thus reduce minimum detection levels. The response of the detector depends on the flow rate of all three gases—with the hydrogen flow rate being the most critical (the ratio of air to hydrogen is usually around 10).

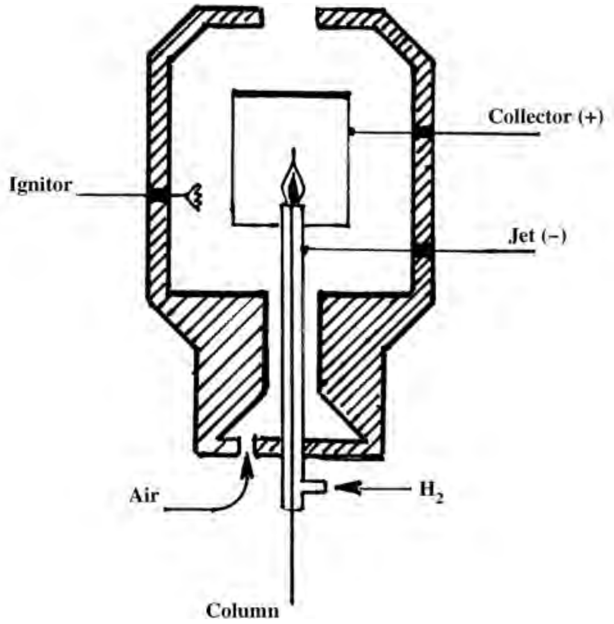

FIG. 8.12w
Schematic illustration of an FID assembly. The capillary column is run up inside the jet to the tip (thus minimizing detector dead volume). The collector is positively polarized usually with +300 volts. The flame is supported by an external sheath of air.

The response of the FID, which varies with the identity of the component in the flame, depends primarily on the number and type of carbon atoms being oxidized. However, the identity and manner in which other atoms are combined with the carbon also influences the response. The concept of effective carbon number (ECN) has been introduced[12] as a means of relating the various responses. The ECN is the sum of the contributions made by the individual carbon atoms modified by the functional group contributions (a sample of these ECNs is given in Table 8.12x).

A number of compounds cannot be detected by the FID. These include the fixed gases, oxides of nitrogen, H_2S, SO_2, COS, CS, CO, CO_2, H_2O, NH_3, and the noble gases. However, if the carrier gas is doped with an ionizable gas (such as methane), even these gases can be detected (yielding negative peaks as they dilute the concentration of ionizing gas during the elution). Also, in the case of carbon dioxide, monoxide, or formaldehyde, chemically reacting the gases as they emerge from the column to form methane makes them FID responsive. Thus, most suppliers of PGCs offer a *methanizer*, which is placed between the end of the column and the FID. Hydrogen is also *teed* in at this point. The methanizer consists of a length of 1/8-in.-o.d. tubing filled with a catalyst of 10% (wt/wt) nickel on Chromosorb P, over which the reducing reaction occurs. The reaction is nonselective in that all hydrocarbons are converted to methane.

The FID is a very inefficient ionizing source, and it is only its very low noise level (10^{-14} A), allowing large amplifications, that makes this detector so sensitive. As shown in Figure 8.12y, high-gain, low-noise, electrometers mounted as close to the detector as possible are required to exploit the full range of this detector. In addition, to maintain this low noise level, highly purified gases should be used.

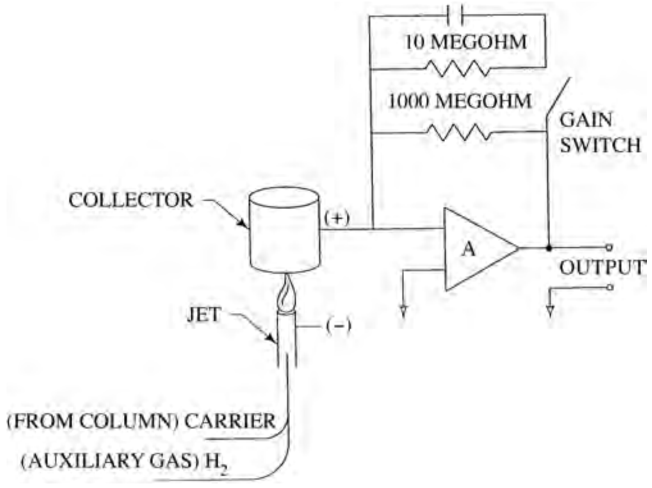

FIG. 8.12y
Schematic of a simple high impedance current amplifier circuit used for the measurement of the small currents generated by the FID. FIG. 8.12z
Basic flame photometric detector.

Flame Photometric Detector

The flame photometric detector (FPD), illustrated in Figure 8.12z, is essentially a flame emission spectrometer design optimized for use as a GC detector. It is an element-specific detector and is used primarily for the determination of sulfur- or phosphorus-bearing compounds (e.g., H_2S, CS_2, SO_2, COS, mercaptans, and alkali sulfides in various pulp milling processes and in petroleum fractions).

The column effluent is fed to a hydrogen/oxygen-rich flame where individual atoms contained in the sample or the reactants of these atoms with hydrogen and oxygen are excited to higher electronic states by the energy of the flame. These excited atoms and molecular fragments subsequently return to the ground state with the emission of characteristic atomic or molecular band spectra. For sulfur, the S_2 species at 394 nm is used, while the 526-nm emission from HPO is used for phosphorous. A narrow-band-pass filter is used to isolate the appropriate wavelength, and its intensity is measured with a photomultiplier tube (PMT).

This detector has a number of severe limitations. These include response dependency on the O_2/H_2 ratio, the H_2 flow rate, the type of sulfur compound, quenching of the sulfur emission by large concentrations of other organic compounds, and even the length of time that the flame is lit.

The quenching of the sulfur emission by other organic compounds and the flame extinguishing problem caused by large concentrations of organics such as the solvent peak are largely overcome by the dual-flame assembly shown in Figure 8.12aa, but at the expense of detection limits as the sample is diluted in passing to the second flame. In addition, the sulfur compound response dependency is eliminated with

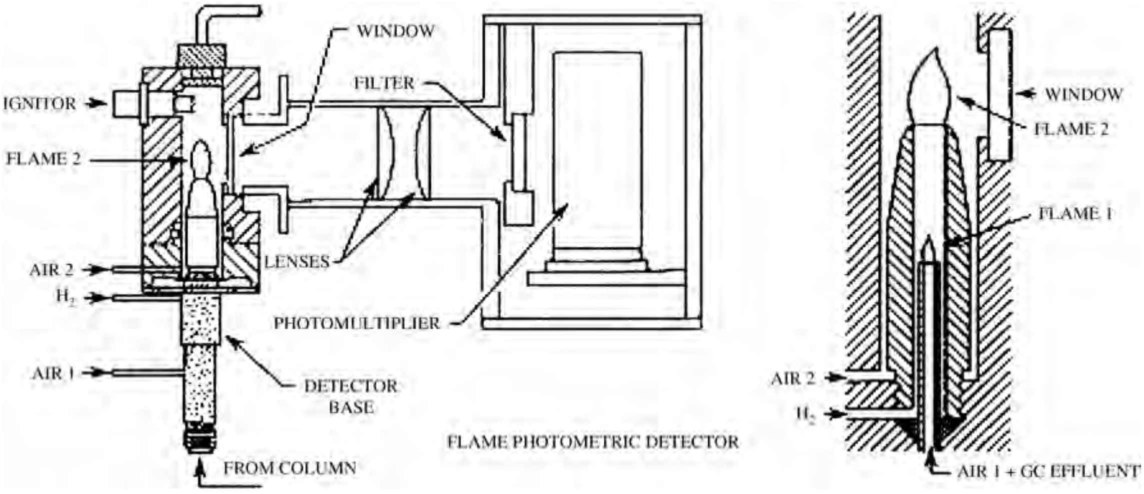

FIG. 8.12aa
Schematic of a FPD showing details of a dual flame assembly. The dual flame scheme is used to minimize the quenching of the sulfur emission by other organic compounds and also to eliminate the flame quenching problem when large concentrations of organics are present. It also provides the same sulfur response for all compounds since they are all oxidized to SO_2 in the lower flame. (Courtesy of Varian Associates.)

this detector because all the sulfur compounds are converted to SO_2 in the lower flame.

The FPD response to sulfur and phosphorous is 10^4 greater than its response to hydrocarbons, and its MDQ is at the nanogram level. However, since the detector signal is due to the emission of the S_2 species, it is not a linear function of concentration. Theoretically, it should be proportional to the square of the sulfur concentration (in practice, a factor of 1.8 provides a better fit to the calibration curve), and thus become much more sensitive to changes in sulfur concentration as the concentration increases. The reduced detectability and response characteristic at trace levels of the sulfur sample due to the detector's quadratic response can be improved by doping the carrier gas with a volatile sulfur compound (methyl mercaptan is a good choice) to bring the signal further up on the calibration curve. Finally, the PFD response is greatly dependent on carrier gas identity and flow rate, as well as oxygen (or air) flow rate to the flame. Clearly, it is not a very robust detector.

Pulsed Flame Photometric Detector[13]

In a conventional FPD, the detectivity is limited by light emissions of the continuous flame combustion products. Narrow-band-pass filters used to isolate the wavelength also limit the fraction of the element-specific light that reaches the PMT, and are not completely effective in eliminating the flame background and hydrocarbon interference. In a pulsed FPD (PFPD), the fuel gas (H_2) flow is set so low that a continuous flame cannot be sustained. By inserting a constant ignition source into the gas flow path, the fuel gas ignites and propagates back through a quartz combustion tube to a constriction in its path where it is extinguished; then it refills the detector, ignites, and repeats the cycle. Carbon light emissions and the emissions from the hydrogen–oxygen combustion flame are complete in 2 to 3 msec, after which a number of heteroatomic species give delayed emissions that can last up to 20 msec. These delayed emissions are filtered with a wide-band-pass filter, detected by a PMT. By using the leading edge of the flame background emission to trigger a gated amplifier with an adjustable delay, heteroatomic emission can be amplified to the virtual exclusion of the hydrocarbon background emission. The PFPD is thus uniquely characterized by the addition of this time domain information (illustrated in Figure 8.12bb), which allows the detector to selectively detect many other elements (such as As, Sn, Se, Ge, Te, Sb, Br, Ga, In, Cu, etc.) with no hydrocarbon interference.

In the PFPD illustrated in Figure 8.12cc, hydrogen and air (3) is continuously fed into the small pulsed flame chamber (6), together with sample molecules eluted from the GC column (14). The combustible gas mixture is also separately flowing into (4), a light-shielded, continuously heated wire igniter (12). The ignited flame is propagated back to the gas source through the pulsed flame chamber (6) and is self terminated in a few milliseconds, since the pulsed flame cannot propagate through the small hole at the bottom of the combustion chamber. The continuous combustible gas flow creates another ignition after a few hundred milliseconds in a pulsed (~3 Hz) periodic fashion. The emitted light is transferred with a light pipe (8) through a broad (not narrow)-band-pass filter (9) and detected with a PMD (10).

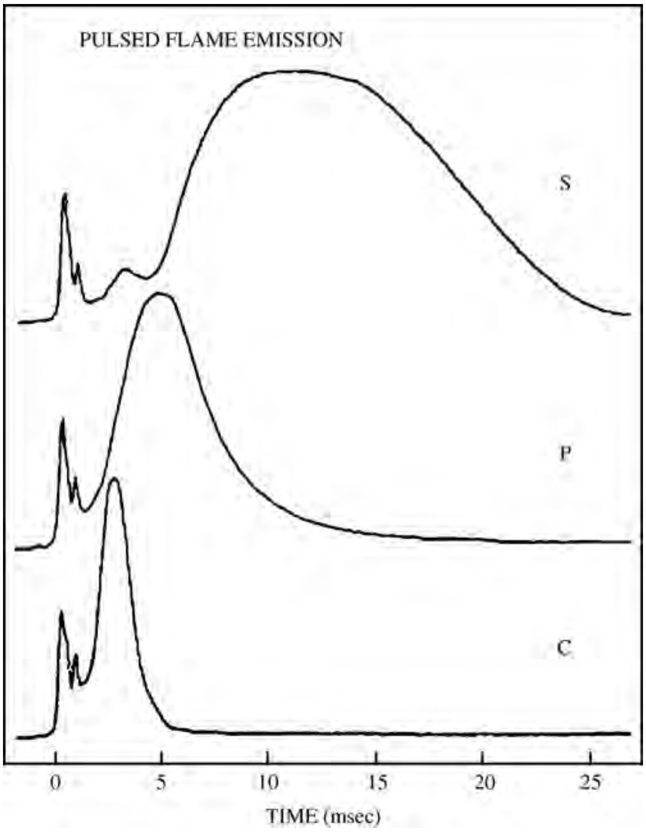

FIG. 8.12bb
Emission spectra of sulfur, phosphorous, and carbon from a PFPD showing their separation in the time domain. The initial hydrocarbon emission spike serves as an excellent reference from which to time the appearance of the selected emission. This provides infinite selectivity against hydrocarbon emission as well as unique heteroatom identification capability. (From Amirav et al., Pulsed Flame Photometric Detector for Gas Chromatography report Tel Aviv University, Tel Aviv, Israel, 2001.)

The PFPD is much more sensitive than the continuous flame version (2×10^{-13} gS/sec, 1×10^{-14} gP/sec, and 2×10^{-12} gN/sec) and much more selective from unwanted hydrocarbon emission, with total discrimination against hydrocarbon compounds (selectivity greater than 10^7). The PFPD sulfur mode has similar detection limits as that of the sulfur chemiluminesce detector (SCD), but its detection of signal to noise is better at practical detection levels (due to its quadratic response). Quenching is still a problem, however. It can be reduced by injecting smaller samples, but at the expense of sensitivity. The real advantage of this detector is with mass limited samples, such as when using capillary columns rather than packed columns, and for trace analysis.

Orifice-Capillary Detector

The orifice-capillary detector (OCD) schematically illustrated in Figure 8.12dd was used in a fully functional, commercially available PGC whose operation was based totally on pneumatic power.[2,14] Designed as a transmitter primarily for control applications, this PGC measured one or two components of the sample. It traded sensitivity for increased reliability and lower installed cost. An intrinsically safe product was ensured by eliminating all electrical power for its operation (the oven was heated by steam and the temperature was regulated by a pneumatic temperature regulator).

The chromatogram generated from the detector was produced by the variation in differential pressure generated across an orifice by a density change in the carrier gas resulting from the elution of sample components from the column. This differential pressure was amplified by a pneumatic amplifier and fed to a pneumatic computer programmed to detect and measure the peak height of the two desired sample components and transmit these measurements to a controller as updated analog trend signals.

There has been a proposal in the literature[15] for increasing the minimum detection levels of such a device. The differential pressure from the OCD is converted directly to a frequency modulated optical signal, and the complete chromatogram is transmitted over optical fiber to a remote station for more sophisticated computer data processing. In addition, the capability of the pneumatic PGC is also expanded to that of a multicomponent analyzer. This design modification changes this PGC to one of a split architecture with the nonelectric analyzer unit in the field and the electronic programmer-controller (PC) remotely positioned. Such an instrument has not yet been commercialized.

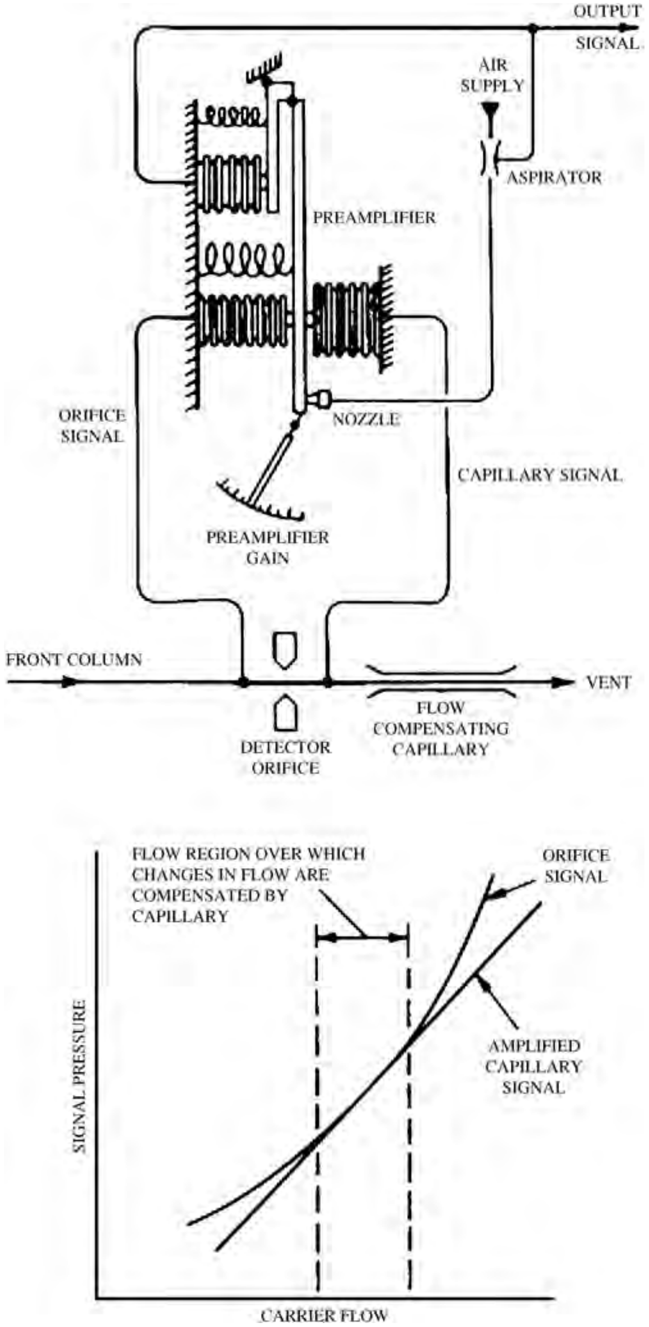

FIG. 8.12dd
Orifice-capillary detector and pneumatic preamplifier. A properly designed capillary compensates for any differential pressure fluctuations across the orifice due to changes in flow rate so that the final differential pressure signal output of the amplifier is the result only of changes in density of the carrier gas due to elution of sample components from the column.

Miscellaneous Detectors

There are a number of other detectors that have been introduced since the birth of GC, but because of issues such as high maintenance requirements, high customer burden, and unreliable operation over extended periods in the field, they have been limited primarily to laboratory applications. However, there are times when the minimum detection limits of the application cannot be satisfied by the basic detectors normally used in process GC. In those cases, some of these less-than-robust detectors have been used.

Photoionization Detector The photoionization detector (PID) functions by irradiating the column effluent with high-energy ultraviolet (UV) light generated by a high-voltage discharge lamp containing a noble gas (e.g., krypton) (Figure 8.12ee). The ions are collected at a polarized electrode, and the resulting current is measured with a FID-type electrometer. This detector is selective in that only compounds whose ionization potential is less than the UV radiation will be ionized. Compounds with aromatic ring structures give the highest sensitivities (as much as 10 times the FID), while compounds like methane and ethane with ionization potentials greater than 12.98 eV give no response with the commonly used PID tubes (9.5, 10.0, 10.2, 10.9, and 11.7 eV). The PID has a dynamic range of 10^7, extending from 2 pg to 30 mg. An advantage to this detector is that it does not require auxiliary gases, as does the FID. This advantage is offset by the fact that it does not respond sensitively to many of the compounds of interest, and it requires much maintenance to maintain quantitative accuracy.

Electron Capture Detector The electron capture detector (ECD) (see Figure 8.12ff) is yet another type of ionization detector. The column effluent passes between two electrodes, one of which has been treated with a radioactive source (tritium or nickel-63; the latter is preferred because of its extended detector stability) that emits high-energy electrons. These electrons produce large quantities of low-energy thermal electrons in the carrier gas, which are in turn collected by the other electrode to produce a steady-state current in the presence of pure carrier gas. Compounds eluting from the column that have an affinity for thermal electrons reduce this steady-state current, thereby producing the chromatogram.

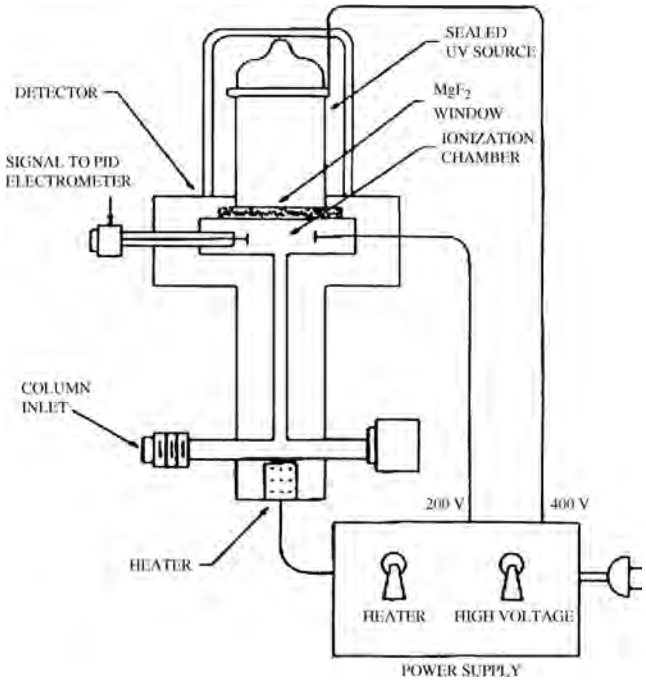

FIG. 8.12ee
Principal elements of a PID showing a 200 V supply for the collecting electrodes and a separate 400 V supply for the UV lamp. (From Driscol, J.N. and Spaziani, F.F., "PID Development Gives New Performance Levels," Research/Development, May 1976.)

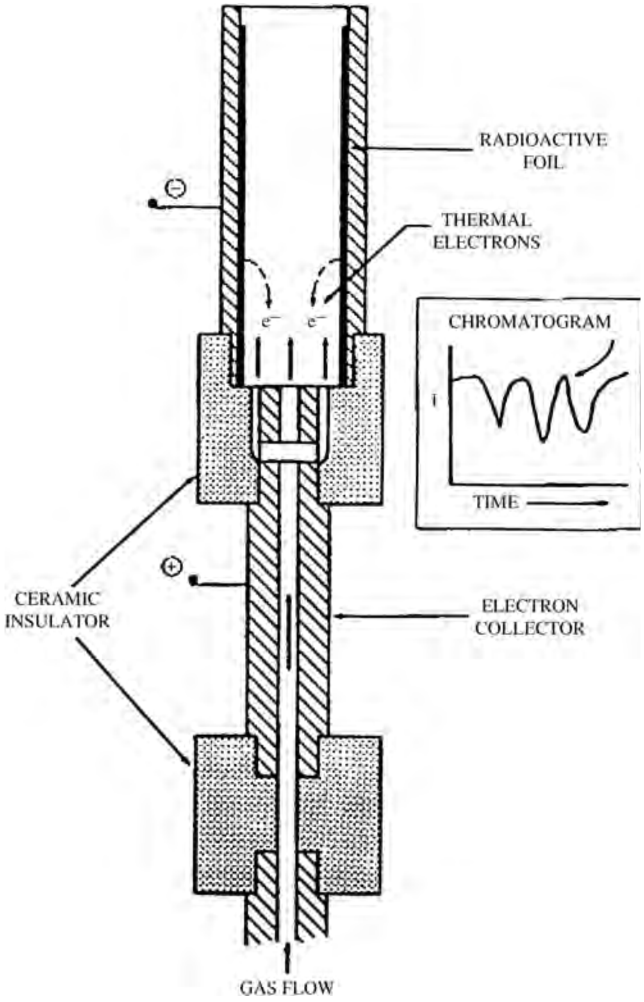

FIG. 8.12ff
Schematic of an ECD arranged for constant voltage operation. Also shown is the chromatogram produced by the reduction of the standing current when compounds of higher electron affinity than the carrier gas are eluted from the column and pass through the detector. (Courtesy of Varian Associates.)

The detector is thus highly selective, with halogenated compounds being the most responsive (detection at the picogram level). Other groups exhibiting good selectivity include anhydrides, peroxides, conjugated carbonyls, nitriles and nitrates, and sulfur-containing compounds.

Maintenance is of critical importance with this detector, more so than with any other GC detector (except the helium ionization detector, discussed next). It responds exceptionally well to oxygen, necessitating leak-free systems and oxygen-free carrier gases. Also, response to water vapor can cause unstable baselines so that molecular sieve traps (which require periodic maintenance) are required in the carrier gas lines. Finally, care must be taken to use this detector only with columns of very low bleed, as the condensed stationary phase in the detector can easily be polymerized (by radiation and electron bombardment) to a hard insoluble deposit, which is almost impossible to eliminate and which interferes with the proper functioning of the detector.

Although a pulsed mode of operation has improved the linear range of the ECD, it has not improved its robustness, and all of the above-outlined concerns still apply.

Discharge Ionization Detectors In contrast to the older-design ionization detectors that required a radioactive source of strontium, nickel, or tritium to produce metastable helium atoms by collisions with the high-energy electrons generated by the source, the newer designs require only helium. Two electrodes support a low-current arc through the helium makeup gas flow. The helium molecules between the electrodes are elevated from their ground state to form a helium plasma cloud. As the helium molecules collapse back down to the ground state, they give off a high-energy photon that will ionize all compounds having a ionization potential lower than 17.7 eV. Thus, the ionization detector will respond to volatile inorganics that the FID does not (such as NO_x, CO, CO_2, O_2, N_2, H_2S, and H_2). The ions are collected at polarized electrodes to produce a current, as in any ionization detector.

One version of this detector utilizes a steady-state helium plasma cloud, while a more recent design (see Figure 8.12gg) pulses the discharge (pulsed discharge detector (PDD)). Performance of the discharge ionization detectors is equal to or better than that of the older-design ionization detectors that require radioactive sources. In its helium photoionization mode of operation, it is a universal, nondestructive, high-sensitivity detector responding to fixed gases in the low parts per billion range. Its response to both inorganic and organic compounds is linear over a wide range (10^5).

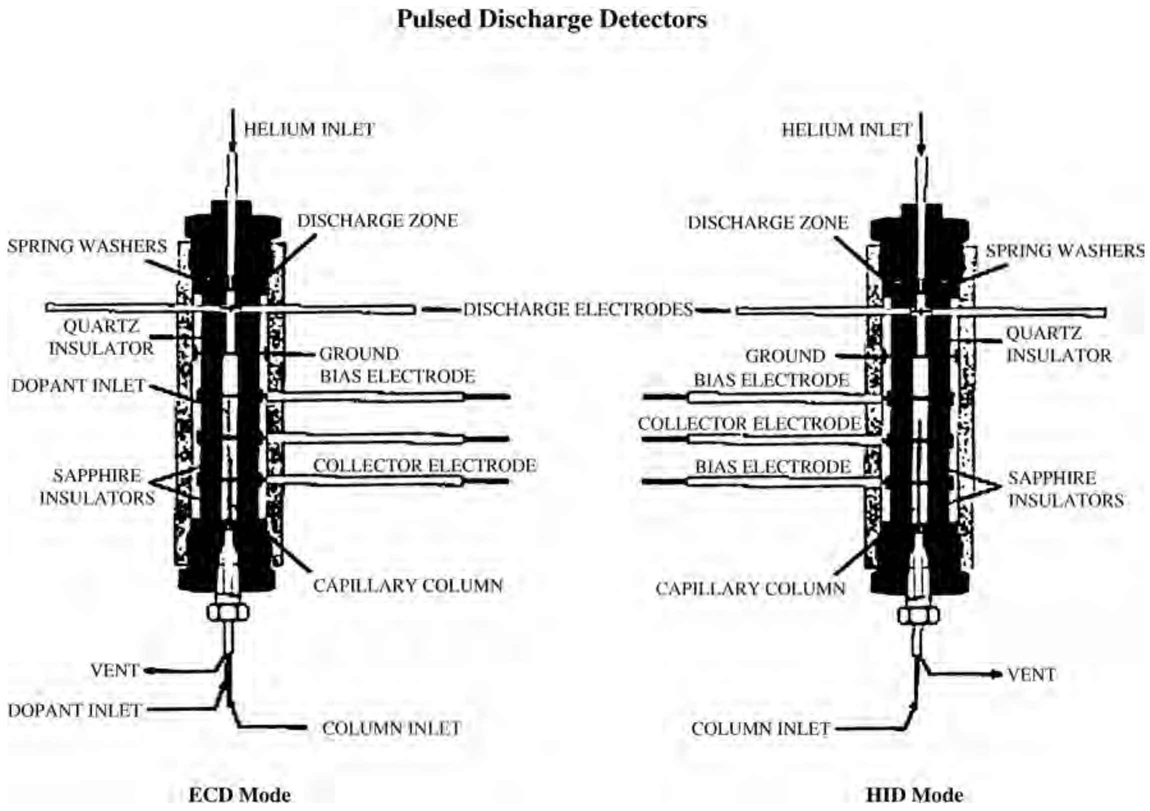

FIG. 8.12gg

Schematic of a pulsed discharge detector configured as a PHID and as a PECD. A stable low power, pulsed DC discharge, in helium is utilized as the ionization source. Eluents from the GC column flowing counter to the flow of helium from the discharge zone are ionized by photons from the helium discharge and the resulting electrons are focused toward the collector electrode by the two bias electrodes. The principal mode of ionization is photoionization in the range of 13.5 to 17.7 eV. (Courtesy of Valco Instrument Co. Inc.)

The PDD is extremely versatile. If the carrier gas is doped with methane at the column exit (see Figure 8.12gg), the PDD can operate as an electron capture detector with sensitivity and response characteristics similar to those of a conventional radioactive ECD. Its MDQ for halogenated compounds ranges from 10^{-15} to 10^{-12} g.

In addition, when the helium discharge gas is doped with a suitable noble gas such as argon, krypton, or xenon (depending on the desired final ionizing power), the PDD can function as a specific PID for selective determination of aliphatics, aromatics, etc., as discussed in the section devoted to photoionization detectors.

The HID is a high-maintenance item. It is the only detector that can measure permanent gases at the 1-ppb level. Therefore, leak-free plumbing is an absolute necessity. It responds to trace impurities, including water, in the carrier gas, thus requiring traps in the carrier gas stream to ensure the removal of these trace impurities. Clearly, this is a disadvantage for users not willing to devote maintenance time to monitor and frequently replace these traps. In addition, the HID is easily fouled by deposits from column bleed, which also contributes to a high noise level. Thus, its lowest detection limit is reached only with active solid supports such as molecular sieves.

CARRIER GAS FLOW CONTROL

Controlling carrier gas flow rate is of critical importance if one is to reproduce peak areas and retention times, and thus automate the analysis. Two methods, pressure control and flow control, may be used, but pressure control is by far the favored procedure used in process gas chromatographic instrumentation, for the following reasons:

1. A pressure regulator has an almost immediate response to downstream upsets (such as valve switching). A flow controller responds to flow upset only as fast as its flow set point allows.
2. A pressure regulator has the ability to provide some compensation for variation in retention time caused by changes in temperature.
3. A pressure regulator has the ability to supply the proper carrier gas flow rate to the column even in the presence of downstream leaks between it and the sample valve.

All pressure regulators are, to some degree, sensitive to temperature and input pressure. Tank regulators will not provide sufficiently stable output pressures under varying conditions of temperature and tank pressure. Thus, another regulator is mounted in the line close-coupled to the analyzer. Ideally, it should be mounted in the analyzer oven compartment to ensure a stable temperature environment, but few if any can withstand the 398°F (200°C) temperatures that are sometimes used. Therefore, it is important that this regulator have a minimum temperature coefficient (not as important a requirement when the analyzer is mounted in an analyzer shelter that has a fairly stable temperature environment) and that it can tolerate the input pressure changes it will experience from the tank regulator that is likely to be located outside, exposed to the varying temperatures of the environment.

For pressure drops across the column of 75 psi (5.3 bars), the relative error in peak area will be 1.7 times the relative error in the pressure drop. Therefore, to limit the error from this source to 0.5%, one must control pressure to within 0.4 PSIG (0.03 bars). In addition, assuming one is using a pressure regulator that is referenced to ambient pressure, the error caused by variations in ambient pressure will be 1.4 times the relative barometric pressure variation. Thus, errors of 0.2 to 0.5% due to changes in weather are difficult to eliminate.[16]

Recently, electronically controlled pressure regulators have become available and have been incorporated into PGCs. The heart of such a regulator is a solid-state pressure transducer that produces an electrical output proportional to pressure. This output is used to operate the integral control valve and to produce an output signal. In the case of the transmitter, miniature fluidic thermistors (fluistors) are used as pressure/flow controllers. Such an addition to the PGC is a tremendous advantage for maintenance staff since it allows for control of carrier gas flow rate from the remote analyzer maintenance station (AMS) rather than at the unit.

PROGRAMMER-CONTROLLER

The PC section is an extremely important part of a modern PGC, containing all the electronics to power the system, the controller, the data reduction hardware and software, and, of increasing importance, the communications package. Its design has changed radically over the past few years with the advances in electronic technology.

The PC unit can in theory be located in the field at the analyzer (stand-alone) or in a remote area such as the control room or instrument room close by (split architecture). The stand-alone design is by far the most popular. Although in this option the analyzer electronics are also usually located within the PC section, the primary purpose of the PC is to control all the functions in the analyzer. These include sample injection and column switching as well as various housekeeping tasks, such as modification of the detector signal, auto-zeroing, peak gating, integration, conversion of area units to concentration, and data transfer to the proper location. The transmitter utilizes what looks like a split-architecture design in that the electronics are packaged separately from the analyzer, but the two are close-coupled to each other in the field to yield a stand-alone PGC.

Most PC designs allow for operation in a Division 1 area when used with X or Y[*] air purge, and in Division 2 areas without purge.

Programmer

Programming tasks are managed by an on-board microprocessor-based computer. In older microprocessor-based PGCs, the PC was contained on several plug-in circuit boards located in a separate compartment from the analyzer. Current designs reflect the advances in electronics and focus on completely modular designs that allow for complete replacement of large portions of the electronic package (plug and play) for rapid repair and ease of maintenance. A number of provisions are made in the design to ensure the unit's rapid return-to-service in case of power failure.

Peak Processor

The peak processor section of the programmable controller has as its primary functions the detection of chromatographic peaks produced by the sample constituents of interest and the determination of the appropriate peak areas or peak heights. Peak detection is performed by comparing the instantaneous slope of the original (i.e., the rate of change) to some reference value. The objective is to differentiate between noise and the true onset of a peak. The peak detector can be disabled except for distinct time intervals (defined by so-called gates) and integration performed only if a peak is found within these gates, or alternatively, integration can be forced between the gates.

Most systems have the capacity of measuring different types of peaks and allocating areas on the basis of some internal logic. This peak allocation is usually determined as follows:

1. Incompletely resolved peaks: Areas are allocated by dropping a perpendicular from the valley minimum to the baseline.
2. Proportional area allocation: Areas are allocated in proportion to the gross areas of the peaks.
3. Tangent skimming: Used for small rider peaks on the tail of major peaks. A tangent is drawn from the valley point to the back of the rider peak.
4. Forced integration: Bypasses slope detector logic and forced integration between start and stop points.
5. Peak height: Value of the peak maximum used as direct measure of concentration.

The peak areas are then converted to concentration using information obtained previously from the analysis of calibration standards. Both the peak selection and peak measurement procedures are selected by the user from a menu of choices at the time of setup.

Data Acquisition

In modern microprocessor-based PGCs, the amplified detector signal is sampled by an analog-to-digital (A/D) converter and the digital values are stored in the RAM for processing. This is in contrast to the older procedure for acquiring chromatographic data, that is, monitoring the detector signal as a function of time with a potentiometer recorder. Recorder outputs are still present in some currently available PGCs to assist in setup and maintenance purposes. However, the record that is produced may not be as diagnostically useful as in the older designs, since, in many cases, it is not a record of the raw detector signal but an analog signal reconstructed from the RAM-stored filtered digital values.

Input–Output The term *process control* generally implies the direct control of a process variable by an on-line instrument. Commonly, adjustments are made continuously in process conditions in order to reduce to zero the difference between the measured value of this variable and a desired (set point) value. For instruments whose output is a continuous-trend representation of the measured variable (e.g., pH, conductivity, pressure, temperature, or flow), there is no problem in using this signal directly in a control scheme by comparing it to the set point and generating an error signal that is used to drive the process back to the set point. However, if the process variable is the concentration of one or two process stream constituents, the use of a chromatograph for the measurement presents special problems. The chromatographic signal is not continuous, but rather is transient. Furthermore, more than one component is represented in the information contained in the chromatogram, and this information is encoded as a function of time. Therefore, to be useful as a control instrument, the output must be deciphered and presented to the control loop in a form that is useful. For the traditional analog controller, this consists of a continuous analog signal (4 to 20 mA) whose magnitude is proportional to the concentration of the desired process variable. For an *intelligent* controller, this consists of a digital signal encoding the desired value of the process variable. Thus, a modern chromatograph must be able to deliver either of these outputs.

The input–output (I/O) characteristics of a typical PGC are summarized in Figure 8.12hh. Cyclically updated 4- to 20-mA analog trend signals proportional to the concentration of the analyzed peaks are available, as well as digital communication lines, RS-232 or RS-485. Various alarm signals are also generated. Additionally, provision is sometimes made to accept inputs from other devices where these data are required for a calculation of the desired process variable (e.g., flow rate and density measurements for BTU analysis).

Communication

Communication with the plant's distributed control system (DCS) is a must for modern PGCs. However, because of the large number of different DCSs in place—all using communication systems proprietary to the manufacturer of that

---

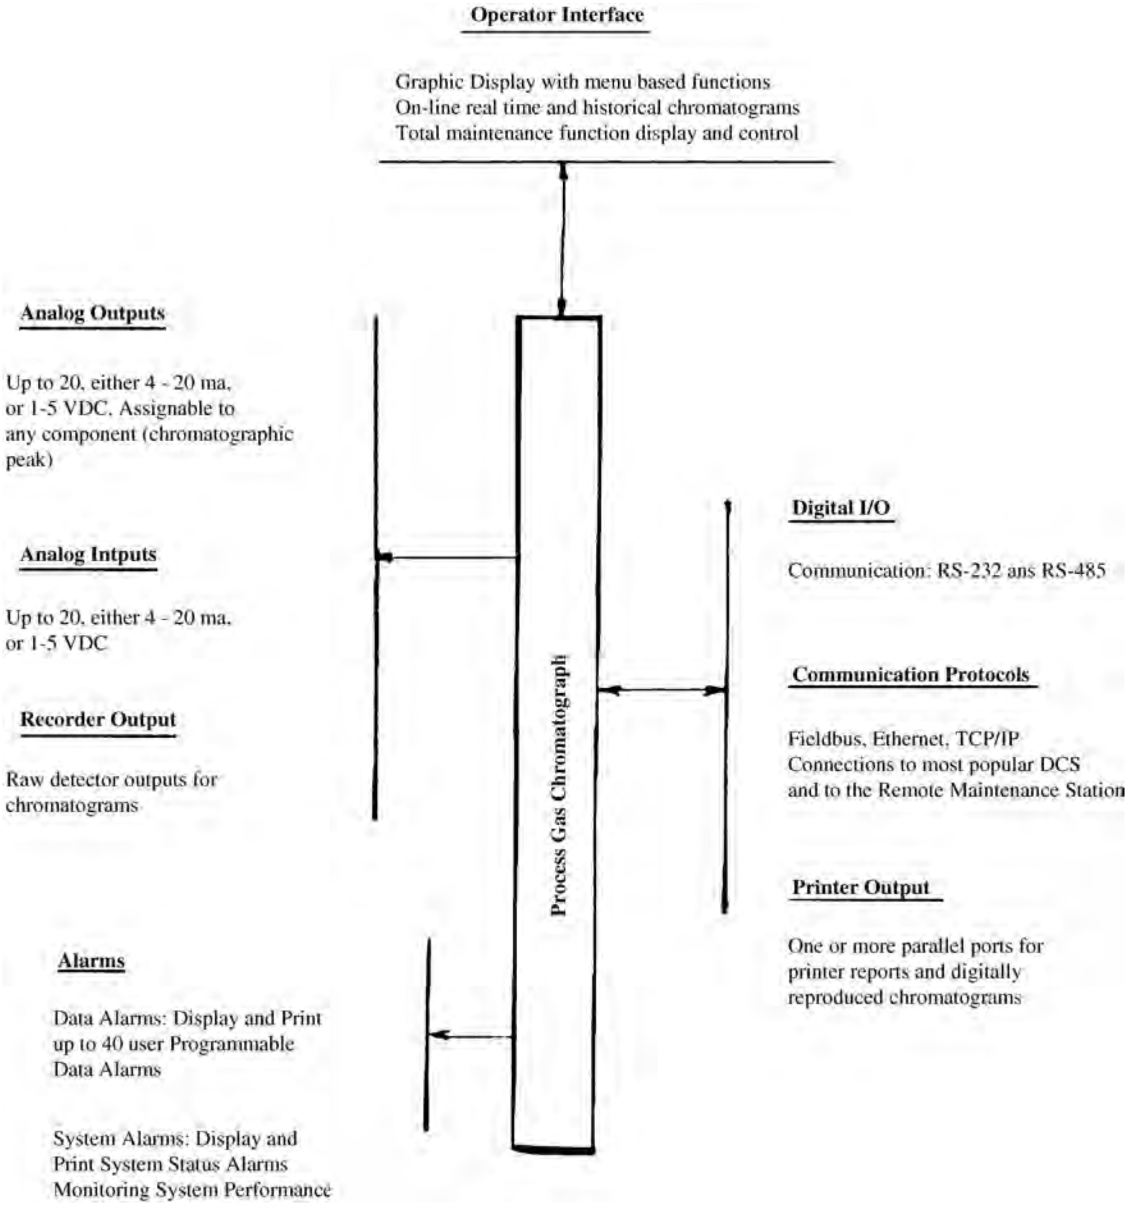

FIG. 8.12hh
I/O characteristics of a typical microprocessor-based PGC.

system—direct interfacing with all networks is all but impossible for the user to ascertain that a *gateway* is available to interface the PGC to his or her control system.

Over the years there has been much discussion and research into the development of a digital communication system to replace the traditional 4- to 20-mA analog standard. Worldwide adoption of an industry standard is still in the future. However, emerging from the various discussions within standards groups is a consensus that the local PGC will never be connected directly to the main data highway, but rather, communications will take place on a so-called fieldbus.

Fieldbus is a generic term that describes a new digital communication network that will be used in industry to replace the existing 4- to 20-ma analog signal standard. The network is a digital, bidirectional, multidrop, serial-bus communication network used to link isolated field devices. The bidirectional specification allows data to be transmitted in two directions at the same time, multidrop can be interpreted as a single bus with many nodes connected to it, and serial means that the data are transmitted serially according to RS-232 or RS-485 protocol.

Currently, there are two advanced protocols for all digital communication with field devices for measurement and control of continuous processes. These are the Foundation Fieldbus (FF) and the Profibus-PA (also in the field is a hybrid analog/digital protocol called HART, which uses a frequency-based digital signal superimposed on the 4- to 20-mA analog signal).

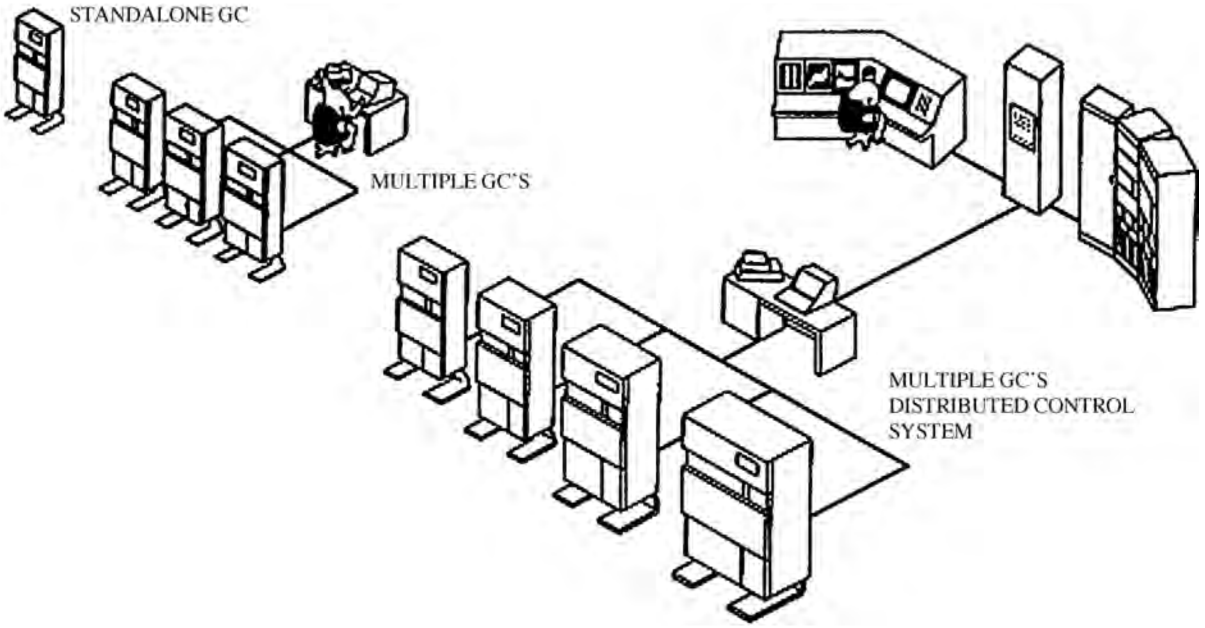

FIG. 8.12ii
Illustration of the various hardware and communication configurations that must be supported by a PGC. (Courtesy of The Foxboro Co.)

In the midst of this fast-changing environment, current PGC design must allow for operation in a number of modes—stand-alone or multiple—reporting either to a single process measurement, control computer, and compound computer, or to the DCS (Figure 8.12ii). Thus, many modern designs support the popular local area network (LAN) Ethernet protocol, as well as the new FF and Profibus-PA and older Modbus protocol.

Operator Interface

The operator interface has undergone many changes during the years following introduction of the gas chromatograph as a process control measurement device. In the original, rather crude chromatograph (from a modern technology viewpoint), the operator interface for control data also served as the maintenance technician's interface. However, in the modern system, the two functions have been largely separated. GC data, status, and validation inputs necessary to control and evaluate the process are sent to the control room, and the DCS console thus becomes the process or plant operator's interface. Maintenance and management data required to achieve maximum uptime are sent to a separate I/O interface called an analyzer maintenance station. This station can be positioned at the analyzer or at a remote location close by, with access to the system made with the ubiquitous industrial-hardened personal computer, or through a modem at a remote location some miles away. At the PC-based network workstation, any analyzer can be programmed and monitored. Graphical displays are available as an operator aid for simple operation, maintenance, and diagnostics. In addition, most programmer-controllers have a close-coupled I/O interface that includes a keyboard or display panel (illustrated in Figure 8.12jj) providing access to the application and data reduction programs. Real-time chromatograms can be displayed here as well as hours of stored chromatograms complete with voltage and cycle times for future comparisons to simplify ongoing maintenance. Thus, from either of these locations, the maintenance technician can monitor the performance of the analyzer and reprogram the unit if necessary.

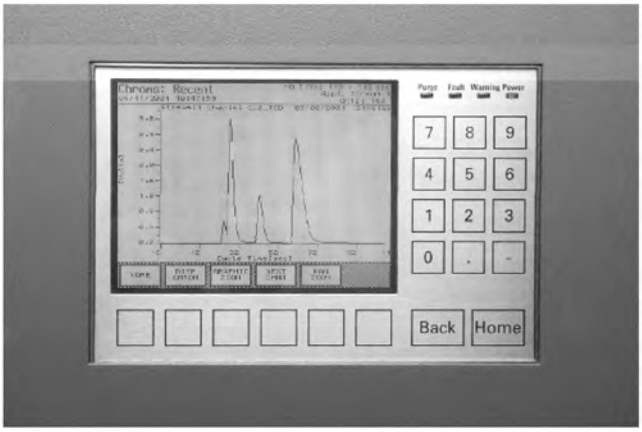

FIG. 8.12jj
Close-coupled full function AMS panel. (Photo courtesy of Siemens Applied Automation.)

The full-featured close-coupled I/O interface described above is not available for the transmitter. Instead, a panel of LED indicator lights visible through a window in the electronics enclosure (see Figure 8.12kk) provides the technician

FIG. 8.12kk

Close-up view of the see-through LED panel in the electronic enclosure. (Courtesy of Rosemont Analytical Inc.)

with an overview of the instrument's operational status. Further information and programming options are available through a PC-based AMS.

A communication structure that combines all of the above-discussed options is shown in Figure 8.12ll. The user requirements will vary depending on the size and complexity of the plant or process under consideration. Thus, the PGC is designed to satisfy simple as well as complex requirements.

Alarms and Diagnostics

The amount of self-checking and diagnostic features that will continuously monitor the health of the instrument and alert personnel to problems and their source will continue to increase in importance as an integral part of the PGC design.

Present units have two types of alarms: system alarms and data alarms. System alarms are concerned with the pneumatic, mechanical, and electrical operation of the system. They include low carrier gas pressure, low calibration gas pressure, low sample flow, detector failure, oven temperature high/low, PROM error, and EEPROM error.

The data alarms (Hi/Lo) are used to monitor the results of the analysis. In some cases, these alarms alert only the operator; in other cases, action is taken automatically (such as not updating the trend signal with a new value when larger- or smaller-than-expected deviations occur). Retention time drifts and low area counts obtained for a calibration sample are examples of this type of alarm. Additionally, continuous read and write tests on the RAM memory are performed by the central processing unit (CPU) to detect the failure of a particular cell.

Quantitation

Since peak area is less sensitive to instrument variables than peak height, it has become the method of choice for translating the chromatographic record into process sample composition.

There are four principle methods used to relate the record of detector response to the sample composition. They are:

1. Reference to calibration standards
2. Relative response factors
3. Internal normalization
4. Internal standard

All of these methods rely on some form of calibration of the detector by comparing its response to a calibration standard containing a known concentration of selected compounds. It is not always possible to prepare a standard of the process components (because of instability of the compounds, dew-point problems, expense, etc.) However, the preparation of stable mixtures of reference compounds for which the relative detector responses to the compounds of interest are known may be possible. Process sample composition is then calculated using this information. The advantage over direct calibration is that all components of the sample do not need to be separated, only the components of interest. This leads to faster and simpler solutions to some application problems. The disadvantage of these direct calibration procedures is the direct effect that instrument variables (such as pressure of the sample loop) have on the accuracy and precision of the analysis. Normalization, on the other hand, eliminates sample volumes and pressure as variables, but requires that all sample components be measured. The normalization procedure involves taking the individual component measurements and adjusting each according to its response factor, and then dividing by the sum of these individual adjusted areas to yield the percent composition of the sample.

SAMPLE HANDLING

The importance of the sample handling system and sample conditioning system (SHS/SCS) for ensuring reliability to the operation of the PGC and validity to its output cannot be overemphasized. In the author's experience, over 70% of the problems encountered in maintaining gas chromatographs can be traced to failures in the SHS/SCS. The reader who wishes to read detailed information on this subject should refer to Section 8.2 and the bibliography at the end of this section.

Unlike the laboratory chromatograph, when samples are usually held in an appropriate container and hand-carried to the laboratory where the chromatograph is situated, the PGC must receive a sample straight from the sampling point, untouched by human hands. Moreover, for the PGC

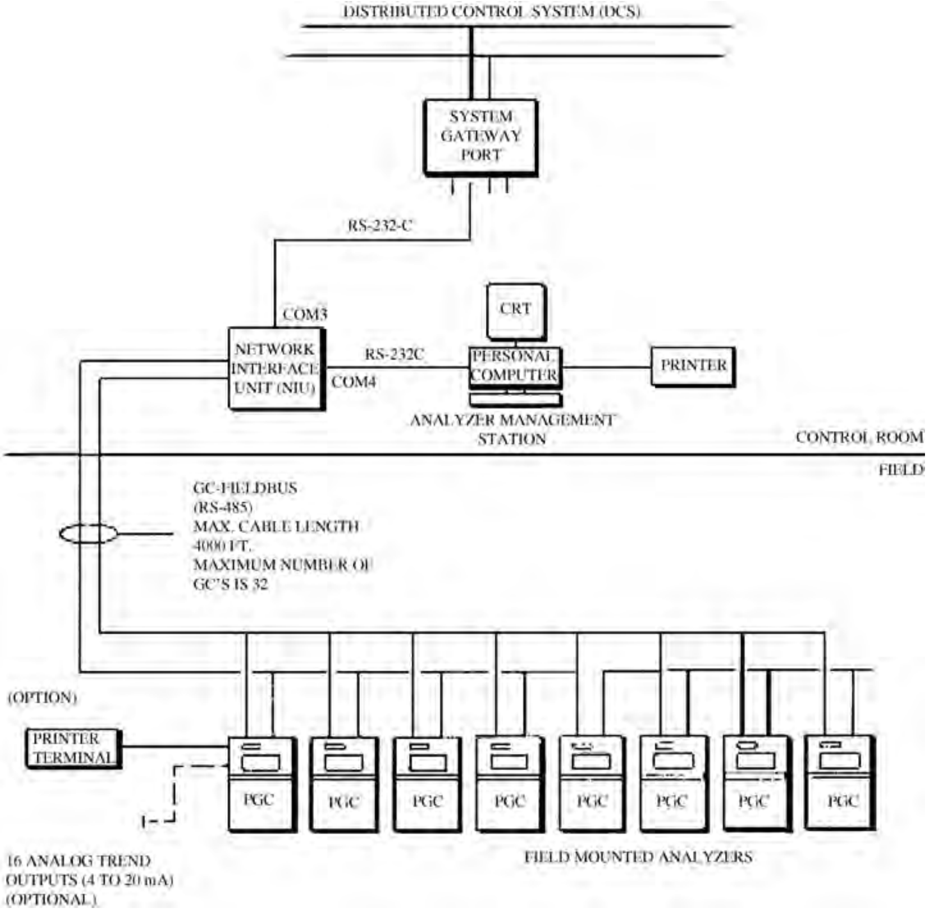

FIG. 8.12ll
A typical multi-PGC interface to the DCS. Some variation will exist among the various vendors. In this configuration only PGC data, validation, system alarms, and stream sequence control are available to the DCS operator. All control and data communication is available to the AMS operator. (Courtesy of The Foxboro Co.)

to provide an accurate analysis of the process stream, a sample must be made available that is representative of the process composition. This is no trivial task, since the process sample may be quite hot, may be under considerable pressure, or may contain water vapor, solids, condensed liquids, and so on. Thus, the PGC requires a sample handling front end to obtain, transport, and condition the sample.

The sample handling and conditioning system must:

1. Obtain a sample of the process stream that is representative of its bulk composition
2. Transport this sample to the analyzer within a time period such that the transport time plus the analysis time (i.e., the turnaround time) is short enough to satisfy the requirements of the control algorithm
3. Condition the sample (i.e., clean, vaporize, condense, adjust pressure, dilute, etc.) and present it to the analyzer in a condition appropriate to the analyzer specifications
4. Return the unused sample either to the process or to a waste disposal system

Sample Probe

Because the low-velocity portion of the sample that is found along the walls of a process pipe is not representative, and also because debris is likely to accumulate along the walls, a simple tap into the process line to obtain a sample is not acceptable. A sample probe is required, which by virtue of its design can also serve quite effectively as a preliminary stage of conditioning. This is accomplished by 1) removing the sampling point from the walls; 2) orienting the probe so that the sample must turn 180° at the point of entry, thus excluding larger particles that cannot make the turn due to their momentum; 3) including a large-porosity filter in the probe; and 4) designing the probe to be large with respect to the sample line and allowing gravity to assist in separating particles from the gas phase.

Sample Transport

The sampling point and analyzer may be separated by hundreds of feet. It is necessary, therefore, to divert a portion of the process stream (through an appropriate probe), transport it to the analyzer, and return it either to the process stream at a lower pressure point or to a suitable waste disposal system. The time necessary to transport the sample to the analyzer can, in some cases, constitute the largest share of the system dead time or turnaround time. Mounting the analyzer closer to the sampling point is the most direct way of decreasing this time. Lacking this alternative, the next best solution is to increase the flow sample in the line. An added plus to using a so-called fast loop is that it provides additional mixing due to turbulent flow, and thus further ensures a representative sample.

Sample transport time is a function of sample line length, line diameter, the absolute pressure on the line, and the sample flow rate. Neglecting compressibility, the transport time for a gas sample is given as

$$t_{lag} = \frac{VL(p+14.7)(530)}{F(14.7)(t+460)} \qquad \textbf{8.12(4)}$$

where

V = volume of sample per unit length, ml/cm
L = length of sample line, cm
F = volume flow rate (ml/min) of sample under standard conditions (14.7 PSIA, 70 °F)
t = temperature of sample, °F
p = sample line pressure, PSIG

Additional time must be allowed to purge sample conditioning equipment and any unswept volumes that are present due to poor design. Commonly, systems are designed to provide sample flow rates between 0.5 and 15 GPM (2 and 50 l/min).

Sample Conditioning

Conditioning of the sample either to allow easier handling or to put it into a form acceptable to the analyzer is always required to some degree. Conditioning may be as simple as pressure reduction and filtering or as complex as scrubbing and drying. Pressure reduction is the most effective way to prevent condensation of a condensable gas sample, and maintenance of a minimum pressure is the most effective way to prevent a liquid sample from vaporizing. Thus, pressure regulators for vaporization and pressure reduction are a common element of a conditioning system. In all cases, conditioning must be accomplished without affecting the sample composition. Some common sample conditioning elements are given in Table 8.12mm.

The basic technology of sample conditioning has not changed much over the last 40 years. Currently, a SCS is constructed using components (listed in Table 8.12mm) that have evolved from industries such as pneumatic and hydraulic service. These are mounted in a cabinet (which is usually secured to the outside wall of the analyzer shelter) and interconnected with tubing and fittings. Not being designed specifically to fit process analyzer needs, they have large dead volumes that are difficult to purge, thus leading to decreased sample system performance.

Recently, there has been some initiative directed toward changing the above-discussed conventional design to fit the specific requirements of the process analyzer.[17,18] The potential of a smart modular miniature process analyzer sampling system integral to the analyzer is being explored with the idea of decreasing the installed cost of the analyzer, increasing reliability of the system, and, at the same time, decreasing cost of manufacture. One problem with sampling systems, however, is that they are application dependent. Thus, the design must allow for the convenient connection of simple modules to form the more complex one required for the particular application. A proposed design (borrowed from the gas management systems used in the semiconductor industry) shown in Figure 8.12nn[19] uses a substrate assembly that provides the flow path for a process sample and consists of a variety of sample conditioning components. In turn, it is attached to a manifold system that will also accept various flow components and provide a flow path between two or more substrates.[20,21]

Thus far, implementation of these ideas has been restricted to fairly simple and straightforward applications such as clean, dry, light hydrocarbon streams.[22] The SHS used in this case is diagrammed in Figure 8.12oo and consists of four substrate assemblies manifolded together to produce the product shown in Figure 8.12pp.

The PGC transmitter described previously is offered as a single- or dual-process stream analyzer (with two sample calibration streams) complete with a modular sample handling system for close-coupling to the sample tap.

Unfortunately, sampling systems usually fail during process upset conditions (just when the analysis is most needed to bring the process back into control). Thus, whenever possible, these systems should be overdesigned to be able to handle the upset condition. A process data sheet containing the information summarized in Table 8.12qq is required to design a proper sample conditioning system. This definition of all the process conditions such as pressure, temperature, phase, particulates, chemical composition, physical properties (viscosity, density, etc.), and any possible process upsets that might occur, such as breakthrough of contaminants and runaway thermal reactions, ensures a design that will guarantee a correct sample presentation to the analyzer or, alternatively, a controlled shutdown or process hold with accompanying alarm signal.

Multistream Analysis

The PGC must be able to accommodate at least two streams, the process stream and the calibration or standard line. The clean calibration sample can bypass the SHS and be plumbed directly into a stream-switching valve that will allow the process stream to be diverted while the standard sample is flowing through the analyzer sample loop (Figure 8.12rr).

The sharing of one PGC among a number of process streams is not recommended but, unfortunately, is common

TABLE 8.12mm
Common SHS/SCS Elements

Element	*Function/Comments*
Filter	Remove particulates from the sample. Filtering below 10 microns requires vigilant preventive maintenance unless some sort of self-cleaning filter can be devised (e.g., cyclone separation with automatic cleanout).
Vaporizing regulator	If possible, at least in the case of a PGC, it is best to present the sample as a vapor. The vaporizing regulator is best located at the sampling point (to provide short transport times for the sample), but it can be placed at the analyzer.
Condensors/separators	Used in applications where condensables are to be removed from the vapor sample
Coalescers	Used to force finely divided liquid droplets to combine into larger droplets so they can be separated by gravity
Knockout pots	Used to collect liquid that has been separated from the sample. Should be provided with automatic drains.
Aspirators, ejectors	This is the preferred pump (by creating a vacuum) if the sample pressure is not sufficient to drive the sampling system. It is inexpensive and quite reliable because of the absence of moving parts
Rotameters	Consists of a ball or float in a tapered tube. Commonly used to measure flow. It is quite **unreliable** as the float tends to stick when the steam becomes dirty. It is a good indirect indicator of filter integrity.
Pressure regulators	Nonbleeding type, using corrosion resistant stainless steel and Teflon. Used to regulate pressure between sampling point and the analyzer as a means of controlling sample flow rate. Since the quantity of sample is directly proportional to the sample in the loop, in most cases a “block and bleed” configuration is used at the analyzer to equilibrate the sample to atmospheric pressure (this still does not eliminate inaccuracies due to changes in atmospheric pressure).
Pressure gauges	Installed downstream from regulators as an aid in setting regulator pressure and as an aid in maintenance checks. Installing in high speed by-pass lines and downstream of the analyzer eliminates extended turnaround problems that can occur because of the time required to flush sample from the pressure gauge bourdon tubes.
Steam or electrical heat tracing	To avoid condensation in the sample lines.

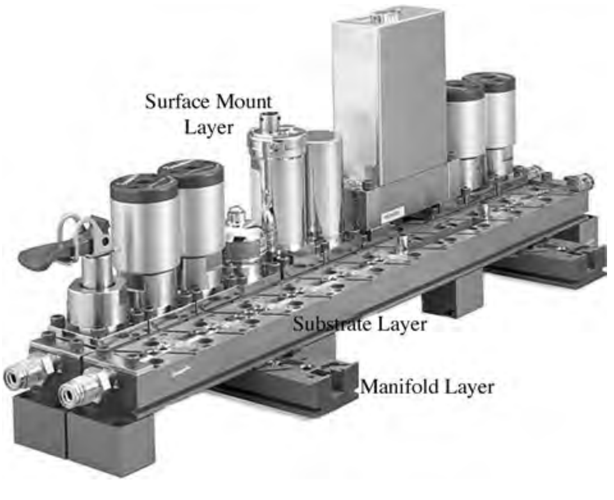

FIG. 8.12nn
Illustration of the architecture of a modular SHS with the various miniature SHS components surface mounted amd interconnected on a so-called substrate. Individual substrates can then be manifolded together to form the comple sample handling system. (Photograph ©2002 Swagelok Company; text ©2002 R. Annino.)

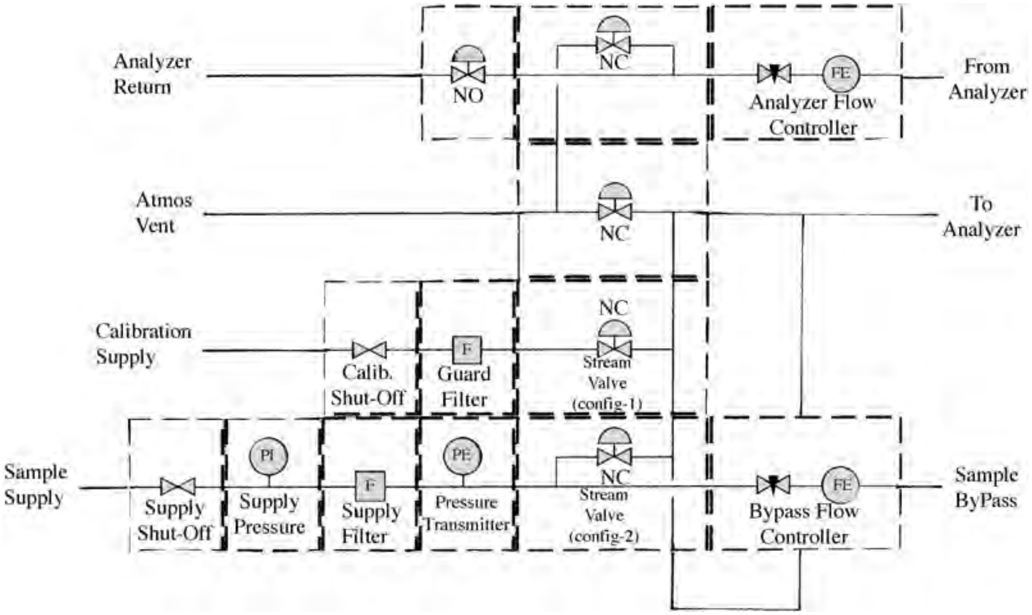

FIG. 8.12oo

practice in the industry as a way of justifying the cost of the PGC. It is questionable if the savings are real when one considers the increased complexity of the SHS/SCS (one for each stream) and the maintenance problems that are incurred. Add to this the fact that if the analyzer goes down, the analysis of more than one stream is affected—a result that may have more impact on product cost than purchasing separate analyzers. The availability of a lower installed cost PGC with its simpler modular SHS may affect a shift in this paradigm in the future.

In any case, stream switching requires a design that prevents mixing of the process stream samples. The double-block-and-bleed-with-bypass purge illustrated in Figure 8.12rr is probably the most efficient circuit for accomplishing this objective. In this circuit, all sample streams are flowing continuously, even in the unselected lines, thus ensuring up-to-date sample composition when selected. Sample stream 2 is selected in this case and continuously flushes the PGC sample loop and all other sample lines.

Sample Disposal

The vent of the PGC is almost totally carrier gas and is usually vented to the atmosphere, as is the sample loop vent line, unless the sample is toxic or otherwise environmentally harmful. In such cases, the sample must be vented to a specific waste disposal area. Alternatively, if a low-pressure point in the process stream is available, the sample can be returned to the process. Since the accuracy of the analysis is directly

affected by the pressure of the sample loop (unless one is using normalization procedures), provision must be made to either measure this pressure or provide hardware to maintain a constant pressure.

In summary, the SHS/SCS is a very important part of PGC hardware. Proper design and maintenance of this part of the system will ensure a large uptime for the analyzer.

There has been some attempt to utilize the micromachined type of GC that has been used with some success, in the laboratory and as portable GC devices, as the analyzer portion of a PGC.[23] The advantages of adopting such a design are, analytically, to achieve faster analysis and, engineeringwise, to design a smaller analyzer. Such a design puts an even greater burden on the SHS to provide an absolutely particle-free sample.

INSTALLATION

Typical utility provisions for PGCs are outlined in Table 8.12ss. Additional support services may be required, such as refrigerated or heated sample runs, an analyzer shelter, etc. As a result, installation costs account for the principal portion of a traditionally designed PGC system. One of the prime advantages offered by the PGC transmitter is a significant reduction in installation and operating costs. However, severe environmental conditions can prevail at many industrial locations that can have an impact not only on the instrument but also maintenance personnel. Thus, mounting the PGC in a walk-in environmentally controlled analyzer shelter may be necessary for the protection of maintenance personnel while they are working on the instrument.

A very approximate breakdown of these installation costs is given in Table 8.12tt. The difference between the installed transmitter cost and that of the traditional PGC may be more striking when one considers the cost of running heat-traced sample lines. However, one must not be misled by claims that in all cases the sample lines to a transmitter will be shorter since it will be mounted close to the sample point. Where the transmitter is mounted will always be a compromise between short sample lines and accessibility for maintenance purposes.

In addition, provision must be made for space to house the analyzer maintenance station. This unit may be located close by in a general-purpose area or located off-site and connected to the analyzer through a modem. Required gases (such as carrier gas, calibration gas, FID fuel, etc.) are stored as compressed gases in cylinders that should be placed in an easily accessible area outside, but fairly close to the analyzer shack.

TABLE 8.12ss
Typical Utility Requirement

Item	*Specification*
Instrument air	4 scfm per heated zone, 2 scfm purge
Instrument air quality	Clean, dry, –40°C dew point, oil free, particles ≤ 5 ppm microns, ISA grade hydrocarbon free
Carrier and other gases	Compressed gases, application dependent, may include helium, nitrogen, hydrogen, air, etc.
Compressed gas quality	Hydrogen, 99.995% ultra pure grade Burner air, ≤ 1 ppm hydrocarbons and ≤ 5 ppm water Helium, ≤ 99.995% ultra pure grade Nitrogen, 99.995% ultra pure grade
AC power	115 VAC, 50/60 Hz 10 amp service (per oven) or 220/230 VAC, 50/60 Hz

TABLE 8.12tt
Breakdown of Installation Costs

Item	*Traditional PGC*	*PGC Transmitter*
Analyzer with basic SHS	45,000	33,000
Analyzer shelter (1/4 pro rata)	35,000	NA
Installation and startup	20,000	5,000
Total*	100,000	38,000

* This is a minimum installation cost as each unit may require specific hardware/software depending on the specific PGC and the application.

Sample/Utility Connection Costs

Electrical	
1 in. conduit	$ 28/ft
2 in. conduit	$ 35/ft
Sample Lines	
Bare	$ 24/ft
Heated	$ 85/ft
Instrument Air	
1 in. carbon steel	
Steam Line (insulated 1.5 in.)	$ 30/ft

SUMMARY

Although the PGC is perhaps the most expensive of the commonly used process analyzers, it provides the compositional information that is required for tight quality control. The introduction of the truly field-mountable PGC with the remote diagnostic and maintenance procedures that involve one technician doing a quick field replacement of the designated module may lead to an even greater increase in the use of PGCs in process control applications.

Acknowledgment

The author thanks Stephen Staphanos of Rosemont Analytical and Robert Bade of Siemens/Applied Automation for their fruitful discussions concerning PGC design, and Peter Vanvuren of Exxon/Mobil and the Center for Analytical Process Control for information regarding modular SCS design.

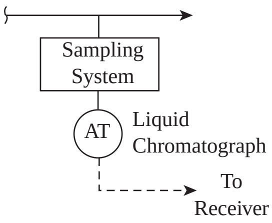
8.13 Chromatographs: Liquid

L. P. ROOF (1982) **B. G. LIPTÁK** (1995, 2003)



Flow Sheet Symbol

Types:	Laboratory: thin-layer and paper chromatography
Column:	Liquid–solid absorption, liquid–liquid partition, gel permeation (exclusion), and ion exchange
Detectors:	Fiber-optic probes, differential refractive index, fixed- or variable-wavelength ultraviolet, dielectric constant, electrical conductivity
Type of Sample:	Liquid
Sample Pressure:	5 to 1000 PSIG (35 to 7000 kPa)
Sample Temperature:	60 to 300°F (16 to 149°C)
Ambient Temperature:	0 to 122°F (–18 to 50°C)
Contacting Materials:	Stainless steel, Teflon standard; all conventional materials available
Utilities Required:	Electrical power, carrier solvent, air at 100 PSI (700 kPa)
Repeatability:	±0.5% for most applications
Cycle Time:	3 to 20 min for most applications
Special Features:	Multicomponent readout, molecular weight readout
Costs:	Laboratory system component costs: HPLC columns cost from $300 to $1800; solvent delivery pumps range from $2000 to $5000; fixed-wavelength ultraviolet–visible (UV-VIS) detectors cost $2500; variable-wavelength ones are about $5000; microprocessor-based data acquisition integrator costs about $3000. Complete process HPLC units cost about $50,000, and their installed cost is about $100,000.

INTRODUCTION

For the types of process samples that cannot be easily vaporized, the liquid chromatograph can be considered. In a liquid chromatograph column, the stationary phase can consist of a finely powdered solid adsorbent packed into a thin metal column, and the mobile phase can be an eluting solvent that is forced through the column by a high-pressure pump.

The mixture to be analyzed is injected into the column inlet and, after separation in the column, it is monitored at the exit by a variety of detectors. A wide variety of liquid chromatograph packings, eluting solvents, and detectors are available. Their combinations are selected to obtain the desired resolution.

COMPARISON WITH GAS CHROMATOGRAPHS

In many ways the liquid chromatograph is similar to the gas chromatograph. The basic difference is that the carrier is a liquid instead of a gas. All the other changes in the instrumentation used result from this difference. In fact, the only components that are significantly different are the components, that are in direct contact with the carrier solvent. These components will be discussed here.

Section 8.12 described the gas chromatograph and should be referred to for a basic understanding of the operation of chromatographs.

Carrier Flow

A typical carrier flow diagram of the liquid chromatograph is illustrated in Figure 8.13a. The sample valve injects a measured volume of sample into the controlled flow of carrier liquid, which transports it through the columns and into the detector. Interaction between the stationary column-packing material and the flowing liquid carrier causes the sample components of interest to move through the column at different velocities, providing the separation. For each sample component, the detector provides an electrical signal proportional to its concentration in the carrier. The electrical signal is recorded as a chromatogram or otherwise displayed in any of the standard chromatographic forms.

The Main Components

The instrument construction is similar to that of the gas chromatograph. The liquid chromatograph is divided into two parts: the analysis section and the control section. The analysis section is located near the process stream and is often contained in an instrument house. This section includes 1) the chromatographic oven containing the valves, columns, and detector; 2) the carrier supply; 3) an electronics compartment containing the circuitry for the detector, temperature control, valve operators, and local data handling; and 4) the sample preparation system, which may be in a separate temperature-controlled oven.

The control section is often located in the control room and includes the programmer to control the instrument and process the data, and the data display, which may include a strip-chart recorder, a digital display, or a digital computer for further data processing. The programmer discussed here includes stream selection, which may be a physically separate unit.

However, the liquid chromatograph operating conditions are different from those of the gas chromatograph. In particular, the carrier pressure is typically 1000 PSIG (7 MPa) at a flow rate of 1 ml/min, and the chromatographic cycle time is typically 3 to 20 min.

HPLC COLUMN SELECTIVITY AND RESOLUTION

As the constituents of interest pass through high-pressure liquid chromatograph (HPLC) columns, they are retarded due to the selective absorption or adsorption effects of the column packing. The more efficient a column, the more able it is to produce narrow peak bands during the elution of the sample.

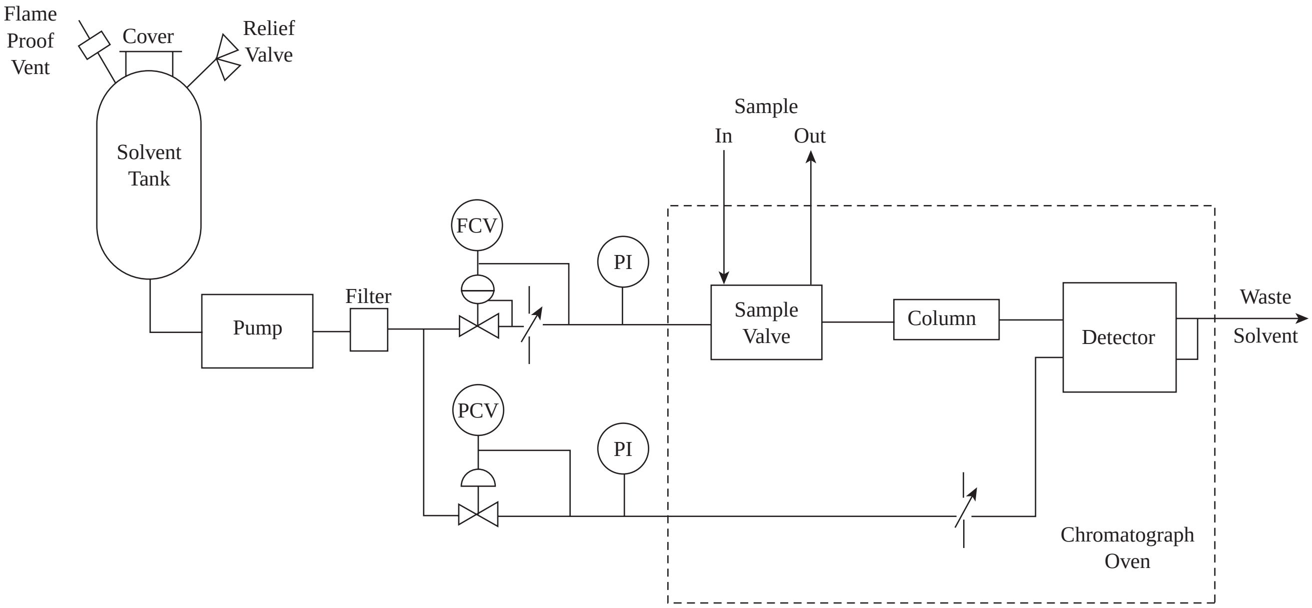

FIG. 8.13a
Carrier flow diagram of the liquid chromatograph.

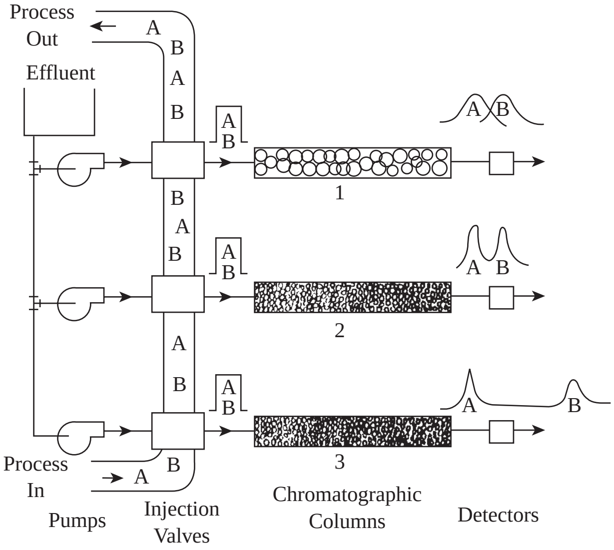

FIG. 8.13b
Relative efficiency, selectivity, and resolution of chromatographic columns.[1]

TABLE 8.13c
Selectivity Coefficient Names Used in Case of Different Columns

Column Type	*Name Used for Selectivity Coefficient*
Liquid–solid adsorption	Adsorption
Liquid–liquid partition	Partition
Gel permeation (exclusion)	Permeation
Ion exchange	Distribution

For example, column 1 in Figure 8.13b is inefficient, while columns 2 and 3 are efficient. Although the efficiencies of columns 2 and 3 are similar, their selectivities—the relative affinity of the sample constituents for the packing—are different, and the selectivity of column 3 is better, or higher.

The coefficient, which expresses selectivity (Table 8.13c), is called by different names as a function of the type of column used. Selectivity can be improved by increasing column size or by raising the ratio of distribution factors. The combined effect of efficiency and selectivity is called resolution. In Figure 8.13a, the resolution of column 3 is the best. Unfortunately, the steps that will improve resolution (smaller tubing diameter, smaller injection volume, finer packing, larger or multiple columns) also tend to extend analysis time and decrease downtime and maintenance due to plugging.

CARRIER SUPPLY

The carrier supply is made up of 1) the liquid carrier, 2) a reservoir to hold it, 3) a carrier pump, 4) pressure and flow controls, and 5) a filter and gauges. The carrier is either a single-component solvent or a blend of solvents. The selection and uniformity of solvents and solvent blends are critical to the liquid chromatograph, affecting both component separation and detector response.

A typical carrier reservoir is a 15-gal (57-1) stainless steel tank equipped with a flame-proof vent and a relief valve for flammable solvents. Some solvents are affected by oxygen or moisture in the air, and an inert gas, such as nitrogen, is either bubbled through or blanketed over the carrier in the tank.

Supply Pumps

There are two types of carrier pumps: air-driven and motor-driven. Both are reciprocating pumps containing check valves to divert the liquid through the pump. Air-driven pumps are powered by a large-diameter air piston, which is connected to a small-diameter liquid piston. The pump recycles at the end of each stroke. The air-driven pump provides a pressure, relatively independent of flow, that is nominally some multiple of the air pressure.

Motor-driven pumps are powered with an electric motor connected to an eccentric that drives one or more liquid pistons. The motor-driven pump provides a flow, relatively independent of pressure, that is controlled by motor speed or piston stroke length.

Pressure and Flow Controls

Pressure and flow control depend on the type of pump used. Air-driven pumps provide a pressure that is reduced to the desired value with a diaphragm pressure regulator. Flow control is provided with a diaphragm-type differential pressure regulator that controls a preset pressure difference across a fixed restriction.

This system has the advantages of flexibility and of providing a continuous, not pulsating, flow, but requires numerous components. Carrier control with motor-driven pumps is generally limited to flow control. Two flow control methods are in use. The first option is to manually set the motor speed or pump stroke to the desired flow. This has the advantage of simplicity, but the quality of control is often insufficient. If automatic, closed-loop control is provided; the quality of control is improved, but the system becomes more complex and expensive.

Valves

Liquid chromatographic valves operate on the same principles as gas chromatographic valves. The air-operated diaphragm valves, plug valves, and rotary valves discussed in Section 8.12 are also used. These valves are strengthened and use higher seal forces due to the high operating pressures. They also have smaller internal flow passage to reduce sample–carrier mixing in the valve.

COLUMNS

Liquid columns are packed in a $\frac{1}{4}$- or $\frac{3}{8}$-in. (6- or 9.6-mm) -outer-diameter straight stainless steel tube 2 to 12 in. (50 to 305 mm) long. The total column length in an instrument rarely exceeds 4 ft (1.2 m) and is more often 1 ft (0.3 m) or less. The columns are filled with particulate packing that is typically in the 5- to 10- micron range. There are four types of liquid columns classified by the principle of separation that is utilized in them: liquid–liquid columns, liquid–solid columns, size exclusion columns, and ion exchange columns. Table 8.13d lists a few typical column applications.

Liquid–Partition Columns

Liquid–liquid columns (liquid–partition columns) are filled with solid support, usually silica, coated with a liquid stationary phase. To prevent loss of the liquid, it is usually chemically bonded to the support. The separation depends on the relative solubility of the sample components in the stationary and mobile, or carrier, phases.

Liquid–liquid separations are subdivided into normal and reverse phase separations. In normal phase separation, the stationary phase is more polar (in the chromatographic sense, not dipole moment) than the mobile phase. While in reverse phase separation, the stationary phase is less polar than the mobile phase. When sample components can be separated with either type, the components elute from the column in reverse order when changing from the normal to the reverse phase.

TABLE 8.13d
Typical Column Applications

Column Type	*Applications*
Liquid–liquid, normal phase	Phenols Esters Pigments Cooking oils
Liquid–liquid, reverse phase	Pesticides Herbicides Organic aromatics Water pollutants
Liquid–solid	Plasticizers Antioxidants Organic acids Water pollutants
Size exclusion	Polymers Resins Carbohydrates Hydrocarbons
Ion exchange	Inorganic ions Dies Detergents Sugars

To improve separation, the binary mixture of solvents can be changed in the carrier. This is called solvent programming or gradient elution and is comparable to temperature programming in gas chromatography. Its use is limited almost exclusively to laboratory analysis.

Liquid–Adsorption Columns

In this case, the liquid–solid columns (liquid–adsorption columns) are filled with an adsorbent. Silica is the most common, but alumina and even charcoal are also used occasionally. Separation occurs as the sample components are retained by the adsorption sites on the packing. The mobile phase competes with the sample for adsorption sites and displaces the sample so it can move through the column. As with liquid–liquid columns, the mobile phase is chosen or blended to provide the desired separation of sample components. Solvent programming can also be used.

Gel–Permeation Columns

In gel-permeation chromatography, sample components are separated on the basis of their molecular size. Large molecules move straight down the column, while small molecules stick in the pores of the porous beads of the gel and are retarded.

Size exclusion columns (steric exclusion columns or gel-permeation columns) are filled with a porous solid, such as silica, or a porous polymer, such as cross-linked polystyrene (Figure 8.13e). The pore size in the column varies uniformly over a specific range, for example, 300 to 600 Å.

While moving through the column in the mobile phase, a sample component with a chain length (or more correctly, hydrodynamic volume) of 400 Å can diffuse into any of the pores that are 400 Å and larger. On the other hand, a sample component with a chain length of 500 Å can diffuse into only

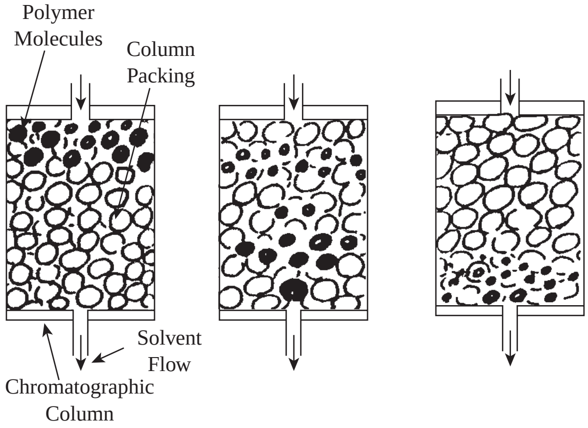

FIG. 8.13e
Three stages in the chromatographic separation of polymers: (left) at sample injection; (center) during separation; (right) at sample elution.

those pores 500 Å and larger. Since it enters fewer of the stationary pores, the 500 Å component moves through the column faster than the 400 Å component. Thus, long-chain or high-molecular-weight compounds elute from the column first. The mobile phase has no direct effect on the separation process in the columns.

Ion Exchange Columns

For process samples containing ions, ion-exchange chromatography can be used. These columns can be packed with ion-exchange resins, which contain exchangeable ions and therefore can separate the ions in the process sample from the neutral or oppositely charged components.

Ion exchange columns are filled with a cross-linked polystyrene resin containing charge-bearing functional groups on its surface. The stationary phase is called anion exchange if the functional groups are positively charged, and cation exchange if negatively charged. For the sample ions to be retained, they must be of opposite charge to the functional groups. The mobile phase is generally water containing a fixed quantity of ions of the same charge as the sample and buffered to a specific pH. The sample ions are separated, depending on how strongly they interact with the functional groups on the stationary phase in competition with the ions in the mobile phase. The quantity, the type of ion, and the pH in the mobile phase control the separation.

Electrophoresis

Mixtures of ions can also be analyzed by using a column of polymeric gel, which is saturated with an electrolyte. In this case, the sample to be analyzed is spotted onto the gel and two electrodes are connected (5000 V), which cause the migration of positive ions toward one and the negative ones toward the other. This method is used in analyzing mixtures of proteins.

DETECTORS

All detectors used in the liquid chromatograph are simplified, small internal-volume versions of other analyzers. The most common ones are based on the measurement of optical absorbance, refractive index, or the dielectric constant.

Optical Absorbance

The optical absorbance detector measures the absorption of a fixed wavelength in the ultraviolet or visible spectrum. It is highly sensitive to many absorbing sample compounds and relatively insensitive to external effects, such as temperature, flow, and carrier composition. It can only measure absorbing compounds in a nonabsorbing carrier.

Refractive Index

The refractive index detector measures the difference between the refractive index of the sample compounds and the carrier. With the proper choice of carrier, it is sensitive to all sample compounds, but the sensitivity is generally lower than that of the optical absorbance detector. It is also quite sensitive to temperature and carrier composition variations.

Dielectric Constant

The dielectric constant detector measures the difference between the dielectric, constants of the sample compounds and the carrier. Because, for compounds with no dipole moment, refractive index and dielectric constant are related, the advantages and disadvantages of this detector and the refractive index detector are similar. However, if, for example, the sample compounds have a dipole moment and the carrier does not, the dielectric constant detector has a higher sensitivity and more uniform response than the refractive index detector.

APPLICATIONS

The liquid chromatograph extends the advantages of the chromatograph to nonvolatile and thermally unstable samples, as well as polymers and inorganic salts. The prime advantages are the ability to both qualitatively and quantitatively analyze multicomponent streams with the versatility to analyze a wide range of samples.

When other instruments provide a satisfactory analysis, the liquid chromatograph is rarely used because it is more complex, more expensive, and sometimes less sensitive, and it requires a longer analysis time. However, there are many sample streams that can be analyzed satisfactorily only with the liquid chromatograph.

8.14 Coal Analyzers

D. H. F. LIU (1995) **B. G. LIPTÁK** (2003)

Types:	Thermogravimetry (TG), oxygen combustion bomb, total sulfur analysis, x-ray fluorescence (XRF), atomic absorption spectrophotometry (AA), coal slurry analyzers, prompt gamma neutron activation analyzers (PGNAAs), and the pulsed neutron type
Precision of Measurements:	Heating value, ±200 to 300 BTU/lb; ash content, ±0.05 wt%; and moisture content, ±0.05 wt% moisture
Partial List of Suppliers:	Fisher Scientific (www.fisher.co.uk) Gammametrics/Thermo Electron (www.gammametrics.com) Kanawha Scales (www.kanawhascales.com) Leco Corp. (www.leco.com) Parr Instrument Co. (www.parrinst.com) Science Applications Inc. (www.saic.com)

INTRODUCTION

Coal is widely used as a source of power and heat by the chemical, paper, cement, and metal industries. In the U.S., there are some 900 coal preparation plants and coal-fired power plants, and some 100 coal analyzers have already been installed in them. One key consideration in operating coal-burning facilities is the control of SO_2 emissions to the atmosphere from coal-fired power plants. Because the most economical method of reducing the sulfur content of coal is through the blending of various coals, on-line coal analyzers are often needed. The characteristics of coal are monitored for environmental protection, quality assurance, and process control.

This section will describe the instrumental methods for:

1. Proximate analysis: Used to establish the rank of coals, to show the ratio of combustible to incombustible constituents, to provide the basis for buying and selling, to evaluate the benefits, or for other purposes
2. Gross calorific value: Provides the basis for buying and selling
3. Sulfur analysis: Used in coal preparation and in the determination of potential sulfur emissions from coal combustion or conversion processes, or in the determination of coal quality against contract specifications
4. Composition analysis of major and minor elements in coal and coke ash: Predicts slagging and fouling characteristics of combusted materials and potential use of ash by-products (see American Society for Testing Materials (ASTM) Standards D346 and D2013 on methods for collection and preparation of coal samples for laboratory analysis)

The various methods for the on-line monitoring of coal streams are described in the paragraphs that follow.

THERMOGRAVIMETRY

Due to the recent addition of microcomputer control and dedicated data reduction, the thermogravimetry (TG) technique has become popular for routine approximate analysis of coal and coal products. The TG unit performs a multistep analytical sequence automatically and unattended.

The sample is loaded into a two-arm furnace tube (Figure 8.14a) and is sequentially dried and burned; the residue is then weighed. The tube allows the active gas (air or oxygen) to enter near the top of the furnace rather than through the balance mechanism. The low-mass furnace provides both rapid heating rates and a short cooldown time. The microcomputer controller provides automatic switching between the purge gas and the active gas.

Bituminous Coal Analysis

Figure 8.14b shows a typical proximate analysis of a bituminous coal using the automated TG system. The furnace is heated to 230°F (110°C) at a rate of 140°F/min (60°C/min) and is held isothermally for 5 min while water is vaporized off from the coal sample. The furnace is then heated at a rate

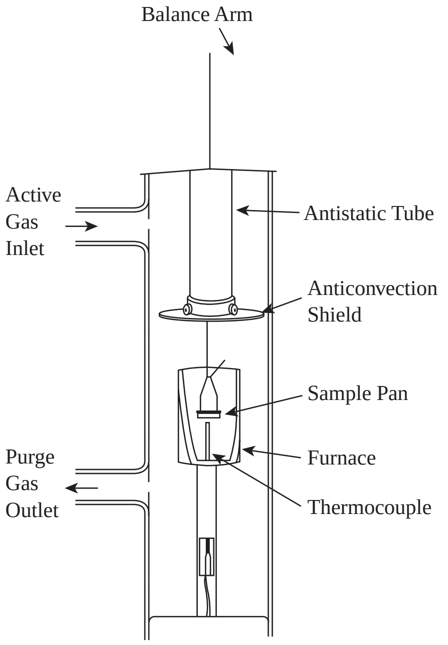

FIG. 8.14a

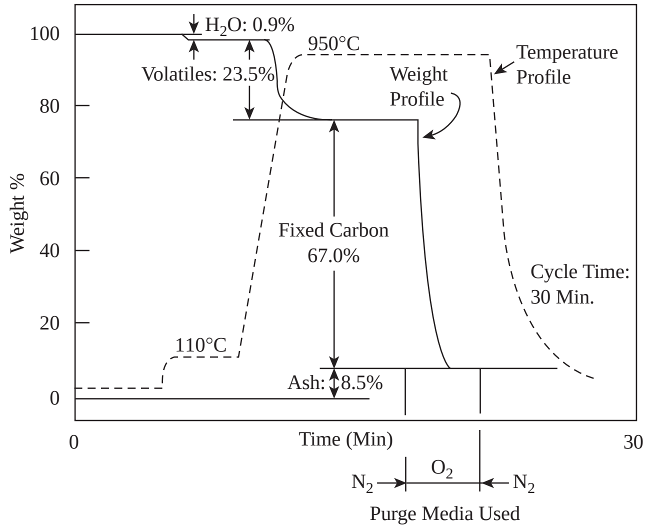

Fig. 8.14b
A typical proximate analysis of coal by microcomputer-controlled thermogravimetry.

of 176°F/min (80°C/min) to 1742°F (950°C) and held for 7 min while nitrogen is flowing through the TG, until all volatile matter is expelled from the sample. After the nitrogen purge, the purge gas is switched to either air or oxygen and the fixed carbon content of the char is oxidized, leaving the ash content as the residue.

The values from these determinations are read directly in weight percent from the chart recorder. The air or oxygen purge is switched back to nitrogen, and the system automatically cools back to load temperature. The elapsed time of the proximate analysis program and cooling of the tube back to load temperature totals 30 min.

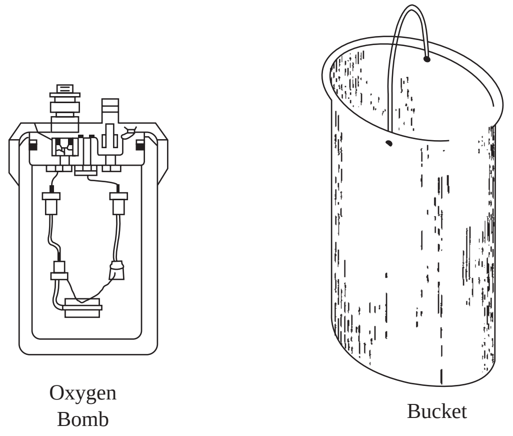

FIG. 8.14c
Oxygen combustion bomb and bucket used in the isoperibol calorimetry. (Courtesy of Parr Instrument Co.)

GROSS CALORIFIC VALUE

Gross calorific value is determined by burning a weighed sample of coal. A calibrated isoperibol oxygen bomb calorimeter is used for that purpose under controlled conditions (Figure 8.14c).

The bucket, which holds the oxygen bomb, provides good circulation and rapid thermal equilibrium for the bomb. Thermal jacketing is provided by a circulating water system, which maintains cooling water flow around the bucket. A microprocessor control system monitors and controls the jacket temperature, fires the bomb, and monitors the temperature in the bucket. The test continues until the controller determines that equilibrium has been reached.

A microcomputer uses the sample weight and temperature data—applying correction for acid, sulfur, fuse, and any added combustion aids—to calculate the gross calorific value.

TOTAL SULFUR ANALYSIS

An ASTM method for determining sulfur in coal uses the washings from the oxygen bomb calorimeter. Sulfur is precipitated as barium sulfate from the washings. The precipitate is filtered, ashed, and weighed. An automatic titrimetric system is also available for rapid sulfur determination using the oxygen bomb washings. The washings are titrated with a lead perchlorate solution to obtain a lead precipitate. The titration takes place in a nonaqueous medium to ensure complete precipitation and a sharp end point with a lead ion-selective electrode.

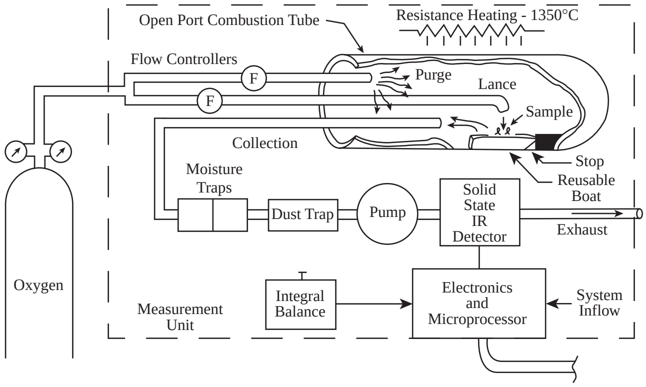

FIG. 8.14d
Apparatus for the determination of sulfur by the infrared detection method.

Other procedures use high-temperature tube furnace combustion methods for rapid determination of sulfur in coal and coke using automated equipment. The instrumental analysis provides a reliable and rapid method for determining sulfur contents of coal or coke.

Figure 8.14d illustrates the high-temperature combustion method of sulfur detection using infrared absorption detection procedures. The sample is burned in a tube furnace at a minimum operating temperature of 1350°C (2462°F) in a stream of oxygen to oxidize the sulfur.

Moisture and particulate matter are removed from the gas by traps filled with magnesium perchlorate. Sulfur dioxide is measured, using an infrared absorption detector. Sulfur dioxide absorbs infrared energy at a precisely known wavelength within the infrared spectrum. Total sulfur as sulfur dioxide is determined on a continuous basis.

ASH ANALYSIS

The major or minor elements in coal ash can be determined using x-ray fluorescence (XRF) techniques. The ash is fused with lithium tetraborate or other suitable flux and either ground or pressed into a glass disk. After that, the pellet or disk is irradiated, using an x-ray beam of short wavelength (high energy).

The characteristic x-rays of the atom that are emitted or fluoresced upon receiving the primary rays are dispersed, and their intensities are measured at selected wavelengths by sensitive detectors. Detector output is converted into concentration by computerized data-handling equipment. All elements are determined and are reported as oxides. They include Fe, Ca, K, Al, Si, P, Mg, Ti, and Na.

These major and minor elements can also be determined by atomic absorption spectrophotometry (AA). See Section 8.22 for a more detailed description of XRF and AA.

ON-LINE MONITORS

Figure 8.14e shows a schematic of a continuous monitor of moisture, ash, and BTU in coal. In this system, a microwave analyzer measures the moisture content of the coal, without requiring physical contact with the solids. (See Section 8.34 for an explanation of the principles of a microwave absorption hygrometer.)

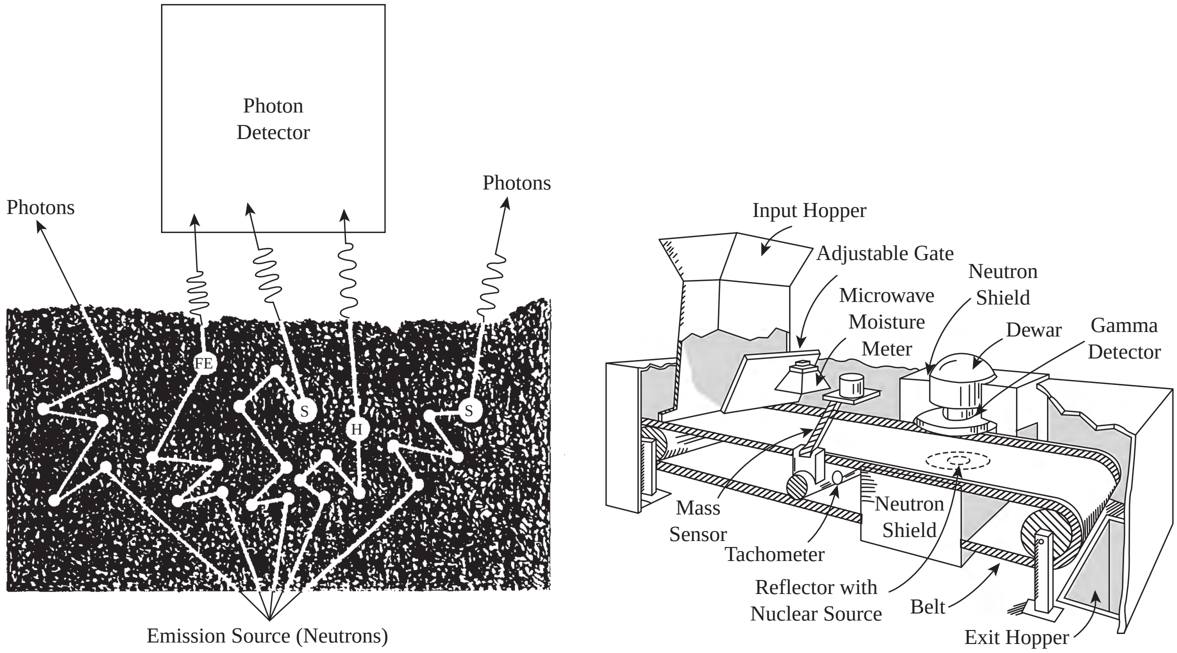

FIG. 8.14e
Coal analyzer. (Courtesy of Science Applications Inc.)

The *fingerprint* of a given type of coal is its distinctive gamma spectrogram. This is produced by the detection and counting of photons released from atomic nuclei in the coal as it passes over a small source of neutron emissions. The precision of the measurements of heating value, ash, and moisture content varies with the type of coal, typically 200 to 300 BTU/lb, 0.05 wt% ash, and 0.05 wt% moisture.

Gamma-Based Analyzers

The Harwell spectrometer is used in the prompt gamma neutron activation analysis (PGNAA) in-line coal analyzer.[1] This package also measures coal density and moisture content. This multiple detector package also includes a feed hopper to direct the coal into the analyzer and a discharge conveyor, which takes away the coal under variable speed control. The system also includes an RS422–RS232 interface and remote displays for reporting the readings made by the analyzer.

An analyzer is also available for determining the ash and solids contents of coal–water mixtures or coal slurries.[2] This analysis is made by the use of three probes, which are immersed into the coal slurry stream. The ash probe uses a source of low-energy x-rays to measure not only the ash content, but also the concentration of iron. The density probe used gamma rays to detect the percent solids (slurry density) of the mixture. The low-intensity neutron source in the aeration probe detects the amount of air in the slurry, so that the density measurement can be corrected for aeration effects.

Recent Developments

Western Kentucky University is developing a prototype coal analyzer operated with microsecond-wide 14-MeV neutron pulses and containing several gamma ray detectors. This analyzer measures the density and sulfur content of coal along with its BTU, moisture, and volatile matter content. This pulsed fast/thermal neutron analyzer is self-calibrating and provides improved accuracy in the determination of elements such as carbon, oxygen, and sodium. If you want to follow this developmental effort, refer to Reference 3.

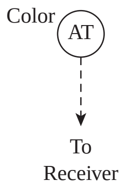
8.15 Colorimeters

J. E. BROWN (1969, 1982) **B. G. LIPTÁK** (1995) **M. W. REED** (2003)



Flow Sheet Symbol

Types:	Spectrophotometers and colorimeters (one-dimensional and tristimulus)
Types of Samples:	Liquid, gas, or solid
Wavelength Ranges:	200 to 1000 nm is typical
Spectral Resolution:	2 to 20 nm
Source Lamp:	Halogen, Xenon flash, LED, IR, fluorescent, fiber optics
Detectors:	CCD and photodiode linear arrays or photocells
Materials of Construction:	Standard materials, ordinary or quartz glass
Cell Length:	From 0.5 to 1000 mm
Sample Pressure:	Vacuum to 150 PSIG (10.6 bars)
Inaccuracy:	1 nm for array spectrophotometers, 1% for colorimeters
Costs:	$100 for a single-channel color analog channel; $1000 for fiber-optic spectrophotometers; on-line scanning systems cost $20,000 to $60,000

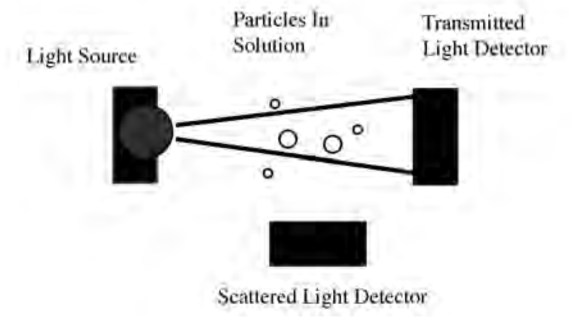

FIG. 8.15a
Turbidity measurement.

INTRODUCTION

Colorimetry involves the transmission, absorption, or reflectance of visible light and can be extended into the ultraviolet (UV) and near-infrared (NIR) spectrum. Gratings used in current spectrophotometers can be specified over a range of 200 to 1200 nm, with the visible range being from 400 to 700 nm. Visible color can be measured as an indication of a concentration or as an indication of pH in titration using dyes. Colorimeters and spectrophotometers associated with autotitrators and wet chemistry analyzers are discussed in a separate section of this chapter.

Visual colorimetry involves the matching of the sample color against standards in cuvettes, Nessler tubes, or thin films. Blood glucose meters use glucose oxidase on test strips and measure multiple-wavelength absorbances proportional to glucose concentration. Simple color wheel kits are used in water quality analysis to match depth of color in the liquid sample with a reference color calibrated in the concentration of the specific chemical end group for such measurements as pH or arsenic concentration. These are being replaced with low-cost hand-held colorimeters and spectrophotometers, which can be programmed for field use. This includes methods for turbidity measurement by nephelometry, which uses the ratio of scattered to transmitted light in suspensions, as shown in Figure 8.15a.

If colored filters such as RGB (red, green, and blue) are used, the device is a colorimeter. If a grating or prism is used, the device is a spectrophotometer. Due to the current technology of matching of CCD and diode arrays to entire spectral images, an entire spectral curve may be measured continuously. This is usually the case when the color of paper, textiles, films, or solids is being measured.

COLOR MEASUREMENT

Color measurements involve that part of the electromagnetic spectrum that is sensed by the human eye and brain. This region is approximately 400 to 700 nm. The colors of the rainbow are associated with specific wavelengths of visible light as listed in Table 8.15b.

TABLE 8.15b
Color and Wavelength Association

Approximate Wavelength (μm)	*Associated Color*
400–450	Violet
450–500	Blue
500–570	Green
570–590	Yellow
590–610	Orange
610–700	Red

Industrial standards involve color matching in which color standards are compared either by eye or with the assistance of a spectrophotometer. In the world of art,[1] separate color-matching methods have evolved that are based on color wheels that could be correlated to machine vision by taking spectral measurements of the subjective reference colors.

Absorbance and Transmittance Colorimetry

Absorbance spectra from spectrophotometers are used in the field of colorimetry of liquids where spectral absorbance curves can be compared one-dimensionally. The reason for converting to absorbance is that a logarithmic relation typically exists between transmittance at a certain wavelength and the concentration of colorants in liquid solutions. This is known as the Beer–Lambert law.[2]

Absorbance curves are generated from transmittance data with absorbance defined as the negative of the natural logarithm of T/T_o, where T_o is the transmittance of the reference standard. This standard might be a white reference tile or a cuvette of distilled water, depending on the sample application. If the spectral curve is from light reflected from a solid, these reflectance curves can also be curve-fit and compared one-dimensionally. This is suitable for quality control of materials. When consumer products are accepted or rejected based on their color perception by humans, tristimulus model parameters such as XYZ, Lch, or Lab are generated from spectral data and tolerances are set.

SPECTROPHOTOMETRIC ANALYZERS

Interference filters are selected for desired wavelengths as determined from the spectral relationship curves. Detector photoconductors are chosen to give spectral response in the visible region. All known photo detectors are least sensitive in the blue end of the spectrum. This can be dealt with by using prefilters or by using narrow spectral ranges, which are calibrated for more sensitivity.

Analyzers have to be built to carry out colorimetric analysis based on existing standards. Hundreds of one-dimensional color standards are used in the process industries. Other organizational databases include the American Public Health Association (APHA), the National Bureau of Standards (NBS), the National Institute of Standards and Technology

Spectrophotometer Design

The design of fiber-optic spectrophotometers is shown in Figure 8.15d. These units are small enough to fit in one's hand and, if purchased in larger quantities, are sold at unit costs of $500. Improvements in spectrophotometers include a flashed xenon light source with dual-beam measurement. This is actually necessary for flashed light sources due to the variability of flashes.

Dual-beam machines measure the spectrum of both the light source and the reflected light for each measurement. Spectrophotometers are characterized by the geometry of the light source and by the view of the photosensitive device. A common geometry is the so-called 45/0 design. This is achieved by illuminating the sample with a ring of light or fiber-optic cables at an angle of 45°. The reflected light is viewed at an angle of 0° or normal to the surface. Other geometries are 0/45 and 0/0.

The processed reflected light may be captured with an integrating sphere. An integrating sphere may or may not be used. Such a device is needed to compare the diffuse and specular components of the reflected light. The number of spectral measurement points has increased from about 16 in the 1980s to about 1000 currently. Sometimes colorimeters are marketed as 0/45 spectrophotometers by using up to 16 different filtered fiber-optic receptors in a ring for a 16-point spectral curve. This is inappropriate for materials having a directional shade. A true spectrophotometer collects the reflected light and then forms a spectrum. The buyer needs to make sure of the basic design inside the machine.

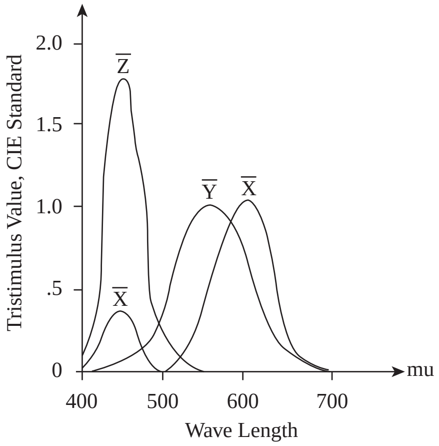

FIG. 8.15e
Spectral response of CIE standard values.

TRISTIMULUS METHOD (REFLECTANCE)

Reflectance color measurements utilize the reflected light from a sample to monitor the surface color of the sample. This measurement can be done with a one-dimensional color standard such as those discussed above, but in applications requiring better color definition, a tristimulus method must be used.

This method uses the Commission International del'Eclairage (CIE) model of human color perception. The method requires that the reflected spectrum from 400 to 700 nm be masked by the three functions shown in Figure 8.15e. The areas under the resulting curves measured as X, Y, and Z are correlated to human color perception. These values are normalized against standard values for different lighting conditions and types of observers. The algorithm has variations depending on the vision model used.

The parameters X0, Y0, and Z0 are defined to be the areas under the white reference reflectance mask curves. Values of X0, Y0, and Z0 will vary depending on the design of the spectrophotometer. To model the human color space, the Lab shade model is used. L is the measurement of lightness and is calibrated to have the values of 0 to 100. Lch (cylindrical coordinates for lightness, chroma, and hue) and Lab (rectangular coordinates) are two three-parameter models.

The Lab Algorithm of the Textile Industry

Following is a section of the computer code, written in BASIC, by the author that takes a 16-point color spectrum and computes Lab. The PX(I), PY(I), and PZ(I) functions are those shown in Figure 8.15e. For tables of spectral data and more information on computing Lab under specific illuminants and angles of observation, see Judd and Wyszecki.[3]

```

The Lab algorithm is commonly used in the textile, automotive, and plastics industry. The parameter a ranges from 0 to ± 128 (red to green), and the parameter b ranges from 0 to ± 128 (yellow to blue). A white reference sample is taken by calibration to have the value 100, 0, 0, while the dark reference is taken by calibration to have the value 0, 0, 0.

Calibration is a very important issue, and vendors employ many methods. The Lab or Lch measurement is often called the shade of the material. Shade measurements can be made from different angles and areas of view. A recent patent[4] that measures shade from different directions both on-line and off-line is given as a reference. Figure 8.15f illustrates how fiber optics can be combined with robotics.

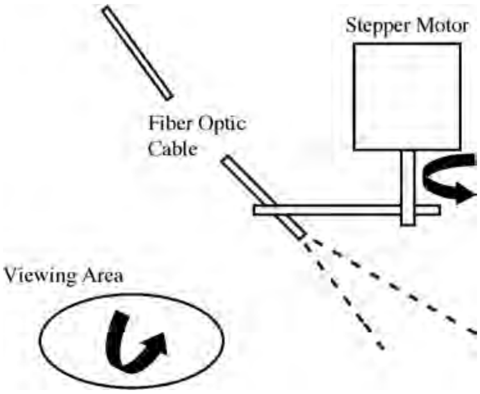

FIG. 8.15f

CONTINUOUS COLOR MONITORS

In-Line Liquid Color Measurement

In-line liquid color measurement is illustrated by Figure 8.15g. Recent advances in fiber optics have allowed the light source and the photosensitive device to be remotely located from the actual sensor windows. Various cells can be installed in flow lines from 0.5 to 6 in. in diameter, or *in situ* probes can be used for batch vessels. Temperature and pressure must be specified.

The width of the light path is a key consideration due to the absorptivity of the liquid. Glass rods of different lengths can be used as cell windows. Pressures may range up to 150 PSIG and temperatures to 250°C. The cost is lower if the sample stream can be reduced in size, pressure, and temperature. Cells can be in housings rated for NEMA 1, 4, 7 or Class 1, Group D, Division 1 explosion-proof.

On-Line Shade Monitors

On-line shade monitors that feature robotics for scanning webs may also use fiber optics to enable scanning while keeping the light source and spectrophotometer stationary. Fiber optics-based spectrophotometers can be interfaced to host computers that also control stepper motors for positioning the fiber optic over a moving web, or the web can be scanned.[4] Driver software is usually available for the spectrophotometer that will run in an application for data storage in large data files for statistical process control and trending.

The output information from continuous systems can be used for alarming or for analog data transmitted by 4 to 20 mA. Spectral information is transmitted serially by RS 232, RS 422, USB (IEEE 1394).

Flow Sheet Symbol

Types:	A. Measurement of filament temperature or resistance in catalytic combustion sensors is most common. Thermal conductivity is used at higher concentrations. Electrochemical and semiconductor sensors can be used when hydrogen and other known gases are to be detected. B. Flame ionization and photoionization with or without a chromatograph can be used for accurate hydrocarbon detection. Response varies and gases of concern need to be known in the design and selection phase of the project. C. Infrared can be used for both point and area (open-path) applications. It cannot detect hydrogen. *Note:* All three types are available as portable and fixed devices, and Type A is also frequently found in a personal (pocket) device version.
Materials of Construction:	Many choices exist and offer the opportunity to select an appropriate one for a given application. Stainless steel and polymer sensor heads with ceramic and metal sensors are usually offered. Various polymer and metal constructions with the appropriate optical window selections for photoionization and infrared applications are available.
Inaccuracy:	A. 5% of lower explosive limit (LEL); linearity and repeatability from 2 to 3% of LEL B. ppm concentrations can be detected and monitored C. ppm and low % LEL levels achievable, but vary dramatically and usually more a function of the application than the instrument
Drift:	A. 1 to 3% of LEL per month B. No generally accepted drift range per value C. No generally accepted drift range per value
Cost:	A battery-operated portable gas leak detector with sensing probe costs from $300 to $1000; a combined oxygen and combustibles sensor, microprocessor based, portable with diffusion sampling, costs $2500. For a permanently installed single-channel monitor with alarm or for a multichannel system, the cost per channel is $1000 to $2500. With sampled remote head installations, the installation cost of tubing can increase the per-channel cost to $3000 to $5000, and when a flame ionization or photoionization detector is used, the cost is more like $5000 to $10,000. A portable chromatograph with electrochemical detector and 50-ppb sensitivity costs about $15,000 to $20,000. Infrared systems cost about $1200 to $2700 for a point system and $7000 to $20,000 for an open-path system.

INTRODUCTION

The principles of operation and the applications of combustibles analyzers will be discussed in this section. These instruments are designed to detect the presence and measure the concentration of combustible gases and vapors on a continuous basis. The methods of detecting the presence of combustible gases and vapors can utilize the phenomena of catalytic combustion, electrical resistance, luminosity, thermal conductivity, infrared (IR) absorption, or gas ionization.

Of the above methods, the most widely used is catalytic combustion, where a change in the resistance or temperature of the sensing filament is caused by the catalytic combustion of the flammable gases, and this change is measured to detect the concentration of combustibles.

The second most widely used and a much newer technique is infrared. As will be seen, both techniques have both advantages and disadvantages. Most suppliers offer a variety of designs, so that the user might select the best choice for his application. The selection process usually considers cost, robustness, selectivity, poison resistance, speed of response, etc.

Selection Considerations

The most commonly used combustibles detectors are the catalytic filament units, which use a self-heated platinum wire as the catalytic surface to initiate combustion. A special portable variation of this unit is one that can be pinpointed at leaks by pointing a sample probe at the seals on manholes, tanks, or other containers that are likely to leak.

In some instruments, two filaments are provided: a catalytic combustion filament for low ranges, and a thermal conductivity filament for higher ranges. When the goal of the measurement is the detection of total hydrocarbons, or if the presence of lead, silicone, chlorinated compounds, or sulfur compounds could otherwise poison the catalytic filament, infrared and flame or photoionization analyzers should be considered.

Flame ionization instruments are discussed in Sections 8.12, 8.25, and 8.59 and involve the burning of the sample in a hydrogen flame. Since the flame of pure hydrogen contains practically no ions, even traces of organic material can be detected by the drastic rise in the number of ions in the flame.

Measuring circuits for catalytic bead-type sensors usually include the Wheatstone bridge for resistance and null-balance potentiometers with thermocouples for temperature measurements.

In addition to the discussion of the measuring means, complete loops consisting of measuring, readout, and alarm devices and their applicability are covered in the following paragraphs.

TERMINOLOGY, DEFINITIONS, AND BACKGROUND INFORMATION

In order to sustain combustion, each combustible gas or vapor requires a particular amount of oxygen. Some combustible gas mixtures ignite more easily than others (Table 8.16a). Additionally, the energy that is required to spark combustion also varies with the composition of mixtures.

Lower explosive limit (LEL): The lowest concentration of gas or vapor in air where, once ignition occurs, the gas or vapor will continue to burn after the source of ignition has been removed.

Upper explosive limit (UEL): The highest concentration of gas or vapor in air in which a flame will continue to burn after the source of ignition has been removed.

Flash point: The lowest temperature at which a flammable liquid gives off enough vapors to form a flammable or ignitable mixture with air near the surface of the liquid or within the container used. Many hazardous liquids have flash points at or below room temperatures. They are normally covered by a layer of flammable vapors that will ignite in the presence of a source of ignition.

The vaporization rates of the various liquids are a function of their vapor pressures, and vaporization rate increases with increased temperature. Flammable liquids are therefore more combustible at higher temperatures.

As can be seen from Table 8.16a, the ranges of air percentages within which some liquids and gases are flammable

TABLE 8.16a
Properties of Some Flammable Liquids and Gases

Material	*Chemical Formula*	*Specific Gravity Air = 1*	*Ignition Temperature in Air* (°F)	*Ignition Temperature in Air* (°C)	*Flammability Limits in Air (% vol.)* Lower	*Flammability Limits in Air (% vol.)* Upper
Methane	CH_4	0.55	1193	645	5.3	15.0
Natural gas	Blend	0.65	1163	628	4.5	14.5
Ethane	C_2H_6	1.04	993–1101	534–596	3.0	12.5
Propane	C_3H_8	1.56	957–1090	514–588	2.2	9.5
Butane	C_4H_{10}	2.01	912–1056	489–569	1.9	8.5
Toluene	C_7H_8	3.14	1026–1031	552–555	1.3	6.7
Gasoline	A blend	3–4.00	632	333	1.4	7.6
Acetone	C_3HO	2.00	1042	561	2.6	12.8
Benzene	C_6H_6	2.77	968	520	1.4	6.7
Carbon monoxide	CO	0.97	1191–1216	644–658	12.5	74.0
Hydrogen	H_2	0.07	1076–1094	580–590	4.0	75.0
Hydrogen sulfide	H_2S	1.18	655–714	346–379	4.3	45.0

are extremely wide. In detecting the presence of such vapors or gases, their LELs are usually of most interest, and, in order to maintain safety, flammable gas and vapor concentrations must be kept below those limits.

Since air is usually the diluent and is almost always present, all concentrations above LEL are usually dangerous. Instruments are commonly calibrated with ranges in LEL units. LEL is selected as a limit on acceptable safety, because in order to reach a buildup of atmospheric concentration of flammables, which is above the UEL, the concentration must have necessarily passed through the full hazardous explosive range. Similarly, bringing the concentration back down to a safe level below the LEL, the concentration must pass again through the full hazardous explosive range.

CATALYTIC COMBUSTION ON A HEATED FILAMENT

When mixtures of flammable gases or vapors in air come in contact with a heated and catalytically treated, fine, uniform, homogeneous platinum filament, combustion is induced at a temperature considerably below the normal ignition temperature of the particular gas or vapor. The heat generated by the combustion is measured by sensing the change of temperature of the filament by using thermocouples or by measuring the change of resistance of the filament.

Limitations

One of the common limitations of catalytic combustion type analyzers is the poisoning of the filament by silicon, sulfur, chlorinated compounds, or lead compounds. When detecting the concentration of leaded gasoline vapors, which contain tetraethyllead, a solid lead combustion product can form (by condensation) on the filament surface, which reduces its catalytic activity. One way to protect the filament against lead condensation is to maintain the filament at a temperature that is high enough to prevent this condensation. Compounds containing silicone can also poison the filaments.

These effects impair the life of the sensor to different extents, depending on sensor packaging. Specially packaged diffusion head sensors (to be discussed shortly) are more likely to last longer on such services than do the flowing sample type systems. Filament poisoning by chlorinated or sulfur compounds is also a serious problem.

In addition to special catalytic bead protective measures, ionization and infrared detectors should be considered as an alternate means of measurement where sensor poisoning is an issue.

A variety of filament protection means have been added to increase the poison resistance of the sensors. Figure 8.16b illustrates one such design, in which the catalyst support consists of a low-density macroporous structure that surrounds the platinum wire deep within the bead assembly. This provides both protection and an increased catalyst surface area. The reported result is a 10-fold or better increase in sensor life expectancy on such services as hexamethyldisiloxane (HMDS), leaded gasoline, Freon-12, ethyl mercaptan, and the like.

Life expectancies are usually defined in terms of exposure concentration hours. One high-concentration exposure of a poison has been known to knock out a sensor, and many do not respond in a fail-safe way. For this reason, nonpoisoning techniques should be considered, when poisoning is an issue.

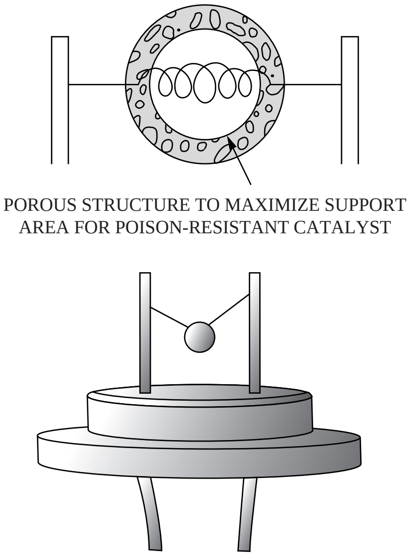

FIG. 8.16b
Porous bead construction provides poison resistance to catalytic combustion-type sensor.

Measuring Circuits

Whether the measurement is based on the change of temperature or resistance, it is convenient to use two filaments. One filament is constantly exposed to the sample (detector filament). The other is hermetically sealed in an inert atmosphere (reference filament). The reference filament is not activated with a catalyst, but its temperature resistance characteristics are similar to those of the detector filament. Its inert surface is usually exposed to the sample in a way that simplifies measurement compensation for changes in sample temperature, flow, and other potentially interfering characteristics.

The active detector filament and often the inert reference filament are mounted in a measuring chamber that is relatively large with respect to the size of the filaments. This permits a relatively large volume of sample to pass through the instrument, which ensures that the measurement filament is in contact with the sample and is measuring the current sample conditions. This design still only allows a relatively small portion of the sample to come in contact with the sensor, thereby increasing its useful life.

Thermocouple Detector In this design two thermocouples are used. One thermocouple is bonded to the reference filament, the other to the detector filament. The two thermocouples are connected in series opposition, so that a differential electromotive force (emf) is developed and applied at the terminals of the potentiometric circuit (see Figure 8.16c).

When a combustible gas or vapor is admitted to the measuring chamber, combustion increases the temperature of the detector filament, resulting in an increased emf for the thermocouple bonded to it. The temperature of the reference filament remains the same as the sample temperature, since no combustion occurs on its bead. The potentiometric transmitter or the indicating, recording, and alarming instruments respond to the resultant differential emf.

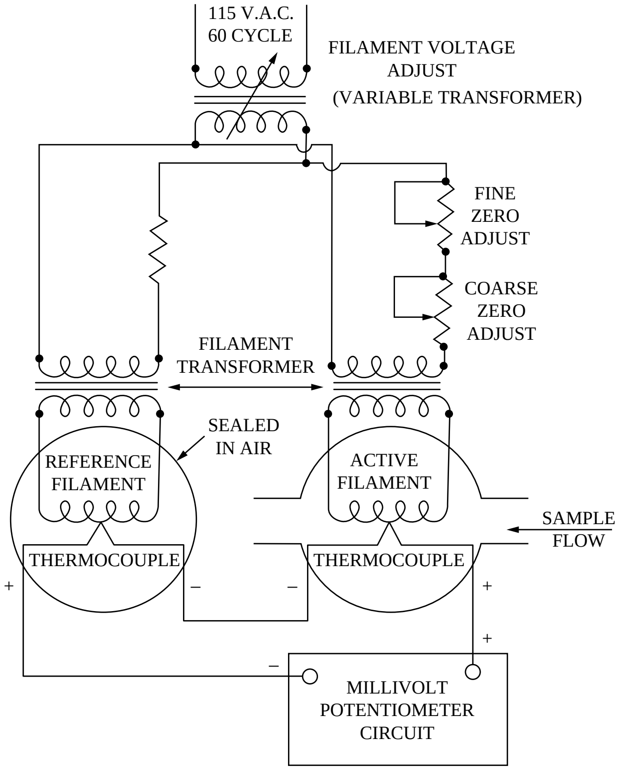

FIG. 8.16c
Thermocouple detector.

Wheatstone Bridge Detector A Wheatstone bridge is typically used for resistance measurement. Its operation is based on the comparison of an unknown resistance to a resistor of known value, as shown in Figure 8.16d. In this figure,

$R_1 = R_2$ = constant
R_3 = reference
R_4 = sensor's measured resistance (compared to R_3)

For current I to be zero,

$$\begin{aligned}
V_1 &= V_2 \\
V_1 &= \frac{R_3}{R_1 + R_3} V \\
V_2 &= \frac{R_4}{R_2 + R_4} V \\
\frac{R_3}{R_1 + R_3} &= \frac{R_4}{R_2 + R_4} \\
R_3R_2 + R_3R_4 &= R_4R_1 + R_4R_3 \\
R_3R_2 &= R_4R_1 \\
R_3 &= R_4
\end{aligned} \tag{8.16(1)}$$

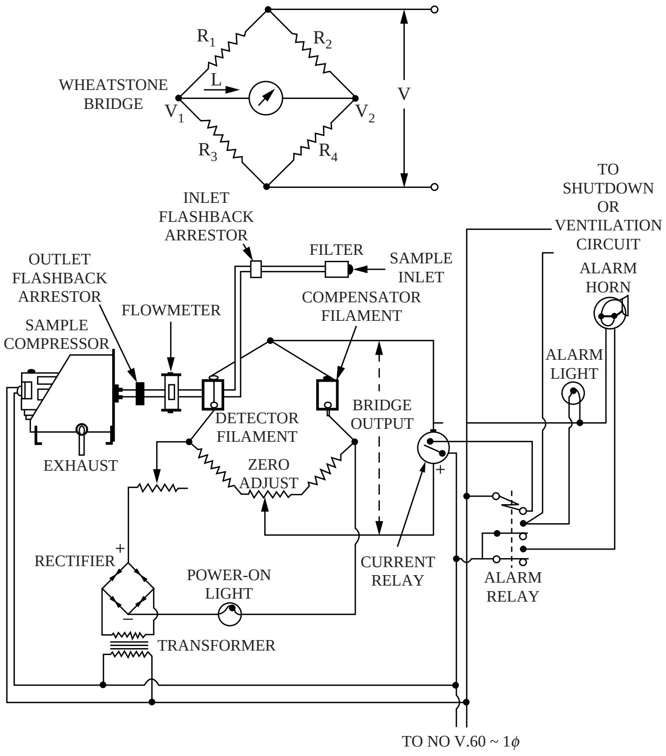

FIG. 8.16d
Wheatstone bridge detector with accessories.

In the catalytic bead-type combustibles detectors, R_3 is the reference filament and R_4 the detector filament. If the sample contains no combustibles, the bridge circuit remains in balance. If, however, there are combustibles in the sample, the combustion will cause heating of the detector filament. The change of resistance of the detector filament due to heating will result in unbalancing the bridge in proportion to the amount of additional heating caused by the combustible material in the sample. The output voltage of the bridge, which is in proportion to the concentration of combustibles in the sample, is detected by a transmitter or is used to operate indicating or recording instruments or to actuate alarms.

Diffusion Head Analyzers

In contrast to most analyzers, the diffusion head analyzer does not require a sampling pump or a controlled sample flow. Rather, the diffusion head type analyzer generates sample movement by diffusion, density difference, convection, or similar effects.

Diffusion-type catalytic bead sensors are available in poison-resistant designs and in intrinsically safe or explosion-proof construction. Figure 8.16e illustrates a conduit-mounted, diffusion type transmitter with 4- to 20-mADC output. This unit is provided with a stainless steel sensor head and a polyvinyl chloride (PVC)-coated anodized aluminum conduit. Diffusion sensors can be used in still air or provided with plant air aspirators or pumps to draw a sample flow over the sensor.

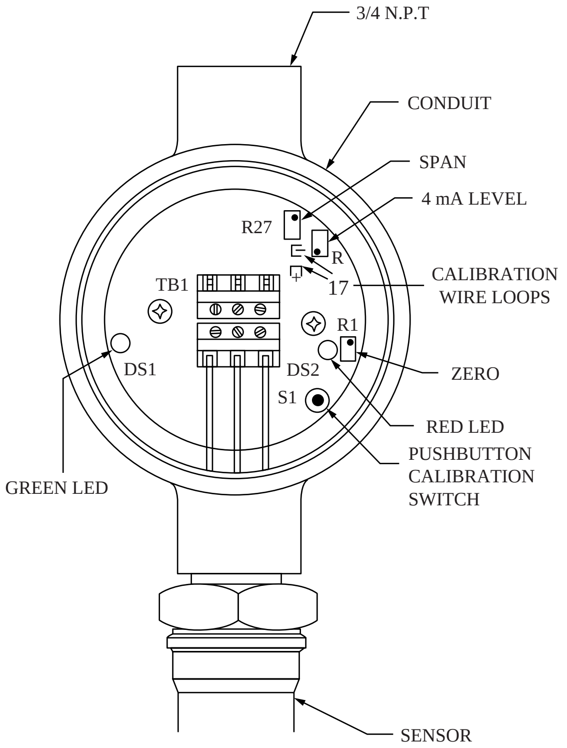

FIG. 8.16e
Diffusion-type sensor in combustible gas transmitter. (Courtesy of Sensidyne Inc.)

Semiconductor sensors are also available in diffusion head designs. Semiconductor sensors respond to a combustible (target) gas that has been absorbed onto the doped surface of a metal oxide semiconductor, by displaying a change in the resistance of the semiconductor surface. By varying the doping layer, the manufacturer can vary the responsiveness of the detector to various materials. As with the catalyst bead surface effect sensors, poisoning is an issue.

Diffusion type electrochemical and semiconductor sensors are also available to detect hydrogen, using a sensor that is not responsive to other hydrocarbons. This is desirable in semiconductor manufacturing plants, where it is a continual task to monitor for hydrogen leaks.

Sampling System

When diffusion-based systems are not adequate, active sampling systems may be required. The sampling systems should be carefully designed. Most importantly, the sample admitted into the analyzing cell should be wholly representative of the combustible components that are present in the monitored area. The sample should also be free of particulate matter and moisture.

In applications where the sample is at excessively high or low temperatures, it is advisable to use sample conditioners. This is particularly important if the sample is hot and humid and tends to cool while passing through the sampling line. The reason is that cooling would result in condensation, which, in turn, could block the sample line or introduce a time lag in the analyzer response. The sampling system should permit transport of the sample to the analyzer cell at the proper rate and minimum transportation time lag.

Since the vapors of all flammable liquids are heavier than air, detection of such vapors requires that the probes be located near the ground. Gases like hydrogen are lighter than air and require elevated probe locations. In dealing with gases, their molecular weight (heavier or lighter than air) will decide whether sampling probes should be near the ground or the ceiling of the monitored area. This may seem trivial, but is still worth mentioning.

Accessories

It is important to make sure to avoid the propagation of flame when the sampled air containing an explosive mixture of gas is ignited on the detector filament. This is not a problem when the concentrations are low or below the LEL, but a leak or spill can result in concentrations exceeding the LEL (within the explosive concentration envelope), and this leak or spill can become a source of ignition in that area of the plant.

Flashback arrestors of coiled copper screen or sintered metal are usually provided at the inlets and outlets of filament chambers. These prevent the energy that is liberated by combustion from propagating to the outside.

Samples containing hydrogen or acetylene, with concentrations of oxygen in excess of that found in normal air, have high rates of flame propagation. In such mixtures, standard flame arrestors cannot dissipate the energy liberated by combustion and, therefore, special flame arrestors have to be used.

To ensure safe operation of the detectors, a variety of alarms are provided. These alarms can signal filament failure, power failure, alarm relay failure, and low sample flow rates (not available for diffusion head type designs). Many alarms do not detect sensor poisoning as a sensor failure. If in a particular application poisoning is likely, one should make sure to thoroughly understand the functioning of the alarms before issuing a purchase order.

To ensure that an adequate amount of sample passes through the measuring chamber, flow meters (rotameters) and needle valves can be provided for all except the diffusion head type of units.

SELECTION OF COMPLETE INSTALLATION

The selection is usually made from among three basic systems, and the choice is based on the plant layout, the required speed of response, and economic considerations. The three choices are 1) remote head (continuous measurement, continuous readout); 2) multiple head (continuous measurement, sequential readout); and 3) tube sampling system (sequential measurement, continuous readout).

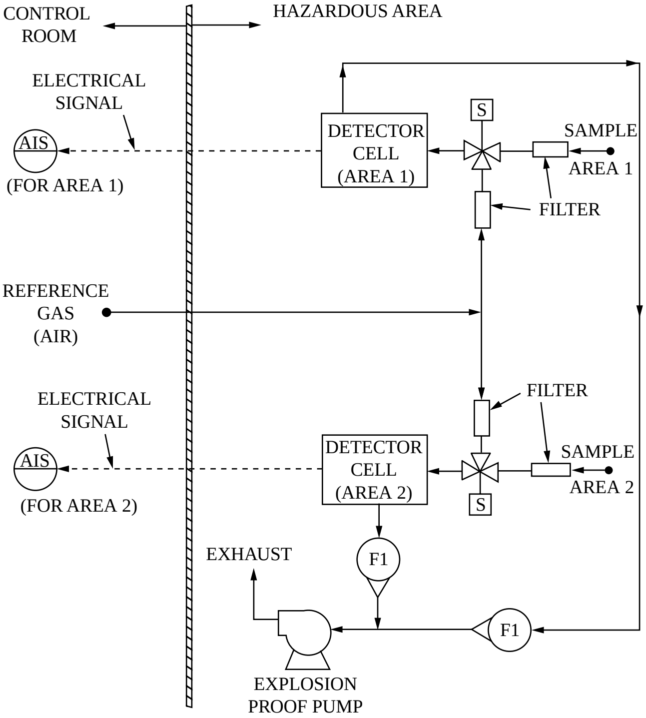

FIG. 8.16f
Remote head system.

Remote Head System

The remote head system offers the maximum application flexibility, but it does that at the highest initial cost. As shown in Figure 8.16f, this system typically consists of a number of locally mounted analyzer heads (suitable for hazardous areas) and an equal number of panel-mounted control and readout devices. The maximum number of areas monitored from one central panel is a function of the capacity of the sample pumps (or aspirators) and of the physical size of the panel. Because the analyzer heads are located in the monitored areas, the speed of response is fast.

Samples are continuously drawn, and the electrical signal corresponding to the measured combustible concentration is instantaneously transmitted to the control unit. The used sample is continuously withdrawn from the analyzer head through the tubing to the aspirator and is exhausted. Since the analyzer head is in the monitored area, it can be temperature controlled to prevent condensation. The remote head system should be selected where fast response is essential and justifies the cost.

Multiple Head System

Multiple head systems are used where at least four or more areas are monitored and a cyclic readout with the accompanying time delay can be tolerated. The multiple head system consists of a number of analyzer heads (one in each area to be monitored), one control unit with readout, and one or more

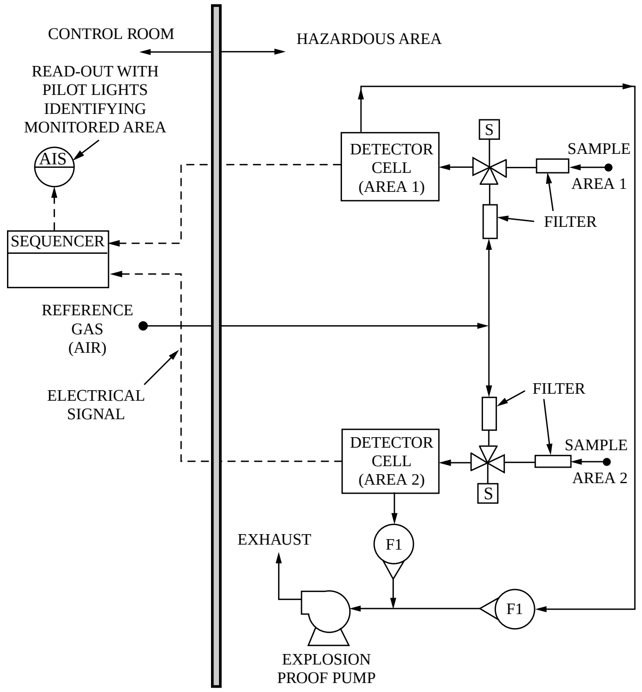

FIG. 8.16g
Multiple head system.

sample pumps. The electrical circuit incorporates a single readout device common to all analyzing cells.

A separate alarm unit is associated with each detecting unit. The sample is drawn continuously to each sample chamber. The pump continuously withdraws the expended sample. The electrical output of each unit is transmitted to the panel, where sequential readout is provided. The dwell time for each area is typically 10 sec; i.e., if four areas are being monitored, 40 sec elapse between subsequent readings for a given area.

This system is less costly than the remote head arrangement, but it can be used only where the combustible concentration buildup is likely to occur at a slow rate (see Figure 8.16g).

Tube Sampling System

The tube sampling system consists of one analyzer head, one readout device, and a sample pump. This may be the least expensive arrangement, but sometimes the tubing cost (purchase and installation) can exceed the amount saved on the instrumentation. Samples from different areas are sequentially admitted to the common analyzer head. The electrical signal is then transmitted to the readout device.

A sample selector unit, consisting of time-sequenced solenoid valves, is arranged to admit one sample to the detector and connect all other sample lines to the sample pump. The sample is drawn continuously through each line. The sample selector is located at the analyzer head; thus lag time between successive analysis and delay due to sample travel is minimized, since a fresh sample is always present at the sample selector.

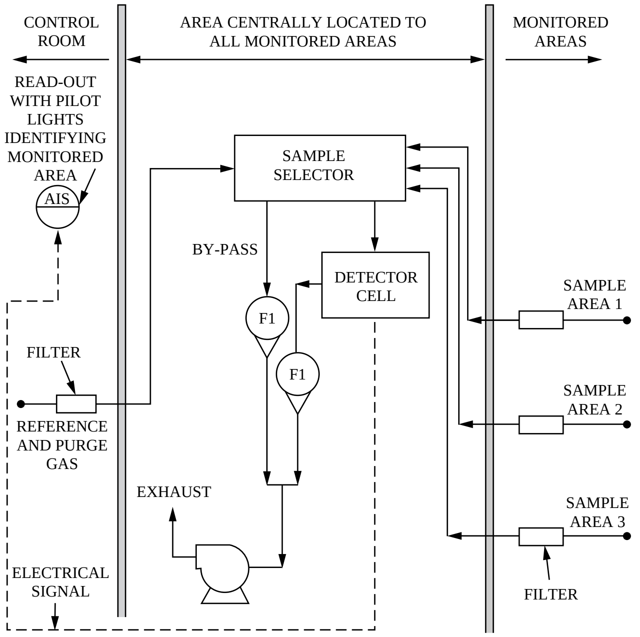

FIG. 8.16h
Tube sampling system.

One possible means of improving the system is to use separate pumps for the sample analyzed and for those that are bypassing the detector. A clean gas purge can be provided after each analysis to prevent an erroneous reading caused by residual carryover in this type of system (see Figure 8.16h).

In order to eliminate the problems associated with condensation in the sample tubes, these arrangements should be used only where true gases and vapors with boiling points well below ambient temperatures are to be detected.

Tube sampling systems usually have a 30-sec dwell time per hour. Therefore, they should be considered only if such slow response can be tolerated. For additional safety, readout devices can be calibrated with full-scale ranges as low as 0 to 20% LEL. The alarm switches contained in the measuring circuit are used to actuate alarms, start ventilation, shut down sparking devices, and so on.

These systems are found in coating ovens, solvent recovery, and soybean extraction plants, just to mention a few typical applications.

CONCLUSIONS FOR CATALYTIC DETECTORS

In the diffusion head type analyzer, the use of sample pump or aspirator is eliminated. Dispensing with any moving part increases reliability. Therefore, the use of a diffusion head analyzer is recommended wherever a flowing sample is not needed or where clean, dry samples are to be analyzed.

Large amounts of particular matter, moisture, and dust can and will cause plugging, which is difficult to detect in diffusion head analyzers since they cannot be furnished with low-sample-flow alarms.

In addition to the above, the selection parameters should include the considerations of plant layout, required speed of response, rate of gas buildup, and economy.

Comparing the Wheatstone and the thermocouple cells, the following should be considered. Whereas Wheatstone bridge cells use a fine, helical filament, the thermocouple cell uses a heavy, straight filament with a much longer useful life. Further, the evaporation on the exposed filament results in a constant change of base resistance of the filament.

In the Wheatstone bridge circuit, this change of base resistance produces a shifting of zero and requires frequent rebalancing of the bridge. The temperature change measured by the thermocouple is independent of filament deterioration. Thus, for the thermocouple detector, the zero drift is reduced to a negligible amount even over long periods of time. Therefore, the thermocouple detector is often superior to the Wheatstone bridge-type detector.

FLAME IONIZATION AND PHOTOIONIZATION DETECTORS

The theory and operation of flame ionization detectors (FIDs) and photoionization detectors (PIDs) are described in greater detail in the sections describing chromatography (Section 8.12), hydrocarbon analyzers (Section 8.25), and total carbon analyzers (Section 8.58). Both detectors are commonly used in chromatography and have been utilized for combustibles monitoring in both portable and fixed installation designs.

Flame Ionization Detectors

The FID actually burns the sample in a hydrogen flame. In a simple combustibles application, no columns or carrier gases are used and the sample is used as an oxygen/air source. The sample is consumed during the combustion process. In a chromatography application, extremely clean air (as the source of oxygen) is introduced into the chromatographic column's effluent (which contains the sample) and is sent into the flame.

In these configurations, the only variable sources for ion formation in the flame are the components of interest in the column effluent or combustible contaminants in the combustibles sample. The appropriate combustible materials in the sample form ions in the flame. An oxygen-rich hydrogen and air flame basically exhausts water, nitrogen, and unconsumed oxygen. None of these are ionic in nature.

A charged electrical field is positioned across the flame, and it can conduct a current utilizing available ions in the flame as its conductor. When most combustible materials are introduced into the flame, they produce ions in their combustion products, and these are detected by the increased flow of current across the electric field (flame).

This detection method has been called a carbon counter, because of its response profile. It essentially responds to each carbon atom in the sample that has been consumed and used to form an ion in the flame. For example, one molecule of ethane has nearly twice the response of one molecule of methane.

This has both advantages and disadvantages in combustibles monitoring applications. The sensor is very sensitive to larger organic molecules. Its response to a mixture that may vary in composition can be difficult to calibrate, since different components have different LEL concentrations (see Table 8.16.a) and different detector responses. Specific and unique calibrations may be needed for each sample or application.

The instrument cannot detect hydrogen (no ions are formed in the flame). These advantages and disadvantages are listed only as examples and are by no means exhaustive. Each application needs to be studied in full detail prior to selecting an appropriate measurement method.

Photoionization Detectors

The PID utilizes a high-energy light source (normally ultraviolet (UV) radiation) as its source of ionization and measures the resulting flow of a current through the ionized sample, across a charged electric field. This detector also has several advantages and disadvantages.

It does not require auxiliary utilities (fuel gases). It can easily be made portable. It does not necessarily respond (depending on the ionization source chosen) to many potential components of interest. It requires frequent calibration and maintenance (as radiation sources deteriorate). Several different lamp strengths are available, and an appropriate one needs to be selected for a given sample. The ionization potential (IP) (eV) of each molecule needs to be matched to the strength of the ionization source being used.

For example, acetone has an IP of 9.71 and can be ionized by most common lamps having IPs of 9.8, 10.6, or 11.7 eV. Of course, each different lamp has a different response factor for acetone, while methanol has an IP of 10.85 and therefore responds only to the 11.7-eV lamp. Methane has an IP of 12.51 and would not respond to any of these lamps.

These advantages and disadvantages are only given as an example and by no means are exhaustive. As mentioned previously, each application needs to be fully studied prior to selecting an appropriate measurement method.

INFRARED COMBUSTIBLES DETECTORS

Infrared combustibles monitors are primarily a simplified and special-purpose version of an infrared filter photometer. In cases of very simple applications, they have even been used as a substitute for an infrared photometer and actually used to monitor a process sample that was introduced to them. For this reason, they have sometimes been called the poor man's IR analyzer.

Infrared photometers and spectrometers, and the technologies that they are based on, are discussed in great detail in Section 8.27, "Infrared and Near-Infrared Analyzers."

Basically, an infrared beam of radiation that will excite the target gas molecules is used to measure the concentration of combustible gas molecules in the sample. For combustible gas monitoring, the radiation wavelength chosen is usually one that is absorbed by the C—H bond of most hydrocarbon molecules.

When the beam of radiation excites the molecules, a portion of its energy is absorbed and the amount of energy absorbed (lost to the beam) can be correlated to the amount of the target gas in the sample. Because many other factors could impact the intensity of the selected beam of IR radiation, these instruments usually also monitor a reference (another) wavelength of radiation that is not absorbed by the combustible gas, but is influenced by several of the other factors that could affect the measured beam's intensity.

Infrared combustibles monitoring instruments are available as both point and open-path (area) monitors. Even the point monitors are sometimes called open, because the IR measurement cell is actually open to the atmosphere. They typically rely on atmospheric diffusion to supply the sample and, consequently, the cell must be open to allow the diffusion of sample into the measurement area to take place.

Open-path instruments, on the other hand, actually use a large, open atmospheric path as their measurement cell (tens to hundreds of meters). IR combustibles monitors are a relatively new innovation in the field of combustibles monitoring, but they have already gained wide acceptance as a niche technology. They perform well on many samples that other technologies have problems with. This is especially true for many gases that can poison other combustibles sensors and for monitoring requirements where the likely points of leakage are difficult or impossible to predict.

Diatomic molecules like hydrogen, oxygen, and nitrogen have no usable IR absorbance and cannot be detected by these IR monitors. Consequently, IR combustibles monitoring systems should not be used for hydrogen or hydrogen-containing combustibles mixtures. The response of each potential gas or mixture to the detection method needs to be considered when selecting a monitor.

Point Infrared Systems

Point IR systems monitor the sample at the measuring head, just like the other previously discussed point style combustibles monitors. If it is intended to monitor a sample that is not diffusing into the sensor head and is not located immediately adjacent to it, the sample must be transported to the sample head using a sample transport system. A couple of point IR designs are shown in Figures 8.16i and 8.16j.

Figure 8.16i depicts a reflector style point sensor design, where the IR source and detector are both located on the same side of the sample chamber. The measurement and reference IR beams are transmitted, reflected off of a mirrored reflector, and pass through the sample twice during the analysis. With this type of sensor there is no chemical reaction of the gas, and as such, the materials that poisoned catalytic beads cannot poison these sensors.

But nothing is perfect or without its own Achilles' heel. For an IR point monitor to do its job, the IR radiation beam must pass through the sample and be partially absorbed by the sample of interest before reaching the detector. If the sample becomes opaque to the IR measurement beam or if the optical path is otherwise blocked (condensation or dirt on the windows, heavy fog, dust, etc.), the instrument can be rendered inoperable. Typically, the mirror and windowed instrument compartment are purged or maintained at

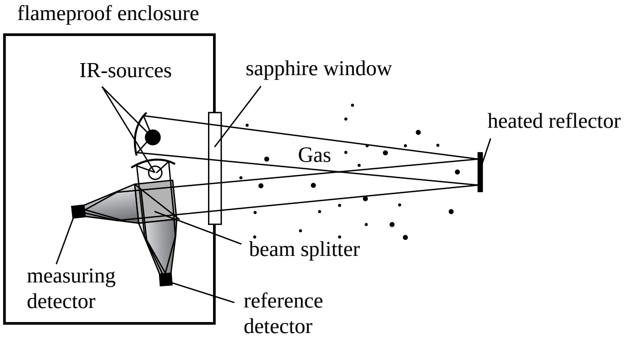

FIG. 8.16i
IR reflector style point sensor. (Courtesy of Draeger Safety Inc.)

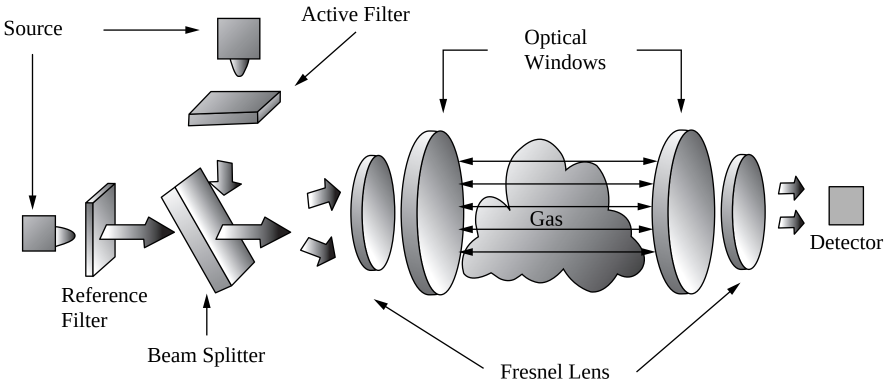

FIG. 8.16j
IR one-pass point sensor. (Courtesy of General Monitors Inc.)

a temperature that is intended to prevent condensation on either the window or mirror.

Figure 8.16j depicts a one-pass point IR sensor design, where the IR source and detector are located on opposite sides of the sample chamber. This analyzer is very much analogous to the reflector style sensor head depicted in Figure 8.16i, except that the beam of radiation only passes through the sample once.

In the reflector style, the beam has the opportunity to interact with the sample twice, and if all else was equal and good, the instrument should depict twice the sensitivity (or twice the interference to things like fog, dust, etc.). In real life, the sensitivities are usually not that different between the different designs, and the benefits are more often expressed in the form of a smaller sensor head or other geometric benefits.

Area (Open-Path) Infrared Systems

All of the previously covered combustibles monitoring technologies can be classified as point monitoring systems. They only measure the atmosphere at the points where they have been located (the gas of interest diffuses to a sensor) or sampled from. To monitor a large area, one would have to locate many monitors (points) and hope that they represent the area's general atmosphere.

Open-path IR combustibles monitors project their IR beams in a path that is typically 10 to 200 m in length and monitor all of the combustibles in that path. This is not really an area (more of a line or path) detector, but the value it determines can be viewed as more representative of an area value, and few instruments could provide a value that more nearly represents an area than would be needed with point monitors.

Figure 8.16k depicts some of the conceptual differences between point and open-path applications. The figure shows examples of leak detection applications under both no-wind and mild wind conditions. It can be seen that the leak cloud shape varies as a function of atmospheric conditions. Leak cloud shapes also vary as a function of the composition and the conditions of the sample.

Lighter and hotter gases rise faster, and samples under different pressures produce different rates of release and dispersion. Therefore, it is very difficult to locate a sensor (point

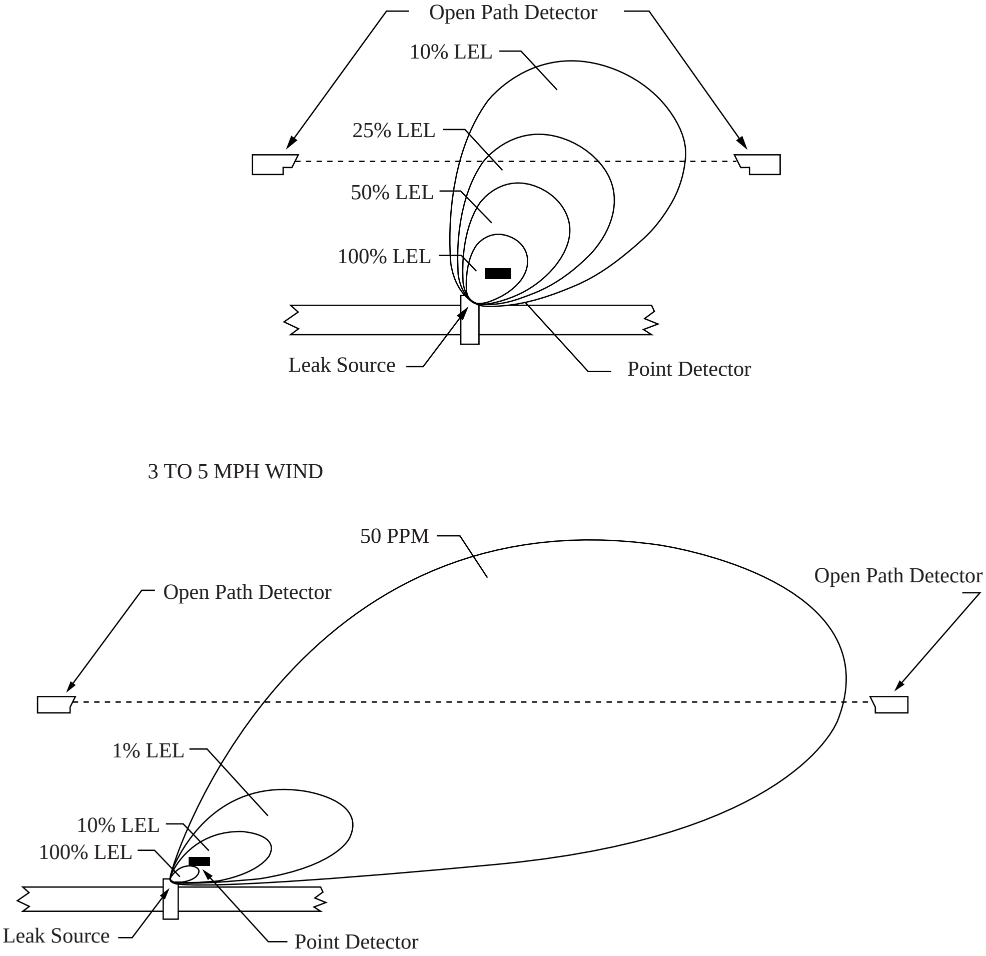

Fig. 8.16k
IR open-path vs. point monitoring concept. (Courtesy of General Monitors Inc.)

or open-path) in a way that will always accurately measure and detect a leak, unless it is located almost exactly at the source of the leak.

Both leak examples in Figure 8.16k show the use of both a point and an open-path monitor. It is easy to see the benefit one can gain by locating a good point monitor at a potential leak source. By so doing, one would get both an earlier and quicker detection, as the sample concentration is always higher closer to the leak.

It is also easy to see the benefits of locating a single open-path monitor along a pipeline that may contain many potential leak sources, as opposed to installing many point sensors, which would be very costly and impractical. Open-path sensors can also better cover a general area, where the positions of potential leak sources may be difficult to predict. Similar benefits can be visualized regarding other applications, like perimeter monitoring, room monitoring, fence line monitoring, or other general-area monitoring tasks.

It is important to note that the point and open-path techniques utilize different reporting values. Point techniques utilize parts per million (ppm) or percent LEL (%LEL) values, as described in the definitions at the beginning of this section and as listed in Table 8.16a. Open-path techniques utilize the units of parts per million or LEL meters (ppm.m or LEL.m). These will be discussed in more detail later in this section. It is fair to say that in most applications, open-path monitors are used more to detect leaks than to determine the absolute degree of hazard associated with the leak. This is because of the various leak cloud shapes that could exist and the way the instruments add or average the concentrations along their path.

Hydrocarbon Gases in the Atmosphere

Properly applied open-path monitors can be effective in monitoring combustible hydrocarbon gases in the atmosphere. Figure 8.16l shows an example of a typical open-path monitor. This installation involves installing two field devices. In this example, they are the source and the receiver or detector sections of the monitoring instrument. In other examples, they may consist of the instrument (source and detector) and a reflector.

In all cases, proper positioning and alignments are crucial to the success of the application. The beam must be positioned in a way that will enable it to detect the leaks of interest. The alignment is typically done with the aid of a vendor-supplied or recommended rifle scope that is mounted on one of the sections of the unit; using it helps in precisely aligning the beam, so that it properly hits the other unit.

The instrument needs to be located not only where it can make the best measurement of the leak, but also where it can perform. It must not be located where it can be exposed to shock or vibration, because this could make the alignment unstable or impossible. The monitor also must not be located where people, cars, or other equipment can block the beam.

Figure 8.16m depicts how an open-path instrument can compensate for partial blockages of its beam by light-obscuring interference, such as rain, fog, dust, etc. Essentially, it calculates the ratio of the measurement and the reference radiation signal. Most partially obscuring interferences will reduce both signals to the same extent. Therefore, the ratio of the signals is relatively unaffected by the interfering obstruction. On the other hand, the presence of a combustible gas will reduce only the measurement signal and therefore will result in a change in the ratio of the two radiation signals. This naturally is not the case if the signals are totally or nearly totally blocked. In that case, the instrument sensitivity and ability to detect a combustible gas are partially or completely lost.

Sunlight, flames, and many other light sources also produce infrared radiation. To reduce or eliminate their effects on the performance of IR instruments, choppers, filters, focusing optics, digital signal processing techniques, and other aids are utilized. In general, these miscellaneous IR sources do not interfere with the performance of today's IR type combustibles monitors. Yet, under extreme situations, they can still reduce sensitivity, by swamping the detector with too much radiation, and consequently, they should be considered when designing the field installation.

Point Measurement

The open-path IR systems monitor the concentration over the length of their optical path, but how can they be used to measure the concentration at any one point along this path? Do they operate like radar and actually monitor the concentrations at various points along the optical path? No, they do not. They essentially measure the number (concentration) of combustible gas molecules along the path in an integrated or cumulative fashion and report a number that incorporates the dimensions of both the concentration and distance.

Figure 8.16n illustrates how these instruments measure and report their readings. It should be kept in mind that the measurement is along a beam or path and, therefore, it is not detecting an area or a point. Percent or parts per million (ppm) readings are obtained by integrating the product of the concentration of the gas (along the length of the IR beam) by the length of the cloud (along the optical path).

In Figure 8.16n, there are three clouds in the optical path of the monitor. Each cloud has a different gas concentration and size, but all three are equal in LEL-meter units. In terms of their open-path reporting dimensions (100% × 1 m = 50% × 2 m = 10% × 10 m = 1 LEL·m each), if all three clouds were in the optical path simultaneously, the instrument would report the total presence of combustible gases as 3 LEL · m.

Clearly, the 1 m 100% LEL cloud is potentially explosive and the most dangerous of the three, but this method of monitoring does allow one to distinguishing between them. It cannot distinguish between small clouds of high concentration and large clouds of low concentration. It simply measures the total amount of target gas in its optical path. For this reason, the use and applicability of open-path IR combustibles monitoring is limited. Yet, this sensor still fills a niche market, and it can make some difficult monitoring applications feasible and practical.

All of the combustibles monitoring technologies reviewed in this section have strengths and weaknesses. Each has some advantages and disadvantages relative to the others. It is up to the user and the supplier to work together in evaluating these differences and picking the most appropriate technology for a given application.

Standard Design Pressure:	To 500 PSIG (3.5 MPa)
Standard Design Temperature:	To 390°F (200°C)
Element Materials:	Cells: glass, epoxy, and stainless steel. Electrodes: platinum, nickel, titanium, and carbon. Electrodeless: epoxy, Noryl, PFA, PEEK (polyether ether ketone), and polypropylene.
Cost:	For \$700 one might obtain an analyzer with these features: panel-mounted monitor, general-purpose electrical class; NEMA 1 environmental protection; ±1% accuracy; RFI/EMI protection; two-electrode contacting sensor with 3/4-in. NPT process connection; single analog output. For \$1500 one might obtain an analyzer with these features: pipe or surface-mounted field monitor; Division 2 electrical class; NEMA 4X environmental protection; ±0.5% accuracy; RFI/EMI protection; high-temperature electrodeless sensor capable of measuring hot acid, base, or salt solutions; dual analog outputs.
Range:	0 to 0.05 μS/cm minimum; 0 to 2 S/cm
Inaccuracy:	Up to ±0.5% of full scale

Conductivity sensors measure a solution's ability to conduct electricity, which is a function of all dissolved ionized solids in the solution. These detectors are packaged either as probes (with isolating valves for removal, without opening up the process) or in the flow-through designs.

INTRODUCTION

Conductivity analyzers measure ionic concentration of electrolyte samples. Cells and instrumentation are designed to measure the electrical resistance (or its reciprocal, the conductance)

TABLE 8.17a

in a volume element of the electrolyte and to limit electrode–solution interfacial contributions to this measurement. A variety of sensors have been developed, some using electrodes in contact with the sample, and others not. These sensors can be combined with modern microelectronics, often with integrated software programs, which improves the quality of measurement of concentration of ionic components in process samples.

THEORY OF OPERATION

The unit of conductance, the reciprocal of the ohm, is the siemens (S). This unit impresses a measurement of the mobility or velocity of ions in an electrolyte under an imposed electric field. The value of this unit depends on the number and hence on the concentration of ions present, which provides its value in analytical measurements. However, since the mobilities of dissimilar ions are different, the measurement response provided by the cell is useful only if the detected component is the sole, or at least the major, contributor to the measured conductivity. *Equivalent conductivity* is defined as the conductance that is reported for one gram-equivalent weight of the conducting ion.

The mobility of ions is affected by temperature and by the total concentration of all ions in the solution. Mobility of ions and hence conductance increases with temperature (about 2% per °C) and also with dilution. Table 8.17a shows values of conductance, expressed as equivalent conductivity, of several ions at 25°C corrected to infinite dilution, together with temperature coefficients.

Figure 8.17b shows the relationship of cell geometry to the measured conductance of the solution. The electric field applied to the cell is E/d. The current density i/A is the sum of the individual charge carriers in the field, and therefore the conductivity L (which from Ohm's law is the current divided by the voltage) is given by

$$L = (a/d)\ \Sigma_i z_i \cdot c_i \cdot \Gamma_i \qquad \textbf{8.17(1)}$$

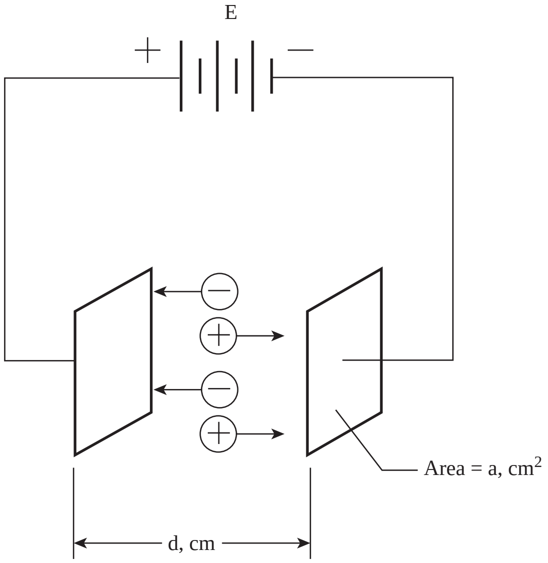

FIG. 8.17b
Simplified schematic of two-electrode conductivity circuit.

where

L = the conductance in ohm^{-1} or siemens

a = the area of electrodes in cm^2

d = the distance between electrodes in cm

c_i = the concentrations of the participating ions in $equiv./cm^3$

Γ_i = the equivalent conductivity of the participating ion in $S \cdot cm^2/equiv.$

z_i = the charge on the participating ion

THE CELL CONSTANT

It is not convenient to measure the ratio d/a geometrically for each cell, but since it is constant for any given cell, it may be assigned a value θ, in cm^{-1}, termed the *cell constant*. It is determined experimentally using solutions of accurately

known concentrations of potassium chloride, for which values of specific conductivity (the conductance of a cube of the solution, 1 cm on each side), denoted by k (in S/cm), have been precisely determined per American Society for Testing Materials (ASTM) Standard D1125–77. A few specific conductivity values are listed in Table 8.17c.

The cell constant is readily determined using the expression $\theta = k/L$, where k (the specific conductivity) is known from the tabulated values, and L (the conductance) is measured using the cell being calibrated. Note that conductance and resistance are values read by measuring instruments and have the units of siemens and ohms, respectively. Conductivity and resistivity are intrinsic properties of solutions; they are obtained after application of the cell constant and have the units of siemens-centimeter and ohm-centimeter, respectively.

Cell Dimensions

As the dimensions of the cell are changed, the cell constant varies as the ration of d to a. For solutions of low conductivity (about 0.05 to 200 μS/cm), the electrodes can be placed closer together, giving cell constants in the range of 0.1 to 0.01 cm^{-1}. Similarly, for more conductive solutions (about 10 to 20,000 μS/cm), electrode separations can be increased to give cell constants of 1, 10, or sometimes 100 cm^{-1}.

This has the effect of adjusting the actual conductance read by the instrument to a conveniently measured range. Signal-to-noise considerations limit resistance measurements to less than about 2 Mohm. Conductance measurements are limited by signal level magnitudes to less than about 0.2 mS.

Composition measurement using conductivity is popular in industrial process measurement and control applications, because of the inherent simplicity and reliability of the technique. Cells are available that cover a resistivity range of 1 to 10^8 in aqueous electrolytes (Figure 8.17d).

Three types of cells are used: two-electrode, four-electrode, and electrodeless. The four-electrode and electrodeless cells and their associated instrumentation are shown in Figures 8.17e and 8.17f, respectively.

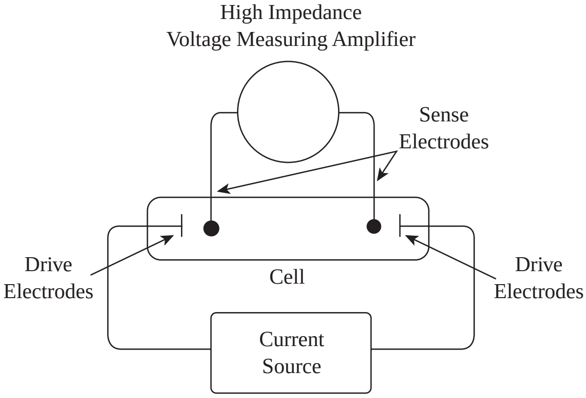

FIG. 8.17e
Four-electrode conductivity measuring circuit.

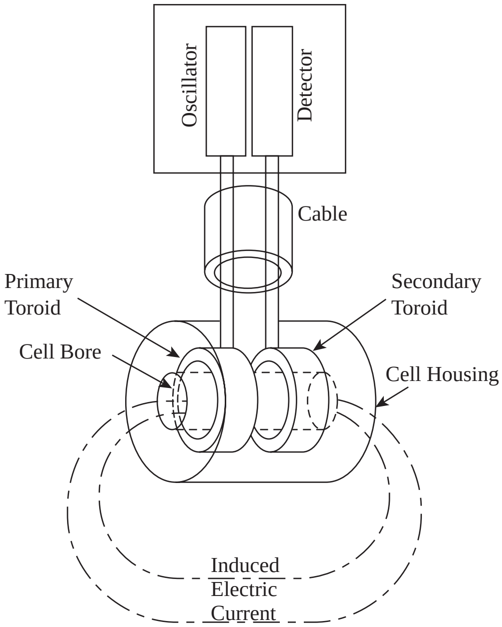

FIG. 8.17f
The electrodeless conductivity cell and instrument. (From Light, T. S. et al. Talanta, 36, 235–241, 1989.)

Two-Electrode Cells

Two-electrode cells are best suited for measurement in clean solutions to avoid errors caused by the formation of coatings and films on the electrodes. In these designs, it is desirable to minimize the interfacial impedance of the electrodes with the solution, because the goal is to measure the bulk conductivity of the electrolyte.

Derivation of Equation 8.17(1) assumed no iR (potential) loss at the electrodes or in the leads to the cell. The cell and instrument are designed accordingly. In order to avoid significant electrolysis, a small-amplitude (usually sinusoidal) waveform having a frequency in the range of 100 to 1000 Hz is used for excitation.

In addition, the electrode materials are selected to reduce polarization or iR (potential) drops at electrode–solution interfaces.[3] Ideally, the electrodes are made of platinum and are coated with a layer of platinum black. As the conductance of the measured solution decreases, polarization and coating effects become less significant, and metals other than platinum, such as Monel and titanium, are considered as inert electrode materials.

Particularly noteworthy is the class of two-electrode conductivity applications, called resistivity measurements, which employ titanium two-electrode cells in monitoring the high-purity water used in semiconductor manufacturing, steam turbine applications, and nuclear reactors.

Four-Electrode Measurement

Four-electrode conductivity is useful for high conductance when coating and fouling of electrodes are a concern. Current is imposed across two drive electrodes, and the potential drop through the electrolyte is detected between two points in the cell using two sense electrodes (Figure 8.17e). The sense electrodes are monitored with a high-input impedance, voltage-measuring amplifier to minimize the current drawn and electrode polarization.

Polarization at the drive electrodes has no effect on the measurement, provided the drive voltage is able to maintain the control current through the cell.[4] This voltage increases with fouling and can be used as a diagnostic tool to signal the user when cleaning is required.

Because of geometrical considerations, four-electrode designs are not suited to probe configurations. Precise measurements require flow-through cells that allow linear distribution of current across the sense electrodes. When used in probes, four-electrode measurements are best applied to setpoint control.

Typical applications include measurement of salts, acids, and alkalis in chemical processes in the mining, metallurgy, pulp and paper, and aluminum industries, where samples often contain solids, oils, or other materials that form insulating coatings on the electrodes.[5]

Electrodeless Cells

One way to eliminate electrode polarization effects is to eliminate the electrodes. Techniques to do this are referred to as electrodeless conductivity measurement or, alternately, as inductive or toroidal sensing of conductivity.[6,7] The probe shown in Figure 8.17f consists of two encapsulated toroids. When immersed in the electrolyte, the solution forms a conductive loop shared by both toroids. One toroid radiates an electric field in this loop, and the other detects a small, induced electric current. Practically speaking, the two toroids form a transformer whose coils are interconnected by the resistance of the electrolyte.

The radiated field is typically 20 kHz, and the induced current, which is proportional to the conductivity, is amplified, rectified, and displayed. These probes are encapsulated in nonconductive, temperature-stable, and chemically resistant materials such as the fluorocarbon polymers.

MEASUREMENT APPLICATIONS

Modern conductivity analyzers, with on-board computers, provide essential features such as temperature correction to reference values, digital display of concentration data from measured values, controller functionality, self-diagnostics, and calculations such as water subtraction and percent rejection.

Concentration Measurements

Temperature compensation and concentration computation data for common acids, bases, or salts are often imbedded in the instrument's software. Data for less common materials may often be loaded by the end user. Concentration can be derived from the conductivity of an electrolyte, when there is a significant increase or decrease in conductivity with increasing concentration.

While concentration measurements are most often applied to a single electrolyte in solution, they can also be applied to mixtures of electrolytes, when the ratio of the components of the mixture is constant. Concentration measurement is also used in batch reactions, where the progress of the reaction is accompanied by a significant increase or decrease in conductivity. Output signals, either digital or analog, are used in control systems for measurement and control of such processes as boiler feed water or the monitoring of gas scrubber solutions, pickling and plating liquors, etc.

High-Purity Water Measurements

A special class of temperature compensation has evolved for measuring high-purity water. Monitoring of high-purity water is used in semiconductor processing. In power and pharmaceutical applications, it is necessary to distinguish the temperature coefficient of pure water from that of ionic purity.

Today's "intelligent" instruments can measure both conductivity or resistivity and temperature. They can therefore compute the value of conductivity or resistivity of pure water at the measured temperature. They can also calculate the measurement contribution due to the impurities and output the conductivity or resistivity of the process water, referenced to a standard temperature, or the concentration of impurity after subtraction of the contribution due to the water (for example, as total dissolved solids (TDS) or particles per million (ppm) NaCl).

Multiple sensors are used in conjunction with ion exchange columns or reverse osmosis systems to monitor and control inlet and outlet resistivity across the bed and the breakthrough of unwanted ions and, as a predictive tool, to signal the need for bed regeneration. If the sample temperature is not controlled, water temperature compensation is necessary for accurate measurements for conductivity values at or below 1 μS/cm, or resistivity readings at or above 1 Mohm·cm. A variant of this temperature compensation, called cation conductivity temperature compensation, is used for high-purity water samples, such as the effluent of a cation exchange bed, which has acid as the major impurity.

Corrosive and Fouling Applications

The other extreme, i.e., highly conductive solutions—those that are highly concentrated, corrosive, and contaminated with fouling materials—is best measured with the electrodeless designs. Here, coatings only affect the measurement response to the extent that they alter the geometry, and hence the cell constant, of the probe. The relatively large size of these probes renders this effect small or negligible. Examples of applications include on-line analysis of oleum in $H_2SO_4—SO_3—H_2O$, measurement and control of alkalinity and solution strength in many industries using lime slaking, industrial dishwashing rinse control, gas scrubber solution concentration control, and many others.[6]

Pulp processing uses extremely corrosive chemicals, high temperatures and pressures, and samples entrained with solids and particles; such processing provides an example of how conductance analyzers are applied. Figure 8.17g shows how the conductivity sensors are integrated into a continuous Kraft digester commonly used in paper pulp making.[9]

Temperature, flow, and alkali concentration data are used by the control systems to control the uniformity of the pulp by manipulating the residual alkali strength in the cooking liquor in response to such changing feed properties as wood chip composition, species, chip moisture, and uniformity of concentration of makeup chemicals. For a summary of conductivity analyzer applications, refer to Table 8.17h.

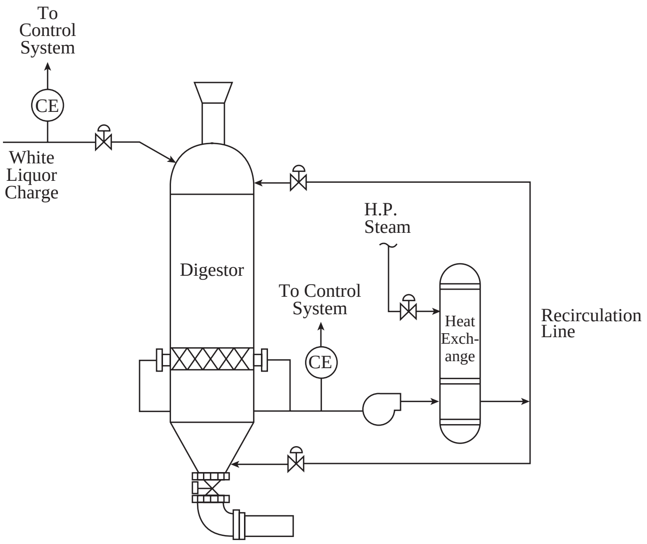

Fig. 8.17g
Example of conductivity measurement used in control of batch digestor for paper making.

TABLE 8.17h
Conductivity Applications

Process	*Application (Usage) and Comments*
Chemical streams	To measure and control solution strength.
Steam boilers	*Blowdown* is a method of lowering the amount of dissolved solids in a boiler by dilution. To control buildup of dissolved solids to prevent scaling and corrosion. *Condensate return* is usually checked for quality before being returned to the boiler. If out-of-limits, it is dumped.
Waste streams	A means of determining the amount of dissolved salts being discharged.
Cooling towers	*Bleed control* is a method of reducing the total dissolved solids in a tower by dilution (similar to blowdown). To prevent scaling and corrosion. For bleed control, the electrodeless conductivity system works best to minimize maintenance and failure.
Fruit peeling	Strong caustic is used, and its strength can be determined by conductivity.
Rinse water	Plating shop running rinse water is monitored for dissolved salts—a method of reducing water consumption.
Semiconductor rinse water	Requires ultrapure water, usually measured in mega-ohms/centimeter.
Interface determination	Usually used in food processing, e.g., dairy and brewing. Most commonly used in cleaning in place (CIP); interfaces in pipes are easily determined and can be diverted by valves controlled by conductivity.
Demineralizer output	Determination of ion exchange exhaustion.
Reverse osmosis	Efficiency of reverse osmosis (RO) operations is usually monitored by comparing inlet and outlet conductivity or TDS ratio (cell 1/cell 2). The inlet conductivity is installed upstream of the RO feed pump to avoid high-pressure requirements. Also, abnormal readings can be used to diagnose membrane fouling, improper flow rate, membrane failure, etc.
Desalination	Similar to reverse osmosis and demineralization process.
Deionization process	Conductivity or resistivity measurement provides capability for monitoring and controlling the acid and caustic dilution. Regeneration of deionizers requires consistent application of acid and caustic to obtain repeatable results. Savings is provided by consistent regeneration, which assures deionized water availability, less frequent regeneration, long resin life, and conservation of costly reagents. More precise control can be obtained by using conductivity ratio measurement. A comparison of inlet and outlet (ratio of cell 1/cell 2) conductivity across the bed can determine the unwanted ions and the need for bed regeneration, which can compensate and control for variations in mineral concentration of feed water.
Ion exchange	Occasionally loses resin. If a resin bead or fines are trapped between the electrodes of a cell, it is shorted and produces a very low resistivity (or high conductivity) reading. This feature is a great help in troubleshooting.

CALIBRATION AND MAINTENANCE

Calibration of Conductivity Sensors

Conductivity measurements can be calibrated using conductivity standards or on-line, by grab sample analysis. The conductivity sensor should be given sufficient time to reach the temperature of the standard solution, or in the case of on-line calibration, the sensors should be calibrated only after the process has been at a stable temperature for some time. By so doing, temperature compensation errors are eliminated, because the temperature element in the conductivity sensor will have had time to reach the same temperature as that of the standard or the process. This is especially important when using electrodeless sensors, which typically have a much larger mass than contacting sensors, and therefore require more time to reach thermal equilibrium.

Conductivity or resistivity measurements in high-purity water applications cannot be calibrated by using standards or calibrated on-line by using grab samples. This is because of the extreme sensitivity of the samples to contamination by trace amounts of electrolytes and even to atmospheric CO_2. It has been argued that the accuracy of calibrations, when using conductivity standards of less than 100 μS/cm, can be questionable.[9]

Therefore, the conductivity sensors on high-purity water applications should be calibrated by calibrating the input to the analyzer with precision resistors (usually done by the manufacturer) and using a conductivity sensor with a predetermined cell constant, which is then entered into the software of the analyzer by the user. Further calibrations are done using a certified reference conductivity system.

Maintenance of Conductivity Cells

Conductivity measuring systems may be designed to be trouble-free and produce reliable measurements; however, some maintenance is required, especially for the electrodes. In addition, the cell may require periodic cleaning depending on the type of application, the quality of the water passing through it, and the type of cell used. Some types of contaminants may not interfere directly with the measured conductivity—e.g., organic materials, rust, and suspended solids—but may form deposits on the electrode surfaces. In most cases, these surfaces can be cleaned with a bristle brush and a weak detergent solution.

Problems may also occur in hard-water applications, where gradual formation of scale will reduce the active area of the electrodes, which over a period of time will result in an apparent decrease in conductivity. For this type of fouling, simple brush cleaning is insufficient, as it will not remove scale from the cell. To remove the scaling, the electrode should be treated with a 10% solution of formic or hydrochloric acid. The presence of bubbles will indicate that the scale is being dissolved. It takes about 2 or 3 min and is complete when the bubble formation ceases. Then the cell should be thoroughly rinsed to remove all traces of acid before it is returned into the process.

Cells with stainless steel electrodes are generally used in applications where a low conductivity is combined with low concentrations of organic contamination. For high-purity water applications, titanium electrodes are used, because of their better performance characteristics in very low conductivity samples.

In applications where fouling or corrosion is anticipated, the need for cleaning can best be minimized by the use of electrodeless conductivity sensors.

CONCLUSION

Selecting the right conductivity cell includes having information on the cell constant for the analyzer, the conductivity range, the materials of construction selected to resist corrosion, and the appropriate mounting of the sensor.

When designing a conductivity measurement system, the first consideration is the conductivity range of the sample. In applications up to 20,000 μS/cm, typically contacting conductivity sensors are used. For higher conductivity ranges, or in samples that can foul or corrode the metal electrodes, electrodeless detectors are the best choice.

For conductivity measurements at 1 μS/cm and below, contacting conductivity sensors should be used in conjunction with a conductivity analyzer, which is provided with high-purity temperature compensation.

Flow Sheet Symbol

Types:	Blade, rotary, probe, optical, microwave, radiological
Element Materials:	Stainless steel and titanium
Normal Design Temperature:	Up to 250°F (120°C)
Normal Design Pressure:	Up to 125 PSIG (8.6 bars)
Range:	0.01 to 15% consistency
Sensitivity:	0.01 to 0.03% consistency
Repeatability:	0.5% of reading
Inaccuracy:	Function of empirical calibration, usually 1% of reading
Cost:	Laboratory units, $3000 to $10,000; continuous industrial units, $6000 to $30,000

INTRODUCTION

By definition, consistency is expressed as a percentage by dividing the mass of solid material by the total mass of a wet sample, resulting in units of mass per unit mass. Mechanically, consistency is the resistance to deformation or shear by fibrous materials, and thus is related to apparent viscosity. Such materials include wood pulp, dough, tomato paste, paint, gelatin, or drilling mud. This section will focus on those methods used for the measurement of consistency in the paper industry, involving pulp–water mixtures. In the laboratory, consistency is measured using a gravimetric method described in TAPPI Test Method T 240 om-88.[1] General industrial methods used for consistency measurement are described in a number of sources.[2–4]

In order to have good control over the basis weight of the paper product, it is necessary to maintain the consistency of the feed constant. An increase in temperature or an increasing inorganic materials content will reduce the viscosity, and thus apparent consistency, while increasing freeness (ability of the suspension to release water), increasing fiber length, or increasing pH will increase the apparent consistency. Pipeline velocity also can influence the consistency reading for mechanical sensors and, therefore, it is advisable to measure consistency in turbulent locations at constant flow rate. Consistency is also related to turbidity and sludge or suspended solids detectors.

IN-LINE CONSISTENCY MEASUREMENT

Forty years ago, consistency was considered to be a mature measurement, almost totally relying on mechanical devices for shear force measurements in the 2 to 5% range. Today, we still rely on mechanical shear force measurements, but in addition, we have devices utilizing light scattering, light transmission, nuclear radiation, radio waves, and microwaves. Mechanical measurement devices might be categorized as either static (a fixed probe or blade) or moving (blades, rotating disks, or propeller). The development of high-intensity light-emitting diodes 25 years ago allowed further development of optical consistency sensors. These gauges relied on scattered or transmitted light for measurement up to 4% consistency.[5]

Several other approaches to consistency measurement have been attempted with varying degrees of success. Gamma attenuation devices measure consistency on the basis of density changes. Recent developments in plastic scintillation detector technology have improved sensitivity and stability.[6] Because the density difference between fibers and water is very small, high sensitivity is a must. Unfortunately, fillers are quite dense, and if present in the pulp, will yield a false high reading. Similarly, the presence of air will yield false low readings.

Microwave measurement techniques offer the promise of being independent of pulp type, fiber length, brightness, color, and flow rate. The most prevalent commercial technique is the measurement of propagation velocity, or time of flight through the stock, which is a function of the relative permittivity of the material. Because of the factor of 10 difference in the dielectric constant of water and wood fiber, velocity is a strong function of consistency. These microwave devices measure both fiber and filler, and compensation must be made for the filler amount and type. In addition, this method is sensitive to air, conductivity, and temperature, for which compensation must be made.

One commercial device quotes specifications of a measuring range up to 8% consistency (C), with a sensitivity and accuracy of 0.0005% C at a flow velocity in the range of 1 to 16 ft/sec (0.3 to 5 m/sec).[7] A similar microwave propagation technique uses the phase difference between an original wave and one that passed through the stock to determine consistency. This device is claimed to be resistant to the effects of contamination and bubbles, with a range of 1 to 10% consistency.[8]

Ideally, the complete process stream should be exposed to the sensor, but in very large flows this is not practical and, therefore, samples are taken. The sample should be taken from the center of the pipe, usually from the discharge of a centrifugal pump so that separation or settling of solids is minimized (Figure 8.18a).

Mechanical Devices

These consistency-measuring instruments detect consistency of the process fluid as shear forces acting on the sensing element for consistencies greater than about 1%. In rotary devices, the shear force is reflected as the torque required to maintain the sensor at constant speed, as the imbalance of a strain-gauge resistance bridge, or as a turning moment. The instruments are calibrated in-line; thus, the output is not in terms of bone-dry consistency, but rather some arbitrary, reproducible value.

Stationary sensors depend on the process flow for measurement, and for such instruments, the output is affected by the velocity of the flow. For blade sensors, the sensor contour is designed to minimize flow effects on the output over the operating flow range. On the other hand, rotating sensors do not depend on process flow for a measurement. While these units are also sensitive to flow velocity variations, they generally can be used over wider flow ranges. In addition, the rotary motion of the sensor produces some self-cleaning action, whereas the fixed sensors depend on either a properly designed contour or an upstream deflector to prevent material hang-up.

Probe Type This sensor transmitter functions as a resistance bridge strain gauge. The bridge elements are bonded to the inner wall of a hollow cylinder that is inserted into the process. The shear force acting in the cylinder, due to the consistency of the process fluid, causes an imbalance of the resistance bridge. The amount of imbalance is proportional to the shear force and the consistency of the process fluid. The resistance bridge is powered from a recorder that also contains the AC potentiometer electronics. Pipeline velocity must be measured as compensating information, and a deflector in the pipe upstream of the probe prevents accumulation of strings and like material.[9]

The sensor is mounted through a threaded bushing furnished with the unit. Flowing velocity must be between 0.5 and 5.0 ft/sec (0.15 and 1.5 m/sec) in order to obtain repeatability, of around 0.1% of bone-dry consistency, up to 16%.

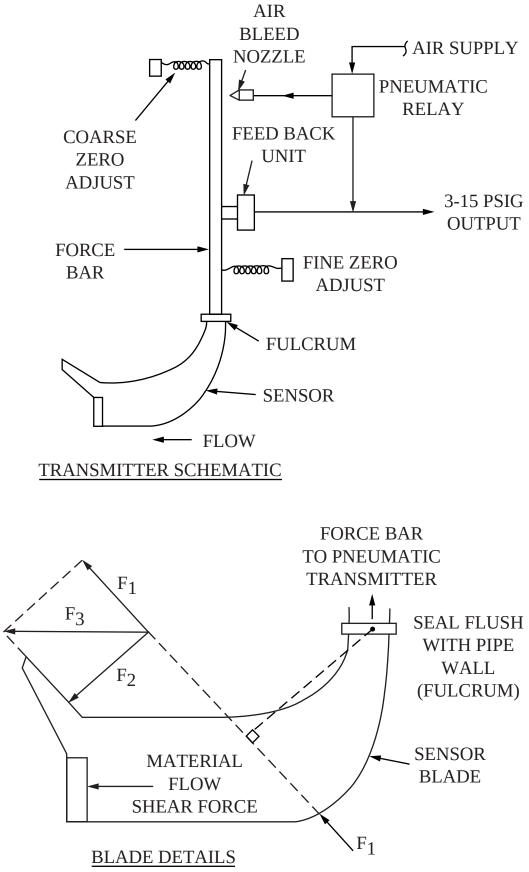

FIG. 8.18b
Stationary blade sensor and transmitter schematic. (Courtesy of Invensys Process Systems/Foxboro.)

Blade Types The sensing element of this instrument is a fixed blade, specially shaped to minimize the effects of velocity. As shown in Figure 8.18b, material flowing past the blade, which is positioned along the line of flow, creates a shear force. Velocity of the process produces two drag forces, F_1 and F_2, whose resultant F_3 acts through the fulcrum. The moment arm of F_3 is therefore zero, and the effect of velocity on the measurement is negligible over a range of 0.75 to 5 ft/sec (0.23 to 1.5 m/sec).

Changes in consistency up to the 12% level are transmitted through the blade to the force bar, causing small changes in the relationship between flapper and nozzle. Therefore, the relay unit output pressure changes until the force due to the feedback unit balances the shear force. The instrument can be mounted on any line 4 in. (100 mm) or larger. Mounting is through a 2-in. (50-mm) flange supplied with the instrument. Most new instruments use electronic systems for force measurement, replacing pneumatic devices.

Moving-blade devices stroke the blade, cutting across the flow in the plane of the blade, measuring the time required to complete the stroke. Higher consistencies will require a longer time, and vice versa. Compensation for velocity is affected by a deflector mounted upstream.

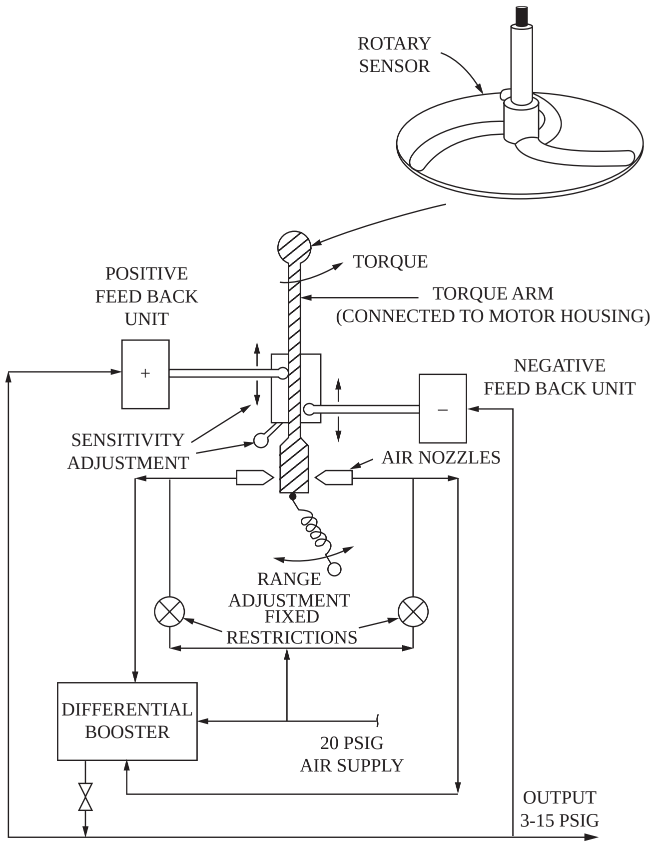

FIG. 8.18c
Air schematic of rotating sensor.

Rotating Sensors This unit consists of a motor-driven, ribbed disk immersed in the process fluid. The disk is rotated at constant speed, and variations in torque output by the motor are sensed by a torque arm. The motor is suspended by flexure bearings and anchored to the torque arm, which senses motor reaction torque. The tip of the torque arm is located between two air nozzles so that minute movements of the arm, caused by torque variations, are reflected as changes in two air output pressures (Figure 8.18c). The nozzle pressures are fed back to bellows that react to the torque arm movement by exerting an opposing force until equilibrium is reached between increased nozzle pressure and the force exerted by the torque arm. In many cases, electronic systems for torque measurement have replaced pneumatic devices.

Although this unit is less sensitive to flow changes than the strain gauge and force balance types, problems are introduced by the shaft seal required for this design. The torque variations must reflect only consistency changes and, therefore, shaft friction variations are detrimental to the measurement.

One of the latest mechanical transmitters has the appearance of two blades on a rotating disk. It is claimed to measure torque and consistency from 1 to 14% on an absolute basis by operating on the pulp while in plug flow. The establishment

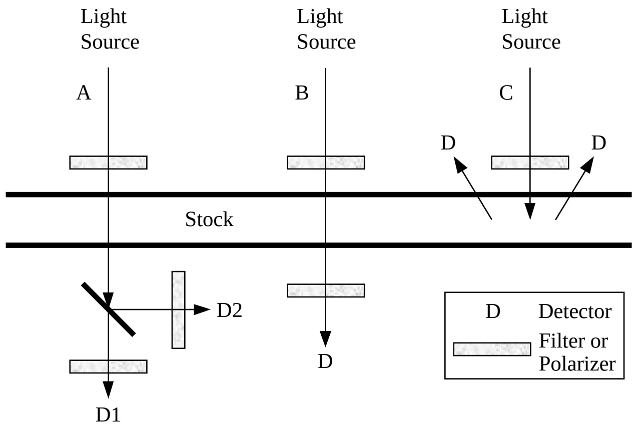

FIG. 8.18d
A variety of optical sensors.

of plug flow requires a calming length (L) determined from the following equation:[10]

$$L = R/[7\ D\%C] \qquad \textbf{8.18(1)}$$

where

L is in feet
R is flow in gallons per minute
D is pipe diameter in inches
%C is percent consistency

Optical Sensors

The range of these measurements is generally 1% and below for transmission devices, and up to 4% for reflection sensors. Accordingly, optical devices, either in transmission or scatter mode, are the sensors of choice for low consistencies, relying on the fiber's interaction with light, as shown in Figure 8.18d for three types of sensors.

Sensor A uses linearly polarized light from either a halogen bulb or a semiconductor laser, which is passed through the measurement cell. The transmitted light is split into two beams, one passing through a second transverse-plane polarizing filter, the other passing through a third in-plane polarizing filter. The beams are detected by photodiodes and combined to produce a relative depolarization signal, which is a function of the total fiber and filler. The signal is insensitive to brightness, color, freeness, or soluble additives.

Sensor B is based on the transmittance of light as a function of consistency. Unfortunately, this sensor is relatively sensitive to changes in freeness and color, exhibiting nonlinear behavior with changes in filler and dissolved solids.

Sensor C uses forward- and backscattered light to produce a signal combined from the several detectors that is proportional to consistency. This type of sensor can be used at much higher consistencies (ca. 4%), and, in general, its sensitivity to variations in the content of nonfibrous substance lies between that of sensors A and B. The exception to this rule is filler, for which this sensor is the most sensitive.[11]

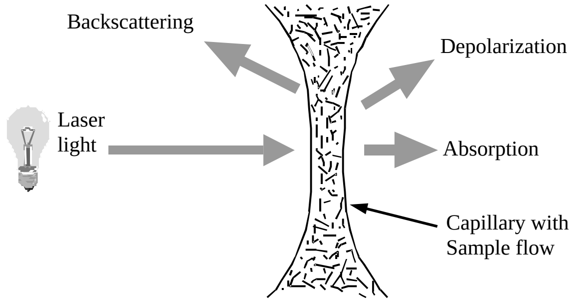

FIG. 8.18e
Measurement principle of the kajaaniRM-200 C for woodfree pulp. (Courtesy of Metso Automation.)

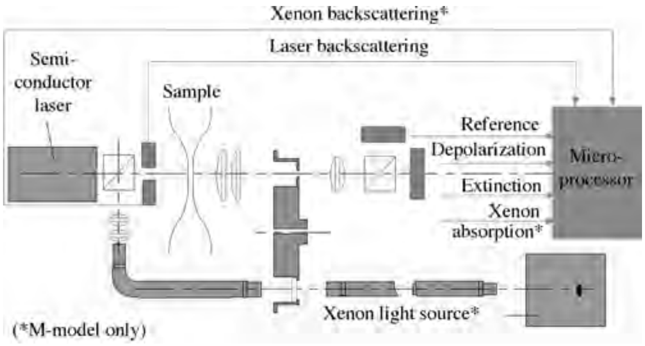

FIG. 8.18f
The kajaaniRMi for wood-containing pulp. (Courtesy of Metso Automation.)

Measuring Woodfree Pulp Optical sensors are frequently used to manage retention on a paper machine by measuring the total consistency at the head box and in the machine white water early and late in the forming zone. One such device, the kajaaniRM-200 C, is illustrated in Figure 8.18e.

This device is similar to sensor A in Figure 8.18d, in that a polarized light beam is directed through a glass capillary cell, where the sample continuously flows. The transmitted light is directed through a special aperature disk for scattering measurements, and then through a second polarizer, which splits the light into cross-polarized and parallel-polarized components that are detected by photodiodes. The depolarization signal mainly indicates the total consistency of the sample, and the attenuation of light is affected by the total consistency and filler consistency. Attenuation is strongly affected by scattering and light absorption. Since backscattering and attenuation are influenced by small particles, filler consistency is calculated from these signals.[12]

Consistency of Pulp Containing Wood For pulp containing a considerable amount of mechanical fibers, and thus a large fraction of lignin, the depolarization scheme loses effectiveness. Another sensor has been developed that uses two light sources and a combination of optical measurement principles, including depolarization, absorption, and scattering at several wavelengths from the ultraviolet (UV) to the near infrared (NIR). An outline of this sensor is shown in Figure 8.18f.

FIG. 8.18g
The BTG Wet-end Consistency Analyzer. (Courtesy of BTG Pulp and Paper Technology AB.)

The near-IR semiconductor laser light is polarized, passed through the cell, and then depolarized, as before, in Figure 8.18e. UV light from the xenon lamp is directed through the cell via a filter and polarizing prism. The forward-scattered light is directed through the lens and aperture disk to photodiodes. Backward scattering is also measured for both the UV and IR lights by detection with a photodiode before the cell. Light extinction, as well as backward and forward scattering, is measured at several different wavelengths. The signals are processed to monitor total solids and filler consistencies and flocculation in the sample.[13]

Figure 8.18g shows the components of an analyzer with a sensing scheme that is similar to sensor A in Figure 8.18d, while Figure 8.18h describes a typical signal trace from this analyzer. A light beam is directed at the suspension, and a photo detector senses the transmitted light. Three independent filters process the detector signal. The first filter determines the mean value V_{DC} of the transmitted light; the second determines the peak value V_P; and the third extracts the AC component V_{AC} of the signal.[14]

The peak method used in the analysis assumes that the suspension is substantially characterized by large and small particles. The large particles (fibers) form a relatively transparent network within which the much greater number of smaller particles (fillers and fines) float freely. Observation of a typical suspension over time reveals that the great number of small particles is relatively constant, whereas the number of large particles is few and variable. The average value of the transmitted light determines V_{DC}.

Deviations from this mean value are mainly due to the large particles passing through the light beam. The highest light intensity and V_P occur when no fibers are passing through the beam and the light is being dimmed only by the suspended fine particles. Thus, the respective amounts of large and small particles in the suspension can be determined by the mean and peak values.[15]

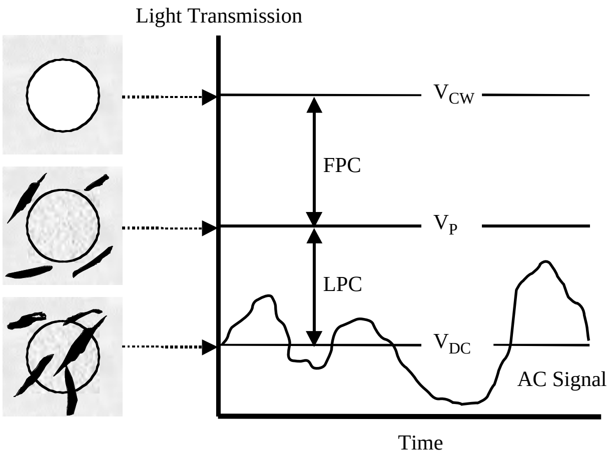

FIG. 8.18h
A sample signal trace from the BTG Wet-end Consistency Analyzer. (From Wold, D., "The Peak Method of Optical Analysis Realizes the Benefits of Low-Consistency Measurement," in UpTimes, No. 5, Säffle, Sweden: BTG Pulp and Paper Technology, 1999, pp. 24–25.)

Referring to Figure 8.18h, V_{CW} is the detector signal for clear water and is used as a reference value. The AC signal, V_{AC}, is plotted along with V_{CW}, V_P, and V_{DC}. The large particle content (LPC) is the difference between V_P and V_{DC}, while the fine particle content (FPC) is the difference between

V_{CW} and V_P. The total consistency is obtained by summing LPC and FPC.

The consistency measurement at 30% for TMP or CTMP pulp is based on dielectric measurement of the water content and an optical measurement using an NIR technique with reflectance spectroscopy. This technique is based on the resonance vibration of water, which appears as absorption bands in the infrared region of the spectrum. A typical sensor uses four fixed wavelengths of the spectrum—two located in the absorption bands of water and two in a region where the effect of water is minimal.[16]

SUMMARY

While convenient from an installation standpoint, mechanical in-line instruments are all sensitive to flow variations. Fixed sensors are more likely to be plagued by material buildup, particularly if the sample contains fibers. Rotating sensors are self-cleaning because sensor motion will tend to spin off any material; however, variations in shaft seal friction can be troublesome. The newer optical sensors have found great utility at low consistencies, and the search for alternative methods for consistency measurement continues.

INTRODUCTION

A detailed tabulation of the chemical resistance of materials is given in Appendix 3 of this volume. A more condensed summary of the corrosion resistance of some widely used materials is also given in Table 8.19a. In selecting the materials of construction for instruments, one should also keep in mind that most process fluids are not pure and that the rate of corrosion is also a function of flow velocity and of dissolved oxygen content.

Nondestructive testing, such as ultrasonic scanning, is also used in inspecting storage tanks, pressure vessels, and piping. If the plant's atmosphere contains corrosive gases, it is also desirable to enclose, purge, or otherwise protect the more sensitive instruments or their components. In such installations it is advisable to protect the stems of control valves by boots.

Corrosion monitoring can be based on 30- or 60-day coupons, which provide data only on the average rate of corrosion. Mobile monitoring laboratories can provide spot checks, or in the more critical cases, permanent monitoring equipment can be installed to provide continuous corrosion rate and pitting tendency readings. In cooling systems, where chlorine is used to control biological deposition, corrosion monitoring is needed because if the chlorine residual is too high, corrosion will occur.

CORROSION MONITORING TECHNIQUES

A variety of corrosion monitoring techniques are listed in Table 8.19b. These can monitor total corrosion, corrosion rate, and the state of corrosion. Some of them can also determine the composition of products and detect the presence of defects or changes in physical parameters. However, any monitoring technique can provide only limited information, and the techniques should be regarded as complementary rather than competitive. Where more than one technique can

TABLE 8.19b
Instrumentation for Corrosion Monitoring

Method	*Measures or Detects*
Corrosion coupon	Average corrosion rate over a known exposure period by weight loss
Linear polarization	Corrosion is measured by electrochemical polarization resistance method
Electric resistance	Metal loss is measured by the resistance change of corroding metal element
Analytical	pH of process stream
Radiography	Flaws and cracks by penetration of radiation and detection on film
Ultrasonics	Thickness of metal and presence of cracks, pits, etc., by changes in response to ultrasonic waves
Eddy current testing	Use of a magnetic probe to scan surface
Hydrogen sensing	Hydrogen probe used to measure hydrogen gas liberated by corrosion
Analytical	Concentration of corroded metal ions or concentration of inhibitor; oxygen concentration in process stream
Potential monitoring	Potential change of monitoring metal with respect to a reference electrode

provide the information required, such a cross-check can be very valuable, and their differences can add to their value.

This section focuses on coupon monitoring and on two frequently used on-line corrosion monitors: 1) the electric resistance monitors, and 2) the linear polarization resistance (LPR) monitors.

Coupon monitoring provides long-term performance data on general corrosion and information on localized corrosion. Electric resistance monitors give medium- to long-term data on general corrosion or erosion. LPR monitors provide real-time operational data on general corrosion and enable engineers to study the dynamics of the corroding system and to observe the effects of the addition of various corrosion inhibitors.

CORROSION COUPON MONITORING

Coupons are the simplest and most frequently used devices in the monitoring of corrosion. Coupons are small pieces of metals, usually of a rectangular shape, which are inserted in the process stream and are removed after a period for study. Specimens for standard corrosion, stress corrosion, crevice corrosion, and galvanic corrosion tests are shown in Figure 8.19c.

The most common use of coupons is to determine average rate of uniform corrosion over the period of exposure. The coupon or specimen is weighed before and after exposure. The average corrosion rate is calculated from the weight loss, the initial surface area, and the time exposed. The rate is usually expressed in mils per year (mpy) (1 mil = 0.001 in.) or millimeters per year (mmpy), since corrosion is generally a long-term effect.

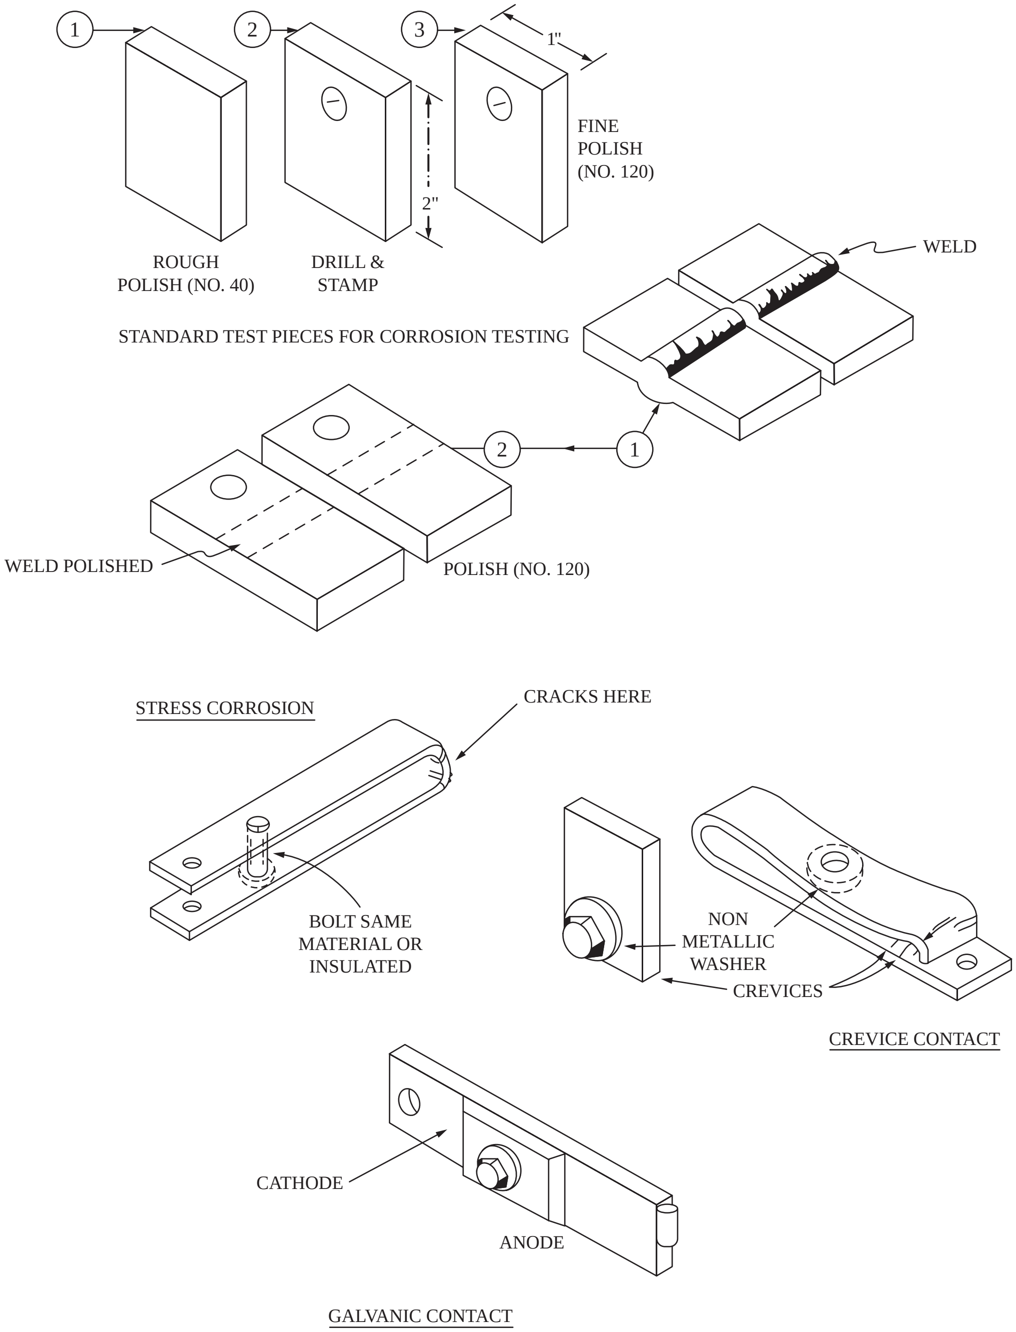

FIG. 8.19c
Specimens for standard corrosion, stress corrosion, crevice corrosion, and galvanic corrosion tests.

Improper cleaning of coupons or specimens after exposure is the main source of error in determining the corrosion rate. American Society for Testing and Materials (ASTM) Standard 61–81 describes the recommended practice for preparing, cleaning, and evaluating test specimens. In addition, Fontana and Greene (see bibliography) have useful information, particularly on techniques for sample cleaning after exposure.

The measurement of the depths even of extremely shallow pits is important. Pit depth should be measured to an accuracy of 1.0 mil using a micrometer.

Time of Exposure

Proper selection of the time the sample will be exposed is critical. In batch processes that involve cyclic exposure conditions, the coupon should undergo all of the batch conditions, including periods of shutdown. Exposure should be made for two or more complete cycles of operations to ensure that an equivalent of 2 weeks exposure time is obtained. Usually a 2-week test is acceptable, but a 1-month test is preferable.

Normally, initial corrosion rates are high, because as the corrosion products form, they tend to protect the surface and, as a consequence, the corrosion rate will drop below the initial rate. Therefore, it will be necessary to conduct tests of sufficient duration to compensate for this effect.

Advantages and Limitations

Advantages of the coupon monitoring technique are as follows:

1. The technique is suitable for all environments.
2. Coupons provide information about the type of corrosion present. Coupons can be examined for evidence of pitting and other localized forms of attack.
3. There are a variety of coupons available for specialized analysis.

Limitations of the technique are as follows:

1. High corrosion rates for short periods of time may be undetectable and cannot be correlated to process upset conditions.
2. The technique requires plant shutdowns for installation or removal. Highly qualified personnel and reasonably sophisticated test procedures are required for the interpretation of the results.

ELECTRICAL RESISTANCE MONITORS

Figure 8.19d is a simplified diagram of an electric resistance corrosion monitor. It shows a probe that has both an exposed measuring element and a protected reference element. They are connected to a Wheatstone bridge measuring an output circuit, and a power supply.

The measuring element is a loop of wire that is exposed to the corrosive environment. The reference element is encapsulated inside the probe body by a thermally conductive plastic so that it will be at the process temperature. The output is directly proportional to the resistance of the thin-wire measuring element, because as corrosion increases, it causes the thickness of the measuring element to decrease (Figure 8.19e).

Advantages and Limitations

Electrical resistance monitors are basically automatic coupons, and they share many characteristics with coupons when it comes to advantages and limitations. The resistance probe must be allowed to corrode for a period of time before accurate corrosion measurements can be made.

Advantages of the electric resistance technique are as follows:

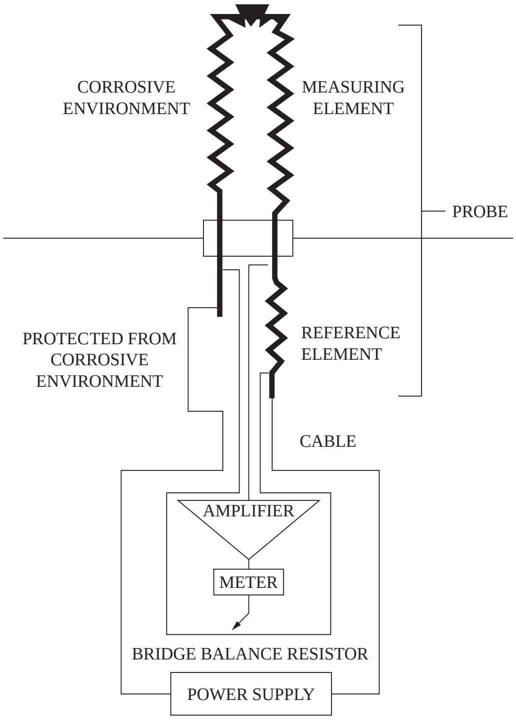

FIG. 8.19d
Basic diagram of electric resistance corrosion monitor with wire loop probe. (Courtesy of Rohrback Instruments.)

1. The technique is suitable for all environments except liquid metals or some conductive molten salts. The process material, which causes the corrosion, need not be an electrolyte (in fact, it need not be a liquid).
2. A corrosion measurement can be made without having to see or remove the test sample.
3. Corrosion measurements can be made quickly—in a few hours or days—or continuously. Sudden increases or decreases in corrosion rate can be detected, so that the user can modify the process to reduce the corrosion.
4. The method can detect low corrosion rates that would take a long time to detect with weight-loss methods. Its accuracy is comparable to the coupon method.

Limitations of the technique are as follows:

1. The technique is usually limited to the measurement of uniform corrosion only and is not generally satisfactory for localized corrosion.
2. The probe design includes provisions for temperature variations. This feature is not totally successful. The most reliable results are obtained in constant-temperature systems.
3. The technique does not provide an instantaneous corrosion rate, so any corrective actions must be delayed until an average corrosion rate can be determined.

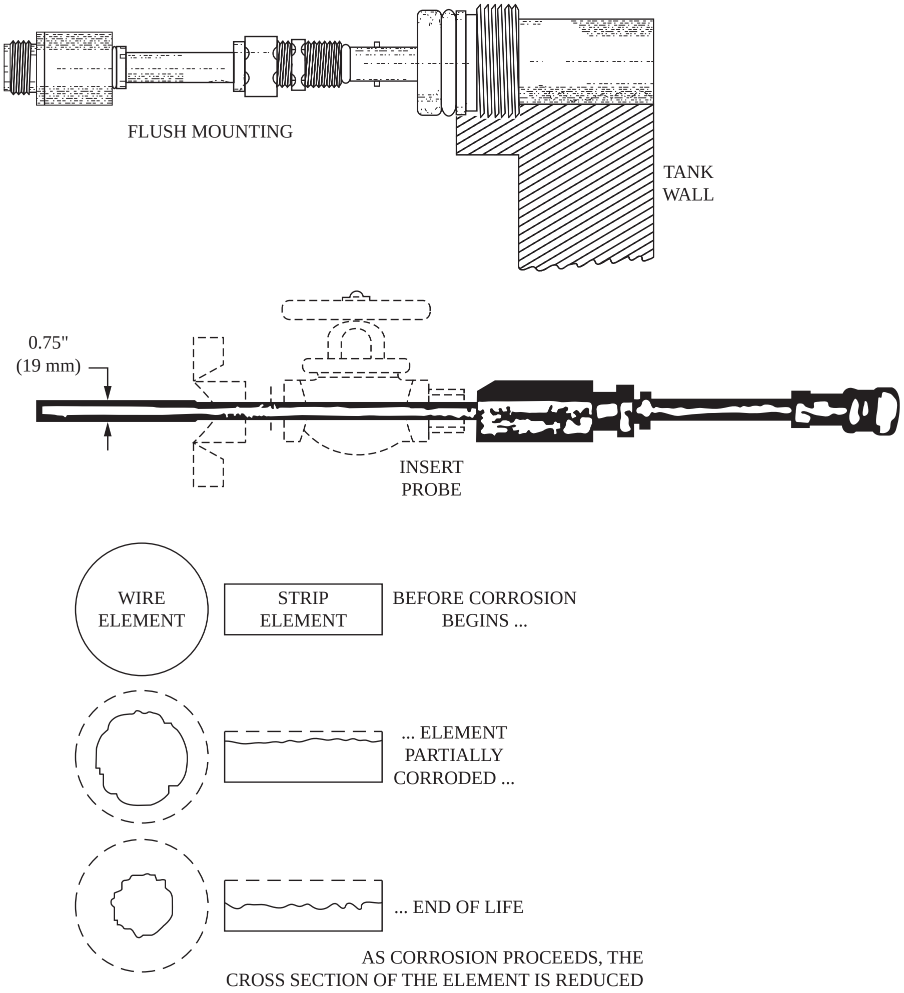

FIG. 8.19e

Probe configurations of corrosion sensors.

4. The resistance method measures a combination of chemical and physical erosion without distinguishing between the two.

LINEAR POLARIZATION RESISTANCE MONITORS

Figure 8.19f shows a three-electrode and a two-electrode linear polarization system. In addition to the electrodes, the three-electrode system includes an ammeter, a voltmeter, and an adjustable current source. The meters have adjustable null features to compensate for normal variations in the surface conditions of the test and reference electrodes.

A small electrical current flows between the test and auxiliary electrodes. Because corrosion occurs at the anode, the test electrode is protected when it is the cathode. The direction of current flow is then reversed, and the test electrode becomes the anode and its corrosion rate is accelerated. The change in corrosion rate caused by the reversal in current causes a change in potential of the test electrode when compared to the freely corroding reference electrode. The relationship between the change in current flow (dI), the change in polarization voltage (dE), and the corrosion rate (CR) of the test electrode is as follows:

$$CR = K\frac{dI}{dE} \qquad \textbf{8.19(1)}$$

Since all corrosion measurements are made at a constant polarization potential of 10 mV, the voltage term becomes constant, so the corrosion equation can be reduced to

$$CR = KI \qquad \textbf{8.18(2)}$$

Under constant polarization voltage, the corrosion rate is directly proportional to the current required to produce that polarization voltage. A value representing the K factor is

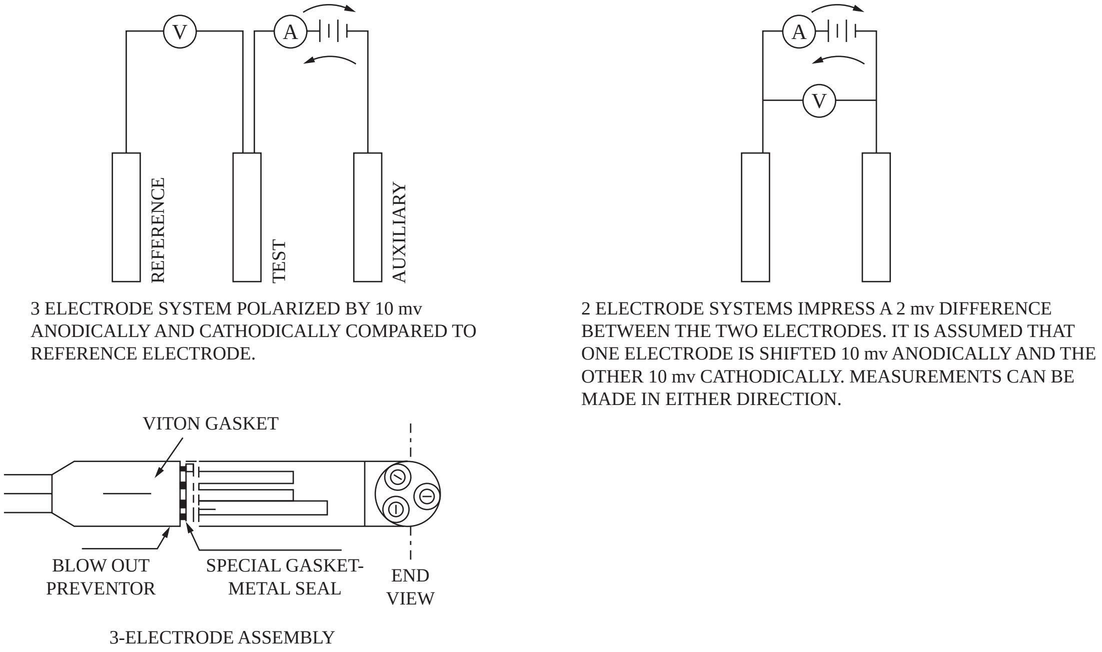

FIG. 8.19f
Linear polarization probes.

designed into the equipment so that the readings are linear and calibrated directly in mils per year.

Advantages and Limitations

Advantages of the linear polarization resistance technique are as follows:

1. The polarization probes measure corrosion rate almost instantaneously. They measure the instantaneous corrosion rate instead of the average corrosion rate.
2. The probes are useful for comparing relative corrosion rates. Thus, it is possible to use the data to determine the process variables that give the lowest corrosion rates.
3. The commercially available polarization probes supply pitting tendency information.

Limitations of the technique are as follows:

1. The probes will not work in nonconductive fluids or fluids containing compounds that coat the electrodes (e.g., crude oil).
2. The absolute accuracy of the corrosion measurement is not as reliable as the one obtained from corrosion coupons.
3. The method measures the combined rate of any electrochemical reactions at the surface of the test sample. If reactions other than corrosion reactions are possible at comparable or greater rates, the measured rate will also include these other reactions.

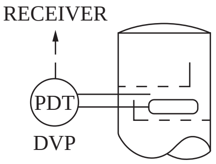
8.20 Differential Vapor Pressure Sensor

B. G. LIPTÁK (1995, 2003)



Flow Sheet symbol

Purpose:	Compare vapor pressure of reference fluid to that of process fluid
Wetted Parts:	316 stainless steel
Typical Ranges:	From 10–0–10 in. H_2O (254–0–254 mm H_2O) up to 425–0–425 in. H_2O (10.8–0–10.8 m H_2O)
Maximum Working Pressure:	1500 PSIG (105 bars)
Maximum Working Temperature:	250°F (121°C)
Ambient Effect:	1% or less per 100°F (55°C)
Repeatability:	0.1% of span
Dead Band:	0.1% of span
Inaccuracy:	0.5% of span (better with microprocessor-based transmitters)
Cost:	The sum of the cost of a d/p transmitter (about $1500), a temperature bulb, and the cost of attaching and filling the bulb with the desired reference fluid; total cost about $2500
Partial List of Suppliers:	Not manufactured as a complete unit. Any d/p transmitter can be converted to act as a differential vapor pressure transmitter by connecting a thermal bulb filled with a reference fluid to one side of the transmitter. For suppliers of d/p transmitters, refer to Section 5.6.

INTRODUCTION

Vapor pressure is the pressure that a vapor exerts when it is in equilibrium with its own liquid. At a constant temperature, the vapor pressure is just as unique a characteristic of a liquid as is its boiling point (Table 8.20a). Therefore, by measuring the vapor pressure of a fluid, one can determine the composition of that fluid.

If the temperature of the process varies, temperature compensation is needed. With microprocessor-based, smart instruments, such compensation is easily provided, if the relationship between vapor pressure and temperature is entered into the compensation software (Figure 8.20b).

DESIGN AND OPERATION

The differential vapor pressure transmitter is a d/p cell with one of its sides connected to a temperature bulb filled with a reference fluid (Figure 8.20c), while the other side is connected to the process. This way the sensor can continuously compare the vapor pressure of the process material with the vapor pressure of the sealed-in reference fluid.

If the reference bulb is inserted into the process, the need for temperature compensation can be eliminated. This way the temperature of the reference fluid is always the same as that of the process. Consequently, if the two compositions are the same, their vapor pressures will also be identical.

Freon-21	$CHCl_2F$	RO	+48	5	31	108	No	Yes	Yes	a. Evaporator under vacuum
Ethyl chloride	C_2H_5Cl	RO	+54	5	27	175	F, I	No	(5)	b. Low compressor discharge pressure
Freon-11	CCl_3F	C	+75	3	18	83	No	Yes	Yes	c. High volume-to-mass ratio across compressor
Dichloro methane	CH_2Cl_2	C	+105	1	10	155	No	Yes	Yes	

Notes: (1) Oil floats on it at low temperature; (2) corrosive to copper-bearing alloys; (3) anesthetic; (4) corrosive in the presence of water; (5) attacks rubber compounds.

[a] $°C = \frac{°F - 32}{1.8}$

[b] PSIA = 6.9 kPa

[c] BTU/lbm = 232.6 J/kg

The operating principle of this analyzer makes it ideal for product quality control applications. For example, it can be used in distillation, dryer, evaporator, or similar applications where the product is a binary material and the goal is to continuously check the composition of the product.

In case of distillation column control applications, a reference fluid-filled bulb is connected to one side of a standard d/p transmitter (Figure 8.20d), and the bulb is inserted into the liquid on the control. The other side of the d/p cell is connected to the vapor space above that tray. This way, if the product being made and the reference fluid are the same, their vapor pressures will be identical and the d/p cell will read zero.

This is a very convenient analyzer for product composition control on optimized distillation columns, where the operating pressure is not constant but is “minimized” as a

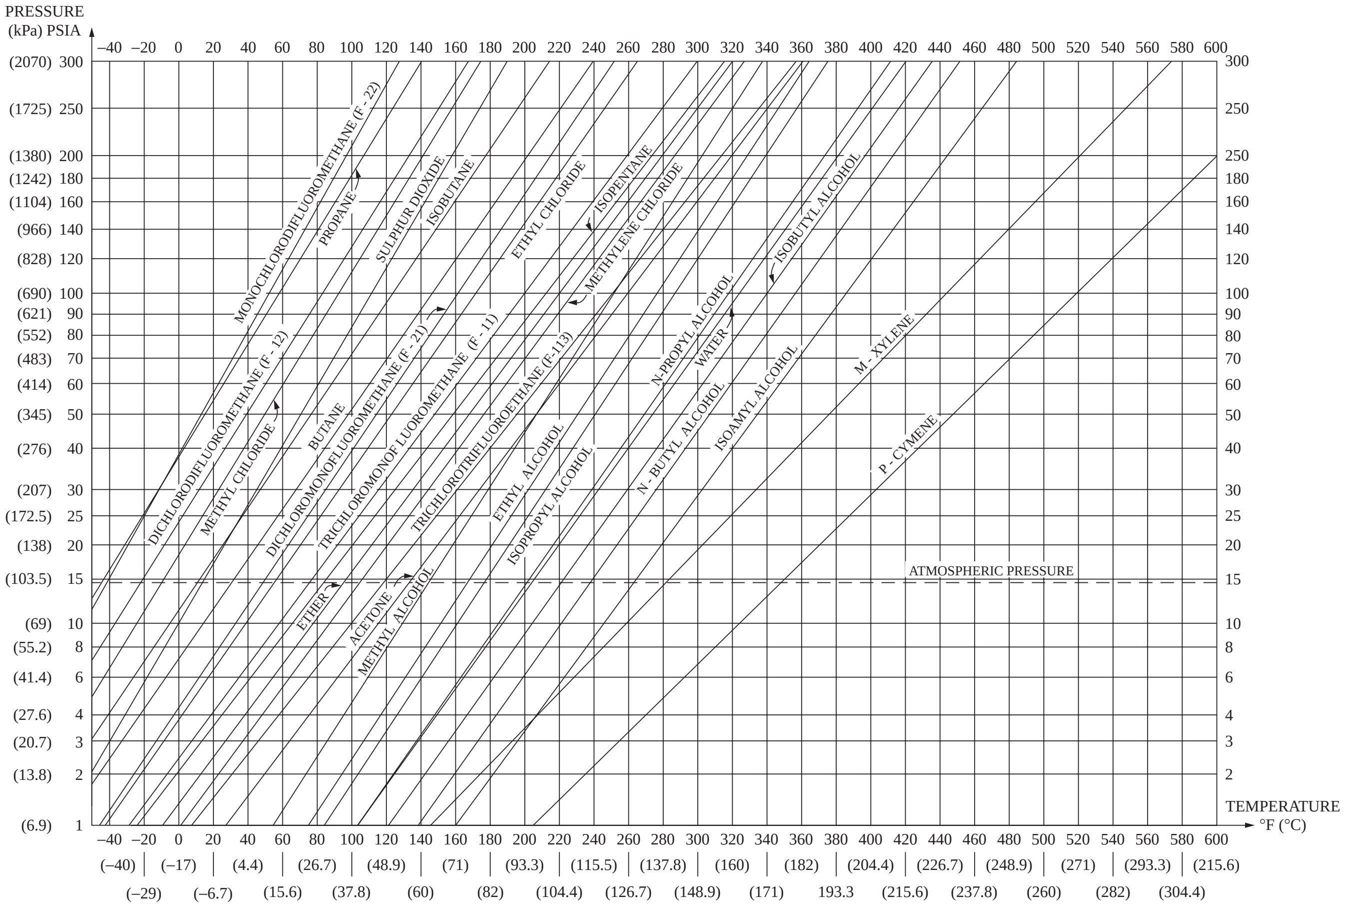

FIG. 8.20b

Relationship between vapor pressure and the temperature of some liquids.

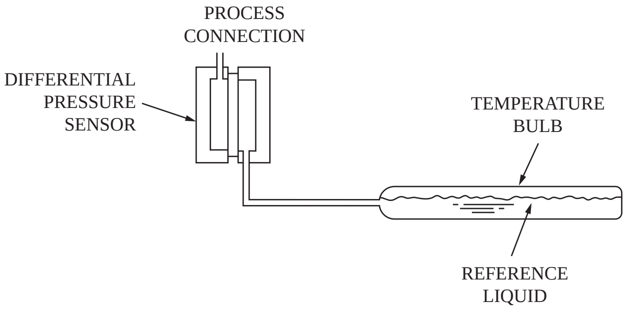

FIG. 8.20c

Differential vapor pressure transmitter.

function of the available cooling tower water temperature. In such applications, a temperature measurement will not accurately reflect composition, because the boiling point varies with pressure.

On the other hand, a differential vapor pressure analyzer will correctly measure the binary composition under variable column pressure conditions, because as the column pressure drops, it also lowers the boiling point on the tray. This in turn will lower the reference bulb temperature and with it the vapor pressure inside the reference bulb. Therefore, as long as the tray composition is constant, the pressure differential will also be constant, even if the column pressure varies.

LIMITATIONS

The limitations of this analyzer include that 1) it correctly reflects the composition of only binary materials; 2) it is essential for a successful installation that the reference fluid be stable; and 3) there can be a transient upset if the column pressure changes faster than the pressure in the reference bulb can follow.

FIG. 8.20d
A "smart" force balance d/p transmitter can be fitted with a reference bulb to serve as a differential vapor pressure transmitter. (Foxboro instrumentation courtesy of Invensys plc.)

INTRODUCTION

This section deals with the sampling and analysis of recalcitrant dioxin compounds. These measurements are required in ecological risk assessment and in the determination of the toxicity of various samples. The U.S. Environmental Protection Agency (EPA) regulates emissions from municipal waste combustors (MWCs) and sets emission limits for polychlorinated dibenzo-*p*-dioxines (PCDDs) and polychlorinated dibenzofurans (PCDFs). This section is a summary of the proposed Method 23 for measuring the emissions of PCDDs and PCDFs from MWCs.

PRINCIPLE OF OPERATION

Figure 8.21a is a schematic of the sampling train that is used to measure the emission of PCDDs and PCDFs from MWCs. A sample is withdrawn isokinetically from the stack through a probe, a filter, and a trap packed with Amberlite XAD-2 resin. Figure 8.21b shows the condenser and absorbent trap. The PCDDs and PCDFs are collected in the probe, on the filter, and on the solid adsorbent.

See Section 8.3 for a detailed discussion of the features and operation of stack sampling systems.

Sample Recovery

At the end of the sampling period, the cleanup procedure begins as soon as the probe is removed from the stack. The procedure is as follows. First, any particulate matter and fibers that adhere to the filter holder gasket are carefully transferred to a container (container 1). Next, the absorbent module (XAD-2 sorbent trap in Figure 8.21a) is removed form the train. After that, the material that is deposited in the nozzle, probe transfer lines, and the front half of the filter holder is quantitatively recovered first by brushing, while rinsing each with acetone. Then the probe is rinsed with methylene chloride and all the rinses are collected. The back half of the filter and the condenser are also rinsed with acetone, and the connecting line is soaked with methylene chloride. All the above rinses are collected in container 2. After that, the rinsing is repeated with toluene as the rinse solvent and the rinses are collected in container 3.

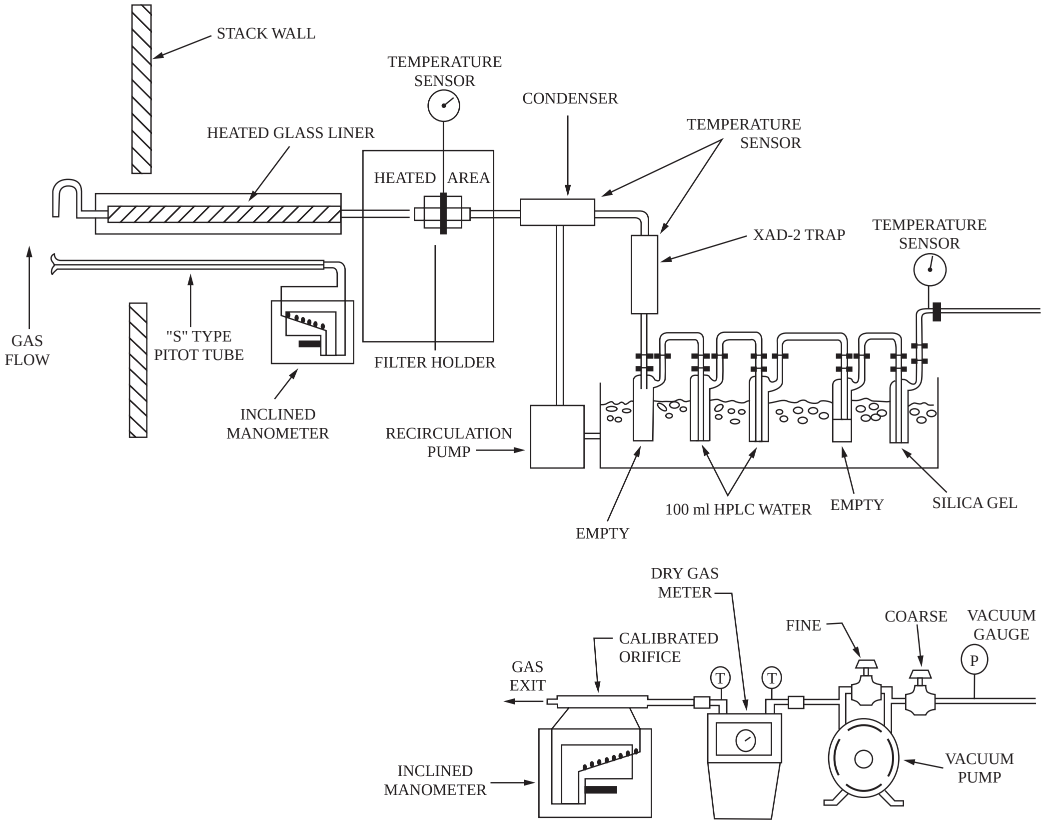

FIG. 8.21a
Sampling train.

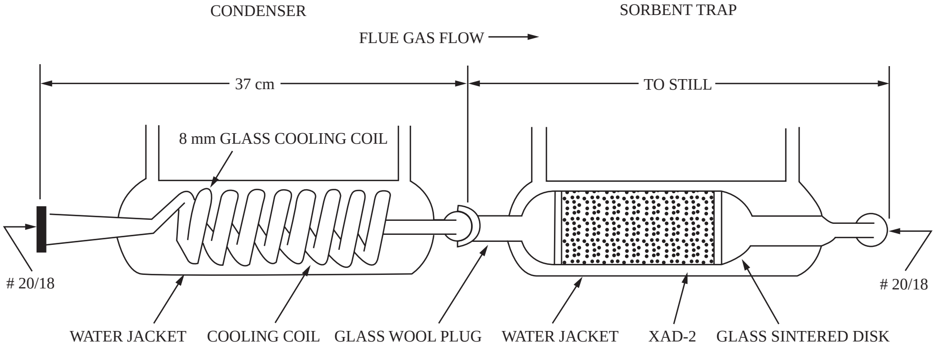

FIG. 8.21b
Condenser and absorbent trap.

Sample Extraction

All the PCDDs and PCDFs are extracted from the particulate matter, the absorbent, and the rinses. The absorbent module (XAD-2) and the particulate cake from the filter are extracted with toluene in the Soxhlet apparatus. The content of container 2 is evaporated at temperatures less that 37°C and is concentrated to dryness. This residue contains the particulate matter removed in the rinse of the train probe and nozzle.

The residue is added to the filter and the XAD-2 resin for extraction in the Soxhlet apparatus. In order to recover all the PCDDs and PCDFs, the material in container 3 goes through a series of multistep treatments.

Analysis

The extracted PCDDs and PCDFs are separated by high-resolution gas chromatography (GC), and each isomer is identified and measured with high-resolution mass spectrometry (MS).

The total PCDDs and PCDFs are the sum of the individual isomers.

The gas chromatograph uses an oven that can maintain the separation column at the proper operating temperature and perform programmed increases in temperature at rates of at least 72°F/min (40°C/min). It uses a fused silica column with a length of 183 ft and an inside diameter (ID) of 0.01 in. (60 m × 0.25 mm ID), coated with DB-5, and a fused silica column that is 91 ft × 0.01 in. (30 m × 0.25 mm ID), coated with DB-225.

In operation, the oven temperature starts at 302°F (150°C) and is raised by at least 72°F/min (40°C/min) to 374°F (190°C), and then at 5.4°F/min (3°C/min) up to 572°F (300°C). The mass spectrometer is capable of routine operation at a resolution of 1:10,000 with a stability of ±5 ppm.

CONCLUSIONS

The complexity of this method is such that to obtain reliable results, testers should be trained and experienced with the test procedures. All glass components of the sampling train upstream of and including the absorbing module should be cleaned. The method is described in Section 3A of the "Manual of Analytical Methods for the Analysis of Pesticides in Human and Environmental Samples."

On ground glass connections of used glassware, any residual silicone grease sealant should be removed by soaking the glassware in chromic acid cleaning solution first.

INTRODUCTION

Since its appearance in the 1960s, atomic absorption (AA) has become a widely used analytical tool. It is a popular analysis technique for elemental analysis in solids, liquids, and loose powders of either organic or inorganic materials. Typical applications include the detection of sulfur (S) and lead (Pb) in refineries; the measurement of oxides in such raw materials as limestone, sand, bauxite, ceramics, slags, and sinters; and the sensing of major and minor elements (Cu, Fe, Ni, etc.) in food and chemical products. Compared to earlier techniques, AA is faster, more sensitive, and free from interference.

The inductively coupled plasma (ICP) atomic emission technique first appeared in the late 1970s and has been recognized as a technique with remarkable selectivity and sensitivity. It has simultaneous or rapid sequential multielement determination capability at the major, minor, trace, and ultratrace concentration levels without change of operating conditions.

X-ray fluorescence (XRF) is an analytical technique that is well suited to on-line applications. It has been used to measure the elemental composition of solids, liquids, and slurries. Solids analyzed have been in such diverse forms as powders, granules, sheets, or discrete parts. XRF is fast, reliable, and nondestructive (Figure 8.22a). It is also less expensive than other techniques, such as neutron activation, and introduces few health or safety hazards.

ATOMIC ABSORPTION SPECTROMETER

Figure 8.22b illustrates the basic operating principles of flame and furnace AA spectrometers. In flame AA, the sample is aspirated, nebulized, and passed into a flame that is burning

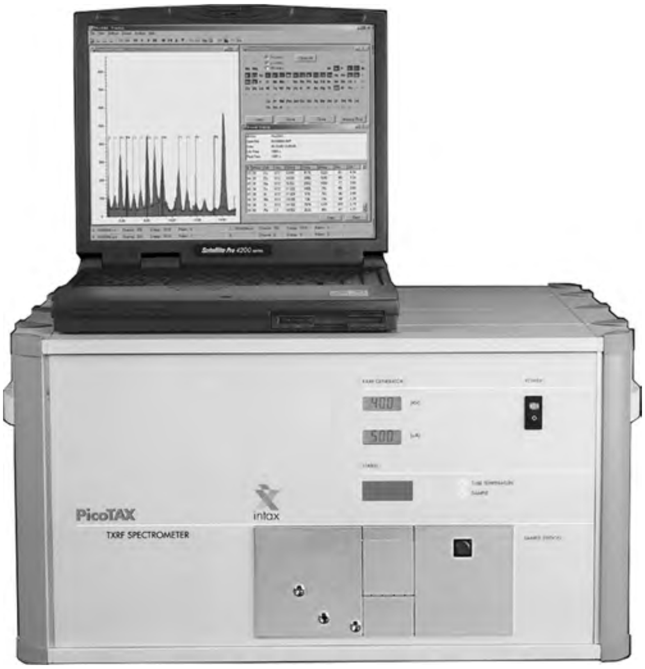

FIG. 8.22a
X-ray fluorescence spectrometer. (Courtesy of Roentec GmbH, Berlin, Germany.)

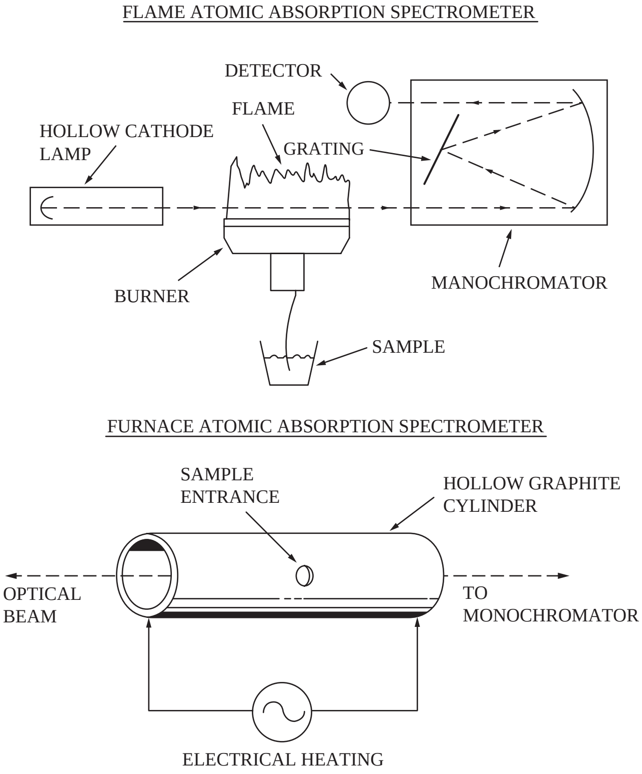

FIG. 8.22b
Atomic absorption spectrometers.

at about 3000°K. The flame causes the sample compounds to dissociate. The sample atoms then can absorb radiation at wavelengths, called resonance lines, that are specific for the elements.

The radiation source is a hollow cathode lamp in which the cathode contains the element being determined, and the monochromator is tuned to the appropriate resonance wavelength. Most commercial AA instruments can determine only one element at a time.

In furnace AA, a hollow graphite cylinder replaces the flame. The cylinder is heated electrically to a temperature high enough to atomize the sample. This unit is called a furnace atomizer, graphite furnace, or carbon rod. The device improves detection limits by 100- to 1000-fold, as compared to flame AA, but the furnace exhibits poorer precision and slower analysis speed, experiences more interference, and costs more.

INDUCTIVELY COUPLED PLASMA DETECTOR

Figure 8.22c shows a schematic of an ICP type detector. A stream of argon passes through a radio-frequency (RF) induction coil, producing considerable heat. When "seed electrons" are introduced, an argon plasma is formed in the fireball region of the plasma from 8000° to 10,000°K.

Argon is used to sustain the plasma because it requires less RF power than other gases. The outer flow supplies the plasma gas and cools the quartz torch. The inner flow carries the sample aerosol into the plasma. An optional middle flow helps to position the plasma and prevents carbon buildup on the tip of the central tube.

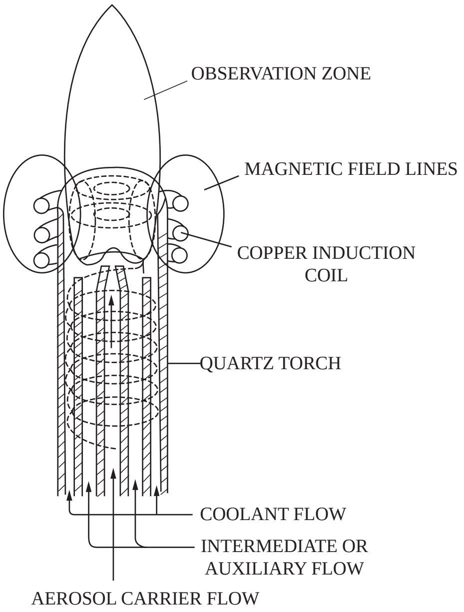

FIG. 8.22c
Inductively coupled plasma.

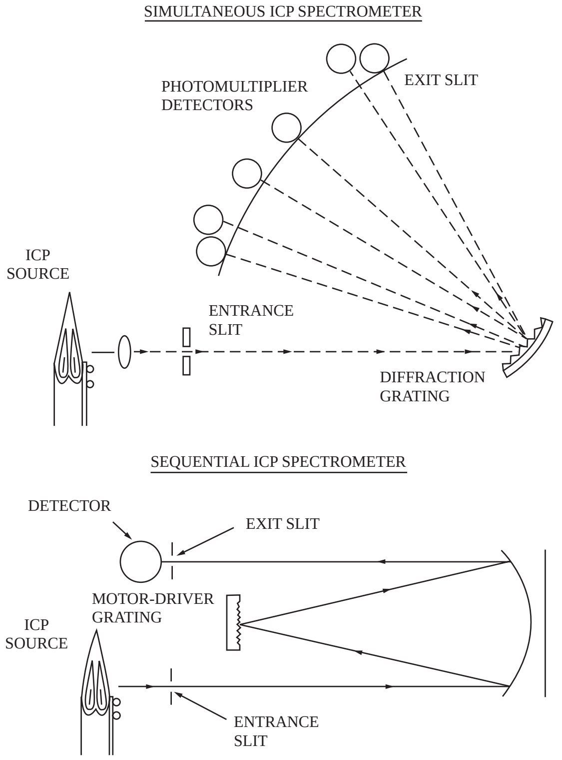

FIG. 8.22d
Inductively coupled plasma spectrometers.

Operating Principle

Figure 8.22d illustrates the basic operating principles of both the simultaneous ICP spectrometer and the sequential ICP spectrometer. In either system, the sample is nebulized and introduced into the center of the plasma. The temperature causes the molecules to dissociate. At the same time, the atoms are excited and the excited atoms emit radiation. Every element emits radiation at its own characteristic wavelength.

In simultaneous ICP, the light passes through the entrance slit of a polychromator and is then diffracted by a grating. Exit slits and photomultiplier (PM) detectors are placed to capture the radiation of the wavelengths from the elements of interest. The electrical current produced by the PM detector is proportional to the concentration of the element emitting that light.

In sequential ICP, the light output from a plasma torch passes through the entrance slit of a monochromator. The grating angle (and hence the output wavelength) is varied by a stepping motor under computer control. The grating stays at each wavelength long enough to make the measurement. It then is driven rapidly to the next desired wavelength.

SELECTING AMONG AA AND ICP

When deciding whether an AA instrument or an ICP instrument is the best option, the following should be considered:

1. Speed of analysis: The higher speed of ICP analysis stems from its capability to analyze several elements in a given sample. This produces a significant advantage in a sequential instrument, and an even greater advantage in a simultaneous instrument. In either case, speed in the two techniques differs by an order of magnitude.
2. Flexibility: The ICP technique gives a highly linear response, which enables simultaneous analysis of elements over a broad range of concentrations. This simplifies sample preparation and calibration. ICP requires no special cathode lamps for specific elements, so the sequential instruments become permanently available for analyzing any element. Also, the ICP technique enables the analysis of elements such as S and P that cannot be handled using the flame AA technique. It also provides increased capability for analyzing large series of elements such as B, W, lanthanides, and refractory in general.
3. Matrix interference: ICP spectroscopy is much more free from chemical and physical interference. An uncommonly high plasma temperature in an inert environment (Ar gas) reduces the problem of matrix interference.
4. Detection limits: The great sensitivity inherent in the technique and its improved signal-to-noise capacity give ICP better detection limits than those available with traditional flame AA. But the detection limits of furnace AA are better than those of a plasma for most elements. The exceptions are rare earth elements (B, U, Zr, etc.) plus nonmetals (S, Cl, I), which the AA furnace cannot measure.
5. Precision: Both systems use a pneumatic transfer system for samples and are very similar with respect to the degree of precision (i.e., repeatability) that can be obtained. There are no limitations to the use of ICP, as it can be used on gases, liquids, and solids (if spark ablation, laser ablation, or slurry introduction accessories are provided), so that vapors can be introduced into the plasma.

In spite of its advantages, the use of ICP has been limited by its relatively high cost, which can be justified only for large-scale analysis tasks or for solving problems that cannot be solved with flame AA. Because of increased productivity and lower prices, many laboratories have replaced AA spectrophotomers with ICP systems and left only the simpler tasks to be performed by flame AA spectrophotomers.

X-RAY FLUORESCENCE SPECTROMETER

XRF spectrometers irradiate the sample with a beam of high-energy x-rays that excite the elements present in the sample, so that they produce characteristic x-rays. This phenomenon is called x-ray fluorescence. XFR provides specific analyses of total elemental concentrations, without regard to chemical combinations.

The sample is excited by a source of electromagnetic radiation. This radiation excites the elements in the sample, causing them to fluoresce (i.e., give off their characteristic x-rays). The energy of these characteristic x-rays identifies the element, and the intensity is a measure of the element's concentration in the sample. The resulting signal is integrated over a period to give an average measure of concentration during this time.

Instrumentation

On-line XRF analyzers can be configured in different ways to excite the process sample or to detect the characteristic fluorescence. The right combination of excitation and detection methods depends on the specific application. The x-ray source may be an x-ray tube or radioactive isotope (iron-55, curium-244, cadmium-109, or americium-241). The detection method may be either wavelength-dispersive (WDXRF) or energy-dispersive (EDXRF) XRF. When choosing either the anode used for the x-ray or a specific radioactive isotope, proper consideration should be given to the range of elements to be measured and the corresponding concentrations.

Figure 8.22e illustrates the principles of WDXRF and EDXRF instruments. With WDXRF, the x-ray energies are separated according to specific wavelengths by diffracting crystals. The respective intensities are then measured by individual proportional counters. Sample excitation is by x-ray tube. With EDXRF, characteristic fluorescence is detected by a low-temperature, solid-state detector or a gas-filled proportional counter and sorted electronically to produce an XRF spectrum of x-ray-intensity energy. In EDXRF, sample excitation is by a low-level radioisotope source.

The WDXRF technique offers the best resolution, shortest analysis time, and highest sensitivity. It is well suited for the most demanding tasks, such as analyzing neighboring elements with large differences in concentrations. An EDXRF can be very compact and economical. It gives excellent sensitivity with good resolution, especially for light element analysis. The EDXRF systems are very useful in quality control, troubleshooting problems, etc.

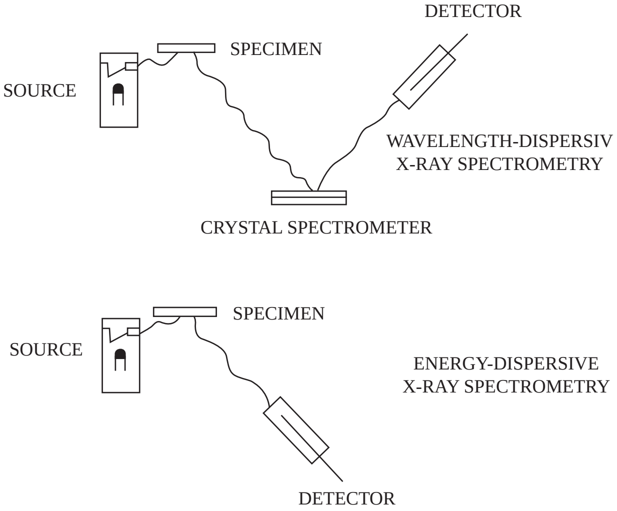

FIG. 8.22e
X-ray fluorescence spectrometers.

Table 8.22f gives a partial list of proven and potential on-line XFR applications. A wide choice of sampling systems is now available for continuous monitoring of liquids in pipelines or tanks, granular solids in chutes, parts on conveyors, coatings on moving sheets of metals, or pigments in moving plastics or paper sheets. As on-line XRF technology advances, continued growth in the number of applications and installations can be expected.

TABLE 8.22f
List of Proven and Potential On-Line XRF Applications

Petroleum Refining

- S in crude, refinery streams, gasoline, fuel oil, diesel, and MEA, DEA, and TEA stripper bottoms
- V, Ni, and Fe in crude residues, cracking catalysts, coke, and bunker fuels
- Ca, Zn, Cu, S, Cl, and Ba in lube-blending operations
- S in sour water

Chemical and Petrochemical

- Ti, Zn, Ca, and other fillers in polyolefins and other polymers
- Sn, Br, Sb, P, Cl, or other fire retardants in fiber (nylon, orlon, etc.) manufacture
- S, Cl, and Br in elastomers
- P in detergents
- Monitoring catalysts—typically Co, Mo, Ni, Mn, Br, Ti, Pt, and Rh in processing
- Blending additives manufacture (Ca, Zn, and Ba)

Inorganic Chemical Processing

TABLE 8.22f Continued

List of Proven and Potential On-Line XRF Applications

- Phosphoric acid manufacture
- Metal treatment (plating) chemical manufacturing
- Inks and paints (Ti, Zn, Pb, etc.); TiO_2 manufacture
- China and other types of clay purification (Ti and Fe)
- Photographic chemicals (As and Br)
- Rare earths and rare earth chemical manufacture
- Extractive hydrometallurgy (Cu, Zn, U, Hf, and Zr)
- Glass manufacture—monitor Si, Fe, Ti, Ca, and K
- Cement industry—monitor Fe, Ca, and Si

Pulp, Paper, and Rayon

- Ca and Ti additives in pulp
- Lignosulfates (S)
- Wood preservatives (As, Cu, and Cr)
- Viscose manufacture (Zn and S)

Catalyst Industry

- Precious metal catalysts (Pt, Pd, and Rh)
- Auto emission, reforming catalysts
- Manufacture of Mo, Co, Ni, and Zn-based catalysts
- Catalyst recovery operations

Plating and Electroplating

- Zn—Ni and Zn—Fe alloy coating of steel
- Metals in pickling baths
- Zn phosphating bath
- Zn—Pb, Au—Ni—K, and Ni—Br in plating baths for PC boards and electronic components

Metal Refining and Hydrometallurgical Operations

- All base metals (Zn, Cu, Pb, Mo, Co, Ni, etc.)

INTRODUCTION

Fiber-optic techniques offer several advantages for chemical and optical analysis, because the probes can be installed *in situ* to monitor the composition of chemical process streams in real time. This method of analysis does not disturb the process, and if the composition can be determined spectrophotometrically, the readout instruments can be several hundred meters from the probe.

The probe can be located in toxic, corrosive, radioactive, explosive, high- or low-temperature or -pressure, and noisy environments. Because the measurement signal is optical, the cables are immune to microwave or electromagnetic interference.

The term *fiber optic* is a misnomer because there are no fibers in the bundle, but rather thousands of glass filaments. Excessive bending of these filaments will cause them to break, which will reduce the light capacity.

PRINCIPLE OF MEASUREMENT

Most present-day fiber-optic sensors use linear diode arrays combined with optical gratings, as shown in Figure 8.23a. Depending on the grating and diode array, spectral data are obtained for remote measurement of absorption, transmission, fluorescence, and reflection in the ultraviolet (UV), visible (VIS), and near-infrared (NIR) regions. An electrically stabilized light source supplies the polychromatic light. Light travels to the sampling probe via one fiber-optic cable and returns to the instrument via a second. This is referred to as a bifurcated fiber-optic cable.

The sample interacts with and transmits or reflects light to the input optics. External lighting may be substituted, and in that case, only a single fiber-optic input cable is needed. Because of the lower cost of today's diode array spectrophotometers using fiber optics and serial bus communications, it is more economical to use multiple spectrophotometers rather than multiplex fiber-optic inputs to just one spectrophotometer. Current instruments can scan at rates exceeding 10 scans per second without diminishing accuracy.

INSTRUMENTATION

Laser excitation permits long-distance transmission of excitation radiation to get a useful signal from the sample. Deuterium-arc and tungsten-halogen lamps provide UV or NIR radiation. See Section 8.61 for other energy sources for UV.

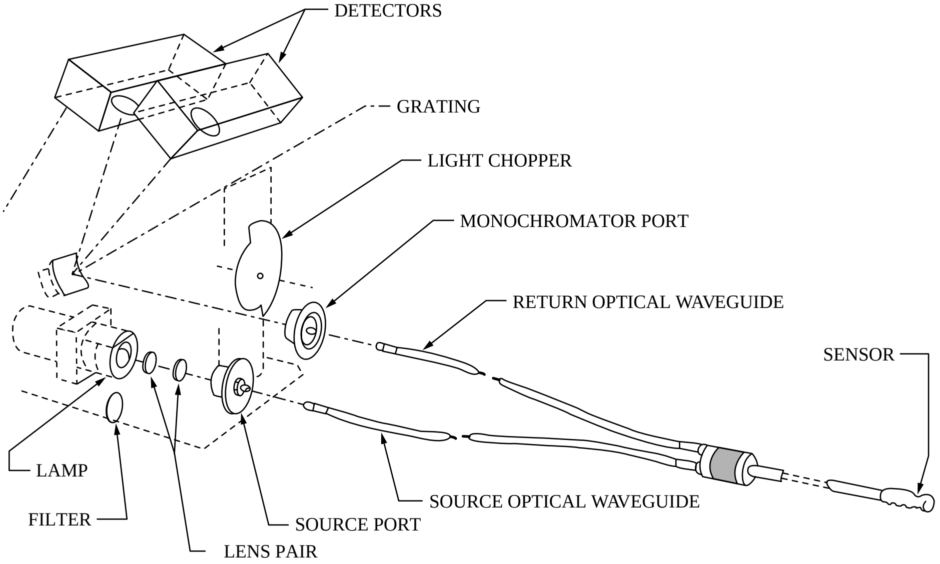

FIG. 8.23a
Modular optical train.

Glass Optical Fiber

The absorption characteristics of silica glass limit it to a spectral range of about 200 to 2200 nm and, therefore, optical quartz fiber optics are preferred. Fluoride glass is used for infrared up to 3200 nm. Two types of silica filaments are available. Certain hydroxyl (—OH) concentrations are needed to pass light in the UV spectrum. High OH filament is needed for the 250- to 800-nm range. Low OH filaments are used for the 400- to 2100-nm range.

As the length of the fiber-optic cable increases, the signal is attenuated. To avoid this problem and the cost of ultra-high-purity glass, it is often now possible to place the spectrophotometers close to the process. This also reduces the effect of cable movement. Long cables allow bundles to shift and bend, which introduces noise. Stainless steel sheathing is normally used. Several thousand filaments can be arranged in random or grouped into different arrangements such as bifurcation. Operating temperatures can range from –140°C to 480°C.

Plastic Optical Fiber

Acrylic monofilaments of different diameters can be enclosed in polyvinyl chloride (PVC) or stainless steel sheaths and used in temperature ranges from –30°C to 70°C. Most glass fiber-optic cables will have a polished epoxy seal at the ends of the bundles to provide a liquid and airtight seal. Thus, the ends of glass, as well as plastic fiber optics, can be destroyed by acidic and caustic environments. To deal with this, cells are made to accommodate the light path and the sample stream. Banner Engineering Inc. offers a wide selection of glass and plastic fiber-optic cables, accessories, and evaluation samples.

Probes

Figure 8.23b shows a variety of probes for UV-VIS-NIR measurements.

Wand Probe Wand or dip-type probes are single-sided probes for optical transmission, absorbance, reflectance, and fluorescence measurements. They can be used in laboratory reactors, process lines, or laboratory bench settings. Designed in single-strand and fiber bundle configurations, the wand probe employs a mirrored tip to reflect from the sending fibers to the receiving fibers.

The absorbance tips are available in a variety of materials and path lengths (i.e., 1 mm to 4 cm). Without the tips, the fiber bundle probes can be used for reflectance and fluorescence measurements. The mirror tip is made of gold, rhodium on brass, or rhodium on gold, and the body is made of 316 stainless steel (others are available, e.g., Hastelloy and Monel). This probe style can be adapted to laboratory robotics systems for automated processing of a high volume of samples.

Spectra-Caliper Probe Spectra-caliper probes are used for transmission measurements through solid samples such as plastic films, fibers, biological tissues, and intact plant leaves. This device provides a precise, variable path length from 0.1 to 5 mm and is also useful for measurement of light-absorbing liquids.

Transmission Probe Transmission probes are always used in pairs for optical transmission and absorption measurements. They are typically installed in a flow cell for liquid analysis, or directly in a sample or process line. The two probes are arranged in 180° geometry to pass light straight

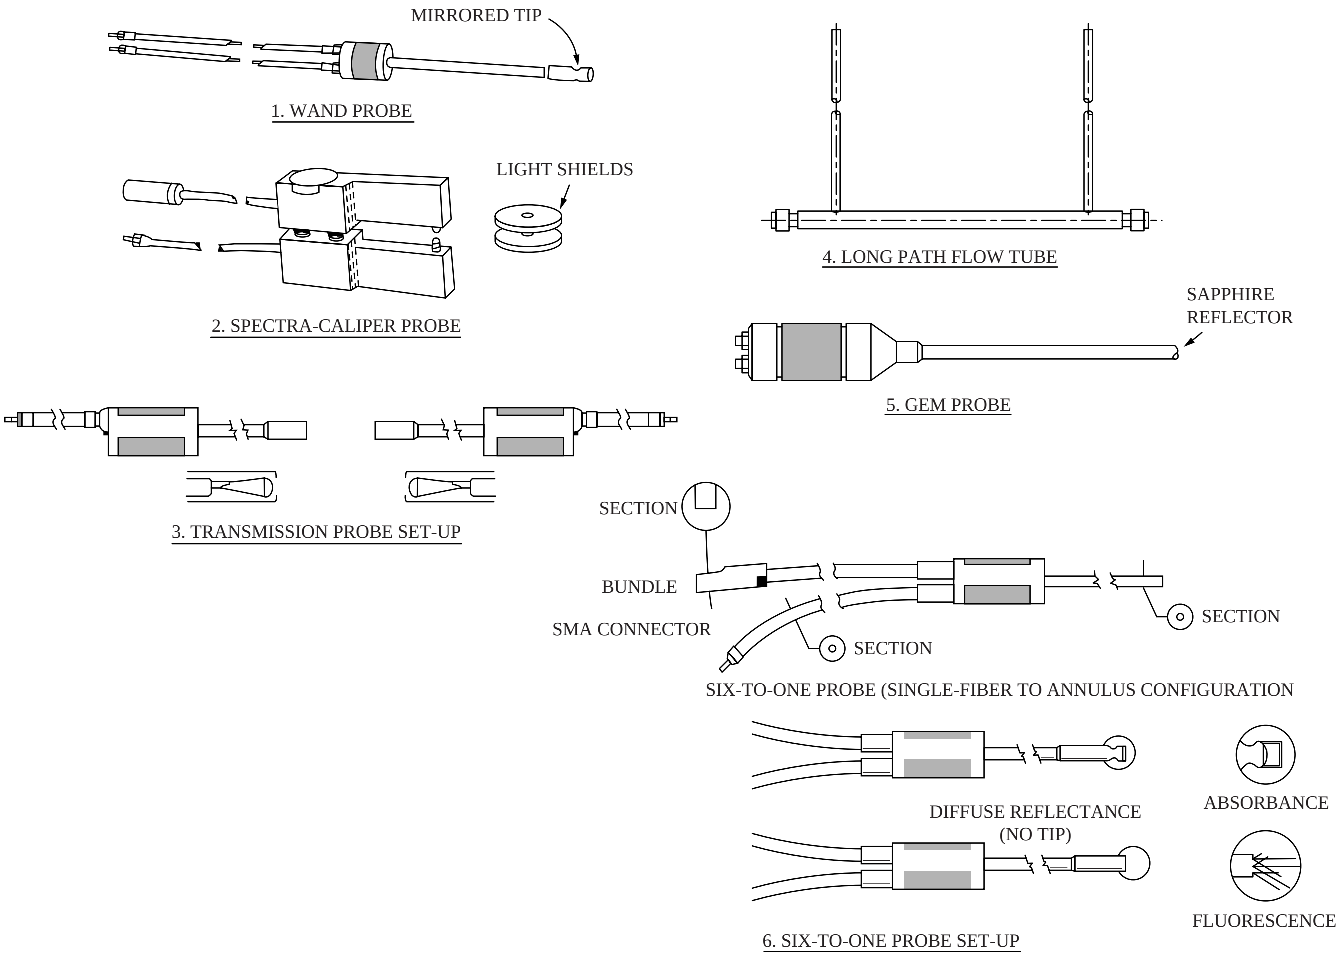

FIG. 8.23b
Sensor probe assemblies for both general and special applications. (Courtesy of Guided Wave Inc.)

through the sample. The probes are constructed of 316 stainless steel (other materials are available, e.g., Hastelloy and Monel). A sapphire window is sealed into the body with a glass frit. The sapphire window is also a lens that collimates light in transmission and refocuses light on receiving.

The path length through the sample may be from 0.5 mm to 10 cm or more. The upper temperature limit for the probe is more than 300°C, and the lower limit is less than 15°K. The probes can operate in high vacuum or at pressures up to 5000 PSIG (352 bars).

Long-Path-Flow Tube The long-path-length gas probe is used for the measurement of gases or vapors in stacks, in process pipes, or through the atmosphere. A pair of probes is required for transmission-type measurements. One probe sends a highly collimated light across the sample, and the second collects the light and focuses it back onto a single fiber. The optics can be purged with inert gas, and the window can be continuously cleaned by an air wipe.

GEM Probe GEM probes use gemstonetips such as saphire. The GEM probe is based on attenuated total reflectance (ATR) concepts and single-strand fibers. In the probe, light is transmitted by a single-strand fiber to the sapphire crystal. The light is internally reflected in the sapphire to a receiving single-strand fiber cable. The spectrum of any strongly absorbing, lower-refractive-index material in contact with the sapphire can be measured. The probe serves as a short-path-length measuring tool. The GEM probe can be used in water and in all common organic solvents.

The remote surface reflectance probe is constructed with a sapphire or quartz window to pass light toward the sample surfaces at an incident angle of 0°. Reflected energy is collected at a 45° angle. Both a liquid cooling loop and a nitrogen purge are included in the probe for heat dissipation. This probe is useful for solid and powder materials.

Six-to-One Probe The six-to-one probe has been developed for fluorescence, reflectance, and Raman. With this probe, it is possible to illuminate the sample with light from an appropriate source (xenon arc, laser, etc.) and then measure the reflected, scattered, or emitted light using six fibers mounted around the light-conducting central fiber.

There are assemblies for use in constructing probes for measuring transmittance through or reflectance from sheets or other flat surfaces, and for working with cuvettes.

Sample Interfaces

In batch or nonpressurized processes that are accessible, fiber optics in dip probes can be used. On continuous processes that are hot or under pressure, the probes must be mounted in a sample stream. Sometimes the sample stream is sent to a heat exchanger for precooling. After the analysis is made, the sample stream may be returned to the process. In order to be able to isolate the probe for replacement and cleaning, block valves should also be installed. Some of the installation options are illustrated in Figure 8.23c.

Detectors

Photomultipliers are commonly used for the UV detectors; silicon photodiodes are used for visible detectors; and germanium photodiodes and photoconductive lead sulfide detectors (both with thermoelectric cooling) are used for NIR detectors. Indium–gallium–arsenide is another material commonly used for NIR detectors. A 512-element silicon diode array with a fixed grating is available for the NIR region (700 to 1100 nm). See Section 8.61 for other types of detectors used in UV analyzers.

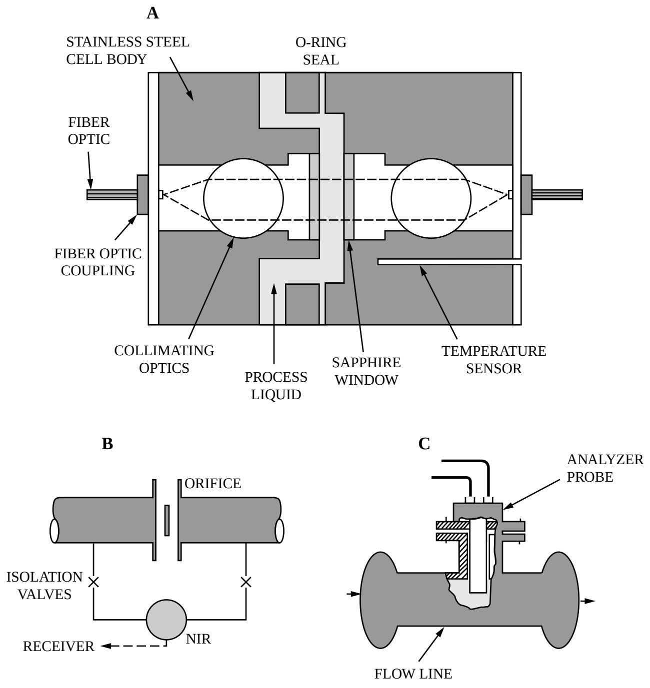

FIG. 8.23c
Alternative methods of on-line installation of NIR analyzers: (A) measurement of the complete process stream, (B) bypass configuration, (C) probe-type design.

Interchangeable dual-detector modules (Figure 8.23a) give high performance over a wide range. A grating positioning system allows rapid scanning at one detector's assigned spectral range and then switches to the second detector to complete the scan.

Successful on-line instrumentation requires a stable measurement system. This means synchronous detection where the instrument senses and compensates for drift in every cycle.

Software

Most fiber-optic spectrophotometers are supplied with spectral data analysis software for windowing desired wavelength ranges. Ocean Optics Inc. provides its SpectraScope™ operating software with features such as automatic calibration, external signaling, and real-time color measurements.

APPLICATIONS

Four approaches can be used for qualitative and quantitative chemical analysis. These techniques include absorption, fluorescence, scattering, and refractive index change.

Absorption

In the UV region, low concentrations of many unsaturated organic compounds can be measured. Some inorganic compounds such as residual chlorine in chlorinated solvents have been measured at 360 nm, and chlorine dioxide at 350 nm. See Section 8.61 for additional examples.

In the visible region, colorimetry of dyes and pigments and metal analysis can be carried out as described in Section 8.15. In the NIR region, concentrations of water and organic compounds with bonds such as CH, OH, NH, and unsaturated bonds can be monitored. The absorbance spectrum can be analyzed for octane numbers of gasolines, polymer properties and cure rates, water in solvents and resins, and food analysis for fat, protein, and sugar.

Fluorescence

Figure 8.23d illustrates the use of remote fiber fluorescence (RFF) for chemical analysis. An RFF system couples a high-intensity light into a single, large-core quartz fiber. Upon exiting the fiber, the rays of light impinge upon the sample, which gives off a characteristic fluorescent emission. The emission travels back to a photodetector, which, with the aid of a computer, can provide both qualitative and quantitative information. The fiber in the sample is called an optrode.

Using the RFF technique, measurements have been demonstrated with uranyl, chloride, iodide, iron, plutonium, and sulfate ions. RFF techniques can be used for monitoring groundwater near hazardous waste dumps. Groundwater does not normally fluoresce, but contaminated water typically does.

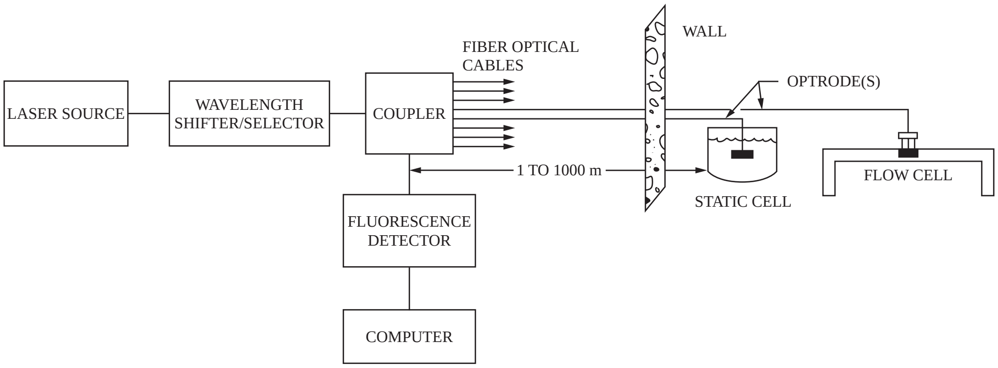

FIG. 8.23d
In RFF, the optical fibers relay the fluorescence signals from a variety of remote sampling sites.

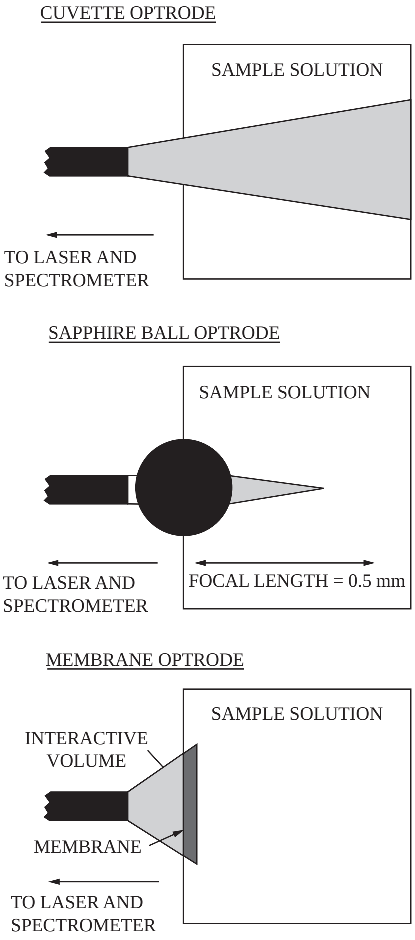

FIG. 8.23e
Optrodes are used in RFF to couple the fibers to samples.

Optrodes Figure 8.23e shows the optrodes used in the RFF. The simplest optrode is just the bare end of the optical fiber inserted into the sample or a fluorescence cuvette. If greater sensitivity is required, a small sapphire ball is used to focus laser light at a point about 0.5 mm into the sample. This ensures that weak fluorescence is concentrated near the fiber.

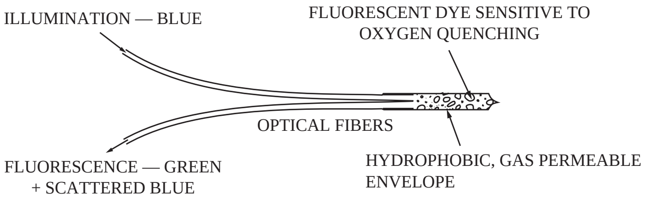

FIG. 8.23f
The construction of a fiber-optic fluorescent probe.

Another option is the membrane optrode, in which the sample flows into a small chamber, where it is interrogated by the laser light. This allows a closer control of the sample environment because fluorescence can be environmentally sensitive.

A material does not have to be fluorescent to work with the technique. A target of known fluorescence can be used. The sample can react with the target and enhance or diminish its fluorescence. Aluminum and other metals have been analyzed by using a reagent immobilized in the form of a powder and attached to a bifurcated fiber-optic cable. The metal reacts with the reagent, giving a fluorescent signal. The response time was 1 to 2 min with a detection limit of 0.027 ppm.

Oxygen Probe Figure 8.23f shows an oxygen probe, based on fluorescence quenching. In this probe, a high-intensity blue light is transmitted to the dye through one leg of a bifurcated fiber-optic probe. The blue light, upon impinging the dye, gives off a characteristic green fluorescence. The level of fluorescence diminishes with the increasing levels of oxygen that pass through the hydrophobic, gas-permeable polypropylene membrane. Oxygen reacts with the dye perylene diburyrate. The partial pressure of oxygen is a function of the ratio of blue light intensity to green light intensity.

Scattering

The scattering concept has been used to determine the volume fraction of one immiscible liquid in another (see Section 8.39) and to characterize smoke in a stack (see Section 8.46).

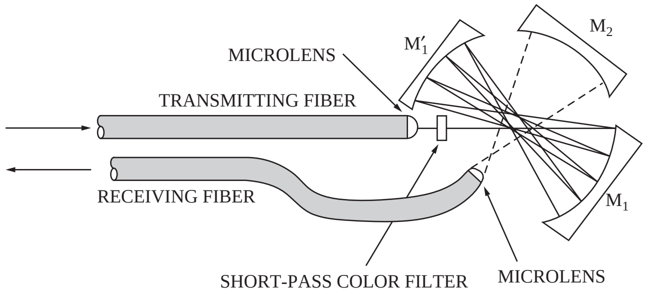

FIG. 8.23g
Multipass reflection sensor used for Raman scattering.

Raman laser scattering has been used to detect low concentrations of various gases. Figure 8.23g shows a multipass sampling probe designed to enhance the system sensitivity. The spherical mirrors labeled M_1 and M_1' provide for multiple passes of the light beam. A portion of the scattered light is injected directly into the receiving fiber, while additional scattered light reflects from M_2 into the receiving fiber.

Refractive Index

Figure 8.23h shows a reflective fiber-optic probe for sensing refractive index change. The index of the prism is sufficiently higher than that of air, so that a condition of total internal reflection will exist within the prism. Light transmitted to the prism is reflected into the fiber-optic probe. If the prism is immersed in a liquid with a refractive index higher than that of the prism, the reflected light will decrease significantly. Such a device can provide a measure of concentration, because many components of a solution alter the refractive index of the liquid, as a function of concentration. For example, sulfuric acid has a refractive index of 1.33 in low concentrations and 1.46 in concentrations over 90% by weight.

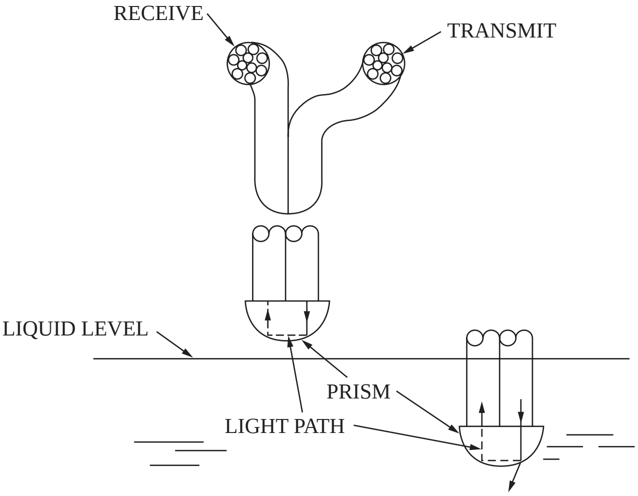

FIG. 8.23h
Reflective fiber-optic probe installed to detect changes in refractive index.

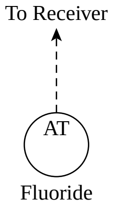
8.24 Fluoride Analyzers

J. S. JACOBSON (1974, 1982) **A. T. BACON** (1995), REVIEWED BY **R. R. JAIN**
B. G. LIPTÁK (2003)



Flow Sheet Symbol

Principles of Operation:	A. Detector tubes B. Electrochemical C. Paper tape D. Ion mobility spectrometry E. Infrared spectrometry F. Ion-specific electrodes G. Silicon dioxide sensors H. Ion chromatography I. Titration J. Colorimetric K. Gas chromatography
Materials of Construction:	Surfaces of equipment contacting fluoride should be stainless steel, Teflon, epoxy, polyethylene, or polypropylene
Concentrations Measured:	Monitoring for worker protection is usually in the 0- to 10-ppm range. Leak detection in the surroundings of hydrogen fluoride (HF) handling equipment requires sensitivity in the high parts per million (ppm) range. Monitoring for low-level environmental damage may require sensitivity in the parts per billion (ppb) range.
Sensitivity Range:	A. 0.1 to 20 ppm B. Low ppm C. Low ppm D. 0.05 to 10 ppm E. Low to mid ppm F. Low ppb to high ppm, function of sampling time, volume G. Qualitative response to high ppm levels H–K. Measurement is usually in the ppm range; sensitivity depends on sampling parameters.
Calibration:	Calibration of vapor analyzers usually is performed with permeation-type devices or with calibrated gas standards. Liquid phase analyzers are calibrated using solutions of an appropriate fluoride compound such as sodium fluoride.
Accuracy:	A. ±20% of actual measurement at low humidities, inaccurate at high humidities B–D. ±10% of full scale E. Varies with type of instrument and humidity level F, H–K. These laboratory and automated techniques are capable of providing high accuracy (±3% of actual measurement) under ideal conditions, but this is often compromised by inaccurate sample collection practices. G. Qualitative only
Cost:	A. $3/analysis, $50/sampling kit B. $1000 to $3000 C. $3500/point D. $17,000

E. $9000 (common IR) to $90,000 (FTIR)
F. $500 for electrode; $1000 to $3000 for associated electronics (for water/lab analysis); $30,000 to $80,000 for automated system
G. $1400/point
H. $10,000 to $20,000 (lab method)
I. $500 (lab method)
J. $1000 to $5000 (lab method); $25,000 (automated system)
K. $10,000 to $20,000 (lab method)

INTRODUCTION

The number of analytical techniques available for the analysis of fluoride is fairly large.[1] In the past, several of these techniques were only used in the laboratory. Table 8.24a lists a variety of automatic and manual methods for the detection of fluorides in ambient air, stacks, and process streams. In order to select the most appropriate method for a given application, the physical state and properties of the fluoride compound must be taken into consideration.

TYPES OF FLUORIDE COMPOUNDS

Fluorides can exist as gases, liquids, and solids. The most common form of fluoride is hydrogen fluoride (HF). This compound is very volatile. Its boiling point is 66.9°F (19.4°C), and therefore it is most often analyzed in the vapor state. All the methods that are described as gas or vapor fluoride analyzers detect this compound.

Other compounds, such as UF6, which exist in the vapor phase, hydrolyze quickly in ambient air or solution to form

TABLE 8.24a
Orientation Table for Fluoride Measurement Methods

	Automatic or Manual Method	*Suitable for Water Analysis*	*Gas or Particulate Measurement*	*Suitable for Stack/Process Monitoring*	*Suitable for Organic Fluoride Monitoring*
Tubes	M	No	G	No	Yes[d]
Electrochemical	A	No	G	Some[c]	No
Paper tape	A	No	G	Some[c]	No
Ion mobility spectrometry	A	No	G	Yes	Yes[d]
Ion-specific electrodes	A/M[a]	Yes	G/P[b]	Some[c]	No
Silicon dioxide sensor	A	No	G	Leak detection	No
Ion chromatography	M	Yes	G/P[b]	Some[c]	No
Titration	M	Yes	G/P[b]	Some[c]	No
Colorimetric	A/M[a]	Yes	G/P[b]	Some[c]	No
Gas chromatography	A/M[a]	Yes	G	Some[c]	Yes
Infrared	A	No	G	Some[c]	Yes

[a] Manual method can be performed in lab; automatic systems are available.
[b] Particulate measurement requires special collection techniques.
[c] Suitability for stack monitoring depends on moisture present, interference, etc.
[d] Required pyrolysis equipment available from manufacturer; other methods may be adapted with custom equipment.

HF, and thus can be analyzed indirectly by these methods.[2] Other liquid and gaseous fluorides are much more stable and do not easily form HF. These compounds must be broken down prior to analysis. A common method of conversion is thermal decomposition, which is followed by analysis of the resulting HF.

Many solid fluorides are soluble in water and form fluoride ions. If fluoride is present in the air in the form of fine particles, these compounds can be collected on filters and analyzed by wet laboratory or automated methods. Since the automated wet methods operate by impinging an air sample into a wet collection stream, if total fluoride concentration measurement is required,[3,4] care must be taken to assure that the particles are freely admitted into the collection vessel.

Other fluoride-containing solids are not water soluble and require thermal decomposition at very high temperatures prior to analysis as HF.

ANALYZER TYPES

In most cases, the goal of the analysis is to determine the quantitative amount of fluoride in a sample. In other cases, only the presence of HF needs to be determined. Qualitative sensors such as silicon dioxide are used to detect HF leakage from valve connections and other joints. These sensors do not provide quantitative information.

Most other devices discussed in this section provide some degree of quantitative information.

Analyzers are also grouped according to their operation, which can be automatic or manual. Purely manual devices such as detector tubes require an operator to collect and read the sample. Some of the manual laboratory techniques have been automated and depend on colorimetric, ion-specific electrodes and gas chromatography (GC) techniques for their analysis. Yet other analyzers are fully automatic and do not require operator attention, except for maintenance.

Fluoride analyzers are also grouped on the basis of the sample phase into vapor and liquid analyzers. In the case of ion-specific electrodes, titration, and colorimetric methods, fluoride analysis requires an aqueous sample. On the other hand, the concentration of airborne fluoride is determined by using an impinged or absorbed sample. The remaining techniques are used for analysis of the vapor phase.

The selection of an analyzer for a particular application will depend on the type of process sample, which is to be monitored, cost, accuracy, speed of response, range, and frequency of maintenance. These considerations are discussed below.

Gas and Vapor Analyzers

Detector Tubes These devices utilize a hand-operated pump to draw a known volume of air through a calibrated tube. The fluoride concentration in this case is indicated by the resulting color. The initial investment in equipment is very low, but this method is acceptable only if infrequent measurements are sufficient. Detector tubes are commonly used for spot monitoring in industrial hygiene applications.

Electrochemical Cells An air sample is presented to the cell, either actively or passively (Figure 8.24b). The sample permeates into the cell, usually through a membrane, where an electrochemical reaction produces a current proportional to the concentration. The initial cost is relatively low. Some types require fairly high maintenance, although this is less of a concern on more modern designs. Cells are most often used in ambient air monitoring and are not easily adapted for process control. Some models are prone to freezing at low temperatures and do not operate well at humidity extremes.

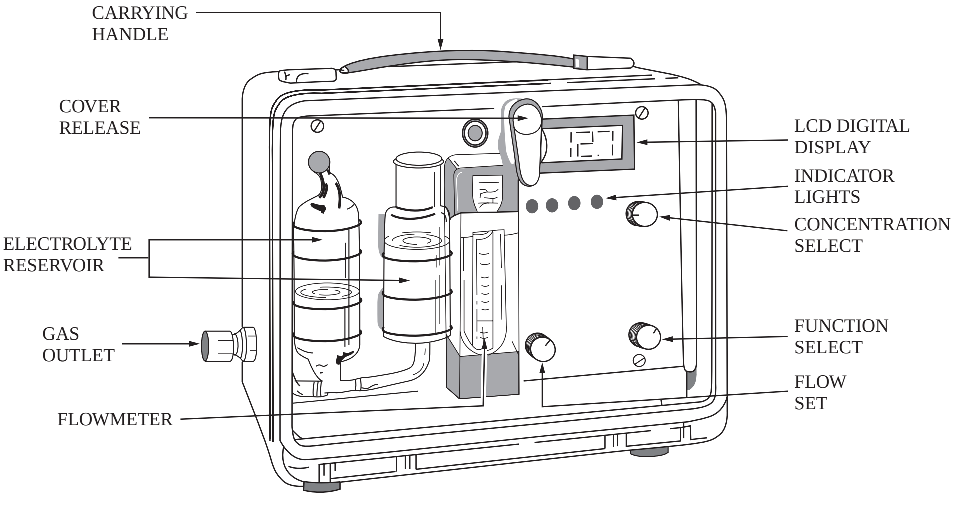

FIG. 8.24b
Portable gas monitor with electrochemical sensor. (Courtesy of Sensidyne Inc.)

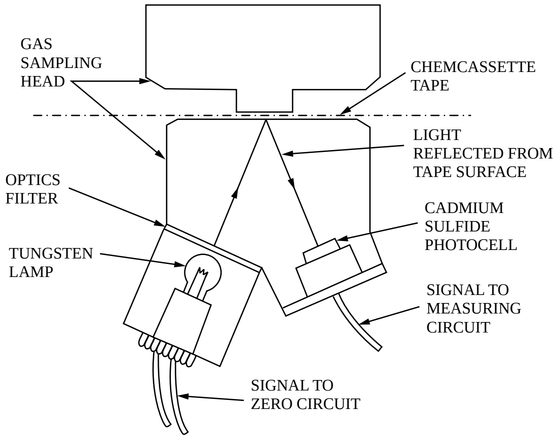

FIG. 8.24c
Fluoride concentration can be detected by monitoring the reflected light intensity from a chemically treated tape. (Courtesy of Zellweger Analytics, which MDA Scientific Inc. joined.)

Paper Tape An air sample is drawn through a chemically treated tape, and the colorimetric change is read with a photometer (Figure 8.24c). The tape is automatically advanced as fluoride is detected. The initial cost is moderate, but expendables can be expensive if fluoride is constantly present. Tape has the advantage of not requiring an independent calibration, as each tape is calibrated at the factory. Tape is most often used for ambient air monitoring and is easily adapted for multipoint sampling. Tape is not commonly used for process control or outdoor applications.

Ion Mobility Spectrometry Air is drawn into the instrument and the sample permeates through a membrane into a cell, where it is ionized by a small radioactive source. The analysis technique is similar to that of time-of-flight mass spectrometry (MS) but is performed at atmospheric pressure. The initial cost is moderately high, but maintenance is minimal.

This technique has found wide acceptance in the petrochemical industry due to its high reliability, good interference rejection, and ability to operate accurately at extremes of ambient temperature and humidity. This technique is most often used for outdoor ambient air monitoring and can be adapted for process control and stack monitoring. The chief disadvantage is the requirement for a constant supply of dry instrument air, and purging in flammable environments.[5,6]

Infrared Spectroscopy A gas sample is drawn into an optic cell where a characteristic infrared (IR) absorbance is used to determine concentration (Section 8.27). Several types are available, including nondispersive infrared (NDIR) and Fourier transform infrared (FTIR). Prices range from moderate to expensive, depending on analyzer type and features. Sensitivity is determined mainly by path length. In most cases, water vapor produces a strong interference, masking HF response.

The advantage of FTIR is the ability to monitor for several gases with the same analyzer. IR analyzers are typically used in applications such as stack monitoring, after sample cleanup. IR analyzers may also be used to monitor for certain fluorinated organic compounds.

Ion-Specific Electrodes The concentration of fluoride ions in solution is monitored by using an ion-selective electrode (Section 8.28), which provides a millivolt output signal in response to the activity of fluoride ions in the solution. The fluoride-selective ion electrode, in conjunction with a reference electrode, develops its potential across a doped fluoride crystal membrane. When the electrode is placed in a solution, the ions from the solution move to the surface of the membrane and the electrical charge of the ions creates a potential difference across the membrane. At equilibrium, this potential difference is proportional to the activity of the fluoride ions in the solution.

These probes are inexpensive for laboratory applications but become expensive when used as automatic on-line monitors in continuous measurement applications. The advantages of selective-ion detection of fluoride include their selectivity, large dynamic range, and good sensitivity.

Disadvantages include relatively high maintenance, which includes the need for buffering the solution sample using concentrated acetate or citrate for pH adjustment between 5.3 and 5.8. In addition, CDTA or EDTA complexing agents are also used to prevent interference from metals. The electrodes are very sensitive to temperature effects and must be carefully controlled. This method is most often used for lab analysis and in applications that demand the selectivity and sensitivity provided.

Silicon Dioxide Sensors Atmospheric HF causes etching of a thin layer of silicon dioxide. A light source and photo-optic receiver are used to monitor the rate of etching. Initial and operating costs are both low. Little maintenance is required other than periodic replacement of the disposable sensor tip. Because of the highly specific nature of the reaction and the ability to respond quickly to relatively high localized concentrations around flanges, etc., this method is most commonly used to monitor for leaks. The output is essentially qualitative.

Laboratory Methods The most common laboratory methods are ion-specific electrodes, ion chromatography, titration, and colorimetric methods.[8] Ion-specific electrodes have been discussed above. Ion chromatography uses modified high-performance liquid chromatography equipment. Although expensive, this equipment can also determine a large number of other ions at the same time. Titration and colorimetric methods rely upon chemical reactions, which produce a color change. Both of these methods rely upon common lab equipment and procedures. All of these lab methods can be used in the analysis of water samples. Automated and semiautomated equipment exist for most of these methods.

Organic Fluoride Analysis

The two most common methods of analyzing organic fluorides, such as Freons, are gas chromatography and pyrolysis followed by any of the conventional analysis procedures. GC methods may make use of a universal detector and simply rely on retention time to identify and quantitate the sample, or a halogen-specific detector such as a thermionic bead may be used.[9] Pyrolysis kits are available for use with detector tubes.

Other Methods

Two other methods have been demonstrated as having potential for the detection of fluoride: mass spectrometry and open-path laser-based systems. Commercial MS analyzers are available for lab and process use, and these instruments have the theoretical capability to identify both organic and inorganic fluorides in the gas phase, although their use would be very limited because of the relative complexity of these devices. Laser-based open-path systems have been demonstrated in the prototype stage but are not yet commercially available.

INTRODUCTION

Hydrocarbon analysis is discussed in several sections in this chapter, including Section 8.12 on chromatographs, Section 8.16 on combustibles detection, Section 8.39 on oil-in-water measurements, and Section 8.58 on total organic carbon analysis. Therefore, it is advisable to also refer to these sections when investigating the features and capabilities of a particular hydrocarbon analyzer type.

The hydrocarbons comprise a large class of individual components (Table 8.25a). The most abundant hydrocarbon, methane, is nonreactive in photochemical reactions and is a less hazardous air pollutant. The remaining hydrocarbons vary widely in their complexity and reactivity. For this reason, the type of hydrocarbon analysis selected depends on the purpose for which data are needed.

To obtain highly detailed analyses for numerous hydrocarbons requires expensive and sophisticated equipment, whereas a single measurement for total hydrocarbons is simpler and somewhat less expensive. There are also methods of intermediate complexity, which permit determination of properties without identification of the individual stream components.

TABLE 8.25a
Atmospheric Hydrocarbon Analyzers

	Hydrocarbon	
Type	*Method*	*Limitations and Interferences*
Total (as carbon)	FID	Some response to carbon-containing nonhydrocarbons
Methane	GC	Expensive equipment (can also be used for carbon monoxide)
Methane-only subtractive	Column preparation fussy column and FID	
	Mass spectrometry	Freeze-out required, expensive
Aromatics, olefins, paraffins	Subtractive columns and FID	Column preparation fussy
	Mass spectrometry	Freeze-out required, expensive, data reduction requirements large
	Infrared spectrometry	Freeze-out required, expensive, not total class coverage
	Ion mobility spectrometry	Clean sample required, limited knowledge in industry
	Laser-induced absorption	Expensive, specialized support required
	Perimeter monitoring	Concentration/unit length rather than point value
Individuals	GC	Expensive, data reduction requirements large

ANALYZER TYPES

Flame Ionization Detectors

Flame ionization detectors (FIDs) are used to measure total hydrocarbons at low concentrations such as for pollution, leakage, or safety monitoring. In the FID analyzer, a flame of pure hydrogen, which contains almost no ions, is used. When even traces of organic compounds are introduced by the sample, the hydrogen flame ionizes the carbon atoms, resulting in a large number of ions in the flame. The resulting ionic current is measured as an indicator of hydrocarbon concentration. In dual-flame detectors, the concentration of total hydrocarbons and methane can be identified separately.

Flame ionization detection is the most suitable means of analysis for most hydrocarbons at the levels found in polluted air. It may be used alone for the measurement of total hydrocarbons or as a detector after separation by a column device such as a gas chromatograph. In FID analyzers, a sensitive electrometer detects the increase in ion intensity in a hydrogen flame when a sample containing organic compounds is introduced. The response is approximately in proportion to the number of organically bound carbon atoms in the sample, so the detector is basically a carbon atom counter. Carbon atoms bound to oxygen, nitrogen, or halogens, however, give a reduced response.

There is no response to nitrogen, carbon monoxide, carbon dioxide, or water vapor. The results are usually expressed in terms of the calibration gas used, e.g., parts per million (ppm) carbon as methane. The response is rapid and can be as sensitive as 0.1 ppm. The response to various hydrocarbons is not perfectly uniform, and such variations should be taken into account in interpreting FID data. The FID analyzer is a reference method for total hydrocarbons in U.S. Air Quality Standards. Basically, it is an air-metering device attached to a FID (Figure 8.25b).

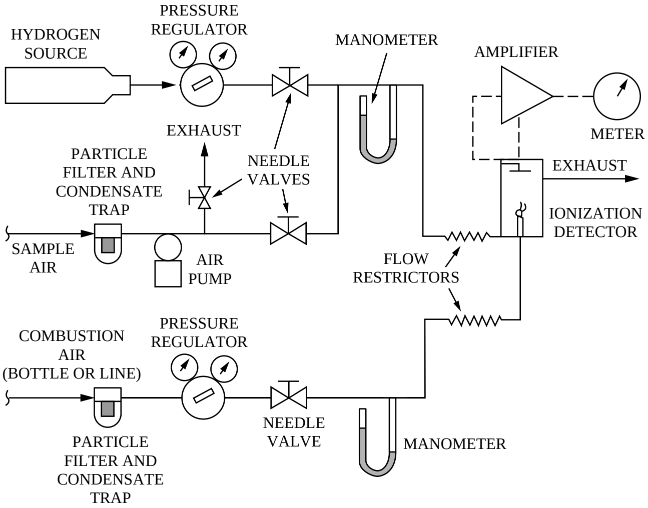

FIG. 8.25b
Hydrocarbon analyzer and hydrogen FID.

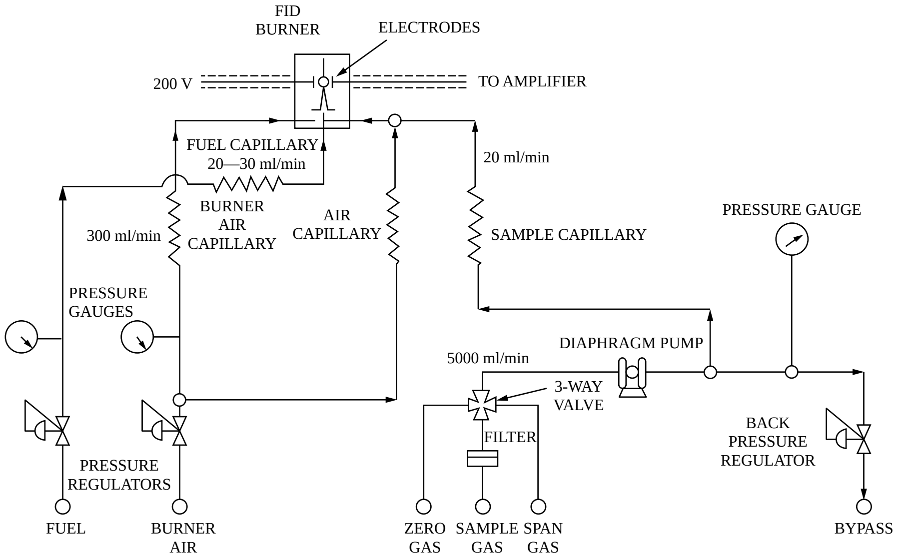

Fig. 8.25c
Sampling system for hydrocarbon analysis by FID.

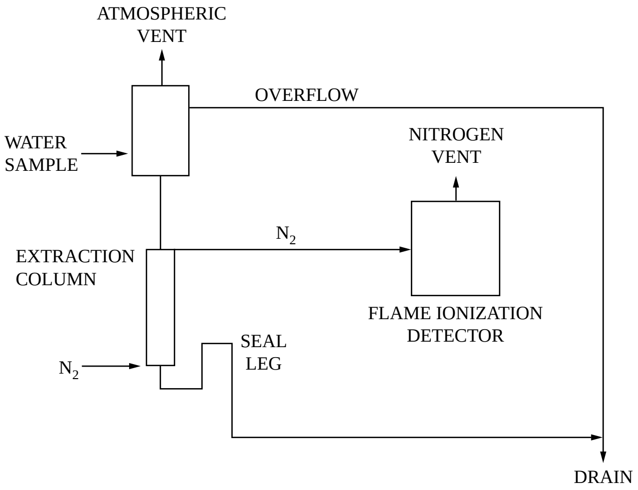

FIG. 8.25d
Detection of purgeable hydrocarbon concentration in water samples. (Courtesy of ThermoOnix, formerly Fluid Data/AMSCOR.)

In microprocessor-controlled hydrocarbon analyzers, up to eight channels can be obtained for the simultaneous analysis of eight samples. Manufacturers also provide sampling systems (Figure 8.25c), which make remote calibration and automatic self-checking possible.

If discrete component analysis is not required, it is also possible to use liquid samples in conjunction with FID-type hydrocarbon analyzers if the hydrocarbons can be purged by nitrogen from the continuous liquid sample. Such a sampling system is shown in Figure 8.25d, where a nitrogen extraction column is used, serving to remove the hydrocarbon, which can be removed by purging. Here the nitrogen is introduced at the bottom of the extraction column, and as it travels upward, it removes the purgeable hydrocarbons. The overflow level in the head tank, which seals the top of the column as the purge nitrogen leaves it, holds the extraction column pressure constant.

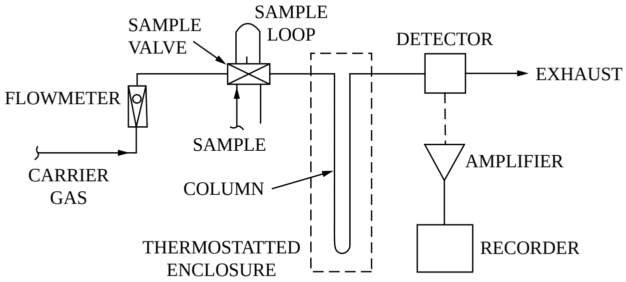

FIG. 8.25e
Gas chromatograph.

Gas Chromatography

The only practical method for the measurement of specific hydrocarbons is gas chromatography (GC). In GC, the basic apparatus (Figure 8.25e) is a carefully prepared tubular column of a finely divided solid with provisions for passing a steady flow of a carrier gas (often helium) through it (Section 8.12). The column is temperature controlled and the packing usually supports or is coated by a nonvolatile liquid phase.

Preceding the column, there is a means for sample introduction (and sometimes sample splitting), and following the column is a detector. A high-sensitivity column usually employs a FID. There are a great many optional variations in the makeup of a GC instrument, involving sample valves, precolumns, columns, programmed temperature and pressure changes, stream splitters, and detectors.

Traditionally, the output was recorded on a strip chart (possibly with a peak integrator) or converted to digital form for computer handling. In full-scale analyses for scores of hydrocarbons, data reduction from analog strip-chart recordings becomes very tedious and time-consuming. Most gas chromatographs use a computer interface to analyze and report the results of each analytical cycle as well as a wealth of related equipment health conditions.

Supplemental techniques increase the utility of GC for atmospheric hydrocarbons. A common method is to pass a sample of air through a small freeze-out trap, sweep out the air with helium, and then warm the trap and introduce the condensables to the GC column in one concentrated slug. This extends the lower limits of sensitivity to the parts per billion range. Subtractive columns may be in parallel or in series with conventional columns to help relate the various recorded peaks to specific hydrocarbon classes.

Calibration Complete GC calibration would require hundreds of different pure hydrocarbons and is never fully achieved. There are usually few unknowns left in careful work except in the more complex higher-molecular-weight ranges. Calibration is based on the fact that under carefully reproduced conditions, a given hydrocarbon will always require the same length of time to pass through the column to the detector. Ambiguities arising where components overlap may be resolved by change in column packing, increasing the analytical cycle time and column length, or sometimes by the use of subtractive columns. An elaborate but useful technique is to attach another analytical instrument such as an infrared (IR) or mass spectrometer to the outlet of the detector for peak identification.

In Figure 8.25f an instrument is described for combined analysis of methane and carbon monoxide. This is a simple GC, set up to determine methane, with a programmed arrangement of valves and a catalytic carbon monoxide-to-methane converter. As a result, the readout has two peaks, one for methane directly and the other for methane formed by reduction of carbon monoxide.

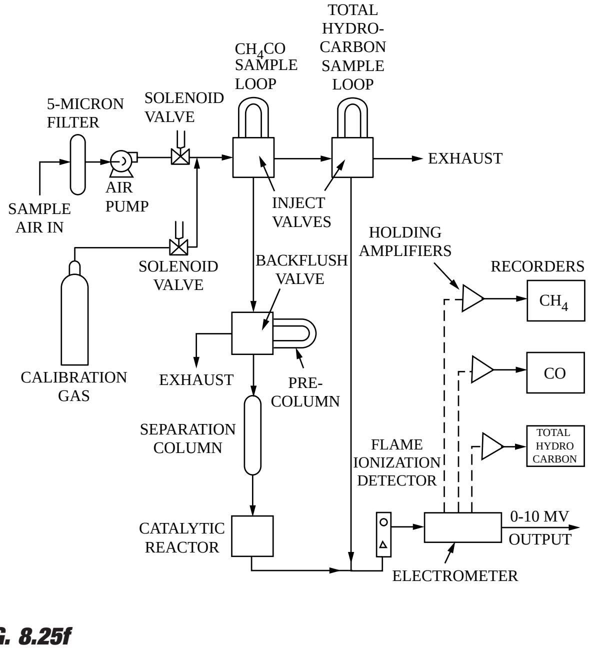

FIG. 8.25f
Methane and carbon monoxide analyzer.

Nonmethane Hydrocarbons A column of adsorptive charcoal may be treated with methane just until breakthrough occurs; that is, no more methane will be adsorbed, but other hydrocarbons are still retained. This column can then be used with a FID as an analyzer for methane only. Used in parallel or in switched alternation with the detector without any column, it allows determination of nonmethane hydrocarbons by difference.

Reactive Hydrocarbons Certain specially prepared columns can be used to adsorb specific hydrocarbon classes. These are useful in GC and could be used with a simple FID analyzer alone to give analysis by broad classes. A column of crushed firebrick supporting mercuric sulfate will adsorb olefins and acetylenes, and one of palladium sulfate will then adsorb aromatic hydrocarbons (except benzene). A combination of these subtractive columns has been applied successfully to automobile exhaust analysis and for use in atmospheric work.

Spectrometric Methods

Either infrared or mass spectrometry may be used with considerable advantage for individual hydrocarbon determination, although the sensitivity of both methods would require concentration such as by a freeze-out trap if used for atmospheric measurements. Both types of instruments are complex and expensive. Since the calibration requirements are about equal to those needed for GC, the data interpretation is generally more complicated and the extent of coverage is less; these methods have been widely supplanted by GC for atmospheric hydrocarbon detection work. These instruments may be useful for analysis of a particular type or class of hydrocarbon and might make it unnecessary to set up a gas chromatographic capability in some cases.

Laser-Induced Doppler Absorption Radar Laser-induced Doppler absorption radar (LIDAR) can be used to remotely measure chemical concentrations in the atmosphere. Two different laser wavelengths are selected so that the molecule of interest absorbs one of the wavelengths while the other wavelength is selected to be in a region of minimal interference. The difference in intensity of the two returned signals is then used to determine the concentration of the gas being measured using the Lambert–Beer law.

By measuring the time taken for the light to travel and return, it is also possible to determine the distance from the base station to the measurement point. It is therefore possible to use LIDAR to "map" the chemical composition of an emission source in three dimensions, and from a great distance.

Spectroscopy Perimeter Monitoring Perimeter monitoring can be done with both ultraviolet (UV) and IR spectral equipment. The selection between IR and UV is determined by the absorption of the gases to be measured. Typical installations have a transceiver at one end and a retro-reflector at the far end. The light, typically at two wavelengths (reference and measurement), is transmitted to the mirror at the other end of the path of interest and then reflected back to a receiver in the same electronics enclosure. The resultant measurement is an average of the concentration of the gas of interest over the distance between the two units.

Newer models have separate transmitter and receiver assemblies, thus making it possible to measure around corners by using the appropriate reflectors. Path lengths of several hundred meters are typical, though distances of greater than 1 km are possible.

Ion Mobility Spectroscopy

Since this technique is not often used to monitor hydrocarbons, it is mentioned here only for the sake of completeness.

This technique is best suited to detect elements in Group VIIA of the periodic table (Cl, Fl, I, etc.), though the range is being expanded and has also been applied to the detection of ammonia as well as other chemical agents, especially those associated with explosives. While in theory this technique can measure multiple gases, the selective membranes, dopants, diluents, and spectrometer configurations are normally optimized to measure a single gas.

Hydrocarbon Dew-Point Meter

The dew point of natural gas is that temperature at which significant condensation starts to be formed on a chilled surface. A chilled-mirror instrument of the dark-spot design can be used for this measurement (Figure 8.25g). With this technique, almost invisible films, having sensitivities on the order of 1 ppm, become detectable. In this instrument, the optical surface is provided with a V-shaped depression.

When the surface is dry, the reflection from it results in a dark spot (as shown in Figure 8.25g). As hydrocarbon condenses on this surface, the scattered light intensity in the dark-spot region is reduced. Optical fibers are used to detect this reduction of intensity, while miniature thermocouples measure the surface temperature of the mirror.

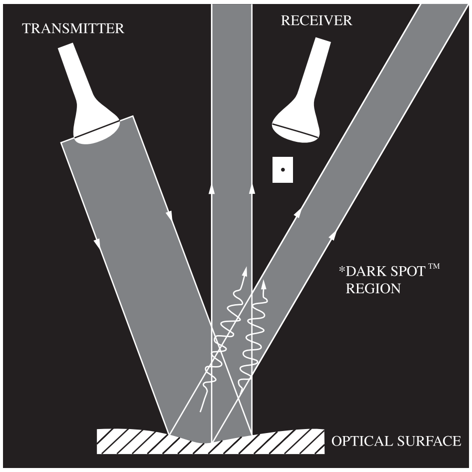

FIG. 8.25g

Measurements principle of the dark-spot-type chilled-mirror analyzer, which is used to measure the hydrocarbon dew point in natural gas. (Courtesy of Michell Instruments Ltd.)

CALIBRATION METHODS

Only dynamic calibration is completely satisfactory. In this procedure, known concentrations of the gases to be measured are passed into the analytical system, preferably in exactly the same way as the unknown samples are collected. This may be difficult to accomplish because of low concentrations or because some components might condense or react with other components.

Standard calibration mixtures of one or several of the common hydrocarbons in carrier fluids are available commercially in high-pressure gas cylinders. These should always be checked against a reference standard, or at least against a previously calibrated analyzer. If much calibration is necessary, it may be useful to set up a gas-handling and dilution system to prepare standard mixtures.

One fairly simple technique for hydrocarbons, such as butane (which can be liquefied at moderate pressure), uses permeation tubes. These are sealed tubes of a specific plastic, partially filled with liquid hydrocarbon. As long as some liquid remains, the hydrocarbon will effuse through the walls of a given tube at a rate depending only on temperature. To generate a known concentration, carrier gas is passed over the tube at a controlled rate in a temperature-controlled vessel. The tube may be calibrated gravimetrically.

In another technique, used to calibrate atmospheric hydrocarbon analyzers, a known amount of hydrocarbon is added by syringe or by crushing an ampoule, either in a large rigid vessel of known air volume or into the metered flow of air passing into a plastic bag. The bag must be of inert plastic; it has the advantage of collapsing as the sample is withdrawn, whereas a rigid vessel must be large in relation to the sample size in order to avoid substantial pressure differentials.

ASSESSMENT

For total hydrocarbon measurement, the flame ionization analyzer is the most generally accepted detector. For proper operation, it requires the attention of operators and it also consumes compressed gases, but it is reliable and accurate.

Nondispersive infrared (NDIR) sensors can only identify hydrocarbon classes, whereas two-wavelength IR detectors are able to identify individual hydrocarbon species. In this design, sensitivity is traded for specificity.

The methods that are capable of identifying specific classes of hydrocarbons are complex and are less precise or reliable, but they are not much more expensive than the flame ionization analyzer. (The spectrometer methods, unless already in use for other reasons, are not as competitive.)

If individual hydrocarbon determination at low concentrations is required, there is no good alternative to GC (frequently augmented with a freeze-out step), even though the data reduction is time-consuming (if manual) or expensive (if computerized), and calibration requirements are also demanding.

Ion mobility spectroscopy and the other spectrometric techniques are only used in special applications.

Flow Sheet Symbol

Analyzer Types:	Electrochemical gas diffusion, solid-state or gold-film sensors, tape staining, UV photometric, gas chromatography
Ranges:	0 to 50 ppm is typical for ambient air monitors, with maximum range up to 0 to 500 ppm. For process applications, ranges up to 0 to 100% are available.
Inaccuracy:	3 to 5% of full scale for air monitors; 1% of full scale for process analyzers
Costs:	Pocket-size, battery-operated monitor costs \$600 to \$1000; portable microprocessor-based diffusion-type unit costs \$2500; for UV photometric and chromatographic analyzers, prices are in excess of \$20,000 (see Sections 8.12 and 8.61).

INTRODUCTION

Hydrogen sulfide (H_2S) is a toxic gas found in many industrial environments. It is commonly monitored for personnel safety, environmental protection, and process control. This section will describe the more frequently used commercial instruments for ambient and on-line measurement of H_2S in process gases and liquids.

ELECTROCHEMICAL CELLS

For portable, battery-operated instrumentation for ambient air monitoring, the most common sensors are the fuel-cell-type electrochemical gas diffusion sensors.

Fuel cells convert the chemical energy of fuel and oxygen into electrical energy, while the electrode and the electrolyte remain unaltered. Fuel is converted at the anode into hydrogen ions, which travel through the electrolyte to the cathode, and electrons, which travel through an external circuit to the cathode. If oxygen is present at the cathode, it is reduced by these electrons, and the hydrogen and oxygen ions eventually react to form water.

The electrochemical sensors are available in pocket-size, battery-operated packaging, with replaceable “pop-out” sensors. The advantage of these units is that they do not require pumps or aspirators to pull in the sample, and they are unaffected by wind or variations in relative humidity.

These pocket-size units are usually configured for a number of channels, which might include H_2S, CO, O_2, and CH_4 (Figure 8.26a).

In the sensor, a pair of polarized electrodes is isolated from the ambient air by a gas-permeable membrane. As hydrogen sulfide diffuses through the membrane, an oxidation–reduction reaction occurs and the resulting electrons cause a current flow, which is in proportion to the H_2S concentration in the air.

Some of the limitations include interferences from background gases such as hydrogen, carbon monoxide, ethylene, sulfur dioxide, chlorine, methyl mercaptan, nitric oxide, and nitrogen dioxide. The units are also available as explosion-proof transmitters (Figure 8.26b) for near-ambient temperatures and up to 10-PSIG (0.7-bar) services. The electrochemical sensors are preferred in pure oxygen or in benign atmosphere applications or where ruggedness is less important than accuracy.

GOLD-FILM AND SEMICONDUCTOR SENSORS

Gold films absorb hydrogen sulfide and respond to its concentration by a proportional change in their electrical resistance. These analyzers usually include an internal pump that draws in the ambient air. One advantage of the gold-film sensor is that it is available in the parts per billion (ppb) range, and it is not sensitive to interference by SO_2, CO_2, or CO.

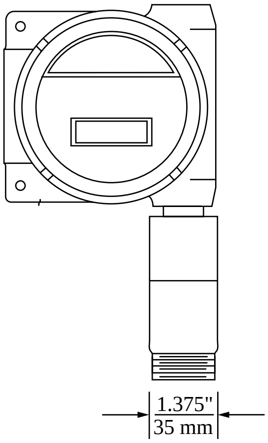

FIG. 8.26b
Diffusion-type electrochemical hydrogen sulfide detector.

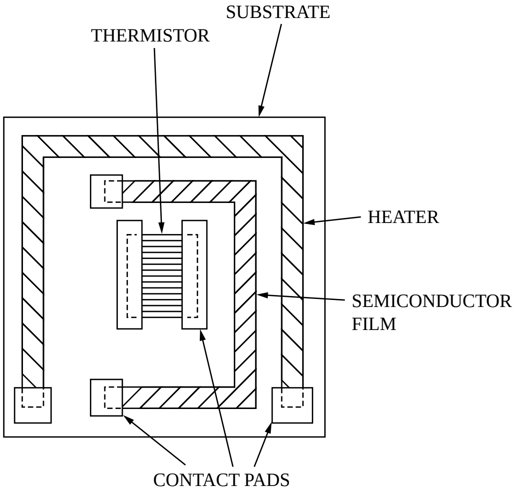

FIG. 8.26c
Schematic of a solid-state H_2S sensor.[1]

Solid-State Sensors

Solid-state sensors are used in combustible gas detection equipment for the measurements of H_2S in ambient air at the parts per million (ppm) level. The advantage of the solid-state approach is that there is no sampling system involved. The solid-state H_2S sensors are formed by depositing thin films on silicon chips, as shown in Figure 8.26c. Separate film layers serve as heaters, temperature-monitoring thermistors, and H_2S-sensitive metal oxide semiconductors. If the semiconductor is heated to a constant temperature in the 150 to 300°C range, a measurable decrease in electrical resistance occurs if exposed to H_2S. The resistance decrease is a logarithmic function of H_2S concentration.

In the case of the solid-state sensor, hydrogen, isopropanol, ethyl, and methyl mercaptan interfere with the measurement. In general, solid-state sensors are preferred to detect high concentrations or to operate under extreme temperatures, vibration, or in corrosive atmospheres.

LEAD ACETATE TAPE STAINING

This type of analyzer system is used by industry for attaining compliance with the U.S. Environmental Protection Agency (EPA) Fuel Gas to Combustion Devices Regulations. It has a history of on-stream field performance and reliability for measuring H_2S in gas streams such as coal gas, natural gas, and mixed propane–butane. It is specific to H_2S. The system's ability to report H_2S levels enables timely corrective actions to be taken to protect against upset, contamination, and corrosion buildup.

Figure 8.26d shows the instrument and its operating principles. Sample at a constant flow rate enters a humidifier where it bubbles through a 5% acetic acid solution. The sample then flows into the reaction window of the sample chamber, where it passes over an exposed surface of paper sensing tape impregnated with lead acetate; the tape is automatically driven by a motor. Hydrogen sulfide reacts with lead acetate to form lead sulfide, causing a brown stain on the paper. The rate of reaction and resulting rate of color change is proportional to the concentration of H_2S in the sample.

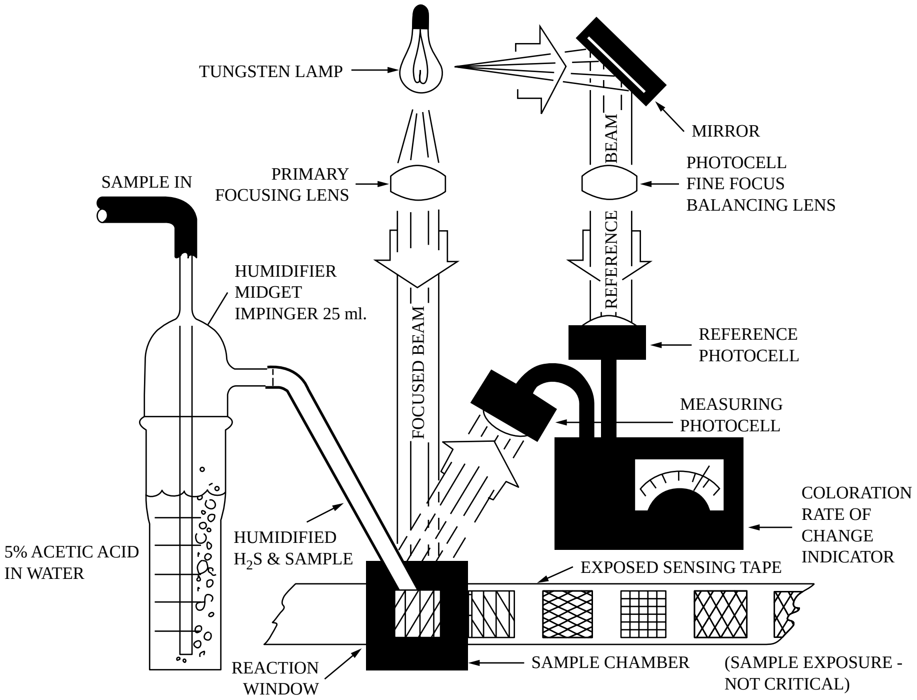

FIG. 8.26d
Rate of change of reflectance-type H_2S readout system. (Courtesy of Houston Atlas Inc.)

An optical system, photocells, and first-rate derivative electronic processor provide an output voltage proportional to the rate of change of the photocell output voltage. This output is proportional to concentration of H_2S in the sample. A reference photocell compensates for light intensity changes.

PHOTOMETRIC ANALYSIS

The measurement of the ultraviolet (UV) absorption of H_2S provides a sensitive and selective technique for monitoring H_2S concentrations in gas streams in which no other UV-absorbing compounds are present. Direct photometric analysis and the analysis systems described below for monitoring low levels of H_2S are all operating successfully in gas processing plants and oil refineries.

Direct Photometric Analyzer

Figure 8.26e shows a flow diagram of a direct photometric analyzer system for monitoring low levels of H_2S in interference-free gas streams. (See Section 8.61 for a detailed description of the split-beam UV analyzer.) The system uses a bypass stream to decrease sample lag and a self-cleaning filter to minimize particulate matter in the sample. The sample pressure is maintained within the sample cell with a back-pressure regulator after the sample cell. The analyzer sample cell is purged with air or nitrogen when automatic zeroing is required for high-sensitivity measurements.

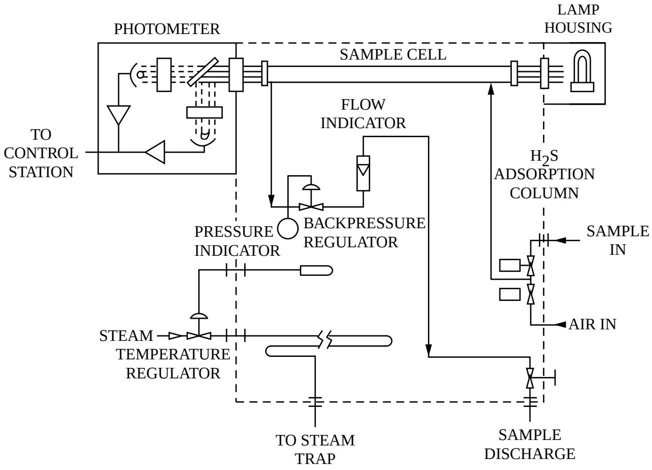

FIG. 8.26e
Direct low-level H_2S photometric analyzer.

Where the level of potentially interfering compounds is relatively low and not rapidly changing, the above system has operated successfully using the sample gas with the H_2S selectively removed as the “zero” reference gas. Potentially interfering compounds are those with conjugated double bonds, such as 1,3-butadiene and aromatics and other sulfur compounds.

Where background absorbance is excessively high and changing rapidly, a special system has been developed for selective H_2S analysis. In this system, H_2S is extracted with a dilute ammonium hydroxide solution, and the strong UV absorption of the ammonium sulfide formed in solution is measured and calibrated for H_2S concentration in the gas stream.

GAS CHROMATOGRAPHY WITH FLAME PHOTOMETRIC DETECTOR

Process gas chromatographs have been designed for environmental monitoring of H_2S at the ppm level using the sulfur-specific flame photometric detector (FPD) (Figure 8.26f). See Section 8.12 for the basic principles of chromatography and a more detailed description of the FPD.

TAIL GAS ANALYZER

For Claus sulfur recovery applications, a top of the pipe analyzer is available, which can measure both H_2S and SO_2. An installed unit is shown in Figure 8.26g.

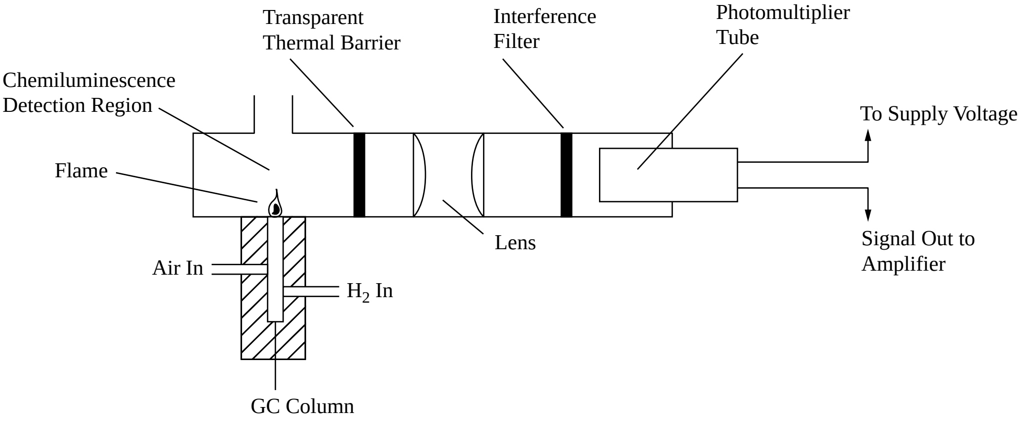

FIG. 8.26f
The flame photometric detector.

INFRARED ANALYZERS

Process Streams:	Gas or liquid, with surface analysis of solids
Application and Minimum Full-Scale Range:	Maximum range is usually 100%, with path length adjustment; minimum range, assuming 10-m path length. Ammonia—100 ppm; carbon monoxide—25 ppm; carbon dioxide—20 ppm; ethylene—100 ppm; hexane—100 ppm; methane—10 ppm; moisture (humidity)—50 ppm; nitrous oxide—10 ppm; propane—100 ppm; sulfur dioxide—100 ppm (*Notes:* 1. Some of these analytes can be done very well in the UV, for example, sulfur dioxide. 2. The minimum range is also a function of the matrix—the minimum for benzene in air is going to be much lower than that for benzene in gasoline. 3. The normal range is a factor of 10, so ammonia could be 10 to 100 ppm or 1 to 10%, but not 100 ppm to 10%. 4. These are examples only, not an exclusive list.)
Operating Pressure:	Standard from atmospheric to 150 PSIG (10 bars); special up to 1000 PSIG (70 bars)
Ambient Operating Temperature:	–40 to 120°F (–40 to 50°C) is standard; probe temperatures can be higher with special arrangements
Humidity Limitations:	Up to 95% relative humidity (normally the instrument is purged, which negates the effect of humidity in the atmosphere.)
Materials of Construction:	Cell bodies are available in all standard materials; windows can be made of sodium chloride, calcium fluoride, barium fluoride, sapphire, or zinc selenide
Cell Lengths:	For liquids, from 0.004 to 4 in. (0.1 to 100 mm); for gases, up to 130 ft (40 m) enclosed and any length for open-path monitoring
Warm-Up Time:	15 to 20 min. (For most stable operation, allow 16 h for warm-up.)
Repeatability:	±1% of full scale
Linearity:	±0.5 of full scale
Inaccuracy:	±2% of span
Drift:	±1% of full scale for zero and the same for span per day
Costs:	Remember that the installation and upkeep costs are normally much larger than the vendor costs given below. Single-beam portable or laboratory units cost $4000 to $5000; an industrial nondispersive infrared analyzer with diaphragm capacitor costs $8,000; a multigas analyzer pulling in up to five gases from 150-ft (50-m) distances costs $25,000 to $27,000; a microprocessor-based portable spectrometer with preprogrammed multicomponent identification capability for ambient air monitoring and with space for 10 user-defined standards for calibration, AC/DC converter, sample probe, and carrying case costs $20,000; an industrial FTIR costs $75,000 to $125,000.

Suppliers of Fiber Optics, Sample Systems, Standards, and Tool Development for Both IR and NIR:	Axiom, samples systems, fibers, both NIR and IR (info@goaxiom.com) Custom Sensors and Technology, sampling tools and analyzers (mike@customsensors.com) Dave Mayes, a developer of spectroscopic tools (www.dsquared-dev.com) Equitech International Corp., fiber switches, fiber connections to the process, sampling systems (www.equitech-intl.com) Fiber Tech Optica, fiber optics only (www.fibertech-optica.com) Remspec Corp. Fiber Optics (www.remspec.com) Solutions Plus, Inc., makers of traceable standards, a division of Ricca Chemical (customerservice@riccachemical.com)

NEAR-INFRARED ANALYZERS

Process Fields:	Gas, liquid, or solid, but mostly liquid and solid
Some Applications:	Octanes of gasoline, 80 to 100 Octanes of components of gasoline, 60 to 120 Benzene in gasoline, 0.2 to 1% Boiling points of gasoline, 50 to 200°C (122 to 392°F) Cetane of diesel fuel Protein content of wheat Molecular weight of small polymers Caustic in water 0.1 to 10% BTU of natural gas (high pressure) Active ingredient in drugs p-Xylene concentration in mixture of aromatics
Operating Pressure:	150 PSI standard (10 bar) 1000 PSI special (70 bar)
Ambient Temperature:	–40 to 120°F (–40 to 50°C) is standard. (Note: Since the ambient temperature changes will affect the spectrometer, it will require temperature stabilization.)
Stream Temperature:	This restricts cell material only; normally one keeps the temperature constant.
Humidity Limitations:	None—NIRs, like IRs, should be purged; this eliminates the humidity problem.
Materials of Construction:	Cell bodies in all standard materials; windows can be quartz (most common), sapphire, and others

Cell Path Lengths:	For liquids, 0.04 to 4 in. (1 to 100 mm); for gas, long (unless high pressure too long to be practical)
Warm-Up Time:	Manufacturers normally quote minutes—recommend overnight for best stability
Repeatability:	±0.01% of full scale
Linearity:	±0.5% of full scale
Inaccuracy:	±1% of span (depends on how well the "modeling" has been done; can be much better)
Drift:	±0.01% of full scale and the same for span per day
Costs:	\$80,000 to \$180,000, depending on number of streams, distance between the analyzer and sample, and sample preparation required. (How can these costs be justified by the user? At one installation, the analyzer is determining 25 properties every 45 sec. At another installation, the plant estimated that the analyzer saved \$15 million the first year it was in service. At some locations, the instrument is looking at multiple streams; with a 45-sec analysis time, it is possible to look at several streams and still update the control system as often as needed.)
Partial List of Suppliers:	ABB Process Analytics—Bomen (www.abb.com/analytical) Bran and Luebbe (www.branleubbe.com) Brimrose Corporation of America (www.brimrose.com) Foss-NIR Systems (info@foss-nirsystems.com) Guided Wave (www.Guided-Wave.com) Hamilton Sundstrand (AIT Division—Analect) (AIT@hs.utc.com) LTI (www.LTIndustries.com)

In the first part of this section, the infrared (IR) analyzers will be discussed, while the near-infrared (NIR) analyzers will be described in the second part of this section. This is not the only section in this chapter where IR and NIR are discussed. As can be seen from the analyzer selection guide provided in Tables 8.1u and 8.1v, IR and NIR analyzers are applicable to a wide range of analytical tasks.

It should also be noted that the boundaries between ultraviolet (UV), visible, NIR, and IR are slowly disappearing. Analyzers are evolving that are capable of operating in all of these spectrums, as discussed in Section 8.22, and as the mathematical tools to handle full spectral ranges are becoming available. The addition of microprocessors or tabletop computers has enhanced the performance of these instruments by providing such features as self-calibration, self-diagnostics, and chemometric tools, for example, partial least squares (PLS) and principal component regression (PCR), to name two, while design modularity has contributed to simplifying maintenance.

INTRODUCTION

This section starts with the description of some general principles of infrared radiation, covering both IR and NIR. That is followed by the definition of some of the basic terms and design configurations. Then laboratory and industrial on-line designs are separately described, and the increasing overlap between the fields is shown. The first part of this section, which deals with IR analysis, concludes with the description of some newer developments in the field of IR analysis, such as the use of tunable crystals and multiple internal reflection configurations.

For an overall view of where process analysis is going, see "Process Analytical Systems: A Vision for the Future," by Jeff Gunnell and Peter Van Vuuren of ExxonMobil, *Journal of Process Analytical Chemistry*, Vol. 6, No. 1, 2001, pp. 1–5. The International Forum for Process Analytical Chemistry (IFPAC) conference is held annually in January and normally contains sessions on process IR and NIR; for more information, see www.ifpac.com. This conference is run by Infoscience: telephone, 847-548-1800; address, P.O. Box 7100, Grayslake, IL 60030.

PRINCIPLES OF IR AND NIR ANALYSIS

IR absorption (or reflection for solids) is a technique that can be used successfully for continuous chemical analysis of a process. The infrared region of the electromagnetic spectrum is generally considered to cover wavelengths from 0.8 to 20,000 μm. NIR normally covers 0.8 to 2500 μm, and classic IR covers the rest. For IR analysis, these limits are normally put in terms of frequency (cm^{-1}, wave numbers or the number of waves per cm): 4000 to 500 cm^{-1}, which corresponds to wavelengths of 2500 to 20,000 μm.

Except for a small overlap region, sources and detectors that are needed in the NIR will not work in the IR, and vice versa.

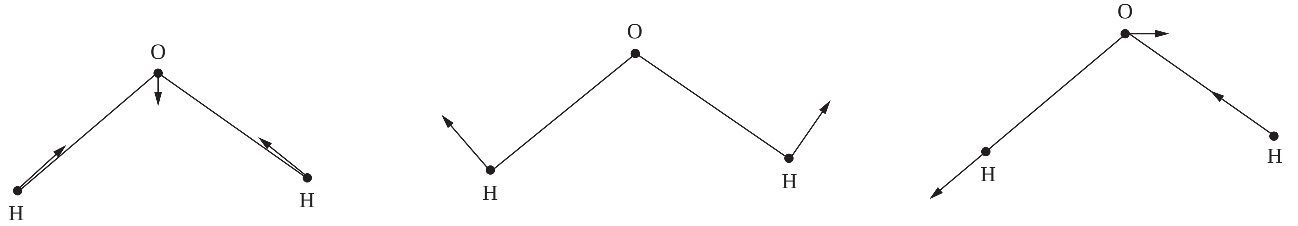

FIG. 8.27a
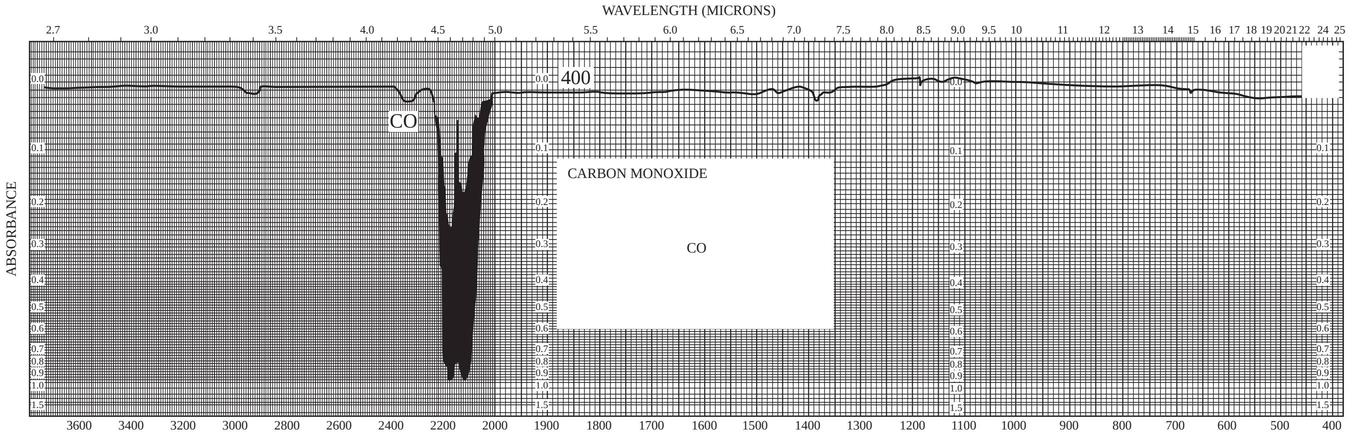
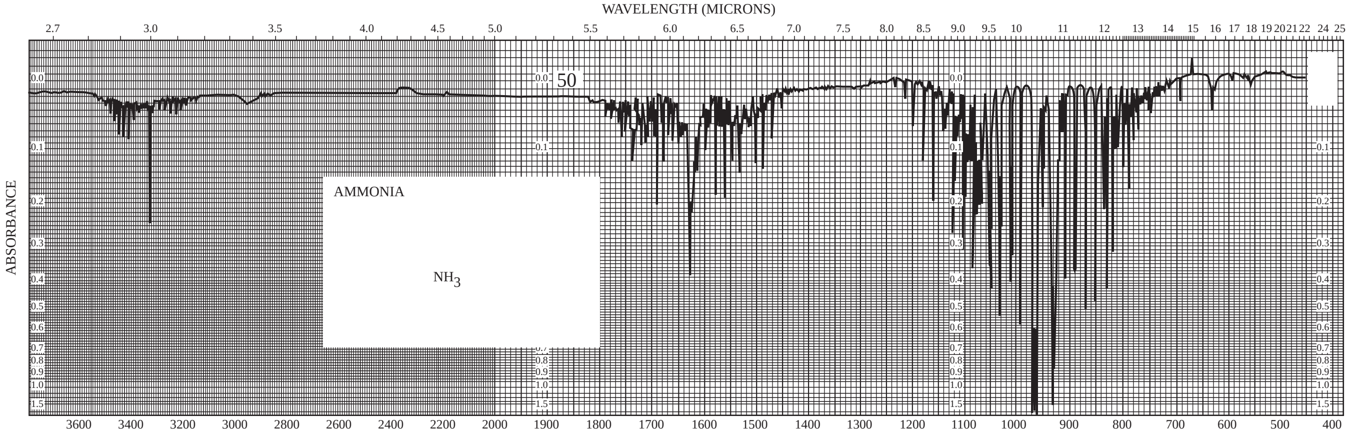
The three fundamental vibrations of the water molecule: symmetric stretch, bend, and antisymmetric stretch; the amplitudes of the vibrations have been exaggerated for clarity.



400 torr of CO out of total of 600. A diatomic molecule has only one fundamental absorption band. Higher resolution shows the band to consist of many sharp lines spaced about 4 cm^{-1} apart (rotational line structure).



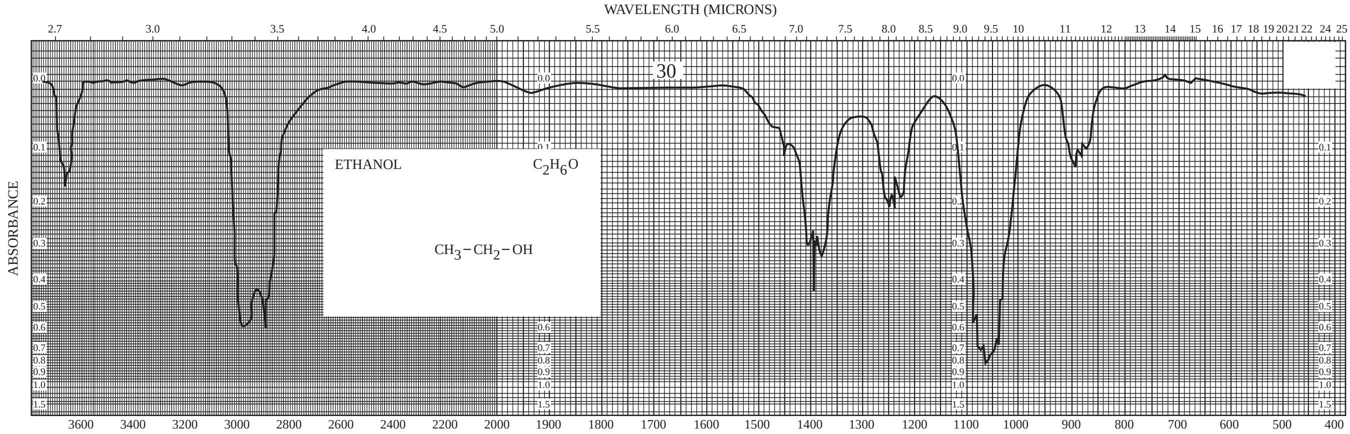
50 Torr of NH_3 out of total of 600.

FIG. 8.27b
Examples of IR spectra recorded using a laboratory double-beam spectrometer. All spectra are gas phase using a 2-in. (5-cm) cell with N_2 added to give a total pressure of 600 mmHg (torr). (Courtesy of Dow Chemical Co.)

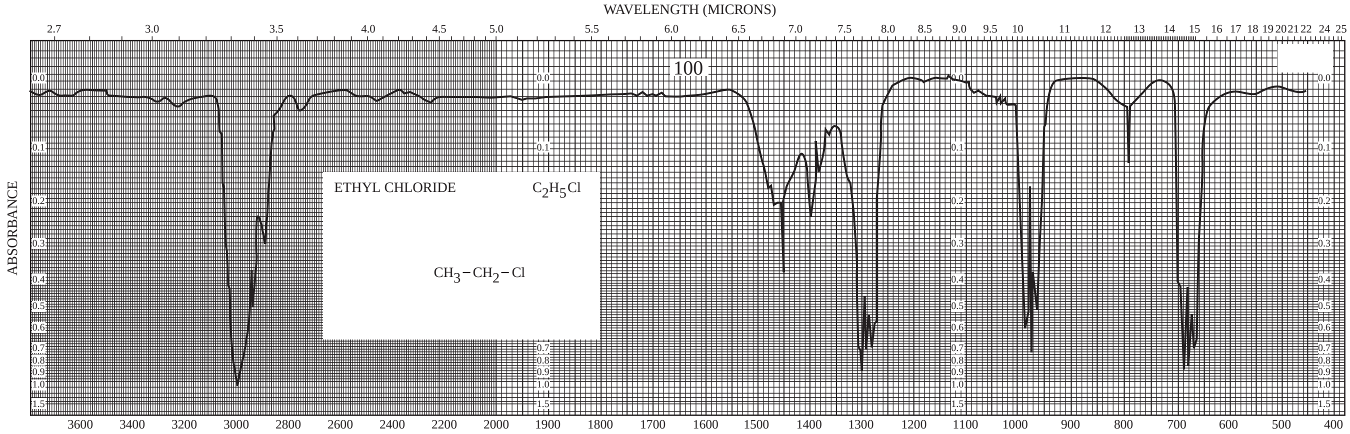
Some laboratory spectrometers have both sources and detectors so they can work in both areas. For the process, most gas analysis is done in the IR and most solid and liquid analysis is done in the NIR. The choice is based on workable path lengths.

Infrared radiation interacts with almost all molecules (except the homonuclear diatomics oxygen, O_2; nitrogen, N_2; hydrogen, H_2; chlorine, Cl_2; etc., and monatomics such as helium, He; neon, Ne; etc.) by exciting molecular vibrations and rotations that affect the dipole of the molecule (Figure 8.27a). The oscillating electric field of the IR wave interacts with the electric dipole of the molecule, and when the IR frequency matches the natural frequency of the molecule, some of the IR power is absorbed.

The pattern of wavelengths, or frequencies, absorbed identifies the molecule in the sample. The strength of absorption at particular frequencies is a measure of the concentration of the species. Analytical laboratory IR is



30 TORR ETHANOL OUT OF TOTAL OF 600



100 TORR ETHYL CHLORIDE OUT OF TOTAL OF 600

FIG. 8.27b Continued

largely concerned with identification, or qualitative analysis, while process IR is concerned with quantitative analysis. Some typical spectra are shown in Figure 8.27b. The NIR consists of overtones and combinations of these IR bands.

Particular groups of atoms tend to absorb at the same frequency with very little influence from the rest of the molecule. These group frequencies are a great help in identifying the molecules from the IR spectra (Figure 8.27c). On the other hand, similar molecules, such as a series of homologous hydrocarbons, have very similar IR spectra.

Infrared analysis is, therefore, most straightforward when the component molecules of the sample have significantly different atomic groupings. A mixture of aliphatic hydrocarbons would be better analyzed by another technique, such as gas chromatography. The part of the spectrum offering the best discrimination between molecules is between 7 and 15 μm, 1430 and 670 cm^{-1}, the so-called fingerprint region. Given the very large signal-to-noise ratio in the NIR, one can make very fine separations between similar species; for example, o-xylene can be measured in a mixture of xylenes, ethylbenzene, and benzene.

Beer–Lambert Law

The starting point for quantitative analysis is the Beer–Lambert law, frequently just called Beer's law, which relates the amount of light absorbed to the sample's concentration and path length.

$$A = abc = \log_{10} I_0/I \qquad \textbf{8.27(1)}$$

where

A = absorbance
I = IR power-reaching detector with sample in the beam path
I_0 = IR power-reaching detector with no sample in the beam path
a = absorption coefficient of pure component of interest at analytical wavelength; the units depend on those chosen for b and c; a newer term, ε, extinction coefficient, is the preferred term in the academic literature
b = sample path length, sometimes l is used
c = concentration of sample component

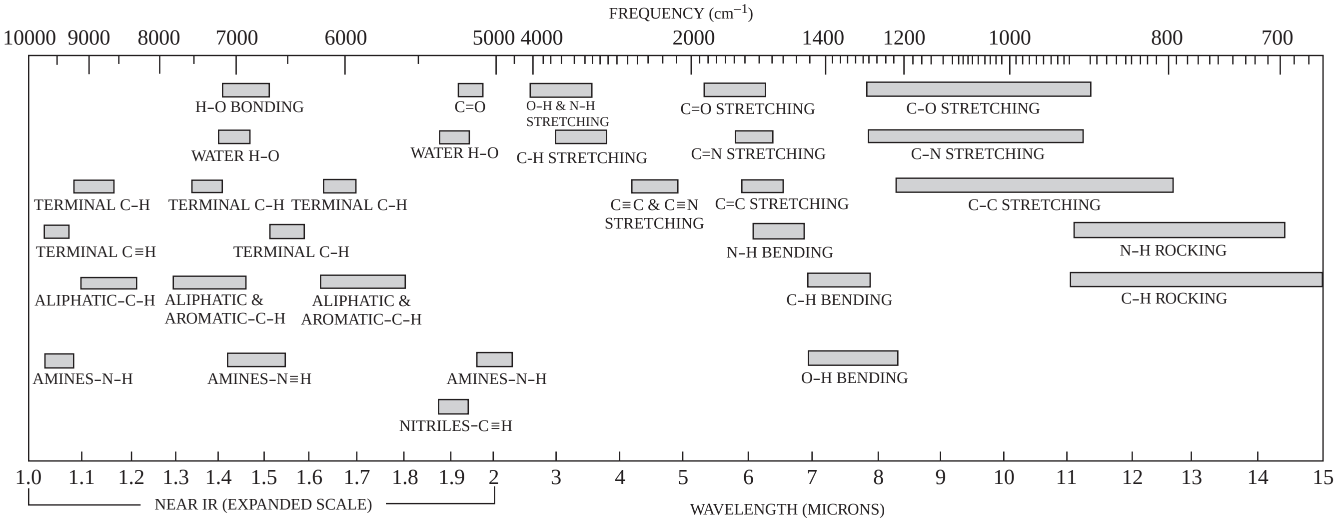


FIG. 8.27c

Functional group frequency chart. Fundamental vibrations absorb in the mid-IR; overtones and combination bond are 10 to 10,000 weaker and absorb in the NIR.

The law states that concentration is directly proportional to absorbance at a given wavelength and path length at specified temperature and pressure. Note, however, the logarithm function—frequently absorbances over 1 show nonlinear behavior, and sometimes problems start as low as 0.7.

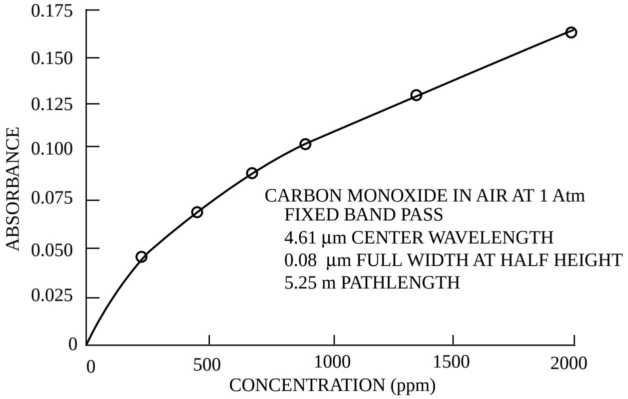
Sometimes isolated peaks in the IR can be found that correspond only to the item of interest; then calibration plots of A vs. c can be made up using known samples and used to analyze unknown ones (Figure 8.27d). Beer's law is also helpful in choosing the optimum path length for accurate analysis. (In some cases, this linear relationship is not observed. See the discussion of linearity later on in this section.)

There is also the case where overlapping spectral lines eliminates the simple application of Beer's law. Note: Not only can concentration of molecular species be identified, but also physical properties can frequently be measured. This is done more in the NIR than the IR, but can be done in both. A statistical approached called chemometrics, PLS and PCR, for example, is used to measure physical properties and solve the overlapping spectral lines problem referred to above. These very powerful programs require care in use and are more frequently used in NIR than IR.

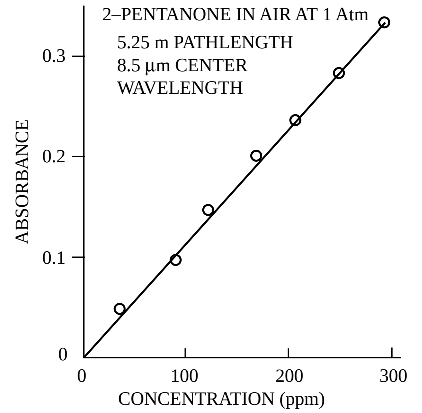
Definitions of Terms and Configurations

Some of the laboratory spectrophotometers are of the dispersive design, meaning that a prism or grating is used to separate the spectral components in the IR radiation of the source.

Most modern laboratory units are of the Fourier transform (FT) type, where a moving mirror generating an interference pattern of the wavelengths accomplishes dispersion, and then the FT converts this detected signal into something useful. See the section on Fourier transform spectrometers. Most industrial process analyzers are nondispersive infrared (NDIR) designs. However, there are some very



CARBON MONOXIDE SHOWS A LARGE DEPARTURE FROM THE BEER-LAMBERT LAW.



2–PENTENONE GIVES A LINEAR CALIBRATION PLOT.

Calibration curves for a typical filter analyzer. Top: Carbon monoxide shows a large departure from the Beer–Lambert law. Bottom: 2-Pentenone gives a linear calibration plot.

good FTIRs on the market for process applications where several components need to be measured. Since oxygen and nitrogen do not absorb in the IR spectrum, dry air is frequently used as a zero reference gas; however, one needs to be aware of the very strong absorbance of CO_2 when one is doing this.

Detectors are mostly solid-state type, with some microphone types still in existence. The solid-state type, the most common today, functions by converting the incoming photons to an electric current. This current is amplified and then sent to the recording device. The microphone-type detectors are filled with an IR-absorbing gas, which is heated by the radiation it receives and expands as a consequence. It is this expansion that is measured. The microphone type usually lacks uniform sensitivity across the spectrum. The solid-state detectors are generally of lower sensitivity than the microphone type at the microphone type's peak sensitivity, but they have almost uniform sensitivity across the spectrum.

IR Instrument Designs

Single-Beam Configuration Designs of IR instruments can be separated into single- and dual-beam configurations. Single-beam analyzers are the main ones used in the process world (Figure 8.27e). They function by alternating filters in the beam path—the reference chosen to not absorb the species of interest, but to offset any other species that would absorb at the measuring wavelength.

(The proper choice of the reference wavelength is not a trivial task. The reference wavelength should be as close to the measuring wavelength as possible, and yet let the measurement be made. Drifts in the source or detector will be compensated best if the measuring and reference wavelengths are close together.)

These filters are put on a chopper wheel in the light beam, and as the chopper alternatively spins one filter or the other into the optical path, the difference or ratio in the energies received at the detector will be a function of the concentration of the component of interest. Because filters normally change absorbance at a given wavelength with temperature, this approach must be temperature stabilized. Also note that dirt on the window will not affect the reading because it should affect both the measuring and reference wavelength the same so the ratio stays constant if the monitoring and reference wavelengths are close enough.

A less expensive design uses just the measuring wavelength, from above, eliminating the filter wheel and reference filter. Problem: If the source varies in intensity or temperature, so will your measurement. If the detector changes in sensitivity, so will your result. In other words, to save the first costs, one needs to rezero and respan these instruments very frequently.

If no lenses or mirrors are used to direct the IR radiation from the source to the receiver, it is necessary to polish the interior walls of the sample cell to make them highly reflective. Sometimes gold foil is used to achieve this goal. The use of reflective walls can be very expensive because it can contribute to drift as contamination of the wall changes reflectivity.

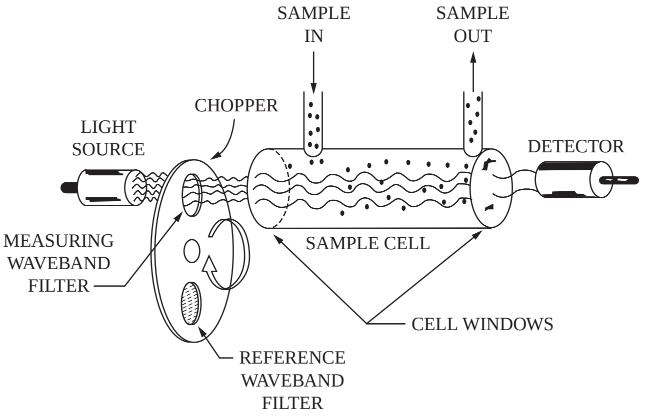

FIG. 8.27e
Single-beam IR analyzer provided with two filters, one for the sample measurement and the other for reference.

Dual-Beam Configuration In the dual-beam configuration, the IR radiation is allowed by the chopper to pass alternately through the sample or the reference tube (Figure 8.27f). The reference tube can provide a true zero when it is filled with a nonabsorbing gas, or it can act to balance out the gases which are not of interest, if filled with those gases. A narrow-band-pass optical filter is placed in front of the detector to limit the IR energy it receives to the wavelength that is characteristic of the component of interest. (Note: This severely limits the amount of energy getting to the detector; the narrower the band pass, the less energy, and the narrower the band pass, the more specific.)

If the sample contains the component of interest, this will attenuate the magnitude of the detected signal in the absorption band of the band-pass filter (Figure 8.27g). The use of the reference cell in the dual-beam configuration reduces the drift caused by power supply, detector changes, or some temperature fluctuations. The use of collimating optics

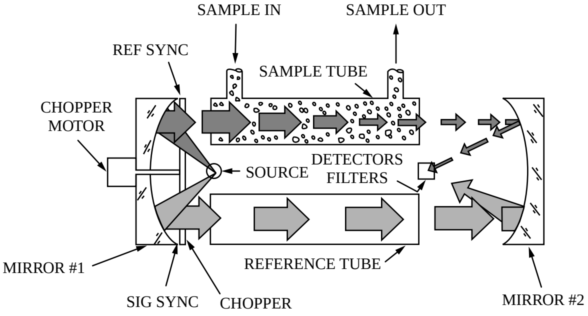

FIG. 8.27f
Dual-beam IR analyzer where the radiation alternatively passes through the sample tube, which contains the component of interest, or the zero-reference tube, which is free of absorbing gas.

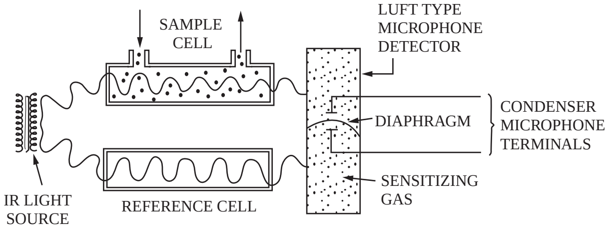

FIG. 8.27g

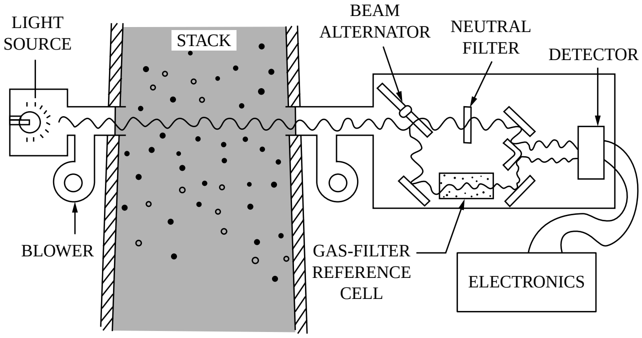

FIG. 8.27h
Dual-beam IR analyzer for stack gas monitoring.[1]

also eliminates the need for internal reflection from the interior surfaces of the tubes, thus simplifying their construction and eliminating the associated drift due to dirt accumulating on the wall of the tubes.

Dual-Beam Design for Stacks

When the IR analyzer is used for *in situ* stack gas analysis, two different approaches can be used: 1) the detectors and source on the same side of the stack, and 2) the detectors and source on opposite sides of the stack. For installation purposes, the first is much easier, but it requires an internal filter to remove any solids from the stream.

In the second system, shown in Figure 8.27h, both the reference and measuring wavelength are affected the same by scattering bodies in the stream; therefore, there is no need for a filter. This system is frequently used in pollution alarm situations. The reference cell is filled with somewhat less than the allowed emission of the gas of interest, and the IR beam leaving the stack is alternated between a neutral filter and the reference cell. When the stack gases are below the level of concern, the reference cell will remove the absorption lines that are characteristic of the gas of interest. Therefore, the total IR energy from the reference cell is at a reduced value. The analyzer is balanced by selecting a neutral filter, which reduces the energy from all the wavelengths to such an extent that the energy levels received by the detector from the neutral and reference gas filters will be the same.

When the pollutant of interest is present in the stack, the energy content of the reference path is unaffected (because the absorption is already complete at the selected wavelength). On the other hand, the IR energy reaching the detector through the neutral filter is reduced (due to the absorption of the pollutant gas) and the ratio between the beams reflects the pollutant concentration at the level of concern in the stack. This measurement is unaffected by particulate concentration variations, within reason, as it affects both paths equally and their ratio is unaffected.

The first configuration is shown in Figure 8.27i. Note that only one opening is required in the stack, with no critical alignment across the stack required, as in the other option. It is very critical to keep the reflector mirror clean; some people use a ceramic filter for that purpose. This is the only type that this author has used, and it has worked well.

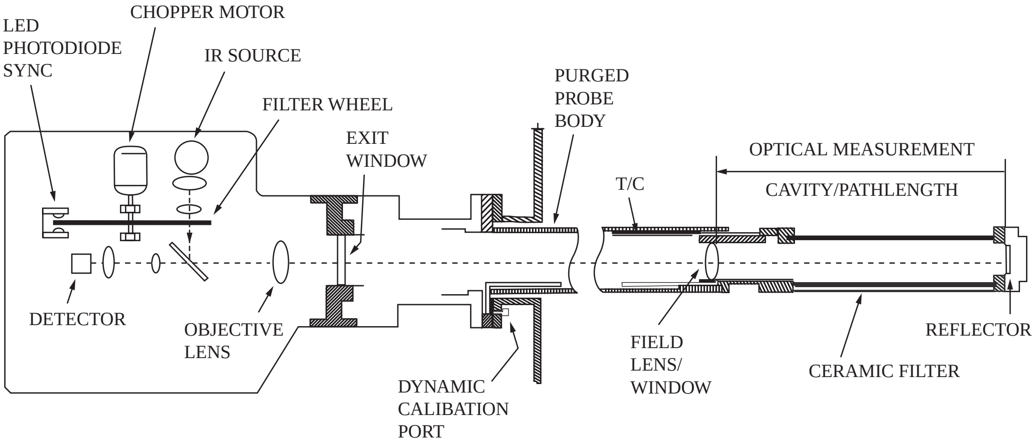

FIG. 8.27i
IR analyzer used for in situ *stack gas analysis equipped with ceramic diffusion cell, reflector, and calibration port.*

INFRARED ANALYZERS FOR THE LABORATORY

Grating Spectrophotometers

The standard laboratory IR instrument was a double-beam, optical null spectrophotometer. Diffraction gratings have completely replaced prisms for separating the IR beam into its component wavelengths. Both approaches have been replaced by FTIR, discussed below. Most IRs, old and modern, use a heated *black-body* source that emits at all IR wavelengths, and the thermal detector responds roughly equally at all wavelengths (Figure 8.27j).

The complete spectrum is scanned by rotating the grating and measuring the light intensity passing through its exit slit. Sample cells are placed in the sample beam and, as the spectrum is scanned, the instrument drives an attenuator into the reference beam until the detector sees equal energy from both beams. These spectrophotometers are ideally suited for qualitative analysis.

There are computer libraries of spectra and search programs that allow the computer to find the major compound in the sample and sometimes some of the minor ones. In many cases, manufacturers have added computer data handling to make possible both qualitative and quantitative analyses.

Filter Spectrometers

A circular variable filter (CVF) selects the wavelength to be measured. Microcomputer-controlled, single-beam analyzers working from 4000 to 690 cm^{-1} have been designed for the quantitative analysis of mixtures. Measurements are made at each analytical wavelength in sequence, and the output is presented as a list of concentrations for mixtures of up to 10 components.

Narrow-IR-band-pass filters consist of multiple layers of dielectrics of alternating refractive index on a transparent substrate. They pass a band of wavelengths while rejecting all others. The width of the band pass is typically 1 to a few percent of the center wavelength of the item of interest. Spectral resolution is low when compared to that obtained with a grating instrument, but signal-to-noise ratios are higher. A CVF is made of dielectric layers of continuously varying thickness so that the wavelength selected depends on the angular position of the CVF wheel.

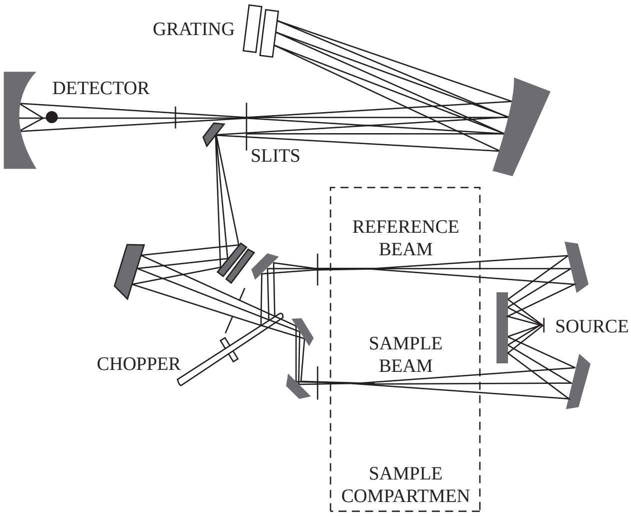

FIG. 8.27j
A widely used laboratory double-beam optical null spectrophotometer.

Fourier Transform Spectrometers

A quite different and very high performance approach to analysis makes use of the Michelson interferometer or some modification thereof. Instead of separating the different wavelengths of light with a filter or a grating for measurement, the compete spectrum is encoded as an interferogram in a few seconds of measurement time, and the spectrum is computed by Fourier transform or fast Fourier transform.

Advantages include speed, full-spectrum method, and light throughput (one is not throwing away most of the light as one is looking at a different wavelength). The disadvantage is the moving parts. There has been a major effort to stabilize the moving parts, but they still require smooth movement for good spectra; there must be an attached computer to do the transform, but this can act as a storage device for some of the spectra.

A schematic of a typical FTIR or FTNIR spectrophotometer is shown in Figure 8.27k. Collimated light from the source is directed through the beam splitter. Approximately 50% of the light passes through the beam splitter to the fixed mirror, M1. The balance of the light is reflected to the moving mirror, M2. When these two beams are reflected off the mirror surfaces, they recombine at the beam splitter to give constructive and destructive interference as a function of the wavelength of light and the distance that M2 has moved.

The included helium–neon laser detection system in the FT analyzer monitors the position and velocity of the moving mirror. This results in excellent wavelength accuracy for the FT analyzers. The displacement of the moving mirror induces phase differences that result in an interferogram. In order to produce a spectrum of absorbance vs. wavelength, the interferogram must be transformed digitally from a plot of detector

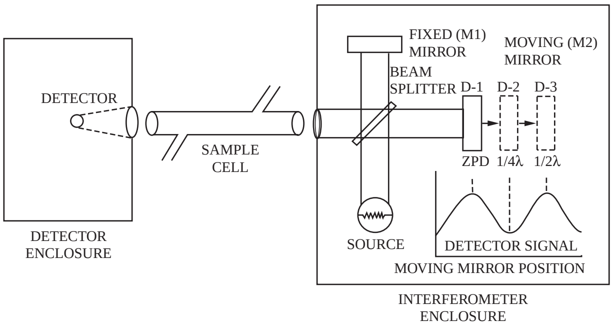

FIG. 8.27k
FTIR spectrophotometer.

response vs. optical path difference. This calculation of the spectrum is carried out using Fourier transform or fast Fourier transform on the attached computer.

Since the FTIR or FTNIR analyzer measures all the wavelengths simultaneously on one detector, the entire spectrum can be used for quantitative analysis. FT spectrophotometers are used for multicomponent applications where the high optical resolution allows separation of interfering components. (Note: One should be careful with the term *optical resolution*. Some suppliers will talk about resolution as the number of data points per unit of the spectrum. This, in most cases, is not the same as their optical resolution. Without high optical resolution, you cannot separate some components, regardless of the data point resolution.)

FTIR and FTNIR spectrophotometers are being used online where the full spectrum is needed for analysis. One big advantage of the full-spectrum measurement is that the associated computer programs can be set up to detect unusual samples or impurities in the sample. These unusual samples are frequently referred to as outliers, but they are sometimes an early warning of an unwanted change in raw materials or in the process.

Tunable Lasers

On the face of it, this is the spectroscopist's dream come true. Laser diodes are available to cover the 4000 to 400 cm^{-1} region. A given diode may cover 200 cm^{-1} with small discontinuities about every cm^{-1} in its tuning. The devices (PbSSe or PbSnTe) have very high spectral resolution and good power output, but require liquid N_2 temperature or below, plus other complex support equipment. They are for the research spectroscopist, but they have been used in isolated cases of process analysis that could not be done by more standard methods.

Laboratory Instruments in Process Measurement

Normally, laboratory instruments cannot be taken from the laboratory and put onto the process line because the laboratory instrument does not meet the fire code for the process area and it is not stable enough to run 7 days a week, 24 h a day without the need for recalibration. Some companies, such as Dow Chemical, have done a good job in moving many laboratory instruments into the process arena, but with a high investment of manpower.

The Fourier transform spectrophotometer has successfully made the move from laboratory instrument to an online tool, as have diode array instruments. In many cases, however, the process instrument no longer looks like its laboratory cousin, and the cost is considerably higher by the time it is temperature stabilized and made explosion-proof. (Process instruments should not need a safe, air-conditioned building to survive in the process world, but this can aid its stability and will certainly aid in its maintenance.)

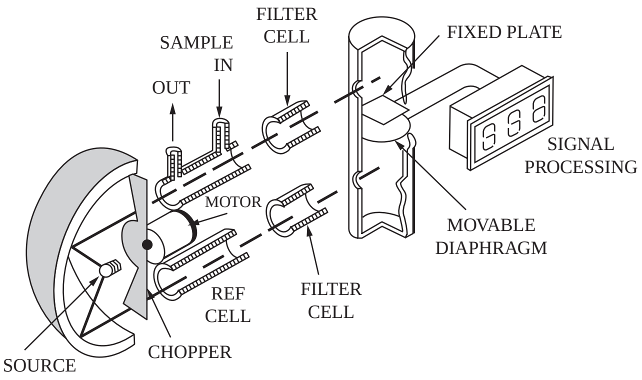

FIG. 8.27l
Typical NDIR analyzer using positive filtering. Both chambers of the detector are filled with a sample of the gas to be analyzed.

INFRARED ANALYZERS FOR PROCESS APPLICATIONS

Single-Component Analyzers

This is a type of process IR analyzer that has no analog in laboratory instruments. It is a NDIR analyzer and is used almost exclusively for gas analysis. These analyzers were invariably double-beam and used gas-selective Luft detectors filled with the gas to be analyzed (Figures 8.27g and 8.27l). (They currently use a solid-state detector.) In the usual positive filtering mode, light from single or dual sources is chopped and passed in phase through the sample or reference cells to the detector. Sample molecules attenuate certain wavelengths, and the difference in power between sample and reference beams is sensed as a change in capacitance. This is amplified and displayed to give an output corresponding to concentration.

Selectivity is improved by adding a narrow-band-pass filter, which selects the wavelengths of interest, and filter cells filled with interfering species, which remove undesirable wavelengths from both beams. The NDIR technique is most sensitive and selective for small molecules whose spectral fine structure is resolved under ambient conditions. The spectral resolution of these instruments is effectively set by the width of the absorptions line and, in many applications, is much better than the typical laboratory grating spectrophotometer.

The Luft detector has excellent sensitivity, but it must be temperature controlled and protected from external vibration. These analyzers need routine calibration for span and zero. (This is true for most process analyzers.)

Design Variations Some important variants of this basic NDIR method with Luft detectors should be mentioned:

1. A second detector placed behind the first can be sensitized to measure and compensate for an interferant.
2. Detector chambers can be placed one behind the other with the chopper alternately delivering each beam

to both. A different pressure of sensitizing gas in each detector chamber provides a built-in reference wavelength.

3. The combined beams, alternately admitted to the same chamber of the detector, cause heating and gas flow in and out of the chamber. A sensitive flow meter gives an output proportional to the sample concentration.
4. In a technique called cross-flow modulation, the mechanical chopper is replaced by a valve that exchanges sample and reference gas between the two beams at a frequency of about 1 Hz. High sensitivity and zero stability are claimed for this technique, but reference gas must be supplied continuously, flow rates and temperatures must be carefully regulated, and response time is slow.

The solid-state detectors do not require the utilities that the Luft detector requires and are fast enough for the filter instruments. (Many of them do not keep up with a scanning grating, however.) For stability and reproducibility, it is hard to beat the filter instrument with a solid-state detector.

Gas Filter Correlation Spectrometers

Gas filter correlation (GFC) spectrometers (Figure 8.27m) use a nonspecific thermal detector with a specifying reference gas cell. This is an example of negative filtering. The technique is most useful when high specificity is required and it is not practical to have a reference beam. The IR beam passes alternately through a cell containing a fixed quantity of the gas to be analyzed and through a similar cell filled with a zero gas, such as N_2. The combined beam passes through the sample, for example, across a smoke stack, and on to a thermal detector.

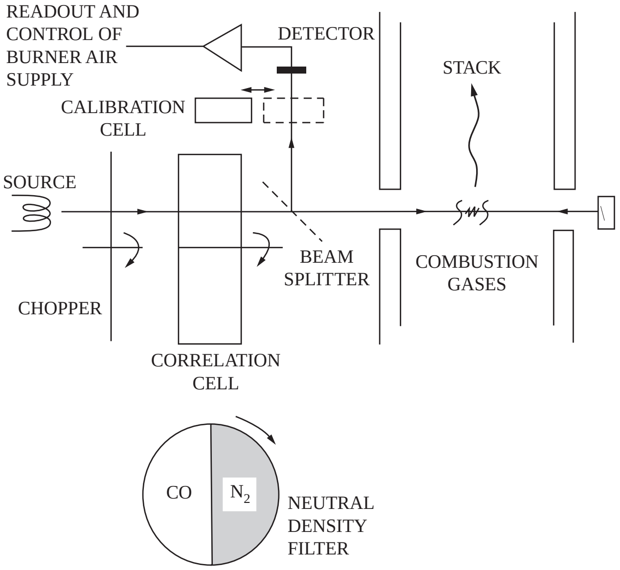

FIG. 8.27m
The gas filter correlation technique is an example of negative-filtering NDIR. The diagram shows how changes can be sensed in stack CO in the 0- to 1000-ppm range and used for burner control.

This system, which is similar to NDIR, works well for analyzing small gas phase molecules whose spectra have well resolved, rotational fine structure in the presence of strong interference from other species. One example is the analysis of carbon monoxide, CO, at the 100-ppm level in combustion gas-containing large concentrations of carbon dioxide, CO_2, and water, H_2O.

For accurate data, the sample must be removed from the optical path periodically to check for zero drift. A sealed calibration cell can be used to check span. (Note: Both of these require installation considerations.) Another configuration of the stack gas analyzer GFC has already been shown in Figure 8.27h.

It is possible to extend the GFC method to several gases with nonoverlapping spectra by placing a gas mixture in the correlation cell and inserting different narrow-band-pass filters sequentially into the beam.

Filter Analyzers

Narrow-band-pass filters are used with nonspecific thermal detectors and are the most common IR units available today. Various configurations exist:

1. Single-beam, dual-wavelength (analytical and reference) (Figures 8.27e and 8.27n)
2. Single-beam, multiwavelength (one reference and up to 10 measurings), same basic construction as shown in Figure 8.27n
3. Dual-beam, single-wavelength
4. Dual-beam, dual-wavelength

The intent of the dual-beam design is to compensate for source output changes or detector or electronic gain changes.

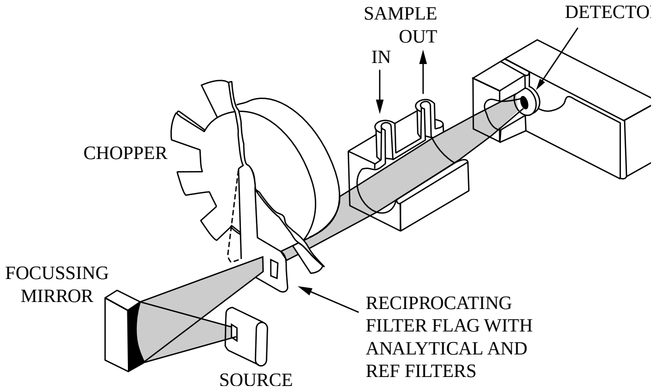

FIG. 8.27n
Optical schematic of a single-beam, dual-wavelength filter analyzer. In an alternate arrangement, larger filters can be mounted directly on the rotating chopper wheel. The principle has been extended to multiple wavelengths. If a microcomputer-controlled circular variable filter wheel replaces the reciprocating filter flag, the optical schematic becomes that of a programmable multicomponent analyzer.

It cannot account for changes in sample cell transmission, such as dirt accumulation on windows or scattering particles in the sample stream.

The dual-wavelength design aims to use a reference wavelength not absorbed by the sample but affected by the above-mentioned sources of error to the same extent as the analytical wavelength. (Therefore, the reference wavelength should be as close to the analytical wavelength as possible.) The single-beam design is optically and mechanically simpler and lends itself easily to interfacing with a wide variety of sample cells.

Multiple-Component Fixed Filter Analyzer

When the components to be analyzed have absorption bands that do not overlap in the spectrum, the single-component analyzers can simply be expanded to measure multiple wavelengths. (Note: Having absorption bands that do not overlap does not imply that the absorption peaks are free from interference—only that some part of the band is free from other species.)

There are NDIR analyzers that use two detectors filled with two different gases, such as carbon monoxide and a hydrocarbon. The IR passes through first one detector and then the other. Filter analyzers are more easily expandable to multiple wavelengths, enabling a wide variety of process and quality control analyses to be made. Filters can be mounted on a rotating wheel or inserted sequentially into the beam by a cam mechanism. ABB can analyze up to 10 different gasses with their multiwave units.

These instruments typically use analog signal processing. It is possible, but awkward, to compensate for spectral interference by cross-coupling between the different wavelength outputs. Digital signal processing simplifies this problem, but it is not widely used in multiple-wavelength fixed-filter analyzers. Note: Digital processing is very common with full-spectrum techniques.

Programmed Circular Variable Filter Analyzer

These microcomputer-controlled analyzers, derived directly from the CVF laboratory analyzers mentioned above, are simple and rugged in optical design. The same basic analyzer can be programmed for any number of analyses up to a maximum of about 10 components. The programmable CVF offers a major advantage over using fixed filters.

It avoids the whole problem of filter selection and filter wavelength manufacturing tolerances and the prohibitive costs of obtaining fixed filters for one-of-a-kind analyses.

The built-in microcomputer makes interference compensation relatively straightforward. Instrument calibration coefficients and analytical wavelengths are obtained using known mixtures of the components of interest and placed in read-only memory (ROM).

The microcomputer enables self-diagnostic and self-checking features to give early warning to trouble and simplify the analyzer service.

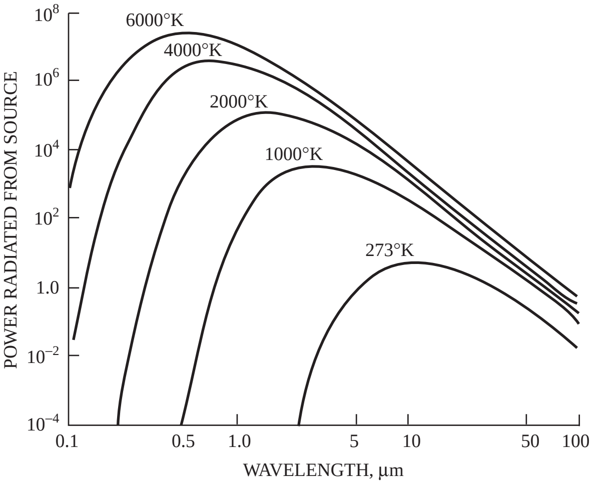

FIG. 8.27o

Radiated power in w./m^2/str/µm from an ideal black body as a function of wavelength and temperature. Practical sources will have lower output for a given temperature to the extent that their emissivity is less than unity. The sun's radiation is close to a black body at 6000°K (5727°C) with peak output in the visible. A Nichrome wire source typically runs a little of 1000°K (727°C) with a peak output near 2.5 µm. Increasing the temperature increases output much more in the NIR than at longer wavelengths.

This technology is most developed for workroom air quality monitoring.

Infrared Sources

With the exception of the tunable diode laser, all the sources used in IR analyzers are of the black-body type (Figure 8.27o). An element is heated to as high a temperature as is consistent with long operating life. The radiation varies as a function of wavelength as the source temperature increases.

Sources used in process analyzers in the mid-IR depend on ohmic heating of an element, such as Nichrome wire, either exposed or embedded in a ceramic matrix. The metal oxide surface layer or ceramic have good emissivity in the mid-IR. The normal source temperature is in the 2000°C range. In NIR, the much hotter tungsten halogen lamp with a quartz envelope is an excellent source. (Remember, the shorter the wavelength, the higher the energy; therefore, the hotter source is required in NIR.) At wavelengths longer than 4 μm, the output drops due to envelope absorption, but even if it did not, the emissivity of tungsten decreases at longer wavelengths. (See the section on NIR for more comments on this source.)

Infrared Detectors

In all cases, IR energy is modulated so that an AC signal is detected and synchronous demodulation can be used to narrow the noise bandwidth. Beam chopping or modulation is best done after the sample. This avoids errors due to the detector sensing emission from hot samples. The error effect can be large, particularly at the longer wavelengths, beyond 5 μm.

NDIR Detectors These are the gas-filled capacitive microphones already described (Figures 8.27g and 8.27h). They use low-modulation frequencies, 19 Hz or below, and are affected by external noise and vibration. They operate in the IR and are very sensitive. One can also use solid-state devices in this application.

Thermal Detectors These are used in the mid-IR by filter analyzers. The pyroelectric detector is usually a wafer of $LiTaO_3$ about 20 μm thick, electroded on each side. It behaves electrically like a capacitor, and a current flows out of it if the temperature changes. It must be used in a chopped beam of IR, most commonly near 50 Hz. The minimum detectable signal is about 10^{-9} w. in a 1-Hz bandwidth, and it is somewhat less sensitive than a typical NDIR detector. Pyroelectric detectors must be mounted and sealed to avoid microphonic and acoustic interference (Figure 8.27p).

The sensitivity of the evaporated thermopile is best at lower-chopping frequencies, below 10 Hz. It is very rugged and less microphonic than the pyroelectric detector, but also less sensitive.

Photoconductive Detectors In NIR, photon detectors such as PbS or PbSe can be used. They are two or three orders of magnitude more sensitive than the thermal detectors and operate best at higher chopping frequencies. The PbSe sensitivity extends almost to 5 μm, if thermoelectrically cooled, and can be used for such common analyses as $CH/CO/CO_2$. Response is strongly temperature dependent, in contrast with the above-mentioned thermal devices.

Selecting the Cell

Path Length Selection There is an optimum cell path length for analyzing a particular sample. Too short a path length means a low sample absorbance, which gives a weak signal in comparison to instrument noise. Too long a path length results in very little energy reaching the detector and Beer's law often fails. Simple theory, based on the detector/preamplifier as the chief source of noise,[3] unaffected by the IR power reaching the detector, predicts that most accurate concentration measurements can be made when the sample transmits 1/e of the incident beam (e = 2.73).

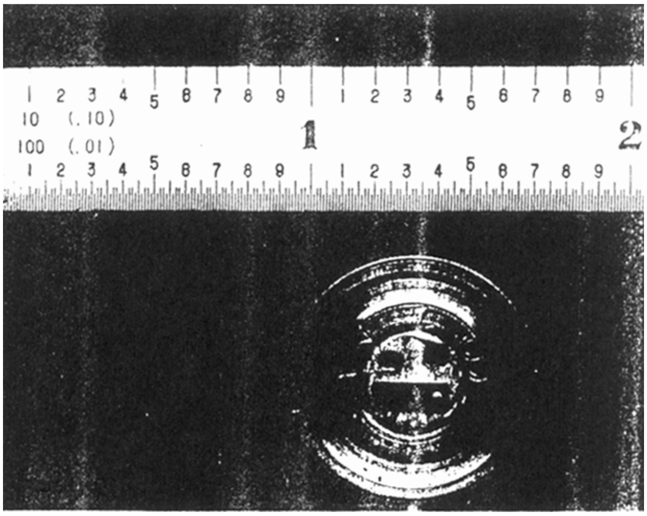

FIG. 8.27p
Photograph of a pyroelectric thermal detector alongside an inch scale; when in use, an IR-transmitting window, or lens, seals the air space in front of the detector.

This corresponds to a transmittance (T) of 36%, or an absorbance (A) of 0.43 A. However, any absorbance between 0.1 and 1.0 A, 80 to 10% T, will normally give good results. Measurements at higher absorbance tend to minimize the effect of certain kinds of electronic drift, while at lower absorbances, they minimize nonlinear ties in the analyzer's response (see "Calibration: Sources of Analyzer Drift," below).

Therefore, the cell path length should be chosen to put the sample absorbance in this desirable range. When analyzing trace gases, the absorbance is often near the lowest detection limit of the analyzer, even when the longest available path length is used, and that is the best that can be done.

Gas Cells Figure 8.27q shows some gas cells used for process analysis. The common type transmits the IR beam straight through to the detector. The path lengths range from 0.1 mm to 50.0 cm (0.004 to 19.5 in.). Some of these long cells, especially those used on NDIR analyzers, are internally gold coated to act as a light pipe. The single-beam analyzers can interface with a wider range of cell type, such as multiple reflection cells with path lengths adjustable between 0.75 and 40 m (30.0 in. and 130.0 ft). These long path cells are especially valuable for analyzing trace contaminants in the air.

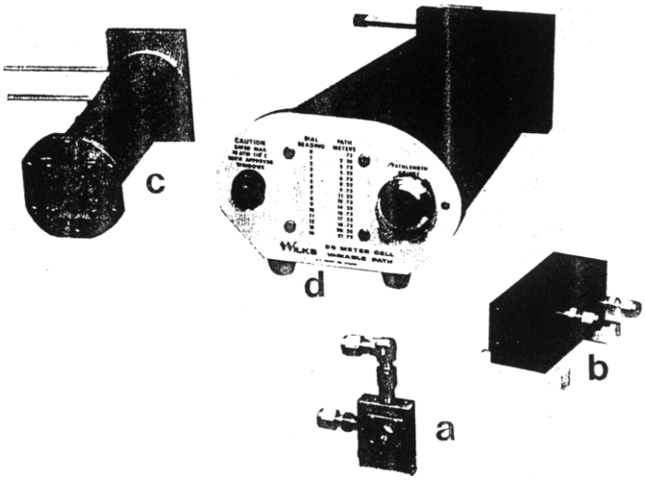

FIG. 8.27q
Cells for use with IR process analyzers. The longer-path-length cells are not conveniently interfaced with single-beam analyzers. (a) 2-mm (0.08-in.) cell, gas, or liquid; volume, 0.4 ml. (b) 10-cm (3.9-in.) gas cell (or liquid for NIR); volume, 50 ml. (c) 50-cm (19.5-in.) gas cell, two passes; volume, 600 ml. (d) 20-m (66-ft) variable-path gas cell; volume, 5.4 l.

In choosing a gas cell, one should consider the volume if only small quantities of sample are available or if faster turnover is required. The most efficient cells have a high path length-to-volume ratio. Sample pressure and temperature must be controlled for accurate results because the instrument response depends on the number of sample molecules in the cell.

Liquid Cells: Transmission Type Liquid cells have much shorter path lengths to compensate for the higher-density samples. Thickness varies from 0.1 mm to 10.0 cm (0.004 to 4 in.), the longer cells being used in the NIR region, where sample absorption coefficients are lower. Sample streams must be carefully filtered to avoid cell plugging, particularly when very short (0.1-mm) IR cells are used.

Liquid Cells: Reflection Type The multiple internal reflection (MIR) technique, also called attenuated total reflection (ATR), is a way of avoiding the problems of thin transmission cells. The IR beam makes multiple internal reflections at the surface of a high-refractive index crystal wetted by the sample liquid of lower index of refraction (Figure 8.27r). The effective path length of the beam through the sample depends on the angle of incidence, the refractive indices of the sample and crystal, and the number of reflections.

The method is being used increasingly in mid-IR, with the sample being brought to the MIR cell via a sample loop from the process stream. Additionally, MIR cells have been put directly into the process stream with an optical connection to each end of the crystal. The big advantages of this approach are that no time is lost in the sample system and there is no need to remove solids, as they will not interfere with the measurement and can be used to follow batch reactions without withdrawing samples.

However, inline applications face a number of problems, including 1) mounting an analyzer directly in the process stream; 2) keeping the surface of the crystal, which is wetted by the process stream, free of contaminating films; 3) problems with running calibration checks on the systems; and 4) the difficulty of servicing the crystal without shutting down the process. (If the cell becomes coated with a film, all the spectrometer will see is that film and, therefore, the output becomes a straight line while the process wanders.)

Solid Samples

Sample composition can be determined by analyzing the spectra of IR diffusely reflected from the sample surface. (Note: One is only analyzing the surface with the IR.) The most common application is moisture measurement in, for example, paper as it is being made or feed stocks, such as wood chips (see Section 8.34). Filter analyzers utilizing this principle are used for analyzing grain and other food products for components as protein, oil, and moisture. Most of this work is done in the NIR, where one sees not only the surface but also into the solid, because of the lower absorption coefficients (more on this later in the discussion of NIR).

CALIBRATION: SOURCES OF ANALYZER DRIFT

All IR analyzers require initial calibration with known samples. In general, the strategies of reference wavelengths and reference beams do not reduce sources of zero drift completely, and once in service, the analyzer zero and span must be checked and reset on a routine basis. The user's manual should give guidance on the steps involved.

With constant temperature and pressure samples, an IR analyzer is inherently span stable and, in principle, requires only that the cell path length be constant. However, depending on the analyzer design and operating environment, the span should be checked on a periodic basis. In general, the frequency of requiring span calibration is a function of

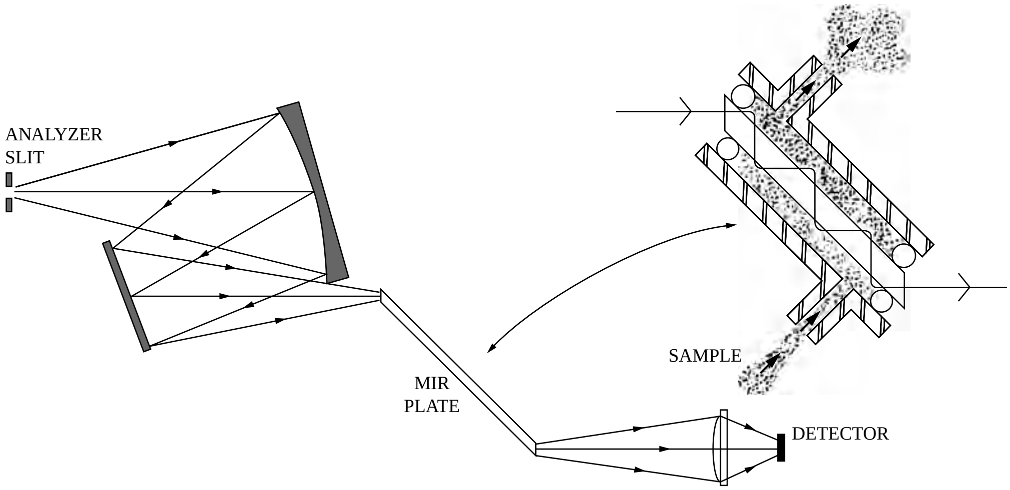

FIG. 8.27r
Optical schematic of an MIR cell suitable for use in a process sample loop interfaced with a single-beam filter analyzer. Materials used for the MIR crystal include sapphire, silicon, germanium, and zinc selenide.

the quality of temperature controls provided for the analyzer and the application. In NDIR and GFC analyzers, the characteristics of the gas-filled cells vary with temperature.

Filter analyzers as well as the NDIR and GFC types contain narrow-band-pass filters that change wavelength and absorbance with ambient temperature. For span stability, these filters must be temperature controlled. Long-term stability will be degraded if a high electronic scale expansion of gain is required, because the cell path length is not optimized for the job (as is frequently the case in the more sensitive analysis ranges).

Zero and span samples can be plumbed to a calibration port for use when required. Gas mixtures in cylinders are often used but should themselves be checked, as they are subject to change with age. (The gas can react with the cylinder wall and disappear from the mixture, or it can liquefy and be removed. The liquefaction can be compensated for by heating the cylinder to raise the temperature and constantly stirring the sample; however, this also increases the probability of reaction.)

For gas analyses, the component of interest can sometimes be removed by filtering or catalytic oxidation to provide the zero gas. The zero check is frequently automated using a timer or is built into the memory of a microprocessor-controlled analyzer. Some instruments employ an automated span calibration analogous to the auto zero by inserting a sealed calibration cell or a secondary standard in the form of an attenuating filter into the analyzer beam.

Linearity

The detector response of an IR analyzer is not linearly related to concentration. The filter analyzers for many samples follow the Beer–Lambert law, and a logarithmic amplifier provides an acceptable linear output. However, if the analyzer cannot resolve the sample's absorption features, as is the case for most small gas-phased molecules and some liquids, the measured absorbance will fail to increase linearly at the high absorbances. This is the case with carbon monoxide (Figure 8.27d). These problems, and the nonlinear output of the NDIR and GFC analyzers, are frequently corrected by a linearizing circuit board.

Packaging

There is some uniformity of packaging among manufacturers of NDIR analyzers for panel mounting. At present, there are no intrinsically safe IR analyzers, and they must be packaged in a purged or explosion-proof housing to be acceptable in a hazardous area. Plumbing and sample cells containing flammable samples should be kept outside the enclosure containing the analyzer source and electronics unless flame arrestors are used in the sample lines.

It may be necessary to purge the analyzer head to prevent corrosion or to eliminate absorbing ambient gas molecules from the optical path outside the cell. Many analyzers have a remote readout and control panel option so that the analyzer head can be located close to the measurement site. The IR components are usually mounted on a vibration-isolated rigid structure, and the analyzer head is temperature controlled to some extent.

APPLICATIONS AND ADVANCES

Table 8.27s gives a summary of some common process applications for IR analyzers.

The advances in this technology involve several areas of development. The microprocessor has contributed to the

TABLE 8.27s

development of self-diagnostic and self-calibrating designs. Autocalibration was also helped by the use of multiple reference cells when stable reference gases are available. Modular design in conjunction with self-diagnostics has simplified maintenance.

The growth of fiber-optic technology (Section 8.23) made the probe-type IR analyzer practical and extended the spectrum by allowing the same probe to use UV, visible, NIR, and IR forms of radiation. One should be careful with such extended spectrum applications, because windows that are transparent in one region of the spectrum may be opaque in another portion.

The in-line use of MIR or ATR crystal probes (Figure 8.27r) is also promising, although the task of keeping the probe surface clean is not easy to meet.

Another area of development is to minimize the number of moving parts, choppers, shutters, or beam alternators and eliminate the need for multiple paths in the IR analyzer. The goal can be met by the use of acousto-optic tunable filters (AOTFs), which are made of thallium–arsenic–selenide (TAS). This crystal can be tuned by a radio-frequency oscillator, ultrasonic transducer, over a spectrum of 2 to 5.5 microns.[1]

The TAS AOTF is an electronically controllable narrow-band filter that can be tuned to any desired IR frequency (Figure 8.27t). It can provide a series of chopped and tuned IR beams to simultaneously measure a variety of stack gases. The required frequencies can be selected in milliseconds, and the solid-state AOTF is small and rugged. Therefore, it is insensitive to vibration, but must be maintained at a constant temperature.

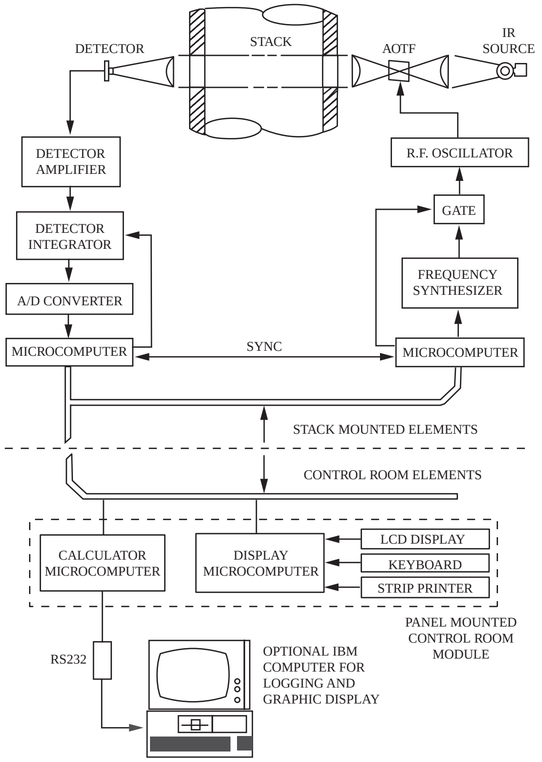

FIG. 8.27t
The solid-state tunable crystal eliminates most of the moving parts from the IR analyzer and allows simultaneous measurement of many gases in the process stream.[1]

TABLE 8.27u
Typical Applications for NDIR Analyzers

Gas	*Minimum Range (ppm) (for 10-m cell)*	*Maximum Range (%)*
Ammonia (NH_3)	0–100	0–10
Butane (C_4H_{10})	0–300	0–100
Carbon dioxide (CO_2)	0–20	0–100
Carbon monoxide (CO)	0–25	0–100
Ethylene (C_2H_4)	0–100	0–100
Hexane (C_6H_{12})	0–100	0–5
Methane (CH_4)	0–10	0–100
Nitrogen oxide (NO)	0–10	0–10
Propane (C_3H_8)	0–100	0–30
Sulfur dioxide (SO_2)	0–100	0–30
Water vapor (H_2O)	0–50	0–5

Table 8.27u lists the minimum and maximum ranges of some of the gases and vapors that are commonly detected by NDIR analyzers. Note: These numbers assume that there are no interfering compounds in the stream.

NEAR-INFRARED ANALYZERS

NIR absorptions are the overtones and combination bands of the IR, particularly involving a hydrogen atom. There are two major effects of this from the on-line analyzer point of view: 1) It is very difficult for a human being to say which band represents which compound. 2) The absorbances are much weaker than in the IR region (about 1/10 weaker per overtone).

This means that the first overtone is 1/10 weaker than the IR, and the second overtone 1/10 weaker than the first. At first glance, both effects appear to be undesirable. Yet, the second turns into a major advantage for analyzing either liquids or solids—the path length is much longer. For solids, this means that more than just the surface is seen and can be analyzed.

With hydrocarbon samples like gasoline, the path length in the IR region would be about 0.1 mm, while in the first overtone of the NIR, it can be about 1 mm, in the second overtone about 1 cm, and in the third overtone about 10 cm. For process applications, the longer path length has three advantages: 1) more uniform sampling, 2) fewer plugging problems, and 3) the window fouling is much less of a problem.

Short path lengths in the IR region can be handled with an ATR or MIR cell, but fouling remains to be a major problem. (Fouling is normally just a surface layer, and with a 10-cm cell, it is not seen.)

Interpreting the Absorption Bands

Returning to the first item, difficulty in interpretation of the absorption bands. Normally in the NIR the objective is not to do qualitative analysis, but quantitative analysis with a trained computer. The computer can distinguish quantities of individual chemical species, for example, p-xylene in a mixture of aromatics, including both o-xylene and m-xylene. However, the normal task is to do quantitative analysis of physical properties like hardness of wheat, octane number of gasoline, boiling points of gasoline, cetane number of diesel, etc.

How is the computer trained? A set of samples, normally 30 to 50, is prepared covering the range of interest of all the analytes and "I don't cares" in the system. The spectrum for each sample is determined and paired with the known analyte concentrations. These data are all put into a computer with a chemometric program that uses a system to fit the spectrum to the data. Once that fit has been determined, the generated model can be used for future samples within the range of the initial data.

It is important to remember, that:

1. Before using the model on real samples, it should be tested on some new samples that were not used to make the model. Doing this is desirable, even if time-consuming and inconvenient. Normally one is using 30 to 50 samples, each having 700 to 1000 spectral data points attached; the computer can find a fit, but does it mean anything? The only way to find out is to test it.
2. Extrapolations from that initial data set are done at your risk. For gasoline, we used about 30 samples of each grade and time of year to build complete models to predict the various properties of the gasoline. Note: The 30 samples per grade per time of year are considered as a starting set, and the working models are based on 50 to 100 samples.[4]

Sample Temperature Control

If the sample contains water and one is measuring the ionic solutes, then temperature control is absolutely required. Liquid water exists in different forms related to the number of hydrogen bonds, as a function of temperature, and the change of forms causes spectral shifts that will overcome any other measurements one wants to make concerning the ions dissolved in the water. In hydrocarbon streams, the jury is still out—some claim that sample temperature control within 1°C is required for good analysis, while others say they can compensate for changing temperatures.

Because, in any optical measurement, one is counting molecules in the optical path, temperature will affect the spectrum. Therefore, it is easiest to control the temperature rather than try to compensate for it when doing high-quality work.

Fiber Optics

One of the big advantages of using the NIR range is the availability of optical fibers. Careful, there are optical fibers and there are optical fibers. To be useful for spectroscopic applications, the fiber needs to be insensitive to outside light, temperature changes, and movement (vibrations). The outside light problem can be solved by proper choice of jacket or keeping the fiber encased in an opaque case. (Remember that just because the jacket is opaque in the visible spectrum does not mean it will be opaque in the NIR.)

Temperature changes can cause major problems.[5] In Reference 5, Vickers shows that a 50°C temperature change on a 10-m fiber will cause a change in absorbance at over 1.0 A. K. The solution in such a case is to have a buffer that extracts the cladding modes and have the core, cladding, and buffer coiled inside the jacket to allow for thermal expansion and contraction without straining the fiber.

This system, in addition to adding expense to the fiber, lowers the total light throughput of the fiber, but makes it usable so that one is analyzing the light from the stream rather than from the fiber. Plastic-clad silica fiber is very inexpensive and therefore attractive, but it is totally unacceptable for hydrocarbon analysis; one sees the plastic cladding, and the depth of penetration is a function of temperature, which makes background correction very difficult.

Types of NIRs

NIRs come in four basic types:

1. The filter instrument uses two or more filters to pick out reference and measuring wavelengths. These are the lowest-cost instruments and generally only measure one to a few analytes in the stream.
2. The dispersive units with single detectors and moving grating. The moving grating causes some wavelength instability that becomes a major problem with very sensitive measurements.
3. FTNIR is very similar to FTIR; however, since the frequency and wavelengths are inverse scales, at the shorter wavelengths in NIR there is a higher reproducibility factor required for the mirror movement. However, these have been successfully applied in some very rigorous applications, such as measuring the octane of gasoline.
4. The diode array instrument with no moving parts—note that the material of construction in the diode array sets the usable range of the instrument. The most common diodes are made from silicon that become transparent at wavelengths longer than 1100 nm; therefore, these diode arrays are only usable in the third overtone. [The diode array instrument has no moving parts but requires extreme temperature stabilization to prevent wavelength changes due to different distances between the grating and detector array as a function of temperature.

One unit on the market controls the spectrograph temperature to ±0.1°C, while the outside temperature varies from –40 to 120°F (–40 to 50°C).]

Sources

The optical source for any spectrophotometer is important, but it is even more critical with systems based on fiber optics. The only light that is important in a fiber-optic instrument is the light that can be reproducibly launched onto the fiber. Therefore, big bulbs are not needed when trying to put light into a 200-μm-inner-diameter fiber; the key is to have a short, *stable* filament.

Many filaments are long, compared to the fiber diameter, and the hot spot that is giving off the light moves along the filament. Therefore, sometimes the fiber is in focus of the hot spot and sometimes it is not. This is totally unsatisfactory. What one wants is a short filament, where the hot spot stays fixed and the filament does not sag, which requires a larger-diameter filament. This allows the light to be focused onto the fiber and gives a light bulb with a very long life, exactly what is needed for process analysis.

Gases

The only known NIR application on gas samples involves the BTU content of natural gas.[6] In order to make this measurement, the natural gas line would have to be under high pressure, normally 1000 psi or so, in order to provide a sufficient number of molecules in the optical path to make the measurement.

Liquids

Under stable temperature conditions, ions in water can be measured. One analyzer measures the hydroxide ion concentration in a neutralization bath using a filter instrument with the reference chosen to eliminate effects of any other ions. Using third overtone diode array instruments, the octane numbers of gasoline can be determined and, at the same time, measure the MTBE concentration, the boiling points of the gasoline, the Reid Vapor Pressure (RVP), etc.

Crude oil properties have been measured using the second overtone region. The key is to properly model all these values when starting up the analyzer. (These same measurements have been made in the second overtone of the NIR using the FT approach.)

Solids

Modern NIR got its start with Dr. Karl Norris measuring such characteristics of agricultural products as the hardness of wheat, the protein content in wheat, the food value of alfalfa hay, etc. Because in the solids, the natural bandwidth was very wide, the original NIR instruments had poor optical resolution, but very high signal-to-noise ratios to see very small differences in the materials. When Dr. James Callis, University of Washington, CPAC, used one of these instruments to determine the octane of gasoline, it became evident that a great deal of information was discarded due to the poor optical resolution.

The diode array instrument that was developed improved the optical resolution by a factor of 3 and actually also improved the signal-to-noise ratio, which made it a very usable instrument. This resolution is used, for example, to measure MTBE in gasoline by measuring the small shift in the methyl group attached to the oxygen of the MTBE vs. all the other methyl groups in the gasoline.

Calibration Transfer

One of the earlier problems associated with NIR analyzers was that each instrument was different. If a calibration model was build on instrument A, then it could not be used on B, even if B was from the same manufacturer and had the same model number. Dr. Bruce Kowalski and his group at the University of Washington, CPAC, developed methods to solve this problem that have now been incorporated into some of the commercial analyzers.

Since there is a significant amount of time put into developing a model, one should make sure that the model is transferable to a different analyzer or to the same analyzer after maintenance is done on it, for example, when the light bulb is changed.[7]

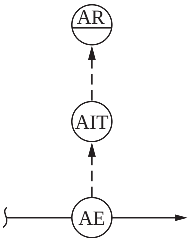
8.28 Ion-Selective Electrodes

R. T. OLIVER (1972, 1982) **S. S. LIGHT** (1995) **W. P. DURDEN** (2003)



ION SELECTIVE
Flow Sheet Symbol

Types of Electrode:	Glass, solid state, solid matrix, liquid–ion exchanger, gas sensing
Standard Design Pressure:	Generally dictated by electrode holder; 0 PSIG for solid state and liquid–ion exchanger; 0 to 100 PSIG (0 to 7 bars) for most electrode types; over 100 PSIG (over 7 bars) for solid-state designs
Standard Design Temperature:	32 to 122°F (0 to 50°C) for solid matrix and liquid–ion exchange; 23 to 176°F (–5 to 80°C) for most others, with 212°F (100°C) intermittent exposure being permissible
Range:	From fractional parts per million (ppm) to concentrated solutions
Relative Error:	For direct measurements, an absolute error of ±1.0 mV is equivalent to a relative error of ±4% for monovalent ions and ±8% for divalent ions; for end-point detection or batch control, ±0.25% or better is possible; for expanded-scale commercial amplifiers, error is better than ±1% of full scale.
Costs:	Similar to those of pH installations (Section 8.48); electrodes: \$120 to \$300; systems: \$600 to \$8000; hand-helds: \$50 to \$500
Partial List of Suppliers:	(Suppliers who manufacture only pH probes are not listed here; they can be found in Section 8.48.) Advanced Sensor Technologies Inc. INTRODUCTION

Ion-selective electrodes comprise a class of primary elements used to obtain information related to the chemical composition of a process solution. They are electrochemical transducers that generate a millivolt potential when immersed in a conducting solution containing free or unassociated ions to which the electrodes are responsive. The magnitude of the potential is a function of the logarithm of the activity of the measured ion (*not* the total concentration of that ion) as expressed by the Nernst equation (Equation 8.28(6)).

The familiar pH electrode for measuring hydrogen ion activity is the best known of the ion-selective electrodes and was the first one to be made commercially available

TABLE 8.28a
Ion-Selective Electrodes

Ion/Species	*Type of Electrode*	*Lower Detectable Limit, ppm*	*Principal Interferences*
Ammonia	Gas sensing	0.009	Volatile amines
Bromide	Solid state	0.04	CN^-, I^-, $S^=$
Cadmium	Solid state	0.01	Ag^+, Hg^{++}, Cu^{++}, Fe^{++}, Pb^{++}
Calcium	Solid matrix/liquid membrane	0.2	Zn^{++}, Fe^{++}, Pb^{++}, Cu^{++}, Ni^{++}, Sr^{++}, Mg^{++}, Ba^{++}
Carbon dioxide	Gas sensing	0.4	Volatile weak acids
Chloride	Solid state	0.2	Br^-, CN^-, $S^=$, SCN^-, I^-
Chloride	Liquid membrane	0.2	ClO_4^-, Br^-, I^-, NO_3^-, OH^-, F^-, OAc^-, $SO_4^=$, HCO_3^-
Copper (II)	Solid state	0.006	Ag^+, Hg^{++}, Fe^{+++}
Cyanide	Solid state	0.01	$S^=$, I^-
Divalent cation[a]	Solid matrix/liquid membrane	0.001	
Fluoroborate (BF_4^-), (boron)	Liquid membrane	0.11	I^-, HCO_3^-, NO_3^-, F^-
Iodide	Solid state	0.006	$S^=$, CN^-
Lead	Solid state	0.2	Ag^+, Hg^{++}, Cd^{++}, Fe^{++}
Nitrate	Solid matrix/liquid membrane	0.3	Cl^-, ClO_4^-, I^-, Br^-
Nitrite	Gas sensing	0.002	CO_2, volatile weak acids
Perchlorate	Liquid membrane	0.7	Cl^-, ClO_3^-, I^-, Br^-, HCO_3^-, NO_3^-, etc.
Potassium	Liquid membrane	0.04	Cs^+, NH_4^+, H^+, Ag^+, $Tris^+$, Li^+, Na^+
Redox (platinum)	Solid state	Varies	All redox systems
Silver/sulfide	Solid state	0.01 Ag 0.003 S	Hg^{++}
Sodium	Glass	0.02	Ag^+, H^+, Li^+, Cs^+, K^+, Tl^+
Thiocyanate	Solid state	0.3	OH^-, Cl^-, Br^-, I^-, NH_3, $S_2O_3^=$, CN^-, $S^=$
Sulfur dioxide	Gas sensing	0.06	CO_2, NO_2, volatile organic acids

[a] Water hardness electrode is also known as the divalent cation electrode.

(see Section 8.48 for pH measurement). With few exceptions—notably the silver-billet electrode for halide measurements and the sodium–glass electrode—the pH electrode was the only satisfactory electrode available to the process industry prior to 1966.

Currently more than two dozen electrodes are suitable for industrial use. Table 8.28a lists many of the commercially available electrodes for which process applications have been reported. Many other research sensors have been reported.

THE NERNST EQUATION

The potential developed across an ion-selective membrane is related to the ionic activity as shown by the Nernst equation:

$$E = \frac{2.3\,RT}{nF}\log\frac{a_1}{a_{int}} \qquad \mathbf{8.28(1)}$$

where E is the potential developed across the membrane; a_1 is the activity of the measured ion in the sample of process; a_{int} is the activity of the same ion in the internal solution; 2.3 RT/nF is the Nernst slope, or slope of the calibration curve, and is a function of the absolute temperature T and the charge on the ion being measured n; and R is the gas law constant.

Table 8.28b shows how the Nernst slope changes with temperature and the charge on the ion. When the ratio of the two activities is unity, the potential across the membrane is zero.

Equation 8.28(1) assumes that the membrane has identical selectivity properties on both sides. If for some reason this is not true, the equation is written

$$E = E_{asy} + \frac{2.3\,RT}{nF}\log\frac{a_1}{a_{int}} \qquad \mathbf{8.28(2)}$$

where E_{asy} is the asymmetry potential and amounts to a few millivolts. This equation is simplified by the fact that a_{int} is fixed by the internal structure of the electrode, giving

$$E = E^{\circ\prime} + \frac{2.3\,RT}{nF}\log\, a_1 \qquad \mathbf{8.28(3)}$$

where $E^{\circ\prime}$ is a new constant.

TABLE 8.28b
Nernst Slopes

Electrode Temperature		*mV per Decade of Activity*[a]	
°C	*°F*	*n* = ±1	*n* = ±2
0	32	54.19	27.10
10	50	56.17	28.08
20	68	58.17	29.08
25	77	59.16	29.58
30	86	60.15	29.58
40	104	62.15	29.58
50	122	64.12	32.03
60	140	66.10	33.05
70	158	68.09	34.04
80	176	70.07	35.04
90	194	72.05	36.02
100	212	74.04	37.02

[a] The slopes are positive for cations and negative for anions.

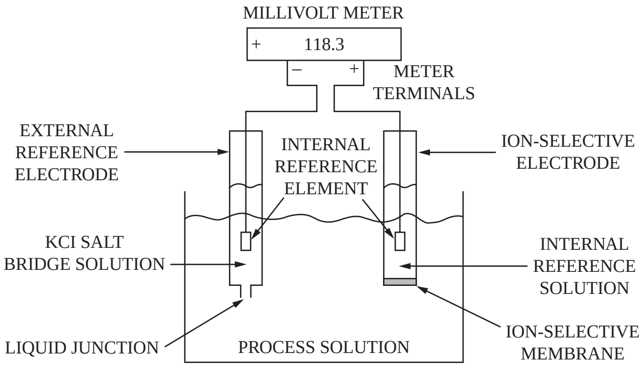

FIG. 8.28c
Ion-selective electrode measuring system.

A more complete equation takes into account electrode interferences and defines the selectivity coefficient. It is known as the Nicolsky equation:

$$E = E^{\circ\prime} + 2.3RT/nF \log (a_1 + k_{ij}a_j)^{zi/zj} \qquad \mathbf{8.28(4)}$$

where k_{ij} is the selectivity coefficient of interfering ion j with respect to measured ion i, each ion with charges z_i and z_j.

The Reference Electrode

In actuality, the potential of a single electrode cannot be measured by itself. It can be measured only in conjunction with a reference electrode and a high-input impedance voltmeter (Figure 8.28c). The latter is necessary to prevent current from flowing through the electrode, an action that would tend to cause electrochemical reactions in the solution phase around the membrane.

The potential read on the voltmeter is equal to the algebraic sum of the potentials developed within the system. That is, the observed meter potential is the sum of the potentials developed by the measuring electrode, E, the reference electrode, E_{ref}, and a small but important liquid-junction potential, E_j.

$$E_{meter} = E - E_{ref} + E_j \qquad \mathbf{8.28(5)}$$

Under normal operating conditions, the reference electrode is assumed to be constant, as is the liquid-junction potential. However, this is not always the case. Substituting Equation 8.28(3) into Equation 8.28(5) and combining constant terms, including E_{ref} and E_j, gives the general form of the Nernst equation:

$$E_{meter} = E^\circ + \frac{2.3\,RT}{nF} \log\ a_1 \qquad \mathbf{8.28(6)}$$

where E° is a constant for a given electrode system at a specific temperature. It depends on the choice of reference electrode and includes the liquid-junction potential.

The Nernst equation for the electrode pair can be written as an instrument input–output equation:

$$\text{Output} = A + B \log (\text{input}) \qquad \mathbf{8.28(7)}$$

where the output is a millivolt signal to a meter, A is a zero adjustment, and B is a span or slope adjustment around a temperature-independent, or isopotential, point. The input to the electrodes is the composition of the solution in terms of activity. Equation 8.28(6) states that the output of an electrode pair is linear with respect to the logarithm of the activity of the ion being measured (Figure 8.28d). The slope of the curve relating E_{meter} to log a_1 is 59.16 mV (at 25°C for n = 1) or 29.58 mV (at 25°C for n = 2).

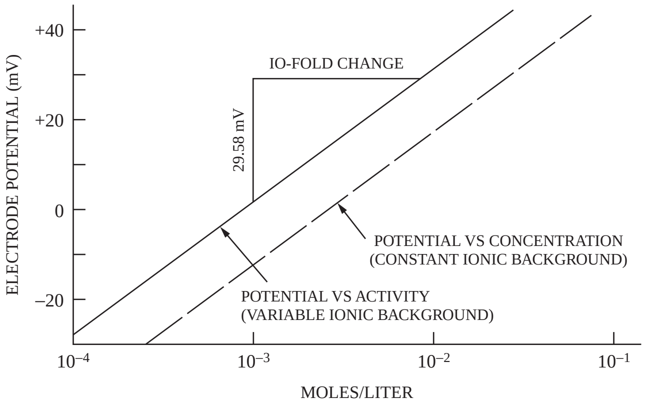

FIG. 8.28d
Electrode potential for calcium chloride solutions as a function of concentration and activity.

Concentration and Activity

Ignoring the effects of chemical reactions that would tie up ions, the activity of the ions is related to the analytical concentration, C, as follows:

$$a = \gamma C \qquad \textbf{8.28(8)}$$

where γ is the activity coefficient and is a measure of the interaction among ions in solution. It can be thought of as an empirical factor to explain the difference between the actual behavior of ions in solution and the ideal behavior. At zero ion concentration, that is, no ionic interaction, γ is taken as unity and the activity is equal to concentration. As the concentration increases, γ decreases at first, passes to a minimum value, and then rises, often to values greater than unity in very concentrated solutions.[1]

The activity coefficient is constant when the ionic composition of the solution is constant. Substituting Equation 8.28(8) into Equation 8.28(6) gives

$$E_{meter} = E + \frac{2.3\,RT}{nF} \log\ (\gamma C) \qquad \textbf{8.28(9)}$$

or, at constant total ionic conditions,

$$E_{meter} = E^\circ + \text{constant} + \frac{2.3\,RT}{nF} \log C \qquad \textbf{8.28(10)}$$

where the constant term is RT/nF log γ. Equation 8.28(10) is linear with respect to the concentration term (Figure 8.28d). However, if the ionic background of a solution varies, as in the preparation of a series of standards by dilution, the activity coefficient is no longer constant and Equation 8.28(9) is nonlinear (Figure 8.28e).

Equation 8.28(6) can predict the change in potential to be expected from a given change in activity or concentration (constant activity coefficient). For instance, if the activity changed twofold (100% change), then

$$E_{meter} = E^\circ + \frac{2.3\,RT}{nF} \log\ 2a_1 \qquad \textbf{8.28(11)}$$

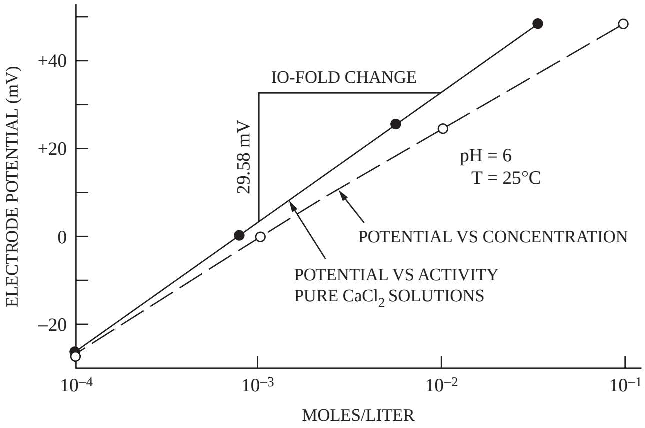

FIG. 8.28e
Concentration and ion activity vs. electrode potential.

Subtracting Equation 8.28(6) from Equation 8.28(11) gives

$$\Delta E = \frac{2.3\,RT}{nF} \log 2 \qquad \textbf{8.28(12)}$$

or 18 mV at 25°C for n = 1. A similar argument would show that for the same sample, an 18-mV decrease would be observed if the initial activity was cut in half (50% change).

This change is not dependent on the magnitude of a_1 and is the same whether measuring fluoride at the parts per million (ppm) level, chloride in 4% salt solutions, or the pH of a 15% sulfuric acid solution. Table 8.28f lists the changes in potential to be expected for up to a 10-fold change in activity. Column 1 shows the ratio of the original activity a_1 to the final activity a_2.

The last column shows the equivalent pH change if the [H^+] were being measured. The data indicate that for precise measurements of small changes in activity, it is necessary to use an expanded-scale meter. For example, a span of 60 mV would allow a 10-fold change to be measured, using the full scale of the measuring instrument.

Ionic Strength Adjustment Buffers

Introduction of the concept of the high-ionic-strength medium serves to remove or minimize two of the disadvantages of ion-selective electrodes. The concentration, rather than the activity, may be interpreted directly from the observed

TABLE 8.28f
Changes in Meter Potential for Changes of Activity[a]

$\frac{\sigma_1}{\sigma_2}$	ΔE to mV (77°F (25°C)) n = 1°	ΔE to mV (77°F (25°C)) n = 2°	Equivalent pH change (n = 1)
0.1	−60[b]	−30[b]	−1.0
0.25	−36	−18	−0.6
0.5	−18	−9	−0.3
0.79	−6	−3	−0.1
1.00	0	0	0.0
1.26	+6	+3	+0.1
2.00	+18	+9	+0.3
4.00	+36	+18	+0.6
10.00	+60	+30	+1.0

Note: Data are for positive ions. For negative ions, sign should be reversed.

[a] See Equation 8.28(12).

[b] Values rounded off from 59.16 and 29.58 (see Table 8.28j).

TABLE 8.28g

Composition of TISAB, a High-Ionic-Strength Buffered Complexing Medium for Measuring Fluoride Ion Concentration[2]

Sodium chloride	1.0 *M*
Acetic acid	0.25 *M*
Sodium acetate	0.75 *M*
Sodium citrate	0.001 *M*
Ionic strength	1.75 *M*
pH	5.0

electromotive force (emf) (see Equations 8.28(9) and 8.28(10)); some *chemical* and electrode interferences are removed.

The high-ionic-strength media are frequently designated by the acronym ISAB, which stands for ionic strength adjustment buffer. Table 8.28g illustrates the composition of total ionic strength adjustment buffer (TISAB).[2] TISAB is used for rendering the fluoride ion electrode virtually specific for the measurement of the total concentration of fluoride ion in solution, even if the test solution has a pH outside of the acceptable range and fluoride-complexing ions such as iron or aluminum are present.

In spite of small contributions from the test solution, the high concentration of sodium chloride fixes the ionic strength at a virtually constant value. The acetate–acetic acid buffer holds the pH into the optimum range for the fluoride electrode, and the citrate complexes commonly interfering ions such as iron and aluminum more firmly than does the fluoride.

ISAB solutions for other ions have been described in the literature and are available commercially. To utilize ISAB solutions for continuous process measurements, reagent addition systems are employed that mix the test and ISAB solutions together, utilizing process pressure or peristaltic (or other types) pumps.

Temperature Effects[3]

There are three temperature effects on ion-selective measurements, including the T term in the Nernst equation (see Table 8.28b), the thermal characteristics of the electrodes, and the thermal characteristic of the solution.[3] The T term in Equation 8.28(6) states that the potential produced by the electrode system is a function of temperature as well as of ion activity.

This effect can be compensated for, manually or automatically, by manipulating the input signal to the converter to indicate the true activity at the measured temperature. Temperature can also be compensated for by so designing the electrode pair that there is a zero temperature error at a particular ion activity. Figure 8.28h shows this effect for the fluoride electrode used to control the fluoridation of public water supplies.

The Isopotential Point The point at which the temperature curves intersect, 1 mg° F/I, is the control level for fluoridation. This point of intersection is called the isopotential point, and temperature effects are negligible on either side for a 18 to 27°F (10 to 15°C) change in temperature. The isopotential point for pH-measuring systems is normally about pH 7 and has a potential value of 0 mV.

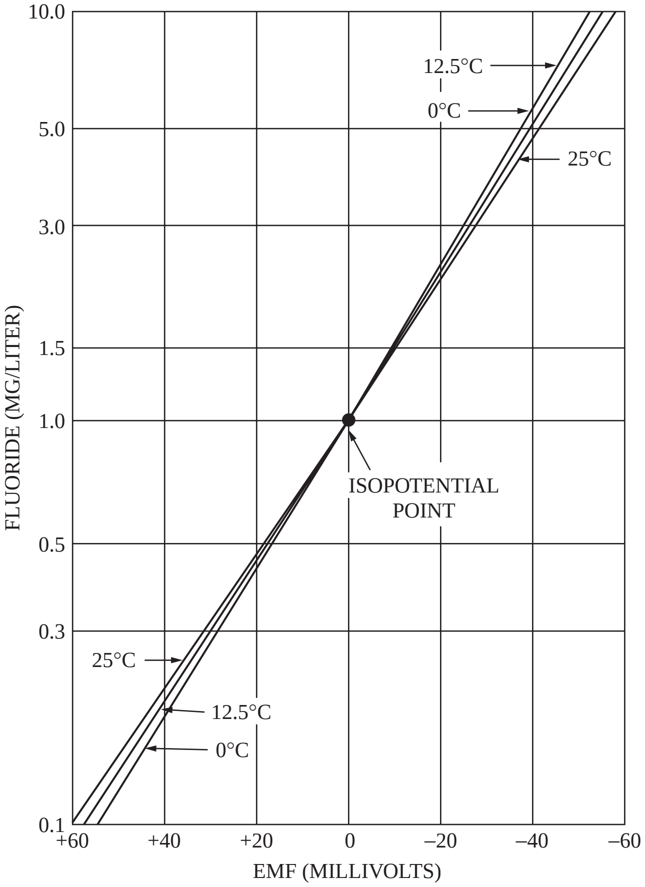

FIG. 8.28h

Isopotential point for fluoride electrode.

The activity coordinate of the isopotential points of the solid-state electrodes is fixed during manufacture, whereas the millivolt coordinate is also dependent on the choice of reference electrode. However, due to the construction of the liquid-membrane electrode, the isopotential points can be changed to fit the process.

Role of Electrode Internals and Calibration The second effect associated with temperature is created by the different internal thermal characteristics of the measuring and reference electrodes. This effect can be minimized if the internal elements of the measuring electrode are matched to the reference electrode. Most commercial pH systems employ matched internal elements for both electrodes.

The temperature effect on the chemistry of solutions is the third factor that can create an apparent error in measurement. This effect is difficult to quantify but can be offset by calibrating the system with preanalyzed process samples at the expected process temperature.

It should be noted that this is not a system error. The electrode indicates the true activity as a function of temperature changes. As long as the status of the process is what is required, the solution temperature effect is not important because the true activity is the quantity desired. This effect is usually not compensated for by the measuring instrumentation.

After sudden changes, time is required for a new state of thermal equilibrium to the reached (approximately one-half hour for a 18 to 27°F (10 or 15°C) change). Therefore, it is important to remember that when electrodes are moved from process samples to standard samples, which are at a different temperature, or when sudden and large process temperature changes occur, one should wait until a new thermal equilibrium is reached. During this time, the potential of the electrode system will drift. The duration of the drift depends on the particular electrode system and the magnitude of the temperature change. Therefore, it is important to avoid changes in temperature during calibration or to allow thermal equilibrium to be established.

System Accuracy

The accuracy of measurements derived from an analytical system is a composite of all contributing variables. These variables for ion-selective measuring systems are the measuring electrode; the reference electrode, including the liquid-junction potential; the selective-ion potential converter; the recorder; and the temperature and solution errors.

The relationship between overall emf errors (ΔE) and ionic concentration (C) may be derived from the Nernst equation 8.28(6) by substituting the values of the thermodynamic constants R and F and assuming that the activity coefficient (γ) is unity in Equation 8.28(8) at 25°C.

$$\Delta E = (59.16/n)\log\,(1 + (RE)/100) \qquad \textbf{8.28(13)}$$

where RE represents the percent relative error in the concentration

$$RE = 100\Delta C/C \qquad \textbf{8.28(14)}$$

A plot of Equation 8.28(13) is given in Figure 8.28i.

The *relative* error in measuring activity is dependent only on the *absolute* error in the emf and is independent of the activity range and of the size of the sample being measured. This is similar to an equal percentage valve in which equal incremental changes in valve opening (electrode potential) produce equal percentage changes in flow (RE in activity) for all valve openings—assuming constant differential pressure (constant temperature). Being a logarithmic device, an electrode gives a constant precision throughout its dynamic range. Concentrated solutions can be analyzed with the same accuracy as dilute solutions.

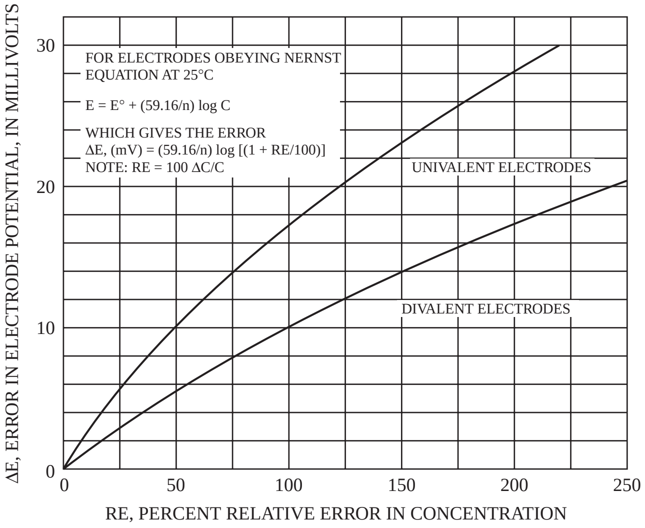

FIG. 8.28i
Relative error in concentration as a function of theoretical error in potential.

Laboratory Devices Laboratory measuring instruments for ion-selective electrode measurements with an uncertainty of ±0.1 mV have become commercially available. It is possible to make laboratory pH measurements within an error of ±0.002 pH units (equivalent to ±0.12 mV). Similarly, under carefully controlled conditions, ion-selective electrodes may be made repeatable within 0.1 mV. The accuracy attained to date in process instruments has been limited by the reference rather than by the ion-selective electrodes.

Process Applications Ion-selective measurement systems for process applications are repeatable to ±1 mV. For an electrode responding to univalent ions, an overall error of 1 mV corresponds to a 3.9% relative error in activity; for an electrode responding to divalent ions, the relative error is 7.8% per millivolt.

This means that they are roughly 5% (of value in activity) devices when measuring univalent ions, including H^+, in acidic or basic solutions or 10% (of value in activity) devices when making divalent ion measurements. These figures apply only to direct electrode measurements. When electrodes are used as end-point detectors in titrations or batch reactions or in differential systems, relative errors of 0.1% are possible.

TYPES OF ELECTRODES

Glass

Ion-selective electrodes are classified according to the type of sensing membrane employed. Glass electrodes are constructed from specially formulated glass and respond to ions by an ion exchange of mobile ions within the membrane structure. The membrane is fused to a glass body so that the outer surface makes contact with the sample or process stream, while the inner surface makes contact with an internal filling solution

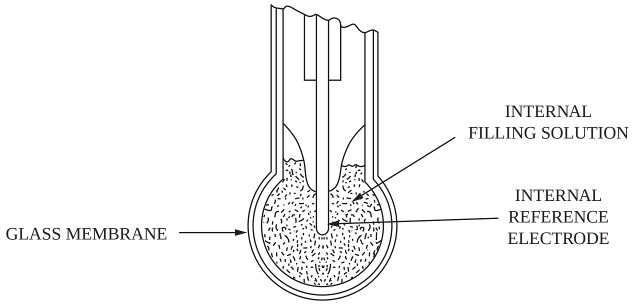

FIG. 8.28j
Conventional glass pH electrode.

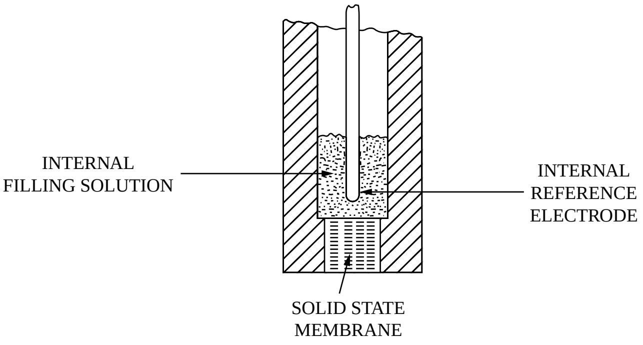

FIG. 8.28l
Solid-state membrane electrode.

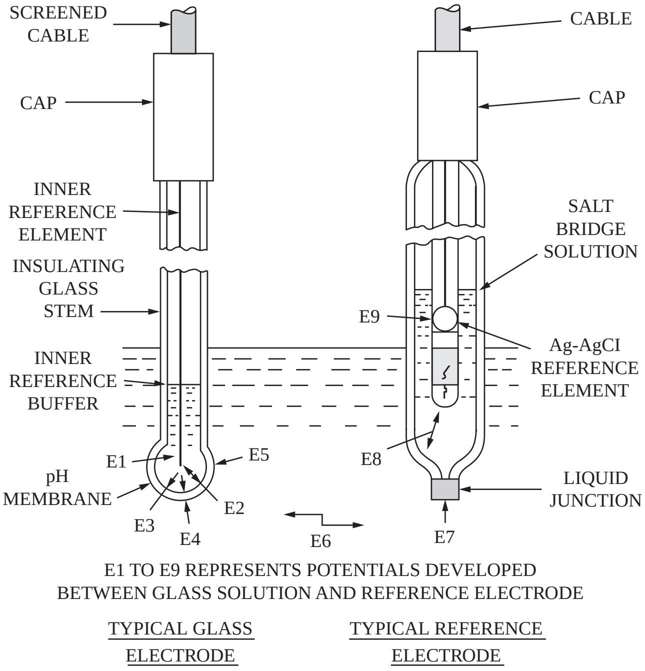

FIG. 8.28k
pH electrodes.

TABLE 8.28m
Solid-State Electrodes and Their Membrane Composition

Electrode	*Membrane*	*Form*
Fluoride	LaF_3	Single crystal
Silver/sulfide	Ag_2S	Pressed pellet
Chloride	AgX^a	Single crystal
Bromide or iodide	$AgX—Ag_2S$	Pressed pellet
Cyanide	$AgI—Ag_2S$	Pressed pellet

^{a}X = Cl, Br, or I.

containing a constant activity of the ion for which the membrane is sensitive (Figure 8.28j).

A stable electrical contact is made with the internal solution by a silver wire coated with silver chloride. Other internal contacts have been used (mercury–mercurous chloride or thallium amalgam thallous chloride), but the silver–silver chloride is the most popular. The internal filling solution must contain a constant chloride–ion activity and be saturated with silver chloride so that a stable potential is maintained at the metal salt–solution interface (Figure 8.28k).

In the conventional glass electrode, the internal solution is buffered at a pH of 7 and contains a chloride level similar to that in the external reference electrode (for details of reference electrodes, see Section 8.48). Other glass electrodes in process use are the sodium, ammonium, and potassium ion electrodes.

In addition to the concentration already described, the sodium electrode can also be prepared by slicing a thin section from a rod of sodium-sensitive glass and cementing it to an epoxy body (Figure 8.28l). This eliminates the familiar glass body of the pH electrode. Epoxy construction is not yet available for pH measurement due to difficulties inherent in cementing pH glasses to epoxy.

A carbon dioxide and an ammonia electrode can be made from a pH electrode by covering the membrane with a permeable-membrane sac filled with pH buffer. The respective gas in solution will selectively diffuse in or out of the permeable membrane, causing a pH change. The latter is dependent on the activity of the gas in the process solution.

Solid State

Solid-state electrodes are made of crystalline membranes, and there are scrupulous requirements for the size and charge of the mobile ions within the membrane. The composition of the membrane varies as a function of the required measurement. For instance, the fluoride electrode has a single crystal of doped lanthanum fluoride for a sensing membrane.

The silver and sulfide membranes are pressed pellets of insoluble silver sulfide. The small solubility of silver sulfide in solution prevents the coexistence of silver and sulfide ions, except in extremely small amounts, and the electrode can be used to measure either of these ions. Like the sodium electrode, these membranes are sealed in epoxy bodies (Figure 8.28l). Table 8.28m lists some of the commercially available solid-state electrodes and the composition of their sensing membranes.

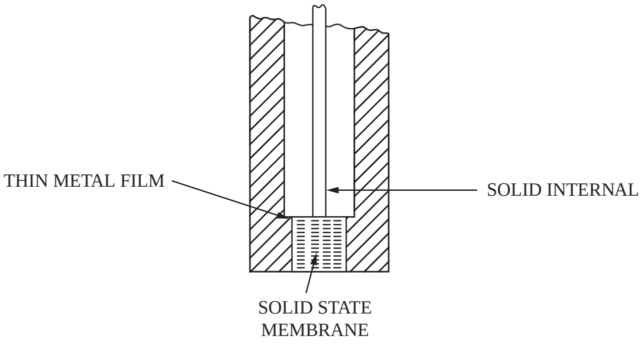

FIG. 8.28n
Solid-state membrane electrodes with solid internals.

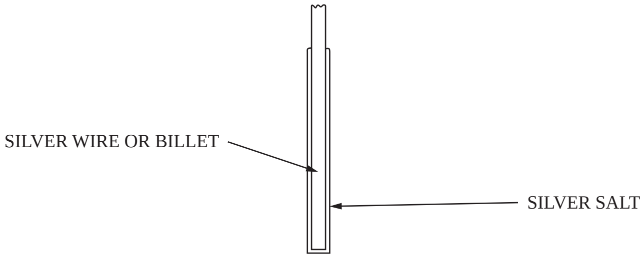

FIG. 2.28o
Conventional silver–silver electrode.

Some pressed pellets and the single crystalline silver–salt membranes are capable of having a metal deposited on the surface and an electrical lead connected to the metal deposit (Figure 8.28n). A solid connector permits the use of the electrodes in any position without breaking electrical continuity. Also, there are no internal solutions to deteriorate with time or temperature.

Figure 8.28o shows a conventional silver wire or silver-billet electrode that behaves identically to its corresponding solid-state electrode. However, small imperfections in the silver–halide coating expose free silver metal to the process solution, thereby developing variable oxidation–reduction potentials, and these electrodes have not found wide use in industrial applications. When placed in clean, controlled environments, such as the inner-filling solution of ion-selective electrodes, they produce stable reference potentials.

Liquid–Ion Exchange

There are many ions for which no glass or crystalline membrane can be found that is suitable for process measurements. Fortunately, chemistry is a versatile field and by using techniques familiar in ion exchange and solvent extraction technology, electrodes can be built for some of these ions. An inert hydrophobic membrane, such as a treated filter paper, can be made selective to certain ions by saturating it with an organic ion exchange material dissolved in an organic solvent.

This feature requires a construction of the electrode, as shown in Figure 8.28p, which is a cross section of the tip of a liquid–ion exchange electrode. This electrode has two filling solutions, an internal aqueous filling solution in which the silver–silver chloride reference electrode is immersed, and an ion exchange reservoir of a nonaqueous water-immiscible solution, which *wicks* into the porous membrane.

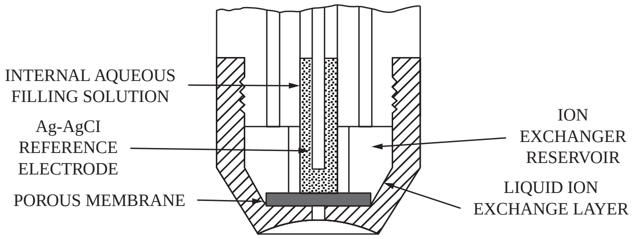

FIG. 8.28p
Divalent cation electrode tip in cross section.

The membrane serves only as a support for the ion exchange liquid and separates the internal filling solution from the unknown solution in which the electrode is immersed. In effect, there is a sandwich, with the bottom layer being the unknown process solution, the filling being the nonaqueous liquid–ion exchange solution, and the top layer being the internal aqueous solution. For example, if the liquid–ion exchanger is selective for calcium, a potential across the membrane is created by the difference in calcium activity between the internal filling solution and the process solution.

The electrode is designed so that the liquid–ion exchanger, used as a sensing element, has a very small positive flow into the process stream. Therefore, liquid–ion exchange membrane electrodes require recharging with an ion exchanger. Liquid–ion exchange membrane electrodes come in kit form. The kit contains an electrode body and sufficient ion exchanger, internal filling solution, and membranes to recharge the electrode many times. A single recharging should last several months in a properly designed system. Unlike the solid-state or glass electrodes, liquid membrane electrodes cannot be used in nonaqueous solutions because they would dissolve the liquid–ion exchanger. The body of the electrode is a chemical-resistant plastic.

Solid-state matrix electrodes are an improvement over liquid–ion exchange electrodes. The ion exchanger is permanently embedded in a plastic matrix, such as polyvinyl chloride, with a nonporous membrane. Rebuilding or solution replenishment is not required, and improved analytical performance and lower limits of detection are obtained.

MEASUREMENT RANGE

The upper limit of detection for ion-selective electrodes is the saturated solution. However, due to the problems of making measurements with reference electrodes that have large liquid-junction potentials (Section 8.48), the electrodes are specified as having an upper limit of 1 *M*. If the problems of large liquid junctions are brought under control, measurements can be made in saturated or nearly saturated solutions.

The lower limit of detection is usually determined by the solubility of the solid-state-sensing element or the liquid–ion exchanger. The solution pH sometimes determines the lower limit of detection. Some dilute solutions are unstable, but activity measurements may be made if the solution is buffered with respect to the ion being measured, that is, if the free ion is in equilibrium with a relatively large excess of complexed ion. This is the case when free silver is measured in photographic emulsions or sulfide, cyanide, or fluoride in acid solutions.

INTERFERENCES

All ion-selective electrodes are similar in principle of operation and use. They differ only in the details of the process by which the ion to be measured moves across the membrane and by which other ions are kept away. Therefore, a discussion of electrode interferences will have to be in terms of the membrane materials.

The glass electrodes and the solid matrix/liquid–ion exchange electrodes both function by an exchange of mobile ions within the membrane, and ion exchange processes are not specific. Reactions will occur among many ions with similar chemical properties, such as the alkali metals, alkaline earths, or transition elements. Thus, a number of ions may produce a potential when a given ion-selective electrode is immersed in a solution.

Even the pH glass electrode will respond to sodium ions at a very high pH (low hydrogen ion activity). Fortunately, an empirical relationship can predict electrode interferences, and a list of selectivity ratios for the interfering ions can be obtained by consulting the manufacturers' specifications or the chemical literature. Selectivity constants will be described in connection with Equation 8.28(3).

Solid–state matrix electrodes are made of crystalline materials, and interferences resulting from ions moving into the solid membrane are not to be expected. Interference is usually by a chemical reaction with the membrane. One, which is observed with the silver–halide membranes (for chloride, bromide, iodide, and cyanide activity measurements), involves reaction with an ion in the sample solution, such as sulfide, to form a more insoluble silver salt. As already mentioned, specific details of electrode side reactions can be found in the manufacturers' specifications and chemical literature.

Solution Interference

A true interference is one that produces an electrode response that can be interpreted as a measure of the ion of interest. For example, the hydroxyl ion, OH^-, causes a response with the fluoride electrode at fluoride levels below 10 ppm. In addition, the hydrogen ion, H^+, creates a positive interference with the sodium ion electrode.

Often an ion will be regarded as interfering if it reduces the activity of the ion of interest through chemical reaction. It is true that this reaction (complexation, precipitation, oxidation–reduction, and hydrolysis) results in an activity of the ion that differs from the concentration of the ion by an amount greater than that caused by ionic interactions. However, the electrode is still measuring the true activity of the ion in the solution.

An example of solution interference will illustrate this point. Silver ion in the presence of ammonia forms a stable silver–ammonia complex that is not measured by the silver. Only the free, uncombined silver ion is measured. The total silver ion may be obtained from calculations involving the formation constant of the silver–ammonia complex and the fact that the total silver is equal to the free silver plus the combined silver. Alternately, a calibration curve can be drawn relating to the total silver (from analysis or sample preparation) to the measured activity. The ammonia is *not* an electrode interference.

Most of the confusion stems from the fact that analytical measurements have been in terms of concentration without regard to the actual form of the material in solution, and electrode measurements often disagree with the laboratory analyst's results. However, the electrode reflects what is actually taking place in the solution at the time of measurement. This may be far more important in process applications than the more classic information. With some of the techniques suggested, the two measurements are often reconciled.

CALIBRATION SOLUTIONS

Calibration solutions for ion-selective systems are not normally buffered to resist changes, as are the standard solutions for pH systems. They can therefore be affected by dilution, evaporation, oxidation, or contamination by foreign matter in the process fluid. Thus, more care must be taken in preparing and handling these solutions than is generally needed in a typical pH application. Attention should be paid to eliminate carryover from one test solution to another from distilled water rinses.

Calibration solutions should be prepared in accordance with accepted principles of analytical chemistry. Many common chemical standards are available as stock solutions from laboratory supply houses. Generally, only solutions at a reasonably high concentration level (greater than 0.01 *M* or 100 ppm) should be made for storage. Serial dilutions of these stock solutions should be made at the time of use because very dilute solutions are particularly likely to lose some of their ions by absorption of the walls of the storage vessels. Use of high-grade plastic storage bottles is recommended.

Table 8.28q lists some solutions frequently used to check the performance of an ion-selective measuring system. When the ionic background is held constant (sulfide, chloride cyanide, and pH), the potential difference between two of these solutions is Nernstian (see Table 8.28b). For others, the potential difference should be normalized to decide changes in activity.

TABLE 8.28q
Calibrating Solutions for Ion-Selective Electrodes

Electrode	*Chemical Composition*	*Ionic Concentration*	*Approximate Ion Activity*	*Approximate emf vs. 1.0 M KCl, AgCl, Ag Reference at 77°F (25°C)*
Hydrogen (pH)	0.05 *M* KH phthalate	4.008 pH buffer at 25°C	$10^{-4.008}$ *M* H^+/L	+143 (+178)[a]

	1.00×10^{-4} *M* $CaCl_2$	1.00×10^{-4} *M* Ca^{++} or 10 mg/l as $CaCO_3$	0.92×10^{-4} *M* Ca^{++} or 9.2 mg/l as $CaCO_3$	–18

[a] Vs. 4 *M* KCL, AgCl, Ag reference electrode at 25°C.

To achieve the utmost in accuracy and meanin1397 1397gful measurements, the ion-selective measuring system should be standardized, and thus optimized, in a solution carefully chosen to be chemically similar to the process solution at the point of prime interest. This solution should be at a stable temperature near the actual process temperature (±3.6°F (±2°C)). A grab sample of the process solution analyzed in the laboratory may be the best and most convenient standard to use.

ADVANTAGES AND DISADVANTAGES

Compared to other composition-measuring techniques, such as photometric, titrimetric, chromotographic, or automated-classic analysis, the ion-selective electrode measurement has an impressive list of advantages. An electrode measurement is simple, rapid, nondestructive, direct, and continuous, and, therefore, easily applied to closed-loop process control. In this respect, it is similar to using a thermocouple for temperature control. Electrodes can also be used in opaque solutions and viscous slurries. In addition, the electrodes measure the free or active-ionic species in the process, under process conditions, and consequently the status of a process reaction.

However, there are several disadvantages. The specificity of ion-selective electrodes is not quite as good as that of the glass pH electrode. Interferences vary from minor to major; the literature and manufacturers' data on limitations need to be consulted for each electrode. Also, the electrodes do not measure the total concentration of ions, the parameter that is often requested. The reason is that prior to the introduction of electrodes, concentration information was the only information available from the chemist due to his classic measurement techniques. Control laboratory chemists and process engineers are not accustomed to thinking in terms of activity, even when making pH measurements (Section 8.48). This habit may well disappear as this new ion-selective technique becomes more popular.

There are some manufacturers that have begun packing the electrodes separately and installing them in a junction head. This allows the ion-selective electrodes to be independently replaced and stored dry. The reference electrodes are also independently replaced and stored wet. This allows the best of both worlds for storage life and cost of replacement.

However, there are times when concentration is a desirable measurement, for example, material balance calculations or pollution control. The knowledge of material balance allows a prediction as to where a process reaction will be in the future. This information is necessary if a process is to be controlled by introducing changes that will nullify those predicted.

In pollution control, it is generally accepted that many ions, even in the combined state, are detrimental to life forms. Fluorides, cyanides, and sulfides, to name a few, are harmful to fish and humans in many combined forms. Yet, their sum total is not measured, but they are detected individually by ion-selective electrodes. Consequently, pollution control agencies usually require concentration information.

The electrodes can be used for this purpose if they are calibrated with solutions matching the process or with ISAB solutions (see below). If this is not satisfactory, an electrode can be used for on-line control, and separate grab samples can be analyzed by other procedures to obtain the information needed to comply with regulations.

Precision and Accuracy

Another disadvantage derives from a misunderstanding about precision and accuracy. Many classic analytical techniques name a relative error of ±0.1%. Ion-selective electrodes name relative errors of ±4 to 8% (see "System Accuracy" earlier in this section). In terms of pH, this is equivalent to a measurement of ±0.02 pH units—ordinarily regarded as a satisfactory measurement.

When used with some degree of understanding, ion-selective electrodes can supply satisfactory composition information and afford closed-loop control that was previously unattainable. When in doubt, the user should consult with the electrode manufacturers or his own analytical chemists.

CONCLUSIONS

It is evident from the preceding discussion that ion-selective electrode measurements and pH measurements using the glass electrode are not only identical in theory, but also similar in practice. The electrodes are generally the same size and fit the pH holder assemblies.

Electrical insulation of the electrodes is as important as with the glass electrode. In addition, the electrodes are subject to the same fouling by oils and slimes as glass electrodes and can, in general, be cleaned using methods already proven for the pH electrodes. Because of these similarities, discussion of the application of ion-selective electrodes is omitted here.

Flow Sheet Symbol

Type of Sample:	Vapor
Standard Design Pressure:	Atmospheric
Sample Temperature:	122 to 424°F (50 to 200°C); sufficient to provide vapor sample with no condensation
Ambient Temperature:	68 to 77°F (20 to 25°C)
Contacting Materials:	Inlet materials of construction designed to be compatible with sample
Auxiliary Utilities Required:	Sometimes cooling water
Cost:	\$3000 to \$200,000, depending on analyzer section, application complexity, and data report and collection accessories Time-of-flight section: \$149,000; with specialized data acquisition systems: \$175,000 Magnetic section (food processing industry): \$120,000 RGA: \$3500; multiple purchase: \$3000 Quadrupole section: \$45,000 to \$90,000 Ion-trapping section: \$90,000 \$150,000
Inaccuracy:	±0.5% for most applications
Repeatability:	±0.2% for most applications
Cycle Time:	0.5 to 4 sec per stream, depending upon applications
Special Features:	Multicomponent readout, database of mass spectra, programmable temperature control, coupled to gas or liquid chromatography units

INTRODUCTION

Closed-loop computer control is a major requirement of many industrial chemical processes. Knowledge of the composition and concentration of a chemical process stream is an important element if a modern closed-loop computer control scheme is to be developed. The mass spectrometer is widely used as an analytical tool in the process industries. It provides multicomponent analysis with the accuracy, reliability, and cycle time that are necessary for closed-loop computer control of a process. For example, typical instruments can sample multiple streams for concentrations of 8 to 12 components in less than 5 sec. The increased use of mass spectrometers in the process industry is the result of properly combining the sample stream, the analyzer, and the data acquisition system into a reliable working unit.

PRINCIPLE OF OPERATION

Mass spectrometers create and then separate ions of a particular atomic or molecular species by their mass-to-charge (m/e) ratios. For example, a diatomic nitrogen molecule with a mass of 28 might become a single charged ion, and it would have an m/e ratio of 28. If that diatomic molecule became a double charged ion, its m/e ratio would be 14. A mass spectrometer employs a vacuum environment in which ions are created, separated, and ultimately detected. This vacuum requirement allows collisions between the ions and molecules to be minimized. This is possible when the mean free path for the ions is very large. Typically, a vacuum in the order of 10^{-4} to 10^{-6} torr (mmHg) is required. Consequently, a mass spectrometer must include a sampling port into, as well as a vacuum pumping system that maintains the required vacuum envelope within, the spectrometer.

In general, a very small gas sample is introduced from atmospheric pressure through the inlet port into the ion generator section of the spectrometer. Sample ions are produced by the collision of rapidly moving electrons with the gas molecules to be analyzed. The electrons ionize the sample by knocking out one or more electrons from an outer orbit of a neutral sample molecule. The positive sample ions are extracted from the ion generator as fast as they are formed by means of electrostatic fields created by sets of electrodes that also accelerate and focus these ions into an ion beam. This ion beam is directed into the ion separation section of the instrument. Finally, these separate segregated ion groups are directed to an ion collector or detector, which provides an electric signal that is proportional to the number of ions in the detected group. Nonionized molecules exit the spectrometer to the atmosphere via the vacuum pumping system.

Sample Input

The sample system and sample conditioning for a mass spectrometer are similar to those used for gas chromatographs (Section 8.12). In fact, it is very common to connect a gas chromatography system to the sample input port of a mass spectrometer. In any event, vapor samples are drawn by suction into the mass spectrometer through several possible types of inlet leaks.

A sintered metal leak device is a commonly used input port because it allows a uniform molecular flow into the instrument based on the differential pressure across the sintered metal plate. Thin diaphragms made from Teflon may be used for corrosive service, and ultrafine metering valves can also be used. Also available are automatic metering valves that maintain a sample flow based on the pressure in the spectrometer's ionization chamber. While a variety of inlet leaks are available, one must be chosen that produces a stable flow of sample gas into the spectrometer and is compatible with the desired sample and the system's analyzer. Fortunately, most mass spectrometer companies provide instruments with appropriate inlet port options and offer help in making the proper input port selection.

Sample Ionization

Several methods are available for producing ionic species from the sample gas. Electron bombardment is the most popular but requires periodic filament replacement. Spark generation and optical and chemical ionization methods are also used. Atmospheric ionization mass spectrometry is available and has been shown to be applicable to a wide range of compounds. Although this approach promises to open up a wide range of new applications for mass spectrometry, most instruments currently used in process applications use vacuum environment-based systems with heated filaments. Since filament life and ease of replacement are of primary concern, most process mass spectrometers have dual-filament assemblies that allow switching from one to the other filament without any downtime. Filament replacement is then postponed until occurrence of the next scheduled preventive maintenance event.

Figure 8.29a shows the operation of a heated filament ion source. In this example, the molecules are shown entering the spectrometer from the top. After passing through a negatively charged repeller screen, these neutral molecules interact with a focused electron beam to form a variety of products, including an ion cloud that contains positive ions. These ions are pushed out of the ion generator section of the spectrometer by the repeller screen and then accelerated through an exit slit into the ion separation section of the spectrometer. The sample ions are now z-axis aligned and directed into the magnet region of the ion separation section of the instrument. The bulk of the sample molecules and any other electron impact reaction products are removed by the vacuum system.

In general, there are at least four options for the sample ionization section of a mass spectrometer: 1) an open ion source for general high-vacuum applications; 2) a closed ion source for process and gas analysis; 3) a differential ion source for running both process pressure and high-vacuum applications simultaneously; and 4) a cross-beam ion source to enhance the minimum detection level for many different gas species. As with the case of the instrument's sample inlet port, most mass spectrometer companies provide these options and offer help in making the proper ion generator selection.

Ion Separation

Although the four major sections of a mass spectrometer—the input port, the ion generator, the ion separation section, and the ion detector—are equally important, the behavior of the spectrometer is characterized by its ion separation section. There are several ion separator section options available. For

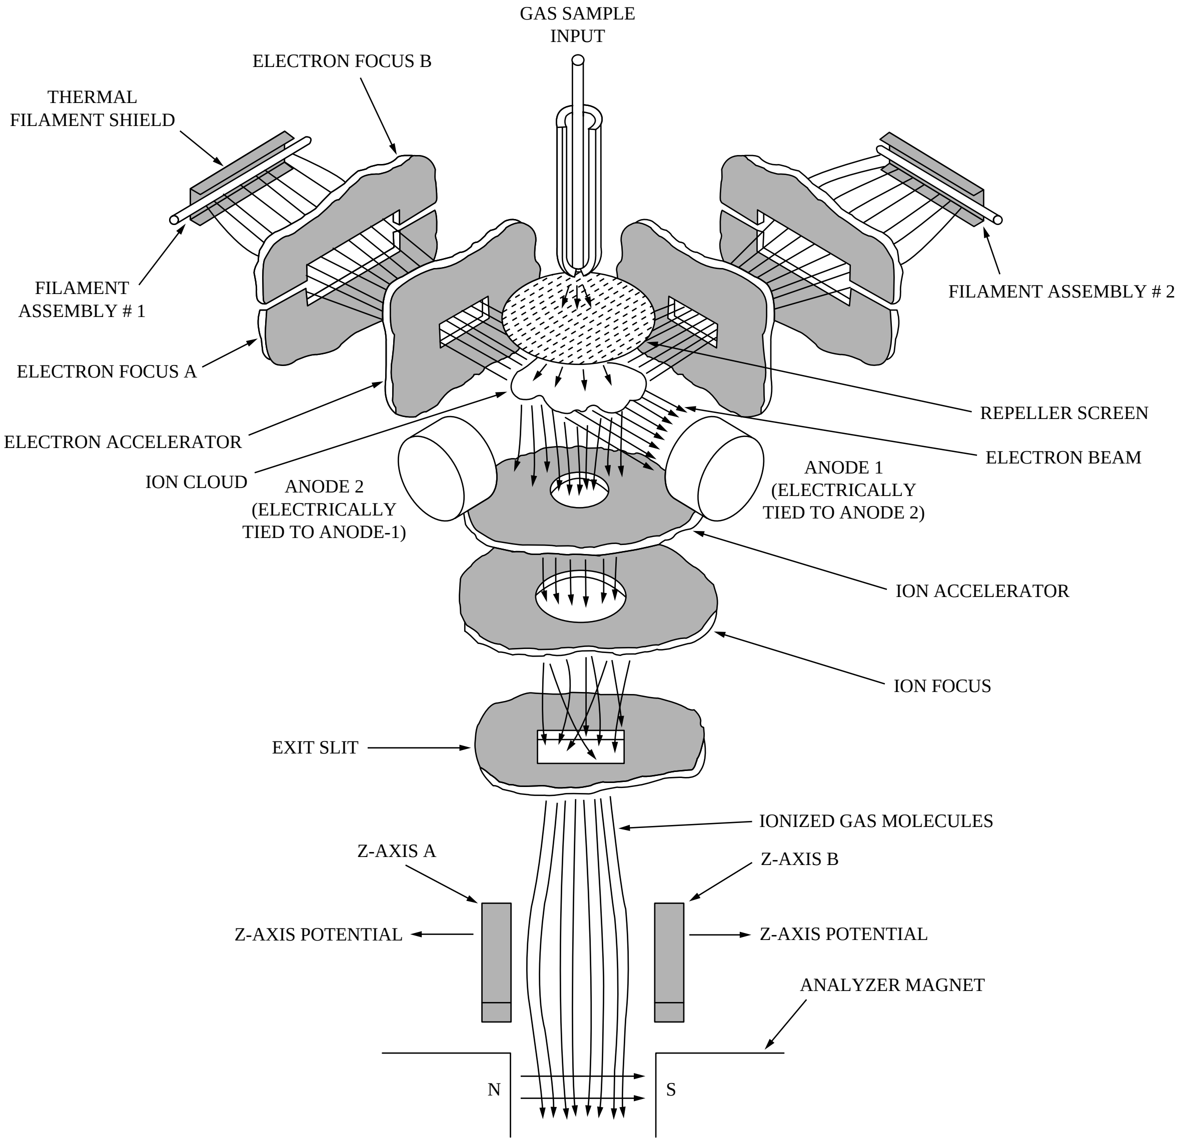

FIG. 8.29a
Ion source operation.

instrumentation and process personnel, the selected instrument design must stress simplicity, automatic operation, and reliability; require a minimum of operator attention; and still meet the analysis needs. Further, it must be serviced and maintained by personnel with minimal mass spectrometer technical expertise. The various separation options are discussed below.

Magnetic Sectors There are two types of magnetic sector instruments: fixed magnetic sector and electromagnetic-focusing sector. The fixed magnetic sector instrument utilizes a permanent magnet to produce a magnetic field at right angles to the direction of motion of the ion beam that exits the instrument's ion generation section. This normal interaction forces the ions to bend in a circular trajectory proportional to their m/e ratios.

The concept of the fixed magnetic sector ion separation process is shown in Figure 8.29b. The top section of the illustration is the sample ionization section of the instrument and succinctly summarizes all of the details provided in Figure 8.29a. The center portion of the diagram shows the fixed magnetic sector ion separation portion of the instrument. In this case, multiple collectors are employed to obviate the need for scanning, which vastly simplifies the electronic system and does not require an external programmer to select the operational parameters. For each process application, the collectors are located at a predetermined point in the instrument focal plane.

For example, if the situation required the instrument to measure the atmospheric composition of a process stream sample, the ion collectors would be placed along the magnetic sector focal plane to intercept the ion beams for nitrogen (m/e = 28), oxygen (m/e = 32), and argon (m/e = 40). This will require three of the eight possible real-time mass-to-charge ratio measurements that could be made by the instrument.

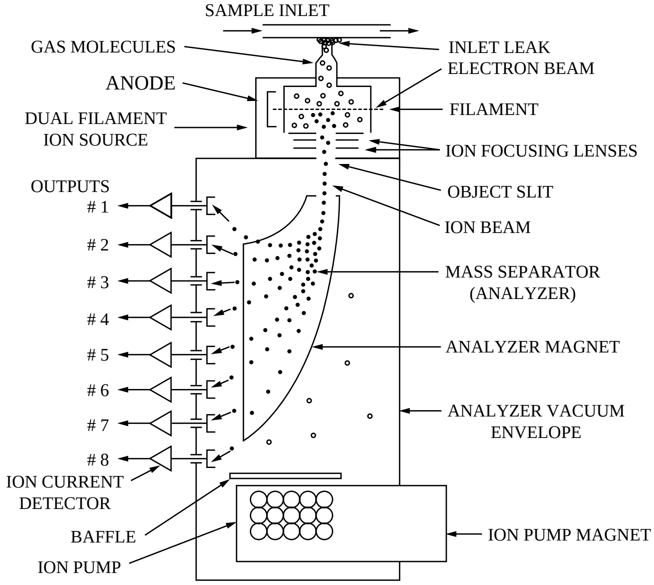

FIG. 8.29b
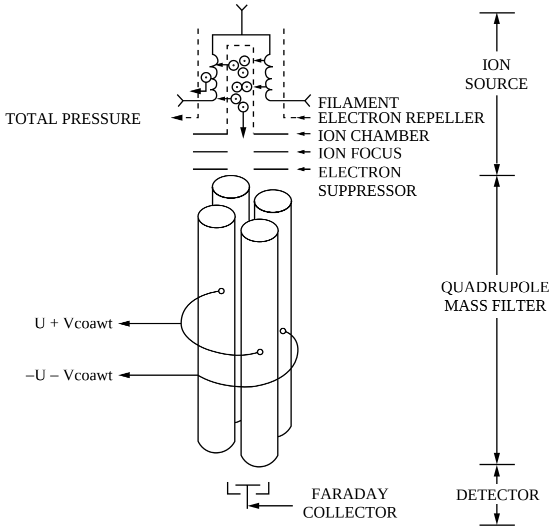
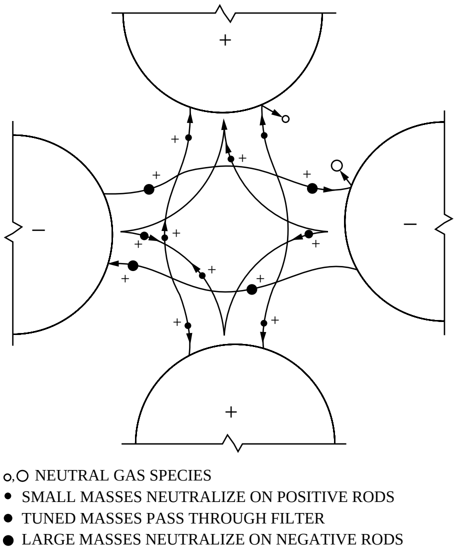
Fixed magnetic sector mass spectrometer operation.



QUADRUPOLE MASS SPECTROMETER



QUADRUPOLE MASS FILTER

FIG. 8.29c
Top: Quadrupole mass spectrometer. Bottom: Quadrupole mass filter.

With these three measurements, the output of the instrument could continuously monitor the atmosphere composition of the process stream and provide data for an appropriate control decision. In addition, there would be five additional spectrometer output channels to monitor other components of the process stream.

The concept of the electromagnetic-focusing sector ion separation process is distinctly different from the multiple collector idea shown in Figure 8.29b. The electromagnetic-focusing sector utilizes changes in either the accelerating voltage or magnetic field to focus the desired ionic species onto a single collector. When accelerating voltage is used, the ions are focused and accelerated as a beam into a magnetic field. The acceleration voltage is varied to select the ions with a particular mass. For various ionic mass selections, the product of mass and acceleration voltage is a constant. Since the multiple mass ion beam entering the magnetic field contains ions of essentially equal energy, the momentum of each ion depends upon its mass. Because the radius of curvature of the ions in the magnetic field is different for ions of different momentum, only ions corresponding to one particular mass are focused on the collector. This signal is amplified and displayed as a signal proportional to the particular concentration (partial pressure) of the gas type with that mass.

Magnetic field variation is an alternate way to make a single mass ion beam exit an electromagnetic-focusing sector in a mass spectrometer. The principal advantage of magnetic field scanning is the wider mass range achieved. Although the mass is not directly proportional to the magnetic field, circuits have been designed to provide linear spacing of masses. When changing the magnetic field, the accelerating voltage is held constant at a value that corresponds to the higher mass of interest. When magnetic field variation is used to sort sample ions, the relative heights of different mass peaks do not occur in the same proportion as they do when the ion separation is accomplished by changing the accelerating voltage. In the latter case, the low-mass peaks are enhanced in both magnitude and resolution because of the more favorable accelerating voltage at which they appear. When the magnetic field is varied at an acceleration voltage corresponding to the highest mass of interest, this enhancement does not occur. Therefore, both the magnitude and resolution of mass peaks will be less.

Quadrupole Filter The use of a quadrupole mass filter to separate the sample ions that leave the ion generation section of a mass spectrometer is also possible. Figure 8.29c illustrates the operation of this type of ion separation section. Again, the top portion of the upper panel of this figure shows the ion generation section of the instrument. The sample ions exit this ion source through the electron suppressor and then enter the quadrupole filter region of the instrument. A quadrupole m/e filter consists of four high-precision crafted cylindrical rods located precisely in an orthogonal array. The m/e-separated ion groups exit the quadrupole separation section and strike a single detector, which produces a signal proportional to the number of ions with the selected m/e ratio.

The lower panel of Figure 8.29c provides a top-down view of the travel path for ions entering the quadrupole ion separation portion of the instrument. As an ion moves at uniform speed among these rods, it undergoes complex oscillatory spiral motion transverse to its travel axis. The actual ion motion is considerably more complex than shown, and the path lines in the figure only represent outer boundaries of particle motion. This motion pattern is created because diametrically opposing rod pairs are electronically connected to also form positive and negative rod pairs. The positive pair has a radio frequency (RF) voltage superimposed on a positive DC voltage, while the negative pair has a negative DC and RF voltage that is 180° out of phase with the positive pair. The varying electromagnetic field that results creates an environment that separates the ions by their mass-to-charge ratio.

For a given set of voltages, all ions below a given mass interact with the positive set of rods. These low-mass ions are neutralized and removed from the ion beam, while higher-mass ions remain in the ion beam. In turn, the negative set of rods interacts, neutralizes, and removes ions above a given mass value. The lower-mass ions remain in the ion beam and continue traversing the quadrupole section. By adjusting the RF-to-DC ratio, an ion pass-band can be created so that only ions with a specific narrow m/e ratio can exit the quadrupole ion separation section of the instrument. Under high-resolution conditions, the passed ions barely miss the rod pairs at the extremes of their transverse oscillatory motion, and the mass range that is allowed to exit the quadrupole filter is very narrow. A unique property of the quadrupole mass filter is the fact that the number of m/e ions that are passed is directly proportional to the voltage applied to the rods. Thus, by changing the voltages, various ionic masses of interest are allowed to pass through to the collector where they are measured.

Ion-Trapping Section Figure 8.29d illustrates an ion-trap mass spectrometer that uses an interesting twist for its ion separation section. In this case, the geometry of the section plus the RF voltages applied combine to create an environment in which the ions undergo stable oscillations and remain trapped in that environment. Three electrodes, two end-cap electrodes that normally are at ground potential, and between them a ring electrode to which an RF mega-Hertz voltage is applied, generate the quadrupole electric field that can trap the sample ions.

The ion separation is accomplished by introducing a change in operating voltage. This alters the quadrupole electric field and allows trapped ions of a particular mass-to-charge ratio to adopt new but unstable trajectories. Thus, if the amplitude of the RF voltage applied to the ring electrode is systematically varied, ions of successively increasing m/e ratios are made to adopt unstable trajectories and to exit the ion trap, where they can be detected using an externally mounted electron multiplier.

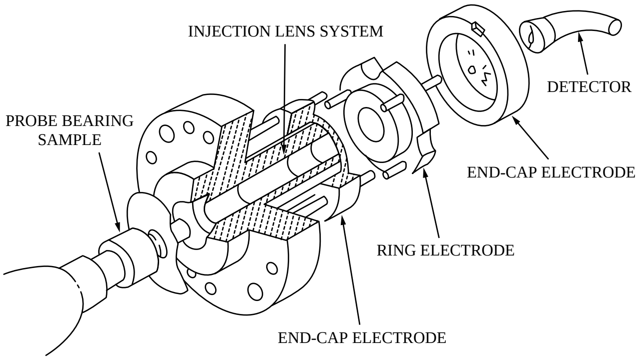


FIG. 8.29d
Ion-trap mass spectrometer.

Time-of-Flight Filter In time-of-flight mass spectrometers, the ionized sample is subjected to a negative-polarity-accelerating field, and then the ion beam is directed into a time-of-flight drift region. This drift region is the ion separation section of the spectrometer. The lighter ions travel faster through this region than the heavier ions, producing mass separation by the amount of time it takes for the ions to traverse this drift tube.

To accomplish this type of mass separation, the ionized sample is introduced in discrete pulses of 20,000 to 35,000 pulses per second. On each cycle the sample ions enter the flight tube (drift region) where the separation by mass values is accomplished. Upon exiting, the ions are then converted to electrons and amplified using an electron multiplier. The final amplified signal is detected by the detector's anode and fed to a suitable data acquisition system. Figure 8.29e illustrates the operational concepts for time-of-flight spectroscopy.

Ion Detection

It is important to understand that the ion collectors are not selective detectors. They will provide a signal if an ion with the appropriate mass-to-charge ratio emerges from the ion separator and strikes the detector surface. Thus, for this example, the conclusion that the atmospheric composition of the process stream is being monitored depends on the assumption that only ions created from the nitrogen, oxygen, and argon in air contribute to the collector signals at m/e ratios of 28, 32, and 40, respectively. If the process gas stream has other sources for these atoms, the conclusion is not immediately valid.

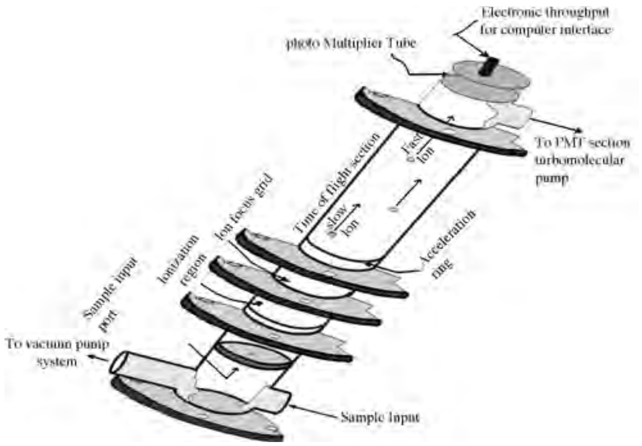

Fig. 8.29e
Time-of-flight mass spectrometer.

Ion detection errors develop for a variety of reasons. Errors that originate in the spectrometer's ion generation source or because of changes in conductance of the inlet leak are common. For the process stream atmospheric composition example, the three m/e ion collector outputs would be electronically scaled to create equal sensitivities for each measurement and then summed to create an analog of the sampled atmosphere. This error adjustment scheme is accomplished within the instrument with analog or digital circuitry. In either case, the sum is then compared to a fixed reference, and if it is properly calibrated, no error is created by this comparison. If a hypothetical drift is introduced, an error correction signal is created and is fed back to each channel through the instrument's gain adjust elements. The gain gives an equal percentage change in each channel and drives the error to zero. The effectiveness of this technique for stabilizing calibration over extended periods has been proven in process applications. Error adjustments are accomplished by amplifier feedback circuits or digital correction techniques.

Vacuum Environment

To maintain the needed vacuum level within a mass spectrometer, it is common to employ two vacuum pumps in series. With this pump arrangement, the removal of molecules from the instrument's vacuum environment becomes a two-stage pumping process. At the high-vacuum stage, the molecules enter the pumping system at a pressure of 1×10^{-5} or 1×10^{-6} torr and are compressed to a pressure of 1×10^{-2} torr. At this low-vacuum stage of the pumping process, the molecules enter the second pump and are compressed from 1×10^{-2} torr to atmospheric pressure. The turbomolecular pump is a common selection for the high-vacuum pumping stage, while a roots blower or a rotary vane pump is a candidate for the low-vacuum-to-atmosphere pumping stage. Pump choice depends on required environmental conditions within the process being monitored. The pressure at both vacuum stages is monitored, and the vacuum sensor signals are used for diagnostic and control purposes. Vacuum sensors are discussed in Section 5.14.

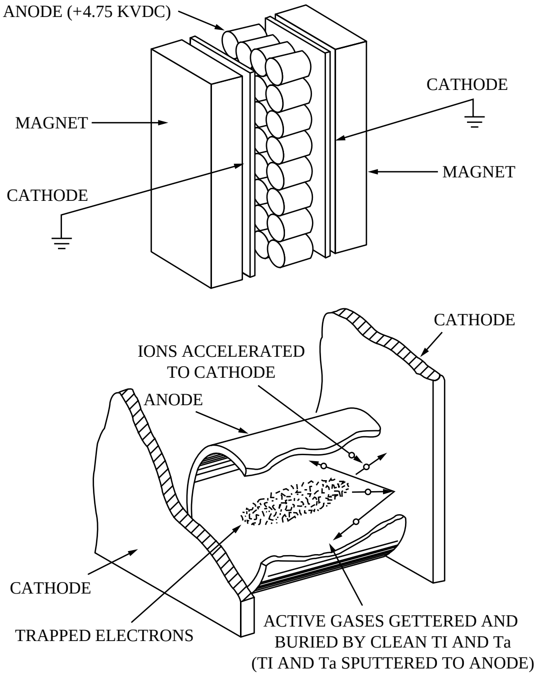

FIG. 8.29f
Ion pump operation.

For the spectrometer example presented within this section, an ion pump has been selected for the high-vacuum pumping stage. This choice is representative of an alternative pump type and is essentially a passive device that pumps by a combination of chemical gathering and physical burial. Like the cryopump, it does not require an additional pump connected in series; however, most systems include a parallel pumping turbomolecular pump or roots blower to lower the overall system-pumping burden.

Figure 8.28f shows a typical ion pump. An electric field is established between the anode structure and the two cathodes, and a magnetic field is created by a permanent magnet. This creates a trapped electron cloud that continuously ionizes the neutral gas in the pump. The ions are accelerated out of the anode and impinge upon the cathode surface where they sputter cathode material. The tantalum and titanium cathode materials coat the pump structure. These two materials are very active getters and chemically combine with most of the ions present to remove them from the vacuum environment. Inerts are removed by actual burial under the sputtered material or by direct implantation.

Data Reduction and Presentation

Today's mass spectrometers are usually packaged with a complete computer-based data reduction system. In fact, for online industrial applications, there may be too many data manipulation options too easily available to shift operators. In any event, the manufacturers will be able to initially help design

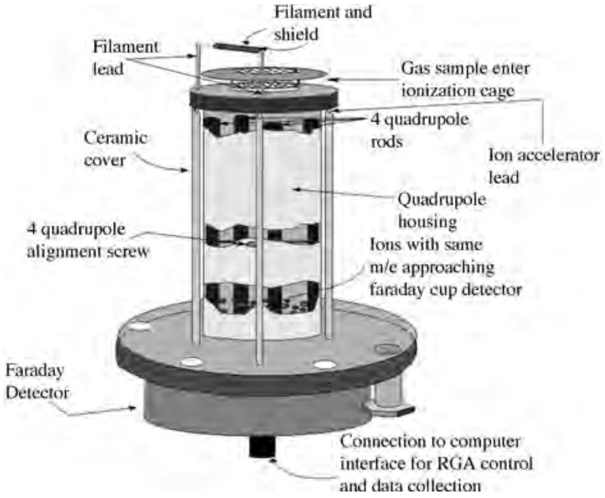

FIG. 8.29g
RGA operational concept.

the spectrometer output capabilities to meet your stated needs. In addition, there are an ample number of third-party venders that can provide compatible software to meet the needs appropriate to any specific and special application.

RESIDUAL GAS ANALYZERS

The residual gas analyzer (RGA) represents a major advancement in mass spectroscopy with respect to industrial applications. Over the last 10 years, this technology has been refined and is now a cost-effective way to meet the needs of several process applications. Figure 8.29g provides a conceptual view of the operation of an RGA. The technology is fundamentally a small quadrupole mass spectrometer that provides m/e resolutions that are suitable for certain types of process environments. In this illustration, the outer case to establish a vacuum environment is not shown. The gas sample enters the ionization cage from the right and is ionized by electrons emitted from a hot filament. The ions are accelerated into the quadrupole section and then separated by their mass-to-charge ratio. Figure 8.29c provides more detail about a quadrupole mass filter. Similar m/e charge ratios enter the detector at the same time and are counted and displayed as an intensity signal at the specified m/e.

The integrated semiconductor and the thin-film industries are two examples for extensive industrial application for RGAs. In both cases, the RGA serves as a diagnostic tool for monitoring the status of the process equipment vacuum environment and the characterization of the process within that vacuum environment. The RGA is almost always added into sputter tool clusters and other unit operations within these two industries. Although the RGA can also be inserted within control loops for semiconductor and thin-film manufacturing, to date it does not have widespread use in this manner.

CONCLUSIONS

Mass spectrometers are typically classified by the technology they use to separate the ionic masses into clusters. Mass spectrometer examples include the quadrupole mass spectrometer, the magnetic sector mass spectrometer, the time-of-flight mass spectrometer, and the ion-trap mass spectrometer. The residual gas analyzer is an example of a quadrupole mass spectrometer.

For mass spectrometer application to the process industry, the requirements of a dedicated, on-line analytical instrument might be stated as follows. The instrument is expected to perform a specific analytical task, on a continuous basis, for extended periods. It must exhibit long-term stability and accuracy while operating over its environmental range. An advantage of quadrupole instruments over electromagnetic-focusing ones is that the fields required to focus a particular mass can be changed very rapidly ($<10^{-3}$ sec), which is especially valuable for computer-controlled measurements that require multiple-ion monitoring. The quadrupole ion trap is a mass spectrometer that has a broad mass range and provides molecular weight and structural information on biopolymers. It also has the greatest sensitivity of all mass spectrometers. The somewhat lower m/e resolution of the RGA is an acceptable trade-off when it is in situations where pressure, process stream disturbances because of contamination, and ease of assembly are the focus of attention.

INTRODUCTION

Because the mercury concentration of interest in ambient air is in the range of nanograms per cubic meter (ng/m^3), no direct method of analysis exists and all measurements require the use of concentrators in sampling systems. Therefore, this section will start with descriptions of the various sampling and concentrator designs.

Instruments used in the measurement of mercury in air or gas samples are covered in other sections of this handbook: chromatographs in Section 8.12, atomic absorption spectrophotometers in Section 8.22, ultraviolet analyzers in Section 8.61, and autotitrators in Section 8.66. Therefore, the treatment of these analyzers is not very detailed here.

Air saturated with mercury will contain between 4 and 100 mg/m^3 of mercury in the temperature range between 45 and 110°F (7 and 43°C). Since saturation is not even approached under normal circumstances when the air is moving, sensitive analytical and sampling methods are needed when data are required on the actual ambient levels of mercury. For practical use, the methods employed must be relatively insensitive to interference and be otherwise appropriate for the collection of data under a wide range of operating conditions. For regulatory purposes, related to emissions, three or four levels of sensitivity are of importance: 100, 50, 10, and perhaps 5 μg/m^3 of mercury in the air. Accuracy within ±10% at these levels is required. However, ambient air monitoring requires the ability to determine levels in the 1 to 200 mg/m^3 range.

Sample Collection and Concentration

Collection of mercury samples for accurate determination of concentrations found at ambient conditions or in industrial plants requires that:

1. The size of the sample taken must be adequate to satisfy the sensitivity threshold requirements of the analytical technique utilized.
2. The rate of sampling must be controlled so that efficient collection is achieved.
3. The sampling interval selected must be appropriate for the required monitoring function.
4. The collection device or procedure must be compatible in capacity and chemical reactivity of material components with the levels and properties of mercury and mercury compounds to be sampled.
5. Effects of potential interference must be avoided.
6. Elapsed time between collection and analysis must be minimized in order to avoid losses.
7. It must be possible to evaluate all unknown factors in collection and analysis by using the appropriate calibration procedures.

In the sampling of mercury and its compounds from the air, two basic procedures are available. These procedures utilize either the chemical reactivity of the sampled components in various aqueous media or the extraordinarily efficient extraction (amalgamation) of mercury from air by the noble metals.

In the latter case, reduction of mercury compounds to elemental mercury is required before the sampling process is carried out. Currently, a wet chemical procedure for sampling is recommended by the Environmental Protection Agency. This procedure requires considerable labor and upkeep to perform effectively.

Impinger Collection Methods

In conjunction with the publication of the National Emission Standards for Hazardous Air Pollutants,[1] the Environmental Protection Agency has published two methods for sampling and analyzing mercury in gaseous and particulate emissions. The methods are similar with the exception that particulates must be sampled isokinetically, whereas gaseous samples are passed through filters to remove particles. This latter procedure requires equilibration of the filter prior to generation of accurate data at low mercury levels.

In principle, samples are drawn through acidic aqueous iodine monochloride solutions utilizing stringent controls over flow rates, acidity, and other process variables. This procedure gives excellent recovery of organic mercury compounds and of mercury vapor. Samples obtained with this procedure may be stored.

Particulate Sampling Figure 8.30a shows the sampling train utilized for particulate and vapor samples. It consists of a Pyrex-lined, heated probe section containing a thermocouple for temperature measurement and a pair of pitot tubes and a manometer for gas flow measurement. This section is followed by five impingers of the Smith–Greenburg type placed in an ice bath and a filter for particle removal prior to passage of the gases through the two final absorber stations.

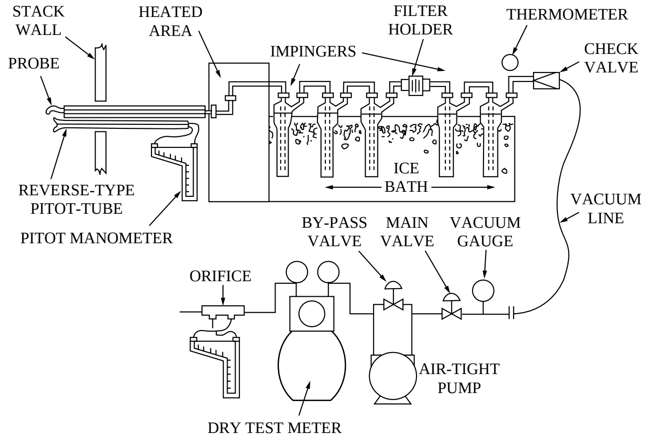

FIG. 8.30a
Particulate-sampling train.

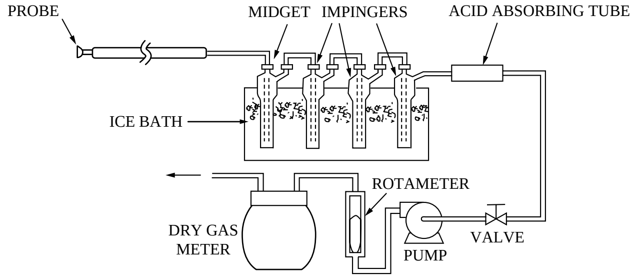

FIG. 8.30b
Vapor-sampling train.

These components are followed by miscellaneous components for control and calibration of the sample airflow.

For sampling particulates, the initial rate of gas flow is 2 scfh (57 slph). Flow should be maintained at a rate proportional to the flow through the stack sampled.

Vapor Sampling Figure 8.30b shows a simpler technique used for sampling of vapors without particulates. In this method, particulates are removed by a filter, at the inlet into the absorption train. Samples obtained by this procedure may be analyzed by a procedure utilizing a flameless atomic absorption spectrophotometer, which has been accepted by the Environmental Protection Agency for investigations.

A number of other collection procedures employing impingers have been examined. These utilize water, ethyl alcohol, isopropyl alcohol, potassium permanganate–sulfuric acid, potassium permanganate–nitric acid, or iodine–potassium iodine. However, for effective collection of alkyl mercury compounds, acidic iodine monochloride solutions are preferable.

Amalgamation on Wettable Metals

A number of less laborious methods of sampling mercury vapor, compounds, and particulates have been developed that utilize absorption (amalgamation) of vapor on silver, gold, and alloys of these materials. In order to sample particulates and compounds of mercury, the trapping procedure must be preceded by a decomposition step. A catalytic process that achieves this objective is described later.

FIG. 8.30c
Absorption tube mercury collection device.

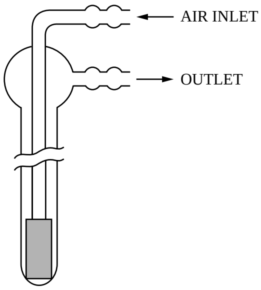

FIG. 8.30d
Mercury gas-sampling tube.

Examples of procedures for collecting elemental mercury vapor include the method shown in Figure 8.30c, which shows a simple absorption tube filled with gold or silver wool. The tube may be sized to satisfy any specific parameters of the sampled gas stream. Fine wire may also be used as packing for flow rates under 50 l/min, and mercury vapor removal can be made quantitative. Gold materials are required for gases containing hydrogen sulfide or sulfur dioxide.

When a simple absorption tube of this type is employed, the mercury vapor collected may be released for analysis in a flameless atomic absorption spectrometer (AAS) by utilizing an induction furnace (Section 8.22). In this procedure, extensively used by the U.S. Geological Survey, a continuously flowing airstream is used to pass the pulse of the mercury vapor into the AAS cell. This pulse is generated during the heating in the furnace.

Sampling Tubes The Canadian Department of the Environment employs a versatile method of sampling of gas streams. It uses a packing, which consists of finely woven silver mesh (Figure 8.30d). One version of the sampling tube is 5 in. (125 mm) high and utilizes a $\frac{1}{4}$ in. (6-mm)-inner-diameter Pyrex tubing. Separation between the inner and outer tube is $\frac{3}{64}$ in. (0.1 mm). In order for this collection procedure to function effectively, relatively low airflow rates through the wire mesh must be used. Sampling rates of 1 to 5 l/min have been employed, but long sampling periods are required to make measurements at low air concentrations.

Figure 8.30e shows the schematics of a collection device, which is contained in an integrated mercury analyzer. In the collection section of this device, air at rates from 0.03 to 7 scfm (1 to 200 l/min) is passed through a grid containing 160 ft (48 m) of 22-gauge wire arranged in a carefully spaced annulus. Mercury vapor is desorbed by direct passage of

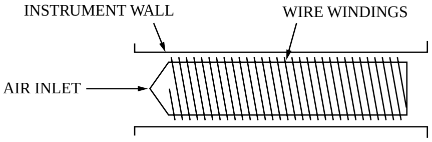

FIG. 8.30e
Mercury collection device.

electrical current through the wire. Analysis is achieved by the flameless atomic absorption method in a photometer.

Activated Absorption

Use of a silver on a charcoal absorbent is highly efficient and may be used to remove mercury vapor from many gas streams. Extraction of the mercury vapor as a concentrated pulse for analysis, however, is relatively difficult. Induction heating is required to maximize the vapor concentration. Trapping is also possible with iodine-activated charcoal and mineral wool. Regeneration of these materials for repeated use presents difficulties not yet resolved.

Conversion of Mercury Vapors

In order to analyze for total mercury including particulates and vapor, reduction of compounds such as mercuric chloride, mercuric sulfide, dimethyl and diethyl mercury, pesticides, and fungicides to the elemental form must be achieved. Three techniques are in use: 1) thermal decomposition at 1500 to 2000°F (816 to 1093°C); 2) catalytic reduction or disproportionation, usually at 1200 to 1300°F (648 to 704°C) over materials such as cupric oxides; and 3) chemical conversion in solutions such as acidic iodine monochloride. Commercial equipment is available, which may be used in conjunction with sampling and analysis instrumentation.

Methods of Detection

No direct analytical method is capable of attaining accurate measurements in the range required for ambient air without the use of a concentrator, discussed earlier.

Ultraviolet Light Absorption

A wide variety of methods have been developed to measure airborne mercury-containing materials in the atmosphere based on the strong absorption of ultraviolet light at 253.7 nm by an elemental mercury vapor. Since many other compounds absorb light in this range, although they do that at a much higher concentration than does mercury, some method of separating out these interferences is needed when low levels of mercury are to be measured.

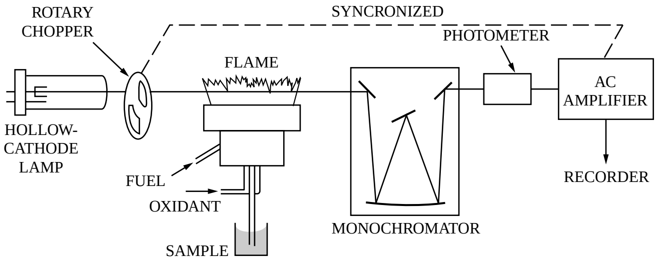

FIG. 8.30f
Atomic absorption spectrophotometer.

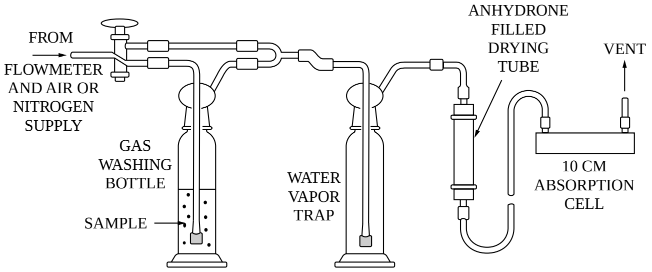

FIG. 8.30g
Apparatus for flameless atomic absorption.

Atomic Absorption Spectrophotometry Mercury is conveniently analyzed by atomic absorption techniques because the elemental vapor exists in atomic form under normal ambient conditions. Thus, when a cloud of mercury vapor is irradiated at an appropriate wavelength, mercury atoms absorb a portion of the energy of the beam.

In the standard atomic absorption technique, liquid samples are aspirated into an acetylene air flame where the atomic mercury is released and the absorption of light at 253.7 nm is measured by a spectrophotomultiplier (Figure 8.30f). The sensitivity of 0.01 μg of mercury per milliliter of sample is readily attained by this procedure. A continuous series of calibration checks are required for maximal precision and accuracy.

Flameless Atomic Absorption Spectroscopy The burner–aspirator and flame indicated in the schematic of the conventional AAS (Figure 8.30f) may be replaced by a quartz-windowed glass cell, and the sample may be generated by reducing an aqueous sample of mercury compounds to elemental mercury.

Figure 8.30g shows the apparatus that may be used in conjunction with an AAS. In this procedure, a sample collected by utilizing a separate collection train is pipetted into the gas washing bottle. To this is added a solution of a reducing agent such as hydroxylamine sulfate or stannous chloride, and the bottle is closed.

With clean air supplied at a rate of 1.3 l/min, aeration is commenced and continued until a maximum peak height readout is obtained on the recorder. By calibration against acidic mercuric chloride standard solutions, the peak heights obtained with unknown samples can be compared with the calibration curve for direct determination of the mercuric ion concentration. This value may be converted to the gas phase concentration of mercury.

A number of commercial units are available that use the principle of flameless atomic absorption spectroscopy for determination of mercury. Some designs require that samples be taken by use of a liquid-sampling train and transported to the instrument, while others accept gas samples.

Other devices based on the use of absorption of radiation at 253.7 nm have been developed by Barringer Research and by Williston and Morris (Cordero Mining Company).[2] The Barringer method takes advantage of the pressure broadening of the mercury emission lines to minimize interference caused by other compounds.

Colorimetric Methods

Dithizone In this method, air is drawn through an acidic solution (10% H_2SO_4) of potassium permanganate (4 g/100 ml), where the elemental mercury, inorganic mercury compounds, and the readily decomposable mercury–organic compounds are converted to mercuric ions.

Methyl mercury compounds require the use of permanganate at 212°F (100°C). The determination of mercury may be concluded colorimetrically whence the sample is titrated with dithizone and compared with the colors developed by standards. A spectrophotometer may also be used for quantitative comparison between the color developed by test samples and those of controlled standard quantities of mercury.

In the method developed by the American Conference of Government Industrial Hygienists, the sample is collected from the air by passing it through an aqueous solution of iodine (0.25%) and potassium iodine (3%). Mercury is extracted from a buffered solution (ammonium citrate, hydroxylamine hydrochloride, and phenol red at pH 8.5) with dithizone in chloroform (20 mg of dithizone/5 ml) until all color is removed. After washing the chloroform phase, the mercury is extracted into acidic (0.1 *N* HCL) potassium bromide (8%), shaken with a chloroform solution of 10 mg/l of dithizone, and filtered through cotton into a colorimeter cell. The optical density at 485 mm is used to determine the mercury. Calibration is carried out with mercuric chloride.

The dithizone method is relatively insensitive, requiring the use of large samples (about 10 μg are required) when the levels of mercury are low. It also requires considerable care on the part of the chemist to avoid the loss of organic mercury compounds.

Selenium Sulfide and Others Active selenium sulfide applied to paper as a coating may be used to detect the presence of elemental mercury vapor. The paper develops a black color on exposure to air containing mercury. The degree of blackening is a function of the concentration of mercury and the times of exposure. Quantitation may be made with a simple densitometer.

Mercury can also be detected with copper, iodine paper, selenium paper, and gold chloride on silica gel. These methods appear to have a limiting sensitivity in the 500 to 1000 μg/m^3 range and a measurement error of ±5%.

Gas Chromatography for Mercury Organics

Organic mercurials can be determined at levels of approximately 1 ppb by gas chromatographic methods. Samples must be extracted into benzene and injected into a gas chromatographic column (Carbowax 20M on Chromasorb W) operating at 356°F (180°C), which separates methyl mercury, ethyl mercury, methozyethyl mercury, phenyl mercury, and dimethyl mercury. Quantitation is obtained with an electron capture detector. Dimethyl mercury requires conversion into methyl mercury halide for analysis, however. Precision is reported to be about 12%, with 30% reliability.

Atomic Fluorescence Spectroscopy

Samples collected by any of the liquid impinger techniques (Figures 8.30a and 8.30b) may be analyzed by use of atomic fluorescence flame spectrophotometric methods. Figure 8.30h provides a schematic diagram of a typical fluorescence spectrophotometer and of some typical calibration data. Figure 8.30i shows an actual x-ray fluorescence spectrometer. A mercury concentration of 0.1 ppm in a collection fluid is the detection limit of this method.

Other Analytical Procedures

A radiochemical procedure for the determination of mercury vapor has been developed based on the isotopic exchange that takes place when air samples containing mercury are passed through a solution of Hg^{203} mercuric acetate. The method potentially has good sensitivity but requires precautions, which are normal in handling radioisotopes.

Mercury that has been extracted from the air may be determined utilizing a neutron activation procedure. The measurement error and precision of this method is in the range of ±2%.

Flow Sheet Symbol

Pretreatment of Sample: Wet oxidation is used for the detection of the total mercury level, and solvent extraction is used for the detection of organic mercury.

Method of Detection:
A. Colorimetric detection of total mercury level
B. Atomic absorption spectrophotometry of total mercury level
C. Gas chromatograph with electron capture detector for organic mercury
D. Thin-layer chromatographic detection of organic mercury
E. Ultraviolet detector preceded by wet chemistry package

Ranges: The detection ranges for A and D are approximately 0.02 to 0.5 ppm of mercury in water, and for B and C, approximately 0.1 to 10 ppb of mercury in water. For E, the measuring ranges are from 0–1 μg/l to 0–100 ppm.

Costs:
A. Colorimetric spectrophotometers for laboratory applications range from \$2000 to \$5000.
B. About \$100,000, depending on pretreatment of sample
C. About \$35,000 for laboratory application
E. \$50,000 or more

INTRODUCTION

While Section 8.30 described the analyzers used in the monitoring of mercury concentration in ambient air samples, this section is devoted to the measurement of mercury in water. There is unavoidably some overlap between the two sections.

The analyzers used for the measurement of mercury are discussed in more detail in other sections of this chapter: chromatographs are covered in Section 8.12, colorimeters in Section 8.15, atomic absorption analyzers in Section 8.22, ultraviolet (UV) analyzers in Section 8.61, and wet chemistry analyzers in Section 8.66. Because these analyzers are mostly on-line, the emphasis in this section is placed on, but not limited to, the laboratory procedures, while the discussion of on-line units is not as detailed in this section.

The continuous on-line mercury monitors are used in many industrial processes, including both effluent and quality controls in chlorine–alkali plants, quality controls of drinking water and of sulfuric acid, control of industrial sewage and purification plants, monitoring the scrubber water in power plants and of waste incinerators, just to mention a few.

TOTAL MERCURY DETECTION

Sample Treatment

Mercury is present in the environment in organic and inorganic compounds, either dissolved in water or adsorbed on particulate matter or sediments. The total mercury level is the sum of organic mercury and inorganic mercury in a sample.

To analyze a variety of mercury compounds by the commonly available methods, it is necessary to digest the sample in order to effect decomposition of the accompanying substances, and thereby to convert the mercury present in the sample into inorganic mercury (Hg^{2+}). This digestion is carried out by mixing the sample with a mineral acid and a strong oxidizing agent and heating it.

The combinations in common use are H_2SO_4—$KMnO_4$, HNO_3—$KMnO_4$, H_2SO_4—H_2O_2, H_2SO_4—HNO_3, and HCl—$KClO_3$. The combination of H_2SO_4—$KMnO_4$ or HNO_3—$KMnO_4$ is best suited for analysis of water. The concentration range most often used is 1 to 5 *N* for the acid and 1 to 5% for $KMnO_4$.

Heating is either by a water bath or by direct flame. The digestion must be carried out in the presence of excess $KMnO_4$ and, therefore, a fresh addition must be made whenever the color of the permanganate fades (the digestion being complete when the color of $KMnO_4$ no longer fades).

In case of biological materials where the samples are rich in organic matter, the samples can best be digested by heating with H_2SO_4—HNO_3 until white fumes (sulfuric acid) evolve. The digestion is complete when the solution becomes clear. When carbonization of organic matters occurs, the digestion is continued with fresh addition of nitric acid. An apparatus such as that shown in Figure 8.31a prevents the small losses due to vaporization of mercury during the digestion.

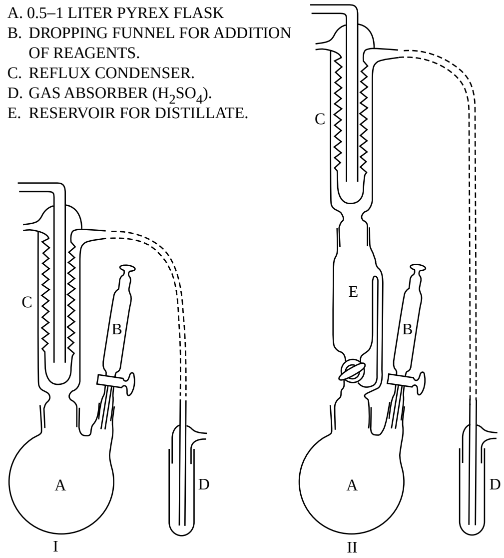

FIG. 8.31a
Digestion flasks for detection of mercury (I) in water and (II) in organic materials.

Since upon completion of the digestion an excess of the oxidizing agent is present in the digested solution, it becomes necessary to reduce the remaining oxidizing agent. Hydroxylamine is best suited for the reduction of NO_2 or $KMnO_4$. Hydroxylamine alone, however, cannot reduce nitrous acid completely with nitric acid as a digesting liquor, and simultaneous addition of urea is advisable. The samples thus digested are then analyzed for mercury by one of the detectors described below.

Colorimetric Detection

Dithizone is widely used in the colorimetric analysis of mercury, where the absorption of visible light is detected as a measure of mercury concentration. When an aqueous solution of mercury with a wide pH range (0 to 13) is shaken with a solution of dithizone in chloroform, carbon tetrachloride, or benezene, a mercury complex is formed that dissolves in the organic layer. Dithizone is designated H_2Dz, the mercuric (Hg^{2+}) dithizonate is represented as Hg $(HDz)_2$, and the mercurous (Hg^{1+}) dithizonate as Hg (HDz).

A solution of Hg $(HDz)_2$ in carbon tetrachloride shows a maximum absorption at the wavelength of 485 to 490 nm. Mercury forms Hg (HDz) in the absence of water or a secondary dithizonate, HgDz, in aqueous alkaline solutions, which are deficient in dithizone. This compound gives a violet color.

Dithizone reacts with silver (Ag), copper (Cu), gold (Au), palladium (Pd), and platinum (Pt) in addition to Hg under acidic conditions, but it is generally sufficient to consider interference of Cu alone in environmental analysis. Metals such as lead (Pb), cadmium (Cd), zinc (Zn), nickel (Ni), cobalt (Co), and iron (Fe) are not extracted from an acidic solution. Moreover, tin (Sn) and bismuth (Bi) are not extracted from a strongly acidic solution unless they are present in large quantities.

Interference by Copper Interference of Cu may be eliminated by one of the following methods:

1. When a small flow of a dithizone in carbon tetrachloride solution is added to a weakly acidic solution containing Hg and Cu, extraction of Hg is completed before that of Cu begins. Separation of Hg and Cu is thus possible.
2. Extraction of Hg and Cu can be carried out simultaneously with excess dithizone and then treated with a masking agent such as KBr, KI, and $Na_2S_2O_3$ to decompose only Hg $(HDz)_2$ and to transfer Hg^{2+} into the aqueous layer. Thereafter, Hg is again extracted with dithizone.
3. Ethylenediaminetetraacetic acid (EDTA) in the form of the disodium salt can be added as a masking agent of Cu, and Hg alone is extracted with dithizone. The extraction is carried out at a pH of 2.5 or higher, preferably 5.5, at which level Cu–EDTA is stable.

A relatively large quantity of Cl^{2-} also interferes with the extraction of Hg^{2+} under strongly acidic conditions. For instance, the extraction of Hg can be done without difficulty, when up to 1 *M* of Cl^- is in 50 ml of 1 *N* sulfuric acid. Extraction becomes incomplete as Cl^{1-} exceeds 2.5 *M*. Under neutral to alkaline conditions, some interference is also observed when NH_4^{1+} is present in large quantities.

Analysis Procedure The procedure generally followed in the colorimetric determination of mercury by dithizone is as follows: The sample solution is extracted repeatedly with excess dithizone, and Hg^{2+} is captured in the solvent layer as Hg $(HDz)_2$. Contaminants are also removed in this step. The Hg $(HDz)_2$ is then decomposed by a suitable masking or oxidizing agent, and the Hg^{2+} is liberated and transferred into the aqueous layer. Here it is reacted with a given excess if dithizone, under specified conditions, and its concentration are measured colorimetrically.

The extraction immediately preceding the colorimetric determination is carried out under acidic conditions. The color developed is a mixture of orange (due to Hg $(HDz)_2$) and green (due to the excess of dithizone). The absorbance of such mixed colors can be measured directly, or measurements may be made at 485 to 490 nm, which is the maximum absorption wavelength of Hg $(HDz)_2$. Higher sensitivity and accuracy can be obtained at 605 to 620 nm, which is the maximum absorption wavelength of dithizone.

With the single-color method, mercury is extracted with a solution of dithizone. The excess dithizone is removed by shaking it with dilute aqueous ammonia. The absorbance is measured at 485 to 490 nm. With this method, changes in the concentration of dithizone do not affect the results. Hg $(HDz)_2$ gradually fades in the light. This tendency becomes pronounced when impure dithizone is used, whereas a solution of high-grade dithizone remains stable for several hours in a lighted room.

Atomic Absorption Spectrophotometry

In atomic absorption spectrophotometry, a solution containing mercury is introduced directly into a flame. This technique does not give high sensitivity in the analysis of mercury, and it is difficult to detect mercury at a concentration below 0.2 ppm. Mercury can be analyzed with high sensitivity if the aqueous solution is first reduced to mercury vapor and then sent to the absorption cell by aeration, where it is analyzed by atomic absorption spectrophotometry without the use of flame. Stannous salts are best suited for reducing mercury in an aqueous solution. Mercuric (Hg^{2+}) ions are reduced by stannous salts to metallic mercury (Hg^0) according to Equation 8.31(1):

$$Hg^{2+} + Sn^{2+} \rightarrow Hg^0 + Sn^{4+} \tag{8.31(1)}$$

The metallic mercury thus formed is vaporized by aeration and is sent to the absorption cell (with quartz windows), where its absorbance is measured at a wavelength of 253.7 nm.

Figure 8.31b illustrates both the closed and open systems of measurement. Beer's law holds for the mercury levels of

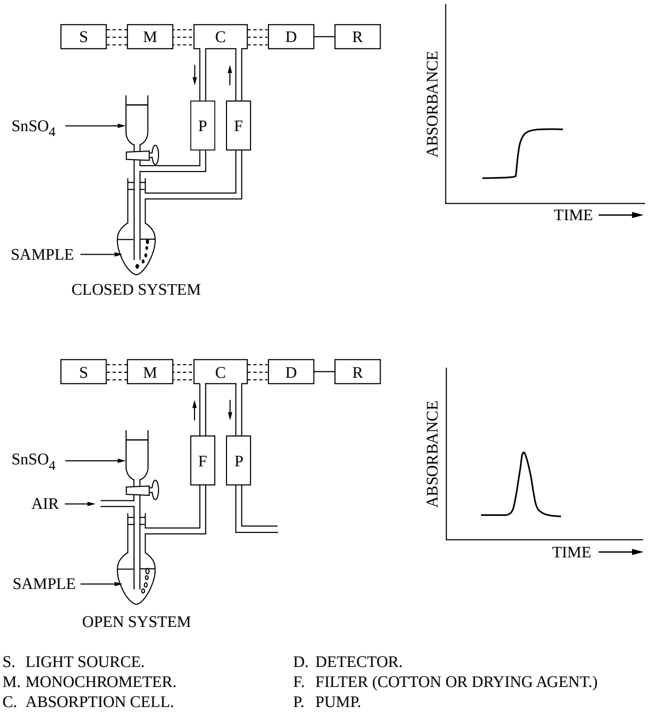

FIG. 8.31b
Flameless atomic absorption spectrophotometer with reduction–aeration hardware.

0.1 to 10 μg involved in this method. An atomic absorption spectrophotometer is best suited for this measurement, but simpler apparatus are also commercially available.

If large quantities of metal ions are present, it can be reduced by the addition of stannous salts. If these ions are not reduced, they may interfere with the reduction of mercury. Interfering elements, however, are rarely present in ordinary environmental samples in sufficient quantities to cause interference. If the aeration causes the vaporization of organic substances, which absorb UV rays, it will interfere with the analysis of mercury. Hence, it is necessary to decompose organic substances thoroughly.

Analysis Procedure A suitable amount of water sample is introduced into a 500-ml flask and 20 ml of sulfuric acid (1 + 1), plus 15 to 20 ml of $KMnO_4$ (6%) is added. After mixing, a reflux condenser is attached to the flask and the mixture is boiled. The $KMnO_4$ solution is replenished when it has been consumed. The flask is cooled when the color of $KMnO_4$ no longer disappears, and the excess $KMnO_4$ is reduced with a hydroxylamine sulfate solution.

A portion (containing 10 μg or less of mercury) is transferred into a flask such as the one shown in Figure 8.31b. Two milliliters of sulfuric acid (1 + 1) and 2 ml of stannous sulfate (10% in 2 *N* H_2SO_4) are added, and aeration is started at a rate of 2 l/min.

The vapor thus formed is driven into the vapor phase and circulated in a closed circuit. The UV absorption at 253.7 nm is detected in the optical cell of an atomic absorption spectrophotometer. A typical record of the UV absorbance is shown in Figure 8.31c. A calibration curve is prepared with standard solutions containing known amounts of mercury to assist in the quantitative analysis. The relative standard deviation for this method is reportedly between 2 and 10%.

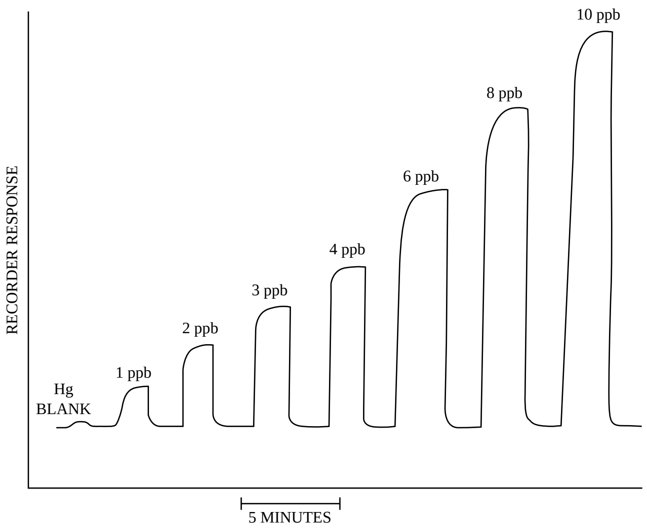

FIG. 8.31c
UV absorption record of vapor sample produced by aeration.

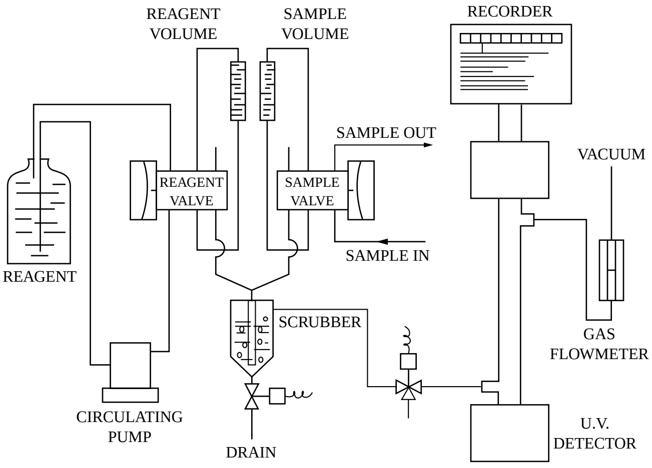

FIG. 8.31d
Continuous mercury monitor.

On-Line Measurement

Figure 8.31d illustrates the components of an automatic mercury monitor with an UV detector. In the first step, the mercury is reduced to the elemental state by the addition of tin(II) chloride or $NaBH_4$. Subsequently, mercury is stripped from the aqueous phase by an airstream and is carried into an optical detector cell, which can be made of silica (Suprasil). Here the mercury concentration is detected by UV absorption measurement at a wavelength of 253.7 nm.

This method of analysis is referred to as cold vapor atomic absorption spectroscopy (CVAAS). It is both sensitive (lowest range is 0 to 1 μg/l) and selective for mercury. Measuring ranges are available from 0.01 ppb to 100 ppm. The reagent requirement is 3 l per week for each reagent. Transmitter outputs can be 4 to 20 mA analog or bidirectional RS 232. Some of these analyzers are fully automated.

Automatic operation can include unattended operation guaranteed by self-diagnostics for alarming when malfunctions are detected, for example, the loss of reagent, sample, or stripping airflows; leakage of fluids; photometer lamp burnout; or need for recalibration. The continuous-measurement mode can also be switched to a periodic one. Automatic calibration can also be performed. This is done by automatically switching from the sample stream to a calibration solution. Similarly, the zero can also be automatically reset, and rinsing steps can be automatically initiated for the purpose of providing automatic self-cleaning. This analyzer is illustrated in Figure 8.31e.

ORGANIC MERCURY DETECTION

Sample Treatment

In organomercury compounds of the RHgX type, R is an organic group, such as alkyl and phenyl, and X is an electronegative group, such as halogen and hydroxyl. Those carrying

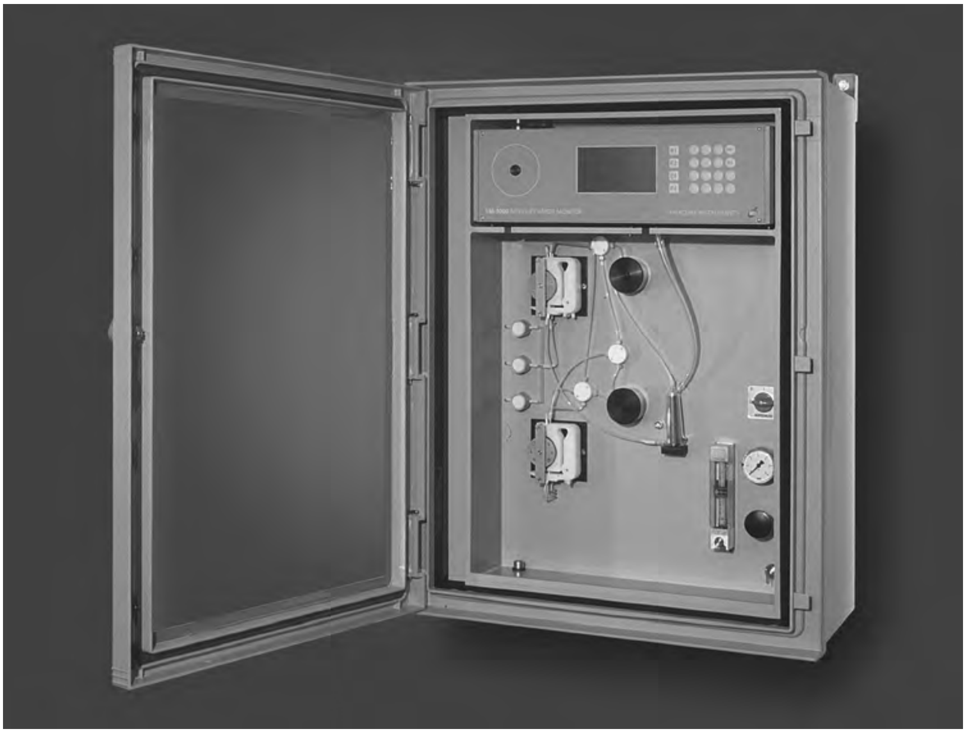

FIG. 8.31e
Mercury process analyzer. (Courtesy of Mercury Instruments GmbH.)

methyl, ethyl, and propyl groups are known to be the causes of Minamata disease (a severe neurological disorder resulting from poisoning by organic mercury and leading to severe permanent neurological and mental disabilities or death). When these compounds are present in water, it is first necessary to extract them with a suitable solvent.

The solubility of a compound of the RHgX type in organic solvents varies. If X is a halogen, the compound is soluble in aromatic hydrocarbons such as benzene and toluene. If X is an ion such as SO_4^{2-} OH^- or $CH_3CO_2^{1-}$, the solubility in hydrocarbons is extremely low. Therefore, it is necessary first to convert X to a halogen, and then the RHgX compound can be extracted with an organic solvent such as benzene and toluene. The aqueous solution is made acidic by addition of hydrochloric acid before extraction. The lower alkyl mercury compounds are moderately soluble in water, and a relatively large amount of solvent is necessary to effect quantitative extraction.

The organomercury compounds extracted in the organic solvent are generally contaminated and must be cleaned. The cleaning of an RHgX-type compound can be performed effectively by backextraction with an aqueous solution of a sulfur-containing compound such as cysteine. Organomercury compounds react with a sulfhydryl compound according to Equation 8.30(2) and move from the organic solvent phase to the aqueous phase.

$$\mathrm{RHgX} + \mathrm{R'SH} \rightarrow \mathrm{RHgSR'} + \mathrm{HX} \qquad \mathbf{8.31(2)}$$

where both R and R′ are organic groups and X is an electronegative group. Many of the organic compounds remain in the organic solvent phase, and the purpose of cleaning is thereby accomplished.

The transfer of the organomercury compounds from the organic solvent phase to the aqueous phase is quantitative. Therefore, when the backextraction is carried out by using a smaller volume of the aqueous solution against a known volume of the organic solvent, concentration of the organomercury compounds may be determined simultaneously with cleaning up.

The organomercury compounds extracted back into the aqueous layer are again liberated as RHgCl by addition of hydrochloric acid to the aqueous solution according to Equation 8.31(3).

$$\mathrm{RHgSR'} + \mathrm{HCI} \rightarrow \mathrm{RHgCI} + \mathrm{R'SH} \qquad \mathbf{8.31(3)}$$

The RHgCl liberated is extracted with a small amount of benzene and analyzed by gas chromatographic techniques.

Gas Chromatography

Lower alkylmercury and phenylmercury compounds vaporize upon heating and can be analyzed by gas chromatography. The use of an electron capture detector gives high sensitivity and is best suited for analysis of traces of organic mercury. For example, methylmercury can be detected to a level of 1×10^{-11} g.

Organomercury compounds are highly reactive with metals; consequently, it is not desirable to use metal tubing as column materials. A glass column is preferable. Also, a polar substance as a liquid phase in the column yields better results. The liquid phases most frequently used are polyethylene glycol, polydiethylene glycol succinate, and polybutanediol succinate.

The amount of the liquid phase to be coated on the support is preferably 5 to 10% for analysis of alkylmercury and about 2% for analysis of phenylmercury. An increase in the coating amount causes an increase in bleeding gas and a decrease in the standing current of the detector, with resultant lower sensitivity when a high column temperature is used. The size of the liquid phase is reduced for high-sensitivity analysis.

The use of the substractive technique is recommended for simplified identification of organomercury compounds by gas chromatography. When an organic solvent, such as benzene or toluene, which contains organomercury compounds, is mixed with the aqueous solution of a bivalent sulfur compound, such as $Na_2S_2O_3$ or cysteine, the organomercury compounds disappear from the organic solvent. If one compares the gas chromatograms before and after this treatment, one will be noticed that the peaks corresponding to the organomercury compounds disappeared or diminished markedly after treatment.

The analysis procedure is as follows: Ten milliliters of concentrated hydrochloric acid is added to 500 ml of the sample water containing methylmercury compounds. The resultant solution is mixed with 100 ml of benzene, and the mixture is allowed to settle. The aqueous layer is separated and is extracted again with 100 ml of fresh benzene. This is repeated three times, the aqueous layer is discarded, and the combined benzene layer is washed with distilled water.

The benzene layer is separated and is extracted back with 10 ml of a 0.1% aqueous solution of 1-cysteine. The aqueous layer is also separated, and 1 ml of concentrated hydrochloric acid and 2 ml of benzene are added. After mixing, the benzene layer is separated and dried over a small amount of anhydrous sodium sulfate. A 10-μl sample is analyzed by gas chromatography.

The column recommended contains 5% polydiethylene glycol succinate on Chromosorb W, 60 to 80 mesh, packed in glass tubing, 1 m long, and with a 3-mm inside diameter. Column temperature is set at 266°F (130°C), and the flow rate of carrier gas is maintained at 60 ml/min. Methylmercury chloride is eluted in 3 to 5 min under these conditions, and concentrations of 1 μg/l or less can be detected by this method.

Thin-Layer Chromatography

Thin-layer chromatography offers a simple and inexpensive method for analysis of organomercury compounds. Silica gel and alumina are mainly used as the adsorbent layer. The R_f values of organomercury compounds for a variety of developers are shown in Tables 8.31f and 8.31g. The mercury compounds are visualized by spraying the plate with a solution of dithizone. Ordinarily, mercury of the order of 0.5 μg can be identified visually in this manner. When developed as organomercury dithizonate, visualization becomes unnecessary and mercury on the order of 0.1 μg can be identified visually.

INTRODUCTION

Leonardo da Vinci was the first to attempt the measurement of humidity by weighing a ball of wool. Air is a mixture of oxygen, nitrogen, and water vapor. Water vapor follows the ideal gas laws in this mixture. The amount of water vapor per unit volume of air can vary by about 100,000 to 1 as one compares the water content of hot, saturated air to bone-dry arctic air.

The most frequently used units in expressing the amount of water vapor in air include relative humidity (0 to 100% RH); dew point (saturation) or wet bulb temperature (both expressed in °F or °C); and volume or mass ratio, expressed as part per million (ppm) volume or weight.

The sensors described in this section are most often used in weather monitoring or HVAC-related applications, although they also are used in industry. The moisture analyzers described in the next section are more oriented toward process industry applications and are less widely used for HVAC, but this separation is not a clear one. For this reason, the illustration that gives the operating ranges of a number of humidity sensors (Figure 8.32a) also includes the electrolytic hygrometer, which will be discussed in the next section.

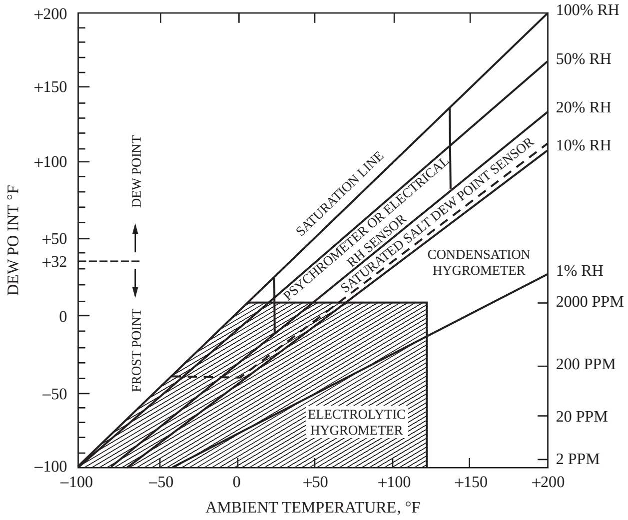

FIG. 8.32a

The operating ranges of different humidity sensors. Most humidity/dew-point detectors can make measurements at higher values of humidity and temperature but are limited in their performances at low temperatures and low concentrations of moisture. With the exception of some of the thin-film capacitance probes, they are also limited to a maximum temperature of 200°F (95°C).[1]

This section starts with some definitions and then provides the descriptions of the individual designs.

DEFINITIONS

Absorption—The taking in of a fluid to fill the cavities in a solid.

Adsorption—The adhesion of a fluid in extremely thin layers to the surfaces of a solid.

Dew point—Saturation temperature of a gas–water vapor mixture (the temperature at which water condensation occurs as a gas is cooled).

Hygrometer—An apparatus that measures humidity.

Hygroscopic material—A material with great affinity for moisture.

Partial pressure—In a mixture of gases, the partial pressure of one component is the pressure of that component if it alone occupied the entire volume at the temperature of the mixture.

Relative humidity—The ratio of the mole fraction of moisture in a gas mixture to the mole fraction of moisture in a saturated mixture at the same temperature and pressure. Alternatively, the ratio of the amount of moisture in a gas mixture to the amount of moisture in a saturated mixture at equal volume, temperature, and pressure (the ratio of how much water vapor is in the air vs. the maximum it could contain at the particular temperature).

Saturated solution—A solution that has reached the limit of solubility.

Saturation pressure—The pressure of a fluid when condensation (or vaporization) takes place at a given temperature. (The temperature is the saturation temperature.)

Specific humidity—The ratio of the mass of water vapor to the mass of dry gas in a given volume.

RELATIVE HUMIDITY SENSORS

Humidity refers to the water vapor contained in the air at a particular temperature. Warm air has a greater capacity for water vapor than does cold air.

Relative humidity (RH) is the ratio of the actual partial pressure of the water vapor to the saturation vapor pressure at a particular temperature. Therefore, in a room that has 50% RH at 20°C, the RH will drop to 37% if the temperature rises to 25°C. (Note that temperature has no effect on the dew point temperature, which in the above example stays constant at 9.3°C.)

Wet and Dry Bulb Hygrometers

When water changes phase from liquid to vapor, an amount of heat equal to the latent heat of vaporization must be supplied from the environment for each unit mass of water evaporated. The vaporization, in addition to its dependence on the amount of heat available, is also a function of the degree of saturation or relative humidity of the atmosphere surrounding the water. The wet and dry bulb hygrometer takes advantage of this fact to obtain a relative humidity measurement.[2]

The instrument consists of two temperature-sensitive elements exposed to the atmosphere whose moisture level is to be measured. One of the two elements, the wet bulb, is wrapped with a wick soaked in water; the other element, the dry bulb, is left bare. Water evaporating from the wick lowers its temperature and that of the temperature element. The temperature values indicated by the two thermometers are related to the relative humidity of the sample atmosphere. Relative humidity can be calculated as shown on the following pages using the wet and dry bulb temperature readings, or relative humidity can be read from a psychrometric chart such as the one shown in Figure 8.32b. For a dependable measurement, the sample velocity should be well in excess of 10 ft/s (3 m/s). The sensing elements should therefore be mounted where there is adequate circulation, or forced circulation must be provided by means of a fan.

Figure 8.32c shows a sling psychrometer consisting of wet and dry bulb thermometers and mounting arranged so that the unit can be whirled manually when a reading is to be made.

Wet-Dry Bulb Hygrometers Figure 8.32d shows a wet and dry bulb assembly for mounting in a duct. The wick is kept wet by a water reservoir mounted externally, or a continuous water supply can be piped to the unit. A similar device is

FIG. 8.32b
Psychrometric chart. See Appendix A.1 for SI units.

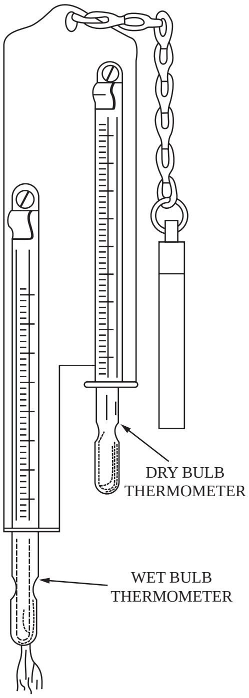

FIG. 8.32c
Sling psychrometer.

available for mounting in a room or compartment. Generally, these units are connected to a two-pen recorder, which provides continuous, automatic monitoring of the moisture level in the atmosphere.

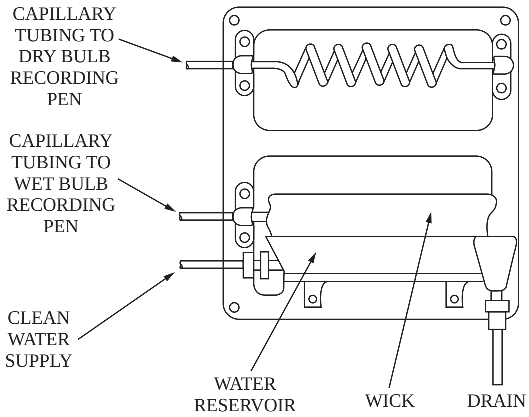

FIG. 8.32d
Wet-dry bulb hygrometer using filled system temperature sensors arranged for duct mounting.

Figure 8.32e shows a wet bulb element for installation in a duct of pipeline operating at elevated pressures. In this design, a porous sheath replaces the wick. Through this sheet, water can evaporate. The water supply pressure to the porous sleeve must be slightly higher than the process pressure. For process lines at constant low pressure, a standpipe at the wet bulb element can be used to provide the required water pressure. Usually, however, a differential regulator, as shown in the diagram, is used to maintain the differential pressure across the porous sheath.

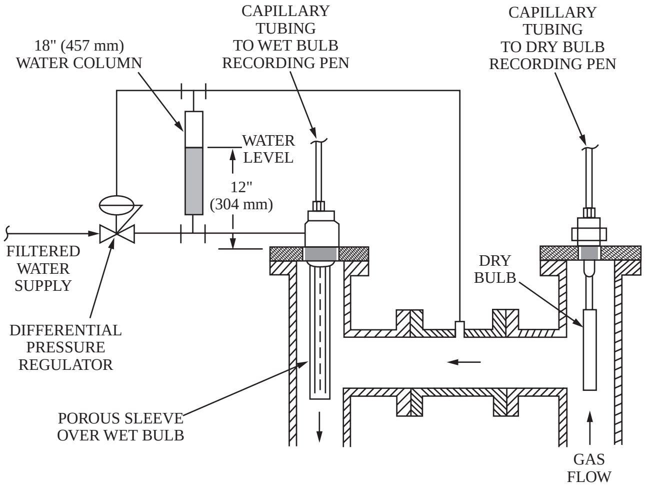

FIG. 8.32e
Wet-dry bulb hygrometer using filled system temperature sensors arranged for pressure pipe mounting.

Assman Psychrometers Laboratory-type (Assman) psychrometers are thermally shielded from radiation and are aspirated at high air velocities to provide accurate readings. In industrial applications, the psychrometer's performance is limited by wet bulb contamination and by its inability to read humidities below 10 to 20% RH (see Figure 8.32a). The reason for this is in the difficulty of reaching the low wet bulb (high differential) temperature when the air is dry, and the high dry bulb temperature tends to prevent cooling. Other limitations include the inability to operate below 32°F (0°C) because of freezing and the inconvenience that it requires a continuous source of water to keep the wick wet.

Calculation of Relative Humidity

Relative humidity can be calculated directly from the wet and dry bulb thermometer readings by using a steam table. However, the calculation is valid only for air at ambient conditions and should not be applied to other gases or if the temperature/pressure conditions differ significantly from ambient. Specific and relative humidity can be calculated by using Equations 8.32(1) through 8.32(4). Equations 8.31(1) and 8.31(2) are derived from the definition of specific humidity assuming water vapor in an ideal gas. Equation 8.31(3) is derived from the first law of thermodynamics. Equation 8.31(4) is the definition of relative humidity for an ideal gas.

$$S_2 = \frac{0.622 Pv_2}{P - Pv_2} \qquad \mathbf{8.32(1)}$$

$$S_1 = \frac{0.622 Pv_1}{P - Pv_1} \qquad \mathbf{8.32(2)}$$

$$S_1 = \frac{0.24(t_2 - t_1) + S_2 he_2}{hv_1 - hw_2} \qquad \mathbf{8.32(3)}$$

$$\text{Relative Humidity (\%)} = \frac{Pv_1}{Ps_1} \times 100 \qquad \mathbf{8.32(4)}$$

where
S_1, S_2 = specific humidity
t_1, t_2 = temperature
he_2 = enthalpy of evaporation
hv_1 = enthalpy of saturated vapor
hw_2 = enthalpy of saturated water
Pv_1, v_2 = partial pressure of water vapor
Ps_1 = saturation pressure
P = total gas pressure

Subscripts 1 and 2 refer to dry and wet bulb conditions, respectively. Values of Ps_1, Pv_2, hv_1, hw_2, and he_2 are obtained from a steam table.

Example Determine the relative humidity of air at atmospheric pressure when the dry and wet bulb thermometer readings are $t_1 = 80°F$ (27°C) and $t_2 = 60°F$ (16°C), respectively.

For t_1 and t_2 from the steam table,

$Ps_1 = 0.5069$ PSIA
$hv_1 = 1096.6$ BTU/pound mole
$Pv_2 = 0.256$ PSIA
$hw_2 = 28.06$ BTU/pound mole
$he_2 = 1059.9$ BTU/pound mole

and, therefore, the specific humidity, using Equation 8.32(1), is

$$S_2 = 0.622 \frac{0.256}{14.7 - 0.256} = 0.011 \qquad \mathbf{8.32(1)}$$

$$S_1 = \frac{0.24\,(60 - 80) + 0.011\,(1059.9)}{1096.6 - 28.06} = 0.00642 \qquad \mathbf{8.32(2)}$$

$$0.00642 = 0.622 \frac{Pv_1}{14.7 - Pv_1}$$

$$Pv_1 = 0.150 \text{ PSIA} \qquad \mathbf{8.32(3)}$$

$$\text{Relative Humidity} = \frac{0.150}{0.5069} \times 100$$

$$\text{Relative Humidity} = 29.6\% \qquad \mathbf{8.32(4)}$$

If, instead of calculating, it is preferred to read the psychrometric chart (Figure 8.32a), a value of 30% relative humidity can be read.

Hair Hygrometers

The principle of measurement utilized by this device is based on the change of length of certain organic and synthetic fibers when they are exposed to a moist atmosphere. A mechanical

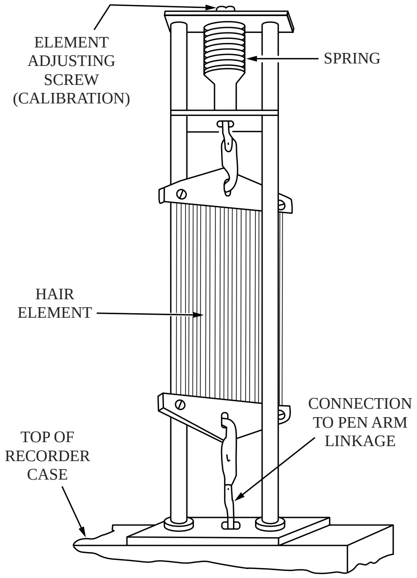

FIG. 8.32f
Hair hygrometer element.

linkage is used to amplify the movement of the element movement to amplify the readout.

Figure 8.32f shows a hair hygrometer consisting of several fibers mounted together to form a band; one end of the band is fixed while the other end is free to move, driving a pen arm through a linkage. Hair hygrometers, similar to wet and dry bulb hygrometers, require good circulation of the measured gas. In ducts, there is generally adequate gas velocity to ensure a dependable measurement; however, if the instrument is to be mounted in a room, the location must be carefully chosen.

The instrument should not be mounted near doors or other openings where it will be exposed to spurious drafts; flush mounting on a panel should be avoided, because the atmosphere in the back of the panel is stagnant. The hair element can be mounted on the top or back of the instrument case, depending on the installation. The element can also be mounted on an extension in the back of the instrument so that the sensing portion is in the room or compartment where relative humidity is to be measured while the readout device is surface mounted on the wall outside. Recorders are generally available as two-pen instruments, with the second pen recording temperature.

Transmitters are available in both digital and analog designs, and the analog ones can be electronic or pneumatic. Figure 8.32g shows a pneumatic transmitter with the fiber element connected to a nozzle-baffle bleed to vary air output pressure as a function of relative humidity. The transmitting units can be installed in a room or directly in a duct.

Cellulose Hygrometers

Cellulose strips and other shapes are also used to measure humidity. Like human hair and synthetic materials, cellulose changes its dimensions as the water vapor concentration

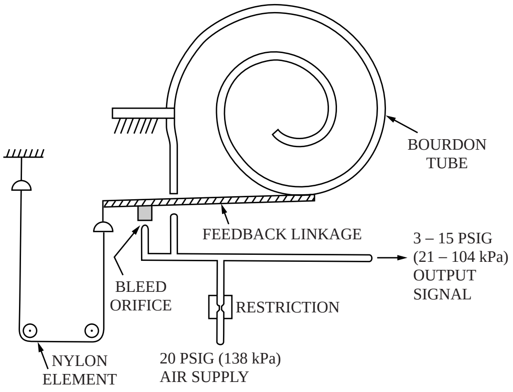

FIG. 8.32g
Schematic arrangement of hygrometer transmitter.

varies. This elongation has been used to build dial and digital indicators and also relatively inexpensive HVAC-type thermostats, transmitters, and recorders. The operation of the cellulose element instruments is similar to the previously described human hair hygrometers.

Solution Resistance Elements (Dunmore Cells)

The Dunmore sensor consists of a wire grid on an insulating substrate that is coated with lithium chloride solution. Lithium chloride is hygroscopic and therefore takes up moisture from the air. The resulting resistance of the sensor is an indication of the relative humidity in the air. One disadvantage of this otherwise widely used, inexpensive, and good sensor is its narrow range.

Figure 8.32h illustrates the ranges of ten color-coded elements that are used by one manufacturer to cover the full range of 0 to 100% RH. Wide-range Dunmore sensors can be configured by placing several narrow-range elements in a single housing and connecting them to a microprocessor-based readout.

Polystyrene Surface Resistivity (Pope Cells)

The Pope cell is similar to the Dunmore element but, instead of lithium chloride solution, it uses polystyrene as a substrate for the conductive wire grid. In this design, the polystyrene is treated with sulfuric acid, which produces a thin hygroscopic layer on its surface. Changes in humidity cause large changes in the impedance of this layer and, because the operating portion of the sensor is only its surface, its speed of response is fast—only a few seconds. An AC-excited Wheatstone bridge circuit can be used to measure the impedance. The output signal is nonlinear and can cover a range of 15 to 99% RH. This type of humidity probe can be mounted on the wall or in ducts (Figure 8.32i).

Thin-Film Capacitance

Most manufacturers use some form of a capacitance measurement to detect humidity or dew point in air.

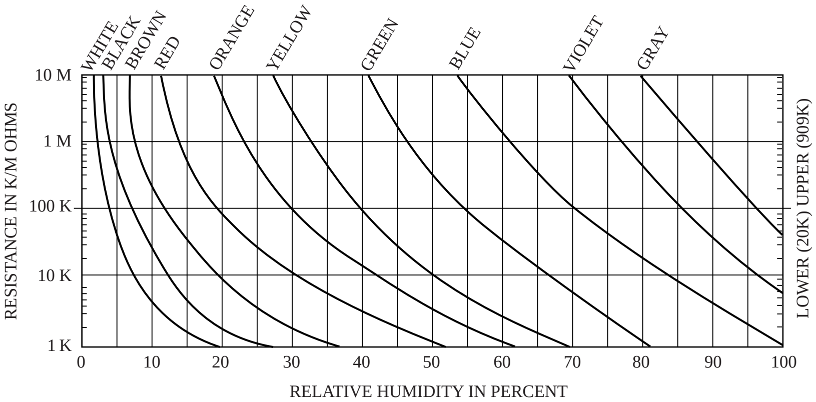

FIG. 8.32h

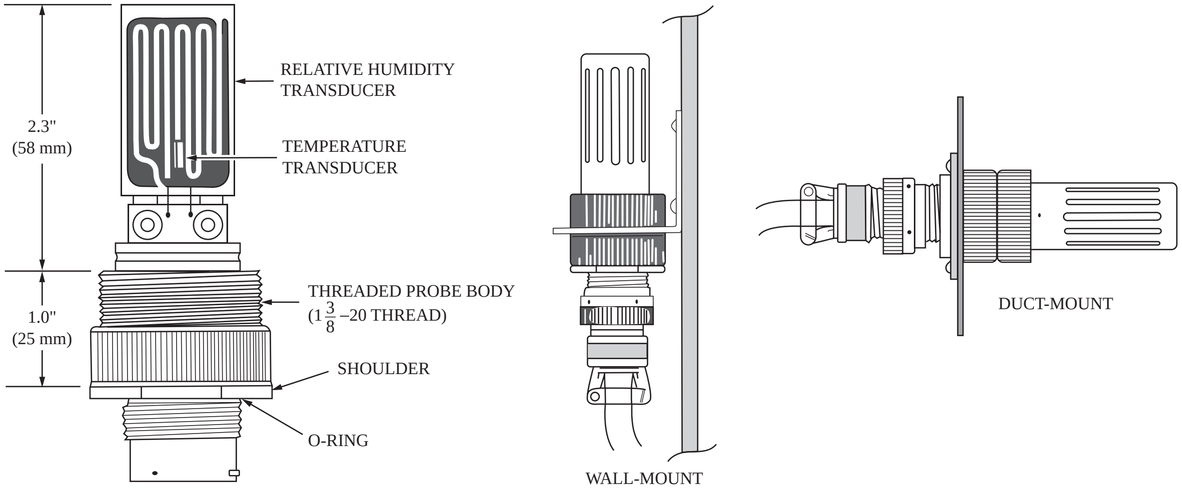

FIG. 8.32i
Polystyrene surface conductivity humidity element. (Courtesy of General Eastern, used to be Phys-Chem Scientific Corp.)

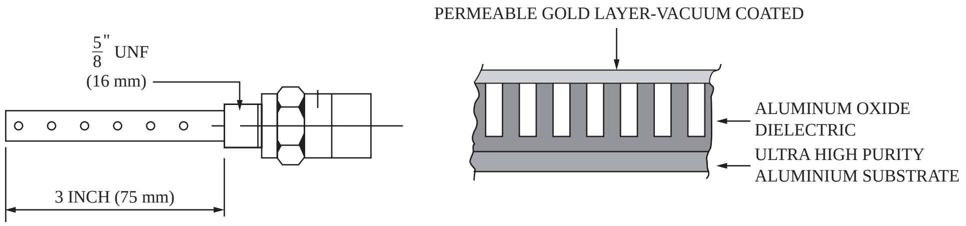

FIG. 8.32j
Thin-film aluminum oxide capacitance element, which can be packaged as a probe. (Courtesy of Michell Instrument Ltd.)

Metal Oxide Sensor One variation is to form a capacitor by depositing a layer of porous aluminum oxide on a conductive aluminum substrate and coating the oxide with a thin film of condensation from evaporated gold. The aluminum substrate and the gold film serve as the electrodes of the capacitor (Figure 8.32j).

When exposed to air, the water vapors pass through the gold layer into the aluminum oxide dielectric and are absorbed by it. The amount of water absorbed determines the capacitance registered by the sensor. Some suppliers "dope" the aluminum oxide dielectric with lithium chloride to extend its range down to dew points of –94°F (–70°C). The disadvantages of lithium chloride doping include the need for individual calibration, the slowing of the response, and the potential for shorting due to condensation.

The accuracy of the aluminum oxide moisture sensor is low, each sensor requires a separate nonlinear calibration curve, and the unit must be periodically recalibrated to compensate for aging and contamination. These sensors are designed for low dew-point measurements but can be disabled if exposed to high humidity or if wetted. The advantages of these sensors include their small size, their probe-type packaging, and the fact that their measurement range is wide and well suited for the detection of low dew points. As a consequence of these characteristics, they are widely used in such applications as HVAC, where cost is the primary concern, and measurement accuracy is not critical.

Polymer Sensor Design variations of the capacitance-type humidity sensor include the replacement of aluminum oxide dielectric with hygroscopic polymer dielectrics. These units consist of a capacitive polymer sensor bonded to a resistive temperature sensor. The polymer sensor detects humidity directly, while dew point is calculated by a microprocessor, which also reads the temperature. These sensors are claimed to provide better linearity and allow the use of longer lead wires because their low-frequency operation reduces the effects of stray capacitance. Other advantages include resistance to contamination by various chemical vapors.

Polymer sensors are immune to condensed water and therefore can have a wider range than metallic oxide ones. These units are available as transmitters with intelligent electronics, are capable of detecting low dew points, and require less maintenance as a result of their stability.

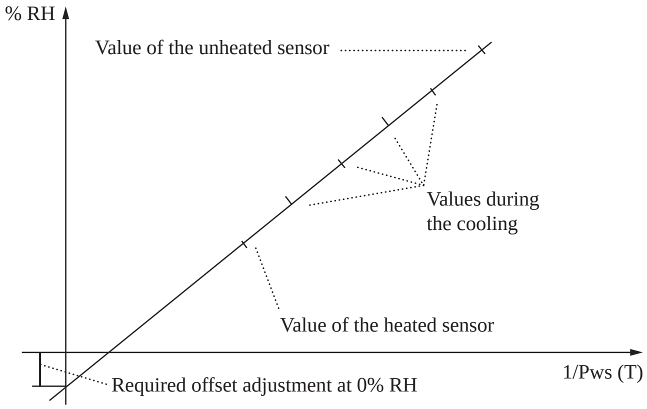

FIG. 8.32k
As the sensor cools to ambient, the RH reading is used to determine the required offset adjustment, which is read where the reading crosses the RH axis. Pws is the temperature dependent saturation pressure of the water vapors. (Courtesy of Vaisala Oyj.)

Autocalibration During autocalibration, the sensor is heated and then, as it cools down to ambient temperature, both the humidity and temperature values are monitored. It is thereby evaluated to determine whether the humidity reading at 0% RH is correct. If it is not (Figure 8.32k), the drift is corrected by the microprocessor. This autocalibration allows the readings of low dew-point values down to –96°F (–60°C) with errors under ±2°C.

Figure 8.32l illustrates another design variation that is a combination dew point and dry bulb temperature transmitter, capable of operating at up to 350 PSIG (25 bars) pressure and up to 365°F (185°C) temperature.

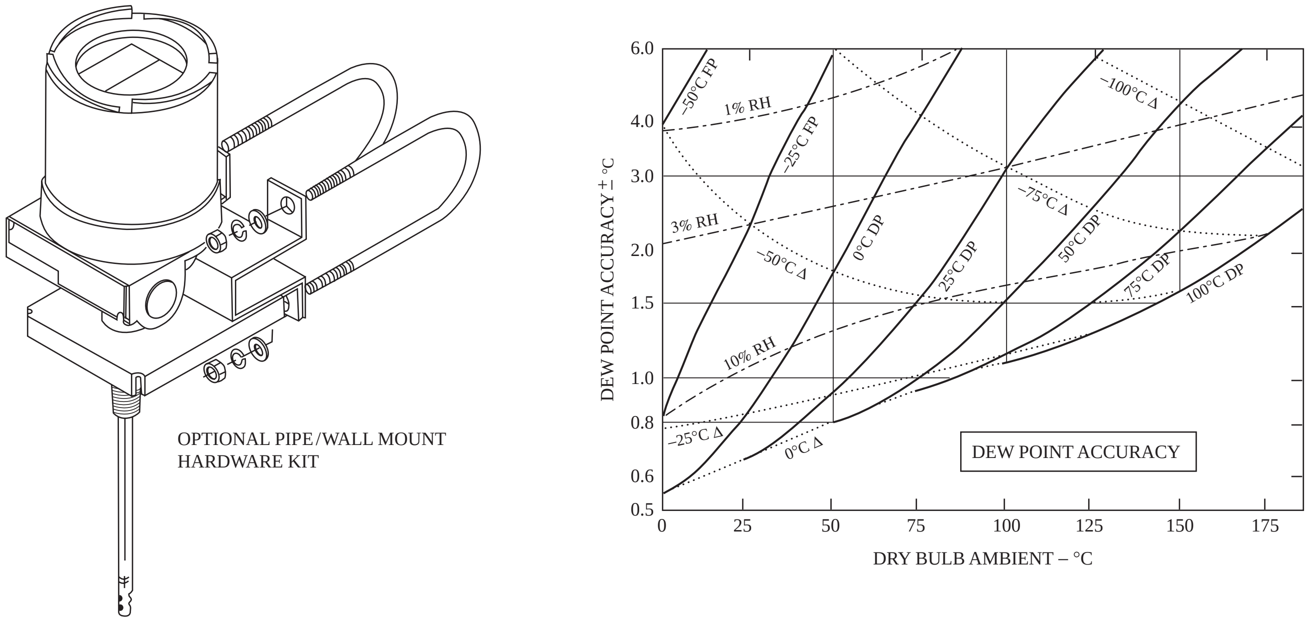

FIG. 8.32l
Packaging and accuracy of combination dew-point and temperature transmitter capable of operation at 365°F (185°C). (Courtesy of Honeywell, used to be Hy-Cal Engineering)

DEW-POINT HYGROMETERS

The temperature at which water starts to condense on a surface (the dew point) can be measured from –112 to 212°F (–80 to 100°C). The dew-point reading of an air sample is affected by the air pressure and by the amount of water vapor in the sample. An increase in air pressure increases the dew-point reading, whereas the temperature of the air does not affect it.

The three most widely used sensors for the detection of dew point are (1) aluminum oxide or polymer sensors, (2) lithium chloride saturated salt sensors, and (3) surface condensation type sensors. The aluminum oxide and polymer type thin-film capacitance designs have already been discussed under RH sensors. Therefore, here, the solution-conductivity type, lithium chloride detectors will be discussed first.

Solution-Conductivity Type

All solids condense and absorb minute quantities of water on their surfaces. If the solid is soluble, a layer of saturated solution is formed whose vapor pressure is lower than that of pure water at the same temperature. Some solids form saturated solutions in water whose vapor pressure is less than the partial pressure of water vapor in the atmosphere contacting the solution. When that is the case, water vapor will continue to condense until the vapor pressure of the solution equals the partial pressure of the water vapor. On the other hand, water vapor will evaporate from the solution should the water vapor partial pressure decrease below the vapor pressure of the solution. Under steady-state conditions, solution vapor pressure equals water vapor partial pressure, and knowledge of the former can be used to determine the moisture content of the atmosphere.

The sensing element consists of thin-walled, hollow-metal socket wrapped with tape impregnated with salt crystals (lithium chloride). Two wires are wrapped over the tape and connected to a regulated AC voltage source. The salt crystals complete the electric circuit between the wires. When the sensing element is exposed to the sample atmosphere, water condensing on the crystals forms an ionic solution, which permits an electric current to flow between the wires.

This current, in turn, heats the solution and raises its vapor pressure. As more water condenses, more current flows, resulting in a further increase of the solution vapor pressure until equilibrium is reached. On decreasing moisture content of the measured gas, water evaporates from the element, decreasing the current flow and resulting in a new equilibrium at a lower solution vapor pressure. A temperature sensor inside the hollow socket is used to detect sensor temperature and to provide a signal for readout.

The output calibration can be in terms of dew-point temperature, water vapor pressure, or specific humidity. Values of specific humidity must be corrected for the pressure variations of the sample. The correction factor is $(P_c - P_s)/(P - P_s)$, where P_c is the sample pressure the instrument is calibrated for, P_s is the water saturation pressure at the sample dew point, and P is the actual process pressure. Relative humidity is obtained by the use of a chart converting sample operating and dew-point temperature readings to percent relative humidity. Therefore, a sample temperature measurement is required if moisture level in terms of relative humidity is desired (Figure 8.32m).

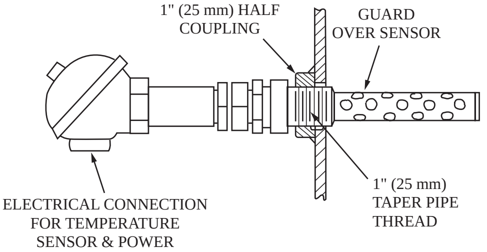

FIG. 8.32m
Solution conductivity probe with resistance temperature element.

Installation The instrument does not require a high-velocity sample to perform satisfactorily; in fact, sample velocity in excess of 1 ft (0.3 m) per second will result in a poor measurement and shortened element life. The reason is evident when one considers the measurement principle involved, namely, the change of solution vapor pressure and temperature on the sensing element by heating to establish equilibrium with the sample. At high sample velocities, connective heat losses swamp the measurement signal, and operation at higher power causes a reduction of element life.

The sensing element therefore must be located in a relatively quiescent zone or must be protected from direct impingement of the sample. In ducts, a sheet metal hood installed over the element and open on the downstream side is adequate. In pipelines, the element can be installed through the side outlet of a tee or can be mounted separately in a sampling chamber piped to the process line. The latter installation is preferred for samples under pressure, because the element can be services without shutting down the pipeline (Figure 8.32n).

Sampling System A sampling system is required when (a) the sample temperature is above the operating limit of the sensing element [operating limit approximately 200°F (93.3°C)], or (b) the process line cannot be shut down for maintenance of the element.

When the process temperature is above the operating temperature limit of the sensor, a sample cooler must be installed upstream of the measuring element. The sampling system must be designed so that the sample will never be cooled to its dew point under any possible process or ambient conditions. Sample tubing should be small in diameter. The sensing element is to be mounted in a larger diameter sampling chamber, as shown in Figure 8.32o, to reduce sample velocity at the element.

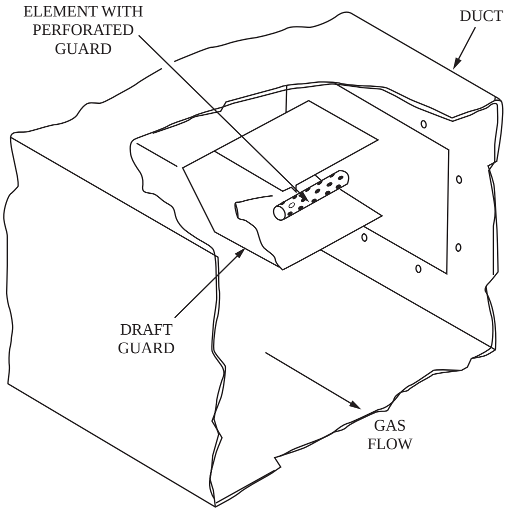

FIG. 8.32n
Duct installation with draft guard.

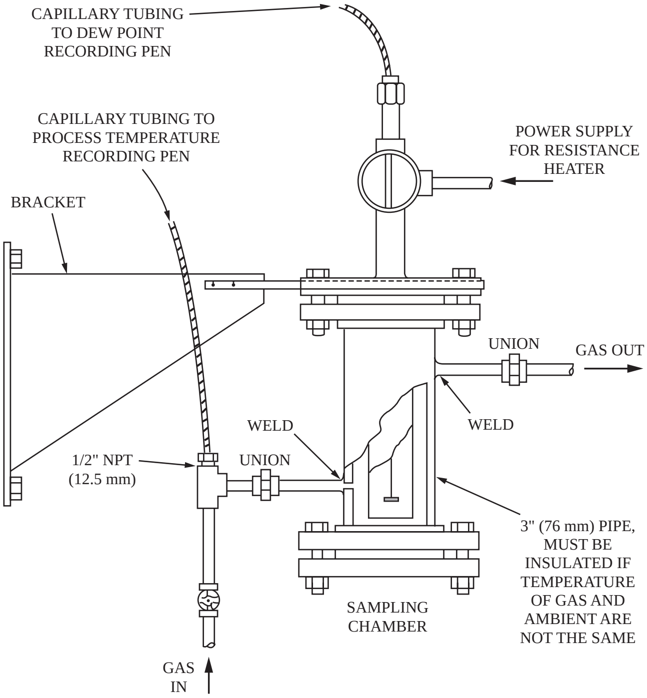

FIG. 8.32o
Probe installed in sampling chamber.

The sensor requires periodic maintenance and must be removable from the line. Whenever such removal would result in a process shutdown, the sensor should be installed in a separate sampling chamber and shutoff valves provided in the sample piping.

Limitations The instrument can be used on all noncorrosive gases that do not react with the salt crystals or water. Specifically, such gases as ammonia, sulfur dioxide, sulfur trioxide, and chlorine react with water, and this instrument is therefore not applicable for such service. The instrument is not suitable for samples containing diethylene glycol or triethanolamine, is relatively slow in its response, and cannot detect relative humidity under 12% RH (Figure 8.32a).

Condensation on a Chilled Surface

The temperature of a surface is at dew point when the first molecular layer of condensation appears on it. Dew-point sensors of this type can be grouped according to the method used to detect the appearance of this condensate into conductivity and optical (mirror) types.

Surface Conductivity Type Every object in a moist atmosphere has water molecules on its surface. The concentration on these molecules is related to the temperature of the object and to the dew point of the atmosphere. If the temperature of the surface is above the dew point of the atmosphere, the thin layer of the water molecules will be invisible. However, as the surface is cooled to the dew point, the density of water molecules at the surface becomes so great that water condenses on the surface, and dew can be seen.

At surface temperatures above the dew point, the moisture density at the surface can be detected electrically, although the water vapor is not visible to the eye. This water vapor will permit a current to flow on the surface of even an excellent insulator. This current flow is a function of the surface material and moisture density at the surface. For a given material and fixed applied potential, the current will increase logarithmically as the surface temperature decreases to the dew point of the atmosphere. Below the dew point, the logarithmic relationship does not hold, and thus surface conductivity can be related to a dew point. Of course, dew formation can also be observed optically; however, visual observation is more difficult, because dew will form at or below the dew-point temperature, whereas conductivity is a continuous function of temperature.

The measuring element consists of a highly polished inert surface inlaid with an intermeshed gold grid and a thermocouple imbedded in the surface. A fixed potential is maintained across the gold grids, and the current flow is compared to the reference current flow at dew point. This signal is amplified and used to modulate a cooler so that the surface is maintained at the dew point of the sample. The cooler is a bismuth-telluride crystal that pumps heat away from the sensor when electric power is supplied to it.

From the thermocouple imbedded in the surface, the output is normally presented as dew-point temperature; however, readout in terms of relative or specific humidity is also possible (Figure 8.32p).

Sampling System A sampling system is required where the sample gas is outside the operational limits of the instrument. At high temperatures, a sample cooler is required to bring the sample temperature below the operating limit of the sensor. The sample cooler, however, must be chosen so that the sample will never be cooled to its dew point under any

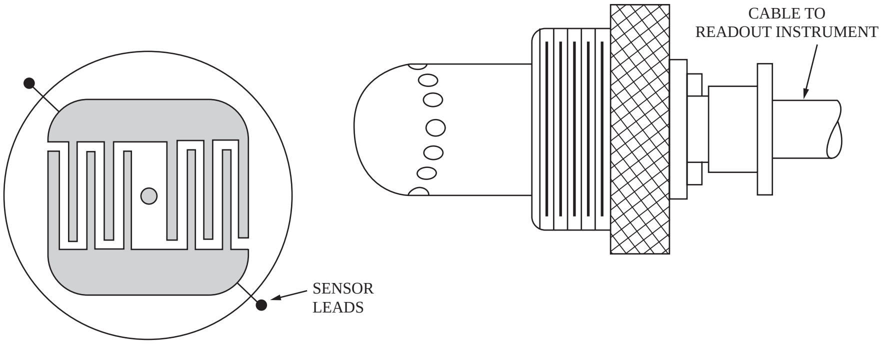

FIG. 8.32p
Sensing surface and housing of the surface conductivity type dew-point detector.

possible operating or ambient condition. At high sample pressures, a pressure-reducing valve is required. For measurement of stagnant atmospheres, low-pressure samples, or closed systems, a pump may be required to draw the sample over the sensor.

Limitations The instrument can be used with all the common atmospheric gases such as nitrogen, oxygen, and carbon dioxide. The instrument is unsuitable for samples containing components that react with water, such as chlorine or sulfur dioxide, and components with a dew point higher than that of water.

The main advantages of this design include its wide range; its accuracy, which is limited only by the quality of the thermometer used to detect the temperature of the cooled surface; and its self-calibrating nature. Self-calibration is achieved by allowing the surface to heat up and then checking whether, upon recooling it, the dew point detected is the same value as before. Cooling or heat-up rates are reasonably fast—about 3°F (1.5°C) per second.

Chilled-Mirror Type The optical chilled-mirror dew-point technique is a fundamental measurement, because the saturation temperature determines the saturation partial pressure of the water vapor. These relationships have been experimentally and theoretically determined and tabulated by Goff and Gratch, Keenan, and Keyes,[3] and in the Smithsonian tables,[4] and they are constantly being refined. The Smithsonian tables, in particular, are used by the National Institute of Standards and Technology (NIST, formerly the National Bureau of Standards) as the reference documents for humidity sensor calibration. They list the saturation vapor pressures over plane surfaces of pure water and pure ice corresponding to the equivalent dew points or frost points. Once the water vapor partial pressures are determined, all definitions encountered in humidity as outlined earlier can be conveniently expressed.

Figure 8.32q illustrates that, at equilibrium partial pressure, when the gas mixture is saturated with water ice, the rate of water molecules leaving the atmosphere and condensing on the chilled surface is the same as the rate of water molecules leaving the chilled surface and reentering the atmosphere. At equilibrium saturation, the water vapor partial pressure of the condensate is equal to the water vapor partial pressure of the gas atmosphere. To establish this dynamic equilibrium at the mirror surface, it is necessary to precisely cool and control the mirror at the saturation temperature. A temperature element is then placed in thermal contact with the mirror, and the mirror temperature is utilized directly as the dew-point or saturation temperature.

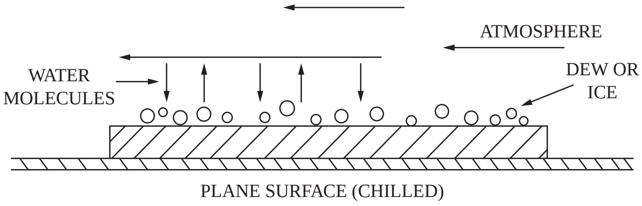

FIG. 8.32q
Equilibrium partial pressure illustration.

Cooling Methods Historically, the cooling of the mirror surface has been accomplished with acetone and dry ice, liquid CO_2, mechanical refrigeration, and, more recently, thermoelectric heat pumps. Detection of the condensation has been observed visually, and the equilibrium cooling is manually controlled. Newer versions utilize optical phototransistor detection designs to control automatically the surface at the dew point or frost point. The temperature instrumentation has included the entire spectrum from glass bulb thermometers to all types of electrical temperature elements.

The manually cooled, visually observed hygrometer is commonly known as the *dew cup.* It is a relatively inexpensive technique, and, when operated by an experienced and skilled technician, it is quite accurate. However, it does suffer from some limitations.

1. It is not a continuous measurement.
2. It is operator dependent, so readings may vary from operator to operator.
3. Versions using expendable coolants require replacement supplies.

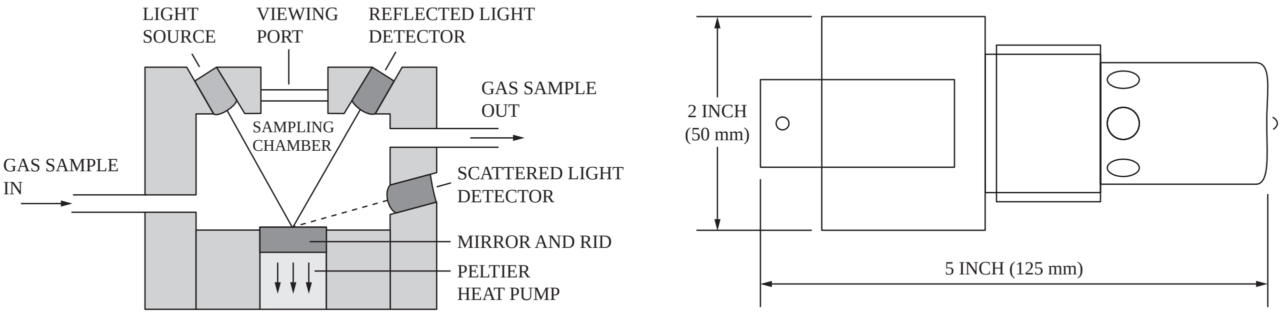

FIG. 8.32r
The cooled-mirror-type sensing element and the probe protector that houses it. (Courtesy of Michell Instruments Ltd.)

All of these difficulties are overcome by the thermoelectrically cooled, optically observed dew-point hygrometer. An instrument of this type is shown in Figure 8.32r. The mirror surface is chilled to the dew point by a thermoelectric cooler while a continuous sample of the atmosphere gas is passed over the mirror. The mirror is illuminated by a light source and observed by a photodetector bridge network. As condensate forms on the mirror, the change in reflectance is detected by a reduction in the direct reflected light level received by the photodetector because of the light-scattering effect of the individual dew molecules. This light reduction forces the optical bridge toward a balance point, reduces the input error signal to the amplifier, and proportionally controls the drive from the power supply to the thermoelectric cooler. This continuously maintains the mirror at a temperature at which a constant-thickness dew layer is retained. Independently, embedded within the mirror, a temperature-measuring element measures the dew-point temperature directly.

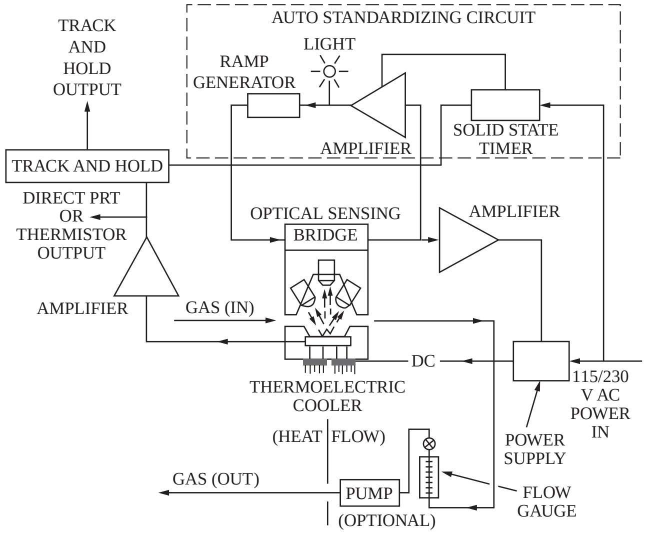

FIG. 8.32s
Automatic standardization (balance) circuit.

Automatic Standardization An additional feature of the optical hygrometer that renders it suitable for long periods of unattended operation is the automatic standardization (balance) feature, as shown in Figure 8.32s. Since moisture on the mirror surface can coexist in equilibrium with the gas adjacent to the mirror at only one unique temperature (i.e., the dew-point temperature), the measurement of the mirror temperature is a fundamental and primary measurement of dew-point temperature. However, the control loop is sensitive to change in reflectance from the mirror surface and, therefore, may be susceptible to changing baseline reflectance as a function of contamination. For this reason, the instruments are equipped with a balance mode whereby the optical bridge output may be readjusted for changing dry mirror reflectance characteristics on a time-sequential basis.

Limitations The limitations of the optical dew-point hygrometer are (1) the sampling system, (2) the depression capability of the instrument, and (3) the absolute dew point being monitored. In the sampling system, considerations of leakage, pressure and temperature gradients, and moisture absorption/desorption characteristics must be considered.

The problem of leakage is relative; that is, if the dew point being measured is close to the ambient dew point, leakage into the system may not bias the reading substantially. If the system is pressurized above atmospheric pressure so as to create a leakage out of rather than into the system, the error introduced will be less.

The temperature stability of the sampling system components is also quite important. For any given equilibrium sampling condition, a specific amount of moisture will be absorbed onto the sampling system wetted surface, so control of the sample line temperature may be necessary to ensure an equilibrium condition.

Of equal importance is the effect that material absorption/desorption characteristics have on overall system response. Stainless steel and nickel alloy tubing are the best nonhygroscopic materials and should be used for dew points from 0 to –100°F (–17 to –73°C). Copper, aluminum alloys, Teflon,® and polypropylene are suitable above –20°F (–29°C) dew point. Most other plastic and rubber tubing is unacceptable in all ranges.

The depression capability of the instrument is a function of the size and efficiency of the thermoelectric cooler. Recent advances in the technology of the thermoelectric coolers have made possible for the first time a practical instrument utilizing

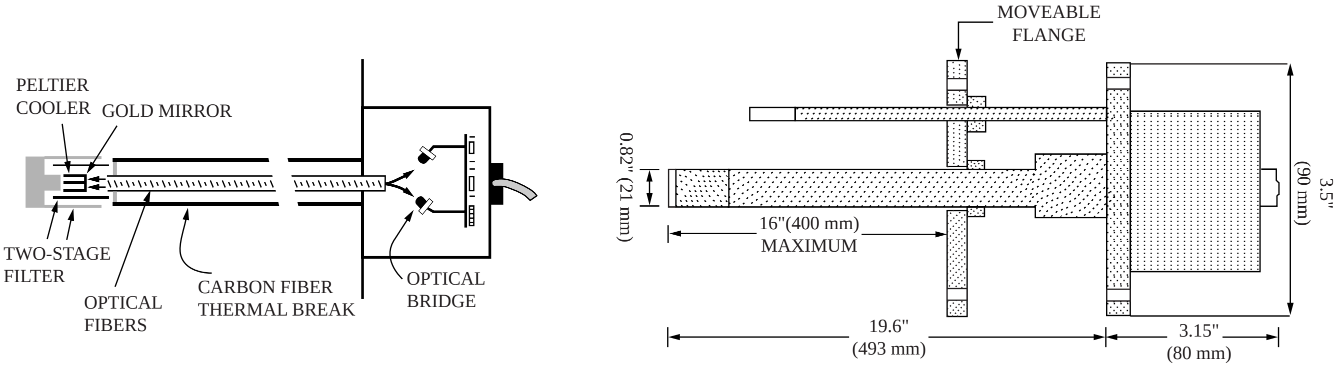

FIG. 8.32t
Cycled, fiber-optic, chilled-mirror probe. (Courtesy of Protimeter.)

three serial stages of thermoelectric cooling, capable of depression in excess of 160°F (71°C). Thus, newer instruments are capable of monitoring virtually all dew-point ranges encountered in current industrial processes.

The final limitation on the optical hygrometer is the absolute amount of moisture available in a gas sample. At –100°F (–73°C), or 1.5 ppm water vapor, the time required to stabilize on a frost point is dependent on the sample flow rate to the hygrometer. This type of instrument requires a very small flow rate to provide a continuous monitoring capability and is not sensitive to flow within a specified range. However, at very low frost points, it is advisable to increase the sample flow rate to provide more samples because of the very low percentage of water vapor available.

Cycled Chilled-Mirror Probe Figure 8.32t illustrates the probe design of the cycled chilled-mirror-type dew-point detector. The advantages of cycling the mirror temperature include simplicity, which also reduces the cost, and lower maintenance, because by making the periods of dew formation short (5% of the time), the probability of contaminant condensation on the mirror surface is also reduced. The mirror surface is visually monitored by a fiber-optic link.

The sensor is protected by an outer (25 μm) and inner (1 μm) filter. The unit is also provided with a dry bulb temperature sensor. The error in temperature measurement is about 0.2°F (0.1°C), and the error in dew-point measurement is 1°F (0.5°C) over a dew-point range of 68 to 185°F (20 to 85°C). An integral pressure sensor is also available to provide dew-point compensation from vacuum to 150 PSIG (10.7 bars).

MOISTURE INDICATORS

Sometimes it is desirable to detect only a change in the amount of moisture in the sample, while the exact concentration is of only secondary importance. Such may be the case on the outlet of drying beds where moisture breakthrough will indicate the need for regeneration. Certain salt crystals indicate the presence of moisture by a change in color, and these are the most economical methods for detecting changes of moisture level. The crystals are packed into a small chamber with a glass window for observation of the color. A sample side stream is piped through the chamber, and increase of moisture in the sample is indicated to the operator by a color change.

FIG. 8.32u
Portable Dew Point Analyzer. (Courtesy of Nova Analytical Systems Inc.)

Microprocessor-Based Indicators

The capacitance-type elements are used in portable, battery-operated indicators or in microprocessor-based instruments that are capable of displaying the moisture content of the air in %RH, ppm, or dew-point units. These sensing elements are also packaged as wall- or duct-mounted transmitters for both HVAC and process industry applications. The probe-type designs can also be used to measure the water content of hydrocarbons and other liquids, as will be discussed in the next section.

For checking dew points in furnace atmosphere gases, transmitting indicators are available with built-in sampling pumps and 4- to 20-mA outputs (Figure 8.32u).

CONCLUSION

The instruments discussed above are generally applicable to such easy-to-handle fluids as the atmospheric air. Operating temperature and pressure are usually limited to near atmospheric conditions although, with some designs (such as capacitance), the operating limits can be extended. The principal feature common to all the above instruments is that the output signal is not related directly to moisture content but to a parameter that is related to moisture content. Accuracy varies widely depending on design. The best accuracy can be obtained with the surface condensation hygrometers. Sampling systems are usually not required, as most designs are available in the probe form.

INTRODUCTION

There is a certain amount of overlap between the three sections that are devoted to the subject of moisture measurement in this handbook. (Section 8.32 describes the measurement of moisture in air; Section 8.33, in liquids and gases; and Section 8.34, in solids.) Some of the instruments, such as the chilled-mirror or the thin-film capacitance-type sensors discussed in Section 8.32, can operate not only as dew point or humidity sensors in air but also as moisture analyzers in other gases. Similarly, the electrolytic hygrometer, which is discussed in this section, could also be used to measure humidity or dew point in air. Similar overlaps exist between the coverage of this section and Section 8.34, dealing with moisture in solids, particularly with respect to microwave, neutron, and infrared analyzers. The reader is also reminded that separate sections are devoted to some of the analyzers that can also be used for other analytical tasks besides moisture detection, such as infrared (Section 8.27) and autotitrators (Section 8.66). The reader is advised to refer to these sections as well for additional information concerning their suppliers and features.

LABORATORY ANALYZERS

An old but still useful method of determining the moisture of a sample is to heat it and measure the resulting weight loss. Some drying ovens are provided with built-in weight scales and displays that indicate the sample moisture content directly in weight percentage. The reliability of this technique is primarily a function of the presence or absence of volatile materials other than water and the weighing procedure. Some built-in scale oven systems even have experience issues with the weighing procedure and air current effects on the sample holders.

Another widely used and accurate (sensitive to 5 ppm) method of moisture analysis in gas or liquid samples is by titration. The reagent is referred to as the Karl Fischer reagent, which consists of a solution of sulfur dioxide, iodine, and pyridine in methanol. The titration end points can be found automatically (see Section 8.66) by the measurement of the current flow through the solution. Recent concerns regarding the toxicity of pyridine have led to the use of substitute buffers like imidazole. The iodine water reaction is the same, and it is still classified as a Karl Fischer titration.

PROCESS ANALYZERS

Some of the industrial process analyzers are of the probe type (capacitance, fiber-optic infrared probes), others can look through the process stream in the pipe (microwave), and the majority require some form of a sampling system. Table 8.33a provides a summary of the ranges and other features of many of the process moisture analyzers. The subject of sampling (which has already been covered to some extent in Sections 8.2, 8.3, and 8.12) will also be addressed in the next section.

Sampling Systems

Some sampling system features are peculiar to moisture analyzers, and these are covered below. The function of any sampling system is to deliver a clean, appropriately representative

TABLE 8.33a

Summary of Moisture Analyzer Features

Type	*Range*	*Sample Phase*	*Sample System Required*	*Remarks*
Electrolytic hygrometer	0–2 to 0–2000 ppm	Clean gas Special sampling for liquids	Yes	Sample flow must be constant
Change of capacitance	0–10 to 0–1000 ppm	Clean gas or liquids	*	Sample temperature must be constant
Impedance type	0–20,000 ppm	Clean gas or liquids	No, only for liquids	Sample temperature of liquids must be constant
Piezoelectric type	0–5 to 0–25,000 ppm	Clean gas only	Yes	
Heat of absorption type	0–10 to 0–5000 ppm	Clean gas or liquid Special sampling for liquids	Yes	Sample flow must be constant
Infrared absorption	Gas: 10.1–100% Liquid: 6–100%	Gas, liquids, and slurries	**	
Microwave absorption	0–1 to 0–70%	Liquids, slurries, and pastes only	No	

*Available in probe form, but can be direct pipeline-mounted only if flow velocity is under 1.6 fps (0.5 m/s).

**Fiber-optic probe (FOP) designs can be direct pipeline-mounted without sampling.

sample to the measuring element at the required pressure, temperature, and flow rate. Measurement of moisture, although simple in principle, is complicated by the fact that most materials adsorb and desorb moisture.

At moisture levels in the percent range, moisture absorption is not normally a serious problem; however, at moisture levels in the low parts per million (ppm) ranges, sampling system materials must be selected so as to minimize their effect on the moisture concentration in the sample. Depending on the levels being monitored, materials that are less likely to interfere with the moisture content in the sample are stainless steels, Teflon,® Viton,® Kel-F,® nickel and nickel-plated materials, and cadmium and cadmium-plated materials. Materials that should almost always be avoided are copper and its alloys, rubber, neoprene, and elastomers in general.

It is important to apply the material considerations to all parts of the sampling system, including the internals of valves and filters.

Electrolytic Hygrometer

The principle of measurement utilized involves the electrolysis of water into oxygen and hydrogen. Since two electrons are required for electrolysis of each water molecule, the electrolysis current is a measure of the water present in the sample. If the volumetric flow rate of the sample gas into the electrolysis cell is controlled at a fixed value, then the electrolysis current is a function of water concentration in the sample (Figure 8.33b). This relationship is illustrated in the following example.

Determine the water concentration in a sample when the sample flow rate is 100 cc/min (0.212 ft^3/h) at 100°F (37.8°C) and 10 PSIG (68.9 kPa). The electrolysis current is measured at 320 μA.

$$\text{electrolysis current} = 320 \times 10^{-6} \text{ coulombs per second}$$

$$1 \text{ coulomb} = 6.25 \times 10^{18} \text{ electrons}$$

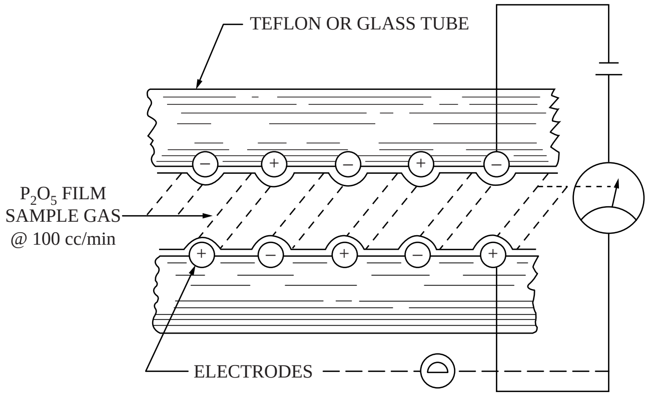

FIG. 8.33b

Operating principle of the electrolytic hygrometer.

Therefore, the electrolysis current is equal to the electron flow of 2×10^{15} electrons per second. Since two electrons of charge are required to electrolyze one water molecule, the water flow into the cell is equal to 10^{15} molecules per second. If, for purposes of this example, the water present in the sample is considered an ideal gas, the volume of water entering the sample can be calculated using the ideal gas law.

$$V_2 = \frac{P_1}{P_2}\frac{T_2}{T_1}V_1 \qquad \textbf{8.33(1)}$$

Avogadro's Law Avogadro's law states that equal volumes of different ideal gases at the same pressure and temperature contain the same number of molecules. The volumetric flow rate of water vapor can be calculated as

$$V_1 = 379\ N/A \qquad \textbf{8.33(2)}$$

where

N = the flow of water in molecules per second

A = Avogadro's number ($A = 2.73283 \times 10^{26}$ molecules/(lb·mol)

379 = volume of a pound-mole of ideal gas in cubic feet

Subscripts 1 and 2 refer to standard and sample conditions, respectively.

$$V_1 = \frac{379 \times 10^{15}}{2.73 \times 10^{26}} = 1.39 \times 10^{-9}\ \text{ft}^3/\text{sec} = 5.0 \times 10^{-6}\ \text{ft}^3/\text{h} \qquad 8.33(3)$$

$$V_2 = 5 \times 10^{-6} \times \frac{560}{520} \times \frac{14.7}{24.7} = 3.2 \times 10^{-6}\ \text{ft}^3/\text{h} \qquad 8.33(4)$$

Since the sample flow is controlled at 0.212 ft^3/h (100 cc/min), the volume concentration of moisture is: $3.2 \times 10^{-6}/0.212 = 15.1 \times 10^{-6}$. Expressed in parts per million (ppm), the moisture content is 15.1 ppm. The example above is intended to illustrate the fact that the hygrometer cell sees only a mass flow of water—number of water molecules electrolyzed per unit time. To obtain an output in the form of moisture content, the sample flow rate must be a known, constant value. Furthermore, the accuracy of the output can never exceed the accuracy with which the sample flow is controlled.

The commercial electrolysis hygrometer cell consists of a small chamber containing two noble metal electrodes that support a thin layer of desiccant. Moisture in the sample is absorbed by the desiccant and electrolyzed by means of a voltage-regulated power supply connected to the electrodes. Units are available for use in nonhazardous areas with the sample flow control, electrolysis cell, and electronics packaged as a single unit. When used in hazardous areas, the cell and flow controller are housed in an explosion-proof conduit, and the electronic circuitry is remote-mounted (see Figure 8.33c).

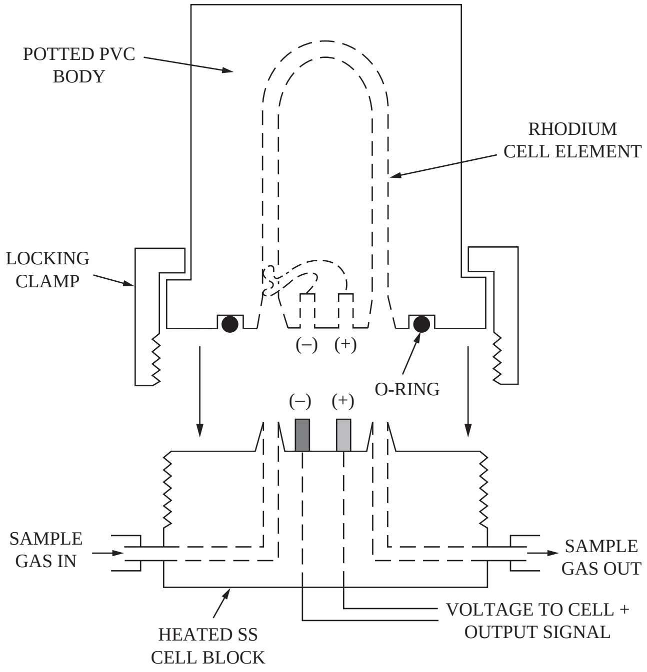

FIG. 8.33c
Electrolytic hygrometer cell.

Recombination Effect Although this instrument will operate satisfactorily with a variety of samples, a phenomenon called the *recombination effect* introduces large errors at low moisture levels in hydrogen-rich or oxygen-rich samples. Recombination is the reversion to water of the electrolysis products; it introduces an error into the measurement when the recombined oxygen and hydrogen are re-electrolyzed. Apparently, all electrodes catalyze this reaction, although some electrode materials do so more than others. The use of rhodium as the electrode material has been found to minimize recombination.

When monitoring very low moisture levels in oxygen-rich or hydrogen-rich atmospheres, the recombination produces a relatively large error even with the best choice of electrode materials. For such an application, two sensors are used; one measures at sample flow rate X and the other at sample flow rate 2X. Because the error due to recombination is a constant, subtraction of the two sensor outputs yields a signal that is independent of recombination.

Cell Limitations The cell will perform satisfactorily with a variety of samples; however, a number of sample materials will cause problems or should not be monitored with this instrument. Gases known to cause problems are hydrogen and oxygen. These gases have already been discussed in terms of the recombination effect, above. Some other gases for which this instrument is unsuitable are unsaturated monomers, alcohols, amines, ammonia, hydrogen fluoride, and $CHClF_2$ (Freon®) refrigerant.

Alcohols are seen by the cell as water. Amines and ammonia usually react with the desiccant. Hydrogen fluoride can corrode the internals of the cell. The data collected on $CHClF_2$ refrigerant indicates an anomaly, although the reason for this is not fully understood. Unsaturated hydrocarbons such as butadiene or monomers with a strong tendency to polymerize cannot be monitored, as the cell will be quickly coated with polymer.

Generally, the instrument should not be used with samples whose components may deposit in the cell (condensable vapors). When a cell becomes contaminated, it will show a memory for polarity; that is, the outputs under forward and reverse flow through the cell will not be equal. The electrolytic hygrometer is suitable for most inert elemental gas applications and for other gases that do not react with P_2O_5.

A cell will lose sensitivity when exposed to moisture levels of a few parts per million over a period of weeks. This sensitivity loss is due to the elution of desiccant with the sample. However, this process occurs over a long period of time and the cell can be recoated fairly easily in the field during periodic maintenance.

Liquid Samples The electrolytic hygrometer cell can be exposed only to gases. When the process sample is in the liquid state, there are two ways of using the electrolytic hygrometer. Recall that this process must not result in transporting to the sensor vapors that will condense or be absorbed.

1. *Sample vaporization*. If the liquid sample has sufficiently high vapor pressure, the sample can be vaporized, and the measurement is then made as a gas sample. The sample is vaporized by means of a vaporizing regulator located as close as possible to the sample take-off point to minimize lag. The remainder of the sampling system is the same as for gas samples.
2. *Sample stripping.* If the sample cannot be vaporized, this method can be used to obtain a gas sample at the cell. The moisture is stripped from the liquid sample in a falling film column. Liquid sample is continuously metered into the top of the column, where it descends as a thin film. Dry nitrogen, metered into the bottom of the column, ascends and removes moisture from the descending film of liquid sample. A filter located at the top of the column removes any droplets entrained in the nitrogen before the gas is passed through the measuring cell.

A drain valve at the bottom of the column facilitates removal of stripped sample. The nitrogen is dried before entering the column by passing through an electrolytic dryer, similar to the measuring cell, where moisture is removed by electrolysis. The supply nitrogen moisture level should be fairly low (less than 500 ppm) to avoid overloading the dryer (Figure 8.33d).

Sampling System As pointed out previously, the electrolytic hygrometer is sensitive only to the mass flow of water into the cell; the concentration of moisture is inferred from the known sample flow rate. Therefore, the accuracy of the readout is partially dependent on the accuracy of the sample flow control and the accuracy of the moisture measurement can never exceed that of the sample flow control. This fact should be kept in mind when selecting a sample flow controller.

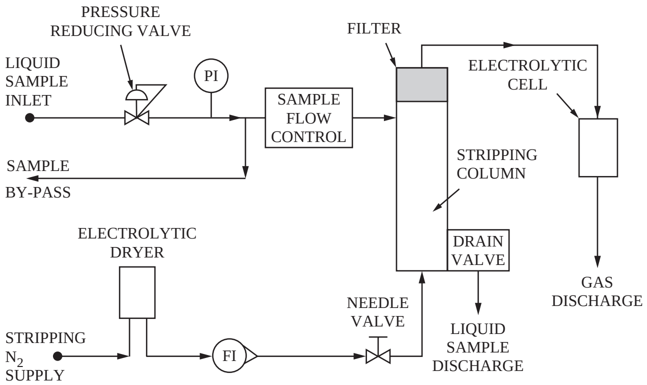

FIG. 8.33d
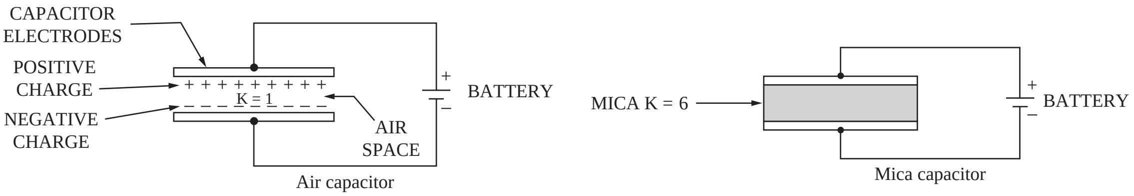
Liquid sample stripping.

Capacitance Hygrometer

The principle of measurement utilized is the change of capacitance associated with a change of the sample dielectric constant between capacitor plates. The value of capacitance is a function of plate area, plate spacing, and the dielectric constant of the material between the plates. The dielectric constant of a material has a unique value for each substance and is related to the polarity characteristics of the molecules. This property can, therefore, be used to detect the presence of a specific substance in a pipeline stream.

Figure 8.33e shows an air capacitor connected to a battery and the same capacitor with mica between the plates. The capacitance of mica is six times that of air because the dielectric constant, K, of mica is 6, and the K of air is 1. If the mica were inserted gradually between the plates, then the capacitance would increase correspondingly from minimum to maximum. Water, with a dielectric constant of 80, would increase the capacitance to 80 times the value of the air capacitor.

The measuring cell of the hygrometer consists of two electrically insulated concentric metal cylinders to form the measuring capacitor plates (Figure 8.33f). The annulus between the cylinders is filled with alumina desiccant. Two porous metal discs support the cylinders and retain the desiccant in the annulus. The sample is allowed to flow through the annulus, and process water is absorbed or desorbed by the desiccant, which remains in equilibrium with the sample in terms of percent saturation. The desiccant thus amplifies the moisture content of the sample because the saturation level of the desiccant that is in equilibrium with the sample is very much higher than that of the sample.



Air capacitor

Mica capacitor

FIG. 8.33e
The capacitance is a function of the dielectric constant of the material filling the space between the capacitor plates.

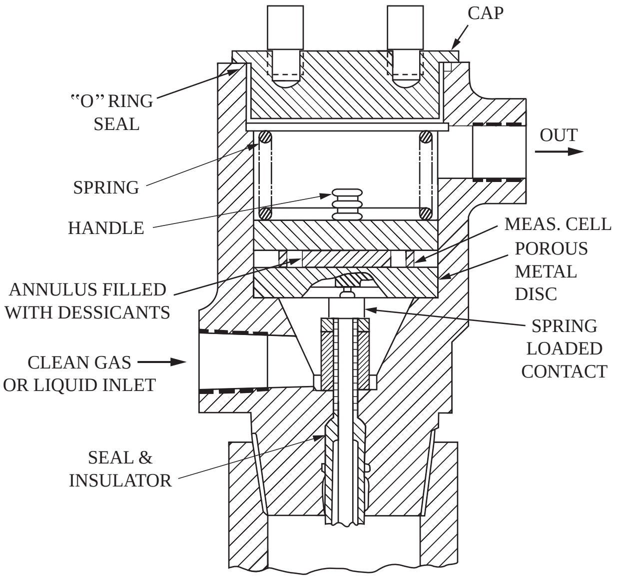


FIG. 8.33f
Capacitance-type measuring cell.

The measuring capacitor is part of an electrical circuit that includes a reference capacitor. This circuit is usually powered by a 15-kHz fixed-amplitude sinewave. The measuring and reference capacitors are switched alternately into the circuit such that its output voltage is a function of the connected capacitance. The output signal is a sinewave of the same frequency as the power signal and whose amplitude varies with the measuring and reference capacitors as they are switched into the circuit. This difference in amplitude is related to the measured capacitance, which, in turn, is a function of the moisture content of the sample.

The electronic chassis is normally mounted near the measuring cell and sampling system, which should be close to the sample take-off. In addition to an integral indicator and output signals of standard serial, milliampere, and millivolt ranges, the electronic chassis can be provided with multiple range switching and alarm contacts.

Sampling Systems It was pointed out previously that the desiccant in the measuring cell is the equilibrium with the sample in terms of percent saturation. For this reason, it is necessary to maintain the sample and measuring cell at constant temperatures. For example, propane at 100°F (38°C) will dissolve 300 ppm of water; at 70°F (21°C), it will dissolve 150 ppm. With a moisture level of 15 ppm, the propane would be 5% saturated at 100°F and 10% saturated at 70°F. Therefore, the output signal would change 100% with no change in moisture content if temperature were allowed to vary from 100 to 70°F.

The sample is maintained at constant temperature by passing it through a coil immersed in a constant temperature bath immediately upstream of the measuring cell. Additional temperature control of the sample is recommended even if the process stream is temperature controlled, because ambient conditions can affect the sample temperature.

Thin-Film Capacitance Probes The design and operation of thin-film capacitance probes have been described in the previous section in connection with Figure 8.32j and 8.32k. These units are also suitable for explosion-proof area classifications and can be used in measuring the moisture content of many gas and liquid samples (many liquid hydrocarbons, for example). The probe units are suitable for installation of high-pressure processes and are provided with microprocessor-based electronics capable of self-diagnostics and of multiple measurements or unit conversions (Figure 8.33g). These probes are available with a variety of covers/shields that can be used for a variety of sampling situations (particulate, bubbles, various viscosity liquids, etc.).

A unique configuration of a thin-film capacitance ceramic sensor is one with an integral calibration system. The *in situ* and automatic calibration is performed against a reference gas. The precision of this system is the result of the use of a chilled-mirror dew-point hygrometer to measure the moisture content of the reference gas used in the calibration (Figure 8.33h).

Limitations The capacitance instruments are not suitable for polar materials such as alcohols, because these become conductive at the 15-kHz operating frequency and short the measuring capacitor. Data on instruments operating at higher frequencies were not available.

Free sulfur and iron oxide concentrate on the desiccant will short the element.

At sample viscosities above 500 Saybolt Seconds Universal (SSU), moisture should not contact the desiccant

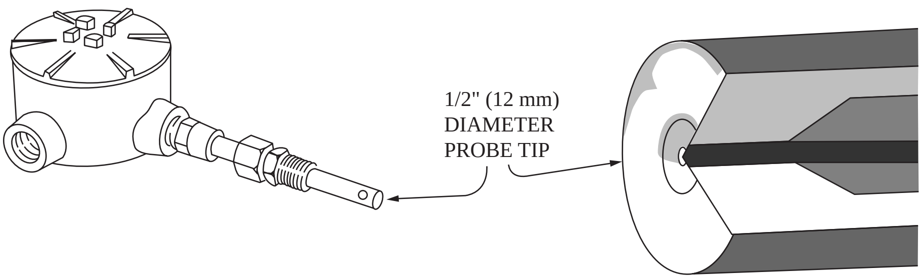

FIG. 8.33g

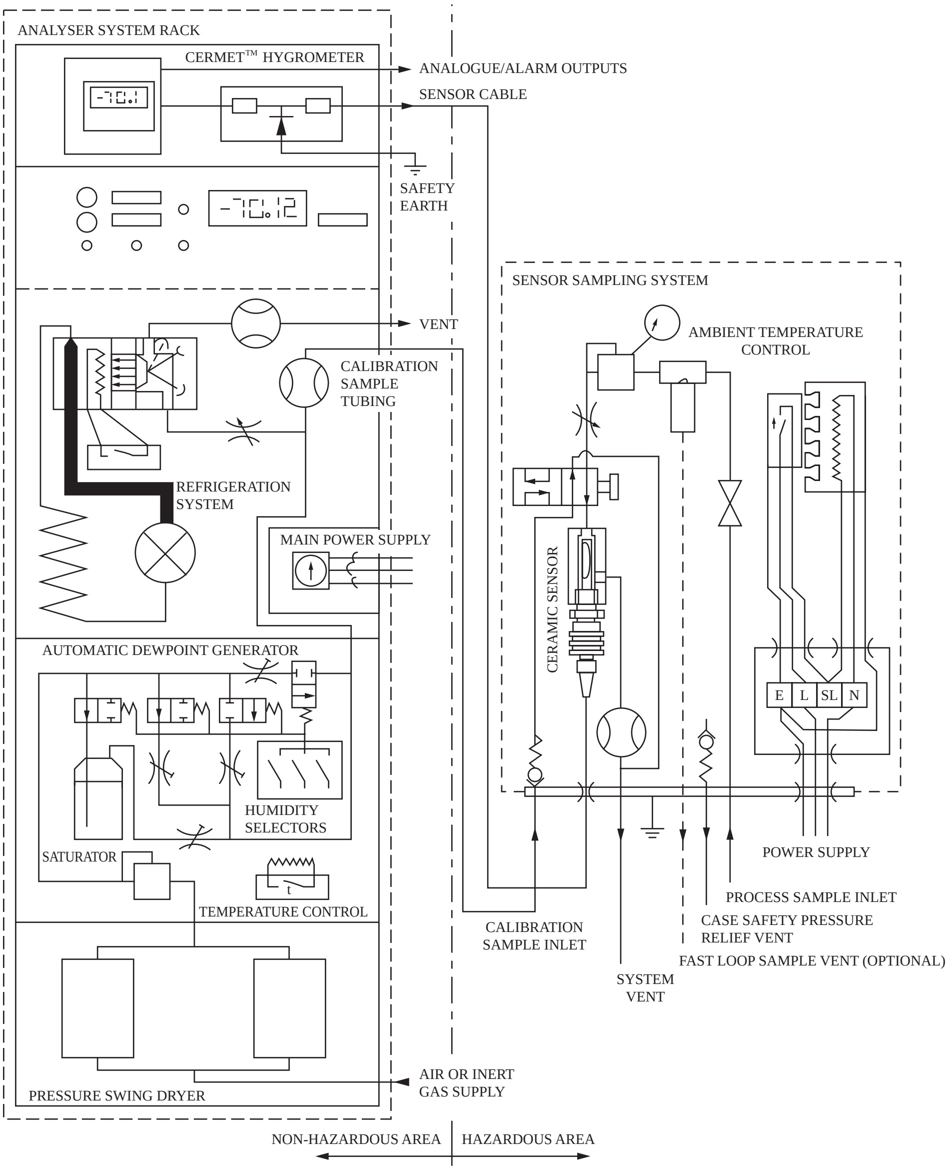

FIG. 8.33h
Thin-film ceramic sensor provided with integral and automatic means for recalibration. (Courtesy of Michell Instruments Ltd.).

at reasonable flow rates, and the measurement becomes meaningless.

The life of the desiccant is partially a function of solids in the stream, which pass through the filter. While the desiccant can be replaced very readily, the short life of the desiccant excludes the use of this instrument on sample streams containing large quantities of fines.

Impedance Hygrometer

This instrument measures the water content of a sample by means of a probe whose electrical impedance is a function of the vapor pressure of moisture in the fluid. Impedance is the apparent opposition to the flow of alternating current. The probe consists of an aluminum strip that is anodized to form a porous layer of aluminum oxide. A thin coat of gold is applied over the aluminum oxide. Leads from the gold and aluminum electrodes of the probes connect the sensing element to the measuring circuitry (Figure 8.33i).

Water vapor penetrates the gold layer and equilibrates on the aluminum oxide. The number of molecules adsorbed to the aluminum oxide is a function of the water vapor pressure in the sample. Each water molecule adsorbed contributes a distinct increment to the total conductivity of the aluminum oxide. The total probe impedance, the reciprocal of probe conductivity, is thus a measure of water vapor pressure in the sample. Water vapor pressure of a gas sample uniquely determines the dew-point temperature and moisture content of the sample. The output is normally calibrated to these units, as they are more convenient to use than vapor pressure. In the case of certain liquid samples, the moisture content can be measured through the application of Henry's law.

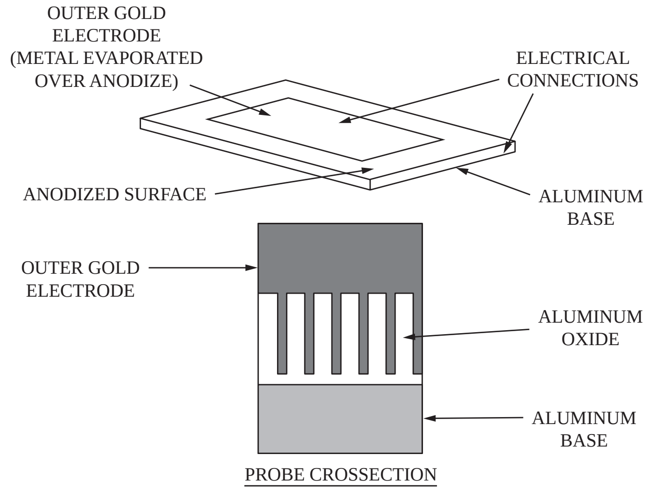

FIG. 8.33i
Impedance-measuring sensor.

In terms pertinent to this measurement, Henry's law states that, at constant temperature, the mass of water vapor dissolved in a given volume of liquid is in direct proportion to the partial pressure of water vapor in the sample. Henry's law can be restated in simpler form to read that the weight concentration of moisture in the sample is equal to the partial pressure of water vapor times a constant. However, Henry's law holds only for liquids with moderate solubility for water vapor, such as pure hydrocarbons, silicone oils, etc. The instrument cannot be used on liquid samples with a high solubility for water such as the alcohols, because the relationship expressed by Henry's law does not hold.

Installation The probe is designed for direct installation into the process stream. However, where danger of explosion exists, the probe is inserted into a small sample chamber connected to the process line with flashback arrestors located at the sample inlet and outlet. For liquid samples, temperature must be controlled and/or monitored and compensated for. Several probes can be connected to a single readout device and each probe can be monitored directly or by means of an automatic scanner. A serial, milliamp, and voltage output signals are available for recording or other functions; single or multiple range measurements are standard (Figure 8.33j or 8.33k).

Sampling System Often a sampling system is not required on gas samples. On liquids, sample temperature must be held constant or monitored and compensated for. These probes are available with a variety of covers/shields that can be used for a variety of sampling situations (particulate, bubbles, various viscosity liquids, etc.). Often these shields can eliminate the need for, or simplify the design of a full-blown sampling system.

Limitations The instrument can be used on all gases that are not corrosive to the probe and that will not spontaneously polymerize on contact with the probe materials. On liquids, the instrument is limited to those fluids with a moderate solubility for water vapor; thus the instrument is not suitable for measurement in polar liquids such as the alcohols.

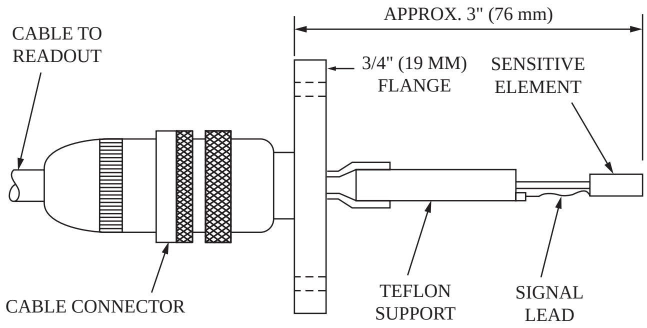

FIG. 8.33j
Flanged probe.

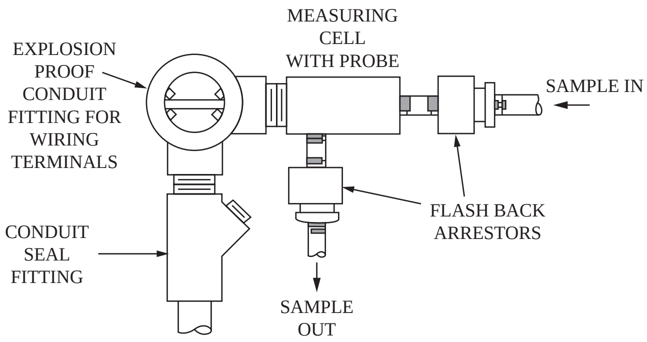

FIG. 8.33k
Impedance hygrometer installation for hazardous areas.

This sensor is suited for moisture measurement in hydrocarbons that consists of only hydrogen and carbon atoms or in halogenated hydrocarbons, amides, esters, many silicone oils, etc. The aluminum oxide probe is suited for moisture detection in cyclohexane, diethyl ether, liquefied natural gas, ethane, propane, butadiene, butane, styrene, and propylene. It is not recommended for applications where conductive solid particles, mercury, salts, or acids and bases are present. Hydrofluoric acid, for example, can damage the sensor, even in such low concentrations as 1 ppm.

The analyzer requires recalibration about twice a year and must be protected against excessive ambient temperatures (158°F, or 70°C) and against excessive flow velocities. If the process stream flows at a velocity in excess of 1.7 fps (0.5 m/s), it is advisable to place the sensor in a slow bypass. The viscosity of the sample also needs to be taken into consideration.

Piezoelectric Hygrometer

Piezoelectric quartz crystals have a number of uses: in communications, to control frequencies; in industry to measure temperature and thickness of metal films; and to generate ultrasonic waves. In moisture measurement, advantage is taken of the oscillating crystal's sensitivity to deposits of foreign material on its surface. Commercially available crystals will show a frequency change of 2000 Hz per microgram of materials deposited.

For moisture measurement, the quartz crystals are coated with a hygroscopic material and exposed to the sample. Water from the sample is absorbed by the coating, which increases the total mass and decreases the oscillating frequency of the crystals. To measure changes of decreasing moisture concentration and to simplify the frequency measurement, two crystals are used. One crystal is exposed to a wet sample and the other to a dry reference gas for a short period. Then, sample and reference gas flows are switched so that moisture is absorbed by one crystal while being desorbed by the other. A cycle timer controls this switching. The frequency changes between the two crystals are in proportion to their mass changes and the moisture content of the sample gas.

Sampling System Dry reference gas is obtained by passing part of the sample gas through an integral dryer, or an external source of dry of nitrogen can be used. Two solenoid valves located upstream of the measuring cell switch the sample and reference gases from one crystal to the other. Sample gas flow to each crystal is regulated, although small variations of sample flow rate will not affect the measurement. For samples near atmospheric pressure, a vacuum pump may be used to draw sample through the measuring cell (Figure 8.33l). Some versions of this instrument design are being supplied with integral permeation tube calibration/benchmark systems to help ensure that the measurement is still accurate.

Limitations The instrument is not capable of measuring moisture in liquid phase samples. For this reason, it is applicable to only those liquid samples that can be stripped or completely vaporized within the operating limits of the instrument. In addition, monomers with a strong tendency to polymerize, such as butadiene and styrene, may coat the crystals and prevent proper operation.

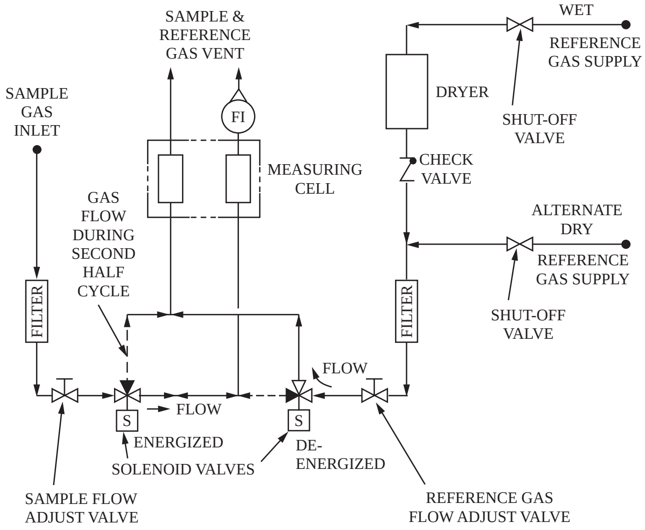

FIG. 8.33l
Piezoelectric hygrometer sampling system.

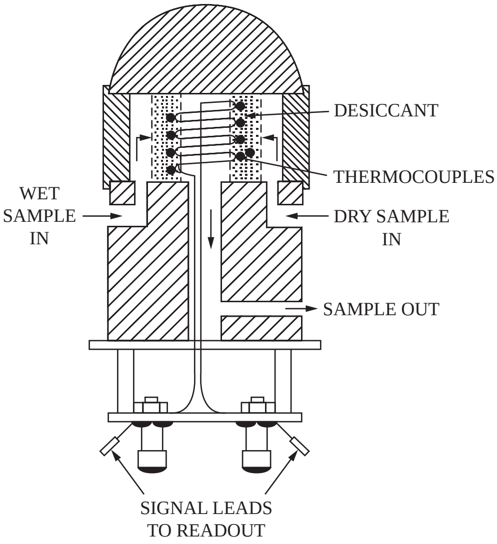

FIG. 8.33m
Measuring cell for the heat of an adsorption-type hygrometer.

Heat-of-Adsorption Hygrometer

The process of adsorption and desorption involves an exchange of energy. During adsorption, energy is released to the environment, and, during desorption, energy is removed. When a wet gas is passed through a column of adsorbent, which selectively adsorbs moisture, the temperature rise due to heat liberation is in proportion to the amount of moisture being adsorbed. Other factors can affect the heat of adsorption. They include things like the nature of the adsorbent and operating temperature, and they are selected to maximize the heat of adsorption (Figure 8.33m).

The sensing element consists of two desiccant columns, each containing a number of thermocouples connected in series. This assembly is housed in a temperature-controlled, thermally insulated housing. In operation, wet sample gas is passed through one column and dry reference gas through the other. Since adsorption and desorption occur simultaneously, the net thermocouple output voltage represents the algebraic sum of the heat gained by one column and lost by the other. The reference gas and sample gas streams are switched on a time-cycle basis to maintain dynamic conditions necessary for measurement in the sensing element. Sample flow is closely regulated, because moisture concentration is inferred from the known sample and reference flow rates (Figure 8.33n).

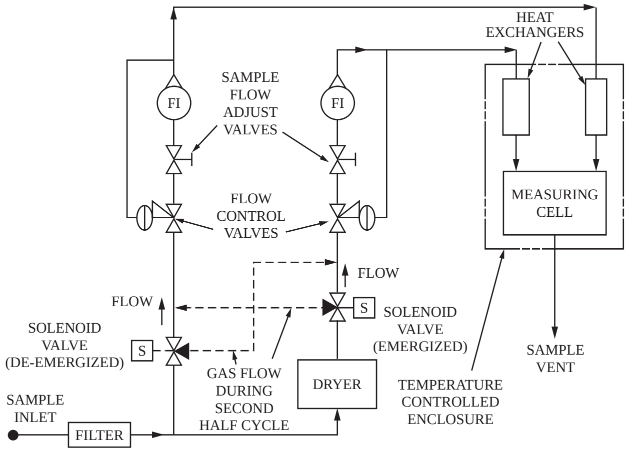

FIG. 8.33n
Sampling system for the heat of an adsorption hygrometer.

Sampling System The sampling system contains the following:

1. A dryer to remove all moisture from the sample gas so that the gas can be used as the reference.
2. Solenoid valves and cycle timer to switch reference and sample gas between the two desiccant columns.
3. Flow regulators to hold sample and reference gas flows constant.
4. Heat exchangers within the insulated enclosure to heat both reference and sample gas to the operating temperature of the sensing elements. The sample flow to the instrument is split into two equal flow rates at the sampling system; one half is the measured sample, and the other half is dried for use as the reference gas. The timer actuates solenoid valves in the sample and reference gas lines so that each desiccant column is exposed alternately to reference and to sample gas.

Limitations The sensing element cannot be exposed to liquid samples; however, the moisture content of liquid streams can be measured by one of two methods. Liquids with low boiling points can be vaporized at the sample take-off points by means of a vaporizing regulator, and the measurement is then performed on a gas sample. Or the moisture can be stripped from the liquid sample with dry gas, and from the moisture content of this gas the moisture concentration in the liquid sample can be inferred. Sample stripping is described in conjunction with electrolytic hygrometers.

Infrared Absorption Hygrometer

Water absorbs electromagnetic radiation in the infrared (IR) region of the spectrum. Specifically, infrared radiation of 1.4 and 1.93 μm wavelength is absorbed strongly by water. By measuring the attenuation (decrease of light intensity) of a beam of this wavelength as it passes through a sample, the moisture content of the sample can be determined. However, other factors such as reflection and dispersion of the radiant energy will contribute to the attenuation. Therefore, it is necessary to either calibrate these factors out of the measurement or to use a reference wavelength that is not absorbed by moisture but is affected by all other factors to the same extent as the measuring wavelength. The difference in the attenuation of the measurement and reference wavelength is then a function of moisture content only.

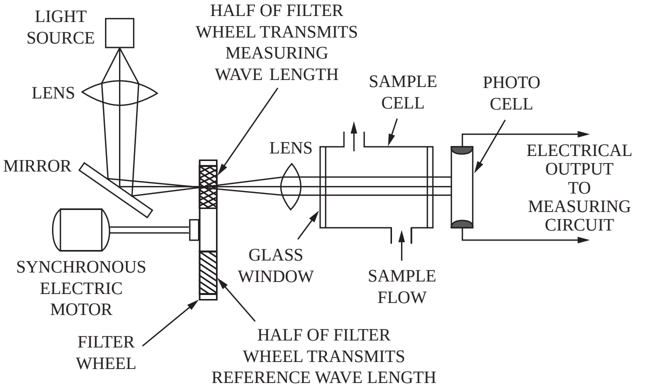

FIG. 8.33o
Schematic representation of the infrared moisture detector.

The sensing element consists of three groups of components: an IR radiation source, sample cell, and radiation detector. The radiation source consists of a lamp, filters to pass the measuring and references wavelengths, and optics to direct the beam through the glass sample cell. The radiation pickup consists of optics to collect the transmitted radiation and a photocell to convert the electromagnetic energy to an electric current.

The measuring and reference wavelengths are allowed to impinge alternately on the photocell so that two sets of current pulses are produced. These pulses are converted into two direct current (DC) signal levels whose ratio represents the moisture content of the sample (Figure 8.33o). For more details on IR analyzers, refer to Sections 8.23 and 8.27.

More complex spectrometers (IR, FTIR, NIR, and TDLAS) are also being used for moisture detection and monitoring applications when the application requires or justifies it (lower levels of detection, multiple simultaneous components [including moisture], complex sample matrices, etc.). One of the newer one is tunable diode laser adsorption spectroscopy (TDLAS), which claims measurements down to the ppt range with an appropriate sample.

Sampling System There are no special sampling system requirements for this instrument. Selection of hydrophobic (lacking affinity for water) materials for sampling system components is not critical, given that the instrument can measure only relatively high moisture content, where moisture contributed to the sample by the sampling system is insignificant in its effect on the measurement. When fiber-optic probes (FOPs) are used, the need for sampling systems is eliminated (Section 8.23).

Limitation There are several general limitations to the field of application of this instrument. The sample fluid must not be corrosive to the glass sample cell. It must have some minimum transparency for the measurement and reference wavelengths. Additionally, there cannot be any other components present in the sample that will selectively absorb either the measuring or reference wavelength.

Microwave Absorption Hygrometer

In the microwave frequency band of 20 to 22 GHz (K band), the wavelength is about 13 to 15 mm. In this frequency band, moisture (free water) responds uniquely. Only the water molecule produces molecular resonance. The microwave radiation can be guided by waveguides or transmitted through the process stream from its source to a detector.

The operating principle of this instrument is the same as that of the infrared absorption hygrometer, namely, selective absorption of electromagnetic energy by moisture in the sample. However, in this case, radiant energy in the microwave region is used. A transmitter provides a microwave beam that can either be transmitted through or reflected by the sample material. The receiving unit senses wave attenuation and phase shift and provides an output. The unit senses the mass of moisture in the beam path so that the readout is normally in terms of the mass of moisture per unit volume. However, with proper calibration, readout in weight percent can be achieved.

Several probe configurations are possible, depending on the application. Figure 8.33p shows the transmitting and receiving probes welded into a section of pipe. Internally, Teflon® contacts the sample. This type of arrangement can be advantageous on slurries and pastes, because there are no obstructions to flow. The units described above measure the attenuation of a microwave beam in the sample by moisture.

The reflectance-type unit contains the source and detector in a single housing. Rather than detecting the transmitted microwave energy, this design measures the amount of energy reflected by the sample. The probe of the reflectance unit does, however, require contact with the process material. Selection of the type of probe to be used is determined by the reflective and absorptive properties of the sample at operating conditions and by the physical installation. An advantage of the microwave hygrometer over the infrared unit is that there are no optical windows that may coat and effect the measurement.

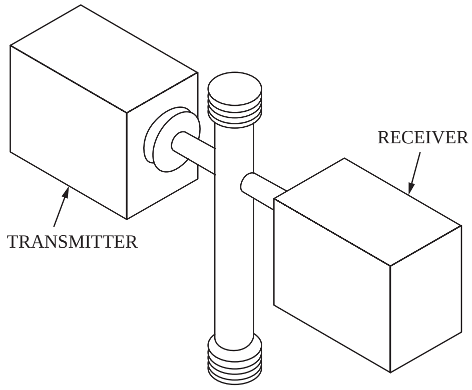

FIG. 8.33p
Microwave sensor installed in pipe.

Limitations The unit is not suitable for moisture measurement in gases.

Dipole Polarization Effect Moisture Sensor

The principle of this measurement relies on the fact that water molecules are formed by covalent bonds. These bonds share electrons unequally between the hydrogen and oxygen atomic nucleuses, and the result is an electrical asymmetry around the molecule (two slightly positively charged hydrogen atoms and a slightly negatively charged oxygen atom). When these molecules are subjected to an electric field, they tend to align with the electric field because of their dipole nature. Unfortunately, other influences such as surface polarization, ions, etc., can also create an electrical effect in the field.

By selecting an appropriate sensor field frequency (e.g., 20 kHz), the influence of these other influences can be reduced. Other polar molecules can interfere, but, because water molecules are very specific, this is not considered a significant factor in most analysis. Ammonia (NH_3) is the closest to water, and its interference effect is listed as about 1:50 (±50 gm/m^3 NH_3 equals about ±1 gm/m^3 of water).

A dipole probe is depicted in Figure 8.33q. The sensor measurement chamber is an open capacitor that is protected from coating or attack by the process steam components by a membrane filter. The measurement output is directly proportional to the number of water molecules in the field and is reported as a mass per unit volume output. The probe can be made from several materials (stainless steel, inconel, etc.) and can even be coated with nonstick materials. The result is an available probe for most needs. The probe is usually heated to about 10°C above the highest process temperature to provide a constant measurement temperature and to minimize potential condensation and fouling. Versions of this probe design have been used to measure moisture in processes as hot as 430°C.

Because the measured signal is directly proportional to the number of water molecules in the chamber, calibration is very easy. A zero-reference capacitor is hermetically sealed in the probe and, once the zero reference is established and because the measurement is linear, you need only one other calibration point for the entire 0 to 100% range. The calibration will not change for the life of the instrument as long as the physical integrity of the measuring and reference chambers are maintained.

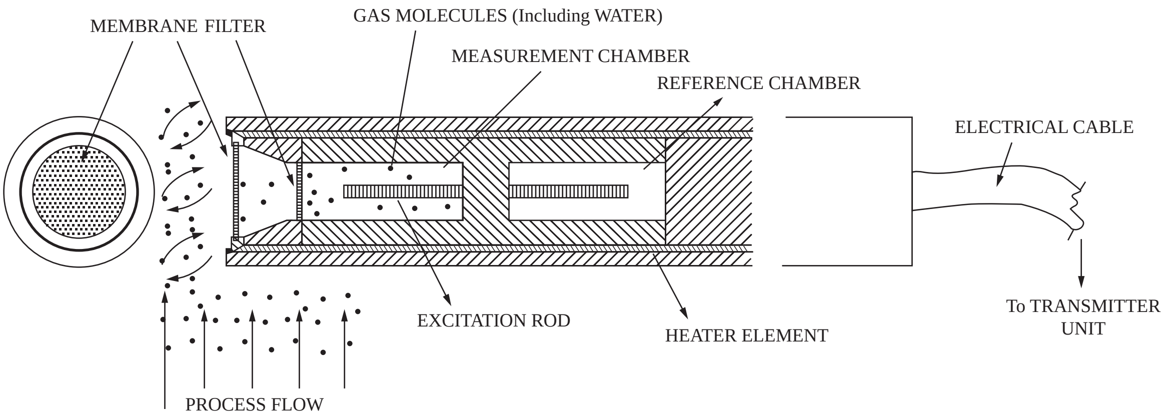

FIG. 8.33q
A dipole polarization effect moisture sensor. (Courtesy of Dewcon Instruments Inc.)

Sampling System There are no special sampling system requirements for this instrument. The probe is designed to insert directly into most processes. Extreme sample conditions may require some sample conditioning.

Limitations The unit is not suitable for moisture measurement in liquids.

Cavity Ring-Down Spectroscopy (CRDS) Moisture Analysis

This spectroscopic technique is different enough from those previously discussed that it will be discussed here on its own. The measurement principle is based on absorption spectroscopy. The difference between this and more traditional absorbance spectroscopy is that this measurement is based on time rather than just the magnitude of the absorbance. The actual measurement is based on a light intensity decay rate. By measuring the time it takes for the appropriate molecular absorbance light fingerprint to fade or ring-down, you can measure extremely low levels of the absorbing contaminants.

A CRDS instrument is depicted in Figure 8.33r. A continuous-wave laser emits a beam of light energy through a highly reflective mirror into the absorbance cell (cavity). This cell is capable of reflecting the light back and forth many times and, by this multiple path design, will typically achieve total path lengths in the range of 100 km (vs. typically 100 m for typical absorbance multiple pass cells). Once the detector sees a preset level of light energy, the light source is diverted from the cavity. On successive passes of light, a small amount of light is sensed and, once the light *rings down*, the measurement is complete.

The sample concentration is determined from the shape of the ring-down decay curve. Figure 8.33s shows an example of a ring-down decay curve.

Because the measurement is time based, it is not subject to small variations in laser intensities. Because of its very long path length, where molecules in the sample are frequently exposed to the light, the sensitivity of the instrument is enhanced to a level of actually achieving part-per-trillion (ppt) levels of measurement on water in gases. This technology has been utilized primarily in the semiconductor industry, on ultrapure gases, and for bio-safety. Robust process-hardened instruments for more typical process applications are under development.

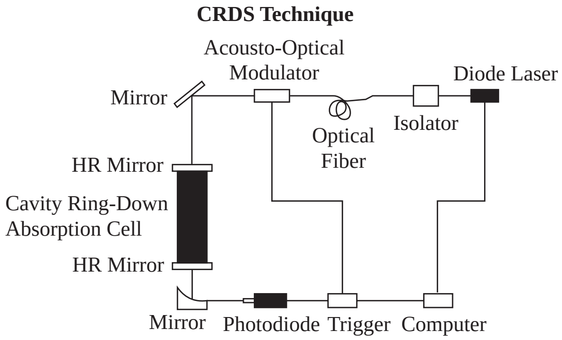

FIG. 8.33r
Cavity ring-down spectroscopy instrument. (Courtesy of Tiger Optics LLC.)

Sampling System Special sampling systems are required for this instrument. The sample must be clean, temperature controlled, pressure controlled, and noncondensing in addition to being compatible with materials that it will contact.

Limitations The unit is not suitable for moisture measurement in liquids or condensing vapors. Gas samples should be adequately cleaned and/or conditioned in an appropriate sampling system.

Neutron Backscatter Moisture On-Line Analyzer

This measurement principle is essentially the same as that of the nuclear moisture gauge discussed in greater detail in Section 8.34. It is a neutron radiation source that is focused on a sample, and the neutron backscatter is measured and

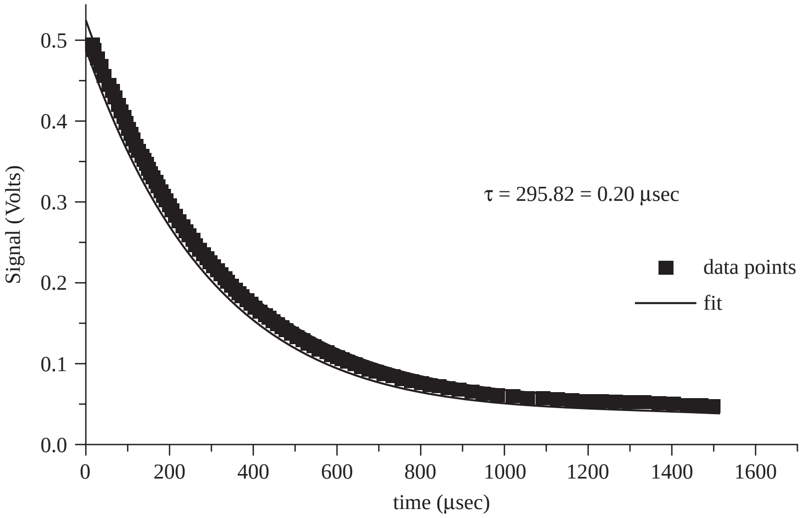

FIG. 8.33s
Typical ring-down decay curve. (Courtesy of Tiger Optics LLC.)

correlated to an appropriate moisture content. High-energy neutrons are focused on the sample. Backscattered low-energy neutrons that have interacted with a hydrogen nucleus are detected and correlated to the hydrogen/moisture density. As a result of the advancements in this design, it is now also being considered for some nonsolids applications, although the majority of its applications is still on solid samples. Figure 8.33t depicts a typical installation.

Because the measurement is so focused on the neutron and hydrogen nucleus interaction, it is not an appropriate measurement where hydrogen-containing species, other than water, can vary in concentration. This essentially eliminates the world of hydrocarbons, but it is still suitable for inorganic chemicals, salts, mineral applications, etc. Moisture in blast furnace coke is still the dominant application. Optional density compensation systems are available but are generally not required. This could be factor if you are encountering foam or slurries of significantly varying densities.

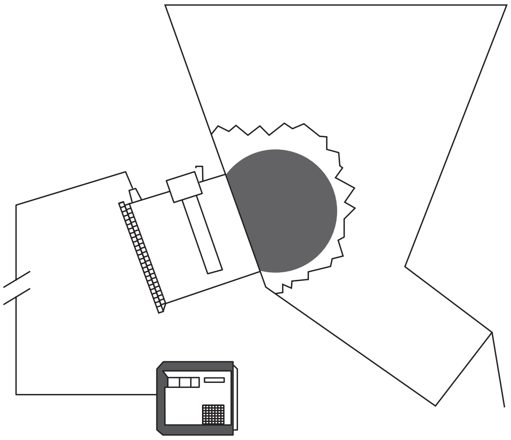

FIG. 8.33t
Example of a neutron backscatter moisture sensor installation. (Courtesy of Thermo Electron Corp.)

A sensor can typically measure a semisphere sample volume of approximately 18-in. (46 cm) radius. If one is monitoring a sample of varying consistency, the overall measurement accuracy can be increased by placing the sensor where it monitors a flowing sample. This effectively will give an integrated or averaged moisture value.

Sampling System There are usually no sampling system requirements for this instrument. The sensor is typically mounted directly on the process.

Limitations The unit is not suitable for moisture measurement in gases or samples with varying levels of hydrogen atoms (like most hydrocarbons). If the sample density varies significantly, a density measurement should be made for compensation.

Calibration of Moisture Analyzers

Moisture calibrators are available in two conceptual designs. They are based on either saturated gas dilution or permeation tube designs. Some moisture analyzers include a calibration system integral to the instrument or as an available option. In addition to calibration, these can be helpful to test/ensure that the moisture sensor is still alive and responding.

The first design that will be reviewed is the saturated gas dilution system concept. Figure 8.33u depicts a standard range and a lower range design. Both start out with a water-saturated vapor stream at a known temperature and, consequently, known moisture content. This stream is then diluted in a controlled (ratio) fashion with a dry gas stream to yield the desired value. Obviously, the larger the single-stage dilution ratio, the more difficult it is to maintain precise control.

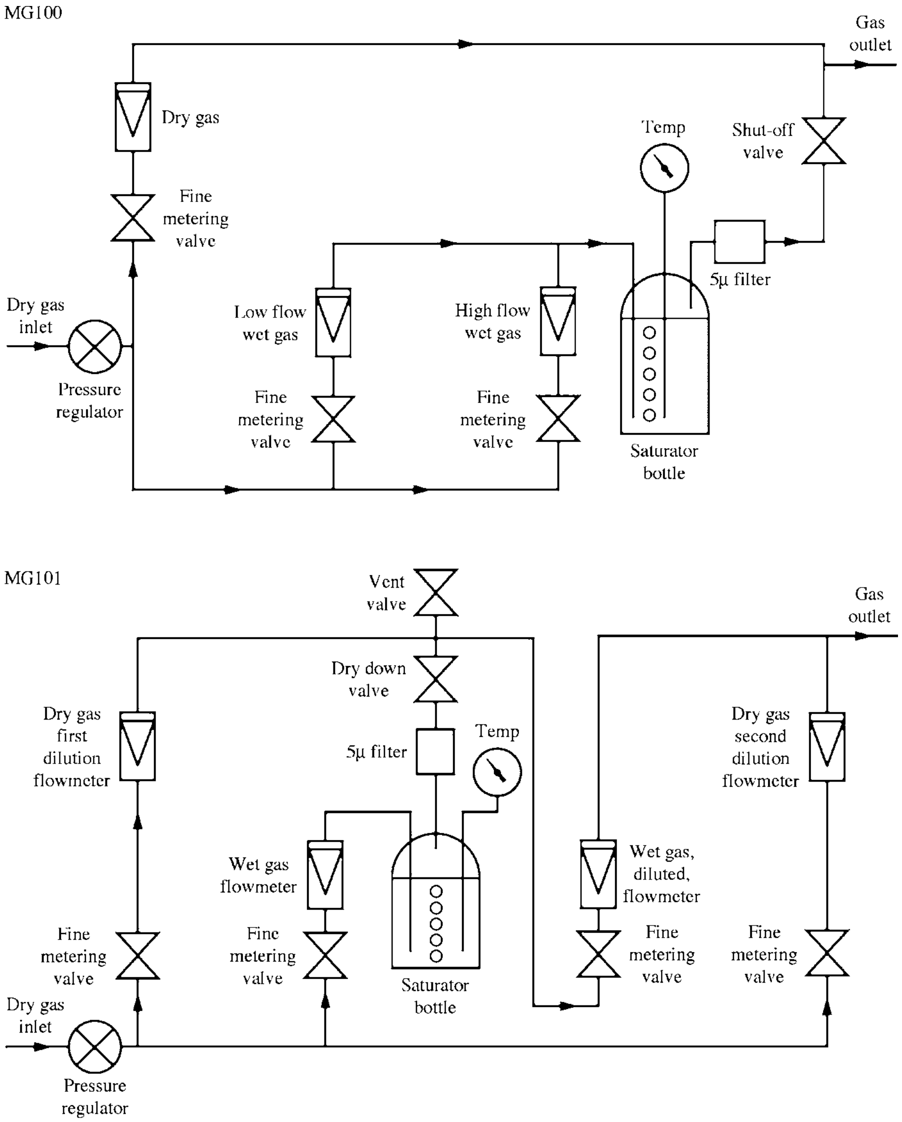

FIG. 8.33u

Example of gas dilution based moisture calibration systems. (Courtesy of Panametrics Inc.)

The lower system in the figure offers multiple opportunities (stages) to dilute the saturated stream with dry gas and will allow you to achieve more precise control of calibration samples at lower values than a large-ratio single-stage dilution approach.

The second design concept is the permeation tube design. Figure 8.33v depicts a simple permeation tube moisture calibration design. Permeation tube designs can be used to generate known standards from dry gases or to make known standard additions to samples or standards. They are based on the concept that, under controlled conditions, the rate/volume of moisture that will permeate through a permeation tube (its membrane wall) is constant. By also controlling these conditions and the dilution gas flow rates, one can at least generate a reproducible and predictable moisture standard. If one is adding it to a system, and if the dilution gas is truly dry or constant, it is possible to generate an actual moisture value. Typically permeation systems operate at much lower flow rates than saturation dilution systems.

A recent advancement of the permeation tube design is depicted in Figure 8.33w. It depicts a permeation tube system that is designed to introduce moisture into gas streams that contain reactive components. Some examples of reactive gas components that were considered include ammonia, HCl, HBr, chlorine, silane, and others. The reactive component does not come in contact with the permeation tube, and the reactive matrix is formed by dilution after the water addition. These need to be evaluated on an individual application basis and surely won't work for all situations, but they are a nice addition to the analyst's toolbox.

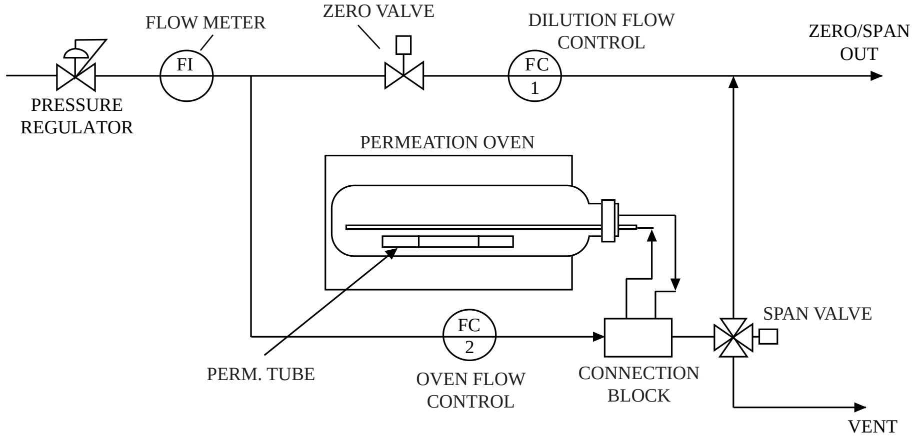

FIG. 8.33v
Example of a permeation tube based moisture calibration system. (Courtesy of Kin-Tek Laboratories Inc.)

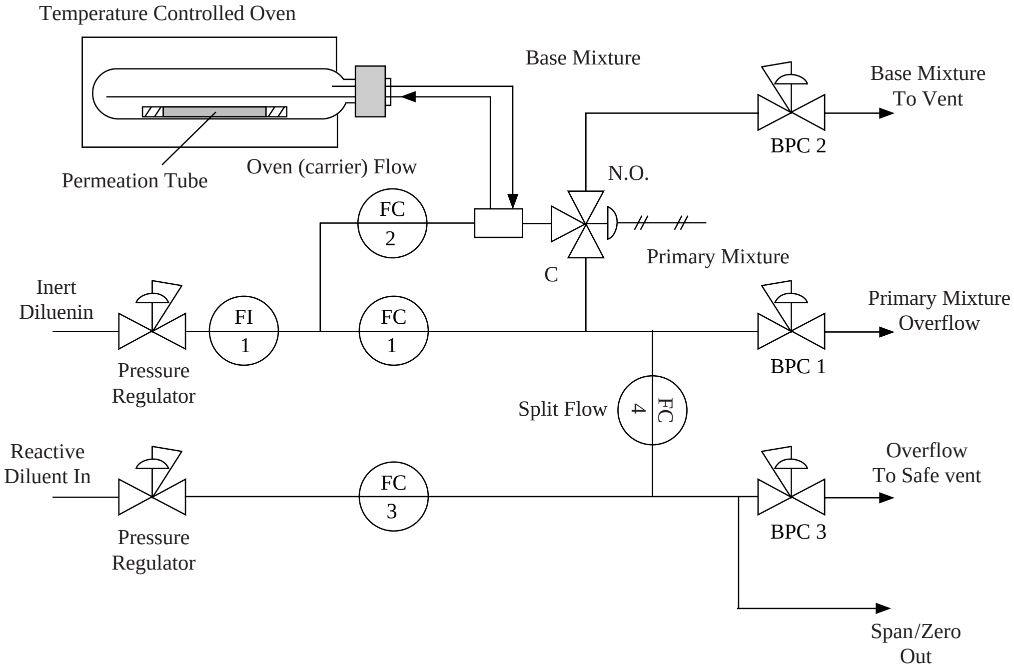

FIG. 8.33w
Example of a permeation tube based moisture in reactive gases calibration system. (Courtesy of Kin-Tek Laboratories Inc.)

Limitations Generally speaking, the saturated gas dilution design concept is better for generating higher concentration standards and higher standard flow rates. The permeation designs are better for lower concentration standards.

INTRODUCTION

In some cases, the moisture content of solids can be measured by the same types of analyzers that are used for the detection of moisture in liquid or gas samples. These devices, such as capacitance, infrared, and microwave sensors, have already been discussed in Sections 8.32 and 8.33 and, therefore, will be treated only briefly in this section. The laboratory-type moisture analyzers, such as the oven and the Karl Fischer type units, can also be used on both liquid and solid samples.

It should also be noted that the main purpose of this section is to describe the available choices for solids moisture analyzers and is not to give detailed descriptions of the families of analyzers involved. These descriptions are given in separate sections, such as Section 8.27, dealing with infrared analyzers, and Section 8.66, devoted to autotitrators and the like.

LABORATORY ANALYZERS

There are several discontinuous methods for moisture determination. One such method is to heat the solid sample in an oven and measure the resulting weight loss caused by the evaporation of the water in the sample. Some of the weight scale displays are provided with built-in indicators to display moisture content directly in weight percentage. For this method to be accurate, it is necessary that the sample contain no other volatile materials (besides water).

The moisture content of a sample can also be determined by monitoring the water vapor concentration in the atmosphere of a drying oven. To do that, an electrolytic hygrometer can be used, with it's output integrated during the period of drying.

Still another method utilizes the conversion of calcium carbide to acetylene as an indication of moisture in a preweighed sample. The quantity of the evolving acetylene is indicative of the moisture content of the sample.

None of these methods provides continuous output signals, and each requires a considerable lag between the taking of a sample and obtaining a measurement.

Karl Fischer Titration

The other widely used laboratory method of moisture analysis (accurate to 5 ppm) is Karl Fischer titration. When solids are analyzed, the sample must first be dissolved in a solvent. If the solids are not soluble, a solvent must be used to leach the moisture out of the solids. Once the moisture is transferred into the solvent, the titration is performed using the Karl Fischer reagent, which consists of a solution of sulfur dioxide, iodine, and pyridine in methanol. The titration end point can be obtained automatically (see Section 8.66) by detecting the current flow through the solution.

INDUSTRIAL DETECTORS

Instruments for continuous moisture measurement in solids are specialized, not because of their unique operating principles but because of the difficulty of handling solids samples. Instruments that infer the moisture content from such properties as dielectric constant and conductivity are not as reliable as those that measure moisture directly. This is because conductivity or dielectric constants are also affected by factors such as particle size and packing density, and the variations of such parameters are very difficult to predict and compensate for.

Nuclear Moisture Gauge

In this instrument, the neutron moderating characteristics of the hydrogen atoms; are used for moisture detection. Neutrons are subatomic particles that are emitted during the atomic decay of certain radioactive materials. These particles are electrically neutral and have a mass approximately equal to the mass of a hydrogen atom.

Theory of Operation Neutrons, because they lack an electric charge, are not deflected by the negative and positive charges associated with atoms; they are deflected or reflected only on impact with the atomic nucleus. Such an impact involves a change of momentum of the neutron and of the impacted nucleus. Because of the conservation of energy and momentum, after the impact, the energy of the neutron is decreased by an amount equal to the energy transferred to the impacted nucleus. The energy of the neutron after the impact is a function of the mass of the impacted atom.

This fact is explained by Equations 8.34(1) and 8.34(2) below. In these equations m_1 and m_2 respectively equal the mass of the neutron and the impacted atom. V_1 and V_3 are the neutron velocities before and after impact, and V_2 is the velocity of the impacted nucleus, which was initially at rest.

$$m_1V_1 = m_2V_2 + m_1V_3 \text{ (conservation of momentum)} \qquad \textbf{8.34(1)}$$

$$\tfrac{1}{2}m_1V_1^2 = \tfrac{1}{2}m_2V_2^2 + \tfrac{1}{2}m_1V_3^2 \text{ (conservation of energy)} \qquad \textbf{8.34(2)}$$

From Equation 8.34(1),

$$V_2 = \frac{m_1(V_1 - V_3)}{m_2} \qquad \textbf{8.34(3)}$$

Substituting 8.34(3) into Equation 8.34(2) and simplifying the results yields

$$V_3 = \frac{-V_1(m_2 - m_1)}{(m_1 + m_2)} \qquad \textbf{8.34(4)}$$

If the mass of the impacted nucleus is equal to the mass of the neutron, all of the neutron's kinetic energy is transferred to that nucleus, and V_3 becomes zero.

The hydrogen atom, because it is most nearly equal in its mass to the neutron, is the most efficient energy absorber (or moderator) of neutrons. Therefore, the number of reflected or moderated neutrons can be used as a measure of the number of hydrogen atoms present in the sample, which relates to its moisture content.

However, density also affects the amount of neutrons reflected. Therefore, it is necessary for a nuclear density gauge to be also included as part of the moisture measurement system. The output of the density gauge is used to compensate the neutron moisture measurement for sample density variations.

The Measuring System The measuring system contains a high-energy neutron source of plutonium-beryllium or americium-beryllium and a low-energy neutron detector. The density measurement is made by a gamma-ray source and detector arranged to measure reflected or transmitted gamma rays. The moisture and density measurement signals are fed to an electronic chassis where they are scaled to engineering units and presented for readout as a compensated moisture concentration.

The sensing unit can be mounted over conveyors, as shown in Figure 8.34a, on bins, or on pipelines. The sample volume should be fairly large, 16 in. (400 mm) wide and a minimum of 2 in. (50 mm) thick for conveyors, or a minimum of 8 in. (200 mm) diameter pipe size.

On conveyors where the solids bed may be of nonuniform thickness, a scraper plow or a roller should be installed ahead of the measuring head. When measuring moisture in a bin or chute, care must be taken to prevent material buildup on the vessel walls. For applications involving solids with a tendency to cake, the vessel wall should be lined with a nonsticking plastic such as Teflon® or be provided with a bin vibrator.

Limitations Because the instrument is sensitive to all hydrogen atoms, chemically bonded hydrogen in the sample is also seen as water. This can be corrected for by calibration only if the quantity of bonded hydrogen in the sample is constant and the amount of hydrogen present as free water is of the same order of magnitude as the amount of bonded hydrogen. If they are not of the same magnitude, a change in moisture concentration might not result in a detectable signal change.

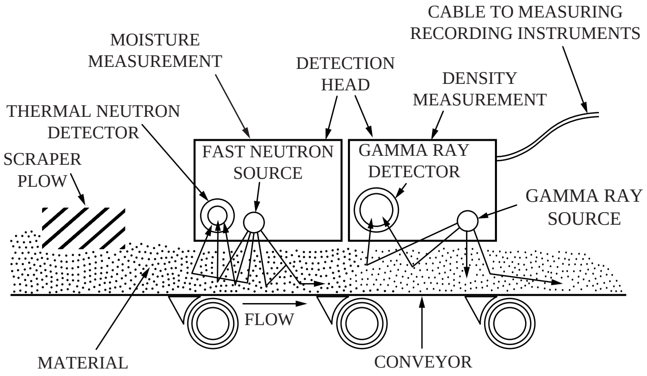

FIG. 8.34a
Nuclear moisture measurement.

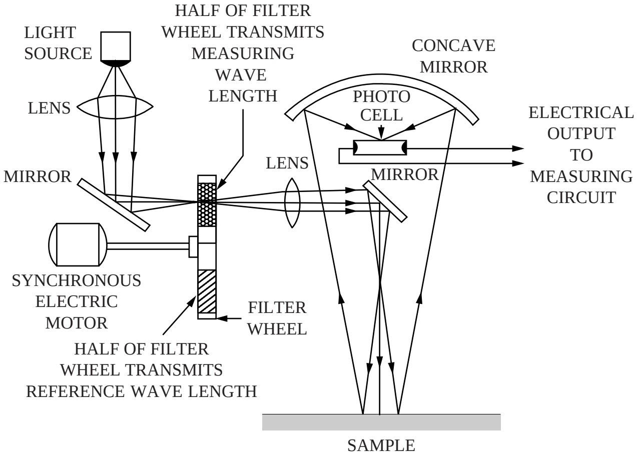

FIG. 8.34b
Infrared moisture measurement (reflectance). In microprocessor-based "quadra-beam" designs, four channels are used, and the measured reflections are ratioed to reduce drift and stabilize the measurement.

Infrared Absorption or Reflection

Infrared energy is selectively absorbed by water. When infrared analyzers are used for moisture measurement in solids, the measuring and reference beams are not transmitted through the sample, but they are reflected off the sample.

Measurement and Installation The sensing element consists of a light source, filters to pass the measuring and reference wavelengths, optics to direct the light beam onto the sample and to collect the reflected light, and a photocell to convert the reflected light into electrical current (Figures 8.34b and 8.34c). The sensor should be mounted so that the light aperture is a few inches from the sample.

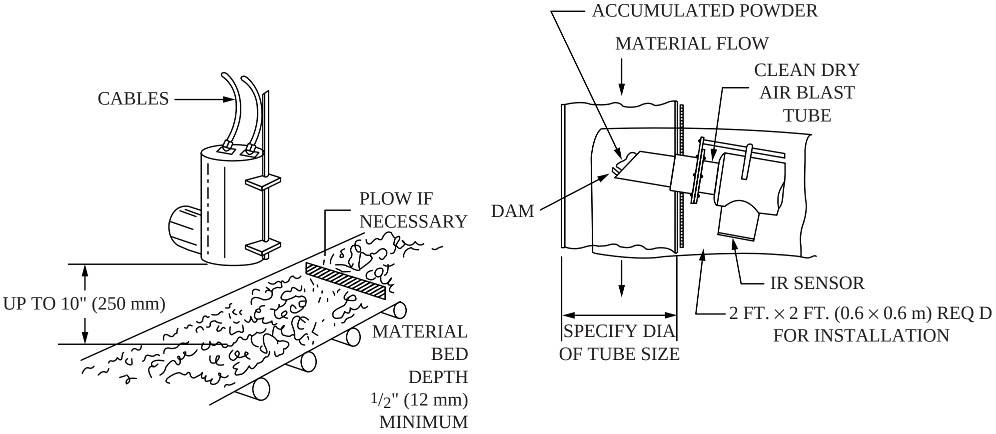

FIG. 8.34c
Installation of infrared moisture analyzers for belt and duct applications. (Courtesy of Aqua Measure Instrument Co., formerly Moisture Register Products.)

The two current pulse outputs of the photocell, which correspond to the reflected measurement and reference wavelengths, are converted into two DC signals. The ratio of these signals is read out as moisture content.

Limitations If the reflectivity of the sample is not above a minimum value, the amount of light reflected (and the change due to absorption) will be too small to produce a useful output. Graphite, coal, metal powders, and inorganic pigments are all poor reflectors of infrared, so this instrument cannot be used to analyze their moisture content.

Because infrared waves do not penetrate very far below the surface of the sample, the moisture measurement obtained will be representative of the moisture content on the surface of the material. If the surface moisture content is not representative of the average moisture content of the sample, this sensor cannot be used. This is usually the case when the sample is exposed to the ambient atmosphere. Due to drift in the instrument, periodic recalibration is necessary.

Microwave Attenuation

The operation of the microwave-type moisture analyzer has already been described in Section 8.33, and that discussion will not be repeated here.

Microwave-type solids moisture analyzers have been used to measure the water content of plastic powders, chips and pellets, soaps, grains, powdered clay, paper, hardboard, and plastic products. To measure the moisture content of moving webs or other materials that are thinner than 0.02 in. (0.5 mm), multiple transmission is required.

Because the absorption of microwaves is affected by both bulk density and solids temperature, both of these variables must be measured and compensated for if precise readings are desired. Such a compensated unit is illustrated in a gravity flow (or pneumatically conveyed) bypass application in Figure 8.34d.

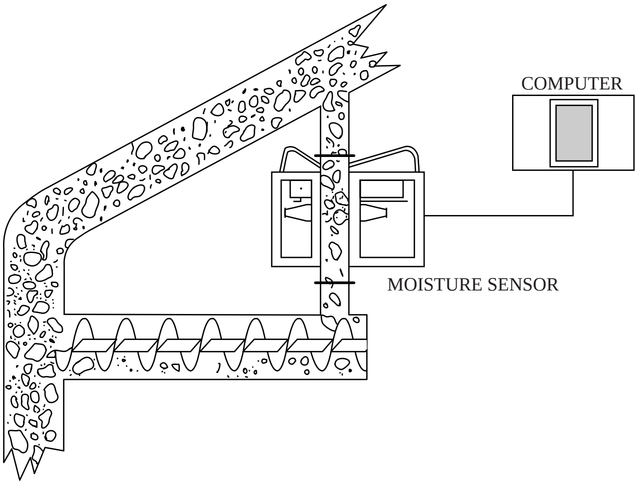

FIG. 8.34d
Microwave-type solids moisture analyzer with radiation densitometer correction. (Courtesy of ThermoMeasure Tech, formerly Kay-Ray/Sensall Inc.)

Basis Weight Compensation If contactless moisture detection is desired for a conveyor belt application where the product density varies, a microwave type analyzer can be compensated. Basis weight compensation can be obtained by the addition of a low-activity gamma radiation source as shown in Figure 8.34e. Basis weight compensation is available not only on conveyor belt installations but also for measurements in chutes and in vertical ducts and pipes.

Moisture in Coal Microwave analyzers can also be used to measure the moisture content of coal as it is being conveyed on a belt, without sampling or crushing (Figure 8.34f). These units are also automatically corrected for density and temperature variations and can detect the moisture content within about 0.5% over a range of 0 to 20%.

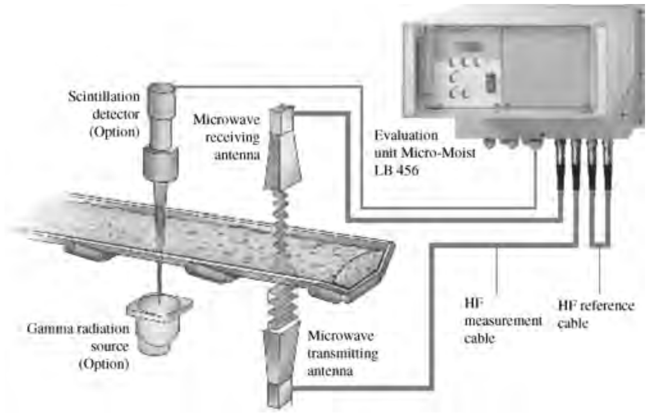

FIG. 8.34e
Noncontacting moisture analyzer can be provided with gamma radiation densitometer to compensate for variations in process density. (Courtesy of Berthold Technologies.)

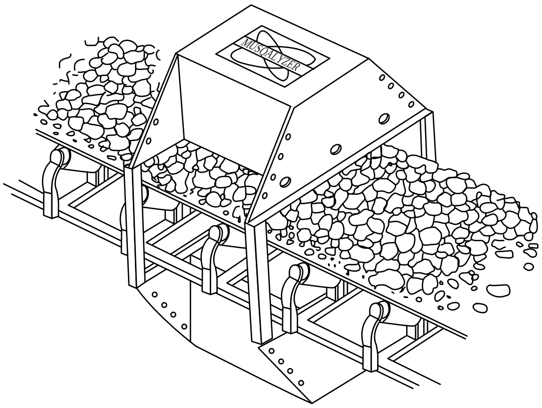

FIG. 8.34f
Continuous moisture-in-coal analyzer utilizing the microwave principle.

Sugar Industry Applications Microwave moisture analyzers have also been developed for such applications as the measurement of the dry substance content in the process of sugar extraction. These sensors can measure the sugar concentration both in the pipelines and in the sugar tanks or crystallizers. The pipeline units are flanged at both ends, whereas the tank mounted ones can be inserted through the nozzles of the crystallizers or other containers (Figure 8.34g).

Capacitance Moisture Gauge

The capacitance-type hygrometer has been described in connection with Figure 8.33e in Section 8.33. In capacitance-type measurements of moisture, the great difference in dielectric constants between the dry sample and water is utilized to perform the measurement. As the changes in moisture content affect the dielectric constant, the measured capacitance reflects that change and the variations are read as changes in moisture level.

FIG. 8.34g
Sugar concentration measurement by the use of microwave analyzers. (Courtesy of Berthold Technologies.)

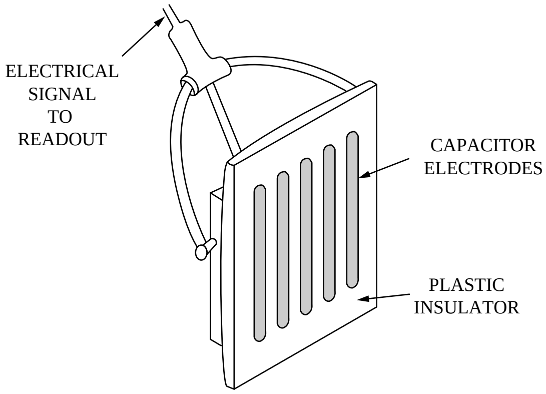

FIG. 8.34h
Capacitance-measuring head for moisture detection in solids.

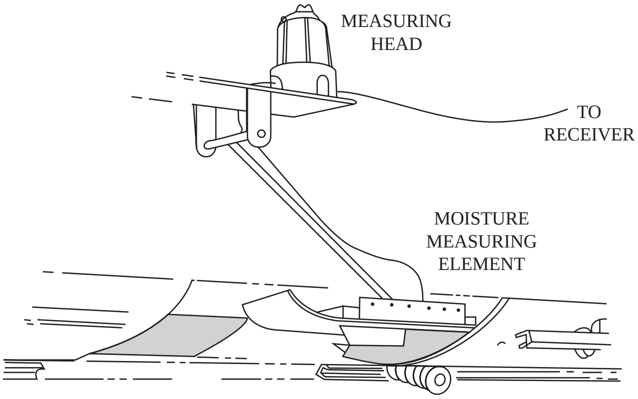

FIG. 8.34i
Ski-type probe for solids moisture detection.

Sensor Designs The measuring probe may consist of stainless steel electrodes embedded in plastic or in other insulators to form the measuring head of a capacitor (Figure 8.34h). The probe or measuring head lightly contacts the process material, which serves as the capacitor dielectric (the nonconducting material between the capacitor plates).

Another type of capacitive element is designed for moisture measurement in powders that are transported on conveyors. In that case, the capacitor plates are mounted at right angles to each other as shown in Figure 8.34i. In this design,

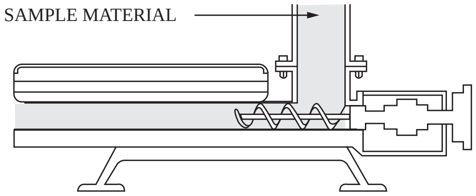

FIG. 8.34j
Force-fed measuring cell.

FIG. 8.34k
Dielectric constant monitoring probe for the remote measurement of soil moisture. (Courtesy of Automata Inc.)

the horizontal electrode rides on the powder surface while the vertical electrode is submerged. Other variations include force-fed measuring cells as shown in Figure 8.34j.

Capacitance is also used to detect the moisture content of agricultural products such as grains. The same principle can also be utilized to detect the moisture content of the soil by the insertion of a probe. Such a probe might consist of two electrodes with an insulating gap between them, and the capacitance circuit is used to measure the soil moisture as the dielectric constant of the insulator varies with the soil's moisture content.

The probe of the soil moisture monitor shown in Figure 8.34k is 3/4 in. in diameter and 27 in. long. It is normally installed vertically with intimate contact with the soil. The top 9 in. of the probe are passive, and only the bottom 18-in. section is used for measuring the soil moisture. The probe generates 0 to 5 V or 4 to 20 mA outputs, and several probes can be connected to a central computer, which can sound alarms or can automatically operate irrigation systems.

Capacitance Measurement Capacitance can be measured by two methods. One utilizes a capacitance bridge, which is analogous to the Wheatstone bridge, used for resistance measurement. Here, the bridge is excited by a radio frequency (RF) alternating current (AC) signal while a servomotor continuously balances the capacitive reactance of the measuring capacitor with the reactance of a known capacitor. (Capacitive reactance of an AC circuit is the part of the impedance that is due to capacitance.)

Alternatively, the measuring capacitor can be connected in parallel with a known inductance to form a parallel resonant circuit. This circuit is powered by a constant frequency source. In this case, the output voltage becomes a function of connected capacitance. At resonance, this output is a maximum and decreases nonlinearly for larger and smaller values of capacitance. The nonlinearity can be minimized by an appropriate choice of circuit parameters and by narrowing the operation of the instrument to a limited portion of the resonance curve.

Limitations In all capacitance measurements, the capacitance of the solids is a not a unique function of the moisture content of the process material; it is also affected by such factors as particle size, packing, and material density. Therefore, such moisture measurements will be accurate only if these variables are constant or can be compensated for.

Resistance Moisture Gauge

The electrical resistance of nonconducting solids is also a function of their moisture content. Instruments that take advantage of this fact use a balanced bridge circuit to detect these resistance changes (Figure 8.34l).

In this design, the measuring electrodes form a part of the bridge circuit as they contact the process solids. A regulated voltage is applied to the electrodes so that a small current flow is maintained through the solids. The changes in the moisture level result in a change of electrode current. Therefore, the amount of bridge imbalance is related to the moisture content. This probe also detects the capacitive reactance caused by the moisture level changes, but this portion of the measurement is continuously balanced by servomotor driven reference capacitor.

Limitations The accuracy of this measurement is strongly influenced by the contact pressure between sample and electrodes, the operating temperature, packing density, and particle size. In addition, the resistance values that are measured are very high, so good insulation is required at the electrodes to prevent leakage currents from introducing an error.

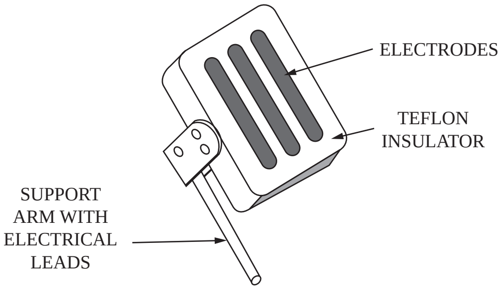

FIG. 8.34l
Resistance measuring head.

Impedance Moisture Gauge

The moisture content solids can also be measured indirectly by detecting the moisture in the atmosphere above or near the process solids. The atmosphere near the solids is in equilibrium with the moisture content of the process materials. Therefore, several of the instruments discussed in Sections 8.32 and 8.33 can be used in this type of measurement.

In particular, the change-of-impedance type of hygrometer is well suited, because its sensing element is small and can be easily mounted close to the solids surface (see Figure 8.33j). However, for this measurement to be effective, the element must be situated so that no drafts or convection currents occur, because even small air movement will influence the moisture measurement.

Nuclear Magnetic Resonance

A rather expensive solids moisture analyzer design is based on the phenomenon of nuclear magnetic resonance (NMR). NMR is capable of distinguishing the different atoms within a sample. When these atoms are in a constant magnetic field, the absorption characteristics of the nucleus of these atoms will be different and will be reflected by their RF energy. The advantages of the NMR method of moisture measurement include speed, accuracy, and nondestructive nature, whereas its disadvantage is high cost.

Radio Frequency Absorption

Similar to microwaves, the attenuation of RF radiation by the process solids can also be used to detect moisture. The water molecules absorb the RF energy in the form of molecular motion. By means of special electrodes, portable units have been marketed for sheet-paper moisture measurements. On-line, continuous moisture analyzers are also available for paper, food, chemical, gypsum wallboard, lumber, and other flat products. The analyzer must be calibrated to the particular product under test.

High-temperature RF moisture transmitters are also available for services up to 500°F (260°C). The analyzer can be installed inside dryers or kilns and is capable of continuous operation in contaminated atmospheres. All electronic components are mounted outside the kiln.

CONCLUSIONS

Of the methods available for moisture measurement in solids, the nuclear moisture gauge represents the most refined and accurate design. Other methods, such as infrared, microwave, and RF absorption, can also be used, particularly when the other process variables that affect the reading, such as temperature and particle size, are kept constant or are compensated for.

Capacitance-type instruments can be used effectively on sheet paper, cardboard, and other materials where such factors as particle size and packing density are constant.

INTRODUCTION

Molecular weight measurement of gases and vapors has already been discussed in the chapter on density in Section 6.10 and in several sections of this chapter. Therefore, this section will concentrate only on the measurement of liquid molecular weights. Some of the instruments used in the measurement of the molecular weights of larger molecules, such as viscometers or gel-permeation chromatographs, are treated in more detail in Sections 8.13, 8.29, and 8.64 of this chapter.

THE AVERAGE MOLECULAR WEIGHT

Polymers consist of large molecules formed by the bonding of relatively simple and similar parts. The size and shape of the polymer molecules are determined by the number of basic building blocks and by the way these are linked together. For example, the basic blocks might be arranged in chains of various lengths, in chains with branches, or in two chains linked in several places. Thus, while the molecular weight of the basic building blocks might be known, polymers are a mixture of molecular species covering a wide range of sizes, and no definite molecular weight can be assigned to them.

However, an average molecular weight of this molecular weight distribution can be determined and is useful in predicting the physical properties of the polymer. Among the methods available for the determination of the average molecular weight are osmometry, light scattering, viscometry, gel-permeation chromatography, end group determination, electron microscopy, ultracentrifuging, sedimentation, and diffusion.

Each of these methods yields an average that must be defined, since the averages obtained are not identical, as is illustrated by the following example.

Example Consider 10 lb of polymer consisting of the following:

5 lb of molecular weight 10,000
3 lb of molecular weight 20,000
2 lb of molecular weight 120,000

The average of the weight fractions yields

$$10\overline{M} = 5\times 10,000 + 3\times 20,000 + 2\times 120,000$$
$$\overline{M} = 35,000 \tag{8.35(1)}$$

The average molecular weight obtained is called the weight average and is designated by Mw.

The average of the mole fraction yields

$$\frac{10}{\overline{M}} = \frac{5}{10,000} + \frac{3}{20,000} + \frac{2}{120,000} \tag{8.35(2)}$$
$$\overline{M} = 15,000$$

This average is called the *number average molecular weight* and is designated by Mn.

The averages obtained are not identical. The weight average emphasizes the large molecules, and the number average the small ones. For this reason, an average molecular weight must always be defined. In general, Mw and Mn are defined as:

$$\mathrm{Mw} = \frac{\Sigma \mathrm{WiMi}}{\Sigma \mathrm{Wi}} = \frac{\Sigma \mathrm{niMi}^2}{\Sigma \mathrm{niMi}} \tag{8.35(3)}$$

$$\mathrm{Mn} = \frac{\Sigma \mathrm{Wi}}{\Sigma \mathrm{ni}} = \frac{\Sigma \mathrm{niMi}}{\Sigma \mathrm{ni}} \tag{8.35(4)}$$

where ni represents the number of moles, Wi the weight of the fraction, and Mi the molecular weight of molecules of size i. Additional averages can be defined as

$$M_z = \frac{\Sigma niMi^3}{\Sigma niMi^2} \qquad \textbf{8.35(5)}$$

and

$$Mv = \left(\frac{\Sigma niMi^{a+1}}{\Sigma niMi}\right)^{1/a} \qquad \textbf{8.35(6)}$$

where a is defined by the equation

$$[\eta]K(Mv)^a \qquad \textbf{8.35(7)}$$

and $[\eta]$ is the intrinsic viscosity of the polymer, and K is a constant. The definition of intrinsic viscosity is given under the discussion of viscometers in this section.

OSMOMETERS

Osmotic pressure is defined as the pressure that must be applied to the solution to stop osmosis from the pure solvent. Osmotic pressure, π, is related to solution concentration and molecular weight of the solute as given by Equation 8.35(8).

$$\pi = \frac{RT}{M}c + Bc^2 + Cc^3 \qquad \textbf{8.35(8)}$$

where R is the ideal gas constant, T is absolute temperature, c is the solution concentration, and B and C are virial coefficients.

The first term of the equation is the van't Hoff relationship for ideal solutions. However, polymer solutions are anything but ideal, so at least the second term of Equation 8.35(8) can never be neglected. Because there are two unknowns, M and B, in the equation, at least two measurements are required. Equation 8.35(8) is therefore rewritten as

$$\pi/c = \frac{RT}{M} + Bc + Cc^2 \qquad \textbf{8.35(9)}$$

The measured values of π are plotted as π/c vs. c. The measurement points are linearly extrapolated to c = 0 where the terms containing the unknown virial coefficients go to zero. The value of M can then be calculated from the relationship given in Equation 8.35(10).

$$M = \frac{RT}{(p/C)_c} = 0 \qquad \textbf{8.35(10)}$$

The molecular weight M thus obtained is the number average molecular weight Mn.

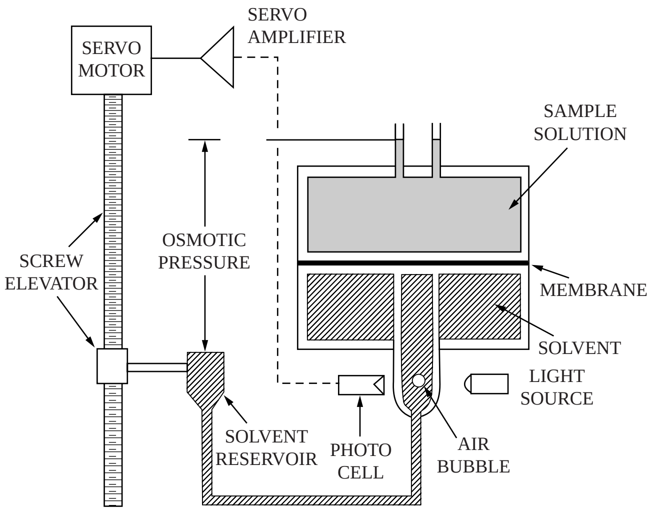

FIG. 8.35a
Membrane-type automatic osmometer.

The Membrane Osmometer

The membrane osmometer (Figure 8.35a) consists of two compartments separated by a semipermeable membrane. A pure solvent and a dilute polymer solution are introduced into the two compartments, respectively. The membrane acts as a filter to permit passage of solvent molecules but not that of the polymer. Migration of solvent molecules into the solution results in a change in pressure between the two compartments until osmotic pressure is reached. Osmotic pressure is defined as the pressure that must be applied to the solution to stop osmosis from the pure solvent. It is used to obtain the number average molecular weight.

Static osmometers are provided with a capillary connection to the solution compartment so that osmotic pressure can be read as hydrostatic head. The principal disadvantage of the static osmometer is the long time, which is required to reach equilibrium 1 to 2 hr and longer. Automatic osmometers (Figure 8.35b) are available, which determine osmotic pressure dynamically. In these units, the rate of solvent flow through the membrane is measured as a function of externally applied pressure.

Automatic Osmometers One type of automatic osmometer has a solvent reservoir mounted on a screw elevator and connected to the solvent side of the membrane by a capillary in which there is a small air bubble. A light source and photocell sense the position of the air bubble as it tends to move with any flow of solvent in the capillary. The photocell output activates a servomotor, which, in turn, positions the solvent reservoir to reduce pressure on the solvent compartment, thus stopping osmotic flow. As a result, the static head of the solvent is exactly opposed to the osmotic pressure of the solution. The hydrostatic head on the solvent side can be continuously displayed in digital form, or the pressure can be recorded providing a permanent record of the measurement (Figure 8.35c).

Another automatic osmometer utilizes a diaphragm to sense an increased pressure in the solvent compartment, which results in a change of capacitance in an oscillator. A signal to a servomotor positions a plummet in the manometer to reduce the pressure on the solvent side of the membrane by an amount equal to the osmotic pressure.

Automatic osmometers are thermostatically controlled, because temperature enters into the measurement. With automatic osmometers, the operating temperature is a minimum

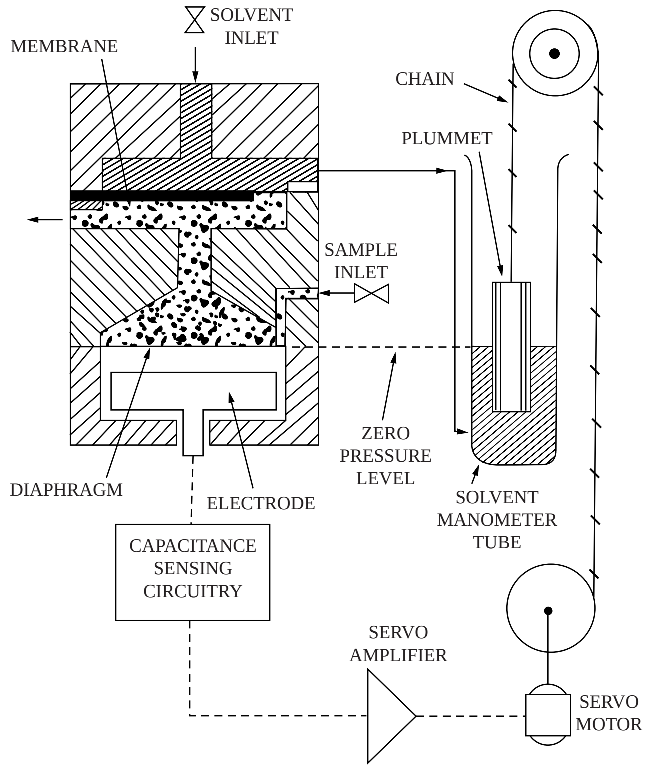

FIG. 8.35b
Automatic osmometer.

Sample: Polystyrene Temperature: 36°C Solvent: Toluene

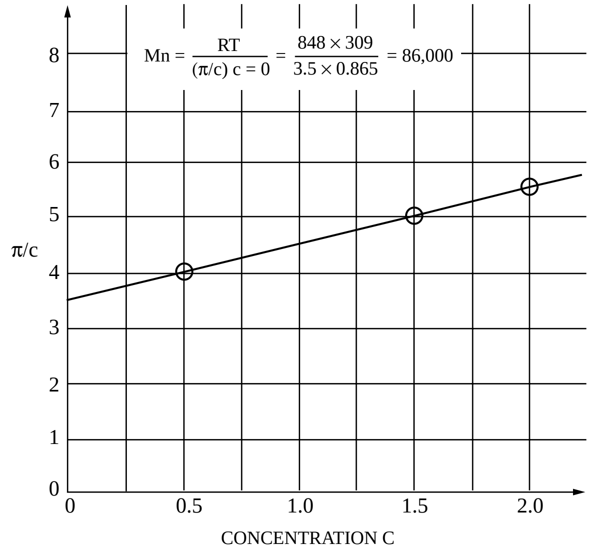

FIG. 8.35c
Membrane osmotogram.

of 10°F (6°C) above ambient to ensure good temperature control. However, for a given sample, the lowest possible operating temperature is selected to ensure longer membrane life and to inhibit possible corrosion.

Static osmometers are not provided with temperature control, so some means of maintaining a constant temperature must be provided. Usually, the measurement is made in a constant-temperature bath. The operating temperature depends on the melting point of the sample and the lowest temperature required to keep it in solution.

Vapor Pressure Osmometers

The vapor pressure of any solvent is lowered by the addition of solute. If a pure solvent and a solution are placed in two containers and connected in a closed system, the pure solvent will evaporate and condense into the solution. The resultant temperature difference, due to the latent heat of evaporation of the solvent, can be detected as an indication of the molecular weight of the solute. In practice, the temperature difference is read as the output voltage of a resistance bridge using high-accuracy temperature sensors (Figure 8.35d).

The relationship between the bridge output voltage ΔV, the solution concentration c, and the average molecular weight Mn is given by Equation 8.35(11).

$$\left(\frac{\Delta V}{c}\right)_{c=0} = \frac{K}{Mn} \tag{8.35(11)}$$

where K is the calibration constant for the particular combination of solvent and type of thermistor used.

Although the amount of drop in vapor pressure is only a function of the amount of solute in solution and of the solute molecular weight, ΔV is a relative quantity depending on the

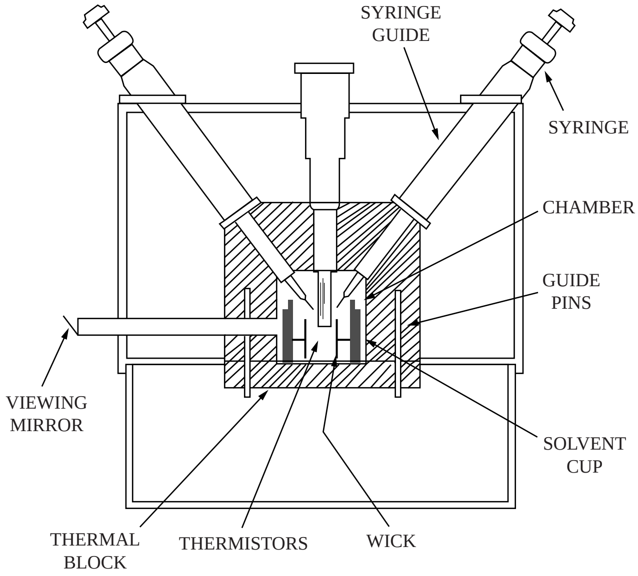

FIG. 8.35d
Vapor-pressure osmometer.

Sample: Fatty Acid Temperature: 35°C Solvent: Toluene
Calibration Factor K = 350

Concentration C gm/liter	5	7.5	1.5
1. Output ΔV	1.40	2.15	4.35
2. Output ΔV	1.40	2.16	4.35
3. Output ΔV	1.41	2.14	4.35
ΔV average	1.40	2.15	4.35
ΔV/C	0.280	0.287	0.290

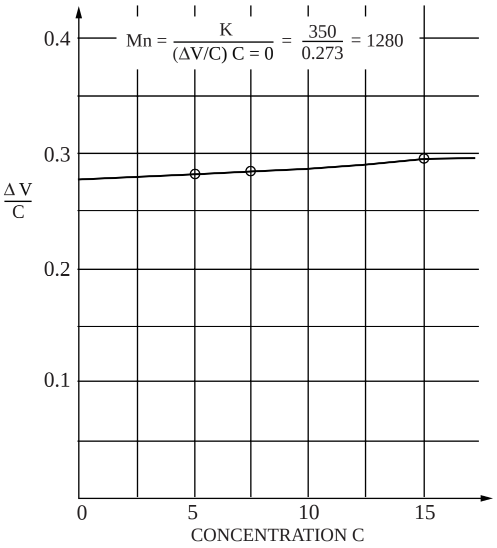

FIG. 8.35e
Vapor-pressure osmotogram.

solvent, operating temperature, and temperature-sensing element used. The instrument, therefore, must be calibrated with a known solution.

In practice, several values of ΔV are obtained at different concentrations, and these are plotted on a graph of ΔV/c vs. c (Figure 8.35e). The graph is than extrapolated linearly to c = o and the value of K determined. Once the value of K is known, Mn can be determined in the same manner for any polymer in the solution.

The vapor-pressure osmometer consists of a thermostated chamber saturated with solvent vapor. Two thermistor beads are suspended in the chamber, and syringe guides are built into the chamber. Using the syringes, a drop of solvent and a drop of solution are placed on the reference and measuring thermistor, respectively.

As the solvent condenses, it warms the measuring thermistor. Therefore, its electrical resistance decreases. The thermistors are part of a resistance bridge whose output is in proportion to the temperature difference between measuring and reference thermistor. The resistance bridge output ΔV is plotted on a graph of ΔV/c vs. c.

The applicability of this instrument is limited because of the small difference in temperatures that need to be detected. Typically, for a 1% solution of 50,000 molecular weight polymer, the temperature difference is on the order of 0.001°F (0.0006°C).

LIGHT-SCATTERING PHOTOMETER

Polymer molecules dissolved in a suitable solvent cause scattering of the incident light. From the intensity and distribution angle of the scattered light, the weight average molecular weight, Mw, can be determined. When the molecules are small in comparison to the wavelength used, the scattered light has the same intensity for all angles of observation except for its polarization. For such molecules, a single observation at 90° to the incident light beam is sufficient.

If molecular size approaches the wavelength of light used, the light is scattered by portions of the molecule, which are widely separated. The light will undergo destructive interference, reducing the intensity of scattering. Destructive interference is a function of the light beam's angle. In other words, interference will be zero in the direction of the incident light and will increase with the angle of observation.

The Zimm Plot

The Zimm plot (see Figure 8.35f) utilizes data taken over as large an angular range as possible and extrapolated to

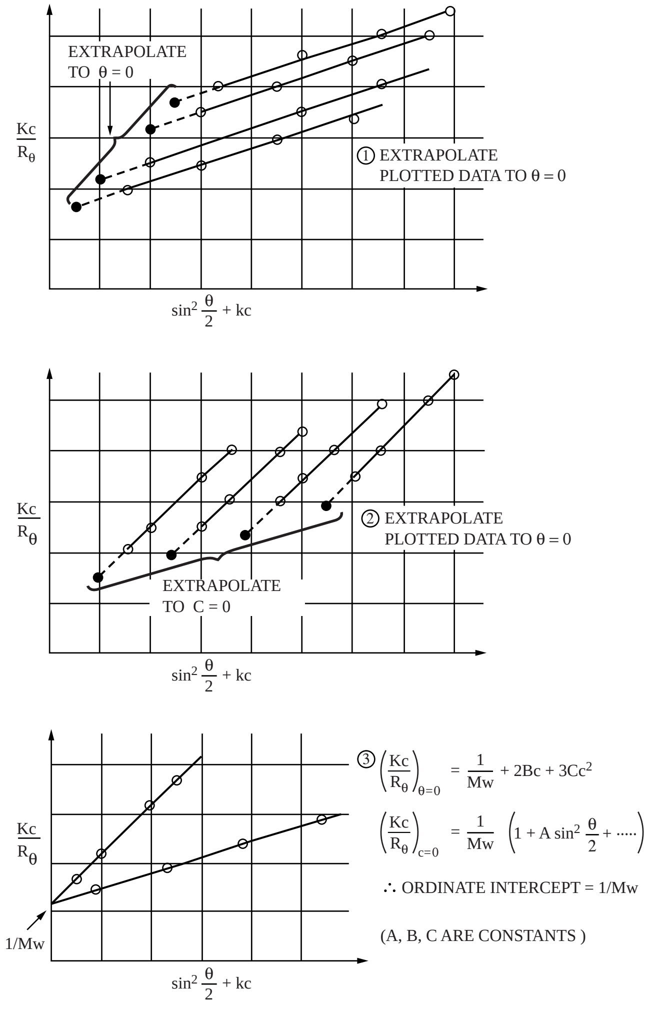

FIG. 8.35f
Zimm plot construction.

zero angle. The ordinate is intercepted at zero angle, when the concentration (1/Mw) is zero. The ordinate of the Zimm plot is Kc/R_θ and the abscissa is $\sin^2(\theta/2) + Kc$, where

$$K = \frac{2\pi^2 n^2 \left(\frac{dn}{dc}\right)}{A\lambda^4} \qquad \textbf{8.35(12)}$$

where

$n =$ index of refraction of the solution
$A =$ Avogadro's number
$\lambda =$ wavelength of light used
$\theta =$ angle of observation
$R\theta =$ Rayleigh ratio at the wavelength used for the fluid the sample cell is immersed in (ratio of intensities of scattered light to incident light)
$c =$ solution concentration
$K =$ arbitrary constant chosen to give a convenient spread between data points
$\frac{dn}{dc} =$ change of refractive index with concentration

To obtain the Zimm plot, four concentrations are usually prepared along with pure solvent, and the data are collected at a number of incident light angles (10 or more). The scattered intensity for a reference substance (I_s) is measured at 90°. The change in refractive index with concentration (dn/dc) is obtained with a differential refractometer.

Step 1 $I\theta = I_s$ (calibration factor, which is supplied with instrument)

If the scattered light intensity ($I\theta$) of the material in which the cell is immersed is being measured, $I\theta$ is obtained directly.

Step 2 Correct each measurement for solvent scattering,

$$I_\theta = I_\theta \text{ solution} - I_\theta \text{ solvent}$$

and correct for incident light polarization,

$$I \text{ corrected} - I_\theta \times \alpha$$

where $\alpha = \sin\theta$ for vertically polarized incident light and $\alpha = \frac{\sin\theta}{1+\cos^2\theta}$ for unpolarized incident light.

Step 3 Calculate K from Equation 8.35(12).

Step 4 Calculate the Zimm coordinates from Equations 8.35(13) and 8.35(14).

$$\frac{Kc}{R_\theta} = \frac{K}{I \text{ corrected}} \times \frac{I\theta}{R\theta} \text{(ordinate)} \qquad \textbf{8.35(13)}$$

and

$$\sin^2\left(\frac{\theta}{2}\right) \times kc \text{ (abscissa)} \qquad \textbf{8.35(14)}$$

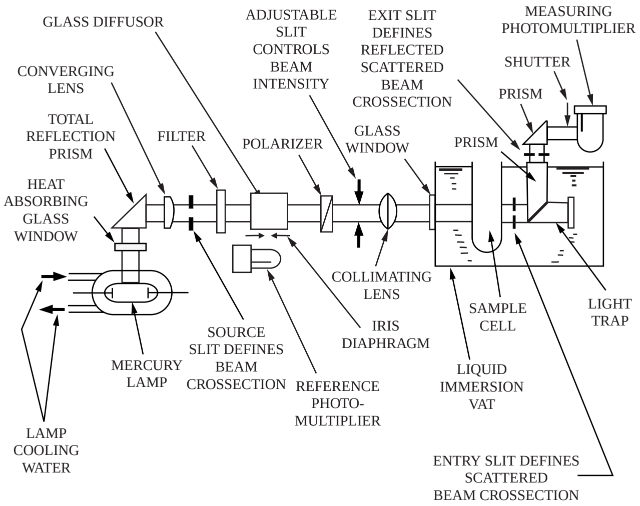

FIG. 8.35g
Light-scattering photometer.

The Photometer

A narrow, high-intensity beam of light is generated by a light source, which usually is a mercury vapor lamp. It is provided with a filter to provide green light at 5461 Å or blue light at 4358 Å (Figure 8.35g). This beam is focused on the sample cell, and light that is passing through the sample cell is absorbed in a light trap to avoid reflective interference with the measurement. The light, which is scattered by the sample, is converted by the measuring photomultiplier to an electrical current whose intensity is measured.

The photomultiplier is mounted on a platform, which can be rotated so that the viewing angle can be varied from 30 to 150° to the incident light beam. Since the light source intensity always varies somewhat, part of the generated light beam is permitted to impinge on a reference photomultiplier. The reference photomultiplier output can then be used to automatically compensate the measurement. Another way to perform the compensation is as follows: $I_\theta = i_\theta/i_s$, where I_θ represents the true measurement intensity, i_θ is the output of the measurement photomultiplier, and i_s is the output of the the reference photomultiplier.

Design variations include the use of an immersion vat for the sample cell. This vat is filled with a fluid whose refractive index is the same as that of glass to eliminate refraction at the sample cell.

The sample for this instrument must be very carefully de-dusted by filtering to remove all suspended particles. The use of a sample vat does not eliminate the requirement for removing all dust from the sample.

VISCOMETERS

The various devices that are available for viscosity measurement are discussed in Sections 8.62, 8.63, and 8.64.

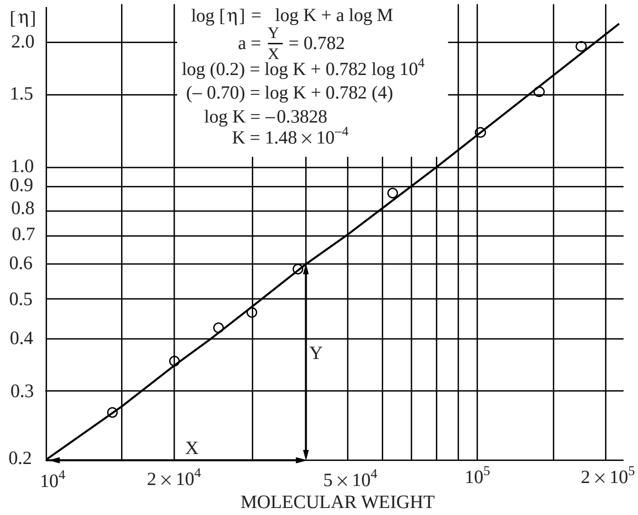

FIG. 8.35h

Viscometer calibration for K and a.

Viscosity vs. Molecular Weight

To determine the molecular weight of a polymer from viscosity measurement, the polymer's intrinsic or limiting viscosity must first be determined (Figure 8.35h). Intrinsic viscosity $[\eta]$ is defined by the relationships below:

$$[\eta] = \lim_{c\to 0}\frac{\eta-\eta_0}{\eta_0 c} = \lim_{c\to 0}\frac{\eta_{sp}}{c} \tag{8.35(15)}$$

$$\eta_{sp} = \frac{\eta-\eta_0}{\eta_0} \tag{8.35(16)}$$

where η is the viscosity of the solution, η_0 is that of the solvent, and c is the solution concentration in grams per milliliter or grams per deciliter.

Another definition of intrinsic viscosity is

$$[\eta] = \lim_{c\to 0}\frac{\text{In}\ \eta/\eta_0}{c} \tag{8.35(17)}$$

Intrinsic viscosity is related to the molecular weight in accordance with the Mark-Houwink equation,

$$[\eta] = KM^a \quad \text{or} \quad \log\ [\eta] = \log\ K + a\ \log M \tag{8.35(18)}$$

where K and a are constants for a given polymer-solvent system at the temperature of the viscosity measurement.

Intrinsic Viscosity

Viscosity measurements are made of a well fractionated or monodisperse polymer whose molecular weight is known or has been measured by some other method (Figure 8.35i). The intrinsic viscosity is calculated by plotting $(\eta - \eta_0)/\eta_0$ vs. c and by extrapolating linearly to c = 0. If the plot of $(\eta - \eta_0)/\eta_0$ vs. c does not fall on a straight line, log η/η_0 can be plotted vs. c for better linearity.

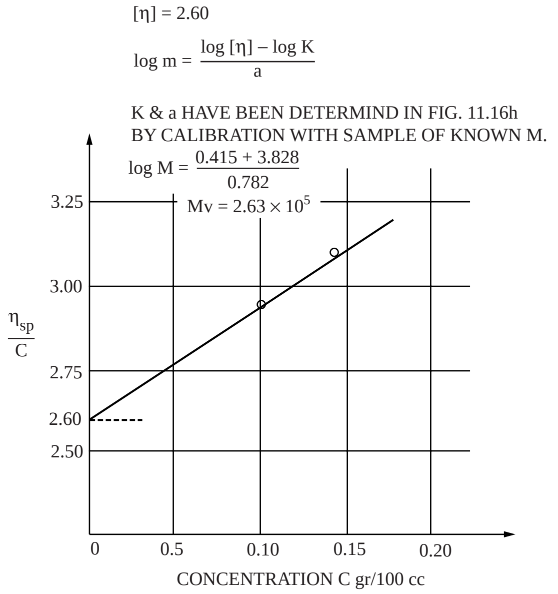

FIG. 8.35i

Determination of intrinsic viscosity and average molecular weight.

The values of intrinsic viscosity $[\eta]$ obtained are plotted as a function of the known molecular weight on log-log paper, and the constants a and K are evaluated. Once K and a are known, Mv for a polydisperse sample can be calculated.

The limitation of this method is that the empirical relationship $[\eta] = KM^a$ is valid only for linear polymers.

GEL-PERMEATION CHROMATOGRAPHY

This technique is based on the chromatographic separation of molecules by size. A solvent stream is split, and a polymer sample is added to one half of the stream. The solution is directed into a column packed with a rigid, cross-linked styrene gel. As the polymer moves into the column, the smaller molecules diffuse into the gel pores while the larger ones cannot penetrate and thus follow a shorter path. Molecules are therefore eluted from the column in the order of their sizes, with the smallest molecules eluting last (Figure 8.35j).

Differential Refractometer Sensor

Solution and solvent are passed through the measuring and reference cells of a differential refractometer in which the difference in refractive index between the sample and solvent is measured (Figure 8.35k). The output curve represents the relative abundance of molecules of a particular size from which a molecular weight distribution can be plotted and average molecular weights can be determined.

The differential refractometer utilizes a collimated light beam, which is passed through the reference and sample solutions and then is reflected back through both solutions by a mirror. The beam is split by another mirror, guaranteeing

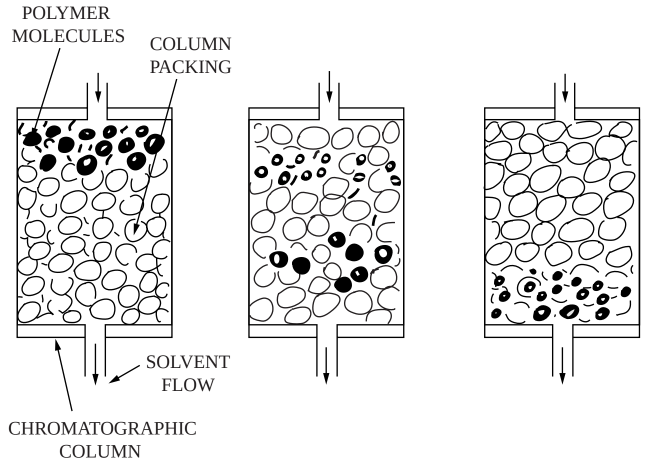

FIG. 8.35j

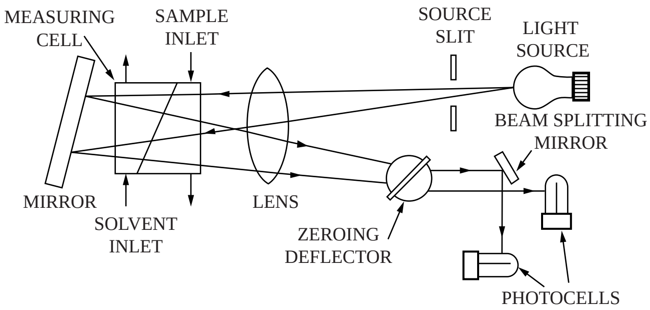

FIG. 8.35k
Schematic of refractometer used with gel-permeation chromatograph.

that equal amounts of light will fall on the two photosensors. The photosensor and two resistors form a resistance bridge whose output is proportional to the difference in the amounts of light falling on the photocells.

Changes in refractive index of the solution cause the light beam to shift so that unequal amounts of light will fall on the two photosensors. These refractive index variations are related directly to solution concentration. Thus, elution time and resistance bridge output will signal the relative abundance of molecules of a particular size.

The Complete Instrument

The instrument consists of a free-standing assembly containing the chromatograph portion refractometer, recorder, and control electronics.

The chromatograph portion consists of two sets of columns with column switching valves, sample injection valves, and solvent loop. Solvent from a reservoir is degassed in a heater, and flow is controlled by a positive displacement pump (Figure 8.13a).

The total solvent flow is split into two equal streams. One half is passed through the sample loop, and the other half serves as the reference. Both the sample and solvent are passed through two column banks, respectively, before entering the refractometer cell. The solvent is then returned to the reservoir, and the sample is discharged to a sample collector. Each 5-ml increment of sample volume discharged is marked automatically on the recorder trace to indicate elution time.

The electronics consist of several subassemblies, including refractometer controls, automatic sample injection controls, and the main control assembly.

Molecular Weight from Chromatograph Output

For the steps used in determining the molecular weight from the refractometer output curve, refer to Figures 8.35l, 8.35m, and 8.35n. To determine molecular weight from the

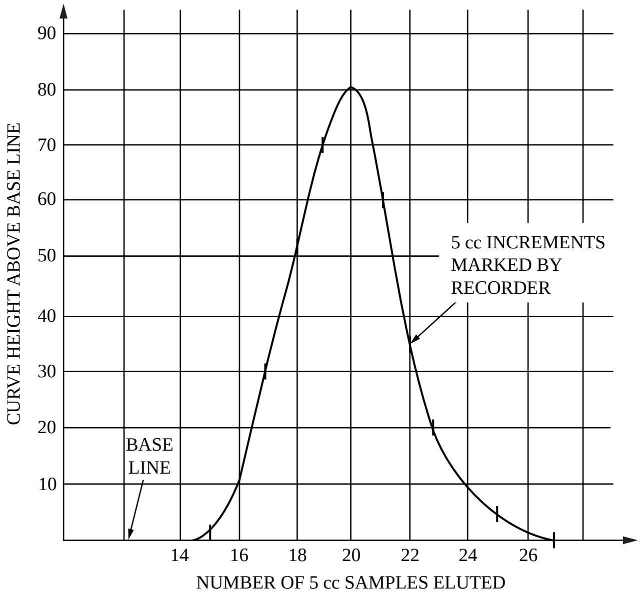

FIG. 8.35l
Chromatograph output distribution curve.

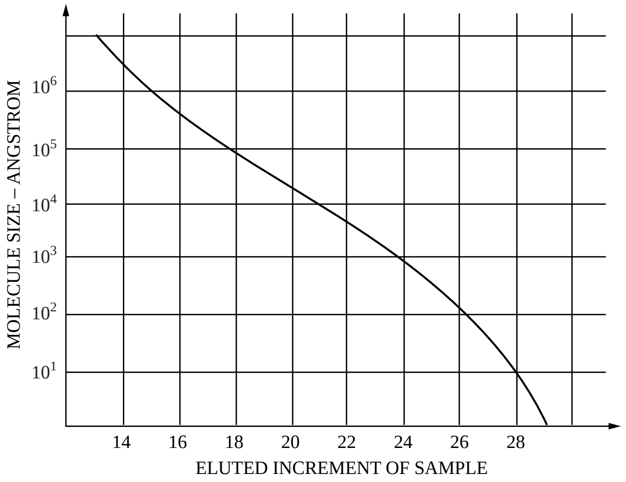

FIG. 8.35m
Calibration curve furnished with instrument.

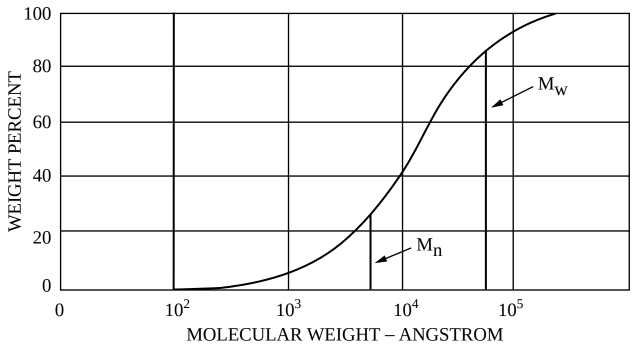

FIG. 8.35n
Weight percent cumulative plot.

gel-permeation chromatograph output, a table similar to Table 8.35o should be prepared. In the table, the columns are obtained as follows:

Column 1 In this column, each successive 5-ml fraction that is obtained from the chromatograph is numbered on the distribution curve (Figure 8.35l).

Column 2 Next, measure the height from the baseline to each numbered point on the distribution curve. The baseline in Figure 8.35l is drawn by the operator as shown in the diagram.

Column 3 Add successive heights to obtain cumulative height as shown.

Column 4 Normalize the data in Column 3 (0–100) by taking the individual cumulative heights and dividing them by the total cumulative height and multiplying the result by 100.

$$\left(\frac{\text{Col 3}}{374}\times 100\right) \qquad \mathbf{8.35(19)}$$

Column 5 Tabulate the chain length from the calibration curve of count number vs. chain length in Figure 8.35m.

Column 6 Divide Column 2 by Column 5.

$$\frac{19,565,810}{374} = 352,300\text{Å} \qquad \textbf{8.35(21)}$$

Figure 8.35n is obtained by plotting Column 4 vs. Column 5.

END GROUP DETERMINATION

Molecular weight determination by functional group analysis requires that the polymer molecule contain a known number of distinguishable groups. Such groups are carboxyl and hydroxyl groups or amino end groups. In linear polymers, the number average molecular weight is obtained as

$$\text{Mn} = \frac{2\text{m}}{\text{x}_\text{e}} \qquad \textbf{8.35(22)}$$

In Equation 8.35(22), m is the number of pounds of sample and x_e the number of moles of end groups. However, this method can only be used where the number of end groups is known, as is the case with linear polymers. The number of end groups can be determined chemically or by means of an infrared spectrometer, which was calibrated with a known sample. This method fails at molecular weights above approximately 30,000 because the fraction of end groups becomes too small to be detected.

ELECTRON MICROSCOPE

The optical microscope is limited in its power of resolution to the detection of objects that are larger than one-half of the wavelength of the shortest visible light used. This corresponds to approximately 8000 Å.

Electrons, however, do not behave only as particles but also as waves, with a wavelength of about 0.5 Å. Consequently, a beam of electrons can be used to detect particles much smaller than those visible by means of the optical microscope. In the electron microscope (Figure 8.35p), a heated filament provides a stream of electrons, which pass through a magnetic coil, acting as a condensing lens. Upon emerging from the object, the electrons pass through two additional magnetic coils, which act analogous to the objective and projector lenses of the optical microscope.

The focused electron beam impinges on a photographic film, where a much enlarged image is produced. The photographs can be further enlarged without distortion. Magnifications of 100,000:1 are possible. The lower limit of resolution obtainable is on the order of 15 to 20 Å.

FIG. 8.35p
The electron microscope. (Courtesy of LEO Electron Microscopy.)

Transmission Electron Microscope

Transmission electron microscopes (TEMs) use electrons as *light source*, and their much lower wavelength makes it possible to get resolutions that are 1000 times better than those of a regular light microscope. The electron source at the top of the microscope emits electrons that travel through vacuum. The TEM uses electromagnetic lenses to focus the electrons into a thin beam, which travels through the process sample.

Depending on the density of the sample, some of the electrons will scatter and thereby disappear from the beam. At the bottom of the microscope, the unscattered electrons will hit a fluorescent screeen and produce a *shadow image*. The image can be studied directly by the operator or can be photographed and transmitted for evaluation by others.

Advantages and Limitations

The magnifying power of the electron microscope is sufficient to permit visual observation and measurement of polymer molecules. From a photograph of the polymer sample, the size of the molecules can be measured and plotted as molecular size distribution. Essentially, this distribution curve should be the same as the output curve of the gel-permeation chromatograph shown in Figure 8.35l. However, while the chromatograph automatically counts the number of molecules within each size range, the grouping and counting of molecules must be performed by the operator.

Since the microscope shows only molecular size, the makeup of the polymer molecule—the composition of its building blocks and distance between adjacent blocks—must be known before molecular weight can be calculated from the measured molecular size. One advantage of the electron microscope is that the molecular structure can be observed along with molecular size. In other types of measurements, the structure must be determined by independent measurements.

ULTRACENTRIFUGE

Sedimentation and diffusion measurements of polymer solutions both involve the frictional properties of the polymer molecules. Therefore, they are closely related, and both are needed to interpret the data obtained from the velocity ultracentrifuge.

Not all polymers are suitable for analysis by means of the ultracentrifuge. For the measurement to be successful, the polymer and solvent must differ in refractive index, the solvent must have a low viscosity, and the polymer must be soluble near room temperature. Finally, mixed solvents must be avoided because of complex corrections that must be made to the measurement.

Sedimentation Velocity

There are two different types of ultracentrifuge measurements. In the sedimentation velocity method, the centrifuge is operated at from 20,000 to 60,000 rpm rotational speeds. These produce centrifugal fields that equal several hundred thousand times the acceleration of gravity. Under these conditions, the polymer molecules move under the influence of these centrifugal forces against the opposition of frictional forces.

The instrument determines the rate of movement and provides a rapid means of estimating the size, shape, and molecular weight of macrosolutes. It also allows the calculation of the coefficients of sedimentation and diffusion if the sedimenting components are well separated, and it allows the calculation of effective mass of solute components, particle asymmetry, and molecular weight.

The rate of sedimentation is related to the ratio of molecular weight to the frictional force. The frictional force is determined independently by diffusion or viscosity measurement. The fact that a second, independent measurement is required is one of the principal disadvantages of the sedimentation velocity method, because a viscosity measurement alone can also be used to determine the average molecular weight.

Sedimentation Equilibrium

In the sedimentation equilibrium method, the centrifuge is operated at 10,000 to 30,000 rpm speeds for periods of several hours to days or weeks. Under constant conditions, the polymer will not pellet at the bottom of the cell but will be redistributed over time, with increasing concentration of solute as the distance from the center of rotation increases solely as a function of its molecular weight.

After a period of about a day, the effect of centrifugal forces on the solute particles will be balanced by diffusion, and the apparent concentration will no longer change. If the measurements are made with thermodynamically ideal solutions, the weight average molecular weight and higher averages can be obtained. In addition, homogenity with respect to Mw, association constants and aggregation states can also be calculated.

Instrument Construction

The ultracentrifuge consists of an aluminum alloy rotor, which is several inches in diameter, and a solution cell mounted within the rotor near its periphery. The rotor is mounted in an evacuated chamber that is provided with windows for observation of the solution in the cell. The rotor may be driven by air or by an electric motor operated oil turbine. Polymer concentration along the solution cell is measured by refractive index or light absorption detectors along the length of the cell.

CONCLUSIONS

Of the methods available for the determination of polymer molecular weight, none is ideally suited for in-line measurement, but the techniques of gel permeation and viscometry can be applied using automated sampling systems.

None of the methods produces a direct output in terms of molecular weight. Sedimentation and diffusion methods are not very useful for process applications because of the time required to obtain a measurement.

Gel-permeation chromatography, while its analysis time is in the order of 2 to 3 hr, provides a complete molecular weight distribution in addition to molecular weight averages.

Automatic membrane osmometers are relatively fast, but their useful range is between 10,000 and 300,000 molecular weight. At the lower end, special membranes can be used to extend the range to about 5000 molecular weight. Vapor pressure osmometers complement the useful range of the membrane osmometer at the lower end of the scale. The operating range of these instruments is up to approximately 20,000 molecular weight.

The analysis time and range of viscometers are comparable to those of the osmometers; however, their usefulness is limited to linear polymers. In terms of accuracy, range of application, and speed of analysis, the light-scattering photometer and the electron microscope offer the best choice. These instruments, however, are much more costly than other types, and their advantages rarely can justify the expense.

INTRODUCTION

The measurement of nitrogen in its different forms (ammonia, nitrite, nitrate, total nitrogen) can involve in a variety of laboratory operations or utilize a variety of process analyzers. The analyzers that can be used in the industrial process environment include chromatographs, ion-selective electrodes, ultraviolet analyzers, and wet chemistry analyzers using colorimetric end-point sensors. Each of these types of analyzers has already been discussed in other sections of this chapter; therefore, in-depth coverage of these analyzers will not be repeated here.

ENVIRONMENTAL SIGNIFICANCE

Although the air is 79% nitrogen, the supply of nitrogen to plants and animals is limited by its availability in the usable chemical compounds. Atmospheric nitrogen is an inert gas that relatively few organisms can convert to usable forms such as ammonia, nitrate, and nitrite. Until the advent of large-scale industrial fixation processes for nitrogen, the major problem with nitrogen was its limited availability. The amount of nitrogen fertilizers produced since 1950 has increased many-fold, and it is estimated that production may exceed 100 million tons by the year 2000.

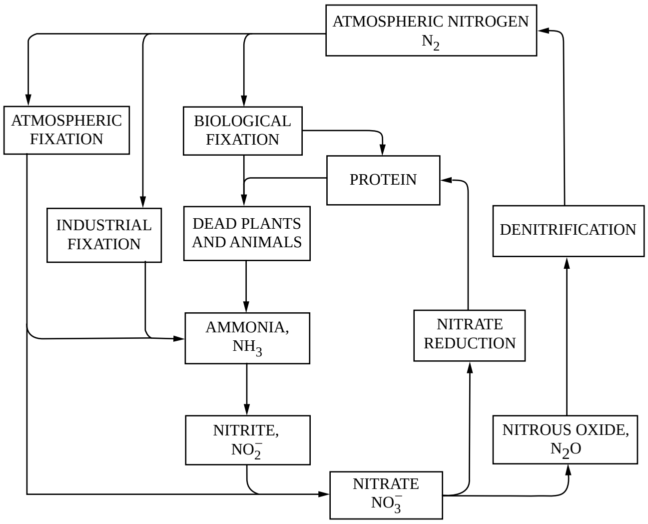

FIG. 8.36a
Nitrogen cycle.

Because not all of the nitrogen fertilizer is retained in the soil long enough for its intended use, several environmental problems have arisen in recent years. Nitrogen compounds in streams and lakes result in an increased growth of algae, which depletes the available oxygen for oxygen-dependent organisms. The rapid eutrophication of lakes is at least partly a result of excess nitrogen compounds in the runoff.

Nitrification and Denitrification

Another process, termed *nitrification*, in which ammonium ion is oxidized to nitrate or nitrite, can also create problems in the aquatic environment by depleting the available oxygen. Ammonium ion in normally alkaline waters is in equilibrium with free ammonia, which is toxic to fish and other aquatic forms. Microorganisms decompose organic nitrogen compounds by a process called *ammonification*, which converts organic nitrogen compounds such as amino acids to ammonium ions. The ammonium ions created add to the problems described.

Another process that is part of the nitrogen cycle, *denitrification*, converts the nitrates or nitrites produced by nitrification into inert molecular nitrogen. Figure 8.36a shows the nitrogen cycle. Nitrate concentration, if higher than 45 mg/l in drinking water, causes an illness in infants called *methemoglobinemia*. The problems caused by nitrogen compounds in water have made it necessary to analyze for nitrogen in its many forms or oxidation states. The oxidation states of nitrogen are listed in Table 8.36b.

AMMONIA NITROGEN[1,2]

The direct Nessler method is sensitive under optimal conditions to about 0.02 mg/l ammonia nitrogen. As a result of interferences such as hardness, iron, acetone, organic amines, and aldehydes, most water samples require a preliminary cleanup distillation. The Nessler reagent produces a yellow-to-brown color that can be compared visually to standards or can be read against a standard curve photometrically between the wavelengths of 400 and 500 nm (1 nm = 1 mμ = 10 A), depending on the photometer light pathlength chosen and on the concentration of the sample.

TABLE 8.36b
Oxidation States of Nitrogen

Oxidation State	*Name*	*Symbol*
+5	nitrate ion	NO_3^{1-}
+3	nitrite ion	NO_2^{1-}
0	nitrogen	N_2
–1	hydroxyl amine	NH_2OH
–3	ammonia	NH_3

The direct phenate method, which uses the reaction of ammonia, hypochlorite, and phenol catalyzed by manganous ion to produce an intense blue color (indophenol), is subject to interferences from acidity and alkalinity. The blue color has a maximum absorbance at the wavelength of about 630 nm. Because of interferences, cleanup distillation is desirable if subsequent determinations are to be made for other forms of nitrogen.

The average relative standard deviation for the sample concentration range of 0.2 to 1.5 mg/l ammonia nitrogen by the above methods has been reported as 20.3% for the direct Nessler and 27.0% for the direct phenate methods. After cleanup distillation, both methods have an average standard deviation of 13%. If the sample is distilled from a phosphate buffered at a pH of 7.4 into a standard boric or sulfuric acid absorbent solution, the excess acid can be titrated with a standard base to determine the ammonia nitrogen. The relative standard deviation for this method, however, averages about 40%.

For certain water samples, it may be useful to distinguish the *free* ammonia nitrogen, distilled from a neutral solution (pH 7.4), the *fixed* ammonia nitrogen, distilled from solution at pH 10.5 or greater, and the *albuminoid* nitrogen obtained by conversion with permanganate and alkaline distillation. Ammonia concentration can be rapidly determined by microcoulometry or by gas chromatography.

Ammonium and Total Nitrogen Probes

Probes are available to detect the ammonium ion concentration or total nitrogen (in the form of ammonium) in liquid streams. The probe measures the change in pH, which occurs in a thin film that is located between a permeable membrane and the pH glass electrode. The ammonia passes through the gas-permeable membrane in quantities proportional to its partial pressure (concentration) and causes a corresponding change in the film pH. Therefore, the measurement of pH

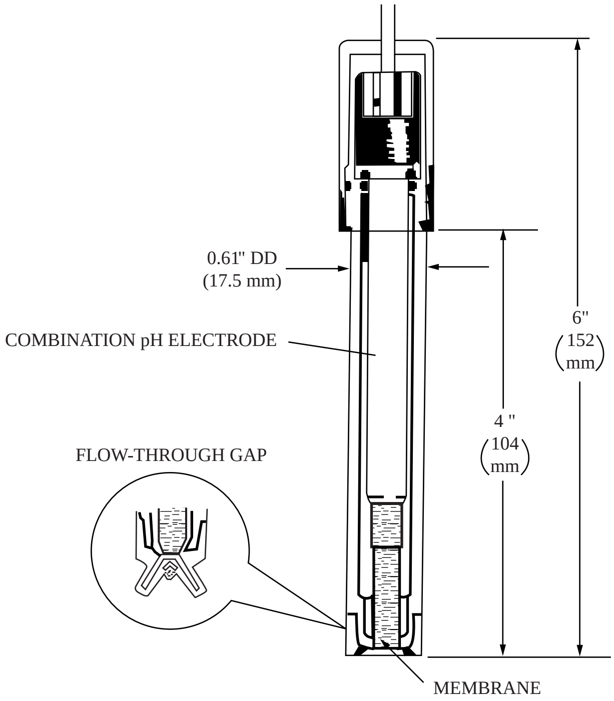

FIG. 8.36c
Probe for the direct determination of ammonia. (Courtesy of Ionics Business Group.)

reflects the concentration of ammonia. Figure 8.36c shows both the probe and the cap that can be added to its tip for use in continuous analysis in a closed-flow system.

Chemiluminescence

A more sensitive method involves the indirect detection of ammonia using chemiluminescence. Chemiluminescence is produced when a chemical reaction produces an electronic excited species. As the excited species returns to the ground state, light is emitted. As ammonia consumes the hypochlorite, the chemiluminescence signal of the luminol-hypochlorite complex decreases leading to negative peaks.[3] Another method involves the reaction of ammonia with hypochlorite, yielding a volatile compound that is combusted at 600°C. The NO produced reacts with ozone, and the resulting chemiluminescence is detected. The total time for the analysis is less than 3 min. Determination limit of as low as 1×10^{-8} M can be achieved using this method.[4]

NITRITE MEASUREMENT

Nitrite, an intermediate stage in the nitrogen cycle, can result from the decomposition of natural protein. Another source of nitrite ion in water is its use as a corrosion inhibitor.

Nitrite analyses by standard methods are based on the diazotization of sulfanilic acid with nitrite in strong acid followed by coupling with alpha naphthyl amine hydrochloride. The purple color formed can be read on a photometer at a wavelength of 520 nm or compared visually to standards. The best concentration range for the use of this method is below 2 mg/l, but higher concentrations can also be determined by appropriate dilution with distilled water.

An alternative method for the higher concentration ranges uses the yellow-brown color of the reactant of nitrite with metaphenylene diamine in acid solution. Both these methods are pH dependent but otherwise suffer few significant interferences except for chlorides when present in concentrations greater than 15,000 mg/l. Many diazotization reactions have been proposed and used to eliminate or minimize these interferences. A critical review by Sawicki[5] compares 52 methods for photometric nitrite analyses.

Another way of measuring nitrite involves its chemical reduction to NO by reducing agents such as NaI, V(III), Ti(III), Cr(III), and Mo(VI) + Fe(II).[4,6] The NO generated is detected using chemiluminescence.

NITRATE MEASUREMENT

Phenol disulfonic acid reacts with nitrate to produce a yellow color that can be measured at the maximum wavelength absorption between 410 to 480 nm, depending on sample concentration range and on colorimeter cell path length. Chlorides, even at 10 mg/l, represent a severe negative interference. Silver ion precipitation of chlorides has been used, but excess silver ion causes a brown precipitate, which interferes with the measurement. Nitrites at concentrations greater than 0.2 mg/l are a positive interference that can be removed with sodium azide.

The ultraviolet absorption at 220 nm wavelength can be used to measure nitrate. Chlorides represent no interference, but organic matter that absorbs at or near the same wavelength causes a positive variable interference. Hexavalent chromium and nitrite ions also interfere. Empirical correction for the normal interferences has been used successfully.

Nitrate can also be directly measured using ion-exchange chromatography.[7,8] Detection limits of 50 mg/L N have been reported.[7] This method allows for sequential analysis of different anions. However, anions that have the same retention time as nitrates will interfere. Furthermore, an excessive amount of chlorides (greater than 400 mg/l) results in decrease in signal for nitrates.[8]

In the brucine method, nitrate reacts with brucine sulfate in a glacial acetic and dilute sulfuric acid mixture. The rate and intensity of color change with time and with temperature so that simultaneous development of the color to its maximum is also necessary for the calibration standards. At concentrations below 1 mg/l, results have significant negative bias. Chlorides above about 1000 mg/l and nitrites both interfere with the measurement.

Nitrate has been analyzed by reduction to ammonia or nitrite,[9] which is then analyzed by one of the several methods

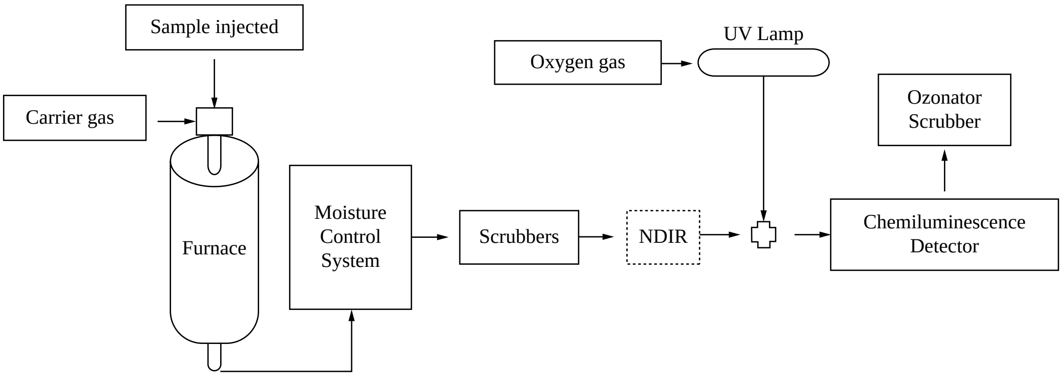

FIG. 8.36d
Chemiluminescence total nitrogen analyzer.

previously described. Several different metals and alloys have also been used to determine nitrate and nitrite, but ferric and fluoride ions interfere with the analysis. An infrared method has also been reported for determining both nitrate and nitrite simultaneously, but it requires extensive concentration and cleanup procedures.

A specific ion electrode for nitrate is available that is sensitive to less than 1 mg/l nitrate ion, but interferences due to the normal ranges of chloride and bicarbonate ion activities make the results far from acceptable. However, for water systems in which these interferences are absent, or for higher nitrate (>10 mg/l) concentrations, the electrode is rapid and convenient. The electrode's liquid ion exchanger deteriorates with time, causing a significant error if it is not recalibrated frequently and rejuvenated at least monthly. Although $C1^{1-}$ and HCO_3^{1-} ions can be removed by precipitation, the procedure is difficult and time consuming. Automated systems have been developed for the several reductions and determinative colorimetric reactions.

TOTAL NITROGEN

The increasing use of organic amines and other nitrogen compounds in manufacturing processes has led to increase in regulation in Europe for wastewater to be treated before being released in the environment. Standards such as ISO/TR 11905 Part 1 and 2, DIN 38 409, and DIN 38 406-E 5–1 include methods for the determination of nitrogen. The European Council requires that all wastewater treatment plants in major cities to measure total nitrogen (TN) by instrumental analysis.[10]

Kjeldahl Method

The total or Kjeldahl nitrogen standard method determines free ammonia and organically bound nitrogen in the –3 valence state but does not determine nitrites, azides, nitro, nitroso, oximes, or nitrates. Organic nitrogen is determined by subtracting the separately determined free ammonia nitrogen from the total nitrogen. The original analysis consists of several hours of digestion in boiling sulfuric aid, addition of toxic mercury compounds, then ammonia distillation and detection. The automated Kjeldahl has improved the inherent hazard of the test to the operator.

Chemiluminescence Analyzer

Figure 8.36d shows a flow diagram for a total nitrogen chemiluminescence analyzer. An aliquot of the sample is injected into a high-temperature furnace in an atmosphere of pure oxygen where nitrogen is converted to NO. The carrier gas transports the resulting steam and gases through the moisture control system. Inside the chemiluminescence detector, the NO formed reacts with ozone to produce an excited state of nitrogen dioxide (NO_2^*).

A photomultiplier tube adjacent to the reaction cell detects the photons (light) emitted as the NO_2^* returns to its ground state. The integrated signal is proportional to the amount of nitrogen in the sample. Concerns about recovery for different types of nitrogen species have been raised. Some manufacturers have employed more efficient catalysts, a NO_x converter, or swept the stream of gases through a reducing chamber containing a very strong reducing agent such as vanadium (III) chloride.[10] Simultaneous measurement of carbon (see Section 8.58) can be conducted by allowing the gas stream to pass through an NDIR detector before the CLD detector.

A typical range of measurement is 0.05 to 4,000 mg/l N. Speciation of the different nitrogen species can be accomplished by using a gas chromatograph with the chemiluminescence detector. For higher levels of TN measurements, such as 30 mg/l to % levels, the NO_x produced during combustion is converted to N_2, which is detected with a thermal conductivity detector.

The NO produced from the combustion of a nitrogen-containing sample can also be analyzed by reacting with an electrolyte in an electrochemical cell. This reaction produces a measurable current, which is directly proportional to the amount of nitrogen in the original sample. The analytical range of measurement is 0.1 to 1,000 mg N/l and precision of 1 to 10% can be achieved, depending on the sample matrix.

INTRODUCTION

The oxides of nitrogen are measured both in ambient air and in the gases emitted by industry. While the types of analyzers used for these two applications do overlap, here, an attempt will be made to separate them. Therefore, in this section the devices more often used for industrial emission monitoring will be discussed first. These include infrared, ultraviolet, chemiluminescent, gas chromatographic, and electrochemical devices. Colorimetric and coulometric analysis is more often used for ambient air analysis and will be discussed later in this section.

INDUSTRIAL EMISSION MONITORING

Paramagnetic Analyzers

Nitrogen oxide is attracted by the magnetic field and therefore is detectable by a paramagnetic analyzer. This instrument is described in this chapter under Oxygen Analyzers (Section 8.42) and is not widely used for the measurement of nitrogen oxide concentration.

Thermal Conductivity Analyzers

The thermal conductivity (see Section 8.57) of nitric oxide (NO) is slightly less than that of air—about 90%. Therefore, although thermal conductivity measurements have been attempted for NO analysis, it is neither a sensitive nor a selective means of measurement.

Nondispersive Infrared Analyzers

Nondispersive infrared (NDIR) analyzers are suitable for the determination of nitric oxide (NO) concentration. These devices are most often used in stack gas analyzer packages, which, in addition to NOx, also detect the concentrations of carbon dioxide, carbon monoxide, sulfur dioxide, and opacity. Section 8.27 described the nondispersive infrared analyzers, and Figures 8.27h and 8.27t show some of their stack-mounted variations.

Ultraviolet Analyzers

The absorbance of nitrogen dioxide in the ultraviolet range is shown in Figure 8.37a. Because, in most combustion processes, there is an interest in determining the concentrations of the both NOx and SO_2, some of the suppliers of ultraviolet analyzers have combined the two tasks into a single analyzer whereby their concentrations are simultaneously measured (Figure 8.37b). Because nitric oxide (NO) is essentially transparent in the visible and ultraviolet regions, it must be converted to NO_2 before it can be measured.

In Figure 8.37b, this conversion is achieved by contacting the sample gas with oxygen pressurized to five atmospheres. Once the NO is converted, the total NO_2 concentration is measured as NOx. Ranges can be as narrow as 0 to 100 ppm or as wide as 0 to 100% NOx, and the measurement error is about 2% of full scale.

Chemiluminescent Analyzers

Another method of nitrogen oxides[1] determination makes use of the fact that nitric oxide (NO) reacts with ozone to form nitrogen dioxide (NO_2), and this reaction is accompanied with the release of light (chemiluminescence).

$$NO + O_3 \rightarrow NO_2 + hv\ (\text{light } 0.6 - 3\mu) \qquad \textbf{8.37(1)}$$

If excess ozone is present, the light emission is proportional to the amount of nitric oxide present in the sample. Instruments that operate on the basis of this principle are commercially available.

For the determination of NO_2 (which reacts with ozone rather slowly), some analyzers are provided with a catalytic converter to first reduce NO_2 to NO and then determine the sum of NO_2 and NO directly. The apparatus is schematically shown in Figure 8.37c.

Electrochemical Sensors

Portable or permanently installed probe-type electrochemical sensors are available for NO, NO_2, and NOx measurement

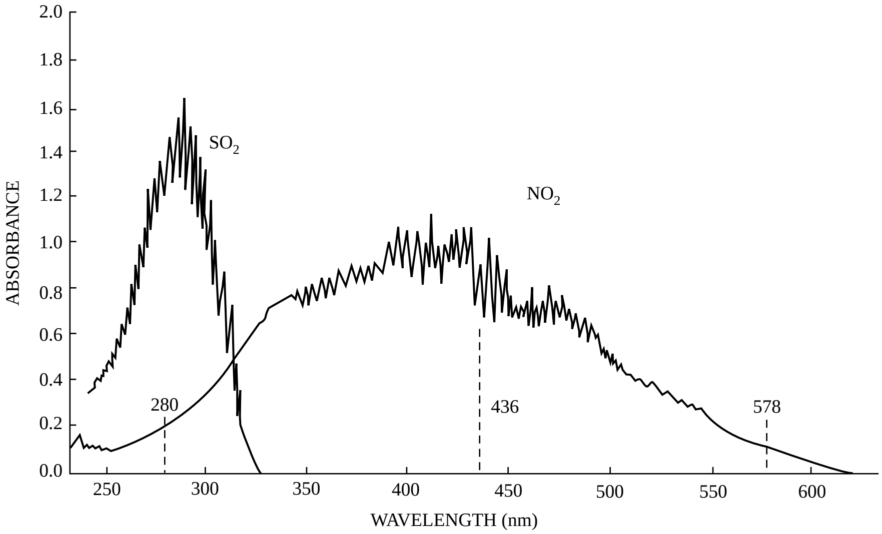

FIG. 8.37a
The absorbance of SO_2 and NO_2 in the ultraviolet range.

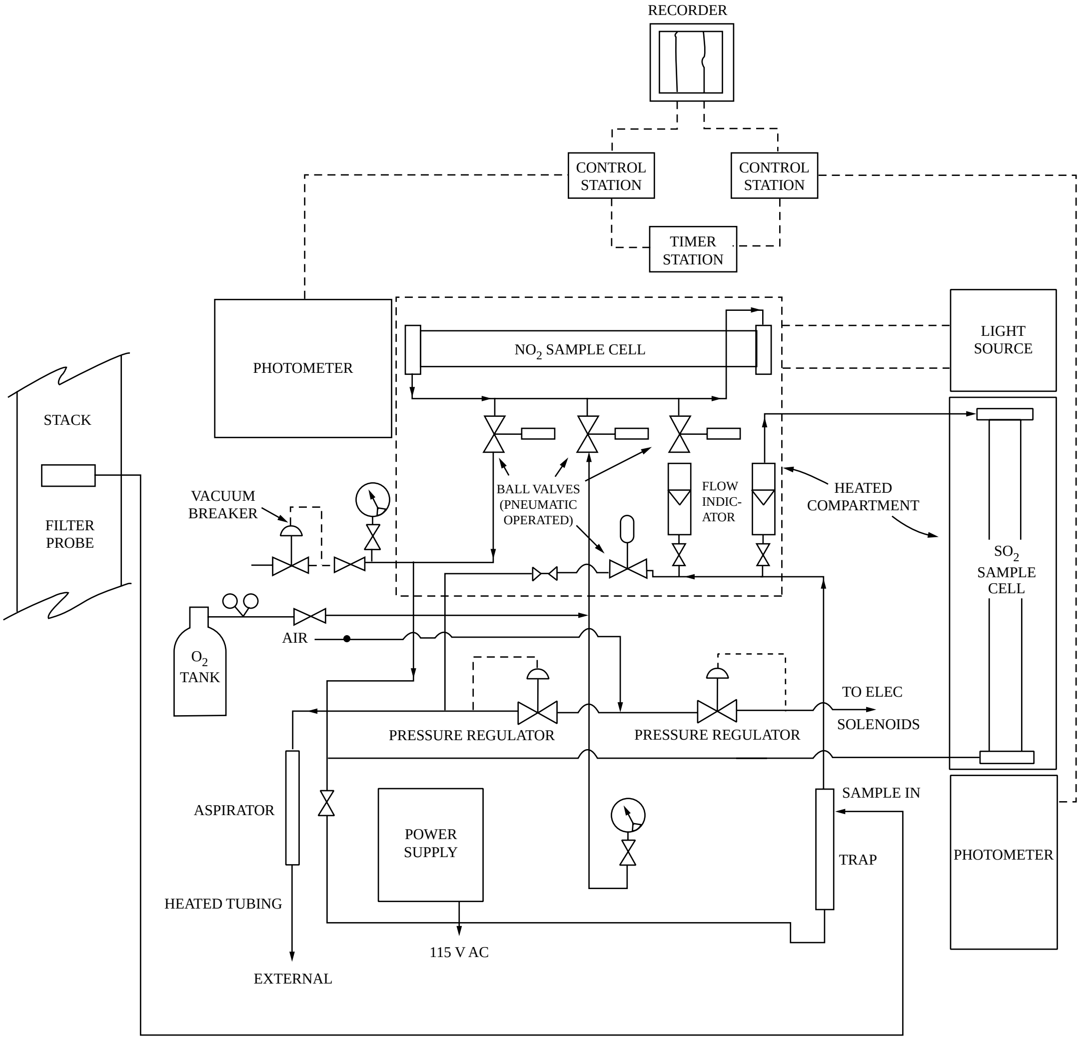

FIG. 8.37b

FIG. 8.37c
Chemiluminescence nitric oxide analyzer.

in stacks. These units are microprocessor based, are available with 4 to 20 mA transmitter outputs, and include self-diagnostic and self-calibration features. The probe can be exposed to continuous temperatures of 1550°F (850°C), which for short periods can rise to 2200°F (1200°C).

Gas Chromatography

There have been a limited number of reports of applications for analysis of oxides of nitrogen by gas chromatography. Such chromatographic columns are fairly short and are provided with electron capture detectors. These are the same types of chromatographs that are used for the analysis of peroxyacyl nitrates. For added details on gas chromatography, see Section 8.12.

AMBIENT AIR MONITORING

Calibration Methods

The reliability of dynamic calibration of gas analyzers is always superior to that of static calibration, but it is also much more difficult. This is because, in high concentrations, nitric oxide (NO) is rapidly oxidized to nitrogen dioxide (NO_2) by air, and NO_2 condenses and dimerizes at high concentrations. For these reasons, dynamic calibration for NO and NO_2 requires great care. In colorimetric or coulometric analysis, the NO in fact is not measured directly at all but is measured only after its oxidation to NO_2, so these analyzers are calibrated only for NO_2.

Dynamic Calibration Dynamic calibration for NO_2 requires preparation of a sample of inert gas containing a known concentration of NO_2. This sample may be obtained by gas-dilution techniques (with special precautions in handling NO_2), gravimetrically, electrolytically, or by use of a permeation tube. The permeation tube (as used with hydrocarbons) is described in Section 8.25. However, NO_2 permeation tubes are moisture sensitive. Therefore, during storage, these tubes should be protected from moisture, and only dry gases should be used for dilution. If these precautions are observed, the permeation tube is probably the most convenient method for the dynamic calibration of NO_2.

Static Calibration Static calibration is carried out with standard solutions of nitrite. Because this procedure does not detect the components of the gas in the sampling line, it is not as complete a test as is the dynamic calibration, but it is much simpler. The stoichiometric ratio of nitrite to NO_2 under controlled conditions is usually a constant value.

In the Griess–Saltzman method, the consensus (although there has been controversy) is that 0.72 mole of nitrite gives the color of 1 mole of NO_2. Using the Jocobs–Hochheiser method, this factor has been found to be 0.63.

NO–NO_2 Combination Analysis

In continuous analysis, it is customary to determine both NO and NO_2 as NO_2 (Table 8.37d). The NO is oxidized to NO_2 by means of potassium permanganate or dichromate or by chromium trioxide, in various formulations. The efficiencies of conversion seem to depend on the length of service and, for the chromium oxidizers, they also depend on humidity.

TABLE 8.37d
Nitrogen Oxide Analyzers

General Method	*Type*	*Advantages*	*Disadvantages*
Colorimetric	Griess–Saltzman	Precise, thoroughly tested, widely used, continuous analysis	Short life of collected sample, sensitive reagents, NO oxidation required.
	Jacobs–Hochheiser	Precise, stable after collection	Not adapted to continuous analysis, sensitive reagents, NO oxidation required.
Coulometric		Simple apparatus, continuous analysis	Sensitive to other oxidants, NO oxidation required.
Chemiluminescent		Dry gases only, sensitive photometry, continuous analysis	Requires ozone generator NO_2 catalytic reduction.
Gas chromatography		Specific, frequent analysis	Not a developed instrument, expensive and complex.
Electrochemical		Simple apparatus, continuous analysis	Sensitivity not high, NO oxidation required.

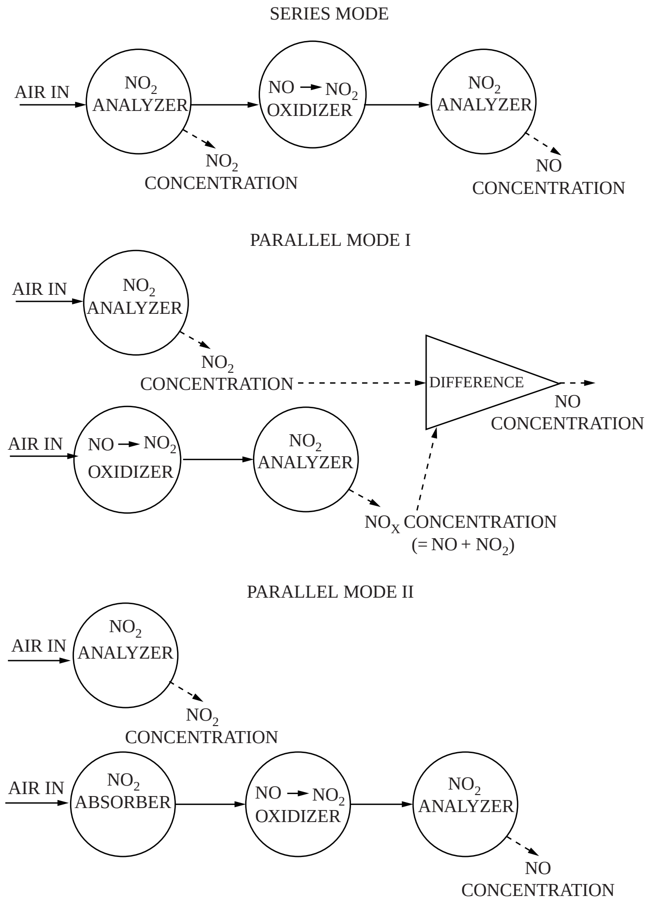

FIG. 8.37e
Nitrogen oxides analyzer modes.

Aqueous permanganate seems to be the best choice, even though it may not be completely efficient (hence, NO may be underestimated).

Series Analysis In series analysis for NO and NO_2 (Figure 8.37e), the air passes through an NO_2 analyzer for measurement and removal of NO_2, then through an oxidizer to convert NO to NO_2, and finally through a second NO_2 analyzer. The second analyzer gives a measure of NO concentration. In one type of parallel analysis, two equal air streams are analyzed for NO_2, one of them after passage through an oxidizer. The latter gives total oxides of nitrogen ($NO + NO_2$) from which NO is found by difference from the other parallel analyzer. In a second type of parallel analysis, one stream is analyzed directly for NO_2, and the second is scrubbed free of NO_2 by passage through ascarite, followed by oxidation of NO to NO_2 and NO_2 analysis.

Colorimetric Determination

There are two important colorimetric methods[2] for NO_2 determination. They are the Griess–Saltzman and the Jacobs–Hochheiser methods.

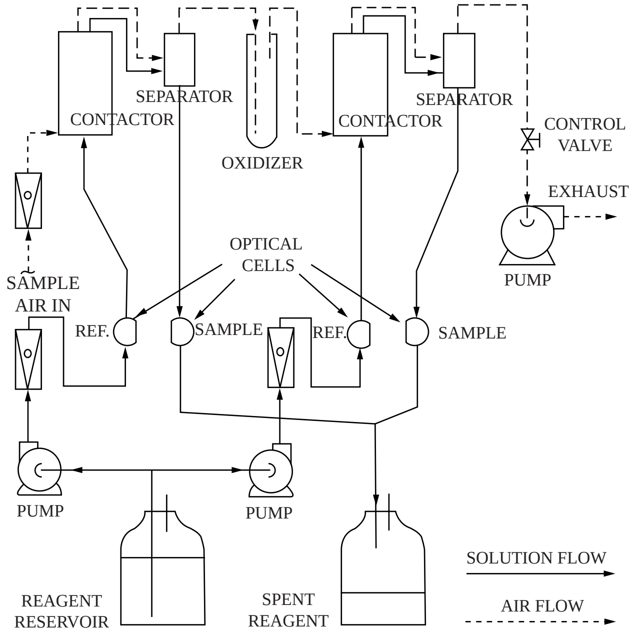

FIG. 8.37f
Colorimetric nitrogen oxides analyzer.

The Griess–Saltzman Method The Griess–Saltzman method is used in most continuous colorimetric NO_2 analyzers. It is based on the reaction of NO_2 with sulfanilic acid to form a diazonium salt that couples with N-(1-napthy1)-ethylenediamine dihydrochloride to form a deeply colored azo dye. Air is passed into the reagent solution for not over 30 min. After that, time is allowed for development, and the color is measured at 550 nm.

The measurable range of concentrations is from 0.02 to 0.75 ppm. In manual use, the color is developed for 15 min and should be read within 1 hr (on a colorimeter or spectrophotometer). In a continuous analyzer (Figure 8.37f), the gas and liquid flow rates are adjusted for optimal response, and the developed color is potentiometrically read in a flow cell using a 550 nm filter. Response times are usually 5 to 15 min.

The Jacobs–Hochheiser Method The Jacobs–Hochheiser method is the standard reference method used for U.S. National Air Quality Standards. The reason for this is that the standards are based on the annual average, and this method allows collection of up to 24-hr integrated samples and delays in analysis of at least 2 weeks. In contrast, with the Griess–Saltzman method, samples must be quickly analyzed.

In the Jacobs–Hochheiser method, the air is passed through aqueous sodium hydroxide so that the NO_2 is concerted to nitrite ion. Sulfur dioxide is removed from the solution by treatment with hydrogen peroxide and is acidified. The rest of the procedure is the same as for the Griess–Saltzman method except that sulfanilamide is used instead of sulfanilic acid. Efficiencies found with this procedure in the U.S. National Air Surveillance Network are approximately 35%.

TABLE 8.37g
*Typical Range, Sensitivity, and Alarm Setpoints of Portable Personal Protection Monitors**

Gas	*Range*	*Resolution*	*Alarm Set Points (low/high)*
O_2	0–30%	0.1%	19.5/23.5%
CO	0–500 ppm	1 ppm	35/200 ppm
H_2S	0–100 ppm	1 ppm	10/20 ppm
SO_2	0–20 ppm	1 ppm	2/10 ppm
NO	0–250 ppm	1 ppm	25/50 ppm

Portable Monitors

For purposes of personal protection, battery-operated portable units are available. These units are usually provided with one or two alarm set-points and with memory for some thousands of data points along with their times and dates. Table 8.37g lists the ranges, resolutions, and alarm set points for a number of gases including NO and NO_2.

These pocket-sized, battery-operated, portable electrochemical detectors are usually provided with digital displays and audible alarms. They can be configured for one or more monitoring channels.

CONCLUSIONS

The most widely used conventional method of ambient air analysis is colorimetric. It is most often based on the use of the Griess–Saltzman reagent (a diazotization method). This is a fairly precise and dependable method but requires a great deal of attention.

The colorimetric method is specific for nitrogen dioxide. To analyze for nitric oxide, an oxidation step is required. Of various oxidizer columns, the most commonly used is the permanganate one, but none is completely satisfactory. It is important to calibrate it over a range of nitric oxide concentrations and at various humidity levels.

The chemiluminescent method utilizes the reaction between ozone and nitric oxide. This is a dry gas method requiring an ozone generator and compressed gas. In the chemiluminescent method, a catalytic reduction of nitrogen dioxide to nitric oxide is required.

For industrial applications, the most often used analyzers are the nondispersive infrared, ultraviolet, and electrochemical types. The chemiluminescent and gas chromatographic techniques are less frequently used.

INTRODUCTION

Odor is a sensation associated with smell, which can be hard to quantify. The same quantities of different materials cause different odor intensities. The unit of odor intensity is based on the odor of tertiary butyl mercaptan (TBM; W = 1.0). Using that reference, H_2S, for example, has an odor intensity of 0.08 or 8% of TBMs. Most odorant substances contain sulfur. Table 8.38a lists a number of odorant substances and their relative odor intensities (W).

THE MEASUREMENT OF ODOR

This section compares organoleptic and chemical/instrumental methods for odor measurement. The organoleptic methods, which utilize the human olfactory system, are completely subjective. However, techniques are available that can convert subjective measurements into useful objective results.

Recent improvements in technology and increased research in the area of instrumentation have made dramatic improvements in the creation of instruments that are capable of surpassing the human olfactory system. In fact, the instruments of today are approaching the sensitivity of the canine olfactory system, which is thought to be as much as a million times more sensitive than that of humans. These developments have overcome the two major shortcomings generally suffered by chemical/instrumental methods: sensitivity and flexibility.

Sensitivity

The human olfactory system is generally three orders of magnitude more sensitive than currently available chemical/instrumental methods. Humans can detect and identify odors present in quantities to which commercially available instrumentation and chemical methods are completely insensitive.

Flexibility

The human olfactory system is capable of detecting and identifying a wide variety of chemical structures and giving different responses to different materials. Commercially available instrumentation and chemical methods are generally restricted to particular chemical structures and give a similar response to all compounds with that structure.

The Gas Chromatograph

The most successful instrumental method for the measurement of odor has been the gas chromatograph. Gas chromatographs, which monitor the Kraft paper mills and use flame photometric detectors, can determine the concentrations of sulfur dioxide, hydrogen sulfide, and other odorous gases down to about 0.01 ppm.[2] Success in detecting these sulfur-containing compounds using a coulometric cell with platinum electrodes has also been reported.[3] Levels as low as 0.1 ppm were detected by this method.

The threshold levels detected by the human nose[4] are as low as 0.00021 ppm (trimethylamine). Thus, it was apparent that, except for special situations, the human nose, with its attendant sociological, psychological, and physiological complications, was the only odor sensor available for general odor measurement.

However, the detection of odor using chemical or chromatographic methods for determining measurable levels of individual chemicals in a vapor phase is not really odor detection but gas or chemical detection. The detected chemical(s) have an odor and, based on experience, the output of the chromatograph can be interpreted into an odor associated with, for example, the smell of a peach.

True odor analysis will not only determine that the odor is a peach, but whether it is a green, ripe, or rotten peach. Today's instruments can now determine the *quality* of the odor in near real time. These odor detectors and analyzers are trained to recognize the odors and the levels of distinction by

TABLE 8.38a
The Relative Odor Intensity of Different Chemicals[1]

Abbreviation	*Name*	*Formula*	*Odor Intensity (W)*
EM	Ethyl mercaptan ethanethiol	CH_3H	1.08

Section of an olfactory epithelium.

exposure to standards of odor. Once trained, these devices will provide a proportional reading of the odor, much the same as a human olfactory system but without the subjectivity.

THE HUMAN OLFACTORY SYSTEM

The human olfactory system actually involves more than the nose. As a stream of air is drawn in through the nostrils, it is warmed and filtered by passing over the three baffle-shaped turbinate bones in the upper part of the nose (Figure 8.38b). Some of the air swirls past the olfactory receptors located high up in the nasal passages just below the brain.

These odor receptors consist of hairlike filaments attached to the end of the fibers of the olfactory nerve and the trigeminal nerve endings (Figure 8.38c). Upon being stimulated by odorous materials, these receptors send signals to the olfactory bulb, where they are relayed to higher centers of the brain. In these higher centers, the signals are integrated and interpreted in terms of the character and intensity of the odor.

Sample Preparation

Because of the extreme sensitivity of the human nose, the concentrations of odorants in air can be extremely low yet can produce a strong response. These low concentrations present a problem with regard to the manner by which samples are presented to the human sensor. Improper handling of an ambient air sample or improper preparation of an odorant standard can result in erroneous results because of adsorption of the odorants on the walls, incomplete mixing of an odorant with dilution air, or impure dilution air.

Errors can also result from the type of system used to bring the sample in contact with the olfactory sensors. The use of syringes or other means by which the nose is not immersed in the sample yield lower apparent odor intensities than do methods whereby the nose is fully exposed to the sample.[5]

The use of an odor room can also yield misleading results because of natural odors generated by the body and adsorption by clothing. The best approach appears to be the *sniff box* shown in Figure 8.38d. In this case, the human sensor is kept in an air-conditioned room into which charcoal-filtered air is blown to maintain a slight positive pressure. This prevents the sample in the sniff box and other contaminated air from entering the room. For measurement, the whole face is placed in the sample stream within the sniff box.

ODOR PANELS

The use of humans as measurement instruments introduces a variability that is difficult to control. This variability is due to the moods, biases, and other vagaries associated with the human sensor. Each human being is a unique creation, with differences in intelligence, persistence, sensitivity, experience,

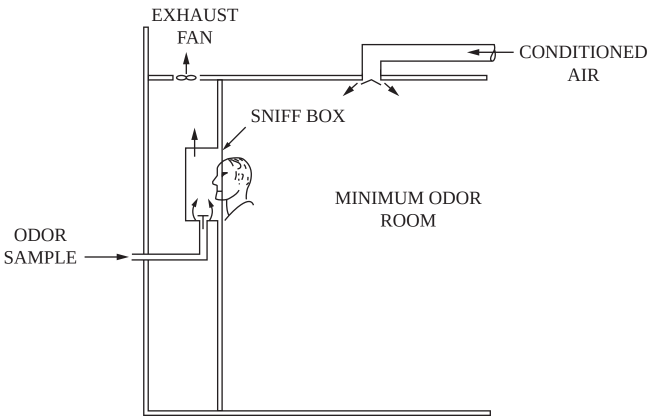

FIG. 8.38d
Diagram of sniff odor test system.

and interests. These differences make the response of an individual an unreliable indicator in itself. The use of a panel of individuals for the measurement of odor levels statistically eliminates the unreliability of the individual.

An odor panel generally consists of 5 to 10 people. The people who compose the odor panel need not have unusual olfactory abilities. However, they should be able to distinguish among odors of different intensities, discriminate among different odor qualities, and communicate the perceived sensations in terms of reference standards. They should also be emotionally receptive to making quantitative and discriminatory judgments without expressing their preference.

Training of an Odor Panel

The primary tasks of an odor panel are the following:

1. Judge the relative intensity of an odor at different dilutions.
2. Discriminate among the different odor qualities.
3. Combine the intensity and quality of an odor to give a composite profile that can be communicated to the scientist in charge of the test.

The panelists are expected to follow instructions and also to render independent judgment reflecting their own sensations.

Tests In addition to exposing the panelists to various levels of odors similar to those to be measured, three tests can be used for training purposes. These are the triangle test, the intensity rating test, and the multicomponent identification test. In the triangle test, three samples are presented to the panelist at the same time. Two are identical, and the third is different in either intensity or quality. The panelist must select the odd sample.

The intensity rating test consists of a series of perhaps 20 dilutions of an odorant in an odorless medium. One sample is removed from the series, and the panelist is asked to determine the sample's proper place in the series according to its odor intensity.

The last test is the multicomponent odor identification test, in which three mixtures are presented to the panelist. These mixtures contain, in sequence, two, three, and four odors out of a possible total of eight known standards. The panelist is told how many components to look for and is asked to identify each of them.

This group of three tests develops a panelists' ability to distinguish between different odor intensities, discriminate among odor qualities, and communicate their sensations in terms of predetermined standards. After the group has some experience working together under a competent test director in actual measurement situations, highly accurate measurements of odor levels can be made.

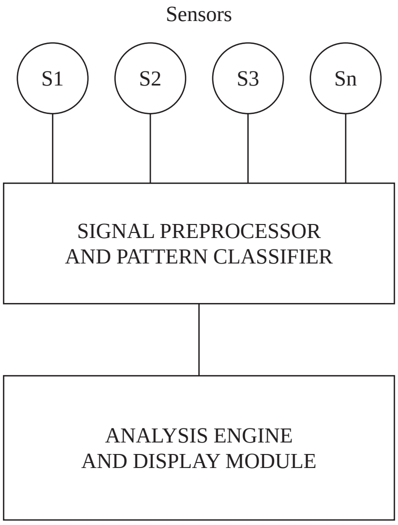

FIG. 8.38e
Typical schematic of an electronic nose.

THE ELECTRONIC NOSE

Advances in technology have led to significant improvements, both in analysis and in size, in the electronic nose. The basic technology relies on the use of solid state sensors—either chemoresitors, chemodiodes, or electrodes. All electronic noses use the same basic method of sensing and analysis (Figure 8.38e).

Primary odors are composed of polar molecules, organic vapors, and phthalocyanines. New sensors such as the chemosensors are devices that convert chemical composition into a quantifiable electrical format. Other new types include conductometric, optical, gravimetric, amperometric, calorimetric, potentiometric, and chemocapacitor sensors.

Polymeric Film Sensors

Conductometric sensors are made up of conductive polymers and metal oxide semiconductors. The first are composed of a polymeric film composite. This technology was developed concurrently in the U.S. and the U.K. The work in the U.S. occurred at the California Institute of Technology in a joint effort with Jet Propulsion Laboratory (JPL). The developments in the U.K. occurred at the University of Manchester Institute of Science and Technology.

In both cases, the developed sensors consist of an array of pairs of electrical contacts that are electrically connected by a composite film. The composite film is composed of a special nonconductive polymer, which is mixed with carbon black in a homogeneous blend. This forms a conductive bridge between the electrical contacts.

The composite film is selected to absorb specific vapor analytes. As it does so, it swells, thereby increasing the distance between the carbon black particles. This first changes its resistance characteristics and then breaks the electrically conductive path in the film. The variance in the resistance between the electrical contacts is used as the output of the sensor. Because of the selected polymer, each sensor in the array is sensitive to a different level of concentration of a chemical. This allows relative concentrations to be determined.

Metal Oxide Sensors

The second type of sensor, metal oxide, employs a similar method of odor detection but uses metal oxide sensors in an array, reacting to the chemicals, changing the semiconductors' conductance, and producing the reading. The use of metal oxide sensors falls into two categories, thin and thick film. The thin film targets NO_x, H_2, and NH_3. The thick film is used for the detection of odors of alcohols, ketones, and combustible materials.

Other Sensors

Potentiometric sensors, using MOSFET semiconductors, react to the chemicals in an odor, which change the resistance of the sensor to generate the reading. Chemocapacitors perform the same function by reacting to the chemicals in the odor by generating a change in the sensor capacitance.

Gravimetric sensors use gas chromatography (GC) coupled with surface acoustic wave (SAW) and quartz crystal microbalance (QCM) measurements. The GC separates the gas and deposits the chemical compound on a vibrating quartz crystal. This causes a change in the acoustic or sound propagation characteristics as a result of the mass change caused by the chemical absorbed. Response time is approximately ten seconds.

Amperometric sensors use the catalytic oxidation of a chemical analyte to generate heat proportional to the amount of chemical present.

Optical sensors use specially coated optical fibers. The coating consists of specifically formulated fluorescent dyes with unique characteristics that cause the fibers to react to very specific chemicals, changing the optical characteristics in proportion to the amount of chemical present.

Calorimetric sensors are thermal sensors that measure the heat generated by the absorption of an analyte into the sensor coating. The more chemical present, the greater the heat generated.

Training

All electronic noses must be trained to recognize the odors as specific smells. Known samples are used to generate defined patterns, odor fingerprints, or (as they have been called) *smell prints*. These standards are used to define the parameters by which the training occurs. A major challenge is to interpret the odor signals into a specific reading of a specific odor with no false readings. The intelligence in the analyzer must emulate the human equivalent of subjective comparison. This is done through prediction algorithms and sophisticated pattern analysis such as multivariate, fuzzy logic, genetic algorithms, cluster analysis, discriminate function analysis, and adaptive models.

Applications

This technology allows the analyzers to be small—at least desktop size and, in some cases, easily handheld. There are indications that credit card size devices will eventually be developed. A sensor can be designed to be as specific or as broad in application as desired. There are many possible applications in industrial and commercial safety, drug interdiction and enforcement, explosive detection, pharmaceuticals, medical, food and beverage, perfumes, breweries, wineries, etc.

Anywhere an odor can be used to detect the presence or even absence of a substance, these electronic noses can be used. The cycle time is typically a few seconds but can be longer, depending on the chemical and the vapor state. Temperature dramatically affects the vaporization of most chemicals, thereby reducing the amount of chemicals to cause an odor. When a sensor/analyzer is used for batch applications, there is an additional time required to purge and clear the sensor array, allowing it to return to a baseline state.

One manufacturer has recently introduced a sensor and analyzer to detect the odor of hydrocarbons in water.

INTRODUCTION

The measurement of oil in or on water is an important requirement in both industrial and environmental pollution protection related applications. Both applications are discussed in this section, starting with the industrial process applications.

PROCESS INDUSTRY MEASUREMENTS

The most common applications of these sensors are for interface measurements between the layers of oil and water in tanks and pipelines. Conductivity, capacitance, and ultrasonic level probes (Sections 3.3, 3.4, 3.20) and probe or flow-through

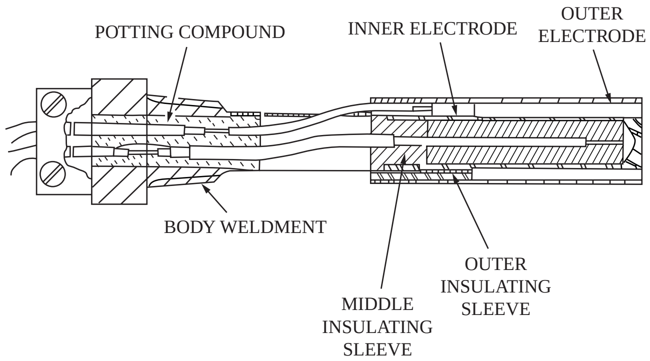

FIG. 8.39a
Dual-concentric capacitance probe for the detection of water in oil.

conductivity analyzers (Section 8.17) are widely used for detecting such interfaces. To avoid redundancy, these devices will not be discussed in this section, but other capacitance and radio-frequency (microwave) types will be covered in the paragraphs that follow.

In other applications, it is desirable to detect the amount of oil that is dispersed in a water stream. Ultraviolet analyzers are well suited for the measurement of oil in water and are discussed in Section 8.61. When the dispersed oil content increases, float- and displacement-type level sensors (Sections 3.7 and 3.8) and density detectors (Chapter 6) can also be considered. A radio-frequency (RF) type oil concentration detector will also be described below.

Capacitance-Type Water-in-Oil Detectors

The capacitance of water is much higher (its dielectric constant is about 80) than that of oil (about 2), so measuring the dielectric constant is a convenient way to tell them apart. In addition to conventional capacitance probes, special dual-concentric designs (Figure 8.39a) are also available to detect the interface between water and oil in tanks. In addition, flow-through sensors are also available for in-pipeline applications.

The flow-through version of the dual-concentric electrode design is illustrated in Figure 8.39b. Here, the electrodes consist of two concentric pipes that are insulated from each other, thereby forming the capacitor through which the process stream flows. The flanged spool piece is available in sizes from 2 to 8 in. (50 to 200 mm) and is designed for operation up to 150 PSIG (10.6 bar) and 212°F (100°C). The unit is available with switching or transmitting (4 to 20 mA) electronics.

The water-in-oil sensor is most often applied for the purpose of setting the maximum amount of water that is allowed to be present in the oil. When that concentration is reached, the flow is diverted or other corrective action is taken.

Radio-Frequency (Microwave) Sensors

When a cup containing water and oil is placed in a microwave oven, the water will heat up, but the oil will not. This is because shortwave RF energy is absorbed much more efficiently by water than by oil.

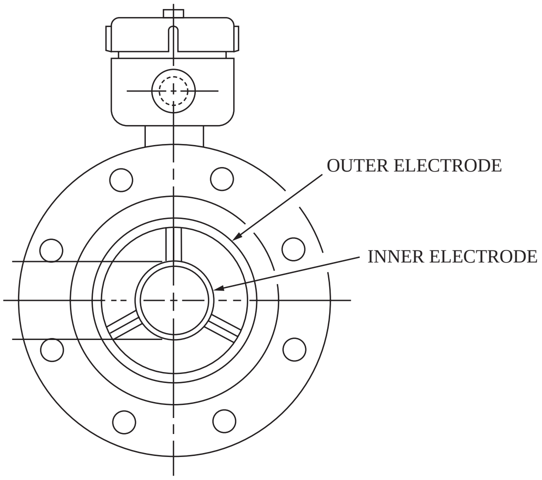

FIG. 8.39b
Flow-through water-in-oil detector utilizing two concentric capacitance electrodes. (Courtesy of Endress+Hauser.)

In a radio-wave detector, the transmitter produces waves that are of fixed frequency and contain a constant amount of energy. The more of this energy that is absorbed by the process fluid (the more water is in the mixture), the lower will be the voltage at the detector. The advantages of this design (relative to capacitance systems) include wider range (0 to 100%), lower sensitivity to buildup, insensitivity to temperature and salinity variations, and suitability for higher-temperature operations (up to 450°F, or 232°C).

Rag Layer and Tank Profiler Sensors The radio-wave oil-in-water sensors are available as probe-type sensors for water–oil interface control. A typical application is free water knockout (Figure 8.39c), in which the probe is installed horizontally at an elevation of one-third of the diameter from the bottom and is set to open the water dump valve when the emulsion concentration drops below 20% oil (80% water). This way, the emulsion (rag layer) will build up above the probe. These instruments can also provide a 4 to 20 mA transmitted output signal and can detect water concentration within an error of about 5%.

A portable tank profiler is also available that uses the same principle of operation. Here, the tape-supported radio-wave element is gradually lowered into a tank, which can be up to 100 ft (30 m) tall. As the sensor is lowered, it measures both the location of the interface (within an error of 0.12 in., or 3 mm) and the emulsion concentration throughout the tank height (from 0 to 100% within an error of 1%) (Figure 8.39d).

Water-in-Oil Probes A water-in-oil monitoring probe is also available that can detect the water concentration over a range of 0 to 100% in tanks or pipelines (Figure 8.39e) within an error of 0.1%. All of these devices are available in explosion-proof construction and can be provided with digital displays.

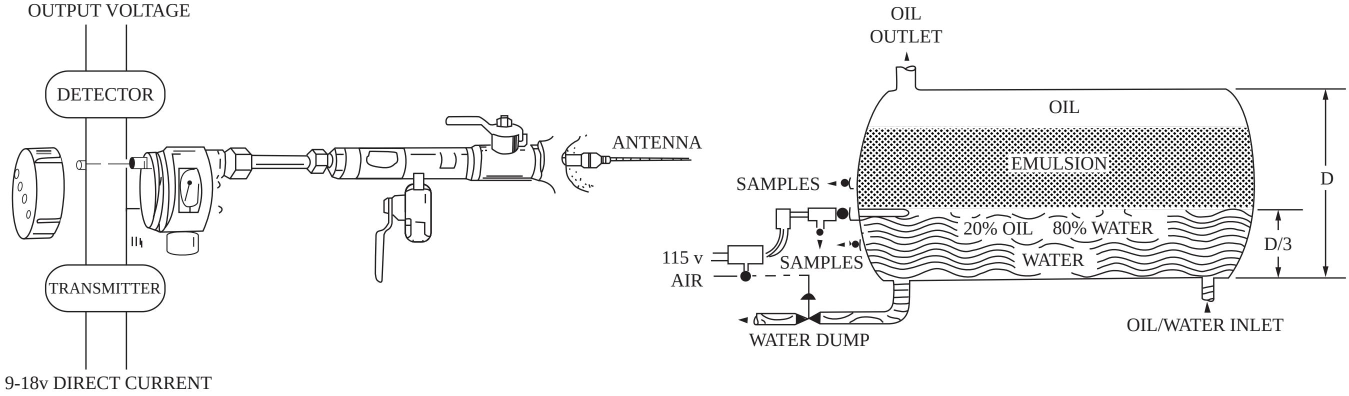

FIG. 8.39c
Radio-wave oil–water interface detector probe. (Courtesy of Agar Corp.)

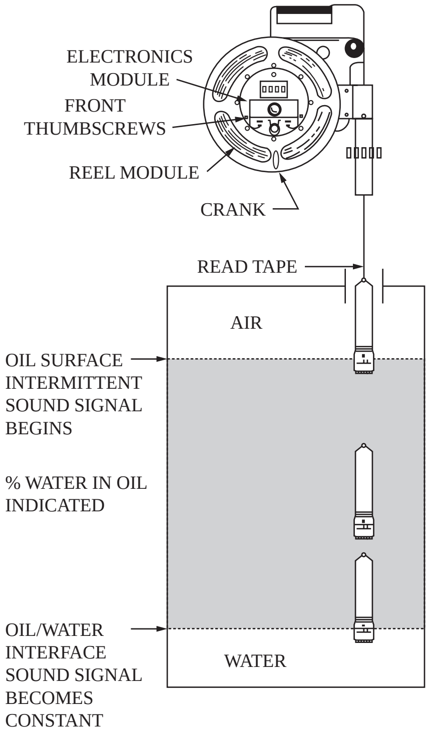

FIG. 8.39d
Tape-type tank profiler using radio-wave oil–water sensor. (Courtesy of Agar Corp.)

When applying this technology to measure oil in water, one must remember that there is a crossover point, at around 80% water concentration, at which the solution changes from being *water continuous* to *oil continuous*. This crossover results in a discontinuity in the analyzer output. Therefore, these devices suffer a significant loss in accuracy around this measurement point. In addition, many of these sensors are also sensitive to the salinity of the water phase. This can be corrected through the use of strapping tables, which should be selected by the user during calibration.

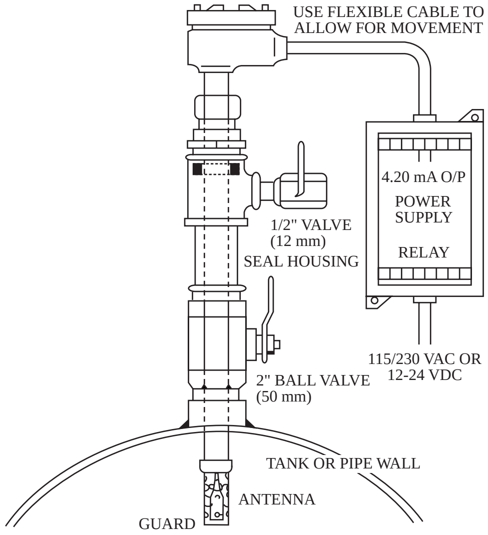

FIG. 8.39e
Water-in-oil concentration can be detected within a 0.1% error. (Courtesy of Agar Corp.)

Conductivity and Capacitance Sensors

There is a substantial difference between the conductivities of water and hydrocarbons. This difference is often used as the basis for detecting the interface between these two fluids.

Vessel profiles can also be estimated by using an array of self-contained capacitance cells on a common mounting frame. If the appropriate software is available, the resultant capacitance profile of the vessel can be used to signal the multiple interfaces in that vessel to a resolution as good as 1 cm.

Ultrasonic Sensors

As was illustrated in Figure 6.7b, a flow-through ultrasonic densitometer is available for mounting between a pair of pipe flanges. It measures and transmits an analog signal

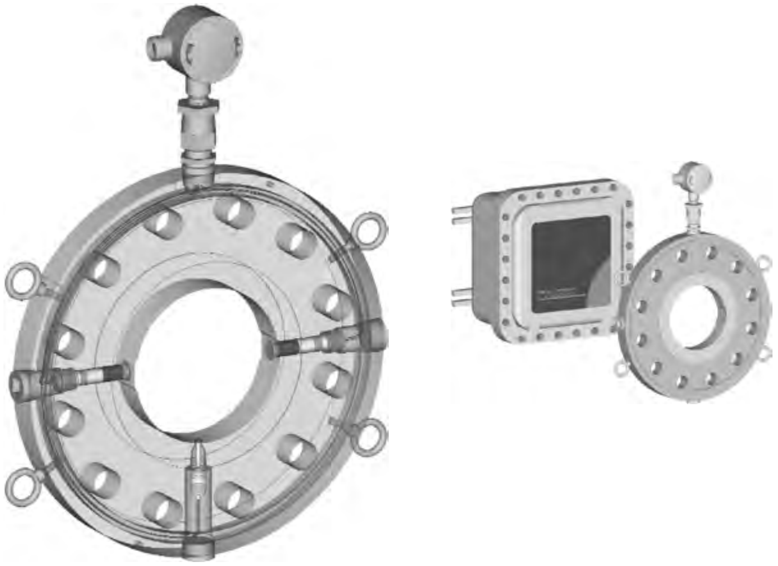

FIG. 8.39f
Wafer-type ultrasonic pipeline interface detector. (Courtesy of Caldon, Inc.)

proportional to the density and, hence, the amount of hydrocarbon in the flowing stream.

By using a number of pipeline interface detectors (Figure 8.39f), it is possible to use this meter to estimate fluid viscosity, thus making it useful as an interface detector between batches of product in a pipeline. The time of passage of the ultrasonic pulse and the attenuation of the signal are used to calculate both the density and the viscosity of the flowing fluid.

The viscosity is calculated from the slight rarefaction and compaction of molecules in the liquid, which cause viscous shearing of the fluid that absorbs acoustic energy. Kinematic fluid viscosity is determined from the energy loss of the meters' acoustic pulses as they pass through the fluid.

The analog outputs, which correspond to relative density and kinematic viscosity, can be used to detect the passing of an interface between two liquids in a pipeline. This information can be used to properly divert the flow into the correct tank. Relative density is determined by the change in sound velocity as a function of density and, because the object of the measurement is to compare the density of water against that of oil, an estimate of water or oil content can be made.

Nuclear Sensors

Several companies use the attenuation of gamma radiation to measure the density of the fluid between a source and detector, thus allowing a complete vessel profile and hence an estimation of the *composition* inside. One manufacturer of this technology uses an array of fixed sources and detectors, and others use a matched source and detector moving up and down in a well to provide a density profile (Figures 8.39g and 8.39h).

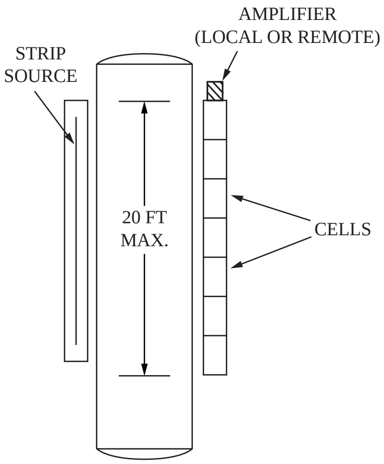

FIG. 8.39g
Strip source and cell receivers can be used for tank profiling.

As was the case for the conductivity array, software is then used to determine the actual interfaces between the phases. This interface is normally at the inflection point between two layers of differing densities.

Ultraviolet Oil-in-Water Analyzer

Figure 8.39i illustrates the sampling system of a continuous oil-in-water analyzer used for the monitoring of steam condensate, recycled cooling water, and refinery or offshore drilling effluents.

The UV analyzer used in this system is a single-beam, dual-wavelength analyzer. This is superior to the single-wavelength designs, because it is able to compensate for variations in sample sediment content, turbidity, and algae concentration, and for window coatings. The cell operates

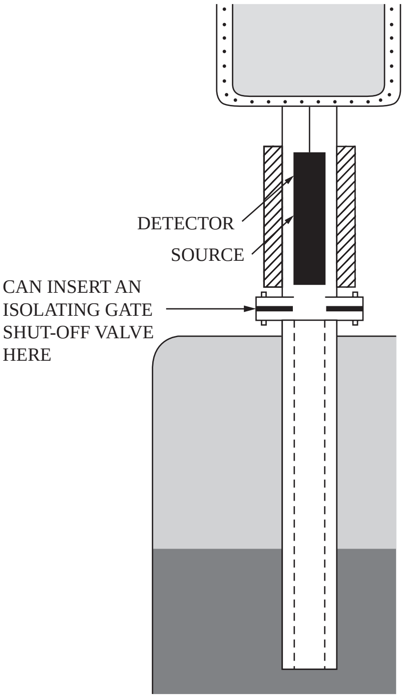

FIG. 8.39h

according to Beer's law [Equation 8.27(1)], which relates oil concentrations to UV energy absorption by the fixed length cell. The UV measuring band is centered at 254 nm, and the readings are sensitive to 0.1 ppm with a range of 0 to 10 ppm and provide a 90% response in 1 sec.

The instrument is automatically zeroed by the sample water being sent to both the measurement and the zeroing sides of the conditioning system. When in the measurement mode, the sample is sent through a high-speed, high-shear homogenizer, which disperses all suspended oil droplets and the oil, which is adsorbed onto foreign matter so that the sample sent to the analyzer becomes a uniform and true solution.

Once per hour, the analyzer is automatically rezeroed. In this mode, the sample water is sent through a filter that removes all the oil, and, after sparging, it is sent to the analyzer. This oil-free zero-reference sample still contains all the other compounds as contained in the measurement. Therefore, it can be used to zero out this background.

ENVIRONMENTAL POLLUTION SENSORS

Oil floating on water forms a mechanical barrier between the air and the water. It prevents oxygenation and kills oxygen-producing vegetation on the banks of streams. By coating the gills of fish, these materials also prevent breathing and cause the fish to suffocate. Outfalls from ships and municipal or industrial waste treatment plants must therefore be monitored for oil, and oil must be removed to prevent oil-bearing wastes from entering the receiving waters.

Continuous monitors are available to detect any hydrocarbons that are floating on the surface of the water. Oil in the water is equally undesirable, because it contributes to the biochemical oxygen demand (BOD) and can also be toxic to aquatic biota, to the fish food in water, and possibly to the fish themselves.

Optical methods of detection, when used for both types of contamination, require regular, conscientious maintenance for continuous and reliable performance. The capacitance approach used for the monitoring of oil film thickness on the water appears to require less maintenance but is limited to detection of floating oil. Each application must be evaluated separately, because presently available sensors have limited capabilities.

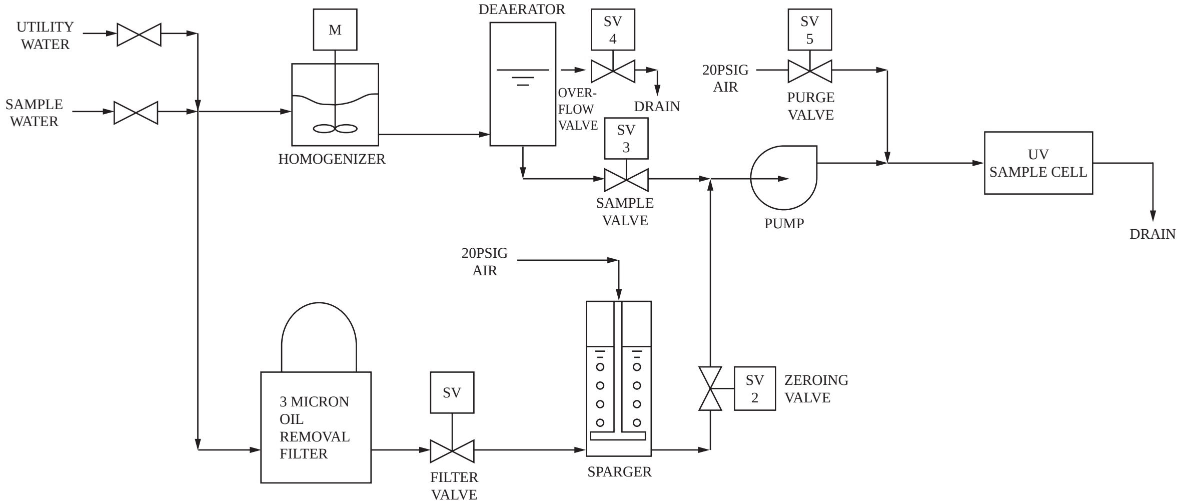

FIG. 8.39i
Ultraviolet oil-in-water analyzer with automatic-zero feature. (Courtesy of Teledyne Analytical Instruments.)

On-Off Oil-on-Water Detector

The nephelometer is intended to detect visible oil (hydrocarbon) slicks that are floating on fresh or salt water. It consists of two parts: a sensing head and a controller. The sensing head is inside an explosion-proof housing, which is supported on pontoons or floats in the body of water. An S-shaped baffle directs the flowing water past the sensing head.

A beam of light is focused through a lens onto the surface of the water. A second lens refocuses the reflected light onto a photocell. When there is no oil on the water, only a minimum amount of reflection occurs. When floating oil is present, the reflected light intensity increases substantially.

The measurement is based on the differential between the outputs of the reflected light photocell and a reference photocell, which is measuring the output of the light source itself. This instrument can provide an output signal that is proportional to the intensity of the reflected light, and it can also perform alarm functions.

Care must be taken when using such reflected light measurements to block out sunlight and/or other stray light sources because, if they are allowed to be also reflected, they will introduce an error (typically on the high side).

Continuous Oil-on-Water Detector Sensors similar to that deployed in the on-off detectors are also available to estimate the amount of oil floating on the water. The difference between the two applications is that, in this case, the Lambert–Beer law [Equation 8.27(1)] is used to determine the concentration from the detected light intensity.

Oil-Thickness-on-Water Detector

The previously described devices detect the presence or absence of oil floating on the water. This device permits the measurement of the thickness of the oil layer. The detector consists of a floating sensing head that is connected by a shielded cable to a remote controller. The sensor measures the thickness of the oil layer on the water by capacitance measurement (Figure 8.39j).

The operating principle is that of a series capacitor. The formula given is in Equation 8.39(1).

$$\frac{1}{C} = \frac{t}{\varepsilon A} = \frac{t_{oil}}{\varepsilon_{oil} A} + \frac{t_{water}}{\varepsilon_{water} A} \qquad \textbf{8.39(1)}$$

where
A = effective area of one capacitor plate
t = thickness
ε = dielectric constant

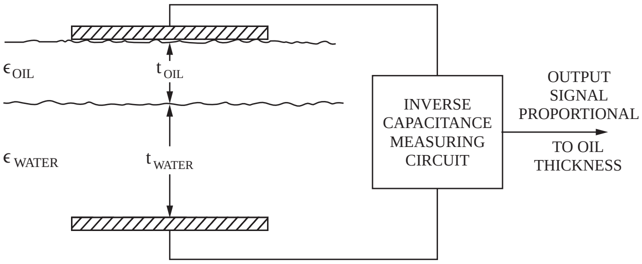

FIG. 8.39j
Parallel-plate capacitor detecting the thickness of an oil layer on water.

Because ε_{oil} = 1.9 to 2.1, whereas ε_{water} = 80, Equation 8.39(1) can be simplified by eliminating the second term, as shown in Equation 8.39(2).

$$\frac{1}{C} = \frac{t_{oil}}{\varepsilon_{oil} A} \qquad \textbf{8.39(2)}$$

Thus, the inverse of capacitance is detected as a value that is proportional to the oil thickness. The circuit generates a DC signal in proportion to the inverse of capacitance and is used for remote transmission. The sensor takes advantage of the large differential in dielectric constants between oil and water. It is claimed that it is not confused by the presence of emulsified sludge (having a large dielectric constant) or by oily froth, which cannot pass under the float.

Oil-in-Water Detector

When UV radiation is sent through an oil-contaminated water sample stream at a peak intensity of 365 nm, visible radiation is emitted. The intensity of this radiation can be measured by a photocell. The intensity of this radiation increases as the concentration of the fluorescent substance rises. At low concentrations (below 15×10^{-6}), the relationship between concentration and the visible radiation is essentially linear. In higher concentrations, some nonlinearity is experienced as a result of a saturation effect.

The most common configuration is to pass the process sample through the sensing head in an upflow direction (Figure 8.39k). The head is equipped with two windows that are set at right angles to each other so as to minimize the intensity of direct radiation from the source striking the photocell and also to reduce the effect of multiple scattering of the visible radiation. Optical filters at the incident and at the

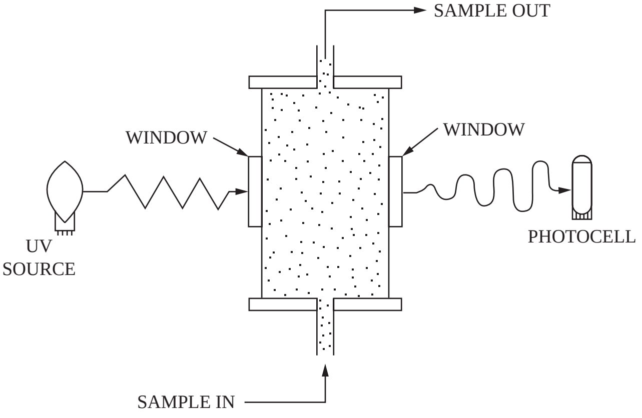

FIG. 8.39k
Oil-in-water detector.

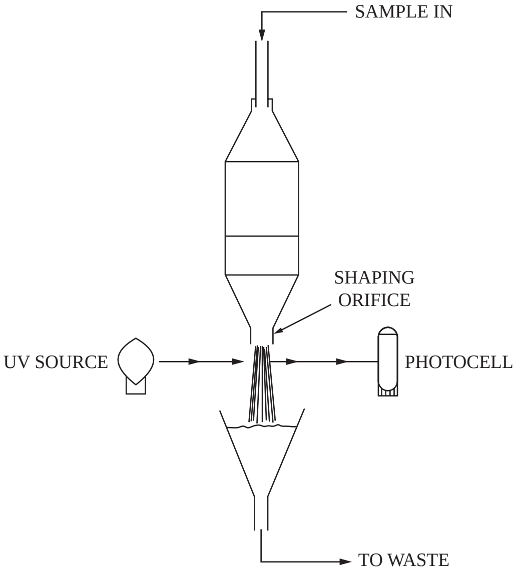

FIG 8.39l

Falling-stream oil-in-water detector.

emergent windows are used (not shown) to reduce this effect to a negligible level.

For the detection of oil concentration in water, a falling-stream type of detector is also available. In this device, the sample stream is shaped into a rectangle (Figure 8.39l) as it falls through the viewing field of the ultraviolet beam and the photocell. Efficient optical filtration is important to overcome the unavoidable effects of direct reflection of incident radiation from the surface of the shaped stream.

CONCLUSIONS

The on-off oil-on-water detector is capable of measuring as little as a few drops of petroleum floating on the surface of water, thus making it possible to detect those oil pollution levels that are visible to the human eye. It therefore serves a useful purpose as an alarm device downstream of plant outfalls and especially during and immediately after oil loading and unloading operations from tankers and tank trucks. This device presents the maintenance problems usually associated with optical measurements, which is that windows must be kept clean. The air column between the water surface and the window does reduce fouling due to splashing, but window cleanliness must be maintained for maximum sensitivity.

The oil-thickness device (Figure 8.39j), being nonoptical, requires less maintenance. Because both devices can detect the absence or presence of oil slicks, they might also find application as oil spill monitors after oil transfer operations.

Floating on the surface of wastewater storage sumps or lagoons, the output of the oil thickness monitor can be used to start and stop oil reclamation equipment. These devices cannot be calibrated for a specific oil fraction, but just respond to any floating hydrocarbon.

The oil-in-water devices are optical, and even the falling-stream types require clean windows, although they are less subject to fouling than the sample chamber types. They must be calibrated for a specific type of oil, and other oil fractions will introduce errors. They were originally developed to monitor engine oil contamination in boiler feed water and condensate, which can be introduced by steam-driven feed water pumps.

These devices detect the presence of a specific hydrocarbon fraction in well segregated waste streams. Where particle size is expected to exceed 5 μm, sample preparation prior to the UV analysis is necessary. Use of a high-shear mixer such as a blender has been found to produce a well dispersed suspension suitable for measurement.

INTRODUCTION

The information in this section is used to augment the sections on air quality monitoring (8.5), carbon monoxide (8.10), hydrogen sulfide (8.26), nitrogen oxide analyzers (8.37), ozone (8.44), sulfur oxide analyzers (8.56), and toxic gas monitoring (8.59). For combustible monitoring, this section augments information in sections on combustibles (8.16) and hydrocarbons (8.25).

From the standpoint of instrument design, there is also some overlap of information with sections covering infrared analyzers (8.27) and ultraviolet and visible analyzers (8.61).

This section confines itself to the discussion of instruments based on absorption. It omits discussion of LIDAR (acronym for LIght Detection And Ranging, an abbreviation formed in analogy with RADAR) techniques because of their very specialized nature. Also omitted is the discussion of gas cloud imaging technology, which is based on backscatter absorption. This technology is very new and has not yet been widely adopted in practical industrial situations.

Applications

Open path monitoring is used for analytical measurements in remote and inaccessible locations. The technique is also used for perimeter monitoring of structures and facilities. Such monitoring is either to detect the release of low levels of toxic and hazardous vapors, or it is to signal the releases of combustible hydrocarbons at relatively much higher levels. The use of open path monitoring is driven by either the need for probing an area without physical intrusion or by the need to monitor an area that is larger than one that can be cost effectively monitored with a requisite number of point detectors.

Open path monitoring is a subset of the techniques collectively called long path monitoring. Long path monitoring includes the use of multipass reflection cells to cover distances as great as hundreds of meters and achieve high detection sensitivity.

The two general uses of open path vapor detection, toxic and combustible detection, have resulted in instruments that have evolved specifically for each application. Open path toxic gas detection is generally used for very low-level detection—often in fence-line monitoring roles for estimation of emissions from a facility.

There are many more open path combustible hydrocarbon (OP-HC) detectors in use than there are toxic detectors. In a petrochemical plant, there can be as many as 150 OP-HC detectors, but only about half a dozen or fewer open path toxic detectors. Combustible detection requires much less instrument sensitivity, but instruments are highly engineered to provide much more protection against false alarms and to deliver high availability in excess of 99.9%. Immunity to false alarms is very important, because, when an alarm is actuated, executive action is frequently taken. Nondispersive infrared (NDIR) spectroscopy is most often used in OP-HC detectors.

Toxic Sensor Types

The types of open path toxic gas detector designs include open path Fourier-transform infrared (OP-FTIR) spectroscopy. This is a very commonly used technique that utilizes a number of very specific absorption bands in the infrared spectrum. A single instrument can be configured for the measurement of a wide variety of multiple components, and these sensors are highly adaptable for survey work.

In applications in which FTIR does not have sufficient sensitivity, open path ultraviolet (OP-UV) spectroscopy is frequently employed. This methodology can be used for applications involving the detection of homonuclear diatomic molecules (chlorine, bromine, etc.), which have no infrared absorption, or of molecules that absorb only weakly in the IR region, such as benzene, sulfur dioxide, and nitrogen oxides.

Because low-cost, highly reliable, solid state diode lasers have been developed and became available for high-volume telecommunications applications, a new class of open path detectors has been developed and applied to a subset of toxic measurement applications. Instruments in this category utilize the ability of the diode laser to scan over very short wavelength intervals. This method of measurement is referred to as open path tunable diode-laser absorption spectroscopy (OP-TDLAS).

INSTRUMENT DESIGNS

The four measurement technologies, OP-FTIR, OP-UV, OP-TDLAS, and OP-HC, all basically employ spectrophotometers designed for operation in a particular part of the spectrum. All spectrophotometers contain a light source, some transfer optics, a spectral dispersion element or optical filters, and optical detectors.

Figure 8.40a shows the primary components or all four classes of sensors. All these designs have a light source that illuminates the gas in the open path. The light source is collimated with transfer optics and is directed through the open path length to the receiving optics. The light is transferred through dispersing and filtering elements and is finally received by the optical detector. Table 8.40b shows how these elements differ in the four designs.

Note in Figure 8.40a that the dispersion elements can be utilized to predisperse the light prior to its passing through the open path sample, or it can be dispersed after passing through the sample. In OP-FTIR, the interferometer dispersing element is most often configured to modulate and predisperse the light prior to passing through the sample. This configuration

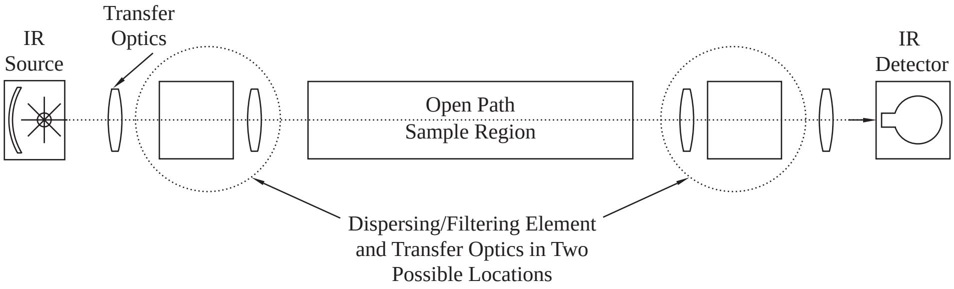

FIG. 8.40a
A schematic of a generalized open path sensor.

TABLE 8.40b
Common Components of Open Path Spectrophotometers

	OP-FTIR	*OP-HC*	*OP-TDLAS*	*OP-UV*
Wavelength range (μm)	Atmospheric transmission windows between 2.94 to 4.16 and 8.0 to 14.3	2.3 plus an adjacent reference wavelength band	Single wavelengths between 0.8 and 1.7	Atmospheric transmission window starting at 0.260 extending to visible
Light source	Heated globar	Xenon flash lamp or tungsten filament	Solid-state diode-laser	High pressure xenon arc
Dispersion element	Michelson interferometer*	Narrow-band optical filters*	None required except for electronics to scan laser wavelength	Grating spectrometer
Transfer optics	Gold coated mirrors	Glass lenses or mirrors	Glass lenses or mirrors	Silver mirrors
Optical detector(s)	Liquid nitrogen cooled mercury cadmium telluride photodiode	Indium galium arsenide photodiode	Indium galium arsenide photodiode	Linear CCD array

*These items are not dispersion elements in the classical sense but nevertheless serve the eventual purpose of isolating wavelengths for subsequent radiometric analysis by the optical detectors.

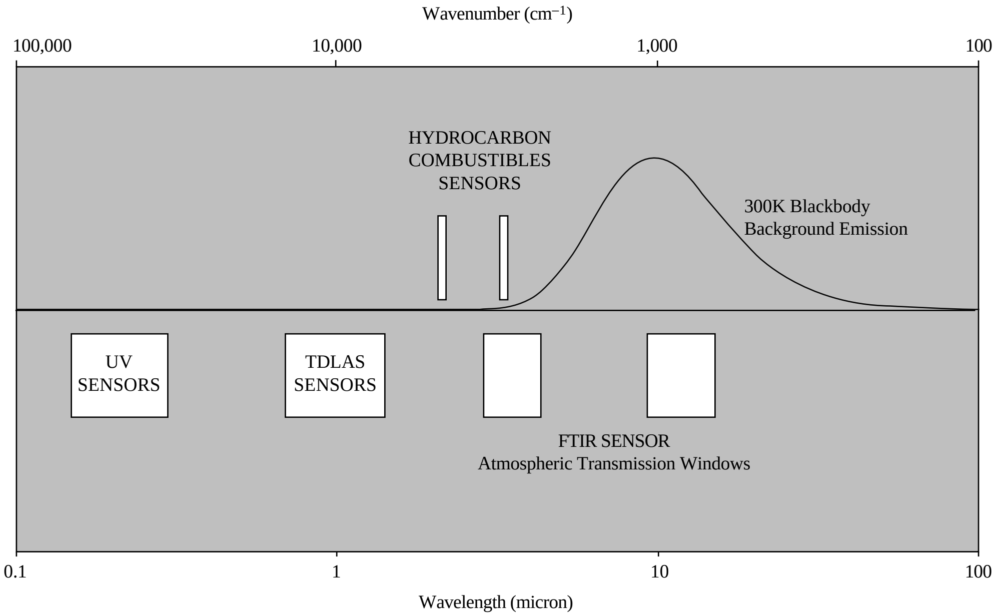

FIG. 8.40c

prevents thermal (blackbody) radiation from being added to the spectrum of the IR source.

Blackbody Radiation Interference

As shown in Figure 8.40c, there is significant IR emission in the ambient (27°C) blackbody curve that lies within the usable wavelength range of OP-FTIR systems. (The principles behind FTIR are discussed in more detail in Section 8.27.) The effect of uncompensated thermal background radiation is to introduce a bias and/or variability in the measured gas concentrations that have absorption bands that lie in this region.

The amount of ambient blackbody radiation is generally insignificant at the shorter wavelengths and has little affect on OP-HC, TDLAS, and OP-UV measurements. For these instruments, the dispersing element generally resides with the detector. This architecture provides a convenient, compact, and simple instrument implementation.

There can be extenuating circumstances, however, if the detector occasionally is pointed in a direction that has reflected sunlight. Sunlight approximates a 6000 K blackbody and subsequently has significant radiation through the visible portion of the spectrum into the UV. If proper consideration is not given to this potential interference in the design of the instrument, incorrect concentration measurements will be made.

Interferometry

Before the 1980s, infrared measurements were made using dispersive spectrometers employing diffraction gratings. Today, as a result of low-cost computing, improved optical designs, and optical detectors, Fourier transform interferometers have almost totally replaced dispersive spectrometers for this task.

Interferometers have much increased optical efficiency and, as a result, yield readings faster and with higher signal-to-noise ratios, and offer higher spectral resolution than corresponding dispersive instruments. Additionally, as a fundamental consequence of interferometry, wavelength measurement precision is vastly improved over dispersive spectrometers.

However, as advantageous as interferometry is in the infrared portion of the spectrum, the advantages quickly disappear at shorter wavelengths. At visible and UV wavelengths, the optical efficiency advantage is nullified by vastly more efficient optical detectors and light sources. (The principles behind UV spectrometry are discussed in more detail in Section 8.61.) The mechanical tolerances for interferometery at short wavelengths become prohibitive as well. Therefore, dispersive spectrometry is still widely used for short wavelengths.

Beer's Law and Path Integrated Concentrations

Open path absorption spectrophotometry takes advantage of the fact that a beam of photons can interact with molecules in the atmosphere, depending on the photons' wavelength. As the photons interact with and are absorbed by the molecules, they are removed from the beam. The reduction in the number of photons in the beam is a measure of the number (or concentration) of molecules in their path.

Beer's law describes the light absorption phenomenon. For light at a given wavelength, $I(\lambda)$, and a gas concentration profile that varies as a function of position, $c(l)$, over the optical path, L, this phenomenon can be expressed in the differential form in Equation 8.40(1).

$$\frac{dI(\lambda)}{I(\lambda)} = \varepsilon(\lambda)\cdot c(l)\cdot dl \qquad \textbf{8.40(1)}$$

The term $\varepsilon(\lambda)$ is called the absorptivity coefficient. This coefficient is determined by the characteristics of the absorbing molecule and depends strongly on the wavelength and more weakly on the temperature and pressure.

Generally, the concentration profile, $c(l)$, is not known. If the concentration is assumed to be a constant and uniform average value over the optical path, $\bar{c}$, refered to as the path average concentration (PAC), then the equation can be integrated to a more familiar form of the Beer's law in Equation 8.40(2).

$$\int_{Io}^{I}\frac{dI(\lambda)}{I(\lambda)} = \varepsilon(\lambda)\cdot\int_{0}^{L} c(l)\cdot dl \Rightarrow -\ln\left[\frac{I(\lambda)}{Io(\lambda)}\right] = \varepsilon(\lambda)\cdot\bar{c}\cdot L \qquad \textbf{8.40(2)}$$

In this equation, $Io(\lambda)$ is the original intensity of the optical beam at a given wavelength, and $I(\lambda)$ is the intensity of the beam after absorption by the molecules in the atmosphere. The fraction $I(\lambda)/Io(\lambda)$ is termed the *transmittance*, as it denotes the fraction of transmitted light through the atmosphere. The negative logarithm of the transmittance is termed *absorbance*.

Path Integrated Concentration The concentration profile integrated over the path length is termed path integrated concentration (PIC). It is simply the PAC multiplied by the measurement path length. PIC has units of mass per unit volume (often $\mu g/m^3$) times pathlength in meters. Using the ideal gas law, the temperature and pressure at which the measurements were made and the molecular weight of the species being measured, these units can be converted to the more familiar volumetric units of ppm*m or ppb*m in the case of toxic vapor determination. For combustible gas determination, the more appropriate units are in terms of the lower explosive limit, LEL*m.

An open path instrument natively measures PIC. This is frequently misunderstood by newcomers to the field. An open path instrument operating over a 100-m path length will produce the same PIC reading for a narrow, concentrated 1-m thick plume having a vapor concentration of 300 ppm as it will for a 3-ppm vapor cloud dispersed across the entire 100-m path length. In each of these situations, the PAC would be 3 ppm. This is illustrated in Figure 8.40d.

OPEN PATH FTIR SPECTROMETRY

Open path FTIR (OP-FTIR) instrumentation consists of five major components: an IR light source, interferometer, transmitter and receiver transfer optics, IR detector, and data system/controller. The IR light source is generally a glow bar with high emissivity across the IR spectrum.

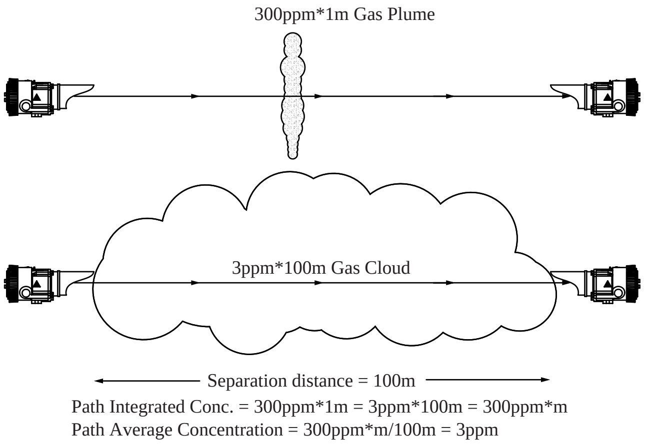

FIG. 8.40d
Illustration of path integrated concentration and relationship to path average concetration for narrow plumes and widely dispersed vapor clouds.

Interferometer

The interferometer is generally one of the Michelson variants and is used to modulate the light as a function of wavelength. The interferometer utilizes a moving mirror to generate an optical path difference between two beams of light that are allowed to interfere with each other. The position of the moving mirror must be measured to a tolerance of a fraction of the wavelength of light. This is frequently accomplished by using a highly stable tracking laser and counting interference fringes.

The moving mirror and the requirement for high-precision measurement of the optical path difference are two of the vulnerabilities of the interferometer mechanism. They limit reliability over time, operating temperature, and vibration. Much effort has been put into the design of interferometer systems to increase their reliability.

Transfer Optics and the Detector

Transfer optics are generally telescopes of the Newtonian or Cassegrainian configuration. Reflective optics are required, because inexpensive lenses that can cover the full useful range of wavelengths are not available.

The optical detector receives the modulated light. A cooled mercury cadmium telluride (MCT) detector is most often used to obtain the required sensitivity for the measurement. The detectors are cooled using liquid nitrogen (LN_2) or by a Sterling cycle heat pump.

The LN_2 dewar must be refilled every few days, which adds to operating maintenance costs. Sterling cycle coolers reduce the daily maintenance burden but are relatively expensive and have relatively short lifespans. In some applications, in which a relatively low-resolution measurement can be tolerated, deuterated triglycine sulfate (DTGS) detectors operating at room temperature can be used to address this maintenance issue.

Data System/Controller

Finally, the data system/controller performs a myriad of functions. It monitors the operation of the interferometer and synchronizes the collection of spectral data from the IR detector. It demodulates the spectral data using a fast Fourier transform algorithm and then does spectral manipulation to ratio the background and to compensate for background interferences and variation. As a final step, the corrected spectrum is processed by a pattern recognition and/or quantification algorithm that calculates path average concentration (e.g., average ppm) or path integrated concentrations (e.g., ppm*m).

Configurations

There are a number of instrumental configurations for OP-FTIR instruments. The simplest OP-FTIR systems are the so-called *bistatic* configurations. In these configurations, either a light source illuminates the open path region and is post-modulated with the interferometer, or the light source is premodulated before illuminating the open path region. The arrangement of the components of this design is shown in Figure 8.40e. This configuration derives its name from the fact that both the transmitter and receiver must be fixed in a static position and precisely aimed at each other.

The first real-time OP-FTIR systems had a direct source, postmodulated bistatic configuration. This configuration has the advantage of simplicity and hence is the least expensive design, but it also has a major disadvantage. This a result of the varying thermal emission of near field objects that produce a varying spectral background at frequencies below 2000 cm^{-1}. If uncompensated, this background will produce a negative bias on the measured concentration.

Most of this varying background emission and its effects can be compensated. This is done by turning off the source and by subtracting the spectrum while it is off. The direct source configuration has the advantage of being easily adaptable to a passive monitoring configuration where the thermal emission from the background or hot gas plumes act as the infrared source.

The premodulated bistatic configuration solves the background emission problem, because the source modulation occurs much faster than do changes in background emissions. However, since the detector and interferometer are separated by some distance, an additional cable is required to communicate between them.

Bistatic configurations in general have the requirement of supplying power at both the receiver and transmitter, which can be a disadvantage in some locations. Additionally, there is a requirement for alignment at both receiver and transmitter, which can be time consuming for mobile systems. It may be less of an issue for permanent fixed systems.

The so-called monostatic configurations were developed to address issues raised with bistatic designs. In a monostatic configuration, all of the optical components of the transmitter and receiver are in the same location, and a retroreflector is used to return the light from the transmitter to the receiver. This configuration derives its name from the fact that only the transceiver portion of the instrument needs to be precisely pointed, as the retroreflector returns light to its source regardless of orientation. A diagram of two monostatic configurations is shown in Figure 8.40f.

The single-telescope monostatic configuration is relatively simple to implement and is inexpensive. The use of a single telescope makes alignment simpler and lowers costs. The corner-cube array returns the light to the direction from which it came. This property reduces the divergence of the beam on its return path back to the detector compared to the divergence that would result from a flat mirror. Also, the retroreflector array can be very large so as to capture and return essentially all of the divergent signal from the telescope.

However, this design requires a beam splitter in the optical path that removes 50% of the light from the outgoing beam and 50% of the light from the return beam for an overall loss of 75% of the total light intensity.

The dual-telescope monostatic configuration has greater optical efficiency, as it does not utilize a beam splitter in the

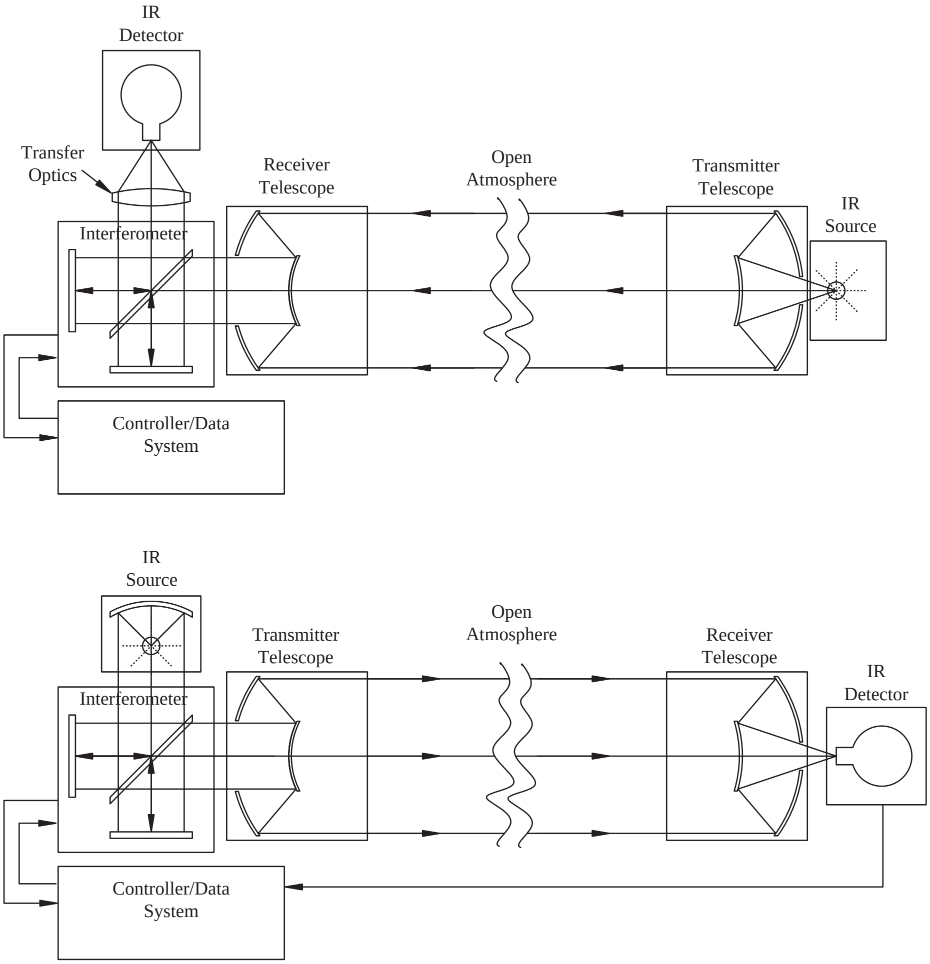

FIG. 8.40e
Bistatic configurations for OP-FTIR. Post-modulated configuration (top) uses interferometer to modulate the light after it passes through the open path. The premodulated configuration (bottom) uses the interferometer to modulate the light prior to passing through the open path.

optical path. It utilizes a translating retroreflector, which is essentially a portion of a very large cube. This single, large retroreflector does not have the divergence reversal properties of the corner cube array. The second telescope adds cost and complexity to the system.

OP-FTIR sensitivities for various molecular species are listed in Table 8.40g.

OPEN PATH ULTRAVIOLET SPECTROMETRY

Open path ultraviolet (OP-UV) spectrometry can be used to measure vapors or gases that have weak absorption characteristics and therefore low sensitivities in the IR spectrum. These include such compounds as nitrogen oxides, sulfur dioxide, benzene, and also homonuclear diatomic molecules, such as chlorine, that have no IR absorption spectra but acceptably strong UV absorption.

The UV spectra are much less specific than the IR spectra and do not have well-defined and separated absorption features. The number of compounds that can be determined by UV are much fewer than ones that are absorbing in the IR spectra. Still, the above listed and environmentally very important compounds make OP-UV an important complementary methodology.

The OP-UV Spectrometer

A schematic of an OP-UV spectrometer with a monostatic configuration is shown in Figure 8.40h. Bistatic configurations are available as well and are generally provided with fixed source.

Sources are generally high-pressure xenon arc lamps that emit a continuum from the UV to the visible spectra. The spatial extent of the arc can be very small, on the order of 250 μm, which lends itself to collimation with very low divergence. As a result, UV instruments can operate with path lengths up to several kilometers.

The long distances are facilitated by the low optical divergence and by the fact that water vapor and carbon dioxide do not absorb in the UV spectra as they do in the infrared. On the other hand, the short UV wavelengths can be strongly

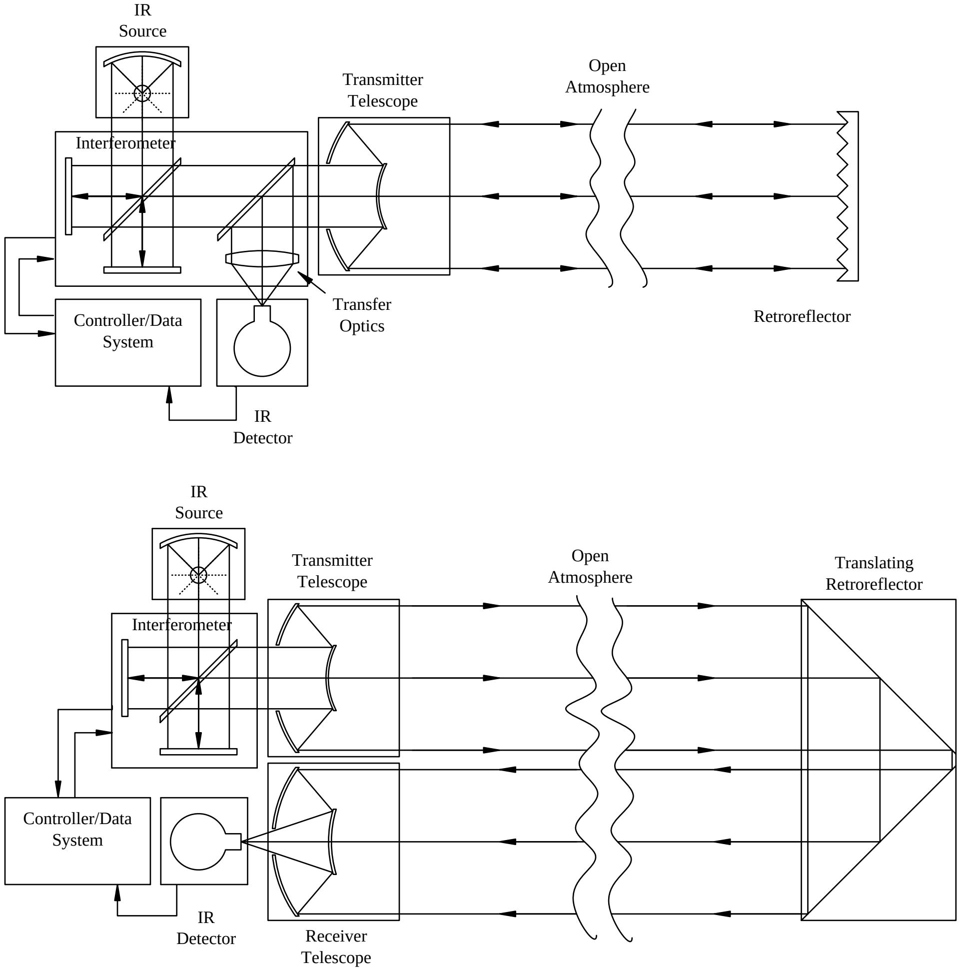

FIG. 8.40f

Two monostatic configurations for OP-FTIR both using premodulated configurations. The single telescope configuration (top) uses a corner-cube retroreflector array and is less optically efficient. The dual telescope configuration (bottom) is more optically efficient, but requires more telescope complexity.

scattered by aerosols such as fog, snow, smoke, and dust, which greatly degrade their performance. The short wavelength limit is determined by interference of molecular oxygen at wavelengths shorter than 260 nm.

The detector depicted in Figure 8.40h is a solid state array detector such as a CCD. The array detector permits the acquisition of intensities from multiple wavelengths simultaneously and without mechanically moving parts.

The spectra of many molecules in the UV, notably SO_2 and NO, in most cases have periodic absorption patterns resulting from the interaction of the vibrational energy levels with the electronics absorption. The overall absorption band can be quite wide and broadly overlapping. However, the periodicity can be used to identify the absorbing species. A Fourier transform of the UV absorption spectrum is often used to pretreat the data to isolate the absorbing species based on the spatial periodicity. The peaks thus produced can be further treated with spectral quantification algorithms such as the classical least squares method.

OP-UV has been used to detect and quantify the following gases: NO, NO_2, NO_3, formaldehyde, ozone, SO_2, benzene, toluene, and o, m, p-xylenes. Table 8.40i lists selected gases and detection limits available with OP-UV.

OPEN PATH TUNABLE DIODE LASER SPECTROMETRY

Open path tunable diode laser spectrometry (OP-TDLAS) is a relatively recent technology that has been applied commercially only to air monitoring within the past decade. Recently, these instruments have been made sufficiently rugged and reasonably simple to use in other applications.

Previously, lead salt diodes were used, emitting laser radiation in the 3–20 μm mid-IR portion of the IR spectrum. Instruments based on these lasers were capable of making very sensitive measurements, sometimes in the parts-per-trillion range. They were also very fast, having measurement times as low as 1/10 sec.

Benzene	42–150
Ammonia	310–5870

*From Reference 1.

**Integration times vary from 1 to 5 min. Pathlength varied from 100 to 250 m.

On the other hand, complexity and cost limited their commercial acceptance. The lead salt lasers required liquid nitrogen cooling for operation, and IR absorptions accessible to the lasers were subject to pressure broadening effects, which limited their use to point monitoring applications using multipass cells operating at reduced pressure.

Diode Lasers

Diode lasers originally developed and manufactured in large volumes for telecommunications applications have been adopted to OP-TDLAS applications.

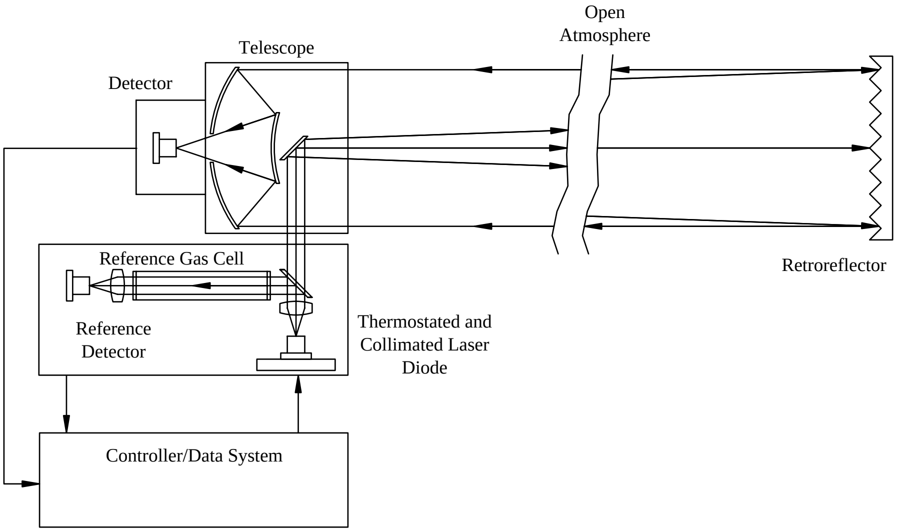

FIG. 8.40j
Schematic representation of an OP-TDLAS spectrometer in monostatic configuration.

Various diodes operate at or near room temperature and emit radiation between 0.6 and 2.5 μm in the near-IR portion of the spectrum. Wavelength tuning over relatively short wavelength ranges is achieved by temperature tuning as well as by varying the injection current into the diode itself. Temperature tuning is most often performed using a thermostat, which controls a thermoelectric cooler. Current tuning is performed using a programmable current source and is done at relatively high frequencies in the kilohertz range.

The absorption ranges that are accessible with these near-IR wavelengths are less sensitive than those in the mid-IR, but they are less susceptible to pressure-broadening effects. This permits their use in the open path monitoring applications. The reduction in detection sensitivity is partially recovered by the use of high-frequency wavelength modulation and by improved signal-detection techniques. Detection limits in the range of low ppm*m of target molecules are generally achievable.

Because these diode lasers are used in large volumes for telecommunications applications, their costs are an order of magnitude or two lower than those of lead salt diodes. Additionally, with near-IR wavelengths, traditional and low-cost glass optical materials can be used to fabricate the supporting optical assemblies instead of exotic and expensive mid-IR optical materials.

Applications

Molecules having absorption spectra that are accessible with diode lasers include NO, NO_2, HF, HCl, HCN, HI, NH_3, C_2H_2, CO, CO_2, H_2S, and CH_4. In some fortuitous instances, diode lasers have wide enough tunability to simultaneously measure multiple gases that have closely spaced absorption features. This is the case with HF and CH_4 and with CO and CO_2. Generally, however, a separate laser is required for each gas analyte of interest. Some commercial devices permit the fitting of more than one laser into a device so that multiple gases can be measured.

Principle of Operation

A schematic diagram illustrating the principle of operation of an OP-TDLAS is shown in Figure 8.40j. The monostatic configuration using a retroreflector is representative of commercial architectures.

In this configuration, laser light from a diode laser is directed to a beam splitter and then onto a steering mirror in the telescope, which directs the light out into the open atmosphere. The light interacts with the target gas molecules over a one-way optical path of up to 1 km and eventually falls onto a retroreflector array. The retroreflector array returns the light back to the telescope, which serves to focus it onto the optical detector.

The small portion of the light intercepted by the beam splitter is directed through a reference cell where a sample of the target analyte gas is present. The absorption of light by the gas in the reference cell is used to generate a feedback signal to the diode laser thermostat to keep the laser wavelength accurately tuned to the center of a gas absorption line.

Wavelength Modulation Spectrometry All commercial OP-TDLAS devices use some form of wavelength modulation to perform the measurement. The principle of wavelength modulation spectrometry is shown in Figure 8.40k. With this methodology, the laser, which is tuned to the center of an absorption line, is modulated at high frequency about the absorption maximum.

Temperature tuning is used to adjust the diode laser output to the center of the absorption line. Current tuning using a programmable current source is used to modulate the laser wavelength at kilohertz frequencies. As the laser wavelength

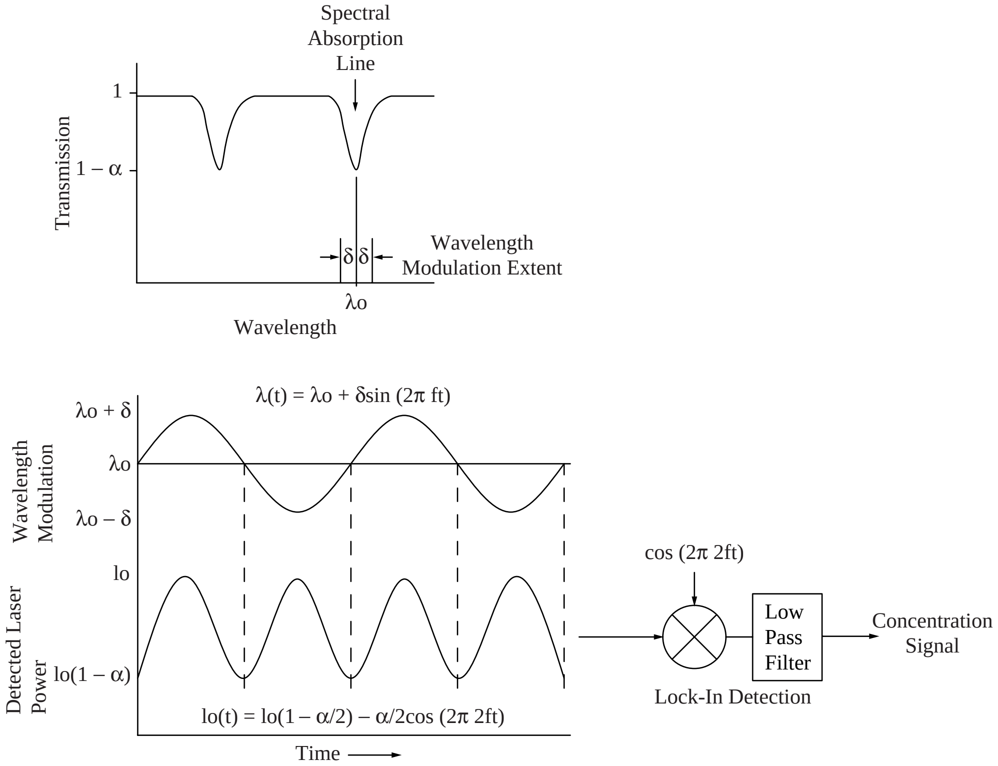

FIG. 8.40k
Principle of wavelength modulation spectrometry—The laser wavelength is tuned to an absorption line and modulated at frequency f. The laser intensity as it passes through the sample is modulated at frequency 2f. The concentration signal is recovered using lock-in detection techniques.

passes through the peak absorption wavelength, the detected laser intensity drops and then increases as the laser moves to one side of the line or the other.

A laser wavelength modulation frequency of f produces an intensity modulation of the laser at frequency 2f because of absorption of the analyte gas. The 2f intensity modulation is detected using lock-in detection. Lock-in detection at high frequency provides signal-to-noise enhancement that somewhat negates the general low absorptivity of the absorption lines. Measurements are typically made at a rate of one sample per second.

Table 8.40l lists some representative gases of interest for air monitoring that can be measured using TDLAS along with their approximate detection limits. For industrial applications, HF monitoring by OP-TDLAS has proven to be very useful because of the low detection limits achievable and because of the lack of interference.

OPEN PATH DETECTION OF COMBUSTIBLES

A very important use of open path gas detection is to measure the concentration of combustible vapors. These vapors typically are hydrocarbons such as methane, ethylene, and so on, so the abbreviation OP-HC is frequently used. Detection is not strictly limited to pure hydrocarbons but can also be used to detect a number of organic vapors having a near-IR absorption spectrum due to CH bonds.

In terms of numbers of detectors sold, this application far dominates the market. OP-HC detectors can be found in the hundreds in oil and gas production facilities and, in lesser numbers, in downstream transportation and distribution facilities as well as petrochemical facilities. In recent years, OP-HC detectors have seen increased usage to augment detection by traditional point hydrocarbon detectors, especially in situations where the probability of detecting a leak with a point detector is low.

OP-HC detection is especially useful for perimeter monitoring of tank farms, process areas, and other places where combustible vapor leaks can happen over a widely dispersed area. Because the emphasis is on safety applications, these detectors are optimized for low maintenance, avoidance of false alarms, and low costs.

These detectors typically are housed in flameproof enclosures and are suitable for deployment into Class 1, Division 1, or CENELEC Zone 1 hazardous areas. These devices typically have on-board heaters to melt snow and ice so that they can operate unattended and uninterrupted in inclement weather.

OP-HC Detector Design

Figure 8.40m shows a simplified schematic representation of an OP-HC detector. The bistatic configuration is most commonly used. Monostatic configurations using a retroreflector require electrical power for heaters and subsequent flameproofed enclosure, which somewhat reduces the advantage of that configuration for this application.

The detection principle relies on a two-channel nondispersive photometer. The active channel is equipped with an optical filter that limits light to the detector to the hydrocarbon absorption region of the spectrum. The reference channel observes the intensity of light in an adjacent portion of the spectrum that is free from hydrocarbon absorption. The optical filters are carefully specified to minimize false gas signals from differential absorption resulting from moisture as well as changes in the spectral output characteristics of the source over time.

Sources and Interference These devices utilize bright, modulated sources with receiver detection electronics tuned to the modulation frequency. Typically, a xenon flash lamp is used; less typically, a modulated tungsten filament or microfabricated IR source is used. The source is modulated to mitigate against solar interference, either directly as the sun enters the field of view of the detector at sunrise or sunset or indirectly as reflections from waves in offshore installations or other background objects.

Solar radiation that falls within the field of view of the receiver and that has intensity modulated frequency components within the acceptance bandwidth of the receiver electronics can result in a false gas signal. Source modulation is performed at frequencies where there is minimal solar modulation. The short pulse duration of the xenon lamp permits the utilization of a very narrow acceptance bandwidth filter in the receiver electronics.

Transmitter–Receiver Separation Distances between the transmitter and receiver vary typically between 10 and >120 m. Most vendors supply at least two models: a short-range unit for operation from 10 to 60 m, and a longer-range unit operating to the >120-m distance. The primary difference between the units is the efficiency of the collimation and condensing optics. In most cases, the worst-case visibility, resulting from fog and other atmospheric phenomena, presents the practical limit to transmitter–receiver separation.

Table 8.40n illustrates this point by showing how the maximum acceptable transmitter–receiver separation varies

TABLE 8.40n*

Typical Maximum Distance Between Transmitter and Receiver Over Which Proper OP-HC Operation can be Maintained at a Worst-case Fog Visibility

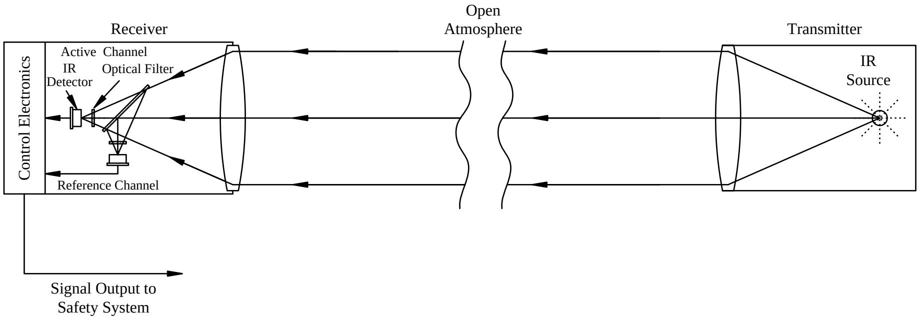

FIG. 8.40m

Schematic representation of an NDIR-based OP-HC detector.

with visibility in fog. Additionally, for very short-range applications <10 m, such as in ventilation ducts and small enclosures, the units can be equipped with optical attenuators fitted to the transmitter to keep the intensity of light within acceptable levels for the receiver.

The PIC range of the devices are usually set at around 0 to 5 LEL*m (LEL = lower explosive limit). This corresponds to a range of from 0 to 25%*m for methane (where 1 LEL of methane is 5%). Low and high alarms are generally set for 2 and 3 LEL*m, respectively.

Advantages and Limitations The use of PIC for open path has been the source of much debate and confusion, especially when attempts are made to correlate the range with point hydrocarbon detectors that are generally ranged from 0 to 1 LEL (0 to 100% LEL). Using PIC, it is clearly possible that the concentration of gas will exceed, in some location, in the beam's path the lower explosive limit. On the other hand, many point sensors would be required to be able to place a point detector at the precise location where such localized concentrations occur.

Much discussion and research has been done to arrive at a rational range setting strategy for OP-HC devices. There has been considerable work done at the Christian Michelson Institute in Norway on vapor cloud explosions. It has been found that, for oil and gas facilities, where largely unconfined explosions can be expected, flame front velocities below 100 m/s will not produce significant damage to personnel or facilities. Experiments have also demonstrated that flames need a run-up distance of approximately 5.5 m. Therefore, vapor clouds with dimensions less than this may not cause substantial damage.[3,4]

The primary signal output from an OP-HC detector is almost always a 4 to 20 mA current loop. The output is generally tied into a dedicated fire and gas safety system that can trigger some form of executive action in the facility. Secondary outputs are frequently available as well. Digital protocols such as HART and Modbus are common and permit the devices to be tied to PLCs and asset management computer systems.

INTRODUCTION

The measurement and control of oxidation-reduction potential (also called ORP or redox potential) is applied in many applications in both industrial processing and in wastewater treatment. The more important applications include the following:

1. In ore leaching, metal is leached from the ore and converted to the desired state for further processing.
2. Toxic cyanides are oxidized to harmless reaction products in an oxidation-reduction reaction as part of the process to remove toxic heavy metals (Figure 8.41a).
3. In the pulp and paper industry, pulp is bleached with a variety of oxidants under ORP measurement and control.
4. Hexavalent chromium is reduced to the trivalent oxidation state as part of the process for removal of toxic chromium from metal finishing or from cooling tower blow-down wastewaters (Figure 8.41b).
5. The manufacture of chlorine bleaches is controlled by ORP.
6. In sanitary wastewater treatment, ORP is used to control the addition of an oxidant for odor control.

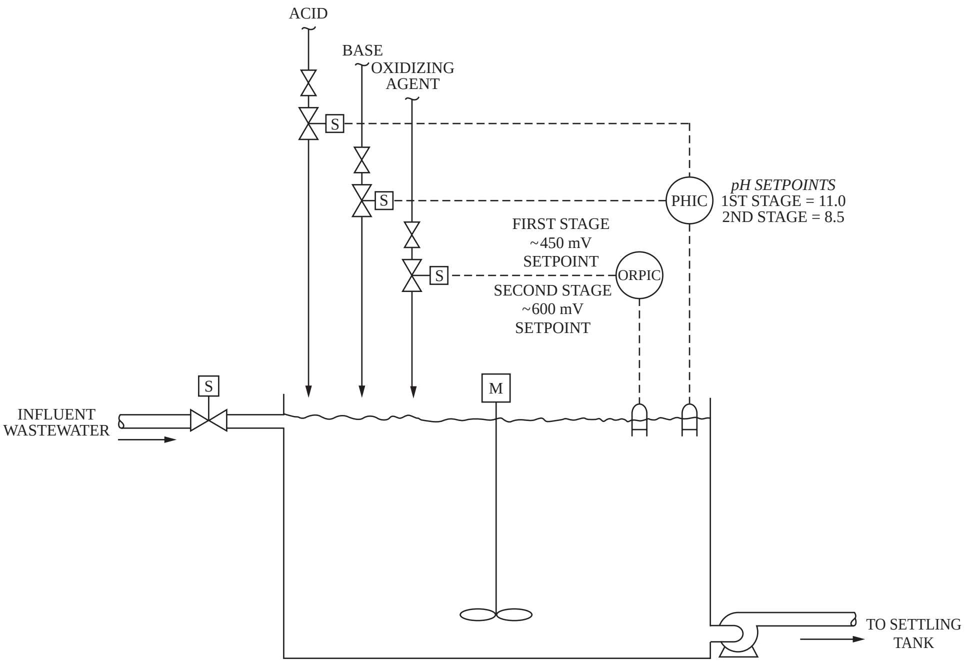

FIG. 8.41a
Batch oxidization of toxic cyanides.

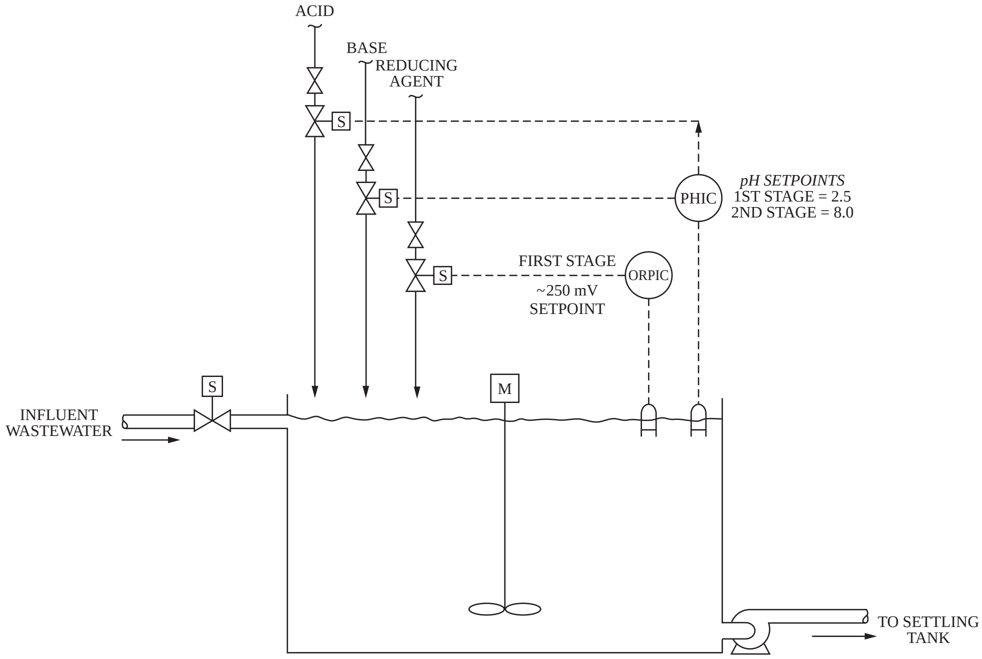

FIG. 8.41b
Batch reduction of toxic hexavalent chromium.

ORP MEASUREMENT PRINCIPLES

The reacting molecules in the oxidation-reduction reactions either gain or lose electrons and therefore end up with different electron configurations after the reaction.

Oxidation in a chemical reaction is the overall process by which a molecule loses one or more electrons and increases its state of oxidation. An oxidant is a substance that is capable of oxidizing another chemical specie in a process in which it acquires one or more electrons, which are lost by the specie being oxidized. In this overall process, the oxidant itself is reduced.

Reduction is the overall process in which a specie in a chemical reaction gains one or more electrons and decreases its state of oxidation. A reductant is a substance that is capable of reducing a chemical specie. The reductant loses the electrons, which are gained by the specie and is itself oxidized in the overall process.

The ORP Reaction

An ORP reaction involves an electron exchange that is capable of doing work. This capability is expressed in terms of potential for a half-cell, or electron, reaction. The potentials listed in Table 8.41c are for standard conditions, that is, where reactants and products are at unit activity. Voltages in this table are referenced to the standard hydrogen electrode (SHE), which is assigned the value of 0.000 V.

TABLE 8.41c
Reduction Potentials of Solution in ORP Measurement

Reduction	*E°, Volts*
$O_3 + 2H_3O^+ + 2e^- = O_2 + 3H_2O$	+2.070
$Cr_2O_7^{2-} + 14H_3O^+ + 6e^- = 2Cr^{3+} + 21H_2O$	+1.330
$ClO^- + H_2O + 2e^- = Cl^- + 2OH^-$	+0.890
$Fe^{3+} + e^- = Fe^{2+}$	+0.770
Ag/AgCl electrode 4 M KCl	+0.199
$2H_3O^+ + 2e^- = H_2 + 2H_2O$	0.000
$Zn^{2+} + 2e^- = Zn$	−0.763
$CNO^- + H_2O + 2e^- = CN^- + 2OH^-$	−0.970
$Na^+ + e^- = Na$	−2.711

Note that the Table 8.41c reactions are written as reductions, which is the most often used convention. The term *ox/red* is used to indicate the oxidized form on the left side of the equation and the reduced form on the right. For example, the standard potential for ferric iron, Fe^{3+}, being reduced to ferrous, Fe^{2+}, is written as

$$E°Ox/Red = +0.770 \text{ V} \tag{8.41(1)}$$

It will be noted that $E_{Red/Ox} = -E_{Ox/Red}$, which simply means that polarity is reversed when the reaction is written as an oxidation reaction. For example,

$$Fe^{2+} = Fe^{3+} + e.^- \; E°_{Red/Ox} = -0.770 \text{ V} \tag{8.41(2)}$$

Half-Cell Reactions It is customary in dealing with oxidation-reduction reactions to write down separately the two half-cell reactions that make up the overall reaction. These are written so that known reactants are on the left and known products on the right. The following is a general equation in which the hydronium ion participates in the reaction, and therefore the potentials are pH-dependent.

Half-Reaction

$$\mathrm{aOx_2 + yH_3O^+ + n_2e^- \rightleftharpoons bRed_2 + wH_2O E_{Ox_2/Red_2}} \qquad \textbf{8.41(3)}$$

Half-Reaction

$$\mathrm{cRed_1 \rightleftharpoons dOx_1 + n_1e^- E_{Red_1/Ox_1}} \qquad \textbf{8.41(4)}$$

Overall Reaction

$$\begin{aligned}&\mathrm{n_1aOx_2 + n_2cRed_1 + n_1yH_3O^+ \rightleftharpoons n_1bRed_2}\\&\mathrm{+ n_2dOx_1 + n_1wH_2O}\end{aligned} \qquad \textbf{8.41(5)}$$

The Cell Potential

$$\mathrm{E_{overall} = E_{Ox_2/Red_2} + E_{Red_1/Ox_1}} \qquad \textbf{8.41(6)}$$

At any point in the reaction, the solution or cell potential is given by

$$\mathrm{E_{cell} = E_{Ox_2/Red_2} + E_{Ox_1/Red_1}} \qquad \textbf{8.41(7)}$$

which, at 77°F (25°C), is

$$\mathrm{E_{Ox_2/Red_2} = E^\circ_{Ox_2/Red_2} + \frac{0.059\ \log}{n_2}\frac{[Ox_2]^a[H_3O^+]^y}{[Red_2]^b[H_2O]^w}} \qquad \textbf{8.41(8)}$$

and

$$\mathrm{E_{Ox_1/Red_1} = E^\circ_{Ox_1/Red_1} + \frac{0.059}{n_1}\log\frac{[Ox_1]^d}{[Red_1]^c}} \qquad \textbf{8.41(9)}$$

Setting Equations 8.41(8) and 8.41(9) to equal each other and rearranging, we get

$$\begin{aligned}&\mathrm{(n_1 + n_2)E_{cell} = n_2E^\circ\ Ox_2/Red + n_1E^\circ_{Ox_1/Red_1} + 0.059\ \log}\\&\qquad\mathrm{\times\frac{[Ox_2]^a[Ox_1]^d}{[Red_2]^b[Red_1]^e} + 0.059\ \log H_3O^{+\mathit{y}}}\end{aligned} \qquad \textbf{8.41(10)}$$

Two other relationships can also be given, one for any reaction point and the other for the equivalence point. At any point in the reaction after the start,

$$\mathrm{Red_2 = \frac{n_1b}{n_2d}[Ox_1]} \qquad \textbf{8.41(11)}$$

and at the equivalence point,

$$\mathrm{Ox_2 = \frac{n_1a}{n_2c}[Red_1]} \qquad \textbf{8.41(12)}$$

Cell Potential at Equivalence Point Substitution of the ratio relationship $\mathrm{Ox_2^a/Red_2^b}$ or $\mathrm{Ox_1^d/Red_1^c}$, as derived from Equations 8.41(11) and 8.41(12), into Equation 8.41(10), will provide the cell potential for the equivalence point. It can be an interesting exercise to see how this equivalence point potential changes when differing values of $\mathrm{H_3O^+}$ (that is, pH) are substituted into Equation 8.41(10). By so doing, the profound effects that pH can have on equivalence and control point potentials will become apparent. This then shows that when hydronium, $\mathrm{H_3O^+}$, or hydroxyl, $\mathrm{OH^-}$, ions participate in ORP reactions, close control of pH may become just as important as close control of ORP.

Note again Equations 8.41(7), 8.41(8), and 8.41(9), which state that

$$\begin{aligned}&\mathrm{E^\circ_{Ox_2/Red_2} + \frac{0.059}{n_2}\log\frac{[Ox_2]^a[H_3O]^y}{[Red_2]^b[H_2O]^w}}\\&\mathrm{= E^\circ_{Ox_2/Red_2} - E^\circ_{Ox_1/Red_1} + \frac{0.059}{n_1}\log\frac{[Ox_1]^d}{[Red_1]^c}}\end{aligned} \qquad \textbf{8.41(13)}$$

and

$$\mathrm{\frac{0.059}{n_1n_2}\log\frac{[Red_2]^{n_1b}[Ox_1]^{n_2d}[H_2O]^{n_1w}}{[Ox_2]^{n_1a}[Red_1]^{n_2c}[H_3O^+]^{n_1y}} = E^\circ_{Ox_2/Red_2} - E^\circ_{Ox_1/Red_1}} \qquad \textbf{8.41(14)}$$

The equilibrium constant is given by

$$\mathrm{\frac{[Red_2]^{n_1b}[Ox_1]^{n_2d}}{[Ox_2]^{n_1a}[Red_1]^{n_2c10}} = \left(\frac{E^\circ_{Ox_2/Red_2} - E^\circ_{Ox_1/Red_1}}{0.59/n_1n_2}\right)\times[H_3O^+]^{n_1y}} \qquad \textbf{8.41(15)}$$

Again, using the relationships of Equations 8.41(11) and 8.41(12) and substituting them into Equation 8.41(15), it is possible to determine the reaction's degree of completion for the specie of interest at the equivalence point for various pH levels.

Chromium Example As an example, consider a common industrial process in which hexavalent chromium is reduced with a ferrous sulfate solution. The half-reactions are as follows:

$$\begin{gathered}\mathrm{Cr_2O_7{}^{2-} + 14H_3O^+ + 6e^- = 2Cr^{3+} + 21H_2O}\\\mathrm{E^\circ_{Ox_2/Red_2} = 1.330}\\\underline{\mathrm{Fe^{2+} = Fe^{3+} + 16e^-}}\\\mathrm{Cr_2O_7{}^{2-} + 6\ Fe^{2+} + 14H_3O^+ = 2Cr^{3+} + 6\ Fe^{3+} + 21\ H_2O}\\\mathrm{E^\circ_{Red_1/Ox_1} = -0.770}\end{gathered} \qquad \textbf{8.41(16)}$$

For this reaction, we have the following:

$$\mathrm{Ox}_1 = \mathrm{Fe}^{3+},\ \ \mathrm{Red}_1 = \mathrm{Fe}^{2+}\ n_1 = 1\ \ \ a = 1\ \ b = 2\ \ y = 14$$

$$\mathrm{Ox}_2 = \mathrm{Cr_2O_7}^{2-},\ \ \mathrm{Red}_2 = \mathrm{Cr}^{3+}\ n_2 = 6\ \ \ c = 1\ \ d = 1\ \ w = 21 \qquad \mathbf{8.41(17)}$$

Assume pH = 0, that is, $[H_3O^+] = 1$, and that at equivalence point $[Cr^{3+}] = 10^{-3}$. The equivalence point is calculated from Equation 8.41(10) as follows:

$$(n_1 + n_2)E_{cell} = n_2E^\circ_{Ox_2/Red_2} + n_1E^\circ_{Ox_1/Red_1} + 0.059\ \log \frac{[Ox_2]^a[Ox_1]^d}{[Red_2]^b[Red_1]^c} + 0.059\ \log\ [H_3O]^y. \qquad \mathbf{8.41(18)}$$

Using the ratio relationships determined from Equations 8.41(11) and 8.41(12), we get

$$7E_{cell} = 6(1.330) + 0.770 + 0.59\ \log \frac{1}{2[Cr^{3+}]} + 0.059\ \log\ [H_3O^+]^{14} \qquad \mathbf{8.41(19)}$$

and for varying levels of H_3O^+, we get the following equivalent point potentials:

$$\text{for } H_3O^+ = 1 \qquad E_{cell} = 1.273\text{ V}$$

$$\text{for } H_3O^+ = .01 \qquad E_{cell} = 1.037\text{ V}$$

$$\text{for } H_3O^+ = 10^{-4} \qquad E_{cell} = 1.793\text{ V}$$

Using Equation 8.41(15) along with Equations 8.41(11) and 8.41(12), we can determine the degree of completion at the equivalence point. This equation reduces to

$$\frac{[Cr^{3+}]^8}{[Cr_2O^{7}]^{7}} = \frac{3^6}{6^6}10^{56.9}[H_3O^+]^{14} \qquad \mathbf{8.41(20)}$$

$$[Cr_2O_7] = (10^{-24} \times 6.4 \times 10^{-58.9} \times [H_3O^+]^{14})^{1/7}$$

and therefore the following values can be calculated:

$$pH = 0, [H_3O^+] = 1 \qquad [Cr_2O_7^=] = 4.9 \times 10^{-12}$$

$$pH = 2, [H_3O^+] = 0.01 \qquad [Cr_2O_7^=] = 4.3 \times 10^{-8}$$

$$pH = 4, [H_3O^+] = 10^{-4} \qquad [Cr_2O_7^=] = 4.9 \times 10^{-4}$$

It now becomes obvious that the reaction is not complete at pH 4.0 but is substantially complete at pH 2.0, assuming that a concentration of 10^{-6} M is considered to be completion.

In industrial and laboratory work, the ORP cell potentials are measured not against a SHE electrodes but against an Ag/AgCl, 4 M KCl reference, with $E^\circ_{Ox/red} = +0.199$ V, or against a saturated calomel electrode (SCE) whose E° = 0.244 V. To convert to the measured potential, designated as $E_{AgCl\ ref}$, we use

$$E_{meas} = E_{cell} - E_{AgCl} \qquad \mathbf{8.41(21)}$$

For example, the E° for the following cell:

$$Fe^{3+} + e^- - Fe^{2+}\ E_{Ox/Red} = 0.770\text{ vs SHE} \qquad \mathbf{8.41(22)}$$

and the potential measured vs. the silver-silver chloride reference is

$$\begin{aligned} E_{meas/AgCl\ ref} &= +.770\text{ V} - .199\text{ V} \\ &= 0.571\text{ V} \end{aligned} \qquad \mathbf{8.41(23)}$$

Absolute potentials in ORP measurement are not always used. Most equipment manufacturers use slightly modified pH analyzers for ORP measurement. These instruments are normally provided with the standarized or zero adjustment of the parent pH meter. Futhermore, in general, the polarity is reversed merely by reversing inputs.

Microprocessor-Based Units Microprocessor-based ORP analyzers generally provide wide rangeability with high-resolution digital displays, alarm/control set points, and output signal scaling limits.

Most chemical reactions that involve electron exchange are controlled near the equivalence point. A controlled excess of reagent is added to ensure that the reaction is driven to completion. Thus, most ORP reactions will be controlled just beyond the steep portion of the titration curve.

ORP SENSORS

The basic instrumentation used for ORP measurement closely parallels that used for pH measurement. In fact, many instrument suppliers use slightly modified pH analyzers for ORP detection, the main difference being changed sensitivity and a millivolt (mV) scale in place of a pH scale. The electrode hardware (that is, the equipment used to install the electrodes in the process stream) is generally the same as that used in pH systems (Figures 8.41d and 8.41e).

There are two major differences between an ORP system and a pH system. One is the sensing electrode, which in case of ORP measurement, is normally a noble metal (typically platinum or gold), although other metals and carbon have also been used on occasion. The second major difference is in temperature compensation. Process pH systems are typically temperature compensated, whereas ORP systems almost never are.

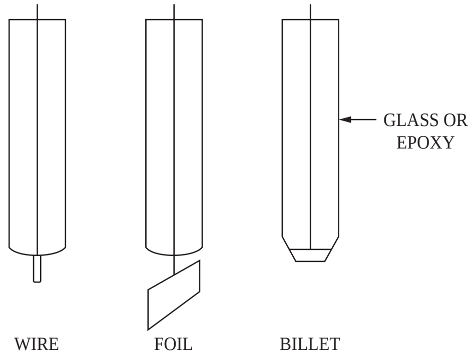

FIG. 8.41d
The various types of metallic ORP electrodes.

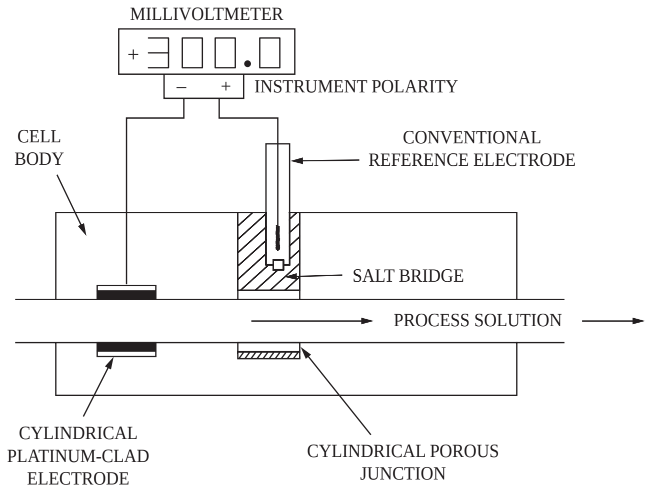

FIG. 8.41e
Cylindrical ORP electrode cell.

The Nernst Equation

The basic thermodynamics apply to both pH and ORP, expressed by the classical Nernst equation. For oxidation-reduction half-cell reactions, this may be represented as follows:

$$E_{cell} = E^{\circ}_{Ox/Red} + \frac{2.303\,RT}{nF}\log\left[\frac{Ox}{Red}\right] \qquad \mathbf{8.41(24)}$$

where

E° = potential under standard conditions of unit activity referred to the SHE
R = the gas constant, 1.986 cal per mol degree
F = Faraday's constant
T = temperature in Kelvins
n = the number of electrons exchanged in the reaction

In the Nernstian representation of pH, n always equals 1. Note that, even in the very abbreviated listing of Table 8.41c, the n values vary among reactions. This, plus the fact that a given ORP reaction may encompass side reactions, makes it quite clear why it is difficult, if not impossible, to temperature compensate an ORP reaction.

In Equation 8.41(24), the standard potential $E^{\circ}_{Ox/Red}$ can be found in handbook tables, and values are usually given relative to the standard hydrogen electrode. Therefore, E_{cell} in Equation 8.41(24) for the prevailing concentration is also relative to SHE.

E_{meas} is the value that is read on the meter. If E_{cell} is known from calculation or from actual measurement, its potential value for other systems can be readily converted by

$$\text{E vs SHE} = \text{E vs SCE} + E_{SCE/Red} \qquad \mathbf{8.41(25)}$$

or

$$\text{E vs SCE} = \text{E vs SHE} - E_{SCE/Red} \qquad \mathbf{8.41(26)}$$

or

$$\text{E vs Ag/AgCl Ref} = \text{E vs SHE} - E_{Ag/AgCl/Red} \qquad \mathbf{8.41(27)}$$

Electrode Mounting

ORP and pH electrodes can often be mounted in the same tees or flow-through chambers and can have practically identical appearances. The electrode shown in Figure 8.41f is a ruggedized, flat glass electrode having identical dimensions for both pH and ORP services. In case of the ORP probe, the only difference is the gold or platinum wire tip.

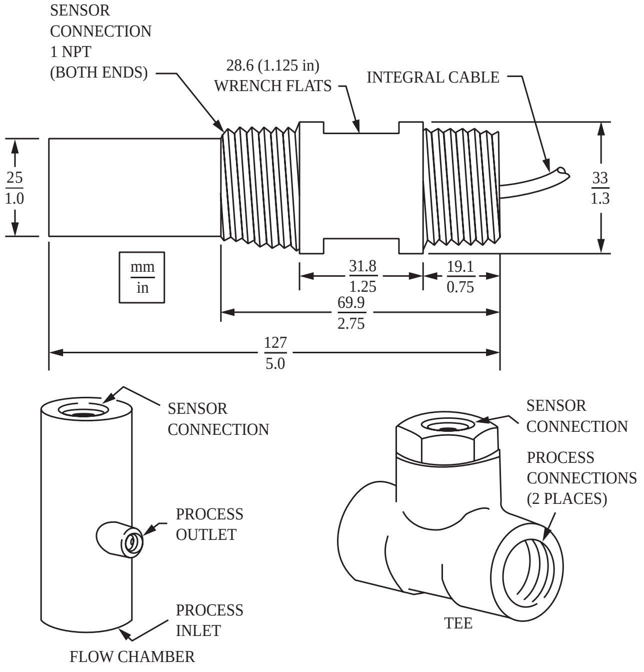

FIG. 8.41f

ORP APPLICATIONS

It is certainly possible by use of the equations developed earlier to determine the equivalence potential for an ORP control reaction. For a reaction involving H_3O^+ or OH^- ions, Equation 8.41(10) shows the rather profound effects of pH on the equivalence point potential. Equation 8.41(15) can be used to calculate the degree of completion of the reaction, and, again, this relationship also shows the effects of pH. A reaction that pointedly illustrates these effects is the reduction of hexavalent chromium with sulfur dioxide or with bisulfite. However, many prefer a more empirical approach, as exemplified by chromium reduction.

Chromium Reduction

The chromium reaction typically takes place at a pH of about 2.0 to 2.5 (Figure 8.41b). At this pH, there is a smell of sulfur dioxide when the sulfite ion is in slight excess. An experienced operator might adjust the control point potential to attain a slight odor of sulfur dioxide and then make further adjustments based on laboratory analysis for hexavalent chromium.

It is certainly possible to set up a system based on calculation when all reactants and products are known. However, this is seldom the case in industrial processes, and only the very innocent would proceed without analytical verification of the results.

The ORP responses in two of the most common ORP applications are illustrated by the titration curves in Figures 8.41g and 8.41h. These curves are only examples. Response can vary considerably from one specific installation and from one process composition to another. Actual control points must be finely adjusted after the startup of a system. For details on how to configure and operate such control systems, refer to the *Process Control* volume of this handbook.

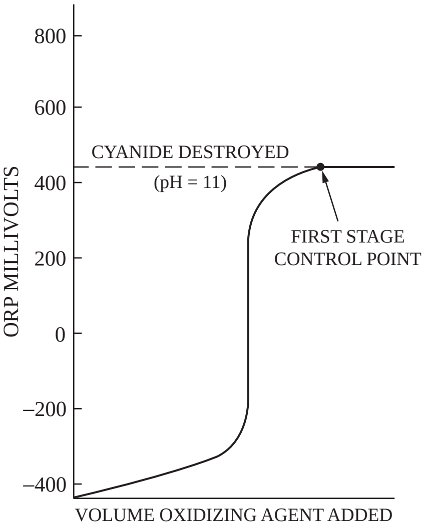

FIG. 8.41h
Cyanide oxidation titration curve.

ORP MAINTENANCE

Maintenance of an ORP measuring and control system is generally comparable to that of a similar pH system. This includes the need to keep the probes clean, which can be accomplished by scrubber-type probe cleaners shown in Figure 8.41i. However, because standards analogous to pH buffers are less common, there is sometimes a tendency to shortcut maintenance. The single most pressing problem source in case of ORP detectors is the noble metal electrode. It is subject not only to coating but also to poisoning, both of which may result in sluggish or inaccurate measurement of potential. This measurement error, in turn, may result in charging the wrong amount of reagent and not maintaining the desired reagent excess.

Jones[1] recommends utilizing standards that use quinhydrone-saturated pH buffers to establish known potentials as a check on the condition and response of the electrode system. When either a change in span or a shift in potential is noted, the recommended corrective treatment is cleaning with aqua regia. Data for selected quinhydrone-saturated buffers are given in Table 8.41j.

ORP CONTROL

ORP instruments are usually installed for control purposes. Because the measurement of ORP is quite similar to that of pH, it follows that many pH control considerations also hold for ORP. If, for example, an oxidizing solution such as dichromate in acid media is titrated with a reducing solution of ferrous ion, a titration curve that is quite similar to that of an acid-base titration can be generated. However, a more common practice is the reduction of hexavalent chromium with gaseous sulfur dioxide. Whereas it would be quite simple to catch samples of an acid waste and to titrate these samples

FIG. 8.41i
Scrubber type probe cleaner. (Courtesy of Universal Analyzers Inc.)

TABLE 8.41j
ORP Values (in Millivolts) of Quinhydrone-Saturated pH Buffer Solutions (Using Saturated Silver-Silver Chloride Reference Electrode[2])

pH Buffer	*68°F (20°C)*	*77°F (25°C)*	*86°F (30°C)*
4.01	267	263	259
6.86	100	94	88
7.00	92	86	80
9.00	−26	−32	−39
9.18	−36	−43	−49

with a standard sodium hydroxide solution, doing a titration of hexavalent chromium with sulfur dioxide would present some problems.

A more expedient way of determining reagent demand is by catching representative samples and having them analyzed chemically to determine hexavalent chromium. The reagent demand of sulfur dioxide can then be determined from the balanced oxidation-reduction overall reaction. From these data, a number can be assigned to the trivalent chromium concentration at the equivalence point and the operating pH level assigned. From Equation 8.41(10) and 8.41(15), equivalence point potential and unreacted hexavalent chromium at the equivalence point can be determined.

Residence Time

Unlike acid-base neutralizations in which the reaction is virtually instantaneous, ORP reactions are frequently time dependent. The reaction vessel might be sized accordingly to provide the required residence time. A case in point is the oxidation of cyanide with available chlorine.

The reaction between free cyanide, CN^-, with the hypochlorite ion, OCl^-, is quite rapid. However, in many cases where cyanide oxidation is employed, part of the cyanide may exist as metal-cyanide complex ions. The fraction of free cyanide ions is extremely small. For some metal cyanide complexes, many hours of reaction time may be necessary to completely destroy the cyanide.

As was emphasized earlier, in ORP reactions involving hydronium, H_3O^+, or hydroxide, OH^-, ions, the measured potential at the equivalence point and the degree of completion of the reaction are both pH dependent. Therefore, pH control becomes as important as is ORP control (see Figures 8.41a and 8.41b). A constant potential is not indicative of an excess of reactant if pH is variable.

Most of the pH-related considerations that will be discussed in Section 8.48 also apply to ORP control. Of special importance is the provision of facilities to equalize the reagent demand by use of equalizing tanks or bleed-in tanks used to store and slowly emit strong solutions to the reaction vessel.

J. F. TATERA (2003)

Design Types:	A. Deflection-type paramagnetic, dynamic dumbbell B. Thermal-type paramagnetic C. Dual-gas (differential pressure) paramagnetic D. Catalytic combustion E. Low-temperature electrochemical (galvanic, coulometric, polarographic) F. Zirconium oxide, voltage-mode high-temperature electrochemical G. Zirconium oxide, current-mode high-temperature electrochemical H. Alarm, pocket-size, battery-operated I. NIR spectroscopy
Sample Requirement:	All require a sampling system except F, G, and I, which can be inserted into the process as probes or utilize fiber optics process interfaces.
Sample Pressure and Flow:	Generally, near atmospheric pressures and low flow rates in the range of a few SCCM to a few SCFH
Materials of Construction:	Most are suitable for corrosive service, and types F, G, and I are also suitable for high-temperature service.
Speeds of Response:	Most will reach 90% of full scale in <1 min; response times of types F and G are in milliseconds, I and J are in seconds.
Operating Temperatures:	Most designs are suited for 200°F (93°C) service. Types F and G can operate at up to 1150°F (621°C) with stainless steel, up to 2200°F (1204°C) with mullite, and up to 2900°F (1593°C) with silicon carbide materials.
Ranges:	A, B. 0 to 25% C. 0 to 100% D. 0 to 2000 ppm E. From 0 to 1 ppm up to 0 to 25% F, G. Most often used for 0 to 5%, 0 to 10%, and 0 to 25%, but can be obtained with ranges as wide as 1 ppm to 20% or 0.5% to 100% H. Usually set to alarm at about 18% oxygen concentration I. From 100 ppm, typically 0 to 2% or 0 to 100% range
Inaccuracy:	Generally between 1% and 2% of full scale A. Error 0.02% oxygen between 98% and 100% oxygen D. 5% of span
Costs:	B, C. \$6,000 to \$10,000 D. \$5000 E. Portable monitoring units from \$1,200; industrial analyzers with spans in the ppm range from \$5,000 to \$20,000 F, G. \$5,000 to \$15,000 H. Portable, battery-operated, pocket-size, low-oxygen alarms \$500 to \$1000 I. \$20,000 to \$25,000

INTRODUCTION

Oxygen (O_2) is vital to a large variety of industrial and biological oxidation and combustion processes. Many industries use pure oxygen or inert gases that are allowed to contain only a few parts per billion of oxygen as a contaminant, and both of these applications usually require analyzers to determine their oxygen concentrations.

Specialized oxygen detectors are used for each type of application. Oxygen analyzers can depend on the paramagnetic and electrochemical properties of oxygen or can utilize the catalytic combustion techniques. Some spectroscopic techniques are also gaining in use and popularity to monitor O_2 while also monitoring other constituents in the process.

PARAMAGNETIC OXYGEN DETECTORS

Oxygen has a strong affinity for the magnetic field. This uncommon property, called *paramagnetism*, is shared by a few other gases such as nitric oxide, which has a susceptibility of about 43% of that of oxygen (Table 8.42a). These gases

TABLE 8.42a
*The Magnetic Susceptibility of Different Gases, with Oxygen Given as 100**

Acetylene (C_2H_2)	–0.24
Ammonia (NH_3)	–0.26
Argon (Ar)	–0.22
Carbon dioxide (CO_2)	–0.27
Carbon monoxide (CO)	+0.01
Ethylene (C_2H_4)	–0.26
Hexane (normal) (C_6H_{14})	–1.7
Hydrogen (H_2)	+0.24
Methane (CH_4)	–0.2
Nitric oxide (NO)	+43.0
Nitrogen (N_2)	0.0
Nitrogen dioxide (NO_2)	+28.0
Oxygen (O_2)	+100.0

*From *Guide to the Selection of Oxygen Analyzers*, Delta F. Corp.

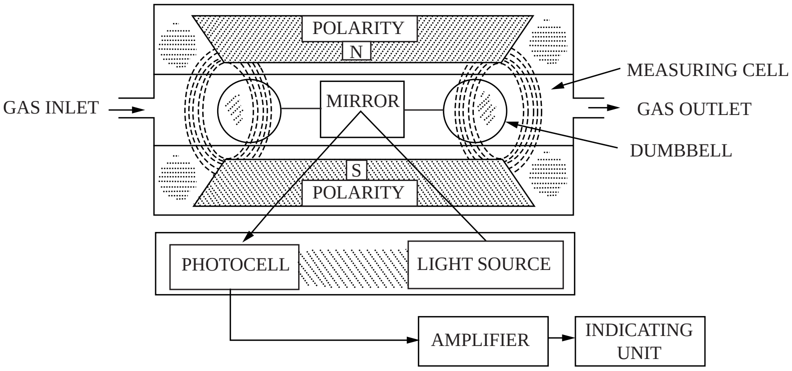

FIG. 8.42b
Deflection- or dynamic-type paramagnetic oxygen and analyzer.[1]

are not normally encountered in processes where oxygen analysis is required.

Some gases are repelled by the magnetic field. This diamagnetic effect is exhibited by methane, ethane, ethylene, carbon monoxide and dioxide, hydrogen, and argon. Of this group, methane exhibits the greatest negative susceptibility, about −1% relative to the positive susceptibility of oxygen.

The paramagnetic property of gaseous oxygen has been utilized in three oxygen analyzer designs.

1. The *deflection type* design requires that the paramagnetic property of the background gases be constant so as to permit the accurate measurement of oxygen concentration.
2. The *thermal* design depends on the decrease of the paramagnetic effect as the temperature of the paramagnetic gas (oxygen) increases.
3. In the *reference-gas* design, two gases with different oxygen contents are combined in a magnetic field, and a differential pressure is generated.

Deflection Analyzer

In the deflection-type analyzer (Figure 8.42b), the magnetic force acts on a test body that is free to rotate about an axis. The force is in proportion to the difference in the volume magnetic susceptibilities of the test body and of the gas around the body.

The dumbbell element is usually made out of glass and is filled with nitrogen or some other low magnetic susceptibility gas. Due to the nitrogen filling, the dumbbell deflects slightly away from the point of maximum magnetic strength. When the sample gas contains oxygen, this oxygen is attracted to the point of maximum field strength and thereby displaces and rotates the dumbbell farther from the point of maximum field strength. The highly paramagnetic oxygen concentrates the magnetic field, and the resultant rotation or imbalance force on the test body can be detected as a linear function of the oxygen concentration.

When the test body begins to swing out of the magnetic field, the mirror also rotates, thus upsetting the light balance. The result is a corrective imbalance in the electrostatic force on the test body. This imbalance force is opposite and almost equal to the magnetic force, which is a function of the oxygen concentration. This delicate sensor is mounted on shock absorbers. Dirt in the sample is likely to cause major difficulties; therefore, sample filtering should ensure the cleanliness of the stream.

The most significant limitations of the dumbbell-type paramagnetic oxygen analyzer are its delicate nature and its sensitivity to vibration and precise positioning. Variations in the magnetic susceptibility of the background gases in the sample or variations in sample temperature (if not compensated) can also contribute to errors. The applications of this unit include the monitoring of combustion efficiency and the monitoring of purity of breathing air or of protective atmospheres.

Thermal Analyzer

A flow-through type of *ring* element is illustrated in Figure 8.42c. In other designs, the sample gas diffuses into dead-ended cavities. In the case of the flow-through element

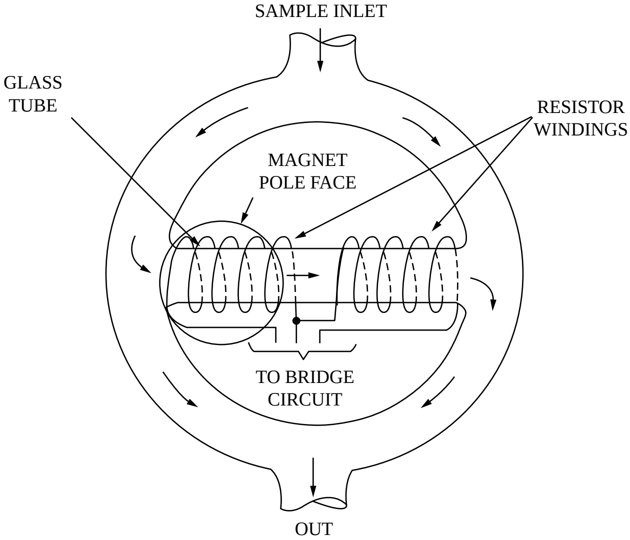

FIG. 8.42c
Measuring element in a thermal paramagnetic O_2 analyzer.

illustrated, the paramagnetic oxygen content of the sample—after it enters the ring—is attracted by the magnetic field in the horizontal tube, where resistors heat the gases. These resistors are connected in a Wheatstone bridge circuit to detect the resistance variations resulting from changes in flow rate.

The oxygen in the heated sample loses much of its paramagnetism, thus attracting cooler oxygen from the incoming sample, which then displaces the hot, less magnetic oxygen. This action produces a convection current commonly called a *magnetic wind*. The wind flow rate is a function of oxygen concentration and is detected by thermistors (thermal loss sensing heated resistors). The gas flow cools the left-hand winding and heats the right-hand winding, and the resulting temperature difference unbalances the bridge.

Because the heating and cooling of the resistors is not only a function of the flow rate but also of the composition and pressure, errors can be introduced by variations in these properties. The presence of diamagnetic materials can also introduce errors by affecting the magnetic wind. Errors can also occur as a result of a change in sample pressure, because the magnetic susceptibility of oxygen varies as the square of the static pressure.

Some manufacturers offer pressure compensation in the form of special cells with compensating resistors that are also made part of the Wheatstone bridge circuit. Other suppliers require that precise pressure regulation be provided, within a few inches H_2O. Variations in barometric pressure can also cause measurement errors of up to ±2% on narrow ranges, because the effect of atmospheric pressure change is about 0.02% O_2 per inch H_2O (250 Pa).

In comparison to the dumbbell-type dynamic sensor, the advantage of the magnetic wind analyzer is its rugged design. Its disadvantages include the need for compensating for both temperature and for the thermal conductivity variations in the background gases of the sample. High temperatures can also cause degrade stability and reliability.

Dual-Gas Analyzer

Figure 8.42d shows a dual-gas cell. Two gases with different oxygen contents are brought together, producing a differential pressure. The reference gas can be 100% oxygen, nitrogen, or air. The reference gas passes through two ducts, one of which meets the sample gas in the magnetic field. Because both ducts are connected, the pressure, in proportion to the oxygen content of the gas sample, produces a flow that can be measured. All wetted parts can be made of stainless steel or tantalum.

The dual-gas or differential-pressure-type oxygen analyzer is rugged, but it is sensitive to vibration, for which some manufacturers are able to compensate. As with all other paramagnetic analyzers, this one is also limited in its sensitivity to the percentage range and is not suited for trace oxygen measurements.

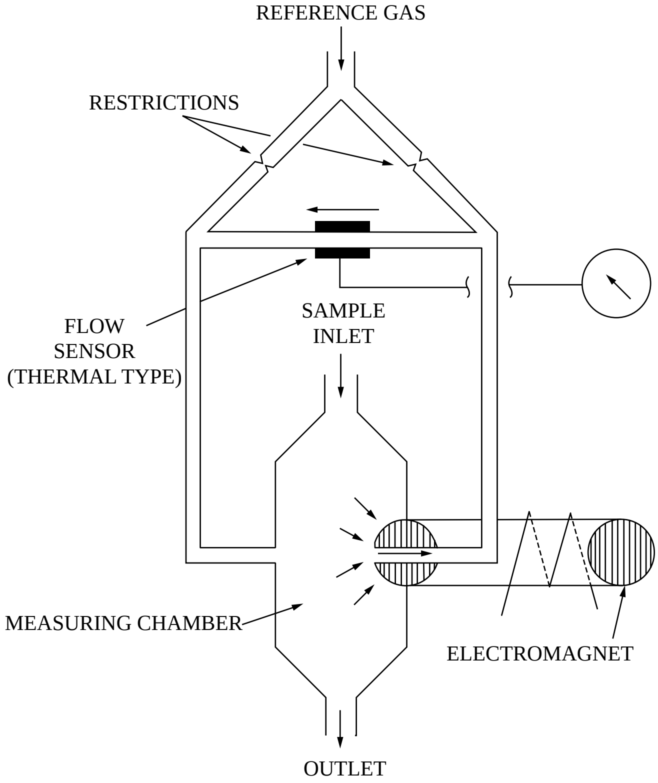

FIG. 8.42d
Measuring element in a dual-gas paramagnetic O_2 analyzer.

CATALYTIC COMBUSTION OXYGEN DETECTORS

This approach to oxygen analysis is very similar to the techniques outlined in Section 8.16 in connection with combustible gas detection, and the reader is referred to that section for additional details (Figures 8.16c and 8.16d).

Analysis is accomplished by oxidizing a fuel and measuring the amount of heat generated. The sensor consists of a measuring cell and a reference cell, with a filament in each. The measuring filament is provided with a catalytic surface to oxidize the fuel, while the reference filament serves only to compensate for variations of temperature and thermal conductivity in the sample. In some designs, the unit is thermostatically maintained at a constant temperature (see Figure 8.42e). The filaments are connected in a bridge system.

First, the sample and fuel are mixed, and then they enter both the measuring and reference cells. In the measuring cell, the fuel is burned in the presence of the noble metal catalyst filaments. The resulting filament temperature is measured by detecting its resistance, which is a measure of the oxygen content of the gas sample.

In the reference cell, the temperature of the mixture is sensed, but no combustion takes place. The temperature difference between the two cells is attributed to the heat generated by combustion in the measuring cell and is used to calculate the amount of oxygen that was present to support the combustion.

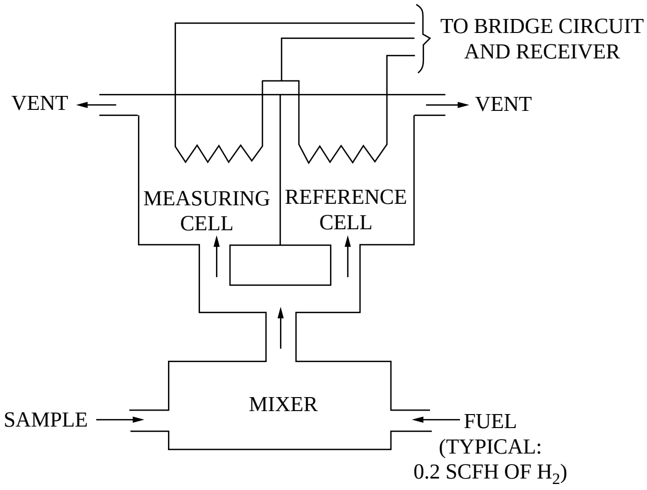

FIG. 8.42e
Catalytic combustion oxygen analyzer.

ELECTROCHEMICAL OXYGEN DETECTORS

Electrochemical oxygen detectors fall into three main categories, which are

1. The high-temperature fuel cell detectors, utilizing the conduction of oxygen ions (O^{-2}) from one electrode to another through a solid oxide electrolyte (e.g., zirconium oxide)
2. Ambient-temperature galvanic detectors, which operate by oxygen reduction at the cathode and dissolution of an active anode such as cadmium or lead in an electrolyte
3. The polargraphic detectors, consisting of three electrodes (cathode, anode, and a reference) and an electrolyte

The operation of a polargraphic detector is similar to that of the galvanic detectors except that, here, an external potential is applied to the cathode to drive the oxygen reduction reaction.

The high-temperature fuel cell oxygen detectors are used for measurements of gaseous oxygen, whereas the galvanic and polargraphic oxygen detectors can be used for both gaseous and dissolved oxygen measurements in liquids.

All three types of electrochemical oxygen detectors measure the partial pressure of oxygen and require either temperature control or temperature compensation. Some galvanic-type oxygen detectors also require the control of gas flow rate or compensation for its variation.

High-Temperature Zirconium Oxide Fuel Cells

In these oxygen detectors, the oxygen is ionized in both a sample and a known reference gas stream. The sensing cell consists of a calcium-stabilized zirconium oxide solid electrolyte, which is provided with porous noble metal (typically platinum) electrodes on the inner and outer surfaces of the solid electrolyte (Figure 8.42f).

The cell typically operates at temperature of (147°F) 800°C. When sample and reference gas streams come in contact with the electrode surfaces, the oxygen ionizes into O^{-2} ions. The oxygen ion concentration in each of the streams is a function of the partial pressure of oxygen in the stream.

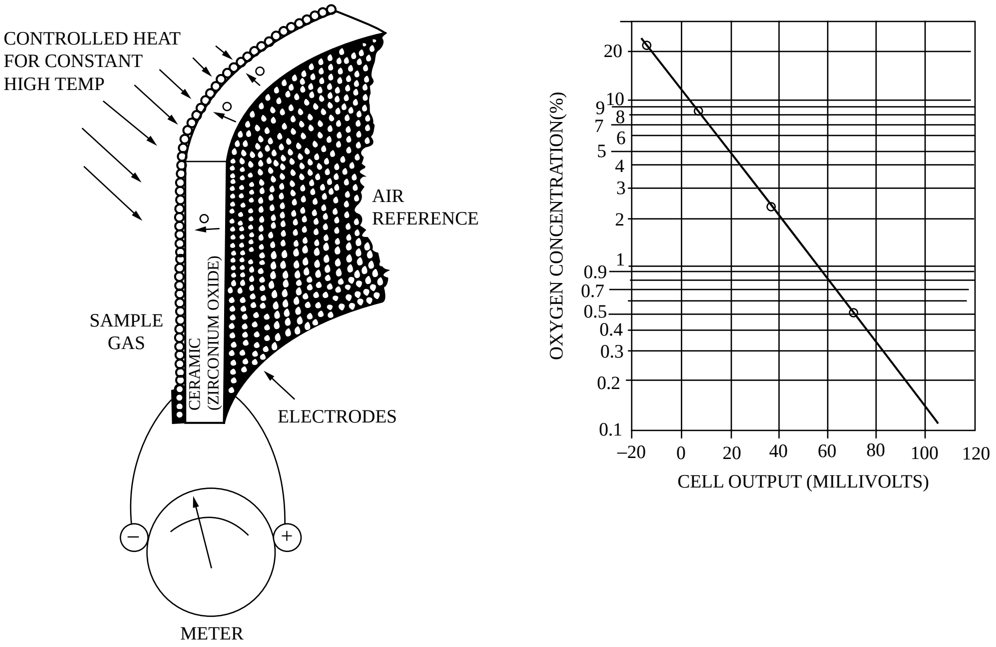

FIG. 8.42f
The flow of oxygen ions through the hot zirconium oxide electrolyte causes a voltage difference across the thickness of the element. (Courtesy of Ametek Inc.)

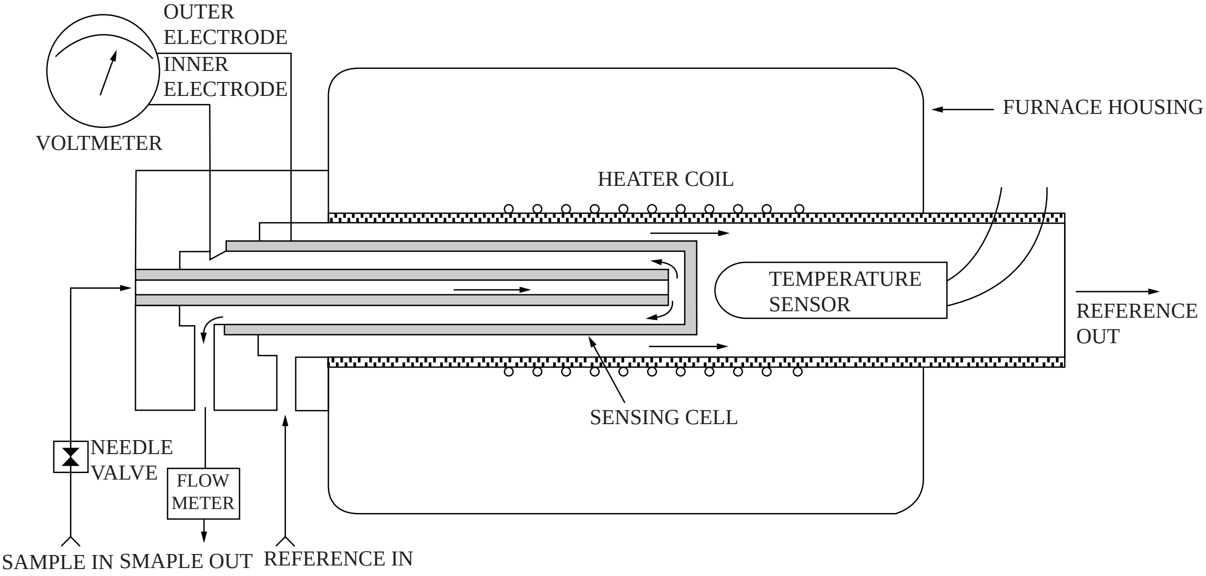

FIG. 8.42g
High-temperature electrochemical oxygen detector.

The potential at each electrode depends on the partial pressures of oxygen in the gas stream.

The electrode with higher potential (higher oxygen concentration) will generate oxygen ions, whereas the electrode with lower potential (lower oxygen concentration) will convert oxygen ions into oxygen molecules. The cell reaction at the two electrodes can be expressed as

$$O_2 + 4e^- \rightarrow 2O^{-2} \quad \text{(at the cathode)} \qquad \textbf{8.42(1)}$$

$$2O^{-2} \rightarrow O_2 + 4e^- \quad \text{(at the anode)} \qquad \textbf{8.42(2)}$$

The open-circuit voltage relates to oxygen partial pressure by Equation 8.42(3), which is also referred to as the Nernst equation,

$$E = \frac{RT}{nF} \ln \frac{O_2 \text{ partial pressure in reference gas}}{O_2 \text{ partial pressure in sample gas}} \qquad \textbf{8.42(3)}$$

where

E = the open-circuit voltage developed
R = the universal gas constant
T = the temperature
n = the number of electrons transferred per molecule of oxygen
F = Faraday’s constant

From the above equation, it can be seen that the cell output signal changes logarithmically with the partial pressure of oxygen in the sample stream when the partial pressure of oxygen in the reference stream is constant.

The maximum detectable oxygen concentration in the sample stream is equal to the oxygen concentration in the reference stream. When the oxygen concentration in the sample reaches this point, the open-circuit voltage will be zero. If the oxygen concentration in the sample stream exceeds the oxygen concentration in the reference stream, the oxygen ions will move in the opposite direction, and the open-circuit voltage will be of the opposite polarity.

It should also be noted that the open-circuit potential is directly related to the temperature of the cell. Therefore, accurate control of the cell temperature or temperature compensation is required.

Cell Design and Limitations Figure 8.42g illustrates the design of a typical cell. The temperature of the cell is maintained at about 1472°F (800°C). The sample and reference gas streams flow near the porous platinum electrodes, which are in contact with the solid oxide electrolyte. Oxygen ionizes at the electrode surfaces. Equilibrium between oxygen and oxygen ions is established at the electrode surfaces, and the concentration of oxygen in the sample stream is determined by measuring the open-circuit voltage.

Such oxygen detectors should be used only for those applications in which the sample contains no combustibles, because, at the elevated temperatures, the oxidizable material in the sample gas will stoichiometrically combine with oxygen. Consequently, if combustibles are present, the oxygen concentration in the sample gas will decrease, thereby causing an error in measurement. This limitation reduces the possibility of applying such oxygen detectors for the measurement of oxygen at sub-ppm levels.

Some versions of this design are available as transmitters, and others are marketed with integral indicators for both portable and permanent installations. These analyzers are available with very wide ranges. An analyzer scale might have graduations between 1 and 200,000 ppm or might cover a range of 0.5 to 100%.

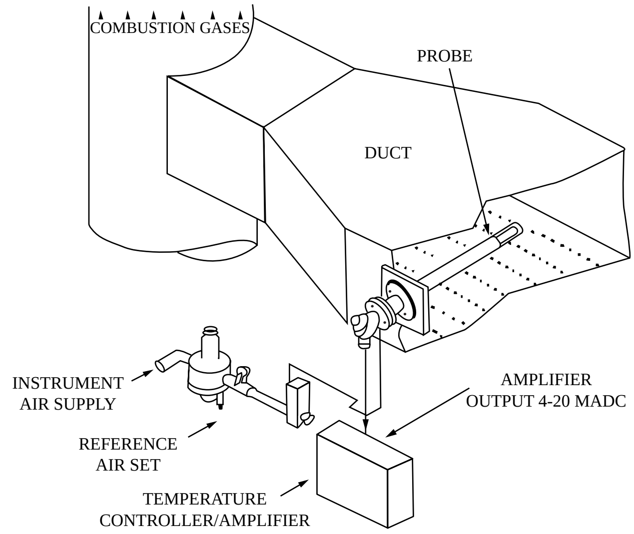

FIG. 8.42h
In-leakage through the duct joints and operating temperature must both be considered in selecting the location for installing the probe.

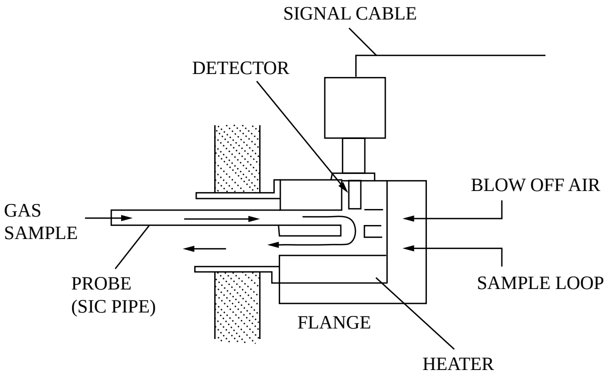

FIG. 8.42i
Self-cleaning high-temperature probe allows for use at operating temperatures up to 2990°F (1593°C), due to built-in temperature-controlled cooler.

Self-Diagnostics and Self-Cleaning Zirconium oxide stack probe analyzers are available with features of in-place calibration and self-diagnostics. Some designs can be serviced without removing the probe from the stack.

Probes are available in lengths of 1.5, 3, 6, 9, and 12 ft (0.5, 1, 2, 3, and 4 m) and should be inserted to 40 to 50% of duct diameter to reach the most representative area. In some designs, the zirconium oxide sensing element is located at the tip of the probe (Figure 8.42h). In that case, the installation must be made at a location where the operating temperature is under 1472°F (800°C); otherwise, the sensor could not be maintained at its constant temperature of 1472°F (800°C).

In other designs, the sensing element is located outside the duct, and aspirators are used to bring the samples to it. These designs can be utilized for samples with higher operating temperatures, because the gases can be cooled as they are brought to the sensor (Figure 8.42i).

Because ductwork is likely to leak, and because combustion processes are operated under vacuum, the farther the sample point is from the burner, the larger is the potential for measurement error caused by oxygen in-leakage. Therefore, zirconium oxide probes should be installed as close to the burner as their temperature limitation allows.

Other limitations of this sensor include its relatively short life (1 to 2 years) and its relatively high replacement cost. Sensor failure can be caused by shorting out the cell, which results in the diffusion of the platinum electrodes through the zirconium oxide layer. As the sensor ages, it also becomes more difficult to calibrate it. For these reasons, these analyzers are not recommended for trace oxygen measurement in the ppm range. Their primary application is in measuring the percentage of excess oxygen in combustion or steel-producing blast furnace processes.

High-Temperature Current-Mode Oxygen Detectors

In this detector, a zirconium oxide cell to which a small excitation has been applied has a cavity in which it has reduced the oxygen partial pressure to near zero. As oxygen diffuses into the cavity and is pumped out by cell action, positive current flow is generated in the excitation circuit. The output is in direct proportion to the oxygen content of the sample (Figure 8.42j).

The cell can be used with samples of high sulfur dioxide content and can operate at temperatures of up to 2880°F (1582°C).

Galvanic Detectors

Similar to the high-temperature solid metal oxide fuel cell O_2 detectors, galvanic-type O_2 detectors consist of a cathode, an anode, and an electrolyte. The principle of operation of

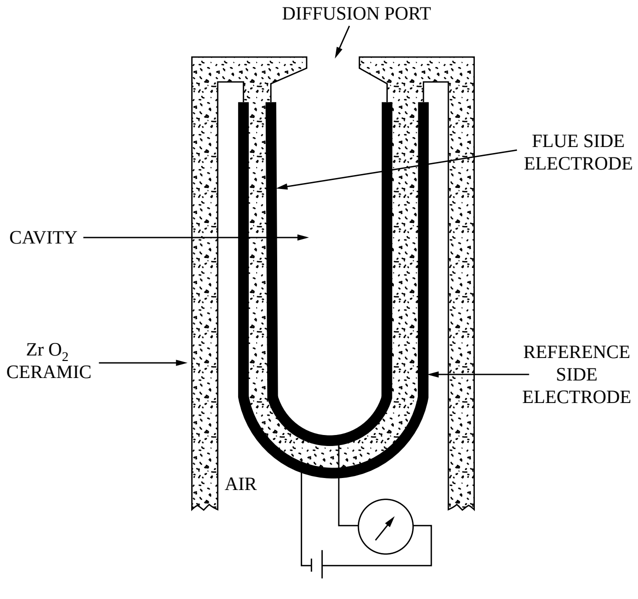

FIG. 8.42j
High-temperature diffusion-limited current-mode cell.

the galvanic-type O_2 detectors will be described in more detail in Section 8.43.

The sensitivity of these detectors is determined by their construction and by the choice of sensing cathodes. These analyzers are used for a variety of applications from ppm-level measurements to breathing air applications (20 to 25%).

Material technology advances have enabled manufactures to develop fuel cells that are made of a variety of polymeric and composite materials. Galvanic detectors can be made very small and can operate at very low voltage and current levels. Consequently, they are extensively used for intrinsically safe and portable (even pocket-sized) applications.

Capillary Systems In addition to sample introduction through the traditional membrane, some fuel cell designs utilize a capillary system to introduce the sample. Like most changes, these have advantages and disadvantages. For example, the capillary systems adjust more quickly to pressure and concentration changes but are also more prone to problems caused by the presence of mists and condensables.

In contrast, the membrane designs are less responsive to pressure changes and fast concentration changes and are more prone to problems caused by coating with dusts and powders. The capillary designs therefore offer us an additional option to meet application requirements. Several manufactures offer both capillary and membrane systems.

Detector Design The O_2 detectors that employ smooth metal cathodes can achieve sensitivity for gaseous oxygen to sub-ppm levels with an excellent signal-to-noise ratio. However, sensitivity for gaseous oxygen in the sub-ppb level is achieved by using a high surface area, metal-catalyzed gas diffusion electrode as the O_2-sensing cathode. The high surface area metal-catalyzed gas diffusion electrode consists of a porous hydrophobic electronically conductive Teflon®-carbon backing layer bonded to a thin layer of high surface area metal catalyst dispersed on a carbon support.

This type of electrode provides an effective surface area of up to 600 times the geometric area of the electrode, thus generating high signal output per unit O_2 concentration.

A typical galvanic O_2 detector utilizing a high surface area metal-catalyzed gas diffusion electrode with a sensitivity for gaseous oxygen of 1 ppb is illustrated in Figure 8.42k. The main body of the detector is made of a polymeric material and generally has a U-shaped configuration that contains electrolyte, an anode, and a thermistor. The cathode is mounted on one side of the detector wall.

A stainless steel plate with gas inlet and outlet tubes is attached to the same wall, with an O-ring between the plate and the detectors wall. The top of the detector is sealed with a stainless steel plate and an O-ring to eliminate the exposure of inner components to ambient air. This place also contains a port to fill the detector with electrolyte or charge the detector with water for continuous operation. The O_2 dissolved in the electrolyte is removed by bubbling oxygen-free gas through the porous frit at the bottom of the detector to minimize interference during analysis.

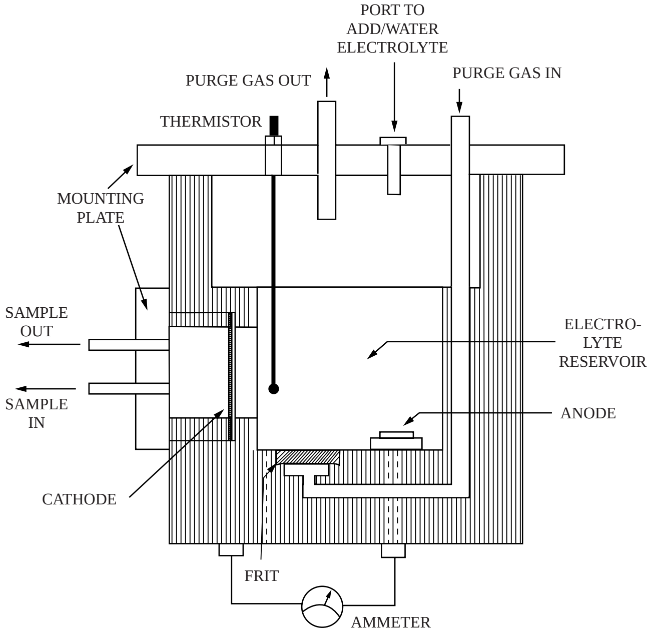

FIG. 8.42k
Electrochemical oxygen detectors utilizing high-surface-area metal-catalyzed gas diffusion electrode as the oxygen-sensing cathode. (Courtesy of Teledyne Analytical Instruments.)

The gas to be analyzed enters the cathode cavity via an inlet tube and then leaves via the outlet tube. During this process, it diffuses through the porous backing layer, reaches the catalyst surface exposed to the electrolyte, and immediately reacts, generating an electrical signal proportional to the partial pressure of O_2 in the gas mixture. Such detectors generally require temperature and gas flow rate compensation.

Advantages and Limitations A significant advantage of this type of O_2 detector is the reduced susceptibility to contamination of the sensing element by particulates in the sample gas. This is because particulates cannot enter the main cell body. The sensing element allows the diffusion of gases only through the back surface of the electrode to the catalyst surface exposed to the electrolyte. Analyzers utilizing such O_2 detectors are useful for long-term on-line operations.

The galvanic sensor is insensitive to shock and vibration but might read low as a result of a loss of sensitivity from aging. Therefore, it might need periodic recalibration. Also, if exposed to large concentrations of oxygen, the sensor can take a long time to recover from the *oxygen shock*.

Its applications include such things as ppb trace measurements to validate semiconductor quality gases used in potentially hazardous or explosives atmospheres, food-processing and storage, and more traditional percentage level measurements of stack gases and breathing air. It is not suitable for most high-temperature applications, as galvanic sensors tend to dry out the electrolyte and accelerate cell aging.

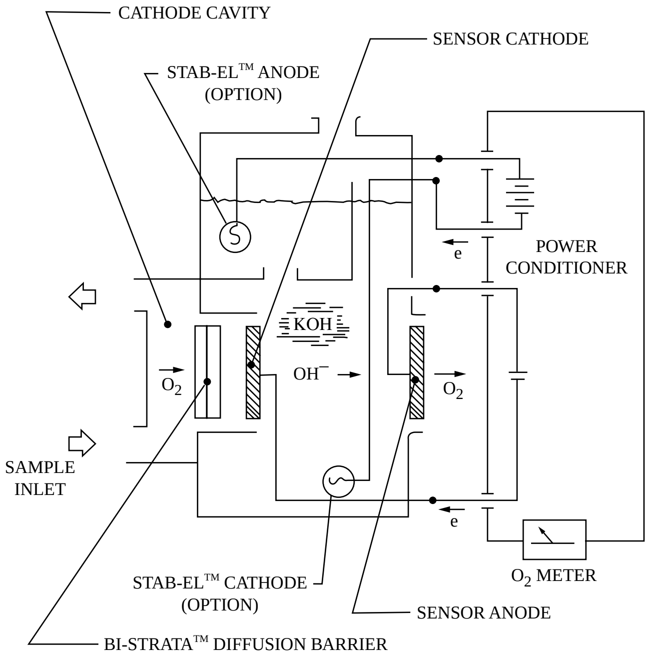

FIG. 8.42l
The coulometric electrochemical oxygen analyzer. (Courtesy of Delta F Corp.)

Coulometric Sensor

In the coulometric sensor, the sample gas diffuses through a diffusion barrier to the cathode of the electrochemical cell, where it is reduced to hydroxyl ions. Because of the conductivity of the potassium hydroxide electrolyte, the ions migrate to the anode, where they are oxidized back to oxygen. An external voltage drives this reaction, which results in a cell current that is proportional to the oxygen concentration in the gas sample (Figure 8.42l).

A main advantage of this design is its nondepleting nature, as neither electrode undergoes a chemical change during measurement. On the other hand, the effective area of the electrodes can change with time as a result of contaminant deposition on the electrodes. Therefore, the sensor could require periodic recalibration and eventual replacement.

Furthermore, this sensor could also be subjected to oxygen shock similar to galvanic-type sensors, which use a gas diffusion barrier to control the amount of oxygen that enters the sensor. This sensor is suited for ppb, ppm, and percentage measurements up to 25%. Its areas of application are similar to those of the galvanic sensor.

Polarographic Sensor

The polarographic cell is shown in the next section (Figure 8.43b). It consists of a sensing electrode (cathode), a reference electrode (anode), and an electrolyte, which is usually potassium chloride. The cathode is separated from the sample gas by a permeable membrane that permits the diffusion of oxygen through the electrolyte onto the sensing surface of the cathode. A voltage is applied between the two electrodes, causing the oxygen to be electrochemically reduced and producing an ionic current that is linear with the oxygen content of the sample.

This sensor is rugged and is insensitive to position and sample flow-rate variations. On the other hand, it is slow to respond, because of the time required for the oxygen to diffuse through the membrane. It also requires pressure and temperature compensation and periodic (about yearly) replacement, as both the anode and the electrolyte are consumed during operation. This sensor is seldom used on gas services; its most common application is in dissolved oxygen measurement in liquids (Section 8.43).

SPECTROSCOPIC OXYGEN DETECTION

In this handbook, the spectroscopic techniques are discussed in depth in Sections 8.27, 8.29, 8.40, and 8.61. They will be discussed here only briefly.

It might seem like overkill to consider using a spectrophotometer to measure oxygen when there are so many simpler, less expensive and effective ways to detect it. On the other hand, one might need to monitor a process for more than just oxygen, and it might be an advantage to monitor multiple components simultaneously. On yet another hand, the use of the same analyzer for multiple-component measurements also increases the consequences of instrument failure. Therefore, critical measurements always should be made by dedicated instruments, and the only reason why spectroscopy is even being mentioned here is that it is being used increasingly in applications where oxygen-specific analyzers were used in the past.

Mass Spectroscopy

Mass spectroscopy is used to monitor oxygen in a number of applications, including semiconductors, fermentation, pharmaceuticals, and other specialized areas. This instrument ionizes the sample and separates the ions according to their mass. In these applications, mass spectrometers are sometimes called *residual gas analyzers* because of the way they are used. Mass spectrometers (Section 8.29) are used when the determination (qualitative and quantitative) of more than one component is required in the sample. The application of this technique for the measurement of oxygen is in no way unique or special. The same techniques that are used for most other gases are also utilized for oxygen.

Near Infrared Spectroscopy

Many gas concentrations can be measured by monitoring their ability to absorb light in the infrared region. Near infrared (NIR) spectroscopy (Section 8.27) has been marketed for stack monitoring and other gas monitoring applications that include an oxygen measurement.

For a molecule to absorb infrared light and be measured in the infrared region, traditional thinking leads one to believe that it must have an electric dipole moment with which the IR radiation can interact. This typically requires a molecule that is made up of atoms in a structure that has generated an unbalanced electric field. Homonuclear molecules such as H_2, O_2, and N_2 contain two identical atoms and do not have a dipole moment. For this reason, they have long been thought of as being invisible in the IR spectrum.

For example, HCl has a hydrogen and a chlorine atom and is bound in a way that results in the chlorine being more electronegative than the hydrogen. The resulting molecule has an electrical dipole moment with which IR radiation can interact easily. By contrast, most homonuclear molecules absorb radiation only in the ultraviolet region of the spectrum. Molecular oxygen is one of the few exceptions.

The detection of molecular oxygen by the NIR spectroscopic technique involves a measurement that is often described as "a forbidden transition." Many molecules can absorb radiation (energy) and enter a temporary excited or radiative state. Usually, they quickly release this extra energy in the form of radiation. These levels of excitation typically occur within the bounds of traditional quantum rules, and the released energy (reradiation) is typically described as fluorescence. The lifetime of these excited states is a small fraction of a second in duration.

Sometimes, when the reradiation is not in compliance with the more traditional quantum rules, phosphorescence instead of florescence can be obtained, and the reradiation can experience large time delays from the initial absorption. In the case of molecular oxygen, there is such a transition that can be monitored in the NIR region of the spectrum near 760 nm. It is described as a highly forbidden singlet delta state of oxygen. The fact that the state lies close to the oxygen molecular ground state means that oxygen can be measured in this "forbidden region" by NIR methods such as tunable diode laser absorption spectroscopy (TDLAS).

TDLAS Designs For a more detailed discussion of TDLAS, see Section 8.40. TDLAS that, in the NIR region, is successfully used to make oxygen measurements is called *single line absorption spectroscopy*, in which a diode laser is scanned across a chosen absorption line. The selection and application of the O_2 spectral line is proprietary to most vendors, but it is usually one of the oxygen lines around 760 nm (Figure 8.42m).

Suppliers employ wavelength modulation to enhance sensitivity. The laser source wavelength is modulated slightly as the absorption line is scanned. The resulting output signal is mathematically massaged (i.e., decomposed into frequency components; usually, the second harmonic is used to generate the measurement). The result is an oxygen measurement by a spectroscopic technique that previously was not considered possible. It has been made possible only by advancements in laser technology, computing, and optics.

These analyzers are being used in incinerator stacks and other applications where samples are typically dirty or corrosive, and if high detection speeds are required. The incorporation of fiber optic technology provided a high degree of installation flexibility. Figures 8.42n and 8.42o depict several of the installation layouts and sampling configurations that are in use.

Although neither NIR nor mass spectroscopic techniques will probably ever be used to measure oxygen only, they can be justified to simultaneously measure oxygen and a multiplicity of other components in a sample.

OTHER OXYGEN DETECTION METHODS

Several additional methods of oxygen detection can be considered, especially if sample components other than oxygen are of interest. For example, gas chromatography (Section 8.12) can be valuable for atmospheric analysis and to check the levels of oxygen, hydrogen, carbon monoxide and dioxide, organic solvents, Freon, methane, and others.

Chemical analyzers of the manual Orsat type are also available for a large variety of ranges from 0–20% to 100% oxygen. Orsat gas analyzers have been designed for specific applications, such as combustion and blast furnace testing, and for checking the purity of medical and industrial oxygen.

Flow Sheet Symbol

Types:	A. Polarographic B. Galvanic C. Coulometric D. Multiple-anode E. Thallium F. Fluorescence
Operating Pressure:	Up to 50 PSIG (3.5 barg) or submersion depths of up 25 ft (8.3 m)
Operating Temperature Range:	32 to 122°F (0 to 50°C); special designs up to 175°F (80°C)
Flow Velocity at Sensing Membrane:	Preferably in excess of 1 ft/sec (0.3 m/s); some can operate down to 0.2 ft/sec (0.06 m/s)
Materials of Construction:	Typical material for sensor housing: PVC or stainless steel; possible electrode materials: platinum, gold, silver, zinc, lead, cadmium, and copper; for membrane assembly, ABS plastic or stainless steel mesh-reinforced silicone and/or Teflon® membrane
Speed of Response:	90% in 30 sec; 98% in 60 sec
Ranges:	Common ranges are 0 to 5, 0 to 10, 0 to 15, and 0 to 20 ppm; special units are available with ranges up to 0 to 150 ppm or down to the 0 to 20 ppb range used on boiler feedwater applications. Systems can also be calibrated in partial pressure units.
Inaccuracy:	Generally, ±1 to ±2% of span; industrial transmitter errors are generally within 0.02 ppm over a 0 to 20 ppm range. Thallium cells are available with a 0 to 10 ppb range and can read the dissolved oxygen (DO) within an error of 0.5 ppb.
Costs:	Portable, battery-operated, 1.5 to 2% FS units that also read temperature cost from $500 to $2000; replacement probes range from $250 to $1000; 1% FS, microprocessor-based portable benchtop units for laboratory or plant service cost from $1000 to $2000; industrial-quality (0.02 ppm error limit) DO probe and 4 to 20 mA transmitter range from $2000 to $3500; cleaning assemblies cost from $500 to $2000.

INTRODUCTION

Section 8.42 was devoted to the discussion of oxygen analyzers in gas. This section deals with oxygen analysis in liquids. The distinctions between the analyzers used for these two services are not clear cut. The different electrochemical cell-type sensors (e.g., polarographic, galvanic, coulometric) can be used for both applications, as discussed in the previous section. Therefore, their treatment is somewhat shortened in this section. The most commonly used dissolved oxygen (DO) probe is the polarographic type.

Probe Cleaners and Newer Sensors

Similarly, probe cleaners have already been discussed in Sections 8.1, 8.2, 8.28, 8.33, 8.41 and will also be discussed in Section 8.48 in connection with pH probes. Therefore, their treatment here will also be abbreviated, although Figure 8.43a does describe a vibratory paddle-type probe cleaner. This unit cleans the membrane surface by a back-and-forth motion close to the surface. The agitator paddle is coated with a biological growth-inhibiting substance that minimizes the biological growth on the membrane surface.

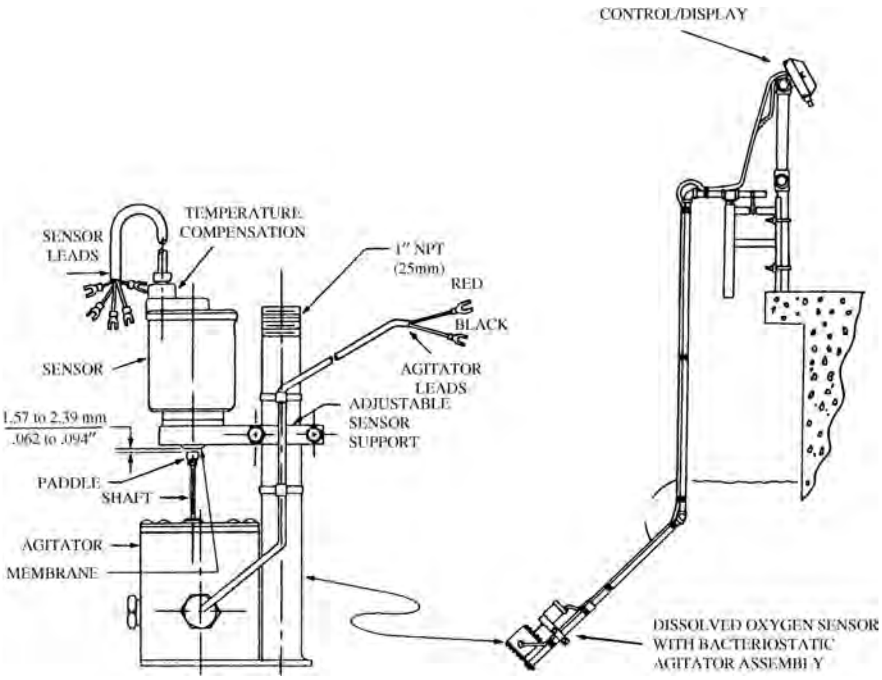

FIG. 8.43a
Cleaner assembly for keeping the membrane surface of a dissolved-oxygen probe free of buildup or biological growths.

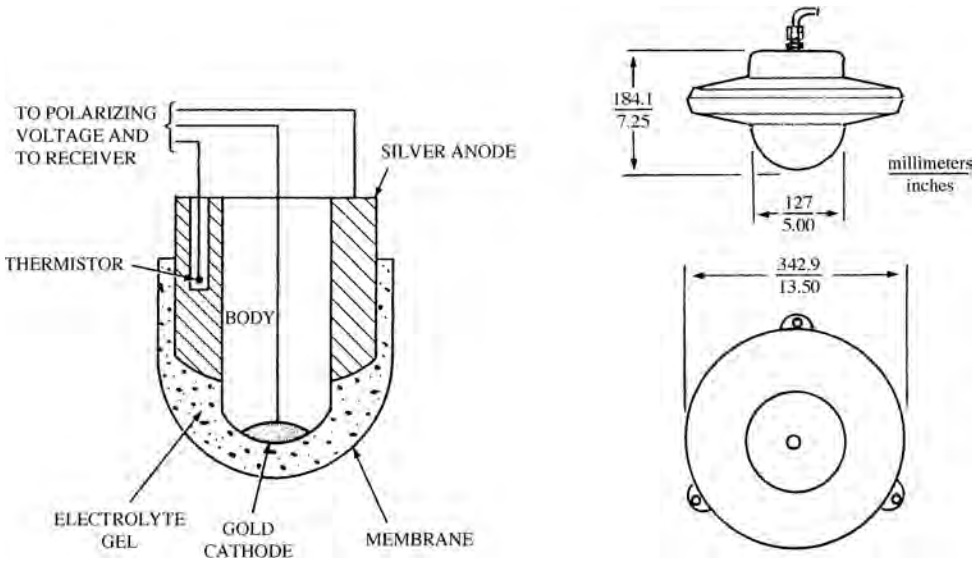

FIG. 8.43b
Probe-type polarographic cell oxygen detector and flotation collar in which it can be mounted.

Galvanic and polarographic sensors continue to dominate the dissolved oxygen measurement applications for both on-line and off-line analysis. However, significant advances have been made with the introduction of equilibrium-state voltametric and fluorescence-based probes. These have the advantage of analyte sensitivities, which are relatively independent of membrane coating, and, since they consume little or no analyte as a result of the measurement process, they are able to work in processes where there is little or no flow past the face of the sensor.

All oxygen detectors used for gaseous samples can also measure the oxygen concentration in liquid streams if the oxygen is first removed from the liquid. This approach has the major advantage that only a clean gas mixture will contact the oxygen detector.

POLAROGRAPHIC CELL

The basic polarographic cell is illustrated in Figure 8.43b. It is very similar to the galvanic cell discussed in the next paragraph. However, the polarographic cell has *two* noble-metal electrodes and requires a polarizing voltage to reduce the oxygen.

The dissolved oxygen in the sample diffuses through the membrane into the electrolyte, which usually is an aqueous KCl solution. If there is a constant polarizing voltage (usually 0.8 V) across the electrodes, the oxygen is reduced at the cathode, and the resulting current flow is proportional to the oxygen content of the electrolyte. This current flow is detected as an indication of oxygen content. The oxidation-reduction reactions, in the case of a gold-silver cell and with KCl electrolyte, are as follows:

At the gold cathode,

$$O_2 + 2H_2O + 4\text{ electrons} \rightarrow 4(OH^-) \qquad \textbf{8.43(1)}$$

and at the silver anode,

$$4Ag + 4(Cl^-) \rightarrow 4AgCl + 4\text{ electrons} \qquad \textbf{8.43(2)}$$

A variety of designs are available to extend the working life of the cell to several months. These include a number of membrane and electrolyte reservoir designs in addition to the use of a larger silver anode. The silver chloride at the anode can be converted back to silver by reversing the polarizing voltage.

Sample Temperature and Flow

The polarographic cell, like galvanic cells, is affected by temperature. Therefore, it is necessary to either control the sample temperature or to provide temperature compensation to attain high-precision measurements. In case of DO measurement, high precision corresponds to ±1 to ±2% error. If the sample temperature is allowed to vary between 32 and 110°F (0 and 43°C), the measurement error in some designs will rise to approximately ±6%.

Both galvanic and polarographic cells require a minimum sample flow velocity. This is necessary to eliminate stagnant layers of sample over the membrane, which otherwise would interfere with the continuous transfer of oxygen into the cell. The higher sample velocities are also beneficial because of their scrubbing action. Some suppliers provide a combination cell that, for maximum cleaning effect, includes a sample pump that directs a 5 ft/sec (1.5 m/s) flow velocity against the membrane.

GALVANIC CELL

The operating theory of the dissolved oxygen galvanic cell is the same as that of the galvanic cell used for gaseous samples. With the exception of the considerations related to

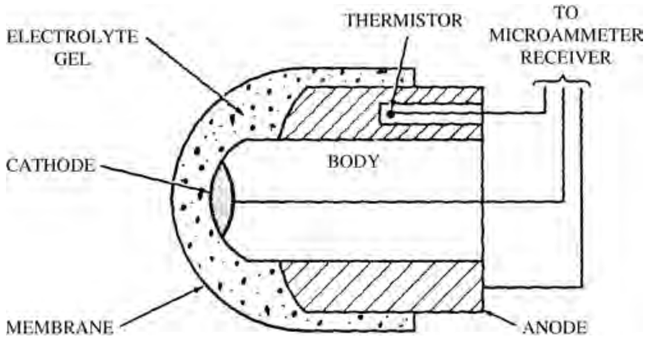

FIG. 8.43c
Probe-type galvanic cell oxygen detector.

the drying-out problem, all the design considerations are identical. The main difference is that most dissolved oxygen sensors are installed in dirty water, so they require special cleaners, agitators, and specialized sample systems.

The ranges of the galvanic cell dissolved oxygen analyzers can be as low as 0 to 20 ppb for applications such as the measurement of dissolved oxygen (DO) content of boiler feedwater.

Cell Designs

All galvanic cells consist of an electrolyte and two electrodes (Figure 8.43c). The oxygen content of the electrolyte is equalized with that of the sample. The reaction is spontaneous; no external voltage is applied. In this reaction, the cathode reduces the oxygen into hydroxide, thus releasing four electrons for each molecule of oxygen [Equation 8.43(3)]. These electrons cause a current flow through the electrolyte. The magnitude of the current flow is in proportion to the oxygen concentration in the electrolyte.

The most common electrode materials are gold, silver, copper, and lead, and the most frequently used electrolyte is potassium hydroxide (KOH). The cathode must be a noble metal (silver or gold) for the cathode potential to reduce molecular oxygen when the cell circuit is closed. A base metal is selected for the anode (lead, cadmium, copper, zinc, or silver) with good stability and without any tendency toward passivation. The electrolyte [KOH, potassium chloride (KCl), or potassium bicarbonate ($KHCO_3$)] is selected to minimize its dissolution of the anode when the cell is open.

In the case of a lead anode, the cell reactions can be expressed as follows:

$$\text{Cathode:} O_2 + 2H_2O + 4 \text{ electrons} \rightarrow 4(OH^-) \qquad \textbf{8.43(3)}$$

$$\text{Anode:} 2Pb \rightarrow 2(Pb^{++}) + 4 \text{ electrons} \qquad \textbf{8.43(4)}$$

The galvanic-cell designs are subject to various degrees of contamination by background gases in the process stream. As a very general rule, the following background gases can be considered harmless: argon, butane, carbon monoxide, ethane, ethylene, helium, hydrogen, methane, nitrogen, and propane. However, the following gases are likely to contaminate the cell: chlorine and other halogens, high concentrations of carbon dioxide, hydrogen sulfide, and sulfur dioxide.

Special and Flow-Through Cells

Special cells have been developed to minimize the effect of the background gases. When an acid gas (such as CO_2) is present that would neutralize a potassium hydroxide electrolyte in the background, a potassium bicarbonate electrolyte can be considered. Special cells are also available for the measurement of oxygen in acetylene and fuel gases.

In flow-through cell designs, sampling systems are usually required to bring the process stream to the analyzer and to filter it, scrub it with caustic, or treat it in other ways as preparation for the measurement. The probe-type membrane design does not require a sampling system if it can be located in a representative process area where the pressure, temperature, and velocity of the process stream are compatible with the cell's mechanical and chemical design.

Probe Design

In this design (Figure 9.43c), the electrodes are wetted by an electrolytic solution that is retained by a membrane (usually Teflon) that acts as a selective diffusion layer, allowing oxygen to diffuse into the electrolyte solution while keeping foreign matter out. The sensor is usually mounted in a thermostatically controlled housing, and a thermistor is provided to compensate for minor temperature variations.

The ion current established in the electrolyte can be expressed by the following equation:

$$i_x = \frac{nFAPmCs}{L} \qquad \textbf{8.43(5)}$$

where
i_x = the ion current
n = the number of electrons involved in the electrode reaction
A = the area of the cathode surface
F = Faraday's constant
Pm = the permeability coefficient of the membrane
L = the thickness of the membrane
Cs = oxygen concentration

Equation 8.43(5) shows the relationship among the cell components. The Nernst equation [Equation 8.43(1)] also applies to the galvanic cell and explains why electrode potentials are a function of the absolute temperature. In addition, the ionic activity also varies with temperature, thus causing additional temperature sensitivity.

The characteristics of the membrane are critical to performance. The ideal membrane would be inert, stable, strong, permeable to oxygen, and impermeable to water molecules or other ions. In most cases, a compromise solution is accepted.

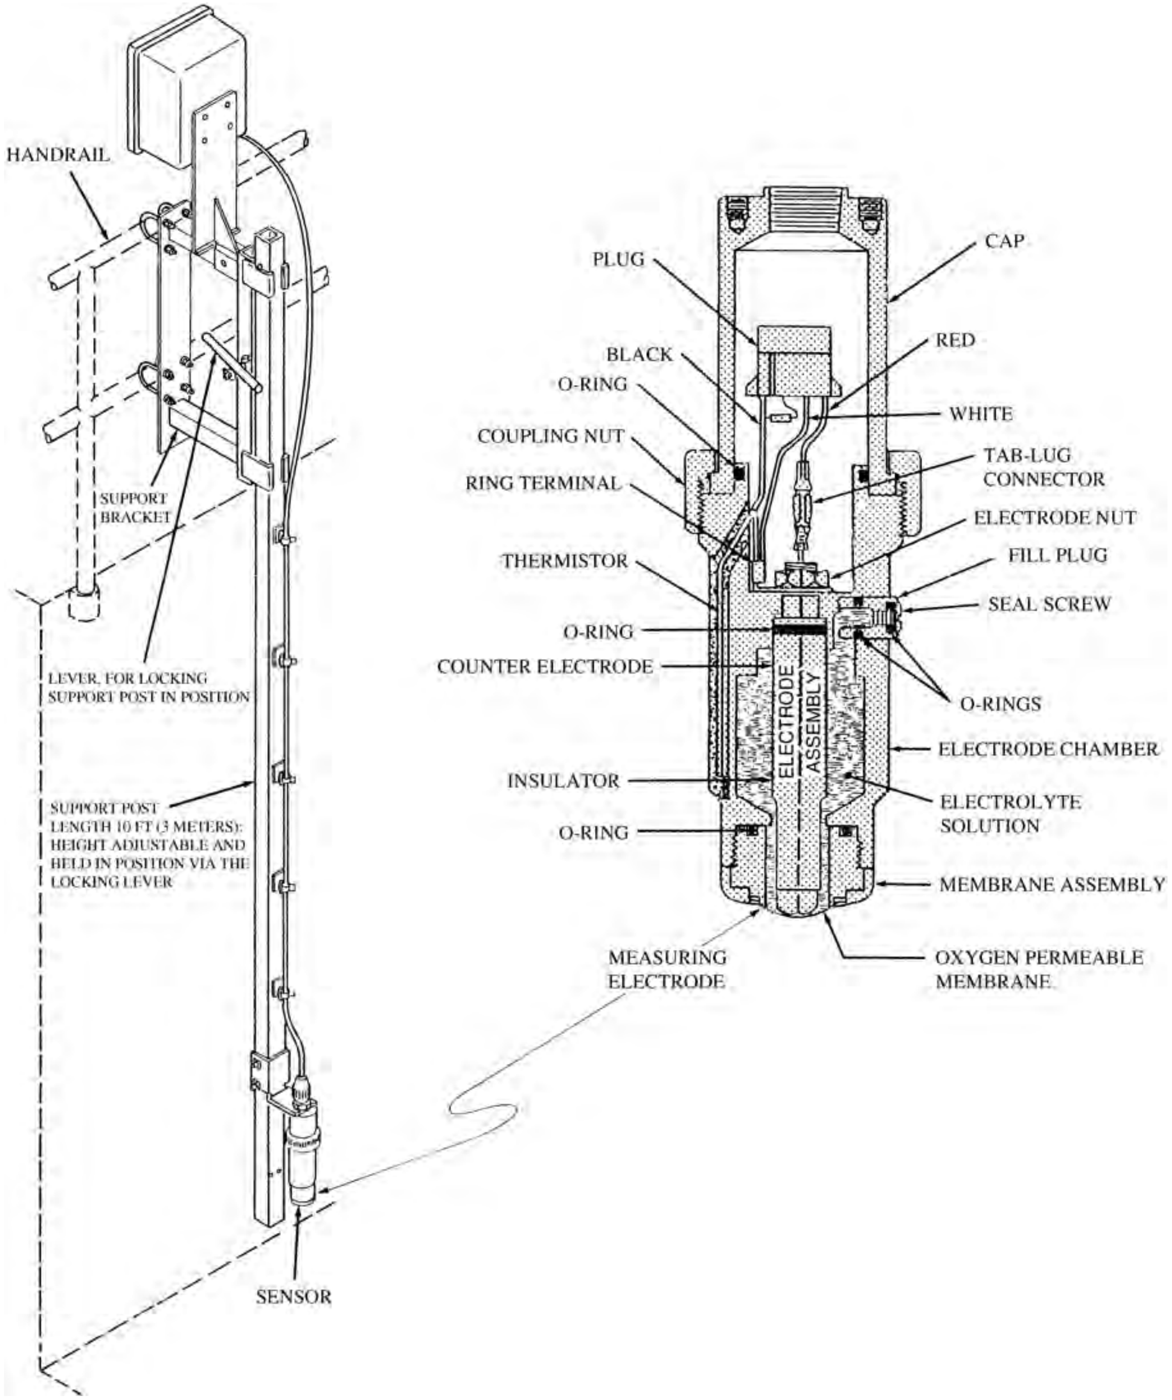

FIG. 8.43d
The design of a galvanic DO cell and its rail mounting installation. (Courtesy of ABB Inc., formerly Fisher & Porter Co.)

Installation The design of a galvanic (amperometric) cell with gold-copper electrodes designed for rail mounting is shown in Figure 8.43d. The maintenance requirements of this design have been reduced by providing an electrolyte supply that lasts for two to three years and by making the membrane assembly easily replaceable. These analyzer systems are available in weatherproof housing, with 1% of span inaccuracy and with 4 to 20 mA transmitter output.

Flow-Through Design

In the flow-through cells, the process sample stream is bubbled through the electrolyte. The oxygen concentration of the electrolyte is therefore in equilibrium with the sample's

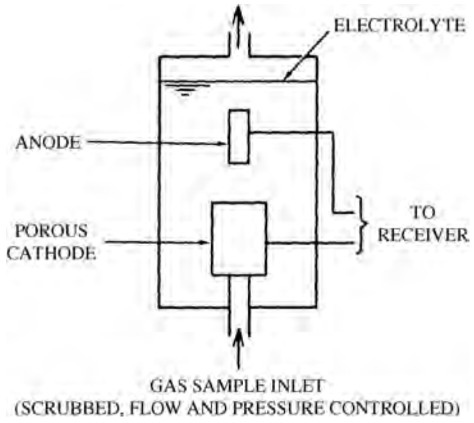

FIG. 8.43e
Flow-through trace oxygen analyzer cell.

oxygen content, and the resulting ion current between the electrodes is representative of this concentration.

In some trace analyzer designs, the cathode is made out of a porous metal, and the sample gas passes through this electrode, immersed in the electrolyte. Oxygen reduction tends to be complete within the pores of this electrode (Figure 8.43e).

These types of cells are usually provided with sampling consisting of (but not limited to) filtering and scrubbing components and flow, pressure, and temperature regulators.

COULOMETRIC SENSOR

In the coulometric sensor, the sample gas diffuses through a diffusion barrier to the cathode of the electrochemical cell, where it is reduced to hydroxyl ions. Due to the conductivity of the potassium hydroxide electrolyte, the ions migrate to the anode, where they are oxidized back to oxygen. An external voltage drives this reaction, which results in a cell current that is proportional to the oxygen concentration in the gas sample.

A main advantage of this design is its nondepleting nature, as neither electrode undergoes a chemical change during measurement. Also, there is no need for periodic sensor replacement, and the unit is not subject to *oxygen shock*. This sensor is suited for ppb, ppm, and percentage measurements up to 25%. The areas of application of the coulometric analyzer are similar to those of the galvanic sensor.

MULTIPLE-ANODE DETECTOR

The multiple-anode detector (Figure 8.43f) has three electrodes. Two are interspaced (noted by + and – in the figure) and covered with electrolyte. Oxygen is consumed at many cathodes but is generated at many anodes.

$$2H_2O \rightarrow O_2 + 4H^+ + 4e^- \qquad \textbf{8.43(6)}$$

Because a balance exists in this cell, there is no net generation of products. A number of advantages are claimed for this technique. These include that fouling affects only the response time, there is no deterioration of electrodes, and membrane replacement is not required.

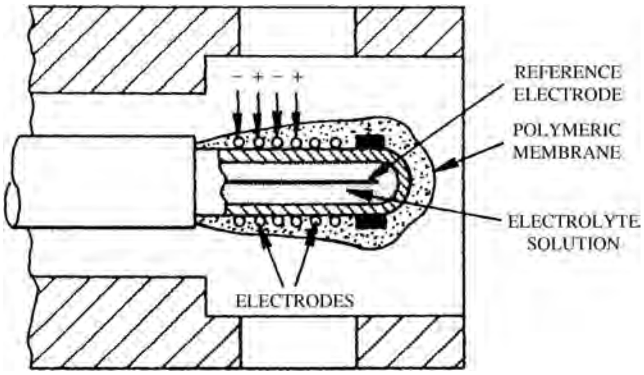

FIG. 8.43f
Multiple-anode oxygen detector.

THALLIUM CELLS

Thallium cells are somewhat unique in their operating principle and cannot be classified into the category of either galvanic or polarographic cells. At the same time, they are of the electrochemical type. One thallium-electrode cell design is somewhat similar in appearance to the unit illustrated on Figure 8.43b except that it has no membrane or electrolyte. This cell has a thallium outer-ring electrode and an inner reference electrode. When oxygen contacts the thallium, the following reaction takes place:

$$4TI + O_2 + 2H_2O \rightarrow 4TI(OH) \rightarrow 4(TI^+) + 4(OH^-) \qquad \textbf{8.43(7)}$$

The potential developed by the cell is a function of the thallous ion concentration at the face of the electrode, and the ion concentration is in proportion to the concentration of dissolved oxygen.

Thallium Differential Conductivity Analyzer

Another cell involving the reaction between thallium and oxygen is the thallium differential conductivity analyzer. This sensor detects the amount of thallous hydroxide formed by the measurement of conductivity. The sample conductivity is sensed both before and after the reaction, and the difference in conductivities is detected as a measure of dissolved oxygen content.

To eliminate temperature gradient problems, the actual instrument has both a sample and a reference flow stream. They are maintained at the same rate, and they flow through a similar flow path. Due to the high sensitivity of this measurement, accuracies of ±0.5 ppb are obtained over the minimum range of 0 to 10 ppb. The response speed of this sensor is relatively slow; 95% of the response can be expected in about three minutes.

FLUORESCENCE-BASED SENSORS

A new class of dissolved oxygen sensors operates on the principle of fluorescence quenching. Some chemical compounds have the ability to absorb light of a particular wavelength and then to re-emit light at a different (longer) wavelength. The intensity of the emitted light can be diminished when another chemical compound interacts with the compound responsible for the fluorescence. Because its intensity is lower than expected, the emitted fluorescence intensity is said to be *quenched*. This phenomenon can be used for the measurement of oxygen.

Sensor Design and Operation

In this case, a compound containing ruthenium is immobilized in a gas-permeable matrix called a *sol-gel*. Sol-gels are very low-density, silica-based matrices suitable for immobilizing chemical compounds such as the ruthenium compound used in this measurement technique. Effectively, the sol-gel is equivalent to the membrane in a conventional DO sensor.

Using fiber optics, light from a light-emitting diode is transferred to the backside of the sol-gel coating. The emitted fluorescence is collected from the backside of the sol-gel with another optical fiber and its intensity is detected by a photodiode. A simplified sensor design is shown in Figure 8.43g. If no oxygen is present, the intensity of the emitted light will be at its maximum value. If oxygen is present, the fluorescence will be quenched, and the emitted intensity will decrease.

The ratio of the emitted intensity when no oxygen is present (Io) to the emitted intensity in the presence of oxygen (I) can be related to the oxygen partial pressure (which can be converted to concentration) through the Stern–Volmer equation below:

$$\frac{I_O}{I} = 1 + K(P_{O2}) \qquad \textbf{8.43(8)}$$

where

K = a temperature dependent constant

P_{O2} = the partial pressure of oxygen

This equation shows that, in the absence of oxygen, the ratio I_O/I will be 1.0 and that it will increase linearly as the oxygen concentration increases.

To determine the oxygen content of a solution, it is first necessary to determine I_O when the oxygen concentration is zero. Hence, calibration consists of a minimum of two points; one measurement is made in a zero-oxygen environment, and the other is at near normal oxygen concentrations where measurements are to be made.

The dynamic range for this sensor type is from single-digit ppb through 40 ppm. Response times are approximately 30 sec, and inaccuracy is typically 1% of the measurement range. The sensing element can be damaged by solutions having pH values greater than 10 and by solutions containing high levels of aggressive solvents such as aromatic compounds and ketones. The sol-gel membranes are available with a coating (such as silicone) to provide protection against abrasion.

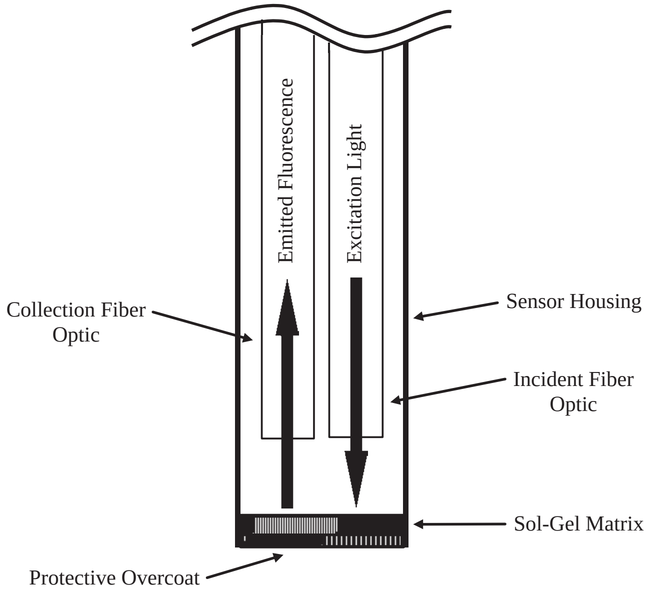

FIG. 8.43g
Simplified diagram of a fluorescence-based dissolved oxygen sensor.

OTHER DETECTION METHODS

Another method of dissolved oxygen detection involves wet-chemistry analyzers. These devices operate intermittently by taking a small sample and adding reagents to it. The reagents develop a color in the sample if a certain component is present. This technique can be applied to dissolved oxygen detection (in addition to many other applications) by colorimetrically determining the concentration of the unknown component.

OPERATIONAL CONSIDERATIONS FOR ALL SENSORS

For the purposes of the discussion that follows, it is assumed that oxygen is dissolved in ordinary water. For most applications, the sensors are actually inserted into more complex solutions. However, the major component is usually water and thus, for the sake of the discussion that follows, the physical and chemical properties of such a solution usually can be treated as pure water.

Dissolved oxygen sensors can also be used for measurements in solutions consisting primarily of organic solvents. In this case, one must be aware that the solubility characteristics of oxygen in such a solution can be very different from that in a solution consisting primarily of water. Therefore, the oxygen solubility algorithms preprogrammed into the transmitter for water may not accurately reflect the true oxygen concentration in a solvent.

Calibration Methods

Many dissolved oxygen systems are designed to operate over a very wide concentration range—for example, from 0 to 100 mg/l or up to 500% saturation. Calibration can be based on either one or two points. Additionally, calibration can be performed in air- or oxygen-saturated media or in air (or oxygen) that is saturated with water vapor. The method of calibration will have an influence on accuracy and is often dictated by the desired measurement range.

Given this, manufacturers may suggest different calibration schemes based on the level at which the determination is to be made. For example, if all measurements are to be made at concentrations greater than 0.5 mg/l, then a one-point calibration will usually suffice. (This is not true for fluorescence-based sensors, as was discussed earlier.) In this case, the intercept of the calibration plot is set to equal zero current at zero concentration. This assumption is often valid, given that the background current for most sensors is usually very small in comparison to the values being measured.

On the other hand, if measurements are to be made at levels below 0.5 mg/l, then one will want to set the low calibration point (the zero signal) in an oxygen-free medium and then set the second calibration point in a medium of higher (and known) oxygen content. This procedure will ensure greater accuracy at lower concentrations.

Special care must be observed when calibrating membrane-covered sensors that consume oxygen (e.g., polarographic or galvanic) in a zero-oxygen environment. For this case, the sensor must be exposed to the oxygen-free medium (and polarized) for approximately 1 hr prior to calibrating the zero point. Otherwise, residual oxygen in the electrolyte within the sensor will cause an erroneously high current measurement.

Temperature Compensation

Temperature is an important factor in dissolved oxygen measurements for two reasons. First, the solubility of oxygen in a liquid is temperature dependent and, second, the rate at which oxygen moves across the permeable membrane is also temperature dependent. The change in solubility is inversely proportional to solution temperature, as shown in Figure 8.43h(I). If the user is interested in oxygen concentration values, then a solution temperature change must reflect a

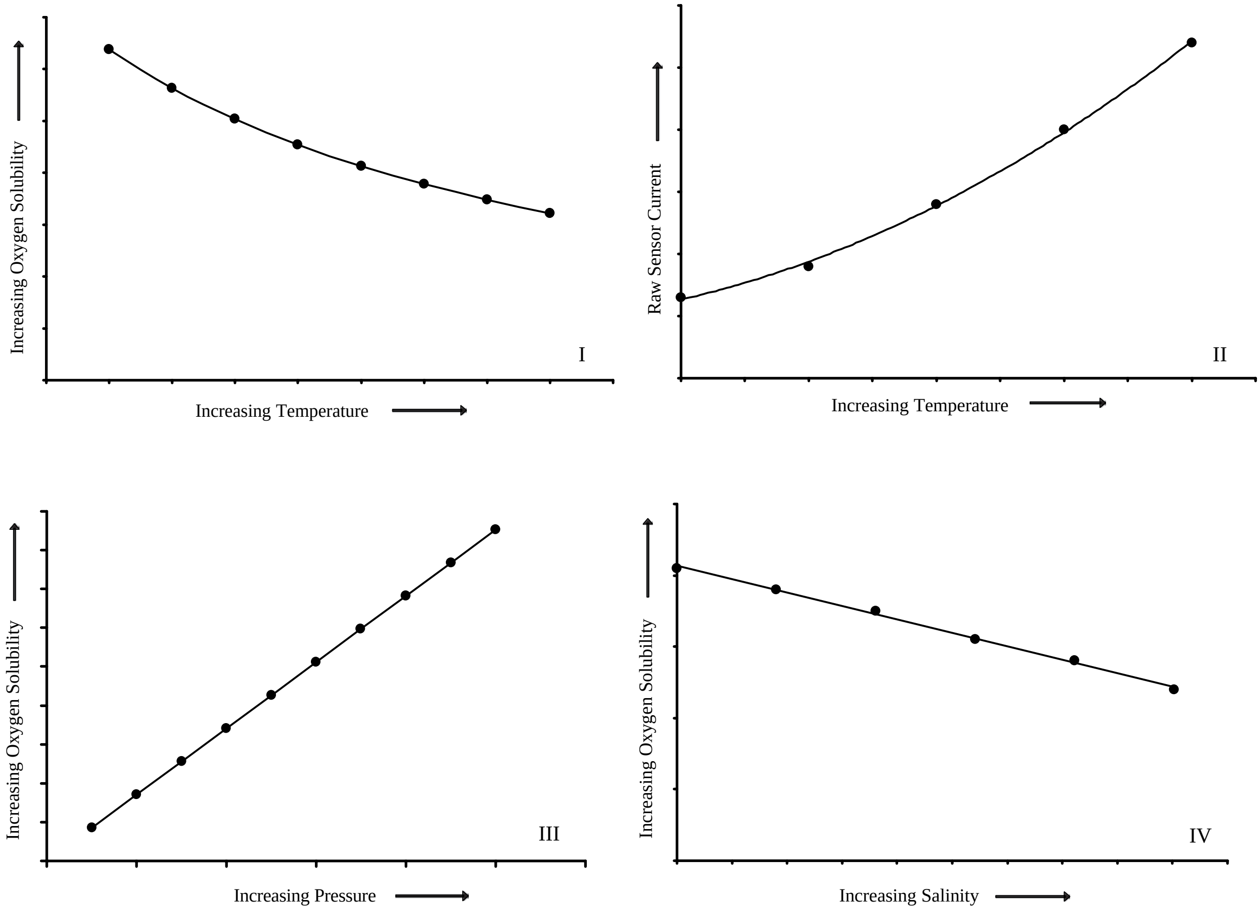

FIG 8.43h

Variation of (I) dissolved oxygen concentration with liquid temperature, (II) sensor current with temperature, (III) dissolved oxygen concentration with pressure (total pressure or oxygen partial pressure), and (IV) dissolved oxygen concentration with salinity. (Graphs generated from data tabulated in Hitchman, M. L., Measurement of Dissolved Oxygen, John Wiley & Sons, New York, 1978.)

change in oxygen concentration on the transmitter display. Practically all dissolved oxygen meters/transmitters employ an algorithm to determine oxygen concentration based on a solution temperature measurement.

Dissolved oxygen sensors are designed to operate under steady-state oxygen transport across the membrane. Ideally, the membrane permeability should never change after calibration. However, membrane permeability increases with increasing temperature. Hence, the sensor signal will increase with temperature, as shown in figure 8.43h(II). For an uncompensated sensor, the change in signal with temperature can be 1 to 6% per degree Celsius.

Erroneous results will be obtained if we do not account for this. Therefore, all dissolved oxygen sensors employ specific algorithms to correct for this effect. Algorithms are usually manufacturer specific, because membrane materials play an important role in determining the final mathematical form.

Both solubility and membrane permeability factors are accounted for by temperature compensation employed by the measurement loop. Dissolved oxygen sensors have built-in or adjacent temperature measuring devices that are actively monitored by the transmitter.

Pressure Effects

Dissolved oxygen sensors respond to the amount of oxygen that is present in a liquid. Because oxygen is a gas under normal conditions, the amount of oxygen in a liquid is usually expressed as the partial pressure of oxygen (P_{O2}) or the mole fraction of oxygen (X_{O2}, equal to 0.209 for air). The two quantities are related through the total gas pressure (P_T) of the system as follows:

$$P_{O2} = X_{O2}P_T \tag{8.43(9)}$$

Furthermore, the solubility (concentration) of oxygen dissolved in a liquid at a given temperature and pressure follows a relatively simple relationship known as Henry's law,

$$S_{O2} = K_H P_{O2} = K_H X_{O2} P_T \tag{8.43(10)}$$

where K_H is a constant that depends on both temperature and liquid composition. This equation shows that solubility varies linearly with partial pressure and total pressure [Figure 8.43h(III)].

This is an important relationship, because dissolved oxygen transmitters require the input of a pressure value (barometric or system pressure) during calibration and operation. Some will even provide real-time pressure corrections using input from an external pressure sensor.

Some dissolved oxygen analyzers are suitable for measurements in both gas and liquid-phase applications. Additionally, calibration can be performed in either the gas or the liquid phase. In this case, the contribution of water vapor pressure to the total gas pressure (and hence the oxygen partial pressure) must be accounted for so as to achieve the highest possible accuracy. Therefore, some dissolved oxygen transmitters are designed so that the influence of water vapor can be entered as a relative humidity value during calibration and operation.

For example, oxygen sensors can be calibrated in water saturated with air, in air saturated with water vapor (in each case, the relative humidity being essentially 100%), or in ordinary air (in which case, the relative humidity is less than 100%). In each case, the appropriate water vapor (relative humidity) correction factor can be entered into the software.

Salinity Effects

The salinity (i.e., the amount of a salt dissolved in water) is usually expressed in terms of mass of salt per mass of solution or mass of salt per volume of solution (gr/1000 gr, $^{o}/_{oo}$). In more general terms, this quantity can be expressed as the mass of chloride per volume of solution (gr/l). A salinity value is directly obtainable from conductivity measurements.

The solubility of oxygen in water decreases nonlinearly with increasing salinity, as shown in Figure 8.43h(IV). The effect is most noticeable for salinity values greater than 2 gr/1000 gr. For comparison purposes, saltwater has a salinity of approximately 35 gr/1000 gr. At 20°C and 1 atm of pressure, the solubility of oxygen in salt water is approximately 7.3 mg/l. The solubility of oxygen in pure water at the same temperature and pressure is 9.l mg/l. Therefore, if salinity compensation were ignored, an error of almost 20% would result.

Application Considerations

The applications in which dissolved oxygen sensors are used include biopharmaceutical, water and wastewater, food and beverage, and chemical processing. Each application category dictates slightly different requirements for the sensor and transmitter. Biopharmaceutical applications require that the sensor body be of a hygienic design to allow for cleanability and to resist clean-in-place and sterilize-in-place conditions. Therefore, the sensor bodies are usually polished stainless steel and have no exposed grooves or crevices where matter can accumulate.

Additionally, membranes usually have an outer layer of Teflon to resist the buildup of coating. In contrast, in wastewater applications, the specifications are less stringent, so sensors are usually constructed from polymer materials, have lower temperature and pressure ratings, and are less resistant chemically.

Similar to biopharmaceutical applications, food and beverage usage usually requires that the sensor be of a hygienic design. However, it does not necessarily need to withstand sterilization conditions. Often, in food and beverage applications, the sensor is exposed only to temperatures that are high enough to pasteurize the process liquid.

Chemical process applications require sensor characteristics similar to those for biopharmaceutical and food and beverage applications. In these applications, too, the materials used must withstand higher temperatures and pressures than polymer materials can provide and must have good chemical resistance characteristics. For hazardous area applications, an intrinsically safe sensor must be considered, and manufacturers are usually able to supply intrinsic-safety-related information.

Mounting Considerations The specific application will determine whether a housing or other mounting structure is required. Dissolved oxygen sensors other than portable-unit types are usually mounted in a support structure that offers a secure mounting point or protection from the process environment.

The mountings used for dissolved oxygen sensors are essentially the same as the ones used for pH sensors (Section 8.48). For simple wastewater applications, the sensors are usually mounted in plastic pipe such that the electrical connections are protected from moisture and debris. In more demanding applications, sensors are mounted in a sturdier (usually stainless steel) housing that is resistant to high temperature, high pressure, and aggressive chemical environments. In these cases, the sensor/housing combinations are most often mounted in a weld-in socket on the process vessel or pipe.

Dissolved oxygen sensors can also be mounted in retractable housings; however, this is usually done only for applications in which the sensor can be cleaned, calibrated, and perhaps sterilized within the housing after being retracted from the process.

INTRODUCTION

Ozone is an unstable gas that occurs naturally in the atmosphere. Its concentration is usually below 0.1 ppm at sea level but can be substantially higher concentrations at high altitudes[1] or in urban areas during the summer, where outdoor ozone can reach 0.2 ppm or more.

At ground level, it is produced by nature through the interaction of sunlight with the oxygen in the air. In the upper atmosphere, it is produced by electrical storms, and in the lower atmosphere by lightning, or by the interaction of sunlight, oxygen, and organic pollutants (such as hydrocarbons) at ground level. The concentration of ozone at ground level (in smog) has been used as an indicator of the extent of pollution in the air.

Ozone is a powerful oxidizing agent and a very strong disinfectant. In industry, it is generated from air or oxygen by means of electrically powered devices called ozone generators. The major uses of ozone include the following:

1. Ozone can be used for the oxidation of pollutants (e.g., organic vapors, odorous materials) and also for disinfection.
2. It is also used for the oxidation of pollutants in water and wastewater treatment, for micro-flocculation, and for disinfection.
3. In the process industries, ozone is used for the bleaching of pulp paper, as a chemical oxidant, and for decolorization.

Ozone Monitoring

Gas phase ozone monitoring and analysis is most frequently done on air or oxygen streams, serving one of the following purposes:

1. Monitoring atmospheric ozone concentrations
2. Monitoring and controlling the ozone concentration in the output of ozone generators
3. Monitoring ozone concentrations in the off-gas streams of ozone treatment systems
4. Monitoring ambient ozone concentration in ozone generator rooms

For workspace safety, the Occupational Safety and Health Administration limits the allowable ozone concentration to 0.1 ppm. In areas where the general public is present, many guidelines and regulations set the limit at 0.05 or even 0.03 ppm.

Ozone monitoring devices can have “cross sensitivities” with oxides of nitrogen (NOx) and with chlorine compounds. For these reasons, it is recommended that the areas where ambient ozone is monitored not only be isolated from the outdoor air but also be separated from chlorine and hydrocarbon fumes.

The ambient ozone monitors should be installed at the height of the operators’ head so as to detect the air that is breathed. The monitor should be located in still air, isolated from the outside air. It also should be kept out of sunlight, because sunlight can create interfering gases as it strikes plastics or hydrocarbons. If the ozone monitor is provided with a high alarm, it should be set just below 0.1 ppm, or the required limit.

After the ozone monitor is installed, its calibration should be checked on a quarterly basis. If the area of operation is dusty, wet, or potentially damaging in any other way, the calibration should be checked monthly.

Monitor Designs

References 2 and 3 list several methods that been used for the analysis and monitoring of ozone concentration in gas streams. The most commonly used ozone monitors employ ultraviolet (UV) spectroscopy as the method of detection (see Section 8.61).

Other methods include the amperometric method, in which an electrochemical cell is isolated from the sample gas stream by a gas-permeable but liquid-impermeable membrane, similar to the ones used in dissolved oxygen measurement (Section 8.43). This method permits the use of the same monitor for both gas and liquid phase measurements.

For ozone leak detection applications, the small and portable thin-film semiconductor-type monitor is well suited.

ULTRAVIOLET ANALYZER

Ozone is a strong UV absorber at the wavelength of 253.7 nm (See Tables 8.1c and 8.1v). These instruments are available in a wide variety of complexity and sophistication, as is discussed in some detail in Section 8.61.

The generally accepted value of the ozone absorption coefficient is 3000 ± 30 M^{-1} cm^{-1} at 273 K and at 1 atm.[4] The UV measurement is an absolute method for the detection of ozone in the gas phase, because it does not need to be calibrated by using some other type of sensor.

Single-Beam Design

The single-beam design uses one UV light absorption cell. Figure 8.44a illustrates both a ppm and a percent concentration design. In these designs, every 5 to 20 sec, the sample gas stream and the ozone-free reference gas stream are alternately passed through the absorption cell. The UV light detector measures the intensity of the UV radiation as it leaves the sample cell.

The difference between the UV intensities that are detected when the sample is flowing and when the ozone-free reference sample is used is the basis for computing the ozone concentration in the sample. The computation is based on the Bee–Lambert law below:

$$A = abc = \log_{10}\frac{I_0}{I} \qquad \mathbf{8.44(1)}$$

where

A = absorbance

I = UV light intensity-reaching detector with sample in beam path

I_0 = UV light intensity-reaching detector with no sample in beam path

a = absorption coefficient of pure component of interest at analytical wavelength; the units depend on those chosen for b and c

b = sample path length

c = concentration of sample component

Double-Beam Design

The double-beam monitor employs two UV light absorption cells. One monitors the sample stream and the other the ozone-free reference gas stream. Because this design does not require the frequent switching of gas streams, it requires less maintenance. It is also capable of correcting for monitor

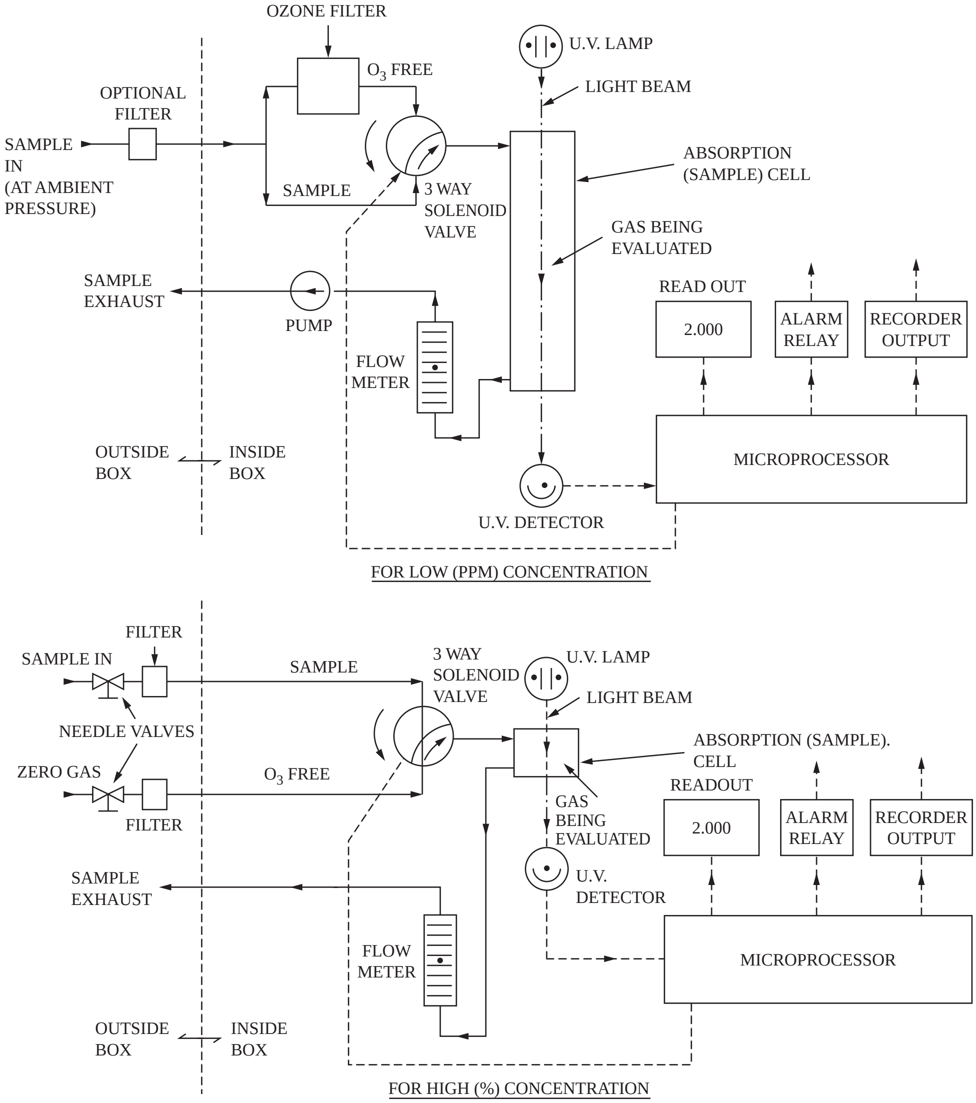

FIG. 8.44a
Single-beam ultraviolet analyzer can be used for both ppm and percent concentration detection of ozone.

cross sensitivity to the presence of other gases in the sample gas streams and for dirt buildup on the windows.

Both types of UV monitors are available with pressure and temperature compensation. UV measurement is usually specific to ozone, because components normally present in the atmosphere or in the off-gases of ozone water treatment systems do not absorb UV at the 253.7 nm wavelength. Naturally, if ozone is being detected in an atmosphere that contains NOx or chlorine, the UV measurement will not be specific, and compensation is required.

AMPEROMETRIC DESIGN

Figure 8.44b illustrates an amperometric electrochemical cell.[5] The cathode is gold, the anode is silver, and the electrolyte is aqueous potassium bromide (similar to Figure 8.43c).

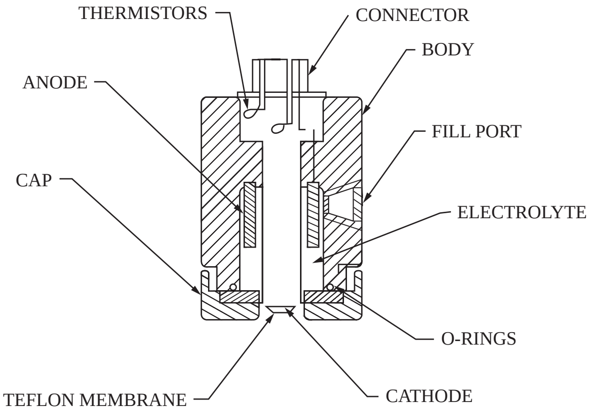

FIG. 8.44b
Membrane type amperometric probe.

The cell is isolated from the sample by a gas-permeable, water-impermeable perfluoroalkoxy (PFA) membrane. The cathode and anode reactions are as follows:

$$\text{Cathode:} \quad O_3 + H_2O + 2e^- = O_2 + 2OH^- \qquad \mathbf{8.44(2)}$$

$$\text{Anode:} \quad Ag + KBr = AgBr + K^+ + e^- \qquad \mathbf{8.44(3)}$$

Calibration

The instrument can be calibrated by chemical methods,[2] against UV-type monitors, or by the air calibration method. The latter method is based on the fact that the ratio of permeation rates of any two gases is constant. Therefore, air calibration involves the determination of the current from the cell when the power supply is –0.7 V and the cell is in the air (which has a known oxygen concentration).

Once this "air current" is determined, the ozone concentration in the gas sample can be computed from the "ozone current" signal of the sample measured at 0.25 V and from the known O_2/O_3 permeation ratio. This air calibration method renders the monitor more convenient to use, but it also makes it less accurate relative to UV or chemical reference calibrations. The inaccuracy of the monitor is about 5% when air calibration is used.

THIN-FILM SEMICONDUCTOR DESIGN

This monitor uses a sensor consisting of an alumina substrate sandwiched between a thin-film platinum heater and a thin-film platinum electrode (Figure 8.44c). The electrode is coated with a thin film of semiconductor.

During measurement, the semiconductor is kept at an elevated temperature by the heater. Because of the adsorption and decomposition of ozone, the resistance of the semiconductor varies substantially in the presence of ozone. The change in resistance is measured, and a corresponding voltage signal is generated that is linearly proportional to the ozone concentration.

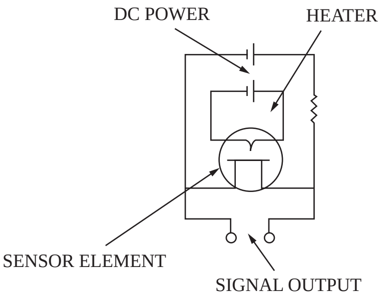

FIG. 8.44c
Thin-film semiconductor ozone monitor.

FIG. 8.44d
Shirtpocket Size Ozone Sensor. (Courtesy of ECO Sensors Inc.)

The unit is available with a 0 to 10 ppm range and a 0.02 ppm sensitivity. It is a portable ozone monitor that is available with a belt clip pouch. It weighs about 6 oz and can be powered by 12 Vdc batteries (Figure 8.44d).

INTRODUCTION

Dissolved ozone concentrations can be detected from as low as ppb to as high as 200 gr/m^3. Ozone monitoring is used for (1) dissolved ozone measurement in water treatment, (2) in ozone treatment of wastewater, (3) ozone contactor monitoring, and (4) industrial ozone treatment process monitoring.

Ozone is primarily used for the treatment of water, wastewater, and water slurries such as paper pulp.[1–3] For these applications, ozone is generated from air or from oxygen by electrically powered ozone generators. The output of a typical ozone generator contains 1 to 10% ozone by weight.

The ozone is transferred into the water in *ozone contactors*, which act as mass transfer devices as well as reactors for the treatment. The efficiency of the mass transfer in the contactor is monitored by measuring the ozone concentrations in the gas phase (see Section 8.44) at both the contactor's inlet and discharge. The dissolved ozone concentration in the ozone contactor is an indication of the progress of the treatment reaction or of disinfection.

In most water and wastewater treatment applications, when the ozone is generated from air, its solubility under ambient conditions is approximately 4 mg/l. When the ozone is generated from oxygen, its solubility is 15 mg/l.[4]

In these applications, the ozone is used for disinfection, chemical oxidation, or microflocculation. In paper pulp applications and in some wastewater treatment processes, it is also used for decolorization, bleaching, and disinfection.

Drinking Water Disinfection

The Surface Water Treatment Rules of the U.S. EPA[5] specify the use of CT values as the standard for drinking water disinfection using ozone or other chemical disinfectants. The CT value is the product of ozone (or disinfectant) concentration (C) in mg/l and the time of exposure of the water to the disinfectant in minutes (T). Therefore, to ascertain that the disinfection meets the U.S. EPA standard, the ozone concentration in the water (C) must be accurately monitored.

The methods in use for the monitoring and analysis of ozone in water solutions[6] fall into two categories.

1. *Methods specific to ozone*. These methods are able to determine the ozone concentration with no or very little interference from the other chemicals. These methods are suitable for monitoring the progress of disinfection or of chemical oxidations. They include the indigo method, the amperometric-membrane method, the stripping and gas phase detection method, and the UV method (for deionized high-purity water).
2. *Methods that are not specific to ozone*. These methods determine the concentration of total oxidants and, if no other oxidant is present, they are suitable for controlling ozone generators or for controlling the rate of dosing ozone into the water. These methods include the amperometric-bare electrode method and the potassium iodide chemical method.

AMPEROMETRIC SENSORS

Amperometric analyzers utilize an electrochemical cell for the determination of ozone.[7] Two types are in use. In the first design, the bare-metal electrodes are in direct contact with the water, whereas, in the second design, the electrochemical cell is separated from the process water by a semipermeable membrane, as in Figure 8.44b.

Bare Metal Electrodes

In the bare-metal electrode design of the amperometric ozone monitor, the water, as it flows through the galvanic cell, serves as the electrolyte. The oxidizing agents present in the water are reduced at the cathode. The generated current is proportional to the concentration of all the oxidants. Therefore, ozone monitors of this type are not specific for ozone. Measurement errors caused by the presence of other oxidants and oxidation by-products can be mitigated by the proper choice of the galvanic electrode pairs (e.g., Au/Cu, Au/Ag, Pt/Cu, and Ni/Cu), and this choice depends on the other oxidants that are expected to be present.

In water treatment plants, when the predominant oxidant is ozone and the concentration of other oxidants is zero or is nearly constant, the rugged and reliable bare-metal-electrode monitors can be used effectively. They can control both the ozone generators and the settings of ozone dosage controllers (Figure 8.45a).

Membrane-Type Designs

Membrane-type amperometric ozone monitors are more selective to ozone, because the membrane keeps most of the other

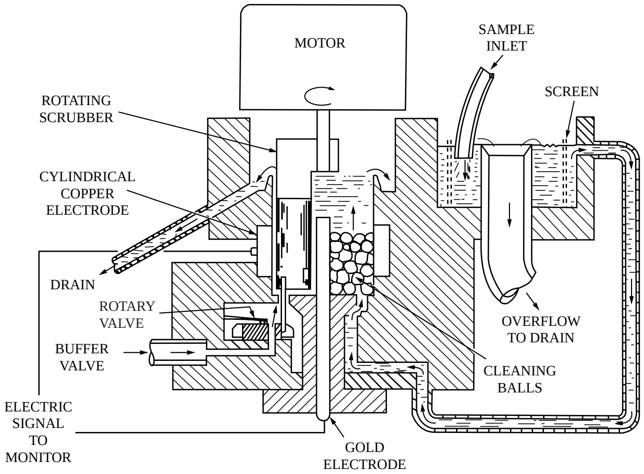

FIG. 8.45a
Amperometric ozone detector.

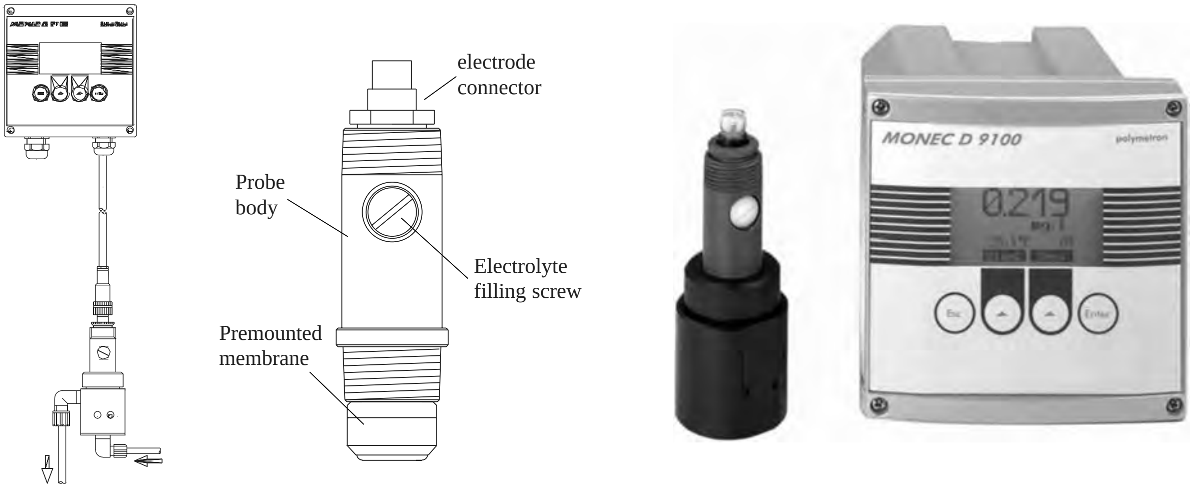

FIG. 8.45b
On-line dissolved oxygen monitor for water treatment plants. (Courtesy of Polymerton SA.)

oxidants out of the electrochemical cell. The membrane is permeable only to gas—not to water. These monitors can be employed for the measurement of ozone in both water solutions and in the gas phase (Section 8.44). However, when the membrane is semipermeable to water, the monitor can measure ozone only in water solutions—not in the gas phase.

The unit illustrated in Figure 8.45b has a gold cathode, a silver anode, and a measuring cell that can be made out of PVC or 316L SS. It has a measuring range of 0 to 2 ppm and a repeatability that is the greater of 5 ppb or 5% of measurement. Its response time is 60 sec. It is available with two smart outputs, four dry-contact NO/NC relay outputs, and automatic recognition of its own status.

Amperometric ozone analyzers need to be calibrated every one or two months against some reference method such as the stripping, the UV, or the colorimetric indigo methods, which are described below.

STRIPPING AND GAS PHASE MONITORS

In this method, the dissolved ozone is stripped from the water by the use of inert gases such as nitrogen, oxygen, and air, which are bubbled through a packed-tower-type scrubber. UV monitors are used to analyze the gaseous ozone, which is stripped from the water. This method eliminates the potential interference by oxidants that are present in the water.

The stripping method is cumbersome and is subject to operational problems such as incomplete stripping, ozone decomposition during the stripping, and entrainment of liquid droplets into the gas sample. Therefore, calibration by a more reliable method is desirable. This can be obtained by determining the dissolved ozone concentration in the water prior to stripping by means of the indigo method.

ULTRAVIOLET ABSORPTION

The concentration of dissolved ozone in water can be measured by the absorption of ultraviolet (UV) light at wavelengths from 253.7 to 260 nm. However, there is an uncertainty concerning the molar absorption coefficient of aqueous ozone in natural waters. Values of 2600 to 3600 M^{-1} cm^{-1} are reported in the literature.[3]

Another complication is caused by the fact that water from natural sources such as lakes, rivers, and wells is likely to contain dissolved organic compounds that have strong UV light absorption at the wavelengths that are used for ozone detection. Therefore, the use of the UV absorption method is recommended only for the measurement of dissolved ozone in deionized, high-purity waters. UV absorbance of ozone in pure water is reported to be 2950 M^{-1} cm^{-1} at 258 nm.[8]

COLORIMETRIC METHOD

The best known, most frequently used colorimetric method is the indigo trisulfonate method for the measurement of ozone dissolved in water. This method was developed by Hoigne and Bader from 1979 to 1982.[8] It is considered to be the most selective, sensitive, precise, and fast method among all chemical methods. Interference by manganese ions, chlorine, hydrogen peroxide, and by the decomposition and oxidation products of ozone are all the lowest for this method.

The Indigo Method

The indigo method utilizes the decolorization of the the stock solution of blue potassium indigo trisulfonate by dissolved ozone. The disappearance of this blue color is monitored spectrophotometrically at the wavelength of 600 nm. The dissolved ozone concentration is calculated from the difference in light absorption of an untreated blank and of a treated sample, as follows:

$$\text{dissolved } O_3 \text{ mg/l} = \Delta \text{ absorption} \times 100/f \times b \times v \qquad \mathbf{8.45(1)}$$

where

b = path length of the cuvette in cm

v = the volume of the ozone-containing sample added in ml (normally 90 ml) to raise the total volume of the sample plus the indigo solution to 100 ml

f = 0.42 ± 0.1 cm^{-1} per mg/l indigo, based on molar absorptivity = 20,000 $\text{M}^{-1}\ \text{cm}^{-1}$

The grab sample analysis can be carried out with standard laboratory wares when the method is used for the calibration of other methods.

The indigo method is employed in the "AccuVac Ampul" ozone measurement. For this measurement, all the necessary chemicals are prepackaged under vacuum into a cuvette-ampul device. The sealed glass tip of this device is submerged in the ozone-containing water sample, and the tip is broken open to allow the water to enter the device and dissolve the chemicals therein. The cuvette-ampul is used directly for the spectrophotometric determination of the dissolved ozone.

The indigo method can also be automated by the use of gas diffusion-flow injection.[9] In this procedure, the dissolved ozone in the sample stream is allowed to diffuse into an indigo solution stream through a 0.45-μm pore size Teflon® membrane. This causes the decolorization of the treated indigo solution stream, which is analyzed spectrophotometrically.

INTRODUCTION

This section is devoted to smoke and dust density measurement, which is performed most often by detecting opacity, or optical density. There are two major families of applications for these types of instruments. One is the measurement of the quality of ambient air, and the other is stack emission monitoring. The two applications overlap somewhat and some of the sensors discussed in this section can be used for both applications. Ambient air quality detectors are also described in Sections 8.5 and 8.40 of this chapter, and the subject of stack emission samplers is covered in Section 8.3.

This section is so organized that the definitions and theoretical concepts applicable to particulate measurement are discussed first. This is followed by the discussion of stack gas monitoring and the analyzers used for ambient air monitoring are discussed last.

DEFINITIONS AND THEORETICAL CONCEPTS

Suspended solids in gas will absorb, reflect, and scatter radiation (Figure 8.46a). These effects all attenuate the energy of radiation that is received at the detector. If the particle size is smaller than the wavelength of radiation, the attenuation is caused mostly by absorption. When the particle size is equal to or larger than the wavelength, the dominant form of attenuation is scattering.

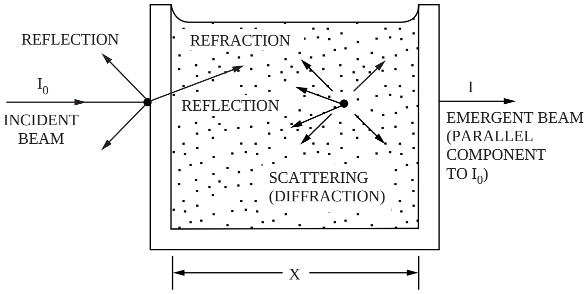

FIG. 8.46a
When parallel mononchromatic (single-wavelength) light (I_0) enters a stack, parts of it are reflected, refracted, scattered, and absorbed, and only the remaining attenuated (I) light emerges from the stack.[1]

Most particle sizes in industrial emissions fall between 0.1 and 50 μm, and the wavelength of light used for opacity measurement is in the range of 0.38 to 0.78 μm. Because light attenuation decreases with particle size when measuring

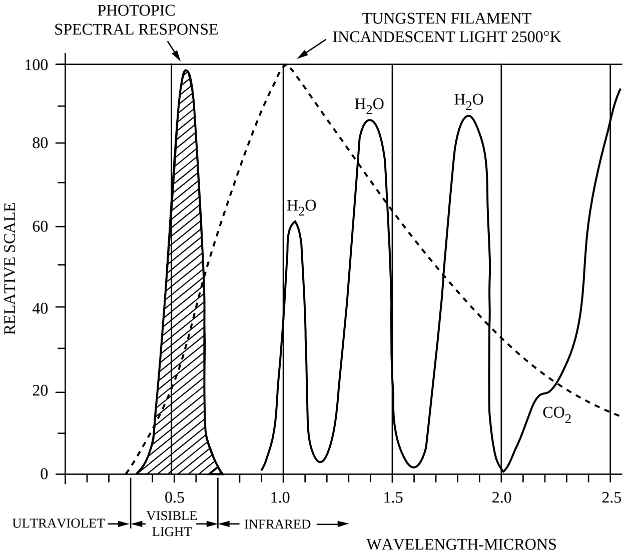

FIG. 8.46b

The spectral responses of "photopic" and "incandescent" light sources. With incandescent light, errors resulting from water absorption and low readings of submicron particulates will occur.[2]

submicron particles, it is desirable to use short wavelengths (0.38 to 0.78 μm) when measuring particulates in stacks.

Opacity Measurement

The objective of opacity measurement is to observe visible emissions the same way they are observed by the human eye. The spectral sensitivity of the light-adapted human eye is *photopic*, having its maximum sensitivity at a wavelength of about 0.55 μm. To reproduce the human eye, the spectral distribution of the light source in an opacity meter should also be photopic.

Figure 8.46b shows the outputs of both a photopic and an incandescent light source. If an incandescent light source is used in an opacity meter, the readings will be in error. One component of the error will be the result of water absorption in the near-infrared region, and the other error component, which will cause a low reading, will be caused by the effect of submicron particulates, to which the human eye is more sensitive. Therefore, transmissometers used for compliance with opacity regulations must operate in the visible photoptic spectrum.

Units and Definitions

The ratio of I/I_0 (Figure 8.46a) is called transmittance (T). It is usually expressed as a percentage, with 100% corresponding to zero attenuation ($I = I_0$). Percent opacity (O) is the difference between 100% opacity and transmittance (T) ($O = 100 - T$). The Beer–Lambert relationship defines transmittance (T) as follows:

$$T = e^{-naql} \qquad \textbf{8.46(1)}$$

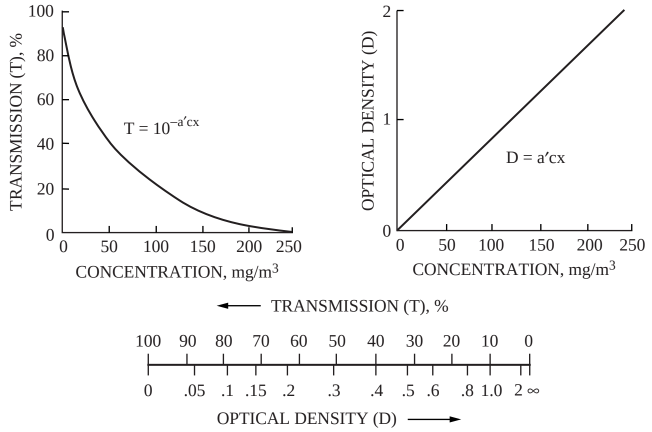

FIG. 8.46c

The relationship between transmission (T), concentration or dust loading, and optical density (D).

TABLE 8.46d

*Standard Ranges of Smoke Density Monitors**

Optical Density	*% Opacity*
0 to 0.09 and 0.18	0 to 18.7 and 33.9
0 to 0.18 and 0.45	0 to 33.9 and 64.5
0 to 0.45 and 0.90	0 to 64.5 and 87.4
0 to 0.90 and 1.80	0 to 87.4 and 98.4

*Courtesy of Lear Siegler Inc.

where

T = fraction of light transmitted (transmittance)
n = number of particles per unit volume
a = mean particle projected area
q = particle extinction coefficient
l = length of effluent path
e = base of natural logarithm

The product of n, a, and q is often referred to as the *turbidity attenuation coefficient.*

Dust Loading The Lambert–Beer law can also be used to determine the dust loading in the stack (mg/m^3), because dust loading can be determined for transmittance (T), as shown in Figure 8.46c. Optical density is a measure of light attenuation and is proportional to both path length and particulate concentration.

$$D = \text{opacity density} = \log_{10}[1/(1 - \text{opacity})] \qquad \textbf{8.46(2)}$$

Therefore, optical density can also be determined (Figure 8.46c) once the dust loading (mg/m^3) is known. Numerically, one might say that transmittance becomes very small (<10%) or opacity very large (>90%) when optical density reaches 1.0; when it rises to 2.0, transmittance is almost 0%, and the substance is completely opaque. Some of the standard ranges for stack monitoring applications are given in Table 8.46d in both units of percent opacity and of optical density.

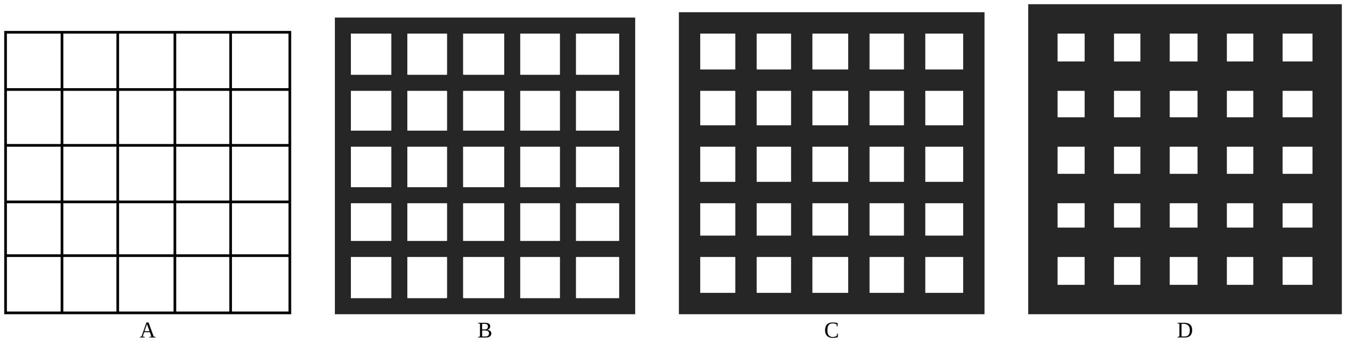

FIG. 8.46e

Ringelmann's scale for grading smoke density. A, Card 1 (equivalent to 20% black) has black lines 1 mm thick, 10 mm apart, leaving white spaces 9 mm square; B, Card 2 (equivalent to 40% black) has black lines 2.3 mm thick, 10 mm apart, leaving white space 7.7 mm square; C, Card 3 (equivalent to 60% black) has black lines 3.7 mm thick, 10 mm apart, leaving white space 6.3 mm square; D, Card 4 (equivalent to 80% black) has black lines 5.5 thick, 10 mm apart, leaving white spaces 4.5 mm square. Not shown: Card 0 (all white) and Card 5 (all black).

Ringelmann Card Numbers Another opacity measurement unit is based on Ringelmann card numbers. Ringelmann cards consist of a series of five cards that present graduated shades of gray from white to black for the evaluation of smoke density or opacity. The system utilizes a rectangular grill of black lines of definite width and spacing on a white background, which can be accurately reproduced (Figure 8.46e). The rule by which the chart may be reproduced is as follows:

Card 0. All white
Card 1. Black lines 1 mm thick, 10 mm apart, leaving white spaces 9 mm square
Card 2. Lines 2.3 mm thick, 10 mm apart, leaving white spaces 7.7 mm square

STACK GAS AND PARTICULATE MONITORING

When all the components in the stack gas are to be simultaneously monitored, a combination system is required. This is because the absorption bands of the different components of interest are in different parts of the radiation spectrum.

Particulate Sampling

Particulate sampling has already been covered in Section 8.3 and therefore it is only briefly mentioned. A complete Environmental Protection Agency (EPA) particulate-sampling system (Reference Method 5) is composed of a pitot probe, a sampling unit, and a control unit with a vacuum pump. Figure 8.3a has shown this EPA particulate-sampling train.

In some of these sampling packages, a microprocessor directs the automatic sampling (Figure 8.46f) method, which can be selected to follow U.S. EPA Method 5 or other international methods specified by VDI, BS, or ISO. The microprocessor stores all measurements, reviews and diagnoses all inputs, controls the required parameters, calculates isokinetic conditions, and reports the results either in a printed form or by transferring it to a floppy disk.

Besides the controller, such a package usually consists of a probe, a filter (hot) box, a cold box, a flexible sample line, glassware, a node box, and a monorail system. The probe is usually 3, 5, 7, or 10 ft (0.9, 1.5, 2.1, or 3 m) and made of stainless steel with a glass liner. Most probes are jacket heated and are provided with both a liner thermocouple and a stack temperature thermocouple.

Stack Gas Monitoring Packages

Opacity is measured in the visible region (Table 8.46d); SO_2 and NO_2 absorption bands fall in the ultraviolet region (Figure 8.46g), whereas the absorption bands of CO, CO_2, and hydrocarbons fall in the infrared region (Figure 8.46h).

Some of these stack monitoring packages have been discussed in Sections 8.3, 8.27, and 8.42, and that coverage is not repeated here. On the other hand, it is important to realize that packages for multicomponent analysis are available (Figures 8.46i and 8.46j), and some of them can also include excess oxygen analysis (Figure 8.42n).

Light Attenuation and Transmissometers

Transmissometers are the most accepted and frequently used means for the automatic and continuous monitoring of particulate in stack gases.[4] In its most basic form, a transmissometer consists of a light source and a detector (Figure 8.46k). By referencing all measurements of the partially obstructed optical path to the clear path measurement, the transmissometer essentially provides a measurement of light attenuation, which can be expressed in units of optical density or opacity.

Optical density, which is sometimes called *extinction*, varies linearly with particulate concentration if a relatively uniform distribution of particle size, composition, and path length exists.[5] Opacity, on the other hand, varies from 0 to

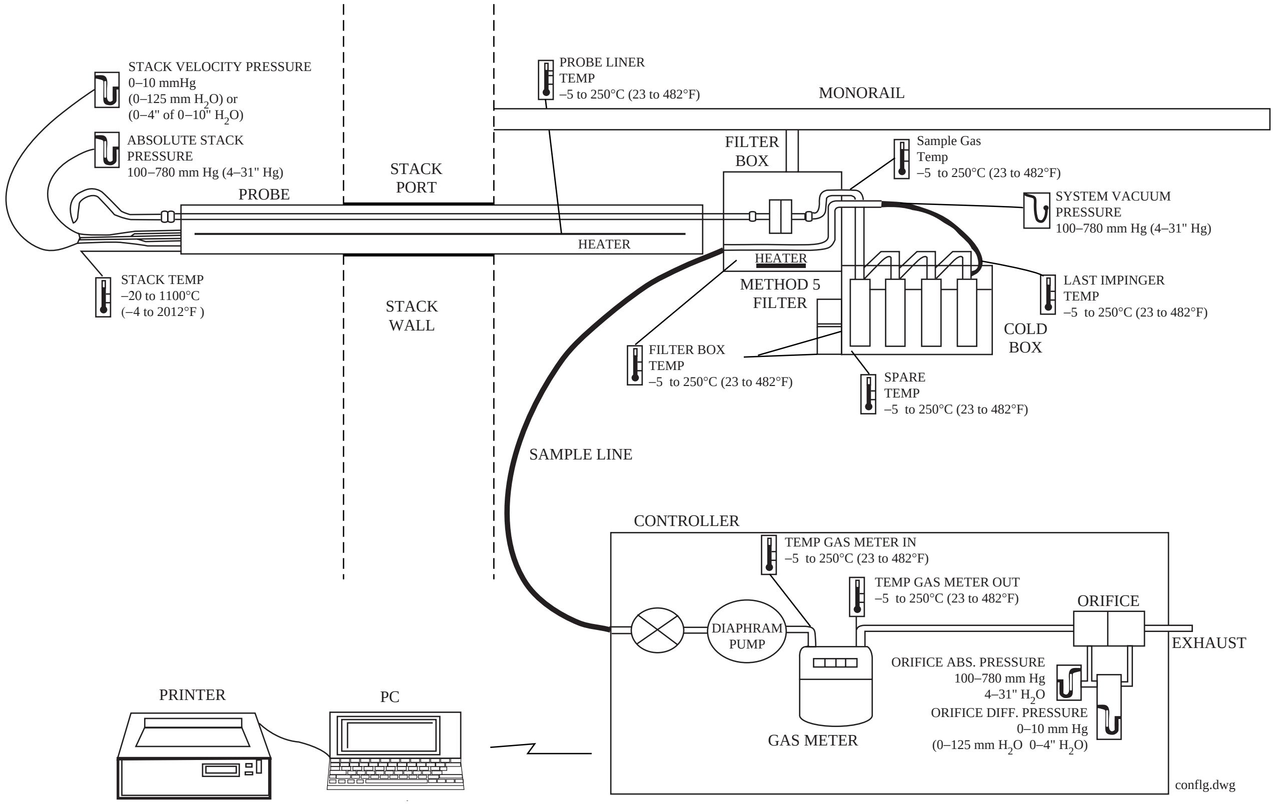

FIG. 8.46f

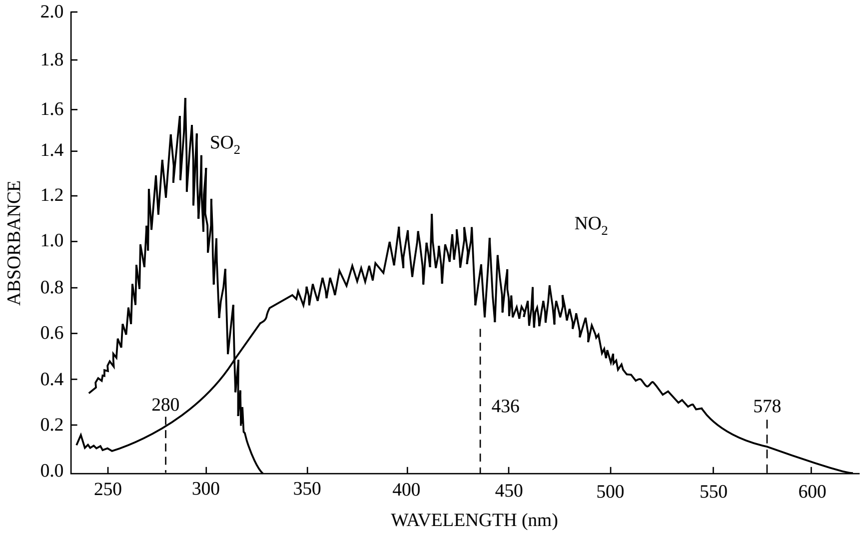

FIG. 8.46g

The absorbance of SO_2 and NO_2 in the ultraviolet range.

100%—from clear to opaque conditions, respectively. Opacity can be related linearly to the Ringelmann numbers used by human observers. It is also the parameter typically regulated by the EPA to ensure proper operation and maintenance of particulate control equipment.

Transmissometers have become rather sophisticated, having been developed to achieve exceptional accuracy and reliability.[6]

Single-Pass Configuration In a single-pass system, the light source is mounted on one side of a duct, and the detector is mounted on the other (Figure 8.46k). Consequently, the light passes through the gas or medium of interest only once. The major difficulty imposed by this configuration is its calibration. This is because the detector cannot be easily calibrated or exposed to a known light source without adding an additional

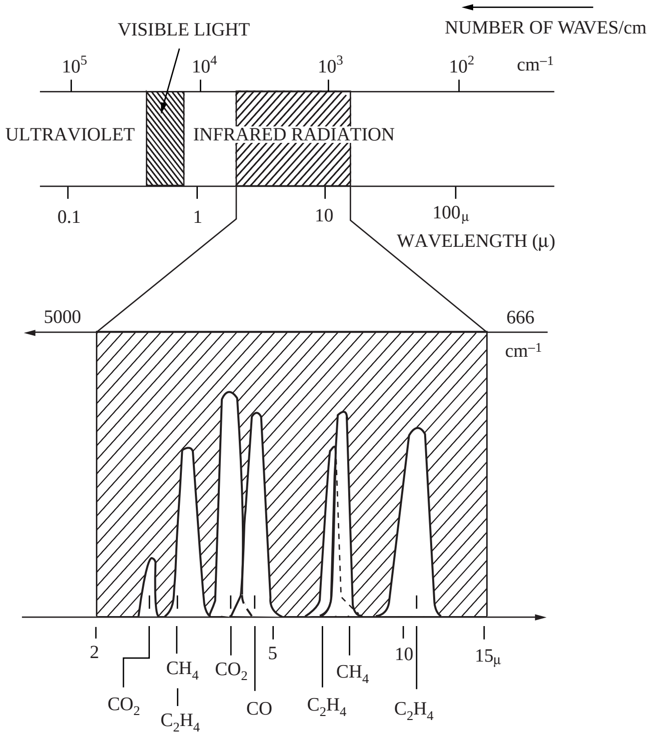

FIG. 8.46h

The absorption bands of CO_2, and CO_2 and hydrocarbons fall into the infrared region.

light source specifically for that purpose, or by using other means that are not required in the normal measurement.

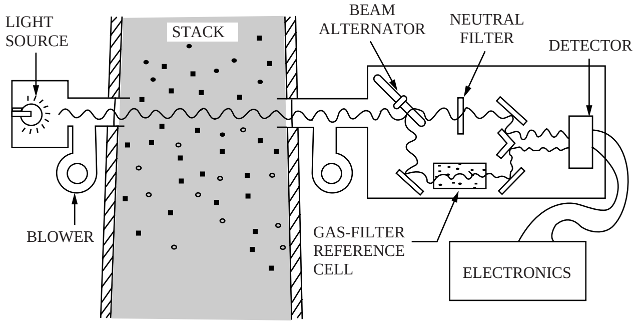

FIG. 8.46i

Dual-beam IR analyzer for multicomponent stack emission monitoring.

Double-Pass Configuration A double-pass system incorporates both a light source and a detector on the transceiver side of the stack, and it provides a retroreflector on the opposite side. With this configuration, the light passes through the gas of interest twice, thereby increasing the sensitivity of the measurement. Furthermore, this configuration allows all the active components to be contained in the transceiver and permits a simple solenoid-mounted reflective surface to be incorporated into the transceiver to provide a simulation or calibration check of the zero-opacity condition. Internal filters can be activated sequentially to provide upscale checks of calibration.

The operation of the double-pass opacity analyzer shown in Figure 8.46k is as follows. The light from the lamp is filtered to generate a *photoptic* light energy profile as described in connection with Figure 8.46b. The chopper wheel A_1 (with holes in it) is located at the focal point of the condenser lenses. The half-mirror beam splitter splits the light beam into measuring and reference light beam segments. By the use of the beam gating wheel (A_2), the measurement single is periodically gated, making the analyzer insensitive to variations in ambient light.

The reference beam is established and used as a continuous indication of the intensity of the unattenuated light source. When the measuring beam is allowed to pass through the stack, it traverses the distance to the retroreflector (R_2), thereby increasing measurement sensitivity as it passes

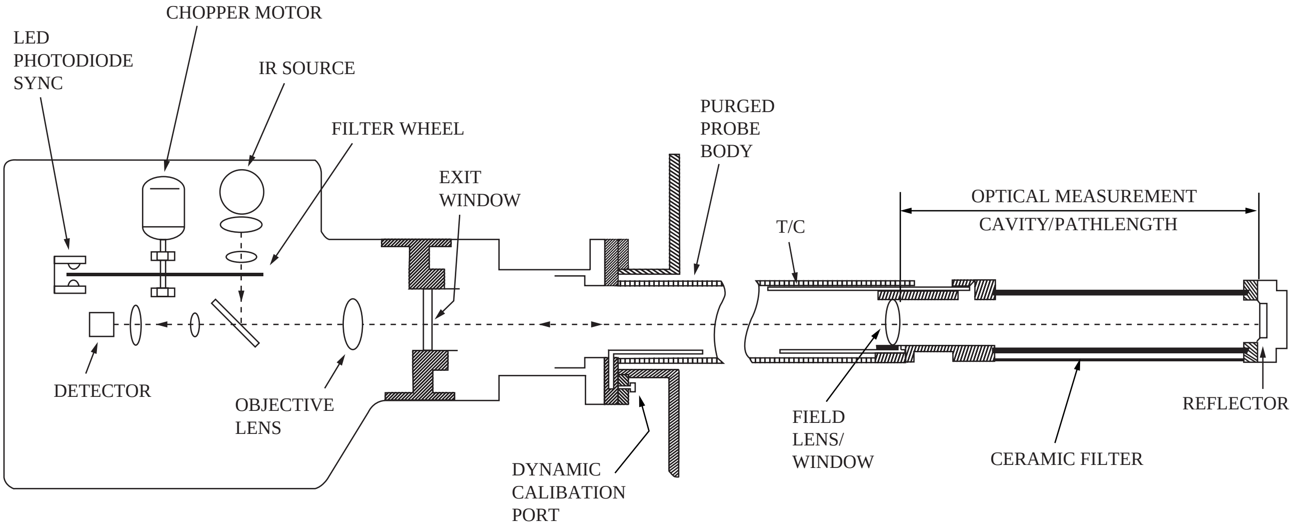

FIG. 8.46j

Stack gas monitor with ceramic diffusion cell.

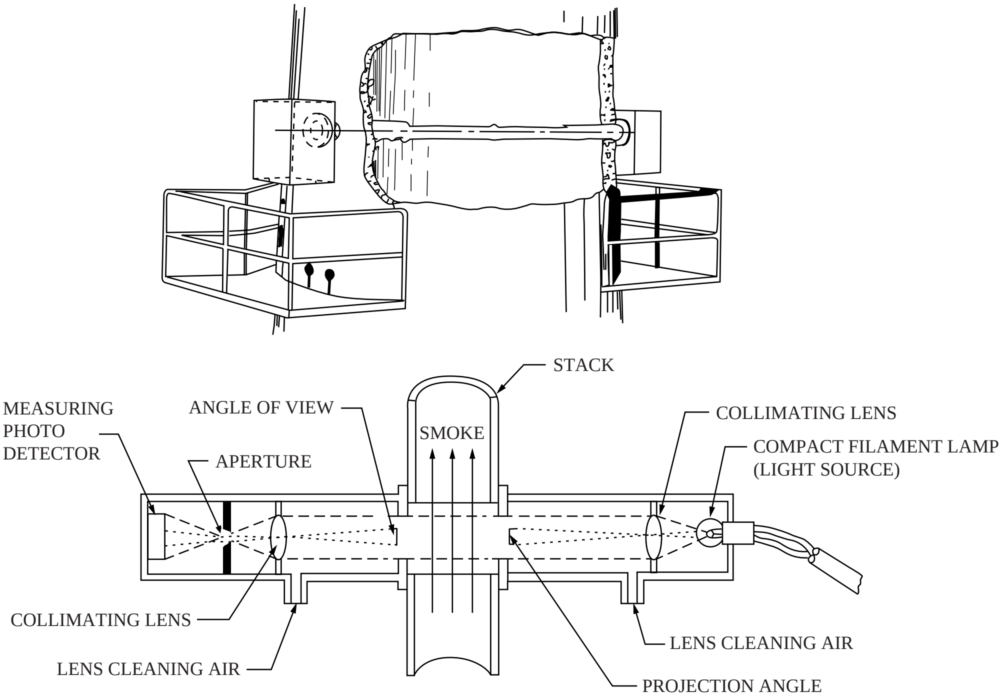

FIG. 8.46k
Single-pass transmissometer can detect smoke opacity. It is insensitive to minor alignment error or vibration but is affected by light again and by dirt building on the optics.[3]

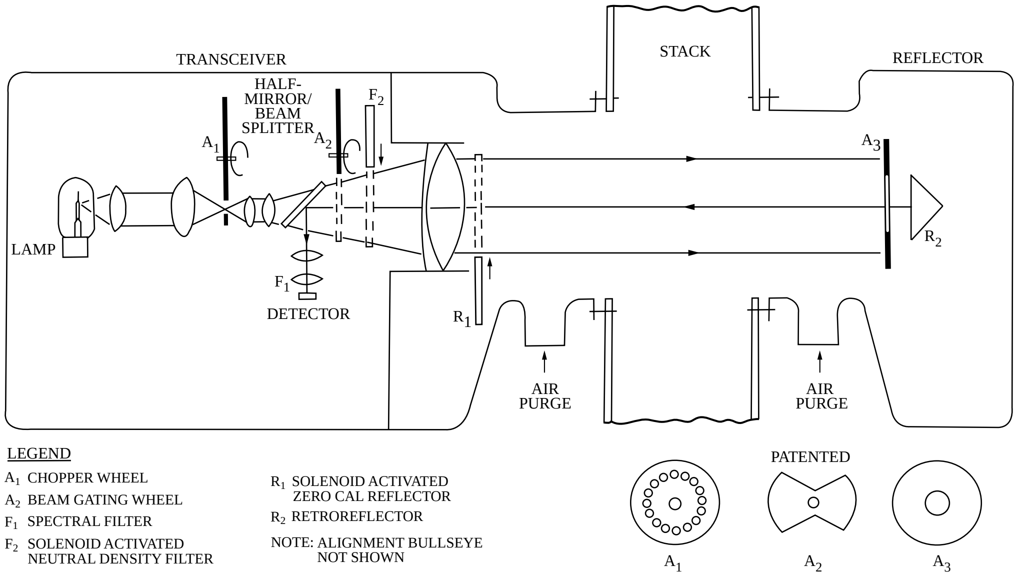

FIG. 8.46l

through the stack twice. The zero calibration reflector (R_1) is used to automatically rezero the instrument and thereby correct for dirt buildup on the windows; the neutral density filter (F_2) allows for span correction. The zero and span checks correct for lamp aging, dirt buildup, and drift. These checks can be performed automatically, under microprocessor control, once every hour.

Relative Performance Single-beam configurations (Figure 8.46k) essentially measure the detected light without compensation for changes in optics or in source or detector characteristics. Obviously, this is the simplest, most inexpensive, but least accurate technique.

Dual- or double-beam configurations (Figures 8.46j and 8.46l) internally split the light emitted from the source into

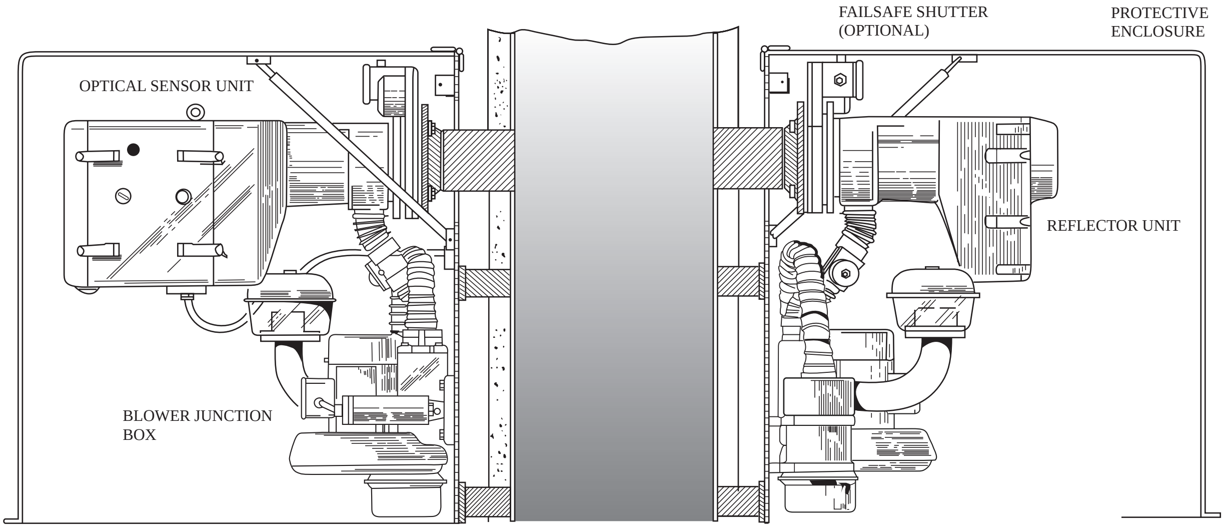

FIG. 8.46m
A 60 SCFM (1.7 m^3/min) fan is provided to provide a curtain of clean and cold air between the instrument and the gases in the stack. (Courtesy of Lear Siegler Corp.)

two beams. The measurement beam is projected through the optical medium of interest and is referenced to the second (reference) beam, which is totally contained within the instrument. If a separate detector is provided for each beam, as is done in so-called dual-beam configurations, compensation is continuously provided for light source variations. Furthermore, as long as the detectors for each beam are matched, only their differential errors appear in the overall measurement.

If the two beams can be modulated or time-sequentially gated into a single detector, automatic compensation is provided for both light source and detector variations, which is typical of the more advanced forms of double-beam measurement systems (Figure 8.46l). Measurement accuracy can be further improved by the regulation of lamp voltage supplies and by automatic control of reference light levels.

Optical Divergence The angles of both viewing and projection should be minimized to reduce the potential interference of scattered light. Most precision units exhibit less than 5° total angular divergence.

Spectral Characteristics The spectral response of the system determines its sensitivity to particulate size. Typically, the systems are matched to the photopic response of the light-adapted human eye so that the transmissometer sees exactly as does the human eye. This characteristic provides a peak response at 550 nm and provides a somewhat uniform response for particles as small as 0.3 μm. Longer wavelengths, such as 3.39 μm, can be used to provide more uniform response with respect to particle size as desired of a mass monitor.[7] Multiwavelength devices have been designed that provide some indication of relative particle size distribution.

Optical Characteristics Typically, the more modern and precise instruments also incorporate a chopped light system, which makes the instrument insensitive to variations in ambient light. Also, by providing a uniformly illuminated beam much larger than the reflector or detector and by using an autocollimated retroreflector technique, the overall system can be made essentially insensitive to variations in alignment such as those caused by temperature and wind. Alignment bullseyes are usually provided to facilitate installation and to allow proper alignment to be maintained.

Air Purge Nearly all stack-mounted systems are provided with a forced-air purge system, which ensures a curtain of clean air between the exposed optical surface and stack gas. These units include both an air filtration system and a blower (Figure 8.46m).

Manual Stack Samplers

Manual stack sampling techniques have been established by both the EPA and the American Society for Testing and Materials (ASTM). The stack sampling equipment required by the EPA technique designated as Reference Method 5 is shown in Figure 8.46n.[8]

This method uses an isokinetic sampling technique whereby the velocity of the sample gas being drawn into the probe is made equal to the velocity of the flue gas at the sampling point. Correspondingly, the sample probe assembly incorporates a sampling nozzle, an S-type pitot tube, and (usually) a thermocouple for sensing gas temperature. In practice, the operator draws samples from a variety of points within the stack cross-sectional area to minimize the effects of particulate and velocity stratification within the gas volume of interest. The probe is inserted or withdrawn manually from various access ports on the stack to achieve the desired sampling strategy.

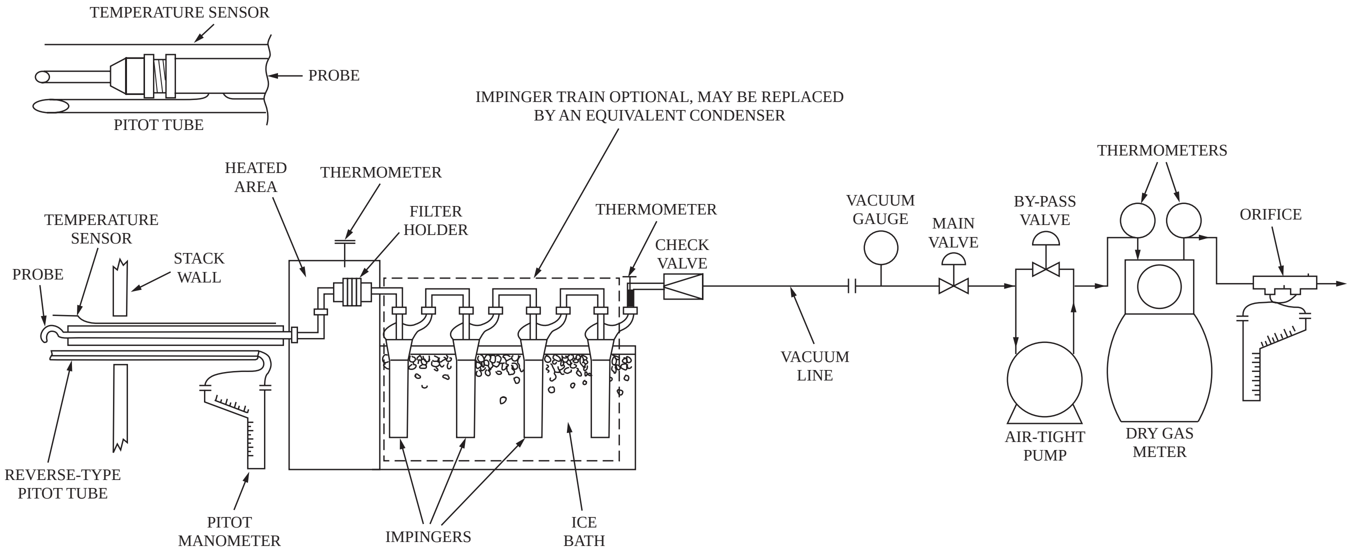

FIG. 8.46n
Manual stack sampler.

The probe is attached to an adjacent hot box where the particulate is separated from the gas on a filter paper and/or cyclone separator. After removal of particulate, the gas proceeds to a cold box where the gas is cooled to 32°F (0°C) by a series of ice bath-cooled impingers. The gas then flows through a heated umbilical to the control unit where the gas flow is controlled and timed. The stack gas velocity and temperature are also read out from this unit.

Automatic Stack Samplers As discussed earlier, a variety of options have been developed to make the system both easier to use and expandable to other gas measurements. Automatic microprocessor-controlled systems (Figure 8.46f) have been introduced that greatly reduce the required operator time and attention.

EPA Method 5 is one of the most widely used techniques available today and has been used to establish the data base for particulate-emitting stationary sources.

Broken Bag and Runway Visibility Sensors

Simplified transmissometer configurations are often used for detecting bag breaks in bag-house particulate control applications.[9] Transmissometers have also been widely used for highway visibility, runway visual range, highway tunnel, and roof vent monitoring. Exceptional accuracy and drift characteristics are required in such applications.

Typically, stack-mounted transmissometers are capable of up to 75-ft (22.5-m) separation, whereas visibility-monitoring units may have larger optics that provide path lengths of several hundred meters. For a more detailed discussion of open path spectrometry, refer to Section 8.40.

AMBIENT AIR OPACITY MONITORING

Particulate matter is the world’s most ubiquitous air pollutant. Its natural sources include fires, volcanic action, vegetation, and the wind. Man-made sources include combustion, heating and abrasion processes, and material-handling activities, and these constitute another major source of the particulate burden on the atmosphere.

Airborne material can be measured as particulate matter in a wide range of sizes and characteristics, but larger sizes are limited as a result of the associated higher settling velocities. Small, inhalable particulate matter less than 15 μm in mass is the most damaging to human health. Consequently, techniques have also been developed to characterize and measure the size distribution of particulate matter (Section 8.47).

Particulate Concentration

Particulate material in ambient air is typically measured in terms of concentration, or weight per unit volume, although its presence may also be observed and measured in terms of visibility or light attenuation. The monitoring of air pollution has already been discussed in Sections 8.5 and 8.40.

Visibility as a measured variable is a much more complex parameter than particulate concentration, as it involves the characteristics of the human eye. In addition to light attenuation, visibility is a function of contrast and background luminance, which are required to establish visual range measurements of runways for airport applications.

Particulate matter generated by combustion can also be measured in terms of concentration, but it is often specified according to optical density or opacity, which are light-

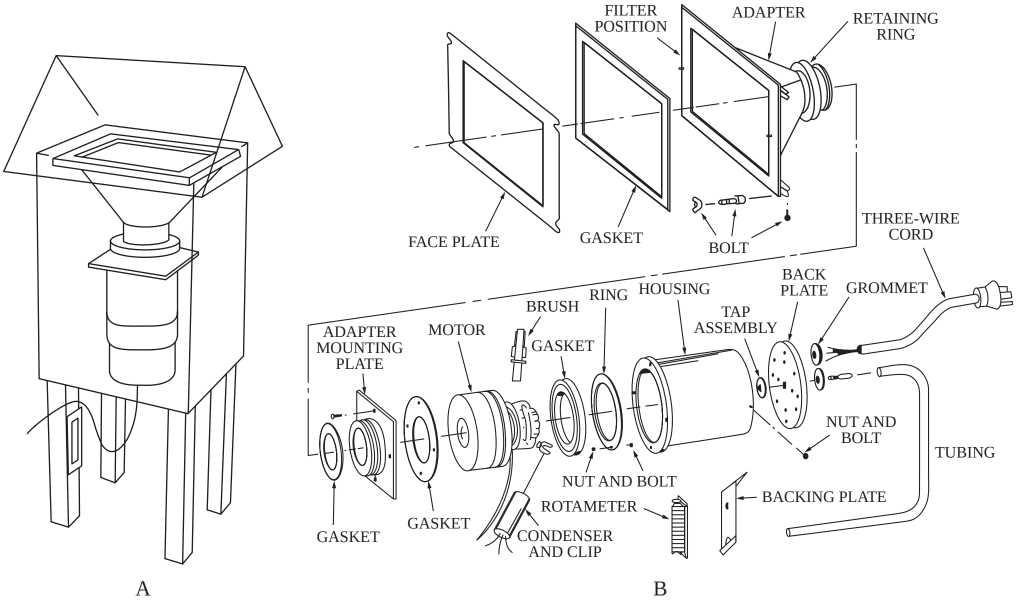

FIG. 8.46o

High-volume sampler. (A) Assembled sampler and shelter, (B) exploded view of typical high-volume air sampler.

attenuation measurements. Opacity of smoke plumes is often related to the visual effects seen by a human observer.

Particulate concentrations range from that corresponding to a visibility of 50 mi (80 km) to the nearly opaque smoke plume arising from a coal-fired boiler without particulate emission controls. To measure such a range of concentrations, a wide variety of techniques have been developed for such monitoring.

In situ techniques generally mean those that can be used to measure particulate concentration in place. *Extractive* techniques include those that remove a sample from the medium to be measured and transport that sample to the measuring instruments.

High-Volume Sampler

The basic instrument for determining the airborne concentration of particulate matter in the United States is the high-volume sampler (Figure 8.46o). The high-volume sampler provides data on the actual mass concentration of particulate matter in the air. A high-speed, multistage blower is used as the suction source. An adapter section allows the use of a flat 8 × 10 in. (203 × 254 mm) glass fiber filter. This filter has an efficiency of well over 99% for 0.3-μm particles.

An orifice plate is included on the back of the blower, which allows the monitoring of the airflow rate through the sampler. Twenty-four hours is a common sampling time period. During this period, the buildup of particles increases the filter resistance and decreases the airflow rate. When the decrease is small (e.g., less than 10%), the initial and final readings are averaged to determine the sampling rate.

If the decrease is significant, as might be expected in locations where the particulate concentration is high, it is desirable to use a recorder and determine the flow rate from that record. Alternatively, more precise measurements can be obtained by using instruments that include a self-regulating flow controller, which maintains a constant flow rate independent of filter loading.

The roof of the standardized sampling shelter has an annular opening sized so that particles larger than a nominal size of 100 μm are not drawn into the sampler. Because of the varying airflow rate and the effect of winds, this method provides only an approximation of a particle size. On the other hand, it can furnish a large body of ambient air quality data, and air quality standards have been promulgated based on the use of this standardized instrument.

EPA Air Quality Goals As shown in Table 8.46p, and as discussed in more detail in Section 8.5, the U.S. Environmental Protection Agency (EPA) has selected some ultimate air quality goals (secondary standards). These include that the maximum 24-hour concentration of particulates must not exceed 150 $\mu g/m^3$ more than once per year and that the annual geometric mean, as measured by the high-volume sampler, must not exceed 60 $\mu g/m^3$.[10]

Dichotomous Sampler

Subsequent to the EPA's promulgation of the total suspended particulate standards, efforts have been made to establish the health effects of particulates in relation to their size. As a result of these studies, further data have been collected on the harmful effects of inhalable particulates less than 15 μm in size. In concert with this regulatory activity, the dichotomous sampler has been developed to meet the need for size-specific particulate collection.

TABLE 8.46p
Secondary Air Quality Standards
(Levels of air quality that are deemed adequate to protect the public welfare from any known or anticipated adverse effects)

Pollutant	*Long-Term Concentration Level ($\mu g/m^3$)*	*Short-Term Concentration Level* ($\mu g/m^3$)*
Particulate	60—annual geometric mean	150—maximum 24-hr concentration
Sulfur dioxide	60 (0.02 ppm)—annual arithmetic mean	260 (0.1 ppm)—maximum 24-hr concentration
Carbon monoxide	—	10,000 (9 ppm)—maximum 8-hr concentration or 40,000 (35 ppm)—maximum 1-hr concentration
Photochemical oxidants	—	160 (0.08 ppm)—maximum 1-hr concentration
Hydrocarbons	—	160 (0.24 ppm)—maximum 3-hr concentration (6–9 AM)
Nitrogen dioxide	100 (0.05 ppm)—maximum arithmetic mean	

*Stated concentration not to be exceeded more than once per year.

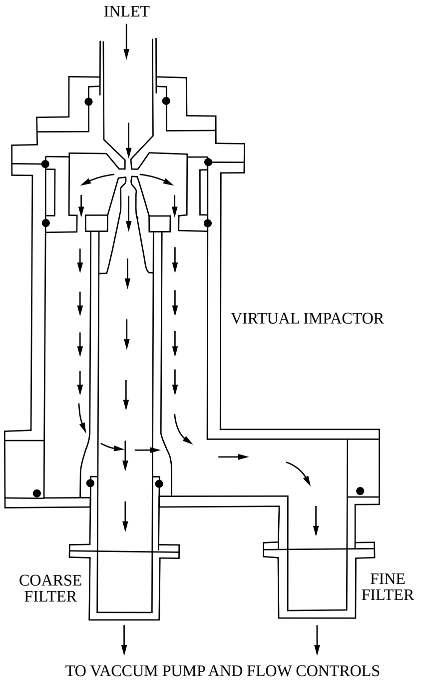

FIG. 8.46q
Virtual impactor.

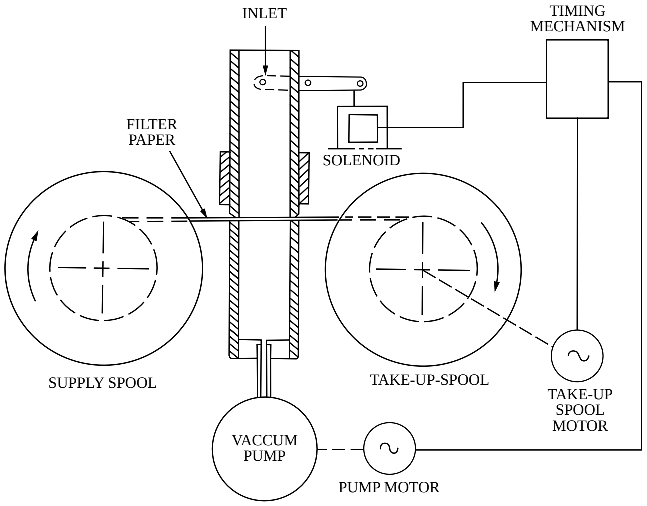

FIG. 8.46r
Tape sampler.

The dichotomous sampler is generally designed to remove the particulates that are greater than 15 μm at the very the inlet sampling and transport mechanism. The remaining sample stream is then segregated into two size-specific regions, hence the name *dichotomous*.

A virtual impactor (shown in Figure 8.46q) is often used to draw off particulates that are smaller than 2.5 μm. As shown in Figure 8.46q, two sample streams are created. When these streams are collected on filters, one yields the particulate in the 15 to 2.5 μm size range and the other in the $\leq$2.5 μm size range.

Filters are typically 1.46 in. (37 mm) in diameter and may be of either glass fiber or membrane construction. Flow rates are accurately controlled to ensure the stability of the size cut points. Both automatic and manual models are available. Automatic units also provide for the automatic changing of the filters after a preselected sampling time interval has passed. Filters are also often analyzed using x-ray fluorescence to determine the elemental composition of the particulate.[11]

Tape Sampler

The tape sampler (Figure 8.46r) provides an indication of the soiling properties of the sampled air. It operates by drawing air through a paper tape at a rate of about 0.75 actual cubic feet per minute (ACFM) for periods of one, two, or more hours. Both filter paper and membrane tapes have been used.

The soiling index (optical properties) of the filtered particulate is measured either by reflectance or transmittance. These optical measurements cannot be directly correlated with the mass concentration of particulate matter in the atmosphere except where particle size, shape, and color are constant and a series of comparative tests have been made using the high-volume sampler.

Soiling Index Soiling index results are expressed in coefficients of haze per 1000 linear feet (COH/1000 LF) for transmittance measurements and in reflectance units of dirt shade (RUDS) for reflectance measurements. Coefficient of haze (COH) units are defined as 100 times the optical density determined by transmittance.

The reflectance unit of dirt shade is defined as 100 times the optical density determined by reflectance. RUDS are expressed either in terms of 10,000 LF of air (American Society for Testing and Materials unit) or 1000 LF of air.

Some older tape samplers use an air pump, which is quite sensitive to system resistance. It is advisable to measure the airflow rate through both a clean spot and a dirty spot to determine whether an air volume correction to an average rate is advisable. The diameter of the spot is not a variable, because the results are expressed in terms of the length of the air column that is drawn through the spot.

Light Scattering

When light strikes a particle, it scatters as a function of the particle's size, shape, and color. Light scatter can be measured as forward scatter, angular scatter, or backscatter.

Suspensions of particulate matter in the air scatter the light in all directions. Sophisticated devices are available for determining the concentration of particles in air and the size of these particles. Laser-based scattering devices measure particulate concentration and/or particulate size distribution. Such devices appear to be particularly useful in evaluating the behavior of particulate control equipment. For an in-depth discussion of open path laser spectrometry, refer to Section 8.40.

Nephelometers The nephelometer has had some use in air pollution studies. This device measures the angular scatter of light over a wide range in a flowing air sample. The instrument measures the scattering coefficient, which is in inverse proportion to the visual range. Thus, the nephelometer can be used to obtain a point measurement of visual range. The span of measured range with the nephelometer is from approximately 1 to 100 mi (1.6 to 160 km).

In industrial applications, instruments based on the Tyndall effect have been built. These instruments (nephelometers) utilize the phenomenon that particles that are invisible when viewed directly in the path of a strong light become visible when viewed from the side. The reflected Tyndall light intensity is proportional to the number of particles in the path of the light. This analyzer consists of a cylindrical sample cell with two Tyndall windows at each end, with their common axis perpendicular to the path of the entering light.

Piezoelectric Crystal Mass Balance

Some crystals, when excited by an alternating current, exhibit a resonant frequency that is proportional to the crystal mass. Quartz is commonly used and is readily available for this purpose. This principle is used to continuously monitor the mass concentration of particulate matter in air by trapping particulate from the impinging air stream on the sensing crystal while keeping the reference crystal clean.

Thereby, the resonant frequency of the sensing crystal changes, and a beat frequency develops. The particle mass is determined based on the mass vs. the frequency response characteristics of the crystal. Commercially available quartz crystals show a frequency shift of 2000 Hz/μg of material deposited.

A major limitation is the deposition and retention of particles on the sensing crystal. Two techniques, impaction and electrostatic precipitation, have been used commercially. Both approaches have weaknesses in collecting and retaining particles over the wide size range encountered in atmospheric aerosols.

Impaction Devices

Determination of the particle size distribution in aerosols is frequently desired. Although light-scattering devices can provide an indication of particle size distribution, most atmospheric measurements are made using impaction devices. In principle, more inertial energy is required to impact small particles than large ones when they are impinged on a plane surface. This characteristic has been utilized through a series of impaction stages, with succeeding stages operated at higher velocities (Figure 8.46s).

The upper practical size limit for impaction devices is about 10 μm. They are particularly useful in the size range of 0.5 to 7 μm, which corresponds to the approximate size range of most particulate matter in the ambient air.

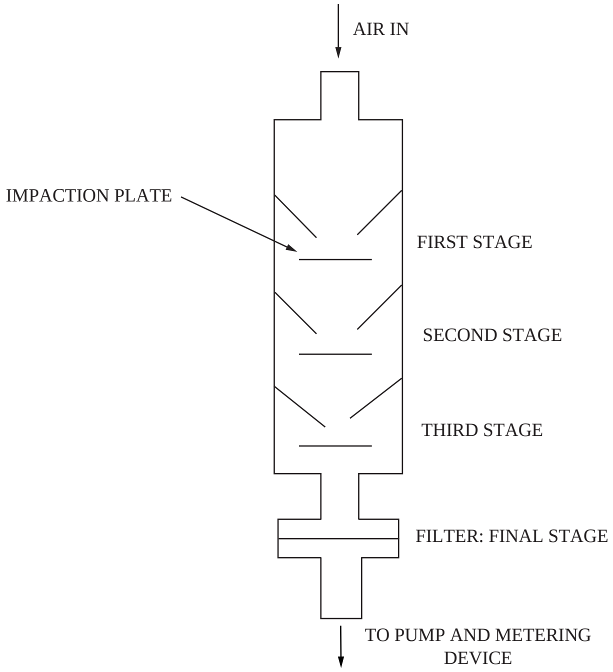

FIG. 8.46s
Impaction device schematic.

A cascade impactor can be added to a manual stack sampling probe to evaluate stack emissions, and a fractionating sampler can be added to a high-volume sampler for ambient air analysis. In most cases, the impaction plate is removed from the sampling device and is weighed to determine the amount of sample. High plate tare weight is a potential source of inaccuracy.

Calibration Calibration of impaction devices is difficult. The normal practice involves the generation of a mono-disperse aerosol of known particle size. Polystyrene spheres, such as manufactured for latex paint, have been used. Assuming that the dispersion technique generates a monodisperse aerosol (often the most difficult part of the procedure), the calibration is performed using a series of sizes. The calibration is in terms of aerodynamic size; that is, the inertial properties, which are a combination of particle size and specific gravity. The results from impaction sampling must state the specific gravity, whether measured or assumed, with the stated size distribution.

Radiometric Devices

Radiometric measurements of particulate are primarily accomplished using a radiation attention technique or by measuring the ionization effect of a radioactive source on ambient air. Typically, low-energy beta-type radioactive sources are used to minimize the human exposure considerations and associated regulatory problems.

In the typical beta gauge shown in Figure 8.46t, the air to be measured is drawn through a tape filter medium, where the particulate is collected. The radiometric transmission or attenuation of the filter medium is measured in the clean state (before collection) and in the dirty state (after collection). By appropriate processing of these two measurements, a measure is obtained that corresponds to the mass of collected particulate. The gas volume is usually accurately controlled so that the sample volume is precisely defined.

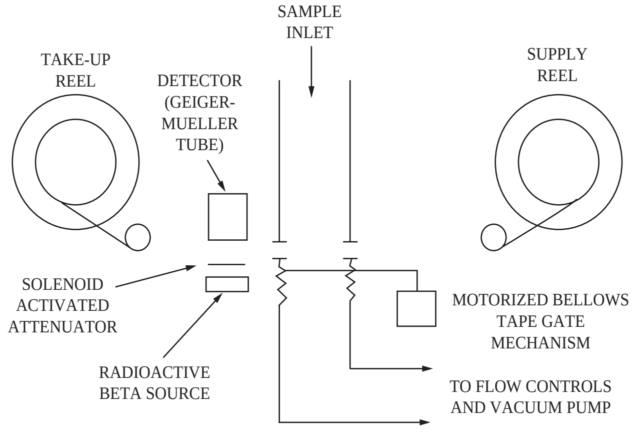

FIG. 8.46t
Beta-gauge particulate monitor.

The system is relatively insensitive to the normal chemical variation of particulate matter; however, it is especially responsive to hydrogen compounds. This technique has been widely applied to stack gas and ambient air measurements. The mechanical complexity and high costs, both the installed initial cost and maintenance costs, have limited the acceptance of these systems.

The ionizing technique has been applied to a variety of low-cost fire/smoke detectors. In this application, ambient air is exposed to a radiation source that partially ionizes the air molecules and allows a current flow through a pair of electrodes. As particulate concentrations increase, the radiation is absorbed as the particulate matter decreases the ionization and, hence, the current through the electrodes.

Charge Transfer (Triboelectricity)

Both of these techniques utilize an *in situ* probe exposed, typically, to the stack or flue gas stream of interest. Using the charge transfer technique, a measurement is produced by detecting the charge transferred to an electrode surface on impaction with particulate matter.

The charge transfer mechanism requires that only dissimilar materials be involved. The same holds for the triboelectric charging phenomena. With appropriate electronic amplification and scaling, the output can be related to particulate concentration. This technique has not gained wide acceptance, presumably because of the difficulty in correlating charge transfer with particulate concentrations and in keeping the probe mechanism operable under the severe and diverse operating conditions experienced in stack applications.

Surface Ionization

In the surface ionization technique, airborne particulate decomposes when it impacts a hot wire, and there is a resultant release of ions that are then collected on an electrode. By detecting both the average ion current and analyzing the pulse height and rate, this instrument is able to provide an indication of total mass concentration and the relative distribution of particle sizes, respectively.

This technique has a high sensitivity to low particulate concentrations. Both techniques are essentially point measurements that provide no averaging effect including the overall stack or duct cross-sectional area.[13]

Visual Observation

Human observation of smoke and dust was, of course, the initial stimulus to develop better techniques for control and monitoring. Human observation still remains one of the primary enforcement tools used by the Environmental Protection Agency (40 CFR 60 Appendix A, Reference Method 9) to ensure the proper operation and maintenance of particulate control equipment.

The EPA does provide training in smoke reading, and only certified observers are used for such enforcement activity.

Studies have been undertaken to quantify the errors of such measurement techniques, and human frailties certainly are involved in addition to the angle of the sun, the sky cover, contrast, type of particulate, and condensables such as steam.

Remote Sensing

Several techniques that enable an observer to monitor smoke plume characteristics from a remote location were discussed in Section 8.40. Telephotometers have been used manually to establish smoke plume opacity based on the luminance of the smoke plume as measured with different background characteristics.

Light direction and ranging (LIDAR) has been developed as a research tool using a laser to quantify smoke plume characteristics. LIDAR is relatively expensive and complex but has proven useful in the research environment. It is normally contained in a mobile laboratory that can be driven to remote locations so as to provide good observations of a particular smoke plume. Aircraft have also been equipped with proper instrumentation to permit observation and measurement of smoke plume characteristics while they are flown through the plume.

CONCLUSIONS

Particulate-monitoring methods have been developed that achieve high standards of accuracy and reliability. Under the impetus of the EPA, such methods have become widely used in the United States. Future developments are anticipated in the particle sizing area as regulatory agencies become less concerned with the visual effects of smoke and more concerned with its health effects. Visual effects, highway and airport visibility in particular, will continue to be of substantial interest as will the conditions of scenic vistas and parks.

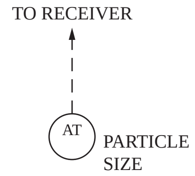
8.47 Particle Size and Distribution Monitors



Flow Sheet Symbol

R. A. HERRICK (1974) **A. WERTHEIMER** (1982)
B. G. LIPTÁK (1995, 2003)

Measurement Technique:

A. Optical imaging
B. Electron imaging
C. Image analysis (with A or B)
D. Optical diffraction and laser scattering
E. Electrical resistance change
F. Sieving
G. Sedimentation (photo or x-ray)
H. Ultrasonic attenuation
I. Bulk property—absorption, permeability
J. Aerodynamic time of flight

Ranges:

A. Over 1.0 μm
B. 0.006 to 0.01 μm resolution
D. Laser scattering analyzer range covers from 0.02 to 2000 μm for air-suspended particles. For water-suspended particles, the minimum size is around 1 μm.
E. Over 0.5 μm
F. Usually >75 μm but, with careful design, down to a few microns
G. 1 to 100 μm
H. 25 to 600 μm

For continuous airborne particle counters: 0 to 10 million or 0 to 1 billion particles/cubic foot; ranges are selectable to count particles that are larger than 0.3, 0.5, 1, 3, 5, or 10 μm. Sensitivity can be as high as 1 mg/m^3, and particles down to microns are detected.

For on-stream particle-size monitors (dry powders or slurries), particle-size distribution data can be measured between 2 to 300 μm.

Inaccuracy:

5% (particle size distribution)

Costs:

A, E, G. \$6000 to \$18,000
B. \$25,000 to \$100,000
C. \$40,000 to \$80,000
D. \$15,000 to \$40,000
F, I. \$1000 to \$8000
H. \$6000 for regular sludge densitometer, up to \$50,000 for size distribution detection with referee method

INTRODUCTION

As is the case with many other sections in this handbook, the coverage of this section also overlaps with some of the others. Particle-size-based particulate separation has been discussed in Section 8.46, whereas optical and laser-type suspended solids detection is also discussed in Section 8.60.

This section starts with a discussion of the subject of particle size distribution. After that, the designs of the various laboratory-type particle monitors are described. These units are classified according to sample size into small (a few 0.01 g in the sample), intermediate (a few grams), and large (a few 100 g) units. The last topic in this section is a discussion of continuous, on-line particle-size analyzers.

PARTICLE SIZE AND DISTRIBUTION

When the purpose of measurement is to monitor clean rooms, semiconductor production facilities, and other atmospheres that are kept clean by HEPA filters, the analyzers must be able to detect particles down to 0.3 μm in size and must be sensitive down to the concentration of 1 mg/m^3.

When the purpose of the measurement is product quality control in dry-powder or slurry processes (e.g., pigments, catalysts, clays, cements, and plastic powders), the analyzers provide data on both particle size distribution and cumulative (percent smaller than) data in the range of 3 to 200 μm (Figure 8.47a).

Application Objectives

Accurate determination of particle size and distribution is critical in many industrial processes, such as grinding, agglomeration, crystallization, and emulsification. Objectives may include improving final product quality, as in ceramics, paints, and pigments; improving final product performance, as in abrasives and catalysts; improving process efficiency, as in crystallization and wastewater treatment; or minimizing energy consumption, as in grinding of ore for subsequent processing. In many processes, more than one of these objectives may be involved.

This section discusses the range of particle size measurement from approximately 0.01 to about 1000 μm. The goal of these measurements is determining the quality of material in a process rather than the detection of contaminants in an otherwise particle-free stream. The performance characteristics noted in this section are attainable from standard commercial instruments.

Detectors and Sampling Systems

Particle size detectors differ in measurement principles and in size range, resolution, and concentration capabilities. Choosing the right measurement principle for the parameter of interest is important, but, irrespective of the method used, the reported particle size can also be affected by other factors such as shape or physical properties. Therefore, it is important to understand the critical particle characteristics for a particular process before the method of measurement is selected.

Accurate size measurement also depends on obtaining a representative sample of the bulk material. Bias toward smaller or larger sizes can occur if sampling is done at the wrong place or time in the process, or if a sample is extracted from a settled heap. The size measurement will be of value only if the sample represents the process.

The amount of material required for the analysis depends on the measurement technique. In some processes, it can be difficult to obtain a representative sample when only a small fraction of the collected material is inspected. One of the criteria by which particle size measuring techniques are classified is the amount of material inspected.

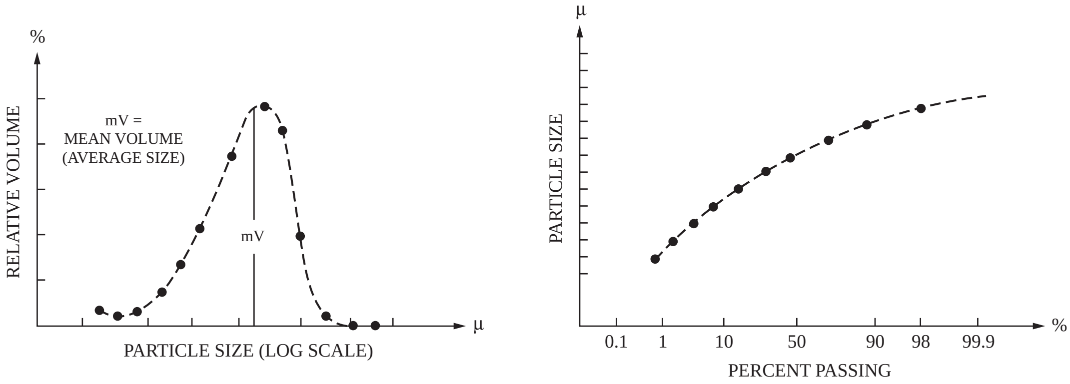

FIG. 8.47a
Typical displays of particle size distribution.

LABORATORY MONITORS

From the perspective of sample size, the measurement technique can use small (a few hundredths of a gram), intermediate (a few grams), or large (hundreds of grams) amounts of sample material. These three categories will be separately discussed in the following paragraphs.

Sensing Small Samples

Optical Microscopy Optical microscopy is often used as a standard method for particle size analysis to calibrate other particle-sizing instruments. Size determination is based on the operator's criteria and judgment of parameters such as the longest dimension, the diameter of a sphere of equivalent cross section, and so on. When there is a large range of particle sizes, many particles must be counted to convert a number distribution to a weight distribution.

Size resolution is limited by the wavelength of light, which restricts the practical use to particles that are larger than about 1 μm. The depth of the field, or the region in which an object is in sharp focus, decreases as the magnification is increased. Size errors can arise from out-of-focus imagery, especially with spherical particles.

Electron Microscopy In this case, a fine electron beam is scanned across a sample, producing secondary electrons and other emissions from the material. The emissions are detected and displayed on a cathode ray tube to form an image, such as in a TV picture.

Operator interaction and judgment are required to determine the size. The size resolution is limited by the energy of the electron beam, and 0.006 to 0.01 μm resolution is typical for modestly priced equipment. Depth of field of the image is about 300 times greater than in the case of optical microscopy. However, a common source of error is in the evaluation of too few fields of particles.

Image Analyzers Automating the analysis of the image of a particle field reduces much of the tedium of counting large numbers of particles. Sophisticated electronic routines, augmented by an editing pointer, provide for rapid and error-free analysis of complex shapes. The input to an image analyzer is a high-resolution TV camera. Therefore, this technique must be combined with another device, such as an optical or electron microscope.

Electrical Sensing (Coulter Principle) When this method is used, the sample is suspended in an electrolyte, and the particles are drawn through a small orifice that is immersed between two electrodes. Each particle, as it passes through this orifice, displaces its own volume of the electrolyte and produces a momentary resistance change in proportion to the volume displaced.

The pulses are then amplified, scaled, and separated into counting bins. Some level of training and skill is required to obtain good reproducibility, but, with such skill, high resolution can be achieved for narrow distributions. The size range is determined by the orifice diameter. For very broad distributions, blockage of the orifice can be troublesome, and different orifice sizes must be used to cover the full range. The practical lower particle size limit is around 0.5 μm.

Optical Scattering (Single Particle) When a light beam interacts with a particle, light is scattered or diffracted. The angular distribution and amount of scattered light depend on the particle size. The passage of individual particles generates scattered-light pulses, which are detected as they pass a probe beam. These pulses are assigned to counting bins according to their sizes.

The dynamic range of the electronics used will limit the size range, and the measurement accuracy is influenced by the composition of the particles, which are less than a few micrometers in size. The lowest size commonly measured is about 1 μm for a water-suspended material and a few tenths of 1 μm for an air-suspended material. Low signals for small particles and coincidence at high sample concentrations are the principal limitations.

Sensing Intermediate Samples

Light Scattering (Multiple Particle) When many particles are viewed by a light beam at the same time, a composite scattering pattern is generated. Several algorithms have been developed to extract the size distribution information from this scattering pattern.

By using low-angle scattering and optical analog filtering, the Microtrac approach generates a signal in proportion to the volume of material present in the light beam. The volume size histogram is calculated through a microprocessor program. By adding signals collected at high angles, which are used for measuring particle sizes under 1 μm, the range obtained by this technique can cover from 0.1 to 1000 μm.

Resolution is lower than for single-particle analysis. Inaccuracy is a function of composition effects for particles below a few micrometers, but no special training or skill is needed to make the measurement. Material can be suspended in either air or liquid. Other instruments also exist that utilize intermediate-size samples and operate on principles of forward scattering, but they are limited to particles larger than 1 μm.

Sedimentation (Photo and X-Ray) Photo sedimentation combines gravitational settling with optical attenuation. The sorting of the particles is based on their hydrodynamic properties, and sizing is based on the cumulative particulate cross section as a function of settling time. Care must be taken to avoid too rapid settling, convection currents, and improper or incomplete correction for optical scattering variations as a function of size and composition.

Photo sedimentation is limited to the size range of 1 to 100 μm. By replacing the optical beam with a well collimated x-ray beam, this range can be extended to cover particles of a few tenths of 1 μm in size. Centrifugal sedimentation is also useful in this submicrometer size range.

Sensing Large Samples

Sieving This method is best suited to particle sizes that are predominantly coarser than 75 μm. In the sieving operation, the sample is shaken through a series of containers whose bases have regularly spaced, uniform-sized openings. The primary measure is the mass of material retained in each sieve, and the distribution is most often plotted as cumulative fraction vs. the nominal sieve aperture.

Several sieve series exist, including Tyler and the American Society for Testing and Materials (ASTM) in the United States, and British and German standards in Europe. Fixed ratios of sizes of square root or fourth root of 2 are common.

For particles smaller than about 75 μm, sieving becomes difficult. Problems include the increased cost of producing sieves with uniform apertures and the greater sophistication required of the mechanics of the sieving process. Wet, sonic, and air-jet sieving have all been used for this range, and, with care, particles down to a few micrometers can be handled.

Optical Methods Laboratories can also use transmissometry (light absorption across a sample), turbidity detection (light scattered at 90° to the light beam), and backscattering techniques, but because all three of these methods are also sensitive to particle size and composition changes, they are best suited for on-line monitoring of process streams.

Ultrasonic Attenuation When ultrasonic energy is transmitted through a slurry (Figure 6.7b), the amount of energy absorbed is dependent on the particle size, concentration, and ultrasonic frequency. In one approach, two pairs of sensors, each consisting of a transducer and a receiver, operate at two different frequencies.

For a given material, a correlation can be established between the size distribution as measured by a referee method and the attenuation of the higher-frequency beam. Corrections resulting from loading changes are based on the lower-frequency signal. This technique is restricted to particles between 25 to 600 μm, but high concentrations can be accommodated, which makes this approach attractive for on-line control. Entrained air bubbles can cause errors, so they must be avoided or eliminated.

ON-LINE MEASUREMENT

Particle size analysis for industrial process control is especially valuable if the measurement can be rapid and continuous. The fully automated system can be complex, even if the size measurement technique is simple.

Optical Multiple-Particle Analyzer

As an example of a complete system, Figure 8.47b illustrates the a package that includes components designed to extract

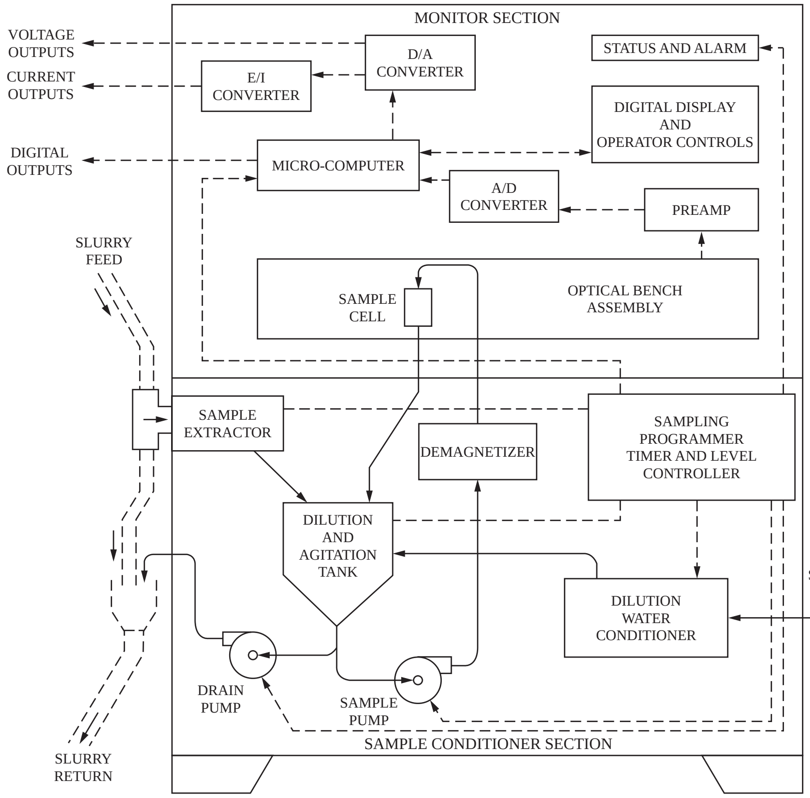

FIG. 8.47b
Block diagram of complete system for outline process control using an optical particle analyzer.

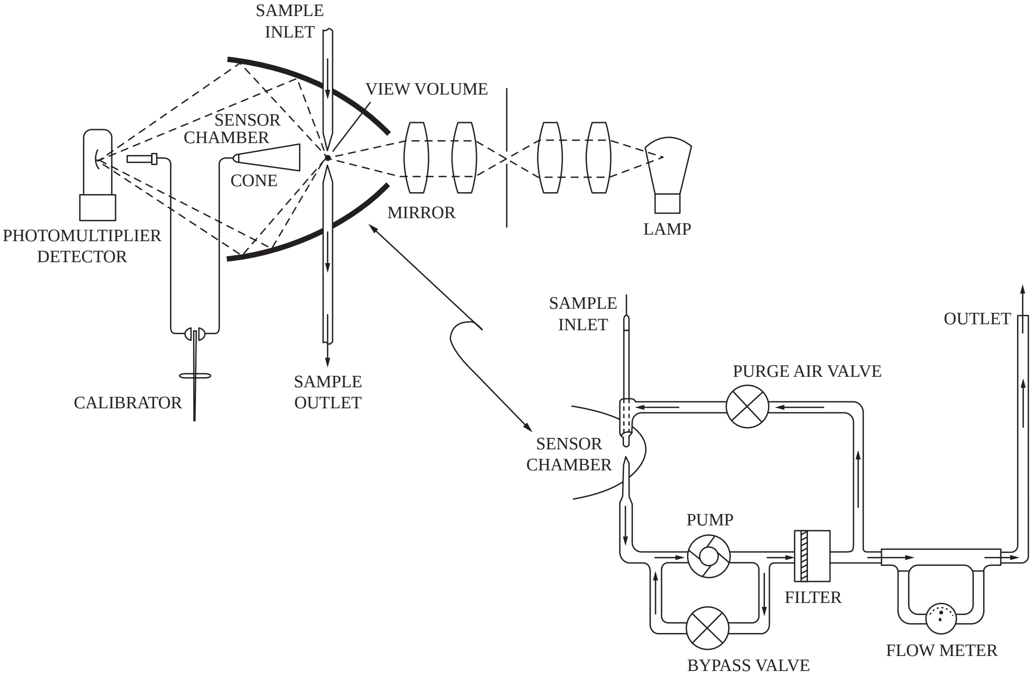

FIG. 8.47c

a sample, measure the particle size through an optical multiple-particle analyzer, and report a specific measurement of the distribution for control.

As shown in Figure 8.47b, in the first step of an analysis cycle, water is charged into a mixing chamber through a debubbling circuit that prevents the air bubbles from the entering water. A circulating pump then agitates the water in the mixing chamber and circulates it through the sample cell, where the laser beam detector of the monitoring section is located.

When the slurry extraction by the sample extractor is actuated, a particulate sample is drawn and deposited into the mixing chamber. The circulating water carries the particles of the slurry through the sample cell. At the end of the measurement cycle, the mixing chamber is drained, rinsed, and refilled with water in preparation for the next sample.

The analyzer is capable of operating with wet slurry or with dry powder samples, and successive samples can be analyzed every few (2 to 15) min. The sample size is between 3 and 10 g, and the results are printed or displayed on particle size distribution curves (Figure 8.47a). The analyzer consumes about 1.5 gal (6 li) of water per cycle and 4.2 SCFH (120 l/h) of air. The range of the analyzer is 0 to 200 μm, with 2.8 μm being the minimum reading.

Airborne-Particulate Counter

Figure 8.47c illustrates the elliptical-mirror-type airborne-particle counter used in sizing and classifying powdered products or in inspecting the performance of HEPA filters, which are widely used in clean rooms.

The unit operates with a 0.25 SCFM (1 lpm) sample, which is directed to the focal point of its elliptical mirror, where the focused incident light is scattered by the particles in the sample. The scattered (Tydall) light is collected by the elliptical mirror and is focused onto the photomultiplier detector.

Because the mirror completely surrounds the particles in the sample, it collects more light energy and therefore is capable of detecting smaller and fewer particles. The minimum particle size it is capable of detecting is about 0.3 μm, and the unit can operate at particle densities of up to 10 million particles/ft^3 (353 million particles/m^3).

The air sampling system includes a positive-displacement pump and a pressure regulator (Figure 8.47c). The return air from the sensing chamber is filtered by an absolute filter and is reused as purge air. This purge air fills the sensor chamber and also surrounds (sheathes) the sample airstream to prevent the particles in the sample from entering the sensor chamber.

INTRODUCTION

The pH detectors belong to the family of ion-selective electrodes, so the reader is advised to refer also to Section 8.28 in this chapter, which discusses the general topic of ion-selective electrodes.

One of the important considerations in the design of pH systems is the means by which the probes are kept clean. Probe cleaners are also discussed in other sections of this chapter, so the reader might also refer to Figures 8.1m, 8.1p, and 8.41i in addition to Figures 8.48u, 8.48x, and 8.48z for the description of various probe-cleaning designs.

Measurement Error

The pH measurement error in process applications is an order of magnitude larger than the normally stated electrode error, which is a result of varying glass surface conditions, dissociation constants, streaming potentials, concentration gradients, and diffusion or liquid junction potentials of actual installations.

Optimistic users and suppliers who provide one electrode per point in the process may believe that they have achieved accuracies of 0.02 pH or better. Results of installations with three electrodes per point in the process show that the inaccuracy over a month is at best 0.25 pH and can be obtained only after frequent process calibration adjustments. In fact, if all three electrodes agree within a tenth of a pH for more than a few minutes in an industrial application, it indicates that the electrodes are probably coated, broken, or still have protective caps on them.[1]

FIG. 8.48a
The logarithmic nature of pH.

Measurement Range

The measurement of pH covers an incredibly wide range of extremely dilute acid and base concentrations (Figure 8.48a). For strong acids and bases, it can track changes from one to one millionth of a percent.[2] Thus, pH can be used as a sensitive indicator of deficient and excess acid and base reactant concentrations for chemical reactors and scrubbers.

For example, a few millionths of a percent of excess of sodium hydroxide (a strong base) is needed for chlorine destruction with sodium bisulfite. pH measurement is used to reduce sodium hydroxide addition to its bare minimum and still ensure complete use of sodium bisulfite.

Applications

In addition, pH measurement is used to correct the inference of hypochlorite concentration from an oxidation-reduction potential (ORP) measurement (Section 8.41). Since ORP curves drastically shift with pH, the use of ORP to infer the concentration of oxidizing or reducing species must be accompanied by an accurate pH measurement.[3]

Biological reactors use acids and bases to supply food to or neutralize the waste products of organisms. Cells are extremely sensitive to pH fluctuations. Genetically engineered bacteria tend to be weak and need particularly tight pH control. Thus, pH is critical to cell growth rate, enzyme reactions, and extraction of intercellular products.[4]

The sensitivity of cells to pH has even wider significance in that any food, drink, or drug ingested or injected, and any waste discharged to the environment, must have pH specifications to prevent damage to living matter and ecological systems. Stricter environmental regulations have increased the number and importance of pH measurements. Some environmental regulations have instantaneous limits on pH. An excursion outside the acceptable range for a fraction of a second can be a recordable violation.

The pH measurement system must be designed to prevent violation indications from spurious readings due to installation effects. For most discharges, the acceptable range lies between 6 and 9 pH. To ensure that a surface impoundment can be declassified (nonhazardous), the pH of all entering streams must always be between 2 and 12.5 pH.[5]

Whereas materials of construction are generally less sensitive to pH than are living cells, a range of pH must be maintained to prevent corrosion of metals or disintegration of plastics. Intermediate pH control is often needed to prevent damage to vessels, piping, and instrumentation.

THEORETICAL REVIEW

In pH measurement systems, a pH responsive glass takes up hydrogen ions and establishes a potential at the glass surface with respect to the solution. This potential is related to the hydrogen ion activity of the solution by the Nernst relationship,

$$E_g = E_g^o + \frac{2.303RT}{F}\log_{10}a \qquad \textbf{8.48(1)}$$

where

E_g = sum of reference potentials and liquid junction potentials, which are constants (in millivolts)
E_g^o = potential when a = 1
a = hydrogen ion activity
T = absolute temperature in kelvins (°C + 273)
R = 1.986 calories per mol degree
F = Faraday (coulombs per mol)
2.303 = logarithm conversion factor

The process variable pH is the negative logarithm of the hydrogen ion (i.e., proton) activity.

$$pH = -\log(a_H) \qquad \textbf{8.48(2)}$$

If both sides of the equation are multiplied by –1, and the definition of an antilogarithm is used, the result shows that the hydrogen ion activity is equal to 10 raised to the negative power of pH. The lowercase p designates the mathematical relationship between the ion and the variable as a power function; the H denotes the ion is hydrogen.

$$a_H = 10^{-pH} \qquad \textbf{8.48(3)}$$

For dilute aqueous (water) solutions, the activity coefficient is approximately unity, and the hydrogen ion concentration is essentially equal to the hydrogen ion activity. As the concentrations of acids, bases, and salts increase, the crowding effect of the ions reduces the hydrogen ion activity. Thus, an increase in salt concentration can cause an increase in pH reading, even though the hydrogen ion concentration is constant.

An acid is a proton donor, and a base is a proton acceptor. When an acid dissociates (breaks apart into its component ions), it yields a hydrogen ion and a negative acid ion. When a base dissociates, it gives a positive base ion and a hydroxyl ion that is a proton acceptor. When water dissociates, the result is both a hydrogen ion (proton) and hydroxyl ion (proton acceptor).[6]

Thus, water acts as both an acid and a base. Neutralization is the association of hydrogen ions from acids and hydroxyl ion from bases to form water. The following equations show the dissociation (forward arrow) and association (backward arrow) of an acid, base, and water, respectively.

$$HA = H^- + A^- \qquad \textbf{8.48(4)}$$

$$BOH = B^+ + OH^- \qquad \textbf{8.48(5)}$$

$$H_2O = H^- + OH^- \qquad \textbf{8.48(6)}$$

TABLE 8.48b
Concentrations of Active Hydrogen and Hydroxyl Ions at 25°C at Different pH Values (in Gram-Moles/Liter) and Some Examples of Fluids That Have Corresponding pH Values

The product of the hydrogen and hydroxyl ion concentrations in water solutions is equal to 10 raised to the negative power of pK_w where K_w is the water dissociation constant.

$$[H^+][OH^-] = 10^{-pK_w} \qquad \textbf{8.48(7)}$$

Ion Concentrations

At 25°C, pK_w is 14, and the product of the hydrogen and hydroxyl ion concentrations is 10^{-14}. This relationship is shown in Table 8.48b for the pH range of 0 to 14. This means that a pH measurement can track 14 decades of hydrogen ion concentration and detect changes as small as 10^{-14} (at 14 pH). The concentration changes of strong acids and bases also follow the decade change per pH unit within this range. No other concentration measurement has such rangeability and sensitivity. This has profound implications for pH control.[7]

Concentrated strong acids and bases have a pH that lies outside this range. For example, concentrated sulfuric acid has a pH of –10, and concentrated sodium hydroxide has a pH of 19 as measured by a hydrogen electrode. However, the set point of a pH loop is usually well within the 0 to 14 range.

Some feed-forward pH loops might need measurements outside this range, but the shortened life expectancy and increased error from the electrode at the extremes of the range make such measurements impractical. When the nominal pH value is expected to be near the extremes of the 0 to 14 pH range, conductivity (Section 8.17) is usually a better measurement choice for detecting acid and base concentrations.

The neutral point is where the hydrogen ion concentration equals the hydroxyl ion concentration. At 25°C, this

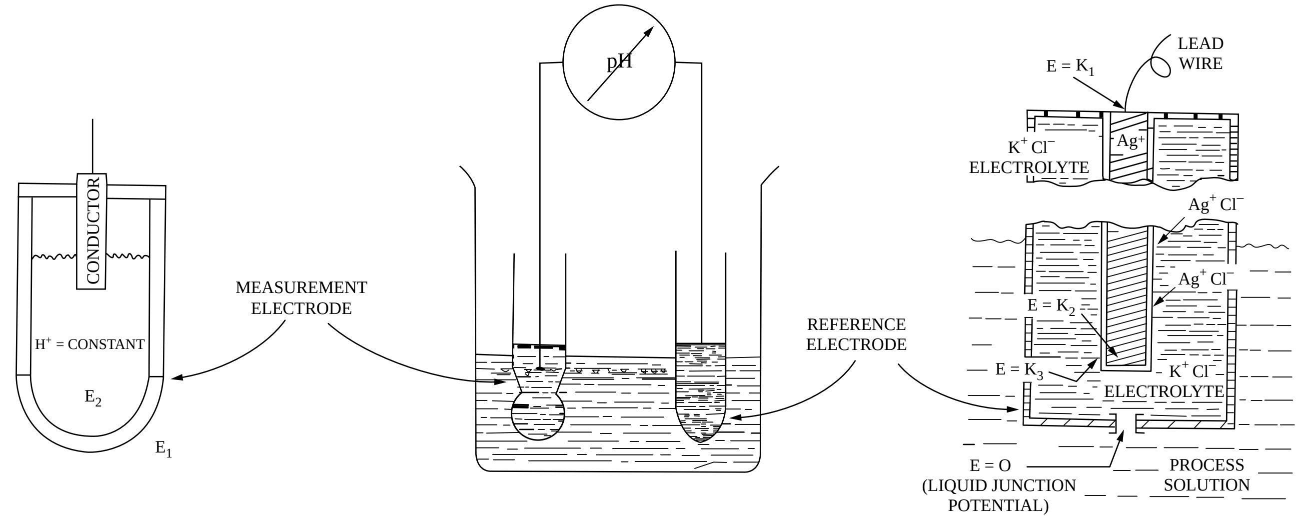

FIG. 8.48c
The traditional configuration of a glass measurement electrode and a flowing junction reference electrode.

occurs at 7 pH. However, the pK_w decreases by about –0.35 pH per 10°C. A decrease in temperature will raise the neutral point and the pH reading of alkaline solutions, even though the concentration of acids and bases is constant. For example, a stream with strong electrolytes will change from 8 to 11 pH as it cools down from 90 to 25°C.[8]

Temperature compensators correct for the change in millivolts per pH unit per the Nernst equation but do not correct for this change in the actual pH of the solution with temperature. Since the change in pH readings with temperature of solution pH changes is often larger than that per the Nernst equation, microprocessor-based pH transmitters have added algorithms for solution pH correction.

pH MEASUREMENT

The hydrogen ion does not exist by itself in aqueous solutions. It is associated with a water molecule to form a hydronium ion (H_3O^+). The glass measurement electrode (Figure 8.48c) develops a potential when hydronium ions get close enough to the glass surface for hydrogen to jump and become associated with hydronium ions in an outer layer of the glass surface as illustrated in Figure 8.48d.

This thin hydrated gel layer is essential for electrode response. The input to the pH measurement circuit is a potential difference between the external glass surface that is exposed to the process (E_1) and the internal glass surface that is wetted by a 7 pH solution (E_2). If the external glass surface is in exactly the same condition as the internal glass surface, the Nernst equations simplify to the following equation, where the potential difference in millivolts is proportional to the deviation of the process pH from 7 pH at 25°C.

$$E_1 - E_2 = 0.1984 * (T + 273.16) * (7 - pH) \tag{8.48(8)}$$

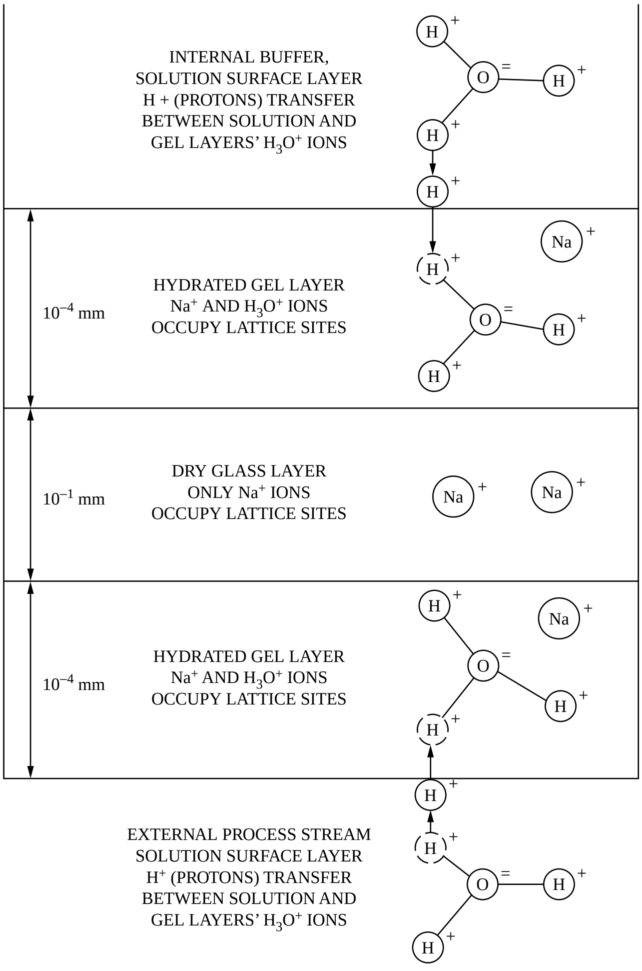

FIG. 8.48d

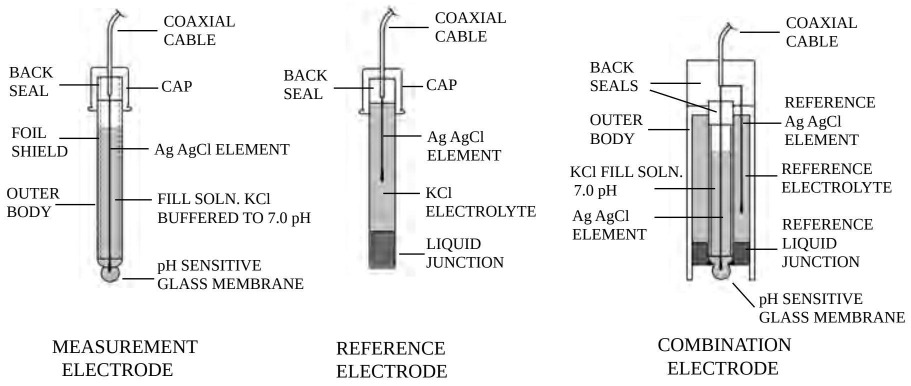

FIG. 8.48e
Basic electrode configurations.

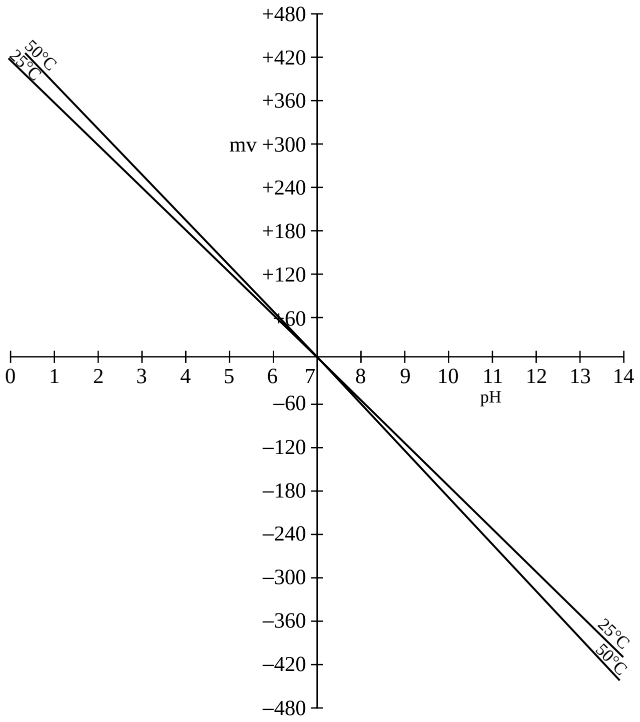

FIG. 8.48f
Nernst temperature effect on millivolts vs. pH.

The basic components of measurement, reference, and combination electrodes are shown in Figure 8.48e.

Temperature Effects

Change in the process temperature in kelvins changes the millivolts generated in an amount proportional to the deviations from 7pH, as shown in Figure 8.48f. When the process is 7 pH, the millivolt potential is zero, and temperature has no effect on the number of millivolts.

The point of zero temperature effect is called the *isopotential point*, which depends not only on the temperature effect on the pH electrode but also on the temperature effect on the reference electrode. The actual isopotential point will change with temperature as a result of changes in the condition of the external gel layer from dehydration, abrasion, etching, and contamination.

Conventional temperature compensation circuits correct the millivolts only for the Nernst temperature effect and assume that the isopotential point is fixed at 7 pH. Some microprocessor-based transmitters provide an adjustable isopotential point. This is particularly important for nonglass measurement electrodes.

The isopotential point is obtained by differentiating the equation for the entire pH measurement cell, which includes both the pH electrode and the reference electrode, setting the result to zero, and solving for the isopotential pH. The $E^0(T)$ terms in this equation include the potential inside the glass electrode, which consists of the inside surface of the glass electrode and its internal silver–silver chloride wire, and the reference electrode.

$$E(T) = E^0(T) + [dE^0(T)/dT] * (T - 298.16) - 0.1984 * (pH)$$

8.48(9)

pH Electrodes and Sensors

Most glass measurement electrodes use bulbs. Various shroud designs (Figure 8.48g) are used and represent a compromise for the conflicting goals of bulb protection from breakage and abrasion and bulb exposure to flow to ensure a representative reading and prevent areas of stagnation and material buildup.

The standard design has slots or holes to allow the flow of process around the bulb. Recessed shrouds are used for pulp and abrasive applications. The recessed area can get clogged or caked up and cover the bulb and reference junction. When the material breaks loose, it can take the bulb with it. A tapered shroud creates eddies that help keep the electrode surfaces clean.

Flat Glass Electrodes Flat glass electrodes have been developed to minimize glass damage and maximize a sweeping

action to prevent fouling. The usable pH range of flat glass electrodes is often lower than bulb electrodes. The stated range of small button electrodes is 0 to 10 pH, and that of large flush flat glass electrodes, illustrated in Figure 8.48h, is 2 to 12 pH.

High sodium ion concentrations and low hydrogen ion activity (alkali error) can also have a larger effect on flat glasses, which lowers their upper pH range limit.

Some manufacturers offer several different glass formulations that are tailored to a process application. Figure 8.48i shows the temperature and pH range for four different types of glass. Figure 8.48j illustrates how lower alkali error improves accuracy above 10 pH.

Higher glass impedance normally corresponds to higher resistance to chemical attack from strong bases (e.g., sodium hydroxide) and strong acids (e.g., hydrochloric acid). Thick and flat glass is more abrasion resistant, but low-impedance glass must be used, which reduces its chemical resistance.

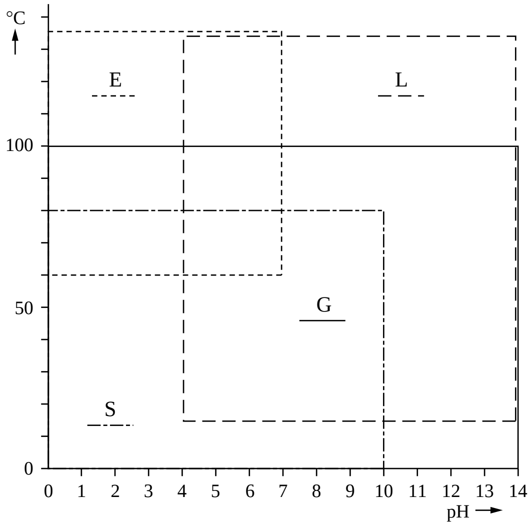
In the late 1980s and early 1990s, progress was made in reducing the impedance of sodium ion and chemical-resistant glass so it could be used at temperature as low as 5°C. In general, the specifications of a manufacturer's glass formulation should be checked against the needs of the pH application.

Glasteel Pfaudler has patented a measurement electrode made of Glasteel,® a unique material formed by the fusion of glass and steel (Figure 8.48k). The probe has greater structural endurance, greater corrosion resistance, and a higher temperature rating (140°C below 5 pH) as depicted in Figure 8.48l.

This probe is designed to withstand the rigors of heat, pressure, and dynamic agitation in reactors. It needs a modified or microprocessor-based transmitter, because its zero potential point lies between 1 and 3 pH. The cost of the Glasteel electrode is much higher than that of any other pH electrode.

Metal Oxide pH Electrodes Before the glass measurement electrode was developed for industrial measurements, the antimony electrode was used. Antimony is a hard and brittle material. The electrode responds to pH by surface oxidation. Because oxidant accumulation on its surface deteriorates the accuracy and repeatability of the measurement, periodic cleaning is necessary.

The electrode's response is nonlinear and requires narrow calibration spans or special polynomials for adequate accuracy. The measurement range is reported to be 3 to 8 pH by



"G" glass: used for membranes of electrodes in processes where the nominal pH value varies around pH 7; wide application range, also termed "general purpose" glass.
"L" glass: application is for measurements in alkaline media with high process temperatures.
"E" glass: application is for measurements in acid media; also suitable for use at higher process temperatures.
"S" glass: low ohmic glass for use at lower temperatures and for acid media; at higher pH values, the alkaline error may be significant.

some and 3 to 11 pH by others. This sensor is very temperature sensitive. The millivolt output, which is approximately 50 mV per pH unit, will increase from 1 to 3 mV/°C as the pH increases.

The isopotential point is near 2 pH, so modified or microprocessor-based transmitters are required for temperature compensation. Yet another limitation is that antimony is also an oxidation-reduction potential (ORP) electrode. Therefore, it will respond to oxidizing and reducing species, and its reading will be affected by as little chlorine as a fraction of a ppm.

Antimony is usually used as a last resort. It has been used in applications where abrasion from slurries or etching from hydrofluoric acid causes glass measurement electrode failures. It cannot be used in the food, beverage, or pharmaceutical applications because of its toxicity. In recent years, work has been conducted toward developing glass electrodes with resistance to high concentrations of hydrofluoric acid, which, if fruitful, will eliminate many antimony electrode applications.

Other metal oxide electrodes have been evaluated for use as pH electrodes. Iridium oxide in particular was given considerable focus as a possible substitute for the conventional glass

electrode in the early 1990s. It had the potential for a temperature rating of 200°C and held the promise of eliminating the problems of dehydration, etching, sodium ions, and breakage associated with glass measurement electrodes, as well as being able to make repeatable measurement outside the 0 to 14 pH range.

Unlike antimony, iridium oxide has excellent linearity and repeatability. However, as with other metal oxides, iridium oxide responds to oxidizing and reducing agents, which tend to severely offset the pH reading, even at low parts per million concentrations. Attempts were made to circumvent the effects of oxidizing and reducing agents through the use of polymer coatings, but these proved unsuccessful; therefore, the development efforts toward industrial iridium oxide sensors have largely been abandoned.

Ion-Selective Field Effect Transistors The most promising new pH sensor technology of the last decade has been the development of the ion-selective field effect transistor (ISFET). Its greatest advantage is that it has a relatively small, integral pH sensitive area instead of the glass bulb found in common pH electrodes, which can break and contaminate the process sample with broken glass. This makes the ISFET especially appealing for food applications, in which on-line pH measurements have been avoided in consideration of the risk of contamination by broken glass electrodes.

An ISFET (Figure 8.48m) functions like a metal oxide semiconductor field effect transistor (MOSFET), but it uses a pH-sensitive membrane over the gate or channel region, which is exposed to the process solution, rather than the conductive gate terminal used by a MOSFET.

When an ISFET is operated at a constant drain current, the measured gate-source voltage is a result of the potential of the conventional reference electrode and of the pH sensitive membrane, which responds to pH in a Nernstian manner, similar to a conventional pH electrode. The special circuitry required to handle an ISFET measurement can be embedded

Flat glass (2 to 12 pH)	+	–	+	–	+	+	–	+
Glasteel (0 to 10 pH)	+	+	+	+	+	+	+	–
Antimony (3 to 11 pH)	–	–	–	–	–	+	+	+
Photometer (0 to 14 pH)	+	+	–	+	+	+	+	–

+ = good
– = poor

in the pH analyzer or in an electronics module, which allows the ISFET sensor to be used with a conventional pH analyzer.

The major drawback of ISFET sensors relative to conventional glass electrodes has been their lack of robustness, and this has created problems in the food industry, which often requires exposure to strong alkaline solutions that are used for clean-in-place (CIP) sanitation. The robustness of ISFET pH sensors is likely to improve in the future.

Fiber-Optic pH Measurement Photometer-type pH measurements using fiber optic sensors and pH sensitive color dyes have been used *in vivo* in medical applications (Figure 8.48n). If the sample system is properly designed, measurements using this technology should be free of problems due to sodium ions as well as temperature, coating, and abrasion. On the other hand, the time delay caused by the temperature lag in the sampling system, along with the higher cost and maintenance, are disadvantages.

The most promising on-line application of fiber optic pH measurement would be for low-conductivity pH measurements, because the problems of flow sensitivity and electrokinetic effects observed with convention glass and reference electrodes are eliminated.

Relative Performance of pH Sensors The relative performance of the different types of measurement electrodes under various operating conditions is summarized in Table 8.48o, where the (+) sign refers to good, and the (–) sign indicates poor performance or rating.

Reference Electrodes

The reference electrode should provide a standard reference potential at a given temperature plus an electrical continuity between its internal electrode and the glass measurement electrode (Figure 8.48c). The standard reference potential is the result of a reproducible silver ion concentration maintained by a silver-silver chloride wire in contact with a potassium chloride solution.

The reference electrode has a junction where the internal electrolyte is in contact with the external process fluid. A liquid–liquid junction or diffusion potential develops as electrolyte ions and process ions migrate into the junction. When the charge accumulation becomes large enough to oppose further ion migration, the potential stops changing.

This potential introduces an error that is often overlooked in pH measurements. Figure 8.48p shows the error for various concentrations of potassium chloride liquid fills and different

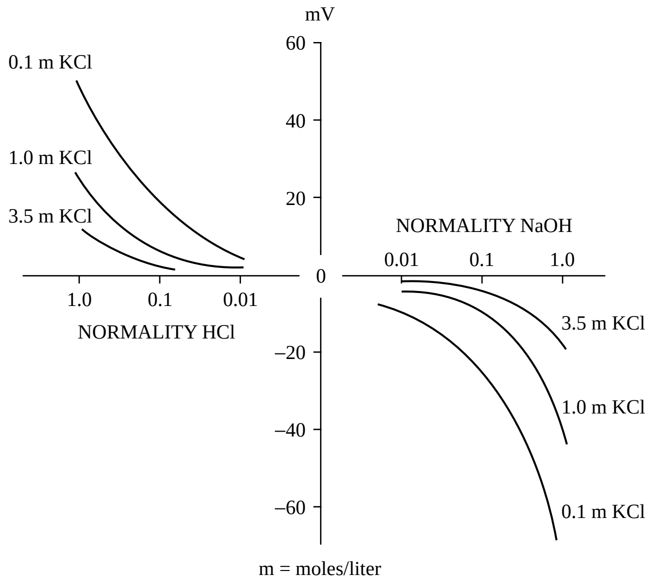

FIG. 8.48p
Charge accumulation at the liquid–liquid junction can oppose ion migration and introduce an error. The values of this error are shown for different concentrations of electrolyte (KCl) and different concentrations of acidic (HCl) or basic (NaOH) process fluids. (Courtesy of Yokogawa.)

concentrations of hydrochloric acid and sodium hydroxide in the process fluid. The junction potential magnitude and time to equilibrium generally increase for gel-filled or solid-state reference electrodes.

Flowing and Double Junctions The reference junction is also an entry path of process material into the internals of the reference electrode. Electrolyte contamination can cause large shifts of the pH measurement. This happens when the equilibrium between the silver–silver chloride wire and the dissolved silver ion in the reference electrolyte is disrupted, typically by precipitation or complexation of the dissolved silver, most notably by sulfide, iodide, and bromide in the process.

A flowing junction helps reduce such contamination and helps establish a quicker and more constant reference junction potential. However, flowing junctions require electrolyte pressurization above the process pressure and periodic refilling of the electrolyte. Figure 8.48k illustrates the use of pressurized remote-mounted reservoirs. The reference electrode is mounted in the external reservoir for additional protection against contamination and for improved temperature stability.

Flowing junctions are much more common in European applications. Unlike a flowing junction, which maintains electrolytic contact with the process by transport of the electrolyte solution, a nonflowing junction relies on the diffusion of reference electrolyte ions into the process, and, as a result, will always be susceptible to the diffusion of process material through the liquid junction.

Combination Measurement/Reference Electrode In the United States, the combination electrode is used mostly to reduce the maintenance and replacement cost of electrodes. It has a sealed reference electrode that surrounds the measurement electrodes and an annular reference junction (Figure 8.48q).

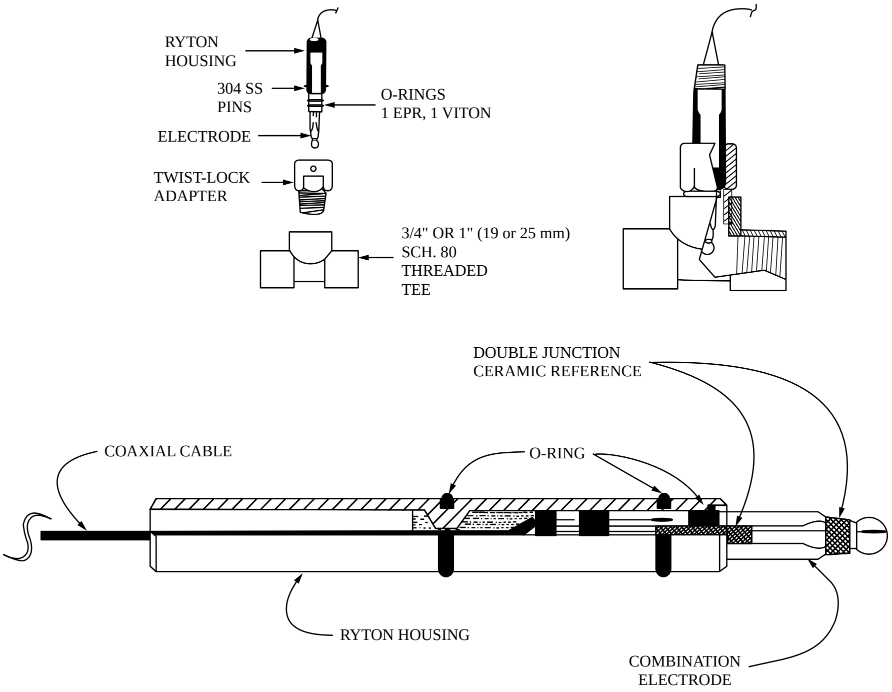

FIG. 8.48q
Combination electrode with double junction. (Courtesy of Van London.)

The construction features of a particular reference design in a combination electrode present a tradeoff between (a) the effort to quickly establish and minimize a constant junction potential and (b) the goal of resisting contamination and coating. The user must decide which is more important for a given application.

A decrease in the area of the reference junction reduces contamination but increases coating problems. A thickening or solidification of the internal fill, the addition of junctions, and a decrease in the porosity of the junction reduce contamination problems but delay equilibrium and often increase the magnitude of the junction potential. Figure 8.48q shows the cross section of a combination electrode with a double-junction reference.

The potassium chloride solution is saturated and has a tendency to crystallize and reduce the diffusion rate and the associated potential at the junction. Also, silver from the silver–silver chloride internal element gets into the potassium chloride fill, reacts with sulfides and halides, and clogs the junction.

Multiple Junction References The most common approach to preventing contamination of nonflowing reference electrodes in combination pH sensors has been the use of multiple junction references (Figure 8.48r). These designs retard the diffusion of contaminants that reach the reference element by requiring them to sequentially diffuse through each junction of the reference.

The electrolyte solutions in the reference are typically gelled to prevent transport of the contaminant to the next liquid junction by convection. The electrolyte solution in contact with the outermost liquid junction can be an electrolyte with a low silver ion concentration, such as potassium nitrate, to prevent precipitation of silver halides at the outermost liquid junction and precipitation of heavy metals in the process with chloride in the electrolyte solution.

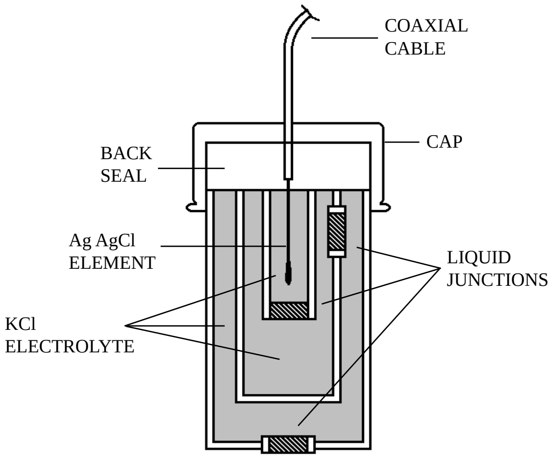

FIG. 8.48r
Triple junction reference electrode.

Stiff Gel Reference Mettler-Toledo has developed an Argenthal reference system that has a stiff gel with silver ion traps to catch contaminants that would precipitate silver ion. It can use multiple liquid junctions or an aperture diaphragm to provide a direct contact between the process and the reference electrolyte. It provides performance advantages in streams with high salt concentrations, emulsions, suspensions, proteins, sulfides, hot alkalis, and pressure fluctuations.

Differential Reference Another approach has been to dispense with the conventional silver–silver chloride reference altogether. Figure 8.48s describes Great Lakes Instruments' patented differential reference electrode. It uses a second glass measurement electrode behind a double junction in a buffer solution for the reference electrode. The glass bulb isolates the silver–silver chloride element of the reference from sulfides and halides in the process. The buffer solution is chosen to be compatible with the process fluids to ensure a constant buffer pH and constant reference potential.

A ground rod prevents errors and noise from ground potentials. The smaller positive ions in the buffer solution tend to move through the reference junction out into organic and pure water streams. This creates an offset in the pH reading. The differential electrode has an excellent performance record in wastewater streams with inorganic acids and bases.

Because of the lower thermal conductivity of most solid-state media, it is especially important for the temperature compensation sensor to be as close as possible to the tip to minimize thermal lag.

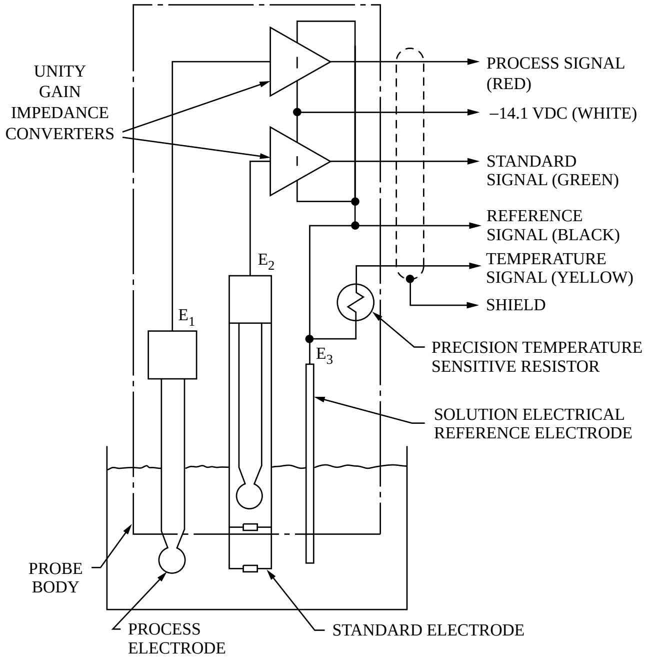

FIG. 8.48s

ELECTRODE CLEANERS

Significant natural self-cleaning by turbulent eddies requires a velocity of ≥5 ft/sec past the electrode. A velocity of greater than 10 ft/sec can cause excessive measurement noise and sensor wear. The area obstructed by the electrode must be subtracted from the total cross-sectional area when estimating the total area that is open to flow around the electrode.

Shrouds and Filters

The pressure drop at the restricted cross section should be calculated to ensure that there will be no cavitation. Some shroud designs such as the tapered shroud in Figure 8.48g create more effective eddy action. Flat surface electrodes get adequate cleaning action at velocities of 1 to 2 ft/sec.

The addition of filters shifts the maintenance from the electrode to the filter. The filter usually needs to be changed more often than the electrode has to be cleaned. An extra filter is not recommended unless it is self-cleaning (Figure 8.48t) or can be automatically backwashed. This design is described in more detail in Section 8.2. It serves not only to keep the solids out through filtration, it also keeps the 10-μm metal filter clean by periodically reversing the flow and applying pulses to loosen the particles that might have settled into the filter pores.

Automatic Cleaners

The four types of automatic cleaners are ultrasonic, brush, water-jet, and chemical. The components of some of these assemblies are shown in Figure 8.48u and their performance ratings for a variety of applications are given in Table 8.48v. These methods tend to concentrate on the removal of coatings from the sensing electrode. Particles caught and material clogged in the porous reference junction are generally difficult to dislodge. The impedance of plugged reference junctions

can get so high that it approaches an open circuit. The pH reading goes off the scale in the high direction.

Ultrasonic Cleaners The ultrasonic cleaner uses ultrasonic waves to vibrate the liquid near electrode surfaces. Effectiveness depends on the vibration energy and velocity past the electrodes. Heavy-duty electrodes are needed to withstand the ultrasonic energy. The ultrasonic cleaner works well in processes where fine particles and easily supersaturated sediments are formed or in suspension. It can move loose and light particles and oil deposits. Most of the disappointments with ultrasonic cleaners come from applications in which coatings are difficult to remove. In general, their use has declined in recent years in favor of water-jet and chemical cleaning.

Brush Cleaners A brush cleaner removes coatings by rotating a soft brush around the measurement bulb. The brush does not reach the reference junction. It has an adjustable height and a replaceable brush, and it can be electrically or pneumatically driven. Soft brushes are used for glass and ceramic disks are used for antimony electrodes. Sticky materials can gunk up the brush and smear the bulb.

Water-Jet Cleaners The water-jet type of cleaner directs a high-velocity water jet to the measurement bulb. The reading of the loop will become erratic during washing. Therefore, the cycle timer that starts the jet should also freeze the pH reading and switch the pH controller to manual during the wash cycle and for at least two minutes after the wash period to provide for electrode recovery. The water jet works well in removing materials that are easily dissolved in water.

A flow-through brush cleaner and water-jet combination assembly is shown in Figure 8.48z, and a high-pressure flanged assembly, which can be installed in a pipe tee, is shown in Figure 8.48x.

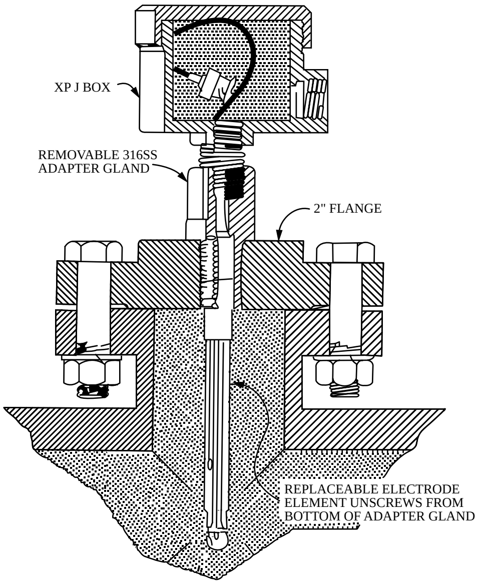

FIG. 8.48x
High-pressure electrode cleaning assembly. (Courtesy of Van London.)

Chemical Cleaners Chemical probe cleaning uses a chemical jet such as a dilute acid or base that is compatible with the process. A base is typically used for resins, and an acid for crystalline (carbonates) and amorphous precipitations (hydroxides). A dilute hydrochloric acid solution is frequently used.

Chemical cleaning tends to be the most effective of the available methods, but acid and base cleaners chemically attack glass. In addition, cleaning cycles that are too frequent or too long will cause premature failure of the glass electrode. As with the water jet, the cycle timer must hold the last pH reading and suspend control action during the wash cycle.

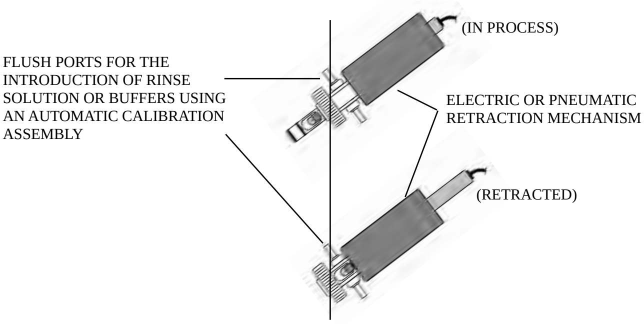

FIG 8.48y
Retraction assembly.

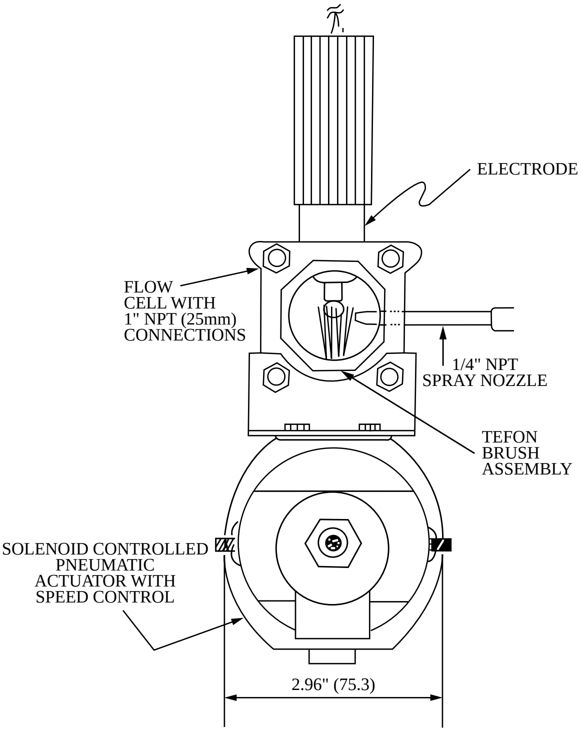

FIG. 8.48z
Brush cleaner with optional water jet.

Redundant pH sensors can be installed in parallel so that while one electrode assembly is being reconditioned, the other is in control. In such installations, after the wash cycle, the reconditioned assembly is automatically returned to control.

Automatic Retraction An electrically or pneumatically retractable pH assembly can be used in automated on-line cleaning applications and for storage, regeneration, and calibration (Figure 8.48y). This design is particularly useful in applications where the duration of probe exposure must be short so as to protect it from glass surface deterioration and to avoid forming contamination of the reference fill. Such contamination can be caused by the hot caustic or by nonaqueous solutions.

In any mounting method, the electrode tips must be pointed down to prevent the air bubble inside the electrode fill from residing in the tip and drying out the inside surface. The air bubble is necessary to provide some compressibility to accommodate thermal expansion. An installation angle of 15° or more from the horizontal is sufficient to keep the bubble out of the tip. Some electrode designs eliminate the bubble and provide a flexible diaphragm for fill contraction and expansion.

Manual Cleaning Electrodes can be manually cleaned by soaking them for several hours in a dilute hydrochloric acid solution. In general, the solution used for cleaning should be chosen for its effectiveness in removing the contaminant while not attacking the wetted materials of the pH sensor. Exposure to cleaning solutions should be minimized, as it can cause contamination of the liquid junction.

Electrodes that are sluggish or have an insufficient span or efficiency can be reactivated by soaking them for 1 min in a dilute solution of hydrofluoric acid in a nonglass container. The reactivation is created by the hydrofluoric acid dissolving part of the aged gel layer. The electrode should then be soaked overnight in its normal storage solution (typically, 4 pH buffer).[10]

On-line electrode cleaning systems should be considered when manual cleaning becomes a maintenance burden. Selection of the cleaning method should be done in consultation with the manufacturer of the cleaning system, given that several factors are peculiar to each process and cleaning method, and these can determine the difference between success and failure.

APPLICATION PROBLEMS

High Salt Errors

Alkalinity error is caused by positively charged alkaline ions that move into the outer glass surface, displace the hydrogen ions, and decrease the activity of the hydrogen ion in the gel layer. The millivolts developed at the surface are proportional to the ratio of the activity of the hydrogen ion in the process fluid to that in the gel layer. Therefore, the decrease in activity in the gel layer increases the millivolts developed, which decreases the pH reading.[11] The result is a perceived increase in hydrogen activity of the process and a lowered pH reading.

The error disappears when the electrode is removed and inserted in buffer solutions. The smaller alkaline ions can more easily penetrate the glass matrix and cause a greater shift. Thus, lithium ions cause a larger error than sodium ions, and sodium ions cause a larger error than potassium ions. Because sodium ions are much more common, the effect is often called the *sodium ion error.*

Tight-matrix, high-pH glass formulations such as glass L in Figure 8.48i and general-purpose wide-range glass formulations such as glass G in Figure 8.48i minimize the alkalinity error. For alkalinity error caused by high salt concentrations, the decrease in pH readings is offset by the increase in pH caused by the decrease in the hydrogen ion activity.

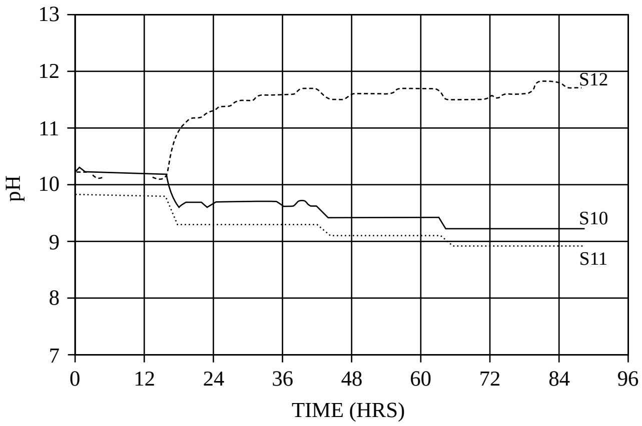

FIG. 8.48aa
High salt (NaCl) effect on electrodes.

High Salt Effect on Electrodes For an increase in sodium chloride concentration from 1 to 4 molarity at 25°C, the pH reading from a general-purpose glass dropped by only 0.2 pH in a test with Tris buffers. For lithium chloride, the pH reading decreased by 1.0 pH. For potassium chloride, the pH reading actually increased by ≈0.4 pH.

A separate test, documented in Figure 8.48aa, with three electrodes installed in a circulation line showed that pH measurement decreased slightly for three additions of sodium chloride as expected for glass bulb measurement electrodes (S10 and S11) but went upscale by 1.5 pH for a flat glass measurement electrode (S12). Subsequent tests and calibration checks of the flat glass electrode confirmed that it was in good condition.

Sodium hydroxide solutions above 12 pH and hydrofluoric acid solutions below 3 pH will greatly shorten the life of the electrode. The chemical attack rapidly increases with temperature and may cause failure within a day. Sample cooling and dilution are often the only alternatives.

High Acid Errors

Acid error is attributed to the adsorption of acid molecules into the gel layer and the associated increase in the hydrogen ion activity of the gel layer.[12] Exposure to concentrated acids also dehydrates the gel layer and reduces the efficiency of the electrode. The net result is an increase in the pH reading. Acid error typically starts below 1 pH and becomes worse as the pH decreases and exposure time increases. A periodic water soaking or water-jet washing of the measurement electrode helps replenish the gel layer.

Temperature Errors

The actual pH of the process stream changes with temperature due to changes in dissociating constants with temperature. Figure 8.48bb shows the pH change with temperature for a neutral solution and 6.0 pH and 9.0 pH solutions with strong acids and bases. Figure 8.48cc shows the temperature effect on the pH of strong electrolytes.

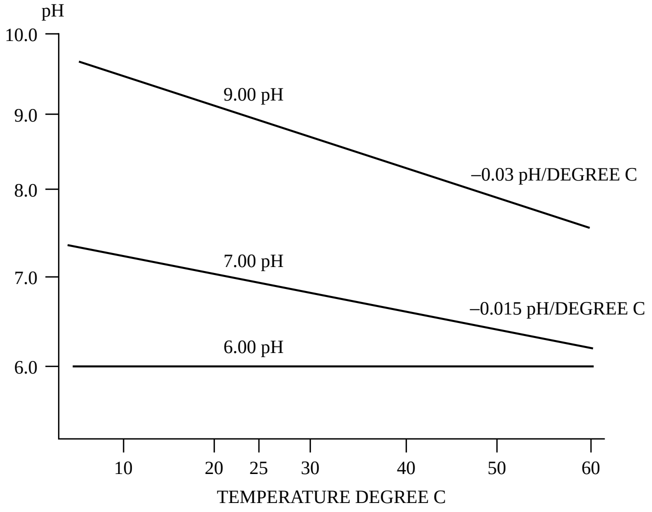

FIG. 8.48bb
Temperature dependence of water and strong acid and base solutions.

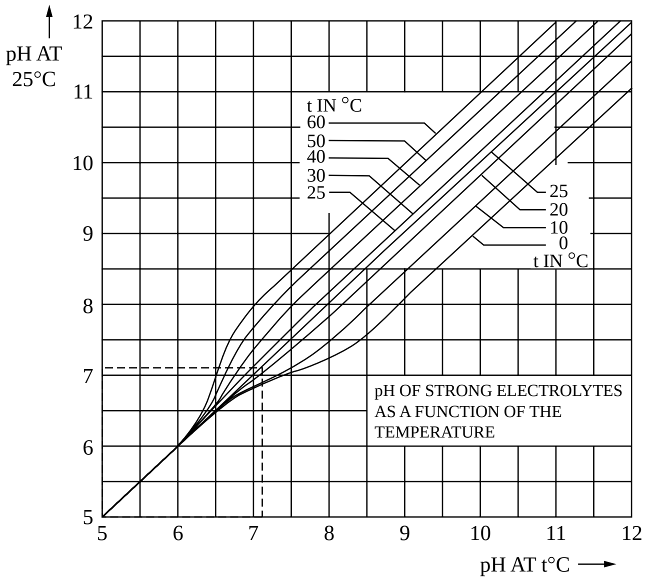

FIG. 8.48cc
The pH of strong electrolytes changes with temperature. (Courtesy of Yokogawa.)

The dissociation constants of strong acids and bases are off the scale, and the effect shown in this figure is primarily the result of changes in the water dissociation constant. Strong acid solutions have virtually no temperature dependence, but neutral and strong base solutions will always exhibit temperature dependence. For weak acids and bases, the dissociation constants are on the scale, and their effect on pH is more difficult to predict. It usually requires a laboratory test.

Microprocessor-based transmitters offer polynomial or straight-line fits of the data to temperature-correct the measurement for actual pH changes. Most of these algorithms cannot correct for changes in the glass or in the internals of the electrode.

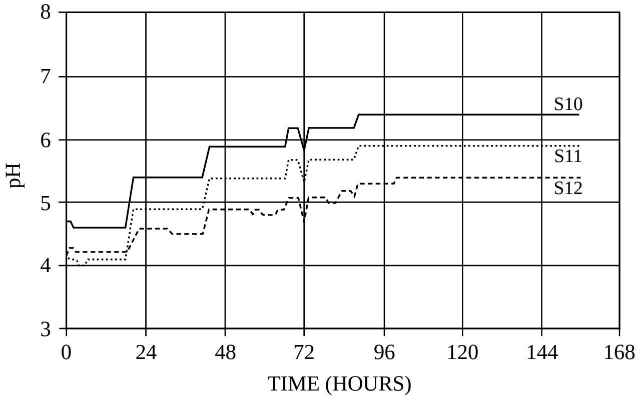

FIG. 8.48dd
Low water effect on three electrodes, produced by the addition of propylene glycol.

Water Concentration Errors

Water concentrations below 40% can also cause shifts in the pH measurement. When the addition of a solvent causes the water content to drop below 40%, the change in hydrogen ion activity can be significant enough to cause a noticeable change in pH. The addition of propylene glycol causes a decrease in the hydrogen ion activity and an increase in the pH reading.

For the same three electrodes (S10, S11, and S12) in the circulation line that were subjected to the high salt test shown in Figure 8.48aa, four successive additions of propylene glycol were made to perform a low water test. The incremented pH measurements are shown in Figure 8.48dd.

For applications with low water content, it helps to use a glass formulation with a large number of active sites and to automate the periodic water soaking or water-jet washing of the glass to hydrate the gel layer.

Nonaqueous Solutions

In nonaqueous solutions, the solvent can be an acid, base, alcohol, or hydrocarbon instead of water. An acid solvent acts as a proton donor, and the pH scale is shifted down. For example, the pH scale for an acetic acid solvent is −6 to −1 pH, and for a formic solvent is –9 to –2 pH.

A base solvent acts as a proton acceptor, so the proton activity is decreased, and the scale is shifted up. An alcohol solvent acts as both a proton donor and acceptor like water so that changes in proton activity are moderated. The pH scale occupies about the same region as water but may extend slightly farther upscale and downscale. For example, the pH scale for an ethanol solvent is –4 to +16 pH.

A hydrogen solvent acts as neither a proton donor nor acceptor, so the solvent is passive to changes in proton activity. Consequently, the upper and lower limits of the pH scale are usually much farther apart than for water. For example, the pH scale for acetone solvent is −5 to +20 pH.[13]

If the process is an aqueous solution dispersed with an immiscible, nonaqueous solvent, much of the acid and alkali will be in the aqueous phase. It is better to make the pH measurement in a vessel that allows the phases to separate and confine the pH measurement to the aqueous phase.

When considering applications with a significant nonaqueous solvent content, it is important to note that most pH sensors are built with wetted materials designed for aqueous applications. In many cases, nonaqueous solvents can attack the o-rings, seals, and even body material of the sensor, causing the process to leak into the sensor and cause a short.

The presence of nonaqueous solvents can also cause unpredictable behavior at the liquid junction of a nonflowing reference, leading to measurement errors. Therefore, the use of a flowing reference should be considered.

Probe Coating and Low Conductivity

A slime coating of 1 mm thickness slows down the migration of hydronium ions to the glass surface enough to increase the pH measurement time constant from 10 sec to 7 min.[14] The slow electrode response greatly increases the period of oscillation of the control loop and causes poor control. The amplitude of the measurement oscillations is a very attenuated version of the real-world pH fluctuations. For thick coatings, a hydronium ion concentration is trapped, and the pH reading freezes.

Coatings also increase the impedance of the electrode and can cause a reading that steadily climbs up the scale as the coating thickens. Some microprocessor-based transmitters measure the electrode’s impedance and issue a warning under such conditions. Conventional pH transmitters cannot determine whether the measurement bulb or the reference junction is coated or if the conductivity of the process fluid has changed. Better diagnostics of these conditions are expected from the evolving intelligent transmitters.

Conventional pH measurements of low-conductivity water (e.g., boiler feedwater and condensate) suffer from flow sensitivity, electrokinetic effects, sluggish response, changes in hydrogen activity from flow of reference electrolyte, actual pH changes from water dissociation constant changes with temperature, and isopotential point shifts with temperature.

Special systems have been designed to minimize these problems through the use of a constant head device to provide constant flow; stainless steel components to ensure that sensors are completely shielded and earthed; a low-resistance glass sensor in a high-velocity, low-volume cell with minimum distance between reference junction and glass to decrease system resistance; a low-leak reference junction to minimize hydrogen activity changes from electrolyte contamination of the sample; an in-line automated temperature-adjusted buffer facility to reduce thermal equilibrium and flow errors; and full temperature compensation to deal with Nernst slope, actual pH, and isopotential point changes with temperature.[15]

Air bubbles that cling to or pass by the measurement bulb can cause an upscale shift or noise in the reading from the

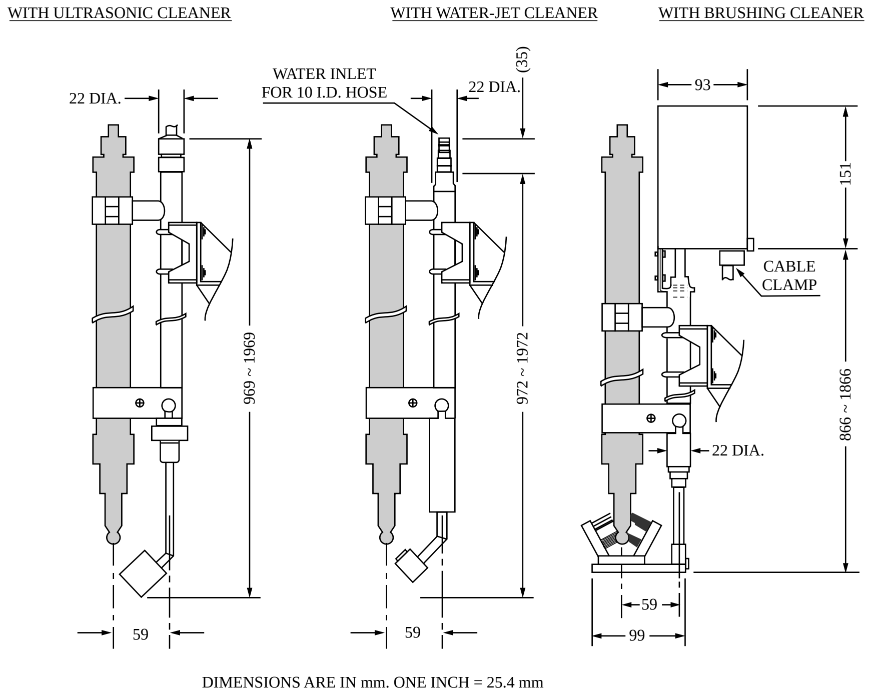

FIG. 8.48ee
Submersion assemblies provided with various cleaners. (Courtesy of Horiba Instrument.)

lack of hydronium ions and high impedance. Particles can have a similar effect. Abrasion reduces the number of active sites on the glass surface and causes a shortened span and slow response.

INSTALLATION METHODS

There are two main principles for installation design. First, for pH control, the sensor location and assembly must be chosen to minimize transportation delays and sensor time constant. The additional dead time from a delayed and slow measurement increases the loop's period, control error, and sensitivity to nonlinearity.

Second, the installation must minimize how often the electrodes must be removed for maintenance (e.g., calibration and cleaning). Removal and manual handling increase error and reduce the life of the electrode. The fragile gel layer is altered by handling and the equilibrium achieved by the reference junction is upset.

Submersion Assemblies

Sample systems are undesirable, because they add transportation delay and increase cost, and there are problems associated with winterization and plugging. Therefore, it would seem that a submersion assembly would be best for control. However, velocities below 1 ft/sec will dramatically slow the electrode measurement response because of the increased boundary layer near the glass surface[16–18] and promote the formation of deposits that can further slow down the measurement.

The bulk velocity in even the most highly agitated vessels rarely exceeds 1 ft/sec and is often much lower. This results in coating problems and a slow response. Removal of a submersion assembly is also time consuming. The addition of various cleaners, such as those depicted in Figure 8.48ee, helps reduce the number of times a submersion assembly must be removed.

Side entry into a vessel with a retractable probe is the standard installation for fermenters, as illustrated in Figure 8.48ff.

Retractable Units

The best location for most assembly probes, except in the most abrasive services, is in a recirculation line close to the vessel outlet. Installation downstream of the pump is preferred, because the strainer blocks, and the pump breaks up, clumps of materials that might otherwise break the electrodes. The retractable electrode provides the most straightforward and economical solution, as compared to simply inserting the sensor, because it allows the sensor to be removed for service without shutting down the process line or draining a vessel. However, accidents caused by removal of the restraining strap or omission of tubing ferrules have caused such assemblies to be banned from many plants.

Flow-through assemblies or direct probe insertions with block, drain, and bypass valves are often used. The flow is returned to the suction of the pump or the vessel. If the flow chamber has a cross-sectional area that is much larger than the process connections, the velocity will drop too low, response time will slow, and coating problems will increase.

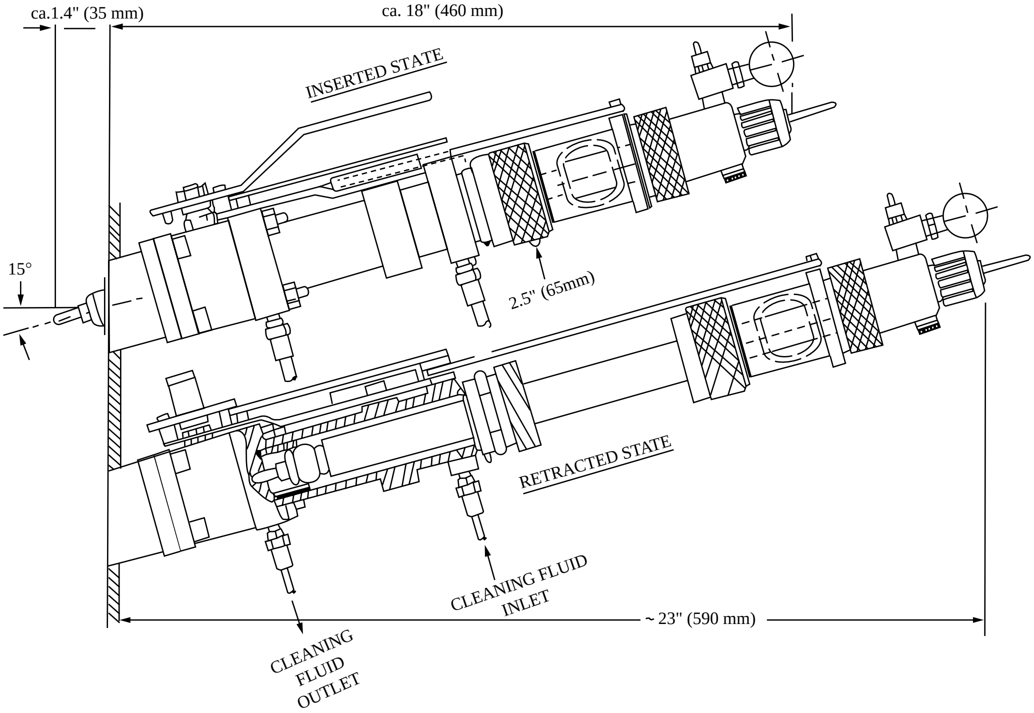

FIG. 8.48ff
Retractable, side entry probes, which are often used in fermenters.

Median Selector

A single pH measurement leads to a false sense of security. The use of two pH measurements creates endless questions as to why they do not agree. An alternative is to install three pH measurement systems and select the middle value (not the average). This method is preferred for pH control loops, especially where environmental limits exist, for the following reasons:[19]

1. It eliminates reaction to unreal spikes and fluctuations.
2. It reduces noise without introducing an additional lag.
3. It improves accuracy (reduces error band).
4. It ignores a single failure of any type.
5. It facilitates calibration while the loop is in automatic control.
6. It allows diagnosis of slow, dead, or inaccurate sensors.
7. It reduces unnecessary calibration requests and work.

A pH electrode is usually serviced only if it deviates from the median pH by more than one pH unit for more than several minutes. Median selection saves money by the elimination of unnecessary calibration and replacement. It can also increase on-stream time, reduce recordable violations, improve product quality, and reduce reagent consumption through improved sensor reliability and accuracy. However, triple redundant measurements do look expensive, and appearances sometimes become more important than performance.

Self-Diagnostics

An alternative to median selection is a self-maintaining installation of a single electrode. Some microprocessor-based transmitters have diagnostics based on electrode impedance measurements (Figure 8.48gg) and recovery time from a jet washing that can detect broken, coated, and unsubmerged sensors.

Glass Impedance Measurements Glass impedance measurements can be made between the glass electrode and a solution ground or the reference electrode, which has negligible impedance compared to the glass electrode. Glass electrode impedance is typically on the order of hundreds of megohms and is highly temperature dependent, decreasing by roughly one-half for every 8°C increase in temperature.

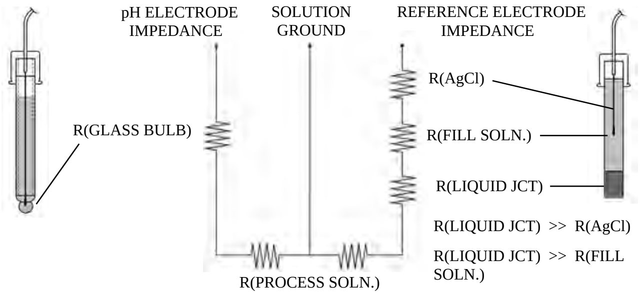

FIG. 8.48gg
pH sensor impedance diagnostic measurements.

As a result, the impedance reading must be temperature compensated to avoid false low-impedance alarms. In some cases with low-impedance glass electrodes at high temperatures, the impedance drops below the measurable range of the diagnostic circuitry, and the analyzer shuts off the low-impedance alarm.

The glass impedance measurement is most useful in detecting glass electrode cracking or breakage, which results in a sudden drop in impedance. Low-impedance alarms are also useful in detecting shorts in the sensor wiring, whereas high-impedance alarms can detect an open circuit or severe coating of the pH electrode.

Reference Electrode Impedance Reference electrode impedance is necessarily measured between the reference electrode and a solution ground and is typically in the low kilohm range. The major source of reference electrode impedance is the liquid junction and, thus, an increase in reference impedance can indicate that the liquid junction is plugged or coated or that the reference electrode is not in the process solution.

The reference electrode impedance is a much more sensitive indication of coating than glass electrode impedance. It should be noted that poisoning of the reference electrode by process components does not result in an increase in reference electrode impedance unless it is accompanied by a plugging of the liquid junction.

A temperature sensor, either internal or external to the pH sensor, is required for temperature compensation and can also be a source of sensor failure. pH sensor diagnostic features can also include detection of opens, shorts, and sense line errors.

Sensor Fault Signaling Sensor diagnostic errors are indicated on the analyzer display, and there is almost always a fault relay contact and fault current output value provided for remote indication of sensor faults. With the advent of pH analyzers with digital communications, the nature of the sensor fault can be identified remotely, enabling maintenance personnel to be better prepared to address the problem before visiting the installation.

CALIBRATION

The electrode should be washed with distilled water between buffer immersions. One should also remember that the actual pH of the buffer of process solutions can change with temperature[20] or with carbon dioxide absorption, and the reference junction can take a long time to equilibrate.

A 10-pH buffer can drop 0.1 pH per day as a result of carbon dioxide absorption, and, in general, all buffers should be discarded after use and the stock buffer containers tightly sealed. The pH sensor should be allowed to come to the same temperature as the buffer solution. All buffers should be checked with an accurate laboratory electrode and for expiration date before use. For flowing junctions, care must be exercised to ensure that the reference electrolyte does not contaminate the buffer. For separate electrodes, polarization should be avoided.

High-ionic-strength buffers should be employed for high-ionic-strength process applications. A process calibration should be performed 1 to 8 hr after the electrode is commissioned. (The wait time depends on the degree of solidification of the reference fill.) A zero or standardization adjustment is used to make the pH sensor agree with a sample that was measured with fast and accurate laboratory electrodes immediately after sample withdrawal.

Buffer Calibration Errors

Microprocessor-based pH analyzers often have features that help the user to avoid buffer calibration errors. Buffer values as a function of temperature are stored in memory for a two-point calibration, which allows the buffer value to be corrected for temperature during calibration. There is also a stabilization feature that prevents that analyzer from accepting a millivolt reading that has not fully responded to the buffer or millivolt changes due to warming or cooling of the sensor. Important diagnostic information is also provided after a buffer calibration in the form of the electrode slope, which is a measure of the sensitivity of the electrode and the zero offset, which indicates the reference electrode offset from an ideal value or asymmetry within the glass electrode.

Warnings are usually provided to prevent acceptance of a calibration that results in a slope and zero offset indicative of a bad sensor or a user error. Analyzers can also perform fully automatic calibrations if provided with the software and relays for controlling withdrawal of the sensor from the process through an insertion valve, rinsing, and introduction of the buffers.

pH electrodes should be stored in either a 4-pH buffer solution to help condition the glass surface or a 7-pH buffer solution to help prevent the loss of ions from the reference fill. Electrodes stored in distilled water for long periods of time will deteriorate as a result of the loss of ions from the measurement glass reference fill.

CONCLUSION

The pH sensor should be chosen to meet the pH range of the application. The mounting method should be chosen to make the sensor easily accessible for maintenance and calibration. Most pH applications that involve water and dilute solutions at near ambient temperature are straightforward and pose few problems.

Special care should be taken with applications involving components that can poison the reference or foul the sensor, nonaqueous solvents, low conductivity, and extremes of temperature and pressure. In applications where the nominal pH is expected to be at the high or low limits of the 0 to 14 pH range, a conductivity measurement should be considered as an alternative measurement of acid and base concentration.

It should be remembered that the pH of solutions can change with temperature. This is particularly the case with solutions that have a neutral or basic pH. It never hurts to consult several sensor suppliers as to the suitability of their various designs to a particular process application.

INTRODUCTION

Analyzers used in measuring the concentration of phosphorus have already been discussed under chromatographic (Sections 8.12 and 8.13) and colorimetric (Section 8.15) analyzers and will also be discussed under water quality and wet-chemistry analyzers (Sections 8.65 and 8.66). For this reason, the detailed designs of these analyzers are not repeated in this section.

Phosphorus in Wastewater

The principal application of phosphorus analyzers is in the control of phosphate removal in sewage treatment plants. By knowing the flow rate and the phosphorus content of raw sewage, the required optimal quantities of chemical additives can be determined. In addition, a measurement of the phosphorus remaining after treatment may be desired.

Phosphorus occurs in wastewater almost entirely in the form of phosphates, including orthophosphates, condensed phosphates (pyrophosphate, metaphosphate, and polyphosphate), and as organically bound phosphates. The various methods of phosphorus detection do not all respond to the total phosphorus present.

Other applications are those specific to the control of phosphate addition to high-pressure boiler water as a corrosion inhibitor, and to the measurement of elemental phosphorus in the effluent from a plant that extracts phosphorus from ore.

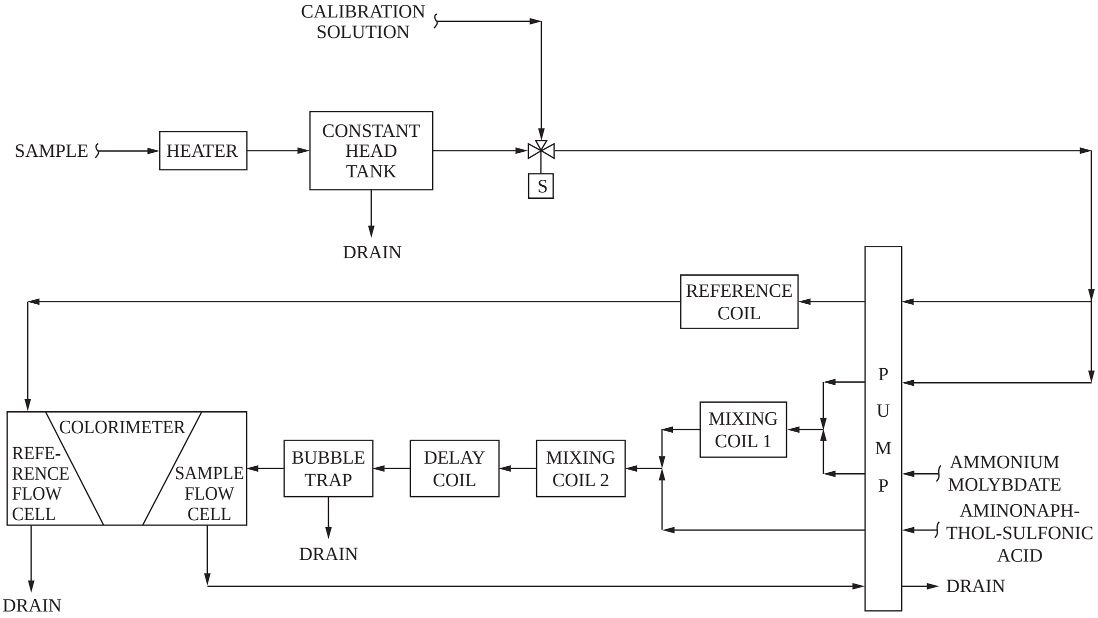

FIG. 8.49a
Orthophosphate analyzer.

COLORIMETRIC ANALYSIS

For a detailed discussion of colorimetric analyzers, refer to Section 8.15.

Laboratory Methods

Colorimetric procedures are available to determine the concentration of soluble orthophosphate. In the commonly used aminonaphtholsulfonic acid method[1] of analysis, ammonium molybdate reacts with a dilute phosphorus solution to produce molybdophosphoric acid. This acid is than reduced to the intensely colored complex, molybdenum blue, by the combination of aminonaphtholsulfonic acid and sulfite reducing agents.

The stannous chloride method,[1] although slightly more sensitive, is similar to the method just described except for the substitution of stannous chloride for aminonaphtholsulfonic acid as the reducing agent.

Continuous Analyzer

A continuous phosphorus analyzer consists of a sample temperature controller, a multiple peristaltic pump for reagent and sample metering, a mixing and time-delay section, reagent storage, a colorimeter, and an electronic readout section.

Referring to Figure 8.49a, the water sample is brought to a constant temperature to ensure uniform sample reaction and rapid response time. The sample stream is degassed in the constant head tank and divided into two paths, one for the reference sample and the other for the reaction sample. A multiple peristaltic pump meters the sample streams as well as the addition of ammonium molybdate and aminonaphtholsulfonic acid solutions.

The reaction and reference samples pass through separate delay coils. In one coil, which gives about a five-minute delay, the reaction sample and the reagents complete the color reaction; in the other delay coil, the reference sample is experiencing the same delay, in addition to the time that the reaction sample spends in the mixing coils. The sample and reference streams from the delay coils are fed into the dual flow cells of a dual-beam colorimeter. A bubble trap ahead of the colorimeter removes any bubbles formed in the analyzer.

The photodetectors sense the difference in color intensity between the reaction and reference samples. In this case, the molybdenum blue complex is measured at a wavelength of 6900 Å. The electronic section amplifies the colorimeter output and, if necessary, linearizes it. The use of a dual-beam colorimeter automatically compensates for the variations in inherent color or turbidity of the sample.

Total Phosphates

Total inorganic phosphate can be measured by first hydrolyzing the sample with sulfuric acid at 95°C (203°F). This converts the phosphates in the meta-, pyro-, and polyforms to orthophosphates. Total phosphates (inorganic plus organic) can be determined by an additional step consisting of oxidizing organic compounds (e.g., by boiling in potassium persulfate) to split off the phosphate moiety, which is then available for reaction. Instruments that use a single-beam colorimeter in either a continuous or batch-type analyzer are also available.

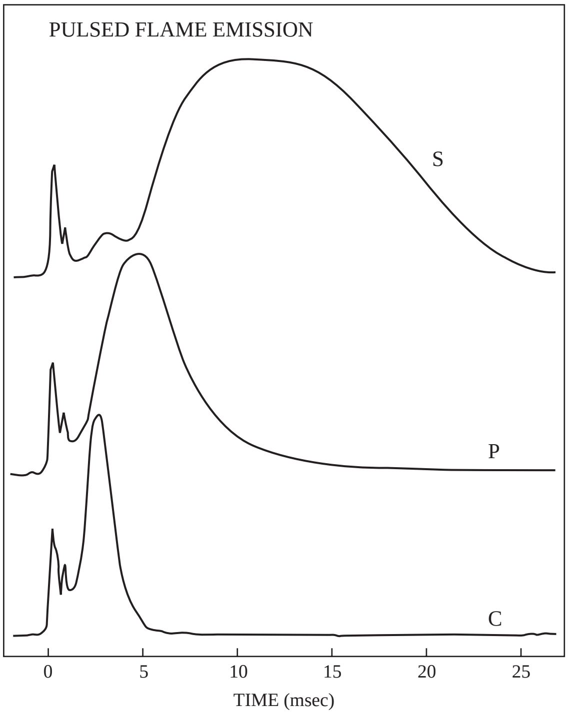

FIG. 8.49b
The separation in the time domain of phosphorus, sulfur, and carbon spectra. This PFPD analyzer provides infinite selectivity against haydrocarbon emission as well as unique heteroaton identification capability.[3]

FLAME PHOTOMETRIC ANALYSIS

This analyzer detects the photometric flame emission of phosphorous compounds in a hydrogen–air flame. This method was developed by Draegerwerk in Germany and was first applied to the detection of phosphorus compounds in air. As discussed in connection with Figure 8.12y, the method later was used as a detector for gas chromatography.[2] Still later, the pulsed flame photometric detector (Figure 8.12cc) was developed, which uses the pulsed flame characteristics of phosphorus shown in Figure 8.49b.[3]

Detector Operation

The detector in Figure 8.49c contains a burner with separate delivery tubes for hydrogen and the air sample. If phosphorus is present in the hydrogen-rich (reducing) flame, it will produce a strong luminescent emission between the wavelengths of 4850 and 5650 Å. This emission is at its maximum at 5260 Å and is isolated by a narrow bandpass interference filter.

The hydrogen and air are burned in a hollow tip that shields the flame from direct view of the mirror and photomultiplier tube. When phosphorus is present, the emission occurs above the shielded flame, and the light is transmitted directly and by way of the mirror through the filter to the photomultiplier tube. The shield offers specificity from carbon dioxide and hydrocarbons with flame emission at 5260 Å. The output from the photomultiplier tube is linear over several decades.

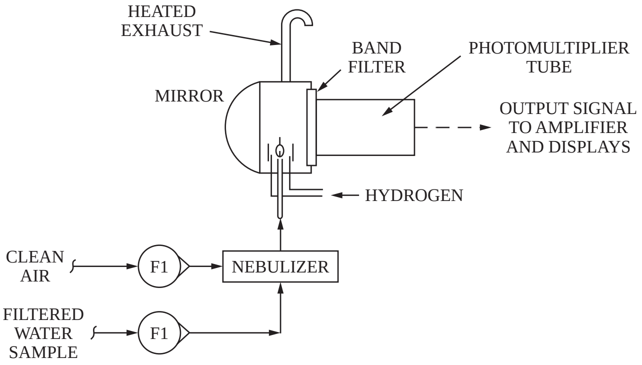

FIG. 8.49c
Flame photometric detector of phosphorus in water.

The detector can measure phosphorus in water by the addition of a nebulizer, which injects a mist of sample water into a clean air stream at a constant rate. The output is linear in the 1 to 100 ppm range.

GAS AND LIQUID CHROMATOGRAPHY

Where elemental phosphorus discharges into water, it has been found that a concentration of a few parts per billion is lethal to fish. Laboratory techniques[4] possessing this sensitivity have been developed.

The phosphorus is partially isolated by extraction in a suitable solvent such as benzene or isooctane. A portion of the extract is injected into a chromatograph utilizing a flame photometric detector. Mud and tissue samples can also be analyzed rapidly by this method.

SAMPLE-HANDLING SYSTEMS

The successful application of the phosphorus analyzers just described depends on reliable delivery of a well filtered sample. Such systems are discussed in Sections 8.2 and 8.65.

The system shown in Figures 8.49d and 8.49e is capable of handling raw sewage. The primary filter is of the motor-driven vane type with alternate stationary and rotating disks, and the clearance between the plates determines the degree of filtration.

The second stage of filtering consists of two disposable cartridge filters. A checkvalve diverts the flow to the second filter when the pressure drop across the first indicates that a change is necessary. The regulating pump between the filter stages ensures a constant flow rate in difficult determinations. Provision for backflushing the system is also advisable in some applications.

The selection of a good sample-handling system from the options discussed in Section 8.2 is just as critical as the selection of the analyzer itself. Provisions for convenient calibration are also an essential part of a complete and successful installation.

INTRODUCTION

This section deals with on-stream analyzers, which measure a physical property of a process stream. More specifically, on-stream analyzers are related to ASTM Standard Test Methods for refinery processes and products. Table 8.50a provides an overall orientation of the various physical property analyzers that are available.

Prior to the introduction of on-stream analyzers, analyses were done in the laboratory on periodic grab samples, and the results were reported to the process unit operator at some later time, permitting set point adjustments of parameters such as flow, temperature, pressure, and level. Continuous on-stream plant analyzers offer many advantages over laboratory analyses, including the characteristics enumerated below.

Advantages of Continuous Analyzers

1. Continuous measurement of the stream, eliminating long time lags
2. Reduction of errors caused by unrepresentative samples or by changes in sample composition caused by sample handling
3. Elimination of human errors characteristic of nonautomated laboratory procedures
4. Ability to recognize process trends, thus permitting the automatic control of a given process variable by closed-loop control
5. Cost reductions resulting from minimization of laboratory analyses
6. Closer control resulting in smaller tolerances in final product specifications and reduction in quality “give-away”
7. Feasibility of implementing in-line blending systems, which result in economic benefits resulting from the elimination of tankage, and from increased system flexibility and better quality control
8. Ability to provide continuous inputs to computerized process control systems for plant optimization
9. Direct measurement of process variables rather than detection of properties by inference

DISTILLATION ANALYZERS

Laboratory Measurements

Distillation analyzers were introduced to provide data on the volatility characteristics of process streams and separation efficiency of distillation units. ASTM Method D 86-IP-123 is the currently accepted laboratory standard for determining the boiling characteristics of petroleum products distilled at atmospheric pressure. The method employs a batch technique and approaches a single plate distillation process without reflux.

The petroleum products analyzed are complex mixtures of components, and a low level of fractionation is achieved. True boiling-point distillation, in columns with 15 to 100 theoretical plates and at reflux rations of 5:1 or more, produce greater separation of components. The apparatus and procedures for true boiling-point determination are not standard, are complex, take longer to perform, and are not as widely used.

Distillation curves for a few hydrocarbons are shown in Figure 8.50b along with a comparison of curves generated by ASTM Method D86-IP-123 and by true boiling-point determinations for kerosene.

ASTM Method D 86-IP-123 A sample is heated in an Engler flask at a prescribed rate. Packing is not used, and some refluxing occurs as a result of condensation (Figure 8.50c). The vapors that are produced flow through a condenser immersed in an ice-water bath, and the distillate is collected in a graduated cylinder. The initial boiling-point temperature is defined as the reading of the thermometer at the instant the first drop of condensate falls from the lip of the condenser tube.

As the higher boiling fractions vaporize, condense, and collect in the graduate, corresponding temperature readings are recorded to permit the plot of a curve of temperature vs. percent of sample recovered. The end point or final boiling point is described as the maximum thermometer reading observed during the test; it usually occurs when all the liquid has been boiled off from the bottom of the flask.

Usually, the percentage recovered does not equal the 100-ml sample charge, partly because of the inability of the apparatus to condense the lightest fractions. A curve of temperature vs. percent evaporation is determined by adding the percent of light ends lost to each of the recorded percentages recovered. The precision of this method is a function of the temperature change vs. boiling rate. Repeatability ranges from ±2 to 9°F (±1 to 5°C), and the reproducibility ranges from ±5 to 20°F (±3 to 11°C).

ASTM Method D 1160 This method provides for measurements under vacuums, ranging from 1 mmHg (133 Pa) absolute to atmospheric, to a maximum liquid temperature of 750°F (399°C). Results are not comparable with other ASTM distillation tests, although they may be converted to corresponding vapor temperature at 760 mmHg by reference to Maxwell and Bonnel vapor pressure charts.

TABLE 8.50a

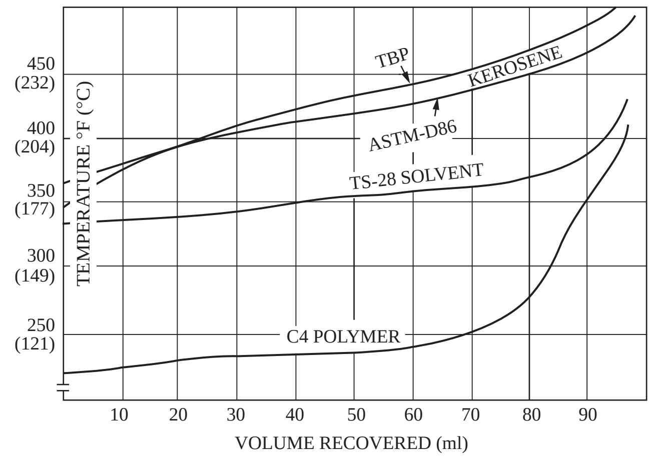

FIG. 8.50b
Distillation curves.

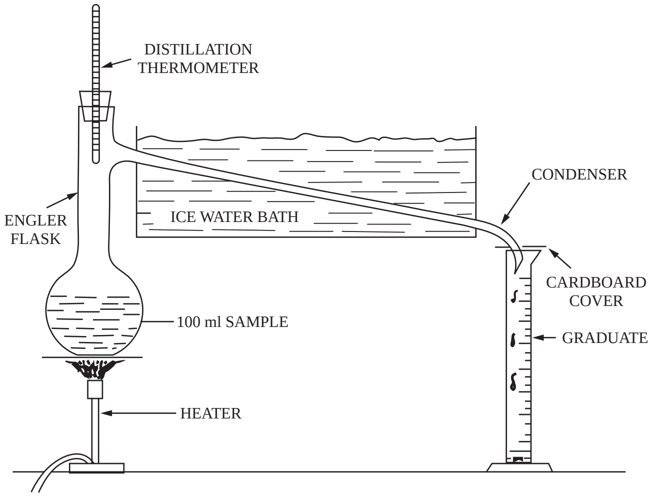

FIG. 8.50c
Apparatus for ASTM D 86 distillation test.

The sample must be moisture free and is equivalent to a volume of 200 ml at the temperature of the receiver in which the condensed overheads are collected. The sample charge is boiled at a rate that produces a recovered distillate of approximately 4 to 8 ml/min. The overhead vapors are condensed in a jacketed condenser and receiver in which the circulating coolant is maintained within ±5°F (3°C) in the range of 90 to 170°F (32 to 77°C).

Measurement of the vapor temperature is by a special Kovar$^{®}$-tipped thermocouple located at the side arm of the boiling flask leading to the condenser. Temperatures for the 5, 10, 20, 30, 40, 50, 60, 70, 80, 90, and 95% recovered volumes are reported unless the liquid's temperature, measured by a mercury in glass thermometer positioned in the boiling flask, reaches a value of 750°F (399°C). In such cases, the test is terminated and the percentage recovered is also reported.

Depending on the percentage recovered and the operating pressure, repeatability varies from ±8 to 10°F (±4.4 to 5.6°C), and reproducibility is from 15 to 30°F (8.4 to 17°C). This method required considerably greater skill to obtain optimal results and is more complicated than ASTM Method D 86-IP-123.

ASTM Methods D 2887–89, D 3710–88 These methods employ gas chromatographic analysis to determine boiling range distributions. D-2887 is for compounds that value an initial boiling point higher than 100°F (55°C) and a final boiling point less than 1000°F (538°C). Sample is injected into the analysis column, and the hydrocarbon temperature is raised at a repeatable rate during the analysis. The boiling-point temperature is related to time by injecting a calibration standard with known compounds and relating their boiling points to time.

The data gathered in this are not equivalent to data from ASTM D-86 or D-1160. Those are single-plate distillations. Results are close to those obtained by ASTM D 2892, true boiling-point chromatography. Repeatability as defined by ASTM is 3 to 12°F (2 to 7°C), depending on the value of the percent recovered. Reproducibility is 6 to 24°F (3 to 14°C) based on the value of percent recovered.

ASTM D-3710 is similar to D-2887 but is applicable to gasoline and gasoline components only. The maximum final boiling point is 500°F (260°C). Conditions are modified to allow discrete measurements of isopentane and lighter compounds. Temperature is related to time in the same manner. Repeatability and reproducibility are given as values based on the temperature/percent recovered slope and can range from 2 to 10°F (1 to 6°C).

On-Line Distillation Analyzers

Continuous plant distillation analyzers may be correlated with the results obtained by the ASTM laboratory methods, but they are not an exact duplication. In the laboratory (a batch technique), the temperature (of a given percentage that has been evaporated) is read off a rapidly rising vapor temperature as the sample is being evaporated, whereas, in the plant, the analyzer measures temperatures as a continuous process in which an equilibrium has been established for the given percentage evaporated to be monitored. This improves measurement precision but not necessarily accuracy, which depends on off-line analyses.

End-Point Distillation Analyzers As shown in Figure 8.50d, the analyzer is a miniature process unit. There are two modes of operation based on the desired measurements of the percentage, which is boiled off. The following description applies to analyses of boiled-off percentages of 50% and greater. A conditioned and pressure-regulated sample is delivered at a rate of approximately 4 gal/hr (15.2 l/hr) to the top of a packed column through an inlet valve.

The inlet sample flow rate is governed by a float in a boiling pot below the column, which maintains an essentially constant level in the pot. A radiant heater boils the sample

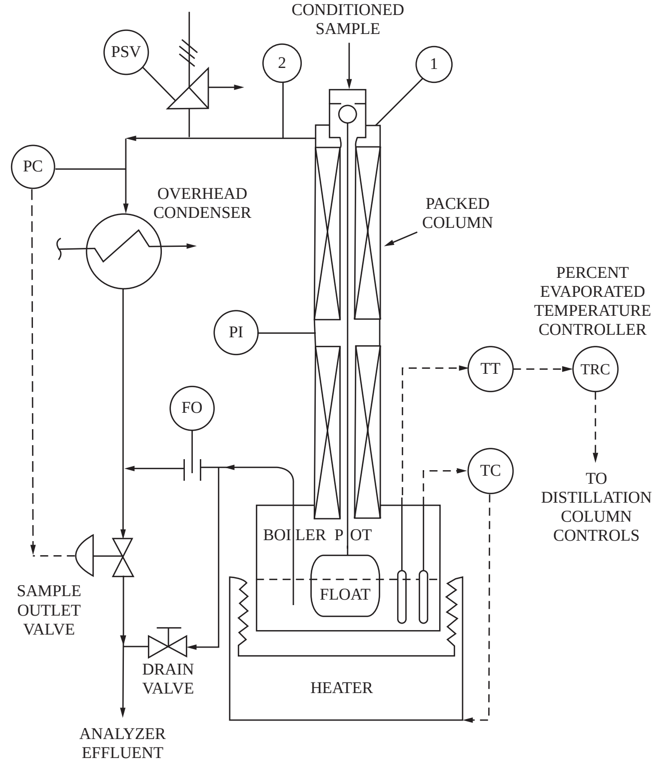

FIG. 8.50d
Packed column end-point analyzer. In an initial boiling point analyzer, the temperature is detected in location 1 and a restriction orifice is added in location 2.

in the pot under an elevated pressure, which is held constant. The overheads are condensed at these pressures. The bottoms' flow from the boiler pot is metered by means of restriction orifice upstream of the outlet control valve.

Because the orifice and the packed columns are subject to the same differential pressure, the ratio of overheads to bottoms is fixed. The orifice size and heater wattage are selected for the particular sample and for the percentage evaporated point to be monitored. The bubble-point temperature of the bottoms can be correlated with the percent evaporated point to be monitored. As the sample's percentage evaporated temperatures changes, the distillation process within the analyzers correspondingly adjusts the temperatures in the boiler pot.

For analyses of 50% boiled off and less, the analyzer operates in much the same manner. One difference is that the conditioned and pressure-regulated sample first enters a preheater coil at the top of the boiler pot and is then fed to the top of the packed column. However, a restricting orifice is located in the overhead line (at location 2) at the top of the packed column. Where required, a restrictor may also be used in the bottoms line.

A thermocouple in the overhead line (at location 1) at the top of the column measures the overhead vapor temperature and serves as the analyzer readout. By the suitable selection of restrictors and heater size, a given percentage of evaporated temperature between the 5% boiling point and the 50% point can be measured. Sample effluent may be returned to the process by an eductor or receiver and pump. A variation on this is a thin-film distillation analyzer that has the capability of measuring temperature at a set percentage boiled-off value or percentage off at a set temperature value.

Vacuum Distillation Analyzer Some hydrocarbon feedstocks have high boiling points or may decompose if boiled at atmospheric pressure. To avoid decomposition and to reduce the boiling point temperatures, the product may be distilled at a reduced pressure. Essentially, the same technique is used as shown in Figure 8.50d except that the column and boiler pot are operated under a controlled vacuum.

A conditioned and pressure-regulated sample enters the top of the column through a metering valve controlled by a float in the reboiler pot so as to maintain a constant sample level in the pot. The sample is preheated in a heat-exchanger above the reboiler pot before entering at the top of the packed column (Figure 8.50e).

A fixed-wattage radiant heater boils the sample. Overheads from the column flow through a water-cooled condenser from which a metering pump at a constant rate withdraws

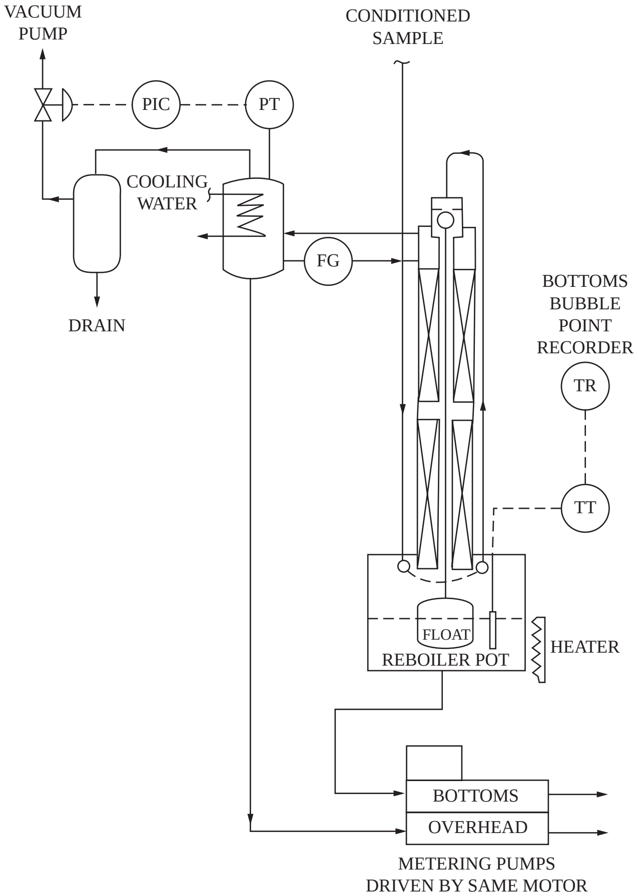

FIG. 8.50e
Packed-column vacuum distillation analyzer.

some of the condensate, and the remaining distillate is refluxed to the top of the column through an overflow tube.

A second metering pump withdraws the bottoms fractions at a constant rate so that the ratio of overheads to bottoms flow fixes the percentage evaporated material to be measured. Both gear pumps are driven by the same motor and maintained at a constant temperature by immersion in individually heated oil baths. A thermocouple in the reboiler pot measures the bottoms' bubble-point temperature, which may be correlated with ASTM Method D 1160.

A vacuum pump removes the noncondensable vapors from the system, a pressure controller modulates vacuum pressures, and a vacuum surge tank stabilizes the system to avoid excessive pressure fluctuation. If wide variations in product end points are expected, the heat input to the reboiler pot may be regulated by an autoformer in the heater circuit to avoid column flooding due to excessive refluxing. A sight glass in the reflux line permits observation of the reflux rate so that optimal column loading conditions may be established.

Horizontal Still Distillation Analyzer This analyzer, shown in Figure 8.50f, has two switch-selectable modes, the first of which permits the measurement of temperature at any preselected bottoms flow rate as a percentage of total sample flow rate through the analyzer. In the second mode, the percentage of bottoms to total sample flow at a specific temperature value is measured.

The distillation unit is an essentially horizontal still constructed with a series of baffles and weirs to promote separation of vapors and liquids at each compartment. The still is heated electrically. When the sample arrives at the last compartment, the vapor overheads and the liquid bottoms are at thermal equilibrium. A thermocouple in the bottoms section of the last compartment senses the temperature of distillation.

Vapor overheads leave the analyzer column at atmospheric pressure. They are condensed and pumped out of the analyzer system. The liquid bottoms are cooled, filtered, and then piped into a variable-speed pump system. Any escaping vapors from bottoms lines are condensed and returned to the bottoms pump. This prevents any significant losses in the volume of the bottoms product leaving the analyzer.

A differential pressure (dP) transducer continuously senses the level of the liquid bottoms at the suction side of the variable-speed pump. Heat exchangers ensure that the inlet pump and the variable-speed bottoms pump operate at the same sample temperature so as to minimize errors in flow measurement.

The voltage output of the dP transducer is generated by a voltage-to-frequency oscillator, which produces the pulse train that drives the stepper-motor-controlled variable-speed bottoms pump. In one control mode, the distillation temperature is preset, and the logic control varies the speed of the bottoms pump until a constant pump suction head is established. The capacity of the sample feed pump is fixed, and

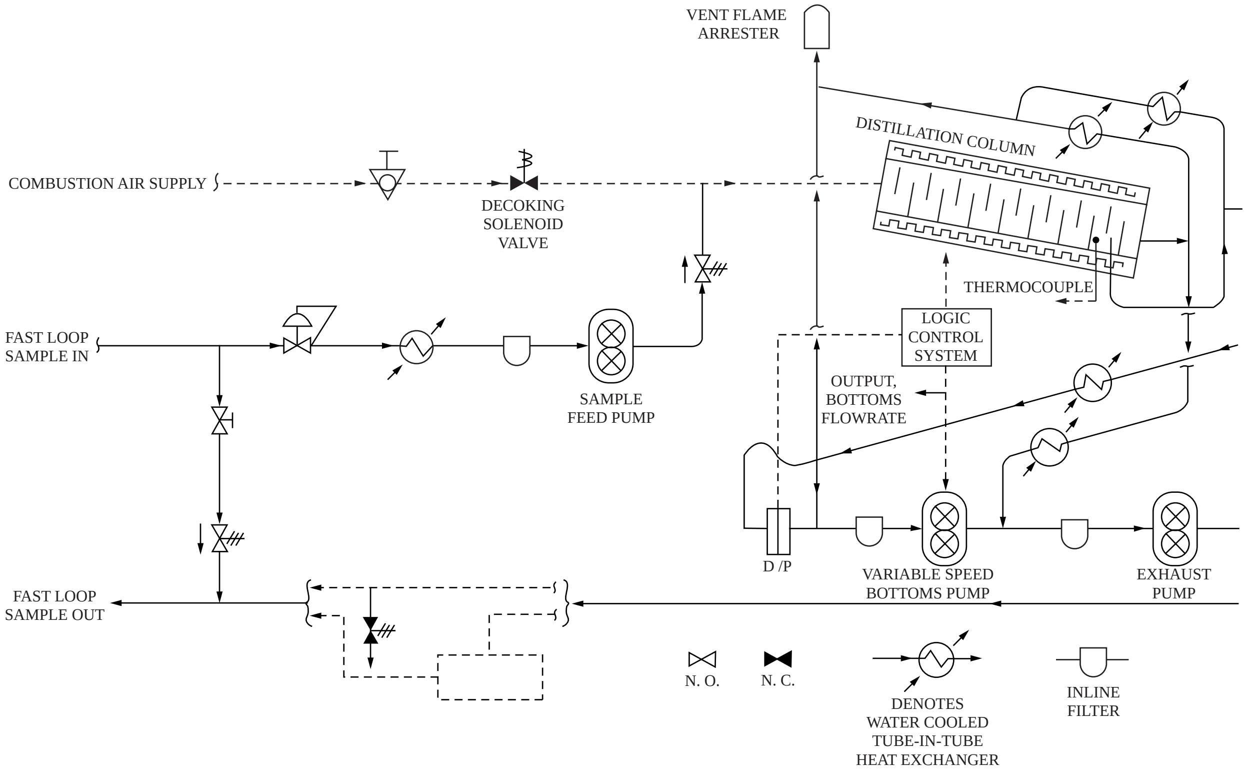

FIG. 8.50f
Horizontal still distillation analyzer.

the pulse rate of the bottoms pump is converted into an equivalent flow volume, permitting the computation of the percentage distilled at temperature. In the second mode, the desired speed of the bottoms pump is preset, thus establishing a specific bottoms percentage. The logic control then varies the voltage to the heater until a constant pump suction head is established at the bottoms pump.

Simulated Distillation by Gas Chromatography Temperature-programmed gas chromatography is discussed in Section 8.12 of this book. The analyzer injects a sample after the temperature-programmed oven has been cooled to ambient or subambient temperature, depending on the expected initial boiling point. The temperature is ramped at a set rate to a level necessary to elute all of the components present. The relatively nonpolar column elutes the sample to the detector in boiling-point order. The detector output is integrated with respect to a time–temperature relationship, and an output for the required temperature or percentage boiled off is calculated and provided as an output. Multiple outputs are available from this type of analyzer.

Calibration and Sampling

Techniques employed in the calibration of distillation analyzers are the standard sample method and the spot (or grab) sample method. In the latter method, a sample is drawn off the process line, and its properties are determined (standardized) by replicate tests using ASTM Method D86–IP–123. For ASTM Method D 86–IP–123, the standard sample is introduced into the analyzer, and the results are compared to the laboratory determinations.

Sampling systems include a reservoir tank for holding a standard sample and the means for its introduction into the analyzer. In addition to establishing a correlation between the analyzer readout and ASTM Method D 86-IP-123, it also serves to check analyzer performance in the event that its output is suspect. Care should be exercised to ensure that the standard sample remains stable and unaltered for the length of use.

The spot (or grab) sample technique involves the collection of samples at the analyzer without disturbing its operation and simultaneously notes the analyzer readouts with due compensation for the system response time. Analyzer readouts are then compared with laboratory determinations of the spot samples by ASTM Method D 86–IP–123. Again, care in collecting and handling the spot samples is of particular importance to ensure accurate results.

ASTM D-1160 calibrations are done in the same manner as for ASTM-86. ASTM D–2887 and D–3710 calibrations are done using a known mixture of straight-chain hydrocarbons as a way of setting the time vs. temperature relationship. The sample is injected and the area calculated for each time interval as defined in ASTM D-2887. The cumulative area for each time interval is calculated and divided by the total area and multiplied by 100. This is the percentage boiled off and corresponds to the temperature established for that point by the time vs. temperature curve established for the analyzer.

Applications

Distillation analyzers have significant use in the control of petroleum-refining processes. They have applications as varied as the production of fuel oils and the blending of gasolines, they are part of crude oil distillation units and alkylation units, and they are used for control of feedstocks and for control of the reflux ratio in fractionation towers.

Simulated distillation by gas chromatography (ASTM D-2887 and D-3710) is making large inroads into boiling-point measurement applications as it becomes more reliable and as refiners make the decision to use these measurements to control product quality instead of the laboratory-based D-86 method. They are primarily used on cut-point control and for blending component control.

VAPOR PRESSURE ANALYZER

Reid Method (ASTM Method D 323–90)

The vapor pressure of petroleum products, except for liquefied petroleum gases and fuels containing oxygenates, is usually determined by the Reid method as given by ASTM Method D 323–90. Sample handling is especially critical with very volatile products because of the hazard of loss of light ends. The method provides four different procedures based on specific applications.

Procedure A For products that have a vapor pressure less than 26 PSIA (179 kPa), a sample volume of a least 1 qt (0.95 l) but not greater than 2 gal (7.5 l) is collected and is placed as soon as possible in a bath maintained at 32 to 40°F (0 to 4°C).

The Reid vapor pressure (RVP) bomb consists of a liquid sample in a lower chamber that is coupled to an air chamber having a volume approximately four times that of the liquid and a Bourdon tube pressure gauge connected to the top of the air chamber. The liquid chamber is filled with a chilled sample and is quickly coupled to the air chamber with the attached pressure gauge.

The assembly is then immersed in a water bath maintained at 100 ± 0.2°F (37.8 ± 0.1°C). After a minimum of five minutes, the apparatus is removed and shaken vigorously, and the pressure is noted. It is then quickly reimmersed in the bath, and, at intervals of not less than two minutes, the procedure is repeated at least twice until two consecutive pressure readings are made that are within 0.05 PSI (0.35 kPa) of each other. This reading is reported in pounds RVP (PSIA). Although the pressure is approximately the true vapor pressure in PSIA for some products, it should be noted that RVP is lower than the true vapor pressure because of the loss of some light ends during sample handling.

Repeatability varies from 0.1 PSI (0.7 kPa) for products of 0 to 5 lb (0 to 22.5 kg) to 0.46 PSIA (3.2 kPa) for products having an RVP between 5 and 15 lb (22.5 and 67.5 kg). Corresponding reproducibility varies from 0.35 to 0.75 PSI (2.4 to 5.0 kPa).

Dry Reid Method (ASTM Method D 4953–90)

This method is a modification of ASTM D 323–90, adding the requirement that the interior surfaces of the liquid and vapor chambers be free of water. Oxygenated compounds would tend to go into the water phase and reduce the measured vapor pressure. The method also describes a semiautomatic method that has improved precision. Repeatability of the manual method is 0.72 PSI (5.0 kPa) and of the semiautomatic method is 0.26 PSI (1.8 kPa). The corresponding reproducibility is 1.0 PSI (7.3 kPa) and 0.94 PSI (6.5 kPa).

Liquefied Petroleum Gases (ASTM Method D 1267–89)

ASTM Method D 1267–89 for the determination of the vapor pressure of liquefied petroleum gases (LPGs) is usually performed at 100 ± 0.2°F (37.8 ± 0.1°C) but may be run at temperatures as high as 158°F (70°C). The use of this method is limited to products whose vapor pressure does not exceed 225 PSIG (111.6 MPa). Essentially the same apparatus is used as in the Reid method. The sample is not air saturated; however, 40% volume of the liquid sample is withdrawn from the completely filled bomb after a prescribed purging procedure to allow space for expansion of the product when it is immersed in the test bath.

The observed pressure is reported as LPG vapor pressure in pounds per square inch gauge pressure (PSIG) after corrections are made for gauge error and for standard barometric pressure at the test temperature. Repeatability is given as 1.8 PSI (12 kPa). Reproducibility is given as 2.8 PSI (19 kPa).

Air-Saturated Vapor Pressure Analyzer—Continuous

Sample is metered by a positive displacement pump at a rate of 100 cc/min through a heat exchanger immersed in a constant-temperature bath at 100°F (37.8°C) (Figure 8.50g). The sample is then sprayed into an air-saturation chamber, also immersed in the bath, where it is saturated with air. A float-controlled needle valve discharges the air-saturated sample and vapors into the vaporizing chamber and also maintains a constant level of liquid in the chamber.

The sample supply pump is double ended and designed so that the exhaust end withdraws a flow of 500 cc/min of liquid and vapor mixture from the vaporizing chamber, thus establishing the 4:1 liquid–air ratio prescribed by the RVP (ASTM D323–90) method. The pressure in the vapor chamber is sensed by a pressure transmitter, which has a calibrated output signal representing the RVP. The exhaust pump jacket is also maintained at the 100°F (37.8°C) bath temperature.

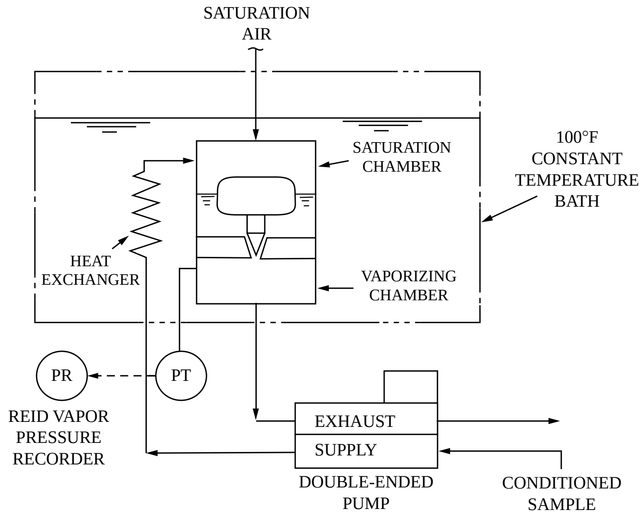

FIG. 8.50g
Air-saturated vapor pressure analyzer.

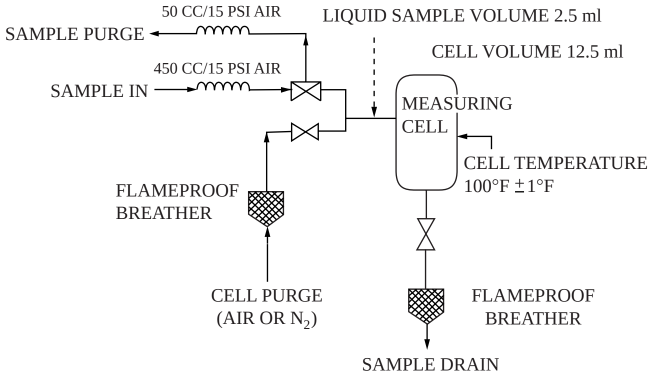

FIG. 8.50h
Cyclic, air-saturated vapor pressure analyzer.

Air-Saturated Vapor Pressure Analyzer—Cyclic

The analyzer uses a sample cell that is designed to meet the 4:1 vapor–liquid ratio. Temperature of the cell is controlled at 100°F (37.8°C) (Figure 8.50h). The analyzer first runs a fill cycle to flush out old sample. This is drained, and the cell is purged with air three times to dry it out. The air inside the cell is then allowed to come up to the cell temperature. Once again, the cell is filled with sample and allowed to come to equilibrium for three minutes. The pressure is measured and is compared to site elevation and a zero pressure measured when the cell was empty and an RVP value calculated. The cell is then drained for the start of the next cycle. The cycle time is about nine minutes.

Dynamic Vapor Pressure Analyzer

This analyzer may be calibrated to measure the vapor pressure of products covered by either ASTM Method D1267–90, ASTM Method D-4953, or ASTM Method DI267–90.

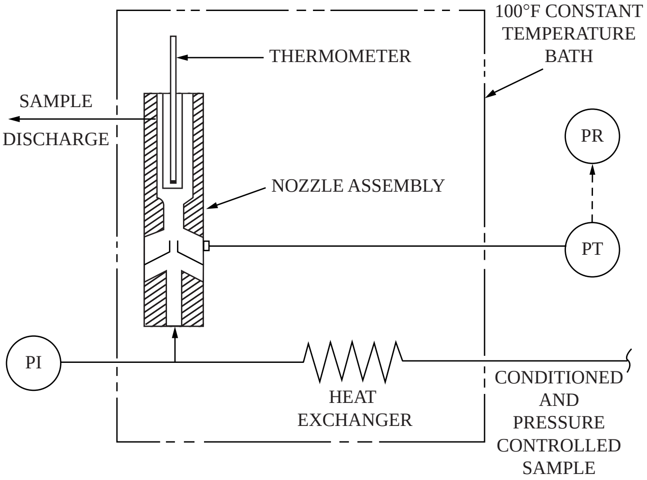

FIG. 8.50i
Dynamic vapor-pressure analyzer.

The analysis is continuous, and the sample effluent may be returned either to a pressurized line or to an atmospheric receiver tank. Incoming sample is filtered and maintained at a constant pressure (Figure 8.50i). The sample is brought to a temperature of 100 ± 0.1°F (37.8 ± 0.06°C) in the heat exchanger, which is immersed in the constant-temperature bath.

The sensing device is a modified jet pump element with the suction side dead-ended into the cell of an absolute pressure transmitter. The velocity of the sample in the small-diameter nozzle causes the pressure head to approach the vapor pressure of the least volatile component in the stream. This value is lower than the RVP, as determined by ASTM Method D323–90. By reducing the efficiency, the system simulates the selective vaporization, which occurs in the 4:1 liquid volume (vapor-liquid ratio) in the RVP test apparatus.

One of the parameters affecting the efficiency of a jet pump, eductor, or aspirator is the location of the tip of the nozzle with respect to the throat of the downstream venturi. By adjusting the location of the nozzle, the operating efficiency may be adjusted so that the analyzer readout provides an essentially one-to-one correlation with the RVP. Figure 8.50j shows the relationship of the analyzer results against RVP for various hydrocarbons and blends.

When the analyzer has to return the sample into a pressurized line, a backpressure regulator is added to maintain a constant backpressure on the system and thereby eliminate the effects of varying return line pressure. An inlet pressure of roughly 45 to 50 PSIG (311 to 345 kPa) is required when the analyzer is discharging to atmosphere and the inlet pressure regulator is set at 40 PSIG (276 kPa). When the sample is returned to a pressurized system, the inlet pressure regulator is set at a value equal to 2.5 times the return line pressure plus 40.

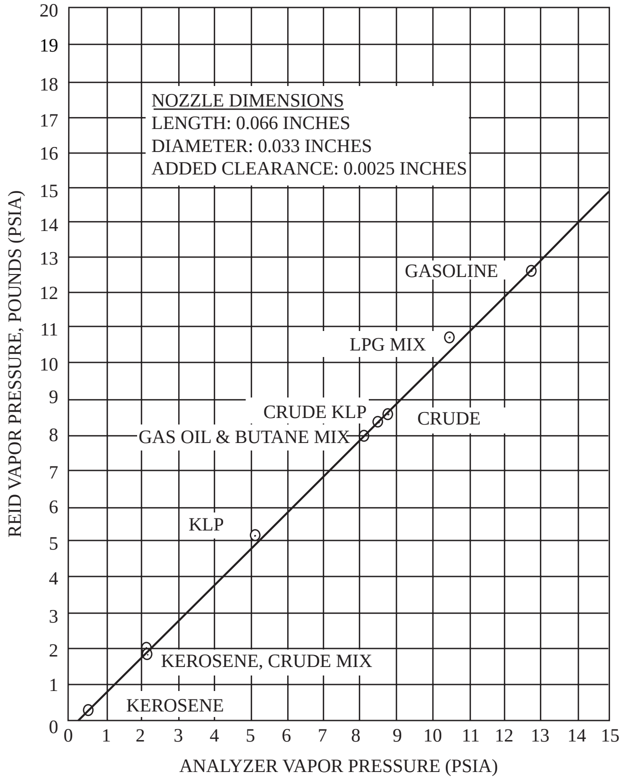

FIG. 8.50j
Dynamic vapor-pressure analyzer results.

Calibration

Calibration of the cyclic air-saturated analyzer is done using a special syringe and pure components. The pressure reading is compared to known values at the 100°F (38°C) cell temperature. The other analyzers are calibrated using the standard sample method and the spot (or grab) sample method, which are equally reliable if carefully performed.

Sample collection and handling are critical in both cases, as is the manner in which a stable and uniform standard sample is preserved during delivery to the analyzer. Standards used for the on-line analyzers should be pressured into the analyzers using a water-displacement system to prevent a vapor space from forming over the standard, thus reducing the standard accuracy.

Application

Recent environmental regulations are putting pressure on refiners to reduce the vapor pressure of gasoline components and therefore the vapor pressure of the product gasoline. This means that more of these analyzers will be installed at the crude, reformer, alkylation, and cracking units to control vapor pressure at the source. They have been used with LPG, but they have been used more extensively to monitor the vapor pressure of pipeline-transported products, thereby avoiding vapor-locking the pumps and minimizing safety hazards during tanker loading operations. They may also be used to detect product interfaces at pipeline receiver stations.

VAPOR-LIQUID RATIO ANALYZERS

Front-end volatility must be closely controlled in a gasoline blend to permit the greatest use of light blending components without incurring vapor lock during operation of a gasoline engine.

The vaporization of a fuel in the carburetor of an engine is predicable neither from distillation temperatures nor from pressure tests. The curves of Figure 8.50k shows how four different fuels (with some similar properties) exhibit different volatility characteristics as determined by measuring their vapor-liquid (V-L) ratios at various temperatures. In the past, front-end volatility was determined by employing indirect measurements such as the RVP; the 10, 20, and 50% evaporated temperatures; and the temperature corresponding to a given V-L ratio (usually 20). This procedure and the required computations are time consuming, cumbersome, and inaccurate.

Volatility Test (ASTM Method D 2533–90)

The laboratory technique determines the V-L ratio by direct measurement for a given reference temperature. ASTM Method D 2533–90 uses a special burette constructed with a stopcock at the top, 0.5 cc graduations, a short bottom arm fitted with a rubber septum, and a long bottom arm connected to a 250-ml leveling bulb by rubber tubing. The burette is filled with pure dry glycerin, and a sample of 1 cc or less is injected into the burette through the rubber septum by a hypodermic syringe.

The burette is then placed in a controlled-temperature bath. As the sample vaporizers, the 250-cc leveling bulb, referenced to atmospheric pressure through the drying tube, is raised or lowered to maintain absolute, which compensates for the prevailing barometric pressure. The volume of vapor is indicated on the beret's graduations, and, because the liquid volume injected is known, the V-L ratio can be calculated. Repeatability for a V-L ratio of 20 using glycerol as the burette fluid is ±4.8°F (2.7°C).

		EVAPORATED TEMPERATURE (°F)		
FULE	RVP	10%	30%	50%
①	8.9	121	153	194
②	8.8	127	199	238
③	8.1	133	177	224
④	6.5	143	175	207

Volatility effects on gasoline vaporization.

Continuous Vapor–Liquid Ratio Analyzer

Figure 8.50l shows a block diagram of the analyzer. A slipstream from a sample loop is conditioned and cooled to approximately 35 to 40°F (2 to 4°C) before it enters a metering gear pump. The differential pressure across the pump is controlled to guarantee the constant delivery of liquid sample to a vapor-liquid separator at a rate of 25 cc/min. The vapor-liquid separator is enclosed in a constant temperature bath controlled at the desired test temperature.

Vaporization occurs at or near atmospheric pressure, with the residual liquid phase being discharged through a liquid seal, and the vapors are measured by a low-pressure drop flowmeter. The meter is maintained at 200°F (93°C) to prevent condensation and to establish a temperature reference for vapor flow measurements. With the inlet liquid flow rate fixed, the V-L ratio may be computed after compensations are made for the vapor temperature and the barometric pressure. In addition to computing the V-L ratio, the deviation of V-L from a preselected V-L set point is also displayed and provided as an output signal.

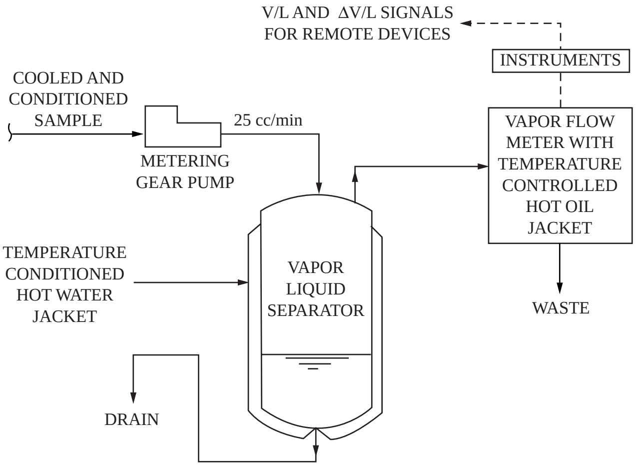

FIG. 8.50l
Continuous vapor-liquid ratio analyzer.

Calibration and Application

A V-L analyzer may be calibrated by the introduction of a sample of known volatility or by the grab sample technique.

These analyzers are primarily applicable to in-line gasoline blending operations. An in-line blending system offers both economic advantages and greater flexibility, speed, and ease in switching blend formulas to meet production requirements. Although precise metering systems provide the means for implementing an in-line blending system, the final blend properties are still only implied rather than precisely known. Vapor pressure alone or in combination with distillation characteristics has been shown to be insufficient to provide efficient control of front-end volatility, because of inaccuracies and lags.

The ability to control light components during blending to meet environmental requirements for volatility provides a very significant economic incentive. A V-L analyzer, in an in-line gasoline blending system, may be used to reset the set point of a butane flow control system.

POUR-POINT TEMPERATURE ANALYZERS

Pour-Point Test (ASTM Method D 97–87)

The standard laboratory procedure for measuring the flow characteristics of petroleum oils is given in ASTM Method D97–87. The sample must be heated without stirring to 115°F (46°C) or 15°F (83°C) above the expected pour-point temperature before starting the test. A thermometer immersed in a jacketed sample test jar and a cooling bath is used.

The cooling rate of the sample is fixed as it is examined at 5°F (3°C) intervals to ascertain whether it will flow when the test jar is tilted. When no sample movement is detected in the tilted jar after a five-second interval, the pour point is reported as 5°F (3°C) above the indicated temperature. All pour-point values are reported in multiples of 5°F (3°C). This point corresponds to a viscosity of about 500,000 cSt. Repeatability is given as 5°F (3°C) and reproducibility as 10°F (6°C).

Pour-point analyzers were developed in an attempt not only to automate a laboratory procedure for process control but also to improve the accuracy of such measurements.

Pour Point by Differential Pressure

This analyzer (Figure 8.50m) is cyclic in operation, with one cycle consisting of five basic sequences. The analyzer is programmed so that it resets to sequence no. 1 on startup or on interruption of any kind. The sequences are as follows:

1. *Forced drain sequence.* Power to the thermoelectric cooler (T/E) module is reversed, warming the cell and draining all of the residue.

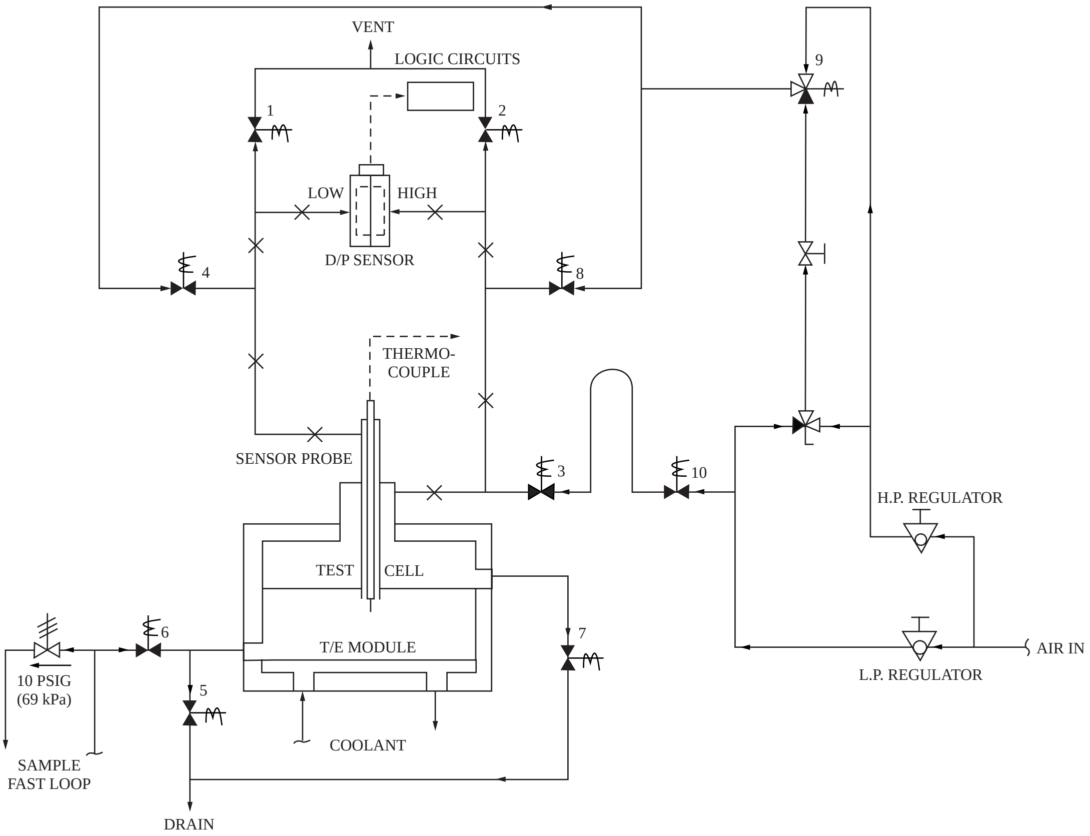

FIG. 8.50m
General pour pointer.

2. *Fill sequence.* The T/E module continues to heat the cell. Depending on product viscosity, either low- or high-pressure air is applied to the test cell while sample flows into the cell and out to drain by way of the overflow. This air pressure prevents the sample from entering the sensing lines of the analyzer.
3. *Level sequence.* Air is used to apply pressure to the surface of the sample and force surplus produce out to drain. Power to the T/E module is applied at normal polarity to initiate sample cooling. At termination of this sequence, all valves deenergize, and the sensing probe is submerged below the surface of the sample.
4. *Equalizing sequence.* The test cell, the differential pressure (dP) sensor, and all lines connecting these two components are vented to atmosphere, establishing a condition of zero differential pressure in the sensing system. At the end of this sequence, all valves close. Low-pressure air is held between two of the valves.
5. *Pulse sequence.* The low-pressure air trapped between valves expands into the test cell, producing a momentary pressure pulse against the surface of the liquid outside the sensor probe and against the high pressure diaphragm of the dP sensor. The output voltage of the dP sensor rises immediately, reflecting this pressure pulse.

The pressure pulse on the surface of the liquid also tends to push liquid into the sensor probe, compressing the air inside the probe. As the sensor probe is connected to the low-pressure diaphragm of the dP sensor, this results in a reduction of the output voltage of the dP sensor.

The control logic of the analyzer has a built-in fixed time delay that gives the sample time to compress the air inside the sensor probe after each pressure pulse. The output of the dP sensor is then compared to an adjustable set-point voltage. If the output of the dP sensor is below set point, another equalizing sequence and another pulse sequence occur.

As the sample cools, its resistance to flow increases, and its ability to compress the air inside the sensor probe decreases. This results in an increase of output voltage from the dP sensor. Eventually, this voltage exceeds set point. A peak-holding relay trips, and the analyzer resets to the forced drain sequence to begin another cycle. A thermocouple installed inside the sensor probe measures the sample temperature at all times. Pour-point temperature is the lowest temperature attained in each measurment cycle.

Viscous-Drag Pour Pointer

Sample flows into a 23-ml cup in which an alloy ball is suspended. A thermocouple is attached to the surface of the ball to sense sample temperature. A thermoelectric cooler removes heat from the sample as the cup turns. When the sample reaches the pour point, the viscosity is great enough to turn the ball, deflecting a light beam that is aimed at the ball and reflected to a detector. The analyzer notes the temperature and then adds 5°F (3°C) to the value to conform to the ASTM requirements. After the pour point is sensed, power to the thermoelectric module is reversed. The sample is heated and flushed out prior to initiation of the next cycle.

Calibration

Either the standard or the grab sample method is suitable. The convenience of a locally available standard sample provides a rapid check on the analyzer performance as well as serving as a means of calibration. The greater initial cost for this feature should be weighed against the delay incurred in obtaining a laboratory analysis of the spot sample.

The repeatability of ASTM Method D 97–87 for pour point is only about 5°F (2.8°C), and its reproducibility is only 10°F (5.6°C). To improve the accuracy of the ASTM results, a sufficient number of determinations is advisable, because the precision of the process analyzer usually exceeds the accuracy of the laboratory method.

Application

Pour-point temperature measurements are used to characterize the heavy end of fuel oil cuts from vacuum and atmospheric distillation processes. Fuel oil grades 1 through 4 are affected by these specifications. When a product is sufficiently free of wax that a cloud-point determination becomes meaningless, the pour point may be used as an index of the temperature at which flow will be impeded due to semi-solidification rather than by the formation of wax crystals.

CLOUD-POINT ANALYZERS

Cloud-Point Tests (ASTM Method D 2500–88)

This method is applicable to products with a cloud point below 120°F (49°C) that are transparent in a layer 1.5 in. (37.5 mm) thick. A cylindrical, flat-bottomed, clear glass test jar 1.25 in. (31.3 mm) in diameter by 4.75 in. (118.8 mm) long, and having a scribed sample fill line 2.125 in. (53.13 mm) above the inside bottom surface is used. A cork holds a thermometer coaxially in the test jar so that its bulb rests at the bottom.

A watertight jacket with an 0.25 in. (6.25 mm) thick cork or felt pad at the bottom holds the test jar when it is immersed in a cooling water bath. The sample must be dried at a temperature at least 25°F (13.9°C) above the approximate cloud point so as to remove any moisture and minimize trace water-haze formation. The test jar is fitted with a cork or felt ring approximate 0.1875 in. (4.69 mm) thick, which is positioned 1 in. (25.4 mm) from the bottom to keep it centered in the jacket.

The test is begun by placing the jar vertically in a 30 to 35°F (–1.1 to 1.7°C) water bath so that the jacket projects no more than 1 in. (25.4 mm) from the bath liquid. At intervals of 2°F (1.1°C), the jar is quickly but gently removed and examined for formation of a wax haze. (This examination should take 3 sec at most.) A water haze is generally uniform throughout the sample, whereas a wax crystal haze always appears first at the bottom of the jar.

If the cloud point is not detected when the sample reaches 50°F (10°C), the sample is transferred to a second bath, which also contains a test jacket, and is maintained at 0 to 5°F (–17.8 to –15°C), and the test is continued. Successively lower temperature baths are used as required for low-temperature cloud-point products. The temperature at which a distinct wax haze is first observed, expressed in increments of 2°F (1°C), is reported as the cloud point. For gas oils, repeatability is 4°F (2°C), and reproducibility is 8°F (4°C). For other oils, both repeatability and reproducibility are 10°F (5.6°C).

Optical Cloud-Point Analyzer

The cloud-point analyzer (Figure 8.50n) detects the temperature at which wax crystals first appear as a liquid hydrocarbon sample is cooled. A measuring cycle begins when a three-way solenoid valve, which normally circulates a slipstream sample, is energized and introduces sample into the test cell. After the cell is flushed clear of all residue from a previously tested sample, the solenoid valve deenergizes, and a thermoelectric module reduces sample temperature until the analyzer detects the presence of wax crystals. At that point, the cloud-point temperature is represented as the lowest temperature the sample attains, as measured by a thermocouple, and the next measuring cycle is initiated.

The detection system is based on a light beam that is directed through a polarizing lens, through the sample cell and a second polarizing lens, and into a photocell. The electrical resistance of the photocell varies with the amount of light to which it is exposed.

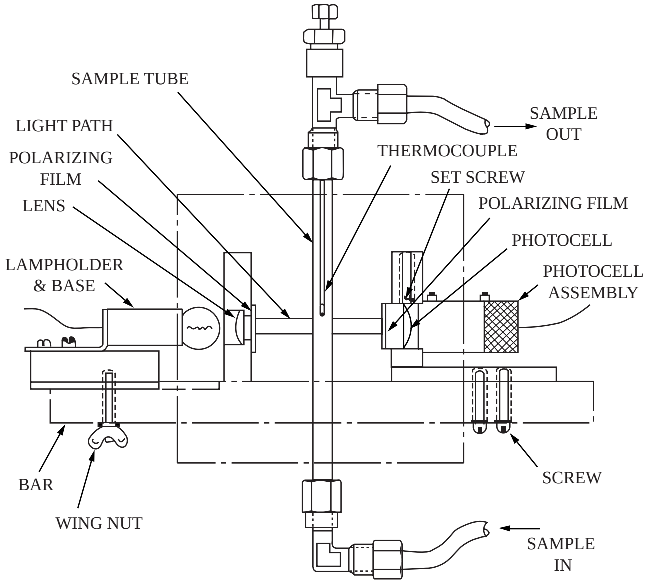

FIG. 8.50n
Optical cloud-point analyzer.

Polarizing lenses permit only light vibrating in a single plane to pass through them. For example, light rays may be controlled so they vibrate only in a vertical plane if the transmission axis of the lens is vertical. If two lenses are installed so that the axis of light transmission of the second lens is perpendicular to that of the first, no light rays will pass through the second lens. The test cell lenses are assembled in this manner, and the photocell senses the presence of light.

As the sample is cooled, it eventually reaches the temperature at which crystals of ice and/or wax appear. These crystals reflect some light rays and bend others so that the plane of vibration of some light rays changes as they pass through the crystals. Some of this reoriented light then passes through the second polarizing lens and to that photocell.

Ice crystals are doubly refractive. As light rays pass through them, ice crystals will change the path of the light rays several times. However, ice crystals have very low refractive angles, so they do not seriously affect the critical direction of the light rays as they approach the second lens. Wax crystals are also doubly refractive but have very high angles of refraction and, therefore, have a very pronounced effect of the light rays passing through them.

The photocell, which senses little light passing through a crystal-free sample, will detect quantities of light rays passing through the lenses as a result of the presence of ice crystals and very large quantities of light as a result of the presence of wax crystals. The photocell, therefore, signals the first appearance of wax crystals by a significant change in its electrical resistance.

Calibration and Application

The technique used to calibrate pour-point analyzers is also used to calibrate cloud-point analyzers. The measurement of the cloud point applies only to petroleum oils that are transparent in layers 1.2 in. (37.5 mm) thick and contain paraffin waxes or other compounds capable of forming crystals prior to total solidification. Its major application has been to gas oils and cycle oils not only to meet specifications but also to facilitate product transport and to prevent filter clogging during cold weather.

FREEZING-POINT ANALYZER

Aviation Fuel Tests (ASTM Method D 2386–88)

The freezing point as defined by this method is the temperature at which the last hydrocarbon crystal (formed during cooling) melts after the sample temperature is allowed to rise. This temperature must be within 3°C (5.4°F) of the temperature at which the appearance of hydrocarbon crystals is first observed.

A jacketed clear-glass tube is filled with either dry air or nitrogen at atmospheric pressure. The tube's outer diameter (OD) is 30 mm, and the tube's inner diameter (ID) is 18 mm, with a 2-mm space between tubes. The overall length is 237 mm. The plug in the sample tube holds a total-immersion thermometer and a stirring rod formed with three spiral loops at the bottom and positioned slightly below the thermometer bulb. The tube is filled with 25 cc of fuel and placed in a clear vacuum flask (70 mm ID and 280 mm long) containing a coolant such as alcohol or solid carbon dioxide.

The sample is stirred vigorously during cooling, and the temperature at which hydrocarbon crystals first appear is noted, ignoring any haze that may form at about 14°F (–10°C) as a result of dissolved water in the sample. The sample tube is then removed and allowed to warm up slowly while the sample is continuously stirred. The temperature at which the last crystal disappears is reported as the freezing-point temperature, provided it is within 3°C of the crystal formation point temperature. Otherwise, the test must be repeated. Results are reported in increments of 0.9°F (0.5°C). Repeatability is 1.8°F (1°C) and reproducibility is 4.5°F (2.5°C).

Freezing-Point Analyzer for Aviation Fuel

The principle of measurement is exactly the same as that of the cloud-point analyzer. The sample cell is cooled by a mechanical refrigeration unit, which is supplied with the analyzer. At detection of the cloud point, the power to the thermoelectric module is removed, and the sample is allowed to warm up. As the crystals disappear, the light falling on the photocell is reduced. Once the light falls below a threshold level, the cycle is terminated, and the freeze-point value is updated.

Calibration and Application

Calibration of the fuel analyzer variation should be based on the comparison of analyzer readouts with multiple laboratory test results. Its principal application is in the processing of aviation fuels such as JP-4, kerosenes, and similar products. Determination of purity is needed in the production of benzene, toluene, ethylbenzene, o-xylene, p-xylene, and phthallic anhydride. These materials must be able to be supercooled and have a specified freezing-point temperature.

Calibration of hydrocarbon purity analyzers is best achieved by using a sample of known purity. A certified standard thermistor may also be used if a sample of known purity is unavailable. Comparison with the ASTM methods can also establish the purity of a sample, which can then be used for analyzer calibration.

FLASH-POINT ANALYZER

Flash-Point Tests (ASTM Methods D 56–90 and D 93–90)

Plant analyzers are intended to correlate with ASTM Method D 56–90 (Tag closed tester) and ASTM Method D 93–90-IP-34/85 (Pensky–Martens closed tester). ASTM Method D 56–90 is for materials with a viscosity less than 5 cSt at 104°F (40°C) and a flash point below 299°F (93°C). A sample of 50 cc is used at a temperature of at least 20°F (11°C) below the expected flash point.

The sample cup is immersed in a bath whose temperature may be raised at a prescribed rate. Thermometers measure the bath and sample temperature. The sample lid prevents loss of sample vapors and directs a small flame into the cup periodically. The flash point is defined as the lowest sample temperature to cause ignition of the vapor above the sample at 1 atm absolute.

Repeatability is 2°F (1.1°C) for flash points below 140°F (60°C) and 3°F (1.7°C) for flash points between 140 and 190°F (60 and 93°C). Reproducibility is 6°F (3.3°C) for flash points below 55°F (13°C), 4°F (2.2°C) for flash points between 55 and 139°F (13 and 59°C), and 6°F (3.3°C) for flash points from 140 to 190°F (60 to 93°C).

The Pensky–Martens closed tester is for materials with an indicated flash-point temperature as high as 698°F (370°C). Approximately 4.2 in.^{3} (6.7×10^{-5} m^3) of sample is used, and the sample cup is heated directly by either a gas or electric heater at a prescribed rate. The sample cup lid is designed to support a sample stirrer, a mercury-in-glass thermometer, and an apparatus for periodically exposing the vapor above the sample to a test flame. The repeatability is 10°F (5.5°C) for materials with a flash point above 220°F (104°C) and the reproducibility is 15°F (8.5°C).

Low-Temperature Flash-Point Analyzer

Sample is fed to the analyzer's heating chamber at a constant rate, and air is added at a rate of 600 cc/min (Figure 8.50o). The air-sample mixture is heated at a controlled rate before it enters the flash cup and overflows to maintain a constant level. The vapor rises into the vapor space and is periodically exposed to a high-voltage spark. Thermocouple 1 in the flash cup measures the temperature of the air-sample mixture, and thermocouple 2 in the vapor space responds to the temperature rise when vapor ignition occurs.

When the sample is heated to its flash point and its vapor ignited, the temperature in the vapor space increases. This shuts

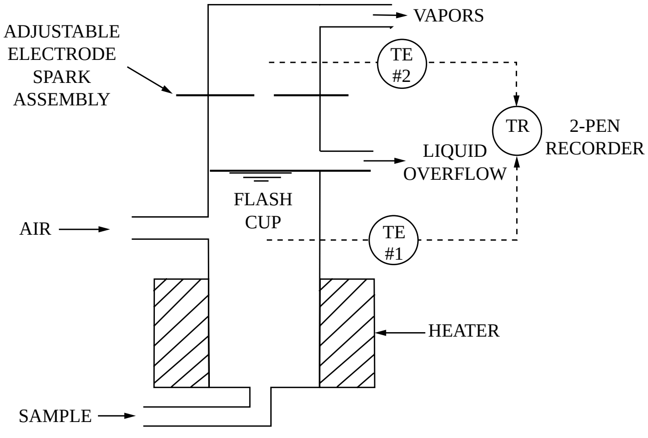

FIG. 8.50o
Low-range flash-point analyzer.

the heater off and causes recorder pen 1 (to which thermocouple 1 is connected) to be driven downscale. The peaks of the resulting sawtoothed record indicate the flash-point temperature for each analysis cycle.

This design is mounted on a frame with all accessory components piped and wired for field installation. The accessories include (1) a sample conditioning system to filter and coalesce free water from the sample, regulate sample pressure, and indicate coalescer bypass flow, (2) a mechanical refrigeration system and temperature controller to cool the sample below its flash point, (3) an air compressor, filter, and flowmeter to supply combustible air, (4) a duplex positive-displacement pump to provide a constant rate of sample flow to the analyzer and return analyzer effluent and coalescer bypass to the pressurized process line, and (5) block, check, relief, and backpressure valves for isolation and the ability to withdraw sample for calibration.

High-Temperature Flash-Point Analyzer

Sample from a slipstream is metered to the system at a constant rate by one head of a duplex positive-displacement pump and is preheated to a fixed temperature below the flash point as determined from the preceding analysis. It is mixed with air at a rate of 1500 cc/min. A final heater provides the additional heat required to bring the air-sample mixture to the flash-point temperature. The liquid entering the flash chamber is returned to process by the second head of the duplex pump, and the rising vapors are exposed to a high-voltage spark every 10 sec.

Ignition is detected by the deflection of a diaphragm caused by the combustion pressure pulse. The control circuit increases or decreases the final heater output depending on whether ignition has occurred. At the same time, the preheater controls are also adjusted to maintain the desired temperature differential. Flash-point temperature is sensed by a thermocouple in the flash chamber liquid and displayed on a recorder chart.

Calibration and Application

Either the spot sample or standard sample method may be used. In either case, care must be exercised when a low-flash-point sample is used so as to prevent loss of light ends. The analyzer can be applied to the control of crude and vacuum distillation, dewaxing, solvent extraction and stripping, deasphalting, blending, residual fuel oil processing, and pipeline interface detection.

OCTANE ANALYZERS

Laboratory Tests (ASTM Methods D-2699 and D-2700)

Treatment of this subject will be brief because of the vast complexity involved. Basically, two methods are employed in which in a standard engine with an unknown fuel is compared with a standard or reference fuel. One method (ASTM Method D-2699) yields a motor octane number (MON) in which the engine is run at 900 rpm, and the second method (ASTM Method D-2700) provides a research octane number (RON) in which the engine is run at 600 rpm.

The difference in octane number obtained by these methods (the spread) is indicative of city driving at low speeds as compared to highway engine performance. Standards fuels are based on normal heptane (zero rating) blended with isooctane (100 rating), with the octane number equal to the percentage of isooctane in the blend. When the unknown fuel produces the same knocking as a standard fuel blend, it is rated equal to the octane rating of the standard blend. The RON is higher than the MON, with the spread increasing with increasing octane numbers.

Standard Engine Octane Comparator Analyzer

These analyzers are based on ASTM Method D-2885, an online comparator system, using a standard engine with a modified carburetor fuel delivery system and standard detonation pickup and knockmeter. Comparison is made between the process stream and a prototype fuel, which serves as the standard or octane number reference point from which an octane number difference is determined as the analyzer readout. Figure 8.50p illustrates the equipment diagram for such an analyzer.

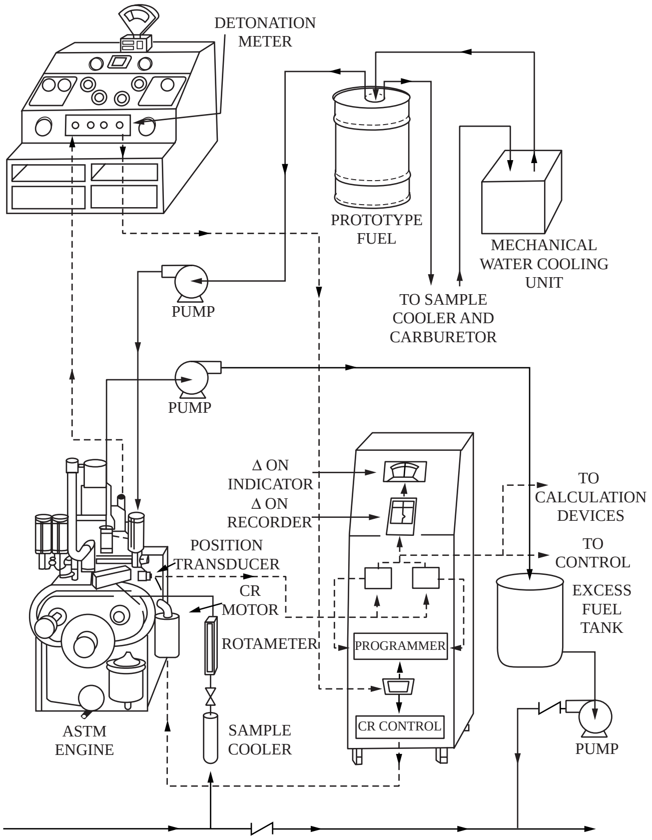

FIG. 8.50p
Octane analyzer equipment.

System accuracy depends on the performance of the standard engine, which must be properly maintained for optimal system operation. Also, the prototype fuel octane number should be determined to within ±0.1 ON (octane number) or better, because it serves as the reference for stream comparison measurements.

Reactor-Tube Continuous Octane Analyzer

This analyzer monitors the reactions that precede engine knocking, the parameters of which may be controlled and correlated with octane number. A fuel and controlled air volume mixture is delivered at a rate of 1 cc/min to a reactor tube maintained at an elevated temperature. Partial oxidation reactions in the tube produce a peak temperature, the location of which is related to octane number.

Higher-octane fuels cause the peak temperature to move away from the tube inlet, whereas increasing the reactor tube pressure moves the peak closer to the tube inlet. Consequently, if the temperature peak location is fixed by varying the reactor tube pressure as fuel octane number varies, the pressure may be correlated with octane number and used as the analyzer readout. This is accomplished by locating two thermocouples in the tube 1 in. (2.54 cm) apart and equidistant from the temperature peak. Any movement of the peak due to a change in fuel octane rating is sensed by a differential temperature controller and causes a compensating change in reactor tube pressure to restore the temperature peak location.

Calibration and Application

The on-line comparator engine automatically calibrates itself by running the proto fuel during its operation. The reactor tube analyzer requires a similar source of calibration gasoline of known octane.

These analyzers can trim octane *give-away* during blending to approximately 0.1 octane above specification requirements. A more important application is to measure the octane of blending components such as reformate, alkylate, and catalytic cracked gasolines so that these units optimize their production.

NEAR-INFRARED ANALYZERS

A detailed description of this category of analyzers is presented in Section 8.27. Near-infrared (NIR) analyzers do not directly measure the physical properties, such as boiling, pour, or flash points. Instead, a model is utilized that provides a relationship between the property of interest and the absorption of near-infrared radiation at one or more wavelengths in the spectrum, which is measured by the analyzer. Consequently, the NIR analyzers represent a secondary technique of measurement.

Chemometrics

Today's powerful microprocessors operating in combination with CCD detector arrays make it possible to capture a full spectra of light vs. one wavelength. In addition, rugged fiber optic probes (Section 8.23) make it possible to measure composition and other process properties by detecting the changes in spectra. The approach used in modeling these relationships is called *chemometrics* and is now an entire field of study for chemists and statisticians. Chemometrics uses mathematical tools and algorithms such as partial least squares (PLS) to assist in identifying correlation between the often small changes in the received spectra and the property of interest. The most commonly used part of the spectrum used for these measurements is the near infrared.

The process of finding such correlation involves the comparison of a large number of process samples that are measured by conventional means while their NIR spectrum is also measured. It is critical that the sample set cover all representative operating conditions that are expected during the operation of the plant; the model is only as good as the data on which it is built. The confidence level of predicting the correlation outside the bounds of the sample set is still relatively low.

Once sufficient samples and spectra have been gathered, this data set is divided into a modeling data set and a validation data set. (One must not use the same data to prove a model as one did to create it, or it is not really a test.) The modeling set is then mathematically manipulated, often taking first and second derivatives of the spectra as a form of *normalization* and to reinforce the magnitude of the changes between the separate wavelengths measured, and compared against the change in the actual data. The software and operator are normally able to identify a combination of wavelengths that vary in a predictable way against the modeling data set. This can be that one wavelength increases while another decreases, that the ratio of two wavelengths changes, or a combination of these affects.

After a model has been identified, it is tested against the validation set to confirm that it indeed predicts the property of interest reliably. If it does, it is ready to be installed in the field and used for process control.

Calibration and Application

The calibration of these analyzers is valid only over the range of the model for which the relationship was established. Therefore, to avoid errors, one should not extrapolate beyond this range. Because of the flexibility of this technique, it has been applied to most of the physical property measurements discussed in this section.

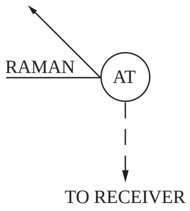
8.51 Raman Analyzers

R. MANOHARAN, N. K. SETHI (2003)



Flow Sheet Symbol

Process Fluids:	Liquids, powders, slurries, emulsions (gases)
Operating Pressure:	Analyzer (ambient), sample interface (3000 PSI)
Operating Temperature:	Analyzer (0 to 50°C), sample interface (350°C)
Humidity Limitations:	20 to 100% noncondensing
Calibration Transfer:	Intra-analyzer transfer after maintenance and transfer between analyzers
Sample Interface:	Invasive, noninvasive
Wetted Material:	Stainless steel, titanium, Hastelloy® and Kynar® probe body, sapphire and quartz windows or lens
Fiber Optics:	Low-hydroxy silica, multimode fibers, hundreds of meters
Update Time:	A few seconds to minutes
Online Analysis:	Yes
Warm-Up Time:	60 min
Measurement:	Continuous
Repeatability:	0.1% or less
Linearity:	Over the entire measurement range
Laser Safety:	Required
Costs:	Analyzers for process applications cost $60,000 to $150,000, depending on the packaging, ruggedness, availability of analyzer standardization, and availability of simultaneous multichannel capability. A benchtop, low-resolution Raman instrument costs $20,000 with probes and other accessories. Laboratory Raman instruments cost $50,000 to $100,000, depending on the technology (dispersive or FT-based) and also available sampling accessories. Optical fibers for process installation cost $15 to $30 per foot per channel (consisting of three cables), depending on the packaging options. The fiber optics probe costs $2,000 to 15,000, depending on the application requirements and required ruggedness.

INTRODUCTION

Raman analyzers can be considered for applications in which infrared (IR) or near-infrared (NIR) detectors are suited for making the measurement. The cost of a Raman process analyzer typically exceeds that of other analyzers. Therefore, gas chromatography is preferred to Raman spectroscopy except in cases where continuous and fast readings are more important than cost and precision. Raman technology is distinctly advantageous for the analysis of viscous liquids such as polymer melts.

This section describes Raman spectroscopy for process control measurement and analysis. The first part of this section deals with the principles of Raman spectroscopy. Next, the technological developments that transformed Raman spectroscopy from an esoteric laboratory technique into an industrial process analytical tool are presented and the components of the Raman process analyzer are described in detail.

Following this discussion, the benefits of Raman spectroscopy are compared with near-IR and mid-IR absorption spectroscopy methods. Finally, the industrial process applications of Raman analyzer technology and its future directions are discussed.

PRINCIPLES OF RAMAN SPECTROSCOPY

Optical Spectroscopy

In optical spectroscopy, light from a source is allowed to impinge on the sample to be examined. Molecules in the sample respond to the incident light by absorbing, scattering, or changing the energy of photons. Optical spectroscopy is the analysis of change between the incident and return light. Optical spectroscopy can be used to detect, identify, characterize, and quantify chemical components in the sample.

Vibrational spectroscopy, where the light characteristics change as a result of various modes of molecular vibrations, is the most powerful form of optical spectroscopy methods for providing quantitative chemical information. Near-infrared absorption, mid-infrared (IR) absorption, and Raman scattering are three major forms of vibrational spectroscopy methods.

NIR and IR spectroscopy methods will not be discussed here, and the reader is referred to Section 8.27 of this handbook for an in-depth discussion of these analyzers. Although reference to NIR and IR methods is essential when discussing the merits of Raman spectroscopy, the focus of this section is on the use of Raman scattering for chemical analysis and process applications. An in-depth theoretical discussion of Raman spectroscopy can be found in References 1 through 3; a brief description of the principles of Raman spectroscopy is provided here.

Principles of Raman Scattering

A pictorial description of the Raman scattering process is shown in Figure 8.51a. When monochromatic light interacts with molecules, most of the photons are scattered without any change in energy.* This process is called elastic or Rayleigh scattering, and it occurs when the electrons in a molecule oscillate in resonance with the applied electric field of the incident light. However, a small number of photons (1 out of 10^6 to 10^9) are inelastically scattered and undergo a change in energy.

The inelastic scattering process is called *Raman scattering.* The change in photon energy occurs because, during the time the electrons oscillate in resonance with the applied electric field, a molecule may vibrate. A vibrational mode that changes molecular polarizability (dipole moment induced by electric field) results in a change of incident photon energy. The difference in energy between the incident photons and inelastically scattered photons is called *Raman shift*. A plot of the intensity of the inelastically scattered light as a function of the energy change is called *Raman spectrum* (Figure 8.51a).

Figure 8.51b shows a schematic of the Raman and Rayleigh scattering processes. There are two kinds of Raman scattering events. In event (a), incident photons lose energy to the molecule, causing it to go to an excited, vibrational state ($v_0 \rightarrow v_1$). As a result, scattered photons will have less energy (Stokes Raman) compared to the incident photon.

In event (b), the incident photons gain energy from the molecule, because the molecules lose energy by going from a higher to lower vibrational state ($v_1 \rightarrow v_0$). In this case, the Raman scattered photon will have higher energy than the incident photons (anti-Stokes Raman). At room temperature, most molecules are in the vibrational ground state (v_0), so there is a greater probability that incident photons will lose energy to the molecules during the interaction, i.e., Stokes Raman. Generally, Raman spectroscopy refers to Stokes Raman unless specified otherwise. Thus, Raman scattering is observed at lower energy or longer wavelength compared to that of the incident light.

Raman Scattering and Spectral Information

Raman scattering intensity is related to the number of molecules in the sample according to the following equation:

$$I_R = I_0 \cdot \sigma_R \cdot N \cdot (\nu_0 - \nu_R)^4 \qquad \textbf{8.51(1)}$$

---

* The relationships between energy, frequency, wave number and the wavelength are as follows:
$E = h\nu$ (h is Planck's constant, and ν is frequency in sec^{-1})
$E = hc\upsilon$ (c is the speed of light in cm/sec, and υ is wave number in cm^{-1})
$\upsilon = 1/\lambda$ (λ is wavelength in nm)

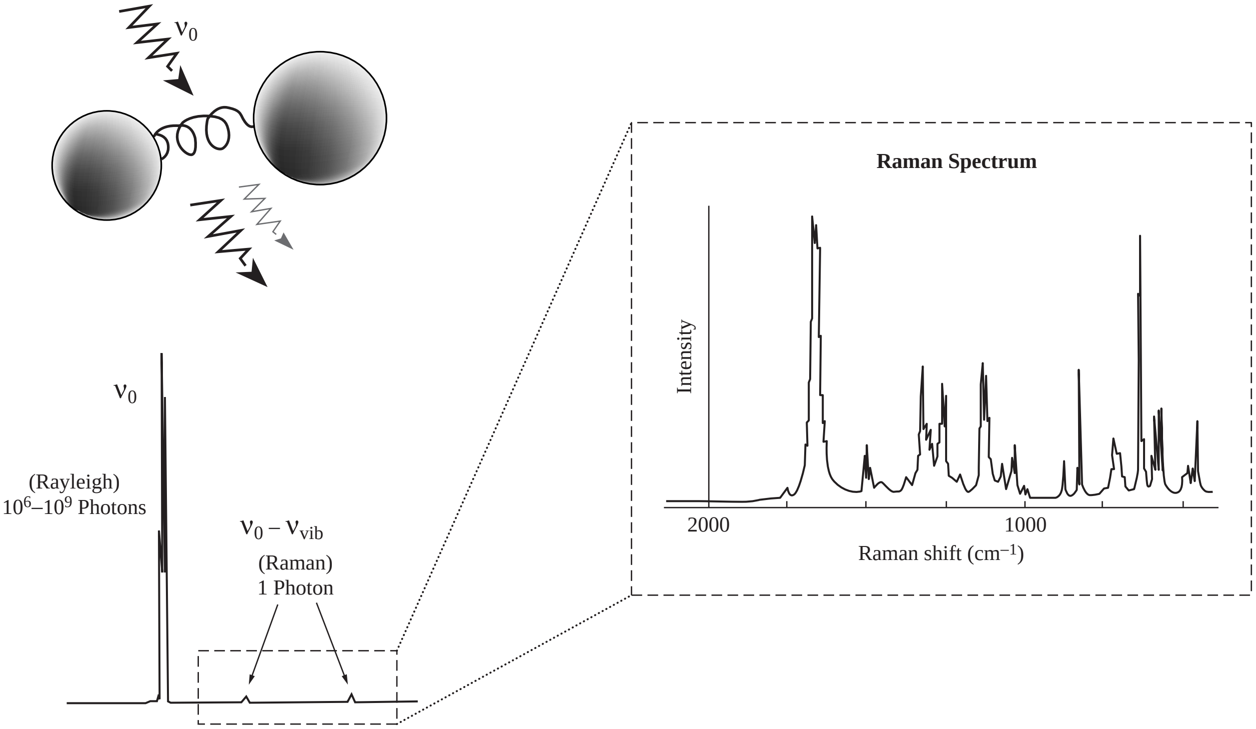

FIG. 8.51a
Pictorial representation of Raman scattering.

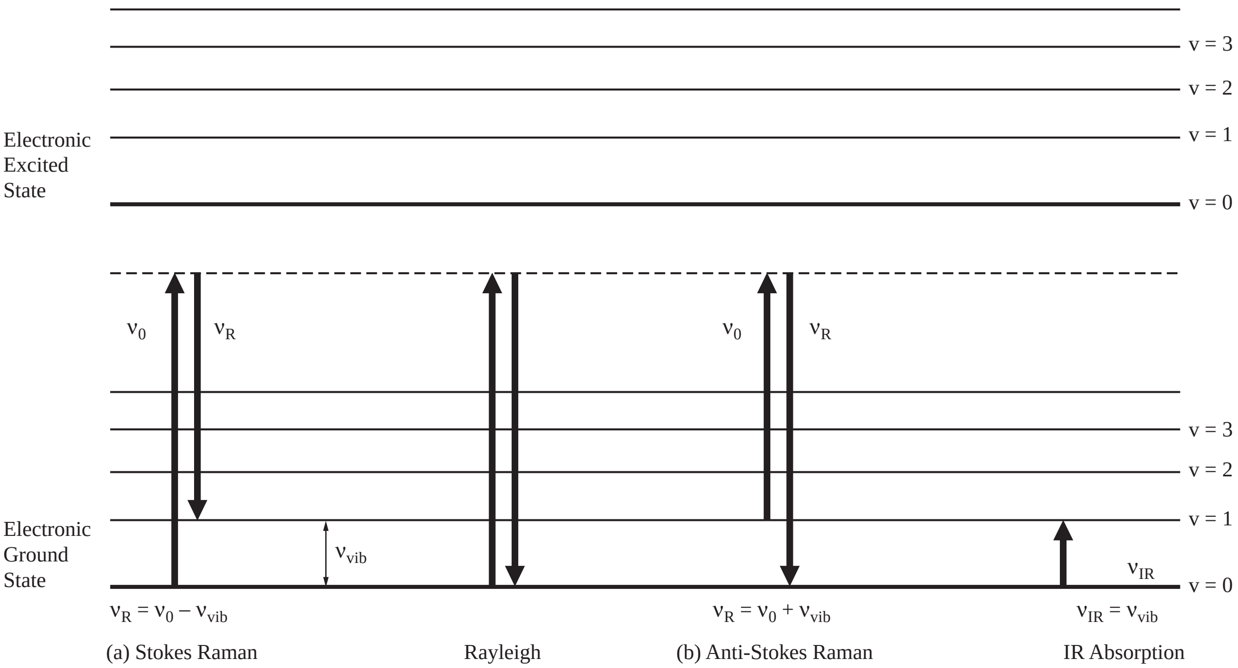

FIG. 8.51b
Schematic of energy level diagram for Raman and Rayleigh scattering processes.

where

I_R = Raman signal intensity
I_0 = incident light intensity
σ_R = Raman scattering cross section that is related to molecular polarizability
N = number of molecules in the sample volume probed by the light beam
ν_0 = frequency of the excitation light
ν_R = Raman scattering frequency

This relationship permits the use of Raman for quantitative analysis.

As in mid-IR absorption, Raman scattering also probes vibrations of the molecular bonds. The Raman shift frequency (υ_R, see Figure 8.51b) is equivalent to energy of mid-IR absorption for vibrational modes of a given group in the molecule (e.g., C—H stretch in CH_4 methane). In a classical model of molecular vibration, the Raman shift [expressed in energy, wave number, wavelength, or frequency (see previous footnote)] is related to molecular properties using an analogy of mass attached to a spring (Figure 8.51a) as follows:

$$\Delta\upsilon_{vib} = \frac{1}{2\pi C}\sqrt{\frac{k}{\mu}} \qquad \textbf{8.51(2)}$$

where

Δv_{vib} = Raman shift or absorption energy in the mid-IR region (expressed in cm^{-1} units)
C = speed of light
k = strength of the bond (or force constant of the spring, in newtons/m)
μ = reduced mass given as $m_1m_2/(m_1 + m_2)$, where m_1 and m_2 are atomic mass attached to the spring or bond

As the relationship shows, the Raman shift is related to the strength of the bond and the atomic masses of the molecule. For instance, for the carbon-carbon vibrations in functional groups with increasing bond strength, C—C, C=C, and C≡C, the Raman shift occurs at increasing frequencies, ~1000 cm^{-1}, ~1650 cm^{-1}, and ~2300 cm^{-1}, respectively.

Although Raman and mid-IR provide similar information, the selection rules for observations are different. Selection rules determine which vibrational modes are observed in the spectrum. Raman scattering arises due to a change in polarizability during vibration, whereas IR absorption occurs due to a change in dipole moment. Thus, for instance, homonuclear diatomic molecules (N_2, O_2, H_2, etc.) show Raman bands but not mid-IR absorption bands, because their only vibrational mode does not change the dipole moment of the molecule.

Table 8.51c lists various molecular functional groups that can be observed and quantitatively analyzed using Raman spectroscopy.

GENERAL INSTRUMENTATION

Raman scattering is inherently weak and is difficult to observe without intense monochromatic excitation and a sensitive detector. Modern Raman spectrometer systems use lasers as excitation sources. Visible laser light (400 to 700 nm)

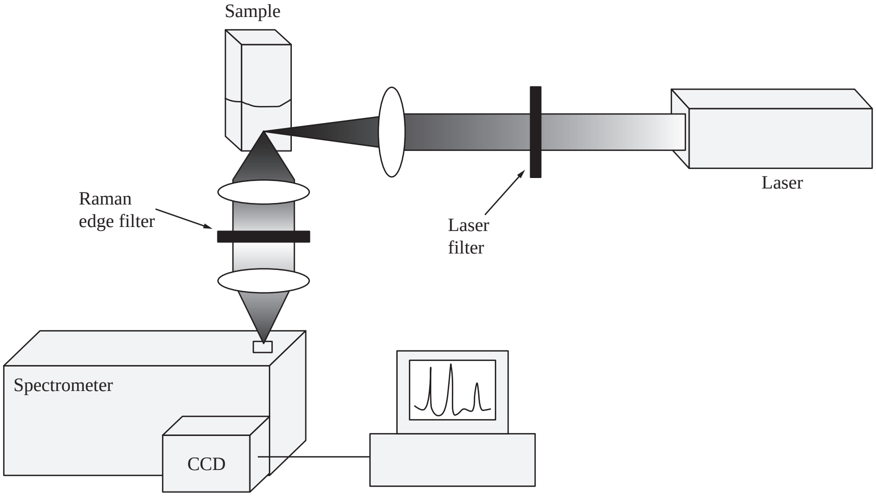

FIG. 8.51d
Schematic of a dispersive Raman instrument.

from an argon ion, helium-neon, or krypton ion laser is commonly used in laboratory Raman instruments. One of the drawbacks of visible laser excitation is fluorescence interference.

Almost all complex samples, especially biological systems, exhibit fluorescence. Because the fluorescence signal is three to five orders of magnitude stronger than the Raman signal, even trace fluorescence from impurities can mask weak Raman signals. For this reason, NIR laser-based Raman instruments have superseded visible laser instruments. Fluorescence decreases rapidly at longer excitation wavelengths, and most materials exhibit little or no fluorescence emission when excited with NIR lasers.

Fourier Transform Raman Instrumentation

Fourier transform (FT) Raman is the first technology to use near-IR excitation to collect fluorescence-free Raman signals.[4] The heart of this system is a wavelength-stabilized Michelson interferometer, one arm of which is scanned in length to produce a time-varying interference signal. The Raman spectrum is computed from the Fourier transform of this signal. FT Raman setup employs continuous-wave Nd:YAG laser ($\lambda = 1.064\ \mu$m) and a cryogenically cooled indium gallium arsenide (InGaAs) detector.

Three advantages of an FT spectrometer are (1) Conne's advantage—excellent wavenumber repeatability, (2) Fellgett's multiplex advantage—information in all wavelengths collected at the same time, and (3) Jacquinot's advantage—increased throughput.

The main disadvantage of FT-based analysis is its lower signal-to-noise ratio (S/N); it is limited by both reduced signal strength at the longer near-IR wavelength or lower frequency (signal strength is proportional to v_0^4) and the relatively high noise levels associated with InGaAs detectors. Furthermore, for remote spectroscopic applications, optical fibers are used for light delivery and signal collection. In such instances, the small numerical aperture (NA) of fibers (0.22) is not readily matched to a Michelson interferometer, thus losing the throughput advantage of the interferometer.

Dispersive Raman Instrumentation

Technological advances in the past decade have resulted in dispersive Raman instruments that employ imaging spectrographs and charge coupled device (CCD) detectors. A schematic of a dispersive near-IR Raman system is shown in Figure 8.51d.

The NIR laser is filtered to remove unwanted sidebands from the laser and is focused on the sample. The scattering signal is collected by a second lens, filtered by a Raman edge filter to reject intense Rayleigh scattering, and focused onto an imaging spectrograph equipped with a grating. A CCD array detector mounted at the output focal plane of the spectrograph detects the Raman signal. Commercial systems also use optical fibers instead of lenses to deliver and collect light. Various fiber optic sampling arrangements have been reviewed in detail.[5]

The primary gain in S/N of a CCD dispersive system as compared to that of an FT system results from the low noise level of a cooled CCD array detector. However, there are two factors to be optimized in selecting the appropriate near-IR excitation laser. First, in the visible wavelength, a CCD has very high efficiency, but fluorescence strongly interferes with the Raman spectra.

In the near-IR region, although fluorescence interference is reduced or eliminated, but the CCD detector quantum efficiency drops considerably as a result of silicon absorption. In selecting the optimal excitation wavelength, a trade-off must be made between these two factors. For most complex samples, the excitation wavelength range generally falls between 750 nm and 830 nm. Comparative signal-to-noise studies have shown that CCD/dispersive system can be several orders of magnitude more sensitive than FT Raman operation.[4,6]

RAMAN PROCESS ANALYZER INSTRUMENTATION

The Raman process analyzer is designed to produce continuous data that are reliable and reproducible for process analysis and control. Some of the key requirements for Raman process analyzers include (1) ruggedness of analyzer, probes, and optical filters, (2) data accuracy and repeatability, (3) long-term stability, (4) operating environment-independent performance, (5) standardized, analyzer-independent data to allow for calibration transfer between analyzers, (6) smart diagnostics for analyzer performance and predictive maintenance, (6) industry-standard communication and outputs for control, (7) availability of outputs, diagnostic parameters, and alarms for operation and maintenance, (8) laser safety for personnel and the process, (9) protection against failure, (10) packaging and certification for field applications, (11) ease of operation and maintenance, (12) multilevel passwords and security features, (13) high uptime (high mean time to failure and low mean time to repair), and (14) low total cost of ownership.

Components of Raman Process Analyzers

Figure 8.51e shows the layout of a typical Raman analyzer that uses fiber optics for process application. In a Raman process system, light is filtered and delivered to the sample via excitation fiber. Raman scattered light is collected by collection fiber(s) in the fiber optic probe, filtered, and sent to the spectrometer via return fiber optical cable(s). The CCD camera detects the signal to provide the Raman spectrum. In a Raman process analyzer, the components and their implementation will be different from those used in laboratory instruments.

Laser Excitation Source To take advantage of low-noise CCD cameras and to minimize fluorescence interference, near-IR diode lasers are used in process instruments. Advances in telecommunications, where near-IR diode lasers are used as a laser pump source, have significantly contributed to the development of NIR diodes.[7]

Available diodes have broad line width, are very compact [as small as 1 × 2 in. (25 × 51 mm) with integrated Peltier cooler, thermistor temperature sensor, and photomonitor], offer tens of watts of power and are relatively inexpensive. However, these multimode devices also exhibit line shape instability, a phenomenon known as *mode hopping* (Figure 8.51f).

Raman spectra obtained with a multimode laser exhibit lower resolution resulting from the broad spectra line shape, and they also show instability. In most applications, lower spectral resolution can be circumvented with the use of multivariate analysis for extracting concentration, much as in NIR. The more significant problem is the instability of the Raman spectrum due to laser mode hopping. To compensate for this, two approaches have been employed.

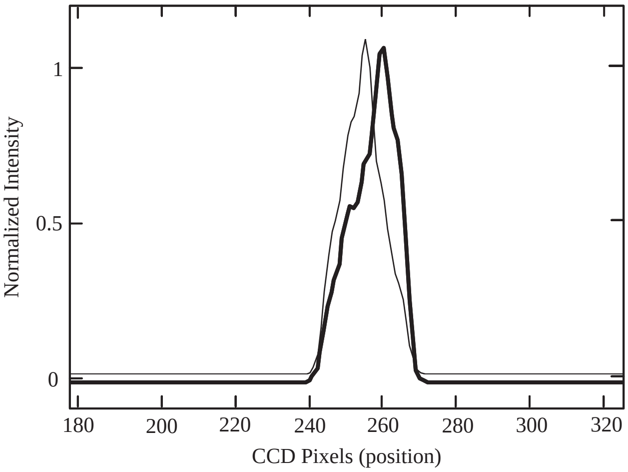

FIG. 8.51f
Instability of multimode diode laser caused by mode hopping, illustrating the need for compensation.

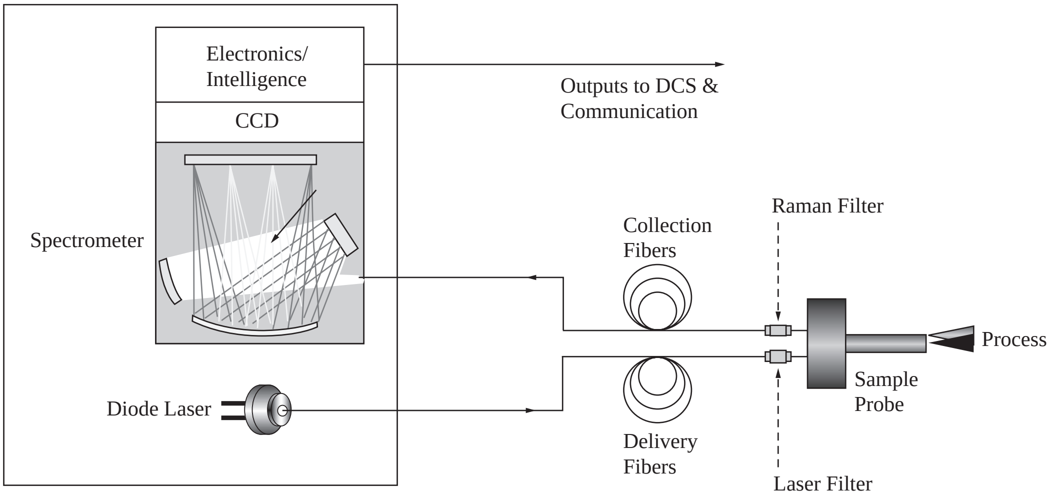

FIG. 8.51e
Schematic of fiber optic Raman analyzer for process measurements.

The first approach uses a Raman reference standard. A small portion of the laser beam is split and sent to a reference channel containing a small sample of a chemically stable material, e.g., an industrial diamond. The Raman output of the reference diamond is sent to the same CCD camera. Thus, for every process sample spectrum, there is a reference spectrum of the diamond. A transfer function (convolution function) is calculated to match the spectrum of the reference material to its true spectrum. The calculated transfer function is then applied on the sample spectrum to produce a true sample spectrum that is independent of laser mode hopping.

In the second approach, a small portion of the laser beam is directly monitored for mode hopping, and this information is used to compensate for the laser instability.

A multimode diode can be made into a narrow-line-width, single-mode laser by forcing one of the modes to lase and providing stabilization using a diffraction grating.[8] A single-mode laser has narrow line width, resulting in high-resolution Raman spectra. However, single-mode lasers are inefficient, relatively large in size, and more expensive compared to multimode devices. The trade-off between resolution and total cost of ownership should be considered for each application.

Some analyzers use visible laser excitation (e.g., green) for high-sensitivity applications where the process sample is free of fluorescence emission. The use of the green laser offers high sensitivity due to ν^4 factor [see Equation 8.51(1)] and allows detection of C-H and N-H stretching modes in the Raman shift region, 2800 to 3400 cm^{-1} (see Table 8.51c). Again, the total cost of ownership, fluorescence interference, required sensitivity, and spectral range desired should be taken into consideration in deciding on a visible laser-based Raman analyzer.

Spectrometer A typical spectrograph consists of mirrors and a grating for dispersion. Ruled diffraction grating spectrographs use aluminum-coated optical surfaces and are not very efficient for NIR region. Further improvement in throughput is achieved by using gold-coated optical components. The development of holographic optics offers highly efficient holographic gratings with additional advantages such as fewer optical elements and compact size, and the light beam acceptance angle can be matched with that of the optical fibers for increased system throughput.[4] The critical requirement of all spectrographs is temperature stability. The analyzer must be very well temperature controlled or located in a temperature-controlled environment.

Detector A CCD detector is the primary choice for dispersive instruments because of its extremely low dark current at low temperatures (as low as 0.05 electrons per second at –40°C). Raman process instruments use detectors that are cooled by two- or three-stage Peltier thermoelectric coolers.

Near-IR Raman instruments use back-thinned CCD cameras that have higher quantum efficiency in the near IR range as compared to front-illuminated devices. A CCD camera is a two-dimensional array device and is available in a variety of pixel formats (512 × 256, 512 × 512, 1024 × 512, 1024 × 1024, etc.). The x-axis is the dispersion axis, and the y-axis is the intensity axis. The number of x-axis pixels determines spectral resolution (if applicable) and spectral coverage. The two-dimensional array allows simultaneous measurement of multiple channels by arranging the light inputs vertically along the y-axis. Thus, the pixel format of the y-axis is chosen to accommodate multiple optical inputs into the spectrometer.

Raman instruments with multiple inputs are available for a variety of reasons.

1. Multiple optical fibers from a single stream can be coupled into the spectrometer for increased optical throughput and sensitivity.
2. The dual-fiber optic input beam, one for referencing and one for the process stream, can be used for dual-channel referenced Raman spectroscopy.
3. A split architecture where the top and bottom portions of the CCD measure two different spectral ranges increases spectral resolution and spectral coverage.
4. In one design, up to six channels can be accommodated for simultaneous measurement of two references and four process streams.

Unlike scanning devices with which one wavelength unit is measured at a time, the two-dimensional array format of the CCD, combined with its very high read rate on the order of megahertz, allows simultaneous measurement of all channels in real time. The advantage of simultaneous measurement is that any transient drift in laser power does not affect the spectral line shape but only overall amplitude, which can be compensated for by normalizing the spectrum.

Fiber Optic Light Delivery and Collection Optical fibers are used to deliver light and collect Raman signals remotely. Silica fibers with a core diameter ranging from 50 to 500 μm are used. The larger the core diameter, the less the bending radius (flexibility). Raman spectroscopy uses low-hydroxy fibers to minimize fiber background interference in Raman data and also to minimize light attenuation caused by fiber absorption.

Different fiber optic configurations are employed in Raman spectroscopy (Figure 8.51g), depending on the required sensitivity. These include one excitation and six

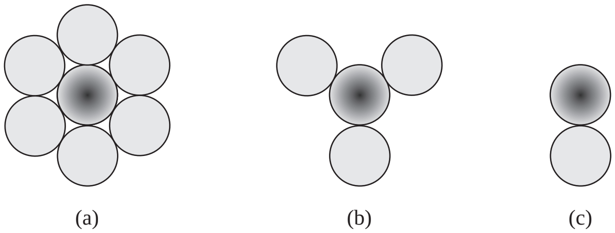

FIG. 8.51g
Various optical fiber geometries for laser excitation (dark circle) and Raman collection (gray circles).

surrounding collection fibers (circular geometry), one excitation and three collection fibers (triangle geometry), and one excitation and one collection fiber.

Although possessing lower sensitivity as compared to other geometries, most analyzers nonetheless incorporate one-excitation, one-collection fiber geometry. This configuration is simple to implement, is less expensive, requires no alignment in fiber-to-fiber coupling, and is easy to install in the field. With low-hydroxy fibers, light can be transmitted over hundreds of meters without a significant decrease in throughput. The main issue is that, as the laser traverses through optical fibers, optical fibers generate silica Raman bands and/or a broad fluorescence background.

Proper filtering is therefore needed (see next paragraph). For field installation, optical fibers are protected with PVC or metal jackets. Fibers are terminated with SMA 905, FC, ST connectors. Reproducible fiber-to-fiber coupling needs to be considered in selecting connectors for the fiber optic cables.

Laser and Raman Filters In order to observe inherently weak Raman signals, the laser needs to be monochromatic, i.e., free of any laser side band interference. In addition, the intense Rayleigh scattering should be completely prevented from reaching the detector. Laser and Raman filters, respectively, serve this purpose. Laser filters must be bandpass filters of very high attenuation (10^7 or more) so as to completely eliminate fiber background and Rayleigh scattering. The filter must also have very high transmission (80% or more) at the laser wavelength to pass laser light efficiently.

Raman filters, on the other hand, are long-pass (or notch) filters. Raman filters have very high attenuation at the laser wavelength to prevent laser radiation from entering the collection fiber and the detector. Raman filters also have very high transmission at the Raman frequency region to pass the Raman light efficiently.

Analyzer manufacturers use either dielectric or holographic filters. Holographic filters are more efficient and have sharp cutoff characteristics that allow Raman spectral lines close (~100 cm^{-1} or less) to the laser wavelength to be measured. Dielectric filters that use hard metal oxide coatings are less efficient but exhibit less temperature dependence. Selection of appropriate filter technology depends on the location of the analyzer (open field, shelter, control room), location of the filters (protected or unprotected), required sensitivity, and how close to Rayleigh scattering the Raman bands need to be measured.

Sample Interface Sample interface is critical in all process applications, because analyzer performance and reliability are highly dependent on the sampling system. (For a detailed discussion of the features and capabilities of fiber optic probes, refer to Section 8.23.)

Typically, there is no need for a sample extraction, handling, and conditioning system for Raman analyzers, because an optic probe can be directly interfaced to the process stream. The probe consists of optical fibers for laser excitation and Raman signal collection. There are several excitation fiber and collection fiber geometries for use in Raman spectroscopy.[5] Most common for process application is one-excitation, one-collection fiber geometry, because of its simplicity and ruggedness.

Raman Probes The two types of Raman probes are invasive and noninvasive. The requirements for an invasive or insertion probe are that it should be industrially hardened, have a high degree of chemical/corrosion resistance, and be able to withstand very high process temperatures and pressures. Developments in glass-metal welding and welded metal pressure seals have made available robust, invasive Raman probes that can withstand up to 350°C and 3000 PSIG and operate under highly corrosive conditions. Different types of sleeves are available; stainless steel, titanium, Hastelloy,® and Kynar® can be used in corrosive applications.

Probes are available with the laser and filters either external to the probe body or integrated within the probe body. Figure 8.51h shows invasive probes with different sleeve constructions. An insertion probe may be used in conjunction with retraction mechanism for safely retracting the probe from the process for maintenance. In applications where the process integrity cannot be breached for hazardous or sterility reasons, and where the processes are operating at extreme pressure, temperatures, or corrosive conditions, a noninvasive probe should be considered.

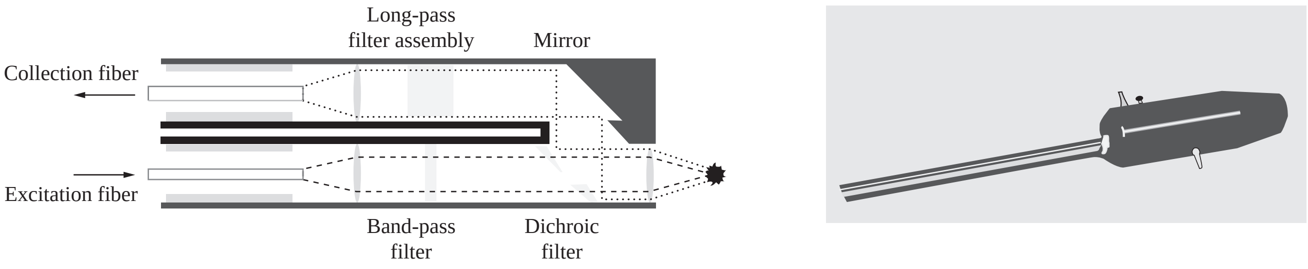
FIG. 8.51h
Raman process probes. (a) Invasive titanium sleeve probe (courtesy of CIC Photonics, Inc.) and (b) invasive probe with stainless steel construction and gold brazing of fibers to the body (courtesy of Rosemount Analytical, Inc.).



(a)

(b)

FIG. 8.51i

Focused probe with integrated laser and Raman filters. (a) Schematic of the beam path and (b) process probe for invasive and noninvasive applications. (Courtesy of InPhotonics, Inc.)

Typically, in noninvasive probe implementation, the probe is placed outside the process container, and the laser excitation and Raman collection are done through optically transparent windows such as quartz or sapphire. Figure 8.51i shows one such design, where a lens at the tip focuses the laser beam and also collects the Raman scattering signal through the transparent window. By changing lenses with different focal distances or by using a variable focal length assembly, measurements can be done through 12 mm thick sapphire windows.

Chlorate bleach reactions in the pulp and paper industry and nitration reactions in the chemical processing industry are examples of hazardous and corrosive processes. Cell culture monitoring and fermentation monitoring are examples of sterile processes that would use noninvasive probes.

Data Analysis, Modeling and Calibration

The Raman spectrum must be processed before it can be used. Spectral processing includes noise filtering, smoothing, normalization, reference compensation, fluorescence background removal, and correction for scattering, especially in a heterogeneous media. The Raman spectrum is then related to a concentration of chemical components via calibration. A simple calibration is the intensity or band area ratio method, which is internally normalized.

Polymerization Application For instance, in a polymerization reaction, the monomer concentration would decrease as the polymer concentration increases. Thus, the ratio of bands associated with monomer and polymer molecules can be used to easily estimate the degree of polymerization. In cases where the spectrum of the mixture can be expressed as a linear superposition of the spectra of individual component line shapes and their Raman cross sections, relative concentration of various components can be easily estimated.[9]

Also, where the Raman signal from the component of interest can be isolated, the signal strength can be related to its concentration by measuring Raman spectra of several known standards that span the range of concentration of interest.

Multivariable Predictive Analysis For most applications, however, a simple linear equation [e.g., Equation 8.51(1)] cannot be used because of noise, variability in measurement, spectral overlap of various bands, internal absorption, diffuse scattering, etc. For such applications, multivariate predictive statistical analysis [such as multiple linear regression (MLR), partial least squares regression (PLS), principal components regression (PCR), etc.] are used to reduce highly correlated spectral information into a few orthogonal (uncorrelated) spectral vectors.

The scaling factors of the spectral vectors are then related to concentration via multidimensional curve fitting or regression analysis.[10] Nonlinear analysis using an artificial neural network is also increasingly being used in Raman spectroscopy.[10] In the multivariate analysis, the analyzer is trained first, using a set of standard samples of known concentration.

Figure 8.51j illustrates such a calibration scheme. Samples are collected from the process (sometimes spiked with components to get the span range desired), and their Raman spectra are obtained. The same samples are then analyzed via standard laboratory chemical analysis. Spectral information and known chemical composition from the laboratory are related using a multivariate model. The model validity is then checked using unknown samples to get an estimate of prediction error. Naturally, the calibration accuracy cannot exceed that of the laboratory analysis used to build the model, although repeatability is usually better.

Calibration Model A calibration scheme built outside of the process environment should be considered preliminary only and must be fine-tuned when the analyzer is operating in an actual process. An effective way to fine-tune an existing calibration scheme, or to build one from scratch, is by periodically collecting samples for laboratory analysis while the analyzer is operational.

Correlating Raman spectral response in actual process conditions with laboratory analysis is the best way to build accurate, process-specific calibration schemes, whether based on peak integration or statistical modeling. This, however, takes time and patience to do well. Also, a good calibration model must include the extremes of the process range.

	px	mx	ox	eb	b
S1	95%	3%	2%	0%	0%

S	62%	12%	3%	16%	7%

FIG. 8.51j
Analyzer calibration scheme using laboratory analysis as the standard. Calibration model is verified for accuracy and robustness and downloaded to the analyzer for online prediction.

For a stable manufacturing process, it can be frustrating to wait for the process to swing from one extreme to another and, perhaps more significantly, to be able to collect lab samples precisely when the process conditions are at the extremes.

It is highly desirable (if possible) to install an automatic lab sampler that can be triggered by the analyzer to collect a sample for lab analysis when the analyzer detects a value in the extreme of its detection range or detects unusual process conditions that are not built into the preliminary model. Such a trigger can be based on predicted data limits or on modeling parameters such as spectral residuals (a measure of how well the model-calculated spectrum matches with the measured spectrum) and/or Mahalanobis distances (a measure of how close the measured spectrum is from the mean of all the data used in the calibration, measured in standard deviation). Clearly, whenever a sample is collected for laboratory analysis, the concurrent Raman spectrum should be saved for diagnostics and for inclusion in future calibration updates.

When the analyzer is fully operational with a satisfactory calibration scheme, it is good practice to continue to routinely check its calibration status. Again, this can be done best with collected samples and laboratory analysis. Use of an automated sampler is preferred to avoid human errors in sample collection. The calibration check frequency can be determined based on process stability, calibration scheme stability, and failure rate. Clearly, access to a well equipped and efficient laboratory is essential for building and maintaining good calibration schemes for Raman analyzers.

Calibration Transfer Generally, a calibration model is valid as long as the analyzer components are not modified. Only a few available analyzers are capable of calibration transfer, after major analyzer maintenance, between two streams on the same analyzer or between two different analyzers made by the same vendor.

Two major approaches to calibration transfer are (1) multivariate standardization, where the spectral domain of one analyzer is mapped onto that of the other analyzer by modeling spectral differences and correcting for those differences, and (2) analyzer standardization, where all analyzers are made to yield identical spectra from a given sample using standards.

Raman analyzer standardization itself is a multistep process.[11] First, laser instability is compensated using, e.g., diamond as Raman reference. Second, the CCD pixel in the x-axis is converted to Raman shift frequency by calibrating it with known emission lines of argon, neon, or one of the recent ASTM standards (sulfur, cyclohexane, polystyrene, etc.) and with a known Raman line of diamond. Third, intensity response of the analyzer is corrected over the entire Raman shift range using a white light source or fluorescence color glasses.[12]

Properly done analyzer standardization ensures spectral reproducibility and facilitates calibration transfer. Calibration transfer reduces redundancy by eliminating the need to develop an entirely new calibration model where one already exists for a similar analyzer and process. Calibration transfer saves tremendous amounts of time and effort in developing a new calibration model for each occasion when analyzer maintenance is performed or a new channel or a new analyzer is installed for the same process application.

Smart Diagnostics and Analyzer Maintenance

An analyzer that has good diagnostic tools allows for safe operation and reduces analyzer downtime. Two areas of diagnostics are calibration model performance and monitoring the mechanical/electrical health of the analyzer.

For multivariate calibration models, spectral residuals and Mahalanobis distance are indicative of the spectral quality and data reliability. Spectral shape changes can provide a variety of diagnostic information such as process change, insufficient process flow, laser performance, probe fouling, etc.

Analyzer health parameters that should be automated include laser life (based on output power/current), fan life (if present), laser current, laser operating temperature, analyzer internal temperature, CCD operating temperature, and loss of purge air. Availability of these parameters to DCS and asset management systems can automatically trigger analyzer maintenance and repair. A Raman analyzer maintenance scheme should include scheduled preventive maintenance to replace analyzer parts that have known average operational life and rigorous data quality monitoring protocols that can identify problems.

Laser Safety

Raman analyzers use Class IIIB to Class IV lasers. Personnel laser safety is of paramount importance in process implementation. Raman analyzers are available with safety features that warn of laser status and can initiate automatic shutdown. In process applications, the analyzer must be capable of shutting off the laser automatically or reducing the energy to nonhazardous level when internal analyzer diagnostics indicate a potential disruption of the laser loop or when the possibility of personnel exposure exists.

In one scheme, a photodiode in the analyzer continuously monitors the Rayleigh scattering light from the process picked up by a dedicated optical fiber in the probe. When the probe is withdrawn or the laser cable is broken, the absence of Rayleigh scattering immediately triggers safe-mode operation. When the fault condition is cleared, the laser automatically returns to normal mode of operation.

Another consideration is the possibility of the laser inducing hot spots in the process line or the sampling cell. Hot spots are an important safety consideration if the process can potentially contain solid particulates or explosive gas mixtures that absorb at the laser frequency. The possibility then exists that particulates or gas mixtures may be heated to high temperatures by the laser and become an explosion hazard in the presence of hydrocarbons.

Although the relative mass of process flow provides a sufficiently large heat sink to eliminate the risk of explosion, caution is prudent if the nature of the process stream warrants it. It is generally best to do a thorough safety review before installing a Raman analyzer and to develop safety guidelines for each installation.

Outputs and Communication

Raman analyzers provide industry standard communication protocols. Generally, a Modbus or Ethernet protocol is preferred over analog (4 to 20 mA) connection, because a large amount of information can be transmitted and monitored remotely, including a number of safety and instrument health factors. Ethernet capability also allows for remote access of the analyzer for technical experts to diagnose and rectify problems both within the plant and from the vendor site.

Packaging

Because Raman analyzer technology is still relatively new compared to, e.g., NIR and GC technologies, standards for analyzer packaging are still evolving. Since Raman analyzers are compatible with fiber optics for remote analysis, some vendors offer benchtop analyzers that can be located in a control room. However, if the analyzer is located very far from the process stream, then the cost of packaged fiber optics can be significant, especially if multifiber geometry is used.

A few Raman analyzers are available with NEMA12 and NEMA 4X ratings. Z-purged analyzers for hazardous applications are also available.

INSTALLATION AND MAINTENANCE

How a Raman process analyzer is installed and calibrated to a large extent defines its future maintenance requirements. While it is true that there is a correlation between installation and future maintenance for any process analyzer, this is particularly true for Raman analyzers because of the range of installation options.

Whether one chooses to install a complicated sampling system, using an invasive or noninvasive probe, has significant impact on future maintenance needs of a Raman analyzer. Other factors, such as whether the analyzer hardware is located in a hazardous or nonhazardous area and whether the analyzer is housed in an analyzer shelter or in a free-standing purged cabinet, also affect the analyzer's maintenance needs.

Beyond the specific maintenance requirements arising from how the analyzer was installed, the other maintenance requirements for the Raman analyzer tend to be minimal and pertain only to replacing consumable items such as filter, laser, and so forth on a scheduled basis or when they break down.

Probe Designs

The most cost-effective way to install and operate a Raman analyzer is by using an invasive or noninvasive probe. The use of fiber optic probes not only lowers the initial installation project costs, it requires less maintenance over the analyzer lifetime. Generally, a sampling system requires more maintenance than the analyzer itself. By eliminating the sampling system, a major need for continuous maintenance of the analyzer is also eliminated.

TABLE 8.51k
Advantages and Disadvantages of Mid-IR, Near-IR, and Raman Methods

	NIR Absorption	*Mid-IR Absorption*	*Raman Scattering*
Selection rule	Change in dipole moment	Change in dipole moment	Change in polarizability
Spectral band profile	Overtone/combination bands, broad (nonspecific)	Fundamental band, narrow (high specificity)	Fundamental bands, narrow (high specificity)
Sensitivity	Moderate (ppm, low percentage)	Very high (ppb, ppm)	Low (low percentage, ppm in favorable cases)
Qualitative identification	Difficult	Yes. Extensive spectral library available	Yes. Comprehensive library not available
Sample	Transparent, bubble and particulate-free liquids Powder samples require diffuse reflectance probe	Transparent liquid, thin solid pellets and ideal for gases. Special ATR probes needed	Same probe is used for all samples; liquids, slurries, emulsions, powders, solids, samples with particulates and bubbles
Signal-to-concentration relationship	Logarithmic	Logarithmic	Linear
Quantitative analysis	Mathematical/statistical modeling	Simple arithmetic possible	Simple arithmetic possible
Transfer of calibrations	Difficult	Difficult	Relatively easy
Sample handling	Yes	Yes	No, noninvasive or *in situ*
Water interference	Good sensitivity to and interference by water	Very high sensitivity to and strong interference by water	No or minimal water interference
Temperature dependence	Sensitive to process temperature variation	Sensitive to process temperature	Wide temperature variation tolerated
Sampling probe	Double sided, single sided when used with reflectance	Double sided or special ATR probes	Single ended
Probe fouling	More likely	More likely	Less likely or not likely with noninvasive
Remote via fiber optics	Long fibers, low hydroxy silica fibers	Short fibers, expensive chalcogenide fibers	Long fibers, low hydroxy silica fibers.
Wetted optical window	Inert (sapphire, silica, quartz)	Fragile (ZnSe, CaF2, KBr)	Inert (sapphire, silica, quartz)

When using a fiber optic probe, the other analyzer hardware (e.g., electronics, detector, laser, computer) can be located in a nonhazardous area by using fiber optic cable to connect the probe. Such an installation scheme eliminates the need for an explosion-proof purged cabinet or an expensive customized analyzer shelter house. Analyzer installation project costs are always a significant factor for a manufacturing site.

All Raman analyzer installations should include an easily accessible sampling point to collect process samples for laboratory analysis. Laboratory analysis is generally required for verifying and updating analyzer calibration. A good practice is to have a sampling feature that allows automatic sampling for laboratory analysis when the analyzer indicates unusual process conditions.

ADVANTAGES AND DISADVANTAGES

A decision to use a Raman analyzer depends on the availability and practicality of alternative analyzer technologies. For example, it is clearly not desirable to employ a Raman analyzer where a gas chromatograph (GC) can perform the same analysis. This is because a GC is more sensitive, more familiar to the average user, and more widely accepted. Therefore, unless a good case can be made based on speed of analysis or low-maintenance requirements of the Raman analyzer, a GC would be preferred.

Generally, a Raman analyzer works where NIR, mid-IR analyzers are applicable. The Raman analyzer, however, combines the best aspects of NIR and IR absorption spectroscopy methods with some of its unique advantages. Table 8.51k lists the advantages and disadvantages of Raman spectroscopy compared to mid-IR and near-IR absorption spectroscopy.

Advantages

Like mid-IR, Raman bands represent fundamental modes of vibration. Bands are narrow, are molecule specific, and provide quantitative chemical analysis. Like NIR absorption, Raman spectroscopy permits the use of optical fibers for remote analysis. Additionally, the following unique advantages of Raman spectroscopy can be noted:

1. It involves minimal or no water interference, an important feature because there is an increasing trend to

move away from organic-based to water-based processes due to environmental considerations.
2. The technology is equally amenable to a variety of samples ranging from gases, liquids, slurries, emulsions, powders, and solids to samples with particulates and bubbles. This enables Raman use in heterogeneous systems such as catalytic process, emulsion polymerization, fermentation monitoring, and cell culture monitoring.
3. Noninvasive probes can be used and are a key feature in many applications where the process must not be breached.

Limitations

The limitations of Raman spectroscopy are its low sensitivity as compared to IR absorption and fluorescence interference from analytes or impurities in the sample. By optimizing sample and collection geometry, sensitivity can be improved, and, by utilizing near-IR radiation as the excitation source, fluorescence can be minimized.

APPLICATIONS

Raman analyzer technology can be applicable for chemical composition analysis in a range of manufacturing industries (e.g., specialty chemicals, petrochemicals, petroleum refining, pharmaceutical, agriculture, and pulp and paper). Raman spectroscopy is a developing technology, and a good amount of research and planning is necessary before deciding on employing Raman technology for a process analyzer. In this regard, it is best for industrial technical experts and analyzer technology providers to work together to develop new applications for Raman analyzers.

Polymer Industry

One application area in which Raman technology is distinctly advantageous is for the analysis of viscous liquids, e.g., polymer melts. Use of a noninvasive probe precludes the necessity of building a sample-handling system. Sampling system designs for handling solids or highly viscous liquids tend to be very expansive and costly, and they have lower reliability than those for free-flowing liquids and vapors.

For polymers, and, in general, for macromolecules, it is typically not the chemical composition but the relationship of the chemical composition to the physical properties of bulk density, viscosity, etc. that is more valuable from a process viewpoint. Raman analysis of the chemical signature of the process stream generally can be correlated to the physical properties using multivariate statistical models. This is one area where the speed, stability, and reliability of Raman analysis offer an attractive means for real-time process control.

The range of applications in which Raman analyzer technology can be employed to provide valuable real-time process information is extensive. A summary of typical Raman applications is provided in Table 8.51l.

TABLE 8.51l
Typical Process Applications for Raman Spectroscopy

Industry	*Process Applications*
Chemical processing	Endpoint determination Reaction monitoring Hydrocarbon analysis Emulsion polymerization Copolymer reactions Heterogeneous catalytic reactions Nitration reactions Esterification reactions Batch and continuous distillations Chemical reactor safety and efficiency monitoring Polymer crystallinity Inorganic analysis
Petrochemical	Monitoring xylene separation process Para xylene purity analysis Styrene monomer/polymer reaction Endpoint determination Reaction monitoring
Pharmaceutical	Fermentation Cell culture monitoring Bromination reaction Raw material verification and screening Intermediate analysis
Pulp and Paper	Pulp bleaching Chlorine dioxide production
Food and Beverage	Modified starch Hydrogenation of oils and fats Sugars Endpoint determination Fermentation

CONCLUSION

The cost of a Raman process analyzer typically exceeds that of other analyzers used in the process industry.

The CCD camera and lasers are the most expensive components of the Raman analyzer. Indeed, to reduce cost on a per-process-stream basis, Raman analyzers often include multichannel capability. Up to four process streams can be analyzed with a single CCD camera by splitting the lasers. Advances in CCD and laser technologies continue to lower the cost of these components, and that will help to reduce overall analyzer cost.

Raman calibration transfer is an important technical area that needs to be improved. Currently, there is no traceability of standards used in x- and y-axis calibration of Raman spectrum. Progress in this direction is being made as ASTM has adapted eight standards for x-axis calibration of Raman spectrum.

The availability of inexpensive, rugged process probes that can work reliably within a high-pressure, high-temperature, and corrosive process environment will enable the Raman analyzers to be used in a wider range of process applications.

There is a need to improve the sensitivity of the technique. Efficient light collection by probes and effective coupling of the Raman signal to the spectrograph, among other things, would enhance Raman sensitivity. Multipass sample cell design should increase Raman sensitivity, especially for gases. Experimental optical probe designs have already been demonstrated for gas sampling using Raman analyzers.

Another inherent problem with Raman spectroscopy is fluorescence interference. As described earlier, the choice of CCDs as low-noise detectors does not allow excitation wavelengths above 850 nm because of the lack of sensitivity in the corresponding Raman region. For complete avoidance of fluorescence, excitation wavelengths above 1000 nm are needed. A number of applications will become germane for Raman analysis by exciting and collecting light beyond 1000 nm and using new generation of CCD cameras.

Continuing efforts to improve detection limits, fluorescence elimination, traceability of calibration standards, calibration capability, mechanical reliability, and lower cost, coupled with its inherent technical advantages, portends a bright future for Raman technology for on-line process analysis.

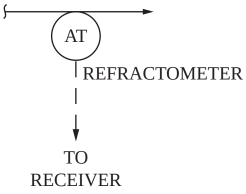
8.52 Refractometers



Flow Sheet Symbol

J. E. BROWN (1969, 1982) **B. G. LIPTÁK** (1995, 2003)

Applications:	Liquids and slurries. Measures the concentrations of dissolved solids or water-soluble liquids.
Materials of Construction:	Stainless steel and glass are standard, with Teflon® gaskets
Operating Pressure:	Up to 1000 PSIG (70 barg)
Operating Temperature:	Up to 2500°F (1371°C)
Recommended Flow Velocity:	For in-line units in excess of 5 fps (1.5 m/s)
Ranges:	Spans of industrial in-line units typically range from 1.25 to 1.65 RI refractive index (RI) units or 0 to 100 Brix(1.333 to 1.54 ORI). Some typical span requirements for a variety of applications are 1.00 to 1.30 (battery acid), 1.333 to 1.360 (urine), 1.333 to 1.520, 1.435 to 1.520, 1.300 to 1.700. Other typical ranges include: in percent salinity, 0 to 10% and 0 to 28%; in % Brix units, 0 to 10%, 0 to 20%, 0 to 32%, 28 to 62%, 58 to 90%, and 0 to 90%; in freezing point of coolants, –60 to 32°F (–51°C to 0°C); in window-washer-fluid concentration, 0 to 100%.
Speed of Response:	3 to 30 sec
Drift:	From 0.5% per month to 1% per 24 hr
Inaccuracy:	The inaccuracy of a good industrial in-line unit, having a span of 0.08 RI, is about 0.0002 RI or 0.25%. The least accurate units are 5% of span. For hand-held laboratory units in % Brix units, for a range of 0 to 95%, the error is 0.1% (0.05% in high-precision refractometers). The corresponding errors in RI units are 0.0002 and 0.0001, respectively.
Costs:	Portable, hand-held, battery-operated refractometers cost from $200 to $600; specialized, digital, hand-held units for battery acid, antifreeze, and window washer applications cost from $800 to $1500; high-precision benchtop laboratory units cost from $2500 to $4500; industrial in-line transmitters cost from $5000 to $10,000; in-line sensors in sizes up to 3 in. (75 mm) cost $8000 and 4 in. (100 mm) cost $10,000; probe sensors cost $8000; beverage analysis system with ±0.02 Brix inaccuracy, $25,000.

INTRODUCTION

A pencil standing in water appears to be broken at the water line. If sugar is added to the water, the pencil will appear to bend even more. This is because light travels slower in water than through air, and even slower when materials are dissolved in water.

RI and Brix Units

The index of refraction, or refractive index (RI), is the ratio between the speed of light in vacuum and the speed of light in the substance of interest. RI therefore is unity when the light travels in vacuum at a speed of 0.98 billion fps or 186,300 mi/s (0.3 billion m/s). The RI of air is 1.0003, and the RI of most gases, liquids, and solids is between 1 and 2. See Table 8.52a for the refractive index values of a variety of substances.

Some industries use their own units rather than the index of refraction. Two examples are the sugar and citrus juice industries. They prefer to use the % Brix scale, which refers to the weight-percent of sugar concentration, corresponding to the number of grams of sugar contained in 100 g of solution. Figure 8.52b provides the conversion between RI and the % Brix units, and Table 8.52c gives the typical % Brix readings on a number of food items and the errors with which refractometers can measure them.

TABLE 8.52a
Refractive Index Table [all data based on 68°F (20°C)]

Acetic acid	1.3718	Formic acid	1.3714
Acetone	1.3588	Glycerol	1.4729
Acrylic acid	1.4224	Glycol	1.4318
Amyl acetate	1.4012	Heptane	1.3876
Benzene	1.5011	Hexane	1.3749
Butyl acetate	1.3951	Hexanol	1.4135
Butyl alcohol	1.3993	Hydrazine	1.470
Butylene	1.3962	Hydrogen chloride	1.256
Carbon disulfide	1.6295	Lead tetraethyl	1.5198
Carbon tetrachloride	1.4631	Menthol	1.458
Chlorobenzene	1.5248	Methyl alcohol	1.3288
Chloroform	1.4464	Methyl ethyl ketone	1.3807

Ethyl acetate	1.3722	Styrene	1.5434
Ethyl alcohol	1.3624	Toluene	1.4969
Ethylbenzene	1.4952	Water	1.3330

THEORY OF OPERATION

A refractometer measures the refractive index (RI), which is the ratio of the velocity of light in a vacuum to its velocity in the material of interest. Refraction of light (angularity change) occurs at the interface of two different media unless the incidence of light is perpendicular.

$$\mathrm{RI} = \mathrm{N}' = \frac{\mathrm{V\ (vacuum)}}{\mathrm{V\ (material)}} \qquad \mathbf{8.52(1)}$$

Snell's law expresses the relationship between the angle of incidence and angle of refraction when light is passed through the interface of two different materials (Figure 8.52d) as

$$\mathrm{n}' = (\sin\alpha/\sin\beta) \qquad \mathbf{8.52(2)}$$

The refractive index of a material is usually expressed in terms of air as a standard.

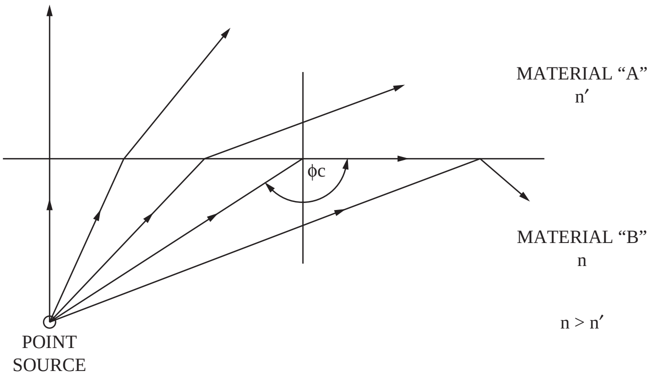

FIG. 8.52e
Illustration of refraction and reflectance.

Critical Angle of Refraction

A second phenomenon is observed with materials of different indices of refraction: when the angle of incidence exceeds a certain angle, the light ceases to be refracted and is totally reflected (Figure 8.52e). This angle is called the *critical angle* and is defined as

$$\phi_c = \arc \sin \frac{n'}{n} \qquad \textbf{8.52(3)}$$

The process refractometers in use today measure either the refraction angle or the critical angle of refraction. Table 8.52f provides a summary of the features and capabilities of both of these refractometer designs.

The differential refractometer measures the refraction angle changes as a function of sample RI. This is generally done by holding the incident light angle constant. In that case, Snell’s law becomes

$$n = (1/\sin \beta) \qquad \textbf{8.52(4)}$$

The refractive indices of all materials vary with temperature, so the temperature must be compensated for unless the

TABLE 8.52f
Refractometer Comparison Summary

Differential	*Critical Angle Refractometer*	*Refractometer*
Measurement principle	Changes in angle of refraction	Changes in angle of total reflectance (critical angle)
Type sample	Clean translucent liquid	Liquids—clean or turbid, slurries
RI ranges (full-scale)	0.1 RI unit to 0.00005 RIO unit	0.1 RI to 0.005 RI
Sample flow rate	2–10 cc/min	Depends on type installation (unlimited)
Type of installation	Requires sample system	Can be used with sample system; can be installed in pipeline or vessel
Pressure rating	40 PSIG (276 kPa)	250 PSIG (1.7 MPa)
Ambient temperature	30–120°F (–1– 49°C)	30–300°F (–1–149°C)

measurement is made at the standard reference temperature of 68°F (20°C). Because temperature affects RI, it must be (a) held constant or (b) measured and compensated for in the process analyzer.

DIFFERENTIAL REFRACTOMETER

Single-Pass Design

Figure 8.52g illustrates the single-pass differential refractometer, which consists of a tungsten filament source, mask, sample flow cell with a sealed reference inner cell, beam splitter, and two opposed phototubes. The reference cell is filled with a solution having an RI value that corresponds to approximately the midscale of the measurement range.

The light beam passes unaltered through the perpendicular cell windows, creating a refraction angle only at the nonnormal window interface. The measured magnitude of the refraction angle is proportional to the difference between the RIs of the sample and of the reference solution.

The detector consists of a beam splitter and two opposed phototubes or photocells. The detector circuit can be designed so that the amplifier reads the ratio of the outputs from the two phototubes as a measurement of the displacement, or as the refraction of the light beam. Phototube irregularities, such as unequal surface response and unequal aging, limit the sensitivity, linearity, and range of this design. Therefore, a null-balance system is usually employed in which the ratio output is used to relocate the beam splitter, thereby rebalancing the light beam equally on the phototubes. The position of the beam splitter is then tracked as the measurement of process RI.

The reference cell angle and the distance between the cell and detector system determine the sensitivity and range of the design. A folded light path using mirrors helps maintain the unit in a reasonable package, even for a 40-in. (1-m) path length.

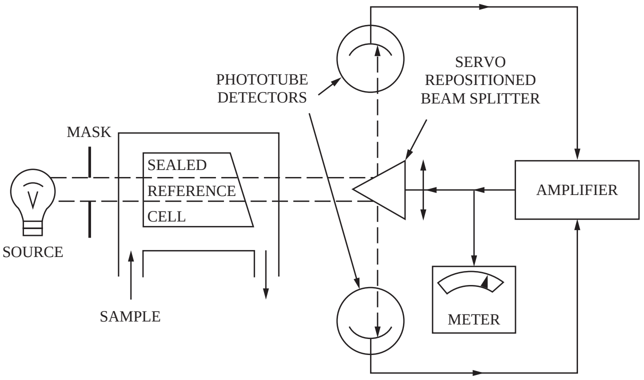

FIG. 8.52g
Single-pass differential refractometer design.

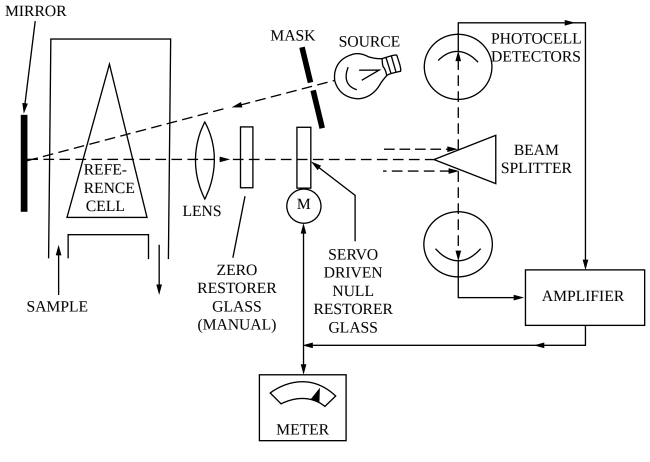

FIG. 8.52h
Two-pass refractometer block-diagram.

Two-Pass Design

The two-pass differential refractometer uses a triangular-shaped reference cell (Figure 8.52h) and a reflecting mirror. The reference cell shape presents two nonnormal surfaces that interface with the sample to create two refraction angles for the forward pass and two for the return pass.

The reference cell is filled with a solution that has an RI value corresponding to about mid-scale of the measured range. The optical system is zeroed using a sample solution with an RI of the zero value and by adjusting the zero meter reading. The displaced light beam (resulting from changes in sample RI) is detected by a change in the light intensities received by the two photocells, or phototubes, which result in more light impinging on one than on the other.

The amplifier senses the unbalance and changes the position of the null restorer glass via a servodrive to rebalance the light on the photocells. The servomotor also drives a helipot that tracks the position of the null glass as the RI measurement varies.

Temperature Effects Sample temperature is critical in obtaining accurate refractive index measurements. The differential refractometer generally employs a sample temperature controller to maintain the sample at a constant temperature. In some designs, the entire prism assembly is also controlled for maximum stability.

The range of this refractometer is determined by the shape of the reference cell (the angle between two refracting surfaces), the thickness of the zero restorer glass, and the span attenuation in the meter circuit. This design is very sensitive, compact, and flexible.

Flowing Reference Cell The sealed reference cell can be replaced by a flowing cell to allow a differential measurement between two process streams. This approach has been used in blending operations to continuously monitor the difference in RI before and after blending. Extraction and filtration processes can use this system to monitor the difference in RI continuously before and after the extraction step.

CRITICAL-ANGLE REFRACTOMETER

The *critical angle* is the angle of incident at which light is totally reflected (see Figure 8.52e). The critical-angle refractometer receives the reflected light from a prism interface with the process sample (Figure 8.52i).

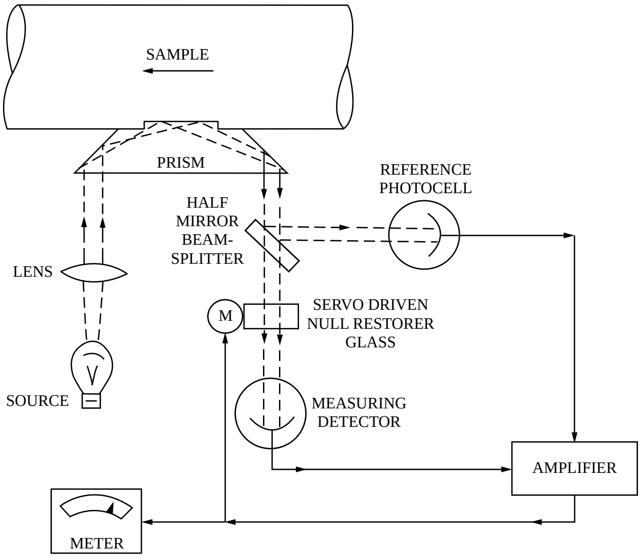

FIG. 8.52i
Schematic representation for the critical angle refractometer.

The light beam is focused on the prism–sample interface with different incident angles progressing across the width of the beam. Some of this light is transmitted into the sample medium, but reflection will occur only when the incident angles are larger than the critical angle. As the RI of the sample changes, the portion of the light beam that is reflected will also change, so the width of the reflected beam will change.

The point at which the change from refraction to reflection occurs is followed by the detector photocells. As the light beam width changes, more or less light falls on the measuring detector, causing an imbalance between the photocells. The amplifier senses this imbalance and repositions a restorer glass using a servo-balance system until the photocells are again in balance. A helipot in tandem with the null glass drive senses the position of the null glass as a measure of the critical angle.

The range of this instrument is determined by selection of prism glass material and restorer glass thickness.

Mounting and Compensation

This unit is frequently installed in line by mounting the prism assembly in a pipe and inserting this pipe section in the process line. The design also allows vessel mounting with the prism assembly inserted in a flange that can be attached to a vessel (storage tank, mixing tank, etc.). Such units can be used on slurry streams, opaque samples, and viscous samples that are not suited for measurement by differential refractometers.

If the temperature varies, temperature compensation can be provided by including a resistance thermometer or a thermistor-type sensor in the analyzer probe.

Design Variations

Figure 8.52j illustrates a probe-type refractometer design that is used in the food, paper, and chemical industries. This critical angle refractometer utilizes fiber optics and is microprocessor controlled.

The prism surface is wetted by the process fluid and, when light rays at different angles are directed at that surface, the rays arriving at a steep angle are mostly refracted, so the corresponding image sector is dark. On the other hand, the rays arriving at a flat angle are mostly reflected, so the corresponding image sector is light. The critical angle of reflection corresponds to the line where the light and dark regions meet. Hundreds of photocells are employed to accurately measure the position of the shadow edge and thereby to detect concentration of the process fluid, which rises as the dark area increases.

REFLECTED LIGHT MEASUREMENT

Some refractometer designs measure the total amount of reflected light, which also varies with the refractive index of the process fluid. One instrument (Figure 8.52k) uses a sapphire rod as a light guide, and it measures both the intensity

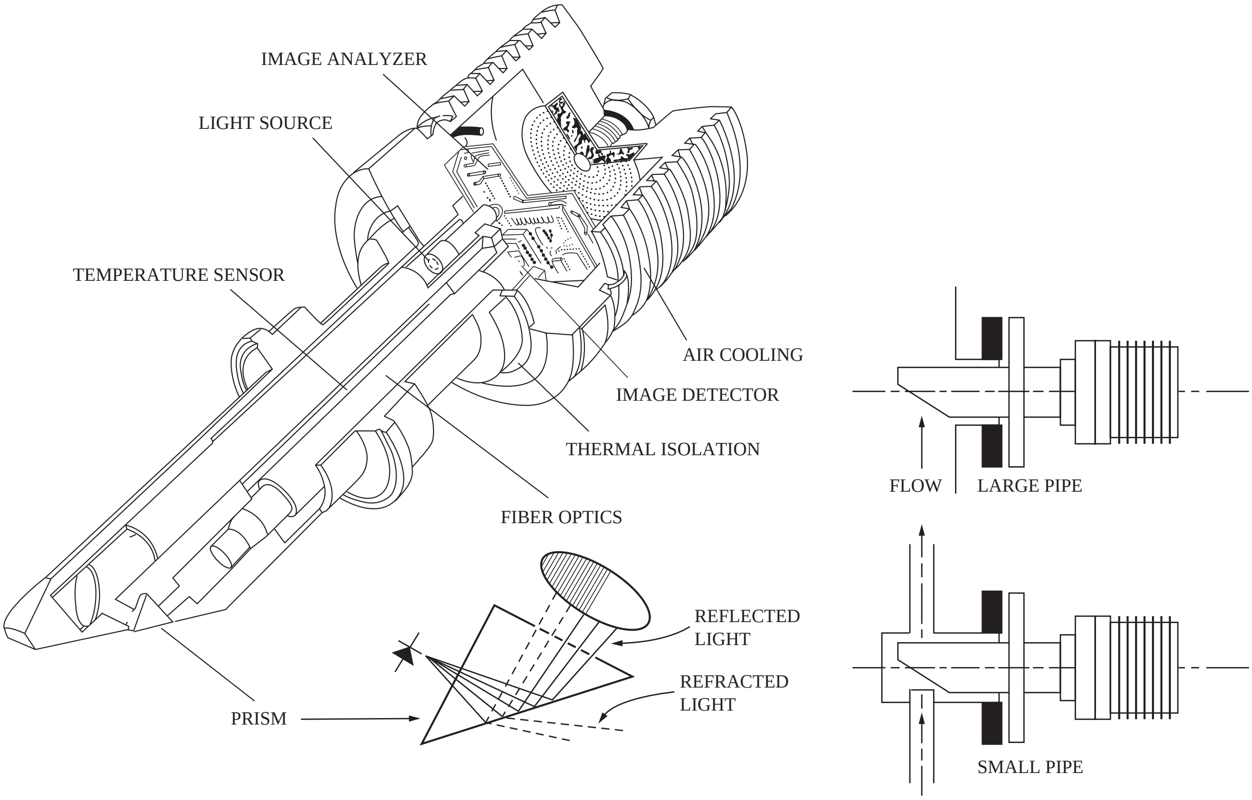

FIG. 8.52j
Probe-type critical angle refractometer. (Courtesy of K-Patents.)

of the light entering the rod and also the intensity of the reflected light. The percentage of reflected light varies with the refractive index and therefore with concentration.

Fiber Optic Probe

Figure 8.52l describes a reflective fiber optic probe design. Here, a small fiber optic probe [0.25 or 0.125 in. (6 or 3 mm) diameter] is used. The light that is transmitted to the prism is reflected into the fiber optic probe. When the prism is immersed in a process fluid that has a higher refractive index than that of the prism, the reflected light will significantly decrease.

Such detectors can measure concentration, because refractive index changes with concentration. One advantage of these temperature-compensated fiber optic probes is that a single readout instrument can monitor up to four probes inserted in four different locations in the process. This lowers the unit cost of measurement.

CAPABILITIES AND LIMITATIONS

The refractometer is a nonselective instrument that measures the RI of the entire sample. The RI of a mixture follows the simple mixture law,

$$N_{\text{mixture}} = C_a N_a + C_b N_b + C_c N_c + \cdots \qquad 8.52(5)$$

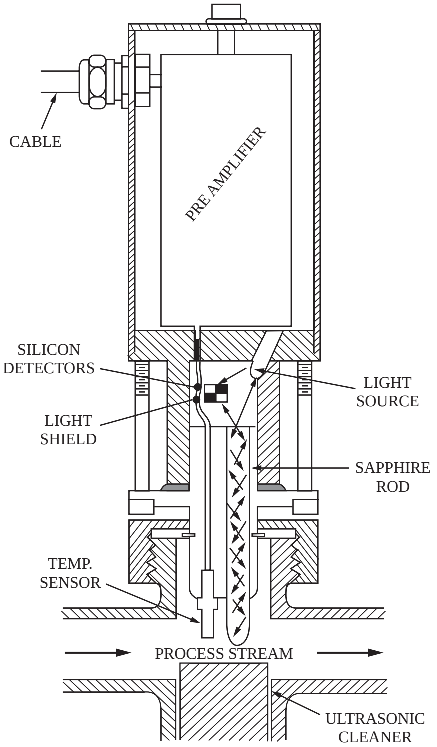

FIG. 8.52k
In-line, reflected-detecting refractometer with ultrasonic cleaner.

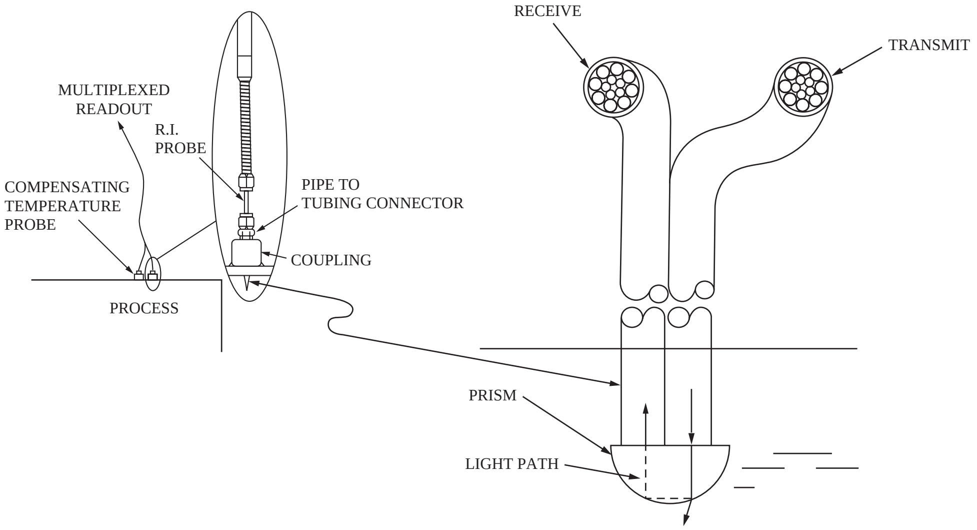

FIG. 8.52l
Temperature-compensated and multiplied fiber optic RI probe.

where

C_a, C_b, … = molecular concentrations of components a, b, c, …

N_a, N_b, … = the respective RI of components a, b, …

Thus, when used as a composition analyzer, the refractometer can monitor only binary mixtures.

Table 8.52f lists the RI ranges that the differential and the critical angle refractometers can handle, and Equation 8.52(5) can be used to determine the RI range required for an expected concentration change.

Because these are optical devices, it is necessary to keep their prism surfaces clean. The types of probe cleaners discussed in Sections 8.2 and 8.48 are also applicable to these instruments. The standard options offered by most suppliers include chemical or water washers, among other options.

Another limitation of this analyzer is a result of the temperature sensitivity of the angle of refraction. All refractometers must be temperature compensated unless used in a constant-temperature process.

CONCLUSIONS

When used for binary mixtures, the refractometer can be a very accurate analytical tool (Figures 8.52m and Figure 8.52n), but it is usually unable to detect trace impurities. Mixtures with trace components having RI values close to one of the major components may act as binary samples and can give satisfactory results. The differential refractometer is more sensitive than the critical angle refractometer, but it requires a sample-handling system and is limited to applications in which the sample is clean. The critical angle refractometer can monitor dirtier streams and can be installed in line.

8.53 Rheometers

J. MAGDA (2003)

Types:	A. Cone-and-plate B. Parallel-disk C. Coaxial-cylinder D. Rectangular torsion E. Bending and tension/compression F. Extensional flow rheometer G. Capillary rheometer
Linear Properties:	A. Elastic storage modulus vs. frequency B. Viscous loss modulus vs. frequency
Nonlinear Properties:	A. Viscosity vs. shear rate B. First normal stress difference vs. shear rate C. Second normal stress difference vs. shear rate D. Extensional viscosity vs. rate of extension
Frequency Range:	0.01–200 Hertz
Pressure:	Atmospheric
Temperature Range:	–150°C to +600°C
Cost:	$30,000 to $200,000
Partial List of Suppliers:	Bohlin (www.bohlinusa.com) Brabender (www.cwabrabender.com) Haake (www.haake.de) Paar Physica (www.paarphysica.com) RheoSense (www.rheosense.com) TA Instruments (www.tainst.com)

INTRODUCTION

Viscometers (Sections 8.62 and 8.63) are used solely for the measurement of the viscosity of fluids. A rheometer by definition can be used not only to detect viscosity but also to measure the viscoelastic properties of fluids, semisolids, and solids. These additional capabilities of rheometers may justify their consideration, in spite of the additional expense, when high-quality polymeric (thermoplastic) raw materials are to be manufactured.

Reasons for Using Rheometers

Some of the justifications for performing rheological analysis on molten thermoplastics prior to molding or extrusion operations are as follows:

1. *Solvent-free characterization of the molecules present in the polymer.* Thermoplastic raw materials are a mixture of molecular species that vary widely in size and degree of molecular branching (see Section 8.35 on molecular weight measurement). Rheological analysis of a small amount of the molten polymer without solvent can be used to detect batch-to-batch variations in the polymeric raw material that may be deleterious to the properties of the final product. An industrial viscometer such as a melt flow indexer will suffice to detect large variations in the average molecular weight of the polymer. However, the entire molecular weight distribution (MWD) of the polymer sample can only be determined with the extra capabilities of a rheometer.

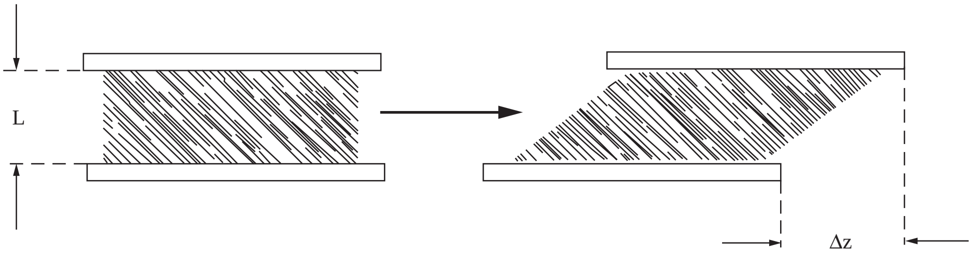

FIG. 8.53a
Stress relaxation test at fixed shear strain.

2. *Measurement of polymer flow properties that are key to the stability of polymer processing flow.* When attempting to switch the raw material used in an existing manufacturing process, it is important to maintain the values of key polymer flow properties, or significant modifications of the manufacturing process will be necessary. Many of these key nonlinear flow properties (viscosity, extensional viscosity, normal stress differences) can be measured using a rheometer at high shear rates or high extension rates under conditions that mimic the conditions present in the actual polymer processing flow.

Dynamic Mechanical Analysis

Rheometers are also useful for analyzing solids manufactured from polymers. Polymer solids, of course, cannot flow in a rheometer, but they nonetheless exhibit both viscous and elastic behavior when undergoing oscillatory deformations and hence are said to be *viscoelastic materials*. Some of the reasons for using oscillatory rheometers to perform dynamic mechanical analysis (DMA) on viscoelastic solids are as follows:

1. *Determination of the glass transition temperature.* The temperature range over which a solid part can be used depends to a large extent on the glass transition temperature (T_g) of the polymer from which it is fabricated. DMA is a very sensitive technique for measuring T_g. For an amorphous polymer, the value of the dynamic shear modulus measured in DMA experiments at fixed frequency drops by three orders of magnitude when the temperature exceeds T_g.
2. *Performance prediction.* Polymeric solids differ from other materials in that the mechanical properties depend strongly on temperature and time as well as on the polymer molecular weight distribution, the presence of additives or fillers, and the process conditions used to fabricate the part. Hence, tabulated mechanical properties for different polymers are of limited accuracy, and DMA experiments used with time-temperature superpositioning (discussed later) provide a better method for estimating the long-term mechanical behavior of a given polymeric solid part.

TESTS TO DISTINGUISH LIQUIDS FROM SOLIDS

The goal of scientific rheometry is to study the mechanical forces in a liquid or a solid sample subjected to a known and controlled velocity field or strain field.

Shear-Strain Tests

A liquid, by definition, cannot resist a shear stress at rest, which means that the shear stress must eventually decay to zero in the absence of flow. Hence, the rheological experiment known as the *shear stress relaxation* shown schematically in Figure 8.53a is an excellent method for determining whether a given polymer sample is a viscoelastic liquid or a viscoelastic solid.

In this experiment, one imposes a chosen value of the shear strain on the sample and measures the resulting shear stress as a function of time. Initially, the sample is in a stress-free rest state between two parallel semi-infinite solid plates separated by a gap L. At time equal zero, the top plate is suddenly moved to the right by a chosen distance Δz while the bottom plate is held stationary. Assuming good adhesion with no slip at the sample/plate interface, this imposes a time-independent shear strain γ on the sample equal to Δz/L.

The horizontal force F exerted to keep the bottom plate stationary is measured as a function of time. The value of this force divided by the sample-contacting area A of the plate is equal to the shear stress τ. If τ eventually decays to zero, the sample is a liquid; otherwise, the sample is a solid. In a linear stress relaxation experiment, the sample is subjected to a small strain that only slightly perturbs the sample on a molecular level from its equilibrium state. For sufficiently small strains, the linear shear stress relaxation modulus G is given by

$$G = \tau/\gamma \qquad \textbf{8.53(1)}$$

The key test for a liquid is, “Does G approach zero after the passage of a long time period (t)?” A more practical way to answer this question is by the use of oscillatory shear experiments in dynamic mechanical analysis (DMA), a technique described in more detail later. The influence of time t in a linear stress relaxation experiment is equivalent to the influence of the period of oscillation in DMA. Hence, the key test for a liquid can be rephrased as, “Does the elastic storage modulus G′ (defined later) approach zero at low frequencies?”

Stress-Controlled Tests

The *shear creep test* is complementary to the stress relaxation experiment. In shear creep, one imposes a chosen value of the shear stress and measures the resulting value of the strain as a function of time. Initially, the sample is in a stress-free rest state between two parallel semi-infinite solid plates separated by a gap L. At time zero, the top plate is suddenly pulled to the right with a constant force per unit area τ (τ = F/A) while the bottom plate is held stationary. This imposes a time-independent uniform shear stress τ on the sample, assuming good adhesion at both sample–plate interfaces.

If, after the passage of a long time period, the top plate is observed to move a certain distance Δz to the right and stop, then the sample is a solid. If, on the other hand, the top plate does not stop moving but reaches a terminal velocity V, then the sample is a liquid, and the velocity field within the liquid is linear and called *rectilinear simple shear flow.* In this case, the shear rate or rate of strain κ is calculated as V/L, and the shear viscosity μ is defined as the shear stress divided by the shear rate.

Unless κ is very small, simple shear flow is a so-called nonlinear flow, because the alignment of the polymer molecules in the sample will be significantly perturbed by the flow. Because the degree of perturbation increases with shear rate κ, it is not surprising that the shear viscosity value μ also varies with κ, which is called *non-Newtonian behavior.*

Nonlinear Shear Flow Properties (μ, N_1, N_2)

A non-Newtonian liquid in shear flow has three independent nonlinear flow properties: viscosity (μ), first normal stress difference (N_1), and second normal stress difference (N_2).

Shear viscosity μ is a measure of the liquid's resistance to flow, and N_1 and N_2 are manifestations of liquid elasticity. For Newtonian liquids such as water, N_1 and N_2 are both zero. However, polymer molecules in steady shear flow are stretched along the flow direction and compressed along the direction perpendicular to the plates in Figure 8.53b, which gives rise to nonzero N_1 and N_2 values. Although N_1 and N_2 are difficult to measure, there is a growing consensus that their values are important to the behavior of thermoplastics in practical polymer processing flows.

In extrusion, when a thermoplastic exits the die into air or another cooling fluid, the amount of extrudate die swell depends strongly on the value of N_1 for the thermoplastic. The value of N_2 is thought to be critical to the stability of multilayer coextrusion, which is a manufacturing process in which two immiscible thermoplastics are extruded through the same die so as to produce a layered product. Even if the two thermoplastics have identical viscosity curves, a difference in N_2 values may result in a flow disturbance that disrupts the layered structure.

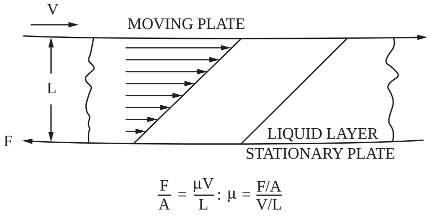

FIG. 8.53b
Rectilinear simple shear flow.

RHEOMETER SELECTION

In selecting a rheometer design to analyze a polymeric sample, the following questions should be considered:

1. What class of deformation or flow is most relevant, shear or extension (elongation) or a combination of these two basic types, such as bending?
2. Should the sample deformation rate be constant or oscillatory? A constant rate of deformation is impossible for a viscoelastic solid. For constant deformation rate experiments, what is the necessary range of shear rates or extension rates? For oscillatory deformations, what is the necessary range of frequencies?
3. Will the rheometer control the amount of stress applied to the sample (i.e., stress-controlled rheometer) or the amount of strain applied to the sample (i.e., strain/strain-rate-controlled rheometer). Strain/strain-rate-controlled rheometers cannot be used to measure the true value of the yield stress for weak solids.
4. Will the sample adhere to the stainless steel fixtures of the rheometer so that the no-slip boundary condition is satisfied, or will it be necessary to clamp the sample? Are large solid particles suspended in the sample, comparable in size to the gap of the proposed rheometer fixture? If so, a fixture with a larger gap must be used.
5. Is the sample corrosive, volatile, combustible, or otherwise destructive to stainless steel rheometer fixtures? To study the gelation of network-forming materials like epoxies, disposable rheometer fixtures will probably be required.
6. What is the required temperature range for testing? Liquid nitrogen cooling may be required for subambient testing temperatures.
7. What is the sensitivity required for stress or strain measurement? What is the maximum stress value to be measured or applied to the sample?

RHEOMETER DESIGNS

Cone-and-Plate Design

In shear creep experiments, all viscoelastic liquids are expected to exhibit the velocity field known as simple shear flow at steady state (Figure 8.53b), barring the occurrence of certain flow disturbances that will be discussed later. For liquids with long relaxation times, the use of rotational shear flow geometries is the most practical method for achieving this steady-state condition in the laboratory.

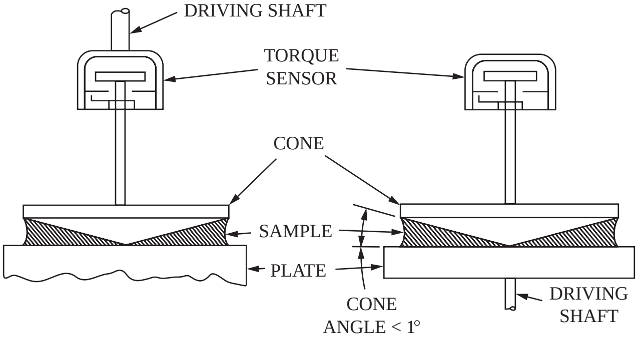

FIG. 8.53c
Cone-and-plate instruments.

The cone-and-plate flow geometry (Figure 8.53c) consists of a stationary flat plate (really, a disk) and a rotating cone with a very shallow cone angle. The tip of the cone is truncated by a small amount, on the order of 50 to 100 μm. During testing, the cone is lowered so that its tip, if it were present, would just touch the center of the plate. The liquid sample fills the narrow gap between the cone and the plate and is held in place during testing by surface tension forces, provided that the inertia is not too large.

The temperature of the sample is often monitored with thermocouples embedded in the rheometer plate. In a strain-rate-controlled cone-and-plate rheometer, a variable-speed motor drives the cone at a precise rotation speed while the torque required to keep the rheometer plate stationary is calculated from the measured deflection of a torsion spring. Hence, the strain-controlled rheometer can be operated in a mode very similar to the idealized stress relaxation experiment (Figure 8.53a).

In a stress-controlled cone-and-plate rheometer, a constant torque is applied to the drive shaft of the cone, and the rotation of the cone that results is measured with an optical encoder. Hence, the stress-controlled rheometer can be operated in a mode very similar to the idealized shear creep test already discussed. For both types of rheometers, the cone rotation speed Ω and the torque T will have chosen or measured values at steady state, assuming that the sample is a liquid. The velocity field in the liquid is expected to be identical on a local level to rectilinear simple shear flow. The cone-and-plate flow geometry is widely used for testing non-Newtonian liquids, because the shear rate value κ is the same everywhere within the sample and is given by

$$\kappa = \Omega/\alpha \tag{8.53(2)}$$

Here, Ω is the rotation speed of the cone, and α is the cone angle. Assuming that the velocity field in the sample is simple shear flow as expected, the torque T on the rotating cone is related to the shear stress τ by fluid mechanics.

$$\tau = 3\,T/(2\pi R^3) \tag{8.53(3)}$$

Shear Flow Properties In Equation 8.53(3), R is the radius of the cone and the plate. The non-Newtonian shear viscosity is defined as

$$\mu = \tau/\kappa \tag{8.53(4)}$$

Equations 8.53(2) through 8.53(4) are solved simultaneously to give the viscosity value for both stress-controlled and strain-rate-controlled cone-and-plate rheometers. Due to elasticity, a polymeric liquid will tend to push the cone and plate apart during flow. By measuring the total vertical force F_N exerted on the plate during testing, one can calculate the first normal stress difference of the sample using a result from fluid mechanics as follows:

$$N_1 = 2F_N/(\pi R^2) \tag{8.53(5)}$$

The third independent shear flow property, N_2, cannot be measured using commercially available rheometers. However, at least one company is attempting to develop a new cone-and-plate design in which N_2 can be calculated from measurements of the difference in pressure between the center and the rim of the rheometer plate.

Torque Ranges The most important cone-and-plate rheometer design feature is the method by which the shear stress is measured (or the strain, in a stress-controlled rheometer).

In a strain-rate-controlled rheometer, the motor that drives the cone has a typical rotation speed range of 0.001 to 100 rad/s. Typical cone angles range from 0.02 to 0.10 rads. Hence, according to Equation 8.53(2), the theoretical shear rate available with the rheometer is 0.01 to 5000 s^{-1}. However, the actual available shear range is usually much smaller as a result of torque transducer sensitivity limitations at low shear rates and flow disturbances at high shear rates (see below).

Because the onset of flow disturbances varies considerably with the material being tested, no shear rate range is given in the feature summary at the beginning of this section. In a rate-controlled rheometer, both the torque T and the total vertical force F_N are usually calculated from the deflection of a spring measured using a displacement transducer of a differential transformer type. Care must be taken that the vertical deflection of the spring used to measure F_N does not cause a significant change in the gap between the cone and the plate. Because rotational friction from the instrument itself is detrimental to sensitivity, top-of-the-line rheometers employ air bearings on the cone drive shaft.

A given rheometer is sometimes said to cover a certain measurable range of fluid viscosities, but it is really more accurate to say that the rheometer covers a certain measurable range of torques. A typical rheometer transducer can be used accurately over a torque range covering perhaps four orders of magnitude, from 0.00001 to 0.1 Nm. Alternative transducers covering both higher and lower torque ranges are also available.

For a given rate-controlled rheometer, the minimum viscosity value that can be measured can be calculated from the minimum measurable torque value, the maximum possible shear rate, and the maximum available cone-and-plate radius using Equations 8.53(2) through 8.53(4). These equations show that, for low-viscosity fluids, the torque value T, and hence measurement accuracy, can be enhanced by increasing the shear rate κ or by increasing the cone-and-plate radius R.

Rheometer Selection The choice between a strain/strain-rate-controlled rheometer and a stress-controlled rheometer often depends on whether stress relaxation data or shear creep data is more desirable. However, the stress-controlled rheometer can be operated in strain-controlled mode through use of a feedback control loop that manipulates the value of the imposed torque; however, time to set strain is longer than for a strain-controlled rheometer. In addition, strain-rate-controlled rheometers should not be used to study the flow properties of a sample that might be a weak solid, because the driven rotation of the cone will damage the sample structure.

Observation of hysteresis in the viscosity curve (μ vs. κ) indicates that the structure of the sample has been damaged by flow. The properties of a fragile solid can be measured by using a strain-controlled rheometer in low-amplitude oscillatory measurements (discussed in a later section) or by using a stress-controlled rheometer. In a stress-controlled rheometer, a strain transducer is used to measure sample strain or rate of strain in response to a chosen shear stress value τ. If the sample has a yield stress value that exceeds τ, then the measured steady-state rotational speed of the cone will be zero, a result that indicates that the sample is a weak solid.

Experimental Difficulties The goal of scientific rheometry as applied to liquids is to study the mechanical response of the liquid when subjected to a known and controlled velocity field. Unfortunately, there is no way to know beforehand whether a given rheological sample will exhibit the expected velocity field in the cone-and-plate device or any other rheometer. If the actual velocity field within the rheometer is disturbed from the expected flow pattern, then the rheometer software will probably calculate incorrect values for the viscosity and other rheological properties.

Because of flow field disturbances, it is virtually impossible to measure μ, N_1, and N_2 values with a cone-and-plate flow geometry at the high shear rate values typical in manufacturing operations ($\kappa = 10 - 1000\ s^{-1}$ for extrusion, $\kappa = 1000 - 50000\ s^{-1}$ for injection molding). Figure 8.53d shows a sketch of one such flow disturbance called *edge fracture*. These flow disturbance are thought to be driven by elasticity or inertia and can be delayed to higher shear rates by reducing the cone angle or the cone-and-plate radius. They do not occur when the cone-and-plate geometry is used for linear rheological measurements. This is a principal reason why linear properties G′ and G″ are more commonly measured in industrial laboratories than N_1 and N_2, even though linear rheological properties have no direct relevance to the flow conditions actually present in thermoplastic processing flows, which are usually very nonlinear.

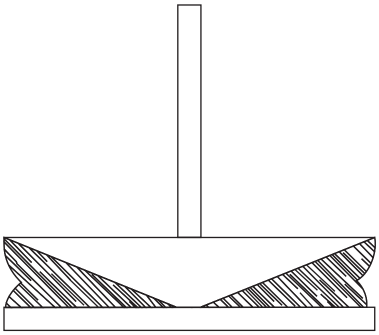

FIG. 8.53d
Flow disturbance due to edge fracture of sample in cone-and-plate instrument.

Dynamic Mechanical Analysis Linear rheological properties are measured when the strain field or velocity field only slightly perturbs the sample on a molecular level from its equilibrium state. For molten thermoplastics, linear rheological measurements have no direct relevance to polymer processing flows, because most practical manufacturing flows are highly nonlinear. However, linear rheological measurements are still very useful for characterizing the polymer molecules or making a rheological *fingerprint* of the raw material.

Linear rheological properties are most commonly measured in oscillatory experiments called dynamic mechanical analysis (DMA). For a liquid in oscillatory shear, the typical experimental setup is identical to that for simple shear flow (Figure 8.53c), with the sole exception being that the cone does not rotate continuously in one direction but, rather, alternates between clockwise and counterclockwise rotations periodically at an angular frequency ω.

The rheometer plate is held stationary, which imposes a sinusoidal shear strain on the sample, as sketched in Figure 8.53e. If $\Delta\Phi$ is the maximum angular displacement of the cone, then the amplitude of the strain curve is given by

$$\gamma_{max} = \Delta\Phi/\alpha \qquad 8.53(6)$$

where α is the cone angle. The torque necessary to keep the plate from rotating is measured and used to calculate the shear stress τ via Equation 8.53(3). Typical behavior for the shear stress τ is also plotted against time in Figure 8.53e. Note that the shear stress and the shear strain are both sinusoidal functions of time, and they both have the same angular frequency ω. However, there is a phase shift between the two curves—the strain curve lags the stress curve by a constant phase angle denoted δ.

Linear Viscoelastic Shear Moduli G′, G″ The amplitude of the shear stress curve divided by the amplitude of the shear strain curve is denoted G*, the dynamic shear modulus. Thus,

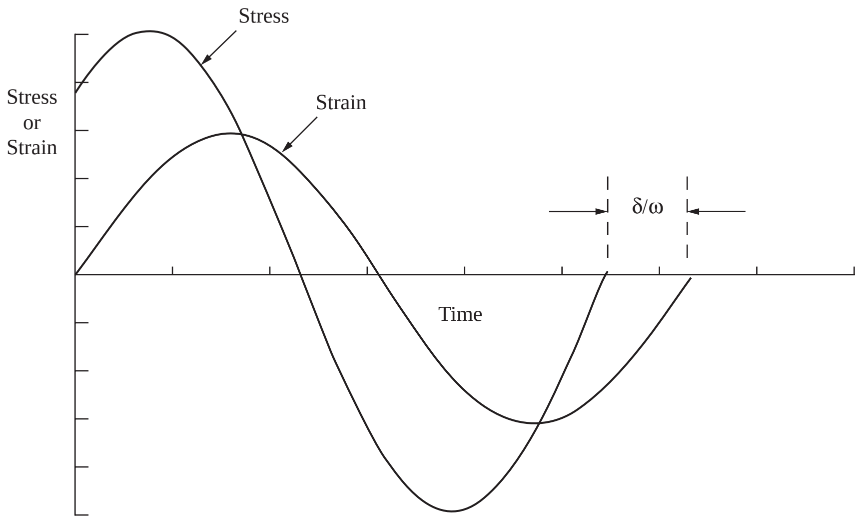

FIG. 8.53e
Typical stress and strain curves in DMA.

the oscillatory shear experiment yields two independent rheological properties: G* and δ. To obtain linear rheological properties, one needs to check that the measured values of G* and δ are independent of γ_{max}. An alternative set of properties are the elastic storage modulus (G′) and the viscous loss modulus (G″), given by $G' = G^* \cos \delta$, $G'' = G^* \sin \delta$.

For a cyclical shear deformation process at frequency ω, G′ is a measure of the sample's ability to store elastic strain energy, and G″ is a measure of viscous energy dissipation. The relative importance of energy dissipation and energy storage is given by the loss tangent tan δ,

$$\tan \delta = G''/G' \qquad \textbf{8.53(7)}$$

The value of tan δ is infinite for a purely viscous liquid, zero for a perfectly elastic solid, and intermediate between these two extremes for a real viscoelastic material. However, the mechanical behavior of most viscoelastic materials (solid or liquid) becomes more like the perfectly elastic solid as the frequency is increased, which may be explained as follows.

When a polymeric sample is subjected to a shear strain, the polymer molecules have many different modes for relaxing the stress with widely varying relaxation times. At very low oscillation frequencies, almost all of these relaxation modes are fast enough to be operative, so energy storage is minimal. Conversely, at very high frequencies, most of the polymer molecules do not have sufficient time to relax during the period of oscillation ($2\pi/\omega$). Thus, the polymer molecules remain stretched throughout the entire oscillation cycle, giving rise to increased elastic energy storage and increased shear modulus G′.

Molecular Weight Distribution Polymeric materials have a wide spectrum of relaxation times, with each relaxation time corresponding to a different possible mode of mechanical relaxation. As explained in the preceding section, one can probe the mechanical relaxation processes that occur at different time scales by measuring oscillatory shear properties at various frequencies. The largest molecules in the sample contribute to relaxation processes occurring at long times or low frequencies, whereas small molecules contribute to relaxation at high frequencies.

In recent years, rheometer companies have introduced software that can be used to invert curves of G′ and G″ vs. ω measured for a molten thermoplastic to give the molecular weight distribution (MWD) of the sample (Section 8.35). This method of estimating the MWD is more sensitive to the presence of polymer branches and high-molecular-weight *tails* in the sample than traditional solution-based methods such as gel permeation chromatography (Section 8.35). However, the theory on which the inversion software is based is still evolving and thus may not work for all types of polymers. Dynamic curves measured on samples in the solid state cannot be inverted to give the MWD.

Time-Temperature Superposition Time-temperature superposition is an approximate method used by experimental rheologists to extend the effective frequency range of a rheometer in DMA experiments. As an example, suppose one is interested in predicting the in-use mechanical performance of a polymeric solid subjected to a constant stress for one week at 25°C. The appropriate frequency range for DMA of the solid at 25°C would be $(1\ \text{week})^{-1} \approx 10^{-6}\ \text{sec}^{-1}$, which might be too low to access with a given rheometer. However, if the empirical time-temperature shift factor for the sample (a_T) is known to be 1×10^{-3} for shifting between 25°C and 90°C, then the appropriate frequency range for DMA at 90°C is $10^{-6}\ \text{sec}^{-1}/a_T = 10^{-3}\ \text{sec}^{-1}$, which may be accessible to the rheometer motor.

If the principle of time-temperature equivalency is valid for this sample, then the value of G* measured at 90°C and a frequency of $\omega = 10^{-3}\ \text{sec}^{-1}$ is approximately equal to the value of G* for the same sample at 25°C and $\omega = 10^{-6}$ $\sec^{-1}$. Unfortunately, this principle fails for many complex polymer materials. In particular, the principle fails if the sample has a phase transition in the temperature range between the use temperature and the testing temperature.

Conversion Among Rheological Properties Linear rheological properties measured in oscillatory shear can be rigorously converted to linear rheological properties defined for stress relaxation tests, shear creep tests, or any other linear experiment. The software needed for the conversion is often supplied with the rheometer. However, the software cannot be used to calculate nonlinear rheological properties such as the non-Newtonian viscosity vs. shear rate.

Parallel-Disc Design

The principal advantage of the cone-and-plate instrument is that it imposes a uniform value of the strain rate κ on the sample in flow experiments and a uniform value of the shear strain γ in DMA experiments. This is particularly useful when analyzing liquids such as molten thermoplastics having properties that strongly depend on κ.

Unfortunately, the cone-and-plate geometry cannot be used to analyze solids. Recall that the cone, which has a truncated tip, should be slowly lowered into the sample until the truncated region is only 50 to 100 μm above the plate, depending on the cone. This cannot be done with solid samples. Probably, it should not be done either with liquid samples containing particles larger than a few micrometers in size, because particles of this size are large enough to disturb the flow field in the narrow gap region of the cone-and-plate instrument.

Parallel-Disc Geometry The parallel-disc rheometer geometry (Figure 8.53f) is obtained by replacing the cone in a cone-and-plate instrument with a stainless steel disc of the same diameter. All other features of the rheometer, including transducers and drive motors, remain the same. The sample must be cut or molded into a disc of uniform thickness and radius equal to the rheometer disc radius. The sample is sheared in between the two parallel stainless steel discs or plates, with the same rheometer gap at all radial positions. The parallel-disc geometry can be used to study a solid sample of any thickness, provided that the sample adheres to the surfaces of the discs. For analysis of suspensions, one can minimize wall-slip errors by choosing the gap to be much larger than the suspended particle size.

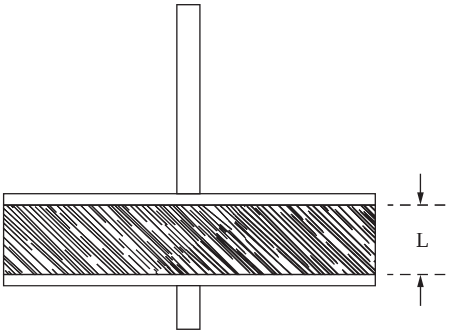

FIG. 8.53f
Parallel-disk instrument.

The parallel-disc instrument, like the cone-and-plate, can be used to make either stress-controlled or strain-controlled measurements on the sample in steady-shear flow or oscillatory shear strain. The flow field in the instrument is expected to be equivalent to simple shear flow (Figure 8.53b) on a local level, but the local value of the shear rate κ increases with radial coordinate. The maximum value of the shear rate occurs in the sample located at the rim of the parallel discs, and is equal to

$$\kappa_{\max} = R\,\Omega/L \qquad \textbf{8.53(8)}$$

Here, R is the radius of the discs, Ω is the angular speed of the rotating disc, and L is the gap between the discs. The parallel-disc instrument can be used to measure the viscosity μ, N_1, G′, or G″.

Limitation The principal disadvantage of the instrument arises from the variation of the shear rate value within the sample. As a consequence, the parallel-disc instrument cannot be used to make a single-point measurement of the viscosity of a non-Newtonian liquid. This may be seen from the fluid mechanics equation used to calculate the viscosity. If the shear rate at the rim of the discs is $\kappa_{\max}$, and the torque on the discs is T, then the sample viscosity value at shear rate equal to $\kappa_{\max}$ is given by

$$\mu = T(2\pi R^3 \kappa_{\max})^{-1}\,[3 + d\,\ln(T/(2\pi R^3))/d\ln(\kappa_{\max})] \qquad \textbf{8.53(9)}$$

Equation 8.53(9) contains the derivative of the torque with respect to the shear rate at the rim, in contrast to the analogous equation [Equation 8.53(3)] used with the cone-and-plate instrument. Hence, to determine the viscosity at a single value of the shear rate, one has to measure the torque at several different rim shear rate values and then numerically evaluate the derivative in Equation 8.53(9).

Rectangular Torsion Design

The parallel disc instrument can be used only with solid samples that adhere to the stainless steel discs so that the *no slip* boundary condition is satisfied. *Slip* refers to the occurrence of relative motion between the steel and the sample located at the steel/sample interface. When slip occurs during DMA experiments, the computer software will use a value for the strain that is larger than the true value imposed on the sample.

One way to detect the occurrence of slip is to see if slight compression of the sample between the parallel plates has a

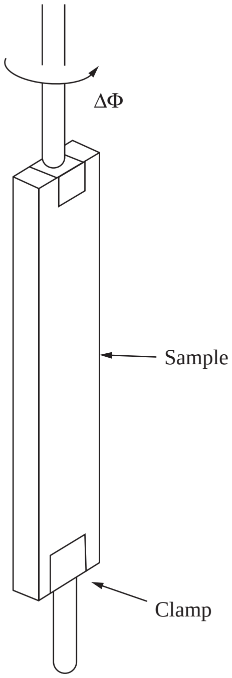

FIG. 8.53g
Rectangular torsion instrument.

drastic effect on the DMA results. When slip is a problem, the rectangular torsion instrument (Figure 8.53g) offers a viable alternative to the parallel-disc instrument for solid samples. The sample must be cut or molded into a thin rectangular specimen of uniform thickness.

The specimen is clamped into the instrument at both ends, and the clamping force is adjusted so that no slip can occur. During testing, one clamp undergoes low amplitude oscillatory rotations at frequency ω while the torque required to keep the other clamp stationary is measured with a torque transducer. The experimentally determined properties are the dynamic shear moduli of the sample, G′ and G″, as a function of frequency.

Torsional DMA can be used to identify the specimen glass transition temperature as the temperature at which G′ drops precipitously at fixed frequency. However, torsional DMA cannot be used to determine the MWD of the specimen.

Coaxial-Cylinder Design

The principal advantage of the coaxial-cylinder instrument (Figure 8.53h) is a large surface area for contact between the sample and the instrument, which increases torque levels and hence is advantageous for measuring low viscosity values. However, the instrument cannot be used to measure normal stress differences and cannot easily be used with solid samples. The liquid sample completely fills the narrow gap or annulus between two concentric cylinders.

During testing, the outer cylinder (called the *cup*) is rotated while the inner cylinder (the *bob*) is held stationary. When the cup is rotated continuously, the flow field in the sample looks like simple shear flow (Figure 8.53b) on a local level. However, as with the parallel-disc instrument, the shear rate value varies with location within the sample. The sample viscosity is calculated from the measured torque on the bob. Linear shear moduli G′ and G″ can also be measured in experiments in which the cup undergoes oscillatory rotations.

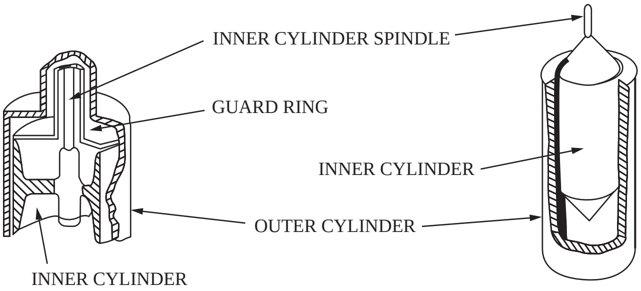

FIG. 8.53h
Coaxial-cylinder instruments.

Tension/Compression and Bending Designs

All of the instruments considered thus far impose a shear deformation (Figure 8.53a) on the sample. However, the behavior of a solid sample during tension, compression, or bending may also be of interest, and instruments are also available for these types of deformations.

In fact, the principal difference between a so-called *rheometer* and a *dynamic mechanical analyzer* is the number of instruments available with the latter for applying various bending and tensile deformations on solid samples. The bending and tensile/compression deformations are usually applied to the specimen as an oscillatory function of time at angular frequency ω. When a small time-independent uniaxial tensile deformation is applied to a specimen, the ratio of the tensile stress to the tensile strain is defined as the linear elastic tensile modulus E.

In oscillatory experiments, one measures at each frequency the tensile storage modulus (E′) and tensile loss modulus (E″), properties which are analogous to G′ and G″, defined earlier for shear. In fact, for a material that does not undergo volume changes during deformation, the dynamic tensile moduli are exactly three times larger than the corresponding dynamic shear moduli.

Extensional Flow Rheometer

The value of the extensional viscosity μ_{ex} is a measure of a liquid's resistance to stretching during flow. For commercial thermoplastics, the value of μ_{ex} is important in plastics-forming operations such as fiber spinning and blown-film extrusion.

Figure 8.53i shows an idealized representation of uniaxial extensional flow. Here, the cylinder of liquid is stretching along its longitudinal axis while contracting in the radial dimension so that the volume remains constant. To obtain a constant extension rate, the stretching force F is adjusted in

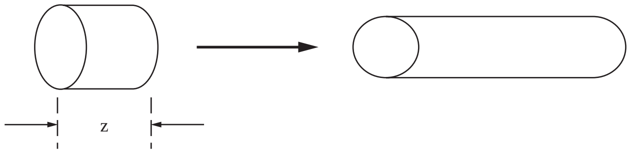

FIG. 8.53i
Uniaxial extensional flow.

such a way that the length z of the liquid cylinder increases exponentially with time t.

$$z \propto \exp(\varepsilon t) \qquad \textbf{8.53(10)}$$

Here, ε is the rate of extension, analogous to the rate of strain κ in shear flow. The stretching force F and the cylinder cross-sectional area A are both functions of time. The extensional viscosity μ_{ex} is a material property defined as

$$\mu_{ex} = F/(A\varepsilon) \qquad \textbf{8.53(11)}$$

Thus, for a given rate of elongation ε, the necessary stretching force increases with the elongational viscosity of the liquid μ_{ex}. Two thermoplastic samples may have identical shear viscosity curves (μ vs. κ) and completely different extensional viscosity curves (μ_{ex} vs. ε).

For some thermoplastics, the measured value of μ_{ex} calculated with Equation 8.53(11) never reaches a steady value, even though the extension rate is constant. There is little doubt that μ_{ex} is a key property for polymer processing flows that has been comparatively neglected in rheometry.

Extensional Viscosity Detectors Rheometers that have been built for measuring the extensional viscosity have used different techniques. These included the capillary breakup, rotary clamp stretching, stagnation point flow, and opposing jets techniques. However, it has proven difficult to build a robust and accurate extensional flow rheometer for industrial use.

Between 1987 and 1990, the International Committee on Rheology organized a round-robin test of extensional flow rheometers. In this test, the value of μ_{ex} was measured for an international standard fluid in various laboratories around the world. The test results were disappointing, with values measured in different laboratories varying by as much as several orders of magnitude. More recently, the filament stretching technique has found favor among academic laboratories for measurements of the extensional viscosity.

Capillary Rheometers

The capillary rheometer is used to study the pressure-driven flow of a molten thermoplastic through a capillary. The viscosity of the process sample can be calculated from measurements of volumetric flow rate vs. pressure drop along the capillary axis. Ordinarily, capillary rheometers are used only to calculate the viscosity, hence, these devices are covered under the discussion of industrial viscometers (Section 8.64).

However, it is possible to use capillary rheometry to measure N_1 as well as the viscosity. This can be done by varying the length of the capillary (at fixed diameter) and noting the effect on the pressure drop within the entrance region of the capillary.

CONCLUSIONS

Molten thermoplastics have several elastic properties in addition to the viscosity that can be measured by using rheometers. True material properties can be measured only if the rheometer subjects the sample to a controlled velocity field or to a controlled deformation. Hence, the popular melt flow indexer, while useful, cannot be used to measure a true material property such as viscosity.

Probably the most significant future innovation will be the development of an on-line process rheometer for use in controlling polymer-processing operations. Currently, there is no commercial rheometer that can be used to continuously measure the true elastic properties of a thermoplastic during extrusion.

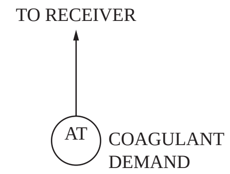
8.54 Streaming Current or Particle Charge Analyzer

W. F. GERDES (1974, 1982) **B. G. LIPTÁK** (1995, 2003)



Flow Sheet Symbol

Applications:	Batch operations, titration, and continuous monitoring; can control the clarification of beverages, dewatering, thickening of suspensions, addition of coagulant chemicals, and treatment demand by measuring the surface charge on particles
Materials of Construction:	Stainless steel, silver, and Teflon®
Sample Size Required:	About 10 cc
Approximate Cost:	$10,000 to $15,000
Partial List of Suppliers:	Automated Aquarium Systems (www.automatedaquariums.com) Colloidal Dynamics (www.colloidal-dynamics.com) Dispersion Technology (www.dispersion.com) Honeywell Inc. (www.honeywell.com) Komline-Sanderson (www.komline.com) Matec Instrument Co. (www.matec.com) Mutek GmbH (www.mutek.com) Panametrics (www.panametrics.com) Particle Sizing Systems (www.pssnicomp.com/)

INTRODUCTION

The accurate measurement of surface charges on the suspended particles is important when studying the adsorption characteristics of colloidal suspensions. In water or waste treatment, the streaming current detector (SCD) can be used to estimate the amount of treatment required and to continuously control the addition of coagulation chemicals by detecting the surface charge on particles.

Less directly, SCD can compare the ability of alternative treating chemicals to influence the electric charge of particles, and it can determine the effect of pH on a chemical's ability to promote or enhance coagulation. The most effective use of chemicals requires a recognition of the role of electrical charges in stabilizing suspensions.[1]

OPERATING PRINCIPLES

In ionic liquids, any interface with a solid or a second liquid will have an electrical charge that is caused by the preferential adsorption or positioning of ions. The liquid adjacent to the interface surface will contain excess charges of the opposite sign, called counter-ions.

If charged particles are attached to a filter or capillary wall, these counter-ions can be swept downstream by a stream of water. This flow of charges of predominantly one sign constitutes a current called the *streaming current.* In the case of an insulating capillary, the return path is by ionic conduction through the liquid in the stream. With suitable electrodes, the return path can be arranged so as to measure this streaming current.

The Streaming Current

The van der Waals force causes particles that carry high charges to be preferentially adsorbed to the surfaces of a cylinder and piston as shown in Figure 8.54a. When such a particle is moved upward by the piston movement, its counter-ions are sheared off as the fluid moves in the opposite direction relative to the piston. The totality of these ions is the streaming potential detected by this analyzer.

Because the energy level of the streaming current is small as compared to the random signals from electrodes and from inadvertent thermocouples, it is advantageous to develop a reversing or alternating signal. This signal of known frequency can be more readily distinguished from noise that occurs at other frequencies.

Determination of polarity of the charge is by phase-sensitive rectification through the action of a switch that is synchronized with the instantaneous flow of the liquid. This alternating design permits a pump and capillary to be combined into a single unit with a loosely fitted piston reciprocating

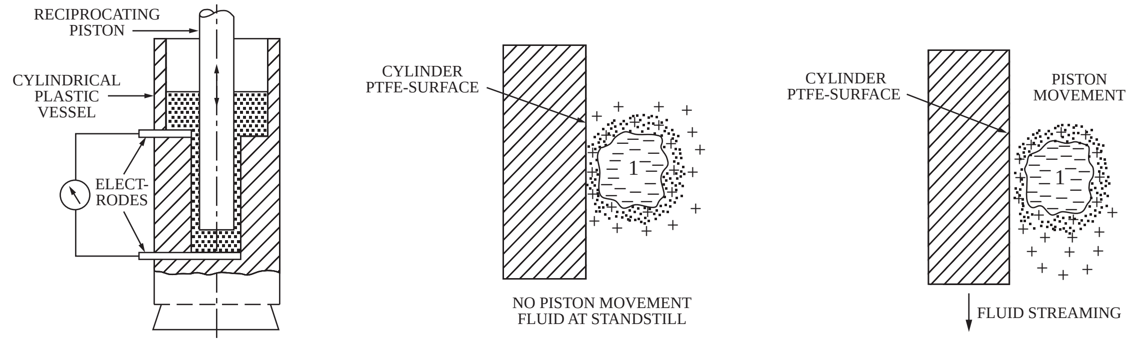


FIG. 8.54a

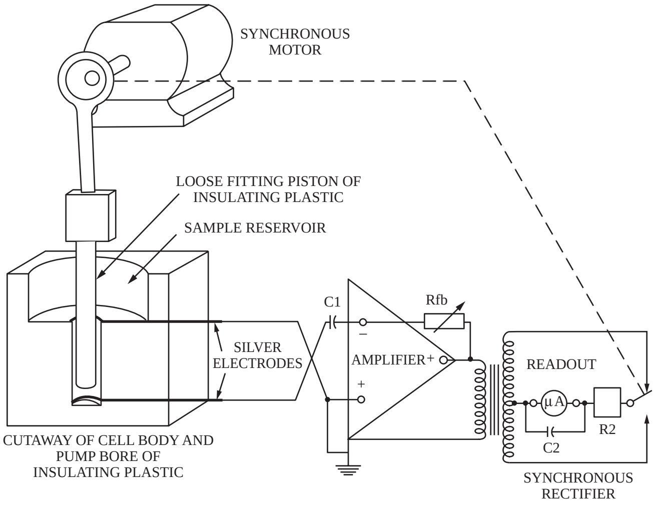

FIG. 8.54b
Streaming current detector.

in a dead-ended bore (Figure 8.54b). Cleaning is easy, because the piston and bore can be separated by disassembly.

CALIBRATION

Although readout is in arbitrary units, reproducibility can be demonstrated by standard samples. Sensitivity is constant, but zero shift can occur as a result of inadequate cleaning or the use of strong surface-active agents. Unfortunately, there is no absolute zero standard. Colloidal suspensions are useless as routine standards, because they become unstable with time. Suspensions made stable by excess surface-active materials leave a stubborn residue on the SCD.

Often, the most useful standards are two buffer solutions chosen so that their pHs are on either side of the isoelectric point of the capillary material. The isoelectric point is defined as the pH at which the material exhibits zero charge. Upscale or downscale shifts of buffer readings will indicate the bias of the instrument caused by contamination of the surfaces. Buffers near pH 4 and 5 are useful.

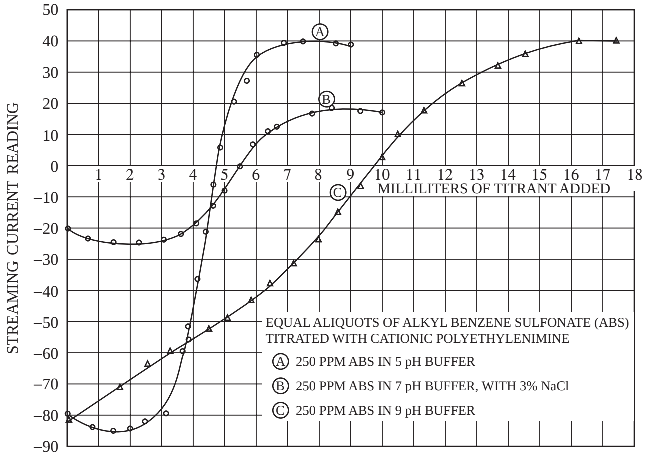

FIG. 8.54c
Titration curves indicating effect of pH and salt on SCD reading.

Dielectric constant, pH, and total ionic content all exert legitimate influences on the streaming current reading. Lowering the pH of a sample shifts its SCD reading upscale, and increasing the salt content by adding a balanced, neutral salt shifts the reading toward zero (Figure 8.54c).

APPLICATIONS

Most applications involve either titration of the sample or prior treatment in the plant, because a single reading on untreated material provides little information. This is because SCD readings are almost independent of the concentration of suspended solids. Titration can be performed with as little sample as will submerge the active part of the instrument.

Treatment Chemical Selection

To estimate the amount of treatment that a process liquid requires, a volumetric sample is titrated with the chemical that is intended for use for treatment at a known concentration until a zero signal is obtained. To compare alternative treating chemicals, identical samples can be titrated with the various chemicals.

When it is desired to study the effect of a change in pH on treating requirements, identical samples are titrated at various pH levels. The pH effect can be significant, because the tolerance of chemicals can be considerably different at low or high pH values.

In the usual treatment plant, the SCD may continuously control the feed of cationic chemicals. The need for changing the charging rate of the chemical additives arises from variations in the flow rate of the process fluid, changes in the loading of suspended solids in the process fluid, variations in the unit demand of the solids, or any combination of these factors.

The main advantage of SCD control is its fast response to changes in the operating conditions. Charge neutralization occurs almost as soon as the treating chemical is dispersed in the stream; therefore, samples may be taken 1 or 2 min after addition of the chemical.

Sampling

If batch samples are used, they should be large enough to permit rinsing the SCD apparatus several times. Skimming or decanting can be used to remove sand, larger solid particles, and oil globules. Little information is lost by the removal of larger particles, because charge is a surface phenomenon, and the fines provide most of the surface.

When a continuous sample is required, a self-cleaning bypass filter should be used (see Figure 8.54d). Periodic backflushing or cleaning of the sampling line is also recommended.

Control System

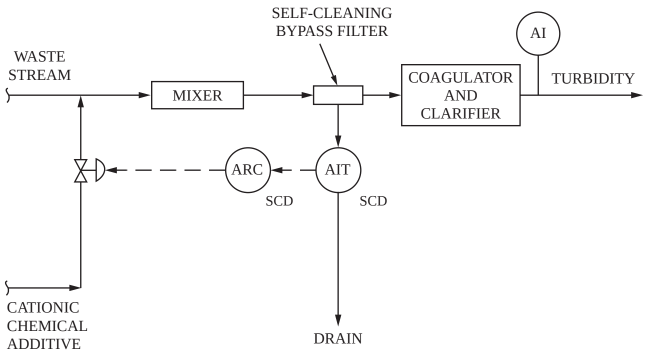

FIG. 8.54e
Chemical addition control utilizing a streaming current detector.

For continuous control, the SCD measurement signal is fed to a two-mode controller that modulates the chemical feed pump or control valve (Figure 8.54e). The transmitter signal can be sent through a 0.1 to 0.2 minute filter to remove noise. The two-mode feedback controller itself is usually set for a PB = 500% and I = 2 repeats/min.

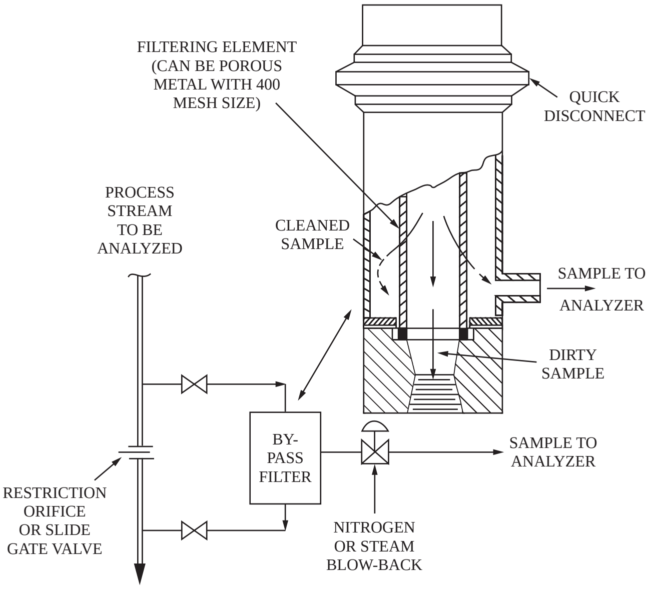

FIG. 8.54d
Self-cleaning bypass filter design and installation.

The maximum and minimum opening of the additive control valve can be limited so that a loss of sample will not cause an open loop. In the old pneumatic systems, pressure regulators provided the limits for valve openings, but today they are electronic.

The SCD controller set point determination is based on the turbidity measurement downstream of the coagulation equipment. If automatic cascade control is preferred, the set point of the SCD controller can be directly adjusted by this turbidity controller in a cascade arrangement. In some processes, more than one chemical additive is involved, so a sequence of additions and attendant interactions must be considered in the control configuration.

CONCLUSIONS

The streaming current detector (SCD) is only one of the methods available for characterizing concentrated colloids. Another method is based on the electroacoustic effect,[2–5] which is claimed to be more efficient.

INTRODUCTION

On-line analysis of sulfur in oil products is imperative, because environmental authorities are tightening the limits on sulfur levels in petroleum products. Limitations of 300 ppm in blended gasoline and 500 ppm in diesel are not uncommon. Even with an excellent hydrotreating capability, these limits are often difficult to meet, so processing must be carefully monitored. The timely information provided by continuous on-line monitoring is necessary to consistently meet sulfur content limits, especially when blending the various product or feed streams.

X-RAY ABSORPTION ANALYZER

The x-ray absorption technique has been used for many years, in the laboratory and on line, to measure total sulfur content in liquid petroleum products. The intensity of x-rays, after they pass through a liquid hydrocarbon sample, depends on the density and elemental composition of that sample.

For x-ray radiation in the region of 10 to 20 KeV, sulfur has a much greater mass absorption coefficient than does carbon and hydrogen. At 20 KeV, the mass absorption coefficients of carbon and hydrogen are about equal, so that changes in x-ray absorption due to C:H ratio are negligible.

Therefore, the changes in x-ray absorption depend mostly on sample density and sulfur content. The ionization current (Is) can be expressed as

$$\text{Is} = \text{Io} \cdot \exp\left[-\rho t\{(\mu_5 - \mu_{\text{CH}}) \cdot \text{C}_5 + \mu_{\text{CH}}\}\right] \qquad \mathbf{8.55(1)}$$

where

ρ = density of liquid to be measured (in g/cm^3)
t = effective length of the liquid cell (in cm)
μ_5 = mass absorption coefficient of sulfur (in cm^2/g)
μ_{CH} = mass absorption coefficient of carbon and hydrogen (in cm^2/g)
C_S = sulfur concentration ratio by weight

Method of Operation

Figure 8.51a illustrates the operation of an x-ray absorption type sulfur-in-oil analyzer. The x-rays emitted from an americium-241 source bombard a target, producing secondary x-rays at 20 KeV. These penetrate a beryllium 5 mm thick back-plate and a thin Teflon® plate, pass through the sample cell, and enter the ionization chamber.

The current from the ionization chamber detector is the input to the sulfur converter. This input is compared with the zero set signal from a standard current source. The difference between these signal currents is the input to the picodiode electrometer, where the differential current is amplified to provide an output signal to the *S-set* sulfur converter unit.

At the S-set unit, the signal is linearized, compensated for density at the zero point by the signal from the density converter, and converted to a voltage signal that is proportional to the sulfur concentration and density. After span adjustment, the signal is transmitted to the divider unit. This unit divides the sulfur concentration signal from the S-set unit by the density signal (calibrated at the sample temperature of the sulfur detector). The divider unit produces a 4 to 20 mA DC output signal proportional to total sulfur content.

The most sensitive range of the system is 0 to 0.5 wt% sulfur, with a repeatability of 0.01 wt%. The density measurement has a sensitivity of 0.0005 g/cm^3.

Figure 8.55b shows a block diagram of the measurement electronics and describes the components of the three separate parts—the density measurement system, the hydrogen content measurement system, and the sulfur measurement system.

X-RAY FLUORESCENCE

X-ray fluorescence (XRF) measurement of sulfur in oil is recognized as an ASTM laboratory procedure. An on-line XRF analyzer system has three main component blocks: sampling, analysis, and control. In these units, a continuous stream of process sample passes through a flow cell with Be-coated window. The coating maximizes both the life and the x-ray transmission of the window. The sample is excited by a low-level radiation source that causes the sulfur atoms to emit their characteristic fluorescent x-rays. The x-ray intensity is measured by a high-resolution proportional counter-detector over a period of time, and the resultant data are processed by a microprocessor to yield the average total sulfur content in the stream.

The assays are updated every 2 to 10 min, depending on the analysis precision desired. Precision is typically 15 ppm at 300 ppm concentration, and the lower detection limit of this sensor is 50 ppm.

PULSED UV FLUORESCENCE

The pulsed ultraviolet fluorescence (PUVF) type of total sulfur analyzer takes a liquid sample and vaporizes it before measuring the sulfur contents. The package, shown in Figure 8.55c, includes the main components of a sample injection valve, carrier gas flow control system, mixing chamber, combustion chamber, and detector subassembly.

The sample injection valve periodically transfers a small amount of sample liquid (approximately 1.0 μl) into an air carrier gas. The air/sample mixture passes through the mixing chamber to ensure complete mixing and then flows to the combustion chamber, where all sample components are combusted into SO_2, CO_2, and H_2O at about 1100°C. The PUVF detector accurately measures the amount of SO_2 produced during combustion of the sample.

The operation of the pulsed UV fluorescence analyzer takes advantage of the fact that SO_2 molecules absorb ultraviolet (UV) light and become excited at one wavelength, then decay to a lower energy state, while emitting UV light at a different wavelength. Specifically,

$$\text{SO}_2 + \text{hv}_1 \rightarrow \text{SO}_2^* \rightarrow \text{SO}_2 + \text{hv}_2 \qquad \mathbf{8.55(2)}$$

The sample flows into the fluorescence chamber, where pulsating UV light excites the SO_2 molecules. The condensing lens focuses the pulsating UV light into a mirror assembly, which contains four selective mirrors that reflect only the wavelengths that excite SO_2 molecules.

As the excited SO_2 molecules decay to their lower energy states, they emit UV light that is proportional to the SO_2 concentration. The bandpass filter allows only the wavelengths emitted by the excited SO_2 molecules to reach the photomultiplier tube (PMT), which detects the UV light emission from the decaying SO_2 molecules. The photodetector, located at the back of the fluorescence chamber, continuously monitors the pulsating UV light source and is connected to a circuit that compensates for fluctuations in the intensity of the UV light.

This analyzer, on a weight basis, measures down to 1 ppm sulfur in diesel, gasoline, kerosene, and jet fuel. It has a repeatability of ±0.02 ppm (2 sigma RSD = 0.25%) making its sensitivity highly suitable for critical process control applications. Such applications might include the measurement of the sulfur content of hydrocarbon products and controlling the fuel blending process.

FUEL ANALYSIS SPECTROMETER

To use fuel analysis spectrometers for on-site sulfur analysis, it is necessary to prevent the atmospheric oxygen from absorbing the sulfur. This is achieved by the use of nitrogen or argon purged optics. Such units can be useful in measuring the sulfur content of gas turbine fuels or of lubricating oils.

Because of the small size of the optics, the purge gas consumption is small, <3 l/min. The minimum detectable sulfur concentration is 40 ppm, and the maximum of the calibrated range is 5% (50,000 ppm). Figure 8.55d illustrates a sulfur calibration curve. The intensity ratio shown on that curve is the ratio between the outputs of the measuring and reference photomultiplier tubes. The reference used is the carbon sensitive wavelength (193.05 nm), while sulfur is measured at 180.73 nm. The measurement error is usually <3% over the calibrated range.

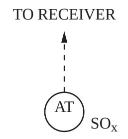
8.56 Sulfur Oxide Analyzers

R. A. HERRICK (1974, 1982) **B. G. LIPTÁK** (1995, 2003)



Flow Sheet Symbol

Methods of Detection:	A. Colorimetric B. Conductimetric C. Correlation spectrometry D. Coulometric E. Electrochemical F. Flame photometric G. Infrared H. Thermal conductivity I. Ultraviolet J. Chromatographic
Applications:	Types A, B, D, E, F, and H are mostly for ambient air monitoring (see Section 8.5 for details), whereas types C, G, and I are for stack gas monitoring (see Sections 8.3 and 8.46).
Reference Method:	A. Pararosaniline; an EPA study (CPA 70–101) found coulometry to be equivalent to this reference method.
Sample Pressure:	Where sampling is involved, the sample pressure is usually near atmospheric.
Sample Temperature:	In ambient air analysis, types A, B, D, E, F, and H are generally limited to about 120°F (49°C). Stack gas monitors (C, G, and I) are not so limited, as they usually are not in direct contact with the sample but are protected by air cooling.
Sample Flow Rate:	Usually between 0.1 and 1.0 ACFM (2.8 to 28 alpm)
Materials of Construction:	Because of the reactivity of sulfur oxide gases, glass, Teflon®, and stainless steel are preferred; PVC should be avoided.
Speed of Response:	Types C, E, F, G, and I are nearly instantaneous; types A, B, and D depend on the liquid capacity of the automated wet-chemistry system.
Ranges:	Concentration in ambient air should stay below 0.1 ppm in the short range and below 0.02 ppm in the long range; therefore, the sensor range should not exceed 0 to 1 ppm. Stack monitors require 0 to 1000 ppm ranges. A, B, D, and F. From 0.01 to 5 ppm, but with dilution systems can measure up to 5000 ppm E. 0 to 15 ppm C, G, and I. From 0 to 100 ppm up to 0 to 100%, but most applications are from 500 to 10,000 ppm (type C can detect down to 5 ppm) H. 0 to 20%
Inaccuracy:	Generally, 1 to 3% of full scale; types G and I can have errors as low as 0.5% of full scale. In ambient air measurement, the absolute limit on precision is 0.005 ppm.
Costs:	Pocket-sized personal monitors start at $500. Ultraviolet laboratory spectrometers cost from $2500 to $5000. Portable ambient monitors for multiple gas detection cost $4000 to $7000, and permanently installed ambient air quality monitors configured for multiple-sample or multiple-gas monitoring is $10,000 to $20,000. Stack gas monitor costs range from $25,000 to $35,000, depending on materials of construction, accessories, and number of components analyzed, which can include opacity. Passive, remote-sensing correlation spectrometers start at $35,000.

Thermal conductivity analyzers cost about \$10,000. Installed chromatographs cost about \$100,000.

The most popular ambient analyzer suppliers are MSA, General Monitor, ABB, and Sensidyne. The most popular stack gas analyzer suppliers are Rosemount-Analytical, Ametek Thermox, Horiba, and Thermo Environmental.

INTRODUCTION

The predominant sulfur oxide in the atmosphere is sulfur dioxide (SO_2). Some sulfur trioxide (SO_3) is also formed in combustion processes, but it rapidly hydrolyzes to sulfuric acid, which is considered to be a particulate matter. Therefore, this section concentrates on the monitoring of sulfur dioxide. In the U.S., the ultimate air quality goals (secondary standards) for sulfur dioxide are 60 $\mu g/m^3$ (0.02 ppm) annual arithmetic average, 260 $\mu g/m^3$ (0.1 ppm) maximum 24-hr concentration not to be exceeded more than once a year.

Applications

The oxides of sulfur are measured both in ambient air, where their concentration is usually a small fraction of one ppm, and in stacks and other industrial emissions, where their concentrations are in hundreds of ppm (see Figure 8.56a). While the analyzers used for these two types of application do overlap, they are discussed separately here.

Industrial monitors are discussed first. The design and operation of the gas chromatograph are not repeated here, so the reader is referred to Section 8.12 for an in-depth description. Infrared,[1] thermal conductivity, and ultraviolet analyzers

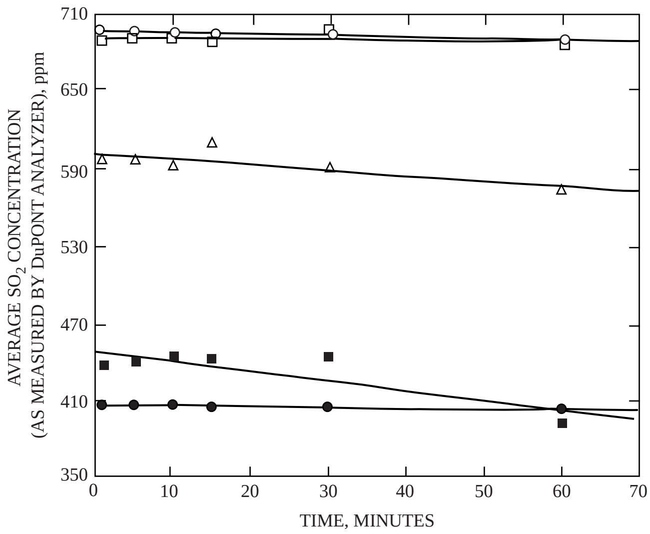

FIG. 8.56a
Sulfur dioxide readings (on different dates) obtained by monitoring the stack of a power-generating boiler burning pulverized coal.[2]

will be discussed briefly, but in-depth coverage is provided in Sections 8.27, 8.57, and 8.61, respectively.

The monitoring of sulfur oxides in the ambient air will be discussed after the coverage of industrial analyzers. This discussion will also be brief, because ambient air monitoring is discussed in Section 8.5, and the electrochemical, colorimetric, conductimetric, and flame photometric methods of analysis are covered, respectively, in Sections 8.4, 8.15, 8.17, and 8.47.

INDUSTRIAL ANALYZERS

Stack Sampling

As discussed in some detail in Section 8.3, stack effluents contain orders of magnitude higher concentrations of sulfur dioxide than does ambient air. Consequently, few of the techniques used to detect the trace amounts of sulfur dioxide in ambient air are applicable to source monitoring, except after massive dilution.

The colorimetric procedure is not applicable to source monitoring at all, mainly because of the interference of nitrogen oxides. The electrochemical method can be used for source monitoring. Analyzers that are generally applicable to source monitoring include infrared (IR), ultraviolet (UV), and correlation spectrometry.

Nondispersive Infrared

Sulfur dioxide absorbs radiation over a broad range of wavelengths, which include both the infrared and ultraviolet regions of the spectrum. Section 8.27 describes the nondispersive infrared (NDIR) analyzers in some detail. Figure 8.56b shows one of their stack-mounted variations.

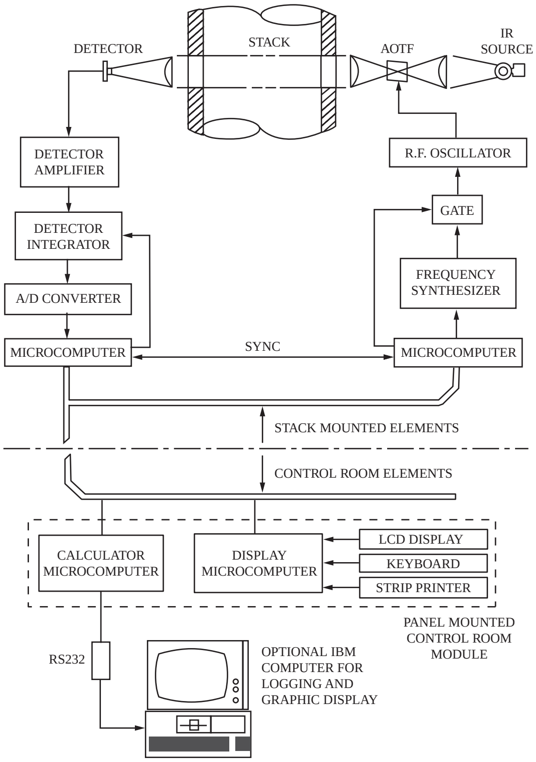

FIG. 8.56b
IR analyzer with solid state tunable crystal, which allows for the simultaneous measurement of many gases in the stack.[3]

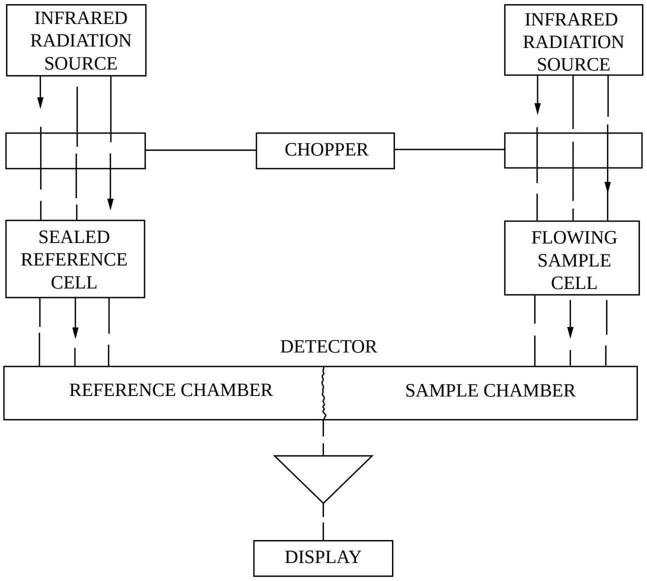

FIG. 8.56c
Nondispersive infrared analyzer.

These devices are most often used in stack analyzer packages, where several stack gases and opacities are measured together. The NDIR analyzer using a positive filtering scheme, illustrated in Figure 8.56c, is one of the design variations described in detail in Section 8.27.

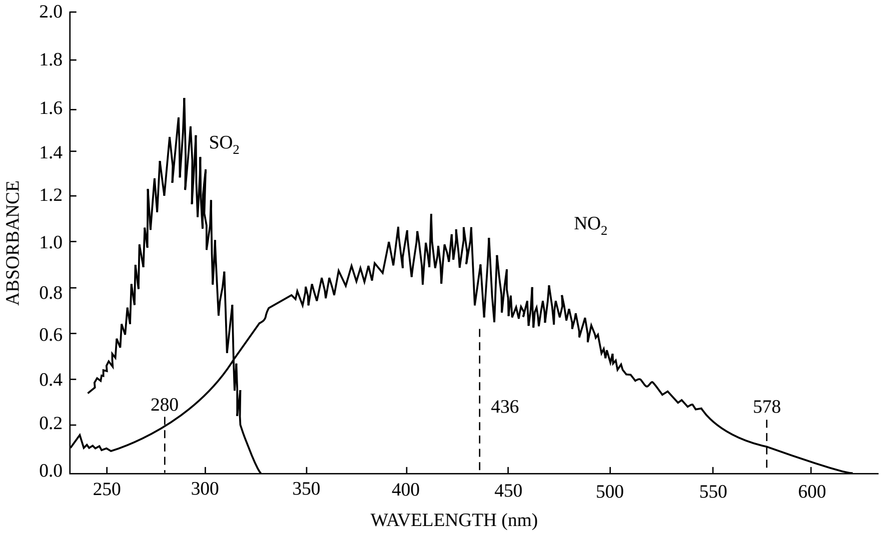

FIG. 8.56d
The absorbance of SO_2 and NO_2 in the ultraviolet range.

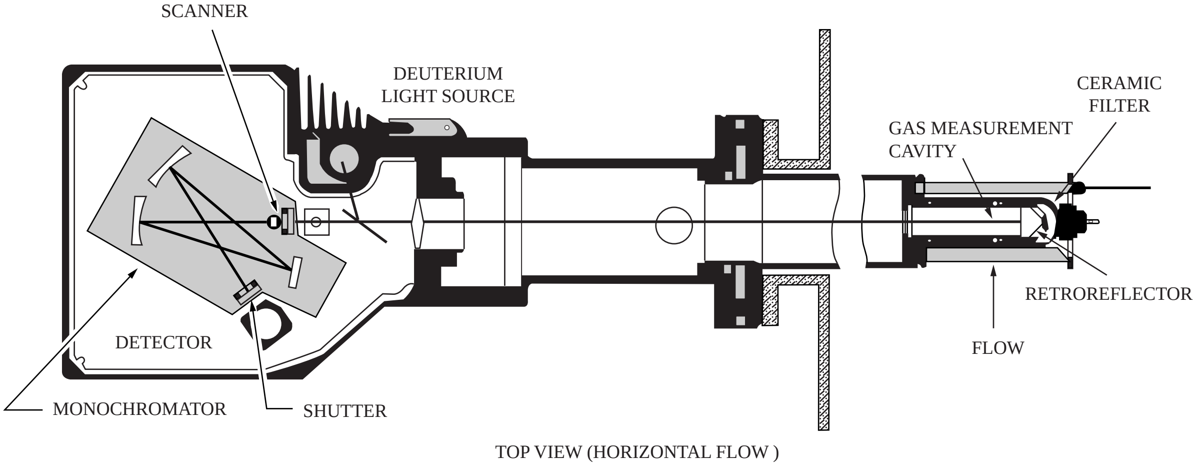

FIG. 8.56e
Self-calibrating, self-cleaning, self-drying probe-type analyzer that simultaneously detects the concentrations of SO_2 and NO_2 at temperatures up to 800°F.

Ultraviolet

The absorbance of SO_2 in the ultraviolet range is shown in Figure 8.56d. Because, in most stack-monitoring applications, there is an interest in measuring the concentrations of both NO_x and SO_2, some suppliers of ultraviolet analyzers offer a single analyzer for the simultaneous monitoring of both gases (Figure 8.37b).

Figure 8.56e illustrates a self-cleaning, self-calibrating, microprocessor-operated probe design, capable of measuring both NO and SO_2 simultaneously. Ultraviolet analyzers are discussed in detail in Section 8.61. They are frequently used on sulfur dioxide applications. When the analyzer is not inserted into the process, but samples are taken from the process into the analyzer, the sample gases must be filtered before they reach the detector cell (sample chamber) to prevent a buildup of particulates in the cell. Similarly, the moisture content of the sample must also be controlled to prevent condensation.

Correlation Spectrometry

As discussed in detail in Section 8.40, the correlation spectrometer can be used at a location remote from the source to determine the sulfur dioxide content of stack gases. The instrument shown in Figure 8.56f is specific for SO_2 because of the photographic optical mask of the SO_2 spectrum.

In use, the natural background level of ultraviolet radiation is used to zero the instrument. When the optics are pointed across a stack plume containing sulfur dioxide, the resulting change in the ultraviolet radiation in the wavelength pattern of SO_2 is detected at the instrument. If the stack plume

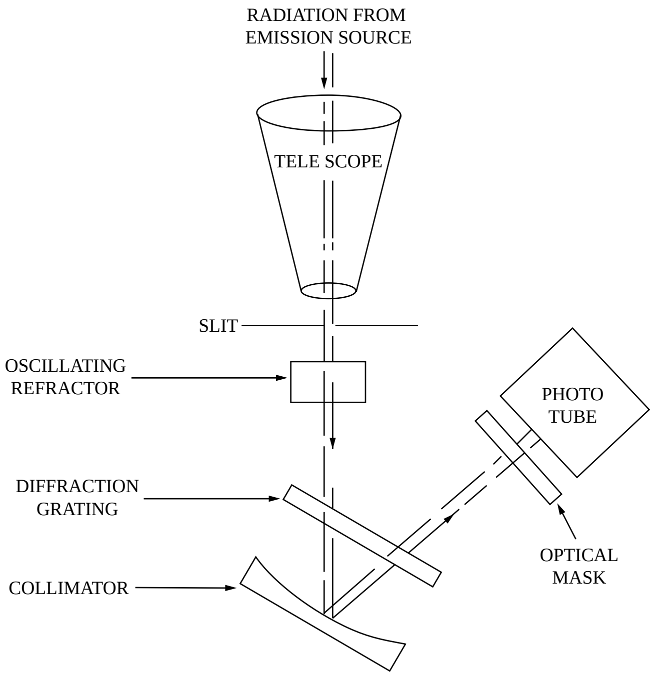

FIG. 8.56f
Remote sensing correlation spectrometer.

diameter and stack gas density are both known, the sulfur dioxide concentration can be determined.

Thermal Conductivity

Thermal conductivity analyzers are discussed in Section (8.57) and therefore will be described only briefly here.

If the thermal conductivity of air is taken as 1.0, the thermal conductivity of SO_2 is 0.344. This difference is substantial enough to allow the measurement of sulfur dioxide in air at higher concentrations. The minimum range of these detectors is about 0 to 3% SO_2 in air and 0 to 1% air in SO_2 full scale. Thermal conductivity analyzers can also be used for measuring sulfur dioxide in nitrogen.

AMBIENT-AIR ANALYZERS

The measurement of sulfur dioxide in air has been performed for many years because of the simplicity of manual analysis based on the ability of sulfur dioxide to reduce a starch-iodine solution. The earliest sulfur dioxide detectors were automated wet chemical devices that measured the increase in the conductivity of a solution after air had been intimately mixed in it by some contacting procedure.

The U.S. Environmental Protection Agency (EPA) has deleted conductivity-type analyses from their approved list of ambient air sampling instruments, because this technique is nonspecific for SO_2 but measures all acid gases. The EPA has designated the colorimetric technique using pararosaniline as the reference procedure, with flame photometric and coulometric detection as acceptable alternative procedures.[4]

Ambient-Air Sampling

In the United States, the ultimate air quality goals (secondary standards) for sulfur dioxide are 60 $\mu g/m^3$ (0.02 ppm) annual arithmetic average and 260 $\mu g/m^3$ (0.1 ppm) maximum 24-hr concentration, not to be exceeded more than once a year. This target also calls for 1300 $\mu g/m^3$ (0.5 ppm) maximum 3-hr concentration, not to be exceeded more than once a year.[5]

Instrument range is generally selected for 0 to 1 ppm full-scale range except where higher levels are anticipated. There is a sensitivity problem, because few instruments are capable of accurately reading at levels of 0.01 ppm and below. Statistical procedures are usually required to determine arithmetic average concentrations.

Calibration

The standard procedure for calibrating sulfur dioxide instruments involves the preparation of known concentrations of SO_2 in air. This can be accomplished with high accuracy when permeation tubes, made of Teflon® tubing and containing liquid sulfur dioxide, are maintained at constant temperature while a constant flow of air is passed over the tube. The most desirable procedure is a system calibration rather than an instrument calibration, with the known concentration introduced at the system inlet.

Colorimetric Analyzers

A detailed discussion of colorimeters can be found in Section 8.15.

The reference technique for determining the sulfur dioxide content of atmospheric air is based on the absorption of SO_2 from an air sample by a solution of sodium tetrachloromercurate, which, upon the addition of formaldehyde and a pararosaniline dye, forms a strong purple dye complex. Several manufacturers have automated this procedure and offer packages such as the one shown in Figure 8.56g.

This family of analyzers requires frequent maintenance because of the complexity of the plumbing and the tendency of the dye complex to plate out on the cell windows, thus reducing sensitivity. Properly maintained, they provide an excellent record of sulfur dioxide concentrations in the air, because they operate on the basis of a chemical reaction, which is specific for sulfur dioxide.

Conductimetric Analyzers

There is more experience with the operation of this family of analyzers than with any other in sulfur dioxide detection applications. The instruments are fairly simple electronically, but the associated piping does create some maintenance problems. The basic electric circuit diagram is shown in Figure 8.56h.

To cause a change in the resistance of the measurement cell (Rm) as the sulfur dioxide concentration of the sample changes, some of the available instruments use a weak

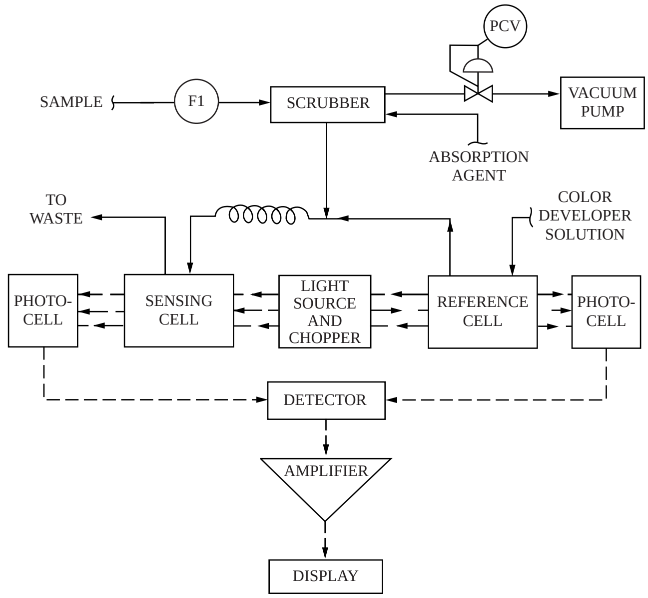

FIG. 8.56g
Automatic colorimetric analyzer for the detection of oxides of sulfur in air.

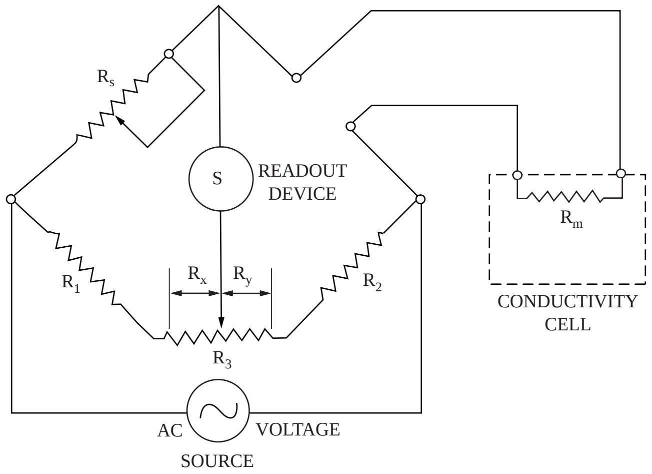

FIG. 8.56h
The electric bridge circuitry for the measurement of conductivity.

solution of sulfuric acid and hydrogen peroxide as an absorbent, whereas others use distilled water. These instruments must be temperature compensated, because the change in resistance (conductance) over the normal ambient temperature range is nearly as large as the conductance changes that can be expected as a result of the variation in sulfur dioxide concentration of ambient air.

Conductimetric analysis is not specific to sulfur dioxide. The presence of acidic or basic gases must be compensated for; otherwise, they will interfere with the accuracy of the reading. Gases such as hydrogen chloride will cause positive interference, and basic gases such as ammonia will introduce a negative interference.

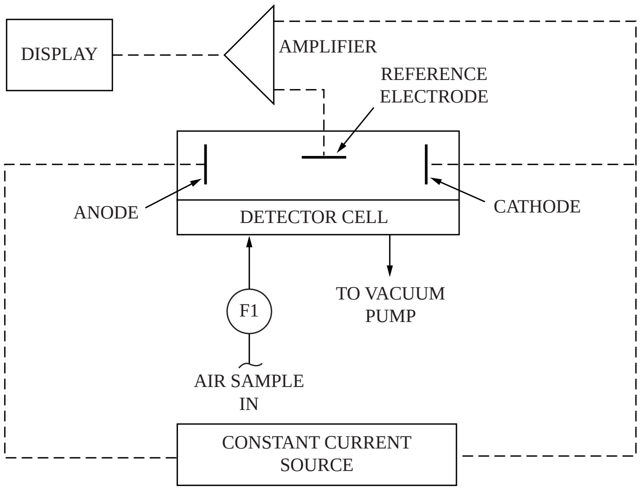

FIG. 8.56i
Coulometric analyzer for oxides of sulfur.

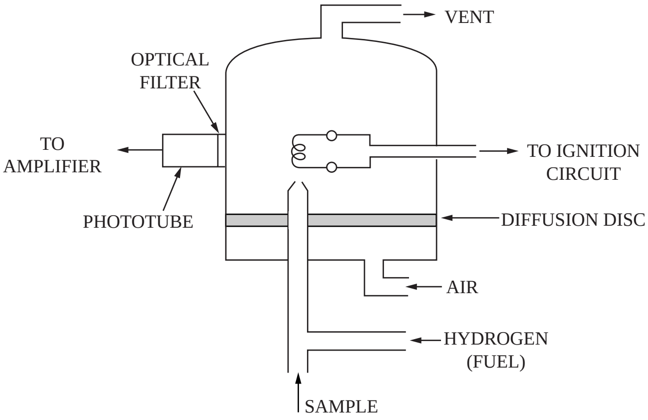

FIG. 8.56j
Flame photometric analyzer.

Coulometric Analyzers

From a solution of bromine or iodine, the reducing action of sulfur dioxide will electrogenerate free bromine or iodine. These elements can than be detected to give an indication of the SO_2 content of the sample air stream (Figure 8.56i).

The required supply of reagents for coulometric analyzers is usually less than the reagent requirements of either colorimetric or conductimetric analyzers. At least one commercially available coulometric analyzer is capable of measuring ozone (Section 8.44) concurrently with sulfur dioxide.

Flame Photometric Analyzers

Flame photometric analyzers are discussed in Sections 8.12 and 8.49. These analyzers utilize the phenomenon that, when an air stream containing sulfur is burned in a hydrogen-rich flame, radiation is generated in a wavelength band centered at 394 μm. Flame photometric detectors can measure sulfur concentrations in air down to levels less than 0.01 ppm. The electrical output signal of this detector (Figure 8.56j) is logarithmic.

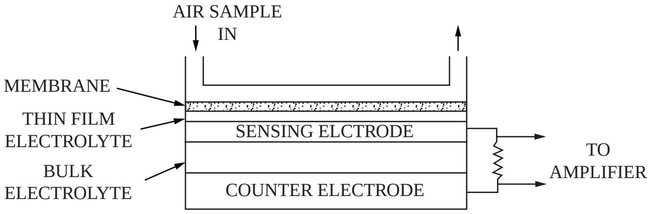

FIG. 8.56k
Electrochemical gas analyzer.

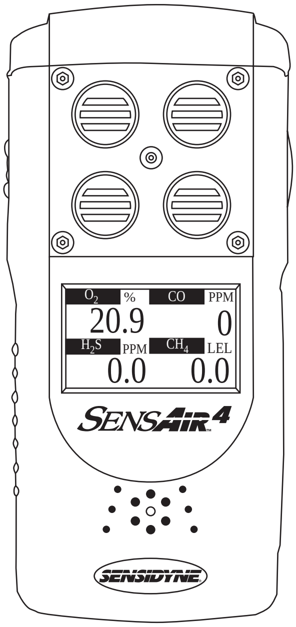

FIG. 8.56l
Portable electrochemical detectors are available for the measurement of up to four gases. (Courtesy of Teledyne API.)

Typical instrument ranges can cover two decades of concentration, e.g., 0.01 to 1.0 ppm, with the capability to switch to a higher range.

This instrument measures total sulfur in the sample stream. To provide discrimination between various sulfur compounds, additional hardware is available from some manufacturers. An all-Teflon gas chromatographic column preceding the flame photometric analyzer can be used to separate the sulfur compounds quantitatively. This combination (Section 8.12) has proved extremely useful for the measurement of reduced sulfur compounds, e.g., hydrogen sulfide and dimethyl disulfide in the air.

Electrochemical Analyzers

When air passes over an element consisting of a semipermeable membrane, an electrolyte, and a voltage-sensitive pickup, some gases will selectively migrate through the membrane and generate a signal in the electrolyte (Figure 8.56k). This phenomenon has been used to measure the concentration of many gases in ambient air, including sulfur dioxide.

The electrochemical principle for the measurement of air pollutants has not had extensive field use, but it is used as the sensor in pocket-sized portable indicators and alarms (see Figure 8.56l). Operational problems can develop in maintaining the proper moisture content of the membrane and the proper electrolyte strength because of the migration of water vapor.

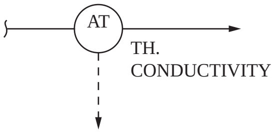
8.57 Thermal Conductivity Detectors



Flow Sheet Symbol

J. E. BROWN (1969, 1982) **B. G. LIPTÁK** (1995, 2003)

Applications:	Gases or vapors; best suited for binary gas applications such as detector on chromatographs or leak detection or for hydrogen and helium analyses, because these gases have high thermal conductivity
Design Pressure:	Near atmospheric
Sample Temperature:	35 to 110°F (2 to 43°C)
Cell Materials of Construction:	Brass, stainless steel, Monel®
Range:	The full span of the analyzer should correspond to a minimum of a 2% change in the thermal conductivity of the gas mixture.
Inaccuracy:	Inaccuracy is 1 to 2% of full scale for binary samples when the thermal conductivity of each constituent is accurately known. Published thermal conductivity data can be in error by as much as 5%. Interpretation of readings on multicomponent mixtures require additional measurements and analysis.
Cost:	A portable leak detector with 10^{-5} cc/sec sensitivity costs $1600; industrial analyzers for binary mixtures range from $2500 to $6000; analyzers with higher sensitivity and/or in corrosion-resistant materials cost from $6000 to $12,000.

INTRODUCTION

Composition measurement by detecting the thermal conductivity of gases is one of the simplest and oldest methods of analyzing process streams. Early developments by the British resulted in an instrument of this type, which was called a *katharometer* or *catharometer*. The name still persists in Europe.

This technique takes advantage of the facts that different substances have a varying capacity to conduct heat energy from a heat source. This ability differs for each gas. It is called *thermal conductivity* and can be expressed in various unit systems such as BTU/hr/ft^2/°F/in.; W/sec/cm^2/°C/cm; kiloergs/sec/cm^2/°C/cm, and so on.

This is a simple, rugged, inexpensive, reliable, and easily maintained, but nonspecific, analyzer that can determine the composition of only binary mixtures. It is not very sensitive, nor is it very fast, but it is well suited for many chromatographic and leak detection applications.

THERMAL CONDUCTIVITY

Thermal conductivity is often expressed as a factor relating the ability of a particular gas to conduct heat to that of air at various temperatures (Table 8.57a). In practice, continuous thermal conductivity analyzers measure a *change* in heat dissipation by comparing the change with a *reference* condition.

TABLE 8.57a
Thermal Conductivity Factors

	R_0*	R_{100}*
Acetone	0.406	0.546
Acetylene	0.776	0.900
Air	1.000	1.000
Ammonia	0.897	1.086
Argon	0.709	0.725
Benzene	0.370	0.573
Carbon dioxide	0.614	0.690
Carbon monoxide	0.964	0.962
Chlorine	0.322	0.381
Ethylene	0.735	0.919
Ethane	0.807	0.970
Helium	6.230	5.840
Hydrogen	7.130	6.990
Methane	1.318	1.450
Nitrogen	0.996	0.996
Oxygen	1.043	1.052
Pentane(n)	0.520	0.702
Refrigerant 12	0.354	0.356
Sulfur dioxide	0.344	0.377

*R_0, R_{100} = Thermal conductivity of gas/thermal conductivity of air at 0 and 100°C, respectively.

Measurement Ranges

It has been known for more than a century that the heat-conducting ability of various gases differs considerably. Therefore, by measuring the thermal conductivity of a binary mixture, one can determine the composition of the mixture. The accuracy of the measurement is a function of the reliability of the thermal conductivity data used for the gases making up the mixture, and those data are not always accurate.

Some of the common thermal conductivity analyzer applications include the measurement of *hydrogen* in air, nitrogen, carbon dioxide, carbon monoxide, argon, blast furnace gases, and reformer gases; *helium* in air or nitrogen; *methane* in air; *propane* in air; *Freon*® in air; and *carbon dioxide* in air, nitrogen, or flue gases.

A general rule is that the full span of the analyzer should correspond to a minimum 2% change in the thermal conductivity of the gas mixture. Table 8.57b gives the full-scale ranges of some binary gas mixtures that will result in at least a 2% change in the thermal conductivity of the mixture. It can be noted that, as the thermal conductivity of a gas (helium, hydrogen) increases, so does the sensitivity of measurement; therefore, the range can be narrower.

TABLE 8.57b
Ranges of Gas Mixture Compositions Suitable for Measurement by Thermal Conductivity

Gases in the Mixture	*Range of Concentrations of the First Gas in the Second*	*An Error of 1% of Full Scale Corresponds To*
Air in carbon dioxide	0–5%	0.05%
Air in helium	0–2.5%	0.025%
Air in oxygen	0–0%	0.4%
Air in sulfur dioxide	0–1%	0.01%
Argon in nitrogen	0–7%	0.07%
Carbon dioxide in air	0–7%	0.07%
Carbon dioxide in nitrogen	0–7%	0.07%
Carbon dioxide in oxygen	0–6.5%	0.065%
Helium in air	0–0.5%	0.005% (50 ppm)
Helium in hydrogen	0–12%	0.12%
Hydrogen in helium	0–10%	0.1%
Hydrogen in nitrogen	0–0.3%	0.003% (30 ppm)
Nitrogen in argon	0–5%	0.05%
Nitrogen in carbon dioxide	0–5%	0.05%
Nitrogen in hydrogen	0–2.5%	0.025%
Nitrogen in oxygen	0–55%	0.55%
Oxygen in air	0–38%	0.38%
Oxygen in carbon dioxide	0–4.5%	0.045%
Oxygen in nitrogen	0–52%	0.52%
Sulfur dioxide in air	0–3%	0.03%

THE TCD ANALYZER

The thermal conductivity detector (TCD) can measure the composition of binary mixtures at moderate sensitivity.

Main Components

The major components of a thermal conductivity analyzer are the measuring cell, regulated power supply, Wheatstone bridge, and case temperature control.

The Detectors The measuring cell consists of a relatively large mass of metal to provide a stable heat sink. Through the metal block, flow passages are drilled or formed, and a recessed cavity is machined for inserting a heat-source and sensing element, such as a hot-wire filament. The cell material must be compatible with the process gas sample and must also have a high thermal conductivity coefficient. Stainless steel is generally employed.

The detector transducers can be resistance wires (filaments) or thermistors (beads of metallic oxide). The operation of these heated elements is similar except that filaments have positive, and thermistors have negative, resistance coefficients. This means that, as the temperature rises, the resistance of filaments also rises, but the resistance of thermistors drops.

The choice between them is based on sensitivity and temperature considerations. In general, thermistors are used for ambient and subambient applications, whereas resistance wire filaments are used at higher temperatures. In terms of sensitivity, the thermistors are superior.

Hot-wire filaments are in prevalent use now as a result of improved filament designs. Up to 1965, thermal conductivity analyzers frequently used thermistors to achieve desired sensitivity. Thermistors are beads of metallic oxides with a thin coating (typically glass) over the surface. This coating tends to crack with excess heat and, when this element is used in gases with high hydrogen content, the oxides are reduced by the hydrogen, and drift is experienced. Glass-bead thermistors develop frequent failures, particularly when used in high-hydrogen-containing gases. The hot-wire filaments develop surface temperatures between 400 and 750°F (204 and 400°C) and are sometimes used with a catalyst coating to promote catalytic cracking of hydrocarbons to further increase system sensitivity.

Once the selection is made, the next step is to pick the right material to withstand the corrosiveness of the sample gas. The filaments are usually made from tungsten or platinum alloy materials, but nickel, rhenium-tungsten, and gold-plated tungsten filaments are also available. The wire diameter is about 0.001 in (0.03 mm).

The TCD Cells Figure 8.57c illustrates a TCD block assembly with the measuring filaments inserted into both the measuring and reference chambers. This is a flow-through design using a single (replaceable) measuring and a single reference filament configured into a classical Wheatstone bridge circuit.

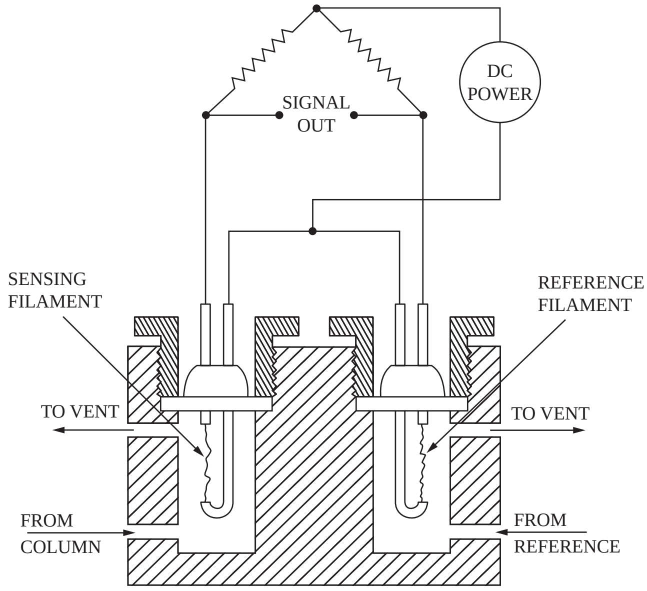

FIG. 8.57c
The design of a two-element, flow-through TCD cell.

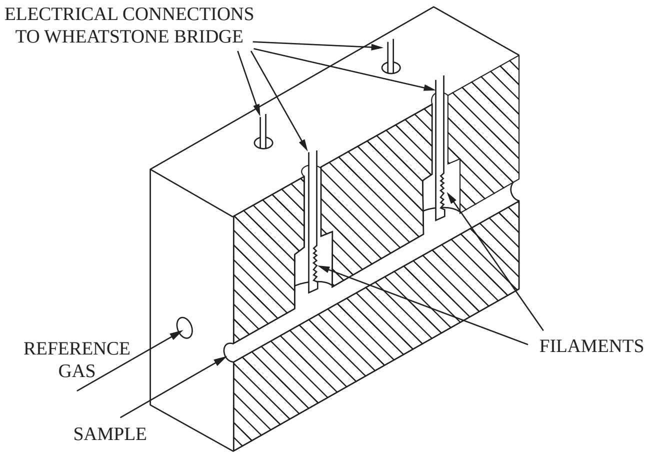

FIG. 8.57d
Four-element thermal conductivity cell.

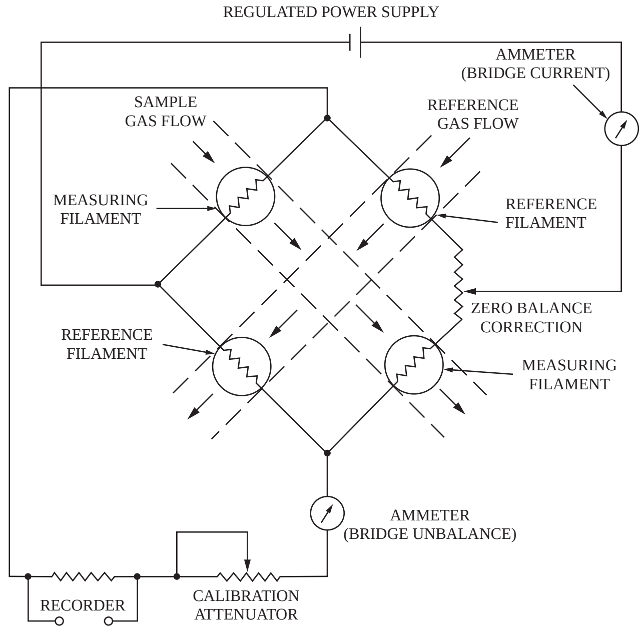

FIG. 8.57e
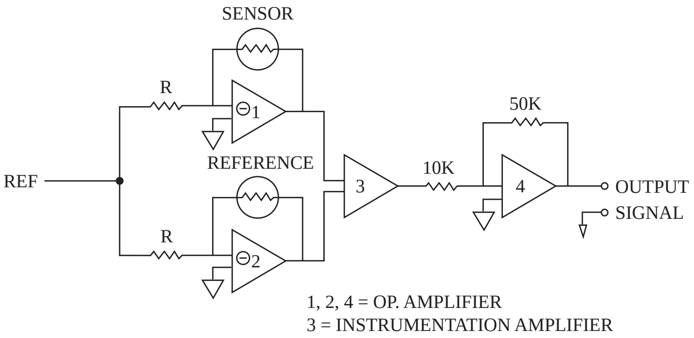
Typical Wheatstone bridge measuring circuit for thermal conductivity analyzer.

In addition to the two-element design, four-element thermal conductivity cell designs with recessed hot-wire filaments are also available, as shown in Figure 8.57d. The elements are used in pairs, one in the sample stream and one in the reference gas. One or two pairs are normally used, but some cell designs include eight pairs to improve sensitivity. Vertical mounting is preferred to prevent sagging of the wire elements. The recessed elements generally provide an improved noise level but poorer response speed.

The response speed of the TCD is a function of the internal volume of the detector cell. The flow through the cell must be constant (usually in the range of 15 to 100 ml/min for chromatographic and 500 ml/min for process analyzers).



The current is determined by the value of E_{ref} and R; $i = E_{ref}/R$

FIG. 8.57f

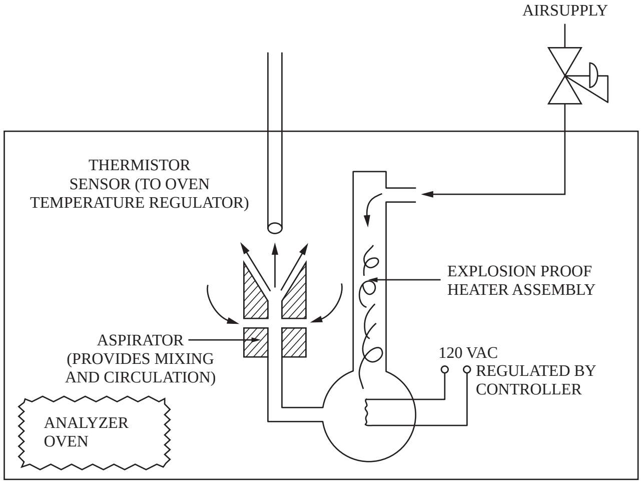

FIG. 8.57h

Oven temperature regulator using thermistor-type sensor provides sensitive temperature control.

Bridge Circuits The sensing system can be a basic Wheatstone bridge that uses a high-quality regulated power supply (Figure 8.57e) rated between 100 and 300 mA. Analyzer stability is primarily a function of power supply voltage regulation. In addition to the means of improving sensitivity, it is more practical to use low-noise operational amplifiers on the bridge output. However, a low signal-to-noise ratio is required of the basic bridge output.

To provide faster response and to protect the filaments if the flow of carrier gas fails, the latest TCD designs favor constant current or constant resistance bridges (see Figures 8.57f and 8.57g).

Temperature Control Case temperature control provides a constant temperature environment for the measuring cell to enhance stability. Various temperature control systems are used, ranging from off/on thermal switches with bare strip heaters to the more refined ones for chromatographic ovens (see Figure 8.57h). Analyzer stability can be adversely affected by inadequate temperature control.

Operation

The thermal conductivity analyzer, when used as a chromatographic detector, operates with a metered sample of 50 to 200 cc/min (flow controlled). The sample flow passes through the measuring cell and across the filaments or glass-bead thermistors, which are “hot” from being heated by the Wheatstone bridge. This resistance heating provides an elevated temperature on the surface of the filament.

Heat energy is conducted from the filament, through the flowing gas, and to the walls of the cell. The quantity of heat thus conducted is a function of the thermal conductivity of the flowing gas. When a sample stream of lower thermal conductivity than that of the zero standard gas is introduced, less heat is conducted away, and the filament surface temperature (and its resistance, if it is a hot-wire filament) increases.

This causes an unbalance in the Wheatstone bridge. The degree of unbalance can be calibrated in terms of composition.

If a thermistor-type detector is used, it has a negative temperature coefficient, so it will unbalance the bridge in the opposite direction, thus requiring a polarity reversal for the ammeter connections. Otherwise, the operation is identical.

The Reference Filament Reference filaments are used to provide compensation for temperature and barometric pressure variations. Because the reference filaments are in opposite legs of the bridge relative to the measuring filaments, small temperature variations in the cell should affect both filaments equally and therefore cancel out. The reference gas can be sealed for this purpose, but a *flowing reference* provides additional compensation, because the venting pressure reflects any variations in barometric pressure.

The reference gas is usually a single gas that is the same as the major component in the sample gas. Reference flow is generally less than the sample flow, 40 to 100 cc/min.

Packaging and Calibration

The packaging of thermal conductivity analyzers varies with suppliers, but most manufactorers separate the electronics (power supply and bridge) from the temperature-controlled case. In some cases, the two parts can be physically separated by a distance of up to 100 ft (30 m). In most designs, the cabinets require little more panel or wall space than do conventional transmitters.

Calibration is accomplished using known samples to establish an empirical calibration reference.

LIMITATIONS

Although simple in design, this analyzer has a major limitation: only binary mixtures can be accurately measured by it. The analyzer is nonspecific; because it measures the total thermal conductivity of the process sample, it cannot distinguish or identify the component that causes the conductivity change in multicomponent mixtures. Therefore, its applications are limited to binary or binary-like mixtures. Some industrial gas streams are binary mixtures and do require analysis.

Hydrogen in Hydrocarbons

One notable exception to the above-mentioned general rule is the analysis of hydrogen in hydrocarbons. From Table 8.57a, it can be seen that hydrogen has a very high R_0 value relative to most hydrocarbon gases. In such cases, the sample often can be considered to be a hydrocarbon-hydrogen binary mixture and calibrated using an “average” background of nonhydrogen components. The error in measurement will depend on the true concentrations of the other components but, in many applications, ±5% full-scale inaccuracy is easily attainable.

CONCLUSIONS

The advantages of the thermal conductivity analyzer include its low cost, simplicity, reliability, and reasonable speed of response. Its main limitation is that it can measure only binary mixtures. In addition to its nonspecific nature, the need for empirical calibration further restricts its use.

It is also recommended that all water vapors be removed from the measurement sample by drying. Because of the above-listed limitations, its applications are few and usually involve binary mixtures for applications such as leakage measurement and chromatography or the detection of hydrogen or helium in applications where the thermal conductivity of the “background” gases is low and relatively constant.

INTRODUCTION

A variety of wastewater parameters can be monitored to assess the pollutant load that these wastes represent. The total organic carbon (TOC) concentration of the waters and wastewaters is often used as a quality indicator. The classical biochemical oxygen demand (BOD) and the chemical oxygen demand (COD) have long been employed for similar purposes. All three readings have their strengths and weaknesses.

Advantages and Limitations

A TOC analysis is very rapid and accurate, but it measures only the organic carbon content and it therefore does not detect the pollutant load that is represented by nitrogen-based molecules. A BOD analysis is slow, but it measures all molecules that exert an oxygen demand on the receiving waters, and its readings will vary if the bioassay used is changed. Thus, the BOD, in addition to being a lengthy five- or seven-day analysis, gives significantly different readings as a function of the bioassay used.

The COD analysis suffers from shortcomings in oxidation efficiencies, although its analysis time is reduced.

Direct correlation between TOC, BOD, and COD usually is not possible. On the other hand, with proper interpretation, the TOC can represent a rapid and frequently accurate method of assessing the pollution load levels of municipal and industrial wastes.

Carbon Measurement Techniques

To determine the TOC content of a sample, its total inorganic carbon (TIC) content first must be eliminated. The TIC present in a water sample is usually in the form of inorganic bicarbonates and carbonates. One of two techniques can be used to remove them.

In one technique, these components are analyzed independently and then subtracted from the total carbon (TC). In this case, the TOC is determined by the difference between TC and TIC.

$$\text{TC} - \text{TIC} = \text{TOC} \qquad \textbf{8.58(1)}$$

The other technique is to acidify the sample down to a pH of 2 to 3, followed by a brief gas sparging to drive off the carbon dioxide formed by the acidification. Any carbon remaining after this sparging should be TOC. Therefore, the TC found in the sparged sample is considered to be equal to the TOC content of the original sample. One weakness in this technique is the possibility that some volatile organic carbon (VOC) that was present in the original sample might be lost during sparging. Additional techniques are available to account for such VOC.

Analyzer Development

As a result of the rapid acceptance and usefulness of TOC analysis as a laboratory method, on-line TOC analyzers became available in the late 1960s. The TOC analyzer was first introduced in 1964 as a single-channel TC analyzer using a catalytic oxidation combustion step followed by the analysis of the resulting carbon dioxide. In this analyzer, the inorganic carbon (IC) was either removed by acid sparging or was determined by titration. A few years later, a second channel was added to this analyzer, which permitted parallel determination of the IC in a second heated reaction chamber.

Since the earlier period, several other techniques have appeared with various changes in the methodology of detection. Their success has been limited by the relative complexity of these continuous analyzers. By 1980, there were at least four distinctly different methods in use to accomplish TOC analysis. Among these detection methods are considerable variations, depending on the instrument manufacturer using them and on the level of carbon concentration in the analyzed process sample.

Official Methods of TOC Determination

A user's choice may also be limited by industry and government standards that apply to a particular analysis. Table 8.58a provides a list of different oxidation/detection techniques and their corresponding U.S. and EU methods.[1] Most TOC analyzers used in the laboratory include an autosampler for higher sample throughput and a PC, which allows easier operation of the instrument. A separate module for the analysis of solids is also available from most manufacturers.

DETECTOR TYPES

Nondispersive Infrared (NDIR) Analyzers

The TOC analyzers first convert all organic matter to CO_2. After this conversion, a continuous flow of oxygen or air carrier gas transports the resulting cloud of steam and CO_2 through a condenser and water trap into a nondispersive infrared (NDIR) analyzer, where the CO_2 concentration is measured. The detector compares the peak area of the sample to the peak area of a calibration standard and calculates the carbon concentration value.

TABLE 8.58a
Official Methods of TOC Determination

Oxidation Method	*Detector*	*Analytical Range*	*Official Methods*
Combustion	NDIR	0.004 to 25,000 mg/l	EPA 415.1, 9060A Standard Method 5310B ASTM D2579 ASTM D5173 DIN 38 409 H3 ISO 8245 AOAC 973.47 USP 643
Combustion	Coulometric	2 to 50,000 mg/l	ASTM D4129 ASTM D513
UV	NDIR or conductivity	0.0005 to 0.5 mg/l	USP 643 ASTM D4839 ASTM D4779
UV/persulfate	Membrane/conductivity	0.0005 to 50 mg/l	USP 643 Standard Method 5310C ASTM 5904
UV/persulfate	NDIR	0.002 to 10,000 mg/l	EPA 415.1, 9060A Standard Method 5310C ASTM D2579 ASTM D4839 ASTM D4779 ASTM D5173 ISO (Draft) 8245 AOAC 973.47 USP 643
Heated persulfate	NDIR	0.002 to 1,000 mg/l	EPA 415.1, 9060A Standard Method 5310C ASTM D2579 ASTM D5173 ISO (Draft) 8245 AOAC 973.47 USP 643

High-Temperature Combustion The original and the expanded high-temperature methods[2,3] both contained a high-temperature furnace and a combustion tube to catalytically oxidize all carbonaceous species (TC) into carbon dioxide (CO_2). Figure 8.58b illustrates a high-temperature combustion analyzer using an NDIR sensor. Sample is delivered into the furnace, which contains a combustion tube. The temperature within the combustion tube is maintained at about 680 to 1000°C. Catalysts such as platinum or cobalt oxide, which are placed on a suitable substrate, promote the conversion of carbon in the sample to CO_2. The stream of gas passes through a halide scrubber and then enters the NDIR detector, where CO_2 is measured.

The high-temperature combustion method has found great utility in monitoring wastewaters, salty waters,[4] and particulate matrices.[5] The next challenge for the high-temperature techniques is the magnitude and variability of the instrument blank.[6] Instrument manufacturers have developed better catalysts and improved their methods to minimize their effects. They have also lowered the detection limit, making these analyzers suitable for drinking water and some pharmaceutical applications.

Wet Chemical Oxidation Wet chemical methods have the advantage of better sensitivity, because they analyze a large volume of sample (up to 20 ml) and thereby increase the intensity of the resulting NDIR signal for a given concentration.[1] In this analysis, the sample is also delivered to an oxidation chamber, where the addition of a persulfate reagent and acid in the presence of UV light or heat (~100°C) results in the formation of a hydroxyl radical (^{-}OH) that converts carbon to CO_2. The CO_2 produced is continuously sparged and is transported to the detector by the carrier gas.

For trace amounts of carbon (less than 1 mg/l), the UV light by itself is sufficient for converting the organic carbon to CO_2. Ultraviolet light, with or without the persulfate reagent, has been widely used in low-level TOC applications in the semiconductor and the pharmaceutical industries. Other wet chemical methods include photocatalytic oxidation, which makes use of a 400-nm near-UV energy source, water, and a titanium dioxide slurry, which are used to produce the hydroxyl radicals.

Another method for producing the hydroxyl radicals is through the reaction of ozone with a hydroxide ion. Exposing

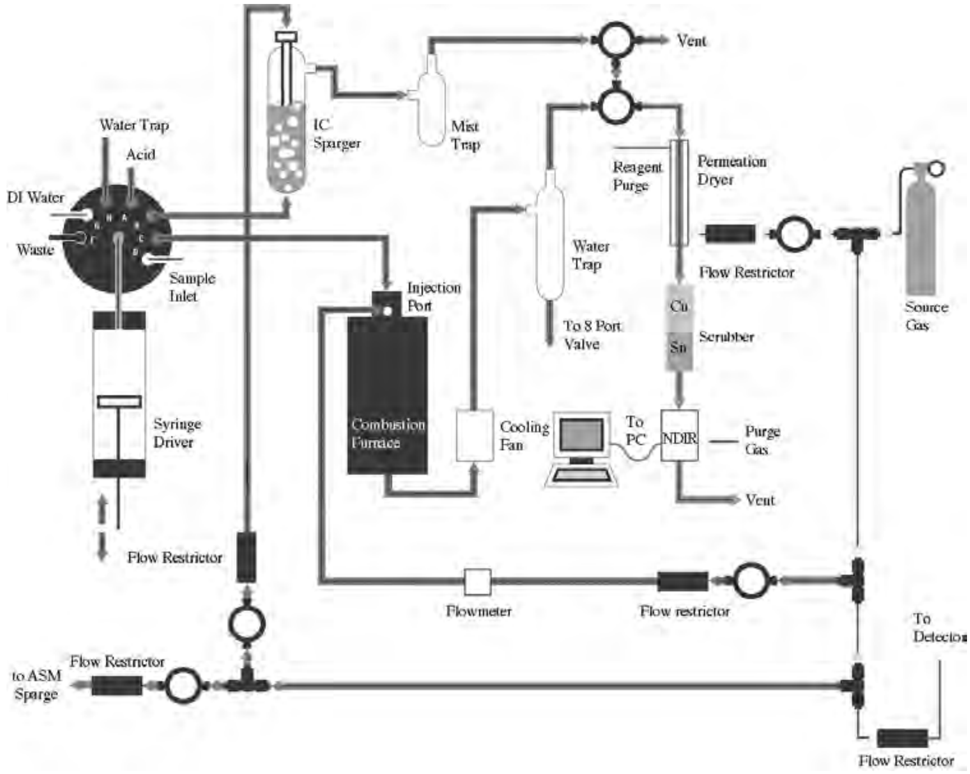

FIG. 8.58b
Catalytic combustion analyzer with NDIR sensor. (Courtesy of Tekmar-Dohrmann.)

oxygen gas to UV radiation produces ozone. This method of oxidation can also be used in TOC measurements when the samples contain high chloride concentrations or high oil and fat content. This technology is currently available only for on-line TOC analysis.

Inorganic Carbon Introducing an aliquot of the sample into an inorganic carbon (IC) chamber and adding some acid results in the IC being converted to CO_2, which can then be measured with an NDIR detector. When the IC concentration is very large as compared with the TOC, such as in drinking waters, the difference method may not be as accurate as the acid sparge technique. For such applications, the IC must be manually or automatically acidified and sparged from the sample before TOC analysis. This method of analysis is available for both laboratory and on-line applications.

Automatic On-Line Design Figure 8.58c illustrates the catalytic- oxidation-type TOC analyzer, which has been adopted for continuous on-line operation. This design incorporates an acid injection system that converts the IC into carbon dioxide. The generated CO_2 is removed in a sparging chamber before the sample reaches the analyzer. If the sparging portion of the sampling system is left off, the analyzer becomes a TC analyzer.

If a second, low-temperature reaction chamber is added in parallel with the one shown in Figure 8.58c, the analyzer becomes a TOC differential analyzer, performing the same manner as the unit described in Figure 8.58b.

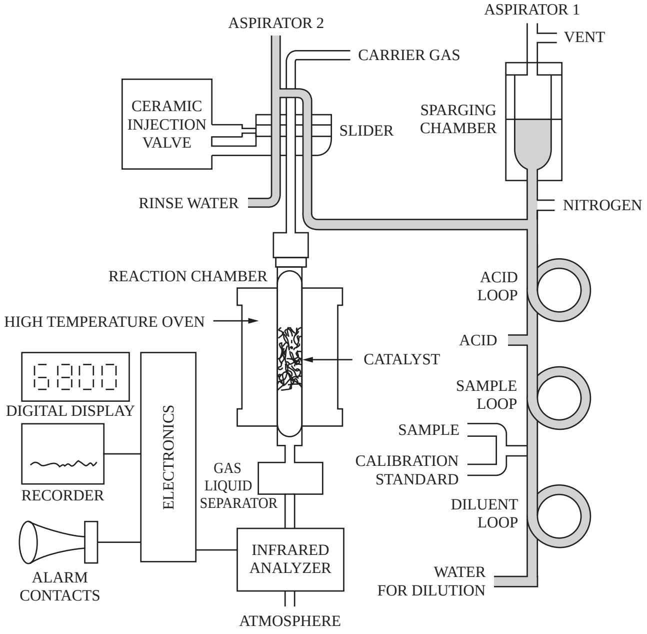

FIG. 8.58c
On-line, nondispersive infrared-type total organic carbon (TOC) analyzer. (Courtesy of Ionics Inc.)

The cycle time of this instrument is 2.5 min in the TC mode of operation and 6 min in the TOC mode. It can operate unattended indoors or outdoors in an analyzer house, and it can handle samples with solids content up to 1000 ppm and with particle sizes up to 200 μm, because an automatic water rinse is applied after each measurement cycle.

The accuracy of the sample size is guaranteed by the design of the ceramic injection valve. The calibration of the instrument is automatically checked every time a known standard is introduced. During autocalibration, the analyzer runs three consecutive calibration standards, averages the results, and adjusts the instrument calibration to within preset limits or activates an alarm.

The analyzer is also provided with dilution and automatic range change capability for conditions when the concentration exceeds the operating range. The carrier gas (nitrogen) consumption is 100 cc/min at 50 PSIG (3.5 barg), and the acid consumption in the TOC mode is about 1.0 gal (3.8l) per month.

Aqueous Conductivity[7]

This method of analysis employs the ultraviolet-persulfate oxidation of organic carbon coupled with the measurement of CO_2 using conductivity. Most systems utilizing the conductivity detection method can be used for both laboratory and online applications.

Samples are introduced using an autosampler or through on-line sample tubing. Figure 8.68d illustrates a high-sensitivity TOC analyzer used in semiconductor and pharmaceutical applications, both in the laboratory and on line. The TOC analysis is performed by conversion of IC to CO_2 after addition of an acid. The CO_2 formed may be removed from the system by degassing, or it can stay in the stream and be measured as IC. The flow stream is divided into two channels for the separate measurement of TC/TOC and IC.

In the TC/TOC channel, the carbon in the sample is oxidized to CO_2 by the action of the persulfate reagent and the UV lamp. The CO_2 in the liquid stream passes through a semipermeable membrane and then dissolves in high-purity water. A conductivity cell located in the stream measures the increase in conductivity caused by the CO_2 and relates this to a calibration data.

A chemometric equation is used to determine the relationship between equilibrium concentrations of H^+, CO_2, HCO_3^-, and OH^- and conductivity. The temperature of the conductivity cell is monitored so that readings can be adjusted to compensate for changes in temperature. Continuous pumping through a mixed bed of ion-exchange resin purifies the water on the conductivity side of the membrane. This method has the advantage of being able to measure very low concentrations of carbon while using relatively small volumes of sample.

This analyzer has found use in semiconductor and power applications where TOC levels of less than 1 μg/l are required. The semipermeable hydrophobic membrane protects against and minimizes the interference from higher concentrations of chloride and other ions. This method of analysis is limited to cases in which carbonaceous matter can be introduced into the reaction zone, because the inlet system limits the size of the particles that can be introduced. In addition, the wet oxidation technique has very low recovery if the samples contain particulate materials.

On-Line Conductivity Another method that has found use specifically in on-line semiconductor reclaiming applications involves differential conductivity measurements, before and after oxidation of the water stream, as it moves through a quartz coil.

This instrument allows for TOC updates once per second. A parallel stream goes through a stopped-flow cell, which captures a 0.3 ml sample-water aliquot. Total organic carbon is measured through a dynamic end-point detection method. The stopped-flow cell serves to calibrate the continuous cell every 2 to 3 min. A typical sample flow rate of 30 to 300 ml/min can be used. The analyzer also includes an alarm for high TOC values.

Coulometric Analysis

In coulometric detectors, the carbon dioxide is indirectly titrated. In this analyzer, the carrier gas with the CO_2 reaches the electrochemical cell containing ethanolamine and an acid-base indicator dye. As the CO_2 reacts with the ethanolamine, a strong titratable acid is formed, and the strong blue color of the solution fades. This change is detected by a photometer.

At the cathode, an equivalent amount of hydroxide is electrochemically generated that neutralizes the acid that has formed and returns the cell to its original color. The current required to produce the hydroxide ions is directly proportional to the concentration of the carbon dioxide from the sample.

This detector does not need calibration standards, nor is it affected by water from the sample. It also gives a linear signal in its entire measuring range.

Colorimetric Analysis

This method provides an inexpensive TOC monitoring method for optimizing treatment processes. However, the results cannot be used to report the TOC values, which are required by the D/DBP rule for drinking water.

In this analyzer, the sample is first acidified and then sparged of TIC. In the outside vial, the organic carbon reacts with the persulfate and acid. The vial is placed for 2 hr in a COD reactor at 105°F (40.5°C) to allow for digestion of the organic compounds. The CO_2 generated diffuses through the inner ampule containing a pH indicator reagent. Carbonic acid is formed, which changes the pH of the solution. The degree of color change associated with the change in pH of the solution is related to the amount of organic carbon present in the sample.

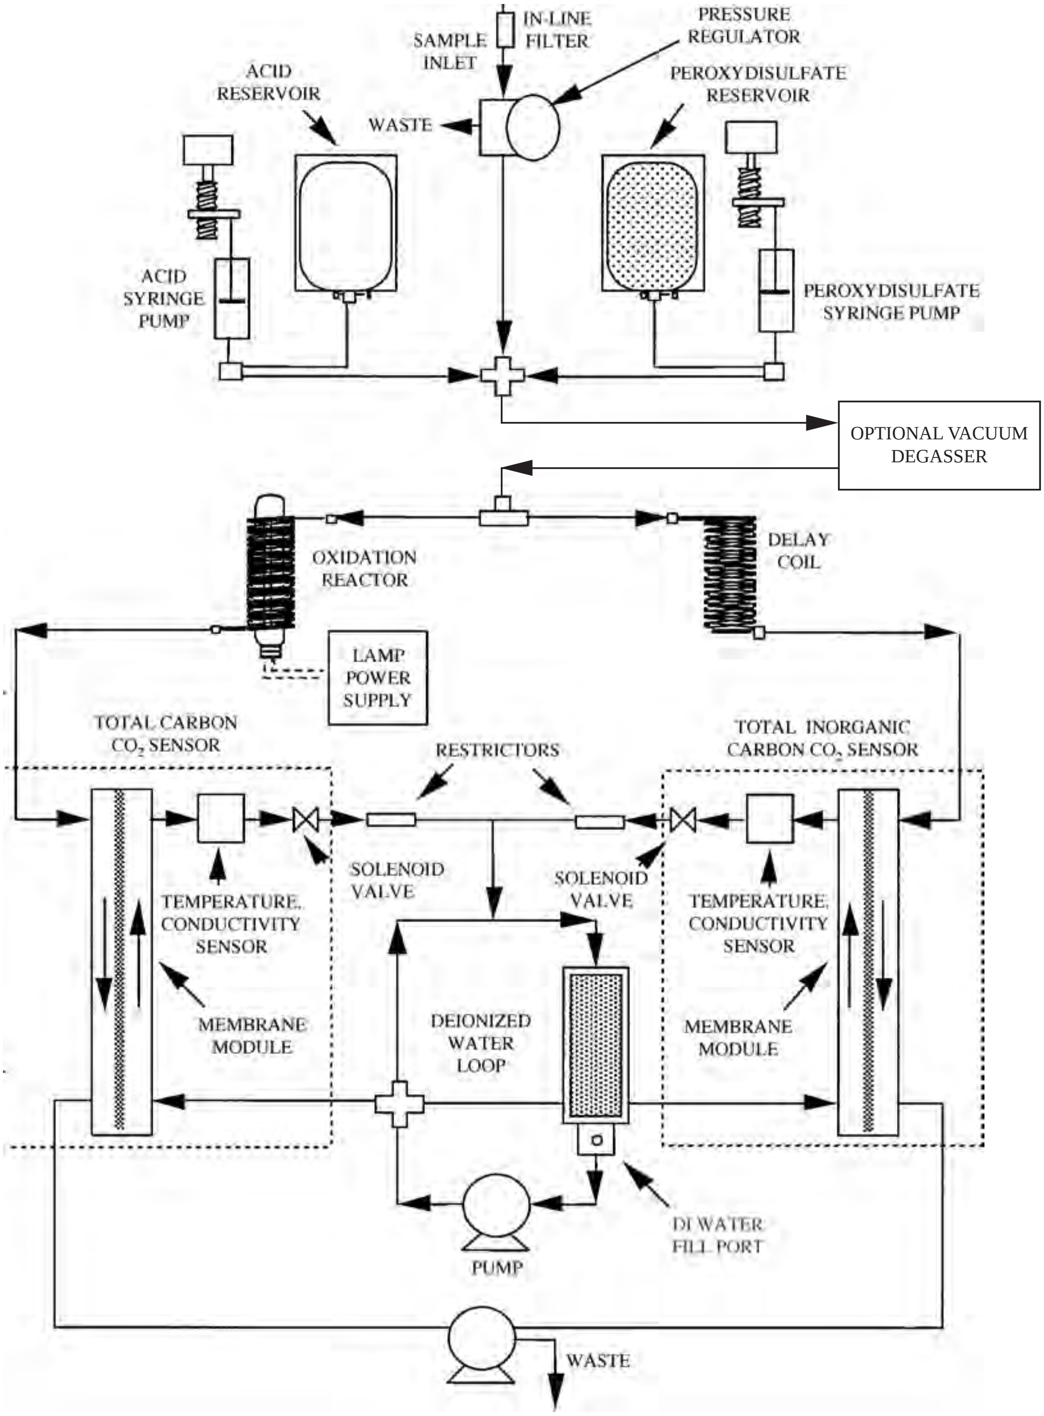

FIG. 8.58d

On-line conductivity TOC analyzer. (Courtesy of Ionics Inc.)

Flame Ionization Detector

Flame ionization detector (FID) analyzers are no longer manufactured for TOC analysis. However, they are still in use for VOC analysis.

In the FID-type analyzer (Figure 8.58e), a small acidified sample is transported in the presence of an oxidizer through a heated vaporization zone. Here, the organic carbon in the form of CO_2, plus any volatile organic carbon (VOC), is driven off. The residual sample is sent through a pyrolysis zone to convert the remaining TOC to CO_2. The CO_2 subsequently is converted to methane in a nickel-reduction step, and the resulting methane is measured by an FID detector. The VOC is separated from the CO_2 in a bypass column, reduced to methane, and routed to the same FID for an additional VOC analysis to be added to the dissolved organic carbon value.

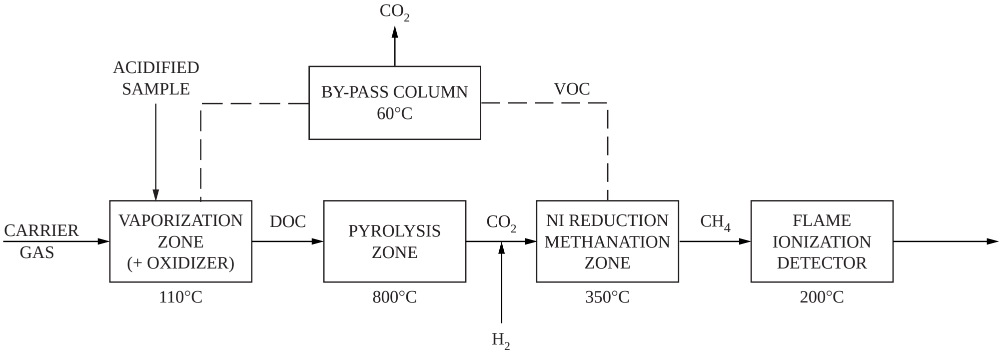

FIG. 8.58e
Flame-ionization detector.

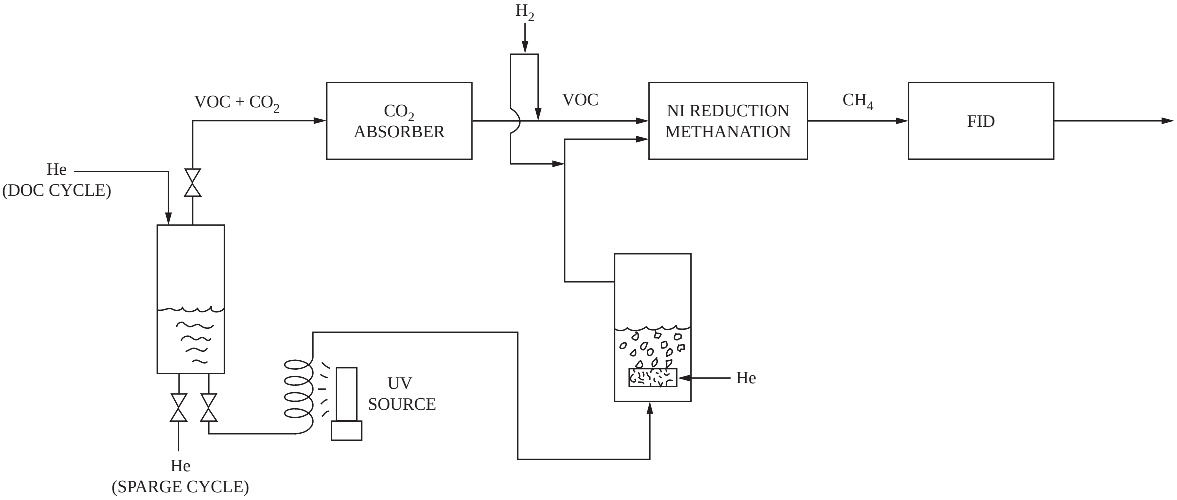

FIG. 8.58f
FID analyzer with wet oxidation.

Another method that also employs the FID to directly analyze the VOC after TIC (CO_2) is removed is shown in Figure 8.58f. In this method, the catalytic oxidation combustion is replaced by a wet oxidation step. Persulfate is added to the sample, and the solution is then exposed to ultraviolet (UV) radiation to enhance the efficiency of oxidation. The resulting CO_2 is sparged and converted in the nickel-reduction methanator, and its concentration is measured in the FID analyzer.

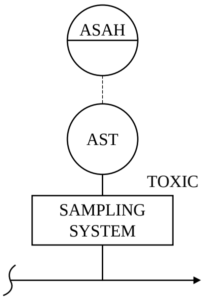
8.59 Toxic Gas Monitoring

E. L. SZONNTAGH (1995) **J. M. JARVIS** (2003)



Flow Sheet Symbol

Applications:	Safety related monitoring of ambient air and enclosed spaces for toxic gases and vapors, reduced oxygen, and radon; also used for the monitoring of fugitive emission sources in manufacturing or processing typically from stacks, valves, and fume hoods
Types of Devices:	A. Personnel protection and dosage sensors A1. Dosimeter and color change badges for exposure monitoring A2. Direct reading dosimeter (indicating) tubes A3. Radon canisters A4. Sorption tubes for thermal desorption A5. Air sampling pumps A6. Thermal desorption instruments A7. Pocket-sized electrochemical monitors A8. Calibrators for toxic gas monitors B. Continuous industrial monitors/alarms/transmitters B1. Electrochemical cells (membrane diffusion) or semiconductor B2. Infrared B3. Ultraviolet B4. Ionization detectors B5. Fluorescence and chemiluminescence B6. Chromatograph B7. Mass Spectrometer
Costs:	A1. \$350 to \$500 for a package of five badges with prepaid analysis A2. \$2 to \$4 per tube; \$200 for hand pump; \$800 for automated pump A3. \$45 to \$250 per point for testing service A4. \$35 to \$120 per tube A5. \$800 to \$2000; about \$1200 for an average pump A6. From \$1700 to \$20,000 A7. \$400 to \$700 for single gas monitors; \$800 to \$2900 for multiple gas monitors A8. \$850 to \$15,000 B1. \$300 to \$1700 per point of detection B2. \$500 to \$2000 per point of detection B3. \$11,300 to \$34,000; see Section 9.63 B4. \$1500 to \$3500 for photoionization B5. Fluorescence and chemiluminescence B6. See Section 9.12; \$35,000 to \$60,000 for unit equipped with sample multiplexer and column program/backflush B7. \$140,000 typical for an instrument equipped with a 64-channel stream multiplexer

HAZARDOUS AND TOXIC ATMOSPHERES

Normal atmospheric oxygen content is slightly in excess of 20%. If the oxygen level is reduced below 10% in an atmosphere, either as a result of oxygen displacement or removal, simple asphyxiation can occur, causing death. This simple asphyxiation can be caused by any gas, including even otherwise nontoxic ones. Most commonly, this hazard exists in enclosed spaces where there is an opportunity of a gas leak or buildup that dilutes or displaces the oxygen in an area. If a person enters the area, unconsciousness and death can occur within minutes.

Occupational Safety and Health Administration (OSHA) regulations require that oxygen concentration in air not fall below 19.5% during an eight-hour workday.

Safety Instrument Performance Standards

The purpose of toxic gas detection is for personnel protection to warn against accidental exposure. Therefore, it is important that the instrumentation be reliable and perform accurately in the application. In the last decade, standards have been developed to ensure that detection instrumentation performs to a minimum set of specifications that will ensure adequate protection. These standards apply beyond those that might otherwise be applicable for hazardous area deployment.

ISA (formerly the Instrument Society of America) has developed a set of standards that are applicable to electrical instruments for the determination of common toxic gases in the context of personnel protection. At this writing, standards exist for hydrogen sulfide (ISA-92.0.01, Part 1–1998),[8] carbon monoxide (ANSI/ISA-92.02.01, Part 1–1998),[9] ammonia (ISA-92.03.01–1998),[10] oxygen deficient/enriched atmospheres (ANSI/ISA-92.04.01, Part 1–1996),[11] and chlorine (ISA-92.06.01–1998).[12]

In the European Union standard, EN 45544[13–16] defines the set of minimum requirements for electrical apparatus used for direct detection and measurement of toxic gases and vapors. This standard, unlike the ISA standards, is generic for all toxic gas and vapor species. The standard is divided into four parts. Part 1 describes general requirements. Part 2 describes requirements for instruments that respond in the region of limit values. Part 3 describes requirements for apparatus designed for measuring concentrations well above limit values. Part 4 is a guide for selection, installation, use, and maintenance.

Factory Mutual Research Corporation (FMRC), at this writing, utilizes FM-6340/6341-Draft for performance approval of toxic gas detection instrumentation. Similar to the European Union standards, the standard provides a generic set of performance requirements irrespective of the toxic gas species.

Types and Levels of Toxicity

The mode of toxicity for some gases results from having a greater affinity for binding with blood hemoglobin than with oxygen. In this case, *chemical asphyxiation* occurs because of the displacement of the oxygen from the blood. Most notable in this category of toxic gases are carbon monoxide (CO) and hydrogen cyanide (HCN). In the case of CO, it is odorless and a nonirritant. If the exposure is chronic, death can result even if CO is present in relatively low concentrations.

The modes of toxicity for other toxic gases are varied. The toxin can be dissolved in body fluids and can be transported within the body to injure biological tissues and organs. The toxicity of a gas or vapor depends on its specific toxicity; on the efficiency and effectiveness at which it is absorbed, transported, and metabolized; and on exposure time.

To describe each gas' specific toxicity, threshold limit values (TLVs) have been established by the American Conference of Governmental Industrial Hygienists (ACGIH),[1] and permissible exposure levels (PELs) have been established by OSHA.[2] These values are generally measured as eight-hour time-weighted averages (TWAs), and the concentrations are expressed in parts per million (ppm).

It is customary to rate a substance with 100 to 1000 ppm exposure limits as moderately toxic, 10 to 100 ppm as highly toxic, and less than 10 ppm exposure limits as extremely toxic. The short-term exposure limit (STEL), which is generally 15 min, and the ceiling threshold limit value (TLV-C) of the concentration during any part of the working exposure have been established to limit exposures during short time periods. More details on the specific health effects of toxic substances can be found in the References 3 through 5.

Extreme Toxicity

Of greatest concern are extremely toxic gases and vapors. By convention, these are substances with TLV, PEL, STEL, or TLV-C values of 10 ppm or lower. A partial listing of gases and vapors with TLVs below 10 ppm is given in Table 8.59a. Literature is noted in Reference 6 describing how measurements should be taken and processed.

A couple of toxic gases deserve special mention because of their uniqueness. Mercury naturally occurs as the elemental metal. It is the only metal that is a liquid at room temperature and hence has significant vapor pressure. Mercury is widely used in industry as a catalyst and as an integral component in fluorescent lamps. Improper disposal of fluorescent lamps and inadvertent incineration provides an important pathway for mercury to enter the environment.

Mercury is a neurotoxin. The “mad hatters” of the nineteenth century suffered from mercury poisoning as a result of the mercury felting process that was prevalent at the time. In the U.S., the disease became known as the “Danbury shakes” because of the large number of hat makers in Danbury, Connecticut, who were afflicted with the disease. OSHA has established the PEL at 0.1 mg/m^3. AGGIH has established the recommended airborne exposure limit of mercury vapor at 0.05 mg/m^3 averaged over an eight-hour work shift.

Radon gas is a radioactive noble gas that occurs in nature through the radioactive decay of radium and uranium in soils. While it is chemically unreactive and hence nontoxic in that sense, it is radioactive and thought to be the leading cause of lung cancer after cigarette smoking.

Most emphasis on radon detection has been in the home and public building settings. The generally accepted maximum permissible level of radon in these facilities is 4 pCi/l.

TOXIC GAS MEASUREMENT

The measurement methodologies for toxic gases is, in a larger sense, a subset of the methodologies used for other industrial substances. The purpose of this section is not to restate the methodologies that are described elsewhere in this volume. The purpose here is to expand on the previous coverage from a safety and personnel protection perspective.

Related Sections

Toxic gases include carbon dioxide (Section 8.9), carbon monoxide (Section 8.10), combustibles (Section 8.16), hydrocarbons (Section 8.25), hydrogen sulfide (Section 8.26), mercury (Section 8.30), nitrogen oxides (Section 8.37), ozone (Section 8.44), sulfur oxides (Section 8.56), and many others. Their measurement and analysis have been discussed and is not repeated here.

Likewise, the measurement methodologies of IR analyzers (Section 8.27), mass spectrometers (Section 8.29), open path analyzers (Section 8.40), Raman spectroscopy (Section 8.51), UV and visible analyzers (Section 8.61), and wet chemistry analyzers (Section 8.66) are not repeated.

One notable exception is the electrochemical cells that are widely used for toxic gas detection. The discussion is expanded to cover positive flow and diffusion-type electrochemical sensors, because they play such a critical role in toxic gas detection systems. The relative merits of the various measurement techniques are also discussed.

CONTINUOUS SENSOR DESIGNS

Electrochemical cells have the advantage of simplicity, low cost, and reliability as compared to other technologies. Technologies such as flame ionization, mass spectrometric,

fluorescence, UV, and IR analyzers provide better sensitivity and/or specificity than do electrochemical sensors.

It is rare for an electrochemical sensor to have sensitivity lower than 1 ppm. Additionally, an electrochemical sensor may have significant cross sensitivity to other substances. In most instances, environmental factors limit the set of substances that are likely to present interference for any given sensor installation, so the sensor provides utility in spite of cross sensitivities.

On the other hand, electrochemical sensors tend to be more stable, selective, and sensitive than sensors built on metal oxide semiconductor (MOS) technology. Because most electrochemical sensors use aqueous-based chemistries, MOS sensors have found utility in environments of either extremely high or low humidity. In these environments, electrochemical sensors tend to either dry out quickly or absorb moisture, resulting in a shortened operating life.

When the sensitivity or specificity of electrochemical sensors is inadequate, or the number of toxic vapors is high, other methodologies must be used.

Chromatography

Chromatography has long been the workhorse of analytical measurements. The chromatograph coupled to an appropriate post column detector can be used for a myriad of toxic vapor detection applications. The chromatograph guarantees the selectivity, and the detector provides the sensitivity.

Detectors can range from the simple thermal conductivity types, to the increasing complexities of flame ionization and flame photometric types of detectors, and even to a mass or mass spectrometric detector. The latter detection scheme provides an additional dimension to the measurement by adding specificity and providing positive confirmation of the vapor composition resulting from the mass spectral fragmentation pattern while still providing quantitative information. Sometimes sample preconcentration techniques are also used to further increase the overall sensitivity of the measurement.

As the sophistication of the chromatography system increases, its cost also rises. Multipoint sampling systems have been developed to multiplex a single chromatograph among a variety of samples. As a result, the cost of the individual measurements is reduced.

Chromatography is, however, slowly losing ground to methodologies that are thought to be more reliable, have lower maintenance, and not require the refilling of consumables. Today, optical technologies have advanced to the point at which they have become alternative detection methodologies. Advances in electronics, optics, and light source designs, including lasers, have served to improve the performance and reliability of the measurement while lowering the installed costs.

Spectrometers

The preference is strong for toxic gas monitors that use solid state technologies and have no moving mechanical parts. As a result, field-deployed instruments with warranties of up to five years are common.

Instruments based on nondispersive infrared (NDIR) absorption, infrared photoacoustic detection, pulsed ultraviolet fluorescence, and chemiluminescence measurements are all available. Fourier-transform IR and tunable diode laser spectrometers have also been utilized for high-sensitivity and high-specificity applications.

In the past decade, mass spectrometry has made tremendous strides. Once thought of as being a maintenance-intensive technology, its reliability has been greatly improved. Advancements in miniaturization have also reduced their size such that some specially designed devices are field portable and smaller than a suitcase.

Several mass spectrometer packages have been designed for ambient air monitoring. Instruments are generally available with 32- or 64-channel multistream sampling capability, which lowers the unit cost per detection point. Published detection limits for some organic vapors are listed in Table 8.59b.

Radon Detectors

The measurement of radon presents special detection challenges because of the low levels and general nonreactivity of the gas. Several very specialized methods have been approved by the USEPA for radon measurement.[7]

The more common methods are (1) adsorption of the gas on activated charcoal followed by gamma ray detection, (2) the use of alpha track detectors where radiation damage of a plastic sheet is measured, (3) monitoring the voltage reduction on an "electret" (electrically charged disk of Teflon®) as a result of exposure to radiation, and (4) continuous monitoring.

Proper placement of detectors and adherence to measurement protocols are necessary for meaningful results. Because of the very specialized nature of radon detection and measurement, the testing is most frequently contracted to laboratories that have demonstrated proficiency in this area.

Electrochemical Sensors

Electrochemical-based detection instruments employ cells that utilize the principles of coulometry or voltametry to effect the measurement (see also Section 8.4).

Electrochemical sensors based on these principles have progressed much in the last 30 years. They have reduced the instability caused by excessive noise and drift, improved sensitivity and specificity, increased the working life span of these instruments, and simplified their calibration procedures. The latest electrochemical monitors are usually microprocessor controlled, stable, and easy to calibrate.

Oxygen Detectors As discussed in Sections 8.4 and 8.42, oxygen detectors often use the fuel-cell amperometric detection principle. Essentially, such a device is a metal/air battery in which the amount of current delivered is a function of how fast oxygen can diffuse to the cathode through a mass-flow-limiting capillary tube. A schematic of a typical oxygen sensor is shown in Figure 8.59c.

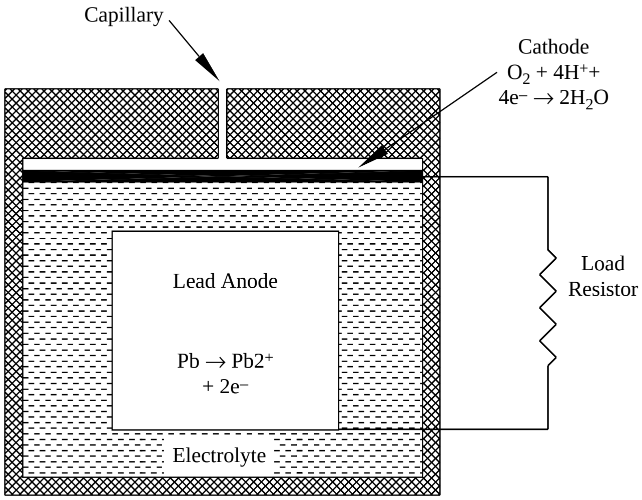

FIG. 8.59c
Diagram of mass-flow-limited oxygen sensor.

In these sensors, the current produced and, hence, the response to oxygen, is determined by the diffusion rate through the capillary. These sensors respond to the actual amount of oxygen available at the cathode and not the oxygen partial pressure. As a result, these sensors are sensitive to atmospheric pressure changes and can be adversely affected by pressure transients that occur as a matter of course in a sample system or when deployed in portable sensors.

Signal processing is employed in the sensor to minimize the effects of pressure transients. This same sensor can be used under a wider range of temperature variations, because the diffusion rate through the capillary is only weakly temperature dependent.[17]

Oxygen sensors can also use a Teflon-like membrane, similar to the technology used in dissolved oxygen electrodes for water analysis (Section 8.43). Sensors using this technology experience less output variation with pressure transients but are ten times more sensitive to temperature changes. On the other hand, because diffusion through a polymer membrane is slower than through a capillary, the response time (t_{90}) of partial pressure sensors is typically 20 to 40 sec, whereas it is between 5 and 10 sec for mass-flow-controlled sensors.

Amperometric Toxic Sensors Sensors for toxic vapors differ structurally from units that detect oxygen, but they still are electrochemical cells that operate in amperometric mode. These cells generate a current that is linearly proportional to the concentration of the gas present in the atmosphere.

The simplest form of an electrochemical cell is a two-electrode design, which consists of a semipermeable diffusion membrane, a reservoir of acid electrolyte, a sensing electrode, and a counter electrode. The toxic gas for which the cell was designed diffuses through the membrane and reacts at the working electrode, typically producing a number of H^+ ions as well as electrons. The H^+ ions travel through the electrolyte to the counter electrode while the electrons travel through the external circuit and combine with the ions at the counter electrode. The current produced and measured in the external circuit is directly proportional to the concentration of the toxic gas present.

In many cases, the electrolyte is an aqueous acid. In some instances, it may be an organic gel or in a solid state. Formulations have been improved to reduce hygroscopic effects in low- and high-humidity environments that can have a negative effect on the working life of the electrolyte. Lifetimes in the latest models frequently exceed two years.

Number of Electrodes Two-electrode sensors are inexpensive and perform adequately on less-demanding applications. For industrial applications, the three-electrode designs are dominant. The third electrode permits the potential between the counter and the working electrodes to vary. This provides optimal catalytic efficiency with the aid of external circuitry and results in a greatly improved cell sensitivity. Additionally, the linearity of response and dynamic range of the cell are improved.

A diagram outlining the operation of both the two- and three-electrode sensor designs is shown in Figure 8.59d. The reader is referred to References 18 and 19 for a detailed explanation of their operations.

Sensor Compensation and Life Toxic sensors respond to the partial pressure of the gas of interest, so the measured concentration will increase linearly with atmospheric pressure.

Toxic sensors also generally require a small amount of oxygen dissolved in the electrolyte for reactions at the counter electrode. As a consequence, the sensors should not be operated for long periods under anaerobic conditions. For short periods (10 min or less), the cell will operate without oxygen, because some dissolved oxygen will be present in the electrolyte. This situation is frequently exploited for sensor calibration, because compressed calibration gas with nitrogen can be used without fear of oxidation or reduction of shelf life.

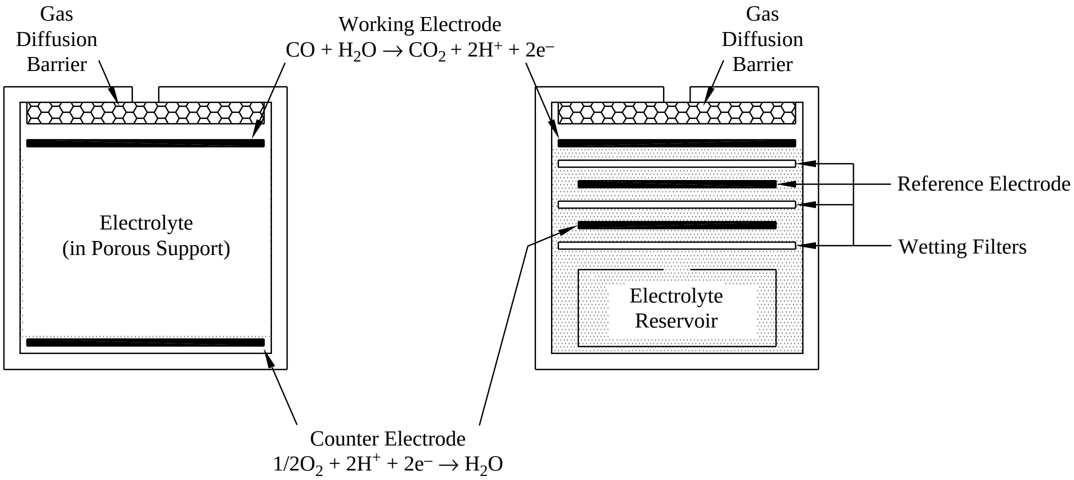

FIG. 8.59d
Diagram of two- and three-electrode sensor.

All electrochemical sensors rely on catalytic reactions that are either accelerated or slowed as the operating temperature rises. This results in both response time and sensitivity changes. Generally, the sensitivity change with temperature variation is very repeatable and can be compensated with software or circuitry. At low temperatures, the speed of response can become intolerably slow. When the temperature becomes too low (around −35°C), the electrolyte can freeze, causing permanent damage to the cell.

The lifetime of the sensor is strongly dependent on relative humidity (RH) of the environment. The classic electrolyte in toxic sensors is generally 5 molar aqueous sulfuric acid. This concentration of acid generates 65% RH. For atmospheric RH above or below this level, the sensor will either absorb water or lose water to evaporation. Sensors can tolerate humidity variations between 15 and 90% RH. When the RH in the environment is over 90%, the cell will absorb moisture, and the electrolyte reservoir may eventually overflow, causing the cell to burst. Below 15% RH, the sensor will continue to lose moisture until there is not enough electrolyte for efficient ion transport, and the cell will fail for that reason.

Fixed Detectors

Electrochemical sensors are used in many permanent installations of toxic gas detectors. These sensors are designed for industrial use and frequently carry hazardous area approvals. Electrochemical sensors are also available with explosion-proof housings that are suitable for deployment in Class 1, Division 1 and CENELEC Zone 1 hazardous areas. Figure 8.59e shows a typical industrial detector with an explosion-proof housing.

Because of the low power requirements of the sensing element, these detectors are frequently designed to be intrinsically safe. Such designs operate on such low power as to be incapable of initiating an explosion. Intrinsically safe detectors tend to be less costly than the ones requiring explosion-proof housing, because they can utilize molded plastic housings rather than the bulky and expensive explosion-proof housings.

Most fixed detectors transmit their readings to the associated control and alarm system using 4 to 20 mA current loop. Usually, detectors that are designed for intrinsically safe operation are powered from a 4 to 20 mA current loop, which reduces the number of wires that must be installed. In the past decade, the low-cost, low-power, high-reliability, spread-spectrum radio telemetry systems found increasing acceptance for communications with central alarm systems.

Alternatively, if a central alarm system is not available, several detector models are available that provide self-contained alarming devices or provide strobe lights, sounders, and relays in addition to the 4 to 20 mA transmission signal loop. Figure 8.59f illustrates a toxic gas detector with built-in alarms.

Portable Detectors

Electrochemical (and semiconductor) sensors are also available in pocket-sized, battery-powered personal monitors and in portable analyzers. Pocket-sized personal monitors are inexpensive and fast (t_{90} in around 20 sec). In addition to indicating toxic gas concentrations, they are provided with alarms and outputs set to actuate when OSHA limits are reached.

Some personal monitors can simultaneously detect several toxic gases. A typical sensor combination might consist of detectors for combustibles (typically, a low-power pellistor bead), for low oxygen, and for high CO and H_2S concentrations (electrochemical cells), for a total of four measurement channels. The sensors have a useful life of as long as two years and are inexpensive to replace. A typical multichannel portable detector is shown in Figure 8.59g. A partial list of available sensor types, their alarm set points, and inaccuracies is provided in Table 8.59h.

DISCONTINUOUS DOSAGE SENSORS

The dosimeters in use include the various color-changing badges, direct reading tubes, and various sorption devices. Each is briefly described in the paragraphs below.

Color Change Badges

These badges are worn by workers and serve to monitor their exposure to hazardous chemicals. Depending on the type of badge, the exposure period can be from 15 min to 8 hr. These badges register the time-weighted average exposure level.

TABLE 8.59h
*Typical Range, Sensitivity, and Alarm Set Points of Portable Personal Protection Monitors**

Gas	*Range*	*Resolution*	*Alarm Setpoints (low/high)*
O_2	0–30%	0.1%	19.5/23.5%
CO	0–500 ppm	1 ppm	35/200 ppm

NH_3	0–50 ppm	1 ppm	25/50 ppm
PH_3	0–5 ppm	0.1 ppm	1/2 ppm
Cl_2	0–10 ppm	0.1 ppm	0.5/5 ppm
HCN	0–100 ppm	1 ppm	4.7/50 ppm

*Abstracted from Cole-Parmer Catalog 2001/02, 2001.

Table 8.59i lists some of the available badges and badge holders. The color change of an exposed badge can be self-developing, or the badge may need to be treated with a developing reagent. The color change can be interpreted by comparison to a color chart or by the use of electronic monitors.

Continuous Color-Change Monitor Continuous color-change concepts have also been employed to build continuous toxic gas monitors (Figure 8.59j) using a chemically treated tape that is incrementally exposed to the sample gas. If the gas of interest is present in the sample, the tape is *stained*, and the degree of staining is detected by measuring the reduction in the reflected light from the tape.

This spectrophotometric approach, coupled with microprocessor technology, is capable of detecting toxic gas concentrations in the ppb range and proving response times of under 30 sec. More than 50 toxic gases are detectable by this technique. A partial list of such detectable gases and their minimum concentrations is provided in Table 8.59k.

Color Detector (Dosimeter) Tubes

Color detector tubes (CDT)[21,22] are devices used for estimating toxic gas and vapor concentrations with an overall accuracy of ±25%. A hand-operated suction device pulls a predetermined amount of air sample through the CDT, and the color progression on the packed sorption bed (which is impregnated with a color-changing indicator material) registers the concentration of the particular toxic gas.

The purpose of these devices is to estimate concentrations before more accurate monitoring is performed. Concentrations by the color-band progression can be read within a few minutes. The disposable CDTs are relatively inexpensive, and

a wide variety of some 250 different tubes are available. Table 8.59l lists some of the available tubes.

Dosimeter tubes are also available in diffusion-based designs. They are used by snapping off the prescored end of the tube and a colored line of demarcation results in front of a scale that is labeled in units of ppm-hours of exposure. Figure 8.59m describes the tube, and Table 8.59n lists the ranges and other data for some available units.

Sorption-Type Dosimeters

These devices absorb the toxic gases either passively (as a result of diffusion) or actively (when an air sample is pulled through them). After some period of exposure, the quantity of toxic gases that have been accumulated by them is measured. This is done by removing the devices and applying heat or solvent to desorb the toxic material.

Personnel dosimeters are either liquid filled or solid filled. The former usually requires wet chemical treatment before it can be analyzed for formaldehyde, ethylene oxide, and other substances, usually by a spectrophotometer. In this case, the time-consuming preparation requirement is a disadvantage (except for the direct-indicating types, which need no preparation or analyzer but are also less accurate). The time delay can be especially bothersome if the dosimeter has to be mailed to a laboratory for analysis.

Passive Personal Dosimetry Passive personal dosimetry (diffusion) is most valuable for double-checking monitoring

data or for calibration. It is also useful when seeking concentration estimates before more elaborate instruments are procured. The solid-filled personnel dosimeters have to be desorbed (by solvents or, more and more frequently, by heat) for gas chromatographic or other instrumental analysis.

Their normal usage includes double-checking calibrations, determining sensitivity ranges of instruments, calculating useful flow rates and sampling-time duration for active sampling devices, and making approximate measurements before stationary instruments are obtained.

Active or Dynamic Sampling Active (also called dynamic) personnel sampling devices also need thermal desorption or wet chemical treatment after sample collection, but they do not rely on diffusion as do passive personnel dosimeters. In active dosimeters, an air-sampling pump continuously passes a known amount of air through the sorbent material. Components of the pure air pass through the sorbent while toxic gases and vapors are held back on the high surface area of the sorbent material. The sorbent material can be either liquid or solid.

Liquid and Solid Fillings Liquid-filled absorption devices are called *impingers*. They are fragile and therefore sensitive to mistreatment, and they are more troublesome to use than solid sorbent tubes. They can also cause injuries if the liquid leaks out.

Solid-filled active sampling devices (also called adsorptive, sorptive, or sorption tubes) are less sensitive to mistreatment

than are impingers. The most frequent problem with these devices is breakthrough, which is a loss of the sorbed toxic gas (desorption), especially if flow rates are too high and/or sorption times are too long. These solid sorbent-filled trapping devices rely on surface adsorption rather than solution absorption.

Table 8.59o lists a number of sorption tubes with different packing solids. Although they can be desorbed by liquid solvents and injected as liquid samples into a gas chromatograph, thermal desorption can also be used by injecting the desorbed sample directly into a gas chromatograph as a vapor or gas. Sometimes, cold traps are also used before injecting, which can concentrate or focus the sample before thermal desorption and injection.

In addition to carbon-based sorption-tube fillings, which are listed in Table 8.59o, alumina, silica gel, Tenax®, and many other gas-solid-chromatography (GSC) packing materials can also be used.

CALIBRATION

Toxic gas and toxic vapor monitors are only as good as is their calibration. Electrochemical sensors can be calibrated by prepared gas concentrations that are stored in pressurized gas cylinders, sampling bags, or calibration bottles (Figure 8.59p). Although high-pressure calibrating gas mixtures are commonly used, their reliability decreases with increasing shelf life and decreasing concentrations. Sorption, chemical reactions, diffusion, and heavy component settling by gravity can also reduce their reliability. Even stainless steel containers and periodic rolling cannot eliminate all the problems; therefore, alternative methodologies are preferred.

Low-pressure static gas mixtures in mixing bags or in rigid containers have the same problems in addition to having very limited capacities. They are still useful when used in syringe calibration for gas chromatography but are practically useless as continuous or semicontinuous calibration gas supplies.

Dynamic Calibrators

Dynamic calibrators operating on the permeation tube principle[24] have been available for decades. The availability of a large number of gases and vapors (about 100 different toxic components) and the relatively high accuracy (±2%) of these systems place permeation systems among the most popular calibrating devices.

Bubbler/Dilution Calibrator Another dynamic calibrator is the bubbler/dilution calibrator. In this design, instead of a permeation chamber, a bubbler or impinger is used. If the gas or vapor of interest is a liquid at 32°F (0°C), an ice/water bath can be used to provide temperature control.

The air is slowly bubbled through the liquid so that the air is saturated by the vapor of the liquid at the controlled temperature. The known flow rate of the saturated air can then be diluted by pure air. The bubbler liquid's vapor pressure can be calculated or can be taken from a handbook.[25] The concentration of the yet undiluted stream can be calculated by Equation 8.59(1).

$$C\% = (100 \times \text{vapor pressure of the liquid}) / (\text{total atmospheric pressure}) \qquad \textbf{8.59(1)}$$

To increase accuracy, the same pressure sensor should be used to detect both the vapor and the atmospheric pressure. If the concentration is too high (it usually is), dilution by a large flow of pure air is necessary.

Electrochemical Calibrating Gas Generators A novel way of providing calibrating gases is to use electrochemical calibrating gas generators. They consist of electrochemical cells that provide coulometrically controlled quantities of specific gases that can be mixed into a fixed air flow. Accuracy is ±10%. Chlorine, chlorine dioxide, hydrogen, hydrogen cyanide, hydrogen sulfide, and ozone calibration gas generators are all available.

Some electrochemical detectors are also available with built-in gas generators so that bump tests can be performed automatically in the field to ensure detector operational integrity. Because, for the purposes of bump testing, absolute accuracy is not important, cross sensitivities can be utilized for testing cell integrity. Detectors with automatic sensor testing are available for bromine, chlorine, chlorine dioxide, fluorine, ozone, ammonia, carbon monoxide, hydrogen chloride, hydrogen cyanide, hydrogen fluoride, hydrogen sulfide, nitrogen dioxide, sulfur dioxide, and iodine.

Because calibration always involves toxic gases, all such procedures must be executed in well ventilated areas, preferably inside high-efficiency exhaust hoods.[24]

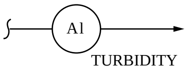
8.60 Turbidity, Sludge, and Suspended Solids



Flow Sheet Symbol

A. BRODGESELL (1969, 1982) **B. G. LIPTÁK** (1995, 2003)

Types:	Laboratory units can be manual or flow-through types; industrial turbidity transmitters in the process industry are available in both probe and flow-through designs.
Design Pressures:	Up to 250 PSIG (17 barg)
Design Temperatures:	250°F (120°C) standard; 450°F (232°C) special
Construction Materials:	Stainless steel, glass, plastics
Ranges:	In ppm silica units, from 0–0.5 to 0–1000 Backscattering designs available from 10–5000 ppm up to 5–15% Ranges in JTU units from 0–0.1 to 0–10,000 In NTU units, from 0–1 to 0–200 In FTU units, from 0–3 to 0–1000 Sludge density probe with reciprocating piston has a range from 0–0.1 to 0–10% of suspended solids
Inaccuracy:	0.5 to 2% of full scale for most designs, 5% of full scale for the reciprocating piston probe type suspended solids sensor, which is used on sludge applications
Costs:	Standard reference solutions for calibration cost $100 per bottle; laboratory turbidity meters cost from $750 to $2000; laboratory nephelometers with continuous-flow attachment cost $2000; industrial turbidity transmitters cost from $2500 to $5000, depending on features and materials of construction. Sludge-density-detecting, self-cleaning probe with internal reciprocating piston and indicating transmitter costs $7500; ultrasonic suspended solids transmitters are $5000 to $6000.

INTRODUCTION

In the area of turbidity measurement, there is some overlap between the coverage of this section and of Section 8.15, which covers colorimeters. Similarly, the discussion of sludge and suspended solids measurements in this section does have some overlap with the discussion of the various densitometer designs in Chapter 6.

Turbidity meters (similarly to the nephelometers discussed in Section 8.46) measure the cloudiness of a fluid by detecting the intensity of transmitted or reflected light. The cloudiness detected by turbidity meters is caused by finely dispersed suspended particles that, when exposed to a visible or infrared (IR) light, will scatter it. The cloudier the process fluid (the higher its turbidity), the more scattering will occur and therefore the less light will be transmitted through a sample. If the sensor photocell is placed at a 90° angle to the light path, the cloudier the process fluid, the more scattered light it will detect.

Light Absorption and Scattering

The turbidity meter detects light scattering, but the colorimeter measures light absorption (Figure 8.60a). If a liquid has no color at all, and the attenuation of light intensity is the result only of the scattering effect of solid particles, a colorimeter (Section 8.15) can also be used to detect turbidity. All that is needed is to convert from the standard units of colorimetry (0 to 100% transmittance or 0 to 2 absorbance) into turbidity units.

Other analyzers can also be used to detect turbidity. For example, sludge density measurements (Section 6.7) can also be converted into turbidity units. Similarly, consistency readings (Section 8.18), which are normally in units of weight percent of solids, can also be expressed in turbidity units. Figure 8.60b illustrates such a consistency meter, which operates with reflected IR light transmitted over optical fibers.

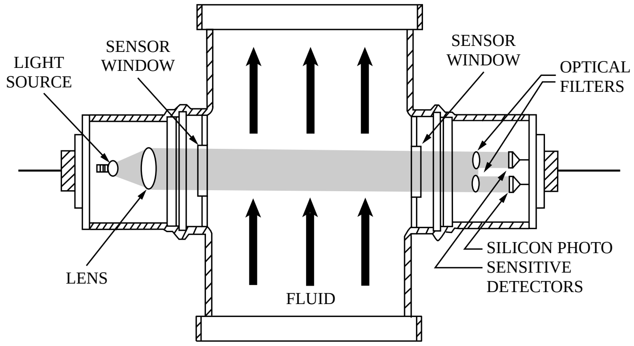

FIG. 8.60a
The design of an in-line color monitor. (Courtesy of Monitek.)

Units of Turbidity

The three main methods of light intensity detection are perpendicular scattering (nephelometry), backscattering, and forward scattering. Different turbidity units have evolved in connection with these different designs.

The Jackson turbidity unit (JTU), for example, is a purely optical scale that correlates well with forward-scattering measurements. The value of one JTU corresponds to the turbidity of a liter of distilled water when 1 mg (1 ppm) of diatomaceous fullers earth (an inert material) is suspended in it.

Nephelometric turbidity units (NTUs) are based on U.S. EPA-approved and stable polymeric suspension standards and correlate well with perpendicular scattering designs. Formazin turbidity units (FTUs) are based on a Formazin polymer standard and also correlate well with perpendicular scattering designs.

Conversion among Turbidity Units The correlation between different turbidity units is given in Table 8.60c. However, because different turbidity instruments respond differently to variations in particle size, color, index of refraction, etc., one

cannot obtain accurate correlation between them. These different scales include two Formazin scales in use. The error in turbidity measurements cannot be less than the precision at which the calibrating reference standard solution is available. In the case of Formazin standards, this variation can approach 1%. The NTU reference standards are more stable and last longer than the FTU ones.

The various turbidity units all measure the amount of solid particles in suspension. When parts per million (ppm) units are used, they can refer to the weight of the particular solids in suspension but, because this would require individual calibration using the particular solids, they usually refer instead to ppm of silica (silicon dioxide). Therefore, if the cloudiness (turbidity) of the process sample is the same as the turbidity that would result when 1 mg of silica is mixed in a liter of distilled water, the turbidity reading is called to be 1 ppm on the silica scale.

TURBIDITY ANALYZER DESIGNS

Forward-Scattering or Transmission Type

Similar to the design of color monitors, in the forward-scattering or transmission-type turbidity sensor design (Figure 8.60d), the light source is on one side of the process sample, and the detector is on the other. Therefore, what is detected in this case is the total attenuation. When this attenuation is the result of absorption by color, the unit is called a *colorimeter* (Figure 8.60a); when the attenuation is caused by light being scattered by solid particles, the unit is called a *turbidity meter.*

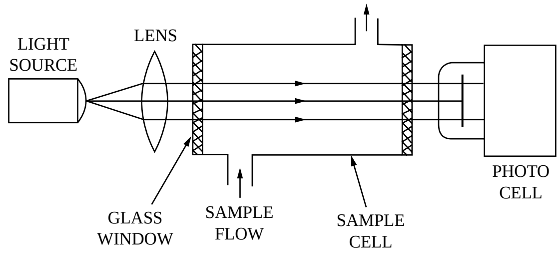

FIG. 8.60d
Schematic of transmission-type turbidity meter.

Dual-Beam Design When both color and solids are present, the total attenuation is the sum of the effects of absorption and scattering. Consequently, the single-beam turbidity analyzer can be used only if there is no color or if the color is constant and its effect can be zeroed out. When the background absorbance or color varies, a dual-beam or split-beam analyzer is needed.

Such a unit is described in Figure 8.60e. It uses two light paths, with one passing through the unfiltered process sample cell and the other through a reference sample cell containing the filtered process fluid. The output of the analyzer is proportional to the difference of optical absorbance between the two cells, which corresponds to the solid particles that are present in the sample but absent in the reference cell.

The particular design illustrated in Figure 8.60e has an oscillating mirror, which alternately directs the light beam (alternating 600 times per second) to the measuring and reference cells. The photocell detector converts the intensity

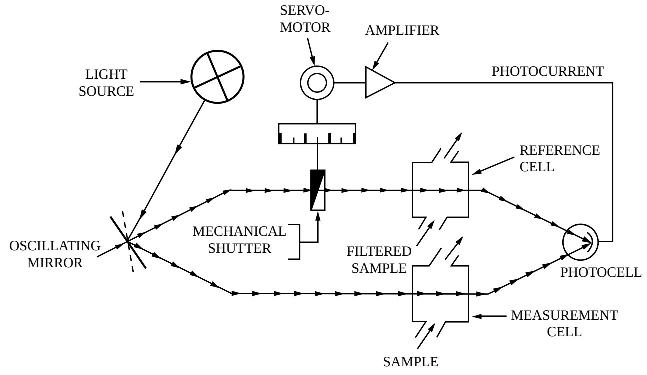

FIG. 8.60e
Oscillating dual-beam, forward-scattering turbidity analyzer. (Courtesy of Sigrist Process Photometer.)

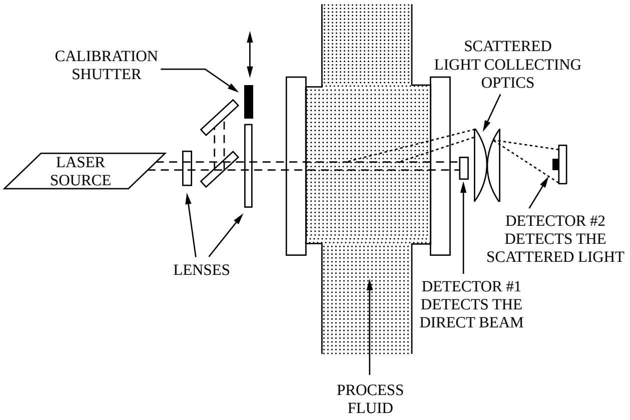

FIG. 8.60f
Laser-type in-line turbidity meter detects separately the total attenuation and the amount of scattering.

differential of the two beams into a photocurrent, which modulates the opening of a mechanical shutter so that the differential between them will be zero. Therefore, the more solid particles present in the sample, the farther the shutter needs to be closed; therefore, the position of the shutter can be read as turbidity.

If, instead of using the filtered sample, the reference cell is filled with other reference materials, this same instrument can be used to measure properties such as color, fluorescence, and so on.

Laser-Type Meter In the in-line laser-type turbidity meter (Figure 8.60f), a thin ribbon of light is transmitted across the process stream and, after it is attenuated by the process fluid, it falls on detector no. 1. If solids are present in the process fluid, some of the light will be scattered. This scattered light is collected and falls on detector no. 2. The ratio of the two signals from the detectors is an indication of the amount of solids in the process stream (turbidity). Because it is a ratio signal, it is unaffected by light source aging, line voltage variations, or background by light intensity variations.

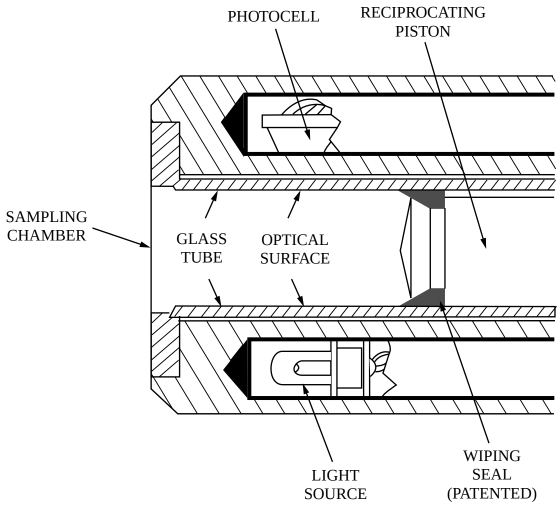

FIG. 8.60g
Probe-type suspended solids detector used on biological sludge applications. (Courtesy of Monitek Inc.)

The laser-type detector is less sensitive to interference by gas bubbles than are other turbidity meters, because the laser-based light ribbon is very thin (about 2 mm). Therefore, when a bubble passes through this ribbon, it causes a pulse that can be filtered out.

In general, in-line turbidity meters are less subject to bubble interference than are the turbidity analyzers, which require sampling. This is because the in-line units do not lower the operating pressure of the stream, so dissolved gases are not encouraged to come out of solution.

Suspended Solids and Sludge Density Sensors Figure 8.60g illustrates a probe-type suspended solids detector, widely used in biological sludge applications. The probe contains a reciprocating piston that, during its forward stroke, expels a sample (every 15 to 40 sec) while wiping clean the optical glass of its internal measurement chamber. After that, it pulls in a fresh sample during its return stroke. This device measures the total attenuation of the light, which, in the case of biological sludge applications, is mostly due to suspended solids. Because of its self-cleaning nature, the need for cleaning and maintenance is minimized.

This unit is available with a 4 to 20 mA transmitter output, which is updated every 15 to 40 sec and has a full-scale inaccuracy of 5% over the suspended solids ranges between 0–0.1% and 0–10%.

Scattered Light Detectors (Nephelometers)

Turbidity instruments utilize a light beam projected into the sample fluid to effect a measurement. The light beam is scattered by solids in suspension, and the degree of light attenuation and the amount of scattered light produced can both be related to turbidity. The light scattering is called the *Tyndall effect*, and the scattered light itself is called the *Tyndall light.*

A constant-candle-power lamp provides a light beam for measurement and, if one or more photosensors are appropriately placed, they can convert the measured light intensity into an electrical signal for readout. Usually, the photosensor is provided with a thermostat-controlled heater that maintains a constant temperature, because this measurement is temperature sensitive.

The supply voltage of the lamp must be kept constant within at least 0.5% to eliminate errors resulting from source intensity variations, because the measured light is referenced to the source. Deposits formed on the flow chamber windows interfere with accurate measurement and, thus, the windows require frequent cleaning or automatic compensation.

Instruments for measuring scattered light vary in design. One type uses a flow chamber similar to the one in Figure 8.60d, except that the window for the measured light is located at 90° to the window for the incident light (Figure 8.60h). One window transmits light beams into the measuring chamber, and the other, at right angles to the first, transmits scattered light to the photomultiplier sensor.

A light trap is located opposite the incident light window to eliminate reflection. With this arrangement, dissolved colors do not affect the measurement; however, instrument sensitivity is decreased if color is present, because some light is absorbed by it. Variations of the basic unit include designs provided with two source beams and with two photosensors in conjunction with two pairs of opposed windows as shown in Figure 8.60i.

Some designs utilize a separate photosensor to monitor the lamp output and to adjust the lamp supply voltage through a feedback circuit, which maintains the light intensity at a constant value.

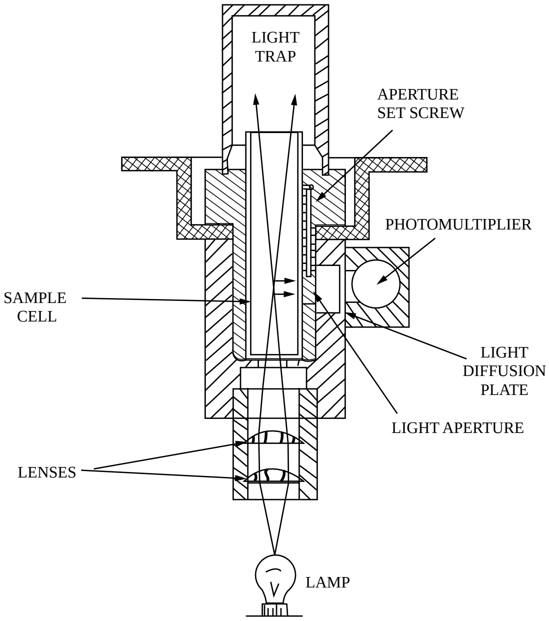

FIG. 8.60h
Light-scattering turbidity meter.

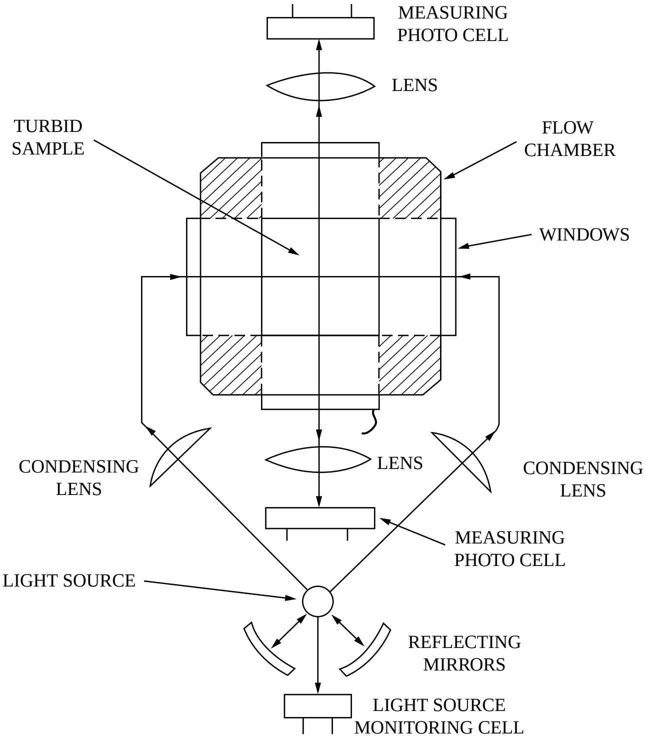

FIG. 8.60i
Turbidity meter with two light beams, two windows, and two measuring photocells.

Probe Design For wastewater and biological sludge applications, probe-type turbidity transmitters are preferred. One design (Figure 8.60j) uses an infrared light source and measures the intensity of the 90° scattered light that results.

These units are microprocessor based and are provided with built-in compensation for ambient light variations. They are also provided with wipers for automatic cleaning of the dip or insertion probe. The cleaning frequency is adjustable between 1 and 6 hr and, while the probe is being cleaned by a wiper, the output signal of the transmitter is held constant at its last value.

Backscatter Turbidity Sensors

The turbidity meters that do not have optical windows are not plagued by the problem of coating and deposit buildup on these windows. Figures 8.60k and 8.60l show two such windowless designs.

The unit shown in Figure 8.60k measures the surface scatter of a light beam. Particles on the surface of the fluid scatter the light in the direction of the photocell sensor. The design in Figure 8.60l projects the light beam into the sample so that, in this design, all particles in the path of the light beam contribute to the measurement.

The principal disadvantage of these designs is that they must operate at atmospheric pressure and at low sample flow rates.

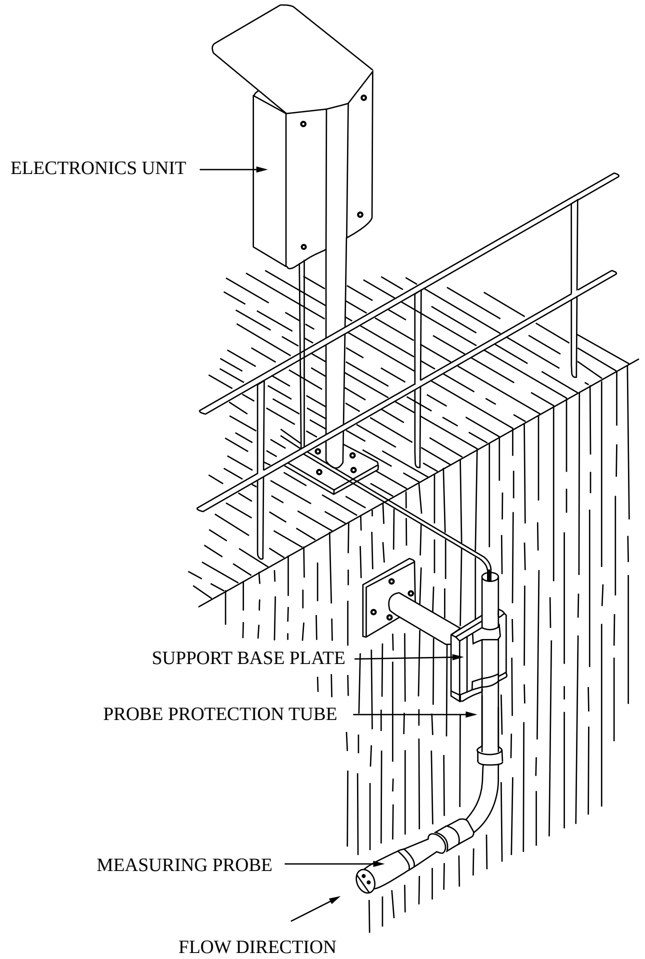

FIG. 8.60j
Automatically cleaned 90° scatterer light-detecting turbidity transmitter. (Courtesy of BTG, a Titan Co.)

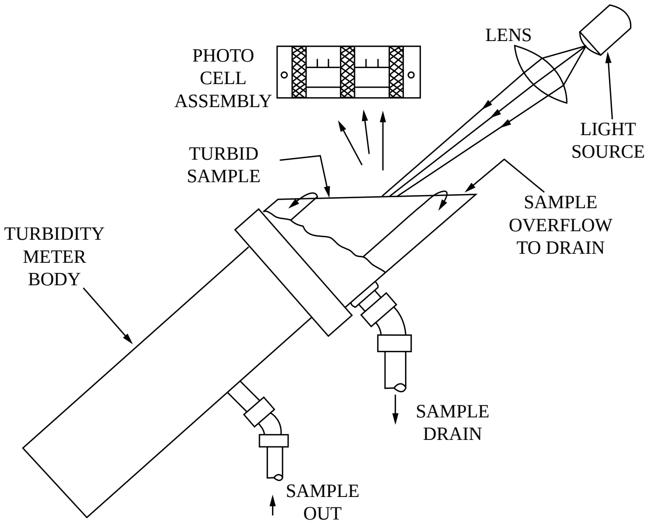

FIG. 8.60k
Surface scatter turbidity meter.

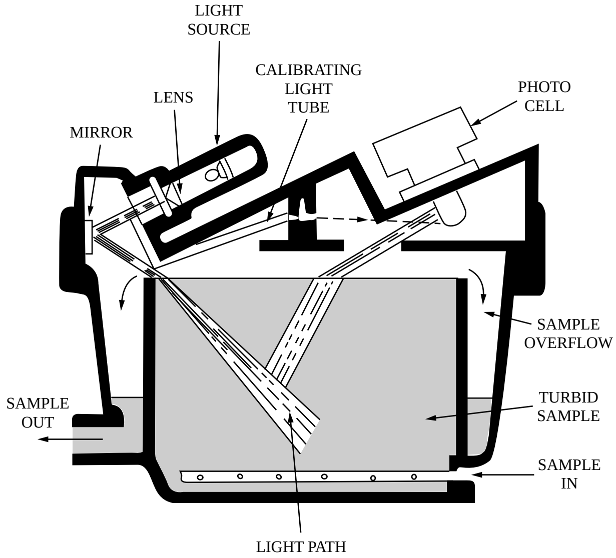

FIG. 8.60l
Atmospheric backscatter-type turbidity meter.

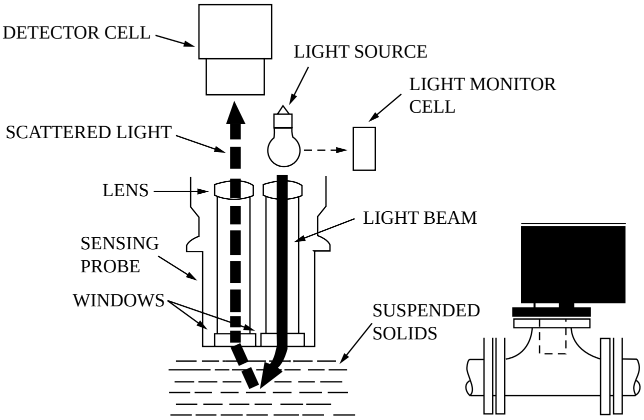

FIG. 8.60m
In-line backscatter-type turbidity analyzer.

In-Line Units Figure 8.60m illustrates the in-line version of the backscatter-type turbidity analyzer, which can be installed in either pipes or vessels. In this design, a 180° backscatter effect is measured. The units are suited for higher temperature applications (up to 450°F, or 232°C) and for high concentrations of solids. Ranges from 10 to 5000 ppm up to 5 to 15% on the silica scale are available.

A backscattering design using fiber-optic light cables is also available (Figure 8.60b).

Density-Based Sensors

If the concentration of suspended solids can be correlated to density, a variety of densitometers can be considered for coating- or sludge-type applications. The common advantage of these designs is that they do not depend on optical sensors and therefore do not require windows, which require cleaning.

A variety of such densitometers are described in some detail in Chapter 6, so only a few references will be made here. The designs that are best suited for sludge-type applications are the ones that consist of only open pipes without any restrictions. Of these, Figure 8.5a illustrates the Coriolis type, Figure 8.6g the radiation type, Figures 6.7b, 8.7c, and 6.7d the sonic and ultrasonic sludge densitometers, Figure 6.8h the vibrating twin-tube design, and Figure 6.9c the weighed U-tube densitometer.

CONCLUSIONS

Turbidity measurement is fairly simple in theory. The practical problems with these instruments include the problems posed by light source intensity changes, deposits on optical windows, and the presence of dissolved colors in the sample. Units are now available that automatically correct not only for these effects but also for the variations in the ambient light intensity and even for gas bubbles. Self-cleaning probe designs are also available.

The turbidity detector should be selected on the basis of the type of information needed (transmission, 90 or 180° scatter), the nature and concentration of the solids that are to be detected, and the materials of construction required for the application.

Configurations:	A. Photometers are nondispersive analyzers in which the source radiates over its full ultraviolet (UV) spectrum, and discrete wavelengths are separated by narrow (2 to 10 nm) bandpass filters. Most process analyzers are nondispersive. B. Spectrophotometers are dispersive analyzers in which a prism is used to separate the spectral components of the UV spectrum. Most laboratory analyzers are dispersive.
Types of Designs:	Optics can be configured as single-beam, split-beam, dual-beam, or flicker photometers. The process stream can pass through a measurement chamber, or probe-type analyzers can be inserted into the process stream using a retroreflector configuration. Most detectors are capable of measuring the intensity of one wavelength at a time, whereas photodiode arrays can detect all wavelengths simultaneously.
Type of Sample:	Gas, vapor, and liquid
Design Pressure:	Normally atmospheric but it can also be pressurized up to 150 PSIG (10.7 barg) to enhance sensitivity when analyzing gas samples. The fiber-optic, diode-array type of in-line analyzer can operate at up to 730 PSIG (50 barg).
Sample Temperature:	Standard units operate from 32 to 302°F (0 to 150°C); stack gas analyzer can operate at up to 800°F (427°C).
Materials of Construction:	Quartz and sapphire windows; other parts available in stainless steel, Hastelloy®, Monel®, titanium, Teflon®, Kynar®, and all other conventional materials
Wavelength Ranges:	Standard ranges include 200 to 800 nm or 400 to 1100 nm.
Cell Lengths:	Standard units are from 0.039 to 39.4 in. (1 to 1000 mm); for fiber-optic diode-array analyzer, 0.3 to 10 mm.
Repeatability:	±1% of full scale
Inaccuracy:	±2% of full scale for most; ±1% of full scale for the fiber-optic diode-array type of UV-visible analyzer
Cost:	Portable battery-operated or benchtop laboratory UV-visible (200 to 1000 nm) photometers, spectrophotometers, and scanning spectrophotometer range from $2000 to $5000. Portable UV stack gas monitors range from $5000 to $7000, and the cost of permanently installed stack monitoring packages is from $25,000 to $35,000 depending on materials of construction, accessories, and number of components analyzed. Industrial UV photometers without sampling systems cost in the range of $20,000 to $25,000; photodiode array spectrophotometers cost from $50,000 to $70,000; fiber-optic spectrophotometers cost from $40,000 to $60,000.

INTRODUCTION

This section is devoted to the description of ultraviolet/visible (UV/VIS) analyzers. UV/VIS analyzers are also discussed in Section 8.23 (Fiber-Optic Probes), Section 8.26 (Hydrogen Sulfide), Section 8.37 (Nitrogen Oxide Analyzers), Section 8.44 (Ozone in Gas), Section 8.56 (Sulfur Oxide Analyzers), and several other sections.

Another related topic is open path IR and UV spectrometry, which is covered in Section 8.40. Infrared and near-infrared analyzers are discussed in Section 8.27, and visible analyzers are also described under the subject of colorimeters in Section 8.15.

UV Absorption

Fewer compounds absorb in the UV region than in the IR region, and the UV absorption pattern of a compound is not as distinctive (not as narrow) as is its IR “fingerprint.” On the other hand, UV analyzers provide better selectivity in applications in which the sample contains air and humidity, because these materials do not absorb in the UV region.

UV analyzers are also more sensitive than IR detectors. Figure 8.61a shows the absorbance of sulfur and nitrogen dioxides in the UV region. On an equal path-length basis, the UV absorbance of liquids is stronger than that of vapors in proportion to their densities.

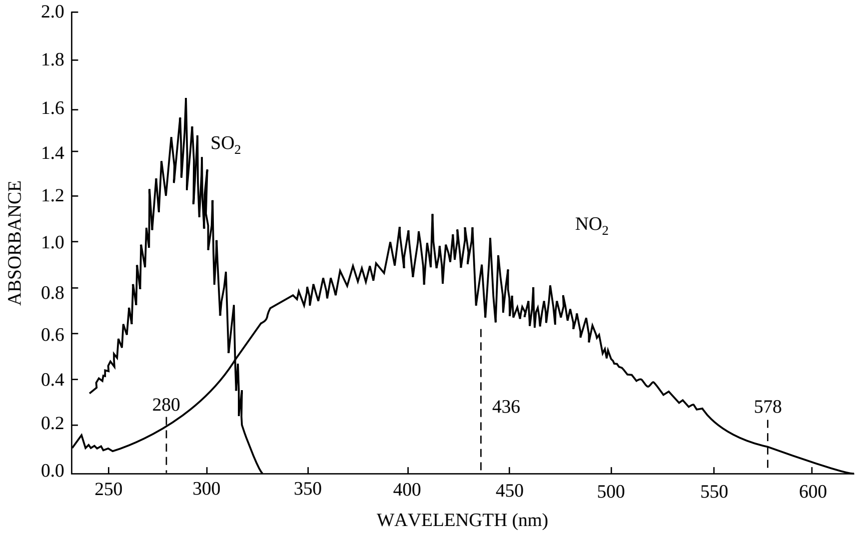

FIG. 8.61a
The absorbance characteristics of both SO_2 and NO_2 in the ultraviolet range.

This section starts with some theoretical discussions of the principles of UV radiation. This is followed by an explanation of different analyzer configurations and their main components.

THEORETICAL ASPECTS

Ultraviolet, visible, and near-infrared photometers and spectrophotometers are widely used in the process industries. On-line UV analyzers have been used since the 1940s.

The Radiation Spectrum

The ultraviolet (UV), visible (VIS), and infrared (IR) regions of the electromagnetic radiation spectrum are shown in Figure 8.61b. The UV region covers the wavelengths from 200 to 400 nm. The visible region extends from 400 to 800 nm, and the near IR (NIR) region covers from 0.8 to 2.50 μm.

Nanometer units are commonly used in the UV/VIS region, and micrometers (or microns) are normally used in the NIR region (Table 8.61c). The UV-VIS-NIR is a relatively small part of the electromagnetic radiation spectrum, and the shorter the wavelength (the higher the frequency) the more penetrating the radiation becomes.

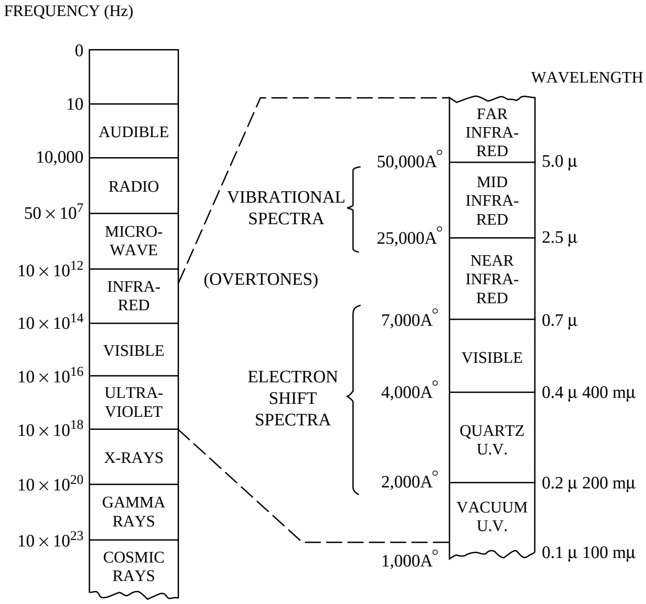

FIG. 8.61b
Electromagnetic radiation spectrum from the audible frequency up to that of the cosmic rays.

TABLE 8.61c
Relationship of Wavelength Terms

Angstrom = Å = 10^{-10} meters
Micrometer = μm = 10,000 Å = 10^{-6} meters
Nanometer = nm = 10 Å = 10^{-9} meters
Meter = 10^3 nm = 10^6 μm = 10^9 nm = 10^{10} Å

Compounds absorb at various frequencies of radiation depending on the energy of their molecular transitions. High-energy electronic transitions are observed in the shorter-wavelength UV-VIS regions. Moderate-energy (vibrational and rotational) transitions are observed in the longer-wavelength IR region.

The Beer–Lambert Law

Absorption spectroscopy is the measurement of radiation intensity at spectral wavelengths that are characteristic of the compound being monitored. When radiation enters a process sample, only part of the light is transmitted through (Figure 8.61d) it. The remainder of the radiation is absorbed or reflected, depending on the concentration of the sample and on the wavelength being measured. If particles are present in the sample, part of the radiation will be scattered.

The Beer–Lambert law is the fundamental law that governs quantitative analysis by absorption spectroscopy. This law states

$$\mathrm{A} = \mathrm{abc} \tag{8.61(1)}$$

where
A = absorbance
a = molar absorptivity
b = sample path length
c = concentration of absorbing species

The molar absorptivity (a) is a constant that is characteristic of the chemical species being measured, and the path length of the sample cell is fixed. Therefore, the only variable that causes the absorbance (A) to vary is the concentration of the component being measured.

The absorbance of a sample is measured indirectly by measuring the transmitted radiation. The relationship between absorbance and transmittance is

$$A = \log(1/T) \tag{8.61(2)}$$

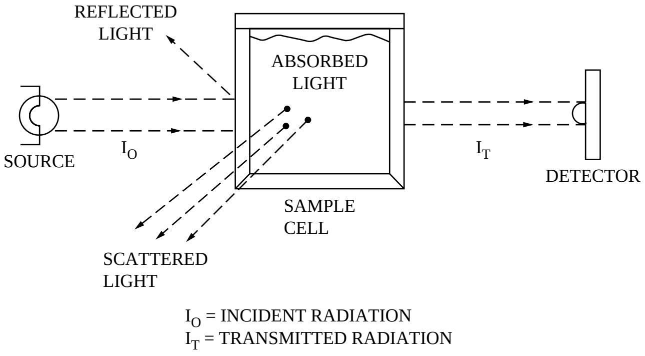

FIG. 8.61d
Absorption of light.

where

T = transmittance

Calibration Calibration methods for photometers involve the measurement of absorbance for several concentrations of the component being measured. When a plot of absorbances vs. concentration gives a linear response, the method obeys the Beer–Lambert law. When the photometer exhibits a nonlinear response, a linearizer circuit is used to compensate for the nonlinearity.

UV-Absorbing Compounds

The UV spectra of some typical absorbers are shown in Figure 8.61e. The characteristics of these spectra are notably different from the spectra of absorbers in the IR region (Figure 8.27b). For this reason, the UV analyzer can be expected to be less specific than an IR instrument.

If other UV-absorbing compounds are also present in the sample, more interference can be expected because of the broad characteristics of its spectra. On the other hand, UV analyzers are generally capable of greater sensitivity than their IR counterparts, so trace analyses are common for UV. This is due in part to the broad energy absorption and greater absorptivity of some compounds and to the availability of stronger sources that permit the use of longer cells.

UV Absorption Spectrum An absorption spectrum of a compound is obtained by plotting the intensity of transmitted light or absorbance as a function of wavelength. Ultraviolet spectra for three typical UV absorbers are presented in Figure 8.61e.

The benzene spectrum was obtained from a vapor phase sample. The acetone and phenol spectra were run on liquid samples dissolved in water. An important observation in these spectra is the high degree of overlap for the absorption bands in the 240 to 280 nm region. Care therefore must be exercised in UV applications to ensure that other compounds present in the process stream do not interfere with the measurement of the component of interest.

A useful feature of the UV region is that water does not absorb UV radiation. This allows for the measurement of trace levels of UV absorbers in aqueous samples. Generally, UV photometers have very good sensitivity.

The ultraviolet is a high-energy region of the electromagnetic spectrum where electronic transitions are observed. Absorption of radiation occurs in the UV region (200 to 400 nm) when an electron is excited from a ground energy state to an excited energy state. UV photometers are used principally to measure aromatic compounds, unsaturated compounds, and other compounds that contain pi electrons or unshared electron pairs. Another group of compounds that absorb in the UV are chromophores such as carbonyls, nitrates, and sulfoxides. A partial list of UV-absorbing compounds is given in Table 8.61f.

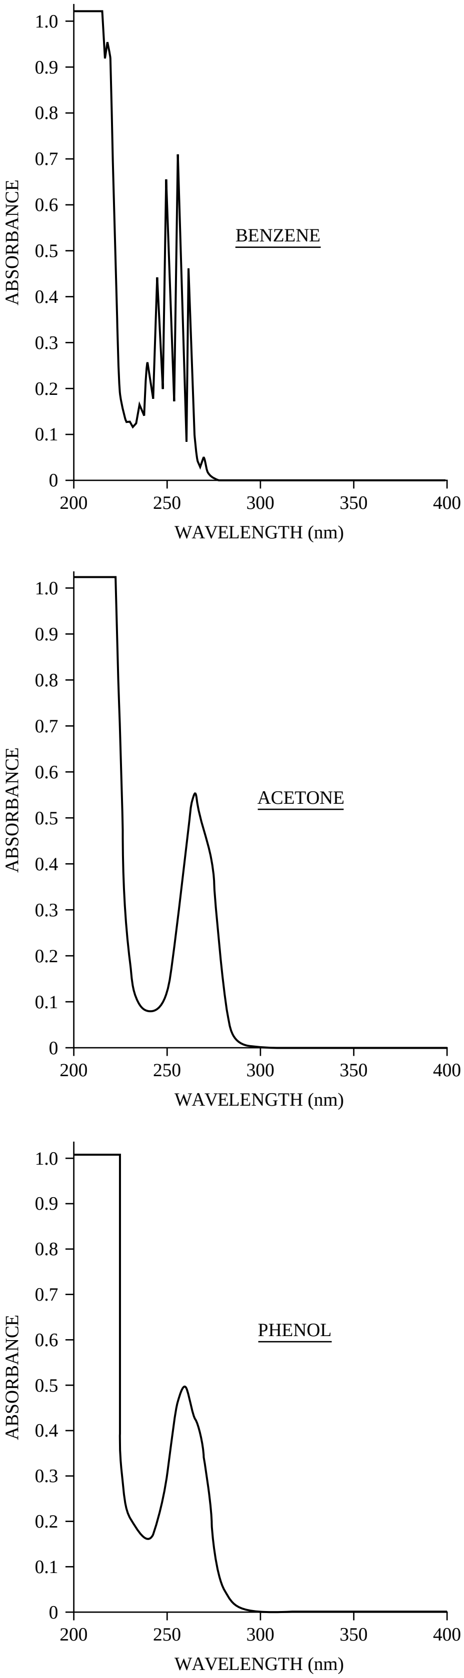

FIG. 8.61e
Ultraviolet spectra of benzene, acetone, and phenol.

TABLE 8.61f
Partial List of UV-Absorbing Compounds

Acetic acid	1,3-Cyclopentadiene	Nitrogen dioxide
Acetone	Dimethylformamide	Ozone
Aldehydes	Elemental halogens	Perchloroethane
Ammonia	Ethylbenzene	Phenol
Aromatic	Ferric chloride	Phosgene
compounds	Fluorine	Potassium permanganate
Benzene	Formaldehyde	Proteins
Bromine	Formic acid	Salts of transition metals
Butadiene (1,3)	Furfural	Sodium hypochlorite
Caffeine	Hydrogen peroxide	Styrene
Carbon disulfide	Hydrogen sulfide	Sulfur
Carbon tetrachloride	Iodine	Sulfur dioxide
Chlorine	Isoprene	Sulfuric acid
Chlorine dioxide	Ketones	Toluene
Chlorobenzene	Mercury	Trichlorobenzene
Crotonaldehyde	Naphthalene	Uranium hexafluoride
Cumene	Nitric acid	Xylene (*ortho*, *meta*, and *para*)
Cylohexanol	Nitrobenzene	

Applications UV photometers are normally used for the measurement of a key single component in a process stream. The following applications are examples of typical UV photometer measurements:

1. Residual chlorine in water in pulp and paper process
2. Total aromatics in wastewater
3. Chlorine in dichloroethane in vinyl chloride processes
4. Hydrogen sulfide and sulfur dioxide in the Claus sulfur recovery process in the petroleum refining industry
5. Sulfur dioxide in incinerator stack emissions

UV ANALYZER COMPONENTS

Photometers and spectrophotometers can be used for on-line monitoring of process streams. A diagram of the five main components that make up a spectrophotometer is shown in Figure 8.61g.[1] These components are enumerated below.

1. Source (provides radiation for the spectral region being measured)
2. Monochromator (a device used to select narrow bands of wavelengths)
3. Sample cell (contains the sample and provides an appropriate path length)
4. Detector (a device that measures transmitted energy and converts it into an electrical signal)
5. Readout device (provides a means of displaying or recording the measurement results)

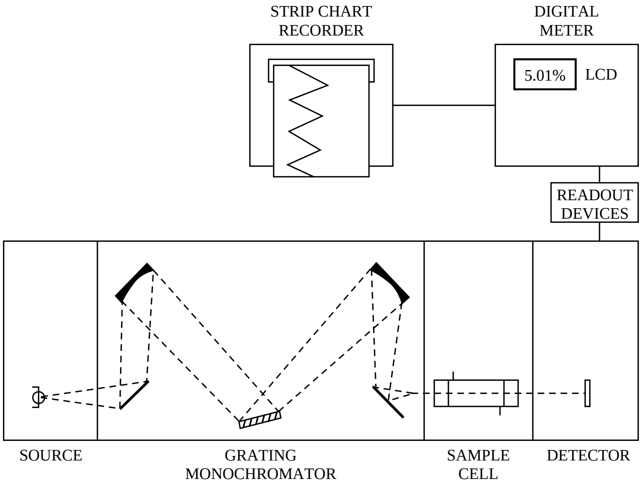

FIG. 8.61g

	Ultraviolet	*Visible*	*Near Infrared*
Sources	Cadmium vapor Mercury vapor Zinc vapor Deuterium arc Tungsten-iodine	Tungsten filament Quartz-halide	Tungsten filament Quartz-halide
Detectors	Photomultiplier tube Silicon photodiode Diode array	Photomultiplier tube Silicon photodiode Diode array	Lead sulfide Germanium photodiode Diode array Pyroelectric

Radiation Sources

The purpose of the radiation source is to provide sufficient energy of radiation to make the desired measurement in the region of spectral interest. Table 8.61h lists some of the sources commonly used in process photometers. The two sources used in the visible and NIR regions are tungsten filaments and quartz-halide lamps.

The cadmium, mercury, and zinc vapor sources that are used in the UV region are *emission line* sources. The output of these sources provides radiation as narrow discrete emission lines at a high-energy level. Mercury vapor lamps are often used because of their long service life. Deuterium arc sources provide a broad range of UV radiation at all of the wavelengths in the UV region. The energy of the deuterium source is relatively lower than the energy of the mercury source.

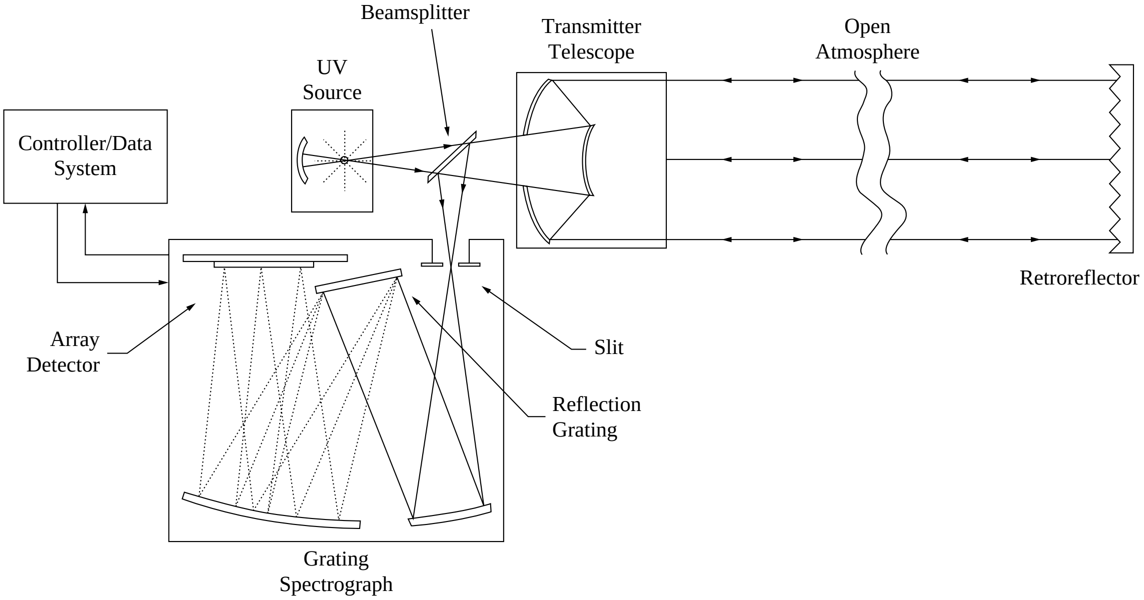

FIG. 8.61i
How the UV source is used in an open-path spectrometer.

Broad and Discrete Line Sources Two types of UV energy sources are used: broad and discrete line emission sources. In open path UV spectrometers (Section 8.40), the most commonly used sources are high-pressure xenon arc lamps, which emit a continuum from the UV to the visible spectra. (Figure 8.61i).

The broad emission sources provide energy in a broad wavelength band, and narrowband filters can be used to isolate the wavelengths of interest. These sources provide all wavelengths in the region, but some have a low-emission or low-energy level at a particular wavelength. Such low-energy sources include hydrogen or deuterium discharge lamps, tungsten lamps, and tungsten-iodine lamps.

Discrete line sources use gas discharge lamps with narrow lines of emission. These sources emit radiation energy at various discrete wavelengths at a high-energy level. The undesired are filtered, leaving only the wavelength of interest. However, the gas discharge lamps are limited to the spectral emissions of mercury, cadmium, zinc, and thallium. Therefore, not all wavelengths are available.

Selecting the Measuring Wavelength Selection of measuring and reference wavelengths is generally a compromise between the maximum absorbance wavelength of the component of interest and the wavelengths available from the gas discharge lamps. This usually leads to the selection of a wavelength on the side of the absorption peak.

Of the radiation sources used in the UV region, the tungsten-filament-type incandescent lamps are the least expensive. These continuous spectrum sources can be used in UV photometers, but they have sufficient energy only at wavelengths exceeding 350 nm. Tungsten-iodine cycle lamps can be used down to 300 nm. Mercury vapor lamps are the most useful UV sources because of their high intensity and long life (up to five years).

Medium-pressure mercury lamps can operate down to 300 nm, and low-pressure ones down to 254 nm. Zinc discharge lamps are useful because of their 214-nm emission line, as are chromium ones for their 228-nm emission line, but they are not as stable as mercury lamps. Hydrogen and deuterium lamps are delicate and expensive, and their lives seldom exceed three months.

The Monochromator

Both dispersive and nondispersive monochromators are used in photometric analysis. Spectrophotometers are dispersive instruments, and photometers are nondispersive devices. The function of the monochromator is to disperse light from a source and selectively send a narrow spectral band to the sample and detector.

The dispersing element is usually a diffractive grating, which is a highly polished mirror with a number of parallel lines scribed on its surface. For each position of the grating, a narrow band of dispersed radiation passes through the exit slit. Spectrophotometers are dispersive devices that are used to scan across a spectrum of wavelengths; they can be used to make measurements at several wavelengths. This capability allows for the analysis of multiple components with a spectrophotometer.

Photometers are nondispersive devices that exclude a large amount of spectral radiation. Photometers are used to make measurements at selected discrete wavelengths. Narrow bandpass interference filters are used to pass radiation at selected reference and measurement wavelengths. A typical bandwidth for UV/VIS filters is 10 nm. The typical bandwidth for NIR filters is 20 to 80 nm.

The UV spectra of benzene, acetone, and phenol were presented in Figure 8.61e. For such measurements, the reference wavelength filter is normally selected where none of the background components present in the process stream absorb radiation. The measurement wavelength filter is selected to match the absorption band of the component being analyzed. The ratio of the transmitted light at the reference and measured wavelengths is measured by the photometer. Normally, photometers are used to measure a single component in a process stream.

The Measuring Cell

The purpose of the measuring cell is to contain a representative sample from the process steam. The major components of the cell are the cell body, windows, and O-rings. The proper selection of cell materials is very important for the successful application of a process photometer. Stainless steel is the material most commonly used for cell bodies. Other metals such as Monel, Hastelloy, and titanium are also used. Plastic cell bodies made of Teflon or Kynar are used in some applications. Quartz, sapphire, and glass cell windows are used in the UV-VIS-NIR spectral regions.

The sealing of the sample in the cell is accomplished with O-ring gaskets. Viton®, ethylene-propylene, and Kalrez® O-rings are commonly used in sample cells. An important parameter for the cell is the selection of an appropriate path length. The distance between the windows determines the path length of the cell. Path lengths from 1 mm to 1 m (0.039 to 39.4 in.) are used in process photometers. The sensitivity of a photometric measurement is dependent on the path length. For a particular measurement, a long path length will provide more sensitivity than a short one.

Detectors

The detectors used in process UV analyzers include phototubes, photomultiplier tubes, and photocells. The photoelectric effect is used in the vacuum phototube to produce a current proportional to the energy striking the tube cathode. A phototube with UV response has a long life and a low temperature coefficient.

The photomultiplier tube offers very sensitive detection of UV and visible light, but large radiation energy levels will damage its light-sensitive surface. This detector has a high temperature coefficient.

The photocell (photovoltaic) is a semiconductor light detector of the barrier-layer type. It develops a current that is proportional to the light intensity, but this current output is not linear with the radiation energy level reaching the detector. This may not be detrimental when used in a null-balance detection system, and the relatively low cost of this device (because a voltage supply is not required) can make it attractive.

Table 8.61h lists the commonly used detectors in the UV-VIS-NIR regions. Photomultiplier tubes (PMT) have traditionally been used in UV/VIS instruments. In the PMT, the photoelectric effect is used to produce a current proportional to the radiation that is striking the cathode of the tube. The gain voltage of the photocathode can be adjusted to obtain the desired sensitivity from the PMT.

Photodiodes are solid state detectors that are smaller in size and lower in cost than PMT detectors. Silicon photodiodes are semiconductor detectors that are used in the UV/VIS region. Germanium photodiodes are used in the NIR region. A more recent development in photometric analyzers is the use of photodiode arrays (PDAs). The PDA detectors are used throughout UV-VIS-NIR regions. Many discrete detectors can be located in a very close space in the PDA.

This array of diode detectors allows for all of the wavelengths to be measured simultaneously. The PDA detectors can be used for multicomponent applications. Lead sulfide, germanium photodiodes, and pyroelectric detectors are used in the NIR photometers.

Readouts

Analog meters, digital meters, strip chart recorders, and video display tubes (VDTs) are examples of readout devices used in photometers and spectrophotometers. On-line photometers are usually microprocessor operated and usually have both a 4 to 20 mA analog output and a digital output, which is sent to the process control computer. Spectrophotometers can incorporate a strip chart recorder to record a spectrum of the analyzed sample. The spectrum is a plot of percentage transmission or absorbance readings as a function of wavelength.

UV ANALYZER DESIGNS

The proven industrial designs used for process UV analyzers include the following:

1. Single-beam
2. Split-beam
3. Dual-beam, single-detector
4. Dual-beam, dual-detector
5. Flicker photometer
6. Photodiode
7. Retroreflector

Single-Beam Analyzer

This simple design is limited to easy applications. The optical system (Figure 8.61j) consists of a source and two photo-tube detectors. The light source and detectors are so aligned that both detectors receive radiation from the same portion of the source. A sample cell and an interference filter are positioned

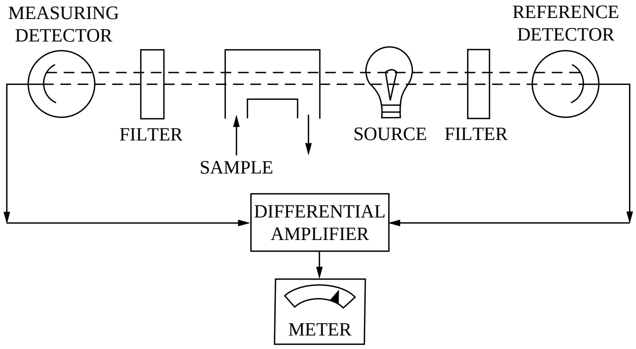

FIG. 8.61j
Opposed-beam UV analyzer.

between one detector and the source. The filter is selected to isolate the wavebands in which only the component of interest will absorb. The cell length is sized to give a sufficiently long absorbing path to provide good sensitivity (i.e., high absorbers require shorter paths). A filter usually identical to the measuring filter is positioned between the source and reference detector.

The amplifier, or control circuit, compares the outputs of the two phototubes, and the difference in their outputs is related to the UV energy absorbed by the sample. The reference detector is used to provide compensation for changes in line voltage and source decay. In the past, some process analyzers were built without this feature. They detected only the energy change at the measuring detector, but these analyzers were found to be subject to drift and unreliable.

The opposed-beam design is a simple, low-cost, moderate-accuracy instrument that is used for simple, low-sensitivity measurements. The output of this instrument is affected by dirt and bubbles in the sample and by drift in the detector circuit.

Split-Beam Analyzer

The split-beam UV analyzers use a single-beam optical system (Figure 8.61k). A single sample cell is located between the source and the detectors. A beam splitter (semitransparent mirror) is placed at the outlet of the sample to create two paths for the radiation energy. There is one beam for the measuring wavelength and one beam for the reference wavelength.

Interference filters and/or broadbrand filters are used to isolate the desired wavelengths. The reference wavelength is selected in a region where the component of interest absorbs weakly or, preferably, not at all.

One beam is directed to the measuring photomultiplier (PMT) tube through an optical filter, which passes light at the measuring wavelength. The other beam is directed to the reference PMT through an optical filter, which passes light at the reference wavelength. The phototubes convert both light signals to electric currents proportional to the light intensity in each beam. The outputs of the phototubes are compared by the amplifier, which provides an output signal that is proportional to the concentration of the measured component. This output signal is reported on the output meter of the control section of the analyzer.

The use of the split-beam design with a reference detector offers the advantage of minimizing or eliminating the effect of other weak UV absorbers in the sample. In addition, changes in source intensity, sample turbidity (dirt or bubbles in the sample), and dirt buildup on the cell windows are seen equally in both wavelengths and do not affect the measurement as long as the absolute energy intensity does not drop below the sensitivity of the detector.

The three housings of the analyzer are easily separated. For most applications, the split-beam system offers high sensitivity and accuracy, low drift, and moderate cost.

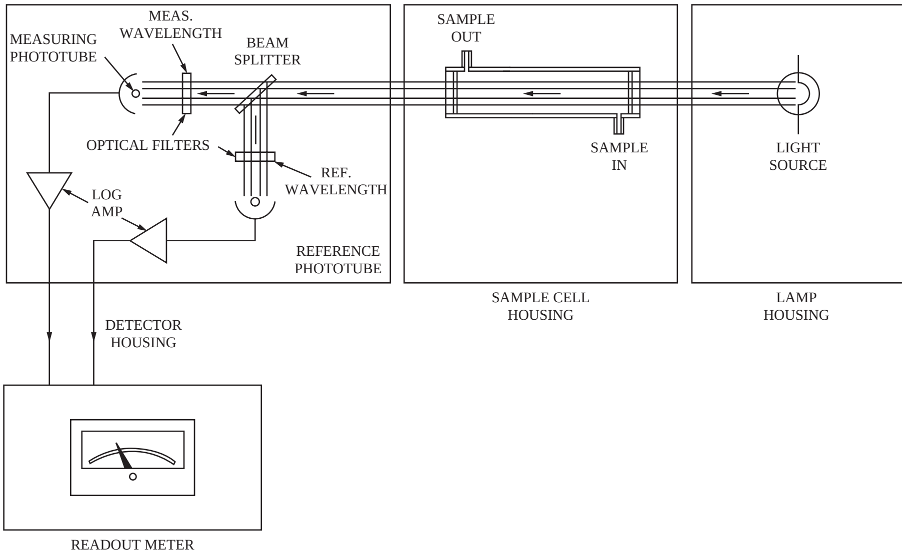

FIG. 8.61k
Split-beam photometer.

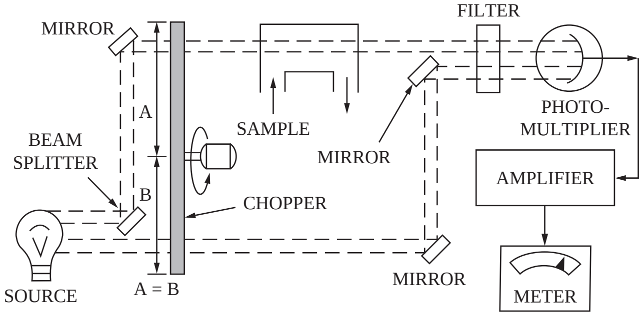

FIG. 8.61l
Dual-beam, single-detector analyzer.

Dual-Beam, Single-Detector Analyzer

The dual-beam, single-detector UV analyzer uses two optical paths, a single sample cell, and a single photomultiplier detector (Figure 8.61l). One path includes the sample cell, and the other path is used for reference, as it does not pass through the sample. The paths are recombined, and both pass through an interference filter that isolates the wavelengths selected for the measurement.

An interrupter or *chopper* is used to alternately block the measuring and reference beams. This creates pulses of energy through the sample cell that are 180° out of phase with the energy pulses through the reference beam. These pulses are received consecutively by the photomultiplier and, if the sample cell is filled with a nonabsorber, they are equal in magnitude.

When the sample contains the component of interest, the energy pulse intensity and the output of the detector for the measuring pulse are both reduced. The control amplifier receives these pulse outputs and demodulates, or converts, their ratio to a usable analog signal.

This design gives good compensation for source intensity changes and detector drift, but turbid samples and samples leaving dirt deposits will cause drift. Samples of this nature sometimes require the use of two sample cells and two separate filters—one in each path.

The filters create a measuring and a reference wavelength as in the split-beam, dual-detector system. The sample cells may or may not experience window coating at the same rate, which only partially solves the drift problem. Use of a chopper introduces a moving mechanical member that increases maintenance.

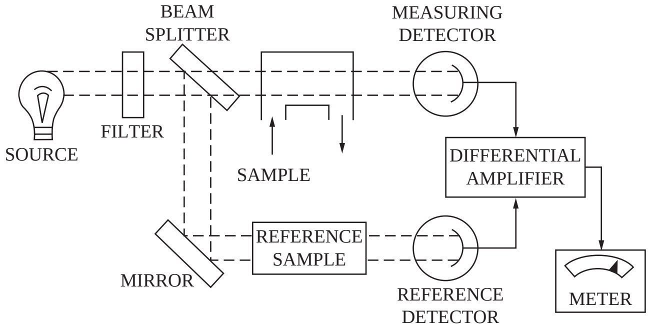

FIG. 8.61m
Dual-beam, dual-detector analyzer.

The dual-beam, single-detector system offers high sensitivity and accuracy at moderate cost, but zero drift may occur if the process sample is dirty.

Dual-Beam, Dual-Detector Analyzer

The dual-beam, dual-detector design isolates the wavelength used for the measurement before the beam splitter (Figure 8.61m) and uses separate phototubes for the measuring and reference wavelengths. This design is a combination of the optics of the dual-beam, single-detector (see Figure 8.61l) and the detector of the split-beam analyzer (see Figure 8.61k).

This design provides performance similar to that of the dual-beam, single-detector design. It provides high sensitivity and good accuracy at a moderate cost, but dirt in the samples can create drift errors.

Flicker Photometer

The flicker photometer uses a single-cell optical bench (Figure 8.61n) and a rotating disc with two interference filters. The radiation transmitted by the sample cell alternately passes through these filters, which are selected to produce the desired measuring and reference wavelengths. The detector

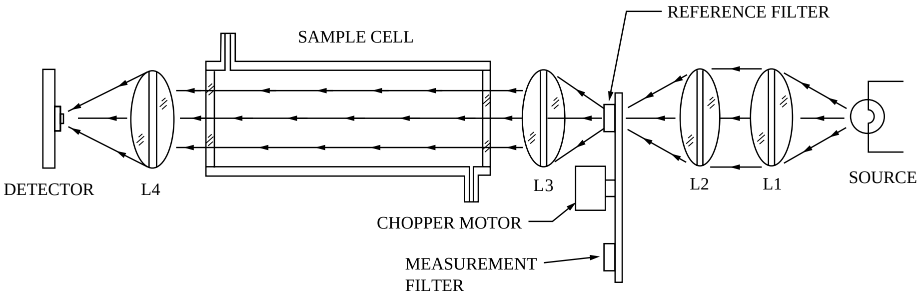

FIG. 8.61n
Rotating fixed filter photometer. (Courtesy of ABB Inc., Analytical Products.)

receives these energy pulses, and the amplifier calculates their ratio, which changes as the concentration of the component of interest varies.

A schematic of a rotating fixed filter photometer is shown in Figure 8.61n. The light from the source passes through lenses L1 and L2 and is focused through the reference, and the measurement filters on the rotating filter wheel. A chopper motor is used to rotate the filter wheel. The light is chopped into reference and measure signals. The chopped light passes through lens L3, where the light is collimated before entering the sample cell. The collimated light passes through the sample cell and onto lens L4, where the light is focused onto the detector.

The electronics of the analyzer calculate the log of the ratio of the reference and measurement signals. This calculated output is proportional to the concentration of the measured component. Rotating-filter photometers compensate for source decay, for dirt or bubbles in the sample, for detector drift, and for cell window obscuration, because these changes equally affect the reference and measurement signals.

The use of a single detector eliminates drift in analyzer response, which can result from uneven aging of multiple detectors. The use of a rotating filter introduces moving parts that require maintenance. Accuracy and stability are good, and cost is moderate.

Photodiode Array Spectrophotometers

Photodiode array (PDA) spectrophotometers monitor all wavelengths in the spectrum simultaneously. A schematic of a diode array instrument is presented in Figure 8.61o.[2]

The light from the source passes through a lens and a shutter and through the sample cell. The light passes into the detector assembly, where it is focused onto a slit and onto a holographic grating, which disperses the light that strikes the PDA detector. The diode array detector is a series of linearly spaced silicon photodiode detectors that measure absorbance at a specific spectral bandwidth.

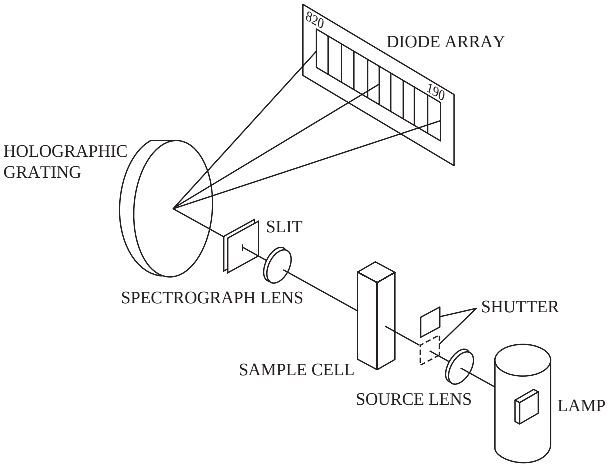

FIG. 8.61o
Photodiode array spectrophotometer.

The advantage of this design is that the spectrum is scanned without any moving parts except for the shutter. Data from the PDA detectors is acquired in parallel, which results in a fast analysis time. Most of the work with PDA detectors has been in the UV/VIS region, but the short-wavelength NIR region (800 to 1100 nm) is utilized in some PDA devices.

Analyzers are also available that couple fiber-optic cables (Section 8.23) with PDA devices (Figure 8.61p). Analysis of

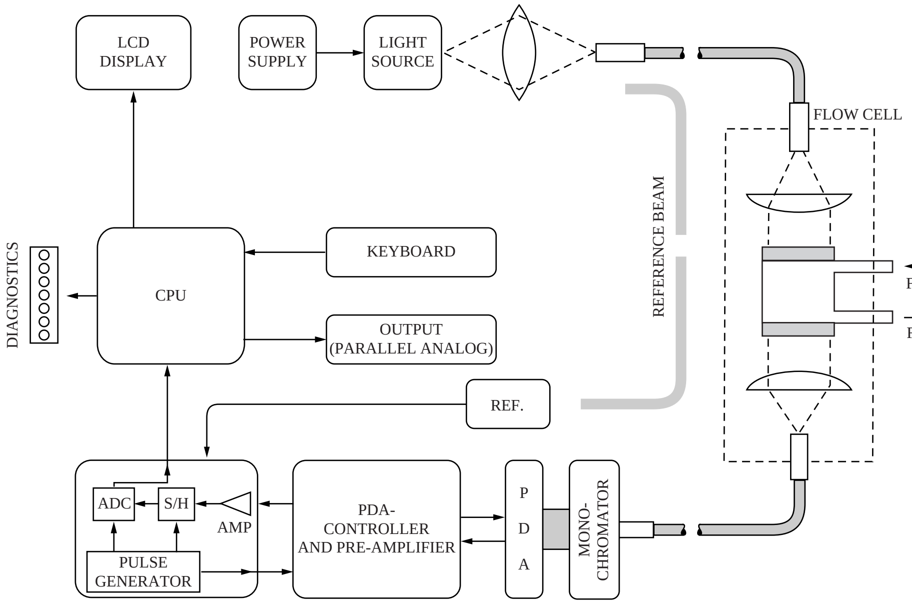

FIG. 8.61p
Photodiode array-type UV analyzer with fiber-optic cables.

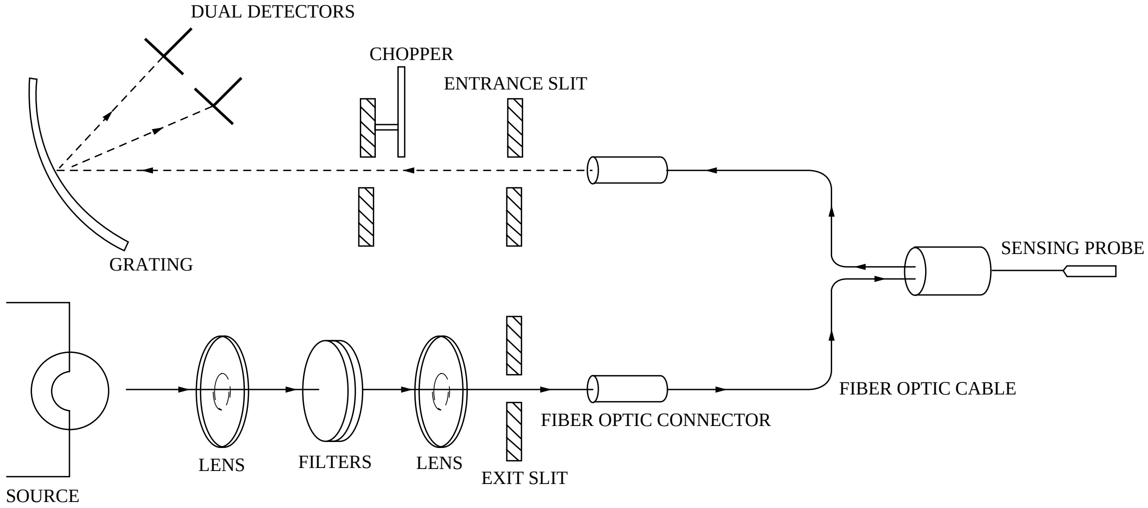

FIG. 8.61q
Scanning spectrophotometer with fiber-optic interfacing sensing probe.

hydrogen sulfide and sulfur dioxide in sulfur recovery and the determination of octane number are two examples of PDA applications.

Scanning Spectrophotometers

Scanning spectrophotometers are dispersive devices that normally utilize diffraction gratings to scan across a spectral region. Scanning devices can be used for multiple-component applications. Scanning spectrophotometers can be used in the UV, visible, and NIR regions.

The measurement of moisture, protein, and carbohydrate in wheat and soybeans by Karl Norris of the USDA was one of the prominent early applications of a NIR scanning device. An important development has been the interfacing of fiber-optic wavelengths with conventional scanning spectrophotometers (Figure 8.61q).[3]

The optical waveguide is usually a single fiber-optic cable. An advantage of using fiber optics is the elimination of the sample handling system. In the fiber-optic design, the polychromatic light from the source passes through lenses and filters and onto the fiber-optic cable. The light is transferred along the cable to the sample probe. The sample modified light is then collected by a second fiber cable and transferred to the monochromator, where it is diffracted into individual wavelengths and measured by the detectors.

The data from the analyzer are processed by a personal computer (PC). The PC allows for the use of multivariate calibration techniques such as partial least squares (PLS). The measurement of multi-component solvent mixtures and the determination of octane number for gasoline samples are two typical applications performed on fiber-optic scanning spectrometers.

Retroreflector Probes

Figure 8.61r illustrates a microprocessor-based UV analyzer probe, which can be used for monitoring both sulfur dioxide and nitrogen oxide in stack gas. In this design, the UV light from a deuterium source is projected through the gas measurement cavity inside the filter at the end of the probe. The retroreflector at the tip of the measurement cell returns the measurement beam to a point at which a monochromator separates the light into discrete spectral bands.

The monochromator has two exit slits, one for sulfur dioxide and the other for nitrogen oxide, that allow their corresponding wavelengths to impinge on the detector. By using the second derivative of the absorption spectra, the measurement is compensated for source aging, line voltage variations, broadband absorption, dirt buildup on the optics, and optical misalignment. A small shutter in the monochromator moves back and forth between the NO and the SO_2 beams, providing sequential reading of both at one minute intervals.

The analyzer is provided with self-calibration capability, including auto-zero correction, auto-span check, and correction. The ceramic filter at the probe tip is self-cleaning and self-drying; at preset intervals, a blast of hot, pressurized instrument air is forced into the measurement cavity, which forces the entrained water or tar out of the probe and dries the filter. The analyzer is suitable for stack gas applications where the particulate loading, water vapor content, and temperature are all high (up to 800°F, or 427°C).

The analyzer measures only NO, so, if evaluations of NO_2 or NO_x are needed, additional measurements must be provided. The life of the deuterium lamp can be as short as three months.

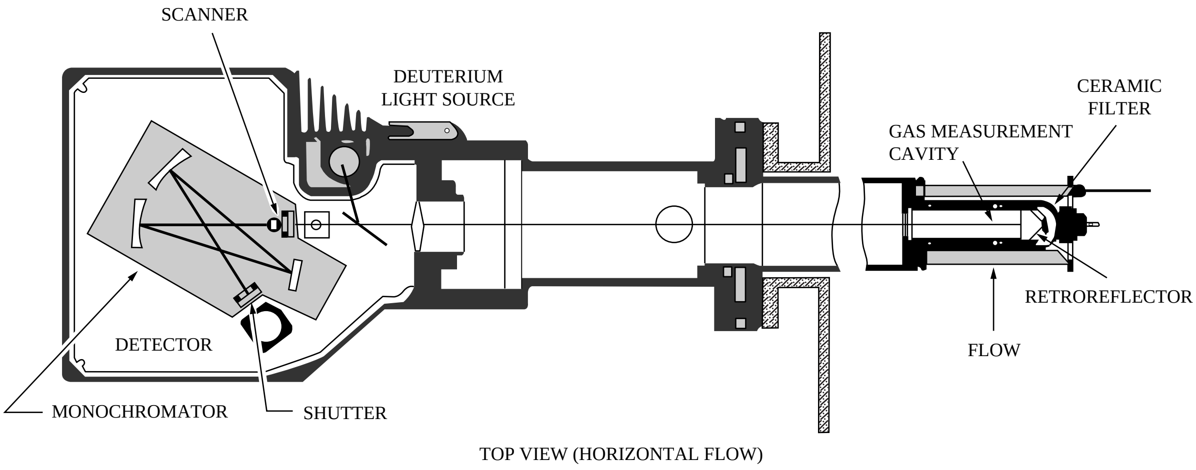

FIG. 8.61r
Self-calibrating, self-cleaning, and self-drying probe-type analyzer simultaneously detects the concentrations of SO_2 and NO at temperatures up to 800°F.

VISIBLE AND NIR PHOTOMETERS

The absorption band and hardware used in visible and NIR photometers are very similar to those used for ultraviolet photometers.

Visible Photometers

Absorption of light in the visible region is also a result of electronic transitions. The visible region of the electromagnetic spectrum (400 to 800 nm) is the region to which the human eye responds. A familiar example of visible light is the dispersion of white light through a prism, which results in a rainbow of colors.

The observation of color arises from the absorption and emission of light by a sample. The intensity of the absorption of light at a characteristic wavelength is proportional to the intensity of the color. Photometers that operate in the visible region are referred to as colorimeters (Section 8.15).

Split-beam and rotating fixed filter designs are also used in visible photometers. The major difference with UV photometers is that a tungsten filament or quartz-halide source might be used. Visible photometers are frequently calibrated to correlate with accepted laboratory color units such as Saybolt, ASTM, and American Public Health Association (APHA). For example, APHA units are used to measure the degree of yellowness of a sample. APHA standards are based on known concentrations of platinum-cobalt solutions.

The following color measurements are examples of visible photometer applications:

1. Yellow color of diesel oil—ASTM units, APHA units
2. Food color—APHA units
3. Color of purified organics—APHA units
4. Process water in paper-making

Near-Infrared Photometers

As detailed in Section 8.27, near-infrared (NIR) photometers have been used for on-line process applications since the 1950s. The absorption bands observed in the NIR are overtone and combination bands of the rotation and vibration bands that occur in the fundamental IR region. Most of the useful bands in the NIR region involve hydrogenic functional groups such as O—H, C—H, and N—H.

The intensity of the overtone and combination bands is much weaker than the fundamental bands. The low molar absorptivity of the NIR region can be used to advantage in process applications, because longer path-length sample cells can be used. The longer cells are less susceptible to plugging by particulate material, and the effects of coatings on the cell windows can also be minimized in the longer cells.

The two methods of sampling used in the NIR are transmission and diffuse reflectance. Transmission measurements are made on clear, homogeneous liquid and gaseous samples. Solid samples that are optically opaque cannot be measured in the transmission mode. Solids and slurries are usually measured by a diffuse reflectance technique in which a portion of the light is transmitted through the sample, and a portion of the light is returned to the surface. The reflected light is measured at the detector.

The measurement of water in organic liquids is a common application for NIR analyzers. Diffuse reflectance measurements of moisture in slurries and solids (Sections 8.33 and 8.34) are also important applications. The following are examples of NIR applications:

1. Water in ethylene dichloride in vinyl chloride processes
2. Water in dimethylacetamide in nylon processes

3. Alcohol in hydrocarbons in the petrochemical industry
4. Moisture in paper slurries to check dryer efficiency
5. Moisture in grain in the food industry

CONCLUSIONS

The packaging of ultraviolet and visible analyzers usually separates the amplifier/controller from the optical system. Some designs provide complete housing separation of the sample cell to isolate the electrical components from the flowing sample. The sample cell can then be temperature controlled when necessary, independent of the remaining optical system.

Vapor bubbles cannot be tolerated in the sample, because they will generate noise in the optical reading. If a gas sample pressurized cell is used, the cell pressure must be kept constant.

The UV analyzer has the unique and convenient feature that it offers a simple means of checking the calibration by use of a selected interference or broadband filter. Once the calibration (using known samples) is completed, a filter that absorbs at the wavelengths of interest can be used thereafter. The filter is selected to give equivalent absorbance of some percentage of full scale when placed in the measuring beam with a nonabsorber in the sample cell. Nitrogen or water is commonly used to purge the cell during this operation.

On-line photometers and spectrophotometers are widely used for composition measurements in the UV-VIS-NIR spectral regions. Photometers are nondispersive devices that are used to make measurements at selected discrete wavelengths. Photometers are normally used for single-component measurements in process control applications. Spectrophotometers are dispersive devices that scan across a spectrum of wavelengths.

Spectrophotometers are often used for multiple-component measurements. The UV analyzer can be used to measure certain compounds having ultraviolet absorption characteristics if other UV-absorbing compounds are not present in the sample or if their presence can be compensated for.

Samples may be gas or liquid, but the sample must be relatively free of dirt and must be in a single phase. Trace measurements are also possible. Fiber-optic diode array designs can provide multicomponent liquid composition analysis, and retroreflector probes can provide self-cleaning and self-calibrating stack gas composition measurement.

8.62 Viscometers—Application and Selection

C. H. KIM (1969, 1982) **B. G. LIPTÁK** (1995, 2003)

Definition of Viscosity:	Absolute viscosity is the ratio of applied stress to resulting shear velocity; kinematic viscosity is absolute viscosity divided by density.
Viscosity Units:	Dynamic (absolute), poise = 1.0 dyne-sec/cm^2 = 100 centipoise (cP) = 0.1 pascal-second (Pas or PI); Pas = 1.0 newton-second/m^2= 1.0 poiseuille (PI) = 1000 cP = 0.67 lbm/ft-sec Kinematic viscosity, stoke = 1.0 cm^2/sec = 100 centistokes (cSt) = 0.00107 ft^2/sec
Types of Viscous Behavior:	Newtonian or non-Newtonian; non-Newtonian fluids include pseudoplastic, dilatant, plastic solid, thixotropic, and rheopectic types.

INTRODUCTION

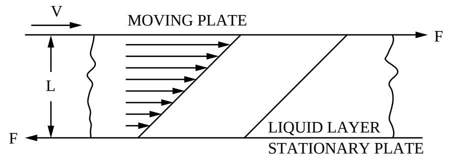
In industrial plants, viscosity measurements serve to determine the resistance of fluids to flow, define the behavior of various concentrations of slurries, or measure the molecular weight of polymers. Absolute viscosity is the ratio of applied stress to resulting shear velocity, whereas kinematic viscosity is absolute viscosity divided by density. Viscometers are available to evaluate these and other characteristics in the laboratory and on line in a producing plant environment.

Sections 8.62 through 8.64 deal with viscosity measurement. This section provides some general orientation on viscometer selection and application, Section 8.63 discusses laboratory units, and Section 8.64 covers industrial viscometers. In addition, the reader is referred to the related detectors that measure consistency (Section 8.18) and molecular weight (Section 8.35).

This section begins with the discussion of viscous behavior as it is governed by the laws of Stokes and Hagen–Posieuille. This is followed by an orientation table that provides guidelines to assist the reader in the selection and application of viscometers, in the form of a listing of the features and capabilities of both laboratory and industrial viscometers. Finally, the section is concluded with some definitions of terms and units that are used in connection with viscometry and with definitions of the different types of viscous behavior exhibited by industrial fluids.

THEORY OF VISCOUS BEHAVIOR

Viscosity is a fluid property that defines the fluid's behavior when in motion. Because a fluid is a substance that is in a state of continuous deformation when subjected to a shear stress (Figure 8.62a), the rate of that deformation is a function of the resistance offered by the fluid, termed its *viscosity.* For gases and newtonian liquids at constant pressure and temperature, this resistance to deformation is called *absolute viscosity.*



$$\frac{F}{A} = \frac{\mu V}{L} : \mu = \frac{F/A}{V/L}$$

FIG. 8.62a
Viscosity is a fluid property that describes the amount of deformation (V/L) that will result from a particular shear (F/A) that is applied to the fluid.

The viscosity of non-Newtonian fluids varies, even when the static pressure and temperature are fixed, because it also changes as a function of the applied shear stress. In some cases, viscosity may also vary with duration of the applied shear stress. The viscosity of non-Newtonian fluid therefore is frequently called *apparent viscosity.*

STOKE'S LAW

Stoke's falling ball principle, published in 1851, was based on his investigations of spheres falling through liquids.

$$\upsilon = \frac{2r^2(\rho_S - \rho_L)g}{p\mu} \qquad 8.62(1)$$

where

v = terminal velocity of fall, cm/sec
r = radius of sphere, cm
ρ_s = density of sphere, g/cm^3

ρ_L = density of liquid, g/cm^3
g = gravity, cm/sec^2
μ = coefficient of viscosity, poise

Hagan–Poiseuille Law

Capillary viscometers measure viscosity by detecting the flow or the pressure drop of newtonian process liquid through a capillary under isothermal laminar flow conditions. According to the Poiseuille law, the pressure drop of a newtonian liquid passing through a capillary tube is directly proportional to its viscosity if the fluid's temperature and flow rate are kept constant.

$$\mu = (\mathrm{K}d^4\Delta \mathrm{P})/\mathrm{VL} \qquad \textbf{8.62(2)}$$

where
μ = absolute viscosity, centipoise
K = a constant
d = inside diameter of a capillary tube, inches
ΔP = pressure drop across the capillary tube, PSI
V = flow rate, GPH
L = length of the capillary tube, inches

Kinematic Viscosity

The capillary-tube viscometer can detect the kinematic viscosity in stokes by measuring both the pressure gradient and the volumetric flow rate in a cylindrical tube of precisely known dimensions. The following equation describes the Hagen–Poiseuille law, which governs the flow of fluids through capillaries:

$$\upsilon = \frac{\mu}{\rho} = \frac{\pi g h R^4 t}{8VL} \qquad \textbf{8.62(3)}$$

where
υ = kinematic viscosity, stokes (cm^2/sec)
μ = absolute viscosity, poises (dyne-sec/cm^2)
ρ = density of liquid, g/cm^3
g = acceleration due to gravity, cm/sec^2
h = vertical distance between ends of capillary, cm
R = radius of capillary, cm
L = length of capillary, cm
V = volume of liquid flowing, cm^3, in time t, sec

Intrinsic Viscosity

To determine molecular weight of a polymer, the intrinsic viscosity or limiting viscosity must be determined (Figure 8.62b). Intrinsic viscosity [η] is defined by the relationship,

$$[\eta] = \lim_{c\to 0}\frac{\eta-\eta_0}{\eta_0 c} = \lim_{c\to 0}\frac{\eta_{sp}}{c} \qquad \textbf{8.62(4)}$$

$$\eta_{sp} = \frac{\eta-\eta_0}{\eta_0} \qquad \textbf{8.62(5)}$$

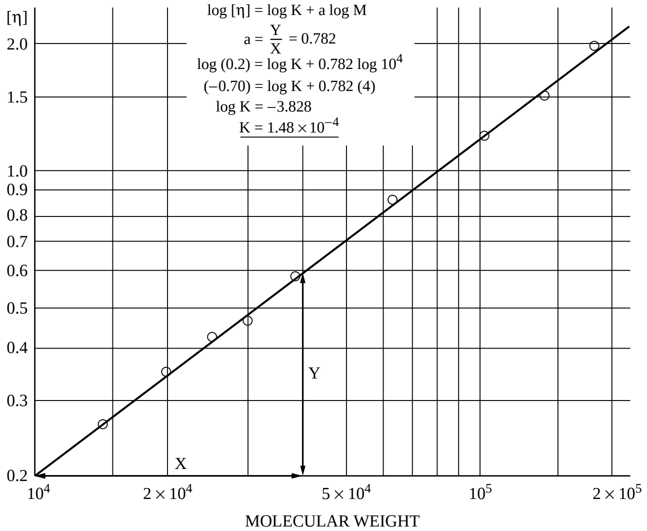


FIG. 8.62b
Viscometer calibration relates intrinsic viscosity to molecular weight.

where
η = viscosity of the solution
η_0 = viscosity of the solvent
c = solution concentration in grams per milliliter or grams per deciliter

Another definition of intrinsic viscosity is

$$[\eta] = \lim_{c\to 0}\frac{\mathrm{In}\ \eta/\eta_0}{c} \qquad \textbf{8.62(6)}$$

Intrinsic viscosity is related to molecular weight as expressed by the Mark–Houwink equation,

$$[\eta] = \mathrm{KM}^a \text{ or } \log\,[\eta] = \log\,\mathrm{K} + a\,\log \mathrm{M} \qquad \textbf{8.62(7)}$$

where K and a are constants for a given polymer-solvent system at the temperature of the viscosity measurement.

Non-Newtonian Fluids

The resistance to deformation (or viscosity) of Newtonian substances is constant as the shear rate (velocity gradient) changes, if other such variables as temperature and pressure are also constant. Their shear stress is a linear function of the shear rate they experience while undergoing continuous deformation.

Non-Newtonian fluids do not have such a linear relationship between shear stress to shear rate, even under constant pressure and temperature. The viscosity of non-Newtonian fluids varies as a function of shear rate and, in some cases, it also varies as a function of time. Therefore, one cannot speak of the viscosity of a non-Newtonian fluid without specifying the shear stress or the velocity gradient (shear rate) at

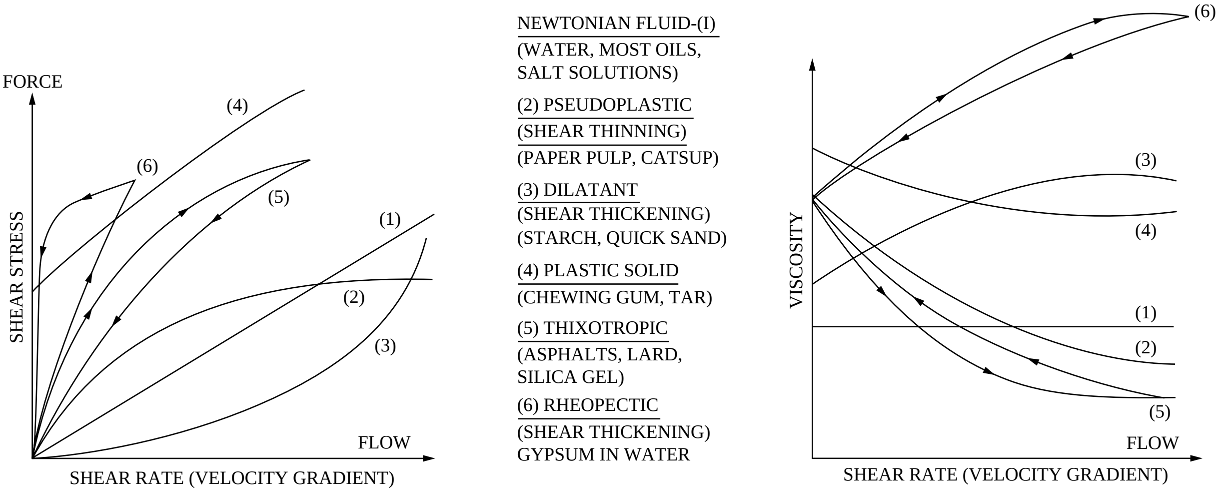

FIG. 8.62c
The viscosity and shear stress of Newtonian and non-Newtonian fluids when these fluids are deformed at various shear rates (velocity gradients).

which the resistance to deformation is of interest. Consequently, the viscometers used to measure non-Newtonian substances must be provided with accurate means of detecting the velocity gradient.

Newtonian Fluids Figure 8.62c illustrates the behavior of newtonian and non-Newtonian fluids. When a fluid is newtonian (curve 1 in Figure 8.62c), its viscosity is unaffected by share rate (flow velocity), and the relationship between force (stress) and resulting flow (velocity) is linear. Some of the newtonian fluids include gasoline, kerosene, mineral oils, water, and salt solutions in water.

Pseudoplastics Pseudoplastics (curve 2) are shear-thinning materials whose apparent viscosity drops as flow (shear rate) rises. Some such substances exhibit a yield stress above which the apparent viscosity drops, so that a unit increase of driving force results in more and more flow. Pseudoplastic materials include catsup, paper pulp, and printer's ink.

Dilatant Fluids Dilatant (curve 3) materials are shear-thickening substances. Their apparent viscosity increases as the flow (shear rate) rises, and more and more stress (force) is required to obtain the same increase in flow. Dilatant materials include quicksand, starch, peanut butter, and many candy compounds.

Plastic Solids Plastic solids (curve 4) are true plastics in the sense that they normally behave like solids, but, when the shear stress (force) reaches their yield point, they start to behave as viscous fluids and start to "cold flow." Most plastics, chewing gum, tar, and some oils exhibit this behavior.

Thixotropic Materials Thixotropic materials (curve 5) are usually pseudoplastics (shear-thinning substances), but they exhibit hysteresis. They seem to "remember" their past history and, for example, when reagitated will require less horsepower than was required during the first agitation. Thixotropic substances include asphalt, lard, silica gel, most paints, glues, and fruit juice concentrates.

Rheopectic Substances Rheopectic substances (curve 6) also display hysteresis, but, instead of a shear-thinning behavior, they display shear thickening. Their viscosity appears to increase, and some will "set" after some duration of agitation. Gypsum in water, for example, behaves in this manner.

Apparent Viscosity Readings It is important to understand that the apparent viscosity of many different substances depends on the design of the viscometer that is measuring it. Each viscometer exposes the process sample to a different experience in terms of shear stress and shear velocity, so non-Newtonian substances will register different apparent viscosity readings.

In process control, this is not a serious problem, because one is likely to use the same viscometer all the time, and we are not interested so much in the absolute viscosity of the product as in making the same product one day to the next. On the other hand, when viscosity specifications are passed on from one plant to another, it is essential that the viscometer used in making the measurement be specified.

Conversion among Units of Viscosity

Newton's hypothesis defines absolute viscosity of fluid as

$$\text{absolute viscosity} = \frac{\text{shear stress}}{\text{shear rate}} = \frac{\text{shear stress}}{\text{velocity gradient}} \qquad \mathbf{8.62(8)}$$

$$= \frac{(F/A)g_c}{(u/l)}, \quad \text{poise}$$

TABLE 8.62d
*Viscosities of Different Materials in Different Units of Viscosity, Measured at Constant Temperature of 70°F (23°C)**

Saybolt Universal (SSU)	*Centistokes (cSt)*	*Centipoise[a] (cp)*	*Typical Liquid @ 70°F[b]*
31	1.00	1.0	Water
35	2.56	2.05	Kerosene
50	7.40	5.92	No. 2 fuel oil
80	15.7	12.6	No. 4 fuel oil
100	20.6	16.5	Transformer oil

lbm/in.-sec	—	0.000056
Pascal-seconds (N-sec/m^2)	Pas	0.001
Poises	Ps	0.01
Poiseuille (N-sec/m^2)	PI	0.001

where

F = total load force, gram force
A = area of plate, cm^2
l = thickness of fluid between plates, cm
u = velocity, cm/sec
g_c = Newton's acceleration caused by gravity, 980.665 (gram mass) (cm)/(sec^2) (gram force)

For the viscosity of common liquids in a variety of units, see Table 8.62d, and refer to Table 8.62e for conversion factors between centipoise (cP) and other units of absolute (dynamic) viscosity. For additional viscosity conversion tables and charts, refer to Tables A.2p, A.2q, and A.2r in Appendix A.2.

Kinematic Viscosity The value of the kinematic viscosity (in cm^2/sec units) can be obtained approximately from the indications of the following viscometers (which all give their readings in seconds) by the associated equations.

Saybolt Universal,

when $32 < t < 100$, $\upsilon = 0.00226t - 1.95/t$
when $t < 100$, $\upsilon = 0.00220t - 1.35/t$

Saybolt Furol,

when $25 < t < 40$, $\upsilon = 0.00224t - 1.84/t$
when $t > 40$, $\upsilon = 0.216t - 0.60/t$

Redwood No. 1 (English),

when $34 < t < 100$, $\upsilon = 0.00260t - 1.79/t$
when $t > 100$, $\upsilon = 0.00247t - 0.50/t$

Redwood Admiralty

(English), $\upsilon = 0.027t - 20/t$
Engler (German), $\upsilon = 0.00147t - 3.74/t$

While the kinematic viscosity unit of stokes are not much used anymore, one stoke is equivalent to 100 centistokes (cSt), or 0.00107 ft^2/sec, or 0.0001 m^2/sec.

VISCOMETER SELECTION AND APPLICATION

Table 8.62f, which is an orientation table, lists all available viscometers and compares the features of the various designs to assist the reader in selecting the right one for the application at hand. When several choices appear to be acceptable for a particular application, the reader is advised to read about each in the following sections before making the final selection. Section 8.63 covers the laboratory-type viscometer designs, and Section 8.64 describes the industrial in-line detectors.

Selection

In selecting a viscometer for a specific task, the following should be determined:

1. Is this instrument for laboratory use or for continuous measurement in the plant for control?
2. What type of materials will this viscometer handle?
   a. Highly volatile? Closed system needed?
   b. Newtonian fluids, non-Newtonian fluids, or both?
   c. Rheological characteristics of the material—plastic, thixotropic, dilatant, etc.

TABLE 8.62f

   d. Corrosiveness of the fluids
   e. Does the fluid contain solids? What are the special characteristics of this slurry or emulsion? Plastic, thixotropic, dilatant, etc.?
   f. What are the operating temperatures and pressures of the fluids?
   g. Do the sample composition and/or viscosity (due to reaction or time lag) change with time? Is a low lag time for manual sampling and testing sufficient, or is on-stream measurement essential?
   h. What is the relationship between viscosity and operating temperature?
3. Area classification—does the viscometer need to be explosion proof?
4. What are the viscosity ranges to be measured?
5. What levels of accuracy (maximum error allowable), sensitivity, and repeatability (for continuous process viscometer) are required?
6. What special features are needed?
   a. Remote indication or recording
   b. Automatic operation
   c. Automatic closed-loop control
   d. Temperature compensating system
7. What is the viscometer response time requirement?
8. What are the flow conditions—laminar or turbulent?

Applications

A viscosity measurement can be of value for one of the following two reasons:

1. It is very difficult to size a pump, pipeline, orifice meter, or agitator without knowing the viscosity of the process fluid. In any operation where liquids are used (spraying, coating, or dipping processes), the viscosity of the fluid determines the effectiveness of the process and the quality of the finished product. In short, viscosity is one of the most important process properties.
2. Viscosity readings can vary as a function of other process variables. These include molecular weight and its distribution in polymers, lubricating oils, and other substances, as well as the concentration, specific gravity, color, size, shape, and distribution of solids in a slurry or in an emulsion. All of these can cause viscosity variations.

Viscometers can be used for several purposes, primarily (1) to ensure that the finished product meets specifications, (2) to perform routine laboratory testing, (3) for scientific research, and (4) for in-line process control. Each is described briefly below.

Finished Product Specification For such applications, the appropriate type of viscometer has been specified by industry standards for product testing. Test procedures should be carefully followed and test results correctly reported.

Routine Laboratory Testing Simple-to-operate, easy-to-clean and direct-reading viscometers should be considered for this purpose. The coaxial-cylinder type viscometer is well suited, because it is inexpensive and meets most of the above requirements. The efflux-cup viscometer is recommended for field laboratory testing work. If the available sample size is small (less than 1 cc), then modified coaxial-cylinder or cone-and-plate rotating viscometers should be considered.

Scientific Research Study For scientific research purposes, accuracy and versatility should be the main selection considerations. Cone-and-plate rotational viscometers are the most versatile units but are also the most expensive. If extreme accuracy is desired, consider the automatic capillary-tube viscometer (See Figure 8.62g). If it is important to record the results to maintain a permanent record, both of the previously mentioned viscometers have the appropriate capability. For the measurement of gas and vapor viscosity, the falling-ball viscometer is the best option.

In-Line Process Control In selecting an in-process viscometer, cost, repeatability, sensitivity, construction materials, reliability, response time, and ease of cleaning should all be considered. Vibrating-reed viscometers are successfully used in the polymer industry. Rotating-cone and agitator power viscometers have been successfully employed in the paper industry. Continuous capillary viscometers are widely applied in the petroleum industry. The manufacture of synthetic rubbers and certain plastics would be almost impossible without the plastometers.

Continuous viscometers are reliable. Viscosity measurement need not be an expensive and time-consuming operation. Continuous in-line viscometers are available to satisfy most process needs. Even such unique applications as the measurement of the viscosity of molten steel can be handled. Viscometer signals can be readily sent over digital networks and be accepted by process computers, which can calculate other related fluid properties or perform closed-loop control.

TERMINOLOGY

Absolute (dynamic) viscosity (μ). Constant of proportionality between applied stress and resulting shear velocity (Newton's hypothesis).

Apparent viscosity. Viscosity of a non-Newtonian fluid under given conditions. Same as *consistency.*

Consistency. Resistance of a substance to deformation. It is the same as viscosity for a newtonian fluid and the same as apparent viscosity for a non-Newtonian fluid.

Fluidity. Reciprocal of absolute viscosity; the unit in the cgs system is the rhe, which equals 1/poise.

FIG. 8.62g

A single process viscosity system can measure absolute (kinematic or dynamic), relative, reduced, and intrinsic viscosities as well as viscosity index. (Courtesy of Brinkmann Instruments Inc.)

Hagen-Poiseuille law (flow through a capillary),

$$Q = \frac{\pi R^4}{8\mu L}(P_1 - P_2) \qquad \textbf{8.62(9)}$$

Kinematic viscosity (υ). Dynamic viscosity/density = $\upsilon = \mu/\rho$.

Pascal-second (Pas). Internationally accepted unit of absolute (dynamic) viscosity. Pas = newton-sec/m^2 = 10 poise = 1000 centipoise.

Poise (μ). Unit of dynamic or absolute viscosity (dyne-sec/cm^2).

Poiseuille (Pi). Suggested name for the new international standard unit of viscosity, the pascal-second.

Relative viscosity. Ratio of absolute viscosity of a fluid at any temperature to that of water at 20°C (68°F). Because water at this temperature has a μ of 1.002 cP, the relative viscosity of a fluid equals approximately its absolute viscosity in cP. Because the density of water is 1, the kinematic viscosity of water equals 1.002 ctks at 20°C.

Saybolt furol seconds (SFS). Time units referring to the Saybolt viscometer with a Furol capillary, which is larger than a universal capillary.

Saybolt universal seconds (SUS). Time units referring to the Saybolt viscometer.

Saybolt viscometer (*universal*, *furol*). Measures time for given volume of fluid to flow through standard orifice; units are seconds.

Shear viscometer. Viscometer that measures viscosity of a non-Newtonian fluid at several different shear rates. Viscosity is extrapolated to zero shear rate by connecting the measured points and extending curve to zero shear rate.

Specific viscosity. Ratio of absolute viscosity of a fluid to that of a standard fluid, usually water, both at same temperature.

Stoke. Unit of kinematic viscosity υ(cm^2/sec).

Stress. Force/area (F/A).

Velocity gradient (shear). Rate for change of liquid velocity across the stream—V/L for linear velocity profile and dV/dL for nonlinear velocity profile. Units are V–L = ft/sec/ft = sec^{-1}.

8.63 Viscometers—Laboratory

C. H. KIM (1969, 1982) **B. G. LIPTÁK** (1995, 2003)

Types:

A. Bubble time
B. Capillary
    B1. Manual capillary tube
    B2. Auto-timing capillary tube
    B3. Capillary extrusion (influx)
    B4. Capillary extrusion (efflux)
C. Efflux cup
    C1. Saybolt
    C2. Ford
    C3. Zahn
    C4. Auto timing
D. Falling ball
    D1. Manual
    D2. Automatic
E. Falling needle
    E1. Manual
    E2. Automatic
F. Rotational
    F1. Coaxial cylinder
    F2. Cone and plate
G. Piston type

Operating Pressures, Temperatures, Ranges, and Inaccuracies: See Table 8.63a

Materials of Construction:

A, B1, B2. Glass
B3, B4. Hardened stainless steel
C. Aluminum, brass, stainless steel
D. Glass and corrosion-resistant alloys
E. Wetted parts are quartz, borosilicate; needles are glass
F. Stainless steel, nickel-plated brass, plastic, ceramic, platinum
G. Stainless steel and Teflon®

Costs:

A. \$100 to \$250
    B1. \$75 to \$300 for capillary tubes; \$500 to \$3000 for thermostatic baths
    B2. \$5000 to \$8000
    B3. \$1500 to \$3000
    B4. \$5000 to \$15,000; computerized processability tester, \$70,000
    C1, C2, C3. \$50 to \$300 for cup; \$250 for calibration; \$500 to \$1500 for thermostatic bath
    C4. \$2000 and up
    D1. \$200 to \$1000
    D2. \$21,000 for research unit used in petroleum industry
    E1. From \$100 to \$250 for hand tubes to \$4000 for units operated with stopwatch; \$10,000 for automatically operated viscometer with computer interface
    F1. Benchtop or battery-operated units (1 to 2% of full scale), \$1750; more automated and more accurate units, from \$2000 to \$10,000; tapered bearing

simulator viscometer, $17,000; digital, computer-compatible, torque transducer with multiple displays, $25,000
R&D high-shear viscometers, from $25,000 to $35,000; high-pressure testing stations with digital temperature control, $40,000
F2. Laboratory units with temperature controls, from $3000 to $5000; portable, self-calibrating units, $7000; Mooney viscometer per ASTM and ISO, $35,000; rubber process analyzer, $85,000
G. Sensor with explosion-proof transmitter, $7000, standard units from $4500

INTRODUCTION

The distinction between laboratory and industrial viscosity analyzers is not a sharp one. In this handbook, most of the in-line, automatic viscometers are discussed in the Section 8.64, which covers industrial viscometers, whereas most units that are of portable or benchtop design are considered to be of the laboratory type and are discussed in this section.

A number of designs (capillary, rotational, cone and plate, piston) are available for both laboratory and in-line applications and therefore are included in both sections. An orientation table providing a summary of the features and capabilities of laboratory viscometers is given in Table 8.63a.

The viscosity ranges in this section are given in centipoise (cP) or in centistoke (cSt) units. For conversions among them and other units, refer to Table 8.62d, Table 8.62e, and Tables A.2p, A.2q, and A.2r in Appendix A.2.

LABORATORY VISCOMETER DESIGNS

In this section, the designs of laboratory viscometers are discussed in alphabetical order, starting with the bubble-time, capillary, efflux-cup, falling-ball, falling-needle, and oscillating-piston types, and concluding with the rotational designs. The sonic and ultrasonic detectors are not covered here, because they are most often used in sludge and slurry density applications, which are discussed in Section 6.7.

Bubble-Time Viscometers

In a bubble-time viscometer, a liquid streams downward in the annular zone between the glass wall of a sealed tube and the perimeter of a rising air bubble. The bubble-time viscometer is used to determine kinematic viscosity of transparent liquids, in the units of bubble seconds or approximate stokes, either by timing or by comparison.

When using the comparison method, the laboratory technician determines the viscosity of a fluid by comparing the speed of bubble rise in a tube having the same dimensions as the standard tube, which is filled with a fluid of known viscosity. A set of 36 standard tubes is available, covering a viscosity range from 22 to 100,000 cSt, in uniform, logarithmically even increments of about 26%. The viscosity of the fluid under test is assumed to be equal to the viscosity of that fluid in the standard tube that had the nearest bubble speed.

Another type, rather than requiring sets of standard tubes, consists of only one standard tube, and it determines the viscosity of the fluid by reading a precalibrated scale in

Saybolt seconds. The distance the bubble travels during a fixed time period is related by the scale to viscosity.

The direct timing of the bubble is based on the observation that the nominal viscosity (in stokes) of the liquid in the bubble tube (10.65 ± 0.025 mm inside diameter) is numerically equal to the time (in seconds) required for the bubble to travel a distance of 73 mm.

Accuracy and Limitations Because of the influence of specific gravity, surface tension, and thixotropy, the accuracy of this detector is low and depends on the scale range being used. For best results, when the timing method is used to obtain kinematic viscosity, precautions must be taken to ensure that the glass tube is completely vertical, that it has a standard bore, and that good temperature control is provided. A tube tipped by only one radius off the vertical axis will give an error of approximately 10% in the time of bubble travel. A temperature variation of only 1°F (0.6°C) will cause a 5% variation in the timed bubble travel.

Care should be exercised to ensure that the bubbles are of uniform size. For low-viscosity liquids with a bubble speed below 5 sec, it is advised to make comparisons against predetermined standard values.

One advantage of this type of viscometer is that it requires no calibration or recalibration. The bubble-time viscometer is well suited for applications where evaporation losses must be avoided. It is not suitable for liquids containing crystal, fiber, or gel particles. Because of its simplicity and low cost, this method of measurement is suited for routine industrial use by operators without special training.

Capillary Viscometers

This manual viscometer consists of a sample reservoir and a capillary tube. As shown in Figure 8.63b, the hydrostatic head of the fluid causes the sample liquid to flow through the capillary. A clock for measuring the efflux time of the fixed liquid volume and a thermostatic bath with temperature controls completes the apparatus.

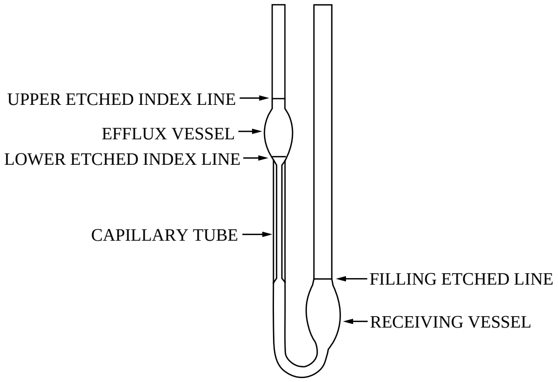

FIG. 8.63b
Ostwald manual capillary viscometer.

The Hagan–Poiseuille equation, which governs viscous flow, has been described in connection with Equation 8.62(3).

Using the Ostwald Viscometer The simplest capillary viscometer, the Ostwald viscometer, is illustrated in Figure 8.62b. The method of measuring kinematic viscosity is detailed in the ASTM D-445 bulletin. In practice, a sample liquid of fixed volume is charged to the lower receiving vessel, and the viscometer is placed in a thermostatic bath. After time is allowed for the sample liquid to reach thermal equilibrium (about 5 min), the sample is drawn up into the efflux vessel by suction until the level is above the upper etched index line.

The fluid is then permitted to flow down through the capillary by releasing the suction. The laboratory technician starts a stopwatch when the fluid surface passes the upper etched index line. The watch is stopped when the surface passes the lower etched index line of the efflux vessel. This efflux time (t) is multiplied by the viscometer calibration constant to obtain the kinematic viscosity of the sample fluid.

Accuracy and Limitations Because of the small driving force provided by the hydrostatic head of the fluid, and because of the change in hydrostatic head with time, the suitability of capillary-tube viscometer is restricted to low-viscosity newtonian fluids. On the other hand, it is a simple, accurate, and convenient detector for the kinematic viscosity range of 0.2 to 120,000 cSt.

If the ASTM test procedure is followed carefully, a repeatability of ±0.10% and a precision of about ±0.35% of reading may be achieved. To achieve this type of accuracy and repeatability, (1) the constant-temperature bath should be maintained with a uniformity of ±0.02°F (0.01°C), (2) efflux times of 100 to 700 sec are required, and (3) precise calibration should be performed at the same temperature at which the device will operate.

In addition to measuring kinematic viscosity, capillary-tube viscometers are used for intrinsic viscosity determinations, for molecular weight measurements (see Section 8.35), and for the study of molecular shapes of natural and synthetic polymers.

Because the Ostwald viscometer is operated under vented (atmospheric) conditions, and because the time lag between taking the sample and making the measurement is large, it should not be used on samples that evaporate or deteriorate when exposed to atmospheric humidity. This type of viscometer is recommended for use under static and stable conditions. Also, the sample liquid should be filtered before making the measurement, to prevent clogging of the capillary tube by solids.

The capillary-tube-type viscometer, if the temperature of the thermostatic bath is well controlled, is capable of very accurate measurements, is inexpensive and easy to operate, and needs little or no maintenance aside from cleaning.

Calibration Before making kinematic or absolute viscosity measurements, the capillary-tube viscometer must be calibrated. This is done by measuring the efflux time using calibrating liquids whose viscosity and density are known.

The liquids used for calibration include water and a number of standard ASTM calibrating liquids described in Tables 8.63c, 8.63d, and 8.63e. The calibration constant is graphically determined using the following equation:

$$\frac{\mu}{\rho t} = A - \frac{m\beta}{t^2} \qquad \textbf{8.63(1)}$$

where

μ = absolute viscosity, poise
ρ = density of liquid, g/cm^2
t = efflux time, sec
A = viscometer constant
m = kinetic energy coefficient
β = kinetic energy constant

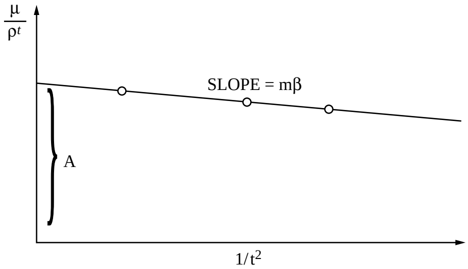

FIG. 8.63f
Calibration of capillary-tube viscometers.

By plotting μ/ρt vs. $1/t^2$ for several known viscosities and connecting the points by a straight line, the value of mβ is obtained from the negative slope of the line, and the value of A is obtained from the intercept of the line with the ordinate (Figure 8.63f).

With viscometer factors A and mβ known, efflux time measurement can be made to determine the kinematic viscosity on any sample.

$$\upsilon = \mathrm{At} - \frac{\mathrm{m}\beta}{\mathrm{t}} \qquad \mathbf{8.63(2)}$$

When the efflux time is very large, the kinetic energy correction (mβ/t) in the viscosity equation will be small and therefore often can be neglected. Once the kinematic viscosity is known, the absolute viscosity is calculated by multiplying the kinematic viscosity by the density of the sample fluid. To obtain accurate viscosity readings, the measurement of liquid density and efflux time are to be made at the same temperature.

Automatic Capillary Viscometer Automatic capillary-tube viscometers provide automatic measurements while using conventional glassware. They consist of a microprocessor-based control package that provides temperature controls, automates the influx and efflux operations, performs the measurement of the efflux time, and generates automatic data display or printout.

Precise results within ±0.01% inaccuracy and ±0.007% repeatability may be obtained while the temperature is maintained within ±0.01°F (0.006°C). Automatic influx controls (same level every time) eliminate drainage errors, while the electronic timing unit provides 0.01-sec resolution.

Once the viscometers have been loaded with samples, the controls start the pump and valves to influx the sample into the measuring bulb. Here, a predetermined time (about 3 min) is provided for the sample to reach bath temperature. At the end of this equilibrium period, the discharge of the sample from the efflux vessel is started. When fluid passes the upper photocell detector, the timing counter starts, and it continues until all the fluid passes the lower photocell detector.

The timing counter utilizes a thermostatic crystal-controlled oscillator that displays the readings in centistokes digitally. It is preferred that the photocells be actuated by light refraction rather than changes in the intensity of transmitted light, because this eliminates the effects of sample color variation.

The utility requirements include an external cooling medium, a nitrogen gas supply, a vacuum source (20 in. Hg [68 kPa] or higher), and a 115/230-V ±10%, 50- or 60-Hz electric power supply. The viscometer might contain several capillary tube assemblies to permit continuous operation so that, while one viscometer is in the measurement cycle, the others can be in the cleaning, drying, loading, or prewarming cycle stages.

Because of the detector response time of 10 μsec, minimum meniscus speeds of 1 in./min are required. The constant temperature bath is controlled between 40 to 275°F (4.4 to 135°C).

Highly viscous liquids and staining liquids cannot be tested if they tend to cling to or stain the capillary tubes. Because of the high accuracy obtainable, this viscometer is well suited for research work, even though it is more expensive than others. This automatic capillary-tube viscometer can be converted for use as a process viscometer by providing an automatic sampling system with adjustable influx pressure regulation. Because such a viscometer will give only intermittent viscosity measurements, it is not suitable for monitoring processes that can experience rapid changes.

Intrinsic Viscosity and Molecular Weight Intrinsic viscosity (also called *limiting viscosity number*, or *LVN*) measurement is useful for determining the molecular weight and/or the shape of polymer molecules in a solution. The intrinsic viscosity of dilute polymer solutions can be detected by efflux time measurements if the polymer solution is dilute enough to allow the sample to have newtonian characteristics. The steps in the measurement are as follows. First, a value for the viscosity ratio (μ_r = relative viscosity) is calculated.

$$\mu_{\mathrm{r}} = \frac{\mathrm{t}}{\mathrm{t}_0} \qquad \mathbf{8.63(3)}$$

where

t = efflux time of the solution
t_0 = efflux time of the solvent

After this step, the specific viscosity (μ_{sp}) is derived as follows:

$$\mu_{\mathrm{sp}} = \mu_r - 1 \qquad \mathbf{8.63(4)}$$

Then, intrinsic viscosity [μ_I] is calculated using either one of the following formulas:

$$[\mu_{\mathrm{I}}] = \left(\frac{\mu_{\mathrm{sp}}}{\mathrm{C}}\right)_{\mathrm{C}\to\mathrm{O}} \qquad \mathbf{8.63(5)}$$

$$[\mu_{\mathrm{I}}] = \left(\frac{\log_{\mathrm{e}} \mu_{\mathrm{r}}}{\mathrm{C}}\right)_{\mathrm{C}\to\mathrm{O}} \qquad \mathbf{8.63(6)}$$

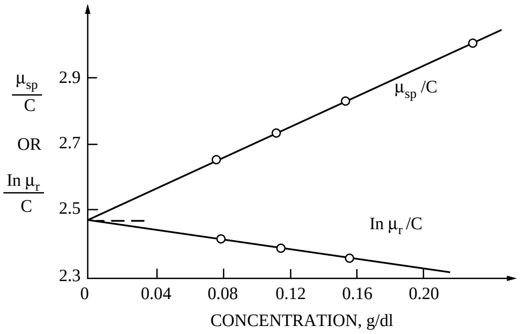

FIG. 8.63g
Intrinsic viscosity determination from specific or relative viscosity.

where
  C = concentration

Either or both of the bracketed quantities can be plotted against concentration and can be extrapolated to infinite dilution to obtain a reading of intrinsic viscosity as illustrated in Figure 8.63g.

Mark–Houwink Equation The Mark-Houwink equation expresses the relationship between intrinsic viscosity and molecular weight.

$$[\mu_I] = KM_w^a \qquad \textbf{8.63(7)}$$

or, in logarithmic form,

$$\log[\mu_I] = \log K + a \log M_w \qquad \textbf{8.63(8)}$$

where
  M_w = molecular weight
  K and a = constants for a given polymer-solvent system

Efflux time measurements are made of well fractionated or monodisperse systems, and intrinsic viscosity readings $[\mu_I]$ are calculated. The molecular weight (M_w) is measured osmotically or by light scattering, and the values of $[\mu_I]$ are plotted against M_w on log-log paper as shown in Figure 8.63h. From this plot, the value of "a" is calculated as the slope, and the value of K is determined from the slope "a" and from a single point on the line.

The intrinsic viscosity of polydisperse systems can be determined on the basis of molecular weight using the following relationship:

$$[\mu] = K\overline{M}_w^a \qquad \textbf{8.63(9)}$$

where
  $\overline{M}_w$ = viscosity average molecular weight

Once K and a have been determined on the basis of measurement of a monodispersed sample, $\overline{M}_w$ can be calculated easily from Equation 8.63(9).

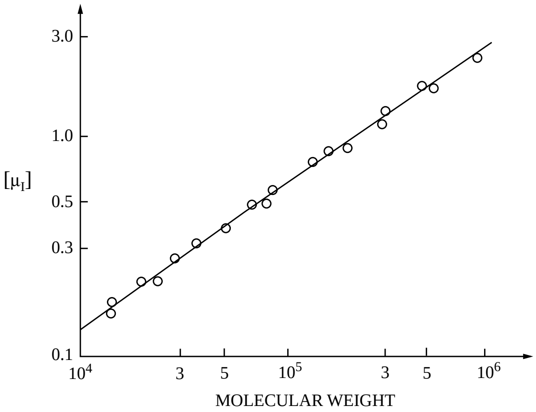

FIG. 8.63h
Molecular weight determination from intrinsic viscosity.

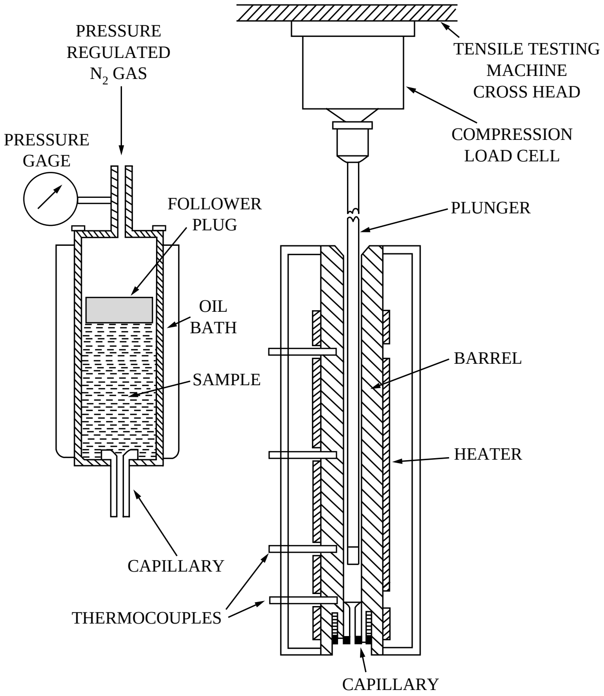

FIG. 8.63i
Schematic diagram of capillary-extrusion viscometer.

Capillary-Extrusion Viscometer The use of capillary-tube viscometers is limited to the measurements of low-viscosity newtonian fluids because of the small driving force available to initiate the liquid flow and because of the inability to vary the shear stress and shear rates during the measurement. As discussed in Section 8.62, the viscosity of non-Newtonian fluids depends on shear rate. Consequently, a number of manufacturers have designed capillary-extrusion viscometers for monitoring non-Newtonian high-viscosity fluids.

The design described in Figure 8.63i utilizes compressed nitrogen gas from a commercial cylinder to drive the sample through a capillary. The process sample is charged to a thermostatically controlled steel reservoir, and a free-floating follower plug rides on top of the sample to distribute the pressure evenly over the surface. A series of extrusions may be made through an orifice at varying pressures. The rate of flow, in cubic centimeters per second, is calculated from the weight of the extruded sample and from the elapsed time during each extrusion. The driving force for the extrusion is measured by a pressure gauge. From these readings, the viscosity in poise, the rate of shear, and the stress are all calculated.

Design Variations Another type utilizes an automated tensile tester with a constant speed to extrude materials through a capillary. A sample is placed in a thermostatically controlled extrusion chamber, and a piston is attached to the moving cross head to force the material through a capillary at a fixed rate. The force required to drive the piston is detected as the compression of load cell attached to the cross head. The load cell signal is recorded on a strip chart recorder.

The rate of flow can be determined by the piston speed or by measuring the weight of the extruded material and the elapsed time of the test. The piston speed can be changed easily, and a series of tests can be performed at different shear rates on the same sample. The recorded load history makes it possible to study dilatant, thixotropic, or other non-Newtonian materials. The flow properties (viscosity, shear stress, and shear rate) are calculated from the measured data and from the constants of the viscometer geometry.

Still another type of viscometer measures the influx time of the material through a capillary. The liquid sample is forced through an open-ended capillary by a constant air pressure, which is generated by a vibrating vertical piston. The influx time (in poise) of the sample liquid to travel a marked distance along the capillary tube is measured as viscosity.

For these viscometers, a variety of capillary lengths and diameters are available. The capillary-extrusion viscometer can serve to characterize non-Newtonian fluids having viscosities up to 10^8 cP (10^5 Pa·s) and over a shear rate range of 1 to 10^4 sec^{-1}. The inaccuracy of these measurements is within ±2% of reading. These viscometers are valuable for the study of materials that are processed in injection molding operations, because the tests themselves are carried out under closely simulated processing conditions.

Limitations The following factors may influence the accuracy of the measurements obtained by using capillary-extrusion viscometers:

1. Nonuniformity of sample shear rate
2. Entrance effects—energy losses at the capillary entrance and discharge points
3. Compressibility of fluids
4. Pressure loss produced by the flow in the sample chamber
5. Temperature gradient created by shear-induced heat

The above factors can result in errors, because they conflict with the assumptions that were made in defining Equation 8.63(4) for newtonian fluid behavior in a capillary tube. When performing scientific research, great care should be taken to correct for these errors. If that is done, the capillary-extrusion viscometers have excellent reproducibility and are well suited for routine industrial and scientific work.

Efflux-Cup Viscometers

Efflux-cup viscometers are most commonly used for field work to measure the viscosity of oils, syrups, varnish, lacquer, paints, and bitumen emulsions, although they have some inherent inaccuracies. The testing procedure is quite similar to that of the capillary-tube viscometers. Here, too, efflux time through fixed orifice at the bottom of a cup of a specified volume of fluid is measured as an indication of the viscosity of the fluid.

Because the viscosities of newtonian liquids are independent of the dimensions of the viscometers used, it is possible to convert efflux times to kinematic viscosities by the use of conversion charts or by formulas such as Equation 8.62(3). To obtain high accuracy in an efflux-cup viscometer, the liquid-holding vessel and orifice are both immersed in a thermostatically controlled temperature-control bath. There are 40 or more design variations of these viscometers, some of which are described in the following paragraphs.

Saybolt Viscometer This viscometer is the standard for testing petroleum products. The standard method of testing for Saybolt viscosity is described in ASTM D88–56. The thermostatic baths have a temperature control uniformity of better than ±1°F (±0.6°C) over a range of 70 to 230°F (21 to 110°C). For accurate viscosity measurements, the laboratory room should be free from drafts and sudden changes in temperature. Accuracies within ±0.1% of reading can be obtained when the standard test procedures are followed.

Each orifice and cup assembly should be calibrated using the ASTM viscosity standards described in Table 8.63e to obtain the correct calibration constant. Three types of orifices are available: for universal, furol, and asphalt applications. Respectively, the furol and asphalt orifices have an efflux time of approximately one-tenth and one-hundredth that of the universal orifice. The cup-orifice combination should always be selected to provide an efflux time within the range of 20 to 100 sec.

Of these three types of efflux cups, the universal orifice (Saybolt universal viscometer) is the most commonly used, and its efflux time is designated as Saybolt universal seconds (SUS). For conversions between SUS and other viscosity units, refer to Table 8.62d. The Saybolt universal viscometer, as shown in Figure 8.63j, measures the time required for 60 cc of sample fluid to flow out through an orifice having the dimensions of 0.176 cm in diameter and 1.225 cm in length. Saybolt universal seconds (t) can be converted to kinematic viscosity (υ) by the following equations:

$$\text{when } t < 100 \text{ sec}, \upsilon = 0.226\,t - 195/t \text{ centistokes} \tag{8.63(10)}$$

$$\text{when } t > 100 \text{ sec}, \upsilon = 0.220\,t - 135/t \text{ centistokes} \tag{8.63(11)}$$

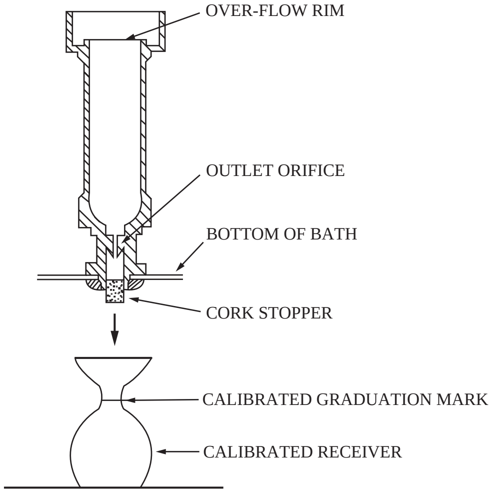

FIG. 8.63j
Saybolt viscometer.

TABLE 8.63k
Conversion of Ford Cup Seconds

Cup Number	*Orifice Diameter*	*Conversion Equation*
2	0.0995 inch*	$\upsilon = 0.013t - 10/t$
3	0.134"	$\upsilon = 0.023t - 8/t$
4	0.162"	$\upsilon = 0.037t - 4/t$

υ = kinematic viscosity, stokes
t = efflux time, seconds
*1 inch = 25 mm.

Ford Cups Ford-cup viscometers are used for the measurement of low-viscosity liquids that do not deviate much from the ideal (newtonian) liquid behavior. ASTM D-1200–58 standard method defines the procedure for determining the viscosity of paints, varnishes, lacquers, and related liquid materials using the Ford-cup viscometers. Ford cups are provided with a conical bottom fitted with a standardized orifice. The measurement results are expressed as efflux time, in seconds, and they measure the time it takes for the liquid to flow through the orifice until the first break occurs in the stream. Efflux time may be converted to kinematic viscosity by the use of the equations provided in Table 8.63k.

The particular cup-and-orifice combination should be so selected as to provide an efflux time within the range of 20 to 100 sec. The test should be performed at a controlled temperature of 77°F (25°C), and the temperature drift during the test should not exceed 0.5°F (0.28°C) as determined by a thermometer in the efflux stream. A wide range of construction materials are available for the test components, but the body usually is made of aluminum, and the orifices are made of brass. The cups and orifices are interchangeable, but the whole assembly must be calibrated each time the orifice is changed. The Ford cups should be recalibrated on a regular schedule to correct for the errors caused by orifice enlargement due to cleaning of material deposits in the orifice.

Ford viscosity cups no. 2, 3, and 4 are normally used for viscosity ranges of 10 to 100 cSt (10^{-5} to 10^{-3} m^2/s). Their inaccuracies are ±2.0% of reading.

Zahn Cups The Zahn-cup viscometer is widely used by paint manufacturers to standardize their products during the manufacturing stages. It is also utilized for measuring the viscosity of many coatings, such as varnishes and lacquers, because of its convenience and speed. It is essentially a bullet-shaped container having a definite volume (44 cc) and an orifice in the bottom. To ensure that it is properly leveled, it is suspended from a ring and ball.

Zahn-seconds represent the efflux time required for the 44 cc volume of liquid to flow through the orifice. The test is made by filling the stainless steel cup with the sample liquid and then measuring the time period during which a steady stream is flowing through the bottom opening of the cup. The measurement is stopped when the cup first begins to drip. For best results, liquids should flow through the calibrated orifice in the bottom of the cup in approximately 20 to 40 sec. Repeatability of ±2% of actual readings can be obtained.

Table 8.63l lists the five different orifice sizes that are available. There is no general formula to convert Zahn-seconds to other viscosity units. As a result, Zahn-cup viscometers are used only for regulating the thickness of coatings and as a guide for coating quality determination.

Automatic Efflux Cup The automatic efflux-cup viscometer is essentially an automated Zahn-cup viscometer that is operated on line, with the steps of filling, efflux timing, and solvent washing operations being controlled by a cycle-time programmer (Figure 8.63m). The programmer allows the liquid to enter the cup until the overflow detector actuates. Drainage of fluid from the bottom of the cup and from the overflow is sensed by deflection of torsion wire-mounted vanes, which operate sensitive switches that control the efflux timer.

The automatic efflux-cup viscometer is a low-cost on-line viscometer. It is recommended for applications in which accuracy is not critical and intermittent measurements with substantial time lags between measurements can be tolerated.

Automatic efflux-cup viscometer.

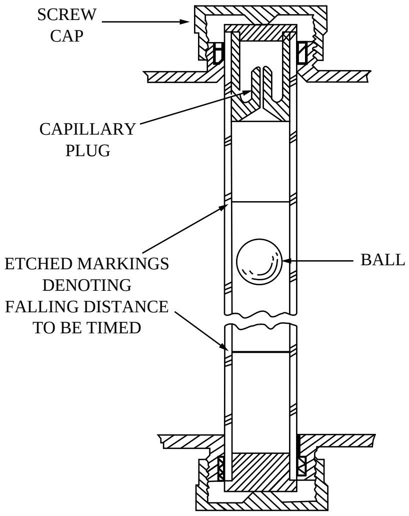

FIG. 8.63n
Falling-ball viscometer.

Falling-Ball Viscometers

This viscometer operates on the falling-ball principle described by Stokes in 1851 and is based on his investigations on spheres falling through liquids [Equation 8.62(1)]. Stokes' law relates the viscosity of gases and liquids to the steady-state velocity of a known-weight sphere falling through a fluid of known density at very low Reynolds numbers.

Manual Falling-Ball Unit The falling-ball viscometer consists of a precision-bore glass tube and calibrated glass or special steel balls of optical precision, as shown in Figure 8.63n. The tube has a length of about 200 mm and a bore of about 16 mm, and it is mounted in a glass water jacket that is held at a specified angle to the vertical.

A special capillary plug provides a positive seal and prevents introduction of air into the column during the tube-inversion process. This permits as many readings to be taken as are desired, using a single sample, when measurements need to be double-checked or when the goal is to determine the rate of variation of viscosity with temperature. The closed system allows operation without the effects of skin formation, surface tension, evaporation, and other losses of material.

Making the Measurement The measurement is made by detecting the time it takes for the ball to fall through an accurately calibrated distance, determined by two marks on the glass tube. The absolute viscosity of the fluid can be found by multiplying that time interval by a factor that reflects the effects of temperature, specific gravity of the fluid, and the characteristics of the ball used, in accordance with the following formula:

$$\mu = \mathrm{t} \times (\rho_{\mathrm{SB}} - \rho_{\mathrm{SF}}) \times \mathrm{B} \qquad \textbf{8.63(12)}$$

where

μ = absolute viscosity, centipoise
t = time interval of the falling ball, sec
ρ_{SB} = specific gravity of the ball
ρ_{SF} = specific gravity of the fluid at the measuring temperature
B = ball constant

The use of several calibrated balls of different sizes in the same glass tube covers the viscosity ranges from 0.01 to 1,000,000 cP. This range covers from various gases (hydrogen, air, carbon dioxide, etc.) to such viscous liquids as will hardly pour through a 16-mm opening. If the temperature of the liquids in the glass jacket is precisely maintained at 68°F (20°C), for the usual range of viscosities (10 to 600 cP [0.01 to 0.6 Pa·s]), viscosity can be determined within an inaccuracy of ±0.1% if the time interval is measured by a stopwatch of 0.02 sec inaccuracy. Outside this viscosity range, a ±0.5% inaccuracy can be expected.

To obtain this level of accuracy, accurate knowledge of liquid density and accurate correction for ball density both become very critical. When using metallic balls, the density of the sample liquid should be known within 0.02 specific gravity (SG). In case of glass balls, the process sample density should be known within 0.005 SG. The variation of ball density with temperature is usually too small to have a measurable effect on the ball constants. However, for extremely high-accuracy measurements, a correction factor should be used as recommended by the manufacturer.

The viscosity of gases at 68°F (20°C) can be calculated from the following relationship:

$$\mu = \frac{\text{period of fall in gas}}{\text{period of fall in air}} \times 0.01836 \qquad \textbf{8.63(13)}$$

A high degree of cleanliness is essential when measuring the viscosity of gases, because the clearances between the tube and ball are very minute.

Calibration and Error Sources It is always good practice to calibrate the instrument with great care and as often as possible. The ball constant can be determined by rearranging Equation 8.59(12) as follows:

$$B = \frac{\mu}{(\rho_{SB} - \rho_{SF})t} \qquad \textbf{8.63(14)}$$

Water at 68°F or ASTM calibrating liquids may be used. The instrument should be carefully cleaned, and the temperature should be held constant within ±0.02°F (±0.01°C).

Care should be taken to minimize subjective errors. A stopwatch of insufficient accuracy is often the cause of error. Lack of attention to temperature is another potential error source, because viscosity at room temperature may vary from 2.5 to 16% for each degree change in temperature, depending on the type of liquid to be tested. Controlling temperature within hundredths of a degree at low temperatures, and within tenths above 100°F (38°C), is absolutely essential for accurate results.

Other possible sources of error are vibration during the time of the fall, inaccurate leveling of the viscometer, foreign matter or gas bubbles in the sample liquid, thermometer errors, and internal heating of the liquid by absorption of infrared radiation from direct sunlight or other sources.

The advantages of this viscometer include its operational simplicity, high speed, and the virtual elimination of subjective variables. It is well suited for routine industrial use as well as for precise scientific measurements of gases and newtonian liquids, including dark or opaque colored fluids as long as they are free from crystal and gel particles.

Automatic Falling-Ball Viscometer These viscometers are provided with automatic controls and timers to measure viscosities of 0.1 cP or higher, with a repeatability of 0.1%. Approximately 70 cc of sample is required to charge this viscometer, which can operate at pressures as high as 15,000 PSIG (103 MPa) and at temperatures as high as 350°F (177°C).

The viscometer consists of two units: the viscosity test assembly (equipped with a precision bore tube, heating and temperature control components, and the ball position detector) and the auxiliary control unit. The auxiliary control unit contains the temperature controller, an electrical timer with reset, and the electrical circuits. The viscosity test chamber, which is mounted on a trunnion, can be rotated to various angular positions. The electrical timer is activated by the ball release signal and, when the ball closes the contact at the lower end of the tube, the timer stops. The timer is accurate to within 0.001 min. The fall time of the ball is proportional to the sample's viscosity, and the readings are interpreted by calibration curves.

The automatic falling-ball viscometer is simple and safe to operate, and it can measure fluid viscosity under simulated process conditions. High accuracy (±0.1%) is obtained by judicious selection of the proper calibrated ball size and by adjusting the angular position of the precision bore tube.

Falling-Needle Viscometer

The replacement of falling balls with falling needles reduces wall correction effects and results in a more stable falling motion. The needles are made of glass, and they are 4 in. (100 mm) in length and 0.065 in. (1.6 mm) in diameter. They fall inside an 0.75-in. (19-mm) ID inner tube. Needles are available in seven specific gravities relative to water (1.01, 1.1, 1.5, 2.0, 3.0, 5.0, and 8.0 SG). When a manual viscometer is used, the measurement is made by establishing the fall time with a stopwatch. In automatic designs, the stopwatch is eliminated.

The velocity of the falling needle is a function of both the difference between the density of the process fluid and that of the needle and of the sample viscosity. The units are also provided with resistance temperature detector thermometers. The automatic falling-needle viscometer is also available with microprocessor control, with a computer interface, and with data-reduction software for printing, plotting, and graphing tasks.

Rotational Viscometers

The rotational viscometer is probably the most widely used rheometer (see also Section 8.53). The operating principle of the rotational viscometers is based on the fact that the torque necessary to overcome the viscous resistance to the induced movement (torque) by the rotation of a spindle is directly proportional to the viscosity of the fluid. In this viscometer, the entire sample is subjected to a uniform (or nearly uniform) rate of shear, so the direct determination of viscosity by measurement of the corresponding shear stress is possible.

The rotational viscometer, if equipped with various spindle sizes and with a variable speed drive, can be used for the measurement of fluid viscosities ranging from 10^{-4} to 10^{8} poise (10^{-5} to 10^{7} Pa·s). The measurement can be performed at a range of shear rates from 10^{-4} to 10^{4} sec^{-1}. The main advantages of this type of viscometer include its ability to perform continuous measurements under varying conditions on the same sample. It can also operate at a given set of boundary conditions for an extended time period.

Rotational viscometers are particularly valuable in the investigation of non-Newtonian fluids. They are classified into coaxial-cylinder types, cone-and-plate types, and plain spindle designs. The cone-and-plate type viscometer is more suitable for the study of non-Newtonian fluids than the coaxial-cylinder type viscometer, and it is also more versatile.

Coaxial-Cylinder Viscometer Figure 8.63o illustrates a coaxial-cylinder viscometer. All these viscometers have three features in common: a mechanical means of driving a spindle at a constant speed, a torque-measuring device, and a means of correlating shear rate (spindle diameter and speed of rotation).

Using weights, one of these viscometer designs measures the force required to rotate a spindle or bob in the sample at a specified speed. The weights are suspended at the free end

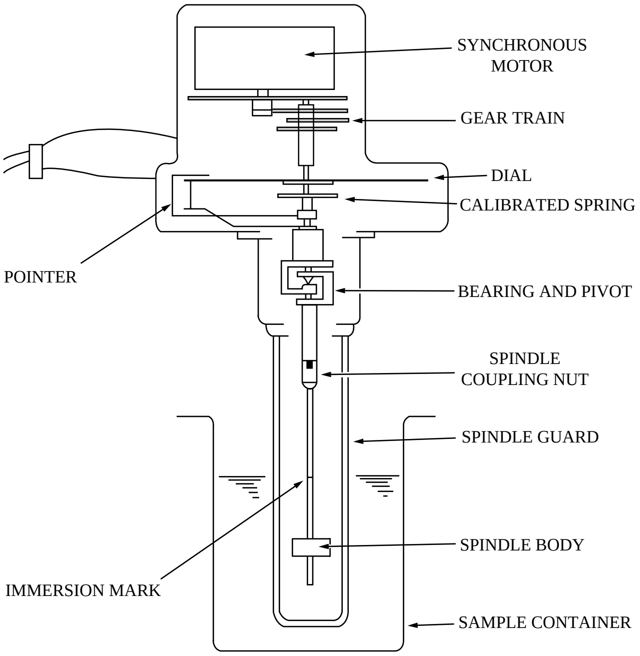

FIG. 8.63o
Rotational viscometer.

of a cable while the other end is wound around a pulley, which is geared to the shaft of the spindle. A standard one-pint friction-top can is used as a container. The weights are a measure of torque, and the shear rate is calculated from the speed of rotation. This unit is inexpensive and is used for viscosity ranges from 0.1 to 5000 poise (0.01 to 500 Pa·s).

Another coaxial viscometer rotates a flat, disc-shaped stirrer at a constant speed in a half-pint size sample container, which is firmly placed on a turntable equipped with torque-measuring capability. A spring is attached to the spindle of the turntable spindle and is used to counteract the torque that is generated by the sample. The angular deflection of the turntable is measured as the viscosity of the sample fluid. This type of viscometer is used for low-viscosity measurements, in the range from 0.1 to 15 poise (0.01 to 1.5 Pa·s).

In another coaxial viscometer design, the sample container is rotated at a constant speed, and the torque required to restrain the freely suspended spindle is measured by detecting the spring-controlled angular deflection of the supporting torque wire. In some cases, the spring movement is converted to a current signal by use of the poles of a magnet, and the current required to restrain the spring is detected as an indication of viscosity. This instrument is good for low- to medium-viscosity fluids and operates at relatively low shear rates.

Still another type coaxial viscometer drives the spindle at a desired rotary speed through a calibrated spring, and the viscosity of the fluid is measured by the degree to which the spring is wound (Figure 8.63p). Constant speed is maintained by a synchronous motor, and speeds of rotation are changed by a gear train (up to eight speeds). The spring torque can be used for remote transmission of measured data.

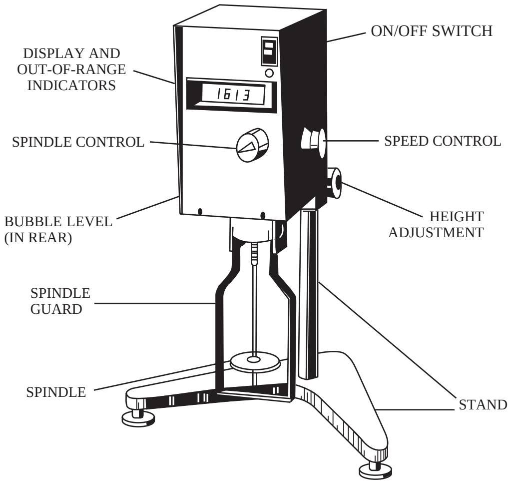

FIG. 8.63p
Rotary viscometer measures the torque required to rotate various spindles when immersed in the test fluid. It can detect viscosities from 10 to 8,000,000 cP with error of 1 to 2% of full scale. (Courtesy of Cole-Parmer Instrument Co.)

Perhaps one of the most versatile of the commercially available coaxial-cylinder viscometers is the one whose rotor speed is changed by line frequency manipulation. With this design, the torque on the rotor is measured by means of potentiometer mounted on the spring, by noting the deflection of the torsion spring mounted between the rotor and the drive transmission.

For the latter two viscometer designs, shear diagrams can be plotted automatically on X-Y recorders, displaying shear stress vs. shear rate or shear stress vs. time of shear, because of their ability to change speed of rotation continuously and because of their ability to transmit the measured torque data. Any X-Y recorder can be used if it has sufficient sensitivity. A minimum frequency response of 1 sec is recommended. This type of viscometer is particularly useful to study such non-Newtonian fluid properties as apparent viscosity relationship, dilatancy, thixotropy, rheopexy, yield value, and plasticity.

Electrical components are usually housed in an explosion-proof housing. The spindle extension can also be adapted for hazardous-area applications or designed for remote testing in a case of a very high-temperature environment. A wide variety of cups, bobs (spindles), and other special attachments are available to extend the viscometer's working range. Viscosities can be measured in the range from 5×10^{-3} to 16×10^{7} poise (5×10^{-4} to 16×10^{6} Pa·s) over a six-decade range of shear rates, from 10^{-2} to 10^{4} sec^{-1}. These coaxial-cylinder viscometers are reasonably inexpensive and are well suited for most routine industrial and research work.

Non-Newtonian Fluids In the design of the coaxial-cylinder viscometer, many assumptions were made to give the appearance of newtonian fluid behavior; i.e., steady laminar flow, isothermal flow, no slippage at the wall, constant temperature, viscosity unaffected by shear rate, etc. Thus, the coaxial-cylinder viscometer provides a rapid means of obtaining reproducible absolute viscosity readings of newtonian fluids by subjecting the sample to a shear stress.

Uncertainty does arise when the process sample is non-Newtonian. The fundamental problem is that the very property that we are interested in measuring is affected by the shear applied by the viscometer. Therefore, it is important to accurately define the limits of the shearing conditions that the viscometer can generate. The major sources of errors in coaxial-cylinder-type viscometers when used on non-Newtonian fluids are as follows:

1. The shear stress, shear rate, and (therefore) the viscosity vary across the gap between the sample cup and the bob used to measure the viscosity.
2. The end effect (i.e., the contribution to the torque that arises in the fluid between the end of the bob and the bottom of the cup) is another error source. The end effect can be minimized by specifying the immersion depth, by using bottomless cups, or by trapping air beneath the bob.
3. The stress-induced heat generation within the fluid at high shear rates can also be problematic.

For the above listed reasons, many different geometrical bob and sample holder configurations have been developed (see Figure 8.63q).

Performance When using the coaxial-cylinder type viscometers, several factors may have significant effects on the overall performance. For that reason, the following operating conditions should be specified:

1. Speed of rotation
2. Spindle size and shape
3. Temperature of liquid
4. Size and shape of sample container
5. Depth of liquid from bottom of the container
6. Spindle immersion depth
7. Elapsed time to rotation before reading is taken

The factors and conditions that are undesirable and therefore should be guarded against include the following:

1. Dirt on the torque measuring device
2. Dirty, corroded, pitted, or deformed spindle
3. Off-center placement of the spindle in the container
4. Incorrect electric power frequency
5. Lack of regular recalibration
6. Turbulent flow (low-viscosity fluid with high speed)
7. Large air bubbles in the sample

Therefore, when measuring the viscosity of non-Newtonian fluids, (1) obtain a viscometer that provides the most uniform shear rate throughout the measured sample, and (2) use a consistent experimental procedure.

Cone-and-Plate Viscometer The cone-and-plate viscometer has been designed to eliminate some of the drawbacks of the coaxial-cylinder viscometer and to provide a rapid and reproducible means of monitoring the flow characteristics of non-Newtonian fluids.

The geometric configuration of a cone and a plate provides uniform shear rate and stress throughout the fluid sample at a given angular velocity as a result of the linear increase in both the sample thickness and the tangential velocity as the distance from the center increases. In addition, the influence of shear-induced heat within the fluid at high shear rates is substantially reduced, because the sample is a very thin layer.

As shown in Figure 8.63r, the cone-and-plate viscometer consists of a flat plate and a cone with a very small angle (less than 1°). The apex of the cone almost touches the flat plate surface, and the fluid sample fills the narrow gap between the cone and the plate. Capillary action keeps the sample materials in place during operation.

The Drive A continuously variable-speed motor drives the rotating platen. The rotary speed is precisely maintained by an electronic velocity control servomechanism. In some cone-and-plate viscometer designs, the flat plate is rotated while the conical disc is held by a torsion measuring head; in others, the conical disc is rotated through a dynamometer while the bottom flat plate is stationary. Torsion bar movement can be measured by a differential-transformer type of displacement transducer. The viscous traction on the cone is measured by an electromechanical torque dynamometer (combination of torque spring and potentiometer).

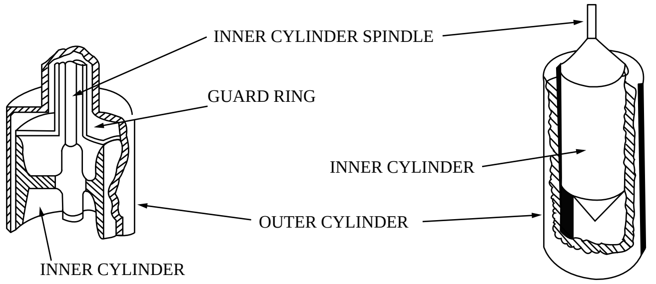

FIG. 8.63q
Coaxial cylinder viscometers.

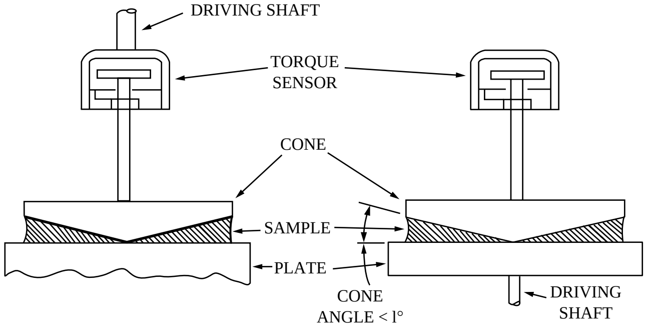

FIG. 8.63r
Cone-and-plate viscometers.

For both types, temperature of the sample is measured by thermocouples embedded in the plate, and precise temperature control is maintained. The gap between cone and plate is kept constant by a servo system. The relative position of platen to cone can be detected by a ceramic proximity gauge or by thermal sensors.

By making an appropriate choice of platen diameter and cone angle, and by modifying the drive gearbox ratios, viscosities from 10^{-4} to 10^{8} poise (10^{-5} to 10^{7} Pa·s) can be measured. The shear rates can be adjusted from 10^{-4} to 10^{4} $\sec^{-1}$.

Oscillating Design To determine the dynamic properties of viscoelastic materials, one cone-and-plate viscometer manufacturer has incorporated the use of a sinusoidal motion over a wide frequency range into this sensor. This oscillatory method of testing allows the moduli of elasticity and viscosity to be derived from the ratio of applied strain and resultant stress, and the phase difference between the two can be in an almost undisturbed state. This is important for materials with unstable structure or yield value and those that can be damaged by continuous rotation.

Advantages and Precautions The chief advantage of the commercial cone-and-plate viscometer is its ability to record rheograms automatically for non-Newtonian fluids that exhibit shear-dependent and time-dependent behavior over a wide range of shear stress and rates. The control unit gives uniform acceleration of the platen up to a selected maximum speed at a preselected acceleration rate. On reaching the preset maximum, the platen automatically decelerates to zero at the selected rate. Quick application and termination of strain or hold speed are also possible. Any X-Y recorder can be used as a plotter. An auto-plotter with a pen-lifting device and a minimum frequency response of 1 sec is recommended.

In connection with cone-and-plate viscometers, the following precautions should be observed:

1. Avoid any air bubbles in the sample.
2. Avoid use of excess amount of fluid around the cone periphery to further minimize the edge effect.
3. Avoid testing high-viscosity materials such as polymers, which tend to ball up and leave a gap between the cone and plate unless the processing temperature is high enough to melt the materials and ensure proper contact.

The cone-and-plate viscometer is the most versatile of all currently available designs and is an excellent rheometer. It is capable of measuring not only absolute viscosity of newtonian fluids but also elasticity and all the other flow properties such as dilatancy, thixotropy, yield value, shear stress/shear rate, and apparent viscosity/shear rate. It can make these measurements over wide and precisely controlled ranges of temperatures and shear rates. The main limitation of this type of viscometer is its high cost.

Oscillating Piston Viscometer

The unit illustrated in Figure 8.64o can be used in the laboratory or as an on-line industrial viscometer. The measurement involves alternately energizing two coils (A and B). The coils cause a piston, located in the inner cavity of the probe, to move back and forth within the cavity. The piston is held within the cavity by the deflector plate, which also serves to direct the process fluid into the measurement cavity. Because movement of the piston is resisted by the viscosity of the process fluid that fills the cavity, its travel time increases as the process viscosity rises. The travel time of the piston is measured as an indication of viscosity. The piston is lightweight, to minimize gravity and vibration effects, and the inward and outward travel times are averaged to minimize flow-force effects. About 30 sec is needed to make a measurement.

This viscometer is provided with an internal resistance temperature detector for temperature compensation. It can operate at high pressures (up to 10,000 PSIG, or 700 barg), and high temperatures (600°F, or 315°C). The wetted parts of the sensor are made of stainless steel and Teflon. It can be provided with a choice of pistons to cover viscosity ranges from 0.1 to 2 cP up to 1000 to 20,000 cP. The process fluid should be free of solid particles that exceed about 25 m in size. The inaccuracy claimed is 2% of actual reading or better. The electronics are available in explosion-proof construction and can serve as both display and transmitter units.

  - H1. Measuring tube torsional movement

Design Pressures, Temperatures, Viscosity Ranges, Errors: See Orientation Table 8.64a

Materials of Construction:

A, B. Hardened stainless steel or other corrosion-resistant metals
C. Same choices as for variable-area flow meters
D1. Wetted parts, stainless steel; sealing ring, silicone rubber
D2. Stainless steel and Teflon®
D3. E, F. Hardened stainless steel
G, H. Wide selection of corrosion-resistant materials and coatings

Speed of Response:

A. From 1 sec to about 5 min
B2. Cycle time from 30 sec to 3 min
C, E, F, H. A few seconds
D1. Strokes every 2 sec, readings averaged over an adjustable number of strokes
D2. About 30 sec
H. Less than 1 sec

Costs:

A1. Balanced dual-capillary element without d/p transmitter for fuel oil service, $3000 to $4000
B1. Falling ball viscometer, from $7000 to $16,000; high-pressure design with digital readout of ball roll time corrected for density, $23,000
B2. From $2500 to $8000; a driven-piston element, $4000
C1 and C2. Two-float indicators with brass or stainless steel fittings in sizes from 0.5 to 1.5 in. (12 to 38 mm), from $1500 to $3000
C3. 1.5-in. (38-mm) transmitter in stainless steel with 300 PSIG flanges, $8000
D2. Sensor with explosion-proof transmitter, $6000 to $8000
D3. Microprocessor-based temperature-compensated transmitter, $15,000
E. $10,000 to $60,000, depending on features and on degree of automation
F1. Variable-speed microprocessor-based units from $15,000 to $25,000
G. $3000 to $5000, depending materials of construction and transmitter features
H. $400 to $20,000, depending on line size for the in-line treatment

INTRODUCTION

This section covers viscometers that can be installed in a tank or pipe in an industrial environment. The portable and bench-top laboratory viscometers are discussed in the previous section. The distinction between the two groups is not a sharp one, and some of the rotary, capillary, cone-and-plate, and piston designs are actually used in both services.

In this section, centipoise (cP) and centistokes (cSt) are the viscosity units used. For conversion between these and others, refer to Tables 8.62d, 8.62e, A.2p, A.2q, and A.2r.

A summary of industrial viscometer features and capabilities is given in the Orientation Table 8.64a. In the following paragraphs, the various viscometer designs are discussed in the same order as listed in the Orientation Table.

CAPILLARY VISCOMETERS

Continuous capillary viscometers are successfully used in oil refineries to control various products such as fuel oils, hydraulic oils, lubricating oils, fuels, and various grades of asphalts. They are also used in fuel oil viscosity control to optimize atomization in the power industry.

As shown in Equation 8.62(2), the pressure drop under viscous flow conditions is linearly proportional to viscosity. Therefore, at constant flow rate, the pressure drop in a capillary can be used as a measure of viscosity.

Sensor for Newtonian Fluids

Newton's hypothesis assumed that the viscosity of a fluid is independent of the rate of shear or of the shearing force of deformation, as long as the flowing temperature and pressure are fixed. Fluids that behave in this manner are called newtonian. Based on Poiseuille's law [Equation 8.62(2)] and Newton's hypothesis, we can observe that, if the flow rate through a fixed capillary tube is held constant, the absolute viscosity of the flowing liquid will be a linear function of the capillary pressure drop.

Continuous capillary viscometers are primarily designed to measure the viscosity of newtonian liquids. Because d/p transmitters are used to measure the viscosity, they are also readily adaptable to the automatic control of processes.

▬ Normal Range. ‒ ‒ ‒ With Special Modifications.

In most capillary-type viscometers, the temperature effect on the measurement is eliminated not by temperature compensation but by temperature controls. This is done by a thermostatic device that keeps the sample at a constant reference temperature as it enters the capillary tube.

This type of viscometer can measure viscosities up to 15,000 poise (1500 Pa·s) and can operate at temperatures up to 900°F (480°C). The viscosity span of this sensor is a function of the bore and the length of the capillary. To minimize the end effects (the nozzle effect at the tip of the capillary), the use of large-diameter bores and long capillary tubes is recommended.

Limitations

Although this type of continuous viscometer is simple enough to be field fabricated (rather than purchased), one of its chief disadvantages is that, for accurate and reliable measurements, the capillary tube must be kept absolutely clean. But fouling is likely to occur, because the capillary tube diameter is very small—usually in the range of 0.05 to 0.2 in. (1.25 to 5 mm).

Because the sample flow rates must be low, this requirement limits the continuous capillary viscometer to by-pass installations, where the goal is to automatically control the processes with minimal time lag.

Other potential error sources include (1) fluctuating flow rates through the capillary tube, (2) a dirty or plugged capillary, (3) leakage in the viscometer, (4) incorrectly set or drifting transducer zero and span, (5) fluctuating fluid pressure, (6) insufficient sample supply pressure, and (7) fluid temperature fluctuations due to thermostat malfunctions or to variation in sample supply temperature.

Calibration

The continuous capillary viscometer can be calibrated using the following equations:

$$d = \sqrt[4]{\frac{6\mu VL}{\Delta P \times 10^9}} \qquad \mathbf{8.64(1)}$$

$$\mu = \frac{\Delta P d^4 \times 10^9}{6VL} \qquad \mathbf{8.64(2)}$$

Equation 8.64(1) is used to calculate the diameter of the capillary tube when the viscosity of the process fluid is known. Equation 8.64(2) is used to prepare the calibration curve of viscosity versus pressure drop using several fluids of known viscosity. Such a calibration should produce a straight line that goes through the zero point of the viscosity and pressure drop coordinates.

There are basically two types of viscometers that utilize the continuous capillary principle. One type measures the pressure drop across the capillary tube, and the other measures the upstream pressure as the sample flows through the capillary tube.

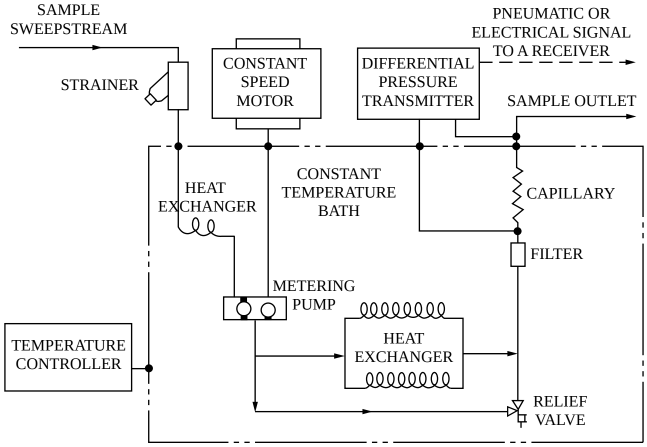

FIG. 8.64b
Schematic flow diagram of a differential-pressure-type continuous capillary viscometer.

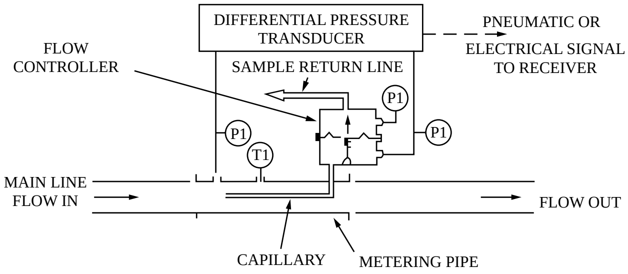

FIG. 8.64c
Schematic diagram of an in-line, differential-pressure-type continuous capillary viscometer.

Differential Pressure Type

Figure 8.64b is a schematic flow diagram of a differential pressure viscometer, which requires a bypass installation. An external strainer is provided to remove any solids from the sample before it enters the viscometer. A constant sample flow rate (at about 1 GPH or 3.8 l/h) is maintained by a precision metering pump, which is driven by a synchronous motor.

Two heat exchangers, before and after the metering pump, are used to keep the sample fluid in thermal equilibrium with the thermostatic bath. A relief valve protects against damage caused by excessive pressures that may occur in a blocked capillary.

The pressure drop across the capillary is measured with a differential pressure transducer, which is connected to the inlet and outlet sides of the capillary. The d/p transmitter output is a linear indication of the process viscosity and is used for indicating, recording, or controlling the process.

This type of viscometer can measure viscosities up to 2500 cP (2.5 Pa·s) and can operate at temperatures up to 240°F (116°C). If high-pressure capillaries and high-pressure metering pumps are used, the viscosity measurement can go up to 15,000 P (1,500 Pa·s) and the line pressures can reach 670 PSIG at 900°F (4.6 MPa at 480°C).

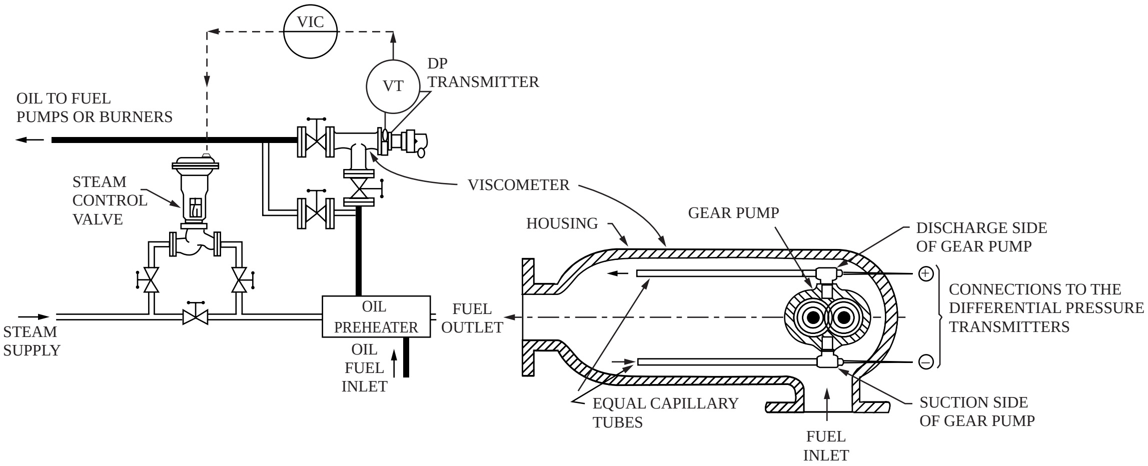

FIG. 8.64d
Balanced dual-capillary viscometer used to control oil viscosity, which guarantees proper atomization and therefore improved combustion efficiency. (Courtesy of Conameter Corp.)

The range and span of the d/p transmitter determine the range of a single capillary tube. Overall inaccuracy is about ±1% of full scale, with repeatability being about the same. The average response time is about 2 min (0.6-min time constant), but it varies with the length of the sample loop.

In-Line Design To reduce the response time of the viscometer to less than 1 sec, the capillary tube can be inserted into the main process stream, and sample flow rate can be increased to about 4 GPH (15.2 l/h), as shown in Figure 8.64c. In this design, the constant flow rate through the capillary tube is maintained by a pressure-regulated, diaphragm-type flow controller.

The error in this measurement is higher than with the external sampling design, and inaccuracy is about ±2.0% of full scale when measuring viscosity in the range of 5 to 30 cSt (5×10^{-6} to 30×10^{-6} Pa·s).

One advantage of this design is its increased speed of response. Another advantage is that, because the viscosity measurements are made at the process stream temperature, this viscometer can be used as a viscosity controller that maintains constant fluid viscosity by adjusting temperature. Such applications include controlling fuel oil viscosity to maintaining optimal atomization patterns in industrial furnaces, heating plants, steam power stations, and marine boilers.

Dual-Capillary Design Figure 8.64d illustrates a dual-capillary viscometer that is used for controlling the viscosity of fuel oil to boilers and other burners. The dual-capillary design is superior to the single-capillary units, because it is unaffected by variations in fuel line pressure.

Dual-capillary viscometers are installed because keeping the viscosity constant guarantees consistent atomization of the fuel, which, in turn, improves combustion efficiency. In this viscometer, a gear pump, which is inserted into the fuel oil pipe, takes a constant flow-rate sample of the oil and discharges it continuously back into the oil stream. As the flow rate is constant, the difference between pump suction and discharge pressures is a linear function of viscosity. This pressure difference is measured by a d/p cell and is kept constant by adjusting the heat input into the oil preheater.

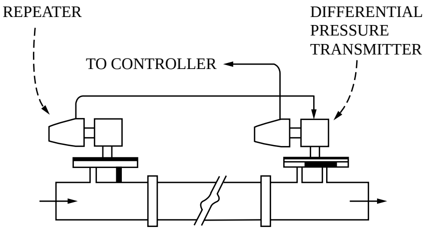

FIG. 8.64e
Differential pressure measurement, using extended diaphragm sensors across any section of process pipe to detect viscosity.

This in-line viscometer is provided with 2-in. (50-mm) DIN flanges, and the flow through it can be up to 100 GPM (380 l/m). The fuel oil pressure can be up to 500 PSIG (35 barg), and the temperature can be up to 300°F (149°C). The differential pressure range of the d/p cell is 0 to 150 in. (0 to 3.8 m) of water, which in units of viscosity can correspond to 0 to 300 SUS, 0 to 200 Redwood 1, or 0 to 6° Engler.

Pipe Section as Viscometer If the flow is constant or is measured, and therefore it is possible to compensate for the variations in flow rate, the pressure drop through any pipe section in the plant (Figure 8.64e) can be used to detect viscosity. As long as the inner walls of the pipe section are clean, and as long as the temperature and flow variations are compensated for, the detected pressure drop will be linearly proportional to viscosity.

Backpressure Type

The operation of this viscometer is quite similar to the differential pressure type except that it measures only the upstream pressure to a capillary tube that discharges to the atmosphere or returns the sample to a pressure-regulated process line.

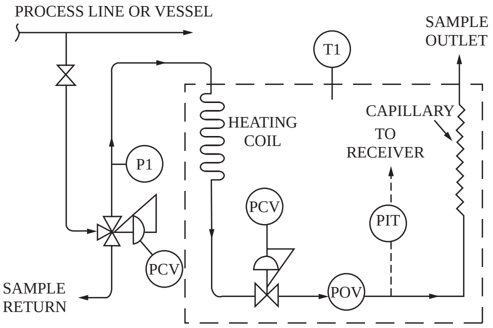

FIG. 8.64f
Schematic system diagram of a backpressure-type continuous capillary viscometer.

As shown in Figure 8.64f, the sample fluid is continuously fed to the instrument from the process line or from a vessel. The sample temperature is maintained by flowing through a heat exchanger, which is immersed in a constant-temperature bath. The sample then passes through a pressure regulator followed by a flow controller. Under these conditions of constant flow rate and constant temperature, the sample pressure at the entrance to the measuring capillary tube is linearly proportional to the viscosity of the liquid.

The inlet pressure to the capillary is sensed by a strain gauge. The strain gauge signal is converted to the desired units of viscosity and is transmitted to indicate, record, or control the process viscosity. Because this viscometer measures only the inlet pressure to the capillary tube, it is extremely important to maintain the outlet side at constant pressure by discharging the capillary to atmosphere or to a pressure-regulated vessel or pipeline.

The backpressure-type viscometer can measure viscosities within the range of 5 to 500 cSt (5×10^{-6} to 5×10^{-4} Pa·s) at temperatures up to 210°F (99°C). Its overall inaccuracy and repeatability are ±1% of full scale, and its response time is 3 to 6 min.

FALLING-PISTON VISCOMETER

The falling-piston viscometer has been used in paper sizing, printing, coating, polymerization, starch conversion, textile sizing, and blending process applications. The working principle of the falling-piston viscometer is quite similar to the falling-ball viscometer, discussed in the previous section in connection with Figure 8.63n. Because of its excellent reproducibility, the falling piston viscometer can be used for the measurement of the viscosity of both newtonian and non-Newtonian fluids.

The measuring element consists of a piston inside a measuring tube as shown in Figure 8.64g. The measuring element can be installed in a tank (open or closed) or in a liquid-filled pipeline, as long as the measuring tube is completely immersed in the fluid.

During the filling phase, the piston, which is resting at the bottom of the tube, is automatically raised by an air lifting mechanism or by a motor-cam mechanism. As the piston is raised, a sample of the liquid is drawn in through the openings in the sides of the tube and fills the measuring tube as the piston is withdrawn.

Process Pressure-Operated Design

In some in-line units, the piston can be raised by the process fluid itself. In such designs, the measuring tube is filled

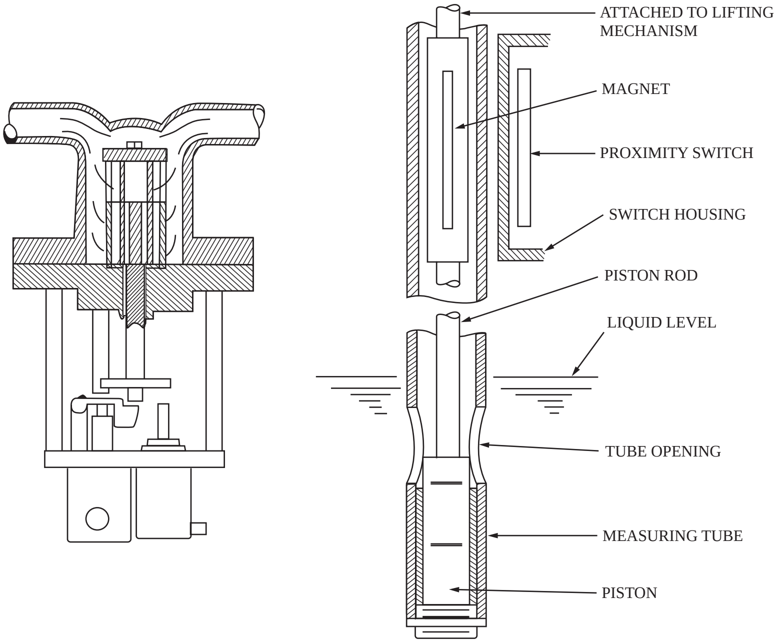

FIG. 8.64g
The falling-piston viscometer.

through an opening at the bottom of the tube, and the filling and measuring cycles are controlled by the periodic opening and closing of a valve. The pressure drop across the measuring tube is about 5 PSI (35 kPa).

During the measuring phase, the piston assembly is allowed to fall by gravity, expelling the sample out of the tube through the same route that it entered. The time of fall is a measure of viscosity, using the clearance between the piston and the inside wall of the measuring tube as the measuring orifice. The timed interval is then displayed on an indicator or recorded. For process control or for high-low alarm purposes, the intermittent time signal is converted to a continuous signal by a simple clutch mechanism or by a sling-wire mechanism that is linked to the recorder pen.

When high-viscosity materials are to be detected, and it is desired to make the measurement within a reasonable cycle, a two-way air cylinder is used to lift and force down the piston. This design also accommodates the use of any mounting position that is desired.

The viscosity range of this sensor is from 0.1 to 10^6 cP (10^{-4} to 10^3 Pa·s). Each piston has a 100:1 range. The inaccuracy of this viscometer is 1% of full scale, and the reproducibility and sensitivity are 0.25% and 0.1% of full scale, respectively.

Because the cycle frequency of the measurement is from once every two minutes up to two cycles per minute, it is applicable to both batch and continuous process applications, with or without automatic process-control capabilities. Pressure and temperature ratings of the standard in-line unit are from full vacuum to 300 PSIG (2 MPa) and for up to 650°F (340°C). A special high-pressure unit is available for operating pressures up to 500 PSIG (3.5 MPa).

Precautions

As in the case of all other viscometers, operating temperature and pressure should be specified and kept constant when using this sensor. The error caused by small variations in the process fluid temperature can be substantial, so the use of either a temperature-controlled sampling system or a temperature-compensated design should be used. Naturally, if compensation is the choice, the viscosity vs. temperature relationship must be accurately known.

Because this viscometer operates in a batch manner, it should not be used where fast (less than one minute) response time is required. Where a sampling loop is used, the rate of sample pumping should be set to minimize the lag time. To obtain reasonable reproducibility, the following should be observed:

1. Avoid any vapor entrainment in the sample liquid caused by agitation or boiling.
2. Avoid turbulence.
3. Calibrate the instrument regularly to correct for measurement drift caused by gradual material buildup or for wear of the piston and tube.
4. The measuring unit should be cleaned at regular intervals—frequency depends on the rate of material buildup.
5. An in-line filter should be used to remove any larger sized solids or foreign materials. The maximum allowable size of solids remaining should be small enough that they will not interfere with the measurement.
6. Sensitivity requirements should be known for blending process applications.
7. Do not use this viscometer if the process liquids have poor flow characteristics.
8. Erratic readings may result if this detector is subjected to severe vibration.

Falling-Slug or Falling-Ball Viscometers

This instrument automatically measures the time required for a cylindrical slug of a specific density to fall a given distance in a vertical tube, which is filled with the process liquid at a constant temperature.

As shown in Figure 8.64h, this viscometer operates by the sample pump first purging the system of the previous sample and then introducing a fresh one. Two separate thermostats control the purge and recirculation cycles by changing the direction of flow through a three-way valve.

In the recirculation phase, the sample pump flow raises the slug to the top of the fall tube. When the sample temperature has stabilized and matches the thermostat set point, the pump and the sample flow stops, thereby permitting the slug to fall. As it does, it actuates two magnetic switches that are attached to the side of the fall tube.

The first switch starts the recorder motor. When the slug sinks to and actuates the second magnetic switch, located at an adjustable distance (1 to 20 in., or 25 to 500 mm) below the first, this switch stops the recorder motor. The resultant time measurement is directly proportional to the viscosity of the sample. Actuation of the lower switch also initiates the system purge phase.

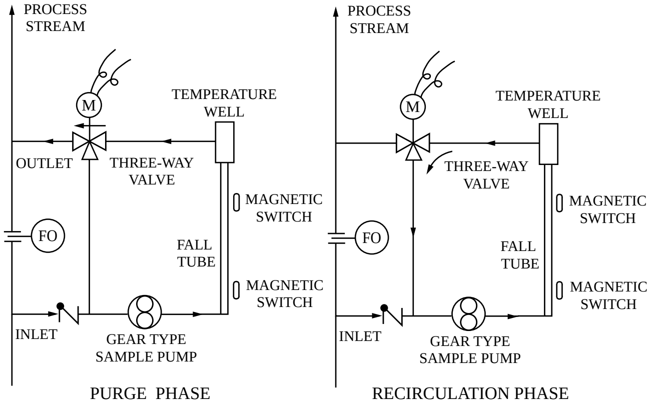

FIG. 8.64h
The purge and the recirculating (measuring) cycle of the falling-slug viscometer.

The viscosity range of this detector is 10 to 1,000,000 cP (0.01 to 10^3 Pa·s). The specific ranges for particular applications are field selectable by adjusting the distance between the two magnetic switches on the fall tube. Full scale indication can be selected from 10 to 250 sec in five steps. The inaccuracy and the reproducibility of this viscometer are both about ±1% full scale, depending on the precision of the thermostat and of the recorder. Errors caused by small variations in the process fluid temperature can be substantial.

The viscometer is designed to operate at temperatures up to 300°F (150°C) and at pressures up to 200 PSIG (1.4 MPa). This detector is suited for continuous viscosity measurement applications in which it is sufficient to make a reading once every 3 min. The falling-slug viscometer is recommended for use only on clean process fluids that are not shear sensitive.

FLOAT VISCOMETERS

The float viscometer has been successfully used to maximize combustion efficiency by controlling the viscosity of fuel oils in marine and stationery boilers. Other areas of application have been in measuring the viscosity of cement slurry, starch, glue, and petroleum products (motor oils).

These viscometers are used both industrially and in the pilot plant to measure the viscosity of process fluids and to continuously indicate, record, or control the process. This type of viscometer is used in a closed-flow system. The operating principle is similar to that of the variable area flow meter (Section 2.27), where the viscous drag force on a float is proportional to the orifice opening required (between float and tapered tube) to move the fluid through that orifice at a constant flow rate.

In a rotameter-type flow meter, the forces acting on the float are affected by the flow rate, by the float and liquid specific gravity, and by the viscosity of the fluid being metered. For flow metering applications, the floats are designed so that the viscous drag area is relatively small, so the float is relatively insensitive to viscosity while being sensitive to flow rate and density changes.

In the viscometer version of this design, the flow rate through the variable area meter is held constant. Therefore, if the position of the float changes, that change is an indication of a change in fluid viscosity and density or in kinematic viscosity. To increase its sensitivity, the viscometer float is designed with a large viscous drag area. To obtain accurate viscosity measurements with float-type viscometers, the flow rate must be constant. Because this required flow control can be obtained in three different ways, there are three different designs: single-float, two-float, and concentric.

Precautions

When using float type viscometers, the following recommendations should be observed:

1. The float viscometer must be installed vertically, with the outlet at the top.
2. The instrument should be installed in a vibration-free location.
3. The process fluid temperature should be carefully controlled, or temperature compensation should be employed. If no automatic compensation is provided, viscosity vs. temperature curves should be available for use by operating personnel.
4. The flow rate and the pressure of the process fluid should both be constant and smooth, pulsating metering pumps should not be used.
5. The process fluid should be free of foreign material to prevent plugging of the small orifice (0.1 in., or 2.5 mm, dia. min.) inside the viscometer. The use of in-line filters is recommended to remove all foreign materials.
6. Install the viscometer in a bypass line to permit the flushing of the main pipeline and to facilitate viscometer maintenance and service.
7. Make certain that the specified operating conditions are not exceeded.
8. The viscometer should be periodically recalibrated using a known viscosity fluid. At the time of calibration, the tube and float should also be cleaned.
9. The sample fluid flow rate through the instrument should be sufficient to give good speed of response and sensitivity, but the rate of flow should not cause turbulence within the viscometer, which would result in erratic readings.
10. All air and vapor entrainment should be removed from the sample liquid.
11. When the process temperature is other than ambient, make sure the viscometer is insulated or stream traced, as required.

Single-Float Design

The single-float viscometer is a continuous and direct reading viscosity instrument. As illustrated in Figure 8.64i, a positive displacement pump (other flow control devices can also be used) provides the constant sample flow rate through the instrument.

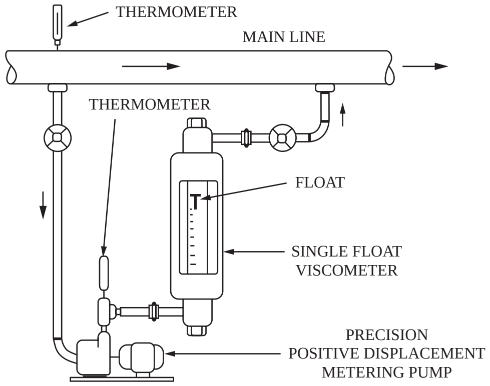

FIG. 8.64i
Typical piping arrangement of a single-float viscometer.

The recommended flow rate is between 0.75 and 2.0 GPM (2.9 and 7.6 l/m). Automatic temperature compensation is not available for this type of direct reading viscometer. If a metering pump is used to generate the constant flow rate, the temperature rise through the pump should be measured and corrected for by the use of a viscosity vs. temperature curve.

The single-float viscometer is also available as a transmitter that is used when remote displays or controls are required. In this case, the float position is detected by the use of an armature attached to the float extension rod with a magnetic sensing device around its outer periphery.

The glass tube viscometer is rated for 450°F (232°C) temperature and for 90 PSIG (621 kPa) pressure. With steel-tube viscometers, the pressure rating depends on the operating temperature, such as a unit for 650 PSIG service at 450°F (4.5 MPa at 232°C).

The single-float viscometer can be used to measure the viscosity of non-Newtonian fluids at less that 400 cP (0.4 Pa·s) and can handle newtonian fluids up to 10,000 cP (10 Pa·s). The rangeability of this viscometer is between 3:1 and 6:1. The inaccuracy of this sensor is ±4% of actual indication, and the reproducibility is ±4% of indication.

Two-Float Design

This is a relatively low-cost viscometer designed to provide intermittent viscosity measurement in the laboratory, on the test bench, or in industry. It is only for local indication, not for transmission.

The design incorporates two floats. The upper float is sensitive to fluid flow rate, and the lower is sensitive to viscosity. When making a measurement, the fluid flow rate is first manually adjusted to a constant value as indicated by the position of the upper float. Under such conditions, but only while maintaining the volumetric flow constant, the position of the other float indicates the viscosity of the fluid on a direct reading scale.

The recommended piping configuration for a two-float viscometer is shown in Figure 8.64j. In the main pipeline, a throttling valve or an orifice plate can be used between the viscometer inlet and outlet connections to produce the required pressure differential to provide sufficient flow through the instrument. The required flow rate is 0.25 to 2.5 GPM (0.95 to 9.5 l/m), depending on size.

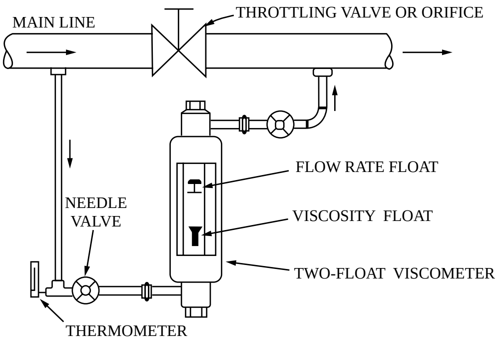

FIG. 8.64j
Typical bypass piping arrangement of a two-float viscometer.

The throttling valve or orifice plate is not required if the outlet can be discharged to a location where the pressure is lower than that of the main pipe. A needle valve should be used on the viscometer inlet to allow sensitive and accurate flow rate adjustment. As a function of size, the unit is rated for pressures up to 300 PSIG at 450°F (2 MPa at 232°C), depending on size.

The two-float viscometer can measure the viscosity of newtonian fluids from 0.3 to 250 cP (10^{-4} to 0.25 Pa·s). It has a rangeability of 10:1 and an inaccuracy of ±4% of indication when the viscosity is higher than 35 cP (0.035 Pa·s). When measuring lower viscosities, the error is ±2%.

Concentric Design

The concentric viscometer (Figure 8.64k) consists of a differential pressure regulator that maintains a constant pressure drop across the meter, and a variable area flow meter, which is provided with a viscosity-sensitivity float. As the fluid enters the instrument, it splits into two streams.

The portion of the fluid that flows upward on the outside, around the differential pressure float, is used to control the pressure drop across the meter. The upper end of the differential pressure float acts as a control valve so that, when the

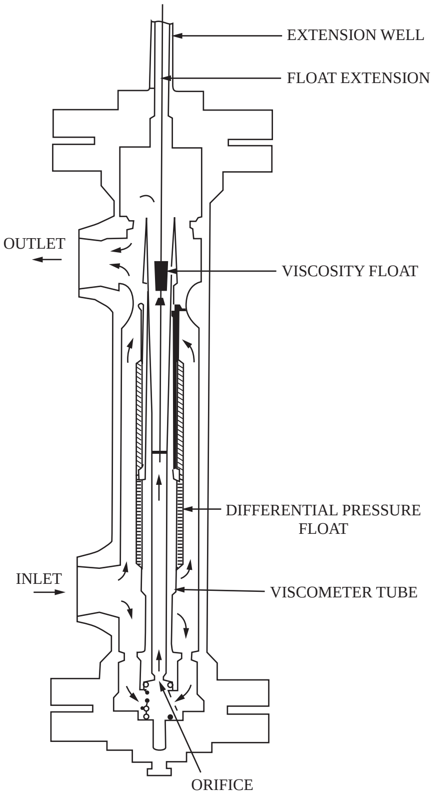

FIG. 8.64k
Cross-sectional view of a concentric viscometer.

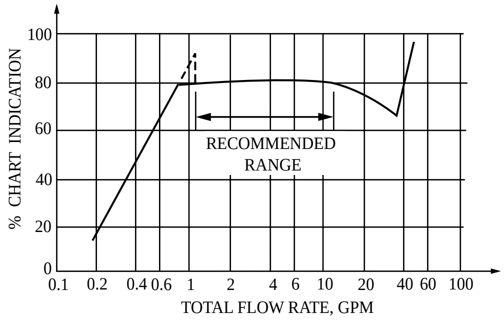

FIG. 8.64l
The characteristics viscosity reading of a concentric viscometer as a function of flow rate through the meter.

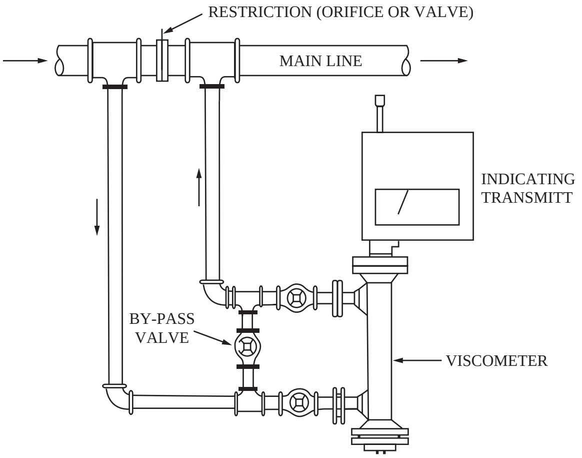

FIG. 8.64m
Bypass installation of a concentric viscometer.

flow rate changes, it throttles the flow to maintain a constant pressure drop. The pressure drop across this portion of the meter is determined by the weight of the d/p float.

The portion of the fluid that flows downward enters the viscometer tube through an orifice and then passes the viscosity-sensitive float. The flow rate through the viscometer tube is maintained constant, because the fluid passes through the orifice at a fixed pressure drop. Thus, constant flow rate is maintained, which is a requirement for the measurement of viscosity.

An extension attached to the viscosity float transmits its movement through a magnetic coupling to a receiver for display, recording, or automatic process control, as desired.

The unit may be placed in either the main process line or in a sample line, depending on the process flow rates. As shown in Figure 8.641, this viscometer does have a flow-insensitive range, so the flow rate through it should not exceed 30 GPM (114 l/m).

The recommended piping configuration for bypass installation is shown in Figure 8.64m. The restriction orifice shown in this figure should be sized for approximately 4 PSI (28 kPa) pressure drop. If a valve is used in place of an orifice, the correct valve position can be determined by slowly opening the valve until the viscometer reading levels off. Further opening will cause the reading to start to fall off and then, when turbulent conditions evolve, rise sharply, as illustrated in Figure 8.641.

The valve openings that produce steady viscosity readings are in the operating range. This procedure should be carried out when the main line flow is at a maximum; after that, the valve should be locked in place to prevent unauthorized adjustments. If the main line flow rate is lower than 2 GPM (7.6 l/m), a booster pump should be used to provide adequate flow rate through the meter. The unit is rated for 650 PSIG pressure at a temperature of 450°F (4.5 MPa at 232°C).

The concentric viscometer can measure viscosities in the range of 0.5 to 550 cP (5×10^{-4} to 0.55 Pa·s) and is available with a span range of 10:1. Its inaccuracy is ±2% of indication for viscosities lower than 35 cP (0.035 Pa·s), and it is ±4% for higher viscosities.

OSCILLATING VISCOMETERS

Oscillating Blade

Figure 8.64n illustrates the oscillating blade viscometer in which, as the blade moves between the fixed side walls, it discharges the process fluid through the openings of one wall of the measuring chamber while pulling in a fresh sample through the other. The blade is rotated around its fulcrum by a plunger/solenoid mechanism as its tip travels the distance between points A and B. When the stroke is completed, the polarity of the current to the plunger coil is reversed, and the blade is returned to its original position.

Adjustable mechanical stops are provided to limit the stroke. The time of travel between points A and B is detected optically as, upon the completion of the stroke, a beam interrupter blocks a light beam. The total stroke time is about 0.2 sec, and the blade makes a stroke about every 2 sec. The average time of several strokes (adjustable) is measured as an indication of viscosity.

This intrinsically safe, indicating in-line transmitter can detect viscosities between 10 and 200,000 cP. It has a minimum span of 20 cP and a maximum span of 200,000 cP. The maximum allowable liquid velocity in the process pipe can be up to 6.5 ft/sec (2 m/s), but the fluid should not contain particles that are larger than 0.04 in. (1 mm) in diameter.

Oscillating Piston

The unit illustrated in Figure 8.64o can be used as an on-line industrial viscometer. In this design, the alternate energization of two coils (A and B) causes a piston, located in the inner cavity of the probe, to move back and forth within the cavity. The viscosity of the process fluid resists the movement of the piston, so the travel time of the piston increases as the process viscosity rises. This travel time is measured as an indication of viscosity. About 30 sec is needed to make a measurement.

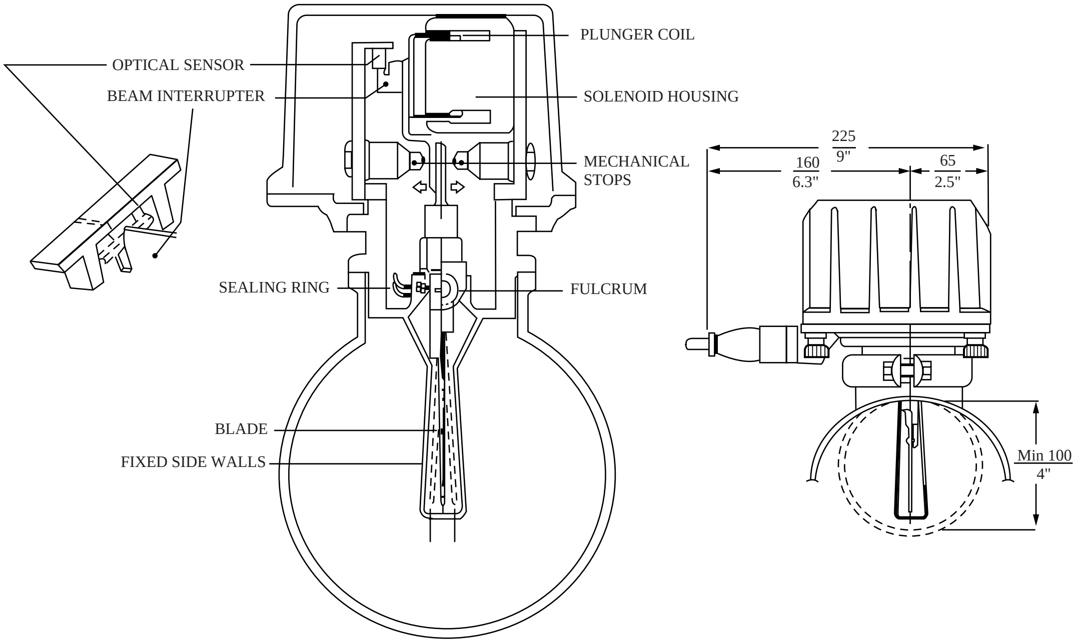

FIG. 8.64n
Oscillating-blade-type viscosity transmitter. (Courtesy of BTG Inc.)

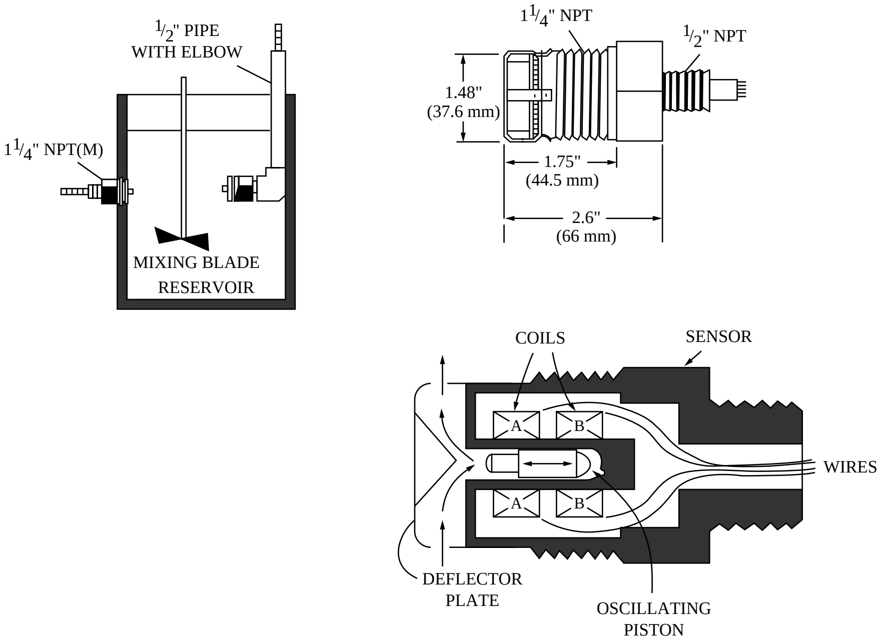

FIG. 8.64o
As the piston is made to oscillate by coils A and B, which are alternately energized, the time of piston travel is registered as viscosity. (Courtesy of Cambridge Applied Systems Inc.)

This viscometer is provided with an integral resistance temperature detector that provides temperature compensation. The oscillating piston viscometer can operate at high pressures (up to 10,000 PSIG, or 700 barg) and at high temperatures (600°F, or 315°C). The wetted parts of the sensor are made of stainless steel and Teflon.

It can be provided with a choice of pistons to cover viscosity ranges from 0.1 to 2 cP up to 1000 to 20,000 cP. To use this sensor, the process fluid should be free of solid particles that are larger than about 25 μm in size. The inaccuracy claimed is 2% of actual reading or better. The electronics are available in explosion-proof construction and can

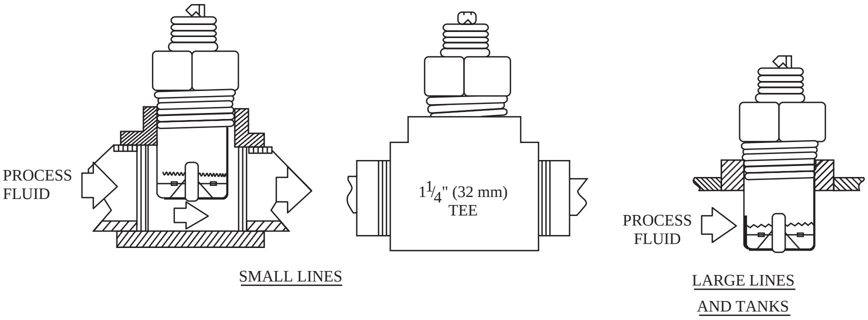

FIG. 8.64p

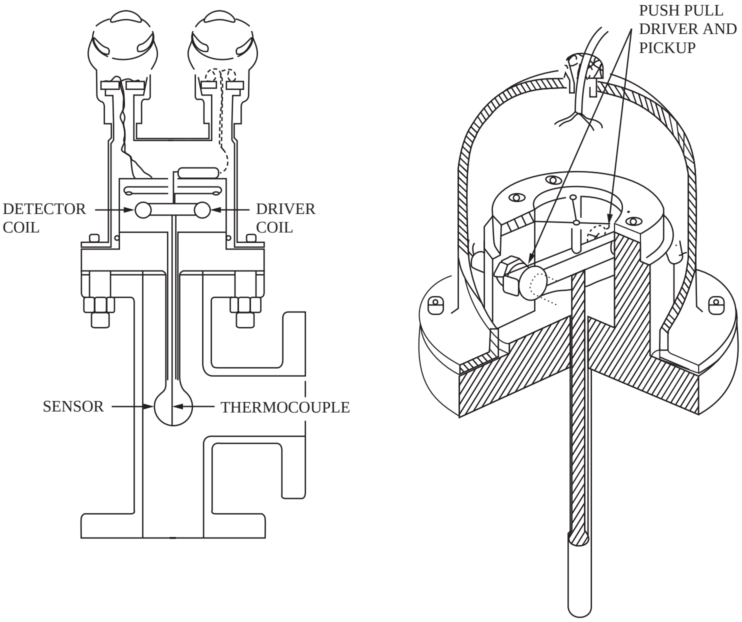

FIG. 8.64q
Torsional oscillation-type viscometers are available with spherical and rod-type probe sensors. (Courtesy of Nametre Co.)

be either the local indicator or the transmitter type. The pipeline installation of this detector is illustrated in Figure 8.64p.

Torsional Oscillation Design

The sensor in a torsional oscillation-type viscometer can either be spherical or rod-shaped. The spherical elements can be used between 0.1 and 200,000 cP, and the rod-shaped ones from 10 to 2,000,000 cP. Both can be exposed to high pressures (5000 PSIG, or 352 barg) and high temperatures (850°F, or 454°C).

As shown in Figure 8.64q, the sensor is electromechanically oscillated in torsion by a rigid inner shaft around its central axis. The amplitude of oscillation is only 1 μm, and the power required to maintain that amplitude is proportional to viscosity. To provide temperature compensation, the temperature of the process fluid is detected by a thermocouple, which is inserted through a central hole in the shaft.

To minimize inaccuracy (error), automatic range switching is available. By always selecting the smallest span to measure the prevailing viscosity, the error can be reduced to 2% of actual reading. In addition, a compensating filter is provided to minimize the effect of pipeline vibrations.

The viscometer reads the product of absolute viscosity (cP) and density. To correct for density variations, the density of the process fluid can be manually dialed in or automatically measured and compensated. These transmitters are available in explosion-proof construction and can be provided with threaded (1.5-in. NPT) or flanged (2-in. Class 150 ANSI) connections.

PLASTOMETERS

Plastometers are employed to study the plastic behavior (melt flow) of plastic materials or the molecular weight distribution of polymers. Some materials do not begin to flow unless the stress has exceeded their yield stress value. Such materials behave as elastic bodies that yield with time as the stresses exceed the yield limit. This phenomenon is called *plastic behavior.*

Plastic Behavior

Prof. Eugene Bingham assumed that the flow rate for such materials was zero when they experienced stresses below a critical value and was linear with stresses above this limit value. A body that behaves in such a manner is called a *Bingham solid* or an *ideal plastic*. Extremely few solids behave in this manner. For most plastic materials, the yield value is not sharp and shows a nonlinear behavior with a delayed and imperfect recovery. The different types of plastics behave differently, and their behavior also changes with temperature.

For this reason, a plastometer gives only a relative indication of polymer behavior, thus characterizing a plastic material. Because the shear stress/shear rate relationship is based on the molecular behavior of materials, the plasticity can be related to the molecular weight of a material or to its distribution. The plasticity of plastic materials is expressed in arbitrary units such as ASTM melt index (MI), Canadian Industries Limited (CIL) flow index, Mooney points, or percent of full scale.

In general, the plastometer consists of a heating chamber to keep the sample at constant temperature, a mechanism to apply a high shear force, and a device to measure torque or flow rate of the sample material and thereby detect the plasticity of the sample. Plastometers can be used in a laboratory (Section 8.63) to study polymeric behavior or used on line to control processes manually or automatically. This type of rheometer is an invaluable tool in manufacturing plastics and synthetic rubbers.

Cone-and-Plate Plastometer

The cone-and-plate plastometer is used to conduct tests in evaluating crude rubber, rubber compounds, or reclaims; in the control of mill breakdown of polymer molecules; in the determination of time to scorch; in the calculation of optimal cure time; and for the evaluation of the processing characteristics of plastics.

This plastometer incorporates the features of the Mooney plastometer and is designed to meet the requirements of ASTM standard test method D-1646. The working principle of this sensor is the same as discussed in connection with laboratory-type cone-and-plate viscometers (Figure 8.63r).

As shown in Figure 8.64r, this detector is designed to eliminate polymer “ball-up” and slippage tendencies by confining the sample in a disc-shaped cavity. Machined serrations provided on all of the die and rotor surfaces prevent slippage. In operation, the sample is introduced into a cylindrical test chamber where integral heaters are used to bring it to the predetermined test temperature (up to 400°F, or 204°C).

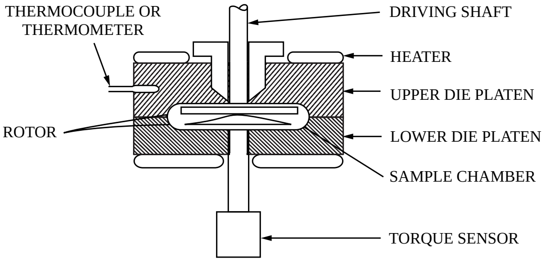

FIG. 8.64r
Cone-and-plate plastometer.

After the warm-up period has been completed, the plastic behavior of the sample is tested by driving the rotor at either a constant speed (normally at 2 r/min) or at various speeds between 0.05 to 2 r/min to test for relative molecular weight. The shearing action that takes place between the rotor and the die cavity is measured by the deflection of a calibrated U-spring, which is attached to the torque sensing rotor.

The deflection of the U-spring is directly proportional to the shearing torque of the specimen being tested. An electronic strain gauge may be attached to the U-spring to transmit this signal for continuous recording. The plastometer operates within a range of 0 to 200 (Mooney) units and has a repeatability of ±0.5 units.

The Unit of Mooney Dr. Mooney gives the following equation to determine the average viscosity ($\bar{\mu}$) of solids:

$$\bar{\mu} = \frac{G\,188.44 g\theta}{2\pi\omega R^3 (R/2a + h/b)} \qquad 8.64(3)$$

where
G = gauge reading
g = acceleration from gravity
θ = pitch radius of worn gear
ω = angular velocity of rotor, radians/sec
R = radius of rotor, inches
a = vertical clearance between rotor and stator above or below the rotor, inches
h = thickness of rotor, inches
b = effective radial clearance between rotor and stator

Kneader Plastometer

This instrument is widely used in measuring the plastic characteristics of plastic, rubber, food, pigment, cement, paint, cosmetics, and coating products. This type of plastometer is equally suitable for both laboratory and on-line measurement and the control of highly viscous flowing materials. The chief advantage of this instrument is that it measures plastic behavior of melt viscosity under conditions that are very similar to those that exist in the processing equipment.

Many different shapes of measuring heads are available (see Figure 8.64s) to accommodate a wide range of viscosities.

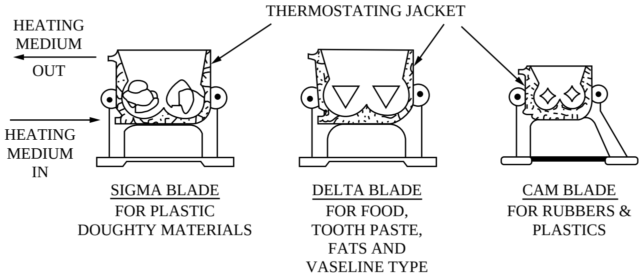

FIG. 8.64s
Measuring heads of kneader plastometer.

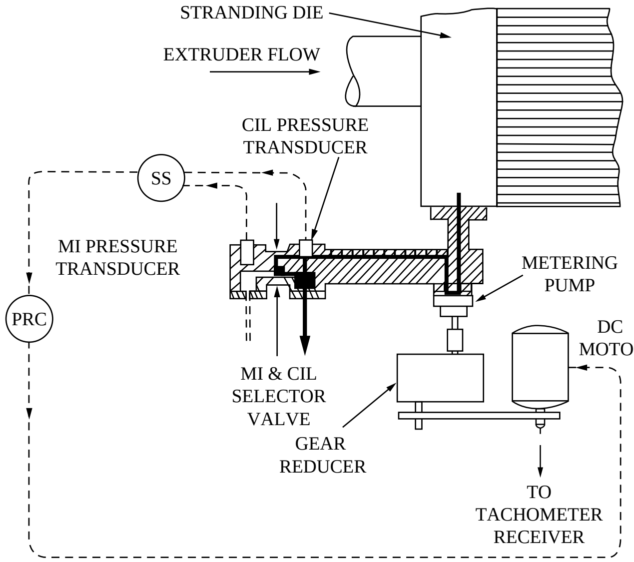

FIG. 8.64t
Pressure-controlled capillary plastomer.

In this plastometer, the jacket heater keeps the sample at a constant temperature (up to 570°F, or 299°C) by the jacketed heater. The kneader is driven by a dynamometer (available with variable-speed and fixed-speed drives). The resistance encountered by the mixing blades is detected and transmitted to the dynamometer housing, which tends to rotate in a direction opposite to that of the driving shaft.

The torque is transmitted for recording or to automatically control processes with medium-viscosity, free-flowing fluids. The readings and recordings are on a 1000-unit division arbitrary scale, used for indicating shearing torque of the specimen being tested. Repeatability is ±1% of full scale. The measurement range can be adjusted.

Capillary Plastometer

This plastometer is designed for use in polymer manufacturing plants and is based on the capillary-tube viscometer principle. The capillary plastometer shown in Figure 8.64t is calibrated to record either ASTM melt index (flow rate of polyethylene through an open-ended capillary at 190°C [374°F] and 43.2 PSIG [298 kPa] pressure). It can also record CIL flow index (190°C and 1500 PSIG [10 MPa] for polypropylene) or can alternately record both ASTM and CIL melt indexes.

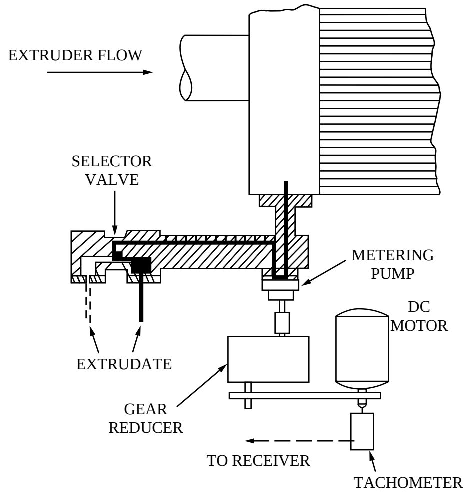

FIG. 8.64u
Flow-sensing capillary plastometer.

These two measurements for a particular polymer can be interpreted as both a molecular weight parameter and as a molecular weight distribution parameter. The capillary-type plastometer is not as versatile as the previously described plastometers.

In feeding the capillary type plastometer, the polymer melt is first conditioned to be at some specific temperature and pressure. It is then extruded through a capillary of suitable dimensions. The rate of flow of the polymer through the capillary is measured by detecting the output of the tachometer on the metering pump and is recorded in units appropriate for the test (Figure 8.64u).

The operating range of this plastometer is 0 to 200 MI and 0 to 100 CIL units, with a repeatability within ±2% of full scale. The unit is designed to operate at up to 570°F (299°C) and up to 5000 PSIG (35 MPa) in pressure.

Advantages One advantage of this instrument is that it can be used as an automatic on-line process control device for both viscous fluids and plastic solids. Especially for the solution polymerization processes, the polymer solution can be directly analyzed in this plastometer as the sample is received from the processing reactors through an autosampling device that flashes the solvent and the unreacted monomers, and melts the polymer prior to sending it to the plastometer.

For plastic solids, the die unit (capillary) can be mounted to the pelletizing extruder of the process stream for measurement. The capillary type plastometer is ideally suited for study of plastic behavior of materials that are processed through injection molding or finishing operations.

Limitations The following conditions might degrade the accuracy of the measurements obtained using capillary-extrusion viscometers:

1. Nonuniformity of sample shear rate
2. Entrance effects—energy losses at the capillary entrance and discharge points
3. Compressibility of fluids
4. Pressure loss produced by the flow in the sample chamber
5. Temperature gradient created by shear-induced heat

When performing scientific research, great care should be taken to correct for these errors. If that is done, capillary-extrusion viscometers have excellent reproducibility and are well suited for routine industrial and scientific work.

ROTARY VISCOMETERS

Rotating-cone viscometers have been applied chiefly to measure non-Newtonian fluids such as paints, printing ink, starch, size solution, and varnishes. They are designed to operate continuously in industrial environments. They measure viscosity by detecting the torque required to continuously rotate a cone, disk, sphere, or spindle in a liquid. In this type of process viscometer application, the sample is continuously replaced and is subjected to a constant shear rate; thus, the measurement of non-Newtonian apparent viscosity is possible, as well as absolute viscosity measurement of newtonian fluids.

Rotary Spindle Design

In the design illustrated in Figure 8.64v, a synchronous induction motor (for safety) drives a cage coupled through a calibrated spring to a spindle arm that supports the spindle or cylinder in the fluid being measured. During measurement, the spring tends to wind up until the force it generates equals the viscous drag on the spindle. At this point, the cage and spindle both rotate at the same speed but with a definite angular relationship to each other. This angular relationship is proportional to the torque on the spring.

Two methods are used to convert the angular relationship into a viscosity reading. One method is shown in Figure 8.64v, where one side of a variable capacitor is attached to the cage and the other to the spindle arm. A capacitance is thus made proportional to the angular relationship between cage and spindle.

The other method is based on a potentiometer mounted in the cage with its free member connected to the spindle arm. In this case, a resistance is made that is directly proportional to the angular relationship between cage and spindle. In either case, the measured signal is transmitted to a receiver and is converted into viscosity units.

When measuring low viscosities, the variable capacitor type design is preferred. This type of viscometer can measure viscosity ranges from 0–10 cP (0–0.01 Pa·s) to 0–50,000 cP (0–50 Pa·s). Its inaccuracy is ±1% of full scale between the ranges of 0 to 100 and 0 to 50,000 cP (0 to 0.1 and 0 to 50 Pa·s). Its repeatability is ±0.3% of full scale for all ranges.

The response time of this viscometer is less than 30 sec for detecting a full scale change in viscosity. The measurement range of this viscometer can be varied over a 30:1 ratio by changing the size or shape of the spindle. The standard spindle speed is 50 r/min. In some installations, the maximum range can be increased to 0 to 100,000 cP (0 to 100 Pa·s).

Installation This viscometer may be installed on a tank, in an open vessel, or in a sampling line (Figure 8.64w). For in-line installations, the flow rate of the process liquid should be constant, nonpulsating, and laminar (less than 3 GPM [11.4 l/m] for a standard 4-in. [101.6-mm] pipe). Swirling motion in the measurement chamber may be reduced by installation of a spider-type deflector in the inlet port.

The viscometer head is designed to operate at temperatures up to 160°F (71°C) and at pressure ranges of 8 mm Hg absolute to 100 PSIG (1 to 690 kPa). The head should be purged with dry air or other inert gases at a rate of 0.5 ft^3/min

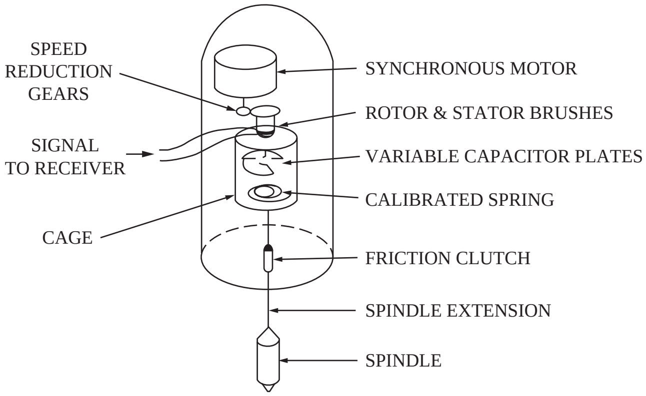

FIG. 8.64v
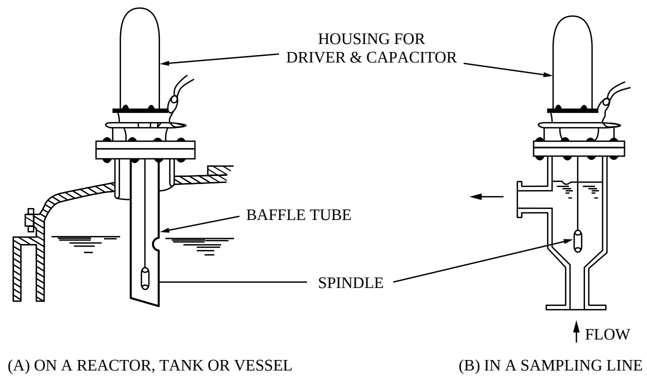
The operation of the rotating-spindle-type industrial viscometer.



(A) ON A REACTOR, TANK OR VESSEL

(B) IN A SAMPLING LINE

FIG. 8.64w
Tank and pipeline installation of the rotating spindle viscometer.

(2.4×10^{-4} m^3/s) or greater. A positive pressure differential of 3 PSI (21 kPa) should be maintained between the viscometer and the process vessel to prevent liquid or vapor penetration into the head.

The temperature of the mounting flange on which the viscometer is placed should not exceed 600°F (316°C). Above 220°F (104°C), it is necessary to use a cooling pad and place it between the flange and the viscometer. The process liquid temperature can be up to 2500°F (1370°C).

Performance The rotating-cone viscometer is not affected by normal industrial vibration. It is provided with overrange protection through a friction clutch on the spindle extension. It is simple to clean the spindle. The sample fluid should be maintained at a constant temperature, or the viscosity measurement should be compensated for temperature variations. Logarithmic temperature-compensating units are available and are matched to the viscosity–temperature relationship shown by the particular process fluid. Logarithmic compensation to within 1% error over a span of 10°F (6°C) can be provided.

A baffle tube should always be installed when this viscometer is used in an agitated tank or reactor to obtain laminar flow condition. However, if very violent agitation or bubbling conditions exist, this viscometer should not be used at all. The spindle should always be immersed, and the liquid level should be kept constant to obtain reproducible readings.

The frequency of the power supply should be checked. Wide deviations from the specified frequency will cause spindle speed changes and can introduce errors in the viscosity measurement of non-Newtonian fluids, because their apparent viscosity is related to shear rate.

The rotating-cone viscometer is an electromechanical device, so a monthly preventive maintenance and cleaning schedule is recommended. If the unit is operated continuously, the speed reduction gears will need to be replaced on a yearly basis.

Because of its simple design, ease of cleaning, and nonclogging features, this viscometer has been successfully used in monitoring solid and liquid blending processes. Rotating-cone viscometers are quite versatile in their application over wide ranges of viscosities and are equally applicable for measuring the viscosities of newtonian and non-Newtonian fluids.

Magnetically Coupled Viscometer

In the rotating-cone viscometer shown in Figure 8.64x, a magnetic coupling is provided between the electronic detector (which is at atmospheric pressure) and the rotating sensor in the measuring cell (which is operated at the process pressure). With this separation between atmospheric and pressurized areas, the requirement for purging is eliminated and, in the measuring cell, operating conditions can be up to 2850 PSIG (19.7 MPa) at 20°C or 1620 PSIG (11.2 MPa) at 300°C.

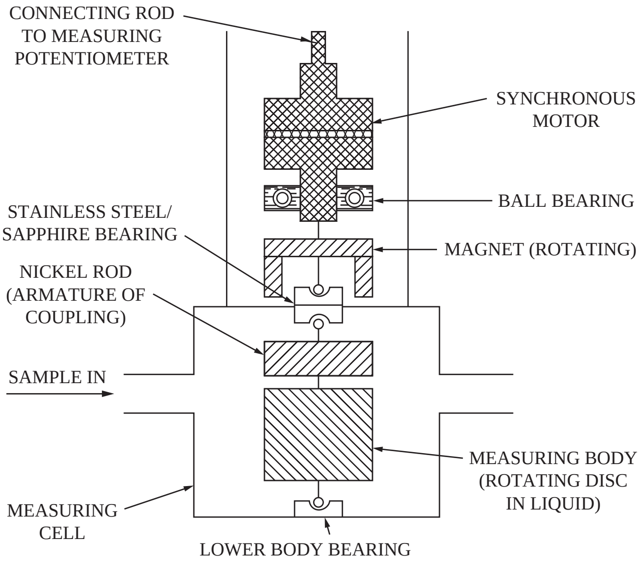


FIG. 8.64x
Magnetically coupled rotational industrial viscometer.

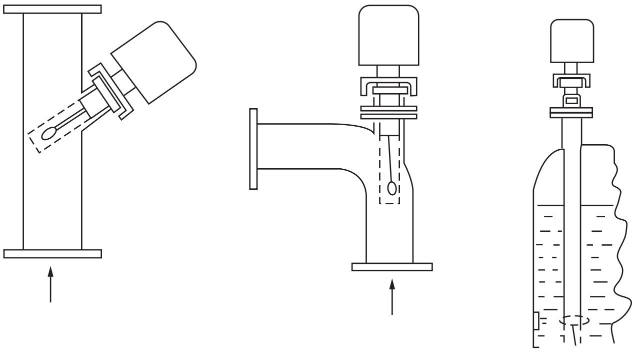

FIG. 8.64y
Pipeline and vessel installations of the gyrating element viscometer. (Courtesy of C. W. Brabender Instruments Inc.)

The magnetically coupled viscometer should not be used to measure fluids that contain fiber, ferrite, or abrasive materials, because they interfere with the operation of the magnetic coupling or can damage the stainless steel–sapphire bearings.

Gyrating-Element Viscometer

The viscometer illustrated in Figure 8.64y differs from the previously described designs in that its element gyrates instead of rotates. This gyrating motion is the result of the drive shaft not being straight. The drive and the torque-sensing mechanism are isolated from the process side by stainless steel bellows that are capable of operating at up to 1000 PSIG (70 barg) operating pressures and 572°F (300°C) operating temperatures.

The drive motor speed is adjustable from 15 to 120 r/min, and the unit can detect viscosities between 10 and 10 million cP (the overall range is subdivided into several working ranges).

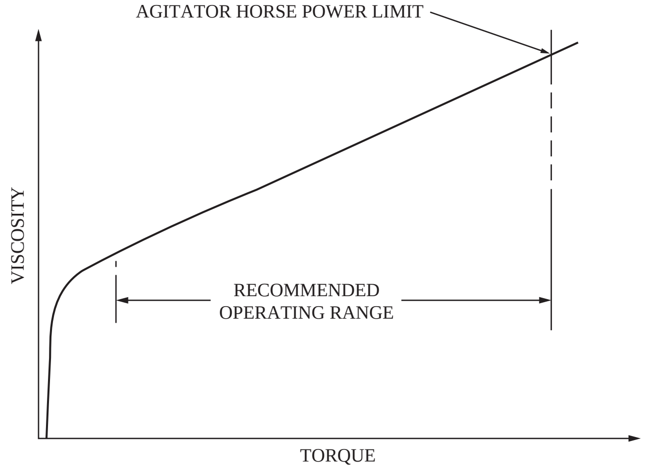

FIG. 8.64z
Relationship between viscosity and torque in agitator power viscometer.

For pipeline installation, the minimum pipe size is 4 in. (100 mm).

Agitator Power

This type of instrument is widely used in the paper industry to control and measure the consistency of paper pulp slurries. In this viscometer, instead of measuring the torque exerted on a rotating cone, a transmitting wattmeter is used to detect the torque exerted on the process agitator. It measures the power consumed as the agitator is being driven in a mixing tank.

As shown in Figure 8.64z, because most of the industrial agitator motors are oversized, the torque response of this sensor is poor at low viscosities. The size of the motor and impeller should be selected so that the agitator will operate in a region where the viscosity-vs.-torque relationship is linear. The motor, reducer, bearing assembly, and pressure seal are all part of the viscometer, and any change in characteristics of these components would also affect the power consumption of the motor and, in turn, the viscosity reading.

This instrument is simple and easy to install, but it has low sensitivity and a low ratio between agitator power consumption and changes in viscosity of the fluid. Many different impeller designs are available to improve the sensitivity and rangeability. Because it is a self-cleaning and agitating design, it is ideal for materials that have a tendency to cling to slow-moving parts or to settle out from suspensions.

This type of instrument should not be used with fluids that are thixotropic or rheopectic (materials whose viscosity changes with duration of agitation or shear). However, it can be used in in-line applications for all non-Newtonian fluids, because the process fluid is continuously replaced by a fresh sample at a reasonably constant flow rate.

The accuracy and sensitivity of this method of viscosity detection are both poor, but its repeatability is reasonable at about ±1% of full scale.

Double-Cylinder Viscometer

Figure 8.64aa illustrates the double-cylinder type of in-line viscometer. It consists of a stationary outer and a rotating inner cylinder. This viscometer provides self-cleaning operation and fast measurement.

The process fluid is drawn into the measuring chamber through the apertures in the stationary outer cylinder by the propeller. The propeller pumps the process fluid downward into the measurement zone, where the sensor cylinder is rotated inside the stationary external cylinder. The measuring zone is the clearance space between the two cylinders. The torque required to rotate the measuring cylinder is proportional to viscosity.

The self-cleaning nature of this viscometer is partially created by the lip on the upper edge of the measuring cylinder, which serves to prevent the entry of larger particles into the measurement zone. In addition, the solids that enter the measurement zone can also leave through two slots that are provided in the outer cylinder. Large particles will not enter the measuring zone at all but will leave through the outlet holes that are provided on the top of the rotating cylinder.

Viscometers are available for in-line installation in pipe sizes from 3 to 10 in. (76 to 250 mm) in diameter. The viscometer can detect viscosities from 5 to 350 cP at pressures up to 145 PSIG (10 barg) and temperatures up to 300°F (150°C). The wetted parts can be made out of stainless steel or Hastelloy C with Viton, EPDM, or silicone O-ring seals. The mechanical seal can be cooled and lubricated by water.

VIBRATING-REED VISCOMETER

The vibrating-reed viscometer is designed for continuous measurement. It can be installed directly into the process vessels or pipelines. As illustrated in Figure 8.64bb, it consists of a frequency generator, a vibrating spring rod, a probe, and a pickup unit to complete a measurement loop through the process material.

The drive coil is excited at a frequency of 120 Hz from a 60-Hz input frequency. This produces a pulsating magnetic field that causes the drive armature to vibrate at the same frequency. The mechanical vibration of the drive armature is transmitted to the probe through an all-welded, pressure-sealed node that is located where the amplitude of vibration is zero.

The principle of operation is based on the fact that the amplitude of probe vibration depends on the viscosity of the process media. The resistance to the shearing action caused by the probe's vibration increases with an increase in the viscosity of the process media. The amplitude of probe vibration is sent through a second welded node point by the upper spring rod to the pickup end of the detector.

The pickup end is similar to that of the driver end, except that a permanent magnet is used to induce a 120-Hz AC voltage in the pickup coil from the vibration of the pickup armature.

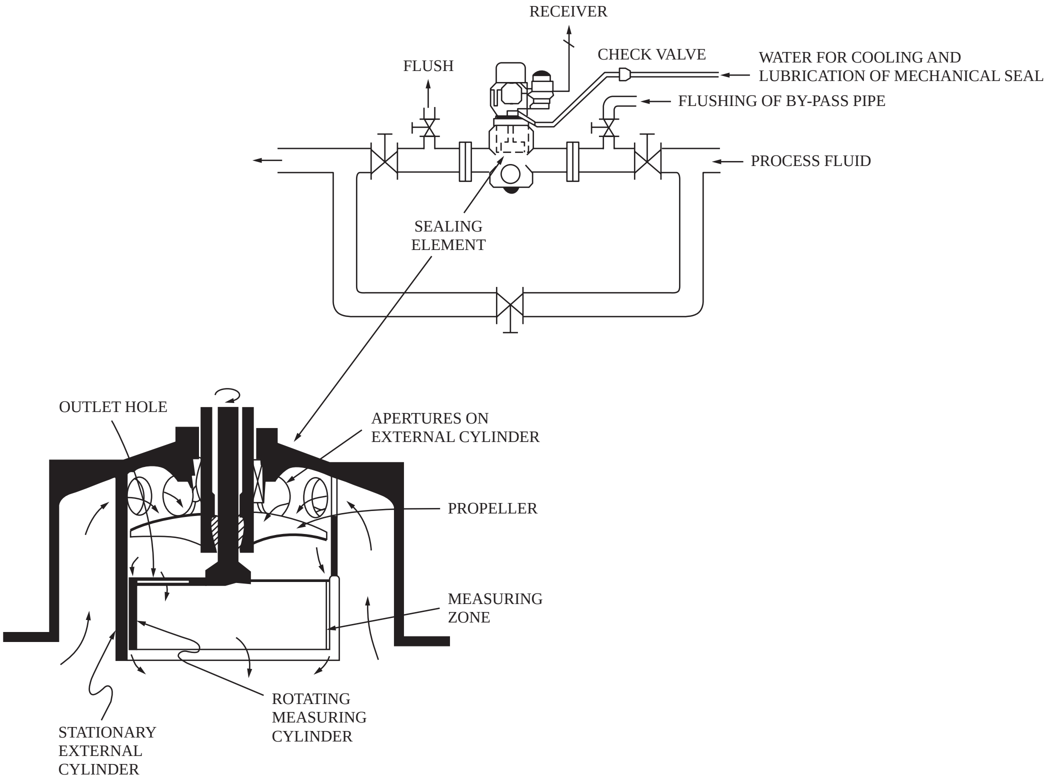

FIG. 8.64aa
Self-cleaning cylinder viscometer. (Courtesy of BIG Inc.)

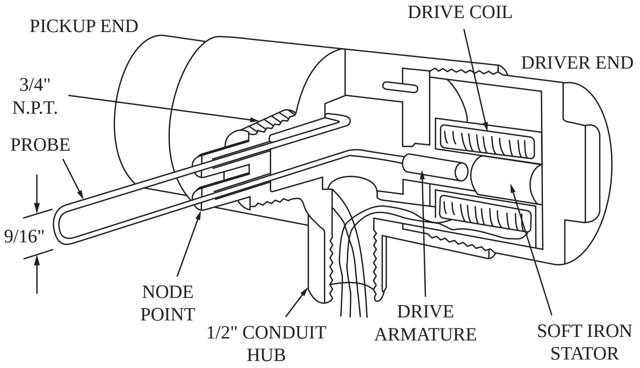

FIG. 8.64bb
Vibrating-reed viscometer.

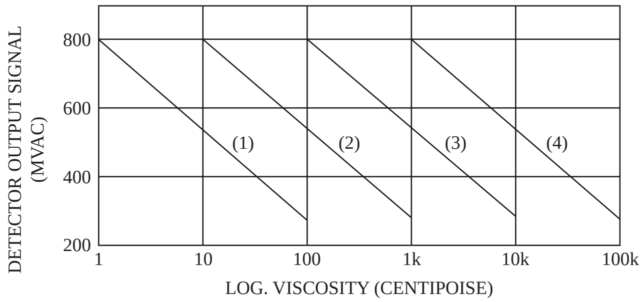

FIG. 8.64cc
The response curves of four vibrating-reed viscometers.

The magnitude of the voltage generated in the pickup coil is a measure of the process viscosity, because it is proportional to the pickup armature vibration. The 120-Hz output signal from the detector is converted into a 0 to 10 mV DC signal to indicate, record, or control the viscosity of newtonian or non-Newtonian fluids.

Performance Inaccuracy of the instrument is about ±1% of full scale, and reproducibility is a little better. There are five different detector units to cover the viscosity ranges from 10^{-1} to 10^{5} cP (10^{-4} to 10^{2} Pa·s) at relatively low shear rate. Typical response curves of four different detector units are shown in Figure 8.64cc.

Because the viscosity of fluids depends on their temperature and pressure, it is mandatory to maintain the process pressure and temperature constant. As shown in Figure 8.64dd, if the fluid temperature must be allowed to fluctuate, temperature compensation is required. Before ordering a viscometer for in-process use, the fluid's viscosity must be measured as a function of temperature so that this characteristic curve can be used in the converter.

For accurate measurements, *laminar* flow conditions should be maintained. Therefore, the installation of this type of viscometer directly in an agitated vessel is not recommended.

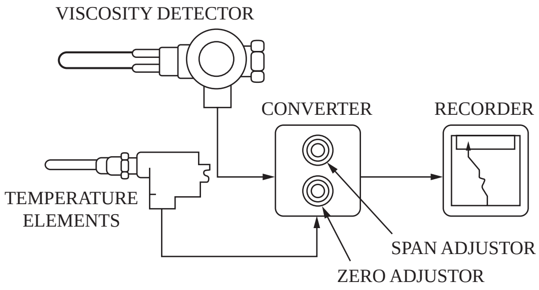

FIG. 8.64dd
Complete loop diagram of a temperature-compensated vibrating-reed-type viscosity recorder.

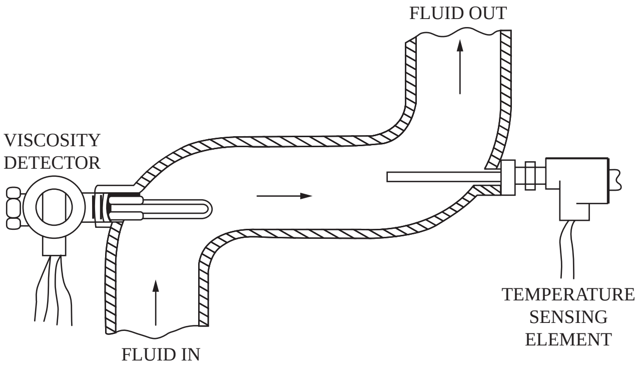

FIG. 8.64ee
Installation recommendation for an in-line vibrating-reed viscometer.

If it must done, the viscosity reading should be taken only when the agitator is off.

Installation and Calibration Complete immersion of the probe in the process fluid is essential. Figure 8.64ee illustrates the recommended pipeline installation of this viscometer probe in vertical upward flow. Complete immersion of the probe is required at all times. To improve the accuracy of measurement, the recommended viscometer installation is in a temperature, pressure, and flow rate controlled sample loop.

The amplitude of vibration will change with condition and age of the probe. It is good practice to calibrate the instrument regularly when it is used for critical operations. Material build-up on the probe can occur if the process material has a tendency to adhere or if it contains long fibrous materials. Slight or loose buildup can be removed by periodic in-line purging. If the buildup can be severe, this type of viscometer should not be used.

Because the detector unit transmits a low-voltage signal, the use of shielded wires is recommended. The wires should be grounded at both ends to minimize noise pickup. Supply voltage variations between 105 and 125 V will have no harmful effects. The *frequency of supply power should be checked*, because the probe vibration frequency is controlled by the line frequency. If the vessel or pipeline vibrates, and this vibration frequency is close to 120 Hz, it can interfere with the reliability of viscosity measurement by this sensor.

CORIOLIS MASS FLOW METER

Measuring Tube Torsional Movement

Coriolis mass flow meters currently are well established in process industry applications and have extremely good functionality and performance. They have proven multivariable measurement capabilities, including mass flow, density, and temperature, that can be transmitted via various methods such as 4 to 20 mA signals, pulse, and various fieldbus links. Ease of installation and maintenance are also well established. Further details on these flow meters are available in another section of this volume.

Very recently (at the time of the writing of this volume), a new development was announced by a manufacturer of Coriolis meters. Viscosity can now be added to the list of multivariable measurements. Viscosity is obviously a key process variable, and to be able to acquire it via an existing proven technique is significant. Four significant process variables can be measured simultaneously with proven in-line technology.

The measurement principle for this viscosity process variable is the torsional movement of the measuring tube. For an optimal balance, and for isolation from external influences, a pendulum is mounted on the single measuring tube that causes an additional torsional movement on it, as shown in Figures 8.64ff and 8.64gg. Based on this technique, torsional movements are created in addition to the lateral oscillation movements of the measuring tube.

A velocity profile is created on the tube cross section by the torsional and lateral oscillation movements. This is shown in Figure 8.64hh. Viscosity measurement is based on the shape of the velocity profile, shear forces, and corresponding

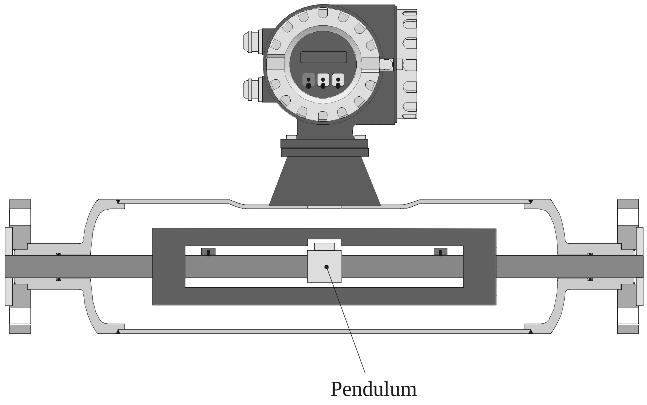

FIG. 8.64ff

shear rates developed in the fluid. This is similar to the rotational element viscometers in which shear rates are related to viscosity.

The shear forces dampen the tube oscillation, so a larger drive force is required to maintain tube oscillation. Thus, viscosity can be determined by measuring the required power or excitation current for tube oscillation and torsional movement.

Repeatability and measurement inaccuracy are both ±5% of actual reading or ±0·5 cP, whichever is greater. The in-line meter is 2 in. in diameter and is provided with 600-lb flanges. The output signal can be 4 to 20 mA or digital. The speed of response of the meter is high and therefore suited for closed-loop process control applications.

CONCLUSIONS

Each viscometer exposes the process fluid to a different shear rate, so, when the process fluid is non-Newtonian, the apparent viscosities will vary with shear rate, and the readings will vary with the viscometer used.

Some viscometer designs provide intermittent readings (falling-ball or falling-piston, oscillating-blade, etc.), and others are continuous. In closed-loop control, the continuous ones are much preferred. Some viscometers require the taking of a sample from the process (capillary, float, rotational), but others can be inserted directly into the process pipe or vessel. Because sampling systems usually increase installation and maintenance costs, and because sampling also adds dead time (transportation lag) to the measurement, the in-line designs are generally preferred.

Viscous process fluids usually also contain solids. For this reason, the designs that cannot tolerate the presence of solids (capillary, float) are less desirable, and the self-cleaning designs (oscillating, vibrational, double-cylinder) are preferred.

In some process applications, the operating viscosity can change over a wide range. If that is the case, measurement error can be reduced by using viscometer designs that are capable of automatic range changing, e.g., the torsional oscillation design.

The torque or shear force measured by most viscometers will also vary with changes in temperature and density. Therefore, viscometer designs that provide automatic temperature compensation and allow for manual or automatic density correction are likely to provide more accurate readings.

A particularly appealing new approach involves using existing Coriolis mass flow technology and extending the principles and techniques to extract process viscosity. This yields a proven industrial in-line continuous measurement technique with three multivariable measurements that can spin out an additional key process variable, viscosity. Installation is easy, and no additional independent complex sensors are required.

In addition, one must also be concerned with the viscosity range, design pressure, design temperature, and required precision of the measurement. Table 8.64a provides a summary of the design features of the viscometers discussed in this section.

8.65 Water Quality Monitoring

C. P. BLAKELEY (1974) **G. L. COMBS** (1995) **B. G. LIPTÁK** (2003)

Measured Water Quality Parameters:	Ammonia, biochemical oxygen demand (BOD), chemical oxygen demand (COD), chlorine, color, conductivity, dissolved oxygen (DO), fluoride, mercury, nitrates, odor, oil, ORP, ozone, pH, phosphorus, temperature, total carbon (TC), total inorganic carbon (TIC), total organic carbon (TOC), total oxygen demand (TOD), turbidity, volatile organic compounds (VOC)
Physical Variables:	Air temperature, rainfall, river flow or stage (level), sunlight, wind direction and speed
Cost:	Costs vary widely, depending on system requirements and components to be measured. For example, a single-parameter measuring system could cost as little as $3000, whereas a completely integrated monitoring system capable of simultaneous measurement of multiple volatile organic components at the ppb level and equipped with a full complement of user-specified data transmission options may cost as much as $75,000. Sample system, installation, and the cost of building a suitable shelter can double the total cost. For the costs of individual sensors, refer to the individual sections in this chapter.

INTRODUCTION

Water quality monitoring systems provide a means of measuring the condition of the water. These systems range from single-parameter measurements to complex systems integrating multiple sensors with data manipulation and recording capabilities and, in many cases, with means for remote communications and data transfer. The rapid growth of the human population and of industry has focused attention on the quality and condition of our rivers, lakes, and drinking water supplies. Stringent laws have been passed to limit the concentration of elements that are hazardous to health as well as to provide a mechanism to monitor the general quality of the environment.

Categories of Monitors

Water quality monitors can be categorized by purpose as described below.

Monitoring for General Use These systems are usually permanent installations used primarily for data collection for public information, notification, and similar purposes.

Regulatory Compliance Monitoring The purpose of these systems is to confirm compliance with a particular regulation or water quality standard that was imposed by a regulating agency, either on the local, state, or federal level. These packages are characterized by the stringent requirements that are implemented in standardizing equipment and techniques as well as implementing formal procedures for operation, calibration, and quality assurance monitoring.

Industrial Monitoring These systems serve a wide range of uses, including regulatory compliance monitoring, incoming water quality monitoring, aqueous process reaction monitoring, process leak detection monitoring, and biological/aeration pond monitoring. These systems are often typified by the use of on-line instrumentation that, in some cases, is suitable for operation in hazardous plant locations in addition to offering continuous operation with minimal attention.

MONITORING SYSTEM COMPONENTS

Regulatory agencies have conducted numerous studies to evaluate and determine the efficiency of a variety of types of systems and technologies. These evaluations have resulted in increasing the required quality and the number of suppliers and monitoring techniques that are available. The reliability of such systems has also improved over the years, as has their flexibility, which was required to meet unique demands of individual installations.

A water quality monitoring system usually consists of a sampling system, a group of sensors, and a data transmission/logging section. For the package to function properly, these components must be fully integrated and coordinated in their automatic operation.

Sampling Systems

A key element in any continuous analysis is the sample transport system. It is essential to provide a reliable and reproducible means of bringing a sample to a sensor or analyzer.

Figure 8.65a depicts a method of placing the sensor directly into the monitored water body for continuous sensing. This technique is used to measure variables such as pH, conductivity, dissolved oxygen, and water temperature. The submersible assembly is anchored directly in the stream and is ideal for monitoring water quality parameters in protected areas.

It is possible in some cases to place the sensor directly into the water, but most installations require a water sample to be transferred to a permanently installed analyzer. Figure 8.65b depicts a permanent water quality monitoring installation. The sampling system in such an installation might include filters, pumps, gauges, valves, and transport lines.

Duckbill Samplers This sampler should be considered when samples are to be collected at remote locations, from below tanks, sewers, channels, sumps, lakes, or rivers. As shown in

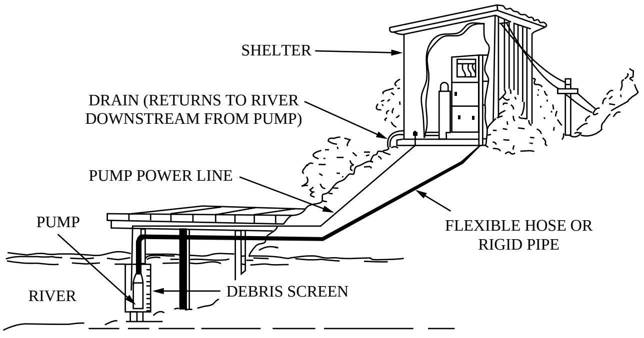

FIG. 8.65b

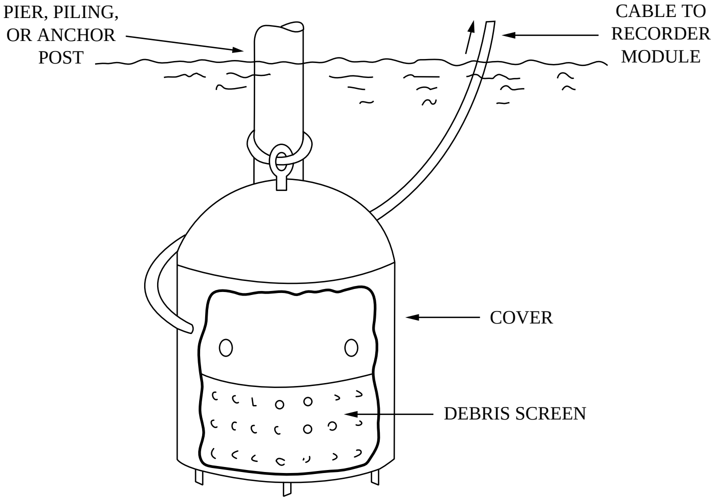

FIG. 8.65a
Submersible sensor housing that can accommodate one or two individual local sensors (pH, conductivity, temperature, etc.).

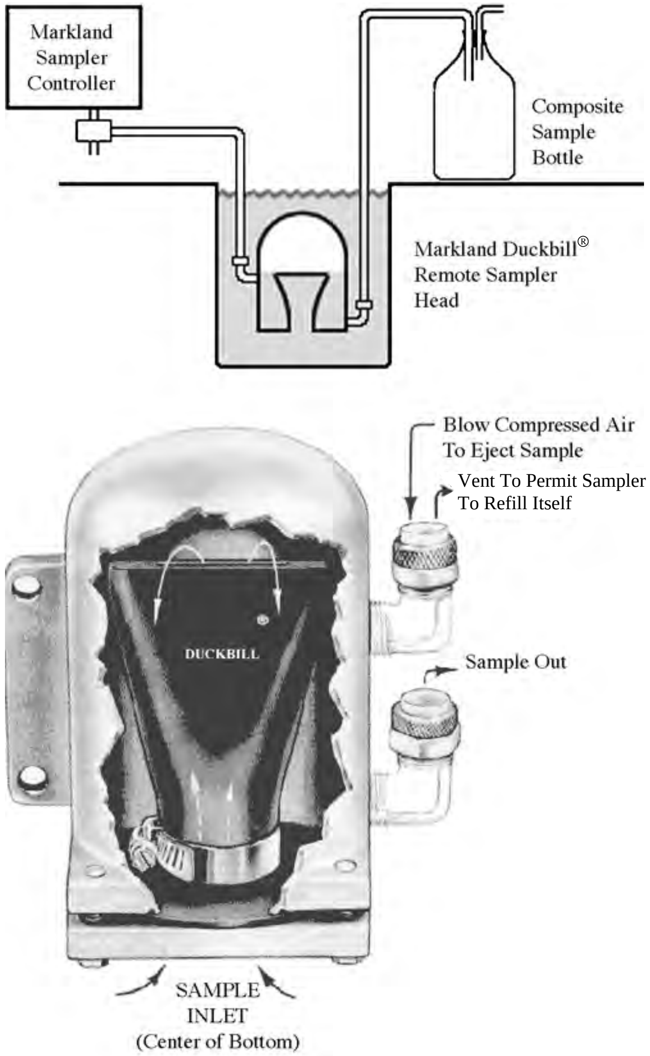

FIG. 8.65c
Remote sampler head for composite sample collection at remote locations. (Courtesy of Markland Specialty Engineering Ltd.)

Figure 8.65c, this device has no moving mechanical components—only a rubber (EPT, Buna-N®, or Viton®) bucket-shaped "duckbill" inside a housing made of PVC, aluminum, or stainless steel. This rubber insert closes around fibers and particulate matter without jamming and is operated by compressed air. An automatic controller is provided with which the user can adjust the frequency at which samples are taken into a composite sample collection bottle.

The sample enters through the bottom of the sampler by gravity. The sampler is installed below the monitored water or process liquid (or sludge) level, and it traps some air at the top of the chamber as it fills. When a sample is required, compressed air is introduced, which closes the duckbill inlet and discharges the sample through the bottom of the chamber. When a new sample is to be drawn into the sample chamber, the compressed air is vented, and a new fill cycle is initiated.

Sample Transport In all applications, care should be taken to ensure that a representative sample is sent to the analyzer. Sampling systems in general, and the components of liquid sampling systems, are discussed in Section 8.2. Figure 8.65d illustrates a typical sample transport system.

Prefiltering may be necessary when the presence of particulate or algae might interfere with the operation of pumps or valves. Screens, Y-type strainers, or cyclone-type filters may be appropriate in other applications. However, for some measurements, filtering of a sample may change the concentration to be measured or change some other characteristics of the sample. Therefore, the effect on the integrity of the sample should be considered before selecting the method of filtering.

Pumps can be submersible. The exact choice of pump should consider the type of analysis being performed. For example, dissolved oxygen and volatile organic compound (VOC) analyses may limit the choice of pumps, because their concentrations can be altered by changing pressures or by any cavitation that occurs in the pump. In industrial applications, the pump must be rated for the correct hazardous location. Care should also be taken to ensure that the pump can

TABLE 8.65e
Partial List of Measured Components in Water

	Typical Instrument Measuring Range	*Analysis Method*
Acidity	1.0–3.0 pH	Titration
Alkalinity	0–300 ppm	Titration
Aluminum	0–50 ppb	Colorimetry
Ammonia	0–10 ppm	Colorimetry, ISE, chromatography
Boron fluoride	0–500 ppm	ISE
Bromide	0–2.0 ppm	ISE
Cadmium	0–20 ppm	ISE, chromatography
Calcium	0–300 ppm	Titration, ISE
Chloride	0.1–200 ppm	ISE, colorimetry
Chromate	0–100 ppb	Colorimetry
Copper	0–20 ppb	Colorimetry, ISE, chromatography
Cyanide	0–100 ppb	Colorimetry, titration, ISE, chromatography
Fluoride	0–2.0 ppm	ISE
Hardness (Ca + Mg)	0–2.5 ppm	Titration
Hydrazine	0–50 ppb	Colorimetry
Hydrogen sulfide/sulfide	0–500 ppb	Colorimetry/ISE, chromatography
Iron	0–20 ppb	Colorimetry
Lead	0–1 ppm	ISE, chromatography
Manganese	0–200 pm	Colorimetry
Nitrate/nitrite	0–1 ppm	Colorimetry
Phenols	0–5 ppm	Colorimetry
Phosphate	0–1 ppm	Colorimetry
Silica	0–10 ppb	Colorimetry
Sodium	0–10 ppb	ISE
Urea	0–100 ppm	Colorimetry

ISE = Ion-selective electrode

handle particulate loading that might be present in the sample on a continuous basis or during excessive runoff (as, for example, might occur during rain).

Transport lines may require heat tracing or other forms of heating to protect the sample from freezing during cold seasons. In addition, the presence of corrosive materials such as chlorides, strong acids, and bases in the sample may also limit the materials of construction that can be used in the sample transport system.

SENSORS AND ANALYZERS

A water quality analyzer may be as simple as a probe inserted into the water and connected to a conveniently located recorder or as complex as a data collection system with multiple sensors distributed in several locations and connected to a centralized data recording and compiling system.

Water Quality Parameters

Table 8.65e lists a number of components that are typically measured in a water sample, plus other water quality characteristics, along with typical concentration ranges and their available methods of analysis. In some instances, there are several suitable methods of analysis. Trace concentrations of components are monitored in drinking, industrial, and ultra-pure water. Other applications include the measurement of specific pollutants in municipal and industrial wastewater streams.

Ion-Selective Electrodes

As shown in Table 8.65f, a wide variety of electrode designs are available for measuring the presence of different ions (see Section 8.28 for more details). These electrodes develop an electrical potential reflecting the ionic activity in the process stream. It is important to realize that the activity, not the concentration, of an ion is actually being measured. In dilute solutions, however, the activity may approach the concentration.

TABLE 8.65f
Specific Ion Electrodes

		Interfering Ions																								
		Anions													*Cations*											
Ion	*Electrode pH Range*	*ClO^-*	*I^-*	*ClO_3^-*	*Br^-*	*$S^=$*	*CN^-*	*$S_2O_3^-$*	*NH_3*	*OH^-*	*Cl^-*	*NO_3^-*	*$HPO_4^=$*	*HCO_3^-*	*Cu^{++}*	*Mg^{++}*	*Ba^{++}*	*H^+*	*Fe^{++}*	*Ni^{++}*	*Zn^{++}*	*Na^+*	*K^+*	*Ca^{++}*	*Sr^{++}*	*Electrode Type*
Chloride	0–14		x		x	x	x	x	x																	Solid state
Sulfide	0–14		None													None										Solid state
Nitrate	2–12	x	x	x	x																					Liquid membrane
Fluoride	1–8.5		x		x					x	x	x	x	x												Solid state
Divalent cation	7–8															Sensitive to most divalent actions										Liquid membrane
Calcium	5.5–11.0															x	x									Liquid membrane
Copper^{++}	2.5															x	x	x	x	x	x	x	x	x	x	Liquid membrane
Lead	4–7														x					x	x	x		x		Liquid membrane
Cyanide	0–14		x		x					x	x	x	x	x												Solid state
Hardness	5.5–11														x		x		x	x	x	x				Liquid membrane

Conductivity Specific conductance or conductivity provides an estimate of the total dissolved ionized solids in water (Section 8.17). It is a nonspecific method of measurement, as it is sensitive to all ions in the sample. Changes in the conductivity of the water are usually indicative of a discharge or runoff of strong acids, bases, or other highly ionizable material. Instruments are typically capable of measuring from 0 to 1000 mS/cm. Conductance of water can vary widely between various bodies and is highly temperature dependent.

pH Measurement pH is a measurement of the hydrogen ion activity in a sample (Section 8.48). It is defined as the negative logarithm of the concentration of the active hydrogen ions, expressed in gram moles per liter. Typical pH values range from zero (high acidity) to 14 (high alkalinity).

A pH of 7 indicates a neutral solution. Rapid changes in pH can signal a discharge or spill, because the pH of open bodies of water would normally change only gradually.

Oxidation-Reduction Potential Oxidation-reduction potential (ORP) is a measurement of the oxidizing or reducing materials in the water (Section 8.41). It is an electrochemical measurement of the potential developed by these materials when present in the water. Under normal circumstances, a body of water will have both oxidizing and reducing components in nearly equal concentrations. A sudden discharge can therefore be detected by detecting the changes in ORP. As are most others, ORP measurement is temperature dependent.

Oxygen Demand Detectors

Biochemical oxygen demand (BOD), chemical oxygen demand (COD), and total oxygen demand (TOD) analyzers (Section 8.7) consist of a sampling and conditioning section that is followed by the analyzer itself. Analysis typically involves quantifying the amount of oxygen uptake by the sample.

The dissolved oxygen concentration of the water is a function of the solubility of oxygen at a particular temperature (Table 8.65g) and barometric pressure (Table 8.65h). Dissolved oxygen (DO) content usually describes the condition of the receiving waters (Section 8.43), whereas BOD, COD, and TOD usually describe the pollutant concentration in the discharged wastewaters.

Biochemical oxygen demand measurements provide information on the amount of oxygen required for the biochemical degradation of the organic matter in the water. Biochemical oxygen demand measurement is rather slow, because it requires a minimum a five-day incubation period for analysis.

Chemical oxygen demand measures the quantity of oxygen that organics and certain oxidizable inorganic compounds that are present in the water will consume. In COD measurements, the oxygen is obtained from the reduction of a dichromate solution. The amount of oxygen required to oxidize the organics in the sample provides information on the COD concentrations in the water.

TABLE 8.65g

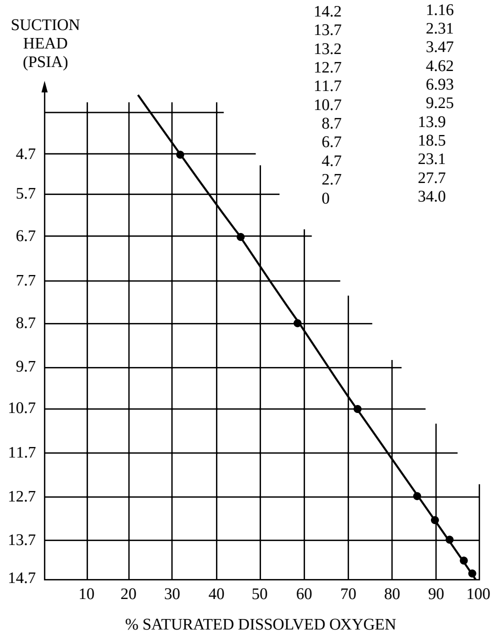
2.7	27.7	18.4
0	34.0	0



Total oxygen demand measures the oxygen demands of both the organic and the inorganic compounds that react with and consume oxygen. The readings reflect the consumption of oxygen in units of mg O_2 per liter of sample or in ppm.

Dissolved Oxygen Sensors

Dissolved oxygen concentration indicates the amount of oxygen present in the water and therefore the ability of receiving waters to support life. Electrochemical probes (Section 8.43) are often used to measure the amount of dissolved oxygen in water. In these probes, the dissolved oxygen passes through a membrane and is reduced at the cathode. The amount of current produced is an indication of the dissolved oxygen concentration.

Total Organic Carbon and Total Carbon Analyzers

Total organic carbon and total carbon (TC) analyzers (Section 8.58) convert the carbonaceous molecules to CO_2, which is then measured by infrared or other detectors. The carbon in the sample can be converted to CO_2 catalytically or by means of high-temperature (750°C) oxidation.

Total organic carbon measurements are often performed by the addition of an acid followed by sparging, which serves to remove the inorganic carbon from the sample. In the TC mode, no sparging takes place, because organic and inorganic carbons are measured together.

Turbidity Meters

Turbidity meters typically consist of a sample cell that is provided with a light source, lens, and photocells for detection (Section 8.60). The water sample flows through the cell, and the cloudiness, caused by the suspended solids, is measured and recorded. Turbidity analyzers detect the amount of light that is either absorbed or scattered by suspended solids before reaching the detector, which is placed 180° to the incident light path.

Nephelometers

Nephelometry measures only the light scatter caused by suspended solids in the sample. Nephlometric measurements are therefore made with their detectors at a 90° angle to the incident light path.

The unit of measurement most often used is the nephelometric turbidity unit (NTU). As the amount of suspended particles in the sample increases, the amount of light scatter also increases, yielding a higher NTU value.

Wet Chemistry and Autotitration

Sophisticated hardware such as autotitrators (Section 8.66) and flow injection analyzers (FIA) are also used in water quality monitoring. Figure 8.65i gives a schematic of a flow

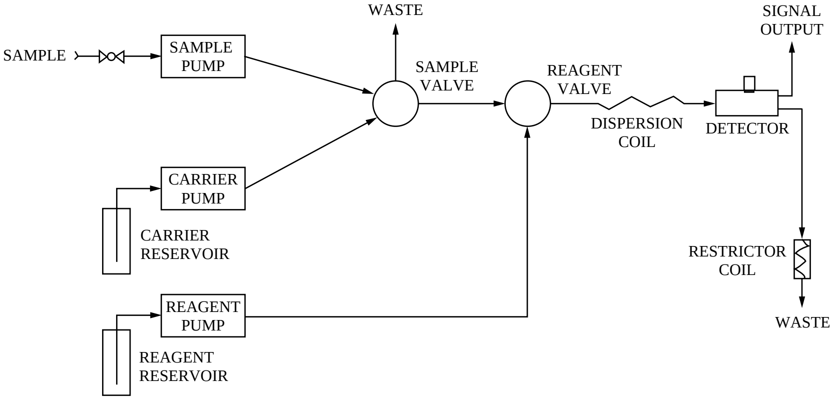


FIG. 8.65i

Simplified schematic of the configuration of a flow injection analyzer (FIA) package.

injection analyzer. These analyzers use wet chemical methods to quantify a wide range of specific ions and other components found in water. These instruments incorporate sophisticated liquid-handling sections.

These analyzers usually include a sampling section, which is followed by the conditioning section that performs the analysis by mixing reagents with the sample. The actual measurement of concentration is done either by end-point titration or by colorimetric evaluation, using ultraviolet or other detectors.

Volatile Organics

The concentration of specific volatile organic compounds (VOCs) in a water stream can provide the plant operator with information about the condition of a process or of a piece of equipment. The reasons for monitoring VOC are varied. The goal can be (1) process monitoring of an aqueous reaction, (2) spill and/or leak detection, allowing the plant operator time to divert the spilled chemical, thus avoiding contamination of a waterway or biological pond, or (3) monitoring effluent discharges to the environment for regulatory compliance purposes.

While TOC and TC are important water quality parameters (see Section 8.58), particularly in the petroleum and chemicals industries, their values often are limited by a lack of sensitivity or by a lack of specific information about a particular compound of interest.

In the past, monitoring for specific organic compounds has been limited to tedious laboratory techniques requiring highly trained personnel and elaborate equipment.[1] In the past decades, a variety of on-line process monitors have been introduced that have automated these techniques and analyses.[2]

VOC Compounds of Interest Table 8.65j lists a number of specific VOCs that are frequently analyzed in wastewater. Under normal conditions, there might be only a very low ppb level of a particular VOC in a wastewater stream. However, during a plant upset or due to other abnormal conditions, concentrations may quickly rise to high concentrations.

TABLE 8.65j
Volatile Organic Compounds Monitored in Water

1,1-Dichloroethylene	1,1,1,2-Tetrachloroethane
Methylene chloride	Ethylbenzene
trans-1,2-dichloroethylene	*m,p*-Xylene
1,1-Dichloroethylene	*o*-Xylene
cis-1,2-dichloroethylene	Styrene
2,2-dichloropropane	Bromoform
Chloroform	Isopropylbenzene
Bromochloromethane	Bromobenzene
1,1,1-Trichloroethane	1,2,3-Trichloropropane
Carbon tetrachloride	1,1,2,2-Tetrachloroethane
1,1- Dichloropropene	*n*-Propylbenzene
Benzene	2-Chlorotoluene
1,2- Dichloroethane	4-Chlorotoluene
Trichloroethylene	1,3,5-Trimethylbenzene
1,2-Dichloropropane	*tert*-Butylbenzene
Dibromomethane	1,2,4-Trimethylbenzene
Bromomethane	*sec*-Butylbenzene
Bromodichloromethane	1,3-Dichlorobenzene
cis-1,3-dichloropropene	1,4-Dichlorobenzene
Toluene	*p*-Isopropyltoluene
trans-1,3-dichloropropene	1,2-Dichlorobenzene
1,1,2-Trichloroethane	*n*-Butylbenzene
Tetrachloroethene	1,2-Dibromo-3-chloropropane
1,3-dichloropropane	1,2,4-Trichlorobenzene
Chlorodibromomethane	Hexachlorobutadiene
1,2-dibromoethane	Naphthalene
Chlorobenzene	1,2,3-Trichlorobenzene

Knowledge of the concentration of a particular compound can provide the operator with precise information as to the location of a particular leak or equipment failure. In addition, because there are regulations that limit the allowable concentrations of particular compound classes or particular compounds, information about a compound's precise concentration is required.

Chromatographs

Generally, chromatographs are the most sophisticated semicontinuous monitors utilized in water analysis. They are often used when the concentration of specific organics in a water stream needs to be determined (Section 8.12). More recently, chromatographs have also been used to measure the concentration of specific ions (hence, ion chromatography) in water.

When used for water analysis, the chromatograph requires the addition of specialized sample conditioning components. Most chromatographs are provided with either sparging or purging and trapping devices to separate the components of interest from the water sample.

Sample Obtained by Sparging Figure 8.65k shows a sparger-type sample conditioning system in front of a chromatograph. The water sample is introduced through a pressure regulator (PCV) to establish a constant pressure. The sample is then heated to a specified temperature to enhance the sparging process, and its flow rate is regulated.

After the flow regulator, the sample is continuously introduced into the sparging vessel, where helium or some other purge gas is sparged through the sample. As the purge gas disperses, it rises through the water and effectively extracts a portion of the volatile organic compounds (VOCs). This purge gas, which now contains some volatiles, is either sent to the chromatograph for analysis or passed through a trap (hence the name *purge and trap*) for further concentration before being introduced into the chromatograph.

The chromatograph separates the sample into its individual components and thus provides specific concentration readings for each. VOC concentrations as low as 0.1 ppb can be detected using these techniques.

Temperature and Environmental Variables

Many water quality parameters are temperature dependent, so their measurement requires temperature compensation. For this reason, the water temperature is always measured by a separate temperature transmitter or by sensors that are included in the analyzers.

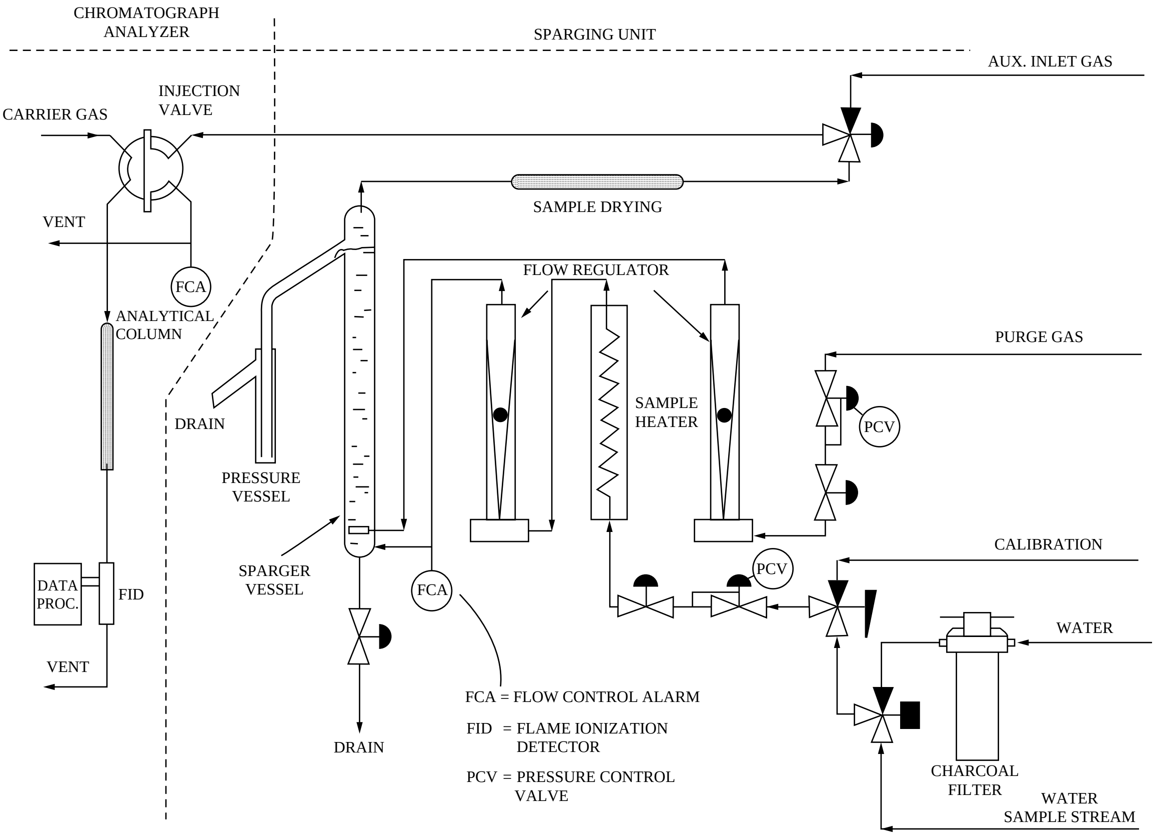

FIG. 8.65k
Volatile organic concentration in a water sample can be detected by gas chromatography where the gas sample for the chromatograph is obtained by sparging.

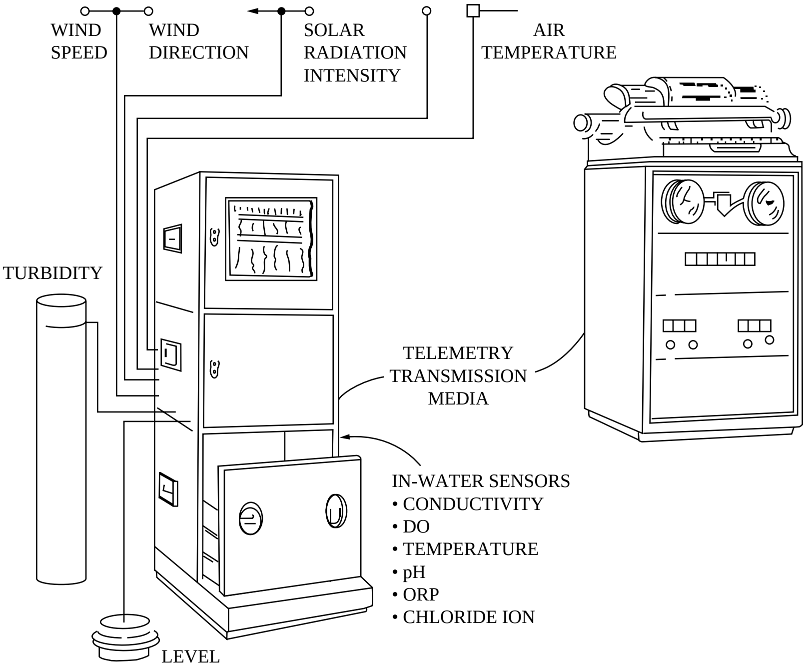

FIG. 8.65l

A complex package of an automatic water quality data measurement, collection, and transmission system.

Other parameters monitored while evaluating the quality of open water include the flow velocity of a river or the level of a water body, the wet and dry bulb temperature of the air, wind speed and direction, and solar radiation intensity (see Section 7.23 for weather stations).

UNATTENDED MONITORING STATIONS

When the purpose of an installation is to monitor water quality of lakes and rivers, the monitoring package must be designed to operate unattended for 30 to 60 days at a time. Such a monitoring station is illustrated in Figure 8.65l.

The unattended monitoring station usually consists of sensors for weather-related data, plus some of the water quality sensors discussed earlier. The measurements are transmitted by telephone lines or through radio telemetry to centralized data collection systems, where the collected data are analyzed and stored.

In industrial applications, the water quality data usually are not transmitted by telemetry but by hard-wired analog transmission or over digital networks. When the water quality analyzer is located in an industrial plant, its housing is usually designed for its intended environment (including explosion proofing if required), without the need for additional analyzer houses.

On the other hand, when the water quality monitoring station is located in a remote area, it is common practice to place the system inside a shelter, near the open water body being monitored (Figure 8.65b).

8.66 Wet Chemistry and Autotitrator Analyzers

C. P. BLAKELY (1974,1982) **B. G. LIPTÁK** (1995) **E. H. BAUGHMAN** (2003)

Types of Designs:	A. Autotitrator, volumetric devices operated to pH or color change end points B. Colorimetric wet-chemistry analyzers C. Flow injection analyzers
Samples:	No suspended solids are allowed when colorimetric units are used, and minimal solids are allowed with the others.
Inaccuracy:	1 to 3% full scale; accuracy a function of the calibration
Costs:	The cost of on-line industrial units ranges from $10,000 to $100,000 depending on what the unit does. Automatic laboratory units for automatic preparation of up to 36 sample tubes, with operations including the dispensing of diluents and titrants into each, stirring, measuring, and recording their pH values, and then automatically moving sample tubes to the rinsing station, cost from $15,000.
Partial List of Suppliers:	Brinkman Instruments Inc. (A, B) (www.brinkmaan.com) Bran & Luebbe Analyzing, Technicon Industrial Systems (B, C) (www.branluebbe.com) Cole-Parmer Instrument Co. INTRODUCTION

Wet chemistry analyzers and autotitrators are jokingly called "chemist in the box" devices, because they automatically and accurately perform the operations that a laboratory chemist would perform manually to gain the same end result. Because of their complexity, one might think of them as the forerunners of robotics in the field of process control.

From the hardware point of view, flow injection analysis (FIA) methods eliminate much of the complexity but add the requirement of precise timing. The laboratory variations of these units actually use robotic arms to automatically and sequentially analyze up to 100 samples while recording the data, rinsing the sample tubes, etc.

Readers who are interested in maintaining contact and staying up to date with the most recent developments in the field of wet chemistry analyzers should participate in the conferences on process analyzers organized by IFPAC.[1]

AUTOMATIC TITRATION

Titration is a volume measurement process in which an unknown concentration of a substance is determined by detecting the volume of a standard reagent that is needed to complete a reaction (to reach a reaction end point). The *point of equivalence* represents the perfect stoichiometric balance between unknown substance and the reagent. The error in titration—the difference between the equivalence point and the actual end point—is called the *indicator blank.*

Types of Reactions and End-Point Detectors

Titrations can be grouped by the *type of reaction*, which can be acid-base, oxidation-reduction (ORP), complexation, or precipitation. Titrations can also be grouped by the *method of end-point determination*, which (1) can be colorimetric, using pH-sensitive dyes, (2) can involve electrochemical electrodes, which can detect voltage (potentiometric, such as pH, specific ions, etc.), current (amperometric), resistance (conductivity), or total charge (coulometric), or (3) can be spectrophotometric or photometric titrations, which use the changes in radiation absorption to detect the end point (a form of the colormetric detector but no added reagent is required).

When titration is done automatically, the sample is automatically delivered to the analyzer, the delivery of the titrant is automatically terminated when it reaches the end point, and the results are automatically recorded or transmitted for control purposes. Autotitrators are usually capable of targeting end points within a 0 to 14 pH or 0 to 2000 mV range.

Continuous and Batch Designs

When used for process control, the autotitrator can be continuous or batch type. For closed-loop control, the continuous titrators are preferred, because their dead time and sample transportation lag times are lower. They detect the titrant flow rate required to bring the sample (at a constant flow rate) to its end point. Autotitrator-based, closed-loop control systems are used for neutralization applications in which the sample (for example, wastewater) is buffered, so pH measurement alone is insufficient to determine the amount of neutralization agent requirement.

The operation of a simple, batch-type, automatic titrator is shown in Figure 8.66a. Here, the sample is continuously received and is returned to the process through a three-way sample valve. When the field-adjustable program calls for a new sample, the three-way valve opens, and the reaction cell is filled with a new sample. The sample is magnetically stirred, and a titrant is added by an accurate piston pump. A less accurate peristaltic pump can be used to add another reagent, such as an indicator.

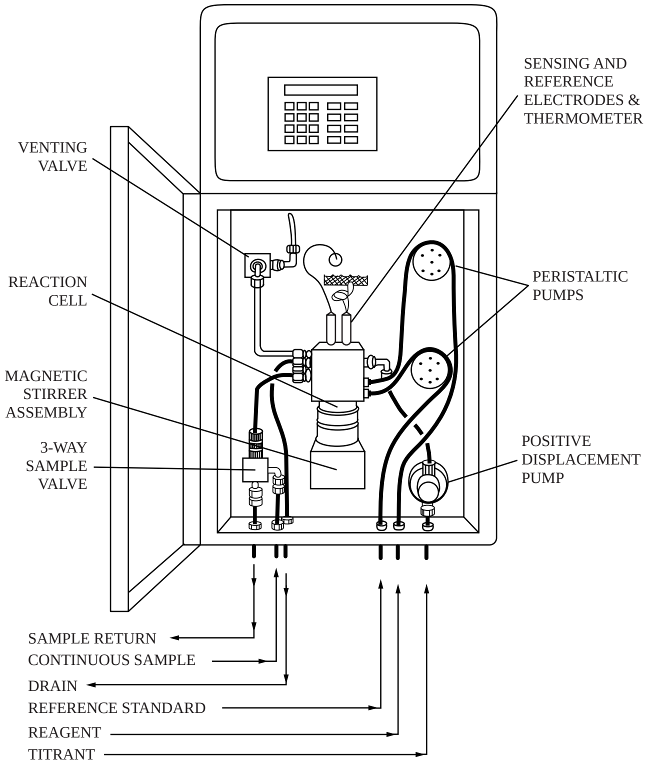

FIG. 8.66a
Field-programmable autotitrator. (Courtesy of Tytronics, a Metrisa Company.)

Temperature-compensated electrodes automatically detect the end points, and, when the data has been registered, the reaction cell is drained and vented. Depending on the programming, the measurement cycle can be followed by an automatic recalibration cycle using a standard reference solution, a rinse cycle, or another sample.

VOLUMETRIC ANALYZERS

Volumetric analyzers are devices that automatically perform titrations either to electrometric end points or to their colorimetric equivalents. High-precision instruments are available as well as simpler standard devices that perform valuable functions with adequate accuracy and repeatability.

Instrument manufacturers have not yet recognized the need for on-line automatic titrations and for the development of a wide array of titrators. (The problem from the manufacturers' point of view is that they do not see a big enough market for any one type of unit to justify the development costs.)

Two distinct types of titrators are available (pH and colorimetric end point) for pollution control work, and these are generally limited to the conventional acid-base tritrations. The development of specific ion activity electrodes and of miniaturized submersible color probes using fiber optics for light transmission and collection are beginning to open the doors to automatic titrations of a wider variety.

High-Precision Volumetric Analyzer

The high-precision automatic titrator performs in the exact same manner as a device used by a chemist in the laboratory. The titration beaker is flushed out with the sample, and then a known volume of sample is added. An electrode assembly measures the sample pH. Under constant, gentle agitation, titrant is added until the desired, preselected endpoint is reached. When that occurs, the titration is stopped and the volume of the titrant that was required to reach the end point is recorded. A typical analyzer of this type, in simplified form, is shown in Figure 8.66b and described below.

Operating Sequence A programmer signals the fill valve (A) to open and to fill the burette (B) with reagent from the storage bottle until the level in the burette reaches the full mark. At this time, the conductivity follower probe (D) is at maximum height. Next, the programmer opens the sample fill valve (E) and drain valve (F) and, after a few minutes of flushing, the sample drain valve is closed, and the cell (G) is allowed to fill and overflow to waste. Then, the sample fill valve and the constant-level drain valve (H) are both closed.

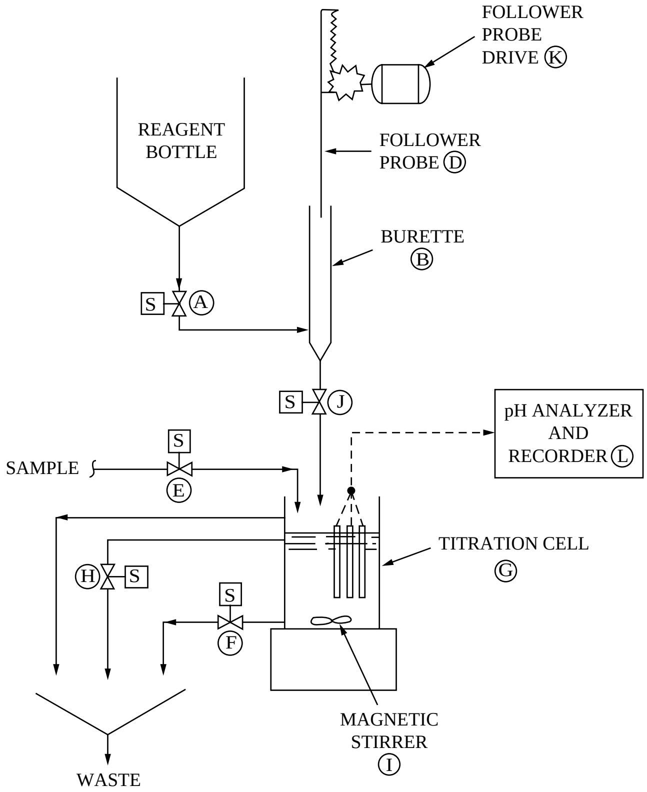

FIG. 8.66b
The main components of a volumetric analyzer (autotitrator).

At that time, the magnetic stirrer (I) is started and the regent valve (J) is opened. The pH of the solution in the titration vessel (G) is continuously measured and recorded. As the titrant level in the burette drops below the tip of the follower probe, the conductivity bridge is broken, and the drive motor (K) drives the probe down until the tip of the probe is again in contact with the solution. When the preset end point has been reached, the pH analyzer (L) closes the titrant valve (J), and the distance traveled by the follower probe is an indication of the volume of titrant used to complete the titration.

Multiple End Points Titrations to two end points can also be made. This permits automation of the classic phenolphthalein– methyl-orange titration, for example, of a dibasic molecule. The first end point is represented by the first plateau and may be stored in the electronic memory of the device. Most units do not use recorder pens anymore but compare the readings against electronically determined plateaus that would be seen if a pen were present

The titration then proceeds to the second predetermined end point. The second plateau of the recording pen corresponds to the milliliters of reagent used for the complete titration. Control can be based on the first end point, the second end point, or a computed value using both end points.

In the classic phenolphthalein–methyl-orange titration with acid being the titrant, the final solution pH is always acidic. It is also possible to titrate acidic samples to one or two basic end points. In these applications, it may be desirable to interpose into the flush-and-fill cycle (before titrations for electrode maintenance) an occasional acid rinse. Such an occasional acid rinse will keep the system operational; without it, the metal hydroxides or carbonates might precipitate out on the windows or electrodes and eventually make them nonfunctional.

This type of volumetric analyzer is not as sensitive to environmental conditions as its colorimetric counterpart, and it does not require as clean a sample. However, it is a relatively sophisticated electronic instrument, so it should be accorded an operating environment quality similar to that of a control room.

Simple Volumetric Analyzer

A simple, continuous automatic titrator is illustrated in Figure 8.66c. It utilizes the classic method of titrating to obtain color change end points. In operation, an indicator solution is added to a known volume of sample, and the titrant is then admitted until the color change indicates that the desired end point has been reached. At this point, the volume

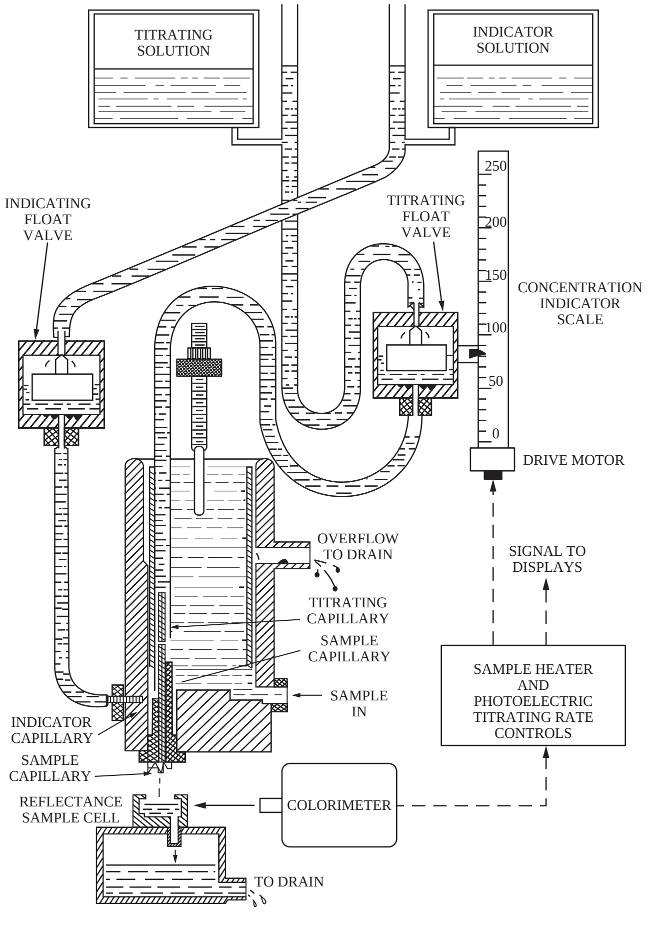

FIG. 8.66c
The operation of a continuous automatic titrator that is using color change as a means of determining the end point.

of titrant used is read as an indication of the concentration of the active species that were present in the sample.

This instrument can also operate as a continuous analyzer. In that configuration, the various flows are detected by measuring the pressure drop (d/p) through capillary tubes that are directly proportional to the laminar flows in those tubes. (The assumption that d/p and flow are linearly related is correct only if the fluid viscosity is constant. This might not be the case if the flowing fluid is a hydrocarbon or if the fluid temperature is not accurately controlled.)

In the titrator, the sample flow is maintained constant by a fixed float valve. An automatic raising or lowering of the titrant float valve can vary the titrant flow. A colorimeter is adjusted to sense the end-point color, and it is set to cause the float valve to open or close (drive up or down) so as to maintain this color. In that case, the float valve elevation (or position) is an indication of the prevailing concentration and can also be recorded.

Because the effectiveness of this device depends on color development and on maintaining the end-point color, it is imperative that the samples be free of suspended matter. To perform a two-end-point titration, two titrators are needed: one for the equivalent of the phenolphthalein end-point detection, and a second for the equivalent of the methyl-orange end-point measurement, which was cited in the classic titration example earlier. It is then necessary to use the outputs from each titrator and to use external electronics for the calculations.

Applications of Volumetric Analyzers

One widespread problem facing the pollution control engineer is the precipitation of heavy metals and similar applications that too often are lumped in with pH control. Consequently, conventional pH instrumentation is frequently used when it has little chance of success or is likely to give constant trouble because of electrode fouling. To overcome these problems, engineers frequently choose highly sophisticated control systems, which might include both feed-forward and feedback control loops, bias and variable ratio stations, and a variety of electrode cleaning devices ranging from mechanical wipers to ultrasonic cleaners.

Most heavy-metal precipitation problems are similar to the hot or cold lime soda softening techniques used in the preparation of water for boiler use and to the preparation of hard water for municipal drinking water suppliers. Cold or hot process softeners are readily controlled by titration. Under manual conditions, a flow meter on the influent flow transmits pulses to a counter for every 100 gal (379 l) metered. The counter accumulates a predetermined number of pulses and activates a repeat cycle timer.

An operator collects a sample of softened water, titrates to the phenolphthalein end point (P reading) and the methyl-orange end point (M reading), and then makes the calculation 2P − M. He then adjusts the timer to feed sufficient lime and soda ash to maintain the desired value, which is close to zero. An automatic titrator can also perform this function, and electronic circuitry can make the computation and adjust the timer settings.

Another simple pH control problem is in the operation of cooling towers where hot water from distillation units is cooled but, because the water tends to pick up CO_2 from the atmosphere, it forms an acidic, corrosive solution. The addition of a base can easily counteract this, and one needs a titrator to determine how much base is to be added.

COLORMETRIC ANALYZERS

For a more detailed discussion of colorimeters, refer to Section 8.15.

A chemist who is well trained, experienced, and working unhurriedly in a well equipped laboratory can analyze samples very accurately. Such conditions seldom if ever exist in a plant where the engineers or operators want answers immediately after they send their sample to the laboratory. In a way, their attitude is understandable, because they want to find out what is going on in their process, and answers that arrive several hours later will not help much.

High-precision, automatic colorimetric analyzers perform in the manner that plant engineers would like the laboratory chemist to perform. In this instrument, the sample and reagents are accurately metered and proportioned. Reagents are added in identical sequences, with mixing and time delay steps between additions, as is required by the chemistry and the laboratory procedure. Where reactions are temperature dependent (and most are), a constant-temperature bath is included in the analysis hardware. Sample preparation by distillation or dialysis can also become part of the automatic analytical procedure if required. The analysis results provide about the same precision that can be obtained by an experienced chemist, and they demonstrate better repeatability.

These analyzers contain delicate, high-precision electronic components that emit low-level signals requiring enormous amplification for recording and control. Therefore, it is generally advisable to make some investment in analyzer site selection and preparation. Vibration, dirt, and dust should be eliminated, and sudden ambient temperature variations should be avoided. An air-conditioned environment is ideal for the analyzer, and proper maintenance is also essential. It should also be realized that wet chemical procedures frequently liberate corrosive or deleterious gases. These must be vented from the analyzer cubicle to prevent corrosion of the electronic components and must be expelled from the temperature-conditioned room.

As colorimetry is a measure of light absorption resulting from the color produced by the chemical reactions, it is essential that the sample fed to the automatic analyzer be free from suspended matter. This requirement can be relaxed somewhat by using a dual-wavelength analyzer to detect the color change, but dual-wavelength colorimeters are uncommon and expensive.

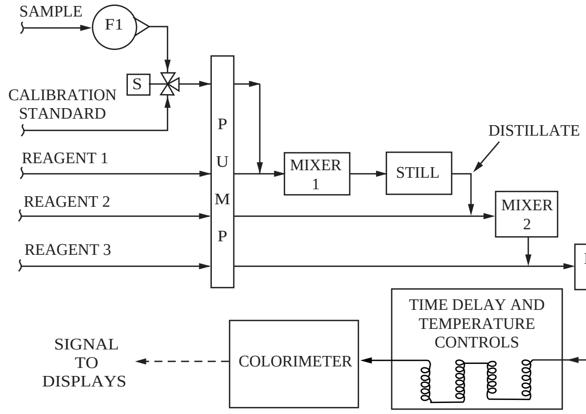

FIG. 8.66d

Precision colorimetric analyzer configuration, which includes a sample distillation step, as might be used for phenol or cyanide detection.

Reagent consumption for colorimetric analyzers of all types varies with the analysis to be performed. Generally, the high-pressure units use proportionately less reagent than the standard devices, but the reagent used by the high-pressure units is usually costlier and harder to prepare.

High-Precision Colorimetric Analyzers

To accurately ratio the flow streams of a sample to the flows of dilution solvents and reagents, most high-precision laboratory analyzers use a multiple-head peristaltic pump that receives several plastic tubes and pumps all these liquids simultaneously.

As shown in Figure 8.66d, the ratio control between the sample and reagent fluids is achieved by the careful selection and control of the internal diameters of the tubes. Mixing is achieved by changing the tube diameters repeatedly downstream of the pump (thereby changing velocities), by changing flow directions, or both. It is difficult to convert this technology to automatic, on-line operation because of the high maintenance requirements of the pump and tubes.

Use of Gas Bubbles One analyzer, called the *segmented flow analyzer*, introduces air through one of the pump tubes to create discrete air gaps between segments of fluid. It then passes these liquid segments through horizontally mounted glass or plastic coils. The air gaps, while keeping the samples separate, permit free-fall of the liquid segments, thus achieving mixing of sample and reagent. Coils provide retention time. Where temperature control is required, these retention time coils can be made part of a constant-temperature bath that is thermostatically controlled and provided with an adjustable set point.

The reacted sample then passes through a "debubbler" and on to the analyzing section that frequently is a colorimeter. The colorimeter establishes a baseline when there is no sample in the stream and compares that to the reading when a sample is present. The advantage of this approach is that it compensates for the drift in light source intensity, electronic drift, and window fouling.

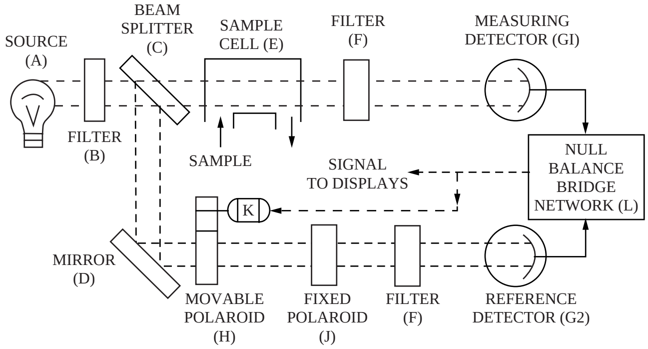

FIG. 8.66e

The main components of a dual-beam colorimeter.

Other approaches use two beams from the same light source and split the beams, but this does not compensate for any window fouling. One needs to calibrate the difference in readings between the baseline and sample concentration, and this is done with standards.

Split-Beam Colorimeter Figure 8.66e describes an older design, the split-beam colorimeter. Here, a single beam from light source (A) passes through an optical wavelength filter (B) and is split into two beams by the beam splitter (C). Next, the sample beam passes through the sample flow cell (E) and through an optical filter (F), which diffuses the light beam over a wide surface area of the measuring photocell detector (G_1). The other beam passes through a movable polarizing lens (H), a stationary Polaroid lens (J), and an optical filter (F) before it strikes an identical, matched photocell (G_2).

With distilled water or a pure solvent in the sample cell, a maximum amount of light is transmitted to cell G_1. With the polarizing lenses aligned in parallel, maximum light is also received by photocell G_2. Therefore, the outputs from the two photocells are equal, and the bridge is in balance.

With a colored solution in the sample cell, the light intensity striking photocell G_1 is attenuated. Output G_1 is now less than output G_2, and the error signal drives the movable polarizing lens through drive motor (K) until the polarizing system has decreased the light intensity striking G_2 so that the outputs of the two photocells are again equal. The distance traveled by the movable polarizing system is a function of color intensity of the sample and can be recorded as the concentration of the constituent analyzed.

Most colorimetric analyses obey Beer's law [see Equation 8.61(1)]. As such, they tend to be nonlinear. Usually, however, the range requirement for a specific application is narrow enough that the pertinent portion of the curve may be considered linear or can be linearized with a log amplifier.

Calibration Colorimetric analyzers are generally equipped with automatic zero and standardization features. At specific intervals, the reagent feed is stopped, and the sample is introduced only into the sample flow cell. After a predetermined period of flushing with pure, unreacted sample, the analyzer reading should be zero. Therefore, under these conditions, the reading is reset to zero, thus compensating for sample or flow cell discoloration and for electronic drift.

Next, the sample is diverted to waste, the reagent system is reactivated, and, instead of a sample, a laboratory-prepared standard solution is introduced. After an interval sufficient to replace all liquids in the sample flow cell with this freshly reacted standard solution, the output signal is automatically compared to the signal level expected for the standard solution strength, and adjustments are made if needed.

The length of the optical path (i.e., the depth of reacted sample penetrated by the light beam) is critical. In an analysis for trace amounts of contaminants in which the color developed by the chemical reaction is expected to be weak, a long optical path is essential. The longer the light path, the less signal amplification is needed and, therefore, the greater will be accuracy of the analysis.

Conversely, if the color intensity is high, a short optical path is preferred so that the high-color intensity does not attenuate the light beam excessively. If the absorbance is too high (greater than ≈1), Beer's law will fail, and the signal will no longer be linear with the log amplifier.

High-precision analyzers generally have interchangeable flow cells that may range from 2 to 10 in. (50 to 250 mm) in optical path length. The longer the path length, the more critical is the requirement to remove solids or light scattering particles from the sample.

Simple Colorimetric Analyzers

The simple, continuous colorimetric analyzers are generally limited to analyses where no more than two or three reagents need to be added simultaneously. Although some of them can proportion the reagents to the sample by individual head vessels and capillaries, other designs employ multiple solution pumping heads coupled to a common drive motor. Each pumping unit operates in the same phase and is individually adjustable.

Mixing of sample and reagent is accomplished in many ways, from mechanical stirring in the sample cell to changes in velocities and direction, to free-fall into a head vessel that, in turn, discharges into the colorimeter flow cell.

Figure 8.66f illustrates such an unsophisticated colorimeter. The light from a single light source (A) is collimated by a lens (B) before it passes through the sample cell (C), in a single or double pass as illustrated. The light then passes through the color filter (E) on its way to the measuring photocell (F_1).

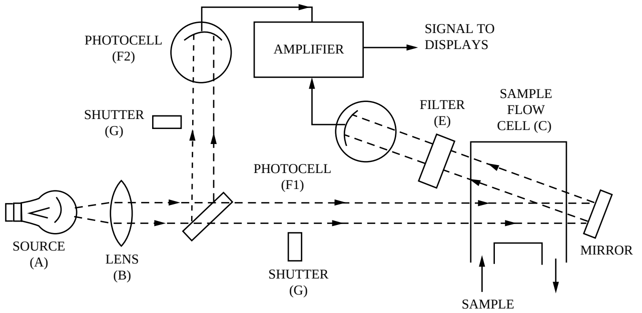

FIG. 8.66f
The components of an unsophisticated, standard colorimeter.

A second light beam passes directly to a second reference photocell (F_2). Both beams can be attenuated by a shutter (G). These shutters are used for zero and full-scale adjustment. The output differential is generally displayed in terms of constituent concentration on a nonlinear meter scale, or the output can be run through a log amplifier and reported on a linear scale. Outputs for recording or other displays are also available.

Calibration Ordinarily, these simple analyzers are manually standardized against calibrated standard slides that are provided by the manufacturers. These may be in the form of one or more calibrated orifices that limit the amount of light striking the measuring photocell, or in the form of optical filters serving the same purpose.

To overcome the effect of ambient temperature changes on photocell output, colorimeters may be equipped with thermostatically controlled heating elements that make the system relatively free from drift. It should be emphasized that if the operator checks only the detector of the colorimeter for drift, he will not know if the complete analyzer is in calibration. The only way to check the whole system is send a standard sample through the sample-conditioning system and into the analyzer.

On/Off Batch Colorimeters

Continuous analysis is not necessary if only an alarm or on/off control is required on process streams that are relatively stable. For these applications, automatic batch analyzers have been developed. These are usually single reagent devices in which the set point for alarm or control is fixed by the reagent.

Hardness analysis is an example. Based on the Versene method, reagents have been developed that undergo a dramatic color change from green to red when hardness exceeds the chelating properties of the reagent. Reagents exhibit this vivid color change for a wide range of water hardness values, such as 0.75, 1.5, 5.0, 9.0, and so on up to 50 ppm or more of calcium carbonate.

This design is shown in Figure 8.66g, where a photosensitive device is employed that sees only green light, a

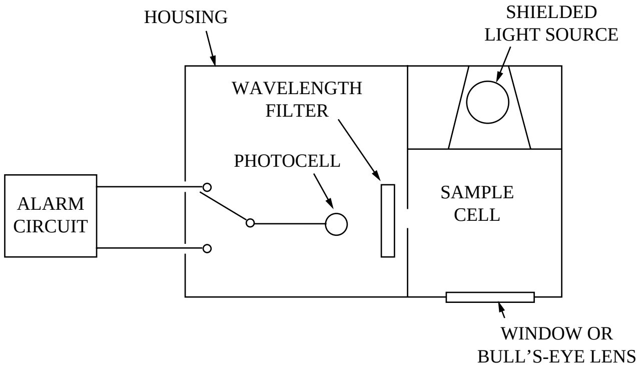

FIG. 8.66g
The configuration of an on/off batch colorimeter.

circumstance denoting that the concentration in the sample being analyzed is below the reagent set point. At the color change from green to red, the wavelength filter screens out all light in the red wavelength. The photocell then receives no light, and an alarm signal is generated.

The sample cell is illuminated from the back and is visible to the operator. Fail-safe features are inherent in this approach. Failure of the light source, the photocell, the reagent, or the sample flow, if not visually detected by the operator, will be noted as a result of energizing the alarm circuit. With this type of analyzer, it is obviously not possible to record analytical values. However, it is possible to use a simple voltmeter-type event recorder that is actuated by the alarm circuitry and will record the time of day and duration of the alarm condition.

Applications of Colorimetric Analyzers

In the control of water pollution, automatic colorimetric analyzers are used in the monitoring of influents into a treatment facility, in the monitoring of effluents from a treatment facility, and in the control of the actual treatment or abatement process.

Table 8.66h lists some of the more common analyses required by pollution abatement legislation, along with the minimum concentration or ranges that are also commercially available. To meet specific monitoring requirements, one can (with the assistance of the instrument manufacturers) develop or adapt chemistry to provide measurements that will satisfy the specific needs.

Chemical oxygen demand (COD)			

If, for example, a manufacturing process generates a waste stream containing hexavalent chromium, Cr^{6+}, and it is to be treated in a batch process, it may be sufficient to perform the following steps. Fill the treatment tank with the waste, and make a manual analysis to determine the amount of treatment chemicals that need to be added. After the treatment is complete, and prior to discharge, just manually analyze the result.

If this same waste is to be treated by a continuous process, it is very likely that conductivity measurements can be used more economically than colorimetry for the control of chemical additions. The effluent from continuous treatment, however, should be monitored for residual hexavalent chromium content after dilution with other wastes.

If, on the other hand, the alkaline chlorination process treats cyanide waste continuously, it may be more economical to monitor the effluent indirectly for residual chlorine rather than for cyanide by colorimetric means. The presence of free available chlorine in excess of 5 ppm would denote the absence of cyanide, because these two chemicals cannot coexist.

Where colorimetric analysis is warranted, efficient sample preparation and careful analyzer site selection are essential.

FLOW INJECTION ANALYSIS

Flow injection analysis (FIA) has been pioneered by Jarda Ruizcka, now at the Center for Process Analytical Chemistry (CPAC), at the University of Washington in Seattle. Flow injection analysis looks at the change in detector reading caused by the interaction of the sample and reagent. Detectors can be electrochemical devices, optical devices, and so on, and the advantage of looking at the change in signal rather than the absolute signal exists because this approach provides a built-in drift correction.

Much has been published about FIA, but its on-line process applications have been few. One such application was described in Section 8.65, where it is used in water quality monitoring applications. Described below are two very different and successful on-line applications of the technology. The laboratory application of the technique will be discussed first.

Laboratory FIA

Classic laboratory FIA consists of a peristaltic pump moving a reagent stream past a detector (Figure 8.66i). The period between samples gives an excellent baseline for the detector. Periodically, sample is injected into the moving stream of reagent, reaction takes place, and the detector responds. For example, if the sample were an acid, the reagent would be a base, which would partially neutralize the sample. The detector, a pH meter, would note the drop in the pH of the stream as the sample passed. The method is extremely reproducible.

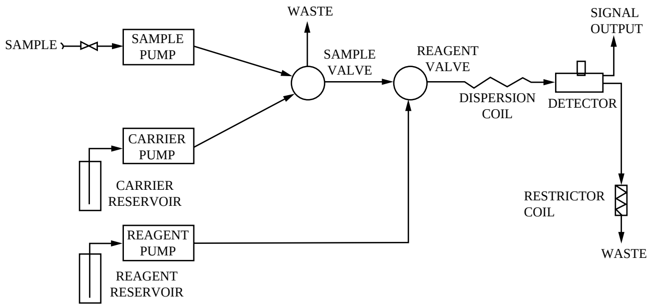

FIG. 8.66i
Laboratory configuration of a flow injection analyzer (FIA) system.

Industrial FIA

The factors that hinder FIA's acceptance by the processing industries include two basic needs.

1. There exists a need to conserve the amount of reagent consumed because, in the process world, there is a lot of sample, and the only way to keep it fresh is to let it flow continuously. For this reason, the roles of the reagent and the sample should be reversed.
2. It is desirable to eliminate the peristaltic pump because of the short lifetime of the pump tubes and because of its lack of long-term reproducibility.

The peristaltic pump is capable of generating low flows. These low flows reduce reagent consumption and allow sufficient time between the sample injection and detection points for the reaction to take place. Another big advantage of the peristaltic pump, when used for FIA, stems from the pump pulses, which promote mixing of the sample with the reagent.

One can provide low flow without a peristaltic pump by using pressurized reservoirs for reagents. If the reservoir is at constant pressure, which is easy to maintain with an air or nitrogen gas pressure, constant flow is guaranteed, because the pressure drop through the piping is also constant. To substitute for the mixing action of the pulses from the peristaltic pump, one can install a coiled piece of tubing or a static mixer.

Application Example 1

To illustrate the problems and advantages associated with the reversing of the sample and reagent, let us look at the problem of detecting 100 to 1,000 ppm of polymer in a butane stream. The polymer is polyisobutylene, and its molecular weight is 1000 to 1500.

It was noted that if the butane sample was put into isopropyl alcohol (IPA), the solution became cloudy. It was also shown that the amount of "cloudy" formation was directly related to the amount of polymer in the butane solution. The problem was that the "cloud" caused by the undissolved polymer would coat the windows of the detector cells and would distort the detector readings.

The solution was found by injecting IPA into the butane stream, which does not result in detector drift and causes no cloud formation, even when polymer is present. This was the case, because the sample had more butane in it than required to cause precipitation when the IPA was injected.

The analyzer devised for this application had a ten-port valve to trap a small sample of butane-polymer between two larger samples of IPA, which are then trapped in the butane solution. In this way, a detectable turbidity from the sample is trapped in the IPA, and the normally flowing stream of butane cleans the turbidity cell. The IPA requirements for this analysis were very small, because only the two "traps" had to be refilled between samples.

Application Example 2

In this application, the problem was to measure the hydrogen sulfide (H_2S) and carbon dioxide (CO_2) in an aqueous amine stream. This process can be found in many natural gas plants and in refineries where the amine streams are used to extract H_2S and CO_2 from a hydrocarbon vapor stream. In this process, the pressure on the amine is reduced after picking up the H_2S and CO_2, and the temperature is raised, which releases the H_2S and CO_2 from the amine so it can return for another load.

From the control point of view, the following two unresolved questions were costing the plant money.

1. How hard do we need to "strip" the amine? If too much stripping is applied, the required heat is wasted, and amine degradation results, which also costs money.
2. What flow of amine is necessary to meet product specifications? If the flow is excessive, it wastes energy, because it has to be heated; in addition, it extracts some of the product from the hydrocarbon stream. If too little flow (or too little heat) is used and the product does not meet specifications, the product is wasted to flare. (One gas plant achieved energy savings of $366,000 per year by optimizing flows, and identified more than $1,000,000 per year in extra gas that had been extracted with their previous control system.)

So the question is, how can we measure H_2S and CO_2 in an aqueous amine stream? Both are acids, and the CO_2 becomes H_2CO_3 when it dissolves in water. Therefore, simple acid-base titration will give only the sum of the two. The laboratory method is to precipitate the H_2S as PbS and then titrate the H_2CO_3. But this approach is not attractive for online use. UV spectroscopy of the aqueous amine solutions "sees" only the H_2S and ignores the CO_2. In addition, the CO_2 amine stream can become very corrosive and destroy the unit.

If the aqueous amine is put into a strong acid solution, the H_2S and CO_2 go into the gas phase. The H_2S has a strong UV absorbance with almost no IR absorption, and the CO_2

has a strong IR absorbance with none in the UV. Therefore, the goal is to inject a known amount of the amine solution into an acid bath and strip the H_2S and CO_2, which, when sent to a UV and IR detector, will provide the required information.

This was achieved by sending the amine stream through a ten-port valve filling the sample loop. In fact, two loops were used, one for the amine coming from the contactor and one for the amine from the stripper. The loops were sized so that each would contain about the same amount of H_2S under normal operation. Periodically, the valve turned, allowing water to carry one of the loops of the aqueous amine to the acid bath. The bath was stripped with nitrogen to mix the solutions and force the gases past the UV and IR detectors.

To avoid excess corrosion while obtaining a fast reaction, 3N H_2SO_4 was used as the acid. While this product was developed at Amoco and they hold the patent on it, Hamilton Sundstrand (Orbital) now has the rights to make and sell it. It should be noted that a small amount of H_2S is released in this analysis and should be vented to a safe place.

Calibration One of the problems with on-line analyzers is that they need calibration. With the H_2S/CO_2 amine analyzer, we chose Solutions Plus Inc.[2] to make us basic NaOH solutions of Na_2S and Na_2CO_3. When these solutions hit the acid, H_2S and CO_2 are released to calibrate the system, yet the method provides an aqueous system that is stable.

Unfortunately, there are not many process FIAs on the market.[3] Most process FIAs are now built to solve a problem that needs to be solved by whatever company has the problem.

A.1 International System of Units

The decimal system of units was conceived in the 16th century when there was a great confusion and jumble of units of weights and measures. It was not until 1790, however, that the French National Assembly requested the French Academy of Sciences to work out a system of units suitable for adoption by the entire world. This system, based on the meter (metre) as a unit of length and the gram as a unit of mass, was adopted as a practical measure to benefit industry and commerce. Physicists soon realized its advantages and it was adopted also in scientific and technical circles. The importance of the regulation of weights and measures was recognized in Article 1, Section 8, when the U.S. Constitution was written in 1787, but the metric system was not legalized in this country until 1866. In 1893, the international meter and kilogram became the fundamental standards of length and mass in the United States, both for metric and customary weights and measures. The tables of conversion factors presented here are intended to serve two purposes:

1. To express the definitions of miscellaneous units of measure as exact numeral multiples of coherent "metric" units. Relationships that are exact in terms of the base unit are followed by an asterisk. Relationships that are not followed by an asterisk are either the results of physical measurements or are only approximate.
2. To provide multiplying factors for converting expressions of measurements given by numbers and miscellaneous units to corresponding new numbers and metric units.

Conversion factors are presented for ready adaptation to computer readout and electronic data transmission. The factors are written as a number equal to or greater than 1 and less than 10 with six or fewer decimal places. This number is followed by the letter E (for exponent), a plus or minus symbol, and two digits that indicate the power of 10 by which the number must be multiplied to obtain the correct value. For example:

$$3.523\ 907\ \text{E–02 is } 3.523\ 907 \times 10^{-2}$$

or

$$0.035\ 239\ 07$$

Similarly,

$$3.386\ 389\ \text{E+03 is } 3.386\ 389 \times 10^{3}$$

or

$$3\ 386.389$$

An asterisk (*) after the sixth decimal place indicates that the conversion factor is exact and that all subsequent digits are zero.

When a figure is to be rounded to fewer digits than the total number available, the procedure should be as follows:

1. When the first digit discarded is less than 5, the last digit retained should not be changed. For example, 3.463 25, if rounded to four digits, would be 3.463; if rounded to three digits, 3.46.
2. When the first digit discarded is greater than or if it is a 5, followed by at least one digit other than 0, the last figure retained should be increased by one unit. For example 8.376 52, if rounded to four digits, would be 8.377; if rounded to three digits, 8.38.
3. When the first digit discarded is exactly 5, followed only by zeros, the last digit retained should be rounded upward if it is an odd number, but no adjustment made if it is an even number. For example, 4.365, when rounded to three digits, becomes 4.36. The number 4.355 would also round to the same value, 4.36, if rounded to three digits.

Where fewer than six decimal places is shown, more precision is not warranted.

[a] Since 1893, the U.S. basis of length measurement has been derived from metric standards. In 1959, a small refinement was made in the definition of the yard to resolve discrepancies both in this country and abroad, which changed its length from 3600/3937 m to 0.9144 m exactly. This resulted in the new value being shorter by two parts in a million.

At the same time it was decided that any data in feet derived from and published as a result of geodetic surveys within the United States would remain with the old standard (1 ft = 1200/3937 m) until further decision. This foot is named the U.S. survey foot.

As a result all U.S. land measurements in U.S. customary units will relate to the meter by the old standard. All the conversion factors in these tables for units referenced to this footnote are based on the U.S. survey foot, rather than the international foot.

Conversion factors for the land measures given below may be determined from the following relationships:

1 league = 3 miles (exactly)
1 rod = $16^{1}/_{2}$ feet (exactly)
1 section = 1 square mile (exactly)
1 township = 36 square miles (exactly)
1 chain = 66 feet (exactly)

[b] This value was adopted in 1956. Some of the older International Tables use the value 1.055 04 E+03. The exact conversion factor is 1.055 055 852 62*E+03.

---

[c] The SI unit of thermodynamic temperature is the kelvin (K), and this unit is properly used for expressing thermodynamic temperature and temperature intervals. Wide use is also made of the degree Celsius (°C), which is the SI unit for expressing Celsius temperature and temperature intervals. The Celsius scale (formerly called centigrade) is related directly to thermodynamic temperature (kelvins) as follows:

1. The temperature interval one degree Celsius equals one kelvin exactly.
2. Celsius temperature (t) is related to thermodynamic temperature (T) by the equation $t = T - T_0$, where $T_0 = 273.15$ K by definition.

[d] This is sometimes called the moment of inertia of a plane section about a specified axis.

[f] In 1964 the General Conference on Weights and Measures adopted the name liter as a special name for decimeter. Prior to this decision the liter differed slightly (previous value, 1.000028 dm^3) and in expression of precision volume measurement this fact must be kept in mind.

TABLE A.2b
Units of Area

1 cir mil[a]
= 0.000000785 sq in.

1 sq in.
= 1,273,200 cir mils
= 0.00694 sq ft
= 0.000772 sq yd

1 sq ft
= 144 sq in.
= 0.01111 sq yd
= 0.00002296 acres

1 sq yd
= 1296 sq in.
= 9 sq ft
= 0.0002066 acres

1 acre
= 43,560 sq ft
= 4840 sq yd
= 4096 sq m

[a] A cir (circular) mil is the area of a circle of 1/1000 in. dia. Thus, a round rod of 1-in. dia. has an area of 1,000,000 cir mils.

TABLE A.2c
Units of Density

1 lb/cubic in.
= 1728 lb/cubic ft

TABLE A.2I

Pressure Head Conversion

The center column, marked “Known,” may be used either for head in feet or for pressure in pounds per square inch—when used as head, the corresponding pressure is found in the column at the left designated as “Pressure Wanted”; when used as pressure, the corresponding head is found in the column at the right designated as “Head Wanted.” For example: a 10-foot head has a pressure of 4.33 pounds per square inch, and a 10-pound pressure has a head of 23.094 feet. By moving the decimal place, quantities larger than 100 may be used.

The viscosity is often expressed in terms of viscosimeters other than the Saybolt Universal. The formulas for the various viscosimeters are given opposite.

If viscosity is given at any two temperatures, the viscosity at any other temperature can be obtained by plotting the viscosity against temperature in degrees Fahrenheit on special log paper. The points for a given oil lie in a straight line.

$$\text{Kinematic viscosity} = \frac{\text{absolute viscosity}}{\text{specific gravity}}$$

$$\text{Redwood K} = 0.26t - \frac{180}{t}(\text{British})$$

$$\text{Redwood Admirality K} = 2.7t - \frac{20}{t}(\text{British})$$

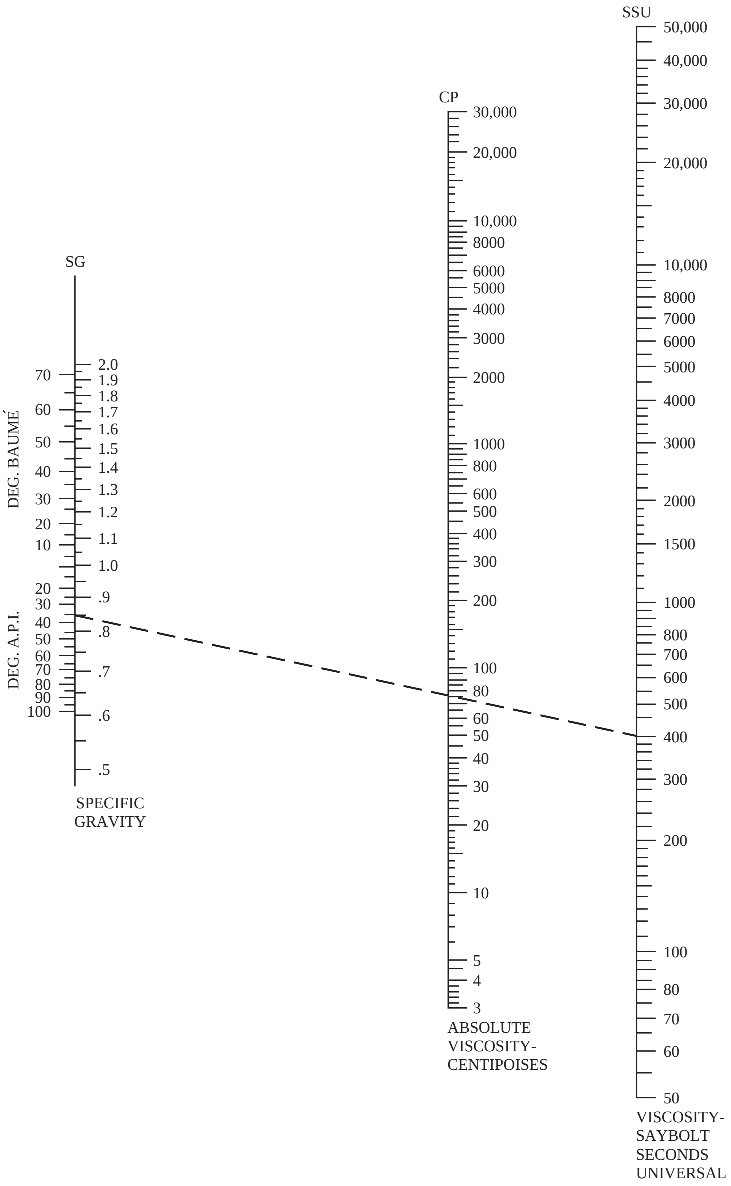
$$\text{Saybolt Universal K} = 0.22t - \frac{195}{t}(\text{American})$$

$$\text{Saybolt Furol K} = 2.2t - \frac{184}{t}(\text{American})$$

$$\text{Engler K} = 0.147t - \frac{374}{t}(\text{German})$$

TABLE A.2q

Viscosity Conversion Chart



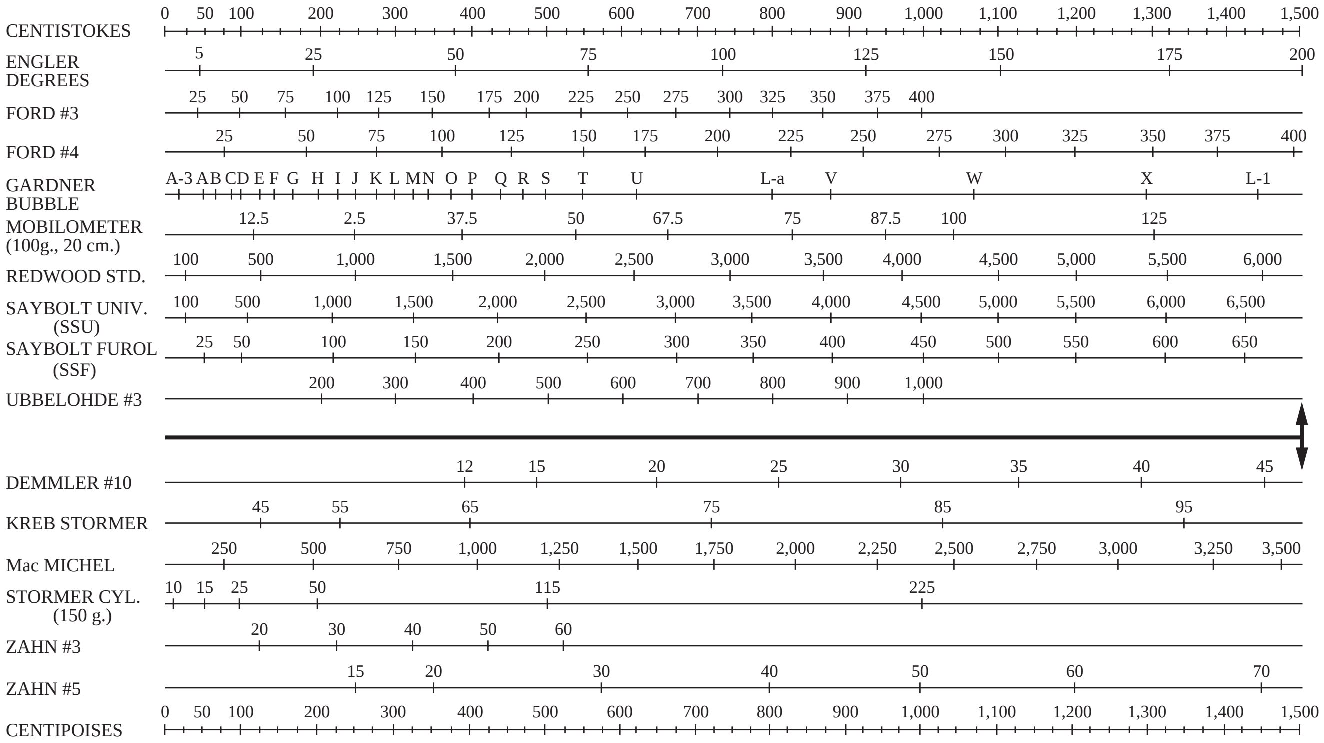
This chart enables the direct conversion of a viscosity in centipoises to a SSU viscosity. As an example, suppose the liquid under consideration has a specific gravity of .85 and a viscosity of 75 centipoises. To determine the viscosity in SSU, lay a straight edge between 75 on the CP scale and .85 on the G scale. The viscosity in SSU can be read directly on the SSU scale. In this instance, the SSU viscosity is 400 (see dotted line).

If the viscosity value is given in centistokes (kinematic viscosity), it can be used directly on the viscosity correction nomograph. The relationship between the absolute viscosity and the kinematic viscosity is expressed by the following formula:

$$\text{Centipoises} = \text{Centistokes} \times \text{Specific Gravity}$$

TABLE A.2r

Approximate Viscosity Conversion Chart



Note: Scales in lower section read directly in centipoises. Those above read in centistokes (to convert into centipoise, multiply by liquid specific gravity).

TABLE A.2s
Units of Volume

1 cubic in.
= 0.00433 gal
= 0.000579 cubic ft
= 0.0000214 cubic yd

1 gal
= 231 cubic in.
= 0.1337 cubic ft.
= 0.00495 cubic yd
= 0.00000307 acre ft[a]

1 cubic ft
= 1728 cubic in.
= 7.48 gal
= 0.0370 cubic yd
= 0.0000230 acre ft

1 cubic yd
= 46,656 cubic in.
= 202.0 gal
= 27 cubic ft.
= 0.000620 acre ft

1 acre ft
= 325,800 gal
= 43,560 cubic ft
= 1613 cubic yd

[a] acre ft of water is the volume in 1 ft of depth covering 1 acre.

Sulfuric Acid (10%–75%)	–		○	×	×	–	–	×	–		–	–	–	–	–
Sulfuric Acid (<10%)	×	×	–		×	–	×	–	×	–	–	×	–	–	–
Sulfurous Acid, H_2SO_3	×		×	×	×	–	×	○	+[**]		×	×			
Sulfuryl Chloride, SO_2Cl_2						×									
Tannic Acid	×	×	×	×	×	×	×				×	×			
Tartaric Acid, $(CHOH\ COOH)_2$	–	×		×	×	×	×	×							
Toluene, $CH_3C_6H_5$	–		×		×	×	×	×	–		–	×	×	×	
Trichlorethylene, Dry, Cl_2CCHCl				×		×	×								
Water, Fresh, H_2O	×	×	○			×	×				×	×	×	×	×
Water, Distilled Lab.						×									
Zinc Chloride, $ZnCl_2$	–			×	×	×	–	×							
Zinc Sulfate, $ZnSO_4$	×			×	×	×	×	×							

**Note*: Duriron is as shown. Durichlor is also satisfactory on chlorides and HCl.
**Durcon 5 would be the preferred formula.

A.4 Composition of Metallic and Other Materials

TABLE A.4
Composition of Metallic and Other Materials

No.	*Material*	*Manufacturer*	*Composition or Description*
		Metals	
17	Aluminum		
19	Aloyco-20	Alloy Steel Products Co.	Fe; 19–21 Cr; 28–30 Ni; 4.0–4.5 Cu; 2.5–3.0 Mo; 1.5 max. Si; 0.65–0.85 Mn; 0.07 max. C
19a	720 Alloy	General Plate	20 Mn; 20 Ni; Cu
54–60	Brass		Various commercial grades ranging 60–65 Cu; 35–40 Zn; 0.5–3.0 Pb
63	Brass, red		85 Cu; 15 Zn
66	Bronze, comm.		90 Cu; 10 Zn
73	Bronze, phosphor, 5% A		94.8–95.5 Cu; 4.3–5 Sn; P
74	Bronze, phosphor, 8% C		Cu; 7–9 Sn; 0.03–0.25 P
75	Bronze, phosphor 10% D		89.5–90 Cu; 10–10.5 Sn; P
76	Bronze, phosphor, spec. free cutting		88 Cu; 4 Zn; 4 Sn; 4 Pb
81	CA-FA20	Cooper Alloy	Fe; 19–21 Cr; 28–30 Ni; 3.5 Mo; 4–4.5 Cu; 0.07 max. C
82	CA-MM	Cooper Alloy	67 Ni; 30 Cu; 1.4 Fe; 0.1 Si; 0.15 C
86	Cast iron		Ordinary unalloyed cast iron
88	Chlorimet 2	Duriron Co.	63 Ni; 32 Mo; 3 max. Fe; 0.15 max. C; 1 Si; 1 Mn
89	Chlorimet 3	Duriron Co.	60 Ni; 18 Mo; 18 Cr; 2 Fe; 0.07 max. C; 1 Si; 1 Mn
111	Copper		99.9+ Cu
112	Copper, Be		97.5 Cu; 2.15 Be; 0.35 Ni
119	Corrosiron	Pacific Fdry.	Fe; 14.5 Si
140	Durichlor	Duriron Co.	Fe; 0.85 C; 14.5 Si; 3 Mo; 0.35 Mn
141	Durimet 20	Duriron Co.	Fe; 20 Cr; 29 Ni; 0.07 max. C; 2 Mo; 4 Cu; 1 Si
142	Durimet T	Duriron Co.	Fe; 19 Cr; 22 Ni; 0.07 max. C; 2 Mo; 1 Cu; 1 Si
143	Duriron	Duriron Co.	Fe; 0.80 C; 14.5 Si; 0.35 Mn
148	Everdur 1000	Amer. Brass	94.9 Cu; 4 Si; 1.1 Mn
149	Everdur 1010	Amer. Brass	95.8 Cu; 3.1 Si; 1.1 Mn
150	Everdur 1015	Amer. Brass	98.25 Cu; 1.5 Si; 0.25 Mn
156	Gold		99.99 Au
156a	Green gold		75% Au; 25% Ag
159	Hastelloy A	Haynes Stellite	Ni; 17–21 Mo; 17–21 Fe
160	Hastelloy B	Haynes Stellite	Ni; 24–32 Mo; 3–7 Fe; 0.02–0.12 C
161	Hastelloy C	Haynes Stellite	Ni; 14–19 Mo; 4–8 Fe; 0.04–0.15 C; 12–16 Cr; 3–5.5 W
162	Hastelloy D	Haynes Stellite	Ni; 8–11 Si; 2–5 Cu; 1 max. Al
163	Stellite 1	Haynes Stellite	Co; 28–34 Cr; 11–15 W

TABLE A.4 Continued
Composition of Metallic and Other Materials

No.	*Material*	*Manufacturer*	*Composition or Description*
165	Stellite 6	Haynes Stellite	Co; 25–31 Cr; 3–6 W
184	Inconel	Int’l Nickel	79.5 Ni; 13 Cr; 6.5 Fe; 0.08 C; 0.2 Cu; 0.25 Mn
191	Lead		99.9 + Pb
192	Lead, antimonial		94 Pb; 6 Sb
193	Lead, antimonial		Pb; 4–12 Sb
196	Lead, chemical		99.93 Pb; 0.06 Cu
200	Lead, Te		99.88 Pb; 0.045 Te; 0.06 Cu
216	Monel	Int’l Nickel	67 Ni; 30 Cu; 1.4 Fe; 0.1 Si; 0.15 C
219	Muntz Metal		60 Cu; 40 Zn
224	Nickel	Int’l Nickel	99.4 Ni; 0.2 Mn; 0.1 Cu; 0.15 Fe; 0.05 Si
224a	Z-Nickel	Int’l Nickel	95 + Ni
226	Nickel–Silver 18% A		65 Cu; 18 Ni; 17 Zn
227	Nickel–Silver 18% B		55 Cu; 18 Ni; 27 Zn
227a	Ni-Span	Int’l Nickel	Ni, Ti, Cr, C, Mn, Si, Al
229	Ni-Hard	Int’l Nickel	Fe; 3.4 C; 1.5 Cr; 4.5 Ni; 0.6 Si
231	Ni-Resist	Int’l Nickel	Fe; 2.8 C; 14 or 20 Ni; 6 Cu (optional); 2 Cr; 2 Si
240	Platinum		99.99 Pt
268	Silver		99.9+ Ag
275	S.S. 301		Fe; 16–18 Cr; 6–8 Ni; 0.08–0.15 C
276	S.S. 302		Fe; 17–19 Cr; 8–10 Ni; 0.08–0.15 C
278	S.S. 303		Fe; 17–19 Cr; 8–10 Ni; 0.15 max. C; 0.07 min. P, S, Se; 0.6
279	S.S. 304		Fe; 18–20 Cr; 8–11 Ni; 0.08 max. C; 2 max. Mn
282	S.S. 310		Fe; 24–26 Cr; 19–22 Ni; 0.25 max. C
283	S.S. 316		Fe; 16–18 Cr; 10–14 Ni; 0.1 max. C; 1.75–2.75 Mo
284	S.S. 317		Fe; 17.5–20 Cr; 10–14 Ni; 0.1 max. C; 3–4 Mo
285	S.S. 321		Fe; 17–19 Cr; 8–11 Ni; Ti, 5xC min.
286	S.S. 347		Fe; 17–19 Cr; 9–12 Ni; Cb, 10xC min.
287	S.S. 403		Fe; 11.5–13 Cr; 0.15 max. C
290	S.S. 410		Fe; 11.5–13.5 Cr; 0.15 max. C
292	S.S. 416		Fe; 12–14 Cr; 0.15 max. C; 0.07 min. P, S, Se; 0.6 max. Zr, Mo
295	S.S. 430		Fe; 14–18 Cr; 0.12 max. C
303	S.S. 446		Fe; 23–27 Cr; 0.35 max. C; 0.25 max. N
360a	Steel		Plain carbon steel
368	Tantalum	Fansteel	99.9+ Ta
390	Worthite	Worthington Pump	Fe; 20 Cr; 24 Ni; 0.07 max. C; 3.25 Si; 3 Mo; 1.75 Cu; 0.5 Mn
		Carbon and Graphite	
401	Karbate (carbon)	National Carbon	Impervious carbon
402	Karbate (graphite)	National Carbon	Impervious graphite
		Ceramics	
611	Lapp Porcelain	Lapp Insulator Co.	Chemical porcelain
614	Pfaudler Glass Lining	Pfaudler Co.	Glass-lined steel equipment
615	Plate Glass		Polished plate glass, flat or bent
616	Pyrex	Corning Glass Wks.	Glass

TABLE A.4 Continued

Composition of Metallic and Other Materials

No.	Material	Manufacturer	Composition or Description
		Plastics	
700	Ace Saran	American Hard Rubber	Vinylidene chloride
710	Geon	B. F. Goodrich	Polyvinyl chloride
711	Haveg 41	Haveg Corp.	Phenolic-asbestos
712	Haveg 43	Haveg Corp.	Phenolic-graphite
713	Haveg 60	Haveg Corp.	Furan-asbestos
714	Haveg 63	Haveg Corp.	Furan-graphite
715	Heresite M 66	Heresite & Chem. Co.	Transparent molding powder
716	Heresite MF 66	Heresite & Chem. Co.	Black molding powder
717a	Kel-F	M. W. Kellogg	Polymerized trifluoroethylene
718	Koroseal	B. F. Goodrich	Plasticized polyvinyl chloride
731	Nylon FM-101	E. I. du Pont	Injection, compression and extrusion moldings (tubing, sheeting, wire covering, gasketing)
731a	Plastisol		Polyvinyl chloride
735	Polythene	E.I. du Pont	Polyethylene
740	Saran	Dow Chemical	Vinyl chloride-vinylidene chloride copolymer
740a	Sirvene	Chicago Rawhide	Synthetic rubber
742	Teflon	E.I. du Pont	Polymerized tetrafluoroethylene
746	Tygon	U.S. Stoneware	Synthetic compounds
		Rubber	
800	Ace Hard Rubber	American Hard Rubber	Vulcanized rubber
805	Butyl (GR-I)	Stanco Distributors	Solid copolymer of isobutylene and isoprene
820	Hycar (GR-A)	B. F. Goodrich	Nitrile type synthetic rubber
829	Neoprene	E. I. du Pont	Polymer of chloroprene
836	Natural (soft)		
837	Natural (hard)		
838	GR-S (soft)		
839	GR-S (hard)		
853	Thiokol (GR-P)	Thiokol Corp.

[a] ft^3/lb = 62.4 l/kg; lb/ft^3 = 0.016 kg/l; PSIA = 0.069 bar (abs.).

Computed from Keenan & Keyes Steam Table.

A.6 Friction Loss in Pipes

Friction loss moduli for laminar flow are shown by the 45° lines in the upper left-hand portion of each chart. Moduli for turbulent flow are shown by the steeper curves in the lower right-hand portion. Both of these regions represent stable states of flow. A diagonal line separates the regions of laminar and turbulent flow and represents the critical zone, a region in which it is difficult to predict the state of flow and, hence, the friction loss. The critical zone usually represents a region of unstable flow. The critical zone line gives approximate moduli on the high side for this region of unstable flow.

The bottom scale of each chart represents flow in gallons per minute, GPM. An auxiliary top scale shows the average velocity in the pipe in feet per second. Read vertically from the GPM scale to find the corresponding velocity in feet per second. The vertical scales, labeled "Friction Loss Modulus for 100 Feet of Pipe," represent values of the ratio:

$$M = \frac{\Delta p}{SG}$$

where

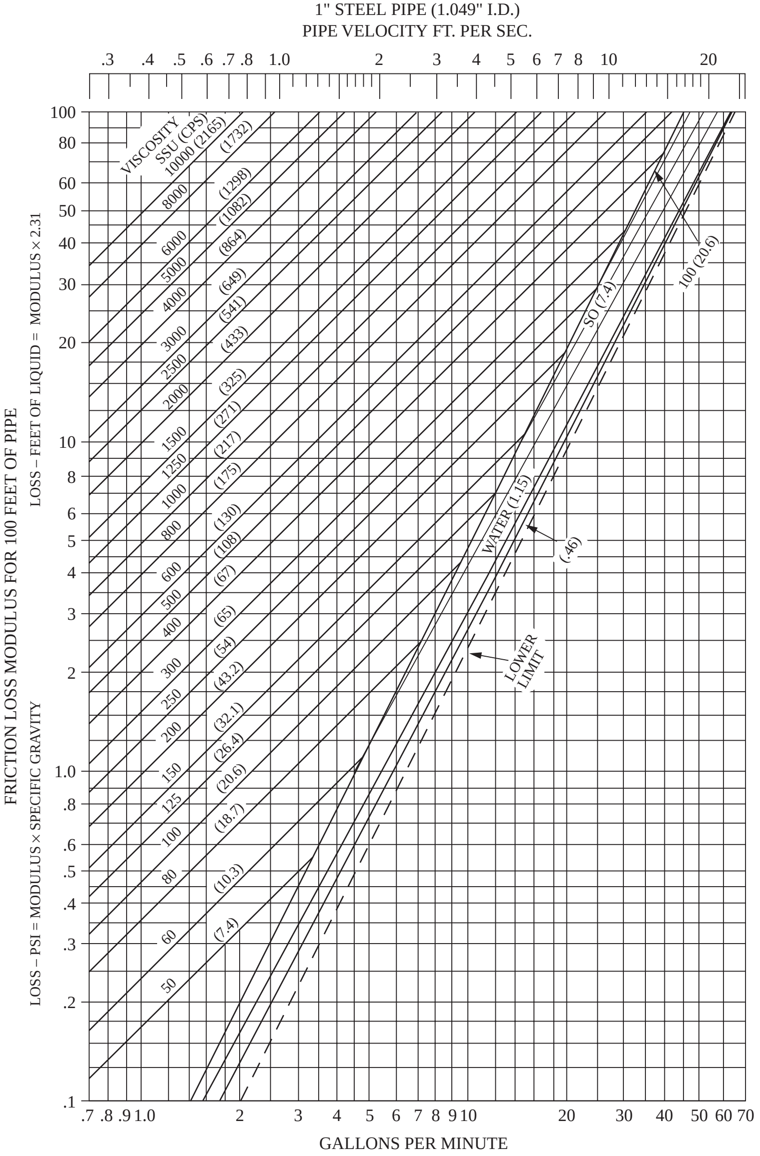
M = friction loss modulus for 100 ft (30 m) of pipe
Δp = pressure loss in lb/in.^{2} per 100 feet of pipe
SG = specific gravity of fluid at 60°F (15.6°C)

The loss due to pipe friction may be obtained as follows:

$$\Delta p = M \times SG$$

To use the charts, proceed as follows:

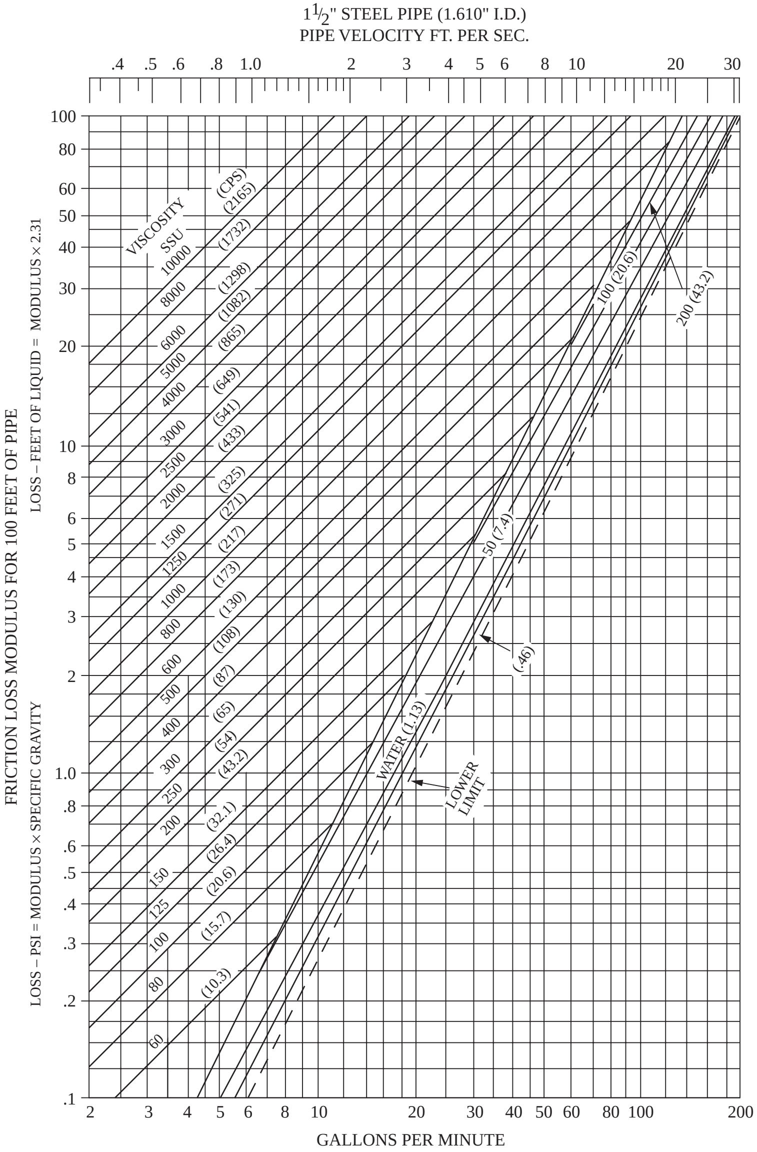
1. Select the chart for the size of pipe in question.
2. Follow the vertical line representing the flow in GPM to its intersection with the desired viscosity curve, and read the modulus at the left.
3. If the vertical line representing the flow in GPM does not intersect the viscosity line in either turbulent or laminar flow, use the intersection with the critical zone line.
4. Compute the friction loss in pressure drop from the equation above.



Loss – lbs per sq in. = modulus × Specific Gravity
Loss – Feet of liquid = modulus × 2.31

*For SI units see Section A.1.

FIG. A.6a
*Friction loss modulus for 100 ft of 1 in. steel pipe.**



Loss – lbs per sq in. = modulus × Specific Gravity
Loss – Feet of liquid = modulus × 2.31

*For SI units see Section A.1.

FIG. A.6b

A.8 Directory of “Lost” Companies

W. H. BOYES WITH S. EDVI (2003)

INTRODUCTION

Between 1990 and 2002, the instrumentation, systems, and automation industries were subject to significant change. Not only was this change of a technical nature, with significant advances in many product areas, but this period has also been one of consolidation among suppliers who manufacture instruments and control systems.

Identified in this appendix are more than 200 companies whose name, ownership, or product line changed significantly during the period from 1990 to 2002. This list is not complete, and the authors believe that there are many more companies, most outside North America, whose names have also changed in the same fashion.

This turmoil among suppliers has had a significant effect on the ability of instrument engineers to locate familiar products or to find companies to service their existing and installed equipment. For example, the Fischer & Porter Company, a well known name in 1990, had ceased to exist as a brand by 2002. The company itself was purchased by Elsag BV and merged with Bailey Controls to form Bailey-Fischer-Porter. Later, Elsag sold the combined companies to ABB, which elected to drop both trade names in favor of ABB Process Instrumentation.

So, an instrument engineer whose company installed Fischer & Porter instrumentation or control systems in the early 1990s may now find it difficult to find information, manuals, and sources for spare parts or service for Fischer & Porter systems. The company, as you will see in the table below, is just one of many manufacturers whose name has changed. We hope that this information will be helpful in making the reader’s life a little easier.

TABLE A.8a
Alphabetic Listing of "Lost Companies"

Prior name	*Intermediate, if any*	*2002*
AEG Automation Systems		Cegelec
AEG Schneider Automation	Groupe Schneider/Schneider Electric	Schneider Automation
Altek Calibrators		Transmation
American Sigma		American Sigma Div. of Danaher
Ametek McCrometer	Ketema-McCrometer	McCrometer Div. of Danaher
Amscor	Fluid Data	ThermoONIX
Anatel	Anatel Div. of Danaher	Pacific Scientific Instruments Div. of Danaher
Anchor Darling		Flowserve Corp.
Applied Automation Inc.	Elsag-Bailey	ABB Process Automation (much of AAI was sold to Siemens)
Arthur Technology		Respirometry Plus
ASAP Software	Xycom Automation/Pro-face America Div. of Digital-Japan	Schneider Electric
Ashcroft-Heise		Ashcroft-Heise Div. of Dresser Industries Instruments
Astro	Hach Co.	Hach Div. of Danaher
Aquamatic Inc.		Osmonics, Inc.
Automax		Flowserve Corp.
Azonix		Crane Co.
Baan Software		Invensys
Badger Meter Ultrasonic Div.		Badger Eastech Inc.
Bailey Controls	Elsag-Bailey	ABB Process Automation
Beta Products	Hathaway-Beta	Beta Calibrators Div. Hathaway Process Instrumentation Corp.
Bettis Actuators & Controls		Emerson Process Measurement
Bindicator	Aaliant	Bindicator Div. of Venture Measurement
Biosynergy Inc.		Biosynergy Inc. Div. of America Clinical Laboratory
Brooks Instruments	Rosemount-Brooks	Emerson Process Measurement, Brooks Div.
Edmond Buhler GmbH	Buhler Montec	Buhler Montec Div. of Danaher (consolidated with Hach)
Eurcontrol	BTG	Hach Div. of Danaher
Cannonbear Technologies	TN Technologies	ThermoMeasureTech
Celtek	Bindicator Celtek; Aaliant	Bindicator Div. of Venture Measurement
Chessell	Eurotherm	Invensys
Chino Works Ltd.		Chino Corporation
Combustion Engineering		ABB Process Automation
Daniel Industries	Rosemount	Emerson Process Measurement, Daniel Div.
Detector Electronics Corp.		Det-Tronics
Dietrich Standard (Annubar)	Rosemount	Emerson Process Measurement, Dietrich Div.
Direct Measurement Corp.	DMC	FMC Energy Systems Group
Drexelbrook Eng. Co.		Ametek Drexelbrook
DuPont Process Instruments		Ametek Process Instruments Div.
Eastech Controls	Neptune Eastech	Badger Eastech Inc.
Eckhardt	Siebe	Invensys
Edward Valve	Invensys Flow Control	Flowserve Corp.
Elsag-Bailey		ABB Process Automation
Ever Ready Thermometer Company		Apogent Technologies Co.

TABLE A.8a Continued
Alphabetic Listing of "Lost Companies"

Prior name	*Intermediate, if any*	*2002*
Fenwal		Kidde-Fenwal
Fischer and Porter Co.	Elsag-Bailey	ABB Process Automation
Fischer and Porter Co. (chlorination Div. only)		Capital Controls Co. Div. of Severn Trent
Fisher Controls Inc.	Fisher-Rosemount Inc.	Emerson Process Measurement
Flow Research	Polysonics	ThermoPolysonics
Fluenta AB		Roxar Flow Measurement
Fluid Data Inc	Thermo ONIX	Thermo Electron
Forma Scientific Co.		Forma Scientific Co. Div. of Thermo Electron
Foxboro	Siebe	Invensys
FTS Systems Inc.		FTS Kinetics
Gas Measuring Technology		RMG Group—Germany
GEMS Sensors	IMO-Delaval Gems	GEMS-Danaher
GE Kaye Instruments		GE Kaye Instruments Div. of GE Industrial Systems
Gilbarco		Gilbarco Div. of Danaher
Great Lakes Instruments	GLI-Viridor	Danaher-GLI
Griffith Industrial		Winters Instrumentation
Groupe Schneider	Schneider Electric	Schneider Automation
Hach Chemical Co.	Hach Inc.	Hach Div. of Danaher
Hart Scientific	Hart Scientific Div. of Fluke	Hart Scientific Div. of Danaher Electronic Test and Measurement
Hartmann and Braun	Elsag-Bailey	ABB Process Automation
Heinrichs Messtechnik		Bopp and Reuther
Heise Instruments		Ashcroft-Heise Div. of Dresser Industries Instruments
Helicoid Instruments		Helicoid Instruments Div. of Bristol Babcock
Hewlett Packard	HP Instruments	Agilent Technologies
Hiac-Royco	Pacific Scientific Inc.	Pacific Scientific Instrumentation Div. of Danaher
Hydrolab Inc.	Hydrolab Div. of Danaher	Hach Div. of Danaher
InLine Measurements		Honeywell Inc.
Intellution	Emerson Process Management	GE Fanuc Automation
Invalco Inc. (Smith Meters)	FMC Invalco	FMC Energy Systems Group
ISA Instruments	Solartron ISA	Solartron ISA Div. of Roxboro
John Fluke Co.	Fluke Inc.	Fluke Div. of Danaher Electronic Test and Measurement
Fluke Inc. (networks and communications only)	Fluke Networks Inc.	Fluke Networks Div. of Danaher Electronic Test and Measurement
Joseph Kaye Co.		GE Kaye Instruments
Kammer		Flowserve Corp.
Kay-Ray	Rosemount-Kay-Ray	ThermoMeasureTech
KDG Mobrey Ltd.	KDG Mobrey Ltd. Div. of Solartron	Solartron Div. of Roxboro
Kent Meter Co.	Kent Taylor	ABB Process Automation
Kistler-Morse	(Ultrasonics to Amer. Sigma)	Kistler-Morse Div. of Danaher
Kollmorgen	Kollmorgen Div. of Danaher	Dahaher Motion-General Purpose Systems
Lakewood Instruments	Fisher-Rosemount Inc.	Osmonics, Inc.
Lear Siegler Measurement Systems	Bowthorpe plc	Spirent plc

TABLE A.8a Continued

Alphabetic Listing of "Lost Companies"

Prior name	*Intermediate, if any*	*2002*
Leeds and Northrop Inc.	Honeywell AIC	Honeywell Inc.
Leeds and Northrup Inc. (DCS only)		ICS
Limitorque	Invensys Flow Control	Flowserve Corp.
Liquid Metronics Inc.	LMI	Milton Roy Flow Controls, LMI Div.
Loveland Controls Ltd.	Love Controls	Dwyer Instruments
Maihak		Sick Maihak
Markal Co.		LA-CO/Markal
Marsh Instruments		Desco Inc.
Marshalltown Instruments		Desco Inc.
Masoneilan	Masoneilan Div. of Dresser	Masoneilan Div. of Dresser Flow Control
Mass Evolution		Brechbüehler AG
MDA Scientific		Zellweger Analytics
Measurex		Honeywell Inc.
Mercoid		Mercoid Div. of Dwyer Instruments Ltd.
Merlin Gerin	Groupe Schneider	Schneider Automation
Micro Motion Inc.		Micro Motion Inc. Div. of Emerson Process Measurement
Milltronics	Siemens Milltronics	Siemens
Modicon (Gould Modicon)	Groupe Schneider	Schneider Automation
Monitek Technologies		Monitek Technologies Div. of Martisa Inc.
Montedoro-Whitney Corp.	Badger Meter Ultrasonic Div.	Badger Eastech Inc.
Moore Industries Inc.		Moore Industries-International, Inc.
Moore Products Co.	Siemens Moore	Siemens
Moore Products-flow and pressure transmitter line only		MycroSENSOR Technologies Inc.
MTI		Agilent Technologies
MultiFluid International		Roxar Flow Measurement
Naf	Invensys Flow Control	Flowserve Corp.
Nametre Inc.		Nametre Div. of Metrisa Inc.
Neotronics		Zellweger Analytics
Neptune Meter Co.	Neptune Schlumberger	Actaris
Neptune-Hersey	Hersey Meter Div.	Aaliant, Aaliant Div. of Venture Measurement
Neslab Instruments Inc.	Thermo Electron	ThermoNeslab
Norriseal		Norriseal, a Dover Resources Company
Pacific Scientific ATC	Pacific Scientific div. of Danaher	Danaher Motion, General Purpose Systems
Panalarm		Panalarm Div. of Ametek Inc.
Panametrics Inc.		GE Panametrics
Patriot Sensors Inc.		Ametek Patriot Sensors
Penny and Giles Ltd.	TRENDview	Honeywell
PID	Sequencia	Rockwell Automation
PMV	Invensys Flow Control	Flowserve Corp.
Polymetron		Hach Div. of Danaher
Powers Process Controls		Moore Industries-International Inc.
Profimatics		Honeywell Inc.
