As a result of costs associated with running field instrument wiring and allocating valuable control room space for field instrument electronics, the current trend is to have the electronics integrally mounted in the top of the detector housing. The detector electronics transmits a 4- to-20 mA DC signal directly to an end-user's digital control system (DCS) or programmable logic controller (PLC). The 4- to 20-mA DC signal can be a simple 4- to 20-mA analog signal or a 4- to 20-mA DC HART protocol signal. The HART protocol signal superimposes a digital signal, used for calibration and diagnostics, on top of the primary process variable 4- to 20-mA DC signal. This output has proven to be very valuable for end-users, because communication is achieved anywhere along the 4- to 20-mA DC wiring. This can preclude personnel from having to enter a hazardous environment (safety or radiological) to communicate and troubleshoot a gauge. Communication is accomplished through HART universal handhelds, or personal computer electronic software packages from the detector manufacturer. Newer digital processor-based electronic designs can also provide a pure digital FOUNDATION™ fieldbus output to take advantage of new plant instrument wiring techniques associated with FOUNDATION fieldbus devices.

CONCLUSIONS AND TRENDS

A trend to expect is continued evolution in digital electronics, as previously discussed, for preventive maintenance considerations. Digital processors hold promise for more complex signal processing, resulting in higher measurement accuracy and stability.

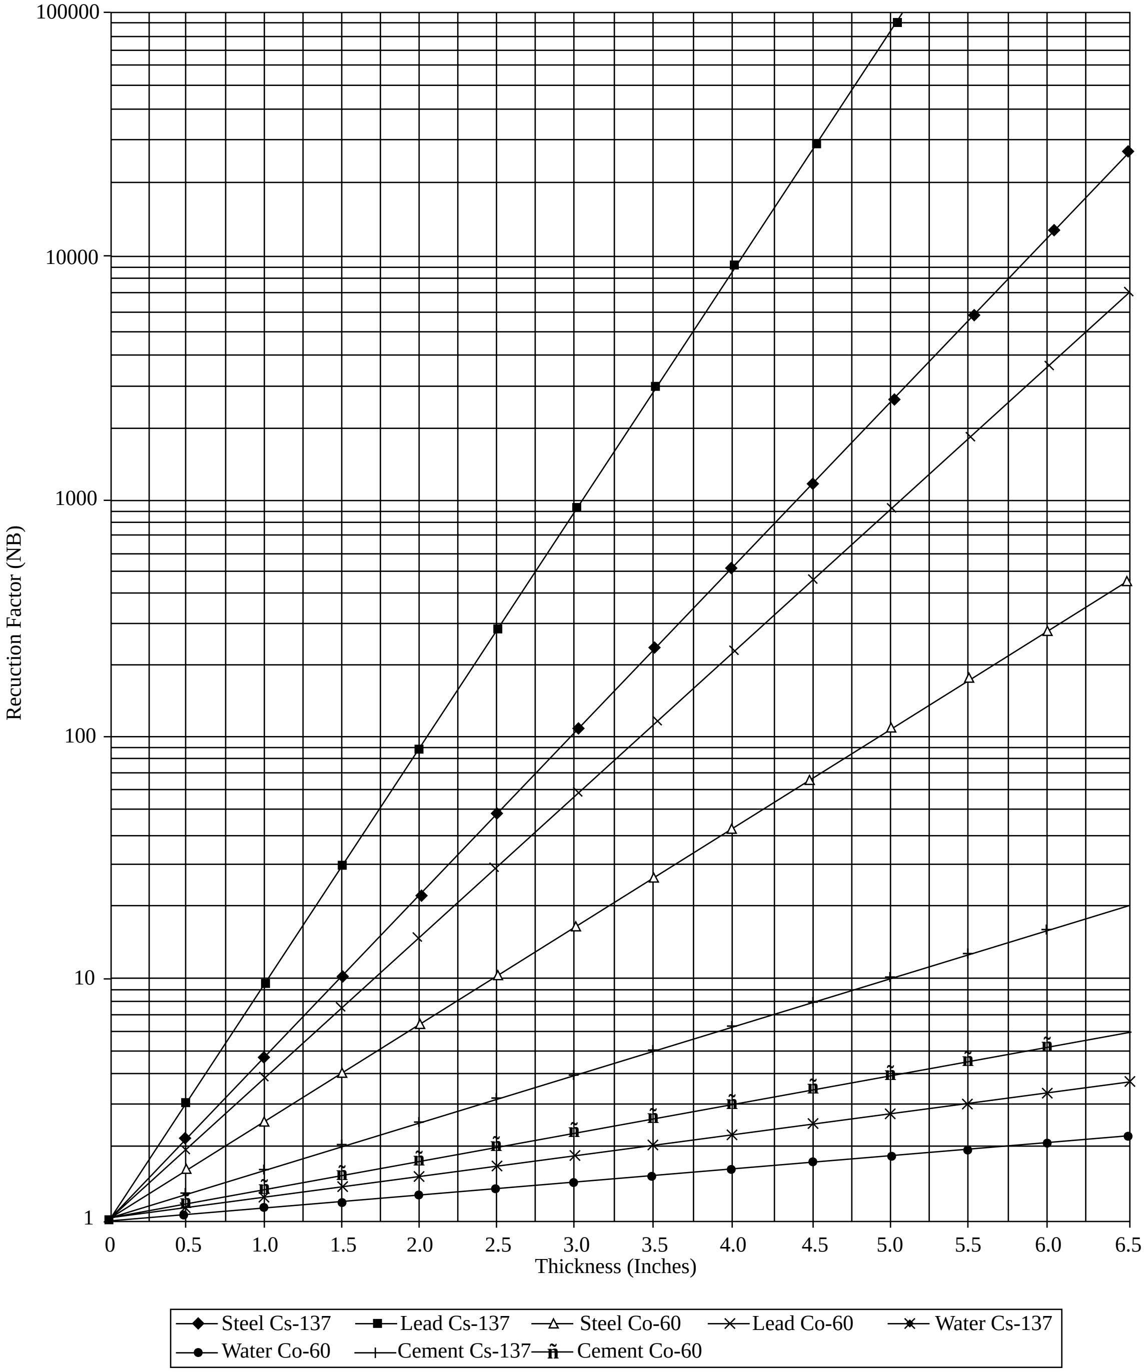

FIG. 3.15n

Radiation reduction (nb) as a function of the source material, the material, which the narrow beam radiation is passing through and of the thickness of this material. So, for example, if the source is Cs-137, which is passing through a 1″-thick steel plate, nb = 4 and therefore the field intensity will be reduced to 25%.

Detector technology will continue to migrate away from ion chambers to more scintillation-based technology. Higher sensitivity and improved stability of detectors can result in lower radiation field requirements, i.e., smaller-activity isotopes.

A very important step in the use of radiation level sensors is the proper sizing of their sources, which generate the gamma radiation at the detector. As the radiation passes the various layers of process and vessel wall materials, it is attenuated to different degrees. To accurately determine the required source size, reliable information is needed. Such information is provided in Figure 3.15n.

Radiation level detection continues to be very appealing for hard-to-handle, toxic, and corrosive processes, because it does not require vessel wall penetrations. Costs and licensing requirements do limit the number of applications but are not serious impediments to carefully designed systems. Although other level technologies are improving and may erode the number of potential nuclear applications, radiation level detectors continue to solve many critical process level applications.

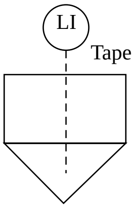
3.16 Resistance Tapes

D. S. KAYSER (1982) **A. D. EHRENFRIED** (1995) **B. G. LIPTÁK** (1969, 2003)



Flow Sheet Symbol

Applications	Liquids including slurries but generally not solids; in addition to level, can measure temperature (see Table 3.16f)
Resolution	0.125 in., which is the distance between helix turns
Actuation Depth (AD)	The depth required to short out the tape varies with the specific gravity of the process fluid (SG) as shown in Figure 3.16c. AD (in inches) = 4/(SG). Therefore, AD at the minimum SG of 0.5 is 8 in. (200 mm). In newer designs, the AD is 5 in. at SG = 1.0.
Temperature Effect	A 100°F (55°C) change in temperature will change the resistance of the nonshorted tape by 0.1%. Temperature compensation is available.
Inaccuracy	0.5 in. if the actuation depth is zeroed out and both AD and temperature are constant. If SG varies, a zero shift based on AD = 4/(SD) will occur. Cold temperature also increases the AD.
Wetted Material	Fluorocarbon polymer film (see Table 3.16f)
Allowable Operating Pressure	From 10 to 30 PSIA (0.7 to 2.1 bars absolute)
Operating Temperature Range	–20 to 225°F (–29 to 107°C)
Costs	The resistance tape unit cost varies with services and tape length. A 10-ft (3-m) tape with breather and transmitter for water service costs from \$800 to \$1500. The added cost for longer tapes is \$30 to \$40 per foot, depending on service.
Suppliers	Metritape Inc. (www.consiliumus.com) R-Tape Corp. (www.rtape.com) Sankyo Pio-Tech (www.sankyo-piotech.co.jp)

Resistance tape for continuous liquid-level measurement was invented in the early 1960s, initially for water well gauging and subsequently for marine and industrial usage. The sensor is a flat, coilable strip (or tape) ranging from 3 to 100 ft (1 to 30 m) in length, suspended from the top of the tank. It is small enough in cross section to be held within a perforated pipe (2 to 3 in. diameter), which also supports the transducer and acts as a stilling pipe if the process is turbulent.

Within the sensing tape, shown in Figure 3.16a, is a gold-finished nichrome resistance wire, which is helically wound around a stainless-steel base strip and insulated on the edges and back. It is provided with a gold contact stripe on its uninsulated front face. The wounded helix is joined to the conducting base strip at the bottom, and lead wires are brought from the base strip and the top of the wound helix through the sensor top end. A compliant sheath, commonly of fluorocarbon film,

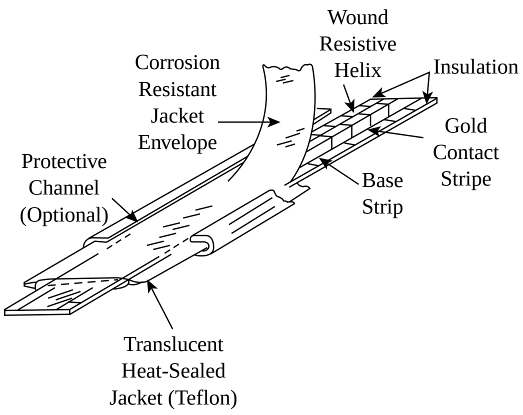


FIG. 3.16a
Construction of resistance tape level sensor.

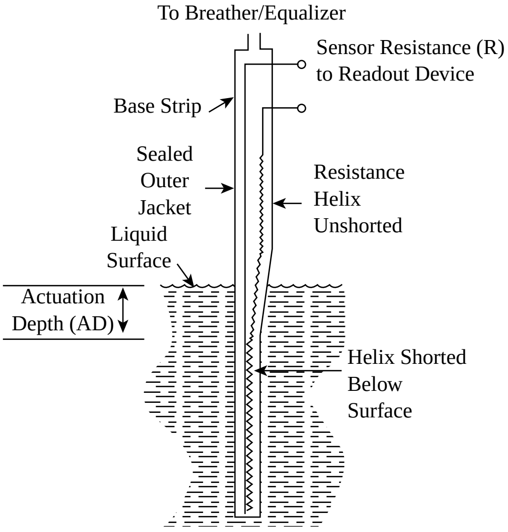

FIG. 3.16b
Schematic diagram of resistance tape sensor operation.

encloses the helically wound inner sensor and acts as an isolation barrier against the infiltration of liquid and vapor.

When surrounded by the process liquid or slurry, the flexible envelope is flattened by its hydrostatic pressure as shown schematically in Figure 3.16b. This presses the resistance helix winding into the gold contact stripe on the base strip.

ACTUATION DEPTH

Because some pressure is required to compress the jacket and thus to short the resistance leg, the tape cannot be shorted out all the way up to the surface of the material. The uppermost electrical contact is made some distance below the surface of the liquid, and this distance, the *actuation depth*, is a function of the density of the process material. For water, the actuation depth is approximately 4 in. (100 mm); for lighter materials, it is increased in proportion to its reduced density. The recommended minimum specific gravity is 0.5. At the time of calibration, this known, and constant offset should be zeroed out. Because of this zero offset, levels cannot be detected below its value.

Sensor resistance, *R*, measured across the two lead wires, changes 1 Ω for each millimeter of level change and corresponds to the length of *unshorted* helix above the liquid. An ohmmeter measurement can indicate the distance from tank top down to the point of shorting. Sensor resistance *R* can be set to equal zero when the tank is full and can equal the full resistance of the helix winding at a liquid level that is low enough that all helix contacts are relieved of pressure and open.

Actuation depth is a function of the sum of the spring rate of the winding and of the jacket, and it causes the uppermost helix contact to lag below the liquid surface by about 100 mm of cold water (SG = 1.00). The gauge is zeroed on the basis of the average anticipated SG anticipated for the particular process. If the specific gravity varies, one can either rezero the instrument or accept the resulting error (Figure 3.16c). The actuation depth usually does not change with aging of the tape, although it does increase as the ambient temperature turns cold, as a result of the stiffening of the sheath material. If it is desired to have the tape read the liquid level all the way down to the bottom of the tank, a sump must be provided at that location to extend the resistance tape below the tank's bottom.

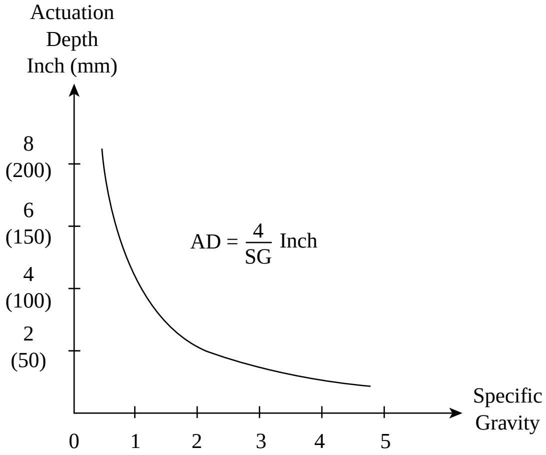

FIG. 3.16c
The relationship between actuation depth and specific gravity.

PRESSURE EFFECT

To maintain accuracy, the pressure inside the tape jacket must equal the pressure in the vapor space of the tank. For atmospheric tank applications, this is accomplished by venting the tape interior to the atmosphere through a small desiccant dryer (Figure 3.16d). For tanks under pressure or vacuum,

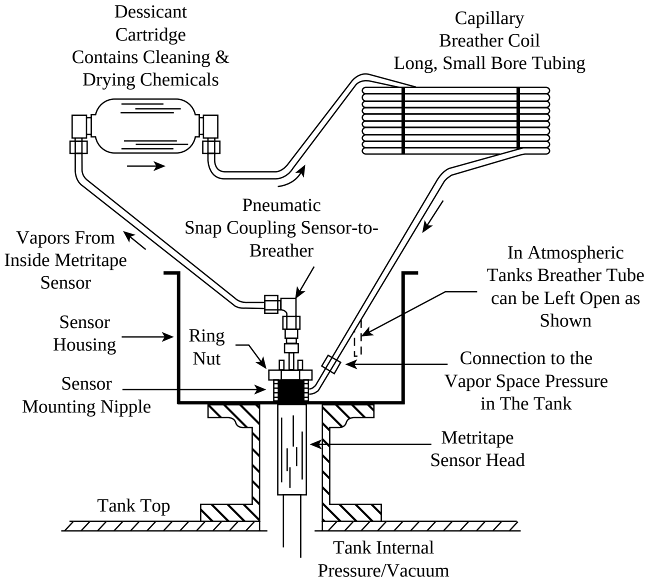

FIG. 3.16d
Capillary breather/equalizer assembly.

the tape's internal and external pressures must be equalized. This can be done by installing a direct-connected equalizing line or by mounting a one-to-one pressure repeater on the tank and tubing the output of the repeater to the vent connection on the tape. However, care must be taken to keep moisture and other contaminants from getting inside the tape jacket.

The sealed sensor sheath is vented at the top through a capillary breather/equalizer assembly. This allows the inner resistance-tape sensor to "exhale" as tank level rises and "inhale" as tank level falls. Air expelled from the sensor is cleaned and dried as it passes through the desiccant cartridge and is held in the capillary breather coil, which acts as a reservoir. When the liquid level falls and some of the sensor contacts open up, the clean, dry air is returned to the inner sensor. At the same time, the pressure inside the previously extended breather tubing is returned to the tank pressure, thereby equalizing the inner sensor chamber to match the pressure surrounding the sensor. This allows resistance tapes to operate in pressurized or evacuated tanks.

A typical installation of the resistance tape sensor inside a protective still pipe is shown in Figure 3.16e. The top-mounted housing has a 1.5-in. (38-mm) diameter threaded nipple that is welded in the bottom and to which the sensor head is secured and sealed with a slip nut. The housing serves to hold the sensor head, the capillary breather, the lead-wire connections, and an optional loop-powered transmitter. The stilling pipe can be perforated or slotted if the viscosity or solids content of the process material requires it. A vent hole at the top is always provided. The sensor may be edge-clamped to allow unobstructed gauging of waves or to detect sewage or slurries having very high solids content. It can also be cable-suspended in deep wells or caverns.

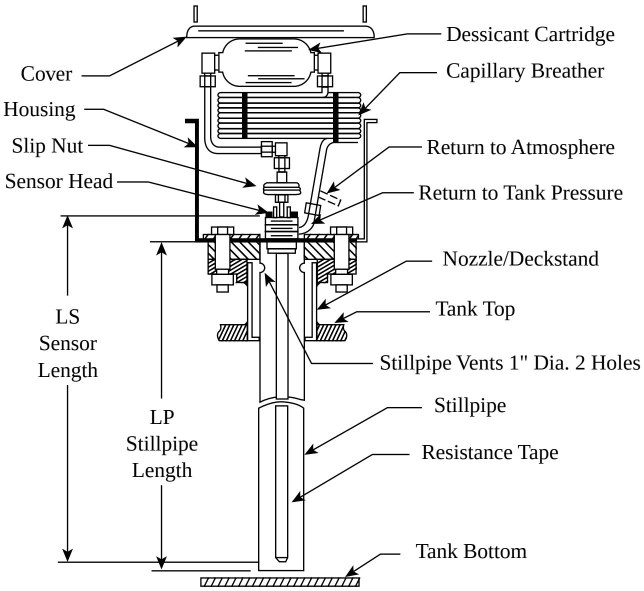

FIG. 3.16e
Typical mounting of resistance tape sensor, housing, and still pipe on tank-top nozzle.

Whereas tank pressure or vacuum is directly equalized through the capillary breather/equalizer, the operating range of equalization is limited by the ability of the standard breather to contain pressure or vacuum without leakage. Resistance tape gauges are used in liquid storage tanks that are vented or pressured by an inert gas blanket. The capillary breather/equalizer requires annual inspection for color change in the desiccant cartridge indicator. Replacement of this component every 3 to 5 years is recommended to prevent corrosion of internal sensor contacts.

The outer sheath of the resistance tape is wetted by the process material and must resist corrosion and permeation. A laminated polyester sheath is used for water and wastewater applications, and a sheath of heat-sealed fluorocarbon film can be added for use in a wide range of liquid applications, including many chemicals and solvents. Certain chemicals, including halogen acids, Freon®, ammonia, and halogenated hydrocarbons permeate this fluorocarbon film. Thus, their level cannot be measured by this design of resistance tapes.

The resistance tape may be provided with built-in temperature detectors for *in situ* temperature measurement. Combined measurements of liquid level and temperature are accomplished by mounting 1 to 3 resistance temperature detectors at selected elevations on the back of the inner sensor and bringing additional lead wires out the sensor top end. A single tank penetration and cable run can thus serve both level and temperature measurement functions.

TEMPERATURE AND OTHER EFFECTS

The unit resistance or resistance gradient, Rg, of a standard tape is 305 Ω/ft, and its temperature gradient, Tg, is 40 ppm/°C. Therefore, if we have a 20-ft. tape in a vessel that is half full (length L of the unshorted tape is 10 ft), and if we want to calculate the error caused in the level measurement if the process temperature changed by $\Delta T = 100°C$, the calculation described by Equation 3.16(1) has to be made.

$$E_{100} = (Tg)(L)(\Delta T)/12 = (40/10^6) \times 10 \times 100/12 = 0.48 \text{ in.} \qquad \textbf{3.16(1)}$$

A built-in temperature detector can be used to compensate for such shift. Resistance tape devices are limited to moderate temperature applications up to 225°F (107°C) so as to stay within the corrosion and permeation capability of the outer fluorocarbon sheath.

Resistance tape cannot operate in a zero-gravity field and cannot be used for liquid–liquid interface measurement. On the other hand, it does have high resistance to mechanical shock and vibration and is therefore well suited for military and seismic services.

Resistance tapes are made in standard lengths of integral feet. The height of the stand-off nozzle at the top of the tank can be adjusted to lift the sensor bottom end to 2 in. above tank bottom.

TABLE 3.16f
Tape Selection Chart (Courtesy of Consilium US Inc.)

Service	*Sensor Type*	*Wetted Materials*	*Temperature Range*	*Level Range*	*Pressure Range*
Water, wastewater, sewage	Aquatape	Polyester, epoxy, polypropylene, stainless steel	5° to 140°F (–15° to 60°C)	3–50 ft (1–15 m)	Atmospheric only
Crude oil, petroleum products	Petrotape	Hastelloy® C276, Nylon 12, glass-filled polypropylene	5° to 225°F (–15° to 107°C)	3–100 ft (1–30 m)	±2 PSI
Chemicals, solvents	Chemtape	Hastelloy® C276 or Teflon, polypropylene	Hastelloy®: 5° to 225°F (–15° to 107°C) Teflon: 5 to 140°F (–15° to 60°C)	3–100 ft (1–30 m)	±2 PSI
Water, wastewater, sewage	LA	Polyester, epoxy, glass-filled polypropylene, stainless steel	5° to 158°F (–15° to 70°C)	3–100 ft (1–30 m)	±15 PSI (±1 atm)
Crude oil, petroleum products	LA-HN	Hastelloy® C276, Nylon 12	5° to 225°F (–15° to 107°C)	3–100 ft (1–30 m)	±15 PSI (±1 atm)
Chemicals, solvents	LA-HP	Hastelloy® C276, polypropylene	–20 to 225°F (–30 to 107°C)	3–100 ft (1–30 m)	±15 PSI (±1 atm)
	LA-AF	FEP Teflon, glass-filled polypropylene			

The resistance helix winding is approved as being intrinsically safe for use in hazardous, explosive liquid, and vapor applications (Class 1, Div. I, Groups A, B, C, and D) and in dust and grain applications (Groups F and G).

CONCLUSION

Resistance tapes measure liquid and slurry levels with only one moving part. The movement is caused by the process medium and produces a resistance output that is stable and independent of most liquid properties. This gauge is suitable for the measurement of levels in liquid storage tanks, sumps, and streams if the pressure is near atmospheric and the temperature is near ambient. It can handle corrosive and slurry-type materials (see Table 3.16f). However, because of limitations caused by *actuation depth* variation, pressure equalization, and dryer maintenance, their applications should be chosen very selectively.

INTRODUCTION

Solids level measurement is made difficult by the wide range of solids properties involved. The densities of some pulverized materials can be as low as 5 lb/ft^3 (80 kg/m^3) while other, sometimes lumpy materials can have densities in excess of 100 lb/ft^3 (1600 kg/m^3). The main purpose of detecting the level of solids is to signal the breakdown in continuous solids flows, which usually occurs as a result of either arching or bridging (the blockage of flow due to the segregation and collection of larger-sized particles) or flushing and "ratholing" (the sudden dumping of large quantities as arches collapse). Tank and bin vibrators are used to maintain uninterrupted solids flows. Some materials (e.g., zinc oxide, lampblack, soda ash, activated carbon, titanium oxide, and hydrated lime) have a higher tendency to arch (bridge). Granular materials such as stone, grain, sand, and coal tend to slide more when moist or when the coarse particles are intermixed with finer particles.

The design of feeders and bins must take into consideration the flowing and arching properties of the solids. These properties are usually expressed in terms of the angle of repose. The angle of repose is that angle with the horizontal at which the solids will not yet slide off the inclined plane. When this angle is low (20 to 30°), such as with rye, barley, oats, or soybeans, it is relatively easy to transport these solids; however, when the angle of repose is greater than 45°, such as with pulverized coal or pulverized phosphate, the problems of moving these solids becomes more difficult. If the angle of repose varies in a particular bin, the high-level switch should be located based on the maximum possible angle, and the low-level switch should be located based on the minimum.

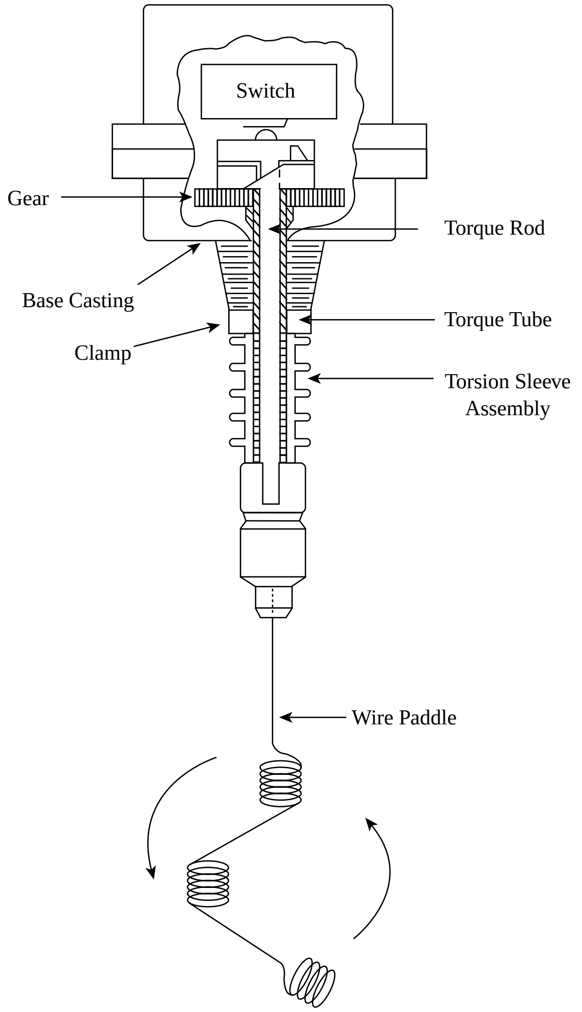

FIG. 3.17a
Rotating paddle switch schematic.

ROTATING PADDLE SWITCHES

The rotating paddle-type level switch is used to detect the presence or absence of solids in a silo. A small, geared, synchronous motor keeps the paddle in motion at very low speed. When solids are absent, there is no torque on the paddle drive assembly. When level rises to the paddle, it is stopped, and torque is applied to the drive assembly. Detection of the torque is used to actuate a switch that, in turn, can be used for alarm or for control of silo filling or emptying equipment.

As shown in Figure 3.17a, one method for torque detection uses a modification of the displacer-type torque tube. When solids are not present (and thus there is no torque on the tube), the entire drive assembly rotates at the speed of the gear in a counterclockwise direction. With solids present, the paddle stops, torque develops on the tube, and the torque rod is forced clockwise relative to the rest of the assembly. This clockwise motion rotates a beveled cam that rises to operate the switch. In some designs, the motor is rated to operate in a continuously stalled condition. In others, the motor is switched off and does not restart until the spring-opposed torque detector returns to the zero-torque position.

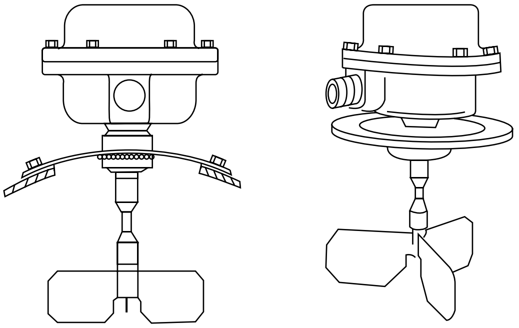

FIG. 3.17b
Paddle switches can be provided with either flat flanges or flexible mounting plates. (Courtesy of Monitor Technology Inc.)

A number of paddle designs are available; larger paddle areas are required to generate sufficient torque in lower bulk density materials. Conventional four-blade paddles, 6 in. (152 mm) wide by 2 in. (50 mm) high, are used in materials with densities below 20 to 30 lb/ft^3 (320 to 480 kg/m^3), whereas vane and wire designs are used in heavier materials. The latter types can be installed through a coupling on the silo wall. The larger paddle designs are furnished with a plate to cover the silo nozzle or cutout through which the paddles are inserted (Figure 3.17b).

Pressure and temperature ratings vary, depending on the unit selected. Standard units have pressure ratings from 7.5 PSIG (52 kPa) to 30 PSIG (207 kPa). When the switch is installed on a pressurized silo, the electrical conduit should be sealed to prevent accumulation of dust in the conduit system in the event that the torque tube or seal ruptures. A common temperature rating for standard units is –30 to 200°F (–34 to 93°C) including the switch and motor housing, although higher ratings are available. These level switches will give repeatable performance on the same solids within 1 in. (25 mm), but their mounting location should be carefully selected, giving consideration to the possible variations in the angle of response. High-level switches have to be lowered in the bin as the angle of repose rises.

Installations

Figure 3.17c illustrates several paddle designs and some methods of installing these switches on silos. Switch locations and immersion lengths are selected after determining the angle of repose of the material and how the orientation and location of the inlet and outlet nozzles will affect average level. Unit A shows a wire design mounted in the side of a silo that may be in the path of falling material. The protective baffle is installed to prevent spurious trips. Unit B shows a conventional top-mounted paddle design with a shaft guard. Unit C is also top mounted and illustrates a rectangular vane design.

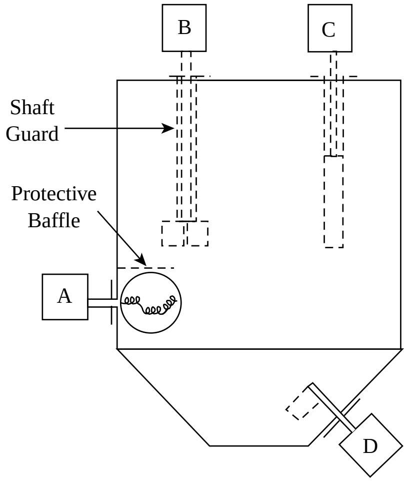

FIG. 3.17c
Rotating paddle solids level switch.

This design, used for heavier material, is located so that the vane will be pinned against the silo wall by the rising level. Unit D is located for low-level detection and depicts a vane design that is suitable for operation in low-density materials.

Paddle switches have the advantage of many decades of application history on different types of services. Their limitations involve the possibility of their rotation being prevented by dirt or rust, their relatively low pressure ratings, and their limited availability for corrosive services.

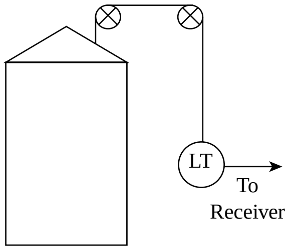
3.18 Tank Gauges Including Float-Type Tape Gauges

D. S. KAYSER (1982) **B. G. LIPTÁK** (1969, 1995, 2003)*



Flow Sheet Symbol

Applications	Tank-farm liquid level detection for accounting purposes and solids level sensing
Types	A. Float operated, wire-guided, inductively coupled B. Servo-operated float type C. Surface detector (plumb-bob) gauges D. Radiation backscatter design (see Section 3.15) E. Radar tank gauges (see Sections 3.13 and 3.14) F. Hydrostatic tank gauges, HTGs (see Section 3.6) G. Hybrid tank gauges
Design Pressure	Surface-detecting solids gauges are used up to 5 PSIG (0.34 bars), standard wire-guided tape gauges are used at 30 PSIG (2 bars), and special designs can be used up to 300 PSIG (20.6 bars)
Design Temperature	Solids level sensors can operate from –4 to 176°F (–20 to 80°C), and tape gauges on liquid tank farms can handle from cryogenic services to up to 300°F (150°C)
Materials of Construction	Mounting flange and housing can be aluminum; wetted parts can be made of aluminum, steel, stainless steel, nylon, PVC, polyethylene, and other plastics or higher alloys.
Electrical Safety	Tape gauges for liquids can be all mechanical or explosion-proof. Inductively coupled float designs are intrinsically safe. The solids level detector plumb-bobs are available in explosion-proof housings.
Range	Standard wire-guided tape gauges are available up to 100 ft (30 m); plumb-bob-type surface sensors are available up to 200 ft (60 m).
Inaccuracy	Error in solids sensors is about 0.2 ft (61 mm); for liquid service automatic tank gauges (ATG) refer to Table 3.18a.
Cost	Plumb-bob solids level sensors start at about $2000. For liquid service automatic tank gauges, refer to Table 3.18a.
Partial List of Suppliers	For the radiation backscatter design, see Section 3.15; for radar tank gauges, see Sections 3.13 and 3.14; for hydrostatic tank gauges, see Section 3.6. MTS Systems Corp. (www.mtssensors.com) (A, B)
Rosemount-Varec (A, B)
Saab Rosemount Tank Control (www.saabradar.com) (C, E)

In this section, we concentrate on types of automatic tank gauge (ATG) designs that are not detailed in the other sections. The radiation backscatter gauges are discussed in Section 3.15, the radar-type tank gauges in Sections 3.13 and 3.14, and the hydrostatic tank gauges in Section 3.6. For that reason, they will be mentioned only briefly.

HISTORY OF CUSTODY TRANSFER

Tank-farm level measurement, particularly in the oil industry, has been the basis for buying and selling products on a volumetric basis. In the 19th century, oil could not be measured more accurately than about 5%, so producers agreed on the size of the 42-gal barrel, thereby making sure that there would be at least 40 gallons in every barrel. A hundred years later, the precision of custody transfer improved to about 0.5% and, today, if every error source except nonuniformity in the tank's cross section is carefully eliminated, the error will be about 0.25%.

When oil is sold, it can be sold by weight or volume. If sold by the volume, it can be metered or sold on the basis of level measurements. The more advanced and most accurate method is flow metering (see Sections 2.19 and 2.25), which definitely should be used when transferring smaller volumes, and the more traditional is level measurement. One can measure the level manually (which involves climbing to the top of the tank) or automatically, and one can detect the drop in the level of the supply tank (*outage*) or the rise in the level of the receiving tank (*innage*). As shown in Table 3.18a, some automatic tank gauges (ATGs) are better suited for outage detection, and others for innage sensing.

When measuring outage, we are detecting the distance from the top of the tank to the oil surface. Multiplying this distance times the cross-sectional area of the tank gives the volume of the vapor space, called *ullage*. Outage detection is less accurate than innage, because the outage distance has to be compared to a *reference height* (the mounting location of the gauge), which, if the ATG is supported from the tank shell or roof (Figure 3.18b), varies with oil depth, temperature, and age. Therefore, if the ATG error is 0.125 in., but the gauge mounting can travel 0.5 in., the actual error can reach 0.625 in. This, if the transfer volume is small (e.g., a 2.0-in. change in level), makes the measurement meaningless. The best way to minimize the variation in reference height is to mount the ATG on a properly supported and slotted gauging well. Figures 3.18c and 3.18d illustrate the bottom-supported wells used on floating and fixed roof tanks, whereas Figures 3.18e and 3.18f describe the installation of shell-supported wells on floating and fixed roof tanks.

As shown in Table 3.18a, HTGs and most smart cable ATGs detect innage by measuring the distance from the tank bottom to the liquid surface. Here, if the tank is on a solid surface so that its bottom does not move, there is no reference height, because the volume of liquid in the tank is determined by multiplying the innage distance with the cross-sectional area of the tank.

TANK GAUGE DESIGNS[1]

As can be seen from Table 3.18a, the largest number of existing ATGs are the *float-operated tank gauges*, which have been used for more than 50 years. They are the least expensive and least accurate and were developed to reduce the need for the operator to climb the tank for manual "dipping." Here, as shown in Figure 3.18g, a perforated tape runs up from the float to the top of the tank and then down to the gauge head. For this reason, the float-operated ATGs double the reference height error, because the gauge head is mounted at grade. They also require high maintenance because of the moving parts, although the newer designs have fewer of such parts.

TABLE 3.18a
Features of Automatic Tank Gauges (Based on Reference 1)

Type of Design	*Number in Use in USA*	*Cost (for 40-ft floating roof tank w/temp. measurement)*	*It Measures*	*Accuracy*	*Maintenance Required*
Float	300,000±	$4000±	Outage	Low	Highest
Servo	10,000±	$6500±	Outage	Good	High
Radar	5000±	$8500±	Outage	Good	Low
HTG	5000±	$8500±	Innage	Low	Low
Smart Cable	5000±	Note 1	Innage	Good	Varies
Hybrid	200±	Note 2	Note 2	Note 2	Note 2

Note 1. Costs vary for the different types of Smart Cable systems. A magnetostrictive system for a 40-ft high floating roof tank costs $3500±, including average temperature measurement.
Note 2. The cost, measurement method, accuracy, and maintenance of a Hybrid ATG depends on the level and temperature measurement system. A pressure transmitter adds $1500± to the cost of the system.

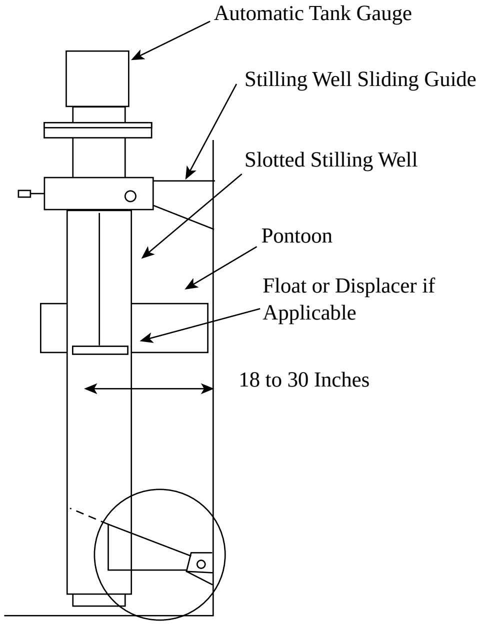

FIG. 3.18e
Shell-supported gauging well for floating roof tank.

In Europe, during the last decades, *servo-operated tank gauges* been used for custody transfer level measurement to detect the outage. They, too, should be mounted on a properly supported slotted gauging well to minimize the error caused by reference height movement. Their maintenance has also been improved during the past five years by the development of a new gauge head with fewer moving parts.

As was discussed in Sections 3.13 and 3.14, *radar tank gauges* can also be used for custody transfer level measurement. They, too, measure outage, so they should also be mounted on a properly supported slotted gauging well. They have no moving parts, so their maintenance is relatively low.

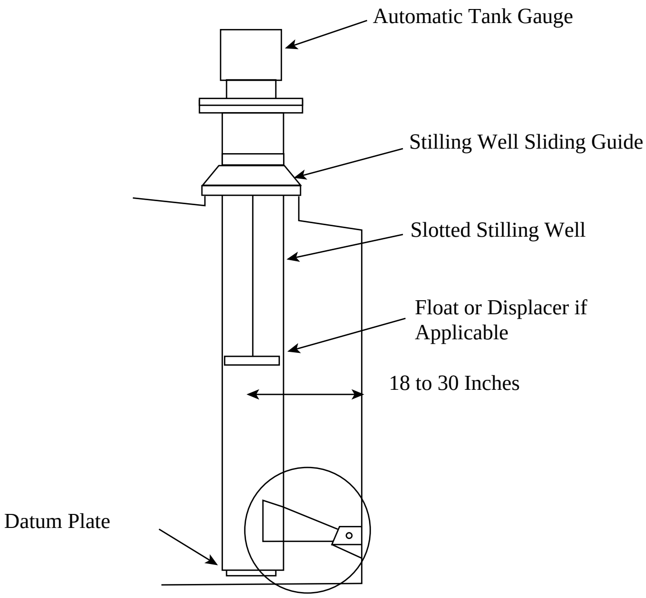

FIG. 3.18f
Shell-supported gauging well for fixed roof tank.

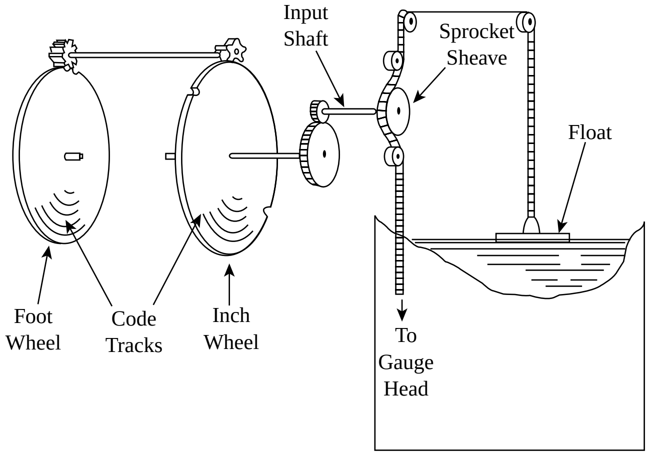

FIG. 3.18g
Schematic of foot and inch wheel drives.

As discussed in Section 3.20, *sonic or ultrasonic* tank gauges also measure an echo, but their accuracy is affected by vapor above the product, and they have not been widely used for tank measurement in the oil industry.

As already discussed in connection with Figure 3.6e, *hydrostatic tank gauges (HTGs)* were developed to convert from volume measurement to the detection of mass. HTGs provide mass measurement, limited only by the accuracy of the pressure transmitters and the tank strapping tables. They are not affected by reference height variation, because they measure innage, but the accuracy of their level measurement drops if the tank contents are temperature or density stratified. The smaller and less expensive hydrostatic interface units (HIUs) represent an improvement over the HTGs.

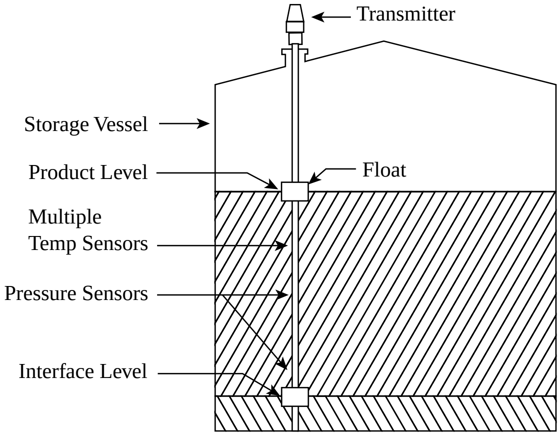

FIG. 3.18h
Level, volume, mass, density, interface, pressure, and temperature can be monitored by the inductively coupled tape system. (Courtesy of the former Sarasota Measurements and Controls.)

If a cable containing the level-measuring element runs from the bottom to the top of the tank, it can be called a *smart cable.* Most types have a float that rides up and down the cable. The best types measure innage, so their accuracy is not affected by changes in reference height, they do not require gauging wells, and (as illustrated in Figure 3.18h) they provide a series of resistance bulbs in the cable to simultaneously measure average temperature. *Capacitance tank gauges* use two capacitance plates. Capacitance varies with level, because the product dielectric constant differs from that of the air or vapor. *Inductive tank gauges* measure level using a digital position signal generated by the inductive interaction with a transponder in the float (Figure 3.18i). *Magnetostrictive tank gauges* measure the time of flight of a torsion wave that pulses up and down a ferromagnetic wave guide, where the wave is reversed by a magnet in the float. *Resistive tank gauges* (see Section 3.15) use a nichrome helix wrapped around a steel core and covered with a Teflon® jacket. The hydrostatic pressure of the product shorts the helix against the core so that the resistance varies with the product level.

Hybrid level gauges (as illustrated by Figure 3.6e) are still evolving and, in addition to level, can also detect volume, mass, temperature, and density. In this configuration, level and volume are measured by the ATG, and mass is measured by the pressure sensor. The design is still evolving. Hybrids can measure density without sampling or laboratory analysis. Because of the redundant measurements, they also provide some error checking.

ACCURACY

According to Berto,[1] quantitatively, the following error contributions can be expected:

1. The error in manual gauging or the ATG is about ±0.125 in.

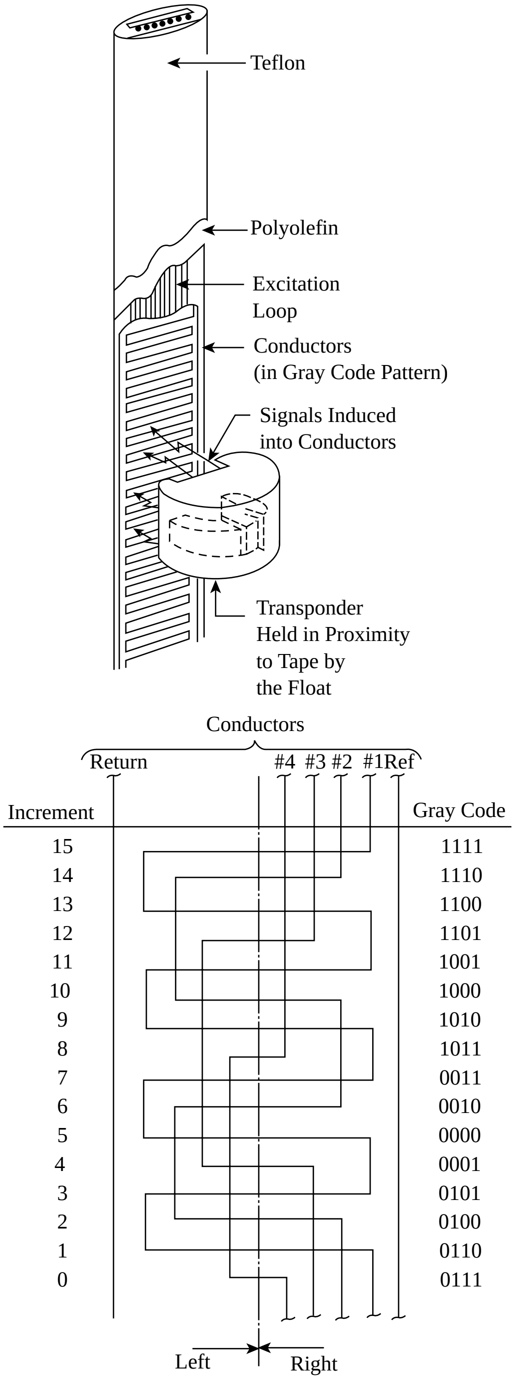

FIG. 3.18i

The inductively coupled tape and float assembly and the arrangement for a 16-increment system. (Courtesy of the former Sarasota Measurements and Controls.)

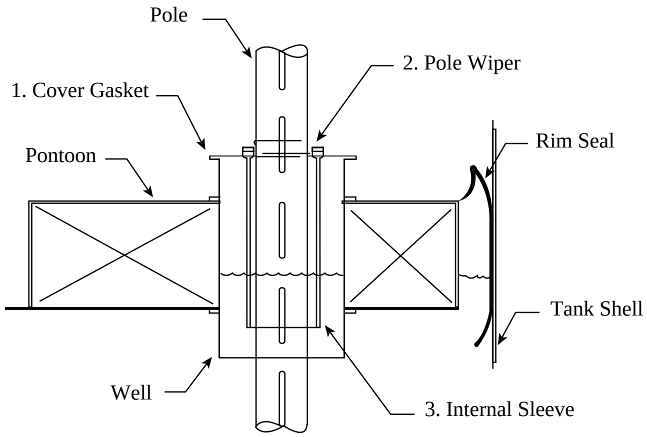

FIG. 3.18j

The improved slotted gauge pole.[1]

2. The error in the tank capacity tables, including the effect of tank tilt and hydrostatic pressure, is about ±0.5 in.
3. Tank shells expand as a result of liquid head as a full tank takes the shape of a barrel. This effect is normally included in the calculation of the tank tables, but the accompanying movement of the lower datum plate or the upper reference point is not included.
4. Tank bottom movement results in undermeasurement (+0.25 in.). This varies with the compressive strength of the soil under the tank.
5. Incrustation may be significant with heavy or waxy products stored in small tanks. It results in overmeasurement.
6. Movement of the gauging well can be ±1 in. Floating roof tanks should be fitted with slotted gauging wells (Figure 3.18j). Vertical movement of the gauging well movement affects outage measurements and causes an error when converting measured outage to innage.
7. Datum plate movement affects innage measurements by ±0.5 in. When a tank is filled and the shell takes a barrel shape, the bottom bulges up adjacent to the shell. Farther inward, the bottom moves down because of hydrostatic pressure. The datum plate should be located 18 to 30 in. from the shell to minimize the effect of bottom movement.
8. Thermal expansion of the tank shell and the gauging well can amount to ±0.125 in. Thermal expansion causes two errors, because both the tank diameter and the tank height change. Tank capacity tables are calculated for one temperature (60°F). They do not correct for the thermal expansion of the tank shell. The amount of error depends on the product temperature and the ambient temperature.
9. Another serous source of errors is poor temperature measurements. With heavy oils, it takes 45 min for a manual temperature measurement using a cup-case, even if the thermometer is continuously moved up and down. This can result in 2 to 3° of error. ATGs are provided with high-performance average temperature sensors, but at a cost of about $2000.
10. In crude oil level measurement, a major error source is the method used in determining the sediment and water content of the oil. Manual sampling is unacceptable,

because it does not provide a representative sample and does not necessarily analyze the sample correctly. Therefore, automatic samplers are recommended.

TRADITIONAL TAPE LEVEL SENSORS

Tape level detectors can be furnished with local or remote readouts and can facilitate inventory control in multiple tanks and silo installations. Liquid level detector tape gauges include the conventional tape gauges (a wire-guided float or displacer), the inductively coupled float, and the wire-guided thermal sensor. The surface-sensing tape gauges (plumb-bobs) used in solids service have a resolution of about 0.1 ft (30 mm) and an error of about 0.2 ft (60 mm). This accuracy on solids level measurement is usually acceptable, as other variables (such as changes in the angle of repose, bridging, rat-holing, and the change in the shape of solids level as the operation is changed from filling to discharging) all cause errors in the correlation between level and volume. As a result of these uncertainties, very precise measurement of the level at a particular point is of no great value.

WIRE-GUIDED FLOAT DETECTORS

Figure 3.18k shows a wire-guided float detector that has a tape connection to a ground reading assembly. This detector has evolved from the float-operated gauge board. The system shown here is suitable for tanks having an operating pressure to 30 PSIG (0.2 MPa) and a height of up to 60 ft (18 m), although other designs are available that are rated to 300 PSIG (2 MPa). The float is about 15 in. (381 mm) in diameter and can be made of aluminum, stainless steel, or other alloys; it can be hollow or filled with materials such as foam glass. To direct the float, guide wires are connected to top and bottom anchors. The top anchors are normally spring loaded to maintain constant tension on the wires; the bottom anchors are tank clips.

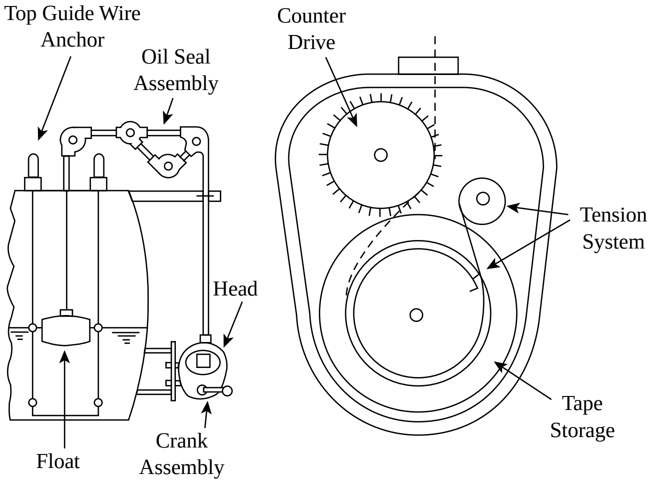

FIG. 3.18k
Wire-guided float detectors and detail of head.

A tape runs from the connection on the top of the float, over sheave assemblies, and down to the gauging head, which is outside the tank at eye level. The detail in Figure 3.18k shows the tape passing through an oil seal assembly. This seal can be used for gauge head corrosion protection or to prevent product condensation in the head, provided that the tank is operated at very close to atmospheric pressure. If the tank is pressurized, it is usually desirable to fill the head with the product, particularly if the product is clean and lubricating.

The tape, which is perforated, enters the gauge head, runs around a sprocketed counter drive, and is taken up on the tape storage reel. Tape tension is maintained by a secondary (spring-wound) take-up device. The shaft on the counter drive rotates as the float moves the tape up and down, and, by proper gearing, this rotary motion can be used to drive a feet-and-inches or metric readout. The counter is located outside of the gauge head, preventing exposure to any liquid fill in the head that may be present.

For lower-pressure designs, the shaft extends out of the gauge head through a gland, whereas, for pressures above 30 PSIG (0.2 MPa), the shaft motion is normally taken out of the head through a magnetic coupling. The gauge head can be equipped with several optional devices. A crank assembly mounted on the head permits lifting the float out of the process. Material buildup on the float that hinders smooth operation may make this necessary. Often, the float can be freed by lifting and lowering it. The head also may be equipped with a variety of switch configurations for high and low level alarms or for control-circuitry actuation.

Figure 3.18b shows installation details for wire-guided floats in low-pressure tanks. Figure 3.18l shows a high-pressure installation rated to 300 PSIG (2 MPa). At the higher pressures,

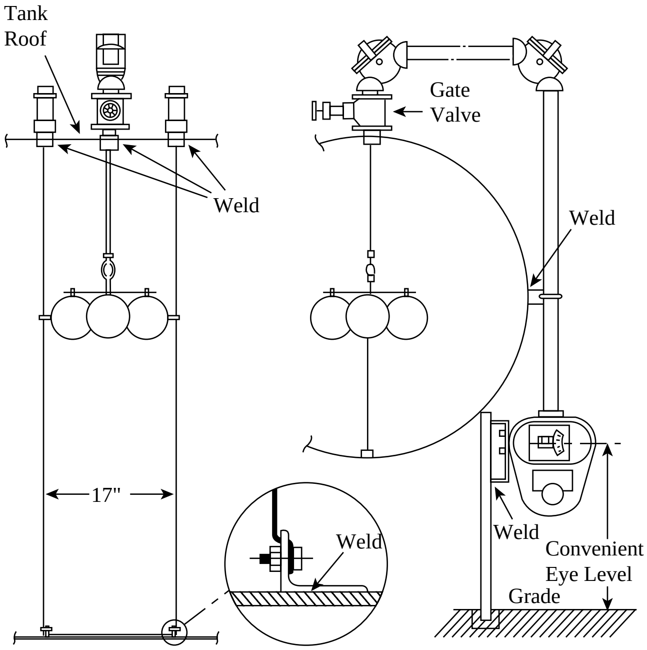

FIG. 3.18l
Wire-guided float detector installation for high pressure tanks.

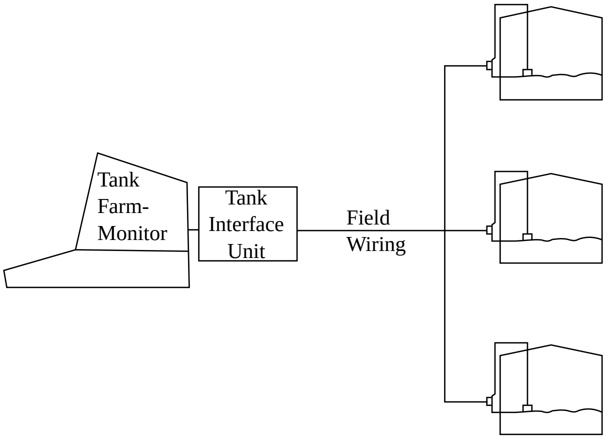

FIG. 3.18m
The use of tank farm unit controllers increases the safety of operation.

the flat, circular float design is no longer suitable, and one or more spherical floats are used. Connections for a high-pressure installation should be flanged, including those for the top anchor assemblies. Another feature to note in Figure 3.18l is the gate valve with rubber plug that is installed at the tank entry, allowing removal of the gauge head without tank depressurization.

One common problem with these level devices is tape hang-up. This can occur if the long guide pipes are not perfectly vertical and the tape rubs against the inside of these pipes. If dirt or corrosion is also present, the resulting friction can hold the tape in place while the float is moving. This has caused accidents in cases where tanks controlled using tape level gauges overflowed because the tape was stuck. One recommended precaution is to install a separate high-level switch.

Another recommended precaution is to use a microprocessor-based tank-farm operations controller as an added level of safety (Figure 3.18m). This unit controller can continuously monitor all operations that occur on the tank farm. It knows the capacity of each tank and the pumping rate of each pump, so it can check whether, under a particular filling operation, the level in the tank should be rising at a particular rate. If it should not (because the level transmitter is defective), the controller can sound an alarm or shut the system down.

Encoding

The wire-guided float detector level must be converted to an electrical signal by using the shaft rotation of the gauge head to drive encoding discs. Figure 3.18g illustrates one conversion method. The input shaft drives the “inches” wheel, and the gear assembly at the left of the sketch drives the “foot” wheel. For purposes of this sketch, the level tape sheave and shaft are set up to rotate 180° for each foot of level change. As the inch wheel completes one-half of a revolution, it steps the foot wheel up or down, corresponding to rising or falling level. Stepping of the foot wheel occurs when the notches on the inch wheel pass the gear. The wheels are coded so that a rotation corresponding to a 0.01-ft level change presents a new and unique digital code to the code take-off assembly. Codes are available for foot, inch, and fraction, or meter and millimeter readouts. Since the principle of operation is the same for all, only the foot, tenths, and hundredths will be covered.

The wheel has a number of concentric tracks on it, each track representing one digit of the digital word. The tracks are designed to produce the zero or one information needed for the digital word. This can be done in several ways. One way is to plate portions of the track with a conductor and allow a conducting brush to ride on the track. If the brush is on a conducting portion of the track, a current path will be formed, and a one will be produced. If the brush is on a nonconducting part of the track, the current path will not be formed, and a zero will be produced. Another encoding method is to use optical coupling. Portions of the tracks are plated with a reflecting material, and a light is beamed on the tracks. If the beam hits a reflecting portion of the track, a light-sensitive transistor conducts, thereby producing a one. If the beam hits a nonreflecting portion, the transistor does not conduct, and a zero is produced.

Figure 3.18n shows how a modified gray code could be used to produce a digital word that is unique for a given wheel position and thus a given level. (Only 8 tracks are shown instead of the 16-track arrangement that would be required for a ±0.01-ft (0.3-cm) resolution over an 80-ft (24.3-m) span. Also, the tracks are shown as being linear whereas, in the actual configuration, they would be on closed circular tracks. The shaded areas represent conducting portions of the tracks, and the light portions are nonconducting. Thus, if the float were at a level corresponding to 6.4 ft, the code produced would be 10100110. The digital code is produced continuously. It is read by the remote device when the tank gauge is addressed as described in the preceding paragraphs.

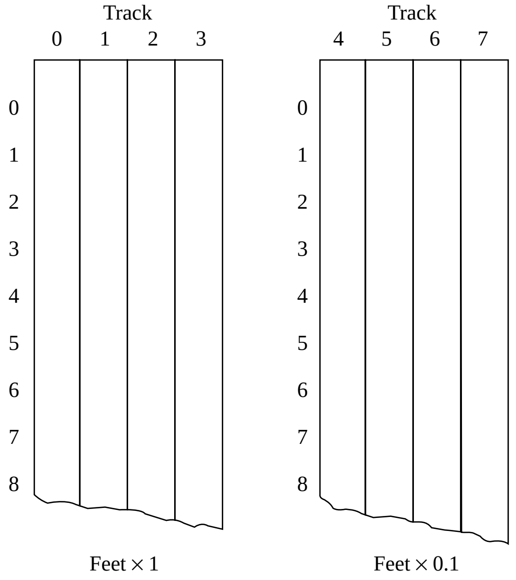

FIG. 3.18n
Encoding with a modified gray code.

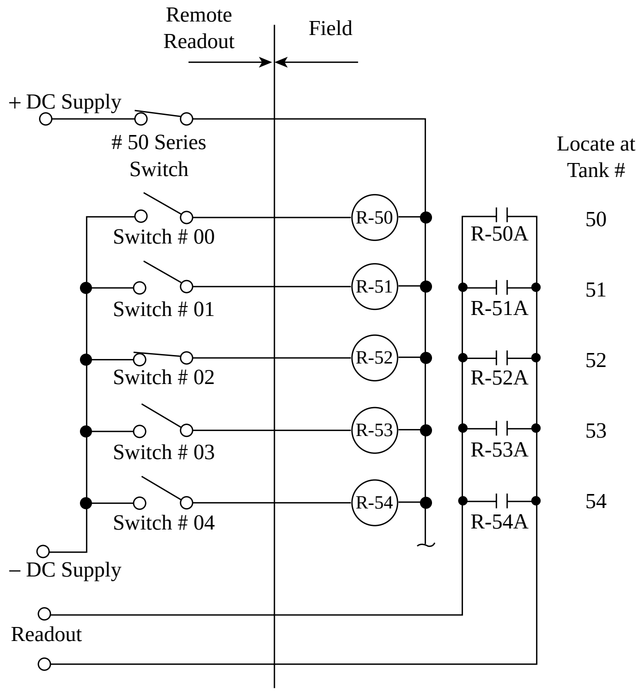

FIG. 3.18o
Multiple tank system cabling.

Temperature Compensation

Because liquids expand when heated, variations in the temperature of the material in the tank will affect the level reading. For this reason, it is quite common to take a temperature measurement of the liquid at the same time that the level is gauged, using the data to make a level correction based on temperature change. Equipment is available to accomplish this automatically. The resistance temperature detector (RTD) sensors at the various tanks can be switched into the remote readout at the same time that the level measurement is being made, using the same type of wiring arrangement shown in Figure 3.18o. A wide array of remote temperature and level readout equipment is commercially available. The simplest is the manually operated unit with pushbutton random access to all tanks. These units generally display the number of the tank called, its level, and its temperature. The more complex systems are microcomputer or minicomputer based and can have automatic logging of temperature-compensated level plus other features such as high- and high-high-level alarm. Most systems can be readily interfaced with larger computers.

INDUCTIVELY COUPLED TAPE DETECTOR

Figure 3.18h illustrates a fixed tape, float-actuated level measuring device. The tape is suspended from the roof of the tank and is anchored to the bottom. The tape is used to guide a float that contains an inductively coupled transducer. The tape consists of a steel ribbon and a number of insulated conductors encapsulated in a Teflon jacket. In addition to providing mechanical strength, the steel tape is used to provide power to the transducer in the float through inductive coupling. At short intervals, this primary coupling is interrupted, and a secondary inductive coupling from the transducer to the conductors on the tape is established.

The conductors are arranged on the tape in coded patterns so that each 0.1-in. (2.5-mm) increment has a unique code. The receiver mounted at the top of the tank reads which conductors have been inductively coupled. From this information, it can determine where along the tape the float is located and thus the elevation of the liquid level. The float is Teflon coated, and the tape-to-float clearance is approximately 0.25 in. (6.3 mm) to minimize float sticking and material buildup on the tape. The receiver can be furnished to transmit an analog signal proportional to level, or it can transmit the digital signal that has already been produced by the tape-and-float assembly, which has a resolution of 0.1 in. (2.5 mm).

The conductors on the tape are arranged to produce a gray code digital word. In the gray code, only one digit in the word changes from one word to the next, so only one conductor must change its position from one 0.1-in. (2.5-mm) increment to the next. The number of conductors required increases with the span of the liquid level to be measured. The span covered is equal to 2^N, where N is the number of conductors. Thus, if four conductors are used, the span would be 16 increments, or 1.6 in. (40 mm). If 14 conductors are used, the span would be 16,384 increments, or 135 ft (41 m). In addition, each system requires a reference conductor and a return conductor.

Figure 3.18i describes, in schematic form, how four conductors might be arranged on the steel tape to produce the gray code digital word for a 16-increment measuring system. If the conductor is on the right-hand side of the tape, it is inductively coupled to the transducer in the float; if on the left, it is not. The reference wire tells the receiver which side of the tape is the right-hand side. The return conductor is common, completing the circuit for all conductors. As shown in the figure, if the float is at increment 7, conductors 1 and 2 will be inductively coupled, and conductors 3 and 4 will not. Thus, the gray code digital word produced is 0011, which is unique for the particular increment. As previously noted, each additional conductor doubles the preceding span; adding a fifth conductor to the arrangement shown in Figure 3.18i would enable measurement more than 32 increments; a sixth conductor would enable measurement over 64 increments, and so on.

The inductively coupled tape level system is intrinsically safe. In addition to accurately measuring the level, it can also determine the density of the process fluid and, based on that information, calculate the mass of the tank contents. Sensors are also provided for pressure, temperature, and interface measurement.

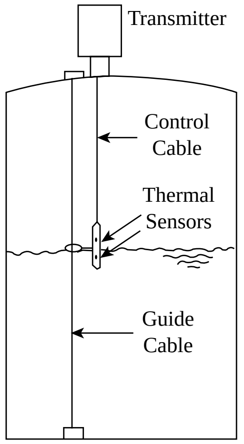

FIG. 3.18p
Wire-guided thermal sensor. Heavy sensor can also provide temperature profile.

WIRE-GUIDED THERMAL SENSOR

Because liquid conducts heat better than does vapor, the liquid surface is bracketed by the two vertically displaced sensors. The lower one is cooler than the upper one. Figure 3.18p gives an installation detail for a wire-guided thermal sensor. The sensor, which is heavier than the liquid being measured, is suspended from an armored control cable and guided by a wire attached to the top and bottom of the storage vessel. The control unit detects the position of the sensor relative to the liquid level and issues step-up or step-down commands to the control cable take-up wheel until the lower sensor is in the liquid and the upper sensor is in the vapor. The system remains at rest as long as these conditions are met. When the sensor is moving, each stepping command adds or subtracts a length unit from the previous controller reading so that sensor position, and thus level, is accurately known.

The unique feature of this instrument is that the sensor is heavier than the liquid, allowing the unit to be lowered to the tank floor so that the control and counter circuitry can be zeroed. The controller contains a cable tension sensor to signal when the level sensor has hit bottom. A controller subroutine permits automatic zeroing. The sensor also can be equipped with a temperature detector to provide a thermal profile of the tank material. This is useful for accurate correction of level measurement and can also be used to detect temperature inversions in cryogenic services.

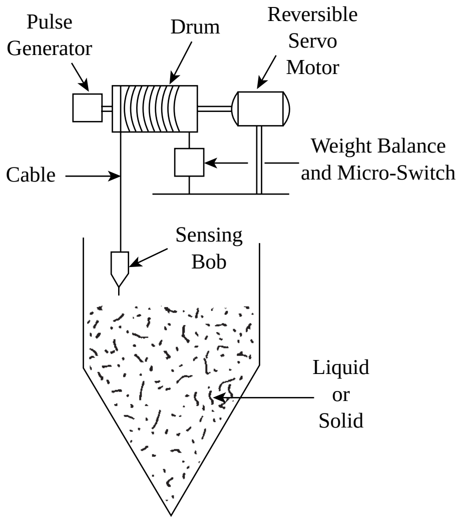

FIG. 3.18q
Surface sensor.

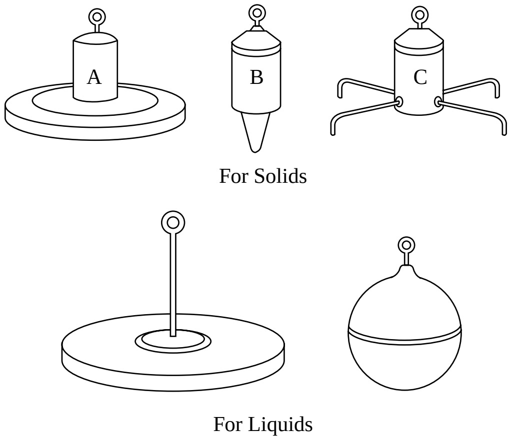

FIG. 3.18r
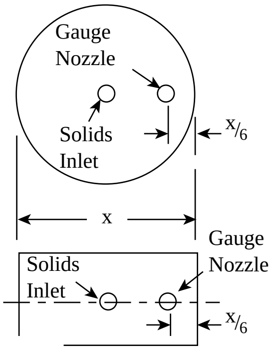
Sounder designs.

SOLIDS LEVEL DETECTORS

Although the gauges described here were originally developed for solids level detection, they can also be used for liquid level detection if equipped with a properly designed sounder. As shown in Figure 3.18q, a sounder is suspended from the winding drum. The wire tension is continuously detected by the weight balance. A reversible servomotor rotates the drum when a starting signal is received, and it releases the wire until the sounder strikes the solid (or liquid) surface. When this occurs, the tension in the wire slackens, causing the weight balance to actuate a microswitch. After the momentary slackening of the cable, the microswitch reverses the motor and returns the sensing bob to its original reference position.

The shape of the sensing bobs (or sounders) varies with the process fluid. Figure 3.18r illustrates some of the typical shapes used on both liquid and solids services. On solids with less than 20 lbm/ft^3 (320 kg/m^3), the type A sensing bob is used. For higher densities, the type B is recommended, and, for coarser solids, the type C design is the appropriate choice.

A pulse generator is coupled to the system to provide an input signal to the counter, which counts down from a preset maximum reference value in steps. When the sounder strikes



Relative locations of solids inlet and gauge nozzles for rectangular and circular bin cross-sections

FIG. 3.18s
Surface sounder installation for solids.

the product surface, the solids level is displayed and, at the same time, the counter is automatically disconnected from the pulse generator. The reading stays on the counter until the next measurement. On receipt of a new start signal, the counter is reset to the maximum reference value, and the measurement cycle is repeated. There are several ways in which the amount of cable paid out can be converted to pulses. In one design, the cable pays out over a measuring wheel with a 6-in. diameter. The measuring wheel drives a five-lobe cam that trips a stationary cam each time a lobe passes by. In this way, ten contact closures are produced for each foot of cable paid out.

In another, higher-resolution design, the measuring wheel drives a disc that has 50 radial slots around its circumference. Here, the slots are counted by a light beam and a light-sensitive transistor, and 100 pulses are generated for each foot of cable "paid out." In either case, the level measurement reference is the top of the tank.

In dust-filled atmospheres, a solenoid-operated pneumatic cleaning assembly should be added to ensure reliable operation. As shown at the top of Figure 3.18s, the relative locations of the gauge nozzle and the solids inlet nozzle are important, because the sounder is used to take an average level reading. At no time should there be any contact between the filling system and the sounder. If the inlet nozzle is in the center of the bin, the surface of granular products will tend to take the shape of a cone. The gauge, therefore, should be located to obtain to obtain average level. As shown in the sketch, this requires the nozzle to be one-sixth of the diameter from the bin wall for circular bins. The sketch on the bottom of Figure 3.18s shows the proper location for installations in rectangular bins.

CAPACITANCE AND DISPLACER TAPE DEVICES

At least two other tape level detector designs are available. In one, the sensor is suspended on a cable and held a short distance above the liquid level. The distance is sensed by a proximity-type capacitance probe (Figure 3.3f). The control unit monitors the capacitance between the sensor and the liquid level, repositioning the sensor as the level changes. Sensor position, and thus level, is determined by measuring the amount of cable that has been paid out. In this respect, it is the same as the wire-guided thermal sensor previously described.

The second design uses a displacer mounted on the end of a cable. In this design, the displacer is continuously repositioned so that it is always immersed the same amount, say, to 50% of its 0.1-in. (2.5-mm) thickness. Level is determined by the amount of cable paid out. The displacer design has cable weight compensation but is not compensated for changes in liquid density. Both the capacitance and the displacer designs are installed in stilling wells.

MULTIPLE-TANK SYSTEMS

As previously mentioned, gauges covered in this section are used in conjunction with remote manually operated and automatically operated multiple-tank gauging systems. Multiple gauging requires cables from each tank to the remote readout. For wire-guided float detectors, the shaft position on the gauge head must be transduced to an electrical signal. The objective in designing the cable system is to wire up all the tank gauges with as few wires as possible, which means that wires must be shared.

Figure 3.18o shows a wiring system used to obtain a level reading for any one of five tanks. Eight wires are used. By closing the tens switch #50 (at the top of the figure), one-half of the circuit to the relays at tanks 50 through 54 has been closed. Closure of any unit switch #00 through #04 will complete a circuit through the relay coil associated with the tank that is to be remotely metered. In the figure, switch #02 is closed; therefore, relay R-52 is energized, and relay contact R-52A is held closed. The remote readout can now obtain the level data that is available at the gauge head at tank 52. This technique allows a great number of tanks to be remotely monitored with relatively few wires. For example, a 100-tank installation can be monitored using 22 wires. The 22 wires would be composed of 10 for the tens position, 10 for the units position, and 2 for the signal. A second group of 100 tanks can be picked up by adding only two more wires, one for the 100s-series tanks and one for the 200s-series tanks.

When the distance from the tanks to the remote readout is long, a satellite multiplexer may be considered. The satellite multiplexer collects level information for tanks in the immediate vicinity and transmits it, on demand, over two wires to the remote readout. The satellite multiplexing system might be used for a pipeline transmission installation where the various bulk storage facilities are hundreds of miles apart. The switches shown in Figure 3.18o constitute a manually operated multiplexer. These switches can be operated by a data logger or by a computer, making inventory monitoring completely automatic.

The reason for monitoring a tank farm with as few wires as possible is to reduce installation costs. In so doing, the gauge head relays and much of the wiring are run in parallel. This means that a short to ground, an open wire, or a malfunctioning gauge head can disrupt the entire system. Many tank farms are located in corrosive and/or humid environments. Therefore, particular care should be taken in the design and installation of the cable system, especially at the terminals in the gauge heads and junction boxes. Lightning strikes can be another source of trouble, given that most tank-farm cabling systems are run overhead. Surge protection should be installed at each gauge head and at the remote readout. Associated loggers and computers should be electrically isolated. As an aid to troubleshooting a crippled system, isolating switches should be installed so that blocks of gauges can be separated from the system to enable a more rapid location of the fault.

CONCLUSION

Flow meters and provers offer the most accurate ways to measure standard volumes of liquids. Tank measurement is much more inaccurate when measuring small parcels. In custody transfer of full or nearly full tank volumes, manual gauging is preferred in the U.S., and ATGs are preferred in Europe. In either case, the inherent tank accuracy is a factor, because the filling of a large tank causes the bottom to sink, the shell to bulge, and the top to sink, and changes in temperature also cause changes in tank dimensions.

Automatic tank gauging systems are found in almost all tank farms of any size. They enable inventory monitoring at a given time each day. The wire-guided float tape gauge systems are most common on the existing tank farms (Table 3.18a) on liquid services. The design of the remote metering portion of these systems has been improved markedly over the past years, and these systems can be expected to perform satisfactorily if they are properly installed and maintained. To protect against tank-farm accidents such as overfilling, they should be backed up with high-level switches, and computer monitoring should be provided to detect for sensor failures resulting from float or tape hang-up.

The inductive tape-and-float systems and the wire-guided thermal capsule systems are more expensive and do not have as great a degree of field exposure as the wire-guided float types. (Table 3.18a). However, the tape-and-float system has fewer moving parts and therefore requires less maintenance. The wire-guided thermal capsule can be zeroed and can also be used for temperature profiling. Some users regard the in-tank electrical circuitry required by these latter designs as a drawback, but intrinsically safe designs should alleviate that concern.

The surface sensor design has been used for some time for solids level measurement. There have been reports that the sensor can become buried or detached from the take-up cable, contaminating product or ruining downstream equipment. A more rugged cable and sounder design should overcome this problem. The surface sensor is not highly recommended for liquid level applications, but it is acceptable for solids level measurement if an error of a couple of inches is acceptable.

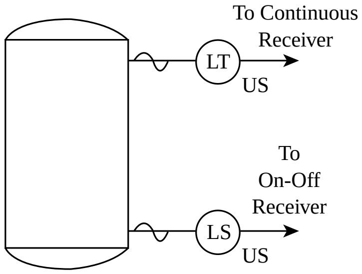
3.20 Ultrasonic Level Detectors

D. S. KAYSER (1982) **B. G. LIPTÁK** (1969, 1995)
J. E. JAMISON (2003)



Flow Sheet Symbol

Applications	Applications are wetted and noncontacting switch and transmitter applications for liquid level or interface and solids level measurement. They are also used as open-channel flow monitors. Advantages: generally, no contact with the product; suitable for various liquids and bulk products. Disadvantages: product must not produce too much surface foam; not suitable for extremely high pressures and temperatures; not applicable in vacuum service applications.
Design Pressure	Probe switches are used up to 3000 PSIG (207 bars = 20.7 MPa); transmitters are usually used for atmospheric-type service up to 60 PSIG (4.1 bar), but some special units are available for use up to 250 PSIG (17.2 bars)
Design Temperature	Switches from –100 to 300°F (–72 to 149°C) with special units to 750°F (399°C); transmitters from –40 to 302°F (–40 to 150°C)
Materials of Construction	Aluminum, type 304/316 stainless steel, titanium, Hastelloy® B/C, Monel®, Kynar, PVC, CPVC, Teflon (TFE), Tefzel®, polypropylene, PVDF, epoxy
Ranges	For tanks and silos (pulse usually travels in vapor space), up to 230 ft (70 m) for some special designs and up to 50 ft (15.3 m) for most standard systems. For wells (usually submerged), up to 2000 ft (600 m).
Inaccuracy	For a horizontal probe switch, 0.040 in. (1 mm). For transmitters, the error varies from 0.2 to 2% of full scale depending on the dust and dew in the vapor space and on the quality of the surface that serves to reflect the ultrasonic pulse.
Costs	Level switches cost from $150 basic to $950 (smart, multipoint); transmitters cost from $650 to $2500, with an average cost around $1200

Sonic (up to 9500 Hz) and ultrasonic (10 to 70 kHz) level switches operate either by the absorption (attenuation) of acoustic energy as it travels from source to receiver or by the frequency change of a vibrating diaphragm face, oscillating at 35,000 to 40,000 Hz. Ultrasonic level transmitters operate by generating an ultrasonic pulse and measuring the time it takes for the echo to return. If the transmitter is mounted at the top of the tank, the pulse travels in air (at a speed of 1087 ft/sec at 32°F, or 331 m/sec at 0°C); therefore, the time of travel is an indication of the depth of the vapor space above the liquid in the tank. If the transmitter is mounted on the bottom of the tank, the time of travel reflects the depth of liquid in the tank, and the speed of travel is a function of what that liquid is. In the case of water at 77°F (25°C), an ultrasonic pulse travels at 4936 ft/sec (1505 m/sec).

THE NATURE OF ULTRASOUND

To understand the capabilities and limitations of ultrasonic instruments, one must understand the conditions that determine the characteristics of sound: temperature, reflection, propagation, and absorption. Temperature compensation is essential in ultrasonic level measurement, because the velocity of sound is proportional to the square root of temperature and, in case of air, it changes by about 2 ft/sec (0.6 m/sec) for each degree Celsius change in temperature. The speed of travel rises with temperature, and it amounts to about 0.1% per degree Fahrenheit (0.18% per degree Celsius).

To measure the time of travel of the echo of an ultrasonic pulse, it is essential that some of the sonic energy be reflected. Liquids as well as solids with large and hard particles are good reflectors. Fluff and loose dirt have poor reflecting characteristics, because they tend to absorb the sonic pulse. It is also important that the reflecting surface be flat, because the angle of reflection equals the angle of incidence. Therefore, if the sonic pulse is reflected from a sloping surface, its echo will not be directed back to the source, and the round-trip travel time (*time of flight*, or *TOF*) will not accurately reflect the vertical distance. Irregular surfaces result in diffuse reflection, in which only a small portion of the total echo travels vertically back to the source.

The travel (propagation) of sound results in its dispersion (loss of intensity). The intensity of sound decreases with the square of distance; therefore, the echo becomes exponentially weaker as the range of the instrument is increased. The decrease in sound energy is caused not only by dispersion (traveling distance) but also by absorption in the substance through which it travels. For example, an ultrasonic (e.g., 44,000 Hz) sound wave traveling in dry and dust-free 60°F (20°C) air is attenuated by 1 to 3 dB for each 3.3 ft (1 m) of travel. It can be seen from the above that an ultrasonic transmitter is subject to many interferences that will affect the strength of the echo. Many of these physical phenomena are beyond the control of the instrument manufacturers, although microprocessor applications help compensate for some of the symptoms of the presence of the phenomena. All the transmitter can be expected to do is accurately compute the round-trip time of flight based on the first segment of the echo, provide temperature compensation or heat if condensation in the transducer is a possibility, and provide a strong and well-focused ultrasonic pulse. It cannot change the reflection, propagation, or absorption characteristics of the process.

Ultrasonic level devices can be used for both continuous and point measurement. The point detectors—for measurement of gas–liquid, liquid–liquid, liquid–foam, or solid–gas interfaces—can be grouped by design into damped sensor or on–off transmitter categories. They also can be categorized by method of packaging as single-element and two-element units. The continuous level detector designs can be categorized as under-liquid sensors and above-liquid sensors. Most designs use a 20 kHz or higher (up to 70 kHz) oscillator circuit as the ultrasonic signal generator. Some designs incorporate filters, discriminatory circuitry in electronics, or software in microprocessors to prevent false readings that might be caused by random noise. Each of these basic design variations will be discussed separately.

LEVEL SWITCHES

Damped Vibration Type

The devices in this category operate on a principle similar to that of the vibrating reed switch (see Section 3.21). As long as the sensor face is in the vapor space of the tank, it vibrates at its resonant frequency but is damped out when the process material contacts it. Some designs incorporate a piezoelectric crystal in the vibrating tip. Figure 3.20a shows some of the elements and their installation. Four units are shown in the figure. Design “A” notes the top-entry installation, where the vibrating face is in the vapor space (and is therefore undamped). This design can be repositioned manually or automatically for flexible adjustment of the control point. Design “B” is a unique design in that it does not penetrate the tank wall and thus is not in contact with the process fluid. When the liquid rises to the opposite side of the wall, the transducer is damped (see Figure 3.20b), and a switch action occurs. Designs “C” and “D” show the side-mounted switch elements, one (“D”) damped and the other in an undamped condition (“C”). These units are normally limited to liquid service, because the damping effect of solids is insufficient in most cases. Design “B” can be used on any liquid, while the others are limited to clean, noncoating fluids.

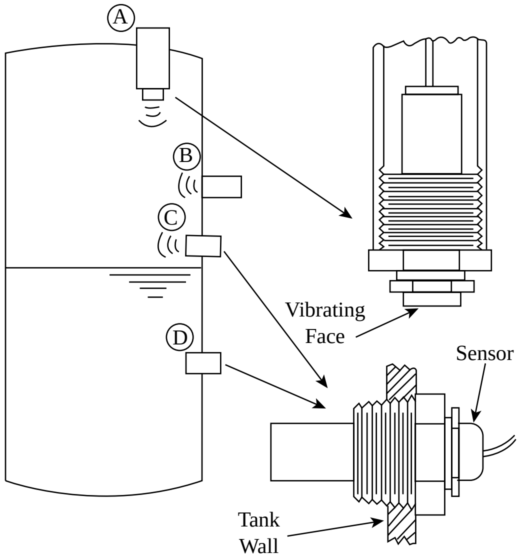

FIG. 3.20a
Dampened ultrasonic sensors.

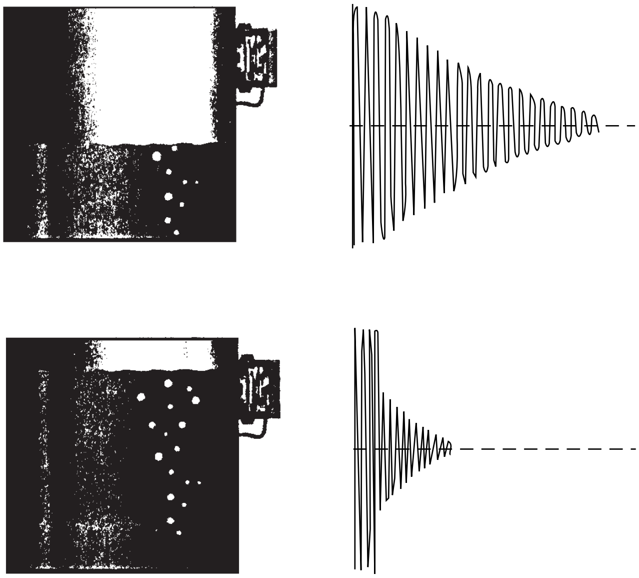

FIG. 3.20b
Dampened vibration ultrasonic level transmitter signals (Design “B” example.)(Courtesy of Endress+Hauser Inc.)

Absorption Type

These ultrasonic switches contain transmitter and receiver elements. The transmitter generates pulses in the ultrasonic range, and the receiver detects these pulses if they are transmitted through the medium in which the probe is located. The transmitter and receiver can be mounted on the same probe, or they can be located on the opposite sides of the tank. Figure 3.20c illustrates some variations of this design. Installation “A” shows a design in which the transmitter and receiver are packaged separately. This design transmits in air; the switch will actuate when the ultrasonic sound beam is interrupted by the rising process material. Reflectors are installed to narrow the sonic beam angle when the distance between source and receiver is more than 10 ft (3 m). Installation “B” is a single-probe design in which the pulses generated by the transmitter will be sensed by the detector only

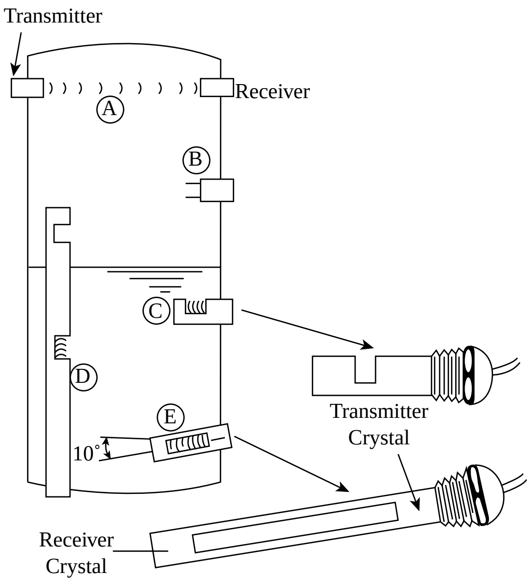

FIG. 3.20c
Transmitting ultrasonic point sensors.

if they are submerged in a non-compressible liquid. The pulses are not transmitted in the vapor space. Design "C," which is similar to "B," transmits only in liquid. When fluid is present in the gap of the single probe, the ultrasonic sound beam is received by the detector in the tip and signals the presence of liquids. Probe "D" is a multipoint variation of "C," allowing the measurement of both high and low levels by the same probe.

Interface Detector

Design "E" is mounted ≈10° from the horizontal, and it can be used for detection of liquid–liquid interfaces. The ultrasonic sound beam generated by the transmitter crystal will be detected by the receiver crystal if the probe is in only one liquid. If an interface is present in the probe cavity, the interface will reflect the signal, preventing it from reaching the receiver. Ultrasonic level switches can also be used to signal when the light layer becomes too thick or too thin. This is achieved by mounting the ultrasonic level switch on a float that continuously follows the total level in the tank.

All of the designs discussed above are applicable to clean liquid service, and none is particularly suitable for slurry or coating services.

For slurry or sludge services, it is desirable to separate the source from the receiver by a more substantial distance (Figure 3.20d) and install them so that the slurry material will drip off when the level drops.

Only design "A" in Figure 3.20c will detect the level of solids. In connection with solids level detection, it should be noted that these devices, being point sensors, will not take into consideration the angle of repose during filling or emptying, nor will they detect rat holes, arches, or bridging.

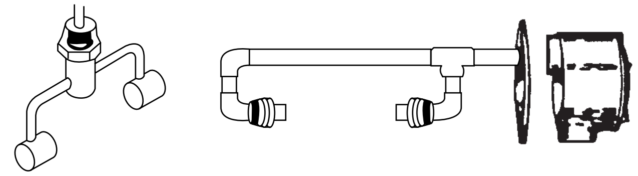

FIG. 3.20d
Top- and side-mounted level switches for sludge or slurry services. (Courtesy of Delavan Inc.)

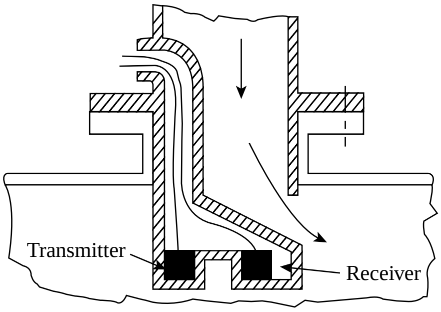

FIG. 3.20e
Ultrasonic filler nozzle.

Figure 3.20e illustrates a special application of ultrasonic level detection for gasoline filling nozzles. The nozzle itself contains a transmitting and receiving element to detect when liquid reaches the nozzle, at which point flow is shut off.

LEVEL TRANSMITTERS

The principle of operation of these units is very similar to that of the echometers used to measure the depth of wells. In that design, a blank shell is fired; the time needed for the echo to return is converted to an indication of the depth. The continuous ultrasonic level detector (SONAR) measures the time required for an ultrasonic pulse to travel to the process surface and back. The source is an oscillator-type ultrasonic speaker, and the receiver, in most designs, is a metal disc that is both electrically and mechanically resonant. The transducer can be mounted either below or above the liquid level.

Figure 3.20f illustrates some of the design features and possible installations. Installation "A" shows a two-element continuous detector (no longer in use) in which the transmitting

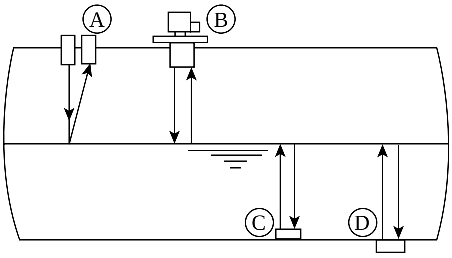

FIG. 3.20f
Continuous ultrasonic level detectors.

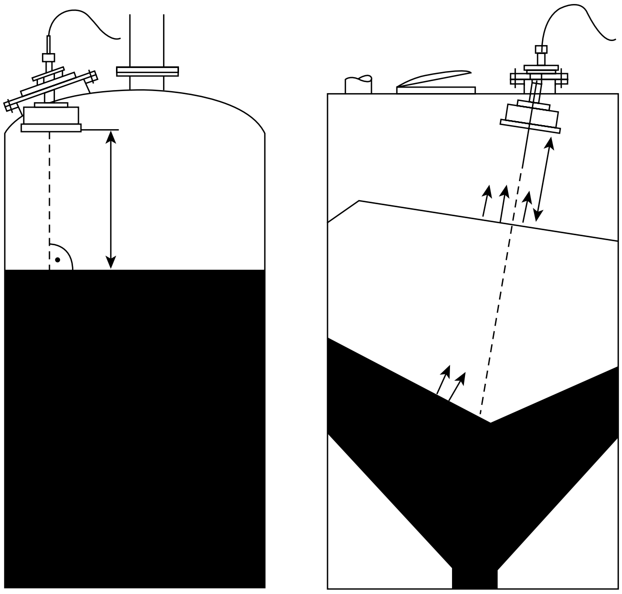

FIG. 3.20g
Adjustable top-mount ultrasonic transmitter for solids level measurement. (Courtesy of Endress+Hauser Inc.)

and receiving transducers are packaged separately. This device transmits in air. The time required to receive the ultrasonic reflection from the surface is the measure of the vapor depth of the space, which is an indirect indication of level. Another, more commonly used version of an "in-air" continuous level system is illustrated in "B." The transducer and receiver are packaged as a single unit. The transducer generates short bursts of ultrasonic energy and, while the acoustic energy is being produced, the receiver is blanked off. When the ultrasonic waves are on their way, the receiver gate is opened to detect the echo. Mounting the transducers in the vapor space has the advantage that the instrument does not contact the process materials, but it has the disadvantage that some energy is lost in traveling through the vapor space.

On liquid level applications, the aiming angle must be within ±5° of the vertical. When measuring levels of solids, the angle of repose should be tested. Current systems incorporate an aiming system to accommodate larger aiming angles (see Figure 3.20g).

In installation "C," the time for the ultrasonic echo is a true indication of level. The transducer can also be mounted on the outside of the tank ("D"), with the added advantage that the sensing element does not penetrate the tank. Design "C" is applicable to continuous detection of clean liquid levels, and designs "A" and "B" also can be used to measure the level of solids. By using several sensors in the same bin, a visual profile can be obtained, showing the angle of repose and indicating if the bin is being filled or discharged.

Figure 3.20h shows an interesting application of the continuous ultrasonic level detector. When hydrocarbons are stored in salt dome wells, the hydrocarbon rests on a brine layer. When additional hydrocarbons are pumped in, the brine is displaced; the hydrocarbons are recovered by displacing them with brine. For reasons of safety, inventory monitoring, and cavity use, it is important to know where the hydrocarbon–brine interface is located. This device is suitable for finding the interface.

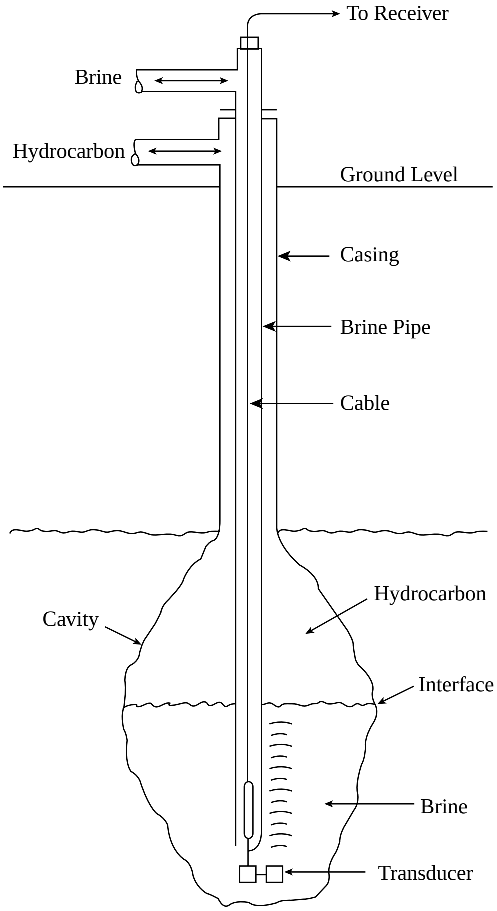

FIG. 3.20h
Interface detector for hydrocarbon storage cavity.

MULTI-TANK PACKAGES

"Intelligent," microprocessor-based ultrasonic transmitters can convert the level in cylindrical, horizontally mounted tanks into actual volume of the contents. Microprocessors can be useful in other ways. For example, for better accuracy of measurement, the transducer can be furnished with a fixed target assembly (Figure 3.20i), and the unit can be automatically recalibrated periodically using that reference. Because the length of the reference bar is known, this will give a very accurate reference if the density of the vapor space is uniform and constant.

Microprocessor-based ultrasonic level sensors can be used in a multi-tank or multi-silo configuration (Figure 3.20j). This tends to lower their per-tank unit cost because, through multiplexing, some of the electronic and display equipment can

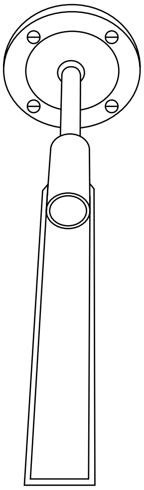

FIG. 3.20i
Level transmitter provided with automatic calibration target. (Courtesy of Inventron Inc.)

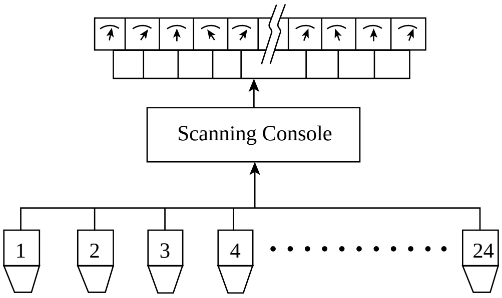

FIG. 3.20j
Ultrasonic silo scanning system.

be shared among the 24 or 48 storage tanks. In such packages, the transmitters are wired to an automatic scanning console, which operates the individual display devices (indicators, recorders, alarms, and so forth). The scanning frequencies are individually programmed to match the requirements of the processes in the different tanks.

RECENT DEVELOPMENTS

In the mid to late 1990s, a number of new developments occurred in ultrasonic level sensor technology. One such improvement involves the continuous monitoring of the depth of sludge blankets. This ultrasonic sensor is provided with a dual-head assembly and a microprocessor, and it is useful in the wastewater treatment industry. Another development was improved filtering capabilities via microprocessor-implemented fuzzy logic technology against interference reflections and against buildups in tanks over time.

Another area of recent advancements involves automatic self-calibration of ultrasonic sensors, which can correct for some of the effects of changing vapor space composition or temperature and can provide more than a single calibration target. The multiple calibration targets are provided in forms of precisely located ridges in a sounding pipe and can result in level measurement inaccuracies within 5 mm over a distance of 30 m.

New techniques in ultrasonic level measurement are revolutionary, utilizing the changes in the speed of sound in the tank wall. According to Lynnworth,[1] this speed does change when the other side of the tank wall is wetted and therefore can be used for level measurement in both the transmission and the echo mode of operation. Such units have been tested in pilot applications.

The mid to late 1990s saw the incorporation of serial data communications links such as RS485, and the HART protocol became available on several manufacturers' systems to link the output data to higher-level systems. In the late 1990s and early 2000s, the use of various digital fieldbus technologies became commonplace as the output signal of ultrasonic level transmitters. FOUNDATION™ fieldbus and Profibus PA and DP are the main fieldbuses currently being employed.

Another interesting and recent development in the ultrasonic or time of flight technology is that several manufacturers have designed their systems to allow the use of the same transmitter between both ultrasonic and microwave (RADAR) technologies (see Sections 3.13 and 3.14). This allows upgrades or changes in requirements between the two related devices but still allows inventories of transmitters to be cross-utilized between the different but similar sensor technologies. The trend is to utilize the similar functionality of the two related technologies from a hardware and software/firmware point of view that benefits application users.

Other interesting developments are in the area of "smart" local microprocessor-driven displays on transmitters that show measurement integrity information. Using the echo envelope curve representation (signal progression) on the local transmitter display shows signal strength versus distance. The curve indicates anomalies within a tank such as nozzles, weld seams, specific tank internals, and so forth for which compensation is required (see Figure 3.20k). This helps the technician in the field to validate the instrument's integrity, even in hazardous locations. The embedded microprocessor can compensate for the spurious signals. False echoes can be suppressed to prevent any misinterpretation by increasing the detection threshold at one or more fixed points. If the reflected signal is strong enough, the transmitter will follow the true echo, even during the increased detection threshold. Should the reflected echo signal be smaller than the threshold, the transmitter will "look around" the increased threshold and will hold the output until the true signal appears again. This can be done on both a per-point basis and automatically.

In addition, many manufacturers have a troubleshooting menu-based system displaying configuration information, diagnostics, and documentation on the local display. If necessary, this information can also be accessed in remote locations via HART protocols or a digital fieldbus protocol (FOUNDATION fieldbus, Profibus-PA).

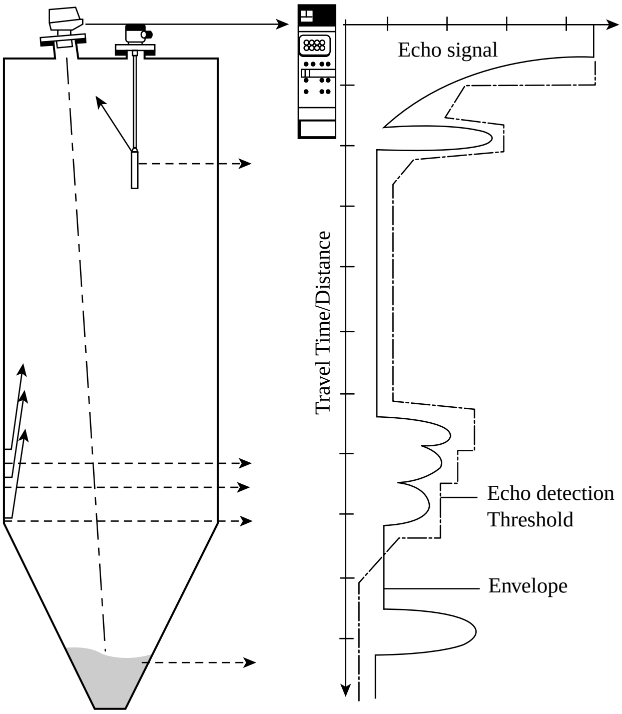

FIG. 3.20k
Echo envelope curve and internal tank anomalies. (Courtesy of Endress+Hauser Inc.)

CONCLUSION

Ultrasonics now can be considered as one of the traditional methods of level measurement. As probe-type level switches, they can give reliable performance, even on difficult slurry or sludge-type services. The main advantages of ultrasonic transmitters are the absence of moving parts and the ability to measure the level without making physical contact with the process material. In some specialized designs, the penetration of the tank can also be avoided. The reliability of the reading is unaffected by changes in the composition, density, moisture content, electrical conductivity, and dielectric constant of the process fluid. If temperature compensation and automatic self-calibration are included, the resulting level reading can be accurate to 0.25% of full scale.

In terms of limitations, the ultrasonic level transmitter is just as good as the echo it receives. The echo can be weak as a result of dispersion (which reduces sound intensity by the square of distance) and absorption (which, in dry air, reduces its energy level by 1 to 3 dB/m). The energy content of the echo will be further reduced if the bin is tall, if the vapor space is dusty, or if it contains foam or other sound-absorbing materials such as water vapors or mists. In addition to the problem of weak echos, another potential problem is the reflective properties and density of the process surface. If that surface is sound-absorbing (fluffy solids), sloping (angle of repose), or irregular, causing a diffused reflection of the ultrasonic pulse, the result can be an error, as the round-trip time of travel might not correspond to the vertical distance between transmitter and level. Therefore, the best guide for using ultrasonic level instruments is past experience on similar installations.

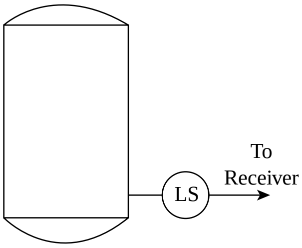
3.21 Vibrating Level Switches

D. S. KAYSER (1982) **B. G. LIPTÁK** (1969, 1995, 2003)



Flow Sheet Symbol

Types	A. Tuning fork B. Vibrating probe C. Vibrating reed
Applications	Can be used to detect the level of liquids, slurry or solids
Design Pressure	A. and B. Up to 150 PSIG (10.3 bars = 1 MPa) C. Up to 3000 PSIG (207 bars = 20.7 MPa)
Design Temperature	A. From –45 to 200°F (–43 to 93°C) B. From 8 to 176°F (–10 to 80°C) C. From –150 to 300°F (–100 to 149°C)
Materials of Construction	Aluminum, steel, stainless steel
Minimum Bulk Density	A. and C. Down to 1.0 lbm/ft^3 (16 kg/m^3) B. Requires an apparent specific gravity of 0.2
Inaccuracy	Generally, 0.25 to 0.5 in; the repeatability of type C is 0.125 in. (3 mm)
Cost	$300 to $500
Partial List of Suppliers	Automation Products Inc. (www.dynatrolusa.com) Bindicator (www.bindicator.com) Endress+Hauser Systems & Gauging (www.systems.endress.com) Monitor Mfg. Technologies LLC (www.monitortech.com) Monitrol Manufacturing Co. (www.monitrolmfg.com) Solartron Inc. (www.solartron.com)

Several level switch designs operate by keeping a probe or other element in oscillation or in natural frequency vibration and triggering a relay when the process material in the tank reaches the vibrating element and damps out the vibration. The reed, probe, and tuning fork variations are distinguished only by the frequencies of their oscillation (reed, 120 Hz; probe, 200 to 400 Hz; tuning fork, 85 Hz) and by their dimensions or physical shapes. Their shapes are similar, although the close spacing between the arms of the tuning fork could make it more susceptible to material buildup in sticky services than the others. This is not necessarily so on all types of coatings because, although any buildup changes the natural frequency of vibration, a limited amount of buildup will not collapse the oscillation.

The applications of vibrating level switch designs are also similar and include powders of different plastics, toners for copiers, detergents, powdered sugar, flour, ground or instant coffee, chocolate, dried milk, tea leaves, cosmetic powders; granules of plastic pellets, rice, wheat, beans, carbon, sugar, and salt; plus slurries and liquids.

VIBRATING LEVEL SWITCHES

The design of the vibrating reed level switch is illustrated in Figure 3.21a. The unit consists of a driver, paddle, and pickup. The driver coil induces a 120 Hz vibration in the paddle that is damped out when the paddle is covered by the process material. The pickup end contains a permanent magnet and a coil that generates a millivolt output signal when the paddle is vibrating. When the paddle is covered, the signal decreases and as a consequence, a control relay

is de-energized. A welded pressure seal is made at the node points. The device will detect liquid–liquid, liquid–vapor, and solid–vapor interfaces, because the switch is sensitive enough to detect relatively small changes in the density of the surrounding process material.

The characteristics of this switch are described by Figures 3.21b and 3.21c. Figure 3.21b is a plot of millivolt signal strength versus paddle coverage. Curve 1 describes the switch behavior in flour, 2 in water, 3 in polyethylene pellets, and 4 in granular sugar. It can be noted that, in all four cases, the switch will actuate before the paddle is fully covered by the process material. For example, in the case of water (2), switch actuation occurs when the water level is about 0.4 in. (10 mm) above the bottom of the paddle.

The curves in Figure 3.21c refer to granular powders at various densities. Curve 1 is for 60 lbm/ft^3 (960 kg/m^3), 2 is for 50 lbm/ft^3 (800 kg/m^3), and 3 is for 40 lbm/ft^3 (640 kg/m^3). As would be expected, the lighter the powder, the more level has to build up before switch actuation occurs. In case of the 40 lbm/ft^3 powder (3), the switch will actuate at 1.0-in. level rise, which corresponds to a level buildup of 0.25 in. (6 mm) above the top of the paddle.

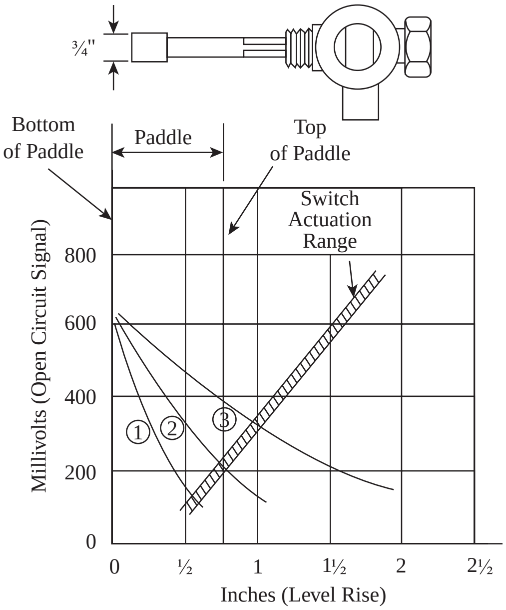

FIG. 3.21c
Reed switch actuating ranges for heavy solids. (Courtesy of Automation Products Inc.)

The vibrating reed level switch can be used to detect both rising and falling levels, and it can be installed in tanks or pipelines. Its use for measuring density and viscosity are discussed in Chapters 6 and 8, respectively. If the process material has a tendency to adhere to the paddle, such buildup can be removed by periodically purging the line through a purge well but, in general, this unit is not recommended for applications where buildup is probable. The sensing wires between probe and receiver should be shielded and grounded at both ends. Supply voltage variations between 105 and 125 V will not interfere with the measurement.

When used on wet powders, the vibrating paddle has a tendency to create a cavity in the granular solids. If this occurs, the vibration amplitude will be the same as if the paddle were in the vapor space. Therefore, this level switch should not be used in applications involving wet powders. Where the solids bins are purposely vibrated and the vibration frequency is close to 120 Hz, this method of level measurement is unreliable and therefore should not be considered.

TUNING FORK

The tuning fork type of level switch is oscillated at its resonant frequency of about 85 Hz by a piezoelectric crystal located near the head of the fork. Another crystal, also mounted in the head, detects the vibration or the lack thereof. The unit can tolerate some limited amount of buildup and

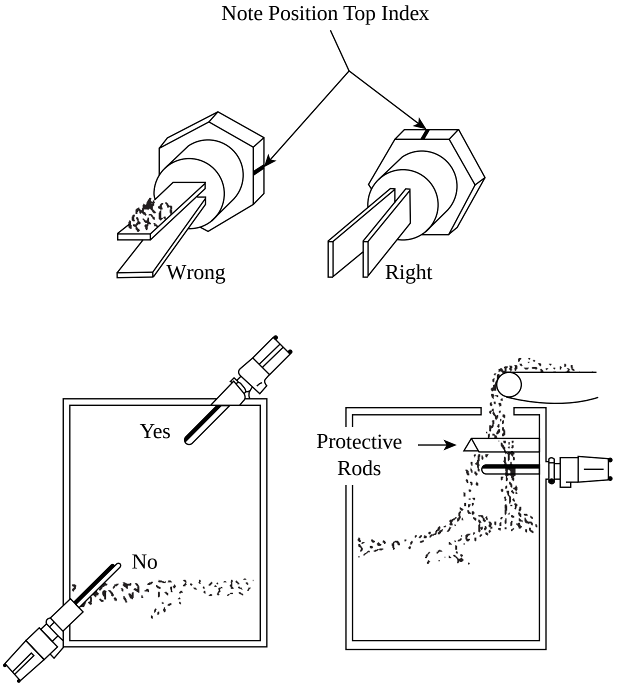

FIG. 3.21d

The installation of tuning fork-type level switches. (Courtesy of Endress + Hauser Inc.)

can also operate at higher than the design temperature if purging is provided to cool the crystals. For mounting recommendations and requirements refer to Figure 3.21d.

When the self-sustaining resonant frequency probe is in the vapor space, an electromechanical oscillator is formed, causing the probe to vibrate at its natural mechanical resonant frequency of approximately 85 Hz. One coil drives the probe, and a second coil monitors the vibration and generates a corresponding AC voltage signal. This feedback signal is amplified and reapplied to the drive coil, sustaining the mechanical vibration. When the process fluid rises to cover the probe, it damps the vibration, causing the feedback signal and drive voltages to collapse. At that point, oscillation ceases. A relay located in the control unit detects the state of oscillation and initiates the contact closures.

The advantage of the self-sustaining resonant frequency probe design is that material buildup on the probe has only limited effect, because, with a limited amount of coating, the resulting change in the natural frequency of the probe but does not collapse the oscillation. Therefore, the sensor is suitable for some slurry services. This design is also applicable for use on low-density solids level detection down to 1.0 lbm/ft^3 (16 kg/m^3).

VIBRATING PROBES

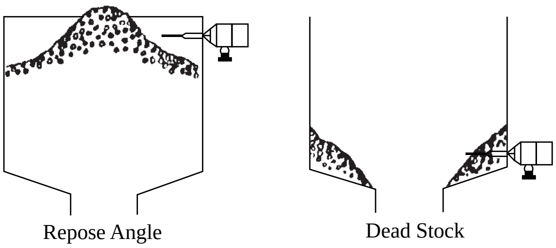

FIG. 3.21e

The cross-section of a vibrating probe and illustrations of false level indications caused by not probably considering the effects.

In the vibrating plate or vibrating probe level switches, the probe is caused to vibrate by applying piezoelectric energy. Two piezoelectric elements are used, one providing vibration (at a frequency of 200 to 400 Hz) and the other receiving it. When the probe is buried by the process material, the vibration decreases, and this decrease is used to trigger the switch. To make it immune to the effects of hopper vibration, the switch has a relatively high resonant frequency. Figure 3.21e illustrates that the sensing probe should be located so that the angle of repose will not cause false level indication when the solids level is low.

CONCLUSION

Vibrating reed switches are reliable devices that operate on a readily understood principle. Because they can detect the presence of materials with a bulk density as low as 1.0 lb/ft^3 (0.016 g/cm^3), they have a wide range of applications, particularly in solids level detection. Their limitation is that the switch setting cannot be changed without changing the length or the mounting location of the switch.

INTRODUCTION

Temperature is as fundamental a physical concept as the three basic quantities of mechanics: mass, length, and time. Temperature is an expression that denotes a physical condition of matter. Yet, the idea of temperature is a relative one, arrived at by a number of conflicting theories. Classic kinetic theory depicts heat as a form of energy associated with the activity of the molecules of a substance. These minute particles of all matter are assumed to be in continuous motion that is sensed as heat. Temperature is a measure of this heat.

To standardize on the temperature of objects under varying conditions, several scales have been devised. The Fahrenheit scale arbitrarily assigns the number 32 to the freezing point of water and the number 212 to the boiling point of water. The interval is divided into 180 equal parts. The Centigrade or Celsius scale defines the freezing point of the water to be 0, and its boiling point to be 100.

In line with the classic theory, some relation to the point where molecular motion is at a minimum had to be established, and the Kelvin scale, using Centigrade divisions, was drawn. Zero Kelvin was determined to be 273.19°C. The Rankine scale places its zero at 459.61°F and uses Fahrenheit divisions in the same arbitrary way in which Lord Kelvin used the Celsius scale.

Orientation Tables

The range in temperature within the universe varies 18 orders of magnitude. It ranges from the near absolute zero of black space to the billions of degrees in the nuclear fusion process deep within the stars. But the practical range on earth can be considered as extending from 1°R upward about 5 decades to around 20,000°R. This is still a tremendous range, and no single sensor could possibly cover it.

Table 4.1a provides the reader of this handbook with an orientation table containing information on the ranges and other features of the various temperature sensors. Table 4.1b is a conversion table, which is convenient when one has to go from Fahrenheit to Centigrade units and back. Therefore, one of the restrictions on the temperature sensor concerns the temperature range over which it can stay reasonably accurate. Table 4.1c provides the approximate temperature ranges of each sensor type. The many types of sensors are listed on the left, while some of their characteristics are shown horizontally across the top. If it is not known what general type of sensor will do a specific job, the table can help point the way to the right selection.

Once the class of sensors has been found, the data in the table will give a rough idea of the applicability of that design. When the possible choices of selection have been narrowed down to a few instrument types, the reader should turn to the corresponding sections of this chapter. In the front of each section there is a listing of range, accuracy, cost, and vendors. Inspecting these briefly, one can determine if the instrument generally meets the requirements or not. If it does, one should read the section for a description of the design and its available variations in detail. If some of the features are unacceptable, one should proceed to the next choice noted in the orientation table (Table 4.1a).

Temperature sensors should be selected to meet the requirements of specific applications. Sensor Selection Table 4.1d can assist the reader in this task.[1] If the application engineer determines the required temperature range, the nature of the information required (point or average temperature), and the nature of the process environment, this table can be used to determine

NOTES

* °C = 5/9 (°F – 32) and –°C = 5/9 (°F + 32)
** Error is greater of two designations
*** t = temperature span

the suitability of various sensors to that application. The suitability for the application may range from using a bimetallic dial thermometer for a water tank with an accuracy of ±2 to 5°F (1 to 3°C) to a temperature transmitter assembly with a resistance temperature detector (RTD) that can measure within ±0.02°F (0.01°C).

International Practical Temperature Scale

The International Practical Temperature Scale is the basis of most present-day temperature measurements. The scale was established by an international commission in 1948 with a text revision in 1960.[2] A revision[3] of the scale was formally

TABLE 4.1d

Temperature Sensor Selection Table

Measured Temperature	*Under 500°C*								*Above 500°C*							
Reading[1]	*Point*				*Average*				*Point*				*Average*

CODE LETTERS:
D - in development
L - limited
F - fair
G - good
E - excellent
P - protective well reduces speed of response
A - detects the average temperature of an area

EXAMPLE: G(D)—This combination of code letters refers to a device which is a good selection for the particular service, but is not yet commercially available.

[1] This device either detects a point or the average temperature of some section of the process or of the refractory.

[2] The term “hostile environment” here is used to mean processes such as fluid beds, where the sensor is likely to experience the mechanical impact of high velocity solid particles.

[3] “Interference” refers to need to overcome temperature interferences due to hot refractories or to temperature differences between the carrier gas and the solid particles in it.

[4] For considerations of measurement error, span, cost stability, response time, linearity, materials of construction, etc., refer to the text.

TABLE 4.1e
Primary Temperature Points Defined by the International Practical Temperature Scale (IPTS-90)

Equilibrium Point	*°K*	*°C*
Triple Point of Hydrogen	13.81	–259.34
Liquid/Vapor Phase of Hydrogen at 25/76 Std. Atmosphere	17.042	–256.108
Boiling Point of Hydrogen	20.28	–252.87
Boiling Point of Neon	27.102	–246.048
Triple Point of Oxygen	54.361	–218.789
Boiling Point of Oxygen	90.188	–182.962
Triple Point of Water	273.16	.01
Boiling Point of Water	373.15	100
Freezing Point of Zinc	692.73	419.58
Freezing Point of Silver	1235.08	961.93
Freezing Point of Gold	1337.58	1064.43

adopted in 1990 and is reproduced in Tables 4.1e and 4.3a. Reproducible temperature points established by physical constants of readily available materials define the scale. Interpolation between these fixed points is made by platinum resistance thermometers when the temperature is below 1832°F (1000°C), and by platinum-platinum and 10% rhodium thermocouples (TCs) when it is higher. The National Institutes of Standards and Technology (NIST—formerly the National Bureau of Standards) has capability for calibrating temperature-measuring devices against these primary temperature points. These devices are secondary standards that are then used by manufacturers and users to calibrate other equipment. NIST's capability for calibrating temperature-measuring devices is illustrated in Figure 4.1f. This figure also shows the error (uncertainty) of other thermometers at different temperatures.

TEMPERATURE SENSORS

It is believed that Galileo invented the liquid-in-glass thermometer around 1592. Thomas Seebeck discovered the principle behind the TC—the existence of the thermoelectric current—in 1821. The same year Sir Humphry Davy noted the temperature dependence of metals, but C.H. Meyers did not build the RTD until 1932. The development of temperature sensors was a slow process until the middle of the 20th century. Today the application engineer can select from among over 20 different types of thermometers. In addition, the old practice of using only filled system thermometers, RTDs, or TCs throughout a particular industrial plant is giving way to the practice of selecting each temperature sensor for a particular application, just as each level or flow meter is individually selected. This requires a better understanding of the features and capabilities of the many thermometers on the market.

Nonelectric Temperature Sensors

Liquid-in-Glass Thermometers Most versions have used mercury or alcohol as the liquid. The element mercury is liquid in the temperature range of about –40 to 700°F (–38.9 to 356.7°C).[17] As a liquid, mercury expands as it gets warmer; its expansion rate is linear and can be accurately calibrated.

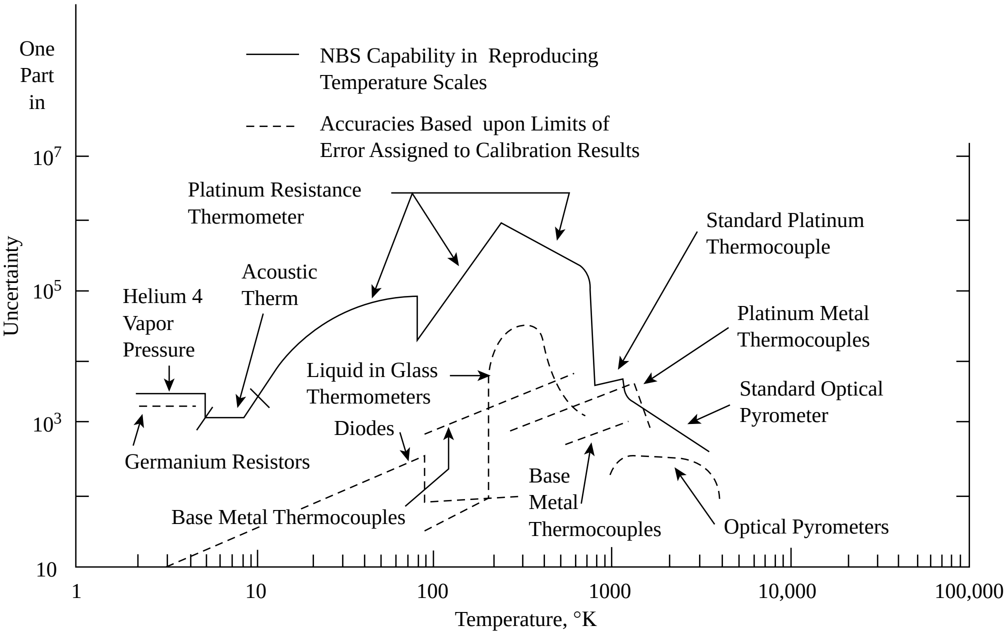

FIG 4.1f
Uncertainties in calibrating different temperature sensors at various temperatures. (From NBS Technical Note No. 262.)

Because of mercury's toxicity and the strict governing laws, the use of the mercury-in-glass thermometer has declined. One manufacturer has recently introduced a line of thermometers with a proprietary fill liquid offering the performance of mercury with none of the toxicity concerns.[8] For high accuracy applications, laboratory grade and reference standard models are available with calibration certification to NIST standards.

Bimetallic Thermometers Bonding two dissimilar metals with different coefficients of expansion produces a bimetallic element. These are used in bimetallic thermometers, temperature switches, and thermostats having a range of 100 to 1000°F (–73 to 537°C). When manufactured as a helix or coil, its movement with a change in temperature can move a pointer over a dial scale to indicate temperature. Dial thermometers ranging from pocket size to 5 in. dials are offered with a variety of local and remote mounting configurations.

Many process applications require use of a thermal well to allow for the removal or replacement of the thermometer while the process is pressurized.[9] Other designs include switches for on-off control that range from the simple wall thermostat to more rugged industrial models for simple process control or over-temperature protection. Other configurations include snap disk switches often used for over-temperature alarm and control. Low-end models are used in home furnaces, clothes dryers, and coffee makers. More rugged units find application in automobiles, trucks, and industrial machinery as over-temperature limits.

Filled System Thermometers Filled system thermometers have been used for decades. They have a useful range of 320 to 1200°F (200 to 650°C). Applications vary in sophistication from those for commercial appliances like cooking ovens and those used in heating, ventilation, and air conditioning (HVAC), to rugged industrial units suitable for a variety of applications. The filled system element can operate switch mechanisms as in ovens or for industrial shutdown controls. Some models have an analog output that may be connected to remote locations. Thermal systems filled with solid materials or mercury have all but disappeared. Most countries mandate the removal of any mercury-filled devices due to its extreme toxicity.

There are some models that use a vapor fill, but these suffer in applications where the temperature crosses the vapor/liquid point and causes liquification and loss of performance (typical is 0.25% per 25°F/14°C). Liquid filled units are the most popular, but consideration must be given to offsets due to the weight of the liquid head and compensation for capillary length. Thermocouples and RTDs are replacing filled systems in industrial process control applications. The low cost of electronic devices to read the output of TCs and RTDs and to indicate or control, together with the ability to locate the sensor independently of the receiving device, has made electronic means more attractive.[9]

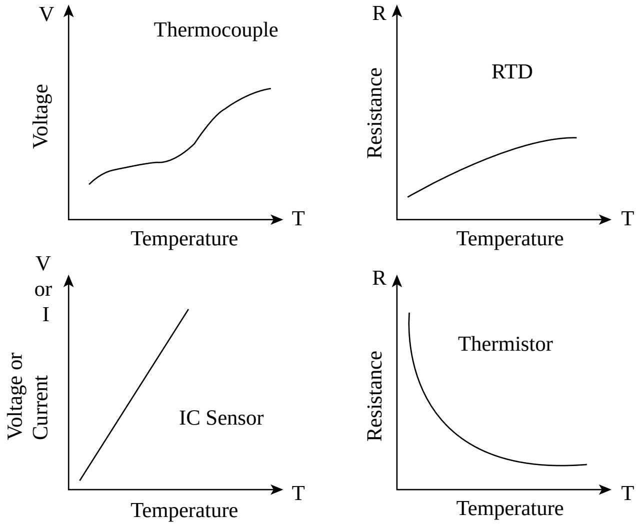

FIG. 4.1g
The characteristics of electronic thermometers.

Bistate/Phase Change Sensors These low cost nonelectric sensors are made from heat-sensitive fusible crystalline solids that change decisively from a solid to a liquid with a different color at a fixed temperature depending on the blend of ingredients. They are available as crayons, lacquers, pellets, or labels over a wide range of temperatures from 100 to 3000°F (38 to 1650°C). They offer a very inexpensive method for surface temperature visual verification within about 1°F. Monitoring minimum and maximum temperatures during shipment of perishable goods is a common application.

Electronic Thermometers/Sensors

Thermocouples A TC is an assembly of two wires of unlike metals joined at one end designated the hot end. At the other end, referred to as the cold junction, the open circuit voltage is measured. Called the Seebeck voltage, this voltage (electromotive force) depends on the difference in temperature between the hot and the cold junction and the Seebeck coefficient of the two metals. For a plot of the relationship between temperature and output signal refer to Figure 4.1g. For most industrial applications, the TC has been the popular choice over the years for a variety of reasons. Thermocouples are relatively inexpensive and can be produced in a variety of sizes. They can be of rugged construction, can cover a wide temperature range from 440 to 5000°F (262 to 2760°C), and are available in both standard and premium grade models.[9,15,16] Refer to Figure 4.1h for the error limits of a Type J premium sensor.

Every credible temperature transmitter, indicator, controller, or data logger will accept a direct TC input. For many applications, this is a viable solution. However, TCs produce a very small microvolt output per degree change in temperature that is very sensitive to environmental influences. Electromagnetic interference (EMI) from motors and electrical

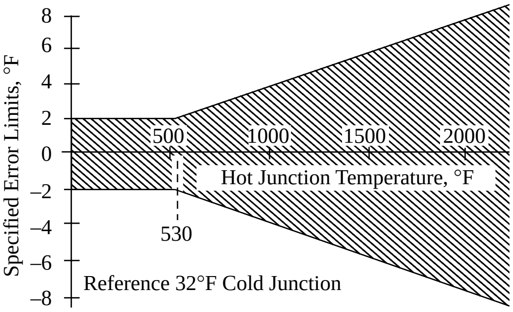

FIG. 4.1h
The error limits of an iron-constantan thermocouple manufactured to meet the "special" limits of ISA.

distribution and especially radio frequency interference (RFI) from walkie-talkies can produce dramatic errors in measuring circuits in these instruments. The user should insist on a noise reduction spec and an RFI immunity spec that will minimize these effects. A top quality instrument will offer Common mode noise rejection of 100 db, Normal mode rejection of about 70 db, and RFI immunity of 10 to 30 V/m.

There are some applications where a bare TC with an exposed junction may be used either by itself or inserted into a protective well. For most process applications, the TC is manufactured with a protective outer sheath that uses an insulating material to electrically separate the TC from the sheath and provide mechanical and environmental protection. In some cases, the TC junction is placed in direct contact with the tip of the sheath to increase speed of response. These sensors demand the use of an electrically isolated measurement circuit. Even insulated TCs will eventually suffer from a breakdown of the insulation and the TC tip will contact the sheath and associated well. It is virtually assured that a ground loop will be present that will cause measurement errors. These errors are usually insidious in that they usually vary over time and may go unnoticed. Recommended practice is to always use an instrument with full isolation to eliminate this concern.[9,10,12]

Another consideration for applying TCs is that their low output (about 40 μV/°C) limits the minimum span of even the best transmitters to about 60°F (35°C). RTDs are the usual choice for narrow span applications.

The most misunderstood drawback of using TCs is their inherent drift. The junction of the two dissimilar metals begins to degrade to some degree immediately after manufacture. For some types, used at low temperatures, this may only be a few degrees per year and may be calibrated out of the system. Other types used at higher temperatures degrade much more quickly. Consideration must also be given to any TC extension wire that is used for long wiring runs from the field location to the measurement instrument. Not only is its accuracy only about half as good as a TC, but also it is often subjected to harsh environmental conditions as it passes through the plant that will cause significant degradation and drift. Some plants replace their extension wire on a regular basis to minimize this effect.

Installing a top quality transmitter in the connection head of the TC will minimize many of the problems and concerns described above. Refer to Intelligent Temperature Transmitters in a later paragraph of this section.

Resistance Temperature Detectors RTDs are constructed of a resistive material with leads attached and usually placed into a protective sheath. The resistive material may be platinum, nickel, or copper with the most common by far being platinum. The relationship between the resistance change of an RTD vs. temperature is referred to as its alpha curve (see Figure 4.1g). The instrument used with the RTD must be configured to use the same alpha curve as the RTD or significant errors will occur.

As with TCs, there are some applications where an exposed sensor is suitable for the purpose. More commonly they are manufactured with a protective sheath that provides a hermetic seal to protect the sensor from moisture and/or contamination.[14] These protective sheaths are offered in a variety of lengths to provide the proper insertion into the process to obtain a representative measurement. The sheathed elements are often installed into a protective well to isolate the sensor from the process. One manufacturer offers a universal model that has only a 1 in. long sheath, but has long leads encased in a spiraled spring. The unit may be cut in the field to fit in any length of thermal well. This greatly reduces the requirements for stocking sensors in varying lengths.[7,11] Figure 4.1i shows this flexible sensor mounted with a transmitter.

There are very few applications for a 2-wire RTD since the error introduced by the leads can cause significant error. Measurement circuits that accept 3-wire inputs include a method of minimizing the effects of lead wire resistance as long as the outer legs are equal. However, factors such as terminal corrosion and loose connections can create significant differences between the lead resistances seen by the measurement circuit. A single ohm of difference between the legs is reflected as a 4.7°F (2.6°C) error.[13] Using a 4-wire measuring circuit eliminates this problem. The design engineer should consider any of the leading brands of temperature transmitters that accept 4-wire RTD inputs as a standard feature. Direct connection to remote devices with 3-wire extension cable will often produce errors that can be significant and will vary with environmental conditions. Refer to intelligent temperature transmitters later in this section for more detail.

Copper RTDs are most commonly used to sense the winding temperature of motors, generators, and turbines. Connecting them to an alarm trip provides an over-temperature shutdown function. Historically, 10-Ω copper RTDs were the norm, and accurate measurements of the small change in resistance change with temperature limited the accuracy to about ±1 to 2°F (1.6°C). Many users have now opted for 100 Ω or even 1000 Ω units to get higher resolution. They have

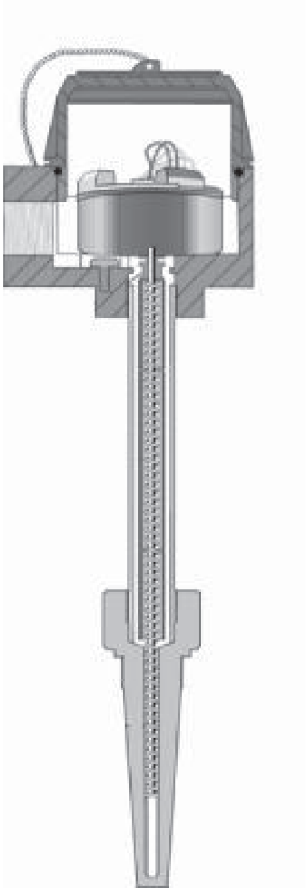

FIG. 4.1i
A flexible WORM sensor in a transmitter system. (Courtesy of Moore Industries-International, Inc.)

a useful range of –58 to 482°F (–50 to 250°C). Nickel RTDs have declined in use over the years primarily due to their limited range vs. the more popular platinum RTDs. The useable range is –112 to 608°F (–80 to 320°C). Most transmitters and alarm trips still offer the capability to accept nickel RTD inputs.

A concern common to all RTDs is that of error produced by self-heating. RTD measurement circuits measure the voltage across an RTD produced by passing a precise current flow through the RTD. A current flowing through a resistance produces heat that will appear as a positive offset to the actual process temperature at the RTD. The lower the measuring current, the less is this heating effect. It will be minimized by good thermal contact to the process fluid and is less of a concern at higher temperatures. A measure of the quality of an RTD measuring circuit is the amount of measuring current used. Circuits in better transmitters use about 250 μA. This current is typically higher for nickel and copper RTDs.

Thermistors Like the RTD, the thermistor is also a resistive device that changes its resistance predictably with temperature. Its benefit is a very large change in resistance per degree change in temperature, allowing very sensitive measurements over narrow spans. Due to its very large resistance, lead wire errors are not significant. However, there are several disadvantages to the thermistor:

1. It is a very nonlinear device and reasonable accuracy is obtained only over narrow spans (see Figure 4.1g).
2. It is quite small and will exhibit errors due to self heating.
3. Exposure to high temperature will cause a dramatic and permanent shift in its output characteristics.

Most applications of the thermistor are in commercial and laboratory applications. Few are used in industrial process control. Thermistors are designated by their resistance at 25°C with the most common value being 2252 Ω.

Radiation Pyrometers An infrared (IR) thermometer is a noncontact radiant energy detector. Every object in the world radiates IR energy. The amount of radiant energy emitted is proportional to the temperature of an object. Noncontact thermometers measure the intensity of the radiant energy and produce a signal proportional to the target temperature. The physics behind this broadcasting of energy is called Planck's Law of Thermal Radiation. This radiated energy covers a wide spectrum of frequencies, but the IR spectrum is most commonly used for temperature measurement. IR thermometers capture the invisible infrared energy that is naturally emitted from all objects warmer than absolute zero (0 K). Infrared radiation is part of the electromagnetic spectrum that includes gamma rays, x-rays, microwaves, ultraviolet, visible light, and radio waves. IR falls between the visible light of the spectrum and radio waves. IR wavelengths are usually expressed in microns with the infrared spectrum extending from 0.65 to 1000 μm.

In practice, the 0.65- to 14-μm band is used for IR temperature measurement over a range from –50 to 6500°F (– 46 to 3000°C). IR technology has become a viable and cost effective alternative to TC and RTD measurements in hostile environments like furnaces and in ovens where food, textiles, plastic, or glass are heated. The TC or RTD can only measure the temperature of its immediate surroundings and therefore cannot measure the actual product temperature. The actual temperature of the product will change due to variations such as line speed, thickness of the product, color, or roughness. The TC or RTD will not respond to these temperature changes quickly enough to permit close control. The IR thermometer will instantly measure the actual product temperature, not the environment surrounding the product.

IR thermometers are ideal for moving targets such as glass, plastic, and steel. They do not interfere with the process. They are also ideal for measuring products with very high temperatures or hostile environments. They can see through windows to measure products in a vacuum furnace or a semiconductor reactor. IR thermometers can measure targets as small as 0.025 in. in diameter and can respond in

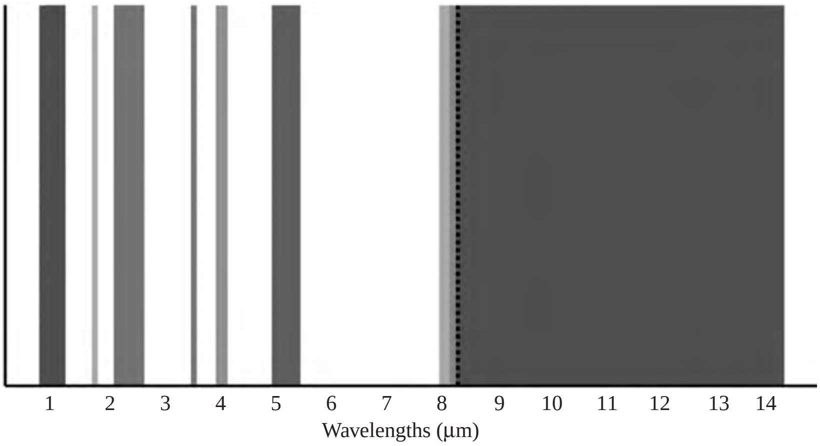

FIG. 4.1j
Infrared spectrum for practical measurement. (Courtesy of Ircon.)

10 ms to a temperature change. IR instruments operate at various wavelengths and Figure 4.1j shows the standard wavelengths that are available from most manufacturers. Each bar represents a series of instruments. The shortest wavelength band utilized is 0.65 μm and the longest is 8 to 14 μm. An instrument using a 0.65-μm wavelength can measure the higher range temperatures from 1400 to 6500°F (700 to 3600°C). Instruments with sensitivity to the 8- to 14-μm range can measure down to –50°F (–45°C).

Here are some guidelines for applications for the various wavelengths:

1. Wavelength bands centered on 0.65 and 2.6 μm are used for metals and can see through quartz windows. Fiber-optic systems for remote sensor applications are optional. Two color systems in these bands use slightly differing wavelengths to make their measurement.
2. The 3.4-μm band (±0.05 μm) and the 7.9-μm band (±0.15 μm) are used to measure thin plastic films. At these wavelengths, films as thin as 0.001 in. are opaque and only the surface temperature is measured.
3. The 5-μm band (±0.2 μm) is used to measure glass windows and containers.
4. The 7.9-μm band is also utilized for ceramics and very thin glass.
5. The 8- to 14-μm wavelength is probably most commonly used for low temperature applications for textiles, paper, and food. It also is a very common wavelength for portable infrared thermometers.

Distance does not affect the measurement. Models are available that can measure from 1 to 300 ft (0.3 to 91 m). However, IR sensors measure the energy from a circular spot on the target, and the size of that spot is a function of the distance between the sensor and target. The farther away from the target the sensor is, the larger the spot (Figure 4.1k). Consequently, distance is limited by the size of the object you want to measure. Some models offer a low power laser that facilitates proper aiming. Where a direct line of sight to the target is not possible, models with a fiber-optic connected sensor system often can solve the problem. Fiber optics allows installations into difficult locations up to 30 ft from the instrument. They can withstand ambient up to 400°F (200°C) without cooling. The lowest target temperature for these systems is about 1300°F (705°C). At least one manufacturer offers an instrument with an optical aiming system that may be viewed on a TV monitor to ensure proper aim at the target.

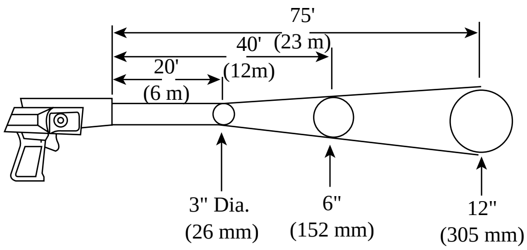

FIG. 4.1k
Typical target sizes and distances of portable infrared thermometers. (Courtesy of Wahl Instruments Inc.)

There are many applications for wire drawing, annealing, and vacuum furnaces where the sighting must be made through dirty windows. Other applications have small windows, obstructions in the sight path, or dusty atmospheres like those found in steel mills. For all these applications, the Two-Color or Ratio Thermometer provides an excellent solution.[20] This instrument utilizes two detectors operating at two wavelengths to measure one hot target. They can measure temperatures from 500°F (250°C) up to 6500°F (3500°C) and, by using sensors with two different wavelengths, can eliminate the interference problems. In addition, they can measure targets that do not completely fill the optical spot size of the instrument.

The installation of an IR thermometer requires attention to detail to ensure successful operation. Figures 4.1l and 4.1m

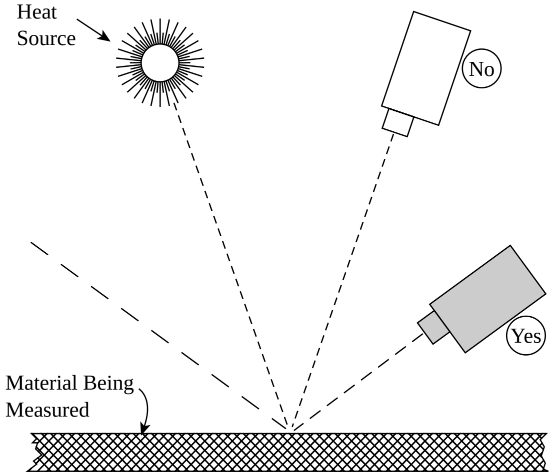

FIG. 4.1m
The infrared thermometer must be carefully aimed to avoid focusing on reflected solar radiation.

explain some of the problems with installation of IR thermometers. Ideally, a clear unobstructed line of sight is required and the target has to be large enough to fill the cone of vision. The spot size required is related to the distance to the sensor, and the user should consult the manual for details. Solid obstructions have to be removed or eliminated from the field of view by possibly aiming the instrument at a different angle or by using a fiber optic remote sensor system. For applications with sighting windows, the instrument must be selected to use a wavelength that will pass through the window material unchanged. The window also must be large enough so as not to obstruct the cone of vision. It also has to be kept clean by possibly using an air purge. Smoke, steam, and dust all cause temperature fluctuations.

Most IR thermometers have an electrical feature called a Peak Picker. This is a simple circuit that picks the peak temperature and does not allow the signal to decay when dust obstructs the field of view. Flames are also a consideration. Clean gas flames are transparent to most thermometers while coal, oil, or garbage flames are opaque and no thermometer can see through them. The actual temperature of oil, coal, or garbage flames can usually be measured with the two-color instrument. Most sensors can operate in environments up to 145°F (65°C). For hotter ambient environments, water or air-cooling is required (Figure 4.1n). IR instruments should be calibrated once a year using a certified blackbody.

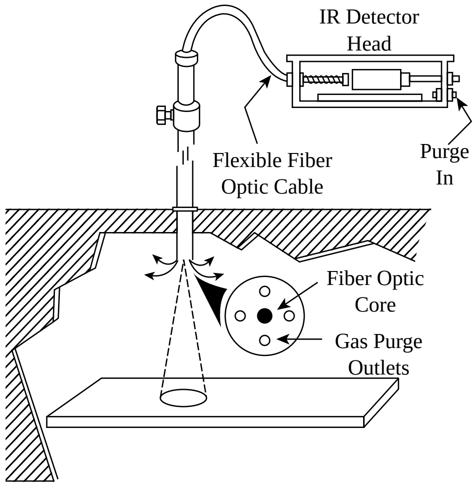

FIG. 4.1n

There is a growing market for line scanners that can produce a two-dimensional thermal image. This type of IR thermometer is used to measure wide webs such as hot strip steel, glass, plastic, and paper. This instrument utilizes one detector and two 45-degree mirrors with one mirror rotating and scanning over a 90° angle as shown in Figure 4.1o. For moving targets, the instrument uses a software technique to create two-dimensional thermal images of the moving web. The software provides temperatures at any location on the web and can provide output signals that can be used for closed loop control or stored for future review.

Thermal imagery is a rapidly growing application of IR technology that is used on some automobiles and by military and law enforcement in night vision applications. Architectural analysis of building insulation, surveillance, and quality control are other uses. This imaging system is an IR thermometer that uses a detector called a focal plane array instead of a single sensor. Its functionality is similar to a digital camera, except that, instead of capturing photographic images, each pixel measures temperature. A two-dimensional image is created using software resident within the system. The detector can have as many as 76,000 pixels. The image of the temperature profile can be used for closed loop control of processes, such as detecting defective personal computer (PC) boards, or stored away for future analysis.

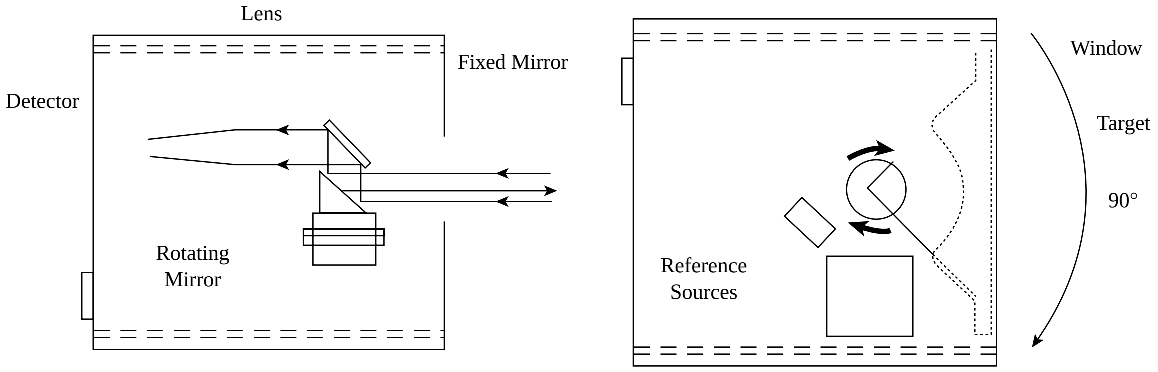

FIG. 4.1o
Schematic of line scanner IR thermometer. (Courtesy of Ircon.)

Most manufacturers of IR instruments continue to refine existing products and offer enhanced capability with newer models. One new model offers bidirectional digital networking communications. Multiple sensors can connect to host systems for monitoring, control, and diagnostics. The design engineer is strongly urged to consult with multiple vendors to get recommendations for selecting the proper instrument for each application.

Solid-State Sensors The small solid-state sensor converts a temperature input into a proportional current output over a range of –67 to 300°F (–55 and 150°C) (see Figure 4.1g). It is especially suited for PC boards or heat sink mounting for special temperature measurement and control applications where solid-state reliability, linearity, and accuracy are required. They can be used to determine minimum, average, and differential temperatures, in addition to being used for TC cold junction compensation and temperature control applications. With prices beginning under $10, these sensors are gaining popularity. Diodes are typically used in cryogenic applications over a range of –455 to 396°F (–271 to 202°C) and can be accurate to 0.05°C when properly calibrated.

Heat-Flow and Thermal-Conductivity Sensors The accurate measurements of heat flow through thermal insulators and of the thermal conductivity of construction materials are both important. Such measurements are of interest not only to architects, but also to engineers who are involved with safety and energy conservation.

A common heat flowmeter design involves the placing of a thin plate of known thermal conductivity on a heat-radiating surface. It has been found that the heat flow through these elements is directly related to the temperature difference through them. This temperature difference is often detected by thermopiles—a large and even number of TCs connected in series in such a manner that their high-temperature junctions are on the inside and their low-temperature junctions are on the outside surface of the sensing element (Figure 4.1p). The heat flows that are encountered in different processes range from about 10 k-cal/m^{2}h through freezer walls to about 100,000 k-cal/m^{2}h through the shells of water-cooled electric furnaces. The thickness of the sensor plates is a few millimeters, and the plates are made of rubber, organic materials, or other heat-resistant materials, sometimes contained in a thin, stainless steel disk case.

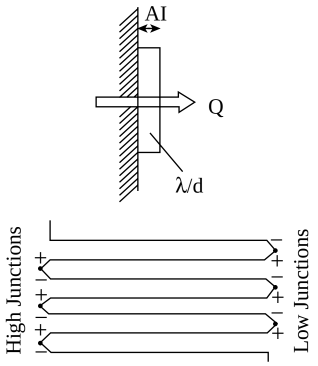

FIG. 4.1p
Knowing the thermal conductivity (λ) and the sensor plate thickness (d), the measurement of temperature difference (ΔT) can be converted into heat flow (Q), because Q = (λd) ΔT.

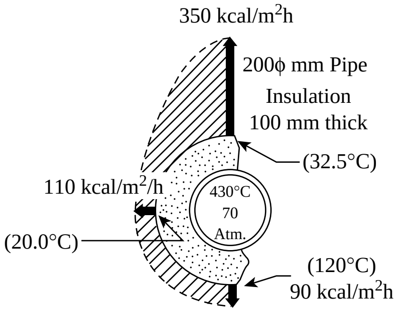

FIG. 4.1q
The measurement of surface heat loss from an insulated steam pipe. (Courtesy of Showa Denko K.K.)

The heat-flow distribution frequently varies with the direction of heat flow. For example, Figure 4.1q shows that the heat loss from the top of a steam pipe was found to be much more than through the bottom surface. Such findings are usually explained by noting that heat flow from a surface is not only a function of the surface temperature, but also of the effects of coating. It has been found that if a surface is coated with bright and glistening aluminum paint, it will radiate much less heat at the same temperature as a surface where the coating has worn off. Sensor elements can measure the variations in heat flow at different points on many shells, from liquefied petroleum gas (LPG) tank walls to electric and blast furnace shells, and their readings can reveal the erosion of linings as well as other hard-to-detect phenomena.

In other processes the interest is in measuring the thermal conductivity of heat insulating substances. Thermal conductivity instruments are designed to measure thermal conductivities of solid materials in the range of 0.001 to 10 W/mK. Typical materials with conductivities in this range are foam, insulation, polymers, composites, glass, silicon, natural fibers, and rock. One vendor offers a model that is an interfacial heat reflectance device that contacts a constant current heat source to the sample. The temperature of the interface is monitored and the rate of temperature rise is related to the thermal conductivity of the unknown sample.[21] Higher thermal conductivity samples produce a lower rate of temperature rise because the heat is being conducted away from the interface. The heating element of the probe provides a one-dimensional heat flow. The entire element must be covered during testing, establishing the minimum flat surface area of 5 × 25 mm. The probe calculates the value of thermal conductivity (k) given known values of heat capacity (Cp) and density (r). If these parameters are unavailable the results give the effusivity of (KrCp)1/2.

The hot wire method of thermal conductivity measurement involves the stretching of a thin heating wire through a sample and applying a constant amount of power (Figure 4.1r). The higher the thermal conductivity of the sample, the lower will be the resulting surface temperature of the heater wire. Therefore, it is possible to read the surface temperature of the heater wire and interpret from that reading the thermal conductivity of the sample.

The thermal conductivity of an unknown substance can be determined by first recording the surface temperature response curve (time vs. temperature) of the wire while the wire is surrounded by a known thermal conductivity material. After that, half of the known sample can be replaced by a material having an unknown conductivity. After repeating the test, the difference in the response curves can be correlated to the thermal conductivity of the unknown substance. In the sensor shown in Figure 4.1r, the heated wire is surrounded on the top by a material of known thermal conductivity; therefore, when it is placed on the flat surface of the unknown sample, its temperature response curve will reflect the thermal conductivity of that substance.

INTELLIGENT TRANSMITTERS AND REMOTE INPUT/OUTPUT (I/O)

This first volume of the *Instrumentation Engineers' Handbook* is devoted to measurement. While the transmission and control related topics are covered in Volume 2 and networks and buses in Volume 3, this paragraph is included here as it relates to the general topic of temperature monitoring.

Microprocessor-based temperature transmitters have continued to evolve in sophistication and capability such that there is no credible transmitter on the market today that does not use this technology. A transmitter includes an input circuit referred to as an analog-to-digital (A/D) converter that converts the sensor input signal from its analog form into a digital representation for presentation to the microprocessor. The microprocessor performs all of the mathematical manipulations of ranging, linearization, error checking, and conversion. The output stage accepts the resultant digital representation of the current value of the measurement and converts the signal back to an analog signal (D/A) that is typically a 4- to 20-mA DC current. For some special applications, 0 to 1 Vdc or 0 to 10 Vdc signals may be used and in others the signal is transmitted digitally using either an open or proprietary protocol. Some countries have adopted 0 to 20 mA as the standard transmitted signal.

Just as microprocessors have evolved in sophistication, so have A/D converters. Eight-bit resolution devices common in the 1960s provided a resolution of about ±0.4%. In 2000, the first 21-bit resolution A/D was used in a temperature transmitter providing a resolution of ±0.00005%. D/A converters have also evolved with resolutions increasing from 8-bit up to the 18-bit versions used in the better transmitters beginning in 2000. The result of combining these technologies is a universal transmitter that accepts inputs from any TC, RTD, mV, resistance, or potentiometer signal; checks its own calibration on every measurement cycle; has minimal drift over a wide ambient temperature range; incorporates self-diagnostics; and is configured using pushbuttons or simple PC software.

The reconfiguration process is quick and convenient, and it tends to allow for lower inventories by making the transmitters interchangeable. Some transmitters are capable of handling dual RTD elements. This allows for temperature averaging, temperature difference measurement, or automatic RTD sensor switchover if the primary sensor fails in a redundant installation. Due to terminal limitations, these models can only accept dual 3-wire RTDs. Caution must be used to minimize lead resistance differences to reduce the error.

Fieldbus Structures

In the 1980s, another level of capability was added to field devices. Rosemount developed the Highway Addressable Remote Transducer (HART) protocol to enable detailed information about the setup and operation of the device to be superimposed onto the 4- to 20-mA signal. This protocol was soon released to the public domain. The HART Communication Foundation promotes its use in industry and supports its maintenance and growth. The benefits of remote configuration and access to diagnostics have encouraged the dramatic increase in use of HART-enabled instruments.[22]

During this same time period, a variety of proprietary protocols emerged supported by many of the larger manufacturers that provided comparable benefits of remote setup and diagnostics. Unlike the HART protocol, these products were limited to use within the manufacturer's system. In the 1990s, a trend emerged for more open protocols to enable plug-and-play of instruments from varying manufacturers to work as part of a fieldbus structure.

Two that have emerged as leaders are Foundation Fieldbus and Profibus. Each has their proponents and support groups that have been promoting their acceptance. Temperature transmitters, as well as other field and control room devices, must incorporate the specific fieldbus technology to be used in these systems. The support tends to favor using fieldbus technology for new plant construction and major upgrades where all new instrumentation and cabling would be required. Existing plants with properly functioning legacy instruments are more likely to stay with existing technology.

In 1979, Modicon introduced the MODBUS protocol as a means of exchanging data between field devices and controllers. This protocol serves as a means to share data among multiple vendor devices. It is now owned by Schneider Automation and is freely available for use. There are several temperature multiplexers on the market that can communicate with a host system using MODBUS, MODBUS Plus, or MODBUS TCP/IP protocols.[23]

Ethernet communication has been used for interconnection of digital equipment in offices and control rooms for many years. Its use is now migrating out onto the factory floor. There are a variety of products introduced beginning in 2002 that will interface process measurements, including temperature, over high speed Ethernet links to host systems using OPC (object linking and embedding for process control) servers.

There is more to making a measurement than the transmitter itself. The weakest link in virtually all measurements is the temperature sensor. The vast majority of temperature measurements are made with either a TC or an RTD. As with the electronic devices described above, sensors have also demonstrated dramatic increases in precision and reliability over the years. Higher purity materials and improved manufacturing processes have provided sensors that more closely match theoretical curves and exhibit lower drift than sensors of the 1980s and the 1990s. It has been generally accepted that the more closely a sensor matched its ideal characteristics, the more accurate the measurement will be since transmitter measuring circuits refer to the ideal data to make the measurement.

Advanced Transmitters

More advanced transmitters incorporate the ability to match the sensor to the transmitter to minimize this error. One method uses the Callander van Deusen method, which defines three experimentally determined constants that define the temperature/resistance relationship specific to an RTD. By entering these data from the RTD tag into the transmitter's firmware, the sensor and transmitter become a calibrated system. Typical accuracies for this technique are about ±0.4°F. For higher precision, at least one vendor offers a bath calibration technique that allows the transmitter to capture actual values output by the RTD or TC at specific temperatures. This method provides system accuracies of about ±0.02°F (0.1°C) for RTDs and about ±2°F (1°C) for TC measurements. Maximum performance is gained by selecting the trim points to bracket the operating point.[24]

Direct connection of temperature sensors to input subsystems of distributed control systems (DCSs) or programmable logic controllers (PLCs) is an alternative to using a temperature transmitter for each measurement. This may sound like a way to cut costs. In actuality, on an installed basis, it is more expensive, far less accurate, and not as robust. It may be suitable for less demanding data acquisition or control applications where wider variations in the measurement can be tolerated. The benefits of using transmitters include higher precision, sensor-transmitter systems calibrated to the range of interest, better RFI immunity and noise rejection, transmitter diagnostics, lower wiring costs, less expensive input/output (I/O) cards, faster loop checks, and shorter start-ups.

The array of intelligent temperature transmitters on the market seems almost endless. Some common features of the leading models are: universal inputs from any TC, RTD, mV, resistance or potentiometer; loop-powered with 4–20 mA output; digital outputs, and configuration with pushbuttons, PC software, or a handheld configurator. Choices must be made for which protocol is required: HART, Foundation Fieldbus, Profibus, vendor proprietary, Ethernet, or just 4 to 20 mA. Some field locations will benefit from local indication and this feature is optional with most manufacturers. There is a considerable cost and performance benefit afforded by purchasing the sensor and transmitter as a system. This saves cost by offering single source responsibility. For applications where it is prudent to separate the sensor from the transmitter, DIN (Deutsch Industrie Norm) rail-mounted transmitters may be grouped in a marshalling cabinet at a convenient location.

TEMPERATURE MEASUREMENT APPLICATIONS

High Temperature Measurement

There are two viable methods for measuring temperatures up to 2000°F (1100°C): special high-temperature TCs and IR pyrometers. At high temperatures TCs are installed into protective wells or protection tubes. When installed horizontally, wells tend to droop causing binding on the TC element when it must be removed for replacement and a new one inserted. The latest design of a TC incorporates a 1 in. sheath with a flexible cable that can easily be inserted into even badly drooping wells.[11] Upper limit for this sensor is about 2000°F (1100°C). Ceramic wells do not suffer from droop but have other limitations of low surface strength, brittleness, and low erosion resistance. IR pyrometers offer a very viable noncontact method to measure temperatures all the way up to 6500°F (3600°C) and would be the best choice for most applications. Refer to the detailed description above for additional detail.

Speed of Response

The fundamental problem of measuring the temperature of a fluid is one of assuring strong thermal coupling. For a fluid temperature measurement to have meaning, the sensor must come to equilibrium with the temperature of the fluid. The difference between the equilibrium temperature of the sensor and the fluid temperature is a direct error. The most common process temperature measurements are made with TC and RTD sensors. Commercial and laboratory applications often use exposed TC beads or RTD elements to obtain fast response in clean environments.

Refer to Figure 4.1s for representative mounting configurations. There are very few industrial measurements where an exposed sensor would be used. This is because the process of taking the sensor out of service would release pressure or product from the pipe or vessel where the measurement is being made. Therefore, most applications use thermal wells to isolate the sensor from the process. Accordingly, the mass of the well and the piping into which it is inserted are the dominant causes of thermal lag and conduction errors. These errors can be almost insignificant for processes with stable temperatures and rapid flow. However, for dynamic temperature fluctuations or where there is little flow across the sensor, the errors can be large.

D-Asperated Shielded Gas Stream Temperature Sensor for High Temperature, High Velocity Gases (Highly Directional Characteristics)

FIG. 4.1s
Fluid stream sensor configurations.

There are various designs of high speed of response sensors but most are limited by being manufactured with a protective sheath that runs the length of the well providing a long and massive path for thermal losses. A new design uses low mass RTDs or TCs in a 1 in. (2.54 cm) sheath to minimize this effect.[11] To further increase the response, the sensor is spring loaded against the tip of the well and inserted with thermally conductive grease. One well manufacturer offers a finned thermal well providing dramatic improvement in the response.[25] Fast response is especially valuable for gas applications. Some of the better transmitters update their output several times per second and therefore are rarely the limiting factor in the measurement.

Surface Measurement

Measuring the surface temperatures of moving objects like webs of paper, plastics, textiles, and metals of rotating cylinders (such as calendar rolls, rotary kilns, or drier cans) requires

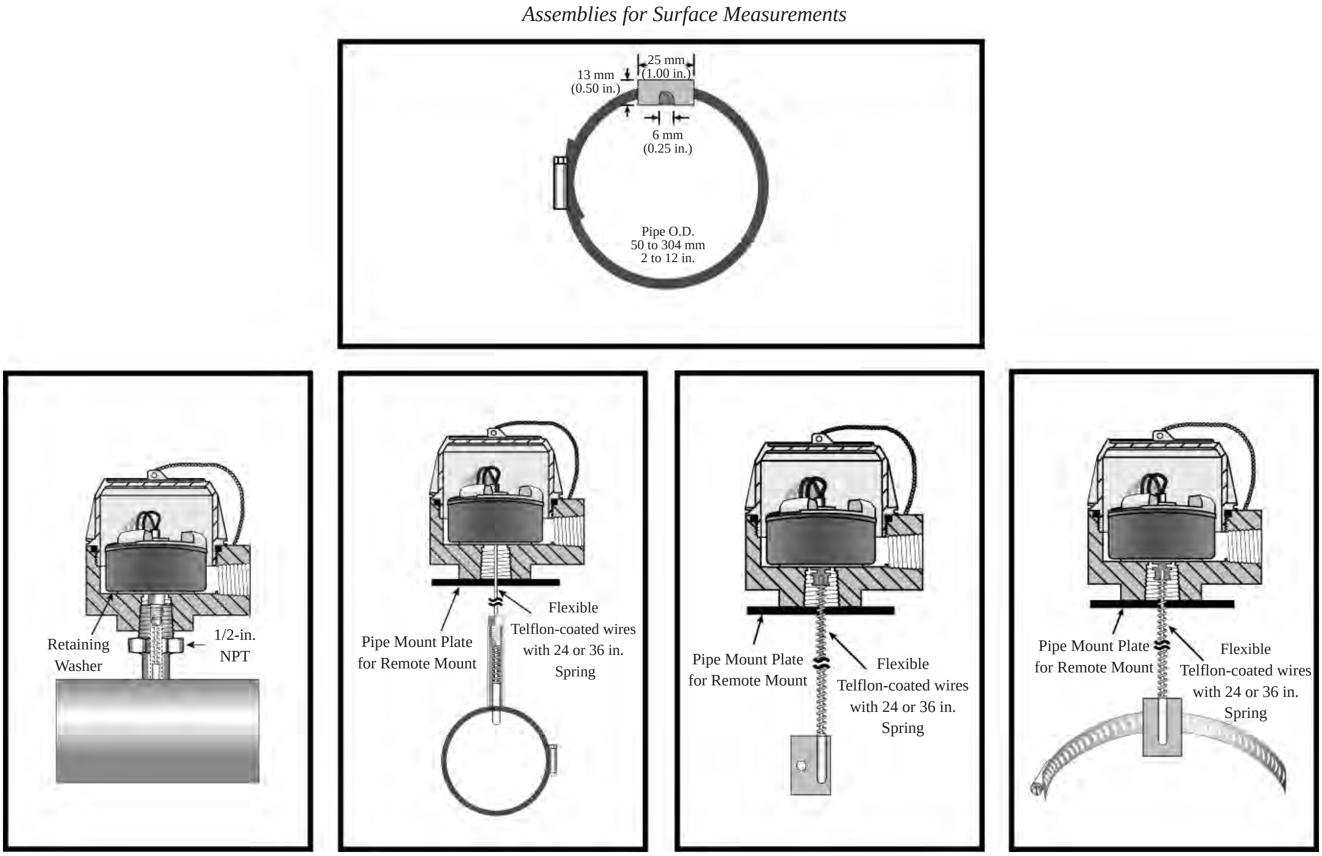

FIG. 4.1t

Mounting configurations for surface mounted thermocouple and RTD sensors. (Courtesy of Moore Industries-International, Inc.)

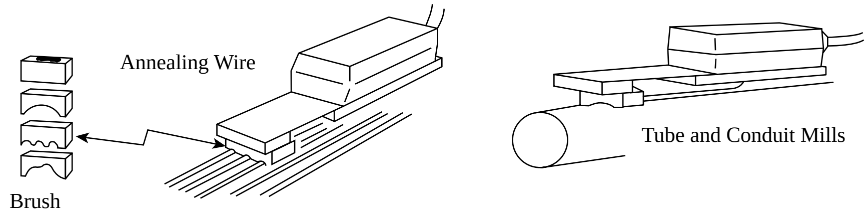
special consideration. IR pyrometers offer a cost effective method as described above for many industrial applications. They offer many advantages, including high accuracy and fast response, and are especially suited to moving surfaces. However, for stationary surfaces, often a less sophisticated and less costly method is called for. The phase shift products offer a visual measurement but have no other output.

There are a variety of mounting methods where either a TC or an RTD may be affixed to the outside of a pipe or vessel and be connected to a transmitter or data logger to get continuous information. The design of the mounting hardware and its proper installation are critical in obtaining a representative surface temperature. The thermodynamics of the application are complicated by the thermal losses to the surrounding atmosphere, thermal lag of the wall of the vessel or pipe, and the rate of change of the medium. A properly designed system will use a low mass sensor with high speed of response inserted into a fixture that places the sensor tip as close as possible to the surface being measured. Refer to Figures 4.1t, 4.1u, and 4.1v for some typical examples of mounting configurations.

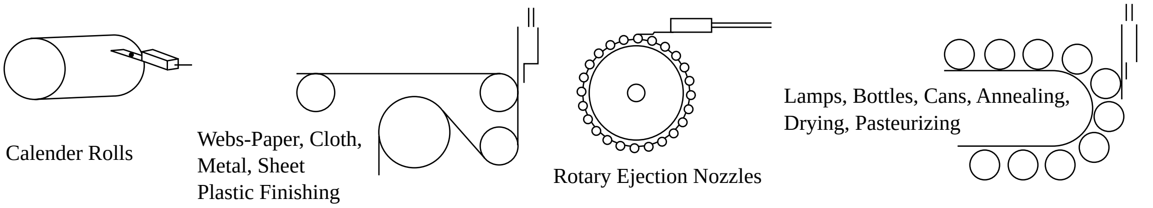
Measuring the Temperature of Solids

Determination of the allowable size and configuration of the sensor requires some knowledge of the heating or cooling conditions together with an estimate of the magnitude of the temperature gradients that are likely to exist in the region in which the measurement is to be made. A simple rule-of-thumb indicator to determine if significant gradients are likely to be present is the magnitude of the Biot modulus (hL/K), where h is the surface heat transfer coefficient, L is the smallest dimension of the solid, and K is the thermal conductivity of the solid. If this modulus is over 0.2, significant temperature gradients are likely to exist in the solid, and care should be exercised in choosing the size, location, and orientation of the sensor within the solid. If the Biot modulus is less than 0.2, no significant gradient is expected and a measurement anywhere on or within the solid should give identical results regardless of size or configuration of the sensor. If significant gradients are likely to exist, the maximum rate of heat transfer to the surface of the solid must be known or estimated, and the maximum gradient at the point measurement must be determined. The following relationship allows the maximum gradient at the surface of a solid to be calculated:

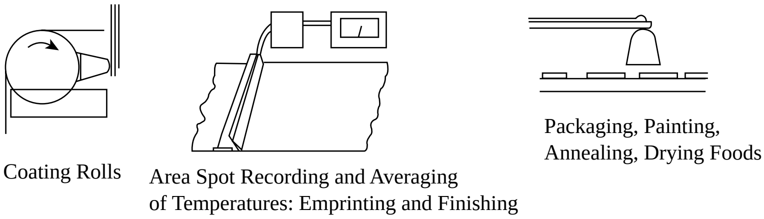
$$\frac{\Delta T}{\Delta X} = \frac{q}{K} \qquad \mathbf{4.1(1)}$$



Brush Sensor



Bather Touch Sensor



Noncontact Sensor

FIG. 4.1u
Thermocouple-type surface temperature sensor designs. (Courtesy of Syscon International Inc.)

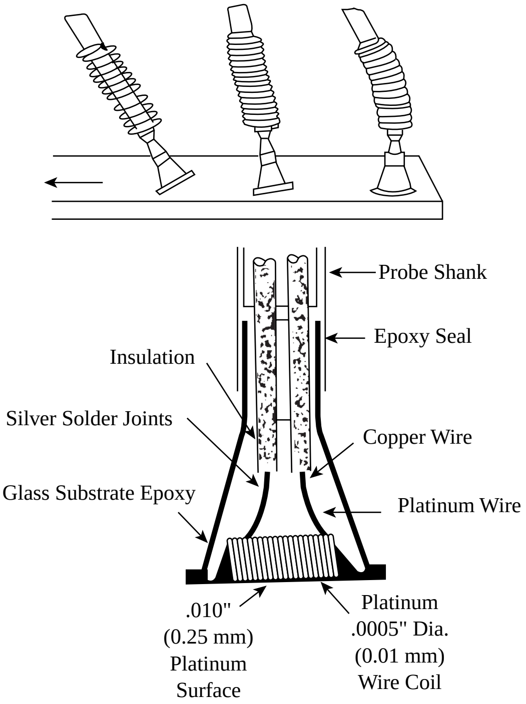


FIG. 4.1v
RTD-based surface-temperature detector. (Courtesy of Wahl Instruments Inc.)

where
$\Delta T/\Delta X$ = temperature gradient at the surface
q = heat transfer rate per unit area at the surface
K = thermal conductivity of solid

Under certain conditions of heating or cooling, if measurements at points other than the surface are important, it may be necessary to evaluate anticipated heat transfer conditions and resulting temperature gradients.[4,5]

On the basis of this gradient, it is possible to establish limits on the size of the sensing device. For example, the length of any one of the three dimensions of the sensor (lead wires excluded) should not be greater than the distance between two points of the process that are different in temperature by more than the acceptable measurement error. It is assumed that the sensors are in satisfactory thermal coupling with the process material, which is not always the case. If the thermal coupling is poor, the sensor will not reflect the true temperature history that was experienced by the solid. This condition can produce dynamic errors.[6]

The best thermal coupling is achieved by direct bonding of the sensor, such as welding a TC to the solid surface or into a cavity within the solid. The bond line between the sensor and the solid should be kept as thin as possible and should not fracture or fail during thermal cycling. Various epoxy and ceramic cements, with fillers to improve their conductivity, have been successfully used for such bonding. For example, a flat RTD, which is bonded to a surface with a 0.005 in. (0.1 mm) thick epoxy bond line will produce a lag time of about 1 s. This will give a dynamic error equal to the rate of temperature rise of the surface, because a dynamic error of 25°F (14°C) corresponds to a rate of surface temperature change of 25°F/s.[6]

Methods of installing temperature sensors on or within solid bodies are shown in Figure 4.1w.

Averaging Measurements

There are different considerations depending on the application. The solution is different for liquids, gasses, or solids and also depends on the accuracy and speed of response required and what is to be done with the measurement results. For a temperature profile in a storage tank that is to be used for volume correction for inventory, an array of high accuracy RTDs would be the appropriate choice. There is one manufacturer that can supply a flexible array of almost any length for easy field installation. The receiving device would then average the input from the various sensors and exclude those not covered by product based on the level measurement. There are tank-gauging companies that specialize in this application.

For a high temperature reactor or furnace, the sensing array would use TCs to generate the signal that can then be averaged in software by a receiving device. For large air ducts for furnaces or clean room circulation, a highly accurate average temperature is obtained by using an RTD sensor that is constructed with a continuous resistive element so as to eliminate hot spots. This special RTD should be a 4-wire construction and be used with a 4-wire measuring circuit like what would be found in a high quality transmitter to obtain an accurate temperature measurement. For gas flow in pipes an RTD and transmitter assembly is an appropriate choice. If the application is for temperature compensation for a mass flow calculation, a 4-wire RTD trimmed to match a quality transmitter will provide the highest accuracy. Such systems are available with accuracies of ±0.02°F (0.01°C).

For stationary or moving surfaces of almost any size, the IR pyrometer is the best choice over any range.

Narrow Span Measurements

When the operating point of an application is stable, higher accuracy can be achieved by reducing the span of the measuring instrument. For example, when measuring temperature of a process that operates at 125° with a variation of ±10°, a range of 0 to 150° would be well suited. An instrument ranged from 0 to 600° would have 4 times less resolution. TCs are generally limited to a minimum span of about 63 to 180°F (35 to 82°C), depending on type, while spans using a 1000-Ω Platinum RTD with a high quality transmitter may be as low as 2°F (1°C). Matching a sensor to its transmitter offers the highest possible accuracy.

INSTALLATION CONSIDERATIONS

When making temperature measurements, two ways have traditionally been employed to get process readings from the point of measurement back to a monitoring and control system.

One method is to utilize sensor extension wires to carry the low-level signals (Ω or mV) generated by field-mounted RTD or TC sensors. Another is to install temperature transmitters at or near the measurement point. The transmitter amplifies and conditions the sensor signal and transmits it over a twisted wire pair back to the control room.

Direct wiring strategies have generally been considered less expensive and sometimes easier. Transmitter use, because of cost considerations, was often reserved for important loops and applications where signal and loop integrity was a must.

Today, highly functional, yet very affordable, microprocessor-based field-mount temperature transmitters are comparable in price to direct wiring strategies. There are additional advantages of using intelligent transmitters that will, in most applications, also save considerable time and maintenance headaches. This is especially true when the measurement point is located a long distance from the readout and control system.

Temperature Transmitters in Place of Direct Wiring

Lower Wiring Costs Direct wiring sensors to a control system requires the use of sensor extension wires. Not only are extension wires fragile, they also cost three times more than the common shielded copper wire used for a temperature transmitter's 4 to 20 mA signal. Using the less expensive wires, transmitters can pay for themselves in wire and conduit costs alone. The longer the wire run, the greater the potential savings.

In retrofit situations, temperature transmitters can be installed at the sensor, and the in-place RTD or TC extension wires can be used to transmit the 4 to 20 mA back to the control system. There is no need to run new copper wires to accommodate the 4 to 20 mA. No additional installation time or material costs (including conduit) are incurred, and you still get all of the advantages of using temperature transmitters.

Protect Signals from Plant Noise Common in nearly every industrial environment, RFI and EMI can negatively affect process signals. Some of the common sources include mobile and stationary radio, television, and hand-held walkie-talkies; radio-controlled overhead cranes; radar; induction heating systems; static discharge; high-speed power switching elements; high AC current conductors; large solenoids and relays; transformers; AC and DC motors; welders; and even fluorescent lighting.

If there is one or more of these in your plant, RFI/EMI problems are likely. The result is sometimes just a minor inconvenience. Other times it can be as serious as a plant shutdown.

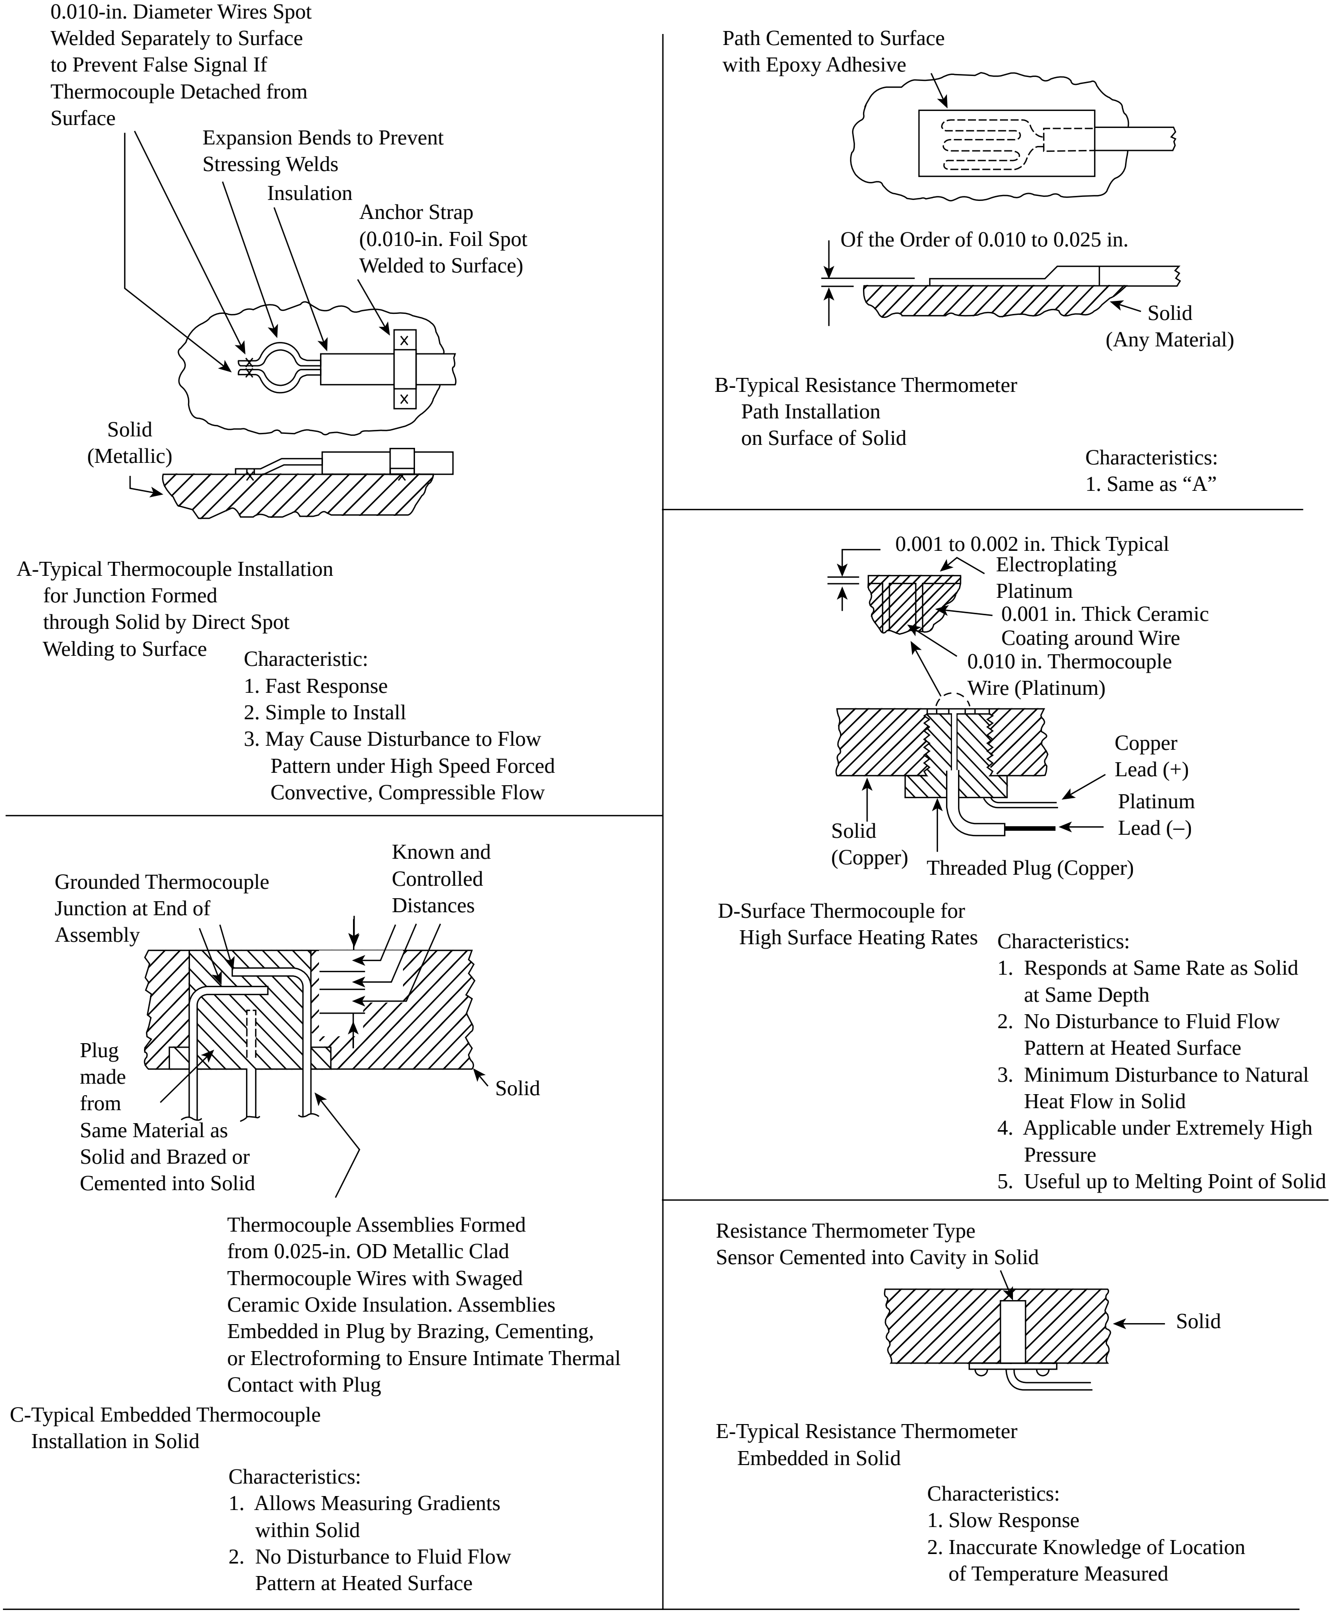

FIG. 4.1w
Some selected methods of installing temperature sensors on or within solids.

In a direct wiring scheme, the low-level signals generated by an RTD (Ω) or TC (mV) are particularly susceptible to the signal degrading effects of RFI/EMI. Compounding the problem, sensor extension wires can behave much like an RFI/EMI antenna by actually drawing plant noise to the wires, and affecting weak, low-level signals.

Conversely, a properly designed temperature transmitter effectively negates the effects of incoming RFI noise by converting a sensor's low-level signal to a high-level analog signal (typically 4 to 20 mA). This amplified signal is resistant to RFI/EMI and can accurately withstand long distance transmission from the field, through a noisy plant, back to the control room. When specifying a transmitter, always check for RFI/EMI protection. If there is no specification given, it is usually because the instrument is not designed to resist noise. It will probably not perform very well in a noisy plant environment. RFI immunity is specified in standard IEC 1000–4–3. A spec of 10 V/m is considered acceptable.

Stop Ground Loops Make sure to choose an isolated transmitter. A transmitter's input/output/power signal isolation protects against signal inaccuracies caused by ground loops. This is important even when using ungrounded TCs because their insulation will eventually break down.

Reduce Hardware and Stocking Costs With direct wiring, it is necessary to match the sensor type to input-specific DCS and PLC input cards. Sensor input-specific cards usually cost a lot more per point than a 4- to 20-mA input card. And since numerous sensor types are routinely used in a plant, a large number of different cards must be ordered and kept on hand as spares. This is not only expensive, but can result in a lot of confusion when installing, maintaining, and replacing equipment. Temperature transmitters incorporate powerful microprocessors that allow them to be easily configured to accommodate nearly any sensor input type. Their 4- to 20-mA output signal is control-system ready. This allows standardization and stocking of less expensive 4- to 20-mA DCS and PLC input cards.

Match the Best Sensor to the Application In an intelligent temperature transmitter strategy, the user can simply change out the sensor and reconfigure the transmitter to accommodate the different sensor type. The loop's twisted pair wiring and existing 4- to 20-mA input boards do not even have to be touched. Because it is difficult to predict what sensor you will end up with as process changes are made over the years, make sure to select a universal transmitter that configures to accept all common temperature sensor types and temperature ranges.

Enhance Accuracy and Stability Using temperature transmitters can substantially enhance measurement accuracy. DCS and PLC systems measure readings over the entire (very wide) range of a sensor. Measuring a narrower range produces far more accurate measurements. Transmitters can be calibrated to any range within a sensor's overall capabilities. Their measurements are more precise than is possible with most direct wiring strategies. Better transmitters deliver accuracy ratings of ±0.23°F (±0.13°C) when paired with a common Platinum 100 RTD sensor over a 200°F (111°C) span.

If better accuracy is required, transmitters can be trimmed to precisely match a particular sensor. Even though sensors are designed to have a high degree of conformance to an established curve, each one (even precision sensors) will vary to some degree from their stated specification. Transmitters without matching capability assume that the sensor matches its published curve. To properly determine the measurement accuracy, the actual sensor offset error must be combined with the transmitter error.

Simplify Engineering and Prevent Miswiring In place of numerous sensor lead-wire and DCS/PLC input board combinations, engineering designs and drawings will only need to show one wire type (twisted wire pair) and one input board type (4 to 20 mA). This one wire and one input board system means maintenance is greatly simplified, and the chances of loop miswiring are virtually eliminated.

Ease Future Upgrades Throughout the lifetime of a process, enhancements are routinely made to accommodate the manufacture of upgraded or even completely new products. Process changes may require different measurement ranges or greater temperature accuracy than was previously required. Either of these conditions may necessitate a change in the type of sensors that are used.

In a direct wired system, changing sensors generally means removing existing extension wire and pulling new wire. This is because extension wire must be matched to the sensor type. Additional costs are incurred when the control system's costly input boards (if also sensor-type dependent) must be replaced to accommodate the new sensors.

Lower Maintenance Time and Expense Temperature transmitters have come a long way since the days of fixed-range, inflexible instruments. High quality transmitters are not only universal in regards to input type and range, they also incorporate powerful sensor diagnostics that save considerable time and money.

Temperature transmitters with intelligent diagnostic capabilities continuously monitor sensor operation and quickly find and diagnose sensor failures. If a wire breaks or otherwise stops sending a signal during operation, the transmitter sends the output upscale or downscale to warn of sensor burnout or other unwanted conditions. Furthermore, these transmitters can tell you which wire has broken via an error message on an integral digital display, using their PC configuration software, or via HART diagnostics. Specific fault messages eliminate the work of removing the sensor or checking all of the lead wires to diagnose a problem. During start-ups, in the middle of the night or in the middle of winter, this can be a huge timesaving advantage.

Avoid Lead Wire Imbalances Where feasible, use 4-wire RTDs, and specify a temperature transmitter that is able to accept a true 4-wire RTD input. The advantage is that the fourth wire in an RTD circuit effectively cancels out errors due to resistance imbalances between the leads. Every ohm of imbalance in an RTD sensor's lead wires can produce as much as a 4.7°F (2.6°C) error in the measurement. Serious imbalances may be present from the very first day of commissioning without the user even being aware of them. Typical causes include manufacturing variances, lead length differences, loose connections, terminal block corrosion, and work hardening from bending and other stresses.

Intelligent temperature transmitters are capable of accepting true 4-wire RTD inputs and provide a constant current source to the outer leads of the RTD. The voltage drop is measured across the inner leads, which is a high impedance loop. There is essentially no current flow in the voltage loop, so voltage is directly proportional to resistance. Lead resistance is ignored. You will get a very accurate measurement providing the resistance value of the RTD plus corrosion, plus wire resistance, is less than 4000 Ω (typically). A 4-wire RTD costs about the same as a 3-wire and can be used with less expensive, smaller gauge wire without concern for added resistance.

Calibration/Certification

For many applications, using an off-the-shelf sensor with a receiving device will provide adequate measurement accuracy. The offset of the sensor from ideal published relationships may be within the acceptable variation. However, the higher the accuracy required, the more important factors like drift, sensor interchangeability, and system repeatability become.

For critical temperatures, there is often a requirement for certifying that a temperature system produces a given accuracy. In some cases, this is a plant standard and in other cases, accuracy must be traced back to NIST. Whatever the requirement, the calibration must be done as a system that includes the sensor and its measuring device. The key point to understand is that the instrument assumes that the sensor matches published relationships of temperature vs. output. If the sensor is offset from this relationship due to manufacturing tolerances or drift, then the measurement will have an error. The only way to have a true calibration is to bring the sensor to a known temperature and then verify that the instrument output agrees with that value. For field-mounted sensors connected to an I/O system in a remote control room, this is quite difficult to achieve, and errors may have to be tolerated or other methods utilized. One alternative is inserting a certified measuring device adjacent to the installed sensor and adjusting the output trim of the instrument to obtain the correct output reading. For integral sensor/transmitter systems, using a calibration bath or a precision oven offer a solution. How often a calibration is required depends on how closely a system can be verified vs. the accuracy required. For example, a TC system with an accuracy requirement of ±5° can be calibrated to about ±2°, but will have an expected drift of 1 to 5°/year. Hence calibration would have to be performed two or three times/year to calibrate out the drift. However, a premium RTD that has been matched to a transmitter using a calibration bath and capture techniques can offer an accuracy of ±0.02°F and a drift expectation of about ±0.08°F/year. If the system accuracy required were only 0.5°F, a calibration every few years would be adequate to ensure this performance.

The insight to be gained is that a proper choice of components and initial calibration may save significantly on calibration labor and potential process downtime. A wise design engineer will consider the cost of ownership, not just the cost of purchase. Should NIST calibration certification be required, there are many vendors and calibration services that can perform the calibration and provide certificates of traceability to NIST. Calibration on a 12-month interval is suggested by NIST guidelines.

Agency Approvals for Hazardous Areas

When electronic devices are mounted in an area that is, or may be, exposed to explosive vapors, very strict rules apply. Almost every plant in every country with these hazardous environments follows specific guidelines as directed by their insurance coverage. Most often, the guidelines are from one of the recognized certification agencies with jurisdiction in the country. These include FM and UL in the Untied States; CSA in Canada; CENELEC, LCIE, ISSeP, and ATEX in Europe; SAA in Australia; and NEPSI in China. Each of these agencies tests equipment submitted by a manufacturer and certifies it for use in specific area classifications and specifies the associated installation details. It is the design engineer's responsibility to determine the appropriate area classification and then select equipment that has the required approvals.

Protection of field devices from moisture, dust, and corrosive contamination is yet another consideration. Solutions include watertight enclosures, powder coat painted surfaces, air-purged enclosures, and special materials of construction.

Proper wiring, grounding, and installation practices are critically important for a problem-free installation. Basic considerations include separating signal and power wiring into different conduit runs and using twisted shielded wire pairs with the shield grounded at only one end. In addition, proper drip loops and conduit seals should also be provided for field instruments, which should be using lagged thermal wells and proper insulation to protect transmitters from the heat radiated from hot pipes or vessels. Lastly, close-coupling sensors with transmitters and properly sized, fused, and surge-protected power supplies should be used.

Safety-Related Applications

For safety-related applications, functional safety is another concern. Safety standards such as the American National Standards Institute/Instrumentation, Systems, and Automation

Society 84.01, IEC 61508, and IEC 61511 offer guidance for maximizing reliability and availability of devices used in safety related applications. The higher the Safety Integrity Level (SIL) required, the higher the availability of the devices in the loop must be to perform their designated task. To prevent nuisance failure situations, consideration is given to the reliability of the devices.

To verify that an instrument loop meets specific SILs, reliability data on all of the loop devices must be used in verification equations as suggested by the standards. Leading transmitter manufacturers offer these data in the form of Failure Modes, Effects, and Diagnostic Analysis reports. Failure probability data from these reports are used in the equations to verify that the loop components selected provide the required SIL. High reliability instruments do not necessarily demand a premium price. It seems a wise choice to standardize within a plant on products that offer documented reliability data from recognized third-party agencies for all applications, not just those that are safety related. It is clear that higher reliability requires less maintenance and produces less downtime of the process.

Flow Sheet Symbol

Temperature Ranges:	Minimum standard span is 150°F (50°C); maximum standard span is 800°F (450°C). Standard ranges in approximately 15 steps are available from –100 to 125°F (–70 to 50°C) up to 200 to 1000°F (100 to 550°C). According to DIN 16203, the heating, ventilation, and air conditioning (HVAC) sector has graduated, indicating ranges from –22 to 392°F (–30 to 200°C).
Materials of Construction:	External parts are made of copper alloys, stainless steel, or CrNi steel with acrylic or industrial sheet glass view windows. The thermowells can be brass, steel, stainless steel, or other special-order materials.
Dimensions:	Dial diameters vary from 1 to 6.5 in. (25 to 165 mm); stem lengths vary from 2.5 to 36 in. (63 to 914 mm).
Costs:	A 3 in. diameter, back-connected unit with a 2.5 in. brass thermowell lists at $60; a 5 in. diameter, multiangle unit with a 6 in. stainless steel thermowell is $65. Thermometers are usually discounted from 10 to 45% when large quantities are purchased.

BIMETALLIC SPRINGS

Bimetallic thermometers make use of two fundamental principles: (1) metals change volume with temperature, and (2) this coefficient of change is not the same for all metals (see Figure 4.2a). If two different straight metal strips are bonded together and heated, the resultant strip will bend toward the side of the metal with the lower expansion rate. Deflection is proportional to the square of the length and the temperature change and inversely proportional to the thickness. A bimetallic spring (Figure 4.2b) can be calibrated to produce a predictable deflection at a preset temperature. This is the basis of operation of the many bimetallic temperature switches in household appliances.

The motion produced by a bimetallic spring is small; to amplify it in a reasonably sized space the bimetal strip may be wound in the form of a spiral or a helix. A classic example of an ambient air temperature thermometer is shown in Figure 4.2c. The outside edge of the spiral is pinned to the frame and a pointer is connected to the center. As the temperature increases, the spiral winds up deflecting the pointer clockwise.

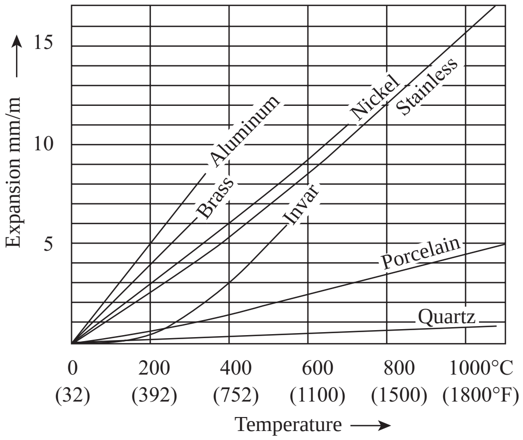

FIG. 4.2a
Thermal expansion of materials for stem-type expansion thermometers. (Courtesy of WIKA Instrument Corporation.)

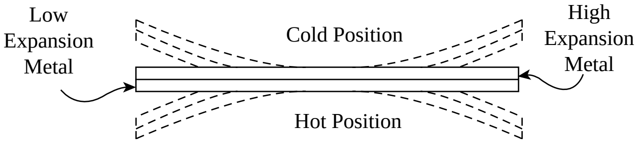

FIG. 4.2b
The operation of a bimetallic spring.

Knowing the coefficients of expansion of the two metals, their thickness, and the desired scale length and range, the total length of the spiral can be computed. A favorite combination of metals is low-expanding Invar (64% Fe, 36% Ni) against high-expanding nickel-iron alloy with chromium or manganese added.

Thermometers

Most industrial or residential bimetal thermometers use a helical coil which can be designed to fit into a stem more easily than the spiral. The element is surrounded by a protecting tube or thermowell (see Section 4.14). The device can be mounted to measure the temperature of the gas or liquid inside a duct. The design is frequently used on domestic furnaces and over the years has replaced most of the glass stem thermometers used earlier. Figure 4.2d illustrates a typical bimetallic thermometer using a helical coil. Also shown is a protective thermowell, which allows the removal or replacement of the thermometer without opening up the process tank or piping. When only periodic checks are needed on a particular temperature point, a thermowell only is installed and is protected from dirt accumulation by a cap.

A single helix moves axially as it winds or unwinds with heat and cold. This requires clearance for a vertical movement of the pointer. The difficulty can be overcome, if desired, by using a multiple element, wound coaxially so as to form coils within coils. This construction is more costly but has an advantage in requiring less immersion depth (Figure 4.2e).

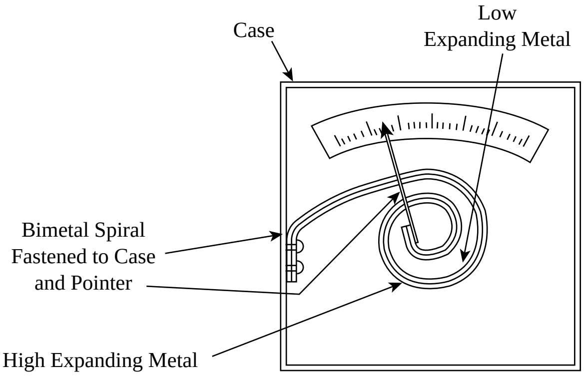

FIG. 4.2c

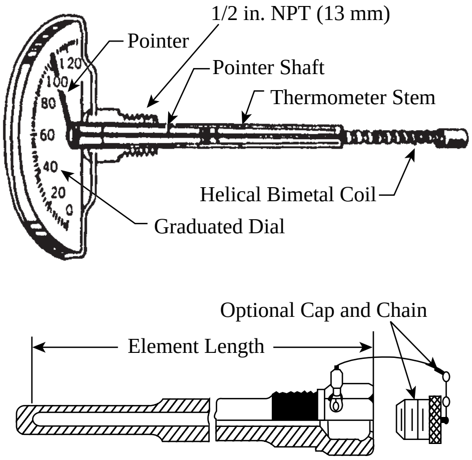

FIG. 4.2d
Bimetallic thermometer and corresponding thermowell.

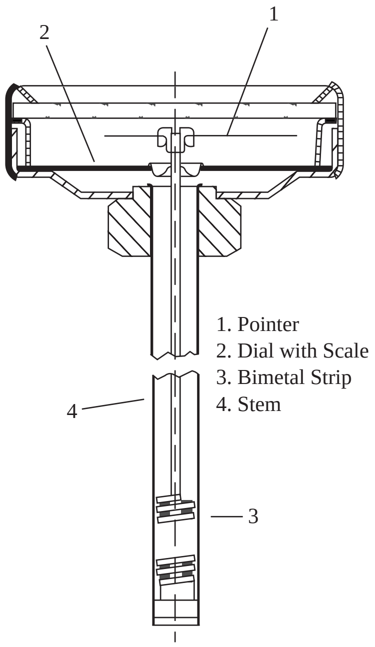

FIG. 4.2e
Bimetal thermometer with dual helical bimetal coil. (Courtesy of WIKA Instrument Corporation.)

Dial Orientation and Size

The thermometer is usually either back- or bottom-connected, depending on which orientation allows the operator better visibility of the dial face. Bimetal thermometers are also made in types that can adjust the dial face at any angle, with respect to the axis of the stem. This can even be a swivel type as shown on Figure 4.2f. Any of these constructions requires a bend in the motion transmission from coil to pointer. This is done with an edge-wound helical spring, which eliminates backlash and requires little torque to operate. Another type available is the Pocket Thermometer.

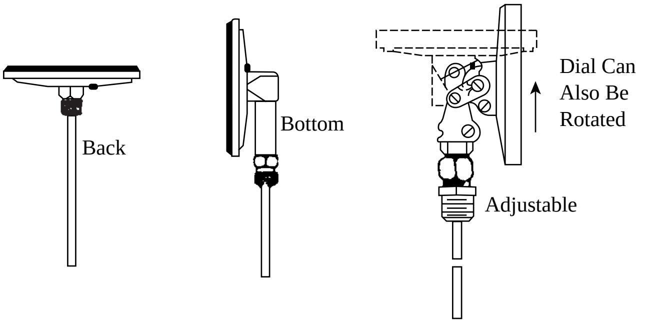

FIG. 4.2f
The bimetallic thermometers can be back- or bottom-connected, or they can be fully adjustable. (Courtesy of Taylor Thermometer Corp. of America.)

Another feature usually included is complete sealing. A dry gas is in the dial face portion of the assembly while silicone fluid fills the stem and surrounds the coil to dampen vibration and accelerate heat transfer.

Readout dials are available varying from 1 to 6.5 in. (25 to 165 mm) in diameter and with stem lengths up to 36 in. (914 mm). Wells made of carbon steel, stainless steel, or other materials are available to facilitate removal or to protect against corrosive environments.

Bimetallic elements can be made sufficiently sturdy to actuate a recording pen. A chart, driven by mechanical clockwork behind the pen, can form a complete measuring and recording system that is independent of outside electric power.

Advantages and Disadvantages

The advantages over glass stem thermometers include that the bimetallic design is less likely to break and is easier to read. Relative to the filled or electronic temperature indicators, the main advantages of bimetallic thermometers are their lower cost and simplicity.

Disadvantages include that the calibration of bimetallic thermometers can change due to rough handling and that the overall accuracy is not as good as that of the glass stem design. The bimetallic thermometers are generally confined to local measurement.

4.3 Calibrators and Simulators

H. L. DANEMAN (1995) **S. EDVI, J. E. JAMISON** (2003)

Types of Designs: A. Calibrators that use simulators (devices that simulate the output signal of thermometers). B. Calibrators that use calibration baths, which provide accurate temperature environments for calibration purposes (systems use hot air, oil, sand, or aluminum blocks for heat storage; some are fluidized beds).

Costs: Simple resistance temperature detector or thermocouple simulator costs start at about \$200. A handheld thermocouple simulator with 10 memory locations and 0.1% inaccuracy is about \$700; a resistance temperature detector simulator with 6 decades and 0.005% inaccuracy is about \$2500; a 4- to 20-mA DC transmitter calibrator with simulation of 11 resistance temperature detectors and 8 thermocouples is about \$6000. Calibration bath costs vary with bath volume, heat storage media, and calibration accuracy. A microprocessor-controlled, programmable bath with IEEE 488 and RS232C interface and 0.002°C stability is about \$12,500; other baths range from \$3000 to \$25,000.

Temperature calibrators range from simple hand-held instruments to large permanently installed baths, chambers, and water-proof test cases. Calibrators reproduce temperatures with an accuracy and stability adequate for the range of devices to be checked. The thermometers are normally calibrated at one specific temperature at a time, although a series of baths can be assembled for sequential immersion to enable a range of temperature points to be checked. Correspondingly, the temperature can be reset in stages or as a ramp function for multipoint checking.

Simulators duplicate the outputs of temperature sensors, enabling measuring instruments to see a simulated but precise temperature value. This output may be a millivoltage to simulate thermocouples (TCs), a resistance to simulate resistance temperature detectors (RTDs), or a light or radiant energy level to calibrate instruments based on optical or infrared (IR) energy. Simulators can usually be connected locally (at the sensor) and then at the readout instrument so as to check the operation of transmitters, multiplexers, and cabling.

A fixed resistor connected to a multipoint monitor is an example of a simulator that continuously checks the calibration of indicators, recorders, and alarms. Some calibrators incorporate both temperature environment and sensor output functions.

TEMPERATURE CALIBRATION BATHS

A bath or chamber creates a temperature environment suitable for the immersion of temperature sensors such as TCs, RTDs, or bulbs. There are two bath types: fixed and adjustable. The earliest fixed-temperature calibrator used was the ice bath. This was supplemented by other so-called fixed calibration points, such as the steam and sulfur points, and later by a full range of freezing, boiling, and triple points (see Table 4.1e). These are based on the principle that materials change state (freeze and boil) at certain fixed temperatures (Table 4.3a). Many of these points have become reference values for defining the temperature scale and are therefore especially appropriate for calibration.

Useful examples of such fixed points are the triple point of water (0.0100°C) and the freezing point of zinc (419.53°C). The triple point of water is obtained in a sealed container in which the solid, liquid, and vapor states of water are in equilibrium (Figure 4.3b). In contrast to the triple point, the ice point can be more easily obtained and used to an accuracy suitable for industrial calibration. RTDs in particular are defined in terms of their R_0 value, or resistance value at the ice point (e.g., 100 Ω Pt.). Immersion in an ice point bath is a useful way of compensating for calibrating drift even though the thermometer is normally used at higher temperatures.

Adjustable temperature baths contain a fluid (liquid or fluidized solid) circulated through a chamber in which the thermometers can be immersed. Controllers maintain a temperature at the desired set point. A block establishes temperature uniformity among sensors at temperatures below 1472°F (800°C), or where conduction is the primary means of heat transfer.

TABLE 4.3a
Defining Fixed Points of the International Practical Temperature Scale (ITS-90)

Point Number	*Temperature* T_{90}/°K	t_{90}/°C	*Substance*	*State*
1	3 to 5	−270.15 to −268.15	He	VP
2	13.8	−259.35	eq. H_2	TP
3	≈17	≈−256.15	eq. H_2 (or He)	VP (or GT)
4	≈20.3	≈−252.85	eq. H_2 (or He)	VP (or GT)
5	24.6	−248.6	Ne	TP
6	54.36	−218.8	O_2	TP
7	83.8	−189.34	Ar	TP
8	234.32	−38.83	Hg	TP
9	273.16	0.01	H_2O	TP
10	302.92	29.77	Ga	MP
11	429.75	156.60	In	FP
12	505.08	231.93	Sn	FP
13	692.68	419.53	Zn	FP
14	933.47	660.32	Al	FP
15	1234.93	961.78	Ag	FP
16	1337.33	1064.18	Au	FP
17	1357.77	1084.62	Cu	FP

FP = freezing point
MP = melting point
GT = gas thermometer point
TP = triple point
VP = vapor pressure point
eq. H_2 = hydrogen at the equilibrium concentration of the ortho- and para-molecular forms

SIMULATORS

Simulators for TCs and RTDs consist of voltage sources and/or resistors having values that correspond to the required temperature readings. TC simulators require provision for reference junction compensation and alloy terminals.

Simulators for optical or total radiation pyrometer calibration may be as simple as a 25-watt lamp or as sophisticated as a controlled output arc furnace. It is usual to use these simulators with comparison standards. By comparing one optical pyrometer with a standard or with a laboratory-calibrated optical pyrometer, one can avoid errors that may arise due to their large ambient temperature coefficients. Such calibrations can, for example, be performed in an outdoor shed or pyrometer shop adjacent to a steel mill.

A typical handheld calibrator is illustrated in Figure 4.3c. A laboratory-type thermocouple calibrator/simulator is shown in Figure 4.3d. This unit combines both the simulation and calibration functions in one unit.

A simulator for optical pyrometry is shown in Figure 4.3e. The unit incorporates a copper fixed point to provide a reference temperature 1985°F (1085°C) independent of a standards laboratory. A very high temperature 3002°F (1650°C) TC and optical/radiation pyrometer calibration system incorporating a palladium freezing point, molybdenum block, and standard lamp was built for a steel mill in Brazil where traceability to a national laboratory was unavailable.

Field and laboratory temperature calibrations are best performed with calibrators and simulators that are adapted for the particular application.

CONCLUSIONS

Table 4.3f provides some recommendations for the type of calibration equipment that is best suited for particular temperature sensors and industrial or laboratory environments.

4.4 Cones, Crayons, Labels, Paints, and Pellets

T. J. CLAGGETT, R. W. WORRALL (1969, 1982) **B. G. LIPTÁK** (1995)
S. EDVI, J. E. JAMISON (2003)

Temperature Settings:	Cones are numbered as in Table 4.4b with each number corresponding to an approximate setting. Crayons and paints are usually rated with a combination of temperature and time, meaning that a color change is expected to occur if a particular temperature is held for a particular time period.
Phase Change Types:	Reversible and nonreversible temperature-indicating labels, strips, and buttons Multi-temperature and Mylar liquid crystal strips and sheets Crayons Pellets Paints or lacquers
Temperature Ranges:	Cones cover a range between 1100 and 3650°F (593 and 2010°C) Reversible liquid crystal strips: range between −20 and 194°F (−30 and 90°C) Nonreversible labels with 4 temperatures on each label: range between 100 and 500°F (38 and 260°C) Reversible liquid crystal Mylar sheets: range between 68 and 113°F (20 and 45°C) Crayons, pellets, and paints: range between 100 and 2500°F (39 and 1371°C)
Costs:	$3 to $6 for a box of 50 cones, $0.50 to $1.50 per plug Reversible liquid crystal strips (seven temperature ranges): package of 10 is $12; package of 30 is $33 Nonreversible labels, monitors, and buttons: package of 10 is $13 to $55; package of 30 is $37 to $55 Reversible liquid crystal Mylar sheets: 12 in. × 12 in. sheets = $22, 6 sheets of 6 in. × 12 in. sheets is $76; 6 sheets, one of each temperature range is $52 Crayons: $9 each to $55 for a 10-crayon set Pellets: $11 per tube of 20 pellets Paints/lacquers: 2 oz bottle is $11, 1 pt is $60; thinners: 2 oz bottle is $4, 1 pt is $13
Applications:	Labels: machinery, equipment, electrical parts, electronic assemblies, aeronautical, heating, ventilation, and air conditioning (HVAC), and appliances Crayons: welding, forging, heat-treating, and accessible work pieces Pellets: furnace temperature Paints: smooth glass, polished metals, rubber, and fabrics
Inaccuracy:	Indication is affected by speed of heat-up and by time spent at target temperature; usual error is about 5°F (3°C) for cones and about 10 to 20°F (5 to 10°C) for crayons, pellets, and paints. The error of most crayons, pellets, and paints is 1% of their rating. Liquid crystal strips can detect skin temperatures within 1°F (0.5°C).

INTRODUCTION

A number of temperature-related physical changes have been used to produce simple thermometers. Crayons, pellets, and paint marks on heated work-pieces, cones, or pellets placed in furnaces change from solid to liquid when their melting point is reached. Paints and heat-sensitive labels change their color, while luminescent materials change their brightness. Liquid cholesteric crystals detect skin temperature, and liquid crystal strips are ideal for motors, transformers, relays, and electronic parts.

For centuries, manually operated furnaces have been temperature-controlled by the operators placing a heat-sensitive object inside the furnace and observing the status of that indicator through a peephole. The most easily observed physical changes were found to be changes in color or melting. Pyrometric cones have been used as temperature indicators and are still used as endpoint indicators in such batch processes as firing in pottery furnaces. They can be small, expendable, plugs, chips, or geometrically shaped objects whose purpose is to accompany the products through a heating cycle. The physical or metallurgical changes that occur indicate the temperature reached in the process.

COLOR INDICATORS

Color indicators are a class of sensors that have the property of changing their original color when a certain temperature is reached. The change is distinct, not just an alteration in shade. For instance, an indicator may change from yellow to gray or from light blue to light brown. Some can go through several color changes at different temperatures.

Paints and Pellets

Paints and pellets are familiar forms of these indicators that are applied directly to a solid object either when it is cold and about to be heated, or when it is already hot. Some indicators can determine the temperature of solid objects immersed in oil. They are not recommended for use in hot gases.

Temperature is indicated by a chemical reaction, where a molecule of a gas such as ammonia, carbon dioxide, or water vapor is driven off the basic stock (colorful salts of metals like nickel, cobalt, or chromium), changing its color. The change is usually permanent after the object cools down. An exception occurs when the gas is water vapor; the indicator may slowly reabsorb this gas from the air and revert to the original color.

Change in color of these types of indicators is not only a function of temperature but also of time. For this reason, the immediate past temperature history of the indicator will influence the exact point at which it will change color. The indicators are usually rated for a specific temperature over a certain time period, for instance, 140°F (60°C) in 30 min. This means that if held at a constant 140°F the color change will occur in 30 min. If the color change occurs in less than 30 min, the average temperature is higher than 140°F, and vice versa. On such an indicator, if the temperature does not exceed 130°F (54°C), the change will never occur because the indicator is stable below this temperature.

Crayons

Figure 4.4a shows typical time-temperature relationships for two different crayons. In the examples shown, the temperature at which color change occurs is quite critical when exposure time is short. For lower soakout temperatures, the changeover will occur in a longer time.

Flatter curves than those shown are possible where changeover will occur within a few seconds after operating temperature is reached, or it will not occur at all.

Many different temperature ratings are available. They can be obtained in a series for every few degrees to the maximum offered (about 2500°F, or 1371°C). This class of indicators is quite inexpensive and is used in industry where only an endpoint is needed and someone can be present to watch for or interpret the results. A disadvantage of these sensors is that the material adheres tightly to the object on which it is placed and presents a problem if it must be removed later.

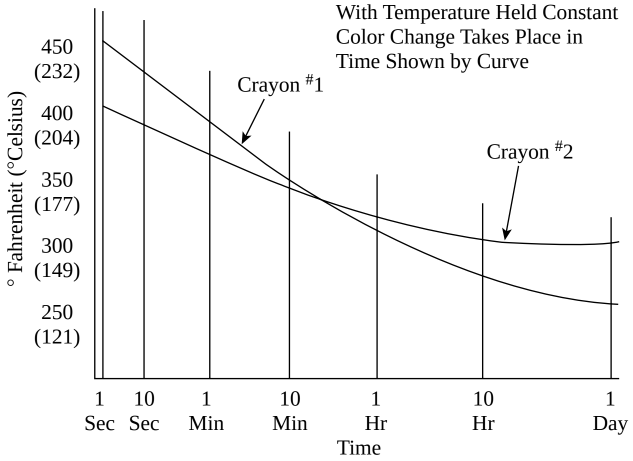

FIG. 4.4a
Time-temperature relationship for color indicators.

PYROMETRIC CONES

The German ceramist Herman Seger invented the first pyrometric cone in 1886.[1] The individual cones look like truncated pyramids. The numbering of the different cones available on the market and the temperatures at which they melt are given in Table 4.4b. The cone melting temperatures listed in the table are based on a heat-up rate of 170°C/h. If the heat-up rate is slower, the cones bend at slightly lower temperatures; if it is faster, it will take a little higher temperature to bend the cones as shown in Table 4.4c.

Because the pyrometric cone measures the effects of both temperature and the length of firing time, it acts as a heat integrator—a function that cannot be easily reproduced by thermocouples or other electronic-type pyrometers. For this reason, the ceramic industry continues to use cones, in addition to recording pyrometers, even in its most modern kilns.

The Ceramics Industry

The indicator material is generally quite similar to the substance of the work under test. Pyrometric cones are actually composed of ceramic materials very carefully blended to soften at a certain temperature. The slender cone is slightly tilted from the vertical; when its softening point is reached, the tip bends over and may actually touch the base. This action can be watched through the window of the firing furnace, or its condition can be studied after cooling. Observation of a fired cone will show the experienced operator if the furnace atmosphere was oxidizing, reducing, or carburizing. If the latter has taken place, the cone will have formed a shell less dense than the interior. Presumably the work will have taken on the same characteristic.

The cones are set in a plaque of fire-clay (called a cone pat) close together and tipped at about 8 degrees from the vertical toward the cone that is expected to bend first. The cone pat is located in front of the peephole where the operator (or a closed-circuit TV camera) can observe its status. Usually three cones are placed on a pat: (1) the controlling target cone is in the center, (2) a cone that melts at a lower temperature is in front of it, and (3) one that melts at a higher temperature is behind it. Figure 4.4d illustrates the visual appearance of a cone pat throughout a batch that was fired to a #4 cone target, corresponding to 2174°F (1190°C). The softening points can be selected very accurately, and accuracies of 2 to 5°F (1 to 3°C) can be obtained.

TABLE 4.4c
The Melting Temperatures of Various Cone Types and Cone Numbers That Can Be Expected at Different Heating Rates[4]

Bar and Hole Indicators

As an alternate to cones, the indicator may take the shape of a long cylindrical bar. The bars are supported at their ends with axes horizontal. On temperature rise they soften and sag at the middle under gravity. The deformation serves as a measure of temperature.

Another group of indicators operates by shrinkage rather than deformation. After removal from the furnace the diameter of a hole in the indicator, or perhaps the indicator's length, is measured and compared with the original dimension.

Like color indicators, pyrometric ceramics should not be considered exact temperature measuring devices. The fusion, bending, and/or shrinking that they undergo is a *time-temperature* relationship and, as such, it is only useful to determine the end point of the specific job. This property is frequently more important than an exact measurement of the instantaneous temperature. The use of this type of indicator may almost be considered an art.

While pyrometer cones are not well suited automatic process control, they are inexpensive and valuable quality

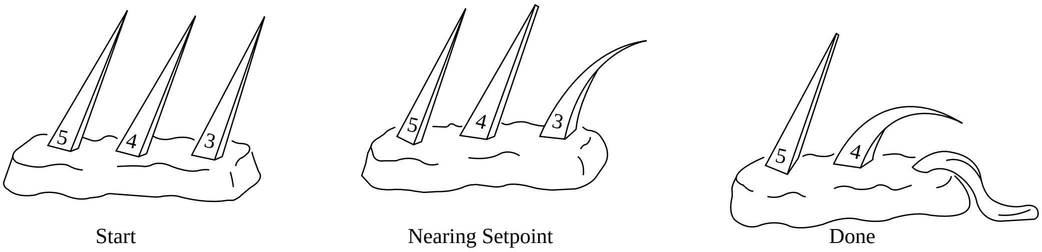

FIG. 4.4d
This is the appearance of the cones at different times during a batch which has a target temperature set by Cone #4.[2,3]

control tools in guaranteeing repeatable qualities of ceramic and similar batch products from kilns and furnaces.

ENGINE TEST RESEARCH

An entirely different material, used in a similar manner, is the metal test plug. This small device can tell temperature by a change in hardness that results from the heat treatment it has received. One use is to have it located carefully in an operating engine, in an otherwise inaccessible spot, where it will respond to the temperatures that occur during operation. When the test is over the plug is removed and carefully analyzed to determine the change in hardness along the horizontal axis.

Time is again a factor, but metal responds much faster than ceramic material. Exposures of less than 1 s duration can be detected. Advantages of this class of temperature sensors are their relative economy and being able to be designed for very specific purposes. Their shortcomings are self evident.

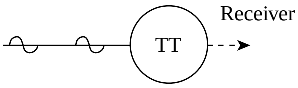
4.5 Fiber-Optic Thermometers



Flow Sheet Symbol

H. L. DANEMAN (1995) **B. G. LIPTÁK** (2003)

Types of Sensors:	Light-pipe, blackbody, dual-wavelength, crystal, gap, and fluoroptic
System Components:	Fiber-optic assembly, infrared detector, and electronic console
Applications:	Temperature measurement of hard-to-reach objects. Used in calendering, crystal growing, engine heads (spark plugs), glass fore-hearths, induction heating, kiln hot spots, medical hyperthermia, microwave packaging, polymer melting, printer operations, reactive-ion etching, transformer windings, vacuum processing, web drying, and welding.
Wavelengths Used:	0.7 to 8 μm for inexpensive total radiation detectors, 2.2 to 3.8 μm for penetrating intervening atmosphere, 2.2 μm for metals, 4.5 μm for flames, under 8 μm for glass
Field of View:	The ratio of target distance to target size can range from 3:1 to 900:1.
Fiber Size and Lengths:	Single fiber is 0.5 mm in diameter, 4-fiber array is 0.9 mm in diameter. The number of fibers per cable ranges from 30 to 400; their lengths range from 10 to 300 ft (3 to 100 m).
Temperature Ranges:	Can detect from 212°F (100°C), but the typical range is from 500 to 5500°F (260 to 3600°C); some units go up to 6500°F (3600°C). Allowable ambient temperature range is from –76 to 535°F (–60 to 315°C). –50°F to 6500°F (–46 to 3600°C) for Spot instruments; 100 to 3500°F (37 to 2000°C) for Line Scanners; 0 to 3500°F (0 to 2000°C) for Thermal Imagers.
Transmission Range:	0.7 to 8 μm
Spectral Response:	2.0 to 2.4 μm
Response Time:	0.3 s or better
Total Acceptance Angle:	22 to 60°
Stability:	Drift is under 0.5°F (0.3°C) over period of 10 days.
Inaccuracy:	From as low as 0.2°F (0.1°C) to 1% full scale.
Costs:	Transmitters are in the $2500 to $4500 range. A 0.1°F resolution microprocessor-based unit with PID algorithm included is about $6000; the same unit with 2, 4, 6, or 8 channels is about $15,000, thermal imaging systems up to $60,000.

Infrared (IR) and radiation pyrometers are discussed in Section 4.9. This section will concentrate on combining those principles with the use of optical fibers, which provide the ability to look at the temperature of small objects or to look around opaque objects.

Noncontact thermometry has many advantages, particularly in regard to measuring temperatures of objects that are extremely hot or corrosive, are moving or fragile, are in strong electromagnetic (radio frequency [RF], microwave, or direct current magnetic) fields, or are subject to measurement error due to heat loss by conduction. Until the glass-fiber optic cable became available, noncontact thermometry required line-of-sight vision between the sensor and the target object. The elimination of this restriction makes it possible for the fiber-optic thermometer to solve many difficult measuring problems.

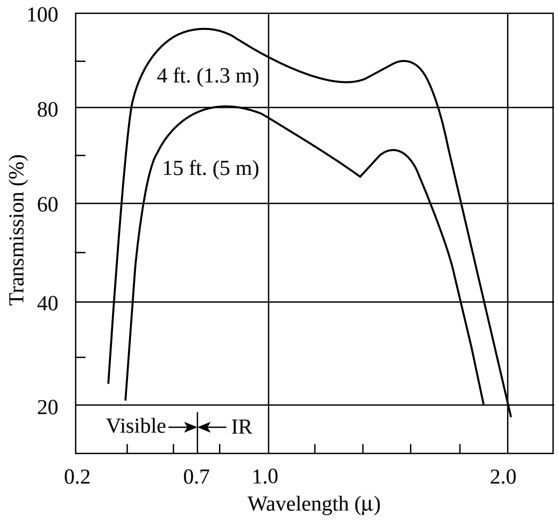

FIG. 4.5a
The infrared transmission of glass fibers designed for high-temperature applications varies according to cable length. The sensors used for this purpose are filtered in the 0.8 µm region.[1]

Optical fiber thermometry (OFT) depends on total internal reflection within a thin fiber element. Absorption of IR energy by glass fibers has limited the low end of the range to 660°F (350°C) (see Figure 4.5a). Developments in telecommunications and glass research now promise to facilitate lower temperature measurements using alternative spectral bands (see Table 4.5b).

Some laboratory-standard fiber-optic instruments offer even greater accuracy than a type S thermocouple—±0.01% at 1832°F (1000°C) with a resolution of 0.01°C.

THERMOMETER DESIGN

Fiber-optic measurement systems consist of three elements: the fiber-optic assembly, an IR detector, and an electric console. A single fiber or bundle of several fibers gather IR radiation from the target, transmit to the detector, and convert the radiation to a voltage suitable to the required function.

Fibers are sensitive only to the IR portion of the spectrum and filter out other forms of radiation; they are not activated by flames and fumes. Even though IR radiation becomes detectable at about 140°F (60°C), it is best to use it at temperatures over 212°F (100°C) in any monitoring application.

Fibers, whether single or in bundles, are always enclosed in metal or ceramic sheaths for protection. A unique characteristic of the special glass fibers is the ability to bend light and to transmit it for distances up to 30 ft (9.1 m) without distortion or loss of definition.

Perhaps the one outstanding feature of fiber-optic systems is the ability of the fibers to withstand and function in hostile environments, including intense heat. Fibers maintain resolution exceeding one degree change at temperatures over 2000°F (1100°C). At extreme high temperatures and under

other severe conditions, the fibers are protected with air or inert gas purging or by water cooling.

The advantages of using fiber optics in noncontact temperature measurement application include their inertness, relatively rugged design, small size, and ability to look around opaque objects (Figure 4.5c). With the addition of a telescopic lens system, the same fiber-optic assembly can be made to monitor different target areas at various focal distances.

Radiation proportional to temperature is conducted along an optical fiber to a sensor connected to a measuring instrument. Variations on this basic principle make it possible to adapt this design to a variety of applications.

As with any optical instrument, a fiber-optic thermometer depends on observations of brightness or on total radiation. The measurement technique most often used is characterized by the distribution of energy by wavelength and field of view.

A number of factors affect the choice of wavelength. For example, general-purpose instruments use a wide energy band (8 to 20 μm). Inexpensive instruments cover 0.7 to 8 μm in order to include most of the total energy radiated by the hot object. For penetration of intervening atmosphere, shorter wavelengths of 2.2 to 3.8 μm are preferred. For metals (which have a high reflectance), the narrow band around 2.2 μm reduces the effect of emissivity variations. (For definitions of terms such as *emissivity*, see Section 4.9.)

Glass is more transparent at the shorter wavelengths (e.g., 0.8 μm). Reflection becomes critical above 8 μm, so the shorter wavelengths are used for molten glass temperature measurement. Flames (preferably clean) can best be measured at a wavelength of 4.5 μm.

Field of view is the other significant parameter characterizing optical measuring instruments. This is described in terms of ratio of the target distance to the target size, and ranges from 900:1 to 3:1. A single wavelength instrument measures the average temperature of the body filling its field of view. A dual-wavelength instrument measures the hottest part of the target within its field of view.

THE OPTICAL FIBER THERMOMETER (OFT) SENSORS

The available variations in fiber-optic probe sensor designs are shown in Figure 4.5d. The fiber-optic sensors fall into four categories: light-pipe, blackbody, dual-wavelength, and gap types.

The light-pipe design transmits the radiation from the target to the detector through an open tip, as shown in Figure 4.5e. The blackbody-type unit radiates heat from a cup of material, such as a thin coat of precious metal, surrounding the tip.

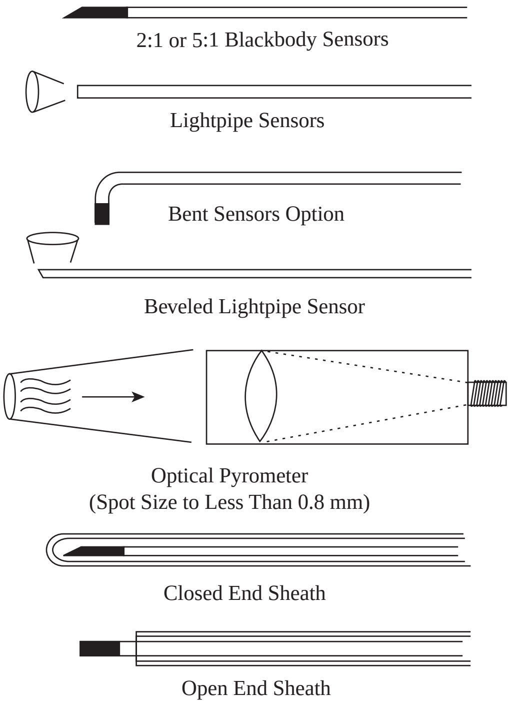

FIG. 4.5d
The sensor portion of the OFT probe can be configured in many ways.

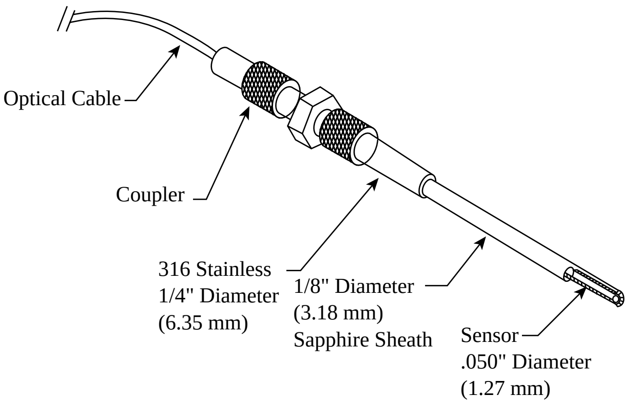

FIG. 4.5e
Open-ended sheath design of the light-pipe sensor. (Courtesy of Accufiber Div. of Luxtron Corp.)

A sapphire optical rod is coated at the tip with a thin film of iridium or platinum and aluminum oxide. At elevated temperatures, the tip emits a band of wavelengths that are transmitted to a detector for measurement (Patent No. 4,576,486). A schematic of the complete system is shown in Figure 4.5f.

In the dual-wavelength optical pyrometer sensor, the radiation is focused through a lens onto the optical fiber link from a distance of up to 16 ft (see Figure 4.5g).

In another design, light of a fixed wavelength spectrum is transmitted from the instrument through the optical fiber to the sensor. Here the light is converted and returned as a different wavelength spectrum, the value of which *depends on the temperature* of the sensor. The *wavelength* of the *returned* light is scanned and presented as a temperature reading on the instrument display or output to one of the optional interfaces.

The Fabry-Perot thermometer uses a temperature-sensitive spacer that varies a gap width, establishing a series of spectral bands by means of optical interference (Figure 4.5h). Because it is entirely optical from the measurement end of the fiber to the detector, it can be made very small. The measuring range is 35 to 55°C with a resolution of 0.1°C. The detector can be a pyroelectric detector amplified by an FET preamplifier.

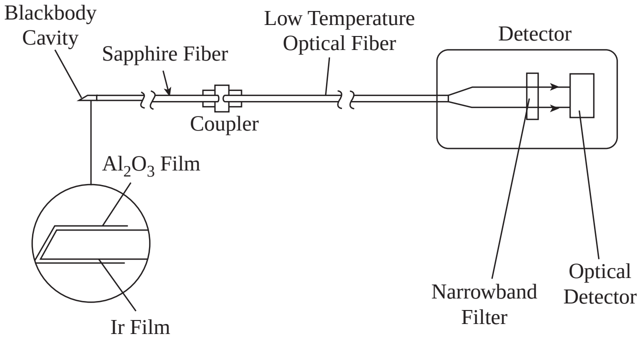

FIG. 4.5f
Blackbody-type OFT sensor system. (Courtesy of Accufiber Div. of Luxtron Corp.)

The fluoroptic sensor measures the decay time of a fluorescent material (magnesium fluorogermanate), which, after being energized by a short-wavelength light pulse, varies proportionally with temperature. The phosphors can be compressed into intimate contact with a surface to measure with little conduction loss (Figure 4.5i).

In Figure 4.5j, the fluorescent signal decay characteristics of the fluoroptic sensor are shown on the top, and the basic calibration curve of the phosphor sensor is shown on the bottom.

CONCLUSIONS

The advantages of OFT pyrometry include: the small size of the sensor, which does not require line-of-sight observation of the object and can be furnished with blackbody fibers. OFTs are not affected by RF, microwave, or electromagnetic fields or by shock and vibration; their range is wide and response fast, and they can average or provide temperature profiles through noninvasive remote measurements of temperatures of solid objects or immersed in liquids.

The main disadvantage of OFT pyrometry is the high unit cost of this measurement. The unit cost can be reduced through multiplexing, so that several OFT sensors are connected (through a multiplexer) to a common set of electronics.

Fiber-optic thermometers offer many options resulting in application to a wide range of industrial temperature measurements. A principal advantage is electrical and, sometimes, even physical isolation from the target. The glass or quartz fibers that transmit the temperature signal to a detector can be an integral part of the measurement, reducing lag and conduction error. This is true in the case of the blackbody

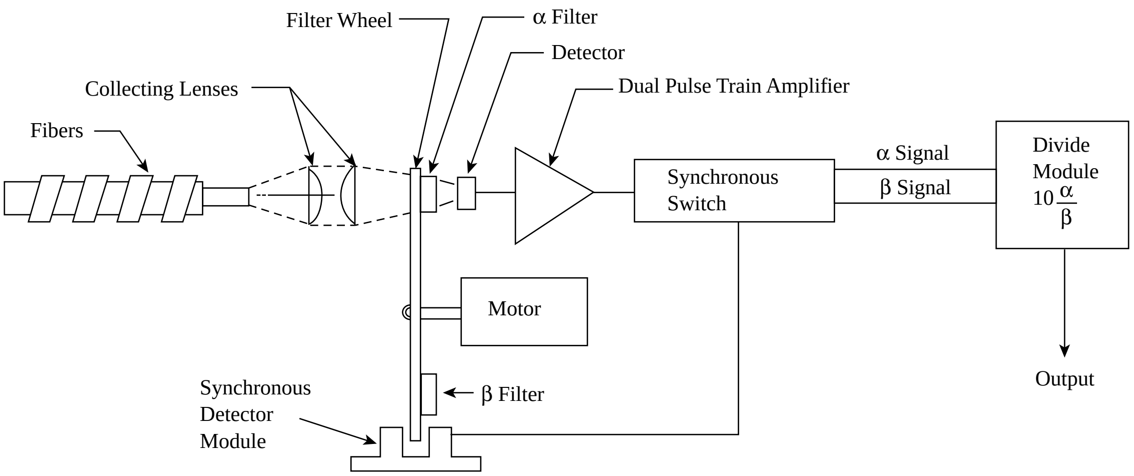

FIG. 4.5g
This dual-wavelength design measures radiant flux at two separate wave bands and calculates the signal ratio to determine target temperature. The technique can measure low and varying emissivity targets and small moving objects that do not fill the field of view.[1]

sensor, which incorporates a blackbody cavity on the surface of the fiber tip, and the surface temperature sensor's adhering to a phosphor emitter pressed onto its tip.

When selecting a fiber-optic thermometer for a given application, it is necessary to review all types of fiber-optic instruments for wavelength and field of view in order to optimize performance.

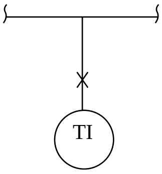
4.6 Filled-Bulb and Glass-Stem Thermometers



Flow Sheet Symbol

T. J. CLAGGETT, R. W. WORRALL (1969, 1982) **B. G. LIPTÁK** (1995)
J. E. JAMISON (2003)

Applications:	Glass-stem units are used only as thermometers; filled-bulb elements are also used as switches, transmitters, and controllers.
Designs:	Glass-stem units are straight, back-angle, and multiangle thermometers; filled systems are frequently surface- or flush-mounted and connected to the process by capillary.
Materials of Construction:	Industrial glass-stem thermometers have aluminum, Cycolac, or other plastic cases; spring-loaded glass or plastic windows; and stainless steel stems. For the filled systems, the cases can be aluminum, brass, phenol, polypropylene, nickel-plated steel, or stainless steel; the thermometer movement is usually either bronze or stainless steel, and the bulb and the capillary can be copper, carbon steel, Monel, Hastelloy, or stainless steel. Thermowells can be brass; bronze; carbon steel, which can be Nickel plated; 304/316 stainless steel; Monel; or Hastelloy B/C.
Scales and Dials:	Glass-stem thermometer scales are usually straight, with 5, 7, 9, and 12 in. (125, 175, 225, and 305 mm) lengths. Filled thermometer scales are usually circular and have 3.5, 4.5, 6, 8.5, or 12 in. (88, 113, 150, 213, or 300 mm) diameters.
Bulb Sizes:	Mercury-, vapor-, and gas-filled bulbs are usually 11/16 × 4 in. diameter (17 × 100 mm), with some available as 3/8 × 3 in. diameter (9 × 76 mm). Liquid-filled bulbs are usually 3/8 × 5 in. (9 × 125 mm).
Capillary Lengths:	Standard lengths from 5 to 80 ft (1.5 to 24 m) with maximum limit of 200 ft (61 m) with gas, vapor, and fully compensated liquid or mercury-filled systems. Case-compensated liquid and mercury systems are limited to 15 ft (4.5 m) and 50 ft (15 m), respectively.
Temperature Ranges:	About a dozen glass-stem thermometer ranges are available between –40 to 110°F (–40 to 40°C) and 50 to 750°F (10 to 400°C). These ranges are similar to those of mercury-filled systems. Gas-filled systems are normally available between –100 and 100°F, and 400 and 1200°F (–100 and 100°C, and 200 and 650°C). Vapor-filled systems have narrower ranges, from –20 to 120°F and 250 to 450°F (–30 to 50°C and 50 to 150°C). Special spirit-filled glass stem models can attain –326°F (–199°C). Some mercury-filled special glass stems can reach 1200°F (649°C).
Inaccuracy:	Glass stem: either 1% of full scale, or one scale division, which as a minimum is 1°F (0.5°C). Filled systems: inaccuracies are also limited to one scale division.
Costs:	A multiangle glass-stem thermometer with stainless steel wetted parts, a 6 in. (150 mm) thermowell, and a 9 in. (255 mm) scale is $250. A 4.5 in. (113 mm) diameter direct-mounted filled thermometer with a 6 in. (150 mm) stainless steel thermowell is about $175, while a 12 in. (300 mm) diameter, flush-mounted unit with 125 ft (38 m) of armored stainless steel capillary is about $1000.

In a glass-stem thermometer the volumetric change resulting from thermal expansion is interpreted into temperature. In a filled system, the pressure inside a closed thermal system is used to measure temperature. The detected pressure is a function of not only the process temperature at the bulb, but also of other factors that can introduce errors. These include: (1) ambient temperature variation, (2) barometric pressure variation, and (3) the hydrostatic head of the liquid in the capillary, if it is at a different elevation from the readout. In order to obtain accurate temperature readings, these error sources must be minimized, as will be explained in this section.

GLASS-STEM THERMOMETERS

The glass-stem thermometer was the first closed thermal expansion system and has been known since Gabriel Daniel Fahrenheit investigated the expansion of mercury in the 18th century.

Mercury or some other liquid (alcohol, pentane) fills the glass bulb (see Figure 4.6a) and extends into the capillary bore of the stem. The space above the mercury column to the scaled top is evacuated, but occasionally it may be filled with an inert dry gas, such as nitrogen, to increase the temperature range.

The expansion of pure mercury is 0.01%/°F (0.005%/°C) and very linear; therefore, the volume of the bulb must be about 10,000 times the volume of the capillary between two marks 1°F (0.56°C) apart.

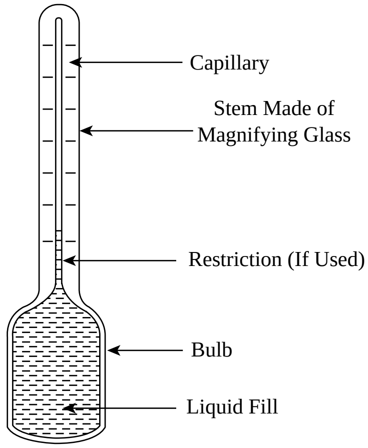

FIG. 4.6a
Liquid-in-glass thermometer.

Although bulb and capillary could be made from the same type of glass, it is more convenient to make the bulb from glass with a good stability factor and the capillary from glass which is easier to work. For accurate measurements, the capillary must be properly annealed after it is drawn to the correct bore. Uniformity of bore is desirable but not absolutely necessary if the thermometer is calibrated at a sufficient number of points.

The glass-stem thermometer can be made for a very narrow range in temperature. For instance, consider a clinical thermometer whose full range may be 96 to 102°F (35.6 to 38.9°C) and with a stem 4 in. (101.6 mm) long, active length. If the bulb volume is 0.03 in^3 (0.5 cm^3), the diameter of the bore is about 0.001 in. (0.025 mm). The stem is frequently designed to magnify such a small column for easier readability.

Another design feature of some glass-stem thermometers, notably the clinical type, is a restriction purposely placed in the capillary that prevents the liquid from returning toward the bulb when the thermometer is removed from the warmer object. This creates a separation of the column in the stem. In this case, it is a desirable feature because it permits a highest point reading or peak picker. If the separation occurs inadvertently in any glass-stem thermometer, the result is an erroneous reading. The column can usually be rejoined by shaking or tapping.

The design of a glass-stem thermometer requires that the filling material be a liquid over the entire range of temperature desired. Mercury is most suitable and can be used from its freezing point (–38°F, or –39°C) up to nearly its boiling point (over 1000°F, or 538°C). At this upper limit the space above the mercury column must be under great pressure with an inert gas to prevent evaporation of mercury from the top of the column. Alcohol and a few other hydrocarbons may be used for low temperatures. Colorfast dyes are usually added to the liquid to increase visibility.

To minimize accident breakage, a metallic thermowell is sometimes used to protect the bulb. This has no effect on the accuracy but may reduce the speed of response. Figure 4.6b illustrates the industrial packaging of the mercury or liquid-in-glass thermometer. These straight scale units have been ruggedized for mechanical strength and are still used in heating, ventilation, and air conditioning (HVAC) applications. In most other industries their use has been discontinued, mostly because of the concern about the toxicity of mercury.

Advantages of liquid-in-glass thermometers are their low cost, simplicity, and long life if treated properly. Disadvantages are difficult reading, confinement to local measurement, and nonadaptability to recording or automatic control. They also break very easily.

FILLED THERMAL SYSTEMS

A filled thermal system is basically a pressure gauge connected by small bore tubing to the bulb acting as the temperature sensor. The whole system is gas-tight, and filled with an appropriate confined gas or liquid under pressure.

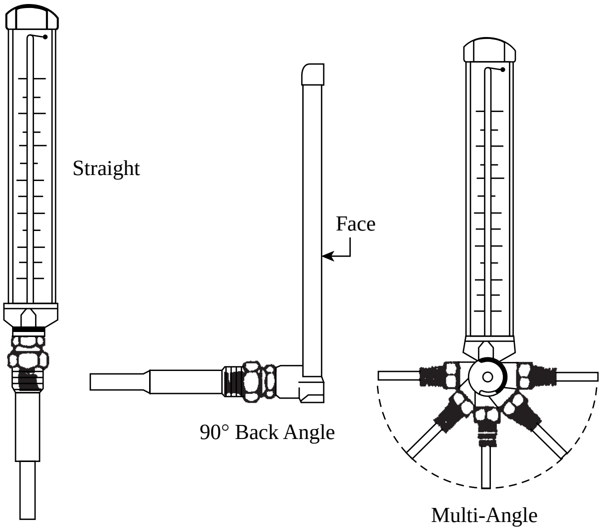

FIG. 4.6b
Industrial glass-stem thermometers. (Courtesy of ABB Automation [ex-Kent-Taylor].)

There are many different types of filled systems, each having certain peculiarities which give it advantages over others.

The Scientific Apparatus Makers Association has classified filled-system thermometers into four major classes according to filling material. Table 4.6c has been prepared to compare some of the properties of the various thermal systems.

The basic components of a filled-bulb capillary thermometer are illustrated in Figure 4.6d. As mentioned previously, the use of mercury filling has been discontinued in most industrial applications because of health concerns. The use of both mercury and liquid fillings have also lost ground because of the expense associated with compensating for the ambient effects on the capillary plus the errors caused by elevation differences between bulb and readout. Still extensively used are the gas and vapor fillings, but these too are limited in their usefulness. The gas-filled bulb is large, as is the temperature span required to operate it. The vapor-filled system is also limited due to its nonlinearity and its potential for problems caused by cross-ambient operation or by errors due to elevation.

BULBS, WELLS, AND CAPILLARIES

The temperature-sensitive element, the bulb, comes in many sizes and shapes to handle the many different applications. It is good practice to use the largest bulb that will do the job. This will cut down on ambient temperature errors, and permit smaller spans and longer capillaries.

Plain bulbs are used where the measured medium is not under pressure and will not harm the bulb material. If this is not the case, a separate well to protect the bulb from the

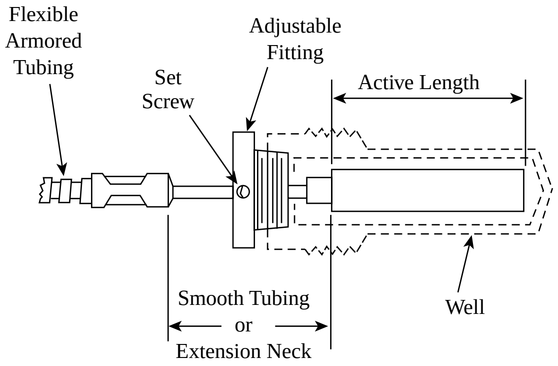

FIG. 4.6e
Plain bulb with adjustable fitting and well.

process medium is needed. This will slow down the response time even more than the 4 to 7 s speed of response range given in Table 4.6c.

The speed of response generally doubles with the doubling of bulb diameter and tends to be the fastest with vapor or gas and the slowest with liquid filling, with mercury and Class IID vapor filling in the middle. When thermowells are added to the bulb, the speed of response slows as follows:

- 12 to 24 s for 0.25 in. diameter (6 mm)
- 20 to 35 s for 0.38 in. diameter (9 mm)
- 25 to 50 s for 0.5 in. diameter (13 mm)
- 40 to 75 s for 0.75 in. (19 mm) diameter

Figure 4.6e illustrates a filled bulb installed in a thermowell.

Higher speed of response can be obtained with a long, thin, bendable bulb used to sense the average temperature in large areas. Another way of presenting a long bulb is by coiling it. For use in low-velocity gas flow temperature measurement, the coil is set at the factory and cannot be uncoiled (Figure 4.6f).

Most bulbs are made of stainless steel, which is relatively inert and will withstand high temperatures. Other materials are readily available.

The relatively fragile thin-wall capillary should be protected by a flexible armored stainless steel or PVC-covered bronze tubing. An extension neck to the bulb prevents the tubing from being immersed directly in the measured medium. Bendable smooth steel tubing might also be used for capillary protection.

Class I: Liquid-Filled Systems

These systems are completely filled with a liquid (other than mercury) and operate on the principle of liquid expansion with an increase of temperature (Figure 4.6g). The filling fluid is usually an inert hydrocarbon, such as xylene (C_8H_{10}),

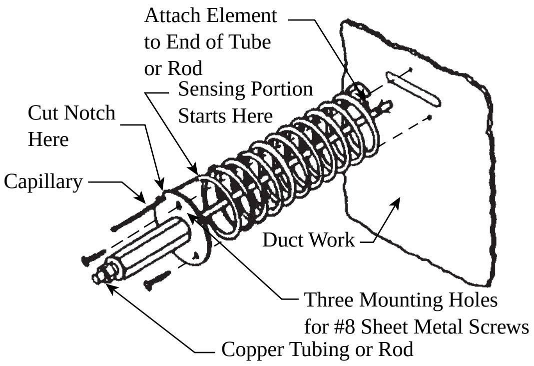

FIG. 4.6f
Averaging capillary for air duct installation. (Courtesy of Johnson Controls.)

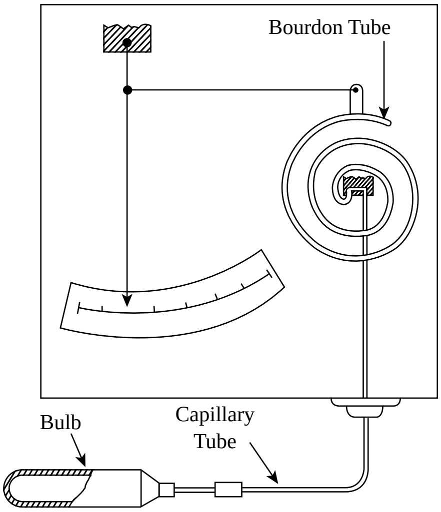

FIG. 4.6g
Liquid-filled capillary-type thermometer.

which has a coefficient of expansion six times that of mercury and makes smaller bulbs possible. Other liquids (even water) are sometimes used. The criterion is that the pressure inside the system must be greater than the vapor pressure of the liquid to prevent bubbles of vapor from forming in the spiral. Also, the liquid should not be allowed to solidify even in storage or the calibration may be affected.

The minimum operating temperature is usually set by the freezing point of the filling liquid, which is usually between –100 and –350°F (–75 and –210°C). The maximum operating temperature is set by the point at which the filling liquid is no longer stable, usually around 600°F (315°C). The minimum span range is a function of bulb size, while the maximum is a function of linearity. With larger bulbs the span can be narrowed to 22 to 45°F (12 to 25°C), while the maximum limit on the span is about 300°F (167°C) due to the nonlinearities caused by expansivity and compressibility of the filling liquids.

The maximum temperature to which the bulb can be exposed without damage is defined as the allowable overrange of the system. Overrange is usually expressed as a percentage of the span over the full range value; in the case of liquid filling, overrange is around 100%. Therefore, if the range of a liquid-filled thermometer is 100 to 300°F and its overrange protection is 100%, its bulb can be exposed to a maximum temperature of 500°F.

Class II: Vapor Systems

The pressure element, capillary, and bulb of a Class II system have the filling medium in both the liquid and vapor form. The interface between the two must occur in the bulb, and this will move slightly with temperature, affecting the pressure.

The pressure within the system is a function of the vapor pressure of the filling fluid at the operating (bulb) temperature. The filling fluid is usually so selected as to give a 100 PSIG (6.9 bars) change in its vapor pressure as the bulb temperature goes through the span of the thermometer. This much change is necessary to keep the error due to barometric pressure changes to less than 0.5% of full scale. The filling fluids used include methyl chloride, sulfur dioxide, butane, propane, hexane, methyl ether, ethyl chloride, ethyl ether, ethyl alcohol, and chlorobenzene. Each has a different vapor pressure–temperature relationship. For lower temperatures ethane filling can be used; it changes its vapor pressure from 20 to 600 PSIG (1.4 to 41 bars) as the temperature rises from –100 to 85°F (–73 to 29°C). For higher temperatures one might use ethyl chloride, which goes through the same vapor pressure change as its temperature rises from 100 to 350°F (38 to 177°C).

Overall, the minimum temperature at which vapor fillings can be used is around –40°F (–40°C), while the maximum is about 600°F (315°C). The maximum temperature is limited by the critical point of the fill, while the minimum limit is a consequence of the loss of reading sensitivity, as the vapor pressure changes less per unit temperature change at low temperatures. The nonlinear nature of the vapor-filled thermal systems is generally considered to be a disadvantage, although if a better reading sensitivity toward the top of the scale is required, it can be a desirable feature.

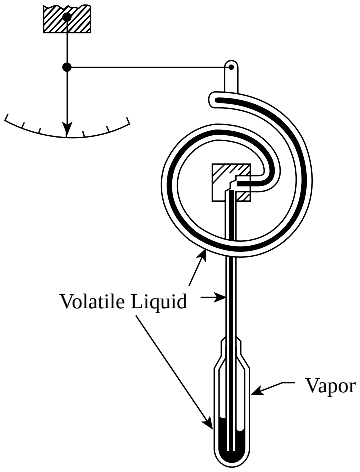

FIG. 4.6h
Class IIA vapor filling.[1]

The speed of response of vapor-filled systems is generally in the range of 1 to 10 s. It is faster than the liquid or mercury fills and as fast as the gas-filled system in most of its configurations, except to Class IID design, which is a little slower.

The overrange limit of the vapor-filled systems is small, because the vapor pressure tends to rise exponentially with temperature. Under some very unique sets of conditions it is possible to obtain higher overage by designing the thermal system so that all liquid will be exhausted at a temperature slightly over the maximum required reading.

Class IIA Systems In a thermal system, which is filled with a liquid that is in equilibrium with its own vapors, the liquid will always situate itself at the cold end of the system and the vapor at the hot end. As shown in Figure 4.6h, in the Class IIA thermal system, the bulb is mostly filled with vapors, while the capillary and the readout instrument are liquid-filled. This type of system can be used only if the temperature at the bulb is *always* above the ambient temperature around the readout instrument. As the process temperature rises, more liquid is vaporized, which increases the vapor pressure in the bulb and in the Bourdon tube of the readout instrument. In this system, the changes in ambient temperature around the capillary will change the volume of the filling fluid and will necessitate using the bulb as a thermal expansion chamber. Consequently, the longer the capillary tubing, the larger the required bulb volume becomes. This tends to limit the maximum capillary length to about 75 ft (23 m).

Class IIB Systems As shown in Figure 4.6i, in a Class IIB thermal system, all the filling liquid is in the bulb, while the rest of the system is vapor-filled. This type of configuration can be used only if the temperature at the bulb is always

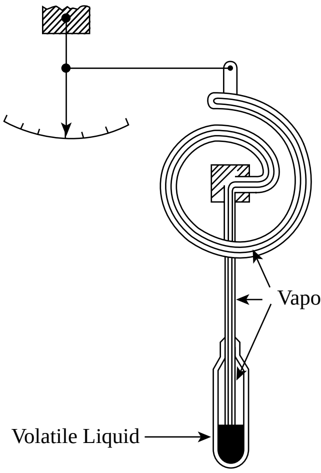

FIG. 4.6i
Class IIB-type vapor filling.[1]

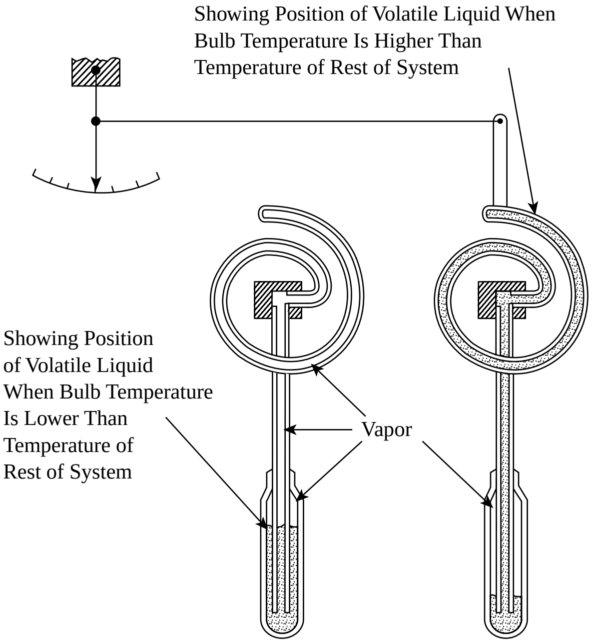

FIG. 4.6j
Class IIC system.

lower than the ambient temperature around the capillary or at the readout device. If this were not the case, the liquid would start boiling in the bulb and recondensing in the Bourdon tube. This transfer of liquid cannot be completed because there is not enough liquid to fill the Bourdon tube and the capillary; while the transfer is taking place, the temperature readings are meaningless. The Class IIB system requires the smallest of the vapor-filled bulbs as it does not have to act as a thermal expansion chamber.

Class IIC Systems Figure 4.6j illustrates the Class IIC thermal system, which is capable of operating as a Class IIA (right) or a Class IIB (left), because its bulb is large enough to accept all the liquid filling from the Bourdon tube and capillary. This obviously means that the bulb required for this design is larger than for either of the two previously described systems. This design can be used when the process temperature is either above or below the ambient, but *it cannot be used when it might cross the ambient temperature*. This is because it takes some time for the filling liquid to transfer itself to the cold end of the thermal system and to settle down after the liquid/vapor interface has been reversed.

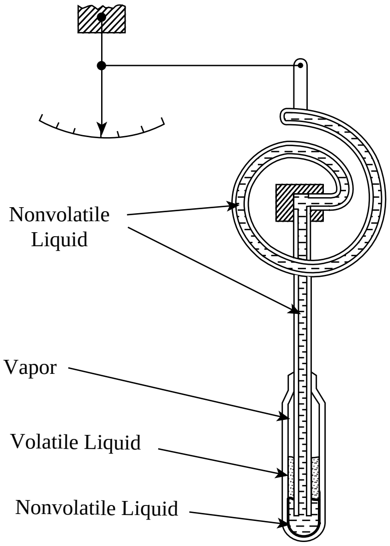

FIG. 4.6k
Class IID system.

Class IID Systems In the Class IID system there are two filling liquids: one is volatile and is always situated in the bulb, while the other is nonvolatile and fills the Bourdon tube, capillary, and part of the bulb (Figure 4.6k). The purpose of the nonvolatile liquid is only to transmit the vapor pressure at the volatile liquid/vapor interface, which is always confined within the bulb. In this design the process temperature can be anything, including the crossing of the ambient. This configuration requires an even larger bulb than that needed by the Class IIA design.

Class III: Gas-Filled Systems

The operating principle for gas-filled systems is that in a perfect gas confined to a constant volume the pressure is proportional to the absolute temperature. The gas is not perfect and not all at the same temperature nor is the volume constant. However, variances are small enough so that measurement of pressure can be used to indicate temperature.

Nitrogen is the favorite fill for a Class III system because it is inert and inexpensive. It does react somewhat with the steel bulb material at temperatures exceeding 800°F (427°C), and it does act less like a perfect gas at extremely low temperatures. Under these conditions helium should be used. Different ranges are obtained by selecting the correct filling pressure.

In general, bulbs should be as large as practical to lessen the influence of temperature variations along the capillary. One way of avoiding long capillaries is to terminate a short capillary at a small diaphragm chamber. The force due to gas pressure on the diaphragm causes it to compress the spring. This motion is amplified and used to regulate another pressure that is transmitted to the spiral. This arrangement, though more expensive, permits much smaller bulbs than could otherwise be used.

Gas-filled systems approximate Charles's law (absolute pressure of a confined gas is proportional to its absolute temperature) by keeping the bulb volume relatively large compared to the rest of the system. Class III systems are primarily used for low and high temperatures. On the low side they are limited by the critical temperatures of the filling gas (usually nitrogen or helium), corresponding to –450°F (–268°C), and on the high side by the temperature limits on the bulb materials, usually corresponding to –1400°F (760°C). The maximum span can be 1200°F (667°C), and is limited only by nonlinearities due to mass flow from the bulb. The minimum span is limited by the pressure at which the Bourdon tube becomes overstressed (usually designed for 400 PSIG, or 28 bars). Therefore, the minimum span with conventional systems is about 400°F (222°C), while with helically wound thin-tube bulbs it can reduced to 120°F (67°C) or even less.

The speed of response of gas-filled systems is usually good. The time constant is only 1 and 4 s because the ratio between bulb mass and surface area tends to be favorable. Class III filling usually can provide 150 to 300% overrange protection, as the maximum temperature is limited only by the permissible pressure and temperature ratings of the bulb. The gas-filled bulb is ideal for measuring the average temperature over large areas, such as in dryers or ovens. This is the case because the bulb volume is not critical and capillary-type bulbs (Figure 4.6f) can cover large areas.

Class V: Mercury-Filled Systems

Mercury is a liquid and in this respect Class V systems are similar to Class I. The two are separated because of the unique characteristics of mercury and its importance as a temperature-measuring medium. Mercury provides rapid response, accuracy, and plenty of power for operating control elements. Pressures within the working system are relatively high—as much as 1200 PSIG (83 bars) for the higher temperatures, dropping to 400 PSIG (28 bars) at the low-temperature end of the range. This high pressure cuts down on any head effect error (difference in elevation between bulb and measuring instrument).

Mercury-filled systems can detect temperatures between the freezing and the boiling points of mercury, or from –40 to 1200°F (–40 to 649°C). Mercury filling also provides the widest range of spans, from 50 to 1200°F (28 to 667°C). The speed of response of mercury-filled systems is faster than that of the liquid-filled ones but slower than that of gas or vapor systems. The Class V systems can have an overrange protection of at least 100%.

AMBIENT-TEMPERATURE COMPENSATION

The measured variable in a filled thermometer is the total internal pressure. This pressure is the result of two factors: the temperature around the bulb and the ambient temperature around the rest of the system. The purpose of the installation is to measure the process temperature around the bulb, and therefore it is desirable to eliminate the effects of ambient-temperature variations on the total reading. The error introduced by ambient-temperature variations is different for the different types of fills, and it also increases as the bulb or span gets smaller or as the capillary length is increased.

When the ambient temperature effects are compensated for in both the capillary and in the readout instrument, the design is called fully compensated. Full compensation is designated by the letter *A* being added to the Class designation number I, III, or V. When the case and the capillary are at the same ambient temperature and the length of the capillary is relatively short, it might be sufficient to leave the capillary portion uncompensated and provide case compensation only. When a Class I, Class III, or Class V system is case-compensated, the letter *B* is added to the designation.

Class II (vapor-filled) systems do not need any compensation because the liquid/vapor interface is always within the bulb. In the case of Class IIA fillings, it is important to keep all sections of the capillary at a temperature which is *below* that at the bulb. Otherwise, the fill fluid could vaporize in the capillary and introduce substantial errors.

Figure 4.6l describes a method of fully compensating Class I, Class III, or Class V systems. Here, the spiral pressure sensor and the capillary are both duplicated. The compensating capillary is closed, and its length is the same as the active capillary without the bulb. The two capillaries are run parallel to each other and the two Bourdon spirals are connected in such a way as to cancel the ambient effects.

In the case of mercury-filled Class V systems, full compensation can be provided without the expense of duplicating most of the thermal system. This cost-saving approach is

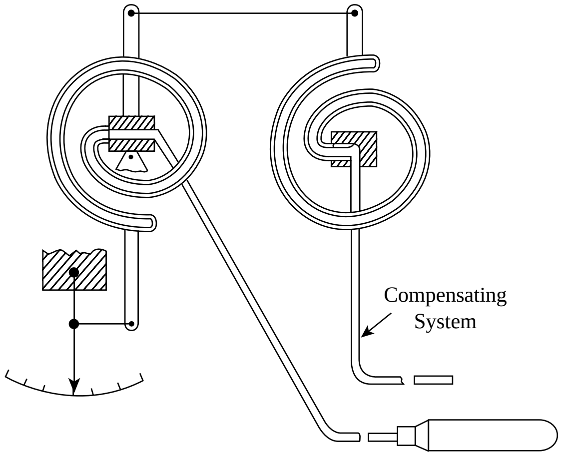

FIG. 4.6l
Full compensation.

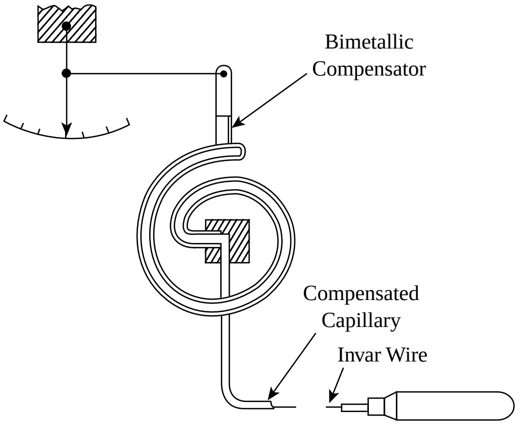

FIG. 4.6m
Class V full compensation with internal wire.

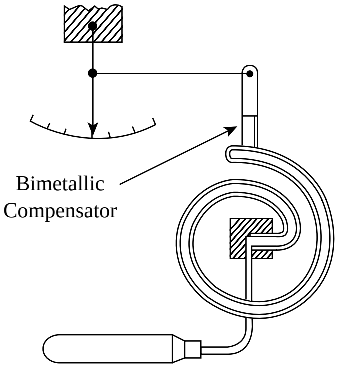

FIG. 4.6n
Case compensation.

illustrated in Figure 4.6m where an Invar wire is inserted inside the single active capillary. Invar is a nickel alloy that has a low coefficient of thermal expansion. Therefore it is possible to select the diameters of the Invar wire and of the capillary in such a manner that an increase in ambient temperature will increase the annular space between the wire and the capillary by just about the same amount as the volumetric expansion of mercury. Therefore, a change in ambient temperature around the capillary does not change the pressure inside the thermal system.

When both the capillary and the case are at the same ambient temperature and the capillary volume is very small relative to the total volume of the system, it is possible to leave the capillary uncompensated and limit the compensation to the case. Case compensation (Class IB, Class IIIB, or Class VB) can be achieved by the addition of a bimetallic spring that generates a force nearly equal to the one caused by the changes in ambient temperature (Figure 4.6n). Because the volume of the Bourdon spiral varies as the internal pressure changes with the measured temperature, the case compensation provided by the bimetallic spring is effective at only one bulb temperature. The bimetallic spring is usually set at midrange, resulting in under-compensation at the top and overcompensation in the bottom half of the range.

Uncompensated operation (Figure 4.6g) is possible with liquid-filled Class I systems when the capillary is very short and with all types of Class II vapor-filled systems. Class III and Class V units must always be compensated. In gas-filled Class III systems, the capillary error rises rapidly with bulb temperature and can be reduced by increasing bulb volume and/or span.

EFFECTS OF BULB ELEVATION

In a filled system, a pressure gauge is used to measure temperature. If the thermal bulb is above the readout instrument, the hydrostatic head of the filling fluid will be added to the total pressure at the spiral Bourdon element. If the bulb is below the case, the hydrostatic head will be subtracted from the total pressure. Therefore, when the bulb is high the thermometer will have a positive error; when it is low, it will have a negative error. The relative size of the error is a function of the size of the hydrostatic head relative to the total pressure.

In the case of liquid- or mercury-filled systems (Class I and Class V), the hydrostatic head caused by the elevation difference between the case and the bulb is a constant and can be zeroed out. Depending on whether the bulb is above or below the case, the hydrostatic head must be subtracted or added at the readout Bourdon tube. This is done with suppression or elevation springs, respectively. The amount of elevation or suppression that is available is not unlimited. Due to the high density of mercury in the Class V systems, the hydrostatic head due to bulb elevation is much greater than with other fillings. Therefore, with mercury-filled systems the maximum elevation difference that can be tolerated is about 30 ft (9 m). Needless to say, if the readout of the bulb is moved, the system must be rezeroed.

In the case of Class I and Class V systems, if the bulb is above the case, the manufacturer must also pressurize the filling liquid by something more than the hydrostatic head in order to make sure that the pressure in the bulb does not drop to zero. This increase in the initial filling pressure reduces the overrange capability of the system.

For Class IIA, Class IIB, and Class IID vapor-filled systems, correction of the elevation error is similar to correction for Class I and Class V, using elevation or suppression to compensate for the hydrostatic heads and rezero the system. In the case of Class IIC systems the height of the liquid column in the capillary varies with temperature and therefore cannot be zeroed out as a fixed quantity. Consequently, Class IIC systems *should not be used* when the case and bulb are at different elevations.

In the case of Class III gas filling, the density of the gas (and therefore its hydrostatic head) is too small to cause any errors. No correction is needed to protect against bulb elevation errors.

BAROMETRIC ERRORS

The Bourdon spiral is a differential pressure sensor. Its deflection is a function of the difference between the pressure of the filling fluid on the inside and the atmospheric pressure on the outside. Because the atmospheric pressure is not a constant, its changes can also result in readout errors. The barometric pressure can change by about 0.5 PSIG (25 mmHg). This may or may not be large enough to introduce an error, depending on the filling pressure. The pressure in the readout spiral varies with the type of filling fluid. In Class I and Class V systems it is high enough to make the barometric effect insignificant.

Class II vapor-filled systems are generally designed for a minimum of 100 PSIG (6.9 bars) pressure change across their span, and the barometric effect can result in a 0.5% error. Class III gas-filled systems are usually designed to produce a 400 PSIG (28 bars) pressure change across their ranges. Therefore the barometric effect can result in an error of about 0.1%.

CONCLUSIONS

The filled systems are superior to bimetallic elements but are generally inferior to electronic thermometers. Their advantages include being rugged, simple, self-contained, inexpensive, easily maintained construction, and having acceptable sensitivity and accuracy without the need for auxiliary power sources. They are inherently explosion-proof and can operate displays or records at some distance from the measurement using only head-wound spring drives.

Their disadvantages include the bulky bulbs that are space-consuming and result in a relatively slow speed of response (about 20+ seconds with a well), an inability to provide narrow spans, and a limitation on the distance between bulb and readout (usually under 200 ft, or 60 m). Relatively difficult maintenance of the pressurized thermal elements, which is usually done at the factory, is also a disadvantage. Filled systems are not suited for high-temperature measurement and can be easily misapplied if the user is not familiar with the unique characteristics of each system.

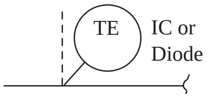
4.7 Integrated Circuitry Transistors and Diodes



Flow Sheet Symbol

B. G. LIPTÁK (1995, 2003)

Applications:	Because of their low accuracy, integrated circuitry sensors are used in heating, ventilation, and air conditioning (HVAC) type services and to detect hot or cold spots in piping. IC sensors are most often used in near-ambient temperature measurement; germanium diodes are often used in extreme cryogenic applications, and silicon diodes are used from –60 to 300°F (–51 to 149°C).
Ranges:	Integrated circuitry sensors, from –65 to 300°F (–54 to 149°C); silicon diodes, from –60 to 300°F (–51 to 149°C); germanium diodes, from –420 to 110°F (–251 to 43°C). Some diodes can cover the range of 1.4 to 475°F (–271.8 to 202°C).
Outputs:	Some integrated circuitry sensors generate a linear output with a slope of 1 μA/°C; others produce an output of 10 mV/°C.
Linearity:	1% of range
Inaccuracy:	For integrated circuitry sensors the error can range from 1 to 9°F (0.5 to 5°C) with sensitivities on narrow spans approaching 0.1°F (0.06°C). For calibrated diodes the error is 0.2°F (0.1°C) for temperatures above ambient and 0.2% of range below that. Some calibrated diodes are accurate within 0.05°C (0.1°F) between 2 to 305°K (–271 to 32°C).
Costs:	The basic integrated circuitry transistor elements can cost less than $10. Uncalibrated diode sensor costs range from $75 to $400; calibration can cost an additional $200 to $300. A calibrated diode with packaging and mounting for cryogenic service costs $600. Indicating monitor readouts for diode elements cost about $800.

Diodes are two-terminal electronic (usually semiconductor) devices that permit current flow predominantly in only one direction. Transistors are three-terminal, solid state electronic devices. They are usually made of silicone, gallium-arsenide, or germanium and used for amplification and switching in integrated circuits.

INTRODUCTION

Diodes and integrated circuitry (IC) transistors have been available as temperature sensors for several decades. The silicon (and germanium) transistors are small and inexpensive, but before they can be used as part of an industrial system (such as an intelligent thermostat), they need to be packaged.

One of the first applications of the IC transistor was to provide cold junction compensation for thermocouple (TC) circuits. They are also used in multipoint temperature-sensing cables and in handheld portable temperature monitors. Today both the diode and the IC transistor sensors are available as fully packaged, off-the-shelf units; some of them are also integrated with microprocessors, resulting in a so-called smart sensor. Diodes and transistors can both provide sensitivities approaching 0.1°F (0.06°C) on narrow span applications, but in the case of the diodes calibration is needed to achieve that level of sensitivity.

INTEGRATED CIRCUIT TEMPERATURE SENSORS

Transistors are sensitive to temperature variations. It has been found that if two identical transistors are operated at a constant ratio of collector current densities, then the difference in their base-emitter voltages will be directly proportional to absolute temperature. Therefore, as temperature decreases the base bias must be increased to maintain the collector current constant. The base bias voltage is usually converted to a current by a low-temperature coefficient thin film resistor.

The temperature-proportional characteristic is what allows IC transistors to produce output signals that are proportional to absolute temperature (Figure 4.7a). The IC temperature sensors are available in both voltage and current output configurations. The current output units are usually set for a 1-μA output change per degree Kelvin (Celsius), while the voltage output configuration generates 10 mV per degree Kelvin.

If a digital voltmeter is used as the readout, the current output is detected as the voltage drop through a 10,000-Ω resistor (Figure 4.7b). The temperature-proportional characteristics of IC sensors are highly linear and in the range of –67 to 302°F (–55 to 150°C). It is superior to all electronic sensors, including resistance temperature detectors.

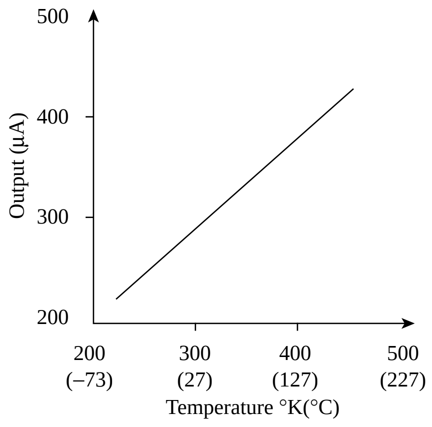

FIG. 4.7a
The temperature-proportional characteristics of the silicone transistor. (Courtesy of Analog Devices Inc.)

Because they produce an analog voltage that is proportional to temperature, IC transistors have been used for some time for cold junction compensation in TC circuits. IC sensor modules have also been packaged in flat cables, where they are attached to the cable at regular (several feet) intervals. The cables can be as long as 10,000 ft (3,050 m) and can have as many as 1,000 sensing modules.

These cables are an economical way of detecting pipe surface temperatures or cold or hot spots. IC sensors are also being used in the heating, ventilation, and air conditioning (HVAC) industry and in other applications where their low cost and strong linear output outweighs their low accuracy and limited range. Other disadvantages of IC sensors include that they require an external power source (4 to 30 V) and that they are fragile and subject to errors due to self heating.

DIODE-TYPE TEMPERATURE SENSORS

Diodes are highly sensitive and linear temperature sensors. Silicone and germanium diode temperature elements are available from –458 to 395°F (–272 to 202°C). They are accurate to 0.2°F (0.1°C) for temperatures that are above ambient and to 0.2% of their full scale range below that. Figure 4.7c depicts the diode-based thermometer circuits of a silicone diode with a 1 mA constant current source, and Figure 4.7d shows the circuits of a germanium diode with a 6-V power supply.

Germanium diode thermometer circuit.

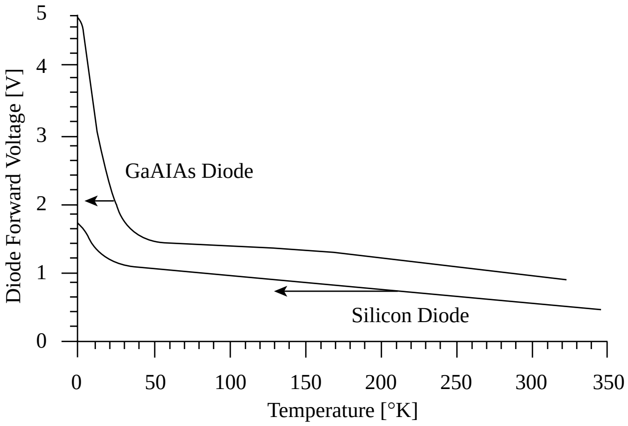

FIG. 4.7e
Characteristics of silicone and gallium-aluminum-arsenide diodes.[1]

The current through the silicon diode thermometer readout could be anywhere from 10 μA to 10 mA, but because higher currents result in higher errors due to self-heating, the currents are usually kept between 100 and 500 μA. The meters used with germanium diodes usually have a range of 0 to 50 μA. Because of the low source impedances, a simple microampere indicating meter can be used.

This sensor can also be used to detect small temperature differences. The main advantages of the diode-type sensors are their high accuracy, particularly at cryogenic temperatures; small size; low cost; and good linearity (Figure 4.7e). The diodes are small enough for most applications, but where sensor size is a problem, microdiodes can be used. One of the disadvantages is that the variations between diodes require a calibration procedure for absolute accuracy, which also increases their costs.

4.8 Miscellaneous and Discontinued Sensors

T. J. CLAGGETT, R. W. WORRALL (1969, 1982) **B. G. LIPTÁK** (1995, 2003)
J. E. JAMISON (2003), REVIEWED BY **K. C. SLONEKER**

Pneumatic and Suction Pyrometers

Applications:	Temperature profiling of boilers and furnaces during commissioning
Length of Probes:	6 to 30 ft (2 to 10 m); the permissible insertion length is a function of the maximum operating temperature.
Inaccuracy:	2% of actual temperature
Response:	98% in 10 to 20 s
Probe:	Stainless steel water-jacketed units with 2 to 3 in. (50 to 75 mm) diameters
Temperature Range:	0 to 2900°F (0 to 1600°C) with thermocouple and 0 to 4500°F (0 to 2500°C) with pneumatic probes
Fan or ejector requirements:	The fan must generate about 20 in. of water column (0.05 bar, or 37 mmHg) vacuum and pull a flow rate of about 40 cfm (2000 lpm) of furnace gas.
Former Supplier:	Land Combustion, a Division of Land Instruments International

Quartz Crystal Thermometry

Applications:	Temperature and temperature difference measurements, usually in the laboratory
Temperature Range:	–112 to 482°F (–80 to 250°C)
Inaccuracy:	0.135°F (0.075°C) throughout the full range; 0.072°F (0.04°C) for the range of –58 to 302°F (–50 to 150°C). For temperature difference measurement over an 18°F (10°C) span, the error under laboratory conditions is within 0.018°F (0.01°C).
Former Supplier:	Micro Crystal of Switzerland

In this section, several unrelated methods of temperature measurement will be briefly discussed. Some of these are still in the experimental stage, while others have not been exploited commercially because they are not yet competitive with the more common sensors. This fast-changing field is so broad that only select examples will be covered.

SELF-MEASURING DEVICES

Sometimes temperatures can be measured by allowing a material to serve as its own thermometer. This can be done by measuring the pressure of a constant volume of confined gas, because that indicates its mean temperature. The proportional relationship of pressure to temperature is given by the relationship: $pv = nrt$. This relationship can be exploited in industry where fixed volumes of gas may exist and where the pressure is known. A constant volume gas thermometer is precisely this type of device.

Similarly, the resistance of an electric heating coil can be measured and used to define its own temperature, because the resistance changes as a function of temperature.

Actually, any property having a consistent rate of change for a temperature variation will serve to indicate temperature. The frequency of the chirp of crickets on a summer night is an indication of their temperature environment. The rate at which a viscous substance, such as oil drips through a small hole in the bottom of its container, is just as much an indication of its temperature (provided the time-temperature relationship is known) as would be obtained by inserting a glass-stem thermometer into the fluid itself. All of these relationships may be derived by equation, but reasonably accurate measurements can be made from empirical data. These indirect measurement techniques are quite useful for correlating known temperatures. For example, in a fixed volume of gas having a measured temperature, the pressure gauge should read the appropriate pressure for that temperature. Because of the known relationship the parameters can confirm each other.

In addition to such self-measuring devices, there are also many new configurations of older systems. For example, the bimetallic spring can now be used as an optical temperature switch. In this design, the bimetallic element (Section 4.2) is upwardly convex until the temperature is reached. At that point it becomes downwardly convex, which blocks an optical light path. The number of devices that exploit old concepts in new ways is very large, and no attempt will be made here to fully cover them.

ACOUSTIC TIME DOMAIN REFLECTOMETRY

This thermometer operates on the principle that in solids ultrasound pulses travel at speeds, which are a function of the temperature of the solids (Figure 4.8a). The measurement is made by detecting the time needed for the acoustic pulses to travel from the transducer to the impedance demarcation point (which may be the junction between the wire and the wall of the tank) and back to the transducer. This device is in the development stage and shows good potential, although some drift in the measurement has been reported.

Gas temperature can be measured by detecting the time needed for an ultrasonic pulse to travel through a fixed distance in the hot gas (Section 4.15). This type of measurement is useful where conventional techniques may be less suitable, such as nuclear reactor environments. Often referred to as acoustic thermometers (see Section 4.15), these devices can be highly accurate and much consideration has been given to using this apparatus to define the lower end of the temperature scale. Accuracies in the sub-milli-Kelvin range are achievable.

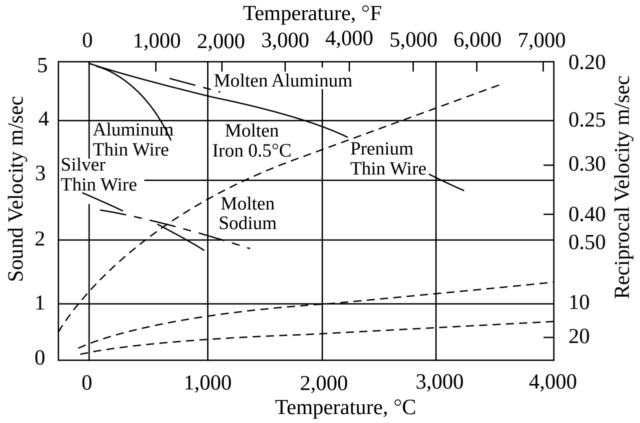

FIG. 4.8a

The velocity of sound is higher in thin wires when they are cold, and it drops as the wires are heated.[2]

CARBON RESISTORS

Commercially available carbon resistors have been used as temperature sensors in the cryogenic temperature area near absolute zero (from about –424°F, or –253°C, downward to below –458°F, or –272°C). One major benefit of the carbon resistor at low temperature is its lower susceptibility to adverse effects caused by a magnetic field. They are somewhat less accurate than competing sensors and do require individual calibration to keep the measurement error under 1%. Carbon resistors may be incorporated into resistor networks to improve linearity in some ranges.

Resistor sizes of 0.1 to 1 W and ambient resistance values up to 150 Ω exhibit a large increase in resistance below –424°F (–253°C). Reproducibility on the order of 0.2% are obtainable when calibrated individually. Small size, low cost, and general availability make their use attractive in cryogenic work.

The influence of stray radio interference and a loss of sensitivity are drawbacks. Variation in the resistors make calibration difficult and generally impose an individual device calibration requirement.

In addition to carbon resistors and conventional resistance temperature detectors (RTDs) (Section 4.10) or thermistors (Section 4.12), there is a variety of special resistors used as temperature sensors. One example consists of a thin nickel film deposited onto an electrically insulating substrate in a reducing atmosphere. The sheet resistance is a function of the heat treating temperature, cycle time, and thickness. The different designs of special temperature-sensitive resistors are too numerous to mention. These systems are engineered for specific applications and lack the widespread applicability required of most temperature measurement systems. They are, however, a very effective method of solving specific measurement problems.

CAPACITANCE CABLE FOR DETECTING HOT SPOTS

A cable consisting of an electrical conductor, a dielectric, and a conductive plastic can be used to detect hot spots. The polymer in the over-temperature locator cable increases its electrical resistance with temperature. Therefore when a hot spot evolves anywhere along the length of the cable, this will result in a drop in capacitance, as measured from one end of the cable. The location of the hot spot can be determined by comparing the measured capacitance from the control end of the cable with the capacitance of the full length of the cable.

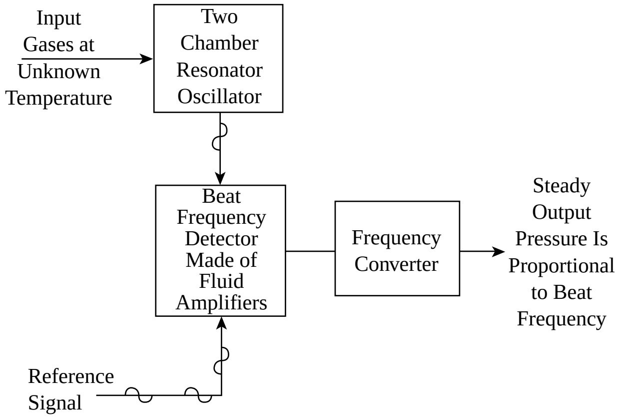

FIG. 4.8b
Fluidic temperature-to-pressure converter.

FLUIDIC SENSORS

The fluidic sensor is a device for converting gas temperatures into gas pressure. Actually, it is a beat-frequency detector system, which contains no moving parts other than the gas.

One type of design is shown in Figure 4.8b. The oscillator is a two-chamber resonator in which the entering gases are split by a knife-edge. The gases that are reflected from one chamber into the other, set up oscillations whose frequency is proportional to the square root of the absolute temperature.

A reference signal input from a temperature-sensitive resonant oscillator is compared with the unknown in a beat-frequency detector made of beam-deflection fluid amplifiers. The frequency of its output is the beat frequency of the combined reference and oscillator signals. The components in the frequency converter create a steady pressure proportional to the beat frequency. Accuracies of about 2% and temperatures up to 2000°F (1093°C) are claimed for the system.

JOHNSON NOISE THERMOMETER

Investigation into noise thermometry has been evolving over the last few decades. All resistive devices produce a random noise power level based upon their absolute temperature. In most cases this noise is considered interference and electronic circuit designers work to reduce it. Equation 4.8(1) gives a general relationship that relates temperature to the V_{RMS} value:

$$V_{\mathrm{RMS}} = \sqrt{4KT \int_{f2}^{f1} R\, df} \qquad \mathbf{4.8(1)}$$

For very high temperature measurements, tungsten rhenium thermocouples viewed in terms of a resistive device will provide a corresponding temperature that is determined using the Johnson noise measurement technique. It is interesting that much of the current research in this area is centered around cryogenic temperatures. Inaccuracies of 0.001% may be achievable in the range from 84 to 430 K. This type of instrument and sensor is collectively referred to as Johnson noise thermometers.

LIQUID CRYSTALS

Used in nondestructive testing for surface temperature measurements, liquid crystals undergo a series of color changes as temperature varies. They are organic compounds that are physically liquid, but exhibit optical properties that are similar to those of a crystalline solid.

A number of solutions are available, from the minimum temperature of about 68°F (20°C) to a maximum of approximately 340°F (170°C). The solutions are packaged in kit form for various ranges within these limits. Mixtures are made covering spans as narrow as 4°F (2.2°C) within the selected range.

Temperature is read by comparing the color exhibited when a thin coating is subjected to the conditions under question to a standard reference color. Response speed is less than 1 s. The indication is continuous and reversible. Cost is low. Disadvantages include manual preparation and limited range, in addition to lack of automatic readout.

Liquid crystals have also been used in fiber-optic thermometers. A pellet of liquid crystal is inserted at the tip of an optical fiber. As light at different wavelengths is sent through the fiber, the reflection peaks from the liquid crystal are related to temperature.

PARAMAGNETIC SALTS

Magnetic thermometry has been developed chiefly to measure temperatures near absolute zero (below –458°F, or –272°C). The temperatures are obtained by adiabatic demagnetization of a paramagnetic salt. An isothermal magnetization at the lowest attainable liquid helium temperature (about –458°F, or –272°C) followed by an adiabatic demagnetization is used. The entropy is decreased, with a simultaneous heat flow from the sample, when the magnetic ions are oriented parallel to the field. During subsequent adiabatic demagnetization the entropy of the salt remains constant, if demagnetization is reversible, and temperature decreases.

To obtain the temperature, some temperature-dependent quality of the salt under investigation is used, such as the magnetic susceptibility.

If a sphere or rotational ellipsoid of an isotropic paramagnetic salt is located in the homogeneous part of the magnetic field of a coil of a mutual inductance or a self-inductance, the inductance of the coil is a function of the temperature. Inductance can be measured with an AC bridge (as shown in

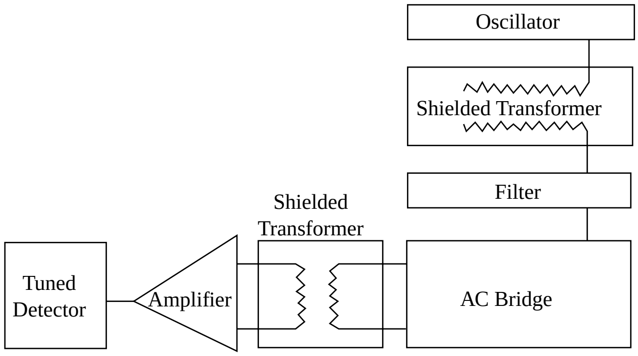

FIG. 4.8c
Circuitry for temperature measurement by paramagnetic salts.

Figure 4.8c) whose balance is independent of frequency. A galvanometer can be used for detection. Effective shielding is a requirement.

In a paramagnetic salt with a coil surrounding it, self-inductance is related to temperature. An Anderson AC bridge has been used to measure magnetic temperature in such a situation. The relationship between self-inductance and susceptibility of a salt has been found to be linear when the ellipsoidal or spherical salt piece is placed in the homogeneous part of the measuring field.

Accuracy of the magnetic method has been estimated on the order of 0.001°F (0.00056°C). The method is the best available for measurements near absolute zero.

SPECTROSCOPIC TEMPERATURE MEASUREMENT

Spectroscopic methods are often used to measure the temperature of hot gases. They are, in fact, the only possible way to measure the surface temperature of stars.

The spectroscope in its simplest form is the familiar triangular glass prism, which breaks up light from a hot object into its constituent colors (its spectrum). The chemical composition of glowing gas is determined from the pattern of dark (Fraunhofer) lines that appear across the spectrum.

Many procedures for temperature determination from the spectrum have been developed, such as measurement of brightness and actual color, reversal temperatures, population temperature estimates, measurements made of spectral line shifts in ionized gases, and many others. These are all laboratory techniques seldom employed industrially because of their complexity and relatively high costs. For further information on this subject, refer to Chapter 56, “Spectroscopic Methods of Temperature Measurement,” in *Temperature: Its Measurement and Control in Science and Industry*, Vol. III, Pt. I.

THERMOGRAPHY

The strong temperature dependence of the brightness of certain luminescent materials may be converted into a pattern of color that can be recorded photographically. A thin layer of this material is placed on the surface to be investigated and is excited with ultraviolet (UV) radiation in a darkened room. The brightness of the coating is compared to the brightness of the same coating at a known temperature as an indication of the unknown temperature.

The sensitivity of the phosphors used gives a 10% brightness change per °F and this can be picked up with a relatively crude system of photometry. Temperature range for this type of measurement is from 32 to about 750°F (0 to about 400°C).

FIBER BRAGG GRATING TEMPERATURE SENSORS

The Fiber Bragg Grating (FBG) offers a promising technology for future temperature-sensing applications as well as possible strain sensor applications. Research has been done indicating considerable promise for FBG to be a viable temperature measurement technology.

In this optical technology, Bragg wavelength shifts are measured to determine the temperature of a specifically treated section of the fiber core material. FBG technology can be measured in a distributed manner by wavelength division multiplexing. This would make it suitable for petrochemical plant applications in hazardous, classified locations.

An FBG is formed by exposure to a fringe of UV light. Only the specified Bragg wavelength as related to its grating period is reflected from broadband-source input light. As a temperature change occurs, a Bragg wavelength shift occurs that can be measured and can correlate back to the measured temperature. The measurement hardware can be completely placed within a conventional thermowell just like a thermocouple and its sheathing would.

DISCONTINUED TEMPERATURE SENSORS

While the temperature sensors described in these paragraphs are not marketed at this time, they are still in use. Whether they will or will not be manufactured in the future is unknown. For sake of completeness, they are described here.

Pneumatic and Suction Pyrometers

The measurement of hot gas temperature of combustion processes does not give accurate results with conventional thermometers because of interference from the radiated heat of the surroundings. When a conventional thermocouple (TC) is used, the amount of interference is a function of the relative values of the radiant heat transfer coefficient of the surroundings and the convective heat transfer coefficient of the gas. When a standard TC is used in a cold furnace, the resulting error can be several hundred degrees. Pneumatic and suction pyrometers have been developed in order to reduce this error.

Suction Pyrometers The suction pyrometer consists of a sheathed TC (sheathed against chemical attack) located inside a radiation shield at the tip of a suction pipe (Figure 4.8d).

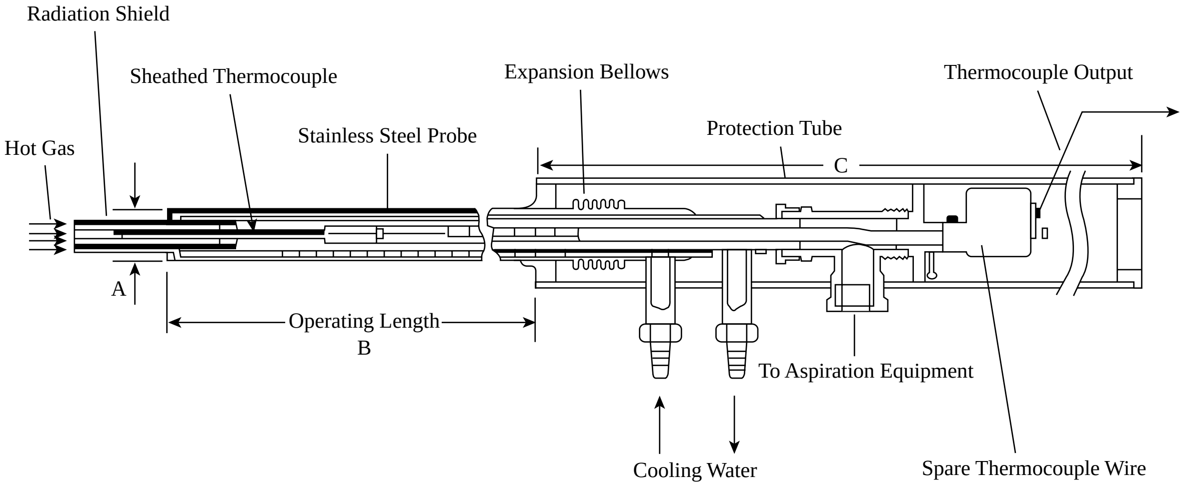

FIG. 4.8d

Sheathed thermocouple detects the hot gas temperature in an aspirating suction pyrometer. (Courtesy of Land Combustion, a Division of Land Instruments International Inc.)

The combustion gases are sucked through the shield and over the TC at high velocity by aspirating equipment. The efficiency of this aspirating TC is a function of the quality of the radiation shield and of the suction flow rate. If, for example, a suction pyrometer has a 100°C error without suction and a 10°C error when the suction flow is on, it is said to have an efficiency of 90%.

The suction pyrometer probe is usually made of stainless steel and is water-cooled. These probes are designed for high gas velocities of 500 fps (152 mps). At such velocities the radiation shields usually produce better than 90% pyrometer efficiencies. The furnace gases can be pulled out by fans or by air or steam ejectors. The main limitations of this design include plugging of the probe when the combustion products are dusty (as in pulverized coal burners). In addition, they cannot be used in applications where the temperatures exceed 2912°F (1600°C).

Pneumatic Pyrometers The pneumatic probe was invented in 1893 for use in blast furnaces. It is superior to suction pyrometers in that dust in the combustion gases does not plug it as easily and that it can measure very high temperatures, such as in turbojet engines or rockets. This pyrometer can detect higher gas temperatures than can the aspirating TC because the thermometer does not need to reach the gas temperature (Figure 4.8e). The pneumatic probe can handle gases heavily laden with dust because it does not have a radiation shield, which is prone to plug.

The pneumatic pyrometer measures the pressure drop of the hot combustion gases through one restriction at the probe tip and measures their pressure drop again after they have been cooled through an identical restriction (see Figure 4.8e). Because the mass flow rate of the gas is the same across these restrictions, the only reason these two pressure drops are different is because of the change in the gas temperature, which affects its density. The pressure differentials across the hot and cold venturi are inversely proportional to the densities of the hot and cold gas. Therefore they are directly proportional to the absolute temperatures at the hot and cold venturi. As the temperature at the cold venturi (T_c) is measured, the hot gas temperature (T_h) can be calculated by multiplying T_c and a configuration constant K with the ratio of P_h/P_c. Therefore, the absolute temperature of the gas is:

$$T_h = KT_c(P_h/P_c) \qquad \textbf{4.8(2)}$$

Relative to the suction pyrometer, the pneumatic pyrometer requires more utilities and more design attention as almost all units must be uniquely designed.

Quartz Crystal Thermometry

The effect of temperature on the frequency of quartz crystal controlled oscillators has been known since work on this subject been published in 1946. Temperature measurement using quartz thermometers is based on the very linear change that occurs in resonant frequency in response to a change in temperature. Under ideal conditions, this temperature sensitivity is on the order of 0.0005°F (0.0003°C), and temperature deviations on the order of 10^{-6}°F have been measured in the laboratory.

A reference and a sensor oscillator are used. The reference oscillator frequency is selected to provide zero reference beat when the probe is at 32°F (0°C). Sensor oscillators provide a sensitivity of 500 cps/°F and dividers are arranged to obtain a sample period of .01 s. A resolution of 0.2°F (0.1°C) has been obtained with a digital readout (Figure 4.8f). When arranged for differential measurement, gating circuits are added to enable the oscillators to be heterodyned against each other.

In past applications, probes were provided with the quartz crystal hermetically sealed inside a well, formed from a 3/8

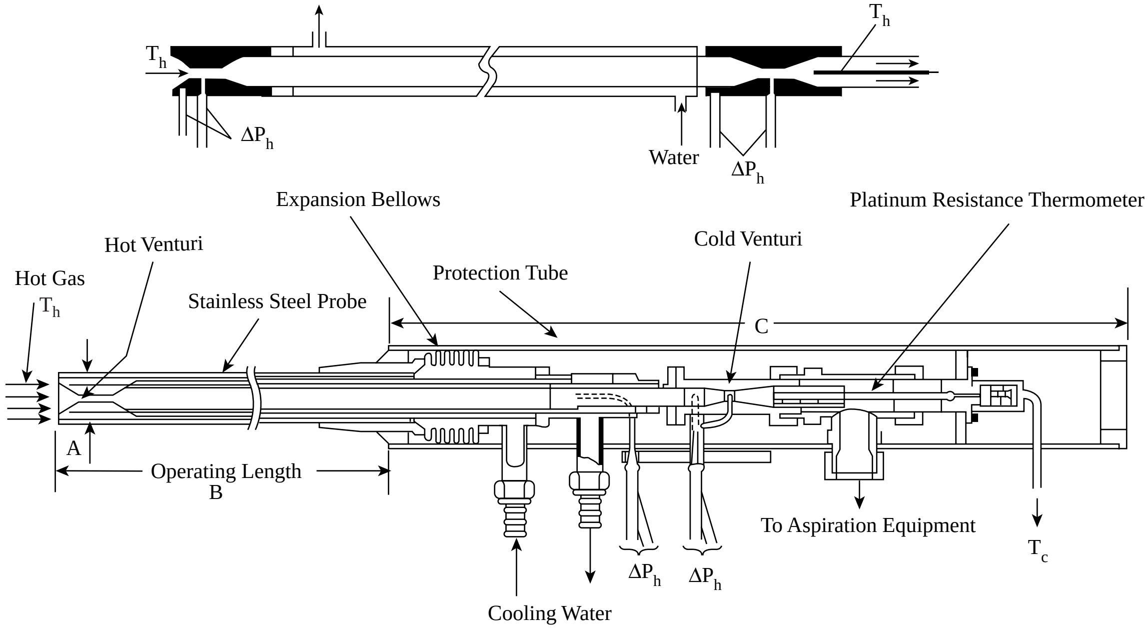

FIG. 4.8e
Pneumatic pyrometer determines hot gas temperature by multiplying cold and temperature (T_c) with the ratio of pressure drops across the hot and cold venturis. (Courtesy of Land Combustion, a Division of Land Instruments International Inc.)

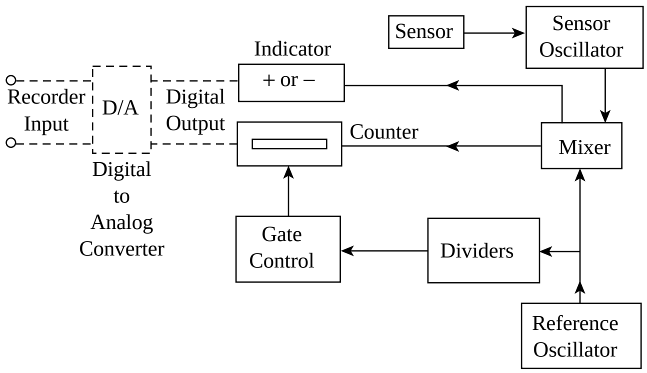

FIG. 4.8f
Quartz thermometer system block diagram.

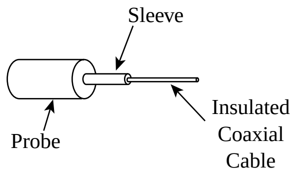

FIG. 4.8g
Quartz crystal sealed in a capsule.

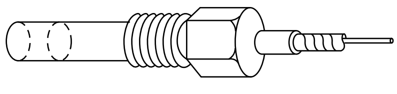

FIG. 4.8h
Quartz crystal in stainless steel well.

in. (9.5 mm) outside diameter stainless steel cylinder (Figures 4.8g and 4.8h). The probes can be used at pressures up to 3000 PSIG (21 MPa) and can stand shocks of 10,000 *g* without changing their calibration.

In a well-stirred water bath, the response time for a step change is 1 s. Long-term stability, for periods of a month or more, is on the order of 0.02°F (0.01°C). Oscillator drift can lower the stability, but, in an environmentally controlled area, this is not much of a problem.

Advantages and Disadvantages The main advantages of quartz crystal thermometry are that:

1. There are no lead resistance or noise problems because the temperature is converted to frequency.
2. It has excellent short-term stability.
3. It has good accuracy.
4. It has a 1-s response time.
5. It has accurate differential measurement.
6. It is rugged—it can withstand shocks without changing calibration.

The disadvantages include that:

1. These units are expensive.
2. Their accuracy is somewhat lower than those of resistance thermometers or thermistors.
3. Their probe size is larger than TC or resistance temperature detector.
4. They are better suited for the laboratory environment.

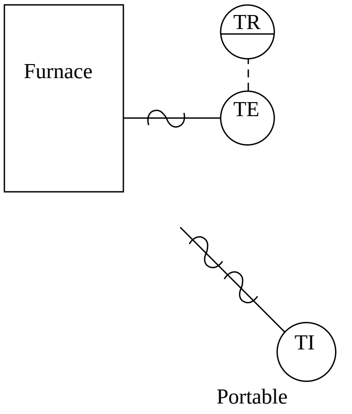
4.9 Radiation and Infrared Pyrometers

T. J. CLAGGETT, R. W. WORRALL (1969, 1982)

B. G. LIPTÁK (1995, 2003)



Flow Sheet Symbol

Types:	(A) Optical (brightness); (B) Ratio (two-color); (C) Total (wide-band) (D) Narrow-band. Note: Fiber-optic designs are covered in Section 4.5.
Applications:	Applications are not limited to noncontact high-temperature processes, such as hot metal working, plastic film processing, and glass manufacturing. Infrared is also used in low-temperature applications. These include infrared photographs of accident victims to locate internal bleeding, aerial photographs to detect pollution of water bodies, the detection of the need for crop irrigation, and many others.
Wavelengths Used (Microns):	Inexpensive total radiation detectors operate over the range of 0.7 to 8 μm. To penetrate the intervening atmosphere, the 2.2- to 3.8-μm range is used; for applications involving metals, a narrow band around 2.2; for flames, 4.5; for glass, below 8 μm are typical.
Temperature Ranges:	–50°F to 6500°F (–46 to 3600°C) for Spot instruments; 100 to 3500°F (37 to 2000°C) for Line Scanners; 0 to 3500°F (0 to 2000°C) for Thermal Imagers, 1400 to 6300°F (760 to 3500°C) for optical; –40 to 7000°F (–40 to 4000°C) for narrow-band and total radiation pyrometer designs.
Distance and Target Size:	Maximum distance (D) to target is about 100 ft (30 m); minimum target diameter (d) is about 0.05 in (1.5 mm). The field of view of the pyrometer is its D/d ratio and varies from 3:1 to 900:1. Single-wavelength units detect average temperature of field of view; dual-wavelength units detect the hottest part of target within the field of view.
Linearity:	Nonlinear, most vary with the 4th power of absolute temperature.
Main Sources of Errors:	Variations in the emittance of the target and background; aging of radiation source; background interference; lack of focusing or target is too small to fill the view; radiation absorption by dust, smoke, moisture, atmosphere, or by dirt on the windows.
Methods of Focusing:	Most units use lenses to focus on the target. (For alternate methods, refer to the fiber-optic designs in Section 4.5.)
Inaccuracy:	Generally from 0.05 to 2% of reading with significant variation due to application details. The error when using designs A and B is generally around 1% of full scale (FS), but on narrow spans can be reduced to 0.5% of reading. (C) is 0.5 to 1% FS, and (D) is 0.25 to 2% FS. Under laboratory conditions, the precision can reach 0.1°C (0.2°F).
Costs:	The total range of costs is from \$500 to \$5,500 with thermal imaging systems up to \$60,000. Portable general purpose infrared thermometer units start at around \$500 and can reach over \$3000 in optical (A) designs. Permanently installed general-purpose, two-wire industrial transmitters start at about \$1,500. These can be wide- or narrow-band ([C] and [D]) units. Ratio-type transmitters (B) start at around \$4,000. The optical

(A) transmitters cost over $5,000 and are not widely used. When installing pyrometers on a furnace or on boilers, accessories such as cooling jackets, air purge assemblies, safety shutters, and sighting or target tubes are also needed and can more than double the cost of the pyrometer itself. Additional costs involve testing, maintenance, and periodic calibration. When all costs are added up, the total cost is likely to be higher than that of any other thermometer category.

An infrared (IR) thermometer is a noncontact radiant energy detector. Every object in the world radiates IR energy. The amount of radiant energy emitted is proportional to the temperature of an object. Noncontact thermometers measure the intensity of the radiant energy and produce a signal proportional to the target temperature.

INTRODUCTION

It was only a few hundred years ago that physicists abandoned the view that heat is a substance and accepted that it is a form of energy that is transferable from one material to another by conduction, convection, or radiation. Since that time it

Blackbody radiation is a function of temperature. Dotted line on the left describes a gray body having an emissivity of 0.1. (See definitions at the end of this Section.)

was discovered that all materials, at all temperatures, down to near absolute zero, radiate electromagenetic energy, which travels at the speed of light (186,000 miles per second). It was also learned that the wavelength at which this radiation occurs depends on the temperature of the material.

The temperature of the material determines both the quantity and the type of energy radiated. As the temperature rises, the wavelength of radiation drops and its frequency rises (Figure 4.9a). For example, at −100°C, the range of radiant energy wavelengths is between 10 and 100 μm, while at 1000°C they are between 1 and 10 μm. As the temperature rises, the dominant form of heat radiation shifts toward the shorter wavelengths: IR (2 to 20 μm), near IR (0.7 to 2 μm), visible (0.4 to 0.7 μm), and UV (0.04 to 0.4 μm). At extremely high temperatures, the hot objects will also radiate x-rays and gamma rays. In industrial applications the bulk of thermal radiation occurs in the IR range, and therefore these thermometers are often referred to as IR thermometers.

This section begins with a discussion of some theoretical aspects of pyrometry, including such topics as emissivity. The description of the specific thermometer designs, features, and installation requirements follows. The section concludes with some definitions of terms used in radiation pyrometry and a list of material for further reading.

THEORETICAL RELATIONSHIPS

Radiation pyrometry stems from Plank’s quantum theory, developed around 1900, and from Stefan-Boltzmann’s law for total radiated energy. According to the Stefan-Boltzmann equation, the total radiant power density emitted (W) by an object is directly related to the emissivity of that object (E) multiplied by a constant (SB) and by the 4th power of absolute temperature (T):

$$W = (E)(SB)T^4 \qquad \textbf{4.9(1)}$$

where
W is in W/cm^2
E is a fraction (unity for a blackbody)
SB is the Stefan-Boltzmann constant, having a value of 5.6×10^{12} W cm^{2}K^4
T is absolute temperature of the object in degrees Kelvin

Planck’s law of radiation goes one step beyond Equation 4.9(1) and predicts the level of radiation emitted per unit surface area of a blackbody at each specific wavelength. Planck’s equation is rather complex and therefore is not used much in the everyday work of instrument engineers. According to Plank’s law, the radiation emission peaks at shorter and shorter wavelengths as the temperature rises. This is why one can estimate the temperature of a hot iron in a fire (the shorter the wavelength emitted the whiter and therefore the hotter it is) and why the dotted line connecting the peaks at different temperatures is leaning to the left in Figure 4.9a.

This shift in peak values is expressed by Wien’s law of displacement, relating the wavelength at maximum radiation (W_1) to absolute temperature (T) and Wien’s constant (Cw) as follows:

$$W_1 = Cw/T \qquad \textbf{4.9(2)}$$

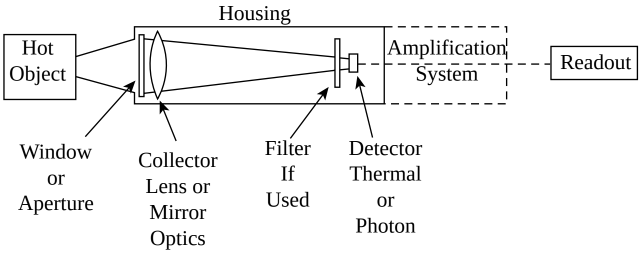

FIG. 4.9b
General radiation pyrometer system.

where
W_1 is in μm
C_w is in units of μm K and has a value of 2897

Based on the above laws, one can build thermometers by measuring either the radiation at specific wavelengths (optical and narrow-band) or all the radiation (total or wide-band). Changes in process material emissivity; radiation from other sources; and losses in radiation due to dirt, dust, smoke, or atmospheric absorption can introduce errors into the total- or single-wavelength pyrometers. For these reasons many users decide to use the more expensive ratio pyrometers.

Thermal radiation is a universal property of matter that is absent only when the material is an inert gas, like helium, or is at absolute zero temperature. From this property of matter, the technique of radiation pyrometry has been developed so that it is possible to infer the temperature of an object without contacting it. This is done with an optical system, which collects some or all of the visible and/or IR energy, sometimes through a filter, and focuses it on a detector (see Figure 4.9b). The detector converts the concentrated energy to an electrical signal, a complex function of the absolute temperature.

The Theoretical and Real Targets

Only the energy given off between about 0.3 and 20 μm is of sufficient magnitude to be of any consequence. This encompasses the visible spectrum (0.35 to 0.75 μm) and the near IR. The intensity and distribution of this energy from a substance may be compared with that of a blackbody which radiates its energy in a theoretically predictable spectral distribution and intensity, such as that shown for several temperatures in Figure 4.9a. The area under the curve represents the total amount of power radiated at all wavelengths.

Real targets, however, always deviate from an idealized blackbody to some degree. The ratio of energy radiated by a real body to that of a blackbody under similar conditions is termed the emittance (E). Two other optical ratio characteristics of targets are reflectance (R) and transmittance (T) and for a body whose temperature is constant, the sum of $E + R + T$ for any wavelength is always 1.0. The radiation pyrometer would gather the radiation from all three of these energy sources over the wavelength band to which it is sensitive. In Figure 4.9c, if the purpose were to measure the temperature of Object B, and if A were the same temperature as B, B would absorb, emit, reflect, and transmit radiant energy and would appear to be a blackbody.

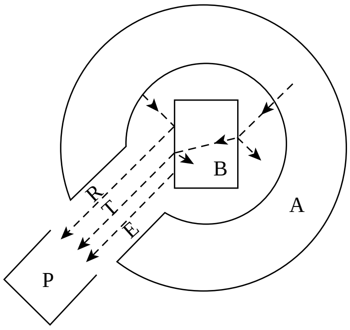

FIG. 4.9c
Emission, reflection, and transmission.

Frequently A is not uniform in temperature nor does it completely surround B. Furthermore, B might be cooler than A or have a high reflectance which causes it to reflect extraneous sources of radiant energy. If any of these conditions prevail, the measurement of the total energy radiated by B cannot be converted exactly into temperature with the Stefan-Boltzmann law.

For best results, emittance should be high and reflectance low. Transmittance of most solid objects (with the exception of glass) will be near zero. If the process material is not solid, the radiant energy detector will actually see beneath the surface, or if the object is thin, right through it.

Emittance, reflectance, and transmittance are not easy factors to derive and they vary considerably with wavelength. Materials like ferrous metals with a matte surface have a high emittance at the short end of the spectrum, but become lesser emitters for the longer waves. On the other hand, glass acts in nearly the opposite way, being practically transparent to visible energy and almost opaque to wavelengths in the 5- to 7-μm region.

Emittance, Emissivity

The amount of thermal radiation leaving an object depends on the temperature and on the emittance of that object. If the object is a perfect emitter (a blackbody), its emittance is unity. The emissivities of almost all substances are known (Table 4.9d), but unfortunately the *emissivity* determined under laboratory conditions seldom agrees completely with the *actual emittance* under actual operating conditions. This is because emissivity is only one component in determining the emittance of an object; other factors (having effects that cannot be found in tables like Table 4.9d) include shape, oxidation, or surface finish. For this reason one is likely to use published emissivity data only when the values are near unity, as is the case for some metal oxides, ceramics, bricks, and glasses.

The uncertainties concerning emittance can be reduced by creating blackbody conditions (target tubes or target holes, which are discussed later) or by using short-wavelength or

ratio pyrometers. The use of short wavelengths is useful because the signal gain is high in this region. This can be seen in Figure 4.9a, where the change in the amount of energy radiated per unit temperature change gets much higher when the wavelength is short. This high output response tends to swamp the effects of emittance variations and makes the performance of the short-wavelength pyrometers acceptable in such applications as iron and steel processes. The high gain of the radiated energy also tends to swamp the absorption effects of steam, dust, or water spray.

The ratio, or two-color, pyrometer overcomes emittance uncertainties, but has other limitations, which will be discussed later. The emissivities of most materials, including metals, vary a great deal, and some emissivities also vary with temperature. When this is the case, the ratio thermometer is also disabled and the only solution is the actual, on-line measurement of emissivity (using laser devices, which are discussed later). The general rule is to measure the tempreature of an object in a location where its emissivity is the highest and/or where the change in radiated energy is more sensitive to temperature changes than to changes in emissivity.

SELECTING THE RADIATION PYROMETER

In selecting the appropriate type of radiation pyrometer to be used in detecting the temperature of a particular process, one would prefer to select a wavelength-band in which the transmittance (T) is near zero (the material is opaque). In addition, one would like to select a wavelength-band that will not be absorbed by the atmosphere the radiation has to pass through. These two considerations result in a requirement for matching the pyrometer wavelength to the particular process.

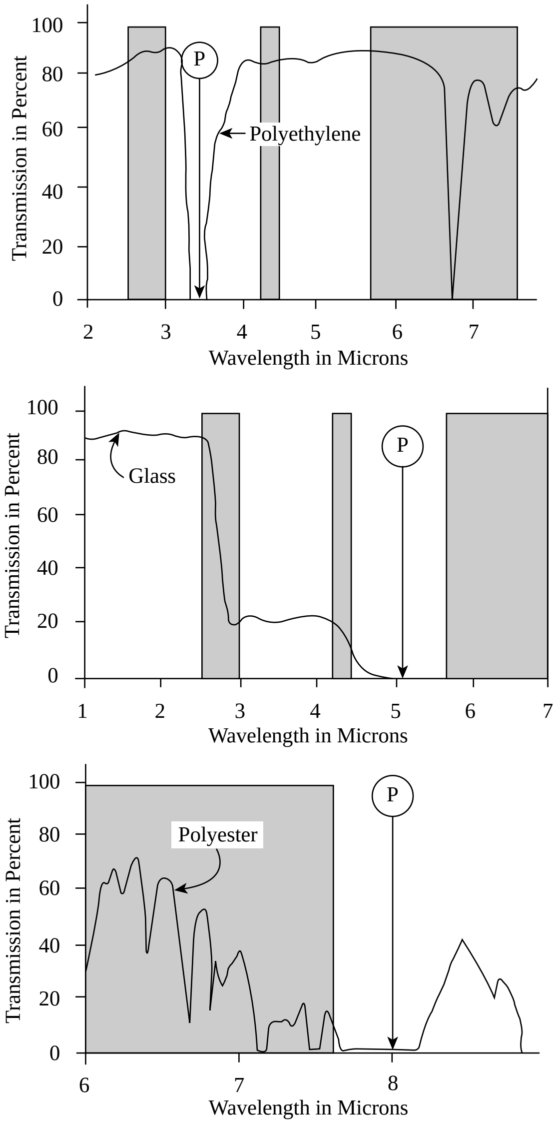

FIG. 4.9e
Radiation pyrometers must be selected on the basis of the transmittance of the process material and the location of the atmospheric absorption bands. (Courtesy of Ircon Inc.)

Figure 4.9e illustrates three different processes showing both the atmospheric absorption bands and the transmittance curves of the particular process materials. The arrow with the letter P for pyrometer indicates the appropriate wavelength-band selection for the radiation thermometer for each process. For polyethylene it is around 3.4 μm, for glass 5 μm, and for polyester 8 μm.

Because of the different needs of the various processes, each radiation pyrometer manufacturer has developed a range of products operating in a variety of wavelength bands as shown in Figure 4.1j and Figure 4.9f. Of the eight bands shown on this illustration, #6 can be considered for use on a polyethylene and #8 on a glass temperature measurement applications. (If the glass is thick enough it can appear opaque even in the near-infrared range.)

Short wavelength units like #1, #2, and #3 can be used in iron and steel processing. Long or broad wavelength pyrometers (#7) are useful at lower temperatures where short wavelength radiation can be undetectable. Materials like glass are transparent to shorter wavelengths (Figure 4.9e). Therefore, shortwave pyrometers would not detect the surface temperature, but would measure the temperature below the surface. In some processes, like lamp sealing, this is actually desirable, and therefore the 3- to 4-μm band is used.

RADIATION PYROMETER DESIGNS

Pyrometers can be portable or permanently installed; the radiated energy can reach them through focusing on lenses or through optical fibers. In addition, they can be categorized according to the number and width of the wavelength-bands used. When the full spectrum of 0.3 to 15 μm is utilized (#5 on Figure 4.9f), the device is called a wide-band or total radiation pyrometer. When a single small segment of the spectrum is used (for example, #8 on Figure 4.9f), the design is called a narrow-band pyrometer. If that narrow band falls within the visible spectrum (#1 on Figure 4.9f), this subgroup of the narrow-band pyrometers is called an optical, color, or brightness pyrometer.

When, instead of measuring the radiation intensity of a single wavelength band, the instrument detects the ratio of the intensities of two wavelengths, the pyrometer is called a ratio, or two-color, thermometer (Figure 4.9g). When a pyrometer operates in the IR spectrum (0.7 to about 15 μm), sometimes the unit is referred to as an IR thermometer.

Of these many design variations, the fiber-optic units will not be discussed here. Section 4.5 is devoted to their description and they are also covered in Section 4.1 (Figure 4.1n). The others are discussed below.

With the passage of time, the use of total radiation pyrometers has dropped and the use of the more accurate (and more expensive) ratio pyrometers has increased. Optical pyrometers are most often used as portable units.

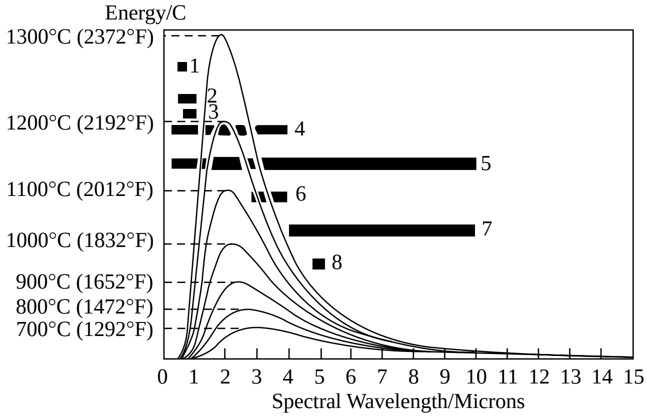

FIG. 4.9f
Pyrometers and their wavelength-bands.

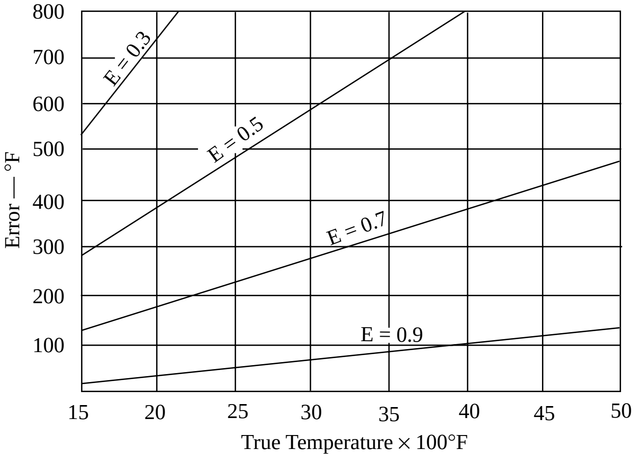

FIG. 4.9h
Error in reading of broad-band radiation pyrometer as function of temperature and emissivity.

Total Radiation Pyrometers

Broadband (total) radiation pyrometers attempt to measure as much of the radiant energy coming from a hot body as possible. The simplest of the three types (total, narrow, ratio), it has substantially no selectivity for specific wavelengths other than a cutoff inherent in the optical system and is dependent on the total emittance of the surface being measured.

Figure 4.9h shows the error in reading for various emissivites and temperatures when a typical instrument of this type is calibrated to read blackbody temperatures. A calibration control on the readout instrument permits the user to compensate for this error, which corrects the reading as long as the emittance does not change. The proper setting of the adjustment is made with the aid of a second thermometer known to be correct; or, knowing the nature of the target and referring to a table giving total emissivities (see Table 4.9d), the adjustment can be set to the correct figure.

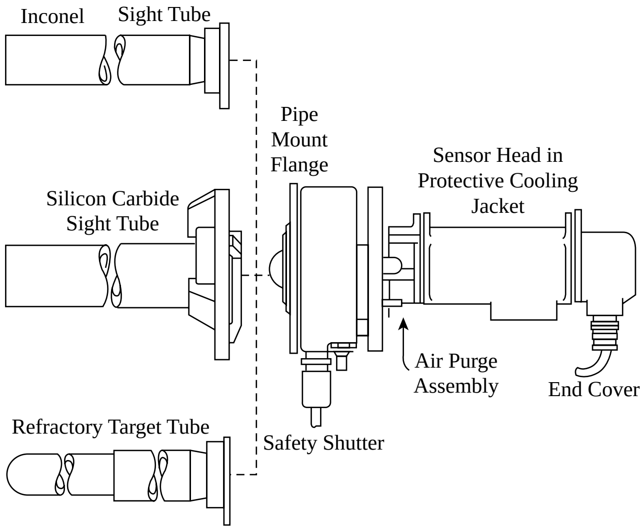

FIG. 4.9i
Accessories required for installing a pyrometer through the wall of a furnace. (Courtesy of Mikron Instrument Co.)

Broadband radiation pyrometers must have an unobstructed sighting path to the target. The presence of smoke or carbon dioxide will absorb some of the radiant energy and cause a low reading. The optical system must be kept clean, with a sighting window protected from any corrosive gases that otherwise would come in contact with it. In furnaces, a closed-end sighting tube is frequently used to protect the optics and to provide a clear sighting path (Figure 4.9i). The back end of the tube assumes the same temperature as the furnace. Water or air cooling is sometimes used to keep the housing temperature cool on these installations.

Ambient temperature compensation is required for those total radiation pyrometers using a thermopile detector. Nickel wire, having a temperature coefficient opposite to that of the thermopile wires, is most often utilized. For low-temperature work, a thermostatically controlled housing is often employed to eliminate any ambient temperature fluctuations.

Narrow-Band Pyrometers

Single-band pass (narrow-band) pyrometers operate over a selected, usually narrow, band of the energy spectrum centered at a desired point. For high-temperature measurement of metals, for instance, the band might be very narrow at the 0.65-μm point, the read end of the visible spectrum where metal emissivity is highest. At this visible point, the instrument might be referred to as a brightness pyrometer.

To measure gas temperatures, a band around 4.3 μm to pick up carbon dioxide might be chosen, while glass surface temperatures, previously mentioned, would be measured in the 5- to 7-μm wavelength.

Emissivity over a narrow wavelength band will not vary as much as it would over the total spectrum, but the limited-band pyrometer will suffer somewhat from a lack of sensitivity because of the reduced energy available. The use of more sensitive photon detectors helps make up this deficiency and also provides a desired band pass. Because the energy content of the radiation increases as the wavelength gets shorter, the narrower bands are most often used to detect higher temperatures (above 500°C, or 932°F). A narrow band is usually less than 0.5 μm wide.

Ratio Pyrometers

The ratio, or two-color, pyrometer measures the energy it receives from two rather narrow bands and divides one by the other. When the two bands are chosen so that there is very little change in emissivity from one to the other, such as would be the case if the bands were close together (Figure 4.9g), the emissivity factor nearly cancels out. Thus, low emissivity bodies, which create the most error for the broad- and single-band pyrometers, do not have such a large effect on the ratio-type instrument.

The selection of the two wavelengths is not arbitrary but, like the single-band pyrometers, is made for the particular application.

Ratio pyrometers are more complex and more expensive than single-band pyrometers, but they provide better accuracies when the target behaves like a gray object or when its emissivity is a variable. (The emissivity of many substances varies with temperature.) In addition to being independent of emissivity, measurements made by ratio pyrometers are also unaffected by dust or other contaminants in the field of view (such as dirty windows), by changes in target size, or by periodic blockage of the sight path.

In some more advanced designs, more than two colors (wavelengths) are used and their evaluation algorithm is more complex than a simple ratio.

Figure 4.9j illustrates the operation of the ratio (two-color) pyrometer where the wavelengths are alternatively selected by a rotating filter wheel. These eliminate emittance errors if the emittance is the same at both wavelengths. Unfortunately this is seldom the case; usually emittance is wavelength-dependent. The only solution is to bring the two wavelengths very close together, but then they become insensitive to temperature.

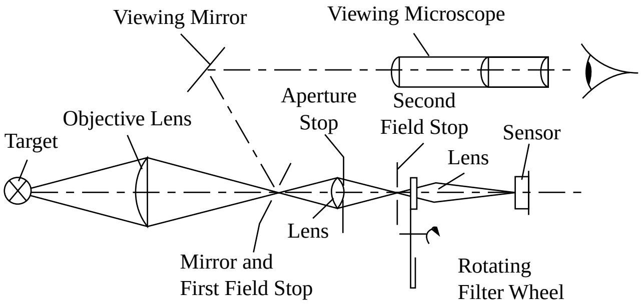

FIG. 4.9j
Ratio pyrometer.[1]

For these reasons the ratio pyrometers are not as widely used as one might expect. On the other hand, they are still very useful on applications where the target is too small to fill the field or view (e.g., in the drawing and coating of wires) or where the target is obscured by cool dust (as in cement kilns).

Manual Optical Pyrometers

Optical pyrometers are narrow-band or two-color radiation pyrometers that operate in the visible spectrum around the 0.65-μm point. The human eye, acting as the detector in the manually balanced type, compares a source of known radiant energy generated within the instrument by a calibrated tungsten lamp to the incoming unknown source. A filter interposed between the eye and both sources of energy cuts out the shorter wavelengths. This serves a dual purpose: (1) it minimizes the difference between eyes, permitting an easier color match, and (2) it permits an extension of the temperature range beyond the point where the eye could no longer tolerate the amount of energy if viewed directly (Figure 4.9k).

The instrument is shaped to be held in the hand and up to the eye so that it may be sighted on the target. An adjustable focus permits the operator to focus an image of the source whose temperature is to be determined. The filament of the standard source is placed on the same plane as this image so that the two appear superimposed on one another when viewed through the eyepiece.

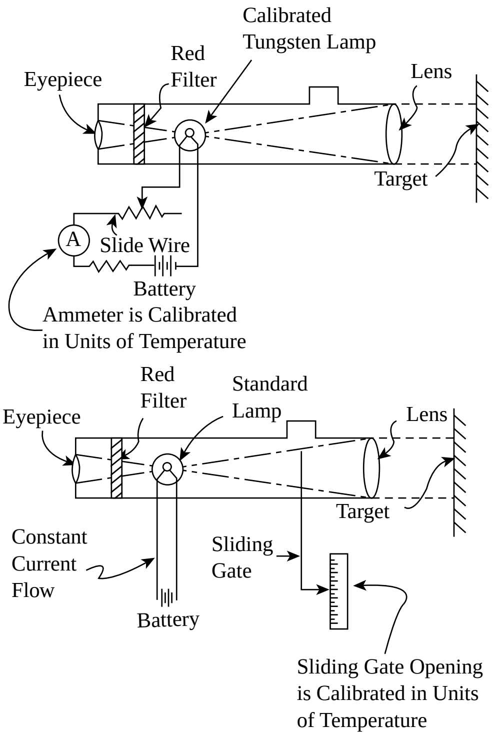

FIG. 4.9k

In optical pyrometers the target radiation is focused on a lamp and is compared to the radiation intensity of the light filament. Matching of the two intensities is determined visually by either adjusting the current flow through the calibrated tungsten lamp (left) or by changing the opening of a sliding gate (right) until the two intensities are balanced. The use of a red filter allows the comparison to be made at a specific color (wavelength).

A null type of balance is usually used where a rheostat, moving against a calibrated dial, is manually rotated to vary the current through the standard source until it just disappears into the field of the unknown. A slight modification of this principle maintains the standard source constant and varies the amount of interposing absorbing gate opening in the optical path.

The range of the manual optical pyrometer is limited on the low end to a minimum of 1400°F (760°C), since there is insufficient emission of visible light for an accurate comparison below this figure. At 2400°F (1316°C), the image would become too bright to look at directly, but filters are usually interposed to permit readings as high as 6300°F (3500°C).

The use of the human eye as the detector restricts accuracy somewhat. This is because the eye responds to both color and brightness rather than directly to energy and no two eyes are alike. However, it is possible to detect both a color and a brightness match by adjusting to the minimum difference between known and unknown.

The manual optical pyrometer is a self-contained unit with its own power supply for operating the current for the known radiant energy source. It can be mounted in place or handheld by an operator as he takes a sighting. Figure 4.9l and Figure 4.1l illustrate the relationship between distance and target size in using portable IR pyrometers.

Its advantages include that it is a light, portable, and self-contained unit of reasonable accuracy if sighted into a near-blackbody furnace. Its disadvantages are:

1. It requires the operator to adjust the temperature dial manually. It is not suitable for alarm or control functions.
2. It can only be used at relatively high temperatures where plenty of visible energy is given off.
3. It is subject to emissivity errors inherent to a narrow-band radiation pyrometer.

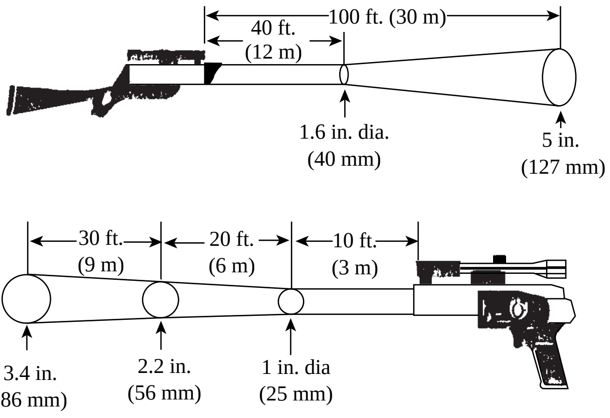

FIG. 4.9l

Target areas and distances applicable to portable infrared pyrometers. (Courtesy of Wahl Instruments Inc.)

Automatic Optical and IR Pyrometers

The automatic optical pyrometer uses an electrical radiation detector rather than the human eye, and consequently it is not limited to the visible wavelengths of the spectrum. It can reach far into the IR or the near UV using a narrow band, a two-color band, or a wide band selection in accordance with the optical system and detector.

Although there are many adaptations, the automatic optical and/or IR pyrometer operates essentially by comparing the amount of radiation emitted by the target with that emitted by an internally controlled reference source. The output is proportional to the difference in radiation between the variable source and the fixed reference. The system usually consists of two components: the optical head and the electronic amplifier.

In some models (Figure 4.9m), the optical head contains a temperature-controlled blackbody source, the required filters, a detector, a preamplifier, and an optical chopper. The chopper, driven by a synchronous motor, alternately exposes the detector to incoming and cavity radiations at a frequency that might be in the 60- to 120-cps range.

Another model (Figure 4.9n) uses the human eye to adjust the focus. Radiant energy passes through the front lens onto a dichroic mirror, which allows visible light to pass through, while IR radiation is reflected onto the detector. The operator adjusts the eyepiece for the correct focus by just filling the circle reticle plate with the visible image.

TABLE 4.9o
Uses of Automatic Optical and Infrared Pyrometers

Spectral Response (Microns)	*Main Areas of Application*
0.2–0.3	Jet Engine Rotor Blades, Vacuum Deposition
0.653	Arc Furnaces, Hot Metal Filaments, Refractory Metals
0.6–1.0	Metal Processing Industry
2.0–2.6	Textiles, Plastics, Ceramics, Food Products
3.43 ± 0.14	Thin Film Polymers, Vinyl, Nylon
4.42	Carbon Dioxide Gas
4.8–5.6	Glass, Dry Chemicals, Oxidized Metals
8–14	Background Land, Sea, Clouds, Profiles for Hot Spot Detection

The calibrate flag is solenoid-operated from the amplifier. When actuated, it cuts off the radiation coming through the lens and focuses the calibrate lamp onto the detector. The known radiation from the lamp allows the entire system to be checked.

Automatic optical or IR pyrometers are closely tied in with radiometers and other optical devices. Telescopic lenses are sometimes employed for their special effects. The instrument may have a wide-angle field of view for large area scanning or it may have a very narrow angle where the target is only 0.05 in. (1.27 mm) in diameter at 8 in. (203 mm) distance.

The entire pyrometer, optics plus amplifier, has been packaged into a single, handheld, and battery-operated device for open fieldwork. It is shaped somewhat like a pistol held in the hand and aimed at the target. Pulling the trigger (Figure 4.9l) energizes the standard reference source and the readout indicator.

A very practical application of the IR pyrometer is to use it in the 8- to 14-μm range as a hot spot detector. The operator can move quickly from one object to another looking for undesirable internal sources of heat generation. It is possible to attach a camera to the unit and take a temperature profile as a picture for immediate or future analysis.

Table 4.9o lists some applications at various spectral responses for this versatile temperature-measuring device.

DETECTORS

The detector receives the radiant energy focused on it by the optical system and generates an electric output signal in response to it. Detectors are grouped into two main classes: thermal detectors and photo-detectors.

Thermal Detectors

Thermal detectors generate an output because they are heated by the energy they absorb. This category includes thermocouples (TCs), thermopiles, pneumatic detectors, the metallic or the thermistor-type bolometers, and the pyroelectric devices. Relative to the photo-detectors, these units have a lower sensitivity, and their output are less affected by changes in the radiated wavelengths. Most are limited in their speeds of response by their mass; others, like the pyroelectric detectors, are rate-sensitive. This means that the output responds not to the temperature of the sensor, but to the rate at which it is changing. While this speeds up the response, it also requires more electronics and complexity. The use of pyroelectric detectors is limited by their need for optical shopping and their sensitivity to vibration.

Advanced thin-film thermopiles achieve response times in the 10- to 15-ms range, while silicon thermopiles also increase the output signal strength. Thermopiles and bolometers respond to radiant energy throughout the whole spectrum and therefore are more suited for detection in total radiation pyrometers. Considering speed, sensitivity, and stability, the best choice for total-radiation applications is the silicon thermopile detector.

Photo-Detectors

Photo-detectors are wavelength-sensitive and therefore are better suited to narrow-band pyrometry. The output produced by the photo-multiplier tubes and photo-detectors is not caused by heat, but by the electrical charges that are released as the radiant energy reaches the detector. The sensitivities of these detectors are in the microseconds. Their main disadvantage is instability at longer wavelengths and when operating at higher temperatures. Consequently, they are used as narrow-band detectors on short-wavelength applications and are frequently provided with cooling.

Photo-detectors can be photo-conductive, photo-voltaic, or photo-emissive devices (Figure 4.9p). The use of photo-emissive devices, such as photo-multiplier tubes, has been diminishing. Photo-conductive detectors change their resistance as a function of temperature and include the lead selenide and lead sulfide cells. They are sensitive in the 1- to 3-μm range and therefore are either used with filters (Figures 4.9k, 4.9m, and 4.9n) in narrow-band pyrometers or in medium temperature (200 to 800°F, or 93 to 427°C) measurement (Figure 4.9a) applications as wideband detectors.

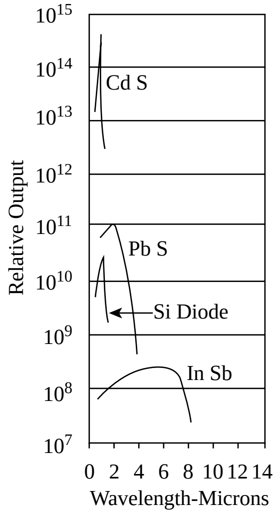

FIG. 4.9p
Response to energy of some photo-detectors.

The photo-voltaic cell's output is a function of the absorbed radiation. The most widely used cell material is silicone, but germanium and iridium antimonide are also used. The silicon cell matches the short-wavelength thermal emissions of high-temperature objects (0.5 to 1.0 μm) at temperatures from 750 to 7000°F (400 to 3870°C). The germanium cell with its 0.7- to 1.8-μm range is suited for medium temperature measurement and is more stable, more reproducible, and faster than the photo-conductive lead sulfide cells.

Iridium antimonide has been used to detect the temperature of hot glass surfaces, but due to its poor sensitivity it has been replaced in many applications with pyroelectric thermal detectors in the 8- to 14-μm range. The speed of the photo-detectors also permits them to be used for measuring the temperature of small objects moving at high speed, where relative energy output would be small.

SELECTION

In selecting a radiation pyrometer for a particular application, consideration must be given to the following:

1. The field of view, or the size-distance relationship
2. The transmission qualities of the collector system and any windows or filters in the optical path.
3. The band pass sensitivity of the detector

Figure 4.9q shows a typical wide-angle field of view. Note how the target size requirement necks down to a minimum at the focal length of lens in such a system. The narrow-angle field of view, shown in Figure 4.9r, flares out more slowly. Cross-sectional areas in either case can vary from circular to rectangular and even slot-shaped, depending on apertures in the housing design. On some designs telescopic eyepieces can magnify the radiant energy so that much smaller targets at greater distances can be viewed. Targets 1/16 in.

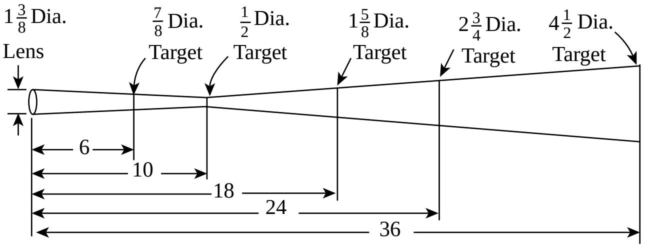

FIG. 4.9q
Sighting path of the wide-angle total radiation pyrometer.

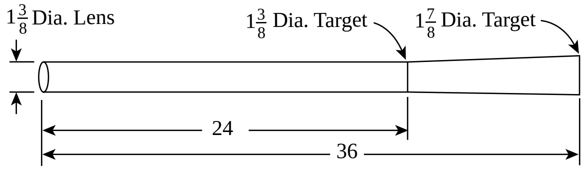

FIG. 4.9r
Sighting path of the narrow-angle total radiation pyrometer.

(1.6 mm) in diameter are feasible with the proper pyrometer design.

The physical shape of the optical system (lens of curved mirrors) and its mounting within the pyrometer housing control the sighting path, while the material from which it is made determines the optical properties. Glass does not transmit well beyond 2.5 μm and is suitable only for the higher temperatures where plenty of output is available. Other popular optical materials are quartz (fused silica) to 4 μm and crystalline calcium fluoride to about 10 μm. Lesser used (and more expensive) materials will increase the transmission even more.

Windows and filters in front of or behind the optical system can alter the transmission properties greatly. A plate glass window in front of a calcium fluoride lens, for instance, will very effectively stop the longer wavelengths which would have passed through the lens. A band pass filter might be purposely placed in front of the detector to cut off unwanted wavelengths.

INSTALLATIONS AND ACCESSORIES

The installation of an IR thermometer requires attention to detail to ensure successful operation. Figure 4.11 has illustrated some of the problems with installation of IR thermometers. Ideally, a clear unobstructed line of sight is required and the target has to be large enough to fill the cone of vision. The spot size required is related to the distance to the sensor and the user should consult the manual for details.

Solid obstructions have to be removed or eliminated from the field of view by possibly aiming the instrument at a different angle or by using a fiber optic remote sensor system. For applications with sighting windows, the instrument must be selected to use a wavelength that will pass through the window material unchanged. The window also must be large enough so as not to obstruct the cone of vision, and it has to be kept clean by possibly using an air purge. Smoke, steam, and dust all cause temperature fluctuations.

The temperature-measuring requirement for industrial applications involves either the surface temperature of equipment or objects that are out in the open or the temperature inside vessels, pipes, and furnaces. Surface-temperature-sensing pyrometers can be portable (Figure 4.9l) or permanently installed. When internal temperatures are of interest, one can look into the process through windows (Figure 4.9s). In such installations, the pyrometer can be mounted on an adjacent pedestal or supported by a bracket attached to the vessel, as long as the pyrometer is shielded from excessive heat. It is advisable to provide an internal purge to periodically clear the dirt that is likely to accumulate on the window.

When a pyrometer is installed through the wall of a furnace a large number of installation-related accessory components are needed. These can easily double the basic cost of the pyrometer itself. In Figure 4.9i, the pyrometer sensor head and its aiming tube, or telescope, are mounted inside the cooling jacket. The coolant flow required is a function of the ambient temperature in the area and varies from 0.2 GPH (0.8 1ph) at 150°F (60°C) all the way up to 20 GPH (76 1ph) at 600°F (315°C). Proceeding to the left on Figure 4.9i, the next component is the air purge assembly followed by the safety shutter, or slide gate shutter, which allows the sealing of the furnace when the pyrometer is removed.

Sighting the pyrometer on the target through a tube purged by a clean and nonabsorbing gas minimizes the need for cleaning the lenses and windows. When interference from flames or other sources cannot be filtered out optically, the purged sighting tube, shown on the left of Figure 4.9i, can be extended almost to the target. In this way the sighting tube allows a more accurate targeting on the point of interest and also makes purging more effective as the air fills the tube.

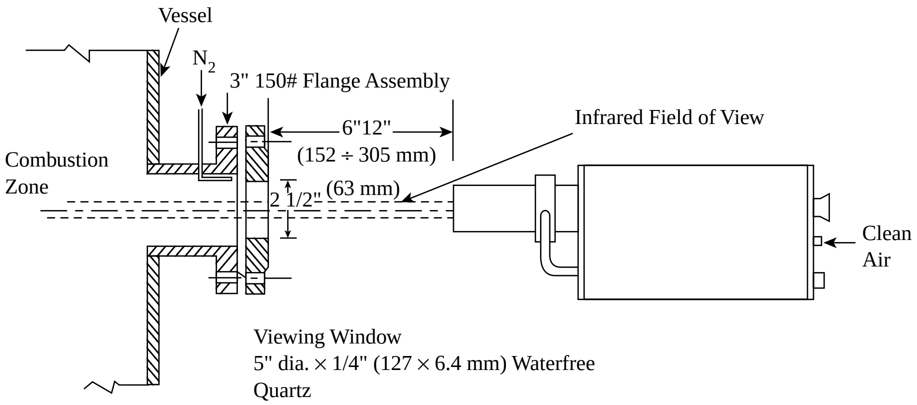

FIG. 4.9s
Radiation pyrometer installed on a combustion process. (Courtesy of Williamson Corp.)

This also reduces the influence of smoke and dust in the atmosphere between the sensing head and the desired target and reduces unwanted background radiation. Sighting tubes are available in different lengths and in constructions of Inconel (for up to 2100°F, or 1105°C), silicon carbide (up to 3000°F, or 1650°C), refractory alumina (up to 2900°F, or 1600°C), or aluminum or stainless steel (below 600°F, or 315°C).

Closed-end target tubes (also shown in Figure 4.9i) are also made of the above listed materials and are used on liquid service or in other processes where the inside temperature of the target tube sufficiently represents the process temperature. In addition to sighting tubes or in place of target tubes, it is possible to form the object of interest into a better or ideal emitter. This is done by forming the object into a concave shape or drilling a hole in the target and sighting the pyrometer onto that hole.

ADVANCES AND NEW DEVELOPMENTS

New technologies such as microprocessors, fiber optics, lasers, buses, and networks have also changed radiation pyrometry. One important new development is the availability of the laser reflectometer (Pyrolaser is a trademark of Pyrometer Instrument Co.) which can measure the emissivity of the process material at the same location, temperature, and wavelength as used in the pyrometer. This eliminates the potential for emissivity error by allowing its value to be continuously and automatically corrected. This device also helps in overcoming errors caused by radiation from hotter surfaces.

This is done by taking a radiant measurement of the hotter refractory surface and compensating for it by calculating its reflectivity as: $R = 1 - E$. As of this writing, the laser-based emissivity compensator operates at only one wavelength (0.865 μm) and therefore is effective only if that is the wavelength of interest. However, it is likely that with the passage of time it will become available at other wavelengths also.

Other advances include the increase in the number of spectral bands available, the reduction in the required target size (1 mm diameter), and the increase in the distance-to-target ratios, which can exceed 200:1. The intelligent pyrometer is more than a sensor—it is a measurement system that routinely provides linear outputs and digital displays and can minimize ambient effects. Intelligent units using two pyrometers are also used to correct for background radiation.

Another area of technological innovation has been in the field of line-scanning pyrometers. These have been developed to monitor the surface temperatures of cement kilns to indicate internal material buildup or refractory deterioration. As the pyrometer scans left to right while the kiln rotates on its horizontal axis, the pyrometer scans its total surface and feeds this information into a small computer for processing. By the same technique, moving sheets of paper, glass, steel, or plastic can be scanned.

There is a growing market for line scanners that can produce a two-dimensional thermal image. This type of IR thermometer is used to measure wide webs such as hot strip steel, glass, plastic, and paper. This instrument utilizes one detector and two 45-degree mirrors with one mirror rotating and scanning over a 90° angle as shown in Figure 4.1o. For moving targets, the instrument uses a software technique to create two-dimensional thermal images of the moving web. The software provides temperatures at any location on the web and can provide output signals that can be used for closed loop control or stored for future review.

Thermal imagery is a rapidly growing application of IR technology that is used on some automobiles and by military and law enforcement in night vision applications. Architectural analysis of building insulation, surveillance, and quality control are other uses. This imaging system is an IR thermometer that uses a detector called a focal plane array instead of a single sensor. Its functionality is similar to a digital camera, except that, instead of capturing photographic images, each pixel measures temperature. A two-dimensional image is created using software resident within the system. The detector can have as many as 76,000 pixels. The image of the temperature profile can be used for closed loop control of processes, such as detecting defective personal computer boards, or stored away for future analysis.

SUMMARY

Most manufacturers of IR instruments continue to refine existing products and offer enhanced capability with newer models. One new model offers bidirectional digital networking communications. Multiple sensors can connect to host systems for monitoring, control, and diagnostics. The design engineer is strongly urged to consult with multiple vendors to get recommendations for selecting the proper instrument for each application.

The broadband pyrometer is used generally in industry for readout and automatic control. It can cover wide temperature ranges and is the least expensive of the three types. Narrow-band and two-color pyrometers are used, where necessary, to minimize the emissivity effects and for special applications where it is desirable to select the particular band pass.

The prospective user of a radiation pyrometer should consider the following points:

1. Target temperature, low, normal, and high limits.
2. Minimum target size and distance factors.
3. Target material and emittance.
4. Angle of observation.
5. Is target stationary or moving? If moving, will the speed of response of the pyrometer be fast enough?
6. Atmospheric conditions between target and detector.
7. Ambient temperature.

8. Can pyrometer sight directly on target or must it sight through a sealed auxiliary window such as required for vacuum or pressure?
9. Is scale to be read directly in temperature units or will an arbitrary reading be satisfactory?

Advantages

IR thermometers are ideal for moving targets such as glass, plastic, and steel. They do not interfere with the process. They are also ideal for measuring products with very high temperatures or hostile environments. They can see through windows to measure products in a vacuum furnace or a semiconductor reactor. Infrared thermometers can measure targets as small as 0.025 in. in diameter and can respond in 10 ms to a temperature change. Other advantages of IR thermometers include:

1. They do not require physical contact with material whose temperature is being measured.
2. They have a fast speed of response—they can be used on moving targets.
3. They can look at small targets (1/16 in. or 1.6 mm in diameter) or measure the average temperature over a wide area.
4. They measure much higher temperatures than TCs.

Disadvantages

The disadvantages of IR thermometers include:

1. They are more fragile and costlier than TCs, resistance temperature detector, or thermistors.
2. They have a nonlinear scale shape, approximating the 4th power of the temperature.
3. Their emissivity of target may cause a low temperature reading if not corrected.
4. A relatively wide temperature span is required.

DEFINITIONS

Absorbance (A)—Ratio of radiant energy absorbed by a body to the corresponding absorption of a blackbody at the same temperature. Absorbance equals emittance on bodies whose temperature is not changing. ($A = 1 - R - T$, where R is the reflectance and T is the transmittance.)

Band pass filter—An optical or detector filter that permits the passage of a narrow band of the total spectrum. It excludes or is opaque to all other wavelengths.

Blackbody—The perfect absorber of all radiant energy that strikes it. The blackbody is also a perfect emitter. Therefore, both its absorbance (A) and emissivity (E) are unity. The blackbody radiates energy in predictable spectral distributions and intensities which are a function of the blackbody's absolute temperature (Figure 4.9a). A blackbody can be configured as shown in Figure 4.9t.

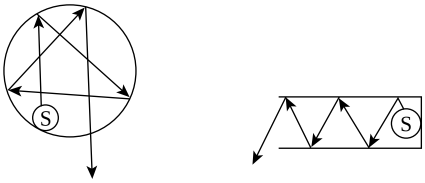

FIG. 4.9t
Emissivity of blackbody sources in the laboratory is around 0.99.

Bolometer—Thermal detector that changes its electrical resistance as a function of the radiant energy striking it.

Brightness pyrometer—Uses the radiant energy on each side of a fixed wavelength of the spectrum. This band is quite narrow and usually centered at 0.65 μm in the orange-red area of the visible spectrum.

Detector—A device that measures the amount of energy radiated by an object. It can be a thermal detector or a photodetector. Thermal detectors respond to radiation by changing their volume, capacitance, or generation of millivoltages; they can be TCs, thermopiles, pneumatic detectors, or bolometers. Their common feature is their relatively slow response. Photodetectors are semiconductors that produce a signal in proportion to the photon flux that strikes them.

Emissivity or emittance (E)—The ratio of radiant energy emitted by an object divided by the radiant energy which a blackbody would emit at that same temperature. If the emittance is the same at all wavelengths, the object is called a gray body. Some industrial materials change their emissivity with temperature and sometimes with other variables also. Emissivity always equals absorption and it also equals 1 minus the sum of reflectance and transmittance ($E = A = 1 - T - R$).

Gray body—An object having an emittance of less than unity, but this emittance is constant at all wavelengths (over that part of the spectrum where the measurement takes place). This means that graybody radiation curves are identical to the ones shown in Figure 4.9a, except that they are dropped down on the radiated power density scale.

Infrared—That portion of the spectrum whose wavelength is longer than that of red light. Only the portion between 0.7 and 20 μm gives usable energy for radiation detectors.

Mechanical emissivity enhancement—Mechanically increasing the emissivity of a surface to near-blackbody conditions (using multiple reflection).

Micron—0.001 mm. 10,000 Å. A unit used to measure wavelengths of radiant energy.

Narrow-band pyrometer—A radiation pyrometer that is sensitive to only a narrow segment of wavelengths within the total radiation spectrum. Optical pyrometers are one of the devices in this category.

Optical pyrometer—Also called a brightness pyrometer, it uses a narrow band of radiation within the visible range (0.4 to 0.7 μm) to measure temperature by color matching and other techniques.

Photodetector—Measures thermal radiation by producing an output through release of electrical changes within its body. They are small flakes of crystalline materials such as CdS or InSb which respond to different portions of the spectrum, consequently showing great selectivity in the wavelengths at which they operate.

Ratio pyrometer—See **two-color pyrometer**.

Reflectance or reflectivity (R)—The percentage of the total radiation falling on a body which is directly reflected without entry. Reflectance is zero for a blackbody, and nearly 100 percent for highly polished surface. ($R = 1 - A - T$, where A is the absorbance and T is the transmissivity.)

Spectral emissivity—The ratio of emittance at a specific wavelength or very narrow band to that of a blackbody at same temperature.

Thermopile—Measures thermal radiation by absorption to become hotter than its surroundings. It is a number of small TCs arranged like the spokes of a wheel with the hot junction at the hub. The TCs are connected in series and the output is based on the difference between the hot and cold junctions.

Total emissivity—The ratio of the integrated value of all spectral emittances to that of a blackbody.

Transmittance or transmissivity (T)—The percentage of the total radiant energy falling on a body, which passes directly through it without being absorbed. Transmittance is zero for a blackbody and nearly 100 percent for a material like glass in the visible spectrum region. ($T = 1 - A - R$, where A is the absorbance and R is the reflectance.)

Two-color pyrometer—Measures temperature as a function of the radiation ratio emitted around two narrow wavelength bands. Also called ratio pyrometer.

Wideband (total) pyrometer—A radiation thermometer that measures the total power density emitted by the material of interest over a wide range of wavelengths.

Flow Sheet Symbol

Applications:	Industrial and laboratory thermometry including the definition of the International Temperature Scale between the oxygen and antimony points, from –297 to 1167°F (–183 to 631°C)
Alpha Curve:	The relationship between the resistance change of a resistance temperature detector (RTD) vs. temperature. In the European alpha curves, the alpha value is 0.00385 Ω/°C; in American curves it is 0.00392.
Ranges:	–328 to 1532°F (–200 to 850°C) is IEC standard for platinum RTDs and –330 to 600°F (–200 to 320°C) for nickel RTDs, Practical applications are usually limited to –328 to 1000°F (–200 to 537°C) (refer to Tables 4.10b and 4.1c).
Spans:	10 and 1100°F (6 and 610°C) for platinum, and 20 and 600°F (12 and 340°C) for nickel. For differential temperature transmitters: 10 and 50°F (6 and 28°C) for platinum, and 20 and 100°F (12 and 56°C) for nickel.
Stability:	Zero and span drift is usually within 0.1% of span for a 6-month period (and frequently longer).
Standard Resistances:	100 Ω at 32°F (0°C) is most common, but elements are available from 10 to 1000 Ω.
Linearity:	Platinum and copper are more linear; nickel and nickel/iron (Balco^{TM}) are less so. The use of gold and silver RTDs is limited to cryogenic temperatures.
Sensitivity:	0.1 to 10 Ω/degree
Inaccuracy:	The error just for a Class A sensors is from ±0.06°F (±0.03°C) or 0.01% of span and for a Class B sensor it is from ±0.6°F (±0.3°C) or 0.12%. In determining the total system error, one must also consider the error contribution of the signal conditioning electronics. The total system error is usually 0.15% of span for platinum and 0.25% of span for nickel RTD elements in standard transmitters. Intelligent transmitters reduce that to 0.05% of span or to about 0.18°F (0.1°C), whichever is higher.
Costs:	Elements alone range from about $35 to $80; RTD assemblies, including thermowells, are from $100 to $250. An RTD sensor with an integral temperature transmitter may cost anywhere from $300 to $2000 depending on its level of intelligence and other features.

In 1821 Sir Humphry Davy discovered that the resistivity of metals depends on their temperature. The application of this property using platinum was first described by Sir William Siemens at the Bakerian Lecture of 1871 before the Royal Society in Great Britain. The necessary temperature limitations and methods of construction were established by Callendar, Griffiths, Holborn, and Wein between 1885 and 1900.

RESISTANCE TEMPERATURE DETECTOR BASICS

Resistance thermometry is based upon the increasing electrical resistance of conductors with increasing temperature (Figure 4.10a). Resistance temperature detector (RTDs) are constructed of a resistive material with leads attached and usually placed into a protective sheath. The resistive material may be platinum, nickel, or copper, with the most common by far being platinum. Platinum resistance thermometers are now the international standard for temperature measurements between the triple point of hydrogen at 24.86°R (13.81 K) and the freezing point of antimony at 1167.35°F (630.75°C). The laboratory application of platinum resistance thermometers recognizes the unsurpassed stability and repeatability of this noble metal sensor. Platinum resistance thermometers for rugged industrial applications also retain their advantage over other conductors.

Detectors and Their Applications

The conductors used for resistance thermometry include platinum, nickel of various purities, 70% nickel/30% iron (Balco), and copper, listed in order of their decreasing temperature range (Tables 4.10b and 4.1c). These conductors are all available as fine wire for sensor winding. For many years wire-wound construction, where a fine highly purified platinum wire was wound around a ceramic mandrel to

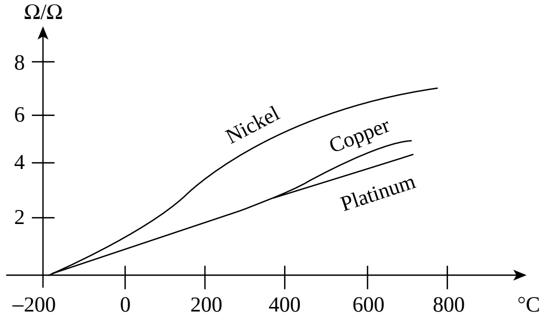

FIG. 4.10a
The temperature coefficient of platinum is 0.00392 ohms/ohms°C at 0°C (the alpha value in the USA) and 0.00293 at 800°C. The alpha value used in Europe is the average value between 0 and 100°C, which is 0.00385. Therefore (as shown), a platinum element of 1 ohm resistance at –200°C will increase its resistance to approximately 4.0 ohm as the temperature rises to 800°C.

TABLE 4.10b
RTD Material Properties of 0°C and Available Temperature Ranges

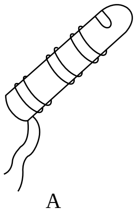
Metal	*Temperature Coefficient of Resistance (Ohms/Ohm°C)*	*Electrical Resistance Per Circular Mil Foot (Ohms)*	*Commercially Available Temperature Ranges °F (°C)*
Platinum	0.00392	59.00	–328 to 1532 (– 200 to 850)
Nickel	0.00672	36.00	–330 to 600 (–196 to 316)
Copper	0.0038	9.26	–320 to 250 (–196 to 120)
Tungsten	0.0045	30.00	—
Gold	0.0040	13.00	—
Silver	0.0041	8.80	—

produce the element, was the most common type. Wire-wound sensors are still the better choice for very high, very low, or widely cycling applications.

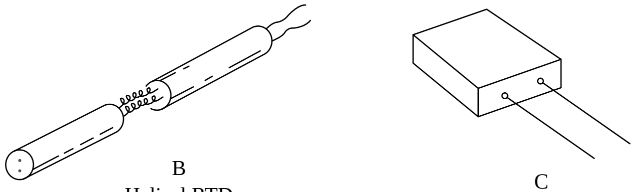
Platinum is also available as a deposited film sensor, which is much less expensive, and platinum, nickel, and Balco are all available in foil-type sensors. Thin film construction uses a precision laser to cut the sensor elements from a layer of platinum deposited over a stable ceramic base material. The sensor has very low mass and is therefore highly resistant to vibration and has a much faster speed of response than a wire wound sensor. All share in varying degrees the characteristics of repeatability, high temperature coefficient, long-term stability, and linearity over a useful temperature range. While no sensor material surpasses platinum in overall performance, each has at least one characteristic that may encourage its selection.

The application of the standard platinum RTD as a temperature standard (SPRT), differs considerably from industrial practice.[1] The temperature standard is 25.5 Ω at the ice point to stay within the range of practical Mueller bridges while providing a nominal 0.1 Ω/°C sensitivity. Wire-type platinum thermometers were constructed in a manner to be almost totally strain-free, using very lightly supported wire of larger size (and cost) than typical in an industrial thermometer (Figure 4.10c).

Temperature coefficients near the theoretical maximum for pure platinum and maximum thermal stability can be obtained at the expense of fragility and large size. The industrial platinum RTD offers ruggedness at a negligible loss in temperature coefficient compared to the standard SPRT, while retaining the best stability and repeatability available in industrial thermometers over a wide temperature range.



A
Sealed Bifilar Winding



B
Helical RTD

C
Film RTD

Fig. 4.10c

RTD elements can be made by winding platinum wire on a glass or ceramic bobbin and sealing with molten glass (A), by threading a platinum helix through a ceramic mylinder (B), or by depositing a platinum film on a ceramic substrate. (A) is limited by the strain induced at higher temperatures, (B) is not suited for extreme vibration, and (C), while small, fast, and inexpensive, is also less stable than the others.

INDUSTRIAL RTD CONSTRUCTION REQUIREMENTS

All resistance thermometers require the following considerations in their manufacture. Wire-wound sensors must be supported on mandrels closely matching the wire in thermal expansion to minimize strain effects. Additional assembly materials, such as cements, should not introduce additional strain in the operating temperature range. The final assembly must be in a stable, annealed condition, trimmed to the required resistance tolerance. Only high-purity materials and clean assembly methods should be used to avoid sources of contamination that might degrade the sensor.

All internal connections should be welded, and connecting leads should be chosen for the required temperature capability and avoidance of thermoelectric junctions. To realize the ruggedness of fully supported elements in the total sensor assembly, all internal connections should be anchored and isolated from effects of thermal and mechanical strains, including shock and vibration. The same requirements apply when deposited film or foil-type resistance elements are used (Figure 4.10c).

For equivalent performance in their respective temperature ranges, base metal RTDs cost the same as 100 ohm platinum RTDs. Construction requirements and materials cost are similar. Base metal RTDs have a materials cost advantage at higher resistance values compared to wire-wound platinum sensing elements. Thin film platinum elements erase this advantage.

Platinum RTDs

In the case of platinum RTDs, the full supported rugged construction using "reference grade" wire has a temperature coefficient (alpha) over the interval 32 to 212°F (0 to 100°C of between 0.00387 and 0.003915 Ω/Ω°C, depending on the manufacturer. Compared to 0.003927 Ω/Ω°C on a SPRT, the reduction in sensitivity is insignificant. For best accuracy, the user should be aware of or specify the actual temperature coefficient. One common value available from most manufacturers is 0.003902 Ω/Ω°C. This is the result obtained for windings on pure alumina mandrels.

The relationship between the resistance change of an RTD vs. temperature is referred to as its alpha curve. The most commonly used is the European curve that has an alpha of 0.00385 Ω/Ω°C. The American curve has an alpha of 0.00392 Ω/Ω°C. The instrument used with the RTD must be configured to use the same alpha curve as the RTD or serious errors will occur.

Standard platinum industrial alpha curves (based on slightly doped platinum wire) have been adopted by most European countries. These curves are all substantially based on an alpha of 0.00385 Ω/Ω°C. This result is reproducible by manufacturers everywhere, and the so-called international grade platinum curve is the most widely used curve, even in the United States. An exception is temperatures below –320°F (–196°C) (LN2), where only reference grade wire RTDs are well characterized.

Platinum RTDs using thick or thin films are also available to the same curve as international grade wire-wound sensors. Performance is often equivalent to wire-wound sensors except maximum temperature may be reduced. Wire-wound platinum RTDs are most common at 100 ice point resistance, with 200 and 500 Ω available at additional cost. Using thin films, ice point resistances of 100 and 1000 Ω are available at the same cost with slightly lower alpha specified at 1000 Ω.

Base-Metal RTDs

Second in usage to platinum is high-purity nickel, which offers the highest temperature coefficient, second-highest temperature range, and lower assembled cost than wire-wound platinum at high resistance values. Nickel RTDs have declined in use over the years primarily due to their limited range vs. the more popular platinum RTDs.

The useable range is –112 to 608°F (–80 to 320°C). Most transmitters and alarm trips still offer the capability to accept nickel RTD inputs. The most common are 120 and 500 Ω resistance, with 1000 Ω available. Nickel is not linear, because it increases its temperature coefficient as temperature rises (Figure 4.10a). Nickel is also highly strain-sensitive and requires great care by the manufacturer to obtain good interchangeability. The temperature coefficient of nickel is highly influenced by both purity and state of anneal. In addition, lower purity nickel, such as 99% nickel (no longer available) or ballast nickel, has been used and provides a somewhat lower temperature coefficient.

The maximum temperature of nickel sensors should not be much more than 500°F (260°C). There is no internationally recognized standard curve for nickel sensors, although there are national standards, and several manufacturers in the United States can provide sensors to a common curve characterized by an alpha temperature coefficient between 32 and 212°F (0 and 100°C) of 0.00672 Ω/Ω°C.

Balco Third in usage is the 70% nickel/30% iron alloy trade named Balco. The sole basis for its use is a very high specific resistance, which makes possible the production of very high resistance windings without increasing size. Ice point resistances are commonly 200 or 10,000 Ω. It has the second-highest temperature coefficient, third-highest temperature capability, and, like pure nickel, is nonlinear with an upward bending R vs. T curve. There is no recognized standard curve for Balco sensors.

Copper Last in usage is pure copper, which is generally available only at 10 or 100 Ω ice point resistance values due to the low specific resistance of the winding wire. Copper RTDs are most commonly used to sense the winding temperature of motors, generators, and turbines. Connecting them to an alarm trip provides an over-temperature shut down function. Historically 10 Ω copper RTDs were the norm, but many users have now opted for 100 Ω or even 1000 Ω units to get higher resolution. They have a useful range of –58 to 482°F (–50 to 250°C).

Copper's temperature coefficient is almost the same as platinum and it is very linear above the ice point. Copper in bifilar windings (Figure 4.10c) is used in electrical machinery due to very low inductive or capacitive reactance, but platinum can also be used. Some traditional applications have also exploited the linearity of copper sensors in making narrow-range temperature-difference measurements where two sensors are connected on opposed arms of a bridge. There is no internationally recognized standard curve for copper, although some national standards do exist.

Relative performance of industrial temperature sensors of all types is shown in Table 4.10d. RTDs, especially platinum RTDs, are clearly superior for temperature measurement requirements below 1000°F (540°C).

MEASURING THE RTD RESISTANCE

By measuring the resistance of the RTD element one can determine the process temperature if the change in total resistance measured is affected by nothing but the process temperature. In actual installations, the RTD element is connected by two, three, or four lead wires to the readout or transmitting instrument.

Two-Wire RTDs

There are very few applications for a two-wire RTD since the error introduced by the leads can cause significant error. If a null-balance bridge is used, the circuit can be as shown in Figure 4.10e. Here the temperature coefficients of resistors R_1, R_2, and R_3 are nearly zero, and the value of R_3 is adjusted until the current flow of G or the voltage read by a digital voltmeter (DVM) is zero. Under these conditions the value of R_3 equals the unknown resistance of the measuring leg (A + B + RTD).

Assuming that the resistance of the RTD (at 0°C) is 100 Ω and assuming that the element is platinum, the resistance of the 100 Ω RTD elements will change by 0.385 Ω/°C. If 500 ft (152 m) of 20 gauge copper lead wire was used to connect the RTD to the bridge, this adds 10 Ω to the total resistance (5 Ω/leg). At null balance $R_3 = A + B + RTD = 10\,\Omega + RTD$. With a temperature coefficient of 0.385/°C these extra 10 Ω will contribute a measurement error (as an increase in process temperature) of 10/0.385 = 26°C.

The previous example illustrates the relatively large lead-wire error in a two-wire RTD installation, and for this reason such installations are not used if accurate temperature measurement is desired and the length of the lead wires is more than a few inches. When the transmitter is mounted directly on the thermowell (Figure 4.10f), the lead-wire length is so small that the resulting error is not very significant. Yet even

in these configurations most suppliers will provide a three-wire RTD to minimize the lead-wire error.

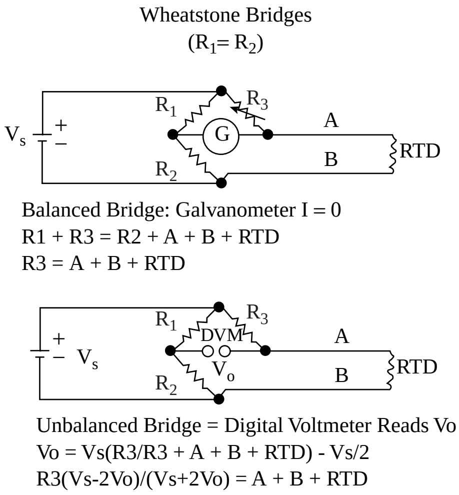
Three-Wire RTDs

Measurement circuits that accept three-wire inputs minimize the effects of lead wire resistance as long as the outer legs are equal. However factors such as terminal corrosion and loose connections can still create significant differences between the lead resistances seen by the measurement circuit, because only one ohm of difference between the legs results in an error of 4.7°F (2.6°C).

As shown in Figure 4.10g, the lead wire C acts as a sense lead and is part of both halves of the bridge and therefore cancels out at balance. The lead wires A and B are in different halves of the bridge and therefore at null balance $R_3 = B - A + RTD$. Therefore, now the lead-wire error is no longer the total lead resistance $(A + B)$, but only the difference between their resistances $(B - A)$.

This is a major improvement in reducing the lead-wire error and is sufficient for the needs of most industrial applications where the lead-wire lengths are short. However, it is not a complete solution because wire resistances are guaranteed only within a 10% tolerance; therefore, if A and B are identical wires of identical lengths, their resistances can still differ within the 10% tolerance. So if nominally they both are 5 Ω, in reality one could be 4.5 and the other 5.5 Ω. If this were the case, the difference of 1 Ω would still introduce an error. With a 100-Ω platinum RTD that error would correspond to $1/0.385 = 2.6$°C.

If the purpose of the temperature measurement is to calculate the exothermic heat release of a batch reactor, this error might still be too much. In that application the temperature rise through the reactor jacket is about 5°F and the span usually selected for the differential temperature transmitter is 10°F (5.6°C). In order to identify the end point accurately, the total heat release must be determined to within 0.5% maximum error. Because the total heat release is calculated



Balanced Bridge: Galvanometer I = 0
R1 + R3 = R2 + A + B + RTD
R3 = A + B + RTD

Unbalanced Bridge = Digital Voltmeter Reads Vo
Vo = Vs(R3/R3 + A + B + RTD) - Vs/2
R3(Vs-2Vo)/(Vs+2Vo) = A + B + RTD

FIG. 4.10e
Null-balance bridge-type two-wire RTD installations showing a galvanometric (G) readout in a balanced condition (left) and a DVM readout in an unbalanced condition (right) where the DVM reads V_0 volts.

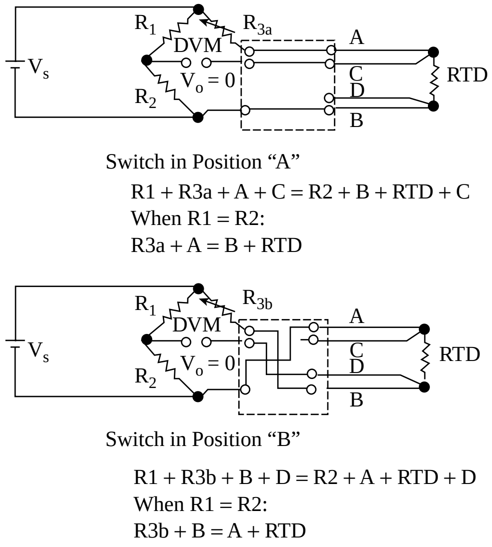
When bridge is balanced: R1 + R3 + A + C = R2 + B + RTD + C
If R1 = R2 this becomes: R3 = RTD + B + A = RTD

FIG. 4.10g
In a three-wire null-balance bridge, the lead-wire effect is reduced to the difference between the resistances of the two lead wires (B − A).



Switch in Position "A"
R1 + R3a + A + C = R2 + B + RTD + C
When R1 = R2:
R3a + A = B + RTD

Switch in Position "B"
R1 + R3b + B + D = R2 + A + RTD + D
When R1 = R2:
R3b + B = A + RTD

FIG. 4.10h
If the leads of a four-wire null-balance bridge are switched as shown and the resulting two equations are added up, the lead-wire effects are eliminated and the resistance of RTD = (R_{3a} + R_{3b})/2.

by multiplying coolant flow with its temperature rise, the flowmeter itself will contribute 0.25% in error and therefore one must measure the temperature rise within 0.25%.

An error of 0.25% over an *actual* measurement of 5°F is 0.0125°F (0.007°C). This is such a small error limit that even three-wire RTD transmitters may not meet it (their usual error limit is about 10 times higher). For this reason, in laboratory situations or for other high-precision measurements, one might consider the use of four-wire systems, which completely eliminate the lead-wire effect.

Four-Wire RTDs

Using a four-wire measuring circuit eliminates the above problem. The design engineer should consider any of the leading brands of temperature transmitters that accept four-wire RTD inputs. Direct connection to remote devices with three-wire extension cable will often produce errors that can be significant and will vary with environmental conditions.

Four-wire RTDs can be connected either to a null-balance bridge or to a constant current source. Both will be described here. Figure 4.10h illustrates a four-wire null-balance bridge. It operates by switching a triple-pole double-throw switch and making alternate null-balance measurements in the two configurations. In one configuration, lead A is measured together with the RTD resistance, while in the other configuration it is

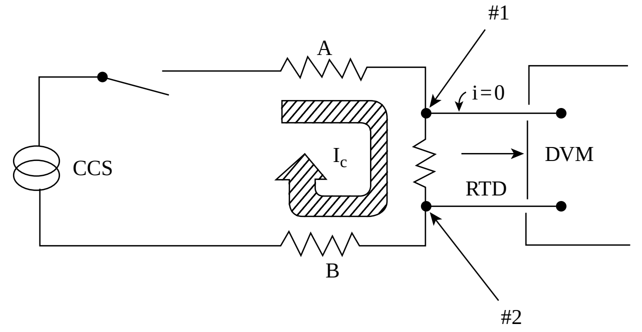


FIG. 4.10i
Offset compensated four-wire RTD measurement using CCS and DVM as readout.

lead B, so they cancel out *completely* and the actual value of the RTD resistance is determined as $(R_{3a} + R_{3b})/2$.

Microprocessors and advanced electronics make it feasible to provide this level of sophistication, but complexity still costs money, so these designs are relatively expensive; in addition, they are still limited by contact resistance considerations. Even the best (gold-plated) switching contacts contribute some contact resistance. The difference between these resistances does introduce some miniscule errors whenever one uses a switching configuration to make a resistance measurement.

Another way to eliminate the lead-wire error is to use a constant current source (CCS) in a four-wire RTD configuration. These miniaturized CCS packages are available at relatively low costs and provide an accurately constant current flow of about 2 mA or less to avoid self-heating errors. As shown in Figure 4.10i, in this configuration the bridge itself is replaced by a DVM, which measures the resistance of only the RTD and is insensitive to lead-wire effects as there is no current flow through the connecting wires. The source lead resistances (A and B) contribute no error because the voltage drop is not measured along them.

For the maximum in precision, it would be prudent to make sure that the current flow (I_c) through the RTD is constant and that the DVM does draw any current ($i = 0$), and also to cancel out the thermocouple (TC) junction voltages at points #1 and #2. This is necessary because as the two wires (platinum RTD and copper lead) at #1 and #2 form TC junctions, the millivoltages they generate will also be registered by the DVM. This effect is eliminated by offset compensation. The offset voltage generated by the unintended TC junctions is measured by the DVM when the CCS circuit is opened and, therefore, $I_c = 0$. The smart RTD readout memorizes the voltage sensed when no current is flowing and corrects the total reading by that amount when the CCS is connected and I_c is about 2 mA.

In general, two-wire RTDs are only used in heating, ventilation, and air conditioning (HVAC)-type secondary applications, three-wire RTDs are still used in some processing industries, and four-wire RTDs are used in most high-precision services or in the laboratory.

SENSOR CONSTRUCTION

Figure 4.10c illustrates some of the RTD sensor elements. The most popular industrial designs are fully encapsulated. In these units a 0.001 in. (0.025 mm) diameter or smaller platinum wire is wound into a coil and is inserted in the multiple bores of a ceramic tube or is wound directly on the outside of a ceramic tube. The ceramic material is usually 99.7% pure aluminum oxide, and the winding is completely embedded and fused onto or into the tube. The RTD thermometers are in direct competition with TCs and therefore are available with the same features.

The elements are manufactured with a protective sheath that provides a hermetic seal to protect the sensor from moisture and/or contamination. These protective sheaths are offered in a variety of lengths to provide the proper insertion into the process to obtain a representative measurement. The sheathed elements are often installed into a protective well to isolate the sensor from the process. One manufacturer offers a universal model that has a 1-in.-long sheath but is provided with long leads within a spiraled spring (Figure 4.10j). The leads can be cut in the field to fit the length of the thermal well, reducing the requirement for stocking a variety of sensors in varying lengths.

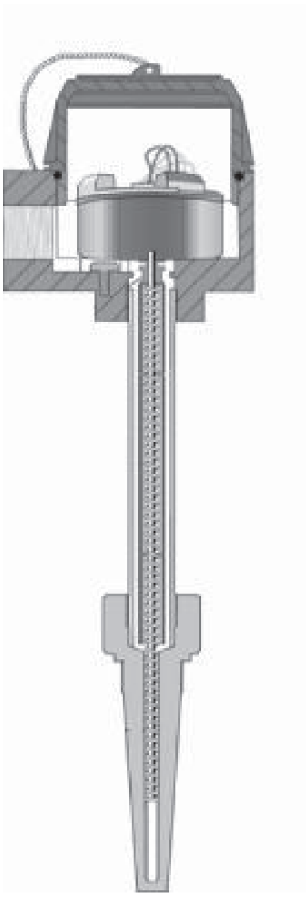

FIG. 4.10j

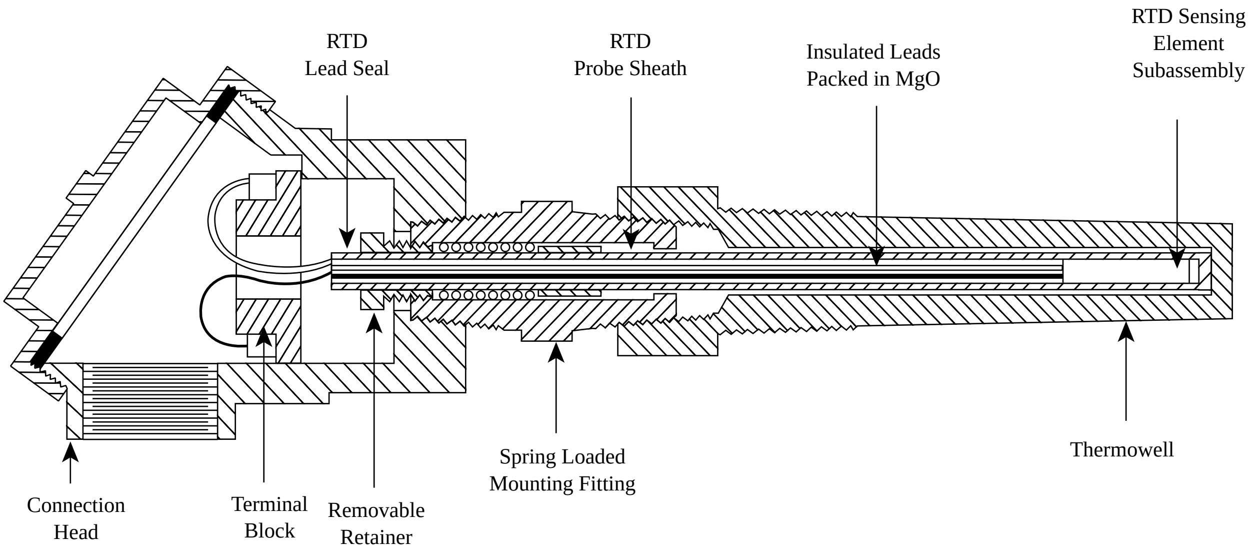

FIG. 4.10k
Industrial RTD/thermowell assembly.

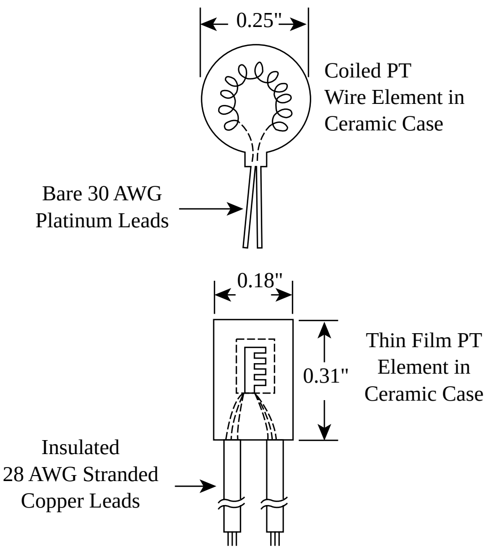

FIG. 4.10l
RTD surface temperature sensors.

Thermowells

Figure 4.10k illustrates a conventional industrial RTD sensor provided with a protective thermowell and fixed length leads. Figure 4.10l shows two designs of surface-temperature-sensing RTDs. Other surface mounting configurations are illustrated in Figures 4.1t and 4.1v. The packaging of the RTD sensor depends on the application. For example, the measurement of temperature inside glass-lined chemical reactors requires special configurations. Figure 4.10m shows an RTD element that can be installed either through the bottom discharge valve of the reactor or at the tip of the reactor baffle. The 63.2% response time to a step change is about 7.5 s; the 95% response time is about 28 s.

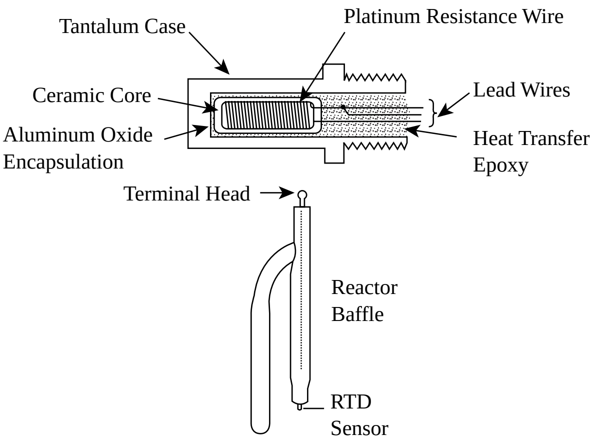

FIG. 4.10m
RTD sensor for glass-lined reactors. (Courtesy of Pfaudler.)

One limitation of the early RTDs (relative to TCs) was size. RTDs tended to be relatively bulky, because in order to obtain the required resistance (usually 100 Ω), the length of the sensor wire must be relatively long, frequently several feet. This limitation has been overcome by the film-type designs (Figure 4.10c), which are suited for miniaturization.

The 63.2% time constants of different RTDs (without thermowells) are given in Figure 4.10n. One might approximate the time constant of the final assembly by doubling the time constants for each layer of material added in the process of installation.

Installation

In terms of installation, RTDs require the same precautions as TCs. The best installation practice is to place all electronics directly on top of the thermowell (Figures 4.10f and 4.10j)

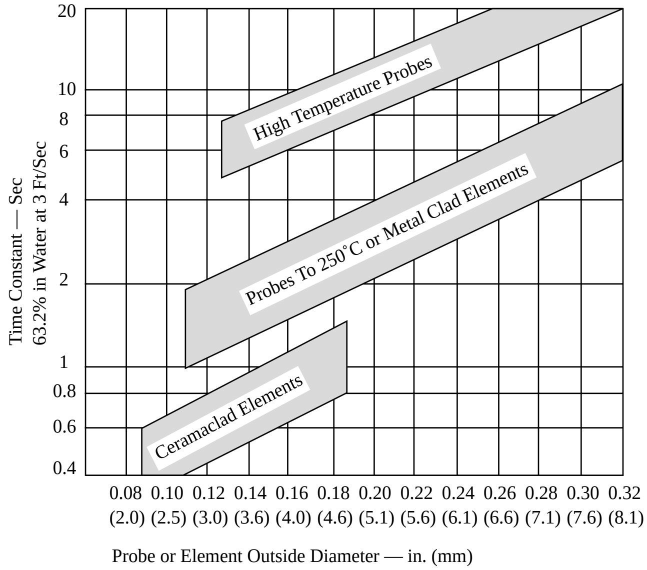

FIG. 4.10n
Response time of typical resistance temperature sensor.

and thereby eliminate lead-wire and noise effects. If for some reason this cannot be done, the lead wires should be twisted and shielded; the wires should also not be stressed, strained, or made to go through steep gradients. The extension wire should be low resistance (large diameter), and the readout instrument should be guarded.

For further discussions on the general topics of surface and solids temperature measurement, refer to Section 4.1 and Figures 4.1t and 4.1v.

TRANSMITTERS

The typical performance capabilities of different RTD transmitters are summarized in Table 4.10o. In general, platinum sensors provide better accuracy and less span shift than do nickel elements. Also, while intelligent transmitters give better performance than do standard ones, they too are limited to a minimum error of about 0.18°F (0.1°C). Table 4.10o also shows that the smart transmitters that have digital outputs provide better performance.

Intelligent Transmitters

In addition to having improved performance, intelligent transmitters are capable of working with any one of eight types of TC or two types of RTD elements. This increases their flexibility and reduces the need for spare parts. The intelligent transmitters are also provided with continuous self-diagnositcs and with automatic three-point self-calibration, which is performed every 5 s and does not interrupt the analog or digital output of the unit.

A transmitter includes an input circuit referred to as an analog-to-digital (A/D) converter that converts the sensor input signal from its analog form into a digital representation for presentation to the microprocessor. The microprocessor performs all of the mathematical manipulations of ranging, linearization, error checking, and conversion. The output stage accepts the resultant digital representation of the current value of the measurement and converts the signal back to an analog signal (D/A) that is typically a 4–20 mA DC current. For some special applications, 0–1 or 0–10 V DC signals may be used and in others the signal is transmitted digitally using either an open or proprietary protocol. Some countries have adopted 020 mA as the standard transmitted signal.

The intelligent RTD transmitter can also be furnished with dual RTD elements that can be used to measure temperature differentials, averages, or high/low sensors, or used as redundant backup elements. This capability also allows for automatic RTD sensor switchover if the primary sensor fails in a redundant installation. Due to terminal

limitations, these models can only accept dual three-wire RTDs. Caution must be used to minimize lead resistance differences to reduce the error. Another convenient feature of smart transmitters is their remote reconfiguration capability, which can change their zero, span, or many other features without requiring rewiring.

The common features of the leading temperature transmitter models are: universal inputs from any TC, RTD, mV, resistance or potentiometer; loop-powered with 0–20/4–20 mA output; digital outputs; and configuration with push buttons, personal computer (PC) software, or a handheld configurator. Choices must be made for which protocol is required: Highway Addressable Remote Transducer (HART), Foundation Fieldbus, Profibus, vendor proprietary, Ethernet, or just 420 mA.

A/D Converters, Digital Protocols

Just as microprocessors have evolved in sophistication, so have A/D converters. Eight-bit resolution devices common in the 1960s provided a resolution of about ±0.4%. In the year 2000 the first 21-bit resolution A/D was used in a temperature transmitter providing a resolution of ±0.00005%. D/A converters have also evolved with resolutions increasing from 8-bit up to the 18-bit versions used in the better transmitters beginning in 2000.

The result of combining these technologies is a universal transmitter that accepts inputs from any TC, RTD, mV, resistance or potentiometer signal; checks its own calibration on every measurement cycle; has minimal drift over a wide ambient temperature range; incorporates self-diagnostics; and is configured using push buttons or simple PC software. The reconfiguration process is quick and convenient, and it tends to allow for lower inventories by making the transmitters interchangeable.

In the 1980s Rosemount developed the HART protocol to enable detailed information about the set-up and operation of the device to be superimposed onto the 4–20 mA signal. During this same time period a variety of proprietary protocols emerged supported by many of the larger manufacturers that provided comparable benefits of remote setup and diagnostics. Unlike the HART protocol, these products were limited to use within the manufacturer's system. In the 1990s a trend emerged for more open protocols and Foundation Fieldbus and Profibus evolved the leaders of these groups.

ADVANTAGES AND LIMITATIONS

RTDs are among the most accurate, reproducible, stable, and sensitive thermal elements available. Some of the precision platinum RTDs can measure within a few thousandths of a degree, and this precision is the reason such instruments are used to define parts of the International Temperature Scale (ITS-90.)

Other advantages include their relatively good sensitivity (0.1 to 10 Ω/°F) and their ability to use conventional copper lead wire (instead of more expensive TC wire). An advantage of copper RTDs is that since both the element material and the lead-wire material are the same, the TC effect is minimized at their junction. Another advantage of RTDs is the convenience of using a single bridge to measure the temperature difference between two RTDs.

A concern common to all RTDs is the error produced by self-heating. Measuring the voltage across an RTD produced by passing a precise current flow through the RTD produces heat that will appear as a positive offset over the actual process temperature. The size of this error rises with RTD size and its resistance. It can be reduced by improving heat transfer and by minimizing or eliminating (null-balance) the current flow through the RTD. The lower is the measuring current; the less is this self-heating effect. It is reduced by good thermal contact with the process fluid and when measuring higher temperatures. Circuits in better transmitters use about 250 μA.

Other disadvantages of RTDs include their higher cost, more fragile construction, and larger size, relative to TCs. Because of their size, their thermal response time is also relatively slow (Figure 4.10n). Errors can be introduced if the RTD insulation resistance is affected by moisture being sealed in the sheath or by contact between element and sheath. Some RTDs are more vibration-sensitive than others. RTDs are also dependable for their precision on stable (insensitive to temperature changes) and constant resistances and power supplies in the associated bridges.

INTRODUCTION

The terms *thermostat* and *temperature switch* are somewhat interchangeable. Temperature switches are on-off devices, while thermostats are narrow (frequently fixed) proportional band controllers. Their common characteristic is that measurement, set point, and control functions are all combined into a single instrument.

A thermostat is a device that controls the temperature in an enclosed space and can be electrical/electronic or pneumatic. It functions either as a proportional-only controller or as an on-off switch with a dead-band.

Figure 4.11a illustrates some of the terminology used in connection with temperature switches. The temperature range within which the actuation point can be set is referred to as *adjustable range*. The switch may actuate at its set point on rising (*high*) or falling (*low*) temperature. The set point is the temperature that actuates the switch to open or close an electric circuit. The set point accuracy defines the band within which repetitive actuations will occur. Differential or dead band is the difference between the set point and reactuation point. For example, if a high temperature switch is set to actuate (close) at 100°F (38°C) on rising temperature, it will close at that point. When the temperature drops, it will not open again until the temperature has fallen to 95°F (35°C). In this case, the differential is 5°F (2.8°C). Tolerance is the repeatable accuracy of the reactuation point.

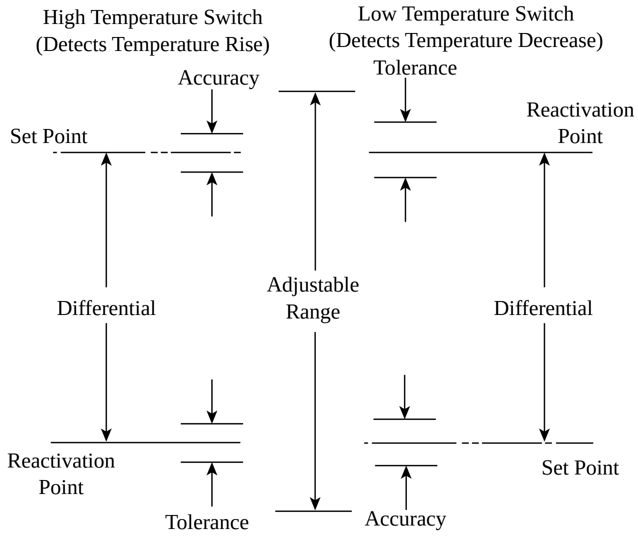

FIG. 4.11a
Temperature switch terminology.

Temperature switches utilize a wide variety of technologies depending on their applications in commercial products, industrial equipment, process control, and even aerospace. They also vary in sophistication from simple snap disc models typically used in coffee makers up through very sophisticated models. An alternate name for them is limit alarms. They can accept temperature sensor inputs from thermocouples (TCs) or resistance temperature detectors (RTDs) and provide multiple alarms at different settings or serve both alarm and equipment shutdown functions. This section will discuss both industrial and commercial switches as well as personal comfort (heating, ventilation, and air conditioning [HVAC]) thermostats.

ELECTRONIC TEMPERATURE SWITCHES

There are two types of electronic temperature switches (some suppliers also call them limit alarms), which are differentiated by the source of their input signals. If the temperature of interest is detected by a temperature transmitter, the high or low temperature switch detects a transmitter output signal of 4–20 mA or 1–5 V DC. If a transmitter is not available, a local process temperature sensor is connected directly to the electronic high or low temperature switch (limit alarm), which is preferably mounted near the sensing point. Both types will be discussed.

Input from Transmitter

Temperature transmitters with 4–20 mA output signals are often connected to a programmable logic controller or distributed control system for monitoring, alarming, and control. However, there are often requirements to have a backup device for monitoring the same signal for redundant alarming and emergency equipment shutdown. It makes economical sense to locate this device near the equipment being monitored so that shutdown commands need not be wired all the way from the control room.

This type of temperature switch uses an analog circuitry and typically has either one or two trip points that are screwdriver adjusted and provide relay outputs. These analog switches require a signal source and a continuity-measuring device to set the trip points. Such an analog temperature switch is shown in Figure 4.11b. Indicating models are also available, which indicate both the detected temperature and the set point for switch actuation. Trip point repeatability as a percent of input span varies from 0.5 to 0.05% of span, as a function of whether the device is an inexpensive analog model or a more accurate digital one. Some models are also provided with an adjustable dead band, which is a range, through which the input can change without causing a state change in the switch position.

High-end digital temperature switches are field-configurable for trip point, dead band, time delay, and latching options (Figure 4.11c). Others also incorporate an indicating display, which is scalable in various engineering units, or provide excitation power for the temperature transmitter and retransmits the received input signal as an isolated 4–20 mA output signal. These temperature switches are available with 1 to 4 relays.

FIG. 4.11c
Configurable and indicating digital electronic switch operating off the output signal of a transmitter. (Courtesy of Moore Industries-International, Inc.)

Input Directly from Sensor

These direct connected temperature switches also range from less sophisticated analog designs to the more sophisticated field-configurable digital models. For the analog switches, the type of sensor input must be specified while the digital models can be field-configured for a variety of sensors. This includes eight types of TCs and a number of RTDs, including two-, three-, or four-wire circuitry and platinum, nickel, or copper elements.

These switches also accept direct resistance input or millivolt signals. A valuable feature of these sensor input devices is their ability to perform sensor diagnostics. One model provides a relay output in the event of a sensor failure while inhibiting the other alarm/shutdown outputs. The benefit is that a nuisance shutdown of a piece of machinery or a process may be avoided and yet the user knows that a sensor must be replaced to maintain monitoring.

If the same temperature, which is detected by the temperature switch, is also needed for control, recording or other reasons, some of these direct-connected devices are able to also act as transmitters and output a 4–20 mA signal (Figure 4.11d). This way, in addition to the temperature switch, the functions of indication and transmission are also provided by the same unit.

Installation Considerations

In The Control Room If a temperature transmitter output is already being sent to the control room, it is logical to also mount the temperature switch there. For direct sensor input, better performance is obtained by installing the instrument close to the sensor, in order to reduce the effects of electrical

FIG. 4.11d
Direct connected configurable electronic temperature switch with display and retransmission capability. (Courtesy of Moore Industries-International, Inc.)

noise (electromagnetic interference and radio frequency interference [RFI]) and the errors introduced by extension cables.

For the installation of high temperature switches, the recommended practice is to connect them in parallel with the rest of the control system, recorder, or logger. Most input circuits to these devices use a 250-Ω input resistor that converts the 4–20 mA signal into a 1–5 V DC signal. By connecting the alarm trip in parallel, it can then monitor this same 1–5 V DC signal and either device can be removed from service without affecting the operation of the other.

While most models can be surface mounted, the (DIN) rail mounting style is the most effective, because the electronic switch units simply clip on a standard DIN rail eliminating the need for drilling and tapping screw holes.

Field Mounting Local mounting is recommended for all direct connected temperature switches in order to minimize the signal degradation caused by the long wiring runs back to a control room. When a high temperature switch also initiates equipment shutdown, wiring costs can be reduced by installing the alarm/shutdown switch near the protected equipment.

When installing any electrical or electronic equipment in the field, the instrument enclosures must meet both environmental and safety concerns. If explosive vapors or dust are present continuously in the area, the enclosure must be a Class 1, Division 1 explosion proof enclosure, which would be needed to meet Class 1, Division 1 requirements of agencies like (FM) and (CSA).

If these vapors or dusts are only present under abnormal conditions, the enclosures must meet the much less rigorous requirements of Class 1, Division 2. Note that both the instrument and the enclosure enter into the consideration. Often a Division 2 enclosure can also meet (NEMA) 4X requirements for watertight and corrosion resistance. Division 2 also mandates that there be no open contacts, and alarm devices must have hermetically sealed relays or use solid-state switching to meet this requirement.

Because temperature switches are often installed to protect critical processes, a false or nuisance trip can be very costly. Frequently the cause of these nuisance trips is RFI generated by walkie-talkies, which are used in most plant locations. Therefore, it is important to specify that the switch must include RFI immunity. (Immunity to 10 V/m according to the SAMA specification 33.1 is considered acceptable.)

Availability and Reliability

Often, a temperature switch will have the critical role of guaranteeing a safe shutdown. Safety Instrumented Systems standards (including ANSI/ISA 84.01, IEC 61508, and IEC 61511) provide guidance and thereby assure the availability and reliability of the devices that are used in safety related applications.

Availability means that the device will be able to perform the assigned task when it is called upon to do so. For example, the probability that an alarm switch or limit device will sense a dangerously high temperature and will trip an emergency shutdown valve when the tripping occurs is referred to as its Probability of Failure On Demand.

Reliability refers to the likelihood of the device suffering a nuisance failure and thereby causing a false trip. This factor is referred to as its Mean Time To Fail spurious. These standards contain equations for the calculation of the reliability of the complete loop. These calculations are performed by inserting numerical values for the availability and reliability of each device in a loop. Only a few suppliers can provide the data required to calculate the reliability of such loops. When a third party tests and evaluates an instrument, it publishes a report known as a Failure Modes Effects, Diagnostic Analysis. That report contains all the required data for the calculations in the standards. Documented reliability does not have to increase costs, because higher reliability often results in reduced maintenance costs.

ELECTROMECHANICAL TEMPERATURE SWITCHES

Temperature switches are used to energize and deenergize electric circuits as a function of the relationship between the process, temperature, and a predetermined set point. The set point error on the best electro-mechanical switches is about ±0.5% of span, but that error can rise substantially as the switch cost and quality drops. The sensing elements are mostly the elastic types including filled and bimetallic elements. The electric switching assemblies are either snap-acting mechanical micro-switches or mercury switches. The latter contain no mechanical moving parts and must be mounted on a vibration-free level surface.

Many applications from furnace protection to local fan controls may not require sophisticated electronic temperature switches, and in such applications bimetallic or filled bulb type switches are used. The lower cost versions are provided only with factory set fixed set points and fixed differentials, while the more expensive ones can be indicating and have adjustable differentials and calibrated, externally adjustable set points and setting scales.

Features Required for Industrial Applications

Temperature switch elements should be selected with service life and maximum operating temperature in mind. Most elastic elements will have a service life of close to a million cycles if the cycle time is not less than 5 s. The service life is related to the amount of current required to switch and the frequency of switching. By increasing the dead-band, the frequency of switching is reduced and the life of the switch increases. Similarly, increasing the margin between the switch rating and the actual current flow handled will also increase switch life. For example, a device that is switching 4 A should have a 10-A and not a 5-A rating.

Selection of the adjustable range for a specific installation should consider both the set point actuation accuracy and the life factor. For greatest accuracy, the set point should fall in the upper half of the range, but for longest service life it should be in the lower half. The usually acceptable compromise is to locate the set point in the middle third of the range.

It is desirable to have an external calibrated knob provided on the temperature switch for set point adjustment. Uncalibrated or internal set point adjustments are generally undesirable on industrial installations. The fixed differential temperature switches are furnished with a single adjustment for set point. These units are factory-set with differentials that range from 0.5 to 1% of span. On double-adjustment-type designs, both set points and reactuation points can be independently adjusted. The maximum differential in such designs is the range of the switch, while the minimum varies between 2 and 8% of span. Temperature switches with dual control are also available. Here, two independent switches mounted in the same housing are responding to the same process temperature in opening or closing two independent circuits.

Safety Considerations

The electrical rating of temperature switches at a 115 V operating level varies from 0.3 to 10 A on AC or DC circuits. Generally, the dual control and the fixed differential switches have lower ratings, and the double-adjustment-type units have higher ratings. The available circuit arrangements are very flexible. Some of the standard arrangements include single-pole–single-throw, single-pole–double-throw, and double-pole–double-throw designs, but units are available with up to four poles.

There are basically three standard case designs: general purpose (NEMA 1), weather-resistant (NEMA 2 and 3), and explosion-proof (NEMA 7) cases. These enclosures and the switches inside them may require certification to meet hazardous area classifications from certification agencies such as FM, CSA, or Underwriters' Laboratories.

In some designs, the control mechanism is an integral part of the explosion-proof case, while in others it can be removed in the field for maintenance. As noted earlier, the set point should be externally adjustable so that the explosion-proof case does not need to be opened in order to change the set point. For added convenience of the operator, some switches also provide continuous process temperature indication. Another optional feature is push-button reset, which must be manually operated before the circuit will be restored to its original state after an automatic operation. This manual reset encourages the operator to verify the safety of the system before restarting.

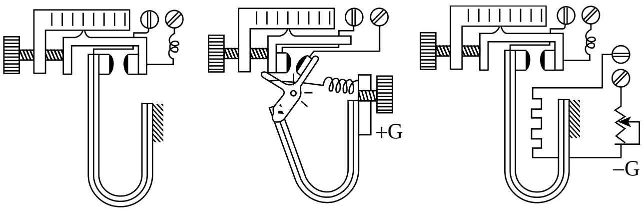
THERMOSTATS

Conventional thermostats are usually uncalibrated devices and their manufacturers usually do not guarantee their accuracy. This is a limitation, because it is possible to have some thermostats with as much as 5 to 10°F (3 to 6°C) error in their measurement. In the last decades a new generation of thermostats has been introduced that guarantee to limit their error to 1°F (0.6°C) or less.

Electromechanical Designs

There is little difference between a two-position thermostat and a temperature switch. The temperature-sensing elements in the thermostats shown in Figure 4.11e are bimetallic springs. In the design shown on the left, the gap between contacts is almost zero and the movement of the bimetallic element directly opens and closes the load contact. In the design shown in the center a positive gap is provided, serving to reduce wear on control equipment. The gap is produced by toggle action and is adjustable by adjusting the spring tension.

In slow processes with long cycle periods, such as in domestic thermostats, anticipation is provided through the use of a negative gap (right of Figure 4.11e). In this thermostat, when the heater in a room is turned on, a small internal heater within the thermostat is also actuated. This causes the bimetallic spring to turn off the room heater before the room temperature reaches the temperature inside the thermostat.



Zero Gap Positive Gap Negative Gap

FIG. 4.11e
Design variations of two-position electromechanical thermostats.

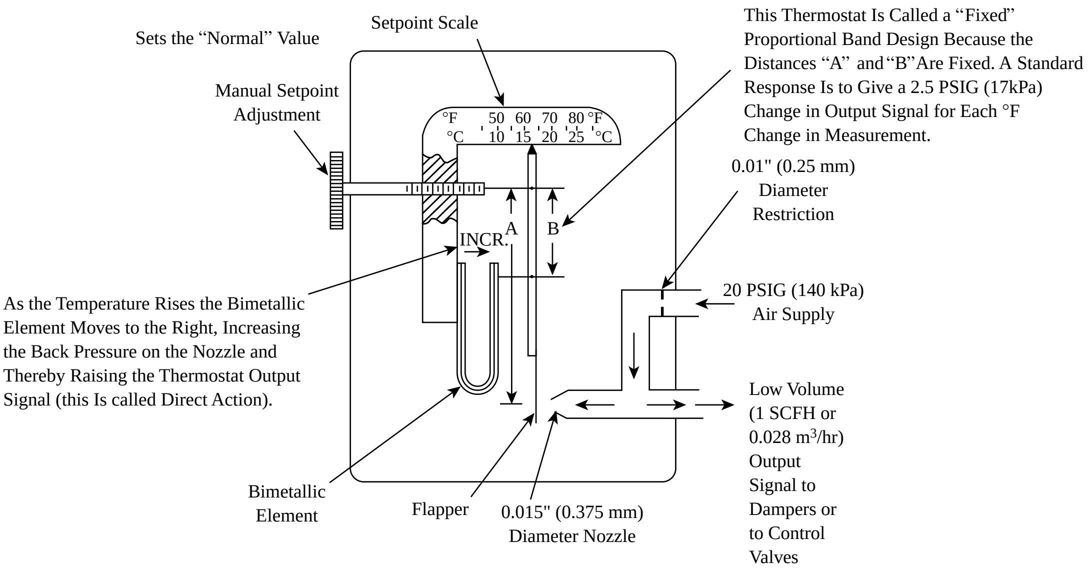


FIG. 4.11f
Direct-acting pneumatic-bimetallic thermostat with manual set point and fixed proportional band. This is a low-volume design since output air flow is limited because there are no relays.

Pneumatic Designs

Pneumatic-Bimetallic The next level of sophistication is to replace the completely on-off action (with or without adjustable gap) of the thermostat with a small amount of throttling. In such throttling thermostats, the room temperature has to move away from set point by a degree or two before the heating (or cooling) valve (damper) is fully opened. One simple way of achieving such throttling action is by letting the bimetallic spring move a flapper in front of a nozzle (Figure 4.11f), thereby causing the pneumatic output pressure of the thermostat to change with temperature.

Throttling Thermostats are distinguished from other controllers in that they provide proportional action only and that their proportional band (gain) is *narrow and fixed.* A conventional room thermostat might have a set point range of 55 to 85°F (13 to 29°C) and a *fixed sensitivity* (gain) of 2.5 PSI/°F (0.3 bar/°C). Assuming that this thermostat operates a control valve having a 9 to 13 PSIG (0.6 to 0.9 bar) spring range, we can convert the fixed sensitivity of 2.5 PSI/°F into a percent proportional band value that is better understood by instrument engineers.

Sensitivity (or gain) is stated as the ratio between a change in measurement and a change in the corresponding controller output. A 1°F (0.56°C) change in measurement is 3.3% of the measurement range of 30°F (55 to 85°F, or 13 to 29°C), while the 2.5 PSI change in controller output is 62% of the controller output range of 4 PSI (9 to 13 PSIG). If a 3.3% change in input results in a 62% change in output, that is a gain of 62/3.3 = 19. Converting this typical thermostat gain to proportional band, we get:

$$P = \frac{100}{G} = \frac{100}{19} = 5.3\% \qquad \textbf{4.11(1)}$$

This controller, having a fixed proportional band of 5% is very sensitive, has a small "offset," and, as its gain is fixed, cannot be tuned.

Offset Error Let us examine the consequences of these characteristics separately. A sensitive controller is suited for the control of very slow, large-capacity processors. Temperature control in the HVAC industry usually fits that description. Therefore, thermostats with fixed, high gains can give acceptable results, if space temperature can change only very slowly. On the other hand, such thermostats cannot control spaces with fast dynamics (short time constants) and will cycle or lose control when applied to such service.

The offset inherent in all proportional controllers is not a serious drawback because the resulting error is small, due to the narrowness of the proportional band. Using our earlier example and assuming that the thermostat output is set at 11 PSIG (0.76 bar) when the error is zero (thermostat on set point), we can calculate the maximum error due to offset. When there is no error, the control valve is 50% open (output is 11 PSIG, or 0.76 bar). As the load changes, an error must be allowed to develop in order for the valve opening to change. Assuming that the valve has been correctly sized and is large enough to handle all expected loads, the maximum error due to offset will be that deviation from set point that is required to move the valve from half to full opening. This 2 PSIG (0.14 bar) change in thermostat output will occur when the deviation from set point is 0.8°F (0.4°C).

Therefore, this is the size of the permanent offset error for a gain of 19:1. There is an inverse linear relationship between gain and offset error, such that if the gain is cut in half, the offset error will be doubled.

From the above discussion it might be concluded that the conventional room thermostat is a good selection for the HVAC-type applications and that more expensive instruments, such as PID controllers, would not necessarily improve the overall performance.

Design Features Application engineers can choose from a fairly large variety of design features when specifying thermostats, because they cannot only be electromechanical, pneumatic, or electronic, but can also be (1) indicating or blind, (2) direct or reverse acting, (3) can automatically switch their actions in response to a pneumatic or electronic signal, (4) can have bimetallic, filled, or electronic sensing elements, (5) can have local or remote set points, or (6) have their set points under key, concealed, or externally adjustable.

Advanced Features If the set point of a pneumatic thermostat is adjusted remotely by an air signal, each 1 PSIG (0.07 bar) change in set point pressure will move the set point by an adjustable preset amount. The range of this adjustment is usually from 0.15 to 1.4°F (0.1 to 0.8°C) per 1 PSI (0.07 bar). If the set point is to change as a function of the time of day, a timer can automatically operate a solenoid and thereby switch the set point signal.

Some of the more recently developed and more advanced thermostat features include the following:

Adjustable Gains or Proportional Bands Another term used to describe the sensitivity of thermostats is throttling range. As shown in Figure 4.11g, it refers to the amount of temperature change that is required to change the thermostat output from 3 to 13 PSIG (0.2 to 0.9 bar). The throttling range is usually adjustable from 2 to 10°F (1 to 5°C).

Dual Set Points These thermostats will switch their settings in response to a change in the air supply pressure. Both set points can be manually adjusted, with the day setting made by external thumbwheel and the night setting concealed internally.

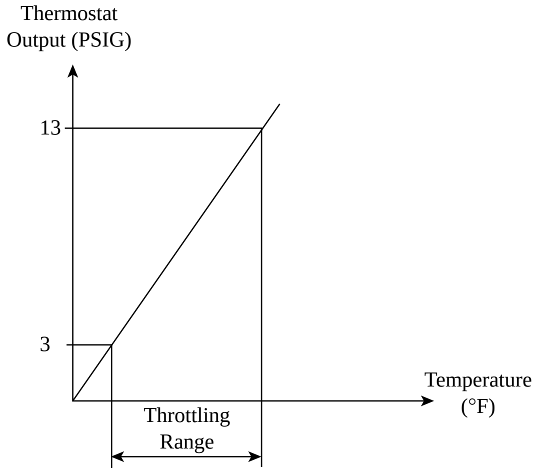

FIG. 4.11g
Definitions of throttling range for pneumatic thermostats.

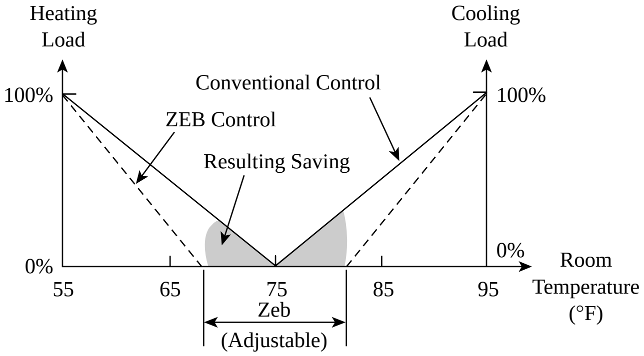

FIG. 4.11h
Zero energy band control.

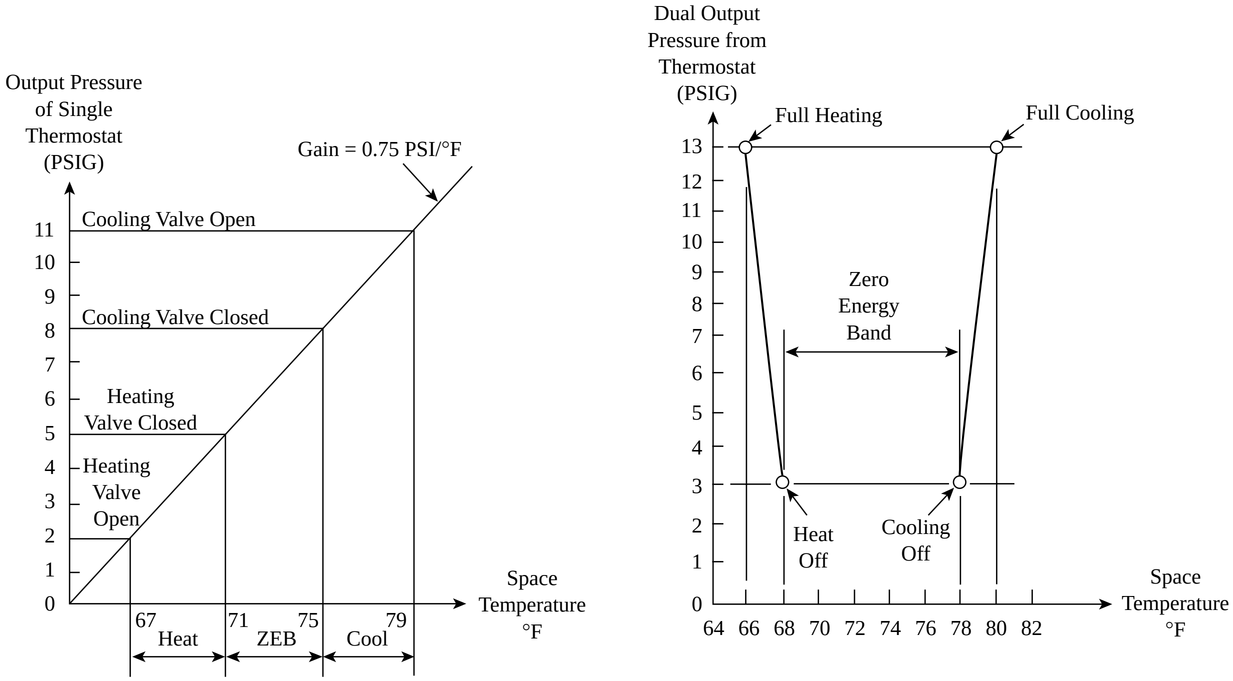
Limited Control Range These thermostats allow the occupant of an office to move the set point to any value desired, but will disregard any setting that exceeds the limit value. For example, in heating applications, the limit could be 74°F (23°C). In this case, the space temperature will be limited to a maximum of 74°F, regardless of the setting by the occupant. Similar limit values can be set for cooling.

Zero Energy Band Control A recent addition to the available thermostat choices is the zero energy band (ZEB) design. The idea behind ZEB control is to conserve energy by not using any when the room is comfortable. As illustrated by Figure 4.11h, the conventional thermostat wastes energy by continuing to use energy when the area's temperature is already comfortable. The comfort gap, or ZEB, is adjustable and can be varied to match the nature of the particular space involved.

ZEB control can be accomplished in one of two ways. The single set point and single output approach is illustrated on the left side of Figure 4.11i. Here the cooling valve fails closed and is shown to have an 8 to 11 PSIG (0.55 to 0.76 bar) spring range, while the heating valve is selected to fail open and has a 2 to 5 PSIG (0.14 to 0.34 bar) range. Therefore, between 5 and 8 PSIG (0.34 and 0.55) both valves are closed, and no pay energy is expended while the thermostat output is within this range. The throttling range is usually adjustable from 5 to 25°F (3 to 13°C). Thus, if the ZEB is 30% of the throttling range, it can be varied from a gap size of 1.5°F (0.85°C) to 7.5°F (4.2°C) by changing the throttling range (or gain).

Split Range Control While the split-range approach is a little less expensive than the dual set point scheme (shown on the right of Figure 4.11i), it is also less flexible and more restrictive. The two basic limitations of the split-range approach are:

1. The gap width can only be adjusted by changing the thermostat gain; maximum gap width is limited by the minimum gain setting of the unit.
2. In this design, the heating valve must fail open; this is undesirable from an energy conservation point of view.



Single Set Point Split-Range System

Dual Set Point System

FIG. 4.11i
Implementation of zero energy band control.

These limitations are removed when a dual set point, dual output thermostat is used. Here both valves can fail closed and the band width is independently adjustable from the thermostat gain. The gains of the heating and cooling thermostats are also independently adjustable. In Figure 4.11i, the heating thermostat is reverse-acting and the cooling thermostat is direct-acting.

Electrical/Electronic Designs

- The most common is the low voltage unit that uses external interposing relays to control heating and/or cooling equipment (typically 24 V AC)
- Line voltage units that directly control AC circuits (120 or 240 V AC)
- Heating only or heating/cooling models
- Digital or analog indication of room temperature
- Bimetallic, filled system or electronic sensing elements
- Direct or reverse acting
- Local or remote set point
- Local set points may be external or internal and may be key protected
- Limited control range thermostats allow the occupant of an office to move the set point to any value desired, but will disregard any setting that exceeds the limit value. For example, in heating applications, the limit could be 74°F (23°C). In this case, the space temperature will be limited to a maximum of 74°F, regardless of the setting by the occupant. Similar limit values can be set for cooling.
- Programmable setback models with 24-hour or 7-day programs

RECENT ADVANCES

Microprocessor-based units continue to incorporate new features. These are programmable devices with memory and communication capability. They can be monitored and reset by central computers using pairs of telephone wires as the communication link. Microprocessor-based units can be provided with continuously recharged backup batteries and with accurate electronic room temperature sensors. They can also operate without a host computer (in the stand alone mode). In this case the user manually programs the thermostat to maintain various room temperatures as a function of the time of day and other considerations.

In 2000, the first residential gateway for the HVAC industry's new open communications standard for residential environmental control was introduced. This gateway enables secure, remote access to residential HVAC systems via touch-tone telephone, standard phone line, and pass code. Some systems offer either dial in or dial out functions. Owners can call in to check the temperature, change the status of their HVAC system, and perform other thermostat-related functions. These telephone access modules enable monitoring of the building's temperature and its heating/cooling equipment. It can report when a furnace filter needs replacing or an electronic air cleaner's cells need cleaning. And it can call up to three phone numbers to immediately alert the owner, contractor, or others of problems, such as freezing temperatures or an extended power outage.

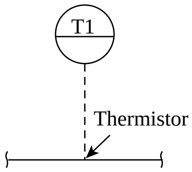
4.12 Thermistors



Flow Sheet Symbol

T. G. CLAGGETT, R. W. WORRALL (1969, 1982) **B. G. LIPTÁK** (1995)
P. M. B. SILVA GIRÃO (2003)

Range:	Typically, from –58 to 302°F (–50 to 150°C). Bead thermistor probes, hermetically sealed into shock resistant solid glass rods, are available from –321 to 572°F (–196 to 300°C) and from –40 to 1652°F (–40 to 900°C).
Span:	Can be as narrow as 2°F (1°C), which can result in extremely high sensitivity
Differential Temperature Same Measurement:	By connecting two thermistors to different halves of the Wheatstone bridge, thousandths of a degree difference can be measured.
Resistance:	From 0.5 to 20,000,000 Ω (usually referenced at 77°F [25°C]). Standard units are about 5,000 Ω. If the resistance of a thermistor element is 5,000 Ω at room temperature, it will drop to about 20 Ω at 572°F (300°C) and will rise to 200,000 Ω if the temperature drops to –58°F (–50°C).
Linearity:	Nonlinear
Sensitivity:	Typically 25 to 250 Ω/°F (50 to 500 Ω/°C), which translates into 0.5 to 5% of sensor resistance change per degree Fahrenheit temperature (1 to 10%/°C). Most industrial units have a sensitivity of about 2%/°F (4%/°C).
Inaccuracy:	Generally between 0.1 and 1°F (0.006 and 0.6°C). Because spans can be extremely narrow, the error with this sensor (if calibrated) can be as low as 0.005°F (0.003°C), but because of long-term stability and self-heating effects, long-range accuracy is much lower.
Thermal Time Constant:	Typically around 10 s in still air and 1 s in oil
Thermal Dissipation Constant:	Typically around 1 mW/°F (2 mW/°C) in still air and 5 mW/°F (10 mW/°C) in oil
Interchangeability:	±0.1°F (±0.05°C) for spans of up to 122°F (50°C); ±1°F (±0.5°C) for spans of up to 392°F (200°C)
Cost:	$10 to $100. The unpackaged elements can be obtained for $10 or less; when packaged for process industry services, their costs are similar to those of resistance temperature detector-based sensors, handheld monitors or transmitters.

Like the resistance temperature detector (RTD), the thermistor is a resistive device that changes its resistance predictably with temperature. It is constructed from ceramic semiconductor materials. Its benefit is a very large change in resistance per degree change in temperature, allowing very sensitive measurements over narrow spans. Due to its very large resistance, lead wire errors are not significant.

INTRODUCTION

Thermistors are thermally sensitive resistors and have either a negative (NTC) or positive (PTC) resistance/temperature coefficient.

NTC thermistors, or NTCs for short, are semiconductors made from specific mixtures of pure oxides of nickel, manganese, copper, cobalt, tin, uranium, zinc, iron, magnesium, titanium, and other metals sintered at temperatures above 1800°F (982°C). The type and proportion of oxides used, the sintered atmosphere, and the sintering temperature dictates the resistance and temperature coefficient of the NTC thermistors. Their distinguishing characteristics are a high temperature coefficient and the fact that their resistance is a nonlinear function of absolute temperature. This makes them very good for narrow span measurement, but more difficult to handle for widespan applications.

PTCs are manufactured from silicon (silistors) or barium, lead, and strontium titanates with the addition of yttrium, manganese, tantalum, and silica (switching PTC thermistors). Silistors have lower sensitivity than NTCs, but their resistance-temperature characteristic is more linear. Switching PTCs have extremely high sensitivity in a narrow range of temperature centered at the Curie temperature of the material.

HISTORICAL NOTE

The first recorded work reporting on a NTC thermistor is from Michael Faraday in 1833. For more than 100 years, the sensors were unstable and not reproducible and were seldom used outside the laboratory. The credit for the development of thermistors as we know them today must be given to Bell Laboratories. They started to manufacture them some 60 years ago, naming them from the term *thermally sensitive resistors.* The Bell project resulted in the development of thermistors stable and reproducible enough to make their large-scale use worthwhile in telephone work around 1940.

The industry in general did not accept these sensors until the 1950s. Bad experiences with commercially available thermistors hampered their acceptance. Variances in resistance at a given temperature and in rate of change of temperature made individual calibration a requirement. Overcoming this difficulty, one manufacturer patented a process for interchangeable thermistors, resulting in production of probes interchangeable to 0.05°F (0.03°C). Boosted by aerospace industry requirements, the 1950s and 1960s witnessed the improvement in the materials used mainly in the manufacture of bead and disk thermistors and the development of chip thermistors. Since the 1970s, and particularly during the 1980s, this type of thermistor was increasingly used in low cost temperature probes for medical applications. Since the 1980s, the use of thermistors increased with demands coming mainly from the transport, medical, and food processing industries.

RESISTANCE-TEMPERATURE CHARACTERISTIC

The negative exponential function that best describes the resistance-temperature (R(T)) characteristic of an NTC can be interpolated using different equations. The Steinhart-Hart equation:[1,2]

$$1/T = A + B(\ln R) + C(\ln R)^3 \qquad \textbf{4.12(1)}$$

where T is the absolute temperature in Kelvin and R the thermistor resistance at temperature T, describes R(T) with the accuracy required in many applications. The determination of coefficients A, B, and C requires calibration at three different temperatures and solving a system of three simultaneous equations. The uncertainty associated with the use of the Steinhart-Hart equation is lower than ±0.005°F (±0.003°C) for a 90°F (50°C) temperature span in the 32 to 482°F (0 to 250°C) range. The inclusion of a squared term reduces that uncertainty, but the calibration must be made at four different temperatures to obtain the four coefficients of the correspondent polynomial.

It is possible to demonstrate that in any range for which the relationship between lnR and 1/T is a straight line, R may be expressed as:

$$R = R_0.\exp(\beta(T_0 - T)/TT_0) \tag{4.12(2)}$$

where R is the resistance at temperature T, R_0 the resistance at a specified reference temperature T_0, and β (material constant) is the slope of the R(T) characteristic. At temperatures above 32°F (0°C), this relationship leads to uncertainties of 0.02°F (0.01°C) for temperature spans of 18°F (10°C) and of 0.5°F (0.3°C) for temperature spans of 90°F (50°C).

Figure 4.12a illustrates the relative behavior of thermocouples (TCs), RTDs and NTC thermistors. On the right side of the figure the characteristics of a particular thermistor are shown, which illustrates both its sensitivity and its nonlinearity.[3]

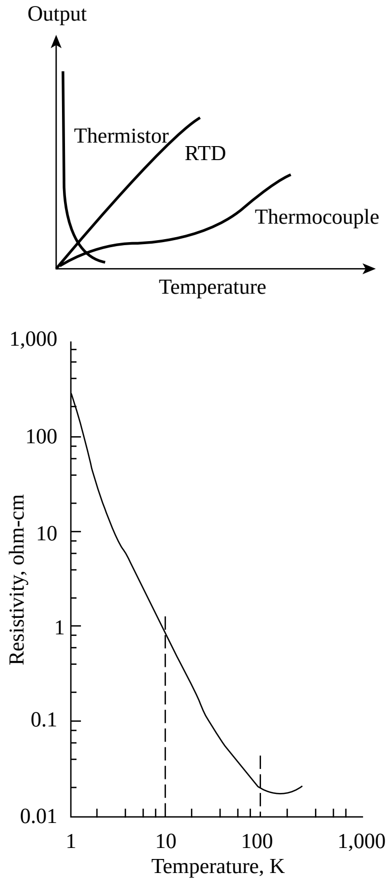

FIG. 4.12a
NTC thermistors are very sensitive and highly nonlinear.[1]

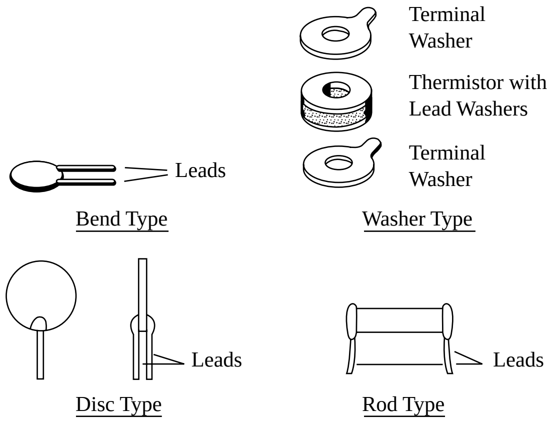

FIG. 4.12b
Variations in thermistor sensor packaging.

SENSOR TYPES

A number of configurations are possible (Figure 4.12b). Most familiar is the bead type, which is usually glass-coated. However, thermistors can be made into washes, discs, or rods. They can also be encapsulated in plastic, cemented, soldered in bolts, encased in glass tubes or needles, or a variety of other forms. These assemblies serve to support the sensor, protect against damage to the wires, direct flow across the unit uniformly, permit sealing of conduits or flow lines, and provide for easier handling (Figure 4.12c).

NTCs can be classified in one of two groups according to the way electrodes are connected to the thermistor body:[4] bead-type thermistors and surface electrode-type thermistors.

Bead-type thermistors have platinum lead wires sintered into the sensor body. This group includes bare and ruggedized beads as well as several glass-encased beads, rods, and probes.

Surface-type thermistors have metallized surface contacts and leads that are radial or axial or nonexisting for surface mounting. They are cheaper to manufacture than bead-type NTCs. Chip and surface mounts are probably the types more used, but disks, rods, and washers are also in demand.

PTCs can be divided in two groups: thermally sensitive silicon resistors (silistors) and switching PTC thermistors.

Silistors are characterized by a fairly constant positive temperature coefficient of about 0.4%/°F (0.8%/°C) in most of its operational range.

TEMPERATURE MEASUREMENT

Microammeter Readout

A simple circuit such as that shown in Figure 4.12d consisting of a battery, a sensor, and a microammeter can be used to measure temperature with a thermistor. In such a circuit, the sensor will have a very high resistance. As long as the voltage is constant, the current flow will be determined only by changes in resistance of the thermistor. The sensor can be

LN0255 Immersion Probe For liquid and semi-solids. Stainless steel. For foods, chemical, pharmaceutical and laboratory work. 0.1°C interchangeablility, 6" long stem, .125" diameter for 12" length option, order, **LN0255-12**. 1.0 Second response time*.

LN0255 Immersion Probe With .05°C interchangeability, .250" diameter.

LN0250 Flexible Immersion Probe Vinyl sheath and .135" diameter epoxy tip. Small and flexible. 3.6 Second response time*.

LN0252 Button Surface Probe Solid .375" diameter button can be attached with pressure sensitive adhesive tape or epoxy. Stainless steel contact surface. 1.1 Second response time*.

LN0253 Screw-In Immersion Probe For measurements in pipes, vessels or reactors. 3.6 Second response time*. Stainless steel shank with 1/8" NPT fitting, 6" standard stem length, 12" option, order **LN0253-12**.

*Response time is based on 63% in water moving at 3 feet per second.

Wheatstone bridge.

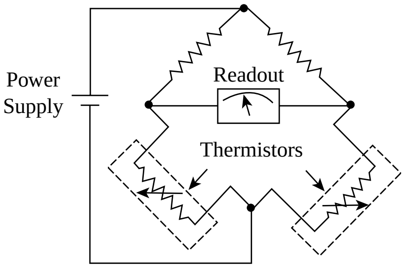

FIG. 4.12f
Differential measurement.

mounted fairly far from the meter and ordinary copper wire can be used for transmission. With a sensor resistance on the order of 10^5 Ω, meter temperature changes and lead wire resistance can be neglected.

Assuming that the thermistor changes its resistance by 2% (2000 Ω) for each degree Fahrenheit of temperature change (4%/°C) and assuming that the total lead wire used was 500 ft of 20-gauge copper wire having a resistance of 10 Ω, the lead wire error would amount to only 0.0045°F (0.0025°C) of temperature error. Even if the thermistor has a total resistance of only 5000 Ω and its 2% temperature coefficient were only 100 Ω/°F, the lead-wire error would still only be 10/100 = 0.1°F. For this reason lead-wire compensation is not a serious problem, and three- or four-wire bridges are not used with thermistors.

Wheatstone Bridge

A DC Wheatstone bridge (Figure 4.12e) is probably the conditioning circuit more widely used with thermistors. Locating the thermistor in one leg of a bridge circuit (Figure 4.12e) with a center zero galvanometer enables very narrow temperature spans to be displayed relatively inexpensively. Range depends upon galvanometer sensitivity and can be as low as 2°F (1°C).

Very accurate temperature measurement can be made with a differential circuit (Figure 4.12f). With two thermistors in different halves in a bridge, the unbalance will be determined by resistance difference caused by temperature difference of the sensors. With a high gain amplifier, differentials of 10^{-3}°C or °F can be measured.

Digital Instrumentation

In recent years, the display of temperature values in numerical format has significantly increased. Low-cost handheld digital thermometers based on an interchangeable thermistor still utilize a Wheatstone bridge to produce a voltage that after amplification (and eventually linearisation) is fed to an analog-to-digital converter. Once in the digital domain, not only can the temperature signal be numerically displayed but it can also be processed using a microprocessor. Interchangeability of thermistors is made possible by storing the R(T) characteristic of the thermistor in a read only memory. This type of solution leads to an accuracy around ±0.2°F (±0.1°C) for temperature spans of some 212°F (100°C).

When higher accuracy is required, calibration of the thermistor at selected temperatures included in the operating range is required to obtain the parameters of the function used to approximate the R(T) characteristic in that range. The instrument can then work with different thermistors, and the accuracy depends on the exactness of the approximation function and on the stability of the thermistor.

THERMISTORS COMBINED WITH RESISTORS

Combinations of thermistors and wire-wound resistors can be connected in networks (Figure 4.12g and 4.12h) to produce either a varying voltage or resistance that is linear with temperature (analog linearization). The basic equation for a divider network of R_1 and R_2 in series is $E_{out} = E_{in}\, R_1/(R_1 + R_2)$, where E_{out} is the voltage drop across R_1. When R_1 is a thermistor and E_{out} is plotted against temperature, the total curve is nonlinear and S-shaped. If R_1 is modified by the addition of another thermistor and resistor of proper values, linearity of the center section of the S curve can be extended to cover a relatively wide temperature range. This section then is considered to follow the general equation of a straight line. For the resistance mode, this would be $R_1 = MT + b$, where M is the slope in ohms per degree, T is the temperature in degrees F, and b is the value of R_1 when T = 0°F. The advantages of such a system are obvious.

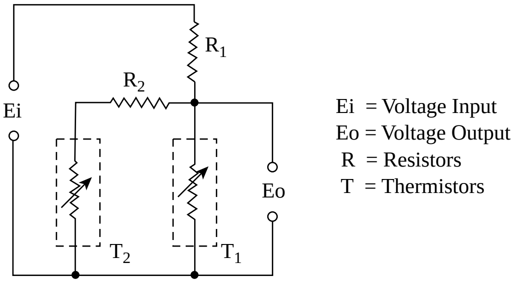

FIG. 4.12g
Two-thermistor network.

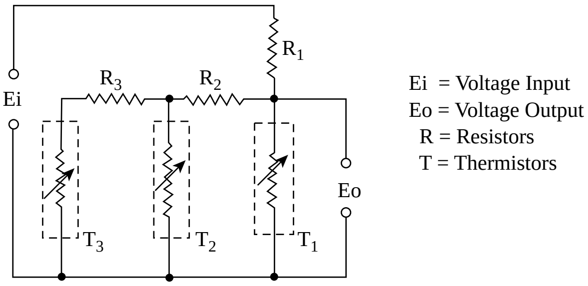

FIG. 4.12h
Three-thermistor network.

SELF-HEATING EFFECT

Even if some applications use the current-time and voltage-current characteristics of a thermistor (thermistor self-heated, i.e., heated above room temperature), the resistance-temperature is the characteristic that accounts for most of temperature measurement applications. In this case, self-heating is generally undesirable and operation is aimed as close as possible to zero power operation.

The electric circuits associated to a thermistor for conditioning purposes originate a current flow in the thermistor. If a small current flows through the thermistor, there is a negligible increase in its temperature due to this flow. The resistance can thus be measured and, since resistance is proportional to absolute temperature, the temperature can be inferred.

If the current flow is slowly increased, the heat generated within the sensor will gradually begin to raise its temperature above that of its environment. This in turn lowers its resistance and more current will flow. Eventually, the current input would reach a level where it is balanced by the heat output of the thermistor. At this point, sensor temperature would be 300 or 500°F (149 or 260°C) above ambient, and sensor resistance would have dropped to a value approximately 10^{-3} times its value at the original low current.

For most temperature measuring applications, self-heating is not a problem, since thermistor currents used are relatively low. If a current of higher magnitude is used, under fixed conditions, an offset allowance may be made for the self-heating effect. However, anything that affects the dissipation constant will change the offset. This could be the result of a number of things, including flow changes in the measured medium, changes in fluid composition, and the like.

The power dissipation constant of a thermistor element can vary from a few microwatts to several watts per degree of resultant temperature rise. In industrial units, a few degrees of self-heating can be expected for each milliwatt of resistive heating. As thermistors are made smaller and smaller in order to increase their response times and to lower their thermal shunting, the effect of self-heating also rises. The I^2R temperature increase is a direct function of the dissipation constant in its mounting environment. Unlike resistance thermometers or TCs, thermistor resistance values are varied by varying their composition to suit the temperature span, range, and sensitivity desired for a given application.

APPLICATIONS

Other than temperature measurement, thermistors can be used in a number of applications where physical phenomena produce a temperature change. Such applications may recur to the current-time, voltage-current, or resistance-temperature characteristic of a thermistor. NTC thermistor applications based on current-time characteristic include surge protection and inrush current limiting. The voltage-current characteristic of a NTC is used namely in voltage regulation, anemometers, manometers, gas analyzers and fluid velocity, liquid level, and microwave power measurement. Utilization of the resistance-temperature characteristic of an NTC can be found in many domains from industry to medicine most of them related with temperature measurement.

PTC applications make general use of either the voltage-current characteristic (resettable fuses, heater and thermostat, liquid and flow sensing) or the current-time characteristic (motor starting, time delaying).

Today it is possible to look for a thermistor that better suits a specific application using the search capabilities available in some sites (e.g., www.globalspec.com/SpecSearch/SearchForm?Comp=16).

Thermistors can be connected to a microprocessor-based memory element and packaged as a portable element. These small micropacks can memorize the temperature history of batch reactor products or can travel with the process material through several steps in processing. When the temperature memory-pack unit is retracted from the process, it can be plugged into a computer for interrogation. This allows the plant to store the temperature history of each batch. The micropack weighs less than 100 g, has a battery life of about 500 hours, and has a temperature range of –40 to 302°F (–40 to 150°C).

CALIBRATION AND TESTING

In some applications, the accuracy requirements are not compatible with the interchangeable capabilities of thermistors. In such cases, thermistors must be calibrated.[4] Calibration is also required whenever an accurate resistance-temperature characteristic of a thermistor is needed.

The National Bureau of Standards has offered a limited calibration service for thermistors over an approximate temperature range of –150 to 200°F (–101 to 93°C). Calibration on the order of ±0.02°F (±0.01°C) is the rule. Users have claimed better than ±0.002°F (±0.001°C) stability over a 2-year period.

The following should be checked to test the operating parameters of thermistors:

1. Zero power resistance. This test is done under conditions that produce negligible heating of the sensor by test current. Most common sources of error are measurement of ambient temperature, self-heating error, thermocouple effects at junctions of dissimilar metals, and accuracy of test equipment.
2. Temperature coefficient of resistance. This is the rate of change of thermistor resistance vs. temperature at the desired temperature.
3. Voltage developed across the thermistor under conditions of thermal equilibrium with a constant current. A current-limiting resistor should be used. Maximum current should not be exceeded, even for short periods. The sensor should not be moved to a medium of lower thermal conductivity during a test. The problem is similar to that of measuring voltage across ordinary resistors; the difference is that stabilization times are longer and small currents are used.
4. Time required for a thermistor to pass a certain current after the voltage is applied.
5. Dissipation constant measurements. This is the ratio at a certain temperature of a change in power dissipation in a thermistor to the resultant body temperature change.
6. Thermal time constant. This is the time for a 63.2% change from initial to final temperatures when, subjected to a step change.

ADVANTAGES AND LIMITATIONS

Thermistors have the desirable characteristics of small size, narrow spans, fast response (their time constant can be under 1 s), and a very high sensitivity (about 2%/°F [4%/°C]), which usually increases as the measured temperature drops.

Thermistors do not need cold junction compensation because their resistance is a function of absolute temperature, and errors due to contact or lead-wire resistance are insignificant because of their relatively small values. Unlike RTDs and TCs, they are well suited for remote temperature sensing.

Thermistors are available in a great variety of configurations, are inexpensive, are not affected by polarity, and their stability increases with age. At present, they are typically more rugged and better able to support mechanical and thermal shock and vibration than other temperature sensors.

They are the most sensitive differential temperature detectors available.

Thermistors also have some disadvantages. Their interchangeability is moderate and they are not linear, although in modern data acquisition systems linearisation is no problem. They are also fragile and are not suited for wide spans. Their high resistance necessitates the use of shielded power lines, filters, or DC voltage.

One of the most serious limitations of thermistors is their lack of stability (drift and de-calibration) at higher temperatures. This is because semiconductors in general change their composition and develop migration, diffusion, or other decomposition properties at high temperatures. Therefore their use is limited to temperatures up to 600°F (316°C), and even at such temperatures extended exposure can cause drifts. (It should be noted that if a thermistor is operated at temperatures far below its maximum, it can be a very stable device.) Thermistors also have a low temperature limit, because as the temperature drops, their resistances rise to such levels that measuring it becomes difficult.

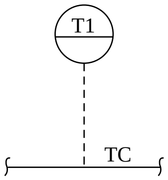
4.13 Thermocouples

T. J. CLAGGETT, R. W. WORRALL (1969, 1982) **B. G. LIPTÁK** (1995, 2003)



Flow Sheet Symbol

Linearity:	Thermocouples are nonlinear devices. They generate from 10 to 60 μV/°C temperature change.
Temperature Ranges:	–346 to 4240°F (–210 to 2338°C) with nine types covering various ranges as listed in Tables 4.1a, 4.1c, and 4.13l
Temperature Spans:	See Table 4.13m. Minimum recommended span is 25°C (45°F) and is available only in types E, J, K, and T. For types S and R, the minimum span is 360°F (200°C).
Inaccuracy:	The total error is the sum of the thermocouple wire error (see Table 4.13m), the extension wire error and the signal conditioning or transmitter error. For standard thermocouple, the error ranges from ±2 to 5°F (1 to 2.8°C); for special thermocouple, half as much. The extension wire error varies with its length and can be equal or more than the thermocouple error. The transmitter error is usually 0.15% of span with standard and 0.05% with intelligent transmitters, or the sum of the cold junction (CJ) and the minimum absolute error (MAE), whichever is greater. With narrower spans the sum of the CJ+MAE error is likely to be the determining one and can be calculated as the sum of CJ = 0.25°C (0.45°F) and MAE = 0.2°C (0.36°F) for types T, J, E, and K; 0.6°C (1.08°F) for types R and S; and 0.8°C (1.44°F) for type B.
Costs:	$1 to $15 for beads; $25 to $60 for detachable probe assemblies with handles, used in the laboratory. A thermocouple provided with a stainless steel thermowell costs about $200, while a thermocouple element, which is integral with a transmitter, can range from $750 to $2000, depending on its design and features

Imparting heat to the junction of two dissimilar metals causes a small continuous electromotive force (EMF) to be generated. One of the simplest of all temperature sensors, the thermocouple (TC) depends upon the principle known as the Seebeck Effect. T.J. Seebeck discovered this phenomenon in 1821, and in the ensuing years the thermocouple has become the most widely used electrical temperature sensor. The word is a combination of *thermo* for the heat requirement and *couple* denoting two junctions.

A TC is an assembly of two wires of unlike metals joined at one end, designated as the hot end. At the other end, referred to as the cold junction, the open circuit voltage or Seebeck voltage is measured. This voltage (EMF) depends on the temperature difference between the hot and the cold junctions and on the Seebeck coefficients of the two metal wires.

THEORY OF OPERATION

An ordinary TC consists of two different kinds of wires, each of which must be made of a homogeneous metal or alloy. The wires are fastened together at one end to form a measuring junction, normally referred to as the hot junction, since a majority of the measurements are made above ambient temperatures. The free ends of the two wires are connected to the measuring instrument to form a closed path in which current can flow. After the TC wires connect to the measuring instrument, the junction inside is designated as reference junction, or the cold junction (see Figure 4.13a)

The EMF developed at wire junctions is a manifestation of the Peltier Effect and occurs at every junction of dissimilar metals within the measuring system. This effect involves the liberation or absorption of heat at the junction when a current flows across it. The resultant heating or cooling depends upon the direction of current flow. Applications of this principle are becoming increasingly useful in electric heating and refrigeration.

A second EMF develops along the temperature gradient of a single homogeneous wire. This is the Thomson Effect. It is most important that each section of wire in a given circuit be homogeneous. This is because if there is no change in the composition or physical properties along its length, the circuit EMF depends only upon the metals employed and the temperature of their junction. Therefore, the circuit EMFs are independent of both length and diameter of wires. Another reason for requiring homogeneous wire is that thermal EMFs within a single strand passing from a warmer to a cooler area, or vice versa, will cancel each other.

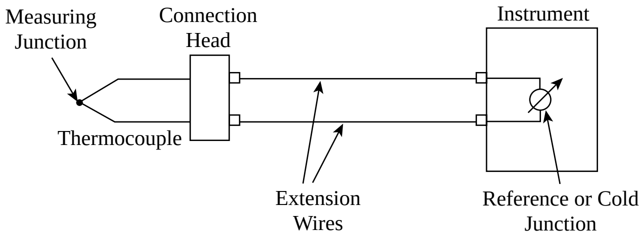

FIG. 4.13a
Thermocouple terminology.

Further, if both junctions of a homogeneous metal are held at the same temperature, the metal does not contribute to the net EMF of a circuit. Since some TCs are made of expensive metals, this fact can be used to cut costs by supplying copper extension wire for long runs.

It follows, then, that by holding temperatures constant at all junctions except one within a given circuit, we can measure temperature as a function of the hot junction temperature with respect to the cold junction temperature.

TCs drift, because of the junction of the two dissimilar metals that degrade. If used at low temperatures, this may only be a few degrees per year and can be calibrated out of the system. At higher temperatures, they degrade more quickly. Further, drift can also be caused by long extension wires; these wires are often of lesser quality than the TC wires and can contribute twice the error if subjected to harsh environmental conditions. Before the use of transmitters, some plants have replaced their extension wires on a regular basis to minimize this effect.

Interpreting the Generated Voltage

The TC reads the difference between the temperatures of its measuring and reference junctions. (Actually, it is a general limitation of human beings that we cannot measure anything in the absolute; all we can do is to compare a known quantity against an unknown.) If we know what the reference temperature is, we can identify the unknown process temperature by measuring the voltage generated by the TC:

$$\text{unknown temperature} = (\text{voltage/Seebeck coefficient}) + \text{reference temperature} \quad \mathbf{4.13(1)}$$

The process temperatures can be obtained from the voltage read by either going to a graph (Figure 4.13b) or, for more accuracy, by going to TC tables that list the voltages corresponding to each temperature with each TC type (such tables are provided at the end of this section).

Unfortunately, the voltage-to-temperature relationship is not a straight-line function, and the Seebeck coefficient is not a constant (Figure 4.13c). For some TCs over certain temperature ranges, such as type K over the range 0 to 1000°C (32 to 1832°F), the Seebeck coefficient is relatively constant (about 40 μV/°C), but in general it changes with temperature. This in the past has resulted in unique scales for each type of TC or in the need to use tables and curves to convert millivolts into temperature. These days the memory capability of the microprocessors has resolved all these problems, and what used to be tedious and time-consuming is now quick and easy. In short, the nonlinear nature of the TCs is no longer a problem.

The same cannot be said about the weakness of the TC signal. As shown in Figure 4.13c, a platinum thermocouple will generate only about 10 μV/°C. On the other hand, even the best industrial transmitters have a minimum span of 1 mV and a minimum absolute error of about 0.01 mV, which is 10 μV. Therefore, it is difficult to obtain a measurement using industrial transmitter and platinum TCs, which would have less than a 1°C error or have a span that is narrower than 60°F (35°C). This is usually acceptable when measuring higher temperatures but is not acceptable at low temperatures or when the temperature span is narrow. For this reason, TCs are not recommended and resistance temperature detectors (RTDs) are used for narrow span or small temperature difference measurements.

Laws of Intermediate Temperatures and Metals

The law of intermediate temperatures states that the sum of the EMFs generated by two TCs—one with its junctions at 32°F (0°C) and some reference temperature, the other with its junctions at the *same* reference temperature and at the measured temperature—will be the same as that produced by a single TC, having its junctions at 32°F (0°C) and the measured temperature.

This concept is illustrated in Figure 4.13d where the measured temperature is 700°F (371°C). By adding an EMF equal to that produced by thermocouple A in Figure 4.13d (with its junctions at 32ºF [0°C] and the reference temperature) to that of thermocouple B, a total EMF equivalent to that generated by the hypothetical thermocouple C results. In most pyrometers, this is done by a temperature-sensitive resistor, which measures the variations in reference junction temperature caused by ambient conditions, and automatically provides the necessary EMF by means of a voltage drop produced across it. Thus, the instrument calibration becomes independent of reference temperature variations.

The law of intermediate metals states that the introduction of a third metal into the circuit will have no effect upon the EMF generated so long as the junctions of the third metal with the other two are at the same temperature. Any number of different metals can be introduced, providing all the junctions are at the same temperature. Thus, in Figure 4.13e the circuits shown all generate the same EMF, even though the second and third circuit diagrams show materials C, D, E, and F inserted between A and B.

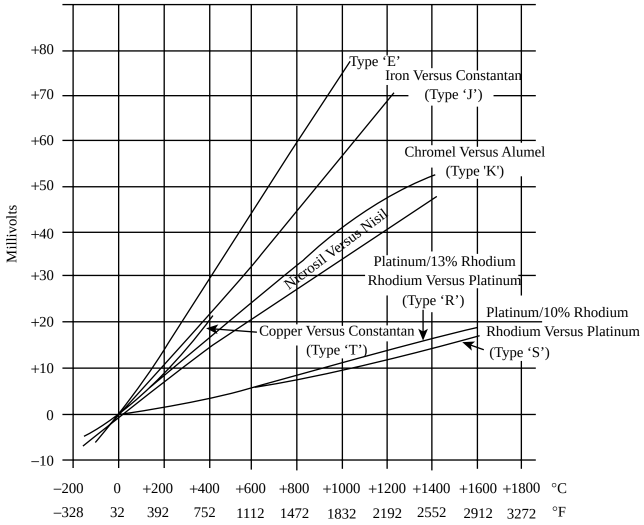

FIG. 4.13b
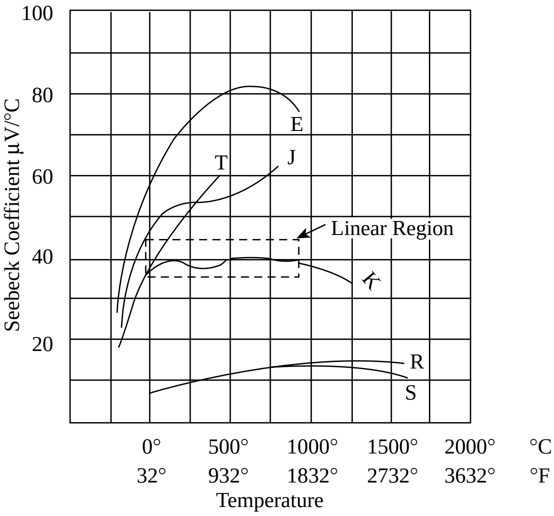
The millivoltage generated by thermocouples varies with wire materials and is a nonlinear function of temperature.

Cold Junction Compensation

When a readout device is employed, it converts the EMF produced by the temperature difference between the hot and cold junctions to record or otherwise display the temperature of the hot junction. To prevent errors due to secondary EMFs produced by variations of temperature at the cold junction



Type	Seebeck Coefficient at Room Temperature (µV/°C)
J	50
K	40
E	60
R	11
S	10
T	38

FIG. 4.13c
The Seebeck coefficient gives the amount of voltage generated (in microvolts) by a one degree change in temperature. The value of the Seebeck coefficient varies not only with thermocouple type but also with temperature.[1]

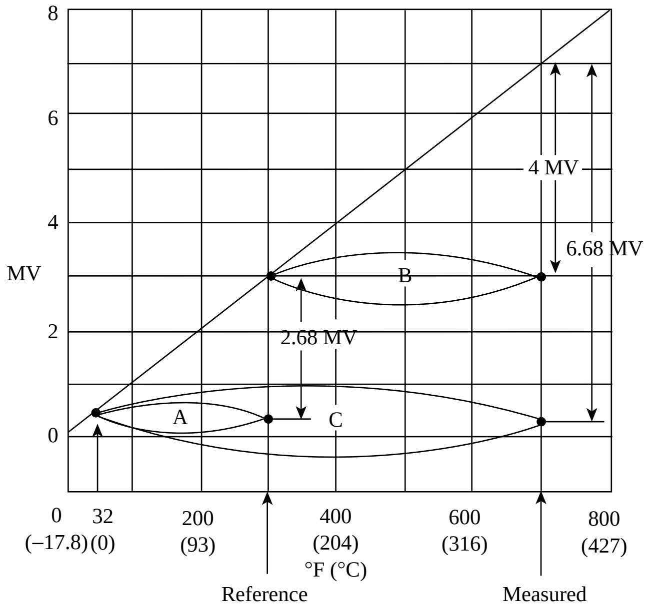


FIG. 4.13d
According to the law of intermediate temperatures, the EMF of thermocouple A plus the EMF of thermocouple B is equal to the EMF of thermocouple C.

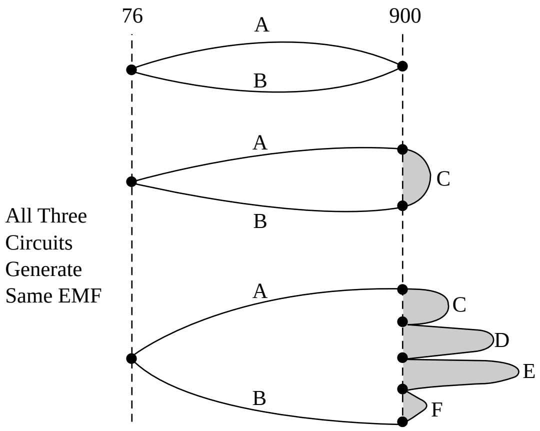

FIG. 4.13e
No harmful effect is caused by introducing any number of metals at a thermocouple junction if all connections are at the same temperature.

and within the readout device, these EMFs must be compensated for. One method is to hold the cold junction at a constant temperature, which can be done in laboratories with an ice bath (Figure 4.13f). An oven can also be used, although keeping an oven temperature constant presents another set of problems.

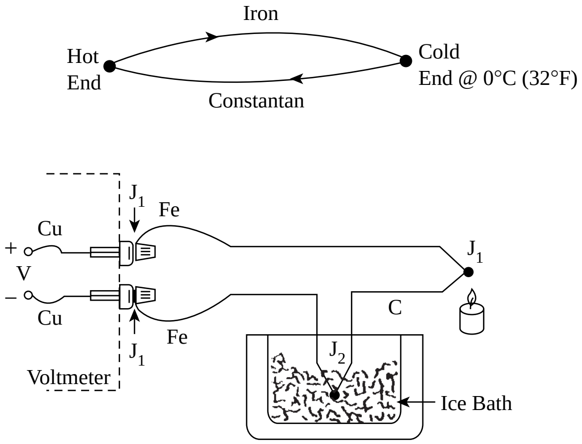

FIG. 4.13f
When an iron-constantan thermocouple measures the process (J_1) and an identical iron-constantan thermocouple reference junction (J_2) is placed in an ice bath, the connection to the readout voltmeter results in two added junctions, J_3 and J_4.[1]

Neither an ice bath nor an oven reference is practical in an industrial environment. In the temperature transmitters used in the process industry, the ice bath reference must be replaced by a variable ambient reference junction. This is achieved by making two changes to Figure 4.13f. The first change is to insert a short copper wire between both voltmeter terminals and the TC leads and to place these new junctions on an isothermal block (Figure 4.13g). This change eliminates the junctions J_3 and J_4 shown in Figure 4.13f because in Figure 4.13g copper is joined to copper at these points. By placing the new J_3 and J_4 junctions on an isothermal block, as shown in Figure 4.13g, their effects cancel out as they are in opposition to each other and are at the same temperature.

The second change was to place the reference junction not in an ice bath (Figure 4.13f), but on the isothermal block. From the law of intermediate metals (Figure 4.13e) we know that when junctions in series are at the same temperature, their number makes no difference. Therefore, J_4 and J_{REF} in Figure 4.13g can be replaced by J_{REF} only.

Figure 4.13h shows the software compensation of the reference junction. Here the voltmeter reads the equivalent of thermocouple B in Figure 4.13d, while the thermometer R_T reads the actual reference temperature of the isothermal block. The thermometer used to measure T_{REF} can be a thermistor (see Section 4.12), an RTD (see Section 4.10), or an integrated circuit transistor. Once T_{REF} is accurately measured (usually within 0.25°C or 0.45°F), the associated software determines the corresponding millivoltage that a TC *would have generated* if its hot junction were at T_{REF} and its cold junction were in an ice bath (thermocouple A in Figure 4.13d). The sum of A and B then represents the measured process temperature (referenced to ice) and can be looked up in the type of tables that are provided at the end of this section.

One might ask, why use a TC at all if another thermometer is needed to measure the reference temperature? The answer to that question is simple: Do not use a thermocouple if another thermometer can measure the temperature. Unfortunately, the sensors, which can accurately detect the ambient temperature (T_{REF}) are not suited for the measurement of high

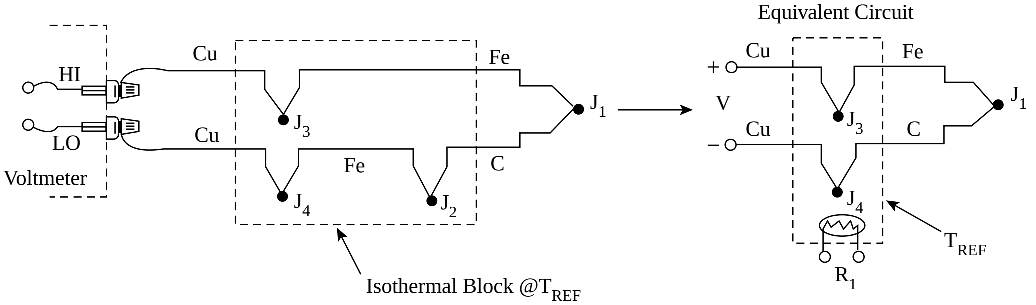

FIG. 4.13g

By using an isothermal block and by inserting copper wires at the voltmeter terminal, an equivalent circuit is arrived at which does not have an ice bath reference.[1]

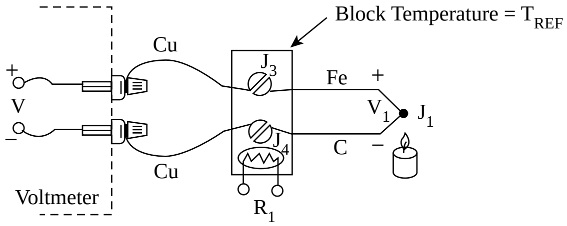

FIG.4.13h

The industrial equivalent of the ice bath reference shown in Figure 4.13f.[1]

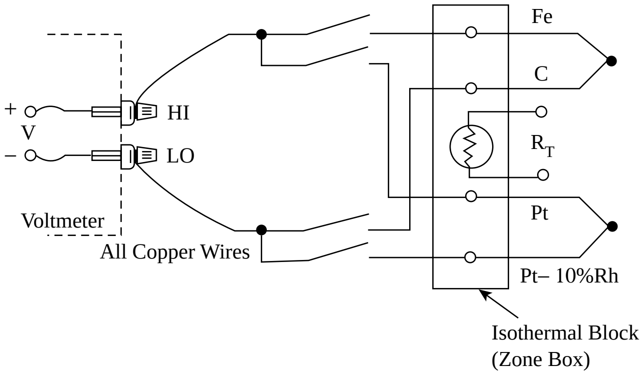

FIG. 4.13i

When many thermocouples are multiplexed, a single reference thermometer is sufficient to provide software compensation.[1]

temperatures or wide spans. For these applications the natural choice is the TC, and when it is used, it must be compensated.

Multiplexing

The cost and complexity of software compensation is reduced when many TCs are multiplexed into the same readout device (Figure 4.13i). In that case, a large number of TCs can be terminated on the same isothermal block and a single thermometer can serve to provide software compensation for all. The disadvantages of TC multiplexing include the necessity of transporting the low-level signals over some distance to the multiplexer (which can introduce common and normal mode noise, discussed later), the relatively high costs of thermocouple lead wires, and the added error due to the variable contact resistances of the multiplexer. Even with gold-plated contacts, there will be at least 1 μV drop through the contacts, which in case of platinum thermocouples corresponds to an error of about 0.2°F (0.1°C).

Hardware Compensation

Prior to the advent of microprocessors and the associated software compensation of TCs, hardware compensation was used. Hardware compensation can be viewed as inserting a battery that cancels out offset voltage produced by the reference junction. These commercially available circuits provide an electronic ice point reference for one or many TCs. Their main advantage relative to software compensation is speed because the computation time is eliminated. The main disadvantage of hardware compensation is that each gain resistor is suited to compensate only a particular type of TC, while software compensation accepts any TC. In practice, hardware compensation is usually accomplished by using resistors whose combined temperature resistance coefficient curves match those of the voltage-temperature curves produced by the reference junctions, canceling any variations in the cold junction temperature.

MEASURING THE EMF GENERATED

The Seebeck EMF can be measured with either a millivoltmeter (Figure 4.13j) or a potentiometer (Figure 4.13k) circuit. We should remember that the thermocouple measures only the difference between its reference and hot junctions. How closely it matches the accepted EMF curve has a bearing on accuracy. EMF tables are usually based upon 32°F (0°C) reference temperatures for convenience (see tables at the end of this section).

To relieve the control engineer of the problem of compensating for temperature instability at the reference junction, a copper or nickel resistor can be placed in a bridge so that

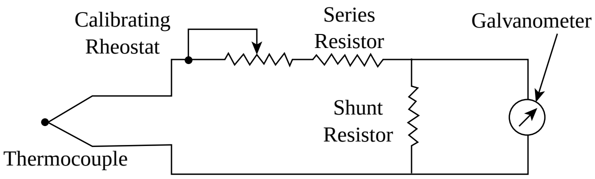

FIG. 4.13j
Millivoltmeter circuit.

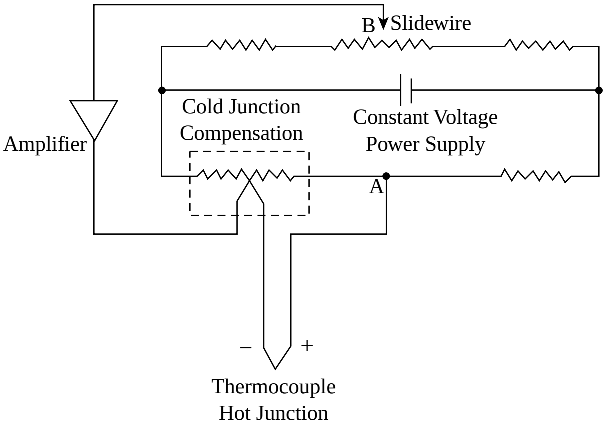

FIG. 4.13k
Potentiometer circuit.

the TC EMF is opposed by an EMF corresponding to the required ambient temperature correction. Operating on the null-balance principle, the resulting potentiometer (Figure 4.13k) tends to reduce any voltage difference between points A and B to zero.

Transmitter Location and Noise

As discussed earlier, TCs produce a very small microvolt output per degree change in temperature. This output is very sensitive to environmental influences, particularly if long extension wires are used. It is recommended to minimize this length, which can be best achieved by mounting the transmitter right inside the thermocouple head.

Electromagnetic interference from motors and electrical distribution and especially radio frequency interference (RFI) from walkie-talkies can be the cause of large errors in measurement. Therefore, the transmitters or other TC readout instruments must have rigid RFI immunity specifications to minimize these effects. TC readouts are considered to be of good quality if their common mode noise rejection is about 100 DB, their normal mode rejection is about 70 DB, and their RFI immunity is 10 to 30 V/m.

Intelligent Transmitters

State-of-the-art transmitters, digital buses, and networks have been discussed in Sections 4.1 and 4.10. The reader is referred to those sections and also to the concluding paragraphs at the end of this section.

THERMOCOUPLE TYPES

Based on possible combinations of metals, there could be countless numbers of thermocouples, but there are relatively few (see Tables 4.13l and 4.13m). Things that determine a metal's usefulness in TC wire include:

1. Melting points
2. Reaction to various atmospheres
3. Thermoelectric output in combination with other metals
4. Electrical conductance, the reciprocal of resistance (listed in Table 4.13n)
5. Stability
6. Repeatability
7. Cost
8. Ease of handling and fabrication

ISA Types J, S, and T

Iron-constantan (type J) can be used in reducing atmospheres. These thermocouples provide a very nearly linear EMF output. They are the least expensive commercially available type.

The platinum-platinum 90%/rhodium 10% (type S) TC is most important. It is used to define the International Temperature Scale between 1166.9°F (630.5°C), the point at which antimony freezes, and 1945.4°F (1063°C), the gold point. This TC is not limited to the above range. It can be used from about 300 to 3215°F (150 to 1768°C) with excellent results. Industrial thermocouples ("Special" in Table 4.13m) of this material will match the standard calibration curve to better than ±0.25%.

Copper-constantan (type T) can be used in either oxidizing or reducing atmospheres. TCs of this type exhibit a high resistance to corrosion from moisture, provide a relatively linear EMF output, and are good from the medium to the very low temperature range.

ISA Types B, E, K, R, and N

Several other TCs are commonly used (see Tables 4.13l and 4.13m), including platinum-platinum 13% rhodium (type R) and platinum 30% rhodium-platinum 6% rhodium (type B), which are recommended for use in oxidizing atmospheres. They are relatively easily contaminated in other atmospheres.

Chromel-alumel (type K) can be used in oxidizing atmospheres. It is the most linear TC in general use.

Chromel-constantan (type E) TCs provide the highest EMF per degree of temperature change. However, it also tends to drift more than the others. It can be used in oxidizing atmospheres.

Tungsten-tungsten 26% rhenium TCs can be used to measure the highest temperatures. It cannot be used in oxidizing atmospheres, and it is also brittle and hard to handle. It is usually used in vacuum or in clean inert gas applications.

A relatively new base-metal thermocouple is designated type N (Nicrosil vs. Nisil). It provides stability as good as

TABLE 4.13l
Thermocouple Comparison Table

ISA Type Designation	Positive Wire	Negative Wire	Millivolts per °F	Recommended Range Limits Temp °F*		Scale Linearity	Atomosphere Environment Recommended	Favorable Points	Less Favorable Points
	Numbers = Percentages			Min.	Max.				
B	Pt70-RH30	Pt94-Rh6	.0003–.006	32	3380	Same as for type R couple	Inert or slow oxidizing	—	—
E	Chromel	Constantan	.015–.042	–300	1800	Good	Oxidizing	Highest EMF/°F	Larger drift than other base metal couples
J	Iron	Constantan	.014–.035	32	1500	Good; nearly linear from 300–800	Reducing	Most economical	Becomes brittle below 32°F
K	Chromel	Alumel	.009–.024	–300	2300	Good; most linear of all TCs	Oxidizing	Most linear	More expensive than T or J
R	Pt87-Rh13	Platinum	.003–.008	32	3000	Good at high temps. poor below 1000°F	Oxidizing	Small size, fast response	More expensive than type K
S	Pt90-Rh10	Platinum	.003–.007	32	3200	Same as R	Oxidizing	Same as R	More expensive than type K
T	Copper	Constantan	.008–.035	–300	750	Good but crowded at low end	Oxidizing or reducing	Good resis. to corrosion from moisture	Limited temp.
Y	Iron	Constantan	.022–.033	–200	1800	About same as type J	Reducing	—	Not industrial standard
—	Tungsten	W74-Re26	.001–.012	0	4200	Same as R	Inert or vacuum	High temp.	Brittle, hard to handle, expensive
—	W94-Re6	W74-Re26	.001–.010	0	4200	Same as R	Inert or vacuum	Same as above	Slightly less brittle than above
—	Copper	Gold-Cobalt	.0005–.025	–450	0	Reasonable above 60 K	—	Good output at very low temp.	Expensive lab.-type TC
—	Ir40-Rh60	Iridium	.001–.004	0	3800	Same as R	Inert	—	Brittle, expensive

the more expensive noble metal TCs up to about 2200°F (1204°C), where type K starts to become unstable. The stability of type N TCs is due to increased percentages of chromium, silicon, and magnesium.

THERMOCOUPLE CONSTRUCTION AND PROTECTION

There are some applications where a bare TC with an exposed junction may be used either by itself or inserted into a protective well. For most process applications, the TC is manufactured with a protective outer sheath that uses an insulating material to electrically separate the TC from the sheath and provide mechanical and environmental protection. In some cases the TC junction is placed in direct contact with the tip of the sheath to increase speed of response.

These sensors demand the use of an electrically isolated measurement circuit. Even insulated TCs will eventually suffer from a breakdown of the insulation, and the TC tip will contact the sheath and associated well. It is virtually assured that a ground loop will be present that will cause measurement errors. These errors are usually insidious in that they usually vary over time and may go unnoticed. Recommended practice is to always use an instrument with full isolation to eliminate this concern.

Measuring Junction Designs

A TC is only as accurate as the wire from which it is made. Therefore, it is common practice for best accuracy to make all TCs from the same coil of wire. This assumes uniformity of the wire. Most manufacturers offer either standard or special calibrations, which imply more care in selection of wire, handling, and manufacturing. The careful selection of materials, proper construction, installation, and handling alone will not maintain highest accuracy; an adequate checking program is also a must.

In order to protect the TC wire, it is usually covered by a thermal insulation and a sheath for mechanical protection. The purpose of this design is to expose only the measuring junction of the TC to the temperature of the process. This can be achieved in three different ways (see Figure 4.13o). The exposed thermocouple junction gives the best speed of response; the time constant can be less than a 1 s with small (down to 0.01 mm diameter) TCs. Their main limitation is that the process materials must not be corrosive to the TC wires.

In the ungrounded junction design, the TC wire is physically insulated from the sheath by insulation material (usually magnesium oxide powder). These designs can be used in corrosive processes, but their speed of response is slow. The grounded junction design is also protected from the corrosive process, but its thermal time constant is shorter (by a few seconds, depending on mass).

Extension Wires

The thermocouple extension wire is usually insulated with Teflon, polyvinyl chloride, nylon, rubber, asbestos, or fiberglass. For higher temperatures refrasil or nextel are recommended. Teflon is used when the TC extension wire must be submerged under water or if resistance to solvent, corrosion, flame, or humidity is critical. Individually insulated duplex wires are usually provided with a protective outer jacket, which can be wrapped, extruded, or stranded. The extension wire to be used for types, E, J, K, and T TCs are designated as EX, JX, KX, and TX extension wires and should extend all the way to the cold junction of the loop.

With connections correctly made, copper extension wire can be used over long distances. However, it is recommended that iron-constantan and copper-constantan always be used with lead wire of the same material. To guard against mistakes in connection, industry practice is to color-code the wires, with the *negative* lead always *red.* Smaller gauge wire provides faster response, but heavier gauge wires last longer and resist contamination or deterioration at high temperatures.

Sheath Materials

The sheath material can be 304 stainless steel if the process temperature is under 1650°F (900°C) and the process is not highly corrosive. In furnaces that operate at up to 2100°F (1150°C), Inconel 600 sheathing is recommended if the atmosphere is oxidizing and there is no sulfur in the atmosphere. Platinum-rhodium alloy sheaths are used up to 3000°F (1650°C) in oxidizing furnaces if no silica or halogens are present. Molybdenum sheaths can be used up to 4000°F (2205°C) to detect molten metal or glass temperatures, but only in oxygen-free vacuum or inert-gas-filled processes. Tantalum sheaths can be used up to 4500°F (2482°C), but only in reducing or noble gas atmospheres where no oxygen is present.

The sheath is usually strong enough to stand up to high pressure (up to 50,000 PSIG, or 3,450 bars), but it is usually not used without a thermowell because the user wants to be able to take out the TC without opening up the process. Figure 4.13p illustrates some high-speed TC assemblies without thermowells.

Thermowells

Protecting tubes or wells are supplied (Figure 4.13q) to protect TCs from harmful atmospheres, corrosive fluids, or mechanical damage; to support the TC; or to permit TC entry into a pressurized system. These tend to reduce the speed of response of the TC, so small-mass, thin-wall, or needle-type installations are supplied where feasible (Figure 4.13p). Disposable-tip thermocouples are supplied in furnace applications (Figure 4.13r). They can also be peened or welded into a tube or tank well. Their low cost makes it feasible to place them in concrete beams while curing or to use them in other single-time operations.

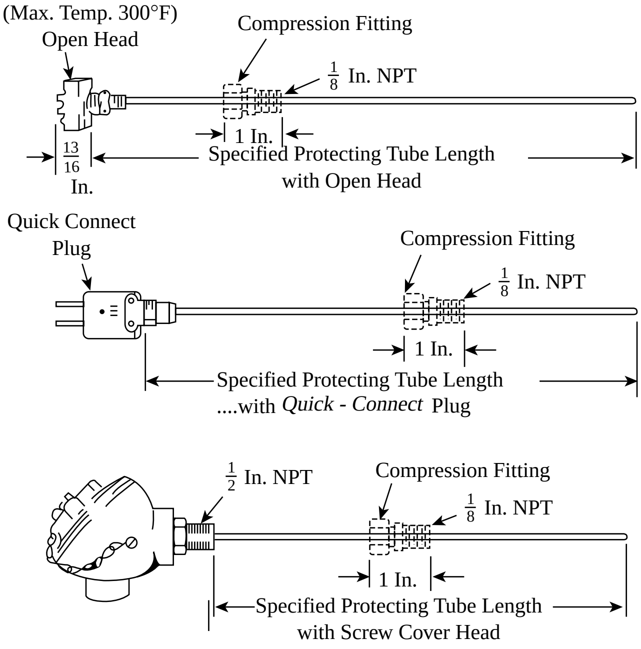

FIG. 4.13p

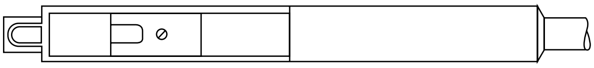

FIG. 4.13r
Molten steel expendable thermocouple.

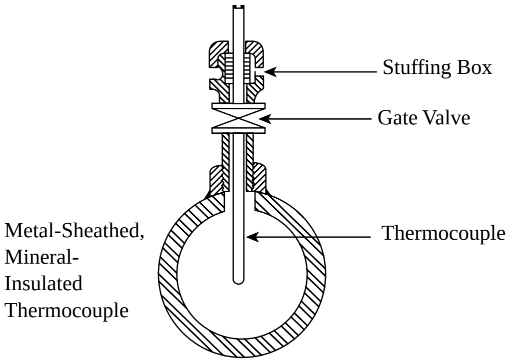

FIG. 4.13s
Installation of thermocouple without thermowells.[2]

When it is desirable to maximize the speed of response of the measurement, but also necessary to periodically remove the sensor, the bare (sheathed) thermocouple can be removed through a stuffing box and gate valve combination (Figure 4.13s). Most TCs are installed in a protecting well. In Figure 4.13t the R dimension is the immersion length, while the U dimension is the insertion length of the well, R should be at least 10 times the diameter of the protective tube (sheath) diameter of the thermocouple. The sheath diameter of different TCs can range from 0.04 to 0.84 in. (1 to 21 mm), while the TCs can range from gauge #36 to #8. The well can

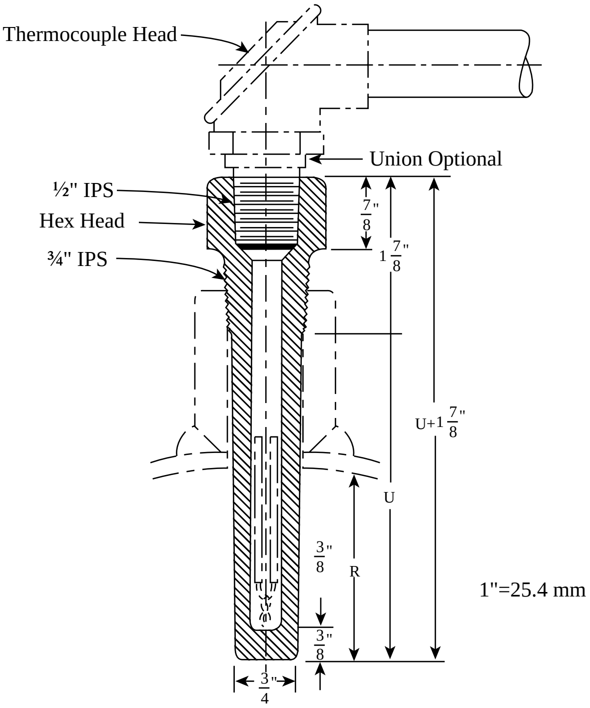

FIG. 4.13t
Screwed thermowell installation.[2]

be inserted perpendicularly into the pipeline if R is not much more than the inside radius of the pipe. Otherwise, it should be inserted at a 90-degree bend in the line.

The most often used well materials are 304 and 316 stainless steel, which are usable up to 1200°F (649°C). At higher temperatures ceramic thermowells are used because metallic ones start to “droop” (bend by gravity). High-purity alumina can be used up to 2200°F (1200°C); the same limit holds for mullite, but this material is not recommended for use with platinum thermocouples as it contains impurities which can contaminate platinum. The thermowell can have screwed connections (Figure 4.13t) or, if frequent inspection is required or if the well is glass-coated, it can be flanged.

Surface Temperature Detectors

When the surface temperature of tubes is to be measured, the TC must be shielded from furnace radiation. The TC can be attached to the heater tube surface by being furnished with stainless steel welding pads (Figure 4.13u, lower part) or by the use of TC attachment blocks (Figure 4.13u, upper part). The multiple holes in these blocks allow for spare TC elements for quick replacement.

Specialized Detectors

Needle Sensors The response time of the needle type sensors illustrated in Figure 4.13v is about 0.25 s. They are made of hypodermic stainless steel in many lengths and diameters. They are available in blunt, center sharp, and hypodermic

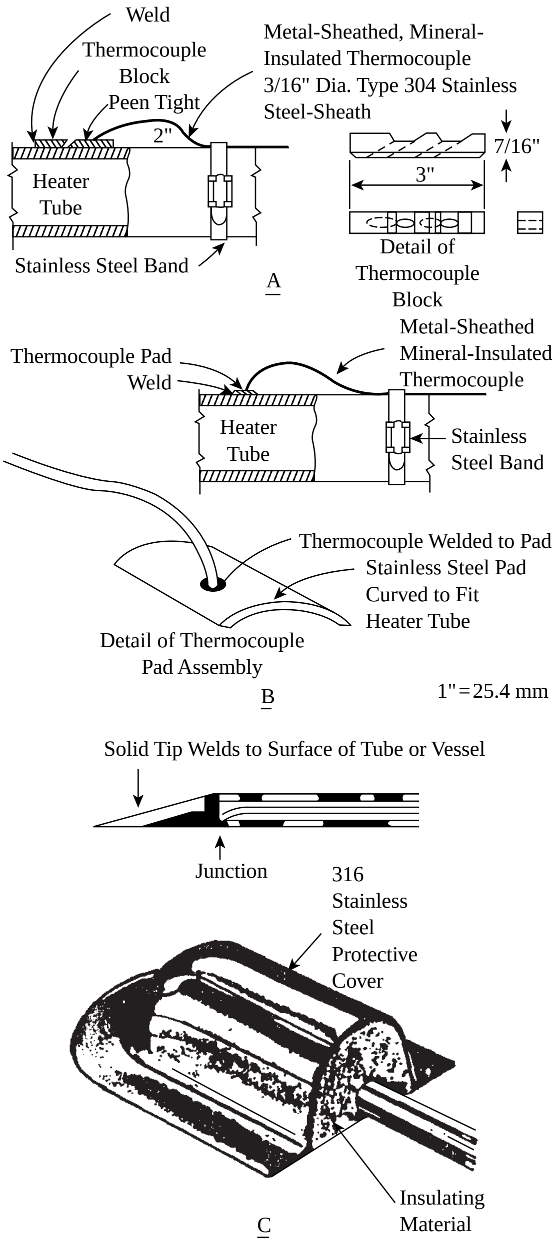

FIG. 4.13u
Tube surface temperature measured by thermocouple block (A) by welded on stainless steel pad,[2] *or by directly welding the thermocouple to the surface (B). A protective cover (C) gives the required mechanical protection.*

FIG. 4.13v

sharp designs and can be made from hard or soft stainless steel. The latter allows for shaping and bending the needle to match the needs of the application.

Suction Pyrometers The suction pyrometer consists of a sheathed TC (sheathed against chemical attack) located inside a radiation shield at the tip of a suction pipe (Figure 4.8d). The combustion gases are sucked through the shield and over the TC at high velocity by aspirating equipment. The efficiency of this aspirating TC is a function of the quality of the radiation shield and of the suction flow rate. If, for example, a suction pyrometer has a 100°C error without suction and a 10°C error when the suction flow is on, it is said to have an efficiency of 90%.

The suction pyrometer probe is usually made of stainless steel and is water-cooled. These probes are designed for high gas velocities of 500 f/s (152 m/s). At such velocities, the radiation shields usually produce better than 90% pyrometer efficiencies. The furnace gases can be pulled out by fans or by air or steam ejectors. The main limitations of this design include plugging of the probe when the combustion products are dusty (as in pulverized coal burners) and being unable to be used in applications where the temperatures exceed 2912°F (1600°C).

INSTALLATION AND PROTECTION

Multiple Thermocouples

The reason for inserting several TCs within the same thermowell can be to obtain a temperature profile over some distance. In this case, each TC junction is located at a different distance from the tip. In order for such sensors to detect the temperature outside the well (and not the air temperature inside it), it is essential that good physical contact be made between the TC junction and the metallic surface of the inside of the well.

Average Temperatures and Temperature Differences TCs can be connected in parallel to provide the average temperature in a system (Figure 4.13w). They can also be used to measure the difference between two temperatures (Figure 4.13x).

In the past, a single TC was often utilized by two separate measuring instruments (Figure 4.13y) because at balance, a potentiometer draws no current from the thermocouple circuit.

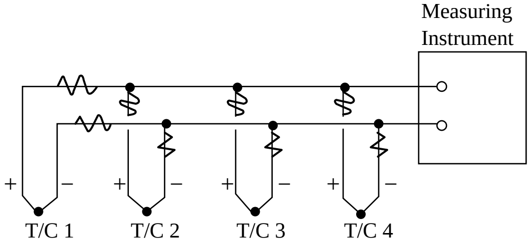

FIG. 4.13w
Average temperature measurement.

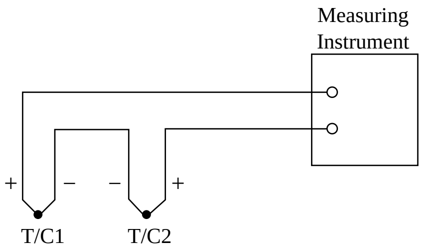

FIG. 4.13x
Temperature difference.

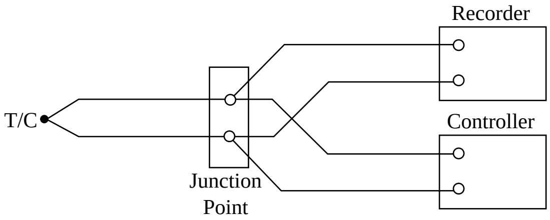

FIG. 4.13y
Parallel operation from common thermocouple.

In case of burnout, a small current circulates through the thermocouple. Today, this kind of configuration is less likely and it is much more common to have transmitters installed directly in the TC head.

Thermopiles Thermopiles are TCs connected in series with electrically insulated junctions (Figure 4.1p). Thermopiles generate large EMFs, reducing sensitivity requirements in the readout instrument. To obtain the mean temperature at several points being monitored by similar TCs in series, divide the total EMF by the number of sensing junctions and relate this EMF value to a corresponding temperature reading in the EMF-temperature table for the type of TC being used. As was discussed in Section 4.1, thermopiles can be used to amplify the output signals in differential temperature measurements and to serve as heat-flow detectors.

The principal objections to the use of thermopiles are the need for electrical isolation of individual TCs and the error that might go unnoticed when the output of one of the TCs is reduced by a short circuit. One satisfactory application for thermopiles is to use them as temperature differential detectors.

Thermocouple Burnout

When a TC detects the temperature in furnaces or superheaters (Figure 4.13z), the extension wire can pass through flames. On high-temperature services, TCs are provided with platinum, tantalum, or molybdenum sheath materials over the insulation, which can be magnesium or beryllium oxide. Hot spots like a burning coal seam can eventually burn through the sheath and the insulation of the extension wire. When the wires melt, a short develops. This is called TC burnout. Under these conditions the TC no longer indicates the temperature of the initial hot junction; instead, it measures the temperature

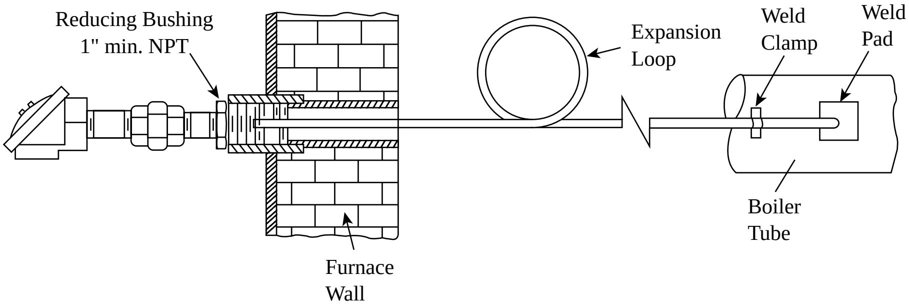

FIG. 4.13z
The expansion loop allows for thermal expansion in furnace applications.

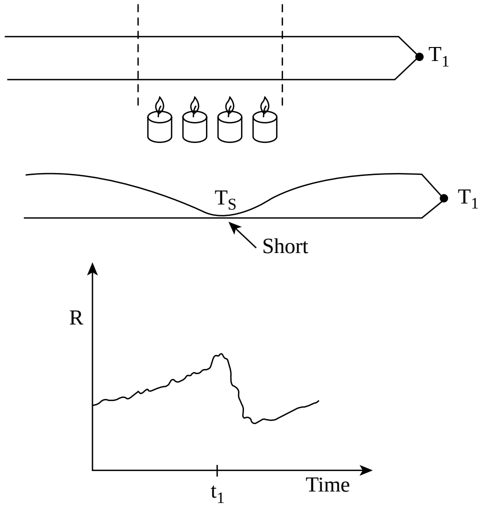

FIG. 4.13aa
Thermocouple burnout can be detected by measuring the resulting drop in thermocouple loop resistance.[1]

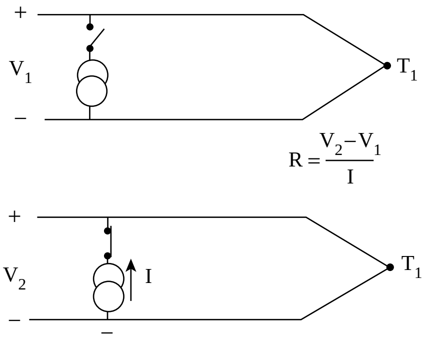

FIG. 4.13bb
Offset-compensated ohms measurement allows detection of the thermocouple loop resistance.

at the hot spot. One cannot detect TC burnout by reading the millivolt signal. However, if one measures the TC resistance (see Table 4.13n), that will signal a change as a result of burnout (Figure 4.13aa).

Under normal conditions, a running record of the thermocouple resistance will show gradual changes with temperature. When the thermal insulation is beginning to fail and a short is beginning to form, the TC resistance will rise first, and when the hot spot burns through and a short is formed, the TC resistance will drop abruptly. The method used to measure the TC resistance is called offset-compensated ohms measurement.

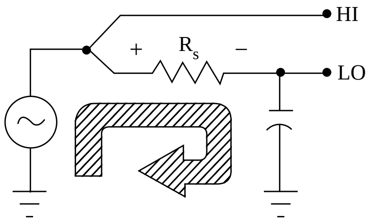
As shown on the top of Figure 4.13bb, normally the millivolts (V_1) are measured across the TC. Then, a current source is connected periodically and the millivolts (V_2) are measured again. The TC resistance is calculated by subtracting the thermocouple millivolts from the total and dividing it with the current flow in the loop: $R = (V_2 - V_1)/I$. By continuously recording this resistance, one can detect when an abrupt drop occurs, signaling TC burnout.

Protection Against Noise

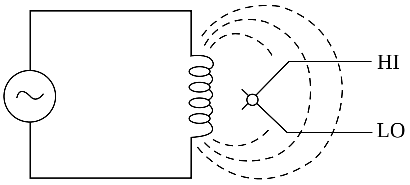
The TC signal is very weak—a one degree change in temperature results in only a few millionths of a volt change in output. Because of this, precautions must be taken against errors due to stray currents resulting from the proximity of electrical wiring (common mode noise) or from capacitive secondary grounds (normal mode interference). Common mode noise (Figure 4.13cc) appears on both TC signal wires and therefore can be filtered out as 60 Hz (or 50 Hz) harmonic noise. The filter does reduce the interference dramatically, but it also causes the voltmeter to be sluggish when responding to a step change. It is also possible to eliminate the common mode interference by using twisted wire leads because each time the wire is twisted, the flux-induced current is inverted.

Another recommended form of protection against any type of common mode noise is guarding and shielding. If the shield surrounding the lead wires is connected to the guard surrounding the voltmeter, the interfering current caused by AC interference does not flow through the TC lead resistance but instead is shunted. Naturally, when TCs are scanned, the scanner guard must be switched to the shield of the TC being read to eliminate ground loops. Harmonics can also be removed by integrating the incoming signal over the power line cycle in

]



Normal Mode



Common Mode

FIG. 4.13cc
Noise interference that enters only one of the lead wires (normal mode) is more difficult to remove than noise that acts on both leads (common mode).

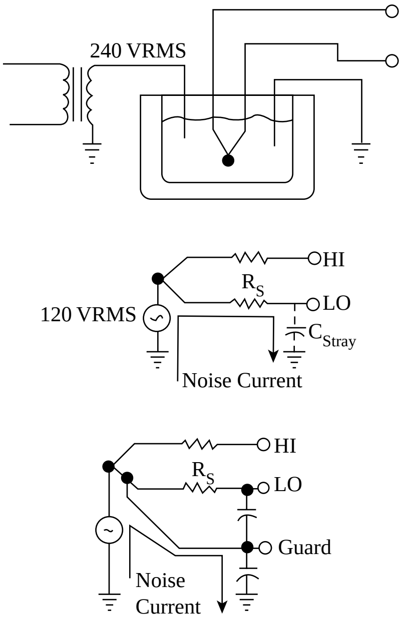


FIG. 4.13dd
The addition of a guard lead wire reduces the normal mode noise.[1]

an integrating analog-to-digital (A/D) converter or voltmeter. In short, common mode noise is relatively easy to remove.

Normal Mode Noise The same cannot be said about normal mode noise. An example of normal mode noise interference can occur in the measurement of the temperature in a molten metal bath, which is heated by electric current. In this case, the TC junction is in direct contact with a common mode noise source. In addition, the capacitive ground (C-stray) from the LO terminal of the TC to the chassis causes a current flow in the low lead and an associated normal mode noise voltage across the resistance R_S (Figure 4.13dd).

If a guard lead wire is installed connected directly to the TC, the current flowing in the LO lead through the resistance R_S is drastically reduced. Therefore, the worst form of interference is DC offset caused by a DC leakage current; whatever normal mode noise remains in the system, it cannot be distinguished from the measurement and, in case of weak signals, even a small amount of noise can represent a large amount of interference.

CALIBRATION, DIAGNOSTICS, AND TRANSMISSION

Calibration

Since all TCs are subject to drift, calibration checks are done regularly in laboratories and industrial plants. For calibrating TCs, depending upon the application, various procedures are used. Primary standard thermocouples of platinum vs. platinum plus 10% rhodium can be calibrated by the National Bureau of Standards to fixed points on the International Practical Temperature Scale. However, these TCs must be handled carefully to retain their accuracy. Most major manufacturers can supply TCs, which are against primary standard thermocouples that are kept in their own metrology laboratories. Secondary reference TCs for in-plant use are usually made of base metal. Comparison of these against the Primary Standard TC is accomplished by placing them in close contact in a checking furnace. Users normally check their ordinary TCs against these secondary standards.

Diagnostics

TC diagnostics can be improved by the use of tip-branched and leg-branched lead wires allowing redundant measurements, verification of system integrity, and other forms of diagnostics. These tools can be useful in detecting the failure of wire insulators, poor junction connections, wire degradation due to overheating, or decalibration due to diffusion of atmospheric particles into the metal. Added to the noise protection and degradation problems are the intermediate wire junctions, which if not at the same temperature (Figure 4.13e), also contribute errors.

Transmission

Because of the problems associated with long extension wires, including noise interference (guarding, shielding, using twisted pairs, and integration), the best alternative is not to send low-level TC signals over long distances at all, but to place the transmitter electronics directly on top of the thermowell (Figure 4.13ee).

In the past it was more economical to run the TC lead wires to the data acquisition systems, and this is still the case in the laboratory and on various test stands. On the other hand, the cost of integral transmitters in most industrial applications has become competitive with the cost of running the thermocouple lead wires to the control room. These integral transmitters are

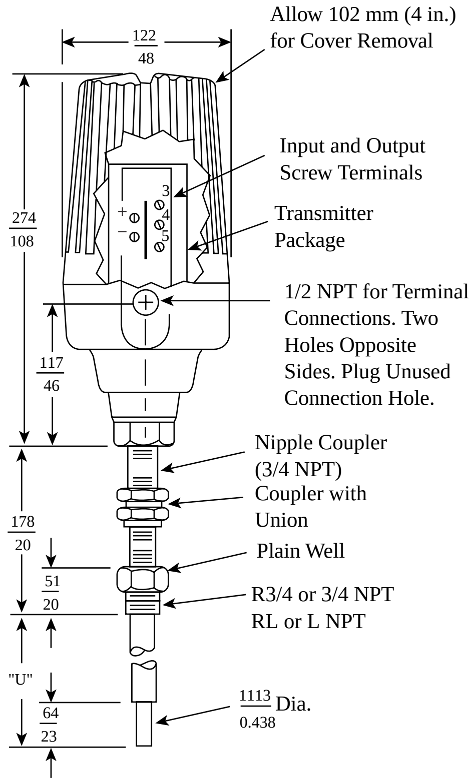

FIG. 4.13ee
Integral thermocouple transmitter mounted directly on top of the thermowell. (Courtesy of The Foxboro Co.)

also explosion-proof. Conventional transmitters are accurate to 0.15% of span, and intelligent units are accurate to 0.05% of span (Table 4.13m). It can be observed that while intelligent transmitters give better performance than the standard ones, they too are limited to a minimum absolute error plus cold junction error, which equals about 1°F (0.6°C).

Intelligent Transmitters During the last decade, microprocessor based temperature transmitters have continued to evolve in sophistication and capability. They usually include an input circuit referred to as an A/D converter that converts the sensor input signal from its analog form into a digital representation. The microprocessor performs the ranging, linearization, error checking, and conversion. The resulting digital value is then converted back, usually to a 4–20 mA DC analog signal. For some special applications, 0–1 V DC or 0–10 V DC or digital signals using either an open or proprietary protocol are also used.

Today, universal transmitters that accept inputs from any TC, RTD, or other resistance and mV source are commonly available. They make transmitters interchangeable and thereby reduce inventories. They check their own calibration on every measurement cycle, minimize drift over a wide ambient temperature range, incorporate self-diagnostics features, and can be configured by the use of simple push buttons or personal computer software. Their reconfiguration process is quick and convenient.

In addition to improved performance, the intelligent transmitters are capable of working with any one of eight types of TCs or two types of RTD elements. This increases their flexibility and reduces the need for spare parts. The intelligent transmitters are also provided with continuous self-diagnostics and with automatic three-point self-calibration, which is performed every 5 s and does not interrupt the analog or digital output of the unit.

The intelligent transmitter can also be furnished with dual thermal elements that can be used to measure temperature differentials, averages, and high/low sensors, or as redundant backup elements. Another convenient feature of smart transmitters is their remote reconfiguration capability, which can change their zero, span, or many other features without requiring rewiring.

ADVANTAGES AND LIMITATIONS

The weakest link in virtually all measurements is the temperature sensor. For most industrial applications the thermocouple (TC) has been popular, because it is relatively inexpensive, can be produced in a variety of sizes, can be of ruggedized construction and covers a wide temperature range. Thermocouples are also small, convenient, and versatile (can be welded to a pipe), cover wide ranges, are reasonably stable, reproducible, accurate, and fast. The EMF they generate is independent of wire length and diameter. While RTDs are more accurate and more stable and while thermistors are more sensitive, thermocouples are the most economical and the best to detect the highest temperatures.

The main disadvantage of the TC is its weak output signal. This makes it sensitive to electrical noise and limits its use to relatively wide spans (usually the minimum transmitter span is 1.0 mV). It is nonlinear, and the conversion of the EMF generated into temperature is not as simple as in direct reading devices. TCs always require amplifiers, and the calibration of the TC can change due to contamination or composition changes due to internal oxidation, cold-working or temperature gradients. Another limitation is that bare TCs cannot be used in conductive fluids, and if their wires are not homogeneous, this can cause errors.

In general, one should use the largest size TC wire possible, and avoid stress and vibration. Use of integral transmitters is also recommended whenever possible (and otherwise use twisted and shielded wires with the shield connected to the guard of the integrating A/D converter). In addition, one should avoid steep temperature gradients, and be careful in selecting the sheath and thermowell materials.

THERMOCOUPLE TABLES

Tables 4.13ff, 4.13gg, 4.13hh, 4.13ii, 4.13jj, and 4.13kk provide temperature vs. millivolts data for types J, K, R, S, T, and E thermocouples. All thermocouple tables in this handbook are

$$^{*}{}^{\circ}C = \frac{{}^{\circ}F - 32}{1.8}$$

based upon a reference junction temperature of 32°F (0°C); therefore, direct conversion from the tables can be made only when an ice bath is used at the reference junction.

If it is not possible to maintain the reference junction temperature at 32°F (0°C), a correction factor must be applied to the millivolt values shown in the TC tables. Note that the millivoltage produced by a given thermocouple is decreased when the temperature difference between the measuring junction and the reference junction is decreased. Correcting for reference junction temperatures other than 32°F (0°C) is described below.

Converting Millivoltage to Temperature

To apply the reference junction correction factor to a given potentiometer millivoltage reading, proceed as follows:

1. From the appropriate TC table, obtain the millivoltage (based upon a 32°F R/J) corresponding to the actual temperature of the thermocouple reference junction.
2. Add the value obtained in step 1 to the millivoltage read on the potentiometer.
3. The corrected millivoltage may then be converted into terms of temperature directly from the same table.

Example 1 A potentiometer indicates a 13.019 mV when connected to a type T thermocouple, and it is desired to convert this value to its equivalent temperature. The actual TC reference junction temperature, as determined by an accurate mercury-in-glass thermometer, is 68°F (20°C). Interpolating* from the type T Table, 68°F = 0.787 mV, based upon

---

* To interpolate between two printed values, add to the smaller value a proportionate part of the difference between the two printed values:
Example 1a (positive temperature)

$$248°\text{F} = 245° + \frac{3}{5}(250° - 245°).$$

In terms of millivoltage from the type T table,

$$\begin{aligned}248°\text{F} &= 5.147 + \frac{3}{5}(5.280 - 5.147)\\ &= 5.147 + 0.0798 = 5.227\text{ mV}\end{aligned}$$

Example 1b (negative temperature)

$$-248°\text{F} = -245° + \frac{3}{5}(-250° - (-245\ °))$$

In terms of millivoltage from the type T table,

$$\begin{aligned}-248°\text{F} &= -4.688 + \frac{3}{5}(-4.747 - (4.668))\\ &= -4.688 + \frac{3}{5}(-4.747 + 4.688)\\ &= -4.688 - 0.0354 = -4.723\text{ mV}\end{aligned}$$

a 32°F reference junction. Adding this value to the potentiometer reading, 13.019 + 0.787 = 13.806 mV, which is the corrected millivoltage based upon a 32°F reference junction. Interpolating from type T table, 13.806 mV = 539°F (282°C).

Example 2 A type T thermocouple under steady operating conditions causes a potentiometer reading of –3.357 mv. The actual TC reference junction temperature is 70°F (21°C). From the type T table, 70°F = 0.832 mV based upon a reference junction of 32ºF. Adding these two millivoltages algebraically, –3.357 + 0.832 = –2.525 mV. Interpolating,* –2.525 mV = –98°F (–72°C).

Converting Temperature to Millivoltage

To determine the proper millivolt input required to check the calibration of an instrument, proceed as follows:

1. From the appropriate table, obtain the millivoltage based upon a 32°F reference junction corresponding to the actual temperature at the input terminals of the instrument to be checked.
2. From the same table, obtain the millivoltage based upon a 32°F reference junction for the temperature to be checked.
3. Subtract the value obtained in step 1 from the value obtained in step 2.

Example 1 It is desired to check the calibration of an instrument at 300°F (149°C). The instrument has a scale graduated in degrees Fahrenheit for a type T thermocouple. The actual temperature at the input terminals of the instrument to be checked, as determined by an accurate mercury-in-glass thermometer, is 70°F (21°C). From the type T table, 70°F = 0.832 mV and 300°F = 6.647 mV based upon a reference junction temperature of 32°F. Substracting these values, the corrected millivoltage input required on the basis of a 70°F reference junction is 6.647 – 0.832 = 5.815 mV.

Example 2 It is desired to determine the correct millivoltage input required to check the calibration of an instrument at –200°F (–129°C). The instrument scale is graduated in

$$*°C = \frac{°F - 32}{1.8}$$

degrees Fahrenheit for a type T thermocouple. The actual temperature at the input terminals of the instrument is 68°F (20°C). From the type T table, 68°F = 0.787 and –200°F = –4.111 mV based upon a 32°F reference junction. Subtracting these values, the corrected millivolt input on the basis of a 68°F reference junction is –4.111 – 0.787 = –4.898 mV.

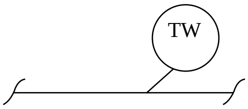
4.14 Thermowells

H. L. DANEMAN (1995) **B. G. LIPTÁK** (2003)



Flow Sheet Symbol

Applications:	Providing mechanical and corrosion protection for thermal elements and for sighting of radiation pyrometers
Temperature Range:	From cryogenic up to 3500°F (1950°C)
Materials of Construction:	Carbon steel, 304 or 316 stainless steel, Carpenter 20, Hastelloy B or C, Inconel, Monel, nickel, titanium, glass-lined, or ceramics (alumina or mullite). See Table 4.14g for a detailed listing of recommended materials for a variety of applications.
Costs:	Steel, 304 or 316 stainless steel well with 0.5 in. (13 mm) NPT threaded connection and 2.5 in. (64 mm) insertion length costs $25 to $35, while with 10.5 in. (268 mm) insertion length the cost is about $75. Flanged units cost about twice as much. Relative to stainless steel, the cost multipliers of other well materials are as follows: 1.1 for Monel; 2.0 for Inconel, Carpenter 20, nickel, titanium, and ceramics; and 3.0 for Hastelloy B and C.

The purpose of thermowells is to protect the thermal elements from mechanical damage and corrosion or to act as sighting tubes for radiation thermometers. Some of these protective sockets have already been discussed in other sections of this volume. These references include Figure 4.2d in connection with bimetallic thermometers; Figure 4.6e in connection with

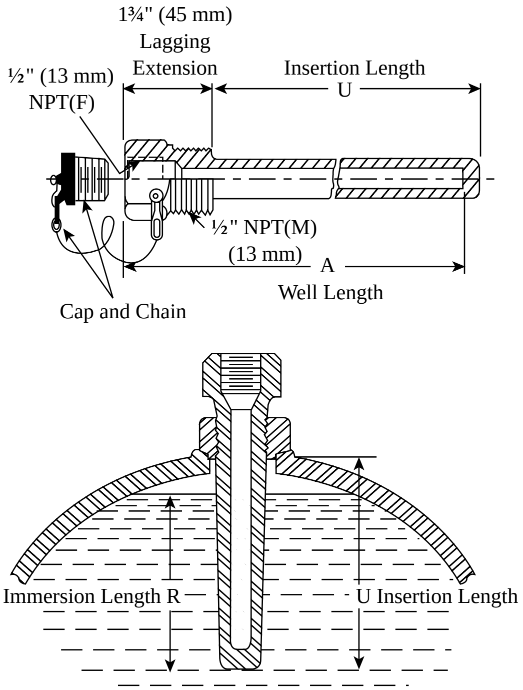

FIG. 4.14a
The test well and its installation.

filled bulb thermometers; Figure 4.9i in connection with pyrometer sighting tubes, Figure 4.10k in connection with resistance temperature detector protection; and Figures 4.13q, 4.13t, and 4.13ee in connection with thermocouple wells. The discussion here will build on (but not repeat) what was already said in connection with the noted figures.

INTRODUCTION

Thermowells permit the removal of thermal elements for calibration, replacement, or repairs and also allow the use of portable sensors. The well or protection tube is permanently inserted into the pipe or vessel and is secured by threads, flanges, or welds, allowing the thermal element to be inserted into the well without causing any stress (Figure 4.14a).

THERMOWELL TYPES

Thermowells are usually metallic and may be coated with other materials to provide additional corrosion protection. Integral flanges or threaded sections enable the wells to be secured to the pipe or vessel (Figure 4.14b). Internal threads secure nipples which extend the head beyond any insulation. It is important to avoid contamination of temperature sensors by oil (such as cutting oils) left on the inner surface of drilled wells or accumulations of foreign materials within wells.

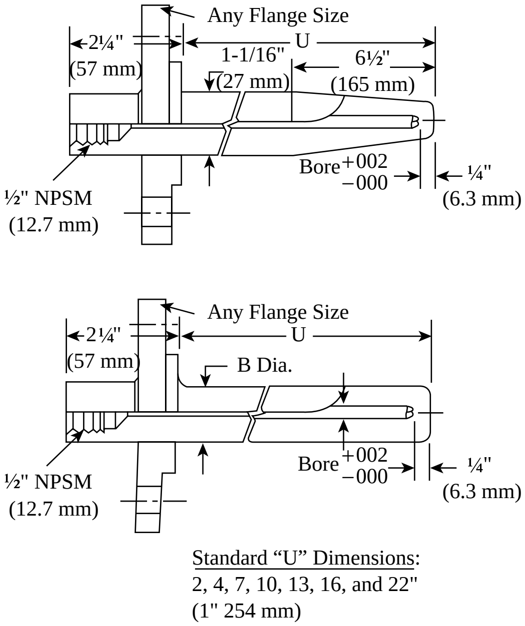

FIG. 4.14b
Flanged thermowells with tapered and straight shanks. (Courtesy of Trend Instruments Inc.)

Protection Tubes

Protection tubes can also be ceramic when used to protect noble metal thermocouples (TCs) or as sighting tubes for radiation pyrometers. While not as strong as metallic thermowells, they do not droop and can withstand higher temperatures; in addition, they are free of contamination which can cause thermocouple drift due to vapor deposition of elements at higher temperatures. Mullite and high-purity alumina are commonly used as ceramic thermowell materials. In addition to being corrosion-resistant, mullite can operate up to 3200°F (1750°C) and alumina up to 3540°F (1950°C). When platinum TCs are used at temperatures exceeding 2200°F (1200°C), mullite should not be used, because it contains impurities that can contaminate platinum. For such applications, high-purity alumina is the proper choice.

Dual protection tubes may be used where the outer tube provides mechanical protection and the inner tube provides corrosion or permeation protection. See Figure 4.14c for an example of protective layers used on a high-temperature TC.

The sheaths are either extruded or woven and are used to protect TCs or other wires. Woven sheaths are similar to those used for electrical insulation and may be made of stainless steel, Inconel, tinned copper, fiberglass, or ceramics. They can withstand temperatures up to 2200°F (1204°C) continuously or 2800°F (1538°C) for short periods of time.

Sheaths

Extruded sheaths can be plastic or metallic. The metallic sheaths are commonly used for mineral-insulated thermocouples in which the wire elements are surrounded by

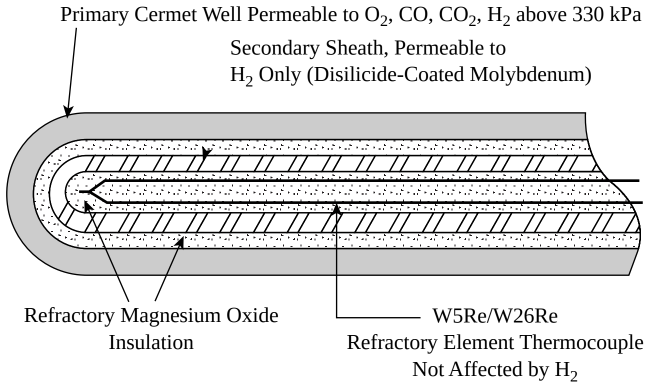

FIG. 4.14c
Multiple layers of protection used on a high-temperature thermocouple.

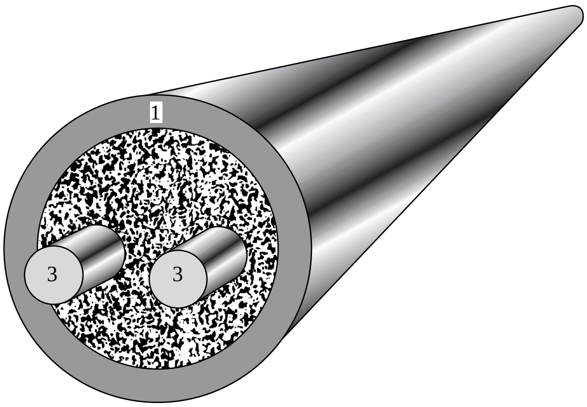

FIG. 4.14d
Thermocouple wires surrounded by magnesium oxide or other mineral insulation and protected by an integral metal sheath of stainless steel or Inconel.

ceramic oxides such as magnesium oxide (Figure 4.14d). After being packed with powdered oxides, the sheaths are swaged or rolled under pressure to reduce their diameter and tightly pack the powdered insulation. While this process serves to reduce intrusion of atmosphere within the sheath, it does not protect against humidity or moisture. Moisture intrusion is rapid and deteriorates insulation resistance to the point of thermocouple failure. Procedures for insulation resistance testing are to be found in the American Society for Testing and Materials documentation. Such testing is vital for mineral-insulated, metal-sheathed TCs stored in the open at construction sites or in repair shops for periods of time. Sheathing can also cause vapor transfer at elevated temperatures, which can result in thermocouple drift. This is the case with stainless steel sheaths used for nickel-bearing TCs such as types K and N. The offending element is manganese, and the problem can be eliminated by specifying low-manganese Inconel or modified Nicrosil sheathing.

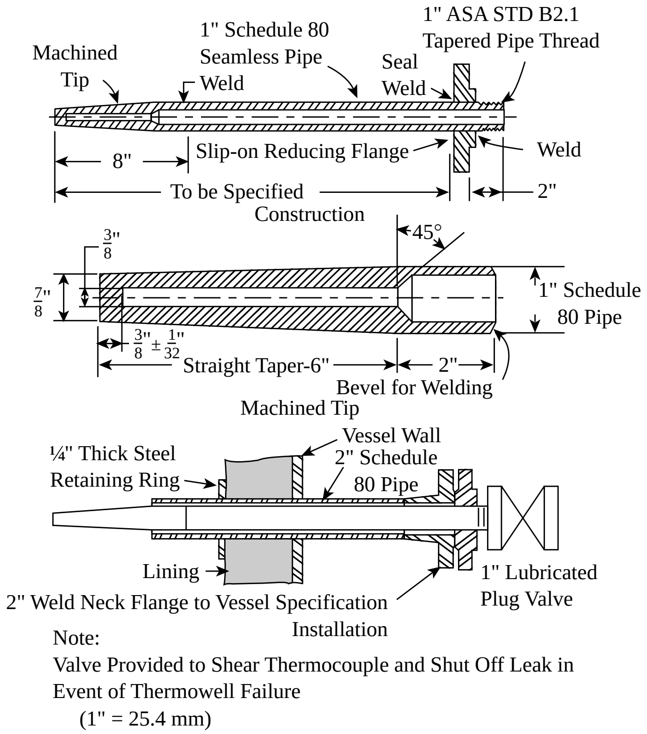

FIG. 4.14e
Flanged thermowell designs used on erosive services.[1]

THERMOWELL INSTALLATION

Well installation should be planned so that the wells are readily accessible for servicing and the thermal elements can be withdrawn without obstruction by adjacent structures. It is desirable to install spare wells for calibration purposes so the working sensor can be compared to a standard temperature sensor.

Vertical installation is preferred for very high temperature use to prevent sagging. Horizontal installation, on the other hand, avoids some contamination by foreign materials (Figure 4.14e). In horizontal installations, consideration should be given to the possibility that construction or repair personnel might misuse the wells as steps.

Immersion Depth

The thermowell immersion depth (U) should be sufficient to eliminate conduction error. A general rule is to use an insertion length equaling a minimum of 10 times the diameter of the protection tube or well. Another rule of thumb is to have the sensitive portion of the sensor immersed to a depth of a minimum of 3 in. (75 mm) plus the length of the sensitive portion. In the case of expansion bulbs, the immersion depth may be specified by the supplier or can be indicated on a calibration report, if furnished.

For pipe installations, such as steam or hot water lines, insertion in an elbow on the axis of the pipe can permit an appropriate immersion depth should the diameter of the pipe be inadequate (Figure 4.14f).

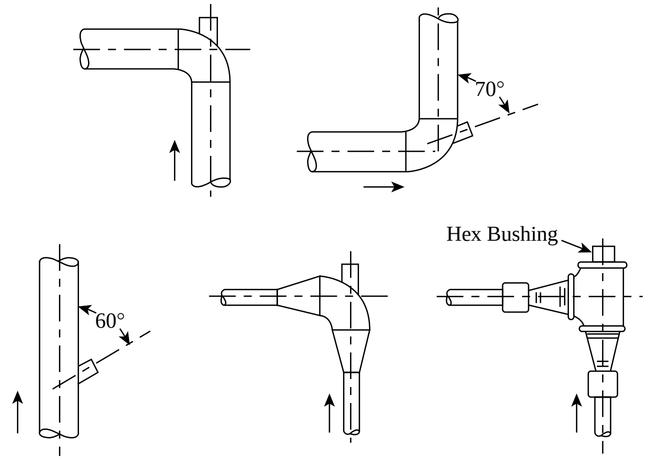

FIG. 4.14f
Alternate ways of installing thermowells in pipes that are 3 in. (75 mm) or smaller in diameter.[1]

When installing thermowells at an angle or in elbows, it is hard to maintain sanitary conditions, which is an important consideration in the food and pharmaceutical industries. Thermowells inserted into small pipes can also cause excessive flow restrictions, pressure drops, or even plugging.

Thermowell Time Constants

The time constant of a thermal element increases with its mass. If time constants of a couple of seconds or less are required, unprotected, small diameter, and bare thermal elements must be used. The addition of even a thin-walled sheath or thermowell increases the time constant to about 5 s as a minimum, and with larger bulbs it can reach 30 s. It is also important to maintain positive contact between the thermal element and the well in order to make sure that the temperature being measured reflects the temperature of the process on the outside and not the air temperature on the inside of the well.

If the process gases include hydrogen and a filled thermal element is used, it might be a good idea to vent the well, since hydrogen can damage the filling material.

In Table 4.14g, well material recommendations are given for a variety of services.

TABLE 4.14g
Selection Guide for Thermowell Materials[2]

Application	*Thermowell Material*
Heat Treating	
Annealing	
Up to 704°C (1300°F)	Black steel
Over 704°C (1300°F)	Inconel 600,[a] Type 446 SS
Carburizing hardening	
Up to 816°C (1500°F)	Black steel, Type 446 SS
1093°C (1500 to 2000°F)	Inconel 600, Type 446 SS
Over 1093°C (2000°F)	Ceramic[b]
Nitriding salt baths	Type 446 SS
Cyanide	Nickel (CP)
Neutral	Type 446 SS
High speed	Ceramic[b]
Iron and Steel	
Basic oxygen furnace	Quartz
Blast furnaces	
Downcomer	Inconel 600, Type 446 SS
Stove dome	Silicon carbide
Hot blast main	Inconel 600
Stove trunk	Inconel 600
Stove outlet flue	Black steel
Open hearth	
Flues and stack	Inconel 600, Type 446 SS
Checkers	Inconel 600, Cermets
Waste heat boiler	Inconel 600, Type 446 SS
Iron and Steel cont.	
Billet heating slab heating and butt welding	
Up to 1093°C (2000°F)	Inconel 600, Type 446 SS
Over 1093°C (2000°F)	Silicon ceramic carbide
Bright annealing batch	
Top work temperature	Not required (use bare type J thermocouple)
Bottom work temperature	Type 446 SS
Continuous furnace section	Inconel 600, ceramic[b]
Forging	Silicon carbide, ceramic[b]
Soaking pits	
Up to 1093°C (2000°F)	Inconel 600,
Over 1093°C (2000°F)	Silicon ceramic carbide[b]
Nonferrous Metals	
Aluminum	
Melting	Cast iron (white-washed)
Heat treating	Black steel
Brass or bronze	Not required (use dip-type thermocouple)
Lead	Type 446 SS, black steel
Magnesium	Black steel, cast iron
Tin	Extra heavy carbon steel
Zinc	Extra heavy carbon steel
Pickling tanks	Chemical lead

TABLE 4.14g (Continued)
Selection Guide for Thermowell Materials[2]

Application	*Thermowell Material*
Cement	
Exit flues	Inconel 600, Type 446 SS
Kilns, heating zone	Inconel 600
Ceramic	
Kilns	Ceramic[b] and silicon carbide[c]
Dryers	Silicon carbide, black steel
Vitreous enameling	Inconel 600, Type 446 SS
Glass	
Fore hearths and feeders	Platinum thimble
Lehrs	Black steel
Tanks	
Roof and wall	Ceramic[a]
Flues and checkers	Inconel 600, Type 446 SS
Paper	
Digesters	Type 316 SS, Type 446 SS
Petroleum	
Dewaxing	Types 304, 310, 316, 321, 347 SS, carbon steel
Towers	Types 304, 310, 316, 321, 347 SS, carbon steel
Transfer lines	Types 304, 310, 316, 321, 347 SS, carbon steel
Factioning column	Types 304, 310, 316, 321, 347 SS, carbon steel
Bridgewall	Types 304, 310, 316, 321, 347 SS, carbon steel
Power	
Coal-air mixtures	304 SS
Flue gases	Black steel, Type 446 SS
Preheaters	Black steel, Type 446 SS
Steel lines	Types 347 or 316 SS
Water lines	Low carbon steels
Boiler tubes	Type 304, 309, or 310 SS
Gas Producers	
Producer gas	Type 446 SS
Water gas	
Carburetor	Inconel 600, Type 446 SS
Superheater	Inconel 600, Type 446 SS
Tar stills	Low carbon steels
Incinerators	
Up to 1093°C (2000°F)	Inconel 600, Type 446 SS
Over 1093°C (2000°F)	Ceramic (primary), silicon carbide (secondary)[a]

Application	*Thermowell Material*
Food	
Baking ovens	Black steel
Charretort, sugar	Black steel
Vegetables and fruit	Type 304 SS
Chemical	
Acetic acid	
10 to 50% 21°C (70°F)	Type 304, Hastelloy C,[d] Monel
50% 100°C (212°F)	Type 316, Hastelloy C,[d] Monel
99% 21 to 100°C (70 to 212°F)	Type 430, Hastelloy C,[d] Monel
Alcohol, ethyl, methyl 21 to 100°C (70 to 212°F)	Type 304
Ammonia All concentrations 21°C (70°F)	Types 304, 316 SS
Ammonium chloride All concentrations 100°C (212°F)	Types 316 SS, Monel
Ammonium nitrate All concentrations 21 to 100°C (70 to 212°F)	Type 316 SS
Ammonium sulphate, 10% to saturated 100°C (212°C)	Type 316 SS
Barium chloride, all concentrations 21°C (70°F)	Monel, Hastelloy C
Barium hydroxide, all concentrations, 21°C (70°F)	Low carbon steels
Barium sulphite	Nichrome,[a] Hastelloy C
Brines	Monel
Bromine	Tantalum, Monel
Butadiene	Type 304 SS
Butane	Type 304 SS
Butyl acetate	Monel
Butyl alcohol	copper, Type 304 SS
Calcium chlorate, dilute, 21 to 66°C (70 to 150°F)	
Calcium hydroxide	Type 304 SS
10 to 20% 100°C (212°F)	Type 304 SS, Hastelloy C
50% 100°C (212°F)	Type 316 SS, Hastelloy C
Carbolic acid, all, 100°C (212°F)	Type 316 SS
Carbon dioxide, wet or dry	2017-T4 aluminum, Monel, nickel
Chlorine gas	
Dry, 21°C (70°F)	Type 316 SS, Monel
Moist, 7 to 100°C (20 to 212°F)	Hastelloy C
Chromic acid, 10 to 50% 100°C (212°F)	Type 316 SS, Hastelloy C (all concentrations)
Citric acid 15% 21°C (70°F)	Type 304, SS, Hastelloy C (all concentrations)

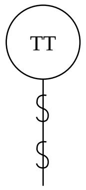
4.15 Ultrasonic and Sonic Thermometers



Flow Sheet Symbol

H. L. DANEMAN (1995) **B. G. LIPTÁK** (2003)

Applications:	Temperature measurement inside nuclear reactors, cement kilns, boilers, and in furnaces. Suited for harsh and abrasive environments.
Types:	Piezoelectric and magnetostrictive. Detects average temperature.
Temperature Ranges:	32 to 3500°F (0 to 1927°C) for boiler/furnace units, higher with quartz probes
Inaccuracy:	1.5%, does not require calibration
Measurement Time:	15 s/path
Number of Paths:	1 or 2
Required Air Supply:	80 to 120 PSIG (5.5 to 8.3 bars)
Waveguide:	316 SS with 3 in. 150# pipe flange
Cost:	\$5,000 to \$10,000 or more
Partial List of Suppliers:	Scientific Engineering Instruments (www.sciengr.com)

OPERATING PRINCIPLE

The speed of sound in a gas is proportional to its temperature. This relationship between sound velocity and temperature has been known for nearly 100 years, but until recently it has been little used. Temperature dependence of velocity in an ideal gas is expressed as

$$v^2 = \frac{\gamma RT}{M_w} \qquad \textbf{4.15(1)}$$

where v is sound velocity, γ is the ratio of specific heats, R is the gas constant per mole, M_w is the molecular weight, and T is the absolute temperature.

A method of temperature measurement in a plasma jet involves the use two quartz probes set a fixed distance apart. The sound velocity is determined by circuitry for the continuous measurement of the ultrasonic wave transit time (see Figure 4.15a).

As temperature is detected by the measurement of time, calibration is not required and this linear sensor is well suited to harsh and abrasive environments. Because the gas itself is the thermometer element, errors such as leakage are absent and fast changes can be followed. Disadvantages include high cost, nonideal gas behavior, pressure correction, accurate determination of γ, and the inability to make point measurements.

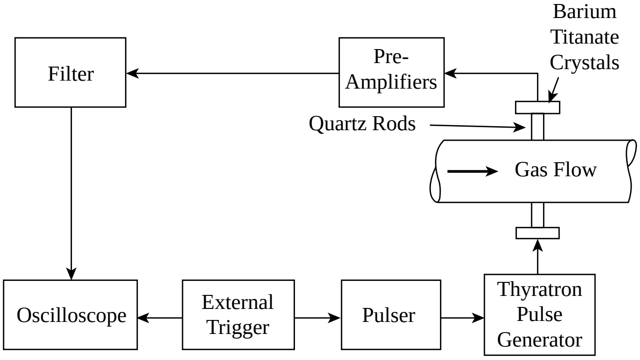


FIG. 4.15a
Simplified ultrasonic temperature measuring apparatus.

Ranges and Applications

Acoustical temperature sensors can theoretically measure temperature from the cryogenic range to plasma levels (20,000°C, or 36,000°F). The accuracy can approach that of a primary

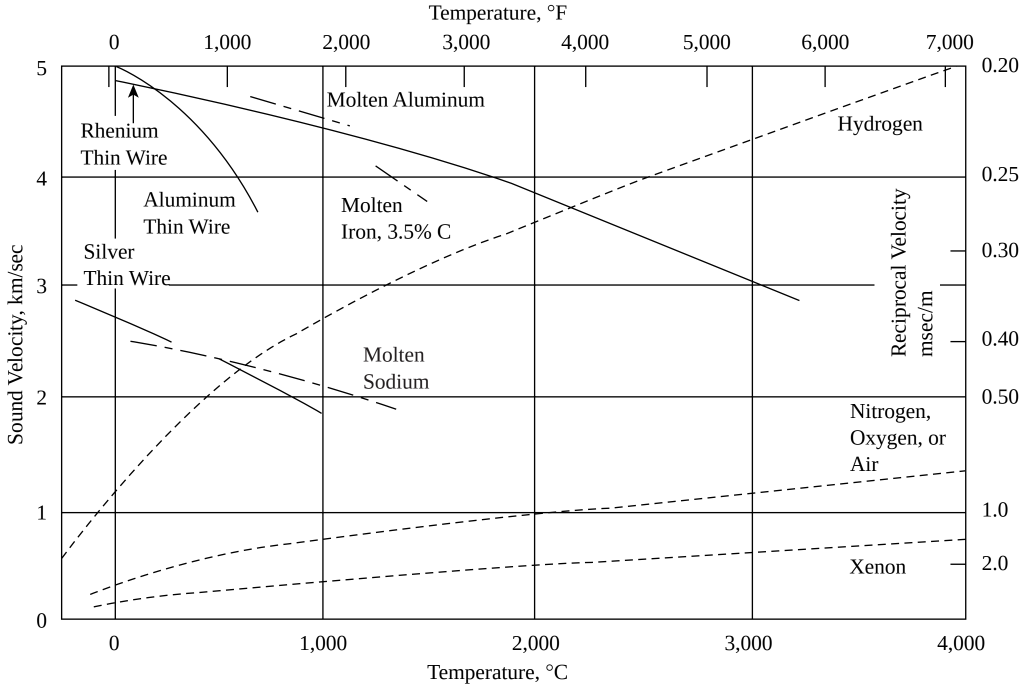

FIG. 4.15b

The velocity of sound increases in gases and decreases in liquids and solids as the temperature rises.[1]

standard as in the example of the ultrasonic interferometer developed by Harmon Plumb and George Cataland of the National Institute of Standards and Technology. A fluidic oscillator in which the resonant frequency of the cavity varies with temperature can be employed as a high-temperature pyrometer.

Ultrasonic thermometers are based on the effect of the temperature on the velocity of sound waves in the medium transmitting the sound waves. Temperature measurements can be made not only in gases, but also in liquids or solids. The relationship between sound velocity and temperature for various materials is shown in Figure 4.15b.

The acoustic velocity can be detected by immersing a rod or wire into the fluid or by using the medium itself as an acoustic conductor. The sensor rod can measure the temperature at a point or, by means of a series of constrictions or indents, can profile or average the temperature within the medium. This is done by measuring the time lags of the sound waves as they are reflected from the consecutive indents (see Figure 4.15c).

When the medium is used as the conductor of the ultrasonic pulse, the transducer can also be located within the vessel, but is usually placed on its external shell. This latter configuration is useful when measuring the temperature of solids or extremely hot or corrosive materials such as molten sodium. The acoustic pulse can be generated by a piezoelectric crystal cut to resonate at a frequency ranging from 0.5 to 3 MHz or by means of magnetostrictive materials.

The thin wire sensor (Figure 4.15c) is installed like a thermocouple (TC). A lead-in wire carries the pulse to the thin wire made of a material suitable for the process medium and its temperature range. Reflection from the beginning and the end of the thin wire provides the time lapse information for temperature determination. The selection of materials is more flexible than for TCs as only one material is involved.

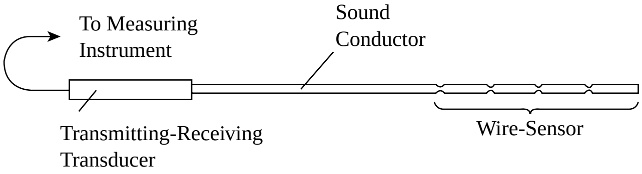

FIG. 4.15c

Ultrasonic thermometer probe.[2]

Boiler/Furnace Applications

An acoustic sound source and a sound receiver can be located on the outside of opposing walls of a boiler, cement kiln, or furnace. Such noninvasive applications employ a transmitting transducer to send acoustic energy through the process medium. Receiving transducers detect the energy, and time delay is measured to determine the velocity of sound and therefore the temperature of the process. A nonintrusive, dual-path ultrasonic thermometer employing pneumatically generated sound waves is shown in Figure 4.15d. It does not require calibration; measures average temperature across two paths; has no moving parts other than the air supply valve; is linear; and can be provided with data display, logging, setup, and diagnostics either locally on a personal computer or remotely, using a modem connection.

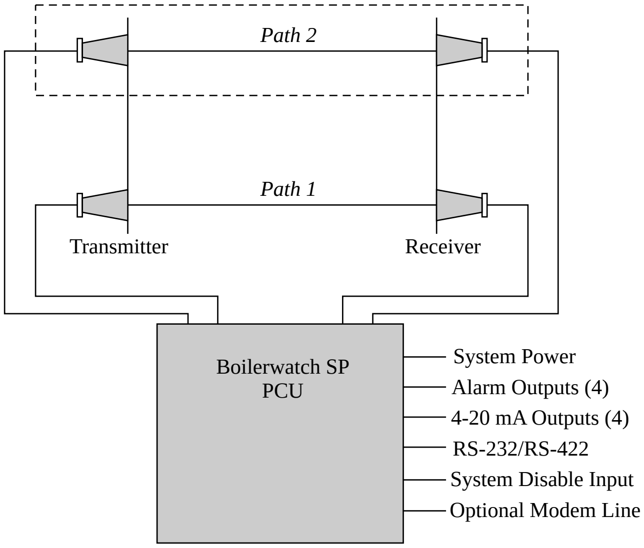

FIG. 4.15d
Dual-path sonic thermometer for boiler/furnace applications. (Courtesy of Scientific Engineering Instruments.)

Ultrasonic thermometry can be used at temperature extremes, in high electrical fields, or when the medium being measured is inaccessible. It is also useful for averaging the temperature of bulk materials or for profiling furnace temperatures. Other applications are tabulated in Table 4.15e.

CONCLUSIONS

Temperature measurement is a fast-changing technology. Today, smart temperature transmitters can be directly connected through data highways to any distributed control system. These transmitters also improve accuracy, because they eliminate the need for analog-to-digital conversion and are able to self-calibrate their spans, self-diagnose their sensor's integrity and automatically make selections from among their multiple sensors in order to provide automatic replacement or to match the prevailing temperature of the process.

Intelligent transmitters (as discussed in more detail in Sections 4.1, 4.10, and 4.13) reduce measurement error and increase measurement rangeability. Sonic and ultrasonic thermometers have a unique role for high temperature applications where the interest is in detecting the average temperature in harsh and abrasive process environments.

Pressure detection devices can be classified on the basis of the pressure ranges they can measure, on the basis of the design principle involved in their operation, or on the basis of their application. In this chapter, the various categories are not separated in any strict manner. Industrial instruments are discussed in detail, with emphasis on the most commonly used devices; laboratory instruments are covered in less detail.

INTRODUCTION

Each section starts with a brief summary of basic features applicable to the group of instruments discussed in that section. This information allows readers to quickly determine whether that category of instrumentation is suitable for their application.

This chapter covers a wide range of pressure sensors, which can measure pressures from ultrahigh vacuums, such as 10^{-13} mmHg, to ultrahigh gauge pressures approaching 400,000 PSIG (2,800 MPa).

The range of the costs and inaccuracies of these instruments are equally broad. A simple, 1.5 in. diameter, 5% inaccurate gauge might cost only $10, while a fused-quartz helix sensor with an error of 0.01% and a digital readout could cost $6000. The cost of pressure transmitters range from a few hundred dollars or less for the disposable models that have limited features, to $2000 for smart models with built-in digital PID control algorithms and/or digital networking capabilities.

Silicon microchip technology continues steadily to reduce the cost of advanced features, reducing the size and weight of hardware and improving their availability and accuracy, while extending the long-term stability their calibration. Many of the sensors are available with digital communication capability, which can serve calibration, adjustment, and reporting of process variables, allowing for complete plant-wide integration.

With so many types of sensors, it might seem that making the proper selection for a particular installation would be difficult and time consuming. Actually, this is not the case. A multitude of devices are covered here for the purpose of completeness, but for a typical industrial installation, the selection is fairly simple, and often repetitive.

Orientation Table

The reader should find Table 5.1a, the Orientation Table for Pressure Detectors, of value in narrowing the choices. For each category of sensors, this table indicates the overall pressure range that the category is capable of detecting. The table also notes whether the unit is available for industrial on-line installation or for laboratory use only. Although any transmitting instrument can easily be provided with an inexpensive analog or digital local indicator, the table differentiates those sensor categories, which primarily serve as local gauges or indicators. Also distinguished are the sensor categories, which are commonly available in microprocessor-based smart configurations.

The table also indicates the type of pressure reference used. When the environmental pressure surrounding the instrument

Applicable Pressure Ranges

Ⓥ - Indicates that the device uses full-vacuum reference in its operation.
Ⓐ - Indicates that the device uses atmospheric pressure reference.
● - Indicates that the operating priciple used does not involve the use of reference pressure.

TABLE 5.1b
Pressure Conversion

To Convert to Pascals (Pa) From	*Multiply by*
atmosphere (standard)	1.01×10^5
atmosphere (technical = 1 kgf/cm^2)	9.81×10^4
bar	1.00×10^5
centimeter of mercury (0°C)	1.33×10^3
centimeter of water (4°C)	98
$dyne/cm^2$	0.1
foot of water (39.2°F)	2.98×10^3
$gram\text{-}force/cm^2$	98
inch of mercury (32°F)	3.39×10^3
inch of mercury (60°F)	3.37×10^3
inch of water (39.2°F)	249
inch of water (60°F)	248
kgf/cm^2	9.81×10^4
kgf/m^2	9.81
kgf/mm^2	9.81×10^6
kip/in^2 (ksi)	6.89×10^6
millibar	100
millimeter of mercury (0°C)	133
lbf/ft^2	47.8
lbf/in^2 (psi)	6.89×10^3
psi	6.89×10^3
torr (mmHg, 0°C)	133

Example: 1 PSI = 6.89×10^3 Pa/PSI = 6890 Pa
= 27.7 in. water
= 2.31 ft. water
= 2.04 in. Hg
= 0.07 kgf/cm^2

is used as reference (for the measurement of gauge pressures), it is noted by Ⓐ for atmospheric. When the reference is an evacuated chamber with almost perfect vacuum sealed inside, which is used for the measurement of absolute pressures, this type of reference is noted by Ⓥ. There is no reference for differential pressure devices because they just compare one pressure against another. A few measurement technologies, such as the thermal and ionization type vacuum gauges, do not depend on the use of reference pressures or vacuums within the instrument itself.

Table 5.1b gives a variety of pressure conversion multipliers.

In addition to the general orientation provided by Table 5.1a, a summary of the features of some of the pressure instruments that are commonly used in the manufacturing, petrochemical, and power industries is given in Table 5.1c. Note that in actual practice the metric ranges are also rounded.

Reference Pressures

Reliable reference pressures are important, because they can be a source of error just as much as an error on the measurement side can. In the case of absolute pressure sensors, the reference chamber cannot be fully evacuated to absolute zero pressure, but full vacuum is only approached within a few thousands of a millimeter of mercury (torr). This means that a nonzero value is being treated as zero, which, when measuring higher vacuums, can cause significant errors. The other potential error source is the possibility of in-leakage of atmospheric air into the vacuum reference chamber of absolute pressure detector.

In case of positive pressure detectors, if the barometric pressure is the reference, atmospheric pressure variations cause a problem. As the atmospheric pressure can vary, by about 1 in. of mercury (13.6 in. or 0.345 m of water), the resulting error can be significant if the process pressure is near atmospheric. In addition, the output signal of the sensor can change even when the process pressure is constant. The resulting error might not be significant when detecting high gauge pressures, but it can be a problem with compound detectors.

A compound pressure sensor is one that operates at near atmospheric pressures and can detect the pressures on both above and below atmospheric. In controlling the pressure in sealed rooms (clean rooms, biohazard containment chambers, ordinary tight buildings, etc.) where the ventilation systems may purposely hold the pressure above or below atmospheric pressure, this variable reference can be a source of problems. In selecting pressure measurement devices for such applications, the design engineer must not ignore this and must either determine that the effect of barometric pressure variation can be safely neglected, or must measure and correct for this variation in the measurement and control systems.

An Example

Take the example of a chemical reactor that has to be evacuated to 10 mmHg before being purged at 1 in. (25.4 mm) H_2O positive pressure. After purging, when the reaction starts, this reactor operates at a higher positive pressure.

Due to the problem with the references, there is no single pressure transmitter that can detect all these pressures. If a vacuum reference is used, the purge pressure of 1 in. H_2O over atmospheric cannot be reliably detected. If an atmospheric reference is used, the 10 mmHg vacuum cannot be accurately detected, because it could be subject to a 25 mmHg error. In the past, the logical solution was to use multiple sensors. Today, we can also use intelligent transmitters, which are provided with multiple references and are capable of switching them on the basis of the batch sequence of the reactor.

TABLE 5.1c
Pressure Detector Errors, Ranges, and Costs

Type	*Range*	*Inaccuracy*	*Approx. Cost*
General-purpose Bourdon-tube indicator	15–10,000 PSIG (1–690 bars)	2%	$100
High-accuracy test gauge	Low vacuum to 3000 PSIG (Low vacuum to 207 bars)	0.1% to 0.01%	$300–$6,000
Bourdon/spiral case-mounted indicator/recorder	Low vacuum to 50,000 PSIG (Low vacuum to 3450 bars)	0.50%	$1,200
Spring-and-bellow case-mounted recorder	Low vacuum to 50 PSIG (Low vacuum to 3.5 bars)	0.50%	$1,600
Nested capsular case-mounted recorder	10–90 PSIG, (0.7–6.2 bars)	0.50%	$1,600
Low-pressure bell case-mounted indicator	–0.1 to 0.1 in. H_2O (–3 to 3 mm H_2O)	2%	$2,200
Beam-mounted strain gauge (sensor only) 4–20-mA DC output	0–1000 PSIG (0–69 bars)	0.25%	$800
Piezoresistive transducer 4–20-mA DC output	0–5000 PSIG (0–365 bars)	0.50%	$500
“Smart” piezoresistive transmitter 4–20-mA DC output	0–6000 PSIG (0–414 bars)	0.10%	$1,200–$2,000
“Smart” field communicator for remote calibration and configuring of “smart” transmitter	—		$1000–$3,000
Capacitive sensor/transmitter	1 in. H_2O–6000 PSIG (25 mm H_2O–414 bars)	0.2%	1000

SELECTING THE PRESSURE DETECTOR

When local pressure indication is required and the process pressure range is between 0 to 10 in. H_2O (2.6 kPa) and 0 to 100,000 PSIG (690 MPa), the conventional pressure sensors, which are described in Sections 5.3, 5.4, 5.5, and 5.11 can be considered. The local pressure gauges, described in Section 5.11, can have ranges from 10 in. H_2O (2.6 kPa) up to 100,000 PSIG (690 MPa).

For the measurement of near-atmospheric pressures, the bellows diaphragm sensors and manometers (Sections 5.3, 5.4 and 5.9) are the most likely choices. Similarly, for local vacuum measurement down to 1 mmHg (0.13 kPa), the diaphragm, the bellows-type, and the vacuum manometers (Sections 5.3, 5.5, and 5.9) will give satisfactory performance. Vacuum sensors, ranging from 10^{-12} to 760 mmHg, are discussed in Section 5.14. See Figure 5.14a for a summary of all the available vacuum sensors and their ranges.

Where remote transmission is required, the force balance or motion balance transmitters (Sections 5.3, 5.4, 5.5, and 5.7) will handle most applications. They can detect vacuums down to 1 mmHg (0.13 kPa) absolute and gauge pressures up to 100,000 PSIG (690 MPa). When small, near-atmospheric or high pressures up to 200,000 PSIG (1,400 MPa) are to be transmitted, the differential pressure or the electronic sensors described in Sections 5.6 and 5.7 should be considered. The high-pressure sensors, described in Section 5.8, are the recommended choices for pressures from 20,000 PSIG (140 MPa) up to 400,000 PSIG (2,800 MPa).

Multiple pressure sensors, including scanners and multiplexers, are discussed in Section 5.10. Pressure repeaters capable of repeating pressures from full vacuum to 10,000 PSIG (69 MPa) are described in Section 5.12. Pressure and differential pressure switches for applications at up to 20,000 PSIG (138 MPa) pressures can be found in Section 5.13.

Accessories

The pressure detectors are often provided with various accessory items (discussed in Section 5.2), which serve to protect them from process conditions and environmental effects, are provided to reduce maintenance. The most common causes of failure or maintenance problems include plugging, vibration, freezing, corrosion, excessive temperatures, and hard-to-handle process materials. The various protection devices discussed in Section 5.2 can assist in making the installation less sensitive to such effects and can reduce the required tasks of periodic servicing, testing, calibration, and maintenance.

Intelligent Transmitters

Microprocessor based pressure and differential pressure transmitters are widely available today. Such a transmitter includes an input circuit referred to as an analog-to-digital (A/D) converter that converts the sensor input into a digital signal before it is sent to the microprocessor. The microprocessor performs the manipulations of ranging, linearization, error checking, and conversion and either transmits the reading digitally or sends the resulting value to the output digital-to-analog converter (D/A), which converts the signal back to an analog signal of 4–20 mA DC, 0–1 V DC, or 0–10 V DC.

Just as microprocessors have evolved in sophistication, so have A/D and D/A converters, increasing their resolution from 8-bit up to the 18-bit, which has been used in the better transmitters since the beginning of 2000. These advanced transmitters also check their own calibration on every measurement cycle and incorporate self-diagnostics, while being configurable by using simple personal computer (PC) software. The reconfiguration process is not only quick and convenient, but also tends to lower inventories by making the transmitters interchangeable.

The benefits of remote setup, configuration, and access to diagnostics has resulted in a dramatic increase in the use of proprietary protocols that are supported by many of the larger manufacturers. A wide variety of intelligent pressure transmitters are available on the market today. Some common features of the leading models include not only digital and analog outputs, but also multiple ranges, remote zero and span settings, configuration push buttons, PC software and Hand Held Configurators. The available bus and network protocols include Highway Addressable Remote Transducer (HART), Foundation Fieldbus, Profibus, Ethernet, or just 4–20 mA. Some field locations will benefit from local indication and this feature is optional with most manufacturers.

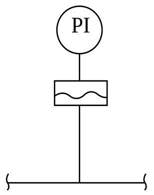
5.2 Accessories (Seals, Snubbers, Calibrators, Manifolds)

B. G. LIPTÁK (1969, 1982) **J. A. NAY** (1995, 2003)



Flow Sheet Symbol

Types of Accessories:	A. Chemical seals B. Snubbers, pulsation dampeners C. Manifolds D. Dead-weight testers, calibrators E. Smart communicators, calibrators
Design Pressure (Seals):	Up to 2500 PSIG (17 MPa) with standard units; specials to 20,000 PSIG (138 MPa) and higher
Design Temperature (Seals):	Up to 600°F (316°C) with standard units; specials up to 1500°F (815°C)
Materials of Construction:	Standard seal lower housing can be Kynar, polypropylene, polyvinyl chloride, chlorinated polyvinyl chloride, glass- or carbon-filled Teflon, brass, carbon steel, 304 or 316 stainless steel, Carpenter 20, Hastelloy B or C, Inconel, Monel, nickel, titanium, or tantalum-plated. Diaphragms can be Buna-N, Kel-F, Teflon, Viton, 316 stainless steel, Hastelloy B or C, Inconel 600 Monel K500, Nickel 200, tantalum, titanium, Carpenter 20, silver, or gold-plated. Several manufacturers can provide other special materials.
Costs:	Snubber and pulsation dampener costs range from \$10 to \$300 depending on features and materials of construction. A few seals are available for less than \$50. A seal similar to Figure 5.2d with carbon steel wetted parts is about \$130; with wetted parts in stainless steel or Monel it is about \$300, in Inconel or Carpenter 20 about \$400, in nickel or titanium about \$500, and in Hastelloy B or C about \$750. A 3-in. (76-mm) flanged seal with a 6-in. (152-mm) extended diaphragm seal with a short capillary with stainless steel wetted parts is about \$900 and with Hastelloy C wetted parts may be over \$2000. Manufacturers may offer only 1 or 2 seal configurations, but many offer more than 50 choices among more than a dozen detail options, providing an extremely wide range of choices and costs. Shutoff valve manifolds range from \$100 up depending on features and materials of construction. For dead-weight testers see Section 5.8. The cost of smart field communicators, which include recalibration capability, range from \$800 to \$4000.

Combined in this section are a variety of devices that might serve as accessories to pressure instruments. They range from simple snubbers and shutoff valves to a wide variety of chemical seal devices. These mechanical components serve to protect the pressure instruments from high or low temperatures, plugging, corrosion, and pulsation, or to provide the means for isolating the instrument for removal or maintenance. Other more sophisticated and more expensive accessories used in connection with pressure instrumentation are the various types of calibrators and electronic communication devices used in combination with the smart transmitters discussed in Section 5.1.

PULSATION DAMPENERS AND SIPHONS

On steam service, it is desirable to prevent the live steam from entering the sensing element, which could cause temperature damage. Such prevention is accomplished by installing a coil pipe siphon between the gauge and the process connection (Figure 5.2a).

Where sudden pressure shocks or rapidly fluctuating pressures are expected, snubbers or pulsation dampers are installed between the gauge and the process. Some of the snubber design variations are illustrated in Figure 5.2b. One design consists of a fitting with a corrosion-resistant porous metal filter disk. Such device delays the equilibrium reading on the indicator by about 10 seconds. Another snubber design depends for its dampening action on a small piston in the inlet fitting; the piston rises and falls with pressure impulses, absorbing shocks and surges. Still another snubber design uses the adjustable restriction created by a microvalve in the inlet fitting to damp pulsations. Where system dynamics are important to the measurement and/or to system safety, the time delay effects of damping must be considered when selecting safety trip settings. Pulsation dampeners should not be used with any instrument installed specifically to measure high frequency pulsations; this may be necessary when investigating the discharge characteristics of a reciprocating pump, or diagnosing cavitation symptoms of a centrifugal machine.

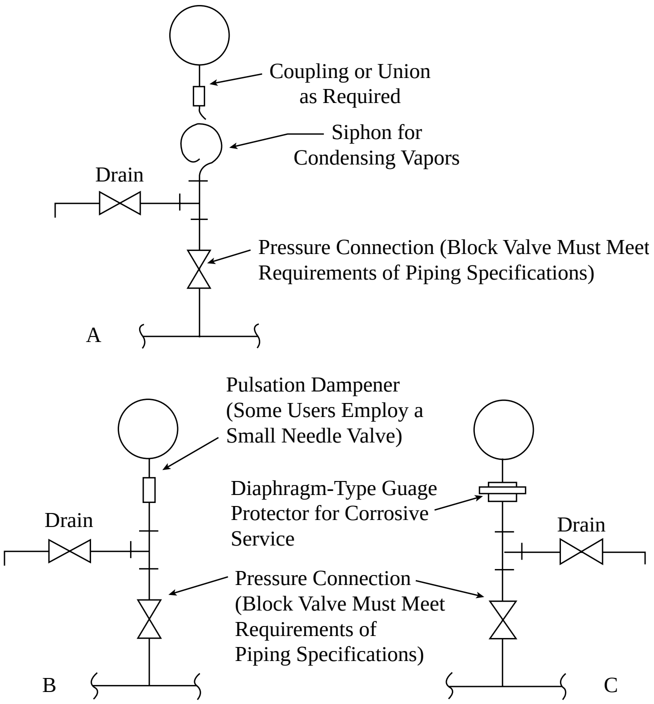

FIG. 5.2a
Pressure instruments can be protected against high temperature (A), pulsating pressure (B), or corrosion (C).

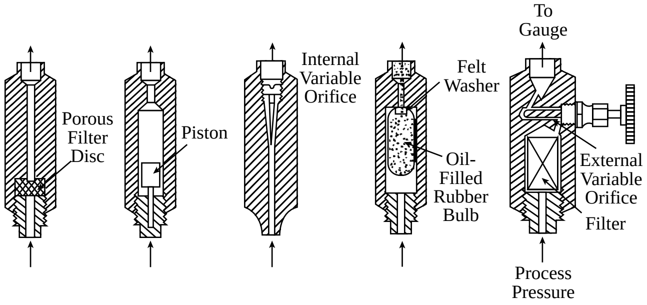

FIG. 5.2b
Variations on snubber designs.

FREEZE PROTECTION

Where there is a possibility that the process fluid might freeze inside the pressure element, steam tracing can be provided or small electric heaters can be installed inside the cases of larger instruments. A heater can provide a temperature rise of about 80°F (27°C) and is available with gauges having dial diameters of 4.5 in. (112 mm) or larger. For smaller instruments, resistance-wire-type heat tracing can be wrapped around the transmitter. When this is done, a thermostat should be included to prevent the case from exceeding normal design temperatures. This is particularly important for electronic instruments. Some manufacturers can furnish hollow bolts in the transmitter housing with provisions for connecting them to a low-pressure steam supply. This can be useful in plants that are provided with steam-tracing systems for the process piping. The need for freeze protection is not limited to water services. Freeze protection is also provided for liquid metal systems (sodium, potassium, etc.) and for high-viscosity fluids such as bunker fuels and molasses. Instruments connected to such processes should always be protected from freezing of the process fluids.

CHEMICAL SEALS

Chemical seals or diaphragm protectors can be provided with most pressure sensors. These components serve the following functions:

1. They avoid freezing, gelling, or settling out of the process fluid in the sensing line due to temperature changes.
2. They prevent poisonous, noxious, radioactive, or corrosive process materials from entering the pressure sensor.
3. They prevent slurries or viscous polymers from entering, plugging the detector element.

In the following discussion, several chemical seal designs are described. All are filled with essentially noncompressible liquids that hydraulically transmit the process pressure to the protected pressure element.

Filling fluids are selected to provide low thermal expansion and low viscosity and to avoid danger of process contamination in case of diaphragm rupture. Table 5.2c lists some filling fluids, their applicable temperature ranges, and their thermal expansion coefficients. One of the popular filling fluids is a 70 to 30% mixture of glycerin and water used between 30 and 300°F (–1 to 149°C). For lower temperatures, ethyl alcohol, kerosene, toluene, or silicon oils are used in the –50 to 100°F (–46 to 38°C) range. Some silicone oils, fluorocarbons, and halocarbons can stretch the range to 500°F (260°C). For high temperatures sodium-potassium alloys are available for the range of 70 to 1500°F (25 to 816°C). The gasketing materials are plastics, elastomers, or Teflon up to 400°F (250°C), while on high temperature services metallic gaskets or special volumetric elements are used. All-welded designs are also available for installations where gaskets are inappropriate.

TABLE 5.2c
Temperature Ranges and Thermal Expansion Characteristics of Chemical Seal Filling Fluids

Filling Fluid	*Temperature Range* °F	*Temperature Range* °C	*Expansion Coefficient (SG/°F)*
Toluene	–40 to 200	–40 to 93	0.00063
Dow Corning silicone (DC-200)	–30 to 300	–34 to 148	0.00075
Kerosene	–30 to 350	–34 to 177	0.00051
Hooker (FS-5)	–20 to 300	–29 to 148	0.00049
Mercury*	–30 to 700	–34 to 371	—
Dibutyl phthalate	20 to 300	–7 to 148	0.0008
22% sodium–78% potassium	20 to 1400	–7 to 760	—
70% glycerin–30% water	30 to 300	–1 to 148	0.00051
Instrument oil	35 to 300	2 to 148	0.00035
Light turbine oil	40 to 300	4 to 148	0.00048
Dow Corning silicone (DC-550)	40 to 500	4 to 260	0.00042
Dow Corning silicone (DC-703)	40 to 600	4 to 316	0.00055
96.5% glycerin	70 to 450	21 to 232	0.00039
56% sodium–44% potassium	70 to 1500	21 to 815	

* No longer used due to environmental/biological hazard. If found in an old installation, it should be removed only by, or under the direction of, a certified health physicist.

Even with the proper selection of filling fluids, the temperature effects will not be completely eliminated. Some expansion coefficients based on specific gravity are listed in Table 5.2c. Resulting temperature effects may typically be about 3 PSI/100°F (21 kPa/38°C). Temperature effects are caused by direct expansion of the fill fluid against the elasticity of the diaphragm, and by variations in the weight of fluid if there is an elevation or suppression between the sensing point and the instrument. Therefore, it is desirable to calibrate critical units at operating temperature to eliminate errors.

The common fill fluids listed in Table 5.2c are not expected to decompose at the highest process temperature listed, and their viscosities are expected to remain low enough to operate the process elements efficiently at the lowest process temperatures. Note that the sodium–potassium (NaK) mixtures freeze not far below room temperature. The eutectic (78% Na–22% K) freezes at 10°F (–12.3°C); other mixtures between 40 and 90% K freeze at increasing temperatures up to room temperature. Since they shrink upon freezing, it is not likely that any damage will occur, but the instrument will suddenly stop working and may become a safety hazard or cause a product deviation due to this loss of function.

Limitations

Other limitations of chemical seal protectors involve the spans and the vacuum applications. The working pressure ranges with metal diaphragm seal protection should have an upper range value greater than 50 PSI (350 kPa), because otherwise the spring rate of the diaphragm will introduce excessive errors. Displacement of the attached instrument over the expected measurement span is also important to selection of a seal; the seal's diaphragm must not bottom out, even partially, as the pressure increases and fluid is displaced into the instrument. This is becoming less of a problem since modern electronic transmitters typically have displacements of less than 0.1 in.^{3} (1.6 cm^3).

The use of diaphragm seals on vacuum service can be troublesome, but careful selection of fill fluid combined with high vacuum filling will usually allow satisfactory operation on low to medium vacuum services. If pressures go below the fill fluid's vapor pressure or if dissolved vapors come out of solution, gas bubbles will be present and the filling fluid will no longer be incompressible. The higher the operating temperature (at any point along the capillary), the more severe this limitation becomes since temperature effects on vapor pressure are exponential. Therefore, it is suggested that devices other than liquid-filled chemical seals be used on high vacuum service. On low to medium vacuum services, Silicone 704 is recommended as the filling fluid, since its vapor pressure is less than 1.00×10^{-6} mmHg at near room temperature.

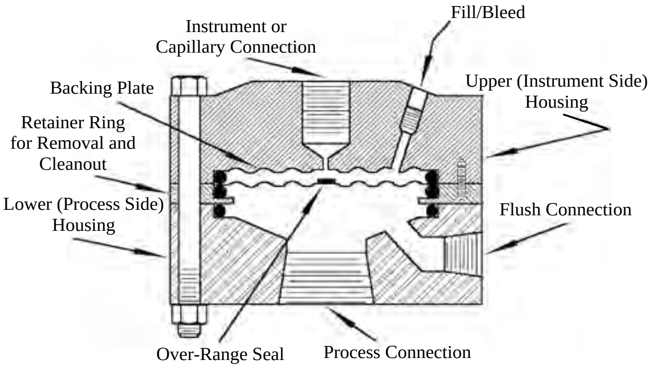

FIG. 5.2d
Components of a representative chemical seal.

The measuring instrument can be direct-connected to the seal, or it can be connected by capillary tubing. In general, it is desirable to limit the tubing length to 25 ft (7.5 m) and to route the capillary through an area where the ambient temperature around the capillary and the instrument case is relatively steady and in the range of 50 to 110°F (10 to 43°C). Heat tracing can be added if the fill fluid can freeze or become unacceptably viscous at normally expected ambient temperatures. Some manufacturers will provide up to 50 ft (15 m) of capillary for special orders.

Standard Seals

Figure 5.2d illustrates the main components of a representative chemical seal: the upper and lower body and the diaphragm. The upper housing is in contact with the filling fluid only; therefore, if the environment is not corrosive, standard construction materials are acceptable. Once the seal is attached to the pressure instrument, either directly or through a capillary, the filling screw is used to fill the total system under vacuum.

Factory-filled seals furnished with the pressure instrument provide the most reliable sealed system, and can be provided by most suppliers if the length of the sensing capillary can be specified. However, field filling is also fairly common and can be accomplished reliably as long as a high vacuum source is available to evacuate the sensing line prior to and during filling, and as long as the fill fluids can be easily handled. It is important that the filling screw be reliably closed off without introduction of air. In some cases, the filling screw is further sealed by welding, or is replaced by a capillary which can be crimped and seal welded. One should not attempt to fill a system by simply pressure purging the fill fluid from one end to the other because even a tiny bubble can cause serious error.

The diaphragm seal assembly shown is a composite of several representative designs. Some seal manufacturers use a single diaphragm element welded to the upper housing. Others use a capsule consisting of a thin lower diaphragm bonded to a sturdy corrugated backup plate, and the whole assembly is screwed into the top housing. It is important that the diaphragm be as slack as possible, within the confines of necessary durability, so that it moves freely and hydraulically transmits the pressure without adding any differential. If the diaphragm is an elastomer, the outer edge of the diaphragm itself may be used as the sealing gasket.

Leakage is the most frequent source of seal failure. When it occurs, the diaphragm is pressed against the corrugated backup plate, which prevents diaphragm distortion and seals in the process pressure. (The instrument, however, ceases to operate.) Many designs incorporate a metal or elastomer valve and seat to stop any further flow into the capillary. The rupture pressure rating of conventional seals is 2500 PSIG (17 MPa). The diaphragm capsule is in contact with the process fluid, and therefore it is available in corrosion-resistant metallic construction or with a lining of Kel-F, Teflon, or a similar material.

The top section and the diaphragm capsule can often be removed while remaining connected to the associated instrument without disconnecting the bottom housing from the process. This feature allows the lower housing to be permanently welded to the process and enables the operator to clean the assembly without refilling or recalibrating the unit. Where elastomer seals are used on the diaphragm, a retainer ring is provided to allow this operation. The bottom housing, which is in contact with the process media as well as the atmospheric environment, is available in many corrosion-resistant metals or plastic materials. A flushing connection can be provided on the lower housing to flush the pressure chamber below the diaphragm. This allows for continuous or intermittent purge to remove the material buildup that may have accumulated below the diaphragm or in the connecting piping.

Selection of the bolting materials may be the primary determining factor in establishing pressure rating. If necessary to replace bolting, be sure to use bolts of the original strength class. Changing from high-strength carbon steel bolts to ordinary stainless steel bolts may reduce the pressure rating by 50%. Some designs do not use bolts, incorporating a pipe union type of joint, or a totally welded system.

Process Connections Every type of process connection, including sanitary spud or tri-clamp, can be accommodated for the process side of the seal. Figure 5.2e shows off-line seal design with screwed or flanged process connections. These units are utilized where the seal is needed to provide protection against corrosion or freezing. Due to the dead-ended cavity between the process line and the seal, these designs are not suitable to protect against plugging.

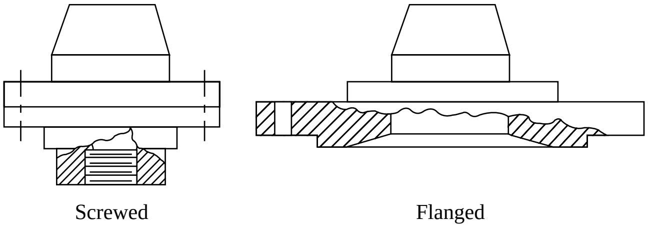

FIG. 5.2e
Off-line chemical seals.

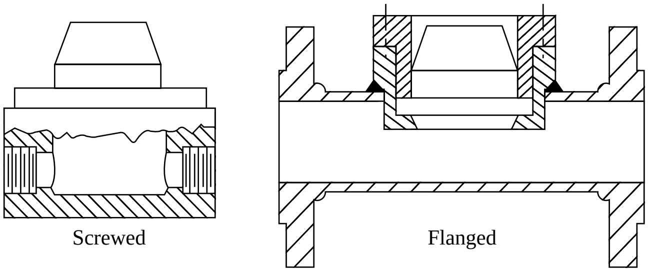

FIG. 5.2f
In-line chemical seals.

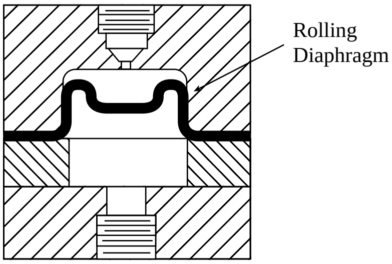

FIG. 5.2g
Large displacement seal.

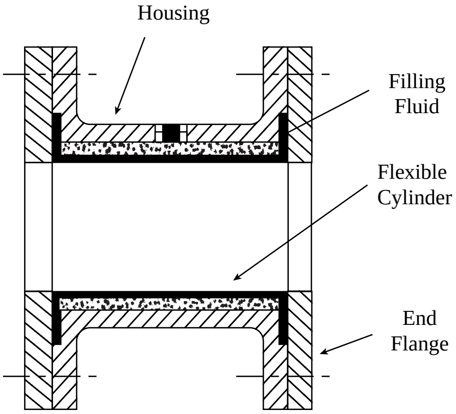

FIG. 5.2h
Full-stream spool seal.

Figure 5.2f illustrates the in-line or flow-through designs in which the dead-ended cavities have been minimized. These units can be considered for both plugging and corrosive services, but their removal for maintenance necessitates the draining of the process pipe. Because the displacement in these seals is small, they are compatible with only small displacement-sensing elements, such as Bourdon tubes, force balance diaphragms, spiral and helical elements, or small-diameter bellows. For instruments with larger than 0.75 in. (19 mm) diameter bellows, the capacity of the standard seal is not sufficient to match the displacement of the pressure element, and large-capacity seals are needed. Such a design using a rolling diaphragm is illustrated in Figure 5.2g.

Self-Cleaning Seals

When plugging or material buildup is a very serious consideration, even the in-line seals shown in Figure 5.2f will not give satisfactory performance, and it is necessary to eliminate all cavities completely. This is achieved with the full-stream seal shown in Figure 5.2h. The three main components of this seal are the flexible cylinder, the cast iron housing, and the end flanges. The space between the flexible sleeve and the housing is filled with the sensing fluid. The sleeve is available in neoprene, gum rubber, butyl, hypalon, ethylene propylene terpolymer, or Teflon, and the end flanges can be of stainless steel or other metals compatible with the process. This design eliminates all cavities and is applicable to low and medium pressure applications up to 200 PSIG (1.4 MPa).

These self-cleaning seals are also available in the wafer design, which can be inserted between 1 to 48 in. (25 mm to 1.22 m) flanges and can take up to 20,000 PSIG (138 MPa) pressure in the smaller sizes. For smaller pipelines, threaded units made out of steel, stainless steel, aluminum, or polyvinyl chloride can be obtained down to 0.5 in. (13 mm) connection size.

Volumetric Seal Elements

Figure 5.2i shows a number of volumetric seal designs, all of them consisting of a flexible member, a housing, and filling liquid to transmit the process pressure to the pressure instrument through a capillary tubing. Each of these devices serves to minimize or eliminate cavities. In the diaphragm units, there is a definite relationship between the process pressure to be detected and the required diaphragm area. Extended or wafer elements with greater than 2 in. (50 mm) diameter diaphragm surface areas can handle pressure spans from 0–50 to 0–1000 PSIG (0–350 kPa to 0–6.9 MPa).

The small button diaphragm designs will work with a minimum span of a few hundred pounds per square inch and can handle ranges up to 10,000 PSIG (69 MPa) or greater. The bellows design is more sensitive than the same diameter button diaphragm and can handle spans from 75 to 1,000 PSIG (0.5 to 6.9 MPa). This element, having flexibility in both directions, is more applicable to compound pressure applications than the other elements. The tube seal element is applicable to spans between 1,000 and 5,000 PSI (6.9 and 35 MPa).

The earlier discussion of chemical seal fill fluids, temperature effects, and spans also applies to volumetric elements. The construction materials for these units are more limited than those for standard seals. Stainless steel is the standard material for wetted parts, but more corrosion-resistant materials are also available. Liquid-filled, extended diaphragm seals can be obtained with extension lengths and diameters as needed to bring the diaphragm surface flush with the inside of the pipe or tank on which the seal is installed.

There may be applications where the requirements for low-pressure span, vacuum service, or process temperature considerations would make the liquid-filled seals undesirable but in which dead-ended cavities cannot be tolerated. If so, the extended diaphragm differential pressure cells discussed in Section 5.6 or the extended diaphragm pressure repeaters covered in Section 5.12 can be considered.

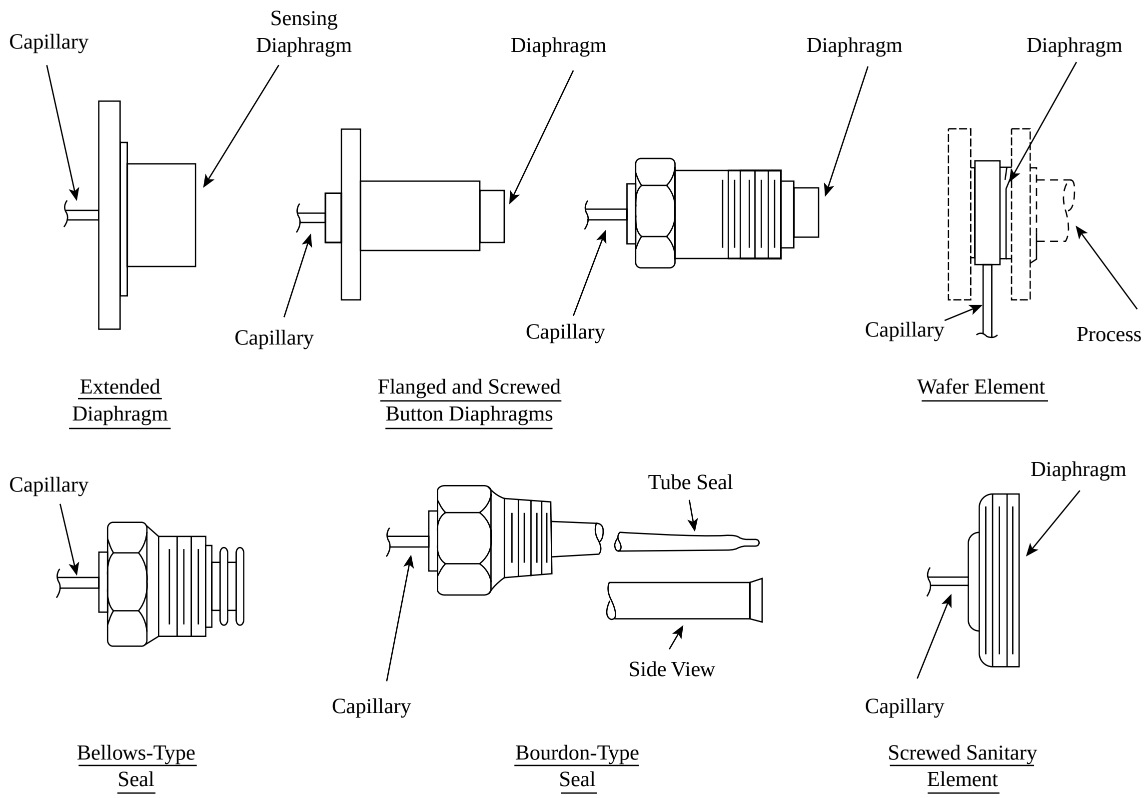

FIG. 5.2i
Volumetric seal elements.

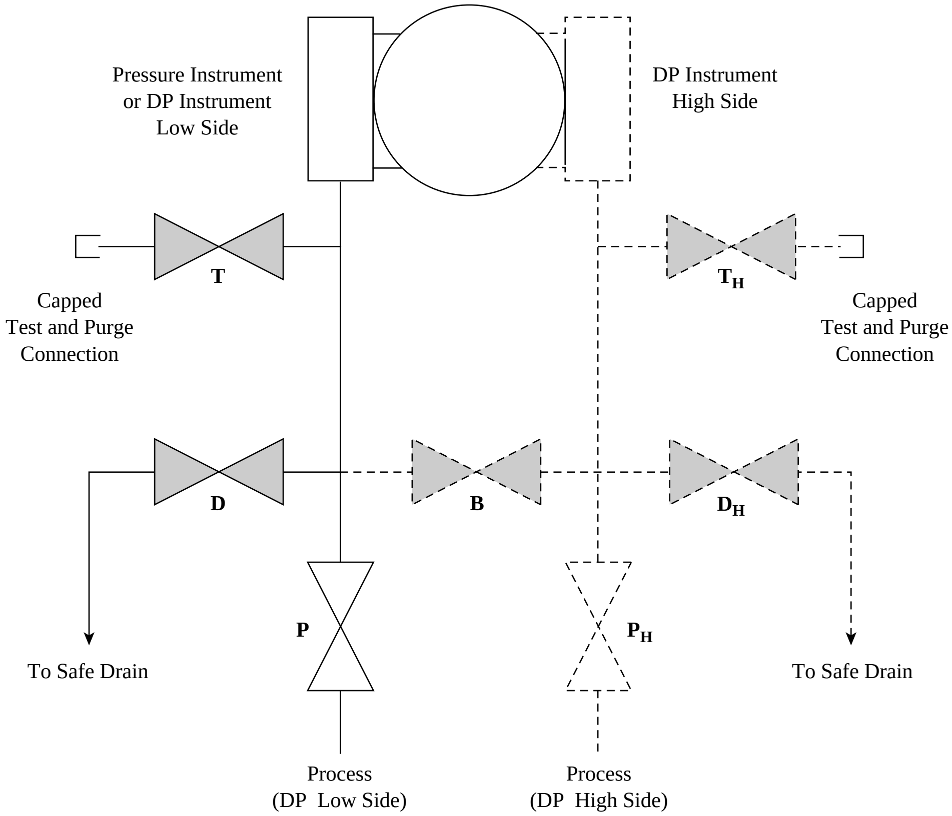

FIG. 5.2j
Valve manifold arrangements used for safe maintenance, draining, and calibration of pressure instruments.

VALVE MANIFOLDS

Valve manifolds serve to simplify periodic calibration of pressure instruments. They can also allow the calibration, and even instrument replacement, during continued operation. This is particularly important for processes that rarely shut down, such as in power plants. Because the process fluids may be toxic, corrosive, radioactive, or otherwise noxious to personnel or the environment, it is necessary to protect against the release of these fluids during calibration.

A three-valve manifold, such as that shown by the solid lines in Figure 5.2j, may be used to serve this purpose. Valve P is used to isolate the process, D is the drain valve which discharges the process fluid from the instrument to a safe containment, and T can be used to flush any trapped fluid to the drain and to apply the calibration or test pressure. When applied to each side of a differential pressure instrument, as shown by P_H, D_H, T_H, and the dashed lines, a bypass valve, B, is usually added. This can result in a seven-valve manifold. Proper operation of the valves (shut the high side process valve P_H then open the bypass B) allows verification of the instrument zero at actual operating pressure.

For pressure instruments with dual connections (the unused connection plugged), the valves T and T_H (or D and D_H) may be connected as individual valves in place of the plug in the otherwise unused connections. This permits flow-through purging of noxious fluids from the instrument. For a relatively low pressure system containing benign fluids, test valves and/or drain valves are often eliminated in favor of a simple straight-thread cap that can be safely loosened to relieve a drop or two residual fluid pressure and serve as the calibration connection. In the extreme, this results in a single valve and test tee. However, the most common choices of manufactured manifolds are the two-, three-, and five-valve arrangements.

With all the valves and connections preassembled into a manufactured manifold, space and field assembly time are saved and the chances for leaks are reduced. Manifolds are available to bolt directly to standard instruments in place of their normal flanged adapters and may be provided preassembled to the instrument.

CALIBRATIONS AND COMMUNICATORS

The dead-weight-type pressure testers and calibrators are described in Section 5.8. Portable, hand-held electronic pressure calibrators are also available. These units are provided with National Institute of Standards and Technology (NIST) traceable pressure readouts with inaccuracies of 0.1% of reading or better. For lower pressures (from a few inches of water to 200 PSIG, or 14 bars), these calibrators can be provided with a small hand pump to provide a pressure source for calibration. Some models can store several sets of configuration data and the calibration procedures for each. Calibration data can be captured and stored for later trending or uploading to a personal computer (PC) or network server. One of the many capabilities of these calibrators is instant conversion between various systems of units.

The smart transmitters (see Section 5.1) can also be provided with digital indication and with memory for trending or record keeping. When integrated into a network or into a distributed control system, (DCS), PC-, or programmable logic controller-operated system, the calibration steps and the use of stored specifications can all be automated. The calibrator/communicator units range from the palm-sized through the suitcase-sized up to the rollaround packages. Most provide storage of multiple device protocol libraries so that communication is possible with almost any manufacturer's transmitter. Some of the protocols in use, and their year of introduction, include ARCNet (1975), WorldFIP (1988), Highway Addressable Remote Transducer (HART) (1989), Foundation Fieldbus H1, (1995), and Profinet (2001).

Smart, microprocessor-based transmitters can be provided with communicators that are integral to, or separate from, the electronic calibration unit. These communication units allow the operator to modify zeroes or spans, change units, or verify the current values. If a PID algorithm is included in the smart transmitter, the communicator can be used to modify its setpoint or tuning values. Where transmitters are networked into a DCS system, it is not necessary to go to the transmitter to communicate with it. In such installations the individual transmitter can be accessed from the control room or engineer's desk through the data highway.

Establishment of an industry-wide communication protocol for digital control systems (similar to the 3 to 15 PSIG [0.2 to 1.0 bar] or the 4–20 mA DC signal ranges that have been developed and accepted worldwide for analog control) still eludes consensus. Nevertheless, sufficient digital bridges and adapters are available so that a completely digital instrumentation system is likely to be possible in any particular plant or system. Also, there are now at least two wireless local area network communication standards—"Bluetooth" and IEEE-802.11b—that may be useful and appropriate for some installations.

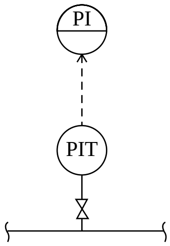
5.3 Bellows-Type Pressure Sensors

B. G. LIPTÁK (1969, 1982, 1995) **J. E. JAMISON, S. EDVI** (2003)



Flow Sheet Symbol

Applications:	Bellows-type sensing elements are for low to intermediate pressures and vacuums with atmospheric (compound) or vacuum (absolute) reference. They are also used in differential pressure applications, which are discussed in Section 5.6.
Design Pressure:	Up to 25 PSIG (172 kPa) with evacuated motion balance type bellows; up to 375 PSIG (2.6 MPa) with evacuated force balance bellows; up to 100 PSIG (690 kPa) with motion balance bellows, which are provided with atmospheric reference; up to 6000 PSIG (41 MPa) with dual bellows element; up to 4000 PSIG (27 MPa) with atmospheric reference force balance bellows.
Design Temperature:	Up to 212°F (100°C) with brass bellows
Materials of Construction:	Brass, stainless steel, beryllium copper, Monel, bronze, copper, Inconel, Ni-Span
Range:	Absolute pressure ranges from 0 to 0.326 PSIA (0 to 2.5 kPa); also, 0–100 mmHg to 0–35 PSIA (0–13 to 0–240 kPa); gauge pressure ranges from 0–2.5 in. H_2O to 0–2000 PSIG (0–0.65 kPa to 0–14 MPa); gauge vacuum ranges are available from –0.326 to 0 PSIG (–2.5 to 0 kPa); compound ranges are available from –0.196 to 0.13 PSIG (–1.5 to 1.0 kPa).
Inaccuracy:	±0.1 to ±2% of span. Standard indicators, recorders, and switches are less accurate than this sensor and the combined loop error therefore increases. Intelligent transmitters contribute the least error.
Costs:	\$150 to \$500 for indicators and switches; \$400 to \$1200 for direct recorders; \$800 to \$2000 for direct controllers and transmitters

INTRODUCTION

Bellows are formed from seamless tubes that are hydraulically or mechanically roll-formed. Seamless bellows are made of brass beryllium copper, phosphor bronze, Monel, Inconel, and stainless steel. Bellows can also be manufactured by welding a number of preformed plates together. Welded bellows are made from stainless steel, Ni-Span C, Monel, and Inconel-X. The main advantages of bellows (relative to diaphragm capsules) are their ability to provide longer strokes and to handle higher forces. They are therefore, well suited as direct input elements into recorders and indicators. Their sensitivity increases with their diameter, which can be as large as 6 in. (150 mm). Bellows are noted for their good linearity and are generally used in the ranges from 0 to 2.5 in. H_2O and 0 to 10 PSI (0–6 to 0–1000 mbar).

Their limitations include their sensitivity to ambient temperature effects, work hardening, drift, friction, and elastic hysteresis. In most cases the elastic action of the bellows is insufficient for accurate measurement, and a spring needs to be added to precisely characterize the relationship between force and movement.

BASIC DESIGNS

Four basic designs of bellows pressure detectors will be discussed. They are classified by the reference pressure used as absolute, gauge, or differential pressure detectors, and can also be grouped as force or motion balance types depending on the instrument design. Direct local indication is available only with motion balance units, while force balance sensors are more accurate. In addition, bellows manostats (self-contained vacuum controllers) are also described in Section 5.14.

Absolute Pressure Sensors

When absolute pressure is to be sensed with bellows elements, it normally involves two bellows, one for measuring and the other for reference. The compensating (reference) element is fully evacuated and sealed, while the sensing element is connected to the process.

Motion Balance Figure 5.3a illustrates the beam balance version of this design, and Figure 5.3b shows the opposed bellows design. In either arrangement, an increase in process pressure will cause the measuring bellows to extend, which results in an increase of readout through the motion balance mechanism. If the process pressure is constant but the barometric pressure changes, force will be exerted equally on the outside of both bellows, causing no change in the readout. The evacuated bellows are capable of compensating for barometric pressure variations as high as 100 mmHg (200 kPa).

Dual bellows detectors are available with spans from 0–100 mmHg to 0–30 PSIA (0–13 to 0–200 kPa). The elements can be exposed to overpressures up to 35 PSIA (240 kPa). These motion balance absolute pressure sensors are inaccurate to ±1% of full scale and, therefore, can give reasonably reliable measurement of absolute pressures down to approximately 5 mmHg (0.7 kPa).

Force Balance The force balance detector shown in Figure 5.3c is available as a pneumatic or electronic transmitter, but not as a direct indicator because there is no motion to drive a pointer. For local indication, an output gauge can be installed.

Because the force balance transmitter mechanism is illustrated in Figure 5.6e, it has not been repeated in Figure 5.3c. The pressure being sensed is applied to the inside of the bellows within the capsule. The space on the outside of the bellows is evacuated, thus providing a zero absolute pressure reference. The process pressure exerts a force on the capsule that is applied to the lower end of the force bar. Due to the force balance nature of the unit, the force bar is constantly

Opposed bellows detector.

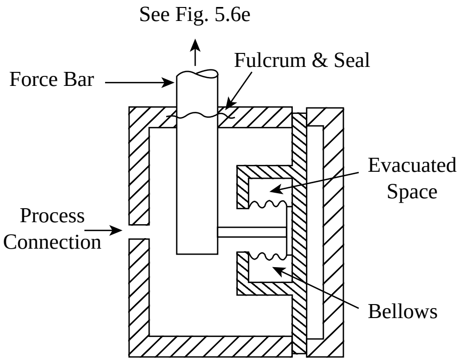

FIG. 5.3c
Force balance absolute pressure sensor.

balanced; the sensing bellows do not move as long as the pressure detected is within the range of the instrument. If the range of the capsule is exceeded, the bellows extend to the right where they are supported by the capsule backup plate.

The standard material for construction of this instrument is stainless steel. The inaccuracy is between 1/4 and 1/2% of span. The minimum span for this unit is 25 PSIA (170 kPa) and the maximum is 250 PSIA (1700 kPa). These spans are adjustable within the 0 to 350 PSIA (0 to 2.4 MPa) range limits of the capsule. The unit will withstand a maximum pressure overrange of 375 PSIG (2.6 MPa). The ambient temperature limits on this device are from –40 to 250°F (–40 to 120°C).

Atmospheric Reference Sensors

When bellows are used as the pressure-sensing element, it is desirable to add a spring for ranging and accurate characterization. Without the calibration spring, temperature effects and work hardening of the bellows would cause a loss of accuracy. The bellows are either brass or stainless steel, and the calibration spring is Ni-Span C, which ensures uniform motion throughout the range with practically no change due to ambient temperature variations.

Motion Balance Figures 5.3d and 5.3e illustrate designs using single-bellows elements. In both designs, the inside of the bellows is open to atmosphere, which represents the pressure reference, and the outside is exposed to the process pressure. The differences in the two designs involve only the location of the calibration springs and the method applied in transmitting bellows motion to the readout pointer.

The spring-loaded metallic bellows are compressed by the process pressure, which is forcing the lower end of the bellows upward against the opposing force of the spring. This vertical movement is transmitted through suitable linkage or a torque tube assembly to the pointer. These units can also act as differential pressure detectors if the inside of the bellows is connected to a process pressure instead of being open to the atmosphere.

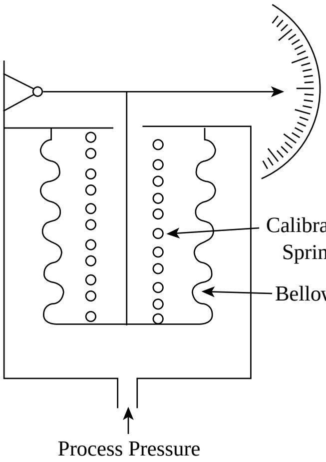

FIG. 5.3d
Bellows sensor with calibrated spring.

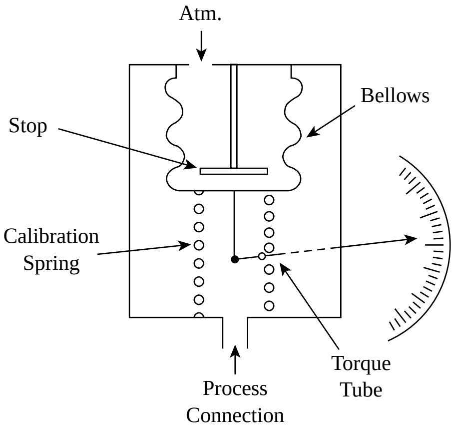

FIG. 5.3e

TABLE 5.3f
Minimum and Maximum Spans of Standard Bellows

Type of Bellows	*Minimum Span*	*Maximum Span*
Large diameter brass	0–5 in. H_2O (0–127 mm H_2O)	0–90 in. H_2O (0–22.3 kPa)
Small diameter brass	0–90 in. H_2O (0–22.3 kPa)	0–450 in. H_2O (0–111 kPa)
Small diameter stainless steel	0–15 PSIG (0–103 kPa)	0–40 PSIG (0–276 kPa)

Single Bellows The spans of the single-bellows element vary with the diameter and construction materials of the bellows. Table 5.3f lists the span ranges of some standard bellows elements. By selecting the appropriate spring for the application, the sensor bellows can detect positive, vacuum, or compound ranges as a function of the location of the atmospheric pressure reference. The inaccuracy of these units is between 1/2 and 2% of span depending on their design and calibration. Their overpressure limitation varies from 25 to 100 PSIG (170 to 690 kPa).

Dual Bellows Dual-bellows elements (Figure 5.3g) are also available as differential pressure sensors. These differential pressure (d/p) elements will be discussed in detail in Section 5.6 (see Figure 5.6c). If either the low- or the high-pressure side is left open to the atmosphere, the unit will detect either gauge pressure or vacuum. The various features and operating principles of this d/p instrument will not be repeated here, but Table 5.3h does give a summary of their available sizes and their corresponding minimum and maximum spans.

These instruments can be designed for overpressures up to 6000 PSIG (41 MPa), can operate between –60 and 200°F (–50 and 93°C) temperature, and are inaccurate to 1/2 to 1%

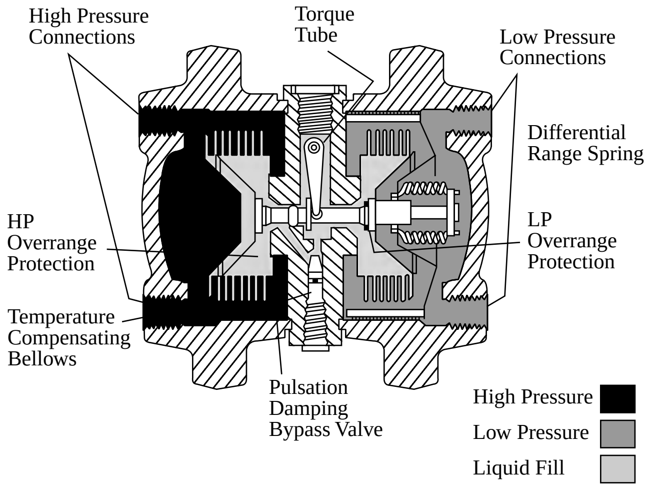

FIG. 5.3g
Differential pressure sensors can be used to detect gauge pressures by leaving the low-pressure side open to atmosphere or can be used to detect vacuums by leaving the high-pressure side open. (Courtesy of Siemens-Moore Automation Solutions.)

TABLE 5.3h
Standard Sizes of Stainless Steel Bellows and Their Corresponding Minimum and Maximum Spans

Type of Bellows (Stainless Steel)	*Minimum Span*	*Maximum Span*
3¾ in. diameter	0–20 in. H_2O (0–5 kPa)	0–400 in. H_2O (0–99 kPa)
2⅛ in. diameter	0–15 PSI (0–103 kPa)	0–50 PSI (0–345 kPa)
1⅝ in. diameter	0–30 in. H_2O (0–7.4 kPa)	0–35 PSI (0–241 kPa)
¾ in. diameter	0–35 PSI (0–241 kPa)	0–400 PSI (0–2758 kPa)

of span. The torque tube shaft in this unit can drive local indicators, recorders, controllers, switches, or transmitters.

Force Balance Figures 5.3i and 5.3j illustrate two gauge pressure sensors of the force balance variety. When relatively low pressures need to the measured, the process pressure is introduced into the inside of the bellows, while for higher pressures, the outside surface of the bellows is exposed to the process pressure. The force of the process pressure is applied to the lower end of the force bar. Due to the force balance nature of the unit, the force bar is constantly balanced; therefore, the sensing bellows do not move as long as the pressure detected is within the range of the instrument.

Because the force balance units do not have enough motion to drive an indicator pointer, they are available only as transmitters (see Figure 5.6e). The bellows are available in brass, stainless steel, or Monel, and inaccuracies are between ±1/4 and 1/2% of span. Table 5.3k lists the spans and overpressures for some of the standard bellows elements (1 PSI = 6.9 kPa), as well as some of their sizes and spans.

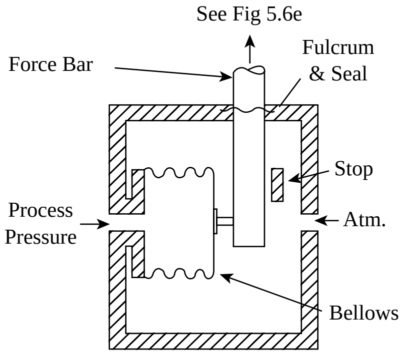

FIG. 5.3i
Force balance low-gauge pressure sensor.

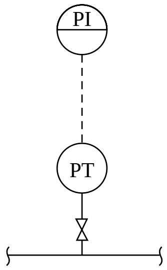
5.4 Bourdon and Helical Pressure Sensors

B. G. LIPTÁK (1969, 1982, 1995) **J. E. JAMISON, S. EDVI** (2003)



Flow Sheet Symbol

Applications:	Sensing elements for the measurements of medium to high pressures using atmospheric reference. For pressure gauges and switches using these elements, see the corresponding sections in this chapter.
Design Pressure:	Up to 100,000 PSIG (690 MPa)
Design Temperature:	Up to 600°F (316°C) with stainless steel Bourdon tube; lower with others; ±1% zero shift per 50°F (28°C) ambient variation
Materials of Construction:	Phosphor bronze, alloy steel, 316 and 403 stainless steel, beryllium copper, Monel, Ni-Span C
Inaccuracy:	1/4 to 5% of span
Range:	Minimum span 15 PSI (100 kPa); maximum span 100,000 PSI (690 MPa)
Costs:	$50 to $300 for indicators and switches, $500 to $1,200 for direct recorders, and $750 to $1,800 for direct controllers and transmitters. Quartz helix units range for $2,500 for an electronic transmitter to $18,000 for an IEEE and RS-232 programmable, stable-alone station.

In 1852, E. Bourdon patented a curved or twisted tube that if held and pressurized at its open end, produced movement at its closed end (tip travel).

THE BOURDON TUBE

Bourdon tube-type pressure elements are used to detect higher pressures (spans exceeding 30 PSI, or 200 kPa), because their spring gradient is insufficient for detecting lower pressures or vacuums. Bourdon tubes are manufactured in C, helical, and spiral forms (see Fig. 5.4a). The C-Bourdon element is made by winding a tubular element circularly to form a segment of a circle, the helical element is made by winding the tube several turns into a helix, and the spiral is formed by winding two or three turns in a spiral around the same axis. In each of these cases the circular cross section of the tube is flattened. When these elements are pressurized, their cross section tends to become more circular, which tends to straighten their shape (see Figure 5.4b). Helical and spiral elements are used when it is desired to reduce the stress in the tube and to increase the tip movement.

The design of Bourdon tubes is based on empirical equations and practical observations. The tubes can be made from strain-hardened alloys (brass, bronze, 304 and 316 stainless steel, or Monel), from heat-treated alloys (403, 4130, or 8630 stainless steel), and from precipitation-hardened alloys (beryllium copper, Inconel X, Ni-Span C, and K Monel). Some of the more desirable features of the Bourdon tube elements include their fast speed of response (usually 0.1 s full scale) and good sensitivity (0.01% of maximum pressure when unrestrained). Their limitations include a nonlinearity of about 0.5% full scale, which can be compensated mechanically or electronically; a 0.2 to 0.5% hysteresis on cycling pressures, which can be minimized by heat treatment; and a sensitivity to temperature variations, which can be reduced by the use of bimetallic compensators or by the use of element materials (Ni-Span C) having moduluses of elasticity that are insensitive to temperature variations.

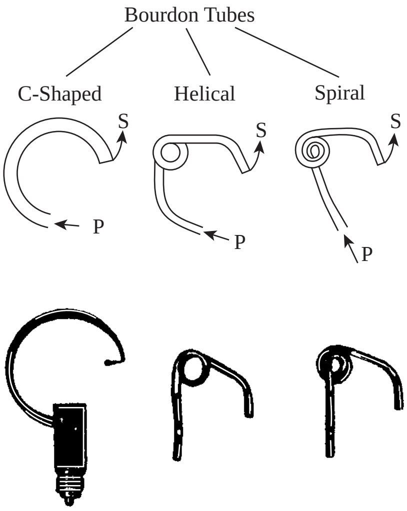

FIG. 5.4a
The main types of flexible measuring elements. (Courtesy of WIKA Instrument Corporation.)

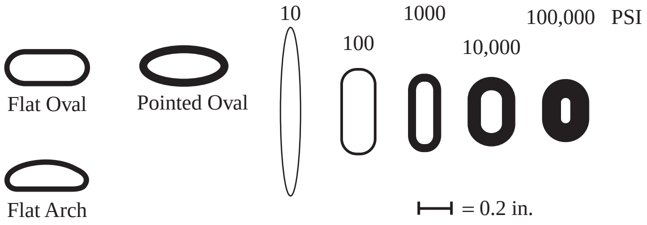

FIG. 5.4b
Cross-sections of Bourdon tubes for various pressure ranges. (Courtesy of WIKA Instrument Corporation.)

C-Bourdon Pressure Sensors

Figure 5.4c illustrates a C-Bourdon tube used in direct indicating gauges, which usually have an arc of 270 degrees. The process pressure is connected to the tube support end of the tube, while the tip end is sealed. Because of the difference between inside and outside radii, the Bourdon tube presents different areas to pressure, which causes the tube to tend to straighten when pressure is applied.

The resulting tip motion is nonlinear because less motion results from each increment of additional pressure. This nonlinear motion has to be converted to linear rotational pointer response. This is done mechanically by means of a geared sector and pinion movement. The tip motion is transferred to the tail of the movement sector by the connector link. The angle between the connecting link and the sector tail is called

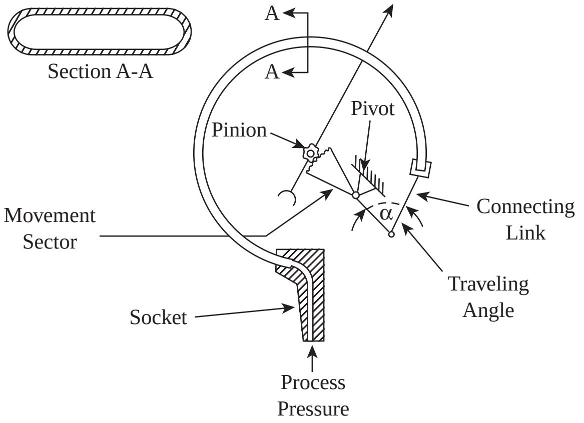

FIG. 5.4c
Pressure gauge with C-Bourdon pressure element.

the traveling angle. This angle changes with tip movement in a nonlinear fashion, compensating for the nonlinearity of the tip movement. It is designed to minimize backlash and provide smooth roll-on and roll-off characteristics in the geared sector. It is also designed to provide pinion movement by using fine pitch gears or by eliminating the gears altogether and using a cam sector that positions on a roller surface.

This design eliminates the gears that eventually wear out and reduces the play that occurs when teeth are worn. On gear and pinion designs, the operation has been improved by the use of nylon and Teflon materials.

Table 5.4d lists Bourdon tube materials, noting some of the important characteristics by the letters P (poor), F (fair), G (good) and also indicating the maximum pressure range that the Bourdon tube can detect.

As stated in Table 5.4d, Ni-Span C seamless tubing, drawn to the profile in Figure 5.4c, is the best choice for Bourdon tube applications in all cases except those at very high pressure or those that are extremely corrosive. Direct indicators or motion balance transmitters using C-Bourdon elements are available with spans from 0–15 PSI to 0–20,000 PSI (0–100 kPa to 0–140 MPa) and can be used for positive, negative, or compound pressure ranges, but the indication on the vacuum side will not be accurate or sensitive. The accuracy of these devices is a function of the Bourdon tube diameter, design quality, and calibration procedures. It can vary from ±0.1 to ±5% inaccuracy, with the majority of these units failing in the area of ±1% (Table 5.11f).

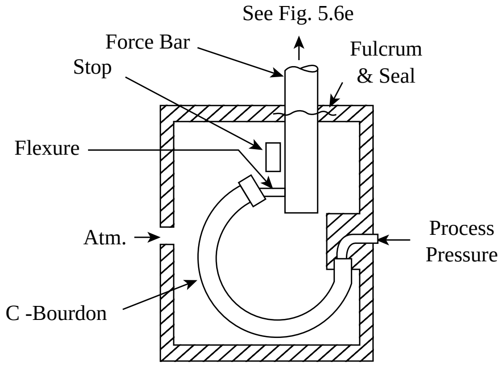

FIG. 5.4e
Force balance C-Bourdon pressure sensor.

The quality of C-Bourdon measurement can be influenced by several factors. The large overhang in the element makes it susceptible to shock or vibration. If a Bourdon element has been calibrated on air and in the process it is filled with liquid, weight of the fluid in the overhang will introduce an error. In some applications, the tubes will need to be flushed, for which purpose tube tip bleed valves are available. On liquid service, air is likely to be trapped in the tube end, which acts as a cushion and results in sluggish performance. Bourdon designs are available with an internal capillary tube that allows entrapped air to escape from the tip.

Figure 5.4e illustrates the design that uses a C-Bourdon element in a force balance transmitter. (See Figure 5.6e for a more detailed view of a force balance transmitter mechanism.) The pressure applied to the Bourdon tube tends to straighten it and move its tip to the left. The flexure transmits the resulting force to the lower end of the force bar.

Due to the force balance nature of the unit, the force bar is constantly balanced; the sensing Bourdon does not move as long as the pressure sensed is within the range of the instrument. If the range is exceeded, the lower end of the force bar moves to the left, where it is supported by a limit stop.

TABLE 5.4d
Pressure Ranges and Other Characteristics of the Different Bourdon Tube Materials (1 PSI = 6.9 kPa = 0.069 bars)

Tube Material	*Corrosion*	*Spring Rate*	*Temp. Coefficient*	*Hysteresis*	*Maximum Pressure*
Phosphorus bronze	P	F	P	F	800 PSIG
Beryllium copper	P	G	P	G	5000 PSIG
316 Stainless steel	G	P	P	P	10,000 PSIG
403 Stainless steel	G	P	P	P	20,000 PSIG
Ni-Span C	G	G	G	G	12,000 PSIG
K-Monel	G	P	P	P	20,000 PSIG

P = poor; F = fair; G = good.

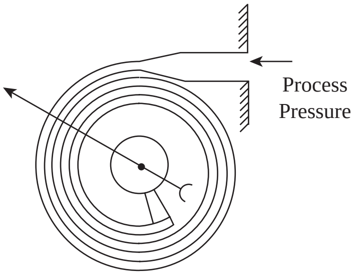

FIG. 5.4f
Spiral Bourdon element.

The Bourdon tube is made of Ni-Span C, and all other wetted components are stainless steel. Available spans vary from 1000 to 12,000 PSI (6.9 to 83 MPa) with 150% overrange protection. The inaccuracy of this transmitter is ±0.5% in the lower and ±1% in the higher ranges. Maximum ambient temperature is limited to 250°F (120°C).

Spiral Bourdon Pressure Sensors

The free end motion of the C-Bourdon tube is insufficient to operate some of the motion balance devices, such as the transmitters. The spiral element shown in Figure 5.4f is essentially a series of C-Bourdon tubes joined end to end. When pressure is applied, this flat spiral tends to uncoil and produces a greater movement of the free end, requiring no mechanical amplification. This increases the sensitivity and accuracy of the instrument because no lost motion or friction is introduced through the links and levers.

Standard spiral materials include bronze, steel, stainless steel, beryllium copper, Monel, and Ni-Span C. Spans as low as 10 PSI (69 kPa) are available for positive, negative, or compound ranges. The various manufacturers use different break points between the spiral and the helical elements. Some start using helical elements at above 200 PSI (1.4 MPa) spans; others stay with the spiral element up to 4,000 PSI (27 MPa) and higher. Unflattened, heavy-wall, spiral tube springs that detect pressures up to 100,000 PSIG (690 MPa) are also available in direct indicators.

Figure 5.4g is a simplified illustration of an old, pneumatic motion balance transmitter operated by a spiral element. While the flapper is substituted with an electronic motion sensor in the majority of today's pressure transmitters, the nature of the sensor's operation has not changed. The sketch would also apply if the process pressure was detected by a C-Bourdon or a helical element.

In this unit, the air supply passes through a restriction before being applied to the top of the relay diaphragm and the nozzle. An increase in process pressure tends to straighten out the spiral, which causes the flapper to move closer to the nozzle. This increases the nozzle back pressure sensed by the relay diaphragm, which will move down, opening up the air supply to the output. The increased output pressure is felt by the feedback bellows and restores the flapper to its throttling position. For each value of process pressure there is a corresponding definite flapper position and output pressure, hence, the name motion balance. The inaccuracy of these motion balance pressure transmitters is generally placed at ±0.5%. As shown in Figure 5.4g, they will read the process pressure even if the air supply is lost.

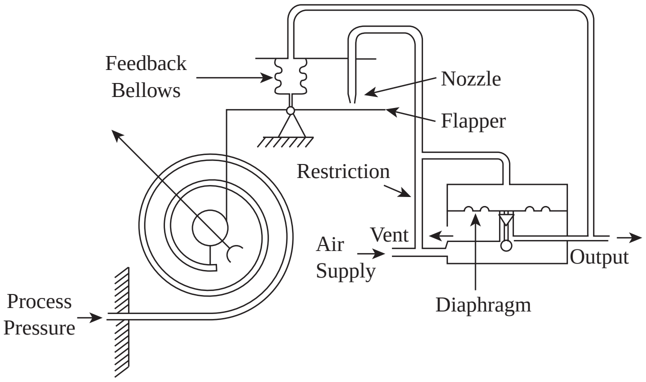

FIG. 5.4g
Motion balance pressure transmitter with spiral element.

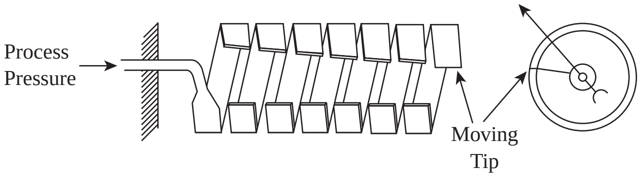

FIG. 5.4h
Helical Bourdon pressure sensor.

Helical Bourdon Pressure Sensors

Figure 5.4h shows the construction of a helical Bourdon element. This sensor produces an even greater motion of the free end than the spiral element, eliminating the need for mechanical amplification.

Other advantages of this design include the high overrange protection available. For example, a 0 to 1,000 PSIG (0 to 6.9 MPa) element may be safely exposed to 10,000 PSIG (69 MPa) pressure, and it is suitable for pressure measurement on continuously fluctuating services. The range of the helical coil is affected by the diameter, wall thickness, number of coils used, and construction materials. High-pressure elements might have as many as 20 coils, while low-span sensors can have only 2 or 3 coils.

Available materials include bronze, beryllium copper, Ni-Span C, and stainless steel. The various suppliers have different practices concerning the pressure levels at which they change from spiral to helical elements. For this reason, helical elements are available with spans from 0–30 PSI to 0–80,000 PSIG (0–200 kPa to 0–550 MPa), depending on the supplier. For pressures exceeding 5,000 PSIG (35 MPa), heavy-duty stainless steel is the standard element material.

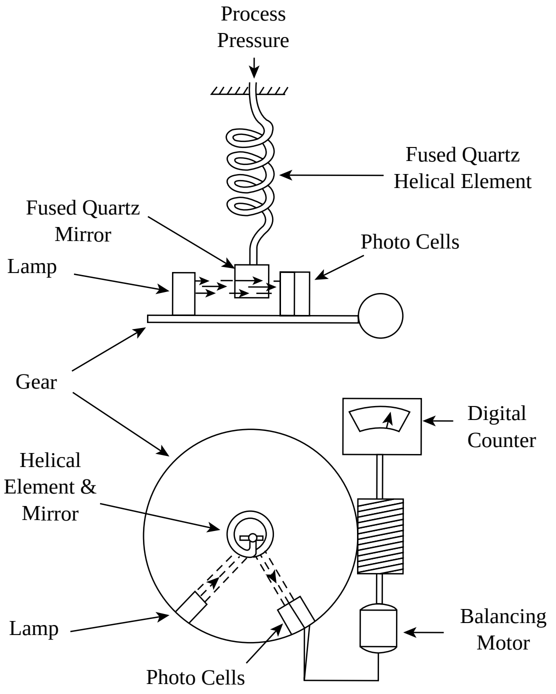

FIG. 5.4i
Fused quartz helical pressure sensor.

Helical coils can also be used as the element in differential pressure sensors if one of the pressures is acting on the outside surface and the other on the inside of the coil.

Motion balance instruments with helical elements include direct indicators, recorders, controllers, switches, and transmitters with either pneumatic or electronic outputs. Their inaccuracy is normally in the area of ±1% of span.

Fused Quartz Helix Sensors As shown in Figure 5.4i, the process pressure causes the free end of the helix to rotate together with the mirror attached to it. The quartz helix is mounted above a large precision gear that can rotate concentrically around the pressure sensor. A lamp and a pair of photo cells are attached to the gear. The light from the lamp is reflected from the mirror and distributed equally on the two photo cells. When the process pressure changes, the free end of the helix rotates the mirror, unbalancing the photo cells. This signal causes the balancing motor to turn the gear until the light falling on the photo cells is equally distributed once more. Consequently, the gear follows the movement of the free end of the helix without mechanical contact. The rotation of the gear is registered by a digital counter that is calibrated in pressure units.

This instrument detects vacuum, absolute, gauge, and differential pressures between 1 μm (10^{-3} mmHg) and 500 PSIG (3.5 MPa) in several ranges with a minimum span of 5 PSI (35 kPa). The device is repeatable to two parts in 100,000 or inaccurate to ±0.01%.

Its resolution and sensitivity are high while its hysteresis is negligible. It is presently used in laboratories, but the principle should make it suitable for industrial installations in which precision pressure detection is desired. The cost is high and the unit is sensitive to, and thus should be protected from, vibration. One of its drawbacks is the slow response speed of 2 min for full-scale travel.

Flow Sheet Symbol

Design Pressure:	Up to atmospheric with evaluated motion balance capsule; up to 50 PSIG (344 kPa) or more with evacuated force balance capsule; up to 200 PSIG (1.4 MPa) with atmospheric reference motion balance capsule; up to 1500 PSIG (10 MPa) with atmospheric reference force balance capsule.
Design Temperature:	Phosphor bronze (–50 to 250°F, or –46 to 120°C). Ni-Span C (–50 to 300°F, or –46 to 149°C), 316 stainless steel (–400 to 600°F, or –240 to 316°C), Inconel (–300 to 1000°F, or –184 to 538°C). The other components besides the diaphragm element can limit the operating to 250°F (120°C) or less.
Materials of Construction:	Buna-N, nylon, Inconel, Ni-Span C, phosphor bronze, 316 stainless steel, beryllium copper, Monel, brass, titanium, tantalum, Hastelloy, nickel, duranickel, Teflon, Kel-F, polytetrafluoroethylene, CrNi, Ni-Cr-Co alloy.
Range:	Absolute pressure ranges from 0–5 mmHg to 0–50 PSIA (0–0.7 to 0–350 kPa); gauge pressure ranges from 0–0.5 in. H_2O to 0–200 PSIG (0–0.12 kPa to 0–1.4 MPa).
Inaccuracy:	0.1 to 1% of span. Standard indicators, recorders, and switches are the least accurate; intelligent transmitters are the most accurate.
Costs:	\$200 to \$500 for indicators and switches, \$500 to \$1200 for direct recorders, and \$800 to \$2000 for direct controllers and transmitters.

FIG. 5.5a

The variety of diaphragm- and capsule-type pressure and differential pressure detectors and transmitters is very great. (Courtesy of Foxboro-Invensys.)

INTRODUCTION

This section is devoted to the description of diaphragm- and capsule-type pressure sensing elements and to the force and motion balance devices that utilize them. As shown in Figure 5.5a, the variety of such pressure detector designs is wide and varied.

These diaphragm-type pressure sensors are also discussed under differential pressure detectors (Section 5.6) and under electronic pressure sensors (Section 5.7) because the strain gauge, capacitance, potentiometric, resonant wire, piezoelectric, inductive, reluctive, and optical transducers can all be provided with diaphragm elements. Similarly, some of the high-pressure sensors (Section 5.8), pressure repeaters (Section 5.12), and vacuum sensors (Section 5.14) can also be provided with diaphragms as their sensing elements.

The full range deflection of a single diaphragm is usually limited to about 0.002 in. (0.05 mm), and the amount of deflection varies with the 4th power of the diameter of the diaphragm. Therefore, for the same amount of pressure change, the diaphragm deflection increases 16-fold if the diameter is doubled. One method of increasing the total deflection is to weld several diaphragms together into capsules.

DIAPHRAGM ELEMENTS

Pressure sensors that depend on the deflection of a diaphragm have been in use for over a century. In the last few decades, the elastic hysteresis, friction, and drift effects have been reduced to approximately ±0.1% of span in the high-quality designs. This has been achieved mostly by the use of microprocessor technology in smart transmitters. In traditional diaphragms the hysteresis error amounted to about 0.25 to 0.5% of full scale and nonlinearity could range from 0.1 to 2% of full scale.

What the microprocessor contributed in improving the performance of diaphragm-type sensors was its ability to recall from its memory the appropriate correction factors for the different values of diaphragm deflections. In other words, the microprocessor does not eliminate the nonlinearity of diaphragms, but it does memorize the amount of nonlinearity and electronically corrects for it.

Materials and Configurations

Diaphragm materials with good elastic qualities, such as beryllium copper, and with very low temperature coefficients of elasticity, such as Ni-Span C, are used. Inconel and stainless steel are used when extreme operating temperatures or a corrosive process requires them. Quartz diaphragms are used when minimum hysteresis and drift are desired.

The diaphragm is a flexible disc, either flat or with concentric corrugations, that is made from sheet metal of precise dimensions. The pressure deflection characteristics of both flat and corrugated diaphragms have been well investigated. The available corrugated profile types include sinusoidal, saw-tooth, or trapezoidal (see Figure 5.5b). The type of seal and peripheral clamping (fixing) used are dependent on the characteristics of the diaphragm.

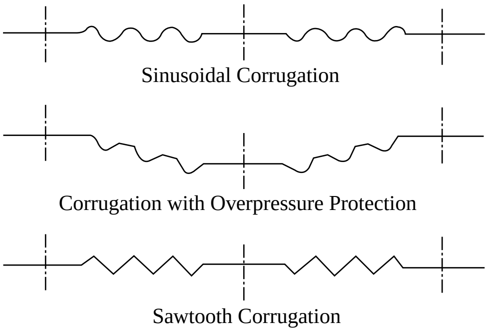

FIG. 5.5b
Common convolution cross-sections. (Courtesy of WIKA Instrument Corporation.)

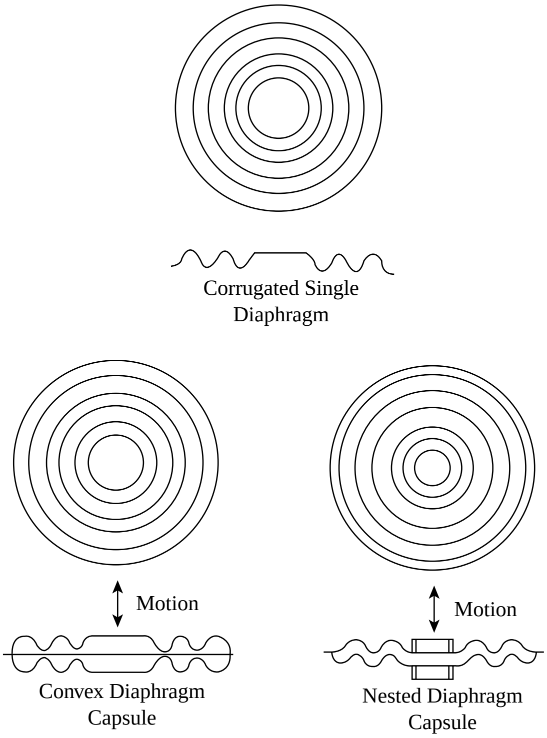

FIG. 5.5c
Standard diaphragm elements.

Some instruments use the diaphragm as the pressure sensor; others use it as a component in a capsular element. Figure 5.5b shows a single corrugated diaphragm and also some capsule designs. The capsules consist of two diaphragms welded together at their peripheries. Two basic types of capsules are illustrated: the convex and the nested. Evacuated capsules are used for absolute pressure detection, and single diaphragms are used for highly sensitive measurements. The sensitivity of a capsule increases in proportion to its diameter, which in the conventional designs varies from 1 to 6 in. (25.4 to 152.4 mm).

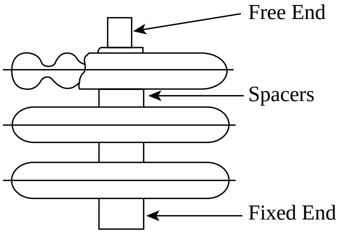

FIG. 5.5d
Multiple capsule element.

Multiple capsule elements can be built from either convex or nested capsules as shown on Figure 5.5d. These elements are useful in increasing the output motion resulting from a pressure change.

SENSOR CONFIGURATIONS

In this section, four basic designs of diaphragm pressure sensors will be discussed. They will be distinguished by the pressure reference used (full vacuum or atmospheric) and by the method of balancing the forces generated by the process pressure into force or motion balance designs. When atmospheric reference is used, the reading is called gauge pressure; when the reference is full vacuum (actually about 0.001 mmHg), the measurement is called absolute pressure. When differential pressure is measured there is no reference, as the two measurements are only subtracted.

Motion balance units are capable of driving local, direct reading indicators but are subject to hysteresis, friction, and dead-band errors. Force balance designs are transmitting devices with high accuracy but without direct indication capability.

Absolute Pressure Sensors

Motion Balance Figure 5.5e illustrates a motion balance type absolute pressure detector. The capsular element is fully evacuated and changes its length as a function of the process pressure in its housing. Because its length depends on the difference between internal and external pressures and because the internals have been fully evacuated, the element's length is a measure of the absolute pressure acting on the outside of the capsule. The capsular element is sealed inside the pressure-tight housing. The meter shaft transmits the capsule motion to the readout device or controller through a bellows seal. This seal protects against air leakage under vacuum and is fairly frictionless.

The capsule and the bellows seal are normally available in bronze, stainless steel, and nickel materials, or they can be silver or gold plated. Because the evacuated diaphragm element would collapse as the pressure on its outside increases, the capsules have been designed to bottom on each other when they are exposed to pressures above the range of the instrument.

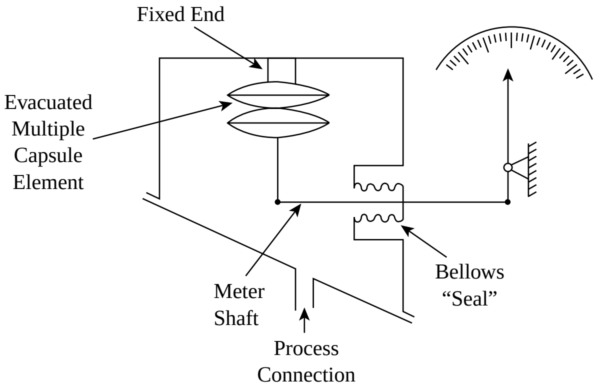

FIG. 5.5e
Motion balance absolute pressure sensor.

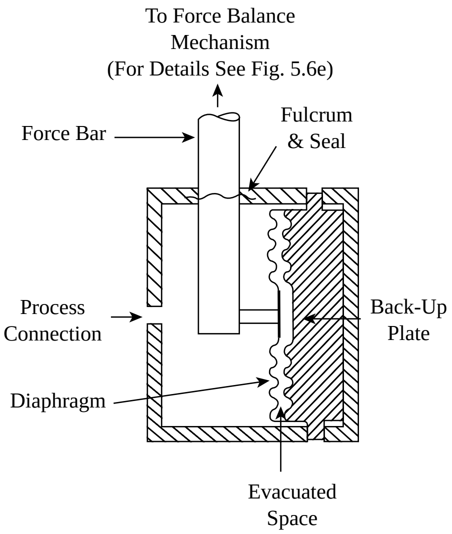

FIG. 5.5f
Force balance absolute pressure detector.

TABLE 5.5g
Features of Force Balance-Type Absolute Pressure Instruments

	Transmitter Range		
Features	*Low*	*Medium*	*High*
Capsule diameter:	5 in. (127 mm)	3½ in (89 mm)	2 in. (51 mm)
Minimum range:	0 to 10 mmHg	0 to 40 mmHg	0 to 375 mmHg
Maximum range:	0 to 40 mmHg	0 to 400 mmHg	0 to 1520 mmHg
Overpressure protection up to:	50 PSIG (3.5 bars)	100 PSIG (7 bars)	150 PSIG (10.5 bars)
Inaccuracy (% span):*	1%	½ to 1%	½ to 1%
Operating temperature:	–40 to 250°F (–40 to 121°C)	–40 to 250°F (–40 to 121°C)	–40 to 250°F (–40 to 121°C)

*"Intelligent" transmitters can reduce this error to 0.25% of span with analog and to 0.1% with digital signal transmission.

Therefore, the unit can be exposed to pressures up to atmospheric without damage to the capsule element.

The ranges available with this instrument can be as low as 0 to 5 mmHg (0 to 0.7 kPa) or as wide as 0 to 760 mmHg (0 to 100 kPa). Inaccuracy can be better than ±1% of full scale for the wide range elements, and for the narrow range capsules, it is a fraction of a millimeter of mercury.

Force Balance Design The force balance detector illustrated in Figure 5.5f is utilized in pressure transmitters, but not in direct indicator, because there is no motion available to drive a pointer. If local indication is desired, an output gauge can be installed on the transmitter. On the smart electronic transmitters this gauge is an integral part of the detector (Figure 5.6d), while on the old pneumatic transmitters, a pressure gauge detects the output air pressure. For a detailed sketch of a pneumatic force balance transmitter see Figure 5.6e.

The main sensing element in a force balance pressure transmitter is the capsule. The pressure being detected is applied to the left side of the diaphragm in the capsule, while the space on the other side of the diaphragm is fully evacuated, providing a zero absolute pressure reference (Figure 5.5f). The force felt by the force bar is related to the difference between full vacuum on the right side of the diaphragm and the process pressure on the other side or to the absolute pressure of the system measured. Due to the force balance nature of the unit, the force bar is constantly balanced; therefore, the sensing diaphragm does not move as long as the pressure detected is within the range of the instrument. If the range of the capsule is exceeded, the diaphragm moves slightly to the right where it can rest on and be supported by a backup plate with matching convolutions. This feature provides the transmitter's high over-range protection.

Transmitter Ranges and Materials The standard material of construction for these diaphragms is stainless steel. Table 5.5g lists some of the important features of this transmitter family. The transmitters are distinguished from one another by the diameter of the capsule. The transmitter ranges are adjustable in the field between the minimum and maximum values listed. Special transmitters are available in all-Monel construction or with Hastelloy body and tantalum capsule.

Atmospheric Reference

Motion Balance Design In this pressure detector, shown in Figure 5.5h, the process pressure inside the capsule is balanced against the spring action of the element. The outside surface of the diaphragm assembly is exposed to atmospheric pressure, which is then the pressure reference for this instrument. This unit is available either as a direct readout recorder or as a transmitter for remote readout. Due to the straight-line expansion of the capsule, the force-to-friction ratio is reasonably high. The diaphragm area is selected to produce a substantially greater force than required to operate the movement.

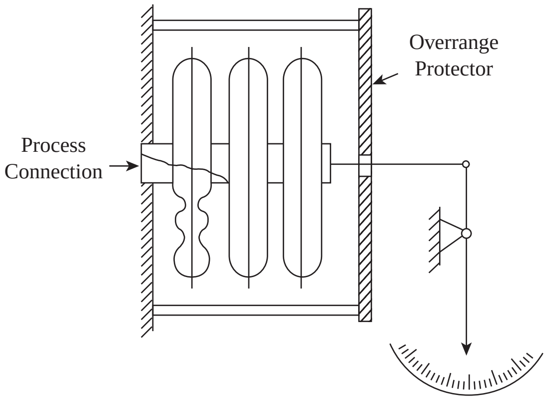

FIG. 5.5h
Motion balance pressure sensor with atmospheric reference.

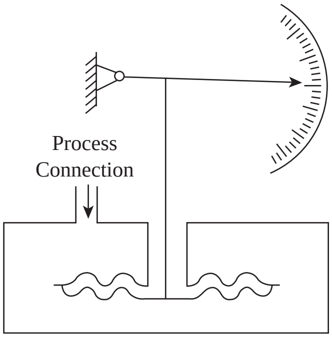

FIG. 5.5i
Nested diaphragm sensor.

The diaphragm capsules can be either convex or nested (see Figure 5.5c). The nested capsule can be exposed to higher overpressures than the convex ones, but all units are designed to withstand at least 100% overpressure over their full range. Figure 5.5i shows the nested capsule made of a convex and a concave diaphragm with the process pressure acting on the outside of the capsule rather than on the inside as in Figure 5.5e. This is the reason why high overpressures can be tolerated with the nested capsule. The range of this element is a function of the materials of construction, capsule diameter, and the particular design.

Materials of Construction and Spans Some of the frequently used diaphragm materials include: Cu-Ni-Mn (60% copper, 20% nickel, 20% manganese), phosphor bronze, Ni-Span C (constant modulus nickel alloy, 42% nickel, 2.4% titanium, 5.4% chrome, 50% iron), 316 stainless steel, and Inconel. The available capsule diameters vary from 2 to 5 in. (50.8 to 127.0 mm), with the larger diameters being sensitive enough to detect the lower pressures.

The nested capsule-type elements illustrated in Figure 5.5i can detect both gauge and vacuum pressures. Gauge pressures compress the space between the nested diaphragms, while vacuums open it up. When used to detect vacuum, the instrument is referred to as a “compound” gauge. Because the vacuum is measured against an atmospheric reference and because barometric pressure can change substantially, this is not an accurate method of detecting vacuums.

The minimum span available with these units is 0 to 3 in. H_2O (0 to 0.7 kPa) either below or above atmospheric, and the maximum span can be as high as 180 PSI (1200 kPa). This can mean, for example, a range of 20 to 200 PSIG (138 to 1400 kPa) or a full vacuum to 165 PSIG (1100 kPa) compound range. This range of pressure is covered by a variety of capsular elements, each having a minimum and maximum span.

For orientation purposes only, a few of the standard capsule spans are given in Table 5.5j. The zero adjustment on the instrument allows the range to be shifted to above or below atmospheric, and the span adjustment on the unit allows for narrowing or widening the range within the minimum and maximum span limits noted. The inaccuracy of these units is normally ±1% of span or better.

Slack Diaphragms Figure 5.5k illustrates the slack-diaphragm type motion balance pressure sensor with atmospheric pressure reference. In this unit the process pressure is balanced against either the spring action of the diaphragm or against a calibrated spring, as illustrated in Figure 5.5k.

This device is the most sensitive pressure detector in the family of elastic element sensors, and as such, it is capable of measuring near-atmospheric draft pressures. If the housing encloses both sides of the diaphragm, the unit can act as a differential pressure detector. The diaphragms are available in metal, such as stainless steel, or can be made of elastomers,

TABLE 5.5j
Features of Motion Balance-Type Absolute Pressure Instruments

Capsule	*Minimum Span*	*Maximum Span*
2 in. diameter Cu-Ni-Mn	20 in. H_2O (5 kPa)	5 PSI (34.4 kPa)
3 in. diameter Cu-Ni-Mn	8 in. H_2O (2 kPa)	40 in. H_2O (10 kPa)
Ni-Span C—large diameter	3 in. H_2O (0.75 kPa)	5 PSI (34.4 kPa)
Ni-Span C—small diameter	5 PSI (34.4 kPa)	15 PSI (103 kPa)
Ni-Span C—nested capsule	12 PSI (82.7 kPa)	180 PSI (1.24 MPa)

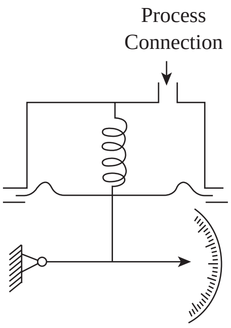

FIG. 5.5k
Slack-diaphragm detector.

such as Buna-N or nylon. The slack-diaphragm elements can actuate local, direct readout devices or transmitters for remote readout. Although the pressures measured are small, the force-to-friction ratio is still satisfactory due to the large diaphragm areas in these designs.

The available spans range from 0–0.5 to 0–120 in. H_2O (0–0.12 to 0–30 kPa). These spans can be either on the positive or vacuum pressure side or can cover compound ranges. Inaccuracy is in the range of ±1 to ±2% of span, and the slack-diaphragm elements can withstand overpressure between 5 and 25 PSIG (35 and 173 kPa), depending on the particular design.

Force Balance Designs The force balance differential pressure detectors (discussed in Section 5.6) can also be used as gauge pressure sensors if the low-pressure side of the differential pressure (d/p) cell is left open to atmosphere. In such installations, the output signal corresponds to the process pressure, which is connected to the high-pressure side of the d/p capsule.

Figures 5.6d, 5.6e, and 5.6f illustrate the design and operating components of these instruments. The minimum span available with these units is 0 to 2 in. H_2O (0 to 0.5 kPa) and the maximum span is 0 to 30 PSIG (0 to 2000 kPa). Only three capsules are required to cover this wide range. The minimum and maximum spans and other features of the standard d/p cells are listed in Table 5.5l.

Features and Construction Choices These capsules can be built into the conventional d/p cell body shown in Figure 5.6a or into the flat and extended diaphragm arrangements illustrated in Figure 5.6f. In the flat diaphragm design, the low-range capsule requires a 6 in. (150 mm) flange, while the medium- and high-range capsules can be accommodated by 3 in. (75 mm) flanges. The extended diaphragm version is available with medium- or high-range capsules only and requires a 4 in. (100 mm) mounting flange.

These transmitters have inaccuracies between ±1/2 and ±1% of span in their standard configurations and 0.1% of span in their microprocessor-based intelligent versions. They can withstand operating temperatures of –40 to 400°F (–40 to 200°C). The maximum static pressure that they can be exposed to varies from 225 PSIG (1.6 MPa) for the 6 in. diameter flanged unit to 6000 PSIG (41 MPa) for the high-pressure version of the standard unit shown in Figure 5.6a.

The parts exposed to the process fluid can be made of a large variety of materials, including carbon and stainless steel, Monel, Duranickel, Hastelloy, tantalum, and nickel, or provided with coatings such as Kel-F or Teflon.

PRESSURE REPEATERS

Pressure repeaters are force balance devices capable of generating an air output signal of the same pressure as that of the process. These units are useful for isolating the process and thereby preventing corrosion, the possibility of plugging in the sensing line, and other hazards. Because these units are discussed in Section 5.12, only a summary of their features is given here.

The flanged repeaters shown in Figures 5.12c and 5.12d are available in 2, 3, and 4 in. sizes (50, 75, and 100 mm), with either flat or extended diaphragm construction. The extended design is used when the main consideration for installing a repeater is protection against plugging. The available materials for wetted parts include stainless steel, Hastelloy, nickel, Teflon, Kel-F, polyvinyl chloride, Penton, and others.

Available spans vary from 0–1 to 0–100 PSIG (0–6.9 kPa to 0–0.7 MPa), and the repeater inaccuracy can be as good as ±1/4% or 0.1 in. H_2O (2.5 mm H_2O) per PSIG repeated.

When positive pressures are to be repeated, the air (or other gas) supply pressure has to be 125% of the highest pressure to be repeated. On vacuum service, the repeater inaccuracy of ±2 mmHg (±0.3 kPa) normally limits use to absolute pressures above 40 mmHg (5.2 kPa).

The repeaters can work either on a vacuum reference source (see Figure 5.12d), in which case the reference vacuum always has to be lower than the lowest absolute pressure to be repeated, or on atmospheric pressure reference with a suppression spring. If the spring is set at 16.5 PSI (114 kPa), the repeater output will be zero-shifted by this amount. When the process is at atmospheric pressure, the output is 16.5 PSIG (114 kPa), and when the process is at full vacuum, the output is 1.5 PSIG (10 kPa).

The operating temperature and static pressure limitations of these units are similar to those of the force balance d/p cells.

TABLE 5.5l
d/p Cell Capsule Capabilities

	Low Range	*Medium Range*	*High Range*
Minimum span—in. H_2O	0–2	0–25	0–30 PSID
Minimum span—kPa	0–0.5	0–6.2	0–210
Maximum span—in. H_2O	0–150	0–1000	0–3000 PSID
Maximum span—kPa	0–37.5	0–250	0–207 bars
Maximum zero suppression	Maximum span	Calibrated span	
Maximum zero elevation	Minimum span

Flow Sheet Symbol

Design Pressure:	Up to 5000 PSIG; some as high as 10,000 PSIG (up to 35 MPa, some as high as 69 MPa)
Design Temperature:	Up to 350°F (177°C) for dry, force balance; up to 1200°F (650°C) on liquid-filled force balance; others up to 200°F (93°C)
Materials of Construction:	Stainless steel, Kel-F, Teflon, Hastelloy, Monel, tantalum, titanium, duranickel for force balance types
Inaccuracy:	±0.5 to ±2% of full scale for indictors and switches. For differential pressure (d/p) transmitters the basic error is from ±0.1 to ±0.5% of the actual span. Added to this are the temperature and pressure effects on the span and zero. For intelligent transmitters the pressure and temperature correction is automatic and the overall error is ±0.1 to ±0.2% of span.
Ranges:	For membrane-type d/p cells the range can be as low as 0 to 0.01 in. H_2O (0 to 2.5 Pa). Standard d/p cells are available from 0–5 to 0–850 in. H_2O (0–1.24 to 0–211 kPa) ranges. Filter status indicators and switches usually detect air fan status or dirt and/or frost buildup on filters or coils with ranges from 0–0.1 to 0–10 in. H_2O, while water flow switches used to detect flow across chillers and condensers can be set from 2 to 60 PSID. Motion balance bellows indicator ranges go up to 400 PSID (2.76 MPa). Some intelligent transmitters provide built-in PID algorithms and claim self-selection of multiple ranges, reaching 40:1 overall rangeabilities.
Costs:	\$50 to \$100 for air filter status indictors and switches; about \$200 for water service switches and \$750 to \$2000 for force balance d/p transmitters, with the higher costs corresponding to intellingent units, special materials, or to the use of special seals. Motion balance bellows indicator and transmitter costs range from \$800 to \$2000.

INTRODUCTION

The differential pressure (d/p) devices discussed in this section include the various filter status indicators and switches, the various wet and dry d/p indicators, the membrane-type very low differential sensing transmitters, and the regular and smart transmitting d/p cells. Some d/p instruments, such as the manometers, are only briefly mentioned, as they are discussed in detail in Section 5.9.

The instruments capable of detecting pressure differentials can be divided into *dry* and *wet* designs. The dry units can be further subdivided into *force balance* and *motion balance* types. The wet units can also be subdivided into *liquid sealed (inverted bell)* and *liquid manometer* versions. In addition, the liquid manometers can be further subdivided into *visual* and *float designs*. This section describes the dry designs and for a detailed description of the wet designs, refer to Section 5.9.

MEASUREMENT ERROR

Before proceeding into the description of the various d/p cell designs, it is desirable to discuss the factors that contribute to the total error in a measurement. This includes the inaccuracy or error (E), which is determined under constant, usually atmospheric, conditions and reflects the linearity, repeatability, and hysteresis errors of the instrument.

Example

For the purposes of this example, it is assumed that E = ±0.2% of *actual span*. Other factors include the zero and span shifts due to temperature variations (T_z and T_s, respectively). For a temperature variation of 100°F (55°C), T_z is assumed to be ±0.5% of *maximum range*, while T_s is ±0.5% of *actual reading*. The effect of static pressure changes on zero and span are noted by P_z and P_s and are based on the physical distoration caused by 2000 PSIG (138 bars) of operating pressure. For the purposes of this example, $P_z = \pm 0.25\%$ of *maximum range* and $P_s = \pm 0.5\%$ of *actual reading*.

Also for the purposes of this example, the maximum range is assumed to be 0 to 750 in. H_2O, and the actual span is assumed to be 0 to 100 in. H_2O. It is further assumed that the actual operating temperature is within 50°F of the temperature at which the unit was calibrated and that the operating pressure is 100 PSIG. If one calculates the total error (E_t) as the square root of the sum of the squares of the errors:

$$E_t = \sqrt{0.2^2 + 1.875^2 + 0.25^2 + 0.9375^2 + 0.25^2} = \pm 2.13\% \tag{5.6(1)}$$

where

$E = \pm 0.2\%$

$T_z = 0.5(750 \text{ in./100 in.})(50°\text{F}/100°\text{F}) = \pm 1.875\%$

$T_s = 0.5(50°\text{F}/100°\text{F}) = \pm 0.25\%$

$P_Z = 0.25(1000 \text{ PSIG}/2000 \text{ PSIG})(750 \text{ in./100 in.})$

$= \pm 0.9375\%$

$P_s = 0.5(1000 \text{ PSIG}/2000 \text{ PSIG}) = \pm 0.25\%$

From the above one might note that the largest contributions to the total error come from the zero shifts caused by pressure and temperature differences between the calibration and the operating conditions. These errors can be reduced by selecting a d/p cell having a *maximum range* that is closer to the actual reading. In connection with the above example one might also note that the total error (E_t) would have been even higher if the actual reading had not been 100 in. H_2O (100% of the actual span), but instead some fraction of it. It should also be noted that the E_t value calculated above is not the full measurement error, but only that part of it that the d/p cell is likely to contribute.

Smart Transmitters Reduce Error

Lastly, one should note that one advantage of the smart transmitters is their ability to reduce the pressure and temperature effects on the span and zero; therefore, if E is ±0.1% in an intelligent transmitter, the total error E_t can be kept within about ±0.3%.

D/P INSTRUMENT DESIGNS

The differential pressure instruments will be discussed in this section starting with on-off indicators and switches. This will be followed by the description of indicating and transmitting d/p instruments.

Filter Status Indicators

As energy costs increase, the cost of material transportation is becoming a greater segment of the total cost of production. Part of the transportation energy is invested in overcoming the pressure drop across dirty filters. In order to identify the filters that are in need of cleaning, filter status indicators have been developed.

One of these units is shown in Figure 5.6a. Here the pressure difference across the filter is applied to a spring-loaded piston. The spring setting represents the maximum allowable pressure drop across the filter. When this setting is reached, the piston lifts and rotates an indication ball to show its red (instead of green) half behind the indicator lens. In this mode the operator is expected to periodically inspect these status indicators and visually note the filters that need cleaning.

D/P Switches

The d/p across filters can be also be monitored by piston-operated switches (Figure 5.6b). In this design the high pressure is applied to the top of a piston and the low pressure to the underside of the piston against which a spring presses. A given differential pressure produces a corresponding spring movement. A magnet is attached to the piston which, through a nonmagnetic body, positions a pivot magnet, thereby driving the pointer or tripping as many as four switches, or both. Since piston movement is not transmitted mechanically, there are no associated moving seals. The only seals required are the piston seals and the static seals for the end caps.

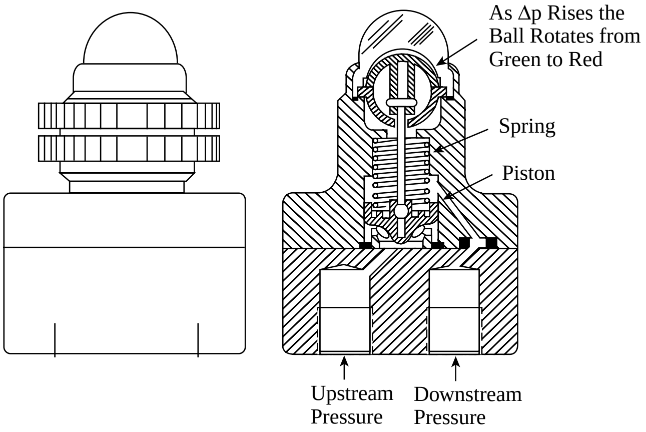

FIG. 5.6a
Filter status indicator changes its color to signal dirty filter condition.

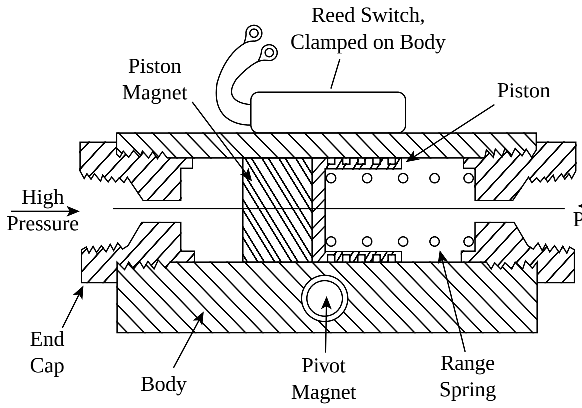

FIG. 5.6b
Piston actuated flow detector switch.

HVAC quality d/p switches can also be used in clean rooms or on air filters, fans, or coils, because they have very wide ranges and can detect very low differentials. They can be set to actuate from 0.05 in. up to 12 in. of H_2O pressure differential. Differential pressure switches are also widely used on such water service applications as to report excessive pressures across chillers or condensers. They are available with either SPDT or DPDT configuration and can be set to actuate anywhere from 2 to 60 PSID.

D/P Indicators

The devices developed for the measurement and indication or transmission of pressure differentials can be divided into dry and wet. Dry units can be further subdivided into force balance and motion detection types. Similarly, wet units have two major categories: liquid seal (inverted bell) and liquid manometer. Liquid manometers are divided into the visual and the float designs. These designs will be discussed below, starting with the motion balance type indicators.

The operation of bellows type dry, motion balance, d/p detectors depends on liquid-filled, double-opposed bellows. They are most useful when local indication or record is required and where compressed air or electric power is not available as the energy source. Their use as transmitters is limited because of the distinct advantages of the force balance units.

Figure 5.6c illustrates the basic components of the unit: the high- and low-pressure chambers, the range spring, and the drive assembly to transfer bellows motion to the readout pointer. The bellows in both chambers and the passage between them are liquid-filled. When the unit is installed, the pressure in the high-pressure chamber compresses the bellows, so that liquid flows from it into the low-side bellows. When the low-pressure (or range) bellows expand, they exert a force against the range spring, which determines the span of the instrument.

The linear motion of the range bellows moves the drive lever, mechanically transmitting a rotary motion through the sealed torque tube assembly to the indicator. The output motion from the torque tube assembly is limited to a few degrees of angular rotation. This is sufficient for most local indicators or recorders, but when the secondary responsive device imposes a considerable load on the torque tube assembly, the accuracy and sensitivity of the unit can be destroyed. For sustained accuracy, the bellows meter depends on the repeatability of its mechanical system, which has proven to be linear within 1/2 to 1% over its full range.

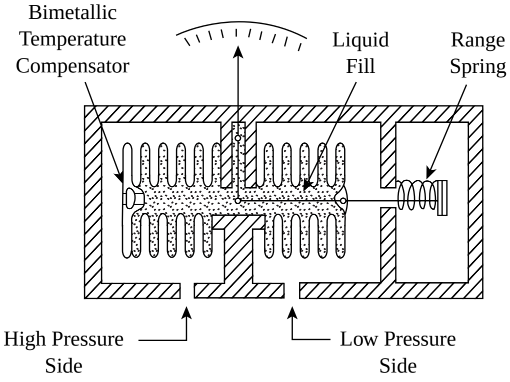

FIG. 5.6c
Motion balance type d/p indicator provided with temperature compensation.

Temperature Compensation and Over-Range Protection A bimetallic temperature compensator inside the high-pressure bellows automatically adjusts the capacity of the bellows assembly to the changing volume of the fill liquid due to ambient temperature variations. By adjusting the restriction in the passage between the two bellows, the device can be damaged.

Each of the bellows meters is provided with an over-range protector. The operation of one of the protection mechanisms is as follows: The bellows move in proportion to the differential pressure applied across them. When they have moved over their calibrated travel, a valve mounted on the center stem seals against its seat, trapping the fill liquid in the bellows. Because the liquid is noncompressible, the bellows are fully supported and cannot be ruptured, regardless of the overpressure applied. This over-range protection is furnished in both directions, protecting both bellows. Another function of the oil fill is to provide pulsation dampening. This is done by the use of an adjustable damper valve that restricts the oil flow from one bellows to the other.

Another design of over-range protectors involves the use of liquid-filled bellows with a number of diaphragm disks and spacer rings between them. As the bellows are subjected to over-range pressures, the diaphragms nest and the metallic spacer rings form a solid stop, fully protecting the bellows from rupture.

Ranges and Materials Bellows meters can detect pressure differentials as low as 10 in. H_2O (2.5 kPa) and as high as 400 PSIG (2.8 MPa). The minimum force required to actuate the motion detector mechanism limits the minimum differential that can be measured. For very high differentials, the limitation is in the mechanical strength of the bellows.

Standard units are available with steel or stainless steel housings and stainless or beryllium copper bellows. On corrosive applications, other materials can be obtained or special high-displacement volume chemical seals can be used. Static pressure ratings of 10,000 PSIG (69 MPa) are available as standard, and the operating temperature is limited to 200°F (93°C) maximum.

Liquid Manometers Since Section 5.9 is devoted to manometers, their discussion here is limited. The desirable features of liquid-sealed d/p detectors are their self-powered nature and their strong outputs. Their disadvantages include the toxic nature of mercury; the many moving parts, some of which are exposed to the process; the relatively high first cost and installation costs; and the various limitations caused by process materials contacting the filling fluid, which might be incompatible with it for reasons of corrosion, temperature, chemical reaction, or plugging.

The dry, force or motion balance type d/p detectors, which are discussed in this section, can handle almost all installations and will require less investment and maintenance than do the wet devices such as the manometers.

D/P Transmitters

Dry, Force Balance Design An advanced force balance d/p transmitter is shown in Figure 5.6d. A pair of diaphragms is welded to opposite sides of the d/p capsule and the space between them is filled with liquid. The differential pressure of the process is applied to the two sides of this diaphragm capsule. When electronic d/p transmitters are used, the bar force is balanced against the magnetic force developed in a coil. The resulting force is then brought out via the force bar and a new state of equilibrium (force balance) is established. As a result, the output signal is made to be proportional with the differential pressure sensed by the cell. The various electronic pressure detectors are discussed in Section 5.7.

As the flowing current is changed, the force balance is reestablished by matching the force on the bar with an equal magnetic force, making the current output signal proportional to the pressure differential in the cell. In the force balance designs, wear and friction are negligible because the motion is limited to a few thousandths of an inch. The displacement volume of the capsule diaphragm is very small, and if exposed to higher differentials than designed for, the diaphragm will be pressed against and will rest on the capsule body without damage to the unit.

FIG. 5.6d
Smart force balance d/p transmitter, provided with local indication and output signal suited for computer controlled systems. (Courtesy of Foxboro-Invensys.)

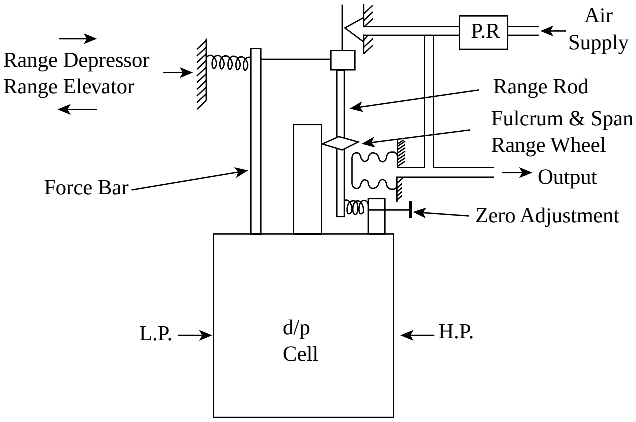

FIG. 5.6e
Force balance pneumatic differential pressure cell with adjustments shown.

Pneumatic Version In the pneumatic version, feedback bellows replace the coil and an output air signal from a feedback bellows replaces the current flow. The adjustment capabilities of this instrument are noted in Figure 5.6e. By moving the span range wheel, the range of most of these units can be adjusted over a 10:1 range. For example, a d/p cell having the full water column range of 200 in. (50 kPa) can be set for its full range to operate anywhere between 20 and 200 in. H_2O (5 and 50 kPa). Cells with full-scale ranges between 1 and 1000 in. H_2O (0.25 and 250 kPa) or more are available and can withstand static pressure up to 5000 or 6000 PSI (35 or 41 MPa).

As shown in Figure 5.6e, zero adjustments or range elevation and range depression adjustments are also provided. As the zero shift errors caused by operating pressures and temperatures (being different from the test conditions) are usually a percentage of the maximum range, the total error can be reduced if the maximum range and the actual span coincide. Table 5.5l lists some typical range values for standard d/p cells.

Suppression and Elevation If the d/p cell is used for level or density measurement or if it is installed with a liquid-filled wet leg, it might be necessary to add a spring force to its high-pressure side (to "depress" or "suppress" the range) or to its low-pressure side (to "elevate" the range). The d/p cell must be elevated, when a certain amount of hydrostatic head *on the high pressure side of the d/p cell* needs to be zeroed out. This is the case when measuring density, where a minimum specific gravity on the process side should result in a zero output.

As listed in Table 5.5l, the amount of elevation available is not unlimited, and it usually corresponds to the minimum span. As the zero suppression capability is usually greater than the zero elevation. On interface or density measurement applications d/p cells are often reversed so that their low pressure side is connected to the tank and their high pressure side to the wet leg (Figure 3.6r). When a wet leg adds a hydrostatic head to the low-pressure side of the d/p cell, it is zeroed out by depression or suppression. The maximum amount of depression that can be applied is usually the same as the maximum span minus the calibrated span.

Flat and Extended Diaphragms The diaphragm-type d/p cell designs were developed for use on viscous, corrosive, or slurry applications. One of the major goals was the elimination of dead-ended cavities, in which solids could accumulate and eventually plug the instrument.

In Figure 5.6f, two of these designs are shown: the extended and the flat diaphragm d/p cell transmitters. Their principle of operation is the same as that of the conventional d/p cells illustrated in Figure 5.6d and 5.6e. The one exception is that in these designs the high-pressure side of the diaphragm capsule is in direct contact with the process, and the force detected by it is transmitted through a flexure to the lower end of the force bar.

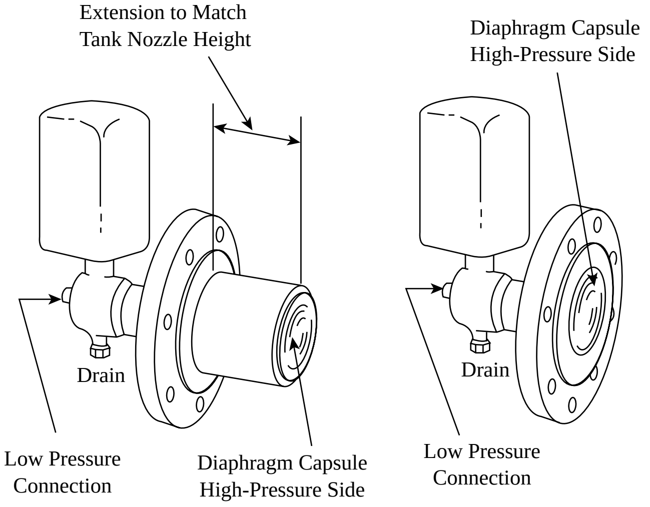

FIG. 5.6f
Extended diaphragm differential pressure cell (left) and flat diaphragm differential pressure cell (right) designs.

When the major need is corrosion protection, the flat diaphragm design can be used with corrosion-resistant lining (Kel-F, Teflon, etc.) or with the high-pressure side being made of corrosion-resistant materials (Hastelloy or titanium). With flat diaphragm installations, an isolating valve can be installed between the d/p cell and the tank nozzle, which allows for maintenance on the instrument while the tank is full.

This unit is also widely used on installations in which corrosion is not a particular problem, but simplicity of installation is desired. The flat diaphragm transmitter, being mounted directly on the tank nozzle, provides a self-supporting installation without the need for additional piping or support materials that tend to increase the installation cost of the conventional d/p cells.

When the main consideration is protection against plugging, the extended diaphragm version is used. These units are also available in corrosion-resistant materials, but their main design feature is elimination of the dead-ended cavity in which process materials can collect and gel, polymerize, or solidify. The unit is installed in the tank nozzle so that the diaphragm is flush with the inside of the tank or extends slightly into the tank.

Ranges and Pressure/Temperature Ratings Both the flat and the extended diaphragm designs are available with ranges up to 1000 in. H_2O (249 kPa) and with inaccuracies of 0.25% of actual span. The error of intelligent units is reduced to 0.1% of calibrated span when an analog output is provided and to 0.1 to 0.5 in. H_2O (2.5 to 13 mm) when digital output is used. These units can be provided with 2, 3, or 4 in. (50, 75, or 100 mm) ANSI Class 150, 300, or 600 flanges or with their DIN and BS equivalents.

The allowable process temperature is 400°F (204°C). Flanges are available in carbon or stainless steel, while the wetted parts can be a cobalt-nickel-chrome alloy, 316 SS, Hastelloy C, Monel, or tantalum. In the intelligent units, the operating temperature and pressure effects are automatically corrected. In standard d/p instruments the changes in process or ambient temperatures can cause zero shifts, as in the case with all similarly designed instruments. To minimize this effect, the d/p cell should be zeroed at the normal operating temperature, and the exposed body of the transmitter should be insulated. In more critical installations, the low-pressure side of the transmitter can be filled with a clean heat-transfer fluid that, in most cases, will eliminate the temperature gradient across the device. (Maximum process temperature for the extended design is 750°F, or 400°C.)

Wafer Elements Another family of force balance d/p cell transmitters has liquid-filled elements. Two basic versions of these designs are the wafer and the chemical seal element types.

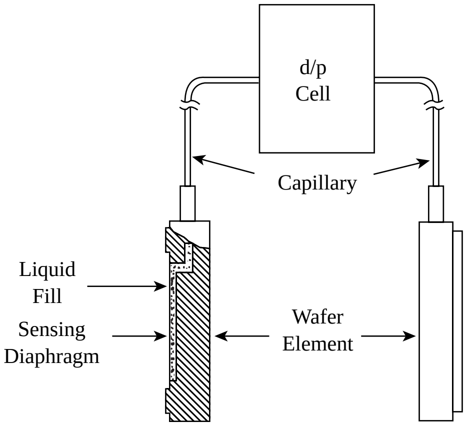

FIG. 5.6g
Differential pressure cell with wafer elements.

Wafer elements are illustrated in Figure 5.6g. These elements mount on pad connections, thereby reducing, but not eliminating, the dead-ended cavity on the process side.

These units are available with ranges up to 750 in. H_2O (187 kPa). The pressure seals are available with 316 stainless steel, Hastelloy C, or tantalum wetted parts and can be provided with capillary lengths of up to 26 ft (7.9 m). Their error in standard construction is about ±0.25% of span, while the intelligent units can reduce that to ±0.1% of calibrated span. These errors include linearity, hysteresis, and repeatability effects but exclude the effects of process temperature. In intelligent units with both seals at the *same temperature*, the total additional error caused by a temperature change of 100°F (55°C) is ±0.25 to ±0.5% of maximum span.

The filling liquid in the elements has a low thermal expansion coefficient, but temperature effects still cannot be disregarded. Actually, the pressure differential detected by the transmitter is the combined result of the hydraulic head in the tank and the differential thermal expansion in the two elements. For example, a 50°F (28°C) process temperature difference at the two elements can cause a zero shift of 4 in. H_2O (1 kPa). Even if the two wafers are at the same temperature, zero and span shifts will occur, as either the process or the ambient temperature changes.

Wafer elements can tolerate up to 1500 PSIG (10 MPa) in static process pressure and can be exposed to up to 1200°F (650°C) process temperatures. When used on vacuum service, the transmitter body should be mounted below the lower wafer element if the static pressure is under 1 PSIA (50 mmHg absolute). In short, this design does not fully eliminate the possibility of plugging, and due to its liquid-filled nature, it will drift with process or ambient temperature changes. The unit is normally considered for high-process temperature applications.

In addition to wafers, a broad variety of chemical seal protectors can also be attached to d/p transmitters to serve as either corrosion or plugging protectors. The extended-diaphragm seals shown in Figure 5.6h are installed in the tank nozzles. This makes the sensing diaphragm flush with the inside of the vessel or extend slightly into the tank, eliminating any cavities in which material could accumulate and solidify. These are liquid-filled elements in which the pressure sensed by the diaphragm is transmitted through the filling fluid via the capillary tubing into the d/p cell, in much the same way as with the wafer elements. Their features and limitations are also similar to those of the wafer design, and they can be provided with 2, 3, or 4 in. (50, 75, or 100 mm) ANSI Class 150, 300, or 600 flanges and 2, 4, or 6 in. (50, 100, or 150 mm) extensions.

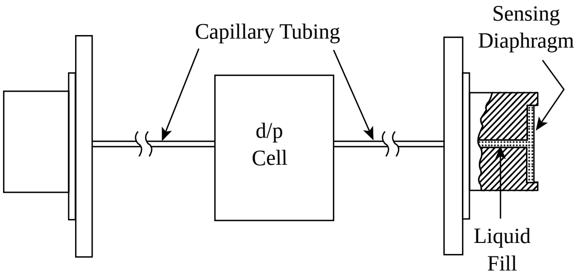

FIG. 5.6h
Differential pressure cell with extended chemical seal elements.

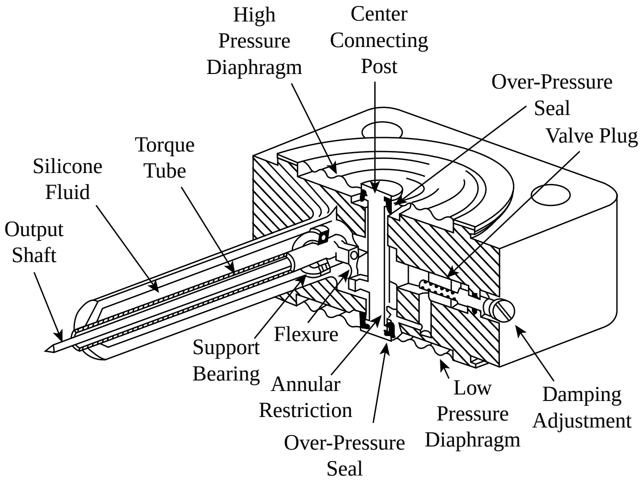

FIG. 5.6i
Combination of differential pressure element and torque tube.

Torque Tube Sensors

In these instruments, torque tubes are subjected to torsion that is proportional to the force (or movement) developed by the sensing element. In pressure instruments, a Bourdon or bellows element produces a linear movement proportional to pressure. In differential pressure units, a diaphragm element produces a linear movement as illustrated in Figure 5.6i. This movement is applied to the torque tube lever arm, which causes an angular displacement of the output shaft. This shaft rotation becomes the input of a motion transmitter that provides an electronic or pneumatic output signal.

These are motion transmitting devices and are not supplied with direct indication. All elements produce the same angular movement; consequently, all transmitters of a given type (i.e., pneumatic or electronic) are identical. Zero and span adjustments are made in the transmitter. Electronic transmitters use two wires that conduct both the signal and transmitter power. These transmitters meet Class 1, Group D, Division 1 explosion-proof and intrinsic safety requirements.

Low-Differential Transmitters

Transmitters with differential pressure spans of 0.01 to 0.05 in. H_2O (2.5 to 12.5 kPa) utilize the *pressure balance* principle. Pressure balance measurement is made possible by the unique characteristics of a device that senses and amplifies pressure by means of a membrane rather than a diaphragm. Since the membrane does not move or displace during measurement, the valve has no moving or mechanical parts to wear or contribute to hysteresis. Thus, the device will accurately sense very low pressures at its input ports, while being insensitive to shock, vibration, and mechanical problems normally associated with high-mass pressure-sensing devices. It consumes less than 1/5 the amount of instrument air of a traditional d/p cell.

Because this transmitter does not have bellows or diaphragms that must fill with air, it responds much faster to an input change than any other device measuring pressure changes at very low levels. This means that in an application measuring turbulent air or gas flow, the transmitter will exhibit a higher output than manometers or similar devices because it will respond to true average flow, which has short-term peaks not seen by a manometer or mechanical device.

This transmitter is not wetted by the process, but rather continuously purges the high and low ports with a low flow of air. This prevents the entrance of water, dirt, or process gases into the sensitive measurement cavities of the transmitter. As a result of this constant purge, some back-pressure, or resistance to flow in the connecting tubing, will develop. Therefore, this tubing must never be blocked, and corrections must be made for the tube pressure drop.

Membrane Type Design In the transmitter illustrated in Figure 5.6j, supply air enters through the orifice. When there is no pressure difference between the high and low ports, the membrane does not exert a force on the supply cavity, and output pressure does not appear at the output port. If output is dead-ended, all the supply flow is relieved through the ports.

When a difference exists between the high and low ports, the membrane exerts a force on the supply cavity, which also appears at the output port. This pressure is a function of the gain, which is a function of dimension *a* and *b*. When the pressure in the supply cavity satisfies the gain equation, supply air flows out of the supply cavity through the low port. At this point, the valve is in equilibrium. If the applied pressure decreases, the reverse occurs. The valve has a stable gain and no measurable hysteresis; therefore, the valves can be cascaded (output of one fed into the input of the next valve) for very high total gains.

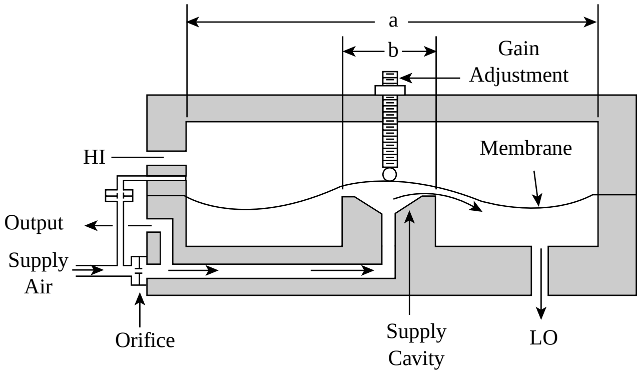

FIG. 5.6j
Membrane low differential pressure transmitter.

Types:	A. Strain gauge (unbonded, bonded wire or foil, bonded and diffused semiconductor) B. Capacitive C. Potentiometric D. Resonant wire E. Piezoelectric F. Magnetic (F1: inductive and LVDT, F2: reluctive) G. Optical
Ranges:	A. 3 in. H_2O to 200,000 PSIG (750 Pa to 1400 MPa) B. From high vacuums in the 1 to 1000 μm range and low differentials starting at 0.001 in. H_2O (0.25 Pa) up to 10,000 PSIG (70 MPa) C. 5 to 10,000 PSIG (35 kPa to 70 MPa) D. Absolute pressure from 10 mmHg to 600 PSIA (1.2 to 4120 kPa); gauge to 6000 PSIG (42 MPa); differential to 750 in. H_2O (180 kPa) E. 0.1 to 10,000 PSIG (0.7 kPa to 70 MPa) F1. 30 to 10,000 PSIG (210 kPa to 70 MPa) F2. 1 in. H_2O to 10,000 PSIG (250 Pa to 70 MPa) G. 5 to 60,000 PSIG (35 kPa to 413 MPa)
Operating Temperatures:	A. –66 to 250°F (–54 to 121°C); with seals, up to 650°F (343°C) B and F1. 0 to 165°F (32 to 74°C) C. 32 to 300°F (0 to 149°C) D. –40 to 250°F (–40 to 120°C) E and F2. From cryogenic up to 600°F (315°C)
Materials of Construction:	Cadmium plated carbon steel, Co-Ni-Cr alloy, 316 stainless steel, Hastelloy C, Monel, Inconel, or tantalum
Vibration Insensitivity:	Excellent (A, E, G); good (D, F2); moderate (B); poor (C, F1)
Inaccuracy:	A. From 0.1% of span to 0.25% of full scale. Drift = 0.25% of full scale over 6 months; temperature effect = 0.25% of full scale per 100°F B. 0.1% of reading or 0.01% of full scale. Temperature effect = 0.25% of full scale per 100°F; drift is negligible C. 0.5 to 1% of full scale. Temperature effect = 1% of full scale per 100°F; drift = 1% of full scale per year D. 0.1% of calibrated span. Drift = 0.1% of reference span per 6 months; temperature effect = 0.2% of maximum span per 100°F E. 1% of full scale. Temperature effect = 1% of full scale per 100°F F. 0.5% of full scale. Temperature effect for F1 = 0, for F2 = 1 to 2% per 100°F G. 0.1% full scale
Costs:	A. \$10 to \$100 for elements only in OEM quantities B. \$1000 to \$4000 C. and F. \$300 to \$500 per transducer E. \$500 to \$1500 A–G. \$750 to \$2000 for force balance d/p transmitters, with the higher costs corresponding to intelligent units, special materials, or the use of special seals

INTRODUCTION

The electronic pressure sensor categories discussed in this section include the strain gauge, capacitance, potentiometric, resonant wire, piezoelectric, reluctive, and inductive types and their many subcategories. Most of these devices are available either as basic sensor elements or as part of either a conventional or an intelligent transmitter. Each category is separately discussed below. Smart transmitters are discussed at the end.

ELECTRICAL SAFETY

While Chapter 7 discusses the safety aspects of control systems, some hazardous area classifications are also listed in this section. Hazards arising from the use of electricity are controlled by standards[1] that specify the housing requirements for electronic transmitters in locations, where fire and explosion hazards might exist due to the presence of flammable gases, liquids, combustible dust or fibers. American National Standards Institute/National Fire Protection Association 70 classifies the industrial areas according to Class, Division, and Group as follows:

Class:
  I – Vapor
  II – Dust
  III – Fiber

Division:
  1 – Always present
  2 – Present only under fault conditions

Group:
  A – Acetylene
  B – Hydrogen
  C – Ethylene
  D – Propane
  E – Metal dust
  F – Carbon dust
  G – Grain dust

The National Electrical Manufacturers Association (NEMA) classifies electrical equipment enclosures that can be used in hazardous locations as follows:

NEMA 7 – For indoor use in Class I, Groups A, B, C, and D locations. These enclosures are designed to withstand the pressure resulting from internal explosion and to contain the explosion from igniting the atmosphere surrounding the enclosure.

NEMA 8 – For indoor or outdoor use in Class I, Groups A, B, C, and D locations. All potentially arcing contacts and connections are immersed in oil to prevent ignition of an explosive atmosphere.

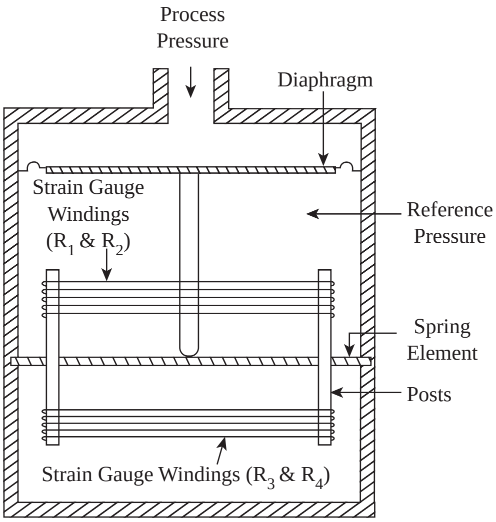

FIG. 5.7a
Pressure transducer with unbonded strain gauge wires.

NEMA 9 – These enclosures are for indoor use in a Class II, Group E or G locations. They serve to prevent the entrance of dust.

NEMA 10 – These are non-ventilated enclosures meeting the requirements of the Mine Safety and Health Administration, 30 C.F.R. Part 18.

STRAIN GAUGE TRANSDUCERS

Strain gauge transducers can be built by using unbonded wire elements that are stretched between a fixed and a moving point on an elastic pressure sensor (Figure 5.7a). These devices are sensitive, but fragile and vibration sensitive. The bonded wire strain gauge was invented in 1938. A wire filament is attached to a test specimen by plastic cement and the strain in the wire is measured in terms of its resistance (Figure 5.7b). Constantan, nichrome, platinum or Karma-type alloy wires, foils, or semiconductor materials can be permanently bonded to the strained surface. Such strain gauge designs are inherently unstable (subject to creep) due to degradation of the bond, temperature sensitivity, and hysteresis caused by thermoelastic strain. In attaching the sensor to the surface, the thin-film sensors use a molecular bond instead of cement. This sputter-deposition technology is also used in the manufacturing of integrated circuitry sensors.

The diffused semiconductor strain gauge, which consists of resistance elements diffused into a single silicon chip, was developed in the 1970s for the automotive field. The silicon wafer acts as the sensor diaphragm, reducing both the size and the cost of the sensor (Figure 5.7c). The silicon wafer is more reliable than the metal diaphragms because after being strained it returns to its original shape due to its excellent elasticity.

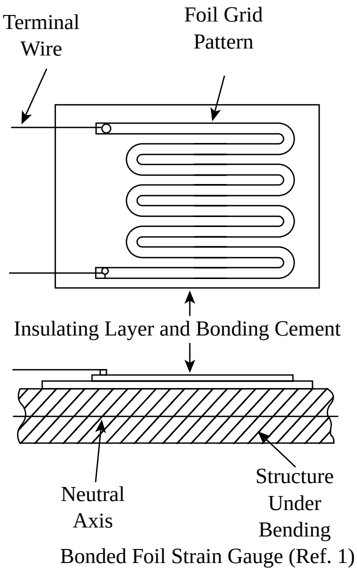

FIG. 5.7b
Bonded foil strain guage.[2]

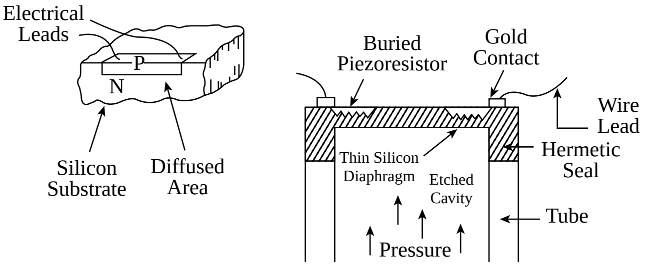

FIG. 5.7c
Diffused semiconductor (piezoresistor) strain gauge.

The sensitivity of semiconductor-type strain gauges is 100-fold greater than that of wire strain gauges. In manufacturing the diffused strain gauge sensor, boron gas is allowed to diffuse into the silicon chip and units with the silicon at the molecular level. The thickness of the wafer is controlled by chemical etching, and it is this thickness that determines the pressure range of the sensor. Standard units are available from 0–1 to 0–250 PSIG (0–7 to 0–1725 kPa), but they are most often used on instrument air service ranges of 3 to 15 PSIG (0.2 to 1.0 bars). These sensors are small, inexpensive, accurate, and repeatable, and they provide a wide pressure range and a strong output signal level. Their limitations include sensitivity to ambient temperature variations, which can be compensated for in the intelligent transmitter designs.

Historical Development

The word strain means changes in dimensions of solid bodies due to the actions of forces exerted upon them. The earliest devices used to detect strain were the extensometers. These instruments simply determine the change in length of bodies, and the change in length divided by the original length was a measure of the average strain. The true strain gauge does not measure extension, but changes its physical characteristics so that its electrical resistance changes as a function of the strain to which it is subjected.

The operating principle of strain gauges is more than 100 years old, and was discovered when Lord Kelvin reported that metallic conductors subjected to mechanical strain exhibited a corresponding change in electrical resistance. This principle was first put to practical use on strain measurement of concrete structures in the 1930s.

These units are called unbonded wire gauges (see Figure 5.7a) because the wire elements are mounted on a mechanical frame whose parts can move in relation to each other, causing a change in wire tension as load changes. Therefore, the change in electrical resistance is a measure of strain.

The Bonded Strain Gauge The bonded strain gauge represented a major advance in strain gauge technology. This design eliminated the mechanical frame by attaching the sensing view directly to the strained surface. The bond was an insulator that forced the conductor wire to follow the strain on the surface without excessive stresses developing in the bond itself. This can be achieved if the conductor cross-sectional area is small in relation to the surface area per unit length. Strain gauge wires of less than 0.001 in. (0.025 mm) diameter have a surface area that is several thousand times more than their cross-sectional area. Therefore, the bond between the strained surface and the wires (mounted on paper or plastic carriers) is sufficiently strong. Foil gauges have also been used, in which the foil thickness can be as low as 0.0001 in. (0.025 mm).

Semiconductors, such as silicon and germanium, also came into use as the gauge elements. The most attractive characteristic of semiconductors is their sensitivity, which is close to 100 times greater than that of metallic wires. When metallic wires are used, they are likely to be chrome-nickel alloys, although pure metals, such as platinum, are also used as temperature compensators. The desirability of a certain alloy used as a wire element is partially a function of its strain sensitivity. Strain sensitivity (S) is defined as the ratio between unit extension (ΔL/L) and corresponding change in specific resistivity (Δr/r).

$$S = \frac{\Delta r/r}{\Delta L/L} \qquad \textbf{5.7(1)}$$

where L is the initial length of the wire and r is the specific resistivity in that unstrained condition. If the strain occurs within a certain portion of the elastic range, the strain sensitivity is constant. This means that by detecting resistance, we are sensing a value that is linearly related to strain. In actual installations, several factors, such as geometry of grid, wire size and material, direction of strain, type of bond, and so on, affect the relationship between axial strain and change in resistance. This is expressed by the constant called gauge factor:

$$\text{Axial Strain} = \frac{\Delta R/R}{\text{Gauge Factor}} \qquad \textbf{5.7(2)}$$

Temperature Compensation When strain-gauge-sensing elements are used, process temperature variations must be compensated for because temperature changes will cause both the base material to which the element is bonded and the element itself to expand or contract. In addition, the coefficient of resistivity of the element will vary with temperature. There are several methods of temperature compensation.

1. In near-ambient temperature ranges (–100 to 150°F, or –73°C to 66°C), thermal errors can be made negligible without compensation.
2. The element can be directly calibrated for the anticipated temperature range, and then by detecting process temperature, the reading can be corrected.
3. The element can be selected so that its thermal properties will match those of the mounting surface material.
4. Dual element gauges are also employed (one having positive and the other negative response to temperature changes) when they cancel out each other's effects within a set temperature range.
5. The most frequently employed method is the use of dummy elements. The dummy gauge is mounted on the same surfaces as the active element, and is exposed to the same temperature, but is not subject to the forces applied. If such a dummy is connected in a Wheatstone bridge arm adjacent to the active element, it will automatically compensate for temperature effects.

Detecting the Change in Resistance

The resistance change of strain gauges being small, precise instrumentation is required to detect it with good accuracy. The Wheatstone bridge is one of the common configurations used for strain gauge measurement. Usually each arm of the bridge contains a strain-sensitive element (see Figure 5.7d). Some of the elements can be active or dummies. The bridge will be balanced when $R_1R_3 = R_2R_4$. After an initial condition of balance, the change in output voltage is:

$$\Delta E = V/4R_0(\Delta R_1 + \Delta R_3 - \Delta R_2 - \Delta R_4) \qquad \textbf{5.7(3)}$$

where R_0 is the initial, equal resistance of each element. From this equation it can be seen that if two elements from adjacent arms of the bridge (R_1 and R_2, or R_3 and R_4), the temperature effects will be minimized because their influence on the output is subtractive. If the active gauges are on opposite arms of the bridge, their effect is additive, and dummy elements are needed to achieve compensation. The Wheatstone circuit can detect both static and dynamic strains and is well suited for temperature compensation.

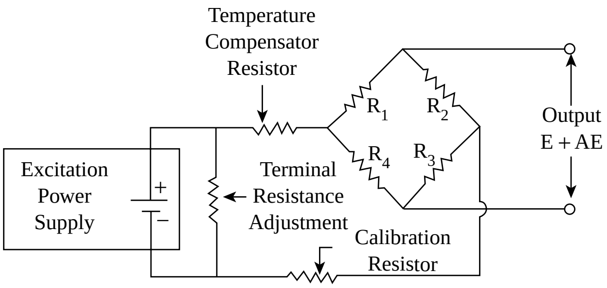

FIG. 5.7d
Wheatstone circuit for strain gauges.

The ballast or potentiometric circuit is arrived at by making R_2 = Infinity and $R_3 = 0$ in Equation 5.7(3). This circuit is simpler than the Wheatstone bridge and has the added advantage of possibility for common ground for the measuring instrument, amplifier, and measuring circuitry. The drawbacks include the difficulty of temperature compensation, and the fact that the circuit is suited to dynamic, not static, strain sensing.

The strain gauge transducers normally have a bridge resistance that varies from 100 to 500 Ω. They can be excited by either AC or DC voltage from a power supply providing an output voltage in the range of 8 to 40 V. The output generated by the bridge can be anywhere from 1 to 4 mV per volt excitation. Calibrated inaccuracy is 0.25% of span or better.

The output millivolt signal from the circuit can be converted to DC milliamperes or sensed directly by analog or digital readout devices, including typewriters or punched tape. Where large numbers of measurements are involved, a switching box with up to 50 channels is provided, which allows a single digital indicator to read any of the measurements. When fluctuating pressures are to be detected, the frequency of vibration has to be taken into account. For frequencies up to 50 cps, conventional recorders are acceptable; up to 2000 cps, galvanometer systems recording on light-sensitive paper are preferred; and at still higher frequencies, the cathode ray oscilloscope is used.

Transducer Designs

In the unbonded design (Figure 5.7a), the pressure to be detected causes displacement of the diaphragm. The force, which is applied to the diaphragm, is transmitted by the force rod to the spring element. Motion of the spring center causes movement of the posts upon which the 0.0003 in. (0.0075 mm) diameter resistive wires are mounted. The strain is increased in two of the windings and is decreased in the other two. These windings in the form of a Wheatstone bridge provide a millivolt output that is a linear function of process pressure.

Bonded Designs One of the bonded designs is shown in Figure 5.7e. Here the process pressure is applied to a flat diaphragm. The strains resulting from the diaphragm deflection are sensed by four strain elements that are bonded directly to the underside of the diaphragm. The changes are resistance of the elements that are measured as an indication of process pressure.

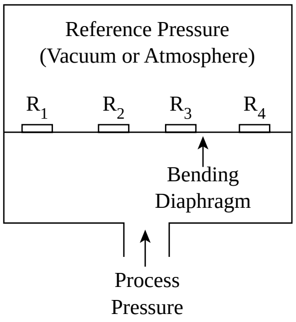

FIG. 5.7e
Strain gauge transducer with diaphragm element.

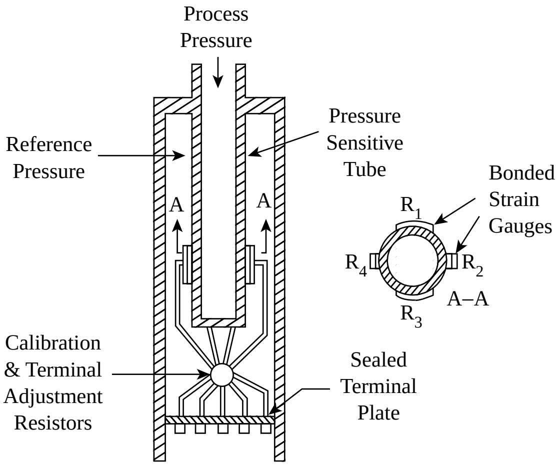

FIG. 5.7f
Strain gauge transducer with elements bonded to tube surface.

The working element of the strain gauge transducer shown in Figure 5.7f is a tube closed on one end, with the other end open to the process pressure. Four strain gauges are bonded to the outside of this tube. Two of the elements are strained under pressure and two are not because they are mounted longitudinally and circumferentially. When the tube is pressurized, its minute expansion changes the resistance of the gauges, which are connected to a Wheatstone bridge (see Figure 5.7d). Calibration and terminal adjustment resistors are provided outside the tube (see Figures 5.7d and 5.7f).

In Figure 5.7g, two bellows are the working elements. When used to detect differential pressure (d/p), both bellows are connected to the process. Otherwise only one is connected, and the other provides atmospheric or full-vacuum reference for the unit. Here, the strain detector elements are bonded to the bending beam as shown.

Force Balance Still another design is illustrated in Figure 5.7h, in which the strain gauge sensors are adapted to the force balance d/p cell. Here, the pressure difference across the diaphragm transmits a corresponding force to the lower end of the force bar. This bar is connected to the strain tube,

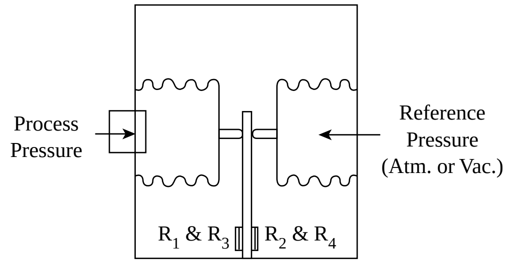

FIG. 5.7g
Bonded strain gauge transducer with bellows elements.

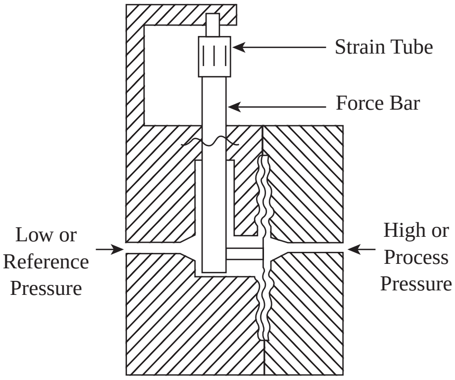

FIG. 5.7h
Force balance d/p cell with strain gauge elements.

and the strain in the tube is in direct proportion to the pressure differential.

In summary, strain gauge elements can detect absolute, gauge, and differential pressures with spans from 30 in. H_2O to 200,000 PSIG (7.5 kPa to 1400 MPa). Their inaccuracy falls between 0.2 and 0.5% of span. Compensated units are available for temperatures between −60 and 250°F (−50 and 120°C). Special designs can handle process temperatures up to 600°F (316°C).

Most transducers are available with steel or stainless steel wetted parts and in very small sizes. They are stable devices with good speeds of response and generate output signals in the range of 15 to 100 AC or DC mV. A large variety of readout devices is available, some of which can be located up to 1000 ft (300 m) from the transducer. Most designs contain no moving parts and are suitable for high overloads; the diffused semiconductor types have good shock and vibration characteristics. All strain gauge installations necessitate regulated power supplies for the excitation voltage.

They are used in installations in which small size, fast speed of response under dynamic loads, or high-static pressures are necessary.

CAPACITANCE TRANSDUCERS

The basic operating principle involved in all capacitive pressure sensors is the measurement of change in capacitance resulting from the movement of an elastic element. The elastic element in most designs is an Inconel, Ni-Span C, or stainless steel diaphragm or a metal-coated quartz element exposed to the process pressure on one side and to the reference pressure on the other. Depending on the reference pressure used, the unit can detect absolute, gauge, or differential pressures.

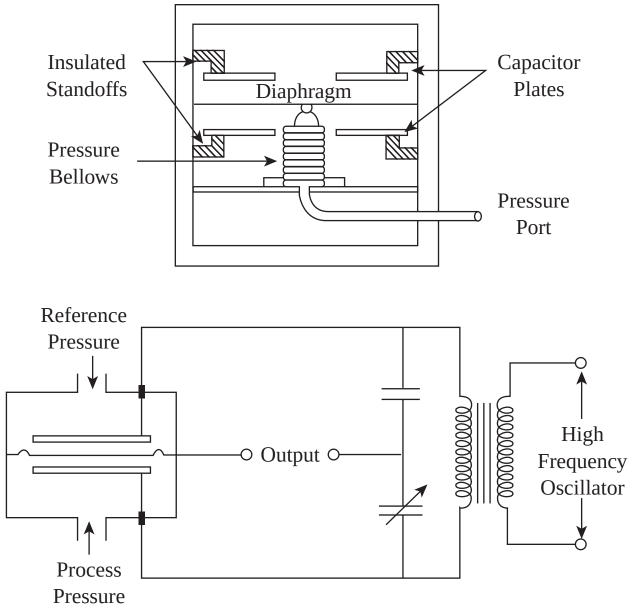

FIG. 5.7i
Capacitance pressure detector.

The unit shown in Figure 5.7i incorporates two capacitor plates, while other designs have only one such plate. A high-voltage, high-frequency oscillator is used to energize the sensing element. Changes in process pressure deflect the diaphragm, and a bridge circuit detects the resultant change in capacitance. The two-plate design can be operated in balanced or unbalanced modes. If the circuit is operated in the balanced mode, the output voltage is fed to a null detector, and the capacitor arms are varied to maintain the bridge at null. In this mode, the null setting itself is a measure of process pressure. If the circuit operates in the unbalanced mode, the ratios between output voltage and excitation voltage are the indication of process pressure.

In the single-capacitor design, the plate is positioned on one side of the sensing diaphragm. The capacitance of the element, being a function of diaphragm deflection, is a measure of process pressure. The element's capacitance is converted and amplified into a DC mA current signal. If desired, direct DC voltage output can also be used when the readout device preference is similar to a digital voltmeter.

Capacitance pressure sensors are accurate to ±0.1 to ±0.2% of span. With the proper selection of diaphragms, they can handle pressure ranges from 3 in. H_2O up to 5000 PSIG (0.08 kPa to 35 MPa) or vacuum measurements down to the micron range.

Capacitance pressure transducers were originally designed to meet the needs of low vacuum researchers; today they are second only to the strain gauges in popularity. They are frequently used as secondary standards, particularly on low absolute and low differential pressure applications. Their advantages include good accuracy, rangeability, linearity, and speed of response. Their limitations of temperature sensitivity, short leads from the sensor, high output impedance, sensitivity to stray capacitance, sensitivity to vibration, low overpressure capability, and corrosion sensitivity have all been reduced in the newer designs. The single-sided electrode designs are now suited to corrosive gas services, and for high-precision applications, temperature-controlled sensors are available.

POTENTIOMETRIC TRANSDUCERS

The wiper arms of potentiometric pressure transducers are usually linked to Bourdon or bellows elements. In such a transducer, a change in process pressure moves the connecting (wiper) rod over a precision potentiometer, which converts the pressure into electric resistance (Figure 5.7j). The contacting wiper tip is usually made of a noble metal. These transducers require the least sophisticated signal conditioning and therefore are the least expensive. Their spans are available from 5 to 10,000 PSIG (35 kPa to 70 MPa), and their measurement accuracy is about 1% of full scale. Their advantages include low cost, small size, and high output signals without further amplification. Their disadvantages are related to mechanical wear that results in short life and high noise levels as the wiper experiences nonlinear mechanical loading, static friction, or loss of its intimate contact with the resistive element.

RESONANT WIRE TRANSDUCERS

The resonant wire pressure transducer was introduced in the late 1970s. In this design an oscillator circuit causes a wire to oscillate at its resonant frequency, while the wire tension is varied as a function of the process pressure. Figure 5.7k illustrates the resonant wire design used to detect differential pressures. The process pressures are detected by the high pressure and low pressure diaphragms on the right and left of the unit. As the pressure difference rises, the fill fluid transmits a corresponding force to the wire, excited by the magnetic field. Backup plates support the diaphragms to prevent overpressure damage.

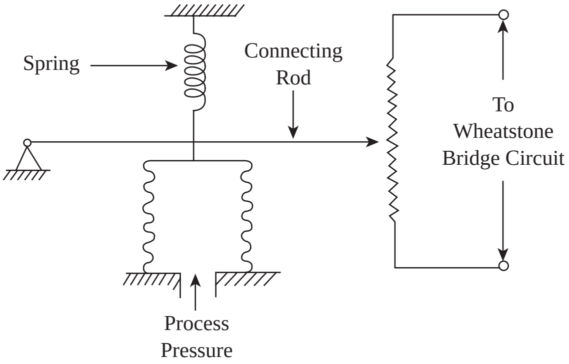

FIG. 5.7j
Resistance pressure sensor.

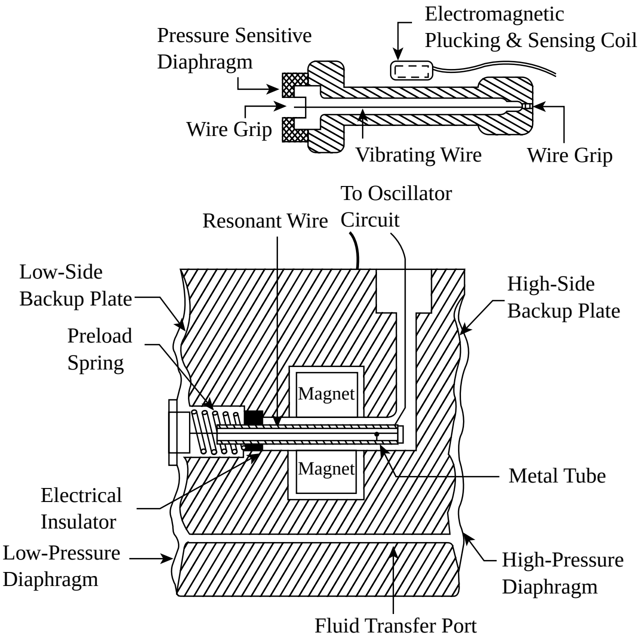

FIG. 5.7k
Resonant-wire-type differential pressure sensor. (Courtesy of Foxboro-Invensys.)

The change in the wire tension modifies the resonant frequency of the wire, which is then digitally counted. Similar configurations are available for the measurement of absolute and gauge pressures. When used as an absolute pressure sensor, the low-pressure diaphragm of Figure 5.7k is covered by a cap and the resulting cavity is evacuated to 0.004 mmHg (0.53 Pa).

The advantages of this design include good repeatability, accuracy, stability, low hysteresis, high resolution, strong output signal, and the generation of an inherently digital signal, which can be sent directly to a stable crystal clock in a microprocessor. The limitations include sensitivity to ambient temperature variations, which requires built-in temperature compensation; a nonlinear output signal; and some sensitivity to shock and vibration.

PIEZOELECTRIC PRESSURE SENSORS

When crystals are exposed to pressures or forces around a particular axis, they are elastically deformed. The experience of deformation produces an electric potential, which results in the flow of an electric charge for a few seconds. As shown in Figure 5.7l, the pressure acting on the sensing diaphragm generates an electrical signal, which is proportional to the amount of force and therefore to the deformation experienced by the crystal. Because the crystal can also be deformed by

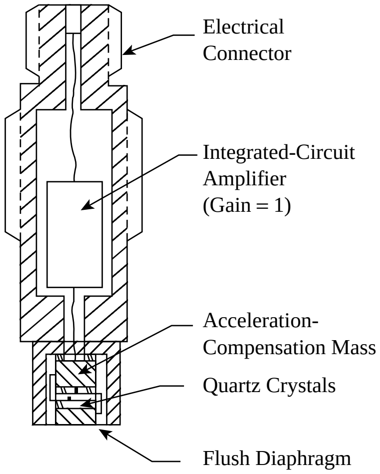

FIG. 5.7l
Piezoelectric pressure sensor provided with an accleration compensator. (Courtesy of PCB Piezotronics Inc.)

acceleration, an acceleration compensator is also provided. These sensors cannot measure static pressures for more than a couple seconds, but are capable of measuring dynamic phenomena such as shock; vibration; pressures associated with blasts, explosions, or pulsation; or the dynamic conditions in rocket motors, engines, compressors, and the like.

Because of the dynamic nature of this sensor, its output is usually expressed in relative pressure units (such as PSIR), where the measurement is referenced to the initial conditions that existed prior to the transient event or to the average of a cycling pressure. Natural or cultured quartz and natural tourmaline are both used as sensors in piezoelectric transducers. Quartz is inexpensive, stable, and insensitive to temperature changes. Tourmaline provides submicrosecond response speeds, which is valuable in blast transducers.

The main advantages of piezoelectric pressure sensors include their small size, rugged construction, high speed of response, and self-generated signal. These sensors are limited to dynamic measurements, are sensitive to temperature variations, and require special cabling and output signal amplification.

MAGNETIC TRANSDUCERS

A number of pressure transducers utilize magnetic phenomenon in converting the elastic movement of a sensor into an electric signal. These magnetic phenomena include induction, reluctance, and eddy currents. As the pressure sensors cause a movement, this changes the inductance or reluctance of an electric circuit. Inductance is the property of an electric circuit which expresses the amount of electromotive force (EMF) induced for a given rate of change of current flow in the circuit. Reluctance is the resistance to magnetic flow, the opposition offered by a magnetic substance to magnetic flux (magnetomotive force).

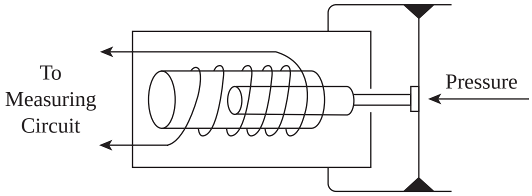

FIG. 5.7m
Schematic representation of a linear motion variable inductance pressure transducer element.

Inductive Elements

Figure 5.7m illustrates a variable inductance element. Here the process pressure moves a magnetic iron core inside a coil, which alters the self-inductance of the coil. The many turns of the solenoid coil are usually wound on a tube of insulating material. As the core is pushed into the solenoid, the inductance of the coil increases in proportion to the amount of metal inside the coil. The ratio inductance element is similar, except that there are two solenoid coils next to each other on the insulating tube and the iron core is always within them. In this design the core movement is detected as a change in the inductance ratio of the two coils. The sensitivity and linearity of the ratio inductance transducers is better than that of the variable inductance units.

As a pressure sensor moves a conductive surface, while the transducing element remains stagnant, the eddy currents cause variations in impedance. Pressure transducers have also been designed to exploit this phenomenon.

Linear Variable Differential Transformer Figure 5.7n illustrates a linear variable differential transformer (LVDT), which can also be called a mutual-inductance element, that operates on the inductance ratio principle. Here three coils are wound onto the same insulating tube containing the high-permeability iron core. Alternating current is applied to the primary coil (P) in the center, and if the core is in the center, equal voltages are induced in the secondary coils (#1 and #2) by the magnetic flux. Usually the secondary coils are wired in series, and therefore when the core is centered, the resulting output is zero. As the core moves to the left or right, the voltage induced in coil #1 or #2 will predominate.

The LVDT-type transducers are also available in the rotary form and can be obtained with ranges from 0–30 to 0–10,000 PSIG (0–210 kPa to 0–70 MPa). Their limitations include mechanical wear and vibration sensitivity.

Inductive Transmitters Figure 5.7o illustrates how the differential transformer design has been adopted for use in a force balance pressure transmitter. The process pressure applied to the elastic element of the unit (not shown) exerts a proportional force on the lower end of the force bar, which pivots on the flexure seal. This force through the levers (shown) is transmitted to an electronic force balance system consisting

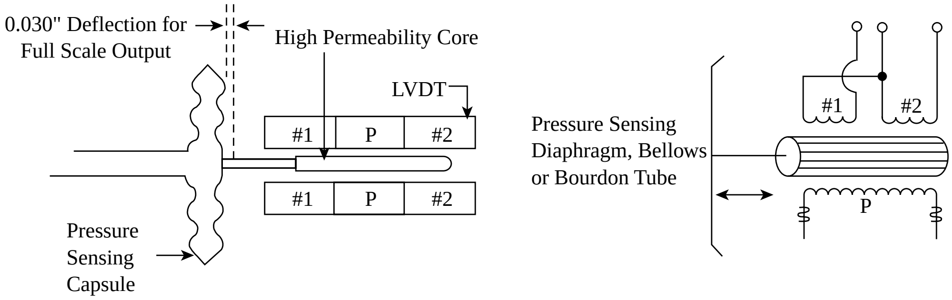

FIG. 5.7n
Linear variable differential transformer.[2]

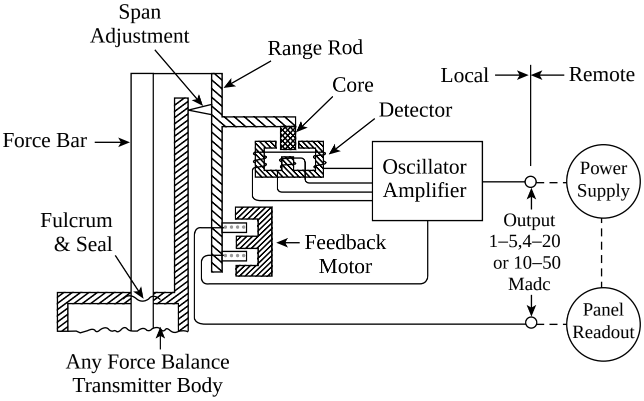

FIG. 5.7o
Differential transformer force balance electronic pressure transmitter.

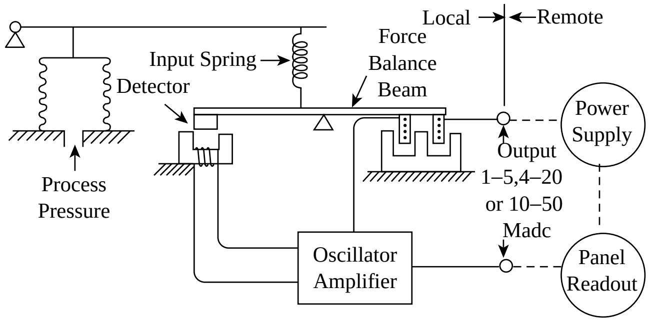

FIG. 5.7p
Inductance electronic force balance pressure transmitter.

of three main components: the detector, the feedback motor, and the oscillator-amplifier. The oscillator-amplifier excites the oscillator.

A change in process pressure results in a slight movement of the laminated core, strengthening the inductive coupling, which increases the secondary voltage to the DC amplifier. The output from the amplifier is fed to the feedback motor in series with the remote readout. As the current in the feedback motor coil increases, an increased force is developed, which repositions the laminated core in the detector. The feedback coil applies an equal and opposite force to that produced by the change in process pressure, and, therefore, maintains the system in continuous force balance.

Figure 5.7p shows a similar electronic pressure transmitter design. Here the elastic sensing element deflects in proportion to the process pressure, thereby exerting a force on the balance beam through the input spring. The resulting motion changes the air gap in the detector assembly. The detector consists of two pieces of ferrite, one mounted on the force beam and the other on the chassis. As the air gap is changed, there is a resulting change in the inductance of the oscillator circuit. When this occurs, the oscillator, acting as a variable resistor, changes the output current correspondingly. The output current is fed through the magnet coil in the feedback motor, producing an equal and opposite force on the beam to balance the force produced by the change in process pressure.

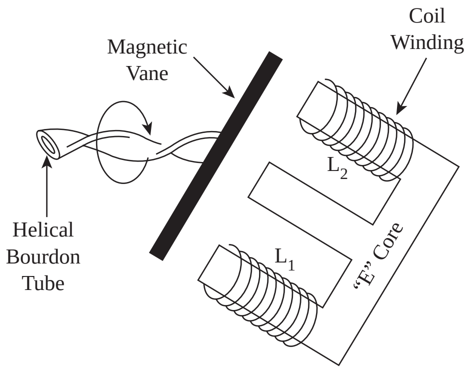

FIG. 5.7q
Variable reluctance pressure transducer.[2]

Reluctive Elements

Electrical reluctance is the equivalent of electrical resistance in a magnetic circuit. Figure 5.7q illustrates a variable reluctance transducer, where a magnetic vane (moved by a helical Bourdon pressure detector) changes the gap in the magnetic flux path of both cores as it moves. The magnetic reluctance varies with the size of these gaps, and the result of the motion of the magnetic vane is a change in the inductance of the two coils (L_1 and L_2). The inductance ratio of L_1/L_2 is therefore related to the process pressure.

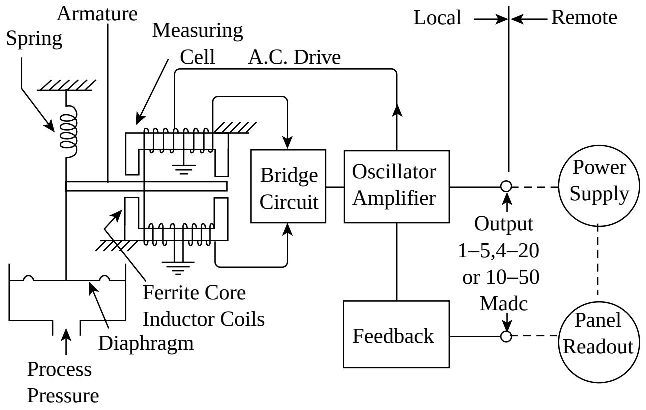

FIG. 5.7r
Variable reluctance electronic force balance pressure transmitter.

The advantages of the variable reluctance transducers include their wide temperature range, their low sensitivity to shock and vibration (due to their rugged construction), and their high output signal (40 mV/V of excitation). Their disadvantages include their temperature sensitivity (2%/100°F), their requirement for AC excitation, and their susceptibility to stray magnetic fields.

Figure 5.7r illustrates the operation of a variable reluctance electronic transmitter. A change in process pressure exerts a force on the metal diaphragm that moves the armature between two ferrite core coils. The air gap change causes a predetermined change in the inductance ratio of the two coils. The resultant change in core reluctance is detected by the amplifier bridge.

The bridge, in conjunction with the amplifier rebalancing circuits, changes the transmitter output current to flow in direct proportion to the process pressure. The function of the amplifier rebalancing circuit is to change the capacitive reactance of the varactors (voltage sensitive capacitors) in the bridge a like amount. Therefore, the feedback adjusts the varactors so that the capacitance ratio of the two varactors equals the inductance ratio of the two inductors.

OPTICAL TRANSDUCERS

The movement of elastic pressure sensors can also be used to operate optical sensors. As the process pressure moves a diaphragm sensor, which in turn lifts a vane in front of an infrared light beam, the amount of light impinging on the measuring diode[2] varies (Figure 5.7s). A reference diode is also provided to compensate for the aging of the light source (LED) or for dirt buildup on the optics. This transducer is insensitive to temperature variations, as such variations affect the measuring and reference diodes in the same way. Because the amount of movement in the sensor is very small (0.5 mm), both the hysteresis and the repeatability errors are negligible.

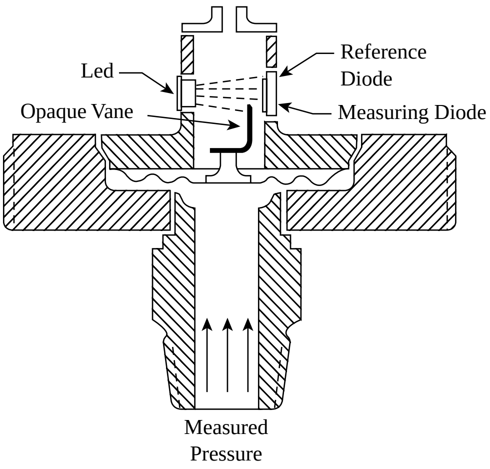

FIG. 5.7s
Optical pressure transducer operates without physical contact and is insensitive to temperature variations. (Courtesy of Dresser Instrument.)

SMART TRANSMITTERS

The smart transmitters (see Section 5.1) can also be provided with digital indication and with memory for trending or record keeping. When integrated into a network or into a DCS-, PC-, or PLC-operated system, the calibration steps and the use of stored specifications can all be automated. The calibrator/communicator units range from the palm-sized through the suitcase-sized up to the roll-around packages. Most provide storage of multiple device protocol libraries so that communication is possible with almost any manufacturer's transmitter. Some of the protocols in use, and their year of introduction, include ARCNet (1975), WorldFIP (1988), HART (1989), Foundation Fieldbus H1 (1995), and Profinet (2001).

Smart, microprocessor-based transmitters can be provided with communicators that are integral to or separate from the electronic calibration unit. These communication units allow the operator to modify zeroes or spans, change units, or verify the current values. If a PID algorithm is included in the smart transmitter, the communicator can be used to modify its setpoint or tuning values. Where transmitters are networked into a DCS system, it is not necessary to go to the transmitter to communicate with it. In such installations the individual transmitter can be accessed from the control room or engineer's desk through the data highway.

Establishment of an industry-wide communication protocol for digital control systems (similar to the 3 to 15 PSIG [0.2 to 1.0 bar] or the 4 to 20 mA DC signal ranges that have been developed and accepted worldwide for analog control) still eludes consensus. Nevertheless, sufficient digital bridges and adapters are available so that a completely digital instrumentation system is likely to be possible in any particular plant or system. Also, there are now at least two wireless LAN communication standards, "Bluetooth" and IEEE-802.11b, which may be useful and appropriate for some installations.

5.8 High-Pressure Sensors

PI High

Flow Sheet Symbol

B. G. LIPTÁK (1969, 1982, 1995, 2003)

Types and Ranges:	A. Optical (Section 5.7), up to 60,000 PSIG (4338 bars) B. Piezoelectric (Section 5.7), up to 100,000 PSIG (6896 bars) C. Magnetic (Section 5.7), up to 100,000 PSIG (6896 bars) D. Dead-weight testers, up to 100,000 PSIG (6896 bars) E. Helical Bourdon (Section 5.4), up to 100,000 PSIG (6896 bars) F. Manganin cells, up to 400,000 PSIG (27,586 bars) or more G. Strain gauge (Section 5.7), up to 200,000 PSIG (13,793 bars) H. Bulk modulus cells, up to 200,000 PSIG (13,793 bars) I. Button type pressure repeater, up to 10,000 PSIG (6896 bars)
Inaccuracy:	For dead-weight testers, 0.1% of span or better; for strain gauges from about 0.1% of span to 0.25% of full scale, for Manganin cells from 0.1 to 0.5% of full scale; for pressure repeaters 0.5 to 1% full scale, for helical bourdon tubes 1% of span; for bulk modulus cells from 1 to 2% of full span
Costs:	For types A, B, C, and G, see Section 5.7; for type E, see Section 5.4. Most transducers are from $300 to $500. The simplest dead-weight gauges with moderate ranges and 0.1% inaccuracy cost around $1200 to $1500; the average portable pressure/vacuum calibrator costs around $5000; the most sophisticated 0.03% hydraulic calibrator units cost about $18,000.

The term *high pressure* is relative, because in an average plant the pressure of 1,000 PSIG (69 bars) is usually considered to be high, while in synthetic diamond manufacturing 100,000 PSIG is viewed as normal. For the purposes of this section, we will define high-pressure instruments as devices that are capable of measuring pressures in excess of 10,000 to 20,000 PSIG (700 to 1,400 bars). Some of these detectors have already been discussed in Section 5.4 (helical Bourdons) and in Section 5.7 (strain gauge, optical, piezoelectric, and magnetic types). Therefore, in this section the emphasis will be on the description of dead-weight piston gauges, bulk modulus, and Manganin cells.

INTRODUCTION

High pressure can be measured by:

1. Dead-weight testers
2. Pressure repeaters
3. Elastic deformation gauges, such as helical bourdon tubes, strain gauges, or bulk modulus cells
4. Detecting the change in electrical resistance in materials like Manganin

One might group these sensors by other characteristics, such as:

1. Mechanical, such as pressure repeaters, helical bourdon tubes, or dead weight testers
2. Electronic, like the strain gauge devices
3. Very high pressure detectors, as the bulk modulus and the Manganin cells.

The only primary high-pressure detector is the dead weight sensor, which is also a rather slow measuring device. The sensors that detect elastic deformation follow Hoke's Law but not with absolute accuracy and all have at least 0.1% hysteresis. The Manganin gauge was first described by the Nobel prize winning physicist Bridgman[1] who recommended it as a secondary gauge.

MECHANICAL HIGH PRESSURE SENSORS

Dead-Weight Piston Gauges

As illustrated in Figure 5.8a, these are piston gauges in which the test pressure is balanced against a known weight that is applied to a known piston area. The test pressure is applied by the secondary piston. The principal purpose of these free-piston gauges is as a primary standard to calibrate other pressure sensors. The National Bureau of Standards (NBS) has been using these devices for many years.

Piston gauges, or dead-weight testers, are normally provided with a number of interchangeable piston assemblies and NBS-certified weights. They can be used to calibrate at pressure levels as low as 5 PSIG (35 kPa) or as high as

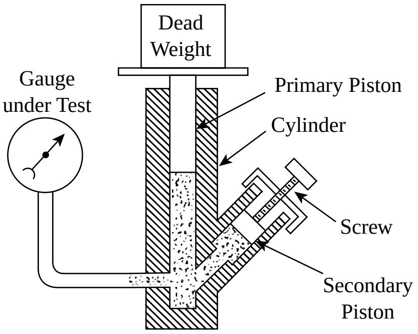

FIG. 5.8a
Dead-weight piston tester.

100,000 PSIG (690 MPa). The range has been extended to even greater pressures, but research on piston and cylinder material and their treatment to withstand loads is a limitation. Assuming that one wants to generate a pressure of 100,000 PSIG while keeping the dead weight under 1000 lb (450 kg), it is necessary to reduce the piston area to 0.01 in^2 (6.4 mm^2). This means that a 0.1 in. (2.5 mm) diameter piston will have to support a 1000 lb weight, while also being rotated.

The accuracy of dead-weight piston testers has improved over the years. For higher pressure services, the main improvement resulted from controlling the piston-cylinder clearance by pressurizing the outside surface of the cylinder. Thus, the piston-cylinder clearance is kept constant, resulting in a slow rate of fall for the piston unaffected by pressure level. The laboratory piston gauges are standardized by NBS, calibrating the associated weights and measuring the piston diameter. NBS has found these dead-weight testers to be inaccurate to 1.5 parts in 10,000 of the measured pressure at values greater than 40,000 PSIG (280 MPa) and to 5 parts in 100,000 at lower pressures. The inaccuracy of industrial dead weight testers is better than ±0.1% of span.

The free-piston gauge is limited to its principal purpose, a primary standard for calibrating other pressure sensors, because it is slow in response and is not practical for direct industrial installation.

The utility of the high-accuracy piston gauges is being extended to the lower pressure ranges by the titling-type, air-lubricated designs. With such design, pressures (and pressure differentials) in the millimeter of mercury range have been detected to one part in 100,000 full-scale error.

Button-Type Pressure Repeater

This instrument (Figure 5.8b) is discussed in more detail in Section 5.12. It has been developed for extruder monitoring and control in the plastics and synthetic fiber industries. It can repeat the process pressures within an error of 0.5 to 1%, and it can operate up to 10,000 PSIG (69 MPa) and at temperatures up to 800°F (430°C).

Helical Bourdon

The detailed features of this instrument (Figure 5.8c) are discussed in Section 5.4. The helical elements used in this instrument are available with spans up to 0 to 80,000 PSIG (0 to 550 MPa) and can detect pressures with an error of about 1% of span.

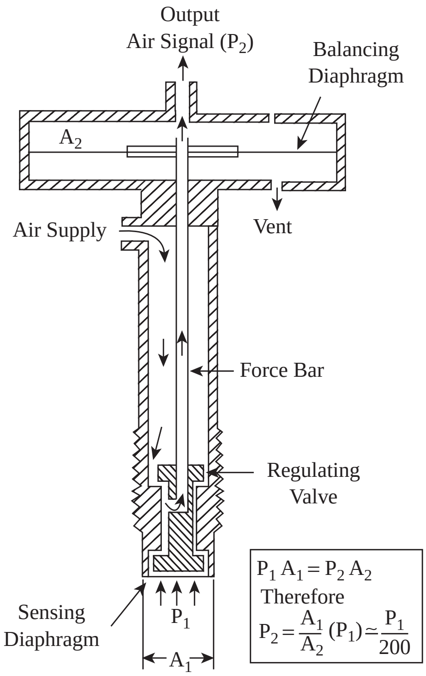

FIG. 5.8b
Button-diaphragm-type pressure repeater.

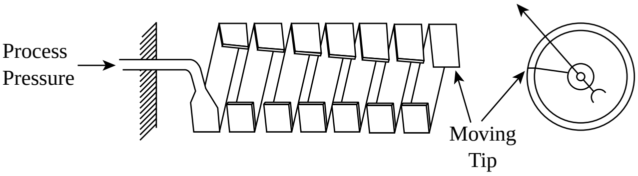

FIG. 5.8c
Helical Bourdon-type pressure sensor.

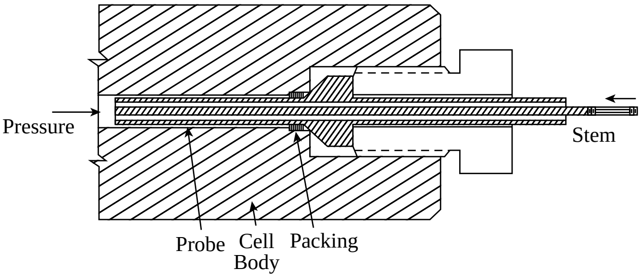

FIG. 5.8d
Bulk modulus cell.

BULK MODULUS CELLS

These cells, shown in Figure 5.8d, are comprised of a hollow cylindrical steel probe closed at the inner end, and a stem that projects beyond the outer end of the probe. When subjected to process pressures, the active part of the probe contracts isotropically, causing its tip to be displaced to the right. As a result, the stem moves outward, increasing the distance it projects beyond the outer end. The stem motion can be detected by electromagnetic pickup, capacitance pickup, or the use of mechanical displacement transmitters (pneumatic or electronic).

The unit is available with ranges of 0–50,000 to 0–200,000 PSIG (0–350 to 0–1,400 MPa), and its inaccuracy is ±1 to 2% of full scale. Its advantages, when compared with other high-pressure sensors, include its relatively fast response, its remote-reading characteristic, and its design that is absolutely safe because the probe is not subject to fatigue. The hysteresis and temperature sensitivity of the bulk modulus cell are similar to those of other elastic element pressure sensors.

PRESSURE-SENSITIVE WIRES

The electric resistance of wires can be changed by applying linear strain or by applying hydrostatic pressure to the surface of a helically wound coil mounted on a core. This second approach is utilized in the operation of the Manganin or gold-chromium wire type pressure sensors. These materials have been selected because their electric resistance changes very little with temperature variations, while it does change appreciably with changes in the applied process pressure.

When a small coil of Manganin wire is subjected to high-process pressures, the coil resistance changes linearly with pressure. The pressure-resistance relationship for Manganin is substantial, positive, and linear, and therefore can be detected by a bridge. Manganin is relatively insensitive to temperature variations.

These cells can be obtained with ranges from 0 to 50,000 PSIG (0 to 3,450 bars) to 0 to 425,000 PSIG (0 to 29,300 bars), and their inaccuracy is between $\pm{}^1/_{10}$ and $\pm{}^1/_2$% of full scale.

The main disadvantage of this cell is its delicate nature. Both the gauge coils and the coil protection bellows can be easily damaged by rapid changes in pressure or liquid viscosity.

The pressure-resistance relationship of other materials, such as platinum, gold-chromium, or lead, have some of the same desirable features as Manganin, and they too have been used as elements in pressure-resistance cells.

CHANGE-OF-STATE DETECTION

One other method for high-pressure sensing is to determine the pressure at which change-of-state occurs in various materials and then to apply that as a standard. Some of the change-of-state points have already been determined. For example, it has been established that the melting point of mercury at 0°C is 109,765 ±30 PSIG (757 ±0.2 MPa). Similarly, the first polymorphic transition point of bismuth has been found to be between 365,000 and 370,000 PSIG (2519 and 2553 MPa).

DYNAMIC SENSORS

The interest in dynamic pressure measurement to detect blast pressures, rapid chemical reactions, combustion pressures of rocket propellants, and so on has increased in recent years. Several electronic transducers have been developed for use with elastic elements. Because these devices were covered in Section 5.7, only a brief listing will be given here.

Electronic transducers for dynamic pressure detection include the piezoelectric transducers; the bonded and unbonded strain gauge elements; and the variable reluctance, differential transformer, and electrical capacitance types.

Strain gauges bonded to diaphragm or bellows elements have given good performance in measuring blast pressures. In connection with underwater explosions and noises, piezoelectric crystals have been successfully used. These units are directionally sensitive to force, necessitating a seal interposed between the element and the process and converting pressure to force for optimum response.

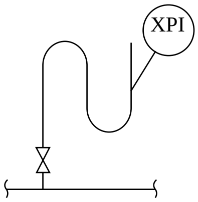
5.9 Manometers

B. G. LIPTÁK (1969, 1982, 1995, 2003), **REVIEWED BY J. WELCH** (1995)



Flow Sheet Symbol

Types:	Liquid sealed designs include the inverted bell, ring balance, U-tube, well type, inclined, float, and barometer types. Laboratory versions include the McLeod and the micro-manometer designs.
Design Pressure:	Generally used in near atmospheric applications, although the float type metallic units are available up to 6000 PSIG (41 MPa).
Design Temperature:	Function of seal fluid, usually near ambient: −70 to 150°F (−57 to 66°C)
Sizes:	Standard lengths from 6 to 140 in. (150 mm to 3.5 m)
Materials of Construction:	Pyrex, brass, steel, aluminum, stainless steel
Ranges:	Minimum span with inclined or micro-manometers is 0 to 0.1 in. (0 to 2.5 mm); maximum span is 60 PSID (0.41 MPa)
Inaccuracy:	Visual manometers can be read within 0.01 in. (0.2 mm); micro-manometers can be read within 0.002 in. (0.05 mm). Special manometers used as primary pressure standards can read within 0.0003 in. (0.001 mm)
Costs:	Laboratory-quality, well-type, glass-tube manometer costs $100 to $150; laboratory-quality, glass U-tube, protected by polycarbonate shield costs about $250; laboratory-quality, glass tube micro-manometer also costs about $250; the cost of National Institutes of Standards and Technology traceable digital manometers with analog or digital outputs range from costs $1750 to $3000.

The term *manometer* is used by some people as a name for a variety of pressure detectors, particularly in the vacuum and low-pressure ranges. They include the *wet* pressure detectors, which utilize a working fluid, and *barometers*, which measure atmospheric pressure against a full vacuum reference. Therefore, such devices as the *capacitance manometers* (see Section 5.7) or *quartz helix manometers* (see Section 5.4) are not discussed here. Similarly excluded from this section are the manometric controllers—the cartesian divers and aneroid manostats—because they are covered under vacuum controllers in Section 5.14.

INTRODUCTION

Manometers are primary standards of the U.S. National Bureau of Standards and of other standardizing institutions. When so used, their visual reading scales are often replaced by capacitance or sonar devices to provide better precision. In order to achieve primary standard precision, it is necessary to compensate for capillary effects; variations in gravity by location; fluid compressibility; and temperature expansion of the filling fluid, which affects its density and thermal expansion of the readout scale.

There are two major groups of wet pressure instruments: the liquid-sealed and the liquid manometer. The liquid-sealed category includes various bell designs and the ring balance units. The liquid manometer group is subdivided into visual and float types. There are a variety of visual manometers, including barometers; well, U-tube, and inclined tube manometers; and micro-manometers.

Barometric pressure can also be detected by bellows type instruments, which are provided with a sealed-in vacuum reference. These differential pressure sensing bellows are usually coupled to the core of a linear variable differential transformer (LVDT), which generates the required electronic output signal as discussed under Weather Stations in Section 7.23.

The simplest design is a U-tube with one leg connected to an evacuated reference chamber, while the other is exposed to the unknown process pressure. The difference between the two column heights indicates the process vacuum. The precision of reading the manometer is limited to about 0.1 mm when detected by the naked eye. Inclining the manometer tube and using lower-density filling fluids (low-vapor-pressure oils) can improve the sensitivity of the readout to about 10 mtorr. When the units are operated at constant temperatures and are provided with micrometer readouts, vacuums down to the 1 mtorr level can be detected.

The main advantage of manometers is their simplicity and low cost. Their limitations include possible vaporization of the filling fluids at high vacuums or at high temperatures. Density variation and light refraction can make it difficult to read the gauge. Other disadvantages include the toxic nature of mercury; their moving parts, some of which are exposed to the process; their relatively high installation costs; and the various limitations caused by corrosion, temperature, chemical reaction, or plugging.

LIQUID-SEALED DESIGNS

Inverted Bells

In all inverted bell devices, the bell dips into a sealing liquid and generates a vertical motion as a function of the pressure differential acting on the inner and outer surfaces of the bell. The bell motion might be balanced against a calibration spring or by the weight of the bell. Depending on the pressure on the reference side of the bell, this device can detect absolute, positive, negative, or differential pressures.

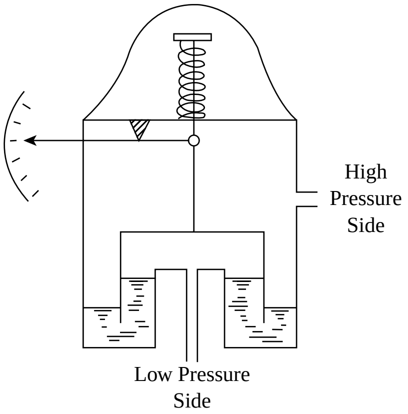

FIG. 5.9a
Inverted bell d/p detector.

Variations include single- and double-bell units, mercury- and oil-sealed types, and designs in which the vertical bell motion is linearly or square-root-related (Ledoux) to the pressure differential sensed.

Cylindrical and Ledoux Bells Figure 5.9a shows the operation of the single cylindrical bell design. If the underside of the bell is evacuated by a vacuum pump, with this full vacuum reference, the unit will detect absolute pressures. If the reference side is left open to the atmosphere, the instrument will measure pressures above or below atmospheric pressure. By changing the calibrated spring, which normally is a temperature-compensated helix, the range of the unit can also be changed.

These instruments are mainly used to measure low-pressure differentials. The two well-known members of this family are the cylindrical and the Ledoux bell designs. Figure 5.9a illustrates the operation of the cylindrical bell unit. Here, the force developed by the differential pressure (d/p) acting on the bell is opposed by a spring. The resulting bell motion is a measure of the pressure differential. Because a large bell acts as a force amplifier, even a small differential can generate a sizeable force to drive the readout mechanism. Depending on design and the type of seal fluid used, these units can respond to full-range differentials from 1 to 15 in. H_2O (from 0.25 to 3.8 kPa) and can withstand substantial static pressures.

The Ledoux inverted bell is different from the cylindrical design in two important aspects. Instead of a spring, the pressure differential on the bell is balanced against the weight of the heavy bell as it rises and falls in the seal fluid, which is normally mercury. Also, the bell is shaped so that its motion corresponds to the square root of the pressure differential acting upon it. This feature makes it suitable to d/p flow measurement, when an inherently linear output signal is desired. The unit can detect differentials up to 200 in. H_2O (50 kPa) can be installed to operate at up to 6000 PSIG (41 MPa) static pressure.

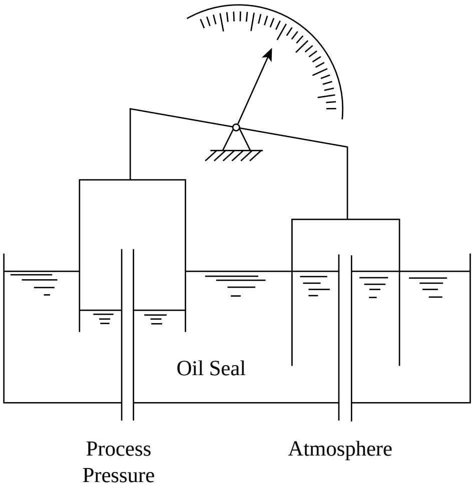

FIG. 5.9b
Double inverted bell manometer.

Double Bell Unit Figure 5.9b illustrates a double-bell unit, one of the most sensitive pressure sensors when measurement of near-atmospheric pressures is required. It can also be used as a d/p detector with the two process pressures connected to the underside of the two bells. As a result of a change in d/p, one of the bells moves up and the other down in direct proportion to the d/p detected. In this design, there is no calibration spring because the weight of the bells balances the pressure differential.

When the bell is shaped so that its vertical motion corresponds to the square root of the pressure differential acting on it, the resulting signal is linear with volumetric flow rate through orifice elements.

All inverted bell units have the common desirable feature that the large bell area generates ample power to operate the mechanical motion detector levers even at very low process pressures. These units are made of materials that are normally suitable for noncorrosive services only, and the process media have to be compatible with the seal fluid used. Their inaccuracy is ±1% of span (Ledoux is ±2%), and they are bulk units sensitive to ambient temperature variations.

The depth of the sealing fluid determines the maximum d/p these units can withstand. If that limitation is exceeded, the seal fluid will be blown out. The same limitation exists for the measurement of static pressures with vacuum or atmospheric references. When the unit is used for differential pressure sensing, the static pressure limitation is determined by the design of the housing. In the Ledoux bell design, housings can withstand up to 6000 PSIG (41 MPa) service pressures. The spans available with the Ledoux bells are higher (up to 200 in. H_2O, or 50 kPa) than the others. The minimum span available with the cylindrical bells is 0.15 in. H_2O (0.038 kPa), and the maximum is about 15 in. H_2O (3.8 kPa). The actual range can be high-vacuum with vacuum-pump reference or near-atmospheric with open-vent reference. Compound ranges are also available.

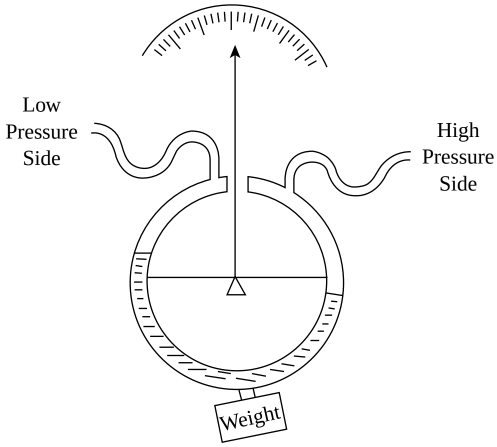

FIG. 5.9c
Ring balance d/p sensor.

Ring Balance Manometers

These meters (see Figure 5.9c) have been widely used in Europe but have found limited acceptance in the United States. Their application and operating principles are the same as those of the inverted bell meters. A tubing ring formed in the vertical plane is pivoted at its central axis, and the pressure differential rotates this ring. The opposing torque is developed by a weight attached to the ring.

Depending on the design and the filling fluid used, the minimum span for these units is 0.2 in. H_2O (0.05 kPa) and the maximum span is 500 in. H_2O (125 kPa). Depending on the reference pressure used, it can detect absolute or near-atmospheric pressures. Although the housings can withstand up to 6000 PSIG (41 MPa), the pressure differential between reference and process pressure should be below that limit, which would cause the sealing fluid to be blown out. Also at high pressures the flexible connections at the sensing leads become a source of errors and require constant maintenance.

McLeod Vacuum Gauges

The McLeod vacuum detector, or barometer gauge, operates by trapping a definite volume of low-pressure gas and compressing this volume with a fixed pressure. The pressurized new volume is then read as a measure of the initial absolute pressure. If the reading is taken at constant temperature, Boyle's Law applies: $V_1P_1 = V_2P_2$. Here P_1 the initial pressure of the rarefied gas is given on the instrument scale, having been calibrated on the basis of $P_1 = P_2V_2/V_1$. The McLeod gauge is considered to be a laboratory standard for calibrating other types of vacuum detectors.

90° Rotation Type Figure 5.9d illustrates the standard 90-degree rotation McLeod gauge. Before measurement, a known volume of mercury is placed into the gauge reservoir, as shown at the left side of the sketch. Then the gauge is connected to the vacuum system to be detected and is rotated

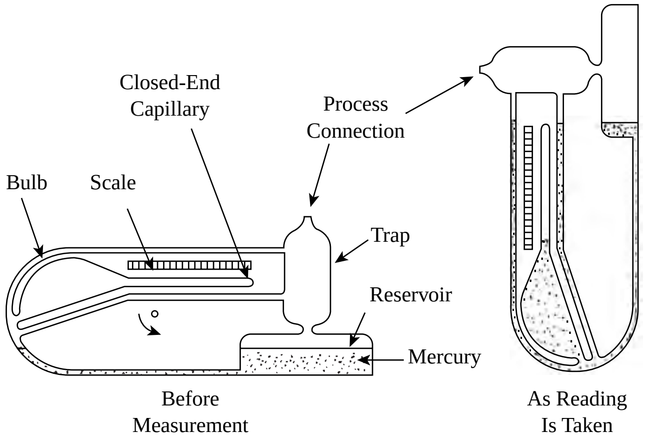

FIG. 5.9d
90-degree rotation McLeod vacuum gauge.

90 degrees, thereby trapping a fixed volume of rarefied gas (the volume of the bulb and capillary), which is compressed by the column of mercury shown at the right side of the sketch. The level to which the mercury rises in the capillary is read on the scale that has been calibrated per Boyle's Law to read in units of initial pressure.

This device has no moving parts, so friction, inertia, or hysteresis does not affect the measurement, making it as basic a measuring instrument as a manometer. Assuming constant temperature and proper quantity of filling mercury, the only limitation of the unit is due to capillary effects. Below 10^4 mmHg, accuracy is affected because it is hard to obtain a flat mercury surface free from capillary effects even at the highest practical compression ratio.

Piston-Type McLeod Gauge Figure 5.9e shows an improved version of the McLeod gauge. In this design, the unit is stationary, and a piston is used to trap in the rarefied gas. One of the advantages of this unit is that it does not use a dead-ended capillary, and, therefore, the problems associated with keeping the capillary clean are eliminated. At the left side of the sketch, the unit is shown just prior to the taking of a measurement. As the piston with micrometer adjustment is moved up, the rarefied gas is trapped when the mercury reaches point D; thus, the initial volume (V_1) is the volume between points A and D. The filling of the gauge with mercury is done through the process connection. It runs down into the well, up the capillary, and syphons over through the bulbs into the reservoir. When the syphon breaks, the mercury level is at point A.

When the instrument is connected to the vacuum system, the mercury level in the reservoir is below point D to allow trapped gases to be liberated. As the piston is moved up, the mercury fills the large bulb up to point C. Here a reading can be taken on the dual scale if the pressure to be detected is in the mmHg range. If the vacuum is higher, the piston is moved further up, increasing the compression ratio until the mercury reaches point B above the small bulb. In this case, the reading is taken on the micron side of a dual scale.

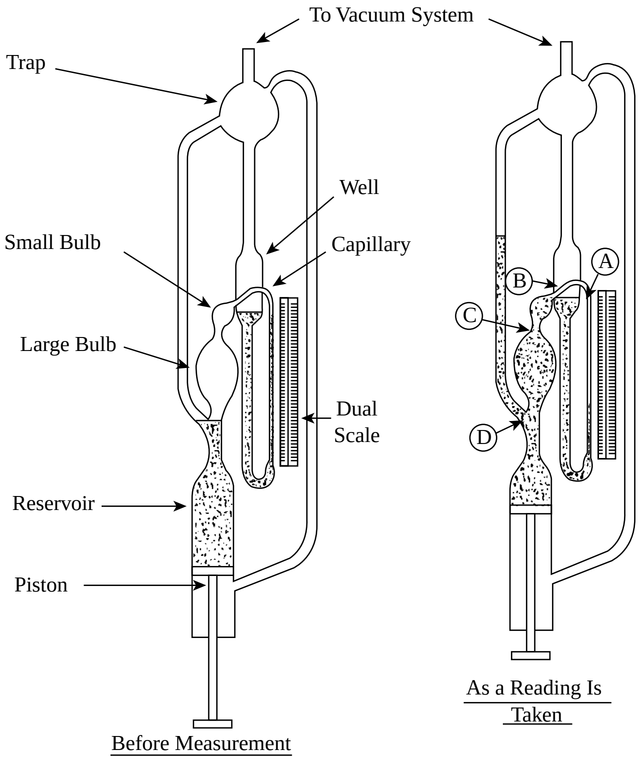

FIG. 5.9e
Piston McLeod gauge.

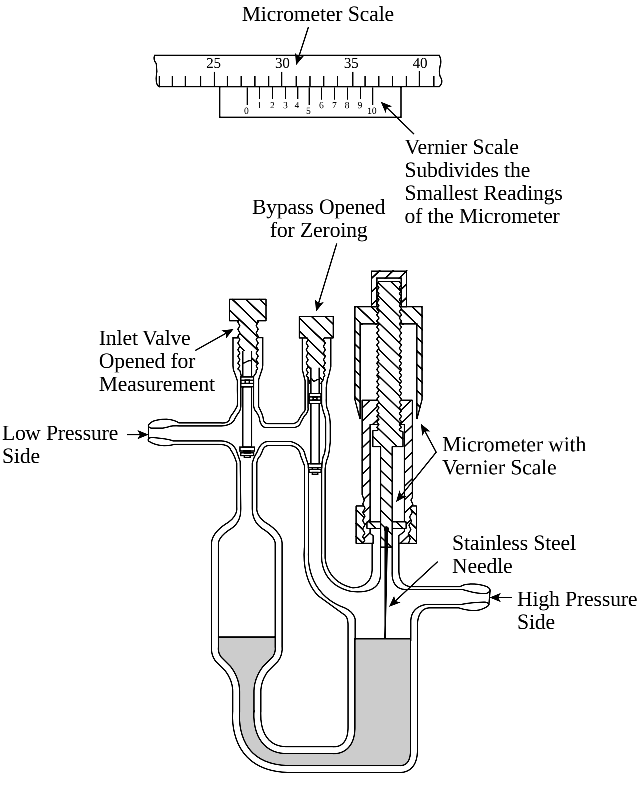

FIG. 5.9f
Micrometer needle position is displayed on a vernier scale for better visibility.

McLeod gauges can cover the vacuum range between 1 and 10^{-6} mmHg (133 and 1.3×10^{-4} Pa). At pressures below 10^{-4} mmHg (1.3×10^{-2} Pa), the reading accuracy is limited by capillary effects. This device is a laboratory instrument that measures on a sampling rather than on a continuous basis, but it is also available for industrial installations where a rugged case is required. No remote readout devices are available. Condensation as a result of compression of the gases can contribute to inaccuracy; therefore, it is desirable to condense and trap the condensable vapors before they are admitted into the gauge.

Micromanometer With Precision Needle As a micromanometer, the gauge can be provided with a precision needle with 20 turns/in., which is lowered until the needle touches the surface of the filling fluid. The position of the needle is shown on a vernier scale, which provides for fine adjustment and readout. The range is usually 0 to 2 in. (50.8 mm) and the reading accuracy is about 0.002 in. (0.05 mm). Both legs are made of large-diameter, precision-bore glass tubing to minimize capillary effects, and the two vapor spaces are connected through a bypass valve that allows for zeroing the instrument.

VISUAL MANOMETERS

Indicator Fluids

The performance of any manometer installation is largely a function of the indicating fluid selected. It has to satisfy several criteria, which in many cases are hard to meet. The filling fluid has to be chemically inert and compatible with the process media and produce a clear, visible interface. The fluid should not coat the glass tube and should not be corrosive to standard materials, such as copper-bearing alloys, aluminum, or steel. Its surface tension should be low to minimize capillary effects, and it should be stable so that no flashing occurs under higher operating temperatures or vacuum conditions.

Similarly, the filling fluid should not freeze due to low ambient temperatures. In general, manometer fluids are available for an operating temperature range of –70 to 150°F (–57 to 66°C). The most important characteristic of a good manometer fluid is its ability to maintain density unaffected by temperature variations, so that the height of its column is a reproducible measure of process pressure. Standard filling fluids are available in a variety of colors covering a specific gravity range of 0.8 to 13.6. None of them satisfies all the requirements listed above; therefore, they have to be selected separately for each installation.

Liquid Barometers

The liquid barometer is a fundamental instrument for detecting atmospheric pressure that is used for precise measurements and for calibration of other sensors. As shown in Figure 5.9g, a glass tube that is open on one end is filled with mercury and then inverted into an open mercury bath. The height of the resulting column in the tube is a measure of the barometric pressure in millimeters of mercury. Accuracy is affected only by the visibility of reading and by capillary effects in the tube. The barometer will act as an absolute pressure sensor if it is well connected to the process.

Glass Tube Manometers

Liquid manometers are the simplest d/p detectors, while at the same time they are economical and accurate. Their main limitations relate to their mechanically fragile nature and to the use of toxic mercury as the working fluid. When local visual indication is sufficient and the static pressures are compatible with the transparent tube design, the glass tube manometers can be considered.

U-tube and well manometers are available in lengths of 6 to 140 in. (150 mm to 35 m). Depending on the density of the manometer fluid used, they can read pressure spans from 5 in. H_2O to about 60 PSIG (1.25 to 410 kPa). The commonly available manometer filling fluid specific gravities are 0.827, 1.00, 1.75, 2.95, and 13.56.

Figure 5.9h illustrates the most elementary type of manometer, the U-tube. The difference between the two columns of liquid is an indication of the pressure differential. There are no moving parts and no friction or inertia involved in the measurement; therefore, its accuracy is limited only by the visibility of the scale.

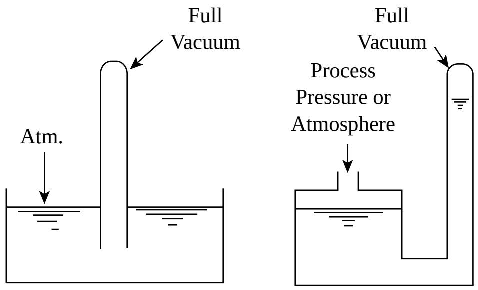

FIG. 5.9g
Liquid column manometer.

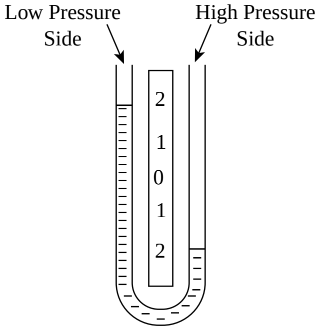

FIG. 5.9h
U-tube.

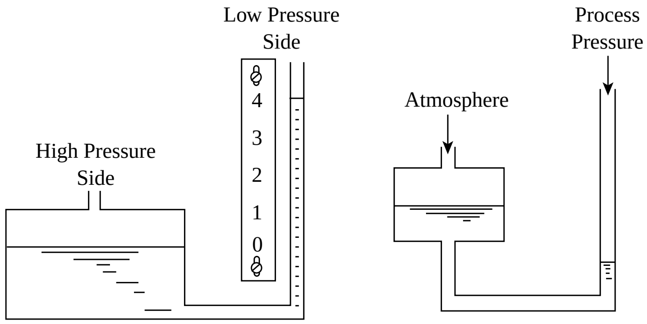

FIG. 5.9i
Raised well-type manometers for the detection of positive (left) and negative (right) pressures.

Well-Type Design An easier-to-read scale can be attached to the well manometer, when the liquid surface area on the high-pressure side is 1000 or more times greater than the area on the low pressure side. Therefore, changes in d/p cause variation only in the column height on the low side, as shown in Figure 5.9i, but leave the high side level practically unaffected. Changes in well liquid level are compensated for by sliding the scale zero to match this level.

The filling fluid is selected on the basis of its chemical inertness to the process materials it comes in contact with. Also important is its compatibility with the process temperature expected, so that it will not freeze or vaporize under operating conditions.

Glass tube manometers are available with up to 120 in. ranges (30 kPa), which is sufficient for most level applications, if the filling fluid is mercury. Design pressure up to 1000 PSIG (6.9 MPa) can be obtained, but their use is discouraged because of mechanical hazards. Because of these considerations and because of the toxicity of mercury, glass tube mercury manometers are no longer used in the processing industries.

The standard construction materials for manometers include brass, steel, aluminum, and stainless steel for the metallic wetted parts, and Pyrex glass for the tube. The glass tube with 1/4 in. (6.3 mm) inside diameter can be exposed up to 400 PSIG (2.8 MPa) pressure, while the extra heavy-wall tube with 1/8 in. (3.1 mm) inside diameter is designed to withstand 2000 PSIG (14 MPa). These pressure ratings must be qualified in two respects.

First, they do not take mechanical damage into consideration. Therefore, if the process material is toxic, hazardous, or should not be allowed to escape for other reasons, glass tube manometers should not be used, even at low operating pressures. Second, the static pressure limitations apply only when the manometer detects pressure differentials. When its purpose is straight pressure measurement, the manometer fluid will be blown out if its range is exceeded. To prevent this from occurring, check valves or return wells can be provided, which will block or collect the seal fluid.

Vacuum Measurement When below-atmospheric pressures are to be detected, two designs can be considered. One is the barometer illustrated in Figure 5.9g, which will give readings in absolute pressure units based on its full-vacuum reference.

The other option is to raise the manometer well (see the right side of Figure 5.9i) and connect the atmospheric reference to the well. This way the manometer will measure negative process pressures relative to atmosphere. In some designs, the well elevation is adjustable, allowing for varying the manometer range from vacuum to compound or to positive pressure detection.

Multitube and Interface Manometers Figure 5.9j illustrates a multitube manometer with atmospheric reference. Up to 50 tubes can be packaged in a common bank; thus the same number of process pressures can be detected from the same reference well. If desired, some or all of the tubes can be provided with separate wells for flexibility.

The accuracy of measurement is largely a function of the operator's ability to read precisely the height of the liquid column. For this reason, designs have been developed that tend to amplify the reading by the use of vernier scales, magnifying eye pieces, or other techniques. One of these units is shown in Figure 5.9k. This design is also called the double inverted-well manometer. If the left leg is filled with a manometer fluid of 1.0 density and the right leg with a fluid of 0.9 density,

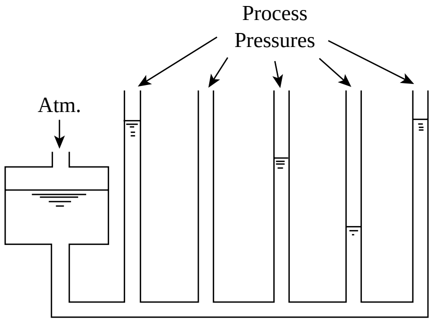

FIG. 5.9j
Multitube manometer.

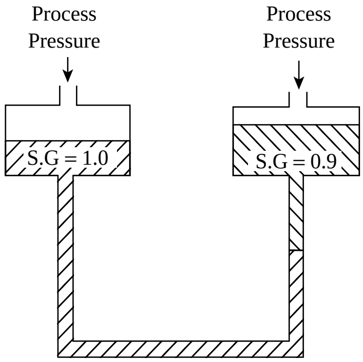

FIG. 5.9k
Double liquid balance manometer.

the movement of interface between the two will be 10 times that of a U-tube manometer filled with water.

Inclined Tube Designs If the vertical tube of a well manometer is laid down into an inclined, almost horizontal position, so that a slight change in process pressure will cause a large movement of liquid column, the reading visibility will be improved. With this design, illustrated in Figure 5.9l, full spans of 0.5 to 4 in. H_2O (0.13 to 1 kPa) are available.

Manometers are normally mounted close to the point of measurement to reduce lag time. They are available for bench, wall, or panel mounting, although in modern plants, remote panel-mounted manometers have been replaced by transmitter-receivers. This is desirable not only from space and time-lag point of view, but also for safety reasons in order to prevent process materials from entering the general purpose central panel. When the pressure to be measured is unsteady, pulsation dampeners are installed to steady the indicating column for better readability.

Visual manometers are normally used only as direct indicators, but they can also be provided with switches to detect the level of indicating fluid in the tubes. For this purpose, either photo cells or electric conductivity switches are installed that actuate alarms, solenoids, or any other electrical devices.

Micromanometers

The inclined and the double liquid balance manometers (Figures 5.9k and 5.9l) are capable of amplifying the movement of the manometer fluid column by an order of magnitude. The micromanometer illustrated in Figure 5.9m achieves the same thing, but its amplification capability is much greater.

The unit consists of two large-diameter tubes connected by a small-bore capillary. The capillary either contains an air bubble to indicate filling fluid movement, or the two large-diameter tubes are filled with two nonmixing liquids of different colors, in which case fluid movement is indicated by interface travel. When both wells are exposed to the same pressure, the air bubble comes to rest in the center. Then if one of the wells is connected to the process, the difference between that and the atmospheric reference causes fluid movement from one well to the other, developing a head differential. If we call the well cross-sectional area A and the capillary bore area Ac, the resulting movement of the bubble in the capillary can be expressed as:

$$X - hA/2Ac \qquad \textbf{5.9(1)}$$

Consequently, the head motion has been changed into air bubble motion and has been amplified by the factor A/Ac. This ratio is limited only by the selection of tubes and can be as high as 100:1 or 1000:1. If the operator is capable of determining the bubble position to an accuracy of 1 mm, the actual pressure can be read to an accuracy of $\pm 10^{-2}$ or $\pm 10^{-3}$ mm H_2O. Depending on the reference pressure, this device can then be used for the sensing of near-atmospheric, absolute, or differential pressures. Its performance as a high-vacuum sensor is a function of the quality of the vacuum reference available.

The speed of response of this instrument is relatively slow because the smaller the bore of the capillary, the longer it takes for the bubble to assume its final position. At the same time, small capillaries are desired to prevent fluid leakage between the bubble and the capillary.

FLOAT MANOMETERS

When remote readouts are required or when the process material is hazardous or is at high pressures, float manometers are used. In these units (Figure 5.9n), the variations in pressure differential cause the level of filling liquid to change, and the float moves with the changing level. The float motion is brought out of the chamber by a lever rotating in a pressure seal bearing. Other designs are also available using torque tube or magnetic followers. The lever rotation can be used to drive local indicators or transmitting devices for remote readout.

These instruments can be exposed to static pressures up to 6000 PSIG (41 MPa) and can detect pressure differentials

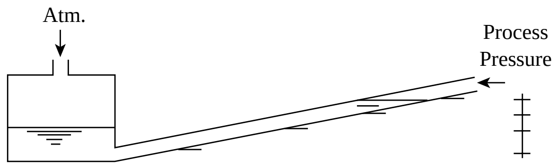

FIG. 5.9l
Inclined manometer.

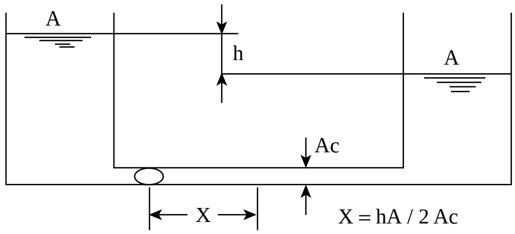

FIG. 5.9m
Micromanometer.

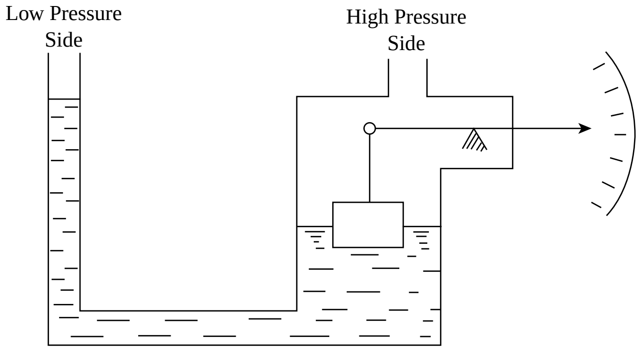

FIG. 5.9n
Float manometer.

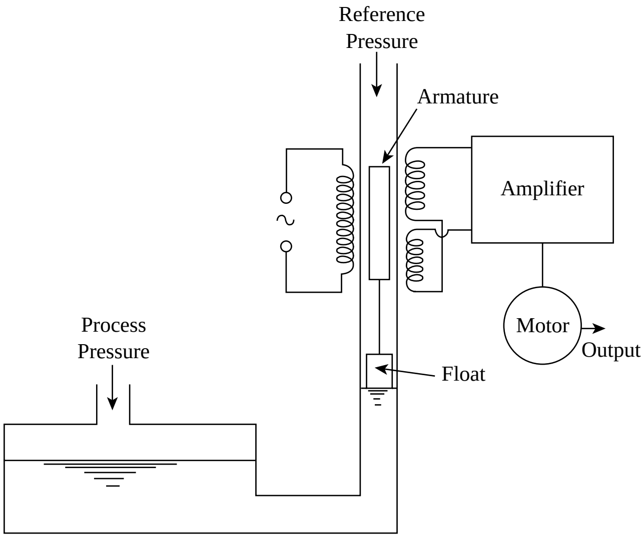

FIG. 5.9o
Metallic tube servomanometer.

from 20 to 1000 in. H_2O (5 to 250 kPa). Lower differentials are not practical from an accuracy point of view, and higher ones would require excessively long reference chambers.

For high precision at static pressures up to 10,000 PSIG (69 MPa), stainless steel U-tube manometers have been used with magnetic floats in both legs. The float positions are detected by electric coils and provide precise measurements of differential pressure.

Figure 5.9n shows the features and the operation of these instruments. When used as a pressure sensor, the process pressure is connected to one side of the manometer and a reference pressure to the other. If the reference pressure is atmospheric, the float movement is related to the pressure differential between the process pressure and atmosphere. Spans are available from 20 to 1000 in. H_2O (from 5 to 250 kPa). The range can be set for positive, negative, or compound pressure detection. Housing is available for up to 6000 PSIG (41 MPa). Measurement inaccuracy is ±1% of span.

Servomanometers

If the float housing is cylindrical, the float motion is linearly related to the pressure differential sensed. By forming the housing tube to variable parabolic cross-sections or other shapes, any desired nonlinear relationship between pressure differential and float motion can be achieved. When precision measurements are required in the area of ±0.05% of reading, the servomanometer illustrated in Figure 5.9o can be considered. The tube of this instrument can be either glass or stainless steel when mechanical strength is desired. The principle of operation is as follows.

Process pressure variations result in float movement that repositions the magnetic armature. A servomotor serves to continuously center a differential transformer about the armature. The shaft position in the servo-transmission is used as a measure of the liquid column height in the manometer tube.

CONCLUSIONS

The main advantages of manometers are their high accuracy, low cost, and simplicity. The measurement precision is limited only by the operator's ability to accurately read the height of the liquid column and by the compensation available for capillary, thermal expansion, and fluid compressibility effects. The main limitations of manometers are related to the potential for mechanical damage and to the problems associated with the filling fluids. There are many processes in which the use of glass is not allowed because toxic or hazardous materials would escape if the glass were to break. The filling fluids themselves also limit the use of manometers. This includes the toxic nature of mercury and the problem of manometer fluid blowout under high-pressure conditions. This second problem can be reduced, but not eliminated, by the use of check valves and return wells.

The filling fluid must be selected for the particular application so that it will not react with the process fluid and will produce a clear and visible interface. If should be stable (should not freeze, flash, or vaporize) under the operating temperature and vacuum conditions, and it should have low surface tension (capillary effect) and low thermal expansion. For high-precision measurements, constant temperature operation or thermal compensation is needed.

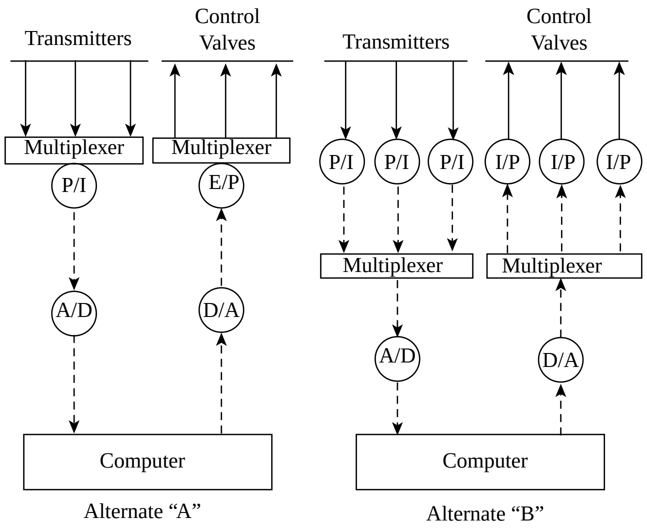
INTRODUCTION

If large numbers of pressures are to be monitored, the sequential scanning of the pressure signals can reduce the total cost of the monitoring system. In aircraft, wind tunnel, and compressor testing or in other applications, where the process materials are air or inert gases, the pressure signals can be connected directly to the scanners. In such applications, the scanned pressures are connected and measured in sequence, by shared transducers, which than transmit their values in analog or in digital form over data buses and networks.

Another application is to integrate a pneumatically instrumented existing plant into a computerized processing facility. In such cases, a large number of analog pneumatic signals need to be converted into their digital electronic equivalents. Figure 5.10a illustrates two alternate methods of providing the required interfacing.

Alternate A illustrates the less expensive solution, where the pneumatic signals are multiplexed prior to being converted into their electronic equivalents; in alternate B, the multiplexer is on the electronic side. Consequently, in alternate B, a P/I



Alternate "A" Alternate "B"

FIG. 5.10a
Alternate methods of computer interfacing for pneumatic systems.

converter has to be provided for each pneumatic signal, while in alternate A the converter is shared between many pneumatic signals. Therefore, alternate A accomplishes the same interfacing with a substantially lower investment. In addition, alternate A is likely to also provide better measurement accuracy (0.1% of full scale), because one can afford to pay for one high-quality transducer, which is then used on a time-share basis.

ROTARY PRESSURE SCANNERS AND DISTRIBUTORS

Figure 5.10b illustrates a rotary pneumatic selector with a 0.016 cm^3 switching volume. This is the volume of the rotating U-tube that connects the individual signals to the common transducer in the middle. This pneumatic multiplexer can scan 48 or 64 input signals, and if one of the ports is used for span and one for zero calibration, the pressure transducer can be automatically recalibrated on every scan. Because of the small volume of the rotating U-tube, the response time is less than 50 ms, which theoretically allows a scanning speed of up to 20 samples/s and in practice provides a speed of about 15 pressure signals/s.

The mechanical-drive mechanism is rated at 6 steps/s for continuous duty, in order to limit maintenance. Presently the mean time between failure for pneumatic multiplexers is between 1 and 2 years. Based on that expected performance, it is advisable to replace the scanner module every 3 to 5 years, if the duty cycle is one scan per minute.

Scanning Frequency

All repetitive scanning programs are a form of ring scan; that is, a series of channels are scanned in sequence with the procedure being repeated on some time base. Therefore, it is advantageous to let the hardware do the scheduling of the scan as the valve steps successively from port 0 to port 63 and back to 0. For example, if one signal needs to be looked at very frequently, it can be connected to several of the 64-ports of the multiplexer.

If it is necessary to speed up the sampling time of a large number of signals, the number of ports per multiplexer must be reduced. Two multiplexers, each with half of the ports, would double the scan speed, three would triple it, and so on.

Differential Pressure Scanning

When large numbers of orifice or pitot tube type flow elements are to be monitored, a pair of rotary scanner modules are used with a single differential pressure transducer mounted

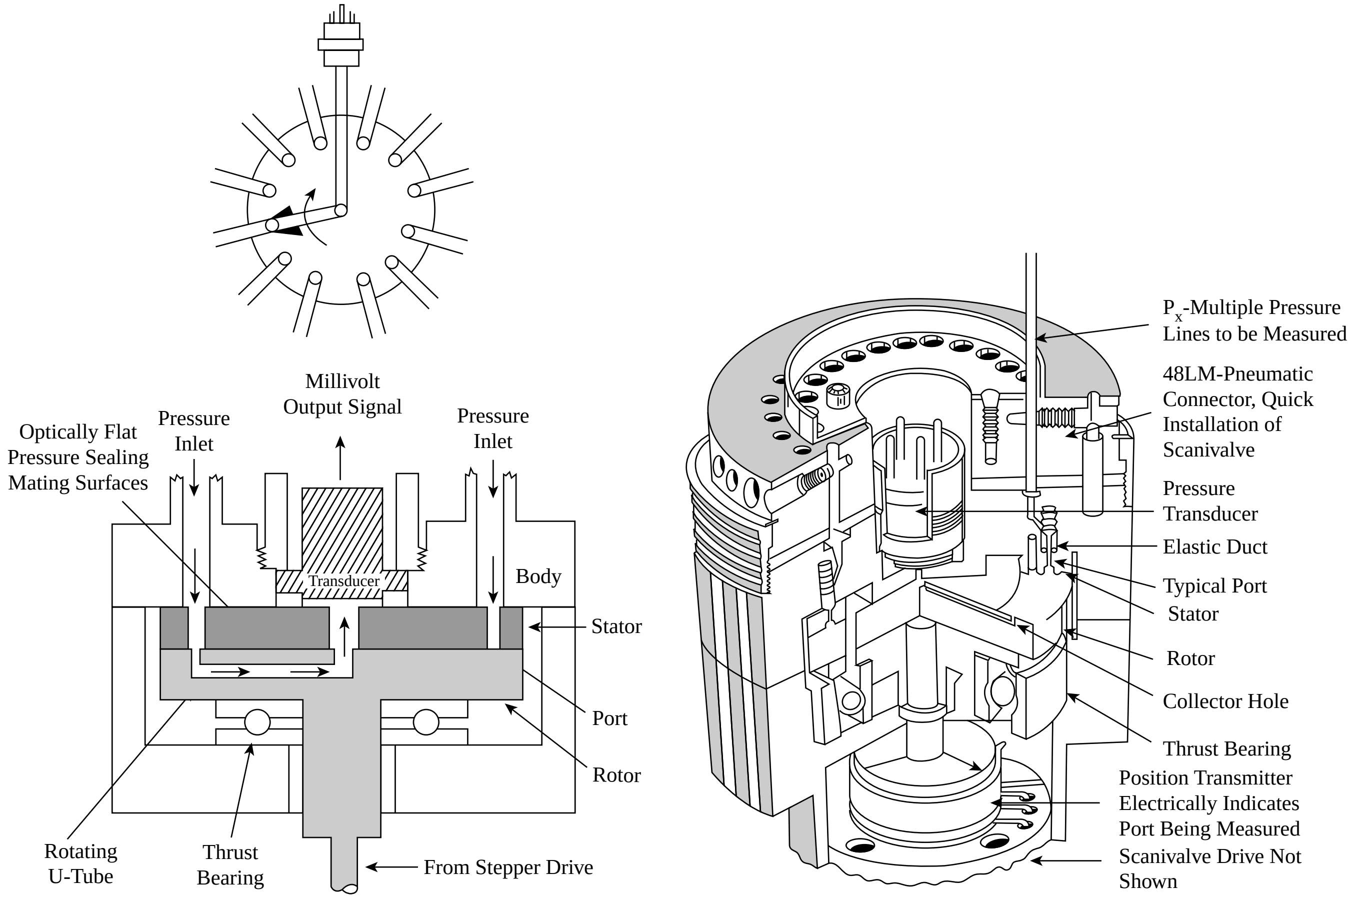


FIG. 5.10b
Scanner module showing "traveling volume" between the various signal ports and the transducer membrane. (Courtesy of Scanivalve Corp.)

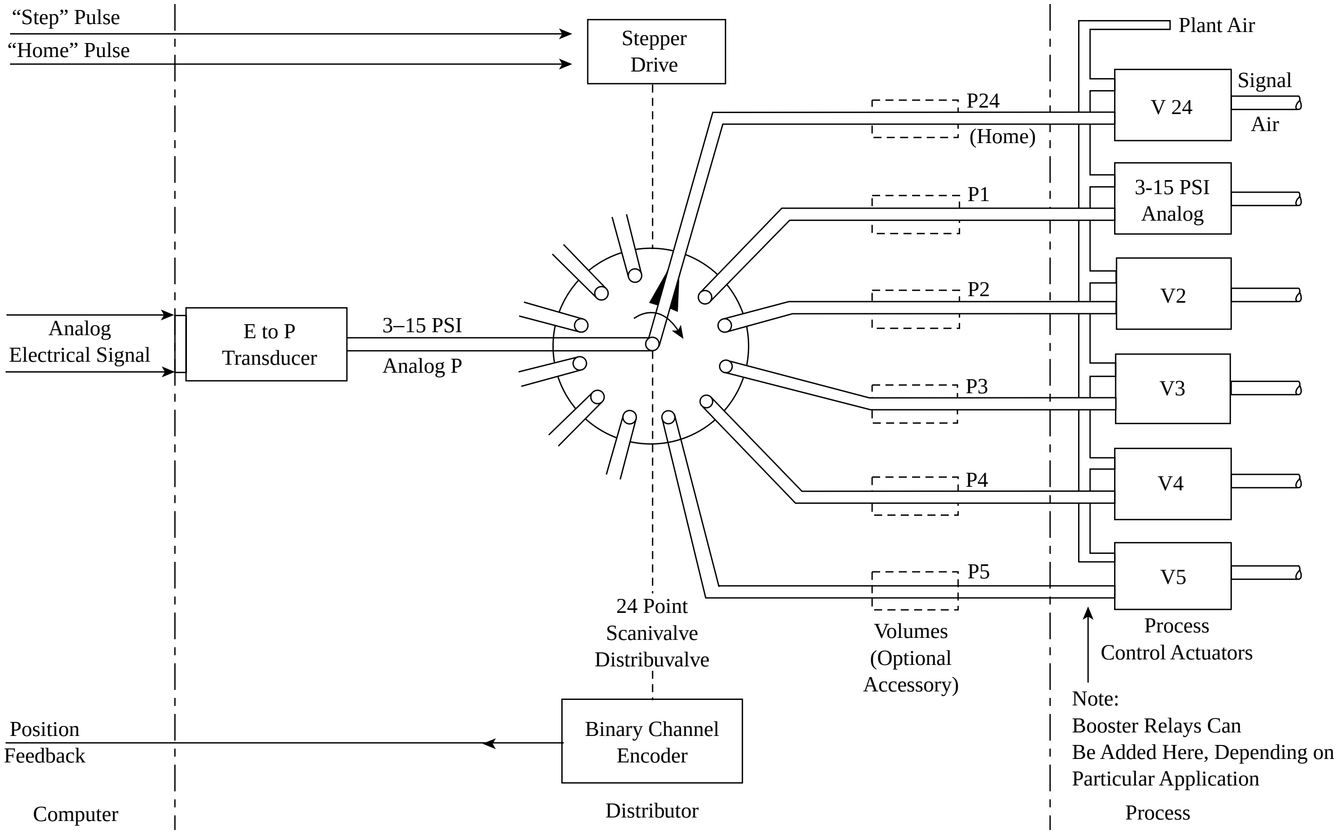

FIG. 5.10c
Rotary signal distributor. (Courtesy of Scanivalve Corp.)

between them. One module scans the pressures on the high (upstream) and the other the low (downstream) side of the flow elements. The two scanning modules are stepped by a timing belt driven by a common stepper drive. Up to 24 pairs of pressures can be transduced and sent to an electronic computer or data logger at a rate of about 1 port/s.

When higher precision is required, 2 of the 24 ports can be assigned for span and zero reference pressures, so that the scanner can be automatically calibrated on every scan.

The scanner is also capable of monitoring high pressure differences, up to 500 PSID.

Digital Interface Units

The digital interface units serve to control the scan cycle and to place the measured values and their addresses in memory. This memory is accessible to the host computer by either RS-232 or IEEE-4888.

Other features of the rotary pressure multiplexers include a nine-track optical disk as a channel encoder. This provides a binary-coded computer address number for each of the pressure input ports and for the home position. Another feature of these scanners is their capability to scan temperatures and pressures at the same address. This requires the addition of a thermocouple scanner module.

ROTARY AIR SIGNAL DISTRIBUTORS

As illustrated in Figure 5.10c, some 24 electronic analog signals can be converted to 3 to 15 PSIG (0.2 to 1.0 atmosphere) signals by time-sharing one E/P transducer. The rotary distributor can be installed in the field, near the actuators served, while being controlled by a central computer. As a stepping motor sequentially connects the 24 outputs, an optical channel encoder provides the required channel position feedback for the computer.

As shown in Figure 5.10c, it is desirable to equalize the volumes of the 24 output tubes. If some of the lines are long, if actuator volumes are substantially different, or if there is substantial leakage at the actuators, the addition of booster relays is recommended. The distributor will spend about 3 s at each port. This means that with 24 outputs, the time between updates is about 1 or 2 min.

AIR SIGNAL DISTRIBUTOR MANIFOLDS

If only a few pneumatic output signals are required or if a manual backup mode of operation is desired when the computer is down, the unit illustrated in Figure 5.10d can be considered.

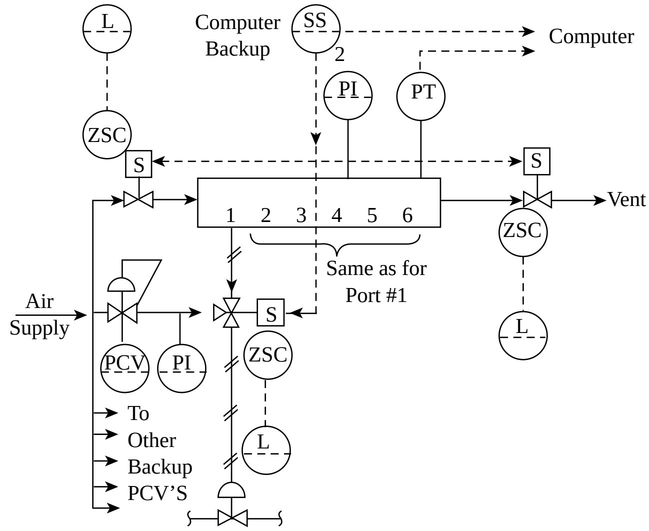

FIG. 5.10d
Air signal distributing manifold.

This type of a multiplexer is capable of sequentially updating six pneumatic output signals. Each line is sequentially pressurized or bled as required, while the solid-state transducer (PT) provides the needed feedback signal. Similar to Figure 5.10c, tube volume equalization and/or boosting should also be considered.

Switchover to the backup mode can be initiated either by the computer or locally by the operator. The manifold cover contains the required toggle switches and light-emitting diodes that serve to indicate the status positions of the solenoid valves within the manifold.

RAMPING PRESSURE SCANNERS

In these scanners all pressure inputs are simultaneously compared to a reference pressure, which changes linearly with time as a linear ramp function. Each input signal will equal the moving reference pressure at different times, and these times will correspond to the signal pressures involved.

Therefore, this system does not use the conventional pressure transducer followed by an analog-to-digital converter. Instead, it uses 64 individual pressure switches and a precision single-slope pressure ramp that has a linear relationship between pressure and time. A binary counter is synchronized to this pressure ramp, providing a digital count proportional to pressure. The multiple pressure inputs are individually compared to this pressure ramp and the digitizing is accomplished as a function of the time at which each comparator trips its enable line. This enable line transfers the binary count into the appropriate memory cell.

At the completion of each pressure ramp, a 64-word memory will contain digital data representing the 64 pressures that are piped into the front panel of the system. The above ramp and update function is completed in less than 800 ms. All or part of the stored data can be accessed, using the appropriate commands. A two-page memory is used so that one page can be updated while the other is being asynchronously accessed by the host system.

ELECTRONIC PRESSURE SCANNERS

Low Level Multiplexer

For cases in which the speed of rotary scanners is insufficient, the electronic scanners illustrated in Figure 5.10e can be used. These units can provide 0.08% of full scale accuracy and are available in 16, 32, and 64 input modules. Each pressure signal is provided with its own field-replaceable sensor.

Because of their large number, these dedicated sensors are usually of relatively low cost and low accuracy, but their performance can be improved by periodic recalibration. As shown in Figure 5.10e, the scanner can be provided with online recalibration capability and a 6-point calibration of all sensors can be completed in 2 min. During calibration all sensors are connected to the calibration manifold while their pressure inputs are blocked.

Figure 5.10e illustrates the system in its purge mode where the pressure applied by the calibration manifold is allowed to enter and purge the pressure input lines. This feature

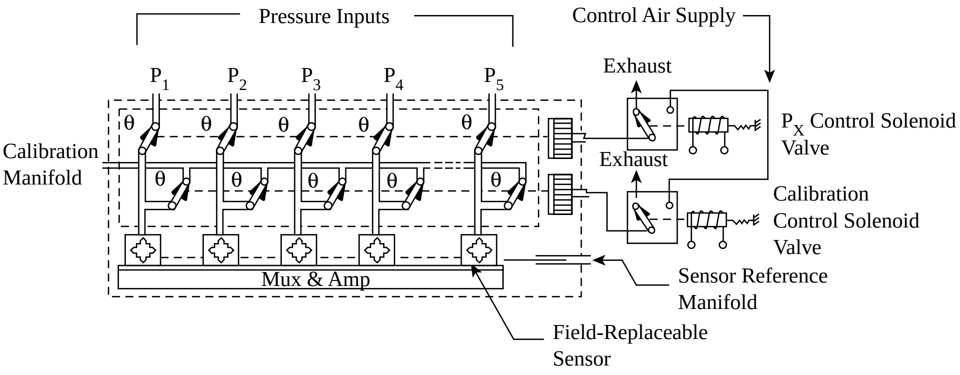

FIG. 5.10e
Electronic pressure scanner shown in its purge position. (Courtesy of Scanivalve Corp.)

is also useful if the scanned pressures are not clean pneumatic transmitter signals but come from combustion turbine engines or other processes where dust might contaminate the inlet lines. These scanners can handle pressures up to 500 PSIG (34.5 bars).

The basic element of the pressure sensor is an integrated circuit diaphragm that incorporates a piezoresistive sensor that changes resistance in proportion to the input pressure. The diaphragm is fabricated from a single silicon crystal on which strain-sensitive elements have been diffused in the form of the four-active-arms of a Wheatstone bridge.

The complete miniature module contains the pressure sensors, low-level multiplexer, instrumentation amplifier, and a valving circuit that allows each sensor to be pneumatically switched from its input pressure to a common calibration manifold as often as desired. Channel selection is controlled by a four-bit binary address input to the assembly.

High Level Multiplexer

In the data acquisition and control units used in flight test or automotive test applications, the electronic pressure scanners are provided with 384 channels. Their scanning rate can be 10,000 readings/s and if on-line rezeroing is included, the worst case inaccuracy will not exceed ±0.25% full scale.

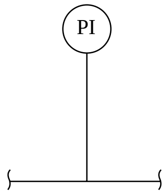
5.11 Pressure Gauges



Flow Sheet Symbol

B. G. LIPTÁK (1969, 1982, 1995) **J. E. JAMISON, S. EDVI** (2003)

Design Temperature:	Pressure gauge is normally kept at ambient temperature through the use of seals or chemical seals.
Design Pressure:	Up to 100,000 PSIG (690 MPa)
Materials of Construction:	Phosphor bronze, alloy steel, 316 or 403 stainless steel, beryllium copper, Monel, or Ni-Span C element in a steel, stainless steel, or phenolic case.
Standard Ranges:	Vacuum: 30 to 0 in. Hg (760 to 0 mmHg) Compound: 30 in. Hg to 0 to 15 PSIG (760 mmHg to 0 to 1. bars); 30 in. Hg–0 to 30 PSIG (760 mmHg–0 to 2.1 bars); up to 30 in. Hg–0 to 200 PSIG (760 mmHg–0 to 13.8 bars). Pressure: 0 to 15 PSIG (0 to 1 bars); 0 to 30 PSIG (0 to 2.1 bars); 0 to 60 PSIG (0 to 4.1 bars); 0 to 100 PSIG (0 to 6.9 bars); 0 to 200 PSIG (0 to 13.8 bars); 0 to 300 PSIG (0 to 20.7 bars); 0 to 600 PSIG (0 to 41.4 bars); 0 to 1000 PSIG (0 to 69 bars); 0 to 3000 PSIG (0 to 207 bars); 0 to 10,000 PSIG (0 to 690 bars).
Dial Sizes:	1 in. (25 mm), 1.5 in. (40 mm), 2 in. (50 mm), 2.5 in. (63.5 mm), 3.5 in. (89 mm), 4 in. (100 mm), 4.5 in. (114 mm), 6 in. (150 mm), 10 in. (250 mm).
Inaccuracy:	0.1% of full scale for test gauges: 0.5 to 1% of full scale for industrial gauges; 1 to 3% of full scale for utility quality gauges.
Costs:	Note: prices mentioned here are full list prices; significant volume discounts are available from most manufacturers. $10 for a 2 in. (50 mm) copper alloy brass utility gauge (with accessories); $20 for a 4.5 in. (114 mm) utility gauge; $40 for a 2.5 in. (63 mm) stainless steel, glycerine-filled utility gauge; $60 for a 4 in. (100 mm) bronze element (not too common any more) industrial gauge; the same stainless case gauge with 316 stainless element and both PSI/kPa scales costs $72, and if also liquid filled costs $80. A 6 in. (160 mm) test gauge with brass/nickle-silver (inaccuracy of ±0.25% of span) element costs $240; a high precision test gauge (inaccuracy of ±0.1% of span) in 10 in. (250 mm) size with stainless element is $2500. A battery-operated, 1% accurate digital pressure gauge costs $160. Quartz helix units range from $2000 for an electronic transmitter to $17,000 for an IEEE and RS-232 programmable, stand-alone station.

INTRODUCTION

The elastic elements used in pressure gauges have already been discussed in connection with Figures 5.4a and 5.4c, when the gauge movements of the Bourdon-type pressure gauges were discussed. These aspects will not be repeated here. In addition to the type of elastic element used, pressure gauges can also be grouped according to their precision or their dial size.

In test gauges the measurement error is held between 0.1 and 0.25% of range, and in order to obtain that level of precision, the dial size tends to be large. In order to provide good visibility, the diameter of test gauges can be up to 12 in. (300 mm) or more. The error in industrial-quality gauges is usually between 0.25 and 1.0% of span, and the most often used dial sizes are 4.5 or 6 in. (114 mm or 150 mm). In the lower quality utility gauges, the measurement error ranges from 1 to 3%, and the dial size can be 1.5, 2, 2.5, 3.5, 4, or 4.5 in. (40, 50, 63, 94, 100, or 115 mm).

THE GAUGE COMPONENTS

The main components of a pressure gauge are the retaining ring, glass lens, lens gaskets, pointer, dial, movement, sensing element, and the case.

The Gauge Housing

Gauge cases are available in drawn steel, cast iron, aluminum, brass, polypropylene, or phenolic resin materials. Drawn steel is the most economical selection, while cast iron is generally used for ruggedness. Brass is selected for decorative value and for antimagnetic applications, aluminum is utilized on limited-weight installations, and phenolic resin or polypropylene case materials are used in corrosive atmospheres. Other materials, such as stainless steel, are available for special applications.

The standard mounting styles include back flange, front flange, and turret types (see Figure 5.11a). The selection is based on the mounting requirements, which can be for surface mounting, flush-mounting, or pipe line mounting.

Gasket and Lens The gasketed lens is held against the case front by rings. The ring can be attached to the case in several ways, including snap, friction, slip, threaded, and hinged designs. The appearance of the gauge can also be affected by ring design variations, including peaked, flat-flared, and beaded gauges.

The lens crystals are available in a variety of materials, including shatterproof, flat, and beveled glass or cellulose acetate, acrylic, and nonelectrostatic plastics.

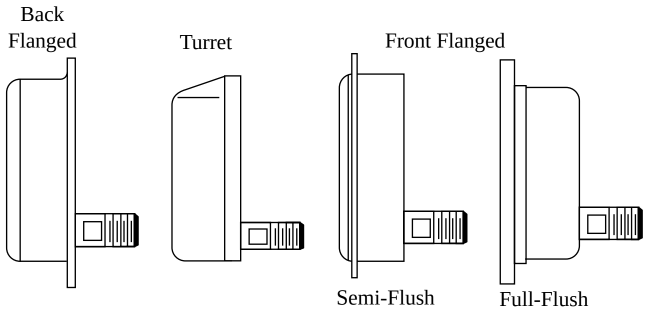

FIG. 5.11a
Pressure gauge case design variations.

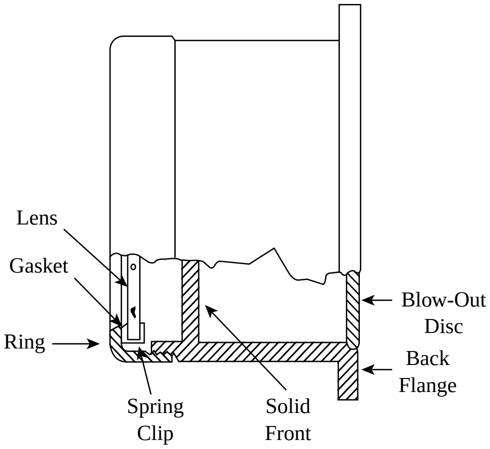

FIG. 5.11b
Safety gauge case.

Sensing Element The elastic pressure-sensing element in the gauge is exposed to the process pressure, and there is a possibility of rupturing this element due to overpressure. Cases are available with various degrees of safety. Almost all industrial gauges are provided at least with a blowout disk that allows the internal pressure to escape. For severe or dangerous services, the solid-front design is recommended. Here, an integrally cast solid wall separates the dial and lens from the sensing elements, and a safety blowout disk covers the entire back of the case (see Figure 5.11b). The disk is gasketed and spring-mounted so that it releases internal pressures as soon as they reach about 1 PSIG (6.9 kPa). As an additional convenience, the full-area disk provides quick access to the element and gauge movement for inspection, recalibration, or repair without need to remove the dial.

Safety Features Figure 5.11c illustrates some additional safety features, such as magnetic coupling between sensor and pointer and an internal pressure relief valve. The sensor in the gauge is a Bourdon tube, available with ranges and characteristics listed in Table 5.4d.

The process connections of most gauges are either 1/4 or 1/2 in. (6.3 or 12.5 mm) in size and are located on either the back or the bottom of the case. Special connection sizes and locations are also available.

Dials and Pointers

Gauge dials are made of steel, brass, aluminum, solid plastic, or laminated plastic, with black graduations on white background or in other color combinations. Numerals are placed at the major graduations. The number of minor graduations usually conforms to gauge inaccuracy. For example, a 1000 PSIG (6.9 MPa) gauge with ±1% inaccuracy will have minor graduations at 20 PSI (138 kPa) intervals. On precision gauges, the major graduations are placed on the inner circle and the subdivisions on the outer circle for easier reading.

To eliminate parallax error, one of the following designs can be considered: raised dial, use of split pointer, or use of mirror ring.

For improved readability, gauges are available with 360 or 720 degree dials. For example, on an 8 1/2 in. (212.5 mm) dial with two revolutions corresponding to full-scale reading, the actual scale length is 45 in. (1125 mm). Another common method of improving readability is the use of suppressed scales, which, instead of being zero-based, are selected to cover ±50% of the average operating pressure.

The pointer adjustment methods are a function of gauge quality. On economy designs, the pointer is fixed, so that the hub has to be lifted from the shaft for adjustment and then repositioned. The standard industrial gauges are furnished with adjustable pointers with friction fit between pointer and shaft. Pointer adjustment is made by turning the hub while the shaft is firmly held. Precision or test gauges are furnished with micrometer pointer adjustment.

Maximum Pointer When it is desired to have a permanent indication of the highest pressure reached, a *maximum* pointer can be added to the gauge. This pointer is useful, for example, for indicating the maximum pressure reached before a burst disk or a safety valve relieved the system. The maximum pointer can be manually reset by the operator. On some installations it is desirable to provide a set pointer, which is permanently positioned for the operator's information at the normal operating pressure desired.

Digital Displays Pressure gauges are also available with digital displays, as shown in Figure 5.11d. The sensors in these units are electronic, such as semiconductor strain gauges. The electric power supply is usually 129 V AC or a 9 V battery. Due to the low power consumption, the battery life in these units can reach 5 years. The 4-digit LCD displays are usually 0.5 in. (12 mm) high and are accurate to 0.25 to 1% of full scale.

DIAPHRAGM-TYPE VACUUM GAUGES

The diaphragm sensors discussed in connection with Figure 5.5e are also used as elements in direct-reading vacuum gauges. The diaphragm gauge indicates the pressure difference between the process vacuum and the fully evacuated reference chamber. A thin, copper beryllium diaphragm isolates the reference chamber from the process, and the diaphragm movement is a measure of absolute process pressure. Mechanical linkage is used to transmit diaphragm motion to scale readout. The measurement is independent of atmospheric pressure variations.

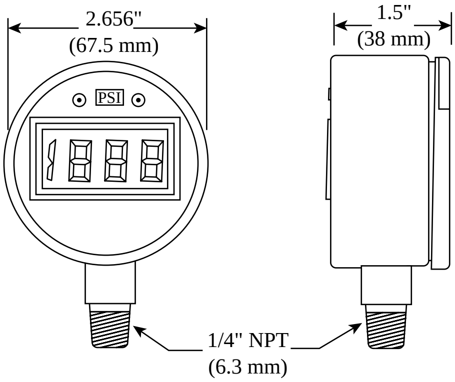

FIG. 5.11d
Battery-operated digital pressure gauge. (Courtesy of PSI-Tronics, Inc.)

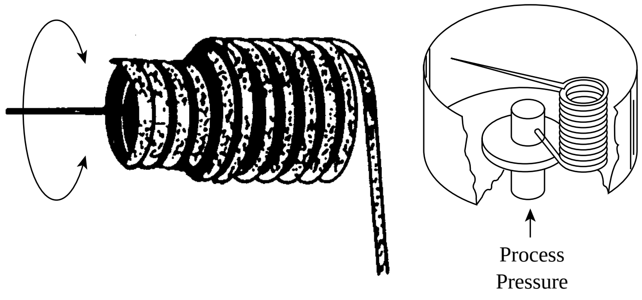

FIG. 5.11e
Gearless gauge movements give longer life and are better suited for heavy-vibration service.

The scale is nonlinear and is expanded for precise reading below 50 mmHg (6.7 kPa) absolute. Above 50 mmHg, the scale permits rough readings only. The full-scale range is 0.1 to 760 mmHg (0.013 to 100 kPa) on a scale length of approximately 8 in. (200 mm). The unit can tolerate overpressures up to 7 PSIG (48 kPa).

When the diaphragm vacuum gauge is considered for corrosive service, a purge flange accessory is recommended for installation between the gauge and the process. A small, controlled quantity of atmospheric air (or the protective gas) is fed through the purge flange into the process. The purge flow is adjusted to displace all corrosive gases and to prevent their diffusion into the gauge. Care should be taken in selecting the proper dimensions, so that the pressure drop through the purge flange will not affect the reading accuracy.

SPECIAL FEATURES

Illumination

When it is desired to read the pressure from a considerable distance, the gauge dial can be illuminated. These dials are normally jet black with white numerals and graduations. The translucent glass dial is illuminated by a number of electric lamps arranged in the case to eliminate all shadows. The lamps can provide standard white or ultraviolet (black) light, and the pointers and graduations can be phosphorescent.

Temperature Compensation

On high-precision gauges, it is necessary to compensate for ambient temperature variations. Temperature changes affect the modulus of elasticity of the sensing element and also cause thermal growth of the linkage members. Compensation is achieved by inserting a bimetallic bar into the linkage between elastic element and the gauge movement.

Duplex and Differential Gauges

When it is desired to indicate two related process pressures on the same dial, duplex gauges can be used. These consist of two independent sensing element, movement, and pointer assemblies. When the differential between two pressures is of interest, a single pointer is available. Differential gauges are available with predetermined or interchangeable high- and low-pressure connections to real differentials in both directions. When severe vibrations exist, the gearless gauges can be considered (see Figure 5.11e).

TABLE 5.11f
*Classification of Pressure Gauges According to Their Inaccuracy**

Accuracy Grade	Permissible Error (±Percent of Span) (Excluding Friction)			Maximum Friction (Percent of Span)	Minimum Recommended Gauge Size (270 deg. Dial Arc)
	Lower $^1/_4$ of Scale	Middle $^1/_2$ of Scale	Upper $^1/_4$ Scale		
4A	←	0.1	→	[Note (1)]	$8^1/_2$
3A	←	0.25	→	0.25	$4^1/_2$
2A	←	0.5	→	0.5	$2^1/_2$
1A	←	1.0	→	1.0	$1^1/_2$
A	2.0	1.0	2.0	1.0	$1^1/_2$
B	3.0	2.0	3.0	2.0	$1^1/_2$
C	4.0	3.0	4.0	3.0	$1^1/_2$
D	5.0	5.0	5.0	3.0	$1^1/_2$

*From Reference 1.

Note: (1) Grade 4A gauges must remain within specified tolerance before and after being lightly tapped.

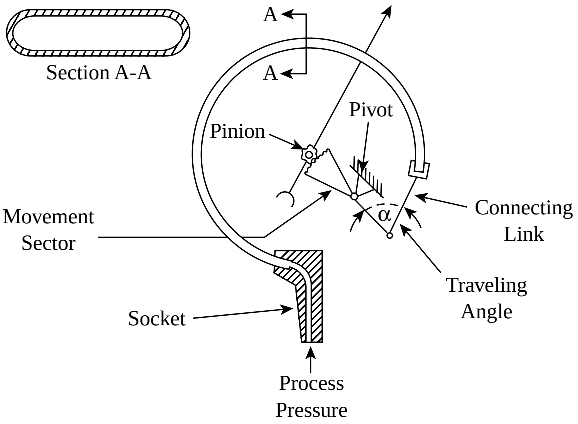

FIG. 5.11g
Traditional pressure gauge design involves many moving parts and therefore they tend to be high maintenance devices.

Failure Causes and Reliability

Table 5.11f provides a summary of the permissible errors of the various grades of pressure gauges. In addition to the precision of pressure gauges, another important feature is their reliability and life span.

The C-Bourdon movement illustrated in Figure 5.11g is a complicated and delicate mechanism consisting of many moving parts: gears, links, pins, and cams. The low reliability and high maintenance of such designs is in contrast with the simplicity of the single Bourdon coil illustrated in Figure 5.11e. Such single-element movements (sometimes constructed of Inconel) provide rugged reliability under vibrating process conditions.

Another frequent cause of pressure gauge failure has been the condensation of ambient humidity inside the case. Such condensation can contribute to corrosion and also to mechanical damage due to freezing in the winter. The liquid (usually glycerin) filling in pressure gauges serves not only to dampen pointer vibration, but also to eliminate the potential for the condensation of ambient humidity by keeping out ambient air. The combination of using single-element Bourdon-coils and providing liquid fillings has contributed to improved reliability and reduced requirements for pressure gauges maintenance.

CONCLUSIONS

Much has been written on the subjects of pressure gauge design, ranges, calibration, and test procedures.[1] The data in Table 5.11f is taken from the American Society of Mechanical Engineers and describes the accuracy grade classifications used in connection with pressure gauges.

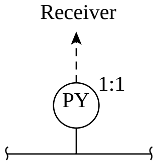
5.12 Pressure Repeaters

B. G. LIPTÁK (1982, 1995, 2003)



Flow Sheet Symbol

Design Variations:	A. Booster relays B. Flange-mounted repeaters C. Button-diaphragm repeaters
Pressure Range:	A. Up to 100 PSIG (6.9 bars) B. Vacuum to 100 PSIG (6.9 bars) C. 1000 to 10,000 PSIG (69 to 690 bars)
Operating Temperatures:	A. Up to 180°F (82°C) B. Up to 375°F (190°C) for diaphragm and up to 600°F (316°C) for bellows design C. Up to 800°F (430°C)
Materials of Construction:	A. Brass, stainless steel, and neoprene B. Wetted parts can be 316 stainless steel; Monel; Hastelloy; tantalum; or coated by Kel-F, Teflon, or Polyphenylene sulfide C. 316 stainless steel wetted parts
Inaccuracy:	A. 0.5 to 5% of repeated pressure B. 0.01 to 0.1 in. H_2O (0.36 to 3.6 Pa)/PSIG repeated. A 100°F (55°C) shift in ambient or operating temperature can result in added error of 1 in. H_2O (249 Pa) C. 1.0% of full scale
Costs:	A. $75 to $250 B. $500 and up depending on materials of construction C. $1000 and up depending on construction
Partial List of Suppliers:	ABB Inc.-Instrumentation (B) (www.abb.com/instrumentation) Fisher Controls (B) (www.fisherregulators.com) Foxboro-Invensys (A,B) (www.foxboro.com/level/acc-repeat-seals) Moore Products, now part of Siemens Inc. (www.sea.siemens.com) Rosemount Div. of Emerson (C) (www.rosemount.com) Siemens Energy and Automation (B) (www.sea.siemens.com)

Pressure repeaters are used to repeat either the pressure of an instrument air signal or to repeat the process pressure with an air signal of equal pressure or vacuum.

BOOSTER RELAYS

When an instrument air signal is being repeated, the device used is called a booster relay. Its purpose is to provide a higher airflow at the same pressure as the input signal (Figure 5.12a). In the design shown, the input pressure acts on the upper diaphragm. The force, which results from the dead-ended application of the input pressure, is balanced by the output pressure. This force is acting on the effective area of the lower diaphragm. If the input pressure rises, this opens up the pilot valve, which then admits more supply air to rebalance the booster.

FLANGED REPEATERS

Figure 5.12b shows a bellows-type pressure repeater. In this design the process pressure acts on the outside of the bellows, and is balanced by the repeated air pressure on the inside of the bellows. This design is capable of repeating pressures up to 200 PSIG (13.8 bars) and can operate at process temperatures from −60 to 600°F (−51 to 316°C). As the airflow through this unit is very low, a booster relay is usually added,

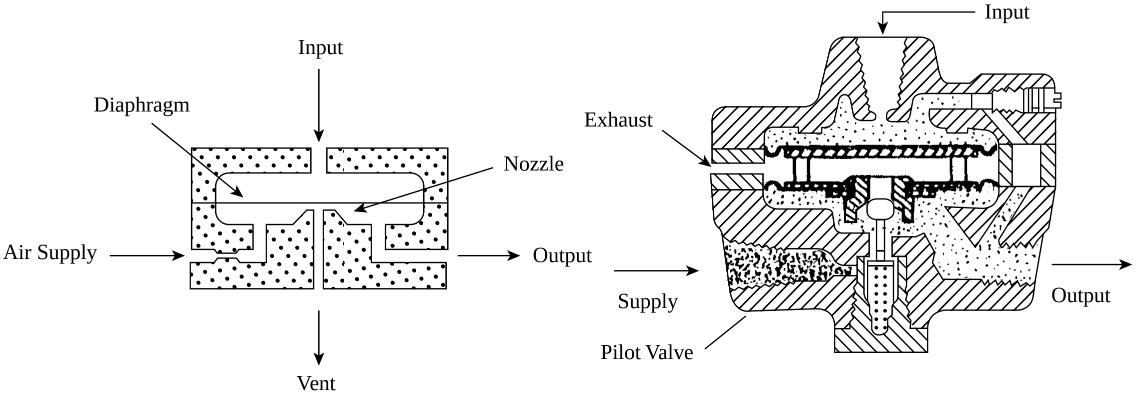


FIG. 5.12a
The configuration of a 1:1 repeater or booster relay. The low flow design on the left does not have a pilot valve; the high flow (up to 10 SCFM or 300 lpm) design does. (Courtesy of Moore Products Co.)

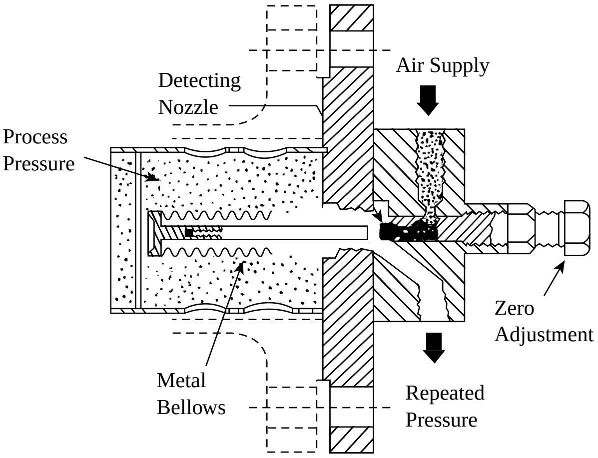

FIG. 5.12b
Bellows-type flanged pressure repeater. (Courtesy of Moore Products Co.)

when the output signal is not dead-ended. As shown in Figure 5.12b, the zero output is adjustable. The flange is available in either steel or stainless steel construction.

FORCE BALANCE PRESSURE REPEATERS

Both the flat and the extended diaphragm differential pressure (d/p) transmitters are available as repeaters, and they can be used to repeat both positive and vacuum pressures. The basic design features for these units are the same as those of their transmitter versions.

Figure 5.12c illustrates the operation of the positive pressure repeater, which can reproduce process pressures up to 100 PSIG (690 KPa) with an accuracy of about 0.1 in. H_2O (3.6 Pa)/PSIG repeated. To repeat higher pressures, a high-pressure relay, which can be obtained on special order, is required. This device is very similar to the transmitting unit, except that the feedback from the relay is piped to the low-pressure side of the d/p cell instead of to the feedback bellows, which have been eliminated. The relay itself is modified for the higher operating pressure and the capsule filling is different, but otherwise the repeater is identical to the transmitter.

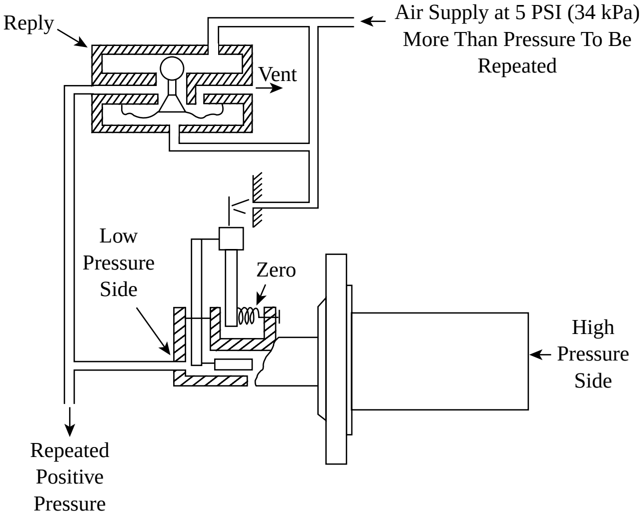

FIG. 5.12c
Extended diaphragm positive pressure repeater.

The operation of the unit is as follows: An increase in the process pressure is detected by the high side of the diaphragm capsule, transmitting additional force to the force bar. This in turn causes the nozzle to be covered by the flapper, which in turn increases the back pressure to the relay. The relay responds to this by restricting the vent connection and opening the air supply to the relay outlet. This increased relay output pressure is then sent to the low-pressure side of the d/p cell diaphragm capsule. When the pressures on the high and low side are equal, the flapper is repositioned in relation to the nozzle in its throttling band and remains in that position until the process pressure changes again. The air signal that is sent to the low-pressure side of the capsule is the same as the process pressure.

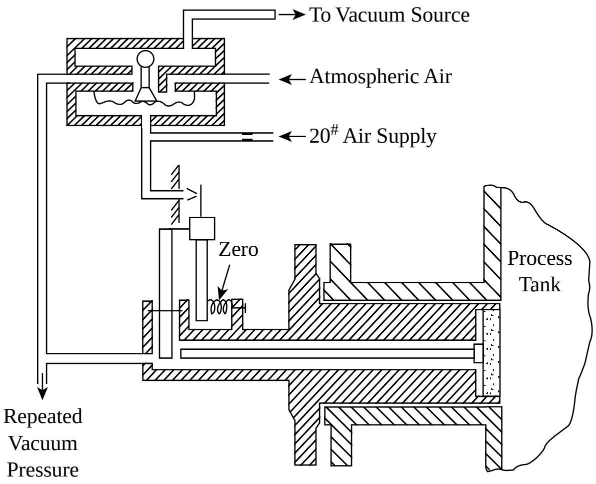

FIG. 5.12d
Extended repeater for vacuum service.

Vacuum Repeaters

When it is desired to repeat vacuum instead of positive pressures, two techniques can be employed. One involves the use of a suppression spring, and the other is an external vacuum source (Figure 5.12d).

The methods of using range depression (or suppression) springs have already been illustrated in Figure 3.6o. For example, if the suppression spring is set for 16.5 PSI (114 kPa), the output signal from the repeater will be the sum of the pressure sensed by the high-pressure side of the capsule and the setting of the suppression spring. Therefore, with the above setting, the output signal from the repeater will be 16.5 PSI higher than the pressure of the process vapors. If the process is at atmospheric pressure, the output is 16.5 PSIG, and if it is full vacuum, the output is 1.5 PSIG (10 kPa). By the use of this bias, the need for a vacuum reference source is eliminated.

With a reference vacuum source that is at least 2 in. of water column lower than the minimum absolute pressure to be repeated, the design illustrated in Figure 5.12d can be considered. This unit incorporates a special vacuum relay. When the absolute pressure in the tank increases, a force is exerted on the force bar. This tends to draw the flapper away from the nozzle, causing a reduction in the pressure on the relay diaphragm. This moves the ball down, closing off the vacuum supply and opening the connection to the atmosphere. The net effect is an increase in the relay output pressure, which is piped to the low-pressure side of the diaphragm capsule to balance the equal pressure on the process side.

When the absolute pressure of the process decreases, the opposite sequence of events takes place; namely, the force bar tends to cover the nozzle, which increases the pressure on the relay diaphragm, pushing the ball up, thereby closing the connection to the atmosphere and opening it to the vacuum source. The net effect is a lowering of the relay output pressure, which then matches the lower process pressure on the other side of the capsule.

BUTTON-DIAPHRAGM REPEATERS

These instruments have been developed for the plastic extrusion and synthetic fiber industries, in which high pressures and temperatures are encountered together with a need to eliminate dead-ended cavities to prevent plugging.

Figure 5.12e illustrates a button diaphragm that operates on a direct force balance principle. Basically, this is a pressure repeater that generates an air signal that is about 1/200 of the process pressure. The main components of the unit are the sensing and balancing diaphragms connected by the force bar and the regulating valve.

The process pressure acting on the sensing diaphragm is in force balance with the air output acting on the balancing diaphragm. The air output is proportional to the process pressure by the inverse ratio of the two diaphragm areas. When the process pressure increases, the measuring diaphragm raises the force bar, thereby opening the regulating valve to the air supply. This causes a corresponding increase in the air output signal, which rebalances the system.

The unit is available with ranges from 0–150 PSIG to 0–10,000 PSIG (0–10 MPa to 0–69 MPa) and can be used on process temperatures up to 800°F (430°C). The temperature effect is relatively small, ±0.5% of span/100°F (56°C) change, and inaccuracy is 1/2 to 1% of full scale. The wetted parts are made of 316 stainless steel, and the button diaphragm requires a process connection size of only 1/2 in. (12.5 mm).

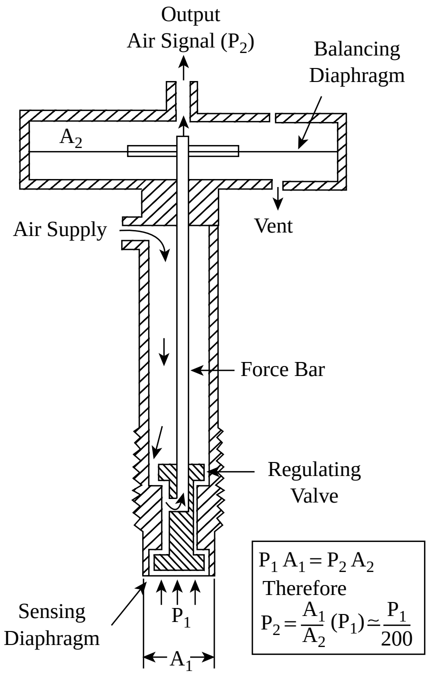

FIG. 5.12e
Button-diaphragm repeater.

PRESSURE REPEATER APPLICATIONS

When detecting the level in pressurized vessels, the vapor space pressure must be connected to the low side of the d/p cell to serve as a reference. On hard-to-handle materials, a one-to-one pressure repeater may be used to provide this reference and simultaneously to isolate the d/p cell from the process. Repeaters develop an air output pressure, equal to the vapor space pressure. They are inexpensive, but their accuracy is limited. The error in the repeated output pressure increases as the repeated pressure rises. At a pressure level of 40 PSIG (0.27 MPa), the error is 2 in. (51 mm) H_2O; at a pressure level of 400 PSIG (2.7 MPa), the error is 20 in. (508 mm) H_2O. Obviously, errors of this magnitude are not acceptable for most process level measurements.

The repeaters discussed in connection with Figures 5.12c and 5.12d are modifications of the d/p cell and are available with a flat or extended diaphragm. Designs are available for vacuum and for positive pressures of up to 150 PSIG (1 MPa). Figure 5.12c illustrates the operation of the positive pressure repeater, which can reproduce pressures from 5 to 35 PSIG (0.35 to 2.4 bars) with an inaccuracy of 0.1 in. H_2O/PSIG repeated. A high-pressure relay is required when the pressure to be repeated is above 100 PSIG. This device is similar to the d/p transmitter except that feedback from the relay is piped to the low-pressure side of the d/p cell rather than to a bellows.

Repeating a Vacuum

When it is desired to repeat vacuum instead of positive pressure, either a suppression spring or an external vacuum source can be applied. The range suppression (or depression) spring is illustrated in Figure 5.6e. If the suppression spring is set for 16.5 PSI (114 kPa), the output signal of the repeater will be the sum of the pressure sensed by the high-pressure side of the capsule plus the setting of the suppression spring. In other words, the output signal from the repeater will be 16.5 PSI (114 kPa) higher than the pressure of the process.

If the process is at atmospheric pressure, then the output will be 16.5 PSIG (114 kPa); if it is at full vacuum, the output will be 1.8 PSIG (12.4 kPa). By the use of this bias, the need for a vacuum reference source is eliminated. The bias added in the repeater is eliminated at the d/p cell by proper setting of its suppression spring.

It should be noted that this approach to repeating vacuum pressures is rather inaccurate as it is referenced to the barometric pressure, which can vary by as much 1 in. Hg (13.6 in. of H_2O, or 0.34 m of H_2O). When a reference vacuum source is available that is at least 2 in. (50 mm) of water column lower than the minimum process pressure to be repeated, the design with the special vacuum relay illustrated in Figure 5.12d can be considered.

Level Measurement Applications

Figure 5.12f illustrates two versions of the continuous level detector, both limited to atmospheric tanks, and to applications where low cost is more important than quality or accuracy of measurement. The diaphragm box unit, shown on the left side of the sketch, is similar in operation to the previously discussed riser pipe diaphragm switches, except that the diaphragm isolates the captive air from the process fluid. The unit consists of an air-filled diaphragm box connected to a pressure detector via capillary tubing. As the level rises above the diaphragm, the liquid head pressure compresses the captive air inside. The air pressure in the capillary tubing is sensed by a pressure element and displayed as level indication.

A one-to-one pressure repeater is illustrated on the bottom part of Figure 3.12f. This unit is submerged in the vessel; the static head of the liquid exerts an upward force on the diaphragm. This upward force increases as the level rises and is opposed by the air supply pressure on the other side of the diaphragm. The force due to rising level moves the diaphragm toward a bleed orifice, restricting its flow to atmosphere and causing the air pressure to build up until it equals the static head pressure. When the forces on the two sides of the diaphragm are equal, the unit is in equilibrium.

The speed of response of the unit is changed by an adjustable restriction, which, if opened, will increase sensitivity by allowing more air to flow onto the diaphragm. Air supply to the unit should be regulated at a pressure of

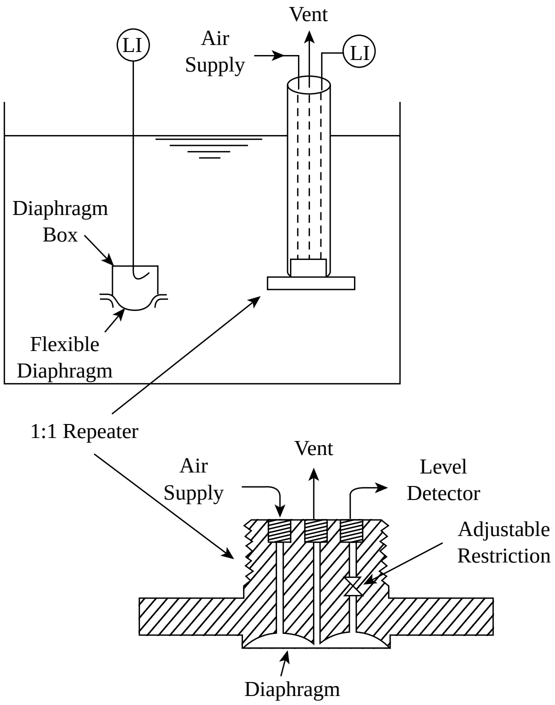

FIG. 5.12f
Diaphragm-type repeaters for continuous level detection.

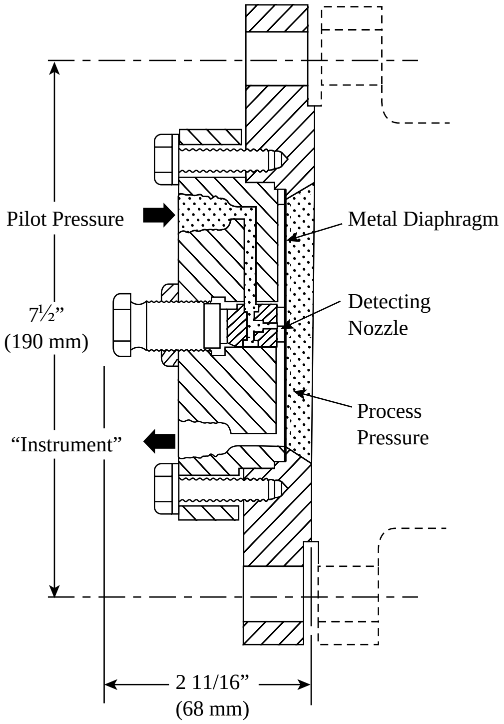

FIG. 5.12g
Tank nozzle mounted pressure repeater.

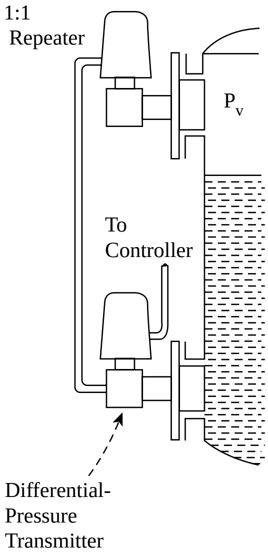

FIG. 5.12h
The vapor pressure (Pv) in the process vessel is repeated and is sent to the low pressure side of the d/p transmitter in the form of a clean and cold air signal.

3 to 5 PSIG (0.2 to 0.3 bars) in excess of the maximum hydraulic head to be repeated.

The pressure repeater can be submerged, as shown in Figure 3.12f, or mounted on a nozzle near the bottom of an atmospheric tank (Figure 3.12g). These flange-mounted units are available with stainless steel diaphragms and steel or stainless steel bodies. They can operate with up to 160 PSIG (11 bars) air supply and can repeat hydrostatic pressures up to within 5 PSI (0.35 bars) of the air supply pressure. The air consumption of these repeaters is under 0.2 SCFM (5.7 lpm).

In pressurized or evacuated tanks, when it is desirable to seal the process vapors inside the vessel, pressure repeaters can serve that purpose. Figure 5.12h illustrates how the extended diaphragm type pressure repeaters (Figures 5.12c and 5.12d) can complement the d/p transmitters in such level measurement applications.

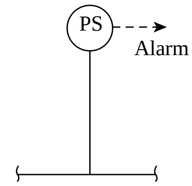
5.13 Pressure and Differential Pressure Switches

B. G. LIPTÁK (1969, 1982, 1995, 2003)



Flow Sheet Symbol

Design Pressure:	Up to 20,000 PSIG (138 MPa)
Operating Temperatures:	Usually kept near ambient by the use of syphons or chemical seals. Ambient limits: –4 to 140°F (–20 to 60°C). Maximum Fluid temperatures: with Buna-N, 180°F (82°C); with Viton, 400°F (205°C); with stainless steel, up to 750°F (399°C).
Materials of Construction:	Wetted parts can be aluminum, bronze, brass, 303 or 316 stainless steel, Monel, Teflon, Buna-N, Viton, or neoprene
Set Point Repeatability:	0.5 to 2% of full scale
Ranges:	From 0.1 in. H_2O to 12,000 PSIG (25 Pa to 83 MPa)
Differentials:	Fixed or adjustable. Fixed differentials are preset to about 2 to 5% of range. Adjustable differentials can be set from a couple of percent up to full scale.
Costs:	From $25 to $500. For example, a NEMA l, general-purpose, SPDT, UL-listed switch with aluminum stem and Buna-N diaphragm costs about $75; a NEMA 4, watertight, SPDT, UL-listed switch with stainless steel stem and diaphragm costs about $100; an explosion-proof, UL-listed unit, having 2 SPDT switches, aluminum housing, Teflon diaphragm, and stainless steel wetted parts, costs about $300. Extras, such as a calibrated set point scale, external setting dial, adjustable differential, or local indication, add to the cost.

Switches are point-sensing safety devices, serving to actuate alarms or initiate safety interlocks. In this section, both pressure switches and differential pressure (d/p) switches are discussed. Pressure switches detect a single process pressure and energize an electric circuit when that pressure has reached its set point. In case of d/p switches, the difference between two process pressures is being monitored and the switch is actuated if that difference reaches the preset limit.

PRESSURE SWITCH FEATURES

Features and Configurations

Pressure switches are used to energize and deenergize electrical circuits as a function of the relationship between the process pressure and a predetermined set point. Figure 5.13a shows some of the typical electrical contact configurations

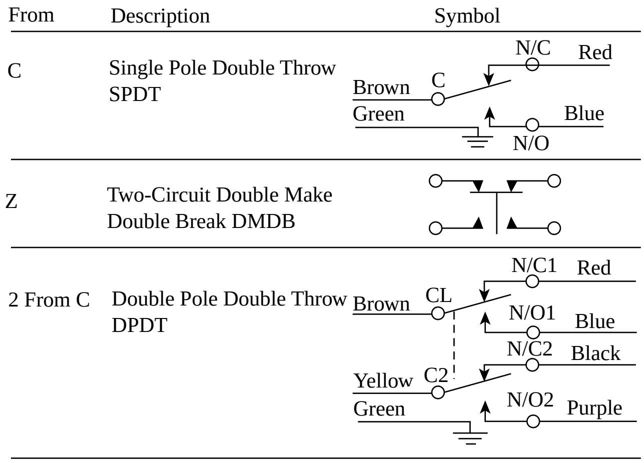

FIG. 5.13a
Standard electric contact configurations used in pressure switches.

and the standard wire colors used. The contacts are designated as normally open (N/O) and normally closed (N/C). In case of a single-pole-double-throw (SPDT) switch, as the process pressure or d/p changes, the normally closed (N/C) contact opens and the common (C) side of the switch is closed to the contact designated as normally open (N/O).

The electrical rating of pressure switches at 115-V operating level varies from 0.3 to 15 A, on AC or DC circuits. Generally, the dual control and the fixed differential switches have the lower ratings, and the double-adjustment units have the higher ratings. The available circuit arrangements are very flexible. Some of the standard arrangements include the single-pole-single-throw (SPST), SPDT, and the double-pole-double-throw (DPDT) designs, but units are available with up to four poles (Figure 5.13a).

Pressure switches are available to detect absolute, compound, gauge, and differential pressures, with inaccuracies up to ±1/2% of span. The sensing elements can be bellows, bourdon tubes, diaphragms, or other elastic sensors, which have already been discussed in Sections 5.3, 5.4, and 5.5. In addition, some designs utilize sealed piston or Belleville disc springs for their operation. The electric switching assemblies can be the snap-acting types, mechanical microswitches, or mercury switches. The latter has no mechanical moving parts and must be mounted level and in vibrations-free locations.

Terminology

Figure 5.13b illustrates some of the terminology used in connection with pressure switches. The pressure range within which the actuation point can be set is called adjustable range. The switch may actuate at its set point on rising or falling pressure as distinguished in the sketch. The set point is the pressure that actuates the switch to open or close an electric circuit.

The set point accuracy defines the band within which repetitive actuations will occur. Differential or dead-band is the difference between set point and reactuation point. For example, if a switch is set to actuate (close) at 100 PSIG (690 kPa) on rising pressure, it will close at that point, and when the pressure drops, it may not open again until the pressure has fallen to 95 PSIG (656 kPa). Here, the differential is 5 PSI (35 kPa). Tolerance is the repeatable accuracy of the reactuation point.

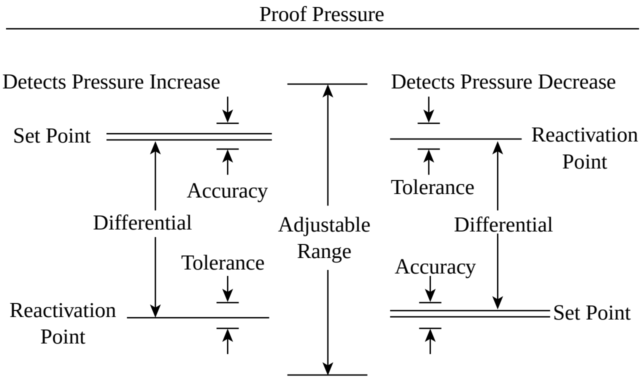

FIG. 5.13b
Pressure switch terminology.

Selection

Pressure switch elements should be selected on the basis of service life and proof pressures. Most elastic elements will have a service life of close to a million cycles, if the cycle time is not less than 5 s. If longer service life or higher cycle frequencies are required, metal fatigue tends to limit the usefulness of elastic elements, and special designs, such as sealed piston elements, should be considered.

Selection of the adjustable range for a specific installation should consider both set point actuation accuracy and the life factor. For greatest accuracy, the set point should fall in the upper half of the range, but for a most favorable life factor, it should be in the lower half. The usually acceptable compromise is to locate the set point in the middle third of the range.

It is desirable to have an external calibrated knob provided on the pressure switch for set point adjustment. Uncalibrated or internal set point adjustments are inconvenient and seldom used on industrial installations (Figure 5.13c).

Differentials

The fixed differential pressure switches are furnished with a single adjustment for set point. These units are factory-set with close differentials amounting to 1/2 to 5% of span. On double-adjustment designs, both set points and reactuation points can be independently adjusted. The maximum differential in such designs is the range of the switch, while the minimum varies between 2 and 8% of span.

Pressure switches with dual control are also available (Figure 5.13d). Here, two independent switches mounted in the same housing are responding to the same process pressure in opening or closing two independent circuits.

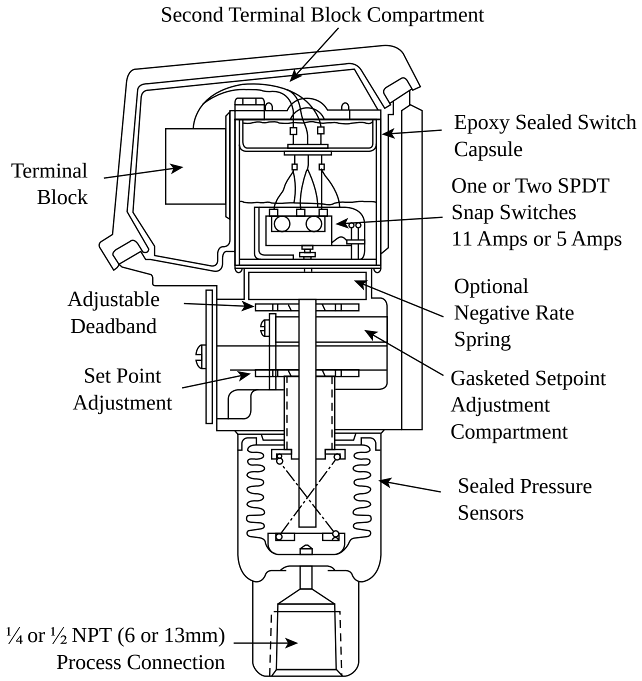

FIG. 5.13c
Set point and dead-band can be adjusted after the removal of a cover plate. Set point adjustment is done in a chamber that is separate from where the terminal block is located. Sensitive to 316 S/S welded; higher pressure. (Courtesy of United Electric Controls Co.)

Designs for Hazardous Area Applications

For pressure switches the electrical area classification is an important consideration. Table 5.13e provides some definitions for both hazardous locations and for the National Electrical Manufacturers Association (NEMA) standards. There are three standard case designs: the general-purpose (NEMA 1), the weather-resistant (NEMA 4), and the explosion-proof (NEMA 7) cases.

In some designs, the control mechanism is an integral part of the explosion-proof case, while in others, it can be removed in the field for maintenance. The set point is preferred to be externally adjustable so that the explosion-proof case does not need to be opened in order to change the set point. For added convenience of the operator, some pressure switches also provide continuous process pressure indication.

As shown in Figure 5.13f, flanged, flat-diaphragm type, explosion-proof switches are also available for those applications in which smaller pressure taps are undesirable, because they are likely to plug up.

Differential Pressure Switches

Transportation energy costs are increased when part of the energy is invested in overcoming the pressure drop across dirty filters. In order to identify the filters that are in need of cleaning, filter status indicators have been developed. One of these units is shown in Figure 5.13g. Here the pressure difference across the filter is applied to a spring-loaded piston.

In this design, the high pressure is applied to the top of a piston and the low pressure to the underside of the piston against which a spring presses. A given d/p produces a corresponding spring movement. A magnet is attached to the piston which, through a nonmagnetic body, positions a pivot magnet, thereby driving the pointer or tripping as many as four switches, or both. Since piston movement is not transmitted mechanically, there are no associated moving seals. The only seals required are the piston seals and the static seals for the end caps.

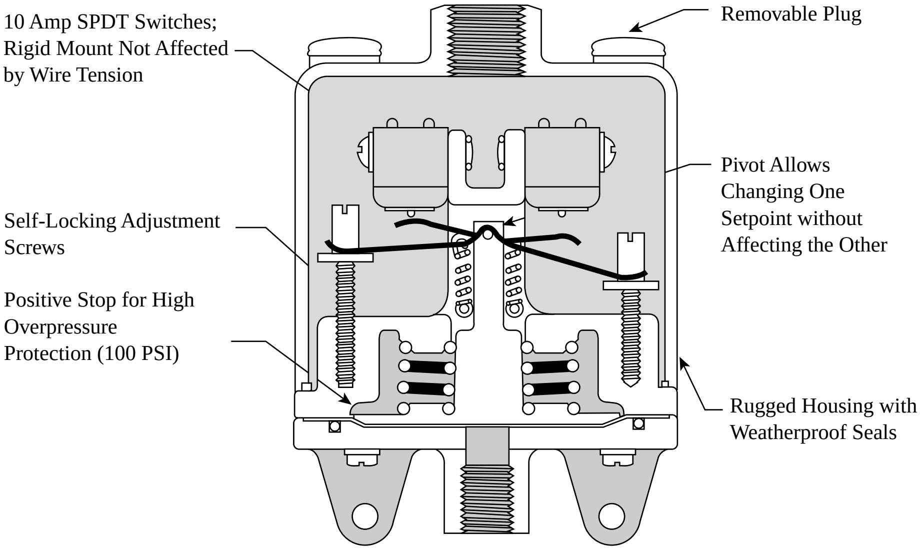

FIG. 5.13d
Two independent switches are acting in response to the same measurement. There is no interplay of dual settings; unique pivot assembly allows independent adjustment of either setting with no effect on the other. (Courtesy of Custom Control Sensors Inc.)

TABLE 5.13e
Definitions of NEMA Standards and of Hazardous Areas

NEMA Standards

Type 1	General Purpose	Indoor	Accidental contact
Type 2	Drip-proof	Indoor	Falling noncorrosive liquids and falling dirt
Type 3	Dust-tight, raintight	Outdoor	Windblown dust, water, sleet, ice-resistant
Type 3R	Rainproof, sleet/ice	Outdoor	Same as above, plus melting of sleet/ice will not damage external enclosure or mechanisms
Type 4	Watertight/dust-tight	Indoor/outdoor	Splashing water, outdoor seepage of water, falling or hose-directed water
Type 4X	Watertight/dust-tight corrosion resistant	Indoor	Same as above, plus corrosion resistant
Type 5	Dust-tight	Indoor	Dust and falling dirt
Type 6	Watertight/dust-tight	Indoor/outdoor	Temporary entry of water, limited submersion, formation of ice on enclosure
Type 6P	Watertight/dust-tight	Indoor	Same as previous, plus prolonged submersion
Type 7	Explosion proof/Class I Group D Hazardous Locations	Indoor	Hazardous chemicals and gases
Type 9	Explosion proof/Class II Hazardous Locations	Indoor	Hazardous dust
Type 11	Oiltight/Corrosion Resistant	Indoor	Oil immersion, corrosive effects of liquids and gases
Type 12	Oiltight/dust-tight	Indoor	Fibers, lint, dust and splashing, seepage, and dripping condensation of noncorrosive liquids

Hazardous Areas

CLASS I	Locations in which flammable gases or vapors are or may be present in the air in quantities sufficient to produce explosive or ignitable mixtures.
CLASS II	Locations that are hazardous because of the presence of combustible dust.
CLASS III	Locations that are hazardous because of the presence of easily ignitable fibers or flyings, but in which such fibers or flyings are not likely to be suspended in air in quantities sufficient to produce ignitable mixtures.
DIVISION 1	Locations in which hazardous concentrations in the air exist continuously, intermittently, or periodically under normal operating conditions.
DIVISION 2	Locations in which hazardous materials are handled, processed, or used, but where such materials are normally within closed containers or closed systems from which they can escape only in case of accidental rupture or breakdown.
GROUP A	Atmospheres containing acetylene.
GROUP B	Atmospheres containing hydrogen, or gases or vapors of equivalent hazard, such as manufactured gas.
GROUP C	Atmospheres containing ethyl-ether vapors, ethylene, or cyclopropane.
GROUP D	Atmospheres containing gasoline, hexane, naphtha, benzine, butane, propane, alcohol, benzol, lacquer solvent vapors, or natural gas.
GROUP E	Atmospheres containing metal dust, including aluminum, magnesium, and their commercial alloys, and other metals of similarly hazardous characteristics.
GROUP F	Atmospheres containing carbon black, coal, or coke dust.
GROUP G	Atmospheres containing flour, starch, or grain dust.

INTRODUCTION

From a working definition perspective, atmospheric pressure is considered to be 1.01 bar, 14.7 psia, 29.9 in. Hg, 760 mmHg absolute, 760 torr, 760,000 μm, or 101,300 Pa. An obvious impact of this statement is the potential for confusion due to the various unit options people have when it comes to reporting pressure. Fortunately, it is not an issue that the atmospheric pressure at sea level is not one fixed value, nor is there any deleterious impact of defining 1 atmosphere of pressure—the pressure at sea level on a clear cold nonstormy day, to be 1,013,250 dynes/cm^2. Industrial vacuum measurements are expressed in pressure units that reflect a pressure range and historic preference of the industrial practice. Thus, it is common for vacuum applications that are near atmospheric pressure to be described in inches of water or mercury. However, it is also expected that the pressure associated with a semiconductor metalization industrial application that uses physical vapor deposition be described in Pascals, microns, or perhaps millitorr units.

The reader should also be prepared to deal with pressure unit selection variations with respect to the pressure units that appear on various vacuum pressure gauges. The unfortunate realities when dealing with industrial applications that require a vacuum environment is that there is no universal vacuum gauge that will work for all applications and that different types of gauges will use different pressure units. The normal measurement ranges for various gauges are summarized in Figure 5.14a. A variety of pressure units will be used in this section.

People new to vacuum gauges and vacuum technology should also be prepared to deal with potentially confusing vocabulary when describing various pressure situations. People with different technical backgrounds may use the terms low vacuum, low pressure, and/or high vacuum, and high pressure imprecisely at different times. The reader should refer to a pressure that is very much lower than atmospheric pressure as a low pressure or a high vacuum environment. For a process situation that is very close to but below atmospheric pressure, the terms to use would be low vacuum or high pressure. In all situations, when a vacuum is referenced or described, the maximum pressure value being considered is atmospheric pressure. Therefore, vacuum chambers located in Denver, CO, or Geneva, Switzerland, have maximum pressure values that are less than 1 atm (760 mmHg).

VACUUM GAUGE CLASSIFICATIONS

There are a variety of ways to categorize vacuum gauges. Grouping gauges by operational principle is one common way. Thus, the Bourdon tube and the bellows gauge are classified as mechanical gauges, but the spinning element gauge is know as a momentum transfer gauge. Figure 5.14a provides a list of vacuum gauges and their operating range grouped by operational principle. Vacuum gauges that function because of a mechanical principle typically perform a differential pressure measurement.

Gauges that operate within the same pressure range can also be grouped together. Pirani gauges work in the same general pressure range as thermocouple (TC) gauges but the

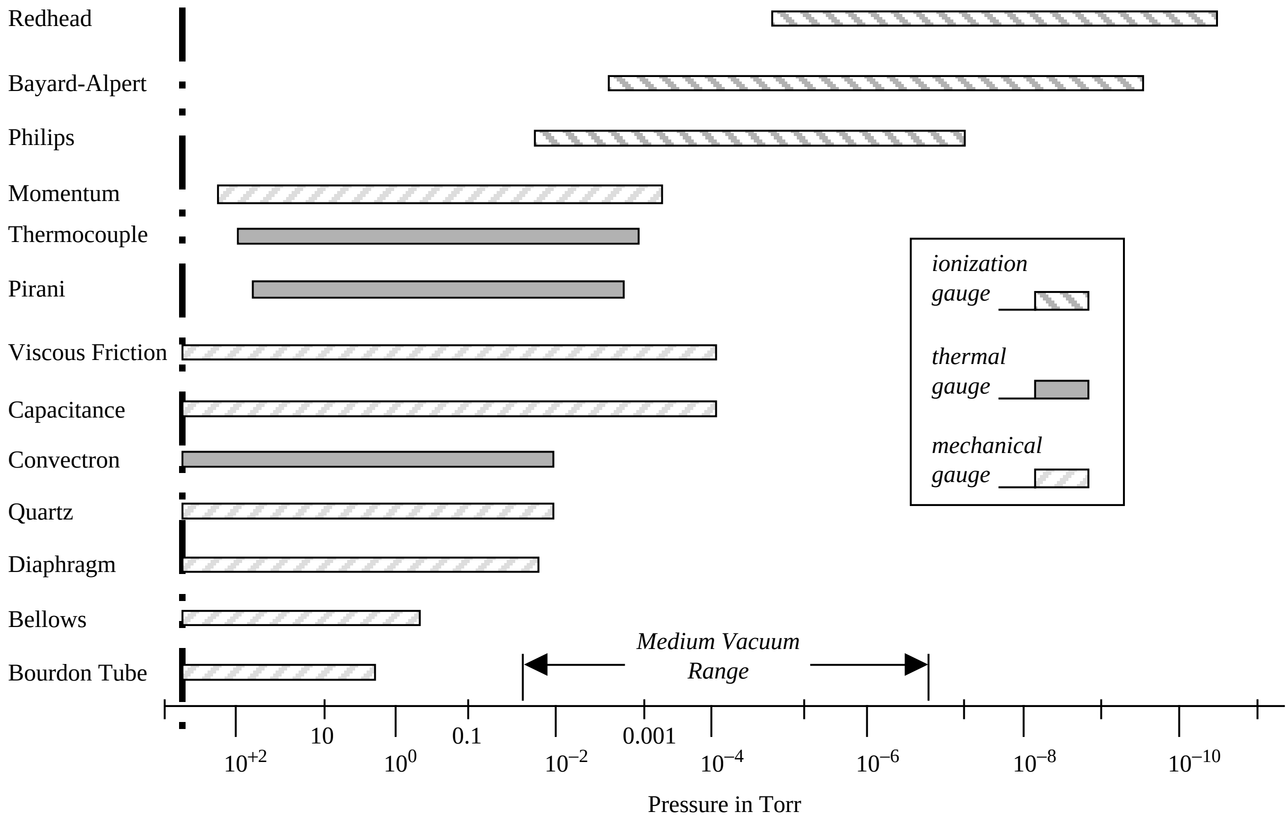

FIG. 5.14a

Ranges of the different types of vacuum gauges.

ion gauge would not be grouped with these two. A third way to categorize vacuum gauges is to identify if they actually make a direct or an indirect pressure measurement. Thus, a direct vacuum pressure measurement gauge will provide a new measurement signal value simply because the pressure being measured changes. The indirect pressure measurement gauge is actually monitoring some other parameter of the system that proportionally responds as the pressure of the system changes. A vacuum gauge that uses a TC as the pressure-sensing element is one example of an indirect pressure gauge. The increase or decrease in pressure near the thermocouple does not directly alter the electromagnetic force generated by that TC. However, that pressure change does reflect a change in the molecular population near the TC. This molecular density change affects the heat transfer near that TC, which, in turn, alters the value of voltage, measured across the TC.

Finally, it is also important to identify if the vacuum gauge performs an absolute pressure measurement. Similar to pressure gauges designed for above atmospheric pressure measurement applications, vacuum pressure gauges may provide an absolute or gauge pressure reading. Naturally, it is important for instrumentation and controls personnel to know which type of pressure measurement is being taken. The adjustment from gauge to absolute pressure is straightforward and may be provided as an electronic correction within the gauges. Elastic element based vacuum gauges are simple and inexpensive examples. If the vacuum is measured against an internal vacuum reference, the instrument is called an absolute pressure sensor; when the vacuum is compared to the barometric pressure, the instrument will measure gauge pressure and is sometimes identified as a compound pressure gauge. Examples of absolute pressure vacuum sensors include the copper-beryllium alloy bellows elements shown in Figures 5.3a, 5.3b, and 5.3c. Diaphragm-type vacuum gauges (Figure 5.5f) use hermetically sealed, thin-walled, copper-beryllium alloy, circular capsules. Similarly to the diaphragm and bellows elements, thin-walled, multiturn spiral Bourdon tube elements can also be used to measure vacuum when a second reference Bourdon tube, containing a near absolute zero vacuum, is also provided as reference.

MECHANICAL VACUUM GAUGES

Manometers

Manometers (Section 5.9) that use a liquid working fluid represent the classical differential pressure measurement device. They are simple and inexpensive and some of their design variations are also shown in Figures 5.9a, 5.9c, 5.9h, and 5.9i. The simplest design for a vacuum pressure measurement application is a U-tube with one leg connected to an evacuated reference chamber, while the other is exposed to the unknown process pressure. The difference between the two column heights indicates the process vacuum. The precision of reading the manometer is limited to about 0.1 mm when detected by the naked eye. Inclining the manometer tube and using lower-density filling fluids (low-vapor-pressure oils) can improve the sensitivity of the readout to about 10 mtorr. When the units are operated at constant temperatures and are provided with micrometer readouts, vacuums down to the 1 mtorr level can be detected. Manometers are not used in vacuum related processes that require medium to high vacuum or a clean vacuum environment. This limitation reflects the possible vaporization of the filling fluids at high vacuums or at high temperatures. Density variation and light refraction can also make it difficult to read the gauge. Although liquid manometers have limited use in today's process environment, the term manometer has become ubiquitous. It is now generally applied to vacuum gauges that make differential measurements, but do not necessarily contain a working fluid.

Capacitance Manometers

The capacitance-type pressure detectors are examples of manometers that do not have a moving fluid as a sensor element. Capacitance manometers have already been described in connection with Figure 5.7i. These gauges provide high precision differential measurements because of their ability to detect extremely small diaphragm movements. The thinnest diaphragms are capable of measurement down to the 10^{-5} torr level, while for the thicker diaphragms the measuring range can be extended to atmospheric or higher pressures.

A single capacitance manometer can report vacuum pressures values over a four- or five-decade range. Their inaccuracy in units of percent reading rises from about 0.1 to about 3% as the vacuum rises from 1.0 torr to 10^4 torr. These devices, also called micromanometers, are differential pressure detectors that use a flexible diaphragm in an electrical capacitance circuit. One plate of the capacitor is the pressure-sensitive diaphragm in the bridge circuit. The DC balancing voltage connected across the plates of the capacitor exerts an electrostatic force. When a pressure change occurs, the diaphragm deflects and the electrostatic force restores the balance that opposes the initial diaphragm movement. The magnitude of this rebalance voltage is a measure of the pressure exerted on the flexible diaphragm.

The materials used in single capacitance manometer detectors include Monel, Inconel, high-nickel alloys, and ceramics. The single-sided design illustrated in Figure 5.14b is corrosion-resistant because only one side of the diaphragm is exposed to the process vapors. Some models can operate at temperatures up to 750°F (400°C). The two main sources of error are nonlinearity and temperature effects. As an alternative to temperature compensation, the sensor can also be heated and operated at a constant temperature.

Quartz Helix Vacuum Gauge

The quartz helix vacuum gauge is an example of a mechanical vacuum gauge that makes a differential pressure measurement without a working fluid element. The quartz helix element and the mirror used to detect its deflection have already been discussed in connection with Figure 5.4i. When used for vacuum detection, two quartz Bourdon elements are formed into a helix. The reference tube contains a sealed vacuum, while the measuring tube is connected to the unknown process vacuum. The pressure difference between the two (at constant temperature) results in an angular deflection, which is detected optically. The optical readout is used to eliminate friction effects and to guarantee high resolution (about one part in 100,000). The main advantages of this detector are its precision and the corrosion resistance of quartz; however, it is an expensive gauge.

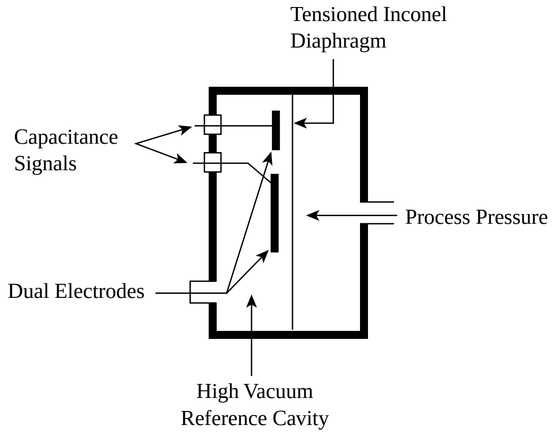

FIG. 5.14b
One-sided capacitance manometer detector can also be used on corrosive services.[1]

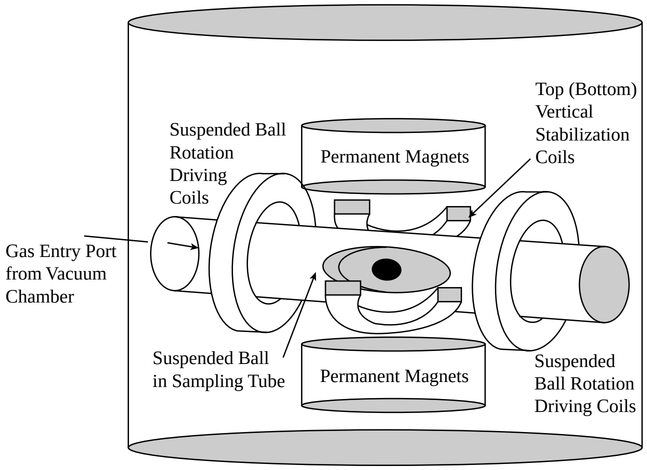

FIG. 5.14c
Spinning ball element type vacuum gauge.

Viscous Friction of Spinning Ball

At high vacuums, viscosity and friction are pressure-dependent. This instrument detects vacuum pressures down to 10^7 torr by detecting the deceleration caused by molecular friction on a levitating and spinning ball in a magnetic field. As suggested in Figure 5.14c, the vacuum is measured in this instrument by first driving the ball until it reaches a rotational speed of about 425 r/s. When the drive is turned off, the rotational speed drops as a function of the viscous friction of the process vapors. When the speed has dropped to 405 r/s, the ball is accelerated again. The pressure of the gas in the gauge is related to the time that it takes for the speed to drop from 425 to 405 r/s. As the process pressure decreases, the time needed to reach the lower rotational speed increases.

This instrument has several process advantages. Since its wetted parts are made of stainless steel, the gauge is suitable for corrosive services. It is also suited for operation at baking temperatures up to 750°F (400°C). When calibrated, the inaccuracy (uncertainty) can be as low as 1.5% of the reading. Without calibration, the uncertainty is 4% or more.

Molecular Momentum Vacuum Gauges

Molecular momentum type gauges have two basic working parts: a rotating and a restrained cylinder. The gas molecules from the vacuum chamber come in contact with the rotating cylinder (at a constant speed of 3600 rpm), experience a momentum change, and are set in motion in the direction of rotation. These molecules acquire energy from contact with the spinning cylinder, and then, in turn, strike and transfer that energy to the restrained cylinder. The pressure measurement is possible because these molecular collisions move the restrained cylinder a distance that is proportional to the energy transferred and represents a function of the number of gas molecules in that space. The number of molecules is related to the absolute pressure of the gas. The pointer attached to the restrained cylinder indicates the gas pressure on the scale, somewhat similar to the operation of the viscous drag gas density sensor in Chapter 6.

The energy transferred in momentum transfer gauges is not just related to the number of molecules (pressure) and the velocity of molecules. The molecular weight of the gas is also a factor. Thus, the full-scale range of the gauge depends on the type of gas to be detected. For air, the range is 20 to 10^{-3} mmHg (2.7 to 1.3×10^{-4} kPa), while for hydrogen, the maximum reading on the instrument is 280 mmHg (37 kPa). Thus, molecular momentum transfer vacuum gauges have to be calibrated for each application.

Molecular momentum transfer gauges give continuous direct readout, but are not usually available as a signal transmitter for remote indication or control. The inaccuracy of the unit is between ±5 and 25%, with accuracy decreasing at lower pressures. Additional inaccuracy can be caused by process temperature variations, which in the range of 50 to 100°F (28 to 56°C), can amount to 2%. External vibration in the range of 50 cps should be protected against by the use of bellows couplings on the process connection. The gauge is not damaged by exposure to atmospheric pressure, but the sample from the process has to be kept clean, free of dust, oil, or other particles.

Mechanical Linkage Vacuum Gauge

The only vacuum gauges that operate by a mechanical linkage are the ones used for vacuum measurements, such as the Bourdon gauge and the bellows gauge. The Bourdon gauge is also know as a C tube gauge and operates by the curving and uncurving of a hollow tube that is connected to the process under vacuum. The movement of this “C” shaped tube alters the position of a needle pointer connected to the end of the sensing tube by a ratchet and spring mechanism. Although inexpensive and robust, the Bourdon gauge will demonstrate a memory effect and does not fit into automated data recording or process control situations. In addition, it has a limited range and is not used in vacuum processes that operate at pressures below 1 torr.

The Bellows vacuum gauge is another example of a mechanical linkage type gauge. In this case, the bellows expands or contracts based on the pressure difference across the inside and outside of the bellows unit. The gauge readout is also the result of a mechanical interaction between the bellows and the needle pointer. These gauges do not have electronic readouts.

THERMAL VACUUM GAUGES

Heat transfer is a useful characteristic of a gas with respect to the operational basis for a grouping of vacuum gauges. If a heated element with constant power input is placed in a vacuum environment, the surface temperature of that element will be a function of the heat conductance of the process gas, which also relates to the pressure of the process gas near the heating element. Thermal vacuum gauges consist of three basic elements: a heater, a temperature sensor, and a compensator for process temperature variations. There are two basic designs, depending on the type of temperature sensor used: the resistance wire and the TC. In general, thermal vacuum gauges measure pressures down to 1 mtorr (10^{-3} mmHg, 0.13 Pa) absolute pressures. Although this limit can be extended with special designs involving special amplifiers and liquid nitrogen cooling around the gauge tube to reduce radiation losses, an ion gauge is the single gauge of choice when the pressure drops below 10^{-4} torr. Usual applications for thermal vacuum gauges include refrigeration, vacuum furnaces, freeze-drying, air conditioning, pharmaceutical productions, and the manufacture of thermal food containers.

Thermal vacuum gauges may be orientation sensitive. Once attached to the vacuum system and calibrated, the pressure readings from the gauge are dependent on that physical location and orientation. If the gauge is remounted at the same location but rotated from its original position, the gauge may need to be recalibrated. Most thermal vacuum gauge manufacturers will indicate if their gauge is position sensitive and also indicate on the gauge housing the recommended gauge orientation.

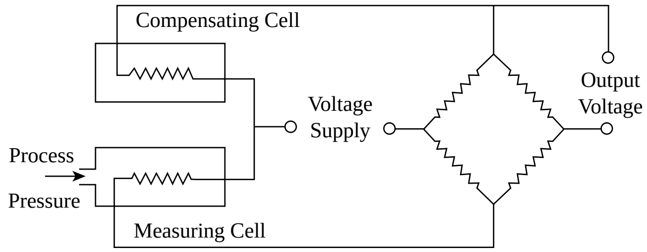

FIG. 5.14d
Resistance wire (Pirani) vacuum detector.

Pirani Vacuum Gauge

The Pirani gauge is a popular example of a thermal vacuum gauge. In this device, a constant current heats a filament that is cooled by the gas present in the vacuum environment. Since the amount of heat transferred changes with the number of molecules, the equilibrium temperature, which is detected as the resistance of the metal wire, ribbon, or thermistor element, is a function of the gas pressure near the wire. Figure 5.14d outlines the components of operation for the Pirani gauge. The heating and sensing elements are often combined as part of a Wheatstone bridge type sensing circuit. A second resistance wire, which is enclosed in a reference vacuum, is used to compensate for process temperature variations. The readout device detects the amount of current or voltage that is necessary to return the bridge circuit to balance after a change in the vacuum being measured.

The standard pressure-sensing range for a Pirani gauge is between 10^{-3} and 1 mmHg (0.13 to 133 Pa) absolute. The inaccuracy of the gauge is about 2% at the calibration pressure and ±10% over the operating range. Maximum output signal is about 0.1 mA at full-scale reading.

Pirani gauges are relatively inexpensive and convenient to use. They are not used for reliable pressure measurements higher than 1.0 torr, because at higher pressures the thermal conductivity of gases does not decrease with the decrease in pressure. The scale of the Pirani gauge is linear between 10^{-3} to about 2×10^{-2} torr. Above these pressures it becomes roughly logarithmic. The two scales, when provided, are usually calibrated in terms of air. However, the gauge is gas dependent since different gases have different thermal conductivity. Therefore, the Pirani gauge is composition-dependent and needs to be calibrated for the process gas in the application.

Pirani gauges are not highly accurate. As they depend on the detection of thermal conductivity, the surface conditions and emmissivity of the heated elements do affect the reading. As these surfaces are coated, oxidized, or carbonized, their temperatures rise and the sensor is likely to read high by as much as 2×10^{-2} torr. This represents a very large error at the low end of the pressure range. Another substantial error source is changes in the bridge voltage.

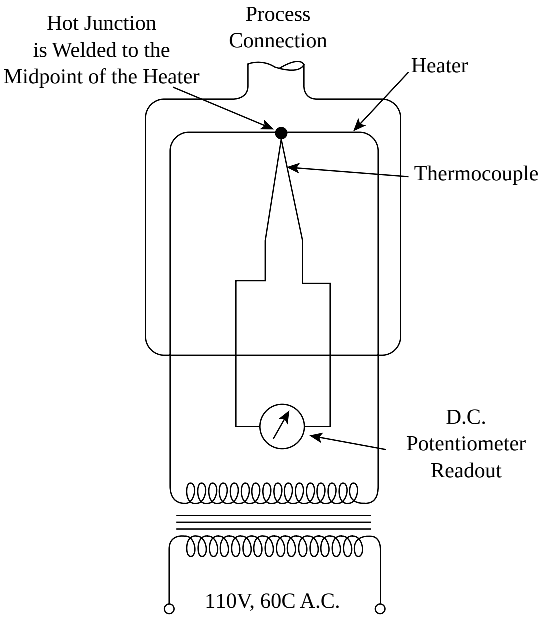

FIG. 5.14e
Single thermocouple vacuum gauge.

Thermocouple Vacuum Gauge

As shown in Figure 5.14e, the single TC detector consists of a wire heated by the passage of constant AC or DC current. A TC is welded to the center of this heated filament, thereby providing means to measure the temperature of the filament directly. An opening in the tube is provided for connection to the vacuum system being measured.

In operation, the constant current passing through the heater wire is in the order of 20 to 200 mA, and the TC sensor develops a full-scale output in the order of 20 mV DC. For any constant value of current through the filament, the temperature increases as the pressure in the tube is reduced. The temperature detected by the TC depends on the thermal conductivity of the gas surrounding the junction. For the same gas, thermal conductivity is related to pressure when the pressure is at or below 1.0 torr. Like the Pirani gauge, TC gauge response is process gas dependent and the gauge must be calibrated for specific applications.

The available readout devices are as varied as the receiving instruments that measure TC output signals. Sensitive millivolt meters and potentiometers are common choices. At higher ranges, such as 5 to 10^{-2} mmHg (665 to 0.13 Pa), dual scales are usually used, while for the standard range, 0.1 to 10^{-3} mmHg (133 to 0.13 Pa), a single scale is sufficient. The reading inaccuracy at midscale is ±2%, while ±10% covers the full range. On multistation installations, a single readout device can serve several TC gauges through a manual selector switch. Because all filaments are on at the same time, the readings are instantaneous.

The filament temperature is kept below 400°F (250°C) to reduce the possibility of the sample gases decomposing or forming a deposit on the gauge tube elements. Compensation can be provided for process temperature variations, which otherwise would introduce an error by affecting the filament temperature. This is achieved by the use of a reference gauge that has been fully evacuated and sealed. The same current and voltage are applied to both the measuring and the reference gauges. The temperature of the two heater wires is then compared, and the difference is used as a measure of process vacuum. The reference tube compensates for ambient temperature changes because the two cells are at the same temperature. Generally, the inherent low accuracy of these sensors does not make it worthwhile to compensate for ambient temperature variations.

It is also important that the filament current and voltage be carefully maintained for stable calibration. Filaments should not become dull or tarnished due to contamination because this would cause radiation losses affecting calibration. One way to overcome this problem is to precoat the filaments so that further contamination would have no effect. Unfortunately, precoating tends to impair gauge sensitivity. However, several precoated TCs connected in series, a thermopile, provide extra potential output that compensates for sensitivity losses due to filament precoating.

Thermopile Vacuum Gauge

To increase sensitivity, thermopiles can be used to detect heater temperature. A thermopile vacuum gauge is a series of TCs, and a typical design is shown in Figure 5.14f. In this design, the TCs (A and B) are heated by low-voltage alternating current so that the heater and the temperature-sensing functions are combined in the same noble (noncorrosive) metal thermopile. A change in process pressure results in a change of thermopile temperature causing a new DC output from the TCs. A third unheated thermocouple (C) is included in the circuit to compensate for operating process temperature variations. This couple is the same size as the heated ones, but it is connected in opposite polarity. A change in process temperature develops voltages in all the TCs, but the transient effects are equal and opposite in the heated and unheated elements. Therefore, compensation is achieved.

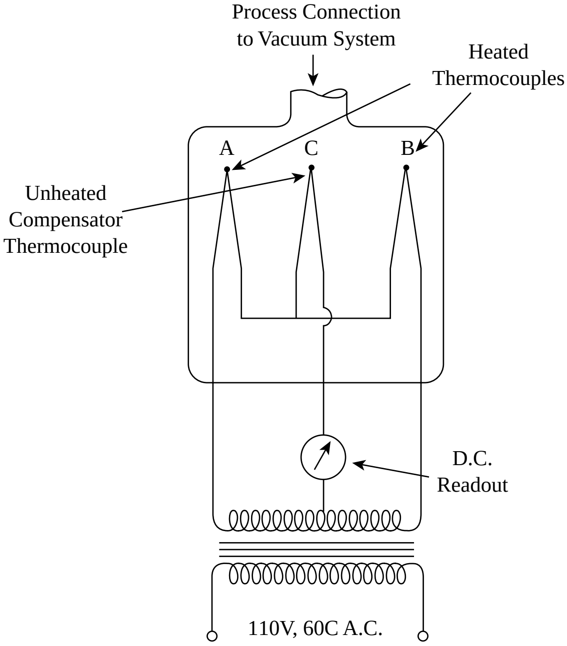

FIG. 5.14f
Multiple thermocouple (thermopile) vacuum gauge.

Thermopile vacuum gauges have the same features and accessories normally associated with a single TC gauge. However, the following additional characteristics should be noted. First, because of the noble metals used in the thermopile, oxidation of the couples does not occur. Second, the operating temperature of the heated thermopile is lower than that of the hot filament used in the single couple design. Therefore, the probability of sample gas decomposition or deposit formation is remote. Third, thermopile gauges that withstand several thousand PSIG overpressures are available. Fourth, the gauges are corrosion resistant, rugged under demanding conditions, and provide stable calibrations. The cold junctions are kept at ambient temperature by heavy mounting studs. Thus, the amplified electromagnetic force generated between the hot and cold junctions tends to be a stable signal that reflects the temperature change at the hot junctions. Finally, accurate readings are obtained in the range of 10^{-1} to 10^{-3} mmHg (13 to 0.13 Pa), but extended coarse detection is feasible over a broader range from 100 mmHg (13 KPa) to 10^{-4} mmHg (1.3×10^{-2} Pa) absolute pressures.

Convectron Vacuum Gauge

A convectron gauge is similar to thermal conductivity type vacuum detectors, except that it provides a wider (six-decade) range, from 10^{-3} to 1000 torr within a single gauge. The heat loss sensor is a temperature-compensated gold-plated tungsten wire that detects both conduction and convection cooling effects. At lower pressures (higher vacuums), it operates as a thermal conductivity vacuum gauge, while at higher pressures (in excess of 1.0 torr), it depends on convective cooling as the sensing principal. In this pressure regime, the process gas molecules are circulated in the sensor tube by gravitational forces.

In most respect, the features and limitations of convectron vacuum gauges are similar to the Pirani and TC gauges, but in addition to the extended range, there are some other notable differences. These include a lower sensor wire temperature, which is likely to reduce the coating and carbonization on the sensor wire surface. The gauge tube is stainless steel and can be baked to up to 300°F (150°C), when not operating. The maximum ambient or operating temperature is 122°F (50°C). The bridge circuit is an integral part of the gauge tube, which is vibration and position-sensitive (it must be horizontal). The gauge is calibrated for nitrogen, and must be recalibrated when used on other gases.

IONIZATION VACUUM GAUGES

Ionization vacuum detectors have been available since 1916. However, practical, reliable, and sturdy ionization vacuum gauges did not come into common use until the 1930s. Today, ionization gauges are routinely used to detect pressure levels from 10^{-4} to 10^{-9} torr. All ionization vacuum gauges detect an electric current that is generated from the ionization of the gas whose pressure is being measured. Ion gauges are distinguished by the method applied in producing the ions. To convert a gas molecule into a positive ion, an electron must be removed. If an atom or a molecule is supplied with energy equal to its ionization potential, an outer orbit electron will escape and a positive ion will be created. The approximate energy values required for ionization range from 5 to 30 eV. If this energy is supplied at a constant rate and sufficient atoms and molecules are available, the ions will be produced at a similarly constant rate. This ion stream is directed to the gauge's cathode, and the current that flows through that cathode is proportional to the pressure of the gas in the gauge. The initial ion current is also proportional to molecular weight. The ionic current generally rises with molecular weight. In any case, calibration is usually done with dry nitrogen or air. The various designs for ionization gauges can be grouped by the method used to generate and direct the ion current. One broad grouping for ion gauges includes hot cathode and the cold cathode gauges.

Hot Cathode Ionization Gauges

In the Bayard-Alpert hot cathode filament vacuum gauge illustrated in Figure 5.14g, the ionization energy is supplied by electron bombardment. The electrons are derived from thermionic emission from the hot filament. As these electrons are attracted to and passing through the helix shaped grid, they acquire kinetic energy. When the electrons finally collide with the gas molecules from the vacuum system, positive ions are produced. These ions are then attracted to the negatively charged collector electrode in the center of the grid to form an ion current. At constant accelerating voltage, the number of ions formed is proportional to the gas pressure if it is below 10^{-3} mmHg (0.13 Pa). Variations on the design include capping the end of the grid to prevent electron escape. A fine wire collection electrode reduces the x-ray-generated photo current. A spare emission filament is also often provided. At higher pressures, the relationship between plate current and pressure is not linear. This is because the mean free path becomes so short that an ionized molecule may pick up a free electron to become a molecule before it reaches the collector plate.

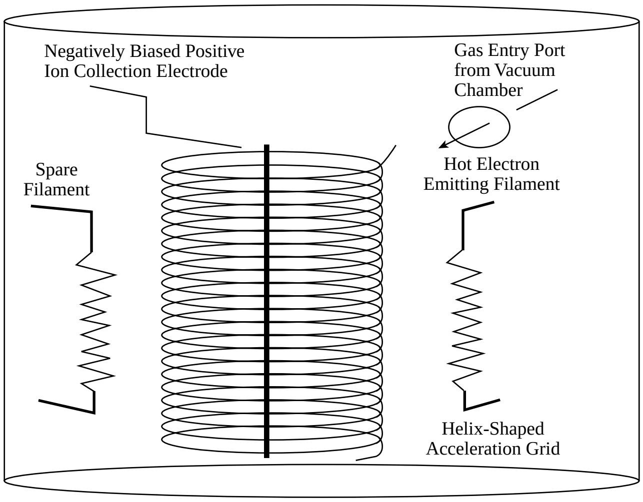

FIG. 5.14g
Hot cathode ionization vacuum gauge. (Courtesy of Bayard-Alpert.)

The accuracy of a hot cathode ionization gauge is poor because the number of gas molecules to be measured is very small. At an absolute pressure of 10^{-5} mmHg (1.3×10^{-3} Pa), the inaccuracy would be about 10%. The vacuum range detectable by the hot cathode gauge is 10^{-3} to 10^{-11} mmHg (1.3×10^{-1} to 1.3×10^{-9} Pa). The minimum span of the readout device is one decade, and it can be furnished with five or six ranges. Range switching can be automatic or manual from the instrument's front panel.

The sensitivity of the hot cathode gauge is 100 μA/μm (10^{-3} mmHg) pressure. The readout device can be combined with thermocouple readout to extend its coverage to vacuums in the range of 1 to 10^{-3} mmHg (133 to 0.13 Pa). This is a common practice, but a protective relay circuit is also furnished to prevent filament burnout by keeping it off at pressures higher than 10^{-3} mmHg. Besides multirange indicators, the readout device can provide signals for actuate electrical control and alarm circuits. When several ionization sensors are involved, the output signals can be multiplexed to reduce the number of signal detectors and pressure monitors, reducing total system cost.

The hot filament vacuum gauge provides a wide pressure reading range with fast response. Its application is limited to gases that will not decompose on the hot filament. The glass ionization tube, by its nature, is subject to mechanical damage. However, gauges for industrial process applications are commercially available. The filament current is controlled in such a way that a constant flow of electrons is emitted from it. In some designs, calibration is maintained by controlling the grid charge so that if emissivity of the filament is decreasing, the grid receives a correspondingly greater charge to maintain the entire circuit in equilibrium.

The limitations of the hot-cathode design are related to the high filament temperatures (about 4000°F, or 200°C) involved. At such temperatures, the incandescent filament tends to deteriorate and is also susceptible to chemical attack. The sorption of gas by the hot filaments and the degassing that follows is another potential error source. These effects are addressed by alternative gauge designs that use large diameter tubes and minimize in vacuum connection lengths.

As suggested above, various modified Bayard-Alpert hot cathode vacuum gauges are available from different ion gauge manufacturers. One example is the Schultz and Phelps modification shown in Figure 5.14h. This gauge covers the vacuum range of 1 to 10^{-5} torr and can be obtained in an integrated unit with the Bayard-Alpert unit, when a wider vacuum range needs to be covered.

Cold Cathode Ionization Gauges

The cold cathode vacuum gauge is a composition sensitive gauge traditionally known as Philips gauges, after its first manufacturer, or a Penning gauge after F.M. Penning, who outlined its operating principle in 1937. The basic difference between cold and hot cathode gauges is in the method by which ions are produced. In the hot filament unit, the electrons are derived from thermionic emission. In the cold cathode design, a high-potential field withdraws the electrons from the electrode surface. Because the rate of electron emission is lower in the cold cathode units, the collision frequency between gas molecules and electrons would also be lower if the electrons traveled in a straight path. To increase the path length of the electrons, a magnetic field is created around the tube to deflect the electrons. Thereby, the emitted electrons spiral as they move across a magnetic field to the anode (Figure 5.14i). This spiraling action greatly increases the electron path of travel and the corresponding chance of electron collision with gas molecules from the vacuum chamber. The overall result is greater sensitivity of the cold cathode gauge than that of the hot cathode.

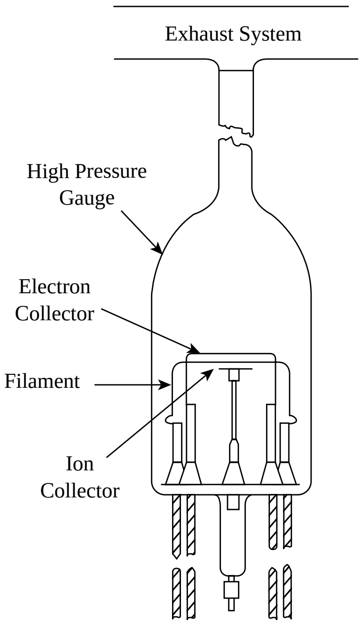

FIG. 5.14h
Hot cathode vacuum gauge. (Courtesy of Schultz-Phelps.)[2]

The inaccuracy of the cold cathode unit is about 20% at an absolute pressure of 10^{-5} mmHg (1.3×10^{-3} Pa). The gauge response is gas molecular weight dependent and its detectable vacuum range is from 10^{-2} to 10^{-7} mmHg (1.3 to 1.3×10^{-5} Pa). As with the hot cathode gauges, the minimum span is one decade and readout devices are available with one, two, or three ranges, which are selected automatically or by manual action at the front of the instrument. The gauge sensitivity is 5 mA/μm micron pressure.

There are several advantages of the cold cathode gauge relative to the hot cathode gauges. First, they cost less. Second, they are more robust and do not burn out as easily. Third, they do not subject the process gas to thermal stress. Cold cathode gauge disadvantages include lower accuracy, nonlinear output signal, and gas take-up caused by the high-voltage operation. In order to remove polymerized organic contaminants, periodic cleaning of the electrodes and the vacuum chamber is required.

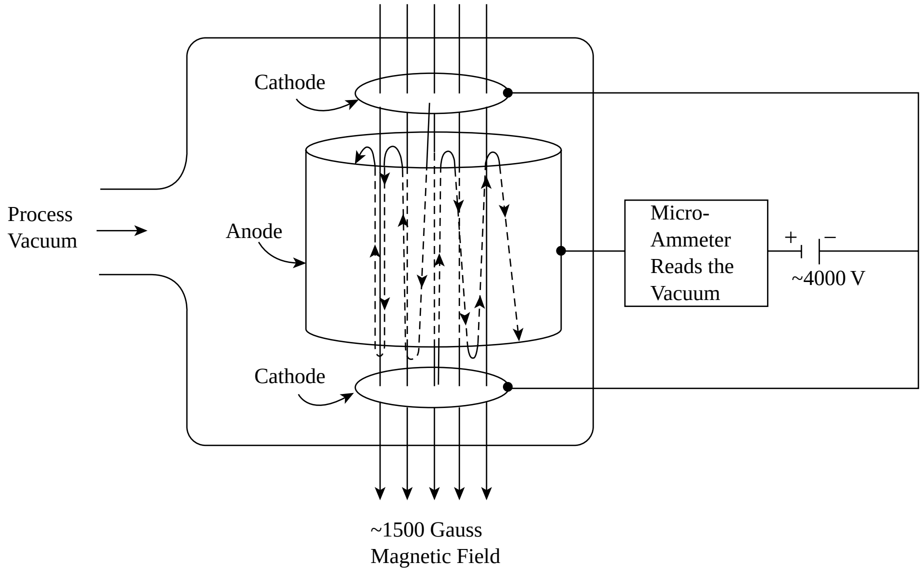

FIG. 5.14i
Philips cold cathode ionization vacuum gauge. (The electrons travel from the cathode to the anode through a path of multiple spiral oscillations which increase the opportunity for them to encounter and ionize molecules.)

Similar to the hot cathode gauge, manufacturers have offered modified designs for the cold cathode gauge. One example is a modification developed by Paul Redhead. In the Redhead gauge, a cylindrical electrode is configured around the anode that has a probe shape at the center axis. This arrangement is like an inverted magnetron: the electrons ionize the gas molecules while they are spiraling in toward the central anode, while the gas ions are collected on the cylindrical cathode surface. The Redhead gauge operates at around 5000 V in a 1000-Gauss magnetic field and can detect vacuums in the 10^{-6} to 10^{-12} torr range.

During the 1990s, a combination ionization gauge was designed. This gauge is basically a cold cathode unit but is furnished with a hot cathode serving to trigger the discharge from the cold cathode. This design extends the detectable pressure range to 10 decades, or from 10^{-4} to 10^{-14} mmHg (1.3×10^{-2} to 1.3×10^{-12}) absolute.

VACUUM GAUGE CALIBRATION

Vacuum gauge calibration is an issue for two reasons. First, a single vacuum gauge type does not work over the total vacuum pressure range. Second, most vacuum gauges do not directly measure pressure, and the pressure reading provided by the gauge is dependent on a property of the gas molecules being measured. Some common ways to calibrate vacuum gauges are provided below.

McLeod Vacuum Gauges

The McLeod vacuum detector, or barometer gauge, is the classic reference or calibration gauge. Figure 5.14j shows one version of this gauge. In this design, the unit is stationary, and a piston is used to trap the rarefied gas. The filling of the gauge with mercury is done through the process connection. This improved design does not use a dead-ended capillary, and, therefore, the problems associated with keeping the capillary clean are eliminated. The diagram on the left side of Figure 5.14j shows the unit just prior to the taking of a measurement. As the piston with micrometer adjustment is moved up, the rarefied gas is trapped when the mercury reaches point D; thus, the initial volume (V_1) is the volume between points A and D. When the instrument is connected to the vacuum system, the mercury level in the reservoir is below point D to allow trapped gases to be liberated. As the piston is moved up, the mercury fills the large bulb up to point C. At this point, a reading can be taken on the dual scale if the pressure to be detected is in the mmHg range. If the vacuum is higher, the piston is moved further up, increasing the compression ratio until the mercury reaches point B above the small bulb. In this case, the reading is taken on the micron side of dual scale.

McLeod gauges can cover the vacuum range between 1 and 10^{-6} mmHg (133 and 1.3×10^{-4} Pa). At pressures below 10^{-4} mmHg (1.3×10^{-2} Pa), the reading accuracy is limited by capillary effects. These gauges are laboratory instruments that measure on a sampling rather than on a continuous basis. They are not recommended for industrial installations.

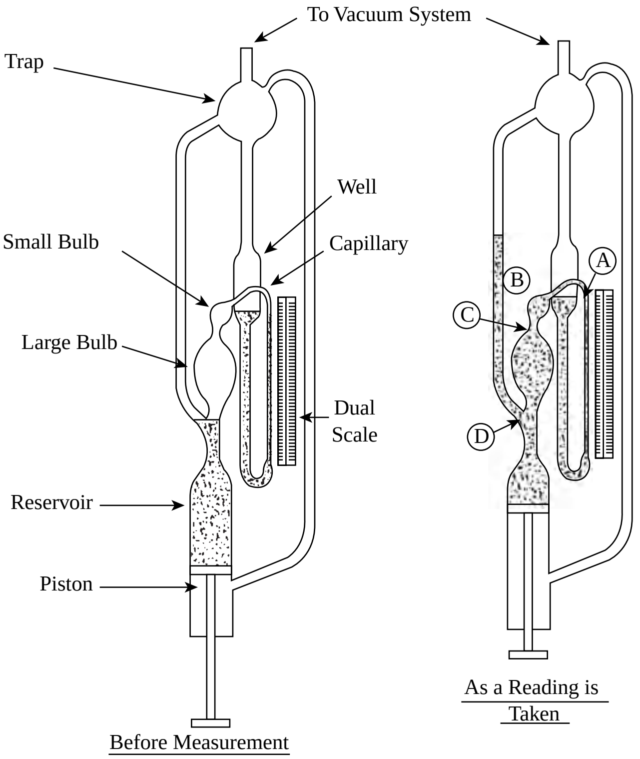

FIG. 5.14j
Piston McLeod vacuum gauge.

Calibration Reference Tubes

A relatively new method of vacuum gauge calibration involves the use of calibration reference tubes. These tubes are available from most gauge manufacturers for application with their specific gauges. These reference tubes are fundamentally evacuated, sealed vacuum tubes accurately calibrated to precisely simulate an operating pressure environment of the gauges to be calibrated. The tubes permit quick and easy gauge recalibration by simply connecting the gauge to be calibrated to the appropriate reference tube and adjusting the gauge's pressure reading to reflect the value stated on the reference tube.

VACUUM CONTROLLERS

Vacuum gauges are one part of a vacuum process instrument system. In the complete instrument system, the process vacuum pressure is compared to a desired set point value, and, if necessary, a corrective signal is sent to a final control element. The vacuum controller is the component of the system that will alter a control signal to adjust the vacuum pressure when a process disturbance occurs. Process controllers do not have to have a pressure readout system; they only require

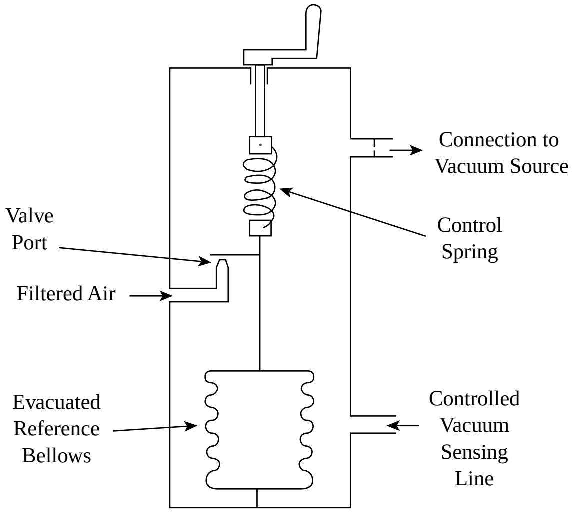

FIG. 5.14k
Aneroid manostat.

a way to determine if the current vacuum is at the desired set point condition. Three types of vacuum controllers are briefly discussed.

Aneroid Manostats

The aneroid manostat illustrated in Figure 5.14k is a self-contained bellows-type vacuum controller. The bellows are fully evacuated to provide a zero absolute pressure reference unaffected by barometric changes. The spring is temperature-compensated, and its tension is adjustable over the entire range of the controller, which is 1 to 60 in.Hg (3.4 to 200 kPa) absolute pressure. The sensitivity of setting is about 0.5 mmHg (0.07 kPa) and the inaccuracy of control is 2% of set pressure.

The aneroid manostat works at above and below atmospheric process conditions. When a below-atmospheric pressure is to be maintained, connections are made both to the vacuum source (usually a vacuum pump) and to the controlled system. The spring tension is set for the desired set pressure, and expansion or contraction of the bellows moves the valve port to control the airflow through the manostat. The manostat is primarily designed for dead-ended service, but it will handle small flows. For example, at a setting of 300 mmHg (2000 kPa) without any restrictions in the vacuum source line, it will pass 0.2 ft^3 (6 l) of air each minute. When an above-atmospheric pressure is to be controlled, the filtered air supply is not atmospheric any longer, but connected to a pressurized supply, and the vacuum source connection is left open to vent the unit.

Cartesian Diver Regulators

Cartesian divers are self-contained pressure, or vacuum, regulators operating on principles somewhat similar to those of the aneroid manostats. As shown in Figure 5.14l, the set pressure for this controller is sealed in under the diver. The process pressure acts on the outside of the diver causing it to sink or rise as pressure varies. If the unit is to control a vacuum process, a vacuum pump (or other vacuum source) is connected to the unit. A process pressure increase causes the diver to sink, opening the control port and connecting the vacuum pump to the process to lower its pressure. If the unit is installed for positive pressure control, a pressure source, not a vacuum source, is connected to the control port, which is closed by an increase in process pressure and opened by its reduction.

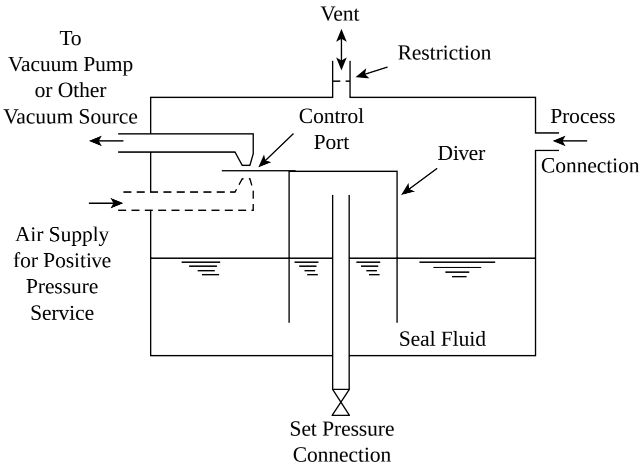

FIG. 5.14l
Cartesian diver.

This device is capable of maintaining process pressures between 1 mmHg absolute to 100 psia (0.13 to 690 kPa) to an approximate inaccuracy of 0.1% of set point. The unit is available in both glass and metal, requires no external power source, and is simple to operate or to change its set pressure. Because of its limited flow capacity, it can control small volume systems only.

Analog Electronic Controllers

Continuous reading, relay action, analog gauge, electronic controllers are also available and used for vacuum control. These instruments provide dependable control with simplicity and economy. The desired set point is established by positioning the gauge need set point indicator at the desired value. The system's integrated vacuum gauge is stable and rugged and provides reliable measurements over the 1 to 50 torr range commonly provided. If the pressure-indicating needle passes the set point, the relay is activated. The relay action is typically available as 115 V 5A SPDT @VAC normally open or normally closed contacts. The relay automatically drops out when set point vacuum value returns.

Mass Flow Controllers

Many vacuum related processes require vacuum control, while process gases are admitted on a continuous basis. A (PID) process control loop for such circumstances is possible with a mass flow controller. Vacuum process mass flow controllers usually detect the temperature change as the gas passes through a small, typically 3-in. flow chamber. The temperature is monitored with a TC gauge, and chambers can have stream splitter bypass elements to allow adaptation to different process gas flow ranges. The differential temperature measurement signal becomes the input to an electronic PID controller and the resulting control signal is sent to the final control element.

There are several final control element choices for mass flow controllers dedicated to vacuum process gas control. The solenoid proportional valve is one widely used cost effective control value that is coupled to a mass flow controller. This final control element uses a solenoid coil, a spring-supported armature, plug, and orifice. The unit can be configured with an elastomer sealed valve. The assembly also usually contains both external seals, which isolate the gas flow path from atmosphere, and an internal seal for the valve seat. All metal versions of the value are available when the process gas is also corrosive.

Other control value options include a pieazoelectric control valve and moving coil actuator valve. In the former, a stack of piezoelectric elements drives the value. This valve type has a fast response time with high valve action force. The counter valve action can be spring or diaphragm driven. Piezo valves are all constructed from metal. For the latter valve option, the actuator is a moving coil that surrounds a permanent magnet. As current passes through the coil, it is displaced. The displacement is transferred by a pivot arm and diaphragm action to the wetted volume on the other side of the diaphragm. This type of valve action produces a low valve sweep volume. This all-metal construction valve is good for contamination-sensitive applications.

INTRODUCTION

By measuring the density of a process stream, one can determine its concentration, composition, or in the case of fuels, one can identify its calorific value. Density measurement is also necessary to convert volumetric flow into mass flow (Section 2.12).

When measuring the mass flow of gases, direct density measurement is simpler and more accurate than the indirect calculation of density, which has to consider pressure, temperature, super compressibility, and humidity.

One method of measuring the density of solids is to weigh a fixed volume. The various aspects of weighing are discussed in Chapter 7.

ORIENTATION AMONG DENSITOMETERS

The features and capabilities of the various densitometers that are discussed in this chapter are summarized in Orientation Table 6.1a. When considering the selection of a density sensor for a particular application, one would consider both the nature of the process fluid (slurry, viscous, or clean) and the operating pressure and temperature conditions. The table also provides information on the density spans and inaccuracies of the various densitometer designs.

For liquid densitometers, the narrowest spans (0.005 SG [specific gravity] based on water) can be provided by the displacement-type units. With such a span, an inaccuracy of 1% corresponds to 0.00005 SG. In the case of gas densitometers, the electromagnetic suspension-type unit provides the narrowest span (0.01 SG based on air), and the lowest error it can provide is 0.0001 SG.

Another important factor in the selection process is the cost of the instrument. Pricing information and data on the suppliers of the various densitometer designs are given at the beginning of each section of this chapter, in the feature summaries.

UNITS AND DEFINITIONS

Density is defined as the quantity of matter per unit volume. The most common unit is kilograms per cubic meter but the units of grams per cubic centimeter, pounds per cubic foot, or pounds per gallon are also used. To convert from one set of density units to another, refer to Table 6.1b. For converting from a variety of density units into the SI unit of kg/m^3, refer to Table 6.1c.

Relative density, which in our everyday language is called specific gravity, is the ratio between the density of a process material to that of water or air at specified standard conditions. Being a ratio, specific gravity has no units associated with it. For liquids, SG = 1.0 corresponds to 1 g/cm^3 or, in the SI system of units, it corresponds to 1000 kg/m^3.

Reference Temperatures

Both density and specific gravity characterize the same physical property of the process media, and they are meaningful only if defined at stated temperature levels. In the case of specific gravity, the temperatures might be different for the process and the reference fluid, which is acceptable, but must be clearly stated. For example, a specific gravity table might list a process fluid as having a specific gravity of $0.87^{80/40}$. This means that this liquid at 80°F (27°C) will have a density of 0.87 times that of water at 40°F (4.4°C).

For gases, the specific gravity is based on air at standard conditions. This means that both the process vapors and the reference air density are measured at 60°F (16°C) and at atmospheric pressures. For ideal gases, the ratio of molecular weights is equal to their specific gravity.

Industry-Specific Specific Gravity Units

A variety of specific gravity scales have evolved in the various industries. They are defined below so that one might be able to convert from one set of units to another.

For petroleum products in the United States, the American Petroleum Institute (API) introduced in 1921 the unit of API degrees:

$$°API = \frac{141.5}{SG\ @\ 60°F} - 131.5 \qquad \textbf{6.1(1)}$$

The brewing and sugar industries use Balling degrees to express the percentage of "worth" or weight percentage of dissolved solids at 60°F (17.5°C):

$$°\text{Ba} = \%\text{ by weight of dissolved solids} \tag{6.1(2)}$$

The tanning and tanning-extract industry expresses specific gravity in Barkometer degrees. Each degree is 0.001 SG above or below SG = 1.0. Therefore, the Barkometer degrees can be negative or positive (+10°Bk = 1.01 SG).

$$°\text{Bk} = (\text{SG} - 1.0)(1000) \tag{6.1(3)}$$

The density of acids and of light and heavy syrups is expressed in Baumé degrees. This scale was introduced by Antoine Baumé in 1768 and consists of two scales, one for "heavy" (above SG = 1), the other for "light" (below SG = 1) liquids at 60°F (17.5°C):

$$\begin{aligned} °\text{Be (light)} &= (140/\text{SG at } 60°\text{F}) - 130 \\ °\text{Be (heavy)} &= 145 - (145/\text{SG at } 60°\text{F}) \end{aligned} \tag{6.1(4)}$$

The sugar industry also uses the Brix degree, which represents the weight percentage of pure sucrose in a 60°F (17.5°C) solution.

$$°\text{Br} = \text{weight\% of sucrose} \tag{6.1(5)}$$

The dairy industry uses the Quevenne degrees in testing the fat content of milk. Each degree corresponds to 0.001 SG in excess of SG = 1.0, so 40°Q = 1.04 SG.

$$°\text{Q} = (\text{SG} - 1.0)(1{,}000) \tag{6.1(6)}$$

The alcohol industry uses Sikes, Richter, or Tralles scales on its alcoholmeters. They each read the volumetric percentage of ethyl alcohol in water.

$$°\text{S}, °\text{R}, °\text{T} = \text{volume\% of ethyl alcohol} \tag{6.1(7)}$$

The alcohol industry also uses the unit of proof, which is °S, °R, or °T multiplied by 2.

$$\text{proof} = 2(\text{volume\% of ethyl alcohol}) \tag{6.1(8)}$$

The sugar, tanning, acid, and other industries working with liquids that are heavier than water all use Twaddell degrees. Twaddell divides the SG range between SG = 1.0 and 2.0 into 200 equal parts, each representing 0.005 SG.

$$°\text{Tw} = 200(\text{SG} - 1.0) \tag{6.1(9)}$$

If one wants to transfer density data from one scale to another, refer to the density conversion table (Table 6.1d).

DENSITY DETECTORS FOR LIQUIDS

Either the density or the specific gravity of process fluids can be measured. Specific gravity is the ratio of the density of the measured substance and that of the density of water. The effects of pressure upon density measurement can generally be disregarded, because the compressibility of most liquids is slight.

In this chapter, a number of liquid density gauges are described. When a selection is to be made for a particular installation, several considerations should influence the decision.

Selection of the Densitometer

If a transmitter is needed, the most economical selections are the hydrostatic head and the displacement-type sensors. Of these two, the hydrometers represent the least expensive choice, if only local indication is required.

The inaccuracy of density detectors is usually expressed as percent full span; the narrower the range of the sensor, the higher will be the precision of the measurement. Where operating temperatures vary, it is necessary to compensate the densitometer readings for these changes. All density detectors can be furnished with means for temperature compensation. As can be seen in Table 6.1a, this feature is standard for a number of the densitometer designs.

Most density gauges are suitable only for use on process fluids that are clean and nonviscous. When that is the case, the densitometer is usually selected on the basis of the allowable error and economics. If the process fluid is viscous or of the slurry type, then the radiation, Coriolis, ultrasonic, vibrating, hydrostatic head, and U- or straight-tube type sensors can be considered.

Of these types, the U- or straight-tube gauges are limited in their pressure and temperature ratings and can handle only moderately viscous or slurry-type streams.

The main limitation of the hydrostatic head-type measurement is in detecting narrow spans of density, because the corresponding standpipe height required becomes excessive. In addition, when the process fluid is a heavy slurry or is very viscous, the low-pressure side of the differential pressure (d/p) detector is likely to be plugged, if piped into the process without protection. If the required protection is provided by purging or by using pressure repeaters, the densitometer cannot be used on high pressure services, because the operating pressure ratings of the pressure repeaters or by the available supply pressure of the purge media is limited.

The limitations and capabilities of the various vibrating densitometers include:

1. The oscillating Coriolis-type design is not suited for measuring the density of gas or vapor mixtures.
2. The vibrating tube and the vibrating cylinder types are not suited for heavy slurry services because of plugging.
3. The vibrating plate design is not suitable for slurry services, if the slurry is abrasive.

The best, but not the least, expensive densitometer choice for viscous and slurry-type applications is the radiation-type density detector.

Indirect Sensors

Density can also be detected indirectly through the measurement of some process property that is related to density.

The detection of boiling point elevation is one of the common methods of indirect density gauging. In this design, resistance elements are used to compare the boiling temperature of the process sample with the boiling temperature of water at the same pressure. In this case, the scale for the boiling temperature difference of the particular solution can be calibrated in terms of density. This method of density detection is also used to determine the end point in evaporation type processes.

GAS DENSITY DETECTORS

While in liquid density measurement, the process pressure has little influence, and the effect of pressure on gas density cannot be disregarded. Because gases are compressible materials, the same detector might not be capable of detecting both specific gravity (or molecular weight) and density at operating conditions.

Composition Measurement

When the purpose of measurement is to determine the composition of a gas stream, the sample gas gravity is detected at ambient conditions, disregarding the actual operating pressures and temperatures. The scales of these gauges are calibrated either in specific gravity units based on air or in molecular weight units. The two scales are interchangeable because:

$$\mathrm{SG} = \frac{\mathrm{M_{wg}}}{\mathrm{M_{wa}}} \qquad \textbf{6.1(10)}$$

This can be proved by considering that:

$$\mathrm{SG} = \frac{\rho_g}{\rho_a} = \frac{\mathrm{P_g Z_a R_a T_a}}{\mathrm{P_a Z_g R_g T_g}} \qquad \textbf{6.1(11)}$$

But the pressures and temperatures are the same,

$$\mathrm{SG} = \frac{\mathrm{Z_a R_a}}{\mathrm{Z_g R_g}} \qquad \textbf{6.1(12)}$$

and,

$$\frac{\mathrm{R_a}}{\mathrm{R_g}} = \frac{\mathrm{M_{wg}}}{\mathrm{M_{wa}}} \qquad \textbf{6.1(13)}$$

therefore,

$$\mathrm{SG} = \frac{\mathrm{Z_a M_{wg}}}{\mathrm{Z_g M_{wa}}} \qquad \textbf{6.1(14)}$$

For gases (substantially superheated vapors), the ideal gas equations are quite accurate at ambient conditions, and, therefore, the compressibility factors can be considered as unity.

$$\mathrm{SG} = \frac{\mathrm{M_{wg}}}{\mathrm{M_{wa}}} \qquad \textbf{6.1(15)}$$

In Equations 6.1(10) to 6.1(15) the letters used are defined as follows:

SG = specific gravity based on air = 1.0
ρ_g, ρ_a = gas and air densities, respectively (lbm/ft^3)
$\mathrm{P_g}$, $\mathrm{P_a}$ = gas and air pressures, respectively (lbf/in.^{2} abs. or bars absolute)
$\mathrm{Z_g}$, $\mathrm{Z_a}$ = gas and air compressibility factor
$\mathrm{R_g}$, $\mathrm{R_a}$ = gas and air engineering gas constant (ft-lbf/lbm °R or cal/g °K)
$\mathrm{T_g}$, $\mathrm{T_a}$ = gas and air temperature (°R or °K)
$\mathrm{M_{wg}}$, $\mathrm{M_{wa}}$ = gas and air molecular weight

MASS FLOW MEASUREMENT

When the purpose of the density measurement is to determine the mass flow of a process gas stream, the density must be detected under actual operating conditions. The relationship between gas properties and density is as follows (using English units):

$$\rho_g = \frac{\mathrm{M_{wg} P_g}}{10.73\ \mathrm{T_g Z_g}} \qquad \textbf{6.1(16)}$$

The volumetric flow rate at standard conditions can be calculated by dividing the mass flow rate with the specific gravity. If, for example, the pressure drop across an orifice plate and the gas density at operating conditions are both measured, then the mass and volumetric flow rates can both be calculated by using the following equations:

$$Q = \frac{C_2 \sqrt{\Delta P \rho_g}}{SG} \qquad \textbf{6.1(17)}$$

$$W = C_1 \sqrt{\Delta P \rho_g} \qquad \textbf{6.1(18)}$$

where

W = mass flow rate (lbm/hr)
ΔP = differential pressure (lbf/in.^{2})
C_1, C_2 = constants containing appropriate orifice and other factors
ρ_g = gas density (lbm/ft^3)
Q = volumetric flow rate (ft^3/hr)

Super-Compressibility Detection

Sensors that are capable of measuring the vapor's density at operating conditions can also be used to determine the compressibility factor of the vapor. Super-compressibility is a measure of the *deviation* between ideal and actual gas behavior. It is defined as the *ratio* between the actual specific weight and the theoretical one, based on the perfect gas law. If the gas pressure, temperature, specific gravity, and flowing density are measured, then the super-compressibility factor is calculated as follows:

$$Z = \frac{P \times SG}{\rho \cdot T \cdot R_{air}} \qquad \textbf{6.1(19)}$$

where

Z = supercompressibility factor (dimensionless)
P = operation pressure (lbf/in.^{2})
SG = specific gravity (dimensionless)
ρ = flowing density (lbm/ft^3)
T = absolute temperature (°R)
R_{air} = gas constant for air 53.3 (ft-lbf/lbm °R)

Selection

When selecting gas and vapor density gauges, the application engineer should first consider the purpose of making the measurement. If it is for composition or concentration gauging, then the information desired is specific gravity or molecular weight, which can be obtained by measuring the sample under near-ambient conditions.

If the purpose of the measurement is direct density detection under operating conditions for the purpose of mass flow rate determination, then the instruments described in Figures 6.10c, 6.10e, and 6.10f should be evaluated.

The important difference between these two groups is that in case of mass flow rate determination, there is no need for separate pressure, temperature, super-compressibility, or humidity measurements. However, when gas composition is the purpose of the installation, these variables must be taken into consideration and their effects compensated for.

Composition Detectors In the category of gas-specific gravity sensors (composition detectors), economics would favor the displacement-type, manually operated indicators (Figure 6.10a). If continuous indication or remote signal transmission is required, the gas column balance and the viscous drag type instruments will be the most economical selections (Figures 6.10g and 6.10i).

When the overriding consideration is high sensitivity and accuracy, the electromagnetic suspension-type sensors will satisfy that requirement (Figure 6.10d).

If the process gas samples are corrosive and therefore the sensing elements should not come in contact with the process stream, the thermal gauges can be considered (Figure 6.10h). All of these units operate at near-ambient conditions. Therefore, in case of nonambient samples, it is necessary to regulate their pressures and temperatures. In addition, it is necessary to establish the moisture content of both the sample and the reference gas, which is usually air.

Direct Density Measurement If the purpose of measurement is direct density detection under operating conditions, the most economical choice is the manually operated displacement indicator (Figure 6.10b). Continuous indication or remote readout can be provided by both the displacement and the centrifugal-type designs (Figures 6.10c and 6.10e). It can also be provided by some of the vibrating densitometers, which are discussed in Section 6.8.

These units are accurate and capable of withstanding high operating pressures and temperatures. An important consideration is to minimize the pressure and/or temperature loss in the sampling system so as to maintain the gas sample under operating conditions. This is achieved by close-coupling the instruments to the process and by providing good thermal insulation for the sample lines. Another important consideration is to protect all restrictions and moving parts from deposits by filtering the sample.

CONCLUSIONS

Some of the mechanical and thermal gas density sensors described here are not widely used anymore. The general trend seems to be to replace such indirect composition (or energy content) measurements as ones based on the detection of specific gravity with direct composition analyzers such as chromatographs. In case of direct density measurement, the various vibration type density sensors, discussed in Section 6.8, seem to be the most popular choices.

J. E. JAMISON, S. EDVI (2003)

Types of Designs:	A. Conventional displacer B. Chain-balanced float C. Electromagnetically suspended float D. Angular position of displacer floats
Design Pressure:	A. C. Up to 1500 PSIG (103 bars) B. Glass tubes up to 100 PSIG (7 bars); others to 500 PSIG (34 bars) C. Up to 200 PSIG (14 bars) D. Up to 1000 PSIG (69 bars)
Design Temperature:	A, Generally in the range of –50 to 450°F (–45 to 230°C); special designs from –350 to 850°F (–212 to 472°C) B. Up to 450°F (232°C) C. Up to 350°F (177°C) D. Up to 500°F (260°C)
Materials of Construction:	A. Displacers available in 316 stainless steel, Monel, polypropylene, or solid Teflon; hanger assembly available in 316 stainless steel, Monel, or Hastelloy C; cage is usually steel or stainless steel B. Wetted parts can include Pyrex, Teflon, 316 stainless steel, tantalum, polyvinyl chloride, Alloys 20, Hastelloy, K-Monel C. Stainless steel D. Aluminum or stainless steel
Minimum Span:	A, B. 0.005 SG C. 0.01 SG D. 0.1 SG
Inaccuracy:	A. 0.5% of span B. The larger of 0.0002 SG or 3% of span C. 0.5 to 1% of span D. 0.0005 SG
Costs:	A. A 32 in. (0.81 m) displacer in a steel cage with an electronic transmitter costs about $2000 B. An indicator in a Pyrex glass tube costs $900; an electronic transmitter with temperature compensation costs about $3500 C, D. Over $3000

INTRODUCTION

Density is the weight of a fixed volume. When an object of a fixed volume and of a known density is submerged in a process fluid, the resulting buoyant force can be detected as an indication of process density. As the density of the process fluid increases, the apparent weight of the displacer will drop.

If the submerged float is lighter than the process fluid, the buoyant force will try to lift it out of the fluid, and a force will be needed to keep the float submerged. If the displacer is heavier than the process fluid, it will have a tendency to sink and a force will be required to hold it in position.

The liquid densitometers covered in this section all operate with floats or displacers that are permanently submerged in the process fluid. They all detect the buoyant force variations as it changes with fluid density.

DISPLACER-TYPE DENSITOMETERS

Archimedes' principle states that a body that is wholly or partially immersed in a fluid is buoyed up by a force equal to the weight of the fluid displaced. When this principle is used to build densitometers, they will be distinguished by the ways this force is detected and how that force-detecting mechanism is sealed from the process.

In this section, the force detecting mechanisms discussed will include the torque tubes, the chain balanced, electromagnetically suspended, and the angular momentum generating designs. In each of these cases, the seal has to be frictionless and suited for a wide range of pressures, temperatures, and corrosive conditions. In case of the chain loaded or magnetically suspended design, the problem of sealing is eliminated, because the float position is detected through the pipe wall by linear variable differential transformer (LVDT) or search coil type electrical methods. In case of the torque tube type buoyant force detector, this tube also acts as the seal (Figure 6.2a), while with the diaphragm type force-balance transmitters, the diaphragm itself is the seal.

The Torque-Tube-Type Displacer

The basic difference between a level and a density displacer is that the displacer float, in the case of level sensing (see Section 3.7), is only partially covered with the process fluid, while for density detection, it is always totally immersed. Therefore, in the second case, changes in buoyant force are only a function of density variations.

Figure 6.2a shows the basic components of a torque-tube-type displacer instrument, and Figure 6.2b illustrates some of the modifications that are desirable when this device is used as a density sensor. The sample fluid enters around the center section of the cage, through a piezometer ring that eliminates the velocity effects of the flowing liquid. If the sample fluid velocity is below 2 ft (0.6 m)/min, the piezometer ring is not essential. The sample fluid leaves the cage through the top and bottom connections. It is recommended that these flows be maintained constant by the use of flow regulating purgemeters.

The above system applies when the density measurement is made in a sample bypass of the process piping. If the density is to be detected in tanks or vessels, the flange mounted displacers illustrated in Figures 6.2c and 6.2d should be considered if the level in the tanks will never drop below the top

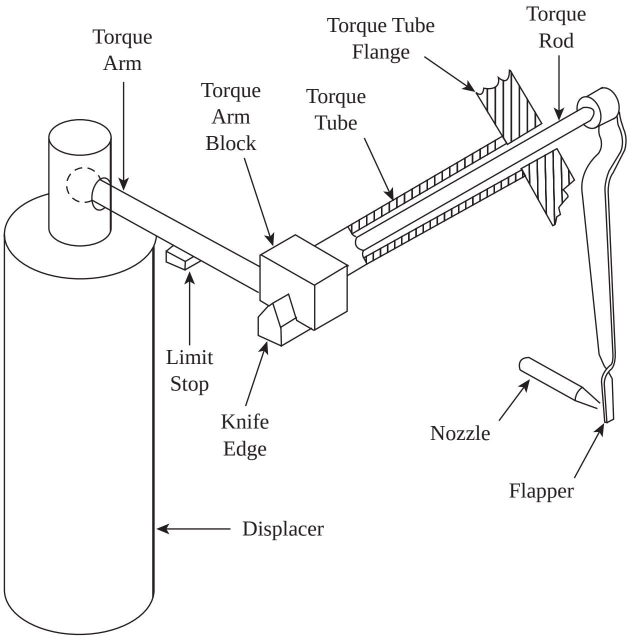

FIG. 6.2a
The buoyant force generated by a suspended displacer can be detected by a torque tube.

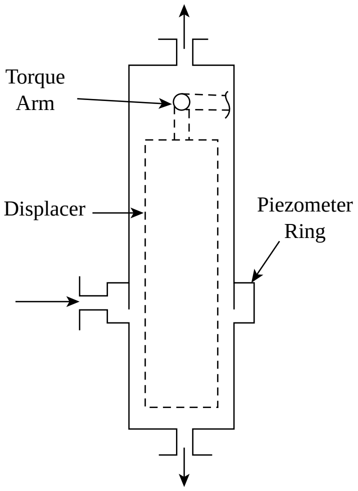

FIG. 6.2b
Displacer density sensor.

of the displacer floats. For dimensional information, construction materials, pressure ratings, and density ranges of some of the standard displacers, refer to Table 6.2e.

Sizing the Displacer Float In a torque-tube-type displacer, the standard force range is 0 to 0.72 lbf (0 to 0.33 kgf), while for a thin-wall tube it is half as much, or 0 to 0.36 lbf (0 to 0.17 kgf). Therefore, the sizing of the displacer involves the selection of a displacer volume that will change its apparent weight by these amounts as a result of the process fluid density changing from its minimum to its maximum value. The required displacer volume can be calculated as:

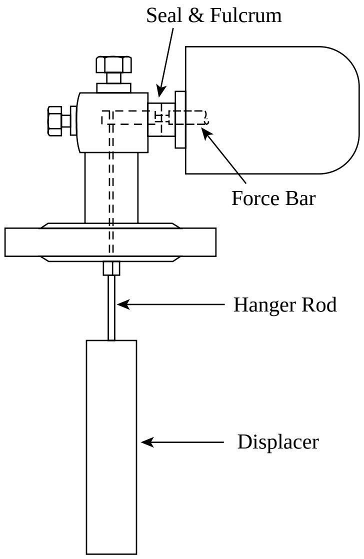

FIG. 6.2d
Diaphragm sealed displacer mounted on top of a flooded tank. (Courtesy of The Foxboro Company, a Division of Invensys.)

$$\text{volume (in.}^3\text{)} = \text{torque tube force}/\text{SG}_{\text{max}} - \text{SG}_{\text{min}}) \times (\text{weight of in.}^3 \text{ of H}_2\text{O}) \qquad \mathbf{6.2(1)}$$

If a thin-wall torque tube is to be used (0 to 0.36 lbf) and if the density range required is between 0.99 SG and 1.00 SG, then the volume (V) required can be calculated as:

$$V = 0.36/(1.00 - 0.99) \times 0.036 = 1000 \text{ in.}^3 \qquad \mathbf{6.2(2)}$$

This would approximately correspond to a 36 in. long, 6 in. diameter (914 mm long, 152 mm diameter) displacer.

Table 6.2f lists some of the standard displacers with their corresponding volumes and the density spans that will generate the required buoyant force change for standard and thin-wall torque tubes. As can be seen from the table, increasing displacer volume will reduce the span, and therefore the minimum span corresponds to the maximum available displacer volume.

Features and Limitations The displacer-type density sensors are available either as transmitters or local controllers. Temperature compensation is available and should be specified whenever high precision is needed.

The displacement-type density sensors are recommended for use on clean and nonviscous services. This is because viscous or slurry-type materials would stick to the displacer, which would change its volume. This is unacceptable because for accurate measurements, both the displacer volume and weight must remain constant.

Displacer-type densitometers should not be placed directly into the process pipeline, but be located in a bypass, where the sample flow to them can be kept low and constant. The velocity effects can be eliminated by the use of piezometer rings (Figure 6.2b). Therefore, the displacement-type density

sensors should only be considered for clean, nonviscous process streams and for bypass installations with sample flow regulated in the low gal/h flow range.

Chain-Balanced Densitometer

Figure 6.2g illustrates this flow-through-type density indicator in which the submerged float and chain assembly displaces a fixed fluid volume. The buoyant force generated by the float is a function of the density of the process fluid, and an increase in density causes the float to rise. As it rises, it will support a larger portion of the calibrated chain until that weight matches and cancels out the increase in buoyancy so that a new equilibrium condition is achieved. The new float position is an indication of the change in fluid density.

The wetted parts of this indicator are available in a large variety of corrosion-resistant materials, including Pyrex, and clear plastics for the chamber. Specific gravity (SG) spans from 0.005 to 0.2 can be obtained within the limits of 0.5 and 3.5 SG. The inaccuracy is the larger of ±1% of full span and 0.0002 SG.

This densitometer should only be used for applications where the process stream has less than 50 cP (0.05 Pa·s) viscosity. The sample flow rate through the instrument should be kept between 5 and 30 gal/h (19 and 114 l/h). Higher viscosities or higher flow rates will introduce velocity and friction effects that will reduce the measurement accuracy.

Transmitters The chain-balanced density sensor is also available as a transmitter. Here the density-related vertical position of the float is detected by the inductance pickup arrangement shown in Figure 6.2h. This arrangement consists of a magnetic core inside the float and a three-winding LVDT

TABLE 6.2f

Chain-balanced density transmitter with automatic temperature compensation. (Courtesy of Princo Instruments Inc.)

outside the chamber. Float movement causes an inductance change in the transformer with a resultant change in the differential voltage output. This output is rectified and detected by a potentiometer as a measure of density.

When the process temperature varies, automatic temperature compensation should be specified to correct the apparent fluid density for the difference between the actual temperature and a predetermined reference temperature. To accomplish this goal, a resistance temperature detector-type temperature sensor is furnished and the readout instrument is provided with adjustments to permit setting the correct compensation values for the application.

The features of the chain-balanced density transmitter are similar to those of the chain-balanced indicator. The only exception is that the chamber can be furnished in corrosion-resistant metallic or plastic-lined materials, and, consequently, pressure and temperature limits can be increased to 500 PSIG (3.4 MPa) and 450°F (232°C), respectively. The specific gravity spans of the transmitters are the same as of the indicators, but their inaccuracy is somewhat greater. These transmitters can be calibrated to keep the measurement error within ±1% at the desired control point, but at the extreme ends of the span, the inaccuracy will increase to about ±3%. The speed of response is a function of sample flow rate, and averages to be around 30 s.

Electromagnetic Suspension Densitometer

The instrument illustrated in Figure 6.2i has a float that is totally immersed in the process fluid and is electromagnetically suspended. A pair of search coils, which are fed by a high frequency supply, detect the position of the gold-plated ferrous alloy float. The float selected should be slightly denser than the maximum density of the fluid to be measured so that it always tends to sink.

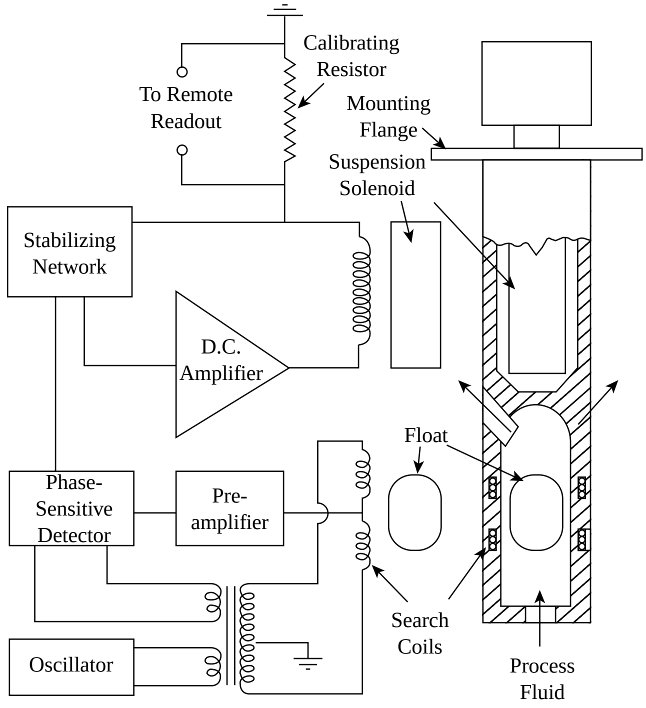

FIG. 6.2i
Magnetic suspension density sensor.

The float is prevented from sinking by the solenoid situated directly above the float, which generates the electromagnetic force required to hold the float in place. The float is maintained centrally between the two search coils by the electronic circuit in the head of the instrument. These circuits adjust the amount of current required for the solenoid to maintain the float centrally between the two search coils.

If the density of the fluid decreases, the float will start to sink. This change in position is detected by the search coils and results in an unbalance signal to the amplifier and demodulator, causing an increase in the current to the solenoid. This increases the force of magnetic attraction on the float and restores it to its original centered position. Thus, a closed-loop servo system within the instrument accurately positions the float by varying the current to the solenoid. Using a stable calibrating resistor, this current is measured as a measure of fluid density.

Design Features Where operating temperatures are expected to vary, the density transmitter is furnished with a temperature compensation unit using platinum resistance wire elements. The adjustments on this unit allow for setting the temperature reference anywhere between 32 and 212°F (0 and 100°C). The temperature coefficient for the particular fluid is also adjustable between zero and 0.009 SG/°F.

The plummet floats inside the lower portion of the epoxy probe housing, touching nothing but the process liquid. Therefore, it is insensitive to the effects of liquid surface tension. This density sensor can be directly immersed into the process by being mounted on a tank or pipeline nozzle. It can also be provided with a sample chamber for mounting in a bypass line. In either case, it is to be mounted within one degree of the vertical, and in a location where magnetic materials will not be closer than a foot (305 mm) from the float.

The wetted parts are made of epoxy, stainless steel, and gold-plated for corrosion resistance. For proper operation, the sample flow rates should not exceed a few gal/h and process viscosities should not exceed a few centipoises. Higher flows or viscosities will cause measurement errors, because they will result in vertical forces on the float. Deposits on the float will also result in measurement errors. For this reason this instrument is not recommended for slurry service.

The available full spans for this instrument range from 0.01 to 0.4 specific gravity units within the limits of 0.4 and 2.0 SG. Measurement inaccuracies are between1/2 to 1% of full span. One reason for this high accuracy is that the instrument detects only the difference between float and fluid densities. Consequently, the highest precision can be obtained when the liquid density to be measured is close to the density of the float. Pressure and temperature limitations are 200 PSIG (138 kPa) and 350°F (177°C), respectively.

Angular Position Densitometer

As illustrated in Figure 6.2j, in this density detector the process fluid sample flows continuously through the detector at a constant rate of under 30 gal/h (114 l/h). The gauge chamber contains three displacer floats, each of different density and volume. The solid displacers are spaced 90 to 100 degrees apart and attached to a common shaft. Any process fluid density causes the shaft to be rotated by the displacers to a precise angular position. This rotation is a function of the float positions and of the buoyant forces. By balancing the three displacer moments, the assembly is continuously in equilibrium. The angular position of the assembly is transmitted to the electrical components through magnetic coupling. The output signal to the remote readout or control devices can be in either analog or digital form.

Because the displacers are made of solid materials, process pressure variations will have no effect on their volume.

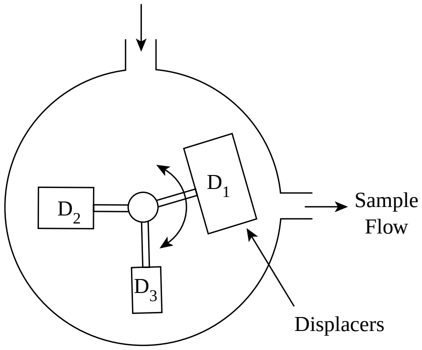

FIG. 6.2j
Angular position density sensor.

Similarly, the influence of process temperature variations is minor because the floats are made of materials with low coefficients of expansion. A change of 200°F (111°C) will result in a measurement shift of only 0.0001 SG.

Performance Detection accuracy is ±0.0005 to 0.001 SG and is unaffected by the span used. Due to the magnetic coupling utilized in transmitting the angular position of the shaft, the design pressure and temperature rating of the unit are high.

It is desirable to maintain the sample flow rate constant and to remove any particles that are 20 μm in size or larger. This density detector is limited to clean, nonviscous services, although viscosities up to 500 cP (0.5 Pa·s) can be tolerated. Temperature compensation can be obtained through the installation of additional sensing and computing elements.

CONCLUSIONS

The various displacement-type density sensors covered in this section are reliable and reasonably accurate instruments. When only local indication is desired and glass or plastic materials can be used, the chain-balanced unit is the logical choice. Where a density transmitter is required and temperature compensation is not essential, the torque tube type conventional displacer is the most economical selection. It is compatible with most corrosive fluids, and its pressure and temperature rating are high enough for most applications.

INTRODUCTION

According to Archimedes' principle, when a body is immersed in a fluid, its weight drops by the same amount as the weight of the liquid that it has displaced. Therefore, all hydrometers will sink until they displace the same mass of liquid as their own mass. The volume of liquid displaced is indicated by the level on the scale and density is the ratio of the hydrometer's mass divided by the displaced volume. As the density of liquids change with temperature, most hydrometers include a thermometer for temperature compensation purposes.

DESIGN VARIATIONS

The hydrometer element consists of a weighted float with a small-diameter indicator stem attachment at the top of the float as shown on Figure 6.3a. The stem is graduated in any of the density units discussed in Section 6.1. The hydrometer has a constant-weight body, which, if immersed in fluids with differing densities, will displace differing volumes of fluid. Therefore, the degree of stem scale submersion is an indication of the fluid's density. Readings are made at the point where the stem emerges from the liquid. The accuracy of

measurement is a function of the combined effects of surface tension, turbulence, and sample contamination.

In-Line Designs

One of the simplest in-line density indicators is illustrated in Figure 6.3b. It consists of a transparent glass tee with a hydrometer and a thermometer inside. Constant level is maintained in this tee, because the process fluid sample enters from the bottom and overflows. The sample flow rate is maintained at less than l gal/m (3.78 l/m) to minimize the effects of velocity and turbulence. If the process temperature varies, a thermometer is added to allow for manual temperature compensation.

Industrial Designs

The hydrometer element can be mounted inside a variable-area flowmeter (Section 2.27) housing. In such designs, as shown in Figure 6.3c, overflow pipes are provided to maintain the constant level inside the glass tube. Standard accessories include needle valves for sample flow rate control at about 15 gal/h (57 l/h) and integral thermometers.

Wetted parts are available in the same range of materials as for variable area flowmeters. These units can withstand up to 200°F (93°C) and 100 PSIG (690 kPa). Specific gravity (SG) spans of 0.1 to 0.5 are available and can be selected within the limits of 0.6 and 2.1 SG. Reading inaccuracy is 1% of span or the smallest division on the scale, which can range from 0.001 to 0.005 SG.

Transmitters

The variable immersion hydrometer element mounted in a rotameter housing can also be obtained as a transmitter for remote readout, as illustrated in Figure 6.3d three-dimensional. This electronic transmitter can be the servo-operated impedance bridge type and can be provided with automatic temperature compensation. Such compensation will convert the actual density, which is detected to the density that it would correspond to at a predetermined base temperature. Ranges, accuracies, and design limitations are the same as given for the local indicator version, discussed earlier.

The stem position of the hydrometer can also be detected optically. In this design, as the stem rises and falls it changes the amount of light that passes to a photocell. The photocell output is calibrated in specific gravity units.

Another transmitting hydrometer design is the capacitance type. Here, a stainless steel hydrometer positions a dielectric cup inside two insulated, concentric cylinders. The resulting change in capacitance is proportional to density. Automatic temperature compensation is provided with this unit so that the transmitted output signal can be referenced to 60°F (16°C). The transmission can either be analog or digital.

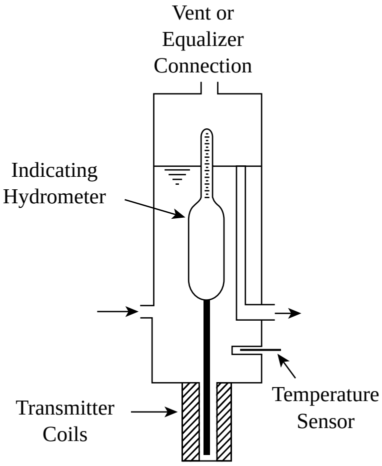

FIG. 6.3d
Hydrometer transmitter in rotameter housing.

CONCLUSIONS

The hydrometers discussed above are basic to density measurement. They are accurate, frictionless, and direct-indicating without the need for mechanical linkages or external energy sources. They are compatible with most corrosive fluids.

Their limitations are also multiple, because the float position should not be affected by anything except the fluid density. Effects of the velocity, friction, turbulence, and viscosity of the process must all be minimized. In addition, material buildup on the float cannot be tolerated, because the basis of hydrometer operation is the assumption that the weight of the float is constant. For these reasons, hydrometers should only be considered for use on clean, nonviscous process fluids when the sample flow rate is controlled at around 1 gal/h.

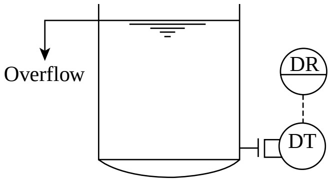
6.4 Hydrostatic Densitometers

C. H. HOEPPNER (1982) **B. G. LIPTÁK** (1969, 1995, 2003)



Flow Sheet Symbol

Types:	A. Bubbler B. d/p cell
Design Pressure:	Up to 5000 PSIG (34.5 MPa)
Design Temperature:	Up to 350°F (177°C); higher with filled volumetric elements
Materials of Construction:	Stainless steel, Hastelloy, Monel, tantalum, titanium, duranickel, or Kel-F and Teflon linings
Inaccuracy:	For standard d/p transmitters, the basic error is ±0.1 to 0.5% of actual span plus the temperature and pressure effects on span and zero. For intelligent transmitters, the total error is between ±0.1 and 0.2% of actual span.
Costs:	A manometer-type indicator costs about \$250. A complete air bubbler assembly costs about \$500. Motion balance bellows indicators cost around \$1000, and force balance d/p transmitters range from \$1500 to \$2500, with the higher costs corresponding to the intelligent units.

INTRODUCTION

The weight or hydrostatic head of a liquid column of fixed height will vary as a function of its density. The hydrostatic head method of density measurement requires the same components and installation as does the measurement of liquid interface levels (see Figure 3.6r). The two features that distinguish density or interface measurement from conventional level detection are:

1. Both hydrostatic head detection taps are located below the liquid surface.
2. The range of the d/p (differential pressure) cell is suppressed.

SIZING THE HYDROSTATIC HEAD TANK

In density measurement installations, the output signal of the d/p cell is expected to be zero when the density of the process fluid is at its minimum. This means that the d/p cell span needs to be elevated (see Figure 6.4a for the definitions of associated terms) by the product of the minimum density (SG_{min}) and the height of the hydrostatic column (H).

The output signal of the density sensing d/p cell is expected to be 100% when the process fluid density reaches its maximum (SG_{max}). Therefore, the required d/p cell span is $H(SG_{max} - SG_{min})$. Knowing the expected minimum and maximum values of the process density and knowing the minimum span available for the d/p cell, one can calculate the required (minimum) height of the hydrostatic head tank, which is used for the density measurement.

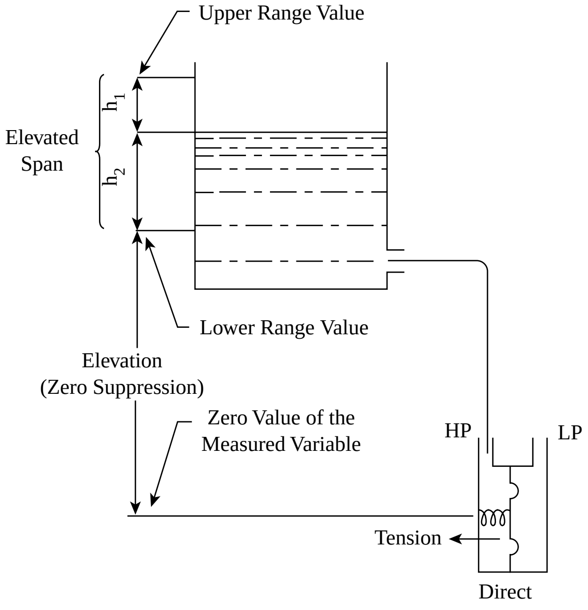

FIG. 6.4a
The terminology associated with an installation—such as density detection—where the d/p cell requires the elevation of its span.

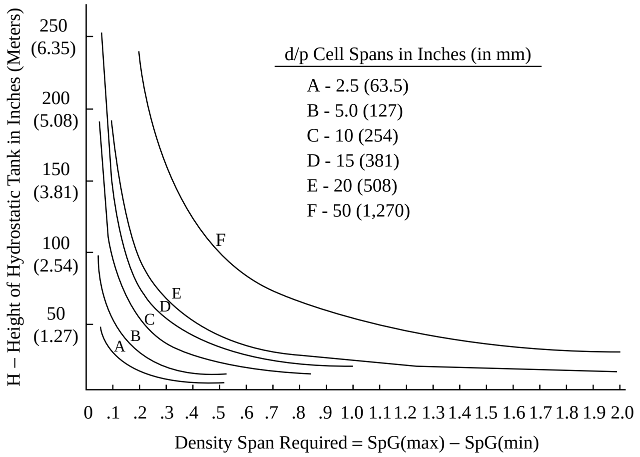

FIG. 6.4b
Knowing the required density span and the span of the d/p cell to be used, one can determine the minimum height required for the hydrostatic tank.

Assuming that the minimum span of the d/p cell is 5 in. (127 mm) of H_2O and the specific gravity (SG) is to be detected from a minimum of 0.65 SG up to a maximum of 0.70 SG, the minimum column height (H) required is:

$$H = 5/(0.7 - 0.65) = 100 \text{ in. (or 2.54 m)} \tag{6.4(1)}$$

Figure 6.4b has been prepared to relate density span (in specific gravity units) and d/p cell range to hydrostatic tank height. It can be seen that the narrower the density range, the taller the hydrostatic tank needs to be. It can also be seen that one way to reduce the tank height is to select a d/p cell with a narrower span.

USING BUBBLERS

One of the oldest methods of hydrostatic density measurement is the use of a dual-bubbler (Figure 6.4c). In this installation two bubbler pipes of different lengths are installed in the tank where the process density is to be detected. The bubbler pipes are inserted to different depths so that the pressure difference they detect reflects the hydrostatic head of the process liquid column having a height of H. Usually an inclined manometer is used as a readout, because it can amplify the visibility of small pressure differences.

A complete dual-bubbler-type densitometer package is illustrated in Figure 6.4d. The components of this preassembled package include a reference tank, provided with the same H dimension as the H dimension in the process tank. If the reference tank is filled with a reference fluid having the same density as the minimum value on the densitometer span (SG_{min}), then by periodically switching the air purge into the reference tank, the inclined manometer can be rezeroed.

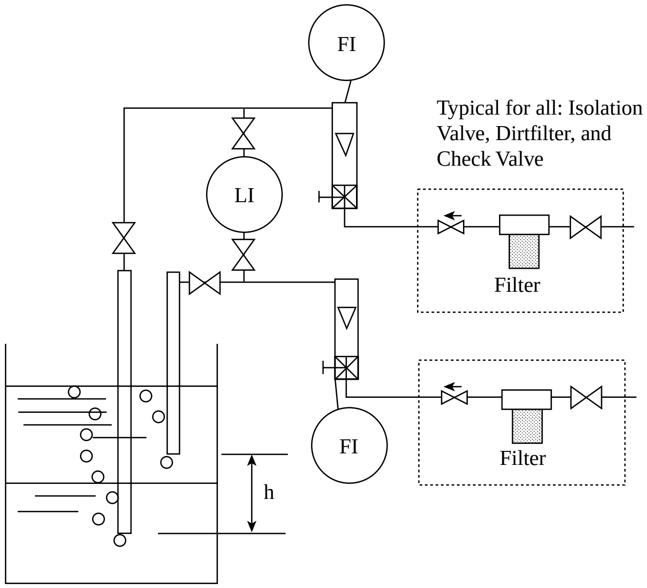

FIG. 6.4c
The measurement of density by using a local d/p indicator in combination with a dual-bubbler system.

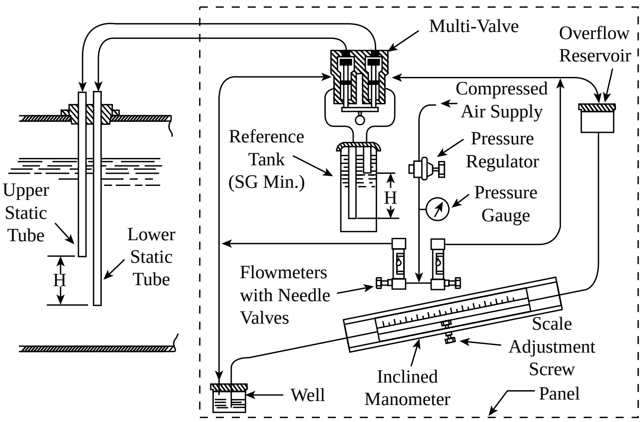

FIG. 6.4d
Reference tank filled with a reference fluid of SG_{min} density and manometer with adjustable scale provide the means for rezeroing the densitometer.

Rezeroing is made convenient by providing a scale adjustment screw to shift the scale on the manometer.

USING D/P CELLS

Figures 6.4e and 6.4f illustrate the basic configurations of using hydraulic head measurement in detecting the density in atmospheric and pressurized tanks. In these figures, H designates the constant liquid column height that is being measured. If it is desired to measure the specific gravity in the range of SG_{min} to SG_{max}, the span (or range) of the d/p detector is always $H(SG_{max} - SG_{min})$, regardless of the type of installation.

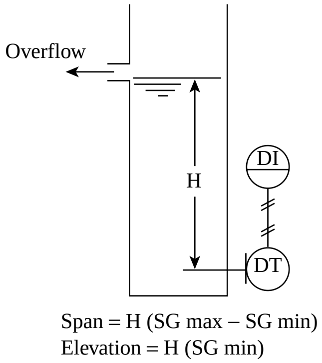

FIG. 6.4e
Density detection in fixed level atmospheric tank.

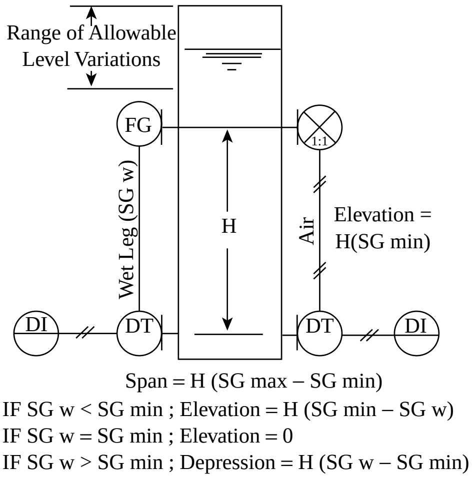

FIG. 6.4f
Density detection in variable level open or pressurized tanks.

Elevation Considerations

If the span is so selected, when the specific gravity of the process fluid is SG_{min}, the d/p cell output must be zero. Therefore, it is necessary to elevate the instrument zero, (suppress the range), allowing the d/p cell to devote its full range to the differential caused by the changes in density. The range is elevated by $H(SG_{min})$ when density is detected in an open tank, operating at a fixed level (Figure 6.4e). The range is also elevated by $H(SG_{min})$ when a pressure repeater is used at the upper sensing point (right side of Figure 6.4f).

When the installation is of the wet leg type (left side of Figure 6.4f), the required shift in the instrument “zero” is a function of the density of the fluid used in filling the wet leg. If the filling fluid is of the same density as the minimum of the densitometer range (SG_{min}), then the d/p cell elevation is zero; it requires no adjustment. If the filling fluid density is below SG_{min}, the zero must be depressed. If the filling fluid density is greater than SG_{min}, elevation is required.

In some d/p cells, only zero suppression (range elevation) is provided, and, therefore, if the wet leg hydrostatic head is higher than the tank side head, the d/p cell is reversed, so that its "high pressure" side will be connected to the wet leg.

The following practical considerations should be kept in mind when designing a hydrostatic density sensor loop:

1. The height of the liquid column detected has to be kept within practical limits.
2. The pressure differential generated due to density variations must be sufficient to match the range of the d/p cell.
3. The elevation (or depression) requirements of the installation must be within the capabilities of the selected d/p cell.

If the above requirements conflict with each other, the method for selecting the best compromise can be illustrated by an example.

Design Example

Assume that the tank contains a slurry and therefore an extended-diaphragm-type d/p cell (Figure 3.6a) has to be used. This type of d/p cell has a minimum differential range of 20 in. (0.5 m) H_2O and a maximum depression of 250 in. (6.35 m) H_2O. Let us also assume that the specific gravity is to be measured between 0.65 and 0.70 SG, and the specific gravity of the filling fluid in the wet leg is 1.20 SG.

Based on the above data, we will first calculate the minimum height (H) of the required fluid column and the required zero elevation or range depression of the d/p cell:

$$H = \frac{\text{span}}{(SG_{\max} - SG_{\min})} = \frac{20}{0.05} = 400'' = 33.4 \text{ ft (or 10.16 m)} \tag{6.4(2)}$$

$$\begin{aligned}\text{Zero elevation} = \text{Range depression} &= H(SG_w - SG_{\min})\\ &= 400(1.20 - 0.65) = 18.4 \text{ ft } H_2O \text{ (or 5.6 m)}\end{aligned} \tag{6.4(3)}$$

Table 6.4g provides some data on the span, suppression (depression), and elevation capabilities of one manufacturer's d/p cells. These values change with both the manufacturer and with the age of the instrument (Table 6.4h). Therefore, when making a specific selection, such as in the example here, it is necessary to check the capabilities of the selected hardware.

The combination of a 20 in. (0.51 m) span and a 220 in. (5.6 m) range depression is available in the d/p cell category shown in Table 6.4h, but is not available in the d/p cell designs described in Table 6.4g. Therefore, if one wants to use the d/p cell represented by Table 6.4g, the d/p cell pressure taps must be reversed, turning its high pressure side toward the wet leg. Such reversals are perfectly acceptable when using conventional d/p cells, but are usually unacceptable with the extended diaphragm design.

TABLE 6.4g
d/p Cell Capsule Capabilities

	Low Range	*Medium Range*	*High Range*
Minimum Span—in. H_2O	0–2	0–25	0–30 PSID
Minimum Span—kPa	0–0.5	0–6.2	0–210
Maximum Span—in. H_2O	0–150	0–1000	0–3000 PSID
Maximum Span—kPa	0–37.5	0–250	0–207 bars
Maximum Zero Suppression (also called range "elevation")	(Maximum span) – (Calibrated span)		
Maximum Zero Elevation (also called range "suppression" or "depression")	Minimum span		

TABLE 6.4h
The Span, Elevation, and Depression Capabilities of Older d/p Cell Designs (1 in. = 25.4 mm)

d/p Cell Type	*Min. Range (in. H_2O)*	*Max. Range (in. H_2O)*	*Max. Range Elevation (in. H_2O)*	*Max. Range Depression (in. H_2O)*
Low	0–5	0–25	50–(Range)	50
Medium	0–20	0–250	250–(Range)	250
High	0–200	0–850	850–(Range)	850

Narrow Spans

To detect narrow density spans using conventional d/p cells, tall standpipes are required. If low-range d/p detectors can be used, the column height can be reduced correspondingly. However when the process fluid is not compatible with low-range d/p cell designs, the only alternate choice is to consider some other method of density detection. For these reasons, hydrostatic densitometers are not practical for specific gravity spans under 0.05.

Temperature Compensation

Temperature compensation is not a standard feature in hydrostatic head type density detectors. It can be provided by the addition of temperature sensors and computing components, but it is required only if high precision measurement accuracy is desired. As shown in Figure 6.4i, the amount of density change resulting from near-ambient temperature variations is relatively small for most liquids.

CONCLUSIONS

The choice of d/p cell designs for density measurement should be based on the same considerations discussed in connection with level sensors (see Figures 3.6h to 3.6k).

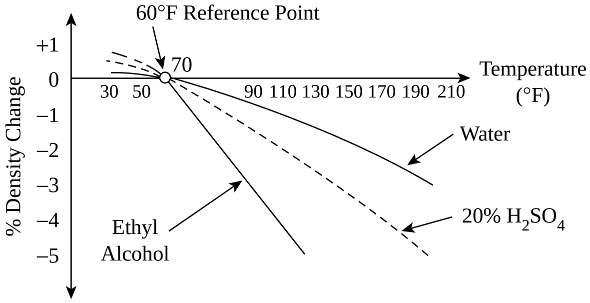

FIG. 6.4i
Density change as a function of near-ambient temperature variations.

Bubblers or purging of the pressure taps should only be considered for open tank applications. Whenever a pressure tap is purged, the speed of response of the density sensor will be slow due to the volume of the purge system. This reduced response speed will in turn degrade the performance of closed density control loops. In addition, due to the many mechanical components of purging systems, frequent maintenance will be required, and without frequent recalibration, the measurement accuracy will also suffer.

Pressure repeaters contribute an error component to the total inaccuracy of the measurement. On vacuum service, they also require an independent vacuum source or biasing of the repeater signal. These considerations place additional restrictions on the achievable density spans and required tank depths.

In hydrostatic head density loops, the force balance d/p cells are the most reliable. When the process fluid is viscous, dirty, or a slurry, the extended-diaphragm type design should be selected.

The main limitation of d/p type density measurement is the maximum available height of the hydrostatic liquid column. Other limitations involve the minimum spans and maximum depressions and elevations of the different d/p cell designs.

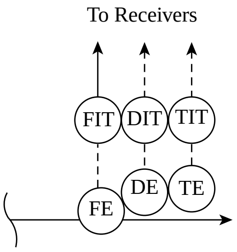
6.5 Oscillating Coriolis Densitometer (Gas, Liquid, and Slurry Services)

C. H. HOEPPNER (1982) **C. APPLE** (1995) **J. E. JAMISON** (2003)



Flow Sheet Symbol

Density Range:	0.0 to 5.0 g/cm^3 (0 to 5000 kg/m^3); can also measure mass flow, volumetric flow, and temperature
Sizes (Diameter):	1/25 to 10 in. (1 to 250 mm)
Flow Range:	0 to 63,000 lb/min (0 to 28,300 kg/min)
Fluids:	Liquids, slurries, compressed gases, liquified gases (not suited for gas-liquid mixtures)
Output Signal:	Linear frequency, analog, digital serial protocols, display, Highway Addressable Remote Transducer (HART), Profibus, Foundation Fieldbus, Modbus, scaled pulse, display, alarm outputs, manufacturer specified protocols.
Detector Types:	Electromagnetic, optical, and capacitive
Operating Pressure:	Depends upon tube size and flange rating; 1400 PSIG (100 bars) is the typical standard; 5000 PSIG (345 bars) is a typical high pressure. At 650°F temperature, the maximum operating pressure is 1160 PSIG (80 bars).
Required Pressure Drop:	From under 10 PSIG (0.7 bar) to over 100 PSIG (6.9 bars)
Operating Temperature:	Depends upon design: –400 to 400°F (–240 to 204°C) is the standard rating; 32 to 800°F (0 to 426°C) is the rating of high temperature units. Special low temperature designs can also be used on cryogenic applications from –40 to 140°F (–40 to 60°C). Temperature ratings can be affected by hazardous area classification.
Materials of Construction:	304/316L/316 Stainless steels, high alloy Ferritic Stainless 17-7PH, Hastelloy C, titanium, Ni-Span C as standard; tantalum, zirconium, Tefzel-lined as special
Inaccuracy:	±0.0002 to 0.05 g/cc, depending upon design; typical is ±0.002 g/cm^3 over a 0.3- to 3.0-g/cm^3 range
Repeatability:	±0.0001 to 0.01 g/cm^3, depending upon design; typical is ±0.001 g/cm^3 over a 0.3- to 3.0-g/cm^3 range.
Digital Communications:	Most manufacturers provide electronics, which are equipped with digital communications that support RS232/RS422 or RS485 physical interfaces and/or protocols such as ModBus. Other electronic transmitters support a variety of other digital communications protocols such as HART as well as FOUNDATION Fieldbus, DeviceNet, and Profibus-PA/DP.
Costs:	1/25th in. (1.0 mm), $5000; typical 1 in. (25 mm) meter, with full-scale flow rate of 400 to 1000 lb/min (180 to 450 kg/min), $7000; typical 3 in. (75 mm) meter, with full-scale flow rate and FOUNDATION Fieldbus transmitter, with full-scale flow of 9800 to 39,500 lb/h (4500 to 18,000 kg/h), $13,500; 6 in. (150 mm), $27,500.

INTRODUCTION

It requires the least amount of energy to cause an object to go into natural frequency vibration. This frequency is a function of the mass of the object. In case of a Coriolis densitometer, the mass of the vibrating object is the sum of the pipe, the fluid within the pipe, and the mass of the driver and sensors (Figure 6.5a). Therefore, since the masses of the pipe, driver, and sensors are constant, a change in natural frequency is a direct indication of a change in the density of the process fluid.

A unique feature of the Coriolis flowmeter is its ability to determine, in addition to its flow rate, the density of the process fluid. This ability can be used even when the measurement of the fluid flow rate is of no interest. The density measurement requires the main components illustrated in Figure 6.5a.

THE SENSOR

One design of a Coriolis densitometer is shown in Figure 6.5b. This density sensor is comprised of either one or two flow tubes (usually two), a driving mechanism for oscillating the flow tubes, detectors for the measurement of natural frequency, and a temperature-measuring device.

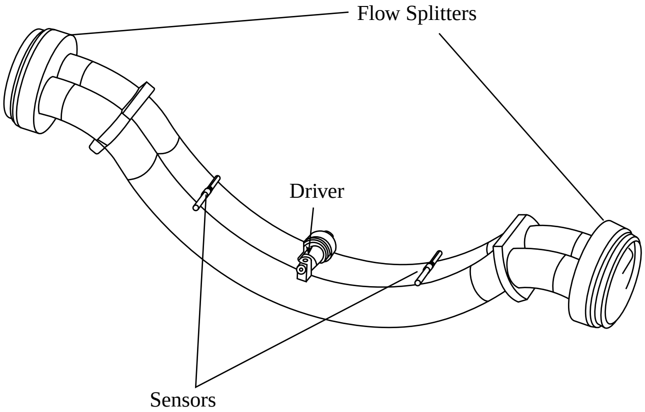

FIG. 6.5a
The components and the tube assembly of a Coriolis meter.

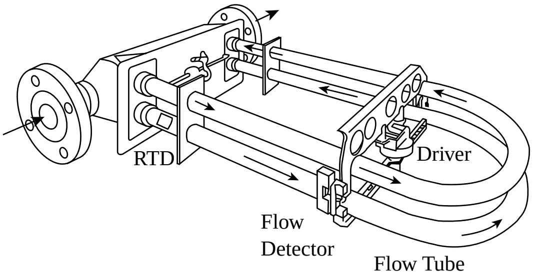

FIG. 6.5b
Design of a typical Coriolis density meter.

The process fluid stream is split into two and flows through the flow tubes. A coil-and-magnet driver is used to oscillate the flow tubes in opposition at their natural frequency. The oscillation of the tubes causes the flow detectors to output a sinusoidal voltage signal that reflects this motion. The frequency of the sinusoidal voltage from the flow detectors represents the natural frequency of the tube vibration. Typically, the flow detectors are electromagnetic sensors, although capacity detectors and optical sensors are also used.

Changes in the density of the process fluid will cause the mass of the fluid-filled flow tube system to change. This in turn will change the natural frequency of the sensor. This change will cause the frequency of the sinusoidal voltage from the flow detectors to change. By measuring the frequency of the sinusoidal voltage developed by the Coriolis detector, the density of the process fluid is determined.

Temperature Correction

The temperature of the tube affects its natural frequency of vibration. If the tube temperature increases, the tube becomes more elastic, which causes the natural frequency to decrease even though the mass of the system has not changed. The measurement of the tube's temperature is used to correct the natural frequency for changes in the elastic modulus of the flow tube material. A resistance temperature detector is typically used to measure the tube temperature.

THEORY OF OPERATION

The natural frequency of vibration is described by the equation:

$$\omega_n = \sqrt{\frac{k}{m}} \qquad \textbf{6.5(1)}$$

where
ω_n = natural frequency, rad/s
k = spring constant, pound-force/in. or lb/s^2 (N/m or kg/s^2)
m = mass of the system, lb (kg)

For the Coriolis meter, the mass of the system is the combined mass of the fluid and the flow tube assembly and can be expressed by the following relationship:

$$m = \rho_f A_f l_t + \rho_t A_t l_t \qquad \textbf{6.5(2)}$$

where
ρ_f = fluid density, lb/in.^{3} (g/cc)
ρ_t = tube material density, lb/in.^{3} (g/cc)
A_f = tube internal area, in.^{2} (cm^2)
A_t = tube cross-sectional area, in.^{2} (cm^2)
l_t = tube length, in. (cm)

The spring constant (k), from Equation 6.5(1), is a function of geometry and material properties and is determined from the following equation:

$$k = \frac{MEI}{I_t^3} \qquad \textbf{6.5(3)}$$

where
M = modal constant
E = modulus of elasticity, pound-force/in.^{2} (kPa)
I = moment of inertia, in.^{4} (cm^4)

The natural frequency (ω_n), from Equation 6.5(1), can also be expressed by the following equivalent relationships:

$$\omega_n = 2\pi f = \frac{2\pi}{T} \qquad \textbf{6.5(4)}$$

where
f = oscillation frequency, cycles/s
T = tube period, s (time for one cycle of oscillation)

Substituting Equations 6.5(2), 6.5(3), and 6.5(4) into Equation 6.5(1) and solving for ρ_f gives the following relationships:

$$\rho_f = \left(\frac{MEI}{4\pi^2 l_t^4 A_f}\right) T^2 - \frac{\rho_t A_t}{A_f} \qquad \textbf{6.5(5)}$$

The Calibration Constant

The variables that depend upon the tube geometry and materials properties can be combined to obtain the calibration constants, such as: $K_1 = (MI)/4\pi^2 I_t^4 A_f$ and $K_2 = (\rho_t A_t)/A_f$. A correction factor C_T is used to compensate for changes in the material modulus of elasticity (E) with temperature. Equation 6.5(5) can then be rewritten as:

$$\rho_f = K_1 C_T T^2 - K_2 \qquad \textbf{6.5(6)}$$

Values for the calibration constants are determined by measuring the period of oscillation of the tube at two known fluid densities. With the two fluid densities and their respective tube periods, two simultaneous equations with two unknowns can be solved to obtain K_1 and K_2. Any two fluids of known density can be used to determine the calibration constant.

Calibration fluids should be so selected as to have sufficiently different densities to minimize the amount of error associated with the calibration constants K_1 and K_2. Air and water are commonly used as the calibration fluids. The value of C_T depends upon the material of the flow tube and is determined by the manufacturer from experimental data.

ELECTRONICS

A typical block diagram of the density measurement electronics is shown in Figure 6.5c. The electronics is comprised of interfaces to the sensor, signal-processing components, and outputs to external devices. The interfaces between the sensor and the electronics include the flow detectors, the drive mechanism, and the temperature detector.

The electronics vibrates the tubes at their natural frequency by minimizing the amount of energy input into the driver while maintaining sufficient tube displacement to produce the forces required to measure the fluid flow rate. The electronics applies an alternating current to the drive coil that is mounted on one of the flow tubes. This alternating current generates an alternating magnetic field in the coil. The alternating magnetic field causes the fixed magnet mounted on the other tube to be repelled and attracted, forcing the tubes alternately away from and toward one another at their natural frequency. The flow detectors generate a sinusoidal voltage signal that reflects the oscillation of the flow tubes.

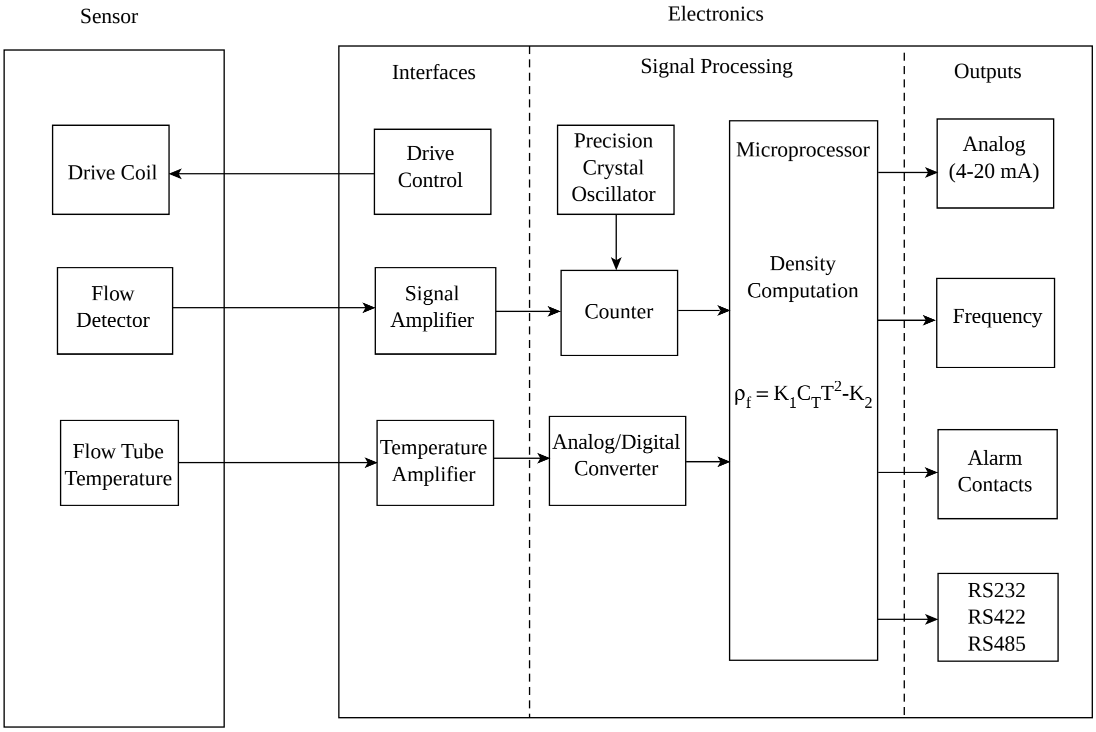

FIG. 6.5c
Signal processing block diagram.

The sinusoidal voltage signal from one of the flow detectors is input into a counter that detects the start and end of each tube cycle. The tube cycles are gated by the counter, which triggers the counter to make a time measurement over the duration of the tube cycle. The time or period over which the tube cycle occurred is obtained from a precision crystal oscillator. The microprocessor reads the counter time measurement and uses this value along with the tube temperature and calibration constants, K_1 and K_2, to calculate the fluid density using Equation 6.5(6).

Output Options

Electronics are available to provide several different output options. The most common output is an analog (4 to 20 mA) output, which can be scaled to represent the desired density range. Some manufacturers provide a scalable frequency output that can also be used to represent the fluid density. Many of the meters are equipped with built-in displays that can be used to directly display the density of the process fluid (or any other process variable acquired by the meter including volumetric flow, mass flow, temperature, and total flow). The user can select a variety of units for the density display, such as g/cc, lb/ft^3, °API, °Baumé, etc.

Most manufacturers provide electronics that are equipped with digital communications that support RS232/RS422 or RS485 physical interfaces and/or protocols such as ModBus. Other electronic transmitters support a variety of other digital communications protocols, such as Highway Addressable Remote Transducer (HART), as well as FOUNDATION Fieldbus, DeviceNet, and Profibus-PA/DP. The latter two can provide high-speed transmission of all sensor process variables back to the host distributed control system (DCS) for display and/or control purposes.

A density output is occasionally optional on some devices. A typical Coriolis flowmeter comes standard with one pulse or frequency output that usually represents flow rate and another output that can represent density. Two analog outputs can be configurable for a choice of flow rate, density, or temperature; a local display can be purchased which is independent of the other outputs. Digital discrete outputs are also normally standard issue including alarm outputs. Several data communications options are available including basic RS-232/422/485 physical links, ModBus, and HART. Other optional multivariable transmitters can provide fieldbus serial digital data communication outputs such as FOUNDATION Fieldbus, DeviceNet, and Profibus-PA/DP, and can send many process variables (flow rate [mass or volumetric], density, temperature, and flow total) back to a host DCS. The number and type of outputs, both standard and optional, vary from one manufacturer to another.

APPLICATIONS

A Coriolis meter can measure the density and the flow rate of a wide variety of process fluids. In addition to indicating density, the electronics can be configured to provide additional information such as the concentration of one or more components in a mixture.

Microprocessors can be programmed to determine the composition of mixtures. Common options that are provided allow for the determination and monitoring of % solids by mass or volume, °Brix, % fructose, % alcohol, and % solids in black liquor. Many of these relationships are temperature-dependent, and the temperature reading from the flow tube is used to correct for the variations in fluid temperature.

Since the flow rate is measured by the Coriolis meter, the net flow rate of one or more components in a multicomponent mixture can also be determined. An example of this is the ability to determine the flow rate of oil in an oil-water emulsion.

DEVELOPMENTS AND TRENDS

In addition to monitoring several variables, the newer systems allow the transfer of calibration and diagnostic related information to and from the host DCS. Some Coriolis meters not only support the use of many different density units, such as °Baume, °Balling, °Plato, but are also able to convert their readings into specialized units as required by the particular industry. For example, in the hydraulic well fracturing process of the oil and gas industry, the sand added per cubic meter of liquid can be monitored.

Two- and three-dimensional polynomial calculations can yield relationships between concentration and reference density or can correlate relationships between concentration, density, and temperature.

The Coriolis electronics can support up to four detector assemblies and can provide high precision under widely variable operating conditions. For example, it can detect the density within an error of ± 0.0005 g/cm^3 over a range of 0.001 to 1.8 g/cm^3, while the temperature varies from 5 to 80°C.

The Coriolis meter is a multivariable sensor. It is hoped that in the future it might become capable of measuring even more variables, possibly including viscosity.

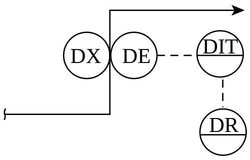
6.6 Radiation Densitometers

C. H. HOEPPNER (1982) **B. G. LIPTÁK** (1969, 1995, 2003),

REVIEWED BY A. J. LIVINGSTON (1995, 2003)



Flow Sheet Symbol

Applications:	Noncontact and nonintrusive density measurement of liquids and solids.
Radiation Sources:	The most commonly used radioisotope is cesium 137, because it decays more slowly (30 years half life). Cobalt 60 is selected when the tank/pipe walls are thick (5.3 years half life). Americum 241 (455 years half life) and radium (1602 years half life) are less frequently used.
Source Sizes:	For external types, generally a few hundred millicuries (mCi) or less. For low level applications: from 0.1 to 2 mCi. For normal applications: from 5 to 2,000 mCi with 10,000 mCi being the maximum. A curie equals 3.7×10^{10} disintegrations/s and is generated by 1 g of radium, 0.88 mg of cobalt, or 11.5 mg of cesium.
Process Pressure:	Unlimited; sensor is external to pipe.
Ambient Temperature:	External detectors are suitable for –40 to 160°F (–40 to 71°C) ambient conditions. Heaters or coolers are available for ambient temperatures outside these limits.
Materials of Construction:	Detector is normally carbon steel or aluminum; other parts are optional.
Inaccuracy:	1% of actual span
Limitations:	Errors caused by entrained air, deposits on pipe wall and stratification. The detector requires a 5% change in the detected radiation intensity as the process density changes from minimum to maximum. Therefore, when detecting narrow spans, compensation is needed for source decay and process temperature. The source decay effect with cesium 137 is 3% per year. A minimum of 6 in. (150 mm) radiation path length is required.
Range (Span):	From 0.3 to 3.0 SG
Applicable to Pipe Sizes:	2 to 30 in. (51 to 762 mm) diameter
Radiation Intensity:	Generally under 5 mR/h at 12 in. (0.3 m) from instrument
Allowable Radiation Dose:	One roentgen is received during a period of 1 h, if spent within 1 m of a 1 Ci radiation source. One receives a dose of 1 rem (roentgen equivalent man), when exposed to one roentgen in any period of time. Allowable limits for the general public are 2 mrem/h, 100 mrem/year. The allowable dose for occupational worker is 5000 mrems/year (see Table 6.6d).
Costs:	A clamp-on unit for a 6 in. (150 mm) pipe with 0.28 in. (7 mm) wall and 1 in. (25 mm) fiberglass insulation, for 80 to 120°F (27 to 49°C) ambient temperature and a range of 1.0 to 1.25 SG, cost from \$ 7000 to \$ 8000. For a 20 in. (0.508 m) pipe, the same unit costs from \$ 12,000 to \$ 14,000.

INTRODUCTION

Radiation is caused by the spontaneous disintegration of the nucleus of an atom. Wilhelm Roentgen discovered x-rays in 1895, while radioactivity as such was discovered by Antoine-Henri Becquerel in 1896. The three forms of radiation are alpha (the emitted particle is the nucleus of helium and travels only a few centimeters in air), beta (electrons are emitted that can travel a few meters in air), and gamma. Gamma radiation consists of high-energy electromagnetic waves that can travel a couple of hundred meters in air.

The range in source sizes for density measurement applications has been lowered in recent years. This occurred partly because of changing regulations and partly because the high sensitivity sodium iodide detectors have been developed. These new detectors allow for the use of reduced (down to 0.1 mCi) source sizes, because the sodium iodide crystal detectors are larger and more stable than their predecessors.

Such density gauges are permitted under a General License, which requires no fees, no wipe tests, and no shutter check, and allows the user to do the initial start-up. These features reduce the overall cost of ownership.

Radioisotopes

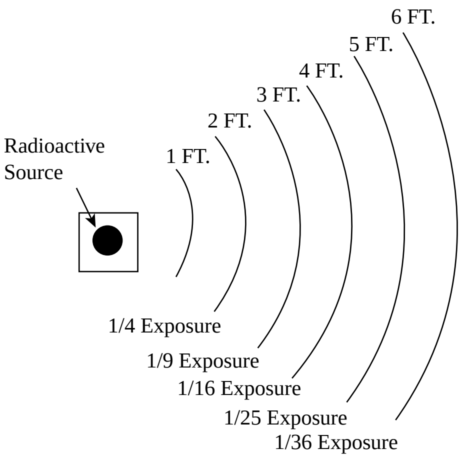
The emitters of gamma radiation and their half-lives in years are listed in Table 6.6a. The size of a radiation source is expressed in millicuries (mCi). One millicurie is defined as 37 million disintegrations. The range of source sizes for level and density applications generally ranges from 5 to 10,000 mCi. The most commonly used isotope is cesium 137. Due to its half-life, the activity of a 100-mCi cesium source will be 50 mCi after 30 years and 25 mCi after 60 years.

TABLE 6.6a
Half Lives of Radioisotopes

Isotope	*Half-Life in Years*
Americum (Am 241)	455.0
Cesium (Cs 137)	30.0
Cobalt (Co 60)	5.3
Radium (Ra 226)	1602.0

The strength of the radiation field is measured in milliroentgens (mR). In a 1-mR radiation field, 2.08 million pairs of ions are produced in a cubic centimeter of air. The intensity of the radiation field is a function of the size (activity) of the source, the distance from the source (Figure 6.6b), and the material that the radiation has to pass through. The higher the density of a material, the more radiation it is likely to absorb. Table 6.6c lists the half-value thicknesses (H) and specific gravities (SG) of some common industrial materials when exposed to radiation generated by Cs137. H is the thickness of a material necessary to reduce incident radiation by 50%.

The amount of radiation exposure received (dose) by an operator is expressed in roentgen equivalent man (rem) units.



$$D = 1000 \frac{K\ mCi}{d^2}$$

Where

D = intensity, mr/hr,
mCi = size of source in millicuries,
d = distance to source in inches, and
K= constant, 1.3 for Ra 226
0.6 for Cs 137
2.0 for Co 60.

FIG. 6.6b
Radiation intensity and therefore exposure drops with the square of distance to the radiation source.

TABLE 6.6c
Half-Value Thickness of Materials When Exposed to Radiation from a Cs 137 Source

Material	Specific Gravity	Half-Value H Inches	mm
0.5 SG bulk material	0.5	7.87	200
Water	1.0	3.9	99
Al_2O_3 refractory	2.25	1.77	45
Aluminum	2.7	1.5	38
Steel	7.86	0.6	15.2
Copper	8.96	0.47	11.9
Lead	11.4	0.25	6.35

TABLE 6.6d
Radiation Exposure Limits in Millirems (mrem)

Exposure Period	General Public	Occupational Workers
Hour	2	
Quarter		1250
Year	100	5000

A rem is the dose received when an operator is exposed to a radiation field of 1 R. In most countries, the radiation dose limit in the workplace is 1250 mrem/calendar quarter, 100 mrem/week, or 2.0 mrem/hr. See Table 6.6d for a more complete set of data.

THE RADIATION DENSITOMETER

The basic components of the density gauge comprise a radioactive source beaming through a pipe and a detector system to measure the amount of transmitted radiation (Figure 6.6e).

When gamma rays pass through a process fluid, they are absorbed in proportion to the density of the process material (see Figure 6.6f). An increase in process density results in a reduced output current because a denser process fluid absorbs more of the gamma rays.

When the density inside large pipes (or containers) is measured, the radiation source and detector would be mounted as illustrated on Figure 6.6e. In a smaller diameter pipe (under 6 in., or 150 mm) the radiation path is not adequate to provide high accuracy and sensitivity. Therefore, the *Z* installation shown on the right side of Figure 6.6f would be used. This method of mounting lengthens the radiation path and consequently increases accuracy.

Radiation Source

For the majority of density measurement applications, cesium 137 is used as the radioisotope. Source sizes normally vary between 200 and 2000 mCi as a function of pipe diameter and specific gravity span. Gauge sensitivity is increased by the use of the collimated (narrow) beam geometry, which restricts radiation in all directions except for a direct path to the detector. This minimizes scatter and permits the use of larger sources with increased measurement sensitivity.

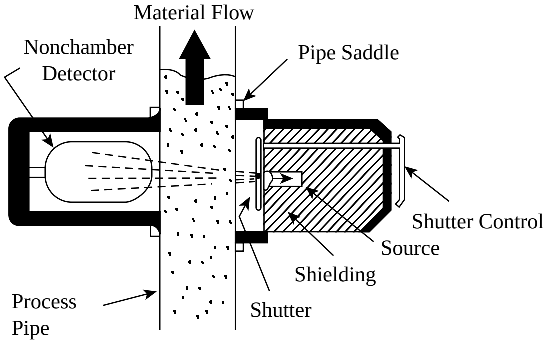


FIG. 6.6e
The gamma source is housed in a lead-shielded holder. When the shutter mechanism is opened, a collimated gamma beam passes through the pipe wall and the process material inside; its intensity at the detector is interpreted into process density.

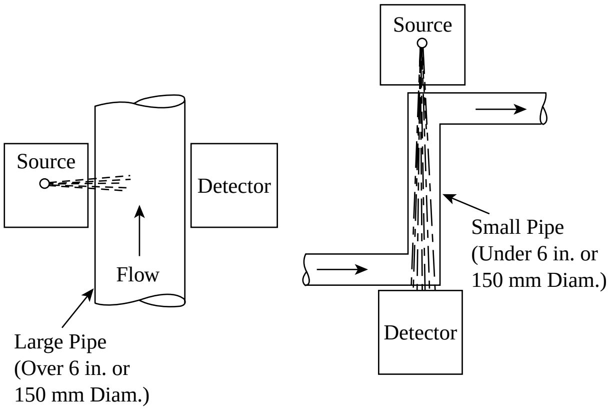

FIG. 6.6f
Radiation density sensors.

Most designs are such that the radiation intensity at one foot from the gauge surface in any direction will not exceed 5 mR/h. This is a safe value for any process area where the operator's occupancy is 20 hours or less per week.

The source holder is provided with a shutter mechanism to close the radiation beam port during installation. Available shutter features include the fail-safe design, which automatically closes the shutter whenever power fails; the shutter switch, which permits remote light display of shutter position; and the remote shutter control, which allows closing the radiation beam from a central control board.

Radiation Detectors

There are three basic types of gamma ray detectors: the Geiger tube, the ionization chamber, and the scintillation crystal/photomultipler tube detector.

FIG. 6.6g
Actual installation of a densitometer.

Geiger Tubes The Geiger tube is a low-accuracy device that measures radiation through the ionization of a halogen gas at about 500 V DC potential.

Ionization Cells Ionization cells operate by the ionization of pressurized gas between two dissimilar metals under incident radiation, generating a low current signal (10^{-10} A). For density gauging, the ionization chambers are used almost without exception (Figure 6.6g). They require stable amplification, but when this is provided they supply simple, accurate, and reliable measurements.

Scintillation Detectors The scintillation detector senses the light photons resulting from gamma rays incident on certain crystal materials. This is the most sensitive but least stable detector. It is particularly affected by variations in environmental conditions such as temperature.

Temperature Control and Calibration It is desirable to heat and thermostatically control the detector chamber to eliminate temperature variation and moisture condensation problems. The process temperature is of no consequence, but it is necessary to use thermal insulation between cell and process, so that detector temperature will not rise above 140°F (60°C).

Calibration checks for both zero and span can be performed by the use of equivalent absorbers. These absorbers are accurately made for the specific measurement and are inserted between source and detector with the pipe empty.

Periodic recalibration is necessary to overcome the effects of source aging and material buildup on the walls. If zeroing and calibration is to be done in place using air and some known density calibration liquid, it is necessary to install a calibration fluid sample valve near (usually below) a densitometer that is mounted in a vertical pipe.

Amplifier and Power Supply

Amplifiers are available in both digital and DC designs. Economics favor the DC design, while the digital amplifier guarantees better accuracy and less drift. The DC amplifier needs weekly or bimonthly standardization, while the solid-state, digital unit requires less frequent standardization.

Span and Error The minimum full-scale span is about 0.05 specific gravity units with a corresponding accuracy of 0.0005 SG or better. When measuring small spans, the zero drift due to source decay becomes an important consideration. The source decay compensator unit is a must for such installations. For wider ranges, it is essential only if the source is cobalt 60. The source decay effect with cesium 137 is only 3%/year.

Densitometers for applications involving process materials with high temperature expansion coefficients are provided with temperature compensation if variations in process temperature are expected.

The output signal from the detector to the amplifier is in digital pulses. Therefore, the signal should be protected by the use of two-wire, shielded cable. The maximum distance between detector and amplifier is about 5000 ft (1500 m), but should be made shorter whenever possible.

BETA RADIATION DENSITOMETERS

Beta-ray absorption has been successfully used in cryogenic density applications. The source in this unit is strontium-90 and the receiver is a silicon surface-barrier detector.

The system counts the number of beta particles that strike the detector with an energy greater than the discrimination level.

The source and receiver are packaged in a small, light, corrosion-resistant probe. In addition to detecting density, it can be used for level and other measurements.

X-RAY DENSITOMETERS

“Soft,” low-energy x-rays have also been used in density measurement applications (Figure 6.6h). x-ray systems do not require lead shielding and produce passive radiation. This means that radiation stops when the power supply to the unit is turned off. In the example shown on Figure 6.6h, safety interlocks can be provided to turn off the power supply if the hopper is empty or when either the source or the detector is removed, or if the hopper access door is opened.

The excitation voltage is about 35,000 V, and the x-rays are collimated (focused) to a beam diameter of about 3 in. (76 mm) at the end of a 40 in. (1.01 m) path through air. The supplier claims that the instrument meets both the U.S. Federal Drug Administration’s 1000 rad limit on radiation absorption of food and the 100 mrem/week limit of Occupational Safety and Health Administration on human exposure to radiation.

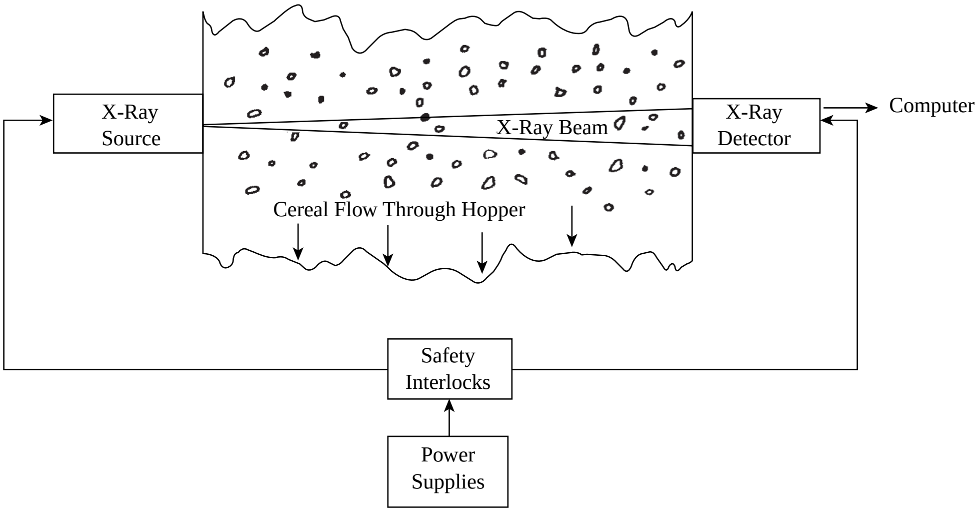

FIG. 6.6h
X-ray densitometer used on cereal hopper contents. (Courtesy of Bedford Control Systems Inc.)

LIMITATIONS

The main limitations of radiation densitometers include air entrainment, pipe wall deposits, source decay (about 3%/year for Cs 137), and stratification. Some of these problems can be minimized by installing the gauge in vertical upward flow with a positive head pressure at the location of the gauge. Other remedies include the use of glass or Teflon-lined pipes and the maintaining of a flow velocity of 5 ft/s (1.5 m/s) at the gauge. Frequent recalibration is also recommended.

Another limitation involves minimum spans, as the detector requires a 5% change in the detected radiation intensity as the process density changes from minimum to maximum. Therefore, on a 2-in. (50-mm) pipe, the minimum span is 0.2 SG, while on a 6-in. (150-mm) pipe or on a *Z* installation, the minimum span is 0.05 SG. Microprocessor-based densitometers can compensate for source decay and can also provide automatic temperature compensation (water density at 176°F [80°C] changes by 0.0005 SG/°C of temperature change).

CONCLUSIONS

For source sizing and licensing information, refer to Section 3.15. Where it is possible for the operator to get in the path of the radiation beam (when moving the gauge or when cleaning a tank), a Specific License must be obtained. In all other cases, a General License is sufficient.

The applications of radiation densitometers include the consistency control in such processes as lime kiln feeds, density measurements of sewage sludges, black and green liquors, food products, granular materials, and the detection of pipeline interfaces. While relatively high in cost, these density detectors, which have no moving parts and require no contact with the process, perform reliably on hard-to-handle (flammable, toxic, hot, corrosive, sticky, etc.) processes.

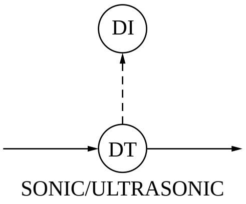
6.7 Ultrasonic Sludge and Slurry Densitometers



C. H. HOEPPNER (1982) **B. G. LIPTÁK** (1995, 2003)

Types:	Sonic and ultrasonic
Design Pressure:	10,000 PSIG (690 bars)
Design Temperature:	–20 to 390°F (–29 to 199°C)
Materials of Construction:	Stainless steel, Hastelloy, epoxy, titanium
Limitations:	Requires constant bulk modulus of elasticity and no gas bubbles in process fluid
Range:	0.5 to 1.5 SG. The range of ultrasonic sludge detectors is 0.1 to 20% (1000 to 200,000 mg/l).
Inaccuracy:	0.1% of span, or 1000 mg/l for ultrasonic sludge sensors
Cost:	Ultrasonic suspended solids monitors, $5000 to $6000
Partial List of Suppliers:	Agar Corp. Inc. (www.agarcorp.com) Delavan Process Instrumentation, an L&J Company (www.ljtechnologies.com) Markland Specialty Engineering Ltd. (www.sludgecontrols.com) Monitek (www.monitek.com) Sigrist (www.chemicals-technology.com) ThermoMeasureTech (www.thermi.com)

INTRODUCTION

Sludge and slurry densities can be detected by several methods, including radiation, sonic/ultrasonic, and optical. The radiation type densitometers have been described in the previous section and their main limitation is their high cost. The photometric densitometers are usually called turbidity analyzers and are described in Chapter 8. They are limited to low solids concentration applications, usually in the ppm range, and are not suited for use on thick slurries or sludges. This is because fouling, abrasion, and coating by slime, scale, or grease would interfere with their operation.

For these reasons, the most popular sludge densitometers are the sonic or ultrasonic types. They are well known and widely used in suspended solids and sludge applications and will be discussed in some detail in this section.

ULTRASONIC SLUDGE DENSITOMETERS

The attenuation of an ultrasonic pulse is a function of the amount of suspended solids in the path of the pulse and of the length of that path (Figure 6.7a). When an ultrasonic pulse is directed across a gap of a probe or across a pipe section, the ratio between the ultrasonic energy emitted and received is related to the sludge density and can be converted into an electronic output signal.

The ultrasonic pulse cannot penetrate through air bubbles or heavy solids, but it can pass through biological and other lighter sludges at concentrations in the 0.1 to 20% range (Figure 6.7b). When the purpose of the installation is to provide a sludge density switch, which can signal the interface between different density layers of slurry, the density switch shown in Figure 6.7c can be considered. This dual-headed sludge blanket

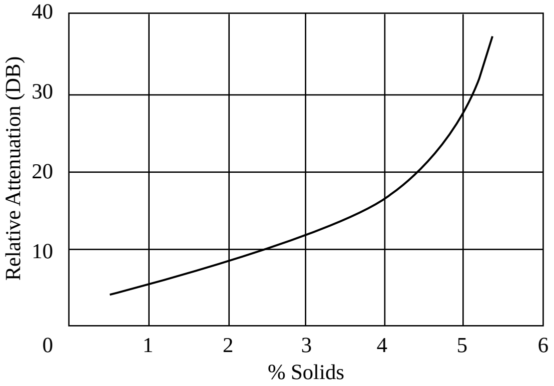


FIG. 6.7a
The attenuation of sonic or ultrasonic pulses increases as the sludge density rises.

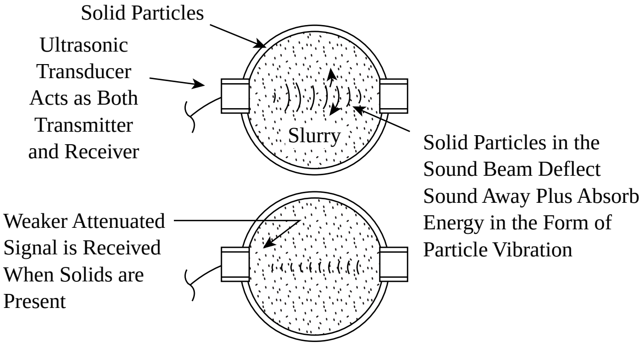

FIG. 6.7b
The operation of an ultrasonic slurry densitometer. (Courtesy of Markland Specialty Engineering Ltd.)

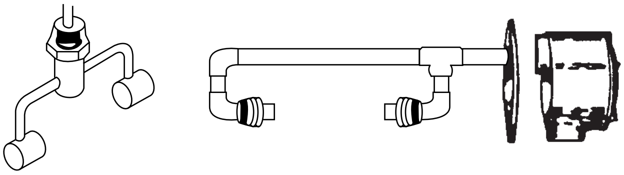

FIG. 6.7c
Sludge density switch can signal the interface between sludge blankets. (Courtesy of Delavan Inc.)

monitor is an ultrasonic sludge density sensor; its main use is in signaling the interface level between sludge blankets.

Calibration

The microprocessor-based sludge-and-slurry densitometer units can be provided with on-site calibration capability. These units are calibrated by filling the gap of the probe or the flow-through sensor first with water, and after that, pushing a button. This automatically sets the zero for the instrument.

Next the sensor head is filled with a sludge of known concentration and the output is adjusted until it reads this known value. At that point, a second button is pressed, and the sludge densitometer is now calibrated and will give linear readings between these two settings.

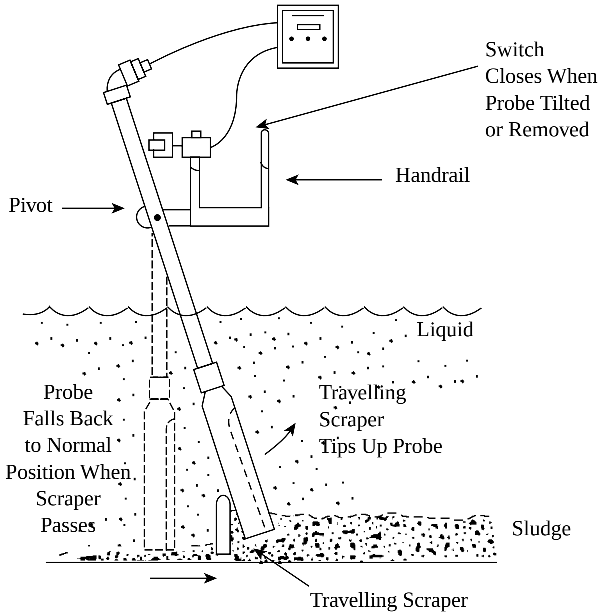

FIG. 6.7d
Sludge densitometer probe lifts to let traveling scraper pass. (Courtesy of Markland Specialty Engineering Ltd.)

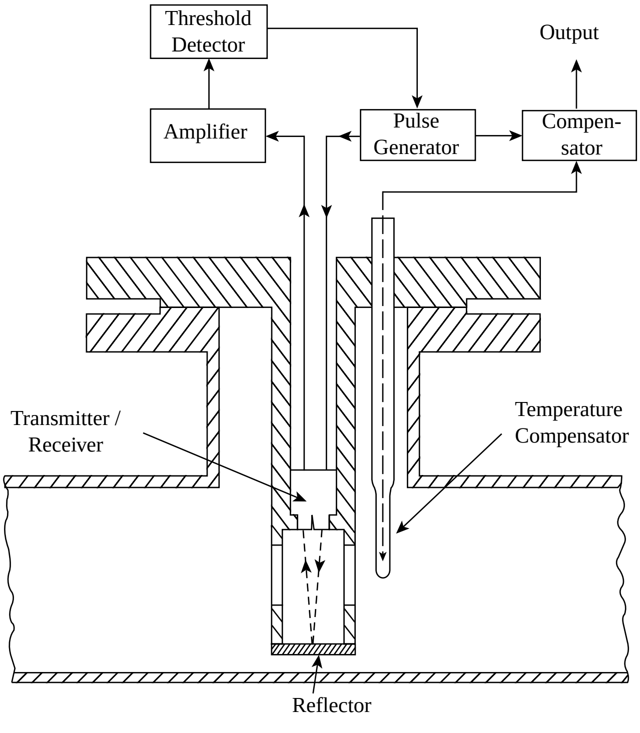

FIG. 6.7e
Sound velocity meter.

Another valuable feature of the microprocessor-based sludge density sensor is its ability to average and thereby damp its fluctuating and noisy measurement signal. This is desirable on closed-loop, on-line control applications, where a relatively steady output is needed for stability.

The probe-type designs, made to lift out of the way of a traveling scraper, are illustrated in Figure 6.7d.

SONIC DENSITOMETERS

This density detector consists of a device for measuring the speed of sound in the liquid, while compensating the detected speed for the effects of temperature and pressure. The speed of sound can be expressed as the square root of the ratio of E/ρ, where E is the bulk modulus and ρ is the mass density of the process fluid.

The sensor is calibrated by being immersed in distilled water, where the temperature is closely controlled at intervals between 32 and 167°F (0 and 75°C), and by measuring cycle repetition frequencies to an accuracy of 0.001% (Figure 6.7e).

Sound velocity meters have several limitations. The liquid must be clear; emulsions, dispersions, and slurries scatter the sound waves and cannot be monitored. Similarly, undissolved gases and bubbles (even those as small as several thousandths of an inch in diameter) cause errors and can render the instrument inoperable. Since the velocity of sound is a function of bulk modulus and density, variations in bulk modulus will cause significant measurement errors.

This instrument is used in pipelines to detect the interface between two different types of hydrocarbon products.

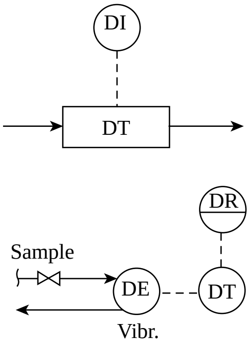
6.8 Liquid/Slurry/Gas Density—Vibrating Densitometers

B. G. LIPTÁK (1969, 1995) **C. H. HOEPPNER** (1982)
G. H. MURER (2003)



Flow Sheet Symbol

Types:	A. Oscillating Coriolis (see Section 6.5) B. Vibrating U-tube C. Vibrating cylinder or straight tube D. Vibrating twin-tube E. Vibrating fork F. Multivariable transducer for density and sound velocity
Applications:	B. Homogeneous liquids, light slurries, gases C. Homogeneous liquids, slurries, gases, gas-liquid mixtures D. Homogeneous liquids, light slurries E. Homogeneous liquids, slurries F. Homogeneous three-component liquids
Designs:	B. Bypass with sample flow required, or in-line for small pipes C. Bypass with sample flow required, or in-line for small pipes; retractable probe designs for large pipes D. In-pipe flange mounted design; bypass with sample flow required, or in-line for small pipes E. Tank or in-line installation F. Bypass with sample flow required, or in-line for small pipes
Design Pressure:	B. Up to 2900 PSIG (200 bars), depends on model and process connections C. Up to 2175 PSIG (150 bars), depends on model and process connections D. Up to 1440 PSIG (100 bars), depends on model and process connections E. Up to 3000 PSIG (207 bars), depends on process connection F. Up to 725 PSIG (50 bars)
Design Temperatures:	B. −13 to 500°F (–25 to 260°C), depends on model C. −328 to 392°F (–200 to 200°C), depends on model D. −58 to 356°F (–50 to 180°C), depends on model E. −58 to 392°F (–50 to 200°C) F. −13 to 257°F (–25 to 125°C)
Materials of Construction/Wetted Parts:	B. Stainless steel, Hastelloy, tantalum, Incoloy, borosilicate glass, and others C. Stainless steel, Ni-Span C, Hastelloy D. Stainless steel, Ni-Span C, Hastelloy E. Stainless steel, Hastelloy, Monel F. Hastelloy, Incoloy
Immunity to Pipe Vibration:	All types: Pipe vibration frequencies near the densitometer operating frequency or multiples thereof and/or mechanical stress introduced through process connections may increase errors; special precautions are recommended.

Interference from Temperature, Pressure, Viscosity, Sound Velocity, and Flow Velocity Changes:	All types: Effects are partially compensated by design. Error increases if certain limits are exceeded or measurement conditions are very different from the calibration conditions. Temperature compensation is usually provided but rapid measuring temperature changes may still cause error. Pressure compensation may be necessary if the line pressure varies. Flow velocity changes should be kept small for the smallest error. Sound velocity changes due to sample composition changes may cause error.
Limitations:	All types (except for special models): not suited for gas-liquid mixtures, foams, and for abrasive slurries B, D, and F. May be plugged by heavy slurries B, C. Not suitable for gases except for special models D, E, and F. Not suitable for gases
Minimum Span:	Most manufacturers now provide microprocessor-based controllers, with which almost any span can be set. For a rough estimation of the minimum span, take 20 times the value given for error.
Error:	B. 0.005 to 0.00005 SG, depending on model and SG range; typically 0.01 SG for gases, relative to dry air C. 0.001 to 0.0001 SG, depending on model; typically 0.01 SG for gases, relative to dry air D. 0.0001 SG E. 0.001 SG F. 0.0001 to 0.00005 SG, % concentration error depends on the application
Repeatability:	B. 0.0002 to 0.000005 SG, depending on model and SG range; typically 0.001 SG for gases C. 0.0001 to 0.00001 SG; typically 0.001 SG for gases D. 0.00002 SG E. 0.0001 SG F. 0.00001 SG
Cost:	B. Liquid density transmitter with 4–20 mA output, \$4,000 to \$6,000; high precision density transducer with separate controller, \$8,000 to \$12,000 C. Gas density system, \$10,000 to \$15,000; liquid density system, \$6,000 to \$10,000 D. \$5,000 to \$8,000 E. Appr. \$6,000 F. \$10,000 to \$15,000

INTRODUCTION

A variety of widely used and accurate densitometers have been designed by exploiting the phenomenon that the natural frequency of oscillation varies with the mass of the oscillating body. Therefore, if the mass varies with density, the frequency of oscillation can be used to measure the density. The shape of the oscillating elements in the densitometers distinguishes their designs, and they are grouped on that basis in this section. The oscillating Coriolis element is not covered here, as it has been discussed in detail in Section 6.5. The other types include the vibrating U-tube; the vibrating cylinder and straight tube; the vibrating twin-tube; the vibrating fork; and multivariable transducers combining vibrating elements with other useful sensor principles for the concentration analysis of multi component liquids. These are discussed in the following paragraphs.

BASIC THEORY

Most of the theory behind vibrating densitometers can be derived from a simple mass-spring model (Figure 6.8a). The start of the derivation is the well-known formula defining

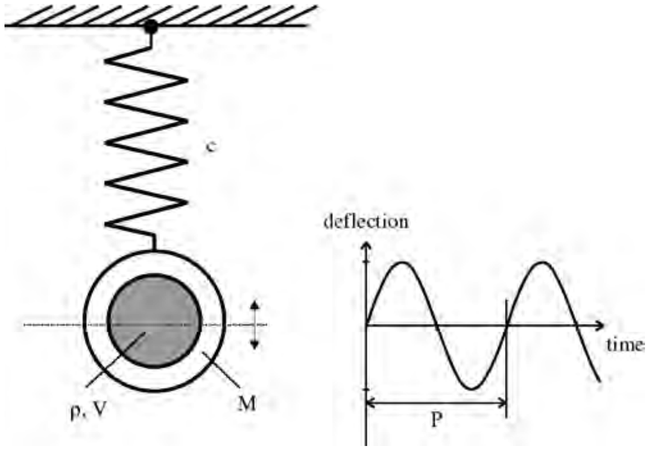

FIG. 6.8a
Mass-spring model of a vibrating densitometer.

the period P of resonant oscillation of a mass-spring model with mass m and spring constant c:

$$P = 2\pi\sqrt{\frac{m}{c}} \qquad \textbf{6.8(1)}$$

The oscillating mass of a vibrating densitometer consists of the following: the mass of the vibrating element M and the mass of the fluid participating in the oscillation, being the volume of the participating fluid V times its density *ρ*.

$$m = M + \rho \times V \qquad \textbf{6.8(2)}$$

Replacing m in Equation 6.8(1) with the right side of Equation 6.8(2) and rearranging leads to:

$$\rho = \frac{c}{4\pi^2 V} \times P^2 - \frac{M}{V} \qquad \textbf{6.8(3)}$$

Equation 6.8(3) relates the period of oscillation of a vibrating densitometer to the density of the fluid it is measuring. The two terms containing c, V, and M are now renamed for reasons of clarity:

$$A = \frac{c}{4\pi^2 V} \qquad \textbf{6.8(4)}$$

$$B = \frac{M}{V} \qquad \textbf{6.8(5)}$$

This leads to the "fundamental" equation for density measurement using vibrating sensors:

$$\rho = A \times P^2 - B \qquad \textbf{6.8(6)}$$

Equation 6.8(6) contains two unknowns, A and B, often referred to as transducer constants, which are determined by a process called calibration. This is carried out by measuring at least two standard materials of known density, typically air and water.

REAL LIFE BEHAVIOR

Now the question arises whether real life densitometers behave in such a simple way. The answer is that they do behave almost as simply as that. However, it is now time to reveal some of the difficulties associated with real life vibrating densitometers.

The first question is: How do damping forces, which are always present, influence the system? The answer is that, in a properly designed vibrating densitometer, the excitation system (an electronic device which keeps the densitometer oscillating at its natural frequency) exactly compensates for the damping effects. Therefore, damping forces do not need to be considered for normal operation.

Effects of Temperature, Pressure, and Flow

What happens with changing measuring temperatures? Looking at Equations 6.8(4) and 6.8(5) it can be seen that both transducer constants should be influenced by temperature, as a volume and a spring constant are involved. Therefore, an extended equation is necessary which is able to compensate for temperature influences on the transducer constants, provided that the temperature t is also measured:

$$\rho = A \times f_a(t) \times P^2 - B \times f_b(t) \qquad \textbf{6.8(7)}$$

$f_a(t)$ and $f_b(t)$ are functions of the temperature t which are again determined by calibration with standard materials of known density, this time at different temperatures within the operating range of the densitometer. Accurate temperature compensation can become very demanding if rapid measuring temperature changes occur.[1]

A very similar extension of the fundamental Equation 6.8(6) can be made if the compensation of pressure variations is needed. However, in many cases, the oscillating element is designed to minimize pressure influences to an extent that pressure compensation is not necessary. Flow variations also have a small, typically negligible influence on vibrating densitometers. As its speed increases, the fluid stream increasingly resists the lateral deflection caused by the oscillation of the sensing element. This can result in slight changes of the oscillation frequency of the sensor and consequential measurement errors.

There is still more to consider. All the equations above are based on a mass-spring model which is supported by an unlimited amount of "countermass." In real life, the countermass is either some additional mass built into or attached to the densitometer, another (counteracting) vibrating element, or, as in the case of circumferential oscillations, a part of the same vibrating element. If the countermass does not behave like an unlimited amount of mass, the volume of fluid participating in the oscillation changes as its density changes. This is due to the fact that the nodal points of the oscillation of the vibrating element shift as the mass load changes with different densities. To compensate for this, for most densitometers a third transducer constant is introduced into Equation 6.8(7). This third transducer constant is multiplied by the period of oscillation or a function thereof.

Effects of Sample Properties

The validity of Equation 6.8(7) is subject to another important limitation:[2] the underlying model is only accurate if all of the fluid participating in the oscillation always follows the movement of the surface of the vibrating element in the same way. In real life, there are three cases in which this rule is broken:

1. The "sound velocity effect:" If the speed of the vibrating element's surface becomes significant in relation to the sound velocity in the fluid, part of the participating fluid will lag behind the movement of that surface depending on the actual sound velocity. This causes the fluid to exert different inertial forces with different sound velocities, leading to different oscillation frequencies of the sensor and consequential measurement errors. In the case of gas density measurement with high frequency oscillating sensors, this effect can lead to excessive error if no countermeasures are provided.

   The "viscosity effect:" If the movement of the vibrating element's surface is such that shear flow is generated in the fluid, the flow pattern will change depending on the actual viscosity of the fluid. This causes the fluid to exert different inertial forces with different viscosities, again leading to different oscillation frequencies of the sensor and consequential measurement errors if no countermeasures are provided. The viscosity effect has to be taken into consideration for high-precision density measurement when the viscosity varies greatly.
2. Measurement of highly inhomogeneous fluids: If the constituents of an inhomogeneous fluid differ considerably in their density and flow behavior, they will move relative to each other when subject to oscillating forces. This leads to different inertial forces depending on the degree of inhomogeneity, again causing different oscillation frequencies of the sensor and consequential measurement errors.

Some additional, practical aspects are as follows: if a fluid forms deposits on surfaces, the mass M of the vibrating element will increase and the fluid volume V will decrease. This leads to drifts of the densitometer and requires suitable periodic cleaning and readjustment of the sensor. If abrasive fluids are measured, M and c will typically decrease and V will increase, again resulting in drifts of the densitometer. The solution is to use abrasion-resistant materials or to carry out frequent readjustments and replace the sensor once it is seriously degraded.

VIBRATING U-TUBE

In this section, two different designs based on the vibrating U-tube concept are discussed. The first design utilizes the period of oscillation measurement for density determination; the second design relies on vibration amplitude measurement.

Vibrating U-Tube with Period of Oscillation Measurement

Figure 6.8b shows a typical design in which the sample fluid flows continuously through a U-shaped tube and the frequency of oscillation is measured. This design is mainly used in high-precision online density measurements, as required for the determination of concentration in the brewing, soft drink, pharmaceutical, and chemical industries. Here, the oscillating U-tube is driven by a magnet and coil assembly and a feedback amplifier so as to maintain the oscillation at the resonant frequency of the system. A resistance-type platinum temperature sensor is attached to the U-tube for automatic temperature compensation. In order to avoid measurement errors at measuring temperatures below ambient, the U-tube is sealed in a metal box to prevent humidity condensations forming.

The resonant frequency of the U-tube and the measured temperature are transmitted to a controller through a twin wire cable which also supplies power to the densitometer. Resonant frequency and temperature are converted into density at measuring temperature, density at reference temperature, and concentration by the microprocessor-based controller. There, analog and digital outputs provide corresponding signals for further processing.

This densitometer type is also available with a built-in controller and 4–20 mA output at the expense of a slightly increased error. Several design variations with special materials for the wetted parts and U-tube diameters from 1/8 in. (3 mm) up to 1 in. (25 mm) are available. Intrinsically safe versions are provided for applications in hazardous atmospheres.

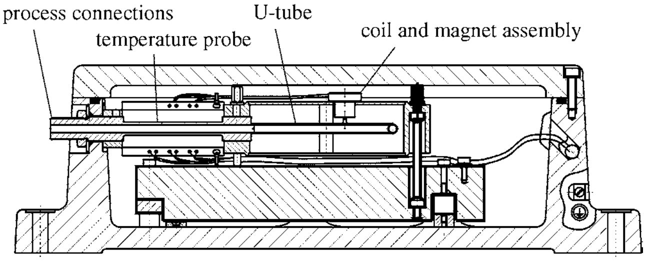

FIG. 6.8b
High-precision vibrating U-tube densitometer. (Courtesy of Anton Paar GmbH.)

This design can handle gases, homogeneous fluids, and light slurries with low to medium viscosities. Larger amounts of entrained gas cause the oscillation to stop due to excessive damping. Therefore, such samples cannot be measured unless increased line pressure causes the gas bubble volume to be compressed to a suitable extent and/or causes the gas to become dissolved in the liquid. Connecting the densitometer to the process with flexible hoses prevents influence from pipe vibration. If the densitometer is used in a bypass configuration, proper means have to be provided to secure a representative sample flow through the bypass (orifice in main line; bypass around pump in main line; pump in bypass; etc.).

Vibrating U-Tube with Vibration Amplitude Measurement

A different, low cost/low accuracy concept is used in the detector illustrated in Figure 6.8c. The process fluid flows continuously through a 1/2 in. (12.5 mm) diameter U-tube section which is welded at the node points. The total mass of the U-tube assembly is affected by the process fluid density. A pulsating current through the drive coil brings the U-tube into mechanical vibration. An increase in process density increases the effective mass of the U-tube and, therefore, decreases the corresponding vibration amplitude. An armature and coil arrangement is provided to detect the vibration at the "pickup" end. The armature vibrates together with the U-tube and induces an AC voltage proportional to the fluid density in the pickup coil. This AC voltage is then converted into DC millivolts, which is more compatible with remote recorders or controllers. In installations where the process temperature is expected to vary, an automatic temperature compensating circuit performs the required temperature correction.

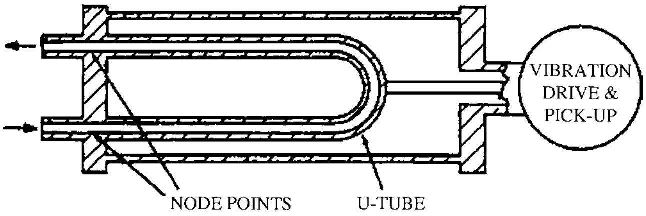

FIG. 6.8c
Vibrating U-tube density detector.

If the process stream contains entrained gases, then low flow velocities can cause separation and trapping of the gas. The measured value then represents some average value of the liquid and gas density. As with most vibrating densitometer designs, the entrained gas influence on the measured density can be compensated to some degree by offsetting the measurement result, provided that line pressure and flow remain suitably constant.

Several different materials for the wetted parts are available for this densitometer, e.g., for applications with aggressive liquids or abrasive slurries. This densitometer can handle homogeneous fluids or light slurries with low or moderate viscosities. High-viscosity streams or heavy slurries are likely to plug the small diameter U-tube. If the densitometer is used in a bypass configuration, proper means have to be provided to secure a representative sample flow through the bypass.

VIBRATING CYLINDER OR STRAIGHT TUBE

These two densitometer designs have a similar shape of vibrating element, but different oscillation modes are applied. In the vibrating cylinder design, circumferential oscillation of a cylinder is used for density measurement. In the vibrating straight tube design, lateral oscillation of a single tube is utilized.

Vibrating Cylinder

In the vibrating cylinder design for gas density measurements as shown in Figure 6.8d, the gas flows around (or both through and around, as in similar designs) a thin-walled cylinder that is located concentrically inside the housing of the densitometer. If circumferential oscillation normal to the cylindrical element is induced and sustained, the element will vibrate at a frequency that is a function of its stiffness and the oscillating mass. Since the gas surrounding the cylinder is caused to oscillate, the mass of the entire system in vibration consists of the mass of the spool plus that of the fluid. If a loop closed around the oscillator exhibits a proper phase

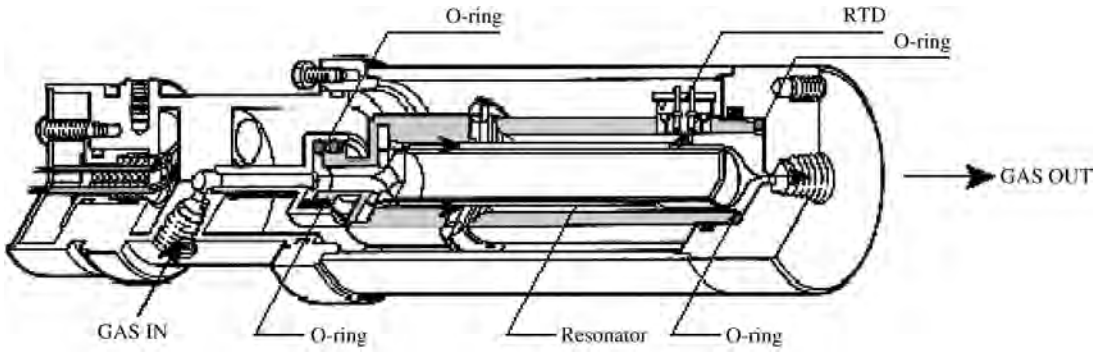

FIG. 6.8d
Gas densitometer using the vibrating cylinder concept. (Courtesy of Yokogawa Corp.)

shift, vibration is sustained at the natural frequency. Thus, for a cylinder of a fixed stiffness and mass, variations in oscillating frequencies are due to variations in gas densities. In this particular design, both fundamental and overtone harmonic oscillations are applied in order to compensate for interferences from other gas and process properties.

Only specific vibrating cylinder densitometer designs are suitable for gas density measurements, whereby special consideration has to be given to measurement errors induced by sound velocity changes due to gas composition changes.[3] When used as a gas mass-flow meter system, the densitometer should be installed in a pocket of the pipeline (Figure 6.8e) in order to keep the gas temperature in the densitometer at the same temperature as in the pipeline.

In a design suitable for liquids as shown in Figure 6.8f, oscillations are induced in a cylindrical spool and sustained by a feedback amplifier. A predetermined number of oscillations is counted and the elapsed time is measured by a high-frequency clock. The density signal is then developed from these data. Variations in spool stiffness and natural oscillating frequencies are minimized by several means. Temperature effects on spool dimensions and elastic modulus are kept as small as possible by alloys such as Ni-Span C. Fluid pressure is exerted on both surfaces of the spool, so that pressure variations have no influence on oscillation. This design is suitable for light and clean liquids of low viscosity such as light hydrocarbon mixtures, and not for slurries and viscous and/or abrasive materials. Typically a bypass type of installation is needed.

The vibrating cylinder densitometers are usually provided with platinum RTD (resistance temperature detector) elements for temperature compensation. Microprocessor-based converters serve to compensate for pressure and temperature effects and also to calculate mass flow rates based on density and volumetric flow rate signal inputs, if required.

Vibrating Straight Tube

The vibrating straight tube design is popular for all kinds of liquid density applications (Figure 6.8g). It utilizes lateral oscillation of a single straight tube of 1 in. diameter. To minimize measurement errors introduced by mechanical stress from the ambient, flexible bellows located between the process connections and the vibrating straight tube are applied. Temperature measurement for automatic temperature

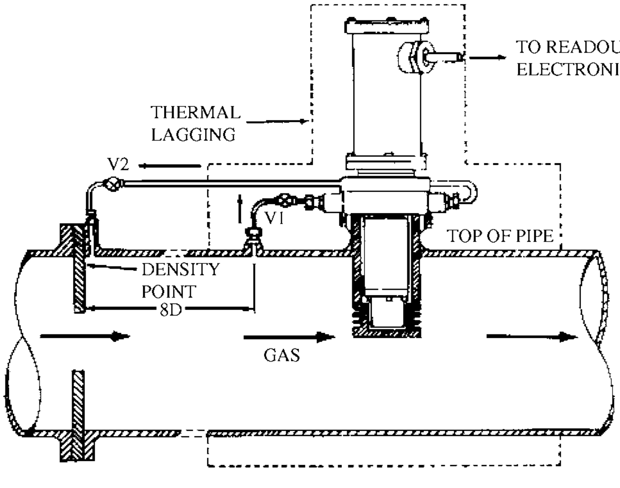

FIG. 6.8e
Vibrating cylinder densitometers are often used to calculate mass flow rates of natural gas or similar flows from orifice pressure drops. (Courtesy of Schlumberger Transducer Division)

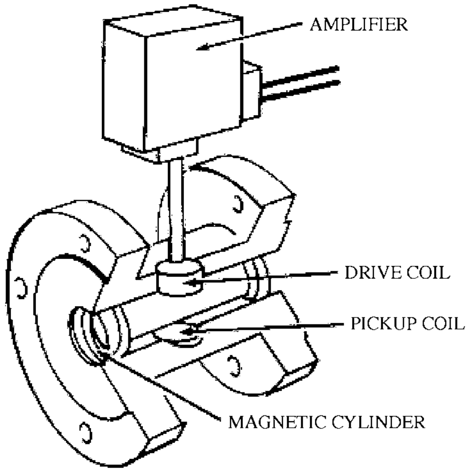

FIG. 6.8f
Thin-walled stainless steel spool, which is secured at one end, is oscillated, and the oscillation frequency is detected as a measure of density. (Courtesy of Sarasota Automation Inc.)

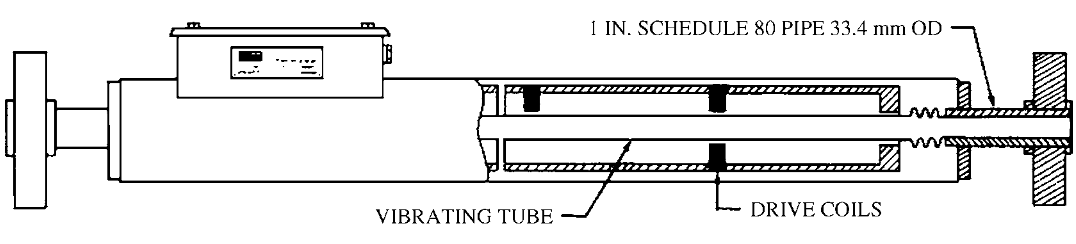

FIG. 6.8g
The 1 in. (25 mm) densitometer can be installed in the process pipe or, when the line size is larger, in a bypass. (Courtesy of Schlumberger Transducer Division)

compensation purposes is provided by a resistance-type platinum temperature sensor.

Due to the single straight tube of 1 in. diameter, highly viscous fluids and heavy slurries can be measured. The design is also applicable for difficult liquids such as crude oils, although regular mechanical cleaning and readjustment[4] is then necessary to avoid measurement errors due to the formation of residue layers on the wall of the vibrating straight tube. Special versions for applications with entrained gas are available. Intrinsically safe versions are provided for applications in hazardous atmospheres. A wide variety of materials for the wetted parts and special versions for hygienic and other applications are offered.

Measurement errors due to the potential separation effects on inhomogeneous samples have to be considered. Specific installation rules must be followed in this case. Sound velocity changes due to sample composition changes may also have some influence on the result. If the densitometer is used in a bypass configuration, proper means have to be provided to secure a representative sample flow through the bypass.

VIBRATING TWIN-TUBE

A successful design to avoid measurement error being introduced by mechanical stress is based on the twin-tube concept (Figure 6.8h). It consists of two parallel tubes of equal geometry through which the sample flows. The sample stream is equally distributed between the two parallel tubes. Ideally, these two tubes have the same natural frequency and oscillate against each other (180° phase shift) driven by a suitable feedback system. The twin-tube concept allows the production of relatively lightweight densitometers providing a reasonable level of accuracy.

Transducers are available as flange-mounted devices for in-pipe installation. Other manufacturers provide designs with 1 in. (25 mm) process connections which are normally applied in a bypass-type installation. Temperature measurement for automatic temperature compensation purposes is provided by a resistance-type platinum temperature sensor. Several materials for the wetted parts and intrinsically safe versions for applications in hazardous atmospheres, as well as special versions for hygienic and other applications are offered. Twin-tube designs can be used for homogeneous, low to medium viscosity liquids. If the densitometer is used in a bypass configuration, proper means have to be provided to secure a representative sample flow through the bypass.

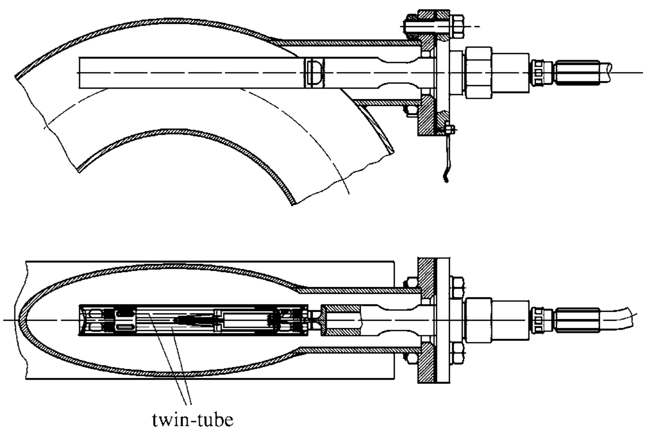

FIG. 6.8h
Vibrating twin-tube densitometer for in-pipe flange-mounted installation. (Courtesy of Anton Paar GmbH.)

VIBRATING FORK

The vibrating fork design became popular in the late 1990s due to its low cost and simplicity (Figure 6.8i). The main feature of this type of densitometer is that it can be mounted directly on a tank or large diameter pipe wall. The sensor acts like a tuning fork immersed in a liquid. Piezo-ceramic elements and a suitable feedback amplifier drive the oscillation of the sensor. Although its natural oscillation frequency is heavily influenced by both the density and viscosity of the liquid, ways have been found to compensate for most of the viscosity influence. Thus density can be measured with reasonable accuracy.

The viscosity influence is compensated by determining both the natural frequency of oscillation and the damping of the oscillation exerted by the liquid. The same sensor design can also be used for liquid viscosity determination. Temperature measurement for automatic temperature compensation purposes is provided by a resistance-type platinum temperature sensor.

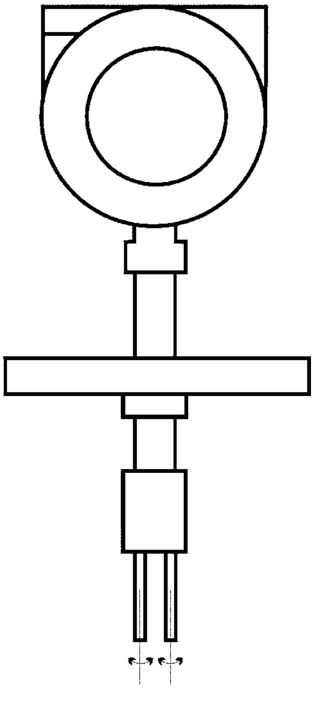

FIG. 6.8i
Vibrating fork densitometer.

An explosion-proof version and a selection of different wetted materials are offered. A microprocessor-driven controller is built into the densitometer, allowing various conversions of density and temperature into density-related properties. A 4–20 mA output and an RS 485 interface are provided. The vibrating fork densitometer can be used for both low and high viscosity liquids and slurries.

MULTIVARIABLE TRANSDUCER FOR DENSITY AND SOUND VELOCITY

High-precision density measurement is often applied for the accurate concentration determination of binary liquids such as alcohol/water solutions, sugar/water solutions, acids, and many other types of binary solvent/solute systems. There was a need for a similarly simple and precise method for the concentration determination of ternary systems such as alcohol/sugar/water or NaOH/NaCl/H_2O. Although such determinations have already been performed for many years by combining, e.g., density with separate refractive index or conductivity transducers, in the 1990s a transducer was developed which combines a vibrating U-tube densitometer and a high-precision sound velocity measurement in one housing (Figure 6.8j).

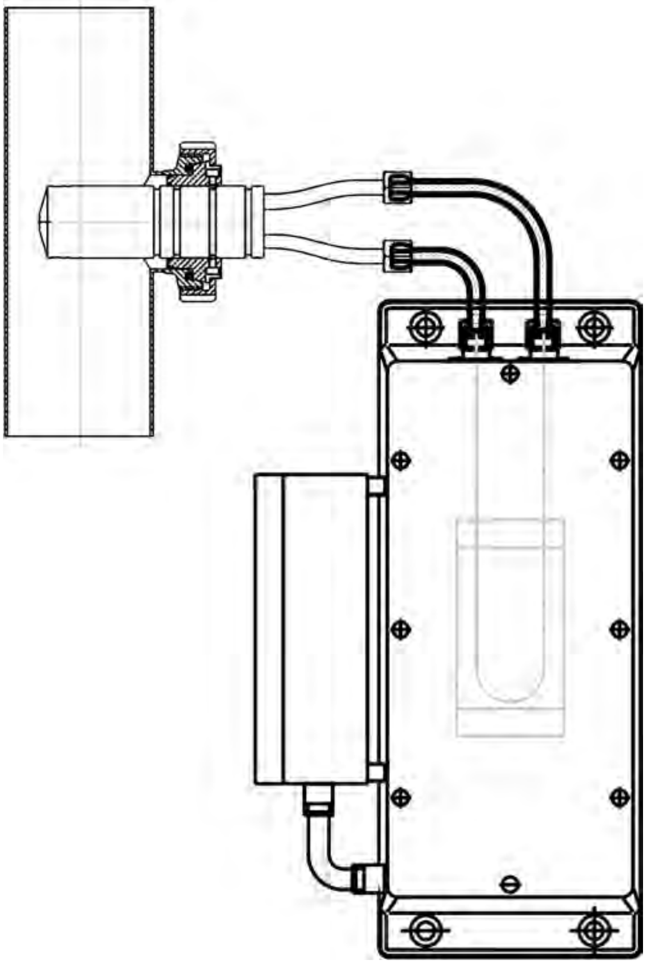

FIG. 6.8j

Combined density and sound velocity transducer for concentration analyses of three component types of liquids. (Courtesy of Anton Paar GmbH.)

Density, sound velocity, and temperature are measured and transmitted to a controller through a twin-wire cable, which also supplies power to the transducer. The controller provides analog and digital signal outputs for further processing. The system is successfully applied for on-line beer and soft drink concentration analyses as well as for the measurement of many ternary systems in the chemical industry.

The transducer is available with a 1/4 in. (6.6 mm) U-tube diameter and is normally applied in a bypass type installation. Several materials for the wetted parts and an intrinsically safe version for applications in hazardous atmospheres are offered. The design can be used for homogeneous, low to medium viscosity liquids.

6.9 Weight-Based and Miscellaneous Densitometers

Flow Sheet Symbol

C. H. HOEPPNER (1982) **B. G. LIPTÁK** (1969, 1995, 2003)

Design Pressure:	2400 PSIG max (16.6 MPa) with solid connections; 200 PSIG max (1.37 MPa) with flexible metallic connectors; 40 PSIG (276 kPa) with rubber connectors
Design Temperature:	500°F (260°C) max with solid connections; 180 to 300°F (82 to 149°C) max with various flexible hoses
Materials of Construction:	For wetted parts: bronze, stainless steel, Carpenter 20, Pyrex, nickel, Monel, Karbate, polyvinyl chloride, or ebonite lining; for flexible hoses: stainless steel, Monel, neoprene, Hypalon, Teflon, Viton-A, butyl, silicone rubber
Inaccuracy:	The larger of 1% of span 0.0003 SG
Minimum Span:	0.01 to 0.5 SG, depending on design
Approximate Cost:	From $3000 for laboratory units up to about $10,000 for larger industrial units in corrosion-resistant materials

INTRODUCTION

In this section a few, lesser-known methods of density measurement will be discussed. Some of these are no longer on the market, while others are used in the laboratory only. While they are not widely used, their operations are based on valid principles. For these reasons and for the sake of completeness, they are included in this chapter.

WEIGHT-BASED DENSITOMETERS

One of the methods of weighing a fixed volume has already been discussed in Section 6.2, where the force of buoyancy of a fixed volume float was shown to be detected by a variety of displacement-type density sensors. Another densitometer family is discussed here, where the density of the process fluids is determined by the measurement of the weight of fixed volumes. All of these detectors consist of a constant volume flow-through chamber that is continuously weighed.

The design variations within this group involve the shape of the weighing chamber, which can be a section of a straight piece of pipe, a U-tube section, or a small tank. Furthermore, the connection between the weighing chamber and the process can be solid or flexible, and the instrument can be a multipurpose device or can only be a controller. Table 6.9a compares some features of the density detectors discussed in this section.

Weighed-Bulb-Type Densitometer

The closed liquid system illustrated in Figure 6.9b consists of a bulb and sample tubing. The use of the vent hole and the siphon tube guarantees that no gases or liquids are trapped in the bulb.

The in and outlet tubes also serve as spring elements of the weighing mechanism. The bulb is suspended from one end of the main beam, which is balanced by the counterweight on the other end. The counterweight is used to zero the instrument by balancing the dead weight of both the bulb and of the zero reference (minimum density) fluid within the bulb. (For example, for a range of 0.65 to 0.75 SG [specific gravity], 0.65 SG represents the minimum density noted above.)

As liquid density increases, the bulb descends. Its descent is resisted by the spring action of the sample tubes. The bulb motion is directly proportional to the density of the process fluid and is transmitted to the main beam so that it also moves in proportion to the changes in specific gravity of the flowing sample. This movement can actuate an indicator, recorder, or controller.

TABLE 6.9a
Comparisons Among Density Sensors that Detect the Weight of Fixed Volumes

	Type of Design			
Features	*Weighed Bulb*	*U-Tube*	*Straight-Tube*	*Direct Controller*
Minimum span (SG)	0.05	0.02–0.05	0.5	—
Maximum span (SG)	0.5	3.5	1.0	—
Inaccuracy (% span)	±1%	±1–2% or 0.0003	±1%	±1% of setpoint
Materials for wetted parts	Brass, stainless steel, Carpenter 20	Stainless steel, Monel, nickel, Karbate, glass or lined with PVC or ebonite	Stainless steel	Stainless steel and Pyrex
Materials for flexible hoses	None	Neoprene, Hypalon, Viton-A, buty1, Teflon or silicone rubber, also stainless steel or Monel	Neoprene, buty1, Viton-A	Neoprene, buty1
Design pressure (PSIG/kPa)	Up to 2400/16,547	40 to 200/276 to 1379	50/345	10/69
Design temperature (°F/°C)	Up to 500/260	180 to 300/82 to 149	180/82	180/82
Weigh chamber volume (gallon/l)	0.265/1	0.2 to 1.0/1 to 3.8	0.5 to 1.0/1.9 to 3.8	5.0/18.9
Sample flow rate (GMP/lpm)	0.265/1	1 to 70/3.8 to 265	125/473	5 to 15/18.9 to 56.7
Sample connection size (in./mm)	$^{1}/_{4}$ /6.35	7/8 to 2/22.2 to 50.8	2/50.8	$1^{1}/_{2}$ /38
Temperature compensation	Automatic to 500°F/ 260°C	Automatic but limited	Nonstandard	No

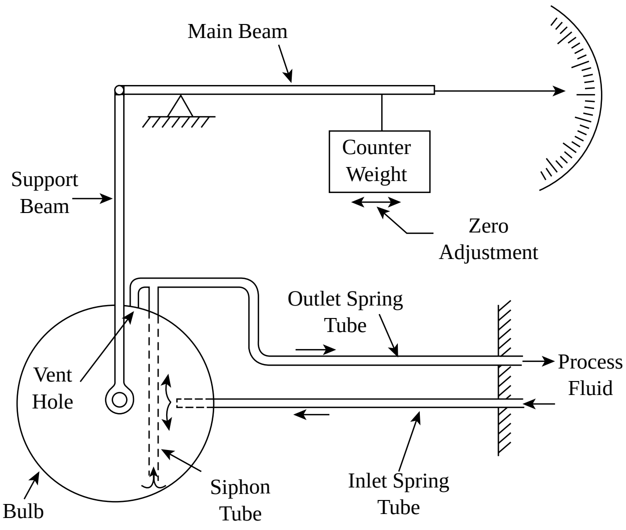

FIG. 6.9b
Weighed-bulb density sensor.

Design Features The unit is also available as a motion balance transmitter. When the readout is located several miles from the detector, telemeter type transmission can be considered, utilizing two-wire circuits, such as telephone or radio channels.

This densitometer is provided with a thermostatic coil that detects the outlet process temperature and automatically corrects the reading for changes in specific gravity due to temperature variations. The compensator can correct for process temperatures from –100 to 500°F (–73 to 260°C).

From Table 6.9a, it can be seen that the main advantage of the weighed-bulb design is that it contains no flexible hoses. Therefore, it can be used on high process pressure and temperature applications.

The unit is designed for low sample flow rates with velocities in the laminar range. The advantage of such design is that the forces created by fluid turbulence are eliminated, while the disadvantage is that the small tubes and small openings provide a potential for plugging. For this reason, the sensor should be considered for use only on clean and nonviscous services.

U-Tube Density Gauge

As shown in Figure 6.9c, the design consists of a U-shaped pipe section pivoted on flexures about the horizontal axis. Process fluid flows through this loop and its weight is transferred to a weight beam. A counterweight on the weight beam balances the pipe section when filled with a fluid of minimum density. An increase in process density produces a proportional additional force on the weight beam, which is then sensed.

While newer installations use electronic transmitters, this type of densitometer can mostly be found in older, existing installations that are still pneumatic. For this reason, in Figure 6.9c, the transmitter is shown as a pneumatic unit.

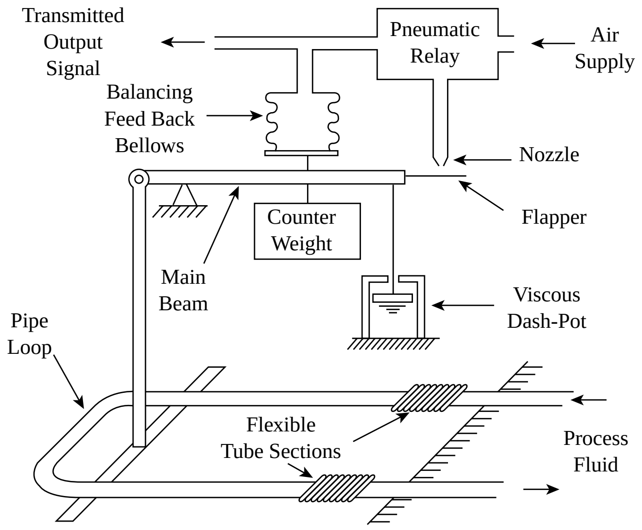

FIG. 6.9c
U-tube density transmitter.

In such designs, the added force caused by an increase in density is sensed by the nozzle-flapper section of a pneumatic force balance transmitter. Increased density increases the back-pressure on the nozzle as the flapper moves closer to the nozzle; this results in an increase in the output signal from the pneumatic amplifier relay. This transmitter output signal is also sent to the feedback bellows, exerting a counter force to rebalance the main beam. Because of the force balance nature of the design, the total motion of the flapper is only a few thousandths of an inch.

Applications The effects of variations in the process pressure or flow rate are minimized by locating the pivots on the vertical center line of the U-tube. This stays the loop against horizontal forces. The viscous dash-pot is used to eliminate vibration effects or other sudden changes in vertical force components. This design has been successfully used on slurries, if the flow velocity was kept high enough to prevent settling. This normally requires velocities in the range of 5 to 8 ft/s (1.5 to 2.4 m/s).

The process fluid can also contain gas bubbles. If it is desired to measure the density of only the liquid phase (without gas entrainment), then a trap or separator has to be installed upstream to the density gauge. If the specific gravity of the total stream (with gas entrainment) is to be measured, then the process pressure must be controlled so that the gas bubbles maintain their volume. Also, the fluid velocity must be high enough to prevent separation or trapping of the gas within the U-tube.

As shown in Table 6.9a, the design pressure and temperature limitations of these sensors are a function of the flexible connectors used. The flexibility of these connectors also affect the accuracy of the measurement. For example, accuracy when using neoprene liners on the braided connectors is twice as good (1% of span) as that when using Viton liners (2% of span).

Temperature Compensation Small variations in process temperature (±20°F, or ±11°C) can be compensated for automatically if the gauge has been factory-calibrated using the actual process fluid at the actual process temperature. If large temperature variations are expected, it is necessary to install a temperature transmitter in the process stream and to add its signal to the output of the density transmitter. The maximum temperature compensation span is a function of the density span used. Determination of the temperature transmitter range is described in the example below.

Assume a density span for the particular installation of 0.08 SG, or a range of 0.60 to 0.68 SG. Also assume that the coefficient of thermal expansion of the particular process fluid is 0.0004 SG/°F. The effect of temperature change on density must not exceed the density span of the detector. For this reason, the temperature span is determined as density span divided by expansion coefficient, which in this case is 0.08/0.0004 = 200°F (93°C). Therefore, assuming that the density measurement is to be referenced to 60°F (16°C), and assuming that the process temperature will always be over 60°F, the actual range of the transmitter can be 60 to 260°F (33 to 144°C). This compensation is illustrated in Figure 6.9d, assuming that the thermal expansion coefficient is linear for the temperature range.

Straight-Tube Density Transmitter

On applications where the process fluid is a heavy slurry or one that contains large solid particles that would not flow through a U-tube loop, the design illustrated in Figure 6.9e can be considered. Its main advantage is that

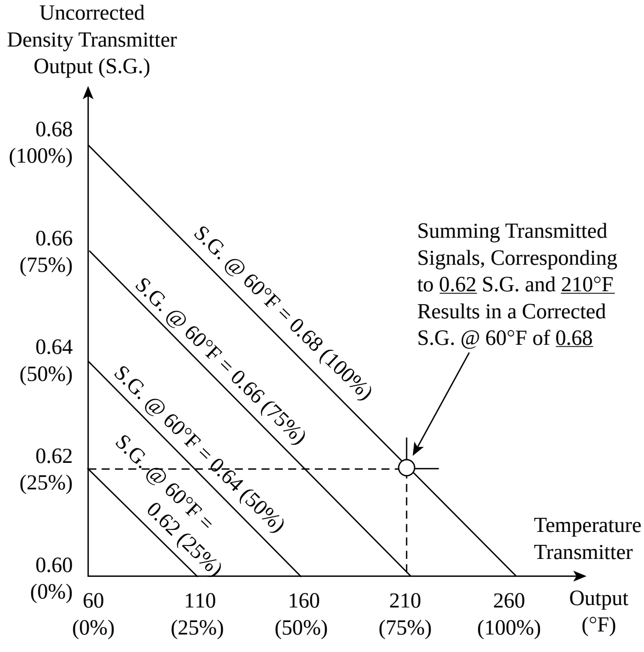

FIG. 6.9d
Temperature compensation of density sensors by summing transmitter outputs.

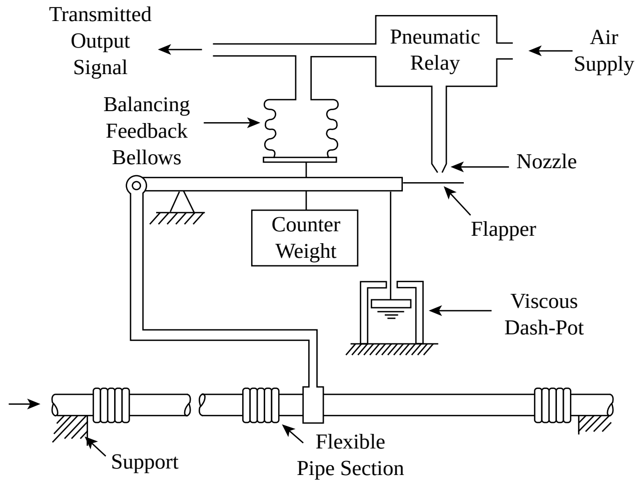

FIG. 6.9e
Straight-tube density transmitter.

any process fluid that will flow through a 2 in. (50 mm) pipe will pass through this detector. The principle of operation is the same as that of the U-tube design, but the quality of performance is lower. The other drawbacks are noted in Table 6.9a and include the fact that narrow density spans are not available. Therefore, the ±1% inaccuracy based on the actual span represents a substantially greater error than with the U-tube design. Temperature compensation can be provided by the use of a temperature transmitter and summing relay.

Direct Density Controller

The previously discussed density sensors use the counterweight for zero suppression only, and their transmitted output is a function of the force generated by a rebalancing loop. The direct density controller shown in Figure 6.9f is different. Here the counterweight on the beam scale is set to balance the sample chamber and the liquid it contains when it is at the desired density. Therefore, the counterweight represents the set point of this controller. Any deviation from this density set point will deflect the beam and that movement will initiate a counteraction by the controller. In other words, the controller detects the position of the beam and counteracts any movement away from the horizontal.

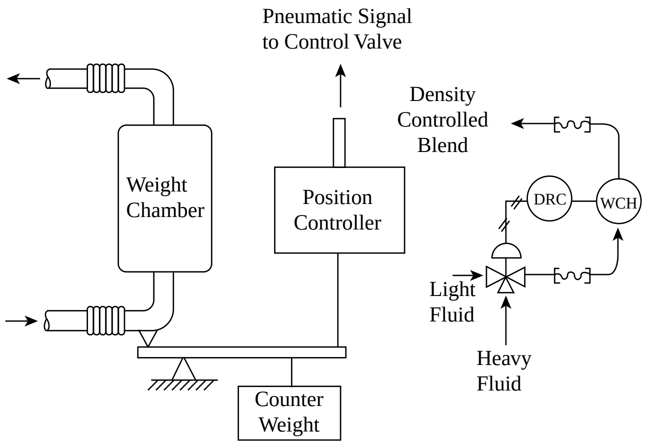

FIG. 6.9f
Density controller and its typical installation.

BALL-TYPE DENSITOMETER

The ball-type density detector consists of a number of $^1/_4$ in. (6.3 mm) diameter, hollow and opaque silica glass balls, typically 10 to 50 of them. Silica glass is chosen because of its low thermal expansion of 0.5 parts in 10^6/°F. The balls are free to move in vertical tubes that are immersed in the fluid to be measured (Figure 6.9g). Each ball has a different density; for example, in the range of 0.7 to 0.9 SG, 20 balls are graded as 0.70, 0.71, 0.72, to 0.89 SG, and the inaccuracy therefore is less than 0.01 SG.

Fiberglass probes conduct light through one side of the tubes in which the balls are contained. Probes through the other side of the tubes pick up the light if the ball is not intervening by blocking it. The last ball to float determines the density of the fluid. The tubes are usually located near the bottom of the tank and are only twice as long as the ball train that they enclose. Alternately, however, the tubes may extend to the full height of the tank to detect density variations and density stratification. The spherical shape of the floats reduces friction to the tube walls, permitting the density meter to be mounted as much as 85 degrees to the vertical.

Photo diodes are used to convert the light signals into an electrical one, which can enter a data highway or be used in an analog readout.

A valuable feature of this densitometer is its intrinsically safe nature. It may be used in explosive mixtures without danger of causing an explosion. It is also unaffected by electric or magnetic fields.

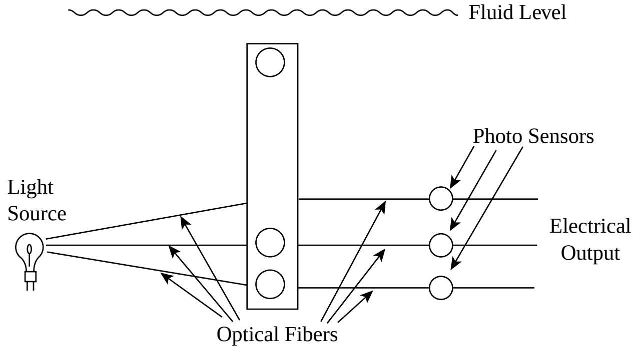

FIG. 6.9g
Multiple free-ball density meter.

CAPACITANCE DENSITOMETERS

The capacitance is proportional to dielectric constant, which, in turn, is proportional to density. Therefore, a capacitance type densitometer can be built from two concentric cylinders. When process fluid fills the cavity between the electrodes and a bridge circuit measures the capacitance between the cylinders, a densitometer results.

Fuel Weight Measurement

This method of density detection can also be applied to measure the total weight of fuel in a tank. To do so, the probe, consisting of two concentric cylinders, extends from the top to the bottom of the tank; the cavity between them fills to same level as the fuel level in the tank. The product of density (inferred from the dielectric constant) and of the liquid volume in the tank (inferred from the total level) is measured and displayed as the total weight of fuel in the tank.

Two features of this system are of interest. First, for irregularly shaped tanks, the electrodes may be contoured to match the shape of the tank, providing a linear output (Figure 6.9h). Second, many probes may be connected in parallel to sum the mass in several tanks or to compensate for tilting of the tank, as is usual in aircraft applications.

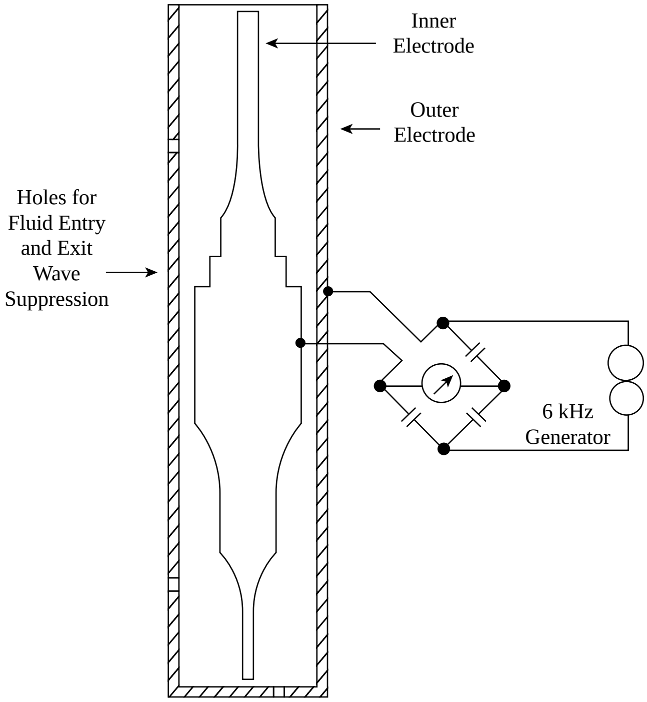

FIG. 6.9h
Capacitance probe contoured to compensate for tank irregularities.

INTRODUCTION

This section gives a historical perspective on gas density measurement techniques, including the mechanical designs, which have been widely used in the past, but have lost their popularity or have been completely discontinued. This is due to their moving parts and their associated high maintenance. This trend toward solid-state instrumentation is a general trend throughout the industry, and in the case of gas densitometers, it resulted in the proliferation of oscillating and vibrating sensors. These are discussed separately in Sections 6.5 and 6.8, but some of their features and suppliers have been also mentioned in the feature summary above under type G, for the reader's convenience.

THEORY OF OPERATION

Gas density measurement relies on some of the same laws of physics that are used in liquid density measurement. Liquids have typical densities on the order of 40 to 80 lbm/ft^3 (600 to 1300 kg/m^3); gases have densities on the order of 0.05 to 0.5 lbm/ft^3 (0.8 to 8.0 kg/m^3). The methods used include the weighing of a known volume either passively or actively. Passive weighing is measuring the static forces created by gravity. An example is a laboratory balance.

Active weighing is the process of moving or shaking the volume and determining the density from the required acceleration or the Coriolis forces (Section 6.5) or container displacement, or the oscillation frequency (Section 6.8). Another scheme varies the gas pressure until the buoyancy force is equal to that air at atmospheric pressure; at this condition, the ratio of the absolute pressures equals the specific gravity (SG). The speed of sound through a gas is inversely proportional to the square root of the density and this relationship has been used. Thermodynamic properties, such as heat capacity, have been used as the basis of instruments. Gas jet deflection has been used; gas jet impact pressure recovery is also sensitive to gas density. The centrifugal fan laws can be the basis for measuring density—see any mechanical engineering handbook. The head pressure generated is a function of the gas density.

Density is mass per unit volume. Relative density (also called specific gravity) is the ratio of the density of a gas to that of air at the same temperature, pressure, and moisture content. Confusing absolute density with specific density can have disastrous effects on engineering calculations and designs. The relative density is equal to the ratio of molecular weights of the gas and of air, which is usually taken as 28.9644. The density of an ideal gas can be calculated from its specific gravity (or molecular weight), the absolute temperature, and the absolute pressure, because equal numbers of moles of gas occupy equal volumes. See Section 6.1 for details.

To avoid redundancy, some of these devices, such as the vibration-based devices (Section 6.8) and Coriolis-type (Section 6.5) designs, are not covered here.

Gas density measurement is of interest for several different reasons. Density compensation is used to correct some flowmeters that are sensitive to density. For this purpose, it is preferred to measure the actual gas density at the flowing pressure and temperature. A flow computer is often used for this purpose when the measurement has sufficient value.

The other major use is to infer or to determine composition. Specific gravity relative to air is most conveniently measured at or near atmospheric conditions. Some of the designs, such as the displacement, centrifugal, and fluid dynamic designs, may also operate at higher pressures and can measure either specific gravity or actual density. Orientation Table 6.1a provides an overview of the capabilities of the different designs.

DISPLACEMENT-TYPE DENSITOMETERS

The buoyant force exerted upon a body immersed in a gas is proportional to the density of that gas. If the gas is at ambient conditions, the buoyant force is a measure of the molecular weight or specific gravity of the sample.

The principle is demonstrated in Figure 6.10a. It consists of a chamber containing a balance beam with a glass cylinder

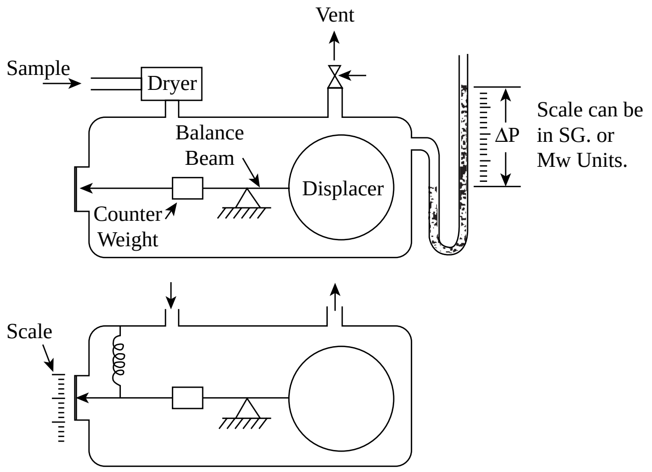

FIG. 6.10a
Displacement-type manual density gauges.

on one end and a counterweight on the other. The manual version requires first filling the chamber with dry air until the beam just balances and noting the corresponding air pressure P_a as shown on the manometer. Then the chamber is evacuated and filled with sample gas, increasing the pressure until the beam is once more balanced. This gas pressure P_g is noted and the specific gravity of the sample gas is calculated as the ratio of the two pressures is converted to absolute and measured in the same units. Pressures are normally moderate and any deviation from the ideal gas laws should not create errors.

$$SP_g = \frac{P_g}{P_a} \qquad \textbf{6.10(1)}$$

It is not necessary to balance the unit in air each time the gauge is used; once it has been balanced, the manometer scale can be calibrated in either molecular weight or specific gravity units. The sample molecular weight is determined by:

$$M_{wg} = M_{wa}\frac{P_g}{P_a} \qquad \textbf{6.10(2)}$$

This sort of instrument is no longer made and is included in this discussion for completeness of the discussion and to illustrate the applied physics.

The lower drawing in Figure 6.10a shows a variation on this design. Here the arc through which the beam swings is the measure of sample density and is indicated on the calibrated scale. If the bulb and beam are balanced in air and the gas sample introduced is at the same pressure, temperature, and humidity as the balancing air, then the gauge can read out either in specific gravity or in molecular weight units. This instrument is no longer available.

The sensors shown in Figure 6.10a operate on the buoyancy gas balance principle, where the buoyant forces of air and gas are compared. In the upper instrument, the operating pressure is adjusted until the gas density is the same as the reference air. In the lower instrument, the calibration accuracy is a function of the calibration of the measuring balance. The accuracy of measurement is largely a function of eliminating those factors (pressure, temperature, humidity) that can influence density. If the air and gas are compared under identical conditions then the accuracy can be as great as ±0.0002 SG. These sensors are used for high-precision laboratory measurements. Their main drawback is that they cannot be adapted for continuous measurement. Issues such as the humidity of the reference air and the sample gas must be addressed. Some instruments use desiccant dryers to take water from the air and the sample.

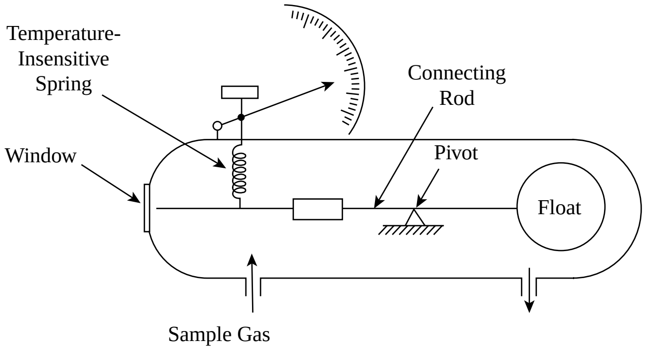

FIG. 6.10b
Manual gas density sensor.

Continuous Units for Pressurized Operation

The densitometer shown in Figure 6.10b measures the gas density at actual flowing conditions. The effects of process pressure, temperature, super-compressibility, or specific gravity changes are eliminated and the density is measured directly. Archimedes' principle is that the buoyant force on a float (displacer) is a function only of the fluid density surrounding the float.

The manually operated version of this gauge is illustrated in Figure 6.10b. It consists of a buoyant float attached to one end of a pivoted beam and a temperature-insensitive spring attached to the other end. The spring tension in this case is adjusted manually using a micrometer until the beam is brought into a null position. The readout linkage is attached to the spring and provides linear density data. These are no longer available.

Besides the manual method described above, the spring tension can be adjusted by pneumatic relays or electric motors. Figure 6.10c shows an electronic densitometer transmitter. This is no longer available, but instruments may still exist.

For accurate measurement of flowing density, the sample must be at the same operating conditions as in the process line. This is improved with the use of short (close-coupled) sample lines and by relatively high sample flow rates (10 SCFH, or 280 1/hr) and good thermal insulation.

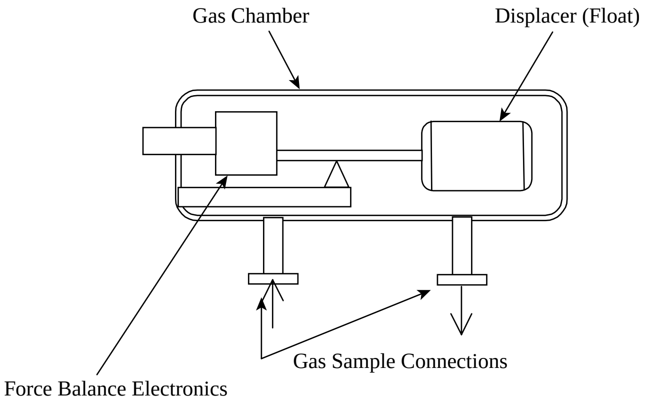

FIG. 6.10c
Continuous gas density sensor electronic transmitter.

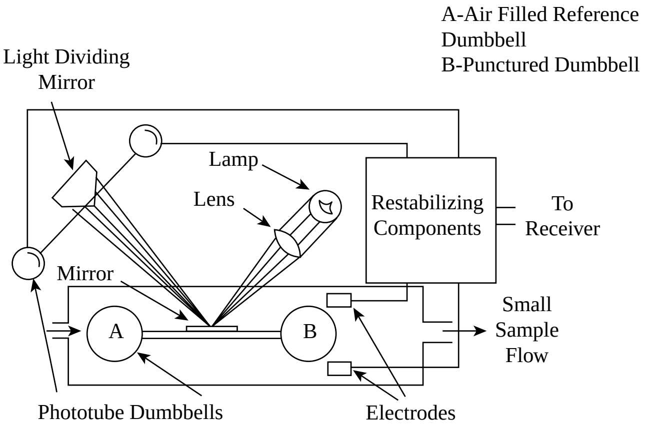

FIG. 6.10d
Electromagnetic suspension-type sensor.

Spans from 1.0 to 25.0 lbm/ft^3 (16 to 400 kg/m^3) can be obtained for measurements at 0.25% of full-scale accuracy.

Electromagnetic Suspension-Type Units

The main working component of this detector is a small dumbbell supported on a quartz fiber. One of the spheres on the dumbbell is sensitive to buoyancy effects (changes in gas density); the other is not. Insensitivity to buoyancy is achieved by puncturing that sphere (see Figure 6.10d).

A mirror fixed to the dumbbell axis reflects a light beam to a dividing mirror that splits the beam equally between two photocells. A change in gas density tends to rotate the dumbbell, causing the light to be unevenly divided between the photocells. Therefore, the signals produced by the photocells will differ; when this difference is amplified it can be applied to recenter the dumbbell. This is achieved by applying a new electrical potential to the electrodes that generate the electrostatic field around one of the spheres. The sphere is made conductive with a coating of rhodium. Measuring the electrical potential required to stabilize the dumbbell gives a linear indication of the torque created by the differential buoyancies, which in turn is an indication of sample density. If the sample is at ambient conditions, the instrument scale can be calibrated in specific gravity or molecular weight units.

In contrast with the manual displacement units, these detectors are adaptable for continuous measurements and generate output signals for remote readout. They are available with spans of 0.01 to 2.0 SG based on air with ±1% full scale accuracy. Single-range units have a total span of 1.0 SG, and multirange designs are available with a 5:1 range ratio. The measurements are performed at near-atmospheric pressures and ambient temperatures, utilizing sample flow rates in the 50 to 500 cc/min range. Depending on this flow rate, the 95% response time of the detector varies from a few seconds to 1 min. Due to the small openings and the optical parts involved, the sample gas must be clean upon entering the sensing cell. This detector is compensated for barometric changes and is manually calibrated on air or other reference gases.

This device was selected for those installations where high precision overrides the cost considerations. This instrument is no longer made.

CENTRIFUGAL GAS DENSITY SENSORS

The centrifugal detector also measures the gas density at flowing pressure and temperature conditions. As shown in Figure 6.10e, a small centrifugal blower operating at constant high speed (3000 to 13,000 r/min) extracts a small sample of gas from a tank or pipeline. The impeller is driven by magnetic coupling to allow removal of the driver and to prevent gas leakage. Gas enters the impeller at the center and is thrown outward by centrifugal force. This action creates a pressure differential across the impeller which is directly proportional to the gas density. The differential pressure (d/p) can be indicated locally or used as the input signal into a d/p transmitter for remote readout.

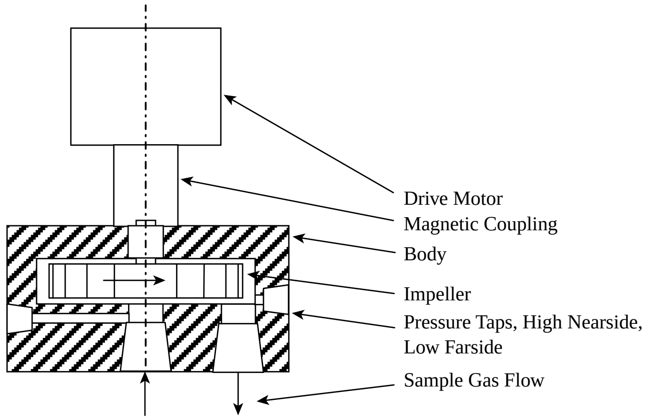

FIG. 6.10e
Density detector with centrifugal element.

Some designs can be close-coupled around an orifice plate in the pipeline; others can be installed directly in tanks or pipes.

When the gas sample is dirty, deposits may accumulate in the unit, affecting the sample flow rate. This will not influence the measurement accuracy until the material buildup becomes substantial.

Errors can be introduced by temperature differences between the process and the density chamber. This temperature difference may be caused by the difference between ambient and process temperatures and also by the motor and friction heat developed in the sensor. The error can be as high as 0.1 or 0.2%/°ΔF. In most installations, close-coupling and insulating the detector is sufficient. In the case of critical measurements, the process and chamber temperatures are detected and automatic correction is applied for the difference.

Available density spans vary from 1.0 to 20 lbm/ft^3 (16 to 300 kg/m^3) with full-scale inaccuracies at ±1% or less. Repeatability can be as good as ±0.05%.

Wetted components are available in cast iron, aluminum, steel, or stainless steel. The detectors can be exposed to pressures up to 2000 PSIG (14 MPa) and temperatures up to 300°F (149°C).

The maximum pressure differentials developed by the blower are a function of the impeller size selected, speed of rotation, and density span. The differential varies between 30 and 100 in. H_2O (7.5 to 25 kPa). The relationship between density and pressure differential developed is linear within the range of 5:1. This technology has been replaced by the vibrating sensor type.

FLUID DYNAMIC DENSITOMETER

The fluid dynamic densitometer (Figure 6.10f) is used to measure the densities of gases and liquids. It is composed of two chambers (A and B) each having a supply nozzle (C_r and C_m) and an opposing receiver port (D_r and D_m). One chamber is used as a reference chamber having only a small outlet port; it is filled with a suitable supply of nitrogen or other fluids (E) such that the dynamic pressure (P_r) of this jet on the receiver port (D_r) serves as a reference value. Directly adjacent to this reference chamber is a similar measuring chamber (B) that has large inlet and outlet ports through which the measured fluid is pumped by the action of the same supply fluid (E). The product whose density is to be measured, being entrained by this supply jet, affects the dynamic pressure (P_m) of this jet on the receiver port, which is inversely proportional to the density. A comparison of the pressure differential produced between the reference chamber and the measurement pressure is a measure of the density of the unknown product.

The fluid dynamic densitometer can be used for measurement of density of process stream and effluents in both liquids and gases. It has no moving parts, a very high sensitivity, and a high rate of response, but it is not particularly suitable for non-Newtonian fluids. It can be made of a wide variety of materials and can be mounted directly in a body or stream of fluid to give precise point measurements. Thus, petroleum and petrochemical refineries, natural gas processing plants, ethylene production, chemical process plants, and the pulp and paper industry are typical applications. There are other embodiments of the general principle of a gas jet and recovered pressure. These seem to be no longer available—another victim of the vibrating sensor. The design described above is only one of a number of schemes that have been used.

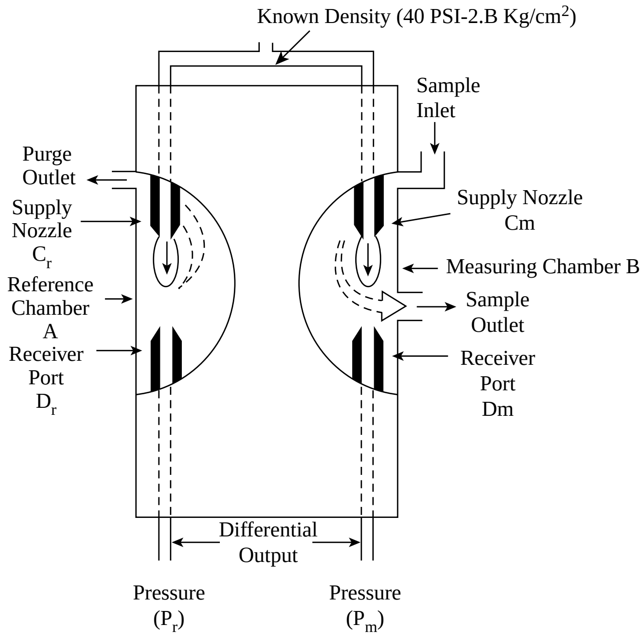

FIG. 6.10f
Fluid dynamic density meter.

GAS COLUMN BALANCE SENSORS

As their name implies, these instruments operate on the principle of measuring the difference in weight between a column of gas and a column of air of equal heights and pressures.

As shown in Figure 6.10g, the gas sample flows continuously to the interior of the oil-sealed working bell on the right and then leaves the bell through a column of set height into the atmosphere. At the same time, dry air enters the interior of the reference bell and exits to the atmosphere through a column of equal height. The weight of gas and air in the columns exerts an upward force on the bells, and the difference in weight between the two columns is the force, which causes the beam movement. Beam movement is resisted by the weight of a pendulum, which allows the pen mechanism to move in direct ratio to the specific gravity of the gas flowing through the unit.

The sample flow rate is 2 SCFH (0.9 l/m) or less at near-atmospheric pressure, limited by the oil seal in the unit.

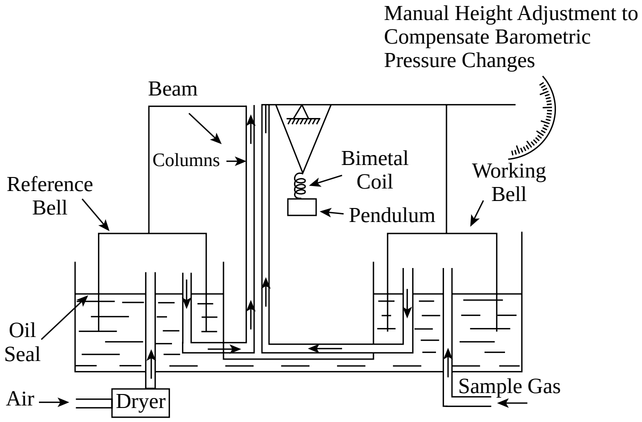

FIG. 6.10g
Gas column balance density gauge.

This corresponds to an approximate measurement time lag of 3 min. Available spans vary between 0.25 and 1.0 SG, and ranges can be selected between 0 and 2.5 SG, based on air. Detection accuracy is ±0.002 SG.

The wetted parts can be made of brass or stainless steel, and a large number of accessories and features are available, including direct recorders, controllers, and transmitters of both electronic and pneumatic types.

Whenever the basis of operation for a density sensor is to compare the gas sample to air in arriving at a specific gravity reading, it is important to compensate for the following:

1. Ambient temperature variations
2. Barometric pressure variations
3. The moisture content of the air

The sensor illustrated on Figure 6.10g is provided with an automatic temperature compensator. This is a bimetallic coil calibrated to shift the pendulum weight center of gravity in direct ratio to the temperature effect on the density. Therefore, regardless of the ambient temperature variations, the specific gravity readout is always based on 60°F (16°C).

The forces acting on the working bell are very small. At 0.5 SG, the total resulting pressure head is 0.036 in H_2O (9 Pa), and the instrument sensitivity of 0.002 SG corresponds to only 0.00014 in. H_2O (0.04 Pa). With such sensitivity, even barometric pressure variations are sufficient to introduce an error. As an example, a change of 0.5 in. Hg (0.065 kPa) in the barometric pressure can result in an error of 1%. Compensation can either be by manual adjustment of column height or by use of an aneroid barometer that automatically corrects for barometric pressure changes.

When air contains moisture, its density at the same barometric pressure is less than what it would be under dry conditions. Changes in humidity have a very definite effect on measurement precision. Therefore, a silica gel drier is installed to keep the reference air purge dry.

From the above discussion, it is clear that this detector can automatically correct its readings for humidity, temperature, and barometric pressure variations. These are no longer manufactured.

THERMAL CONDUCTIVITY DENSITY GAUGES

Thermal conductivity-type sensors are also discussed separately in Section 8.12 and also under Section 8.57. Because the thermal-type elements are most frequently used as analyzers or as components in analyzer systems, their coverage here will be brief and limited to that design that is suitable for direct specific gravity detection.

Figure 6.10h illustrates a design that is suitable for both gas chromatography and on-stream molecular weight determination. A pneumatic Wheatstone bridge with two hot-wire detectors is mounted in the vertical plane. The reference gas tends to cool the thermistors and, as long as the flow is balanced, the two detectors are equally cooled. When a sample gas is introduced, it will upset the system balance if its molecular weight is different from that of the reference gas. Zero balance is checked by introducing the reference gas as sample. If the sample gas is lighter than the reference gas, the sample molecules will tend to rise, partially obstructing the reference gas flow at detector #1, and, therefore, causing a temperature rise at that point. Simultaneously, a corresponding increase of reference gas flow will be experienced at detector #2, causing a drop in temperature at that point. The temperature difference between the two thermistors is a measure of the sample gas molecular weight.

The reference gas selected should have sufficient difference in density from the sample for accurate measurement, and preferably have high molecular weight, high heat capacity, and low viscosity. Nitrogen, argon, or carbon dioxide tend to satisfy these requirements. The sample flow is normally

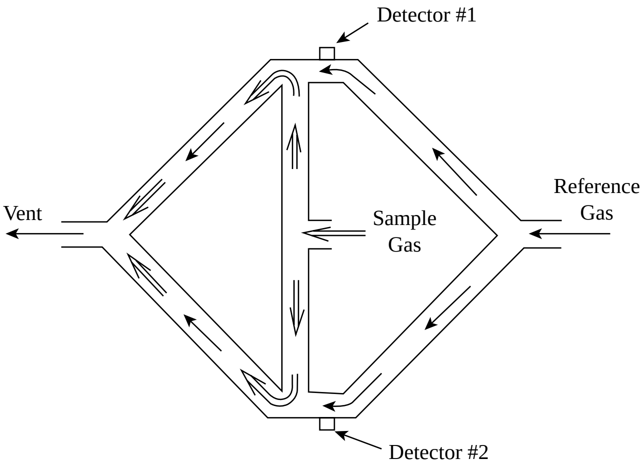

FIG. 6.10h
Thermal gas density sensor.

maintained at about 10 cc/min, while the reference flow is set at about 10 times that to avoid back-diffusion.

The main advantage of this design is that the sample gas never comes in contact with the detectors, and, therefore, they cannot become coated, coked, or contaminated by the sample. Another desirable feature is that the cell contains no moving parts.

Due to the tubular design, brass, stainless steel, Monel, or nickel construction materials can be provided without substantial difference in cost.

Variations in ambient temperature can introduce errors. Therefore, the cell temperature is normally controlled within ±1°F (±0.6°C).

VISCOUS DRAG-TYPE DENSITY SENSORS

Another method of detecting the density of a gas relative to air (specific gravity or molecular weight) is illustrated in Figure 6.10i.

The unit consists of a sample chamber and an air chamber with a motor-driven impeller and an impulse wheel in each. Impeller #1 draws in air and spins it against the vanes of impulse wheel #3, creating a clockwise torque proportional to the air density. Impeller #2 draws in the gas sample and sets it in a counterclockwise rotation. The whirling gas strikes the impulse wheel #4 and imparts a counterclockwise torque to its shaft proportional to the gas density. The difference between the opposing torques is a measure of the sample specific gravity. It is transmitted through a lever and linkage arrangement to the pointer, which moves in front of the scale, which is calibrated in specific gravity, molecular weight, or percent concentration units.

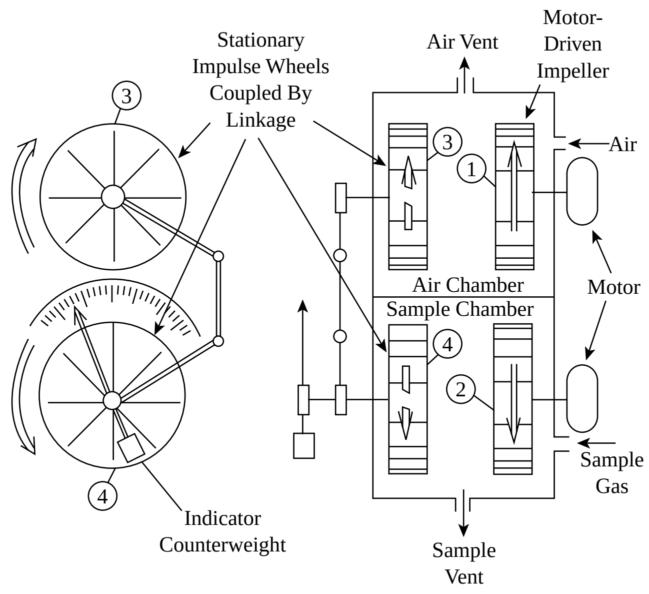

FIG. 6.10i
Viscous drag density sensor.

As in the case of the previously discussed detectors, the sample temperature, pressure, humidity, and solid particle content will affect the precision of measurement.

The sample gas temperature should be the same as that of ambient air. This is normally guaranteed by the large surface area of the sample tubing that brings the gas temperature to ambient without need for auxiliary devices.

Because both the gas and air are vented to atmosphere, the barometric pressure variations are automatically balanced.

If the sample gas is under pressure, it has to be reduced to less than an inch of water pressure before entering the instrument. If it is under vacuum, the two exhausts must be connected into the same vacuum system.

The relative humidity of air and gas should be the same. This can be achieved either by saturating both streams with a humidifier or by drying both streams through a desiccant dryer.

Sample filters are normally used to remove suspended particles or corrosive constituents because the wetted parts are not highly corrosion-resistant. Brass, aluminum, and stainless steel are in contact with the sample.

The sample flow rate of about 20 SCFH (9 l/m) provides a response time of less than 20 s.

Spans from 0.1 to 2.0 SG are available within the limits of 0.1 and 3.0 SG. The measurement inaccuracy varies between 1 and 2% of full scale, and the unit is normally calibrated on the actual sample gas.

This instrument can still be obtained as an indicator, recorder, switch, or transmitter.

ULTRASONIC DENSITY DETECTION

Some models of transit time ultrasonic flowmeters (see Section 2.26) include the ability to report density. Typical applications are for vent and flare stacks. Costs are high and the user should review the claimed specifications for suitability.

CONCLUSIONS

Of the mechanical measurement technologies reviewed in this section, only one—the viscous drag-type sensor is still available. The vibrating surface type devices now dominate the market (see Sections 6.5 and Section 6.8). The high value of natural gas has led to the use of gas chromatographs and Btu analyzers to determine the value of the gas from composition and/or the heating value of fuel gases for a more accurate measurement of value and flow than the composition inferred from density instruments. The American Society for Testing and Materials' "Standard Test Methods for Relative Density of Gaseous Fuels (ASTM D-1070)" includes operating procedures for some of these older instruments.

Applications:	Visual inspection of small, narrow or otherwise inaccessible areas in turbines, piping, engines, tanks, heating, ventilation, and air conditioning (HVAC) systems, boilers, pumps, valves, etc.
Types:	Units can be permanently mounted on bench top or can be portable; units can have battery-operated self-contained illuminators or rechargeable shoulder-pack illuminators; the probe itself can be rigid, flexible, gooseneck sheathed, or provided with a viewing end tip that can flex up to 120°.
Diameters:	From 0.118 to 2.75 in. (3 to 75 mm)
Lengths:	For rigid designs, from 3 in. to 150 ft. (76 mm to 45 m); for flexible designs, up to 96 in. (2.4 m)
Resolution:	Can identify flaws as small as 0.0005 in. (0.013 mm)
Field of View (FOV):	From 20 to 120°
Costs:	A portable fiberscope costs about $1500, a fiber-optic illuminator shoulder-pack costs about $800, and an articulating tip fiberscope costs about $3000. Units designed for an industrial environment can cost $10,000 or more.

INTRODUCTION

Boroscopes (also spelled borescopes) are visual inspection tools providing high image quality. They were originally designed for inspecting gun barrels, but currently have many applications in modern technology. They are used to inspect remote or limited access locations, such as drill holes, vessels and chambers, chemical reactors, heat exchangers, process lines, and much more. Illuminated boroscopes and fiberscopes provide bright, sharp images for visual observations and are camera-adaptable for permanent record keeping. They enable critical internal inspections with speed, safety,

and certainty in the field or on the factory floor. Table 7.1a gives a partial list of applications that speed testing, inspection, and quality control.

ILLUMINATED RIGID FIBER BOROSCOPES

The rigid boroscope operates like a telescope in reverse. A telescope narrows the viewer's field of view, in order to look at a wide area in the distance. A boroscope spreads the field of view for observing a small area.

Figure 7.1b shows an illuminated rigid fiber-optic boroscope. Illumination comes from a high intensity light source, which can be explosion proof, through a fiber-optic bundle. The image is brought to the eyepiece by an objective lens. A boroscope also has relay lenses along its length to preserve precise resolution. Magnification is usually from 3 to 4 times. A single adjustment of the eyepiece focusing ring provides both objective focus and eyepiece correction. This ability for focus adjustment means that the boroscope will provide a much sharper image by expanding the depth of field.

Interchangeable viewing heads provide right angle, bottoming, circumference, forward oblique, or retrospective views. Rigid boroscopes are available in one piece or sectional models, for lengths up to 150 ft (45 m), and in diameters from 0.118 to 2.75 in. (3 to 75 mm). They permit camera and video adaptations. Rigid scopes are good choices for high resolution and rapid examination.

FLEXIBLE ILLUMINATED FIBERSCOPES

The flexible illuminated boroscope or fiberscope (Figure 7.1c) allows for inspection of the most difficult-to-reach spots. The semirigid gooseneck sheathing can be bent through multiple angles to clear almost any obstruction. There are two separate bundles inside the scope. The image bundle contains thousands of fibers precisely arranged at each end so that each fiber is in the same position at both ends of the bends.

The illuminating halo bundle, or the light guide bundle, carries light from an external light source to illuminate the viewing area. The fibers in these bundles are drawn from high-quality optical glass and are coated or clad with another glass which has a lower refractive index. The outer layer prevents light that enters the tube from escaping or passing through the sides to another fiber. The fibers are drawn small enough to be flexible and very rugged. These flexible fiberscopes can withstand repeated bending and flexing.

A fixed-focus objective lens is used to image the object onto the end of the bundle. The image is transmitted through the image bundle to the other end of the fiberscope, where an adjustable eyepiece magnifies the image for viewing. The unit can be used for straight-through viewing or 90° viewing by attaching the right angle tip to the objective lens.

The eyepiece can be adjusted for the individual operator's eye requirements. Like the rigid boroscope, it can be used with camera, video recorder, and TV monitor. Working lengths of up to 96 in. (2.4 m) are available.

The design features of a rigid fiber boroscope.

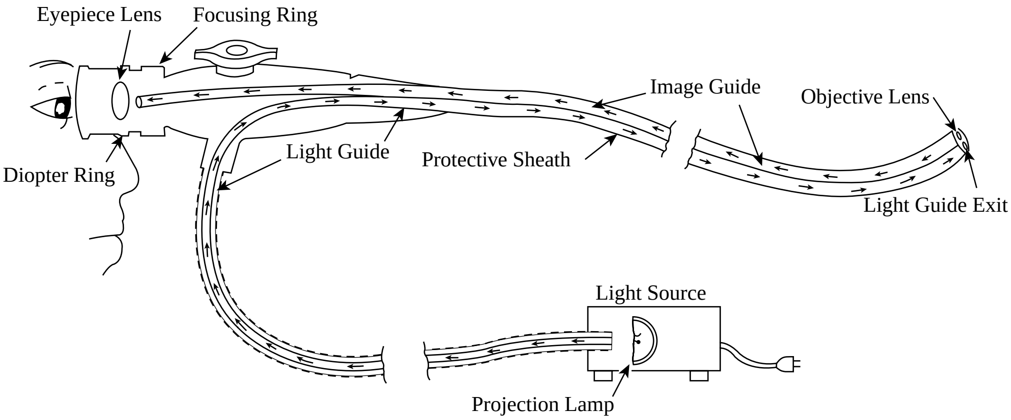

FIG. 7.1c
Design features of a flexible illuminated fiberscope.

SPECIAL-PURPOSE SYSTEMS

Chamberscopes offer greater magnification than conventional rigid boroscopes. They include high-intensity lighting and variable direction of view, and also allow examination of areas in large cavities at a distance up to 36 in. (0.9 m), particularly within vessels and engines.

Periscopes allow examination of hazardous processes or dangerous areas. They are designed for extreme radiation, high pressure or temperature, or underwater applications.

Vacuum and high-pressure boroscopes allow observations and recordings of images inside vacuum chambers and inside vessels under high pressures and temperatures. They allow documentation with photographic or video cameras.

Electrical and intrinsic safety-related worldwide standardization is still in the evolutionary process. The general concepts of electrical safety are internationally accepted, but their implementation is still being modified, and the corresponding standards are taking effect at different times in the various countries. It is advisable to check the prevailing regulations in the particular country at the particular time where and when a particular plant is being built.

INTRODUCTION

There are three ways in which electricity can kill or injure. Two are indirect—the result of fire and the result of explosion. One is direct—electrocution by electric shock.

As an academic matter, a fire and an explosion are basically the same, explosion being simply a very fast-spreading form of fire. They are considered separately for two reasons; one, because the results are so different, and two, perhaps more important, because the precautionary and preventive measures are quite different.

The danger of fire from electrical causes is generally confined to the supply side of instrumentation—from the point where power enters the system up to and including the power transformer found in most process control instrumentation. Transformer secondary circuits within the instrumentation can present a potential fire hazard, but they can be controlled with proper instrument construction. Instrument field wiring, employing the popular signal of 4 to 20 mA DC and lower, operates at energy levels at which fire hazard is remote. The precautions required for personnel protection and reliability automatically result in fire safety.

Power supply to the point of entry into an instrument is subject to detailed rules and regulations. In most of the United States, the National Electrical Code (NEC) has been adopted and has the effect of law. Many states and municipalities have their own codes, which differ slightly from the NEC. These are often obsolete editions of the NEC. It is always wise to check local rules and interpretations when planning an installation.

Safety depends primarily on three fundamental factors:

1. Enclosure of live parts, both to avoid personnel contact and accidental short circuiting
2. Fuses or circuit breakers to open in case of overload
3. Grounding of all exposed metal

ENCLOSURES

For ordinary locations, an enclosure need only be tight enough to prevent entrance of the human finger far enough to contact live parts. Unless ventilation is required for cooling, it should also be tight enough to prevent entrance of foreign material and to prevent escape of sparks or hot material in case of internal short circuit or fire. It is particularly important to prevent the escape of flaming drops from any burning insulation or plastics. The enclosure itself must not support combustion. This does not rule out plastics but does require selectivity in their use.

Because instruments differ in use, the usual rules for electrical enclosures need modification when applied. For ordinary electrical equipment, it is assumed that only a qualified electrician has access to the interior, and, therefore, only unusual interior hazards need be guarded. However, instruments frequently have doors for access by other than qualified technicians for purposes such as recorder chart changing, inking of pens, and controller adjustments. No live parts operating at voltage levels dangerous to personnel should be accessible during operational maintenance.

NEMA Terminology

For special environmental conditions, further requirements are imposed that usually follow the terminology established by the National Electrical Manufactures Association (NEMA) for motor starters and similar equipment. The following is excerpted from NEMA ICS “Industrial Control”:

Type 1 General Purpose A general-purpose enclosure is intended primarily to prevent accidental contact with the enclosed apparatus. It is suitable for general-purpose applications indoors where it is not exposed to unusual service conditions. A Type 1 enclosure serves as a protection against dust, light, and indirect splashing, but is not dust-tight.

Type 2 Drip-Tight A drip-tight enclosure is intended to prevent accidental contact with the enclosed apparatus and, in addition, is so constructed as to exclude falling moisture or dirt. A Type 2 enclosure is suitable for application where condensation may be severe, such as is encountered in cooling rooms and laundries.

Type 3 Weather-Resistant (Weatherproof) A weather-resistant enclosure is intended to provide suitable protection against specified weather hazards. It is suitable for use outdoors.

Type 4 Watertight A watertight enclosure is designed to meet the hose test described in the following note. A Type 4 enclosure is suitable for application outdoors on ship docks and in dairies, breweries, etc.

Note: Enclosures shall be tested by subjection to a stream of water. A hose with a one-inch (25 mm) nozzle shall be used and shall deliver at least 65 gallons per minute (246 1/min). The water shall be directed on the enclosure from a distance of not less than 10 feet (3 m) and for a period of 5 min. During this period it may be directed in any one or more directions as desired. There shall be no leakage of water into the enclosure under these conditions.

Type 5 Dust-Tight A dust-tight enclosure is provided with gaskets or their equivalent to exclude dust. A Type 5 enclosure is suitable for application in steel mills, cement mills, and other locations where it is desirable to exclude dust.

Type 6 Submersible A Type 6 enclosure is suitable for application where the equipment may be subject to submersion, as in quarries, mines, and manholes. The design of the enclosure will depend upon the specified conditions of pressure and time.

Type 7 (A, B, C, or D) Hazardous Locations Class I These enclosures are designed to meet the application requirements of the National Electrical Code for Class I hazardous locations that may be in effect from time to time.

Type 8 (A, B, C, or D) Hazardous Locations Class I Oil Immersed These enclosures are designed to meet the application requirements of the National Electrical Code for Class I hazardous locations that may be in effect from time to time. The apparatus is immersed in oil.

Type 9 (E, F, or G) Hazardous Locations Class II These enclosures are designed to meet the application requirements of the National Electrical Code for Class II hazardous locations that may be in effect from time to time.

Type 10 Bureau of Mines Explosion-Proof A Type 10 enclosure is designed to meet the explosion-proof requirements of the U.S. Bureau of Mines that may be in effect from time to time. It is suitable for use in gassy coal mines.

Type 11 Acid- and Fume-Resistant Oil Immersed This enclosure provides for the immersion of the apparatus in oil such that it is suitable for application where the equipment is subject to acid or other corrosive fumes.

Type 12 Industrial Use A Type 12 enclosure is designed for use in those industries where it is desired to exclude such materials as dust, lint, fibers and flyings, oil seepage, or coolant seepage.

Type 13 Oil-Tight and Dust-Tight Indoor A Type 13 enclosure is intended for use indoors to protect against lint, dust, seepage, external condensation, and spraying of water, oil, or coolant.

IP Terminology

This terminology is used mostly in Europe. According to International Electrotechnical Commission's (IEC) IEC 60529 (2001–02), an enclosure can be defined as a combination of two numerals. The first numeral describes the protection provided against solid foreign objects, while the second refers to the type of protection provided against the penetration of water.

First Numerals:

0. Non-protected
1. Protected against solid objects greater than 50 mm
2. Protected against solid objects greater than 12.5 mm
3. Protected against solid objects greater than 2.5 mm
4. Protected against solid objects greater than 1.0 mm
5. Dust-protected
6. Dust-tight

Second Numerals:

0. Non-protected
1. Protected against dripping water
2. Protected against dripping water when tilted up to 15°
3. Protected against spraying water
4. Protected against splashing water
5. Protected against water jets
6. Protected against heavy seas
7. Protected against the effects of immersion
8. Protected against the effects of continuous submersion

In addition, two optional letters can also be used. The first letter describes the degree of protection against access of hazardous parts. The second letter indicates the degree to which protection is provided against special operating conditions. Neither of these letters is used in the instrumentation and control fields.

Typical IEC enclosure specification for indoor instrument cabinets in a control room ranges from IP20 to IP42. For field mounted transmitters the housing is usually specified as IP65.

FUSES AND CIRCUIT BREAKERS

The conventional 15 or 20 A fuse or breaker in the supply wiring to an instrument is designed to protect the wiring, not the instrument. Component failures or circuit faults within the instrument may result in total destruction of the instrument. To minimize damage and possible fire, a much smaller fuse, usually 1/4 to 3 A, is used in the instrument.

Grounding

A low-resistance, noncurrent-carrying metallic connection to ground should be established and maintained from every exposed metallic surface that can possibly become connected to an electrical circuit. Electrical connection could occur because of a fault, such as a loose wire making electrical contact, or as a result of leakage current through insulation.

Grounding is usually accomplished by bonding all elements together in a system terminated at the ground connection where power enters the premises. It may be a bare or green insulated wire. More often it is the conduit enclosing the wires. It must be securely joined, electrically and mechanically, to each piece of equipment. It is connected at the service entrance to the grounded circuit conductor (white wire) and to ground. Instead of connection to a ground at the entrance connection, other suitable earth ground connections are acceptable. Equipment mounted directly on the structural steel of a building is considered effectively grounded. Water pipes are not effective grounds, particularly since the increasing use of plastic pipe for water connection.

Grounding serves two distinct purposes, both relating to safety. First, since the ordinary power circuit has one side grounded, a fault that results in electrical contact to the grounded enclosure will pass enough current to blow a fuse. Second, possibility of shock hazard is minimized since the low-resistance path of a properly bonded and grounded system will maintain all exposed surfaces at substantially ground potential.

Grounding is effective against hazard from leakage currents. All electrical insulation is subject to some electrical leakage. This may rise to a significant level as insulation deteriorates with age, or as layers of conductive dust accumulate in the presence of high humidity. A proper grounding system with low electrical resistance will conduct leakage currents to ground without developing significant potential on exposed surfaces.

Grounding of exposed metal surfaces is distinct from the grounded conductor of the ordinary power wiring. The latter is a current-carrying ground that is capable of developing significant potential, particularly on long lines, and with surge or even short-circuit currents. Grounding systems are substantially noncurrent carrying, except for possible leakage currents. Potential can build up only during the time required for a fuse to blow as a result of a specific fault that results in direct contact between power and grounding systems. Grounding is customarily not required for signal circuits where either maximum voltage is 30 V, or maximum current under any circumstance cannot exceed 5 mA.

Personnel Safety

The electrical energy necessary to kill or injure a person varies widely with conditions of exposure, especially with contact conditions (i.e., wet or dry skin, contact area, and the path the current takes through the body). A few millivolts applied directly to the heart can cause fibrillation and death. Yet it is a common, though not approved, practice among electricians to ascertain, if a 120-V (or even a 240-V) circuit is energized by putting two fingers of the same hand in contact with the two conductors.

If the person is insulated from the ground, for instance, by standing on a dry wood floor, the current path is through the fingers and the hazard is nil. If the person is standing in water or has a firm grasp on a water pipe, the current path would be through the central nervous system, and it might well be fatal. Much depends also on the nature of the contact. An electrical shock causes muscles to contract, thus a fingertip contact can be broken, but if the live part is gripped, it might be impossible to let go.

In addition to guarding against possible lethal shocks, the surprise factor should not be overlooked. An unexpected, but harmless, shock may induce a sudden reaction and expose a worker to an entirely different hazard, such as falling off a ladder.

Energy Levels

This discussion of energy levels hazardous to humans is limited to those circumstances where the whole body is involved. For medical electronics, where electrodes may be implanted within the body, a much lower set of numbers apply. Consideration of such equipment is outside the scope of this volume.

The significant factor is current through the body. A current of less than 1 mA is imperceptible to a normal man. If it is above 3 mA, it becomes unpleasant. If it is above 10 mA, the victim is unable to let go, and above 30 mA, asphyxiation may result. Still higher levels lead to heart stoppage and death. These values are for sustained contact. Much higher levels can be tolerated for a fraction of a second.

To relate this information to circuit voltage requires knowledge of body resistance. Internal body resistance can be as low as 100 Ω, but the resistance of the whole body is primarily in the skin and in skin contact. Dry fingers grasping a wire or small terminal will have a resistance in the order of 100,000 Ω. Wetting the fingers would lower this. To lower total body resistance to 1000 Ω would require immersion of hand or foot in water and a solid grip on a large object. As a practical working figure, the National Electrical Safety Code requires guarding above 50 V. A measurement of 30 V is considered safe for general use, even in children's toys, though surely not for swimming pools.

The NEC permits circuits up to 150 V if they are incapable of delivering more than 5 mA without special requirements for wire insulation.

If all line voltage circuits are enclosed in properly fused and grounded enclosures, and signal circuits not meeting either the 30 V or the 5 mA criteria are guarded, personnel safety will be assured.

EXPLOSION HAZARDS

Areas in which combustible gas, vapor, or dust may be present in explosive proportions are called *hazardous locations*. Special precautions must be taken with electrical equipment in hazardous locations to eliminate a source of ignition that could touch off an explosion. The specific precautions vary with the nature of the combustible material and the probability of its presence. An atmosphere is considered to be explosive if the concentration of the explosive vapors is within its lower and upper explosive limits (LEL and UEL). Some properties of flammable and explosive vapors and gases and their flammability limits or LEL and UEL values are listed in Tables 7.2a and 7.2b. Note that the data provided by the two tables is *not* identical, because they report the results of different sets of tests.

TABLE 7.2a
Properties of Some Flammable Liquids and Gases

Material	*Chemical Formula*	*Specific Gravity Air = 1*	*Ignition Temperature in Air*		*Flamability Limits in Air (% vol.)*

NEC Definition of Hazardous Locations

The first step in deciding what equipment to use is to determine the nature and the degree of hazard. The NEC[1] describes hazardous locations by class, group, and division. The *class* defines the physical form of the combustible material mixed with air:

Class I—Combustible material in the form of a gas or vapor
Class II—Combustible material in the form of a dust
Class III—Combustible material in the form of a fiber, such as textile flyings

The *groups* are subdivisions of the *classes*:

Group A—Atmospheres containing acetylene
Group B—Atmospheres containing hydrogen, gases or vapors of equivalent hazard, such as manufactured gas
Group C—Atmospheres containing ethyl ether vapors, ethylene, or cyclopropane
Group D—Atmospheres containing gasoline, hexane, naphtha, benzine, butane, propane, alcohol, acetone, benzol, lacquer, solvent vapors, or natural gas

Group E—Atmospheres containing metal dust, including aluminum, magnesium and their commercial alloys, and other metals of similarly hazardous characteristics
Group F—Atmospheres containing carbon black, or coal or coke dust
Group G—Atmospheres containing flour starch or grain dusts

The *division* defines the probability of an explosive mixture being present. Only the breakdown for Class I is given because it is the one most often encountered. Classes II and III are similarly subdivided.

Class I, Division 1—Locations (1) in which hazardous concentrations of flammable gases or vapors exist continuously, intermittently, or periodically under normal operating conditions, (2) in which ignitable concentrations of such gases or vapors may exist frequently because of repair or maintenance operations or because of leakage, or (3) in which breakdown or faulty operation of equipment, or processes which might release ignitable concentrations of flammable gases or vapors, might also cause simultaneous failure of electrical equipment.

Class I, Division 2—Locations (1) in which volatile flammable liquids or flammable gases are handled, processed, or used, but in which the hazardous liquids, vapors, or gases will normally be confined within closed containers or closed system which they can escape only in case of accidental rupture or breakdown of such containers or systems, or in case of abnormal operation of equipment, (2) in which ignitable concentrations of gases or vapors are normally prevented by positive mechanical ventilation, but which might become hazardous through failure or abnormal operation of the ventilating equipment, or (3) that are adjacent to Class I, Division 1 locations, and to which ignitable concentrations of gases or vapors might occasionally be communicated unless such communication is prevented by adequate positive-pressure ventilation from a source of clean air, and effective safeguards against ventilation failure are provided.

As a rule of thumb, any atmosphere tolerable for a person to breathe is not within the explosive range. Except for methane and hydrogen, gases and vapors become toxic or irritating well below their lower explosive limit. An explosive mixture of dust limits visibility to a few feet.

Economic reasons (i.e., cost of lost product) tend to limit Division 1 locations to an area within a few feet of probable leaks such as pump glands and valve stem packing. The American Petroleum Institute has developed a series of detailed criteria for classifying areas at such distances in typical situations.[2]

IEC Definition of Hazardous Locations

Hazardous area definitions by the IEC can be found in IEC 60079–10 (2002–06). The IEC approach is to define the nature of the source, which releases the explosive substance. This can be continuous, primary or secondary, which correspond to a zone definition of zone 0, 1, or 2.

The extension and the shape of the zone is affected by the release rate (the higher the release, the greater the zone), the lower explosive limit (LEL; the lower the LEL, the greater the zone), the ventilation, and the specific gravity of gas/vapor when released. A gas/vapor heavier than 1.2 SG_{air} originates a hazardous zone with the shape lying on the ground, while if lighter than 0.8 SG_{air} it originates a hazardous zone of vertical shape. For specific gravities between 0.8 and 1.2, the hazardous zone encompasses the zones for lighter and heavier gas/vapors.

In Europe, the majority of the countries derived their national regulations from the IEC or have adopted the IEC regulations and although their timing varies, the regulations are consistently applied. In Canada, the IEC standards are compulsory. In the United States, the IEC standards have been accepted on an optional basis.

Explosions

An explosion is dependent upon the simultaneous presence of three conditions (Figure 7.2c). An oxidizer in the form of the oxygen in air is ordinarily present. Fuel, a gas, vapor, or finely divided solid is normally kept confined for economic reasons, if not for safety. However, by definition, a hazardous location is a place where fuel and oxidizer are present in combustible proportions, at least at times. Ignition of this dangerous combination must not be permitted. Electrical equipment must be built and operated in a manner to prevent its becoming a source of ignition. It could ignite this hazardous atmosphere in either of two ways: by surface temperatures in excess of the ignition temperature or by sparks. Some sparks are incidental to normal operation, as in the operation of switches, while some are accidental, as in faulty connections. Both must be guarded against.

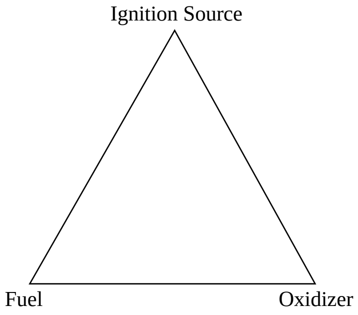

FIG. 7.2c
Prerequisites for an explosion.

PROTECTION METHODS

There are several approaches to safety:

1. Confine explosions so they do no damage (explosion proof)
2. Keep atmosphere away from ignition source (pressurization or ventilation, oil immersion, sealing, or potting)
3. Limit energy to levels incapable of ignitions (intrinsic safety)
4. Miscellaneous (sand filling, increased safety, dust ignitions-proof, nonincendive)

Explosion-Proof (“Flameproof” in Britain)—All equipment is contained within enclosures strong enough to withstand internal explosions without damage, and tight enough to confine the resulting hot gases so that they will not ignite the external atmosphere. This is the traditional method and is applicable to all sizes and types of equipment.

Purging, Pressurization, Ventilation—This depends upon the maintenance of a slight positive pressure of air or inert gas within an enclosure so that the hazardous atmosphere cannot enter. Relatively recent in general application, it is applicable to any size or type of equipment.

Oil Immersion—Equipment is submerged in oil to a depth sufficient to quench any sparks that may be produced. This technique is commonly used for switch-gears but it is not utilized in connection with instruments.

Sealing—The atmosphere is excluded from potential sources of ignition by sealing them in airtight containers. This method is used for components such as relays, not for complete instruments.

Potting—Potting compound completely surrounding all live parts and thereby excluding the hazardous atmosphere has been proposed as a method of protection. There is no known usage except in combination with other means.

Intrinsic Safety—Available energy is limited under all conditions to levels too low to ignite the hazardous atmosphere. This method is useful only for low-power equipment such as instrumentation, communication, and remote control circuits.

Sand Filling—All potential sources of ignition are buried in a granular solid, such as sand. The sand acts, in part, to keep the hazardous atmosphere away from the sources of ignition and, in part, as an arc quencher and flame arrester. It is used in Europe for heavy equipment. It is not used in instruments.

Increased Safety—Equipment is so built that the chance of spark or of dangerous overheating is nil. In practice, this means rugged construction, wide spacings between parts of opposite polarity, extra insulation, nonsparking fans and good mechanical protection. Widely used in Europe for heavy equipment such as large motors. It is also recognized for instruments particularly in Germany. It is not recognized in the United States.

Dust Ignition-Proof—Enclosed in a manner to exclude ignitable amounts of dust or amounts that might affect performance. Enclosed so that arcs, sparks, or heat otherwise generated or liberated inside of the enclosure will not cause ignition of exterior accumulations or atmospheric suspensions of dust.

Nonincendive—Equipment which in normal operations does not constitute a source of ignition (i.e., surface temperature shall not exceed ignition temperature of the specified gas to which it may be exposed, and there are no sliding or make-and-break contacts operating at energy levels capable of causing ignition. Used for all types of equipment in Division 2 locations. Relies on the improbability of an ignition-capable fault condition occurring simultaneously with an escape of hazardous gas.

A summary of the various protection methods is given in Table 7.2d.

Advantages and Disadvantages of Protection Methods

Table 7.2e attempts to rate the various protection methods used for instrumentation. Methods are rated from A to C.

Safety All methods are safe if the equipment is properly installed, maintained, and protected by a correctly selected method that is consistent with the area classification. Intrinsic safety is rated A because recognized standards are most conservative and it is less dependent on day-to-day usage. Ordinary carelessness does not make intrinsically safe equipment unsafe. Explosion-proof equipment is worthless if the cover is left off, and purging is dubious under the same circumstances. Purging is also dependent on reliability of purge air supply.

Cost of the Instrument Purging is usually lowest in cost because it requires no special construction for hazardous location use, except for an air inlet. Since an intrinsically safe instrument does not require the special housing of an explosion-proof instrument, there is a possible saving. The cost difference between an explosion-proof housing and a rugged weatherproof housing is too small to justify two separate designs for small devices, such as field-mounted transmitters. Cost of review and listing by a testing agency, such as Underwriters Laboratories or Factory Mutual, add to the cost of intrinsic safety.

Cost of Installation

Intrinsic safety is at least potentially lowest in cost. The NEC permits wiring for approved intrinsically safe equipment in

TABLE 7.2d
Reference for Protection Methods

	Class I Gas/Vapor Group A, B, C, D		*Class II Dust Group E, F, G*		*Class III Flyings and Fibers*	
Protection Method	*Div. 1*	*Div. 2*	*Div. 1*	*Div. 2*	*Div. 1*	*Div. 2*
Explosion-proof housings	OK	Required only for sparking or hot devices	Not applicable unless also dust ignition-proof		OK if tightly enclosed and no overheating when covered with flyings	
Dust ignition-proof	Not applicable		Dust-proof and no overheating when dust covered		Not applicable	
Intrinsic safety	OK	OK	OK	OK	OK	OK
Purging	OK	OK	Subject of work by NFPA		?	?
Potting	?		OK if no overheating			
Hermetic sealing	?		OK if no overheating			
Oil immersion	Acceptable but not convenient to use for instruments				?	?
Nonincendive	Not applicable	OK	Not applicable unless dust ignition-proof	OK	OK if tightly enclosed and no overheating when covered with flyings	

TABLE 7.2e
Rating the Protection Methods

	Safety	*Cost of Instrument*	*Cost of Installation*	*Maintenance*	*Flexibility*
Intrinsic safety	A	C	A	A	C
Explosion-proof	B	B	B	B	B
Purging	C	A	C	C	A

hazardous locations to be the same as in ordinary locations, such as multiwire cables without special protection. For explosion-proof or purged equipment, all wiring must be in rigid conduit, all fittings must be explosion-proof, and conduits must be sealed. Purged equipment also requires an air supply system with purge failure alarms and in some cases automatic shutdown.

Maintenance Intrinsic safety is rated A because the equipment is accessible for routine calibration checks and adjustments. Explosion-proof equipment must be deenergized before being opened or maintenance must be deferred until the area is known to be safe. Purging is similarly limited and alarms and interlocks must also be maintained.

Flexibility Purging is rated A because essentially any standard or special instrument with reasonably tight housing can be readily adapted to purging. Explosion-proofing is limited to instruments available in that construction or that can be fitted into a standard, explosion-proof box. The need for external adjustments and indication can make this very expensive. Intrinsic safety must be evaluated as a system. In the past a serious problem has been the inability to interconnect apparatus of different manufacturers. Now this problem is overcome through the use of properly selected safety barriers and compliance with the constraints mentioned in the certifications issued by the official bodies.

The marking scheme described in paragraph A-4–2 of the National Fire Protection Association's (NFPA) NFPA Standard 493 provides a convenient way to assess the compatibility of apparatus of different manufacturers with respect to intrinsic safety. This concept facilitates the connection between two-terminal devices such as a two-wire transmitter and barrier.[3]

Purging, Pressurization, or Ventilation

Any reasonably tight enclosure housing electrical equipment can be made safe by providing a continuous flow of air or inert gas. The enclosure can be of any size from a small instrument case or fractional horsepower motor to an entire building, such as control houses.

The essentials are:

1. A source of clean air
2. Sufficient initial flow to sweep out gas that may have been present
3. Sufficient pressure building in the enclosure to prevent entrance of combustible atmosphere
4. Suitable alarms and interlocks

A typical purge assembly is illustrated in Figure 7.2f.

Air Supply For a single instrument or other small device, the instrument air system is the best source of air for pressurization since it is clean and dry. Where a large number of

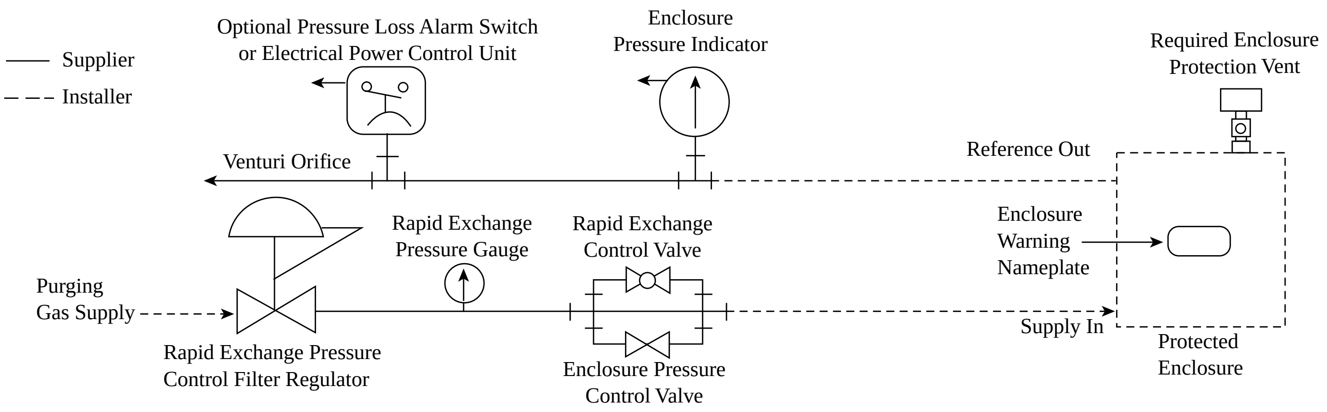

FIG. 7.2f

Packaged purge systems are marketed for Class 1 area and are provided with rapid exchange purging capability. (Courtesy of Bebco Industries.)

units are involved or an entire control house, the large volumes required make this impractical. The best solution varies with individual plant conditions.

Finding a safe place for an air intake requires careful study. An intake 25 ft (7.5 m) off the ground and not within a 45° shadow cone of any potential source of vapor is generally considered adequate for a refinery handling vapors heavier than air. For gases nearly as dense or lighter than air, there is no definitive answer except distance and an upwind location. In any event, the suction line must be of substantial construction and free of leaks where it passes through a potentially hazardous area.

Initial Purging Pressurized apparatus, when put in service after having been open, may contain combustible mixture. Before power may be turned on, sufficient air must pass through it to sweep out the combustible gas or at least reduce it to a harmless concentration. This is usually achieved by requiring a time interval to elapse after closing up the apparatus and starting purge flow before circuits are energized. A flow of four times the internal volume of the case is adequate for the usual instrument housing. Large or compartmentalized enclosures require special consideration.

If natural leakage does not provide the necessary purge volume in a reasonable length of time, auxiliary vents may be provided to accelerate the operation.

Pressure During operation the enclosure must be maintained under a pressure of at least 0.1 in. of water column (25 Pa) to prevent influx of combustible mixture. This figure is equivalent to the wind pressure at 15 mi/h (24 km/h). While higher wind velocities might force outside air into the housing, the potential hazard is considered negligible since at these velocities any combustible vapors would be very rapidly dispersed.

Alarms and Interlocks While some warning of pressurization failure is needed, the specific requirement depends on the nature of the enclosure's content and the degree of hazard outside.

Classification of Purging Systems The Instrumentation, Systems, and Automation Society (ISA)[4] and the NFPA[5] classify purging as follows:

> Type X purging reduces the classification within an enclosure from Division 1 to non-hazardous. Type X purging would permit an arcing switch in a general purpose housing located in a truly hazardous, Division 1 location. Since failure of the purge air supply would soon lead to disaster, immediate automatic shutdown by pressure switch or flow detector is required.
>
> Type Y purging reduces the classification within an enclosure from Division 1 to Division 2. Type Y purged equipment within an enclosure does not normally constitute a source of ignition, hence purge failure present no immediate hazard. Only a visible or audible indication is required.
>
> Type Z purging reduces the classification within an enclosure from Division 2 to non-hazardous. Type Z purged equipment, used in Division 2, where the atmosphere is not normally hazardous, again presets no immediate hazard and visible or audible indication is sufficient.
>
> Temperature of all parts exposed to the atmosphere, in hazardous locations, must not exceed 80% of the ignition temperature of the combustible material.

Explosion-Proof Components

Article 100 of the National Electrical Code defines explosion-proof apparatus as:

> Apparatus enclosed in case which is capable of withstanding an explosion of a specified gas or vapor which may occur within and of preventing the ignition of a specified gas or vapor surrounding the enclosure by sparks, flashes, or explosion of the gas or vapor within, and which operates

> at such an external temperature that a surrounding flammable atmosphere will not be ignited thereby.

Explosion-proof apparatus is not intended to be gas tight. It is assumed that no enclosure that may have to be opened from time to time for inspection or maintenance can practically be maintained gas tight. Hence, if the surrounding atmosphere is hazardous, the atmosphere within will also become hazardous, and an internal explosion may result. If the box holds together and the only openings are long, narrow, and preferably crooked paths, the escaping gases will not be hot enough to ignite the external atmosphere. The British term, *flameproof*, is perhaps more descriptive of the function that the American term, *explosion-proof*.

There are two broad approaches to construction: a relatively tight box with broad flanges and tightly fitted, threaded (5 thread minimum) or rabbet joints, or a relatively loose box with many small passages designed to minimize pressure buildup. The first requires a very strong box to withstand full explosion pressure, up to 175 PSIG (1208 kPa) for Group C or D, and 1000 PSIG (6900 kPa) or greater for Group B or A. This is usually cast iron or cast aluminum. Plastic is used in Europe for smaller boxes.

For the second approach, the pressure rise can be kept down, to 20 PSIG (138 kPa) or less, allowing lightweight construction. Though officially recognized, the latter approach has been little used because of the possibility of vent passages becoming plugged by dirt or by injudicious use of a paint brush.

INTRINSIC SAFETY

The NEC defines intrinsic safety as follows:

> Intrinsically safe equipment and wiring shall not be capable of releasing sufficient electrical or thermal energy under normal or abnormal conditions to cause ignition of a specific flammable or combustible atmospheric mixture in its most easily ignitable concentration.
>
> Abnormal conditions shall include accidental damage to any field-installed wiring, failure of electrical components, application of over-voltage and maintenance operations, and other similar conditions.

A quantity of a combustible mixture must be heated to its ignition temperature for an explosion to occur. A weak spark heats so little mixture that heat loss exceeds heat supply and the incipient explosion dies out. A large spark heats enough mixture for combustion to become self-sustaining and an explosion propagates. If energy is kept at a low level, ignition will not occur. This is the basis of intrinsic safety. It is not sufficient that energy be low in normal operation. It must also be low under any conceivable abnormal operation or fault condition.

Energy Levels

Safe energy levels cannot be defined in any simple form. Ignition depends on specific gas, gas concentration, voltage, current, energy storage elements, contact material, contact size, and speed of opening or closing of contacts. Ignition of hydrogen (one of the most easily ignited gases) has been achieved under laboratory conditions (high voltage) with energy as low as 20 μJ. For common hydrocarbons and the voltages actually encountered in instrumentation, energies circa 0.2 to 0.3 mJ are required.

Curves such as Figure 7.2g show limiting circuit parameters that provide ignition energy for a particular gas. They can be used safely only after careful examination of the specific equipment by one skilled in the art and by application of an adequate safety factor. Actual ignition testing of the specific apparatus is the preferred practice.

System Approach

In evaluating equipment for intrinsic safety, it is always necessary to look at all elements of the complete loop. For example, an ordinary thermocouple (TC), by itself, is unquestionably safe. Add a simple millivolt indicator and it is still safe. Connect the couple to a recorder, powered from a 120 V line, and the question of safety arises. What could happen if the recorder allowed dangerous amounts of energy to reach the TC leads? The problem is easily solved by good recorder design and construction, but it cannot be overlooked.

Thus, there is no such thing as an intrinsically safe instrument unless it operates with a self-contained, low-energy power source, such as a small battery or solar cell that is isolated from all other power sources. Anything that is connected or wired to that instrument must be viewed as components of the system. This requires a careful study of all components of the complete loop and of the relevant constraints given by the official bodies. Someone must evaluate the combination *and assume responsibility for its safety*.

Certification of Intrinsic Safety

The practical answer for the instrument buyer and user is to look for certification by a qualified testing agency. In the United Sates there is the Underwriter Laboratories or Factory Mutual Research Corporation. It is the Canadian Standards Association in Canada, Physikalische-Technische Bundesanstalt in Germany, and the British Approvals Service for Electrical Equipment in Flammable Atmospheres (BASEEFA) in Britain. Many other countries have their own agencies—these are the most well known.

While each testing agency has its own detailed rules and traditions, NFPA 493–1978, "Intrinsically Safe Apparatus for Use in Division 1 Hazardous Locations," outlines a reasonably typical evaluation. As it says, however, "it is not an instruction manual for untrained persons but is intended to promote uniformity of practice among those skilled in the art." The following outline of the procedure will not make

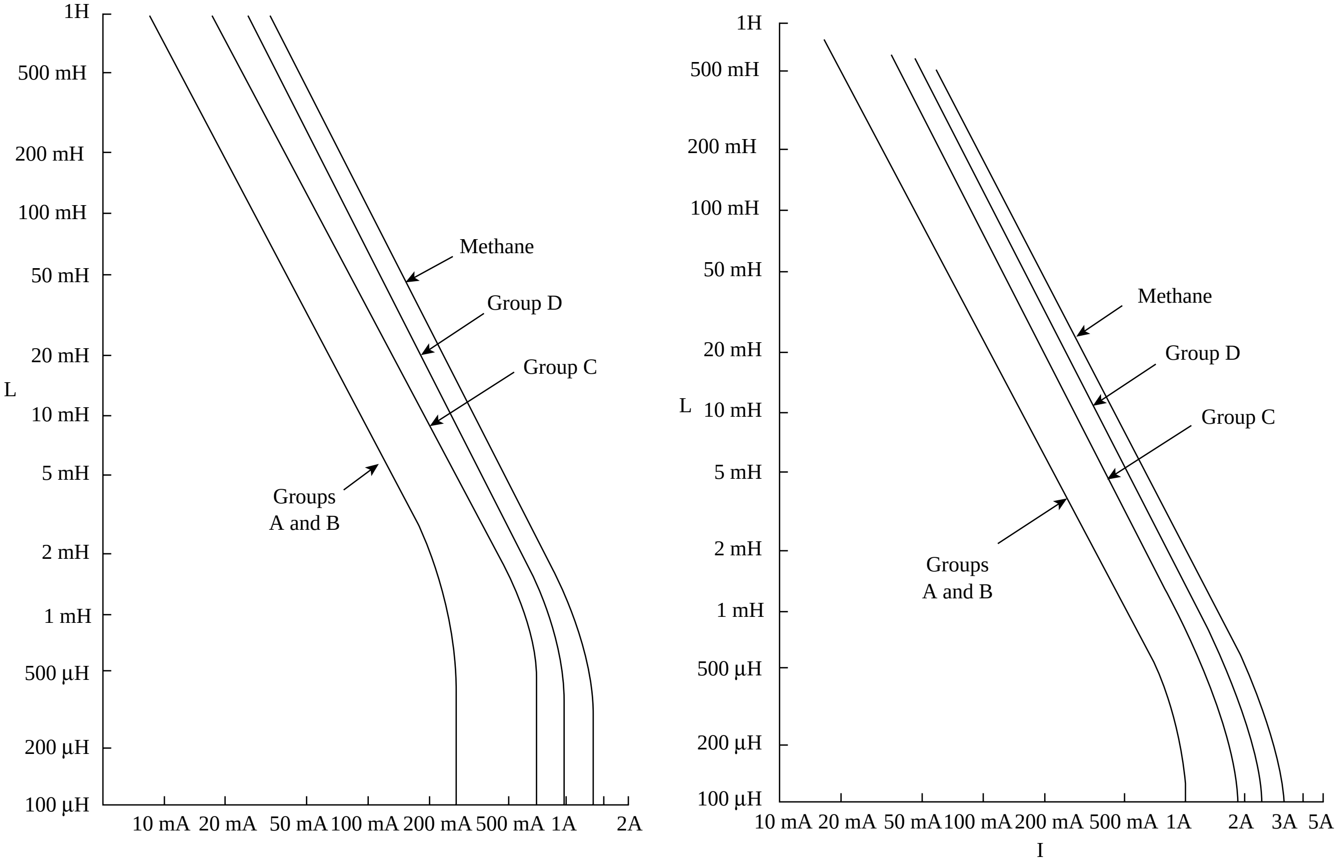

FIG. 7.2g

Left: Inductance circuits (L > 1 mH). Minimum igniting current at 24 V (1 = igniting current). Applicable to all circuits containing cadmium, zinc, or magnesium. Right: Inductance circuits (L > 1 mH). Minimum igniting current at 24 V. Applicable only to circuits where cadmium, zinc, or magnesium can be excluded. (Reprinted with permission from NFPA 493–1978. This reprinted material is not the complete and official position of the NFPA on the referenced subject, which is represented only by the standard in its entirety.)

the reader an expert but will indicate the conservative nature of the approach.

Three steps are involved:

1. Circuit analysis—to determine worst possible fault conditions
2. Evaluation—to ensure a margin of safety under the condition found above
3. Construction review—to ensure that critical components are reliable and that circuit will function as planned

Circuit Analysis *Circuit analysis* is a review of the circuit, component by component, considering the possible mode of failure of each and its effect on energy levels available in the hazardous area. It starts where line power enters the system and includes all parts of the interconnected instrument system wherever located—in the control house or in the field. The object is to pinpoint the fault condition or combination of conditions allowing highest energy in the field circuits.

Evaluation This is the next step in the procedure. The purpose is to ascertain whether or not each fault condition constitutes a possibility of ignition. With the use of the actual circuit, the faults are produced by short- or open-circuiting components with the field leads connected to a test apparatus. The test apparatus consists of pair of contacts operating in a chamber filled with the most readily ignited mixture of a suitable combustible gas with air. The contacts simulate a broken wire, a wire dragging on a surface, or the short-circuiting of a pair of leads.

An internationally accepted form of test apparatus is of West German origin. In July 1967, this test apparatus was tentatively accepted by the IEC meeting in Prague and was later adopted.

It is also possible to use measured voltages, currents, inductance, capacitance, etc., and compare them with the results of previous tests with similar circuit parameters. As illustrated in Figure 7.2g, suitable curves exist,[3,4] but they must be interpreted with care and a suitable margin of safety.

Construction Review This is the final step in the procedure. A circuit component must be of a reliable form of construction if it is to be depended upon for safety. A transformer that will withstand a high potential (1480 V applied primary to secondary) immediately after being deliberately burned out is considered reliable. This presupposes that the transformer is so constructed that consistent performance of this nature can be anticipated. A resistor must withstand gross overloading without significantly changing in value. Live parts, such as terminals, must be so separated that an accidental short circuit is essentially impossible. If an instrument system survives this kind of examination, its safety is assured.

International Regulations

The international approach distinguishes two categories of field mounted instruments:

1. Simple apparatus, such as thermocouples, resistance temperature detectors or contacts that do not require certification, but do need to be connected to other instruments (across barriers).
2. Intrinsically safe apparatus, such as transmitters, I/P converters and solenoid valves, which require installation certification for the specified hazardous area, category of gas, and temperature class. These apparatus must be connected to the associated instruments (across barriers).

The barriers, installed in a safe area, provide the separation between the intrinsically safe devices in the field and the nonintrinsically safe devices (distributed control systems, programmable logic controllers, recorders, indicators, etc.) in the control room. The barriers must also be certified and must be suitable for being connected to field mounted apparatus, which are installed in a particular hazardous area and exposed to a particular group of gases and temperature class. The nameplate and the certificate both must give the following data:

1. Maximum open circuit voltage
2. Maximum short circuit current
3. Maximum allowable external capacitance
4. Maximum allowable external inductance
5. Maximum transferred power

The safety barriers serve to send on the signals between the control room and the field. They must be suitable to handle the maximum voltage (Um) that is present in the control room. This voltage currently in the United States is 240 V. The above considerations are the basic philosophy, while all other mandatory details can be found in the IEC regulations.

Grounding In order to prevent the formation of sparks with energy contents that exceed the intrinsically safe limit or the developing of over-voltages, the selection of the safety barriers must also consider the grounding of the field instruments.

If the grounding is dedicated, equipotential, and the field mounted device is isolated from the ground with an electrical strength of at least 500 V, Zener diode type barriers can be used. If the grounding is not equipotential, galvanic insulation is required. If the circuitry in the field mounted instrument is grounded, the barriers must be provided with galvanic insulation.

Barriers The Zener barriers are inexpensive and reliable passive circuits that consist only of some resistors and Zener diodes. Unfortunately, they do require equipotential grounding, which can make the overall installation expensive. The intrinsically safe apparatus must be connected to the equipotential ground at a properly identified single point and via an isolated conductor having a resistance of not more than 1 ohm.

The intrinsically safe side of the galvanically isolated barriers includes an energy limiting circuit with Zener diodes and limiting resistors. It transfers the signals to and from the hazardous area via such isolating components as transformers, opto-couplers, and relays. The Zener diodes in the barriers are duplicated or tripled to maintain the protection toward the external circuit also in case of failure of one or two of them.

The certificate provided for the barriers must show the total inductance limit, the maximum allowable ratio of inductance/resistance for the wiring, and the capacitance of the circuit (field instrument plus wiring) in the classified area.

Cables and Their Installation In case of a short circuit or the breaking of a circuit, the wiring between the barrier and the field apparatus must not store dangerous quantities of energy, which might cause a spark. The screens must be grounded at only one point and in a safe area. The cables connecting to intrinsically safe apparatus must be identified in a consistent and easily recognizable manner. If the method of identification is by color, all intrinsically safe cables must be light blue and no other cable in the plant can have light blue color. Multicore cables can carry only intrinsically safe signals.

In connection with cable trays, one option is to lay the intrinsically safe cables in different cable trays than the ones carrying nonintrinsically safe cables. Another option is to provide physical separation between the two types within the same cable tray. A third option is to provide armoring, sheathing, or screening for one of the cable types (intrinsically safe or nonintrinsically safe) in the tray. Clearly marked and separate field junction boxes must also be provided for intrinsically safe and for nonintrinsically safe circuits.

Terminations Reliable separation must be provided between intrinsically safe and nonintrinsically safe circuits. This can be done by providing a separating panel or by keeping a minimum of 2 in. (50 mm) distance from other circuits. If this distance method of separation is used, it should be checked to make sure that even if another wire is disconnected, it cannot contact the intrinsically safe terminals. In addition, all intrinsically safe terminals must be so identified.

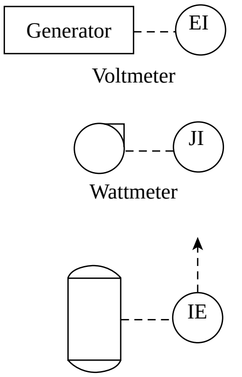
7.3 Electrical Meters and Sensors

P. M. GLATTSTEIN (1972, 1982) **B. G. LIPTÁK** (1995)
P. M. B. SILVA GIRÃO (2003)



Flow Sheet Symbol

Meter Types and Accessories:
A. Permanent magnet moving coil meter
B. Permanent magnet moving coil with electronics
C. Moving iron vane meter
D. Electrodynamic meter
E. Electrostatic meter
F. Digital meter
G. Current transformer
H. Shunt
I. Potential transformer
J. Resistor for DC voltmeters
(Note: See the Orientation Table 7.3a for a summary of volt, watt, and ammeter features.)

Ammeter Choices and Accessories:
For AC current: B, C, or F
For high-range AC current: B, C, or F with G
For DC current: A or F
For high-range DC current: A or F with H

Voltmeter Choices and Accessories:
For AC voltage: B, C, or F
For high-range AC voltage: E; or B, C, or F with I
For DC voltage: A or F
For high-range DC voltage: E; or A or F with J

Wattmeter Choices and Accessories:
For one or three-phase AC power: D or F with G and H
For DC power: D or F
For high-range DC power: D or F with H

Inaccuracy:
A. 0.3 to 2% of full scale
B. 3% of full scale
C, D. 0.5 to 2% of full scale
E. 0.5 to 2% of full scale
F. From a few ppm to 2% of full scale
G. 0.6 to 1.2% of secondary rating
H. 0.25% of shunt rating
I. 0.3 to 0.6% of secondary rating
J. 0.25% of resistor rating

Costs:
A, C, F, and G: about $50
B and I. About $150
D. About $500
E. About $500
F. From about $100 to up to a few thousand dollars for special purpose meters
I. From 230 V AC to 120 V AC at 100 to 500 W, about $50; to 1000 W, about $100.

The cost range of handheld, battery-operated digital multimeters capable of detecting temperature, AC and DC current and voltage, resistance, frequency, and capacitance is about $125. Clamp-type AC current testers also cost about $125. A kW transducer for single or three-phase and three- or four-wire systems costs about $500. A power analyzer that displays and detects 12 energy parameters (including true RMS voltage and current, instantaneous and average power factors, etc.), all at 1% of measurement inaccuracy, costs about \$2500. A universal power analyzer with DC rectifier measurements costs about \$10,000.

INTRODUCTION

The direct measurement of electrical quantities is the topic of this section. Indicators, recorders, and other display devices are discussed in the *Process Control* volume of this handbook and are not covered here. Also not covered are instruments and methods that allow access to electrical quantities values by indirect means such as those using measuring transducers. While this section concentrates on the measurement of current, voltage, and wattage, instruments such as handheld multimeters that are listed in the feature summary at the beginning of this section can also measure other quantities, namely, resistance, frequency, capacitance, and temperature.

Electrical quantities can be measured by either analog or digital instruments. Analog instruments display the value of the quantity by the position of a pointer on a scale, while digital instruments display the same value numerically. In both cases the absolute value of the reading is a function of the selected range.

Digital measuring instruments have many advantages over analog ones making them attractive and popular. They are easier to read, provide higher resolution (up to 1 part in 2×10^8), and better accuracy (up to a few parts per million). They also are capable of remote operation and can provide multifunction capabilities when used with transducers. Analog instruments find their use restricted to special applications, namely, when the advantage of a continuous display provided by the position of a pointer on a scale is important. This is the case in the detection of a critical value or limit and when the rate at which a quantity is changing needs to be detected (e.g., null detection).

ANALOG MEASURING INSTRUMENTS

Analog electric meters have been in use for nearly two centuries thanks to the discoveries of Oersted (1819), Ampere (1821), Faraday (1821), Kelvin (1867), D’Arsonval (1881), and Weston (1889). There are four basic types of analog measuring instruments: permanent magnet moving coil instruments (PMMCs), moving iron vane instruments, electrodynamic instruments, and electrostatic instruments. The permanent magnet moving coil instrument can be upgraded using electronic components (rectifiers and amplifiers) and thermoelectric converters.

There is an element in all analog sensors and to that element a pointer is attached. This element, when subjected to a torque, is allowed to rotate around an axle. A spring might be used to apply a counter-clockwise restoring torque to the axle, while the measured quantity generates an acting torque

TABLE 7.3a
Orientation Table for Ammeters, Voltmeters, and Wattmeters

Meters	*Type of Meter*	*Accessories Required*	*Full-Scale Meter Range (A, Amperes; V, Volts; W, Watts)*	*Permissible Overload in Multiple of Full Scale and for Noted Time Duration*	*Recommended Applications*
AMMETERS					
AC	Rectifier	None	0.5–20 × 10^{-3} A	*For meters:* 1.2×: 8 hr	Low-range, high frequency
	Moving iron vane	None	1–50 A	100× 1 sec	General use up to 750 volts
	Moving iron vane	Transformer	10–8000 A	*For transformer:* 50×: 2 sec	High-range, over 750 volts, long meter leads
	Digital	None	200 × 10^{-6} A–10 A	Varies, often protected	General use, medium frequency
	Digital	Transformer/ Hall effect probe	2–1000 A		High range medium frequency
DC	Permanent magnet moving coil	None	0.02 × 10^{-3} 50 A	1.2×: 8 hr	General use
	Permanent magnet moving coil	Shunt	20–20,000 A	100×: 1 sec	High-range
	Digital	None	200 × 10^{-6} A–10 A	Varies, often protected	General use
	Digital	Current probe	2–1000 A		High range
VOLTMETERS					
AC	Rectifier	None	3–800 V	For meters: 1.2×: continuous	Low-range, high-frequency
	Moving iron vane	None	3–600 V	100×: 1 sec	General use
	Moving iron vane	Transformer	150–18,000 V	For transformer: 1.1×: continuous 1.25×: 1 min	High-range, circuit isolation
	Electrostatic	None	10–1000 V		High range
	Digital	None	100 × 10^{-3}V–750 V	Varies, often protected	General use, medium frequency
DC	Permanent magnet moving coil	None	1–600 V	1.2×: continuous 100×: 1 sec	General use
	Permanent magnet moving coil	Resistor	250–30,000 V		High-range, high-sensitivity
	Digital	None	100 × 10^{-3}V–750 V	Varies, often protected	General use
WATTMETERS					
	1-element electrodynamic	None	125–1000 W	*For current:* 1.2×: continuous 100×: 1 sec	Low power, single-phase 2-wire circuits
	Digital	None	2 mW – 15000 W		General use, single-phase 2-wire circuits
Single-phase AC	1-element electrodynamic	Transformer	1000–100 × 10^{6} W	*For current:* 1.2×: continuous 10×: 1 sec	General use, single-phase circuits
Three-phase AC	2-element electrodynamic	Transformer	1000–100 × 10^{6} W		General use, three-phase, three-wire
	$2^1/_2$-element electrodynamic	Transformer	1 × 10^{4}–1 × 10^{8} W		General use, three-phase, four-wire
	Digital	None	2 mW–15000 W		General use, three-phase, three or four-wire
DC	1-element electrodynamic	None	100–2000 W		General use, low-power
	Digital	None	2 mW – 15000 W		General use

(or motor torque). If this torque exceeds the restoring torque generated by the spring, a new angular position is established. The stability of the system is a function of the acceleration of the rotating system and of the amount of damping (damping torque), which is mainly a function of the speed of the system. Because the inertial and damping torques exist only when the rotating system is in motion, the final position of the pointer depends only on the motor and restoring torques.

For mechanical reasons, the rotating system has a low-pass characteristic with a typical cutoff frequency of 1 Hz, which means that it only reacts to motor torques of frequencies lower that 1 Hz. For normal applications, only the DC component of the motor torque is inside the bandwidth of the system. Therefore, the final position of the pointer results from the balance between that component of the motor torque and the restoring torque.

Permanent Magnet Moving Coil Instruments

More commonly known as the D'Arsonval type, these instruments consist of a pointer attached to a coil of fine wire suspended between the poles of a permanent magnet (Figure 7.3b). Current through the coil creates a magnetic field that reacts with the field of the permanent magnet, causing a motor torque proportional to the intensity of current.[1]

The coil shaft is usually mounted on jeweled bearings, and hairsprings provide the force necessary to restore the pointer to zero (restoring torque). An alternative method is to support the coil by flat metal bands attached to a supporting framework. The bands carry current to the coil and furnish the necessary restoring force. Permanent magnet moving coil meters are accurate and sensitive, consume small amounts of power, possess linear display scales, and are widely used to measure DC current and voltage. Since the field of the permanent magnet is static, the torque depends on the direction of the current in the coil.

The two terminals of the instrument are usually identified either by color (red is positive) or by plus and minus symbols to indicate the connecting mode that produces a correct deflection: clockwise for 0 left meters and clockwise or anticlockwise for 0 center meters. Even if some models are provided with means of switching a current's direction, care should be taken when connecting this type of instrument.

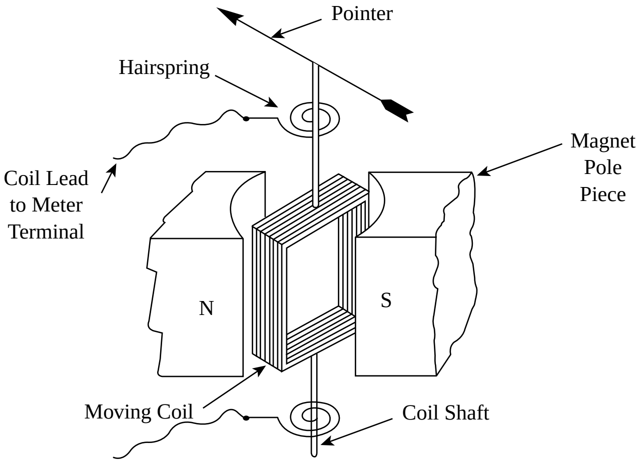

FIG. 7.3b
Internal construction of a permanent magnet moving coil meter.

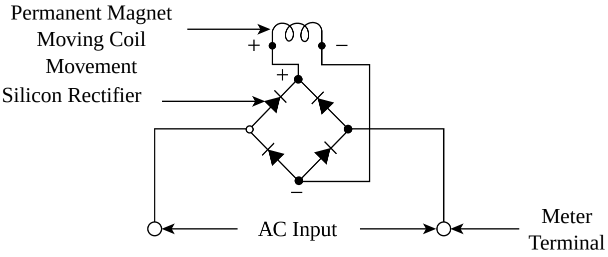

FIG. 7.3c
Rectifier movement with full wave bridge circuit.

Electronic Components The addition of electronic components to a PMMC meter can provide:

1. Extended measuring bandwidth up to the hundreds of megahertz
2. Increased measuring range and sensitivity
3. Improved input impedance

For AC measurements, a PMMC can be combined with silicon rectifiers, which are arranged in a half or full wave bridge (Figure 7.3c). Rectifier current ratings limit these meters to relatively low ranges of AC current and voltage measurements. A wide band of frequencies can be accommodated because accuracy is not affected by frequency. Scales are essentially linear with some crowding at the lower end, because of changes in rectifier values at very low currents. Meters must be calibrated to read effective or root mean square (RMS) values since the instrument responds to average AC values.

The addition of amplifiers to PMMCs improves their measuring range, sensitivity and input impedance. The simultaneous inclusion of amplifiers and rectifiers allows the implementation of instruments that are basically voltmeters, but that can be used to measure current, for instance, by measuring the voltage drop it produces on a calibrated resistor. These voltmeters are sometimes referred to as electronic voltmeters. They have very high input impedance (very low power consumption), are sensitive, and possess both a large bandwidth and a wide measuring range.

The main limitation of these instruments (Figure 7.3d) is that the indication depends on the input waveform. PMMC electronic meters that do not have this limitation are usually identified as true RMS meters. They make use of thermoelectric converters that replace the rectifier and produce a DC quantity whose value equals or is proportional to the root mean square of the AC quantity to be measured. Able to operate up to some 100 MHz, PMMCs with thermoelectric converters and amplifiers are the wider bandwidth true RMS analog electrical measuring instruments and have ranges from millivolts up to a few hundred volts.

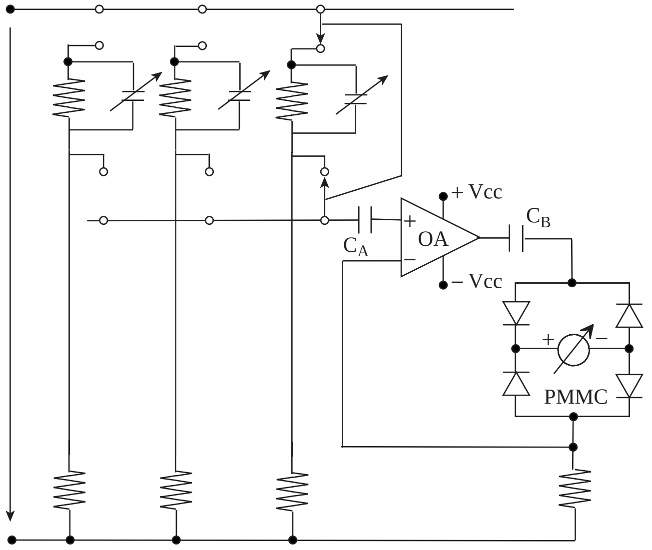

FIG. 7.3d
Block diagram of an AC PMMC based electronic meter.

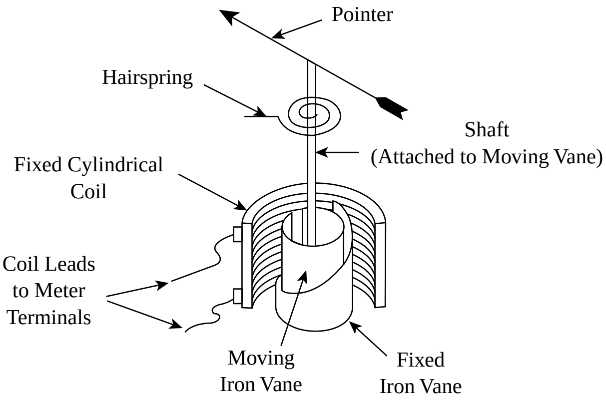

FIG. 7.3e
Internal construction of a moving iron vane-type meter.

Moving Iron Vane Instruments

These instruments consist of two cylindrical soft iron vanes mounted within a fixed current-carrying coil (Figure 7.3e). One vane is held immobile and the other is free to rotate, carrying with it the pointer shaft. Current in the coil induces both vanes to become magnetized, and repulsion between the similarly magnetized vanes produces a proportional rotation (repulsion moving iron vane). The motor torque is proportional to the square of the current in the coil, making the instrument a true RMS meter. A hairspring provides the restoring torque.

Only the fixed coil carries current, and the meter may be constructed so as to withstand high current flows. Moving iron vanes instruments may be used for DC current and voltage measurement. However, small DC errors due to residual magnetism cause them to be more widely utilized for AC current and voltage detection even though sensitivity is low and power consumption is moderately high. These instruments indicate effective or root mean square values and are subject to minor frequency errors only.

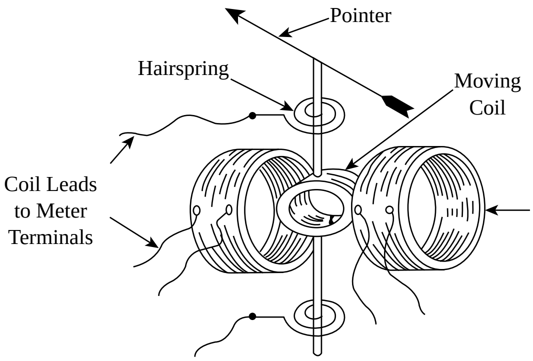

FIG.7.3f
Internal construction of an electrodynamic meter.

Even if their bandwidth can reach the few hundred hertz, their errors depend slightly on frequency. They should be used in a narrower band, usually 40 to 60 Hz. Their scales are nonlinear and somewhat crowded in the lower third, because the deflection of the pointer is approximately proportional to the square of the coil current.

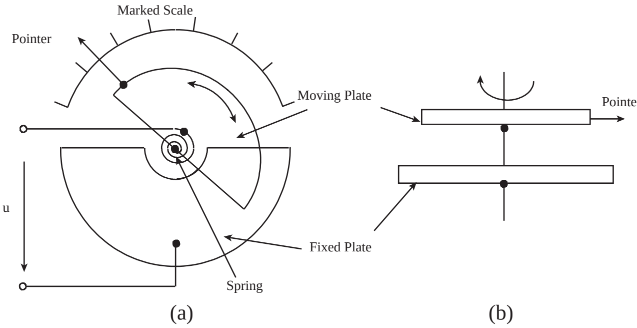
Electrodynamic Instruments

These instruments are similar to the PMMC-type elements except that the magnet is replaced by two serially connected fixed coils that produce the magnetic field when energized (Figure 7.3f). The motor torque is proportional to the product of currents in the moving and fixed coils. These instruments can measure AC or DC current, voltage, and power. In the first two cases, the moving and fixed coils are serially connected. For power measurement, one of the coils (usually the fixed) passes the load current and the other coil passes a current proportional to the load voltage.

Cost and performance compared with other types of instruments restrict the use of this design to AC and DC power measurement. When used for power measurement, its scale is linear (calibrated in average values for AC). Its accuracy is high but its sensitivity is low. The bandwidth of electrodynamic instruments goes from DC to a few hundred hertz. Similarly to moving iron vane instruments, the electrodynamic instruments are true RMS responding meters.

Electrostatic Instruments

In contrast with the three meter types already mentioned, the motor torque of electrostatic instruments is due to electric interaction of charge distributions. Figure 7.3g represents a common implementation of the instrument (rotating-plate type). It is a capacitor with a fixed and a moving semicircular plate. The plates are mounted on a shaft that also supports the pointer. When a voltage is applied to the capacitor, the charge distribution on the plates produces an attractive torque that tends to bring the plates closer. The motor torque is proportional



(a) (b)

FIG. 7.3g
Internal construction of an electrostatic meter.

to the square of the voltage between the two plates and the restoring torque is, as usual, generated by a spiral spring.

Because of their high input impedance, electrostatic instruments are used only as voltmeters. The motor torque also depends on the derivative of capacitor's value. For mechanical reasons, this derivative is small so that a motor torque able to produce a significant angular displacement of the moving plate is only possible for voltages higher than some tens of volts. For this reason, and in spite of its large bandwidth (from DC up to some tens of MHz) and high input impedance, electrostatic voltmeters are used mainly in high voltage measurements. Today the name electrostatic voltmeter is also used to designate electronic voltmeters that measure voltage without charge transfer.[2]

DIGITAL MEASURING INSTRUMENTS

In the last few decades, the development of sensors and instrumentation have been influenced by the technologies of solid state electronics and integrated circuitry. As cost effective analog-to-digital converters (ADCs) became available, instrumentation shifted from analog to digital. This trend was reinforced by the convenience of automation of digital instruments.

Figure 7.3h represents a simplified block diagram of a digital instrument. The value displayed results from the output of an ADC. The input conditioner circuits serve to transform the measured quantity into a proportional DC voltage or current signal that is within the range of the ADC. The nature of the signal conditioner depends on the quantity or quantities to be measured and on the characteristics of the meter. Finally, the controller circuitry supports the required control functions.

For a true RMS digital multimeter, Figure 7.3i details the block diagram in Figure 7.3h. Assuming that the ADC operates on voltage, the input voltage and current must both be converted into a DC voltage. If the input is a DC voltage, only attenuation may be needed. If the input is AC, the attenuated voltage must be sent to a circuit that is able to produce a DC voltage whose value is equal to the RMS of its input voltage.

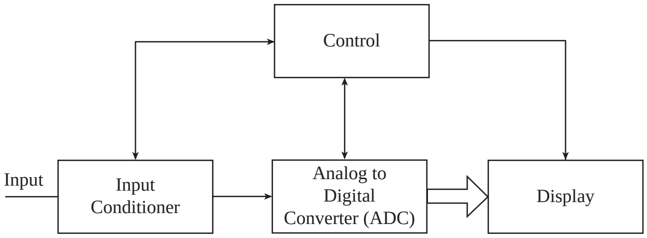


FIG. 7.3h
Simplified block diagram of a digital meter.

There are several possible solutions to implement such a circuit (named RMS converter). These include those that are based on the definition of RMS value and on the thermal effects associated with an electric voltage.

A wide range of measurements can be covered by digital voltage and current sensing instruments. Typical ranges of general purpose $3^{1}/_{2}$ digittrue RMS multimeters are from 2 mA to 2 A, or from 200 mV to 200 V. Their inaccuracy is around 0.5% of full scale and bandwidth 0 to 50 kHz.

Wattmeters

Instantaneous power is the product of the instantaneous values of the current and voltage, while active power is the time-averaged value of instantaneous power. Figure 7.3j shows a possible implementation of a single-phase digital wattmeter. The value presented in the display is calculated from the digitized values of current and voltage. It is obtained by processing the current and voltage signals in conditioning circuits prior to their being converted by the ADCs. The sample and hold circuits are placed before the ADCs to assure DC inputs for the converters during their conversion times.

Since the instrument includes a processing unit, several other electric and nonelectric quantities can be derived and displayed: RMS values of current and voltage, reactive power (sine wave input), phase angle, energy, period, etc. The design shown in Figure 7.3j allows measurement of both AC and DC power.

UTILIZATION OF ELECTRICAL METERS

Current Measurement

AC Current Alternating current indicators are almost exclusively of the moving iron vane type because of their wide range and low sensitivity to frequency variations (less than the electrodynamic type) and waveform errors, and digital.

Moving iron vane meters in ranges from 1 to 50 A full scale can be used for higher current ranges by the addition of external current transformers. Operating voltage is limited to approximately 750 V. Above this level a current transformer must be used even if the current is within the meter rating.

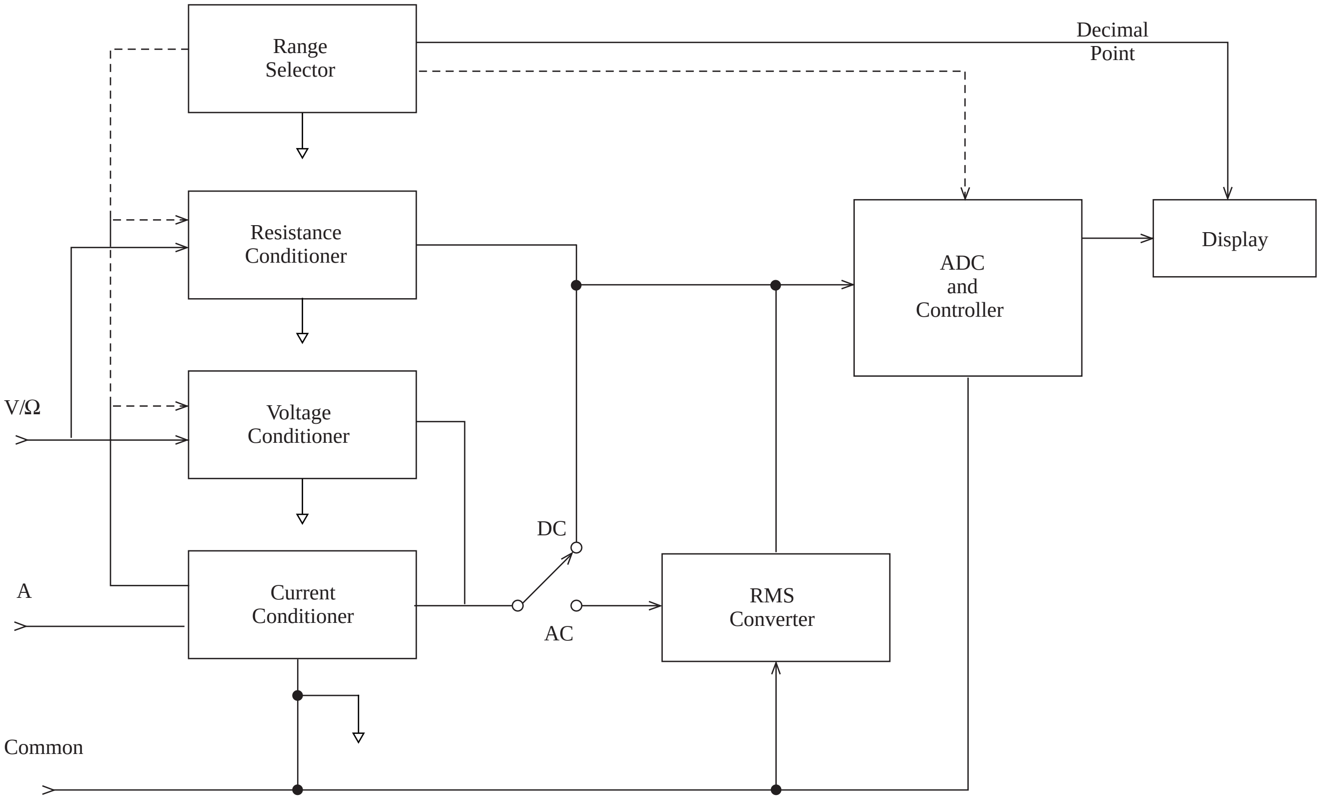

FIG. 7.3i
Digital meter: detailed block diagram.

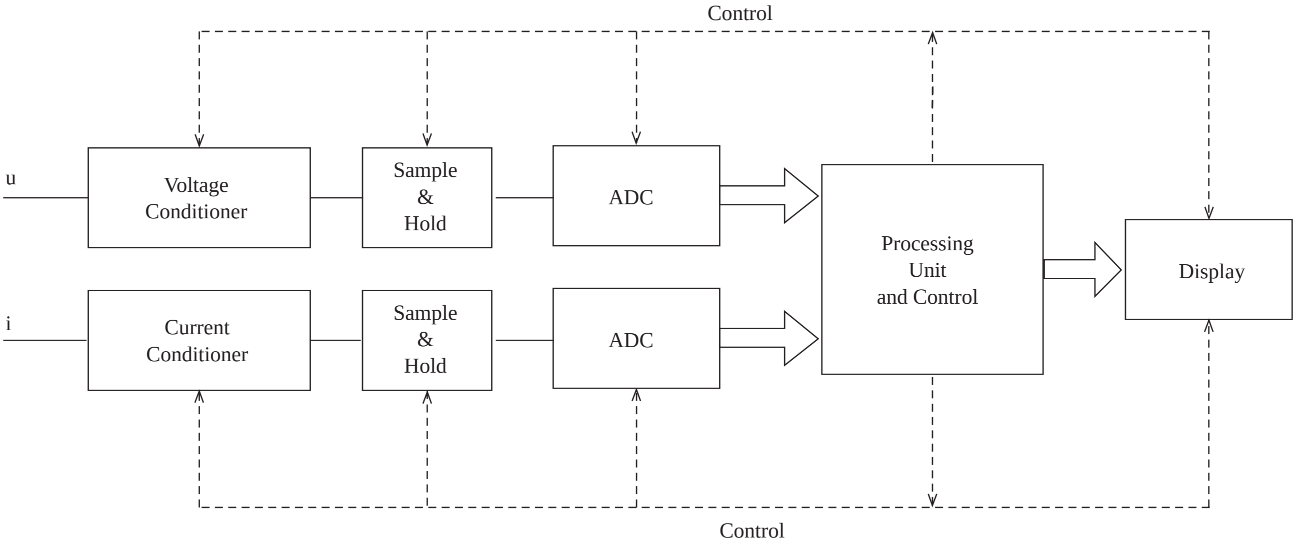

FIG. 7.3j
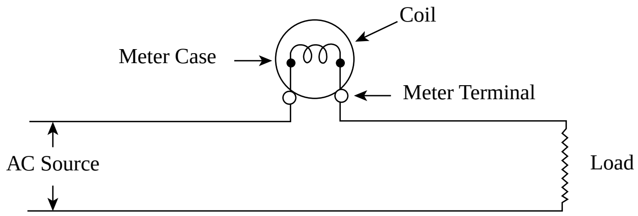
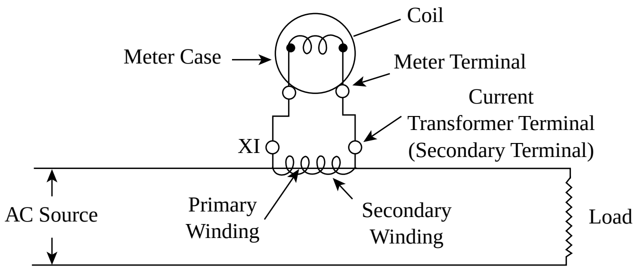
Block diagram of a digital wattmeter (sampling type).

Meters calibrated for 60 Hz are usable from 25 to 400 Hz, with an additional error of only 1/2% full scale and may be recalibrated for use at levels as high as 1000 Hz. For measurement of small currents at frequencies above 400 Hz, or when variable frequencies must be measured, digital meters and electronic PMMC meters should be used.

This meter is available in ranges from 500 μA to 20 mA full scale and may be used from 20 to 10,000 Hz without loss of accuracy on sine wave circuits. The upper limits of current and frequency for digital meters are 10 A and 50 kHz with an inaccuracy of about 5%. For higher values of current, current probes (current transformers or Hall effect type) must be used.



(1) Self-Contained Ammeter Connection



(2) Transformer Rated Ammeter Connection

FIG. 7.3k
Alternating current ammeter connections.

Current Transformers

For current measurement above the range of moving iron vane and digital meters, a current transformer is the easiest and cheapest solution. When inserted in the circuit, it provides the proper ratio between the meter range and the measured current (Figure 7.3k). Most current transformers are designed to deliver 5 A at the secondary terminals when full primary current is flowing. The primary winding can be the current carrying conductor, which is passed through the center of the secondary winding in the form of a single-turn coil. This design requires no mechanical connection or break in insulation.

Primary Turns Selection of the current transformers ratio should be based on the closest standard primary rating over the maximum current to be measured. Because there are large intervals between standard primary ratings for current transformers, it is often desirable to modify the transformer ratio by passing the primary conductor through the center of the secondary winding two or more times. A typical current transformer with a rating of 100 to 5 A has a normal ratio of 1 primary turn to 20 secondary turns or 1:20.

Passing the primary conductor through the center of the secondary winding twice (Figure 7.3l) increases the primary turns to two. Therefore, the ratio becomes 1:10, giving a new rating of 50:5 A. By taking additional primary turns, the rating may be modified to correspond more closely to the desired scale.

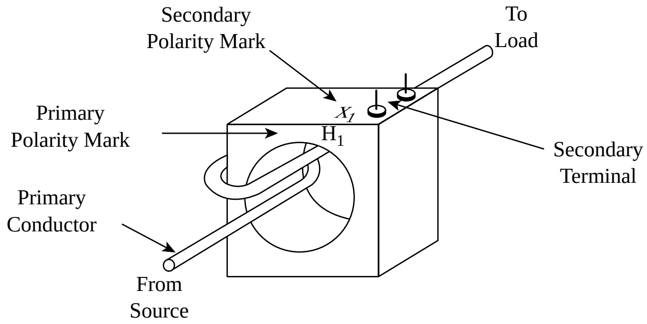


FIG. 7.3l
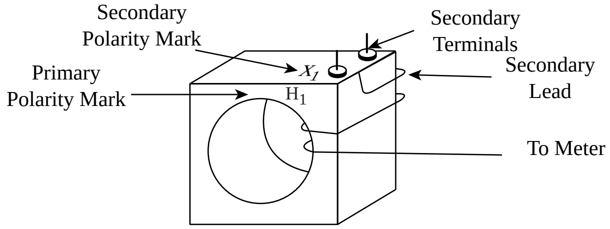
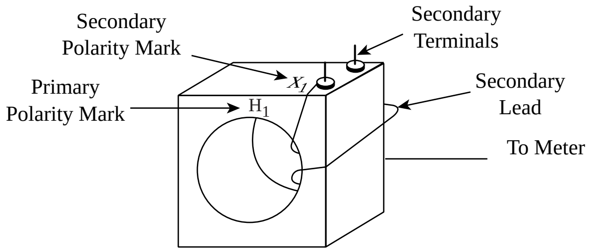
Current transformer with two primary turns added.



(1) Adding Secondary Turns



(2) Subtracting Secondary Turns

FIG. 7.3m
Modifying the number of secondary turns on a current transformer.

Secondary Turns The new primary rating is determined by dividing the original primary rating by the number of turns taken. Small adjustments to the transformer ratio may be made by passing one of the secondary leads through the center of the secondary winding so as to effectively add or subtract secondary turns (Figure 7.3m). A current transformer with a 100 to 5 A rating has 20 secondary turns. Therefore, the addition of one secondary turn changes the turns ratio to 1:21, for a new rating of 105:5 A. By adding or subtracting the required number of secondary turns, the rating may be adjusted to almost any value. The new primary rating is determined by secondary rating, which is 5 A in all cases. When both primary and secondary turns are modified, the new primary rating may be calculated by Equations 7.3(1) and 7.3(2):

$$\text{original secondary turns} = \frac{\text{original primary turns}}{\text{secondary rating}} \qquad \mathbf{7.3(1)}$$

$$\text{adjusted primary rating} = \frac{(\text{total secondary turns})(\text{secondary rating})}{\text{primary turns}} \qquad \mathbf{7.3(2)}$$

Polarity and Inaccuracy Primary and secondary polarity markings are provided on current transformers with the primary identified as H1 and the secondary terminal as X1. To add secondary turns, one should connect a lead to terminal X1 and pass it through the center of the secondary winding from the side opposite the H1 polarity mark, as indicated in Figure 7.3m. To subtract secondary turns, connect a lead to terminal X1 and pass it through the secondary winding from the same side as the H1 polarity mark.

Current transformer inaccuracy is expressed as the maximum error for a particular load class as specified by the United States Standards Institute. Although load inaccuracy data are available from the meter manufacturers, it is seldom necessary to check the meter. This is because if the meter is listed as transformer rated, it is also designed to maintain its accuracy when it is connected with #14 AWG leads at lengths up to 150 ft (45 m) and #12 AWG leads at lengths up to 250 ft (75 m).

Current transformers are generally insulated for use on systems up to 600 V, but 600 V transformers may be used at higher voltages if the primary conductor is fully insulated. Current transformers designed for ammeters are available with 0.6 and 1.2% inaccuracy and in the following standard primary ratings: 100, 150, 200, 250, 300, 400, 500, 600, and 800 A.

Current transformers used to extend the measuring range of AC current meters must operate with a very low secondary load, close to short-circuit, to assure that the magnetization current is small enough. Care must be taken when connecting the transformer. Particularly, one should make sure that the secondary is not left open; if that happens, the magnetization current will be approximately equal to the primary current. Under these conditions the electromechanical stress to which the magnetic material is subjected can destroy it. This can occur in form of an explosion.

Hall Effect Probes

The current range of digital meters with voltage-sensing capability can also be increased using probes designed on the basis of the Hall effect. A Hall sensor detects and displays the magnetic field caused by the current and produces a voltage proportional to that current. Currents up to some hundred amperes can be measured at frequencies up to tens of kilohertz. The inaccuracy of measurement is about 3%.

DC Current

Direct current indicators are either analog or digital. The analog designs can be the PMMC type, which take advantage of the low power consumption and inherent linear scale factor, while avoiding the residual magnetic errors of the iron vane types or the slower response of electrodynamic movements.

Current carrying capacity of the internal connections to the coil of PMMC meters limits the self-contained meters to a range of 20 μA to 1 A full scale. So-called self-contained meters are available for up to 50 A; however, they are actually low-range instruments with an internal shunt. Above this range external shunts are employed. Meters are suitable for use on up to 600 V circuits. Above this value other types of meters or transducer-rated meters are generally used.

Digital current meters are available with ranges from picoamperes (useful in applications such as measurement of conductivity or low conductivity or insulating materials) to some tens of amperes. The use of shunts to extend the upper limit of that range is possible; nonetheless, Hall effect probes are more often used for that purpose.

Ammeter Shunts

Direct current ammeter ranges can be greatly extended by connecting a shunt of the proper resistance in parallel with the meter so that a specific proportion of the current passes through the meter, the remainder being carried by the shunt (Figure 7.3n). Analog meters designed for shunts are rated either at 50 or 100 mV, depending on the voltage drop across the meter terminals at full-scale deflection. When a shunt is used it must have a corresponding millivolt rating. The actual resistance value of the proper shunt does not have to be known since shunts are rated on the basis of full-scale meter current and are available from 5 to 20,000 A, calibrated to ±0.25% inaccuracy.

Shunt-rated ammeters are calibrated for a particular shunt lead resistance, factors that vary from one manufacturer to another, and the correct calibrated shunt leads should be used for maximum accuracy or the meter should be recalibrated for use with different leads. Noncalibrated shunt leads of #14 AWG wire have an additional error of 1/2% for 50-mV meters at distances up to 25 ft (7.5 m) or for 100-mV meters at distances up to 40 ft (12 m).

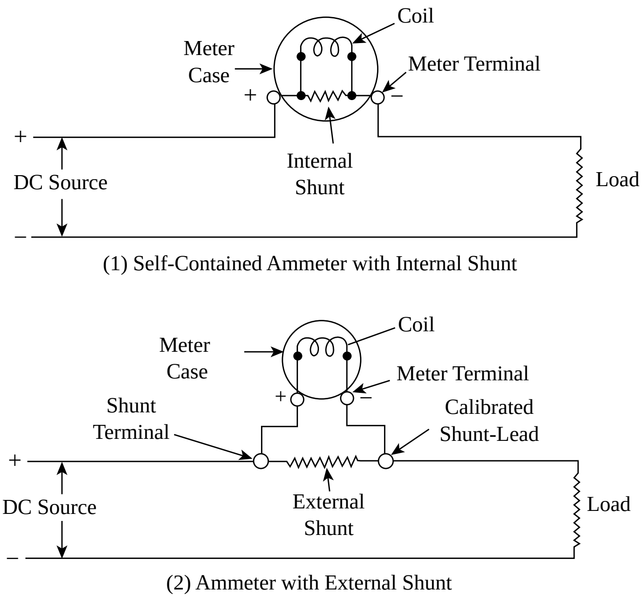


FIG. 7.3n
Direct current ammeters with internal and external shunts.

Voltage Measurement

AC Voltage Indicators for AC voltage measurement can be digital or analog. Analog designs include the moving iron vane, electronic PMMC, or electrostatic types. As discussed below, each has its own advantages and each is preferred for a particular voltage range.

The performance of digital voltmeters is generally superior. Their input impedance is usually higher than 1 MΩ and their ranges extend from microvolts to hundreds of volts. Their sensitivities are better than 1/2000 of full scale and their bandwidths are higher than some tens of kilohertz. Their errors are usually under 1% of full scale.

Moving iron vane voltmeters have the advantage of high accuracy and wide range, although their sensitivity is poor. Voltmeter sensitivity is determined by the coil current, which is required for full-scale detection and is expressed in ohms per volt since the coil current is inversely proportional to the total resistance. A series resistor is generally installed within the meter case to provide the total resistance required by the movement so that full voltage equals full-scale meter current.

Self-contained moving iron vane voltmeters are available in ranges from 3 to 600 V full scale. Their corresponding sensitivities range from 4 to 250 Ω/V. These meters are usually calibrated for 50 or 60 Hz; however, they may be used in circuits from 25 to 1000 Hz when calibrated for a specific frequency.

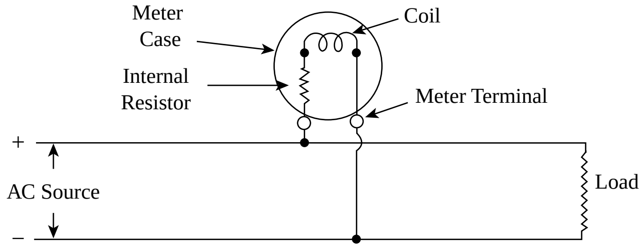
Rectifier-type PMMC meters have an advantage in that their high-resistance coils permit greatly increased sensitivity. However, due to a variety of rectifier losses, they are not as accurate as the moving iron vane type. They are available in full scale ranges from 3 to 800 V and with standard sensitivity of 1000 Ω/V at all ranges. Calibrated for 60 Hz, these meters may be used from 20 to 10,000 Hz without loss of accuracy, although they become inaccurate if used in circuits with wave shapes other than the sine wave (non true RMS meters).

Electrostatic meters have the advantage of extremely high input impedance and large bandwidth but have poor sensitivity.

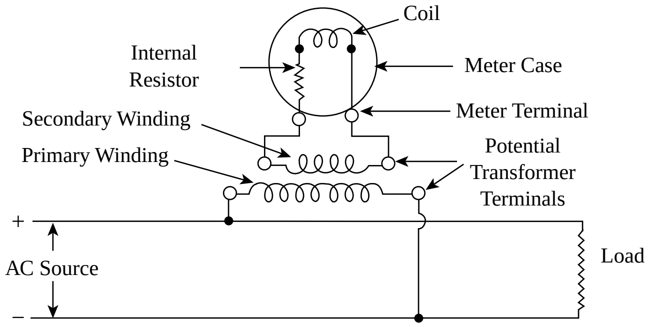
Potential Transformers

For measurements on circuits above 600 V or on lower voltage circuits in which isolation is desirable, a moving iron vane meter is used with a potential transformer to provide the proper ratio between circuit voltage and meter movement (Figure 7.3o). Meters used with transformers are usually provided with a 150 V range having a sensitivity of 100 Ω/V. The corresponding potential transformers are always furnished with a ratio based on a 120-V secondary to permit indication of small over voltages. For this reason potential transformers must be selected on the basis of maximum circuit voltage and not on full-scale meter reading.

Potential transformer errors are specified by the United States Standards Institute in a manner similar to that of current transformer inaccuracy. Checking is seldom required, because the error is not exceeded until the lead lengths exceed several hundred feet. Potential transformers are available with primary ratings from 120 to 14,400 V and with 120-V secondary. Their inaccuracies at frequencies from 50 to 400 Hz are 0.3 to 0.6%.



(1) Self-Contained Voltmeter Wiring Diagram



(2) Voltmeter Installation Utilizing a Potential Transformer

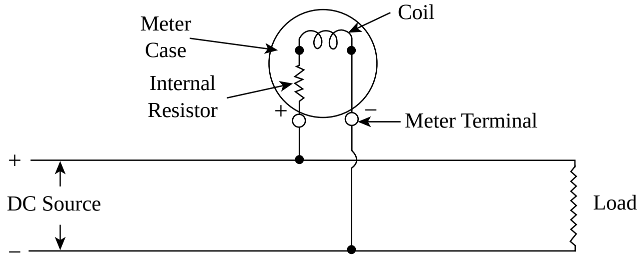
FIG. 7.3o
Alternating current voltmeter installations.

When connecting potential transformers to high voltage circuits it is good practice to connect one of the secondary terminals to ground to assure that the meter and the operator work at low potentials relative to the ground. Due to the capacitance between the primary and secondary windings, allowing the secondary to float may lead to high potentials in the secondary.

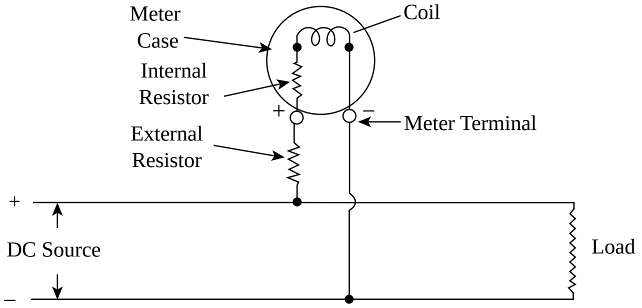
DC Voltage Almost all analog meters for DC voltage measurement are of the PMMC type because of their high sensitivity, linear scale, and wide range. Self-contained DC voltmeters are available in ranges from 1 to 600 V full scale with a standard sensitivity of 1000 Ω/V in all ranges. Above this range, self-contained meters are not available because their internal resistance would become very high and resistor losses would result in excessive heating.

External resistors can be used on circuits above 600 V to extend the measurement range of the PMMC. Circuit isolation is not possible in this arrangement, and the meter will be damaged if the external resistor is accidentally shorted. Instruments with sensitivities of up to 20,000 Ω/V are available, although not in all ranges.

Digital voltmeters for DC voltage measurement have the same metrological characteristics as do the AC digital voltmeters already discussed. To measure voltages that are higher than the upper range of the instrument, voltage dividers are used.



(1) Self-Contained Voltmeter Wiring Diagram



(2) Voltmeter Installation with External Resistor

FIG. 7.3p
Direct current voltmeter installations.

These can be either of the resistive or preferably of the capacitive type.

Voltmeter Resistors Inserting an external resistor of the proper value in series with a PMMC voltmeter (Figure 7.3p) permits measurement of higher voltages or increased sensitivity at low ranges. Meters with external resistors generally have 1 mA movements and 125Ω internal resistance. Standard resistors designed to afford a sensitivity of 1000 Ω/V may be selected on the basis of full-scale meter reading without the necessity of calculating resistance. Standard resistors are available in voltage ratings from 250 to 30,000 V, and resistors for nonstandard voltages may be calculated using Equations 7.3(3) and 7.3(4):

$$\text{total resistance} = \frac{\text{full-scale meter reading}}{\text{full-scale meter current}} \qquad \textbf{7.3(3)}$$

$$\text{external resistor value} = \text{total resistance} - \text{meter resistance} \qquad \textbf{7.3(4)}$$

Instruments requiring less current for full-scale deflection permit greater sensitivity. Once the total resistance has been determined for a particular voltage range, the new sensitivity may be calculated by using Equation 7.3(5) below:

$$\text{sensitivity} = \frac{\text{total resistance}}{\text{full-scale meter reading}} \qquad \textbf{7.3(5)}$$

Measurement accuracy is not noticeably affected by lead length because the value of the external resistor is usually very high. The calibrated inaccuracies of these units are ±0.25%.

Power Measurement

The unit of electric power is the watt, which equals 1 J of work or 1 J of energy per second (W = J/s). The watt is also equivalent to 3.4 Btu/hr or 0.001341 hp. The power in a DC electric circuit is the product of the current flowing through it and the voltage existing across it. In AC circuits, the instantaneous power, p, is:

$$p = iu \qquad \textbf{7.3(6)}$$

where i and u are the instantaneous values of current and voltage, respectively. The active power P is the time average value of the instantaneous power:

$$P = (iu)_{av} \qquad \textbf{7.3(7)}$$

If the circuit is under sine wave regime, 7.3(7) can be written under the form:

$$P = IU\cos(\phi) \qquad \textbf{7.3(8)}$$

where I = RMS value of AC current, U = RMS value of AC voltage, and ϕ = Phase angle between U and I.

The power factor, P.F. = cos(ϕ), can assume values between 1 and 0. It is 1.0 in a purely resistive circuit and is 0 in an ideal (total reactive) capacitor or inductor. In actual circuits it is always between 0 and 1.0. In other words, the power factor is the ratio between the true power and the apparent power (P_{app} = IU).

A wide variety of devices are used to measure electric power.[3] The units most widely used in industry are described below.

AC Power Analog indicators for AC power measurement are usually constructed with electrodynamic movements because the separate fixed and moving coils permit two different types of input signals for the same movement. The fixed coils are usually connected to measure currents, and the moving ones are connected to monitor voltage (Figure 7.3q). Connection of the coils in this way causes a deflection of the moving coil proportional to the instantaneous product of the circuit current and voltage. Inertia prevents the moving coil from responding quickly to current and voltage variations in AC circuits above 25 Hz, and pointer will indicate the average AC power regardless of wave shape. The way wattmeters are wired introduces a certain amount of error; this can be minimized by altering the wire connections as a function of current and voltage values being measured.

Single Element Wattmeters In the wattmeter shown in Figure 7.3q, the current in the current-carrying coils is the true load current. However, the voltage across the potential coil is higher than the load voltage by an amount equal to the voltage drop across the current coils. This arrangement will result in a positive error in power measurement by an

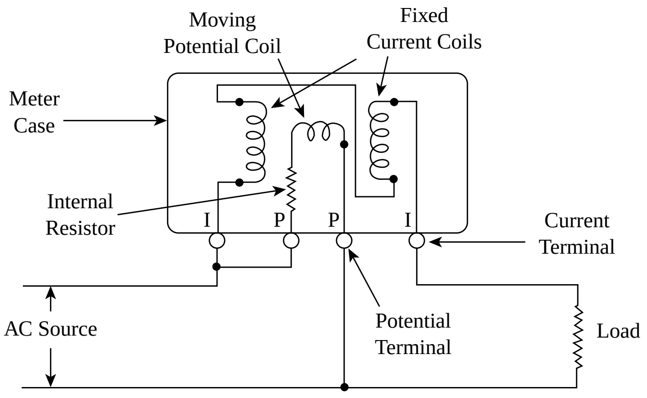


FIG. 7.3q

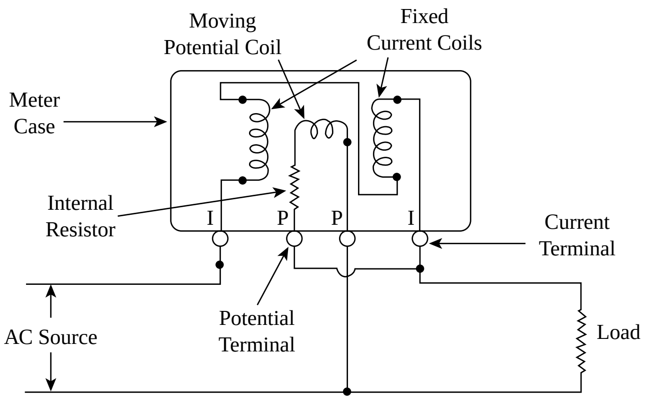

FIG. 7.3r
Single element wattmeter, wired for accurate detection of high-current and low-voltage loads.

amount equal to the power consumed by the current coils. This error will be lowest when the wattmeter is used on high-voltage circuits with low-current loads.

If the external wiring is changed, as shown in Figure 7.3r, the voltage across the potential coil will be the true load voltage. In this case, the current drawn by the potential coil will also pass through the current coil and the wattmeter reading will be high by an amount equal to the power consumed in the potential coil. The error will be lowest when the meter is used in low-voltage circuits with high-current loads.

Meter scales are linear and their accuracy is high, but low sensitivity is the result of the high power consumption. The units are usually calibrated for 50 or 60 Hz and recalibration is necessary when used at frequencies up to 400 Hz.

Wattmeters are rated for maximum current and voltage in addition to maximum wattage. This is because circuits with large phase angle differences between current and voltage (circuits with low power factor) can overload the current or voltage coils without causing large wattage readings. Power measurement in single-phase, two-wire circuits requires a single element wattmeter consisting of two fixed current coils and one moving potential coil.

The fixed current coils are wound with heavy wire as required by the meter current rating. The moving coil is usually wound with fine wire and is provided with a series resistor to ensure a high-resistance, low-inductance circuit for potential measurement.

Self-contained meters have ranges from 125 to 1000 W full scale with current ratings from 1.25 to 10 A at 120 V. Transformer-rated meters are also available. Their rating is 5 A at 120 V and their available scale ranges are from 1000 W to above 100 MW, depending on current transformer and potential transformer ratios.

Also available are wattmeters with a full scale that is a percentage (often 10%) of the product of current and voltage ranges. These instruments (low power factor wattmeters) are particularly suited for power measurement on circuits with low power factors.

Multielement Wattmeters Power measurement in three-phase,[1] three-wire circuits necessitates a two-element wattmeter (Aron method) consisting of two single-element movements with the moving coils attached to a common shaft that is wired as shown in Figure 7.3s. Each of the elements measures a portion of the power drawn by the load and adds to the common moving coil shaft a proportional torque so that the pointer will indicate total power. Using two independent single-phase wattmeters and in sine wave regime, this configuration allows the measurement of reactive power (difference between the readings of the wattmeters) and power factor.[1]

The transformers of multielement wattmeters are almost always rated with 5-A current coils and 120 to 600 V potential coils. Meter ranges from 5000 W to more than 100 MW are common, although ranges as low 1000 W are also available.

Power measurements can be made in three-phase, four-wire circuits by a three-element wattmeter. Such a design is seldom utilized because the two-element wattmeter movement can

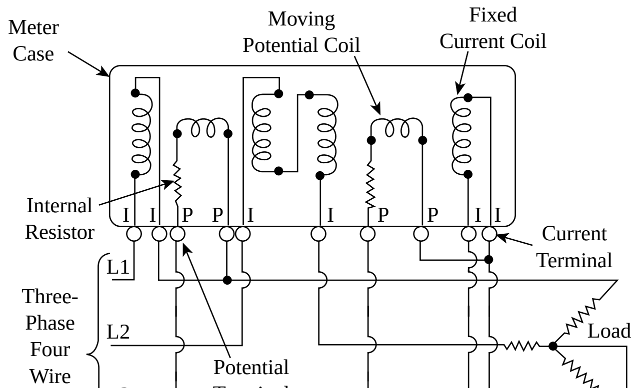

FIG. 7.3s
Two-element wattmeter wired for three-phase, three-wire loads.

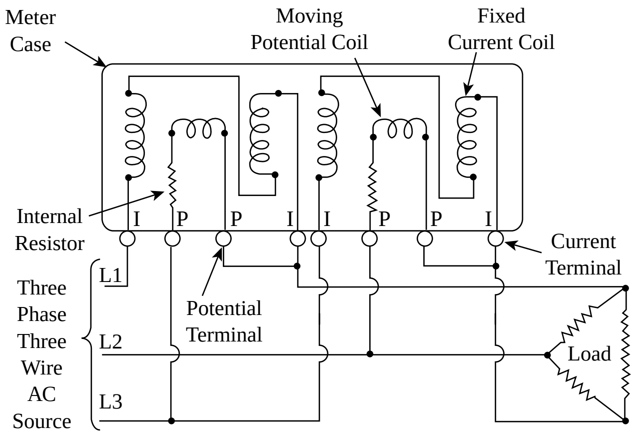

FIG. 7.3t
A $2^1/_2$-element wattmeter wired for three-phase, four-wire loads.

be modified to permit measurement on three-phase, four-wire systems by reconnecting one of the fixed coils for each element (Figure 7.3t). Meters of this type are known as $2^1/_2$-element wattmeters. They will correctly indicate power for three-phase, four-wire loads as long as the lines to neutral voltages are balanced for all three phases. Meter ranges from 10,000 W to more than 100 MW are available in this design, with ratings of 5 A at 120 or 240 V.

Digital wattmeters are available for both AC and DC applications for both single and multiphase measurements. Without using external components, the ranges can extend from a few milliwatts to some tens of thousands of watts. With the use of potential and current transformers or shunts and voltage dividers, the range can be increased depending on the characteristics of these external devices. The two wattmeter (Aron method), as shown in Figure 7.3s, is also commonly used for AC power measurement.

DC Power Direct current wattmeters are the same as single-element AC wattmeters but it is advisable to calibrate them for use on DC circuits. Ranges from 100 to 2000 W are available with ratings from 1 to 20 A at 120 V. Higher ranges may be accommodated by adding an external resistor to the potential circuit for use on high voltages, although this introduces additional errors. Because of these errors, other measuring solutions such as DC watt transducers are often used for higher ranges.

Meter Scales

In general, the best choice of meter-scale range is one in which the maximum anticipated value of current, voltage, or power will fall at 80% of the full-scale reading. Scale selection on this basis provides reasonable utilization of the meter scale, furnishing good visibility with the capability to indicate moderate overloads.

When many analog meters are grouped in a small area, it may be desirable to have all normal readings at the midscale region in order to permit easier identification of abnormal conditions. The midscale pointer position on nonlinear scales corresponds to a value of approximately 65% of full scale, while on linear displays it corresponds to a value of 50% of full scale.

INTRODUCTION

The same amount of electric power can be purchased for less, if the rate of usage is uniform, because the electric power supplier requires smaller generating and distribution equipment. When there is a peak in the demand, the utility company has to turn on more equipment to meet the peak. This equipment becomes idle when the peak has passed. Therefore, the cost of plant operation can be reduced if the non-essential electricity users (sump pumps, hot water heaters, air conditioners, etc.) are turned off for a few minutes, when a peak is approaching, and are turned back on when it has passed. Peak shedding logic systems are configured by identifying those users that can be periodically turned off for a few minutes, and will not be harmed if their electric energy requirements are satisfied a little later.

LOAD SHEDDING SYSTEMS

Load-shedding devices are the simplest and usually the first method employed in managing energy use and controlling energy costs. They are used to regulate the on and off times of selected electrical loads, such as fans, heaters, and motors in a building, in order to reduce electrical demand (KWD) and regulate energy consumption (KWH). The energy management devices used for this purpose can be electromechanical, electronic, or computer-based digital systems.

All but the most primitive designs monitor the energy consumption of the plant by reading the consumption on the electric utility meter. The operation of one or more loads is interrupted for brief periods when it appears that the electrical demand (KWD) would exceed some preselected limit setting.

The more sophisticated systems also consider such variables as internal and outside ambient temperatures, plant operating level, occupancy in case of buildings, and other predictable factors or events. Control actions can involve regulating the operating parameters of heating, ventilation, and air conditioning (HVAC) equipment, energy storage, and cogeneration systems, as well as turning loads on and off. Utility cost savings can be minimal or dramatic and are largely dependent on the skill and imagination of the user. Table 7.4a provides a summary of the features and capabilities of the different energy management systems on the market.

TABLE 7.4a
The Functions and Capabilities of the Various Energy Management Systems

	Mechanical	*Electronic*	*Mini-Computer*
Maximum number of loads	1–6	16–32	64–256
Peak demand limiting	No	Yes	Yes
Time-of-day control	Yes	Yes	Yes
Cycling control	Yes	Yes	Yes
User adjustable	Yes	Yes	Yes
User programmable	No	No	Yes
Remote adjustments	No	Some	Yes
Optimization calculations	No	No	Yes
Printed reports	No	Some	Yes

Peak Shedding System Costs

The cost of procuring and installing energy management devices is dependent on the type of device utilized and the number and complexity of the loads that are selected for control. Simple mechanical time clock devices, serving only a few loads, can be installed for $500 to $1000. Electronic counters and load shedders, capable of controlling about 16 loads, can cost anywhere from $1000 to $10,000, and sometimes more. Fully functional digital energy management systems, including their control programs, can monitor and operate literally hundreds of devices and can cost up to about $25,000. All the devices require ongoing attention and management in order to retain their effectiveness.

Electrical Demand

Electrical demand is defined as the average load connected by a consumer to an electrical power generating system as measured over a short period of time, usually 15 or 30 min. The electrical demand is measured in kilowatts (KWD) and is recorded by the utility meter for each of the measurement periods during the billing period. The highest recorded demand during the billing period is used to determine the cost of each of the kilowatt hours (KWH) consumed. The lower the recorded peak demand, the lower the overall bill. Electrical demand should not be confused with instantaneous load, which is also measured in kilowatts (Figure 7.4b).

Demand Load Shedding

Energy management devices, particularly load shedders, reduce the demand (i.e., average load) during the critical demand periods by interrupting the operation of connected loads for short periods. The result is a reduction in the demand for the critical demand period and a lower utility bill (Figure 7.4c). Equation 7.4(1) below shows the relationship:

$$\text{KWH}/(\text{demand period in hours}) = \text{KWD} \qquad \mathbf{7.4(1)}$$

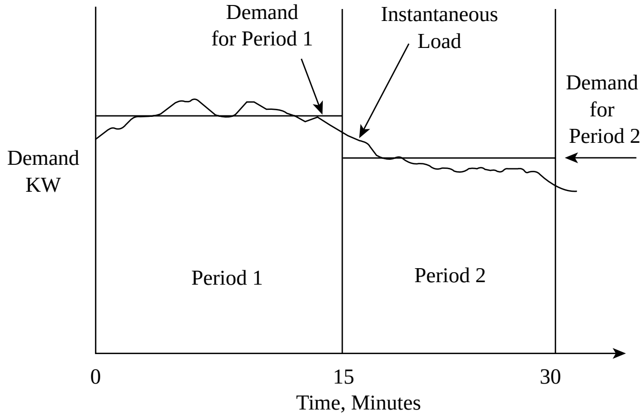

FIG. 7.4b
Relationship between electrical demand and instantaneous load.

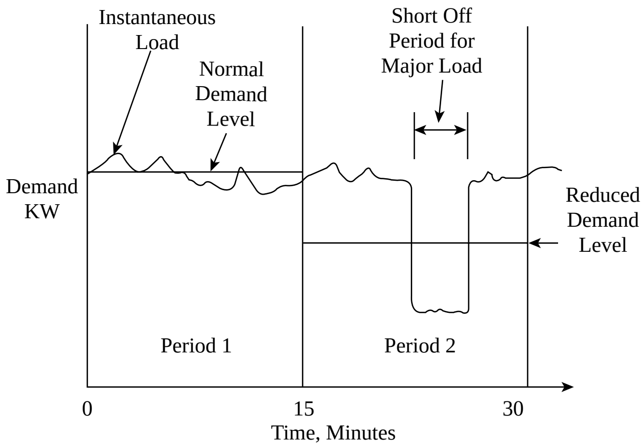

FIG. 7.4c
Effect on demand of cycling a major load off for a brief period.

where

KWH = total energy consumed in the demand period
KWD = the demand in that period

The instantaneous load before the turnoff remains the same. If, without shedding, the current demand period would have produced the highest average load during the billing period, considerable savings will result. In demand periods other than the one having the highest average demand (KWD), energy (KWH) savings will still result. The savings in energy are as important to the user and the environment as the reduction in demand. The availability of inexpensive electronics has made practical some of the more exotic strategies to limit and control energy use. These strategies have less obtrusive effects on plant operation or on building occupants. They can be used to optimize operating times, optimize equipment parameters, select energy sources, and operate cogeneration and thermal storage systems.

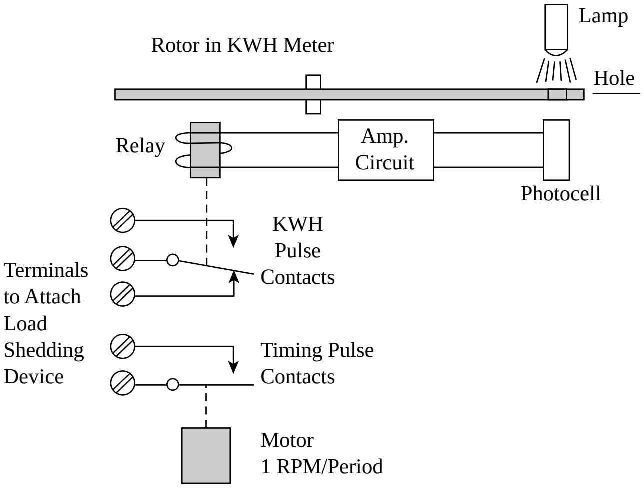

FIG. 7.4d
Electrical connections for meter attachment. The timing pulse contact closes momentarily at the end of each demand period. The KWH pulse transfers once for every rotation of the meter rotor.

Start Signals for Demand Periods

Load-shedding devices and more sophisticated energy management devices base many of their control actions on the projected demand level in each demand period. To define the demand period, they receive two signals from the utility meter. These signals are usually in the form of momentary contact closures of approximately 1/2 s duration, which indicate the start of a demand period or the consumption of a unit of electrical energy (KWH).

Most electrical utilities will provide these signals for a modest fee. Sophisticated control systems are capable of generating their own signals through instrumentation with good results (Figure 7.4d) The energy consumption (KWH) pulse value can be converted to a unit of demand (KWD) by dividing it by the length of the demand period in hours.

$$\text{(KWH per pulse)/(Demand period in hours)} = \text{KWD/pulse} \qquad \textbf{7.4(2)}$$

SHEDDING CONTROLS

Electromechanical Devices

The least expensive and simplest load-shedding device is the time clock. By means of a small electrical motor and a series of cams and switches, electrical loads can be operated in cyclical mode or turned on and off at preset times. In this mode of operation, no attempt is made to synchronize the time clock with the demand period, and savings are primarily through the lowering of energy consumption (KWH).

Demand (KWD) reductions are achieved by reducing the average load in every demand period and hoping that the period with the highest demand will also be reduced.

Electronic Demand Limiters

A wide variety of electronic demand devices are available at constantly decreasing prices. Electronic circuitry is used to monitor actual demand and to provide control actions to limit the operation of the associated equipment when the demand approaches critical levels. In operation, these devices receive a timing and a consumption pulse from the utility meter. One pulse signals that a unit of energy was consumed, while the other pulse signals the start of a new demand period.

Each demand period can be controlled independently of all others. The timing pulse is used to reset the circuitry. Each energy (KWH) pulse is converted into demand (KWD) and used to increment an electronic counter. As the counts accumulate within a demand period, they are compared (on a second by second basis) to the value that corresponds to the desired demand target. As the accumulated value reaches the target value, control actions are initiated. When the next demand pulse is received, additional actions can be initiated if warranted. When the target is not exceeded by the accumulated count, no action is taken or previous actions are reversed.

This procedure is repeated until all control options have been used or the end of the demand period is reached. The timing pulse resets the counter and restarts the process. Different control strategies can be specified for adjacent demand periods or by time of day or day of week. Loads turned off can be restarted when the demand target is no longer exceeded, when the end of the demand period is reached, or when a preset off time is reached.

Some electronic load shedders are somewhat more sophisticated in that the demand target is not fixed, but increases at a steady rate within the demand period. Comparison of the actual demand and the target is done at regular intervals throughout the demand period. When the difference between the accumulated demand count and the incrementing demand target reaches a set value, loads can be turned "OFF." The load will stay off until the difference decreases to a second value or the period ends. In some electronic load shedders, the turn off and turn on set points can be set independently for individual loads.

Digital Systems

The application of computers to the regulation of energy has made a wide range of control options possible. The computer's memory and high-speed decision-making capability combined with special purpose programs are used to maximize energy and cost savings with a minimum impact on operating conditions and occupant comfort. The computer receives inputs from the electrical meter and the sensors monitoring critical parameters within a plant or building. Loads can be regulated based on demand, time of day and day of week, rate of energy consumption, internal and external temperatures, machinery parameters, energy rates, weather predictions, wind direction and velocity, and combinations of all of these factors and more.

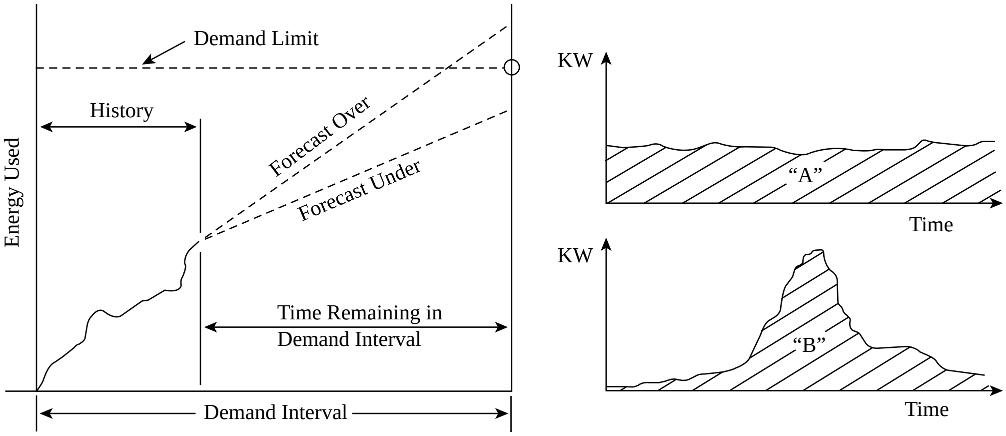

FIG. 7.4e
Electric demand shedding attempts to change electric power use in the plant toward a more uniform rate of usage, which reduces its cost.

The maximum control duration can be adjusted automatically according to these same factors. A second demand target is sometimes used so that if the primary target is exceeded, additional control actions can be taken. Simple demand targets can be made to float according to time of day and other factors forcing control actions. Different operating strategies can be specified for different sections of a plant or building. Multiple plants or buildings can easily be accommodated. Printed reports showing actual consumption by period, day, or month can be provided.

In the area of energy management, computers do much more than simple load shedding and are applied to complex facility management, including optimization of operating times and sets points. Applications include operation of cogeneration and energy storage systems and selection of least-cost energy sources matched to current and anticipated requirements. The computer has provided both the information and the means to make intelligent decisions to obtain maximum energy management.

CONCLUSIONS

If users A and B in Figure 7.4e are using the same total amount of electric energy, user B's bill is going to be higher due to a higher demand charge, which results from the way that total energy was used. B is a more expensive client to serve; the client requires larger generating and distribution equipment, but does not use enough energy to justify operating them all the time.

During each demand period, the total energy use is the basis of a forecast (Figure 7.4e). If the forecast predicts that without correction the plant will exceed its demand limit, electricity users at the top of the shedding list are turned off. If the forecast is that by the end of the demand period the demand limit will not be violated, some of the loads that were previously shed can be automatically restored.

The shedding list includes all electrical devices in the plant that can be turned off for some limited time period. At the top of the list are the low-priority users (sump pumps, HVAC equipment, etc.), while higher up on the list there can be processing equipment that is operated at partial load levels or cycled on and off.

INTRODUCTION

Excess flow check valves serve to detect and stop excessive flows from pressurized systems by shutting off the line. These excessive flows can be caused by pipe rupture or by excessive leakage through various devices. The automatic check valve is closed by the pressure drop resulting from the high velocity of outward flow from the pressurized equipment. It is automatically reopened when repairs are made and the flow stops, so that the pressure drop can be eliminated by the slight seepage through the valve.

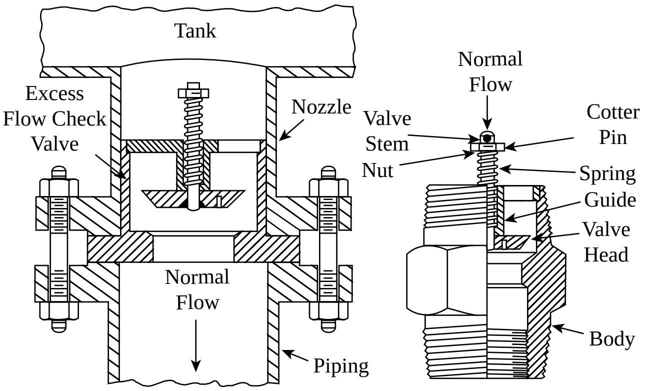
VALVE DESIGNS

Excess flow valves are normally open, in-line safety devices that act to limit flow of liquids or gases out of a pressurized system. While they will pass normal flow rates, they will close when excessive outward flow rates are reached. This occurs in the event when a pressurized system is opened to atmosphere due to pipe or hose breakage or because of misoperation.

The excess flow valve consists of a plug, a seat, and a spring all housed or supported in a cylindrical tube. The valve may be threaded so that it can be screwed into the pipeline or can be flanged for tank nozzle mounting (Figure 7.5a).

Operation

Under normal operating conditions, the force generated by the flowing process fluid is directed against the valve head and attempts to close it. A spring is provided to work against this force and to keep the valve open. As flow increases above the normal level to an excessive rate, the force against the



Flanged for Tank Nozzle Installation

Screwed for Pipe-Line Installation

FIG. 7.5a
Excess flow check valves.

plug and the differential pressure (d/p) across it, overcome the spring force and the valve closes.

There are one or more bleed ports around the plug, so that after valve closure the bleed will allow the pressures to equalization up and downstream of the plug, reopening the valve. However, if a pipe break occurs, the d/p across the valve will remain the same as the pressure difference between the pressurized system and the atmosphere, and the valve will stay closed until the pipe is repaired. Because of the required seepage through these valves, which provides them with their equalizing feature, it should be remembered that they will not give tight shutoff.

Applications

One major application of excess flow valves is on large pressurized storage tanks containing liquefied petroleum gas or other dangerous or expensive materials. In such tanks the use of excess flow check valves is recommended by Factory Mutual. For example, liquid propane gas must be stored under relatively high pressures, if it is to be kept in the liquid state. Propane, for one, has a vapor pressure of 192 PSIG at 100°F (1.3 MPa at 37°C).

If a line to or from a propane tank ruptures when the tank contents are at some high storage pressure, a very large amount of propane will quickly escape and will create an extremely hazardous condition. For this reason, it is good practice to install excess flow valves on every piping connection to and from such a storage tank except for the fill and relief lines. The fill line should have a standard check valve (Figure 7.5b), and the pipe leading to the relief line should be unobstructed. For fill line applications special check valves are available from the suppliers listed at the beginning of this section. These check valves allow an unlimited flow in one direction, but very little or none in the other.

Some excess flow valves used for pressurized storage tanks are constructed so that they may be mounted internally to the tank, protecting them from mechanical damage (Figure 7.5c).

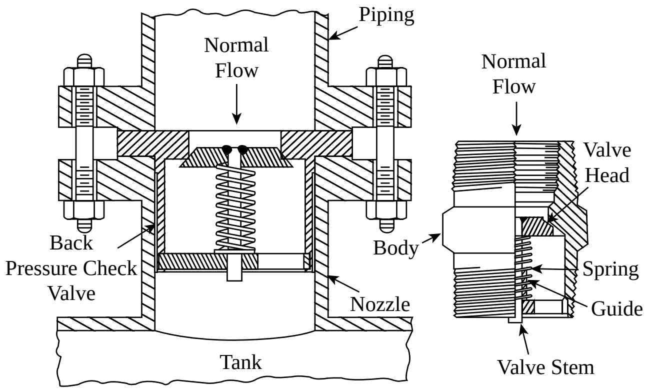


FIG. 7.5b
Flanged and screwed check valves used in full lines.

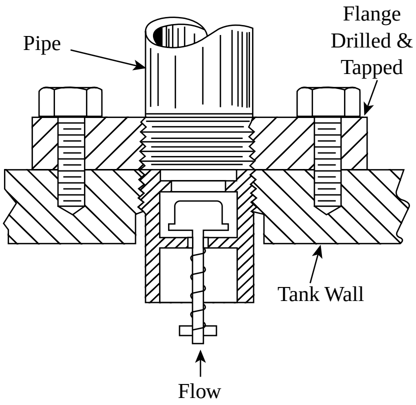

FIG. 7.5c
Excess flow valve installed in tank.

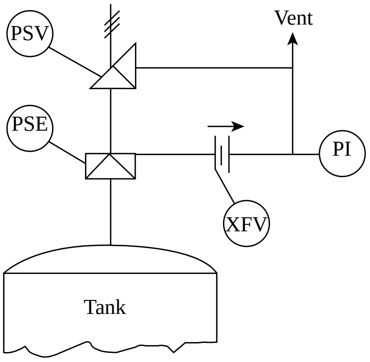

FIG. 7.5d
Excess flow check valve in overpressure protection systems.

Rupture Disc Leakage

A second application for excess flow valves is to bleed off pressures that might build up on top of rupture discs (Figure 7.5d). The installation of such safety devices is recommended by the American Society of Mechanical Engineers code for boilers and pressure vessels.

Rupture discs are differential pressure devices in that the set or burst pressure must appear across the disc before it will rupture. Anytime the downstream side of the rupture disc is sealed away from atmospheric pressure, provision must be made to vent any pressure buildup on the downstream side to atmosphere. Examples of such sealed conditions include when two rupture discs are installed in series or when a relief valve is installed downstream of a rupture disc.

The best way to vent such blocked in spaces is by means of an excess flow valve. The excess flow valve will release small amounts of vapors and release the pressure buildup caused by rupture disc leakage or thermal expansion of the vapors. At the same time, the valve will not pass the large flows that would occur when the disc ruptures.

Gas Station Application

Figure 7.5e illustrates a special-purpose excess flow check valve that is installed underground, below the gas pumps in gas stations. The purpose of this valve is to shut off the gas flow if somebody backs into the gas pump and breaks the pipe on the suction side below the pump. This safety shutoff function is achieved by the pilot valve spring, which keeps the valve closed unless there is a vacuum in the pipeline on the suction side of the pump. Therefore, if the suction pipe is broken (at the internationally preweakened safety shear section), the vacuum is lost and the valve closes. This is particularly important in installations where the gas supply tank is elevated and therefore gasoline could otherwise pour out of it through the broken pipe.

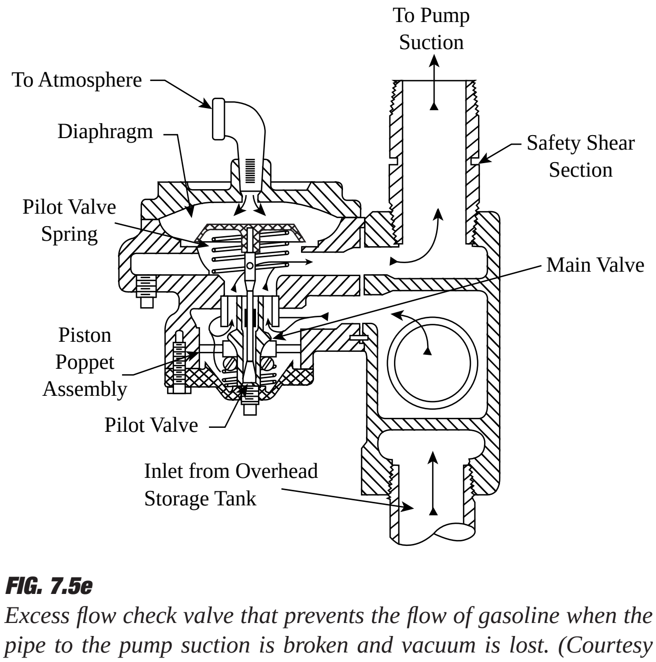

FIG. 7.5e
Excess flow check valve that prevents the flow of gasoline when the pipe to the pump suction is broken and vacuum is lost. (Courtesy of Tokheim Corp.)

Sizing

Since excess flow valves are safety devices, it is important that they be sized, selected, and installed properly. As a general rule for sizing, excess flow valves should be rated to close at about 150 to 200% of normal flow. The 150% figure should be used when the normal flow is well defined, or on installations involving larger valve sizes. In the 150 to 200% sizing range, the valve will be insensitive to surges during start-up and normal operation and will not chatter or restrict the flow. However, it will be sensitive and will close against excess flows caused by pipe breakage.

For proper valve selection, it is important to also specify mounting orientation, flow direction, and the flowing process material, since the valve design is a function of these factors.

Installation

The piping configuration of the installation must guarantee that the excess flow valve represents the greatest resistance to flow of all the restrictions in the downstream pipeline system. The downstream piping should not contain many bends, elbows, and tees. It should also not be reduced in size below the line size of the excess flow valve.

Excess flow valves will not necessarily respond to pipe breakage if it occurs on the discharge side of a downstream pump. This is because the pump will offer considerable resistance to flow even while running. Similarly, excess flow valves will not necessarily respond to partial pipe ruptures.

Testing

One way to check whether an excess flow valve is sized, installed, and functioning properly is to simulate a pipe break downstream of the valve. This is done by opening such a valve to atmosphere that is located away from the excess flow valve at the furthest point in the piping. During such testing, as the valve is opened, product should start to flow out of the system, but it should then stop due to the action of the excess flow valve. This maintenance test should be conducted before start-up and then on a regular schedule at least once a year.

The excess flow check valves must also be protected from foreign materials lodging inside them, which could prevent them from closing. A common cause of excess flow check valve failure is prolonged hammering or tampering with its setting in an attempt to get it to pass more flow than it was designed for.

INTRODUCTION

Explosion suppression and ultra-high-speed deluge systems present an effective approach to combat the hazards of explosion and fire. Traditionally, safety design has stressed two areas of concentration: (1) prevention of explosion when possible, or, if ignition does occur, (2) application of proper measures to reduce the spread of damage. Explosion suppression and ultra-high-speed deluge systems act within milliseconds to extinguish an explosion or fire almost at its inception.

As similar as they may be in their speed of operation, the two techniques are quite different in their application. Each is discussed separately below.

EXPLOSION SUPPRESSION SYSTEMS

Explosion suppression systems are designed to achieve a threefold purpose:

1. To confine and inhibit a primary explosion
2. To prevent a secondary and more serious deflagration or a detonation
3. To keep equipment damage at a minimum

Buildup of pressure is usually kept to within 3 to 5 PSIG (21 to 104 kPa) of normal levels. Under these conditions some damage could be caused to light-walled vessels, but the danger of large-scale damage or fire is minimized.

Explosion suppression systems were developed in England shortly after the Second World War. Their first commercial application began in the mid-1950s. Subsequent installations in the United States date from 1958.

Because chemicals display different explosive characteristics and processes differ in physical dimensions, an explosion suppression system is usually a design package. In many instances, approval for insurance must be obtained from fire underwriters with evidence of design capability demonstrated in a test.

Explosions

A flame can be described in terms of its propagation from the source of ignition. There are three categories of flame behavior:

1. Burning—The flame does not spread or diffuse, but remains at an interface where fuel and oxidant are supplied in proper proportions.
2. Deflagration or explosion—The flame front advances through a gaseous mixture at subsonic speeds.
3. Detonation—Advancement of the flame front occurs at supersonic speeds.

Explosion Bomb Test The first task in the development of an explosion suppression system is to establish the propagation characteristics of the material in question. First a sample of the fuel–air mixture that is to be tested is introduced into a cylindrical or spherical vessel. Oxidation is initiated by the application of energy, usually in the form of a spark. The test data are recorded through a pressure–time relationship generated by a pressure cell coupled to a high-speed oscillograph. A typical dust explosion chart is shown in Figure 7.6a.

The pressure within a spherical vessel after the ignition of a quiescent fuel–air mixture can be predicted by the equation:

$$p = KS_r^3 t^3 P/V \qquad \textbf{7.6(1)}$$

where

K = is a characteristic of the system
S_r = radial flame speed
t = time
P = maximum pressure that would be reached within a closed container (also a function of the system but not dependent on the volume of the container)
V = volume of the vessel

S_r in this equation is the radial flame speed and not the normal combustion velocity. They are related by the equation:

$$S_r = S_n(T_f/T_j)(\overline{M}_i/\overline{M}_f) \qquad \textbf{7.6(2)}$$

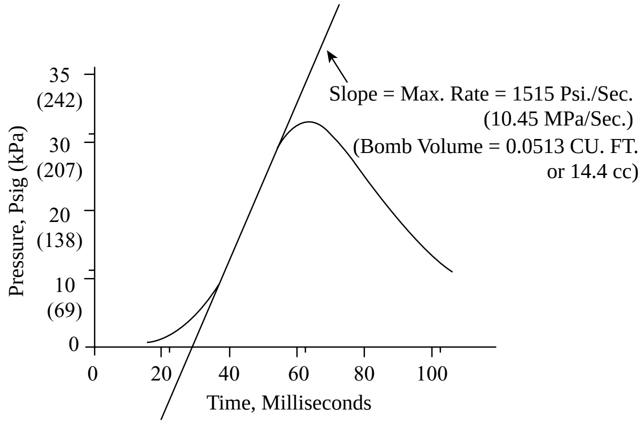

FIG. 7.6a
Typical explosion bomb test.

TABLE 7.6b
Radial Flame Velocities of Explosive Mixtures

Fuel	*Oxidant*	*Typical Material*	*Radial Flame Vel. (S_r) ft/s (m/s)*
Organic dust	Air	Flour, starch	2–5 (0.6–1.5)
Organic vapor	Air	Propane, hexane	9–12 (2.7–3.6)
Hydrogen	Air		30 (9)
Organic vapor	Oxygen		80 (24)

where S_n is the normal combustion velocity and the multipliers are the ratios of the initial and final (before and after combustion) absolute temperatures and average molecular weights. The difference in velocity is quite significant, since S_r will normally be on the order of 10 times S_n. Radial flame speeds for some materials are given in Table 7.6b.

For the purposes of explosion suppression, it is more convenient to rearrange Equation 7.6(1):

$$t = S_r(pV/KP)^{1/3} \qquad \textbf{7.6(3)}$$

To be effective, maximum pressure, P, must be held to 2 to 4 PSIG (13.8 to 27.6 kPa). For a given substance, S_r, K, and P can also be considered constant, which leads to the simplified form:

$$t = CV^{1/3} \qquad \textbf{7.6(4)}$$

Design of actual systems is based on producing explosions within test chambers to determine the parameters characteristic of the system. The information is then adjusted to the size of the real equipment by means of Equation 7.6(4). The corrective action should take less time than the tile required for the explosion to develop the limiting maximum pressure. For example, the explosion test illustrated in Figure 7.6a was performed in a small bomb with a volume of 0.0513 ft^3 (11.4 cm^3). The data from the early part of this test were then used to predict the normal curve for a vessel of 3.38 ft (946 cm^3) volume by using Equation 7.6(4):

$$t_1 = t_s(3.38/0.513)^{1/3} = 1.876t_s \qquad \textbf{7.6(5)}$$

The translated data were then made the basis for the test illustrated in Figure 7.6c.

How Suppression Works

The operation of an explosion suppression system is a race with time. On one hand, there is the physically determined buildup in pressure due to the explosion. The counterplay is detection of the explosion, application of suppressants to extinguish the deflagration, and corrective action to limit the extent of damage. Operation of a typical system is illustrated in Figure 7.6c. The basic relationships that make a process like this practical are:

1. The explosion can be detected early in the process. The pressure front advances at the speed of sound

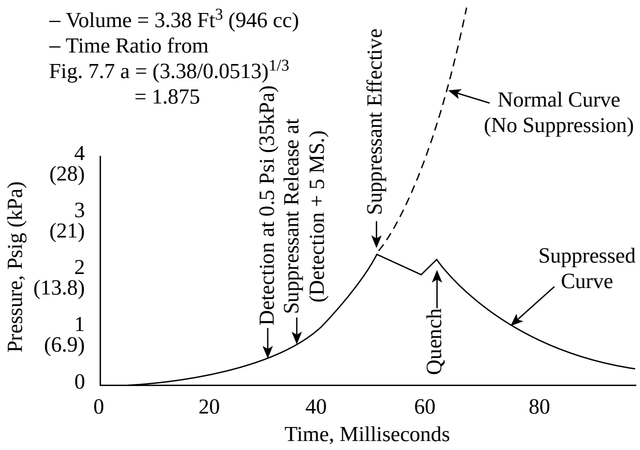

FIG. 7.6c
Explosion suppression sequence.

(on the order of 1100 ft/s, or 330 m/s) while the flame front propagates at about 10 ft/s (3 m/s).

2. The impulse received at a detecting device can be transmitted to the suppressant container at basically the speed of an electrical impulse.
3. Release of the suppressant is promoted by the explosive opening of a suppressant bottle or a high-speed hydraulically balanced system. The time period required for the triggering explosion to take effect is designed to be much less than the one in the vessel. The fill volume of the corrective explosive is kept very small.
4. The suppressant, ejected from several sources, is propelled into the explosive zone at a velocity of 200 to 300 ft/s (60 to 90 m/s).
5. The course of events from initiation of the explosion to its complete extinction can be of very short duration. The specific time depends upon the characteristic of the material and the geometry of the system. Quench time of the explosion illustrated in Figure 7.6c was 60 ms.

Explosion Characteristics Considerable work has been done in measuring explosion characteristics. Typically reported values are average and maximum rate of pressure rise and maximum pressure produced by the explosion. Some of this information is presented in Table 7.6d.The list of materials investigated by the U.S. Bureau of Mines has been extensive. Reports RI 5753 and 5971 provide a tabulation of its results. A note of caution must be injected relating to explosion data of the type given in the table. Starting pressure of the explosion test was atmospheric. Significant correction must be made if the normal pressure before ignition is above 14.7 PSIA (101 kPa), especially in the case of gases and vapors.

As can be seen in Figure 7.6c, the initiation of explosion suppression is delayed because of the low rate of pressure rise during the initial phase of the process. Information on maximum rates of rise is of value, however, when comparing the explosion characteristics of different materials.

Suppressant Chemicals

Effective explosion suppression requires getting sufficient amounts of chemical to the trouble area in very short time, adapting required dispersing equipment to withstand the environment, and immunizing the system to outside influences

TABLE 7.6e
Compounds Used as Explosion Suppressants

Agent	*Chemical Formula*	*Relative Effectiveness % by wt. ($CCl_4 = 100$)*	*UL Relative Toxicity 1 = highest 6 = lowest*
Chlorobromethane	CH_2BrCl	180	3
Bromodifluoromethane	$CHBrF_2$	161	
Bromotrifluoromethane	$CBrF_3$	195	6
Dibromodifluoromethane	CBr_2F_2	201	4
Carbon dioxide	CO_2	95	5
Water	H_2O	72	
Carbon tetrachloride	CCl_4	100	3

(e.g., temperature of the vessel or its surroundings). The suppressant must also be compatible with the other chemicals in the system.

In general, an explosion is considered to be an oxidation reaction. Water and carbon dioxide, two popular materials for extinguishing fires in normal usage, are not generally utilized for explosions. Aside from a possible reactivity with the chemicals in question, relatively large quantities of water would be necessary to limit reactions. Carbon dioxide has a low effectiveness–weight ratio and would require large storage units. Materials have also been known to reignite after having been extinguished by CO_2.

Halogenated compounds, mostly methane derivatives, are popular suppressants. Table 7.6e lists the properties of some of these agents.

Chlorobromomethane and bromotrifluoromethane are most commonly used. While water owes its effectiveness to a cooling action and CO_2 relies upon its ability to exclude oxygen from the fire, the halogenated compounds seem to have a chemically inhibitive effect on the combustion reaction. Therefore, a chemical such as bromotrifluoromethane can be effective in extinguishing fires where oxidizing agents are present. Certain of the halogenated chemicals are also very low in residue so that subsequent interruption for cleaning can sometimes be held to a minimum.

EXPLOSION SUPPRESSION HARDWARE

The hardware for explosion suppression falls into three categories:

1. Detectors, which serve to discern the initiation of the explosion
2. Control units, which initiate the corrective action in one or several directions
3. The actuated devices, which blanket the protected area with the suppressant

The adjacent areas are vented or isolated as required.

Detectors Any physical characteristic that will give evidence of an explosion in its early stages can be detected. Absolute values or rate of pressure or temperature rise have been used in addition to the detection of infrared (IR) and ultraviolet (UV) radiation levels. The characteristics of each of these measurements are discussed below.

Temperature Measurement is accomplished with a thermocouple that has a very low mass exposed hot junction. Even so, temperature is a slowly changing physical characteristic. It would only be suitable under unusual circumstances or when other detection methods cannot be used.

Infrared Radiation Detection by IR radiation is extremely fast and sensitive. On the other hand, there are some factors that must be allowed for when designing a system with these detectors. Since they are a line-of-sight system, they must be placed where they see all of the locations where an explosion might develop. Usually multiple detectors can be used with overlapping coverage. In dusty atmospheres, precautions must be taken to assure that the lens opening is kept clean. The circuit design must incorporate a screening device to guard against false actuation by spurious IR sources. To improve discrimination, a system of filters is often utilized and an adjustable threshold sensitivity is included.

Ultraviolet Radiation Uv detectors are used alternately to IR units. They are alike in their extreme speed of detection and in the design requirements typical of line-of-sight units.

Pressure The most universally applied detectors are those relying on pressure. Activation in these devices is by means of a diaphragm and switch combination that is fast acting and has low inertial mass. The generally preferred form is by absolute pressure. Detectors for equipment that is normally at atmospheric pressure can be activated at 0.5 PSIG (3.5 kPa) or less.

Where pressure fluctuations are expected, or where the normal operating pressure is above atmospheric, a pressure rate-of-rise unit is required. Activation in this case is initiated by pressure drop across an orifice in excess of a preset minimum. Although pressure-activated devices do not respond as quickly as radiation detectors, they are suitable for a broader range of atmospheres.

Control Units

The basic function of the control unit is to convert the weak signal generated by the detector into a form of energy sufficient to operate extinguishing and alarm devices. In the course of assuring system reliability, more than just the one duty is provided. The central control unit must:

1. Operate devices based on the actuating signal from a detector
2. Monitor the suppression system for ground faults that might interfere with proper operation
3. Contain internal and automatic battery backup units that are activated in case of power failure
4. Monitor the shutdown of specific pieces of equipment and give local and remote alarm
5. Provide a test circuit so that operation of the system components can be checked nondestructively
6. Continually supervise integrity of all external circuitry

Actuated Devices

Actuated devices produce a condition that limits the damage caused by the explosion. The most important of these are the suppressors and extinguishers. Additionally, there may be preaction vents, isolation valves, and other corrective measures initiated by detection of an explosion.

Suppressors and Extinguishers The distinction between suppressors and extinguishers is basically in the method of mounting and the mechanism of release of the suppressant. Suppressors are mounted internally to the equipment being protected. They contain a relatively small volume (to 5000 cm^3) and are actuated by detonation of an explosive charge within the container. These units are mounted close to possible sources of ignition and provide a fast source of extinguishing chemicals. Figure 7.6f illustrates a hemispherical suppressor unit.

Extinguishers are much larger in volume, up to 30 l (about 7 1/2 gal), and are mounted outside of the equipment on a boss or flange. They are usually pressurized with nitrogen to 300 PSIG (2070 kPa) and are fitted with a diaphragm that is opened by an explosive charge. These units are used where more suppressant is required than would be available from the small suppressor unit, such as in large ducts and bag filters. They have an additional advantage in that they can be fitted with a new closure and refilled for reuse (Figure 7.6g).

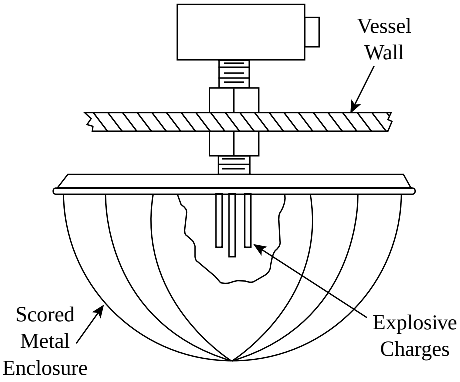

FIG. 7.6f

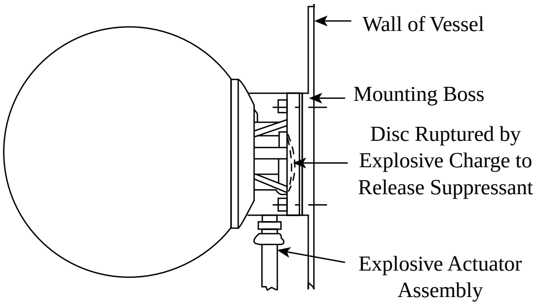

FIG. 7.6g
Spherical extinguisher.

Explosive-Actuated Rupture Discs If an explosion occurs in a pressure vessel, the pressure in the vessel will build up to a point where it causes the rupture disc to blow. These conventional rupture discs, which are used in applications where slow pressure buildup is expected, are discussed in Section 7.17. Due to the high speed at which the pressure rises during an explosion and to the relatively long time needed to stretch a disc until it ruptures, the standard discs are too slow to protect the equipment against explosions.

Detonator actuated deluge discs have been developed to reduce the time needed to rupture the disc (Figure 7.6h). These discs do not rupture due to the pressure forces alone, but use a pressure switch that senses the process overpressure and ignites an explosive charge when it is reached. The main advantage of such a system is in its speed of response. Its main disadvantage is that it is not self-contained, but depends on the proper operation of some outside components and of a reliable power supply.

It is sometimes advantageous to protect some equipment with explosive-actuated rupture discs. In these units, a self-contained explosive charge is used to rupture the disc when an explosion is detected. In this way, the vent is completely open before the pressure wave reaches it and the maximum possible pressure buildup is reduced (Figure 7.6i).

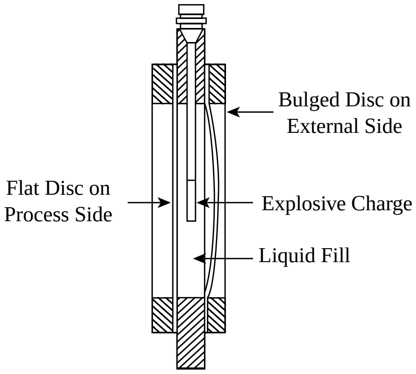

FIG. 7.6i
Explosive-actuated rupture disc.

Other Auxiliary Units Explosion detectors can also actuate other devices. They can be used to open various fast-acting valves and dampers or can activate sprinkler systems by the opening of deluge valves. Pumps, blowers, agitators, and other process equipment can also be interlocked into the system.

Applications

Explosion suppression is used for the protection of extremely hazardous systems in industry. The technique is primarily applied to bins, hoppers, reactors, air conveying systems, bag filters, and other closed arrangements. A particularly well-suited application is the protection of hammer mills and other grinding equipment where the elements of severe explosion are present in the form of well-mixed dust, air, and tramp metal.

There are cases where explosion suppression will not work. Decomposition usually cannot be halted because suppressant chemicals will not stop the reaction. Explosions that develop very high radial flame speeds (such as hydrogen-oxygen) are too fast for existing equipment. Many detonations (ultrasonic) also develop from an initial deflagration. It is possible to arrest the flame if detection and extinguishment can be affected before the detonation develops, but there is no means of dealing with detonation once it has developed.

The key word in system design and application is reliability. Having a unit that is certain to work when it is needed justifies thorough investigation of the physical aspects of each case and the chemical nature of the ingredients. Reliability is assured by using devices that are known to be trouble-free, and by duplicating them. A given installation may have two or more detectors and several suppressors. Frequently, different types are installed in parallel.

ULTRA-HIGH-SPEED DELUGE SYSTEMS

Although ultra-high-speed deluge (UHSD) bears a good deal of similarity to explosion suppression, the unique characteristics of this system require separate study. The two methods resemble each other in the use of certain devices and in the time period in which they must function. But they differ in where they are applied and how they work.

UHSD was developed for extinguishing fires at their inception. Its point of application is generally an open area or room instead of a vessel or container. Where the room is a space capsule or hypobaric chamber, this distinction narrows. Fire in solid rocket fuel processing plant can lead to an explosion unless, with the application of a UHSD system, it is extinguished promptly.

The suppressant for UHSD is almost always water.

Detectors

Since UHSD is applied in open areas and detection must take place within a very short time interval, detection devices that depend on pressure or temperature change are of little value. For UHSD, the speed and sensitivity advantages of UV and IR detectors have been used successfully.

Control Units

The function of the control unit is basically similar to those described under “Explosion Suppression.” In some cases a cycle timer is also included as a part of the package. After a set time of operation, the water is turned off and the detector is reinterrogated. If the alarm condition still exists, the deluge system reactivates for the set period. This feature is desirable to prevent flooding by the large quantities of water released.

Actuated Devices

Deluge systems must apply a lot of water on the source of ignition within a very short time. Density requirements for normal high-hazard applications (Class I, Group D) may

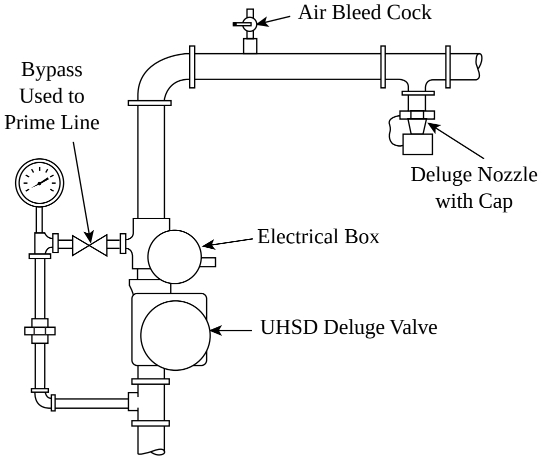

FIG. 7.6j
UHSD system with high-speed deluge valve.

run 0.3 gal/min/ft^2 (12.2 l/min/m^2); in the case of these special hazards, the requirement is frequently 7.5 gal/min/ft^2 (305 l/min/m^2). A plentiful source of water at sufficient pressure is required with the lines sized for low pressure drop. Available head is a significant factor in the speed of response since the water delivery time is proportional to the square root of the supply pressure.

There are two basic deluge system designs: the high-speed deluge valve and the pressure-balanced nozzle. Both of them depend upon a completely air-free, primed piping system to ensure fast action. Tests conducted by one firm have shown that an air pocket amounting to 5% of the total volume will double the operating time.

High-Speed Deluge Valve System An explosive-actuated deluge valve is used to initiate flow. In order to prime the system, a bypass is provided around the valve and the nozzles are sealed with a protective cap. The cap is forced off by pressure in the nozzle when the system is activated. Figure 7.6j illustrates typical piping, and operation of the deluge valve is shown in Figure 7.6k.

Pressure-Balanced Nozzle System The pressures of the main water line and a pilot line are balanced at the nozzle to keep it closed. The pilot line takes off from the main riser through an orifice. Bleed cocks are provided to prime both lines. Upon activation of the system, one or more solenoid valves vent the pilot line. Pressure in the main riser opens the nozzle to cause flow. Figures 7.6l and 7.6m show a typical system and internal construction of the nozzle.

Applications

UHSD systems are used in special hazard locations such as hypo- and hyper-baric chambers, munitions plants, munitions stores on board ships, and rocket fuel processing plants. One application of these systems involves protection of a lathe operation where solid rocket propellant is machined.

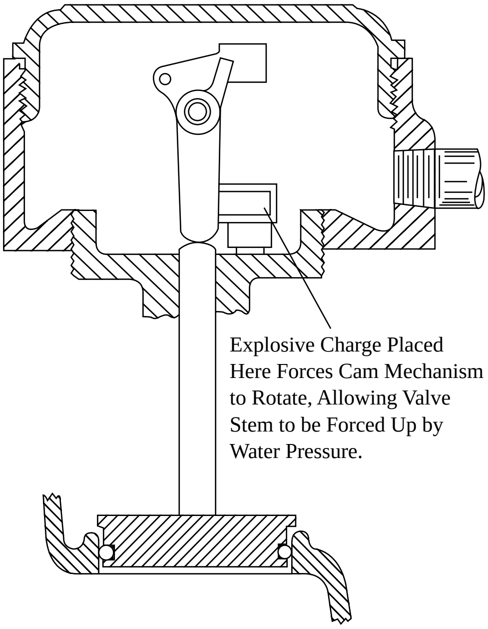

FIG. 7.6k
UHSD deluge valve.

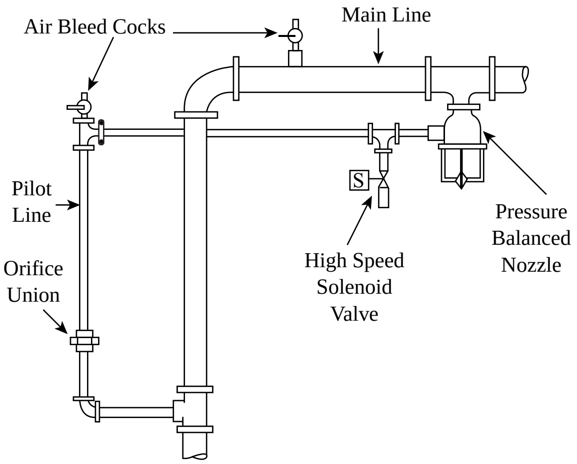

FIG. 7.6l
UHSD system with pressure-balanced nozzle.

A typical deluge system specification used for the protection of an oxygen-rich operating chamber might contain the following requirements:

1. The system must activate within 200 milliseconds of ignition.
2. There must be a discharge at a rate of 7.5 gal/min/ft^2 (305 l/min/m^2) of chamber floor area.
3. There must be a stabilization of water flow within half a second.
4. The system must shut down in 20 s and must be reset within 5 s.
5. Recycling must be conducted as needed.

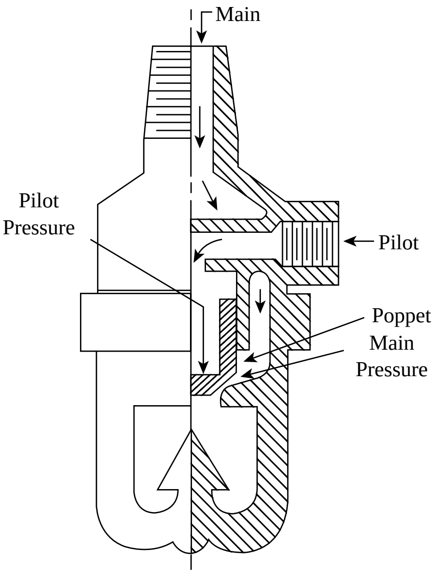

FIG. 7.6m
Pressure-balanced nozzle.

Operating time for UHSD depends greatly upon the system size and configuration. Water is generally applied within 15 to 200 ms, with 90 ms being an average for most applications.

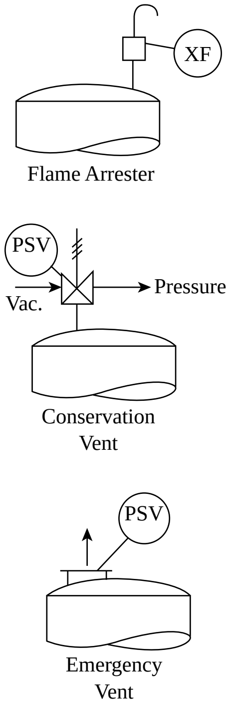
7.7 Flame Arresters, Conservation Vents, and Emergency Vents

D. S. KAYSER (1969, 1982) **B. G. LIPTÁK** (1995, 2003)



Flame Arrester

Conservation Vent

Emergency Vent

Flow Sheet Symbols

Types: A. Flame Arresters
B. Conservation Vents
  B1. Pressure relief only
  B2. Breather valves for pressure and vacuum relief
  B3. Vacuum vents
C. Emergency vents and manhole covers
D. Gauge hatches

Materials of Construction: A. Cast aluminum, cast iron, cast steel, 304 or 316 stainless steel bodies; aluminum or stainless steel pellets or tube banks; also available with heresite and other coatings
B. Bodies are available in low-copper aluminum, cast iron, steel, 304 or 316 stainless steel. Seats can be molded thermosetting phenolic, aluminum, or 316 stainless steel. Diaphragms are available in FEP Teflon.

Sizes: A. Standard units from 1 to 12 in. (25 to 300 mm), special units up to 30 in. (762 mm.)
B. 2 to 12 in. (50 to 300 mm)
C. 10 to 24 in. (250 to 600 mm)
D. 4 to 8 in. (100 to 200 mm)

Connections: A. Screwed or 150# ANSI flanges
B, C, D. 125# and 150# ANSI or API flanges

Pressure Settings: B. Standard pressure and vacuum settings are 0.5 oz/in.^{2} (0.865 in., or 22 mm, of H_2O); maximum pressure and vacuum settings are 24 and 5 oz/in.^{2} (10 and 2 kPa), respectively
C, D. Standard setting is 1.0 oz/in.^{2} (about 2 in., or 50 mm, of H_2O)

Operating Temperatures: B. –50 to 300°F (–50 to 149°C)

Costs:

A. For the 1 to 8 in. (25 to 200 mm) size range in aluminum construction, the price range is $150 to $1700
B. For the 2 to 10 in. size range (50 to 250 mm), the cost of aluminum units ranges from $300 to $1200
C. For the 16 to 24 in. (400 to 600 mm) size range, the cost of aluminum units ranges from $500 to $1200

INTRODUCTION

Tanks and vessels must be protected against rupture due to overpressure or against collapse caused by vacuum. They also need protection from the propagation of flame through the venting system, which could cause fire and/or explosion, if some exterior source caused ignition. In addition, the storage tanks containing flammable liquids or solvents should be allowed to breathe, but should also be protected against costly evaporation losses.

The various breather valve designs (conservation and emergency vents or vacuum breakers) protect the tanks from being exposed to excessive pressures or vacuums during filling or discharging. The purpose of the flame arresters is to cool the vapors below their ignition points as they pass through them. These devices are often used in combination with conservation vents where the flame arrester is placed under the conservation vent and they work as a unit.

The airflow capacities of different size flame arrestors in combination with conservation vents can be determined from Figure 7.7a for units from 2 and 12 in. pipe sizes. The data in these charts provide the capacities for breather valve pressure or vacuum settings from 0.1 to 100 in. for both pressurized and evacuated storage tank applications.

TYPES OF VENTS

The venting requirement is a function of tank design. Several tank constructions have been developed to eliminate or reduce the requirement for reliance on breather or vent equipment. Among these are various floating or lifting roof designs, and diaphragms that have sufficient expansion capacity to take up volume changes that are caused by liquid transfer and thermal expansion. It should be noted that some of these tank constructions are safer and better able to conserve vapors than the standard cone roof tank. This is true even when the cone roof tank is properly vented using breather valves, emergency vents, and flame arrestors. However, there are many applications where the cone roof design is used. This section covers vent sizing and application for those tanks.

Tank breathing capacity should be large enough to match the volume changes due to filling, emptying, and/or thermal expansion. Three kinds of vents are utilized to meet the various venting requirements. The first is the simple free vent breather. This is an open pipe with its outlet screened and usually pointing down to prevent rain and debris from getting into the tank.

Conservation Vents

The second type of vent used is the conservation vent or breather valve. This valve is a low-pressure relief device and vacuum breaker valve, combined in a single housing. Operation of the conservation vent is illustrated in Figure 7.7b. As the pressure builds up in the tank, there is a differential created across the pressure relief pallet. When this differential becomes large enough to lift the pallet, this inner valve lifts and allows the vapors to flow out of the tank. Similarly, when a vacuum is developed inside the tank because of the discharge of liquids, the differential across the inner valve of the vacuum braking valve becomes large enough to lift the vacuum pallet and allows air to flow into the tank.

All large storage tanks are exposed to small changes in internal pressure resulting from (1) vacuums due to liquid thermal contraction or pump-out, and (2) pressures due to liquid thermal expansion or pump-in. These changes are usually small (on the order of inches of water column), but because they act on the large internal area of the tank, their effect can be great. For example, a positive pressure of slightly over 3 in. of water column is enough to rupture the roof to side weld seam on many vertical tanks with cone roofs. Similarly, a small negative pressure over the large wall area may be enough to cause the walls to collapse. It is therefore necessary

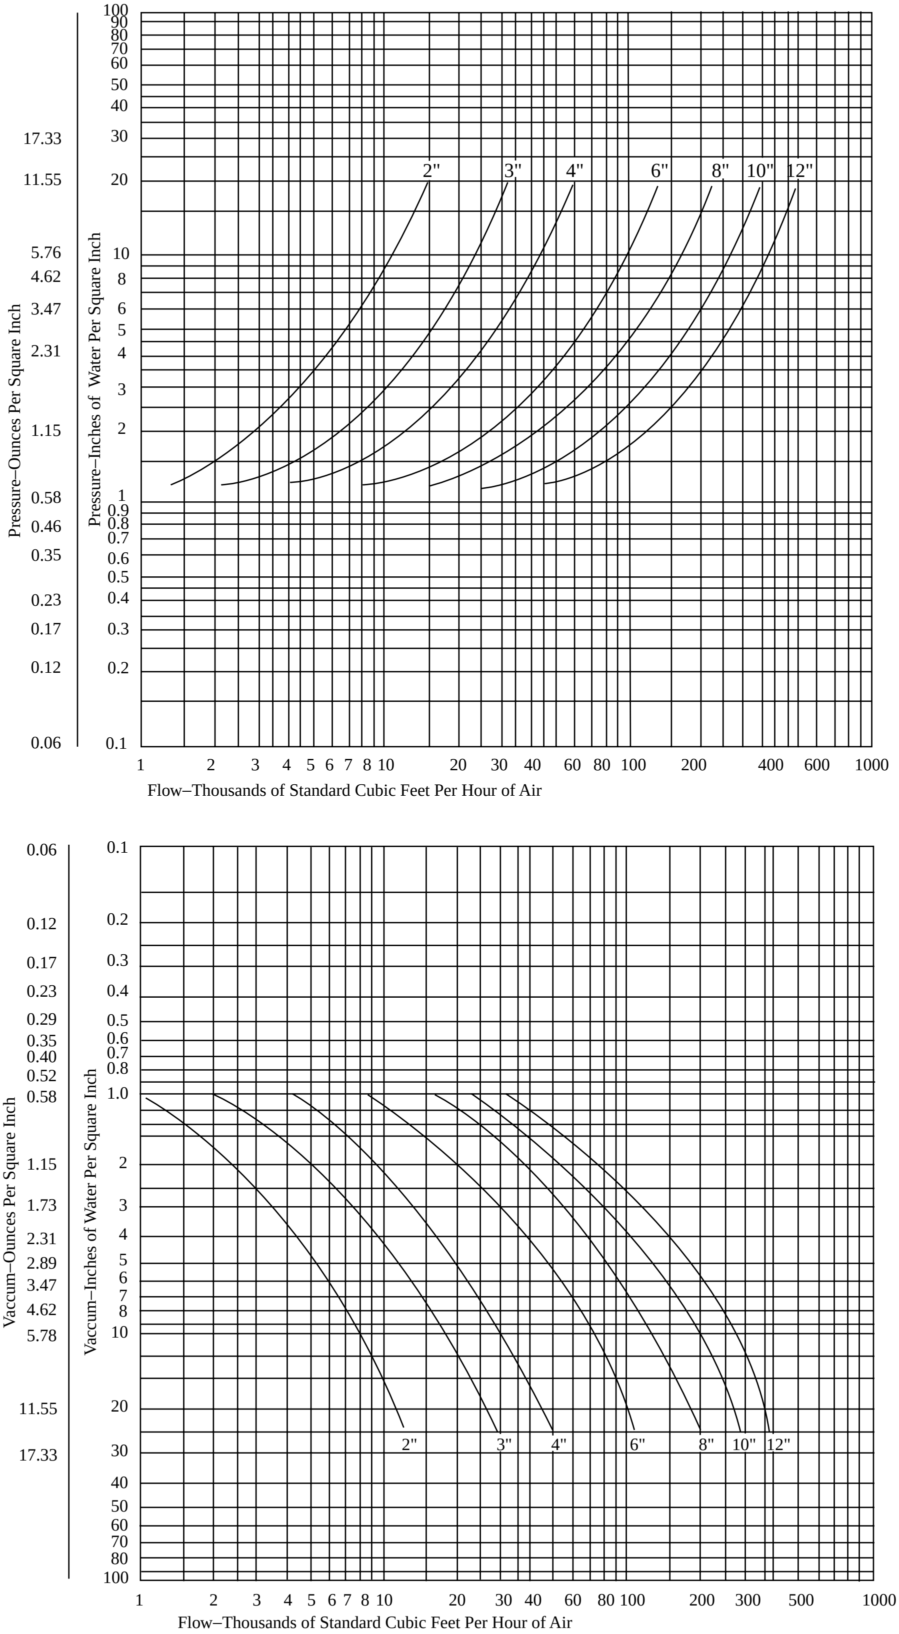

FIG. 7.7a

Airflow capacities of flame arresters in combination with conservation vents. For converting to SI units use: 1 in. = 25.4 mm, 1 ft^3 = 28 l, and 1 oz/in.^{2} = 431 Pa. (Charts courtesy of Sand & Jurs.)

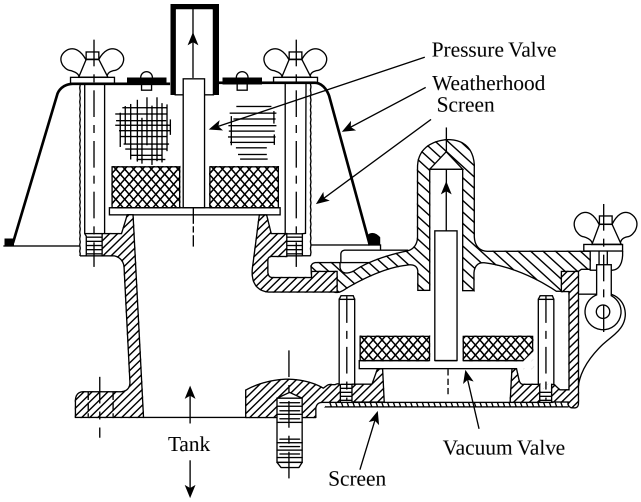

FIG. 7.7b
Conservation vent.

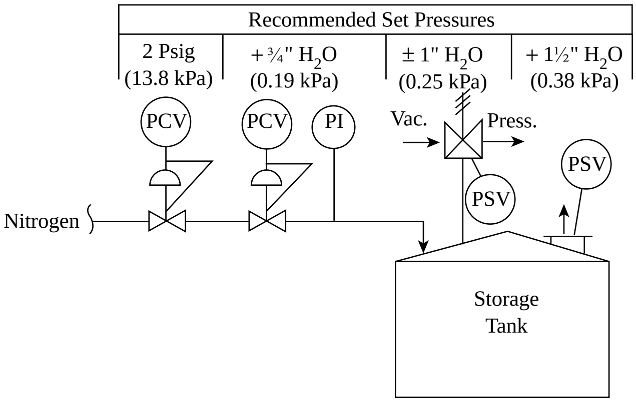

FIG. 7.7c
Venting of blanketed storage tanks.

to provide some mechanism to keep the internal tank pressure within a certain tolerance around the atmospheric pressure during thermal expansion and liquid transfer.

In many cases, a simple vent pipe is not enough. One of these is where the material has a low flash point and would cause a hazard if large amounts were allowed to continuously enter the atmosphere. Another is where the vapor is corrosive, toxic, or expensive, and continuous venting to air is not desirable.

There are several advantages to the use of conservation vents in comparison to the free vent. Conservation vents save the process fluid by reducing the waste of vapors to the atmosphere. For example, a study of the effectiveness of conservation vents by the American Petroleum Institute (API) found that in case of a 30-ft-diameter (9 m) tank having the capacity of 210,000 gal (794 m^3), an annual saving of 1400 gal (5.3 m^3) of material could result from the use of a conservation vent. The study assumed that the stored liquid had a vapor pressure of 5 PSIA (34.5 kPa) at 60°F (16°C), and the conservation vent pressure setting was 3/4 in. (19 mm) H_2O.

By reducing product loss, the conservation vent also reduces the potential for fire and the amount of air pollution around the storage tank. Of course, if at the particular ambient temperature no liquid vaporized at all, a free vent would be sufficient and the value of the conservation vent would drop, as the vapor pressure of the stored liquid increases.

When to Use Conservation Vents

Whether a conservation vent is required, recommended, or not needed depends on the applicable code, the value of the process fluid and the weather. API requires conservation vents on all tanks containing liquids whose flash point is below 100°F (37°C). The National Fire Protection Association (NFPA) requires a conservation vent on all tanks that contain a liquid with a flash point below 73°F (23°C) and a boiling point below 100°F (37°C). NFPA requires a conservation vent or flame arrestor on tanks that contain liquids with flash points below 73°F (23°C) and boiling points above 100°F (37°C) and on tanks that contain liquids with flash points in the 73 to 100°F (23 to 37°C) range.

The flash point of a liquid is the lowest temperature at which sufficient vapors are given off to form a flammable vapor-air mixture above the liquid. Conservation vents are generally recommended for tanks that store liquids have flash points of up to 140°F (60°C). Stored liquids are often heated to prevent freezing and/or to reduce their viscosity. The installation of conservation vents should be considered for all tanks in which the stored liquid is heated to or near to its flash point.

Another application of conservation vents is on tanks that require inert gas blanketing. Inert gas blankets are used to prevent product contamination by air or by the moisture in air and to hold down the vapor layer of low-flash-point materials. Free vents are of no use where a gas blanket is required. One method of venting a blanketed tank is shown in Figure 7.7c.

Determination of Required Capacity There are several guides to tank venting requirements, but one of the most widely used is API's "Guide for Tank Venting." Table 7.7d gives venting capacity requirements for thermal venting, and Table 7.7e gives the required capacities for fire emergency venting of aboveground tanks. In addition, the following recommendations are usually made to cover venting required due to liquid transfer:

For liquids with flash points below 100°F (37°C)—In addition to the capacity requirements for thermal breathing listed in Table 7.7d, provide 17 SCFH (8 l/min) of venting capacity for each gal/min (3.78 l/min) of filling rate and 8 SCFH (3.8 l/min) of inbreathing capacity for each l/min (3.78 l/min) of emptying rate.

For liquids with flash points above 100°F (37°C)—Provide 8.5 SCFH (4 l/min) of vent capacity for each gpm (3.78 l/min) of filling rate and 8 SCFH (3.8 l/min) of inbreathing capacity for each gal/min (3.78 l/min) of emptying rate plus sufficient capacity to meet the thermal breathing requirements of Table 7.7d.

In addition to the above requirements, the diameter of the vent pipe must be at least as large as the largest filling

or emptying line connected to the tank. For small, UL-labeled tanks, the required vent line sizes can be obtained from Table 7.7f.

Sizing Much of the sizing data for venting equipment is empirical. Therefore, once venting requirements are determined, the user should refer to published capacity charts to determine vent sizes. As a guide to conservation vent sizing refer to Figure 7.7g, which gives the recommended sizes as a function of tank volume and discharge pumping rates. These recommendations assume that the flash point of the stored liquid is below 100°F (38°C) and the settings of the conservation vent are 1 in. water column (0.4 kPa) for both the positive and the vacuum settings.

Most published data provide the required venting capacity in units based on the venting of free air. In order to convert these data into the venting capacity requirements of other vapors, the following equation may be used:

$$V = \frac{A}{\sqrt{(SG)}} \qquad 7.7(1)$$

TABLE 7.7f
Vents for Underwriter Laboratory Labeled Tanks

*Tank Capacity (Gallons)**	*Vent-Pipe Size (Inches)**	
	Buried Tanks	*Above-Ground Tanks*
To 500	1	$1^{1}/_{4}$
501–1,000	$1^{1}/_{4}$	$1^{1}/_{2}$
1,001–3,000	$1^{1}/_{2}$	2
3,001–6,000	$1^{1}/_{2}$	$2^{1}/_{2}$
6,001–12,000	2	3
12,001–30,000	3	4

*One inch equals 25.4 mm; one gallon equals 3.78 liters.

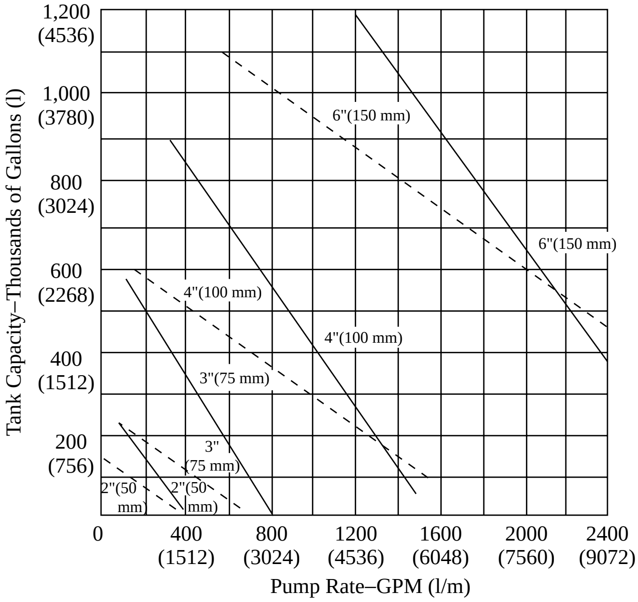

FIG. 7.7g
Conservation vent size required for given tank and pump sizes. Capacity based on pressure and vacuum setting at $1^{1}/_{2}$ in. (38 mm) H_2O. Solid lines for pressure; dotted lines for vacuum relief.

where

V = volume of vapor in SCFH
A = volume of air in SCFH
SG = specific gravity of vapor to be vented (air = 1.0)

If the pressure setting of the conservation vent is other than $1^{1}/_{2}$ in. H_2O (0.4 kPa), the vent capacity in units of free air can be obtained from Figure 7.7h.

Emergency Vents

The third type of venting device, the emergency vent, is used as a secondary or backup relief device on storage tanks, which can be subjected to external heating such as fire. The emergency vent is a large area cover that is opened when excessive pressure develops in the tank (Figure 7.7i).

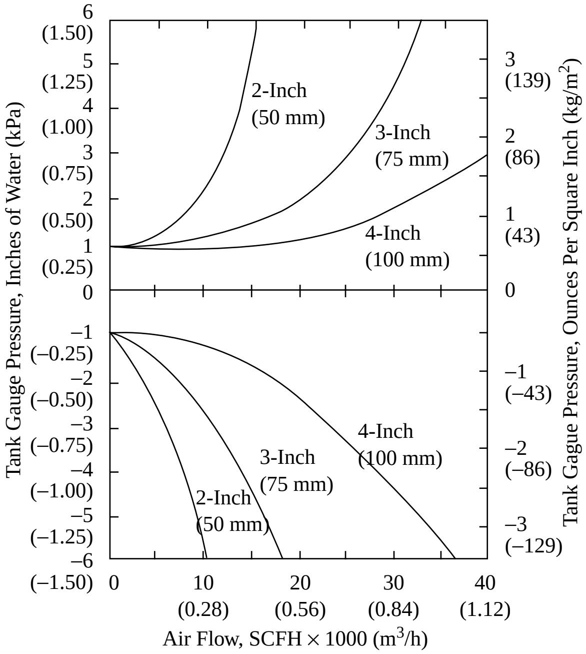

FIG. 7.7h
Approximate capacities for conservation vents with various settings and sizes.

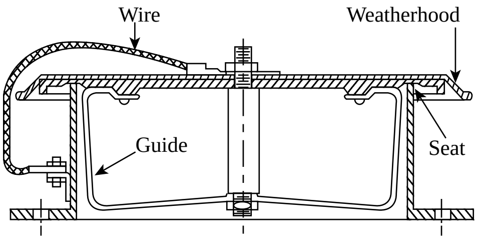

FIG. 7.7i
Emergency manhole cover.

Some constructions of emergency relief devices can be bolted to the tank manhole and also double as manhole cover. NFPA requires that, "Every above-ground storage tank shall have some form of construction or device that will relieve excessive internal pressure caused by external fire." This requirement may be met by use of the emergency vent or by the use of one of several special tank constructions. These special constructions are floating roofs or week-seam constructions.

Dessicating Vents

The desiccant vent air dryer is a device that is sometimes used on storage tanks in conjunction with vents and that may be installed in the vent piping. The desiccant dryer may be required to prevent the contamination of stored liquid due to moisture entering through the tank venting system (Figure 7.7j). It is important to note that the breather valve also has a vacuum relief setting. This is required to prevent vacuum

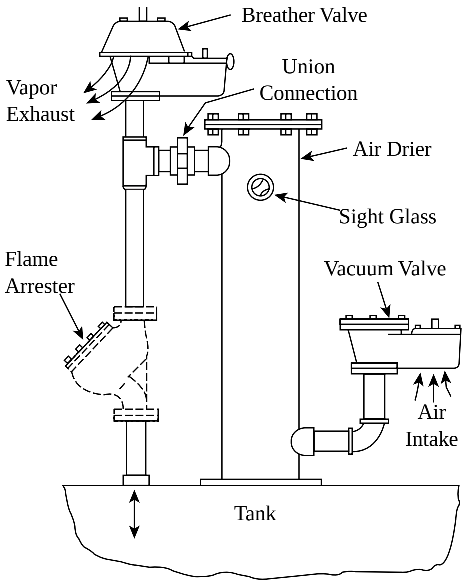

FIG. 7.7j
Breather valve installation with desiccant dryer.

buildup in the tank if the water in the desiccant freezes and thus plugs the dryer. The vacuum setting on the breather valve should be about 1 in. (25 mm) of H_2O below the setting on the vacuum valve.

FLAME ARRESTERS

Flame arresters are in-line or end-of-line venting devices provided with an internal flame-arresting grid. They are designed to prevent an external fire from entering a tank that contains a flammable product (Figures 7.7k and 7.7l). The internal grid or bank of plates is of sufficient size, and the plates are spread so that an external flame that flashes into the arrester will be cooled and extinguished before it can pass through the arrester and into the storage tank. Flame arresters are also available as combination flame arrester/conservation vent units (Figure 7.7m).

When sizing flame arresters, the selected size must be large enough to vent a quantity of air, which equals the volume displaced by product transfer plus the volume generated by thermal expansion. The data given for conservation vents (see Tables 7.7d, 7.7e, and 7.7f) also apply to flame arresters. It should also be noted that a flame arrester of a given size has a lower capacity than the same size conservation vent. Therefore, it is the flame arrester that will determine line and vent nozzle size, if a combination unit is used, or if the two units are installed in series.

Factory Mutual System requires that flame arresters be used under the following conditions:

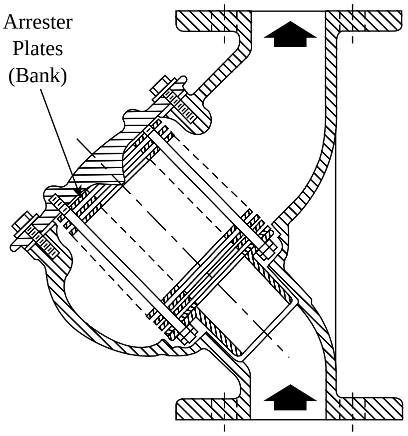

FIG. 7.7k
In-line flame arrester.

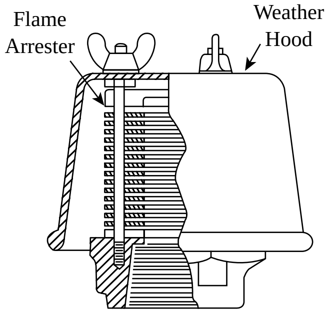

FIG. 7.7l
End-of-line flame arrester.

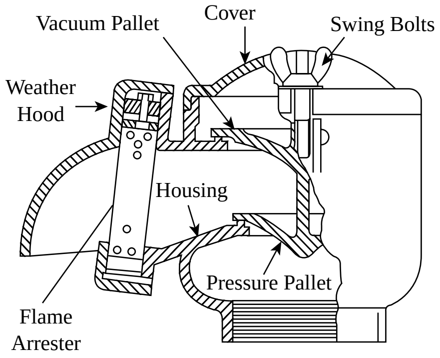

FIG. 7.7m
Combination flame arrester/conservation vent.

1. On tanks that contain liquids with flash points below 110°F (43°C)
2. On tanks that contain liquids with flash points above 110°F (43°C), but where the tank may be exposed to combustibles or other tanks containing liquids with flash points below 110°F (43°C)
3. On tanks where the contents can be heated to their flash points under normal operation

NFPA requires that flame arresters or conservation vents be used on tanks that contain liquids with flash points below 73°F (23°C) and with boiling points above 100°F (38°C). NFPA also requires their use on tanks that contain liquids with flash points in the 73 to 100°F (23 to 38°C) range.

Flame arresters cannot always be relied upon to provide tank venting. Whenever the stored material in the tank can foam, plug, or freeze, it is possible that the space between the flame arrester plates will clog and restrict or stop venting. When this condition is anticipated, the flame arrester can be steam-traced to prevent product freezing. Under these conditions it is advisable to provide a secondary pressure-relieving device that will protect the tank in case of flame arrester plugging.

Flow Sheet Symbol

Types:	A. Flame (pilot and main flame detectors in combustion processes) B. Fire (fire safety devices) C. Smoke (detect smoldering and the incipient of fires)
Smoke Sensitivity:	2%/ft (303 mm) obscuration ±0.6%/ft (UL)
Costs:	Battery-operated household smoke detectors are available from around $10. Addressable, intrinsically safe smoke detectors with software programmable test option and with both smoke and temperature sensors cost about $100. Flame rod or thermocouple-type pilot flame safeguard detectors cost about $500. Optical flame safeguards for burner management cost from $800 to $3000, with the higher priced units having explosion proof packaging and intelligent electronics.

INTRODUCTION

This section covers both the types of instruments that guarantee the maintaining of combustion and the instruments that serve to warn the occupants of a building when a fire starts. The devices used for these purposes operate on similar principles and therefore can be discussed in the same section of the handbook. The fire and smoke detectors will be discussed first. This will be followed by a discussion of optical fire detectors, concluding with a description of fire safeguarding devices used in burner management.

FIRE AND SMOKE DETECTORS

A fire occurs in four distinct phases. In the first, or incipient, phase, warming causes the emission of invisible but detectable gases. In the second phase, smoldering, smoke is formed, so smoke detectors can be used. In the third phase, when the ignition temperature has been reached, flames are present and therefore their emitted radiation (infrared [IR] and ultraviolet [UV]) can be detected. In the fourth and last stage of the fire, heat is released; the temperature of the space starts to rise, and the use of thermal sensors becomes feasible. Obviously, the sooner the evolution of a fire is detected, the less damage it is likely to cause. Therefore, fire and smoke detectors are discussed here in the order of their applicability to the four stages of fires.

Smoke Detectors

Ionization Chamber Sensors In the early warming and incipient stage of fire, combustion products are emitted without visible smoke, flame, or heat release. Ionization chamber type sensors are used to detect the presence of these gases by analyzing the composition of the atmosphere through the measurement of conductance. The ionization chamber contains two electrodes held at different potentials and a radioactive alpha particle source that ionizes the air in the chamber. The ionization current that results reflects the composition of the air and rises as the invisible combustion gas concentration rises.

Photoelectric Sensors Once the fire starts to smolder and smoke is present, photoelectric sensors can be used to activate alarms. Most smoke detectors use a light beam and a photoelectric cell or transistor. As the smoke density rises, less light passes from the source to the receiver and an alarm is activated. Smoke detectors must be maintained so that dust and dirt accumulation will not cause false alarms. In most fires the casualties are not caused by the heat of the fire, but by the toxicity of the combustion gases and by asphyxiation from smoke. Therefore, early warning systems, such as photoelectric smoke detectors, are very important.

Thermal Sensors

There are two types of thermal sensors that are used in fire protection application. One is the rate-of-rise sensor, and the other is the absolute temperature sensor. Rate-of-rise alarms are usually set at 15 to 20°F (8.3 to 11.1°C) per minute. This rate of rise can be detected by either bimetallic pneumatic tube sensors or thermoelectric sensors. The fixed temperature sensors actuate an alarm when the space temperature reaches a present limit. They are usually either bimetallic or fusible link devices. In the fusible link devices, the melting of a low-melting-point solder activates the operation of sprinklers or other extinguishing devices.

Flame Sensors

Once there is a flame, it emits a flickering radiation, which is mostly in the IR wavelength. Therefore, IR sensors can be used to detect the presence of flames. The flickering frequency of open flames (5 to 25 cps) allows the discrimination of flames from infrared radiation generated by light bulbs (at 120 cps) or from unmodulated ambient light sources. False alarms can still be caused by sunlight reflections from windows or rippling water surfaces, or by flickering neon signs. Therefore, the mounting location of the sensor should be carefully selected. Flame detectors should be used when combustible gases or flammable liquids are present, where the ignition is almost instantaneous and has practically no incipient or smoldering stage.

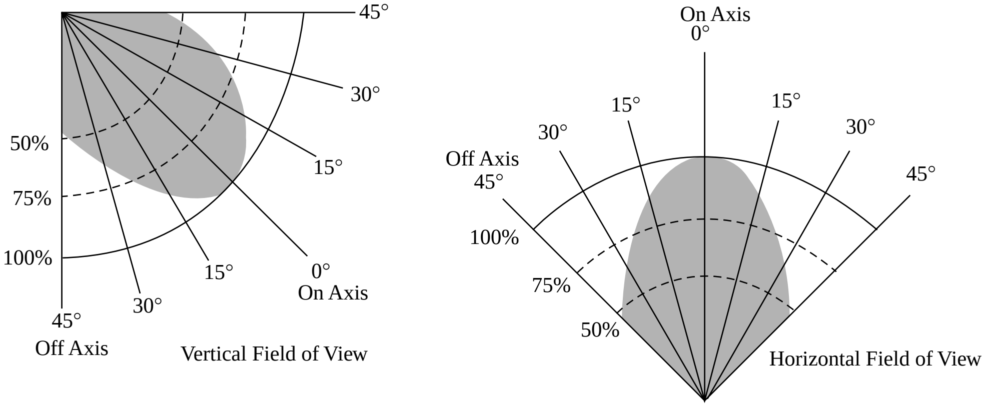

FIG. 7.8a
Cone of vision for a 90° with 50% off axis sensitivity.

Types of Optical Flame Sensors There are basically five types of optical detectors in addition to closed-circuit television (CCTV):

1. UV
2. IR
3. UV/IR
4. Dual IR
5. Multi-IR

Flame detectors are specified by their cone of vision, which is defined by the field of view and the on axis detection distance to the fire (Figure 7.8a). The angle of the field of view is defined by the 50% of the on axis detection capability of the detector. Typically these are about 90° (horizontally) although there are some detectors with fields of view of up to 120°, or with 100% off axis detection capability. A distance to a specified size fuel source (typically 1 ft^2) is also specified. This fuel source is generally *n*-heptane although other fuels are often listed (e.g., gasoline, methane plume, etc.). The manufacturer's data sheet should indicate the off axis detection distance, generally graphically (or as a percentage of the on-axis distance).

When selecting a flame detector, the specifying engineer must take into consideration the fuel source and the cone of vision of the selected detector to ensure adequate coverage of the potential hazard. Because these are optical devices, it is important to ensure that the detector has an unobstructed view to the hazard, and that the selected detector automatically verifies the cleanliness of its lens. Several manufacturers offer an optical integrity check and therefore the ability of the detector to see a fire. The failure of the optical check should generate a fault alarm.

The flame detection algorithms within the flame detectors are highly specific, and often their response and capability to detect a fire will vary from manufacturer to manufacturer. Tables 7.8b and 7.8c provide data on the flame detection distance and the false alarm sources, respectively, of the various optical fire sensors discussed below.

TABLE 7.8b
Typical Optical Flame Detection Distances (Feet)

Type	*UV*	*IR*	*Dual IR*	*UV/IR*	*Multi-IR*
Gasoline	90	85	100	100	210
Diesel	65	65	50	40	150
Methanol	50	50	20	55	150
Methane	80	45	25	90	100
Hydrogen	50	NR	15	NR	NR
Metal fires	15	NR	15	NR	NR
Black powder	15	40	40	NR	NR

Note: NR – no response

Ultraviolet Detectors This optical technology was developed in the early 1970s using UV detection with Geiger Muller tubes. These were the first optical flame detectors and are based upon a Geiger Muller tube. The UV detectors count the number of pulses in the tube and give a total number of counts per second. The detector then alarms when a predetermined threshold has been exceeded. The UV detector is very good for flame detection in enclosed spaces. It is not so good for outdoor applications as there are too many potential sources for false alarms.

UV detectors are good for sensing hydrogen and methanol fueled fires (fires that emit predominantly in the UV spectrum) because these materials burn with a blue flame (i.e., strong UV source). These detectors are generally the fastest responding typically 30 ms. The drawback is that they are prone to false alarming from strong UV sources such as arc welding and lightning. Even if not directly in the field of view, UV reflections will trigger an alarm. UV is attenuated by oil films and is obscured by smoke. Because of the sensitivity of UV detectors to lightning, it is generally not recommended for outdoor applications. Another potential cause of false alarms is static discharges that can be detected by some UV detectors.

Infrared Detectors In general, IR detectors are good for detecting hydrocarbon based fires (i.e., fires that have strong IR emissions). IR detectors are generally not as fast as UV detectors to respond to a fire. A disadvantage of IR is that ice buildup can desensitize the detector (lessen its ability to detect a fire), but this can be overcome with heated optics. IR does not respond to electric arc welding unless the welding is very close to the detector, in which case the detector may alarm due to seeing the burning from the welding process. Some IR detectors have flicker and statistical analysis algorithms to minimize the effects of black body sources, a false alarm source.

UV/IR Detectors These detectors combine the best of both the UV and IR and result in fewer false alarms than UV or IR detectors alone. Depending on how the individual manufacturers use the two signals also affects their performance. Some UV/IR detectors “AND” both signals such that in order to generate an alarm, both UV “AND” IR sources must be present and exceeding their threshold levels. Other designs might “OR” the two sources such that only UV or IR will alarm. Yet others may ratio the two signals; in order to generate an alarm, both sources of UV and IR must not only be present, but also must exceed a certain ratio.

One disadvantage is that the loss of one (either UV or IR) will prevent alarming except in the “OR” design. High background IR (engine body) may meet the IR condition in an “AND”-ed detector such that an arc or lightning would cause a false alarm. Also, it is possible to saturate the UV portion in a ratio-based detector, if it is so designed that the corresponding IR would have to be excessively large to signal a fire alarm.

Dual IR These detectors have two IR sensors. The dual IR sensors seem to be falling behind the more favored multispectrum (triple IR) detectors. These types of detectors generally have longer detection ranges than UV or IR sensors and are more fuel specific in their applications. Dual IRs can be desensitized by high background levels of IR, reducing their ability to detect a fire.

Multispectrum IR These detectors have three IR detectors. Each manufacturer’s multispectrum detector is somewhat different. These differences are due to the differing (patented) flame detection algorithms used by the manufacturers (i.e., how the three optical IR signals are processed). In general, these detectors offer greater detection ranges and give fewer false alarms. They are currently the best performing flame detectors available.

Closed Circuit Television This is an emerging technology and there are only a few products to choose from. These types of detectors come either as black and white or color images that are human viewable. As they are only sensitive to the red-green-blue spectrum they are not suitable for blue/translucent flames from such fuels as hydrogen and methanol. The advantage of CCTV detectors is that the user is able to verify the presence of a fire before taking any action. Since this is an emerging technology, there is little information on their performance.

FLAME SAFEGUARDS (BURNER MANAGEMENT)

In this section, a brief description of the more widely used means of flame detection will be presented. After some basic theoretical discussions, the various devices will be described. The feature tabulation given in Table 7.8i will enable the reader to select the most desirable sensor for the application at hand. Functions of flame sensors as part of burner control systems will be discussed later.

Among the many characteristics of flame, the following have been successfully used to detect the presence flame:

1. Heat generated
2. Ability to conduct electricity (ionization)
3. Radiation at various wavelengths, such as
   a. Visible
   b. IR
   c. UV

Methods of detecting these characteristics are described below.

Heat Sensors

The earliest flame sensors utilized the most obvious characteristics of the flame—namely, the heat generated. These devices were thermocouples, bimetallic elements, etc. For small installations and domestic burners these devices were satisfactory and are still used. Their relatively slow response (2 to 3 min) renders them unsuitable, and indeed dangerous, for larger installations.

Let us take a large reforming furnace as an example. If it requires 1000 SCFM (0.47 m^3/s) of fuel gas, and flame failure is detected only after 2 to 3 min, the 2000 to 3000 ft^3 (56 to 84 m^3) of unburned fuel gas admitted to the furnace will create an explosion hazard. A detector with a response of 4 to 6 s or less will not permit sufficient amounts of gas to enter the furnace to cause an explosion. Another obvious disadvantage of these sensors is that since they only sense heat, they will be unable to distinguish between heat generated by flame or that radiated by the hot refractory.

Conduction-Type Detectors

The first major breakthrough toward fast (but unreliable) detection of the flame was the discovery that flame is capable of conducting electricity. This is true because the flame, being a chemical reaction between a fuel and oxygen, liberates a large number of electrons. Because of ionization, the flame can conduct both DC and AC currents, which are utilized to establish an electrical circuit. A rod immersed in the flame (flame rod) acts as one electrode, the burner as the other. This proved to be fast but unreliable in that a high-resistance electrical short caused by, for example, faulty insulation, could simulate the presence of flame.

Rectification

Any electrical device that offers a low resistance to the current in one direction but a high resistance to the current in the opposite direction is called a rectifier. An ideal rectifier is one with zero resistance in one direction and infinite resistance in the opposite direction.

When AC is passed through a rectifier, the current obtained will be rectified current. It will consist of only that portion of the input current to which the rectifier presented low resistance.

By making the area of one of the electrodes (the burner in this case) much larger than the other, conduction will essentially take place only in one direction (Figure 7.8d).

The Rectification Phenomenon The explanation for the above phenomenon is that when ionization takes place, electrons are liberated from the gas molecules and are free to move about, constituting electric current. In addition to the freed electrons, the negative electrode contains many surplus electrons acquired through the negative side of the external circuit that makes the electrode negative. These surplus electrons repel each other, and, given enough positive ions to attract them, will leave the negative electrode. The number of electrons leaving the negative electrode and entering the positive electrode determines the rate of current flow. It is apparent that the current flow depends on the number of positive ions that get near enough to the negative electrode. Suppose the area of one electrode is made several times large than the other and that electrode is negative. This will increase the flow of electrons to the other (positive) electrode.

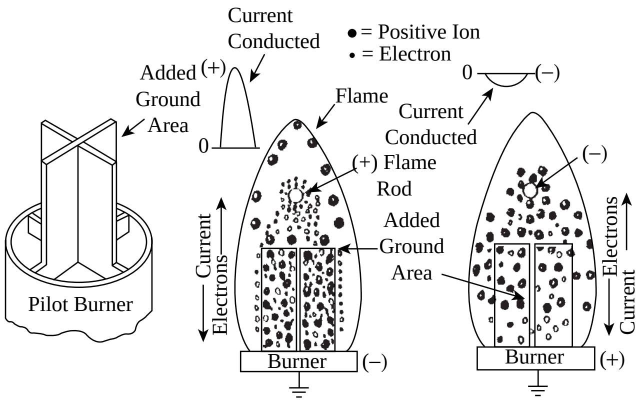

FIG. 7.8d
Rectification by flame.

If AC is applied, the current through the flame will be rectified. Indeed, using this arrangement and thereby obtaining a *half-wave rectified* current, the lack of safety due to simulated flame was eliminated, as the circuitry associated responded only to a half-wave rectified signal. Unrectified alternating current or direct current input to the detecting circuit will result in a safe shutdown. Because flame rods are in direct contact with the flame, they have to be cleaned or replaced often. Above approximately 2000°F (1100°C), very few metals can be used and even these become brittle. Fuels with high sulfur content burn with flames having low resistance, resulting in low flame rod output and leads to nuisance shutdowns.

To avoid direct contact with the flame and the maintenance problems arising from it, another obvious characteristic of the flame—its ability to radiate energy—was used.

Radiation Types

Radiation emitted by the flame covers the energy spectrum for wavelengths corresponding to UV, visible, and IR range (Figure 7.8e).

Visible Radiation Visible radiation occupies about 8% of the total bond of wavelengths radiated by the flame. To detect this position of the radiation, a rectifying phototube is used. It consists of a light-sensitive coated cathode of large surface and an anode encapsulated in a vacuum (Figure 7.8f).

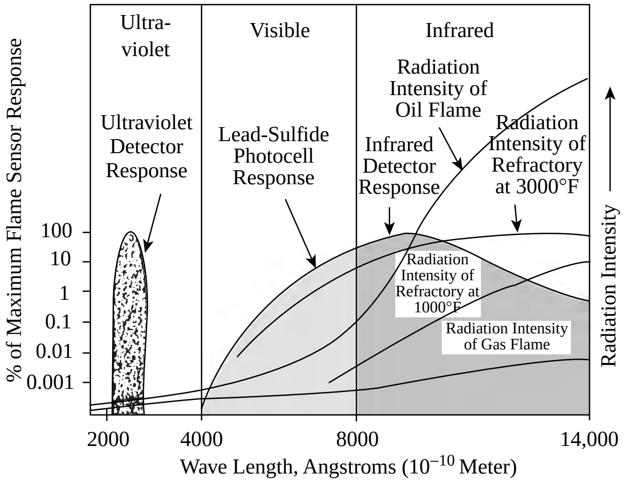

FIG. 7.8e
Applicable ranges of selected flame sensors and the range of hot refractors effect.

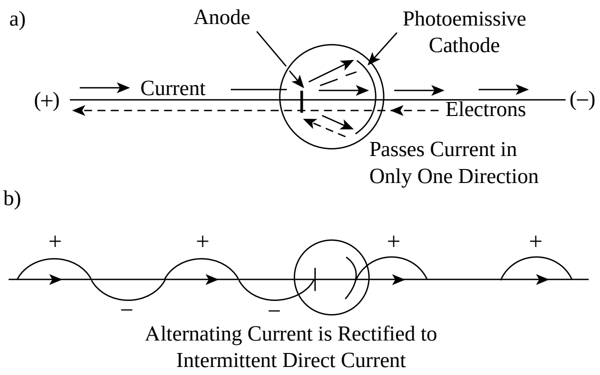

FIG. 7.8f
Rectifying phototube.

The number of electrons emitted by the cathode is approximately proportional to the light intensity. Conduction will take place only when the anode is positive.

If AC is applied, the phototube will act as a half-wave rectifier. The associated electronic circuit will respond only to such a rectified signal, and high-resistance shorts will not simulate flame. At high temperatures, the refractory (noncombustible insulator used to line interiors of furnaces) emits visible radiation. The detector might not be able to distinguish this radiation from the visible radiation emitted by flames; therefore, caution must be exercised in installing the detector in such a position that it will not be able to sight hot refractory. Use of rectifying photocells is limited to oil-fired burners, because visible radiation emitted by gas flame is insufficient to be detected by this type of flame sensor.

Cadmium-Sulfide Photocell The single element of this type of photocell is coated with cadmium sulfide, which is sensitive to radiation in the visible spectrum only. In darkness cadmium sulfide has high electrical resistance. When exposed to light, it conducts freely and almost instantaneously. The electrical resistance of cadmium sulfide decreases directly with increasing intensity of light. Like lead sulfide, it acts as a variable resistor and conducts current equally well in either direction.

This photocell is used in series with the coil of a low voltage relay in an AC circuit. When the cell sees sufficient light to pass a given current, the relay “pulls in.” The sensitive region of the cadmium-sulfide cell is such that it will not respond to gas flames and can, therefore, be used with oil flames only. The performance of this cell will not be affected by the “shimmering” effects of hot refractory.

Infrared Radiation IR radiation covers the largest portion, approximately 90%, of the band of wavelengths emitted by the flame. Its intensity is by far the strongest of all radiation forms emitted. The IR radiation emitted is a more reliable means of detection than the visible radiation. It is emitted by gas as well as oil flames, and the intensity never drops to zero.

Lead-Sulfide Photocell This cell is sensitive to IR radiation and is the most widely used device for such detection. Similar to the principle of the cadmium-sulfide photocell, the principle of the lead-sulfide photocell is to change its resistance inversely to the IR radiation it is subjected to. It is a variable resistor and conducts electricity equally well in both directions without rectification. The current flow is a measure of flame strength.

The signal-sensing circuit responds only to so-called flame frequencies. When looking at a flame, it seems to burn steadily. But if the eyes were sensitive enough to very rapid changes, it could be seen that the flame burns brightly at one instant and less brightly the next. The flame really flickers or pulsates, but much too rapidly for this to be detected by the human eye. The frequency of the flicker is very irregular, but may be detected by an electronic circuit designed to accept only a proper band of frequencies. Such a tuned circuit is selective and will not be affected by IR radiation emitted by hot refractory, nor can a high-resistance short simulate a flame.

Experiments show that a shimmering effect caused by movement of hot gases between the refractory and photocell can fool the circuit and flame simulation can occur. This so-called shimmering can be demonstrated by viewing objects through the heated air over a candle.

Ultraviolet Radiation Seemingly, UV is the least significant portion of radiation. It represents only about 1% of the total radiation and covers 10% of the emitted band of wavelengths. UV radiation is emitted by gas as well as oil flames. The device popularly known as a UV detector is a gas-filled tube with voltage applied between its two electrodes (anode and cathode).

The tube is conductive only if voltage is applied at its terminals, and it is subjected to UV radiation.

It is readily seen that a high-resistance short cannot simulate flame, nor can it be affected by the hot refractory. This is because no UV radiation will be emitted by refractories below approximately 2500°F (1370°C). Compared to the detectors so far mentioned, the UV cell is foolproof.

In addition to all these attributes, some UV detectors have an additional built-in safety feature. This consists of a shutter arrangement that blocks the view of the cell for a fraction of a second about 20 times each second, interrupting the circuit that can reestablish current flow again only if UV radiation still exists. This arrangement makes the detector responsive to flame failure within a fraction of a second, because it has to convince itself 20 times a second that flame exists.

Installation

Proper installation of flame sensors is essential to safe operation. Installations of these sensors fall into three categories:

1. Pilot and main flames supervised simultaneously—Checking the pilot and main flames simultaneously is the most desirable method of flame supervision. When

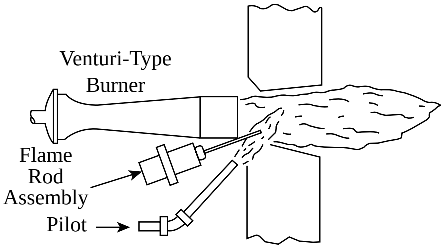

FIG. 7.8g
Pilot and main flame monitored by flame rod.

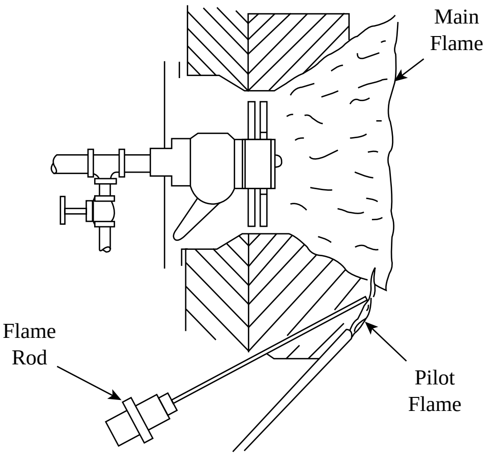

FIG. 7.8h
Mechanical fan-type burner. Pilot flame only is proved.

this arrangement is used, the pilot is capable of safely igniting the main flame (Figure 7.8g). The flame rod in this case is located in the path of both the main flame and the pilot flame.

2. Only pilot and flame supervised—On some installations it may be impossible to prove the pilot and main flames simultaneously because variations of the main flame envelope at different firing rates. This condition prevails, for example, in mechanical fan-type burners. The recommended practice of installation in this case is to supervise the pilot flame (Figure 7.8h).
3. Only main flame supervised—In application where the pilot flame is not lit continuously but only on light-off, the main flame is supervised. It is essential that the sensor be installed in such a way that it will be able to feel or see the flame during all variations in firing rates and draft adjustments.

The above considerations are applicable for flame rods as well as for the different viewing devices. Additional care must be exercised in the installation of rectifying phototubes and lead-sulfide photocells to ensure that incandescence of hot refractory or shimmering of hot air will not simulate the flame. This is accomplished by limiting the view of the devices through a restriction orifice.

Portholes for viewing devices must be cleaned regularly to ensure an unobstructed view and thus prevent nuisance shutdowns.

CONCLUSIONS

The order of presentation for the different types of sensors was intended to show how the limitations of each design have been eliminated.

Flame Guards

Starting with the heat sensors, it was seen that their response time rendered them unsuitable for industrial applications. The flame rods provided for fast response, however, their direct contact with the flame and the consequences, such as brittleness or oil and carbon deposits on the rod, limited their usefulness. Photocells utilizing the visible range of radiation were limited by their inability to reject radiation from the refractory, and their useful range covered only oil flames.

The infrared detector eliminated most of the above shortcomings, but shimmering of hot air could still fool the detecting circuit. It is safe to say that UV detectors can be used reliably in any application. Their relatively high cost demands that the situation be carefully investigated for possible application of other sensors.

In an oil-fired furnace, the cadmium-sulfide cell can be safely used if it is installed so that it will not see the hot refractory. For combination oil and gas furnaces, the lead-sulfide cell will work satisfactorily if it is installed with its view pointed toward the flame through a restricting orifice so that it will not see shimmering hot air.

All devices except the flame rods share the common advantage of not being in contact with the fuel and the flame. The temperature limitations imposed on them are easily satisfied because the temperature outside of the furnace is unlikely to reach 150°F (66°C). The purpose of these installations is safety, and, therefore, cost consideration can be only secondary.

For a summary of flame guard sensor features, see Table 7.8i.

Optical Fire Detectors

In selecting the right fire detection system, the user must analyze the potential hazard and false alarm sources and select the detector that can signal an identified fire with the highest immunity from false alarms (Tables 7.8b and 7.8c). The specific cone of vision of the selected flame detector should be evaluated to make sure that it will give adequate coverage to the particular fire hazard (Figure 7.8a). These detectors must also have an unobstructed view to the fire hazard.

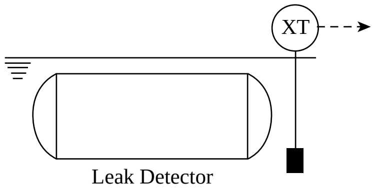
7.9 Leak Detectors

R. K. KAMINSKI (1982) **B. G. LIPTÁK** (1995, 2003)



Leak Detector
Flow Sheet Symbol

Types:

1. Above ground detectors
    - 1A. Pressurization
    - 1B. Bubbles, paints, etc.
    - 1C. Combustible and toxic
    - 1D. Ultrasonic
    - 1E. Thermal conductivity
    - 1F. Halogen leak detectors
    - 1G. Others (vacuum, thermograph, etc.)
2. Underground leak detectors

Sensitivity:

1B. 10^{-4} cm^3/s
1C. See Tables 7.9a and 7.9b
1E. 10^{-5} cm^3/s; see Table 7.9c
1F. 10^{-7} cm^3/s

Costs:

A case of bubbling foam bottles costs \$40. A portable, intrinsically safe combustible gas detector with 100 ppm sensitivity costs about \$300, a portable toxic gas monitor costs about \$600, an ultrasonic leak detector about \$1200, a portable thermal conductivity leak detector with 10^{-5} cm^3/s sensitivity costs \$1600; and halogen leak detectors cost about \$3000. The cost of thermography sensors is around \$10,000, and an average mass spectrometer costs \$25,000, but their cost can range from \$3000 to \$150,000, depending on application complexity and accessories. Underground leak detector systems are available for single- and multiple-point gas monitoring applications (about \$2500 for single-point and \$8000 for up to 12 points). In double walled tank installations, if level sensor sensitivity is sufficient, the cost will be as given in Chapter 3.

INTRODUCTION

This section covers a variety of sensors that are used in leak detection applications, including leakage through valves and steam traps, tightness of aboveground tanks or pipes, and the measurement of tank leakage underground.

When a particular chemical is leaking into the atmosphere in an industrial or laboratory environment, the sensor used to detect its ambient concentration can be a combustible or toxic analyzer or any of a long list of other analyzers, discussed in Chapter 8. In this section, the emphasis is on those types of leak detectors that detect the actual leak as it occurs.

Chemical materials and fuels that leak into the atmosphere represent both a financial loss and a resource loss. Fluid leaks also waste energy because energy goes into the shipment as well as the processing of chemicals. In addition, the safety aspects of leak detection are extremely important because the escape of toxic, flammable, or explosive materials can cause accidents. See Table 7.9a for an orientation of a limited number of leak detection applications and sensor types that are suited for those applications.

ABOVEGROUND LEAK DETECTION METHODS

Pressurization or Hydrostatic Testing

Pressurization by pneumatic or hydraulic means is probably the most widely used method in industry. The fall of a pointer on a pressure gauge can indicate a leak.

Various standards and codes explain specific procedures for piping, pneumatic instrumentation systems, and vessels. The recommended practice of the National Fire Protection Association (NFPA) goes into considerable detail on how to handle underground leaks. American Petroleum Institute (API) Standard 527 describes a method for checking the leakage at the seats of safety relief valves.

Test equipment is available for pressure testing, including special fittings for plugging off lines and testing joints.

Using Paints, Dyes, or Bubble Emission Commercial formulations are available that will bubble or foam at the point of a leak. Safe materials are available for different chemical applications. Once the existence of a leak has been proved

TABLE 7.9a
Orientation Table for Leak Detectors

Application	*Detector Options*
Personnel protection	Gas badges
Gas leaks, general	Handheld gas detectors Personnel protection indicators Wall mounted gas detector
Water leaks	Colormetrics Tracer dyes
Small parts	Immersit immersion fluid Tracer dyes
Unpressurized pipes and containers	Colormetrics Ultrasonic leak detector Tracer dyes
Pressurized pipes and containers	Liquid leak detector Ultrasonic leak detector
Large parts Large containers	Liquid leak detector Hydrostatic leak testing Immersit immersion fluid Handheld gas detectors Ultrasonic leak detector Colormetrics Tracer dyes Inspection penetrants
Oil/fuel leaks	Colormetrics Tracer dyes FuelGuard for AFVs

by pressurization, the bubble emission technique can help to isolate its location.

Aerosols, paints, and papers that change color due to chemical reaction are used in much the same way as the materials that bubble and foam. They are applied to the exact area that is being tested, and the color change spots the leak.

In detecting steam leakage from steam traps, a tape is fastened to the steam trap's outlet piping. If a spot on the tape remains silver, the trap is working. If live steam passes through the trap continuously, the spot turns black because of overheating.

Dyes can be used to label sewage steams to check flows and seepage areas. One company has biodegradable, fluorescent dyes that are still visible after dilution to 1 ppm in water.

Phosphorescent powders can be useful for identifying defective bags and other leaks in dust collectors. The powder is put into the dirty side of the collector, and it works its way through the system in a few minutes. After that time, the inside of the collector is checked with an ultraviolet light to find leakage points that are visible due to the glowing of the powder.

White smoke can be used to locate leaks in sewers, ducts, and other places that cannot be pressurized. Candles, bombs, or smoke generators with blowers produce the smoke that emerges at points of leakage.

Combustible or Toxic Leaks

The sensors that are available for the detection of toxic or combustible materials in the atmosphere are discussed in detail in Chapter 8. If a liquid is toxic or flammable, a wide variety of analyzers can be considered to detect if it is leaking out into the atmosphere. These instruments can use infrared (IR), colorimetric, or a dozen other principles of operation. They range from handheld monitors to continuous, permanently installed sensors.

Portable detector tube units provide measurements of low concentrations of gases and vapors. Most of the tubes have direct reading scales. The length of the discoloration in the tube provides the concentration reading. Some tubes contain chemicals that change color; these require a color comparison for the reading. Manufacturers have tubes for 100 or more specific analyses. Some of these tubes have been certified by the National Institute for Occupational Safety and Health.

For carbon monoxide, hydrogen sulfide, and a few other toxic materials, small badges and stickers (dosimeters) that change color as a function of total exposure are available.

Personnel Alarms Personal alarm units can provide considerable protection against toxic materials. These devices record or continuously integrate toxic levels to provide a time-weighted average (TWA) exposure number. An audible alarm occurs if a preset threshold limit value (TLV) is exceeded at any instant. Table 7.9b provides a summary of the typical alarm set points and inaccuracies of standard gas monitors.

TABLE 7.9b
*Capabilities of Pocket-Sized, Portable Toxic Gas Monitors**

	Alarm Setpoint	*Inaccuracy*
CO	200 ppm	±10 ppm FS; ±5 ppm in 0 to 200 range
H_2S	50 ppm	±10 ppm FS; ±3 ppm in 0 to 100 range
SO_2	20 ppm	±10 ppm FS; ±3 ppm in 0 to 100 range
NO_x	200 ppm	±10 ppm FS; ±5 ppm in 0 to 200 range
NO_2	20 ppm	±2 ppm FS

TABLE 7.9c
*The Detection Limits of Portable Combustible Gas Detectors**

Compounds	*Formula*	*Sensitivity (ppm)*
Acetylene	C_2H_2	50
Alcohols	R—OH	50
Hydrogen sulfide	H_2S	5
Gasoline	—	1
Sulfur dioxide	SO_2	5
Vinyl chloride	C_2H_3Cl	5
Liquid hydrocarbons	—	50

*Courtesy of Cole-Parmer Instrument Co.

The most common type of combustible gas detector utilizes the catalytic combustion principle. A platinum wire filament (in a Wheatstone bridge circuit) is usually mounted in a diffusion-sensing head. Sulfur compounds and halides can prevent proper operation of this sensor. In processes where flammable gases or vapors can escape the technique serious consideration for intermittent and continuous monitoring must be warranted.

Table 7.9c lists the compounds that can be detected and the ppm sensitivity that can be expected of the measurement, using an intrinsically safe portable sensor, which is provided with a probe for focusing the detection to localized points of leaking. The unit is also suited for the detection of ammonia leaks.

Ultrasonic Detectors

Fluids escaping from openings generate sonic and ultrasonic waves. With the acoustic emission technique leaks can be detected from a distance. One vendor's explanation is that a 10 PSIG (68.9 kPa) gas leak might be detectable at 50 ft (15 m), but would be detected at only 10 ft (3 m) if the pressure were 1 PSIG (6.89 kPa). The method can be considered for the location of leakage from buried pipes and tanks. Although the technique has limitations for low-pressure gas problems, it can detect the gurgling of leaks from sewers and other low-pressure liquid lines.

TABLE 7.9d

Minimum Detectable Leak Rates of Some Common Gases Using Thermal Conductivity-Type Leak Detectors

	Minimum Detectable Leak Rate	
Gas	*cc/s*	*cu. ft/year*
Helium	0.00001	0.11
Hydrogen	0.000005	0.06
R12	0.000006	0.07
R1301	0.000006	0.07
R134(A)	0.000004	0.04
SF6	0.00001	0.11
CO_2	0.00003	0.34
CH_4	0.00002	0.23
Argon	0.00002	0.23

One successful application of the ultrasonic leak detector is the detection of the leaking of steam traps from a distance. These portable probe-type units can also detect the in-leakage of atmospheric air into vacuum equipment.

Thermal Conductivity Detectors Thermal conductivity leak detectors have cells that contain coils in bridge circuits. Heat dissipation increases with the concentration of the gas or gases in the sample, and the cooling effect changes coil resistance. The instrument will detect many different gases and has a wide dynamic range.

The portable, handheld leak detectors are provided with microprocessor-based intelligence. The unit is provided with a probe and a small fan that continuously draws in the gas that is present at the tip of the probe. The unit can be automatically zeroed (by pressing the re-zero button) based on the ambient air sample around the probe. Next the operator would identify the gas of interest and direct the probe to the probable point of leakage. The small fan then draws in a sample through the probe, and the sensor measures the resulting minute changes in thermal conductivity. Table 7.9d lists the detectable leak rates of some common gases.

Halogen Detectors

A halogen-bearing sample produces ionization current flow in a specially designed cell. The cell life of this design is shortened by high halogen concentrations. Although this instrument type is very valuable for checking refrigeration systems and for certain kinds of production testing, it is of less value in general industrial applications. One of its disadvantages is that the cell runs very hot, so these detectors cannot be used in a flammable atmosphere.

Electron-capture-type halogen leak detectors are the most sensitive (10^{-7} cm^3/s or even smaller) leak detectors available on the market (Figure 7.9e). Leak testing of reactors or other equipment is done by first evacuating the vessel and then filling it with a halogen gas, such as Freon-12 (dichlorodifluoremethane), and scanning the welds and other joints by a halogen sniffer probe.

When refrigeration systems are being leak-tested, the halogen is the working fluid inside the equipment. It should be noted that such halogens as Freon-12 (also called F-12, Refrigerant-12, or R-12) are not only destructive to the ozone layer around the Earth, but can also be fatal if inhaled. When exposed to high temperature, R-12 breaks down into chlorine, hydrogen, chloride, hydrogen fluoride, and phosgene gas, which is highly toxic.

The American Society for Testing and Materials Standard-E427 and the latest edition of the *Non-Destructive Testing Handbook* provide a large body of information on halogen tracer gases and leak testing. When vessels or heat exchangers are checked for leakage, they are usually filled with a pressurized mixture of air and R-12 gas. Table 7.9f provides information on the detectable leakage rates as a function of the richness of the air and R-12 gas mixture inside the equipment being tested.

Figure 7.9g illustrates how the sniffer probe might be used on a vessel wall in an open atmosphere. Figure 7.9h shows

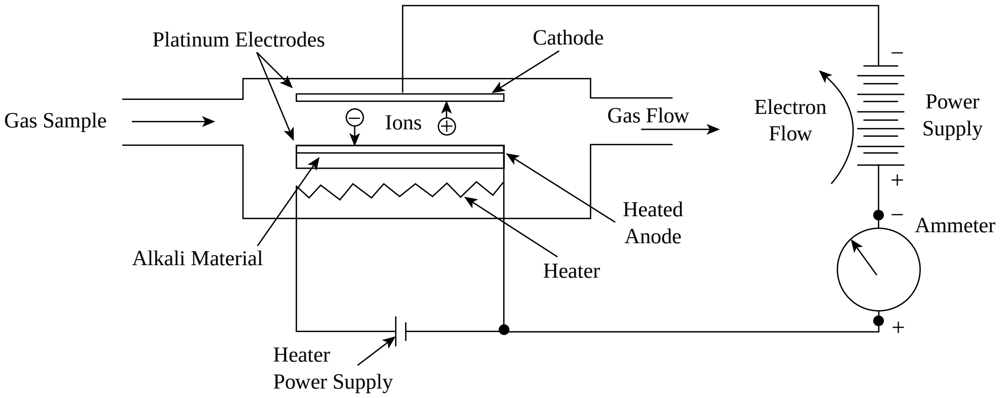

FIG 7.9e

Other Techniques

Loss of Vacuum One obvious method of leak detection is to evacuate the space inside the test object and measure if the vacuum leaks out (pressure rises) over time. In order to do this, any one of the vacuum gauges described in Section 5.14 can be considered.

Thermography Thermography involves the detection of temperature differences by scanning in the IR region of the spectrum. The result is a thermal picture that is usually two colors, but sophisticated systems can convert the measurements into graded colors. If a hot fluid is escaping, it can be detected at a distance, above or below ground, or under insulation. Leaking valves and steam traps are easily located through the use of this technique.

Thermography has already seen many other applications that only involve thermal energy. It is valuable for the inspection of insulation and refractory materials. As a maintenance tool, it can be used to check heater tubes and electrical equipment.

Mass Spectrometer When used for leak detection, the mass spectrometer (see Chapter 8 for details) is usually made sensitive to helium. The helium acts as a tracer gas, inside or outside of the item that is being tested. These expensive instruments would be difficult to use in a chemical plant, but they have considerable value for production (assembly line) leak testing.

UNDERGROUND LEAKAGE DETECTION

Underground leaks at refineries, tank farms, gas stations, and industrial waste sites require monitoring. The monitored materials can be flammable hydrocarbons or toxic substances.

Level Monitoring

The monitoring systems can be based on the measurement of either liquids or vapors. In installations where the tanks are double-walled or where the tanks are installed in line sumps, the measurement of liquid levels can be sufficient (Figure 7.9i). The level sensor can be any detector that is capable of distinguishing between water and hydrocarbons. One such level detector is the thermal dispersion type (Figure 7.9j), which utilizes the differences between the thermal conductivities of liquids to differentiate between them. These sensors have already been described in Chapter 3.

Soil Detectors

When the tanks are not provided with double walls, it is common practice to detect the concentration of hydrocarbon vapors in the soil, instead of attempting to sense the presence

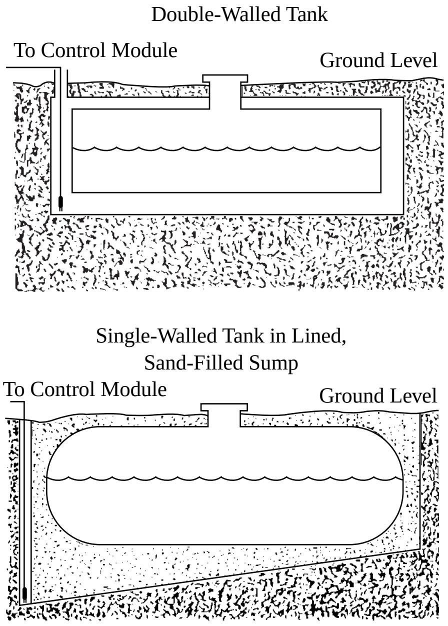

FIG 7.9i
Thermal dispersion-type level switches can be used to detect leakage in double-walled underground tank installations. (Courtesy of Fluid Components Inc.)

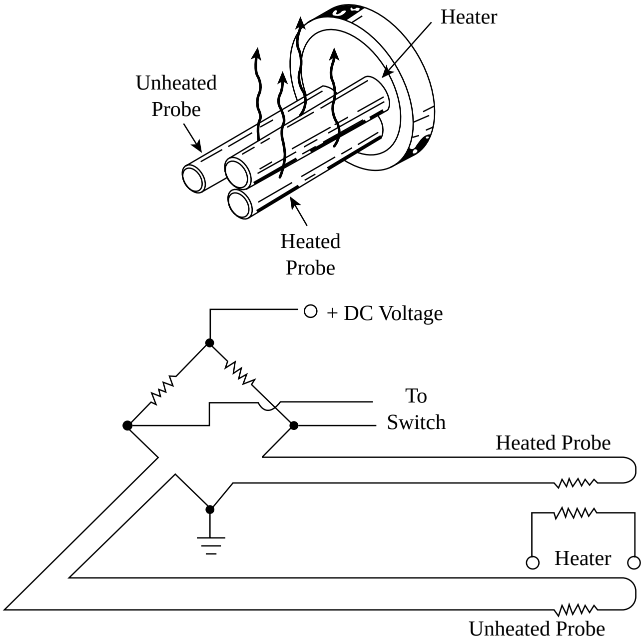

FIG 7.9j
Thermal conductivity-type level switch. (Courtesy of Fluid Components Inc.)

of hydrocarbon liquids. This is because vapors migrate about 50 times faster than liquids.[1] These sensors are usually set at gasoline concentrations of 0.5% by volume (or less) in air, which corresponds to 50% of the lower flammability limit for gasoline. Passive in-ground sensors can measure the concentration of hydrocarbon vapors in the soil. An intrinsically safe in-ground sensor—Van Der Waal—is illustrated in Figure 7.9k.

Aspirated Sensors Aspirated underground leak sensors pull a vacuum inside an underground probe that is provided with slots to allow in-leakage of vapors (Figure 7.9l). The slotted

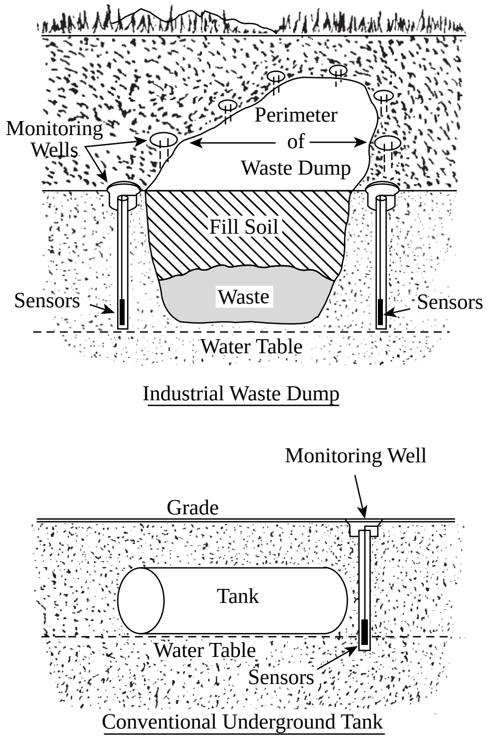

FIG 7.9k
Passive, in-ground sensors detect the concentration of hydrocarbon vapors in the soil.[2]

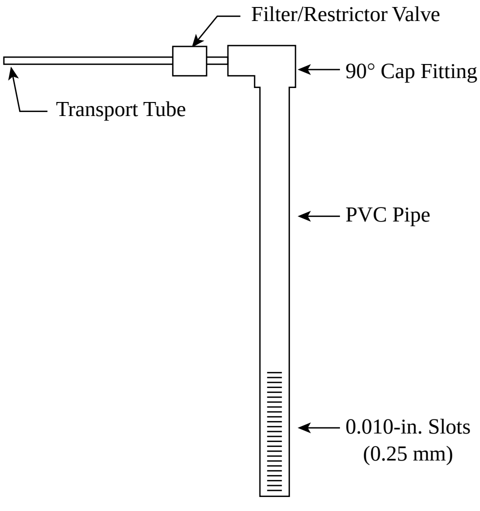

FIG 7.9l
The typical underground test probe.[1]

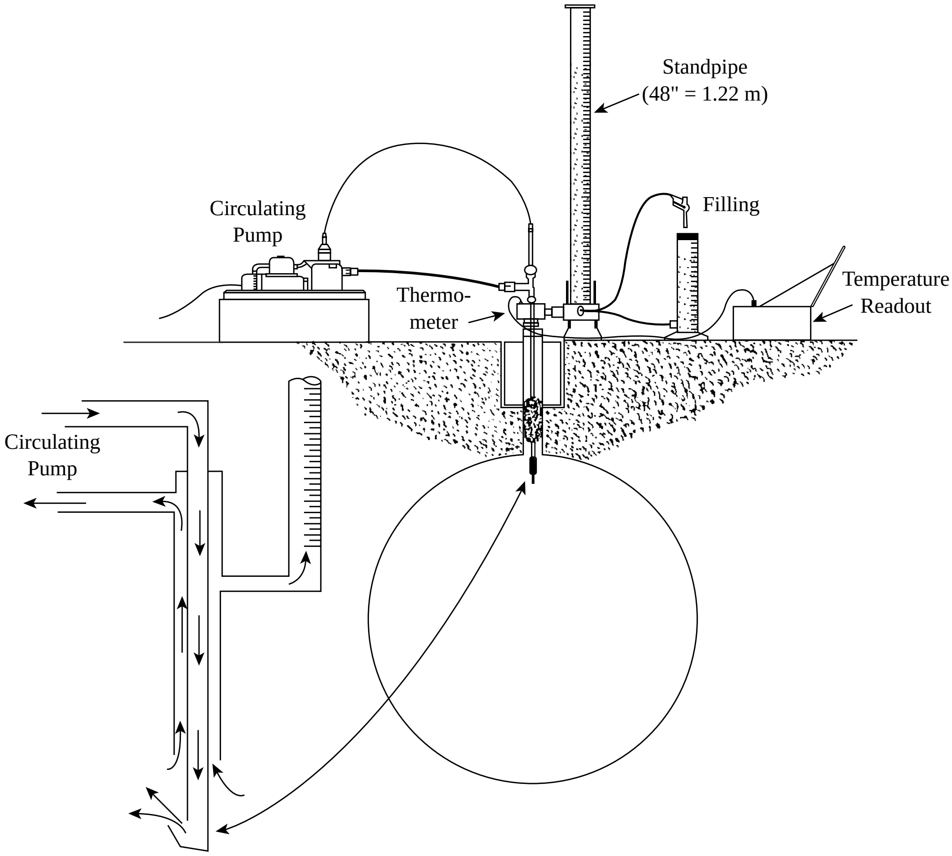

FIG 7.9m
Petro Tite test equipment. (Courtesy of Health Consultants.)

portion must never be fully covered by ground water, and the slots must be protected from plugging. The aspirated vapor sample tends to speed up the measurement, because the hydrocarbon vapors will migrate toward the vacuum created by the slotted probe.

Another advantage of this design is that the sensors can be located in an accessible and clean area. With multiple probes in the ground, continuous concentration profile measurements are possible. The sensor can be a bulk semiconductor vapor analyzer, a combustibles detector, or any of the other leak detectors discussed earlier.

Standpipe Detector Figure 7.9m shows the main components of a testing package that is capable of detecting minute leaks in underground tanks. Before the actual measurement is made, the ground water level is measured and the tank is pressurized to make it grow to reach its stable volume. Next, the tank contents are circulated, so that the temperature of the tank contents will be uniform within a fraction of a degree. Once the tank has been stabilized both in terms of its shape and the temperature of its contents, then the level in the standpipe of Figure 7.10k can signal even a minute leakage.

INTRODUCTION

Industrial applications of linear or angular position measurement include the detection of the position of valve stems/shafts, louvers, dampers, cylinders, etc. Position measurement is also used for inferential measurement of level and pressure as well as bulk-flow. Position is also measured by valve positioners, which provide position feedback in the more critical closed loop control systems.

Applications

In a level application, a wire connects a float to a drum that is fixed to the shaft of a multiturn rotary position sensor. As the level changes, the wire winds or unwinds from the drum and turns it, while its position sensor detects the rotary position. In pressure devices, a position sensor can be used to detect the movement of a bourdon tube or bellows element as the pressure changes. In case of detecting the bulk-flow on a conveyor, a pivot arm can skim the surface of the solids and a position sensor can measure the height of the moving pile.

There is a difference between absolute position sensors and sensors that detect only displacement. These incremental movement sensors are not position sensors. Position is detected for rectilinear (linear) straight-line motion and rotary (angular) turning of a shaft.

Position measurement requires a sensor and transmitter. For the harsh environments usually encountered in industrial applications, the sensors are usually integrated with the transmitter mounted in the field. However, sensors are also available as stand-alone units, having only some built-in signal conditioning, and utilizing a transmitter mounted separately, perhaps near the control room.

Mounting

Mounting of position sensing equipment usually requires some mechanical fabrication work, because for most installations there are no applicable standards for mounting. An exception is the case of control valves for which standards do exist for the detection of both linear and rotary motion. The rotary actuators usually adhere to the applicable standard, but most linear actuators in today’s market do not comply with the standard. Therefore, the mounting bracket in most applications must be custom made.

In some linear position measurement applications, a rotary sensor is used and the rectilinear movement is converted into a quarter-turn motion using a lever. For this arrangement, special care must be taken when mounting and aligning the moving parts.

Many position-sensing technologies have a linearity of only about 1%, which is not impressive, when compared to the linearity of other physical property sensors. In most position measurement applications, repeatability matters more than linearity. This is because the error in valve position detection is corrected by the process control loop. What is important is not the linearity of the measurement, but the elimination of hysteresis or dead band. Therefore, repeatability matters most.

SENSOR TYPES

All modern position sensors convert the position into an electrically measurable signal such as resistance, voltage, current, inductance, pulses, or capacitance. Position sensors consist of one fixed and one moving part. The degree of separation between the two parts makes a big difference for the reliability of the sensor. If the two parts are in contact with each other, there is friction that causes wear and tear, reducing the life of the sensor. Also, when the parts are in contact, vibrations and shock are transmitted from the moving part to the more delicate stationary part of the sensor, causing premature failure.

Conversely, if the parts are not in contact, wear-and-tear is eliminated. This results in longer life and an operation that is more reliable. Although some sensing principles are noncontacting, the mechanical design of the sensor often integrates the two parts together such that friction can still occur and vibration can still be transmitted.

Potentiometric Sensors

The simplest and most widely used position sensor is the potentiometer. Potentiometers are often built into the devices, particularly when rotary motion is detected.

Linear potentiometers also exist, but the most often used industrial potentiometers are the single-turn rotary position sensors. In such devices, the moving part whose position is being detected turns the shaft. As the shaft is turned, a brush/wiper slides along a resistive element which can be made of a wound wire, conductive plastic, or other special material. The potentiometer has three terminals, one for each end of the resistive element and one for the brush. As the brush moves, the resistance between the center tap and end-terminal changes (Figure 7.10a).

Voltage and Current Methods The position can also be determined in a resistive or voltage mode. Voltage method is suitable for high resistance potentiometers and the current method is suitable for low resistance potentiometers. In the

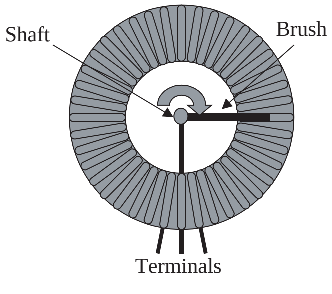

FIG. 7.10a
Wire-wound potentiometer.

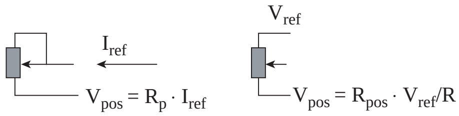

FIG. 7.10b
Transmitter with resistance measurement.

resistive mode, a current is sent to the center tap and to one of the end-terminals, while the resulting voltage drop, is measured by the transmitter. This drop is proportional with the position. In the voltage mode, the potentiometer is used as a voltage divider. A precision reference voltage is applied across the end terminals of the resistive element. The fraction of this voltage measured at the center tap is proportional to the position (Figure 7.10b).

If the resistance of the wires between the sensor and transmitter is significant in comparison with the resistance of the potentiometer, lead wire compensation should be used. If the resistance method is done using a temperature transmitter, this is typically taken care of. The voltage method requires the transmitter to provide the precision reference voltage.

The life span of brush/wiper type potentiometers is reduced by the wear and tear due to contact with the resistive material. The moving shaft of the potentiometer is connected to the fixed assembly, which transmits the vibration to cause wear between the two parts.

Advantages and Limitations Rotary potentiometers are best suited for angular position measurement. Quarter-turn actuators require only a gear to convert the motion for a full-turn potentiometer. Care must be taken to ensure that gears do not jam, gall, or cause excessive hysteresis. For linear motion, a lever is required when used with a rotary potentiometer (Figure 7.10c). This configuration can introduce some hysteresis due to mechanical defects.

A potentiometer has an infinite resolution. Linearity for a precision rotary potentiometer can be as good as 0.25%. However, due to linkages and gears, the linearity for the entire assembly usually is about 0.5 to 1%. The advantages of the potentiometric sensors include that they are simple and well understood. Troubleshooting can be done using a simple multimeter. It is possible to use a temperature transmitter with resistance input for the measurement, thus a special signal conditioner is not required (Figure 7.10d). Many position related devices already are shipped with built-in potentiometers. The potentiometer has essentially no power consumption; the transmitters just provide the resistance sensing current that need not be more than 0.1 mA.

Linear Variable Differential Transformer Type Sensors

A linear variable differential transformer (LVDT) is mostly used in linear motion applications and inside some pressure transmitters. It depends on an inductive principle for its operation. It is essentially a transformer with a primary winding and two counter-wound secondary coils. The circular windings are static, while a ferromagnetic core is moving at the center of the coils. The core is moved by the part or component whose position is being detected.

A sinusoidal excitation signal is applied to the primary coil and coupled to the secondary coils proportionally to the position of the core (Figure 7.10e). In the center-position, the coupling is symmetric; when the core is moved, the coupling becomes asymmetric. The differential signal of the two windings is proportional to the position.

Self-contained signal preconditioning converts the AC signal from the coil to DC in a DC-type LVDT. Because the LVDT operates inductively, there need not be any mechanical contact between the moving core and the coil structure. This eliminates friction and wear, and also provides virtually infinite life, if the core is mounted in such a way that it does not touch the coil assembly.

Hermetic sealing of the coil assembly is important for reliable operation. The inside sealing of the coil structure to the core must be nonmagnetic. LVDTs are available in lengths of up to 45 cm and with infinite resolution and with linearity of about 0.25%. The transmitter must provide the AC signal to drive the primary coil. Because the power consumption is relatively high, LVDT transmitters for position sensors typically require separate power. A rotary LVDT type sensor also exists. Changing between linear or rotary application requires change of the sensor.

Magnetostrictive Sensors

The magnetostrictive (a.k.a. magnetorestrictive) principle, which should not be confused with the giant magnetoresistive (GMR) sensor, utilizes a principle of operation similar to the Hall effect.

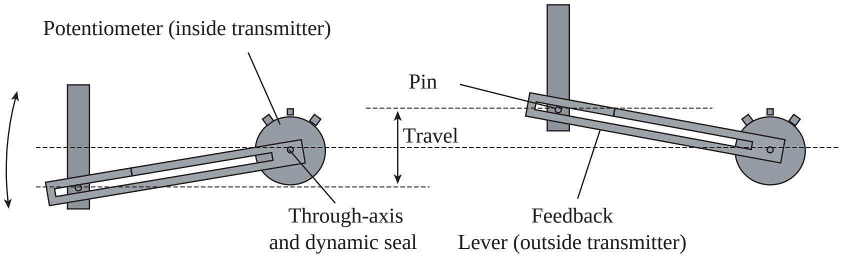

FIG. 7.10c
Lever converting rectilinear to rotary motion.

FIG. 7.10d
Industrial transmitter with resistance input.

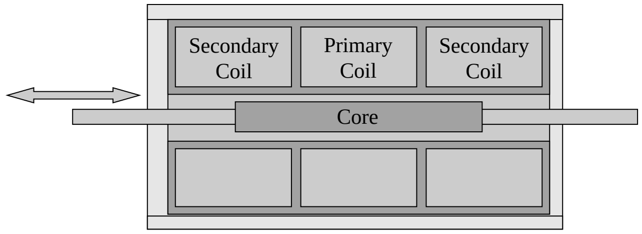

FIG. 7.10e
The operating principle of an LVDT type sensor.

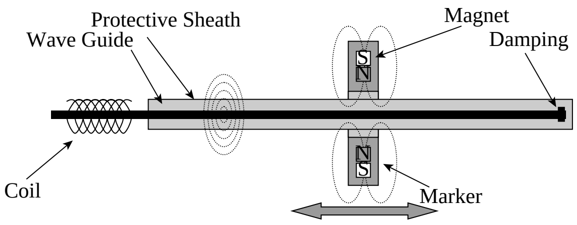

FIG. 7.10f
The operation of the magnetostrictive position sensor.

In the magnetostrictive sensor, a coil in the head-end starts the measuring cycle by periodically sending a trigger pulse down a wave-guide wire encased in a protective tube. A movable magnet assembly slides along the outside of the tube. The magnet assembly is moved by the part whose position is being detected. The wave-guide twist when the magnetic field accompanying the pulse down the wave-guide, intersects the magnetic field from the movable marker. The deformation is elastic and propagates in both directions along the wave-guide but is damped in the remote-end. The mechanical wave travels back down the wire to the head where it is detected by a reversal of the magnetostrictive effect, causing a stop pulse. The duration from the start pulse until the stop pulse is detected is proportional to the position of the magnet (Figure 7.10f).

The pulse duration is very short (in microseconds). Therefore, the signal conditioning circuit usually operates in an analogue mode where a pulse width modulation (PWM) signal is true throughout the duration from the start pulse to the stop pulse, having a pulse width proportional to the position (Figure 7.10g). Using a counter, which can operate at speeds of several megahertz, it is possible to time the duration without going through the analogue domain, keeping the measurement digital all the way.

There is no contact between the marker holding the permanent magnets and the other parts of the sensor. This means that there will be no friction or premature wear. Repeatability can be as good as 0.002%, and linearity as good as 0.05%. The magnetostrictive sensors can be linear and are able to detect movements as long as 3 m.

Because of the high counter frequency, the transmitters tend to have relatively high power consumption and are not suitable for two-wire transmitters. Rotary version is not available.

Hall Effect Sensors

In this sensor, a magnet assembly is moved by the part whose position is being detected. The magnet assembly can be constructed for either linear or rotary motion, but the Hall effect sensor remains the same. The linear magnet assembly consists of two opposing magnets side by side. The strength of the magnetic field along the magnet assembly varies at every point (Figure 7.10h). The Hall effect sensor sits between the two magnets roughly at the center when movement is at half the travel. For linear movement, the length of the magnet must exceed the expected travel.

As the magnet moves along the fixed sensor, the Hall effect sensor picks up the change in the field strength of the magnet (Figure 7.10i). The magnet assembly is designed in such a way as to strengthen the magnetic field between the magnets within the assembly and eliminate external influence.

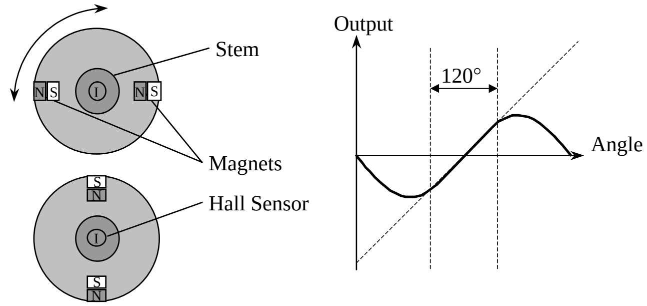

FIG. 7.10j
Rotary magnet assembly.

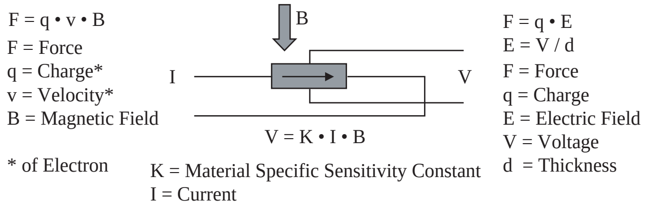

FIG. 7.10k
Hall effect principle.

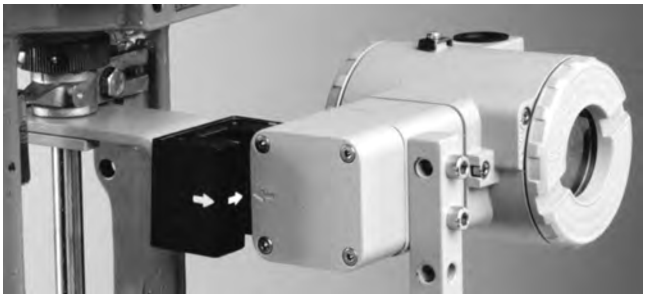

FIG. 7.10l
Industrial position transmitter.

Rotary Sensor For rotary, quarter-turn motion, a round magnet assembly with the two magnets in line is used. The magnetic flux picked up by the Hall sensor is a sinusoidal function of the angle (Figure 7.10j). The near linear part of the function (about 120°) is used for sensing, and complete linearization is done in software.

The Hall effect sensor is at the heart of this operating method. This is a simple semiconductor component protected by a rugged housing. A constant current is sent through the Hall element. As the electrons move through the magnetic field, they experience a force that piles the electrons to one side, creating a voltage. The potential in turn creates an electric field, which subsequently causes an opposing force (Figure 7.10k). At equilibrium, the forces balance. The potential is thus proportional to the strength of the magnetic field.

Transmitters Manufacturing long magnets is difficult. Therefore, this method is only used for rotary motion and for linear travel up to 100 mm, and it is suitable for most valves. The Hall effect sensor has low power consumption and is ideal for two-wire transmitters. The sensor has an infinite resolution. This principle is noncontacting, and the sensor does not cause any friction. There is also no wear-and-tear and life is lengthened. It is also less sensitive to vibration.

Since the magnet can be either linear or rotary, the same transmitter can be used for both angular and rectilinear movement without leaver linkages, etc. This is done simply by the selection of the magnet assembly. Since magnetic coupling is used, the Hall effect sensor can be completely encapsulated in a static seal. This is effective in harsh environments where both moisture and dirt are present (Figure 7.10l). Linearity, including that of the magnet, is about 1% and the repeatability is about 0.1%.

Encoder Type Sensor

Encoders are either absolute or incremental. Incremental encoders detect the distance moved and not the position; thus they are not really position sensors and are not covered here. Even with incremental encoders, it is possible to home the device (i.e., returned to the zero end position) every time it powers on.

Absolute encoders can be linear but are mostly rotary. In the rotary configuration, the encoder shaft is turned by the part whose position is being detected. The shaft then turns a disk that has a radial pattern with a unique code provided for each of a finite number of distinct positions (Figure 7.10m).

For each bit or resolution, there is one track of code pattern. For example, for 12 bits of resolution, there are 12 tracks. The number of distinct positions is determined as 2^N, so for 12 bits/tracks there are 4096 distinct positions, which results in a resolution of better than 0.025%. On the back of the disk there are light emitting diodes for each track, allowing phototransistors to read the disk pattern. The disk track patterns are usually not in natural binary code but in gray code (Figure 7.10n). The advantage of the gray code is the elimination of large rollover as only one bit changes for each position step. This reduces the measurement uncertainty to only one count. The conversion from gray code to natural binary code is a simple logical operation that is performed in software.

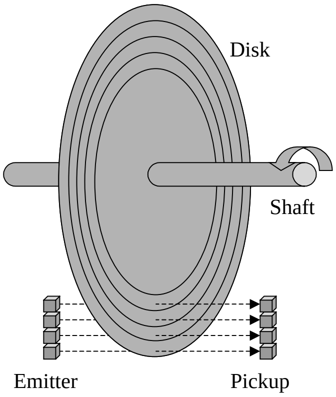

FIG. 7.10m
Encoder principle of operation.

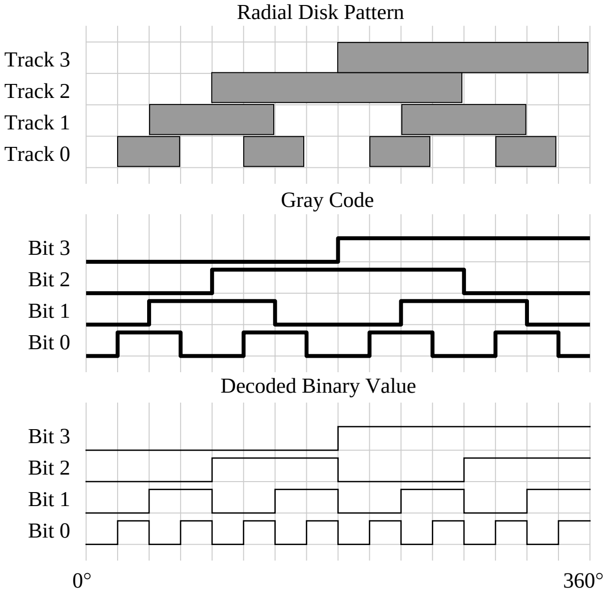

FIG. 7.10n
Gray encoding.

The encoder is a true digital sensor having no drift at all. It has a finite resolution depending on the number of tracks (bits) on the disk. Long linear motion measurement may use a wire on drum connected to a multiturn encoder. Changing from linear to rotary application requires a change of the sensor.

TRANSMITTER TECHNOLOGIES

To integrate the position measurement into the control system, the raw signal from the position sensor must be converted into a standardized analog or digital signal in a transmitter. The sensor may be an integral part of the transmitter, or a separate transmitter can be provided for the sensor. For some position detecting sensors, a temperature transmitter can be used to convert their low-level signals, such as ohms or millivolts from a potentiometer or preconditioned LVDT, into 4 to 20 mA. Most distributed control system/programmable logic controller packages are provided with low-level signal capability in their temperature-input module.

Other functions performed by the transmitter include range scaling, signal reversal (forward/backward, clockwise/counterclockwise), and calibration of sensor end points. Many transmitters are of a two-wire type, meaning that they are connected as part of the system using only two wires. On this pair of wires both the signal is transmitted and the power is also provided for the device.

Analog Transmitters

In a 4- to 20-mA DC transmitter, the output is 4 mA when the position is 0% of the set range, and the output is 20 mA when the position is 100% of the range. This range must be configured and it is important not to confuse range setting with calibration.

If the sensor is low power, the 4- to 20-mA transmitter can operate on a two-wire current loop. Two-wire operation means that the transmitter changes its current consumption proportional to the measurement and the power supply is the output signal. Since the signal never goes below 4 mA (or 3.6 mA during failure to be precise), there is always some current flow to power the device.

Many position-sensors require large quantities of power, and therefore need a third and possibly fourth wire to provide them with separate power supplies. Similarly, a 0- to 20-mA output requires a separate power supply. On the other hand, the two-wire operation reduces the amount of wiring required in a plant. A second advantage of current output is that the signal is not as easily distorted as a voltage signal.

Common voltage output ranges include 0 to 10, 1 to 5, and 0 to 5 V. For voltage output devices, the power supply must be provided separately over a third wire or by a separate pair of wires. A concern with a voltage output is that the signal is attenuated along the wire, resulting in a distorted signal in the receiving end. Voltage output should therefore be used only for very short wire runs.

Fieldbus Transmitters

Intelligent devices have a built-in microprocessor for providing digital communication. In the past, several proprietary communication protocols existed. With the passing of time and with the desire for interoperability, the number of protocols used is dropping. In the field of process control, the leading technologies today are Foundation™ Fieldbus and Highway Addressable Remote Transducer (HART), while Profibus DP is widely used in the automation of machinery. Digital communication can be used by a handheld tool or asset management system for monitoring, configuration, diagnostics, calibration, and other maintenance functions. For details on configuration of intelligent devices, refer to Section 1.6. Digital transmission of the detected position requires no range, but it is important not to confuse range setting with calibration.

HART is a low speed, 1.2 kb/s, since digital communication is superimposed on a 4- to 20-mA two-wire current loop. Digital communication is primarily used for configuration and diagnostics from a handheld device, while the analog signal is still used for connection to controls and interlocks.

Foundation Fieldbus is digital and higher speed, 31.25 kb/s. It makes it possible to connect as many 16 bus powered devices per network into a multi-drop system, which reduces wiring costs. Digital communication is also used for closed loop control where control strategies typically are executed in the field devices themselves. The valve positioner that contains the valve position sensor may also serve as the process controller and also detect position limits, etc. Therefore, Foundation Fieldbus makes the control system architecture leaner by virtually eliminating controller hardware.

INTRODUCTION

To define machine vision, we must define human vision. Human vision is the response of the eye and brain to light.[1] The cornea and lens of the eye image onto the retina, which contains rods and cones, which transmit a color image, through the optic nerve to the brain for processing. Anything that responds to and processes light can be thought of as having vision.

Machine vision is the artificial response of a device to spectral radiation The simplest devices are photocells. Machine vision also extends the human range of the visible spectrum, as in the case of IR absorption for identification of chemical bonds and for thermal imaging and UV spectroscopy or even x-ray inspection. A current challenge with x-ray vision is inspection at airports.

The Hubble Space Telescope, a project of the National Aeronautics and Space Administration, is an example of machine vision being used by humans to see things that otherwise could not be seen. Machine vision can be used by another machine to make decisions faster or more accurately and precisely than a human can. Machine vision systems may or may not use a computer. Many manufacturing operations such as counting, defect detection, edge following or displacement can be controlled by dedicated microprocessor or programmable logic controller-based machine vision. Pattern recognition may require a PC to

store a reference image to be compared with the real time image.

Machine vision technology is the design and use of machine vision to solve problems. Machine vision may combine on-line defect monitors with shade monitoring (see Section 8.15) and then link this database to process control systems for quality control. Table 7.11a summarizes the range of devices.

LINEAR DIODE AND LINEAR CHARGE-COUPLED DEVICE ARRAYS

Linear arrays are integrated circuits making up line scan devices. Line scan diode arrays are available in any number of diode elements, but popular arrays use 256, 1024, 4096, or more pixels. By focusing an image on the array, an object can be viewed as a line, as shown in Figure 7.11b. This is valuable in finding flaws and in following edges. Such a device can be used to detect leading and trailing edges of passing objects with digital logic based on which pixel is illuminated by the reflected beam.

Another application for a linear array or photosensitive device (PSD) is light triangulation depicted in Figure 7.11c. Light triangulation can take the place of manual measurement of thickness or gaps as shown in Figure 7.11d. The span of the PSD data can also be used to generate a 4- to 20-mA analog output signal. Combining lenses, external lighting, and microprocessors yields a wide range of devices from analog and discrete linear gauges to spectrum analyzers where the array is used as the detector following a spectral grating.

Diode array spectrophotometers (see Section 8.15) replaced single wavelength detectors and filters to yield smaller and faster spectrophotometers used for conventional

Optical triangulation. (Courtesy of Banner Engineering.)

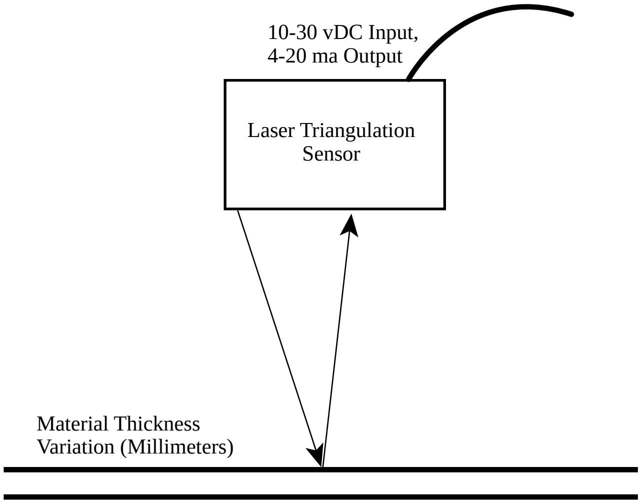

FIG. 7.11d
Optical thickness measurement.

as well as fiber-optic light paths. A large number of pixels (diodes) are not needed for the linear array to be effective. Using lenses and effective lighting can be more practical for image processing than large numbers of pixels.

Example Project

A project to use line scan cameras for a real time color pattern inspection system was implemented by the Oak Ridge National Labs under funding from the American Textile Partnership[2] consortium. It was an in-line web pattern-inspection system consisting of a three-array line scan camera imaging a red-green-blue (RGB) input to be captured by a frame grabber (image processor) stored in tagged image file format (TIFF) and displayed on a graphics monitor. Each charge-coupled device (CCD) array had 2096 pixels with a thin-film filter on the array for each color. A frame was generated by combining scanned RGB lines at a speed of about 300 μs per line. Depending on the speed of the web, an image might have a resolution of 100 pixels per inch of web.

A single camera with ample lighting could image about 3 ft across the web. The complete system was controlled by a 32-bit Virsa Module Europa (VME) bus microcomputer which also recorded an encoder input for web position. Technology developed under this project was shared by a number of consortium members and vendors. Some of these vendors are listed in the list of suppliers at the beginning of this section. Algorithms to make decisions using the line array or the two-dimensional array images have been developed to run in firmware and software.

TWO-DIMENSIONAL CCD AND DIODE ARRAYS

One could take multiple time-lapsed images of line scan arrays, and with a linear encoder, map this into a two-dimensional picture of the field of view as discussed. This technique was used for many vision applications such as currency authentification. Instead of this, a two-dimensional array of CCD photodetectors is used to store all the pixels within a cycle time of about 1 ms. The familiar digital camera and the mini-camera are two good examples. The brighter the light source, the less the integration time for the arrays. The faster the image moves, the less time there is for taking the picture. Two-dimensional arrays may be more deserving of the name machine vision since the human eye contains arrays of rods and cones.

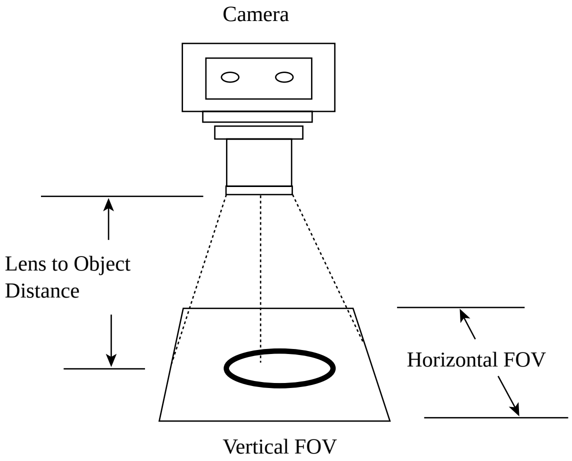

FIG. 7.11e
Camera/sensor used in pixel counting. (Courtesy of Banner Engineering.)

Gray-scale devices are used for pattern and defect recognition. One example is shown in Figure 7.11e, which is a two-dimensional array inspection device that does not transmit pixel data, but allows the user to program discrete outputs based on the filling and shading of pixels in the array. This is called *pixel counting*. Many simple inspection applications can be handled by this method. Thus, processes should be designed ahead of time to incorporate machine vision rather than machine vision being added later and having to compensate for variation in lighting, vibration, and excessive movement. The Automating Imaging Association[4] provides a good website for learning.

Analog Display Modes

Established at the time of the invention of television, National Television Standards Code (NTSC) and Phase Alternation Line (PAL)[4] are formats used in analog video for recording, playback, and storage. If one takes a magnifying lens and looks closely at a color monitor, it is seen that the screen is made up of thousands of dots of red, green, and blue phosphors. These RGB pixels are laid out and controlled by NTSC formats for displaying an output from an RGB transmitting device or recording. The video camera must transmit separate RGB signals for the horizontal and vertical sweeps of the display. This is to serve human vision rather than machine vision, but it is a necessary evil if a human is in the loop.

One finds that if all the red, green, and blue pixels in a group are lit, the human thinks this area of the screen is white.

NTSC and PAL data can be stored and transmitted digitally, but most display monitors are still analog devices requiring conversion of data to analog signals.

Serial Data Transmission

Despite digital imaging, display devices are still analog but these will eventually become totally digital with flat screen technology. Pixel data will still be the first level of data. Serial data transmission with a resolution of 8 bits gives 256 levels of an analog-to-digital (A/D) conversion of a diode's span, 10 bits gives 1024 levels, 12 bits gives 4096 levels, and so on up to 16 bits or more of A/D conversion.

This conversion is best done internally to the camera onboard so that high-speed serial data transmission is used to get the data into a PC. Since serial data is transmitted as bytes, a 16-bit data value for a pixel's gray scale range has to be transmitted in 28-bit bytes, and the driver program has to do the bit twiddling to render the string data in the correct form as numbers. Smaller cameras not needing frame grabbers are desirable to have the device external to a host for small space needs and robotics needs.

With the universal serial bus (USB)[5] protocol, the sending of 16-bit data values is done at about 12 Mb/s, but higher speeds are available up to 1 Mb/s. This type of design will be around for a while due to the cost advantage. Some diode arrays use a 12-bit pixel A/D and send data as high-/low-byte 16-bit words. At the low end, you might have 8-bit data being sent at 19.2 kb/s and at the high end you might have 12-bit data embedded in two 8-bit bytes being sent at 1 Gb/s. Firewire™ (IEEE1394)[6] Ethernet™ serial data takes us to 10 to 100 Gb/s.

Direct memory access is needed for high speed two-dimensional image processing. To use 32-bit data words containing RGB color information takes dedicated graphics boards running at over 1 GHz plus about 10 MB of memory per image. The key is to design your application so that the measurement is representative of the process time constants. A typical image can be scanned at 9600 dpi in gray scale. Lines are scanned at the same resolution resulting in a single page requiring about 10 MB in bit-map mode.

Vector Graphics Formats

A vector file creates an image as a collection of lines rather than as a pattern of individual pixels (bit-mapped graphics). Vector files are much easier to edit than bit-mapped graphics (objects can be individually selected, sized, moved, and otherwise manipulated) and are preferred for professional illustration purposes. Because they are scale and resolution independent, vector images can be enlarged without loss of sharpness.

Some vector file formats are Adobe Illustrator and portable document file (PDF). In order to print or view a PDF file, the user should use Adobe Acrobat Reader, which is freeware. The encapsulated PostScript file (EPS) format is a high-resolution graphic image stored in the PostScript language. The format allows users to transfer high-resolution graphics images between applications.

The images can also be sized without sacrificing quality. Bit-mapped graphics formats are images as a pattern of pixels (square dots) and are limited in resolution (sharpness) to the maximum resolution of the screen on which it is displayed. Bit-mapped images are inferior to vector graphics for most applications because they tend to have stair-stepping, which causes a staircase distortion due to the square shapes of the pixels. Enlarging bit-mapped images accentuates the distortion and jagged edges.

A bit-mapped graphic is stored as a group of bits that represent an image to be displayed on a computer screen. The image on the screen is composed of pixels (dots), similar to the dots in a photograph in a newspaper. Each bit in an image corresponds to one pixel in the screen, so the number of pixels that composes a monitor image determines the quality of the image. Because monitor screen resolution is only 72 dpi, and the resolution needed for printing is 266 dpi, a bit-mapped image limited to 72 dpi cannot be used to produce a quality image for printing.

COMPUTER GRAPHICS AND MACHINE VISION

Today's software graphics design packages offer resolution finer than the unaided human eye can detect. Zooming in eventually belies the discrete nature of the simulation. In the case of fashion and textile printing of art, it makes no economical sense to print an image at a resolution finer than a human can detect it. It does make sense if one is trying to inspect flaws in materials. It also makes sense to image in the spectrum outside of human vision. Infrared (IR) and x-ray vision systems extend human vision for the purpose of advanced military surveillance. This is true machine vision that humans are not allowed to see except by indirect methods such as the colorization of IR-temperature sensor data, or other image mapped data of a surface, such as with radar or ultrasonics.

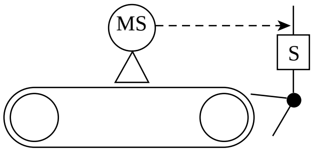
7.12 Metal Detectors

T. A. MAYER (1982) **B. G. LIPTÁK** (1995, 2003)



Flow Sheet Symbol

Applications:	Products in liquid, paste, or solid form on conveyors, in ducts, or in pipes can be monitored for the presence of metal objects. Units are also available to detect the location of underground pipes and cables, or for “beachcombing” for coins or jewelry.
Operating Temperature:	–40 to 120°F (–40 to 49°C)
Operating Pressure:	Atmospheric or vacuum
Materials of Construction:	Search head and electronics are housed in aluminum, plastic, or stainless steel
Search Head Window Sizes:	Highly variable. Typical belt detector window sizes range from 1 × 24 to 12 × 24 in. (2.5 × 61 to 30 × 61 cm)
Range of Detection:	1 to 12 in. (2.5 to 25 cm) for both ferrous and nonferrous metals. The smaller the search head window size and the shorter the range, the better will be the sensitivity.
Sensitivity:	The smallest diameter sphere of ferrous and nonferrous metals that can be detected is about 0.04 in. (1 mm). Distance from the search coil to the object is in direct proportion to the size of the object.
Costs:	Proximity limit switches start at $100. Search coils or search heads installed on belts and provided with interlocks for flap ejectors cost $2500 or more, depending on size, materials of construction, and complexity.

INTRODUCTION

In a metal detector, the magnetic circuit of the search coil is influenced by the differential conductance of the medium surrounding the coil. The greater the difference between the conductance of the medium and that of the minerals or metallic objects, the better the sensitivity of the detector. In case of metal detectors, sensitivity is expressed in terms of the size of the object to be detected and the distance from which it can be sensed. Some metal detectors are available that can automatically correct for variations in the conductivity or other properties of the process material.

Some of the belt mounted sensors can be installed not only horizontally, but at any angle. They can also operate automatic devices (sorters), which will reject the detected metal particle.

DETECTOR TYPES

Types of detectors used include the transmit-receive (T/R) and the beat frequency oscillator (BFO). Both utilize the magnetic field of a search coil and low or very low frequencies of 1 kHz or lower.

The transmitter and receiver coils are located in the search head for T/R types. The transmitter coil, which is actually an antenna, sets up a magnetic field. This field is altered by the metallic objects as they pass the head. The resulting perturbation is sensed by the receiving coil, which then generates the audio and analog output.

For the BFO type, the search coil in the head is driven at the frequency of operation and an internal reference frequency signal is maintained. The operating frequency changes if a metallic object is near enough to the coil, and the change (compared with the reference frequency) is converted to the target identification signal.

Models can be battery-operated. Cost variations between models are due to the power output available from the driving amplifier, water and/or saltwater proofing, oscillator stability, and miscellaneous features. Users of metal detectors are capable, after considerable practice, to differentiate between metals and between objects of various sizes.

INSTALLATION ON CONVEYOR BELTS

Search coils generate high-frequency magnetic fields and can be used on conveyor belts that are made of nonmagnetic and nonconductive materials. The sensitivity of the coil is reduced if there are large metal objects (such as conveyor belt rollers) near the coil, but these effects can be zeroed out if these objects are stationary. When the conveyor belt is wide and the loading height is low, the search coil is often installed under the belt; if the loading is high, the coil sensitivity is increased by installing it above the belt (Figure 7.12a).

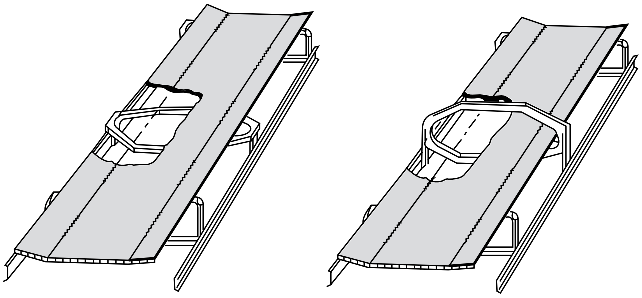

FIG. 7.12a
When the loading is low, the search coil is installed under the belt; when the loading is high, the coil is placed around the belt. (Courtesy of ABB subdivision: ASEA of Sweden.)

Figure 7.12b illustrates the operation of a metal detection control loop. A solenoid-operated flap is located at the end of the belt, and the product slides over the flap as long as no metal is detected in it. When metal is detected, a delay unit holds that information until the contaminated product reaches the end of the belt and opens the flap. As a result, the contaminated product falls into the reject bin. Such control loops are widely used in the food and plastics industry.

For the simpler task of determining the presence or absence of larger metallic objects, such as metal containers inside cartons that are travelling on conveyors, less expensive devices such as proximity detectors or limit switches can be used (see Section 7.14). These switches can actuate lights, buzzers, or reject flappers when the carton is not full (Figure 7.12c).

OTHER APPLICATIONS

A high sensitivity metal detector would be used to locate underground piping or cabling. These sensors are often used during new construction on existing sites or during expansions of existing facilities, when the locations of gas and

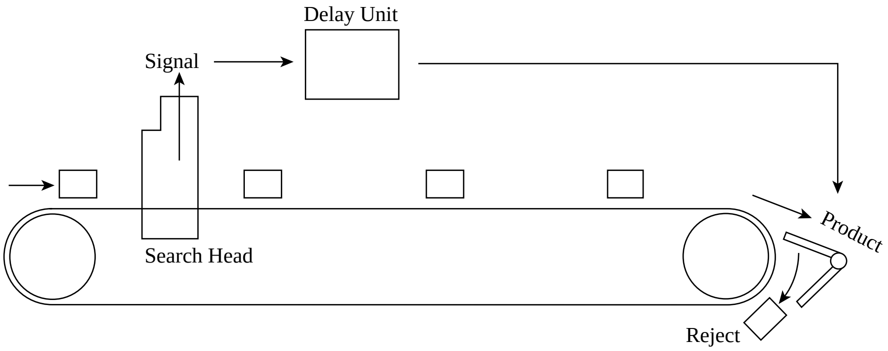

FIG. 7.12b
Product contaminated by metals can be automatically rejected. (Courtesy of Rank Cintel Ltd.)

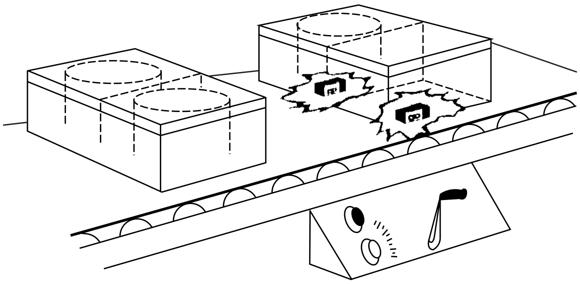

FIG. 7.12c
The presence or absence of metallic containers inside cartons can be detected by placing proximity limit switches under the conveyor belt.

oil pipelines or those of electric utility and telephone cables need to be determined. The highest sensitivity detectors, which are also the most expensive ones, are capable of detecting pipelines at 10 to 20 ft (3 to 6 m) or more below ground level.

In addition to the industrial applications, geologists use metal detectors to locate metal and mineral deposits, hobbyists use them for beachcombing while looking for coins and jewelry, and archeologists also use them for various scientific tasks. The features and capabilities of the nonindustrial, handheld metal detectors are summarized in Table 7.12d.

TABLE 7.12d
Capabilities of Hand-Held Metal Detectors

		*Detection Range**	
Operating Mode	*Medium*	*Object*	*Distance, in. (cm)***
Transmitter-receiver	air	dime	3–6 (7.5–15)
	water	dime	4–7 (10–17.5)
	sand	dime	6–7 (15–17.5)
Transmit-receive, very low frequency	air	dime	6–8 (15–20)
	water	dime	6–8 (15–20)
	sand	dime	6–7 (15–17.5)
Beat frequency oscillator	air	dime	6–7 (15–17.5)
	water	dime	6–7 (15–17.5)
	sand	dime	6–7 (15–17.5)

*Range or distance to target depends on operator skill.

**Instrument sensitivity, i.e., the maximum distance at which a specific target can be detected, is determined by the size of the subject, the purity of the metal, the medium, and the output power of the unit.

7.13 Noise Sensors

H. C. ROBERTS (1972, 1982) **B. G. LIPTÁK** (1995, 2003)

Applications:	A. Noise/sound level measurement for Occupational Safety and Health Adiminstration (OSHA) and Department of Transportation (DOT) compliance B. Sound spectrum and acoustic emission analysis for nondestructive testing and safety applications
Designs:	For sound level measurements in air, microphones are used; for measurements in water, hydrophones are used
Ranges:	30 to 140 dB
Frequencies:	Usually from 20 to 20,000 Hz; special devices can be used to measure from 0.1 to 40,000 Hz
Inaccuracy:	Generally ±2 dB for OSHA and DOT compliance; up to ±0.5 dB in special designs
Operating Temperature and Relative Humidity:	Generally from 15 to 150°F (–9 to 65°C) at up to 95% relative humidity
Weighing of Sound Level Meters:	Different weights are applied at high-, middle-, and low-frequency decibel levels. As shown in Figure 7.13a, the international standard for acoustic weighing includes curve "A," which approximates the human ear; "B" gives combined high- and midfrequency decibels; and "C" reads all frequencies but gives better response at lower frequencies.
Costs:	Hearing protector earmuffs cost about $25. Acoustical calibrators cost about $200. A battery-operated sound level meter operating with "A" weighing and provided with acoustical calibrator costs about $700; a similar meter with "A, B, C" weighing costs about $900. Computerized installations of acoustic emission analyzers for nondestructive testing using piezoelectric sensors can cost up to $100,000.

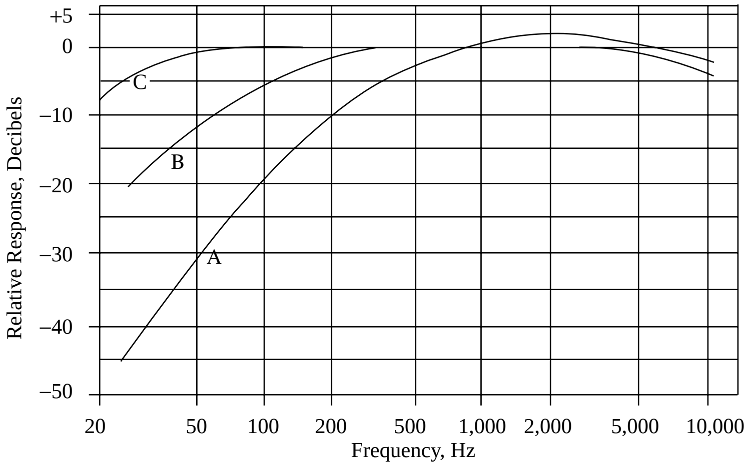
NATURE OF THE MEASUREMENT

Acoustic noise (sound) is defined as an oscillation in an elastic medium, occurring within the frequency range to which the human ear is sensitive: that is, from approximately 20 to 20,000 cycles per second (Hz). The elastic medium is usually air, and occasionally a liquid such as water. Sound waves occur as pressure waves or as particle-velocity or particle-displacement waves; any of these three waveforms can be measured. In water, because of its



Permissible Noise Exposure

½	110
¼ or Less	115

FIG. 7.13a

Curves A, B, and C describe the international standards for acoustical weighing networks, with curve A representing a response similar to the human ear.[1]

limited compressibility, only pressure waves are usually measured.

The pressure variations to be measured are small. At the threshold of audibility for the normal human ear, the root mean square value of pressure is about 20 μN/m^2. At the threshold of feeling for the normal ear, the pressure will be perhaps 200 N/m^2—10 million times as great, yet still only one one-thousandth of the atmospheric pressure. Consequently, the effect of steady pressure must be eliminated; the sensing device does not respond to it.

A scale of logarithmic units is used to describe sound pressure levels because of the extremely wide range of sound pressures that may be measured. In measuring the sound pressure, the measured pressure is compared with a standard pressure (that at the threshold of hearing, 20 μN/m^2) using the following formula:

$$SPL = 20\log_{10}(P_m / P_{\text{ref}})\text{dB re } 20\ \mu N / M^2 \qquad \textbf{7.13(1)}$$

where SPL = sound pressure level, P_m = measured pressure, P_{ref} = reference pressure, and dB = the logarithmic unit, which describes sound levels.

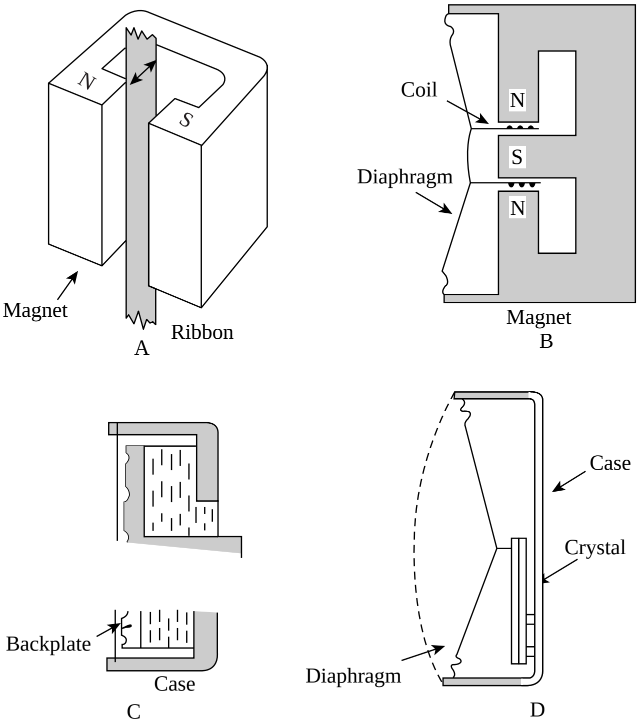

FIG. 7.13b

Construction of microphones.

TRANSDUCER PRINCIPLES

Conversion of pressure variations into an electrical output may be accomplished by several means; the most popular of these are inductive, dynamic, electrostatic, piezoelectric (or electrostrictive), and resistance variation.

The Inductive Principle

The inductive principle uses the variation of reluctance in a magnetic circuit, and iron reed (or a suspended iron armature) is made to vibrate by the sound waves and thus to change the air gap in a magnetic circuit. A coil of wire is placed around an element of that magnetic circuit, and an electromotive force appears at the terminals of the coil; its waveform represents the waveform of the sound. Inductive or magnetic microphones are used mostly for low-quality but high-level applications; they are not usually very precise devices.

The Moving-Conductor Principle

The moving-conductor principle—a conductor moving (and cutting lines of force) in a magnetic field—is used effectively in microphones. One form is the ribbon microphone. Here a very thin, lightweight metal ribbon is suspended in a magnetic field (see A in Figure 7.13b). Sound waves striking the ribbon causes it to move, generating an electromotive force, which is fed to an amplifier input. The ribbon is extremely thin and light; it effectively follows the motion of the air particles. Its velocity is approximately equal to the velocity of the air particle motion, since the entire area of the ribbon is exposed to the sound waves and moves in unison with them.

Dynamic Microphones

Dynamic microphones also employ the moving-conductor principle; a lightweight diaphragm carries a coil of wire that moves within a magnetic field, as shown at B in Figure 7.13b. Sound waves strike the diaphragm; their pressure causes the coil to move, and an electromotive force is produced at the coil terminals and fed through a suitable transformer to an amplifier. These microphones are pressure-actuated, since the diaphragm (and the coil) moves in response to sound wave pressure.

Capacitor Microphones

Capacitor (condenser) microphones depend upon a fundamental principle in electricity: when some amount of electrical charge is held within a capacitor, the electrical potential between the condenser plates will change if the capacitance is changed. Thus, in a capacitor consisting of two plates, one of which is movable—as at C in Figure 7.13b—movement of one plate will change the capacitance and the potential between the plates will change in response. A change in air pressure, caused by sound waves, actuates the capacitor microphone. The initial electrical potential may be supplied from a separate source through a high resistance, or the electrical charge may be provided by making either the backplate or the diaphragm of a material that has been given a permanent electrical charge (an electret).

The carrier-type capacitor microphone is structurally like that illustrated in C of Figure 7.13b, but its electrical circuitry is different. No polarizing potential is used. Instead, the capacitance of the microphone is made a part of an electrical oscillating circuit, so that a change in capacitance causes a change in frequency—the circuitry converts this change to the kind of output desired. This permits operation down to steady pressures (zero frequency), which is not possible with the usual circuitry.

Piezoelectric Microphone

The piezoelectric microphone depends on a specific behavior of some crystalline materials: a deformation of the crystal will cause electrical potentials to appear on the surfaces of the crystal. The magnitude of the potential is in proportion to the force that is causing the deformation. The assembly shown in diagram D of Figure 7.13b indicates a typical construction; a diaphragm receives the sound waves and applies their force to the crystal element, causing it to bend. The crystal element is usually an assembly of thin slices called a bi-morph; this is an efficient and convenient form for the application.

In years past, most piezoelectric microphones used crystal elements made of Rochelle salt or of ammonium dihydrogen phosphate. Recently, various ceramic products have been developed with suitable characteristics for this use; they may be called electrostrictive rather than piezoelectric, but they serve the same function.

MICROPHONE TYPES

The most widely used microphone is the resistive device called the carbon telephone transmitter. Its characteristics make it unsuitable for most quantitative uses, but it is excellent for voice communication.

A useful way of classifying microphones is according to type of response: the instrument can be actuated either by the velocity, displacement, or pressure of the sound waves. The distinction is not always entirely clear-cut.

Ribbon Microphone

The ribbon microphone (in its usual form) responds to velocity; the moving ribbon is light, flexible, and easily moved. Because of this, it needs no added mechanical damping and its motion is very nearly identical with the air particle motion; its electrical output is also proportional to velocity. But a ribbon microphone can be made into a pressure microphone. The sound waves may be made to pass through a pipe before they reach the ribbon, and this pipe may be so damped that it acts as an acoustical resistance, controlling microphone characteristics. This permits some desirable control over frequency sensitivity. The usual form of ribbon microphones does not offer this control. Its damping is a result of its construction, and it is quite insensitive to even large changes in steady pressure.

Diaphragm Microphone

Microphones that employ elastic diaphragms are nearly all pressure types. This is becasue the velocity of the coil motion (in the dynamic microphone), the diaphragm displacement (for the condenser microphone), and the crystal deformation (in the piezoelectric) are all in proportion to the applied force—the instantaneous sound pressure. For this to be true, the microphone structure must be properly designed, the elastic deformations must be linear, and there must be suitable damping.

Air leakage from the interior of the microphone to the atmosphere is usually provided for damping. This leakage occurs through small tubes that add the proper acoustical resistance. Damping in the condenser microphone is difficult because the diaphragm is very close to the back-plate; grooves in the back-plate solve this problem.

Special Microphones

Pressure-gradient microphones are sensitive to the difference in pressure between two points separated by a finite distance; thus, they provide a form of velocity response. They are

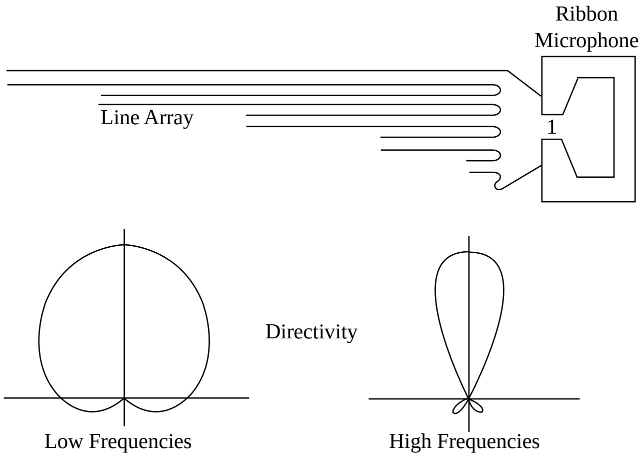

FIG. 7.13c
A line microphone.

usually special purpose devices and can be given some very specific directional characteristics.

Parabolic Reflector Microphone When extremely high directivity is required, other special forms are available. The most popular of these are the parabolic reflector microphone and the line-type microphone. The line microphone uses an array of pickup tubes of varying length; the sound that reaches the microphone through these tubes adds vectorially, making high directivity possible, though uniformity of frequency response suffers. In Figure 7.13c, the array is sketched and the general type of frequency response is shown. Microphones of these two types are often called wave microphones.

Special Purpose and Ultrasonic Units Some special purpose, sound measuring devices have been developed that are sensitive to the energy of sound but not to delineating waveform. Examples include the hot-wire microphone, the Lindval glow microphone, and the Rayleigh disk. They do not seem to be applicable, in general, to industrial use. The Rayleigh disk, however, is still a practical device for calibration.

Ultrasonic microphones form a special class. They respond only to frequencies above the hearing range: about 25,000 to 45,000 Hz. They are widely used in remote control devices, gas leak detectors, guidance devices (as for the blind), and the like. They are usually piezoelectric units; the crystal may be made resonant at some frequency.

MICROPHONE CHARACTERISTICS

In selecting a microphone, the user is seldom particularly interested in the physical principles involved in its construction. It is the microphone's operating characteristics that are of more interest. Table 7.13d provides data on the characteristics of the various microphone designs.

Sound Sensitivity, Incidence, and Direction

The sensitivity of microphones can be given in volts per unit of pressure; a typical condenser microphone might produce about 10 mV for a sound pressure input of 1 N/m^2. Trade practice often describes microphone sensitivities in terms of

TABLE 7.13d
A User's Classification of Microphones

Type of Microphone	*Frequency Response Range, Hz*	*Output, dB**	*Typical Characteristics*	*Typical Use*
Carbon telephone transmitter	300–4,000 (useful range)	–25 to –45	Inexpensive, with high output in the speech frequency range	Telephone
Capacitor microphone	12–15,000	–48	Extremely stable, wide, and flat frequency response	Measurement of sound level
Carrier-type capacitor microphone	0.1–20,000	Depends on auxiliary unit	Widest possible frequency response; uses auxiliary electronics, with any of several microphone units	Measurement of sound in extreme conditions
Crystal microphone	30–12,000	–65	Good frequency response, usually semicardioid pattern; often temperature sensitive	Public address, recording
Cardioid microphone	20–12,000	–80	Good frequency response, cardioid or "unidirectional" pattern	Public address, recording, etc.
Ribbon microphone	20–15,000	–85	Good frequency response; can be used either as pressure or velocity type	Live performance, recording
Wave microphone	80–8,000	–80	Can be highly directional, because of construction	Broadcasting, special uses

* Microphone sensitivity in terms of 0 dB = 1 $V/dyne/cm.^2$

decibels referred to 1 V/dyne/cm^2. (The example just given would be 40 dB.) One dyne per square centimeter is about 74 dB on the usual scale of sound pressure levels. Amplification is always needed; amplifier characteristics must be suited to the microphone characteristics.

The direction from which sound waves reach a microphone usually has some effect on the output produced. A pressure microphone should measure pressure at a point; the smaller the microphone size, the nearer the approach to this condition. At high frequencies, an error may appear, if, for example, the diameter of the microphone diaphragm is equal to one wavelength of the sound. A series of waves striking the diaphragm at nearly grazing incidence may cause almost no net effect—a far different result from that produced by the same series of waves striking normal to the surface (Figure 7.13e) Typically, sound in a room is directed diffusely; it comes from all directions. If high accuracy is required at frequencies above about 10,000 Hz, this must be considered.

In general, microphones are classified as omnidirectional, unidirectional, or bidirectional. These classifications are only approximately accurate, but the terms are useful guides. An omnidirectional microphone (see A in Figure 7.13f) displays early uniform sensitivity to sound coming from all directions; one would probably use such a microphone for measuring sound levels in a room. Bidirectional response (see B in Figure 7.13f) is of great value in such instances as broadcasting and live stage performances. Ribbon microphones provide bidirectional response if both sides of the ribbon are exposed to the sound. If only one side is exposed, the response pattern becomes cardioidal, as shown in C of Figure 7.13f.

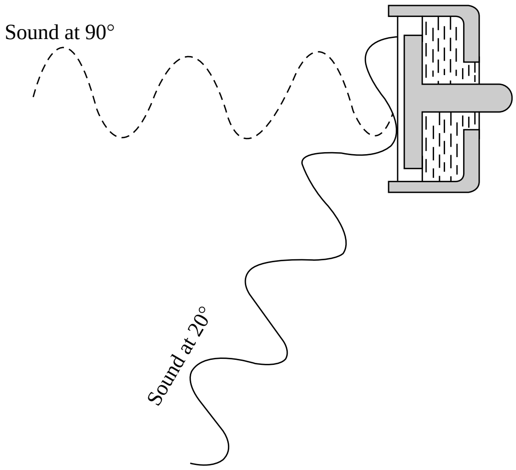

FIG. 7.13e
Normal incidence versus grazing incidence for sound waves.

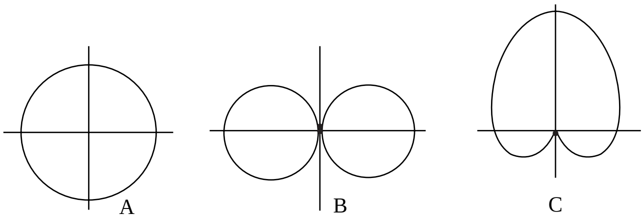

FIG. 7.13f
Typical directivity patterns for microphones.

Frequency and Amplitude Ranges

The possible frequency range of a microphone depends on both its operating principle and construction. Nearly all modern microphones are quite flat over the usual range of the human ear (see Table 7.13d). Dynamic microphones and diaphragm-type crystal microphones depend on good design and construction, including proper damping, to ensure uniform response with no noticeable resonance peaks. Condenser microphones have a much smaller moving mass, as do ribbon microphones, and have fewer mechanical problems; their frequency limitations are more likely to appear in the electronics associated with them. Manufacturers' data usually describe these factors adequately.

The amplitude range, which a particular microphone can accept, depends on its construction; pressures that are too high can cause mechanical damage. Most microphones can tolerate the maximum acceptable to the human ear—perhaps a 140-dB sound-pressure level—but special forms are available that can be used successfully at much higher levels.

Hydrophones

For use under water, special forms are available. These are microphone units installed in strong housings arranged in such a way that the vibratory components of pressure may enter, but because of the depth of immersion, the steady component does not. These are usually called hydrophones. They require special cables and often special electronics.

With modern microphones, the stability of microphones—the constancy of the rates of output to input at all frequencies and under all conditions—is usually more dependent on environmental considerations than on elapsed time. Figure 7.13a lists the permissible noise exposures and describes the international standards for acoustical weighing networks.

ENVIRONMENTAL CONSIDERATIONS

Microphones may be exposed to extremes of temperature and humidity, mechanical shock, magnetic fields, and other factors. Any of these can affect sensitivity and frequency response, either on a temporary or a permanent basis.

Protection from mechanical damage is obviously desirable; the rather delicate mechanical suspensions can be damaged, crystals cracked, etc. Dust can clog the equalizing openings between the interior of the microphone and the outside, thus impairing the frequency response. Reasonable care should be taken to protect this moderately delicate equipment.

Dynamic microphones contain permanent magnets; exposure to strong magnetic fields could weaken these and change the sensitivity of the microphone. If the microphone is used in magnetic fields, there could be noise pickup by either the microphone or its cable. The same is true for ribbon microphones; they may be even more vulnerable to pickup of AC. AC fields should be avoided in the use of any such equipment.

Crystal microphones are not usually greatly affected by temperature within reasonable ranges, though this was not true of earlier models. They can, however, pick up noise from electrical fields.

Condenser microphones are usually extremely stable for most conditions, but moisture can seriously impair their response. They contain high-quality insulating materials, but they are not entirely unaffected by humidity. Their electronic auxiliaries also may be vulnerable to environmental effects.

It is always possible that microphone characteristics may change. However, modern microphones are extremely good. The manufacturer's information is usually a reliable guide.

One environmental effect—wind—is extremely troublesome. Wind produces microphone noise, which can be reduced by windscreens installed on the microphone.

CALIBRATION

Calibration at appropriate intervals will detect, and perhaps correct, most changes that occur over periods of time. Microphones may be supplied with nominal sensitivity values, but microphones intended for measurement are usually supplied with detailed calibration data. The electronic equipment used with the microphone becomes a part of the calibrated system.

Precision calibration of microphones may be done by several procedures; this is beyond the scope of this discussion. The user is interested in day-to-day checks to establish that no perceptible change has occurred. Some manufacturers provide precision calibration for their units at the necessary intervals.

Portable calibration devices are available from most suppliers of microphones. They are usually small sound sources that can be used on individual microphones; it is important that the correct procedure be used. Again, the recommendation of the manufacturer should be followed.

Section 7.10 described the sensors available for the measurement of linear and angular positions. Section 7.20 is devoted to the measurement of thickness and other dimensions. This section concentrates on limit switches and on the measurement of proximity.

INTRODUCTION

Sensors for the measurement of position, displacement, and proximity may use resistive, capacitive, inductive, or photoelectric methods. Displacement sensors can mechanically sense the position of an object relative to a fixed reference point. Proximity sensors can also measure linear or angular motion but without making physical contact with the detected object.

Typical applications include the inspection or detection and control of the position of machine tools, manufacturing systems, or moving components of valves and dampers. They are used as safety sensors or operational limit controls in packaging, printing, molding, and chemical and food processing industries.

CAPACITIVE SENSORS

In these sensors, a high frequency oscillator creates a field in the surroundings of the sensing surface. The presence of any capacitive object in these surroundings causes a change in the oscillation amplitude, and a threshold circuit detects that change and generates the output. The triggering distance depends on the size, shape, and material of the object. If the sensitivity to metals is taken as 1.0, the sensitivity to water is also 1.0, plastic or glass is 0.5, and wood is 0.4. Usually a screw is placed on the capacitive sensor, which allows regulation of the operating distance.

Capacitive sensors are more often used for linear than angular proximity measurements. Either the dielectric or one of the capacitor plates is movable for displacement measurement. Capacitive proximity sensors use the measured object as one plate, and the sensor contains the other plate. The capacitance changes according to the question.

$$C = k/d \qquad \textbf{7.14(1)}$$

where

k = is a constant, depending on the area of the plates and the dielectric constant

d = the distance between the plates

Capacitive transducers are available with packaged signal-conversion circuitry for DC output operation.

Capacitive sensors are widely used for dimensional inspections in large-volume manufacturing operations, such as the filling of containers or the monitoring of the wearing of moving surfaces. In nonconductive materials (glass, plastics, wood), the switch detects the change in dielectric constant; in conductive materials, an additional signal is produced by terminal conductivity. The proximity switches illustrated in Figure 7.14a can detect liquids, glass, plastic, wood, or metallic objects. For the proximity switches shown, the sensing distance can be fixed or adjustable between 0.1 and 1.0 in. (3 to 25 mm).

Proximity switches provided with sensing plates can operate over a range of 0.2 to 5 in. (5 to 127 mm), can detect capacitance changes down to 0.02 pF, and can detect more than 100 operations/s. The switch is operated when the capacitance caused by the approaching object exceeds the reference level set to trigger the switch.

INDUCTIVE SENSORS

In this type of proximity switch, similar to the capacitive one, an electromagnetic field is generated by a high frequency (radio frequency) oscillator circuit in front of a coil. If a metallic object moves inside the field generated by the sensor, an eddy current is generated in the metallic object, which loads the oscillator and causes a voltage drop in it.

Figure 7.14b shows the sensing envelope of the switch for a particular target size. The envelope increases with target size and decreases with nonferrous metals. The target can enter this envelope axially or laterally and is detected when they first touch the envelope. This switch is also called a self-contained proximity switch or an eddy-current killed oscillator design.

The outside appearance is similar to the capacitance units shown in Figure 7.14a. The sensing face of the probe contains the coil. The switch has no moving parts and therefore its mean time between failure is long, about 200,000 hours. It is also immune to shock and vibration and can be connected directly to programmable logic controllers. Detection ranges can vary from 0.1 to 2 in. (2 to 50 mm). Typical applications

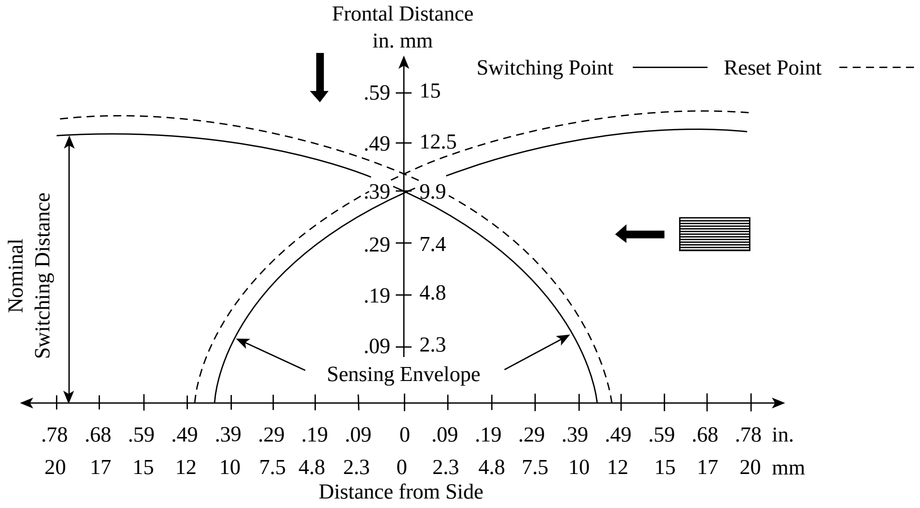

FIG. 7.14b
The sensing envelope of an induction-type proximity switch for a steel target size of 1.6 × 1.6 × 0.03 in. (41 × 41 × 1.5 mm).

include machine tools, material handling, packaging, and conveyors.

MAGNETIC SENSORS

Magnetic sensors are actuated by the presence of permanent magnets. The magnetically actuated reed switch consists of two low reluctance ferromagnetic reeds enclosed in glass bulbs filled with inert gas. The reciprocal attraction of both reeds in the presence of a magnetic field, caused by magnetic induction, closes an electric contact.

For this design to function, the object to be detected must contain a magnet. When the actuating magnet reaches the actuating distance from the reed switch, the contact is closed. These switches can operate the loads directly (without relays) because their contact ratings are around 15 VA. Their natural applications are in the area of counting the rotation or reciprocation of objects. Their speed of closure can approach 100/s, and their life expectancy is in the tens of millions of operations.

A proximity switch that is used less often is the variable reluctance sensor, which alters the voltage generated at its coil terminals as an object distorts its magnetic flux. This principle is more often applied in connection with rotating machinery, such as tachometers for speed measurement.

Hall-Effect Sensors

One of the most successful magnetic proximity switches is actuated by the field of magnets due to the Hall effect. Their most common actuator is a moving permanent magnet. As shown in Figure 7.14c, the magnet movement can be head-on or slide-by. The curves are based on a microswitch standard magnet, which is 1.25 in. (31.8 mm) long and 0.25 in. (6.4 mm) in diameter.

The induction (gauss) of the Hall-effect sensor varies with the distance to the magnet. This switch eliminates the contact-bounce problem of mechanical limit switches and provides a directly computer-compatible output. Speed of operation is about 25 kHz. The Hall-effect switch is not recommended for use in areas where high magnetic fields are present, and its connecting wires should not be run in the same conduit with high-power lines.

Linear Variable Differential Transformer Sensors

Another magnetic effect position sensor is the linear variable differential transformer (LVDT), which produces an AC voltage that is proportional to the displacement of a movable ferromagnetic core. These units are more often used as position or force transducers than as proximity switches, but it is possible to use them in that mode.

Inductive sensors consist of single-coil units, which use a change in self-inductance of the coil, and multiple-coil units, which rely on the change in magnetic coupling or reluctance between coils. Single-coil displacement sensors use a movable core to change the self-inductance. Single-coil proximity sensors use the magnetic properties of the object itself to modify the self-inductance. The change in inductance is usually sensed with a bridge circuit or oscillator.

Multiple-coil inductive sensors consist of the differential transformer and its variations. The LVDT uses three windings and a movable core to sense linear displacement.

A typical LVDT configuration is shown in Figure 7.14d. The transformer's secondary windings are wound to produce opposing voltages and connected in series. With the core in the neutral or zero position, voltages induced in the secondary windings are equal and opposite and the net output is a minimum. Displacement of the core increases the magnetic coupling between the primary coil and one of the secondary

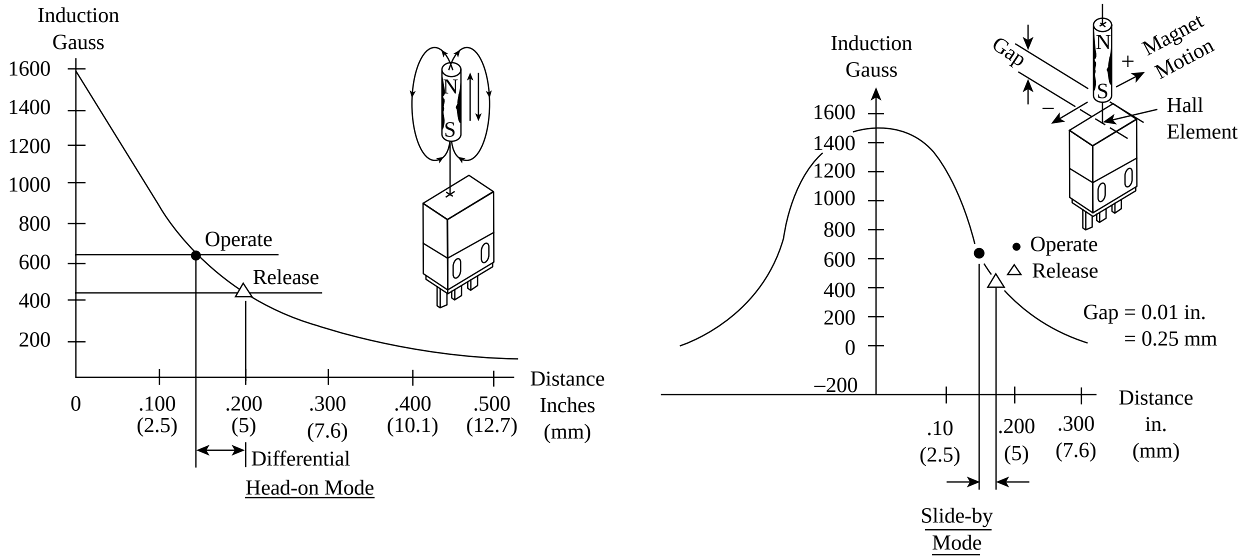

FIG. 7.14c

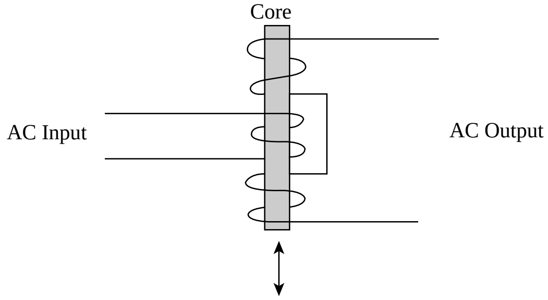

FIG. 7.14d
An LVDT configuration.

coils and decreases the coupling between the primary coil and the other secondary coil. The net voltage increases as the core is moved away from the center position, and the phase angle increases or decreases as a function of the direction in which the core is moved.

A demodulator circuit can be used to produce a DC output from this winding configuration. Differential transformers are also available for angular measurement in which the core rotates about a fixed axis.

Variations in winding configurations are used in synchros, resolvers, and microsyns. Inductance bridge sensors utilize two coils with a moving core to change the inductance of the coils that form one half of an AC bridge. These sensors are available in linear and angular configurations.

MECHANICAL LIMIT SWITCHES

The mechanical limit switches are the oldest position detectors. They were developed before solid-state electronic devices became available. They are installed so that the object that is being detected moves the lever, plunger, or wobble stick of the switch, and when the object has passed, either a spring or gravity acts to return the switch to its original state. The roller lever design of this switch is illustrated in Figure 7.14e. These units are well suited for detecting millions of repetitive operations in relatively dirty industrial environments where water- and oil-tight designs are required.

OPTICAL SENSORS

These sensors consist of a light source (emitter) and light receiver and depend on light-sensitive elements to detect the presence of objects. Three types are available:

1. Direct Reflection—The emitter and receiver are housed together and use the reflected light directly from the detected object.
2. Reflector with Reflector—The emitter and receiver are housed together and require a reflector. In this design, the object is detected when it interrupts the light beam between the sensor and the reflector.
3. Thru Beam—The emitter and receiver are housed separately and they detect the object when it interrupts the light beam between them.

Photoelectric and laser devices are capable of measuring position, thickness, flatness, length, and other dimension-related properties. The available proximity switch designs can be grouped according to the:

1. Light source (incandescent, light emitting diodes [LED], infrared, laser)
2. Detector used (photocells, photo-transducers)

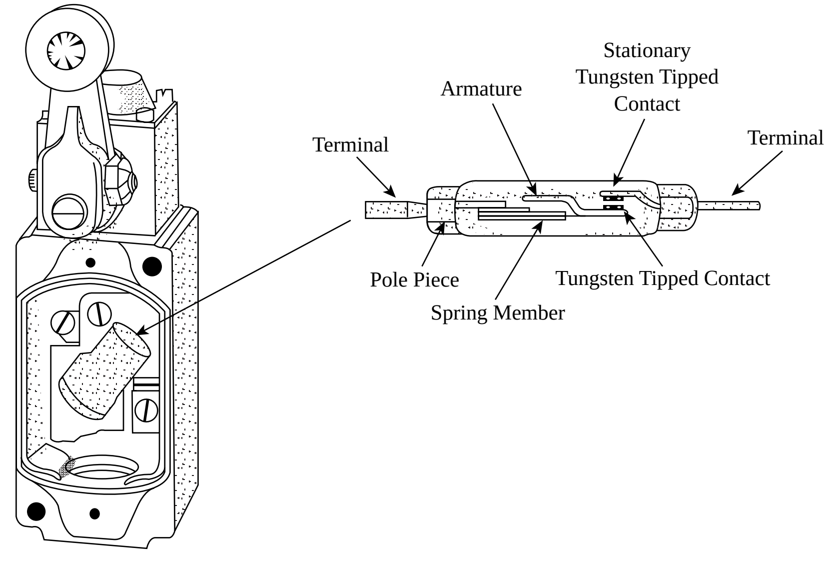

FIG. 7.14e

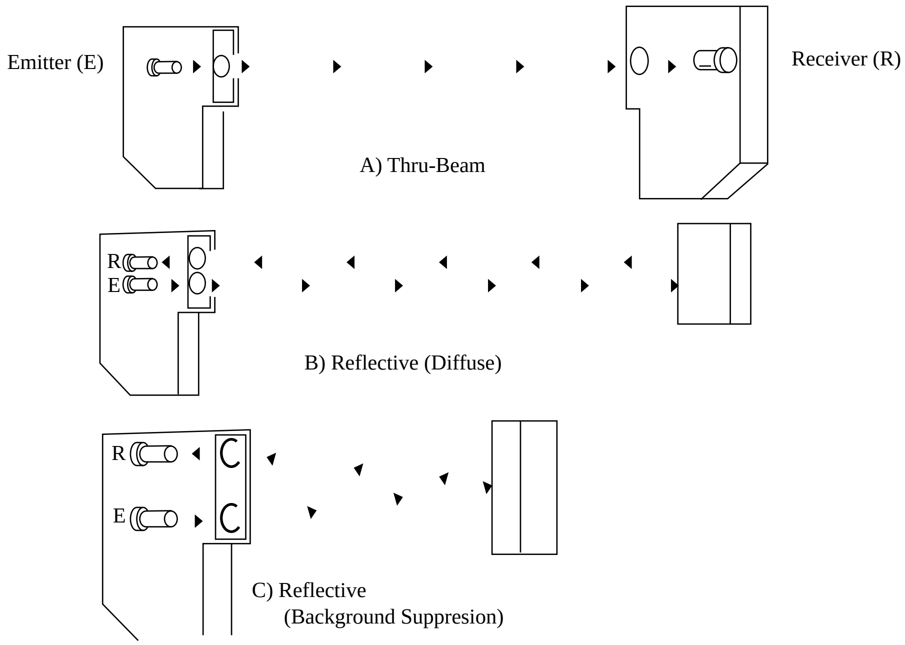

FIG. 7.14f
Thru-beam and reflective installation of photoelectric sensors. (Courtesy of Baumer Electric Ltd.)

3. Light path (thru-beam or the reflective mode, which can be implemented in the diffuse; specular, retro-reflective, or fiber-optic configurations)

Photoelectric sensors can detect the presence or absence of opaque or translucent objects at distances from a few millimeters to several hundred feet or meters. They do not require physical contact; are relatively inexpensive; and are well suited for counting, mail and package handling, security surveillance, and many other applications.

Light Sources

What distinguishes the different light sources is their immunity to interference from sunshine and their loss of intensity as distances increase. For example, laser sources tend to allow for longer ranges, while immunity from natural light is obtained by using pulsed infrared (IR) light.

The IR light can be obtained from infrared emitters (such as gallium arsenic), from incandescent light sources filtered by mechanical choppers, or from LEDs. The LEDs respond only a narrow IR frequency band and therefore are unaffected by visible light. They are superior in their life expectancy, about 100,000 hours, which is ten times that of incandescent lights, and in their suitability for direct modulation.

Incandescent sources, due to their wide spectrum from ultraviolet to IR, have the advantage of being able to distinguish and detect colored targets.

Light Detectors

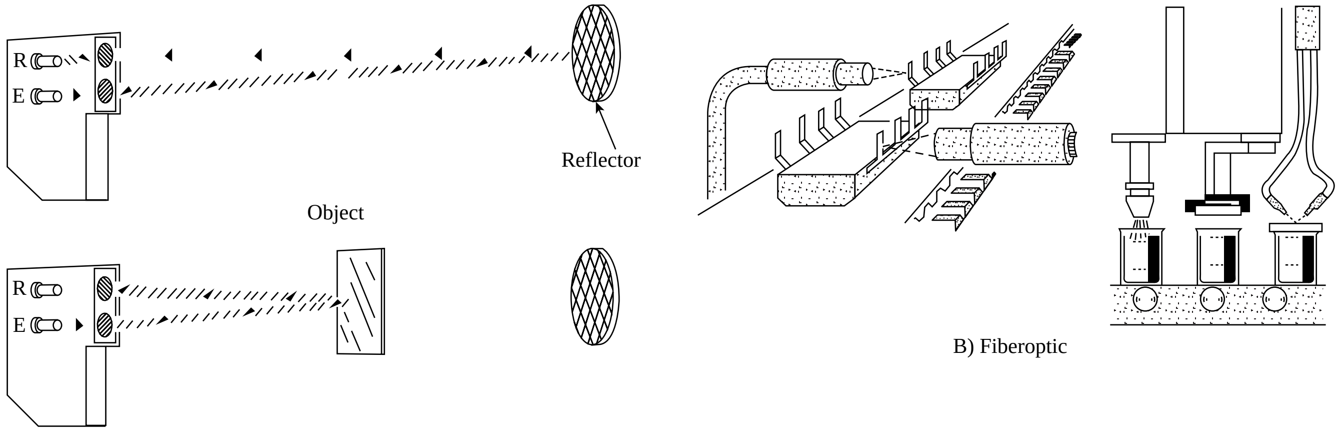
The two main types of light detectors are photocells and phototransistors. Both are photoconductive devices that increase their electric conductivity as they absorb light or radiation at other wavelengths. Photocells are made from cadmium sulfide and cadmium selenide. Their speeds of response change with the amount of light absorbed, and they have a greater response at longer wavelengths (red and IR) than in the blue-violet area.

Phototransistors and photodiodes are ideal matches for infrared LED sources because they are most sensitive in the IR region. Their response is faster than that of the photocells, but they are less sensitive and their response is affected by temperature.

Optical Detector Installations

The photoelectric sensors can be installed in thru-beam or reflective configurations (Figure 7.14f). In the thru-beam configuration, the light emitter and receiver are positioned opposite to each other and the detected object passes between them. The thru-beam configuration offers the longest scanning distances, exceeding 100 ft (30 m). In the standard design, the detected object must have a diameter which is 50% of that of the lens. When converging lenses or laser sources are used, this limitation no longer applies.

Reflective In a reflective installation, the emitter and receiver are located on the same side of the detected object. Figure 7.14f illustrates two reflective installations: diffuse and background suppression (secular). In diffuse sensing, the light beam (usually IR and pulsed) directly hits the target and is diffused (reflected) in all directions. In this configuration, only a small percentage of the light is returned to the receiver and the measurement distance is limited. The design is suited for detecting objects with dull surfaces and for distinguishing between black and white targets.



A) Retroreflective

B) Fiberoptic

FIG. 7.14g
Retroreflective and fiber-optic sensors. (Courtesy of Baumer Electric Ltd.)

Figure 7.14f also illustrates a method of background suppression. There the light is precisely focused within a precisely defined scan range. This technique is suited for the detection of small objects or for detecting the contents within transparent packaging. In specular reflective sensors, the light is directed at a reflective surface at an angle and the receiver is positioned to detect the reflected light at the same angle. This technique is used on shiny plastic, polished metal, and similar applications.

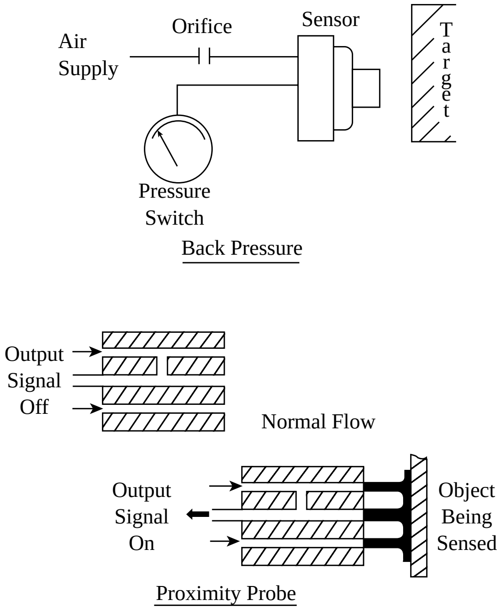
Retroreflective In retroreflective sensors (Figure 7.14g) the emitter and receiver are in the same housing and the light beam is directed at a target that is retroreflective, meaning that it returns the light along the same path over which it was sent. The receiver recognizes the detected object by the returned light beam being interrupted. The detected objects must be opaque and should not be very shiny. The scan ranges available from these units (up to 30 ft, or 10 m) are greater than with diffuse sensing.

Optical Fibers The addition of optical fibers can enhance the performance of both thru-beam and reflective sensors, particularly in terms of their ability to accurately detect objects as small as 0.002 in. (0.05 mm). The triple-beam version of the fiber-optic design can detect objects as small as 0.0002 in. (0.005 mm) at speeds of 0.5 m/s.

The precision of fiber-optic sensors is surpassed only by triple-beam laser detectors, which are capable of detecting dimensions to a resolution of microns.

PNEUMATIC SENSORS

Pneumatic gauging is widely used in manufacturing to check the diameters of holes, the dimensions of manufactured products, or the contour of devices. In proximity switch applications, an orifice-regulated constant air supply is used. When the airflow is obstructed by the object being detected, the back-pressure builds up, and this rise in pressure is detected by a switch (Figure 7.14h). This technique can be used to check dimensions by setting the back-pressure switch to actuate at the desired value.



Back Pressure

Proximity Probe

FIG. 7.14h
Pneumatic proximity switches can detect only small air gaps. (Courtesy of O'Keefe Controls.)

Another pneumatic proximity probe configuration (also shown in Figure 7.14h) detects the presence or absence of an output signal. This miniature proximity probe generates an output signal only when there is an object in its sensing range, causing a reflection of the air jet. These devices are capable of detecting distances up to 0.125 in. (3.2 mm).

ULTRASONIC SENSORS

Ultrasonic sensors are used both as thickness gauges (see Section 7.20) and as proximity switches. Only the proximity sensors will be discussed here. The proximity design detects

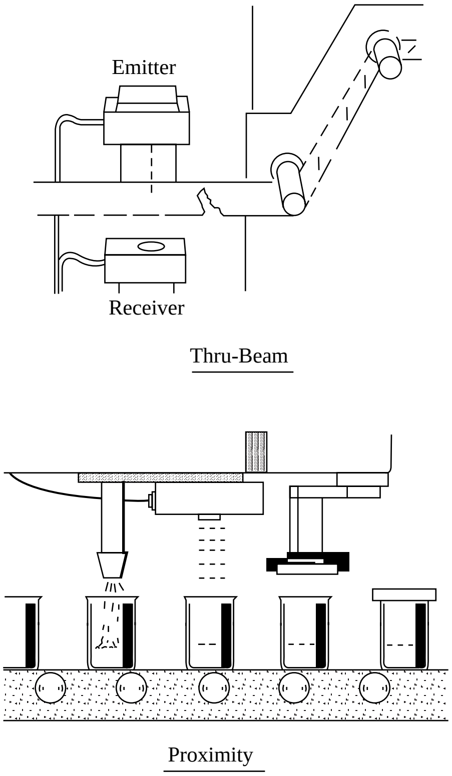


FIG. 7.14i
Ultrasonic proximity switches of thru-beam and proximity designs. (Courtesy of Baumer Electric Ltd.)

the distance between the transducer and the measured object by transmitting an ultrasonic (1 to 5 MHz) burst of energy and sensing the time of arrival of the echo. In the thru-beam type design, the emitter sends out a continuous sound signal and the presence of a detected object is noted by its breaking that sonic beam.

Both of these designs are shown in Figure 7.14i. The high frequency used protects from the interference of most extraneous noise sources. The preferred surface of the detected object is smooth and flat; hot or sound-absorbing surfaces or surfaces in the presence of strong air streams are not suitable for this type of detection. The detectable object size varies with distance and surface quality and, in general, is much larger than with optical sensors.

DIGITAL OUTPUTS AND ENCODERS

Proximity sensors can generate either digital outputs or pulses. They detect the changes that are occurring in either electrical conduction, induction, or photoelectric conduction.

Conducting encoders use brushes or wipers to detect the position of a coded disk or plate. If a single track is employed, a number of pulses are produced as the disk or plate is moved. Direction is detected by adding another track, which is offset to produce sequence logic. Electronic counting circuitry is used to count the number of pulses and perform the conversion to angular or linear measurement. Multiple-track encoders provide a digital or binary coded output, which is a function of the absolute angular or linear position.

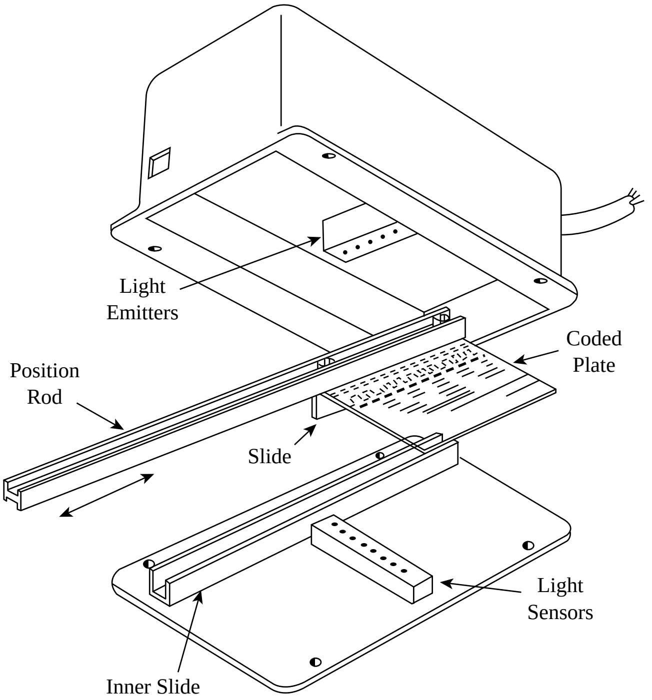

FIG. 7.14j
Digital displacement sensor.

Magnetic proximity sensors can be employed with gears of ferromagnetic material to produce pulses from a change in linear or angular position. Direction sensing can be obtained by shaping the gear teeth in a symmetrical pattern in order to modify the output waveform.

Photoelectric encoders use a light source and the detector with disks or plates of transparent and opaque windows. Operation is similar to conducting encoders except that switching is accomplished by breaking the path of the light beam between the source and detector. Multiple-tracked encoders may use arrays of sources, such as LEDs, and detectors as shown in Figure 7.14j.

The laser interferometer uses a laser beam that is directed as a reflector on the measured object. Changes in the linear displacement of the object produce interference fringes, which are counted by electronic circuitry.

APPLICATIONS

Proximity sensors are selected the same way as most measuring instruments, namely, by first considering the technical and then economic requirements. In DC systems, potentiometric transducers are often used because of their simplicity, strong outputs (50 V or higher), and displacements (up to 24 in., or 0.61 m).

Reluctive transducers with DC-to-DC conversion circuitry offer displacements between 0.01 and 120 in. (0.25 mm and 3 m). Capacitive and inductive proximity sensors as well as photoelectric sensors can be used to detect displacement changes as small as 1 μin. In AC systems, multiple-coil inductive sensors are used more than all others. Maximum accuracy can be obtained with incremental and absolute digital displacement sensors along with photoelectric units such as interferometers.

B. G. LIPTÁK (2003)*

INTRODUCTION

Protection against overpressure is one of the most important design tasks in the chemical, petrochemical, oil, and gas industries. The various causes of overpressure fall into two broad categories: fire conditions and process conditions. The purpose of overpressure protection systems is to reduce or eliminate the potential for overpressure-initiated explosions and fires.

For the sizing, selection, and specification of pressure relief valves (PRVs), refer to the next section; for a discussion of rupture disks, see Section 7.17. In this section, the determination of the required relief capacity is discussed. The section begins with an explanation of the methods for relief capacity determination for fire protection. The second half of the section discusses some relief capacity determination techniques for other, nonfire process causes of overpressure conditions. This section is concluded by a listing of PRV-related terms and definitions, followed by a bibliography.

APPLICABLE CODES AND STANDARDS

Four major sets of codes and standards need to be considered when designing pressure relief systems. These have been prepared by the American Society of Mechanical Engineers (ASME), the American Petroleum Institute (API), the National Fire Protection Association, and the Occupational Safety and Health Administration (OSHA).

ASME Codes

The pressure relief requirements of both boilers and of pressure vessels are covered in the *ASME Boiler and Pressure Vessel Code.* Section I of this code describes the requirements for steam generators, fired boilers, and associated tanks, whereas Section VIII of this code covers the pressure relief requirements of unfired pressure vessels. The requirements of these two sections yield different results, and neither of the two sections covers the pressure relief requirements of storage vessels, which are designed for pressures under 15 PSIG.

Excerpts from ASME Code

UG-125(c)—All pressure vessels other than unfired steam boilers shall be protected by pressure-relieving devices that shall prevent the pressure from rising more than 10% or 3 psi, whichever is greater, above the maximum allowable working pressure except as permitted in (1) and (2). (See UG-134 for pressure settings.)

(1) When multiple pressure-relieving devices are provided and set in accordance with UG-134(a), they shall prevent the pressure from rising more than 16% or 4 psi, whichever is greater, above the maximum allowable working pressure.

(2) Where an additional hazard can be created by exposure of a pressure vessel to fire or other unexpected sources of external heat, supplemental pressure-relieving devices shall be installed to protect against excessive pressure. Such supplemental pressure-relieving devices shall be capable of preventing the pressure from rising more than 21% above the maximum allowable working pressure. The same pressure-relieving devices may be used to satisfy the capacity requirements of (c) or (c)(1) and this paragraph provided the pressure setting requirements of UG-134(a) are met.

(3) Pressure relief devices, intended primarily for protection against exposure of a pressure vessel to fire or other unexpected sources of external heat installed on vessels having no permanent supply connection and used for storage at ambient temperatures of nonrefrigerated liquefied compressed gasses, are excluded from the requirements of (c)(1) and (c)(2), provided:

---

*B. P. Gupta and W. Y. Wong should also be credited for work on this section.

(a) the relief devices are capable of preventing the pressure from rising more than 20% above the maximum allowable working pressure of the vessels;
(b) the set pressure of these devices shall not exceed the maximum allowable working pressure of the vessels;
(c) the vessels have sufficient ullage to avoid a liquid full condition;
(d) the maximum allowable working pressure of the vessels on which these devices are installed is greater than the vapor pressure of the stored liquefied compressed gas at the maximum anticipated temperature that the gas will reach under atmospheric conditions; and
(e) pressure relief valves used to satisfy these provisions also comply with the requirements of UG-129(a)(5), UG-131(c)(2), and UG-134(e)(2).

UG-126(b)—Pilot-operated pressure relief valves may be used, provided that the pilot is self-actuated and the main valve will open automatically at not over the set pressure and will discharge its full rated capacity if some essential part of the pilot should fail.

UG-126(c)—The spring in a pressure relief valve in service for pressures up to and including 250 psi [17.2 bars] shall not be reset for any pressure more than 10% above or 10% below that for which the valve is marked. For higher pressures, the spring shall not be reset for any pressure more than 5% above or 5% below that for which the safety or relief valve is marked.

UG-126(d)—The set pressure tolerances, plus or minus, of pressure relief valves shall not exceed 2 psi for pressures up to and including 70 psi [4.8 bars] and 3% for pressures above 70 psi [4.8 bars].

UG-131(d)(1)—A capacity certification test is required on a set of three valves for each combination of size, design, and pressure setting. The stamped capacity rating for each combination of design, size, and test pressure shall not exceed 90% of the average capacity of the three valves tested. The capacity for each set of three valves shall fall within a range of ±5% of the average capacity. Failure to meet this requirement shall be cause to refuse certification of that particular safety valve design.

UG-133(a)—As permitted in (b), the aggregate capacity of the pressure-relieving devices connected to any vessel or system of vessels for the release of a liquid, air, steam, or other vapor shall be sufficient to carry off the maximum quantity that can be generated or supplied to the attached equipment without permitting a rise in pressure within the vessel of more than 16% above the maximum allowable working pressure when the pressure-relieving devices are blowing.

UG-133(b)—Protective devices as permitted in UG-125(c)(2), as protection against excessive pressure caused by exposure to fire or other sources of external heat, shall have a relieving capacity sufficient to prevent the pressure from rising more than 21% above the maximum allowable working pressure of the vessel when all pressure-relieving devices are blowing.

UG-134(d)(1)—The set pressure tolerance for pressure relief valves shall not exceed ±2 psi for pressures up to and including 70 psi and 3% for pressures above 70 psi [4.8 bars], except as covered in (d)(2).

UG-134(d)(2)—The set pressure tolerance of pressure relief valves which comply with UG-125(c)(3) shall be within –0%, +10%.

API Standards and Recommended Practices

In general, oil refineries tend to base their pressure relief system designs on the API standards and recommended practices (RPs). The most widely used API documents are as follows:

- API Recommended Practice 520, Sizing, Selection, and Installation of Pressure-Relieving Devices in Refineries, 7th ed., January 2000
- API Recommended Practice 521, Guide for Pressure-Relieving and Depressuring Systems
- API Standard 2000, Venting Atmospheric and Low-Pressure Storage Tanks (Nonrefrigerated and Refrigerated), 2000 ed.

The API 2000 standard is also widely used in other industries beyond refineries to set the pressure relief requirements for storage vessels, which are designed for pressures under 15 PSIG. Some of the other API standards and recommended practices that are relevant to PRV system design include the following:

- API Standard 526, Flanged Steel Pressure Relief Valves
- API Standard 527, Seat Tightness of Pressure
- API Recommended Practice 550, Manual on Installation of Refinery Instruments and Control Systems
- API PR 576, Inspection of Pressure-Relieving Devices

NFPA Codes

For determining the required relieving capacity from tanks and storage vessels, when exposed to external fire, both the API and the NFPA codes can be used. The most often used NFPA codes are the following:

- NFPA 30, Flammable and Combustible Liquids
- NFPA 58, Liquefied Petroleum Gases, Storage and Handling

OSHA Codes

The OSHA codes that relate to the design of pressure safety systems are the following:

- OSHA 1910.106, Flammable and Combustible Liquids
- OSHA 1910.110, Liquefied Petroleum Gases
- OSHA 1910.119, Process Safety Management

CAUSES OF OVERPRESSURE

Overpressure can be caused by fire and by nonfire process causes. In the second category, there can be many potential causes. These will be discussed after the treatment of fire protection that follows in the next paragraph. The potential nonfire causes of overpressure include the following:

1. Utility failures, which can be the failure of electric power, instrument air, steam, coolant, or fuel
2. Thermal expansion
3. Blocked outlets
4. Valve or process control failure
5. Equipment failure
6. Runaway chemical reaction
7. Human error

It should be emphasized that part of the goal of a safe plant design is the goal of minimizing the opportunities for human error.

Substituting for Pressure Relief Devices

In general it is not recommended to accept fail-safe instruments or the actions of automatic control loops as substitutes for PRVs. This is because the reliability of control systems has not advanced to the point where they are completely reliable. Their reliability has increased substantially by the invention of high integrity protective systems (HIPSs), emergency power supplies (EPSs), uninterruptible power supplies (UPSs), triple redundancy, and "two out of three" voting systems. Yet, to date, there is no code or regulation that accepts automatic process control as a substitute for the installation of PRVs.

Similarly, the various safety oriented administrative procedures cannot be used as substitutes for PRVs. This is because human error can never be fully eliminated, and no matter what the administrative procedure says, (according to Murphy's Law) if it is possible to forget to drain a pipeline of its toxic or hazardous content, it will happen. One exception involves the use of car seals open (CSO) and car seals locked (CSL) valves, which API RP 520 and 521 accept as means of guaranteeing that equipment will not be blocked in.

In the overpressure analysis of a plant, the design engineer does not need to consider the possibility of the simultaneous occurrence of more than one cause of overpressure. In other words, if, for example, a chemical reactor PRV has been sized to handle the largest of overpressure causes from among fire, run-away chemical reaction, loss of utilities, etc., that is sufficient. It is not necessary to consider their simultaneous occurrence and size the PRV for the sum of two or more of these causes.

FIRE PROTECTION

The ASME Unfired Pressure Vessel Code requires that pressure vessels covered by the code be adequately relieved. External fire is a potential overpressure source; therefore, for fire conditions, the code requires that relief devices be sized such that, at maximum relieving conditions, the vessel pressure does not exceed the vessel design pressure by more than 20%. This is referred to as 20% accumulation.

For vessels with adequate liquid inventory, the required relief capacity under fire conditions is a function of tank area exposed to fire, of the heat flux per unit area of tank surface, and of the latent heat of the process fluid. These three factors will be separately discussed below. The first to be discussed is the determination of the applicable heat flux.

Gas-Filled Tanks

If the vessel does not have an adequate liquid inventory, stress rupture can occur from overheated spots long before the internal pressure in the tank would reach the setting of the PRV. Therefore, gas-filled tanks and vessels with low liquid inventory require different approaches for protection against overpressure, and design engineers should consider API RP 521 for determining the PRV size required when the tank is exposed to fire and some or most of its inner surface is not wetted.

In most cases, PRVs sized in accordance with API RP 520 cannot give overpressure protection to gas-filled tanks. Therefore, when the installation of hydrogen or other flammable gas-filled vessels is being designed, the following options should also be considered:

1. Bury the tank under ground and cover it with earth.
2. Move the vessel away from the process area or surround it by a dike or a firewall.
3. Elevate the vessel over the fire height (API, 25 ft, NFPA, 30 ft above grade).
4. Use a water deluge system or install fireproof insulation.
5. Provide automatic vapor depressurization.
6. Provide automatic fire monitoring and automatic fire fighting capability.

Heat Absorption Across Unwetted Surfaces The effective discharge area of a relief valve required to protect a vessel that is exposed to external fire and has unwetted surface area can be determined by Equations 7.15(1) and 7.15(2).

$$A = (F'A')/\sqrt{P_u} \qquad \textbf{7.15(1)}$$

where

A = the effective discharge area of the PRV valve, in.^{2}

A' = the surface area of the vessel, which is exposed to fire, ft^2

P_u = the upstream relieving pressure, which is the sum of the atmospheric, the set pressure, and the overpressure, PSIA

The environmental factor F′ is calculated from Equation 7.15(2) as follows:

$$F' = (0.1406/CK_d)[(T_w - T_1)^{1.25}/T_1^{0.6506}] \qquad \textbf{7.15(2)}$$

where

C = a constant that depends on the specific heat ratio of the particular gas. For the specific heat ratio (k) of a number of gases, refer to Table 7.15a, and for a curve relating this ratio to coefficient C, refer to Figure 7.15b.

K_d = the coefficient of discharge of the PRV, which, for preliminary sizing purposes, can be assumed to be 0.975

T_w = the expected wall temperature of the tank, which, for carbon steel plate materials, can be assumed to be 1,100°F

T_1 = the gas temperature in °R at the upstream relieving pressure (P_u). It is calculated by Equation 7.15(3) as follows:

$$T_1 = P_u T_n / P_n \qquad \textbf{7.15(3)}$$

where

P_n = the normal operating gas pressure, PSIA

T_n = the normal operating gas temperature, °R

Low Liquid Inventory Tanks

The definition of what is "adequate" in terms of liquid inventory is a function of the time required to evaporate that inventory during a fire vs. the response time of the fire fighters at the plant. Once the liquid is gone, the vessel becomes a gas-filled tank.

The minimum time is 10 to 15 min. This time period has to take into account the location of the fire-fighting equipment and the quality of the automatic fire monitoring instrumentation in the plant. A liquid inventory is usually considered "adequate" if it will last for at least 15 min during an external fire. If it does not, the fire protection rules for gas-filled tanks should be used.

Heat Flux Across Wetted Surfaces

When a vessel is exposed to external fire, the amount of heat absorption will depend on the following:

1. The wetted surface areas of the vessel and the connected associated piping
2. The amount and quality of the insulation provided on the tank and piping surfaces
3. The quality and availability of the fire-fighting equipment in the plant
4. The method applied to drain the flammable materials away from the tank

To determine the required relief capacity of a tank that is exposed to external fire, it is necessary to determine the heat flux. This is the rate at which heat is transferred into the vessel or other process equipment. A number of heat flux determination methods can be considered.

The simplest technique assumes that the heat flux is fixed and does not depend on the type and size of the vessel involved. Under such an assumption, the heat flux is taken to be a constant rate of 20,000 BTU/hr/ft^2 (63 kW/m^2). Other approaches relate the magnitude of the heat flux to the size of the vessel, reasoning that the larger the tank, the less likely it is that it will be completely immersed in flames.

API RP 521 provides one commonly used method for determining heat flux under fire conditions. This bulletin gives two recommendations for calculating the heat flux in BTU per hour per square foot of total wetted surface of a vessel that is exposed to fire. The two formulas are given in Table 7.15c, one for tanks with adequate drainage away from the tank, and the other for tanks without adequate drainage. A graphic representation of the formula for the adequate drainage condition is shown in Figure 7.15d.

Total Heat Absorption

API Recommendation API RP 520, seventh edition (January 2000), presents two widely used equations for determining the total heat absorption of wetted surface areas under fire conditions. Equation 7.15(4) is applicable if the means for both prompt fire-fighting capability and adequate drainage of flammable materials away from the tank are provided (ground with over 1% slope); Equation 7.15(5) is applicable if they are not.

$$Q = 21{,}000F(A)^{0.82} \qquad \textbf{7.15(4)}$$

$$Q = 34{,}500F(A)^{0.82} \qquad \textbf{7.15(5)}$$

where

Q = total heat absorption of wetted surface area exposed to fire, BTU/hr

F = environmental factor, a constant having a value of 1.0 or less

A = the total wetted surface area of the tank, ft^2

The reader should consult the API Recommended Practice 520 for additional details.

NFPA Recommendations Another standard that is commonly used in the determination of heat flux under fire conditions is in the recommendations of *NFPA Bulletin No. 30, Flammable*

and Combustible Liquids. The National Fire Protection Association is an organization of insurance companies and regulatory organizations. Their recommendations are likely to meet the requirements of most insurance companies, as they are generally more conservative than the corresponding API recommendations.

Table 7.15e lists the equations recommended by NFPA for the determination of total heat absorption and for calculating the equivalent air flow for tanks exposed to external fire.

Low-Pressure Tanks For above-ground tanks and storage vessels designed to operate from atmospheric pressure to 14 PSIG (104 kPa) and used for the storage of flammable liquids, still another method of determining heat flux under fire conditions is available. This recommendation is based on the American Petroleum Institute and is presented in their bulletin API-RP-2000. This method is also referred to in the National Fire Codes of the National Fire Protection Association, for informational purposes only.

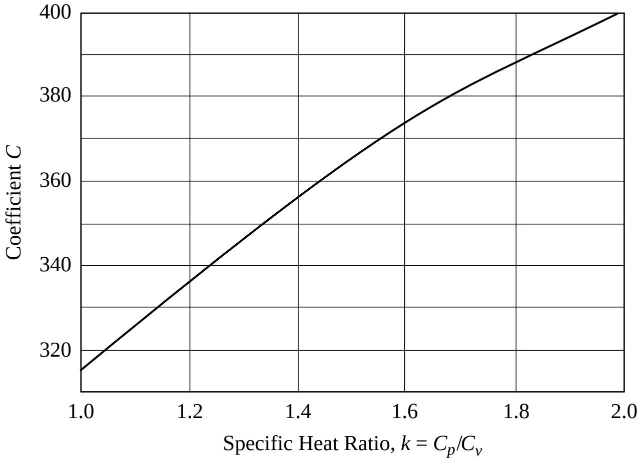

FIG. 7.15b
The relationship between the specific heat ratio (k) of gases and coefficient C. (Courtesy of the American Petroleum Institute from API Recommended Practice 520, Sizing, Selection, and Installation of Pressure-relieving Devices in Refineries, Part I – Sizing and Selection, 7th ed., January 2000.)

TABLE 7.15c
Heat Flux Calculation for Pressure Relieving Systems Based on API RP 521

Type of Tank Drainage	*Heat Flux (q), BTU/hr/f*^{2}***
Adequate	21,000FA$^{-0.18}$
Inadequate	34,500FA$^{-0.18}$

*1 BTU/hr/ft^2 = 3.15 W/m^2

Table 7.16f gives the NFPA-30 heat flux calculation equations as a function of tank design pressure and wetted area. The NFPA recommended values of the environmental factor F are listed in Table 7.15j. For low-pressure tanks with design pressures under 1 PSIG and having wetted surface areas exceeding 2800 ft^2 (260 m^2), they have concluded that complete fire coverage is unlikely, and the maximum total heat input has been limited to 14,090,000 BTU/hr (4,128,370 W/hr). This heat input corresponds to a free air vent rate of 742,000 SCFH.

For a comparison between API RP 521 based heat flux recommendation for adequately drained regular tanks and NFPA's heat flux information for low pressure tanks, refer to Figure 7.15d.

Free Air Calculation This procedure relates the required relieving rate, expressed as cubic feet of free air per hour, to the wetted area. Relieving rates for low-pressure tanks are tabulated as shown in Table 7.15g. The data in this table are based on the physical properties of hexane and utilize the API recommendations for heat flux due to fire conditions. The total emergency relief capacity for any specific liquid may be calculated from Table 7.15g by the use of the following formula:

$$\text{Design cubic feet of free air per hour} = V1337/(\lambda\sqrt{M_w}) \quad \textbf{7.15(6)}$$

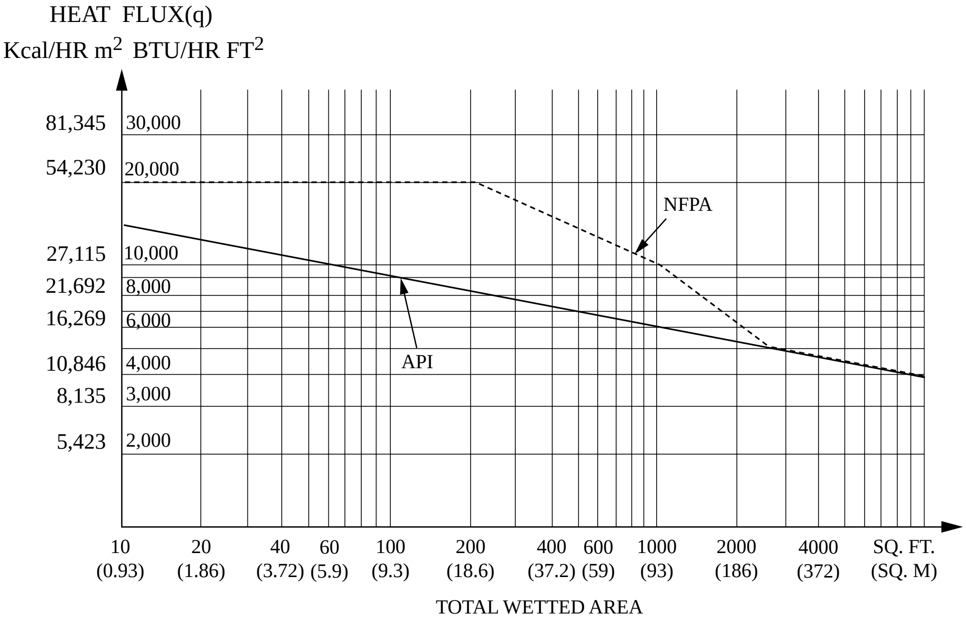

FIG. 7.15d
Heat flux estimates under fire conditions as a function of wetted area recommended by API and NFPA. The solid line is based on API RP 521 and can be used for regular tanks, which are provided with adequate drainage under fire conditions. The dotted line describes NFPA information for low-pressure tanks only. For tanks having over 2800 ft^2 *in wetted area and with design pressures of 1 PSIG or less, NFPA suggests the fixed maximum heat input of 14,090,000 BTU/hr (3,553,000 kcal/hr).*

TABLE 7.15e

Equations Recommended by NFPA Bulletin 30 for the Determination of Total Heat Absorption Q (BTU/hr) and for the Determination of Vent Rate of Free Air (SCHF), when Various Size Vessels, with Design Pressures Exceeding 1 PSIG and Containing Flammable Liquids, Are Exposed to External Fire

Wetted Tank Area (A in ft^2)	*Total Heat Absorption Due to Fire (Q in BTU/hr)*	*Equivalent Vent Rate of Free Air (Air Flow in SCFH at 14.7 PSIA and 60°F)*

1000–2800 (93–260)	< or = 15	$963{,}400FA^{-0.662}$
> or = 2800 (260)	From 1 to 15	$21{,}000FA^{-0.18}$
> or = 2800 (260)	< or = 1.0	14,090,000

*1 BTU/hr/ft^2 = 3.15 W/m^2

Note: For the NFPA recommended values of F, refer to Table 7.15j

where

V = cubic feet of free air per hour, SCFH, listed in Table 7.15f

λ = latent heat of vaporization of the specific liquid in units of BTU per pound

M_w = molecular weight of the specific liquid

For calculation convenience, a table of physical property constants presented in the National Fire Codes of the National Fire Protection Association is reproduced as Table 7.15h.

This calculation, based on Equation 7.15(6), has the potential for oversizing relief valves on vessels in crude oil and other multicomponent liquid applications where the components have a wide range of boiling points. *Latent heat of vaporization* depends on the specific liquid, and, for multicomponent liquids such as crude oil, it cannot be tabulated.

In the case of crude oil, the heat input is initially absorbed by the oil and steel (minor part) as the temperature of the vessel and oil rises. Initially, the specific heat of the oil absorbs the heat, and only a small portion of the heat input is utilized as latent heat generating vapor, which must be relieved. With constant heat input, the amount of vapor generated varies with the temperature of the oil in the vessel. Process calculations must be made to determine the true (maximum) rate of vapor evolution, taking into consideration the actual process fluid. This calculation must consider the worst-case situation when a particular vessel can be used to store different liquids.

TABLE 7.15g

Wetted Area vs. Cubic Feet of Free Air per Hour (14.7 PSIA and 60°F or 101.4 kPa and 15.6°c)

300	265,000	& over	742,000

*ft^2 = 0.093 m^2

**SCFH = 0.0283 m^3/hr

Wetted Area (A)

The factors that need to be considered in calculating the wetted area include the following:

1. The design basis, which can be API or NFPA
2. The tank shape, which can be horizontal, vertical, or spherical
3. The ground area of the fire zone
4. The effective fire height

While relief capacity determination is not directly impacted by it, the effect of fire on nonwetted surfaces can also cause structural failure from the steel softening at elevated temperatures. Thermal insulation or fire-resistant coatings,

if not dislodged by the fire, can reduce the probability of vessel failure caused by steel softening.

API or NFPA As will be noted from the discussions in the paragraphs that follow, there are some differences between the recommendations of NFPA and API. For this reason, it is suggested that design engineers decide which set of recommendations are to be followed in designing the particular plant before considering the shapes of tanks or the expected fire height.

NFPA 58, Liquefied Petroleum Gases, Storage and Handling, requires the design engineer to calculate the wetted area on the basis of a 30-ft fire height above ground, whereas *API RP 520 and 521* require us to consider only a 25-ft fire height above the source of flame.

Tank Shape NFPA RP 521 recommends that, when a tank is exposed to external fire, its wetted area is to be calculated on the basis of a percentage of total exposed area of the vessel. This percentage is 55% for a sphere or spheroid, 75% of total exposed area of a horizontal tank, and the first 30 ft (9 m) above grade of a vertical tank.

API recommendations for calculations of wetted area are similar to NFPA's, except that, for a sphere or spheroid, the total exposed surface up to the maximum horizontal diameter or to a height of 25 ft (7.5 m) is used, whichever is greater. In case of distillation towers, normally, only the heights of liquid layers on the trays are considered in determining the wetted area.

Fire Zone When determining the wetted surface area that is exposed to an external fire, it is necessary to define the ground area of the fire, called the *fire zone.* According to API RP 521, the probable maximum ground area that a fire incident is likely to cover is 2,500 to 5,000 ft^2. For engineering design purposes, this area corresponds to that of a circle having a diameter of 55 to 80 ft.

When a PRV protects several vessels, the design engineers should be conservative and select, from the various possible fire zones, the fire zone (circle of 80 ft in diameter) that would include the largest total wetted surface area protected by that PRV. When several vessels share a single PRV for overpressure protection, no regular block valves are to be installed between them. The use of CSO valves is allowed.

Fire Height If *NFPA 58, Liquefied Petroleum Gases, Storage and Handling,* is selected as the basis of the design, the design engineer must calculate the wetted area on the basis of a 30-ft fire height above ground.

If *API RP 520 and 521* are used as the design basis for the plant, the design engineer must consider only a 25-ft fire height and measure that height, *not necessarily* from ground, but from above the source of flame. In other words, the API code requires the design engineer to also consider the possibility that a pool of flammable materials might accumulate at any elevation (other than ground) and catch fire.

In some cases, the NFPA and API recommendations can give substantially different results. To illustrate, take the example of a vertical tank with its bottom tangent line at 20 ft above ground and containing a 10 ft level of liquid so that the liquid surface is 30 ft above grade level. Let us also assume that, in this case, flammable materials can accumulate only at grade level and, therefore, the "source of flame" is at that level. In this case, the calculated wetted surface area using API will be half as much as if it were determined using the NFPA recommendations.

Vertical Tanks If the liquid level is above the bottom tangent line in a vertical vessel that is provided with an elliptical head, Equation 7.15(7) can be used to calculate its wetted surface (A_w) in square feet.

$$A_w = 1.089D^2 + \pi D[h - (SE\text{-}FH)] \qquad \textbf{7.15(7)}$$

where

A_w = the wetted surface area in ft^2
D = the diameter of the vertical tank in feet
h = the actual liquid level in the tank in feet
SE = the above grade liquid surface elevation in the tank in feet
FH = the fire height in feet (25 for API, 30 for NFPA)

If [h − (SE-FH)] is zero or negative, the vessel is above the effective fire height, so the fire case is not relevant.

Horizontal Tanks Equation 7.15(8) can be used if one desires to calculate the wetted surface area of a horizontal tank provided with ellipsoidal heads.

$$A_w = (2.178D^2 + \pi DL)(S/\pi D) \qquad \textbf{7.15(8)}$$

where

A_w = the wetted surface area in ft^2
D = the diameter of the horizontal tank in feet
L = the length of the cylindrical portion of the horizontal tank in feet
S = calculated by either Equation 7.15(9) or 7.15(10), depending on which is applicable

If the liquid level is below the centerline of the horizontal tank, Equation 7.15(9) is to be used. If the level is above, Equation 7.15(10) is applicable.

$$S = D.\mathrm{Cos}^{-1}\{(D - 2[h - (SE\text{-}FH)])/D\} \qquad \textbf{7.15(9)}$$

$$S = D\{\pi - \mathrm{Cos}^{-1}[(2[h - (SE\text{-}FH)] - D)/D]\} \qquad \textbf{7.15(10)}$$

where

D = the diameter of the horizontal tank in feet
h = the actual liquid level in the tank in feet
SE = the above grade liquid surface elevation in the tank in feet
FH = the fire height in feet (25 for API, 30 for NFPA)

If [h − (SE-FH)] is zero or negative, the vessel is above the effective fire height, so the fire case is not relevant.

Environmental Factors

If certain conditions are met, the value of the environmental factor (F) can be less than 1.0. These reduced values of F are listed in Table 7.15i and can be applied to the API recommended heat flux calculation in Equation 7.15(4) to reduce the required relieving capacity of the PRV. Another set of environmental factors is listed in Table 7.15j. These factors appear in the NFPA National Fire Codes.

TABLE 7.15i
API Recommended Environmental Factors (F) for Tank Installations

Type of Installation	*Factor (F)*
1. Bare vessel	1.0
2. Insulated vessels (listed below are three conductance values expressed in units of BTU/hr/ft^2/°F)	
Conductance of 4.0 (API – 1 insulation)	0.3
Conductance of 2.0 (API – 2 insulation)	0.15
Conductance of 1.0 (API – 4 insulation)	0.075
3. Water application facilities provided on bare vessels	1.0
4. Depressurizing and emptying facilities provided	1.0
5. Underground storage	0.0
6. Earth-covered storage above grade	0.03

Table 7.15j
NFPA Recommended Environmental Factors (F)

Installation	*Factor (F)*
Drainage in accordance with NFPA No. 30 (>1% slope) for tanks with over 200 ft^2 (18 m^2) of exposed wetted area	0.5
Approved water spray (water deluge system) in place	0.3
Approved fireproof insulation installed	0.3
Approved water spray (water deluge system), drainage, and approved (fireproof) insulation	0.15

These environmental factors are suggested values only, and whenever the conditions are not exactly as described in Tables 7.15i or 7.15j, the reader must exercise sound engineering judgment when applying them.

API's Environmental Factors As noted in Table 7.15i, API allows for more factors than does NFPA. A factor of 0.03 is used for earth-covered storage above grade, and a factor of 0.0 is used for underground storage. In addition, credit is given for the thickness and/or conductance of the insulation used. On the other hand, it should be noted that API does not allow credit for water application facilities on bare metal surfaces. Because of uncertainties in the reliability of effective water spray application systems, they feel that no reduction in environmental factors should be allowed.

To take insulation into account when determining heat flux, the insulation should be of the type that will not be damaged or removed by fire or firewater streams, exposing the bare metal surface to the fire. The means of fastening the insulation should be such that it will not fall because of the fusion of the banding material under fire conditions.

API and NFPA Environmental Factors Table 7.15i lists the environmental factors recommended by API, and Table 7.15j lists the NFPA ones. They both relate to the type of fireproof insulation and its thickness as used on the tank. As can be seen from Table 7.15i, API gives an estimate of environmental factors on the basis of insulation thickness; NFPA does not.

From the perspective of NFPA, for a tank insulation to qualify as "fireproof," it must function effectively while subjected to fire temperatures of 1000 to 2000°F for a period of 20 to 60 min. NFPA also requires that the insulation not be dislodged when impacted by firewater—it is to be held in place by stainless steel banding or jacketing. Table 7.15j also shows that NFPA gives credit both for having fireproof insulation and for drainage away from the tank.

The main difference between API and NFPA is that API does not allow credit for water deluge systems, but NFPA does. API's position is that the NFPA rules are too complicated and that the sprinkler systems are not sufficiently reliable. They argue that the sprinklers are not regularly tested; they can freeze in northern regions and are often the first systems to be destroyed when a fire breaks out, because they are fragile.

Calculating the Relieving Capacity

The steps required to determine the relief capacity under fire conditions are as follows:

1. Establish wetted surface area (A_w) of the tank, considering its size, shape, and location within the fire zone.
2. Based on the selected code (API, NFPA, other) and on the type of thermal insulation, water spray, and other installation featured, select the applicable environmental factor F.
3. Based on the wetted surface area (A_w) and based on the selected code (API, NFPA, other), determine the equation to be used to calculate the total heat absorption due to fire. (The equation to be used can be 7.15(4), 7.15(5), or one of the equations in Tables 7.15e and 7.15g.)
4. Calculate the relief capacity required (W) by Equation 7.15(11) as follows:

$$W = Q/\lambda \tag{7.15(11)}$$

where

W = the required relief capacity in pounds per hour (lb/hr)

Q = the total heat absorbed by the tank, calculated by Equation 7.15(4), 7.15(5), or by one of the equations in Tables 7.15e and 7.15g

λ = the latent heat of vaporization at relieving conditions of the liquid in the tank to be protected by the PRV that is being sized. (For calculation convenience, a table of physical property constants presented in the National Fire Codes of the National Fire Protection Association is reproduced in Table 7.15h.)

Latent Heat of Vaporization When sizing PRVs to protect tanks that contain multicomponent hydrocarbon liquids, there is no accurate way to determine the latent heat of vaporization. The actual process during a fire condition is one in which the lighter hydrocarbon components will vaporize first, and the heavier components will follow. Because the latent heat of vaporization varies with not only the composition of the boiling liquid but also with the relieving temperature and pressure, only approximations can be made.

Computer simulation software, if available, is the preferred method of obtaining the latent heat for sizing the PRV that is to protect a multicomponent hydrocarbon storage vessel. These simulations are usually based on the assumption that anywhere from 70 to 95% of the hydrocarbons are still in the liquid state in the vessel when the latent heat is calculated.

When computer simulation is not available, the design engineer can refer to API RP 521, in which the vapor pressure and heat of vaporization of pure, single-component paraffin hydrocarbon liquids are given in Figure A1. Using the relieving pressure and the average molecular weight of the multicomponent hydrocarbon liquid, one can use this chart to estimate the latent heat of vaporization of the mixture at relieving conditions.

Protecting Liquid-Full Tanks

When a liquid-full vessel is exposed to external fire, the relieving process will be initiated by the thermal expansion of the liquid. This will be followed by a period during which both liquid and vapor are simultaneously relieved. This continues until enough vapor space is created for vapor-liquid disengagement in the vessel, which usually starts when 1 or 2 ft of vapor space is cleared.

The PRV for such a liquid-full tank is sized for this last, all-vapor relieving phase, because the relieving area requirement of thermal expansion is small, and the time period of two-phase relieving is short. When a liquid-filled tank is connected to another vessel with a vapor space in it, the control and check valves in the connecting piping should be carefully evaluated. As to the selection of the set pressure of the PRV, it is recommended to base it on the design pressure of the tank's bottom minus the hydrostatic head of the liquid column.

Fluids at the Critical Point If the latent heat of a hydrocarbon mixture is approaching zero, and the sensible heat dominates its behavior, it is said to be at or near the critical point. If, under the relieving conditions, the liquid in a pressure vessel is above the critical point, it should be handled as a gas. If the process fluids under the relieving conditions are below the critical region, and there is no accurate latent heat value available, API RP 520 allows the use of an approximate latent heat of 50 BTU/lb.

Once the design heat flux is determined, calculations are made to determine the rate of thermal expansion of the vessel contents. To calculate this properly, the gas specific heat and the gas compressibility factor must be known. It is inadequate to assume the vapor to be an ideal gas, because, just above the critical point, the compressibility factor of the vapor changes very rapidly. The maximum required valve capacity is often determined not at the critical point but at some point above it where the change in vapor compressibility is less drastic.

It should be noted that, under these conditions, the metal wall of the vessel will rapidly approach the flame temperature and will fail prematurely, because it is not being cooled by the latent heat of vaporization of the boiling liquid contents of the tank. Under these conditions, it is advisable to protect the metal surface of the tank with a cooling water spray to prevent premature failure.

NONFIRE PROTECTION OVERPRESSURE

The possible nonfire causes of overpressure can be utility failures, thermal expansion, blocked outlets, valve or process control failure, equipment failure, runaway chemical reactions, and human errors. In the following paragraphs, the topics of thermal expansion and blocked outlets are discussed.

Thermal Expansion

When a liquid filled system is blocked in and heated, the resulting expansion can cause very high pressures. The heat source of thermal expansion can be a heater, heat exchanger, or heat tracing, or it can be solar or other radiant heat or external fire.

Thermal-expansion PRVs should be installed if a section of the process can be blocked in during maintenance or shutdown. If the plant uses strictly enforced and checked procedures to drain all liquid filled vessels during shutdown, the need for thermal-expansion PRVs is reduced, but human error can never be fully eliminated. Therefore, if the blocked-in section contains toxic or environmentally hazardous materials, the installation of thermal-expansion PRVs is recommended.

On the other hand, no metal seated block valve can provide 100% bubble-tight closure. Therefore, if the blocked-in pipe section is of small diameter and less than 100 ft in length, the required thermal expansion relieving capacity is less than the leakage of the block valve, so a thermal relief valve is not required.

In addition, thermal-expansion PRVs are not required on pipelines that cannot be blocked in or that cannot be heated by any heat source other than the ambient and are normally operating at a temperature exceeding the ambient. Thermal expansion relief valves also are not required if the blocked-in pipe or equipment is not liquid full but has a vapor pocket.

When thermal-expansion PRVs are required, and the trapped in liquid is toxic, corrosive, volatile, or flammable, the PRV must discharge into a closed receiver. Environmentally safe liquids such as water can be discharged directly into a sewer.

Set Pressure and Sizing The set pressure of a thermal-expansion PRV must be high enough that the valve will open only as a result of thermal expansion. In selecting the set pressure, the design engineers should carefully evaluate the backpressure that might be acting on the valve; if it is variable, the selected PRV should be provided with balanced bellows.

If the protected volume is small, sizing calculations need not be performed, and it is sufficient to install a 1/2 × 3/4-in. or 3/8 × 1-in. nominal thermal relief valve. When large vessels or long, large-diameter pipelines are to be protected against thermal expansion, the required relief capacity in GPM (without vaporization) can be calculated using Equation 7.15(12).

$$\text{GPM} = BQ/500(\text{SpG})(\text{Cp}) \qquad \textbf{7.15(12)}$$

where

B = the cubical expansion coefficient per °F for the liquid at the expected temperature (typical values are 0.0001 for water, 0.0004 for hydrocarbons <34.9°API gravity, 0.0005 for 35 to 50.9, 0.0006 for 51 to 63.9, 0.0007 for 64 to 78.9, 0.0008 for 79 to 88.9, and so on)
Cp = the specific heat of the trapped in liquid on the cold side in BTU/°F
GPM = the thermal expansion relief rate required in GPM at flowing temperature
Q = the total heat transfer rate in BTU/hr
SpG = the specific gravity of the process fluid referred to water at 60°F = 1.0

Blocked Outlet Conditions

Whenever an inlet stream pressure can exceed the maximum allowable working pressure of the receiving tank or other equipment, overpressure protection is needed in case of outlet blockage. The blocking of the outlet line can be caused by instrument air or power failure, by control valve malfunction, or by inadvertent valve operation.

The set pressure of the PRV should be selected to correspond to the design pressure at the bottom of the tank minus the hydrostatic head above it. The discharge piping of the PRV should have no pockets. It is advisable to install bleeding valves at the lowest points to eliminate liquid accumulation. When liquid discharges to a flare header, the sizing of the flare header should take the total volume of the discharged liquid into consideration.

Sizing the PRV PRVs must always be installed on the outlets of compressors and of positive displacement pumps. These PRVs should be sized for the rated capacity of the compressor or pump. On other sources, a PRV is required only if the source pressure can be higher than the maximum allowable working pressure of the protected equipment or tank. A PRV is not required if the outlet cannot be blocked. When CSO valves are used, the system is assumed to be not blocked.

The required sizing capacity for blocked-outlet PRVs is not always the normal flow rate of the blocked line.[1] When the liquid outlet is blocked, the PRV has to relieve the liquid accumulation, which might fluctuate. At high levels in the protected tank and with two-phase input, the vapor-liquid separation can become impossible, and the PRV can also be relieving a two-phase flow.

Therefore, when the vessel has a large liquid inventory, it is important to provide the tank with a void space corresponding to 10 to 15 min of inlet flow. This way, after a blockage, the operator will have some time to prevent the level from further increasing. An even safer approach is to provide a high-level alarm when the remaining residence time above the liquid level drops to, say, 20 min, and in addition, install a high-high level alarm when it drops to 15.

PROCESS EQUIPMENT CONSIDERATIONS

In the following paragraphs, some unit-operation related advice will be given on how to protect such equipment as low-pressure tanks, heat exchangers, pumps and compressors, distillation towers, pipe headers, and chemical reactors against overpressure, and how to design their PRV installations.

Low-Pressure Storage Tanks

In designing the "breathing" of atmospheric storage tanks, there are two considerations. One is the need to vent the displaced air when liquid is being pumped into the vessel, and the other is the need to admit air into the tank when liquid is being pumped out of the vessel. This "breathing" is needed to (a) prevent over-pressure while pumping liquid in and (b) collapsing the vessel as a result of vacuum when liquid is being pumped out and the corresponding volume is not replaced with air.

Quoting once again the API Guide for Tank Venting, RP-2000, the following recommendations apply:

- *Inbreathing*—8 scfh (0.226 m^3/hr) air for each gpm (3.78 lpm) of maximum emptying rate
- *Outbreathing*—8.5 scfh (0.24 m^3/hr) air for each gpm (3.78 lpm) of maximum filling rate for fluids with a flashpoint of 100°F (37.8°C) or higher, and 17 scfh (0.48 m^3/hr) air for each gpm (3.78 lpm) of maximum fill rate for fluids with a flashpoint below 100°F (37.8°C)

Thermal Venting Capacity In addition to pumping, provision must be made to accommodate the thermal venting requirements of the vessel. This is defined as the expansion or contraction of the vapors in the tank resulting from changes in the tank's ambient temperature. For example, at the beginning of a rainstorm, the vapors in the tank would cool and contract. Under such conditions, to avoid creating a vacuum in the atmospheric tank, additional air must be admitted into the vapor space of the tank.

The API recommendations are based on an in-breathing capacity of 2 ft^3 of air per hour per square foot (0.61 $m^3/hr/m^2$) of total shell and roof area for very large tanks (a capacity of more than 20,000 barrels or 3180 m^3). For tanks with a capacity of less than 20,000 barrels (3180 m^3), an in-breathing requirement of 1 ft^3 of air per hour (0.028 m^3/hr) for each barrel (0.158 m^3) of tank capacity is recommended. This capacity is based on a rate of change of vapor space temperature of 100°F (37.8°C) per hour. This maximum rate of temperature change is assumed to occur during such events as a sudden cold rain.

It is assumed that the tank roof and shell temperatures cannot rise as rapidly as they can drop under any conditions. It is further assumed that, for liquids with a flashpoint of 100°F (37.8°C) or above, the thermal out-breathing requirement has been assumed to be 60% of the in-breathing capacity requirement.

For materials with a flashpoint below 100°F (37.8°C), the thermal out-breathing requirement has been assumed to be equal to the in-breathing requirement. This allows for vaporization of the liquid and for the fact that the specific gravity of the vapors in tanks containing volatile hydrocarbons is greater than air. The thermal venting capacity requirements as recommended by API were given in Table 7.15g.

The total in-breathing and out-breathing requirements of a tank should always be calculated as the sum of the thermal venting capacity requirements and the requirements to compensate for in or out pumping rates.

Heat Exchangers

Heat exchangers are a class of process equipment requiring special relief considerations because of the potential need for protection against thermal expansion, external fire, blocked outlets, and tube rupture cases.

Blocked-In Exchangers Heat exchangers frequently have valves located on both their inlet and outlet piping. When these valves are all closed, the exchanger is "blocked in." If the cold side of the heat exchanger can be blocked in, relief devices are installed to provide protection against thermal expansion of liquids in the exchanger. This is always done for the cold side of an exchanger, where the liquid can be heated by the hot fluid on the other side or can be heated by ambient temperature while sitting with the inlet and outlet valves closed.

No relief device is necessary for the protection of either side of an exchanger that cannot be blocked in. In such installations, it is assumed that the relief of the unit is taken care of by the relief device on the related tank or equipment.

Liquid Refrigerants In the case of liquid refrigerants, a relief device should always be provided for the protection of the refrigerant side if that side can be blocked in and if the vapor pressure of the refrigerant, when its temperature rises to that of the hot side, exceeds the design pressure of the exchanger. This is also done whenever the vapor pressure of the material flowing at 100°F (37.8°C) is greater than the design pressure of the exchanger. This recommendation is somewhat site specific and is based on an assumed (maximum) ambient temperature of 100°F (37.8°C); this temperature may lower for some geographical areas.

Gas-Fired Tubular Heaters Direct gas-fired tubular heaters are always protected by relief valves on their tube side. The valve is normally sized for the design heat transfer rating of the heater and must initially handle a fluid rate corresponding to the rate of thermal expansion in the tubes when they are blocked in.

When designing fired heaters, there should be no block valve on its outlet. This is because PRVs for high-temperature services exceeding 550°F are not available with dependable seat and seal materials.

Tube Rupture Consideration should be given to relief protection of low-pressure equipment in the event that an exchanger tube ruptures because of corrosion, vibration, or thermal shock. ASME Code, Section VIII, Division 1, Paragraph UG-133(d) require such protection.

This consideration is particularly critical when the low-pressure side design pressure is less than the operating pressure on the high-pressure side. In terms of high- and low-pressure side design pressures, PRV protection against tube rupture is recommended if the design pressure of the low-pressure side is less than 77% of the high-pressure side design pressure.

Reference 2 provides some advice on the sizing of PRVs to protect against overpressure caused by tube rupture. The PRV, which is to protect the exchanger, should be located directly on the exchanger or very close to it.

Pumps and Compressors

Reciprocating compressors should be protected against overpressure on the discharge side in case the discharge piping can be blocked. In the case of positive displacement pumps, a relief device is required to relieve the pumped liquid when the discharge line is blocked in. This relief device is sometimes provided as an integral part of the pump.

The routing of the discharge from the PRVs should be carefully evaluated. In many cases, directing the relieved fluid back to the pump or compressor suction may result in dangerous overheating of the fluid because of the work input by the pump or compressor. This may result in unit overheating, fluid vaporization, seal failure, and so on.

Sizing In sizing the PRV, the type of pumping equipment must be taken into consideration. In the case of rotary pumps with a fairly uniform instantaneous flow rate, the PRV is sized for the rated pump capacity.

In the case of reciprocating pumps, consideration must be given to the fact that the rated flow rate is the average of the total stroke of the piston. It is suggested that, for a single-piston pump, four times the average flow rate be used as the basis for relief sizing. With a duplex or triplex pump, there is some flow averaging, and the engineer must exercise safe judgment.

In general, the PRV should be sized for the maximum capacity that the pump or compressor can generate. Therefore, the design engineer should always consider the maximum impeller size and 105% of the normal speed of the compressor or pump in selecting the sizing capacity.

Set Pressure The design pressure of the weakest part of the system downstream should determine the pressure setting of the relief device used. This may be the design pressure of the pump casing, the design pressure of some valve or equipment in the line, or another appropriate specification. Normally, a set pressure is selected to be below this limit but high enough that the PRV will not open under normal operating conditions.

In the case of turbine pumps, relief devices are generally provided to protect the pump, the associated piping, and the equipment that may be blocked in. In the case of centrifugal-type pumps, it is uncommon that the maximum pump shutoff pressure would exceed the maximum allowable working pressure (MAWP) of any system components, but the design engineer still must fully evaluate the overpressure possibilities.

Distillation Towers

Several conditions and combinations of conditions can result in the overpressure of distillation columns. These can include the failure of power, instrument air, reflux, cooling water, control system, and control valves. Other causes can include abnormal heat input, tube rupture, blocked outlets, and thermal expansion.

In evaluating the above conditions, one must always ask, “When this failure occurs, will the feed, the steam flow to the reboiler, the cooling water flow, etc. continue, or will it stop?” The answers to such questions will help determine if secondary effects such as overhead condenser flooding also need to be considered in the safety analysis.

In all distillation towers, there is a normal heat input at the column reboiler. The vapors generated are normally condensed in an overhead condenser. In the event of the failure of cooling water or cooling medium to the overhead condenser (or a failure of the fan drive unit on air-cooled condensers), a dangerous overpressure situation may develop because of the continued generation of vapors in the reboiler. A relief device must be added to relieve the vapors thus generated, and this PRV is generally rated for the normal heat input of the reboiler.

Overpressure can also develop when the source of heat is continuous and the overhead vapor line from the column is accidentally blocked. In this case, a relief device must relieve the vapors as they are generated by the column reboiler.

Reflux failure to a column where reflux acts as a coolant may also cause an overpressure condition. Similarly, loss of feed may result in an overpressure condition, especially if the reboiler continues to operate when the feed has stopped.

Pipe Headers

The design engineer must always consider that automatic control systems do fail and can accidentally subject some equipment to pressures exceeding their design pressures. Such an overpressure condition can occur because of the failure of steam pressure reducing stations. To illustrate this, assume a case in which high-pressure steam (150 PSIG, or 1035 kPa) is reduced to a lower pressure (30 PSIG, or 207 kPa). Should this control station fail as a result of the control valve sticking open, all equipment connected to the low-pressure steam header could be subjected to high pressure. In such case, a relief device is normally placed on the low-pressure header near the pressure-reducing control valve and is rated for the maximum capacity of that control valve.

As another example, liquid from a high-pressure source may be admitted to a vessel that is operating under either level or flow control. Should the control valve fail, the equipment downstream of the control valve may be subjected to pressures in excess of its design pressure. Here again, relief devices capable of handling the maximum flow through the control valves involved need to be provided.

Bypass Valves When considering overpressure conditions caused by control valve failure, it is also prudent to evaluate the impact of bypass valves around control valves that can be open or partially open. Unless the bypass valves are sealed closed, there can be situations where the bypass valves are intentionally used to obtain additional capacity.

Alternatively, performing maintenance or testing on the control valve while the process is in operation could result in a situation in which the bypass valve is open and the control valve fails open. In considering these possibilities, a conservative approach is to size the relief capacity on the basis of the combined Cv of the control valve and the bypass valve.

However, this oversizing can cause problems such as causing chatter in the relief valve. This dilemma must be resolved based on the individual circumstances for each installation, including an assessment of operating and maintenance practices. The capacity of the process piping should also be examined, because the piping may actually be the limiting factor if a combined Cv approach is used in sizing the relief valve.

Chemical Reactors

Protecting chemical reactors from overpressure is probably the most complex task in process safety design. It is that complicated because of the possibility of runaway reactions, and because the speed of response of some conventional PRVs might not be fast enough to match them. As a result, special (explosive actuated) PRV designs may be needed.

What makes chemical reactors unique among the unit operations in a processing plant is that “runaway” exothermic reactions can occur in them. An example of such a case is a polymerization reactor in which cooling water or agitator failure can cause a runaway reaction. The sizing problems fall into two categories.

The first problem is that it is difficult and sometimes impossible to determine the actual rate of heat evolution during a runaway reaction, because data are often not available for such a condition at high relief temperatures. The second problem is that the PRV does not usually relieve a pure vapor stream but a mixture of liquids, gases, and solids.

When sizing such a relief valve, one approach[3] first recommends the determination of the rate of heat evolution and the conversion of this heat to equivalent vapor generation. When this vapor volume is determined, the PRV is sized under the assumption that the relief device will vent this calculated volume as 100% liquid. This approach appears to be safe and conservative. In these cases, the relief devices sometimes are sized based on past practice. Table 7.15k presents typical relief sizes for PVC reactors as an example.

TABLE 7.15k
Relief Valve Sizes for PVC Reactors

Nominal Reactor Volume, gal (l)	*Relief Valve*	*Orifice Area, in.^{2} (mm^2)*	*In.^{2}/gal (mm^2/l)*
1000 (3780)	2J3	1.287 (830)	0.0013 (0.2218)
2500 (9450)	3L4	2.85 (1,838)	0.0012 (0.2048)
3750 (14,175)	4P6	6.38 (4,115)	0.0017 (0.2901)
5200 (19,656)	4P6	6.38 (4,115)	0.0012 (0.2048)

In cases where relief requirements cannot be quantitatively determined, the design engineer should be careful to use simplifying assumptions that will lead to conservative results.

Discharging the PRVs

The selected discharge system should be a function of the process fluid handled. The following types of discharges are allowable to be sent to open collection systems or to the atmosphere:

1. Vapors that are lighter than air and are not toxic, flammable, or hazardous to humans or the environment can be discharged.
2. Water or nontoxic, nonflammable liquids from waste heat boilers and thermal relief systems can be discharged into open collection systems before further treatment and discharge into the sewer.
3. Local regulations also allow some specific gases/vapors to be discharged to the atmosphere in certain limited volumes.

Discharging to Closed Locations

The PRV discharge must be sent to a closed location in the following cases:

1. The discharged vapor is toxic, corrosive, or flammable and/or will condense at atmospheric conditions.
2. The discharged vapor is heavier than air or is flammable, toxic, or hazardous either to humans or the environment.
3. The discharged fluid is liquid or partially liquid and is toxic, flammable, corrosive, high temperature, or otherwise hazardous to humans or the environment.
4. The discharged amount/volume would exceed local regulations.

When the PRVs are discharged into a closed system, they are sent through a manifold and blowdown drum to a flare system. The blowdown drum separates the liquids from the vapors. The vapors are then sent to the flare system while the liquids are pumped to the treatment and disposal system. In a processing plant, there can be flare header systems for different pressures or for different types of process materials, such as, for example, a separate H_2S flare header or other system.

CONCLUSIONS

Overpressure analysis is more art than science. The design engineer must always exercise care and sound judgment when determining the sizing basis for relief capacity determination. There are so many combinations of installations and circumstances that it is beyond our scope here to do much more than present some generalized advice and a fairly long list of further reading material in the bibliography.

In many cases, it is necessary to calculate relief capacity requirements based on a combination of several considerations, such as fire, cooling water failure, runway reactions, etc., and determine which will require the largest relief device. There can also be installations where the relief capacity requirements based on fire and those based on some other consideration should be additive, because both conditions are likely to exist simultaneously.

Concurrently, the engineer must be aware that oversizing of relief valves can also present problems such as chattering, which creates a dilemma in relief valve sizing and selection. Computer simulations can be very valuable in specific cases, such as when the relieving conditions are near critical. On the other hand, one should always remember that software packages are only as good as the programmer who has prepared them and are applicable only under the same conditions and for the same equipment configuration for which they have been prepared.

TERMINOLOGY AND NOMENCLATURE

Accumulation. This is the pressure increase over the maximum allowable working pressure of a tank or vessel during discharge through the pressure relief valve. It is given as a percentage of the maximum allowable working pressure or in pressure units (e.g., bars or pounds per square inch).

Backpressure. Pressure on the discharge side of a pressure relief valve. This pressure is the sum of the superimposed and the built-up backpressures. The superimposed backpressure is the pressure that exists in the discharge piping of the relief valve when the valve is closed.

Balanced safety relief valve. A safety relief valve with the bonnet vented to atmosphere. The effect of backpressure on the performance characteristics of the valve (set pressure, blowdown, and capacity) is much less than on the conventional valve. The balanced safety relief valve is made in three designs: (1) with a balancing piston, (2) with a balancing bellows, and (3) with a balancing bellows and an auxiliary balancing piston.

Blowdown (blowback). The difference between the set pressure and the reseating (closing) pressure of a pressure relief valve, expressed in percent of the set pressure or in bars or pounds per square inch.

Built-up backpressure. Variable backpressure that develops as a result of flow through the pressure relief valve after it opens. This is an increase in pressure in the relief valve's outlet line caused by the pressure drop through the discharge headers.

Chatter. Rapid, abnormal, reciprocating variations in lift during which the disc contacts the seat.

Cold differential test pressure (CDTP). The pressure at which the PRV is adjusted to open during testing. The CDTP setting includes the corrections required to consider the expected service temperature and backpressure.

Constant backpressure. Backpressure that does not change under any condition of operation, regardless of whether the pressure relief valve is closed or open.

Closing pressure (reseat pressure). The pressure, measured at the valve inlet, at which the valve closes, flow is substantially shut off, and there is no measurable lift.

Conventional safety relief valve. A safety relief valve with the bonnet vented either to atmosphere or internally to the discharge side of the valve. The performance characteristics (set pressure, blowdown, and capacity) are directly affected by changes of the backpressure on the valve.

Design pressure. This pressure is equal to or less than the maximum allowable working pressure. It is used to define the upper limit of the normal operating pressure range.

Effective coefficient of discharge. This is a coefficient used to calculate the minimum required discharge area of the PRV.

Flutter. Rapid, abnormal, reciprocating variations in lift during which the disc does not contact the seat.

Lift. The rise of the disc in a pressure relief valve.

Maximum allowable operating pressure (MAOP). The maximum pressure expected during normal operation.

Maximum allowable working pressure (MAWP). This is the maximum pressure allowed for continuous operation. As defined in the construction codes (ASME B31.3) for unfired pressure vessels, it equals the design pressure for the same design temperature. The maximum allowable working pressure depends on the type of material, its thickness, and the service conditions set as the basis for design. The vessel may not be operated above this pressure or its equivalent at any metal temperature other than that used in its design; consequently, for that metal temperature, it is the highest pressure at which the primary pressure relief valve can be set to open.

Operating pressure. The operating pressure of a vessel is the pressure, in pounds per square inch gauge, to which the vessel is usually subjected in service. A processing vessel is usually designed for a maximum allowable working pressure, in pounds per square inch gauge, that will provide a suitable margin above the operating pressure to prevent any undesirable operation of the relief device. It is suggested that this margin be approximately 10% or 25 PSI (173 kPa), whichever is greater. Such margin will be adequate to prevent the undesirable opening and operation of the pressure relief valve caused by minor fluctuations in the operating pressure.

Operating pressure margin. The margin between the maximum operating pressure and the set pressure of the PRV.

Operating pressure ratio. The ratio of the maximum operating pressure to the set pressure of the PRV.

Overpressure. This is the pressure increase over the set pressure of the primary relief device. When the set pressure is the same as the maximum allowable operating pressure (MAOP), the accumulation is the same as the overpressure. Pressure increase over the set pressure of the primary relieving device is overpressure. Note: from this definition, it will be observed that, when the set pressure of the first (primary) safety or relief valve is less than the maximum allowable working pressure of the vessel, the overpressure may be greater that 10% of set pressure.

Pressure-relieving device. The broadest category in the area of pressure relief devices, it includes rupture discs and pressure relief valves of both the simple spring-loaded type and certain pilot-operated types.

Pressure relief valve (PRV). A generic term that might refer to relief valves, safety valves, and pilot-operated valves. The purpose of a PRV is to automatically open and relieve the excess system pressure by sending the process gases or fluids to a safe location when its pressure setting is reached.

Rated relieving capacity. This is the maximum relieving capacity of the PRV. This rating is normally provided on the nameplate of the PRV. The rated relieving capacity of the PRV exceeds the required relieving capacity and is the basis for sizing the vent header system.

Relief valve. An automatic pressure-relieving device actuated by the static pressure upstream of the valve, which opens in proportion to the increase in pressure over the operating pressure. It is used primarily for liquid service.

Relieving pressure (opening pressure plus overpressure). The pressure, measured at the valve inlet, at which the relieving capacity is determined.

Reopening pressure. The opening pressure when the pressure is raised as soon as practicable after the valve has reseated or closed from a previous discharge.

Safety relief valve. An automatic pressure-actuated relieving device suitable for use as either a safety or relief valve.

Safety valve. An automatic pressure-relieving device actuated by the static pressure upstream of the valve and characterized by rapid and full opening or pop action. It is used for steam, gas, or vapor service.

Seal-off pressure. The pressure, measured at the valve inlet after closing, at which no further liquid, steam, or gas is detected at the downstream side of the seat.

Set pressure (opening pressure). The pressure at which the relief valve is set to open. It is the pressure measured at the valve inlet of the PRV at which there is a measurable lift or at which discharge becomes continuous as determined by seeing, feeling, or hearing. In the pop-type safety valve, it is the pressure at which the valve moves more in the opening direction as compared to corresponding movements at higher or lower pressures. A safety valve or a safety relief valve is not considered to be open when it is simmering at a pressure just below the popping point, even though the simmering may be audible.

Simmer (warn). The condition just prior to opening at which a spring-loaded relief valve is at the point of having zero or negative forces holding the valve closed. Under these conditions, as soon as the valve disc attempts to rise, the spring constant develops enough force to close the valve again.

Start-to-leak pressure. The pressure at the valve inlet at which the relieved fluid is first detected on the downstream side of the seat before normal relieving action takes place.

Superimposed backpressure. Variable backpressure that is present in the discharge header before the pressure relief valve starts to open. It can be constant or variable, depending on the status of the other PRVs in the system.

Variable backpressure. Backpressure that varies as a result of changes in operation of one or more pressure relief valves connected to a common discharge header.

Types of Designs:	Spring-loaded Weight-loaded Balanced by bellows seals Pilot-operated
Design Pressure Ranges:	Screwed designs from 5 PSIG [34 kPag to 10,000 PSIG (69 MPa)], higher as special Flanged steel designs, ANSI CL 150#, 300#, 600#, 900#, 1500# and 2500# ASA Flanged cast iron units in 125# and 250# Ranges of Pilot-Operated Designs Vacuum: –1.7 in. H_2O to –14 PSIG (–43.2 mm H_2O to –96.5 kPag) Low pressure: 3 in. H_2O to 150 PSIG (76.2 mm H_2O to 1034 kPag) Medium to high pressure: 50 to 6,200 PSIG (0.345 to 42.75 MPag)
Design Temperature:	–450 to 1000°F (–268 to 538°C) with suitable material selections for pressure parts, trim, and springs; breaks occur in the temperature ratings at 450°F (232°C) and 800°F (427°C)
Inlet Connection Sizes:	0.5 to 6 in. (12.5 to 150 mm); some suppliers up to 12 in. (300 mm) for special services Pilot-operated PRVs available from 1 to 10 in. (25 to 250 mm) with double outlets starting at 2 in. (50 mm)
Orifice Areas:	API designated orifices: D, E, F, G, H, J, K, L, M, N, P, Q, R, and T (for orifice areas, see Figure 7.16g) Non-API orifices and full-bore orifices are available in areas up to 84 in.^{2}
Materials of Construction:	Pressure parts: cast iron, bronze, cast steel, 300 and 400 series stainless, nickel steel, Monel, Hastelloy, high-temperature carbon steel alloys, materials in compliance with NACE MR0175; trim: basically any machinable alloy, can be cryogenic, NACE, or high-temperature trim
Seat and Seal Materials:	Metal to metal or soft seats Soft seat material options include Aflas, Buna-N, ethylene propylene, Kalrez, Peek, Teflon®, Urathene, Viton®, etc.
Accessories:	Backflow preventer, dual pilots, field test connection with indicator, filter, pilot lift lever, pressure spike snubber, remote blowdown, remote pressure sensor, remote valve lift indicator, valve monitor, valve position indicator
Cost:	See Figure 7.16o
Inaccuracy:	±2 PSI for pressures up to and including 70 psig (483 kPag) ±3% for pressures above 70 to 300 PSIG (483 to 2068 kPag)

---

INTRODUCTION

In Section 7.15, the various overpressure protection codes and standards were discussed along with the terminology and nomenclature that is used in connection with pressure relief valve (PRV) design. Some of these terms are also defined and visually illustrated in Figure 7.16a. The main purpose of Section 7.15 was to explain the methods by which the required relief capacities are determined. The purpose of this section is to assume that the required capacity is known and, based on that, to determine the size, design features, and installation details of the required PRV.

One might note that, during recent decades, the language used in connection with overpressure protection valves went through some changes. In the past, all overpressure protection valves were referred to as pressure safety valves (PSVs). Then, with the passage of time, first the liquid relieving valves and then all nonfire protection valves came to be called pressure relief valves (PRVs). By now, in most plants, these distinctions have disappeared, and all overpressure protection valves are referred to as PRVs. This practice is also used in this handbook.

The Nature of PRVs

Pressure relief valves are the last line of defense in the protection of personnel and equipment from the consequences of the accumulation of energy or mass that is greater than allowed by design limits. One of the prime responsibilities of process plant management is to operate in a safe manner, and one of the most important safety considerations is to protect all equipment against overpressure.

Normally, plant operating instructions and controls keep the operating pressures within design limits. In the event of control malfunction, emergency shutdown systems should serve to bring the system down in a safe and orderly manner. However, if the emergency shutdown systems malfunction, the plant design must incorporate pressure relief devices to dispose of the accumulated energy and thereby avoid damage.

The relative simplicity and the self-contained and self-actuating nature of the PRV valve make it the most reliable device short of the rupture disc (which does not, however, reclose). It is important to remember that a pressure relief valve is installed only to limit the pressure; it will not regulate, reduce, or depressurize the system unless special provisions are incorporated.

The Purpose of PRVs

Pressure relief valves are commonly installed for one or more of the following reasons:

1. To guarantee the safety of operating personnel
2. To prevent the destruction of capital investment as a result of overpressure
3. To conserve process material from loss during and after an overpressure-related accident
4. To minimize unit downtime caused by overpressure
5. To comply with local, state, national, and other court-enforceable regulations
6. To avoid civil suits resulting from property or personal damage external to the plant caused by overpressure

By designing and installing reliable overpressure protection systems, the plant will not only obtain favorable insurance treatment, it will minimize pollution (primarily air pollution) by preventing the discharge of overpressure vapors.

System Integrity and Noise

Because one of the reasons for installing a pressure relief valve is compliance with local codes and regulations, the designer must take into consideration the system integrity, in particular the noise produced by the valve when it opens. The

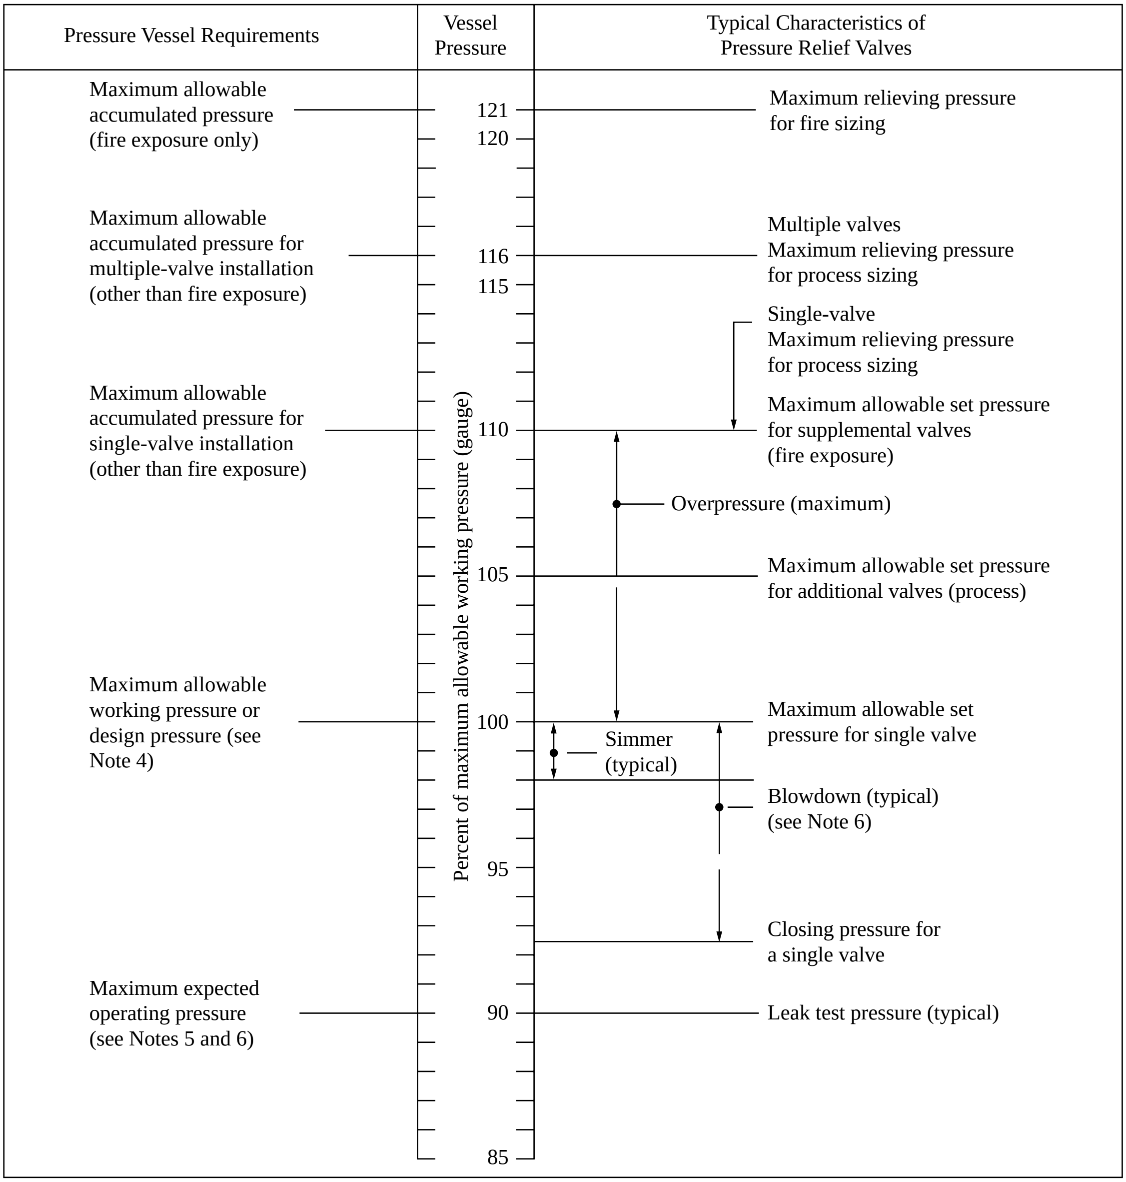

FIG. 7.16a

Definitions of terms used in connection with overpressure relief systems. (Reproduced courtesy of the American Petroleum Institute from API Recommended Practice 520, Sizing, Selection, and Installation of Pressure-relieving Devices in Refineries, Part I—Sizing and Selection, 7th ed., January 2000.)

valve may relieve the required amount of process fluid, but the vibrations caused by the sound power noise of the valve may be beyond the maximum allowable for which the discharge piping was designed.

Failures in relief valve discharge piping have been reported that can be linked to high sound power levels (SPLs) *inside* the piping downstream of the relief valve and at the point where the discharge piping joins the relief system header. There have been cases reported in which excessive velocities in the piping immediately downstream of the relief valve have resulted in a “standing sonic wave” at the juncture of the valve discharge piping and the header piping, i.e., where the first increase in pipe size occurs.

Special care must be taken to review the *actual* maximum flows that can exist in the discharge piping. Velocities must be calculated and noise calculations made to guard against fatigue failures caused by excessive vibration induced by a high SPL. When making these calculations, it is necessary to use the actual installed capacity of the valve. This is because, in most cases, the selected valve has greater capacity than the calculated required capacity. Under certain relieving conditions, at least for some time period, the actual flow corresponds to the size of the actual valve orifice rather than to the calculated required capacity. This consideration is especially important for valves greater than 3 in. (75 mm) and, unfortunately, there is no known technique for assessing this problem.

Reliability, Testing, and Redundancy

The designer may also have to consider the requirements imposed by the insurance underwriting groups. Because the purpose of overpressure protection is to prevent the destruction of capital investment and to provide personnel safety, such considerations as toxicity, polymerization, corrosion, and damage to other equipment in the plant must also be considered when deciding on the discharge destinations of PRVs.

Because unit downtime and loss of material are both to be minimized, it is also important that the PRVs provide tight shutoff against maximum operating pressure while it is below the set point for actuation. Personnel safety and the minimization of property damage lead to requirements for high reliability, both in terms of accuracy and repeatability.

A pressure-relieving valve in a chemical plant is rather unique in that it, hopefully, will never need to operate. Furthermore, it is also rare that any such system would ever be operated for test purposes, although certain of its components might be tested periodically. The capability for system testing is usually not provided because of the cost of the added valves and bypasses that would be needed. Even when such capability is provided, the system test is performed only at rather long intervals.

A pressure relief valve is not tested weekly for its condition as one might test an emergency generator or a fire pump. We expect the PRV valve to work when called upon in spite of the extended periods of stagnation while exposed to process fluids, operating temperatures, and operating pressures, plus to the full range of ambient conditions. This requirement that the valve work when called upon, coupled with the requirement to protect the safety of personnel and equipment, drives the designers to consider redundancy. Such designs are exemplified by duplicate or multiple relief valves, rupture discs plus safety valves, flare valves backed up by pressure relief valves, etc.

Safety Checklist

Section 7.15 listed and discussed the code requirements and practices recommended by standards that have been generated by regulating. In addition, the following considerations and options should be kept in mind:

1. The use of extra safety factors in sizing or rating over and above those established in codes, regulations, and recommended practices
2. The provision of other protective facilities that may result in credits under the codes or regulations
3. The provision of credit for redundancy or other protective facilities, even though such credit may not be clearly established in codes or regulations
4. Preferences, particularly in installation practices, based on operating or maintenance practices
5. The establishment of minimum design pressures for various types of equipment in various services (This would affect the pressure-relieving systems in that operating pressure may not always bear the same relationship to design pressure and smaller relieving valves set at the minimum design pressure may be suitable.)
6. The relationship between operating pressure and relief valve set pressure as affected by the upsets to operating conditions that are acceptable before pressure relief occurs
7. The standardization of relieving device sizes and types and the standardization of relieving device mounting nozzle sizes and locations for various types of equipment in different services
8. The inspection and test procedures established by the company for its pressure-relieving systems or the components of those systems
9. The accounting needs and practices of the company as they might affect flow detection and metering in the pressure-relieving system or at the valve
10. Noise produced and maximum level of noise allowed in the discharge piping and header, depending on its diameter

THE SIZING OF PRVS

Before sizing the pressure relief valve, one must determine if the process material released will be vapor or gas, liquid, or a mixture of liquid and vapor (two-phase). Each of these cases is separately discussed below.

The design engineer should also remember that PRV sizing programs are available on CDs from the manufacturers.[1] While these programs do save time, it is advisable to fully understand the sizing steps and considerations. For these reasons, both graphical methods of approximate PRV sizing and accurate calculations will be described in the following pages.

Backpressure

Backpressure can adversely affect the set pressure, relieving capacity, stability, and life span of all types of pressure relief valves. Figure 7.16b represents the correction curve for the effects of constant backpressure in reducing the flow across the nozzle of conventional, nonbalanced valves when the spring setting has been compensated for the constant backpressure.

The effect of backpressure on bellows sealed valves, whether it is fixed or variable, is a function of the specific valve size and design. There is general acceptance of the fact that a backpressure up to 30% of inlet pressure will not need correction. Above that value, the backpressure effect should be evaluated by considering whether it is superimposed backpressure or built-up backpressure.

Superimposed Backpressure The superimposed backpressure is the pressure that is present at the PRV outlet in the relief header when the valve opens. This pressure is a “gauge” pressure and is expressed in units such as PSIG, $kg/cm^2(g)$ or kPag. Generally, the superimposed backpressure is assumed to be constant, which is an incorrect assumption if more than one PRV is discharging into the same relief header.

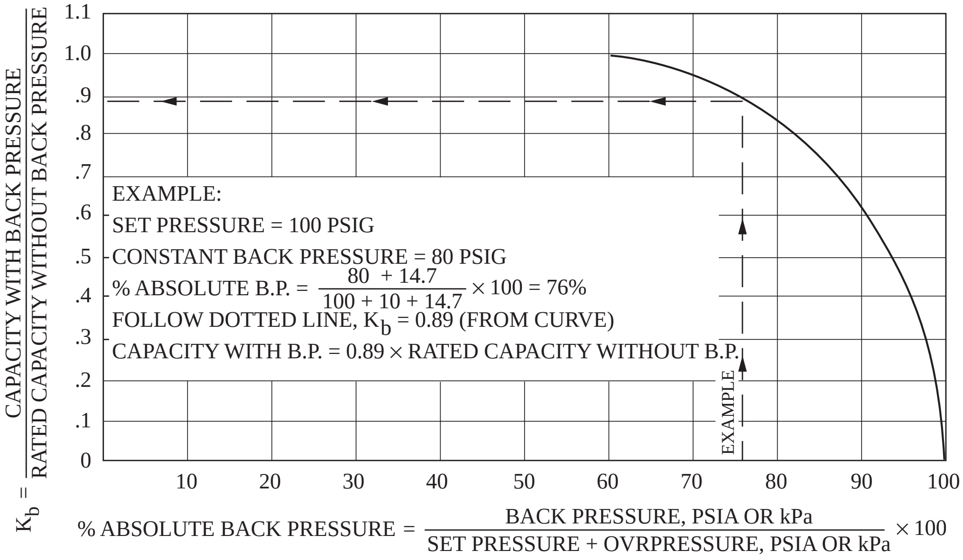

FIG. 7.16b
Constant backpressure sizing factor, applicable when sizing conventional pressure relief valves for gas and vapor services.

In reality, this pressure is variable and is changing as a function of the number of PRVs relieving into the header at any one time.

As was discussed in Section 7.15, a fire zone has an area of 2500 to 5000 ft^2, and a local fire might cause discharges from only one PRV in that area. Similarly, if the cause of the overpressure condition is a blocked outlet, it too might affect only one or two PRVs. On the other hand, if the supply of electric power, cooling water, instrument air, or steam fails, the failure of such utilities can cause many PRVs to be relieving at the same time, and this, in turn, can cause the superimposed backpressure in the relief header to rise substantially.

Built-Up Backpressure The built-up backpressure is the pressure drop between the PRV outlet and the end of the discharge piping. Therefore, it is the sum of the pressure losses in the pipe fittings, valves, and the pipe itself. Its units can be given in PSI, kg/cm^2, and kPa. When choke flow occurs, the built-up pressure can be very high.

The built-up backpressure is a function of the discharge flow rate, the sizes of the outlet fittings and pipe, the number of valves and other restrictions, and also by the compressibility of the discharging vapors and by temperature. The built-up backpressure will therefore be lower if the PRV is connected to a short tail pipe that vents to atmosphere.

Backpressure Effects The backpressure can affect the set pressure of the pressure relief valve. This is illustrated in Figure 7.16c, which considers several valve designs and means for remedying this effect. It is shown in this figure that venting or not venting the bonnet can change the direction of the backpressure effect.

If the backpressure builds up as the valve opens, the valve may chatter and reclose. If the backpressure is constant and is

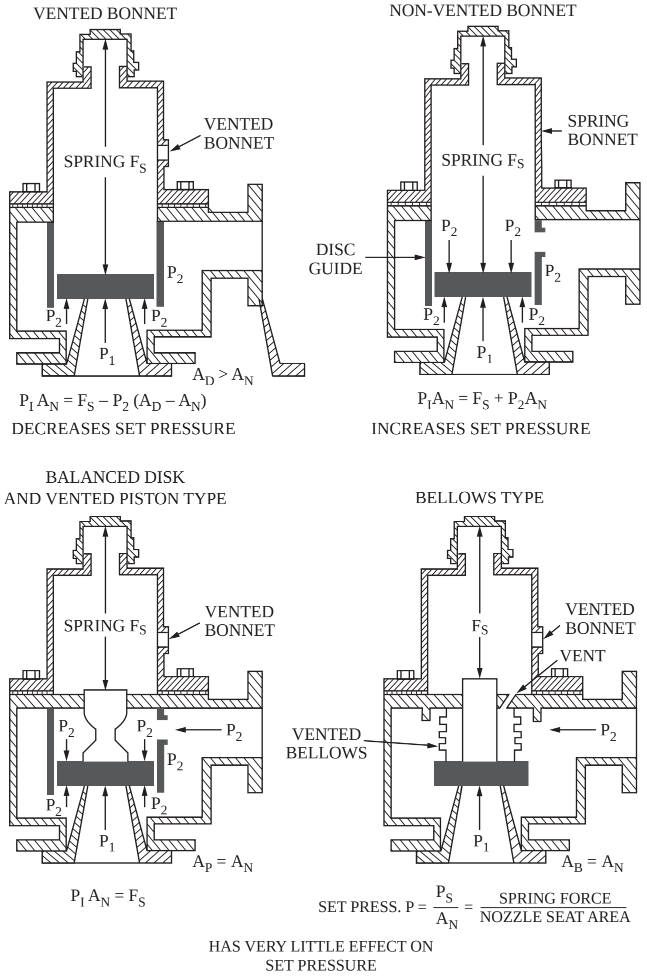

FIG. 7.16c
Effect of backpressure on set pressure. (A_N = nozzle area; A_D = disc area; A_P = piston area; A_B = bellows area.)

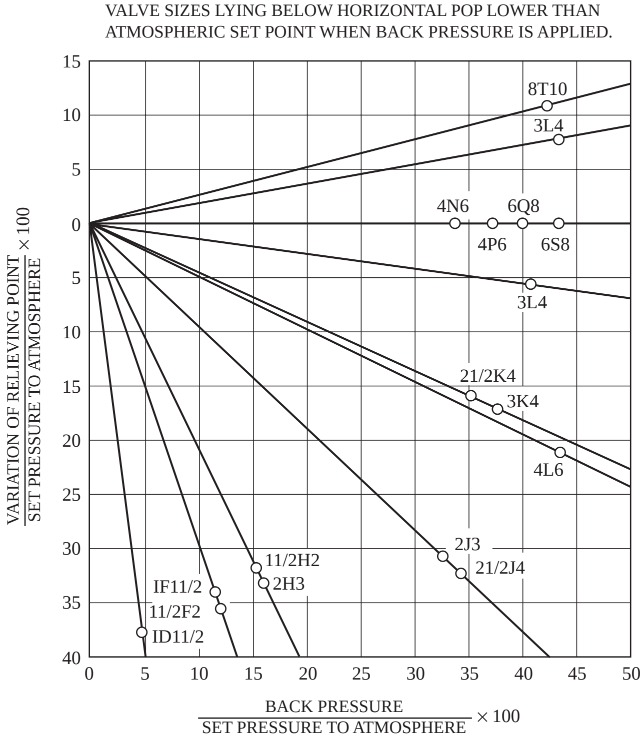

FIG. 7.16d

Manufacturer's tests on effect of backpressure on standard safety relief valves. (Data courtesy of Farris Engineering Corp.)

already present when the valve starts to open, it should be possible (if all code and insurance requirements are fully satisfied) to compensate for it by raising or lowering the spring setting.

In conventional pressure relief valves, constant backpressures up to the critical pressure ratio can be compensated by spring setting without affecting the capacity. Above that setting, compensation can be used, but (as will be discussed later) an appropriate capacity reduction factor must be employed in sizing. All manufacturers provide this reduction factor, and there is virtually unanimous agreement on the factor at any given ratio of constant backpressure to actual relieving pressure for both vapors and liquids.

Figure 7.16d shows that the dimensions and design of the particular valve will establish the change needed in the spring setting and that this change is a function of the backpressure. Therefore, it is *not* suggested that one compensate for backpressure with the spring setting without consulting the manufacturer of the particular valve. In fact, it is suggested that spring setting adjustment be limited to the noncritical applications and that pilot or bellows seal designs be used to guarantee that the PRV will open on set pressure on all critical applications.

Sizing for Vapor and Gas Relief

The basis for almost all pressure relief valve sizing for process industry service is found in the ASME Unfired Pressure Vessel Code Section VIII, Division 1, described in Section 7.15. The basic sizing equation results from capacity conversions for relief valves described in Appendix 11 of that code. This states that the test media capacity is converted to any other *vapor or gas* by Equation 7.16(1),

$$W = K_b CKAP\sqrt{\frac{M}{TZ}} \qquad \mathbf{7.16(1)}$$

where

W = the relieving flow of gas or vapor, lbm/hr
K_b = a correction factor for constant backpressure, which can be obtained from Figure 7.16b
C = a constant for gas or vapor, which is a function of the ratio of specific heats "k"; it can be obtained from Figure 7.15b or from Equation 7.16(2), below,

$$C = 520\sqrt{k\left(\frac{2}{k+1}\right)^{k+1/k-1}} \qquad \mathbf{7.16(2)}$$

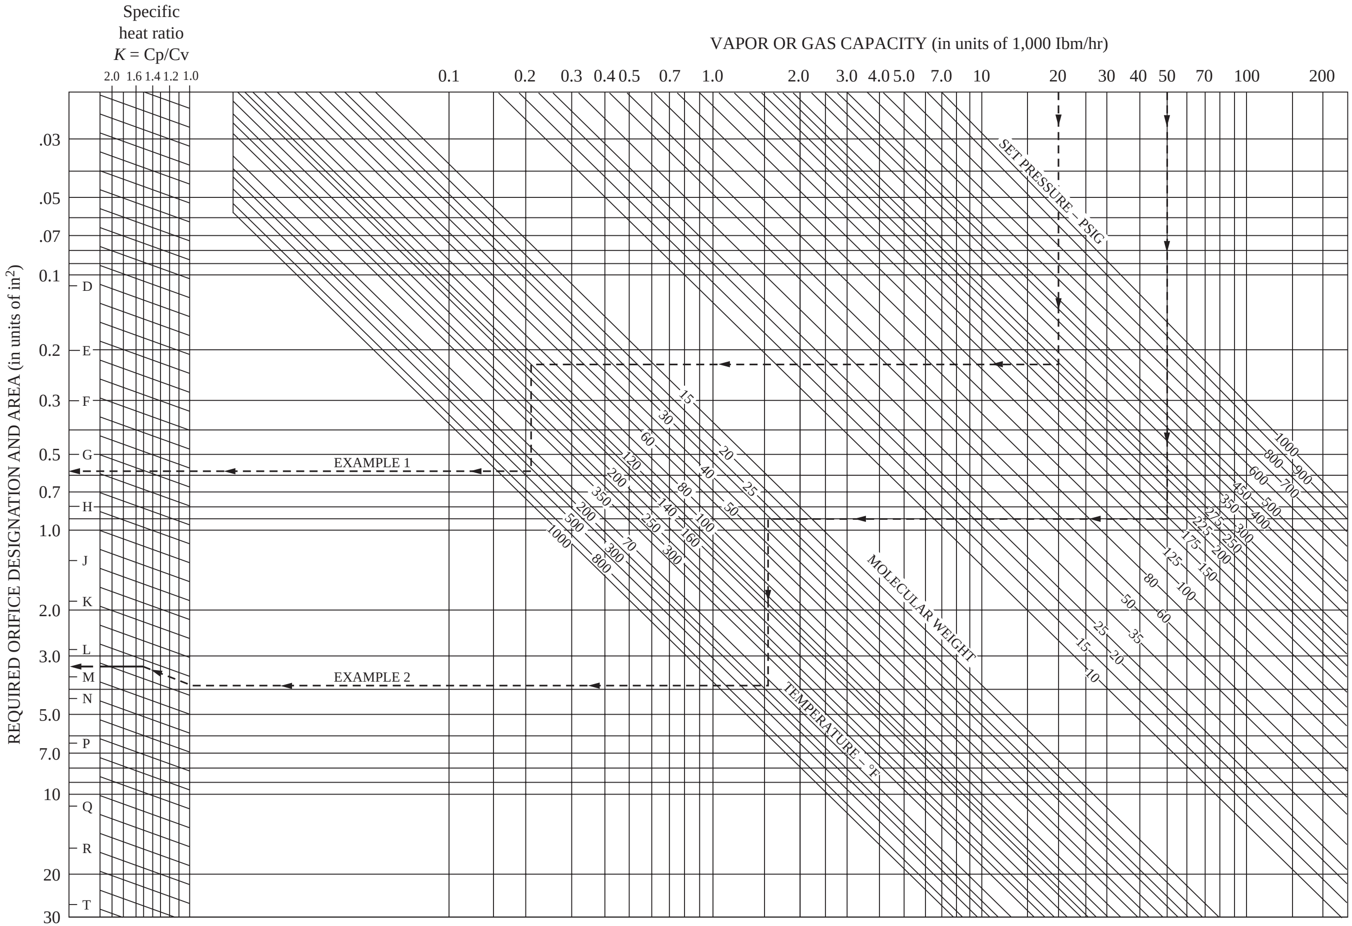
k = the specific heat ratio of the particular gas or vapor, which can be obtained from Figure 7.15a
K = the coefficient of discharge, which is determined from tests
A = the required nozzle area of the valve, in square inches
P = 1.1 × (set pressure) plus atmospheric pressure in PSIA
M = the molecular weight of the gas or vapor
T = the absolute relieving temperature, °Rankine (°F + 460)
Z = vapor compressibility at inlet conditions

The basic equation can be manipulated almost any number of ways, and each manufacturer and designer has its own favorite sizing procedure.

Graphical Method A commonly accepted and easily used graphical approach is shown in Figures 7.16e and 7.16f. Here, the orifice designations of the nozzle areas are those listed in Table 7.16g, which represent the most common API area designations. However, if manufacturer's formulas are used, care must be exercised to use the orifice area with the corresponding recommended formulas. Table 7.16g shows the tabulated nozzle orifice areas and corresponding orifice designations for the API and ASME formulas provided. Using the ASME formula and selecting an orifice based the API area may result in improper valve sizing.

Sizing by Calculation Those who prefer calculations to using the graphical method first have to determine if the flow is critical or subcritical. Critical flow occurs when the gas, as a result of the lower pressure, expands downstream of the PRV's orifice and reaches sonic velocity, which it cannot exceed. The flow rate that corresponds to flow at sonic velocity is called *critical flow.* One can calculate the downstream pressure that, if reached, will result in critical flow (P_{cf}) by Equation 7.16(3).

$$P_{cf} = P_1[2/(k+1)]^{k/(k-1)} \qquad \mathbf{7.16(3)}$$



Note: in^2 = 645 mm^2; PSIG = 0.07 barg; °F = 32 + 1.8°C

FIG. 7.16e

Graphical method of sizing pressure relief valves for vapor or gas services.

where

P_{cf} = the downstream pressure, which results in critical flow in PSIA

P_1 = the upstream relieving pressure in PSIA

k = the ratio of specific heats for any ideal gas

Critical Flow Sizing Table 7.15a lists the critical flow pressure ratio values at standard conditions for a number of gases. When the downstream pressure P_2 is less than or equal to the critical flow pressure P_{cf}, the relieving flow will be in the critical region. Under these conditions, Equations 7.16(4) and 7.16(5) can be used to determine the required PRV discharge area (A).

$$A = [W/CK_dP_1K_bK_c]\sqrt{(TZ/M)} \quad \text{(in US units)} \qquad \mathbf{7.16(4)}$$

$$A = 13{,}136[W/CK_dP_1K_bK_c]\ \sqrt{(TZ/M)} \quad \text{(in SI units)} \qquad \mathbf{7.16(5)}$$

where

A = the required effective discharge area of the PRV in in.^{2} (mm^2)

W = the required flow rate to be relieved in lb/hr (kg/hr)

C = a coefficient that is a function of the specific heat ratio of the gas or vapor at inlet relieving conditions from Figure 7.15b. If C cannot be so determined, it is suggested that one use C = 315

K_d = the effective coefficient of discharge; for preliminary sizing, a value of 0.975 can be used

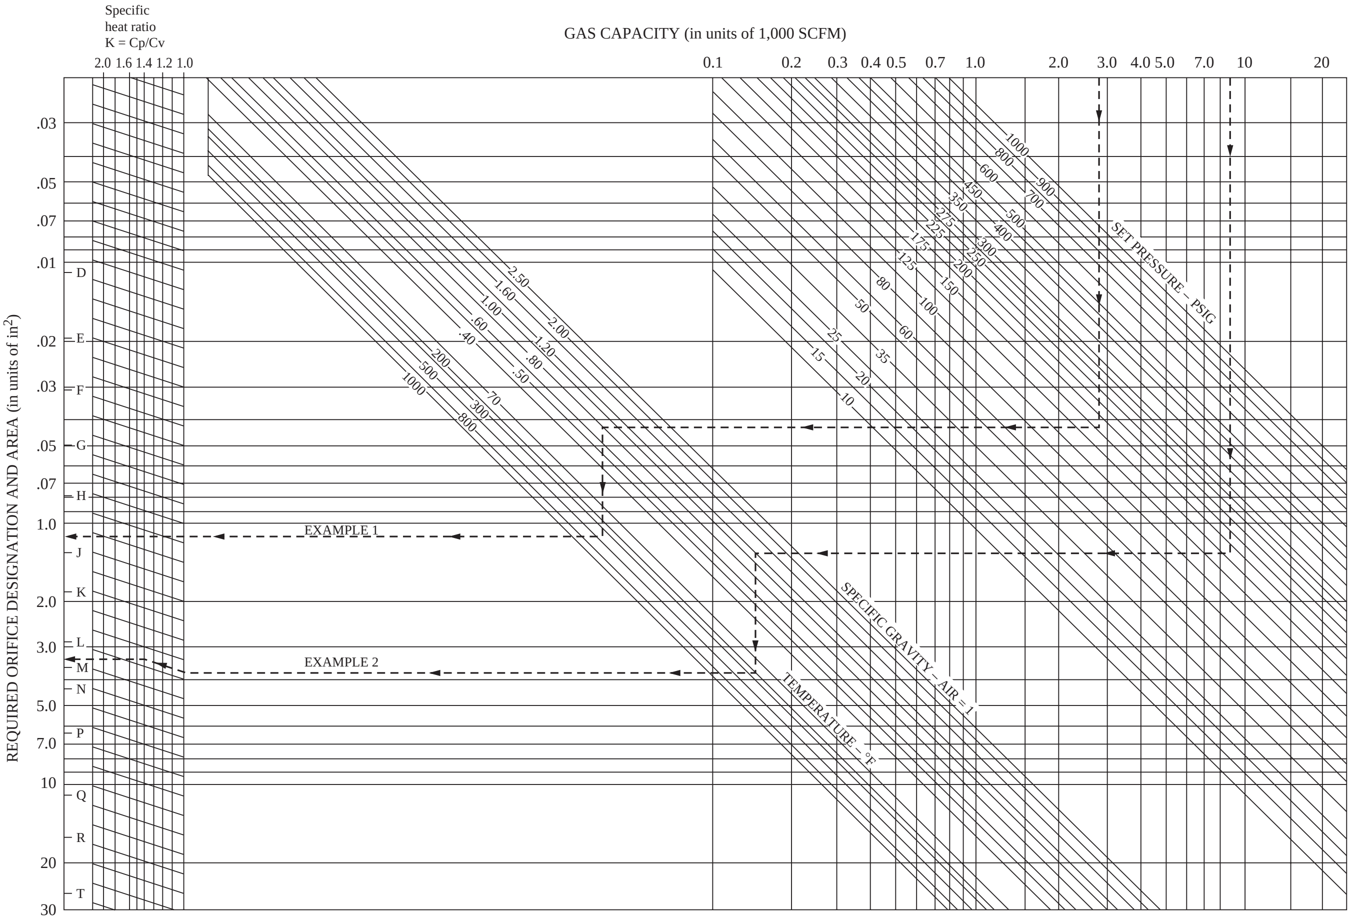
K_b = the capacity correction factor for backpressure, which can be obtained from manufacturer's literature or estimated from the API RP 520 based Figure 7.16h for the preliminary sizing of balances bellows PRVs

K_c = a factor reflecting the affect of a rupture disc being installed upstream of the PRV (Its value is 1.0 if there is no rupture disc. When a rupture is installed and there is no published value available for the combination, use the value of 0.9.)

T = the inlet temperature of the gas or vapor being relieved in °R (°K)

Z = the compressibility factor, reflecting the deviation of the process vapors from an ideal gas under relieving conditions at the PRV inlet

M = the molecular weight of the process gas or vapor being relieved



Note: in^2 = 645 mm^2; PSIG = 0.07 barg: °F = 32 + 1.8°C

FIG. 7.16f

Graphical method of sizing pressure relief valves for gas services.

TABLE 7.16g

PRV Nozzle Orifice Areas in Square Inches (in.^{2} = 645 mm^2)

Q	11.05	12.85
R	16.0	18.60
T	26.0	28.62

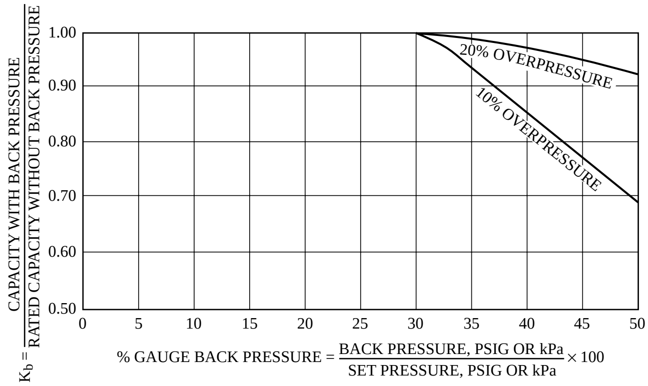

FIG. 7.16h

Variable or constant backpressure sizing factor, K_b, for balanced bellows pressure relief valves on vapor or gas service. The curves represent a compromise of the values recommended by a number of relief valve manufacturers and may be used when the make of a valve or the actual critical flow pressure point for the vapor or gas is unknown. When the make is known, the manufacturer should be consulted for the correction factor. These curves are for set pressures of 50 PSIG (345 kPa) and above. For set pressures lower than 50 PSIG (345 kPa), the manufacturer should be consulted for the values of K_b.

P_1 = (for conventional PRVs) the set pressure × (1 + accumulation allowed by code having jurisdiction) + atmospheric pressure in PSIA (kPaa); (for pilot-operated PRV valves) = the set pressure plus accumulation *minus* ΔP_{inlet} in PSIA (kPaa)

ΔP_{inlet} = the inlet pipe loss upstream to the PRV in PSI (kPa)

Subcritical Flow Sizing If the PRV is provided with bellows seals, the sizing for subcritical flow can be based on Equation 7.16(4) or 7.16(5), but the backpressure correction factor K_b should consider the subcritical flow and the tendency of the disc of the PRV to drop to below full lift. For these reasons, the K_b factor should be obtained from the manufacturer.

When sizing conventional or pilot-operated PRVs for subcritical conditions ($P_2 > P_{cf}$), Equation 7.16(6) or 7.16(7) should be used.

$$A = [W/735F_2K_dK_c]\sqrt{\{TZ/[MP_1(P_1 - P_2)]\}} \text{ (in US units)} \quad \textbf{7.16(6)}$$

$$A = 17.9[W/F_2K_dK_c]\sqrt{[TZ/MP_1(P_1 - P_2)]} \text{ (in SI units)} \quad \textbf{7.16(7)}$$

where

F_2 = the subcritical flow coefficient

Backpressure Effect on Capacity Backpressure affects the capacity and thus the sizing of relieving devices. In a sense, the PRV is similar to an open control valve, because its upstream pressure is the process pressure, and its downstream pressure is that which exists in the relieving header. However, instead of being a *controlling* element, it is *controlled by* the pressure conditions at its inlet and outlet.

Most safety valves will handle flow very similar to a theoretical nozzle as long as they are fully open (at full lift) so that the controlling flow area is established by the nozzle. The capacity of a theoretical nozzle is not affected by the downstream pressure as long as it does not rise to the point where the ΔP drops below the critical pressure drop needed to maintain sonic flow. At higher backpressures, the flow becomes subsonic.

The effect of backpressure on the capacity of a conventional safety valve with an unvented bonnet is shown in Figure 7.16i. Note that the two sources of backpressure (superimposed and built-up) produce different effects. Because of this capacity reduction due to lift action, conventional valves should never be used where backpressure variation can exceed 10% of the set pressure.

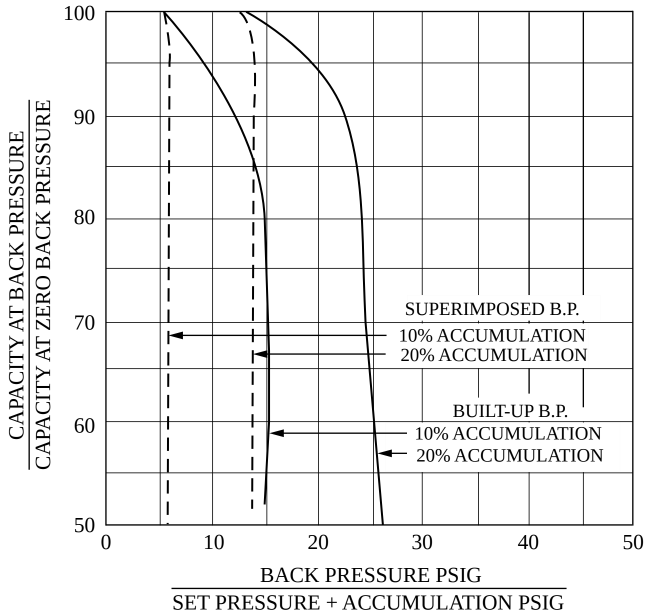

FIG. 7.16i
Effect of backpressure on capacity of conventional safety relief valves.

Sizing for Steam Relief

The need for steam relief sizing is more often encountered in the design of power plants than chemical plants. The sizing method itself is straightforward once the required load and the relieving conditions are established. ASME Code Section I is used in sizing steam PRVs for fired boilers whereas, for nonfired vessels, ASME Code Section VIII is applicable. The basic steam sizing equation is a modification of Napiers.

$$A = W_s/(51.5P_1K_dK_bK_cK_NK_{SH}) \text{ (in US units)} \quad \textbf{7.16(8)}$$

$$A = (190.4W_s)/(P_1K_dK_bK_cK_NK_{SH}) \text{ (in SI units)} \quad \textbf{7.16(9)}$$

where

A, P_1, K_d, K_b, K_c = as defined in connection with Equation 7.16(4)

W_s = the required relieving steam capacity, lbm/hr (kg/hr)

K_N = the Napier correction factor, which is 1.0 if $P_1 < 1500$ PSIA (10,339 kPaa) [For pressures between 1500 PSIA (10,339 kPaa) and 3,200 PSIA (22,057 kPaa), use Equations 7.16(10) and 7.16(11) to calculate the value of K_N.]

$$K_N = (0.1906P_1 - 1000)/(0.2292P_1 - 1061) \text{ (in US units)} \quad \textbf{7.16(10)}$$

$$K_N = (0.02764P_1 - 1000)/(0.03324P_1 - 1061) \text{ (in SI units)} \quad \textbf{7.16(11)}$$

K_{SH} = the superheat correction factor, which is 1.0 for saturated steam (For steam tables, refer to Appendix 5 or see manufacturers' tables.)

Sizing for Liquid Relief

The 1986 edition of ASME UG-131 requires that, for pressure relief valves on incompressible fluid service, a capacity certification test using water at a temperature between 40 and 125°F be conducted. For any other fluid, the manufacturer's tables generally can be used as long as the *equivalent water volumetric rate* in gpm is used to enter these tables.

Division I of the ASME Code Section VIII, since 1980, has required that liquid service PRVs be provided with capacity certification. This certification requires that the rated coefficient of discharge be based on 10% overpressure. Existing PRVs that were manufactured before 1980, were not provided with certification, but were sized with 25% overpressure allowance need not be replaced, but new PRVs must be designed for 10% overpressure operation.

For preliminary sizing purposes, disregarding viscosity and backpressure effects, the graph in Figure 7.16j can be used.

Calculating the Discharge Area For more accurate sizing for liquid service PRVs, refer to Equations 7.16(12) and 7.16(13) below:

$$A = [Q/(38K_dK_wK_cK_v)]\sqrt{SpG/(P_1 - P_2} \quad \text{(in US units)} \qquad \mathbf{7.16(12)}$$

$$A = [(11.78Q)/(K_dK_wK_cK_v)]\sqrt{SpG/(P_1 - P_2} \quad \text{(in SI units)} \qquad \mathbf{7.16(13)}$$

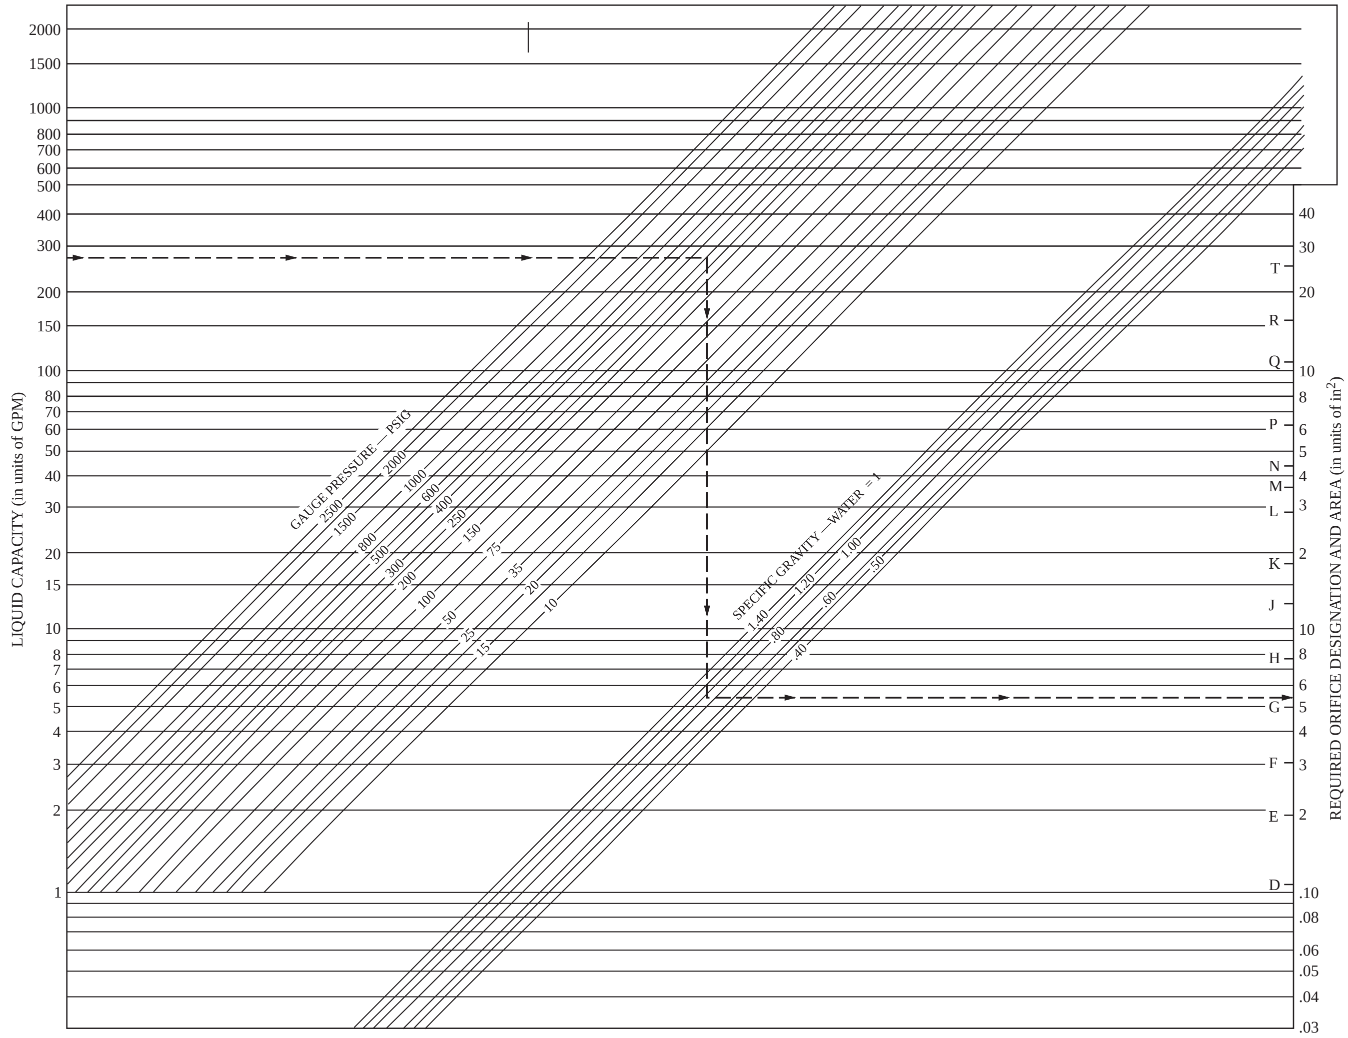
where

A, K_cP_1, P_2 = as defined in connection with Equation 7.16(4)

Q = the relieving flow of liquid in GPM (l/min)

K_d = the effective coefficient of dicharge, which should be obtained from the manufacturer (For preliminary sizing use $K_d = 0.65$.)

K_w = the variable or constant backpressure capacity correction factor, which is required only



GPM = 3.78 Ipm; PSIG = 0.07 barg: in^2 = 647 mm^2

FIG. 7.16j
Approximate relief valve sizing chart for liquids.

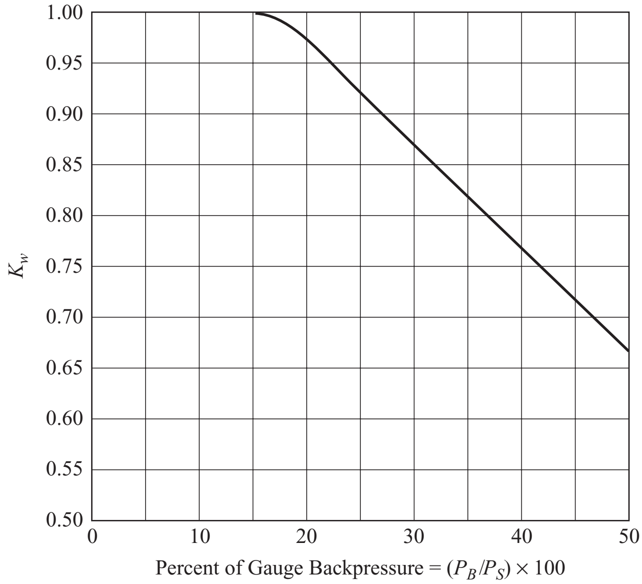


FIG. 7.16k
Curve for the determination of K_w as a function of the ratio of P_B/P_S. K_w is the capacity factor, which is to be used on liquid service pressure relief valves with balanced bellows for correcting the effect of backpressure. P_B/P_S is the percentage ratio of backpressure divided by set pressure (both in PSIG). This curve represents the values recommended by various manufacturers and should only be used if the supplier is not known. Otherwise, the applicable K_w factor should be obtained from the supplier. (Reproduced courtesy of the American Petroleum Institute from API Recommended Practice 520, Sizing, Selection, and Installation of Pressure-relieving Devices in Refineries, Part I – Sizing and Selection, 7th ed., January 2000.)

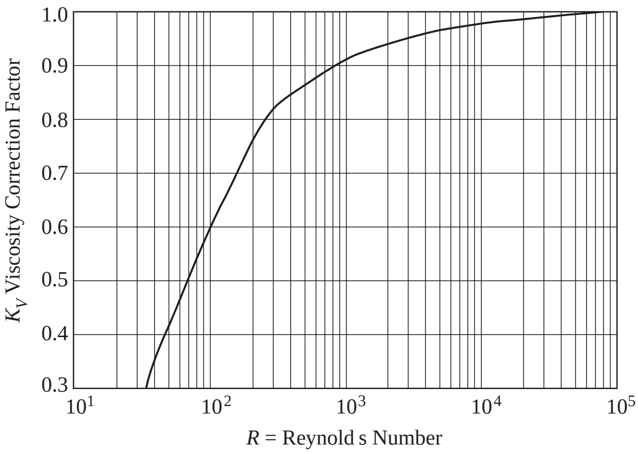

FIG. 7.16l
Curve for the determination of the viscosity correction factor K_V, which is given as a function of the Reynolds number of the process fluid being relieved. (Reproduced courtesy of the American Petroleum Institute from API Recommended Practice 520, Sizing, Selection, and Installation of Pressure-relieving Devices in Refineries, Part I – Sizing and Selection, 7th ed., January 2000.)

for bellows sealed PRV valves (Figure 7.16k) (For conventional or pilot-operated valves, or when the backpressure is atmospheric, use $K_w = 1.0$.)

K_v = the capacity correction factor for viscosity, which can be obtained from Figure 7.16l or from Equation 7.16(14), in which R is the Reynolds number

$$K_v = [0.9935 + (2.878/R^{0.5}) + (342.75/R^{1.5})]^{-1.0} \qquad \textbf{7.16(14)}$$

SpG = specify gravity of liquid at flowing conditions relative to water at 60°F

Viscosity Correction The factor K_v accounts for the fact that the resistance to flow encountered when handling viscous liquids above 50 to 100 SSU may reduce the velocity and thus capacity enough to require a larger orifice size than the usual liquid capacity formula would indicate. Because the correction factor is a function of the flow conditions, and these in turn depend on the orifice diameter, a trial orifice is usually calculated based on no viscosity correction at all, based on Figure 7.16j.

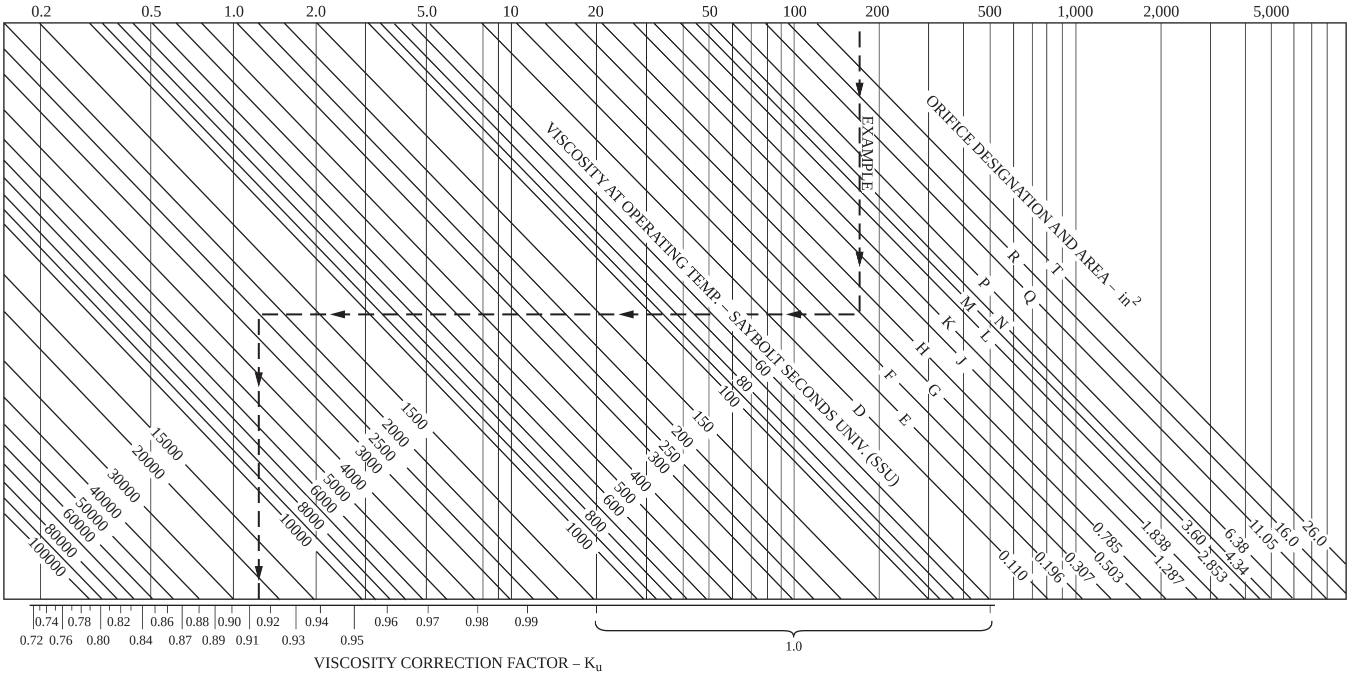
Having determined this "nonviscous orifice size," the next larger standard orifice is selected and used on the graph shown in Figure 7.16m to find the correction factor. This procedure is then repeated, using the corrected value as a trial value, until the corrected *required* orifice area is less than that of the standard orifice that was used to establish the K_v factor.

Sizing for Flashing Liquid Relief

API RP 520 Appendix D (7th ed., 2000) describes a method for PRV sizing on two-phase service, but it is still a somewhat controversial subject. No sizing method has been validated by tests, nor is there any recognized procedure for certifying two-phase relief capacity. Problems associated with flashing include the possibility of autorefrigeration and ice formation, which might require the use of heat tracing or specially selected PRV materials.

While the actual sizing is discussed below, certain features of the valve discharge system can affect both valve sizing and the cost of the installation. Because the amount of flash is influenced by the discharge line size through the actual backpressure developed, the ability of discharge line sizing to suppress vapor generation should be considered. Based on limited experience and some calculation, it appears that the most economical valve size results at about 30% backpressure. Balanced safety valves are usually used in flashing flow to minimize the effects of the flashed vapors and of the resultant backpressure on valve operation and capacity.

In the absence of experience in a particular service, some manufacturers use an enthalpy balance (isenthalpic flash)



GPM = 3.78 Ipm: in^2 = 645 mm^2

FIG. 7.16m
Viscosity correction chart.

across the valve to calculate the expected volumetric rates of liquid and vapor downstream of the valve. The required discharge areas are then established independently for these two rates, which are treated as all liquid and all vapor, respectively. Both sizing calculations must be made at the same overpressure with the appropriate capacity correction factors applied as needed. The discharge area of the PRV is selected to be at least equal to the sum of these two calculated areas.

While this method is not theoretically refined, there have been no reported incidents in which this procedure led to an undersized valve. The method could conceivably lead to an oversized valve, which in turn can possibly result in valve chatter. However, it is probable that the valve plus its discharge piping will come to a stable condition of balance between the effects of flashing and the downstream pressure drop.

Special Cases

There are a number of special cases (such as relieving polymerizing materials, handling high-temperature water, Dowtherm® systems, super pressure steam system, cryogenic fluids, toxic materials relief, etc.) for which manufacturers have developed special designs of valves and sizing experience or special sizing methods. It is recommended that the reader avail himself of all available advice and assistance. Frequently, the recommendations of two manufacturers will not agree. The reader is thus alerted that he has a problem case and that further study may be warranted.

SPECIFICATION AND SELECTION

Pressure relief valves serve to provide relief from overpressure by opening a path for the excess process fluids flow to a safer location. After the excess pressure is relieved, they reclose, thereby not only preventing the further loss of process fluids but also returning the process to normal operation. A properly designed and installed PRV will perform these tasks automatically, reliably, economically, and efficiently.

The most commonly accepted means of providing this is to sense the rising pressure by some sort of force-balance mechanism that, when its set point is reached, opens the required relieving area for fluid flow. Usually, this force balance has the process pressure acting upon a given area on one side; on the other side, that force is compared against the force of springs or weights.

The magnitude of the forces that are being balanced can be reduced, and thus their control improved, through the use of secondary devices such as pilot valves, solenoids, etc. Of the above-mentioned design options, the weight-loaded valves have largely disappeared from process plant services except in extremely low-pressure applications where their high accuracy and the absence of the "spring constant" effect caused by valve travel makes them advantageous.

Figure 7.16n shows a specification form that can be used to list the required features of pressure relief valves before they are sent out for bids by PRV manufacturers. Figure 7.16o provides some cost estimating information on a list price basis, which plant engineers can use if, based on their previous projects, they know their probable discount schedules.

Conventional PRVs

As it is shown in Figure 7.16p, the conventional PRV is a force balance device that is held closed by a spring when the inlet pressure is below its set pressure. When the set pressure is reached, the upward force overcomes that of the spring, and the valve opens. When the inlet pressure drops below the set pressure by some percentage (this difference is called *blowdown*), the valve recloses. The housing of the spring is vented to the outlet of the PRV, and therefore the operation of the valve is directly affected by the backpressure.

The main difference in the operation of a PRV on liquid relief service from that of a vapor relief valve is that it does not have "pop action." This is because, on liquid service, the force that lifts the disc is generated by the reactive forces (the impact of the flowing liquid stream on the disc holder) to achieve full lift. These reactive forces build slowly during the initial 2 to 4% of overpressure, and only after that will the valve suddenly surge to full lift. The blowdown (the percentage by which the inlet pressure has to drop below the set pressure for the valve to close) on liquid service is much larger than on gas service—around 20%.

PRV Bodies and Bonnets The basic requisite for a direct spring-loaded pressure-relieving valve is a suitable valve body, which is usually an angle-type device, having an inlet connection that is suitable for the inlet pressure/temperature requirements under both normal and relieving conditions. The body,

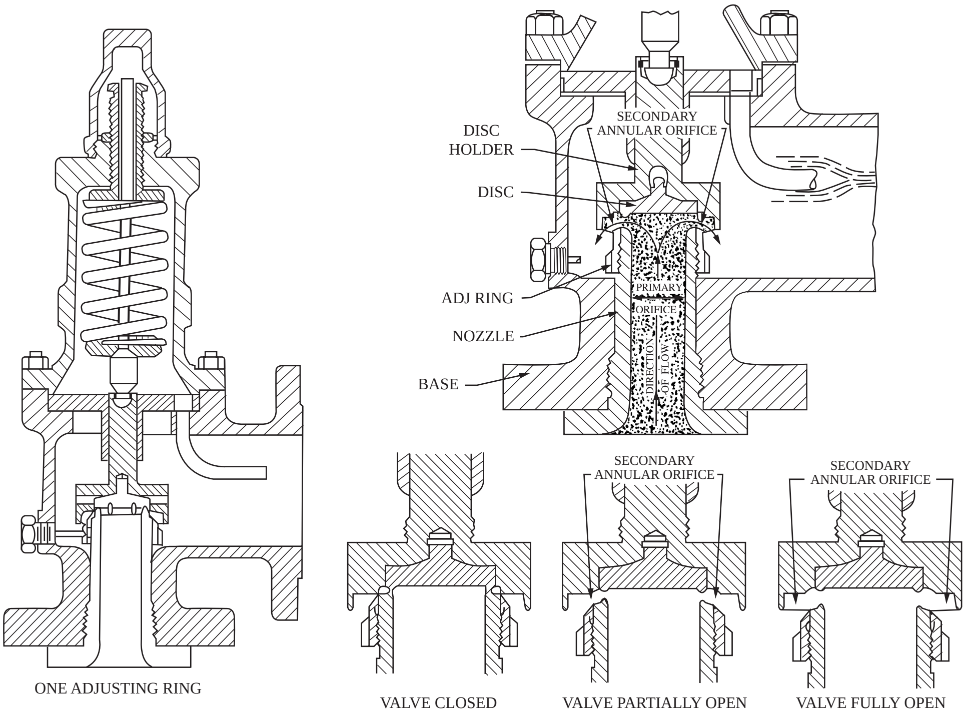

FIG. 7.16p
All the main components of a conventional pressure relief valve are shown on the left. On the lower right, the closed, partially open, and fully open positions of the valve are illustrated. On the top right, the critical working components (nozzle, adjusting ring, disc, and disc holder) are identified.

the outlet, and the bonnet are usually designed for a lower pressure than the process pipeline or the inlet connection of the PRV. Body connections can be flanged, screwed, or welded.

The bonnet is sized to accommodate the spring for the maximum pressure rating of the valve. The bonnet is used when the discharging medium must be confined within the valve body and discharge piping. All bonnet-type valves have either caps over the adjusting bolt or lifting levers, either plain or packed.

Flanged valves for steam boilers usually have an open spring with a yoke in place of a closed bonnet. The spring is exposed on the steam valve, whereas the spring is totally enclosed on the bonnet type valve. Marine boiler valves are of the yoke type except that additional cover plates must be added and sealed to prevent tampering with the spring. The covers are vented (not pressure tight).

Seat and Spring The PRV inlet incorporates a valve seat with a disc for full closure of the inlet port. The disc is usually spring loaded, and the spring force is applied directly on the disc by means of a stem. The disc may be either disc guided or top guided. A bottom (disc)-guided valve has vanes or feathers for guiding in the valve bore (inlet port). Process valve are usually top guided (Figure 7.16p). Boiler valves and liquid relief valves are often disc guided.

The set pressure is determined by the selection of the proper spring and by adjusting the bolt that compresses the spring to the correct opening pressure. Springs are classed in different ranges so that the spring is never overstressed and so that proper clearance between the coils allows for full lift. The spring force at open position must not exceed the lifting force of the flowing medium when the valve is fully open. The spring setting may be adjustable in a narrow range. This adjustment can be 30% or more on low-range springs and 5% on higher-range springs. The manufacturer must be consulted for the acceptable range for a particular spring.

Nozzles and Blowdown Rings The inlet of the PRV may be described as a bushing, semi-nozzle, or full nozzle. The bushing is used on bottom-guided valves. The semi-nozzle is usually found in cast iron valves. Both are screwed into the PRV's body. The full nozzle is utilized on steel valves and is the part of the valve that is designed for the pressure rating of the process line.

The seat, orifice, and flange facing is one piece. The flange of the valve is used for bolting force, which is to ASA standards. The nozzle flange construction is similar to a Van Stone-type flange. The discharge area or orifice of a nozzle type valve is smaller than the nominal inlet. The converging of the nozzle results in a high velocity, which provides the high kinetic energy required to obtain high lift.

Pop Action The capacity of PRVs must be accurately calculated, and their action must be reliable and foolproof over the long run. Reliability is achieved by the maximum use of simple mechanisms such as springs and linkages, and so forth. Accuracy in relieving capacity is achieved by conservatism, by treating the relief device as an orifice, and by attempting to size and install it so that it can always release the process fluid (and thus energy).

In Figure 7.16p, one should note that there is an adjustable ring around the nozzle. Furthermore, the disc has either a fixed or adjustable deflecting lip. The purpose of this lip is to form a huddling chamber, which provides the pop action of these pressure relief valves. The inlet nozzle is used to efficiently generate the required velocity head (and thus capacity), while the lip and the ring on the nozzle form a secondary orifice and a device for reconversion of this velocity energy into static pressure to provide the pop action when sufficient vapor flow develops.

Valve Lift and Capacity Being spring-loaded, PRVs require some increase in force, because the movement of the spring occurs while the valve is opening. The amount of this force increase is determined by the spring constant and by the amount of valve lift required to achieve full capacity. Most PRVs reach their full capacity opening at about 3% above their set pressure. If the pressure rises further, the area of opening does not increase, so the increase in PRV capacity is the result only of increased valve pressure differential.

Therefore, at 3% overpressure, the valve has fully lifted. At this point, the curtain or cylinder area (huddling chamber) between nozzle and disc is greater than the cross-sectional area of the nozzle. The so-called low-lift valves gain more capacity at higher pressure, because they have not reached their limiting dimensions for the curtain area at the low overpressures. In such cases, it is not permitted under the ASME Code to calculate down-ratings for valves at lower pressure based on performance at a higher test pressure, although up-rating above test pressure is permitted, because it will always tend to be quite conservative.

In contrast to gas or vapor PRVs, liquid service relief valves generally do not reach their full capacity dimensions until their full nominal rating overpressure of 10% is reached. In liquid PRVs designed prior to 1980, this overpressure was 25%. Down-rating to lower pressures is permitted and provided by all manufacturers. It is important to understand and design for this up-rating and down-rating, especially when considering actual flow during maximum relief. This can affect pressure losses in inlet and outlet piping.

Balanced PRVs

Two of the most common means of eliminating the effect of backpressure on the set pressures of a PRV's set pressure are the use of bellows seals and of a balancing piston design. Figure 7.16q describes both of these devices. The balanced disc, which is operated by a vented piston, is shown on the left, and the bellows sealed designs are on the right. Note that these devices may or may not provide a true balance, depending on how well they match the nozzle area.

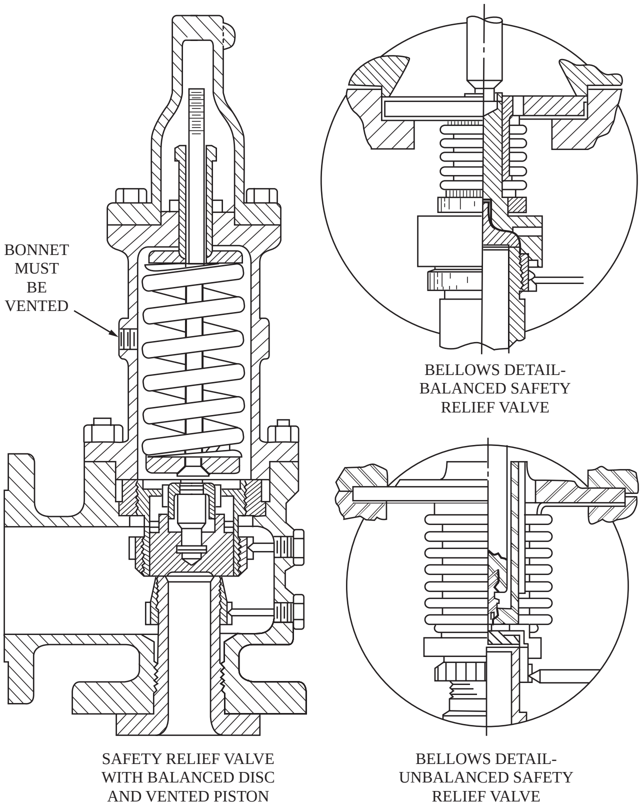

FIG. 7.16q

Balancing devices include balancing pistons (on the left) and bellows seal (on the right), which can be placed on either balanced (top) or unbalanced (bottom) relief valves.

The backpressure effect on the PRV's set pressure has already been discussed in connection with Figure 7.16c. This figure illustrated several valve designs and four different means of remedying this effect. On the lower right, Figure 7.16c illustrates a PRV that is provided with vented bellows seals. In this design, if the bellows area (A_B) is the same as the nozzle area (A_N) of the PRV, the valve will be balanced, and the backpressure will have no effect on the pressure set point at which the valve opens. Such a balanced PRV is shown on the upper right of Figure 7.16q.

If the bellows area (A_B) is *not* the same as the nozzle area (A_N), the valve will be unbalanced, and the backpressure will affect the set point. Even among balanced bellows designs, there are differences among the K_b correction factors of different manufacturers (Figure 7.16r). These variations are a function of the specific valve design.

Equations 7.16(4) and 7.16(5) should be used when sizing balanced bellows PRVs for gas or vapor service. In these equations, the backpressure correction factor K_b serves to correct for the loss in capacity resulting from subcritical flow and for the condition when the valve disc does not lift fully. For preliminary sizing estimates, Figure 7.16b can be used to obtain a K_b correction factor, but, because each manufacturer's PRV design is a little different, the actual value of K_b should be eventually obtained from the selected manufacturer.

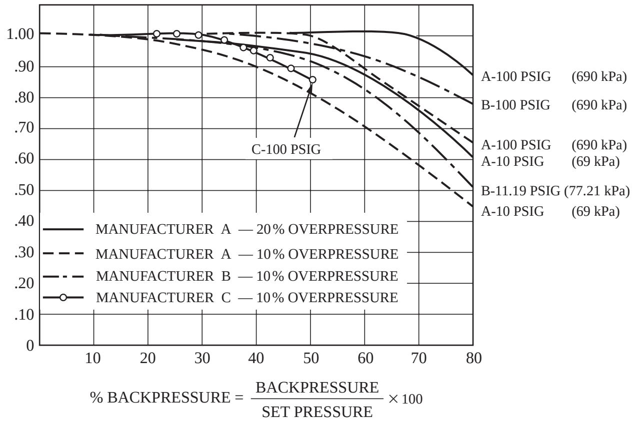

FIG. 7.16r

Backpressure capacity reduction factor (K_b) for balanced bellows PRV valves.

When sizing the PRV for liquid service, it is common practice to use the minimum pressure drop in the standard formula [Equation 7.16(12) or 7.16(13)], which includes the K_w factor for backpressure correction. For liquid applications as well, there is variation in this factor among vendors.

As was shown by Equation 7.16(14), viscous materials adversely affect the capacity of relief valves. Because the required correction depends on the Reynolds number, the point at which a correction is required will be a function of orifice size, flow rate, and flowing viscosity (Figure 7.16l). There is reasonably good agreement among manufacturers as to the viscosity correction, and there is also general agreement that viscosities below 50 to 100 SSU do not require correction.

Pilot-Operated PRVs

The pilot-operated PRV shown in Figure 7.16s consists of an unbalanced floating piston type main valve and an external or integral pilot. During normal operation, because the area of the piston is larger on the top than on the bottom, and because both are exposed to the same process pressure, the resulting net force holds the PRV tightly closed. As the process pressure rises, the seating force increases with it. This feature is an advantage in applications in which the maximum operating pressure is close to the relief set pressure and it is important to prevent leakage.

When the set point is reached, the pilot vents the pressure from the top of the piston, and the piston lifts. When the process pressure drops below the set point of the pilot, it closes its vent, which, in turn, reseats the piston.

The pilot can be pop-action or modulating and can be flowing or nonflowing. The modulating design can save expensive process fluids and can shorten the system recovery time by relieving only as much process fluid as needed to lower the pressure below its set point. For most services except for inert gases, the nonflowing designs are preferred.

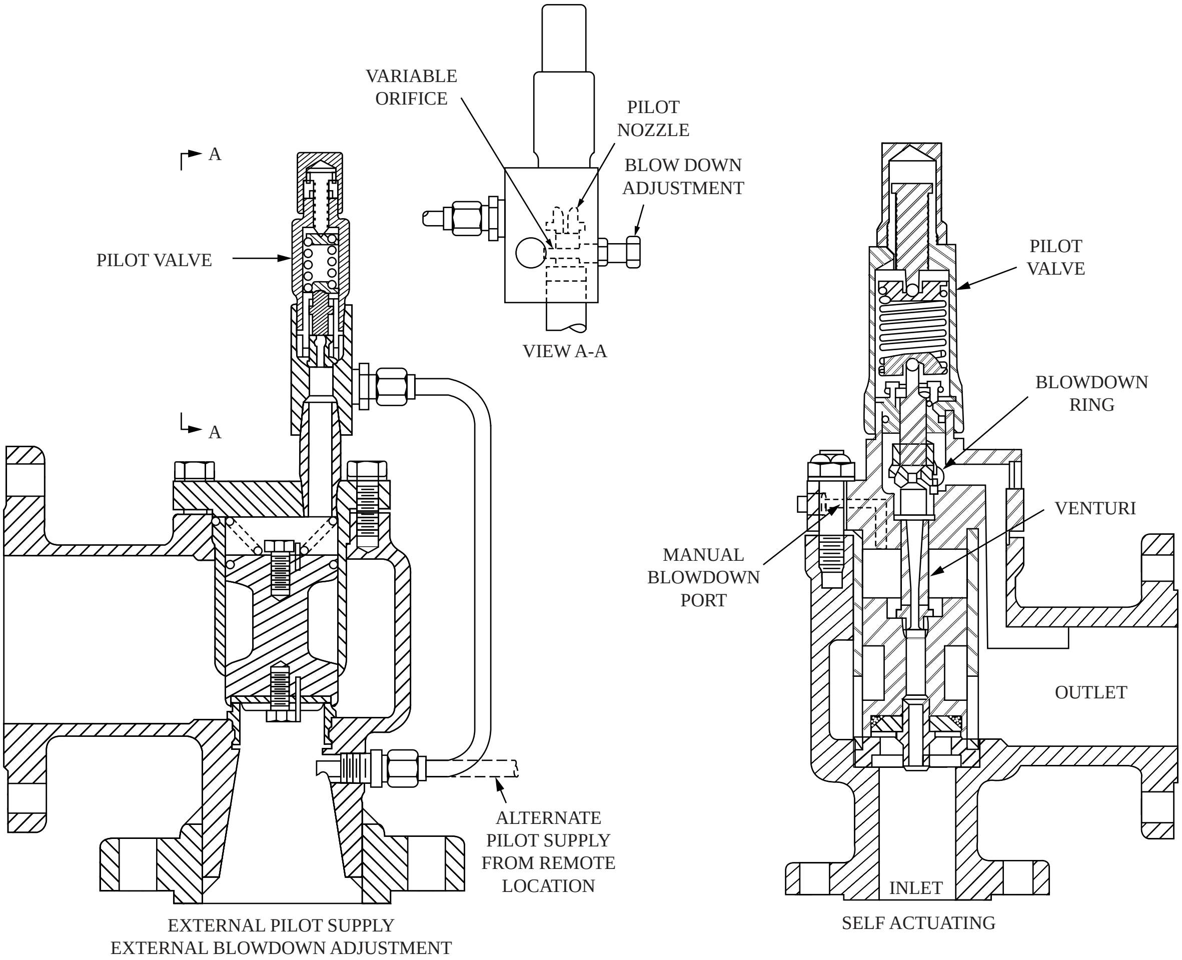

FIG. 7.16s
Pilot-operated relief valve designs showing the external (left) and integral pilot versions (right).

Integral or External Pilot The PRV on the right of Figure 7.16s utilizes an integrally mounted conventional safety valve that, based on the relationship between the process pressure and its set point, sends the process pressure to the top of the main piston or vents it. The external pilot design on the left permits adjustment of blowdown without a need for entering the valve proper and uses an external sensing line to the pilot.

There are also pilot-operated PRVs in which the blowdown and relief settings are independently adjustable through the pilot valves mounted on top of the main piston or disc chamber. Most of these designs have not received wide acceptance because of the large number of static and moving seals they require for proper functioning and because of the small clearances and potentials for plugging in the pilot mechanisms.

Advantages Where operating pressures approach the set pressure, and where the process fluids are toxic and thus present hazardous leakage problems, pilot-operated valves present special economic and safety advantages.

1. The probability of leakage is reduced when the operating pressure approaches the set pressure because, as the process pressure increases, the forces that are holding the piston closed also increase. In contrast, in the spring-operated valves, the differential pressure on the seat decreases under these conditions, causing simmering near the set pressure.
2. Flexibility is provided by the potential for remote operation.
3. Because nozzles are not needed to generate the velocity for pop action, the capacity is larger. The potential increase in capacity over the largest nozzle orifice for a given body size ranges from 150% for smaller sizes to about 120% for the larger sizes.
4. There is improved operability at up to 98% of set pressure due to lower blowdown. Figure 7.16t shows these advantages.
5. There is a reduction in the loss of product loss, downtime, and maintenance.

Disadvantages

1. There is increased potential for failure due to the large number of static and moving parts.

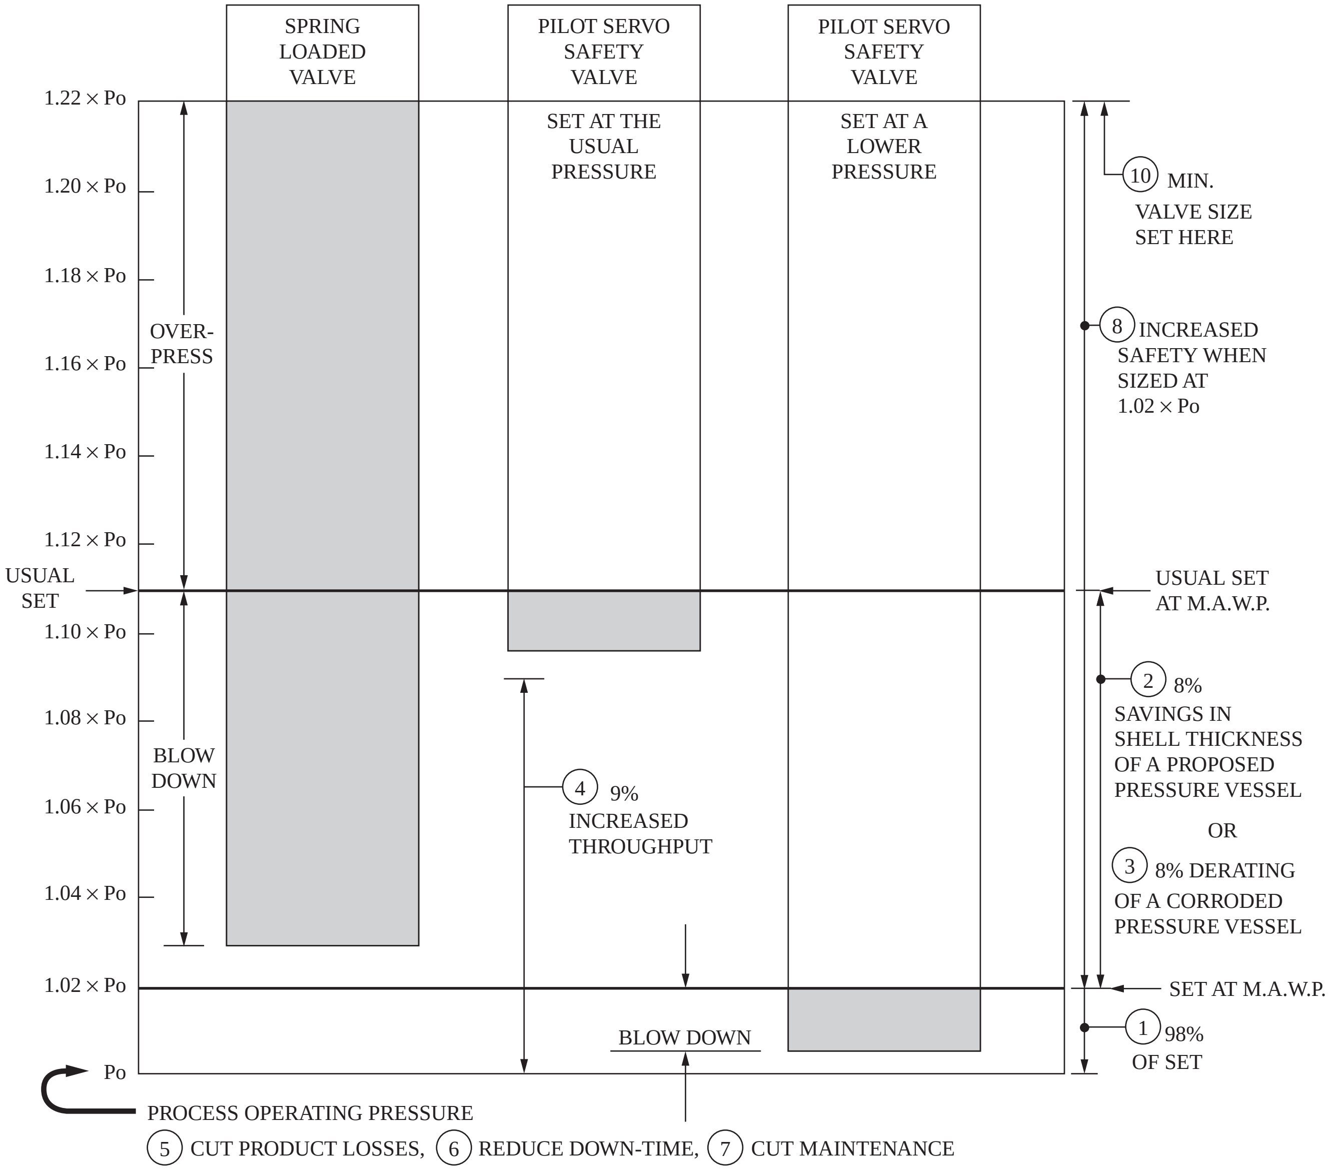

FIG. 7.16t
Comparing the operating ranges of conventional spring-loaded PRVs to the ranges of pilot-operated ones.

2. Small clearances exist in pilot mechanisms that can be plugged by dirty process fluids.
3. The lead lines between the process and the pilot valve and between pilot and main valve are small in size and therefore have a higher potential for plugging.

Modulating Pilot-Operated Valves The modulating pilot-operated relief valve is especially useful where some degree of oversizing is necessary or desirable, because this valve design helps to eliminate chattering. The main feature of the modulating pilot-operated relief valve is that it has a zero blowdown, which allows the main valve to modulate while being approximately at the set pressure.

On gas or vapor service, this valve is at full lift when the overpressure is about 3%, and when it is about 10% on liquid service. Due to the variable orifice feature, the modulating PRV valve opens only to relieve the overpressure and hence reduces both the noise and the upset to the downstream process. Figure 7.16u shows the lift of the valve piston as a function of the process pressure during modulation. It can be seen that this PRV valve changes its lift (opening) as the rate of discharge is surging, thus avoiding chatter.

When to Consider Pilot-Operated PRVs When the following conditions exist, it is justified to consider the use of pilot-operated PRVs (POPRVs):

1. The expected PRV inlet losses are significant.
2. The margin between the operating pressure and the set pressure is less than 10%.
3. The operating pressure is less than 15 PSIG.
4. The lighter weight of the POPRV is a consideration.

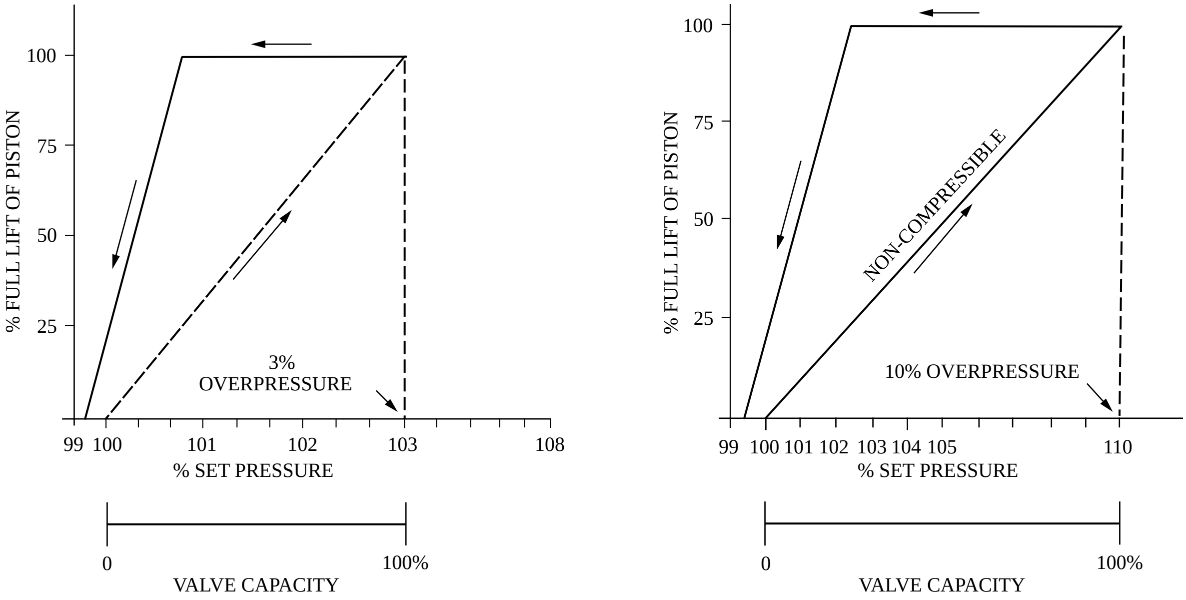

FIG. 7.16u
The operation of modulating pilot-operated pressure relief valves on gas or vapor (left) and on liquid service (right).

5. If the required orifice size is larger than “P,” both cost and operating performance favor the consideration of using POPRVs.
6. A depressuring system is needed.

In connection with “depressuring,” it should be noted that such units should be used only as backups in addition to regular pressure-relieving systems. These backup systems should be sized to lower the process pressure from the set pressure to 50% of design pressure within 15 min. They are considered when the response time of the regular PRVs is insufficient on reactors with potential for runaway reactions, on gas filled tanks exposed to fire, on high-pressure fluid applications in the event of major leakage, and in the reduction of hydrogen partial pressure to minimize the potential for exothermic reactions.

Specification and Selection Checklist

In addition to selecting a particular pressure relief valve for a specific service, it is advisable to review the following checklist of the most frequent PRV system problem areas:

1. Make sure that, from among ASME Section I and VIII, API, NFPA, etc., the right codes have been followed.
2. Specify both maximum and minimum normal operating temperatures and design the PRV for those and not for the temperatures that might be reached during fire relief conditions. Evaluate the high-temperature effects on the seat and seal of the PRV, check for temperature causing disc warpage or spring set-point change.
3. Make sure that the set pressure of the PRV is equal to or less than the tank design pressure. If the PRV protects several vessels, make sure that the hydrostatic head of liquids is considered in selecting its set point so that the design pressure, even at the lowest point, will not be exceeded.
4. Make sure that the inlet and outlet line losses are consistent with the code limits, and consider the use of POPRVs with remote pressure detection when high inlet loss is unavoidable.
5. Select a safe discharge point for the PRV if the process fluid is toxic, corrosive, or flammable to protect both the operators and the environment.
6. Consider the possible process upsets as well as start-up and shut-down conditions when selecting the operating margin (difference between set pressure and operating pressure) for the PRV; if the process fluid is toxic, corrosive, or very valuable, make that margin large.
7. Consider galling or seizing problems in guiding or other close clearance areas, which can be caused by bad materials selection, foreign matter entry, or deposit buildup.
8. Check for atmospheric corrosion effects on the discharge portion of the valve bonnet and other portions of the discharge header system. Check, in particular, the effect on high-stressed elements such as springs. Consider the use of diaphragm seals and bellows seals.
9. Consider the possibility of polymer or other material buildup in throats of valve or operating mechanism after or during relief, which could impair valve action. Consider the use of various seals.
10. Consider the resistance of the PRV valve assembly to vibration.

11. Provide the valve designs that will minimize chatter on pulsating services.
12. Consider the probable condition of the valve and its seating after exposure to external fire.
13. Evaluate whether the inlet, outlet, and/or the PRV itself requires thermal tracing, because winter temperatures can cause freezing of the process fluid. Evaluate the need for steam jacketing to prevent tendencies of solidification or crystallization within the valve. Check, in particular, the degree of steam jacketing required.
14. Make sure the features are provided to accurately guide the disc.
15. Check the need for valve position indicating devices.
16. Check the availability and desirability of augmenting normal disc seating forces or keeping them constant until the valve set point is reached so as to minimize leakage.
17. Select seat and seal materials that are compatible with, and are not dissolved by, the process fluids. On H_2S service, make sure that the valve materials are selected in compliance with NACE MR0175. Also, make sure that the seat will reseat tightly after relieving on specific service.
18. Make sure that the proper design features are selected for countering the effects of all types of backpressures and the resulting variations in set point and blowdown.
19. Evaluate the consequences of, and provide the ability to detect, bellows rupture.
20. Consider open-spring vs. bonneted-spring designs.
21. Evaluate the degree of blowdown needed and answer questions such as: Does blowdown have to be adjustable? Can pop action be destroyed in adjusting blowdown?
22. Evaluate the need for special service valves such as chlorine service, toxic material, LPG storage tank, ICC approved, Coast Guard approved, etc.
23. Evaluate the need for various auxiliary features such as test gags, lifting levers open or packed, screwed vs. bolted adjusting nut caps, etc.
24. Evaluate the level of noise produced and its effect on discharge piping.

PRV OPERATION AND PERFORMANCE

The topics of blowdown, PRV chatter, valve tightness or leakage, and discharge system considerations are discussed in the following paragraphs.

Blowdown

The phenomenon of blowdown is caused by the use of springs in PRVs. The relieving system, when in operation, is a kinetic system in which the PRV is at a point of high kinetic energy in contrast to the equipment that it is protecting. The valve spring balances against a pressure that equals the pressure in the protected tank minus the kinetic effects.

When the PRV is closed, the system is a static one, with no kinetic effects. Therefore, the pressure at the point of spring balance is equal to that in the protected tank. When the PRV is open, its inlet pressure is less than the pressure in the protected vessel because of the inlet pressure drop. This discrepancy between relieving and static conditions requires the allowance for blowdown.

Blowdown is the amount by which the protected tank's pressure has to drop below the PRV's set pressure for the valve to reseat. This pressure difference is needed to ensure that the valve satisfies its force balance once it closes. The normal blowdown of a PRV is between 2 and 7% of set pressure. Pilot-operated PRVs can reduce the blowdown to about 2%, and engineers should always consult the supplier of a particular PRV design for the actual percentage of their design.

Section I of the ASME code for fired boilers requires that the PRVs reach their full lift at a pressure not greater than 3% over their set point and reclose within the maximum blowdown values given in Table 7.16v. Section VIII of the ASME code for unfired vessels does not provide a blowdown requirement, and the industrial practice is about 7%, which means that the normal operating pressure must be under 93% of set pressure.

Setting the Blowdown The position of the adjustable ring on the PRV nozzle (Figure 7.16p) controls the blowdown. This position establishes a secondary orifice area as the valve opens and closes. Blowdown is set by first bringing this ring all the way up to the disc (this corresponds to the maximum blowdown position) and then lowering it a number of turns as recommended by the vendor. This is necessary because most test facilities have limited supplies of gas, and the set pressure is usually tested at zero blowdown.

For process PRVs, the percent blowdown per turn is usually based on methane. A 5% blowdown setting established by using methane can represent about 11% when the valve is handling butane. Very few manufacturers can provide or have published data on this.

If blowdown is an important consideration, field tests usually must be made after the PRV is installed. Even then, it is nearly impossible to simulate actual, desired, or design relieving conditions. Pilot-operated valves are much less subject to these considerations, because they can usually be set for smaller blowdowns. Three percent is fairly standard for a POPRV, and as little as 1% can be achieved in some cases.

TABLE 7.16v
Blowdown Recommendations by ASME for Fired Boilers and Associated Tanks Operating at up to 375 PSIG

Pressure Relief Valve Set Pressure in PSIG	*Maximum Blowdown Recommended*
<67	4 PSI
<67 to <250	6% (of set pressure)
>250 to <375	15 PSI

PRV Chatter

Energy losses in the inlet piping to the PRV and the protected tank (as well as an oversized valve) can lead to a condition known as *chatter*. Under these conditions, the PRV valve repeatedly cycles between its open and closed positions. Variations in backpressure exceeding about 10% while a conventional PRV is relieving will also produce an unstable force balance condition and chatter.

Section II of API RP-520 endorses the widely used limit of 3% of set pressure as the maximum limit for the pressure loss in the inlet piping of a PRV. If, during relief, there are losses much higher than 3%, they can drop the pressure at the PRV seat to the reseating value. When this happens, the valve closes, but as soon as it does, it is immediately subjected to a pressure rise, because closure has eliminated the kinetic effects. This rise in pressure can be enough to cause the PRV to reopen, and the cycle repeats.

Oversized valves can also cause this same condition, because a spring-loaded valve needs to have about 20 to 30% of its maximum flow to establish a stable force relationship to maintain a stable disc position. Chatter has at least two detrimental effects. One is that the valve's seating condition will cause leakage. The other detrimental effect is that bellows failure can be expected if the disc chatters or flutters.

Chatter and Inlet Line Loss in POPRVs Pilot-operated valves are not subject to chatter to the same extent, because they are open or closed and cannot "throttle down" to flows in the 20 to 30% range. Thus, if they are oversized, repeated openings and closings may be needed to hold the system pressure, and the net result is an action approaching chatter. Modulating pilot-operated relief valves overcome the basic problem of oversizing and inlet pressure losses that are the causes of chatter.

As far as their set pressure is concerned, POPRVs can have more than 3% pressure drop in their inlet line if they are using a remote sensor (Figure 7.16s shows a local pressure pilot line). In such situations, the inlet line loss will still limit the relieving capacity of the valve. Therefore, the inlet line loss should always be considered *before* the POPRV is sized. If this is not done, when the inlet loss is calculated, it might be found that a larger valve needs to be used. Naturally, in all high line loss cases, one should consider the relocation of the POPRV to the point where the remote pilot line detects the process pressure.

Chatter on Liquid Service The subject of chatter is of special interest when relief valves are mounted on vessels that are full of liquid. In the past, conventional valves designed for vapor service were also used in liquid service, and this had catastrophic results. This is because, in a liquid system, the pressure profile immediately upstream of the PRV valve can change rapidly when the valve "pops open," especially if there is a significant length of inlet piping between the valve and the vessel being protected. In that case, when the valve opens rapidly, an immediate reduction in pressure (at the inlet to the valve) can make the PRV valve close prematurely. The pressure then builds back up again quickly, the valve must open again, and the cycle repeats; thus, chatter ensues.

Most manufacturers offer a liquid-service trim designed specifically to overcome this problem. The piping between the inlet to the valve and the process being protected should be kept to a minimum. Direct connection of the valve to the process vessels is preferred, if practical. Another potential solution is to use a pilot-operated or modulating pilot-operated PRV valve that is provided with a remote sense line, depending on the process conditions and type of process liquid.

PRV Tightness and Leakage

If fire is the only potential cause of overpressure, the valve tightness in spring-loaded valves can be markedly improved by taking advantage of the 20% accumulated pressure that the ASME Code allows for this condition (Table 7.16w).

If one valve is set for 109% of maximum allowable working pressure (MAWP), and 10% accumulation is allowed, this results in the same size valve as one set at 100% allowing 20% accumulation. However, if the operating pressure is at or near 90% of the maximum allowable, the first valve will have about twice the force keeping the seat tight at the operating pressure as that available in the case of the second valve (Figure 7.16x).

Using Two PRVs Another way to reduce leakage in some installations is to use two PRVs. This is a possibility if, in a particular application, there is a large fire load but relatively

TABLE 7.16w
ASME Section VIII Provides the Following Recommendations for Maximum Set Pressures and Maximum Accumulated Pressures for Both Single and Multiple PRV Installations for Both Fire and Non-Fire Cases

PRV Installation Maximum Pressure	*Single Set%*	*Single Accumulated%*	*Multiple Set%*	*Multiple Accumulated%*
Non-Fire Case, 1st PRV	100%	110%	100%	116%
Non-Fire Case, Additional PRV	N/A	N/A	105%	116%
Fire Case, 1st PRV	100%	121%	100%	121%
Fire Case, Additional PRV	N/A	N/A	105%	121%
Fire Case, Supplemental PRV	N/A	N/A	110%	121%

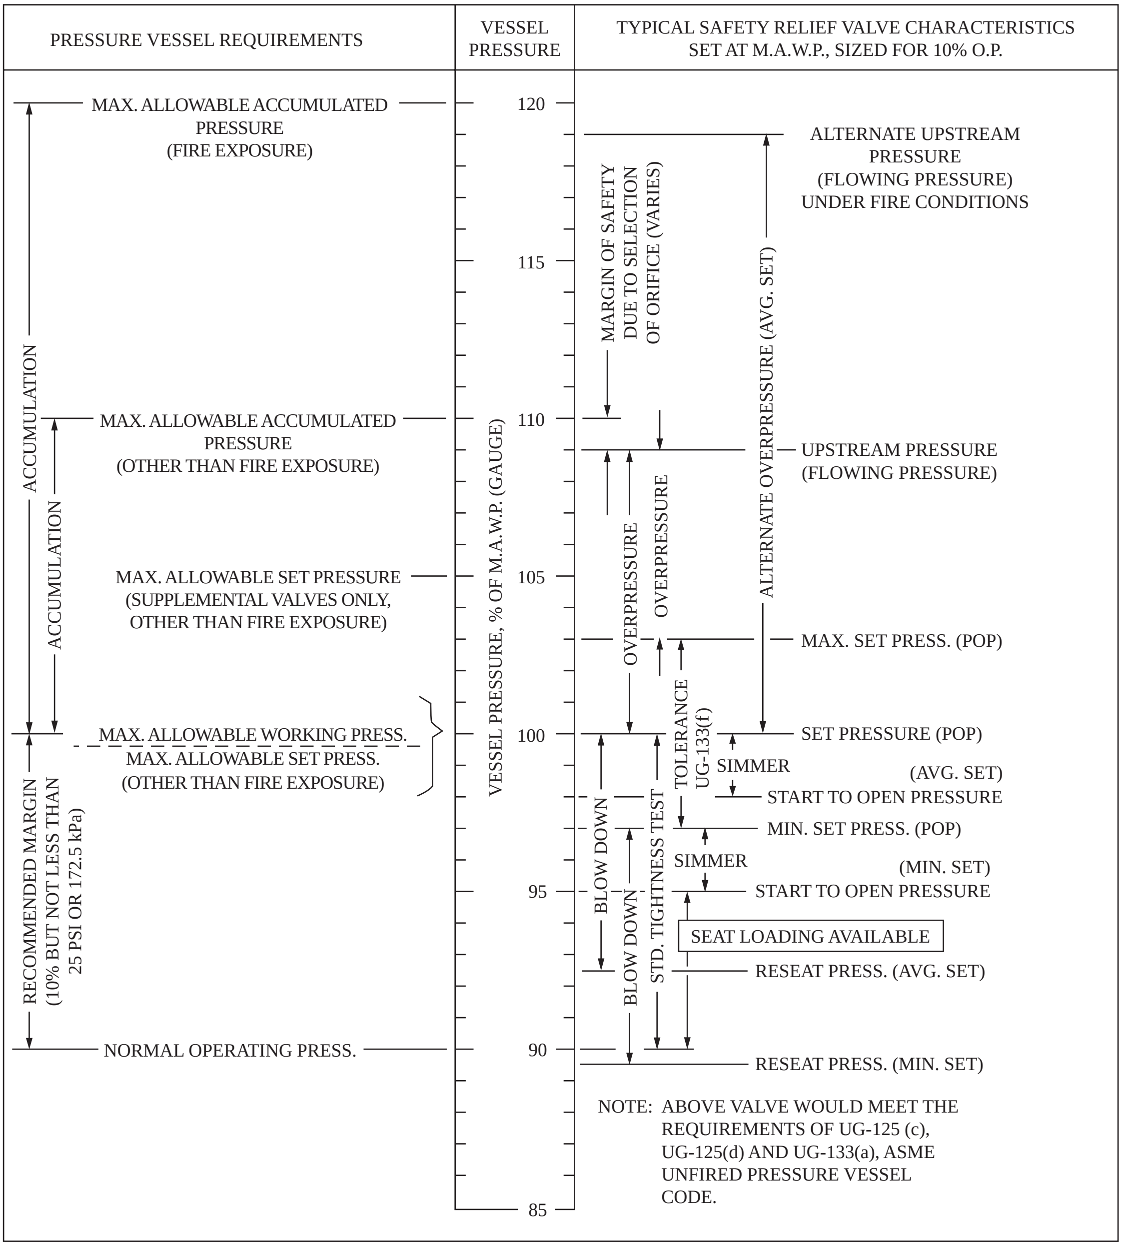

FIG. 7.16x
Characteristics of a single safety relief valve used to protect a pressure vessel having the listed requirements.

small operating load. In such a case, the small valve is set at 100% and sized for 10% accumulation at the operating load, but it will accumulate to 20% under fire conditions. The large PRV is set at 109% and is sized to handle the fire load 10% overpressure. Such a combination of two PRVs will generally reduce leakage quantities (Figure 7.16y).

The use of a pair of PRVs becomes even more attractive if company policy requires the use of two PRVs. Similarly, on low-pressure tall towers, if the API recommendation is followed and therefore the PRV inlet loss is limited to 3% of set pressure, the use of two valves becomes attractive.

Seat Designs, O-Rings, and Temperature Greatly influencing valve tightness are the factors of seating design, cleanliness of the process fluid handled, and installation practices. In the area of seating closure design, some of the mechanical containment designs of the nozzle, disc, and guiding moving parts have been claimed to pay off handsomely in terms of trouble-free service.

The so-called *soft seat designs* and the O-ring seats do much to prevent leakage as long as the PRV does not relieve. However, it is good practice to check the design and question the vendor about what the leakage will be after the PRV

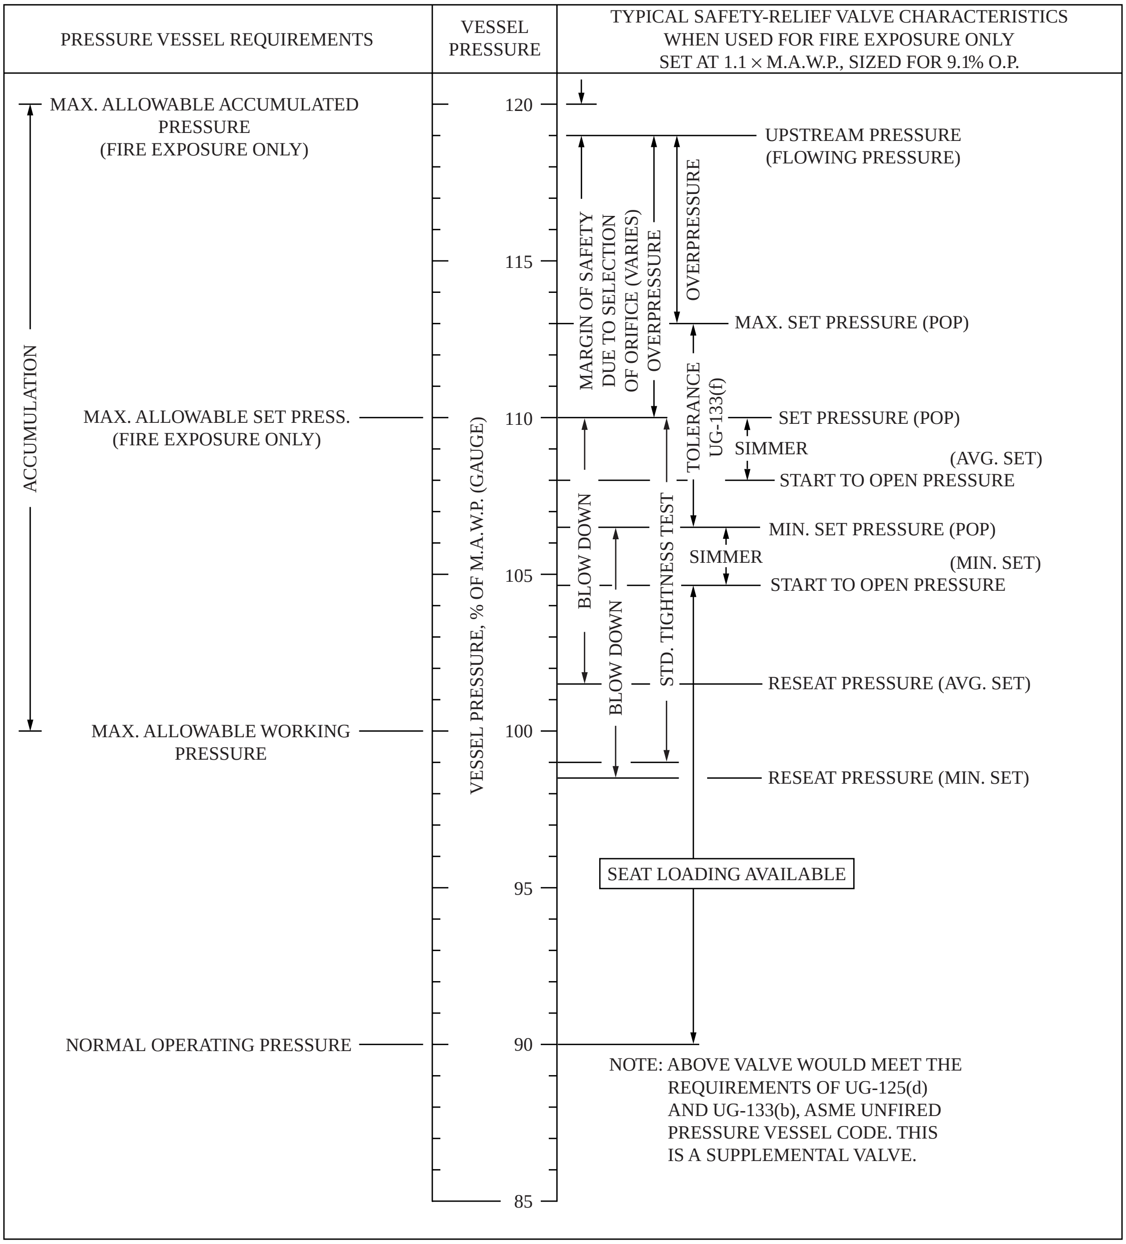

FIG. 7.16y

Illustrating the various pressures in a case where a supplemental valve has been installed to handle the fire load.

reseats. In some designs, the O-ring is actually expected to be shredded or destroyed during relief. Therefore, until the ring is replaced, the PRV will only provide a metal-to-metal secondary seat after the first relief.

Temperature probably provides the most serious limitation on soft seal or O-ring materials. In addition to soft seat sealing, the flexible seat has been well received in some services outside the temperature limits of synthetic seating materials. The knife-edge seat is perhaps the most desirable for services where icing or similar deposits can form on the seat during relief. The knife-edge seat has also been used on liquid services containing fine solids in suspension.

Flatness and Cleanliness Most process service valves as tested and shipped by the manufacturer have a seat finish of less than 5 μin. with a flatness deviation of less than 5 to 15 μin. (0.13 to 0.38 μm). For this reason, even nozzle deformation caused by bolting stresses is a concern.

The method of holding the nozzle in the pressure-containing body to minimize the effects of bolting forces is one of the distinguishing features of some PRV designs. Other design goals include minimizing piping reactions that would tend to deform the nozzle, applying the spring load to the disc, and various disc designs that act to compensate for differential expansion effects. These are refinements that manufacturers have developed as users demanded tighter, longer-lasting valves while the PRV service conditions grew progressively more severe.

The influence of fluid cleanliness on PRV performance is illustrated by contrasting the refinery or chemical industry practices to those of missile service. In a number of refinery and chemical plant applications, experience has shown that the valve will leak once it has opened and reseated. In many plants, it is accepted that you may just as well take it down, clean and lap it, reset it, and reinstall it.

Contrast this with the shop inspection requirements on some missile service PRVs where 200 successive cyclings on clean, high-pressure nitrogen must still leave the valve virtually bubble tight. This requirement is regularly met on a production basis.

PRV INSTALLATION

The inlet and outlet line losses of the individual PRVs are calculated on the basis of their rated capacity, not on their required relieving capacity. This approach should also be used as the basis for sizing PRV manifolds so as to minimize built-up backpressure and PRV chattering.

PRV Location

Pressure relief valves should be placed close to the tank or equipment they are protecting to minimize their inlet pressure losses. Their location should also be selected with the goal of avoiding unstable flow patterns and minimizing inlet turbulence. Therefore, a minimum distance of ten pipe diameters should be provided between such fittings as orifices, elbows, valves, and flow nozzles and the PRV.

Relief valves should be located with full consideration given to the need for convenient maintenance access. Easy and safe access is a very important element in making sure that inspection and testing is regularly performed. If there is no convenient natural access to the valve, the installation of a platform should be considered. PRVs should not be located at the end of long and stagnant horizontal pipes.

PRV Mounting

Vapor relief valves should be mounted on the top of the protected tank and should be connected to its vapor space above the liquid level or to piping that is connected to the vapor space. Liquid service PRVs should be connected below the normal liquid level in the tank. All PRVs should always be mounted vertically, not only because horizontal mounting can adversely affect their operation but also because horizontal mounting violates the ASME code and the API recommended practice.

Pressure relief valves should not be mounted close to vibration or turbulence sources such as orifice plates or positive displacement pumps/compressors. This is because the pressure spikes can cause premature relieving, and the pulsation can alter the PRV's set pressure.

PRVs should not be mounted at the end of horizontal pipes, either. This is because, when the PRV opens, debris such as welding slag, pipe scale, and foreign objects that are present in the horizontal pipe will be transported into the valve and will either cause leaking after the PRV recloses or require immediate maintenance to be performed on the valve.

PRV Inlet Piping

The inlet pipe to all PRVs should be as short and direct as possible and should be the same size or larger than the inlet connection of the valve. The inlet pipe should not connect to locations in the process where unstable or turbulent flow patterns exist. When the PRV is relieving vapors, it should be sloped upward to the PRV so that liquid entrainment would be minimal. If the line has a low point, it should be drained.

If the process is such that the inlet pipe can be plugged, it is recommended to provide a clean, nonreactive liquid purge to keep the inlet line clean. If plugging of the inlet line can be caused by low temperatures, such as generated by the cooling of high-viscosity polymers or by ice formation at ambient temperatures, the PRV inlet line should be heat traced.

PRV Outlet Piping

The outlet pipe size should be the same as or larger than the PRV outlet connection. The outlet pipe should be sized to limit the backpressure when the PRV is relieving so that this backpressure will neither shift the set pressure nor prevent the PRV from operating at its full rated capacity. In case of conventional spring-loaded PRVs, the maximum limit for built-up backpressure is 10% of the set pressure. For PRVs with balanced bellows, it is between 30 and 50%. For pilot-operated PRVs, it is 50% of the set pressure.

The outlet pipe should always be properly drained. The preferred choice is to provide self-draining. When that is not possible, a low-point drain with shut-off valve should be provided, and the drain should be piped to a closed system.

In selecting the materials of construction for the outlet pipe, design engineers should evaluate the possibility of autorefrigeration occurring during PRV relieving. If that is the case, the expected low temperatures should be calculated, and suitable pipe materials should be selected to protect against fracturing the brittle metal.

When the PRV discharges to the atmosphere, long-radius elbows should be used, and both the weight of the outlet pipe and the reaction forces should both be considered in designing the pipe supports. The tail pipes should be angle-cut to reduce both the relieving noise level and the reaction force. Local bylaws should be consulted in setting the allowable noise level, which should be calculated on the basis of API RP 521, Section 5.4.4.3.4, in the 1997 edition.

The discharge location should be selected so that, if steam, hot water, or nitrogen is being discharged, it will not injure the operators. The tip of the atmospheric outlet pipe should be provided with both a screen and a weather cap.

Calculating the Reaction Force Large reaction forces generated by the large volumes and high velocities of discharged fluids as the discharging stream makes a 90° turn at the PRV can overload supports, distort manifolds, and cause leakage related accidents—even fire. When the PRV discharges directly to the atmosphere, the outlet piping should be brace supported and, in case of very large valves, even dual outlets should be considered to balance the reaction forces. The reaction force of an open PRV discharge can be calculated using Equation 7.16(15).

$$F = (W/366)\sqrt{[kT/(k + 1)M_w]} + A_oP_2 \qquad \textbf{7.16(15)}$$

where

F = the reaction force in lb

W = the required relief capacity of the PRV in lb/hr

k = the ratio of specific heats of the relieved gases (Table 7.15a)

A_o = the area of the outlet of the discharge pipe at the point of discharge, in.^{2}

T = the flowing temperature of the relieved vapors at the inlet of the PRV in °R

M_w = the relieved gas or vapor

P_2 = the pressure inside the discharge pipe at the point of discharge in PSIG

When the PRV discharge is sent into a closed system, only at points of sudden expansion is it likely that significant reaction forces will exist. The manifold supports in such cases should be designed on the basis of detailed calculations.

PRV Block Valves

Section I of the ASME Boiler and Pressure Vessel Code does not allow the use of block valves at all. In contrast, PRVs protecting nonfired pressure vessels are permitted to be isolated on both their inlets and outlets if on-line maintenance is impossible. In that case, block valves are permitted if they are provided with a spare PRV and if the service they are in has a history of leakage, plugging, or other causes of frequent maintenance.

When isolating valves are used around PRVs, they must be distinguished by special tagging, and the plant operations should be such that only authorized personnel can operate them. It is also important that the open and closed positions be visible and clearly identified. The plant's operating manual should clearly state the required position of these block valves and should also state the reasons why they are locked open or closed. The operating manual should require not only the periodic checking of PRV isolation valve positions but also the checking of their condition.

Multiple PRVs

One situation in which the use of a small and a large PRV is justified on the same tank or equipment is when the process can have two vastly different relieving capacities. In such a case, the smaller valve is needed, because a single large one would chatter when relieving small flows. The other case, when multiple valves of identical size can be used, is when the total relieving area required is more than that of a "P" orifice (Figure 7.16g). Whenever multiple valves are installed, one PRV should be set at the set pressure and the other(s) at 105% of that pressure, as listed in Table 7.16w.

The use of multiple PRVs can extend their life spans and make it easier to keep their inlet line losses below 3% of set pressure. Another advantage can be the reduction of the PRV inventory of the plant, if the use of multiple valves reduces their variety in the plant.

Among the multiple valves, each should have its own nozzle or other direct connection to the protected vessel or equipment. No tree branching of several PRVs from the same main inlet line should be used.

Spare PRVs

PRVs on critical equipment or processes that cannot be shut down should be provided with spares so that the processing operation can continue even when the PRV fails. The installation of a spare PRV is also recommended if the maintenance history of a particular valve is such that it needs maintenance more often than at regular service intervals.

Spare PRVs are also needed on applications in which the valve needs immediate servicing after each time it relieves because the process fluid is corrosive, fouling, or contains solids. Spares are also recommended if the PRVs operate near their extreme design limits, such as at very low or very high temperatures.

Whenever a PRV is spared, the spare valve must be provided with full-bored isolation valves on both its inlets and outlets. Car seal open (CSO) valve designs are required for these applications, because these block valves must be locked open when the spare PRV is in service.

TEST, INSPECTION, AND AUDIT

There are three levels of continuous status maintenance and reviews of pressure safety systems. Periodic testing serves to make sure that the performance of each PRV is within specifications. The purpose of inspections is to check on the quality and reliability of the testing program, whereas the main purpose of the audits is to make sure that the design of the safety systems has been adopted to the various changes that are always occurring in operating plants.

PRV Testing

All PRVs should be tested before their installation, after each fire event or case of relieving dirty process fluids, and at the frequency of the service intervals set by the plant. Certified technicians are required to perform the PRV tests. Testing is performed either in a test workshop or, if the PRVs are provided with field test connections, *in situ*.

During the test, technicians should look for signs of tampering, process-related damage, leakage, wear, and corrosion. They should also test the set pressure, blowdown, overpressure, and seat tightness of each PRV and make the required adjustment, if any. To test the tightness of the seat, they should follow API Standard 527.

After the testing is done, the staff should prepare a test report for each PRV and mark the PRV tag with the date and test pressure that was checked.

PRV Inspection

The purpose of the inspection is to ensure that the testing was properly performed and that no foreign objects, welding beads, or rust was left inside the PRVs. The inspector will also check for signs of tampering, leakage, erosion, wear, and corrosion and verify that the PRV flanges are clean and in good condition.

The inspectors will also make sure that the PRV's tag is the same one that appears on the P&ID flow sheet and that it is securely tied to the valve. Finally, the inspectors should also make sure that the performance data obtained during testing and reported in the test report are acceptable for the particular PRV application.

PRV Audit

The audit evaluates the pressure safety of a complete processing unit.[2] The main goal of the audit is to confirm that the tasks in the action list of the previous audit have been performed, and the maintenance strategy of the plant has been properly followed. Any process changes that have occurred since the last audit are carefully evaluates in terms of their effects on the pressure safety systems.

If, because of the process changes, PRVs can be removed, or previously acceptable ones have become oversized or undersized, the audit should reveal that. The final product of an audit is a prioritized new action list that will serve to further improve the operating safety of the plant.

INTRODUCTION

Overpressure may occur due to thermal expansion, equipment or control failure, misoperation, external fire, runaway reaction, or a combination of these. The rupture disc has been recognized for many years as a suitable device for relieving overpressure. The rupture disc in its simplest form is a metallic or graphite membrane that is held between flanges and that is designed and manufactured to burst at some predetermined pressure and corresponding temperature. Rupture discs, which are generally installed on or directly above a pressurized vessel nozzle, can be looked upon as the weak link in the pressure system. They will burst and relieve pressure before other system components fail. Another common use of a rupture disc is as single use, fast acting valve in fire suppression systems, aerospace fuel systems, petroleum well drilling tools, laboratory test apparatus, etc.

DEFINITIONS

Rupture Tolerance—The tolerance range on either side of the marked or rated burst pressure within which the rupture disc is expected to burst. Rupture tolerance may also be represented as a minimum–maximum pressure range. Also referred to as performance tolerance in International Organization for Standardization (ISO) standards.

TABLE 7.17a
Typical Characteristics of Rupture Disc Types

	Forward Acting					*Reverse Acting*	
Characteristic	*Prebulged (FAB)*	*Composite (FAC)*	*Scored (FAS)*	*Flat*	*Graphite*	*Knife (RAK)*	*Scored (RAS)*

TABLE 7.17b
Rupture Disc Materials and Operating Temperatures

Material	*Maximum Op. Temp.*
Aluminum	250°F (121°C)
Graphite	430°F (221°C)
Hastelloy® C276	900°F (482°C)
Inconel®/Alloy 600	1000°F (538°C)
Monel®/Alloy 400	800°F (427°C)
Nickel 200	750°F (399°C)
Silver	250°F (121°C)
Tantalum	500°F (260°C)
Teflon®	500°F (260°C)
316 stainless steel	900°F (482°C)

Manufacturing Range—A range around the specified burst pressure within which the marked or rated burst pressure must fall. Manufacturing range is not used in ISO standards.

Operating Ratio—The ratio of the maximum operating pressure to the marked burst pressure expressed as a percentage (common US definition). The ratio of the maximum operating pressure to the minimum of the performance tolerance expressed as a percentage (common ISO definition).

Nonfragmenting—A rupture disc design that when burst, does not eject fragments that could interfere with the operation of downstream equipment (i.e., relief valves).

CODE REQUIREMENTS

Significant changes in the governing codes and standards regarding rupture discs have occurred since the last edition of this handbook and continue to occur. Compliance with the applicable standards can be complex and is beyond the scope of this work. However, key points relating to the most common standards are summarized. It should also be noted that certain standards have specific testing requirements that are different than or exceed normal commercial practice and can increase the cost.

The American Society of Mechanical Engineers (ASME) Section VIII Division 1 (ASME Code) is the primary pressure vessel code used in North America and is also used in various regions of South America, Asia, and the Middle East. It is also used as a company standard by many multinational companies. In the 1997 addenda of the 1995 edition, significant changes were made to the rupture disc requirements. ASME UD code symbol stamping was added, requiring design verification testing and third-party approval as well as changes to the methods used for sizing rupture disc devices. The 2001 edition incorporated additional changes in certification and sizing by recognizing flow resistance values for rupture discs on liquid applications.

ISO 6718 is used primarily in Europe as well as parts of South America, Asia, and the Middle East. The most significant differences in these rules from the ASME rules are in the area of sizing. The coefficient of discharge is different in some cases, and sizing methods beyond the coefficient of discharge method are offered although not described in detail.

ISO 4126–2 and 4126–6 are new standards that are going through their final approvals as of this writing. These standards are based on ISO 6718 with the objective of meeting the requirements of Directive 97/23/EC (pressure equipment directive [PED]). Marking of the rupture disc device with the CE mark identifies it as meeting the requirements of the PED and available for use within the European Union.

The American Petroleum Institute (API) RP520, an industry standard, has more how-to information and in most cases supports the requirements of ASME Section VIII Division 1. RP520 also goes beyond the ASME Code by providing additional guidance in sizing and applying pressure relief devices.

RUPTURE DISCS VS. RELIEF VALVES

Rupture discs and relief valves can be used individually, in series, or in parallel. The greatest difference between relief valves and rupture discs is that relief valves are reclosing devices and rupture discs are not.

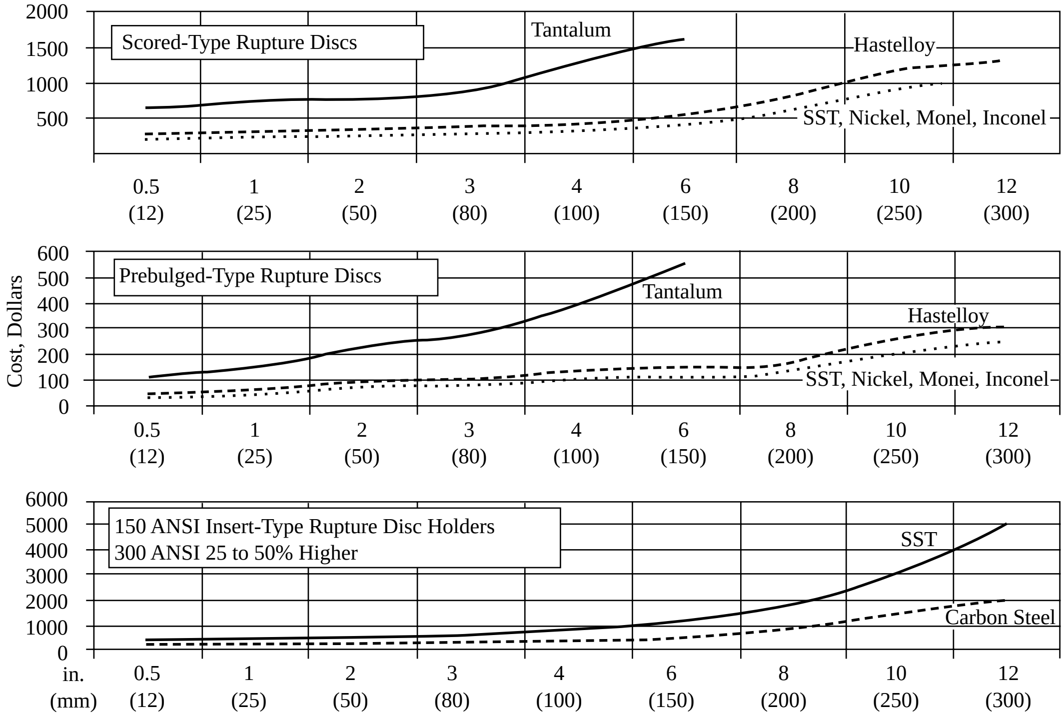

FIG. 7.17c
Costs of rupture discs and holders.

As the process pressure starts to build, a relief valve will gradually open and then reseal the process once the pressure drops. The rupture disc will remain sealed tight until its burst pressure is reached. In order to reclose the process, the disc must be replaced. It follows from this that the rupture disc can be used as a tight seal whereas the relief valve cannot. The only time a rupture disc will leak is if it develops pinholes due to corrosion, or if hairline cracks develop due to metal fatigue caused by the stress of pressure cycling.

A second area of difference is in the construction of the two relief devices. Because rupture discs have a relatively simple construction, they are commercially available in an extremely wide variety of materials at reasonable cost and on reasonable delivery schedules. This cannot be said for relief valves, which are generally limited to copper alloy, steel, and stainless steel constructions. They can become very expensive, long-delivery items if special materials are required.

WHEN TO USE A RUPTURE DISC

With the code requirements and the comparison between discs and valves in mind, the following rules can be used on where and when to specify rupture discs.

As a Primary or Sole Relief Device

As shown in Figure 7.17d, the rupture disc may be used to relieve an inexpensive and inert material to air if the loss of process pressure can be tolerated. At the other extreme, rupture discs may be used to vent highly toxic, poisonous, or corrosive materials into a vent surge or flare header system. The advantage of the rupture disc for this application is that under normal conditions, it will not allow any leakage.

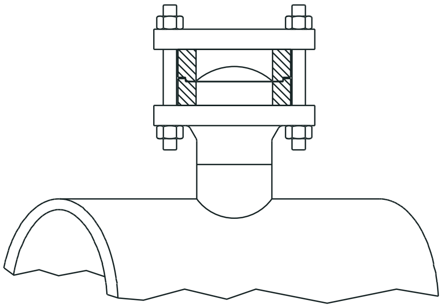

FIG. 7.17d
Rupture disc as primary relief device.

As a Supplemental Relieving Device

When a relief valve is the primary relieving device, the rupture discs are set at the higher relieving pressures as permitted by the ASME Code. The relief valve will open on mild overpressures, relieve a small amount of material, and reclose the process. The rupture disc will not function unless a more extreme condition arises (Figure 7.17e). When such a condition arises, the process must commonly be shut down. Therefore, the complete system pressure loss caused by the rupture of the disc is acceptable.

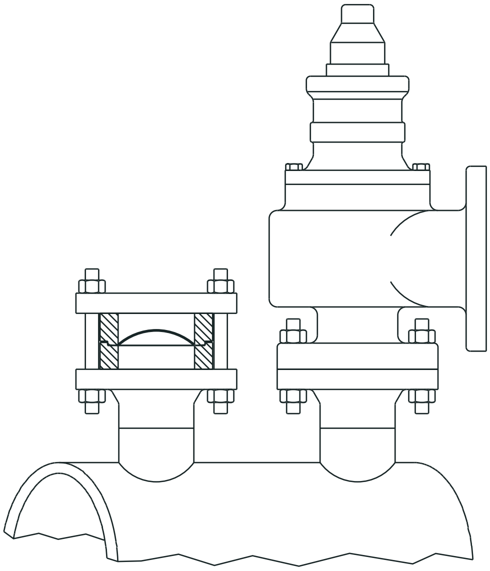

FIG. 7.17e
Rupture disc as supplemental relief device.

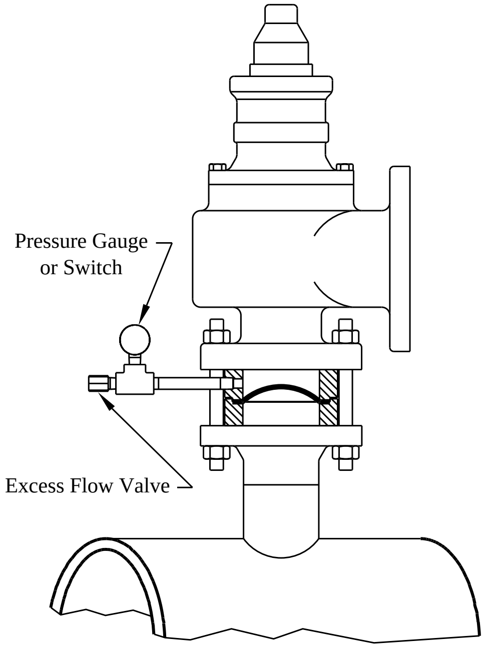

FIG. 7.17f
Rupture disc installed upstream of relief valve.

In addition, the causes of more extreme overpressure, such as external fire, generally require a larger venting area. For a given venting area, the rupture disc is less expensive than the relief valve.

Upstream of a Relief Valve

Being mounted upstream to relief valves is a very useful application for rupture discs (Figure 7.17f). Under normal conditions the rupture disc is sealed tight and protects the relief valve from being contacted by corrosive, plugging, hazardous, freezing, or regulated processes. If the maximum allowable working pressure is exceeded, the disc will break and the relief valve will start to relieve the pressure. As the pressure drops, the valve will shut and reclose the process. Thus, the best characteristics of both devices are utilized.

Another important advantage in this type of installation is that the rupture disc may be used as a break point in piping specification. This means that materials of construction for the rupture disc and the inlet flange of the disc must be compatible with the process. However, the downstream flange of the rupture disc, the relief valve, and all downstream piping may be garden-variety materials such as carbon steel. This is permissible because the rupture disc can be relied on to seal the process away from the downstream items. The resultant savings from using lower-grade downstream materials will in many cases more than pay for the rupture disc.

Because the rupture disc is a differential pressure (d/p) device it is important to prevent a buildup of pressure between the disc and the relief valve. This is accomplished by the use of a pressure switch and/or a pressure gauge and excess flow valve (Figure 7.17f).

Downstream of a Relief Valve

This installation of a rupture disc downstream of a relief valve may be desired when the valve discharges to a vent header that might contain corrosive vapors (Figure 7.17g). A low-pressure rupture disc with a burst indicator can also be used as a means to detect leakage through the relief valve.

Precautions should be taken to prevent the buildup of pressure between the valve and rupture disc due to valve leakage, if conventional relief valves are used. A better option

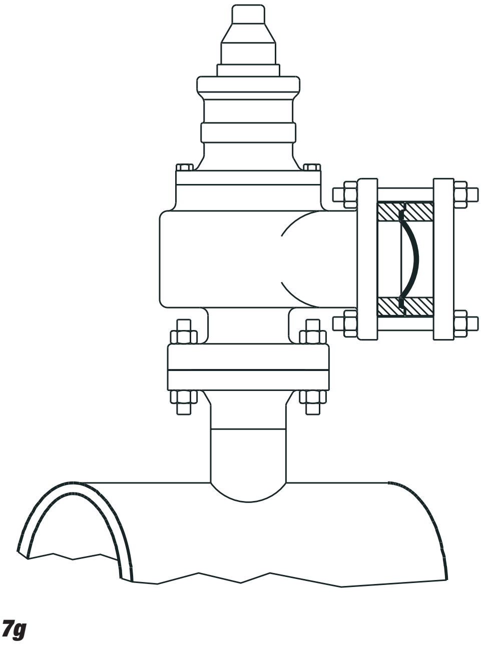

FIG. 7.17g
Rupture disc installed downstream of relief valve.

is to use bellows sealed or pilot-operated relief valves (Figures 7.16c, 71.6q, and 7.16s), whose set pressure is unaffected by the accumulated pressure between the valve and rupture disc. The rupture disc should also have sufficient opening to permit at least as much flow as the rated capacity of the valve.

Explosion Relief

In comparison with relief valves, rupture discs open faster and provide more relief area. Be aware however that the methods for sizing rupture discs (or explosion vents) is quite different than that for traditional pressure relief and the required relieving areas can grow quite large. See the National Fire Protection Association (NFPA) 68 or Verein Deutscher Ingenieure (VDI) 3673 for guidelines regarding explosion relief.

RUPTURE DISC TYPES AND FEATURES

Rupture discs can be classified in two general categories: forward acting or reverse acting. Forward acting discs are pressurized on the concave side of the disc such that the material in the dome of the disc is subjected to tensile stresses (Figure 7.17d). Flat discs are also considered to be forward acting. Forward acting rupture discs can be prebulged, composite, scored, flat, and graphite.

Reverse acting discs are pressurized on the convex side of the disc such that the material in the dome of the disc is subjected to compressive stresses. Reverse acting types include those that use knife edges to cut the disc membrane and are scored (Figure 7.17h). The vast majority of recent rupture disc development has been in the area of reverse acting designs.

Nonfragmenting Discs

Early rupture discs were prebulged solid metal discs that burst in tension and therefore could release metal fragments. These fragments could prevent relief valves from reseating. The newer rupture disc designs protect against this by either using tension-loaded scored or slotted metal discs (with Teflon seals), reverse-buckling discs with knife-edge cutters, or reverse-buckling discs that are preweakened (scored along lines), so that they burst with full opening without fragmentation (Figure 7.17i).

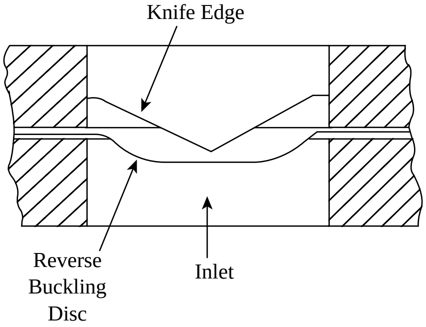

FIG. 7.17h
Reverse buckling, knife-edged design.

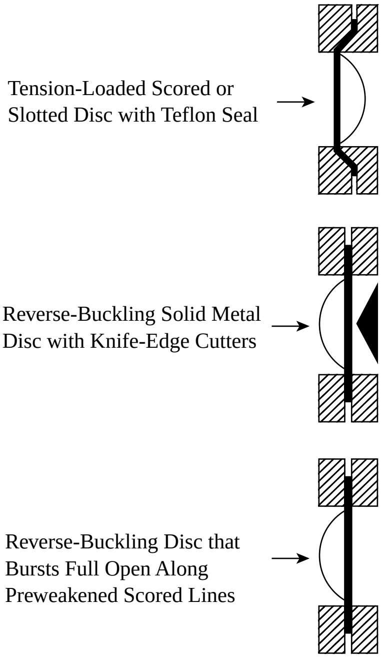

FIG. 7.17i
Disc designs which prevent the fragmentation of the disc.

Graphite Discs

Figure 7.17f shows the installation for a metal disc and Figure 7.17j shows the installation for a graphite disc. As can be noted, the graphite disc requires some extra piping to guarantee its successful operation. First of all, it is not good practice to allow a graphite disc to rupture directly into a relief valve.

The reason is that a graphite disc will fragment rather than tear as a metal disc does. Since the graphite fragments can jam or restrict the operation of a relief valve, it is necessary to provide some kind of downstream pocketing to catch the fragments. A further difficulty arises once the relief valve recloses. If the graphite fragments are pocketed directly over the vessel nozzle, they will drop back into the tank. They can then get into the piping and damage pumps and instruments.

For this reason, the entire relief assembly is shown offset from the vessel nozzle, and an additional pocket is shown upstream of the graphite disc flanges. Graphite discs are best suited for corrosive applications, because they resist almost all chemicals. Another consideration is the margin between normal working pressure and burst pressure, which is about 30% in the case of metal discs because of fatigue. In case of graphite discs, which do not fatigue, this margin can be reduced to 20 to 25%.

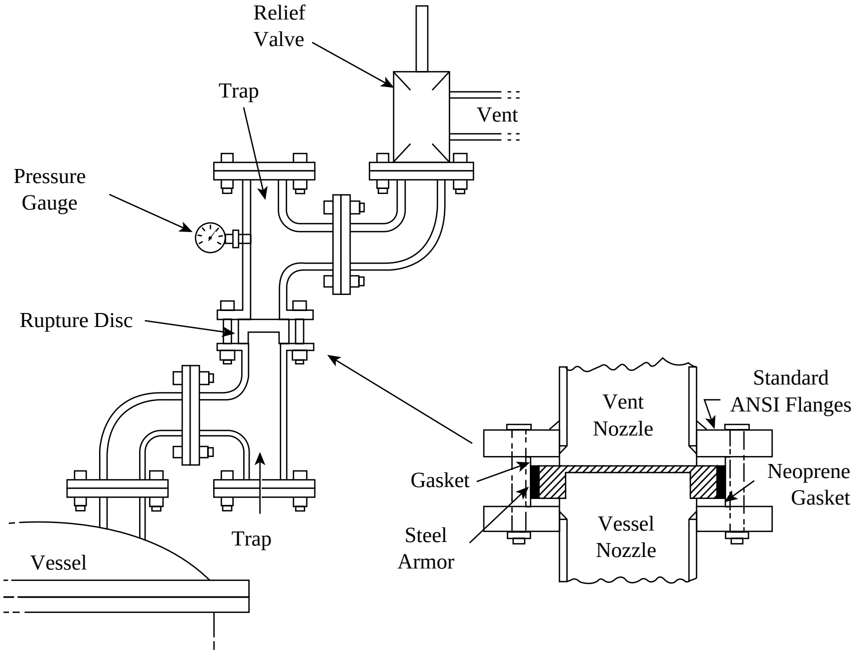

FIG. 7.17j
Graphite rupture disc installed upstream of relief valve.

Vacuum Supports

Some rupture disc models have the capability to withstand vacuum either with or without a vacuum support. A vacuum support typically provides additional strength for the dome of the disc to prevent its collapse. Many models will collapse when exposed to vacuum on the process side so it is important to always check if vacuum could be present during startup and shutdown conditions or under normal operation. Cooling of closed systems is a common cause of developing vacuum and causing rupture disc failure, if this possibility is overlooked when specifying the rupture disc.

Back-Pressure

Similar to vacuum, some rupture disc models have the ability to withstand some back-pressure, while others require special supports to prevent damage or collapse of the dome. Rupture discs that discharge to common headers often are exposed to some low levels of continuous back-pressure and the possibility of periodic increases due to discharges from other sources into the header. Be aware that the presence of back-pressure will cause an equivalent increase in the burst pressure of the rupture disc.

Although not as often as in the past, some users perform in place relief valve testing by pressurizing the cavity between the disc and relief valve until the valve opens. In a spring-loaded relief valve, this test does not give accurate data on the popping pressure or blowdown of the relief valve, but it does confirm that the valve is not frozen shut. When such test is performed, the rupture disc must have the ability to withstand a back-pressure equivalent to the set pressure of the relief valve.

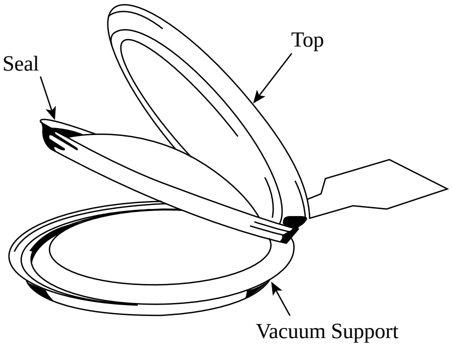

FIG. 7.17k
Composite rupture disc assembly.

Margin between Operating and Burst Pressures

A second commercially available disc construction that may be operated at 75 to 80% of the burst pressure is as shown in Figure 7.17k. This disc consists of a relatively weak disc (seal) plus a heavier metallic backup plate that has been scored or punched so that it will open like orange peels when burst pressure is reached. This construction is less subject to deterioration due to metal fatigue than the plain disc is.

The reverse-buckling rupture disc constructions may be operated to 90% of the rated bursting pressure. Figures 7.17h and 7.17l show the reverse-buckling, knife-edge designs. Rupture discs that are prebulged can be installed with the bulge toward the outside. The reverse-buckling disc is

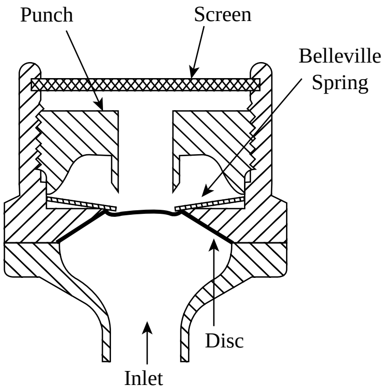

FIG. 7.17l
Belleville spring can provide accurate back-loading for shear discs.

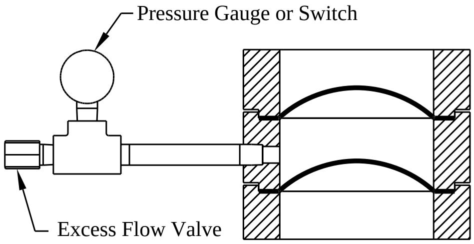

FIG. 7.17m
Double disc assembly.

installed with the bulge facing into the process. Because of this, the disc is not as sensitive to high pressures and pressure cycling. Once the bursting pressure is reached, the reverse-buckling disc will snap its prebulge to the downstream side. As the bulge passes from the upstream to the downstream side, it is cut into segments by sharp knife edges placed against the disc, allowing the process to vent.

Dual Discs or Back-Pressure Loading

There are other disc constructions and methods of installation that allow higher operating to burst ratios. One method is to use two identical discs in series. The idea here is to assume that the first disc will fatigue and fail or leak prematurely because of high normal pressure operation, but the second one will then take over to operate satisfactorily for a period of time. The first disc must, of course, be replaced at the earliest opportunity. A pressure gauge with maximum pointer and an excess flow valve is installed in the pocket between the two discs (Figure 7.17m).

Finally, it is possible to load a back-pressure artificially on the rupture disc. The back-pressure reduces the differential across the rupture disc and allows the normal operating pressure to be any desired percent of the rupture pressure. Back-pressure is unloaded by an external venting system when process overpressure occurs. Here again, this is not a self-contained system; it relies on the proper operation of external components.

Special Applications

Pressure Cycling and Water Hammer A common cause of rupture disc failure is fatigue failure due to pressure cycling. The fatigue life of the disc is a function of the amplitude, frequency, and peak value of the pressure. When specifying rupture discs, both the operating ratio and the severity of pressure cycling should be considered. In general, reverse acting rupture discs tend to provide the best life in severe pressure cycling environments.

The effects of water-hammer on rupture discs should also be considered in liquid full (hydraulic) systems. The rupture disc is a d/p device and, due to its low mass, it can respond to very high amplitude, short duration pressure spikes such as water-hammer. Discs that have burst due to water-hammer often exhibit only partial opening due to a lack of sustained pressure. To avoid this type of problem, it is important to avoid rapid opening or closing of valves in these systems.

Two-Way Relief Rupture discs may be used where two-way relief is required. There are commercially available discs for this purpose. One common installation sketch is shown in Figure 7.17n. The system requirements are as follows. A highly corrosive process is unstable above a certain temperature. Therefore, it is necessary to quench the reaction if the temperature rises above this point. Further, due to its corrosive nature, it is decided to vent the process into a surge system in case of process overpressure (rupture disc as primary relief).

This application calls for a rupture disc to vent overpressure and for a two-way rupture disc to isolate the process away from the quench valve and to prevent quench leakage into the process. The solution is to specify a two-way rupture disc that will burst into the tank if over-temperature occurs, but isolate the valve under other circumstances.

Self-Cleaning and Corrosive Services Many specialized rupture disc and holder designs are available for unique applications and circumstances. Bidirectional designs are used to provide overpressure protection as well as vacuum protection for low pressure storage vessels (Figure 7.17n).

There are several variations of rupture discs available for use in processes where product buildup and plugging of the inlet pipe is a concern. Some designs use the process flow to keep the disc surface free of buildup (Figure 7.17o). Other devices are designed to minimize the space for product buildup by mounting the rupture disc flush with the vessel or pipe wall such as in plastic extrusion equipment (Figure 7.17p).

Double disc assemblies (Figure 7.17m) are also often specified for highly corrosive applications. The space between the discs is monitored and, when leakage due to

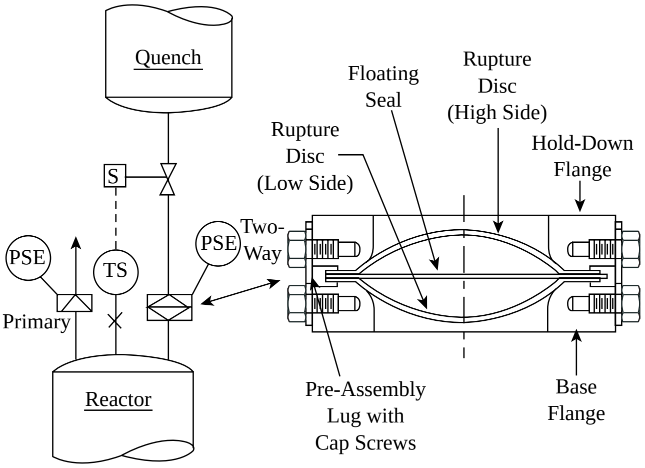

FIG. 7.17n
Application where a two-way rupture disc is used.

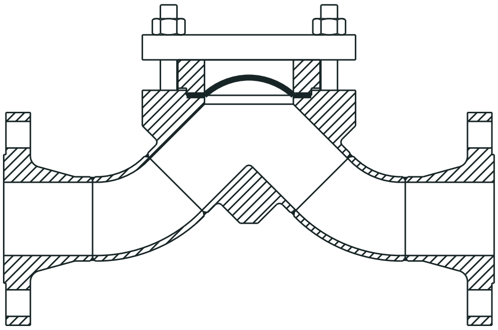

FIG. 7.17o
Design to prevent plugging.

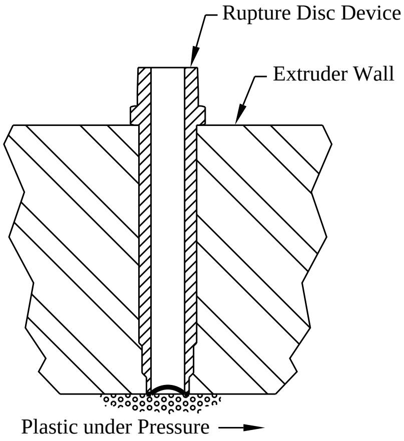

FIG. 7.17p
In-line design for extruder application prevents product buildup.

corrosion is detected, the process can be brought down. By manipulating the pressure between the two discs, a double disc assembly can also be used as a fast acting valve. In all double disc applications consult the rupture disc manufacturer to ensure proper specification for the intended use.

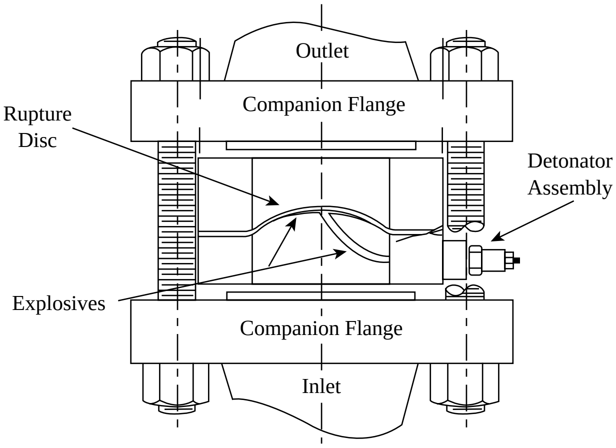

FIG. 7.17q
Detonator actuated deluge disc.

Explosive Actuated Vents Another technique is to use explosive-actuated rupture discs that do not rupture due to the pressure forces alone. The explosion is ignited by a pressure switch that senses process overpressure and closes an electric circuit to ignite the explosive charge. This is not a self-contained unit and its successful operation is dependent on several outside components plus a reliable power source (Figure 7.17q).

SELECTION AND SPECIFICATION

The selection and specification of rupture discs can be a daunting task due to the wide range of safety, operational, and cost considerations and the availability of a large variety of products with varying characteristics. The selection process is an iterative one, especially when it comes to specifying a disc model. Each rupture disc design has characteristics that make it more or less suitable for a particular application.

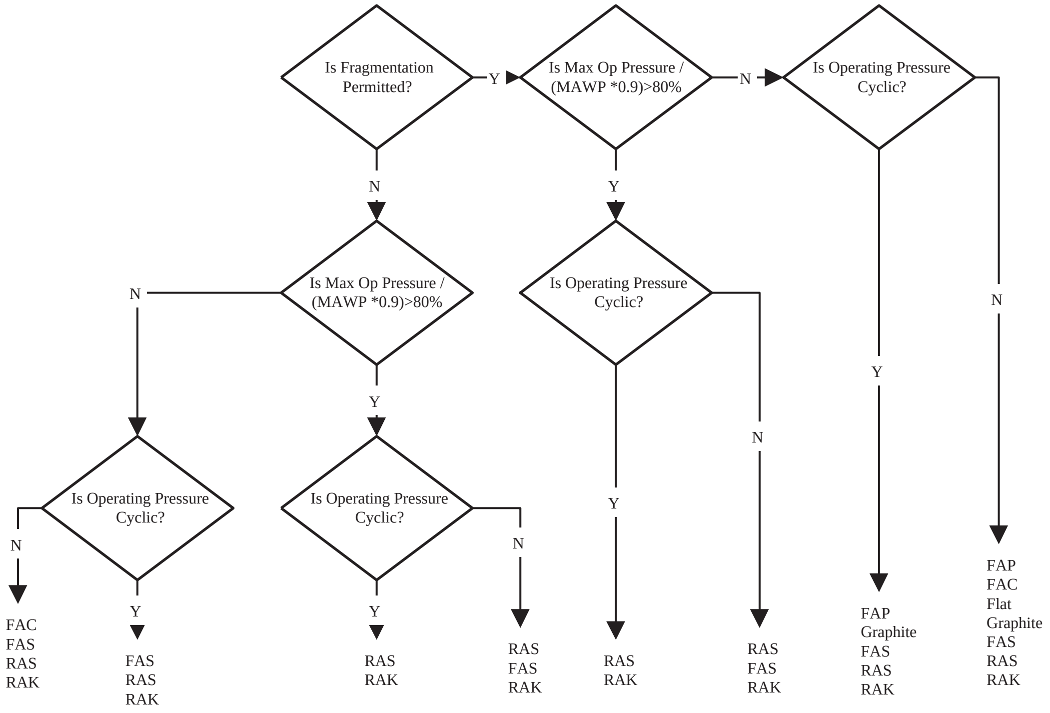

FIG. 7.17r
Method for selecting rupture disc type.

As to disc characteristics, Table 7.17a provides some general guidelines and Figure 7.17r illustrates one systematic method of using basic application information to narrow down the choice of suitable rupture discs. Certainly there are exceptions and the manufacturer's data sheets should be carefully examined prior to specifying a particular model. If in doubt about rupture disc selection or specification, contact a manufacturer for assistance.

Material Selection

Temperature and corrosion are the two primary considerations when selecting the rupture disc material. From a temperature perspective, the material is selected based on the expected temperature when it is expected to burst and also taking into consideration the normal operating temperature. Since metals lose strength as they are heated, the disc material should be selected to withstand the highest expected process temperature with some margin to spare (Table 7.17b). High-temperature applications will also accelerate metal fatigue and creep. Thus temperature becomes a factor where high normal pressures or pressure cycling is encountered.

Rupture discs are readily available in a variety of corrosion resistant alloys (Table 7.17b). Other materials that have been used successfully include niobium, Hastelloy® B, and Hastelloy C22. Graphite can be a good answer to some corrosion problems because it resists almost all chemicals, but keep in mind that the resin binder is typically the limiting factor in regard to temperature or corrosion.

In addition to the option of using solid materials, it is also possible to get the discs plated; coated; or lined with Teflon®, tantalum, gold, Kel-F®, polyethylene, urethane, etc. Coatings should not be heavily relied upon to prevent corrosion of the rupture disc as thermal cycling and damage due to handling often compromise the corrosion-resistant boundary. Consider coatings to provide only a level of protection.

Burst Pressure and Manufacturing Range

Most rupture discs are not marked at the specified burst pressure but are sold with a manufacturing range. This is a tolerance applied to the specified burst pressure within which the rated or marked pressure will fall. The purpose of the manufacturing range is to minimize the amount of time it takes to produce the rupture disc, resulting in a reduced manufacturing cost. The smaller the manufacturing range, the higher is the cost of manufacturing.

Most rupture disc products introduced since 1990 use three manufacturing ranges: +0/–10%, +0/–5%, and 0%. Since the positive side of the range is always zero, the specified burst pressure can be the maximum allowable working pressure (MAWP) or any other burst pressure that is selected.

Many rupture disc models have manufacturing ranges such as +6/–3%. In these cases the user should realize and should be warned that if the specified burst pressure is at the MAWP, it is very possible that the rupture disc received will be marked above the MAWP.

Operating Ratio Another aspect of manufacturing range is its relationship to operating ratio. Once the specified burst pressure and the manufacturing range has been selected, it has to be checked against the operating pressure to insure that the recommended operating ratio has not been exceeded. For example:

A reverse acting rupture disc has a 90% operating ratio
If the specified burst pressure = 100 PSIG @ 72°F
The manufacturing range = +0/–10%
The maximum operating pressure = 85 PSIG
The calculated minimum marked burst pressure = 100 × 0.9 = 90 PSIG
And therefore the calculated operating ratio of 85/90 = 94% exceeds the recommended 90%

A solution for this case is to specify a reduced manufacturing range such as +0/–5%.

In that case, the calculated minimum marked burst pressure = 100 × 0.95 = 95 PSIG, and the calculated operating ratio = 85/95 = 89%, which is within the recommended 90%.

Minimum Burst Pressure Sometimes it is not possible to obtain the conventional rupture disc construction that will burst at the required low pressures. For example, a 2 in. (50 mm) conventional stainless steel disc has a minimum bursting pressure of approximately 160 PSIG (1.1 MPa) (see Table 7.17s). If the corrosion resistance must equal that of stainless steel, but the set pressure must be lower, it is necessary to use a different disc. Some options include:

1. Select a reverse-buckling scored disc (Figure 7.17i), which can be set at less than 10 PSIG in the 2-in. size.
2. Specify some kind of laminated construction such as a Teflon-faced aluminum disc.
3. Utilize the sealed low-pressure design (shown on Figure 7.17k).
4. Specify a larger diameter stainless steel disc.

DISC HOLDERS AND ACCESSORIES

In order for rupture discs to perform as specified, most styles must be installed in special flange-like holders. Rupture disc holders can be manufactured from a wide variety of materials. Holders are also available in a variety of standard and nonstandard configurations to adapt to threaded, flanged, or welded pipe connections. Other specialized or custom connections can also be specified.

The most common type of holder is an insert type holder that fits inside the bolt hole circle of standard piping flanges (Figure 7.17t). In specifying rupture disc holders, it should be remembered that depending on the downstream conditions, the discharge side of the holder could be a lower-grade material, such as carbon or stainless steel, since it will not ordinarily be in contact with the process.

TABLE 7.17s
Minimum Rupture Pressures as a Function of Size, Based on 70°F (21°C) Operating Temperature and on Standard Disc Design***

Size Inch (mm)	*Aluminum*	*Aluminum Lead Lined*	*Copper*	*Copper Lead Lined*	*Silver*	*Platinum*	*Nickel*	*Monel*	*Inconel*	*316 Stainless*

**This data applies to forward acting prebulged discs only. Reverse acting disk designs are not limited by the values listed.

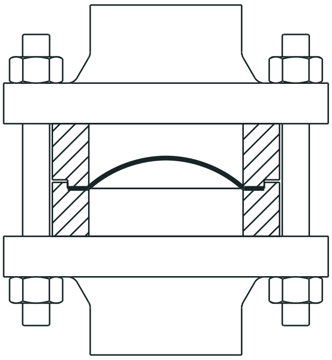

FIG. 7.17t
Insertable holder design fits between flange studs.

Accessories

Several accessories are available with rupture disc flanges that may be specified as required.

Studs and nuts are used to apply the necessary load to grip and seal the rupture disc. The studs will be longer than required for a standard bolted joint and is dependent on the height of the rupture disc assembly.

Jack screws are used to jack the rupture disc joint apart so that the disc can be replaced, and they should be considered on all installations of 2 in. (50 mm) and above.

Pressure taps are often specified in the outlet holder flange for a pressure switch or excess flow valve and pressure gauge installation as required in disc/valve combination or double disc applications.

Eyebolts are specified when size, weight, or location require lifting devices to aid in installation.

Burst indicators typically consist of some type of breakwire configuration. The circuit is a thin or fragile, normally closed conductive circuit that is broken due either to mechanical contact from the rupture disc or the initial pressure wave released from the opening disc. Other pressure, temperature, and flow sensing devices (see Figure 7.5d) are also used to detect disc leakage and/or rupture.

SIZING

Rupture discs may be sized in accordance with the following formulas:

For vapor:

$$d = \sqrt{\frac{W}{146\,P}}\;\sqrt[4]{\frac{\mathrm{T}}{M_w}} \qquad \textbf{7.17(1)}$$

For steam, if dry and saturated:

$$d = 0.205\sqrt{\frac{W}{P}} \qquad \textbf{7.17(2)}$$

Superheated steam:

$$d = 0.205\sqrt{\frac{W(1+0.00065T_s)}{P}} \qquad \textbf{7.17(3)}$$

Wet steam:

$$d = 0.205\sqrt{\frac{W(1-0.012\mathrm{y})}{P}} \qquad \textbf{7.17(4)}$$

For liquids:

$$d = 0.236\sqrt{Q}\;\sqrt[4]{\frac{\mathrm{SG}}{P_1}} \qquad \textbf{7.17(5)}$$

where:

d = minimum rupture disc diameter in.
M_w = molecular weight
P = relieving pressure (PSIA), including allowable accumulation (10% in normal conditions, 20% in fire conditions)
P_1 = relieving pressure (PSIG), including allowable accumulation
Q = relieving rate, gal/min
SG = liquid specific gravity where water = 1.0
T = relieving temperature, °R (460 + °F)
T_s = degrees of superheat, °F
W = relieving rate, lbm/hr
y = percent moisture (100 steam quality)

Note: Where rupture discs are installed upstream of a relief valve, the rupture disc should be the same size as or larger than the relief valve inlet nozzle.

Differences in Assumptions and Standards

Due to differences in the assumptions of the various design standards, it is recommended that one should use Equations 7.17(1) to 7.17(5) only if they match the equations in the applicable standard.

Flashing or reactive multiphase venting or high rate pressure transient methods are beyond the scope of this reference. However, the Design Institute for Emergency Relief Systems (DIERS, www.aiche.org/diers) is a good source of information for complex sizing cases, and API RP520 provides guidance for certain cases of flashing flows. The following will describe the three general methodologies employed in sizing rupture discs.

Coefficient of Discharge Method When this method is used, the coefficient of discharge (K_d) is applied to the theoretical capacity to arrive at the rated flow rate:

$$W_{rated} = K_d \cdot W_{theoretical} \qquad \textbf{7.17(6)}$$

The coefficient of discharge method should be used when sizing simple relief systems. A system is considered simple, if the following are true:

1. There are no more than 8 pipe diameters of piping upstream of the rupture disc device.
2. There are no more than 5 pipe diameters of piping downstream of the rupture disc device.
3. The rupture disc device is equal to or greater than the inlet and discharge piping.
4. The piping discharges to atmosphere.

When these criteria are met, the sizing calculations apply to the entire system of inlet piping, rupture disc device, and discharge piping. Note that for ASME and API calculations, the coefficient of discharge is 0.62. For the ISO standards, the coefficient depends on the shape of the vessel nozzle leading to the rupture disc.

Resistance Method The resistance to flow method is a relief system sizing method in which the rupture disc device is treated as any other piping component and is represented in the calculations as a resistance value or velocity head loss (K_R). The capacity of the system is a function of the sum of all of the resistance values of the piping and piping components (including the rupture disc device). Use this method to size the relief system when the rupture disc is not used in combination with a pressure relief valve and when the conditions of the coefficient of discharge method cannot be met. For ASME and API applications, the capacity of the system calculated using the resistance to flow method must be derated by a factor of 0.90 to account for inaccuracies in the method. Due to the complexity and iterative nature of the calculations, this method is best performed using computer programs. API RP520, API RP521, and Crane TP410 are good sources for additional information regarding this method.

Combination Capacity Method When a rupture disc is used at the inlet of a pressure relief valve, the valve is sized first and then the rupture disc is selected using the same nominal size as the inlet of the relief valve. The capacity of the disc/valve combination is the valve capacity times the combination capacity factor (CCF).

$$W_{combination} = W_{prv\ldots rated} \times \text{CCF} \qquad \textbf{7.17(7)}$$

The default combination capacity factor is 0.90, but some disc/valve combinations have certified test values that are higher.

In some cases the rupture disc and inlet piping size will be increased one size larger than the inlet of the relief valve in order to minimize the inlet line losses between the pressure vessel and the valve. The K_R value of the rupture disc can be used in calculation of the inlet line losses to the pressure regulating valve. However, if both the K_R value and the CCF factor are relatively high, it is evidenced by some rupture discs that a rupture disc mounted directly upstream of the valve has little effect on inlet line pressure drop. This may be due to the rupture disc conditioning the flow into the valve nozzle, the opened rupture disc being outside a boundary layer, or some combination of both.

7.18 Soft Sensors

STEVEN BAIN (2003)

INTRODUCTION

Sensors, as we usually refer to them, are physical objects such as thermometers or pressure gauges. However, it is possible to make sensors that are based only on combinations of other information. To distinguish a physical sensor from a sensor based only on other information, they are called hard and soft sensors, respectively.

Flow from Level

A soft sensor is a sensor that exists only as a mathematical calculation, probably based on measurements from other sensors. These other measurements may come from on-line sensors in real time, or from off-line sources such as laboratory analyses. A simple example of a soft sensor is that of a tank filling with liquid. If the tank's changing level is known, it is practical to calculate the flow into the tank:

$$\text{Flow} = \text{Area} \cdot \frac{\text{Level Change}}{\text{Time}} \qquad \textbf{7.18(1)}$$

This calculation provides a flow measurement, although there is no flow meter; only a level detector exists. The flow meter is a soft sensor.

Mass Flow from Pressure and ΔP

The line distinguishing hard and soft sensors is not always clear. For example, a multivariable mass flow transmitter for orifice plate-based gas mass flow measurement includes three instruments: an absolute pressure element on the upstream side of the orifice, a differential pressure element across the orifice, and a temperature element sensing gas temperature. The instrument provides each of these three measurements individually, and combines them into a single mass flow measurement.

$$\text{Mass Flow} = C_d \cdot E \cdot Y_1 \cdot d^2 \cdot \sqrt{\Delta P \cdot \rho} \qquad \textbf{7.18(2)}$$

There is no doubt that the pressure and temperature instruments are real, or hard, but is the mass flow instrument hard or soft? It would probably be classified as hard because the instrument is dedicated specifically to making the mass flow measurement, but in fact the measurement itself exists only as a calculation that is based on other measurements. If we used three separate instruments to make the required three measurements, and calculated the mass flow in a computer, it would definitely be a soft sensor. However, since the calculation is done in a single purpose-specific package, the instrument is probably hard.

Hard and soft sensors are often difficult to distinguish. In practice most soft sensors depend on combining several process variables, which are measured and used for process monitoring and control in their own right, into another instrument that perhaps cannot exist any other way.

Flow from Pump Speed and Power

For example, the performance of an adjustable speed centrifugal pump can be described by two equations:

$$\text{Characteristic: } P = a_1 \cdot S^2 + a_2 \cdot S \cdot F + a_3 \cdot F^2 + a_4 \cdot \frac{F^3}{S} \cdots \qquad \textbf{7.18(3)}$$

$$\text{Power: } Pw = b_1 \cdot S^3 + b_2 \cdot S^2 \cdot F + b_3 \cdot S \cdot F^2 + b_4 \cdot F^3 \cdots \qquad \textbf{7.18(4)}$$

where

P = pressure
S = speed
F = flow
Pw = power

Adjustable frequency drives (AFDs), particularly those controlled via an instrument network, can provide an output power measurement. Speed can either be assumed to match the output frequency (probably accurate to 2.5%), or be calculated from the motor's slip (accuracy improved to about 1%; the AFD may include slip compensation or vector control).

As a result, flow can be calculated from the Power equation,* with known speed and power. Similarly, pressure can be

---

* If implementing these equations, note that the AFD's power measurement is AFD output power to the motor, whereas the Power equation is shaft power input to the pump, so the effect of motor efficiency should also be included.

calculated from the Characteristic equation, with known speed and flow. This is achieved without any extra instrumentation: The measurements needed to calculate flow and pressure come from the AFD, which is required for speed control. As a result, the pressure and flow sensors are said to be soft; they are soft sensors.

Conceptually, a soft sensor can exist anywhere; an off-line calculation done by hand is one example. However, this section is concerned mainly with soft sensors that are implemented in real time.

Most soft sensors are currently implemented using well-defined and understood equations such as the examples used above. Soft sensors can however be implemented through emerging technologies, such as fuzzy logic, neural networks, and artificial life, although this is beyond the scope of this section.

The Role of Networks

In the future, networked instruments may coordinate their results via the network and report combinations of results to the controller. The example of the mass flow sensor that is based on pressure, pressure differential, and temperature shows what is practical when the three instruments are in a common housing. However, instrument networks remove the requirement for a common housing: any instruments that can communicate with each other could also combine their results and report the combination to the controller.

A first source for soft sensor applications is calculations that are currently done by hand. If operators are calculating process parameters off-line, perhaps by hand or spreadsheet, these are ideal opportunities to introduce soft sensors.

Soft sensors often require considerable computation, so until recently their use was limited, but they are now becoming increasingly practical. This section assumes that the required computer capacity is available.

REASONS FOR USING SOFT SENSORS

Reasons for choosing to implement a soft sensor include:

1. Making measurements that currently cannot be made any other way. In many cases, a soft sensor is the only way to make a process measurement, and in these cases they find a natural application—this is the most common situation.
2. Replacing a failed instrument, perhaps with reduced accuracy, until the instrument is repaired. This replacement may be made automatically in real-time by the process controls based, for example, on a loss-of-signal detector.
3. Monitoring the condition of equipment by estimating its performance using a soft sensor calibrated to the equipment's nominal performance, and comparing the soft sensor result against a measured value.
4. Reducing costs by eliminating potentially redundant instruments.

A guiding principle is always to make the best practical use of the available equipment. If a fault renders an instrument unavailable, perhaps a soft sensor based on other available equipment can allow operations to continue, possibly at reduced performance. Or, if reduced performance is unacceptable, a soft sensor may guide a controlled process shut-down.

APPLICATION EXAMPLES

This section provides examples of soft sensors drawn from a variety of industries. The intention is only to illustrate the concept of soft sensors in more detail, not to limit opportunities in any way. The potential for soft sensors is limited mainly by our ability to describe the process in terms that allow us to make useful inferences based on other available information. These inferences may depend on straightforward calculations, as the examples shown in the Introduction do, or on more advanced techniques.

Detection of Instrument Failure

A differentiator can be used to detect some instrument failures. If a signal changes faster than the maximum possible rate of change of a process variable, this indicates a fault. A wire break causes an extremely high rate of change, but wire breaks are usually detected by loss of signal. Another example of an instrument fault that results in a high rate of change is a bubbler tube that gets blocked, perhaps by silting. A differentiator can detect the blockage by sensing a high rate of change. However, a rate of change fault always occurs when a loss of signal fault occurs. To distinguish them, the rate of change fault can be suppressed while a loss of signal fault is active.

Using Redundant Instruments to Advantage

Although few applications have redundant instruments (that is, multiple instruments making the same measurement), many have parallel process trains where conditions from one train to another are usually similar. An example is a water pumping station that has two wet wells, to allow one to be out of service for maintenance at times of low demand. However, the wet wells usually operate in parallel, connected by a common influent channel. In this situation, both wet wells have level instruments, and usually both level instruments are operational. This gives the opportunity to make extra use of the two measurements.

While both level measurements are available, the mean of their two measurements usually gives a more accurate level than either measurement individually.

If the difference between the two instruments is considerably more than the sum of their errors, perhaps twice as much, for an extended period, this indicates that they need to be calibrated.

If the difference is still more, perhaps four times as much, this indicates that the mean is probably not reliable so another control signal is needed. If another level reference can be used, such as a level switch or operator's input, the logic can check the instruments against that and decide which instrument can be used to control and which needs to be serviced.

While a measurement is not available, for example, because of a rate of change fault, the logic can default to the other measurement.

Sensorless Flux Vector Control

For years, an AFD with an induction motor was more reliable than a DC drive and motor, but the DC combination provided better control. This changed with the advent of flux vector control of induction motors, but initially flux vector control required a motor sensor to resolve the vector. This solution was then superceded by sensorless flux vector control, in which the AFD infers the angle of the flux vector only from information that is already available to it: amps, volts, frequency, and phase. This sensorless flux vector sensing is a soft sensor. It is sensorless because it does not require a dedicated motor-mounted resolver; instead it has a soft sensor that provides the necessary measurement.

Viscosity Control in Rubber Blending

When manufacturing rubber for tires, the final hardness of the rubber is critical. However, the final hardness is determined during the blend process, at which time it is impractical to measure. The process traditionally depends on making a batch, measuring the final characteristics of the rubber in a laboratory, and then making future batches based on the same recipe. This procedure is satisfactory, but it does not compensate for variations in the feed ingredients and therefore can be improved.

Merikoski, et al.[1] report a real time soft sensor based on blend process measurements that provides an output that correlates well with laboratory measurements of final hardness made after the batch is finished. The sensor is based on measurements of blend temperature and pressure and mixer speed and torque. It is not intended as a substitute for recipe-based production, but allows manufacturers to compensate for small deviations.

DETERMINATION OF ERRORS

A soft sensor's measurement will probably be based on several other measurements, each of which will have an associated accuracy. Here a method is described for estimating the inaccuracy of a soft sensor, based on the inaccuracy of the other measurements, and the equation that describes the soft sensor. It also discusses other considerations that influence inaccuracy.

Combining Instrument Errors

The discussion below is based on the work of Zalkind and Shinskey[2] of the Foxboro Company, who extended the well-established theory for statistical handling of discrete measurement uncertainties into the continuous domain. They did so principally to quantify uncertainties introduced by combinations of analog computers, but their work applies equally to instruments used in combination as they are in soft sensors.

Assumptions:

1. The instruments are correctly calibrated (i.e., there are no systematic errors in their output signals).
2. The errors are normally distributed about the mean, and the mean accurately reflects the actual value.

Let the measurement signals be $S_1, S_2, \ldots S_n$, their errors be $E_1, E_2, \ldots E_n$, the soft sensor signal formed from the measurements be S, and its error be E. Then the error associated with those signals in combination is as follows:

Addition or Subtraction $S = k_1 \cdot S_1 + k_2 \cdot S_2$ or

$$S = k_1 \cdot S_1 - k_2 \cdot S_2$$

$$E = \sqrt{\frac{((E_1 \cdot k_1)^2 + (E_2 \cdot k_2)^2)}{2}} \qquad \textbf{7.18(5)}$$

Multiplication $S = k_1 \cdot S_1 \cdot S_2$

$$E = \sqrt{\frac{((E_2 \cdot k_1 \cdot S_1)^2 + (E_1 \cdot k_1 \cdot S_2)^2)}{2}} \qquad \textbf{7.18(6)}$$

Division $S = k_1 \cdot \frac{S_1}{S_2}$

$$E = \sqrt{\frac{\left(\left(E_1 \cdot \frac{k_1}{S_2}\right)^2 + \left(E_2 \cdot k_1 \cdot \frac{S_1}{S_2^2}\right)^2\right)}{2}} \qquad \textbf{7.18(7)}$$

General Expression for the Error Assume a soft sensor having output S with error E. The sensor is based on measurement signals $S_1, S_2, \ldots S_n$ having errors $E_1, E_2, \ldots E_n$, where $S = f(S_1, S_2, \ldots S_n)$. The soft sensor would be affected by a small change in one measurement S_i, such as would be caused by E_i. This effect is given by the small change multiplied by the slope of the function in the S_i dimension, evaluated at the point $(S_1, S_2, \ldots S_n)$. Hence, the effect of E_i on E is:

$$E = f(E_i) = E_i \cdot \frac{\partial f(S_1, S_2, \ldots S_n)}{\partial S_i} \qquad \textbf{7.18(8)}$$

If the errors are randomly distributed about the mean, as we have assumed, then individual contributions to the overall error are combined by the root of the sum of their squares. As a result, the complete expression describing the error E is:

$$E = \sqrt{\frac{\sum_{i=1}^{n}\left(E_i \cdot \frac{\partial S}{\partial S_i}\right)^2}{n}} \qquad \mathbf{7.18(9)}$$

Example: Division

$$S = k_1 \cdot \frac{S_1}{S_2} \qquad \mathbf{7.18(10)}$$

$$\frac{\partial S}{\partial S_1} = \frac{k_1}{S_2}, \qquad \frac{\partial S}{\partial S_2} = -k_1 \cdot \frac{S_1}{S_2^2} \qquad \mathbf{7.18(11)}$$

Hence:

$$E = \sqrt{\frac{\left(E_1 \cdot \frac{k_1}{S_2}\right)^2 + \left(E_2 \cdot -k_1 \cdot \frac{S_1}{S_2^2}\right)^2}{2}} \qquad \mathbf{7.18(12)}$$

Verification:

Zalkind and Shinsky report tests made on combinations of analog computers that verified the practical application of their mathematics.

Implementing the Error Calculation Bear in mind how the basis for the errors of the measurements involved in the calculations are quoted. For these calculations to be completely correct, the errors should be on the same basis. They should not only be in the percentage of actual reading (and not the percentage of full scale) basis, but they should all be given to the same number of standard deviations (2-sigma and 3-sigma are commonly quoted). A 2-sigma measurement will be within the quoted error limit for 95.5% of the time, and a 3-sigma measurement for 99.7%. If necessary, convert from one base to another by:

$$\text{Accuracy on new base} = (\text{Accuracy on old base}) \times \frac{\text{New base}}{\text{Old base}} \qquad \mathbf{7.18(13)}$$

For example, 2-sigma 0.5% error expressed as a 3-sigma accuracy is:

$$\text{3-sigma accuracy} = 0.5 \cdot \frac{3}{2} = 0.75\% \qquad \mathbf{7.18(14)}$$

The results provided here are all based on error. To apply these results rigorously, convert inaccuracy statements to errors. The error can then be used directly or converted back to whatever format is required.

Digital Calculation Errors Errors introduced by digital calculations are well-documented, and are beyond the scope of this handbook. However the following are recommended:

1. Avoid 12-bit computing, because although 12-bit accuracy (1 part in 4095) is better than what most process instruments deliver, 12-bit digital calculation errors quickly become significant.
2. When practical, use floating point calculations, probably based on measurements in engineering units. These are most convenient for users and allow considerable computation without introducing significant errors.

DIGITAL SIGNAL PROCESSING

Soft sensor calculations depend on routine arithmetic, such as addition, subtraction, multiplication, and division, and these are assumed to be available. Beyond these functions, soft sensors benefit from digital signal processing (DSP) techniques. DSP is a substantial topic in its own right, beyond the scope of this handbook, but the following DSP techniques are particularly applicable to process control and soft sensors:

1. Time delay
2. High- and low-pass filters
3. Integrators and differentiators
4. Interpolation filters

Filters are used to extract a specific part of an instrument's signal. Low-pass filters are most common, and are used to remove high-frequency interference, or noise, from a low-frequency signal. Integrators are familiar as totalizers, while a differentiator may be used, for example, to adapt a tank's level sensor to a flow measurement.

Spreadsheets allow DSP techniques to be tested easily, and graphs help to show and explain the functions' effects.

Time Delay

A time delay simply delays a signal a specific amount, by clocking the signal into a buffer periodically and clocking it out after an appropriate delay. A time delay may be useful to simulate a real process delay. For example, if a flow transmitter measures flow into the first of three tanks in series, and the requirement is to add reagents to the tanks in proportion to their influent flows, then it may be practical to estimate the flows into the second and third tanks by delaying the flow measurement by the appropriate transportation lag.

Delays are usually implemented in a rotating buffer of data registers in the controller, such as Registers 101 to 200. The buffer has a pointer that indicates the next register to clock out from and clock into. When it is time to clock a measurement through the delay, clock out from the register indicated by the pointer, and then immediately overwrite that register with the current measurement and increment the pointer. When the pointer increments to 201, reset it to 101—this is what makes the buffer rotating. There are relatively few applications for a simple time delay, but rotating buffers are widely used.

Implementation Considerations Initialize the registers depending on the application. For example, if starting the controller onto a running process, the error may be reduced by preloading all the registers with the current measurement.

Adjust the duration of the delay by either clocking data through the buffer at a varying rate, or by varying the number of registers in the buffer, possibly by using two pointers, one for the start and another for the end.

Integrators and Low-Pass Filters

Integrators find special application in the well-known proportional/integral/derivative (PID) controller, but the PID integrator has the special characteristic that in a correctly-functioning controller, the value being integrated (the error) is equally likely to be positive or negative. As a result, a PID controller's integral term seldom moves far from zero, and their integrators usually run over indeterminate durations. However, general-purpose integrators typically run over specific intervals that are usually time-based, but may be based on other variables too.

Low-Pass Filters

A low-pass filter is normally used to smooth out spurious fluctuations in a signal. The chief disadvantage of a low-pass filter is that it also smoothes out sudden, real changes, which usually interferes with control responsiveness. It also delays, or phase-shifts, a signal (i.e., it has some properties that are similar to a time delay).

Better low-pass filters are based on the mean of the most recent measurements.* This requires a rotating buffer, as for a time delay, that stores the most recent measurements, and the calculation to determine their mean. The measurements may be weighted, in which case the calculation includes the required weighting factors. The low-pass filter's basic formula is:

$$y(n) = {w_1 \cdot x(n) + w_2 \cdot x(n-1) + w_3 \cdot x(n-2)\cdots}\Big/ i \qquad \textbf{7.18(15)}$$

where

$y(n)$ = current filter output
$x(n)$ = current measurement
$x(n-1)$ = previous measurement, etc.
w_1, w_2, etc. = weighting factors, which are often equal and average 1
i = number of measurements used in the filter

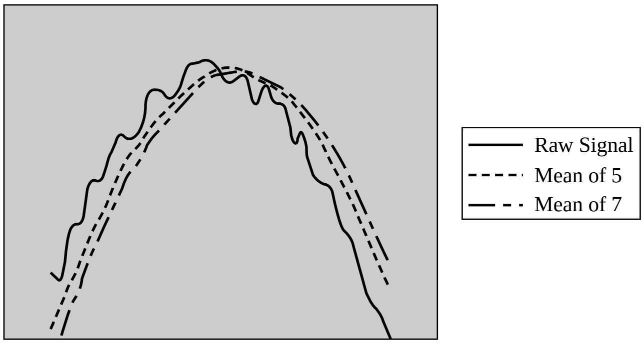

FIG. 7.18a
Low-pass filter I.

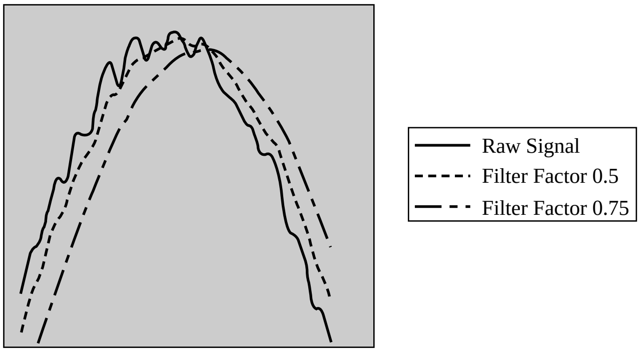

FIG. 7.18b
Low-pass filter II.

Figure 7.18a shows an example of low-pass filtering applied to a noisy signal. The raw signal is a portion of a sine wave (the actual signal) plus 5% random noise, and the two filtered signals are the mean of the most recent 5 or 7 signals. Filtering removes much of the noise, leaving a more accurate representation of the actual signal, but the filtered signal is somewhat delayed in time, or phase-shifted.

A simpler but useful filter that requires comparatively little computational overhead is:

$$y(n) = y(n-1) \cdot Ff + x(n) \cdot (1 - Ff) \qquad \textbf{7.18(16)}$$

where

Ff = filter factor; $0 < Ff < 1$

The effect of the filter increases as the filter factor increases.

Figure 7.18b shows an example of this simpler low-pass filter. It is less effective than the previous type, but is far easier to implement and uses fewer system resources.

Implementation Considerations Regulate when the filter calculations are performed; do not simply execute the filter each scan through the control logic. Ideally, take the measurement

---

* Impulse response and associated detail are beyond the scope of this section.

at precise time intervals; this is probably coordinated in the analog input's hardware and delivered to the logic for processing a few milliseconds later. However, this functionality may not be available. In this case, use a timer to regulate logic execution. The timer may regulate fetching the current measurement, and when it is fetched, executing the filter logic. Also, if the available measurement can be considered current, the timer may regulate executing the filter logic directly.

The degree of filtering depends on both the parameters of the filter calculation (the filter factor in the example shown by Figure 7.18b), and the frequency of execution. If the logic is executed frequently, the filtering is less pronounced, but the result is smoother. As a result, it requires more computation to achieve a lot of filtering with a smooth result.

Initialize the filter appropriately, probably based on the first good measurement after a controller start or after an instrument is brought back into service, for example, after a loss-of-signal shutdown. This logic is similar to that needed to deal with sudden changes, and the functions may share a common routine.

Filter either in the control logic or in the hardware of the analog input. Many analog inputs include a digital filter implemented in the input's firmware. Considerations when choosing where to implement include:

1. *Input Filter*—The logic can be smaller and faster. Timing is likely to be most precise because communications delays are eliminated or greatly reduced. Often a group of inputs must share the same filter characteristics—this disadvantage can be reduced by grouping like signals together, but this may make the consequences of a hardware failure worse.
2. *Logic Filter*—This filter can be more customized and have more features, such as initialization alternatives and better ways of dealing with sudden signal changes that are significant.

Suppose one is using a filter based on the mean of the past measurements with equal weighting factors (as is quite common). Rather than summing all the measurements each time, it is more computationally efficient to use the previous sum, and to add the new measurement and subtract the measurement that is no longer included. For example, assuming a filter based on the mean of the past i measurements:

$$Y(n) = Y(n-1) + x(n) - x(n-i) \qquad \textbf{7.18(17)}$$

$$y(n) = \frac{Y(n)}{i} \qquad \textbf{7.18(18)}$$

This still requires a rotating buffer, but it replaces several add functions with one add and one subtract. However, it has the potential to accumulate error if the add and subtract functions are not exact. Periodically sum all the measurements to eliminate the accumulated error.

The consequences of a low-pass filter's time delay can be mitigated if the amplitude of the noise is comparatively small compared to the signal, which is usually the case. For example, if a signal changes suddenly by an amount considerably more than the noise amplitude, then this probably indicates an actual change, and it may be appropriate to override the filtered signal. Such a sudden change may be detected by a high-pass filter operating in parallel with the low-pass filter, and the override may take the form of overwriting buffer registers with the changed signal.

Integrators

Integrators are familiar to control engineers in the traditional PID controller. However, a PID integrator is a special case in that it integrates only over time, and the time duration is from initialization until shutdown (i.e., an indefinite period), whereas integration is usually over a definite period and may be with respect to any variable, not only time. Integrating over an indefinite period is essentially totalization, and requires only a single register to hold the total. Integrating over a definite period requires a rotating buffer, as for a time delay.

Integration usually is with respect to time, although in principle one can integrate with respect to any variable. The integrator's basic formula is:

$$\begin{aligned} y(n) &= z\cdot x(n) + z\cdot x(n-1) \\ &\quad + z\cdot x(n-2)\cdots z\cdot x(n-i) \end{aligned} \qquad \textbf{7.18(19)}$$

or

$$\begin{aligned} y(n) &= z\cdot(x(n) + x(n-1) \\ &\quad + x(n-2)\cdots x(n-i)) \end{aligned} \qquad \textbf{7.18(20)}$$

$y(n)$ = current filter output
$x(n)$ = current measurement
$x(n-1)$ = previous measurement, etc.
z is the change in the integration variable (probably time) per iteration
i is the number of measurements included in the integration interval

Example (see Table 7.18c):

Assume flow measurements are taken every second from a flow meter calibrated in gallons per minute, and the requirement is to continuously display the volume delivered during the past 10 s:

z = 1 s, which is 1/60th of a minute—the flow is in gallons per minute.
i = 10—there are 10 one second periods in the required 10 s interval.

TABLE 7.18c
Flow Application Example

Time (s)	*Flow (gal/min)*	*Z*	*Volume*
1	10		
2	12		
3	13		
4	11		
5	10		
6	8		
7	7		
8	6		
9	8		
10	7		
	$\Sigma = 92$	$\cdot\frac{1}{60} =$	1.53 gallons/second

Implementation Considerations The discussion of low-pass filter implementation considerations is an introduction to timing requirements, which are similar for integrators.

Some instruments, particularly flow meters, include internal totalizers. These are well suited to totalizing applications, but, as currently available, they may be less useful for flow integration. This because they report* whenever a predetermined volume has passed through the flow meter, rather than reporting the volume, for example, during a predetermined time period. However, totalizing in the instrument can provide the highest accuracy with the simplest controller logic, so this alternative is attractive. Most instruments can be configured to report small volumes (the smaller the volume, the less the timing error) at high rates, so this alternative can be workable.

Differentiators and High-Pass Filters Users of automatic controls are familiar with differentiator usage from the well-known PID controller.

$$\frac{y(n) = x(n) - x(n-1)}{z} \qquad \textbf{7.18(21)}$$

$y(n)$ = the current filter output
$x(n)$ = current measurement
$x(n-1)$ = previous measurement
z = change in variable the derivative is with respect to (probably time)

Figure 7.18d shows an example of high-pass filtering applied to a noisy signal.

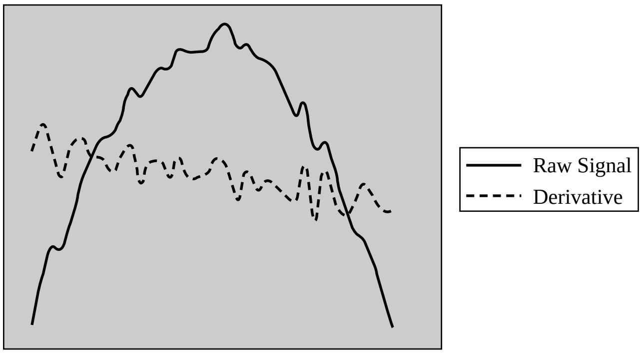

FIG. 7.18d
High-pass filter/differentiator.

Example:

Assume a pipe delivering flow into a cylindrical tank of area 2 m^2. The flow into the tank is metered, and the tank's level is metered. Estimate the flow out of the tank:

$$\text{Outflow} = \text{Inflow} - \text{Area} \cdot \frac{d(\text{Level})}{dt} \qquad \textbf{7.18(22)}$$

Time (s)	*Inflow (m^3/s)*	*Level (m)*	$\frac{dL}{dt}$ *(m/s)*	$Area \cdot \frac{dL}{dt}$ *(m^3/s)*	*Outflow (m^3/s)*
1	0.3	1.1			
2	0.4	1.2	0.1	0.2	0.2
3	0.4	1.3	0.1	0.2	0.2
4	0.3	1.3	0.0	0.0	0.3

Implementation Notes:

Do not form a high-pass filter from the raw signal minus its low-pass output, and do not form a low-pass filter from the raw signal minus the high-pass output. A high-pass output is usually highly random, so there may be little correlation between its output and the actual signal. The instantaneous difference between a raw signal and its low-pass output is usually significantly affected by the low-pass phase shift.

Interpolation and Predictive Filters

Interpolation filters provide maximally accurate ways of estimating what the actual value of a process variable was between samples. For example, assume samples $x(t)$, $x(t+1)$, $x(t+2)$, etc. are available. An interpolation filter provides the best estimate of x at any time, such as $t + 2.6$.

Interpolation technology is well developed for interpolating intermediate results and this may be useful in process control. A more exploratory possibility is to use similar technology to predict future process conditions—a predictive filter—as an advance warning function that may allow the

---

* A report usually takes the form of a pulse. A flow meter may output a pulse whenever another, say, 100 liters has passed. The frequency of the pulses depends on the flow—the smaller the volume, the more frequent the pulses—and frequencies in the 1 kHz range are practical.

controls to anticipate and avert a process upset. For example, at time $t = 0$, assume available samples $x(0)$, $x(-1)$, $x(-2)$, etc. What is the best estimate of x at $t > 0$, for example $x(+2.6)$?

Predictive filters are not yet widely used and the technology is relatively less mature. As a result, this handbook only introduces the concept to highlight the possibility. See current texts for recent progress in this area.

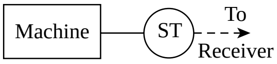
7.19 Tachometers and Angular Speed Detectors



Flow Sheet Symbol

A. BRODGESELL (1969, 1982) **B. G. LIPTÁK** (1995, 2003)

Types:	A. Impulse tachometers B. Optical encoders and photoelectric sensors C. Stroboscopes D. AC and DC tachometers E. Induction sensors F. Magnetic sensors G. Pneumatic sensors
Note:	Most angular position sensors described in Section 7.10 and proximity sensors described in Section 7.14 can also be configured as tachometers.
Range:	Up to 999,990 rpm
Inaccuracy:	Generally 0.01% of reading, or 1 rpm up to a reading of 100,000 rpm
Operating Temperature:	Up to 200°F (93°C)
Costs:	For angular position sensors see Section 7.10; for proximity switches see Section 7.14. Hand-held mechanical tachometers cost about $150. Microprocessor-based handheld contact or noncontact type tachometers cost about $250. Handheld stroboscopes with internal batteries cost $500 with analog displays and $750 with digital displays. For panel-mounted installations, a microprocessor-based programmable display costs about $600; the associated sensor can be optical ($150), proximity, or magnetic ($150). If an analog transmitted signal is desired, a magnetic wheel sensor and signal conditioner can be obtained for $700.

INTRODUCTION

The measurement of linear velocity and speed of rotation (tachometry) is discussed in this section. One common method of tachometry is to detect the speed of rotation by a proximity switch and utilize a counter to register the number of rotations. Since proximity switches have already been discussed in Section 7.14, this approach will not be discussed here. The measurement of linear and angular position has been discussed in Section 7.10. For that reason, such indirect methods of speed measurement, which are based on the timed measurements of positions, are also not covered.

Speed-sensing devices are available in a wide variety of designs, using capacitor impulse, optical (visible, infrared, laser), stroboscopic, electromagnetic induction, voltage generation, and magnetic force measurement techniques. They can be packaged as handheld portable units or as permanently installed industrial transmitters and they can serve as tachometers, rate meters, counters, or totalizers.

HANDHELD TACHOMETERS

These units are available in contacting and noncontacting designs, can measure linear or rotary motion, are battery-operated, and are provided with microprocessors for memory functions and convenient range switching. The modes and ranges available for a particular multifunction design are given in Table 7.19a. The unit is provided with a kit containing linear measuring wheels, adapters for direct contact rpm sensing, and reflective tape for optical measurement. In the noncontacting (optical) mode, the maximum measuring distance varies from 12 to 30 in. (300 to 762 mm). The inaccuracy of measurement is 0.2% in the linear mode and 0.025% in the angular velocity mode.

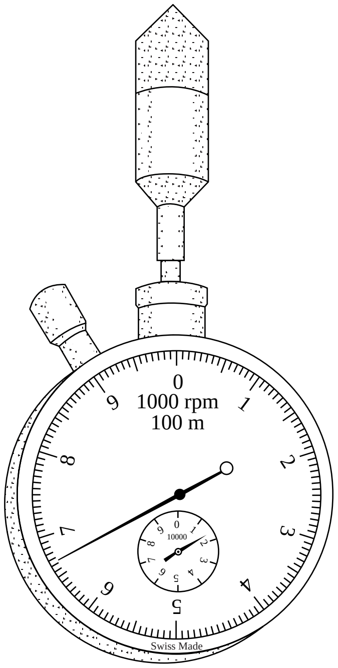

FIG. 7.19b
Mechanical hand-held tachometer.

The simplest and least expensive tachometer is the handheld mechanical unit illustrated in Figure 7.19b.

TACHOMETER OPERATING PRINCIPLES

The same basic operating principles are used in both the handheld and the permanently installed transmitting tachometers. These principles are discussed in the following paragraphs.

Impulse Tachometers

In this device a spindle is used to make physical contact with the rotating object so that the spindle will rotate at the same rpm as the shaft being measured. The spindle operates a reversing switch in the pickup head, which reverses twice during each revolution. The reversing switch connects the charging potential to a capacitor in each direction, and with each impulse a current is passed through a milliammeter readout. The readout registers the average of the rates of the pulses, which corresponds to the rates of spindle rotations. The sensor head and the readout display can be separated by a distance

of 1000 ft (300 m) when the wiring is properly shielded. For ranges and inaccuracies refer to Table 7.19c.

Optical Encoders

In rotary encoders, the shaft turns a disk that has a radial pattern with a unique code provided for each of a finite number of distinct positions (Figure 7.19d).

For each bit or resolution there is one track of code pattern. For example, for 12 bits of resolution there are 12 tracks. The number of distinct positions is determined as 2^N; for example, for 12 bits/tracks there are 4096 distinct positions, which results in a resolution of better than 0.025%. On the back of the disk there are light-emitting diodes for each track, allowing phototransistors to read the disk pattern. The disk track patterns are usually not in natural binary code, but in gray code (see Figure 7.10n for details).

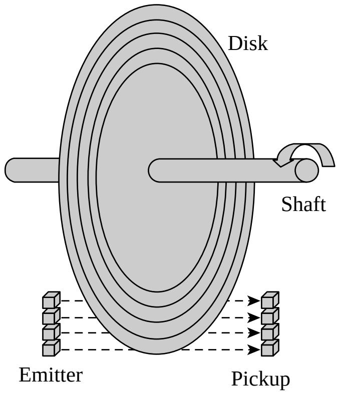

FIG. 7.19d
The principle of encoder operation.

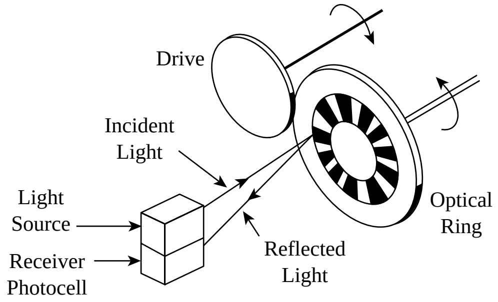

FIG. 7.19e
Photoelectric speed sensor.

Photoelectric Sensors

In this design, a light beam is modulated by a rotating member, and the modulations produce current pulses in the output of a photocell. In the design shown in Figure 7.19e, dark and light areas on the rotating disk alternately absorb and reflect the light of the source beam. The variations in reflected light are sensed by a photocell, which produces current pulses whose frequency is in proportion to the speed of rotation. Alternately, the light source and photocell can be located on opposite sides of a rotating, perforated disk.

Noncontacting Optical Tachometers Microprocessor-based optical tachometers operate from a distance of up to 30 in. (0.76 m) from the target at angles up to 45 degrees. They are often used by marking the rotating object with a reflective substance, such as a tape, and registering the light pulse every time the tape passes in the view of the sensor. Because of the microprocessor, the impulses from the optical encoder can be converted into counts or velocity units as needed. Available ranges and inaccuracies are given in Table 7.19f.

TABLE 7.19f

Stroboscopic Tachometers

When rewinding a tape at high rpm under a 60 Hz incandescent lamp, the patterns on the reel tend to slow and then appear to stop. This is the stroboscopic effect, discovered by Stampfer and Plateau in 1832 and named from the Greek word for whirling watcher. The stroboscope permits intermittent observation of rotating objects in such a way as to produce an illusion of stopped motion. Intermittency of observation can be obtained by intermittent illumination of the rotating object.

In industrial applications, the stroboscope is a light source that is turned on and off very rapidly. With the use of microprocessors and harmonic techniques, speeds up to 1 million rpm can be measured. These handheld or permanently installed units can measure the rotary, reciprocating, or linear rate of moving objects without the need for using reflective tapes or discs. The inaccuracy of measurement is usually 1 rpm.

Fiber-Optic Stroboscopes The short duration, high intensity light pulses produced by the stroboscope can be focused onto a port, which is configured for the mounting of one end of a fiber optic bundle. The other end of this optical fiber projects the light to the detected object. Various fiber optic bundles, nose pieces, and adapters are available to interface the fiber cable with the stroboscope enclosure. The optical, electrical, and environmental specifications for three such units are given in Table 7.19g.

AC Tachometers

The AC tachometer generator is an electromechanical device very similar to a two-phase induction motor. It consists of a primary winding, a secondary winding placed at 90 degrees (mechanically) to the primary, and a rotor. This arrangement is shown schematically in Figure 7.19h. With the rotor stationary and the primary winding excited by a sinusoidal voltage, the induced voltage in the secondary is almost zero due to the relative position of the two windings. However, as the rotor begins to turn, a sinusoidal voltage is induced in the secondary winding whose magnitude is in proportion to the rotor speed.

Since the output signal is a voltage, the readout instrument used with this tachometer should have a high input resistance to give near-zero current flow in the secondary winding. Any current flow in the output winding will cause a voltage drop, which will be subtracted from the true measured voltage, and thus the speed measurement will be in error.

DC Tachometer

In the DC tachometer generator, the magnetic flux is provided by a permanent magnet, and the output winding is located on the rotor. At zero speed there is no relative motion between magnetic field and winding, and the output voltage is zero. As rotor speed increases, so does the relative speed between magnetic field and winding, and hence the output voltage. The voltage induced in the winding is sinusoidal; a commutator and brushes on the rotor convert the AC voltage in the winding to a DC output in the same manner as in the DC generator. The DC tachometer is shown schematically in Figure 7.19i.

Induction Sensors

Several configurations are possible with induction-type sensors. Basically, the unit consists of a coil located in a magnetic field. This magnetic field is made to vary as a function of speed. One design, shown schematically in Figure 7.19j, uses a coil wound on a permanent magnet and located in the proximity of a rotating toothed wheel of magnetic material. As the teeth of the wheel pass the magnet, they disturb the magnetic field, which, in turn, induces voltage pulses in the coil. The pulse frequency is related to rotational speed as expressed by the relationship rpm = 60 f/N, where rpm is rotational speed in revolutions per minute, f is the frequency in Hertz (cps), and N is the number of teeth on the wheel.

Figure 7.19k shows a design in which the magnet is mounted in the rotating member, inducing voltage pulses in the stationary coil.

Magnetic Sensors

Magnetic-type sensors (Figure 7.19l) utilize magnets to accomplish speed detection, as implied by the name. The sensor consists of a multipole magnet mounted on the rotating member and a stationary magnetic reed switch mounted in the proximity of the magnet. Passage of the magnet poles causes the contacts of the reed switch to open and close, thus making and breaking an electrical circuit. The output is thus a pulse train whose frequency is in proportion to the rotation speed.

Magnetic speed sensors rely on magnets as either the sensing element or the sensed target to determine rotational or linear velocity. They are often used as gear tooth speed sensors or are incorporated into stroboscopes or tachometers.

Inductive Sensors In this detector, an oscillator circuit generated a radio frequency electromagnetic field that radiates

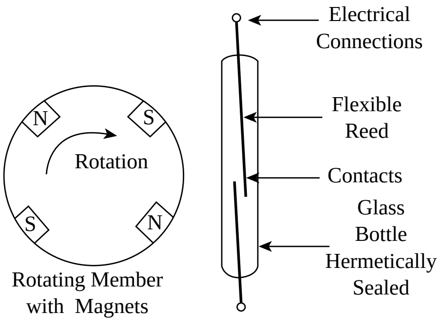

FIG. 7.19l
Schematic of magnetic speed sensor.

Magnetoresistive and Variable Reluctance Sensors In magnetoresistive sensors, the resistance of a sensing element varies with the direction and proximity of a magnetic field.

Variable reluctance sensors are self-generating, meaning that they require no external power. In these sensors, a small voltage is induced when a magnetic surface passes them in close proximity.

Pneumatic Speed Transmitter

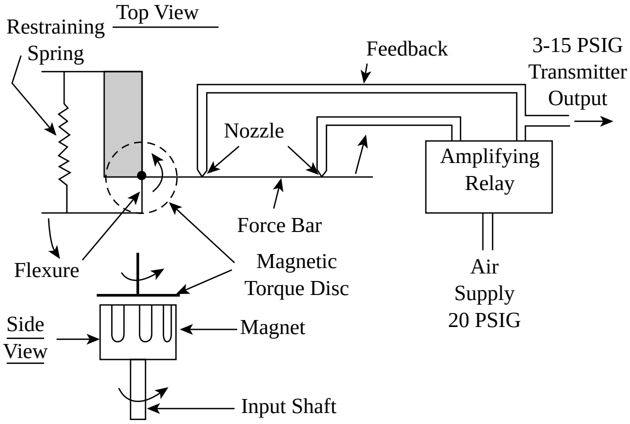

FIG. 7.19m
Pneumatic speed transmitter.

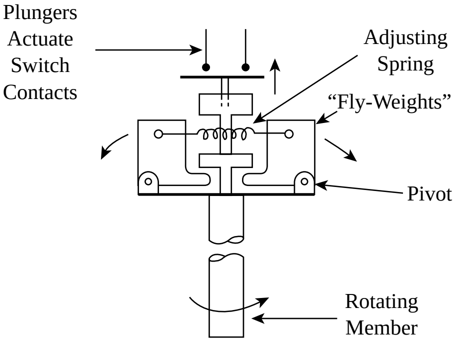

FIG. 7.19n
Speed switch.

An eight-pole permanent magnet is mounted on the input shaft as shown in Figure 7.19m. Flexure strips hold the disk between the base plate and the magnet poles. As the input shaft rotates, magnetic lines of force cutting through the disk tend to rotate it. The force bar is subjected to two forces: (1) the force resulting from the rotation of the magnet, and (2) the opposing force from the feedback unit. Imbalance of these forces results in motion of the force bar so that the air pressure at the nozzle changes.

The pneumatic relay amplifies the nozzle pressure and produces a restoring force through the feedback unit until torque due to magnet rotation and restoring force of the feedback unit are balanced. Since the torque due to rotation of the magnet is in proportion to the speed of the magnet, feedback pressure is in proportion to speed. However, the feedback pressure is also the transmitter output signal, and hence the output pressure is in proportion to speed.

SPEED SWITCHES

Sensors with a continuous output can be provided with relays actuated by the measuring circuitry to provide a contact closure signal for an alarm or shutdown function. Where only a contact closure is required—to signal over-speed, low speed, or zero speed—devices with on-off output action may be sufficient.

One type of switch shown in Figure 7.19n consists of flyweights mounted on a rotating shaft coupled to the machine

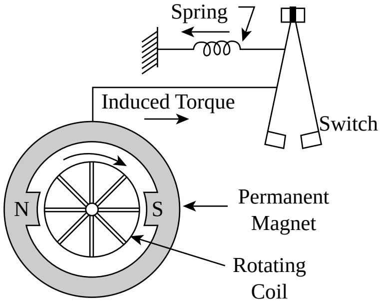

FIG. 7.19o
Zero speed switch.

to be monitored. Under the influence of centrifugal force, these flyweights move away from the center of the shaft against the restraining force of a spring. Toes on the flyweights lift a plunger, which tips a microswitch at the desired speed. The set point can be adjusted by changing the spring tension.

However, the switch is nonindicating, and set point changes must be made on a bench at known speed or the speed of the machine must be measured independently. These switches can be provided with actuation on increasing or decreasing speed. A manual reset feature is available, which keeps the switch in the actuated position, regardless of machine speed, until it is manually reset.

A switch to monitor zero speed is shown in Figure 7.19o. Relative motion between the coil and magnet produces a torque that holds the switch contacts in the operating position. As speed decreases, the electromagnetic torque decreases, until the spring force is sufficient to overcome the torque and the switch contacts transfer. This switch will actuate only on decreasing speed.

CONCLUSIONS

Selection of the type of sensor to be used will generally be governed by the purpose of measurement. Naturally, if an analog signal is required, the tachometer generators whose output is already analog have an advantage. For digital control and readout, magnetic, inductive, and photoelectric sensors offer compatible outputs.

For best accuracy, full-scale speed of tachometer generators should be so selected that the normal operating speed is as close as possible to full scale. Where the inherent speed range of the sensor is insufficient to accommodate the operating speed, reducing the gears on the sensor input can extend the measurement range.

INTRODUCTION

The techniques used for the measurement of dimensions and thicknesses are similar to those that were discussed in connection with position and proximity sensors in Sections 7.10 and 7.14. For that reason the reader is advised to also review these sections, as some of the details of sensor features and operation will not be repeated here.

DIMENSION MEASUREMENT

The National Institutes of Standards and Technology uses a laser interferometer to obtain precision better than one part in 10 million. The PC-based optical micrometer for micromachine (OMMS) provides a thickness evaluation of diaphragms measuring 25 micrometers to 5 mm.

Thin-film deposition thickness is detected by interferometry to measure the reflective properties of a layer of coating to an accuracy of 1%. Ultrasonic devices also measure coating thickness by sending a pulse, which is reflected by the surface below the coating. This section provides information of the above and a variety of other thickness gauges.

Automated Gauging Machines

In automated dimensional inspection systems, the workpiece is mounted on a table and a probe is moved along the x, y, and z axes. First the probe is positioned in a reference hole or against a reference surface, and then it is moved (manually) to the various check locations. When gauging a bore or checking a single dimension against some specification after the part has been machined, pneumatic gauges can also be used, such as the units that were described in connection with Figure 7.14h. The use of air jets can be convenient because the measurement is not affected by ambient conditions such as temperature or by vibration.

Electronic gauging systems (laser, optical micrometer, linear variable differential transformer [LVDT], induction, reluctance, capacitance, resistance) are also widely used (Figures 7.14a to 7.14d) and are well suited for difference measurements, such as mating the inside diameter of a cylinder with the outside diameter of a piston.

Laser gauging has been available since 1970. In one configuration, the laser beam is directed at a rotating (or oscillating) mirror to collimate it into a flat ribbon of light. As the collimated beam scans across an object, the light is blocked by it and the light detector (such as photodiodes) on the other side measures the length of time during which the light was blocked. Therefore, the scan time across the shadow is used as a measurement of dimension. Laser scanners can operate from distances of 6 ft (1.8 m) and at 1 ms frequency, and, therefore, can scan several hundred objects per second.

THICKNESS GAUGING

The thickness gauge designs can be grouped into contacting and noncontacting designs and can use operating principles based on interferometry; induction; capacitance; reluctance; resistance; pneumatic; optical (including laser and optical micrometry); and ultrasonic, x-ray, or beta-ray radiation.

The thickness of web, film, foil, and sheet materials is monitored and controlled during manufacturing by the use of thickness measuring devices. The devices may be those that compare the thickness to a reference length, or those that indicate the thickness based on some physical relationship. (Compare specific vs. nonspecific measurements.)

The former devices are generally considered contacting types, while the latter are typically noncontacting types. The final reading is an averaged indication due to either mechanical or electronic damping of spurious signals. The cost of a specific instrument depends on its sensitivity, which determines

TABLE 7.20a
Thickness Measurements

Instrument	*Type**	*Sensitivity***	*Application****
Micrometer caliper	C	0.0001 in.	Sampling, quality control, calibration, foils, web, sheet, film materials (N)
Interferometry gauge	NC	1% of reading	Measures thin-film deposition layer thickness and uniformity of semiconductors and dielectric layers (Y)
Optical micrometer	NC	0.1 μm	Provides thickness monitoring for silicone wafers (Y)
Laser gauge	NC	0.05 in.	Mounted directly on production line and is used to alarm on any out-of-tolerance condition (Y)
Differential roller gauge	C	20 μin.	Low-speed continuous foils, web, sheet, film materials, calibration, sampling (Y)
Sonic and ultrasonic gauges	C	0.01 in.	Rigid, relatively thick sheets, or pipe walls accessible from one side only (Y)
Capacitance gauge	NC	0.001 in.	Insulating sheets, films (Y)
Radiation gauge	NC	50 mg/cm^2****	Metal foils and plastic films (Y)

*C = contacting; NC = noncontacting.
**1 in. = 25.4 mm; 1 μin. = 2.54 × 10^{-5} mm.
***Whether a device is suitable for continuous process instrumentation is indicated by N (no) or Y (yes).
****Actual sensitivity depends on the specified value for a given instrument divided by its density (g/cm^3).

the complexity of the device. Table 7.20a lists some of the more widely used thickness gauges.

Contacting Gauges

The familiar micrometer or vernier caliper gauges are only suitable for noncontinuous sampling or batch quality control and calibration measurements. This is because the contact points would wear out and the accuracy would be reduced with continuous use.

The differential dial gauge adapts the calipers to continuous measurement by using rolling contact points and indicating the difference between a reference wheel, usually on a calender roll, and the measuring wheel on the sheet stock. The thickness signal is derived from the output of an LVDT (Figure 7.20b). The difference between the secondary voltages caused by displacement of the movable iron core (armature) is linearly proportional to the displacement.

With the proper power source and input mechanism, dimensional gauging from 0.001 in. to several inches (0.0254 mm to several centimeters) is possible. The accuracy is independent of the finish of the calender roll. A single roller dial gauge contacting the stock would rely on the accuracy of the backing roll for overall accuracy.

Ultrasonic Thickness Gauging These sensors are listed under the contacting type gauges because they require a continuous sonic path between the part being measured and the transducer. Sound cannot travel through an air–liquid or air–solid interface; a continuous liquid coupling is required. This can be provided through different techniques, including the total immersion of both the measured part and the transducer in liquid.

These gauges are extensively used for wall thickness measurement of metal, plastic, or ceramic equipment. As sound travels at characteristic velocity and is reflected at acoustic boundaries, the measurement of the time it takes for an echo to return can be used as a measurement of thickness. This method of measurement is called the pulse-echo or transit-time method.

The other configuration of the ultrasonic thickness gauge is called the resonance gauge. In this design, a frequency-modulated continuous wave signal is generated, and when the measured wall thickness equals one-half wavelength (or multiples of it), mechanical resonance (standing wave conditions) occur. These gauges can measure wall thickness to within 1% error.

Sonic gauges are used to measure the thickness of materials accessible from one side only (i.e., the wall of a pressure vessel or a storage tank). The wall is made to resonate by

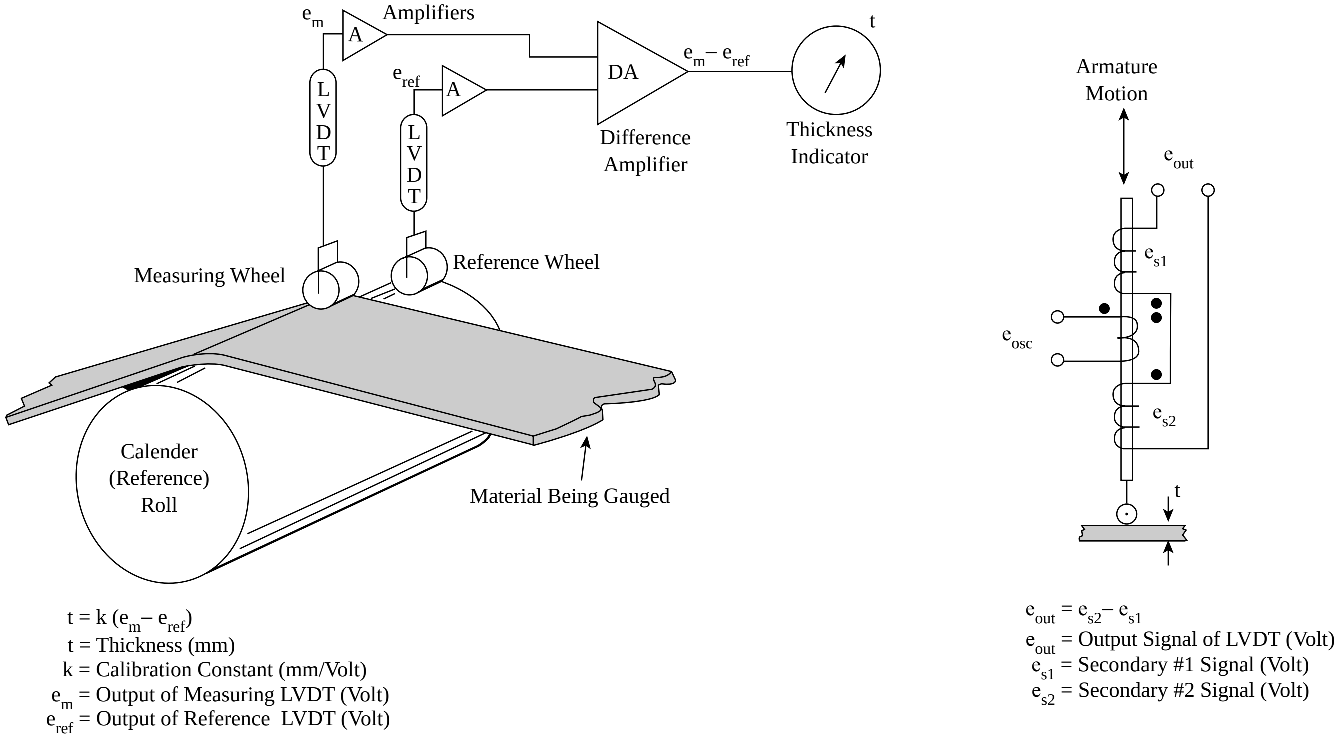

FIG. 7.20b
Left, differential roller gauge with LVDT; right, LVDT schematic.

varying the applied ultrasonic frequency. The resonant frequency is then used to calculate the thickness from the relation.

$$t = 0.5\ v/f \qquad \textbf{7.20(1)}$$

where

t = thickness of the material being gauged (ft) or (m)
v = velocity of sound in material (ft/sec) or (m/sec)
f = frequency of resonance (Hz)

The device is generally not suitable for dynamic reading of moving material because accurate dimensioning requires intimate contact between the generator crystal and the surface of the material.

Under static conditions, thickness from 0.01 to >10 in. (0.254 to >254 mm) may be measured with very great accuracy. When the ultrasonic probe is placed on a coated surface, it sends sound pulses that penetrate the coating through the base material. These pulses are reflected by the different surfaces and transmitted to the transducer in the probe. Based on the time intervals, the microprocessor gives individual and total coating thickness (Table 7.20c).

Noncontacting Gauges

Certain properties of materials may be used to indirectly indicate the thickness of films or sheets of those materials.

Capacitance Gauges For insulating films, the capacitance gauge may be used (Figure 7.20d). Because the capacitance

varies directly in relation to the thickness of the dielectric material between the capacitor plates, it is possible to measure thickness of insulating films if the dielectric constants are a great deal different from that of air.

The capacitor and the material to be measured are part of an electrical resonant circuit, whose output is calibrated to indicate thickness. Moisture content of the material and/or air gap between the plates and the material are the primary sources of error for this instrument. (The principle is applied to moisture measurement.) It also is not usable for conductive films.

Laser Gauging In their industrial applications, laser interferometers are providing precisions of about 20 millionths of an inch (one millionth of a millimeter). These instruments operate by directing two light beams from the same source to the detected surface over two paths that differ in length by as little as 0.1 wavelength. As these light beams are recombined, destructive interference occurs, and the interference patterns (dark and bright lines) can be interpreted into precise distance measurements.

The laser techniques described for dimensional measurements can also be used for the detection of thickness. Figure 7.20e illustrates the method for using laser triangulation for the measurement of the thickness of sheets. Whenever an out-of-tolerance condition occurs, an alarm is actuated. The measurement resolution is 0.002 mm and the sampling rate is 1000/s. These types of direct measurements tend to eliminate errors caused by belt fluctuation, vibration, or thermal expansion.

Optical Micrometer and Interferometers The OMMS is used for thickness monitoring of silicon wafers. Representative specifications for the unit are given in Table 7.20f. These units measure diaphragm thickness from 10 μm up to 5 mm. The operating principle is based on the optical absorption of the double-sided silicon wafer. Silicon wafers of known thickness are used for calibration prior to shipment. The OMMS can also self-calibrate on-site, using built-in thickness standards.

TABLE 7.20f
Representative Specifications for Thickness Sensing by Optical Micrometer for Micromachine (OMMS) Method Produced by Virginia Technologies Inc.

Measurement technique	Nondestructive optical transmission through sample
Measurement array	CCD
Data points	106,000 (pixels)
Computer	High-end PC
Software	LabView custom application
Viewing mode	Backlit surface image
Sample material	Double sided polished silicon
Wafer size	Up to 8 in.
Sample preparation	None
Thickness measurement resolution	0.1 μm
Thickness measurement range	10–200 μm
Spatial resolution	30 μm
Thickness measurement area	5.0 mm × 5.0 mm
Thickness measurement time	5 s/site
Thickness measurement repeatability	14–55 μm: ±0.5 μm 56–101 μm: ±0.5 μm 102–144 μm: ±0.5 μm 145–181 μm: ±1.0 μm
Calibrated operating temperature range	22–27°C
Temperature sensor resolution	0.1°C
Temperature sensor repeatability	±0.3°C
X-Y stage position repeatability	<50 μm
X-Y stage position resolution	200 μm

Interferometry can also be used to measure the reflective properties of a layer as it changes in thickness. This sensor can measure deposition rates, layer thickness, uniformity of semiconductors, and dielectric layers. The instrument is outside the process chamber and can make adjustments to the process recipe before the actual deposition run, in addition to monitoring the deposition process and reevaluating the multilayer structure after the deposition. The inaccuracy of the instrument is about 1% of reading. The spectrometer range is 400 to 1000 nm, the static layer can be from 15 nm to 50 μm, and the growing layer is over 100 nm.

Radiation Type Thickness Gauges Both beta and x-ray forms of radiation are used in thickness gauging. The beta-radioisotope is used to measure the thickness of sheets or the thickness of coatings on sheets. The measurements are usually calibrated in weight per unit area, such as ounces per square foot, and can be detected within an error of 1%.

X-ray thickness gauges are a standard part of computer-controlled rolling mills. They can also be used for hot or cold, stationary or moving strips of paper, plastic, glass, rubber, or metal, over a wide range of thickness. When the strip is moving at a high speed, the speed of response of the x-ray gauge will determine the precision at which defects can be isolated. If a mill operates at a speed of 5000 ft/min (1524 m/min), a gauge with a 50 ms response time will allow reaction to a change in thickness after some 4 ft (1.3 m) of material has passed the sensor.

The attenuation of radiation from x-rays or radioactive decay by matter is utilized in the radiation absorption gauge to measure the thickness of the material. The equation is

$$\Delta I = [1 - \exp(-\mu t)] \qquad \mathbf{7.20(2)}$$

using averaged ionization current for signal, where

ΔI = change in ionization current when absorber is inserted
I_o = ionization current without absorber
μ = absorption coefficient ($cm^2/\mu g$)
t = thickness ($\mu g/cm^2$)

The display is calibrated to indicate thickness.

Radiation gauges are subject to errors from the statistical nature of radioactive decay and from the dependence of the absorption coefficient on the composition of the material being measured (Figure 7.20g).

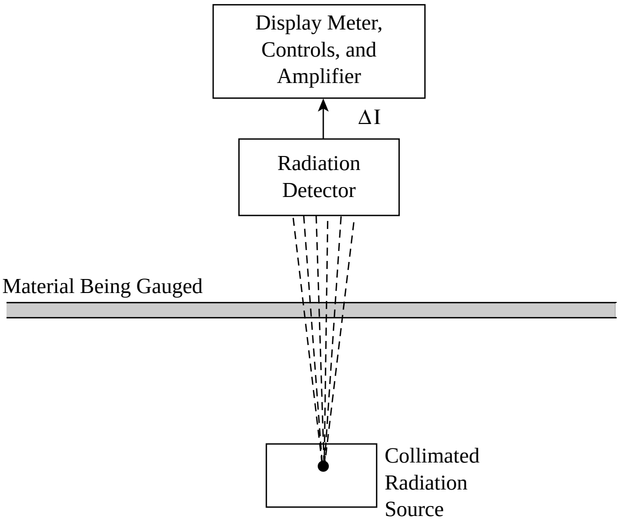

FIG. 7.20g
Radiation absorption gauge.

For all thickness gauges, but particularly for the nonspecific or noncontacting types, frequent calibration checks with samples of the material to be gauged are recommended. Specific or contacting-type gauges are usually calibrated against precision standards.

Coating Thickness Detection by Radiation The thickness of coatings can be measured in one of three ways. One technique is to use two beta gauges. One measures the basis weight of the substrate prior to coating, and the other detects the total basis weight after coating; the difference reflects the thickness of the applied coating. This method of measurement is suitable for the measurement of thick coatings, where the coating represents 25% or more of the weight of the substrate.

Another method of detecting the thickness of coatings on paper or plastics uses the preferential absorption principle. This method is applicable only to coatings having an atomic number, which is at least twice the atomic number of the substrate. Here only a single, low-energy gamma source is used, and the detector measures the absorption by the ingredient with the highest atomic number (the coating).

When the coating thickness of metal strips is to be detected, a nuclear fluorescence sensor can be used. In this type of detector, the gamma radiation excites the electrons in the metal under the coating. As the electrons return to their original (unexcited) state, they release a low-energy form of radiation (fluorescence). Two ion chambers are used in this instrument; one detects the radiation from the metal strip, and the other measures all forms of the back-scattered radiation. The difference between the two readings is a function of the thickness of the coating.

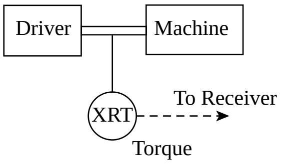
7.21 Torque and Force Transducers

A. BRODGESELL (1969, 1982) **B. G. LIPTÁK** (1995)

P. M. B. SILVA GIRÃO (2003)



Flow Sheet Symbol

Operating Temperature:	–60 to 300°F (–50 to 150°C)
Force Ranges:	Hand-held or portable force gauges can have ranges from 0–1 to 0–500,000 lb (0–0.5 to 0–220,000 kg). Load cells are available with ranges from 1 to 10 million lb (0.5 to 5 million kg).
Torque and RPM Ranges:	Torsion bar type indicators up to 50 lb-in. (60 kg-cm); stationary and rotary strain gauge type torque sensors up to 400,000 lb-in. (500,000 kg-cm) or, in terms of power transfer, up to 75,000 HP. The maximum speed of slip-ring designs varies from 2500 to 6000 rpm, while for inductively coupled torque sensors, it can reach 15,000 rpm. Reaction torque sensor ranges go up to 1.5 million lb-in. (1.7 million kg-cm).
Force Inaccuracy:	Handheld or portable test gauge errors range from 0.2 to 0.5% of full scale. Load cell errors can be as low as 0.02% of full scale.
Torque Inaccuracy:	Torsion bar monitors, 3% of full scale; stationary and rotary strain gauge sensor nonrepeatability, nonlinearity, and hysteresis amount to 0.1% of full scale each.
Costs:	*Test equipment:* Hand-held or portable mechanical force gauges, $500 to $750; electronic digital torque gauges, $1000; and electronic digital force gauges, $500 to $2000. Motorized test stands for manual operation range from $1000 to $3000, while programmable, computer-compatible units cost about $7500.
Force sensors:	Single beam load cells range from $50 to $500. The unit cost of standard load cells ranges from $500 to $1000; a panel-mounted transducer/monitor costs about $1000. A single-component quartz force sensor is about $2000, while a digital dynamometer controller costs $5000 to $7000.
Torque sensors:	Cost of stationary torque sensors for ranges from 100 to 10,000 lb-in. (115 to 11,500 kg-cm) is $1500 to $2000. Rotary sensors for the same range are $2500 to $4000. The cost of a slip-ring assembly is $2000. Reaction torque sensor costs for the above range are between $1000 and $2500. For higher ranges, costs are as follows: up to 100,000 lb-in., $5000; to 200,000 lb-in., $8000; to 500,000 lb-in., $15,000; to 1.5 million lb-in., $18,000.

FORCE MEASUREMENT

Force is a quantity whose measurement is important in fields so different as the petrochemical industry, medicine, robotics, automotive industry, civil construction, and electrical machines. The measurement of force overlaps somewhat with the detection of strain, displacement, load, pressure, and acceleration covered in other sections of this Handbook. For this reason, the reader is advised to also review those sections in order to gain a complete view of the range of devices available for the measurement of force.

Force (F) is a vector quantity that causes a change of momentum in a body of mass m ($F = ma$). If a force applied to a body does not alter its acceleration, then the force and the body constitute a system in equilibrium. Forces that do not change in time are said to be static and are usually due to some potential energy (e.g., weight) forces that change in time, such as those due to shock waves, are said to be dynamic.

Measurement Principles

There are several principles used to sense and measure force. These principles include the following:

1. Balance the unknown force with a known one, such as a standard mass and a system of levers or an electrical force.
2. Measure the acceleration that the unknown force produces on a known mass.
3. Measure the pressure it produces on a known surface.
4. Sense and measure the effects that the unknown force produces on various materials.

These can include mechanical effects, such as strain of a body or displacement of a body or of a spring (e.g., vertical and torsional balances). They can also be optical, such as causing a change of the optical properties of optical fibers (e.g., fiber Bragg gratings[1]). They can also be electrical, including (1) resistive, (2) capacitive, (3) magnetostrictive, and (4) piezoelectric.

In the resistive designs, the change of resistance occurs in force-sensitive polymer resistors. It can also occur due to the change of distance between particles and due to change of contact area between particles of semiconductor materials. In the capacitive designs, when the force is applied it produces a change in the distance between its plates and hence a change of capacitor's value. In magnetostrictive designs the force produces a stress that changes the permeability of a magnetic material with a force produced stress. In the piezoelectric design, the mechanical stress changes the voltage produced between the surfaces of a dielectric. From all the sensing methods, the most often used in industrial applications are the mechanical and the piezoelectric ones.

Mechanical Dynamometers: Load Cells

Most of the transducers used in force measuring instruments (dynamometers) are mechanical of the piezoelectric type above. Their operation is based on the deformation that the force produces on an elastic supported body. Force measurement in this case is converted into a measurement of strain (uniaxial tension or compression or shear) or into the displacement experienced by the elastic body. Mechanical force transducers composed of a supported elastic body and of a strain/displacement sensor are usually called load cells because the force is a load to the body. Nevertheless, the designation load cell is commonly extended to other force sensors, such as those based on the change of oil pressure (hydraulic load cell) or air pressure (pneumatic load cell), when the force is applied to an elastic surface of a closed chamber.

In industrial applications, the primary interest focuses on the measurement of force by electrical means. Therefore, the change in displacement (gross deflection) or strain (local deflection) of the elastic body is converted into an electrical signal by the displacement or strain sensors. The sensing element, which must operate within the particular material's elastic region, is selected for the particular application, and the following parameters are decisive on its choice:

1. Size
2. Shape
3. Modulus of elasticity of the material
4. Sensitivity to local strain and gross deflection
5. Dynamic response and loading effect on the measured system.

For the same type of sensing body, the change of its geometry and material allows different force measuring ranges.

Sensing Elements In terms of type and shape, the basic sensing bodies (elements) belong to one of the four following categories:

1. Beam
2. Proving ring
3. Column
4. Diaphragm

Figure 7.21a shows some examples of such sensing elements.

In the cantilever beam configuration, the maximum deformation is obtained at the free end of the beam, regardless of where the force is applied. For low force ranges up to some tens of Newtons (1 Newton = 0.2248 lb_f), the displacement of that end is converted into an electrical signal using a linear variable differential transformer (LVDT). For higher ranges, strain on the beam is measured using strain gauges, usually four identical gauges, two on the upper surface (operating in tension) and two on the lower surface (compression) of the beam at a distance X from the free end.

An electrical voltage U_0, which is proportional to the force F, is obtained connecting the strain gauges as a Wheatstone bridge. If the power supply to the bridge is E, one obtains:

$$U_0 = \frac{6GXE}{Ybh}F \qquad \textbf{7.21(1)}$$

where G = the strain gauge factor, Y = the Young's modulus of beam's material, and b and h = the width and the height of beam's cross section, respectively.

With both simply supported beams and restrained beams, force should be applied in the middle of the beam, as shown in Figure 7.21a. For the simply supported beam, maximum deformation and maximum strain both occur at that middle point of the beam; for the restrained beam, the maximum deformation occurs at that same point, but maximum strain is at beam's ends. As it happens with the cantilever beam, both strain and displacement can be converted into electrical signals using strain gauges and LVDTs.

Proving rings can be standard and flat as shown in Figure 7.21a. In both cases the maximum deformation and strain occur at the point where the force is applied. In the standard ring, and for practical reasons, strain is detected through strain gauges placed at 90 degrees to the force. At those points strain is almost equal to the maximum and sensibility is only slightly reduced. If four strain gauges are used and mounted in a Wheatstone bridge configuration with a supply E, the bridge's output voltage is:

$$U_0 = \frac{1.092GrE}{Ybt^2}F \qquad \textbf{7.21(2)}$$

where G = the strain gauge factor, Y = Young's modulus of the ring material, r = the radius of the ring, and b and t = the ring's width and thickness, respectively.

Column type sensing elements are particularly suited for the measurement of high force ranges, such as 20,000 N and higher. The column material and ratio of L and h (see Figure 7.21a) determines the characteristics of the column. Usually, strain is detected by strain gauges placed at the point of maximum strain in the middle of the column: two detect the compression along force's line of action, and two detect traction in the direction perpendicular to the force. The sensitivity of the element can be increased with the introduction of a stress concentration hole as shown on the bottom right in Figure 7.21a.

Diaphragm elements (Figure 5.5b) are also force detectors and are used intensively as pressure sensors. They are circular plates of different types continuously fastened around their edges. The applied force causes a strain in the diaphragm, which can be used to translate force into an electrical signal. Diaphragms made of conductive materials can also work well as a capacitance type displacement sensor.

All the sensing elements in the various force transducers should only be subjected to pure compression or tension stresses. Therefore, care must be taken not to produce torsional forces or shear stresses.

Strain Gauges Most load cells use strain gauges to translate the detected force into an electrical signal. The oldest strain gauge design is the foil-type strain gauge, which have been widely used in 4- to 20-mA transmitters. The foil elements are available with unit resistances from 120, 350, 1000, to 5000 Ω. The thin foil (0.0001 in., or 0.0025 mm in thickness) is bonded to the sensing element surface by an epoxy adhesive.

Semiconductor strain gauges are also used in a bonded configuration. In comparison to the bonded foil gauge, the main advantage of the semiconductor gauge is their greater sensitivity (higher unit resistance), while their main disadvantage is their increased sensitivity to temperature. An improvement

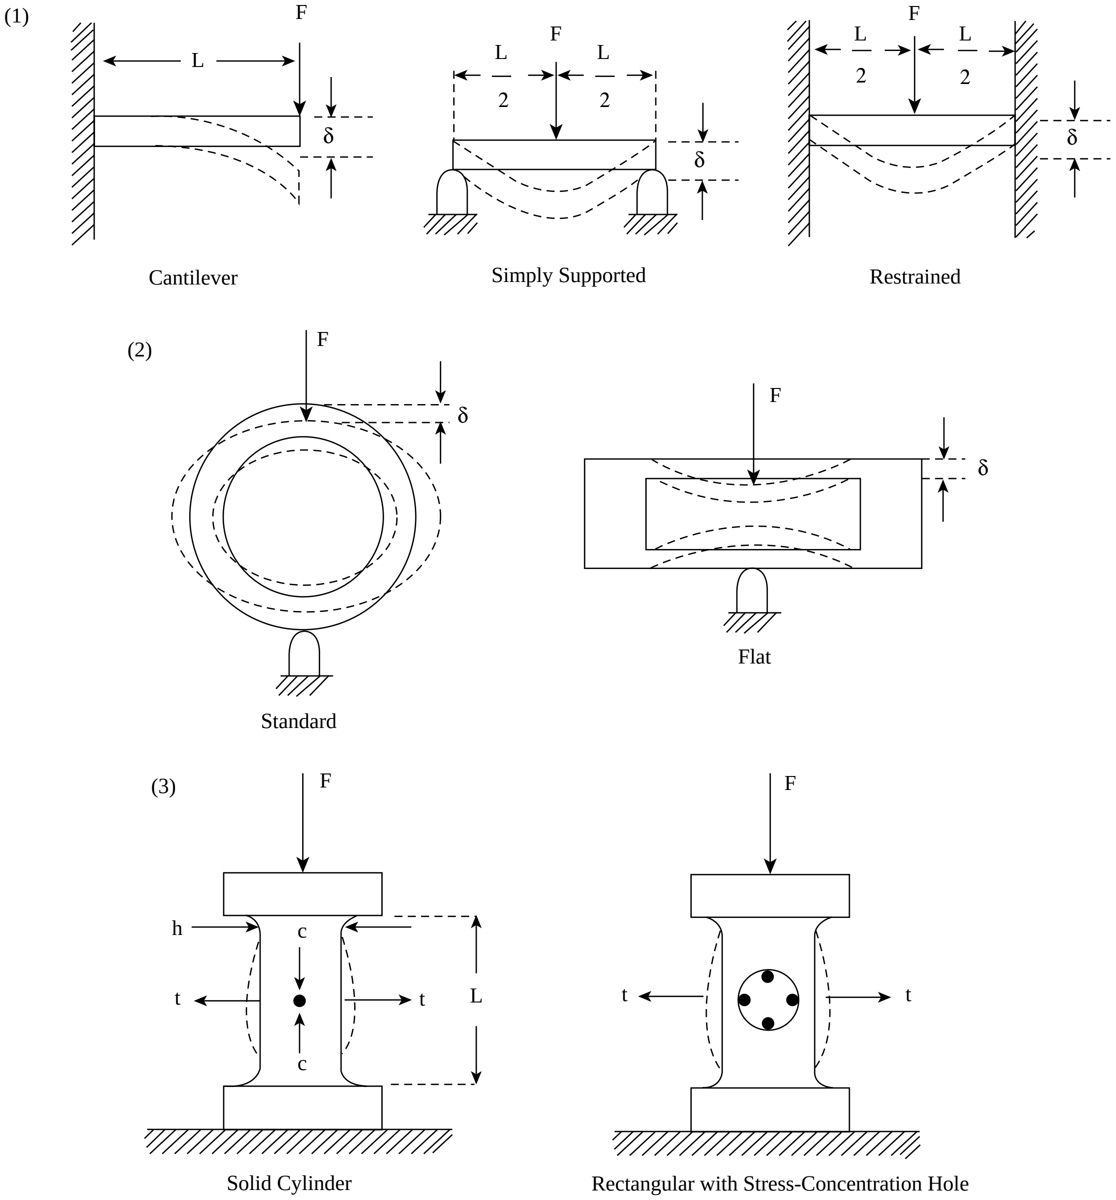

FIG. 7.21a
Examples of load cells sensing elements: (1) beam, (2) proving ring, (3) column.

in strain gauge technology has been the introduction of diffused semiconductor strain gauges. In these devices, by the use of photolithographic masking techniques, the semiconductor is directly deposited on the strained (silicon) member, without requiring the use of adhesives or bonding agents. This eliminates the problems of creep and hysteresis.

A further improvement in strain gauge technology has been the introduction of the thin-film strain gauge. This element is produced by depositing a thin metal alloy layer on a metal surface using vacuum deposition or sputtering techniques. The advantage of this design is in the molecular bonding that results, eliminating the need for a bonding adhesive. The other advantage is that the stressed force detector does not need to be silicone, but can be a metallic diaphragm or beam with a deposited layer of ceramic insulation.

Piezoelectric Dynamometers

The piezoelectric element differs from other force sensors in that it does not detect the deformation of some sensing element, but rather it is the sensing element. The piezoelectric crystal sensor is also different in that although it is used to detect near static forces, it is particularly suited to detect dynamic forces, such as shockwaves or impact forces. This is because the electrical signal that the crystal generates is present only for a short period after the force is applied. Therefore the piezoelectric load washers, force links, or force probes are mainly used for dynamic force detection. Another characteristic of the basic piezoelectric force transducer is that it only responds to compression forces; this limitation can be overcome by preloading the crystal.

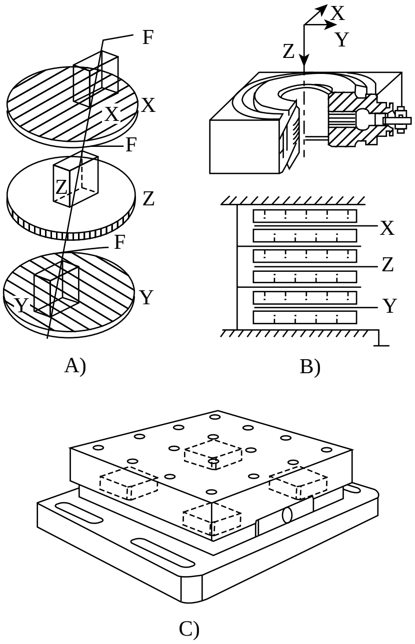

FIG. 7.21b
The three component discs (A) of a piezoelectric force transducer (B) and a multicomponent dynamometer platform (C) are restricted to dynamic force measurement. (Courtesy of Kistler Instrument Corp.)

In this transducer, shown in Figure 7.21b, a stack of quartz discs or plates and electrodes is sandwiched between parallel loading plates inside a steel housing. To detect larger dynamic forces, multicomponent dynamometers (platforms) are built with the four transducers placed in a rectangular arrangement between the loading and base plates. As the individual discs are sensitive to the force vectors around the *x*, *y*, or *z*-axis, their outputs can be tied together in a three-channel system of detection.

TORQUE MEASUREMENT

Torque is defined as the action that tends to produce rotation (Table 7.21c). Specifically, it is the moment due to a tangential force, $T = LF$, where T is torque, L the length of the force arm, and F is the force. If a free body rotates around an axis, torque can be expressed as the product of the body's moment of inertia, I, and its angular acceleration, α, as $T = I\alpha$.

When a torque is applied to one end of a cylindrical shaft while the other end is kept fixed, the shaft will be twisted. This twist can be measured by three methods:

1. Sensing the strain that the shaft has experienced.
2. Measuring the angular difference of a generatrix of the cylinder at both of its ends.
3. Sensing the change of the magnetic properties of a ferromagnetic shaft, which will change due to torque transmitted stresses (magnetostrictive effect).

$HP = \frac{TN}{63000}$ where,	T (lb. in.), N (rpm)

If the shaft rotates and is loaded, torque is more easily measured by opposing a torque that keeps the shaft balanced. The operation of mechanical, electromechanical, optical, and electronic torque measuring transducers are all based on one of the above-mentioned phenomena.

Torque transducers generally consist of two basic components: a structure, which is designed to deform microscopically under applied torque, and a device, which serves to convert this deformation to a measurement signal. For rotary equipment, the two types of torque transducers available are the in-line rotating torque transducers and the in-line stationary transducers.

In addition, there are the reaction torque transducers, which sense the torque on the housing or mount of motors or pumps, instead of detecting it on the shaft. These units are most often used in power transmission installations. The measurement is convenient and can be achieved by floating the machine on bearings, so that the force needed to prevent movement can be measured. Measurements obtained using this type of transducer are not as accurate as those made by direct shaft sensors due to the interference of the connecting pipes and electric conduits. In the case of motors, this technique of torque detection also disregards the inertia of the rotor, which contributes to the inaccuracy of the measurement.

ROTATING TRANSDUCERS

For the monitoring of small torques, the mechanical deflection of rotating torsion bars is used as a means of measurement. These units are available with ranges from 0–0.5 to 0–50 lb-in. (0–0.6 to 0–60 kg-cm). The measurement is bidirectional and the indicator can be a self-contained mechanical display (Figure 7.21d) or can be an electrical signal for remote display.

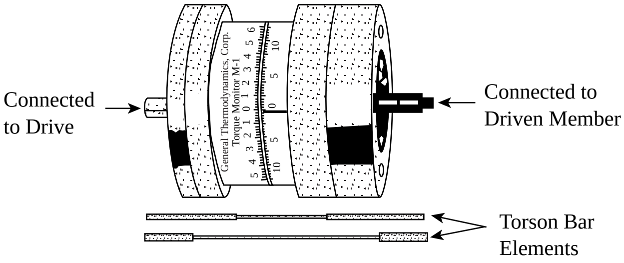

FIG. 7.21d
Torsion-bar-type torque indicator.

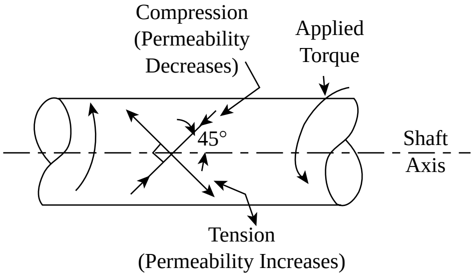

FIG. 7.21e
Tension-compression stresses on the surface of a circular shaft.

The in-line rotating transducer for larger torques consists of a metal shaft with bonded strain gauges electrically connected in the form of a Wheatstone bridge. Figure 7.21e illustrates the stresses acting on a rotating shaft subject to torsion. In one direction, at a 45° angle to the axis, pure tensile stress exists; at 45° in the other direction, pure compressive stress is extant. The rotor shaft is elastic and will deflect minutely under the imposed stresses. The strain gauges are located on the shaft to sense compressive and tensile deformation due to torsion. The Wheatstone bridge output is in proportion to torsion and hence to torque. For rotating shafts, bridge power and output voltage are connected to the sensors through:

1. Slip-rings and brushes (direct contact)
2. Rotating transformer (inductive coupling)
3. Telemetry

Direct Contact Slip-rings and brushes are limited to rotational speeds in the order of 100 ft/sec (30 m/sec) at the brush surfaces. For very high speeds, the rotating transducer can be provided with mist-lubricated bearings and air-cooled brush surfaces. The slip-rings consist of five rotating rings upon which rest five pairs of brushes (spring loaded electric contacts), conducting excitation to and signals from the torque transducer. The rings are usually made out of coined silver, while the brushes are silver-graphite. When measurements are intermittent, brush lifting features are provided to extend the brush life.

The torque transducers usually generate 1.5 or 2 mV of output per volt excitation. In terms of maintenance, the slip-ring assemblies and brush holders require periodic cleaning, while the brushes require periodic replacement. The slip-rings and ball bearings limit the maximum rpm to 2500 at high, 4000 at medium, and 6000 at low torques. Figure 7.21f shows the location of the strain gauges, slip-rings, and bearings. Theoretically, axial tension and compression forces or lateral bending moments have no effect on the torque measurement. However, it is still recommended to install the torque sensor between flexible couplings that have axial play in them in order to protect the transducer from damage.

Inductive Coupling A transducer with noncontacting power supply and signal pickoff is shown in Figure 7.21g. The bridge power and output signals are transmitted between the rotating and the stationary members through transformers. The bridge power is a constant amplitude, high-frequency sine wave, and the output is a sine wave of the power frequency whose amplitude is a function of torque. Consequently, the power supply electronics must include an oscillator to generate the carrier frequency. The output electronics includes a demodulator to produce a DC signal in proportion to the peak of the output sine wave. This sensor is superior to the slip-ring design, because contact resistance and friction does not exist. Therefore, the effects of heating are absent and cannot degrade the measurement.

As the excitation voltage for the strain gauge is inductively coupled and the output signal from the strain gauge circuit is converted to a modulated pulse frequency and is capacitively transferred to the stationary housing, the limitations associated

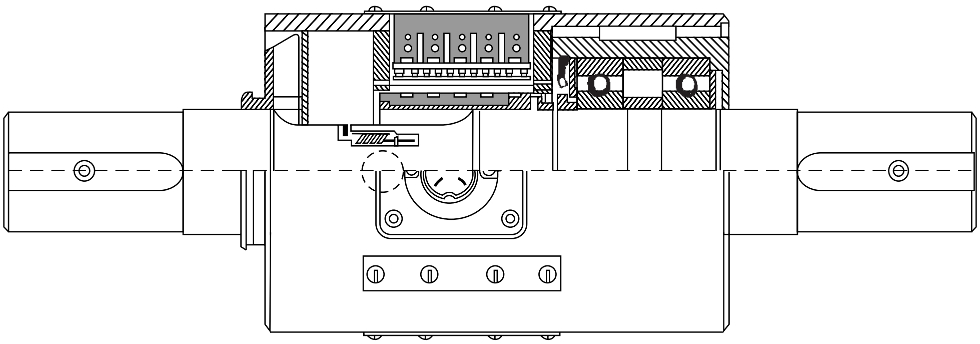

FIG. 7.21f

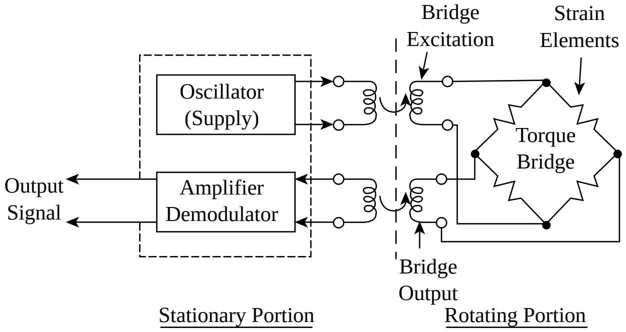

FIG. 7.21g
In-line rotating torque transducer.

with the slip-rings are also eliminated. This means that the maximum rotational speed of the shaft can reach 15,000 rpm. If only the slip-rings are eliminated, the spindle bearings still require lubrication every 16,000 running hours. Designs that have neither slip-rings nor bearings tend to completely eliminate the need for this type of maintenance (Figure 7.21h).

Stationary Transducers

Several stationary transducer designs are available. In many cases, the sensors include a component that is fixed to the shaft, but the sensing section of the torque transducer is stationary and does not rotate. Examples of this type of transducers are the magnetostrictive and several displacement type torque transducers. Such designs as the variable-illumination and the phase displacement photoelectric torque transducers[2] are able to measure the angular displacement between two sections of a rotating shaft.

Magnetostrictive Torque Transducer Magnetostrictive torque transducers utilize the Wiedemann effect in providing a torque measurement. The magnetostrictive effect causes changes in the permeability of the materials subjected to tensile or compressive stresses. Permeability is a magnetic property related to the ability of the material to concentrate magnetic flux. Permeability increases under tensile stress and decreases under compressive stress.

The sensor consists of two primary and two secondary windings mounted near the rotating shaft as shown in Figure 7.21i. The secondary coils, S_1 and S_2, are coupled by magnetic lines of flux through the shaft to the primaries. With no loading on the shaft, the permeability of the shaft is uniform and equal, but opposite voltages are induced in the secondary windings of S_1 and S_2. With the shaft under torsion, permeability and the number of magnetic lines of flux increase in the direction of tension and decrease in the direction of compression. Therefore, the voltages induced in S_1 and S_2 do not cancel out and their algebraic sum is in proportion to the torque.

Magnetically, the windings are arranged to produce a circuit analogous to the Wheatstone bridge. Figure 7.21j shows the Wheatstone bridge analogy with the battery being equivalent to the primary windings, P_1 and P_2, in Figure 7.21i. The reluctances, R_{P1}, R_{P2}, R_{S1}, and R_{S2}, are analogous to electrical resistances and represent the reluctance of the corresponding air gap between winding and shaft in Figure 7.21i. The reluctances of the metal shaft are represented by R_A, R_B, R_C, and R_D. With no loading on the shaft, the bridge is in balance and the output voltage is zero.

A variation of the basic design consists of many primary and secondary windings arranged on a ring fitted around the torsion shaft. This feature eliminates errors in output voltage

due to residual magnetism that will induce an additional voltage in the output windings of the above-mentioned unit. By locating many pole pieces around the shaft circumference, the stresses are integrated with respect to time so that the effect of instantaneous errors is minimized.

Angular Displacement Type Torque Transducers The angular displacement between two sections of a rotating shaft can also be related to torque. The angle is proportional to the amount of the torque and the length of the shaft. Theoretically, it is inversely proportional to the fourth power of the shaft's diameter.

Figure 7.21k shows a possible solution for angular displacement measurement. Two identical toothed wheels are fixed on the shaft a certain distance apart. Two proximity sensors, one at each wheel, produce alternating output voltages whose phase difference is proportional to torque. Alternatively, a light source and photocell can be mounted on opposite sides of the wheels and the amount of light falling on the photocell is related to torque.

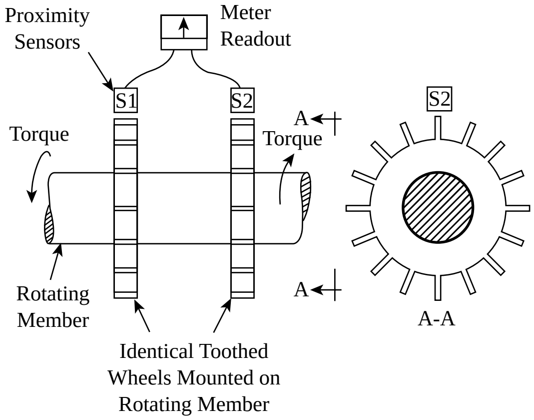

FIG. 7.21k
Proximity sensors used for torque measurement.

Conclusions about Torque Transducers

The displacement caused by torque can be detected not only by optical and inductive sensors, but also by capacitive and potentiometric types as discussed in Sections 7.10 and 7.14. In electrical motors, torque can also be measured indirectly, based on the detection of field and armature currents. This method is inaccurate, because it does not consider the effects of bearing friction and motor inertia.

Of the designs available, stationary sensors measuring variations of permeability lend themselves very well to existing installations where modifications to accommodate a sensor must be minimized. The ring version of this design is preferred since it is less sensitive to speed variations, bending, or side thrust than the single point measurement. Rotating sensors are generally comparable to the stationary types except that they must be installed on the shaft, which may not always be feasible because of space limitations.

Designs using slip-rings to connect power and signal to the rotating member are generally not desirable because of contact wear and the associated maintenance plus the electrical noise introduced into the output. Slip-ring designs should be avoided, especially in dirty environments, where dirt buildup can cause erratic output or result in a complete loss of signal.

All designs discussed are temperature-sensitive and compensation is required.

TEST GAUGES AND TEST STANDS

A variety of handheld or test-stand-mounted devices are available to measure tensile, compression, or torque forces. Their application might include the measurement of spring or sliding friction forces, chain tensions, clutch release forces, peel strengths of laminates, labels or pull-tabs of cans, and many others.

The portable test gauges can be mechanical or battery-operated or can be microprocessor-based with RS-232 output. The digital electronic test gauge is usually provided with a

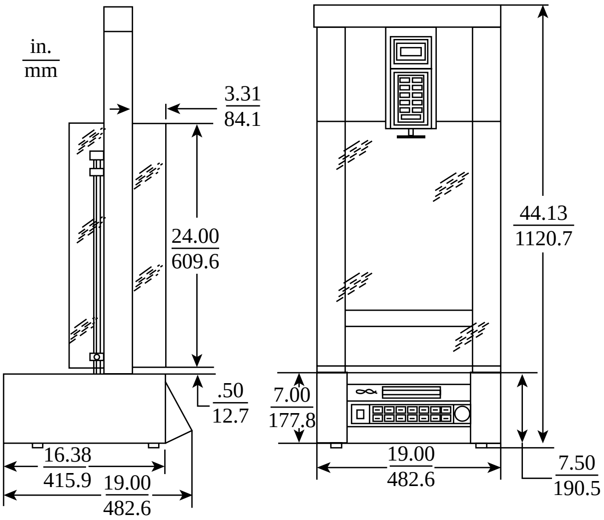

FIG. 7.21l
Motorized test stand can perform tension and compression force measurements up to 500 lb (220 kg) range. (Courtesy of AMETEK.)

universal load cell (detects both tension and compression) and a liquid crystal display. These devices require no switching when the detected condition changes from tension to compression, because the universal sensing heads are suitable for detecting both the compression and the tension forces within scale ranges starting at 0.5 to 500 lb (0.25 to 220 kg). Each gauge is provided with a compression plate and a stainless steel tension hook.

The digital electronic test gauges can also detect torque from full scale ranges of 50 oz-in. to 100 lb-in. (43 to 120 kg-cm). The sensing head is available with a variety of adapters that make it suitable to test the torque required in a variety of operations. An adjustable chuck is available to hold rotating shafts or other adapters to measure the torque required to open bottle caps.

A variety of test stands are also available to mount the force or torque detector gauges. Some of these test stands are manually operated with the travel platform moved by a worm-gear, screw, or hand-wheel systems. Others are pneumatically actuated or electrical motor operated and provided with a microprocessor for programming the test (Figure 7.21l).

INTRODUCTION

Displacement, velocity, and acceleration are products of motion and they are related to each other by time. Because of ease in measurements, acceleration is particularly an important section of kinematic quantities. Other quantities are the position, velocity, acceleration, and jerk, which bear linear relationships with the neighboring ones. This indicates that all the kinematic quantities can be derived from a single known quantity. For example, acceleration can be obtained by differentiating the corresponding velocity or by integrating the jerk. Likewise, velocity can be obtained by differentiating the position or by integrating the acceleration. In practice, only the integration is widely used since it provides better noise characteristics and attenuation.

Acceleration is an important parameter for general-purpose absolute motion measurements, vibration, and shock sensing. Many different accelerometers are commercially available in a wide a range and type to meet diverse application requirements, mainly in three areas:

1. Commercial applications: automobiles, ships, appliances, sports, and other hobbies
2. Industrial applications: robotics, machine control, vibration testing, and instrumentation

3. High reliability applications: military, space and aerospace, seismic monitoring, tilt measurements, vibration, and shock measurements.

The unit of acceleration is the Earth's gravitational acceleration, *g*, which equals 32.3 ft/sec^2 in English units, or 9.8 m/s^2 in metric units. It is this unit that is used to express the amplitude of acceleration.

There are two classes of acceleration measurements techniques: *direct measurements* by specific accelerometers and *indirect measurements* where velocity is differentiated. The applicability of these techniques depends on the type of motion (rectilinear, angular, curvilinear motions) or equilibrium centered vibration. For rectilinear and curvilinear motions, the direct measurement accelerometers are preferred. However, the angular acceleration is usually measured by indirect methods. Accelerometers that measure the acceleration of an object can be classified in a number of ways, including mechanical or electrical types, active or passive types, deflection or null-balance types, and others. Accelerometers used in vibration and shock measurements are usually the deflection types, while those used for the measurement of motions of vehicles, aircraft, etc. for navigation purposes may be either deflection or null-balanced.

The main theme of this section is vibration, shock, and acceleration sensing. We will largely concentrate on the direct techniques that are generally achieved by the accelerometers of the following types:

1. Seismic (Inertial)
2. Piezoelectric
3. Piezoresistive and strain gages
4. Electromechanical
5. Capacitive and electrostatic
6. Micro- and nanosensors
7. Velocity sensors
8. Noncontact proximity sensors
9. Mechanical switches
10. Optical sensors

In recent years, the Integrated Micro-Electro-Mechanical Systems technology is used to produce a sizable portion of sensors and accelerometers along with well-established piezoelectric and bulk-micromachined devices. This article deals with the new technology as well as the traditional established ones.

In the preceding sections, acceleration and vibration as phenomenon are explained to make the users of these devices fully aware of some important concepts for a fruitful and meaningful use and interpretation of their test results.

ACCELERATION AS A PHENOMENON AND DYNAMIC CHARACTERISTICS

Acceleration is related to motion, a vector quantity, exhibiting a direction as well as magnitude. The direction of motion is described in terms of some arbitrary Cartesian or orthogonal coordinate systems. Typical rectilinear, angular, and curvilinear motions are illustrated in Figures 7.22a, parts (a) to (c), respectively. The governing equations of these motions are as follows:

Rectilinear acceleration:

$$a = \underset{\Delta t \to 0}{Lim} \frac{\Delta v}{\Delta t} = \frac{dv}{dt} = \frac{d(ds/dt)}{dt} = \frac{d^2 s}{dt^2} \qquad \textbf{7.22(1)}$$

Angular acceleration:

$$a = \underset{\Delta t \to 0}{Lim} \frac{\Delta \omega}{\Delta t} = \frac{d\omega}{dt} = \frac{d(d\theta/dt)}{dt} = \frac{d^2 \theta}{dt^2} \qquad \textbf{7.22(2)}$$

Curvilinear acceleration:

$$a = \frac{dv}{dt} = \frac{d^2 x}{dt^2} i + \frac{d^2 y}{dt^2} j + \frac{d^2 z}{dt^2} k \qquad \textbf{7.22(3)}$$

where a and α are the accelerations; v and ω are the speeds; s the distance; θ is the angle; i, j, and k are the unit vectors in x, y, and z directions, respectively.

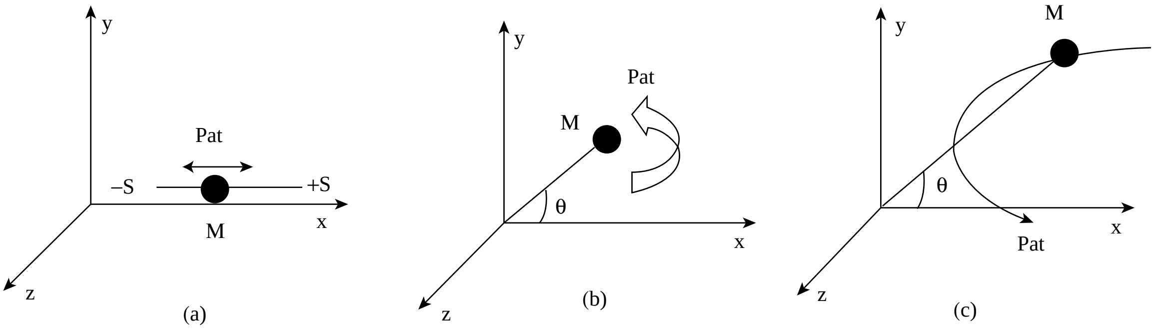

FIG. 7.22a
Types of motions to which accelerometers are commonly applied.

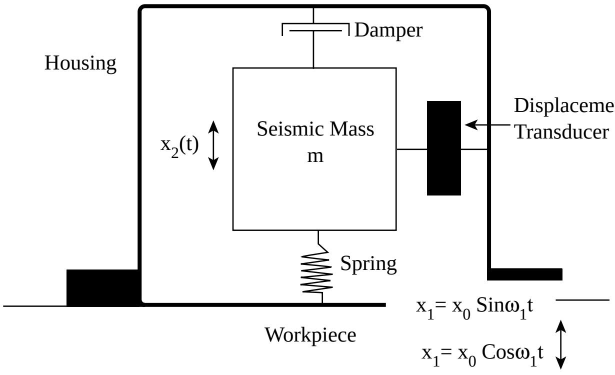

FIG. 7.22b
A typical seismic accelerometer.

The majority of accelerometers can be viewed and analyzed as a single-degree-of-freedom seismic instrument that can be characterized by a mass, a spring, and a damper arrangement as shown in Figure 7.22b. In the case of multi-degrees-of-freedom systems, the principles of curvilinear motion can be applied as in Equation 7.22(3) and multiple transducers must be used to create uniaxial, biaxial, or triaxial sensing points of the measurements.

If a single-degree-of-freedom system behaves linearly in a time invariant manner, the basic second-order differential equation describing the motion of the forced mass-spring system can be written as

$$f(t) = m\frac{d^2x}{dt^2} + c\frac{dx}{dt} + kx \qquad \textbf{7.22(4)}$$

where $f(t)$ is the force, m is the mass, c is the velocity constant, and k is the spring constant.

The base of the accelerometer is also in motion. When the base is in motion, the force is transmitted through the spring to the suspended mass depending on the transmissibility of the force to the mass. Equation 7.22(4) may be generalized by taking the effect motion of the base into account as

$$m\frac{d^2z}{dt^2} + c\frac{dz}{dt} + kz = mg\cos\theta - m\frac{d^2x_1}{dt^2} \qquad \textbf{7.22(5)}$$

where $z = x_2 - x_1$ is the relative motion between the mass and the base, x_1 is the displacement of the base, x_2 is the displacement of mass, and θ is the angle between the sense axis and gravity.

The complete solution to Equation 7.22(5) can be obtained by applying the superposition principle. The superposition principle states that if there are simultaneously superimposed actions on a body, the total effect can be obtained by summing the effects of each individual action. Using the superposition and applying Laplace transform gives

$$\frac{X(s)}{F(s)} = \frac{1}{ms^2} + cs + k \qquad \textbf{7.22(6)}$$

or

$$\frac{X(s)}{F(s)} = \frac{K}{\left(s^2/\omega_n^2 + 2\zeta s/\omega_n + 1\right)} \qquad \textbf{7.22(7)}$$

where s is the Laplace operator, $K = 1/k$ is the static sensitivity, $\omega_n = \sqrt{k/m}$ is the undamped critical frequency rad/s, and $\zeta = (c/2)\sqrt{km}$ is the damping ratio.

As can be seen in the performance of accelerometers, the important parameters are the static sensitivity, the natural frequency, and the damping ratio, which are all functions of mass, velocity, and spring constants. Accelerometers are designed and manufactured to have different characteristics by suitable selection of these parameters.

VIBRATION AND SHOCK

Vibration can be defined in terms of displacement, velocity, or acceleration. It is essentially an oscillatory motion resulting from application of varying forces to a structure. Vibrations can be periodic, stationary random, nonstationary random, or transient. Traditional mechanical tripout devices, such as the spring-loaded magnetic holding types, are all acceleration sensors. These are actuated by changes in the vibration force at the measurement. At low frequencies these devices are severely limited because acceleration decreases with frequency, and large displacement is required to produce sufficient acceleration to trip the device.

In rotary machinery, mechanical degradation causes vibration, and the mechanical health of the equipment is monitored by measuring vibration. Vibration is measured by its frequency and amplitude. The frequency of vibration is a function of the mass of the vibrating body, and the range of vibration that occurs in compressors, turbines, and other rotary equipment is generally between 10 and 2000 Hz, with extreme values falling between 1 and 20,000 Hz. The amplitude of vibration is a function of the design of the rotary equipment, where at one extreme one might measure a vibration amplitude of only 0.01 *g* in a smoothly operating electric motor, while a high-speed gearbox might have a vibration amplitude of 100 *g* at 5000 Hz or above. In shock detection the amplitude of acceleration can reach 100,000 *g*.

If the sensor (velocity or acceleration) is mounted onto the surface of the vibrating object, it will provide a reading of absolute vibration relative to a fixed point in space. If the mass of the rotating object (and therefore its resonant frequency) would be affected by physically attaching the sensor to it, a hole can be drilled through the housing of the bearings.

A noncontacting proximity probe can detect the relative motion between shaft and bearing. The limitation of this approach is that if the shaft and bearing housing are both in vibration because some tie-down bolts are loose, the proximity probe will not detect this.

The electronics associated with the sensor can be integral or remote. The integral designs are less costly and less sensitive to noise, but are more limited in their operating temperatures and their vibration amplitude ranges. The main advantage of self-generating sensors is that they do not require excitation power supplies, while the main limitation is that they are not suited for the measurement of constant acceleration, such as that generated in a centrifuge.

Periodic Vibrations

In periodic vibrations, the motion of an object repeats itself in an oscillatory manner. This can be represented by a sinusoidal waveform

$$x(t) = X_p \sin \omega t \qquad \textbf{7.22(8)}$$

where $x(t)$ = time dependent displacement, $\omega = 2\pi ft$ is the angular frequency, and X_p is the maximum displacement from a reference point.

The velocity of the object is the time rate of change of displacement

$$v(t) = \frac{dx}{dt} = \omega X_p \cos(\omega t) = V_p \sin(\omega t + \pi/2) \qquad \textbf{7.22(9)}$$

where $v(t)$ is the time-dependent velocity and $V_p = \omega X_p$ is the maximum velocity.

The acceleration of the object is the time rate change of velocity

$$a(t) = \frac{dv}{dt} = \frac{d^2x}{dt^2} = -\omega^2 X_p \sin(\omega t) = A_p \sin(\omega t + \pi) \qquad \textbf{7.22(10)}$$

where $a(t)$ is the time-dependent acceleration, and $A_p = \omega^2 X_p = \omega V_p$ is the maximum acceleration.

From the preceding equations it can be seen that the basic form and the period of vibration remain the same in acceleration, velocity, and displacement. But velocity leads displacement by a phase angle of 90° and acceleration leads velocity by another 90°.

In nature, vibrations can be periodic but not necessarily sinusoidal. If they are periodic but nonsinusoidal, they can be expressed as a combination of a number of pure sinusoidal curves, determined by the Fourier analysis as

$$\begin{aligned} x(t) = X_0 + X_1 \sin(\omega_1 t + \Phi_1) + X_2 \sin(\omega_2 t + \Phi_2) \\ + \cdots + X_n \sin(\omega_n t + \Phi_n) \end{aligned} \qquad \textbf{7.22(11)}$$

where $\omega_1, \omega_2, \ldots, \omega_n$ are the frequencies (rad/s), $X_0, X_1, \ldots, X_n$ are the maximum amplitudes of respective frequencies, and $\phi_1, \phi_2, \ldots, \phi_n$ are the phase angles.

The number of terms may be infinite, and the higher the number of elements the better the approximation. These elements constitute the frequency spectrum. The vibrations can be represented in the time domain or frequency domain, both of which are extremely useful in the analysis.

Stationary Random Vibrations These random vibrations are met often in nature, where they constitute irregular cycles of motion that never repeat themselves exactly. Theoretically, an infinitely long time record is necessary to obtain a complete description of these vibrations. However, statistical methods and probability theory can be used for the analysis by taking representative samples. Mathematical tools such as probability distributions, probability densities, frequency spectra, cross-correlations, auto-correlations, digital Fourier transforms (DFTs), fast Fourier transforms (FFTs), auto-spectral-analysis, root-mean-square values, and digital filter analysis are some of the techniques that can be employed.

Nonstationary Random Vibrations In this case, the statistical properties of vibrations vary in time. Methods such as time averaging and other statistical techniques can be employed.

Transients and Shocks Short duration and sudden occurrence vibrations need to be measured often. Shock and transient vibrations may be described in terms of force, acceleration, velocity, or displacement. As in the case of random transients and shocks, statistical methods and FFTs are used in the analysis.

SEISMIC (INERTIAL) SENSORS

Inertial acceleration and vibration sensors make use of a seismic mass that is suspended by a spring or a lever inside a rigid frame as shown in Figure 7.22b. The frame carrying the seismic mass is connected firmly to the vibrating source whose characteristics are to be measured. As the system vibrates, the mass tends to remain fixed in its position, so that the motion can be registered as a relative displacement between the mass and the frame. An appropriate transducer senses this displacement and the output signal is processed further. In practice, the seismic mass does not remain absolutely steady, but it can satisfactorily act as a reference position for selected frequencies.

By proper selection of mass, spring, and damper combinations, the seismic instrument may be used for either acceleration or displacement measurements. In general, a large mass and soft spring are suitable for vibration and displacement measurement, while relatively small mass and a stiff spring are used in accelerometers. However, the term seismic is commonly applied to instruments, which sense very low levels of vibration in the ground or structures.

In order to describe the response of seismic accelerometer, from Newton's second law the following equation of motion may be written as:

$$m\frac{d^2x_2}{dt^2}+c\frac{dx_2}{dt}+kx_2=c\frac{dx_1}{dt}+kx_1+mg\cos(\theta) \qquad \textbf{7.22(12)}$$

where x_1 is the displacement of the vibration frame, x_2 is the displacement of the seismic mass, c is the velocity constant, θ is the angle between the sense axis and gravity, and k is the spring constant.

Taking md^2x_1/dt^2 from both sides of the equation and rearranging gives

$$m\frac{d^2z}{dt^2}+c\frac{dz}{dt}+kz=mg\cos(\theta)-m\frac{d^2x_1}{dt^2} \qquad \textbf{7.22(13)}$$

where $z = x_2 - x_1$ is the relative motion between the mass and the base.

In Equation 7.22(13), it is assumed that the damping force on the seismic mass is proportional to velocity only. If a harmonic vibratory motion is impressed on the instrument:

$$x_1(t)=X_0\sin(\omega_1 t) \qquad \textbf{7.22(14)}$$

where ω_1 is the frequency of vibration (rad/s). Writing

$$-m\frac{d^2x_1}{dt^2}=mX_0\sin\omega_1 t$$

modifies Equation 7.22(13) as

$$m\frac{d^2z}{dt^2}+c\frac{dz}{dt}+kz=mg\cos(\theta)+ma_1\sin\omega_1 t \qquad \textbf{7.22(15)}$$

where $a_1 = mX_0\omega_1{}^2$.

Equation 7.22(15) will have transient and steady state solutions. The steady-state solution of this differential equation may be determined as

$$z=\frac{mg\cos\theta}{k}+\frac{ma_1\sin\omega_1 t}{\left(k-m\omega_1^2+jc\omega_1\right)} \qquad \textbf{7.22(16)}$$

Rearranging Equation 7.22(16) results in

$$z=\frac{mg\cos\theta}{\omega_n}+\frac{a_1\sin(\omega_1 t-\phi)}{\sqrt{\left(\omega_n^2(1-r^2)^2+(2\zeta r)^2\right)}} \qquad \textbf{7.22(17)}$$

where ω_n $(=\sqrt{k/m})$ is the natural frequency of the seismic mass; ς $(= c/2\sqrt{km})$ is the damping ratio, which also can be written in terms of critical damping ratio as $\varsigma = c/c_c$ where $c_c = 2\sqrt{km}$; ϕ (=tan$^1[c\omega_1/(km\omega_1{}^2)]$) is the phase angle; and r $(=\omega_1/\omega_n)$ is the frequency ratio.

For satisfactory system performance, the instrument constant c/c_c and ω_n should carefully be calculated or obtained from calibrations. In this way the anticipated accuracy of measurement may be predicted for frequencies of interest. A comprehensive treatment of the analysis is by McConnell;[1] interested readers should refer to this text for further details.

Seismic instruments are constructed in a variety of ways. In a potentiometric instrument, a voltage divider potentiometer is used for sensing the relative displacement between the frame and the seismic mass. In the majority of potentiometric accelerometers, the device is filled with a viscous liquid that interacts continuously with the frame and the seismic mass to provide damping. These accelerometers have a low frequency of operation (less than 100 Hz) and are mainly intended for slowly varying acceleration and low-frequency vibrations. A typical family of such instruments offers many different models, covering the range of ±1 to ±50 *g* full scale. The natural frequency ranges from 12 to 89 Hz, and the damping ratio ζ can be kept between 0.5 to 0.8 by using a temperature compensated liquid-damping arrangement. Potentiometer resistance may be selected in the range of 1,000 to 10,000 Ω, with a corresponding resolution of 0.45 to 0.25% of full scale. The cross-axis sensitivity is less than ±1%. The overall accuracy is ±1% of full scale or less at room temperatures. The size is about a 50 mm^3 with a mass of about 1/2 kg.

Linear variable differential transformers (LVDTs) offer another convenient means of measuring the relative displacement between the seismic mass and the accelerometer housing. These devices have higher natural frequencies than potentiometer devices (up to 300 Hz). Since the LVDT has lower resistance to motion, it offers much better resolution. A typical family of liquid-damped, differential-transformer accelerometers exhibits the following characteristics: the full scale ranges from ±2 to ±700 *g*, the natural frequency from 35 to 620 Hz, the nonlinearity 1% of full-scale. The full-scale output is about 1 V with an LVDT excitation of 10 V at 2,000 Hz, the damping ratio ranges from 0.6 to 0.7, the residual voltage at the null position is less than 1%, and the hysteresis is less than 1% full scale. The size is about 50 mm^3, with a mass of about 120 g.

Electrical resistance strain gages are also used for displacement sensing of the seismic mass. In this case, the seismic mass is mounted on a cantilever beam rather than on springs. Resistance strain gauges are bonded on each side of the beam to sense the strain in the beam resulting from the vibrational displacement of the mass. A viscous liquid that entirely fills the housing provides damping of the system. The output of the strain gauges is connected to an appropriate bridge circuit. The natural frequency of such a system is about 300 Hz. The low natural frequency is due to the need for a sufficiently large cantilever beam to accommodate the mounting of the strain gauges.

One serious drawback of the seismic instruments is temperature effects requiring additional compensation circuits. The damping of the instrument may also be affected by changes in the viscosity of the fluid due to temperature. For instance, the viscosity of silicone oil, often used in these instruments, is strongly dependent on temperature.

Piezoelectric Sensors

The piezoelectric sensor is a self-generating device that is ideal for the measurement of such dynamic events as shock and vibration. They are basically motion transducers with large output signals and comparatively small sizes. They are available with very high natural frequencies and are suitable for high-frequency applications and shock measurements. Their sensing element is sandwiched between the transducer body and a seismic mass (usually tungsten). Because the seismic mass is constant, the force acting on the sensing element ($F = ma$) is proportional to acceleration. If the sensing element is a quartz crystal or lead-zirconate-titanate (PZT), an electric charge is generated (150 times more for PZT than for quartz) that is in proportion to the experienced force and therefore to acceleration.

These devices utilize a mass in direct contact with the piezoelectric component or crystal. A separation of charge is produced on the opposite faces of the crystal when it is subjected to acceleration forces. The magnitude of the voltage produced is in proportion to mechanical deformation and, hence, acceleration. Generally, these units are provided as two components: a sensor (Figure 7.22c) that mounts on the equipment and includes a solid-state amplifier and alarm switch, and a control unit that contains the readout meter, power supply, alarm reset, and facilities for vibration recording or waveform analysis by oscilloscope. In the event of application of varying motion to the sensor, the crystal experiences a varying force excitation ($F = ma$), causing a proportional electric charge q to be developed across it.

$$q = d_{ij}F = d_{ij}ma \qquad \textbf{7.22(18)}$$

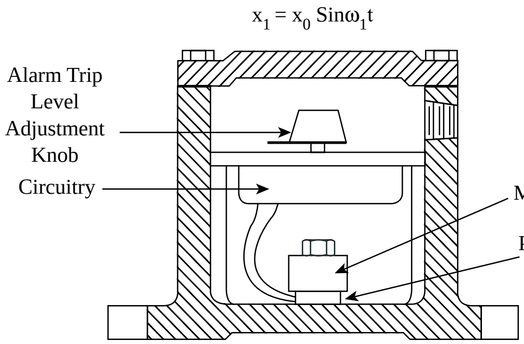

FIG. 7.22c
Piezoelectric sensor.

where q is the charge developed and d_{ij} is the piezoelectric coefficient of the material.

As this equation shows, the output from the piezoelectric material is dependent on its mechanical properties, d_{ij}. Two commonly used piezoelectric crystals are PZT and crystalline quartz. They are both self-generating materials and produce a large electric charge for their size. As a result, PZTs are more sensitive and smaller in size than quartz counterparts. These accelerometers are useful for high-frequency applications.

Mathematically, their transfer function approximates to a third-order system that can be expressed as:

$$\frac{e_0(s)}{a(s)} = \frac{K_q \tau s}{C\omega_n^2(\tau s+1)\left(s^2/w_n^2 + 2\zeta s/\omega_n + 1\right)} \qquad \textbf{7.22(19)}$$

where K_q is the piezoelectric constant related to charge (C cm), τ is the time constant of the crystal, and s is the Laplace variable. It is worth noting that the crystal itself does not have a time constant τ, but the time constant is observed when the accelerometer is connected into an electric circuit, for example, an *RC* circuit.

The low-frequency response is limited by the piezoelectric characteristic $\tau s/(\tau s + 1)$, while the high-frequency response is related to mechanical response. The damping factor ζ is very small, usually less than 0.01 or near zero. Accurate low-frequency response requires large τ, which is usually achieved by use of high-impedance voltage amplifiers. At very low frequencies, thermal effects can have severe influences on the operation characteristics.

In piezoelectric accelerometers, two basic design configurations are used: compression types and shear-stress types. In compression-type accelerometers, the crystal is held in compression by a preload element; therefore, the vibration varies the stress in compressed mode. In a shear-stress accelerometer, vibration simply deforms the crystal in shear mode. The compression accelerometer has a relatively good mass-to-sensitivity ratio and exhibits better performance. Since the housing acts as an integral part of the spring-mass system, it may produce spurious interfaces in the accelerometer output if excited around its natural frequency.

Piezoelectric accelerometers are available in a very wide range of specifications and are offered by a large number of manufacturers. For example, the specifications of a shock accelerometer may have 0.004 pC/g in sensitivity and a natural frequency of up to 250,000 Hz, while a unit designed for low-level seismic measurements might have 1,000 pC/g in sensitivity and only 7,000 Hz natural frequency. They are manufactured as small as 3×3 mm^2 in dimension with about 0.5 g in mass, including cables. They have excellent temperature ranges and some of them are designed to survive the intensive radiation environment of nuclear reactors. However, piezoelectric accelerometers tend to have larger cross-axis sensitivity than other types, about 2 to 4%. In some cases, large cross-axis sensitivity may be minimized during installations by the correct orientation of the device. These accelerometers

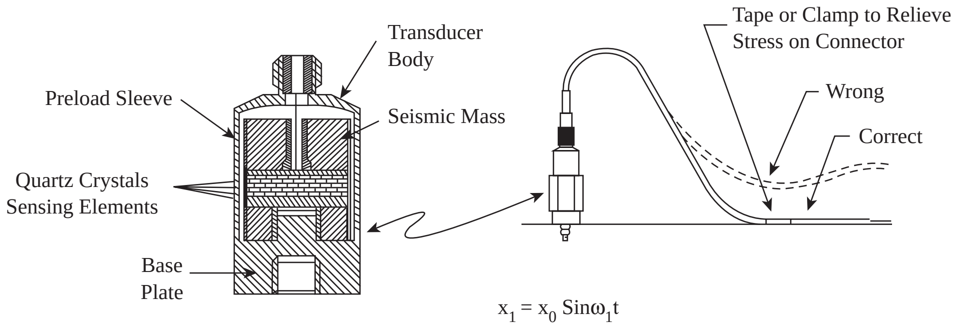

FIG. 7.22d
The main components of a piezoelectric accelerometer are the body, the sensing element, and the seismic mass. (Courtesy of Kistler Instrument Co.)

may be mounted with threaded studs, cement or wax adhesives, or magnetic holders.

Piezoelectric crystals are affected in their output by temperature variations; however, quartz and some of the newer piezoelectric ceramics are superior to such ceramics as barium titanate or PZT in their reduced sensitivity to temperature. In noisy electrical environments, electrical shielding of the crystal is recommended to reduce noise pickup.

Acceleration can expose the crystal element to compression, shear, or bending. When the vibration lifts the sensor in the compression accelerometer, the inertial mass moves downward, further compressing the already preloaded element. Conversely, downward acceleration reduces the amount of compression. In the shear accelerometer, the vibration deforms the crystal in shear. A wide variety of piezoelectric sensors are available. Some are very small in size and weight (from 1 g up), while others are designed for high-temperature service or with abilities for measuring acceleration and vibration at frequencies up to 30,000 Hz and amplitudes of up to 100,000 *g*. PZT elements have high mechanical spring constants and small inertial masses; therefore, they tend to be small and suitable for high frequencies.

The accelerometer can be mechanically connected to the vibrating surface (Figure 7.22d) or can be secured by adhesives or by magnetic means. The lighter-weight sensors are usually attached by glue, while when larger elements are used or if the vibrating surface is irregular, a mounting pad is used to provide a flat mounting surface and ground isolation to prevent ground loops. On ferromagnetic surfaces, magnetic mounts can be used when only a quick test is needed, but only up to about 1000 Hz frequency. Triaxial mounting pads are also available when three accelerometers are to be installed for three-dimensional (orthogonal) vibration analysis.

Other factors affecting the performance of piezoelectric sensors include cable, magnetic, and dynamic effects. In high-impedance accelerometers, the movement or strain on the connecting cable can cause triboelectric (charge trapping due to relative motion) noise. The straining or flexing of the accelerometer base or housing due to thermal expansion or other forces can also transmit error-causing forces to the crystal element. Because the output signal carried by the cable is low level, it needs to be protected against noise. Stray capacitive coupling can cause electrostatic noise; therefore, it should be fully shielded. One should also protect against ground loops by grounding the system at only one point. Common mode noise caused by magnetic coupling can be minimized by using twisted pairs and by not routing the cable near conductors that carry power.

PIEZORESISTIVE AND STRAIN GAUGE SENSORS

Piezoresistive Sensors

Piezoresistive sensors are essentially semiconductor strain gauges with large gauge factors. High gauge factors are obtained since the material resistivity is dependent primarily on the stress not only on the dimensions. This effect can be greatly enhanced by appropriate doping of semiconductors such as silicon. Most piezoresistive accelerometers use two or four active gauges arranged in a Wheatstone bridge. Extra precision resistors are used, as part of the circuit, in series with the input to control the sensitivity, for balancing, and for offsetting temperature effects.

Piezoresistive sensors are not self-generating and they do require a source of excitation power. They are superior to piezo-electronic crystals when low-frequency (under 10 Hz) vibrations, long duration shocks (over 10 ms), or constant accelerations are to be measured. In the wire strain design, the spring wires are usually Nichrome and the frequency range is under 1000 Hz. The bonded-foil-type accelerometer gauges have stable zero outputs and their temperature sensitivity is low. In the piezoresistive design, the wire elements are replaced by higher-sensitivity semiconductor (metallic oxide) chips.

The piezoresistive units are more rugged (but still fragile) and can operate at frequencies of 2000 Hz. Because of their high sensitivity, they are frequently damped by oil filling to suppress their resonant response. While damping makes the design more rugged, changes in the temperature of the filling can effect its frequency response. When excited at its resonant frequency, the piezoresistive element can be damaged.

Strain-Gauge Sensors

Strain-gauge sensors are based on resistance properties of electrical conductors. If a conductor is stretched or compressed, its resistance alters due to both dimensional changes and resistance changes. This indicates that the resistivity ρ of the conductor depends on the mechanical strain applied onto it. The dependence is expressed as the gauge factor

$$\frac{dR/R}{dL/L} = 1 + 2\nu + \frac{d\rho/\rho}{dL/L} \qquad \textbf{7.22(20)}$$

where 1 indicates the resistance change due to length, 2ν indicates resistance change due to area, and $(d\rho/\rho)/(dL/L)$ indicates the resistance change due to piezoresistivity.

Strain gauge accelerometers measure a change in electrical resistance, which is in proportion to the force due to acceleration. The semiconductor strain gauge type consists of semiconductors bonded to a mass whose deformation under acceleration forces is reflected as a change of resistance. The resistance measurement is made by means of a Wheatstone bridge or half Wheatstone bridge with the elements so arranged on the mass that half of them sense tension and the other half senses compression. A bending type of accelerometer with circuit diagram is shown in Figure 7.22e.

At full-scale deflection of the beam, R_{G1} and R_{G2} are a maximum and minimum, respectively, since they are subject to equal but opposite deformations. For an initial resistance of $R_{G1} = R_{G2} = 1000\ \Omega$ and

$$\frac{\Delta R_G}{R_G} = 0.1 \qquad \textbf{7.22(21)}$$

the full-scale output is given by the relationship

$$V_O = E\left[\frac{R_{G1} + \Delta R_G}{(R_{G1} + \Delta R_G) + (R_{G2} - \Delta R_G)} - \frac{R_4}{R_3 + R_4}\right] \qquad \textbf{7.22(22)}$$

$$V_O = 10\left[\frac{1100}{2000} - \frac{1000}{2000}\right]$$

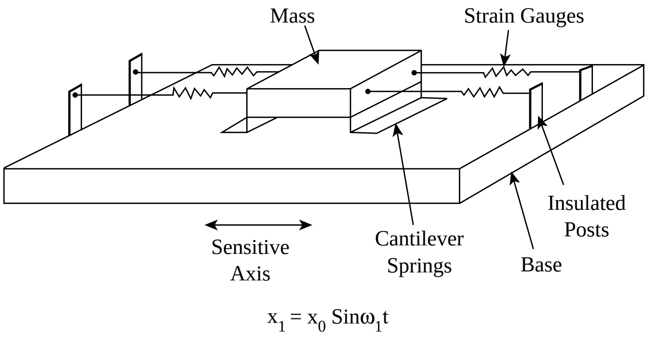

FIG. 7.22e
Strain gauge vibration sensor (acceleration sensitive).

The readout meter must have a high resistance so that for practical purposes the current flow through the meter is zero. In the above example, the accelerometer contained only two active elements. Sensitivity can be improved by the addition of two more elements to complete the Wheatstone bridge.

There are many types of strain-gauges: unbonded metal-wire gauges, bonded metal-wire gauges, bonded metal-foil gauges, vacuum-deposited thin-metal-film gauges, bonded semiconductor gauges, and diffused semiconductor gauges. However, usually bonded and unbonded metal-wire gauges find wider applications. A section of the strain-gauge accelerometers (particularly bonded semiconductor types) known as the piezoresistive transducers are used, but they suffer from high temperature sensitivities, nonlinearities, and some mounting difficulties. Nevertheless, with the recent developments of micromachine technology, these sensors have been improved considerably and are finding many new applications.

Unbonded-strain-gauge accelerometers use the strain wires as the spring element and as the motion transducer. An example of an unbonded-wire-type accelerometer is shown in Figure 7.22f. Mass *m* is attached to the base by cantilever springs, and the resistance elements are connected in the form of the Wheatstone bridge. Usually the entire assembly is contained in an oil-filled case for viscous damping. They are useful for general-purpose motion and vibration measurements from low to medium frequencies. They are available in wide ranges and characteristics: typically ±5 to ±200 *g* full scale, a natural frequency of 17 to 800 Hz, a 10 V excitation voltage AC or DC, full scale output ±20 to ±50 mV, a resolution less than 0.1%, an inaccuracy less than 1% full scale, and a cross-axis sensitivity less than 2%. The damping

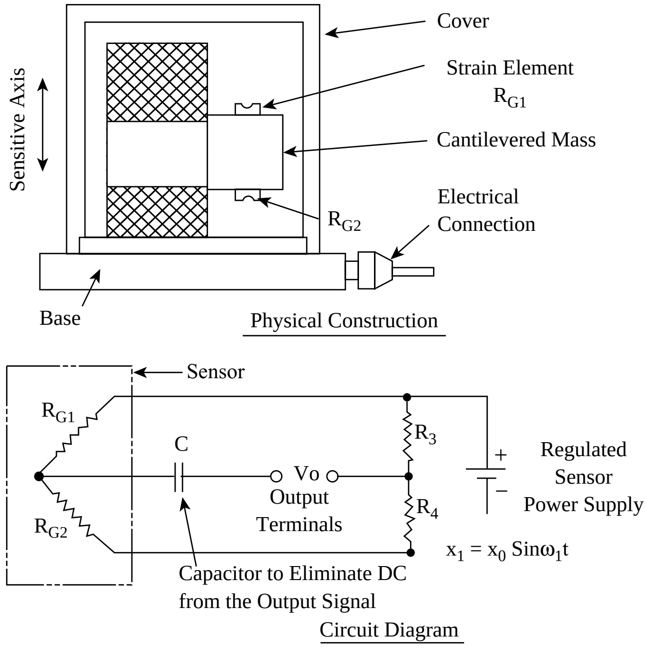

FIG. 7.22f
Bending-type vibration sensor (acceleration sensitive).

ratio (using silicone oil damping) is 0.6 to 0.8 at room temperature. These instruments are small and light, usually with a mass less than 25 g.

Bonded-strain-gauge accelerometers generally use a mass supported by a thin flexure beam. The strain gauges are cemented onto the beam to achieve maximum sensitivity, temperature compensation, and sensitivity to both cross-axis and angular accelerations. Their characteristics are similar to the unbonded-strain-gauge accelerometers but have greater sizes and weights. Often silicone oil is used for damping. Semiconductor strain gauges are widely used as strain sensors in cantilever-beam and mass types of accelerometers. They allow high outputs (0.2 to 0.5 V full scale). Typically, a ±25 *g* acceleration unit has a flat response from 0 to 750 Hz, a damping ratio of 0.7, a mass of about 28 g, and an operational temperature of −18 to 93°C. A triaxial ±20,000 *g* model has a flat response from 0 to 15 kHz, a damping ratio of 0.01, and a compensation temperature range of 0 to 45°C, and is $13 \times 10 \times 13$ mm^3 in size and 10 g in mass.

ELECTROMECHANICAL SENSORS

Electromechanical acceleration and vibration sensors, essentially servo or null-balance types, rely on the principle of feedback. In these instruments, an acceleration-sensitive mass is kept very close to a neutral position or zero displacement point by sensing the displacement and feeding back the effect of this displacement. A proportional magnetic force is generated to oppose the motion of the mass displaced from the neutral position, restoring this position just as a mechanical spring in a conventional accelerometer would do. The advantages of this approach are better linearity and elimination of hysteresis effects as compared to the mechanical springs. Also, in some cases, electrical damping can be provided, which is much less sensitive to temperature variations.

One very important feature of electromechanical accelerometers is the capability of testing the static and dynamic performances of the devices by introducing electrically excited test forces into the system. This remote self-checking feature can be quite convenient in complex and expensive tests where accuracy is essential. These instruments are also useful in acceleration control systems, since the reference value of acceleration can be introduced by means of a proportional current from an external source. They are used for general-purpose motion measurements and monitoring low-frequency vibrations.

There are a number of different electromechanical accelerometers, including coil-and-magnetic types, induction types, and others.

Coil-and-Magnetic Accelerometers

These accelerometers are based on Ampere's law, that is, "a current-carrying conductor disposed within a magnetic field experiences a force proportional to the current, the length of the conductor within the field, the magnetic field density, and the sine of the angle between the conductor and the field."

The coils of these accelerometers are located within the cylindrical gap defined by a permanent magnet and a cylindrical soft iron flux return path. They are mounted by means of an arm situated on a minimum friction bearing or flexure so as to constitute an acceleration-sensitive seismic mass. A pickoff mechanism senses the displacement of the coil under acceleration and causes the coil to be supplied with a direct current via a suitable servo controller to restore or maintain a null condition. The electrical currents in the restoring circuit is linearly proportional to acceleration, provided (1) armature reaction affects are negligible and fully neutralized by a compensating coil in opposition to the moving coil, and (2) the gain of the servo system is large enough to prevent displacement of the coil from the region in which the magnetic field is constant.

In these accelerometers, the magnetic structure must be shielded adequately to make the system insensitive to external disturbances or the earth's magnetic field. Also, in the presence of acceleration there will be a temperature rise due to i^2R losses. The effects of these i^2R losses on the performance are determined by the thermal design and heat-transfer properties of the accelerometers.

Induction Accelerometers

The cross-product relationship of current, magnetic field, and force is the basis for induction-type electromagnetic accelerometers. These accelerometers are essentially generators rather than motors. One type of instrument, the cup-and-magnet design, includes a pendulous element with a pickoff mechanism and a servo controller driving a tachometer coupling. A permanent magnet and a flux return ring, closely spaced with respect to an electrically conductive cylinder, are attached to the pendulous element. A rate-proportional drag force is obtained by the electromagnetic induction effect between the magnet and the conductor. The pickoff mechanism senses pendulum deflection under acceleration and causes the servo controller to turn the rotor in a sense to drag the pendulous element toward the null position. Under steady-state conditions motor speed is a measure of the acceleration acting on the instrument. Stable servo operation is achieved by employing a time-lead network to compensate the inertial time lag of the motor and magnet combination. The accuracy of the servo-type accelerometers is ultimately limited by consistency and stability of scale factors of coupling and cup-and-magnet devices as a function of time and temperature.

Another accelerometer based on induction design uses the eddy-current induction torque generation. The force-generating mechanism of an induction accelerometer consists of a stable magnetic field, usually supplied by a permanent magnet, which penetrates orthogonally through a uniform conduction sheet. The movement of the conducting sheet relative to the magnetic field in response to acceleration results in a generated electromotive potential in each circuit in the conductor. This action is in accordance with the Faraday's principle. In induction-type accelerometers, the induced eddy currents are confined to the conductor sheet, making the system essentially a drag coupling. Since angular rate is proportional to acceleration, angular position represents change in velocity. This is a useful feature particularly in navigation applications.

A typical commercial instrument based on the servo-accelerometer principle might have a micromachined quartz flexure suspension, differential capacitance angle pickoff, air squeeze film plus servo lead compensation for system damping. Of the various available models, as an example, a typical 30-*g* unit has a threshold and resolution of 1 μg, a frequency response that is flat to within 0.05% at 10 Hz and 2% at 100 Hz, a natural frequency of 1,500 Hz, a damping ratio from 0.3 to 0.8, and transverse or cross-axis sensitivity of 0.1%. If, for example, the output current were about 1.3 mA/*g*, a 250 Ω readout resistor would give about ±10 V full scale at 30 *g*. These accelerometers are good for precision work and used in many applications such as aircraft and missile control systems, measurement of tilt angles for borehole navigation, and axle angular bending in aircraft weight and balance systems.

CAPACITIVE AND ELECTROSTATIC SENSORS

Capacitive and electrostatic sensors are based on Coulomb's law between two charged electrodes; therefore, they are capacitive types. Depending on the operation principles and external circuits, they can be broadly classified as electrostatic-force-feedback accelerometers or capacitive accelerometers.

Electrostatic-Force-Feedback Accelerometers

An electrostatic-force-feedback accelerometer consists of an electrode, with mass *m* and area *S*, mounted on a light pivoted arm that moves relative to some fixed electrodes. The nominal gap *h* between the pivoted and fixed electrodes is maintained by means of a force-balancing servo system, which is capable of varying the electrode potential in response to signals from a pickoff mechanism that senses relative changes in the gaps. Mathematically, the field between the electrodes may be expressed by

$$E = \frac{Q}{\varepsilon k S} \qquad \mathbf{7.22(23)}$$

where *E* is the intensity or potential gradient (*dV/dx*), *Q* is the charge, *S* is the area of the conductor, and *k* is the dielectric constant of the space outside the conductor.

From this expression, it can be shown that the force per unit area of the charged conductor (in N/m^2) is given by

$$\frac{F}{S} = \frac{Q^2}{2\varepsilon k S^2} = \frac{\varepsilon k E^2}{2} \qquad \mathbf{7.22(24)}$$

Considering one movable and one stationary electrodes and assuming that the movable electrode is maintained at a bias potential V_1 and the stationary one at a potential V_2. The electrical intensity *E* in the gap can be expressed as

$$E_1 = \frac{V_1 - V_2}{h} \qquad \mathbf{7.22(25)}$$

so that the force of attraction may be found as

$$F_1 = \frac{\varepsilon k E^2 S}{2h^2} = \frac{\varepsilon k (V_1 - V_2)^2 S}{2h^2} \qquad \mathbf{7.22(26)}$$

In the presence of acceleration, if V_2 is adjusted to restrain the movable electrode to the null position, the expression relating acceleration and electrical potential may be given by

$$a = \frac{F_1}{m} = \frac{\varepsilon k (V_1 - V_2)^2 S}{2h^2 m} \qquad \mathbf{7.22(27)}$$

The device so far described can measure acceleration in one direction only, and the output is quadratic character, that is,

$$(V_1 - V_2) = D\sqrt{a} \qquad \mathbf{7.22(28)}$$

where *D* is the constant of proportionality.

The output may be linearized in a number of ways, one of which is the quarter-square method. If the servo controller applies a potential $-V_2$ to the other fixed electrode, the force of attraction between this electrode and the movable electrode becomes

$$a = \frac{F_2}{m} = \frac{\varepsilon k (V_1 + V_2)^2 S}{2h^2 m} \qquad \mathbf{7.22(29)}$$

and the force-balance equation of the movable electrode when the instrument experiences a downward acceleration *a* now is

$$ma = F_2 - F_1 = \frac{\varepsilon k S\left[(V_1 + V_2)^2 - (V_1 - V_2)^2\right]}{2h^2}$$

or

$$ma = F_2 - F_1 = \frac{2\varepsilon k S V_1 V_2}{h^2} \qquad \mathbf{7.22(30)}$$

Hence, if the bias potential V_1 is held constant and the gains of the control loop are high so that variations in the gap are negligible, the acceleration becomes a linear function of the controller output voltage V_2.

The principal difficulty in mechanizing the electrostatic force accelerometer is the relatively high electric field intensity required to obtain an adequate force. Damping can be provided electrically or by viscosity of the gaseous atmosphere in the interelectrode space if the gap h is sufficiently small. The scheme works best with micromachined instruments. Nonlinearity in the voltage breakdown phenomenon permits larger gradients in very small gaps.

The main advantages of electrostatic accelerometers are their extreme mechanical simplicity, low power requirements, absence of inherent sources of hysteresis errors, zero temperature coefficients, and ease of shielding from stray fields.

Capacitive Accelerometers

There are various types of capacitive accelerometers. The differential-capacitance accelerometers are based on the principle of the change of capacitance in proportion to applied acceleration. In one type, the seismic mass of the accelerometer is made as the movable element of an electrical oscillator as shown in Figure 7.22g. The seismic mass is supported by a resilient parallel-motion beam arrangement from the base. The system is set to have a certain defined nominal frequency when undisturbed. If the instrument is accelerated, the frequency varies above and below the nominal value depending on the direction of acceleration.

The seismic mass carries an electrode located in opposition to a number of base-fixed electrodes that define variable capacitors. The base-fixed electrodes are resistances coupled in the feedback path of a wide-band, phase-inverting amplifier. The gain of the amplifier is predetermined to ensure maintenance of oscillations over the range of variation of the capacitance determined by the applied acceleration. The value of the capacitance C for each of the variable capacitors is given by

$$C = \frac{\varepsilon k S}{h} \qquad \textbf{7.22(31)}$$

where k is the dielectric constant, ε is the permittivity of free space, S is the area of electrode, and h is the variable gap.

Denoting the magnitude of the gap for zero acceleration as h_0, the value of h in the presence of acceleration a may be written

$$h = h_0 + \frac{ma}{K} \qquad \textbf{7.22(32)}$$

where m is the value of the proof mass and K is the spring constant. Thus,

$$C = \frac{\varepsilon k S}{h_0 + (ma/K)} \qquad \textbf{7.22(33)}$$

For example, the frequency of oscillation of the resistance-capacitance type circuit is given by the expression

$$f = \frac{\sqrt{6}}{2\pi RC} \qquad \textbf{7.22(34)}$$

Substituting this value of C in Eq. 2.23(34) gives

$$f = \frac{\sqrt{6}[h_0 + (ma/K)]}{2\pi R\varepsilon kS} \qquad \textbf{7.22(35)}$$

Denote the constant quantity $\sqrt{6}/2\pi R\varepsilon kS$ as B and rewrite the Equation 7.22(35) as

$$f = Bh_0 + \frac{Bma}{K} \qquad \textbf{7.22(36)}$$

The first term on the right-hand side expresses the fixed bias frequency f_0 and the second term denotes the change in frequency resulting from acceleration, so that the expression may be written as

$$f = f_0 + f_a \qquad \textbf{7.22(37)}$$

If the output frequency is compared with an independent source of a constant frequency of f_0, the f_a can be determined easily.

A commonly used example of a capacitive-type accelerometer is based on a thin diaphragm with spiral flexures that provide the spring, proof mass, and moving plate necessary for the differential capacitor. Plate motion between the electrodes pumps air parallel to the plate surface and through holes in the plate to provide squeeze film damping. Since air

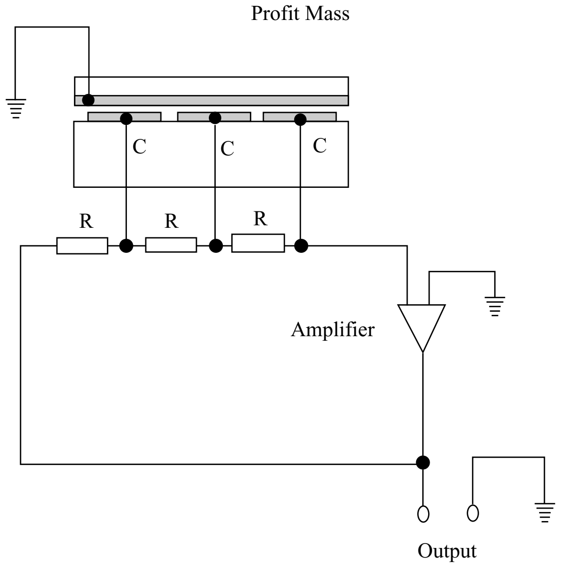

FIG. 7.22g
A differential-capacitance-type accelerometer.

viscosity is less temperature sensitive than oil, the desired damping ratio of 0.7 hardly changes more than 15%. Families of such instruments are easily available with full-scale ranges from ±0.2 *g* (4 Hz flat response) to ±1000 *g* (3000 Hz), a cross-axis sensitivity less than 1%, and a full-scale output of ±1.5 V. The size of a typical device is about 25 mm^3 with a mass of 50 g.

MICRO- AND NANOSENSORS

By the end of the 1970s, it became apparent that the essentially planar processing integrated-circuit (IC) technology could be modified to fabricate three-dimensional electromechanical structures by the micromachining process. Accelerometers and pressure sensors were among the first IC sensors. The first accelerometer was developed in 1979. Since then, the technology has been progressing steadily and now an extremely diverse range of accelerometers are readily available. Most sensors use bulk micromachining, rather than surface micromachining techniques. In bulk micromachining, the flexures, resonant beams, and all other critical components of the accelerometer are made from bulk silicon in order to exploit the full mechanical properties of silicon crystals. With proper design and film process, bulk micromachining yields an extremely stable and robust accelerometer.

The selective etching of multiple layers of deposited thin films, or surface micromachining, allows movable microstructures to be fabricated on silicon wafers. With surface micromachining, layers of structure material are disposed and patterned as shown in Figure 7.22h. These structures are formed by polysilicons and sacrificial materials such as silicon dioxides. The sacrificial material acts as an intermediate spacer layer and is etched away to produce a freestanding structure. Surface machining technology also allows smaller and more complex structures to be built in multiple layers on a single substrate. A typical example of a modern micromachined accelerometer is given in Figure 7.22i. Multiple accelerometers can be mounted on a single chip, sensing accelerations in *x*, *y*, and *z* directions. The primary signal conditioning is also provided in the same chip. The output from the chip is usually read in the digital form.

The operational principles of microaccelerometers are very similar to capacitive force-balance or vibrating-beam accelerometers, discussed earlier. Manufacturing techniques may change from one manufacturer to another. However, in general, vibrating-beam accelerometers are preferred because of better air-gap properties and improved bias performance characteristics.

Vibrating-beam accelerometers, also termed resonant-beam force transducers, are made in such a way that an acceleration along a positive input axis places the vibrating beam in tension. Thus the resonant frequency of the vibrating beam increases or decreases with the applied acceleration.

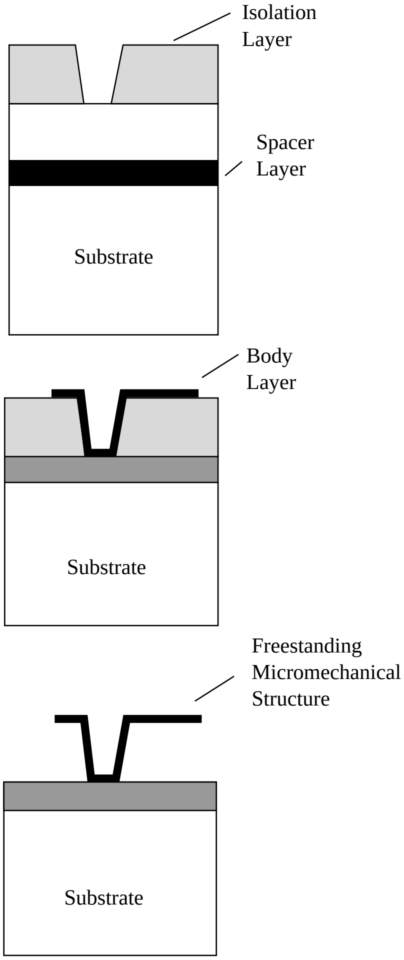

FIG. 7.22h
Steps of micromachining to manufacture micro and nano accelerometers.

In double-end tuning fork (DETF) accelerometers, an electronic oscillator capacitively couples energy into two vibrating beams to keep them oscillating at their resonant frequency. The beams vibrate 180° out of phase to cancel reaction forces at the ends. The dynamic cancellation effect of the DETF design prevents energy from being lost through the ends of the beam. Hence, the dynamically balanced DETF resonator has a high *Q* factor, which leads to a stable oscillator circuit. The acceleration signal is output from the oscillator as a frequency-modulated square wave that can be used for a digital interface.

The frequency of resonance of the system must be much higher than any input acceleration, and this limits the measurable range. In a micromachined accelerometer, used in military applications, the following characteristics are given: a range of ±1,200 *g*, a sensitivity of 1.11 Hz/*g*, a bandwidth of 2,500 Hz, and an unloaded DETF frequency of 9,952 Hz. The frequency at +1,200 *g* is 11,221 Hz, the frequency at −1,200 *g* is 8,544 Hz, and the temperature sensitivity is 5 m*g*/°C. The accelerometer size is 6 mm diameter by 4.3 mm length, with a mass of about 9 g. It has a turn on time less

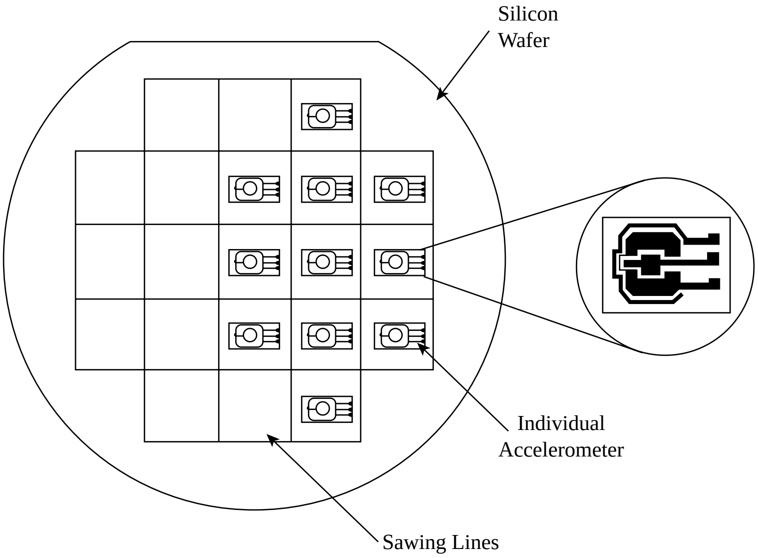

FIG. 7.22i
Multiple accelerometers in a single chip.

then 60 s, the accelerometer is powered with +9 to +16 V DC, and the nominal output is 9,000 Hz square wave.

Surface micromachining has also been used to manufacture specific application accelerometers, such as air-bag applications in the automotive industry. In one type, a three-layer differential capacitor is created by alternate layers of polysilicon and phosphosilicate glass on a 0.38 mm thick, 100 mm long wafer. A silicon wafer serves as the substrate for the mechanical structure. The trampoline-shaped middle layer is suspended by four supporting arms. This movable structure is the seismic mass for the accelerometer. The upper and lower polysilicon layers are fixed plates for the differential capacitors. The glass is sacrificially etched by hydrofluoric acid.

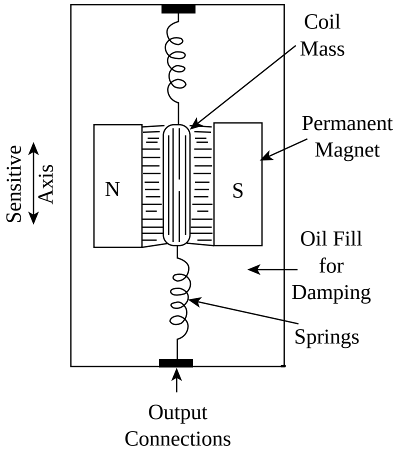

FIG. 7.22j
Schematic representation of a velocity sensor.

VELOCITY SENSORS

Acceleration is the time differential of velocity and can be measured by using velocity sensors. A typical velocity sensor consists of a housing that is attached to the vibrating surface and a magnetic core suspended inside it. Relative motion between the two induces a voltage that is proportional to velocity. The advantages of this sensor include its self-generating nature, strong output signal (250 mV/in./sec), insensitivity to mounting or torque, and low noise pickup due to its low impedance. Its disadvantages are its relatively large size and mass, inability to be suitable for frequencies below 10 Hz, and low output signals at frequencies above 1000 Hz.

Velocity sensors consist of an electrical coil suspended by a spring or springs in the field of a permanent magnet as in Figure 7.22j. The entire assembly may be contained in silicone oil, or, for low-mass coils, the reactive forces caused by the induced currents can be used for damping. The spring coil mass system has a natural frequency below, and the coil moves with the enclosure. Above the natural frequency, the coil remains stationary, and the relative motion between coil and magnet induces a voltage in the coil. This voltage has an amplitude in proportion to the vibration velocity and a frequency equal to the frequency of vibration. With velocity pickup, the output can be in the form of mils (thousandths of an inch) displacement by integration of velocity. A control unit mounted separately is required for these pickups; it contains the readout, amplifier, and power supply. Electronic filtering can be provided where it is desired to look at only specific frequency bands. These devices are fairly rugged, but the oil-damped types are temperature-sensitive because of viscosity changes of the filling oil.

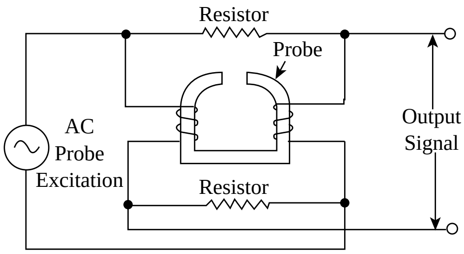

FIG. 7.22k
Eddy current probe schematic.

NONCONTACT OR PROXIMITY SENSORS

As the proximity detectors measure the distance between objects, they can also be used to measure the frequency and amplitude of vibrations. Several proximity sensor principles can be used. The advantage of capacitance types is their simplicity and low temperature sensitivity. Potentiometric units have the advantage of accommodating large amplitudes of movement and strong outputs, while their disadvantage is their low natural frequency. LVDTs and variable inductance units are used in telemetry.

To detect the proximity of conducting materials, an eddy current probe can be used. The schematic arrangement of such a probe is shown in Figure 7.22k. Two identical coils are wound on the probe, and these, together with the resistances, complete a bridge circuit. With no conducting surface near the probe, the bridge is in balance. When a conducting object is brought near the probe, the bridge becomes unbalanced and the output signal is in proportion to the proximity of the object. The excitation is a high-frequency signal, which induces eddy currents in the test object. These currents produce losses in the bridge circuit in such a way that bridge imbalance is related to the proximity of the object. The output signal amplitude is related to the vibration or displacement amplitude, and the frequency of amplitude variations is the frequency of vibration. The bridge is powered by a high-frequency (100 kHz to 2 MHz) oscillator that supplies the rapidly changing magnetic field required for sensor operation.

MECHANICAL-MAGNETIC SWITCHES

The detector mechanism of this switch consists of an armature suspended on a flexure pivot and restrained from moving by a permanent magnet as shown in Figure 7.22l. A compression spring provides an adjustable force opposing the magnet. The armature acts as a lever where the adjusting spring force is balanced by the magnetic force. The armature is constrained to move in only one plane by the flexure pivot. When the entire assembly is subjected to vibration perpendicular to the base, the product of acceleration and armature mass produces an inertial force trying to pull the armature away from the magnet. Since the spring force aids the inertial force, the spring loading is selected to trip the mechanism at the desired acceleration. When the peak acceleration exceeds the preset level, the armature leaves the stop pin and moves to the latch magnet, which holds the armature in the excessive vibration position. Motion of the armature actuates a snap acting switch that opens or closes an electrical circuit. Once the switch has been tripped by excessive vibration, the armature must be returned to the stop pin. Resetting can be accomplished remotely by energizing the reset coil momentarily or by depressing the reset button mounted on the switch. The reset coil requires direct current for operation. If DC power is not available, a rectifier can be supplied with the switch. The rectifier output is sufficient to power several reset coils.

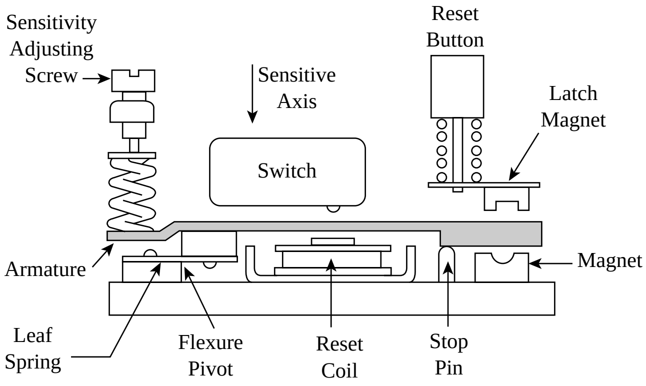

FIG. 7.22l
Mechanical-magnetic switch.

OPTICAL SENSORS

Optical sensors are often used in industrial and laboratory environment for displacement, vibration, and acceleration sensing. They are mainly noncontact devices and are applied where precision is necessary, but they tend to be more expensive than the other devices. There are many different techniques available to suit a particular application. They can broadly be classified as fiber optic sensors, laser optic, interferometric sensors, time-of-flight sensors, Doppler-effect sensors, encoders, and digital displacement sensors. Further, there are many different types in each class. For example, the interferometric sensors include the optical fiber, laser, holographic, and monochromatic light types. In these sensors, Michelson, Sagnac, or Fizeau effects of interference of two or more light beams is used by suitable optical arrangements. The most commonly used optical arrangements are beam splitters, polarizing prisms, and diffraction gratings. Some of these include fringe counting inteferometers, frequency modulation inteferometers, heterodyne interferometers, phase-locked interferometers, laser Doppler and laser feedback interferometers, and fiber interferometers.

CONCLUSIONS

Acceleration, vibration, and shock measurements are very important in all types of industry. Because of the vast market, there are many vendors producing sensors and devices for these measurements. Also, there are many different types. The mechanical sensors are limited to detection of lower frequencies of vibrations. Output signals for waveform analysis are not available with these units. They are used as trip devices to shut down equipment or an alarm on excessive vibration. If vibration sensing is for the purpose of detecting impending malfunction, devices with continuous outputs are required. PZT and peizoresistive acceleration sensors are commonly used for their ruggedness and compactness and their suitability in high frequency applications. Today, mass produced micro- and nano-accelerometers are gaining popularity because of the price, small size, and ease in signal processing requirements. Velocity sensors, however, offer a direct measurement of the energy dissipated in vibration, and thus indicate a quantity directly related to efficiency and the destructive forces.

INTRODUCTION

A typical weather station includes a supporting frame with a number of sensors mounted on it: transmitters, cables, and remote readout devices. All of this equipment can be purchased as a package or separately. In larger installations, the weather information is usually sent to the central computer, and no separate readout devices are required for the weather station.

Many of the sensors that are used in weather stations have already been discussed in other parts of this handbook. Therefore, the emphasis here will be placed on the detectors that are not covered elsewhere.

METEOROLOGICAL STATION

While each station is different, it is useful to briefly describe one. The one selected for description is the Florida Solar Energy Center (FSEC) because their information is in the public domain.

In the FSEC installation, the solar radiation related data (horizontal solar radiation, total radiation, direct normal radiation, total horizontal infrared sky radiation) are collected on the roof, and only the meteorological measurements are made at the weather station. FSEC has over 40 solar radiation instruments. All solar radiation sensors (precision spectral pyranometer and the normal incident pyrheliometer [NIP]) are calibrated annually.

Table 7.23a provides a summary of the data being collected at a field test site. Dry-bulb, dew point, and barometric pressure are recorded once every 6 min. Precipitation is summed continuously and the total in every 6-min period is recorded. The other measurements are made once every second and a 6-min average is recorded. The dry-bulb temperature sensor is mounted in a motor aspirated radiation shield. The barometric pressure sensor is located 17 ft above mean sea level. The precipitation gage is protected by an alter type wind screen. All sensors and translators are calibrated at least annually.

TABLE 7.23a
*The Sensors Used at the Florida Solar Energy Center Field Test Site and Their Inaccuracies**

Parameter	*Sensor*	*Inaccuracy*
Wind speed	3-cup anemometer photon coupled chopper 0.5 mph threshold	±0.15 mph or 1%
Wind direction	Lightweight vane low torque potentiometer 0.5 mph threshold	0.5% linearity
Dry-bulb temperature	Platinum resistance thermometer	±0.1°C
Dew point temperature	Chilled mirror system with platinum resistance thermometer	±0.3°C
Barometric pressure	Piesoresistive element	0.08% of reading
Precipitation	Tipping bucket 0.01 in. resolution	0.5% at 0.5 in./hr

SOLAR RADIATION MEASUREMENT

The intensity of solar radiation can be measured by (1) absorbing the incoming radiation and determining the rate of heat absorption, and (2) making use of photovoltaic or photoresistive transducers. Among the first accurate measurements of solar radiation were those made with miniature water-flow calorimeters in which the flow rate was kept constant and the temperature rise due to absorption of solar radiation was determined by gh-accuracy mercury-in-glass thermometers and later by thermopiles.

Historical Background

C.S.M. Pouillet of France (1830) and J. Ericsson of the United States (1870) devised pyrheliometers that measured the rate of temperature rise of blackened metal masses located at the bottom of tubes that excluded all but the direct rays of the sun. C.G. Abbott of the Smithsonian Institution perfected this technique with his silver-disk pyrheliometers, which are still in use as secondary standards.

He had earlier built a waterflow calorimeter in which a precisely controlled flow of distilled water carried away the heat absorbed by a blackened cone located at the bottom of a collimating tube. A platinum-resistance thermometer was used to measure the temperature rise and then an exactly equal rise was created by passing the water through an electrical heating coil. Precise measurement of the heating current and the coil resistance enabled the user of the instrument to make first-order determinations of the rate at which the incoming solar energy was being absorbed. This instrument was long used as the primary standard for measuring solar radiation.

The inventor of the primary standard radiometer used today was K.J. Angström of Sweden. His instrument, invented in 1899, uses two blackened strips of manganin, each of which can be heated either electrically or by the rays of the sun. The measurement is made by exposing one strip to the sun, and then measuring the current required to heat the adjacent strip to exactly the same temperature. By reversing the operation of the strips several times, an average value of the radiation intensity within 1% of the absolute value can be obtained. The results may be expressed in langleys

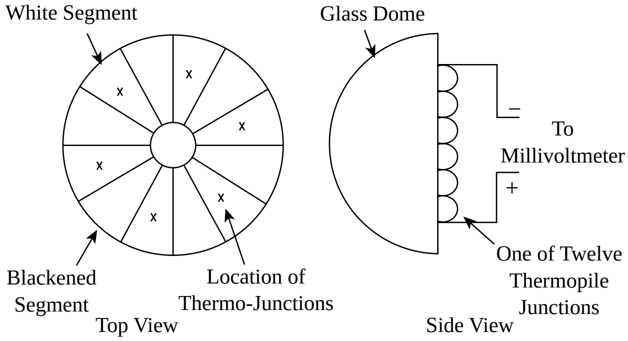

FIG. 7.23b
Thermopile-type pyranometer.

(1 ly = 1.0 g-cal/cm^2/min = 221.2 Btu/hr/ft^2) or in electrical units (1 ly = 69.7 mW/cm^2).

Multijunction Thermopile

One of the solar radiometers in use today employs a multijunction thermopile to detect the difference in temperature between whitened and blackened segments of divided or concentric circles (Figure 7.23b), which are generally protected by hemispherical glass domes. These instruments characteristically produce from 2.0 to 10.0 mV/ly of incoming radiation, and their output can be readily measured with indicating or recording millivoltmeters.

Mechanical or electrical integrators can be used to total daily or monthly solar radiation. Since the response of the thermopile instruments is independent of wavelengths, they can be used with filters to determine radiation intensity in selected portions of the solar or longwave spectrums.

Photovoltaic Cells

This solar radiometer uses silicon photovoltaic cells that produce a short-circuit current that is directly in proportion to the intensity of the solar radiation falling on them. Widely used in the space program to provide power for space probes and satellites, silicon cells are rugged, sensitive, and capable of producing currents large enough to operate self-powered integrators.

Thermal Radiometers

The instrument used to measure solar radiation is called a pyranometer. It consists of a blackened disk containing temperature-measuring sensors. The disk is protected from the environment by two domes of glass. When exposed to the sun, the disk heats up. The glass domes prevent cooling by the wind. The temperature of the disk is a function of the amount of solar radiation hitting it. Calibration against more sophisticated radiation measuring devices gives a repeatable multiplier to convert the pyranometer's output to units of solar radiation.

The term *pyranometer* is applied to a solar radiometer that measures the shortwave radiation coming directly from the sun and diffusely from all parts of the sky. *Pyrheliometer* is the word used to identify an instrument that measures only the direct radiation from the solar disk itself.

Pyrheliometers

Direct or normal solar radiation is coming directly from the sun without bouncing off clouds or the atmosphere. Concentrating solar collectors utilize only this part of the total solar radiation. Its measurement gives an indication of the clearness of the sky. The NIP measures this form of radiation. It consists of a long tube, which, when placed over a pyranometer, blocks out all solar radiation except that which is coming directly from the sun. A tracker, called the equatorial mount, is used to keep the NIP pointed at the sun. The total solar radiation is also measured by a pyranometer, which is also mounted on the tracker. The difference between the NIP and the total pyranometer is referred to as the diffuse solar radiation.

WIND DIRECTION AND SPEED

The wind direction and wind speed transmitters can be either separate units or combined into a single assembly, as shown in Figure 7.23c. Wind speed and direction are measured at a height of 10 m above the ground. This is the standard height for meteorological wind measurements. A special photochopper design is used in the anemometer (wind speed) to enable it to measure wind as slow as 0.2 m/s (1/2 mph). For an in-depth discussion of anemometers, refer to Section 2.2.

Wind Direction

The wind direction is usually detected by a potentiometer, which is mechanically coupled to the wind vane shaft. The resistance at the potentiometer wiper contact is directly in proportion to the angular position of the vane.

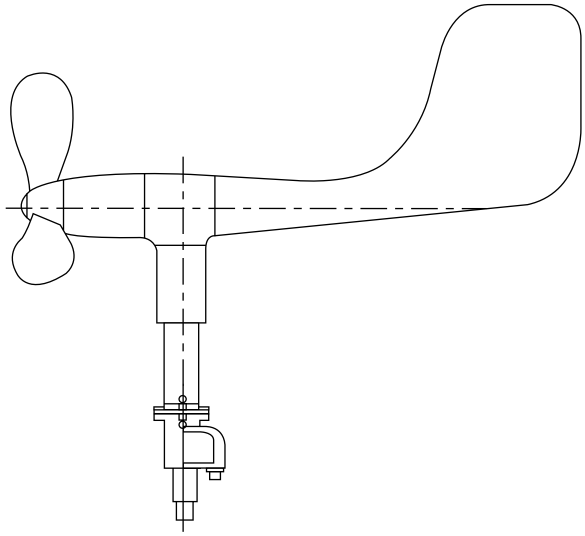

FIG. 7.23c
Wind direction and speed transmitter.

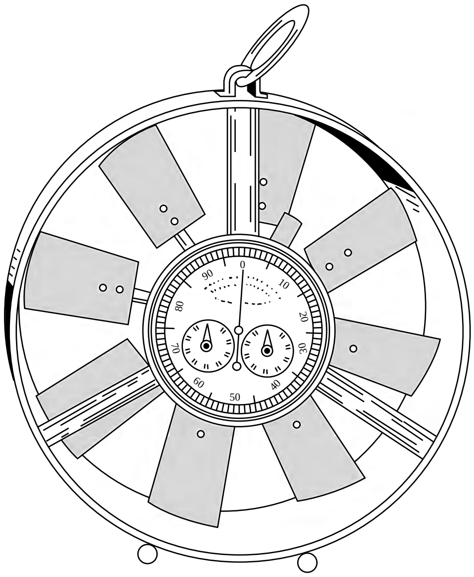

FIG. 7.23d
Vane anemometer with local readout.

Wind Speed

Wind speed is sensed by three- or six-bladed impellers or by anemometers of three- or six-cup configurations. The anemometer shaft can be connected to a photochopper or to a DC or AC generator. If it is connected to the photochopper, a 60-slot disk is rotated to interrupt a light beam with a photosensitive transistor on the opposite side of the disk. This design is more maintenance-free than the DC-type tachometer generators, which require brush contacts for their operation. The contact between rotating and stationary components can also be eliminated through the use of AC generators. Transmitters are usually selected to be sensitive to light winds and yet be strong enough to withstand winds of hurricane force.

Figure 7.23d illustrates the vane design. Air flow causes the vanes to rotate with an angular velocity that is proportional to the wind speed. When a portable unit is required or when the local readout is satisfactory, vane velocity is sent to a local indicator through a gear and spring assembly. When remote readouts are required, a magnetic or capacitive coupling is used to generate a transmission signal.

Figure 7.23e shows a three-cup anemometer, which is insensitive to wind direction. In one design, the shaft drives a DC tachometer, which generates an output voltage that is proportional to the wind speed. This signal can be used as the input to a remote mounted indicator or recorder. The impeller design shown in Figure 7.23c is also provided with a shaft-driven tachometer. Because the tail of this impeller design always points the impellers into the wind, this instrument can detect both wind speed and wind direction.

The response speed of an anemometer is expressed in the “length of wind” that has to pass though the meter before the velocity sensor will respond which amounts to 63% of a step change in velocity. This is known as the distance constant and is expressed in feet. A typical distance constant for commercially available units is 6 ft (1.8 m).

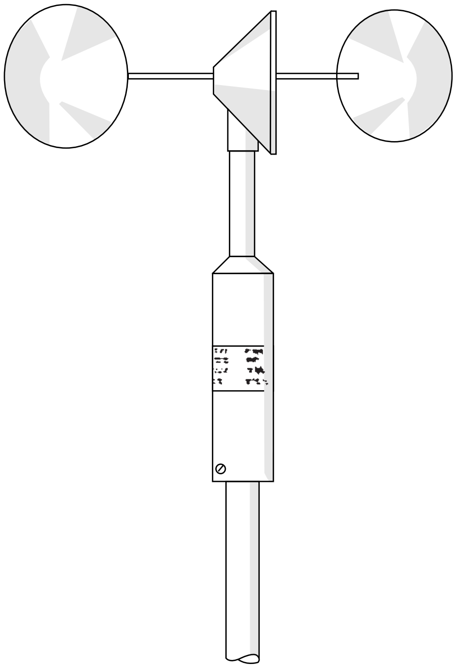

FIG. 7.23e
Three-cup anemometer.

RAIN GAUGES

Rainfall is measured by a tipping bucket rain gauge. Rain is collected in a funnel and alternately fills two small cups (buckets). These two cups are attached together and placed on a pivot such that when one fills up, the assembly tips to the side. At each tip, the full cup is emptied and the empty cup is placed under the funnel.

A collector and a tipping bucket mechanism are provided in this instrument such that each 0.01 in. (0.25 mm) of rain causes the alternate fill and tip of the mechanism. A magnet is attached to the bucket, and causes a momentary closure in a magnetic switch with each tip of the bucket. The resulting electrical impulse can be sent to a counter, an event recorder, or telemetering or data acquisition equipment.

Rain gauges should be installed on a level plot of ground, at a distance from any object of at least two and preferably four times the height of the object above the top of the gauge. All types of gauges must be exposed with the rim of the receiver in a horizontal plane and at a level well above the average level of snow surfaces. Roof-mounting of rain gauges should be avoided when possible. Air currents at heights other than ground level have been observed to cause an apparent decrease in rainfall catch commensurate with the increase in mounting height above the ground level.

Objects, which individually or in small groups constitute a “windbreak,” reduce prevailing wind speed in the vicinity of the gauge. The consequence of this reduction of wind speed will be to reduce possible eddy currents and turbulence around the gauge. The presence of such objects is usually beneficial in providing a more accurate rainfall catch. Ideally, the “windbreak” objects (fences, bushes, etc.) should be generally uniform in height and in their distance from the gauge. Their height above the gauge should not exceed about twice their distance from the gauge.

BAROMETRIC PRESSURE GAUGES

Barometric pressure is detected by bellows against a reference, which is provided by a sealed-in vacuum. These differential pressure-sensing bellows are usually coupled to the core of a linear variable differential transformer, which generates the required electronic output signal.

For locating remote barometric pressure sensors, one should select a site where the instrument will not be subject to rapid fluctuations of temperature or to jarring and continuous vibration. Exposing the instrument to direct sunlight; radiant heaters; or to direct drafts, such as from open windows or doors, should be avoided.

AIR TEMPERATURE DETECTION

Air temperature is measured with a platinum resistance thermometer. This is a very accurate temperature-measuring device. It is placed in a long tube that has been painted white on the outside to reflect solar radiation. A small blower pulls ambient air into the tube and across the thermometer. This allows measurement of the true air temperature without the effect of solar heating.

Ambient temperature can be detected by thermocouples, resistance bulbs, or thermistors. They should be shielded from direct sun exposure as shown in Figure 7.23f.

DEW POINT AND RELATIVE HUMIDITY SENSORS

The sensor most often used for the detection of dew point is the lithium chloride type. If high precision is required, the cooled mirror type sensors should be used.

For relative humidity measurements, the elongation and contraction of hygroscopic elements (organic or inorganic) are usually utilized. For a detailed description of humidity and dew point sensors, refer to Chapter 8.

SENSOR ACCESSORIES

Readouts

The sensors can be 1000 ft (300 m) or more from the readout instruments. Some weather station packages are provided with multiplexers, so that the outputs of six or more sensors can all be read from the same wires. The connection between sensors and readout can be through hard wiring or through radio telemetering. The outputs of six or more sensors can all be recorded on the same chart.

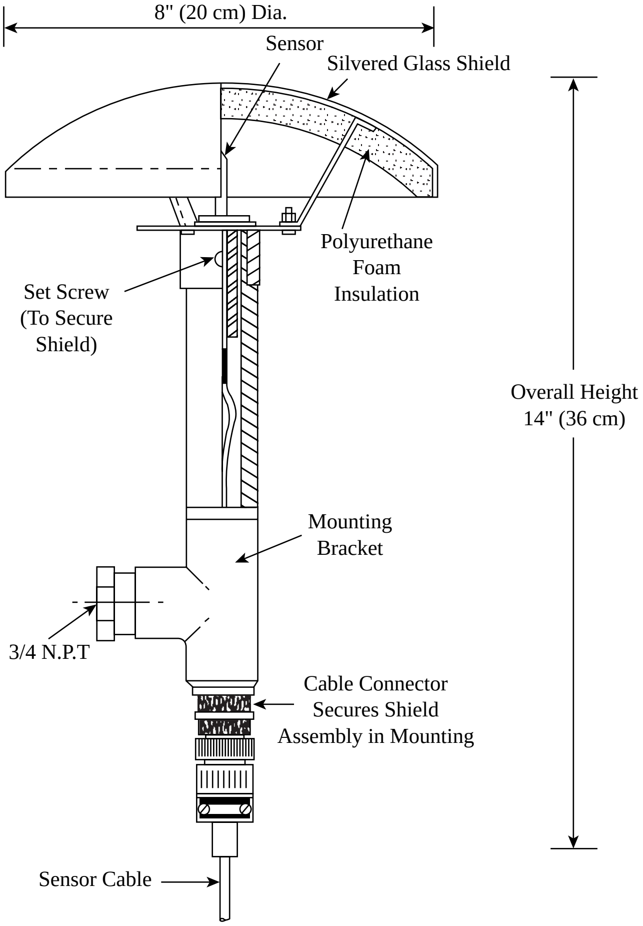

FIG. 7.23f
Temperature radiation shield with natural ventilation.

Locations

The detection of wind speed should ideally be made on an open terrain. If this is not possible, one can minimize the effect of single-story buildings by:

1. Locating the sensor a distance upwind of a building equal to the building height
2. Locating the sensor at least one building-height above the roof
3. Locating the sensor a distance downwind of the building equal to five to ten building-heights

If taller buildings are involved, it is best to erect a small tower to clear any obstruction. If this is not practical, an alternative is to place the instrument on a corner of the building that is upwind the majority of the time, or the corner that is exposed to the greatest frequency of wind. This will generally be the west corner of the building.

FIG. 7.23g
From left to right: 30 ft tower with wind monitor, 10 ft tower with processor-electronics, visibility sensor, present weather sensor, 3-pressure sensors, relative humidity and temperature/dew point; lightning sensor and cloud height sensor; precipitation detector. (Courtesy of Coastal Environmental, Model OS-21 FBS airport weather station.)

Before making a permanent installation, it would be wise to visually monitor a small flag on the end of a pole placed in various locations on the roof to help determine the location that is most representative.

Horizontal-mount booms that extend from existing towers should be fabricated so that sensors will extend a distance of 5 to 10 ft (1.5 to 3 m) from the tower assembly (depending on tower thickness). Wind direction sensors are oriented at the time of installation in reference to either true north or magnetic north.

Instrument Shelters

Whenever possible, instrument shelters, as well as remote temperature and/or humidity sensors, should be installed at a height of 4 ft (1.2 m) (or greater) over earth or sod. They should be at least 100 ft (30 m) from any concrete or other hard-surfaced area, and not closer to any other object than four times the height of the object above the instrument shelter or remote sensors.

Avoid roof installations if possible. If it is necessary to mount shelters and sensors on a roof, they should not be closer than 30 ft (9 m) to any large, vertical reflecting surface (walls, etc.), exhaust fans, or cooling towers. Electronic remote sensors when mounted on a roof should be at least 9 ft (2.7 m) (or greater) above the roof surface. To minimize radiation effects from the roof, remote sensors can also be mounted on a horizontal boom so that they will extend from the side of a building roof or existing tower. Horizontal booms should extend approximately 5 to 10 ft (1.5 to 3 m) from the side of the building roof or tower assembly.

For a photograph of a complete airport weather station, refer to Figure 7.23g.

7.24 Weighing Systems: General Considerations

H. A. MILLS (1969) **H. E. LOCKERY** (1982) **H. I. HERTANU** (1982, 1995)
B. G. LIPTÁK (1995, 2003)

Types of Applications:	Bench of floor scales, drum filling scales, hopper and tank scales, bulk weighing systems, truck scales, monorail and railway truck scales, crane scales
Types of Weight Sensors:	Mechanical designs can be balanced by poise weight, spring, or electromagnetic forces. Load cells can be one of the following electronic designs: strain gauge, capacitance, linear variable differential transformer, magnetostrictive, or photoelastic with the strain gauge being the most popular. Some pneumatic and hydraulic load cells are also used.
Inaccuracy:	Up to 0.01% of full scale (note that gravitational attraction on the surface of the planet varies by as much as 0.5%). For more details, see Section 7.25.
Ranges:	See Section 7.25 for a listing for the different types of sensors covering ranges from grams to thousands of tons.
Suppliers:	Refer to Section 7.25.
Conversion among Different Weight Units:	See Table 7.24a.

INTRODUCTION

The various forms of weighing are discussed in different sections in this handbook. The detection of weight in motion, including belt, gravimetric, and loss-in-weight feeders are covered under the discussion of mass and solids flow metering in Section 2.23. The design and performance of the various solid flow sensors is covered in Section 7.25, while this section discusses the general design considerations in weighing of stationary objects.

The section starts with some introductory paragraphs, including a fairly detailed glossary, because the language used in connection with weighing is somewhat unique and it is important to fully understand the meaning of each term. The introduction is followed by an overview of weighing applications and of the performance of the different sensors used in weighing. The section is concluded with recommendations on how to protect from interference from ambient conditions (temperature, wind, etc.), how to stabilize the weigh-tanks, attach the piping to them, and maintain the system.

WEIGHING GLOSSARY

***Accuracy*—**The intended meaning of the term is inaccuracy and it relates to the size of the error. It is usually expressed as a percentage and it is important to determine if the percentage is that of full scale (% FS) or that of actual reading (% AR). If the measured weight is in the lower part of the detector's range, the % AR error will much exceed % FS. Historically a balance was a device that determined mass by balancing an unknown mass against a known mass as with a 2 pan balance. In modern weighing machines, balances are usually of the design that uses a force restoration mechanism to create a force to balance the force generated by the unknown mass.

***Analog Electronics*—**In case of electronic load cells, this is that segment of the loop, which is between the measuring cell and the analog-to-digital converter.

***Baud Rate*—**The speed of signaling or the rate of communication between two instruments connected by an RS-232 interface. One baud (or bit) is one pulse or one code element per second. The more common rates range from 300 to 9600.

Calibration Error**—**The difference between the size of a dead weight corresponding to near the full capacity of the scale and the actual reading on the digital or analog readout.

Capacity**—**The maximum weight the particular scale is capable of measuring.

Check Weighing**—**Checking a weight against some limits to determine if it is within those preset limits.

Combined Error**—**The error that also reflects nonlinearity and hysteresis. It is defined as the maximum deviation from a straight line, which is drawn between the no-load point and the full rated output. It is expressed as % FS and is measured when the load is increasing and again when the load is dropping.

Cornerload Error**—**This term refers to the variation experienced in the displayed weight as the load is moved within the weighing pan.

Count**—**The smallest increment that the digital display registers.

Creep**—**The change in load cell output signal that occurs with the passage of time, while no change occurs in either the load or the environmental conditions and other variables. It is usually measured while full scale (rated) load is applied and is expressed as a percent of full scale (rated output) over a particular period of time (% FS/h, etc.).

Dead Load**—**The static load (weight) that does not vary and is registered at zero applied load.

Deflection (Load Cell)**—**The displacement along the primary axis of the load cell as the load is increased from no-load to full (rated) load.

Digit**—**The smallest increment of weight that the digital display resolves.

Drift**—**See **Creep**.

Dribble Flow**—**The last increment of charge in batch processes, which is added at a much reduced rate.

Eccentric Loading Test**—**Also called shift test or off center loading test. It is tested by weighing in the center of the four quadrants of the weighing platform.

Excitation Voltage**—**The voltage applied to the input terminals of an electrical bridge circuit.

Flexible Bearings**—**The component in the load cell that allows the force coil to move without friction.

Force Motor**—**See **Measuring Cell**.

Force Restoration**—**A method to measure an unknown load by balancing it with a force generated by coils mounted in a magnetic field.

Gross Weight**—**The total weight of the material of interest plus the container and wrapping or the weight of a vehicle or container when it is loaded with goods.

Gross Weight-In**—**The total weight set-point while charging material into a tank or vessel.

Gross Weight-Out**—**The total weight set-point while discharging material from a tank or vessel.

Heel**—**The material that remains in the vessel after the dump or empty cycle is completed.

Heel Limit**—**The maximum allowable weight setting for the heel, which usually is internally programmable.

Hysteresis Error**—**The variation in the readings that are registered when repeatedly weighing the same object or quantity.

Increment**—**The finest division on a scale.

In-Flight Quantity**—**The material that enters a receiving vessel after the feed valve is closed.

Instability**—**Random, sporadic variation in the displayed reading that has no trend.

Leveling**—**The adjusting of the weighing platform so that it will be completely horizontal. Therefore, its readings will be repeatable if the platform is moved.

Linearity**—**The deviation of the calibration curve (the average of upscale and downscale readings) from a straight line, which is so positioned as to minimize the maximum deviation. Usually tested by placing known weights on the scale between zero and full capacity.

Load Cell**—**A detector device that produces an output signal proportional to the applied weight or force.

Load—Safe Maximum**—**The maximum percent of rated capacity that can be applied without causing a permanent shift in the load cell performance, which would exceed the specified allowable amount.

Load—Ultimate Maximum**—**The maximum percent of rated capacity, which can be applied without causing structural failure.

Measuring Cell**—**The part of the load cell that measures the load (weight or force) and generates an electronic signal related to that measurement. Also called—mechanical system or force motor.

Menu**—**A set of options or parameters that are usually factory set (but can also be set by the user) and serve to determine the characteristics of the weighing system.

Net Batch-Out**—**A weighing mode of operation where the set-point determines the amount to be withdrawn from the vessel.

Net Weight**—**The weight of material excluding its container or wrapping.

Net Weigh-In**—**A mode of weighing where the set-point for the total material to be added is based on zero, which corresponds to the weight that is already in the vessel.

Nonlinearity**—**See **Linearity**.

Off Center Loading**—**See **Eccentric Loading Test**, also called shift test.

Poundal**—**It is the foot-pound-second (fps) unit of force, defined as the force, producing an acceleration of 1 ft/s^2 on a mass of 1 lb.

Primary Axis**—**The axis along which the load cell is designed to be loaded. It normally is its geometric center line.

Rated Capacity**—**The maximum load that the load cell is designed to measure.

Rated Output**—**The algebraic difference between the outputs at no load and at rated load.

Readability**—**The value of the finest division on an analog scale or the smallest increment of weight that a digital display resolves.

Repeatability**—**The closeness of agreement among a number of consecutive measurements of the same weight under the same operating conditions and approaching from the same direction. Usually expressed as a standard deviation of 5 to 10 tests. It does not include hysteresis and is expressed in percent of span.

Reproducibility**—**Same as repeatability, but the measurements can approach from both directions and can be taken over a long period of time. Therefore, it includes hysteresis, dead band, drift, and repeatability.

Resolution**—**The finest division on an analog scale or the smallest increment that a numeric display can indicate.

Shift Test**—**See **Off Center Loading**.

Shunt Calibration**—**Electrical simulation of load cell output by insertion of known shunt resistors between appropriate points within the circuitry.

Side Loading**—**Any load acting 90° to the primary axis of loading.

Slug**—**The fps unit of mass, defined as the mass that will be accelerated by one ft/s^2, when a 1 lb$_f$ acts upon it. It is equivalent to approximately 32.2 lb mass.

Tare**—**The weight of an empty container.

Temperature Compensation**—**The automatic correction of any errors that might be caused by a change in the temperature. On less accurate scales, this compensation is done within the load cells, while on more accurate weighing systems, it is done in software.

Temperature Effect on Rated Output**—**The amount of change in the rated output that is caused by a change in ambient temperature. It is expressed as percentage change in rated output per 100°F change in ambient temperature.

Temperature Effect on Zero Balance**—**The change in zero balance caused by a change in ambient temperature. It is expressed as change in zero balance in percent of rated output per 100°F change in ambient temperature.

Temperature Range—Compensated**—**The range over which the load cell is compensated to maintain the rated output and the zero balance within specific limits.

Temperature Range—Safe**—**The extremes of temperature within which the load cell can operate without permanent adverse affect on any of its performance characteristics.

To Tare**—**The action of deducting the weight of the container from the total weight, so that the indicator directly reads the net weight only. For example, if the capacity of the scale is 500 lb and 200 lb is tared, the remaining net capacity of the scale is 300 lb.

To Zero**—**To reestablish zero when small amounts of material were left on the scale. Zero and tare are often combined on the same key and the terms are often used interchangeably.

Zero Balance**—**The output signal of a load cell with excitation, but with no load applied, expressed in percent of rated output.

Zero Float**—**The zero shift caused by one complete cycle of successive rated tensile and compressive loading.

Zero Return**—**The difference in zero balance measured immediately before rated load application of a specific duration and when the output has stabilized after the removal of the load.

Zero Shift**—**A change in zero balance with time.

Zero Stability**—**The degree to which a weighing system maintains its zero balance with the passage of time, as long as all environmental conditions and other variables remain constant.

What is Weighing?

While the old axiom, “A Pound’s a Pound, the World Around,” is hardly true today, it gives a fair indication of the faith that mankind still has in the process of weighing. This faith is justified because weighing is more accurate than flow, volume, or level measurement. It is also more reliable, as it requires no contact with the material being weighed. In addition, it does not need to have moving parts, and, therefore, it is of low maintenance.

In the sense with which we are presently concerned, to weigh an object is to measure the force of gravity on the mass of the object at the particular location on the planet. Thus, if we establish a standard of mass and agree on a particular location, we may compare objects with our standard and establish a relative relationship between them and can arbitrarily call this ratio weight. It is true that in order to have an agreeable system of weighing for commercial or process control purposes, for all places and locations throughout the world, it is necessary to agree on a standard of mass and on a standard of acceleration due to the force of gravity.

This has been done through convention of various countries (Metric Treaty of 1875). Our system of measurement is based upon a cylinder of platinum-iridium alloy kept at the International Bureau of Weights and Measure at Sevres, France. Although this prototype is actually a standard kilogram, through the use of a factor (1 kgm = 2.2046 lbm), we may derive a corresponding standard mass equal to 1 lb.

The internationally accepted unit of mass is the kilogram (see Table 7.24a for conversion from other units), and the internationally accepted unit of force is called the Newton, which is defined as the force required to accelerate 1 kg by 1 m/s^2. A Newton equals 0.2248 lb$_f$, or about 4 oz.

TABLE 7.24a

Conversion from Different Units of Weight to Kilograms

To Convert to kg From	*Multiply by*
Carat (metric)	2.000 000 E–04
Grain	6.479 891 E–05
Gram	1.000 000 E–03
Hundredweight (long)	5.080 235 E+01
Hundredweight (short)	4.535 924 E+01
Kilogram-force-second^2/meter (mass)	9.806 650 E+00
Kilogram-mass	1.000 000 E+00
Ounce-mass (avoirdupois)	2.834 952 E–02
Ounce-mass (troy or apothecary)	3.110 348 E–02
Pennyweight	1.555 174 E–03
Pound-mass (lbm avoirdupois)	4.535 924 E–01
Pound-mass (troy or apothecary)	3.732 417 E–01
Slug	1.459 390 E+01
Ton (assay)	2.916 667 E–02
Ton (long, 2240 lbm)	1.016 047 E+03
Ton (metric)	1.000 000 E+03
Ton (short, 2000 lbm)	9.071 847 E+02
Tonne	1.000 000 E+03

Note that in the English system of units, the values of pound-mass and pound-force have *different values*. In the past, terms such as poundals for force and slugs for mass have also been used.

The poundal is the foot-pound-second (fps) unit of force. It is defined as the force that produces an acceleration of 1 ft/s^2 on a 1 lb mass. The slug is the fps unit of mass, defined as the mass that will be accelerated by 1 ft/s^2, when 1 lb$_f$ acts upon it. It is equivalent to approximately 32.2 pounds mass.

Force and Weight

One frequently encounters the terms force and weight. What is their fundamental relationship? To understand this, one must consider Newton's law of universal gravitation, which points out that all material objects attract all other material objects. Thus, everything on or near the earth's surface is attracted toward the earth's center. By agreement, this attractive force of gravity has been termed the object's weight.

However, if we recognize that the gravitational attraction varies from place to place over the earth's surface (as much as 0.55%), we can readily see that in order for force and weight to be equal, we must *assume* that gravity is constant. In the United States, this has been done and is established as 980.0 cm/s^2 or 32.15 ft/s^2. All calibration standards used in this country and all standard expressions of weight are based on practices and standards established by the Department of Commerce, National Institutes of Standards and Technology. Thus, one may use the terms force and weight interchangeably, provided one accepts that the standard value for gravity is assumed to be valid at all locations (an inaccurate assumption).

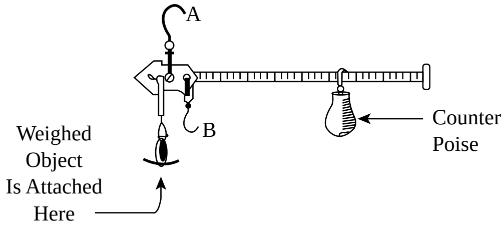

FIG. 7.24b

The steelyard is supported from the hooks A or B, the object being weighed is attached to the shorter arm of the lever, and the counterpoise is moved along the longer arm until balance is established.

Historical Considerations

Although the discovery of the principle of the lever as a means of weighing is attributed to Archimedes (287–212 B.C.), it is a fact that the common steelyard was in use throughout the Orient and India many centuries before Archimedes (Figure 7.24b). While Archimedes may have first adroitly defined the mathematical principles involved, simple first class lever balance systems were frequently referred to in the earliest records of civilization. Mankind thus acknowledged the principle of exchange based on weight. Other early standards and equipment may have been crude in comparison with those of the present.

It is interesting to note that nearly 16 centuries went by without any important addition to the fundamental teaching of Archimedes. Not until the time of Leonardo da Vinci (1452–1519) were the various classes of levers investigated. Da Vinci sketched out and described many styles and designs of lever weighing systems. The basic principle of the lever platform scale, the multiple lever (articulated) scale, and the first direct indicating scale are all attributed to the genius of da Vinci. Although the principle of the simple spring balance was enumerated by Hooke in 1676, da Vinci had illustrated and described such a system of weighing nearly two centuries earlier.

From the 17th century to the present, while vast improvements have been made in the methods of fabrication and in the materials that are available to build scales, no fundamental changes in principles of the lever scales and spring balance have occurred. Even today, the majority of scales and weighing systems are based on the early principles set forth by Leonardo da Vinci.

Not until about 100 years ago, with the advent of the hydraulic load cell, and more recently with the discovery and development of the electrical strain gauge, have there been significant changes in the principles and equipment involved in weighing.

Advantages of Weighing

As compared to volumetric measurement, weighing has several outstanding advantages. Perhaps the most fundamental advantage is the freedom from temperature effects on volume.

In volumetric measurement, one must always take into consideration the temperature of the material being handled, and apply correction factors to obtain results based on mass. Weight is unaffected by temperature, and if the material can be physically handled, it can be weighed. Consider, for example, the weighing of molten metal, for which temperatures of 2400 to 2600°F (1300 to 1400°C) are commonplace. The difficulty of accurate volumetric measurement is easily visualized. Yet highly accurate (0.1%) weighing is possible with modern strain gauge weighing equipment.

In many manufacturing operations and in process control systems, the gravimetric (weight) control may provide the most direct and most accurate measurement. Consider, for example, the problem of maintaining constant proportions between solvent and solute where the solvent may enter the process at widely varying temperatures. If volumetric measurement of the liquid solvent is employed, constant temperature correction must be applied; if both ingredients are controlled by weight, then direct control is maintained and more accurate results may be expected.

In the handling of liquids and solids, the weighing techniques provide commerce and industry with an accurate and direct method of control, relatively independent of process media characteristics, physical location, time, atmospheric conditions, and temperature. Units of weight are easily convertible to various monetary values, facilitating commerce and exchange.

In the handling of such material as chlorine, liquefied petroleum gases, and other like materials, it should be noted that the weighing process provides a safe and convenient method of control without container penetration, external sight-glasses, etc. In the case of dangerous or highly corrosive materials, this is a very important advantage. The same may also hold true for cryogenic materials.

WEIGHING APPLICATIONS

Weighing System Specification

Table 7.24c lists the data the user has to specify before the manufacturers can properly bid on a weighing system. The information in the table describes the weigh tank, the process in which the tank is used, and the instrumentation required to fit into the overall, plant-wide system.
