
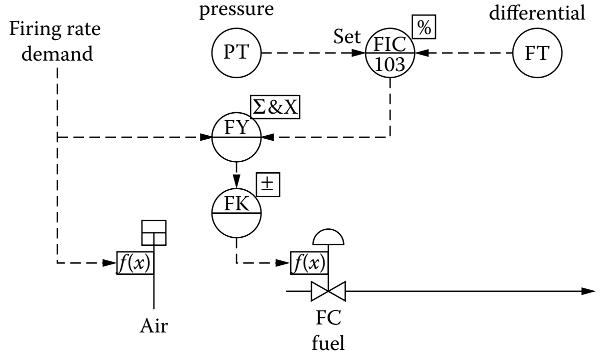

FIG. 8.6nn
Proportional compensation in air/fuel ratio control.

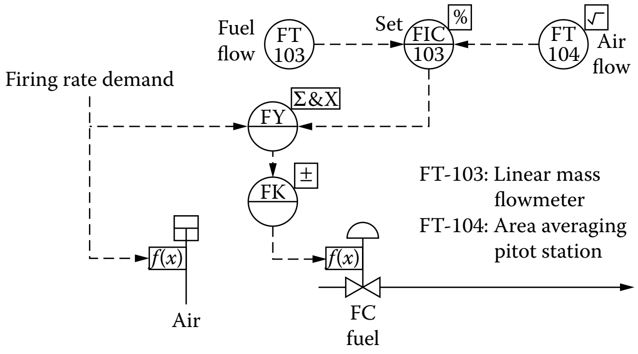

FIG. 8.6oo
Proportional compensation with accurately measured flows.

In this system fuel and air flow are open-loop controlled, and only secondary use is made of their measurements. The undesirable consequence is that fuel disturbances need master controller action for correction, and the fuel and air loops can interact with each other. The effect of interaction and disturbances in the fuel and air control loops can be minimized by the use of closed-loop fuel and air control. The system shown in Figure 8.6pp (which uses essentially the same equipment) is more desirable from the noninteracting, self-linearizing standpoint but must be provided with high turndown flow sensors and signal transmission that does not contribute a time lag.

In the systems shown in Figures 8.6oo and 8.6pp, fuel flow and air flow signals for proper fuel/air ratio are matched. This is done by matching air to fuel in the field combustion test calibration of the air flow measurement. Field testing is less stringent with the system shown in Figure 8.6pp, because the self-linearizing feature of the closed-loop system reduces the work to characterize the fuel and air control devices.

The systems shown here are for measurable fuels. In burning coal, wood, and refuse, fuel flow is often inferred from steam flow, and the steam-flow/air flow relationship is used as a control index.

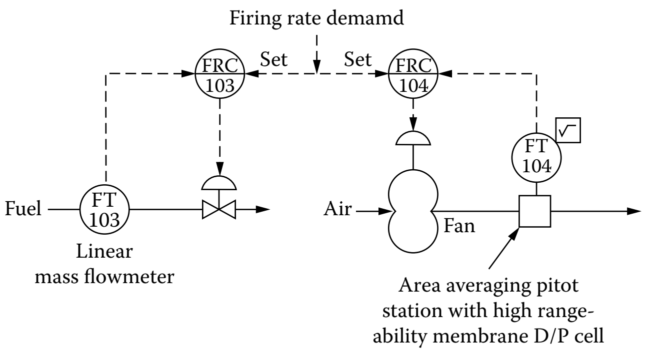

FIG. 8.6pp
Closed-loop air/fuel ratio control.

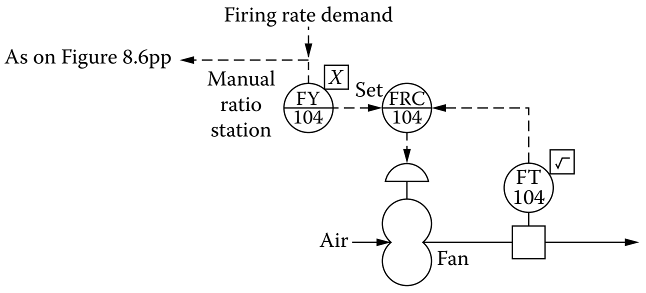

FIG. 8.6qq
Closed-loop air/fuel ratio control with manually adjusted ratio station.

In the event that the heat of combustion or flow rate of the fuel varies unpredictably, as frequently happens during feeding of coal, wood, or refuse, air flow should be set in ratio to the heat released by the fuel. For a boiler, heat release is indicated by steam flow combined with the rate of rise of steam pressure. This is the same calculation that was made in Figure 8.6bb to recalibrate the coal flow measurement. In the steady state, the heat release, coal flow, and total heat demand signal are identical, so any of the three may be used to set air flow.

The fastest response to a change in demand will be achieved if total heat demand sets air flow. The best response to an unmeasured change in coal flow or heating value would be obtained if air flow is set by calculated heat release. If the higher of the two signals is selected to set air flow, then excess air will be provided in either event.

A manual adjustment of the fuel/air ratio can be provided with either of the systems illustrated in Figures 8.6oo and 8.6pp. This adjustment can be inserted as shown in Figure 8.6qq to keep from changing the gain of the loop as adjustments are made. If ratio adjustment is manual, flue-gas analyzers, such as oxygen, carbon monoxide, or combustibles analyzers, should be provided for the operator's guidance or as feedback control of the ratio desired. A measurement of percentage of oxygen in the combustion gases is most necessary for operator guidance when multiple fuels are being burned or when fuel properties vary.

Fuel and Air Limiting Maintaining the correct fuel/air ratio also contributes to limiting the fuel rate to available air and limiting air minimum and maximum to fuel flow, air leading fuel on load increase, and air lagging fuel on load decrease. This arrangement also protects against a fan failure or a sticking fuel valve.

Though not normally furnished on smaller boilers, the following limiting actions are desirable for safety purposes:

1. Limiting fuel to available air flow
2. Minimum limiting of air flow to match minimum fuel flow or to other safe minimum limit
3. Limiting minimum fuel flow to maintain stable flame

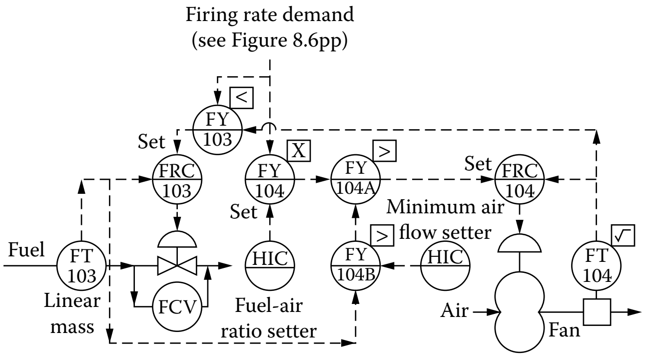

FIG. 8.6rr
Parallel, closed-loop control with air and fuel limiting.

These limiting features are simple to apply with the basic noninteracting, self-linearizing system in Figure 8.6pp. Figure 8.6rr shows the necessary modifications that can provide these features without upsetting the set point of the fuel/air ratio.

The following is accomplished by the illustrated system:

1. If actual air flow decreases below firing rate demand, then the actual air flow signal is selected to become the fuel demand by low selector (FY-103).
2. If fuel flow is at minimum and firing rate demand further decreases, actual fuel flow becomes the air flow demand, because FY-104A will select the fuel signal if it is greater than firing rate demand signal. A manual air flow minimum is also available to come into use through FY-104B, such that if fuel flow signal drops below the HIC setting, this manual setting will become the air flow set point.
3. Fuel is minimum limited by separate direct-acting pressure of flow regulator (FCV).

The combined control system in Figure 8.6l also shows air and fuel limiting on its air/fuel ratio system, but it is configured differently from the scheme shown in Figure 8.6rr. Figure 8.6l does not show a minimum air setter (HIC), the air/fuel ratio relay (FY-104) is located on the measurement signal to the air flow controller (FIC-104), and its ratio setting is not adjusted manually (HIC) but is optimized by "tie-in #1." Otherwise, the two loops are quite similar.

In the combined control system of Figure 8.6l, the fuel flow is detected by a high-rangeability, accurate mass flowmeter (FT-103). The set point for the fuel flow controller (FIC-103) is the smaller of either the biased air flow or the firing rate (FY-103). The set point of the air flow controller (FIC-104) is selected as the higher of either the biased fuel flow or the firing rate (FY-104).

These high and low selectors provide the so-called cross-limited parallel metering system.[15] The coefficients in the system are adjusted so that the pairs of signals provided to the high and low selectors are equal under steady-state conditions. When the firing rate demand increases, the high selector provides it as an air flow set point while the low selector transmits the air flow process variable as the fuel flow set point. Air flow, therefore, starts to increase immediately; fuel flow rises only after the air flow responds.

When the firing rate demand signal decreases, the low selector provides it as the fuel flow set point while the high selector transmits the fuel flow process variable as the air flow set point. Fuel flow starts decreasing immediately; air flow drops only after fuel flow responds. Likewise, if a disturbance causes air flow to drop, the low selector transmits the air flow signal to the fuel flow controller. Fuel flow then decreases regardless of the steam demand, preventing a fuel-rich condition.

The disadvantage of the system is that overall response is constrained by the slower of air flow or fuel flow response to changing demand signals. For example, if the firing rate demand rises slightly, the system first positions the damper to increase air flow; then, as air flow rises, the system opens the fuel valve.

The bias and gain modules FY-103 and 104 were added in Figure 8.6l to improve the system response to *small* load changes. These reduce the effective fuel flow signal presented to the high selector while raising the air flow variable provided to the low selector.

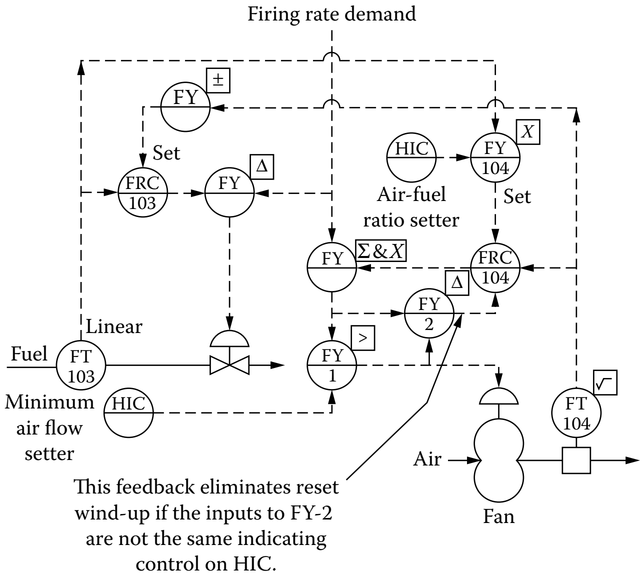
Under steady-state conditions, the firing rate demand is presented as the set point to both controllers. Likewise, if the firing rate demand changes only slightly, it will still be transmitted by both signal selectors and will cause the fuel and air flows to increase or decrease accordingly. If the changes in firing rate demand exceed the offset introduced by the bias and gain modules, the system will operate like a cross-limited system. As a result, fuel flow can respond to small increases in firing rate demand without raising air flow. Similarly, air flow may be adjusted slightly downward if firing rate demand falls, without having to decrease fuel flow.

In open-loop systems, the fuel and air limits are more difficult to apply. The application of these limits to an open-loop system is shown in Figure 8.6ss. Here, the fuel set point is determined (limited) by actual air flow, and a "fuel cutback" necessitated by reduced firing rate demand is accomplished at the expense of temporary fuel/air ratio offset.

Limiting combustion air flow to a minimum or to the rate at which fuel is being burned creates special problems because when the limit is in force, provision must be made to block the integral action in the air flow controller.

It may seem that a better way to limit fuel would be to have the firing rate demand directly set the air flow, with fuel being controlled through the combining relay (Figure 8.6tt). In this arrangement final fuel/air ratio correction occurs through the integral mode correction of the fuel/air ratio controller. This system is only partially effective, however, because on a sudden decrease of firing rate demand, the resulting reduction in fuel flow will occur only after the air flow has already been reduced.

A further consideration in setting fuel rather than air directly by the firing rate demand is that the parallel boilers can be more easily kept in balance, because balancing fuel directly balances the heat input without consideration of excess air between boilers.



This feedback eliminates reset wind-up if the inputs to FY-2 are not the same indicating control on HIC.

FIG. 8.6ss
Parallel, open-loop control with fuel and air limiting applied.

Feedwater and Drum-Level Control

Feedwater control is the regulation of water to the boiler drum. This water is admitted to the steam drum and, after absorbing the heat from the furnace, generates the steam produced by the boiler. On most boilers, makeup water for the feedwater system is filtered, deionized, treated, and deaerated prior to entering the boiler. It is usually preheated through one or more feedwater heaters and an economizer boiler tube section. The final control elements for feedwater are control valves, pump speed, or some combination. Pumps may be driven by electric motor or steam turbine.

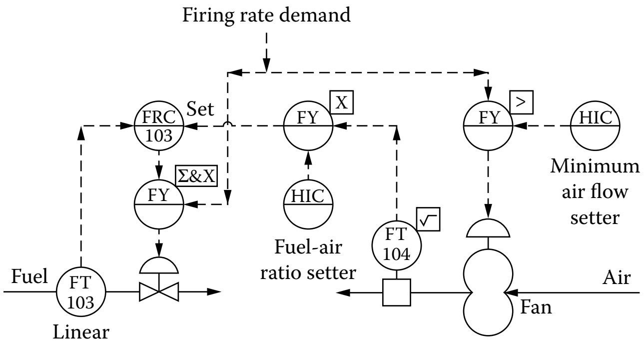


FIG. 8.6tt
Firing demand determines air flow, while fuel set point is adjusted by air flow.

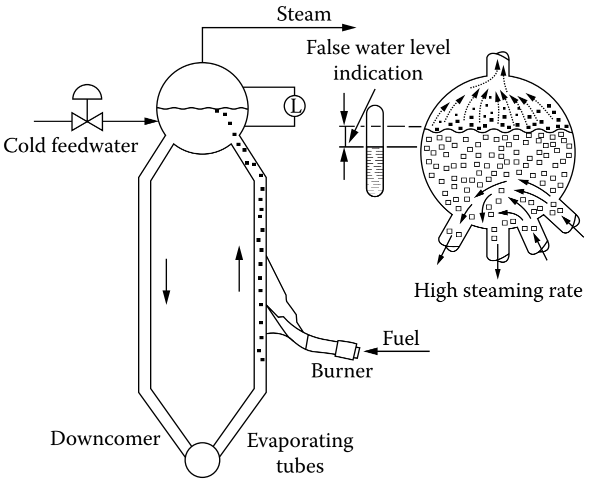

FIG. 8.6uu
Partial vaporization in the evaporating tubes causes drum level to shrink when feedwater flow increases and when pressure rises. On the other hand, an increase in the demand for steam causes the level to "swell."

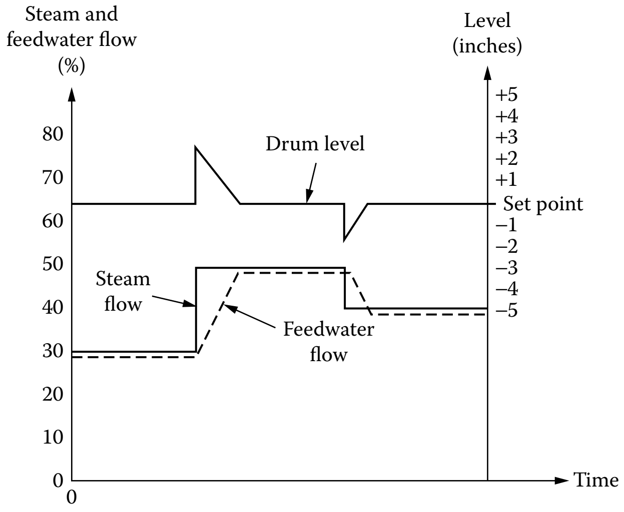

FIG. 8.6vv
Response relationship among steam flow (load), feedwater flow (manipulated variable), and level (controlled variable) in a properly designed system.

Proper boiler operation requires that the level of water in the steam drum be maintained within a certain band. A decrease in this level may uncover boiler tubes, allowing them to become overheated. An increase in this level may interfere with the operation of the internal devices in the drum that separate the moisture from the steam and may cause liquid carryover that can damage the steam turbine.

The water level in the steam drum is related to, but is not a direct indicator of, the quantity of water in the drum. At each boiler load, there is a different volume in the water that is occupied by steam bubbles. Thus, as load is increased there are more steam bubbles, and this causes the water to "swell," or rise, rather than fall, because of the added water usage (Figure 8.6uu). Therefore, if the drum volume is kept constant, the corresponding mass of water is minimum at high boiler loads and maximum at low boiler loads. The control of feedwater, therefore, needs to respond to load changes and to maintain water by constantly adjusting the mass of water stored in the system.

Feedwater is always colder than the saturated water in the drum. Some steam is then necessarily condensed when contacted by the feedwater. As a consequence, a sudden increase in feedwater flow tends to collapse some bubbles in the drum and temporarily reduce their formation in the evaporating tubes. Then, although the mass of liquid in the system has increased, the apparent liquid level in the drum falls. Equilibrium is restored within seconds, and the level will begin to rise.

Nonetheless, the *initial* reaction to a change in feedwater flow tends to be in the wrong direction. This behavior, called "inverse response" or "nonminimum phase response," causes an effective delay in control action, making control more difficult. Liquid level in a vessel lacking these thermal characteristics can typically be controlled with a controller gain of 10 (proportional band of 10%) or less. By contrast, the drum-level controller needs a controller gain closer to 1 (proportional band of 100%) to maintain stability. Integral action is then necessary, whereas it can usually be avoided when very narrow proportional band settings can be used.

Control of feedwater addition based on total drum level alone tends to be self-defeating, because on a load increase it tends to decrease water feed when it should be increasing. Figure 8.6vv shows the response relationship among steam flow, water flow, and drum level that should be present in a properly designed system if constant level under variable load is desired. For special reasons, one may wish to increase level with load. Boilers are designed for constant level operation, however.

Single- and Two-Element Feedwater Systems For small boilers having relatively high storage volumes and slow-changing loads, a simple proportional control may suffice, imprecise as it is. Integral action should not be used, because of resulting instability that is a result of integration of the swell on load changes that must later be removed. Control of this type, therefore, involves the addition of feedwater on straight proportional level control.

For larger boilers and particularly when there is a consistent relationship between valve position and flow, a two-element system (Figure 8.6ww) can do an adequate job under most operating conditions. Two-element control involves adding the steam flow as a feedforward signal to the feedwater valve (or boiler feed-pump speed). Two-element control is primarily used on intermediate-size boilers, in which volumes and capacities of the steam and water system would make the simple "total" level control inadequate because of

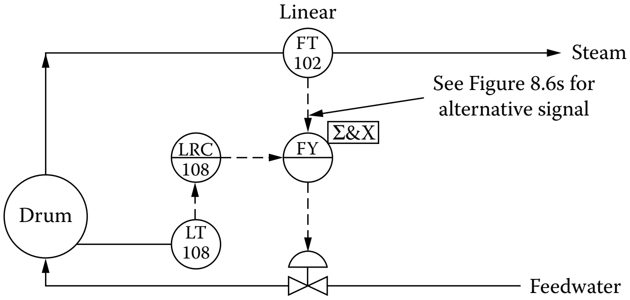

FIG. 8.6ww
Two-element feedwater control.

"swell." Total level control is undesirable when it is detected by sensors that are insensitive to density variations, such as the conductivity type. Displacement and d/p cell-type sensors are preferred from this perspective because they respond to hydrostatic head. Smaller boilers, in which load changes may be rapid, frequent, or of large magnitude, will also require the two-element system.

Field testing, characterization, and adjustment of the control valve are required so that the relationship of control signal to feedwater valve flow matches that of the steam flow to the flow transmitter output.

Any deviations in this matching will cause a permanent level offset at the particular capacity and less than optimal control (Figure 8.6xx). The level controller gain should be such that, on a load change, the level controller output step will match the change in the steam flow transmitter signal.

Three-Element Feedwater Systems As boilers become greater in capacity, economic considerations make it highly desirable to reduce drum sizes and increase velocities in the water and steam systems. Under these conditions, the boiler is less able to act as an integrator to absorb the results of incorrect or insufficient control. A three-element system is used on such large boilers to arrest disturbances and react to load changes more rapidly, as they occur.

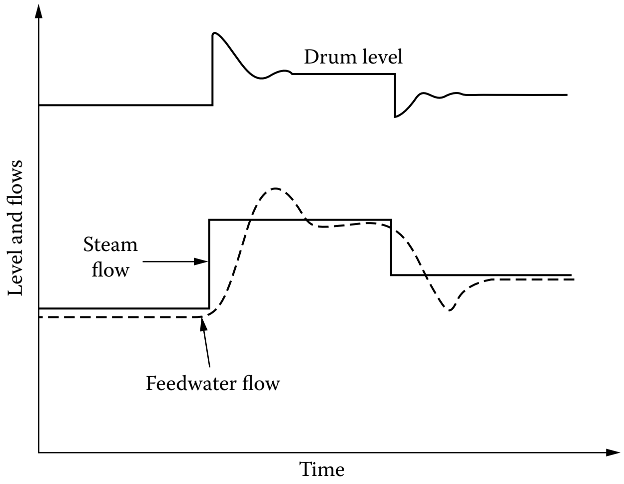

FIG. 8.6xx
The effect of mismatching between steam flow transmitter and valve flow characteristics.

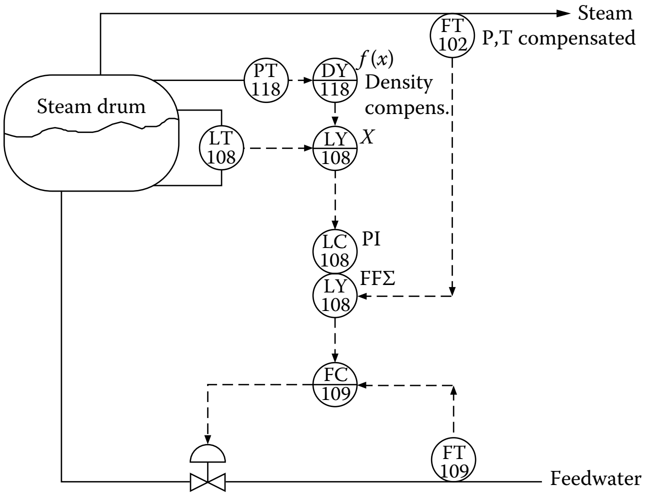

FIG. 8.6yy
Three-element feedwater system, plus density compensation with drum pressure.

Three-element control is similar to the two-element system, except that the water flow loop is closed rather than open. In this way, pressure disturbances that would affect feedwater flow are handled immediately by the fast response of the feedwater flow loop. There are several ways of connecting a three-element feedwater system, each of which can produce the results shown in Figure 8.6vv. Figure 8.6yy illustrates the most common way of connecting this system.

In addition to the three primary control variables (three elements)—drum level, steam flow, and feedwater flow—drum vapor-space pressure can be utilized to compensate for density changes.[16] The pressure is passed through a calculator, DY-118 in Figure 8.6xx, that calculates a multiplier to apply to the raw level signal. The multiplier is based on the density change vs. pressure for saturated steam, as taken from the steam tables.

In making gain adjustments on a three-element feedwater system, the first step is to determine the relative gains between level and flow loops. By observing a change in boiler load one can note the particular boiler "swell" characteristics. Maximum system stability results when the negative effect of swell equals the positive effect of flow. For example, if a 20% of maximum flow change produces a 2.4 psi (0.16 bar) change in flow transmitter output and this flow change also produces a 3 in. (75 mm) swell on a 30 in. (750 mm) range transmitter or a 1.2 psi (0.08 bar) transmitter output change, then the gain of the level loop should be double the gain on the flow loop.

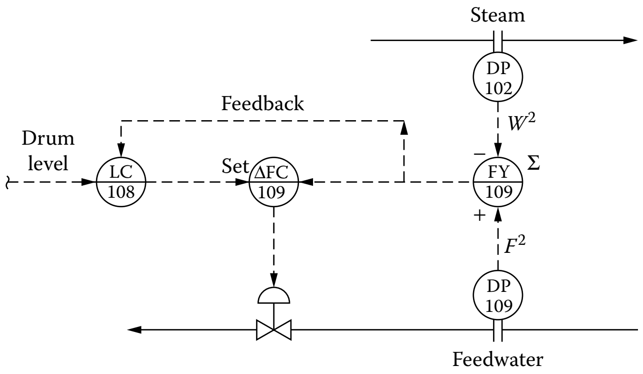

FIG. 8.6zz
Feedforward control of drum level.

Feedforward Control A feedforward variation is recommended by Shinskey to maintain a steam-water balance, reducing the influence of shrink-swell and inverse-response phenomena. The system shown in Figure 8.6zz causes feedwater flow to match steam flow in absence of action by the level controller. The two flowmeters have identical ranges, and their signals are subtracted. If the two flow rates are identical, the subtractor sends a 50% signal to the flow-difference controller. An increase in steam flow will call for an equal increase in feedwater flow to return the difference signal to 50%.

Errors in the flowmeters and the withdrawal of perhaps 2.5% water as “blowdown” (which is not converted to steam) will prevent the two flow signals from being identical. Any error in the steam–water balance will cause a falling or rising level. Therefore, the level controller must readjust the set point of the flow-difference controller to strike a steady-state balance.

The system assumes orifice-type flow sensors and does not use square-root extractors, because the period of oscillation and dynamic gain of a two-capacity level process varies directly with flow. The gain of the feedwater control loop without square-root extraction seems to compensate correctly for the process gain change.

Figure 8.6zz also shows external feedback from the flow-difference measurement applied to the level controller. This will precondition the level controller during start-up or at other times when feedwater is controlled manually or otherwise limited. Otherwise, an increase in steam or blowdown flow will increase the feedwater flow immediately, without depending on the level controller. This means that the feedback portion of the loop (LC-108) will need only to trim the ΔFC-109 set point to correct for flowmeter errors.

Because the role of the feedback portion is reduced from manipulating feedwater flow across its entire range to adjusting only for flowmeter errors, deviations in level from the set point will be minimized. Controller mode settings are not as critical in this situation, and incorrect actions caused by shrink, swell, and inverse-response are reduced.[6]

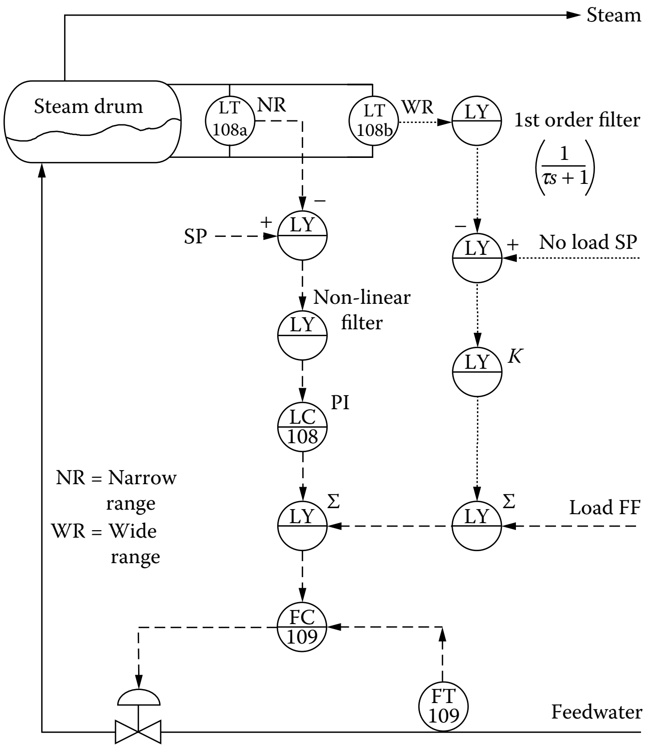

FIG. 8.6aaa
Wide-ranging proportional feedback drum level control, to help reduce performance degradation due to shrink–swell effect.

Shrink–Swell Compensation Another variation of level control proposed by Shinskey to overcome shrink–swell effects involves the use of proportional feedback from a wide-ranging level measurement.[17] On large boilers, primary drum level control is often accomplished with a narrow-range transmitter for more accurate control, with a wide-range transmitter present to show large excursions and handle alarms and trips outside the narrow control range.

The wide-range transmitter can be utilized to provide proportional feedback to sum with the output of the narrow-range (NR) level control (Figure 8.6aaa). When rising vapor volume in the water, resulting from an increasing load, causes the water to swell, the wide-range (WR) measurement, sensing much more of the total water inventory, will tend to properly measure lower, while the narrow-range instrument may indicate a rising level. Used with the proper filtering and tuning, the wide-ranging signal can be used to offset the narrow-range control loop’s tendency to initially respond in the wrong direction.

Feedwater Valves During start-up, when the boiler tubes and drum are being filled, the feedwater control valve must absorb the large pressure drop from the full feedwater pump discharge or feedwater header to the unpressurized drum (less dynamic head and elevation losses). Initial flows can be relatively small. At operating pressure, the pressure drop across the feedwater control valve is much smaller and the flow much larger. Due to this drastic variation in service conditions, it is common on large units to split feedwater control into a parallel-piped system with two control valves, one for start-up and one for normal operation.

On small to medium-sized units, it is possible to handle the full range of service conditions with one valve, but sizing, trim design, and material selection are critical to the success of control with a single valve. The start-up valve in a parallel two-valve system, or the regulating/start-up valve in a single-valve system, requires an anticavitation trim design (Figure 6.1y in Section 6.1).[18]

The duty required of a feedwater control valve is quite heavy, not only because of the large energy dissipation as the water passes through the valve, but also because the high-purity water normally used in boilers tends to be "metal-hungry." This, combined with high water velocity, produces corrosion, erosion, and cavitation effects that call for a chrome-moly or 400 series stainless steel valve body and trim (or other suitably resistant materials).

A general criteria has been proposed for an acceptable trim exit kinetic energy at all flows, for single-phase fluid applications.[19] The guideline set forth states that valve trim exit kinetic energy should be limited to 70 psi (480 kPa), equivalent to about 100 ft/s (30 m/s), and, for cavitation-prone applications, limited to 40 psi (275 kPa), equivalent to about 77 ft/s (23 m/s). At trim exit velocities of around 150 ft/s (50 m/s), boiler feedwater valves are reported to consistently fail within 3 years. Care in selecting the right valve design can result in much longer service life.

To keep the feedwater flow controller gain independent of load variations, the feedwater control valve should have a linear installed flow characteristic. An equal-percentage or modified equal-percentage inherent characteristic is appropriate for electric utility boilers with dedicated feedwater pumps for each boiler. On systems where multiple feedwater pumps supply a pressure-controlled header, which, in turn, supplies two or more boilers, a linear inherent characteristic may be appropriate. A characterizing positioner can be used to further ensure the linearity of the feedwater control valve. If there is noise in the loop, then dampening may be required, as well.

Valve Sizing For control valve sizing, a system "head" curve showing the relationship between system pressures and capacities should be developed. A typical head curve is shown in Figure 8.6bbb. The head curve demonstrates a basic problem in selecting the flow rate and pressure drop when the feedwater control valve is sized. Capacity C_2 and differential X are the most desirable from a control standpoint. Capacity C_3 and differential Y or Z are often used in an attempt to furnish sufficient water to the drum with safety relief valves blowing. It is not necessary to provide all this capacity in the primary feedwater regulating control valve; this will result in an oversized valve and will degrade control performance. It is not uncommon to see a valve that was designed for more than required capacity and for a 30 psi (207 kPa) differential, operating at a 500 psi (3.45 MPa) differential and at a fraction of its design capacity. Capacity for relief valve service can be provided with bypass valves.

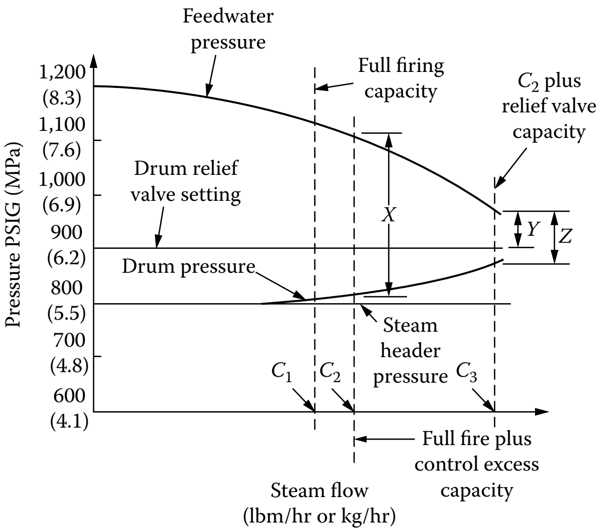

FIG. 8.6bbb
Head curve of the feedwater pump (top), the setting of the relief valve (horizontal) and the drum pressure curve (bottom).

In addition to the feedwater control valve(s) regulating water to the boiler, there is a feedwater recirculation valve controlling flow back to the deaerator (or sometimes the turbine condenser). This valve is a very severe service application, with the valve having to take the extreme pressure drop from the feed pump discharge back to the deaerator. In some plants, this may be from 5500 PSIG (38 MPa) down to 150 PSIG (1 MPa).[18] Cavitation abatement trim is required (Figure 6.1y in Section 6.1). The most efficient control strategy for this valve is to modulate it to maintain the net positive suction head (NPSH) available on the boiler feed pump greater than the NPSH required to prevent cavitation in the pump.

Pump Speed Control Control of pump speed to regulate feedwater flow can be accomplished if the pump is driven by a steam turbine or is furnished with variable-speed electric drive. This can be used in place of a control valve to save pump power on single-boiler systems. In systems in which several boilers are operating in parallel, the speed control can be used to save pump power by controlling the discharge pressure at a constant differential pressure above boiler pressure.

When pump speed is being used in place of a feedwater valve on a single boiler system, a large part of the speed control range is used in developing pump head at low flow. Characterization of the signal is, thus, necessary for good operation and constant gain throughout the operating range. On large units, there is still usually a start-up feedwater control valve for filling and low load, with pump speed taking over as load rises past some threshold.

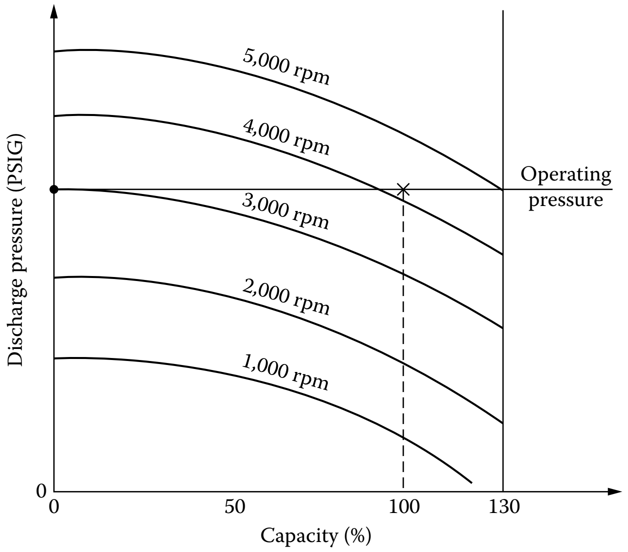

FIG. 8.6ccc
Feedwater pump on speed control. Speed range at 0 capacity to reach operating pressure is 0–3000 rpm. Speed range for 0–100% capacity is 3000–4200 rpm.

Figure 8.6ccc shows typical pump characteristics. Considerable pump speed is necessary just to build pressure in the system, before any significant load is being supplied. (Further discussion of variable-speed pumping is provided in Section 8.34 of this volume and in Section 2.14 of the *Process Measurement and Analysis* volume.)

Steam Temperature Control

The purpose of steam temperature control is to improve the thermal efficiency of steam turbines. Its most common application is for steam turbine electric power generation. The factors affecting steam temperature in a convection-type superheater are superheater area, flue-gas flow pattern across the superheater, flue-gas mass flow, temperature of flue gases leaving the furnace, and steam flow through the superheater. Additionally, furnace temperature affects radiant superheaters. Some superheaters may be designed for a flat curve, combining radiant and convection surface, but most superheaters are the convection type.

Control-station steam temperatures are limited to approximately 1050°F (566°C), whereas those in industrial units may be considerably less. If these temperatures can be controlled with extreme precision, they can be pushed closer to the allowable limits. Temperature can be controlled by adjustment of the amount of recirculation of the flue gas or by "attemperation," which is an energy-wasting method of superheat removal through feedwater spraying.

The required positions of burners or recirculating and bypass dampers as a function of load are well-established for any given boiler design. Therefore, it is common practice to program their positions directly from load. Readjustment to correct for inaccuracies in the program and changes in the characteristics of the boiler is accomplished by feedback control of temperature, using proportional and integral action (Figure 8.5ddd). Being applied through a multiplier, the feedback loop gain varies directly with load, and according to Shinskey this tends to cancel the inversely varying process gain.

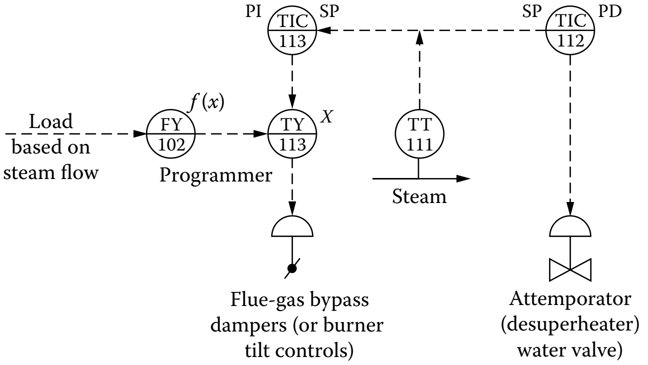

FIG. 8.6ddd
Steam temperature control.

Desuperheater Spray Controls Temperature control by attemperation is more responsive and can be used to supplement flue-gas manipulation. To minimize water usage, however, and to avoid conflict with flue-gas manipulation, proportional-plus-derivative control should be used for attemperation. The controller may be biased to deliver a nominal amount of feedwater at zero temperature deviation. The control system is described in Figure 8.6ddd.

To use a desuperheater spray for steam temperature control, the boiler would normally be provided with added superheater area. Figure 8.6eee demonstrates the effect of the water spray (which is usually between a primary and a secondary superheater section) for temperature control.

Provision must be made to prevent reset windup when in the uncontrolled load range. Control of this system is shown in Figure 8.5fff.

Large boilers may have burners that tilt up and down approximately 30° for steam temperature control. This effectively changes the furnace heat-transfer area, resulting in temperature changes of flue gases leaving the boiler. Spray is frequently used with these systems as an override control. These systems are used on large power plant boilers and normally require the type of controls illustrated in Figure 8.6ddd.

Work efficiencies are maximized by operating at the highest steam temperature at which the metals are capable of operating. In central stations, this limit is 1050°F (566°C); in industrial applications it is lower.[6] If improved control can elevate the TIC set point from 1000°F (538°C) to 1040°F (560°C), this will increase the available work by 17 BTU/lbm (9.4 cal/kg) in the steam.[6]

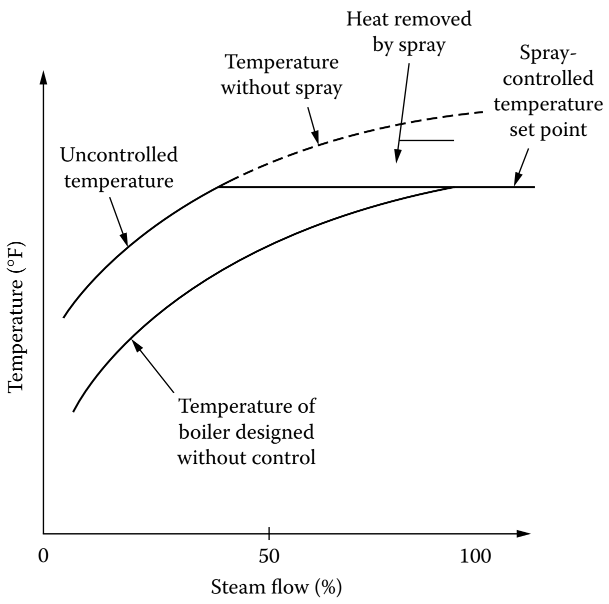

FIG. 8.6eee
Desuperheater characteristics.

Flame temperature does not vary much with load, but the hottest gases do tend to propagate further at higher loads. To increase the steam temperatures at low loads, recirculation blowers or tilting burners are used, which will direct the heat at the superheater sections. At high loads, the rise in the steam temperature is prevented by opening up some of the flue-gas bypass dampers or by desuperheating the steam through attemporation with water. For each boiler, the relationship between load and the required damper, recirculation fan, or burner tilt positions is well-established and, therefore, can be preprogrammed.

Figure 8.6l shows the input signal to the programmer as coming from FT-102, the steam flow transmitter. (Vortex shedding meters are limited to about 750°F, or 400°C.) In other designs, the input to the programmer is taken from the combustion air flow signal (FY-104). In either case, the preprogrammed relationship does need to be adjusted to overcome inaccuracies and changes in boiler characteristics.

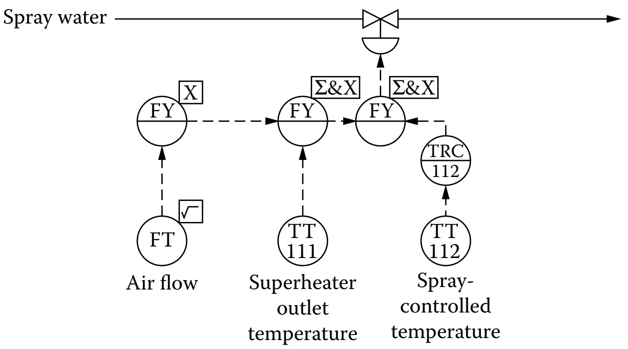

FIG. 8.6fff
Desuperheater spray control system.

TIC-111 throttles the set points of both slave controllers in cascade. Reset windup in TIC-111 is prevented by the external feedback (FB). Without it, windup would occur at low loads, when high temperatures cannot be maintained.[20] The task of temperature control is split between two slaves. The slower of these slaves—the PI controller—modulates burner or damper positions for long-term control. The desuperheater controller is faster; actually, it is faster than its cascade master. In order to use that speed, to minimize water usage (an irreversible waste of available work), and to avoid conflict with the PI controller, only P&D control modes are used.[6]

The desuperheater control loop can also be configured as a cascade loop, as illustrated in Figure 8.6ggg. Here, the

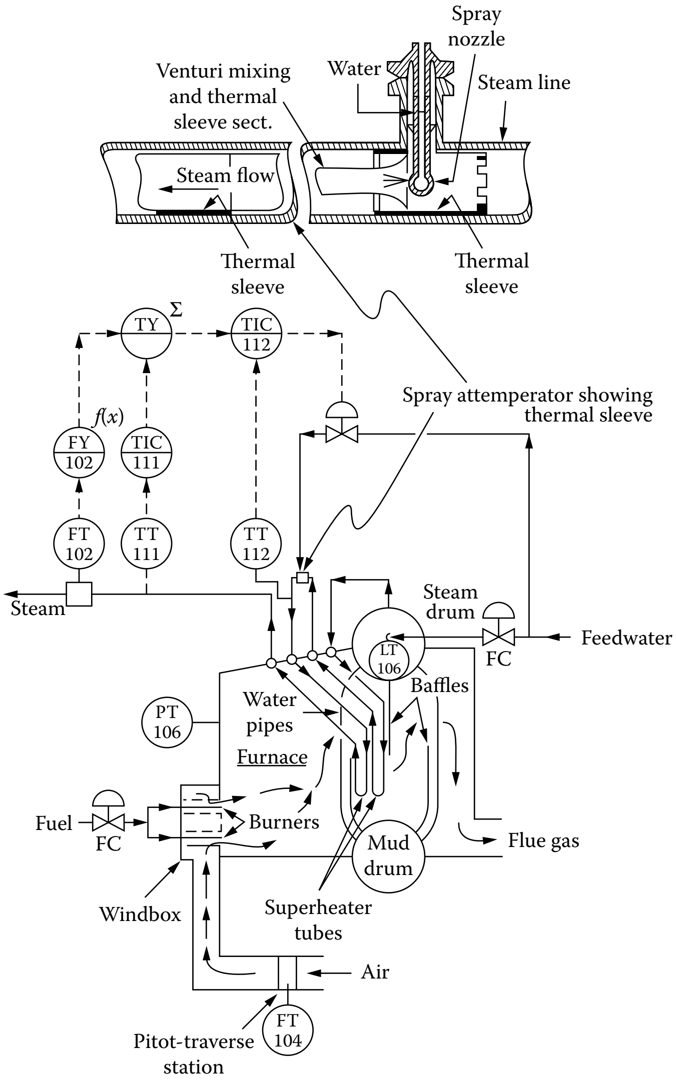

FIG. 8.6ggg
Cascade configuration for controlling the desuperheater control valve.

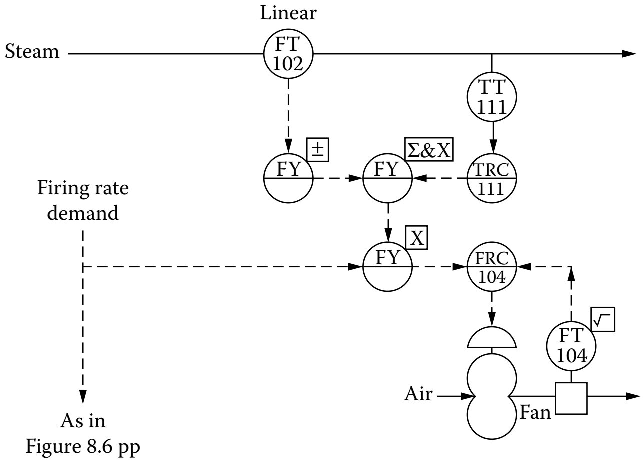

FIG. 8.6hhh
Steam temperature control by adjustment of excess air.

saturated steam from the steam drum is returned back into the furnace, where it is superheated. If the amount of superheat is excessive, then water is sprayed into the steam, and it is returned once more to the furnace to make sure that all water is vaporized.

The slave temperature controller (TIC-112) is placed right after the spray attemperator, while the cascade master (TIC-111) is located at the steam outlet. In Figure 8.6ggg, the feedforward correction is based on steam flow (FT-102), and the relationship between load and uncontrolled temperature (Figure 8.6eee) is predicted by the FY-102 function relay.

Cooling by Variable Excess Air Because mass flow of flue gas affects steam temperature, variation in excess combustion air can be used to regulate steam temperature. This method may be used on a boiler that was not specifically designed for temperature control. Although increasing excess air flow increases boiler stack heat losses, turbine thermal efficiency will also increase, and maintaining steam temperature can provide the greater economic benefit. The control arrangement in Figure 8.6hhh implements this method.

Flue-Gas Temperature

Flue-gas temperature is important for two reasons: first, as an indicator of boiler efficiency, and second, because if it drops below the dew point, the condensate formed will dissolve the oxides of sulfur in the flue gas, and the resulting acid will cause corrosion.

Figure 8.6l shows the temperature control loop TIC-110. The purpose of TIC-110 is to keep the flue gas dry and above its dew point. The flue-gas temperature at the cold end of the stack is usually arrived at as the average of several sensor outputs, measuring the temperature at various points in the same plane. When this averaged temperature drops near the dew point, TIC-110 will start increasing the set point of the air preheaters (TIC-114). Through the use of steam or glycol coils in the combustion air, the inlet air temperature to the boiler is increased, which in turn raises the flue-gas temperature.

Integration of Loops

Loops and subsystems can be combined to create an integrated control system (Figure 8.6l). Other combinations of the subsystems can similarly be put together to form a coordinated system. When designing, it is advisable to break the overall system down into these subsystems and examine them individually. Only then should the subsystems be put together into the total system.

Major design and operation problems in complex systems are created by inadvertently creating additional interaction, positive feedback, or tracking and initialization problems. In a complex system, as a result of adding, subtracting, multiplying, dividing, and comparing control signals or transmitter signals, it is difficult to get the system on “automatic” control easily and quickly.

The chief points to remember include

1. The systems often interact, e.g., air flow affects steam temperature, feedwater flow affects steam pressure, and fuel flow affects drum level and furnace draft.
2. For flexibility and rangeability, linear flow signals are necessary. Control valves and piston operators need linearizing positioners.
3. Fuels should be totalized on an air-required basis.
4. Tie-back arrangements, which simplify the task of getting quickly on automatic control, are very important in complex systems.
5. The flows of fuel and air should be controlled such that the flow rates reaching the burner always represent a safe combination.

POLLUTION CONTROL

Today, most electric utility-related environmental regulation is directed at reducing emissions of sulfur dioxide (SO_2) and nitrogen oxides (NO_x) as well as carbon dioxide (CO_2), mercury, volatile organic compound (VOC), particulate, stack opacity, wastewater, and other greenhouse gas pollutants. NO_x, CO_2, particulate, and opacity are considerably influenced by the boiler design, operation, and control. However, reduction or removal of some of these pollutants from the flue gas often must be accomplished between the boiler and the stack.

Electrostatic precipitators are commonly used for removal of particulate. Scrubbers are commonly used for removal of particulate and SO_2. From a process control viewpoint, two commonly regulated pollutants, NO_x and SO_2, are of particular interest. Their formation and control will be discussed in more detail.

NO_x Control[21,22]

Reduction of NO_x emissions is a major goal of the Clean Air Act amendments because of its known role in the formation of ground-level ozone and acid rain. A number of NO_x control technologies have been successfully applied to utility and industrial boilers. (For a discussion of the various nitrogen oxide sensors and analyzers, refer to Section 8.37 in Chapter 8 of the first volume of this handbook.)

NO_x Formation NO_x is formed by two primary mechanisms, resulting in thermal NO_x and fuel-bound NO_x. A third mechanism, “prompt NO_x,” also accounts for a minor share of NO_x formation. Thermal NO_x formation occurs only at high flame temperatures when dissociated nitrogen from combustion air combines with oxygen atoms to produce oxides of nitrogen, mainly NO and NO_2. Formation of thermal NO_x increases with combustion temperature and the presence of oxygen. However, the reactions are reversible.

Thermal NO_x usually comprises 25% of emission for a coal-fired plant, but the majority of emissions for gas-fired combustion. Fuel-bound NO_x formation is not limited to high temperature, but is dependent upon the nitrogen content of the fuel. In addition to the high flame temperature, quantity of excess air, nitrogen content in the fuel, the characteristics of the combustion process and the residence time at high temperature also play important roles in NO_x formation.

NO_x Reduction Strategies The best way to minimize NO_x formation is to reduce flame temperature, reduce excess oxygen, or burn low-nitrogen-containing fuels. NO_x reduction strategies and technologies for combustion sources can be classified by three major categories: precombustion processing (fuel switching), combustion modifications, and post-combustion processing. Combustion modifications include, but are not limited to, derating, burner system modification, low NO_x burners, and diluent injection. Major post-combustion processing techniques include selective catalytic reduction (SCR) and selective noncatalytic reduction (SNCR).

Low NO_x Burners These burners effectively reduce the formation of fuel and thermal NO_x. These burners generate air-fuel mixing patterns that lower peak flame temperature and oxygen concentrations. Reducing local oxygen concentration can be achieved by introducing flue-gas recirculation zones, air or fuel staging combustion zones, or flameless oxidation burners. Installation of these types of burners can reduce NO_x emissions by up to 50%.

Injection of water, steam, or flue gas (*diluent injection*) also helps to lower the NO_x level. By injecting a small amount of water or steam into the immediate vicinity of the flame, the flame will be cooled and the local oxygen concentration reduced. This would result in decreased formation of thermal and fuel-bound NO_x. However, this process generally lowers the combustion efficiency of the unit.

Flue gas can also be injected with the influent gas ahead of the burner to reduce the prompt NO_x formation. Advanced overfire air, in which air is injected in the combustor, can usually reduce NO_x emissions by 10–25%.

Excess air optimization also benefits NO_x reduction (see the forthcoming paragraphs on boiler optimization).

Selective Catalytic Reduction Claimed to be the most effective technology currently available for NO_x removal, selective catalytic reduction is a post-formation NO_x control technology that uses a catalyst to facilitate a chemical reaction between NO_x and ammonia to produce nitrogen and water. This process is implemented by injecting ammonia/air or ammonia/steam mixture into the exhaust gas, which then passes through a catalyst. The major NO_x reduction reaction is often presented as follows:

$$4NO + 4NH_3 + O_2 \rightarrow 4N_2 + 6H_2O \qquad \textbf{8.6(3)}$$

To optimize the reaction, the temperature of the exhaust gas must be in a certain range when it passes through the catalyst bed. Depending on the catalyst type (usually vanadium/titanium) and the location (usually economizer outlet), the typical flue-gas temperature should be in the range of 600–750°F (315–400°C). Removal efficiencies above 80% can be usually achieved, regardless of the combustion process or fuel type used.

Among its disadvantages, SCR requires additional space for the catalyst and reactor vessel, as well as an ammonia storage, distribution, and injection system. In the United States, the SCR control system is designed for operation during the ozone season (May–October), and for bypass operation in the non-ozone season.

The SCR typically consists of an NH_3 injection flow control system, an ammonia injection grid, and inlet and outlet NO_x monitoring equipment. Precise control of ammonia injection is critical. An insufficient amount of ammonia can result in unacceptable high NO_x emission rates, while excess ammonia can lead to ammonia “slip,” or the venting of undesirable ammonia to the atmosphere. NO_x reduction efficiency is directly proportional to the NH_3:NO_x ratio up to about 90%.

Specifically, the stoichiometry of the reaction is such that 1 mole of NH_3 reacts with 1 mole of NO_x, producing nitrogen (N_2) and water (H_2O). Adjustments to the molar ratio must be made to account for ammonia slip, i.e., the portion of the injected NH_3 that passes through the SCR unreacted.

In practice, as illustrated in Figure 8.6iii, the NH_3 flow control system anticipates the ammonia demand for NO_x emissions based on the boiler load (or the reactor inlet NO_x). This ammonia demand (FY-203) can be used to derive the ammonia feed rate and anticipates demand changes due to load swings. This ammonia demand signal is then trimmed using a feedback controller (XIC-202) that compares the

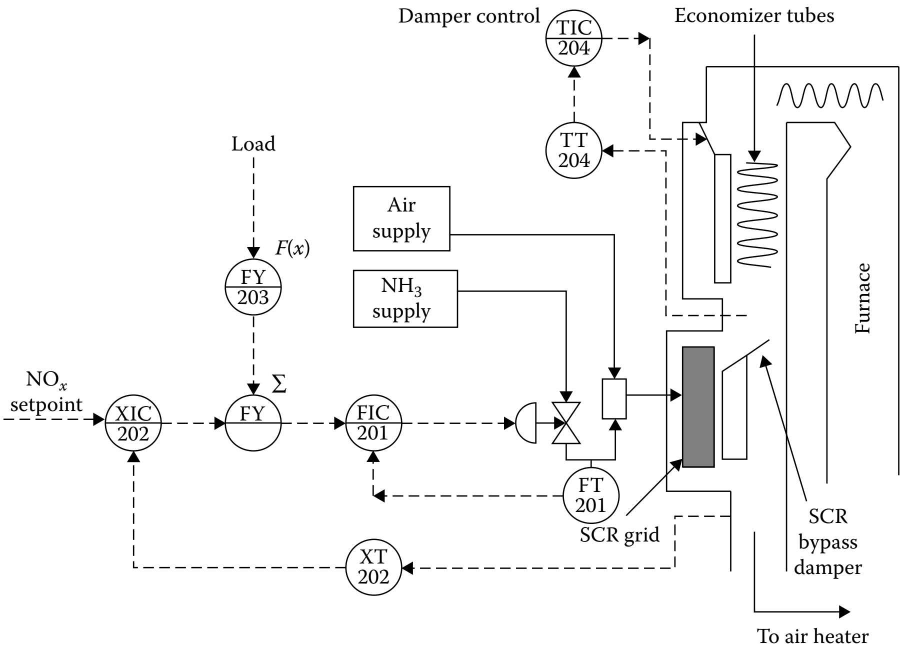

FIG. 8.6iii
NO_x control by using the selective catalytic reduction (SCR) process.

measured SCR outlet NO_x to the required outlet NO_x. Finally, the resulting ammonia demand signal is compared to the measured ammonia flow rate. The difference is conditioned by another slave controller (FIC-201), and the resulting control signal is used to modulate the ammonia flow control valve.

In order to maintain the flue-gas temperature above the minimum required, a set of dampers and a divider are often installed in the economizer, concurrently with the SCR project. The dampers will block only a portion of the economizer, restricting the flue-gas flow that passes through the economizer tubes. As the dampers close, they will force more flow through the open section, effectively reducing the area of economizer tubes that are exposed to the flue-gas flow. This control can be automatic (TIC-204), which compares the economizer outlet temperature (TT-204) to the set point and adjusts the position of the dampers accordingly.

Interlock functions need to be set up to prevent the ammonia system from starting or from continuing operation in abnormal situations. Important failures include, but are not limited to, NH_3 vaporizer outlet temperature too low, flue-gas flow too low, SCR flue-gas inlet temperature too low, dilution air flow too low, or vaporizer ambient NH_3 level too high.

Selective Noncatalytic Reduction Utility applications of SNCR processes involve the injection of a nitrogen-based reagent into the upper furnace or convective sections, where the injected chemical reacts with NO_x to form molecular nitrogen and water vapor. The most common types of reagent used commercially on large utility boilers are urea and ammonia. The optimum injection temperature when using ammonia is 1850°F (1010°C), at which 60% NO_x removal can be approached. The optimum temperature range is wider when using urea. Below the optimum temperature range, ammonia is formed, and above, NO_x emission actually increases.

The success of NO_x removal depends not only on the injection temperature, but also on the ability of the agent to mix sufficiently with flue gas. Compared to SCR, this technology is relatively capital inexpensive and used for smaller boilers. Typical NO_x reduction efficiency is 30–60%. In principle, the general control philosophy of an SNCR system is similar to the SCR control.

SO_2 Control

The formation of sulfur dioxide (SO_2) is a major concern with coal-fired boilers, due to the relatively high sulfur content in the fuel. For these units, post-combustion removal of SO_2 is realized through the flue-gas desulfurization (FGD) system. FGD systems can be classified into two basic categories: wet scrubbers and dry scrubbers.

Wet SO_2 scrubbers are the most widely used FGD technology for SO_2 control. Calcium-, sodium-, and ammonia-based sorbents are normally used in a slurry mixture, which is injected into a specially designed vessel to react with SO_2 in the flue gas. The most popular sorbent in operating wet scrubber is limestone, followed by lime. They are favored because of their availability and relative low cost. The overall

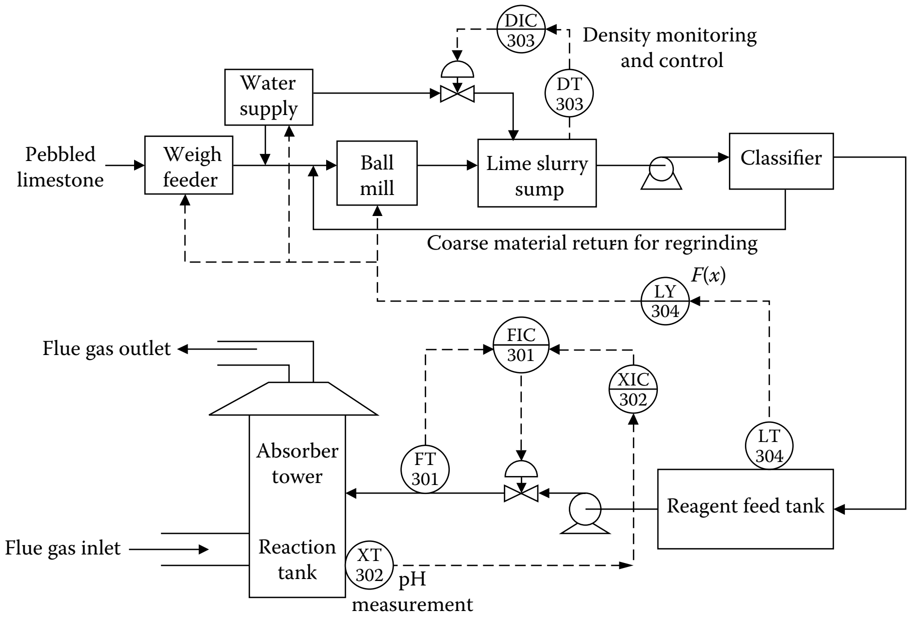

FIG. 8.6jjj
The control of a flue-gas desulferization (FGD) system.

chemical reaction that occurs with a limestone or lime sorbent can be expressed in a simple form as:

$$SO_2 + CaCO_3 = CaSO_3 + CO_2 \qquad \textbf{8.6(4)}$$

A typical FGD system should consist of several major subsystems, i.e., the limestone grinding and supply system, reagent feed system, absorber/reaction tank system, forced oxidation system, process water distribution system, dewatering system, filtrate system, and possibly, flue-gas reheat system. A simplified FGD system is illustrated in Figure 8.6jjj.

The limestone grinding loop is designed to supply limestone slurry containing 40% solids to the reagent feed loop. Usually, pebbled limestone from the limestone storage silo is conveyed by a variable-speed conveyor to the ball mill. Limestone is mixed with water and ground in the ball mill. The resultant slurry flows from the ball mill into the mill slurry sump, where it is pumped to the riser in the classifier. The slurry then flows from the riser into the cyclones that separate the coarse and fine slurry. The overflow (at about 40% solids) goes to the reagent feed tank, and the underflow goes back to the ball mill for regrinding. The reagent feed tank, which stores the slurry, allows for extended periods of operation with the ball mill out of service.

The SO_2/reagent reaction occurs in the absorber/reaction tank. The major equipment associated with the absorber loop typically are absorber feed tank (reaction tank), absorber spray pumps, wetted film contactor and its associated pump, and demister. The goal of the absorber loop is to absorb the SO_2 in the flue gas in the spray tower and wetted film contactor sections and precipitate calcium sulfite in the reaction tank. This is accomplished by controlling the reaction tank at proper pH level and density.

Reaction tank pH is the most important process variable in terms of total tower SO_2 removal efficiency and scale control. Operating at a lower pH would decrease the efficiency and increase the tendency of scale formation. Higher pH operation would cause high limestone consumption overall and decrease by-product quality. The pH value can be controlled by adjusting the reagent feed valve. The master control (XIC-302) compares the difference between the desired pH set point and the measured pH in the reaction tank. The output becomes the set point to the inner-loop slave controller (FIC-301), which compares this set point to the actual measured lime slurry flow rate and sends a command signal to adjust the valve opening.

Operating at lower density would remove valuable seed crystals from circulation, making control of the crystal types and the formation location difficult. Operation at a much higher density would increase pump horsepower requirements. Operation within a range of 5–15% solids is tolerable. A density element (DT-303) can be located in the mill slurry sump to measure the density of the mill slurry. Dilution water can be fed into the mill slurry sump to control the density via DIC-303.

Because the lime slurry flow from the reagent feed tank to the reaction tank results in a rising and falling level in the reagent feed tank, the reagent feed tank level control is also important. As shown in Figure 8.8jjj, the level in the reagent feed tank can be controlled by the signals (LT-304 and LY-304) transmitted to the ball mill, limestone conveyors, and ball mill water supply to adjust the limestone feeding and grinding. The reaction tank level is often monitored. However, it can also be controlled by adjusting the reagent slurry flow and the tank makeup water flow, subject to tank pH and density constraints.

Other important control loops (not shown in the figure) may involve the oxidation air blower control and the flue-gas reheat control. The oxidation air system normally consists of several air compressors and is designed to oxidize the solids in the reaction tank. The purpose of oxidizing the solids is to convert calcium sulfite ($CaSO_3$) to calcium sulfate ($CaSO_4$), which dewaters much more easily to achieve a drier waste product. The automatic control can be placed either on the oxidation air blower discharge pressure or the absorber mass flow.

Sometimes, a reheat system is designed to increase the temperature of the gas in the absorber outlet duct. To prevent acid condensation and to allow the gas to have enough buoyancy, the outlet temperature must be maintained at a minimum of around 180°F (82°C). Reheating of the gas is accomplished by passing the gas exiting the tower through reheater coils that are internally heated with steam. Whenever the flue-gas temperature exiting the reheater drops below the desired set point, the appropriate steam flow valve starts to open and effectively raises the temperature of the flue gas as it exits the absorber tower.

In practice, gypsum ($CaSO_4$), the by-product resulting from this process, can be reused in other applications. Modern post-combustion SO_2 technologies, however, consume as much as 1% of the energy produced in coal-fired power plants.

OPTIMIZATION OF BOILERS

The purpose of optimization is to continuously maximize the boiler efficiency, as variations occur in the load, fuel, ambient, and boiler conditions. When the yearly boiler fuel cost is in the millions, even a few percentage points of improved efficiency can justify the costs of added instruments and controls. In the following paragraphs, a number of optimization techniques will be described. The various goals of optimization include:

1. Minimize excess air and flue-gas temperature
2. Minimize steam pressure
   a. Turbines thereby open up turbine governors
   b. Reduce feed pump discharge pressures
   c. Reduce heat loss through pipe walls
3. Minimize blowdown
4. Measure efficiency
   a. Use the most efficient boilers
   b. Know when to perform maintenance
5. Provide accountability
   a. Monitor losses
   b. Recover condensate heat

The first three methods of optimization are achieved by closed-loop process control and can be superimposed upon the overall boiler control system shown in Figure 8.6l. The tie-in points for these optimization strategies are also shown in that figure. The benefits of the last two methods (efficiency and accountability) are not obtained in the form of closed-loop control signals, but they do contribute to better maintenance and better understanding of heat losses and equipment potentials.

Excess Air Optimization

If a boiler is operating on a particular fuel at a specific load, it is possible to plot the various boiler losses as a function of air excess or efficiency, as shown in Figure 8.6kkk. The sum total of all the losses is a curve with a minimum point. Any process that has an operating curve of this type is an ideal candidate for instrumental optimization. Such process control systems operate by continuously determining the

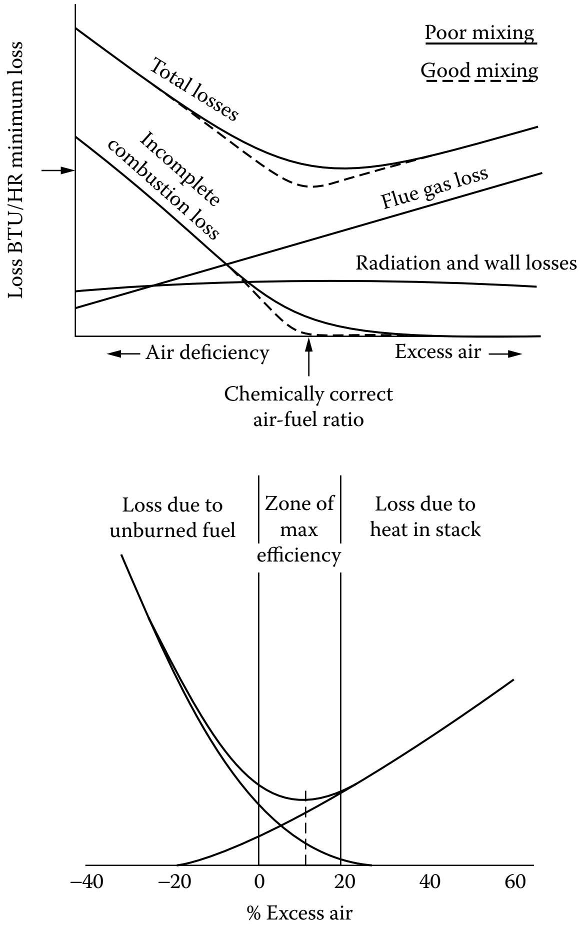

FIG. 8.6kkk

Boiler losses can be plotted as a function of excess air (top). The minimum of the total loss curve of a boiler is the point where optimized operation is maintained (bottom). Most efficient operation of a boiler occurs when the amount of excess air in the stack balances the losses in unburned fuel. (Adapted from Reference 2.)

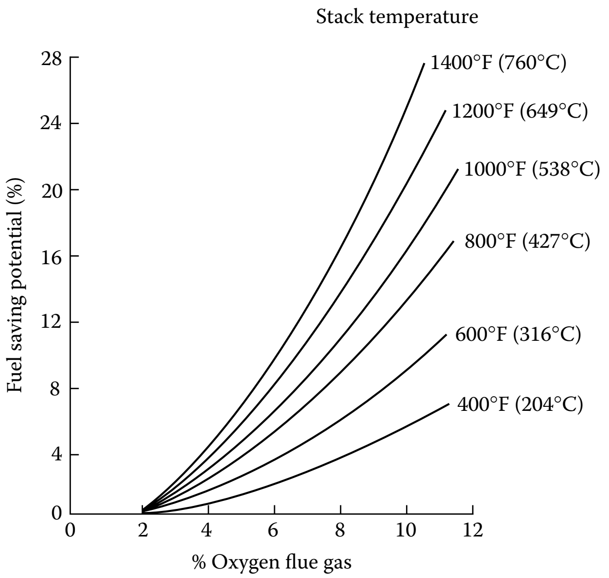

FIG. 8.6lll
The percentages of fuel-saving potentials in a boiler that operates most efficiently at 400°F stack gas temperature and 2% excess oxygen.

minimum loss point of the system at that particular load and then shifting the operating conditions until that point is reached.

As shown in Figure 8.6kkk, the radiation and wall losses are relatively constant. Most heat losses in a boiler occur through the stack. Under air-deficient operations, unburned fuel leaves, and when there is an air excess, heat is lost as the unused oxygen and its accompanying nitrogen are heated up and then discharged into the atmosphere. The goal of optimization is to keep the total losses at a minimum. This is accomplished by minimizing excess air and by minimizing the stack temperatures (Figure 8.6lll).

The minimum loss point in Figure 8.6kkk is not where excess oxygen is zero. This is because no burner is capable of providing perfect mixing. Therefore, if only as much oxygen would be admitted into the furnace as is required to convert each carbon molecule into CO_2, some of the fuel would leave unburned, as not all O_2 molecules would find their corresponding carbon molecules. This is why the theoretical minimum loss point shown by the dotted line in Figure 8.6kkk is to the left of the actual one. This actual minimum loss or maximum efficiency point is found by lowering the excess oxygen as far as possible, until opacity or CO readings indicate that the minimum has been reached. At this minimum loss point the flue-gas losses balance the unburned fuel losses.

Assume that for a particular boiler design using a particular fuel at normal loading, the optimum flue-gas temperature is 400°F (204°C) with 2% oxygen. The potential fuel savings through optimization can be estimated by determining the fuel loss using Figure 8.6lll, where the present, unoptimized stack gas conditions are entered.

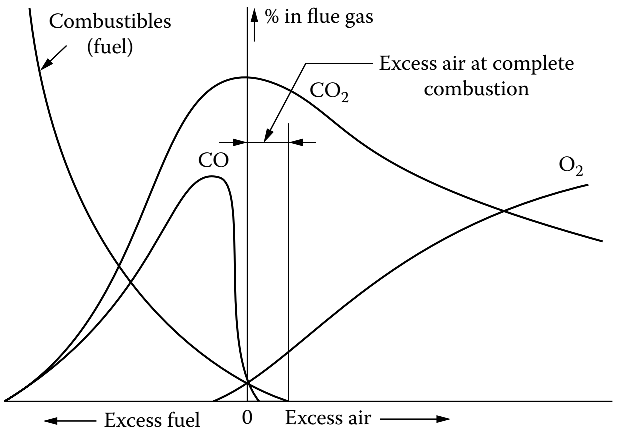

FIG. 8.6mmm
The major components of the flue gas are oxygen, carbon dioxide, carbon monoxide, and unburned hydrocarbons. (Adapted from Reference 2.)

Flue-Gas Composition Figure 8.6mmm shows the composition of the flue gas as a function of the amount of air present. The combustion process is usually operated so that enough air is provided to convert all the fuel into CO_2, but not much more. This percentage of excess oxygen is *not* a constant. It varies with boiler design, burner characteristics, fuel type, air infiltration rates, ambient conditions, and load.

The top portion of Figure 8.6nnn shows that the percentage of excess air must be increased as the load drops off. This is because at low loads the burner velocities drop off and the air flow is reduced, while the furnace volume remains constant. This reduces turbulence and lowers the efficiency of mixing between the fuel and the air. This loss of mixing efficiency is compensated for by the higher percentage of excess oxygen admitted at low loads.

The upper curve shown in Figure 8.6nnn theoretically illustrates the relationship between the excess O_2 requirement and load, and the lower plot provides actual test data for a specific boiler. Because each boiler has its own unique personality, this relationship must be experimentally determined. Once established, it can be used with a fair degree of confidence, although small shifts are still likely to occur as the equipment ages.

A simple demonstration of this law is the union of 1 lb of carbon with oxygen to produce a specific amount of heat (about 14,100 BTU, or 3,553 kcal). The gaseous product of combustion, CO_2 can be formed in one or two steps. If CO is formed first, it produces a lesser amount of heat (about 4,000 BTU, or 1,008 kcal), which, when it is converted to form CO_2, releases an additional 10,100 BTU (2,545 kcal). The sum of the heats released in each of these two steps equals the 14,100 BTU (3,553 kcal) that evolve when carbon is burned in one step to form CO_2 as the final product.

The Effect of the Fuel Used In a boiler furnace (where no mechanical work is done), the heat energy evolved from the

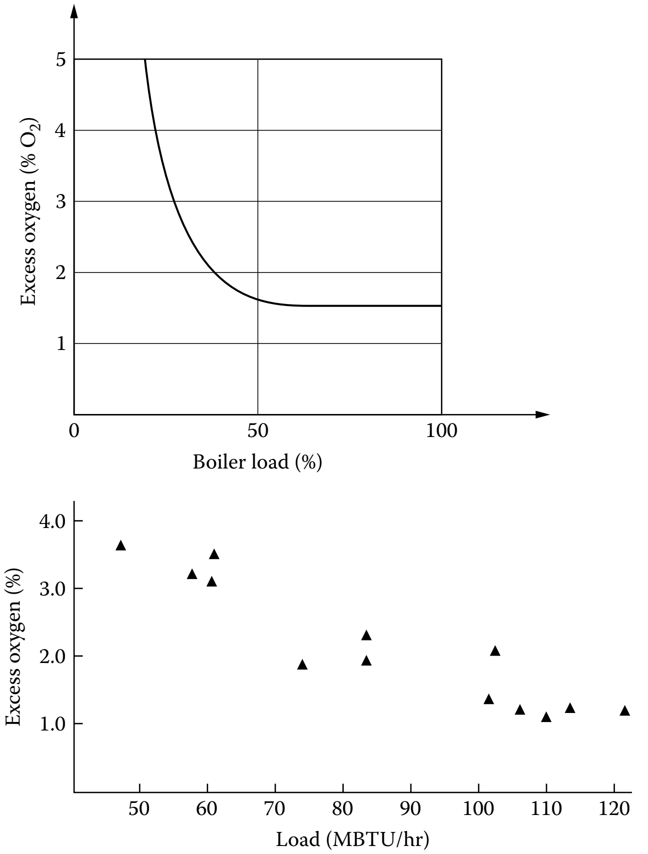

FIG. 8.6nnn

The top portion of this figure shows the theoretical relationship between load and excess oxygen. The bottom portion of the figure shows the test-based relationships between load and O_2. (Adapted from Reference 33.)

combustion of the fuel with oxygen depends on the heating value (calorific value) of the fuel, the degree to which the combustion reaction goes to completion.

Because of the weight ratios of oxygen and nitrogen in air (0.2315 and 0.7685, respectively), to supply 1 lb (0.45 kg) of oxygen for combustion it is necessary to supply 1/.2315 = 4.32 lb (1.96 kg) of air. In this amount of air, there will be 4.32 × .7685 = 3.32 lb (1.5 kg) nitrogen, which does not enter directly into the combustion process but which nevertheless remains present.

When burning carbon to carbon dioxide, 12 parts by weight of carbon (the approximate molecular weight of C) combine with 32 parts by weight of oxygen (the molecular weight of O_2) to form 44 parts by weight of carbon dioxide (the approximate molecular weight of CO_2). By simple division, 1 lb (0.45 kg) of carbon plus 2.66 lb (1.2 kg) of oxygen will yield 3.66 lb (1.66 kg) of carbon dioxide.

The theoretical amount of air required for the combustion of a unit weight of fuel can be calculated as follows:[4]

$$A{:}F = \frac{2.66\text{C} + 7.94\text{H}_2 + 0.998\text{S} - \text{O}_2}{0.232} \qquad \textbf{8.6(5)}$$

where $A{:}F$ is the air/fuel ratio, and C, H_2, S, and O_2 are the mass fractions (as-burned basis) of carbon, hydrogen, sulfur, and oxygen, respectively, in the fuel.

If theoretical or total air is defined as the amount required on the basis of the above equation, then excess air is the percentage over that quantity. Table 8.6ooo lists the excess air ranges required to burn various fuels. It can be seen that excess air requirement increases with the difficulty to atomize the fuel for maximum mixing.

Figure 8.6ppp also illustrates that gases require the lowest and solid fuels the highest percentage of excess oxygen for complete combustion. The ranges in Table 8.6ooo and the curves in Figure 8.6ppp also illustrate that as the load drops off, the percentage of excess oxygen needs to be increased.

Figure 8.6qqq illustrates the relationship between excess air and excess oxygen for a particular fuel. The optimum

TABLE 8.6ooo

Usual Amount of Excess Air Supplied to Fuel-Burning Equipment[*]

Fuel	*Type of Furnace or Burners*	*Excess Air %*
Pulverized coal	Completely water-cooled furnace—wet or dry-ash-removal	15–20
	Partially water-cooled furnace	15–40
Crushed coal	Cyclone furnace—pressure or suction	13–20
	Fluidized bed	15–20
Coal	Spreader, vibrating, and chain grate stokers	25–35
	Underfeed stokers	25–40
Fuel oil	Register-type burners	3–15
	Multifuel burners and flat flame	10–20
Acid sludge	Cone and flat flame-type burners, steam-atomized	10–15
Natural, coke oven, and refinery gas	Register-type burners	3–15
	Multifuel burners	7–12
Blast-furnace gas	Register-type burners	15–30
	Intertube nozzle-type burners	15–18
Wood/bark	Traveling grate, water-cooled vibrating grate	20–25
	Fluidized-bed	5–15
Refuse-derived fuels	Completely water-cooled furnace—traveling grate	40–60
Municipal solid waste	Water-cooled refractory covered furnace reciprocating grate	80–100
	Rotary kiln	60–100
Bagasse	All furnaces	25–35
Black liquor	Recovery furnaces for kraft pulping processes	15–20

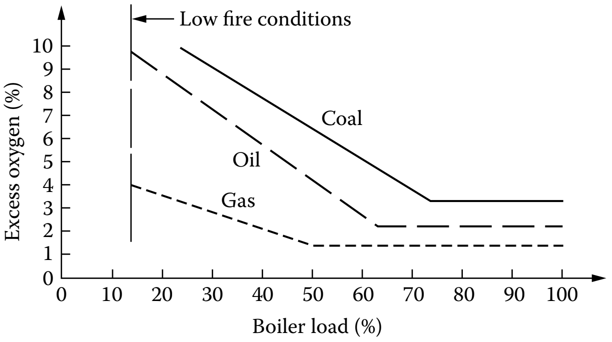

FIG. 8.6ppp
The ideal amount of excess oxygen provided to a boiler depends on the load as well as on the fuel properties.

excess oxygen percentages for gas, oil, and coal are around 1, 2, and 3%, respectively.

Detectors of Flue-Gas Composition The analyzers available for the detection of carbon dioxide, carbon monoxide, and excess oxygen are discussed in Sections 8.9, 8.10, and 8.42, respectively, in Chapter 8 in Volume 1 of this handbook. As shown in Figure 8.6mmm, excess air can be correlated to O_2, CO, CO_2, or combustibles present in the flue gas. Combustibles are usually detected either as unburned hydrocarbons or in the form of opacity. These measurements are not well suited as the basis for optimization, because the goal is not to maintain some optimum concentration, but to eliminate combustibles from the flue gas. Therefore, such measurements are usually applied as limit overrides.

The measurement of CO_2 is not a good basis for optimization either, because, as shown in Figure 8.6rrr, its relationship to excess O_2 is very much a function of the type of fuel burned. The CO_2 concentration of the flue gas also varies slightly with the CO_2 content of the ambient air.

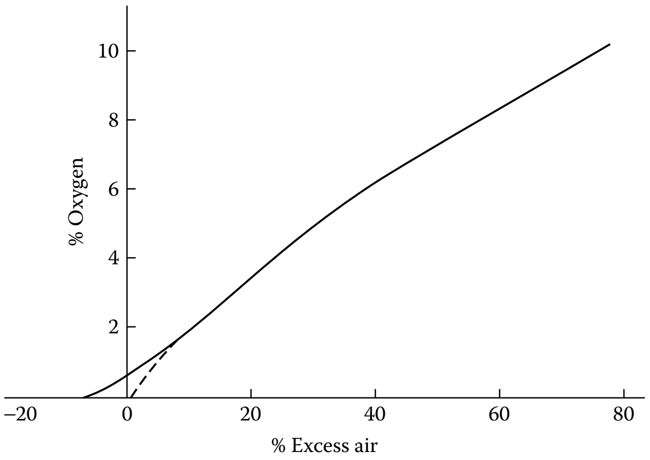

FIG. 8.6qqq
The amounts of oxygen and excess air in the flue gas can be correlated as shown.[2]

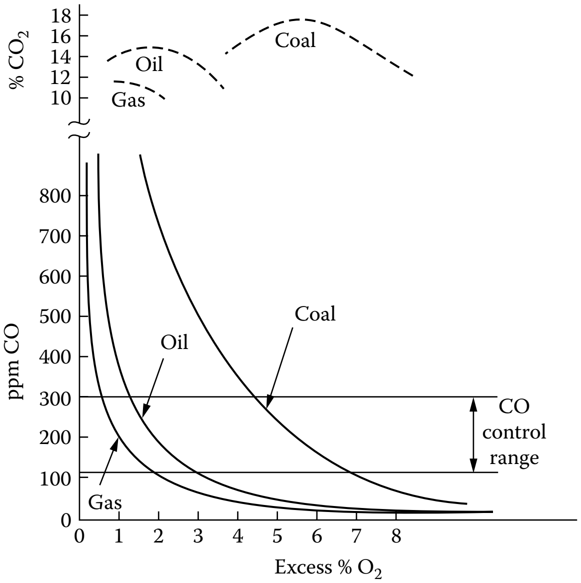

FIG. 8.6rrr
The relationship between excess O_2 and CO or CO_2 in the flue gas of a boiler operated at a constant load is a function of the type of fuel burned.[24]

It can also be noted from Figure 8.6mmm that CO_2 is not a very sensitive measurement. Its rate of change is rather small at the point of optimum excess air. In fact, the CO_2 curve is at its maximum point when the combustion process is optimized.

Excess O_2 as the basis of boiler optimization is also a relatively insensitive measurement, but it is popular. It uses zirconium oxide probes. In order to minimize duct leakage effects, the probe should be installed close to the combustion zone (Figure 8.6sss) but still at a point where the gas temperature is below that of the electrically heated zirconium oxide detector.

The flow should be turbulent at the sensor location, if possible, to ensure that the sample will be well mixed and representative of flue-gas composition. The output signal of these zirconium oxide probes is logarithmic. According to Shinskey[6] this is desirable. The correct location of the probe will reduce but will not eliminate the bias error caused by air infiltration. Ambient tramp air enters the exhaust ductwork (which is under vacuum) not only through leakage but also to cool unused burners and registers. The O_2 probe cannot distinguish the oxygen that entered through leakage from excess oxygen left over after combustion.

Another limitation of the zirconium-oxide fuel cell sensor is that it measures *net* oxygen. In other words, if there are combustibles in the flue gas, they will be oxidized on the hot surface of the probe and the instrument will register only that oxygen that remains *after* this reaction. This error is not

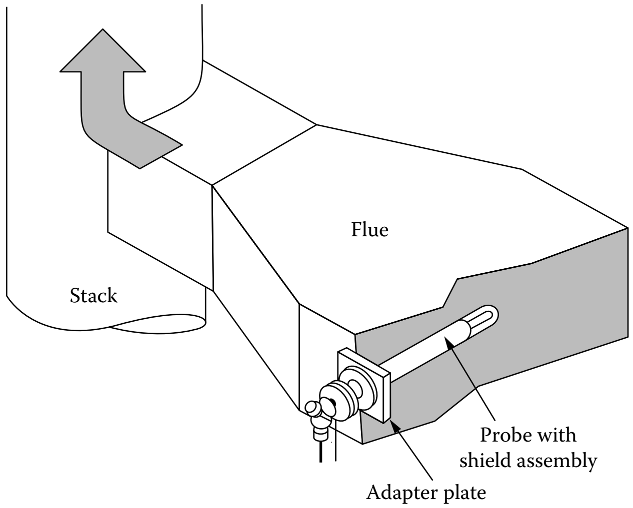

FIG. 8.6sss
The probe-type oxygen analyzer should be installed close to the combustion zone but at a point where the temperature is below the limit for the zirconium oxide detector.

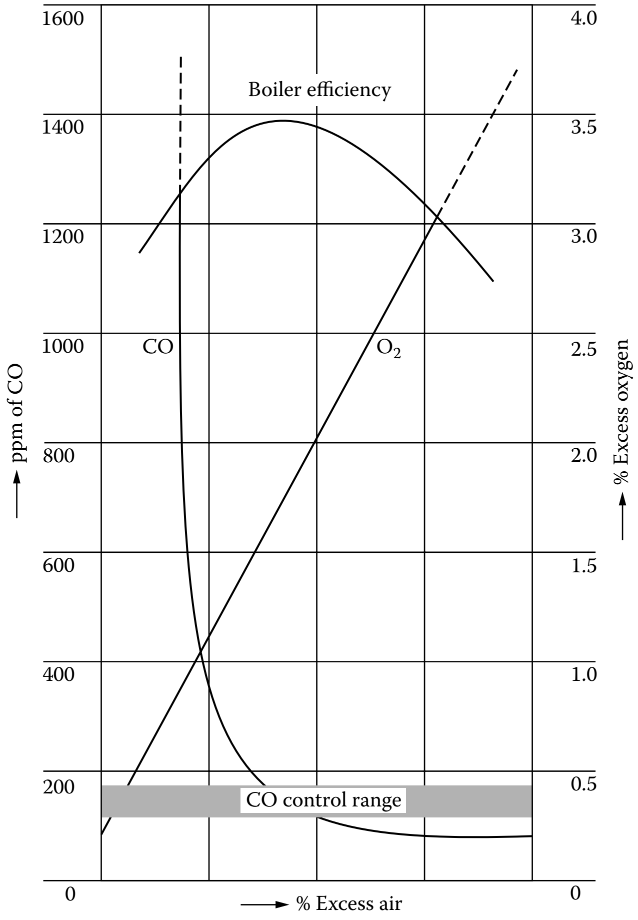

FIG. 8.6ttt
Gas burning boiler efficiency is maximum when CO is within the control range shown. (Courtesy of Econics Corp.)

substantial when the total excess oxygen is around 5%, but in optimized boilers in which excess oxygen is only 1%, this difference between total and net O_2 can cause a significant error. As infiltration tends to cause an error toward the high side, while the fuel-cell effect results in a low reading, the amount of uncertainty is too high to rely on O_2 sensors alone when maximum efficiency is desired.

Other limitations of optimization based on excess oxygen include the fact that local problems at the burners can result in incomplete combustion, even when the excess oxygen in the flue gas is normal. Another limitation is the precision and accuracy of such excess oxygen curves, as shown in Figure 8.6nnn. This precision is a function not only of the resolution at which the curve was prepared but also of changes in fuel composition and boiler conditions.

CO Measurement As shown in Figure 8.6mmm, the most sensitive measurement of flue-gas composition is the detection of carbon monoxide. As can be seen from Figures 8.6rrr and 8.6ttt, optimum boiler efficiency can be obtained when the losses due to incomplete combustion *equal* the effects of excess air heat loss. These conditions prevail at the "knee" of each curve. While the excess O_2 corresponding to these "knee" points varies with the fuel, the corresponding CO concentration is relatively constant.

Theoretically, CO should be zero whenever there is oxygen in the flue gas. In actual practice, maximum boiler efficiency can usually be maintained when the CO is between 100 and 400 ppm. CO is a very sensitive indicator of improperly adjusted burners; if its concentration rises to 1000 ppm, that is reliable indication of unsafe conditions. Because CO is a direct measure of the completeness of combustion and nothing else, it is also unaffected by air infiltration, other than the dilution effect.

For these reasons, control systems utilizing the measurement of both excess O_2 and carbon monoxide can optimize boiler efficiency, even if load, ambient conditions, or fuel characteristics vary. Also, when these systems detect a shift in the characteristic curve of the boiler, that shift can be used to signal a need for maintenance of the burners, heat-transfer units, or air and fuel handling equipment.

Nondispersive infrared (IR) analyzers can be used for simultaneous in situ measurement of CO and other gases or vapors such as that of water. This might signal incipient tube leakage. Most IR sensors use a wavelength of 4.7 μ for CO detection, because the absorption of CO peaks at this wavelength, whereas that of CO_2 and H_2O does not. CO_2 is also measured and is used to determine the dilution compensation factor for CO.

The CO analyzers cannot operate at high temperatures and therefore are usually located downstream of the last heat exchanger or economizer. At these points, the flue-gas dilution due to infiltration is frequently high enough to require compensation. The measurement of CO_2 is used to calculate this compensation factor.

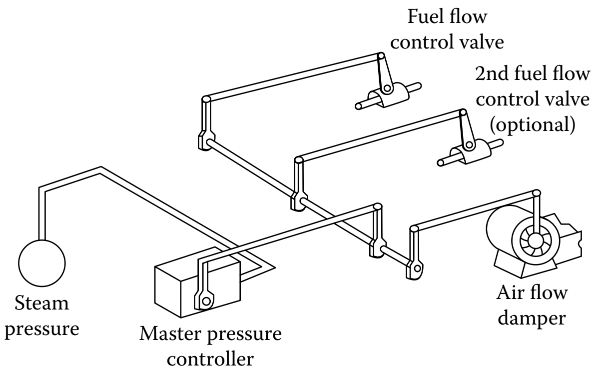

FIG. 8.6uuu
Early small boilers often used a direct positioning jackshaft modulated combustion control system with air/fuel ratio established through fixed mechanical linkages.[1]

Setting the Air/Fuel Ratio In Figure 8.6l, the set point of the air/fuel ratio relay is designated as the #1 tie-in point for the optimizer controls. This was done to emphasize the importance of this setting and to show that the method used to determine the correct air/fuel ratio will determine if the boiler is optimized or not.

In the early designs of small boilers, the air/fuel ratio was set by mechanical linkages between valve, damper, and the common jackshaft, as illustrated in Figure 8.6uuu. Even at fixed loads, these controls were only as good as the setting of the linkages that had to be readjusted manually as conditions changed.

When the importance of feedback control based on flue-gas analysis was better understood, such mechanically linked boiler controls were retrofitted as shown in Figure 8.6vvv. In this system the excess oxygen content of the flue gas is used to provide a feedback trim on the present relationship between firing rate (ZT) and damper opening (AZ). The influence of this trimming signal is bounded by the high/low limiter (AY-3) as a safety precaution to prevent the formation of fuel-rich mixtures as a result of analyzer or controller failure.

Air/Fuel Ratio with Excess Oxygen Trim Figure 8.6www shows an example of automatic fuel/air ratio correction based on load and excess air indicated by percentage of oxygen. In this control system, FY-102 provides the relationship between the load (steam flow) and the corresponding excess oxygen set point for optimum performance. Therefore, FY-102 memorizes the characteristic curve of the boiler for the particular fuel being used (see Figures 8.6nnn and 8.6ppp) and generates the excess oxygen set point based on that curve.

To obtain some of the advantages of the closed-loop fuel system, noninteracting oxygen analysis may be used to calibrate continuously the inherently poor fuel flow signal, if it could not otherwise be used with accuracy. An example of how a satisfactory coal flow signal can be obtained by continuously calibrating a summation signal of pulverizer feeder speeds is shown in Figure 8.6xxx.

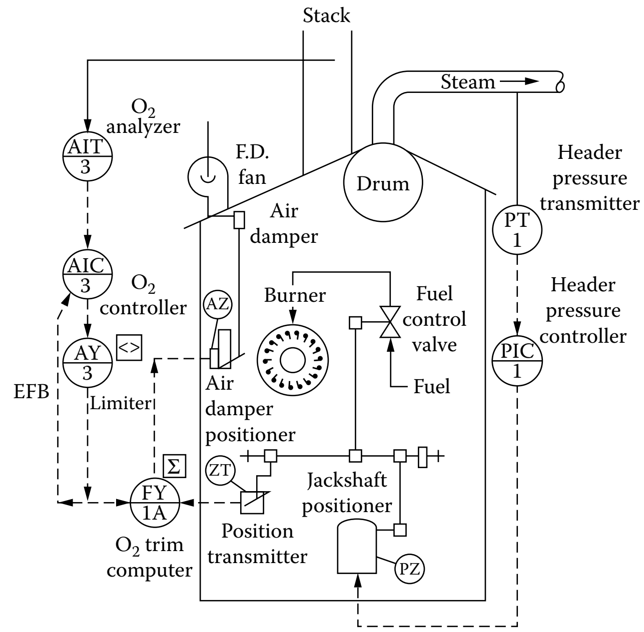

FIG. 8.6vvv
Parallel positioning combustion control systems can be retrofitted with excess oxygen trim.[34]

In both Figure 8.6www and Figure 8.6xxx, the set point of the excess oxygen controller is based on the steam flow.

Figure 8.6yyy illustrates a closed-loop control system corrected by oxygen analysis and provided with safety limits to protect against air deficiency. For the dual-selector system to function, air and fuel flows must be scaled on the same heat-equivalent basis.

The dual-selector system forces air flow to lead fuel on an increasing load and to lag on a decreasing load. Then, flue-gas oxygen content tends to deviate above the set point on *all* load changes. If the oxygen controller were allowed to react proportionally to these deviations, it would tend to defeat the security provided by the selectors. Consequently,

FIG. 8.6www
Air/fuel ratio control, with load vs. excess air curve (Figure 8.6nnn) considered.

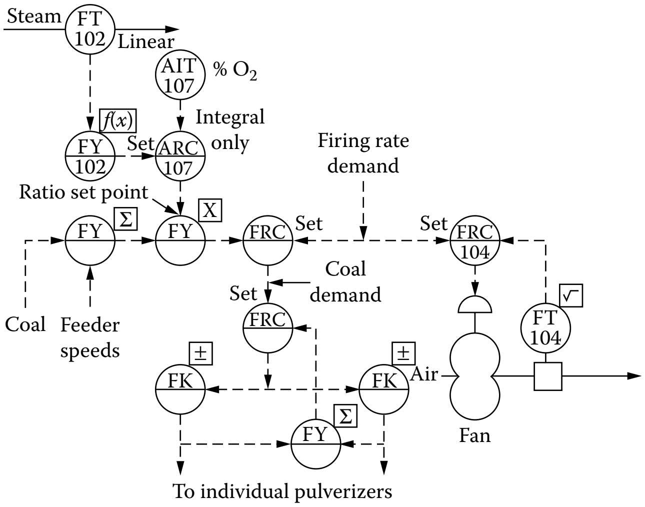

FIG. 8.6xxx
Load vs. excess air correction applied to the air/fuel ratio of a coal-burning boiler.

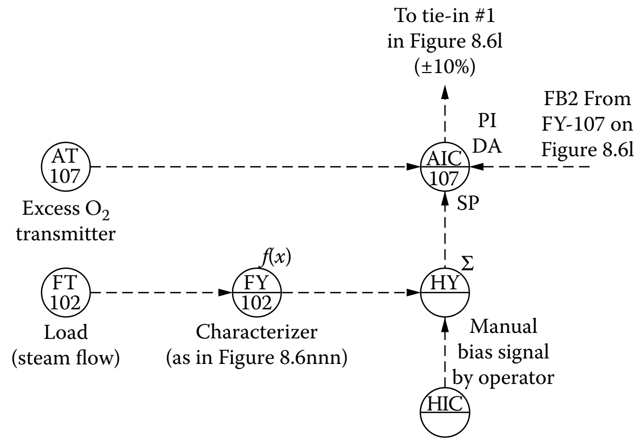

FIG. 8.6zzz
In this control system configuration, the excess oxygen trim has been characterized for load variations.

the integral control mode alone is used on the oxygen signal, so that reaction to rapid fluctuations is minimized. The principal function of the controller is to correct for long-term deviations caused by flowmeter errors and variations in fuel quality.

A variation of the previously described control system is shown in Figure 8.6zzz, in which FY-102 represents the relationship between load and excess oxygen. The input to FY-102 is steam flow (in other systems, firing rate is used as the input), and the output is the set point of the excess oxygen controller, AIC-107. The summer (HY) provides a bias so the operator can shift the characterizer curve up or down to compensate for changes in air infiltration rates or in boiler equipment performance.

The oxygen controller compares the measured flue-gas oxygen concentration to the load-programmed set point and applies PI action to correct the offset. Antireset windup and adjustable output limiting are usually also provided. The oxygen controller is direct-acting; the air/fuel ratio adjustment factor, therefore, increases if oxygen concentration in the stack rises because of effects such as reduced fuel heating value at constant flow. Increasing the air/fuel ratio adjustment factor raises the compensated process variable transmitted to the air flow controller, FIC-104 in Figure 8.6l.

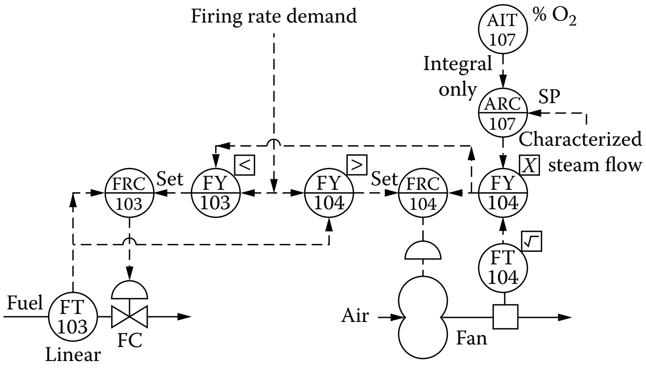

FIG. 8.6yyy
Feedforward control system that automatically maintains excess air during upsets.

The control system in Figure 8.6zzz can be further improved by increasing its speed of response. The transportation lag in a boiler can be as much as a minute. This lag is the time interval that has to pass after a change in firing rate before its effect can be detected in the composition of the flue gas. This dead time varies with flue-gas velocity and usually increases as the load drops. In boilers in which loads are frequently shed or added at irregular intervals, this dead time can cause control problems.

The feedforward strategy[25] shown in Figure 8.6aaaa can substantially lower this dead time. Here, the air flow damper position is controlled in a closed loop based on a set point developed through a characterization curve from the firing rate command. This loop acts to adjust the excess oxygen in a feedforward manner.

Feedback trim is provided by an oxygen measurement that modifies the set point to the damper position controller. This system anticipates the need for excess oxygen changes by responding to load swings, then correcting oxygen concentration to correspond with the excess air curve. A further refinement can be implemented using the corrections provided by the oxygen controller to adapt the damper characterization curve for a particular fuel to the current position in a learning mode.

Multivariable Envelope Control Multiple measurements of flue-gas composition can be used to eliminate the manual bias in Figure 8.6zzz and to obtain more accurate and faster control than what is possible with excess O_2 control alone.

Figure 8.6bbbb shows a control system in which the manual bias is replaced by the output signal of a CO controller,

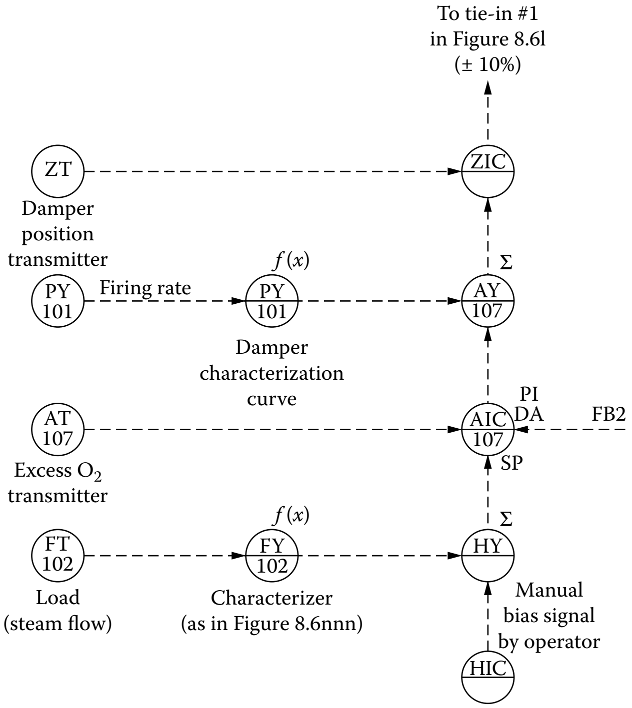

FIG. 8.6aaaa
The feedforward correction that is based on the characterized damper position increases the sensitivity of the control system. (Adapted from Reference 25.)

trimming the characterized set point of AIC-107. This trimming corrects the characterized excess O_2 controller set point for changes in the characteristic curve. These changes can be caused by local problems at the burners, resulting in incomplete combustion, or by changes in fuel characteristics, equipment, or ambient conditions.

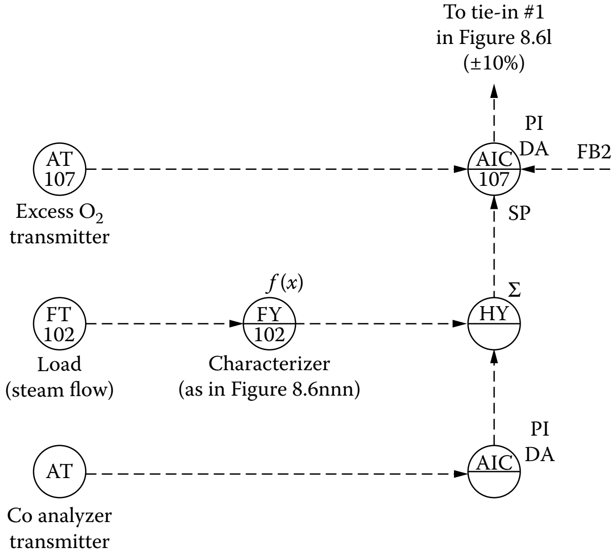

FIG. 8.6bbbb
In this configuration, the need for manual biasing is eliminated by the addition of fine trimming based on CO. (Adapted from Reference 25.)

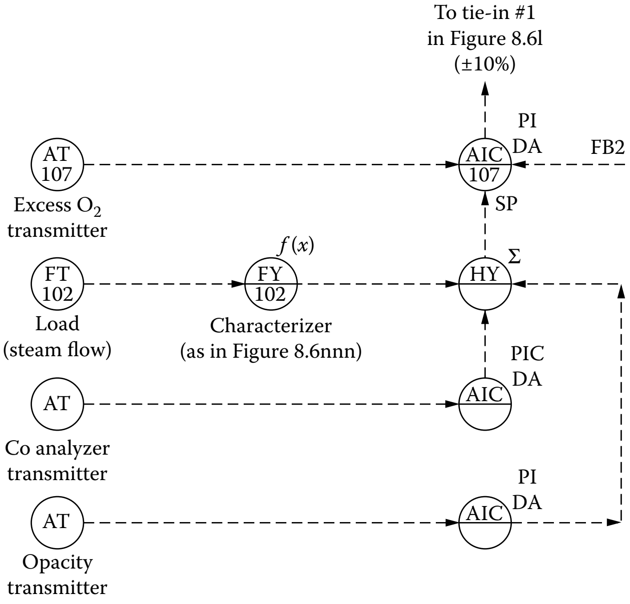

FIG. 8.6cccc
An opacity override has been added to the characterized CO to O_2 cascade system of Figure 8.6bbbb to meet environmental regulations. (Adapted from Reference 42.)

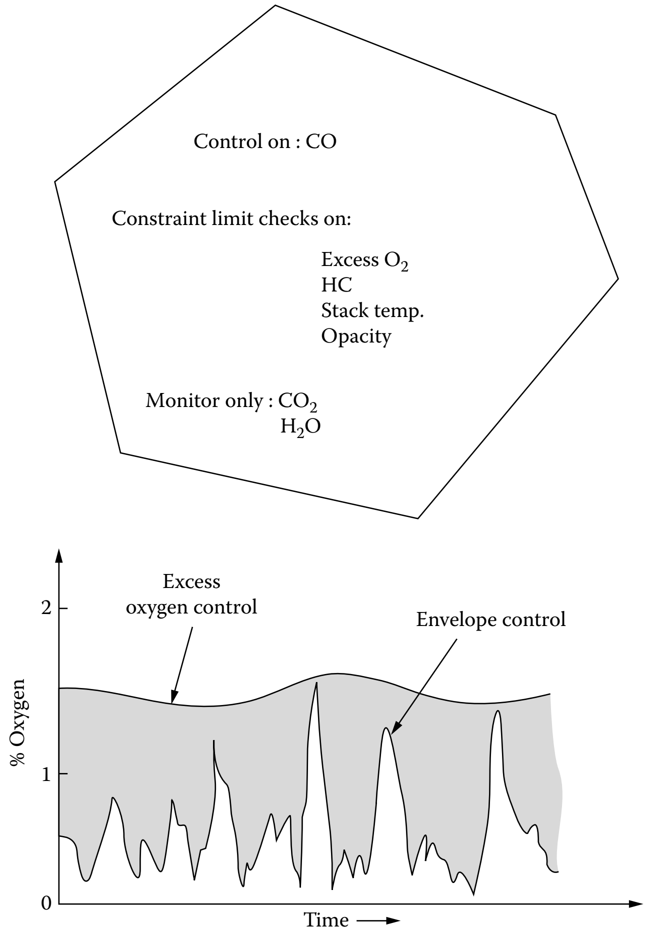
The control systems shown in Figure 8.6bbbb could be further improved if the CO measurement signal was corrected for dilution effects due to air infiltration, or if the CO controller set point was also characterized as a function of load. As was shown in Figure 8.6rrr, such characteristics can be determined for each fuel and firing rate. The control range for CO tends to remain relatively constant. As CO gives an indication of the completeness of combustion, it is *not* a feasible basis for control if the boiler is in poor mechanical condition or if the fuel does not combust cleanly.

Figure 8.6cccc provides the added feature of an opacity override to meet environmental regulations. In this system, under normal conditions, the cascade master is CO, just as it was in Figure 8.6aaaa. Similarly, the cascade slave is excess O_2, but when the set point of the opacity controller is reached, it will start biasing the O_2 set point upward until opacity returns to normal.

With microprocessor-based systems, it is possible to configure a control envelope, such as that shown in Figure 8.6dddd. With these control envelopes, several control variables are simultaneously monitored, and control is switched from one to the other, depending on which limit of the envelope is reached.

For example, assuming that the boiler is on CO control, the microprocessor will drive the CO set point toward the maximum efficiency (“knee” point in Figure 8.6rrr), but if in so doing the opacity limit is reached, that will override the CO controller and will prevent the opacity limit from being violated.

Similarly, if the microprocessor-based envelope is configured for excess oxygen control, it will keep increasing



Measured variable	Method of detection
CO	Infrared
Excess O_2	Zirconium oxide
HC (unburned hydrocarbons)	Infrared
Opacity	Visible light
CO_2	Infrared
H_2O	Infrared

FIG. 8.6dddd
Multivariable envelope-based constraint control can lower overall excess oxygen. This can be achieved by monitoring both carbon dioxide and water and by performing constraint limit checks on excess oxygen, hydrocarbons, stack temperature, and opacity.

boiler efficiency by lowering excess O_2 until one of the envelope limits is reached. When that happens, control is transferred to that constraint parameter (CO, HC, opacity, and so on); through this transfer, the boiler is "herded" to stay within the envelope defined by these constraints. These limits are usually set to keep CO under 400 ppm, opacity below #2 Ringlemann, and HC and NO_x below regulations.

Microprocessor-based envelope control systems usually also include subroutines for correcting the CO readings for dilution effects or for responding to ambient humidity and temperature variations. As a result, these control systems tend to be both more accurate and faster in response than if control was based on a single variable. The performance levels of a gas-burning boiler under both excess O_2 and envelope control are shown on the lower part of Figure 8.6dddd.

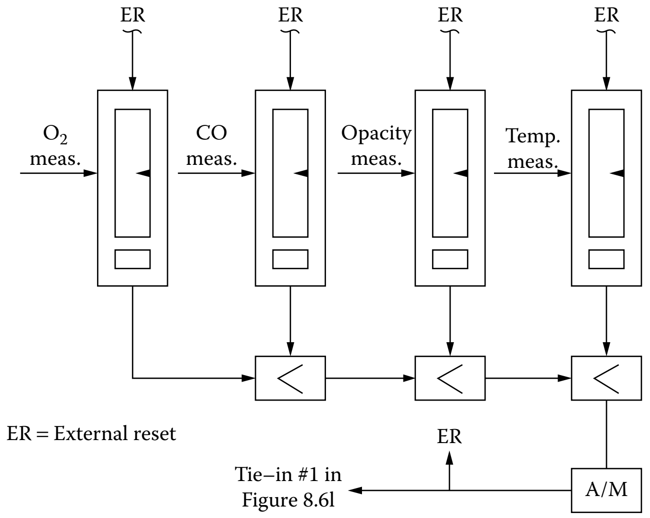


FIG. 8.6eeee
Analog controllers configured into a multiple selective loop can also be used to implement envelope control.

Envelope control can also be implemented by analog controllers that are configured in a selective manner. This is illustrated in Figure 8.6eeee. Each controller measures a different variable and is set to keep that variable under (or over) some limit. The lowest of all the output signals is selected for controlling the air/fuel ratio in Figure 8.6l, which ensures that the controller that is most in need of help is selected for control. Through this herding technique, the boiler process is kept within its control envelope. As shown in Figure 8.6eeee, reset windup in the idle controllers is prevented by the use of external reset, which also provides bumpless transfer from one controller to the next.

Operator access is shown to be provided by a single auto/manual (A/M) station. A better solution is to provide each controller with an A/M station. Then, if a measurement is lost, only the defective loop needs to be switched to manual, not the whole system.

Flue-Gas Temperature

The amount of energy wasted through the stack is a function of both the amount of excess air and the temperature at which the flue gases leave. The flue-gas temperature is a consequence of load, air infiltration, and the condition of the heat-transfer surfaces. Like any other heat exchanger, the boiler will also give its most efficient performance when clean and well maintained.

In optimized boiler controls, a plot of load vs. stack temperature is made when the boiler is in its prime condition, and this plot is used as a reference baseline in evaluating boiler performance. If the stack temperature rises above this reference baseline, this indicates a loss of efficiency. Each 50°F (23°C) increase will lower the boiler efficiency by about 1%.

On a 100,000 lb/hr (45,450 kg/hr) boiler, this is a yearly loss of about $20,000.

The reason for rising flue-gas temperatures can be fouling of heat-transfer surfaces in the air preheater, scale build-up on the inside of the boiler tubes, soot build-up on the outside of the boiler tubes, or deteriorated baffles that allow the hot gases to bypass the tubes. Some microprocessor-based systems will respond to a rise in flue temperature by taking corrective action, such as automatically blowing the soot away, or by giving specific maintenance instructions (see the paragraph on Soot Blowing Optimization).

If the stack temperature drops below the reference baseline, this does *not* necessarily signal an increase in boiler efficiency. More likely, it can signal the loss of heat due to leakage. Cold air or cold water can leak into the stack gases if the economizer or the regenerator are damaged. The consequence of this is loss of efficiency and the danger of corrosive condensation (sulfuric acid formation), if the temperature drops down to the dew point. Minimum flue-gas temperatures are approximately 250°F (121°C) for natural gas and 300–325°F (149–163°C) for heavy oil and wood.[5] A drop in flue-gas temperature will also lower the stack effect, thus increasing the load on the induced-draft fan.

For the above reasons, the advanced envelope control systems (Figure 8.6dddd) include both high- and low-limit constraints on stack temperature, using the above-described baseline as a reference.

Fuel Savings through Optimization

The overall boiler efficiency is the combined result of its *heat-transfer efficiency* and its *combustion efficiency.* Heat-transfer efficiency is reflected by stack temperature, which at the hot end should not exceed steam temperature by more than 150°F (65°C) when excess air is near optimum.[23] Combustion efficiency is tied to excess oxygen, which is brought as low as possible without exceeding the limits on CO (usually 400 ppm), opacity (#2 Ringlemann), unburned carbon, and NO_x (although reduction in excess O_2 is usually accompanied by reduction in NO_x).

When optimization reduces the flue-gas losses, the resulting savings can be estimated from the amount of reduction in these losses. In the case of a 100,000 lb/hr (45,450 kg/hr) steam boiler, a 1% reduction in fuel consumption (a 1% increase in efficiency) will lower the yearly operating costs by about $20,000 if the fuel cost is estimated at $2 per million BTU.

With the current average efficiency and the projected or actual efficiency after optimization, fuel savings can be calculated with Equation 8.6(6):

$$S = \left(1 - \frac{\eta_b}{\eta_i}\right)(F) \qquad \textbf{8.6(6)}$$

where S is the fuel savings, η_b is the base efficiency, η_i is the improved efficiency, and F is the current or base fuel usage.

The fuel savings resulting from the lowering of excess O_2 can be estimated from graphs, such as those shown in Figures 8.6ffff and 8.6gggg. On these graphs the temperature is the difference between the stack and ambient temperatures. If, in a boiler operating at a 500°F (260°C) stack temperature difference, optimization lowers the excess O_2 from 5 to 2%,

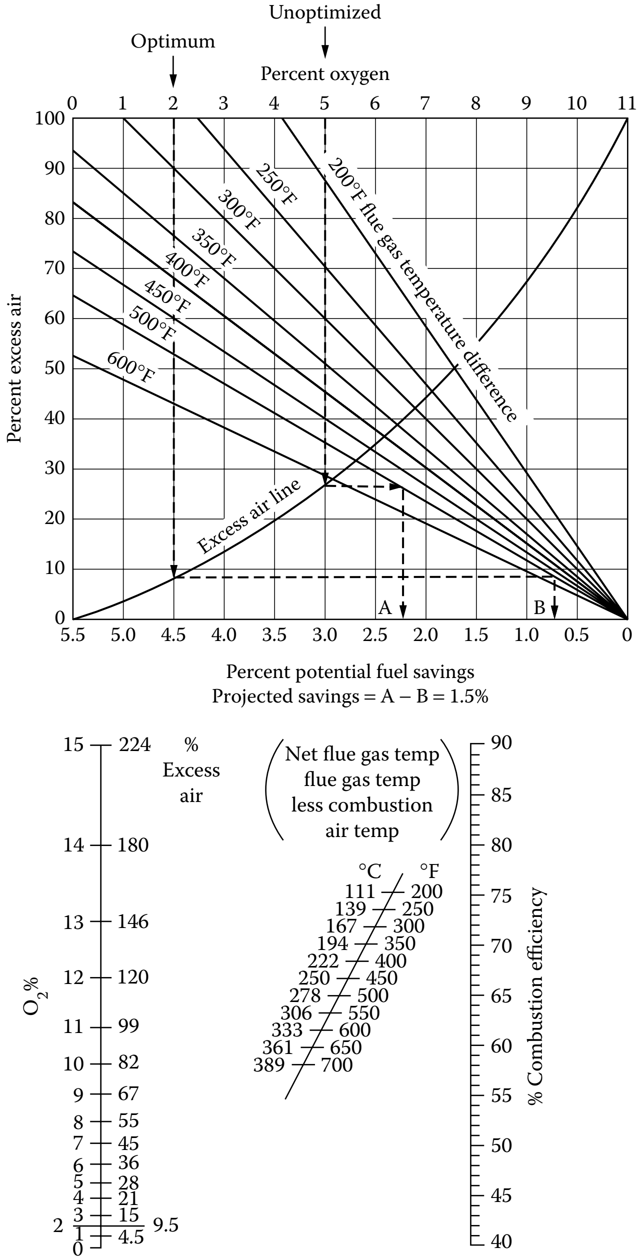

FIG. 8.6ffff

In the upper portion of this figure, one can determine the achievable fuel savings resulting from the reduction in excess oxygen. From the lower portion, one can obtain the combustion efficiency by drawing a straight line through the points corresponding to the applicable excess oxygen and flue-gas temperature. (Adapted from Reference 36.)

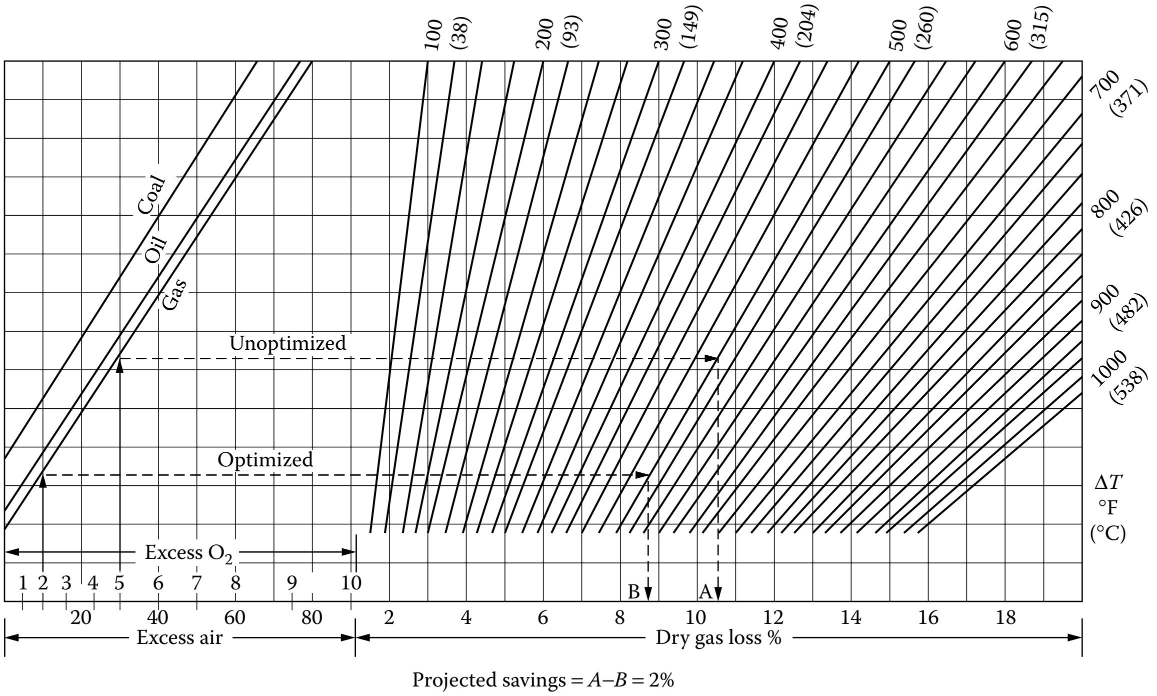

FIG. 8.6gggg
The fuel-savings potential can also be computed as shown here. (Courtesy of Dynatron, Inc.)

this will result in a fuel savings of 1.5% (2.25% − 0.75%), according to Figure 8.6ffff.

For the same conditions, Figure 8.6gggg gives a savings of 2% (10.5% − 8.5%). Such differences are acceptable, as the size and designs of the equipment do influence the results. Although optimization has lowered the excess O_2 in some boilers to around 0.5%, the value of these last increments of savings tends to diminish in proportion to the cost of accomplishing them. Lowering excess O_2 from 1 to 0.5% will increase boiler efficiency by only 0.25%, a savings of about \$5,000/yr in a 100,000 lb/hr (45,000 kg/hr) boiler, and the controls needed to sustain such operation need to be as sophisticated as the ones described in Figure 8.6dddd. For these reasons, an optimization target of 1% excess O_2 on gas fuel is reasonable.

The fuel savings resulting from improved thermal efficiency can be estimated from Figure 8.6gggg or Figure 8.6hhhh. Lowering the stack temperature difference from 500°F (278°C) to 400°F (222°C) at an excess O_2 of 2% will result in a savings of 1.7% (8.5% − 6.8%), according to Figure 8.6gggg. Assuming an ambient temperature of 60°F (16°C), these same conditions are marked in Figure 8.6hhhh at 560°F (293°C) and 460°F (238°C), resulting in a savings of about 2%. Therefore, as a crude approximation, fuel savings of 1% can be estimated for each 50°F (28°C) reduction in stack gas temperature.

As was already discussed, stack gas temperature reductions must be limited to achieving a temperature above dew point that is high enough to provide the required stack effect.

Consequently, the total savings from improved thermal and combustion efficiencies can be estimated on the basis of both stack temperature and excess oxygen being lowered to their limits. The resulting total fuel savings can be around 5%.

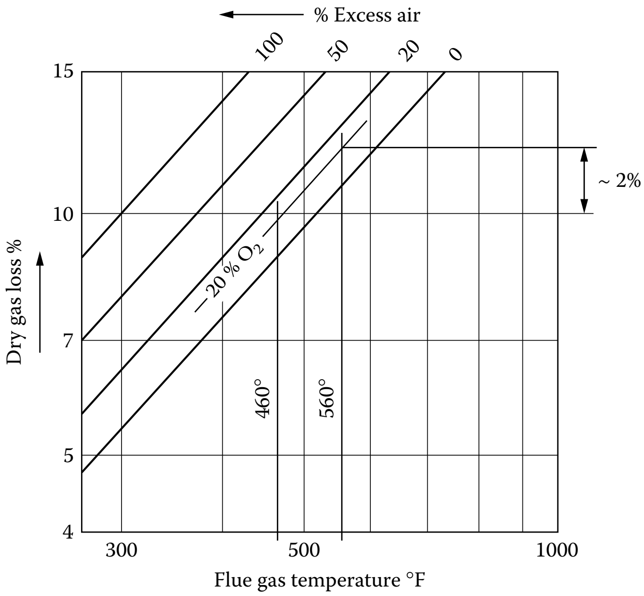

FIG. 8.6hhhh
Temperature of flue gas leaving a medium-size boiler has a direct effect on combustion efficiency. (Adapted from Reference 2.)

Steam Pressure Optimization

In Figure 8.6l, the second tie-in point for the optimizer is the set point of the pressure controller PIC-101. In basic boiler operation, the steam pressure is maintained at a constant value. Optimization is possible by allowing this pressure to vary.

In co-generating plants, in which the boiler steam is used to generate electricity and the turbine exhaust steam is used as a heat source, optimization is obtained by maximizing the boiler pressure and minimizing the turbine exhaust pressure, so as to maximize the amount of electricity generated (Figure 8.6iiii).

In plants that do not generate their own electricity, optimization is achieved by minimizing boiler operating pressure. This reduces the pressure drops in turbine governors by opening them up further, lowers the cost of operating feedwater pumps because their discharge pressure is reduced, and generally lowers radiation and wall losses in the boiler and piping.

In electric utility plants, optimization is achieved through sliding-pressure or free-pressure control strategies that allow the pressure to vary with load, within certain constraints. This reduces temperature fluctuations in the steam turbine, thereby reducing fatigue and improving turbine life, and it improves heat rate at lower loads. In basic sliding pressure control, the turbine governor valves are run wide-open (full-arc admission), and pressure reducing valves are used upstream to control pressure, or the boiler itself is cycled to change header pressure with load.

Pump power is particularly worth saving in high-pressure boilers, because as much as 3% of the gross work produced by a 2400 PSIG (16.56 MPa) boiler is used to pump feedwater. Figure 8.6jjjj illustrates the method of finding the optimum minimum steam pressure, which then becomes the set point for the master controller PIC-101 in Figure 8.6l.

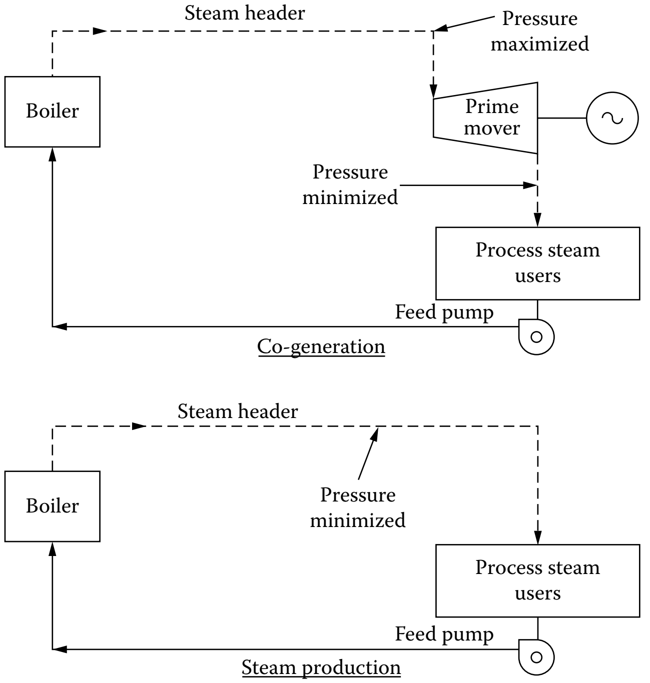

FIG. 8.6iiii
The optimum steam pressure at the boiler depends on the purpose that the steam serves.

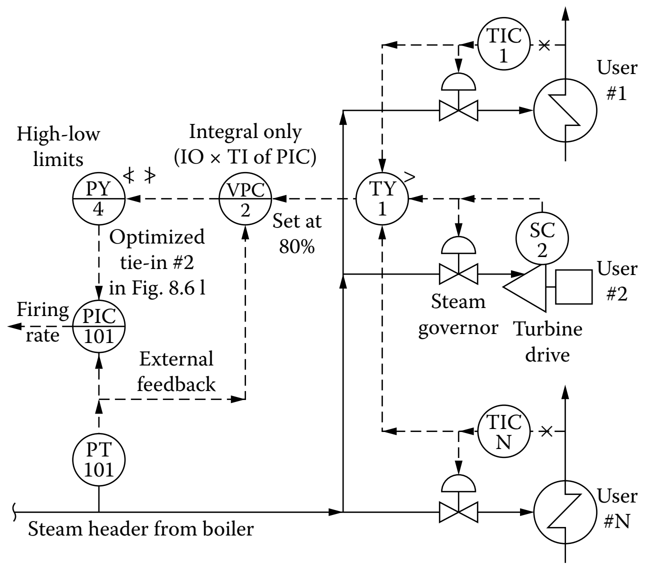

FIG. 8.6jjjj
The set point of the steam supply header pressure controller (PIC-101) can be floated, so as to keep the most-open user valve nearly full open.

As long as all steam user valves (including all turbine throttle valves) are less than fully open, a lowering in the steam pressure will not restrict steam availability, because the user valves can open further. The high-signal selector (TY-1) selects the most-open valve, and the valve position controller (VPC-2) compares that signal with its set point of, for example, 80%. If even the most-open valve in the plant is less than 80% open, the pressure controller set point is slowly lowered. VPC-2 is an "integral only" controller; its reset time is at least ten times that of PIC-101.

This slow integral action guarantees that only very slow "sliding" of the steam pressure will occur and that noisy valve signals will not upset the system, because VPC-2 responds only to the integrated area under the error curve. The output signal from VPC-2 is limited by PY-4, so that the steam pressure set point cannot be move outside some preset limits. This necessitates the external feedback to VPC-2, so that when its output is overridden by a limit, its reset will not wind up.

This kind of optimization, in which steam pressure follows the load, not only increases boiler efficiency but also does the following:

1. Prevents any steam valve in the plant from fully opening and thereby losing control
2. Opens all steam valves in the plant, thereby moving them away from the unstable (near-closed) zone of operation

3. Reduces valve maintenance and increases valve life by lowering pressure drop
4. Increases turbine drive efficiencies by opening up all steam governors

The total savings in yearly operating costs resulting from optimizing the steam pressure to follow the load is a small percentage of the total cost.

Steam Temperature Optimization

Dynamic Feedforward Although the feedforward function FY-102 in Figure 8.6ggg is commonly used in superheater steam temperature control, the transient response due to major disturbances (e.g., load swing) is not properly compensated under this design. The reason is that the process dynamics are not taken into account. By incorporating dynamic models in the feedforward control design, the transient error, such as the temperature overshoot, can be effectively eliminated. The dynamic feedforward compensator can be simply chosen in the form of a causal transfer function that is equivalent to a lead-lag type compensator readily available in most control systems' algorithm library.

Refer to Figure 8.6ggg and let the dynamics from the set point of TIC-112 to TT-111 be modeled by the transfer function $G(s)$, and the dynamics from FT-102 to TT-111 be represented by the transfer function $G_d(s)$. This assumes no control action from TIC-111. Let us also assume the steam flow disturbance can be transformed as $d(s)$, and the static feedforward compensator FY-102 is replaced by a dynamic controller $G_{ff}(s)$. To completely eliminate the transient error, the following equation should hold if there is no mismatch between the model and the actual process:

$$G_{ff}(s) \cdot G(s) \cdot d(s) + G_d(s) \cdot d(s) = 0 \qquad \textbf{8.6(7)}$$

This immediately yields

$$G_{ff}(s) = -\frac{G_d(s)}{G(s)} \qquad \textbf{8.6(8)}$$

If the feedforward controller $G_{ff}(s)$ is designed as such, the disturbance effect can be completely eliminated before it creates any transient error. However, partly due to the complexity of data collection and modeling task, this approach has not been widely used in current industrial practice. In fact, for steam temperature dynamics modeling purposes, much of the existing plant data stored for the conventional control design can be utilized.

For example, as part of the unit calibration and tuning process, the relationship between the steam flow rate and the spray water control valve input signal needs to be determined by testing at the design steam temperature while operating at different boiler loads. Much of the test data can be directly used for dynamic modeling purposes, although these data are mainly used to characterize the steady-state relationship in a conventional scheme.

In order to make the dynamic feedforward controller practically useful, the process model $G(s)$ has to be a minimum-phase transfer function. This means that the process model cannot have inverse dynamics at the beginning of the transient. Details about the dynamic feedforward design can be found in Section 2.9 in Chapter 2. Due to process nonlinearity, multiple linear models should be identified and used for control design at different loads.

It is suggested that the flue-gas temperature at the superheater inlet is a better signal to be used for feedforward compensation. Although the firing rate master signal and its associated variables (e.g., air/steam flow) are often indicators for steam temperature change, the relationship that can be derived is really a coarse estimate. It is the flue-gas temperature and mass flow that directly influence the convection area and the resulting steam temperature. A dynamic feedforward control scheme based on radiation pyrometry is briefly introduced in Reference 35.

Model-Based Multivariable Control The steam temperature control strategies discussed so far are mainly for superheater sections. In reality, many large utility boilers have at least one reheater section. Although the reheat steam temperature control is similar to the superheat steam temperature control in principle, the subtle differences are often overlooked. First, in the current practice, the flue-gas bypass damper and burner tilting, whenever available, are normally used as the first choice for reheat steam temperature control.

Spray water will be engaged in control action only when other methods are ineffective (possibly due to control output saturation). This measure can significantly reduce spray water usage and help to improve unit heat rate. Second, the reheat outlet steam temperature control is usually more challenging due to the fact that more flue-gas variation is expected in the reheat section.

Given the fact mentioned above, it is obvious that the superheat and reheat steam temperature control is a highly coupled process. Manipulation of flue-gas bypass damper or burner tilts will inevitably affect both superheat and reheat steam temperature, either in the same direction or in the opposite directions. For boilers with split furnace, sometimes the burner tilting and bypass damper movement can have different impact on steam temperatures of different sides. Moreover, as the steam temperature control fights against the interactions, load changes might be called for. The changing firing rate may introduce a number of other disturbances that do not necessarily come in the same fashion.

These include, but are not limited to, air flow, furnace-to-windbox differential pressure, steam flow, and steam pressure. More interactions are identified in Reference 12. A coordinated multivariable control design becomes a natural choice to achieve better performance for the steam temperature regulation. The manipulated variables may include the burner tilting angles, flue-gas damper positions, and spray water flows. The controlled variables will be superheater and reheater outlet steam temperatures. The details of model-based multivariable control system design can be found in Section 2.13 in Chapter 2.

Water Side Optimization

The optimization of the water side of a steam generator includes the optimized operation of the feedwater pump at the condensate return system and of the boiler blowdown. As pumping system optimization is the subject of a separate chapter in this book, only the boiler blowdown will be discussed here.

Blowdown Optimization In Figure 8.6l, the third tie-in point for the optimizer is the set point of the blowdown flow controller. The goal of optimization is to minimize blowdown as much as possible without causing excessive sludge or scale build-up on the inside surfaces of the boiler tubes. The benefits of such optimization include the reduction in the need for makeup water and treatment chemicals and the reduction in heat loss as hot water is discharged. About 90% of the blowdown should occur continuously, and 10% would result from the periodic blowing down of the mud drum and of the headers.

Blowdown can be optimized by automatically controlling the chloride and conductance of the boiler water. The neutralized conductivity set point is usually around 2500 micromhos. Automatic control maintains this set point within ±100 micromhos. The required rate of blowdown is a function of the hardness, silica, and total solids of the makeup water and also of the steaming rate and condensate return ratio of the boiler.

The amount of blowdown can be determined as follows:

$$\mathrm{BD} = \frac{S - R}{C - 1} \qquad \mathbf{8.6(9)}$$

where

BD = blowdown rate, lb per hour
R = rate of return condensate, lbs per hour
S = steam load, lbs per hour
C = cycles of concentration based on makeup

The value for cycles of concentration is generally determined on the basis of the chloride concentration of the boiler water divided by the chloride content of the makeup water. The value is also given by dividing the average blowdown rate into the average rate of makeup water, assuming no mineral contamination in any returned condensate.

Figure 8.6kkkk illustrates that the rate of blowdown accelerates as the boiler water conductivity set point is lowered. A reduction of about 20% can result from converting the blowdown controls from manual to automatic.[31] In the case of a 100,000 lb/hr (45,450 kg/hr) boiler, this can mean a reduction of 1,340 lb/hr (600 kg/hr) in the blowdown rate. If the blowdown heat is not recovered, this can lower the yearly operating cost by about $10,000 (depending on the unit cost of the fuel).

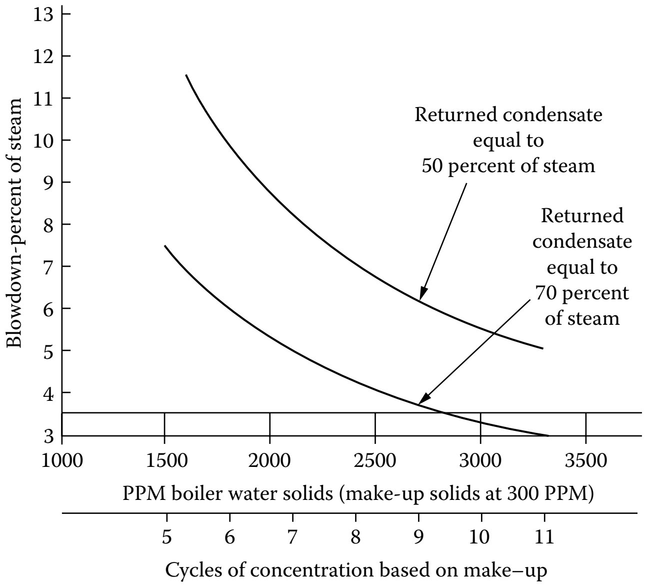

FIG. 8.6kkkk
The rate of blowdown increases as the boiler water conductivity set point is lowered.[31]

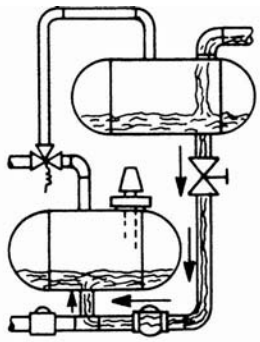
Overall boiler efficiency can also be increased if the heat content of the hot condensate is returned to the boiler. Pumping water at high temperatures is difficult; therefore, the best choice is to use pumpless condensate return systems. Figure 8.6llll illustrates the operation of such a system, which uses the steam pressure itself to push back the condensate into the deaeration tank. This approach eliminates not only the maintenance and operating cost of the pump but also the flash and heat losses, resulting in the return of more condensate at a higher temperature.

Alternatively, blowdown heat can be recovered by using a heat exchanger to preheat boiler makeup water. Consider a boiler producing 400,000 lb/hr (180,000 kg/hr) steam at a drum pressure of 900 PSIG (6.2 MPa), with a blowdown rate of 5% (percentage of feedwater); Assuming makeup water at 60°F (16°C), a heat exchanger “approach” ΔT of 2°F (1.1°C), and 90% heat recovery from blowdown, energy savings would be nearly 9 million BTU/hr (9.5 million kJ/hr).

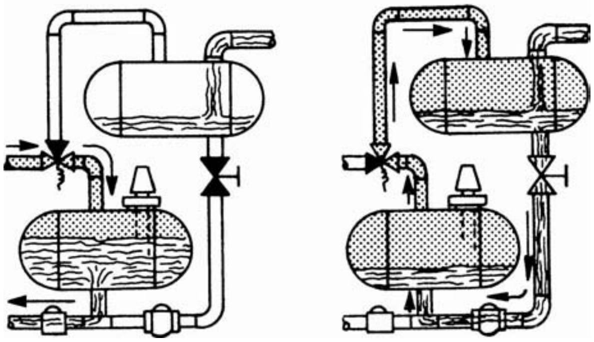
The performance of the steam and condensate piping system in the plant can also be improved if steam flows are metered. Such data is helpful not only in accountability calculations but also in locating problem areas, such as insufficient thermal insulation or leaking traps.

Load Allocation-Based Optimization

The purpose of load allocation between several boilers is to distribute the total plant demand in the most efficient and optimized manner. Such optimization will reduce the steam



Fill cycle



Equalization and discharge cycles

Vent cycle

FIG. 8.6llll
The "pumpless" condensate return system uses the steam pressure itself to push the condensate back into the deaeration tank. (Courtesy of Johnson Corp.)

production cost to a minimum. Such computer-based energy management systems can operate either in an advisory or in a closed-loop mode. The closed-loop systems automatically enforce the load allocation, without the need for operator involvement. The advisory system, on the other hand, provides instructions to the operator but leaves the implementation up to the operator's judgment.

The load allocation techniques discussed in this section, which are often referred as economic dispatch, only cover the scenario where all units in consideration are located in one plant or in a nearby neighborhood. Load allocation at grid level is more complicated, because the transmission loss, transmission flow constraints, reactive power constraints, fuel transportation, production scheduling, and many other factors need to be taken into account.

In simple load allocation systems, only the starting and stopping of the boilers is optimized. When the load is increasing, the most efficient idle boiler is started (Figure 8.6a); when the load is dropping, the least efficient one is stopped. In more sophisticated systems, the load distribution between operating boilers is also optimized. In such systems, a computer is used to calculate the real-time efficiency of each boiler. This information is used to calculate the incremental steam cost for the next load change for each boiler.

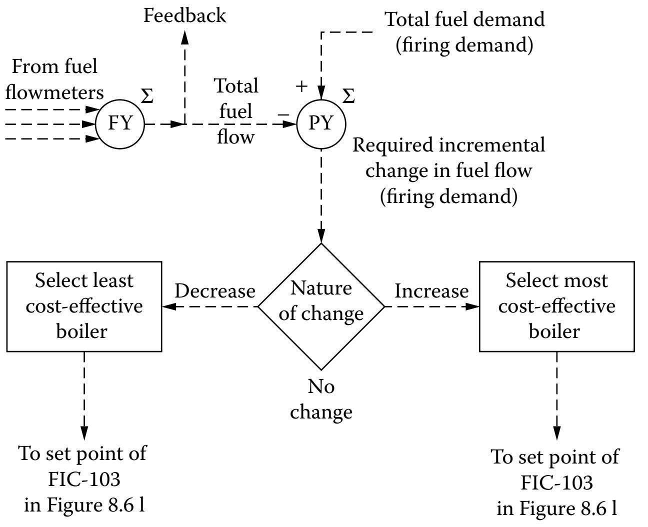


FIG. 8.6mmmm
Computer-based load allocation directs load increases to the most cost-effective boiler and sends load decreases to the least cost-effective boiler.

For example, if the load increases, the incremental increase is sent to the set point of the most cost-effective boiler. If the load decreases, the incremental decrease is sent to the least cost-effective boiler (Figure 8.6mmmm). The required software packages with proven capabilities for continuous load balancing through the predictions of costs and efficiencies are readily available.[32] With the strategy described in Figure 8.6mmmm, the most efficient boiler either will reach its maximum loading or will enter a region of decreasing efficiency and will no longer be the most efficient.

When the loading limit is reached on one boiler, or when a boiler is put on manual, the computer will select another as the most efficient unit for future load increases. On the other hand, the least efficient boiler will accept all decreasing load signals until its minimum limit is reached. Its load will not be increased unless all other boilers are at their maximum load or in manual. As shown in Figure 8.6a, some boilers can have high efficiency at normal load while being less efficient than the others at low load. Such units are usually not allowed to be shut down but are given a greater share of the load by a special subroutine.

If all boilers are identical, some will be driven to maximum capacity and others will be shut down by this strategy, and only one boiler will be placed at an intermediate load.[6] Boiler efficiency can be monitored indirectly (by measurement of flue-gas composition, temperature, combustion temperature, and burner firing rate) or directly (through time-averaged steam and fuel flow monitoring).

For the direct efficiency measurement, it is important to select flowmeters with acceptable accuracy and rangeability (Table 8.6d). In order to arrive at a reliable boiler efficiency reading, the error contribution of the flowmeters, based on actual reading, must not exceed $\pm 1/2$ to $\pm 3/4$%.

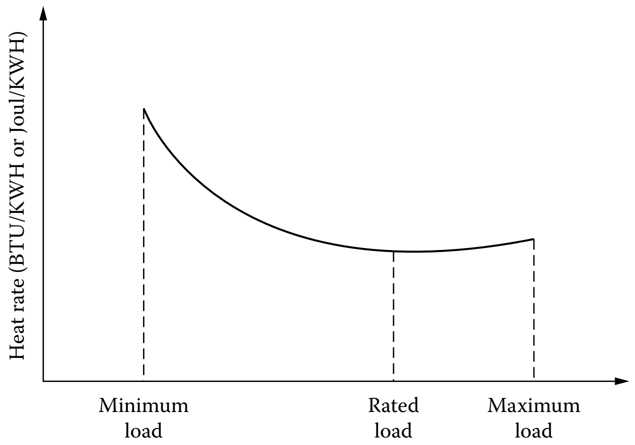

FIG. 8.6nnnn
Heat rate vs. load.

Boiler allocation can be based on actual measured efficiency, on projected efficiency based on past performance, or on some combination of the two. The continuous updating and storing of performance data for each boiler is also a valuable tool in operational diagnostics and maintenance.

The load allocation strategy described above is sometimes based upon heat rate curve (particularly for electric utility units). Most plants' heat rate characteristics are nonlinear, in that they have a high value at the low load and are flat out at the high end (Figure 8.6nnnn). Usually a unit's heat rate curve can be approximated by a polynomial function of the load. The incremental heat rate curve can be obtained by taking derivative of the heat rate curve with respect to the load.

Whether the load allocation is based on the incremental steam cost curve or the incremental heat rate curve, the simple method discussed so far suffers from the following deficiencies:

1. The incremental cost curves do not take operating constraints into account. Especially in the past decade, emission constraints are imposed on almost every power plant. Pollution control credits and penalties should all be taken into account when the optimal load allocation is considered.
2. Methods simply based on the change of incremental cost curve do not usually work well with nonsmooth and nonconvex cost functions, as is often the case for plants that have combined cycle units. The overall heat rate curve for multiple combustion turbogenerators is discontinuous.[33]

To overcome the disadvantage of incremental cost curve-based approach, a relatively complete, yet still simplified, economic load allocation method can be formulated as the following optimization (We assume there are total number of N units available for generation.):

$$\text{Minimize} \quad J = \sum_{i=1}^{N} (F_i + H_i - C_i) \qquad \mathbf{8.6(10)}$$

subject to constraints:

$$\sum_{i=1}^{N} L_i = L_{\text{total}} \qquad \text{(Total load constraint)}$$

$$L_{i,\min} \le L_i \le L_{i,\max} \qquad \text{(Single load constraint)}$$

$$E_i \le E_{i,\text{limit}} \qquad \text{(Single unit emission constraint)}$$

where

L_i = the ith unit load (the decision variable)
$L_{i,\min}$, $L_{i,\max}$ = the low and high limits for the ith unit
L_{total} = the total load demand
E_i = the ith unit emission ($E_{i,\text{limit}}$ is the corresponding limit)
F_i = the ith unit fuel cost
H_i = the ith unit emission control cost
C_i = the ith unit emission credit

ED: Superscript OK?

The fuel cost for each unit is a function of its load level, heat rate, and fuel price. The emission output is also a function of the load. The emission credit C_i can be the result from the emission credit trading market. A negative C_i would indicate penalty. This constrained optimization is nonlinear in general and can be directly solved by a state-of-the-art nonlinear programming algorithm. Alternatively, this problem can be tackled by a standard linear programming approach if nonlinear models are piecewise linearized first.

Note that many electric utility units have implemented automatic generation control (AGC). In AGC mode, raised or lowered pulses of varying lengths are transmitted to the unit from a central location. The control logic changes the unit's load set point up or down in proportion to the pulse length. If the optimal load allocation program is not integrated with the AGC program, then the unit under AGC mode has to be tuned out from the load allocation program.

Soot Blowing Optimization

The impact of soot deposit and soot blowing on boiler performance is complicated (Figure 8.6oooo). The complication is not only due to the obvious fact that the fouling reduces the heat transfer, but also because the fouling changed the heat distribution pattern along the flue-gas path. Besides the heat-transfer pattern, soot blowing can also affect steam temperature, thermal NO_x emission, and stack opacity. For example,[34] one study shows that soot-blowing impact on NO_x can be as high as 6%, change in steam temperature can be as much as 40°F (22°C), and change in the heat rate can be up to 110 BTU/kWh (116 kJ/kWh).

Efficient removal of fireside soot deposit has long been a challenging task. Frequent operation of soot blowers wastes

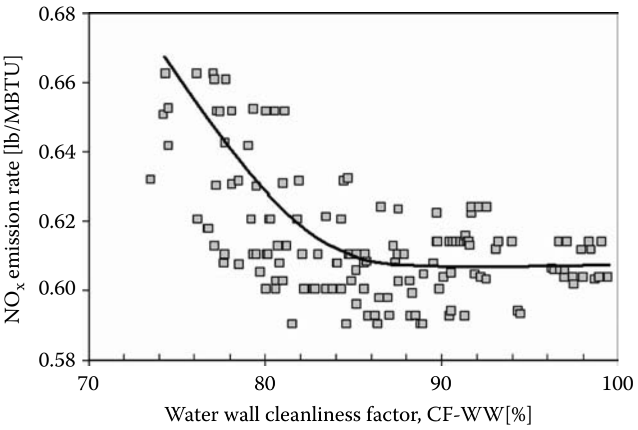

FIG. 8.6oooo
Effect of water wall cleanliness on NO_x *emissions in a coal-fired boiler. (Courtesy of Energy Research Center, Lehigh University.)*

steam, increases blower maintenance cost, and aggravates the tube erosion. Conversely, far less frequent blowing allows too much soot accumulation and, hence, decreases efficiency. It may also cause high stack opacity when a heavily fouling area gets blown. Therefore, intelligent adjustment of the cleaning schedule according to the actual cleaning need becomes the means of achieving our primary goal: efficiency improvement. This is realized through advanced control software involving a cleanliness factor calculation and a rule-based expert system.

Cleanliness Factor Calculation Boiler section fouling status can be quantified by the section cleanliness factor (CF). By usual definition, the heat-transfer effectiveness ε is the ratio of actual to design heat-transfer rate, i.e.,

$$\varepsilon = \frac{Q_{\text{actual}}}{Q_{\text{ideal}}} \qquad \mathbf{8.6(11)}$$

where Q_{actual} and Q_{ideal} are the actual and ideal section heat absorption rate (BTU/hr or kJ/hr), respectively.

Then, the cleanliness factor is defined as the ratio of the actual effectiveness vs. the baseline effectiveness.

$$\text{CF} = \frac{\varepsilon_{\text{actual}}}{\varepsilon_{\text{baseline}}} \qquad \mathbf{8.6(12)}$$

The baseline effectiveness is determined by design and can usually be calibrated in the field. Because the baseline heat-transfer effectiveness is most likely assumed to be a constant in practice, the cleanliness factor CF can be conveniently represented by the $\varepsilon_{\text{actual}}$.

A conventional method of calculating the heat absorption rate is the log-mean-temperature-difference approach, which requires steam (water) and flue-gas temperature measurements at each heat-transfer section inlet and outlet. The formula is

$$Q = \mu A T_{lm} \qquad \mathbf{8.6(13)}$$

and

$$T_{lm} = \frac{(T_{g_i} - T_{s_o}) - (T_{g_o} - T_{s_i})}{\log((T_{g_i} - T_{s_o}) / (T_{g_o} - T_{s_i}))} \qquad \mathbf{8.6(14)}$$

where

μ = surface heat-transfer coefficient (same as ε)
A = heat exchange section area
T_{g_i} = flue-gas temperature measured at section flue-gas inlet
T_{g_o} = flue-gas temperature measured at section flue-gas outlet
T_{s_i} = steam temperature at section steam inlet
T_{s_o} = steam temperature at section steam outlet

The steam/water temperature can be measured at many places along the boiler heat-transfer path. On the other hand, flue-gas temperature measurements are usually only available around air heater inlet and outlet. At all other locations, flue-gas temperatures have to be obtained by backward computations according to a system of energy balance equations.

Another method for calculating heat absorption and cleanliness factor is empirical model based.[35] Given the steam flow rate, temperature, and pressure at each section inlet and outlet, the actual heat absorption can always be calculated as

$$Q = F_s \cdot (H_o - H_i) \qquad \mathbf{8.6(15)}$$

where

F_s = steam flow rate (lb/hr)
H_i = steam enthalpy at section inlet (BTU/lb)
H_o = steam enthalpy at section outlet (BTU/lb)

Enthalpy H, as a function of steam temperature and pressure, can be determined from the standard ASME steam tables.

In order to model the ideal heat absorption for a clean section, fire-side influence (i.e., the flue-gas temperature) needs to be identified. The idea is that the steam temperature at section outlet is largely decided by section inlet flue-gas temperature and section fouling status. So, in the ideal clean section situation, if all required measurements are available, the calculation of ideal heat transfer can be modeled as

$$Q_{\text{ideal}} = f(F_s, T_{s_i}, G_i) \qquad \mathbf{8.6(16)}$$

where G_i generically represents all variables that have influence on the section inlet flue-gas temperature.

This empirical method relies on the system's ability of identifying all fire-side influencing variables and correctly interpreting the acquired data that represents a clean boiler section. A typical boiler will have cleanliness calculation for

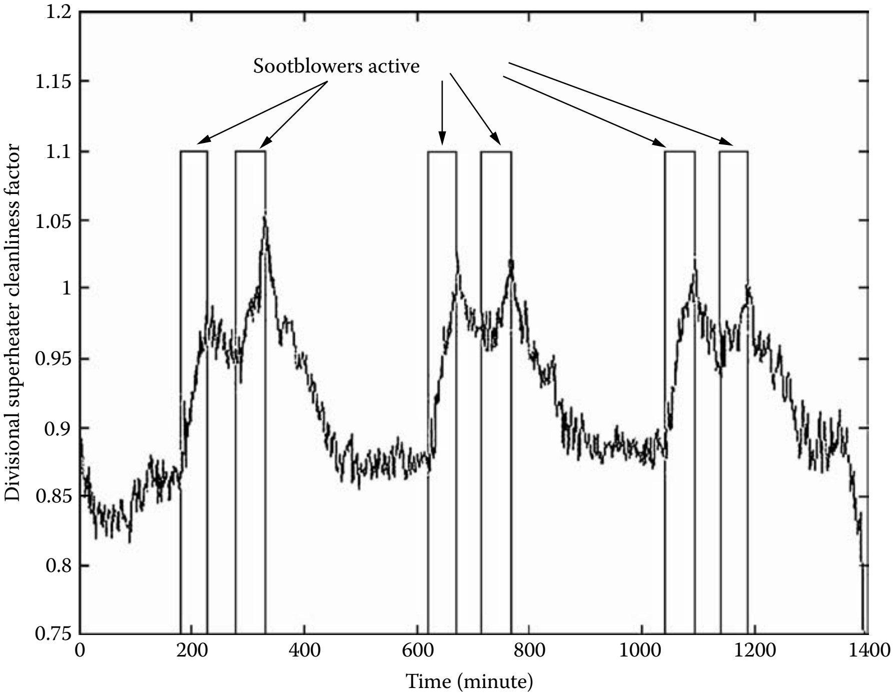

FIG. 8.6pppp
Trend recording of the cleanliness factor.

the furnace wall section, the economizer section, the air heater section, and each of the superheater and reheater sections.

Figure 8.6pppp shows an example of the cleanliness factor calculation results. Also worth mentioning is that, in order to directly measure heat absorption rate for the furnace wall, in situ heat flux sensors can be installed in the wall area. However, the cost is high for purchasing, installation, and maintenance.

Rule-Based Expert System In addition to cleanliness factor considerations, expert systems also play a key role. Because operators are most familiar with the daily operation, their experience in detecting and handling different fouling scenarios is important and, therefore, should be incorporated into the rule base.

Expert rules can be implemented from the following perspectives.

- Determine the desired cleanliness factor for each boiler section. The soot-blowing decision can be made based on the difference between the desired and actual cleanliness factors.
- At low loads, the fouling is built up slowly, and hence longer idle time between running sequences is expected. Therefore, allowing the furnace wall to have relatively low cleanliness factor will leave more heat for the following convection sections. This also increases the opportunity to blow convection sections more, and should raise steam temperatures without having to lift the firing rate.
- At high loads, the fouling is built up rapidly, and hence shorter idle time between running sequences is expected. In this situation, superheat temperature tends to run too hot, requiring attemperating spray water to prevent overheating. Therefore, convection sections should be allowed to have relatively low cleanliness factors and the furnace wall section should be cleaned more often.
- In order to limit stack opacity, the fuel/air ratio, operating status of precipitator, and fuel burner will be frequently checked, and the result will be taken into account by the rule base.
- Regardless of cleanliness factors, there should be a minimum idle time between runs for each blower sequence.
- Regardless of cleanliness factors, each blower sequence will have a maximum allowed off-time so that slag will not be heavily accumulated in one area.

Model-Based Boiler Optimization

Once surrounded by skepticism, model- and computer software-based boiler optimization schemes have now been applied and proven successful in many utility and industrial boiler applications. Optimization typically involves O_2 and CO, and is targeted at efficiency improvement and, often, NO_x reduction as well. NO_x reduction of 10–30%, and heat rate

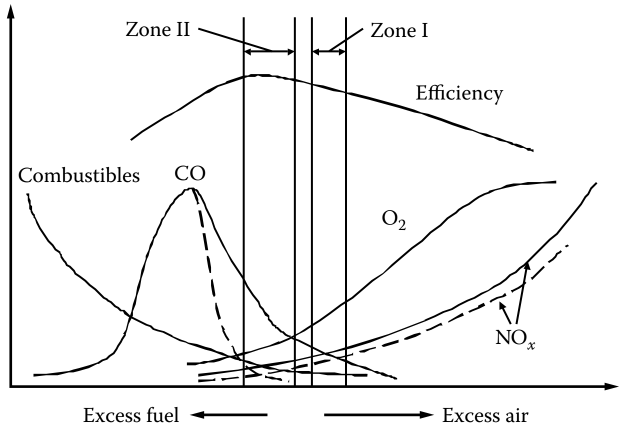

FIG. 8.6qqqq
Zones of optimum boiler performance.

improvement of 1–2% are possible.[36,37] Successful NO_x reduction through this kind of optimization can avoid or postpone large capital expenditures for low NO_x burners, over-fire air modifications, and SCR/SNCR.

Depending on the type and size, a fossil-fired generating unit may contain as many as hundreds of highly correlated, nonlinearly related, and time-varying variables. The Zone I shown in Figure 8.6qqqq is the optimal region for a traditional excess air-based efficiency optimization. However, the curve in the figure is usually obtained from design, or from simple experimental characterization at specific load levels for a specific control system setting.

The basis for boiler combustion optimization lies in identifying the relationship of important fuel/air parameters affecting the mixture and distribution of fuel and air within the firebox. By finding a better combination of all variables that affect fuel and air distribution, the NO_x curve in Figure 8.6qqqq can be shifted to the right and the CO curve can be shifted to the left. This would open up more room for improved optimization compared to strategies that rely only on excess air (O_2 trim) control. Advanced model-based control techniques can result in reduced O_2, CO, and NO_x, while keeping the boiler operated at a stable low oxygen zone (Zone II in Figure 8.6qqqq). Conditions leading to improved efficiency generally also result in better control and emissions performance.

Modeling The models are a set of equations that relate key performance measurements to the major influencing combustion control variables. Due to the complexity and uncertainty of the analytical models that are derived from physical principles, empirical models based entirely upon the plant data are typically used for practical boiler optimization control. Modeling starts with identifying potential controlled variables (CVs), manipulated variables (MVs), and disturbance variables (DVs).

The controlled variables are those performance variables that we would like to drive to the most cost-effective and regulatory compliant region. The manipulated variables are those that affect the CVs and can be directly adjusted by the control strategy. In the boiler optimization context, they are various supervisory set points (or their biases). The disturbance variables are the variables that affect one or more performance variables. They are measurable but cannot be adjusted by the control strategy directly. In the boiler case, it is usually the load (or steam flow) change. Depending on boiler size and configurations, the following controlled and manipulated variables are normally selected for the initial experiment.

Potential CVs are CO, NO_x, O_2, and boiler efficiency/heat rate.

Potential MVs are feeder speed bias, mill exit primary air temperature bias, O_2 trim bias, FD/ID fan bias, furnace pressure, auxiliary air damper bias, fuel flow bias, flue-gas damper bias, burner tilt bias, and secondary over fire air (SoFA) damper bias.

Step tests are normally carried out at different load levels, e.g., high, medium, and low load. Although it is desirable to exercise most parameters to values beyond those encountered in normal operation, due to operating constraints in most plants, the magnitude of the test signal is normally selected at 5–10% of the overall operating range. Correlation analysis can be performed to sort through the large number of variables involved and to identify the variables that have significant impact on the performance.

Modeled relationships can take the form of step response, impulse response, state-space representation, or a neural network (a direct nonlinear form). If a linear form is assumed, then the model is linearized about some operating point, or a series of linear models is produced; each represents a specific operating condition (usually load level). The obtained model can be used for solving a static optimization problem to find out the optimal operating point. The "optimal" criterion can be user selectable. For example, the selection can be minimizing NO_x, minimizing heat rate, or a combination of both. The model can also be used for carrying out closed-loop control, i.e., to use the identified MVs and drive the CVs to the region of optimal performance.

Closed-Loop Control and Optimization Closed-loop multivariable boiler control has to be planned and performed carefully, because plant operators are not traditionally willing to reduce air/fuel ratios due to concerns about CO and other symptoms associated with oxygen-deficient combustion. Model predictive control (MPC) is by far the most widely used technique for conducting multivariable boiler optimization and control. Forms of MPC that are inherently multivariable and that include real-time constrained optimization in the design are best suited for boiler application.

For example, when NO_x and CO are selected as CVs, in a constrained optimization they do not have to be controlled to any specific set point as long as they are all held below specified limits. NO_x limit can be specified either by regulation or by the plant operator. The CO limitation can be specified by the operator as a performance constraint.

Fuel quality, boiler loading, heat exchanger surface fouling, ambient condition, and aging of equipment will all cause process to drift and affect the model accuracy. Adaptive tuning computations can be built in to take care of known quantifiable relations (e.g., variation of dead time with load). Online training, incorporating an adaptive learning algorithm, can be used to automatically train models in real time, combining recent results with the initial and historical training data.

Certain results from the optimization calculation may be very intuitive. For example, it might call for reducing the top elevation mill coal flow whenever feasible, or removing the top elevation mill from service whenever the load can be sustained with the lower level mills.[29] This coincides with our intuition that reducing the fuel input for the upper level mill will result in a lower fire-ball position, and effectively lower the upper furnace flame temperature, which in turn reduces the thermal NO_x formation.

CONCLUSIONS

The various goals of boiler optimization include the following.

- To minimize excess air and flue-gas temperature
- To measure efficiency (use the most efficient boilers; know when to perform maintenance)
- To minimize steam pressure (open up turbine governors; reduce feed pump discharge pressures; and reduce heat loss through pipe walls)
- To minimize blowdown
- To provide accountability (monitor losses; recover condensate heat)
- To minimize transportation costs (use variable-speed fans; eliminate condensate pumps; and consider variable speed feedwater pumps)

If the potentials of all of the above optimization strategies are fully exploited, the unit costs of steam generation can usually be lowered by about 10%. In larger boiler houses, this can represent a savings that will pay for the optimization system in a year or less.[38]

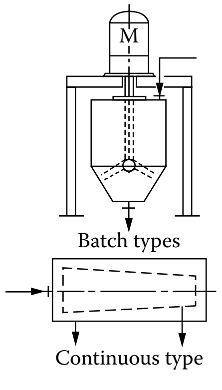
8.7 Centrifuge Controls

C. J. SANTHANAM (1970, 1985) **B. G. LIPTÁK** (1995, 2005)



Flow sheet symbol

This section reviews some of the basic centrifuge control systems used on both sedimentation and filtering centrifuges. The sensors used in measuring the product quality are also discussed.

CENTRIFUGE TYPES

Centrifuges can be used for both liquid–liquid and liquid–solid separation. The centrifuge designs can be classified into two main groups: sedimentation and filtering centrifuges.

Sedimentation centrifuges: These designs have solid walls, and separation occurs by sedimentation. This process is illustrated in the top portion of Figure 8.7a, where the feed enters a solid-walled bowl, which is rotating about a vertical axis. Centrifugal force and gravity both act upon the solid and liquid phases. The dominant force is the centrifugal one, which moves the heavier liquid phase or the heavier solid particles to the perimeter and thereby the separation of solid and liquid phases (or heavy and light liquid phases) takes place as shown.

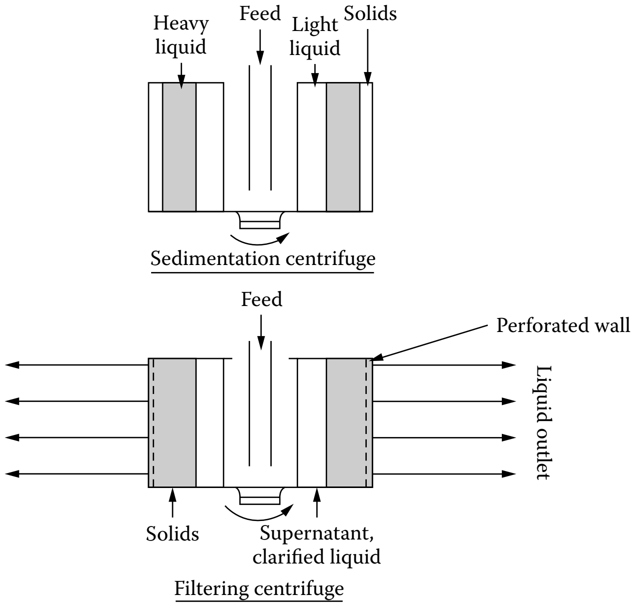


FIG. 8.7a
The operating principles of the sedimentation (top) and filtering (bottom) centrifuge designs.

Filtering centrifuges: These machines have perforated walls that retain the solids on a permeable surface through which the liquid can escape. This design is shown in the bottom portion of Figure 8.7a. The operation that takes place is similar to that of a filter but with a much higher "g force" than what can be obtained in gravity or pressure filtration. In these filtering centrifuges, nearly all the liquid is removed, leaving behind an almost dry cake.

The centrifugal force obtained in industrial machines is several times the force of gravity. If a particle is rotating with an angular velocity w and is located at a distance r (radius) from the axis of rotation, the centrifugal separating effect or g force is:

$$G = \frac{wr}{g} \qquad \textbf{8.7(1)}$$

Filtering centrifuges operate at a g force range of 400 to 1,800, whereas the g force in sedimentation units ranges from 3,000 to over 60,000 in laboratory machines (ultracentrifuges).

The critical speed phenomenon must be considered in the design and operation of centrifuges, as with any high-speed machine. At critical speed, the frequency of rotation matches natural frequency of the rotating member. At this speed, even the minute vibrations that can be induced by slight imbalances are drastically reinforced. Centrifuges pass through the critical speed during acceleration and deceleration, because their normal operating speeds much exceed the

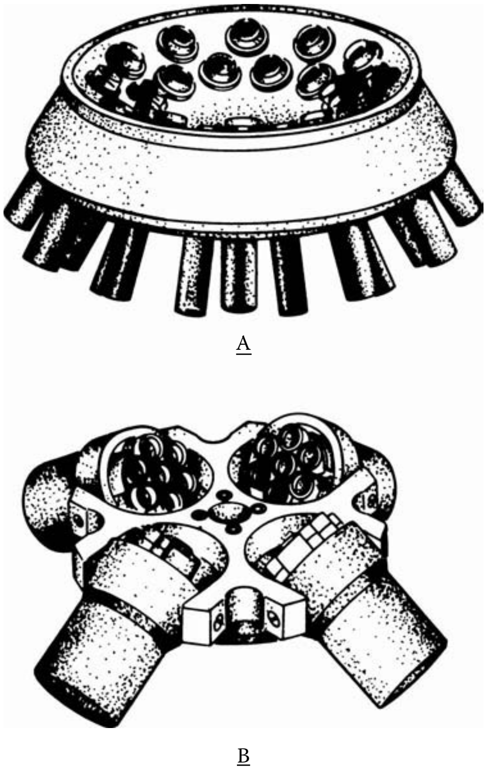

FIG. 8.7b
Tube holders in laboratory centrifuges can be of the fixed-angle (A) or the swing-out (B) design. (Courtesy of Cole-Parmer Instrument Co.)

critical. Therefore, except in case of major bowl imbalance, this does not cause problems.

Laboratory Centrifuges

Laboratory centrifuges are usually compact benchtop units. The samples that are to be centrifuged are usually placed in sample tubes, which are inserted into either fixed-angle or swing-out tube holders (Figure 8.7b). The sample sizes that the individual sample tubes can hold usually range from 1.5 to 15 ml, although special tubes are available for samples from 0.5 to 100 ml. The rotor assemblies can usually hold from 1 to 24 sample tubes. The speed of centrifuging can be fixed at around 3,500 rpm, or it can be variable, usually up to 14,000 rpm.

The maximum rotational centrifugal force (RCF) that can be obtained varies with the dimensions of the machine and with its rpm, from about 1,000 g to about 16,000 g. Some of the more sophisticated units can be microprocessor-controlled and provided with refrigeration and temperature controls. A simple fixed tube unit with 3,600 rpm and RCF equal to 1,400 g can be obtained for about $1,000; nonrefrigerated universal units cost about $2,500, while the refrigerated, microprocessor-controlled ones cost about $10,000.

INDUSTRIAL CENTRIFUGES

In selecting a centrifuge, several factors need to be considered, including (1) the ability of the machine to process the given feed slurry or emulsion to provide the desired degree of separation, (2) the reliability of the machine, (3) the operating and maintenance requirements, and (4) the investment.

Table 8.7c provides an overall orientation among the types of centrifuges, their sizes, *g* forces, capacities, and methods of solids and liquid discharging.

In the majority of cases, equipment manufacturers have standard machines that are adapted to the applications specified by the customer. Sedimentation machines are usually chosen on the basis of small-scale tests in laboratory centrifuges. Filtering centrifuges are chosen on the basis of tests in batch machines. Based on such tests, the manufacturers will offer specific machines and will outline the anticipated performance.

One important consideration in the selection among centrifuge designs is the size of the particles that are present in the feed slurry and are to be separated from it (Figure 8.7d).

Another important consideration in the centrifuge selection is the percentage of solids that are present in the feed slurry (Figure 8.7e).

The process control engineer should concentrate on two main control systems when working on a process centrifuge installations:

Feed slurry control: Regulation of the feed slurry at the correct continuous flow rate or in the right batch sizes. This is very important, because the machine cannot usually tolerate major variations in feed rate or feed composition. The accurate control of the wash liquor feed flow rate is equally important.

Sequencing operations: All batch machines are sequentially operated, and the related interlock design is one of the important steps in engineering a system. Figure 8.7f illustrates the sequencing of the program flow in a semiautomatic centrifuge operation.

In the semiautomatic system, the program can be run manually, one module at a time. The individual sequences can be started manually or by a higher level overall control system. This type of configuration is particularly suited for control systems where the sequencing program can be preset for making several products. Figure 8.7g illustrates the sequencing of the operation of an automatically operated centrifuge.

Sedimentation Centrifuges

Sedimentation units are used as clarifiers, desludgers, and liquid-liquid phase separators. Particle size in this processing is usually such that separation obeys Stokes' law. Sedimentation units are generally of small diameter and run at high speed. These can be classified into the following types: (1) tubular, (2) disk, and (3) solid-bowl. Overall data on present-day machines are presented in Table 8.7c.

TABLE 8.7c
Classification of Centrifuges

Rotor Type	*Range of Bowl Diameter in Inches (mm)*	*Maximum Centrifugal Force (g)*	*Method of Solids Discharge*	*Method of Liquid Discharge*	*Maximum Capacity*	
					gals/hr or ft^3/batch short tons/hr	*(liters/hr or m^3/batch) (short tons/hr)*
I. Sedimentation Centrifuges						
Tubular	2–6 (50–150)	60,000	Manual (batch)	Continuous	3,000 g/hr	(11,250 l/hr)
Disk	9–32 (230–800)	2,500–8,000	Batch or semi continuous	Continuous	12,000–24,000	(45 to 90,000 l/hr)
Solid bowl						
Constant-speed (horizontal)	14–36 (350–900)	1,000–3,000	Automatic batch	Continuous overflow	60 ft^3/batch	(1.7 m^3/batch)
Variable-speed (vertical)	12–84 (300–2 m)	Up to 3,200	Automatic batch	Continuous	15 ft^3/batch	(0.42 m^3/batch)
Continuous		Up to 3,200	Continuous	Continuous	Up to 65 tons/hr solids	(59 tons/hr)
II. Filtering Centrifuges						
Conical screen						
Wide-angle		Up to 1,400	Continuous	Continuous	15,000 g/hr	(56,250 l/hr)
Differential scroll		Up to 1,800	Continuous	Continuous	70 tons/hr solids	(63.5 tons/hr)
Vibrating screen		Up to 500	Continuous	Continuous	100 tons/hr solids	(90.7 tons/hr)
Pusher		1,800	Batch	Continuous	10 tons/hr solids	(9.1 tons/hr)
Cylindrical screen						
Pusher		1,500	Continuous	Continuous	40 tons/hr solids	(36.3 tons/hr)
Differential scroll		1,500	Continuous	Continuous	40 tons/hr solids	(36.3 tons/hr)
Horizontal		1,300	Batch	Intermittent	25 tons/hr solids	(22.7 tons/hr)
Vertical		900	Batch	Intermittent	10 tons/hr solids	(9.1 tons/hr)

The *g* concept is often used to compare the performance of solid-wall centrifuges. This equivalence converts the geometry, size, and speed of the bowl to the area of a settling tank theoretically capable of the same separation in a gravity field of unity.

The control strategies used for these centrifuges are different for batch, semicontinuous, and continuous applications.

Batch Centrifuge Control All laboratory centrifuges and also some of the smaller sedimentation machines in industry

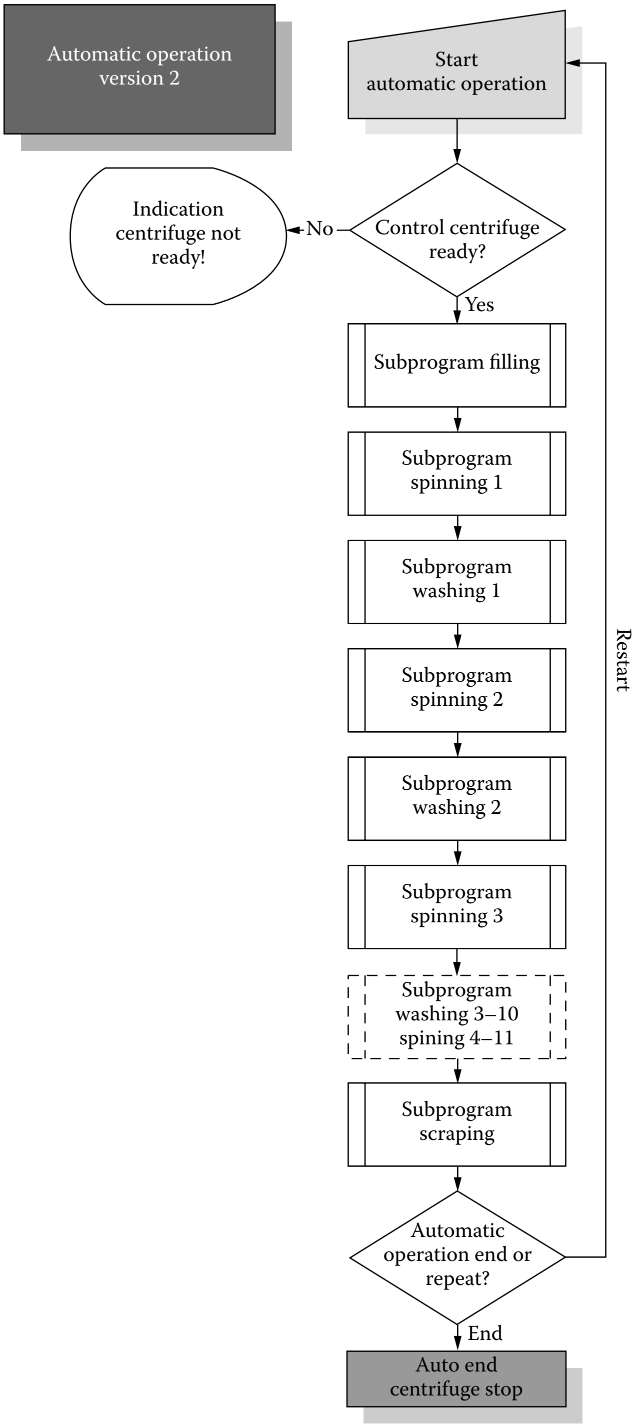

FIG. 8.7g

Sequencing of the operation of an automatic centrifuge. (Courtesy of Ferrum Ltd.)

are operated as batch units with manual control of the feed and of the discharge of solids. In such instances, little automatic control is required, because all sequencing is done manually.

In the category of automatic batch-type centrifuges, one finds the fall disk-type machines, such as the desludging centrifuges, and also some solid-bowl types. A simple control scheme for a desludging, or a clarifier-type, centrifuge is shown in Figure 8.7h. In this control system the controls are operated strictly on a time sequence, without any feedback controls of product quality.

The feed to the machine is introduced from a sludge or magma feed tank by gravity through valve #1. This valve is open throughout the cycle, except during flushing. Valve #2, the purge valve, is closed throughout the cycle, except during flushing, while valve #3, the sludge valve, is operated intermittently to discharge solids.

If a minimum head of 10 ft (~3m) is available, gravity flow is adequate for control. Feed tank location and tank and pipe size are determined to match the capacity of the specific application. The feed enters this unit at a predetermined rate and is continuously clarified. The clarified effluent is then discharged. The sludge accumulates in the system and is periodically ejected. The unit may or may not run at full speed while sludge is ejected. The interlock system or

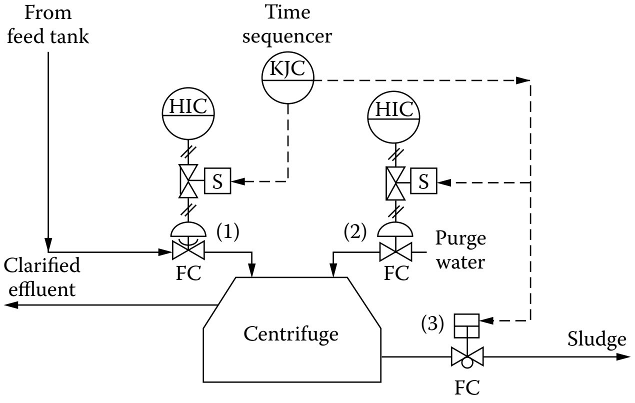

FIG. 8.7h
The most basic controls that can be provided for a desludging or clarifier-type centrifuge.

sequencing software requires a sequence timer and three working contacts to control the three control valves: 1) feed, 2) purge water, and 3) sludge. Usually added to this basic control system are partial desludging and other refinements, such as water sprays in specific parts of the unit.

In these units the choice of control valve is of major importance. For on/off service, properly chosen ball- or plug-type valves work satisfactorily. For throttling applications, refer to the slurry service valve designs shown in Figure 6.1ee and the associated discussion in Chapter 6.

In one modification of this machine, the sludge accumulates in an outer chamber. When this chamber is full, a sensing device initiates the desludging operation. Such centrifuges can tolerate significant variations in the sludge concentration in the feed liquor.

Continuous Centrifuge Control Among the most versatile centrifuge designs used in the petrochemical processing, polymerization, and waste treatment industries are the fully continuous solid-bowl type sedimentation centrifuges.

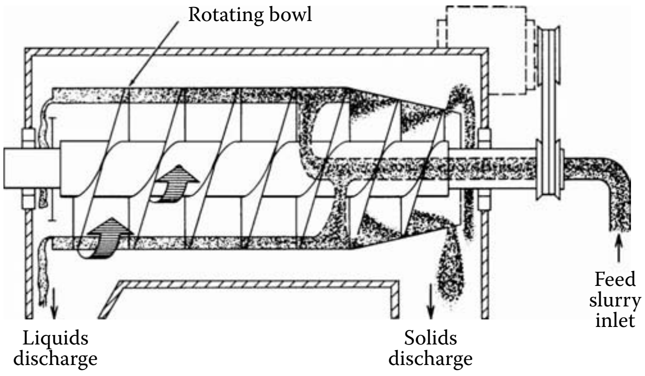

FIG. 8.7i
The operation of the rotating solid-bowl-type continuous centrifuge.

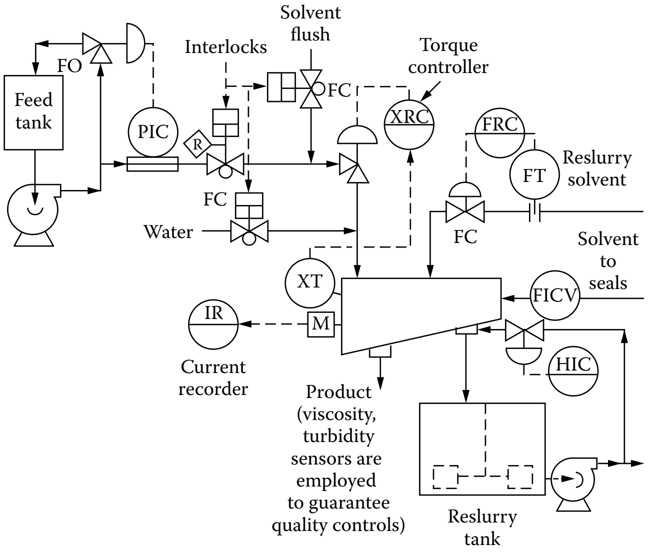

FIG. 8.7j
Solid-bowl centrifuge with feed pressure and machine torque controls.

One example of a solid-bowl centrifuge design is shown in Figure 8.7i. The slurry is introduced in the revolving bowl of the machine through a stationary feed tube at the center. It is acted upon by centrifugal force, and the solids (denser phase) are thrown against the wall. Inside the rotating bowl is a screw conveyor, which rotates in the same direction as the bowl, but with a slight speed differential with respect to the bowl rotation. This screw conveyor moves the solids up the beach and out of the liquid layer. Solids and clarified liquid are continuously discharged.

Control of these solid-bowl machines requires that the torque, which is developed by the unloading plow, be controlled. The control scheme shown in Figure 8.7j automatically adjusts the feed rate, in order to maintain the torque at a constant value.

The torque can be detected by rotating torque transducers with slip-rings and bearings, by inductively coupled torque transducers, or by noncontacting torque sensors, which are all discussed in Section 7.21 in the first volume of this handbook. Load cells are also frequently applied in such installations as torque detectors (Figure 8.7k).

The safety interlocks, not shown in Figure 8.7j, result in the shut-down of the centrifuge by closing the feed and opening the flush valve. Such shut-downs are usually initiated by the following conditions: (1) low coolant or flush flows to seals, (2) low flow or high temperature in the lubricating oil system, (3) high motor current, or (4) high torque. Other, less severe conditions, such as low reslurry solvent flow, might temporarily stop the feed and open the flush valve, but without shut-down.

It is important that a reasonably uniform slurry feed be supplied to the centrifuge. For this purpose, a circulating pump with a recycle line is usually installed to keep the slurry in motion and thus prevent the settling out of crystals in the tank or in the pipelines. In case the slurry does not settle

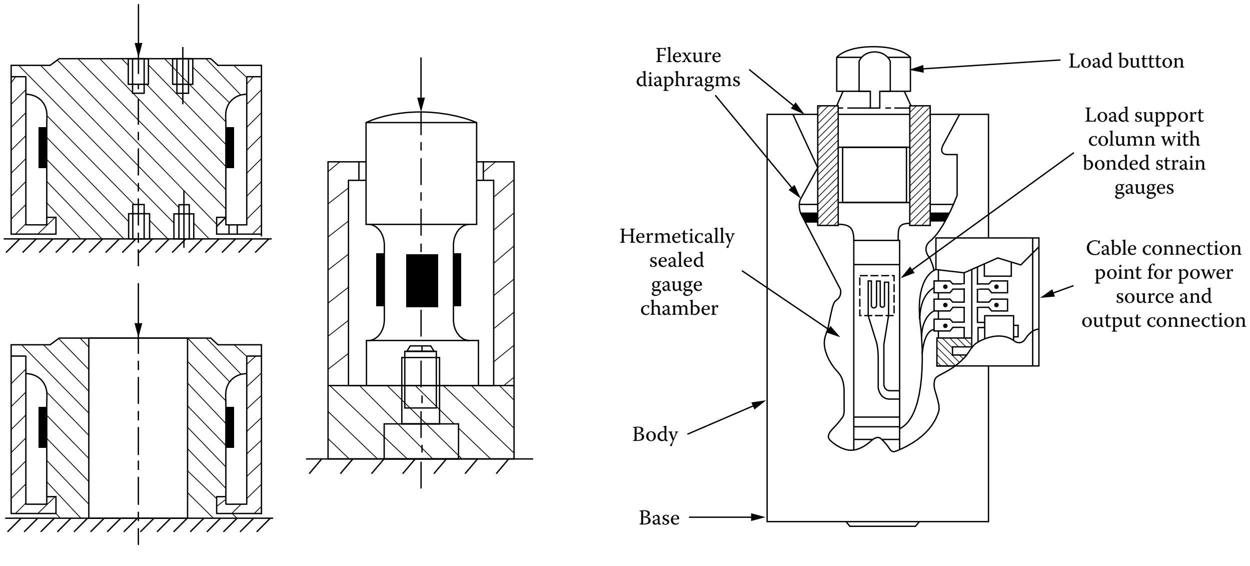

FIG. 8.7k
The force caused by torque can also be detected by canister-type load cells.

quickly, magma extraction can be performed by siphon. In Figure 8.7j, the recycle flow is throttled so as to keep the slurry feed flow to the centrifuge at constant pressure. On slurry service, it is important to protect the pressure sensor from plugging, and Figure 8.7l shows one of the chemical seal designs that can serve that purpose.

If the process slurry feed to the machine must be on flow control, the torque controller can throttle the relative speed of the conveyor and the bowl to balance the unloading requirements. The adjustment of the differential on the scroll (conveyor) is a manipulated variable that is also available to control other variables besides the torque on the machine. Product quality indicators, such as turbidity or viscosity, can also be controlled by feedback control of the speed differential in some applications.

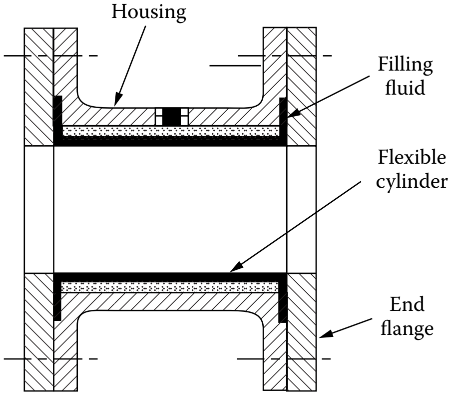

FIG. 8.7l
A full-stream spool-type seal can be used to protect the pressure sensor from plugging.

Filtration Centrifuges

Filtration centrifuges can also be batch, automatic-batch, and fully continuous. In all of them a cake is deposited on a filter medium held in a rotating basket, which is then washed and spun dry. The method of solid discharge is the main distinction among the various designs. Table 8.7c and Figures 8.7d and 8.7e provide performance data for some of the more common designs.

Automatic Batch Units Figure 8.7m illustrates two versions of intermittent feed controls for a horizontal cylindrical basket machine (also called a “peeler”) on automatic-batch sequence control. In the upper portion of the figure, a circulating pump feeds one or more centrifuges against a head tank, and the overflow from this tank is returned to the crystallizer. In the

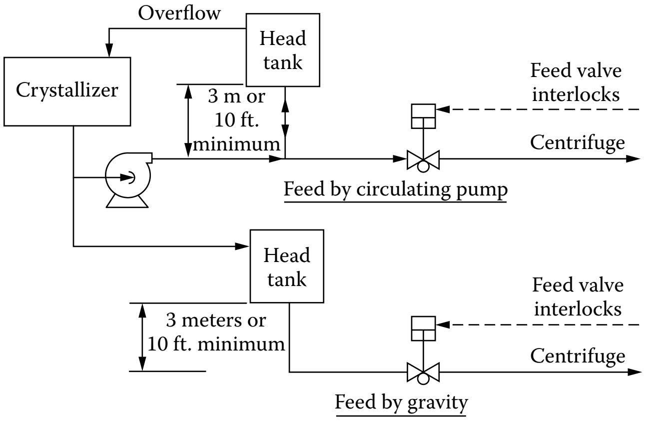

FIG. 8.7m
The intermittent feed controls of automatic batch centrifuges can utilize pumped (top) or gravity flow systems (bottom).

configuration shown at the bottom, the feed is charged by gravity alone.

A typical constant speed, automatic-batch machine will operate on the following cycle sequence:

1. *Screen rinse:* Residual layer of crystals is rinsed prior to loading.
2. *Loading:* Feed is admitted through the feed valves.
3. *Cake rinse:* After the crystal layer is established, feed is stopped and rinsing is started.
4. *Drying:* The cake (after washing) is spun dry.
5. *Unloading:* The unloading knife is cut into discharge solids.

In these machines the feed slurry and wash liquor line pressure are assumed to be reasonably steady, and therefore feed flow controllers are often not used. A variable-speed machine has a similar sequence, but in that sequence, at the appropriate points, periods are provided for acceleration and deceleration.

Continuous Centrifuges In a fully continuous machine, which can be the reciprocating pusher type or the differential scroll type, the only controls required are flow control loops to maintain the slurry and wash-water feed rates constant.

When the magma is continuously extracted, the total quantity of solids withdrawn must be controlled. This requires the measurement of the volumetric flow rate and of the solid concentration in the centrifuge feed and the throttling of the laundering fluid flow to maintain the solid charge rate to the centrifuge constant. However, in some cases this approach is considered to be too expensive.

There are less expensive methods for the continuous withdrawal of crystal magma at controlled rates: One is the removal in small batches but at such high frequency as to make the flow virtually continuous. This can be achieved by the use of ball-check-type or pulsing valves with adjustable stroke and frequency.

Another method of magma extraction involves the use of an elutriation leg attached to a crystallizer and the throttling of the laundering fluid inflow to control the magma density. One version of this control configuration is shown in Figure 8.7n. The laundering fluid is on flow control with its set point adjusted to maintain density as a measure of solid concentration. Measurement of the differential pressure between two points in the crystallizer can be a method of density detection.

An important aspect of this control system is the measurement of density in the elutriation leg. The measurement of differential pressure in this leg or between some other two points in the crystallizer can be used as a method of density detection (Figure 8.7o).

If higher accuracy is desired, ionization chamber-type radiation detectors can be used (Figure 8.7p). If they are provided with stable amplification, simple, reliable, and accurate density measurements can be obtained from them.

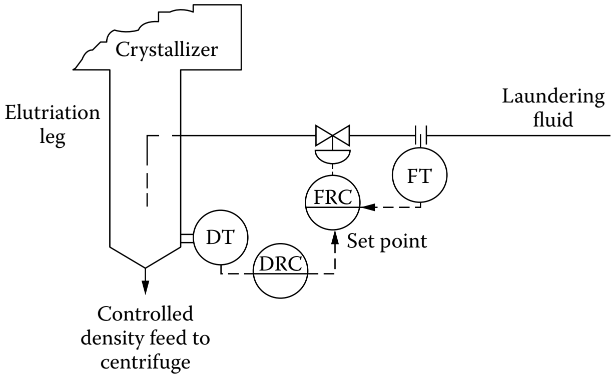

FIG. 8.7n
Controlling the density of the centrifuge feed can utilize an elutriation leg on the crystallizer.

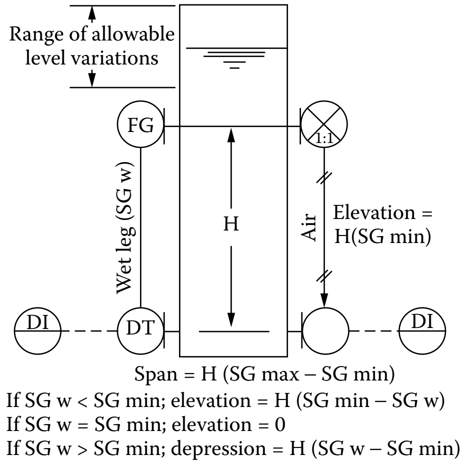

FIG. 8.7o
Density detection in the elutriation leg can be based on differential pressure measurement.

FIG. 8.7p
Ionization cell-type radiation detectors can be used to more accurately measure density.

In the crystallizer, occasionally, raw feed may be used as laundering fluid, but filtrate is more commonly used. Washing in these machines is also fully continuous, and wash fluid flow is on automatic control.

A special application is that of a scraped surface crystallizer, which is producing the slurry for separation in a continuous centrifuge. In such cases the liquor can be fed by a metering pump, and the centrifuge can be mounted in series with the crystallizer.

CONCLUSIONS

In addition to the main control aspects discussed, the actual centrifuge operation also involves a number of auxiliaries, such as wash lines for preventing the solid build-up in various parts of the unit, lube oil pumps and coolers, and discharge hoppers, which are provided with devices to prevent bridging.

Over the years, manufacturers have developed standard units that are adapted to specific applications. Operating characteristics of the various designs vary significantly, and the nature of the sludge and solids involved can necessitate extensive testing in order to minimize handling problems.

INTRODUCTION

This section concentrates on batch reactor automation and its component parts. Batch processes in general are covered in Sections 8.3 (Batch Control Description, Terminology, and Standard S88) and 8.4 (Batch Processes and their Automation). These sections should be studied when integrating a chemical reactor into a larger processing facility or into the whole plant.

Refer to Section 8.9 (Chemical Reactors: Control and Optimization) for the regulatory control and optimization strategies associated with chemical reactors, including the control of temperature and pressure and the determination of reaction endpoint. Section 8.10 (Chemical Reactors: Simulation and Modeling) describes the modeling and simulation of chemical reactors. The various aspects of DCS-based batch control systems were discussed in Chapter 4.

Control issues associated with external heat transfer equipment and transfer pumps are further described in Sections 8.11 (Chiller Control), 8.28 (Heat Exchanger, Condenser, and Evaporator Controls), and 8.34 (Pump Controls and Optimization). Many reactions require control of dissolved oxygen, redox potential, pH, or inerting systems, which are respectively covered in Sections 8.1 (Aeration and DO Controls), 8.31 (ORP Controls), 8.32 (pH Control), and 8.29 (Inerting Systems).

A batch process produces discrete quantities of material in a discontinuous fashion, such that the equipment states, process conditions, and batch composition vary with time. The starting of a pump, the opening of a valve, the completion of charging of a particular material into the reactor, and the reaching of the endpoint of a reaction are all events in time, requiring different operator responses and automated control actions. Designers and users of batch control systems must deal with time-varying process conditions and transition phenomena.

The control system will frequently serve the creation of multiple products and accommodate idle times between batches. Start-up and shutdown procedures are integral to the operation of each batch and are often automated to improve cycle time (for higher throughput) and repeatability (for quality and regulatory compliance). Preparatory procedures that must execute periodically or before every batch, such as cleaning, sterilizing, and pressure testing, may be automated as well.

Batch chemical processing has increased in importance in those industries that manufacture low-volume and high-value-added chemicals. The main advantage of batch processes is their great flexibility and rapid response to changing market conditions, but their unsteady-state operation makes tight quality control difficult. In these markets, increased customer demand for rapid commercialization of differentiated high-quality products has fueled the construction of highly flexible and highly automated batch facilities.

BATCH CONTROL CHARACTERISTICS

Sequential control encompasses all control functions (discrete and analog) triggered by events (time-based or process-based), whether normal or abnormal. In its simplest form, this comprises basic control functions analogous to those seen in continuous processes and relies on the operator to coordinate all control actions and status reporting required before, during, and after each process step. This can be overwhelming, causing overall performance to deteriorate. In a fully automated batch plant, these coordination functions are executed by the control system for multiple simultaneous batches queued from a production schedule, using preprogrammed product-specific material, equipment, and processing requirements for each batch.

Traditional batch automation is characterized by high project costs, lack of revision flexibility, and difficulties in maintaining the system. A desirable batch automation system, on the other hand, is easy to use and modify by the chemical and production engineer. It is also standardized and therefore can be designed by configuration and not by programming, plus it avoids costly maintenance and support associated with custom software. A desirable system should also be hierarchically built from a reusable library of preprogrammed and user-definable modules (application objects), so as to further simplify application development and eliminate re-engineering of commonly used components.

As shown in Table 8.8a, the automation of batch reactors can be structured in layers. Table 8.3b and Figure 8.4d have also defined such levels or layers. This section will discuss

TABLE 8.8a
Five Levels of Batch Automation

Process	*Control*
Plant	Plant management
Production	Batch scheduling, resource allocation, and reporting
Unit	Recipe-based unit control
Basic operations	Equipment control
Devices	Regulatory sequences, and discrete control safety interlock

the bottom three levels in Table 8.8a, which corresponds to Levels 2 and 3 in Table 8.3b. For detailed information about the automation of higher-level functions relating to production and plantwide automation, refer to Sections 8.3 (Batch Control Description, Terminology, and Standard S88) and 8.4 (Batch Processes and their Automation).

BATCH CONTROL STANDARDS

As covered in Sections 8.3 (Batch Control Description, Terminology, and Standard S88) and 8.4 (Batch Processes and their Automation), standards for batch and sequential automation have been prepared by the ISA SP88 Standardization Committee (1988, USA), based upon earlier work of the NAMUR Advisory Committee on Instrumentation and Control (1986, Europe).

The American National Standards Institute and the International Electrotechnical Commission have adopted the recommendations of the SP88 committee as U.S. Standards ANSI/ISA S-88.01 (1995), 88.00.02 (2001), and 88.00.03 (2003) and with minor revisions as European Standards IEC 61512-1 (1997) and 61512-2 (2001). These standards have enabled industrywide development of project methodologies and batch control system capabilities that facilitate organizing, communicating, and implementing batch automation requirements, and enable efficient skills transfer and database portability among disparate platforms. These developments should be taken into consideration when designing the automation of chemical batch reactors.

Standard Terminology

The following summarizes some of the core terminology identified in the international Purdue Workshop on Industrial Computer Systems[1] and the ISA S88.01/IEC 61512-1 standard[2] for precise definition, discussion, and solution of batch control problems:

BASIC CONTROL Continuously executed algorithms that drive the process or equipment to a specified state and keep it there, such as indicators, regulatory and device controls, and interlocks.

BATCH The product that is produced by one execution of a recipe.

CAMPAIGN The total production run of one product, for example, for a single order or season, consisting of one or more lots.

COMMON RESOURCE An equipment entity that services more than one unit, either simultaneously (shared-use resource) or one at a time (exclusive-use resource).

CONTROL MODULE Lowest-level equipment grouping that acts as a single entity from a control standpoint, but cannot execute procedural elements. May be an individual measurement (with suitable signal conditioning or state names) or a grouping of directly coupled actuators with their associated measurements, alarms, and control actions, including subordinate control modules as appropriate. Examples are an uncontrolled temperature, a flow control loop, an automatic block valve with limit switches, or a header containing interlocked (mutually exclusive) block valves.

COORDINATION CONTROL Control functions existing at multiple levels to schedule batches and manage recipes, procedural control execution, equipment entity allocation, and batch data.

EQUIPMENT CONTROL The procedural, basic, and coordination control capability that enables an equipment entity to perform its function. It is not part of a recipe, but may be directed by a recipe.

EQUIPMENT ENTITY A set of process and control equipment and associated control capability that has been grouped together to provide some specified process or equipment functionality.

EQUIPMENT MODULE An equipment entity incorporating necessary devices, control modules, and application-specific states and modes to execute some basic process-oriented task or group of tasks. May include equipment procedural elements (typically phase logic) or subordinate equipment modules, but may not overlap other equipment modules. Examples are a common (exclusive-use) weigh tank, a recirculation/transfer pump within a unit, and a shared-use ingredient dosing system.

FORMULA The list of process inputs, outputs, and data (operating set points, reported values, timing) required to execute the batch procedure.

LOT A collection of batches prepared using the same recipe. Typically, all batches of a lot are prepared from the same homogeneous source of raw material.

OPERATION A major programmed processing action or set of related actions, normally consisting of one or more phases.

PHASE The lowest level of procedural control to accomplish a process-oriented task. Phases may be further subdivided into equipment-oriented steps and transitions for executing a defined task, as described in

European Standard IEC 60848 (1988) for specification of sequential function charts. Normally, the phase boundaries represent points of process transition, hold, or activity. The boundaries define major milestones and possible points of safe intervention. Phases may exist either as part of a recipe procedure (recipe phase) or independently for equipment control (equipment phase); however, any constituent steps are always part of the equipment phase.

PROCEDURAL CONTROL Control that sequentially directs subordinate procedural elements or basic controls to execute the steps required by its defined process-oriented task.

PROCEDURE A user-defined set of instructions that define the strategy for making a single batch of a particular type or grade of product.

PROCESS CELL A grouping of equipment that comprises one or more complete trains and defines the immediate local domain for production scheduling (analogous to a work cell in discrete manufacturing).

RECIPE The complete set of data and operations that define the control requirements for a particular type or grade of final or intermediate product. Specifically, each recipe comprises a header, formula, procedure, and equipment requirements.

TRAIN A grouping within one process cell of units and associated lower-level equipment that is capable of making a batch of material. A train may define a single equipment path for a batch or multiple possibilities, of which one will be selected based on availability during execution of the control recipe. Multiple batches can be processed simultaneously in the same train (but different units).

UNIT An equipment entity that contains and performs some major processing activity or activities (e.g., react, crystallize, make solution) on one batch at a time. A unit normally comprises a major piece of equipment and directly associated control modules or equipment modules that are not shared with other units.

UNIT PROCEDURE A major programmed processing action or set of related actions, normally consisting of one or more operations. Unit procedures are naturally related to a distinct regime of production: for example, all processing carried out in one batch unit of a multiunit production line.

BATCH REACTOR CONTROL

Regardless of whether the ISA S88/IEC 61512 standards will be fully applied in the automation of a particular batch reactor, their basic concepts should be understood to provide a common basis for analysis, modularization, and communication of the control requirements. The following summary identifies key points of Sections 8.3 (Batch Control, Terminology) and 8.4 (Batch Processes and their Automation) that are required to discuss batch reactor control in this context.

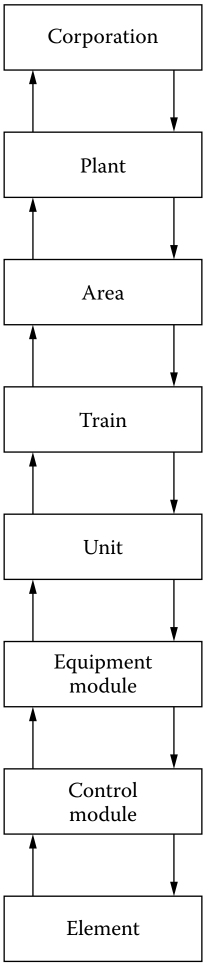

FIG. 8.8b
The equipment model of hierarchically grouped physical assets.

The physical assets of a manufacturing enterprise are hierarchically grouped within a physical model into the following levels: enterprise, site, area, process cell, unit, equipment module, and control module (Figure 8.8b).

The ISA S88/IEC 61512 documents identify a standard structure for batch control at the bottom four levels of this hierarchy (see Definitions above). Suitable decomposition of process cells into units, equipment modules, and control modules underpins successful application of the standards, as does the long-term development of well-constructed specification and component libraries for recurring module and procedural element functionalities. Table 8.8c illustrates how the various conceptual models defined in the standards and summarized below align with this physical model.

Control Concepts

Batch control spans multiple levels of the physical model and comprises three distinct types of control:

TABLE 8.8c
Conceptual Model Relationships in ISA S88/IEC 61512

Physical Model Structure	*Batch Control Concepts*	*Process Model Structure*	*Procedural Model Structure*	*Recipe Types*	*Basis of Recipe Procedure Definition*
Enterprise				General recipe	Process model (general processing requirements)
Site				Site recipe	
Area					
Process cell	Coordination control			Master recipe	Procedural model (procedure to deploy process model using available equipment)
		Process	Procedure	Control recipe	
Unit*	Procedural control	Process stage	Unit procedure		
		Process operation	Operation		
		Process action	Phase		
Equipment module*					
	Basic control				
Control module*					

* May comprise common resources that service multiple units, either simultaneously (shared-use resource) or one at a time (exclusive-use resource).

Basic control is responsible for establishing and maintaining associated process and equipment variables in defined states based on external commands, analogous to continuous process control. It comprises continuously executed functions of control modules and equipment modules such as process indication, regulatory (including PID, fuzzy, multivariable, and custom algorithm) and discrete control, interlocking, and cyclic operations (such as sump pump or bag house solenoid control). These control functions may be executed automatically, manually, or external to the control system.

Procedural control comprises both equipment-specific (equipment control) and product-specific (recipe control) functions that are hierarchically organized to determine the execution order of equipment phases and, through those phases, provide supervisory commands to basic control. Recipe control requires definition of a procedural control element at the recipe procedure level and supporting equipment phases at the unit or equipment module level, with peer-to-peer transference from recipe control to equipment control occurring at some level of the recipe and equipment procedure hierarchies.

Coordination control operates primarily at the process cell level to schedule batches and manage recipes, procedural control execution, entity allocation, and batch data. Status, availability, and control mode propagation (downward or upward in the control hierarchy), however, are parts of coordination control that are best managed by the equipment entities themselves (units, equipment modules, and control modules).

Recipe Types

A recipe typically defines the product-specific procedural control requirements for producing a single batch of a specific product. Additional recipes may be defined to separately schedule ancillary activities for production equipment, such as cleaning and sterilizing. Four standard recipe types defined at various levels of the physical model are used as follows:

General recipes are defined at the enterprise level and tightly controlled by R&D to standardize the process across multiple sites and support multisite production planning. These material-centric recipes define a complete process from raw materials or intermediate products to final product and are generally represented in material-centric Process Procedure Chart (PPC) notation defined in Section 7 of ANSI/ISA-88.00.03.

Site recipes are defined in PPC notation based on corresponding general recipes, with some added site-specific information. They standardize the process across the site, support long-term production scheduling, and reflect only that portion of each general recipe that can be executed locally.

Master and Control Recipes *Master recipes* unique to each product or intermediate product made in each process cell are constructed from corresponding site recipes either manually or automatically, reflecting only the portion of the production activity that can be completed in that cell. These standardize the actual production procedure to be used based on the type of equipment available in the process cell and support detailed production scheduling.

Master recipes are generally represented in equipment-centric Procedure Function Chart (PFC) notation defined in Section 6 of ANSI/ISA-88.00.02. Ancillary master recipes may also be defined to efficiently schedule and execute product-independent recipes for such activities as equipment cleaning and sterilization, which are excluded from general and site recipes because they are not process-related.

Control recipes are batch-specific and identify the specific equipment used to make the batch. They are normally created by a batch server from the corresponding master recipe upon scheduling and initialization of each batch and include all associated schedule details, parameter changes, and results.

Recipe Structure Each recipe is defined by four basic elements, with a fifth category for ancillary design and operation data. The content of each category varies with recipe type as follows:

Header contains administrative information (e.g., recipe name, product identification, and version control).

Procedure hierarchically defines the processing strategy, based on the process model (process, process stage, process operation, process action) for general and site recipes and based on the procedural model (procedure, unit procedure, operation, phase) for master and control recipes. Each level of the hierarchy is defined by a recipe-specific series and parallel combination of subordinates and transition conditions.

Equipment requirements are listed for the entire batch and for each procedural element. These comprise design data in general and site recipes (such as materials of construction and design temperatures) vs. selection criteria for master and control recipes (such as first available sterilized "type 2" reactor).

Formula comprises all parameters to properly execute the procedure. All recipe types require process operating conditions, but general and site recipes may include acceptable parameter ranges and detailed heat and mass balances vs. master and control recipes with settings related to the local equipment type and capabilities.

General information, optionally provided, can range from special safety considerations and conceptual process flow diagrams in general and site recipes to links to material safety data sheets, standard operating practices, and P&IDs in master and control recipes.

Programming Concepts

Three underlying concepts that also must be understood for successful implementation of these models relate to object-oriented programming, object commands and states, and exception handling. These concepts apply to the models described above as follows:

Object-Oriented Programming The power of the S88 models lies in the separate layering, modularity, and reusability of equipment and procedural elements. Object-oriented programming is an enabling technology for efficient implementation (and specification) of these structures, whereby the functionality (including commands and state definitions), data links, and parameters associated with each control element are encapsulated in a single object.

Similar objects may be generated through simple replication with new data links and parameter values, but this creates multiple copies of the program that must be individually corrected and retested for validation. If the same objects are instead *instantiated* from an object class with the same properties, then a single copy of the source code provides the designed functionality. In this case, full validation is required for only one instance and data links and parameter values checked for all instances.

Combining object classes with minor functional differences into a single class can yield even greater efficiency. Depending upon the target system capabilities, this may be accommodated through either additional parameters or subclasses. Following validation, the specifications and code for each object class and subclass should be stored in a library for reuse on subsequent projects.

Object Commands and States *State* is defined in S88.01 as "the condition of an equipment entity or of a procedural element at a given time." Equipment states are represented by user-defined enumerations, which normally relate to availability for units (e.g., reactor with states of dirty, clean, sterile, and out of service) and combinations of input/output (I/O) states for control modules (e.g., block valve with states of open and close) and equipment modules (e.g., pumping station with states of stop, recirculate, and transfer).

Unit objects do not normally receive commands, as in principle they are just containers for lower-level entities and procedural elements. Control module and equipment module state commands comprise requests to set the module's output(s) to the indicated state, based on an internal lookup or hard-coded correlation (note that the outputs are not commanded directly, and the receiving module ultimately decides if the requested transition is permitted).

Phase objects have a standard set of states and commands, which usually corresponds to the example given in S88.01. Under this model, the phase executes normal logic and monitoring functions in the running state and optional exception logic in the pausing, holding, stopping, or aborting state before entering the quiescent paused, held, stopped, or aborted state, respectively.

These state transitions may be triggered by the operator (if permitted by system security) or automatically (via its internal exception monitoring functions or cascaded from higher-level procedural elements) and may be required to cascade upward through the procedural hierarchy. Higher level procedural elements have the same state enumerations and propagation capabilities, but generally handle exception conditions through normal transition logic.

Exception Handling *Exception handling* is defined in S88.01 as "those functions that deal with plant or process contingencies and other events which occur outside the normal or desired behavior of batch control." Due to transient behavior of batch processes, they are inherently more problematic to operate than continuous units and must respond appropriately to a large number of possible failures in the context of what is happening at the time. The problems encountered may relate to unavailability of material or equipment, process problems, or equipment malfunctions. This occupies a large portion of the control definition and is usually underestimated by engineers lacking batch control experience.

Pushing exception handling as far down the control hierarchy as possible and maximally utilizing low-level object classes simplifies the task by minimizing the amount of detail required in supervisory logic. For example, process alarms and device failures (e.g., failure to reach the commanded state) should be monitored and alarmed by the responsible control modules and responded to by operational interlocks.

Exception handling by associated phase logic need only enable and adjust any process-dependent alarm settings, confirm that commanded device states are permitted, and trigger its own exception logic when warranted. If recovery requires aborting one phase and executing another (such as reheating to reaction temperature following a feed loss and subsequent cool-down in a semibatch operation), then it must be dealt with manually or through appropriate transition logic above the phase level. Either way, appropriate interlocks must be present at the control module level (e.g., to prevent feed resuming below minimum temperature).

SEQUENCING LOGIC CONTROLS

A batch reactor control system is a combination of analog and discrete control functions supervised by procedural control logic. The various analog loops used in reactor control are discussed in Section 8.9 (Chemical Reactors — Control and Optimization). The discrete controls provide the capability to turn things on and off, and the procedural controls serve to initiate and step through the various process phases in logical sequence, as shown in Figure 8.8d. The equipment phases in a unit or common resource execute distinct minor processing activities in the batch cycle, such as charge, mix, heat, and transfer.

Equipment phase logic details can be reduced to a time-ordered combination of a few basic state transitions, resulting

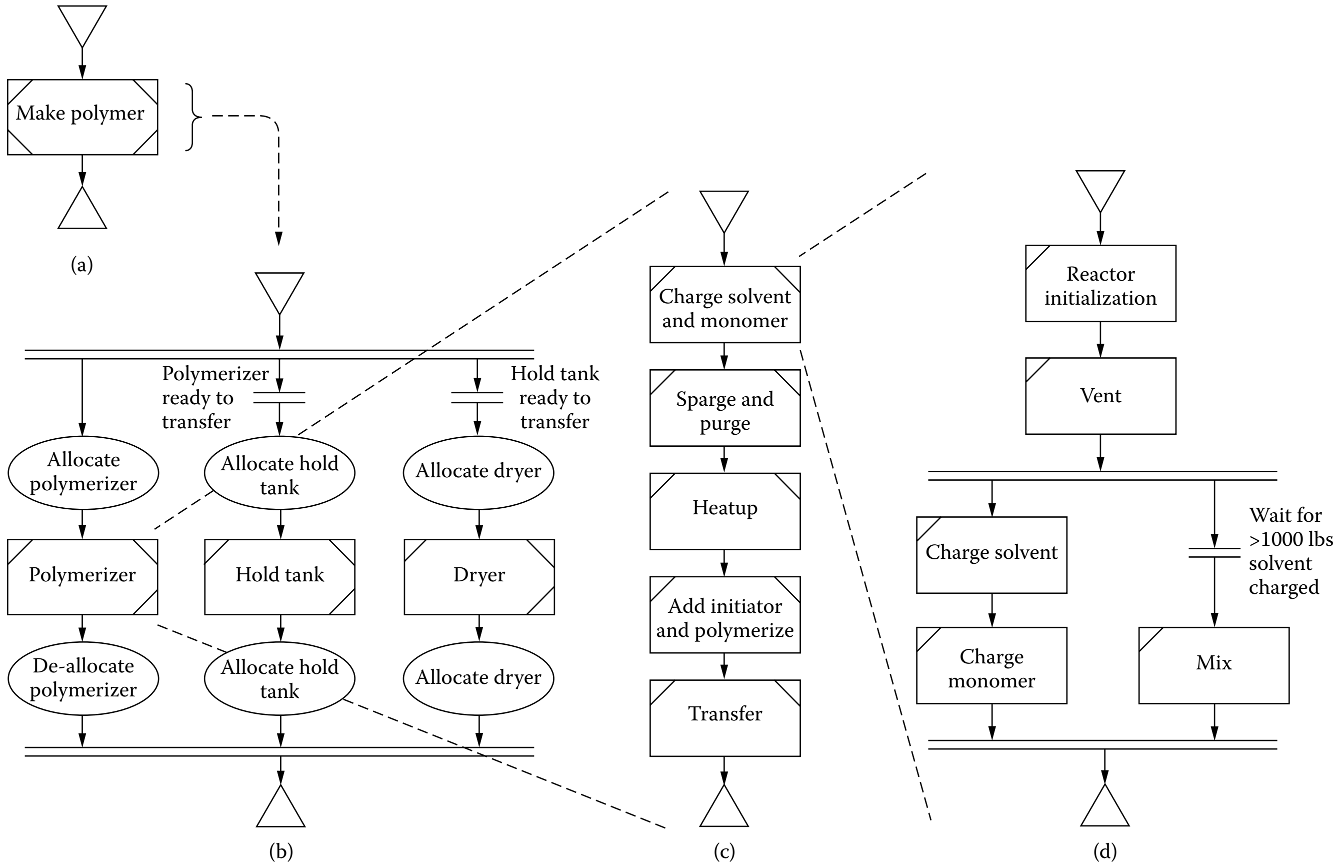

FIG. 8.8d

The sequence of steps required to produce a polymer product are shown in a hierarchy of increasingly detailed Procedure Function Charts (PFCs). These PFCs are comprised of recipe procedural elements down to the phase level for one operation of one unit procedure in a recipe: Procedure for recipe "Polymer X," (b) PFC for procedure "Make polymer," (c) PFC for unit procedure "Polymerizer," (d) PFC for operation "Charge solvent and monomer."

from the procedural steps described in Figure 8.8d. These actions are listed below:

1. Operate on/off devices (pumps, valves, and so on)
2. Activate or deactivate control loops
3. Open and close cascade loops
4. Supply control loop parameters, such as set point, ramp rate, alarm limits, tuning parameters, and flow integrals
5. Integrate flows
6. Initiate times or delays between processing steps
7. Perform calculations
8. Compare values, measurements, and test indicators and branch according to the results of the comparisons
9. Initiate alarm status or operator messages
10. Release control if nothing more can be done until the next sequencing interval

It is important to note that the data acquisition and loop control functions are not included as part of the phase logic. Rather, the equipment phase logic plays a supervisory role, communicating changes to the control modules and equipment modules as required in the same way that an operator would adjust set points and alarm limits during the course of a batch. In turn, the execution of equipment phases within each unit is coordinated and parameterized by the currently operating control recipes (or in some circumstances by the operator). Additionally, when purely manual actions are required, the phase will trigger an operator message to perform the activity and confirm after it is complete.

Figure 8.8e gives a specific example of the above generalized description. The upper portion of the illustration shows the physical equipment involved, including the nine controlled devices whose states are being logically sequenced. The lower portion of the illustration identifies the sequenced process states. During process state A the required quantity of raw material A is being charged. The prerequisites for the initiation of state A are that 1 and 4 be on and 6 be off. This means that the agitator must be on, the vent valve must be open, and the drain valve must be closed.

When these prerequisites are satisfied, state A is initiated by turning 2 on. This means that the charge valve of reactant A is opened and a control loop, such as that shown in Figure 8.8f, is activated. The required quantity of this ingredient is set by the recipe as Q_A. When this target is reached, process state A is terminated and process state B is initiated, which then performs its own tasks defined by the sequencing logic. In a more sophisticated reactor control system, the number of controlled devices and the number of logical sequence steps is much greater, but the basic concept is the same.

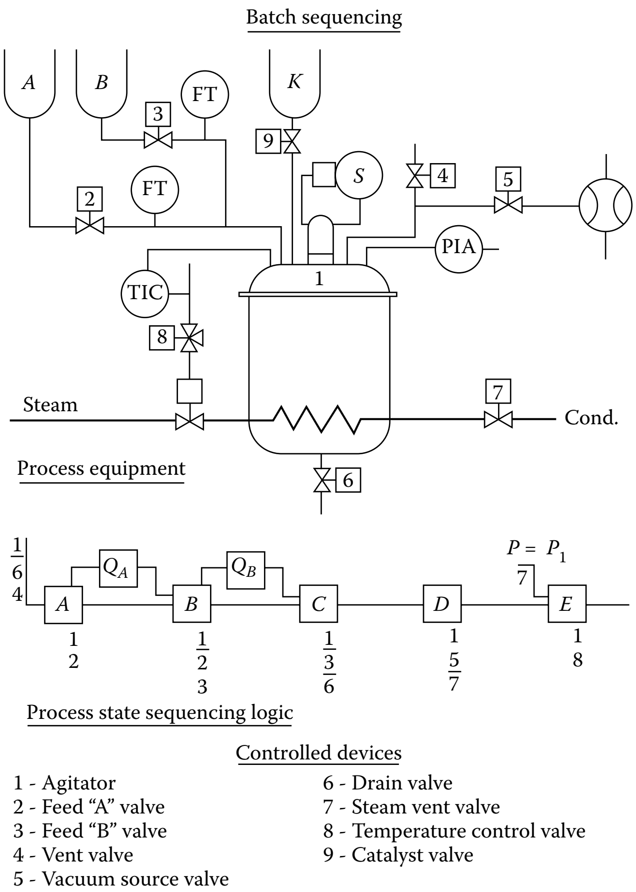

FIG. 8.8e

Example of batch reactor sequencing logic. On top is the physical equipment used; on the bottom is a flowsheet of the sequenced process states.

Recipe Procedures

The standard graphical notation for representing complex procedural control is the Procedure Function Chart for master and control recipes and the Process Procedure Chart for general and site recipes, which are respectively defined in the S88.00.02 and S88.00.03 standards. S88.00.03 also defines a more convenient tabular method that may be used in lieu of the PFC or PPC to specify procedural logic that is not highly branched. This method simply lists the operations and phases in sequence, using icons and path numbers to identify each parallel series of steps.

A simple example of a PFC is illustrated in Figure 8.8d. The triangles at the top and bottom of each PFC represent

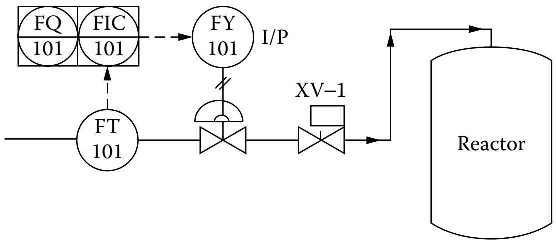

FIG. 8.8f

Flow control loop for charging reactant A.

its start and endpoints and rectangles indicate the procedural elements, with corner markers distinguishing the symbols for a procedure, unit procedure, operation, and phase. Ovals are used to indicate equipment allocation steps, and connecting arrows represent the sequence in which procedural elements are initiated at the next lower level, upon the prior element completing its execution.

Transition markers, indicated by a short double line, may be inserted at any point to provide additional conditions for initiation of the subsequent element. (Note that a procedural element may be notified when the transition below it goes TRUE, which provides a simple mechanism for requesting early termination of that element.) Parallel paths with a connecting double line above and below, as illustrated in Figure 8.8d(d), are initiated simultaneously and executed independently, with control passing beyond the endpoint after all paths have completed their execution.

Branching (not illustrated) among two or more alternative paths is possible simply by splitting the connecting line and placing a transition condition at the start of each path. This feature can be used in a reaction operation, for example, to repeat periodic catalyst booster charge and product sampling phases until a satisfactory lab result is obtained (i.e., operation-level exception handling).

Procedure Function Chart Execution

Execution of the illustrated procedure will be as follows. Procedure “Make Polymer” in Figure 8.8d(a) commences operation when a batch has been scheduled to execute on some train (which may specify a single product path or multiple options), initialized, and started. Figure 8.8d(b) specifies parallel execution along three paths for different unit procedures. The first branch causes an immediate attempt to allocate a polymerizer for the batch, selected polymerizers in the designated train.

If no polymers are immediately available (i.e., they are in use for other batches) or none are in the correct state (e.g., they have been cleaned by a separate equipment recipe that manages equipment and cleaning fluids), execution is suspended pending allocation of a polymerizer for the batch. The next step initiates the polymerizer unit procedure and waits for it to complete before deallocating the unit. Meanwhile, the parallel path for the hold tank waits for the transition condition “Polymerizer ready to transfer,” which becomes TRUE when the polymerizer reaches its transfer phase.

(Because this phase must work in tandem with the hold tank’s charge phase to move material between the units, it is necessary that both units be allocated to the batch during the transfer and that the unit procedures appear in parallel on the PFC. The transition condition prevents premature allocation of the hold tank, which might rob the unit of valuable operating time on another batch.)

After the transition goes TRUE, the hold tank unit level sequencing is analogous to the polymerizer (except that connecting pathways are also validated before allocating a hold tank); likewise for the dryer after “Hold tank ready to transfer” is satisfied. The “Make polymer” procedure is complete when all three paths have fully executed.

Continuing with this example, execution of one unit procedure, “Polymerizer,” triggers the PFC sequence illustrated in Figure 8.8d(c), in which each operation simply begins and executes to completion after its predecessor is complete. The “Polymerizer” unit procedure is complete when the entire series of operations is finished. The details of the “Charge solvent and monomer” operation, illustrated in Figure 8.8d(d), reveal how the recipe ultimately sequences the phases.

The progression of series and parallel execution for this typical operation is analogous to that described previously for the unit procedure. The mechanism for control propagation, however, differs significantly in that recipe phases merely contain parameters, links to equipment phase parameters, and equipment phase states and commands, with all of the procedural details located in the equipment phase. Moreover, these links are established only at run time within the control recipe, based on the currently allocated units for the associated batch. This is because each recipe phase (product-specific) must be able to interface with any corresponding equipment phase (equipment-specific) that might be selected to run the product.

Likewise, each equipment phase can be commanded at different times by a number of recipe phase instances, which may appear in the same or different recipes. Although the recipe phases and equipment phases belong to different object classes, this interface requires that all phases that are defined in the recipe unit class be present in the equipment unit. The corresponding phases in different equipment units need not be of the same object class, provided they expose the same parameter interface for the recipe phase. (It should be noted that this transference from recipe to equipment control may be done at any procedural level, but it usually occurs at the phase level and is discussed here only in that context.)

Equipment Control Sequence Logic

The sequential control functions of equipment phases, equipment modules, and control modules represent the heart of batch control functionality and the vast bulk of control software that must be defined and implemented. Various tools and methods have been used to describe the intended functions, including ladder and Boolean diagrams, state diagrams, matrix diagrams, time-sequence diagrams, Gantt charts, and sequential function charts, usually supplemented by a written description of the control objectives for each control object. Time-sequence diagrams are used here to illustrate detailed sequences of events.

Time-Sequence Diagrams

The time-sequence diagram shows the sequential changes in control actions and their time relationships. The sequence of events can be followed along dotted lines for vertical time coincidence and along the solid lines in a horizontal direction for sequence control.

The diamond symbol is used to indicate a trigger event, and a vertical dotted line indicates the time coincidence trigger events. When two or more diamonds occur in the same relative time line, an "AND" logic condition is assumed.

The format of the time-sequence diagram proceeds from left to right in discrete time steps, with relative time being the horizontal coordinate.

Figure 8.8g illustrates a time-sequence diagram for a flow loop, such as the one shown in Figure 8.8f. First, the valve XV-1 is opened and the controller FIC-101 is placed in automatic (t_0). When XV-1 is open and FIC-101 is in "auto," the continuous task of flow integration is started (t_1). When the desired total is reached (t_2), XV-1 is closed. When XV-1 is closed (t_3), the integration of flow continues to check for leakage. If, at the end of a preset time interval, the total flow is still zero, FIC-101 is switched back to manual (t_4).

Figure 8.8h describes a control system in both ladder and time-sequence terminology. Here, when the start button is closed and XV-1 is open (its contact is closed), motor coil *M* is energized. When the coil is energized, its auxiliary "M-contact" closes. Once the M-contact is closed, it keeps the coil energized even if the start button contact reopens. If at any time the XV-1 valve would fail closed, its limit switch contact will open to de-energize the M coil. Once the coil is de-energized, the auxiliary M-contact reopens.

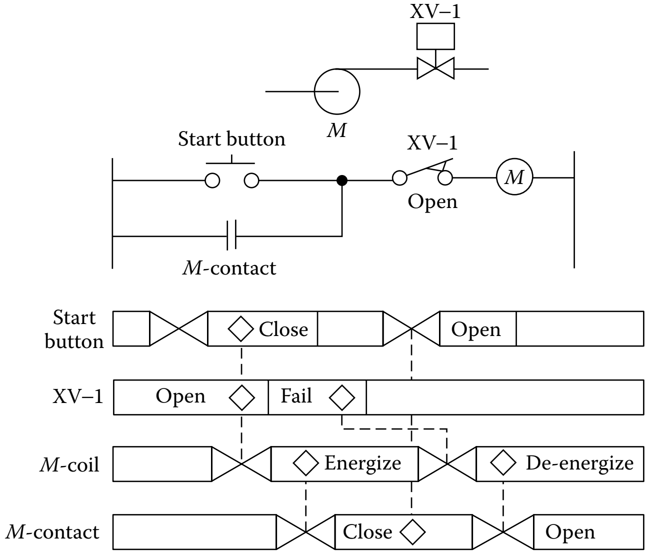

FIG. 8.8h
The time-sequence diagram of the flow control loop in Figure 8.8f is described in ladder diagram format at the top and by time-sequence diagram in the lower part of this figure.

In batch process units, the batch sequence is subdivided into *process states*. Each state is given a unique name, such as CHARGE, REACT, HEAT, COOL, HOLD, DISCHARGE, WASH, and EMPTY. Within each state, discrete

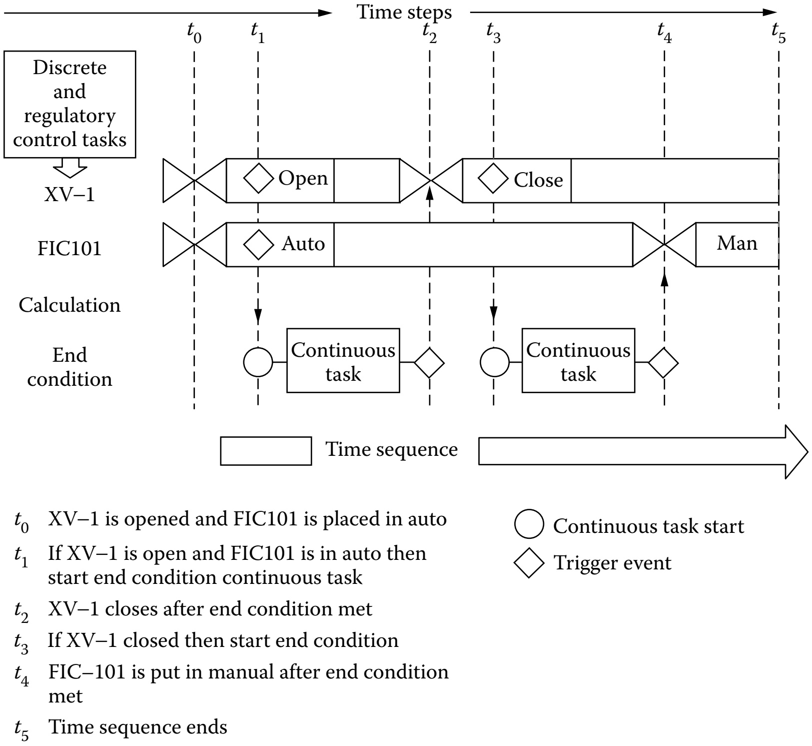

FIG. 8.8g

control functions, continuous-regulatory control functions, and safety and permissive interlocks are performed.

ENGINEERING A BATCH CONTROL STRATEGY

When microprocessor-based controls are used, the control system design follows the step-by-step approach described in Figure 8.8i to specify the functional requirements. The iterative nature indicated by the decision at the bottom is due to refinement of P&IDs, process definition, and control logic interactions over the duration of the project. Of the eight steps shown, steps 1-2 provide an overall foundation for the work to follow. Steps 3-5 specify equipment-centric requirements, steps 6-7 define the process sequencing and supervision, and steps 8-9 identify exception handling and reporting requirements.

Designing a suitable degree of control modularity at the equipment module level is the most important and challenging aspect of establishing overall design modularity and maximizing reuse of prior engineering efforts. Typical sequence control tasks and events to consider are shown in Table 8.8j.

Preparatory Steps

In the first step of Figure 8.8i (step 1), the process control engineer should review the P&ID flow sheets to make sure that the measurement and control devices and control strategies are accurately represented and that they are capable of meeting the requirements of the applicable general/site recipes or process description, standard automation practices, and expected cycle times. Ancillary automation requirements that are not covered by general/site recipes, such as clean in place (CIP), should also be reviewed. Any subsequently identified P&ID deficiencies must be noted as soon as possible to avoid costly rework later in the project.

In the next step (step 2), the engineer must identify and tabulate the process cells, units, trains, and common resources. As defined by ISA S88/IEC 61512 standards, process cells identify the physical limits for any single recipe/batch. Units and their associated controls may be allocated to only one batch at a time, so vessels that sequentially hold the same batch within a process cell line must be identified as separate units if they are to simultaneously process successive batches.

Equipment and controls that service more than one unit (e.g., a shared transfer pump) must be separately identified as common resources. Similar assignments must be made for continuous parts of the process, as units also define the common basis for alarm groupings and database structure.

Equipment-Related Requirements

In step 3, the process control engineer should identify on the P&IDs the discrete and analog measurement and control devices and tag them in terms of input and output signals. (If the instrument index is available at this time, the I/O list items may easily be extracted from it. Once the I/O list is established, it should be checked against the P&ID for recent changes. Note that assigning I/O to units and common resources may not be necessary, but will be helpful for sorting purposes during detailed design.)

In step 4, the engineer must define all basic control requirements (control modules and equipment modules, except phase logic) associated with each unit and common resource identified in step 2. In general, control modules are at least structurally well-defined by the P&ID, but equipment modules entail coordinated control (usually command- or event-driven) of multiple devices that is more subjectively defined based on P&ID symbols and notes, coupled with the engineer's analysis of operational requirements.

A control specification comprising a written description (or cause-and-effect matrix for simple interlocks) or control diagrams (based on ISA symbology, Boolean or ladder logic, sequential function chart, or time-sequence notation) is required to define each unique module class. If such classes have been well designed on previous projects, most new requirements will be drawn from a previously developed specification library, supplemented with a project-specific tabulation (sorted by unit or common resource) of tags, connections, and parameters that are unique to each required instance.

In order to maximize future reuse, specifications for each class of new modules should be as general as practical, consolidating similar types by using internal parameters to select features. Operating modes, human and supervisory control requirements, indicators (e.g., states, fault, module performance statistics), and relevant process calculations (e.g., material and heat balances and recipe corrections based on quality control data) should also be defined.

In step 5, the equipment procedural control is defined for each equipment module and unit, comprising phases and higher-level elements as appropriate. Supervisory control and parameter interfaces for each phase and suitable transition conditions and actions for each phase state must be identified.

Phase logic is the workhorse of procedural control, administering the real-time control functions primarily by sequentially manipulating and monitoring states of the various equipment modules and control modules via the previously defined basic controls. Equipment procedural elements, like basic control entities, can be reused across multiple products and projects by creating libraries of flexible and modular object classes for previously specified functionalities.

To be usable, however, such classes must be based on indirect addressing schemes that reference tag names generically within the unit or equipment module. Procedural control object classes, like those for basic control, can thus be documented in detail just for a single instance, with an appended tabulation of suitable linkages and parameter values for each instance.

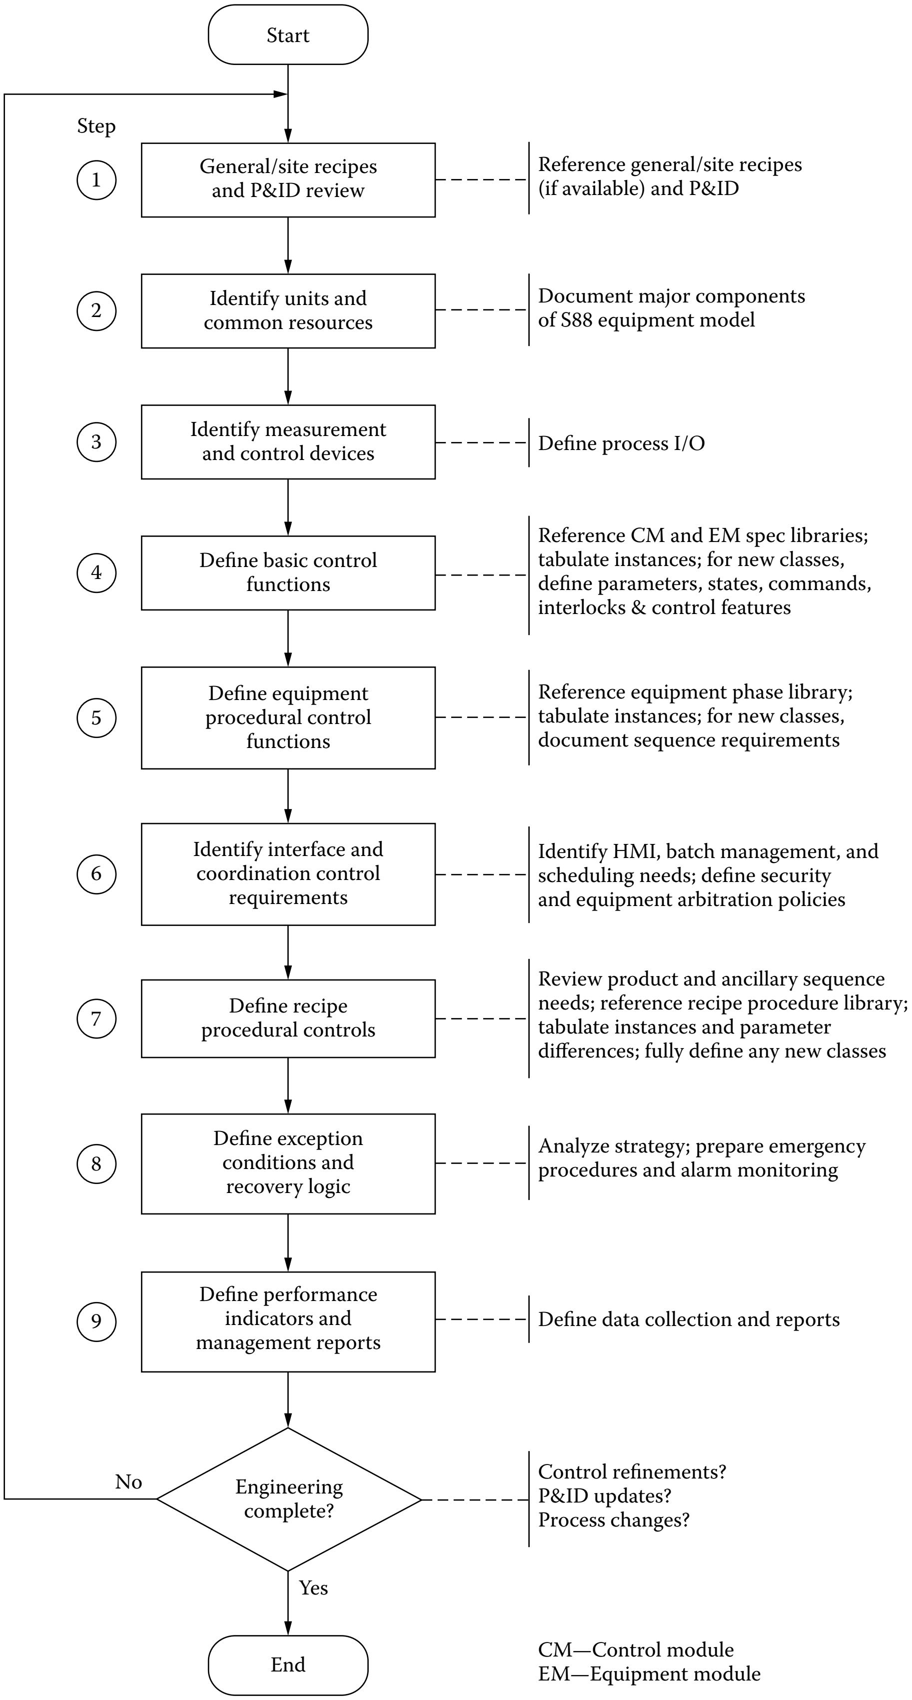

FIG. 8.8i

Step-by-step approach to specifying a microprocessor-based batch control system.

TABLE 8.8j
Typical Sequence Control Tasks and Events

1. Sequence start prerequisites and permissives (e.g., unit available, previous batch complete, interlocks satisfied)
2. Discrete element and devices (e.g., outlet valve, inlet value, manifold, agitator)
3. Regulatory control loop setpoint changes, mode changes, output changes, profiles, etc. (A/M-PID algorithm, SP profile, output)
4. End conditions
5. Timers
6. Calculations (e.g., heat or mass balance)
7. Operator action request/response (e.g., clean, take laboratory analysis, check batch end)
8. Process failure conditions (e.g., level too high, pressure too low)
9. Failure actions (branch to alternative sequence)

Process Sequencing and Supervision

In step 6, the engineer must identify the interface (human and data) and coordination control requirements, including how recipe management, production planning and scheduling, and production information management will work. If a commercial batch server will be used to implement the upper-level procedural control requirements, it will also perform most coordination control functions; otherwise, custom programming must be specified for this purpose (not usually cost-effective unless the required capability is very limited).

Guidelines must be developed for equipment arbitration, batch historization (including product genealogy tracking and electronic signatures, as needed), and application security. A custom operator interface may be required (along with extra phase logic for setting display variables such as status, step descriptors, prompts, fault messages, and parameters) to monitor and control phase execution details. Custom interlock displays and faceplates (and module-based display variables) may be required to adequately monitor and control nonstandard basic control functions.

In step 7, the master recipe is defined for each product, based on the process information identified in step 1, and for each ancillary equipment operation (e.g., CIP) that will be routinely scheduled. The procedure, unit procedure, and operation levels of the control strategy must be defined, as well as the equipment (unit and common resource) and formula requirements. Depending upon the equipment controls specified in step 5, the product recipes may be either unit-specific or not. Definition of master recipes can also utilize component libraries for rapid construction, particularly in circumstances where tabulation of formula differences is sufficient to accommodate most products.

Exception Handling and Reporting

In step 8, an overall failure analysis must be done, with the plant considered in its entirety. The consequences of potential device and equipment malfunctions, unexpected process delays and events, and abnormal process and quality measurements must be evaluated relative to the need for alarms or messages to alert the operator, for automatically holding or aborting the batch, and for any special response or recovery procedures. Various adjustments of the previously designed strategies may be required.

In step 9, all the historical data trending and reporting necessary for adequate production and performance management are designed and formatted. Batch processes have unique data storage and retrieval requirements, as information must be identified with individual batches as they move through the plant, as well as their ultimate material origins and disposition. Adjustments of the previously designed strategies may be required to cover unanticipated data requirements.

Implementation

Various microprocessor- and computer-based systems are specifically designed to perform the wide variety of control tasks involved in batch processes.

In the area of continuous (regulatory) control, a fill-in-the-blank-type language supported by CRT-based operator consoles has become an accepted standard. The fill-in-the-blank language is used to configure the control system database and to create many of the necessary control algorithms.

The discrete functions (direct on/off control, interlock control, sequence control) require *programming.*

Many programming languages available for generating control software are of the “high-level” type, meaning that the instructions are expressed in English. Various structures and procedures contained in the programming languages offered for control applications include:

- Processing discrete inputs and outputs
- Timing and counting routines
- Special routines applied to start up electric motors sequentially, in order to limit the inrush current imposed on the power supply
- Integration of analog variables
- Message triggering
- Transfer routines for synchronization of dual processors (whenever 100% redundancy is required).
- Dynamic links of discrete variables to P&ID-type graphic displays for monitoring batch processes
- Interface routines for linking recipe data files with the main control program

Process management functions are programmed using high-level languages that are well suited for data manipulations.

The application software development for a certain defined and specified project is considered finished when all the programs are debugged and are running within the constraints of the operating system and the hardware configuration. To avoid unexpected control interactions during start-up,

TABLE 8.8k
Performance Capabilities of Batch Charging Instruments

Detector	Type	Min. Error	Rangeability
Load cell weighing	Mass	±0.1% FS	NL
Turbine-type flowmeters	Volumetric	±0.25% AF	10:1
Positive displacement flowmeters	Volumetric	±0.25% AF	10:1
Metering pumps	Volumetric	±0.5% FS	20:1
Mass flow meters	Mass	±0.2% AF	20:1
Vortex shedding flow meters	Volumetric	±0.75% AF	10:1
Level	Volumetric	±0.25% in.	NL

AF—Actual flow.
FS—Full scale.
NL—No limitation.

a full simulation of the sequential control functions (run using the as-designed operator interface) is an essential debugging aid for complex batch processes.

Batch Charging

Reactants and catalysts can be charged into the reactors, either by weight or by volume, using flow meters, pumps, feeders, and weighing systems, as shown in Table 8.8k. The main considerations in making the selection are accuracy and reliability of the data obtained. Because material balances are always based on the weight (not the volume) of the reactants, all things being equal, the mass- or weight-type sensors would be preferable; using such sensors would eliminate the need for density or temperature compensation. If they cannot be considered for some reason, the solid-state volumetric sensors (vortex) would be preferred over the ones with moving parts (turbines, pumps, positive displacement meters), because sensors with moving parts tend to be high-maintenance devices, with frequent need for recalibration.

Therefore, in a new installation with no restrictions on hardware selection, it might be advisable to place the reactor on load cells and charge all ingredients that weigh more than 10% of the total batch by weight. Reactants and additives that are needed in lesser quantities can be added under the control of Coriolis mass flowmeter-based measurements with the load cells providing only backup. Catalysts or ingredients needed in extremely small quantities, representing less than 1% of the total batch, can be added by metering pumps or by specialized feeders.

UNIT OPERATIONS CONTROLLERS

In the last decade, manufacturers of shared, distributed controllers (which started out as microprocessor-based multiple PID controllers) have added more and more logic capability to their products. At the same time, manufacturers of PLCs (which started out as microprocessor-based programmable logic controllers) added more and more PID capability to their products. The result today is the merging of these products into devices that are capable of handling both analog and logic sequencing control tasks. Although the control industry does not yet speak in these terms, a new era of process control has arrived: the era of the “unit operations controller.”

The unit controller is capable of controlling a unit operation in the plant. That unit operation can be a reactor, a distillation tower, a compressor, or any other subsystem. This represents a major step forward because it makes it necessary to stop thinking in terms of controlling single loops—such as pressures, flows, or temperatures—and to start thinking in multivariable terms, controlling the overall unit operation.

This is a prudent and logical direction to take because plants do not produce and sell pressures, flows, or temperatures: they sell a product. Therefore, the truly relevant control variable is maximum productivity. To move from the age of single to multivariable mentality, the unit controller is required. The microprocessor is needed to memorize the complex nature of the unit process in order for control to take place on this new and higher level.

The chemical reactor is a natural candidate for control by unit controller. The number and types of input and output signals required and the types of control actions to be performed on them are within the capabilities of many microprocessor-based multiloop products on today’s market. Therefore, the user can implement right now all that is discussed in this section and in the previous section.

Today’s process control industry is somewhat software-limited. A large variety of well-designed “empty boxes” are available, which are provided with a library of low-level software subroutines for PID, logic, and other functions. Unfortunately, with few exceptions, it is up to the user to educate this box to become a reactor controller or some other unit operation controller. Depending on the manufacturer, these empty boxes are more or less “friendly” to the user.

High-level software packages will be developed in the future to give “personality” to the previously empty boxes. One plug-in cassette or floppy disk might educate an empty box to become a distillation tower controller, and other disks could give it the personality of a dryer, evaporator, reactor, or other controller. It goes without saying that these high-level programs would also require adjustment to fit the universal unit controller to the particular process, but this “custom fit” would occur at a much higher level.

All user inputs could be provided by process engineers. These inputs could deal with recipes, temperature profiles, equipment or piping configuration, and so on. While such high-level, all-purpose packages are not yet available, flexible and reconfigurable reactor control packages (available with or without the reactor equipment) have been developed. One such reactor unit controller is described in the following paragraphs.

REACTOR UNIT CONTROLLER

Reactor control systems can be distinguished based on many criteria. One of these is flexibility. If a reactor control system is specifically designed for a particular product to be made in a particular unit, the control system has no flexibility at all. Flexibility can be built into the controls, so that they might be used even if operating condition, raw material, or product specifications change ("static flexibility"). A higher level of flexibility is one where the control system can be used to make different products and to maintain different operating conditions ("dynamic flexibility").

If the equipment configuration and the associated piping connections can also be changed, this is called structural flexibility in a control system. In plants where products change often, such as in pharmaceutical plants, flexibility in the reactor control is an important consideration, because it allows for the implementation of new production strategies without loss of time or need for additional engineering design.

Figure 8.8l shows a reactor control system that is provided with some structural flexibility. The control system is basically a unit controller, which is initially "empty" in the sense that it has a certain I/O, display, and memory capability. That capability is not utilized by the supplier to configure a single reactor control system (nonflexible system) but rather is used to configure a variety of control systems, which can be selected by the operator as a function of the desired equipment and operations.

Figure 8.8l illustrates how a flexible reactor control system might be reconfigured into different control structures. In the "nonflexible" (dedicated) reactor control systems, the operator would only adjust the controller set points, tuning parameters, and the quantities of ingredients in the recipes.

With a flexible reactor unit controller, the same reactor might be used for reaction, stripping or distillation, or crystallization, and for each operation a different control configuration and different tuning constants are needed. Because of the many operations taking place within the same reactor, the sensors must have wide rangeability and the controllers must be adapted for variable gain operation, because the time constants (dynamics) of the process changes with time.

The equipment accompanying this reactor unit controller is shown in Figure 8.8m.[3] The most important piece of equipment is the reactor itself. In addition, the following equipment modules exist and will be described in the following paragraphs:

1. Jacket system, with pump, on/off and control valves, and steam ejector
2. Distillation system, consisting of reflux cooler, condenser, water separator, and receiving tanks
3. Charging system, with weighing equipment and other instruments
4. Feeding system, consisting of a feeding tank, a dosing pump, and control devices

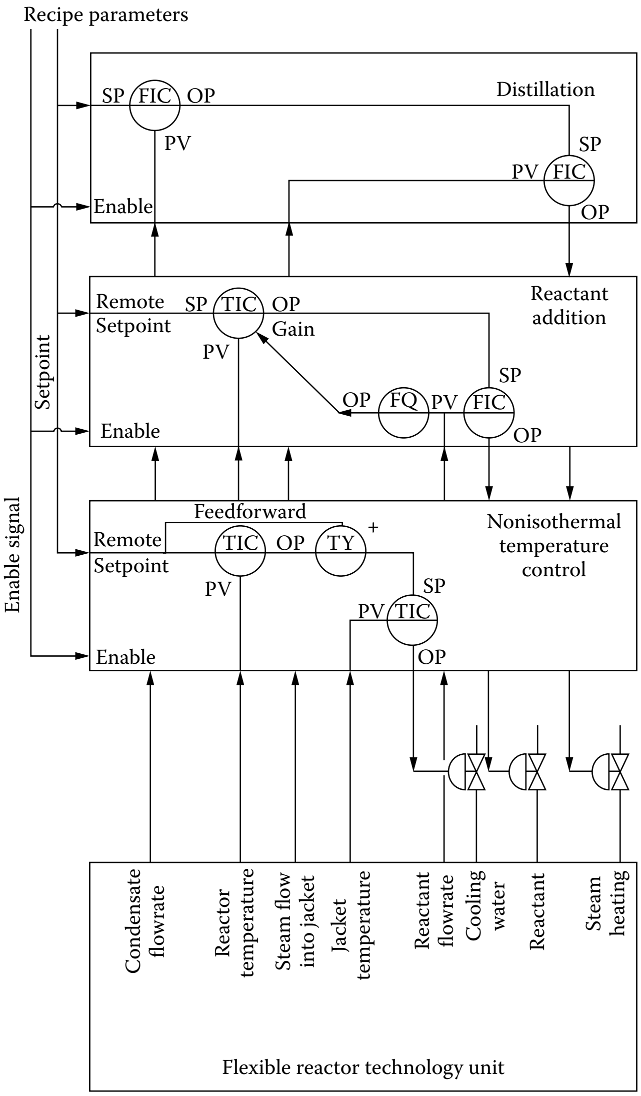

FIG. 8.8l
Illustration of the flexibility that a unit controller can provide.

5. Auxiliary systems, with equipment to perform operations such as clean in place, material transfer, inertization, and so on

Each equipment module is provided with the measurements necessary for operations and control.

Jacket Equipment Module

In addition to the jacket itself, the jacket equipment module consists of a pump, a steam ejector, two control valves (TCV-1 and -2), and ten on/off valves (V1 to V10). The various options on the operation of the jacket controls are described in Section 8.9. The jacket system can be in several states, as shown by the state diagram in Figure 8.8n.

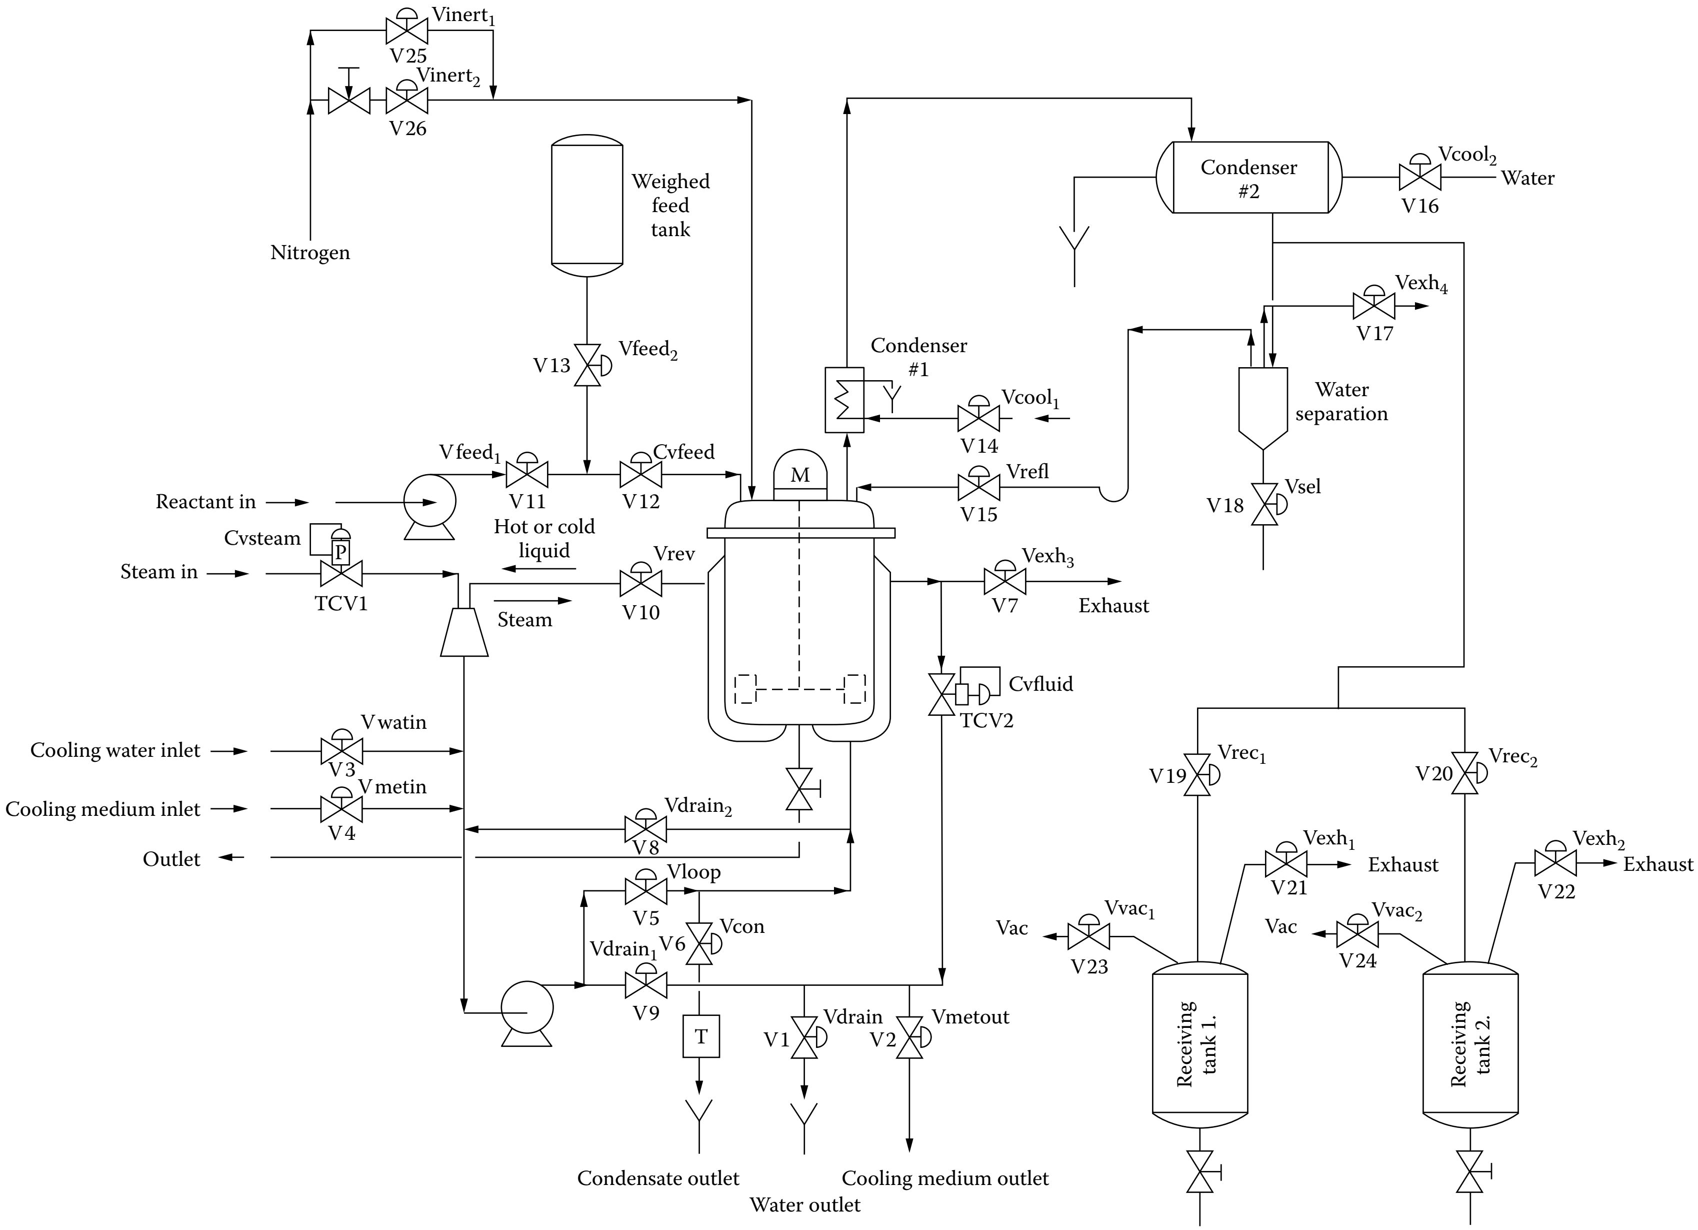

FIG. 8.8m
Prepackaged and automated reactor control system.[4]

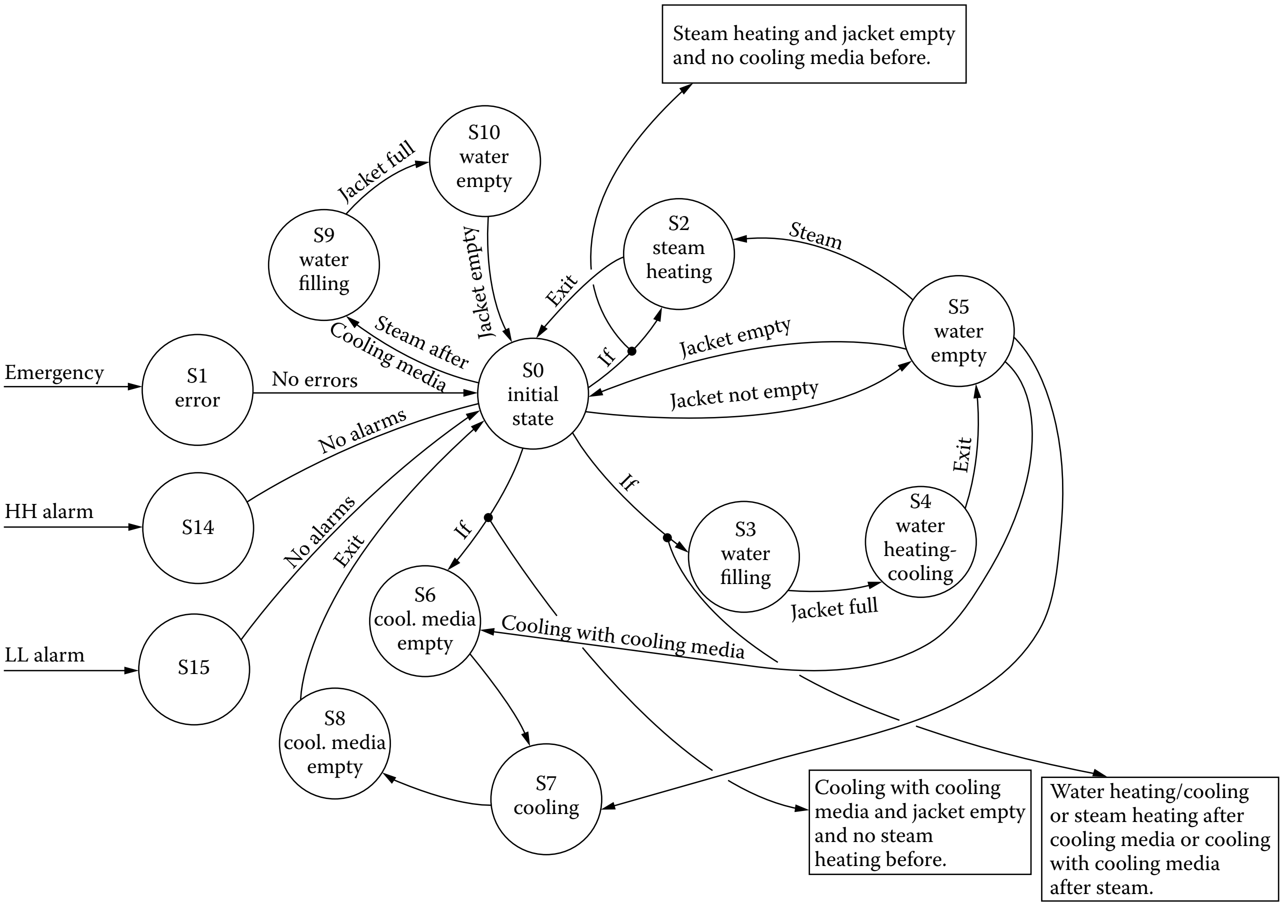

FIG. 8.8n
State diagram of a reactor jacket system.[4]

In state S0 all the valves are closed except the vent valve V7, which is open. If any of the safety interlocks are activated, hardware errors or device malfunctions are detected, and the system is returned to state S1, which is the "error state." In this state the control is returned to the operator. If the controlled process variables are not on set point and high or low alarms are registered, these bring the system into states S14 or S15, where those corrective responses are initiated that have been preprogrammed for such conditions.

When either the higher level of software or the operator is ready to initiate the steam heating state (S2), valves V10 and V6 are opened and TCV-1 is assigned to throttle the steam. In order to make sure that the steam condensate will not be contaminated, if prior to the steam heating state the jacket was filled with a cooling media (such as methanol or brine), the jackets will be first flushed with water (V3, V5, TCV-2, V1, and pump on), and then drained (V7, V8, V9, V1, and pump on).

Because of the multiple heat-transfer media used, automatic controls are provided not only to protect against cross-contamination but also to protect the glass lining of the reactor against damage by excessive temperature differences.

Therefore, if the particular batch sequence calls for consecutive stages that could thermally shock the glass lining (direct steam heating followed by cooling, or the other way around), the jacket interlocks automatically guarantee that intermediate temperature operations will be inserted, to make the transition gradual and thereby protect the glass.[4] Therefore, when direct steam heat is followed by cooling, states S9 and S10 are interposed to bring the jacket temperature to an intermediate value to avoid shocking the glass.

Prior to starting to heat or cool with water, the jacket is filled in state S3 (V3, V5, V7 opened, and pump on), and only when the jacket is full does the heating (V10, TCV-1 open, while V7 closes) or cooling (TCV-2 and V1 open) state (*S*4) start. When this is over, the water is drained from the jacket (V1, V8, V9, V19 open, pump on), and when the jacket is empty, it might return to the initial state (S0).

When a cooling media other than water is used (methanol or brine), the same sequence of filling (S6), cooling (S7), and draining (S8) states is initiated as was the case with the water-based operation. With these various control states, it becomes possible to match the desired batch temperature profile for a particular reaction with a profile of jacket temperatures that is reasonably close to it.[4]

Recipe Charging Module

The reactants, catalysts, solvents, modifiers, and other chemicals are charged into the reactor either before or during the reaction. The operation that takes place prior to starting the reaction is called charging, while the continuous addition during the reaction is often called feeding. The chemicals can be added on the basis of their weight or their volume, and the devices used in charging them include mass or volumetric flowmeters, metering pumps, feeders, or weighing systems.[5]

When weighing is applied, it can be done by weighing the reactor itself or by providing a separate weighed charge tank, as is the case in Figure 8.8m. The accuracy, reliability, and rangeability of the charging devices are the main criteria for selection, as was discussed in connection with Table 8.8k.

The ingredients that are fed while the reaction is in progress can be charged all at once (dumped), or they can be charged as a function of time, temperature, pressure, pH, or other variables. They are usually charged from a separate feeding tank under level or flow control or added by dosing pumps. In Figure 8.8l the on/off valves V11, V12, and V13 serve to control feeding. For an example of an installation in which the reactant is added under temperature control, refer to Figure 8.8o.

Stripping or Distillation Module

The addition of the distillation equipment module to the reactor provides the capability to perform the type of batch distillation that is illustrated in Figure 8.8p. The resulting quality of separation is naturally lower than if a distillation column is used. During this stripping phase the reactor is either in the hot water or in the direct steam heating mode, which guarantees a state of slow boiling in the reactor. During the stripping phase, valves V15, V16, and V17 are open. This state of slow boiling can be terminated on the basis of time or on the basis of the rise in vapor pressure in the reactor. If desired, water can be separated before the reflux is returned to the reactor.

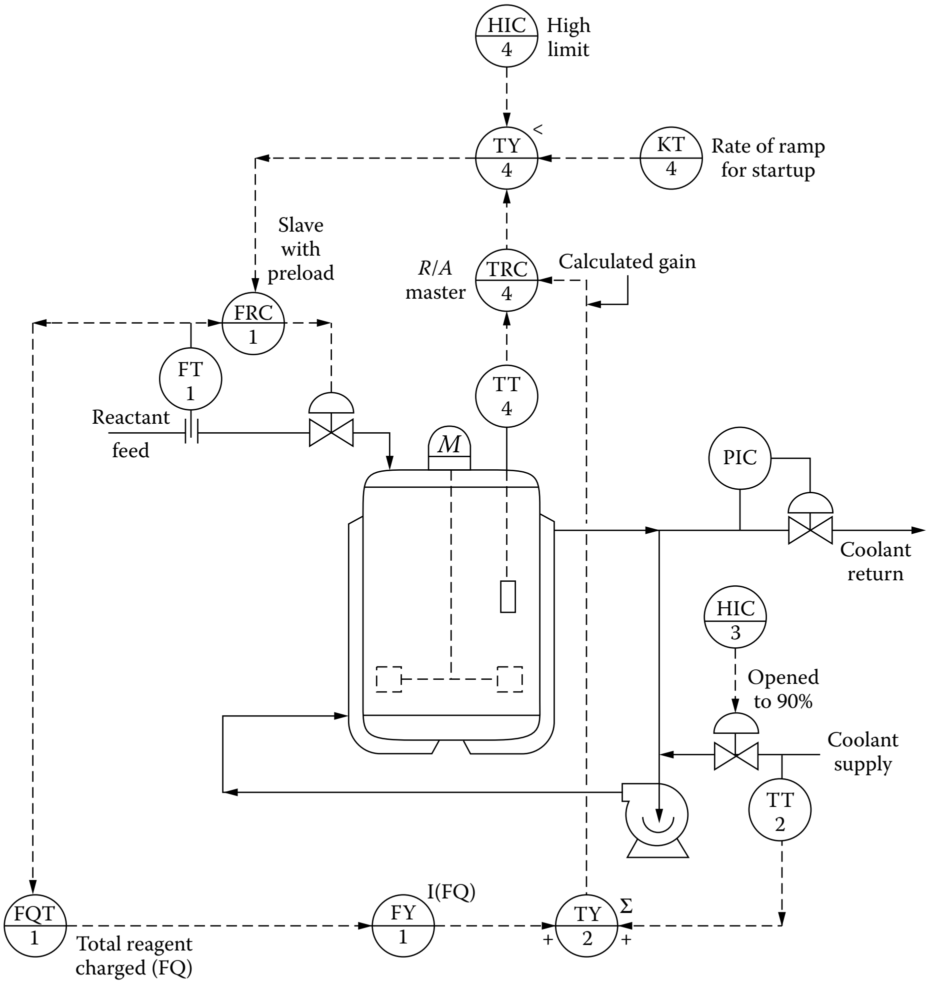

FIG. 8.8o
With constant coolant flow rate, the reactant flow can be the cascaded slave; because the process gain drops as the amount of reactants converted to products increases, the gain of TRC-4 is automatically increased as a function of total reactant charged.

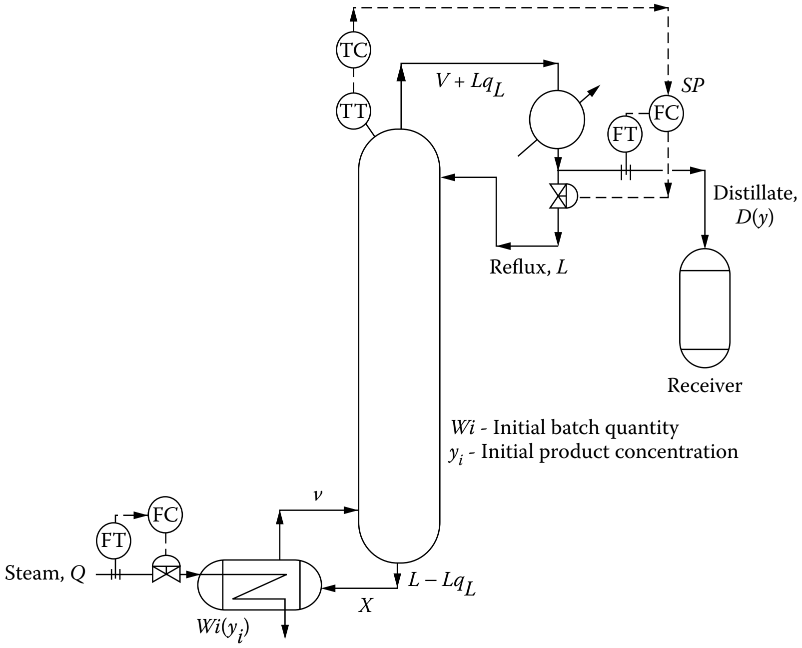

FIG. 8.8p
Batch distillation.

When stripping is to take place at atmospheric pressure, the valves V16, V19, V20, V21, and V22 are opened. If reflux is needed, V14 is also opened. The heat input into the reactor is limited by the cooling capacity of the condensers and by the foaming characteristics of the batch. If the stripping is to take place at a temperature lower than the boiling point of the solvent, the process is operated under vacuum, by closing V21 and V22 and by opening V24. The states of the other valves remain unaltered.

When more than one chemical is to be stripped off and separated, the distillation configuration is similar except that during the early phase of stripping V19 is held open (when the first chemical has been removed, V19 is closed and V20 opens). The switching of the valves is based on endpoint analyzer control, which is discussed in Section 8.9 (Chemical Reactors: Control and Optimization).

Cleaning and Interting Modules

In the food, pharmaceutical, and fine chemicals industries, it is important to clean the reactor equipment before or after each batch. Cleaning in place is usually done using the appropriate solvent, which is applied through jets that reach all parts and surfaces that require cleaning. While CIP is effective, it cannot meet all the requirements of all industries.

Figure 8.8m also shows the components needed to create an inert atmosphere in the reactor. The inertization sequence can be started by purging the vapor space with nitrogen (V25 open) until the oxygen content of the exhaust drops below the required limit. The purge phase can be terminated on the basis of time or by the use of on-line oxygen analyzers (see Section 8.42 in the first volume of this handbook).

During the reaction the nitrogen blanket is by V26 (V25 closed), which admits the continuous flow of purge nitrogen that sweeps the vapor space; if only the reactor is to be intertized, the nitrogen leaves through V17.1f other components also need to be intertized, the nitrogen might leave through V21 or V22.[4]

Recipe Controls

In the reactor process described in Figure 8.8m, the recipe formula and procedure contain all of the instructions needed to produce a particular product. Consistent with collapsibility of the procedural control model defined in S88.01, the procedure level has been eliminated in this example because it is not needed in a single-unit recipe, and the operation level (which is an optional convenience used for bookmarking purposes) was also eliminated. The recipe procedural control for a particular product thus consists of a single unit procedure and its sequentially executed phases, which provide parameter values (formula) for the reactor's equipment phases (Figure 8.8q).

Each unit procedure can be broken down into a number of recipe phases, which are building blocks linking the equipment phases to such parameters as time, temperature, or other quantities or variables. Each recipe phase corresponds to a particular equipment phase presented in a form that is suitable for automatic execution by the system. The actual building of a recipe from a sequence of phases is illustrated in Figure 8.8r. When an equipment phase is linked to a particular phase of a recipe, it is also provided with the associated parameters and endpoints, which serves the completion of the phase and the need to transfer to the next.

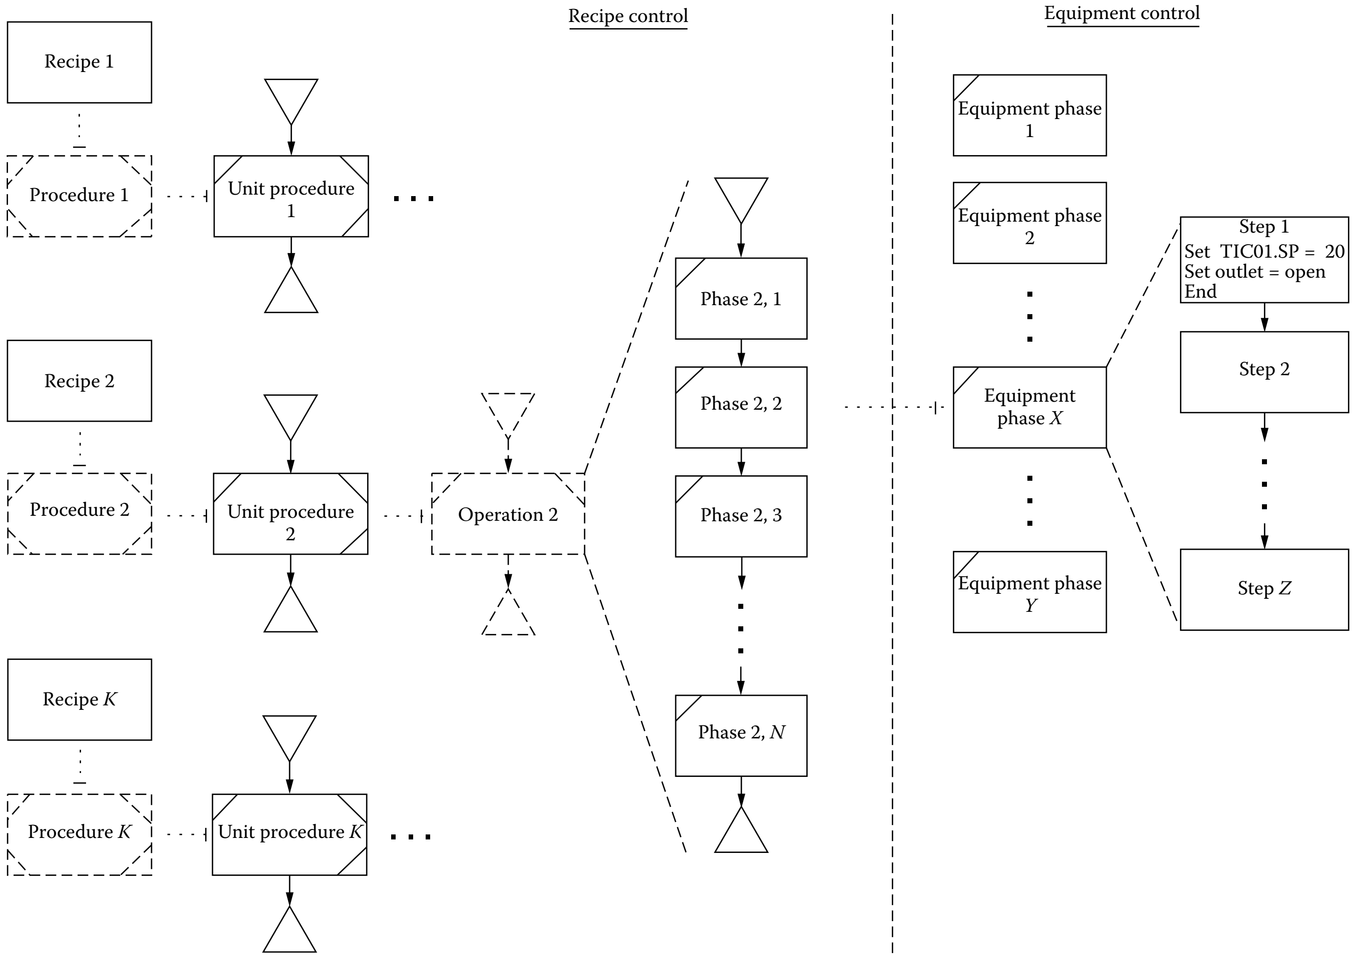

FIG. 8.8q
Building blocks of the unit controller recipe (dashed borders indicate implicit elements of S88 model).

Some of the more complex phases are made up of several steps, while the individual steps, in this case, are made up from structured text statements. The execution of each recipe is controlled by the coordination control software, which serves to organize the execution of the recipe. This function is illustrated in Figure 8.8s.

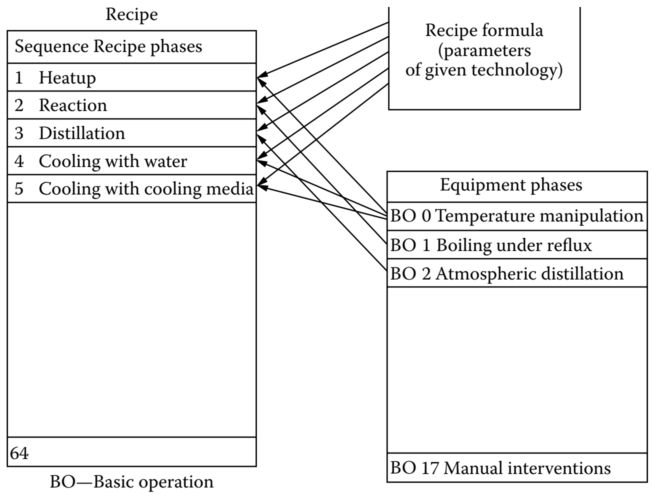

FIG. 8.8r
Recipe building.

Equipment Phases

This unit controller utilizes the fact that most processes consist of the same basic operations—only the set point and the parameters vary. Therefore, the equipment operations can be separated into the algorithm, which does not change from recipe to recipe, and the variable part, which contains the parameters and settings that are adjusted by the recipe. The larger the variable portion of a phase, the more flexible its operation but also the more engineering work will be needed for the application. The use of phases provides for the reuse of canned knowledge and for the efficient building of recipes.

Some of the equipment phases configured for the chemical batch reactor unit controller are listed in Table 8.8t. The parameters that need to be set prior to or during the phase include the set points at the beginning and during the phase, the controller mode (auto, manual, cascade) and the tuning settings, the operation times, alarm settings (LL, L, H, HH),

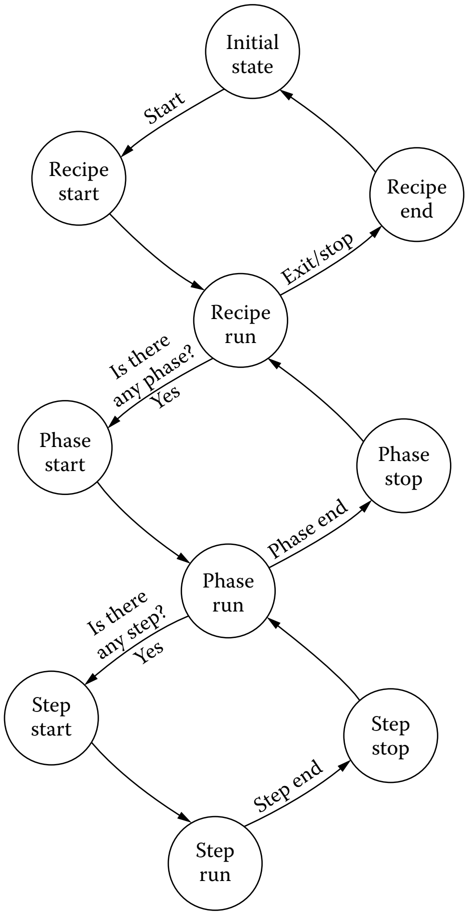

FIG. 8.8s
One function of the custom coordination control software in the example "unit controller" is to sequentially execute both the phases comprising each unit procedure and the steps comprising each phase.

the desired actions initiated by the alarms, and the conditions that must prevail before the process can be transferred to the next phase.

One of the critical equipment phases involves temperature control. A temperature-related equipment phase must be parameterized to define the associated jacket mode (steam or water heating, water or methanol cooling), the required controller configuration (slave or cascade), maximum allowable temperature difference between batch and jacket temperatures, and so on.

In some processes the temperature controls are reconfigured when the reaction starts, and therefore two equipment phases might be used. When the phase is for stripping or distillation, additional parameters need to be set for the jacket operation (water or steam heat), for temperature limits, and for receiver tank selection and switching.

The phases that describe charging are provided with parameters to state the required quantities, rates, and sequences. Similarly, the phases that define feeding must state such parameters as the jacket mode (steam or water heating, water or methanol cooling), the safety limits for the jacket medium, preload settings (flow rates at the start of the phase), maximum limits on flow, total quantity of reactants to be fed, and controller configuration.

TABLE 8.8t
Equipment Phases (EP) Available in a Flexible Read Package[4]

Designation	*Name of Equipment Phase*
EP 0	Temperature manipulations
EP 1	Boiling under reflux
EP 2	Distillation at atmospheric pressure
EP 3	Vacuum distillation
EP 4	Reflux with water separation
EP 5	Evaporation at atmospheric pressure
EP 6	Evaporation under vacuum
EP 7	Fractional distillation
EP 8	Steam distillation
EP 9	Feeding as a function of time
EP 10	Feeding as a function of temperature
EP 11	Feeding as a function of pH
EP 12	Cleaning in place
EP 13	Forwarding under suction
EP 14	Forwarding under pressure
EP 15	Inertization
EP 16	Initial charging
EP 17	Manual interventions (dummy operation)

The basic operation of reactor inertization operates parallel with other operations and also has parameters such as jacket modes, number of rinsing cycles, start points, and endpoints.[4] To accommodate this while maintaining a simple linear recipe flow, the inertization sequencing can be programmed as part of the equipment module's basic functionality, which is merely set up and initiated by the equipment phase execution.

In general there are two methods of setting up equipment phases. They can be simple (valve opens/closes, motor starts/stops) or complex, where the process is divided into larger, more complicated operations such as feeding, distillation, and crystallization. The above example illustrates the second, more complex approach, where the manufacturer of the reactor package has already designed and checked out the details, and therefore the uncertainties associated with a development project are eliminated. Such predesigned packages also reduce installation time and engineering design costs, while they also allow for fast changeover between products and fast implementation of new developments.

Component or Device Control

The lowest level of reactor automation is the control of individual devices. This includes continuous regulatory control functions, discrete control functions, safety and permissive interlocks, time-sequencing controls, and the like.

The continuous regulatory control functions of batch processes are similar to those of continuous processes; however, batch processes have additional requirements: for handling transients (e.g., heat-up without overshoot), for adaptation to varying process dynamics, and for operating against constraints.

In DCS systems the fill-in-the-blank-type language supported by CRT-based operator consoles became an accepted standard. The fill-in-the-blank language is used to configure the control system database and to create many of the necessary control algorithms (Table 8.8u).

In industrial controllers continuous recording charts are also frequently used. One possible cascade configuration for batch application is shown in Figure 8.8v. Other manufacturers approach the task of loop configuration by a statement list using function blocks as subroutines (Table 8.8u).

The design of discrete control functions (direct on/off control, interlock control, sequence control) first requires the definition of the logic using ladder diagrams, flowcharts, decision tables, function charts, function plans, time-sequence diagrams, or logic diagrams.

Once defined, the logic can be entered into the controller package by programming or by configuring. Methods describing discrete control functions are theoretically equivalent, but they each have different application areas. For example, ladder diagrams are preferred by maintenance engineers, and function charts are preferred by control engineers.

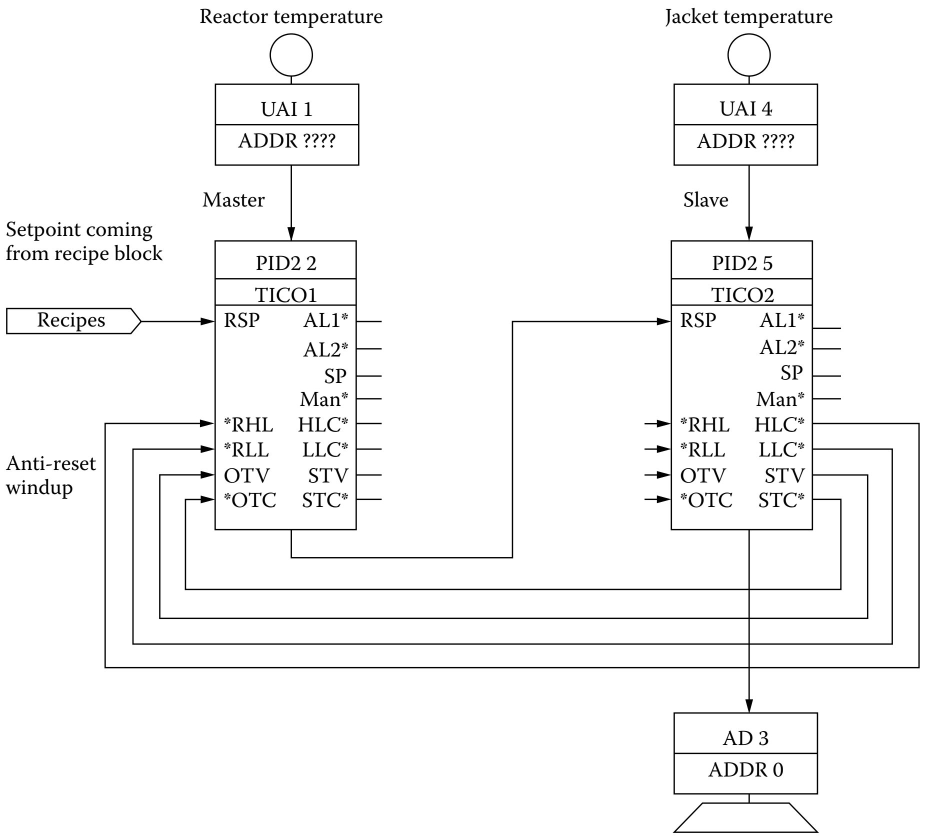

FIG. 8.8v

Building continuous regulatory functions on the continuous control chart.

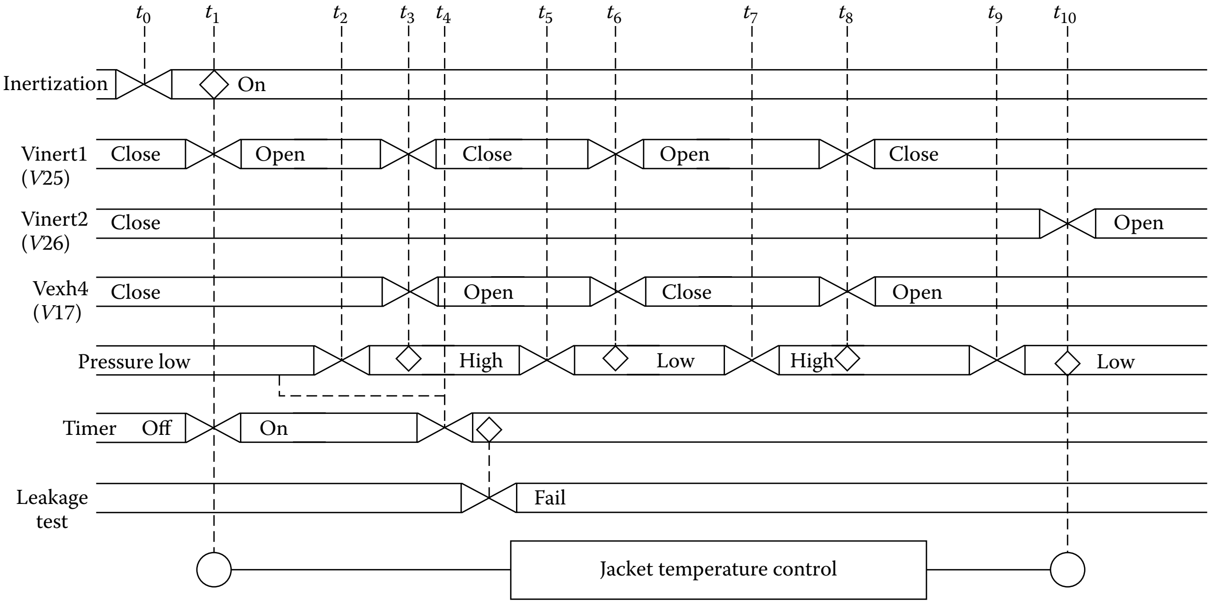

FIG. 8.8w

Time-sequence diagram for reactor inertization.

In high-performance process control, high-level control languages are now standard.

As was discussed earlier, for batch processes, time-sequence diagrams have an important role. The time-sequence diagram shows the sequential changes in control actions and their time relationships. The sequence of events can be followed along dotted lines for vertical time coincidence and along the solid lines in the horizontal direction for sequence control. The diamond symbol is used to indicate a trigger event, and a vertical dotted line indicates the time coincidence of trigger events. When two or more diamonds occur in the same relative time line, an "AND" logic condition results.

As an example, the time-sequence diagram for inertization in Figure 8.8w shows the basic operation of inertization. When the operation is started, valve V25 is opened and the timer is started. If the pressure in the reactor does not reach the given value (e.g., 2 bar) by the preset time, a leakage is assumed and the system goes into error state. In the normal sequence the system has two cycles of rinsing (t_1 to t_6 and t_6 to t_{10}), and after completion of these cycles all valves except V26 and V17 will close and inertization continues at a predetermined constant flow of inert gas.

Safety interlocks are designed to ensure the safety of operating personnel and to protect plant equipment and environment. These types of interlocks differ from ordinary process interlocks, in that they detect equipment malfunction or shutdown. These interlock functions are frequently implemented on a separate set of control equipment.

CONCLUSIONS

Many batch reactors must consistently execute complex product-dependent sequences of discrete events to produce a variety of products through multiple unit operations over a broad range of operating conditions and compositions, often in regulated industries that demand a detailed accounting of each step. This requires a very flexible and intricate control system.

The tasks associated with designing modular sequential control strategies for such an application and several reactor sequence control examples have been discussed in this section, based on the batch control standards developed by ISA and approved by ANSI and IEC. Batch server packages based on these standards greatly facilitate and enhance high-end coordination control capabilities, while design efficiency is maximized by good modularization practices and reuse of flexible previously engineered control. Because the role of the operator is especially important in batch plants, the project's overall business success often depends upon such things as adequately addressing operator interface and exception handling needs and on adequately defining and enforcing the operator's responsibilities.

INTRODUCTION

It should be noted that the coverage of this section and that of the next one (8.10) are similar. If you are interested in reading a detailed and complete treatment of the subject of chemical reactor control, read this section. On the other hand, if you have little time and are an experienced process control engineer, familiar with the basics of chemical reactor control, and want only to refresh your memory about the most important aspects of their control and optimization, read Section 8.10.

This section is started with a description of reactor characteristics, reaction rates, and time constants. This is followed by a discussion of the various methods of reactor temperature control, initial heat-up control, end-point detection, pressure, and safety controls. Other aspects of reactor control are covered in Sections 8.8, 8.10, and 8.11, covering the topics of batch sequencing, optimization, and modeling of chemical reactor controls.

Chemical reactor designs include the continuous stirred tank reactors (CSTRs), the batch stirred tank reactors (BSTRs), the tubular reactors, and the packed bed reactors. The optimization of batch and continuous chemical reactors has many potential benefits, including increase in productivity and improvement in safety, product quality, and batch-to-batch uniformity. The combined impact of these factors on plant productivity can approach a 25% improvement.[1]

Such overall results are the consequences of many individual control loops and control strategies. These loops will program temperature and pressure and maintain concentration and safety, while providing sequencing and record-keeping functions. All elements of the overall chemical reactor control system are discussed in this chapter.

REACTOR DESIGNS AND CHARACTERISTICS

In a batch cycle, there is no steady state and therefore no "normal" condition at which controllers could be tuned. The dynamics of the batch process vary with time; thus, the process variables, the process gains, and time constants also vary during the batch cycle. In addition, there are the problems of runaway reactions and batch-to-batch product uniformity.

Runaway reactions occur in exothermic reactions, in which an increase in temperature speeds up the reaction, which in turn releases more heat and raises the temperature further. In order to counter this positive feedback cycle, highly self-regulating cooling systems are required. One of the most self-regulating cooling systems is a bath of boiling water, because it needs no rise in temperature to increase its rate of heat transfer. Endothermic reactions are inherently self-regulating.

Batch-to-batch uniformity is a function of many factors, from the purity of reactants, catalysts, and additives to the repeatability of controllers serving to maintain heat and material balance. Before addressing such complex topics, it is necessary to review the basic batch process.

Most batch cycles are started by charging reactants into the reactor and then mixing and heating them until the reaction temperature is reached. The reaction itself is frequently started by the addition of a catalyst. *Exothermic reactions* produce heat, and *endothermic reactions* consume heat. The reactor itself can be *isothermal*, meaning that it is operated at constant temperature, or *adiabatic*, meaning that heat is neither added nor removed within the reactor; the reaction is controlled by other means, such as the manipulation of pressure, catalyst, and reactants.

Chemical reactions can follow quite complex paths and sequences, but for engineering purposes such as equipment design and control system analysis, most reactions can be considered as one of four types: irreversible, reversible, consecutive, or simultaneous. Most reactions are reversible — that is, there is a ratio in product-to-reactant concentration that brings about equilibrium. Under equilibrium conditions the production rate is zero, because for each molecule of product formed there is one that converts back to its reactant molecules.

The equilibrium constant (K) describes this state as the ratio of forward- to reverse-rate coefficients. The value of K is also a function of the reaction temperature and the type of catalyst used. K naturally places a limit on the conversion that can be achieved within a particular reactor, but conversion can usually be increased, if at least one of the following changes can be made:

- Reactant concentration can be increased
- Product concentration can be decreased through separation or withdrawal
- Temperature can be lowered by increased heat removal in reversible exothermic reactions
- A change in operating pressure can be affected (this increases conversion only in certain reactions)

The catalyst does not take part in the reaction, but it does affect the reaction rate (k). Some catalysts are solids and are packed in a bed; others are fluidized, dissolved, or suspended. Metal catalysts are frequently formed as flow-through screens. Whatever their shape, the effectiveness of the catalyst is a function of its active surface, because all reactions take place on that surface. When it is fouled, the catalyst must be reactivated or replaced.

The time profiles of heat release, operating temperature, and chemical concentrations are illustrated in Figure 8.9a for a consecutive reaction,[2] in which first ingredient A is converted into intermediate product B, and then intermediate product B reacts to form final product C. The reaction temperature is controlled so as to maximize the production of C while minimizing the cycle period.

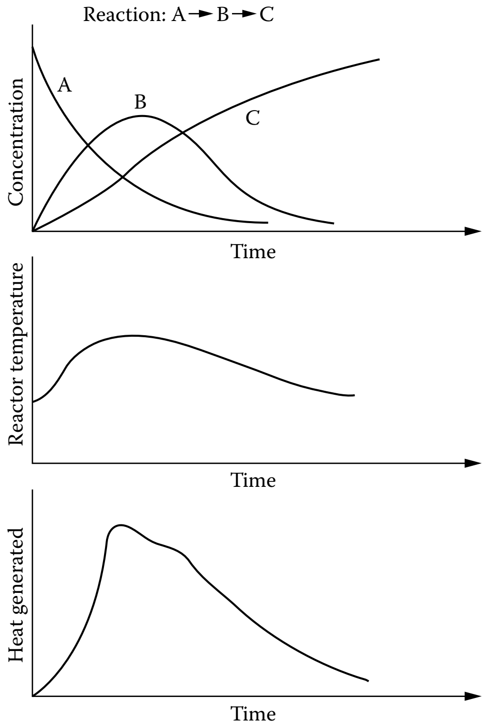

FIG. 8.9a

Concentration, temperature, and heat variables are shown as a function of time for a consecutive reaction, where A is first converted to B and then B into C. In this reaction the heat generated by the reaction is greater during the conversion of A to B, but the reactor temperature is controlled at an optimum setting to ensure maximum conversion in a minimum amount of time.[2]

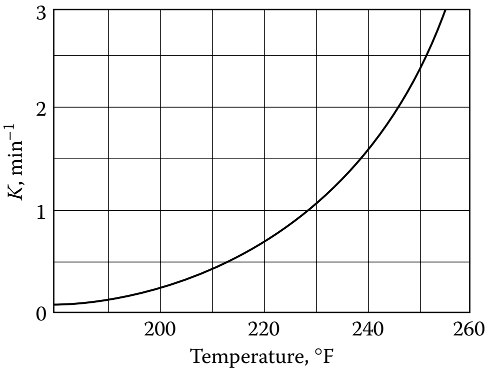

FIG. 8.9b

The influence of temperature on reaction rate coefficient is substantial.[3]

Reaction Rates and Kinetics

The reaction rate coefficient exponentially increases with temperature. The activation energy (E) determines its degree of temperature dependence[3] according to the Arrhenius equation:

$$k = \alpha e^{-(E/RT)} \qquad \textbf{8.9(1)}$$

where

k = specific reaction rate coefficient (min^{-1})
α = pre-exponential factor (min^{-1})
E = activation energy of reaction (BTU/mole)
R = perfect gas constant (1.99 BTU/mole·°R)
T = absolute temperature (°R)

Figure 8.9b illustrates the strong dependency of the reaction rate coefficient (k) on reaction temperature[3] for the values of $\alpha = e^{29}$ and $E/R = 20{,}000$.

Figure 8.9c illustrates the three basic reactor types: 1) plug flow, 2) continuous stirred tank, and 3) batch; it mathematically defines their fractional conversion of the reactant(s) into product (y).

Because the continuous plug flow-type reactor is dominated by dead time, its temperature control is difficult. On the other hand (as shown in Figure 8.9c), the plug flow reactor gives higher conversion than a back-mixed reactor operating under the same conditions. If the reaction rate is low, a long tubular reactor or a larger back-mixed reactor is required to achieve reasonable conversions.

In a batch reactor, after the initial charge there is no inflow or outflow. Therefore, an isothermal batch reactor is similar in its conversion characteristics to a plug-flow tubular reactor. If the residence times are similar, both reactors will

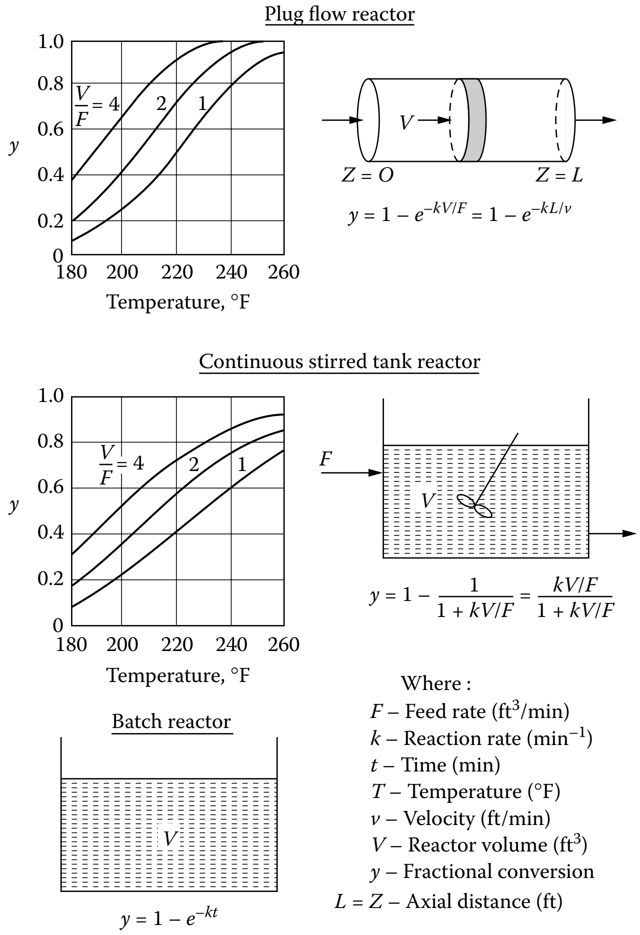

FIG. 8.9c

Conversion equations and conversion vs. temperature characteristics vary with reactor design.[2,3]

provide the same conversions. Batch reactors are usually selected when the reaction rates are low, when there are many steps in the process, when isolation is required for reasons of sterility or safety, when the materials involved are hard to handle, and when production rates are not high.

As shown in Figure 8.9d, the batch (or tubular) reactor is kinetically superior to the continuous stirred tank reactor.[2] The batch reactor has a smaller reaction time and can produce the same amount of product faster than the back-mixed one.

Reactor Time Constants

The amount of heat generated by an exothermic reactor increases as the reaction temperature rises. If the reactor is operated without a temperature controller (in an open loop), an increase in the reaction temperature will also increase heat removal, because of the increase in ΔT between process and coolant temperatures. If an increase in reaction temperature results in a greater increase in heat generation than in heat removal, the process is said to display positive feedback; as such, it is considered to be "unstable in the open loop."

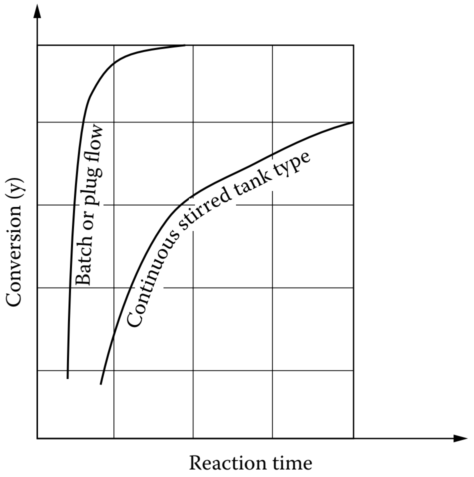

FIG. 8.9d

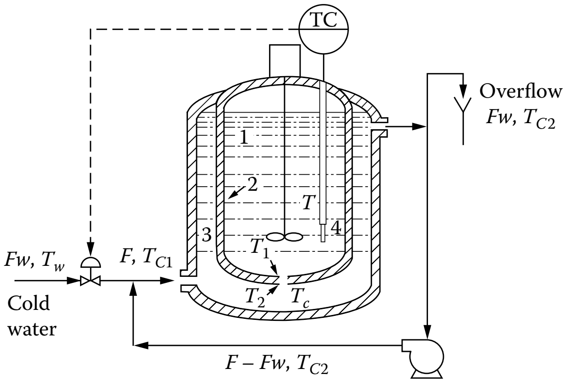
Batch reactors have better conversion efficiencies than back-mixed reactors.[2]

The positive feedback of the open-loop process can be compensated for by the negative feedback of a reactor temperature controller, which will increase the heat removal rate as the temperature rises. The addition of such a feedback controller can stabilize an open-loop unstable process only if the control loop is fast and does not contain too much dead time. Cascade control can increase speed, and maximized coolant flow can reduce dead time. Shinskey[3] suggests that if the dead time can be kept under 35% of the thermal time constant of the reactor, the process can be stabilized, whereas if it approaches 100% the reactor will not be controllable.

A real reactor has several lags and delays, including those of measurement and heat removal, as illustrated in Figure 8.9e.



The process gain: $K_P = \dfrac{T_{C2} - T_w}{Fw}$

FIG. 8.9e

There are four interacting time lags in a chemical reactor process. By minimizing the process gain, the controller gain can be maximized, and the narrower the proportional band the more sensitive the control loop will be.[3]

The equations for calculating the thermal, reactor wall, coolant, and thermal bulb time delays are listed below.[3] Typical values of these time constants are:

τ_1 = thermal time constant = 30–60 min
τ_2 = reactor wall time constant = 0.5–1.0 min
τ_3 = coolant time constant = 2–5.0 min
τ_4 = thermal bulb time constant = 0.1–0.5 min (can be minimized by the use of bare bulbs)

$$\text{Thermal time constant: } \tau_1 = \frac{W_1C_1}{k_1A} = \frac{W_1C_1}{Q}(T - T_1) \quad 8.9(2)$$

$$\text{Reactor wall time constant: } \tau_2 = \frac{W_2C_2l}{k_2A} = \frac{W_2C_2}{Q}(T_1 - T_2) \quad 8.9(3)$$

$$\text{Coolant time constant: } \tau_3 = \frac{W_3C}{k_3A} = \frac{W_3C}{Q}(T_2 - T_c) \quad 8.9(4)$$

$$\text{Thermal bulb time constant: } \tau_4 = \frac{W_4C_4}{k_1A_4} \quad 8.9(5)$$

where

A = heat-transfer area, ft^2
A_4 = surface area of bulb, ft^2

The total dead time in the loop is the sum of jacket transport lag, the dead time due to imperfect mixing, and miscellaneous smaller contributing factors. The dead time due to jacket displacement can be reduced by increasing the pumping rate. This should be kept under 2 min in a well-designed reactor.[3] The dead time caused by imperfect mixing can be reduced by increasing the agitator pumping capacity. In a well-designed reactor it should be held to less than 10% of the thermal time constant τ_1.

In the case of a typical reactor, the period of oscillation might be around 30 min. This period approximately equals four dead times; therefore, the total dead time of such a loop is around 7.5 min. In the case of interacting controllers, the correct setting for such a controller would be 7.5 min for both integral and derivative times.

Two types of reactors are used in chemical plants: continuous reactors and batch reactors. Continuous reactors are designed to operate with constant feed rate, withdrawal of product, and removal or supply of heat. If properly controlled, the composition and temperature can be constant with respect to time and space. In batch reactors, measured quantities of reactants are charged in discrete quantities and allowed to react for a given time, under predetermined controlled conditions. In this case, composition is the function of time.

TEMPERATURE CONTROL

The control loop features required during heat-up are substantially different from those needed during an exothermic reaction or those required during stripping or refluxing. Each will be discussed in the following paragraphs, starting with the controls of exothermic reactors.

Reaction temperature is frequently selected as the controlled variable in reactor control. It may be necessary to control reaction rate, side reactions, distribution of side products, or polymer molecular weight and molecular weight distribution. All of these are sensitive to temperature. It is frequently necessary to control reaction temperature to within 0.5°F (0.28°C). Many reactions are exothermic. In order to control reaction temperature, the released heat must be removed from the system as it is liberated by the reactants.

A simple temperature control scheme is depicted in Figure 8.9f. The reaction temperature is sensed, and the flow of heat-transfer medium to the reactor jacket is manipulated. For many installations this scheme is considered to be unsatisfactory because of the reactor nonlinearity and dynamic features. This "once-through" method of cooling is undesirable

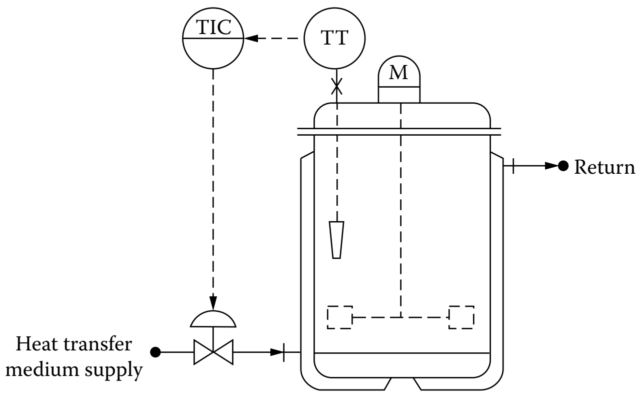

FIG. 8.9f
In chemical reactors with once-through cooling, the coolant temperature is not uniform and the process dead time varies with load.

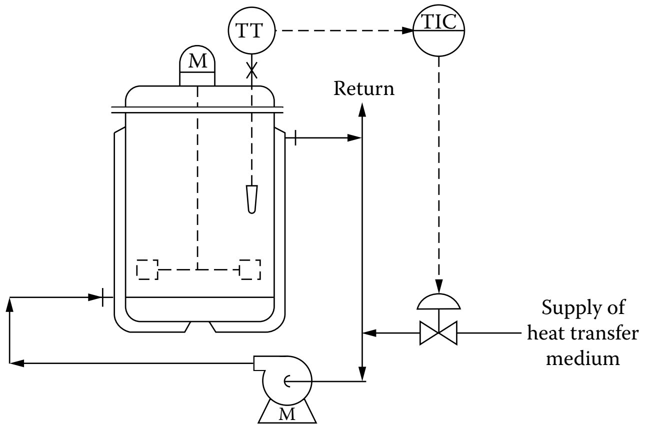

FIG. 8.9g
If the cooling water is recirculated around the jackets of chemical reactors, the water temperature will be more uniform, the process dead time will be minimized, and the heat transfer will be maximized.

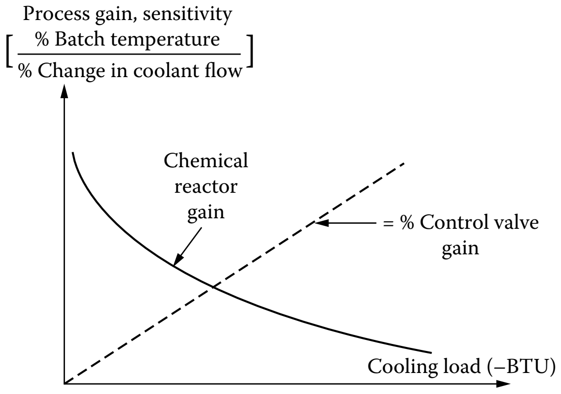

FIG. 8.9h
The sensitivity (gain) of a jacketed reactor drops in a nonlinear manner as the cooling load rises because the increasing amount of heat must be transferred through a fixed heat-transfer area. Because the gain of an equal-percentage coolant control valve linearly rises with load, using such a valve will partially compensate for the nonlinearity of the gain of a jacketed reactor.[6]

because the coolant temperature is not uniform. This can cause cold spots near the inlet and hot spots near the outlet.

Another disadvantage of this configuration is the variable residence time of the cooling water within the jacket as the flow rate changes. This causes the dead time of the jacket to vary, which in turn necessitates the modification of the control loop tuning constants as the load varies. In addition, when the water flow is low, the Reynolds number will drop off, and with it, the heat-transfer efficiency will also diminish. Low water velocity can also result in fouling of the heat-transfer surfaces.

For all the above reasons, the recirculated cooling water configuration shown in Figure 8.9g is more desirable, because it guarantees a constant and high rate of water circulation. This keeps the jacket dead time constant, the heat-transfer coefficient high, and the jacket temperature uniform, thereby eliminating cold and hot spots.

The fluid velocity in the reactor jacket is maintained high enough to produce satisfactory film coefficients for heat transfer. The fluid velocity can be further increased by additional jets. In addition, the liquid is circulated at a high enough rate to keep the temperature gradient in the heat-transfer medium, as it passes through the jacket, at a high enough level to maintain the jacket wall temperatures throughout the reactor. This keeps the jacket dead time constant and eliminates fouling of the heat-transfer surfaces.

Because the jacket provides a constant heat-transfer area, when the cooling load is low, the process is sensitive and the process gain is large. As shown in Figure 8.9h, as the load rises, the process gain drops in a nonlinear manner. The variable process gain can be partially compensated for by using a variable gain control value (equal-percentage valve); thereby, when the process gain drops, the valve gain rises and the total loop gain remains relatively constant.

Figure 8.9i illustrates the temperature response of any uncontrolled chemical reactor to a step change in load, assuming that the coolant is applied in a once-through manner (Figure 8.9f), without recirculation. The solid line depicts the temperature response at low loads, and the dotted line depicts temperature response at high loads.

Both dead time and the process gain increase as the load drops. In other words, at low loads it takes longer for the process to start responding, but once it has, the full response develops quickly. At high loads the opposite is the case.

Cascade Control

A superior method of reactor temperature control, a cascade loop, is depicted in Figure 8.9j. Here the controlled process

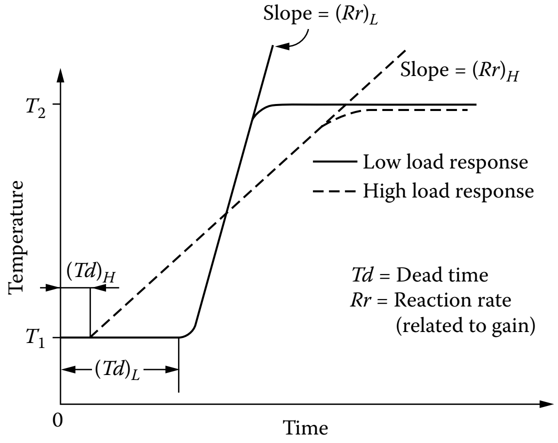

FIG. 8.9i
In a chemical reactor with a once-through jacket, without a water circulating pump, both the dead time and the gain of the process drop as the cooling load rises.

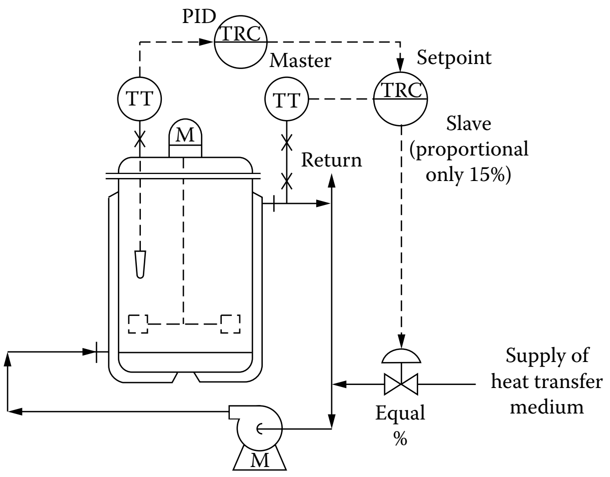

FIG. 8.9j
The addition of a cascade control loop to a chemical reactor that is provided with coolant recirculation reduces the period of oscillation of the master temperature controller.

variable (reactor batch temperature, hereafter called reactor temperature), whose response is slow to changes in the heat-transfer medium flow (manipulated variable), is allowed to adjust the set point of a secondary loop, whose response to coolant flow changes is rapid. In this case, the reactor temperature controller varies the set point of the jacket temperature control loop.

The purpose of the slave loop is to correct for all outside disturbances, without allowing them to affect the reaction temperature. For example, if the control valve is sticking or if the temperature or pressure of the heat-transfer media changes, this would eventually upset the reaction temperature, if the control system was configured as in Figures 8.9f or 8.9g but not in Figure 8.9j.

This is because in Figure 8.9j the slave would notice the resulting upset at the jacket outlet and would correct for it before it had a chance to upset the master. As pointed out in the detailed discussion of cascade systems in Section 2.6, the process lags should be distributed between master and slave loops in such a way that the time constant of the slave is one tenth that of the master. Cascade loops will not function properly if the master is faster than the slave.

It is preferred that the slave controller be used to maintain the jacket outlet (and not inlet) temperature, because this way the jacket and its dynamic response is included in the slave loop. Another advantage of this configuration is that it removes the principal nonlinearity of the system from the master loop, because reaction temperature is linear with jacket-outlet temperature.

The nonlinear relationship between jacket-outlet temperature and heat-transfer-medium flow is now within the slave loop, where it can be compensated for by an equal-percentage valve, whose gain increases as the process gain drops off (Figure 8.9h). In most instances the slave will operate properly with proportional-plus-derivative or proportional only control, which is set for a proportional band of 10–20%.

The period of oscillation of the master loop is usually cut in half as direct control is replaced by cascade. This might mean a reduction from 40 to 20 min in the period and a corresponding reduction of perhaps 30 to 15% in the proportional band.[3] The derivative and integral settings of an interacting controller would also be reduced from about 10 min to about 5 min. This represents a fourfold overall loop performance improvement.

Using jacket-inlet temperature as an override or measurement for the slave may be useful in cases in which the jacket temperature must be limited, e.g., when the reactor is used as a crystallization unit, or in safety systems that serve to protect glass-lined reactors from thermal shock. Such protection might be needed when hot water is generated by direct injection of steam (see Figure 8.9k).

If it is desired to reduce the heat-up time by applying direct steam heating to the reactor jacket and to use both water and methanol as cooling media in the same system, the configuration in Figure 8.9k can be considered. In order to guarantee that water and methanol will not intermix, even accidentally, in addition to the coolant control valve (TCV-2), tight shut-off on/off valves are provided on both coolants (V3 and V4). Such a control system can be operated in a variety of modes.

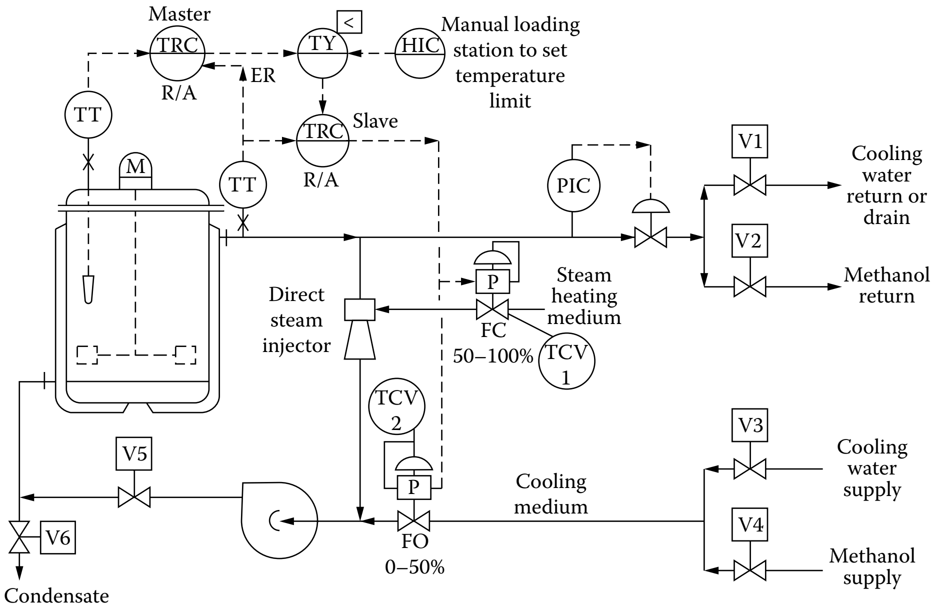
In Figure 8.9k five operating modes are listed. These can be implemented with positive interlocks. The return flow path is selected to match the type of coolant supply and is provided with a back-pressure regulator to prevent draining of the jacket.

If heat needs to be added in some phases of the reaction while in other phases it must be removed, the controls must be configured in a two-directional manner. Figure 8.9l depicts a cascade temperature control system with provisions for batch heat-up. The heating- and cooling-medium control valves are split-range controlled, such that the heating-medium control valve operates between 50 and 100% control output signal and the cooling-medium control valve operates between 0 and 50%.

It is important to match the characteristics of the valves (zero point) and to avoid nonlinearity at the transition, which can result in cycling. It is equally undesirable to keep both valves open simultaneously, because it results in energy waste. The control system shown in Figure 8.9l is a fail-safe arrangement, because in case of air failure the heating valve is closed and the coolant valve is opened.

Figure 8.9l also shows an arrangement whereby an upper temperature limit is set on the recirculating heat-transfer-medium stream. This is an important consideration if the product is temperature-sensitive or if the reaction is adversely affected by high reactor wall temperature. In this particular case, the set point to the slave controller is prevented from exceeding a present high-temperature limit.

Another feature shown is a back-pressure control loop in the heat-transfer-medium return line. This may be needed to impose an artificial back-pressure, so that during the heat-up



Heat transfer mode	Valve status (O = open)							
	TCV1	TCV2	V1	V2	V3	V4	V5	V6
Direct steam heat	0							0
Heat by water	0		0		0		0	
Cooling by water		0	0		0		0	
Heat or cool by water	0	0	0		0		0	
Cool by methanol		0		0		0	0	

FIG. 8.9k

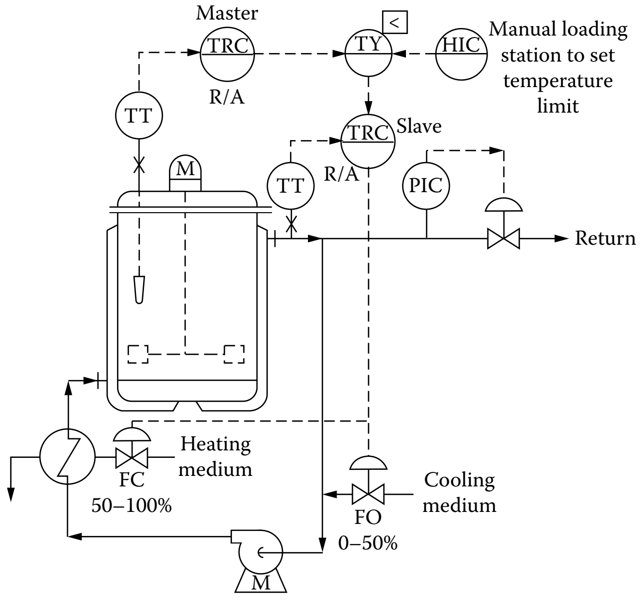

FIG. 8.9l
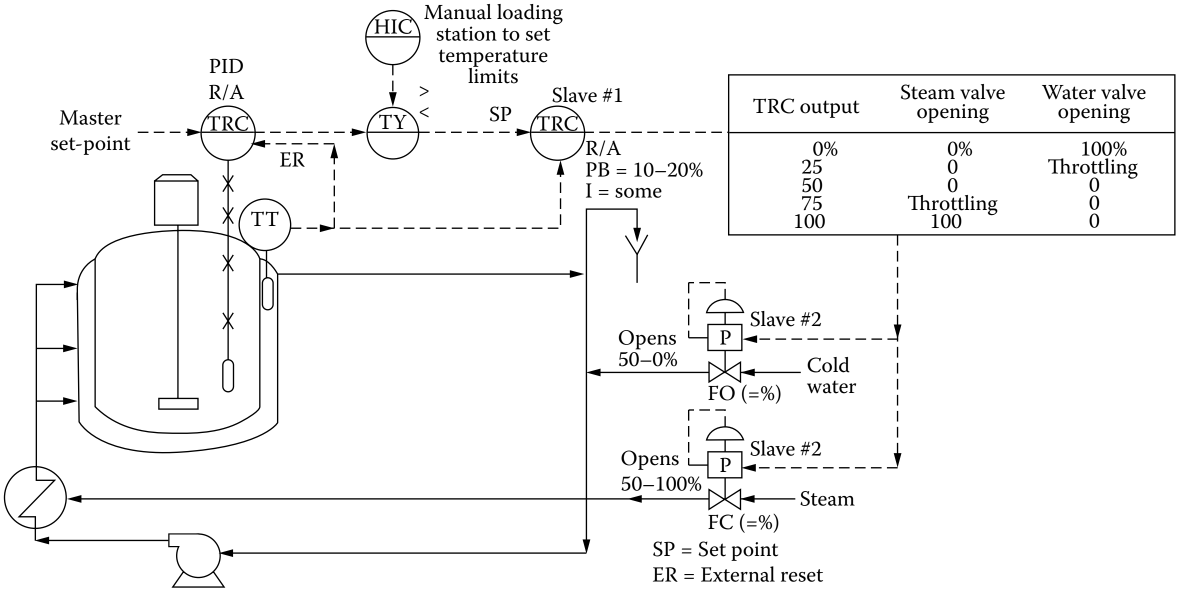
Two-directional cascade loop with a maximum limit on jacket temperature allows heat to be added in some phases of the operation and removed in others.

cycle no water leaves the recirculation loop and therefore the pump does not experience cavitation problems.

Limitations of Cascade Control Figure 8.9m illustrates a cascade loop consisting of three controllers in series. The master is the reaction temperature controller, the primary slave is the jacket temperature controller, and the secondary slave is the valve position controller (see Sections 6.2 and 6.12).

A positioner is a position controller that detects the opening of the valve and corrects for any deviations between measurement (the mechanically detected position) and set point. In such a hierarchical arrangement, only the master can control its variable independently; the slave controller set points must be freely adjustable to satisfy the requirements of the master.

Reset Windup Whenever the master is prevented from modifying the set point of the slave — because of a limiter, such as in Figure 8.9m, or because the slave has been manually switched from remote to local set point — reset windup can occur. Reset windup is the integration of an error that the controller is prevented from eliminating. Consequently, the



TRC output	Steam valve opening	Water valve opening
0%	0%	100%
25	0	Throttling
50	0	0
75	Throttling	0
100	100	0

FIG. 8.9m

If the control valves are provided with positioners, there will be three controllers in series in a cascade loop. It is recommended that all cascade masters be provided with an external reset from the measurement of their slave controller.

controller output is saturated at an extreme value. Once saturated, the controller is ineffective when control is returned until an equal and opposite area of error unsaturates it.

This problem is eliminated by the external reset (ER) shown in Figure 8.9m. The external reset signal converts the contribution of the integral mode to just a bias (Equation 2.28[7]) and thereby stops the integral action whenever the slave is not on set point. This feature eliminates the need for switching the master to manual and thereby also eliminates the need for the auto/manual station. In addition, it eliminates reset windup upset due to start-ups, shutdowns, or emergency overrides. Whenever external reset is used the slave must have some integral to eliminate the offset; otherwise, the slave offset would cause an offset in the master.

Another limitation is that the cascade loop will be stable only if each slave is faster than its master. Otherwise, the slave cannot respond in time to the variations in the master output signal, and a cascade configuration will in fact degrade the overall quality of control. A rule of thumb is that the period of oscillation of the slave should not exceed 30% of the period of oscillation of the master loop. This requirement is not always satisfied.

For example, in Figure 8.9m it is important to select valve positioners that are faster than the slave temperature controller on the jacket. Similarly, the jacket control loop should contain less dead time than its master, which would usually not be possible if a once-through piping configuration (Figure 8.9f) is used.

One possible method of reducing the dead time of the cascade slave loop is to move the measurement from the jacket outlet (Figure 8.9j) to the jacket inlet. This usually is not recommended, because when this is done, the slave will do much less work because the nonlinear dynamics of the jacket (Figure 8.9h) have been transferred into the master loop.

Multiple Heat-Transfer Media The use of a single coolant and single heating media (shown in Figure 8.9m) is often insufficient or uneconomical. If one type of coolant (or heating media) is less expensive than another—for example, the cold water used in the system in Figure 8.9n might be less expensive than the chilled water—it is desirable to fully utilize the first before starting to use the second.

For best performance, the fact that there are three valves should be transparent to the temperature controllers. Their gain should be the same, and their combined range should appear as the straight line in Figure 8.9h. This is not easy to achieve, particularly when the valves are nearly closed (see Figure 6.7e in Chapter 6 for a discussion of valve gains), which happens to be the case when the controller output is 11 PSIG in Figure 8.9n.

Therefore, some users prefer to provide some overlap so that the water valve might start opening at 11 PSIG, while the steam valve does not close fully until the signal drops to 10.5 PSIG. Overlapping at the transition points improves control quality but at the price of energy efficiency.

Figure 8.9n also shows that the destination of the returning water should not be selected on the basis of the origin of that water but rather should be based on temperature. This will reduce the upset caused in the plant utilities when a reactor switches from heating to cooling.

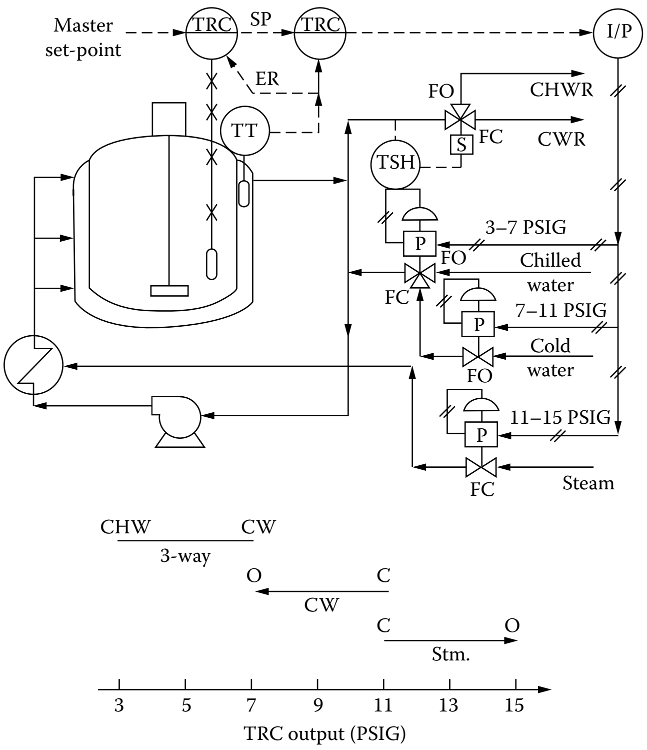


FIG. 8.9n
When multiple coolants are available, the total cost of cooling can be minimized by split-range sequencing of the valves.[4]

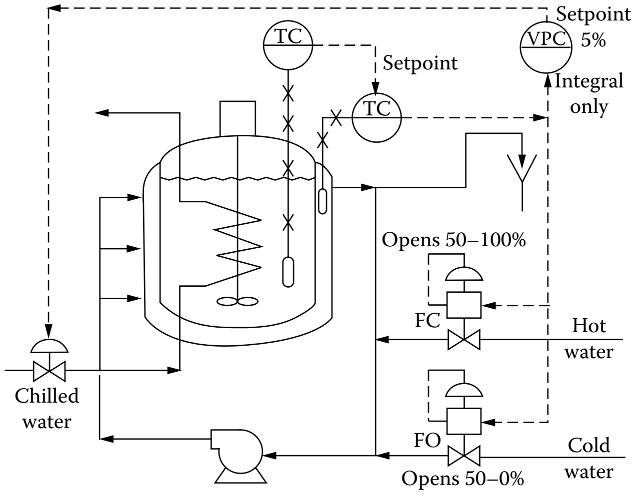

FIG. 8.9o
In this configuration, the higher-cost chilled water is used only when the availability of the lower-cost cold water is insufficient to meet the total demand for cooling.[3] *In all cases, when a separate heat-transfer surface is used for auxiliary cooling, the valve position controller (VPC) is needed to manipulate the flow of the auxiliary coolant.*

Figure 8.9o describes a reactor with a separate chilled water coil. This coil is inoperative until the cold water valve approaches full opening. When the valve position controller (VPC) detects that condition, it starts opening the chilled water valve. The resulting increased heat removal will cause the temperature cascade loop to close the cold water valve until it drops to the setting of the VPC.

Figure 8.9p serves the same purpose as the system depicted in Figure 8.9k, except that the designer placed the throttling valve for the coolant into the return flow path so that a separate back-pressure regulator would not be needed.

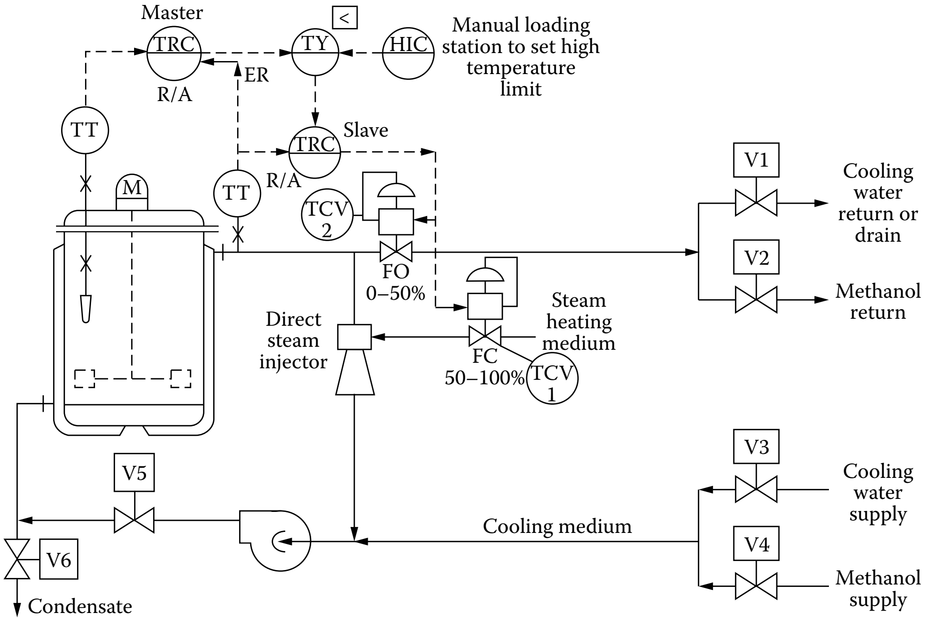

FIG. 8.9p
Multimedia temperature control system with coolant control valve in the return line.

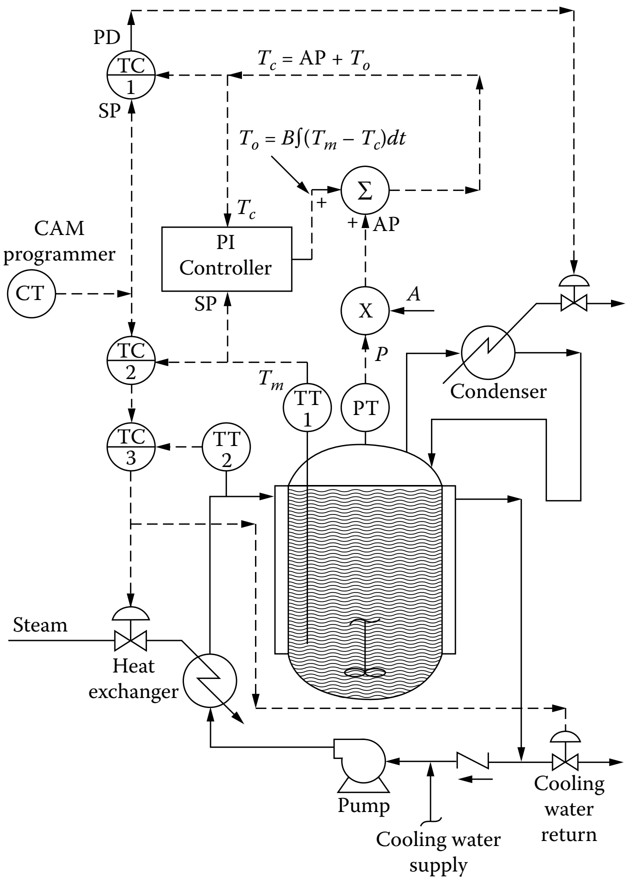

FIG. 8.9q
Pressure-compensated temperature control can be used to improve the control system's speed of response. (Adapted from Byrd Hopkins, U.S. Patent No. 3,708,658.)

Pressure-Compensated Temperature Control

In a process where the reactor pressure is a function of batch temperature (e.g., the reactor pressure is essentially the vapor pressure of one of the major components in the reaction), this pressure may be sensed and used to speed up temperature control. In large polymerization reactors having low heat-transfer coefficients and large changes in heat evolution, the conventional temperature cascade loop is not fast enough. On the other hand, pressure measurement gives an almost instantaneous indication of changes in temperature.

Figure 8.9q illustrates the application of a pressure-compensated temperature control system to a reactor with both jacket and overhead condenser cooling (U.S. Patent No. 3,708,658, January 2, 1973, assigned to Byrd Hopkins of the Monsanto Company). This same approach can also be applied to reactors with jacket cooling only. Under steady-state conditions the reactor temperature (T_m) is on setpoint, set by the cam programmer, and therefore the calculated temperature $T_c = T_m$.

When an upset occurs, the pressure transmitter (PT) will detect it first, causing the calculated temperature (T_c) to change as the AP part of the expression is changed. This will make the measurement of TC-1 much faster than it otherwise would have been; it also allows the overhead condenser to start removing the excess heat even before the temperature transmitter (TT-1) is able to detect it. After each dynamic upset, the PI controller slowly returns the calculated temperature (T_c) to equal the measured temperature (T_m). This then automatically reestablishes the correct pressure-temperature relationship as the composition in the reactor changes.

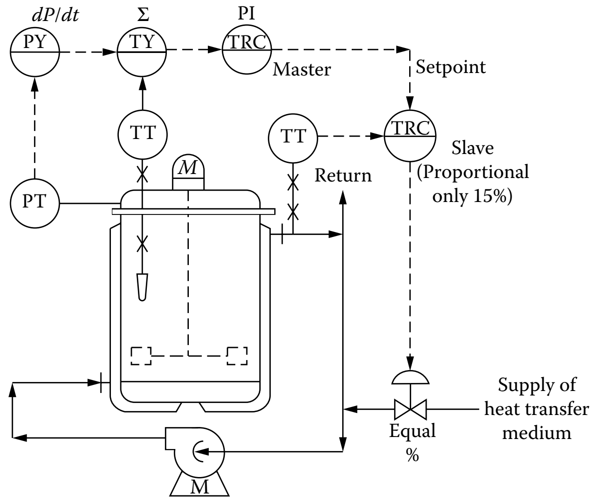

FIG. 8.9r
The derivative mode can be applied to the quickly responding process variable (pressure), and the integral mode can be applied to the more slowly responding process variable (temperature).

The net result is the ability to operate the reactor at a much higher reaction rate, thereby obtaining higher productivity than was possible with temperature control alone.

TC-1 in Figure 8.9q would normally be provided with proportional and derivative control modes only. When TC-1 is on set point, the output signal returns to a value set by an adjustable internal bias. If the preferred means of cooling is through the jacket, then this bias will be set to a low value, but not to zero.

If there is only a single manipulated variable, the control system would be configured as in Figure 8.9r. The control modes are distributed between the measured variables so that integral action will act on the slowly responding temperature, while derivative action is applied to the more sensitive pressure.[5]

The derivative time setting will be much shorter than the integral, because pressure responds faster than temperature. Integral action cannot be applied to the pressure measurement, because the pressure can vary even under constant temperature conditions (as a result of variation in feed composition or catalyst activity), and the intent here is to use the pressure loop only in the unsteady state.

Naturally, integral action is applied to the temperature measurement signal, because it is steady-state temperature

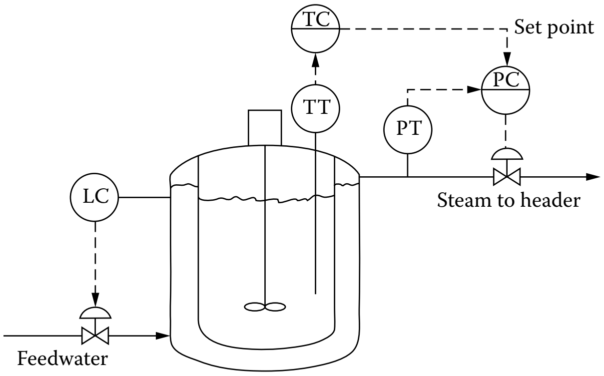

FIG. 8.9s
Exothermic reactors can be stabilized by the internal heat sink, which is provided by the boiling coolant in the jacket.[5]

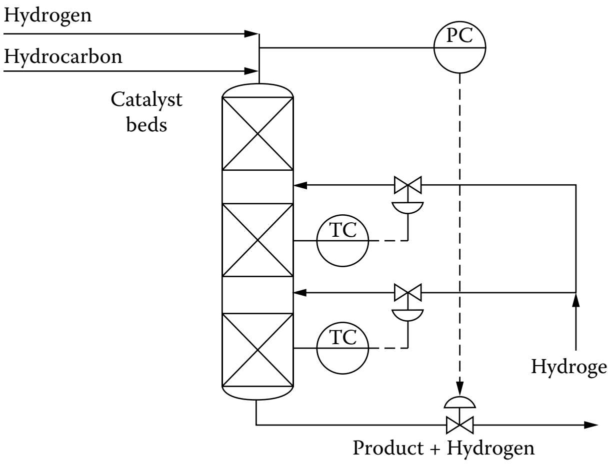

FIG. 8.9t
In some processes, the reaction rate (and reaction temperature) can be reduced by lowering the concentration of the reactant. This is usually done by introducing more diluent (in this case, hydrogen).[5]

that determines product quality, and integral action will ensure its return to set point.

Temperature Controlled by Boiling Coolant Gas phase reactions (such as ammonia synthesis) are usually conducted at relatively high temperatures and pressures. Because of the competing reactions taking place in parallel with the main reactions, productivity and partial pressures are interrelated.

For example, in an ammonia synthesis process, a pressure increase is required to increase production when the ammonia concentration is low. On the other hand, a pressure decrease is required to increase production when the ammonia concentration is high.[5] If inerts are also present, partial pressures are usually determined by detecting both the total pressure and the gas composition.

In such processes, which are both temperature- and pressure-sensitive, a very stable heat removal system is desired. If the reactor jacket is filled with boiling water, the rate of heat removal can vary without causing a change in the jacket temperature. Figure 8.9s illustrates such a cascade system. In order to increase the sensitivity of the loop, pressure is selected as the controlled variable for the slave controllers.

Temperature Controlled by Feed Rate In a hydrocracking reactor (Figure 8.9t), product quality, catalyst life, and productivity are each a function of accurate temperature control. In this process, the reaction rate is fast, residence time is a few seconds, and reactant concentration is low. This combination would allow the reaction temperature to be controlled by manipulating the feed rate. If it is desirable to set production rate, and therefore feed rate independently of cooling capacity, the temperature can be controlled by throttling a diluent.

In Figure 8.9t the diluent is hydrogen, which is admitted under separate temperature controls into each zone. The introduction of hydrogen diluent lowers the reaction rate by reducing the reactant concentration and also by cooling.

The temperature of the batch at any one time is a function of the balance between the exothermic heat that is generated and the quantity of heat that is being removed by the coolant. If the two are not in balance, the batch temperature changes.

In the previously described control schemes, the exothermic heat was uncontrolled, and the cascade loop controlled the batch temperature by adjusting the coolant flow to match that load. In some of the fast and more stable processes, this configuration can be reversed, as shown in Figure 8.9u. Here the rate of cooling is fixed (at a relatively high rate) and the temperature controller (TRC-4) is adjusting the reagent flow (exothermic heat generation) to maintain a balance.

At the beginning of the batch the concentrations of precharged other reactants are high, the concentration of the product in the batch is low, and therefore the process gain is very high. As the reaction progresses, product concentration rises, unreacted reactant concentrations drop, and, as a consequence, the gain of the process also drops. By the end of the reaction, the process gain (*Gp*) can be reduced 10- or 100-fold.

As was shown in Figure 2.1x in Chapter 2, good control requires that the gain product of the loop be constant. Therefore, as *Gp* drops it is necessary to increase the controller gain (*Gc*) in proportion. This is done by FY-1 in Figure 8.9u, which measures the total amount of reactant charged and increases the gain of TRC-4 as that total rises. The function of the reaction rate (FY-1) is nonlinear reaction-specific. TT-2 provides a feedforward signal so that if the coolant temperature would rise and thereby the cooling rate would drop off, this would also decrease the gain of TRC-4, thereby making it cause a smaller change in slave set point.

The set point of the slave (FRC-1) is limited by the low-signal selector TY-4. It compares two limits to the set point of FRC-1, generated by TRC-4 and picks the lowest of the three signals. During start-up, safety is served by KT-4, which

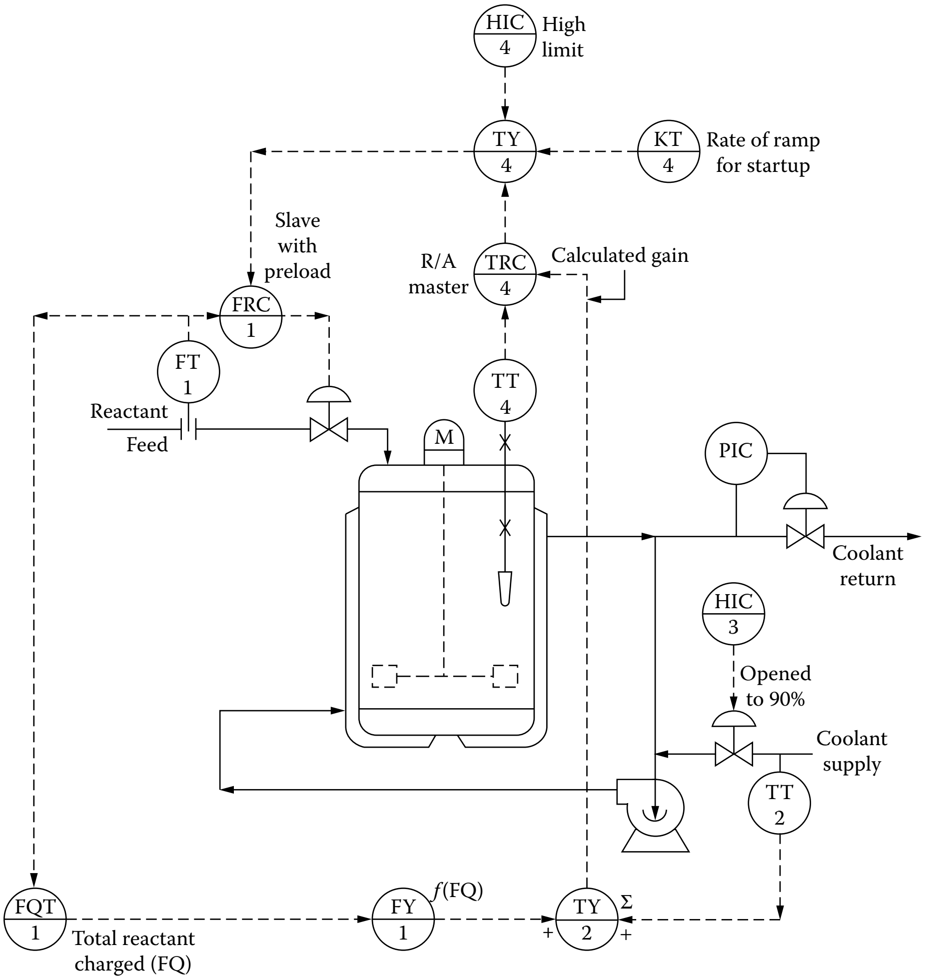

FIG. 8.9u

If the amount of cooling is constant, the cascade slave of the reactor temperature controller can be the reactant flow controller. Because the process gain drops off as the production rate rises, the gain of the cascade master controller (TRC-4) can be automatically increased as a function of total reactant charged.

ramps the slave set point up at a safe rate to protect against overshooting. The slave (FRC-1) is preloaded to minimize start-up overshoot or transients.

The amount of preload is based on experience and serves to stabilize the loop more quickly than if the initial value of the FRC-1 output was zero. The main advantage of such control systems is that they minimize the batch reaction time and thereby maximize plant productivity.

Model-Based Temperature Control

When a reaction is highly exothermic and if runaway reactions can occur, the use of a model-based control system is justified. In order to develop the total model, three component models need to be developed:

1. *Equipment model*, describing the effect of heat-transfer media on reactor temperature (T_r)
2. *Kinetic model*, describing the effect of T_r on the chemical reaction
3. *Calorimetric model,* describing the effect of reaction rate on T_r[7]

When an exothermic reaction is taking place within the reactor, a feedback cascade loop such as that shown in Figure 8.9m is needed to provide stable temperature control by matching the rate of heat removal to the rate of heat generation. If the TRC in Figure 8.9m was tuned at a time when there was no reaction taking place within the reactor, it will not perform properly when exothermic heat is being generated.

If the gain of the master TRC is fixed, the loop might become unstable if the reaction is autocatalytic (does not require a catalyst). Model-based controls can improve on such performance. One such model-based approach is to use a heat-release rate estimator. The rate of heat release (Q in Figure 8.9v) can be estimated on the basis of reactor

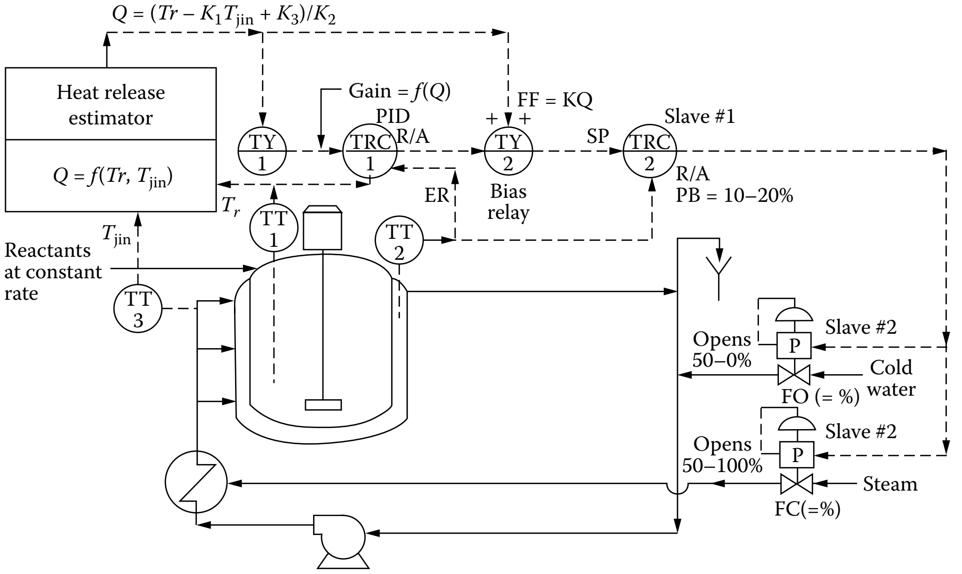

FIG. 8.9v

Heat-release estimator increases the gain of the master temperature controller (TRC-1) when the estimated total exothermic heat release rises and, as a consequence, the process gain in a batch reactor drops.

temperature (T_r) and jacket-inlet temperature (T_{jin}) in accordance with:

$$Q = (T_r - K_1\, T_{jin} + K_3)/K_2 \qquad \textbf{8.9(6)}$$

In exothermic reactions, Q is the major load variation that tends to upset the stability of the temperature controls. Once this disturbance load is estimated, it is possible to feedforward that estimate to the slave set point as a bias. This bias relay is TY-2 in Figure 8.9v, and the feedforward bias (FF) it adds to the slave set point is a function of Q. The feedback master (TRC-1) naturally corrects the total effect on the jacket temperature set point and thereby overcomes the errors in the feedforward model.

The gain of the feedback master (TRC-1) is varied as a function of Q [Gain = $f(Q)$]. As Q increases, the process gain drops, and therefore the gain of this nonlinear adaptive-gain feedback controller is increased in order to keep the gain product for the loop constant.

INITIAL HEAT-UP

In most chemical reactions, a certain temperature must be reached in order to initiate the reaction. An ideal reactor temperature controller will permit rapid automatic heat-up to reaction temperature without overshoot and then accurately maintain that reaction temperature for several hours. This is a difficult goal to accomplish, because the dynamics of the controlled process will go through a substantial change as the heat load first drops to zero and then the cooling load gradually evolves when the reaction is started.

The master temperature controller is usually a three-mode one, tuned for the exothermic phase of the reaction cycle. It might have a 30% proportional band and a 5 minute setting for both integral and derivative. If such a controller were kept on automatic during heat-up, a substantial temperature overshoot would result (Figure 8.9w) because of windup. Therefore, the conventional PID controller must be supplemented with added features to provide it with the required start-up characteristics.

The added feature is either the “batch unit” or the “dual mode unit,” depending on the proportional band. If it is less than 50%, the batch unit will give good results, whereas if a

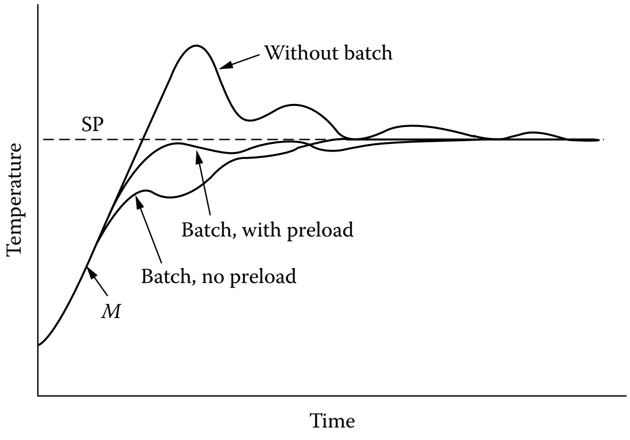

FIG. 8.9w

Temperature overshoot can be eliminated by properly adjusting a “batch unit.”[3]

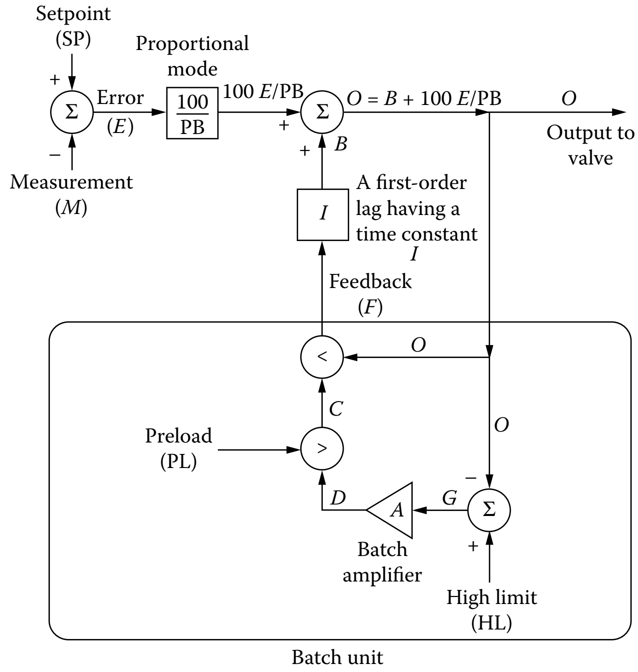

FIG. 8.9x

The batch unit disables the integral control mode until the error is nearly zero.[3] *Thereby, the batch unit maintains the controller output at its limit.*

proportional band wider than 50% is required, the dual-mode unit will be more effective.

The Batch Unit

Without the batch unit, the PI controller illustrated in Figure 8.9x would receive a feedback signal (*F*) equaling the output (*O*). Therefore, whenever there is an error (*E*), the output signal is driven continuously by the positive feedback through *I* (a first-order lag, having a time constant *I*) until *B* reaches the saturation limit. Once in this saturated state (the reset is wound up), the output signal "*O*" will equal "*B*" even if the error has returned to zero. This is the reason that in Figure 8.9w the temperature keeps rising even after it has reached set point (SP = *M*, *E* = *O*).

Without the batch unit, therefore, control action cannot begin until an equal and opposite area of error is experienced. This is why reset windup always results in overshoot and why this windup must be eliminated by the addition of the batch unit shown in Figure 8.9x.

Under normal operation, the output to the valve is below the high limit. Therefore, *G* is positive and the amplifier drives *D* upward, which causes *O* to be less than *C*. In this state, the low selector selects *O* as the feedback signal, and the controller behaves as a conventional PI controller.

When *O* exceeds HL, the amplifier drives down *D*, *C*, *F*, and *B* and thereby limits *O* from exceeding the HL setting.

It is also necessary to provide a low limit (called preload) to the feedback signal; otherwise, the opposite of an overshoot would be experienced—an excessively sluggish approach to set point, as shown in Figure 8.9w by the "no preload" curve. If the PL setting did not prevent the feedback (*F*) from dropping too low at times of high error (such as at the beginning of heat-up), *B* could saturate at the low limit, keeping output (*O*) below zero even when the measurement has returned to set point. With preload, the controller output "*O*" will equal PL when the error is zero.

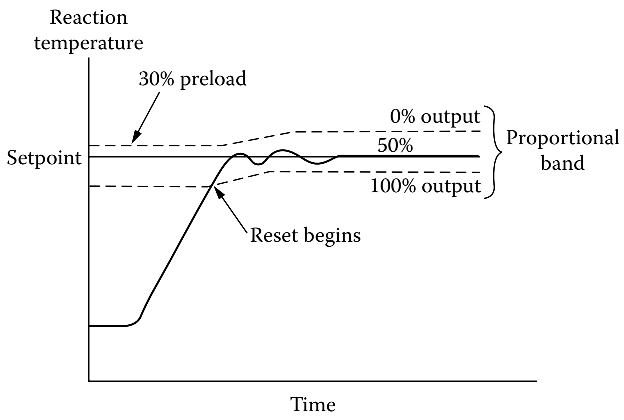
It can be seen from the above that a PID-type batch controller requires a total of five adjustments, because HL and PL must be set and the three control modes must be tuned. HL should be set at the maximum allowable jacket water temperature, which would then eliminate the need for a separate limit, such as the HIC in Figure 8.9l.

The correct setting for PL is the master controller output at that time when reaction has started and a steady state has been reached between the generation and the removal of the heat of reaction. If, for example, the jacket water temperature during steady state is 90°F, this value could be selected as the preload setting, which will be the output of the master (and the set point of the slave) when the reaction temperature has been reached.

Actually, the PL setting should be a few degrees lower than this value, say 87 or 88°F, to allow for the contribution of the integral action of the controller from the time the proportional band is entered to the time where the set point is reached. This is illustrated in Figure 8.9y.

Dual-Mode Controller

The effectiveness of the batch unit, described earlier, is lost when the reactor requires a wide proportional band, say in excess



100% output means full heating
0% output means full cooling
30% output might correspond to the normal level of cooling at steady state

FIG. 8.9y

If preload is correctly set, overshoot will be eliminated and heat-up time will still be held at a minimum.[3]

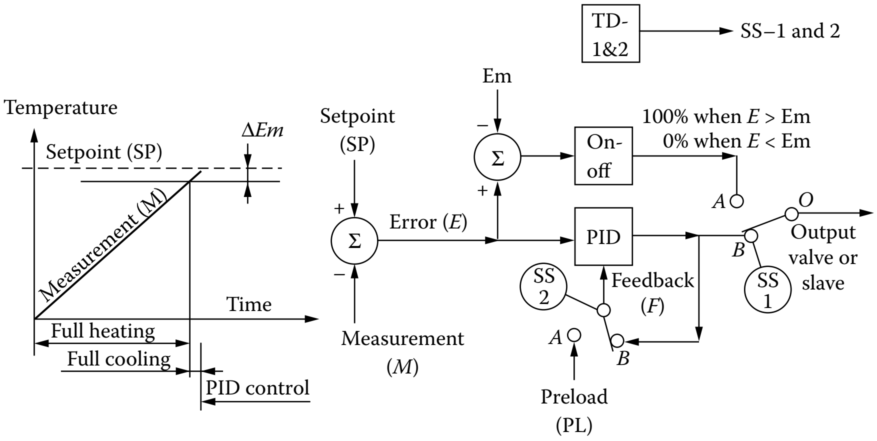


FIG. 8.9z

The dual-mode controller switches from full heating to full cooling, which is then followed by switching to PID control with preload. It is used for optimum start-up of potentially unstable batch reactors. The value of ΔE_m *is the minimum error setting, which corresponds to a state when the measurement has approached the set point to within 1 or 2%.*

of 50%. With a wide band (as shown in Figure 8.9y) reset action would begin much earlier, which would lengthen the heat-up time. In such a case, the dual-mode unit (Figure 8.9z) is the proper selection.

In the dual-mode unit, the preload is estimated as in the case of the batch unit, but it is not reduced for integral correction. It is not lowered from 90°F to 87 or 88°F in our example, because in this case reset does not begin until the error is zero.

The sequence of operation is as follows:

1. Full heating is applied until the reactor is within 1 or 2% of its set-point temperature. This margin is set by the minimum error setting (Em). During this state SS-1 and SS-2 are in position "A."
2. When E drops to Em, time delays TD-1 and -2 are started, and full cooling is applied to the reactor for a minute or so to remove the thermal inertia of the heat-up phase. When TD-1 times out the period required for full cooling, SS-1 switches to position "B" and the PID controller output is sent to the slave as set point. This output is fixed at the preload (PL) setting, which corresponds to the steady-state jacket temperature (estimated in our example as 90°F).
3. When the error and its rate of change are both zero, estimated by TD-2, this time delay will switch SS-2 to position "*B*." This switching also transfers the PID loop from manual to automatic, with its external feedback loop closed.

If properly tuned, the dual-mode unit is the best possible controller, because by definition, optimal switching is unmatched in the unsteady state by any other technique.[3] On the other hand, this loop requires seven settings. Three of these—*P*, *I*, and *D*—pertain only to the steady state of the process; the other four—PL, Em, TD-1, and TD-2—will determine start-up performance. The effect of these adjustments is self-evident:

Em should be increased in case of overshoot and lowered if undershoot is experienced.
PL has the same effect as in Figure 8.9w.
TD-1, if set too long, will bring the temperature down after the set point is reached.
TD-2 is not very critical.

Figure 8.9aa illustrates that from the start-up performance of the reactor, it can be determined which setting needs adjustment.

Rate of Temperature Rise Constraint

In highly unstable, accident-prone reactors that have a history of runaway reactions, an added level of protection can be provided, based on the permissible rate of temperature rise

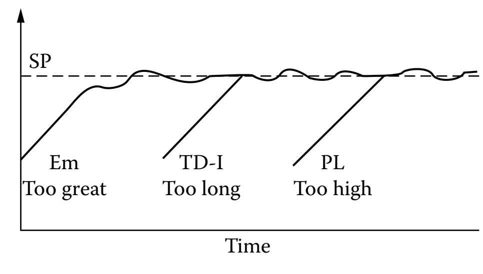

FIG. 8.9aa

It is possible to diagnose the tuning constants used in dual-mode loops on the basis of the reactor's start-up performance.[3]

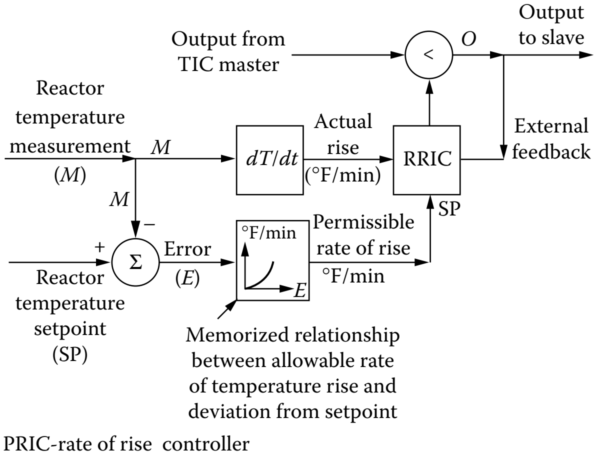

FIG. 8.9bb
The rate of temperature rise constraint is usually incorporated as added protection.

during heat-up. This is usually superimposed on the previously discussed control systems on a selective basis as a safety backup. The protection is provided by first calculating the actual rate of temperature rise in units of °F/min and then sending it as the measurement signal to the RRIC controller in Figure 8.9bb.

The set point of this controller is programmed as a function of the heat-up state. Toward the end of the heat-up period, when the reaction temperature has been almost reached (the error is near zero), the value of the permissible rate of rise is set to be much lower than at the beginning of heat-up. Doing so prevents the process from building up a thermal inertia as it approaches the region of potential instability.

Model-Based Heat-Up Control

Model-based heat-up algorithms can be configured in two blocks, the "predictor block" and the "corrector block." The predictor block is a process model of the reactor and serves to determine the amount of heat input required (*Qh*) at any point in the batch heat-up cycle, so as to minimize the heat-up period while eliminating overshoot.

The corrector block serves to refine the model by correcting the constants and calculation parameters in the process model by comparing the model to the actual process. Figure 8.9cc illustrates the operation of such a model-based heat-up control system.

The variable manipulated by the "predictor" is the heat input rate (*Qh*), which initially is set to maximum, similar to the action of the dual-mode control algorithm in Figure 8.9z. The difference with the dual-mode strategy is that here (in Figure 8.9cc), as the reactor temperature approaches its target set point, the manipulated variable is not switched to cooling but to a minimum rate of heating (*Qh*)min. The switching from (*Qh*)max to (*Qh*)min occurs when the steady-state reactor model indicates that with the amount of heat already introduced, once the reactor reaches its new steady state, its temperature will match the set point.

Adaptation The nature of the batch reactor process is such that it never reaches a steady state. The process is in a continuous state of transformation and change; therefore, the control system parameters should also be in a continuous state of change. Some of these changes are rather drastic; for example, when the system switches from heating to cooling. When such changes occur, the controller parameters must be changed immediately and equally drastically, which is usually done by "programmed adaptation," meaning that the PID algorithm settings for the various stages of the reaction cycle are stored in a table and are recalled as needed.

Adaptation of tuning constants can also occur slowly using various adaptive algorithms (Chapter 2) as a function of various measurements, such as, for example, the rising of the level (mass) in the reactor or the reduction in the exothermic heat release as the reaction rate drops off. Adaptation can also be based on various rules of thumb, such as utilizing the rate of temperature rise during heating up the reactor to predict the reactor time constants, which in turn can be used to tune the temperature controller.

Initialization, Preload, and Feedforward When the transition from heat-up to the reaction phase takes place, it is important that the temperature controller be properly "initialized" (placed into the correct initial state). That means that the controller must be provided with the proper tuning constants and bias (output signal at zero error) that will make the transition smooth. This initialization of the controller is often called preloading. As was shown in Figure 8.9w, the use of the right amount of preload is essential to obtain maximum heat-up rate without overshoot.

In a batch process, where the same product is made in consecutive batches, preload is often determined empirically. This means that if in batch #19 the transition to reaction phase was stable and the controller output at the beginning of that phase was 52%, it is a fairly safe assumption that in batch #20 the same 52% preload will also provide stable transition. In some reactor heat-up applications the preload can also be predicted on the basis of the rate of temperature rise during heat-up.

Feedforward features can also be incorporated into the overall control system. For example, in Figure 8.9n one could feedforward a change in the set point in the master directly into a change in the set point of the slave, if a bias unit was inserted to detect the master set point and to generate the correct amount of change based on that measurement. By such feedforward action, the integral-mode offset error, caused by set point change, can be reduced.

This is a good feature, because even if the control algorithm is so configured that the proportional and derivative modes act only on the measurement (Section 2.3 in Chapter 2), the integral mode usually acts on the total error, and therefore it is responsive to set-point changes.

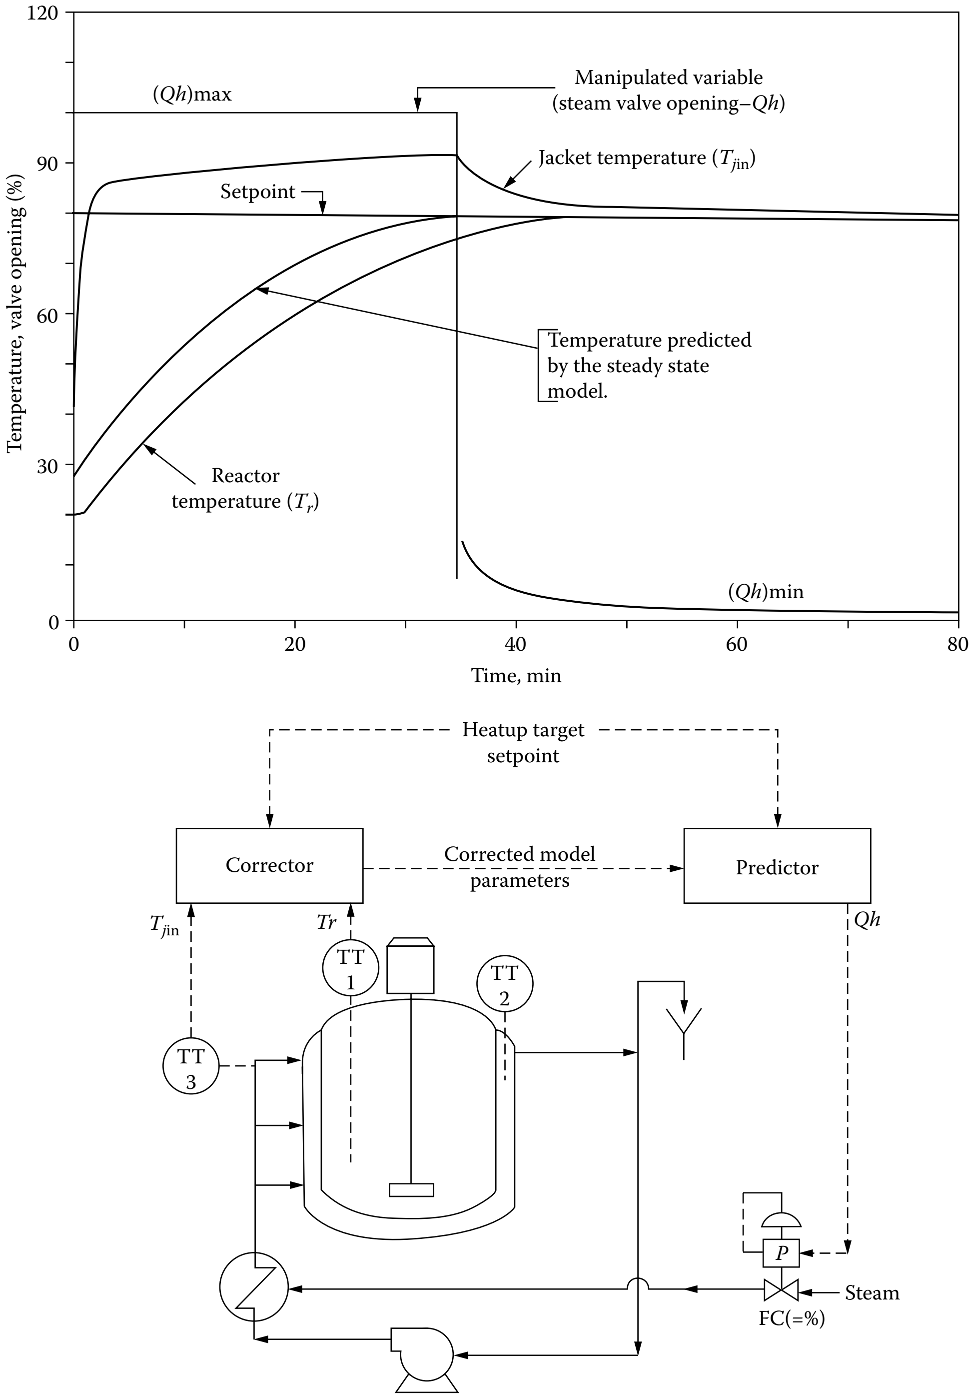

FIG. 8.9cc
The model-based heat-up strategy controls the point of switching from maximum to minimum heating. This switching occurs when the model predicts that enough heat has been introduced for the reactor temperature to reach its set point (top), once the new steady state is reached. The lower half of the figure shows the roles of the corrector and predictor segments of the system.

SPECIAL AND OPTIMIZING STRATEGIES

Maximized Production by Constraint Optimization

In exothermic reactions, one of the critical safety constraints is coolant availability. That limitation is automatically configured into the control loop of a continuous reactor, illustrated in Figure 8.9dd. Here, the optimizing controller (OIC) detects the opening of the coolant valve, and if it is less than 90% open, it admits more feed by increasing the set point of the FRC. Thus, production rate is always maximized, but only within the safe availability of the coolant. When the

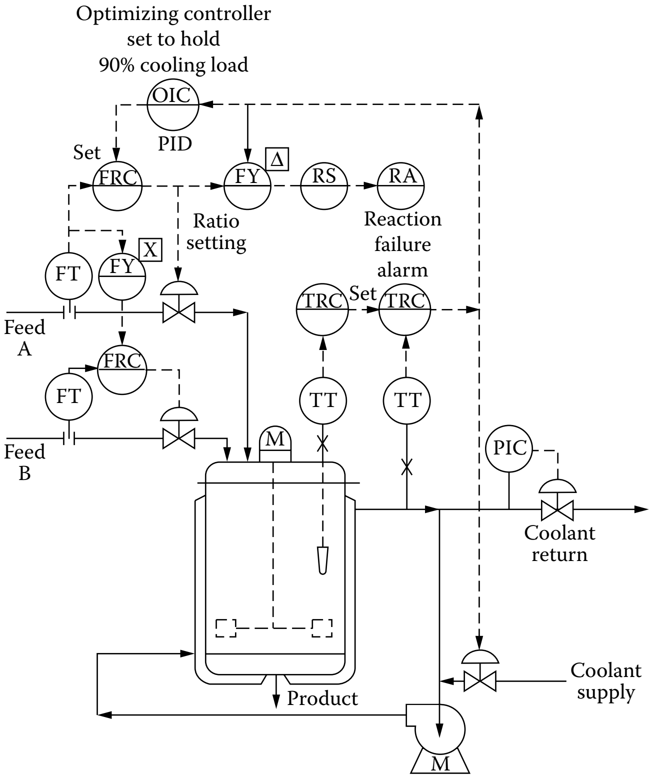

FIG. 8.9dd
The reaction rate in this continuous reactor is continuously matched to the full available capacity of the cooling system.

coolant valve opens beyond 90%, production rate is lowered so that the reactor will never be allowed to run out of coolant.

Another safety feature shown in Figure 8.9dd is the reaction failure alarm loop (RA). This loop compares the reactant charging rate to the reactor with the heat removal rate from the reactor and actuates an alarm if the charging rate is in substantial excess.

In Figure 8.9dd, the valve position controller (OIC) maintains the feed rate as high as the cooling system can handle. This results in a variable production rate, because changes in coolant temperature or variations in the amount of fouling of the heat-transfer areas will change production.

The dynamic response of the reactor temperature to changes in reactant flow is not favorable. A change in feed flow must change the reactant concentration before a change in reaction rate (and therefore in heat evolution) can change the reaction temperature.

Reactant concentration adds a large secondary lag to the valve position control loop. This necessitates the use of a three-mode controller,[5] which in turn limits the application to stable loops only. The slower the OIC loop (the longer its lag), the lower should be the set point of OIC in Figure 8.9dd, to provide the required margin for stability.

Maximizing Batch Reactor Production In a batch reactor, production rate increase with temperature, and therefore production can be maximized by maximizing temperature. This can be accomplished by a valve position controller that raises the batch temperature set point whenever the coolant valve is less than 90% open.

Unfortunately, the dynamic characteristics of this loop are also undesirable because of the inverse response of the loop.[5] When the coolant valve opens to more than 90%, the VPC will lower the set point of the temperature controller. This will temporarily *increase* the demand for coolant, although once the excess sensitive heat is removed, it will lower it. The longer the dead time introduced by this inverse response, the large the margin needed for safety and stability, and hence the lower the set point of the VPC.

When the concentration time constant is equal to or larger than the thermal time constant, temperature control through feed flow manipulation is no longer practical.[5] In such reactors, only the manipulation of the coolant will give stable operation. The strategy of valve position control is still useful in such applications, but in these cases it must manipulate supplementary cooling.

Heat Release Control

By multiplying the jacket circulation rate by the difference in temperature between inlet and outlet, it is possible to determine the amount of heat released or taken up by the reaction. The reaction is in an endothermic state when the value of Q in Figure 8.9ee is negative, and it is in an exothermic phase when Q is positive.

Under steady-state conditions, at high circulation rates the difference between T_o and T_i is about 5°F or less. The

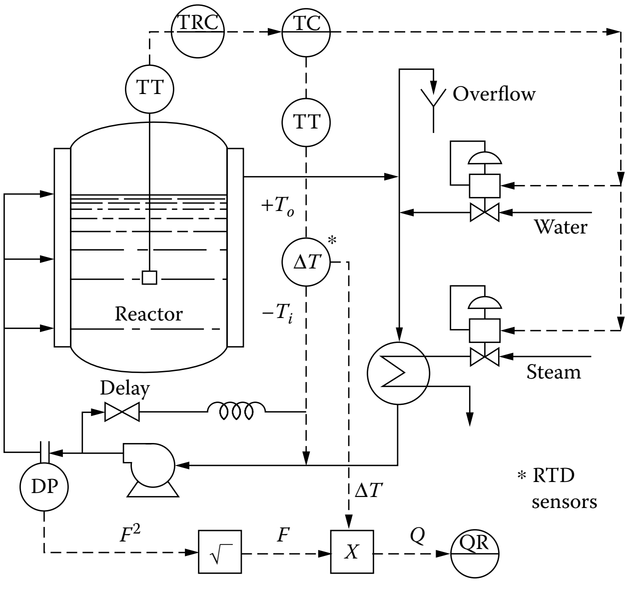

FIG. 8.9ee
To correctly determine the instantaneous amount of heat release, the jacket inlet temperature reading must be delayed by the residence time of the jacket, so that the ΔT transmitter will be dynamically compensated.[3]

method of reading this ΔT is critical, because during load changes, dynamic compensation is needed. As more cooling is requested, the jacket inlet temperature will drop, and the jacket outlet temperature will stay unaffected until the jacket contents are displaced. If Q is to be used for control purposes, such dynamic errors must be removed by compensation.

This is accomplished by delaying the jacket inlet temperature into the ΔT transmitter by a time equal to the delay through the jacket.[3] In Figure 8.9ee, this is accomplished by simulating the jacket using a length of tubing whose dead time is adjustable by changing the flow rate through it. A similar result can be obtained by placing an inverse derivative relay, set for a jacket displacement time of, say, 30 secs, into the transmitter output signal; the desired goal can also be reached by electronically simulating the transportation lag in digital systems.

The correct selection of the ΔT transmitter is very important, because in order to be able to detect Q within a ±1% error, the ΔT must be detected within ±0.2°F (±0.01°C). This can be accomplished only by using the best quality RTD-type transmitters that can provide spans, which are as narrow as –5 to 0 to +5°F. When the absolute value of the jacket temperature can vary from, say, 50 to 250°F throughout the reaction cycle, it will also be necessary to correct the calibration of the ΔT transmitter as the absolute temperature changes.

Once the value of Q is accurately determined, it can be used for many purposes. The instantaneous value of Q signals the rate of heat removal or addition, and the time integral of Q gives the total heat that has been added or removed. A change in the value of ΔT under standard conditions can signal fouling and the need for cleaning the reactor heat-transfer surfaces.

Stripping and Refluxing Controls

During stripping or refluxing phases, the reactor might be controlled on the basis of heat input (Q), because refluxing tends to be done at constant temperature, and the increase in temperature during stripping is usually too small for control purposes. Therefore, the system would be switched automatically from temperature control (Figure 8.9ee) to heat input control (Figure 8.9ff) whenever the reactor enters a stripping or refluxing phase.

The heat input during refluxing is usually set to be sufficient to maintain a state of slow boiling. During stripping, the heat input is usually set to complete the stripping in some empirically established time period; for example, an hour or two.

The time integral of Q represents the total reaction heat, which is an indicator of product concentration or percentage conversion. It can be used to introduce additives at predetermined conversions and to determine reaction endpoint. Through these automated steps, the need for taking grab samples can be eliminated. This in turn will result in reduced overall cycle time and, therefore, in increased production rate. The control of vacuum strippers will be discussed in the Pressure Control subsection.

FIG. 8.9ff
Control can be switched from temperature control to heat input control as the reaction cycle enters a stripping or refluxing phase.

Constant Reaction Rate

Optimization of a chemical batch reactor usually means that its throughput is maximized while the operating costs are minimized. These goals can be met by simple, traditional techniques such as by optimizing the utility distribution in such a way that no reactor is held up in its reaction sequence because it has to wait for the availability of a particular resource.

Other obvious optimization techniques include the increasing of the reactant charging rates, the maximization of reactor heat-up or cool-down rates, and the maximized utilization of coolant availability during the exothermic reaction itself (Figure 8.9dd). When attempting to maximize the heat removal capability of a reactor, one can also precool the reactants prior to charging them to the reactor.[7]

Figures 8.9ee and 8.9ff show how the reaction rate can be measured in a reactor by detecting the exothermic heat release. Figure 8.9v shows a method to estimate the rate of heat release. Whether an accurate measure or just an estimate of the heat release rate (Q) has been made, that information can be used for control.

In Figure 8.9v, the heat release rate was used only as the basis for adjusting the gain of the TRC master and as a feedforward anticipator. However, it can do more, because by converting the nonlinear reaction rate of the batch into a linear rate, the batch reaction time is much reduced.

As shown in Figure 8.9gg, the batch reaction is completed much faster when the reaction rate is constant (linear) than when a nonlinear (first- or second-order) curve describes

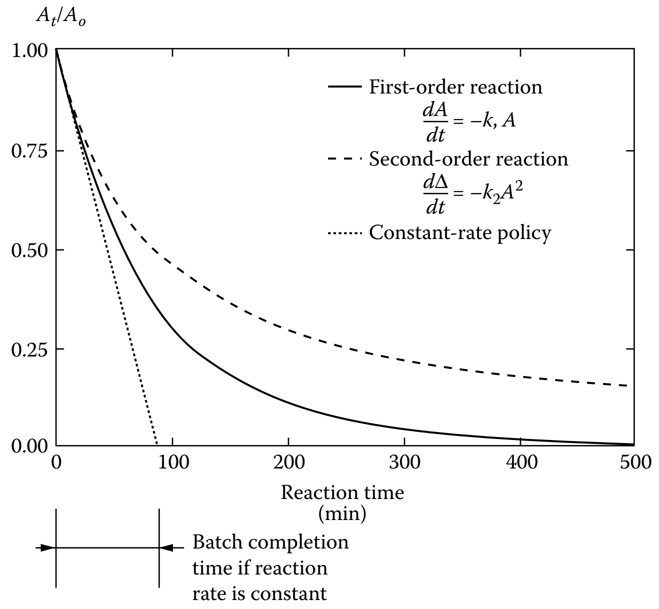

FIG. 8.9gg
The batch reaction time is a function of the reaction rate within the reactor. If constant rate is maintained, the batch reaction time can be drastically reduced.[7]

its time characteristics.[7] In order to keep the reaction rate from dropping off, the reaction temperature has to be increased (it is a nonisothermal batch reaction).

Changing the operation of a batch reactor from a constant reaction temperature to a variable reaction temperature mode (Figure 8.9b) is not an easy proposition to carry out.[11] One of the disadvantages of a nonisothermal operation is that the formed products might change as the reaction temperature changes. Yet, in some processes, the economic advantages outweigh the required complexities in modeling and control.

One possible configuration is to use the reactor shown in Figure 8.9v, in which the reactant is charged at constant rate, and use the heat-release estimator in that figure to modify the set point of TRC-1 in such a way that the reaction rate will be held constant. For some reactions the temperature settings required to provide constant reaction rates can be calculated, while for more complete reactions it is necessary to determine them experimentally.

Figure 8.9hh shows a cascade configuration in which the reaction rate controller (XRC-4) is the master, and it adjusts the batch temperature (TRC-1) set point so as to keep the reaction rate constant. The measurement to the reaction rate controller can come from a heat-release estimator (Figure 8.9hh) or from the actual measurement of the exothermic heat release (Q in Figures 8.9ee and 8.9ff).

ENDPOINT DETECTION

The reliable determination of batch cycle endpoint is important for two reasons:

1. One way to increase plant productivity is to reduce batch cycle time.

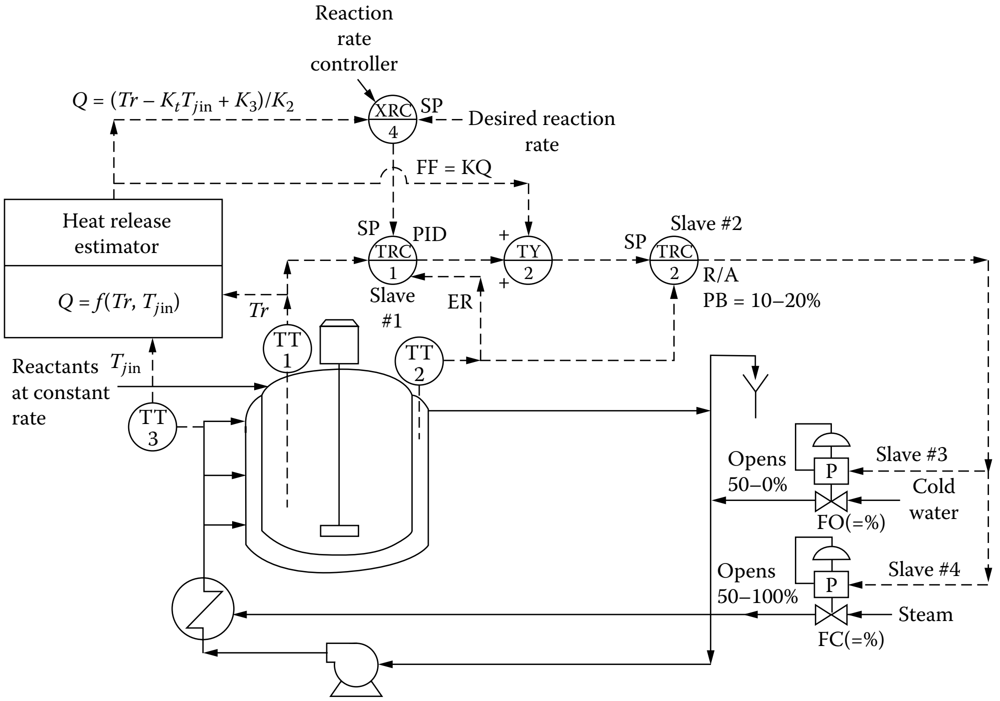

FIG. 8.9hh
Nonisothermal (variable reaction temperature) batch reactor control can shorten the batch cycle time by keeping the reaction rate constant.

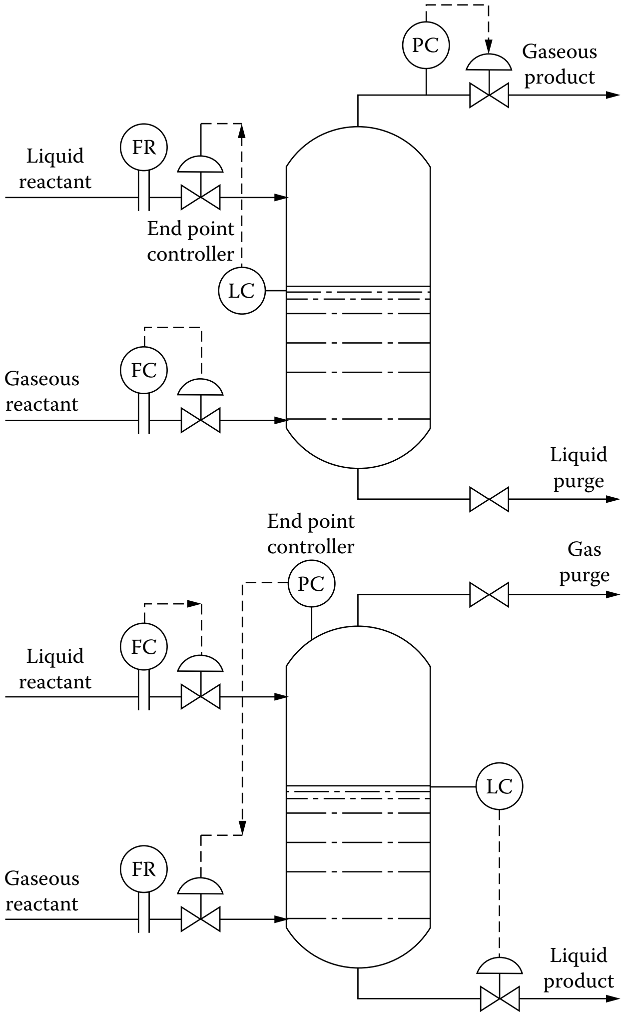

FIG. 8.9ii
One of the reactants can be added at the same rate as it is consumed (inventory control), if the phase of that reactant is different from the phase of the other streams entering the reactor.[3]

2. If the reaction continues beyond the optimal endpoint, the process yield can be reduced due to side reactions.

In batch reactors, if the completion of the reaction cannot be reliably detected, it is common practice to terminate reactant flow on the basis of total charge. This can be based on flow or weight measurements. In other reactions, the endpoint is accompanied by the fall or rise of the reaction pressure. This change in pressure can be used to have a pressure switch or pressure controller to shut off the reactant flow (Figure 8.9ii). In still other reactions, the total reaction heat signals the endpoint, as was illustrated in Figures 8.9ee and 8.9ff.

pH Endpoint If some analytical property, for example, pH, is used in detecting the endpoint, it is important to realize that during most of the reaction the measurement will be away from set point. Therefore, integral action must not be used, because it would saturate and overshoot would result. This is one of the few processes in which the proper selection of control modes is a proportional plus derivative with zero bias, modulating an equal-percentage reagent valve.

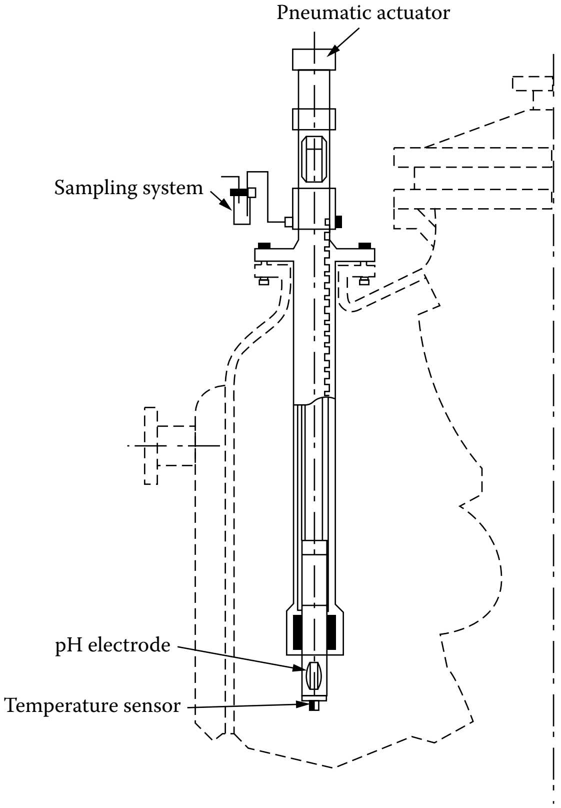

FIG. 8.9jj
The immersion-type pH probe can be used in chemical reactors.

If the derivative time is set correctly, the valve will shut quickly as the desired endpoint pH is reached. With excessively long derivative time setting, the valve will close prematurely, but this is not harmful because it will reopen as long as the pH is away from the set point.

For the measurement of pH, conductivity, and resistivity, on-line analyzers are available. The pH probe shown in Figure 8.9jj can be used for on-line measurement in a glass-lined reactor. When maintenance or recalibration is needed or when the reactor is empty, the probe can be lifted by a pneumatic actuator and immersed into buffer a solution to protect it from getting dry.

In some cases it might be preferred to keep the pH sensor outside the reactor and bring a sample of the reactor contents to it. Figure 8.9kk illustrates such a design configuration.

In other installations, such as in fermenters, the preference is for the use of side entry, retractable pH probes. These are illustrated in Figure 8.9ll. Other pH probe designs are described in Section 8.48 in Chapter 8 of the first volume of this handbook.

If one reactant is charged to the reactor in substantial excess to the others, this will usually guarantee the complete

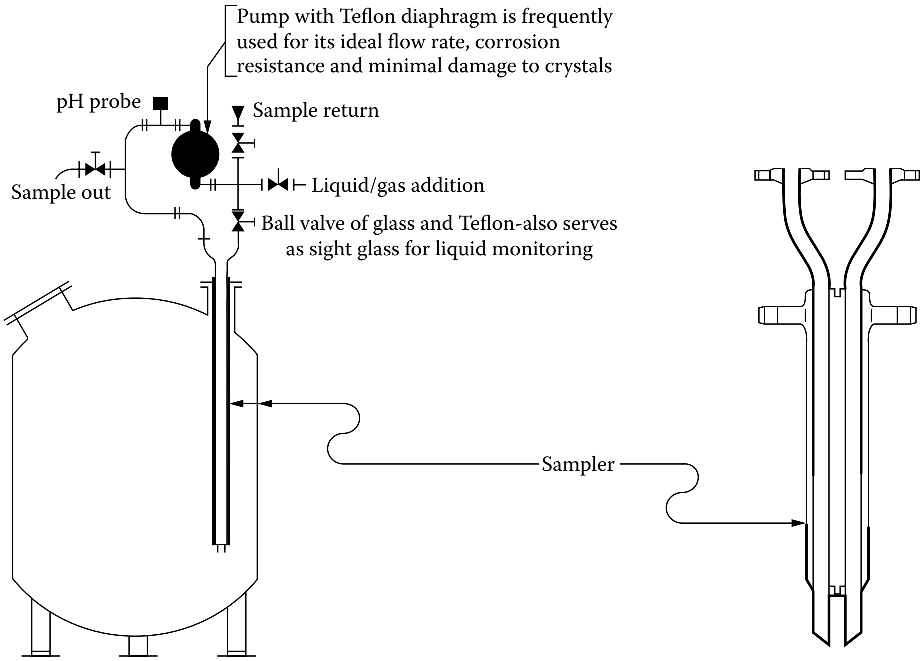

FIG. 8.9kk
The design components of a chemical reactor sampling system.[12]

conversion of the other reactants, and endpoint control is not required, unless the product is also used as the recycle stream. If the reactants are fed to the reactor in the same proportion in which they react, endpoint control is required. If the reactants and product are all in the same phase (all liquids or all gases), the endpoint is usually determined through the use of an analyzer, such as the pH unit.

On the other hand, when the reactants are in different phases, the endpoint can be controlled on the basis of level or pressure. As was shown in Figure 8.9ii, if the product is

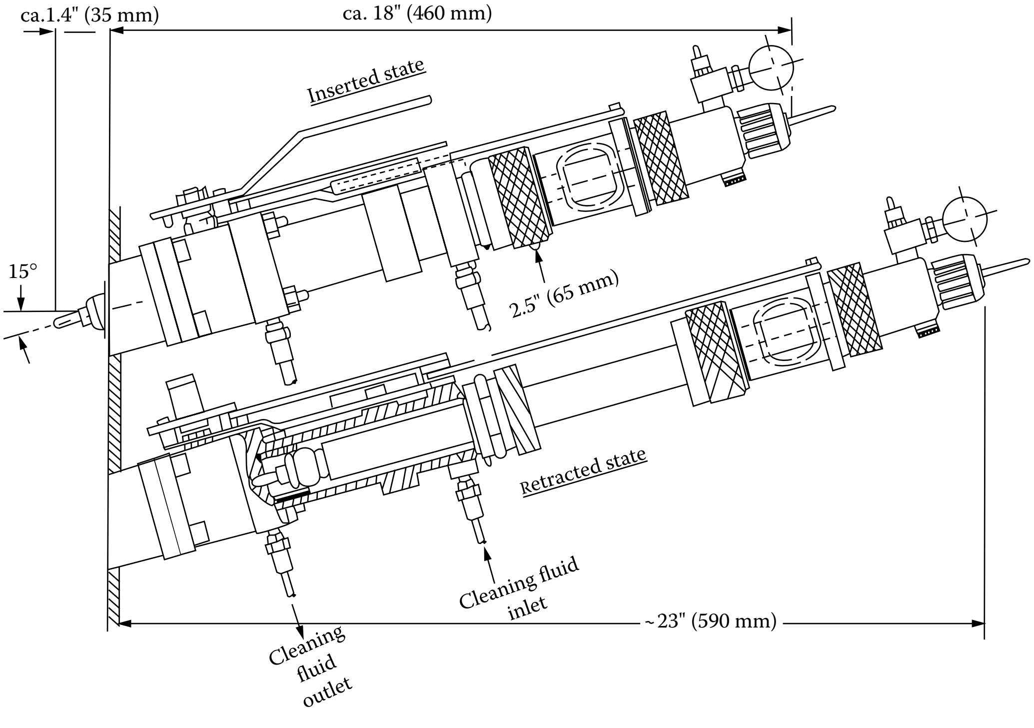

FIG. 8.9ll
Retractable, side-entry probe designs.

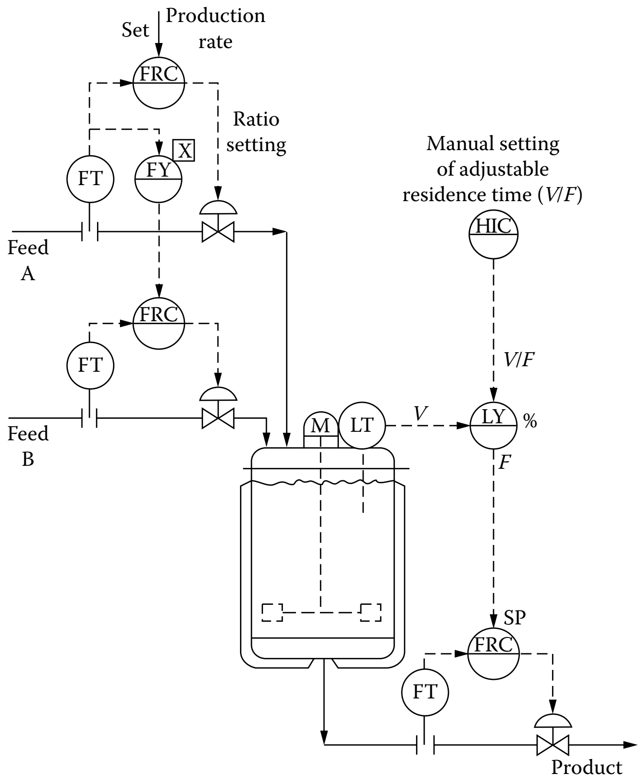

FIG. 8.9mm
Residence time control is accomplished by maintaining a constant ratio between reactor volume and reactor outflow.

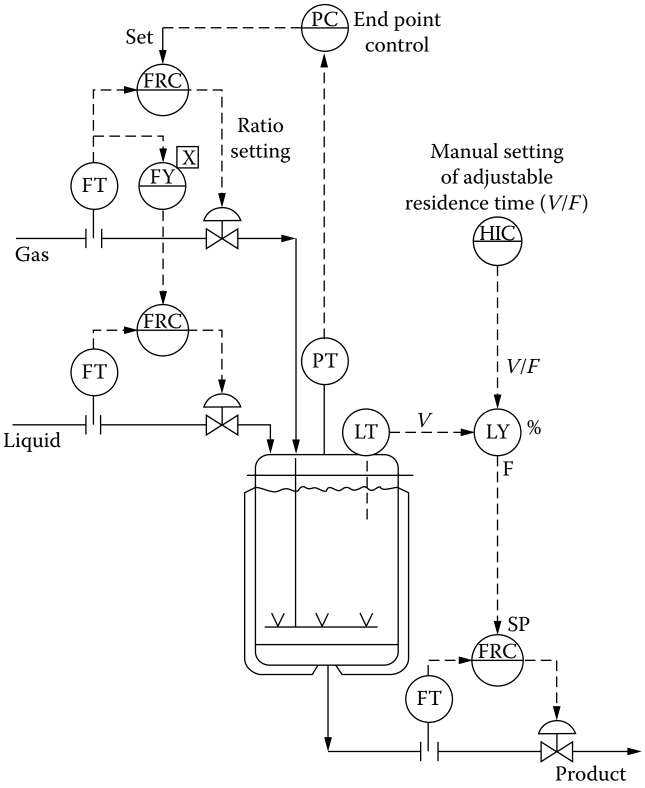

FIG. 8.9nn
In this control system, where the product is in the liquid phase, the endpoint control is based on pressure, while the residence time control is based on level.

gas, the endpoint is maintained by the level controller, whereas if the product is liquid, the endpoint control is based on pressure. When this pressure rises, that is an indication of excess gaseous reactant accumulation in the reactor. In response, the pressure controller (PC) will lower the gas flow; thereby, it will increase the liquid reactant concentration by increasing its relative flow. This in turn will increase gas consumption, and the balance will be reestablished and the correct endpoint maintained.

Residence Time Control

In continuous reactors it is usually desirable to provide a constant residence time for the reaction. If the production rate (inflow to the reactor) varies, the most convenient way of keeping the residence time constant is to maintain a constant ratio between reactor volume (V) and reactor outflow (F). The ratio V/F is the residence time, where the volume (V) can be approximated by a level measurement, and F can be measured as outflow. Figure 8.9mm illustrates a residence time control system using this approach.

All reactions with a liquid product can benefit from residence time control. This requires the combination of the features in the control system shown in Figures 8.9ii and 8.9mm, resulting in Figure 8.9nn.

Analyzers for Endpoint Detection

Probe-type analyzers do not require sampling systems, because the analyzer itself is inserted directly into the process. In the case of chemical reactors, analyzers can be inserted into either the reactor vessel or the discharge piping. Regardless of their locations, probes will give accurate readings only when clean. Therefore, automatic cleaning of such on-stream analyzer probes is a good idea.

Figure 8.9oo illustrates a flow-through, brush-type probe cleaner assembly that is provided with a sight glass, allowing visual observation of the cleanliness of the probe. Such units are also available with spray nozzle attachments for water or chemical cleaning of the electrode.

One common method of endpoint detection is the measurement of viscosity either by monitoring the torque on the agitator or by using viscosity sensors. Such a viscometer can be inserted in pipelines or directly into the reactor. It is essential that they be located in a representative area and be temperature-compensated.

In reactions in which the endpoint can be correlated to density, some of the more sensitive and less maintenance-prone densitometers can also be considered (Chapter 6 in Volume 1). The radiation-type design tends to meet these requirements if pipe line installation is acceptable. These

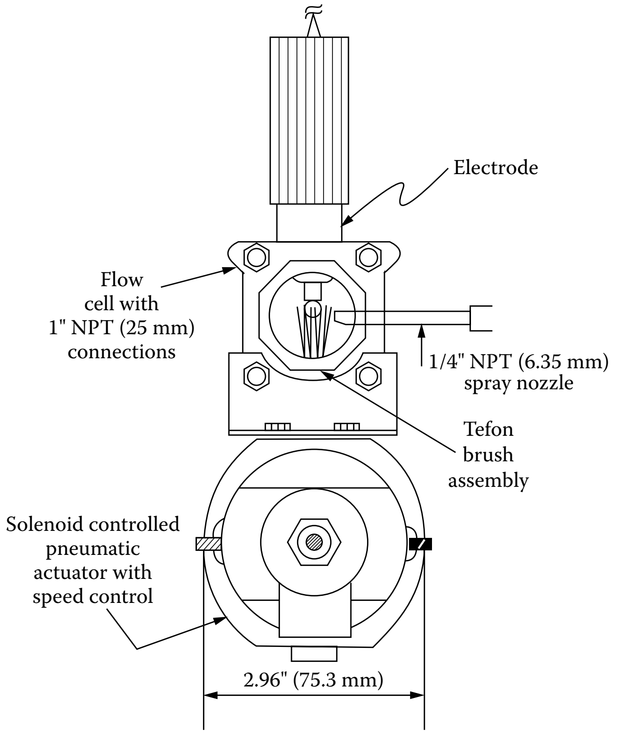

FIG. 8.9oo
Brush cleaner with optional water jet.

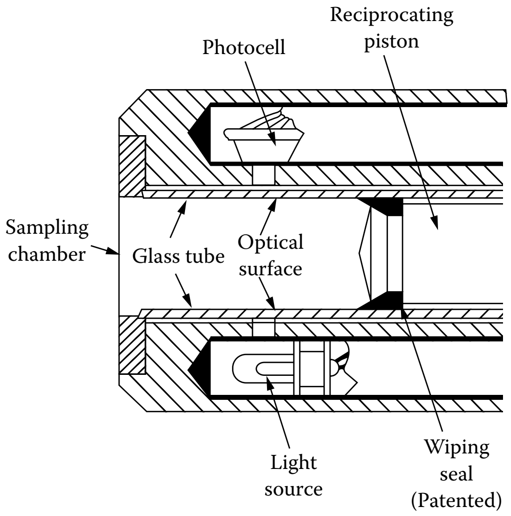

FIG. 8.9pp
Probe-type, self-cleaning suspended solids detector. (Courtesy of Monitek Technologies Inc., a Metrisa Company, http://www.monitek.com)

units can operate with a minimum span of 0.05 specific gravity unit and an error of ±1% of that span, or an absolute error of ±0.0005 specific gravity.

In a number of reactions, refractometers (Section 8.52 in Chapter 8 in Volume 1) have been found to be acceptable solutions to endpoint detection. In many installations, they are used as laboratory devices: A grab sample is brought to the bench analyzer. In other installations, they are used on-stream. When the refractive index (RI) analyzer is on-stream, human error tends to be reduced and analysis time is shortened, with a corresponding increase in productivity.

On the other hand, an on-stream installation requires more maintenance attention, because the RI measurement must be made to high precision, such as ±0.0005 RI units. This requires accurate temperature compensation, plus protection of the heat-sensitive photocells through cooling, which are time-consuming and expensive to replace when ruined by high temperature.

If the endpoint of a reaction is detectable by such measurements as a change in color or opacity, or the concentration of suspended solids, the self-cleaning probe shown in Figure 8.9pp can be considered. Here, the reciprocating piston in the inner cavity of the probe not only serves to clean the optical surfaces with its wiping seals but also guarantees the replacement of the sample in the sampling chamber by fresh material upon each stroking of the piston. The temperature considerations and limitations mentioned in connection with the RI analyzer also apply here.

If the endpoint of the reaction is detectable by infrared (IR) beam attenuation, such analyzers can also be put on-stream or can be inserted in pipelines and will detect the attenuated total reflectance of the IR beam. This type of analyzer is particularly suitable for the detection of water in hydrocarbons.

In addition to the analyzers discussed above a wide variety of computer-supported fiber-optic probes (FOPs) are also available for on-line analysis. Other analyzers, such as the gas chromatograph (GC), the high-pressure liquid chromatograph (HPLC), and the mass spectrometer (MS), are also powerful analytical tools and are available both as laboratory or on-line devices. For an in-depth discussion of all the analyzers available, refer to Chapter 8 in the *Process Measurement and Analysis* volume of this handbook.

Product Quality Control

Measuring the composition of the contents of a chemical reactor is a method that can help maintain product quality in continuous reactors and can detect endpoints in batch reactors. The analyzers are limited by sampling difficulties, by the intermittent nature of some models, and by incomplete mixing within the reactor. Because sampling and sample preparation result in dead time, sampling time should be minimized or eliminated altogether; this can be done by placing the sensor directly into the reactor, which results in tight control and fast response.

Because analyzers in general are low-reliability and high-maintenance devices, most users are reluctant to close an automatic loop around them. The main concern is that the failure of the analyzer might cause a hazardous condition by driving the reactor into an unsafe state. As shown in Figure 8.9qq, this concern can be alleviated by the use of

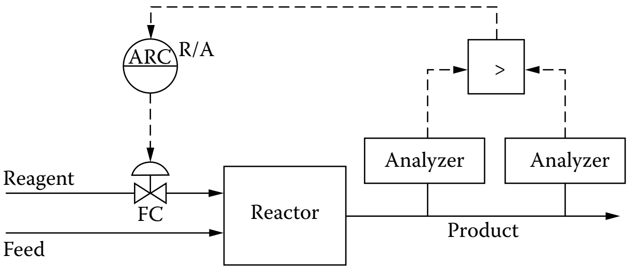

FIG. 8.9qq
If an unsafe condition can only arise in one direction (high or low concentration), a high or low signal selector can protect the reactor from the consequences of analyzer failure.[3]

redundant sensors through a high signal selector.[3] In case of a "downscale" failure of one of the analyzers, the backup unit takes over automatically. An "upscale" failure in this arrangement would shut down the reactor, providing safety at the cost of production.

If neither an accident nor an interruption of production can be tolerated, three analyzers are required, arranged in a "voting" configuration. In such an arrangement, if one of the sensors disagrees with the others, it is automatically disregarded and the "majority view" is used for closed-loop control. Maintenance and recalibration of the defective sensor are then initiated. Another solution is to use a median selector in combination with the three analyzers.

PRESSURE CONTROL

In gas phase reactions, in oxidation and hydrogenation reactions, or in high-pressure polymerization, the reaction rate is also a function of pressure. If, in a batch reaction, the process gas is completely absorbed, the controls in Figure 8.9rr would apply. Here, the concentration of process gas in the reactants is related to the partial pressure of the process gas in the vapor space. Therefore, pressure control results in the control of reaction rate. This loop is fast and easily controlled.

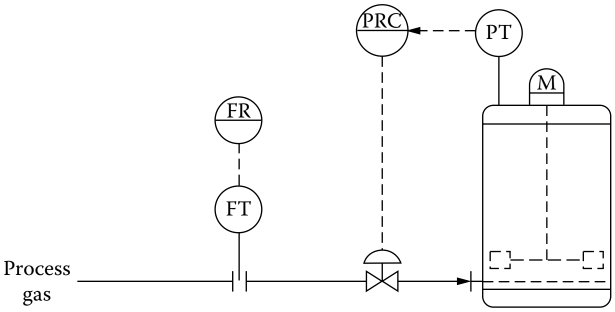

FIG. 8.9rr
Reactor pressure controlled by gas makeup.

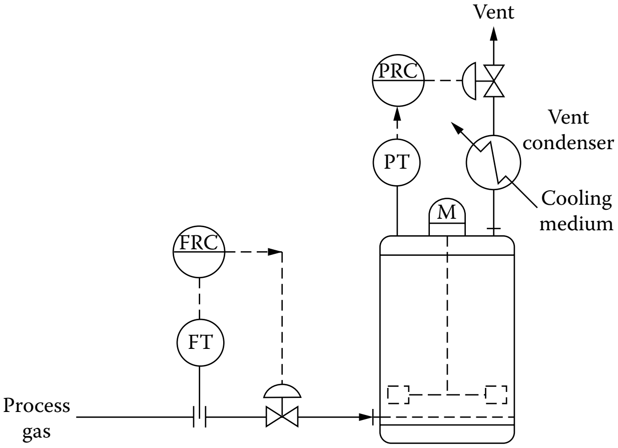

FIG. 8.9ss
Reactor pressure controlled by vent throttling.

Certain reactions not only absorb the process gas feed but also generate by-product gases. Such a process might involve the formation of carbon dioxide in an oxidation reaction. Figure 8.9ss illustrates the corresponding pressure control system. Here, the process gas feed to the reactor is on flow control and reactor pressure is maintained by throttling a gas vent line. This particular illustration also shows a condenser, which is used to minimize the loss of products through the vent.

In the case of continuous reactors, a system such as shown in Figure 8.9tt is often employed. Here the reactor is liquid full, and both the reactor liquid and any unreacted or resultant by-product gases are relieved through the same

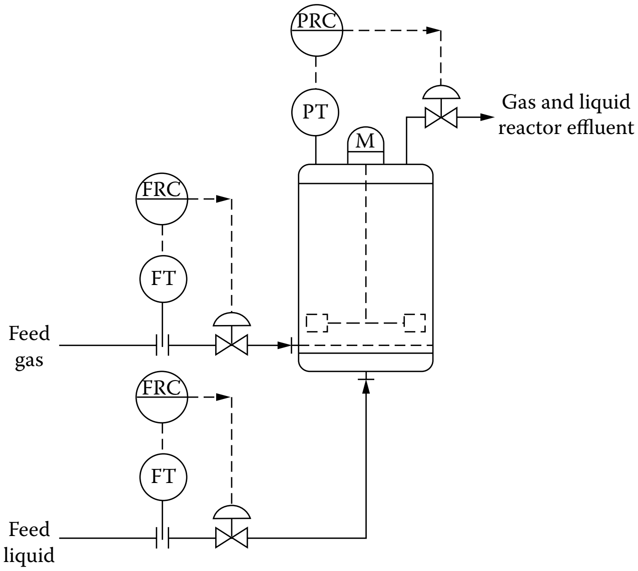

FIG. 8.9tt
Arrangements such as this can be used to control the pressure in continuous reactors.

outlet line. Reactor pressure is sensed, and the overflow from the reactor is throttled to maintain the desired operating pressure. Process gas feed and process liquid feed streams are on flow control.

All these illustrations are simplified. For instance, it may be desirable to place one of the flow controllers on ratio in order to maintain a constant relationship between feed streams. If the reaction is hazardous, and there is the possibility of an explosion in the reactor (for example, oxidation of hydrocarbons), it may be desirable to add safety devices, such as a high-pressure switch, to stop the feed to the reactor automatically.

If one of the reactants differs in phase from both the other reactants and the product, inventory control can be applied (Figure 8.9ii). In the case of gaseous products, the reactor level is controlled by modulating the liquid reactant; with liquid products, the gaseous reactant is modulated to keep reactor pressure constant. A purge is needed in both cases to rid the reactors of inerts either in the liquid or in the gas phase.

Vacuum Control

Some reactions must be conducted under vacuum. The vacuum source is frequently a steam jet-type ejector. Such units are essentially venturi nozzles with very little turndown. This constant-capacity vacuum source is frequently matched to the variable capacity reactor by wasting the excess capacity of the ejector. This is done by creating an artificial load through the admission of ambient air.

When the vapor generation rate in the reactor is low, the steam jet is still operating at full capacity, sucking in and ejecting ambient air. The corresponding waste of steam can be substantially reduced if the system shown in Figure 8.9uu is applied. Here, a low-load condition is detected by the fact that the air valve is more than 50% open, and this automatically transfers the system to the "small" jet. A later increase in load is detected as the air valve closes (at around 5%), at which point the system is switched back to the high-capacity jet.

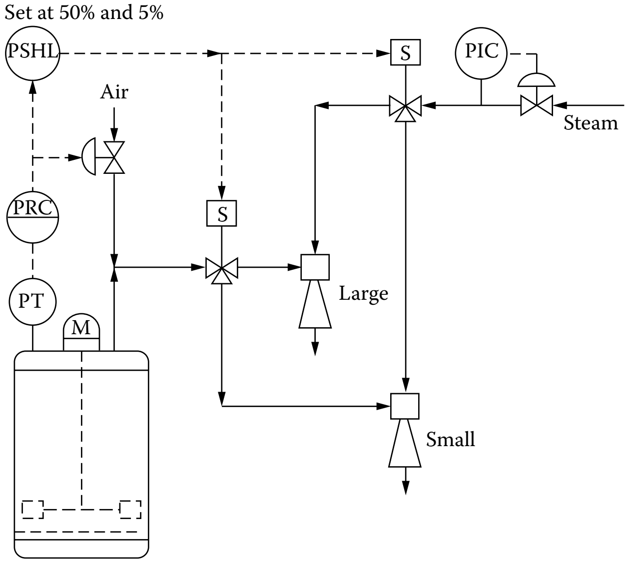

FIG. 8.9uu
Cost-effective operation of vacuum pressure controls can substantially reduce the waste of steam.

Vacuum Stripping

When stripping is done by direct steam injection, the controls shown in Figure 8.9ff are not applicable. The controls of a vacuum stripper serve to remove the solvent and the unreacted monomers from the batch in minimum time but without causing foaming.

The steam addition to the stripper (FIC in Figure 8.9vv) is usually programmed as a function of time (FY). As the batch gets more concentrated with polymer products and leaner in monomers or solvent, the more likely it is to foam, and therefore the rate of addition is reduced. This is usually controlled by hardware or a software program (FY) that relates steam flow to time. This relationship is adjustable, and if foaming is experienced during a stripping cycle (LSH in Figure 8.9vv), the steam rate curve programmed in FY can be lowered to avoid the repetition of foaming in the next batch.

The temperature of the batch is a function of (1) the balance between the amount of heat introduced by the steam and (2) the amount of cooling caused by the vaporization of the monomers. The vacuum level in the stripper is therefore controlled by temperature. This guarantees that the vacuum is low enough so that all the solvents and monomers are removed, but that it does not drop too low, to the point where the stripping steam would condense and would not be removed by the vacuum but would cause dilution of the batch.

REACTOR SAFETY

For a more detailed discussion of plant and control system safety, the reader is referred to Sections 4.11 and 5.8 of this volume. Here, only some of the "reactor-specific" safety concerns will be considered.

Safety problems can arise in chemical reactors as a result of many causes, including equipment failure, human error, loss of utilities, or instrument failures. Depending on the nature of the problem, the proper response can be to "hold" the reaction sequence until the problem has been cleared or to initiate an orderly emergency shutdown sequence. Such actions can be taken manually or automatically.

After a "hold" or "emergency" condition has been cleared, an orderly sequence of transitional logic is required to return the reactor to normal operation. It makes no difference whether the emergency was caused by a pump or valve failure or whether the reactor was put on hold to allow for

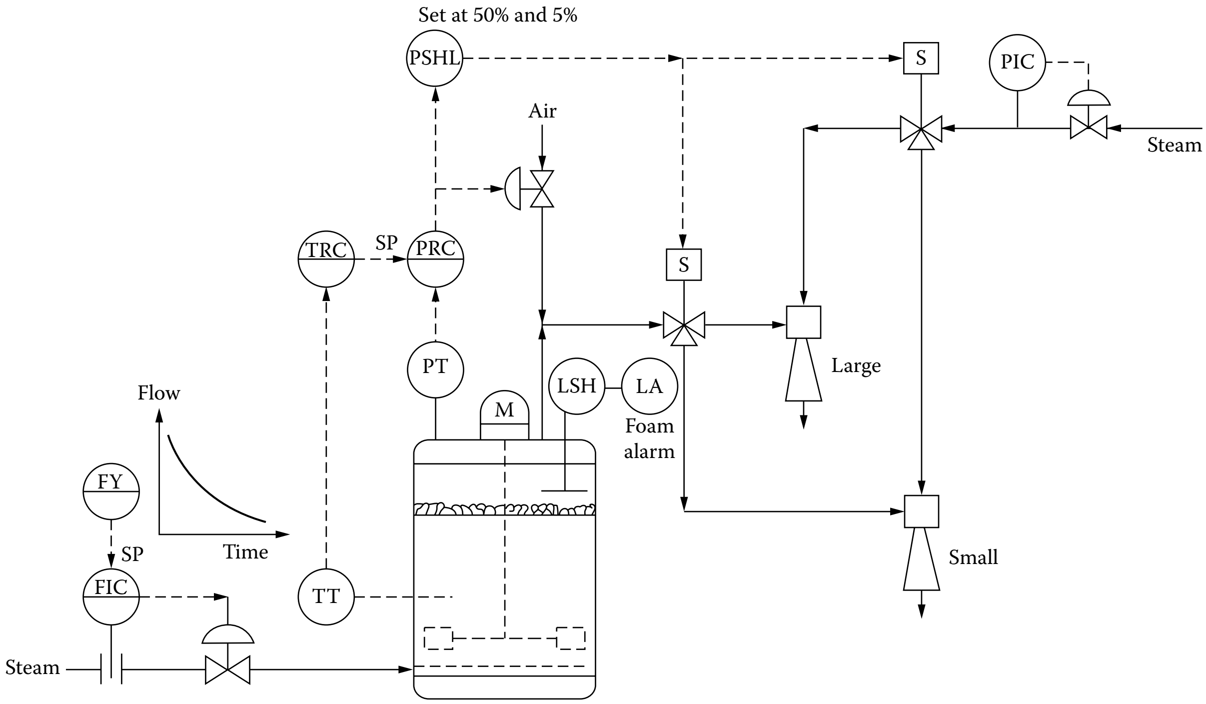

FIG. 8.9vv
The controls of a vacuum stripper serve to remove the solvent and the unreacted monomers from the batch in minimum time but without causing foaming.

manual sampling and laboratory analysis of the product: A return sequence is still required. The reentry logic determines the process state when the interruption occurred and then decides whether to return to that process state or the previous one in order to reestablish the conditions that existed at the time of the interruption.

A reactor control system should provide the following features:[9]

- The ability to maximize production
- The ability to minimize shutdowns
- The ability to maximize on-line availability of the reactor
- The ability to minimize the variations in utility and raw material demand
- The ability to provide smooth operation in terms of constant conversion, yield, and product distribution
- Easy start-up and shutdown

However, the overriding, primary design objective is that the reactor must be safe for both the operating personnel and the environment.

Safety is guaranteed by monitoring both the potential causes of emergencies and their consequences. If the cause is detected and responded to in time, the symptoms of an emergency will never develop. It is for this reason that the monitoring of potential causes of safety hazards is preferred. Some of the potential causes of emergencies and the methods used to sense them are listed in Table 8.9ww.

Each of the above failures can actuate an annunciator point to warn the operator and can also initiate a hold or shutdown sequence, if the condition cannot be corrected automatically. Automatic correction will require different responses in each case.

TABLE 8.9ww
Methods of Detection and Potential Causes of Reactor Emergencies

Causes	*Methods of Detection*
Electric power failure	Volt or watt meters
Instrument air failure	Pressure switch
Coolant failure	Pressure or flow switches
Reactant flow failure	Pressure or flow switches
Catalyst flow failure	Pressure or flow switches
Loss of vacuum	Vacuum switch
Agitator failure	Torque or RPM detector
Pump failure	Pressure or flow switch
Valve failure or mispositioning	Position-sensing limit switches
Measuring device failures	Validity checks

Unsafe Reactor Conditions and the Sensors That Can Detect Them

Symptom	*Detectors*
High reactor temperature	High temperature switch
High jacket temperature	High temperature switch
Low jacket temperature	Low temperature switch
High reaction rate	High heat release detector
Reaction failure	Low heat release detector
High rate of temperature rise	Rate of rise detector
High pressure	High-pressure switch and relief valve
Abnormal level	Level and weight switches
Abnormal composition	On-stream analyzers

For example, in case of electric power failure, a diesel generator or steam turbine might be started. If instrument air failure is detected, an alternate compressor might be started, or an alternate gas, such as dry nitrogen, might be used. In addition, the safe failure positions for all control valves must be predetermined, as in Figure 8.9m. In case of loss of coolant, an alternate source of coolant might be used, or the type of automatic constraint control that was shown in Figure 8.9dd might be applied.

It is also desirable to provide intelligent human–machine interfaces that will protect against unsafe operator actions. The simplest example of such limits is to prevent the operator from moving set points outside safe limits.

If reactant or catalyst flow fails, automatic ratio loops (Figure 8.9dd) can cut back the flow rates or related streams; alternatively, if there are alternate storage tanks from which the reactant can be drawn, these tanks might be accessed. A loss of vacuum can also be corrected by switching to an alternate vacuum source if such redundancy is economically justifiable.

Critical pumps and valves can be provided with spare backup units, and agitators can be furnished with multiple drives. Failed sensors and defective instruments can be automatically replaced by redundant and voting systems.

If the cause of an emergency goes undetected, eventually it will affect the operating conditions of the reactor. These symptoms might involve temperature, pressure, composition, or other conditions listed in Table 8.9xx.

Runaway Reactions

The control system will respond to the symptom of an abnormal process variable condition much as it did to the previously discussed failure causes, but here the probability of an emergency shutdown is higher. For example, if, in a potentially unstable reactor, the temperature or pressure has exceeded its high limit, it is possible to make sure that the reactor is on full cooling and that the reactant feeds are shut off, but after that little else can be done. Once such conditions have evolved, only drastic action can prevent a runaway reaction, such as depressurization or even the transferring of the reactor contents into a blow-down tank.

The consequences of high jacket temperature are less serious, and the limit shown in Figure 8.9l is usually sufficient to prevent the formation of hot spots. In some processes, the critical consideration is low jacket temperature,[9] because that can cause "frosting" or "freezing" the reactants onto the inner wall of the reactor. As the frozen layer thickens, heat transfer is blocked and the reactor must be shut down. If used on such a process, the control system in Figure 8.9l would also be provided with a low limit on the slave set point.

When the reaction rate suddenly rises or when it approaches the capacity of the cooling system, it is necessary either to increase the heat removal capacity quickly (Figures 8.9o and 8.9bb) or to cut back on the reactant flows (Figure 8.9i). It is also necessary to detect if the reaction has failed by comparing the reactant feed rate with the heat removal rate (Figure 8.9dd) or by monitoring heat release (Figure 8.9ee). In yet other processes, it is desirable to limit the rate of temperature rise (Figure 8.9bb).

Glass Lining Protection

Some of the chemical reactors are glass-lined to resist corrosion or to protect against contamination or discoloring of the product. When a reactor is glass-lined, the integrity of the lining can be damaged, because the thermal expansion characteristics of glass and metal are different. Therefore, it is necessary to provide control systems that serve to protect the lining against cracking (Figure 8.9yy) and that are able to detect if such damage has occurred (Figure 8.9zz).

The integrity of various glass-lining materials are guaranteed for different temperature differentials between the metal and the glass. The lining protection controls serve to keep the difference between the temperature of the lining (batch temperature detected by TT-1 in Figure 8.9yy) and the temperature of the metal (jacket temperature detected by TT-2) under the guaranteed limit.

Figure 8.9yy illustrates the protection loop for a situation in which the maximum differential is 100°. The goal of the controls is to keep the set point of the slave (TRC-2) within 100° of the batch temperature (TT-1). The purpose of TY-3 and TY-4 is to make sure that the slave set point does not drop too low. Therefore, TY-3 subtracts 100° from the TT-1 signal, while TY-4 selects the higher between that signal and the master (TRC-1) output. Similarly, the purpose of TY-5 and TY-6 is to prevent the slave set point from rising too high. TY-5 adds 100° to the TT-1 signal, while

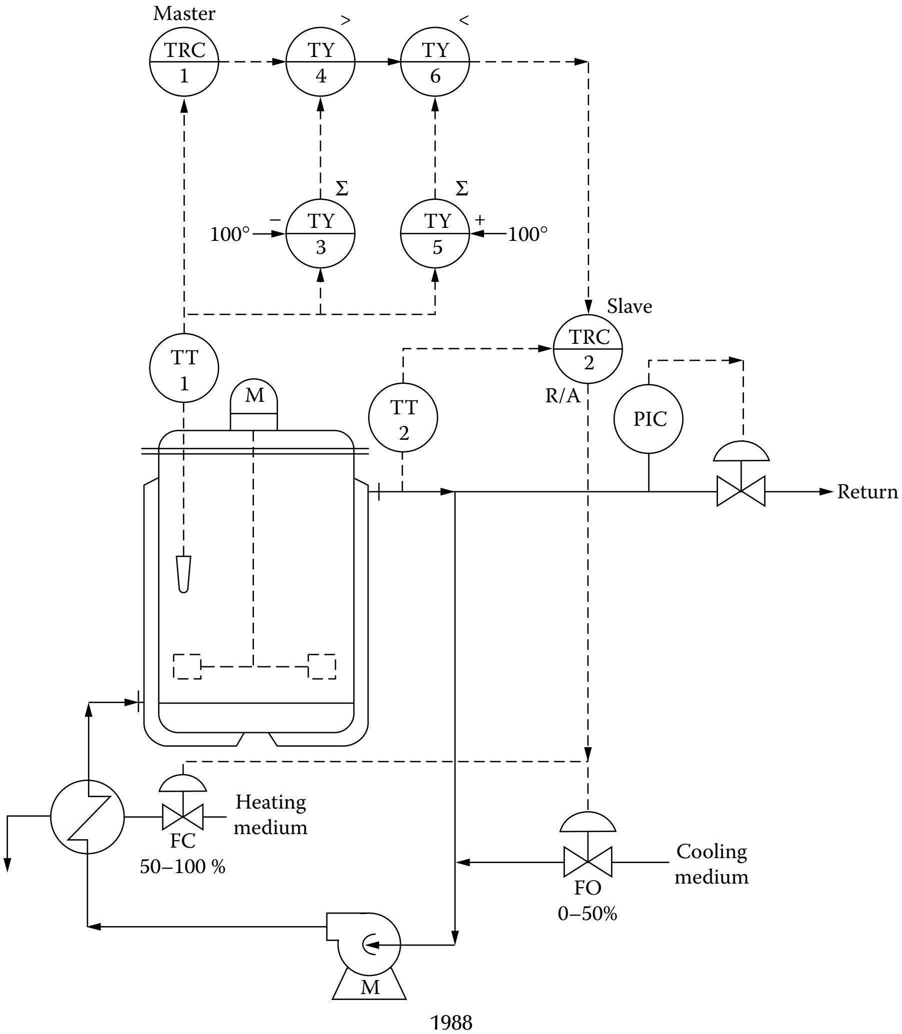

FIG. 8.9yy

The illustrated glass-lining protection strategy guarantees that the slave set point (jacket temperature) will never be more than 100° away from the batch temperature.

TY-6 selects the lower between that signal and the TRC-1 output.

Figure 8.9zz shows the control system used to monitor the integrity of the glass lining, when the batch is electrically conductive. The fault test is made by inserting a probe into the batch and checking the resistance between that and the metallic tank wall. If the glass lining is damaged, the resistance drops as the metal is exposed to the conductive batch. The fault monitor shown in Figure 8.9zz is designed for the scanning of ten glass-lined reactors.

Multiple Sensors

In connection with the topic of increasing the reliability of composition analyzers, we have already seen some options on using redundant measurements in our control systems. Figure 8.9qq described one possible option, where a pair of redundant analyzers in combination with a high signal selector can increase reliability.

Multiple temperature sensors can also be used for safety or maintenance reasons. In a fixed-bed reactor, for example, in which the location of the maximum temperature might shift as a function of flow rate or catalyst age, multiple sensors would be installed and the highest reading selected for control, as shown in Figure 8.9aaa.

On the other hand, if the reason for the use of multiple sensors is to increase the reliability of the measurement, the use of median selectors is the proper choice (Figure 8.9bbb). A median selector rejects both the highest and the lowest signals and transmits the third. This type of redundancy protects against the consequences of sensor misoperation, while

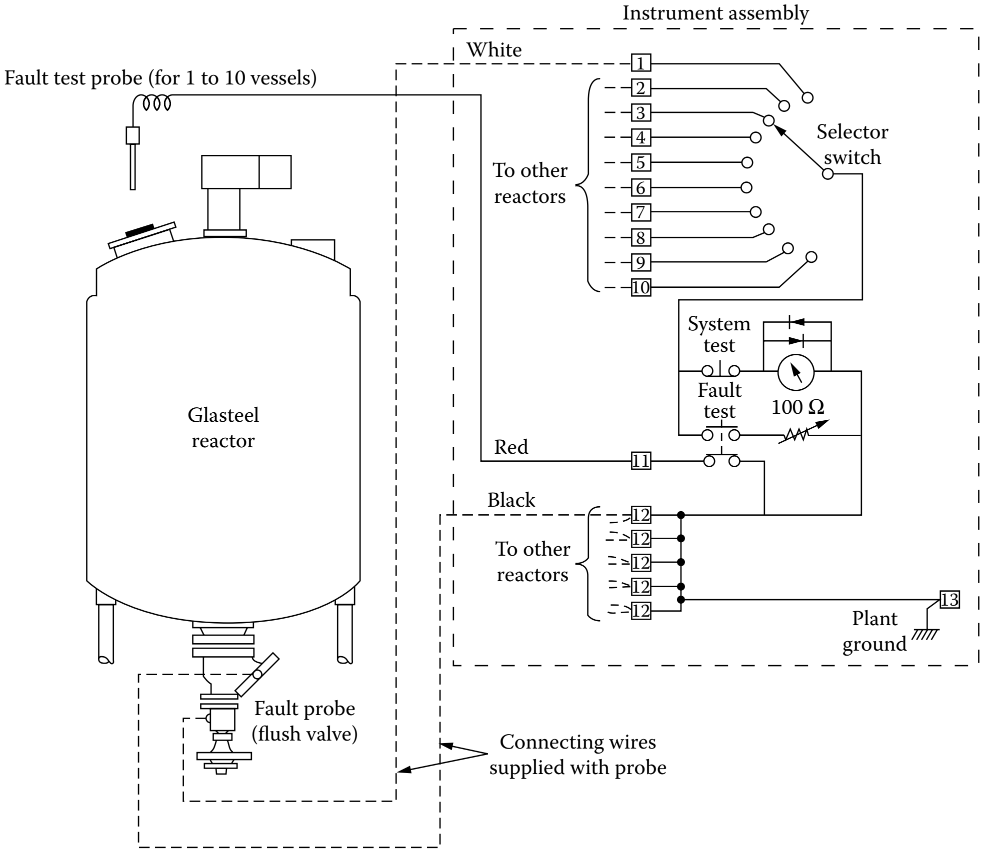

FIG. 8.9zz

The illustrated fault finder signals if the glass lining of a reactor is damaged. (Courtesy of Factory Mechanical Systems.)

also filtering out noise and transients that are not common to two of the signals.[5]

Another method of increasing sensor reliability is the use of voting systems. These also consist of at least three sensors. Reliability is gained, as the voting system disregards any measurement that disagrees with the majority view.

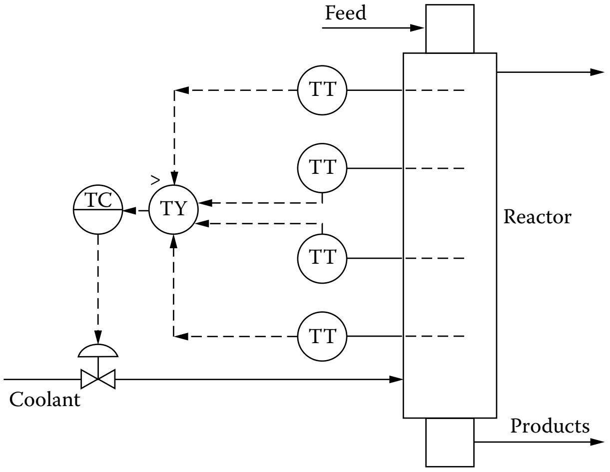

FIG. 8.9aaa

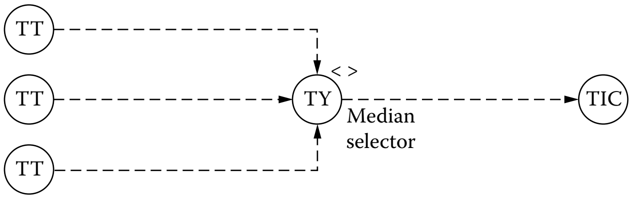
This method can be used to control the highest temperature in a fixed-bed reactor.[3]

Instrument Reliability

A risk analysis requires data on the failure rate for the components of the control system. Such data has been collected from user reports; the findings of one such survey are shown in Table 8.9ccc. When the mean time between failure (MTBF) of the individual instrument components has been



*

FIG. 8.9bbb

Median selector rejects both the highest and the lowest signals and can be the logical choice in some applications.

TABLE 8.9ccc

*Failure Rate for Control System Components**

Variable	*Instrument*	*Mean Time between Failures*
Level	Bubbler	1–2 yrs.
	d/p transmitter	1–5 yrs.
	Float and cable	0.2–2 yrs.
	Optical	0.1–5 yrs.
Flow	Flume and weir	0.5–5 yrs.
	Venturi, etc.	2 mo.–5 yr.
	Propellers	1 mo.–1 yr.
	Positive displacement	1 mo.–1 yr.
	Magnetic	0.5–10 yrs.
Density	Nuclear	1–3 yrs.
	Mechanical	1–6 mos.
Analysis	pH and ORP	1–4 mos.
	Dissolved O_2	1–9 mos.
	Turbidity	1–6 mos.
	Conductivity	1–4 mos.
	Chlorine gas	0.5–1 yr.
	Explosive gas	0.2–1 yr.
	TOC	0.1–1 mo.
Miscellaneous	Temperature	0.5–2 yrs.
	Pressure	0.1–5 yrs.
	Speed	0.6–5 yrs.
	Weight	0.6–2 yrs.
	Position	0.1–1 yr.
	Sampling	0.1–1 yr.

*Adapted from Reference 10.

estimated, the MTBF of the various control loops can be established.[9]

An example of predicting the MTBF of a system, based on the MTBF of its components, is illustrated in Table 8.9ddd. Once the MTBF of each loop has been established, the reliability of the whole reactor control system can be increased by increasing the MTBF of the loops that pose the highest risks. This usually is done through the use of self-diagnostics, preventive maintenance, backup devices, and, in critical instances, the technique of "voting," which was described in connection with Figure 8.9bbb.

While risk analysis is complex and time-consuming (see Sections 4.11 and 5.8), a plant can be designed for a particular level of safety, just as it can be designed for a particular level of production. The reliability of the result is as good as the data used in the analysis. For this reason, data collected by users, testing laboratories, or insurance companies should be used, instead of manufacturers' estimates. For instrument reliability and performance data, good sources are the International Associations of Instrument Users, SIREP and WIB.

TABLE 8.9ddd

The Mean Time between Failure (MTBF) of a Control Loop Can be Calculated by Considering the MTBF of its Components[9]

	Flow Transmitter	*Flow Totalizer*	*Solenoid Valve*	*On/Off Valve*
Failures/10^6	10	10	30	50
Operations/Process Cycle	100	100	2	2
Mean Cycles between Failure	1,000	1,000	16,000	10,000
Mean Time between Failure, Days	250	250	4,000	2,500

CONCLUSIONS

As was discussed in the previous paragraphs, the goals of good chemical reactor control and optimization include the following:

- Precise recipe charging
- Minimum heat-up time without temperature overshoot
- Maximized reaction rate within limits of coolant availability
- Accurate and fast endpoint determination

These goals can be met by various levels of automation. As the requirements for safety and optimized production are increased, higher and higher levels of automation become necessary. The trend is towards model-based anticipation and towards the integration of the individual control loops into integrated multivariable reactor controller systems.[13]

8.10 Chemical Reactors: Control and Optimization

F. G. SHINSKEY (2005)

INTRODUCTION

It should be noted that the coverage of this section and of the previous one (8.9) are similar. If the reader is interested in a detailed and complete treatment of the subject of chemical reactor control, it is recommended to also read that section. On the other hand, if you have little time and you are an experienced process control engineer who is familiar with the basics of chemical reactor control and want only to quickly refresh your memory about the most important aspects of this area of process control and optimization, you should read this section.

OBJECTIVES

The optimization of batch and continuous chemical reactors has many potential benefits, including increase in productivity and improvement in safety, product quality, and batch-to-batch uniformity. Such results are the consequences of many individual control loops and strategies. These loops will maintain material balances, hold optimum temperature and pressure, and control concentrations, while providing safe operating conditions. All elements of the overall chemical reactor control system are discussed in this chapter.

The reactor is the heart of most chemical production facilities. Other operations such as heat transfer, separation, recycle, purification, and drying all are dependent on the reactor's production and demands for services. Most reactors are "base-loaded," i.e., their feed rate is fixed, as determined by market demand and constraints. All other operations are then dependent on the reactor's production rate.

Therefore, it is essential that the reactor operation be stable. If the reactor is run efficiently, with steady product of uniform quality, all other operations may proceed smoothly and the plant should be profitable. But if temperature control is erratic, for example, product quality will suffer and all downstream plant operations will be upset.

Safety

Several objectives must be met for successful reactor operation. The first is always *safety.* Most chemical reactions in production facilities are *exothermic*, which means that they produce heat, much like the combustion of fuel. That heat must be removed as it is produced, to maintain a constant temperature. If it is not, the temperature will rise, which increases the rate of reaction, creating the possibility of a thermal runaway—in the extreme case resulting in a fire or explosion. For the protection of life, equipment, and the environment, such an outcome must be prevented. But less extreme conditions can damage product, deactivate catalyst, and foul heat-transfer surfaces—these also must be avoided.

Maximizing Yield

Operating a reactor safely is not enough. It must also operate profitably. This means maximizing yield and minimizing operating costs. *Yield* is the fractional or percentage salable product that can be made from a given feedstock.

Ideally, 100% of the ethylene fed to an oxidation reactor should be converted to ethylene oxide, but some is invariably converted to carbon dioxide and other by-products of the reaction. If the reaction that produced some of the by-products is reversible, then they may be recycled to reduce their further production and do not represent a loss in yield. But some, like carbon dioxide, will have to be purged from the system and therefore lost.

To maximize yield, it may be necessary to limit *conversion*, which represents the fraction of the feed that is converted to product on one pass through the reactor. The unconverted feed must be separated from the product and recycled. Operating costs increase with recycling, as it increases the loading on pumps, compressors, and separation equipment. So, there must be a balance struck between yield and conversion, reflecting the cost of lost yield and the operation of the equipment carrying the recycle, along with their constraints.

The Catalyst

Most reactions are catalyzed, as well. A *catalyst* is a substance that does not change during the reaction, but increases the reaction rate, allowing a higher yield, or higher conversion, or production to take place under less severe conditions of pressure and temperature. Reactions take place on the catalyst surface, so that a large, active surface is essential. Most catalysts are porous, and pore size can affect their selectivity for particular reactions. Many are inert ceramics coated with active metals like platinum.

The catalyst may be fixed, such as shaped material packed or spaced in a bed. Some catalysts are very fine and fluidized by the upward flow of the reaction mass, as in a fluid cat-cracker, which breaks heavy oil into smaller gasoline molecules. Some catalysts travel with the reaction mass as a slurry, or may even be dissolved. Polymerization reactions usually require an initiator, which is used to create an active site on a molecule, attracting other molecules into a chain reaction.

Catalysts are costly, many having active surfaces of noble metals. While they are not changed by the reaction, they can be degraded, and even poisoned. Degradation consists of clogging the pores or coating the active surface with coke or tar, for example. The fluid cat-cracker contains an auxiliary unit for burning the coke continuously off the catalyst, thereby regenerating its surface and recirculating it to the reactor.

A fixed catalyst bed must be regenerated off-line, which takes time and interferes with production. Some catalysts are poisoned by heavy metals and sulfur, which may require their eventual replacement. Close control of operating conditions can minimize the cost of catalyst loss and regeneration.

CHEMICAL REACTION KINETICS

The conduct of chemical reactions follows an exact science called *chemical kinetics*, which describes the relationships that produce reactions. The first relationship is one of *equilibrium*. Most chemical reactions are reversible and terminate in a condition of equilibrium, where forward and reverse rates are equal. As an example, consider the partial oxidation of ethylene to ethylene oxide:

$$C_2H_4 + \tfrac{1}{2}O_2 \Leftrightarrow C_2H_4O + \text{heat}$$

This equilibrium is defined by an equilibrium constant K, defined as

$$K = \frac{[C_2H_4O]}{[C_2H_4][O_2]^{1/2}} \qquad \textbf{8.10(1)}$$

where the bracketed terms are molar concentrations of the components. To shift the equilibrium to the right, i.e., to make more product, the concentration of either ethylene or oxygen may be increased, or the concentration of ethylene oxide reduced. The reactant concentrations can be increased by increasing the operating pressure, as they are gases, and the product concentration can be reduced by condensing it to a liquid.

This forward reaction is of 1.5 order, in that it depends on the first power of ethylene concentration and 0.5 power of oxygen concentration; the reverse reaction is first-order. Many reactions are second-order, but most ultimately can be treated as first-order. The reason for this is that favorable conditions for most reactions have one reactant in dominant concentration and the other in a much smaller concentration, the smaller thereby controlling the reaction. At equilibrium, forward and reverse reaction rates are equal, the equilibrium constant being their ratio.

Batch Reactions

In a first-order reaction, the rate of conversion of reactant of concentration x varies linearly with that concentration and rate coefficient k, expressed in units of inverse time:

$$-\frac{dx}{dt} = kx \qquad \textbf{8.10(2)}$$

In a batch reactor, that concentration will change with time t, as the rate equation is integrated between initial and final conditions:

$$\int_{x0}^{x} \frac{dx}{x} = \int_{0}^{t} -k\,dt$$

where x_0 is the initial concentration and x is its value at time t.

The solution of the above is

$$x = x_0 e^{-kt}$$

where e is 2.718, the base of natural logarithms. The fractional conversion of feed to product in a batch reactor at time t is

$$y = \frac{x_0 - x}{x_0} = 1 - e^{-kt} \qquad \textbf{8.10(3)}$$

Continuous Plug-Flow Reactors

Continuous reactors operate with a uniform flow of feed in and product out. The average time spent by a molecule in a continuous reactor is called its *residence time* and is simply reactor volume V divided by total volumetric flow F, i.e., V/F. In an ideal plug-flow reactor, ingredients flow from inlet to outlet without any longitudinal mixing. In this way, the ideal plug-flow reactor resembles a batch reactor, in that the fractional distance a molecule travels from inlet to outlet is also its fractional residence time in the reactor. As a result, fractional conversion at the exit of a plug-flow reactor is

$$y = 1 - e^{-kV/F} \qquad \textbf{8.10(4)}$$

At $kV/F = 1$, fractional conversion is 0.632. Actual plug-flow reactors may have some longitudinal mixing, but the intent of the design is to avoid it, as *back-mixing* reduces conversion.

Continuous Back-Mixed Reactors

If a vessel is thoroughly mixed, reactant concentration is the same everywhere, including in the product stream withdrawn. The rate of reaction is therefore determined by the outlet concentration, which is lower than that at any point within the plug-flow reactor. Production rate in a perfectly back-mixed reactor is its volume times the rate of loss of reactant concentration, which is also its feed rate multiplied by the loss in reactant concentration from inlet to outlet.

$$-\frac{V\,dx}{dt} = kVx = F(x_0 - x)$$

Solving for exit concentration gives

$$x = \frac{x_0}{1 + kV/F}$$

And fractional conversion is

$$y = 1 - \frac{1}{1 + kV/F} \qquad \textbf{8.10(5)}$$

For the same residence time and rate coefficient, conversion will always be less in the back-mixed than the plug-flow reactor, as shown in Figure 8.10a. At *kV/F* = 1, fractional conversion is 0.5. However, a back-mixed reactor is lag-dominant and is, therefore, easier to control than the plug-flow reactor, which is dominated by dead time.

Effect of Temperature

Temperature has a profound effect on reaction rate, through an exponential relationship to the rate coefficient:

$$k = ae^{-E/RT_r} \qquad \textbf{8.10(6)}$$

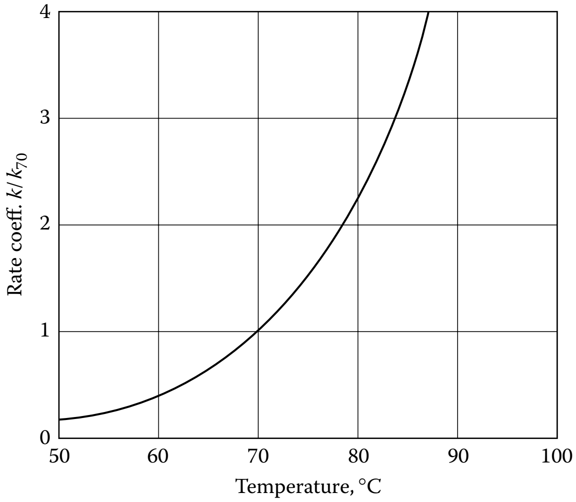

FIG. 8.10b
Reaction increases exponentially with temperature.

where *a* and *E* are constants particular to the reaction, *R* is the universal gas constant, and T_r is the absolute temperature of the reaction mass. The nature of the relationship is that reaction rates tend to double with each increase in temperature of about 10°C (18°F). The rate coefficient for a typical reaction normalized to what it would be at 70°C is plotted vs. temperature in Figure 8.10b. This effect is so dominant that precise control of temperature is the most important aspect of operating reactors of any type.

For all reactors, then, conversion is a function of both temperature and time. Because conversion in plug-flow and back-mixed reactors differs as a function of residence time, they can also be expected to differ as a function of temperature.

This is shown in Figure 8.10c, where both reactors are operated at *kV/F* = 1 at 70°C. Other values of *V/F* produce

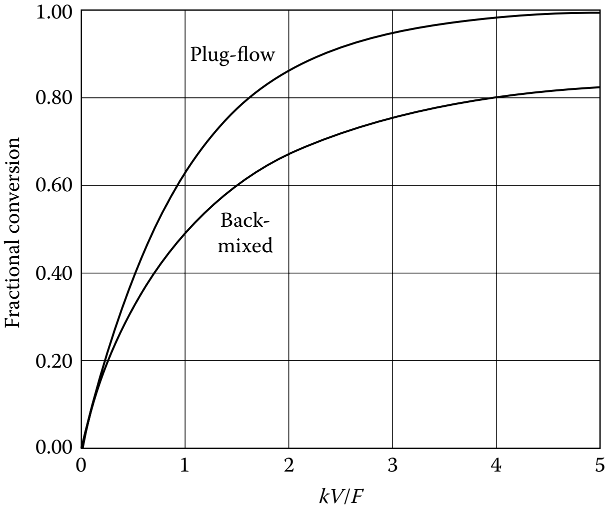

FIG. 8.10a
Plug-flow reactors are used for their higher conversion.

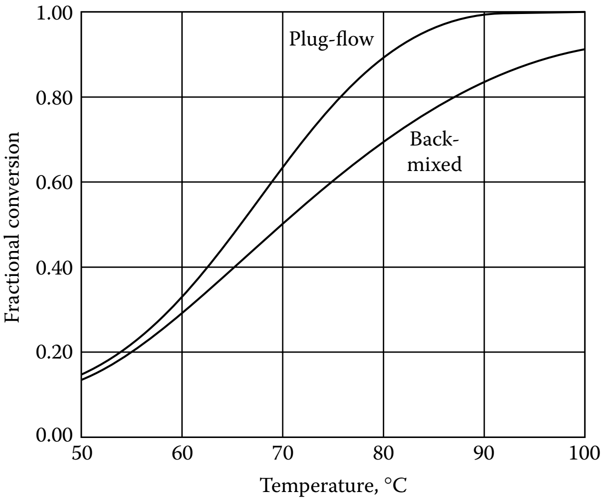

FIG. 8.10c
Conversion in a plug-flow reactor is more temperature-sensitive.

parallel curves. Because Figure 8.10b shows a doubling of k for about 9°C temperature rise, parallel curves for doubling or halving of V/F will be spaced 9°C apart. For example, the plug-flow reactor will produce 63.2% conversion at 61°C and half the feed rate, and also at 79°C with twice the feed rate.

EXOTHERMIC REACTOR STABILITY

Endothermic reactions are inherently self-regulating, because heat must be continuously applied for them to proceed—remove the heat and they die. Ordinary heat transfer is also self-regulating. Increasing the temperature of a hot fluid entering a heat exchanger will increase the rate of heat transferred to the coolant without any change in its flow. Exothermic reactors, by contrast, can be steady-state unstable—depending on their heat-transfer capability—and even uncontrollable. Moreover, some have been observed to change between stable and uncontrollable states.

Steady-State Stability

Consider an exothermic reactor operating at steady-state—constant temperature—in the open loop. A small upset causes its temperature to rise, which increases the rate of reaction, thereby releasing more heat. The increase in heat release then raises the temperature further—positive feedback. At the same time, however, the rising temperature increases the rate of heat transfer to the coolant—negative feedback. Which has the stronger influence will determine the steady-state stability of the reactor. Figure 8.10d compares the heat-release and heat-transfer capabilities of a stable exothermic reactor.

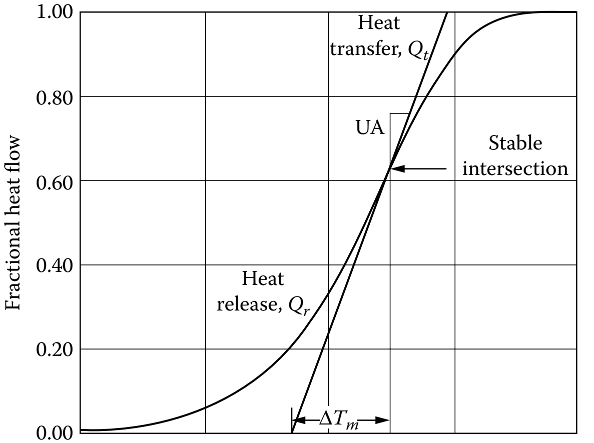

FIG. 8.10d
Steady-state stability is provided by sufficient heat-transfer surface.

In Figure 8.10d, the conversion vs. temperature plot of the plug-flow reactor is equated to heat release by multiplying by the reactant feed rate F and the heat of reaction H_r:

$$Q_r = yx_0FH_r \quad \textbf{8.10(7)}$$

Here, it is normalized to 100% conversion at nominal feed conditions. On the same plot is a line representing heat transfer from the reactor to the coolant:

$$Q_t = UA\Delta T_m \quad \textbf{8.10(8)}$$

where U and A are the heat-transfer coefficient and area respectively, and ΔT_m is the mean temperature difference between the reactor and the coolant. (If the reactor were a well-mixed vessel and the coolant rapidly circulated past its heat-transfer surface, ΔT_m could be a simple difference between reactor and coolant temperatures. In practice, this is not likely to be the case, but a mean temperature difference formula can be fitted to whatever heat-transfer configuration exists.) Heat flow in and out of the reactor is set equal at 70°C, the control point.

If the slope of the heat-transfer line exceeds that of the heat-release curve at the operating point, as is the case in Figure 8.10d, the reactor is stable. A rise in temperature transfers more heat than is released, resulting in a stabilizing of temperature. The key to achieving this stability lies therefore in designing the heat-transfer system to have sufficient area for the expected heat load. Area cannot be traded for colder coolant—they are not equivalent as a guarantor of reactor stability. Note that ΔT_m for the stable reactor in this example is only 16°C.

The slope of the heat-release curve can be determined by differentiating the conversion curve. For the plug-flow reactor, the slope is

$$\frac{dy}{dT} = -\frac{E}{RT^2}(1-y)\ln(1-y) \quad \textbf{8.10(9)}$$

And for the back-mixed reactor, it is

$$\frac{dy}{dT} = \frac{E}{RT^2}(1-y)y \quad \textbf{8.10(10)}$$

The maximum slopes of both curves occur where $kV/F = 1$. At that point, the slope of the plug-flow curve is exactly twice that of the back-mixed curve. The plug-flow reactor is therefore twice as demanding of the heat-transfer surface to remain stable.

For pilot-scale reactors, jacket cooling may be sufficient for stability, especially with stirred tanks. However, there is a scale-up problem: Production increases with volume, which increases with the cube of diameter, whereas jacket area increases only with its square. At some scale, jacket cooling is insufficient, and additional heat-transfer surface is required. This can be provided by internal coils, by a reflux condenser, or by an external exchanger through which reactor contents are circulated. Most full-scale plug-flow reactors have external exchangers.

Unstable but Controllable

The heat-transfer surface in Figure 8.10e has been reduced by half from that in Figure 8.10d—increasing ΔT_m to 32°C—and now the reactor is steady-state unstable. Any rise in temperature above the control point will release more heat than is transferred, augmenting the rise until the upper stable intersection of the line and the curve is reached. Conversely, any drop in temperature will cause heat release to fall more than heat transfer until the lower stable intersection is reached. In the open loop, the temperature will seek one of the two stable intersections, running away from the desired control point.

A simple model of the unstable reactor is the inverted pendulum—a stick balanced vertically in the hand, for example. Its balanced position is an unstable steady state, in that the slightest disturbance will cause it to accelerate away from that state. However, it is possible for a person, or even a trained seal, to balance a stick for a time. To be successful in doing so reveals the control effort required. As soon as the stick begins to deviate from a true vertical position, the hand must move *farther* in the same direction to restore balance. In other words, the gain of the (human) controller must exceed unity to succeed in controlling a steady-state-unstable process.

That is, the process is controllable if the gain of the controller can be set high enough. Reference 1 identifies the limit of controllability of the steady-state-unstable process as when the dead time in the loop approaches its time constant. In other words, a lag-dominant unstable reactor is controllable, whereas a dead time-dominant one is not.

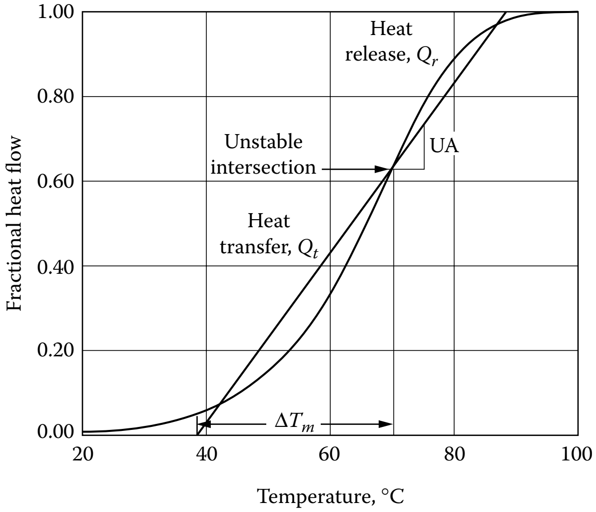

FIG. 8.10e
Insufficient heat-transfer surface makes a reactor unstable.

A stirred tank is more likely to be stable than a plug-flow reactor, because the maximum slope of its heat-release curve is only half as great. But even if unstable, it is controllable because it is dominated by the large lag of its well-mixed contents. To be sure, its control loops need to be properly structured, a subject to be covered. But the proportional gain of a typical temperature controller on a back-mixed reactor is in the order of 3:5, which is entirely capable of controlling it even if it is unstable.

Uncontrollable Reactors

Plug-flow reactors are dominated by dead time and, if unstable, are therefore also uncontrollable. During start-up, as temperature is raised, they may behave well because reaction rate is low at the lower temperatures. But as the desired operating temperature is approached, there is a tendency for the reactor to speed right past it. Even a carefully structured control system will not be able to stop it in time. As the temperature rises further, the slope of the heat-release curve moderates, and the manipulated cooling begins to bring the temperature down. But it then goes past the control point in a downward direction, until the control system arrests the fall.

The result is a limit-cycling of the temperature—at a given set of conditions, the cycle will be of uniform amplitude and period and nonsinusoidal, possibly sawtooth in shape. Its amplitude will depend on the difference between the slopes of the heat-release curve and the heat-transfer line at the control point.

One of the characteristics of a limit cycle is its resistance to change. Variations in the tuning of the temperature controller(s) tend to have little effect—its period and amplitude may change slightly, but the cycle persists. The only way to stop the temperature from cycling is to lower the production rate, which reduces the slope of the heat-release curve, or to improve the heat-transfer condition. A reactor that was once controllable and is no longer, may be suffering from a fouled heat-transfer surface—cleaning has been observed to restore stability.[2]

TEMPERATURE CONTROL

Unless reactor temperature can be controlled precisely, product quality will vary. This is especially true of polymerization reactions, where molecular weight, density, and viscosity are all functions of reactor temperature. Variations as small as 1°C may produce unsatisfactory product.

Measuring Temperature

Resistance-bulb sensors are universally used to measure reactor temperature, as they are more accurate than thermocouples. In a well-stirred tank, the measurement may be made anywhere within the mixed zone, velocity being necessary for dynamic response and to avoid fouling. The sensor must be protected against corrosion and erosion, requiring installation in a well in most cases—then close thermal contact of the sensor with the well is necessary to maximize dynamic response.

The temperature will vary along the length of a plug-flow reactor, due to the variable rate of reaction within. In an adiabatic reactor (no heat removal), temperature will rise throughout. For one that is cooled by a jacket, a peak temperature will usually be reached along the first third of travel from the inlet.

In a packed bed, that hot spot may move downstream gradually as catalyst decays. There may also be a radial gradient. Therefore, most plug-flow reactors have multiple sensors, one of which may be manually selected as the control point. Selection may even be automatic, as the highest of several measurements. An average of two or more temperatures may also be used for control, or the median of three or five measurements, as being more representative of the reaction mass. However, if the combined sensors are spaced too far apart, a difference in their dynamic responses may require the controller settings to be compromised.

Reactor pressure, or rather its change, has been used to predict reactor temperature change. The rationale is that pressure changes directly with temperature, but faster, because it lacks the lags in the bulb and thermowell. However, the steady-state value of pressure is misleading, because it is too easily influenced by variations in composition, particularly the presence of noncondensible gas.

Therefore, the predicted temperature is best calculated as the measured temperature plus a gain factor times the rate of change of pressure. This method was tried by the author on an uncontrollable reactor, but unsuccessfully. The predicted temperature led the measured temperature when falling, but not when rising, and so was ineffective in stabilizing the loop. It was only a half-predictor.

Manipulating Coolant Flow

It is possible to control the temperature of a continuous reactor by manipulating feed rate at a constant coolant flow—but it is also very dangerous! If the reaction mass is cold, reaction rate and heat release will be low, and adding more feed will not raise the temperature. Under these conditions, it is possible to overfeed a reactor, so that when reaction temperature is reached, there will not be enough cooling available to remove the heat released, resulting in a thermal runaway. But even beginning at a steady state, manipulating feed rate is poor practice.

A change in feed rate must first change reactant concentration through the concentration lag, and then change temperature through the thermal lag. These are two large lags in series. The concentration time constant[3] is

$$\tau_x = \frac{1}{k + F/V} \qquad \textbf{8.10(11)}$$

and the thermal time constant is

$$\tau_T = \frac{MC}{UA} \qquad \textbf{8.10(12)}$$

where M and C are the reaction mass and specific heat, respectively. There is also the problem of inverse response: Increasing the flow of cold feed will cause the temperature of the reaction mass to fall before the effect of the increased concentration of the reactant causes it to rise. This reversal could last for several minutes, resulting in very unfavorable dynamic response. This scheme is not recommended to control an exothermic reactor.

Manipulating the flow of coolant is necessary for successful temperature control. If it can be injected directly into the reaction mass, then the lags associated with heat transfer are avoided. If not, then a boiling coolant is the best heat sink, as it is isothermal, but such a fluid may not be available or safe or economical in the temperature range desired. Boiling part of the reaction mass and condensing it in a reflux condenser is another self-regulating means of heat removal. However, the most common coolant used for exothermic reactors is water flowing past a heat-transfer surface.

Tempering Loops

Manipulating coolant flow in a single pass by the heat-transfer surface is not good practice. Consider, for example, the jacketed batch reactor shown in the previous section in Figure 8.9f, whose cooling load varies with time. When little coolant is required, its low flow through the jacket creates a long dead time—jacket volume divided by the low flow. At higher demands, this dead time decreases. The temperature controller cannot be optimally tuned for all of the possible flowing

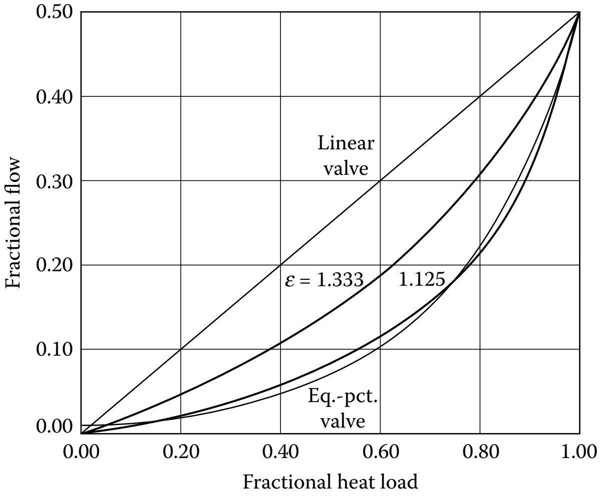

FIG. 8.10f
The nonlinear relationship of coolant flow to heat load is compensated by an equal-percentage valve.

conditions, and must favor the worst case of low flow, giving less-effective control during the major portion of the reaction.

This dead time varying with flow also creates a limit-cycling condition in the temperature loop. A rising temperature causes the controller to increase coolant flow, which decreases jacket dead time and thereby drops temperature quickly. But a falling temperature causes the controller to decrease coolant flow, which increases dead time and delays temperature response.

A temperature cycle is created that then has sharp peaks and flat valleys, and tuning may not be able to remove it. As the cooling load increases, higher flow rates tend to decrease the period and amplitude of the cycle, and it may even disappear at the highest rates.

This behavior can be avoided entirely by the use of a circulating pump on the coolant, as shown in the previous section in Figure 8.9g. Adding coolant lowers the temperature of the jacket contents without affecting internal velocities. The coolant enters the jacket at constant flow and variable temperature, instead of constant temperature and variable flow.

Valve Selection

The rate of heat transfer is not linear with coolant flow. Consider, for example, a batch reactor controlled at 70°C by cooling water supplied at 20°C. If there is no cooling load, then the coolant in the circulating loop will be at the same temperature as the reactor, with no fresh coolant added. Opening the coolant valve will add water at the supply temperature of 20°C while displacing water at 70°C—each increment of water carries away heat proportional to that 50°C of temperature rise. However, at full heat load, the coolant exit temperature will be much lower, possibly as low as 30°C. Now the same change in water added removes heat proportional to a temperature rise of only 10°C.

The gain in converting coolant flow to heat transfer varies by 5:1 between zero and full load.

When a logarithmic-mean temperature difference is used to relate heat transfer to coolant temperatures in a jacketed stirred tank, the ratio of fresh coolant mass flow W_C to circulating flow W is derived as a hyperbolic function of heat load:

$$\frac{W_C}{W} = \frac{1}{WC_C(T_r - T_C)/Q_t - 1/(\varepsilon - 1)} \qquad \mathbf{8.10(13)}$$

where C_C is the specific heat of the coolant, and

$$\varepsilon = e^{UA/WC_C} = \frac{T_r - T_{C1}}{T_r - T_{C2}}.$$

Temperatures T_{C1} and T_{C2} are those of the circulating coolant entering and leaving the jacket, respectively, at any given steady state; if U, A, and W are constant, ε is also constant.

This relationship is plotted for the reactor described above as the numbered curves in Figure 8.10f, for a range of coolant flow up to half the circulated flow, and two values of ε. $\varepsilon = 1.125$ corresponds to jacket inlet and outlet temperatures of 25 and 30°C, and 1.333 corresponds to jacket inlet and outlet temperatures of 30 and 40°C at full heat load. The latter case represents a value of UA/WC_C that is 23% higher. Linear and equal-percentage valve characteristics are plotted for comparison, with the rangeability of the equal-percentage valve being 50:1. The latter matches the required characteristic for $\varepsilon = 1.125$ almost perfectly. Matching the process curve by the valve means that heat flow will be linear with valve stroke, and therefore so should temperature.

However, the curve for $\varepsilon = 1.333$ shows that such a close match of valve characteristic to the heat-transfer process is not always attained. In fact, Reference 2 describes a gas-phase plug-flow reactor cooled by recirculation of gas through a counterflow cooler, where the process curve is closer to that of $\varepsilon = 1.333$. The equal-percentage valve is still the preferred choice, because its variable gain compensates the loop for the effect of changes in coolant supply temperature and reactor temperature set point.

Equation 8.10(13) shows that the relationship between coolant flow W_C and heat transfer Q_t is affected by the temperature difference $(T_r - T_C)$ as a gain factor. A lower temperature difference decreases the process gain dQ_t/dW_C and requires a higher coolant flow for the same level of heat transfer. But the gain of an equal-percentage valve increases directly with flow delivered, thereby compensating for the process-gain change.

Cascade Control

Cascade control is recommended for critical variables that are difficult to control and subject to several disturbances, and the temperature of an exothermic reactor certainly fits this case. Cascade control is possible whenever the process can be divided into separate dynamic pieces by the measurement of an appropriate secondary variable. In the case of an exothermic reactor, the two pieces are the reactor itself and its cooling system, and the secondary variable is the temperature of the coolant as it enters or exits the heat-transfer surface.

As shown in Figure 8.9l in the previous section, the secondary or slave loop is closed by a temperature controller whose set point is adjusted by the primary or master temperature controller. The primary controller sees the secondary closed loop and the reactor in series. It is imperative that the secondary loop be faster than the primary, and yet it should contain significant dynamics and disturbance variables to be effective.

The periods of the two loops should differ by a factor of 4 or more to avoid resonance. For the stirred tank, controlling the jacket outlet temperature closes the loop around the jacket, thus speeding the response of the primary loop and preventing cooling-system disturbances from upsetting the reactor. But plug-flow reactors are faster, and controlling coolant inlet temperature as the secondary variable gives the two loops better dynamic separation.[2]

Batch exothermic reactors require heating as well as cooling, both for startup purposes and to cure the product and drive off solvent at the end of the reaction. The secondary controller therefore opens cooling and heating valves in split range. The split-ranging is usually accomplished with valve positioners as shown in the previous section in Figure 8.9m, calibrated to open the heating valve from 50 to 100% of the controller output, and the cooling valve from 50 to 0% (the cooling valve fails open).

Because of the difficulty of controlling exothermic reactors and of the critical role played by valves, smart digital positioners are recommended.[2] They eliminate stiction and dead band, and maximize response speed. Each valve positioner closes a loop around its valve and therefore constitutes a second level of cascade control, as was shown in Figure 8.9m.

With the provision of heating, additional precautions are advised. A high limit should be set on coolant temperature as shown, and for glass-lined reactors, the temperature difference between the reactor and jacket should be limited to avoid excessive thermal stress. Some polymerization reactors are also fitted with interlocks that prevent heating after the initiator has been introduced into the reactor.

In some polyvinyl-chloride (PVC) processes, the reaction mass is heated to about 70°C without any initiator, and allowed to stabilize at that temperature without any reaction taking place. Then initiator is injected, and the heating valve locked out for safety. A rising temperature then signals the beginning of the reaction. The temperature controllers respond by opening the cooling valve, and after a peak deviation of 2–3°C is reached, the temperature returns toward set point, and in fact, overshoots.

At this point, the secondary controller output rises above 50%, but the heating valve is locked out, so that the secondary loop is open. The temperature slowly begins to rise again, but during the open-loop condition, the primary controller has been winding up—it has raised the set point of the secondary controller, which was unable to respond because of the interlock. As a result, the secondary set point is too high, causing the primary temperature to rise past its set point again. The scenario then repeats, settling into a limit cycle of ±1°C or thereabouts, which does not respond to tuning changes and adversely affects product quality.

The limit cycling is avoided through the use of *external reset* (ER) from the secondary temperature measurement to the integral-feedback port of the primary controller, as was shown in Figure 8.9m. As long as the secondary temperature is at its set point, the ER signal and the primary controller output are identical, allowing the primary controller to integrate normally. But when the secondary is prevented from controlling (by the locked-out valve, or any other obstacle such as a set-point limit), primary integration stops. The secondary controller must have integral action for this strategy to be successful, because any secondary-loop offset will cause a proportional primary-loop offset.

This feature successfully eliminated limit-cycling in the PVC reactors with the locked-out heating valve. It was also used on batch reactors for latex paint and found to be very robust. In trials, the primary time constant of the reactor was varied over a range of 4:1 by changing batch size and heat-transfer area, each by a factor of 2:1—yet the control system did not require any tuning adjustments. The rate of temperature change was obviously affected by these process conditions, but the dynamic response of the secondary temperature altered the rate of integration of the primary controller sufficiently to accommodate them.

The secondary controller in a cascade system must be tuned before the primary, as it is a part of the primary loop. It should be tuned for optimum *load* response—not set-point response—regardless of having to respond to its set point. The set-point changes that it sees are gradual, not stepwise, and therefore affect the loop dynamically much the same as load changes do. For the same reason, filtering should never be applied to the secondary set point, and the set point should receive full proportional action (some controllers have the option of eliminating proportional action to the set point). Otherwise, the secondary control action will effectively lag the primary output, negating the dynamic benefit of cascade control.

Batch Reactor Start-Up

The problem of integral windup is particularly troublesome during start-up of a batch reactor. The goal is to raise reactor temperature from its initial value (possibly ambient) to an elevated set point (where the reaction proceeds) as quickly as possible, but without overshoot. In this situation, a conventional PID controller will invariably overshoot set point.

Following a large set-point change, its output will saturate, and during the rise time, the integral mode will also saturate. The result is that the output remains at its high limit until the set point is crossed. If the new steady state requires no heating or cooling in absence of a reaction, the new steady-state value of the controller output should be 50%; if an exothermic reaction has begun, the new output should be even lower. As a result, there will be an unacceptable temperature overshoot, such as that shown in the top curve in Figure 8.10g.

Integral windup in the start-up of a batch process can be overcome by the circuit, which was shown in the previous section in Figure 8.9x. The output of the controller is compared with a high-limit setting, and their difference sent to a high-gain amplifier, whose function is to control the controller output at that limit by manipulating the integral feedback term.

If the controller output is below the high limit (say 100%), that output is selected by the low-signal selector (<)

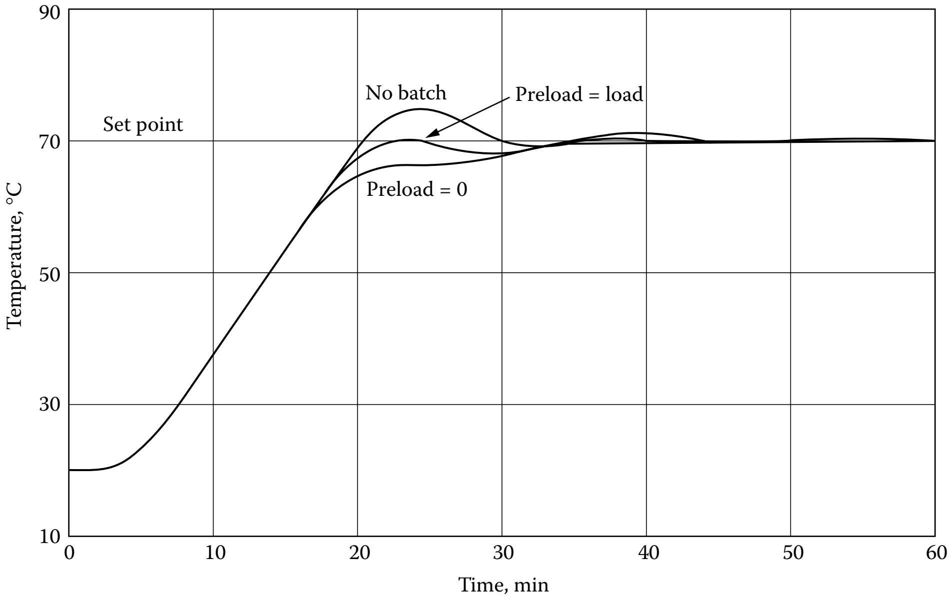

FIG. 8.10g
A preloaded batch PID controller can avoid overshoot.

as integral feedback, allowing the controller to integrate normally. If the output moves above the limit setting, the amplifier will manipulate the integral feedback term as needed to hold it at the limit. However, the feedback term can only be reduced to the point where the preload setting is selected by the high-signal selector (>); preload is adjustable to match the expected load when the new steady state is reached.

Overshoot is caused by the integral term staying at the high output limit until set point is reached. Reducing that term to match the expected load—the controller output required to hold temperature at set point in the new steady state—should eliminate the overshoot, and it does.

Without preloading the controller, however, *undershoot* will result, as shown in the lowest curve in Figure 8.9g. These curves were produced by an interacting PID controller having derivative action on the measurement (derivative was not shown in Figure 8.9x), which also assists in limiting overshoot. If derivative is not used, then the preload setting will have to be reduced somewhat below the expected load, because integration begins as soon as the controller output leaves its limit, which is well before the set point is crossed.

Another method of avoiding overshoot while minimizing start-up time has been used successfully on polystyrene reactors—the *dual-mode* control system. It consists of an on/off controller for start-up and a PID controller to take over at the new set point, as was schematically depicted in the previous section in Figure 8.9z.

The on/off controller applies full heat until the temperature has almost reached set point—it then switches to full cooling. After a set time delay, control is transferred to a preloaded PID. Switching from full heat to full cooling takes place within 2–3°C of set point, and the time delay is long enough to replace the hot water in the jacket with cold.

The sequence of operation is as follows:

1. Initial conditions have both switches in the A position. Full heat (100% output) is applied by the on/off controller until the deviation falls to the set point of Em.
2. The on/off controller output then drops to zero, producing full cooling. It also starts two time-delay relays: TD-1 and TD-2.
3. When TD-1 times out, the period of full cooling terminates, and the system output is switched by SS-1 to the preloaded PID controller, without integration.
4. When TD-2 times out, the temperature should be settled at set point. It then transfers switch SS-2 to the B position, enabling integration.

While this system is capable of minimizing start-up time, it is not foolproof. It has three settings more than the batch controller: Em, TD-1, and TD-2. Furthermore, these settings need to be changed with process conditions such as batch size and reactivity, temperature set point, and heat-transfer coefficient, the last typically decreasing with the number of batches produced, as surfaces foul.

Efforts to adapt these parameters to changing conditions, or to program them with each recipe, have met with limited success. The preloaded batch PID controller with external reset feedback from secondary temperature is much simpler, more universally applicable, and more robust under changing conditions.

MATERIAL BALANCE CONTROL

Most chemical reactions require the precise matching of two reactants to produce a product. One of the challenges of process design is to ensure that all of each reactant is converted to product, regardless of the fractional conversion in the reactor.

A simple example is the neutralization of acid and base—their individual concentrations in solution must be typically matched within ±0.01% for the solution to fall within the pH range of 6–8. A pH sensor is sensitive enough to detect such a minute imbalance, but on-line analyzers are not always available and even when they are, end-point control can be difficult, both in a batch and in a continuous plant.

Even when there is but a single reactant, as a monomer being polymerized, end-point control is necessary to terminate the reaction at the desired chain length or molecular weight or density.

Stoichiometry

Stoichiometry is the term used to describe the balancing of a chemical reaction so that all of the reactants are converted to the desired product. A typical example is the oxidation of hydrogen sulfide to elemental sulfur, which is condensed:

$$H_2S + \tfrac{1}{2}O_2 \rightarrow H_2O + S\downarrow$$

A simple enough reaction, but if too much oxygen is fed, it will oxidize sulfur to sulfur dioxide in a consecutive reaction:

$$S + O_2 \rightarrow SO_2$$

Simply metering the gas and air is not accurate enough, and the H_2S content of the gas is also usually variable. The key to controlling this reaction is establishing an equilibrium between H_2S and SO_2 in the tail gas leaving the reactor:

$$H_2S + \tfrac{1}{2}SO_2 \Leftrightarrow 1\tfrac{1}{2}S + H_2O$$

At equilibrium, where the reaction stops, H_2S has twice the concentration as SO_2 in the gas phase, and Reference 4 demonstrates that this ratio results in the minimum sulfur loss.

So an analyzer on the tail gas reports both concentrations, and a ratio controller manipulates the air-to-gas flow ratio to hold the H_2S/SO_2 ratio in the tail gas at a value of 2.0. The system is shown in Figure 8.10h. There is no fixed or set value for either H_2S or SO_2; they float with production rate and other conditions, but are always at a minimum as long as their ratio is maintained at 2:1. (Note that control of the ratio is achieved without the use of a divider—placing a divider in a closed loop is inadvisable, because its gain varies with the value of the denominator.)

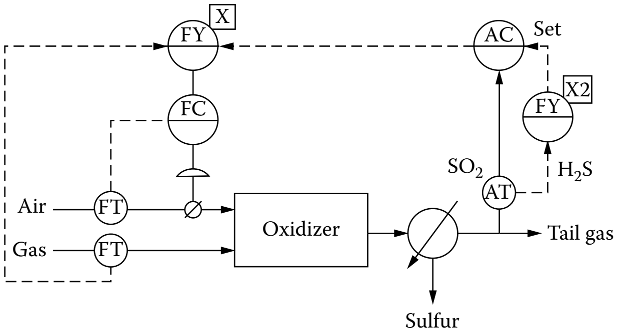

FIG. 8.10h
Minimum sulfur is lost when the ratio of H_2S to SO_2 in the tail gas is controlled precisely at 2:1.

Controlling Inventory

When one of the reactants differs in phase from the product(s) and other reactants, its inventory is measurable independently from the others, and it can be fed at the rate at which it is consumed. Two examples were shown in Figure 8.9ii.

A gaseous reactant forming a gaseous product in a liquid-phase reactor will consume the liquid reactant at the rate of reaction. Loss of liquid inventory is sensed by the level, which can be controlled to keep inventory constant. The manipulated flow of liquid feed then directly indicates reaction rate. Because no liquid product leaves the reactor, however, liquid or solid contaminants could accumulate at low points. There should be a liquid purge, either continuous or periodic—just like boiler blowdown—to eliminate the problem. Most plants have facilities for recovering feedstocks and by-products from purge streams—some are only operated periodically, as waste inventory builds.

Similarly, if the product(s) leave in the liquid phase, consumption of a gaseous reactant lowers pressure, indicating a loss in its inventory. A pressure controller can add gaseous reactant as it is consumed. In this case, a small gas purge is required to eliminate inerts such as nitrogen or carbon dioxide. Molecular sieves are often used to recover valuable gases from purge streams.

When feeds and products are in the same phase, inventory control is more difficult. For example, isobutane reacts with butylenes in a 1:1 ratio to produce high-octane gasoline called alkylate, but they are fed to the reactor in a 10:1 ratio to minimize formation of butylene polymers. The process therefore contains a large inventory of liquid isobutane, which must be controlled as it is consumed.

The reactor effluent, containing isobutane, alkylate, and inerts such as normal-butane, must be separated by distillation, with the isobutane being recycled. The recycle storage tank provides an outflow that is 10 times the rate of consumption and make-up of isobutane, and so its time constant is large compared to that of typical liquid-level loops. Proportional-only level control is recommended to allow the tank to absorb variations in production rate without the oscillations that integral action brings to slow level loops.

A similar refining process is the hydrocracking of heavy oil into gasoline fractions. Hydrogen and oil are heated and fed into a series of packed-bed reactors, where partial conversion takes place. Lighter products in the effluent are then removed by distillation, with the unreacted oil recycled under flow control from the column base to the reactors.

The oil is eventually all consumed, but at a rate that varies with temperatures and so on. Its inventory is sensed as the liquid level in the base of the distillation column, and that level controller is used to add more oil. It has also been used to set reactor temperature to convert a fixed flow of oil, but this is more difficult dynamically, as it places a temperature loop within a level loop.

Reactor Dynamics

Closing the composition loop on a reactor can be difficult, depending on the reactor dynamics. Ideally, a plug-flow reactor is pure dead time In fact, static mixer elements are often used in a plug-flow reactor to maximize radial mixing and minimize longitudinal mixing. Actually, however, the step response will appear more like a series of noninteracting lags, between 20 and 50 in number, as shown in Figure 8.10i. This would be equivalent to 20–50 ideal back-mixed reactors in series. The response does approach dead time, with 50% completion reached when the elapsed time is equal to the residence time, *V/F.* It also should be noted that the effective dead time is variable with flow, although large variations are not expected in production reactors.

Ideally, a back-mixed reactor is a pure first-order lag. But perfect mixing is unattainable, and therefore the actual step response reveals a small amount of dead time, dominated by a first-order lag. The sum of the dead time and time constant is the residence time, *V/F*—at that point, the response curve crosses 63.2% complete, just as does a single lag.

The back-mixed reactor curve in Figure 8.10i was simulated by 20 *interacting* lags, although increasing the number above 20 does not change the shape of the curve. It is essentially a distributed lag that is an accurate representation of a heat exchanger, where heat capacity and heat-transfer surfaces are distributed throughout the exchanger.

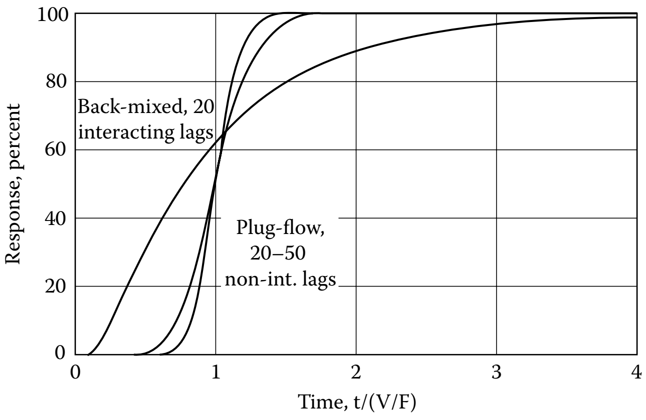

FIG. 8.10i
The plug-flow reactor is simulated by 20–50 noninteracting lags, the back-mixed-reactor by 20 interacting lags.

Reactor composition loops are ordinarily self-regulating, their step response approaching a final steady state as the figure shows. However, many reactors are enclosed in recycle loops that bring positive feedback into the process and eliminate their inherent self-regulation.

Consider, for example, an acid-base reaction carried out in an organic solvent. At the reactor exit, gaseous product is withdrawn, but any excess acid or base remains in the solvent and is ultimately recycled to the reactor. So if z concentration of excess base remains in the solvent, and the acid-base ratio is not adjusted to allow for its presence in the recycle stream, the concentration will increase to $2z$ the next time around, and continue to accumulate.

The integrating time of this recycle loop is the residence time of the solvent in the system—the time required to circulate the entire solvent inventory through the reactor. The significance of this loss of self-regulation cannot be understated. End-point control must be applied, or the composition of the reactor effluent will never reach a steady state. And integral-only control cannot be used to close the loop, or the composition will cycle endlessly—proportional action is essential for stability.

Batch End-Point Control

There are two basic types of batch reactors: pure-batch and fed-batch. A pure-batch reactor has all of its ingredients charged at once, and the reaction is allowed to proceed over time until complete. In a fed-batch reactor, one or more of the ingredients is left out of the charge and then fed at a controlled rate over time until the reaction is complete. In both cases, some determination must be made of the reaction's approach to completion, to avoid wasting both chemicals and time.

Polymerization converts light hydrocarbons into high-molecular-weight products having low vapor pressure. They are often conducted as pure-batch processes, with the initial charge under pressure. At reaction temperature, initially the pressure is close to the vapor pressure of the monomer. As the last of the monomer is consumed, the pressure starts falling, indicating completion of the reaction.

Another indication is the decline in heat evolution as the last of the reactant is consumed. Still another is the total quantity of heat transferred to the coolant, which must be determined by calculation and integration. Others measure or infer density or viscosity of the product to determine completion.

Fed-batch processes require termination of feed at the end point, to avoid loss of reactant. This can be done simply by stopping feed when a desired total is delivered, but this may not be accurate enough in some cases. The use of end-point analyzers is recommended, where available. A case in point is the control of pH in a batch of wastewater from a small processing plant—it must meet environmental specifications before discharge is allowed.

This is not a typical composition loop requiring a PID controller, because a batch process has no flow leaving it—it is essentially a no-load process. Integral action is needed to eliminate offset whenever a controller must move its steady-state output to match the current plant load. But when the load is zero and stays there, integral action is unnecessary and, in fact, causes irrecoverable overshoot.

Consider a tank filled with impounded industrial wastewater at pH 3—its pH must be raised to 6 prior to discharge, and so 6 is the set point of the pH controller. The large initial deviation of 3 pH will drive the caustic valve fully open, and it will remain open as long as necessary to neutralize the waste. During this time interval, if the integral mode is active it will wind up to the controller output limit, and the output will not fall below that limit until the pH crosses set point. That is clearly too late, and by the time the caustic valve closes, the pH will have risen well beyond set point—perhaps to 9 or 10.

In a continuous plant, overshoot is temporary, because its outflow will eventually purge away excess reagent. But not in a batch plant—the overdose is permanent. The batch will require re-treating with acid or more wastewater to lower the pH.

Because the load is zero, the controller output should also be zero when the controlled variable is at set point. This is achievable by elimination of integral action, replacing it with an output bias of zero—the controller must be proportional-only or proportional-plus-derivative.

This is not simply a matter of shutting off integration, as this leaves the constant of integration in place of an output bias, and it floats, changing every time the controller is transferred from manual to automatic. The bias must be a hard, permanent zero, and some controllers—of the incremental or velocity type—do not have this capability. If a pure proportional controller is unavailable, build one out of a calculation block, as follows:

$$m = K_c(r - c) \qquad \textbf{8.10(14)}$$

where m is the controller output, K_c its proportional gain, r the set point, and c the controlled variable. If derivative action is desired—usually helpful in a composition loop—a lead-lag function can be applied to the controlled variable before it enters the controller.

It is possible to feed two reactants simultaneously into a batch reactor with no outflow. The control problem is like trying to fill a bathtub in minimum time. To reach the right temperature at the desired volume, it really needs to be controlled *throughout* the filling process. This requires finding the flow ratio that produces approximately the right temperature at the start of the filling process, and adjusting it as necessary until the final volume is reached.

Initially, changing the ratio produces a large temperature change, but as the tub fills, this gain gradually decreases. In fact, the dynamic gain of the process varies inversely with the volume of the fill. To effectively control the composition of the variable-volume batch, the gain of the composition controller needs to be changed in direct proportion to the liquid level in the reactor.

REACTOR OPTIMIZATION

After satisfactorily controlling reactor temperature, material balance, and end-point, at the necessary production rate, optimization may be attempted. Optimization generally means maximizing economic return on the plant capital and operating costs, but there are many aspects of this, because there are many cost factors.

In an unlimited market, maximizing production maximizes return on both capital and labor. When the market is limited, meeting production goals with a minimum cost of utilities is essential. Maintenance is also costly, and operating a plant in a way that minimizes cleaning and wear has its savings.

Maximizing Production

Production rate from a reactor is determined by the rate coefficient and residence time. To increase flow rates through a reactor of fixed volume reduces residence time and conversion per-pass, and therefore does not result in a proportional increase in production. The production rate of a first-order reaction is

$$P = x_0 F y$$

Increasing production by raising the feed concentration x_0 of the controlling reactant is not often an option, in that it tends to reduce yield, through side reactions and consecutive reactions. In the case of isobutane alkylation, for example, increasing the ratio of butylenes to isobutane above 1:10 increases the formation of polymers having undesirable properties as motor fuel, and consumes more catalyst.

Increasing production by raising feed rate is viable, but inefficient. To determine the effect of feed rate on production it is necessary to differentiate Fy as a function of F. For the plug-flow reactor,

$$\frac{d(Fy)}{dF} = y + (1-y)\ln(1-y) \qquad \textbf{8.10(15)}$$

And for the back-mixed reactor,

$$\frac{d(Fy)}{dF} = y^2 \qquad \textbf{8.10(16)}$$

For the plug-flow reactor operating at $kV/F = 1$, $d(Fy)/dF = 0.264$, and for the back-mixed reactor it is 0.250. Therefore, increasing feed rate by 1% increases production only

0.25%, while increasing the load on the separation and recycle systems by 0.75%—not a favorable result.

To increase production without this penalty requires increasing reaction temperature along with feed rate, following the reaction-rate coefficient curve. Only small changes are required, given the rate coefficient doubling approximately every 10°C. In the region around 1.0 in Figure 8.10b, the normalized rate coefficient increases about 10% for each 1°C.

Maximizing production in a back-mixed exothermic reactor amounts to operating at the cooling constraints. Figure 8.9dd described how this is done when manipulating feed rate(s) to a continuous reactor. The position of the coolant valve is sent to an optimizing controller (OIC), which adjusts the feed rate(s) to drive the valve to about 90% open. In other applications, such a valve-position controller would have only the integral mode, but for an exothermic reactor, all three PID modes are necessary for stable operation.

In addition, if a large difference develops between the positions of the feed and coolant valves—or more accurately between feed and heat-transfer rates—this is an indication that the reaction is not proceeding normally and should be shut down before excessive amounts of reactant(s) have been fed. The OIC loop must be slower than the temperature loop that is inside it, and great care must be taken in closing it. The OIC loop arose out of operators' practice of observing the steady-state position of the coolant valve and gradually increasing the feed to a fed-batch reactor to drive the valve almost fully open.[2] The same operators respected the conditions under which this could be done safely, namely that the reactor had been properly charged and initiated, and was already at the controlled temperature.

There is no feed rate to manipulate in a pure-batch reactor. Furthermore, the reaction rate tends to vary as reactants are consumed. To minimize run time then requires the OIC to adjust the temperature set point to drive the coolant valve to 90% open. This is a difficult loop, however, exhibiting inverse response. To open the coolant valve further requires increasing temperature set point. However, when its set point is increased, the temperature controller responds by *closing* the coolant valve first. As the temperature then begins to rise, the controller will eventually open the coolant valve more than before, but this takes time. Again, the OIC requires full PID control, and must be much slower than the reactor temperature controller.

Maximizing production based on the position of the coolant valve is not always applicable on plug-flow reactors. If the coolant valve is obviously limiting production, as can happen during peak summer weather, then it may work. However, Reference 2 describes an uncontrollable reactor limit-cycling in winter, when the equal-percentage coolant valve was only 10–20% open.

Production rate was limited by the heat-transfer surface of the cooler and not by the coolant valve or supply temperature. The maximum controllable production rate of a plug-flow reactor is determined by the slope of the heat-transfer line in Figure 8.10d. At the limit of stability, the slopes of the heat-release and heat-transfer curves are the same. The slope of the heat-release curve is

$$\frac{dQ_r}{dT_r} = x_0 F H_r \frac{dy}{dT_r} \qquad \textbf{8.10(17)}$$

and that of the heat-transfer curve is *UA*. Therefore, the maximum controllable feed rate is

$$F_{\max} = \frac{UA}{x_0 H_r (dy/dT_r)} \qquad \textbf{8.10(18)}$$

To monitor *UA* requires the calculation of the logarithmic-mean temperature difference across the cooler:

$$UA = \frac{Q_t}{\Delta T_m} \qquad \textbf{8.10(19)}$$

where for counter-current heat transfer,

$$\Delta T_m = \frac{(T_{H1} - T_{H2}) - (T_{C1} - T_{C2})}{\ln \dfrac{T_{H1} - T_{C2}}{T_{H2} - T_{C1}}} \qquad \textbf{8.10(20)}$$

Q_t may be calculated either from fresh or circulated coolant flow:

$$Q_t = W_C C_C (T_{C2} - T_C) = W C_C (T_{C2} - T_{C1}) \qquad \textbf{8.10(21)}$$

T_{H1} and T_{H2} are temperatures of the reaction mass entering and leaving the heat-transfer surface, respectively.

For a plug-flow reactor prone to fouling, *UA* or ΔT_m should be monitored regularly and compared to production schedules. In this way, cleaning can be scheduled in advance, instead of waiting until a limit-cycling condition develops that forces a maintenance shut-down at an inconvenient time.

Supplemental Cooling

Some reactors have two sources of cooling, at different costs. For example, cooling water can be used up to the point where its valve is fully open, and then a supplemental medium such as chilled water may be used for additional cooling. If the two media can be mixed, then accommodating the additional source is as simple as sequencing the two valves. For example, the cooling-water valve could open from 50 to 25% of controller output, and the chilled-water valve from 25 to 0.

However, the media are likely to be separated from each other to avoid cross-contamination, with auxiliary cooling by chilled water passing through an internal tube bundle, and cooling water circulated through the jacket. This complicates a control system that features cascade control of jacket outlet temperature. The cascade system should be retained for its effectiveness, and the supplemental cooling manipulated to keep the jacket temperature operating in its control range.

This is done by the use of a valve-position controller (VPC) connected to the secondary output, as was shown in Figure 8.9o in the previous section. Using integral-only control, it manipulates the chilled-water flow to keep the cold-water valve about 90% open, which corresponds to a controller-output signal of 5% (its range being 50–0%).

As long as the heat load stays in the range of the cold-water valve, the chilled-water valve would remain closed. But when the VPC set point is passed, the chilled-water valve will be opened as necessary to match the load. This loop is not fast, but it need not be any faster than the expected load changes, because the jacket-temperature loop is always in control.

Whether the additional cost of the chilled water can be justified depends on the demand for product. In most cases where supplemental cooling is used, it is only needed during peak load, which only represents part of a typical batch operation.

INTRODUCTION

In order to be able to control a process, the process control engineer must understand it and know how the process will respond to changes in loads or other inputs. Modeling and simulation are important tools that can be used in analysis of physical systems and in the understanding of the functioning of processes. Besides, the physical equipment to be controlled does not yet exist, and consequently, no experimental data exists for them. Even if the process equipment is available for experimentation, the procedure usually is very costly, and, consequently, it is preferred if one can use a model to predict the behavior of the processing systems.

The fundamental models can be derived from the basic principles and from thorough knowledge of the process. In characterizing a processing system, one needs (1) a set of fundamental variables describing the state of the system, and (2) a set of equations for these variables, which describe how the state of the given system changes with time. The dynamic characteristics of a process, the knowledge of which is fundamental to designing the control systems, are described by the dynamic models in their general time-dependent form from which the steady-state models can be obtained as limiting cases forcing the time derivatives to zero.

Model Building

In the case of a chemical reactor, several factors enter into the model-building process. The set of physical characteristics is described by the balance equations of three fundamental quantities: mass, energy, and momentum.

Reaction kinetics is the other main consideration in choosing conditions for carrying out a reaction. Quantities such as density, heat capacity, and other physical–chemical parameters also are part of the overall model. An important element in the overall model can be an economic submodel containing a cost or profit objective function, useful in evaluating the possible process variables and in optimizing the system. Statistical elements can also be incorporated into the model on the basis of which future behavior of the system can be predicted.

Once a model has been built it can be used for examining the process behavior, for operator training, and also for developing different control algorithms and configurations. Early predictions of the likely conditions that the reactor is approaching can also be predicted from the model, thereby giving time for the control system to correct such trends.

Steady-state simulations are often used in equipment design. Discrete dynamic simulations serve to optimize schedules, maximize production, and minimize equipment and inventory requirements. Continuous dynamic simulation is useful for improving control strategy, reducing start-up and heat-up times, and improving on-stream times. Real-time simulation is used both for operator training and for debugging DCS and PLC systems, thereby providing both improved performance and safety.

SIMULATION

All the control programs must be tested under simulated plant conditions before the control system is connected to the process. A step-by-step simulation and checkout must take place in order to ensure the validity of all control strategies designed for a particular application. Prior to the simulation, it is usually necessary to wire to the simulator a number of analog input signals (DC source and individual potentiometers), analog output signals (DC meters), discrete input signals (AC/DC source and individual switches), and discrete output signals (AC/DC lights).

These tools play an important role in control system analysis and design, and are still used today to some extent. However, these days most simulation work is carried out by means of digital computers, which allow engineers to analyze and design more sophisticated control strategies and systems. Digital computers offer a lot of function blocks by means of which practically all linear and nonlinear process and control elements can be modeled. Although simulation with digital computers is more effective, the methodologies of testing and checkout of control systems are similar.

As the first step in the testing, all continuous (regulatory) loops are tested under both open and closed conditions, while the discrete controls are deactivated. For inherently stable processes, usually open-loop testing (without process dynamics) is adequate. Whenever dynamic process conditions must be simulated, a program is required to generate these conditions. The process variables of the models are monitored to determine the responses and stability of algorithms to the set point and simulated process load changes, respectively.

The next step is the simulation and checkout of the discrete functions, namely direct on/off control, interlock control, and sequential control. Using the simulator or the simulation program, one can imitate normal or abnormal conditions and check the system responses. If a very large number of discrete I/O is required in order to check a very complicated sequential control strategy, a simulator program can be generated, and the test can be conducted in the same manner as a dynamic test for continuous (regulatory) control described earlier.

In addition to the previously described simulation, when the system is fully installed in the field, a test run is recommended prior to actual start-up.

Control System Simulation

The simulation of instrumentation and control systems includes the measuring or detecting devices, the controllers, and the actuating or manipulating of output elements. Most measuring devices may be simulated by one or more simple lags for dynamic representation, with added static nonlinearities for device characteristics, sensitivity, or operating point modeling.

For special functions, such as logarithmic input/output relationships (pH measurements), the general-purpose function-generating units may be used, or the functions may be generated by implicit techniques. When the measuring device puts out a discontinuous (pulse-type) signal, the signal-generating circuits may be applied.

A direct, three-mode (PID) controller has the transfer function:

$$M(s) = \frac{100}{\mathrm{PB}}\left(1+\frac{1}{T_I s}\right)\left(1+\frac{T_D s}{1+T_0 s}\right)E(s) \qquad \textbf{8.11(1)}$$

where (all variables are in Laplace representation)

$M(s)$ = controller output
$E(s)$ = actuating error, $E(s) = R(s) - Y(s)$
$Y(s)$ = measured (controlled) input variable
$R(s)$ = set point
PB = proportional band
T_I = integral (reset) time
T_D = derivative time
T_0 = filtering (stabilizing) time constant

The filtering time constant is usually made as small as possible and is often a fraction of the derivative time constant T_D (such as $T_0 = T_D/16$). Often, the proportional band is replaced by the proportional gain expressed as

$$K_c = \frac{100}{\mathrm{PB}} \qquad \textbf{8.11(2)}$$

The controller transfer function in Equation 8.11(1) is of the interacting type, which is the common case in most industrial applications. A noninteracting controller is obtained by means of the transfer function

$$M(s) = \left(\frac{100}{\mathrm{PB}}+\frac{1}{T_I s}+\frac{T_D s}{1+T_0 s}\right)E(s) \qquad \textbf{8.11(3)}$$

in which all three modes can be adjusted independently.

In general, the proportional band should have an overall adjusting effect, which leads to the practical noninteracting controller with the transfer function

$$M(s) = \frac{100}{\mathrm{PB}}\left(1+\frac{1}{T_I s}+\frac{T_D s}{1+T_0 s}\right)E(s) \qquad \textbf{8.11(4)}$$

Modern controllers often limit the derivative action to respond only to measured variable changes and not to rapid set-point changes, which could upset the process. This is stated in the modified transfer function

$$M(s) = \frac{100}{\mathrm{PB}}\left[\left(1+\frac{1}{T_I s}\right)E(s)-\frac{T_D s}{1+T_0 s}Y(s)\right] \qquad \textbf{8.11(5)}$$

which is of the noninteracting type.

Digital Control Simulation

Digital control may be simulated directly with a discrete controller, where the measured variable $y(t)$ and the set point $r(t)$ in the time domain are sampled at fixed intervals ΔT, called sampling period, and $t = nT$. Denoting now the actuating error by $e(nT) = y(nT) - r(nT)$, or $e_n = y_n - z_n$, the numerical approximation of the controller algorithm 8.11(5) is

$$\Delta m_n = \frac{100}{\mathrm{PB}}\left[e_n+\frac{T}{T_I}\sum_{k=1}^{n}e_k-\frac{T_D(y_n-y_{n-1})}{T_0 T}S_n\right] \qquad \textbf{8.11(6)}$$

where the term

$$S_n = \sum_{k=1}^{n} e^{-\frac{(n-k)T}{T_0}} \qquad \textbf{8.11(7)}$$

is due to the convolution of functions.

This is referred to as the position form of the PID control algorithm, because the actual control output is computed. An alternative form of this algorithm is the velocity form, in which the change of the controller output from the preceding period is computed rather than the actual controller output itself. In this case, the velocity form corresponding to 8.11(5) becomes

$$m_n - m_{n-1} = \frac{100}{\mathrm{PB}}\left[\left(1+\frac{T}{T_I}\right)e_n - e_{n-1} - \frac{T_D}{T_0 T}\right.$$
$$\left.\times[S_n y_n - (S_n + S_{n-1})y_{n-1} + S_{n-1}y_{n-2}]\right] \qquad \textbf{8.11(8)}$$

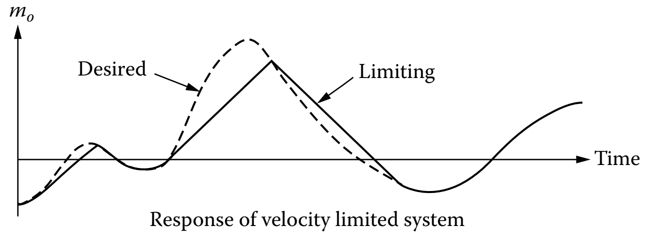

FIG. 8.11a
Velocity-limiting response.

The track-store operation is controlled by the pulse P occurring once during each time interval T to produce an output pulse $\Delta m_n = m_n - m_{n-1}$ of amplitude corresponding to the desired change in the control variable.

Control Valve Simulation

The most important actuating or manipulating output element is the control valve, which may have several distinct aspects in computer simulation. The flow characteristics can generally be linear, equal-percentage, hyperbolic, quick opening, or square root. The valve characteristics can be modeled by special computer circuits or by function-generating blocks for true representation. Additional factors, such as limiting or backlash in valve stem movements, must be included.

The dynamic behavior of a control valve may be represented by a time lag of first or second order, with a limited velocity in stem movement. The time lags are simulated by lag or lag-lead elements. Velocity limiting may be expressed by the differential equation

$$\frac{dx}{dt} = \min\left(v_L; \frac{dx_{\text{ideal}}}{dt}\right). \qquad \mathbf{8.11(9)}$$

where x is the stem position, v_L denotes the velocity limit, and x_{ideal} is the input position of an ideal, unconstrained valve.

The response of a velocity-limited device is shown in Figure 8.11a. This can respond perfectly to a driving function as long as the maximum velocity does not exceed the limit v_L. When the velocity exceeds the limiting value, the gain of the actuator decreases and its phase lag increases as shown in Figure 8.11a.

REACTOR MODELS

In any production system where a chemical change is taking place the chemical reactor is the heart of the process. The remaining operational units of the plant serve for preparing the reactants to make one or more products of greater value, and for the separation, purification, and formation of the products produced in the reactor or reactor system. Thus, the plant efficiency hinges to a great extent on the efficient operation of the reactor.

Chemical reactors may be divided into two main categories: homogeneous and heterogeneous. In homogeneous reactors only one phase, usually a gas or a liquid phase, is present. In heterogeneous reactors two, or possibly three, phases are present. Common examples are gas-liquid, gas-solid, liquid-solid, liquid-liquid, and gas-liquid-solid systems. In cases where one of the phases is a solid, it quite often serves as a catalyst.

The basis for the mathematical model of a chemical reactor are the fundamental physical and chemical laws such as the conservation of mass, energy, and momentum, as well as chemical equilibrium and chemical kinetics. The detailed mathematical model of a process reactor, however, often consists of a large number of nonlinear differential and algebraic equations, which usually involve more information that is relevant to the objectives of simulation and control. As a consequence, usually simplified, reduced models are used to model the flow conditions of process reactors.

The two basic types of flowing reactors are shown in Figure 8.11b. In the continuous stirred tank reactor (a) the agitator thoroughly disperses the reactants into the reaction mixture immediately as they enter the tank. In the tubular-flow reactor (b) there is as little mixing as possible between the reactants, which are flowing through the tube. These two reactors are described by the perfect mixing model and plug-flow model, respectively. These represent the two limiting cases of flow models.

Reaction Kinetics

The principle of chemical kinetics determines the rate at which a reaction proceeds toward the maximum extent determined by the chemical equilibrium. The reaction rate depends on the concentrations of the reactants and on temperature. For gas

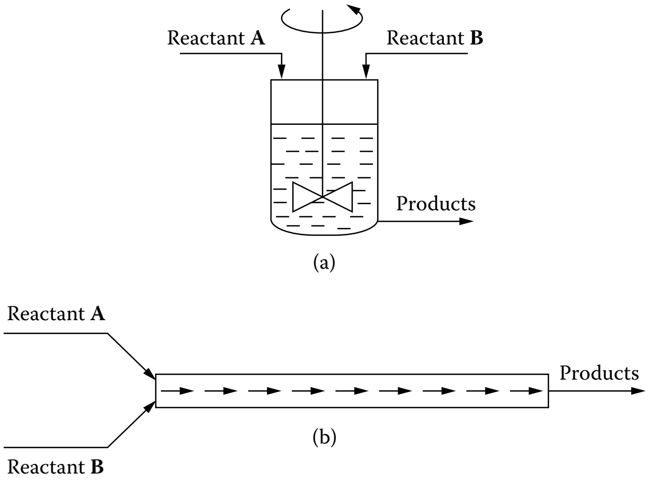

FIG. 8.11b
Two basic types of flowing chemical reactors are the continuous stirred tank (a) and the plug-flow variety (b).

phase reactions the concentrations are proportional to the pressure, and therefore the pressure also affects the rate of reactions.

In case of a homogeneous reaction:

$$a\mathbf{A} + a\mathbf{B} \rightarrow q\mathbf{Q} + s\mathbf{S} \qquad \mathbf{8.11(10)}$$

where: "*a*" moles of species **A** react with "*b*" moles of species **B** to produce "*q*" moles of species **Q** and "*s*" moles of species **S**. **A** and **B** are therefore the reactants, **Q** and **S** are the products, and *a, b, c,* and *d* stand for the corresponding coefficients in the stoichiometric Equation 8.11(10). Such a reaction is called irreversible, and it will stop when either reactant is completely consumed.

For homogeneous irreversible reactions the rate of reaction is measured as moles of one of the reactants transformed per unit volume of reacting mixture and unit time:

$$r_A = -\frac{1}{V}\frac{dn_A}{dt} \qquad \mathbf{8.11(11)}$$

where r_A is the rate of consumption of reactant **A**, and n_A denotes the total moles of **A** in volume V. The rate of reaction, however, can be expressed also in terms of other reactants and products. Because in this case the direction of change of species **Q** and **S** are reversed, these rates are related to rate r_A as

$$r_B = \frac{b}{a}r_A, \quad r_Q = -\frac{q}{a}r_A, \quad r_S = -\frac{s}{a}r_A \qquad \mathbf{8.11(12)}$$

The reaction that does not proceed to completion is called reversible, and it is necessary to include also the kinetics of the reverse reaction:

$$a\mathbf{A} + b\mathbf{B} \leftrightarrow q\mathbf{Q} + s\mathbf{S}. \qquad \mathbf{8.11(13)}$$

The arrow pointing to the left indicates that the reaction is reversible; i.e., both forward and reverse reactions take place simultaneously. Therefore, the state of chemical equilibrium is regarded as a dynamic balance between the forward and reverse reaction.

The equations that express the rate of reaction in terms of concentrations of the reactants and products are called the kinetic model of the reaction. A typical model for the reversible reaction represented by Equation 8.11(13) could be

$$r_A = -k_f\left(c_A^{\alpha}c_B^{\beta} - \frac{1}{K}c_Q^{\varsigma}c_S^{\sigma}\right) \qquad \mathbf{8.11(14)}$$

where c_A, c_B, c_Q, and c_S are the concentrations of the corresponding species in moles per unit volume. The exponents in this expression are often equal to *a, b, q,* and *s*, respectively, and then the reaction is said to be elementary.

If the exponents differ from the coefficients of Equation 8.11(13), the reaction is not elementary, meaning that the actual mechanism of the reaction consists of a series of intermediate elementary steps that are summarized by Equations 8.11(13) and 8.11(14). When the functional relationship has the form of Equation 8.11(14), the reaction is said to be of order α, β, ς and σ, with respect to the species, while the orders of the forward and reverse reactions overall are $\alpha + \beta$ and and $\varsigma + \sigma$, respectively.

In Equation 8.11(14), parameter k_f is the rate coefficient of the forward reaction, and K is the equilibrium constant for which the relationship

$$K = \frac{k_f}{k_r} \qquad \mathbf{8.11(15)}$$

holds where k_r is the rate coefficient of the reverse reaction. For irreversible reaction $k_r = 0$, so that $K \rightarrow \infty$ and the second term in parentheses in Equation 8.11(14) becomes 0.

Both the rate coefficient and the equilibrium coefficient are functions of temperature. Experimentally, the influence of temperature on the rate coefficient is well represented by the Arrhenius equation

$$k_f = k_{f0}e^{-\frac{E}{RT}} \qquad \mathbf{8.11(16)}$$

where E is called the activation energy of the reaction, R is the universal gas constant (1.98 BTU/(lb-mole °R) or in the SI system 8.314 J/(mol °K)), and T is the absolute temperature of the reacting mixture.

A kinetic model is essential for the simulation of a process reactor. The functional relationship and the parameters are identified with the aid of reaction rate data measured in the laboratory or pilot plant, fitting a rate equation of general form to a set of experimental data. However, the kinetic model does not have to be as accurate for control simulation as it would have to be for designing the reactor.

Perfectly Mixed Flow Reactor

The essential feature of the continuous stirred tank reactor is the assumption of complete uniformity of concentration and temperature throughout the reactor volume. Because with perfect mixing, the reactor contents are completely uniform, it is also called the perfectly mixed flow reactor in which the conversion takes place at unique concentration and temperature levels.

The mathematical model is developed using the principle of the conservation of energy and mass:

$$\begin{pmatrix}\text{rate of}\\ \text{quantity}\\ \text{accumulation}\end{pmatrix} = \begin{pmatrix}\text{rate of}\\ \text{quantity}\\ \text{in}\end{pmatrix} - \begin{pmatrix}\text{rate of}\\ \text{quantity}\\ \text{out}\end{pmatrix} + \begin{pmatrix}\text{rate of}\\ \text{quantity}\\ \text{produced}\end{pmatrix} - \begin{pmatrix}\text{rate of}\\ \text{quantity}\\ \text{consumed}\end{pmatrix} \qquad \mathbf{8.11(17)}$$

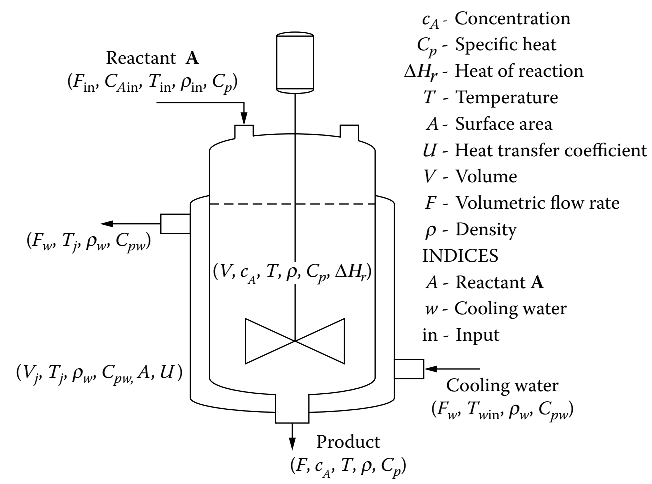

FIG. 8.11c

The parameters used in modeling a perfectly mixed flow reactor with a cooling jacket.

where the quantity may represent mass, mass of individual components, and energy. Equation 8.11(17) is called balance equation of the given quantity.

If an irreversible, exothermic reaction resulting in **A** → *Product* is carried out in the reactor, which is cooled by water flowing through a jacket, the total mass balance in the reactor (shown in Figure 8.11c) can be written as

$$\frac{d(V\rho)}{dt} = F_{\text{in}}\rho_{\text{in}} - F\rho \qquad \mathbf{8.11(18)}$$

where V is the volume and ρ is the mean density of the reacting mixture, and F denotes the volumetric rate of flow. The subscript in is referred to the inputs of the system.

If the density of the reacting mixture is not changed appreciably by the reaction ($\rho_{\text{in}} = \rho$), then Equation 8.11(18) can be simplified as

$$\frac{dV}{dt} = F_{\text{in}} - F \qquad \mathbf{8.11(19)}$$

describing only the change in volume of the reacting mixture as a function of time.

The mass balance equation on reactant **A** is given by

$$\frac{d(Vc_A)}{dt} = F_{\text{in}}c_{A\text{in}} - Fc_A + Vr_A \qquad \mathbf{8.11(20)}$$

where c_A denotes the concentration of reactant **A**, and r_A is the reaction rate expressed in terms of concentration of reactant **A**.

Taking into account that

$$\frac{d(Vc_A)}{dt} = V\frac{dc_A}{dt} + c_A\frac{dV}{dt} \qquad \mathbf{8.11(21)}$$

Equations 8.11(19) and 8.11(20) can be combined, which results in the equation

$$\frac{dc_A}{dt} = \frac{F_{\text{in}}}{V}(c_{A\text{in}} - c_A) + r_A. \qquad \mathbf{8.11(22)}$$

The ratio F_{in}/V is the reciprocal of the mean residence time of the reactor, which is, in principle, the time constant of the perfectly mixed reactor.

The Energy Balance The energy balance equation on the reactor is written as

$$\begin{aligned}\frac{d(V\rho C_pT)}{dt} &= F_{\text{in}}\rho_{\text{in}}C_{p\text{in}}T_{\text{in}} - F\rho C_pT \\ &\quad + V(-\Delta H_r)r_A - UA(T - T_j)\end{aligned} \qquad \mathbf{8.11(23)}$$

where T and C_p are the temperature and the mean specific heat of the reacting mixture, and, again, index in denotes the corresponding input variables. ($-\Delta H_r$) denotes the heat liberated in the reaction per unit mass of **A** reacted, T_j is the temperature of the cooling water in the jacket, A is the effective heat-transfer surface area between the reactor and the jacket, and U is the overall heat-transfer coefficient.

Assuming that the density and the specific heat are constant and using similar reasoning that resulted in Equation 8.11(22), Equation 8.11(23) can be reduced to the form

$$\frac{dT}{dt} = F_{\text{in}}(T_{\text{in}} - T) + \frac{(-\Delta H_r)}{\rho C_p}r_A - \frac{UA}{V\rho C_p}(T - T_j). \qquad \mathbf{8.11(24)}$$

Finally, the energy balance on the jacket gives the equation for the temperature of the jacket T_j taking the form

$$\frac{dT_j}{dt} = \frac{F_w}{V_j\rho_wC_{pw}}(T_w - T_j) + \frac{UA}{V_j\rho_wC_{pw}}(T - T_j) \qquad \mathbf{8.11(25)}$$

where F_w, C_{pw}, and T_w are the volumetric flow rate, the specific heat, and the inlet temperature of the cooling water, respectively.

Gas Phase Reactors In gas phase reactors, the reactor pressure significantly affects the performance of the reactor so that the description of the changes of pressure should be included into the model. In this case the density varies with pressure and composition, and the flow out of the reactor passes through a control valve. The density usually is computed using the perfect gas law

$$\rho = \frac{Mp}{RT} \qquad \mathbf{8.11(26)}$$

where M is the mean molecular weight of the reacting mixture and R is the universal gas constant. The concentration of reactant **A** is expressed as

$$c_A = \frac{p y_A}{RT} \qquad \textbf{8.11(27)}$$

where y_A is the mole fraction of species **A**.

In Equation 8.11(18), the outflow through the control valve can be expressed as

$$F = C_V \sqrt{\frac{p - p_{\text{out}}}{\rho}} \qquad \textbf{8.11(28)}$$

where C_V is the valve sizing coefficient, and p_{out} is the constant pressure controlling the out-flow. Equations 8.11(26)–8.11(28) can be substituted into Equations 8.11(18), 8.11(20), and 8.11(24) to express them in terms of ρ, p, y_A, and T to obtain the mathematical model of the gas phase reactor. Naturally, in this case the volume of the reactor V is constant.

Plug Flow Reactor

Plug flow is a simplified and idealized view of the motion of a fluid, whereby all the fluid elements move with a uniform velocity along parallel streamlines. It is also assumed that the concentrations and temperature are uniform across the cross-sectional area of flow. Tubular reactors, such as shown in Figure 8.11d, with very high velocities, tend to approach plug flow conditions.

Whereas composition and temperature are functions of time only in the perfectly mixed reactor, in the plug flow reactor they are functions of time and distance x from the entrance. Thus, the plug flow reactor is a distributed parameter system, having a dynamic model, which consists of partial differential equations. To solve a partial differential equation it must be approximated by a number of ordinary differential equations. However, a special case of a model containing N equal-size perfectly mixed tanks, called compartments in the present context, arranged in series forms, is a useful and frequently used approximation of the plug flow reactor. This method will be shown here.

The tubular reactor in Figure 8.11d, in which an irreversible, endothermic reaction **A** → *Product* is assumed to be carried out, is divided into a number of compartments, as is illustrated in Figure 8.11e. The compartments are assumed to be connected in cascade without any back-flow. The length of each compartment is Δx and its volume is $A\Delta x$, where A is the cross-sectional area of flow. As a consequence, if the volume of the reactor is V and N compartments are used in the modeling, then the length of a compartment is derived as $\Delta x = V/NA$. Further, if the linear velocity of flow is denoted by v then the volumetric velocity is Av.

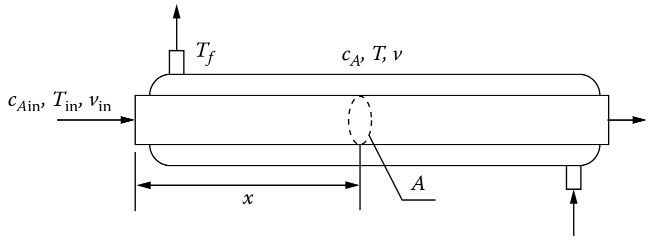

FIG. 8.11d
Plug flow reactor with heating jacket.

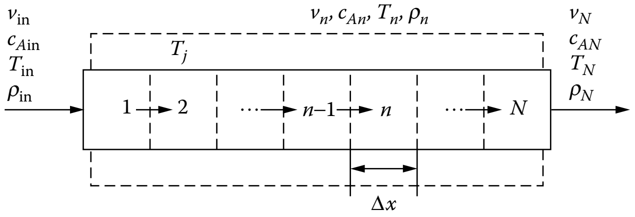

FIG. 8.11e
The model of a plug flow reactor consists of a number of compartments.

The mathematical model of the system now can be developed by sequentially applying the principle expressed in Equation 8.11(17) for each compartment. The mass balance around the nth compartment, shown in Figure 8.11f, can be written as

$$\frac{d(A\Delta x \rho_n)}{dt} = A v_{n-1}\rho_{n-1} - A v_n \rho_n, \quad n = 1,2\ldots N \qquad \textbf{8.11(29)}$$

where ρ_n is the mean density and v_n is the mean linear velocity of the reacting mixture in the nth compartment. For the first compartment $\rho_0 = \rho_{\text{in}}$ and $v_0 = v_{\text{in}}$, where the subscript in denotes the input variables to the reactor. In liquid phase reactors, the density is assumed to be constant. In gas phase reactors Equation 8.11(26) is used to compute the density from the pressure and temperature of the compartment.

Because the parameters x and A are constant, Equation 8.11(29) can be simplified to give

$$\frac{d\rho_n}{dt} = \frac{1}{\Delta x}(v_{n-1}\rho_{n-1} - v_n\rho_n), \quad n = 1,2\ldots N,$$
$$v_0 = v_{\text{in}}, \rho_0 = \rho_{\text{in}} \qquad \textbf{8.11(30)}$$

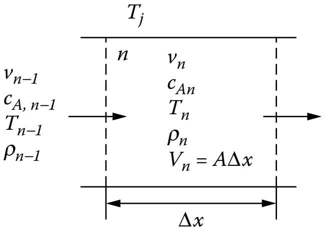

FIG. 8.11f
The compartment model of the nth compartment of a plug flow reactor.

The mass balance equation on reactant **A** becomes

$$\frac{d(A\Delta x c_{An})}{dt} = Av_{n-1}c_{A,n-1} - Av_n c_{An} + A\Delta x r_{An},$$
$$n = 1,2\ldots N, v_0 = v_{\text{in}}, \rho_0 = \rho_{\text{in}}, c_{A0} = c_{A\text{in}} \qquad \mathbf{8.11(31)}$$

where c_{An} is the concentration of reactant **A** in the nth compartment, and r_{An} is the reaction rate. Again, this equation can be simplified writing

$$\frac{dc_{An}}{dt} = \frac{1}{\Delta x}(v_{n-1}c_{A,n-1} - v_n c_{An}) + r_{An}, \quad n = 1,2\ldots N,$$
$$v_0 = v_{\text{in}}, \rho_0 = \rho_{\text{in}}, c_{A0} = c_{A\text{in}} \qquad \mathbf{8.11(32)}$$

The Energy Balance The energy balance equation around the nth compartment takes the form

$$\frac{d(A\Delta x \rho_n C_p T_n)}{dt} = Av_{n-1}\rho_{n-1}C_p T_{n-1} - Av_n\rho_n C_p T_n$$
$$+ A\Delta x(-\Delta H_r)r_{An} + Ua\Delta x(T_j - T_n)$$
$$n = 1,2\ldots N, v_0 = v_{\text{in}}, \rho_0 = \rho_{\text{in}}, T_0 = T_{\text{in}} \qquad \mathbf{8.11(33)}$$

where a is the perimeter of the tube, so that $a\Delta x$ is the heat-transfer area of one compartment, and T_j is the temperature of the jacket assumed to be uniform along the tube, as it takes place, for instance, in a firing box. This last equation can also be written in simplified form

$$\frac{dT_n}{dt} = \frac{v_{n-1}\rho_{n-1}}{\Delta x \rho_n}(T_{n-1} - T_n) + \frac{1}{\rho_n C_p}(-\Delta H_r)r_{An} + \frac{Ua}{A\rho_n C_p}(T_j - T_n)$$
$$n = 1,2\ldots N, v_0 = v_{\text{in}}, \rho_0 = \rho_{\text{in}}, T_0 = T_{\text{in}} \qquad \mathbf{8.11(34)}$$

Often, the pressure drop in the reactor is sufficiently large to be necessary to account for it, instead of using an average value. Then the velocity from each compartment to the next can be computed by using the usual Bernoulli equation

$$p_n - p_{n-1} = k_F\rho_n v_n^2 + \alpha\rho_n v_n(v_n - v_{n-1}),$$
$$n = 1,2\ldots N,\ v_0 = v_{\text{in}}, \rho_0 = \rho_{\text{in}} \qquad \mathbf{8.11(35)}$$

where the constant k_F is proportional to the Fanning friction factor, which can be computed using fluid dynamics correlation. α is a conversion factor in the Fanning pressure drop equation. In liquid phase reactors, the velocity can also be assumed constant, thus Equations 8.11(32), 8.11(34), and 8.11(35) by themselves form a closed model of the reactor.

Gas Phase Reactions In gas phase reactors, however, the mathematical model consists of Equations 8.11(30), 8.11(32), 8.11(34), and 8.11(35), and this set of equations can be closed by also applying Equation 8.11(26). If the temperature of the jacket T_j cannot be considered constant, then a heat balance equation, similar to Equation 8.11(33) without reaction term, should be added to the model.

The greater the number of compartments in this compartments model, the better the model approximates the distributed parameter plug flow model. However, in accordance with the engineering heuristics, five compartments usually are sufficient to describe the performance and behavior of plug flow reactors.

Nonideal Flow

The flow patterns of process reactors often deviate from the ideal flow conditions of perfect mixing and plug flow. In stirred tank reactors, this can be caused by such elements in real equipment as corners, baffles that can lead to stagnant regions, or nonuniform flow paths that can induce bypassing of fluid.

The way to model this type of imperfections is to divide the reactor into more compartments of different volumes. These compartments can be connected with each other using volumetric flows of different flow rates. The sum of the volumes of the compartments must equal the volume of the reactor. A simple model of a real stirred tank with bypassing and dead space is shown in Figure 8.11g.

The nonideal flow in tubular reactors can be modeled simply by adding back-flow from a compartment to the preceding one in the N compartments in series model. In this manner, one can allow for some mixing in the axial direction of the tube, as it is illustrated in Figure 8.11h.

Increasing the rate of back-flow, the model will approach that of the perfectly mixed reactor. In the case of fixed finite back-flow, when the number of compartments, N, approaches infinity, the model approaches the so-called plug flow with axial dispersion model.

Another type of nonideal flow occurs in a tubular reactor in which the velocity, temperature, and concentration varies across the radius of the tube. If axial symmetry is present, these phenomena may be modeled by assuming some velocity

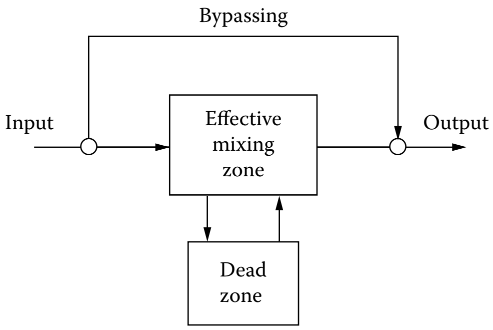

FIG. 8.11g
The model of a real stirred tank reactor includes both bypassing and dead space components.

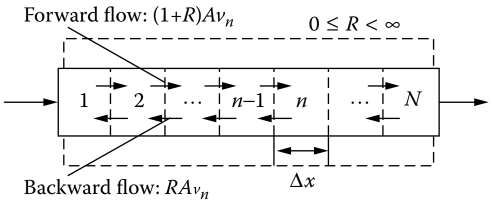

FIG. 8.11h
Plug flow reactor model that includes back-flow among the compartments.

profile along the radius that further can be combined with diffusion of chemical species and conduction of temperature in radial direction.

In such cases, the reactor can be divided into a number of "rings," and the balance equations can be written for each of these rings. For the transfer of heat and mass between the rings, appropriate flow models and interfacial heat and mass transfer equations must be used.

Heterogeneous Reactors

Modeling and simulation of multiphase heterogeneous reactors falls into a special category because an additional complexity, namely the transfer of mass and energy between phases, enters into the problem. In general, mass and energy balance equations must be written for each phase, and appropriate interfacial transfer equations must be used for describing the transfer of reactants and products between the phases.

The transport of mass and energy inside the phases are described by models discussed in the case of homogeneous reactors, while the interfacial mass and heat transfers are expressed in terms of appropriate driving forces as:

$$\Phi_A = k_L(c_{Ak} - c_{Ai}) \qquad \textbf{8.11(36)}$$

where Φ_A is the mass flux through the interface, k_L is the mass transfer coefficient, and $(c_{Ak} - c_{Ai})$ denotes the driving force expressed as a difference of concentrations of species **A** in the *k*th and *i*th phases. For this model, it is important to determine the interfacial surface area between the phases, which could be difficult. The two most significant physical properties of the system are the solubility and the phase equilibrium relationships.

For fast reactions and low diffusion or mass transfer rates, the rate of mass transfer has greater influence on the rate of chemical reactions than does the kinetics of the reaction. In such cases, the mass transfer is the step that determines the rate, and the reaction rate equations may be quite different compared with the previously discussed ones.

Catalytic Reactors

In catalytic reactors, the catalyst speeds up the reaction without being consumed or produced by it. The reaction rate coefficient is then a function of the temperature, catalyst concentration, and catalyst activity or age. Catalysts frequently lose a large portion of their activity while in operation. The age of the catalyst, being a measure of loss of the catalyst activity, is measured as the accumulated time that has passed since the catalyst was replaced or regenerated. These values usually are not readily available and must be determined experimentally in order to be incorporated into the model.

When the catalyst is a solid, the additional complications of heterogeneity arise in the modeling process. In fluid-solid catalytic reactors, the reaction itself takes place on the surface of the solid. For this reason, it is advantageous to have the particles of catalyst in a porous form making a large internal surface area available for the reaction. In this case, the rate of transport of gas to and from the surface within the pore structure will significantly affect the performance of the reactor and has to be taken into consideration. The effectiveness factors usually provide a useful tool to make the model of the reactor treatable. In general, this is defined as

$$\eta = \frac{\text{rate of reaction with pore diffusion resistance}}{\text{rate of reaction without pore diffusion resistance}} \qquad \textbf{8.11(37)}$$

and the actual reaction rate that would be observed is

$$(r_A)_{\text{observed}} = \eta (r_A)_{\text{ideal}} \qquad \textbf{8.11(38)}$$

where the reaction rate $(r_A)_{\text{ideal}}$ is derived with surface conditions. The effectiveness factor depends on the shape of catalyst particles.

Sometimes, especially in fixed-bed catalytic reactors, the equations can be considerably simplified by expressing the rate of reaction on the basis of unit mass of catalyst instead of on the basis of unit volume.

CONCLUSIONS

Presented in this section were methods for developing the equations that describe process reactors. Because the reactor is only one part of the total control loop, for a complete simulation of the loop, it is necessary to include the equations that represent the temperature, level, pressure, and concentration sensors, transmission lines, controllers, and control valves.

A reactor control simulation allows the control engineer to tune the controllers without any loss of production or risk of an accident. Simulation also provides the perfect tool to train plant operators for smoother and safer start-ups. In addition, it serves as a "live" model with which to try new control ideas that will result in safer and more efficient operation of the reactor; it gives an insight into the behavior of the reactor equivalent to several years of reactor operation. This last advantage derives from the ability to look at variables in the simulation that are impossible or impractical to measure in the process reactor.

When modeling on digital computers, one must recognize the following:

1. The digital computer is a discrete time device; therefore, all the computations required to implement must be expressed in discrete time forms.
2. Numerical integration involves approximating continuous differential equations with discrete finite difference equations. The accuracy and stability of these approximating equations must be constantly considered.
3. Interactive environments of digital computers provide convenient and effective tools and some kind of graphical capabilities for modeling, simulating, and analyzing dynamic, multidomain systems and control system design. It lets you accurately describe, simulate, evaluate, and refine a control system's behavior through standard and custom block libraries, also allowing you to develop and build your own special process and control elements.

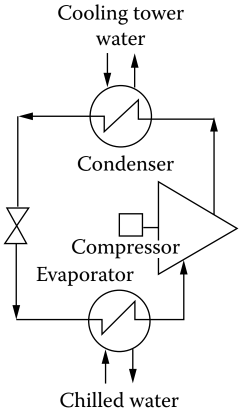
8.12 Chiller Control

B. G. LIPTÁK (1970, 1985, 1995, 2005)



Flow sheet symbol

INTRODUCTION

The chiller process and its basic controls are discussed in this section, while the next section covers various methods of chiller optimization. As the overall cooling process also includes cooling towers, compressors, fans, and pumps, the reader should also refer to the sections that discuss the control of these systems in this chapter.

The unit of refrigeration is the ton. The rate of cooling represented by the three widely used definitions of a ton of refrigeration are listed below:

Standard Ton	200 BTU/min (3520 W)
British Ton	237.6 BTU/min (4182 W)
European Ton (Frigorie)	50 BTU/min (880 W)

The performance and operating features of the various chiller designs vary over a wide range. Some of these are listed below:

Compression ratios (per stage): 3:1 to 8:1
Maximum turndown ratios: 8:1 for conventional, over 30:1 with hot gas bypass (HGBP)
Typical superheat at evaporator outlet: 9°F, or 5°C
Coefficients of performance: 2.5–3.5 for conventional, 5–7 for optimized chillers

When the operation of a chiller is optimized (subject of the next section) its yearly cost of operation is reduced by 1.5% for each °F reduction in chiller ΔT.

The Heat Pump

Heat pumps serve to transport heat from a lower to a higher temperature level. They do not make heat; they just transport it. This is similar to a pump transporting water from a lower to a higher elevation. The required energy input to a regular pump is a function not so much of the amount of water to be transported but of the elevation to which it is to be lifted. Similarly, the required energy input of a heat pump is a function not only of the amount of cooling it has to do but also of the temperature at which it must reject the heat, because it is this elevation against which it is pumping.

Each °F reduction in the temperature difference (ΔT), across which the heat pump is transporting the heat, will lower the yearly operating cost by 1.5% (each °C by 2.7%). As it will be discussed in the next section, there are not many unit operations whose efficiency can be doubled through optimization; chiller optimization is one of these few.

In this review of chiller controls, the thermodynamic aspects of the refrigeration process will be discussed first, after which conventional chiller controls will be discussed. The nomenclature and abbreviations used in connection with chiller controls and optimization are listed below.

Nomenclature

CHWP: Chilled water pump
CTWP: Cooling tower water pump
FAH, FAL: Flow alarm; H = high, L = low
FC: Fail closed
FO: Fail open
FSH, FSL, FSHL: Flow switch; H = high, L = low, HL = high-low
HLLS: High-low limit switch
HWP: Hot water pump
LCV: Level-control valve
$M_{1–5}$: Motors that drive equipment; 1 = cooling tower fan(s), 2 = cooling water pump(s), 3 = compressor(s), 4 = chilled water pump(s), 5 = hot water pump(s)

P-1: Pump
P, P_{1-3}: Pressures
PAH: Pressure alarm; H = high
PB: Pushbutton
PCV: Pressure-control valve
PDIC: Pressure-differential indicating controller
PI: Pressure indicator
PSH, PSL: Pressure switch; H = high, L = low
Q_H: Amount of heat delivered to cooling tower water
Q_L: Amount of heat removed from chilled water
RD: Rupture disk
S: Solenoid
SC: Speed controller
SIC: Speed-indicating controller
SP: Set point
SV: Solenoid valve
T_c: Temperature of refrigerant in condenser inlet
T_e: Temperature of refrigerant in evaporator inlet
T_H: Temperature of cooling water at condenser exit, absolute
T_L: Temperature of chilled water at evaporator exit, absolute
T_{chwr}: Temperature of chilled water return
T_{chws}: Temperature of chilled water supply
T_{ctwr}: Temperature of cooling tower water return
T_{ctws}: Temperature of cooling tower water supply
T_{hwr}: Temperature of hot water return
T_{hws}: Temperature of hot water supply
T_{wb}: Temperature of wet bulb
TAH, TAL: Temperature alarm; H = high, L = low
TCV: Temperature control valve
TIC: Temperature-indicating controller
TSH, TSL: Temperature switch; H = high, L = low
TT: Temperature transmitter
TY: Temperature relay
VPC: Valve position controller
W: Work
XLS: Limit switch
XSCV: Superheat control valve

THE COOLING PROCESS

Figure 8.12a illustrates how heat pumps can transport heat from a lower to a higher elevation and thereby provide cooling of a relatively low temperature process. The heat pump removes Q_L amount of heat from the chilled water and, at the cost of investing W amount of work, delivers Q_H quantity of heat to the warmer cooling tower (or condenser) water.

In the lower part of this illustration, the idealized temperature-entropy cycle is shown for the chiller. The cycle consists of two isothermal and two isentropic (adiabatic) processes:

1→2: Adiabatic process that occurs in the expansion valve
2→3: Isothermal process that takes place in the evaporator

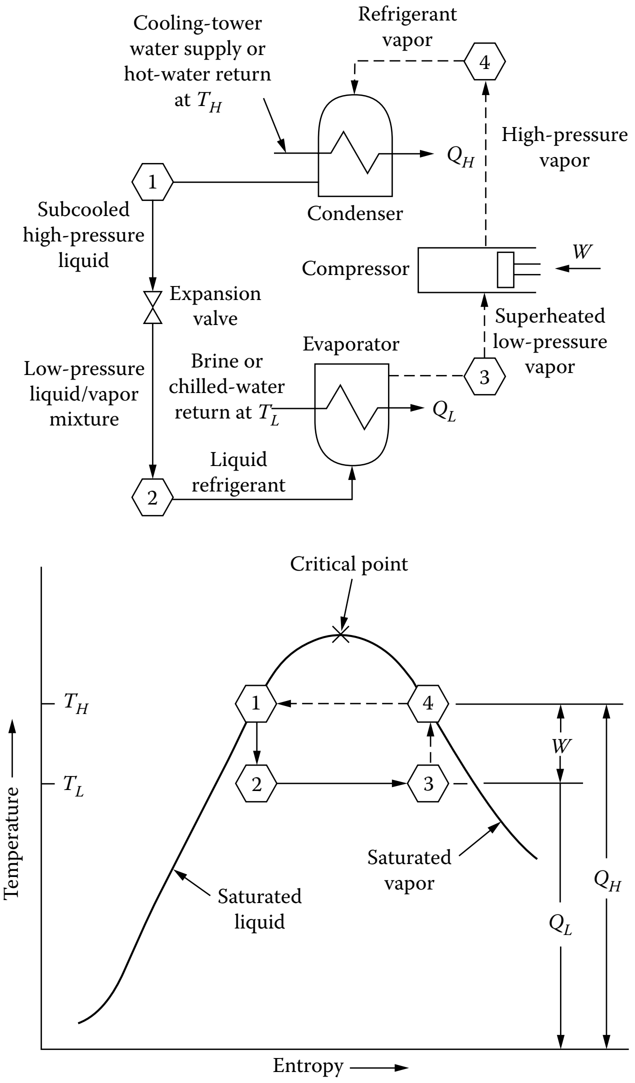


FIG. 8.12a
The top portion of this figure shows the main components of a refrigeration system. The bottom portion describes the refrigeration cycle, which consists of two isothermal and two isentropic processes.[1]

3→4: Adiabatic process that occurs in the compressor
4→1: Isothermal process that takes place in the condenser

The isothermal processes in this cycle are also isobaric (constant pressure). The efficiency of a heat pump is defined as the ratio between the heat removed from the process (Q_L) and the work required to accomplish this heat removal (W).

$$\beta = \frac{Q_L}{W} = \frac{Tl}{Th - Tl} \qquad \mathbf{8.12(1)}$$

Coefficient of Performance

Because the efficiency of a chiller can be much more than 100%, it is usually called the *coefficient of performance*

(COP). If a chiller requires 1.0 kWh (3,412 BTU/h) to provide a ton of refrigeration (12,000 BTU/h), its coefficient of performance is said to be 3.5. This means that each unit of energy introduced at the compressor will pump 3.5 units of heat energy into the cooling tower water.

Conventionally controlled chillers operate with COPs in the range of 2.5 to 3.5. Optimization can double the COP by increasing T_L, by decreasing T_H, and through other methods that will be described in the next section.

Figure 8.12a shows the four principal pieces of equipment that make up a refrigeration machine. In path 1→2, as it passes through the expansion valve, the high-pressure subcooled refrigerant liquid becomes a low-pressure mixture of liquid and vapor. In path 2→3, in passing through the evaporator, this mixture is vaporized into a superheated low-pressure vapor stream, whereas in the compressor (path 3→4) the pressure of the refrigerant vapor is increased. Finally, in path 4→1 this high-pressure vapor is condensed at constant pressure. The liquid leaving the condenser is usually subcooled, whereas the vapors leaving the evaporator are usually superheated by controlled amounts.

Refrigerants and Heat Transfer Fluids

The fluid that carries the heat from a low to a high temperature level is referred to as the refrigerant. Table 8.12b provides a summary of the more frequently used refrigerants.

The data in Table 8.12b assumes that the evaporator will operate at 5°F (−15°C) and that the temperature of the cooling water will keep the condenser at 86°F (30°C). Other evaporator

and condenser temperatures would have illustrated the relative characteristics of the various refrigerants equally well.

It is generally desirable to avoid operation under vacuum in the evaporator or any part of the cycle because of the resulting sealing problems. At the same time, very high condensing pressures are also undesirable because of the resulting structural strength requirements. From this point of view, the most desirable refrigerants are listed in Table 8.12b between propane and methyl chloride, because they display favorable characteristics.

An exception to this reasoning is when very low temperatures are required. For such service, ethane can be the proper selection in spite of the resulting high condenser design pressure.

Another consideration is the latent heat of the refrigerant. The higher it is, the more heat can be carried by the same amount of working fluid and, therefore, the smaller the corresponding equipment size will be. This feature has caused users in the past to tolerate the undesirable characteristics of ammonia.

One of the most important considerations in the selection of the refrigerant is safety. In industrial installations, the desirability of nontoxic, nonirritating, nonflammable refrigerants cannot be overemphasized. It is similarly important that the working fluid be compatible with the compressor's lubricating oil. Corrosive refrigerants are undesirable for the obvious reasons of higher initial cost and increased maintenance.

Most of the working fluids listed in Table 8.12b can be used with reciprocating compressors. Only the last four fluids in the table, which have high volume-to-mass ratios and low compressor discharge pressures, can justify the consideration of rotary or centrifugal machines.

Freon-12 is suited for the largest number of applications, but it does have the disadvantage of contributing to ozone depletion in the atmosphere.

In the majority of industrial installations, the refrigerant evaporator is not used directly to cool the process. More frequently, the evaporator cools the chilled water, which is then piped to cool the process.

For temperatures that are too low for water to be used as a coolant, brine is frequently selected. The limitation of weak brines is that they may freeze, while strong brines can plug the evaporator tubes, if they are not true solutions. For operation around 0°F (–18°C), the sodium brines (NaCl) are recommended, while for services down to –45°F (–43°C), the calcium brines (CaCl) are the best.

Care must be exercised in handling brines, because they are corrosive if they are not kept at a pH of 7 or if oxygen is present. In addition, brine will initiate galvanic corrosion between dissimilar metals.

REFRIGERATOR AND CHILLER DESIGNS

The more conventional heat pump controls are discussed below. For the more sophisticated and optimized control systems, refer to the next section in this chapter.

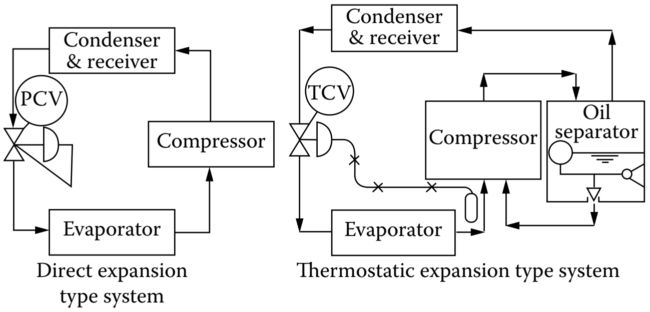

FIG. 8.12c
The small industrial refrigerators are usually provided with either direct expansion (left) or thermostatic expansion-based throttling control.

Small Industrial Refrigerators

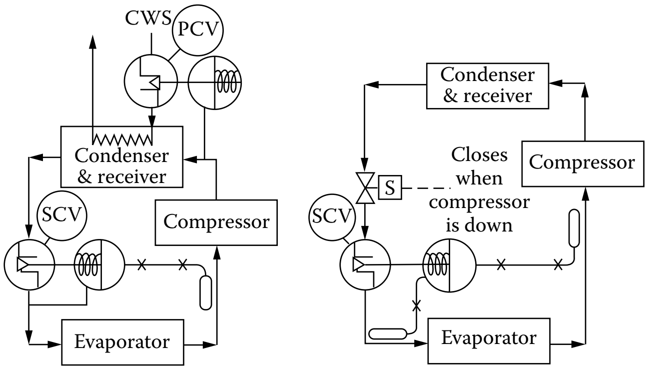
The direct expansion-type control of a refrigerator is shown on the left side of Figure 8.12c. Here a pressure-reducing valve keeps the evaporator pressure constant. The pressure setting is a function of load, and therefore these controls are recommended only for constant-load applications. The pressure setting is set manually by adjusting the pressure until the frost just stops at the end of the evaporator. This indicates that liquid refrigerant is present all the way to that point.

In the direct expansion-type system, shown on the left side of Figure 8.12c, when the load increases, all the refrigerant will vaporize before the end of the evaporator, causing low efficiency, because the unit is "starved." Starving can be eliminated by manually changing the pressure setting. When the evaporator is down, the pressure-control valve closes, isolating the high- and low-pressure sides of the system. This guarantees that the desirable high start-up torque on the compressor will be present.

The thermostatic expansion-type control is shown on the right side of Figure 8.12c. This system, instead of maintaining the evaporator pressure constant, controls the superheat of the evaporated vapors. This design is not limited to constant loads, because under all conditions it guarantees the presence of liquid refrigerant at the end of the evaporator.

Figure 8.12c also shows a typical oil separator.

Expansion Valves Figure 8.12d illustrates some expansion valve design variations. On the left side of Figure 8.12d, a fairly standard superheat control valve is shown. It detects the pressure at the inlet and the temperature at the outlet of the evaporator. If the evaporator pressure drop is low, these measurements (the saturation pressure and the temperature of the refrigerant) are an indication of superheat. The desired superheat is set by the spring in the valve operator, which together with the saturation pressure in the evaporator opposes the opening of the valve. The "superheat feeler bulb" pressure balances these forces when the unit is at equilibrium and is operating at the desired superheat (usually 9°F, or 5°C).



Expansion valve system for low evaporator drop with water regulating valve

Differential temperature expansion valve with overload protection

FIG. 8.12d
The control of the chiller's expansion valve depends on the type of operation. In installations with low evaporator drops, a superheat control valve is recommended (left), while at low-temperature applications, the differential temperature-type valve (right) gives more sensitive performance.

If the process load increases, it causes an increase in the evaporator outlet temperature. An increase in this temperature results in a rise in the "feeler bulb" pressure, which in turn further opens the superheat control valve. This greater flow of refrigerant liquid from the condenser to the evaporator increases the saturation pressure and temperature, and the increased saturation pressure balances against the increased feeler bulb pressure at a new (greater) valve opening in a new equilibrium. As the controls adjust to an increased load, the evaporator pressure increases, but the amount of superheat (set by the valve spring) is kept constant.

On the left side of Figure 8.12d, the operation of the cooling water regulating valve is also illustrated. This valve maintains the condenser pressure constant and at the same time conserves cooling water. At low condenser pressure, such as when the compressor is down, the water valve closes. It starts to open when the compressor is restarted and its discharge pressure reaches the setting of the PCV valve. The water valve opening follows the load by further opening at higher loads in order to maintain the condenser pressure constant. This feature too can be incorporated into any one of the refrigeration units.

When operating at very low temperatures, a small change in refrigerant vapor pressure results in a fairly large change in temperature. For example, a 5°F (2.8°C) temperature change when Freon-12 is at the temperature of –100°F (–73°C) will result in a 0.3 PSIG (2.1 kPa) change in saturation pressure. Therefore, a more sensitive measurement will result if a thermal bulb is used to indirectly detect the saturation pressure in the evaporator. On the right side of Figure 8.12d, a differential temperature-type expansion valve is shown, which takes advantage of the high temperature sensitivity at low operating temperatures.

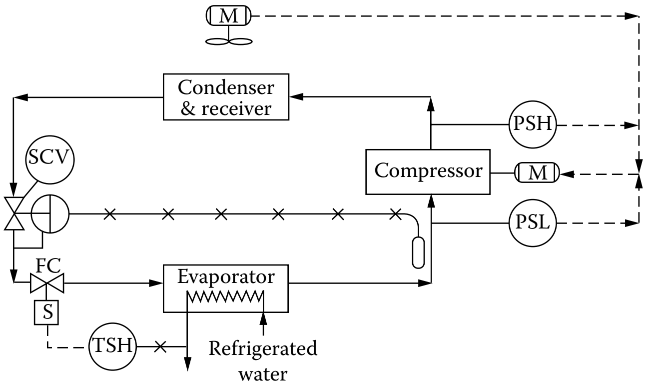


FIG. 8.12e
Small industrial refrigeration units can be controlled in an on/off manner. In this configuration the machine is started when the refrigerated water temperature reaches a preset high and stopped when it reaches a preset low limit.

On/Off Control of Small Units Figure 8.12e shows the controls for a fairly simple and small refrigeration unit. This system includes a conventional superheat control valve, a low-pressure-drop evaporator, a reciprocating on/off compressor, and an air-cooled condenser. The purpose of this refrigeration package is to maintain the temperature of a chilled water supply to the plant within some set limits.

The high-temperature switch (TSH) shown in Figure 8.12e is the main controller. Whenever the temperature of the chilled water drops below a preset value (usually 38°F, or 3.3°C), the refrigeration unit is turned off, and when the chilled water temperature rises to some other level (such as 42°F, or 5.6°C), it is restarted. This on/off cycling control is accomplished by the temperature switch, which is opening and closing a solenoid valve to keep the water temperature low enough. The closing of this valve causes the compressor suction pressure to drop. When it reaches the set point of the low-pressure switch (PSL), it stops the compressor.

While the unit is running, the expansion valve maintains the refrigerant superheat constant and the safety interlocks protect the equipment. These interlocks include such features as turning off the compressor if the fan motor stops or if the compressor discharge pressure becomes too high (PSH) for some other reason.

This unit cannot throttle its level of operation, it can operate only at full compressor capacity or not at all. This type of machine is referred to as a unit that has two-stage unloading. When continuous load following and therefore the varying of the cooling capacity is desired instead of turning it on and off, two possible control techniques are available. One of these approaches is the multistep unloading of reciprocating compressors. In a three-step system the available levels of loading are 100%, 50%, and 0%, whereas with five-step unloading, 100%, 75%, 50%, 25%, and 0% loads can be handled.

Multistage Refrigeration Units It is not practical to obtain a compression ratio outside the range of 3:1 to 8:1 with the compressors used in the process industry. This places a limitation on the minimum temperature that a single-stage refrigeration unit can achieve.

For example, if Freon-12 was the refrigerant, in order to maintain the evaporator at −80°F (−62°C) and the condenser at 86°F (30°C), which is compatible with standard supplies of cooling water, the required compression ratio could be calculated as follows:

$$\text{compression ratio} = \frac{\text{refrigerant pressure at } 86°\text{F}}{\text{refrigerant pressure at} - 80°\text{F}} = \frac{108}{2.9} = 37 \qquad \textbf{8.12(2)}$$

(In the next section, where chiller optimization is discussed, the control of multiple positive-displacement compressors, used in parallel and serving an unlimited number of evaporator coils, will be described.)

Industrial Chillers

The refrigeration unit shown in Figure 8.12f, although far from a "standard" system, does contain some of the features typical of conventional industrial units in the 500 ton (1760 kW) and larger sizes. These features include the capability for meeting continuous changing loads in a continuous manner, as contrasted with stepwise unloading. Other features included are the economizer expansion valve system and the hot gas bypass, which serve to increase rangeability.

The illustrated system provides refrigerated water at 40°F (4.4°C) through the circulating header system to the users of an industrial plant. If the flow rate is fairly constant, changes in the process load will be reflected by the temperature of the returning refrigerated water. Under normal load conditions, this return water temperature is controlled at 50°F (10.6°C) by TIC-2.

As process load decreases, the return water temperature drops correspondingly. With the reduced load on the evaporator, the refrigerated water supply temperature to the plant also drops and the direct acting TIC-1 gradually closes the suction damper or the prerotation vane of the compressor. By throttling the suction vane, a 10:1 turndown ratio can be accomplished. If the load drops below this ratio, the hot gas bypass system has to be activated.

Hot Gas Bypass The hot gas bypass is automatically controlled by TIC-2. Its purpose is to keep the constant-speed compressor out of surge. Therefore, when the load drops to levels sufficiently low to approach surge, this bypass valve is opened. If the chilled water flow rate is constant, the difference between chilled water supply and return temperatures is an indication of the load.

If full load corresponds to a 15°F (8.3°C) difference on the chilled water side of the evaporator and the chilled water supply temperature is controlled by TIC-1 at 40°F (4.4°C), then the return water temperature detected by TIC-2 is also an indication of the load.

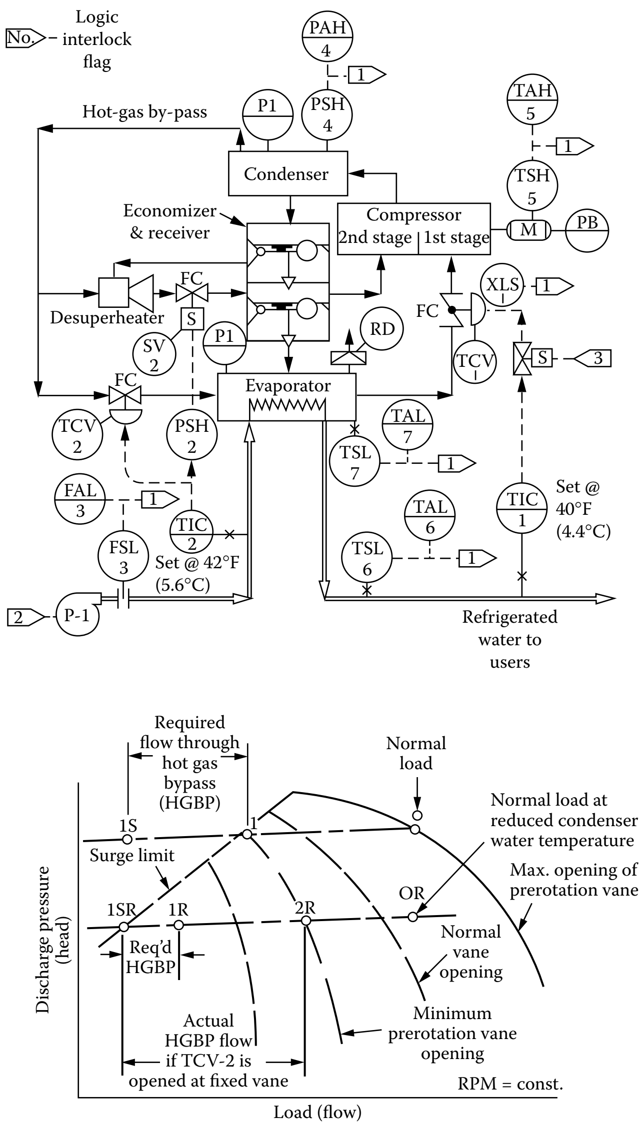

FIG. 8.12f

The rangeability of a conventionally controlled industrial refrigeration system is increased by the addition of a hot gas bypass. (Bottom part of this illustration adapted from Reference 2.)

If the compressor goes into surge at 10% load, this would correspond to a return water temperature of 41.5°F (5.3°C). In order to stay safely away from surge (for a detailed discussion of the phenomenon of surge, refer to the section on compressor control in this chapter), TIC-2 in Figure 8.12f is set at 42°F (5.6°C), corresponding to a load of approximately 13%.

When the temperature drops to 42°F (5.6°C), the bypass control valve TCV-2 starts to open, and its opening can be proportional to the load detected. This means that the valve is fully closed at 42°F (5.6°C), fully open at 40°F (4.4°C), and throttled in between. This throttling action is accomplished by a plain proportional controller (TIC-2), which has a 2°F throttling range. If the span is 0–100°F, this corresponds to a proportional band of 2% or a gain of 50.

The hot gas bypass makes it theoretically possible to achieve a very high turndown ratio by temporarily running the machine on close to zero process load. This operation can be visualized as heat pump, which is transferring heat energy from the refrigerant itself to the cooling water. During this process, some of the refrigerant vapors are condensed, resulting in an overall lowering of operating pressures on the refrigerant side.

The main advantage of a hot gas bypass, therefore, is that it allows the chiller to operate at low loads without going into surge. The price of this operational flexibility is an increase in operating costs, because the work introduced by the compressor is wasted in the form of friction through the hot gas bypass valve (TIC-2). As will be shown in the next section, optimized control systems eliminate this waste through the use of variable-speed compressors, which can respond to a reduction in load by lowering their speed instead of throwing away the unnecessarily introduced energy in the form of friction in TCV-1 and TCV-2.

Instead of controlling the hot gas bypass on the basis of return water temperature (as in the upper part of Figure 8.12f), other conventional packages control it on the basis of the opening of prerotation vanes. This is illustrated in the lower portion of Figure 8.12f. The problem with opening the hot gas bypass when the prerotation vane has closed to some fixed point is that this control technique disregards condensing temperature. This causes the hot gas bypass to open sooner and to a greater extent than needed.

This is also illustrated in the lower section of Figure 8.12f, where under normal loads the compressor operates at point "O." As the load drops off at constant discharge pressure (constant condenser temperature), the prerotation vane is gradually closed to its minimum allowable opening, until at point "1" the hot gas bypass is opened, to protect the compressor from going into surge. If the actual load drops to "1S," the HGBP will furnish the differential flow between "1S" and "1."

Now, if the cooling water temperature is reduced, normal operation falls to point "OR." As the load drops, the fixed minimum setting on the prerotation vane is reached at point "2R." This is much sooner than necessary. It is possible to obtain optimized controls that recognize the impact of cooling water temperature variations and in this case will open the HGBP only when load drops to point "1R."

Economizer Controls The economizer shown in Figure 8.12f can increase the efficiency of operation by 5–10%. This is achieved by the reduction of space requirements, savings on compressor power consumption, reduction of condenser and evaporator surfaces, and other effects. The economizer shown in Figure 8.12f is a two-stage expansion valve with two condensate chambers.

When the load is above 10%, the hot gas bypass system is inactive. Condensate is collected in the upper chamber of the economizer, and it is drained under float level control, driven by the condenser pressure. The pressure in the lower chamber floats off the second stage of the compressor, and it, too, is drained into the evaporator under float level control, driven by the pressure of the compressor second stage. Economy is achieved as a result of the vaporization in the lower chamber by precooling the liquid that enters the evaporator and at the same time desuperheating the vapors that are sent to the compressor second stage.

When the load is below 10%, the hot gas bypass is in operation, and the solenoid valve SV-2, which is actuated by the high-pressure switch PSH-2, opens. Therefore, some of the hot gas goes through the evaporator and is cooled by contact with the liquid refrigerant, and some of the hot gas flows through the open solenoid into the economizer. This second portion is desuperheated by the injection of liquid refrigerant upstream of the solenoid, which protects against overheating the compressor.

Safety Interlocks Operating safety in Figure 8.12f is guaranteed by a number of interlocks. The first interlock system prevents the compressor motor from being started when one or more of the below listed conditions exist, and it also stops the compressor if any except the first condition listed below occurs while the compressor is running:

- Suction vane is open, detected by limit switch XLS-1
- Refrigerated water temperature is dangerously low, approaching freezing, as sensed by TSL-6
- Refrigerated water flow is low, measured by FSL-3
- Evaporator temperature has dropped near the freezing point, as detected by TSL-7
- Compressor discharge pressure (and, therefore, pressure in the condenser) is high, indicated by PSH-4
- Temperature of motor bearing or winding is high, detected by TSH-5
- Lubricating oil pressure is low (not shown in Figure 8.12f)

The second interlock system guarantees that the following pieces of equipment are started or are already running upon starting of the compressor:

- Refrigerated water pump (P-1)
- Lubricating oil pump (not shown)
- Water to lubricating oil cooler, if such exists (not shown)

The third interlock usually ensures that the suction vane is completely closed when the compressor is stopped.

CHILLED WATER PIPING CONFIGURATIONS

The proper control and optimization of chilled water distribution systems can only be accomplished if the piping layout of the plant allows for it. Figure 8.12g illustrates both a desirable and an undesirable piping layout.

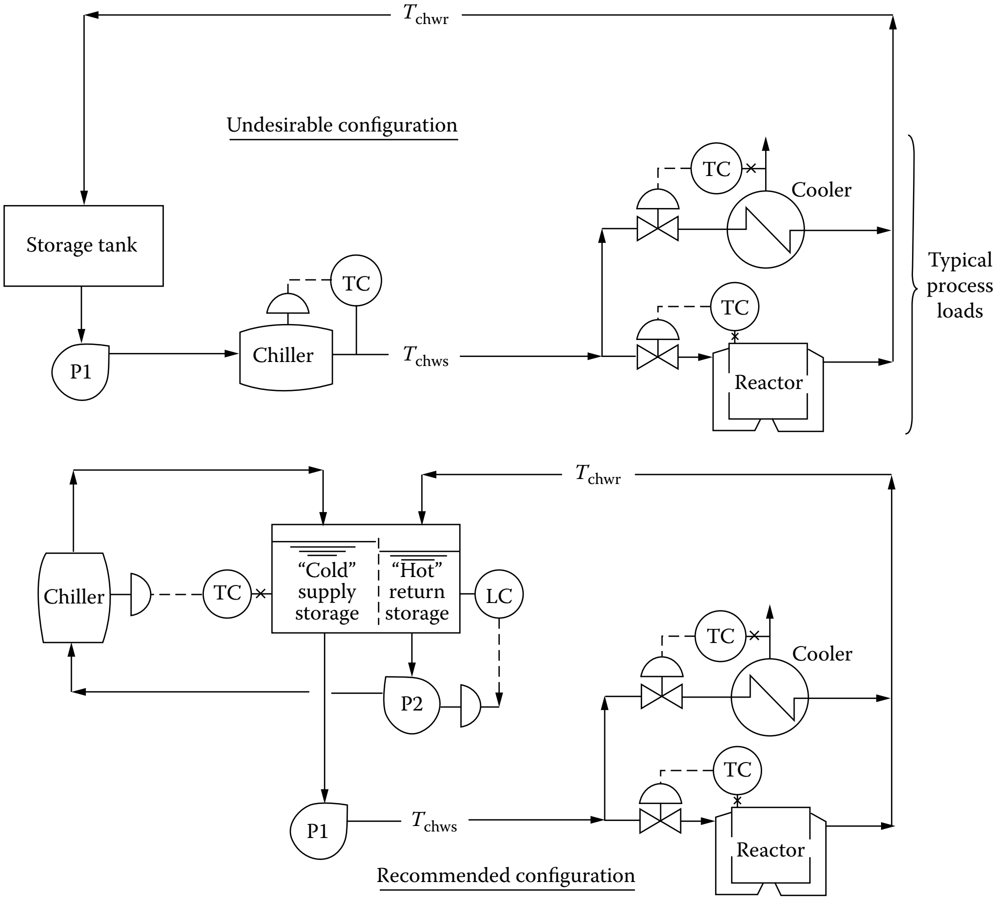

FIG. 8.12g

The proper configuration of the chilled water piping system is an essential element in minimizing upsets. The chiller should not be connected directly to the process loads (top). It is recommended that a storage tank be provided for both the supply of the cold chilled water and the water returning from the process (bottom).

There are two problems associated with the undesirable configuration shown at the top of the figure. One problem is that the layout does not provide chilled water storage, and therefore, if the chiller fails, the plant has to shut down. The other, even more serious problem is that if one of the loads (say the reactor) upsets the return water temperature (T_{chwr}), this in turn will upset the chilled water supply temperature (T_{chws}) to the whole plant.

The reason for this upset can be visualized by assuming that the reactor shown at the top of Figure 8.12g is a batch reactor that has just completed its heat-up phase, and the batch in the reactor is just starting to react. At this point exothermic heat is beginning to be generated, and therefore the jacket is switched from heating to cooling. If the operator is not careful, it is possible that as the chilled water enters the reactor jacket, it will displace the hot water still inside the jacket into the chilled water return line back into the storage tank.

As this slug of several hundred gallons of hot water travels through the storage tank, it will raise T_{chwr}, but the chiller will not know about that until this slug of warm water reaches it. At this point it is already too late, because the chiller can only start to increase its rate of cooling when the T_{chws} has already risen above the set point of the temperature controller (TC).

As a result, the chilled water supply temperature to the whole plant will be upset at each such occurrence. Actually, each of these occurrences will upset the plant's supply temperature twice: once when the slug of warm water arrives at the TC and once again when it had passed and therefore the T_{chws} temperature drops.

Adding Storage

The lower part of Figure 8.12g illustrates how one might eliminate both of these problems if the proper tanks and piping configuration are provided. Following the same sequence of events in this recommended piping layout, the same slug of warm water will not upset the whole plant, because it is received and blended in the "hot" return storage tank. Pump P2 takes the blended hot water from this tank (or tank section) and sends it through the chiller, which discharges it into the "cold" chilled water supply tank.

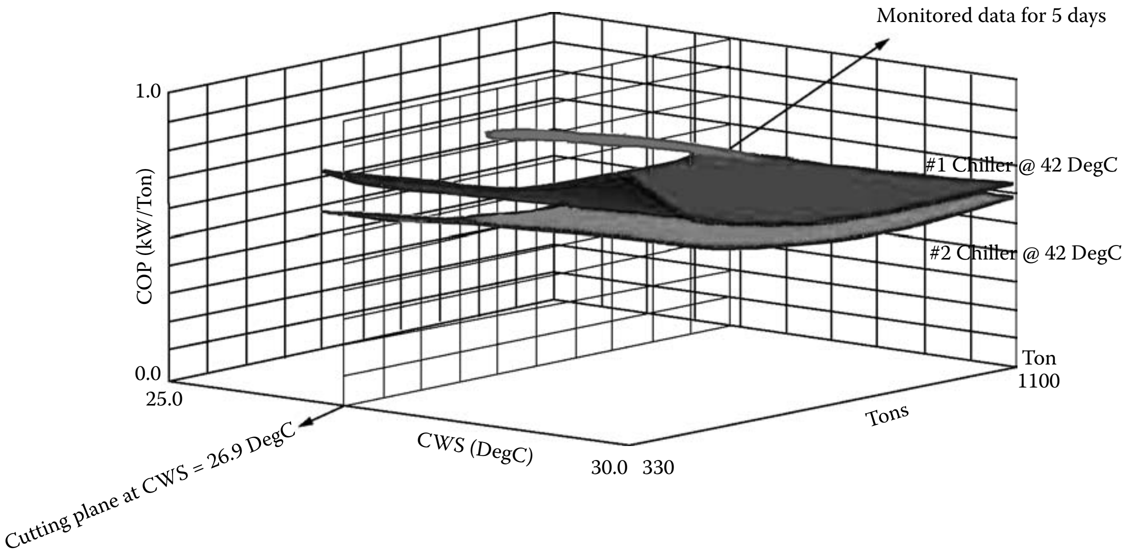

FIG. 8.12h

The differences between the performance of chillers and the changes in the coefficient of performance with load and temperature can be utilized to reduce operating costs.

In this configuration the TC is continuously maintaining the temperature of a fairly large amount of chilled water at the desired T_{chws} temperature. Therefore, the slug of warm water will not upset the supply to the plant at all. Even more important, the plant will be provided with a supply of ready-made chilled water. This safety storage of coolant can be very handy during emergencies, in power failures, or when the chiller is in need of maintenance.

CONCLUSIONS

The control of chillers is well understood. If the piping layout is properly configured and if both the cooling tower controls and the pumping controls are correctly designed, a well designed cooling system can be configured.

Figure 8.12h shows that the performance varies not only with the selection of the particular chiller, but also with the cooling load and with the temperature of the cooling water supply. These variations and other means can be exploited to continuously minimize the cost of meeting the cooling load of a plant. For a discussion of chiller optimization, refer to the next section.

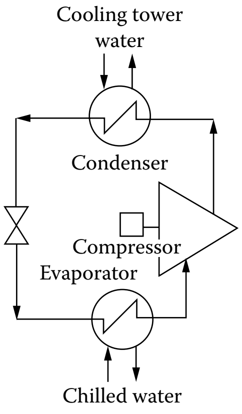
8.13 Chiller Optimization

B. G. LIPTÁK (1970, 1985, 1995, 2005)



Flow sheet symbol

INTRODUCTION

There are not many unit operations whose efficiency can be doubled through optimization. The chillers are one of these few. One unit of energy introduced at the chiller can remove 5, 6, or even 7 units of heat energy from the process, if the chiller controls are optimized. The previous section discussed the conventional chiller controls, while this section is devoted to chiller optimization.

Listed below are some of the performance characteristics of optimized chillers as contrasted to conventional ones:

- Coefficients of performance: 2.5–3.5 for conventional, 5–7 for optimized chillers.
- Operating cost reduction: 1.5% of yearly chiller operating cost per °F reduction in chiller ΔT, 1% of total cooling system operating cost per °F decrease in the cooling tower's approach (see Figure 8.13b for the definition of "approach"). A 10°F reduction in cooling tower water temperature cuts chiller operating costs by 30%.
- Pumping cost savings: 50–60 cents/gpm for each psid.
- Operating cost distribution: 60% chiller compressor, 15% ea. cooling tower and chilled water pumps, 10% cooling tower fans.
- Maximum turndown ratios: 8:1 for conventional, over 30:1 with hot gas bypass.
- Typical superheat at evaporator outlet: 9°F (5°C).

In order to fully optimize a cooling system, in addition to the chiller, it is necessary to also optimize cooling tower controls, the water distribution, and the pumping systems, as will be discussed in the sections that follow.

THE TOTAL COOLING SYSTEM

The piping layout of a conventional cooling system is illustrated in Figure 8.13a. In order to develop a completely generalized method for controlling and optimizing such systems, the duplication of equipment will be disregarded, and all chiller systems will be treated as if they were configured as shown in Figure 8.13b. Here any number of cooling towers, pumps, or chillers are represented by single units, because variations in their numbers will not affect the overall optimization strategy.

In this generalized cooling system, the first heat transfer step is when the cooling load from the process is transferred to the chilled water. In the second step, the heat carried by the chilled water is transferred to the refrigerant in the evaporator. The refrigerant takes the heat to the condenser, where in the third step the heat is transferred to the cooling tower water, so that it might finally be rejected to the ambient air.

This heat pump operation involves four heat transfer substances (chilled waster, freon or other refrigerant, cooling tower water, and air) and four heat exchanger devices (process heat exchanger, evaporator, condenser, cooling tower). The total system operating cost is the sum of the costs of circulating the four heat transfer substances ($M1$, $M2$, $M3$, and $M4$ in Figure 8.13b).

In the traditional (unoptimized) control systems, such as the one illustrated in Figure 8.12f, each of these four systems were operated independently in an uncoordinated manner. In addition, the conventional control systems did not vary the speed of the four transportation devices ($M1$ to $M4$). By operating them at constant speeds, they introduced more energy than was needed for the circulation of refrigerant, air, or water and therefore they had to waste that excess energy.

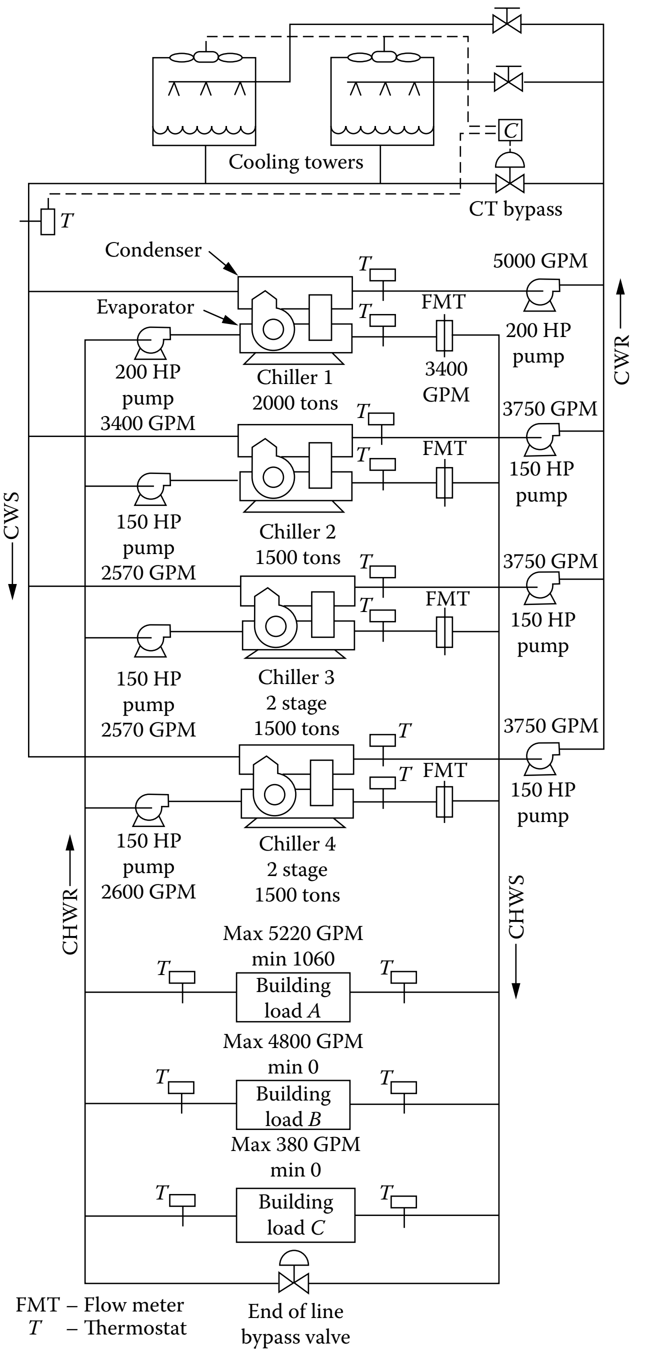


FIG. 8.13a

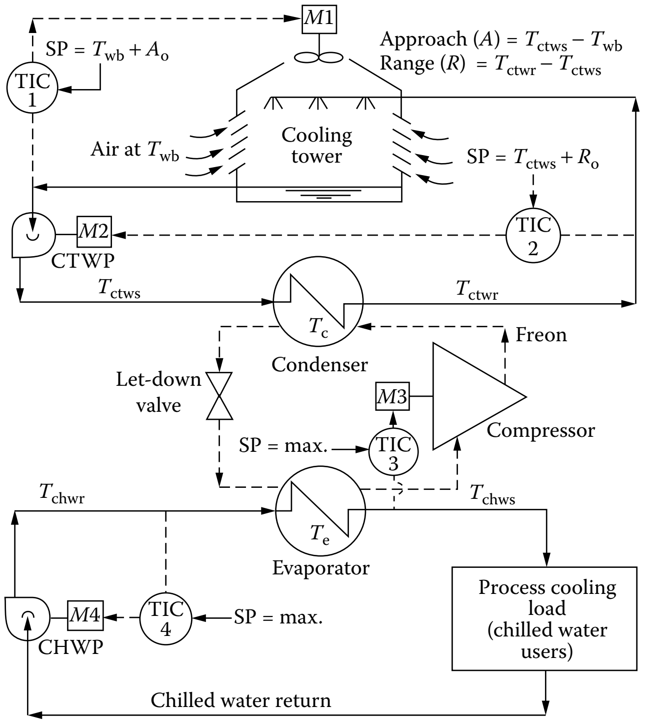
A typical overall cooling system utilizes four heat transfer substances (CWS, CWR, CHWS, CHWR) and four heat exchange devices (cooling towers, chiller condenser, chiller evaporator, process heat exchangers).[1]



Abbreviations:

A_o : Optimum approach
R_o : Optimum range
T_{wb} : Wet bulb temp.
T_{ctws} : Cooling tower water supply temp.
T_{ctwr} : Cooling tower water return temp.
T_{chws} : Chilled water supply temp.
T_{chwr} : Chilled water return temp.
CTWP: Cooling tower water pump
CHWP: Chilled water pump
T_c : Freon temperature in condenser
T_e : Freon temperature in evaporator

FIG. 8.13b

In order to optimize a cooling system, the cooling tower(s), the pumping stations, the chiller(s), and the process equipment should be treated as an integrated single system.[2]

OPTIMIZING MECHANICAL REFRIGERATION SYSTEMS

Load-following optimization eliminates the waste resulting from constant speed operation by operating the aforementioned four systems as a coordinated single process, with the goal to keep the cost of operation at a minimum. In this control system, the controlled variables are the supply and return temperatures of chilled and cooling tower waters, and the manipulated variables are the flow rates of chilled water, refrigerant, cooling tower water, and air.

If water temperatures are allowed to float in response to load and ambient temperature variations, the waste associated with keeping them at arbitrarily selected fixed values is eliminated, and the operating cost of the cooling system is drastically reduced.

In order to control the total refrigeration system depicted in Figure 8.13b, four control loops must be configured. In these four loops the controlled (measured) variables are the four water temperatures, and the four manipulated variables are the four motor speeds ($M1$ to $M4$) that drive the four transportation devices. Table 8.13c lists the controlled and the manipulated variables in each of these loops and also indicates the optimization criteria for determining the set points of the four controllers.

TABLE 8.13c
Control Configuration and Optimization Criteria for the Four Loops Controlling a Chiller

Loop No.	Controlled Variable	Manipulated Variable	Optimization Criteria (Set Points of the Temperature Controllers)
1	CT water supply temperature (T_{ctws})	Air flowrate obtained by level of fan operation ($M1$)	Optimum approach (A_o) is selected to keep the sum $M1 + M2 + M3$ to a minimum. Therefore, TIC set point becomes: $T_{\text{ctws}} = T_{\text{wb}} + A_o$
2	CT water return temperature (T_{ctwr})	Rate of CT water pumping ($M2$)	The optimum range (R_o) of CT is found as a function of the A_0. Therefore, the TIC set point becomes: $T_{\text{ctwr}} = T_{\text{ctws}} + R_o$
3	Chilled water supply temperature (T_{chws})	Rate of chiller compressor operation ($M3$)	The optimum TIC set point is the maximum T_{chws} temperature, which will satisfy *all* the process loads
4	Chilled water return temperature (T_{chwr})	Rate of chilled water pumping ($M4$)	The optimum TIC set point is the maximum T_{chwr} temperature that will satisfy all the process loads

Minimizing the Operating Cost

The yearly cost of operating the total cooling system can typically be broken down as follows:

$M1$ (Fans)	10%
$M2$ (CT Pumps)	15%
$M3$ (Compressors)	60%
$M4$ (CH Pumps)	15%
TOTAL:	100%

These costs vary a great deal. The proportion of $M1$ increases in warm weather regions. $M2$ and $M4$ increase when water transport lines are long and the proportion of $M3$ is lowered as the maximum allowable chilled water temperature rises. But regardless of these proportions in a particular installation, the goal of optimization is to find the minimum chilled water and cooling tower water temperatures that will result in meeting the needs of the process at minimum cost.

The overall control system can be reviewed in two steps: First one can look at the chilled water side (the evaporator side), then at the cooling tower water side (condenser side).

The Chilled Water Side The optimization of the lower (evaporator) portion of Figure 8.13b is easily comprehended, because the sum of $M3$ and $M4$ will be the minimum when both the chilled water supply and return temperatures (T_{chws} and T_{chwr}) are as high as the process will permit. This is true under all load conditions, because the amount of work that the chiller compressor has to do is reduced as the suction pressure rises, and this is the case whenever the evaporator temperature (T_{chws}) rises.

Therefore, the optimum set point of TIC-3 is the allowable maximum chilled water supply temperature. Consequently, the minimum cost of operation will be achieved when the chilled water supply temperature has been maximized, but it can be maximized only to the point where it can still provide all the cooling that is required by any part of the process. The method of finding that maximum value will be discussed later.

The chilled water pumping cost ($M4$) depends only on the ΔT across the process users. The higher this ΔT, the less water needs to be pumped to remove the required amount of heat. As the chilled water supply temperature is set by the load, this ΔT can be maximized only by maximizing the chilled water return temperature (T_{chwr}). Therefore, the optimum set point for TIC-4 is the allowable maximum. By increasing this return temperature, the following benefits result:

1. The power consumed by $M3$ is lowered by 1.5% per °F rise.
2. The heat transfer efficiency of the evaporator is improved by increasing the ΔT through it.
3. Assuming that on the average the ΔT is 15°F, increasing it by 1°F will lower $M4$ by about 6%.

As $M3$ is about 60% and $M4$ about 15% of the total operating cost, a 1°F decrease in ΔT will lower the yearly cost of operation by about $(1 \times 60)/100 + (6 \times 15)/100 = 1.5\%$.

The Cooling Tower Water Side Finding the optimum cooling tower water temperatures is more complicated, because changing the cooling tower water supply and return temperatures will increase some costs, while it will also lower some others. For example (as it is shown in Figure 8.17d), an increase in the cooling tower water supply temperature (T_{ctws}) will increase the tower's approach and the cost of chiller operation but will reduce the amount of work the cooling tower fans need to do.

Therefore, the optimum temperature in not necessarily the minimum temperature (or approach) that the towers are capable of providing, but rather the temperature that can meet the particular load at the minimum total cost of operation of all the equipment ($M1 + M2 + M3$). Figure 8.13d illustrates that this is a function of the load and of the weather. When the conditions are such that a lowering of the approach (or T_{ctws}) would require a large increase in fan operating costs ($M1''$), the minimum point on the total cost curve (A_0'') will be above the minimum attainable approach (A_0').

Inversely, if the approach can be reduced with a small increase in fan operating costs ($M1'$), the optimum operating point for the total system will correspond to the minimum T_{ctws} temperature and therefore to the minimum attainable approach (A_0'). Whichever is the applicable total cost curve

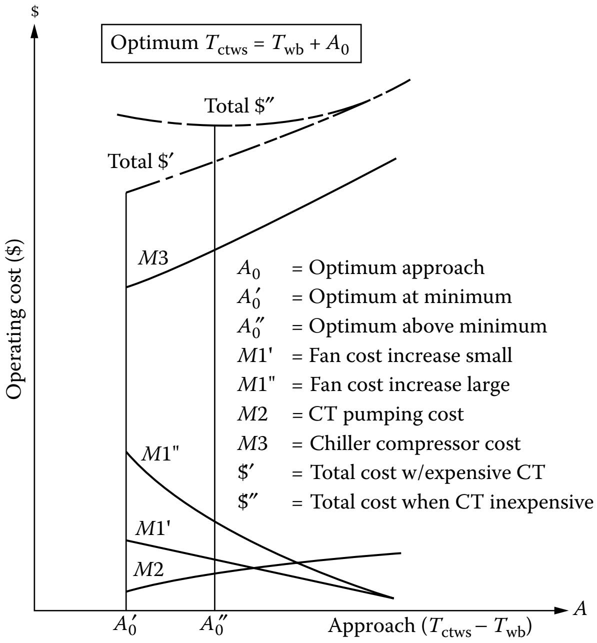


FIG. 8.13d
The empirically determined operating costs are shown as a function of the approach at two cooling loads. The optimum approach at each load is the one that corresponds to the minimum total cost of operation.

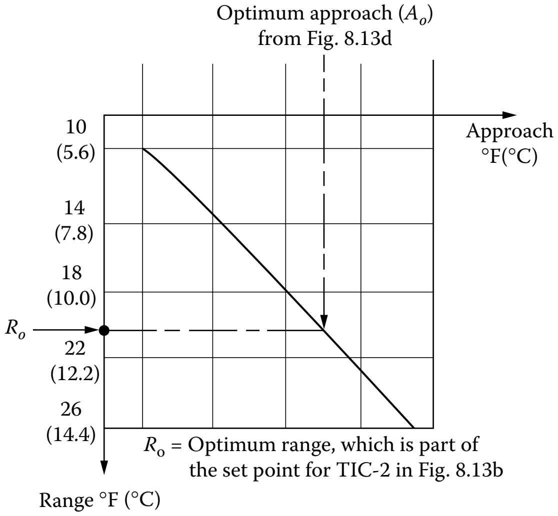

FIG. 8.13e
The optimum range for a particular cooling tower is a function of the approach at which it is operating. Therefore, R_0 can be found on the basis of A_0.

($′ or $″), the T_{ctws} temperature that corresponds to the minimum point becomes the set point for TIC-1 in Figure 8.13b.

The curves in Figure 8.13d can be based on the measurement of the actual total operating cost, on a projected cost based on past performance, or on some combination of the two. The continuous storing and updating of the operating cost history as a function of load, ambient conditions, and equipment configuration will not only provide the curves required for optimization but can also be used to signal the need for maintenance.

In Figure 8.13d the optimum T_{ctws} is found by summing $M1$, $M2$, and $M3$. In most installations the major cost element is $M3$, which increases by about 1.5% of compressor operating cost (or 1% of total cooling system cost) for each 1°F reduction in approach.

The cost-vs.-approach curve is not necessarily a smooth one, because if constant-speed machines are stopped and started or if positive-displacement compressors are loaded and unloaded, there will be steps in the $M3$ curve. This also is true for constant speed fans ($M1$) or pumps ($M2$). The pumping cost also increases as approach rises, but $M2$ is usually only a fraction of $M3$, unless the piping is very long or undersized.

The fan cost $M1$ tends to drop off as approach rises. If the load is low relative to the size of the cooling towers, the rate of increase in $M1$ with a reduction in approach will also be small. In such cases ($M1'$) the optimum approach (A_0') corresponds to the safe lowest temperature that the tower can generate. If, on the other hand, the load is high, the fan cost of lowering approach will also increase ($M1''$). In that case, the optimum approach (A_0') is at some intermediate value.

The optimum return water temperature back to the cooling tower (T_{ctwr}) can be found by determining the optimum range (R_o) for the particular set of operating conditions. The relationship between operating approach and range is a function of the particular cooling tower design. Therefore, if one has determined the optimum approach for a particular set of conditions A_o (from Figure 8.13d), that value can be used to arrive at the optimum range (R_o) in Figure 8.13e.

The set point for TIC-2 in Figure 8.13b then becomes the sum of the already-determined T_{ctws} and the optimum range:

$$T_{\text{ctwr}} = T_{\text{ctws}} + R_o \qquad \textbf{8.13(1)}$$

Chilled Water Supply Temperature Optimization

The yearly operating cost of a chiller is reduced by about 1.5% for each 1°F (0.6°C) reduction in the temperature difference across this heat pump. In order to minimize this difference, T_H must be minimized and T_L maximized. Therefore, the optimum value of T_{chws} is the maximum temperature that will still satisfy all the loads. Figure 8.13f illustrates a method of continuously finding and maintaining this maximum value.

It should be noted that an energy-efficient refrigeration system cannot be provided by instrumentation alone. Equipment sizing and selection also play an important part in the overall result. For example, the evaporator heat transfer area should be maximized so that T_L is as close as possible to the average chilled water temperature in the evaporator.

Similarly, the refrigerant flow should be made to match the load by adjusting the compressor motor speed and not by refrigerant throttling. TCV-1 and TCV-2 in Figure 8.12f in the previous section represent sources of energy waste, whereas

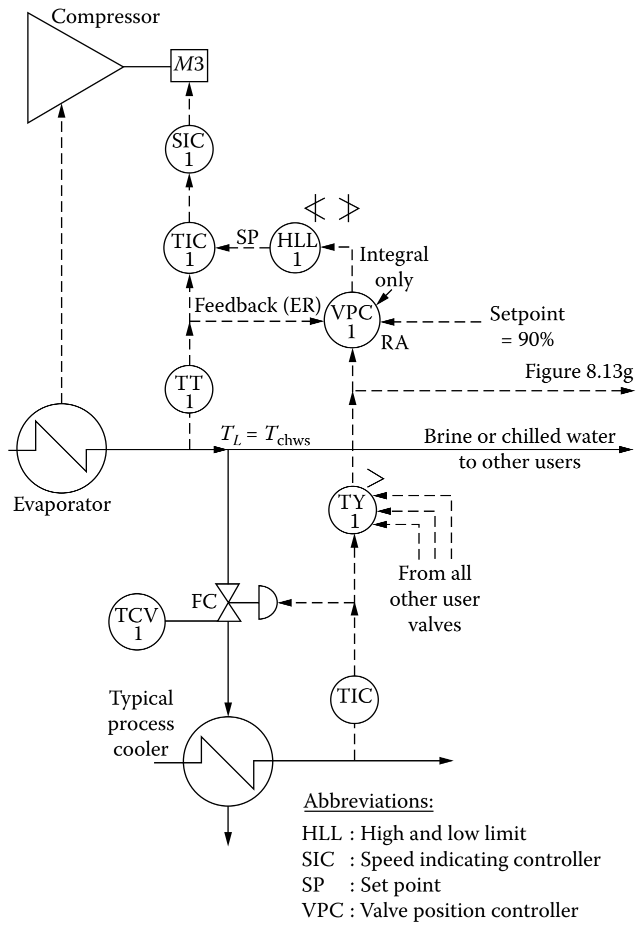

FIG. 8.13f

Maximizing the chilled water supply temperature by load-following floating control is a means of continuously finding and maintaining this temperature at its optimum value.

Figure 8.13f shows the energy-efficient technique of motor speed control by eliminating TCV-2. This load-following mode of operation can be achieved by using variable-speed drives on electric motors or by using steam turbine drives.

If several constant-speed motors are used, then all compressors except one should be driven to the loading level at which they are most efficient (TCV-1 and TCV-2 in Figure 8.12f fully open). The remaining one compressor should be used to match the required load by throttling.

Maximizing T_{chws} Figure 8.13f shows the proper technique of maximizing the chilled water supply temperature in a load-following, floating manner. The optimization control loop guarantees that all chilled water users in the plant will always be satisfied while the chilled water temperature is maximized. This is done by selecting (by TY-1) the most open chilled water valve in the plant and comparing that opening with the 90% set point of the valve position controller, VPC-1. If even the most open valve is less than 90% open, the set point of TIC-1 is increased; if the valve opening exceeds 90%, the TIC-1 set point is decreased.

This technique allows all the process users to obtain more cooling (by further opening their chilled water supply valves) if needed, while the header temperature is continuously maximized. The VPC-1 set point of 90% is adjustable. Lowering it gives a wider safety margin, which might be required if some of the processes that are being cooled are very critical. On the other hand, increasing the set point will maximize energy conservation at the expense of a reduced safety margin.

An additional benefit of this load-following optimization strategy is that because all chilled water valves in the plant are opened as T_{chws} is maximized, valve cycling is reduced and pumping costs are lowered. This is so because when all chilled water valves are opened they require less pressure drop and therefore less discharge pressure from the pumps. Similarly, valve cycling is eliminated, because by increasing the opening of all user valves, they are moved away from the unstable region near their closed position.[2]

In order for the control system in Figure 8.13f to be stable, it is necessary to use an integral-only controller for VPC-1, with an integral time that is tenfold that of the integral setting of TIC-1 (usually several minutes). This control mode selection is needed to allow the optimization loop to be stable when the valve opening signal selected by TY-1 is either cycling or noisy.

The high/low limits (HLL-1) on the set-point signal to TIC-1 guarantee that VPC-1 will not drive the chilled water temperature to unsafe or undesirable levels. Because these limits can block the VPC-1 output from affecting T_{chws}, it is necessary to protect VPC-1 against reset windup. This is done through the external feedback signal shown in Figure 8.13f.

Chilled Water Return Temperature Optimization

The combined cost of operating the chilled water pumps and the chiller compressor ($M4 + M3$) is a function of the temperature drop across the evaporator ($T_{chwr} - T_{chws}$). Because an increase in this ΔT decreases compressor operating costs (suction pressure rises) while also decreasing pumping costs (the higher the ΔT the less water needs to be pumped), the aim of this optimization strategy is to maximize this ΔT.

Maximizing T_{chwr} This ΔT will be the maximum when the chilled water flow rate across the chilled water users is the minimum. As T_{chws} is already controlled, this ΔT will be maximized when T_{chwr} is maximum. This goal can be reached by evaluating the opening of the most-open chilled water valve in Figure 8.13f and, if even the most-open chilled water valve is not yet fully open, making adjustments to further open it.

The steps that can be taken include increasing the chilled water supply temperature (set point of TIC-1 in Figure 8.13f), or increasing the temperature rise across the process users by lowering the ΔP across the users (set point of PDIC-1 in Figure 8.13g). Both methods can also be used simultaneously.

Increasing the chilled water supply temperature reduces the yearly compressor operating cost ($M3$) by approximately 1.5% for each °F of temperature increase, whereas lowering

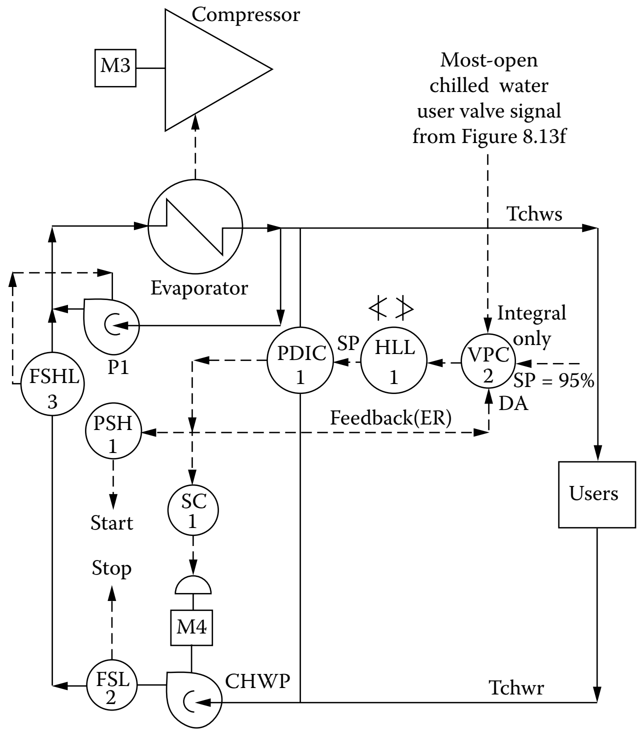

FIG. 8.13g

Adjusting the chilled water flow rate such that the most open user valve is nearly full will keep the evaporator ΔT and chilled water return temperature always at their maximum (optimum) values.

the ΔP across the users reduces the yearly pump operating cost ($M4$) by approximately 50 cents/gpm for each psid.

The set points of the two valve position controllers (VPC-1 in Figures 8.13f and VPC-2 in 8.13g) will determine if these adjustments are to occur in sequence or simultaneously. If both set points are adjusted to be the same, simultaneous action will result, while if one adjustment is economically more advantageous or safer than the other, the set point of the corresponding VPC should be set lower than the other.

This will result in sequencing, which means that the more cost-effective or safer correction will take place before the less effective one is started. In Figures 8.13f and 8.13g, it was assumed that increasing T_{chws} is the more cost-effective step. This is not always the case, and even when it is, there might be process reasons that make it undesirable to allow the floating of T_{chws} up or down.

If the settings are as shown, the system will function as follows: If the most open valve is less than 90% open, VPC-2 in Figure 8.13g will lower the set point of PDIC-1, and VPC-1 in Figure 8.13f will increase the set point of TIC-1. When the opening of the most-open valve reaches 90%, VPC-1 in Figure 8.13f will slowly start lowering the TIC set point, while VPC-2 in Figure 8.13g will continue to lower the set point of PDIC-1.

If VPC-1 in Figure 8.13f did not lower the TIC set point sufficiently (or if the lowering was not fast enough) and the most-open user valve continues to open, and at 95% the VPC-2 in Figure 8.13g will take fast corrective action by quickly raising the set point of PDIC-1. Thus, no user valve will ever be allowed to open fully and go out of control as long as the pumps and chillers are sized so as to be capable of meeting the load.

Pump Speed Control VPC-2 in Figure 8.13g is the cascade master of PDIC-1, which guarantees that the pressure difference between the chilled water supply and return is always high enough to motivate water flow through the users but never so high as to exceed their pressure ratings. The high and low limits are set on HLL-1, and VPC-2 is free to float this set point within these limits to keep the operating cost at a minimum.

In order to protect against reset windup when the output of VPC-2 reaches one of these limits, an external feedback is provided from the PDIC-1 output signal back to VPC-2. The VPC is an integral-only controller, which is tuned to be much more responsive (shorter integral time) than is VPC-1 in Figure 8.13f.

The high speed of response of the VPC in Figure 8.13g is also important from a safety point of view. This is because without it, in a conventional control system, the response can be too slow. In such a case, when the demand for cooling suddenly increases (because of some process difficulty), once the valve (TCV-1 in Figure 8.13f) is fully open, the amount of cooling provided cannot be increased faster than the rate at which the chiller can lower the chilled water supply temperature. This does take time, and therefore, if the cooling load evolves faster (runaway reaction in a reactor), accidents can occur.

This is not the case when the control system shown in Figure 8.13g is implemented, because as soon as the most-open chilled water valve has opened to 95%, VPC-2 will quickly speed up the chilled water pump (CHWP). Because water is incompressible, this will immediately increase the chilled water supply pressure in the main supply header, therefore, the water supply pressure to TCV-1 in Figure 8.13f will also rise, thereby immediately increasing the water flow and therefore the amount of cooling of the process.

This practically instantaneous action, utilizing the already-chilled water stored in the distribution headers, can be fast enough to arrest a runaway reaction. Naturally, once the chiller has had time to respond to the increase in load by lowering the chilled water supply temperature, this emergency action will no longer be needed and the water supply pressure will be lowered back to its normal setting.

Multiple and Bypass Pumps When the chilled water pump station consists of several pumps, only one of which is variable-speed, additional pump increments are started when PSH-1 in Figure 8.13g signals that the pump speed controller set point is at its maximum. When the load is dropping, the excess pump increments are stopped on the basis of flow, detected by FSL-2. In order to eliminate cycling, the excess pump increment is turned off only when the actual total flow has dropped to less than 90% of the capacity of the remaining pumps.

The load-following optimization loop in Figure 8.13f and 8.13g will float the total chilled water flow to achieve maximum overall economy. In order to maintain efficient heat transfer and the required turbulence within the evaporator, a small local circulating pump (*P*1) is provided at the evaporator. This pump is started and stopped by FSHL-3 in Figure 8.13g, guaranteeing that the water velocity in the evaporator tubes will never drop below the adjustable limit of about 4 fps (1.2 m/s).

Cooling Tower Supply Temperature Optimization

As discussed in more detail in Section 8.17, minimizing the temperature of the cooling tower water is one of the most effective contributors to chiller optimization. Conventional control systems in the past produced constant cooling tower temperatures of 75°F (23.9°C) or higher.

It is an enemy of efficiency and therefore of optimization to maintain a utility at a constant value. Each 10°F (5.6°C) reduction in the cooling tower water temperature will reduce the yearly operating cost of the compressor by approximately 15%. For example, if a compressor is operating at 50°F (10°C) condenser water instead of 85°F (29.4°C), it will meet the same load while consuming half as much power. Operation at condenser water temperatures of 50°F (10°C) or even less can be quite practical during the winter months. Savings exceeding 50% have been reported.[3]

Minimizing T_{ctws} As shown in Figure 8.13h, an optimization control loop is required in order to maintain the cooling tower water supply continuously at an economical minimum temperature. This minimum temperature is a function of the wet-bulb temperature of the atmospheric air. The cooling tower cannot generate a water temperature that is as low as the ambient wet bulb, but can approach it. The temperature difference between T_{ctws} and T_{wb} is called the *approach*, as was shown in Figure 8.13d.

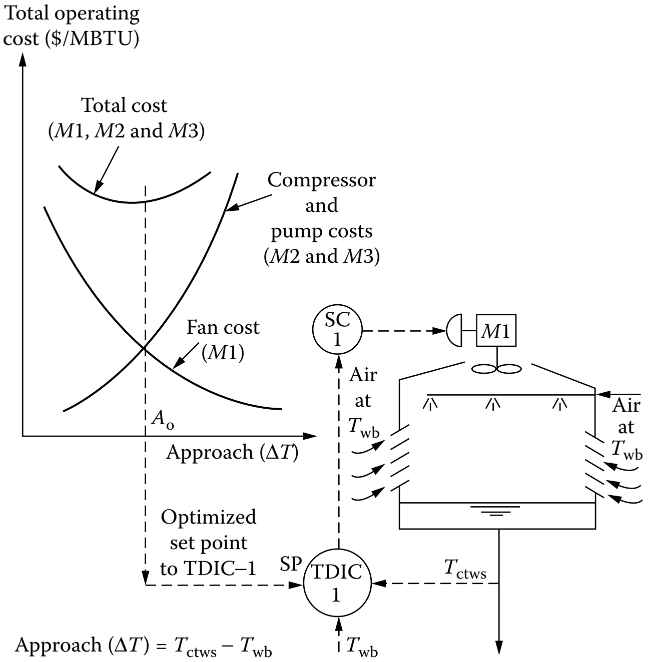

FIG. 8.13h
Optimizing (minimizing) the cooling tower water supply temperature requires that the fan speed be so modulated as to keep the approach ($T_{ctws} - T_{wb}$) at a value that corresponds to the minimum cost of operation.

Figure 8.13h illustrates the fact that as the approach and the cooling tower supply temperature increases, the cost of cooling tower fan operation drops, while the costs of pumping and of compressor operation increase. Therefore, the total operating cost curve has a minimum point that identifies the optimum approach, which corresponds to the minimum cooling tower temperature that will allow operation at an overall minimum cost. This approach (ΔT) automatically becomes the set point of TDIC-1, and this optimum approach will increase if the load on the cooling tower rises or if the ambient wet bulb increases.

If the cooling tower fans are centrifugal units or if the blade pitch is variable, the optimum approach is maintained by continuous throttling. If the tower fans are two-speed or single-speed units, the output of TDIC-1 will start and stop the fan units incrementally in order to maintain the optimum approach. In cases in which a large number of cooling tower cells constitute the total system, it is also desirable to balance the water flows to the various cells automatically as a function of the operation of the associated fans.

The water flows to all cells whose fans are at high speed should be controlled at equal and relatively high rates, while the cells with fans operating at low speeds should receive water at equal low flow rates. Cells with their fans off should be supplied with water at equal minimum flow rates. Subjects such as these and the cooling towers in general are discussed in more detail in Sections 8.16 and 8.17.

Cooling Tower Return Temperature Optimization

The optimum setting for T_{ctwr} is based on the optimum approach (A_o) obtained from Figure 8.13h, using the characteristic curve of the cooling tower depicted in Figure 8.13e. This curve relates the approach to the range for the particular tower design, and therefore once A_o is known, R_o can be obtained from it.

As shown in Figure 8.13i, the ΔT corresponding to this optimum R_o automatically becomes the set point of TDIC-1 in the optimized control loop. This controller is the cascade master of PDIC-1, which guarantees that the pressure difference between the cooling tower supply and return water flows is always high enough to provide the required flow through the process users but never so high as to cause damage. The high and low limits are set on HLL-1. TDIC-1 floats the PDIC-1 set point within these ΔP limits, to keep the operating cost at a minimum.

In order to protect against reset windup (when the output of TDIC-1 reaches one of these limits), an external feedback is provided from the output of PDIC-1 to TDIC-1.

When the cooling tower water pump station consists of several pumps, only one of which is variable-speed, additional

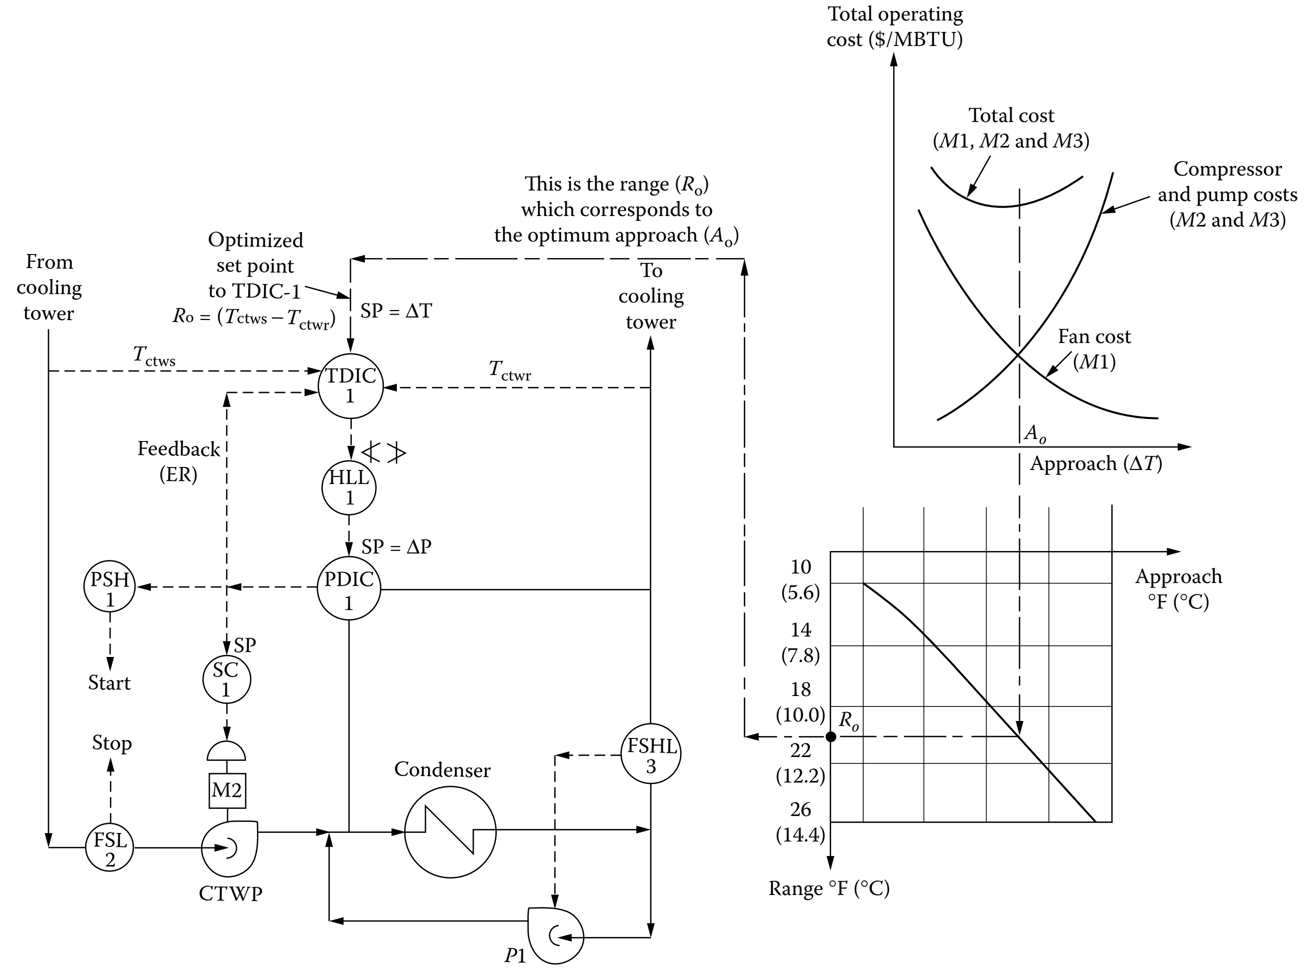

FIG. 8.13i

The cooling tower water flow rate is modulated to keep the ΔT of the chiller's condenser (R_0, the range of the cooling tower) at the value that corresponds to the optimum value of the approach.

pump increments are started when PSH-1 signals that the pump speed controller set point is at its maximum. When the load is dropping, the excess pump increments are stopped on the basis of *flow,* which is detected by FSL-2. In order to eliminate cycling, the excess pump increment is only turned off when the actual total flow is less than 90% of the capacity of the remaining pump(s).

The load-following optimization loop shown in Figure 8.13i will float the total cooling tower water flow to achieve maximum overall economy. In order to maintain efficient heat transfer and appropriate turbulence within the condenser, a small local circulating pump ($P1$) is provided at the chiller's condenser. This pump is started and stopped by FSHL-3, guaranteeing that the water velocity in the condenser tubes will never drop below the adjustable limit of 4 fps (1.2 m/s).

Heat Recovery Optimization

Figure 8.13j depicts the optimizing control loop required when the heat pumped by a chiller is recovered in the form of hot water and the hot water temperature is continuously optimized in a load-following floating manner.

If, at a particular load level, it is sufficient to operate with 100°F (37.8°C) instead of 120°F (48.9°C) temperature hot water, this technique will allow the chiller to meet the same tonnage of refrigeration load at 30% lower operating cost. The reason for this operating cost reduction is that the required discharge pressure of the chiller compressor depends on the hot water temperature in the split condenser.

The optimization control loop in Figure 8.13j guarantees that all hot water users in the plant will always obtain enough heat while the hot water temperature set point of TIC-1 is minimized. In this system TY-1 selects the most open hot water valve in the plant, and VPC-1 compares that with its 90% set point. If even the most open valve is less than 90% open, the set point of TIC-1 is decreased, and if this opening exceeds 90%, the TIC-1 set point is increased. This allows all users to obtain more heat (by further opening their supply valves) if needed, while the header temperature is continuously optimized (minimized).

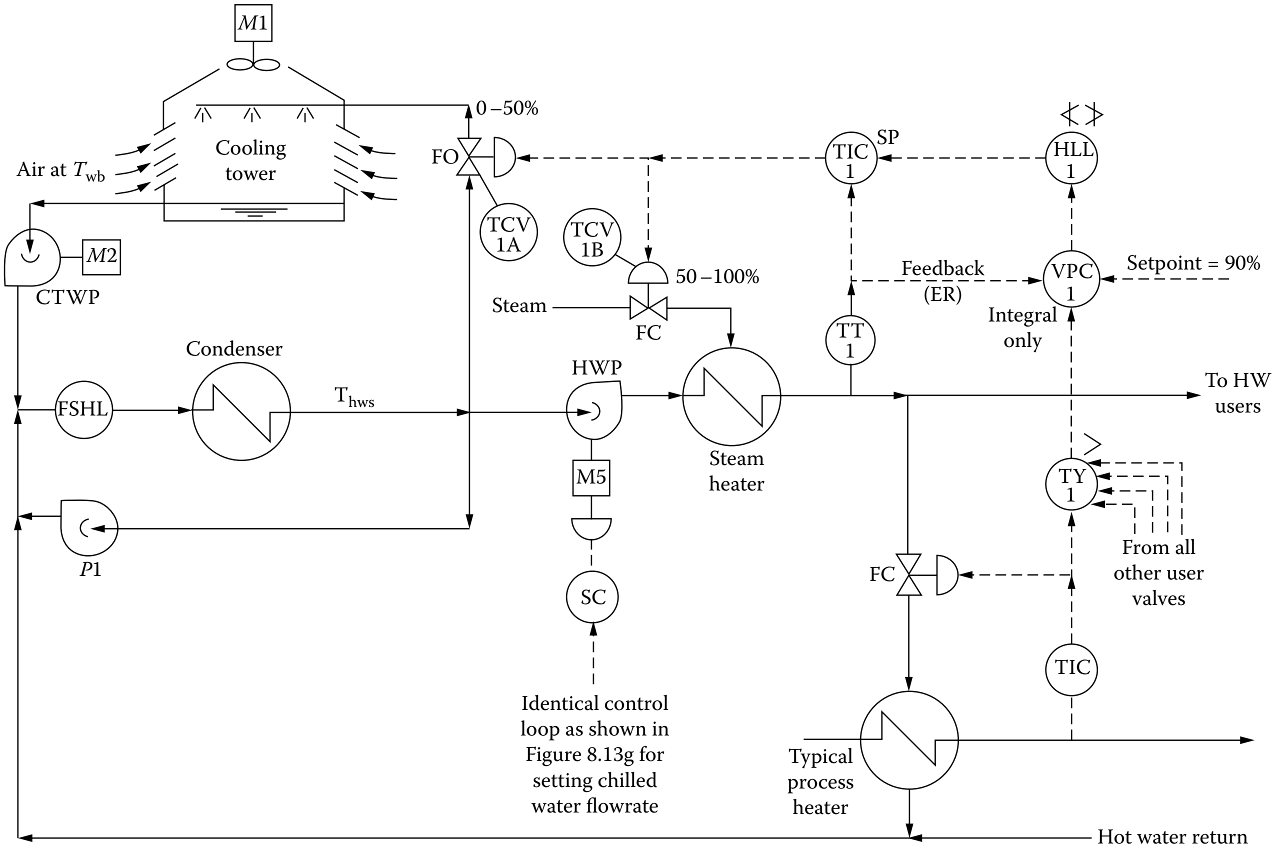

FIG. 8.13j

When the heat pumped by a chiller is recovered as hot water, a load-following cascade master controller (VPC-1) can be used to set the hot water temperature controller's (TIC-1) set point.

Figure 8.13j also shows that an increasing demand for heat will cause the TIC-1 output to rise. An increase in the heat load of the plant will cause a decrease in the heat spill to the cooling tower through TCV-1A when the TIC-1 output is between 0 and 50%. At 50% (0.6 bar) output, all the available cooling load is being recovered and TCV-1A is fully closed. If the heat load continues to rise (TIC-1 output signal rises over 50%), this will result in the partial opening of the "pay heat" valve, TCV-1B. In this mode of operation, the steam heat is used to supplement the freely available recovered heat to meet the prevailing heat load of the plant.

A local circulating pump, P1, is started by FSHL whenever the flow velocity is low. This prevents the formation of deposit in the condenser tubes. P1 is a small 10–15 hp pump that is operating only when the flow is low. The main cooling tower pump (usually larger than 100 hp) is stopped when TCV-1A is closed.

OPTIMIZATION BY OPERATING MODE SELECTION

The cost-effectiveness of heat recovery is a function not only of the outdoor temperature, but also of the unit cost of energy from the alternative heat source and the percentage of the cooling load that can be used in the form of recovered heat.

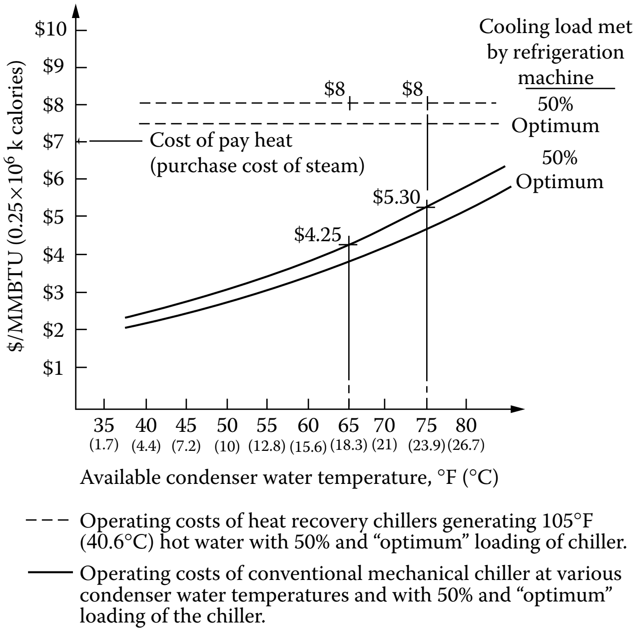
When the outside air temperature is below 65°F (18°C) and steam is available at $7/MMBTU while only half of the cooling load is required in the form of hot water, it is more cost-effective to operate the chiller in the regular cooling mode than in heat-recovery. In that case, according to the data in Figure 8.13k, it is cost-effective to use steam as the heat source.

Conversely, when the outdoor temperature is above 75°F (23.9°C), the penalty for operating the split condenser at hot water temperatures is no longer excessive; therefore, the plant should automatically switch back to the heat-recovery mode of operation. This cost-benefit analysis can be a continually used and automatic element of the overall optimization scheme.

Artificial Heat Sources

In locations such as the southern United States, where there is no alternative heat source, another problem can arise because all the heating needs of the plant must be met by recovered heat from heat pumps. It is possible that during cold winter days there might not be enough recovered heat to meet this load. Whenever the heat load exceeds the cooling load and there is no alternative heat source available, an artificial cooling load must be placed on the heat pump.

This artificial heat source can in some cases be the cooling tower water itself. A direct heat exchanger between the cooling



Example[*]

Temperature of Condenser Water	*Cost Components*	*Mechanical Refrigeration Mode*	*Heat Recovery Mode*
65°F (18.3°C)	Cost of Cooling	$4.25	$8.00
	Cost of Heating	(0.5)(7.0) = $3.50	$0.00
	Total	$7.75	$8.00
75°F (23.9°C)	Cost of Cooling	$5.30	$8.00
	Cost of Heating	(0.5)(7.0) = $3.50	$0.00
	Total	$8.80	$8.00

[*] This example is based on the following assumptions:

a. The actual cooling load is 50% of chiller capacity (CL = 0.5 CAP).

b. The heating load (the demand for hot water) is 50% of cooling load. (HL = 0.5 CL)

FIG. 8.13k

The decision of operating in either the free cooling mode or in the heat recovery mode can be made automatically on the basis of cost-effectiveness.

tower and chilled water streams is also advantageous in the case when there is no heat load but there is a small cooling load during the winter. At such times, the chiller can be stopped and the cooling load can be met directly by the cooling tower water (Figure 8.13l).

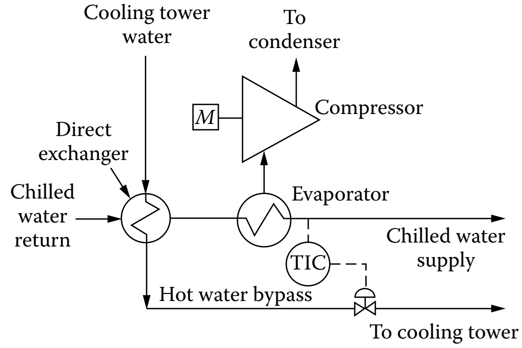


FIG. 8.13l

When the chiller compressor is on, the cooling tower water can be used as an artificial heat source; with the compressor off, it can be used as a means of direct cooling.[4]

OPTIMIZATION BY SYSTEM RECONFIGURATION

In most plants, coolant can be provided from many sources, so another approach to optimization is to reconfigure the system in response to changes in loads, ambient conditions, and utility costs. For example, during some operating and ambient conditions, the cooling tower water may be cold enough to meet the cooling load of the process directly.

Alternatively, if the cooling tower water temperature is below the chilled water temperature required by the process, the chillers can be operated in a free cooling or thermosiphon mode, which will be described in more detail later in connection with Figure 8.13o. In this case, the refrigerant circulation is driven by the temperature differential rather than by the compressor, because the cooling tower water in the condenser is colder than the chilled water in the evaporator. In this thermosiphon mode of operation, the chiller capacity drops to about 10% of its rating.

When the compressor of a chiller or heat pump is in operation, the process is in the so-called *mechanical refrigeration mode* (Figure 8.13m).

When the process is cooled directly by the cooling tower water, without the use of chillers or refrigeration machines, it is in the *free cooling mode.* Most modern cooling systems are provided with the capability of operating in several different modes as a function of load, ambient conditions, and utility costs.

The decision to switch from one operating mode to another is usually based on economic considerations. Such a control system will automatically select the mode of operation that will allow the meeting of the load at the lowest total cost. Figure 8.13k illustrates the decision-making process by which one can decide if the heat recovery or the mechanical refrigeration mode will provide the better cost-effectiveness for the prevailing conditions. The same kind of logic is applied when the choice is between free cooling or mechanical refrigeration.

Once it is decided to switch modes, the actual reconfiguration of the associated piping and valve positions are selected automatically. In larger, more complex cooling systems, there can be dozens of different modes of operation (such a system was designed by the author for IBM corporate headquarters at 590 Madison Avenue in New York). In this chapter, only four basic modes will be discussed.

The cooling system illustrated in Figure 8.13m is configured as a mechanical refrigeration system. The controls for this configuration have been described in Figures 8.13g

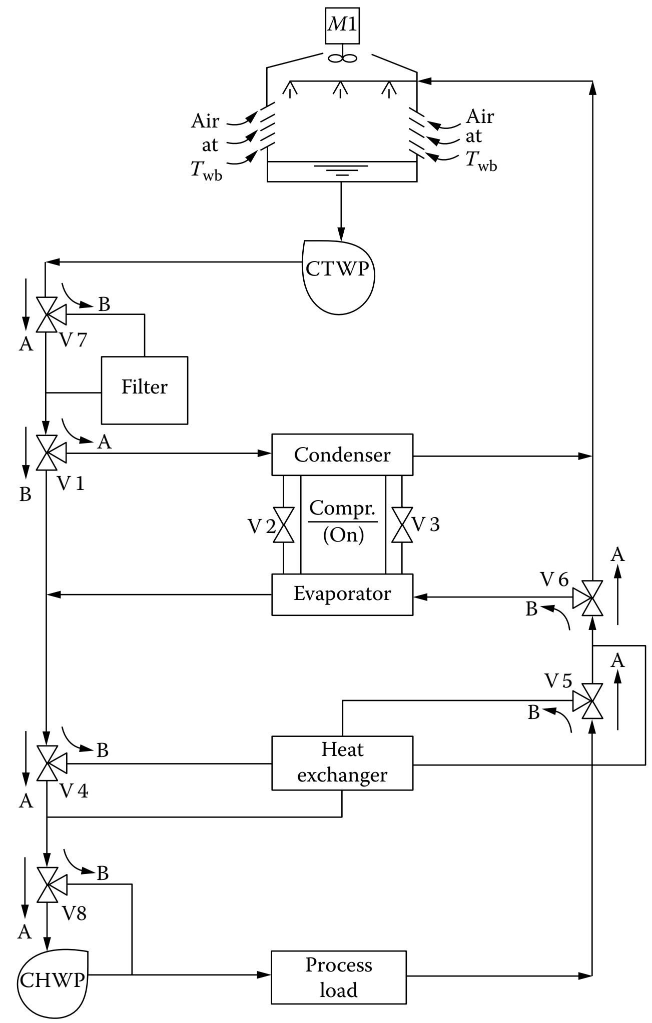

FIG. 8.13m
This mechanical refrigeration system can be automatically reconfigured to operate in any of the three "free cooling" configurations, which are listed in Table 8.13n.

and 8.13j. The heavily drawn pipelines show the flow paths that are active in this mode of operation.

When the load drops off or when the ambient temperature decreases, it is possible to switch to one of the free-cooling modes after the compressor has been stopped. Table 8.13n lists the equipment status and valve positions for each of the operating modes that the system in Figure 8.13m can support.

Indirect Free Cooling by Thermosiphon

Free cooling can be direct or indirect. When indirect free cooling is used, the compressor is off and the refrigerant transports the heat to the cooling tower water from the chilled water by evaporating in the "condenser" and condensing in the "evaporator." This is mode 2 in Table 8.13n. In this indirect free-cooling configuration the compressor is off and the heat is transferred from the evaporator to the condenser through the natural migration of refrigerant vapors (Figure 8.13o).

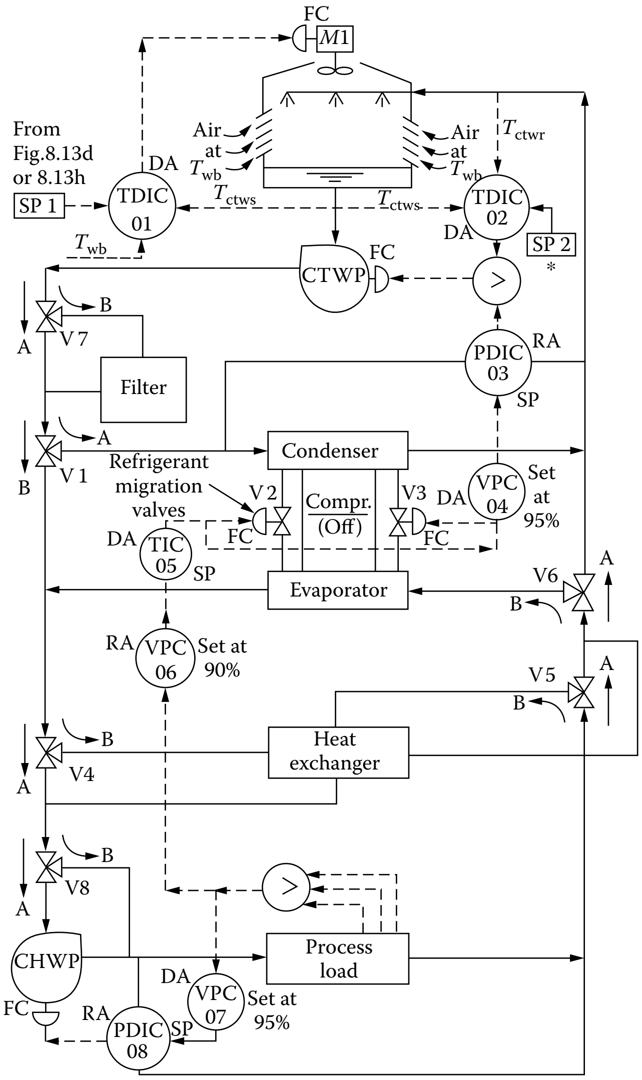
Opening the refrigerant migration valves (*V*2 and *V*3) equalizes the evaporator and condenser pressures. Because the condenser is at a lower temperature, the refrigerant that is vaporized in the evaporator is recondensed and returns to the evaporator by gravity flow. The cooling capacity of a chiller is about 10% of full load in this mode of operation.

The cooling system is operated in this mode when the load is low and the cooling tower water temperature is about 10°F (5.6°C) below the required chilled water temperature. This usually means 40–45°F (4.4–7.2°C) cooling tower and 50–60°F (10–15.6°C) chilled water temperatures. Such high chilled water temperatures are not unrealistic in the winter, because the air tends to be dry and dehumidification is not required.

This (mode 2 in Table 8.13n) can also be implemented without controls. Under manual controls both sets of pumps are operated and the temperatures are allowed to float as a function of load and ambient conditions.

TABLE 8.13n
Equipment Status in Four Operating Modes of a Refrigeration System

Equipment	*Mode 1 (Mechanical refrigeration)*	*Mode 2 (Vapor migration based indirect free cooling)*	*Mode 3 (Indirect free cooling by the use of heat exchanger)*	*Mode 4 (Direct free cooling with full filtering)*
Compressor	On	Off	Off	Off
Cooling-tower pumps	On	On	On	On
Chilled-water pumps	On	On	On	Off
Valve V1	A	A	B	B
Valve V2 and 3	Closed	Open	Closed	Closed
Valve V4	A	A	B	A
Valve V5	A	A	B	A
Valve V6	A	B	A	A
Valve V7	A	A	A	B
Valve V8	A	A	A	B



* From Figure 8.31i.

FIG. 8.13o

In the free-cooling mode (mode 2 in Table 8.13o), the compressor is off. The refrigerant evaporates in the "condenser" and freely migrates to the evaporator, where it condenses, because the condenser is colder than the evaporator.

Optimized Operation To optimize this operation, the control strategy shown in Figure 8.13o has to be implemented. Here TDIC-01 maintains the optimum approach and TDIC-02 maintains the optimum range, unless these controls are overridden by VPC-04 when the refrigerant migration valves approach their full openings, signaling that increased heat transfer is needed at the condenser in order to meet the load.

The migration valves $V2$ and $V3$ are throttled by TIC-05. The set point of TIC-05 is maximized by VPC-06 by allowing all user valves to open until the most-open valve reaches 90% opening. The rate of chilled water pumping is minimized by VPC-07, which modulates the set point of PDIC-08.

As VPC-06 normally keeps the most-open user valve at 90% opening, therefore the set point of VPC-07 is not reached under normal conditions. Therefore, under these conditions, the PDIC-08 set point is kept at its allowable minimum. This in turn results in minimizing the chilled water pumping cost so long as all the users are satisfied. If any of the user valves would open to over 95%, VPC-07 will quickly increase the pumping rate to guarantee sufficient coolant to that valve.

When this occurs, the system is using up the cooling capacity stored in the circulated chilled water. Once this is exhausted, control will be lost. Therefore, it is advisable to switch to a different mode of operation when this condition is detected.

Indirect Free Cooling by Heat Exchanger

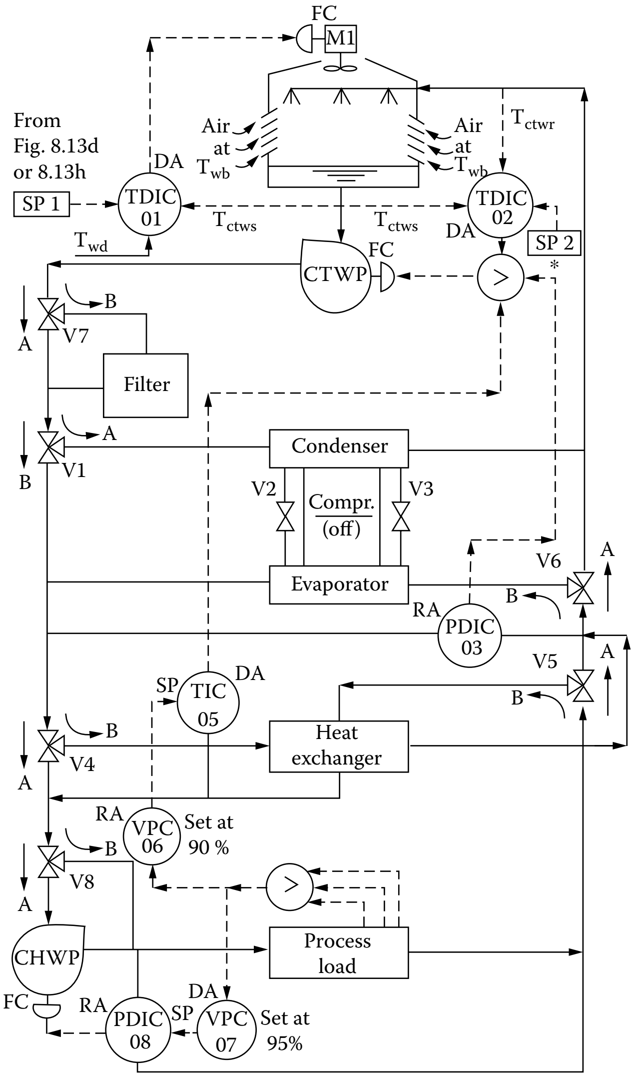
Another method of indirect free cooling is to transfer the heat directly between the cooling tower water and the chilled water through a heat exchanger (mode 3 in Table 8.13n). This allows the complete bypassing of the refrigeration machine. This system has no heat transfer capacity limitation, because any cooling load can be handled as long as the plate-type heat exchanger is large enough to handle it. Therefore, the main advantage of mode 3 over mode 2 is that it is not restricted to loads of 10% or less of chiller capacity. Its main disadvantage is the need for an additional major piece of equipment, namely the heat exchanger.

Indirect free cooling using the plate-type heat exchanger can be operated manually, without any controls. In that case, the chilled water temperature will float as a function of the process load and the ambient temperature, while the pump stations operate at full capacity.

Optimized Operation If it is desired to optimize the operation of mode 3, the control system described in Figure 8.13p can be implemented. Here, on the cooling tower, TDIC-01 maintains the optimum approach and TDIC-02 maintains the optimum range. TDIC-02 can be overridden by PDIC-03 or by TIC-05. The pumping rate of cooling tower water circulation will therefore be set by the highest of the three controller outputs. The purpose of PDIC-03 is to guarantee the minimum pressure differential required for the plate-type exchanger, while TIC-05 can override TDIC-02 and PDIC-03 if more cooling is required.

The set point of TIC-05 is set by VPC-06 to prevent the most-open user valve from exceeding a 90% opening. Under normal conditions, the pumping rate of chilled water is kept at a minimum by PDIC-08, which maintains the minimum ΔP required across the process load. When VPC-06 is unable to keep the most-open user valve at a 90% opening and this opening rises to 95%, VPC-07 will start raising the set point of PDIC-08, thereby increasing the pumping rate.

This is only a temporary cure, because the added cooling capacity is available only at the expense of heating up the stored chilled water in the pipe distribution system. Therefore, it is advisable to detect if this condition occurs for more than a minute or so and, when it does, automatically switch the system to a cooling mode that can handle the increased



* From Figure 8.13i.

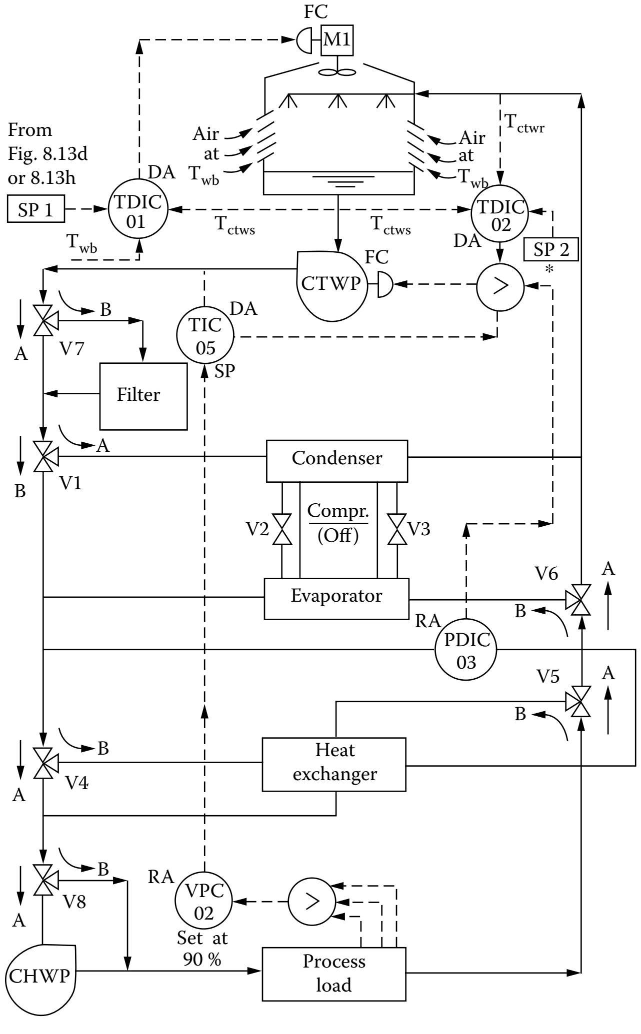
FIG. 8.13p
Indirect free cooling is obtained by sending the chilled water that is returning from the process to a heat exchanger in which it is cooled by the cooling tower water (mode 3).

load. This can be mechanical refrigeration (mode 1) or free cooling through interconnection (mode 4).

Direct Free Cooling

In direct free cooling, the cooling tower water is piped directly to the process load, as shown in Figure 8.13q. This method (mode 4) is the most cost-effective mode of cooling, because both the compressor and the chilled water pump station are off. In the winter, this mode of operation can handle high process loads, as it is limited only by the size of the towers and their pumps.

The main disadvantage of direct free cooling is that it brings potentially dirty cooling tower water to the process users, causing plugging and build-up on the heat transfer surfaces. This problem can be solved either by full flow filtering (also called strainer cycle), which is shown in Figure 8.13q, or by the use of closed-circuit, evaporative cooling towers. In such “noncontact” or “closed-loop” cooling towers, the water has no opportunity to pick up contaminants from the air.



* From Figure 8.13i.

FIG. 8.13q
In the direct free-cooling mode, the cooling tower water is sent directly to the process load.

This configuration is also frequently operated manually, without automatic controls. In that case, the cooling tower water temperature floats as the load and ambient conditions vary, and the fan and pumping rates are not optimized.

Optimized Operation If optimization is desired, the controls shown in Figure 8.13q can be implemented. In this figure, TDIC-01 serves to keep the cooling tower approach at an optimum value, and TDIC-02 optimizes its range. The range controller can be overridden by PDIC-03 or by TIC-05 when either of these controllers require a higher pumping rate than does TDIC-02, the range controller. The set point of TIC-05 is optimized to keep the most-open user valve from exceeding a 90% opening.

Operating Mode Reconfiguration

The number of possible modes of operation can be rather high, if the cooling system of the plant includes optional storage, heat recovery, and alternate types of motor drives. Switching from one mode to another is not as simple as it might first appear, because reconfiguration necessitates the stopping and starting of equipment and because the reconfiguration of control loops often requires the modification of pump discharge heads.

For example, when switching to mode 4, illustrated in Figure 8.13q, the water circulation loop served by the cooling tower pumps becomes much longer. This in turn shifts the operating point of the pumps and can lower their efficiency if the system is not carefully designed and evaluated for each operating mode.

The control loop configuration requirements for all four modes are tabulated in Table 8.13r. When the control loops are automatically reconfigured and their manipulated variables are changed, it is important to also revise their tuning constants, because the time constants of the loops are also changed. This should preferably be done automatically to minimize the potential for human error.

Whenever the process can tolerate an interruption of a few minutes in its cooling system, the switching from one mode to another should be done in a stagnant state, while the equipment is turned off. This usually is acceptable for all motors except for the pumps, which are serving the process load. These pumps usually can be left running, and during switching they can utilize the coolant storage capacity of the water distribution piping. Transferring to another mode while the pumps are running can be accomplished, because the slowly diverting three-way valves will never completely block the pump discharge but will only gradually change the destination of the water.

TABLE 8.13r
Listing of the Manipulated Variables That Are Assigned To Be Throttled by the Various Controllers in the Four Modes of Operation

	Manipulated Variables Controlled by the Controller			
Controller	*Mode 1*	*Mode 2*	*Mode 3*	*Mode 4*
TDIC-01	Fan	Fan	Fan	Fan
TDIC-02	CTWP	CTWP	CTWP	CTWP
PDIC-03	CTWP	CTWP	CTWP	CTWP
VPC-04	—	PDIC-03 Set point	—	—
TIC-05	Compressor	V2/3	CTWP	CTWP
VPC-06	TIC-05 Set point	TIC-05 Set point	TIC-05 Set point	TIC-05 Set point
VPC-07	PDIC-08 Set point	PDIC-08 Set point	PDIC-08 Set point	—
PDIC-08	CHWP	CHWP	CHWP	—

If the mode changes are frequent or if the coolant capacity of the piping headers is very small (insufficient to meet the process load for even a few minutes), all systems must be switched while running. Dynamic switching requires more planning and a higher level of automation, because the automatic starting of certain pieces of equipment (such as chillers driven by a steam turbines) requires a more comprehensive set of safety interlocks.

Automatic operating mode reconfiguration is one of the most powerful tools of optimization, because it provides flexibility to a previously rigid system. The mode reconfiguration technique is not limited to cooling systems. It can be effective in any unit operation in which the system must adapt to changing conditions.

RESPONSIVENESS AND PRIORITIZING

In some processes it is critical that the chillers be able to respond to fast and drastic changes in the process cooling load. In other processes, the plant's cooling system simultaneously serves high- and low-priority users, and it is much more important to meet the needs of the high-priority users than the others. The control systems described in the following paragraphs are designed to improve responsiveness and to consider user priorities in chilled water distribution.

More Responsive Control

Feedforward anticipation can increase the responsiveness of the control system while also providing more precise temperature control. Such precision is desired when, for example, the goal of optimization is to maximize chilling without freezing.

When in a heat exchanger the heat transfer area is fixed (such is the case in an evaporator with constant refrigerant level), the rate of heat transfer (load) is a function of the temperature difference between the process fluid and the boiling refrigerant. Therefore, as the load changes, the boiling temperature (and pressure) must also change.

Figure 8.13s shows the main components of such a responsive control system. In this case the instantaneous load is calculated by multiplying the flow rate of the cooled process fluid (in FY-05) by the drop in temperature (TY-04) that it should experience. Based on this flow rate and the desired process temperature (set point of TIC-01), FY-06 determines the desired refrigerant temperature. The value of K in this summing device is adjustable to reflect the actual slope of load vs. refrigerant temperature. PY-07 serves to convert the desired boiling temperature to the corresponding vapor pressure set point.

Dynamic compensation is provided by FY-03 to match the response of process temperature to refrigerant pressure.[5] A valve position controller can be added to detect the refrigerant control valve opening and to keep that valve over 90% open by varying the speed of the compressor, in order to minimize the operating cost of the compressor.

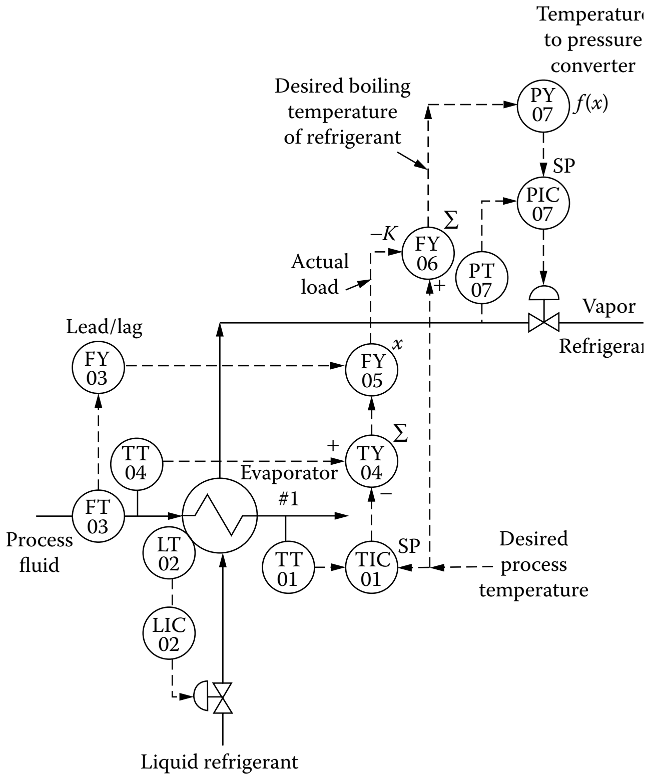


FIG. 8.13s

Increased responsiveness can be obtained by the feedforward adjustment of refrigerant pressure. (Adapted from Reference 5.)

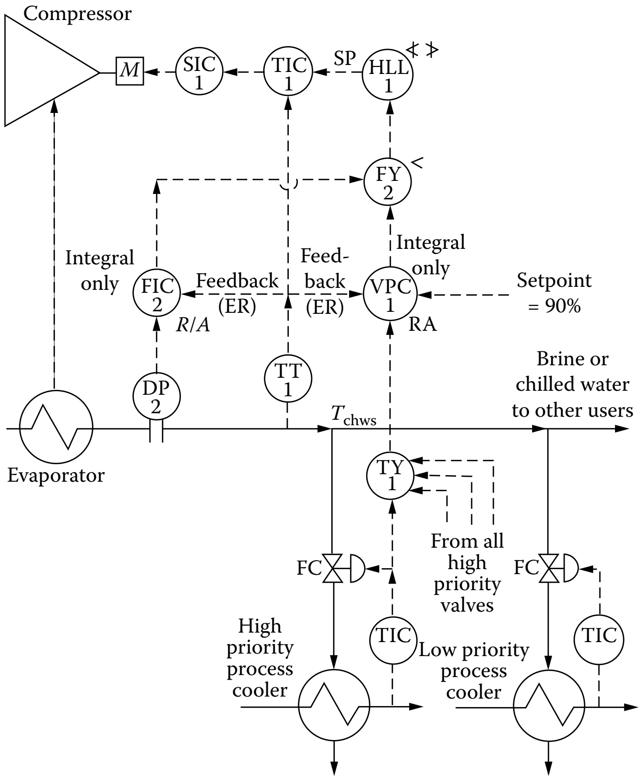

FIG. 8.13t

The chilled-water supply temperature can be optimized by keeping the most-open high priority user valve at 90%. (Adapted from Reference 2.)

Water Distribution Optimization

Figure 8.13f illustrates the ideal water distribution system, in which the individual users are served by two-way valves and the optimum supply temperature is found by keeping the most-open valve at 90% opening. Although this is a very effective control configuration, it is not always used when some of the chilled water users are not critical.

If the number of user valves is very high and if the valves are distributed over a large area, or if the loops are not properly tuned and the valves have a tendency to cycle from fully closed to fully open, the control shown in Figure 8.13f is not practical. In such situations, the concept illustrated in Figure 8.13f can still be applied by selecting a few representative user valves that are not cycling and by basing the optimization on those.

If the chilled water user valves are grouped into high- and low-priority categories or into other groups, the water distribution and supply temperature can still be optimized. Figure 8.13t illustrates a control system in which the high-priority users are treated the same way as they were in Figure 8.13f. The low-priority users, on the other hand, are grouped together, and their demand is detected through the measurement of total flow.

If all low-priority valves are the two-way type and if supply temperature is constant, flow will vary directly with cooling load. If valve-position-based optimization were applied, it would attempt to maximize valve opening, which in turn would maximize flow by raising T_{chws} to the highest acceptable level. This same goal is achieved by FIC-2 in Figure 8.13t. As the flow drops off as a result of a reduction in demand for cooling, FIC-2 will raise the supply temperature, which in turn will increase the total flow, as the valves open up. Therefore, the total flow is kept constant, and load variations result in supply temperature variations. VPC-1 and FIC-2 should both be integral-only controllers, with time constants of several minutes.

The control of total flow alone in Figure 8.13t can satisfy the average user, but not all the users. Therefore, the critical users cannot be treated in this manner, but must be protected by valve position control. Such control is provided by VPC-1, which overrides the flow controller whenever a high-priority valve reaches 90% opening.

Three-Way Valves to Optimize HVAC Systems In many older or air-conditioning-type applications, three-way control valves are used. This is a highly undesirable practice, because the use of three-way valves unnecessarily increases the required amount of pumping and it also lowers return water temperature. Yet, these badly designed systems can also be optimized. A control system that will do that is shown in Figure 8.13u.

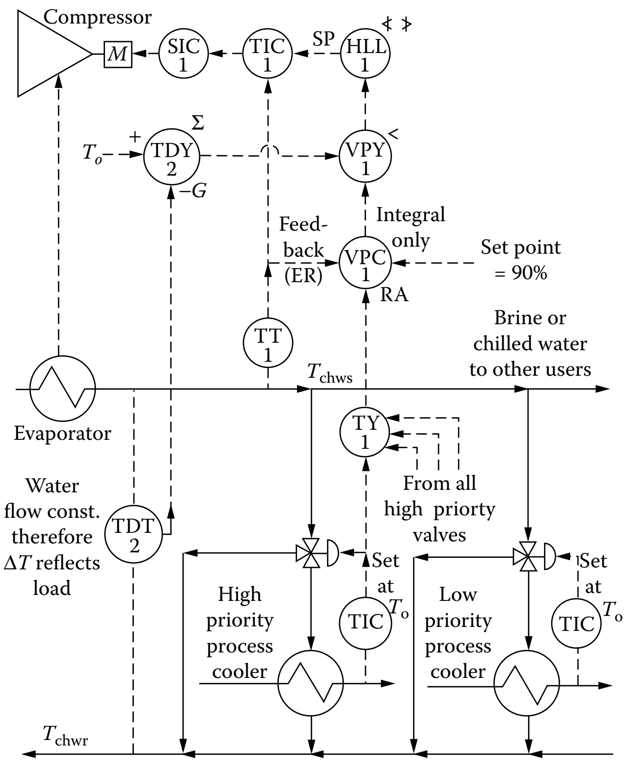

FIG. 8.13u

The optimization of chilled water supply temperature on the basis of keeping the most open high priority three-way user valve 90% open. (Adapted from Reference 4.)

When three-way valves are used, the total flow is relatively constant, and it is the return water temperature that reflects the variations in the cooling load. Therefore, the control system in Figure 8.13u determines the set point for TIC-1 by relating the temperature rise ($T_{chwr} - T_{chws}$) and the desired space temperature set points (T_o) as follows:[5]

$$\text{TIC-1 setpoint} = T_o - G(T_{chwr} - T_{chws}) \qquad \textbf{8.13(2)}$$

If the thermostats are set at T_o = 80°F (27°C) and if, at full load, T_{chws} = 50°F (10°C) and T_{chwr} = 65°F(18°C), the value of G can be determined as follows:

$$G = (T_o - \text{setpoint})/(T_{chwr} - T_{chws}) = (80 - 50)(65 - 50) = 2 \qquad \textbf{8.13(3)}$$

TDY-2 in Figure 8.13u therefore calculates the desired set point for TIC-1 at any load. For example, if the load drops to 50%, the space temperature T_o will begin to fall, and the thermostats will divert more coolant into the return line. This will reduce T_{chwr} from 65°F (18°C) to 57.5°F (14°C). In conventional systems, this then would become the new steady state. With the control system shown in Figure 8.13u, TDY-2 will respond by revising the TIC-1 set point as follows:

$$\text{set point} = 80 - 2(57.5 - 50) - 65°\text{F} \qquad \textbf{8.13(4)}$$

As T_{chws} is slowly increasing, the space thermostats will divert less and less water until they come to rest at the same percentage of water diverted as at full load. The benefit of this optimization strategy is in reducing the temperature differential across the chiller, which in turn lowers the operating cost by 15% for each 10°F (5.5°C).

The setting of G determines the percentage of coolant diverted by the average valve. If G is set too low, some valves will be 100% open to the chilled water supply and therefore out of control. If G is set too high, the chilled water supply temperature will be lower than needed, and compressor energy will be wasted.

In order to protect the high-priority users from running out of coolant, when G is set low, a valve-position-based override is used in Figure 8.13u. Whenever a high-priority valve is more than 90% open, VPC-1 will override the set point of TIC-1 and will lower it until all high-priority valves are less than 90% open.

OPTIMIZING STORAGE AND LOAD ALLOCATION

The total cost of cooling can also be reduced by making the coolant when it is less expensive to make it and placing it in storage until it is needed. When a variety of equipment is available to meet the cooling load of the plant, the total cost of operation can also be minimized by always using the most efficient combination of equipment. These are the topics of the next paragraphs.

Optimized Storage

If storage tanks are available, it is cost-effective to generate the daily brine or chilled water needs of the plant at night, when it is the least expensive to do so, because ambient temperatures are low and night-time electricity is less expensive in some areas.[6]

When demand is low, operating costs can be reduced by operating the chillers part of the time at peak efficiency rather than continuously at partial loading. Efficiency tends to be lower at partial loads because of losses caused by friction drop across suction dampers, prerotation vanes, or steam governors.

Cycling is practical if the storage capacity of the distribution headers is enough to avoid frequent stops and starts. When operation is to be intermittent, data such as the amount of heat to be removed and the characteristics of the available chillers are needed to determine the most economical operating strategy.

When the chiller is cycled, the thermal capacity of the chilled water distribution system is often used to absorb the load while the chiller is off. For example, if the pipe distribution network has a volume of 100,000 gallons (378,000 l), this represents a thermal capacity of approximately 1 million BTUs for each °F of temperature rise (1.9×10^6 J/°C).

So, if one can allow the chilled water temperature to float 5°F (2.8°C) (such as from 40°F to 45°F, or from 4.4°C to 7.2°C) before the chiller is restarted, this represents the equivalent of approximately 400 tons (1405 kW) of thermal capacity. If the load happens to be 200 tons (704 kW), the chiller can be turned off for 2 hours at a time. If the load is 1000 tons (3,514 kW), the chiller will be off for only 24 minutes. This illustrates the natural load-following, time-proportioning nature of this scheme.

If the chiller needs to be off for a longer period than the thermal capacity of the distribution system can provide, three options are available:

1. Storage tanks can be added to increase the water volume.
2. A second chiller can be started (not the one that was just stopped).
3. The load can be distributed among several chillers of different sizes, keeping some in continuous operation while cycling others.

Optimized Load Allocation

Continuous measurement of the actual efficiency ($/ton) of each chiller can enable the plant to meet all loads with the most efficient combination of machines. In plants with multiple refrigerant sources, the cost per ton of cooling can be calculated from direct measurements, and it can be used to select the most efficient combination of units to meet any existing or anticipated loads. The differences between the cost per ton characteristics and the efficiency-vs.-load characteristics of the individual coolant sources can be combined and used as in Figure 8.13v.

In simple load allocation systems, only the starting and stopping of the chillers is optimized. In such systems, when the load is increasing, the most efficient idle chiller is started, and when the load is dropping, the least efficient one is stopped. In more sophisticated systems, the load distribution between operating chillers is also optimized. In such systems, the real-time efficiency of each chiller is calculated. This determines the incremental cost for the next load change for each chiller.

If the load increases, the incremental increase is sent to the set point of the most cost-effective chiller. If the load decreases, the incremental decrease is sent to the least cost-effective unit (Figure 8.13w). Software packages are readily available that have proven capabilities for continuous load balancing through the predictions of efficiencies and operating costs.[7]

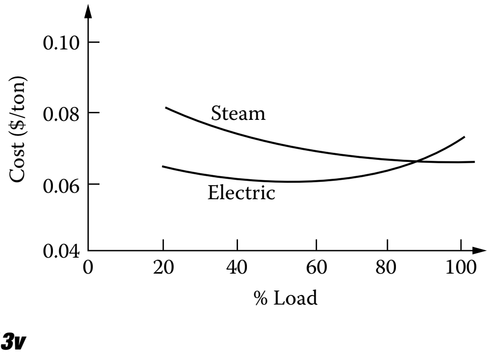

FIG. 8.13v
The unit cost of refrigeration is a function of both the load and of the characteristics of each chiller. Installed systems should be used as the basis of obtaining the operating cost curves.[6]

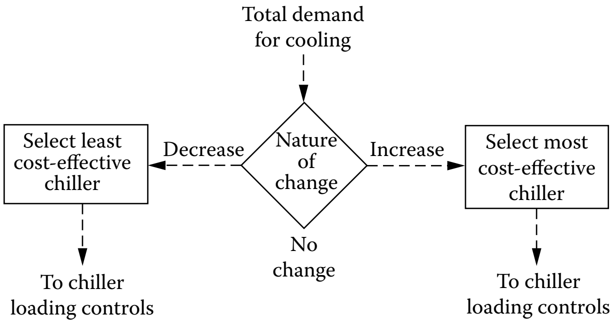

FIG. 8.13w
Optimized, computer-based load allocation will direct load increases to the most cost-effective chiller, while sending the load decreases to the least cost-effective chiller.

With the strategy described in Figure 8.13w, the most efficient chiller will either reach its maximum loading or will enter a region of decreasing efficiency and will no longer be the most efficient. When the loading limit is reached on one chiller, or when a chiller is put on manual, the computer will select another unit as the most efficient one for future load increases.

The least efficient chiller will accept all decreasing load signals until its minimum limit is reached. Its load will not be increased unless all other chillers are at their maximum load or when it is in manual. As shown in Figure 8.13v, some chillers can have high efficiency at normal loads while being less efficient at low load. Such units are usually not allowed to shut down, but are given a greater share of the load by the control system.

If all chillers are identical, some will be driven to the capacity corresponding to maximum efficiency while others will be shut down by this strategy, and only one chiller will be placed at an intermediate load.

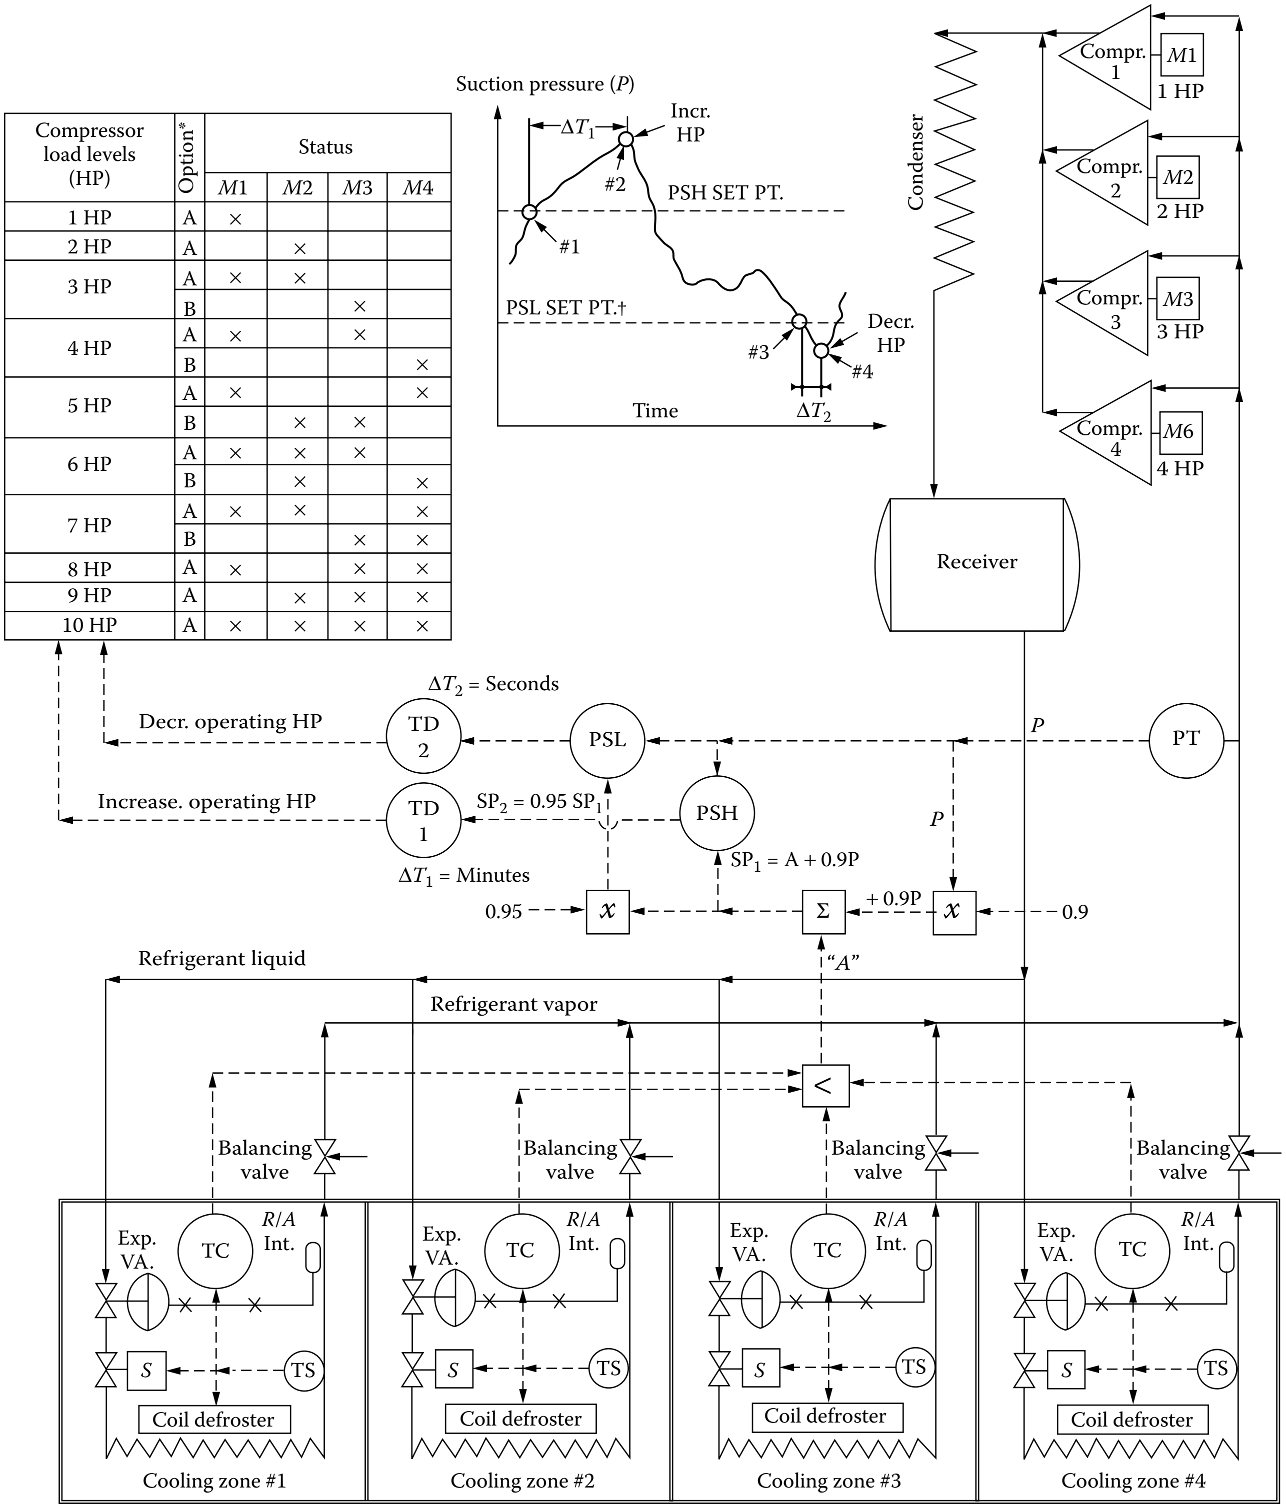
In starting up chiller stations, the optimization system "knows" how many BTUs need to be removed before start-up and the size and efficiency of the available chillers. Therefore, the length of the "pull-down" period can be minimized and the energy cost of this operation can also be optimized.

OPTIMIZATION OF SPECIAL CHILLERS

In the following paragraphs the optimization of some special chiller configurations will be discussed. These will include the commercial chillers that utilize a number of positive displacement refrigerant compressors. Also discussed will be the multistage refrigeration units that are needed to generate very low temperature coolants and the multiple-user systems.

Optimized Commercial Chillers

In supermarkets, warehouses, and other commercial facilities, there usually are a large number of loads (zones, each served by an evaporator coil), and there are a number of



Compressor load levels (HP)	Option*	Status			
		M1	M2	M3	M4
1 HP	A	×			
2 HP	A		×		
3 HP	A	×	×		
	B			×	
4 HP	A	×		×	
	B				×
5 HP	A	×			×
	B		×	×	
6 HP	A	×	×	×	
	B		×		×
7 HP	A	×	×		×
	B			×	×
8 HP	A	×		×	×
9 HP	A		×	×	×
10 HP	A	×	×	×	×

FIG. 8.13x

Here a control system is shown that will minimize the energy cost, while equalizing the operating times of multiple chiller compressors, which are serving an unlimited number of evaporator coils.[8]

positive-displacement refrigerant compressors, which are turned on or off to follow their loads. The goals of optimization are to minimize the cost of operation (to meet any cooling load with a minimum of compressor horsepower) and to select the operating compressors in such a way that the total run time of each machine is about the same.

Figure 8.13x illustrates such a control system, which incorporates some of the ideas contained in the patents listed in Reference 8. In Figure 8.13x each of the cooling zones can be a separate room, freezer, or other cooled area, which is provided with its own temperature controls (TC). Each of the zones is cooled by an evaporator coil, which is kept cold by its boiling liquid refrigerant.

The liquid refrigerant is admitted into each coil by an expansion valve, which controls the superheat of the evaporated vapors by detecting both the pressure and the temperature of those vapors. The expansion valve admits as much refrigerant liquid as is required to keep the evaporator superheat (the temperature above the boiling point at the operating pressure of the refrigerant) constant.

A manual balancing valve is also provided for each zone. These valves are located in the refrigerant vapor lines leaving the zones. If all zones are to be kept at the same temperature, all balancing valves can be kept fully open. This will minimize the pressure drop on the suction side of the compressors and thereby will maximize their efficiency.

If some of the zone temperatures are to be controlled (by their TCs) at a higher temperature than the others, the balancing valves on these higher temperature zones must be throttled to increase the vaporization pressure and thereby the boiling temperature of the refrigerant in the coils of those zones.

Defrosting and Sequencing Controls If the zones are operated below or near to the freezing temperature (below 35°F, or 2°C), it is also necessary to provide defrosting controls because of the ice build-up on the cold evaporator coils. The defrosters are controlled by coil surface temperature detector switches (TS), one in each zone (TS). These switches are continuously detecting the coil surface temperatures, and when that temperature drops below some low limit for some preset time period, the switch first shuts off the refrigerant liquid supply by closing a solenoid valve.

Once all refrigerant has been vaporized, the switch turns on a coil defroster heater for a short time, to remove the ice. During the defrosting cycle, the zone temperature controller (TC) is disabled by setting its measurement and set point to be equal and thereby causing its output signal to stay constant.

The nonoptimized method of turning the refrigerant compressors on and off is by sequential controls, where each added compressor unit is turned on when the suction pressure to the overall compressor station has dropped to an even lower level. This approach is inefficient, because the reaching of these lower levels of suction pressure requires added compressor horsepower.

Optimized Controls The control system shown in Figure 8.13x eliminates the waste of added compressor horsepower by turning added compressors on (PSH) or turning unnecessary compressors off (PSL) at the pressure settings of PSH and PSL. This is achieved by both pressure switches actuating a time delay (TD), and whenever the pressure switch is actuated for the time period set on the time delay, it changes the operating horsepower level of the system. TD-1 increases it while TD-2 decreases the horsepower level.

TD-1 is set in minutes, while TD-2 is set in seconds. Therefore, a response to a load increase is relatively slow (minutes), while the response to a load decrease is fast (seconds), which serves energy conservation.

Further optimization is obtained by pushing the control gap between the pressure switches (PSH and PSL) as high as the loads will allow. This continuous floating of the controlling suction pressure gap is achieved by feedforward action based on zone temperature control. As any one of the zone temperatures rises above the zone thermostat (TC, a reverse-acting, integral-only controller) set point, the output signal of that TC drops. A low-signal selector selects the lowest of the TC outputs (A) and thereby identifies the zone with the highest cooling load (the critical zone, which, if satisfied, will result in all others being satisfied).

The set point of PSH is obtained by taking 90% of the suction pressure of the compressor station (0.9P) and adding to it the output signal (A) of the critical TC. The set point of PSL is 95% of the PSH set point. Both the 90% and the 95% values are adjustable and can be varied from one installation to the next.

The energy consumption of the system can be minimized and its operation optimized by maximizing these set points. This is because whenever all the zone temperatures are on set point (or below), the suction pressure of the operating compressor station is increased, and therefore the amount of work the compressors need to do is reduced.

The graph of suction pressure (P) vs. time in Figure 8.13x illustrates the operation of the system. As the suction pressure rises, at point #1 the set point of PSH is reached and the time delay TD-1 is actuated. At point #2 the time delay that was set on TD-1 has run out, which increases the operating horsepower level by one unit. As a result, the suction pressure starts to drop.

If at this point the operating compressor capacity exceeds the cooling load, the suction pressure will continue to drop, and when it reaches the set point of PSL (point #3), TD-2 will be energized. After the time delay of TD-2 has run out (point #4), the operating horsepower level of the system is reduced by one unit.

Minimum Maintenance In addition to energy optimization, the system is also optimized from a maintenance point of view by keeping all compressor running times approximately the same. This is accomplished by the use of the horsepower table in the top left of Figure 8.13x. Let us assume that the system is operating at the 4 hp level when PSH calls for an increase to 5 hp. The 5 hp level can be met by either operating compressors 1 and 4 (option A) or by operating compressors 2 and 3 (option B). In this situation the least used compressor pair will be started.

If at some time later PSL calls for reducing the operating level to 4 hp, there again are two options. Option A is to run compressors 1 and 3, while option B is to run compressor 4.

Here, the choice is made in such a manner that the most used compressor will be turned off. The net result is a continuous balancing of running times between machines. According to Reference 8, the total energy savings obtained by this control system amounts to about 20%.

Multistage Chillers

It is not practical to obtain a compression ratio outside the range of 3:1 to 8:1 when using the compressors usually installed in the process industry. This places a limitation on the minimum temperature that a single-stage refrigeration unit can provide. For example, in order to maintain the evaporator at –80°F (–62°C) while the condenser is operating at 86°F (30°C), the required compression ratio for Freon-12 is calculated as

$$\text{compression ratio} = \frac{\text{refrigerant presure at } 86^\circ\text{F}}{\text{refrigerant presure at } -80^\circ\text{F}} = \frac{108}{2.9} = 37 \qquad \textbf{8.13(5)}$$

For a single-stage machine, such a compression ratio is not practical, and therefore, a multistage system is required to provide it. Figure 8.13y illustrates a multistage refrigeration system, with ethylene as the lower and propane as the higher temperature refrigerant. In order to minimize the total operating cost, the loading of the two stages must be coordinated to balance the total work between the stages.

The higher the interstage temperature (evaporator #2), the more work is done by stage #1 and the less work remains for stage #2. If the compression ratios (and therefore the temperature differences) of the two stages are the same, the work will be nearly equally distributed. If true equality is to be achieved, the differences in the properties of the refrigerants and the added load on the higher stage caused by the work that is introduced by the lower stage compressor must also be considered.

Optimized Controls One of the goals of optimization is to maximize the rangeability of the multistage refrigeration units. This rangeability will be maximum when the two stages approach their surge limits at the same time. This can be guaranteed by redistributing the load between the stages in such a manner that they maintain equal distance from their respective surge lines as the load drops.

In Figure 8.13y, TIC-01, the temperature controller of the chilled utility supply to the process, sets the speed of the first stage compressor #1 by modifying the set point of its suction pressure controller PIC-01. The speed of compressor #2 is set in speed ratio to that of compressor #1 by PY-01. The set point of PY-01 is optimized by an envelope algorithm that attempts to minimize the operating cost and to maximize rangeability, as it is moving the PY-01 set point to its optimum.

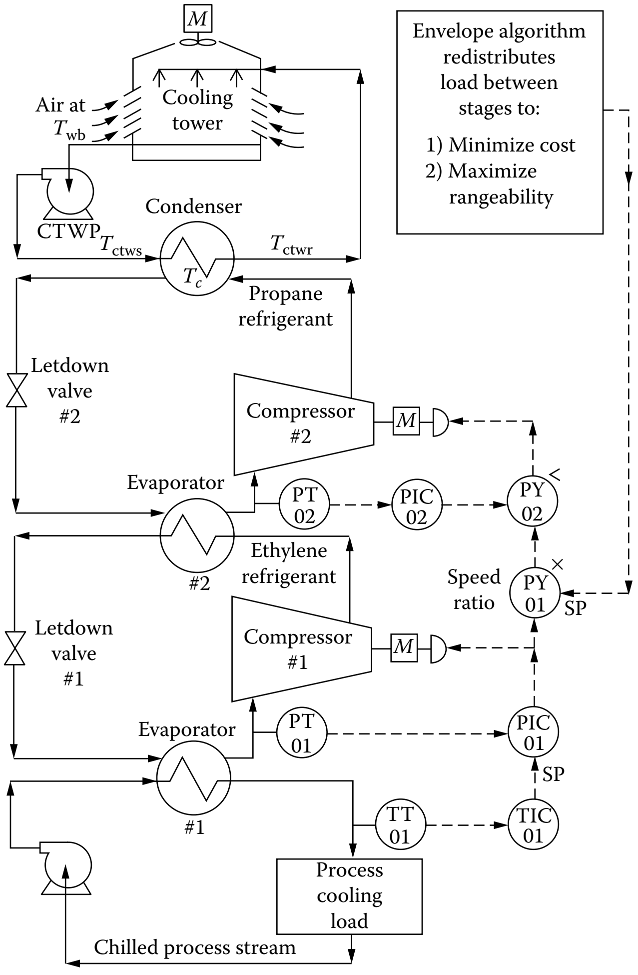


FIG. 8.13y

The operation of multistage refrigeration units can be optimized by automatically balancing the work load between the stages. (Adapted from Reference 5.)

As long as both stages are far from surge, the algorithm redistributes the load to minimize total operating cost. When one of the stages is nearing surge, the envelope algorithm increases its loading to keep the system out of surge. Therefore, at high loads the goal of load distribution between the stages is to minimize the total operating cost, and at low loads the goal is to keep the system out of surge.

As ambient temperatures drop, the cascaded stages will operate against a lower total temperature difference, and therefore, each of the stages will require less work. As the condenser temperature drops, suction pressure of compressor #2 will also drop. This in turn will cause the temperature in evaporator #2 to drop, which will result in the lowering of the suction pressure of compressor #1.

As the suction pressures drop, PIC-01 and PIC-02 will reduce the speeds of their respective compressors, thereby reducing the total work introduced by the heat pumps. Using these controls, this multistage refrigeration system will respond to ambient variations in a flexible and efficient manner.

Optimized Control of Multiple Users

When the same compressor serves several evaporators in parallel, either the evaporator temperature or the refrigerant level in the evaporators can be varied to follow the load. Figure 8.13z shows the controls for a configuration, where the evaporator levels (their wetted heat transfer areas) are kept constant, and therefore the load variations result in changes in the evaporator temperature. In the control system shown, TY-03 selects the most open TCV valve opening and keeps that valve from opening to more than 90% by speeding up the compressor when the valve opening reaches 90%.

The resulting reduction in compressor suction pressure lowers the evaporator temperature and increases the rate of heat transfer. Thus, no user is ever allowed to run out of coolant, and the compressor operating costs are kept to a minimum. This type of load-following optimization system, where compressor speed varies with the requirements of the most heavily loaded user, is very sensitive to dynamic upsets. Therefore, VPC-03 must be tuned for slow adjustment of the compressor speed to avoid upsetting the other users that are not selected for control.

If one of the user valves is consistently more open than the others, it might be possible to repipe the other loads to the interstage of the compressor. This might provide a better balance between users.

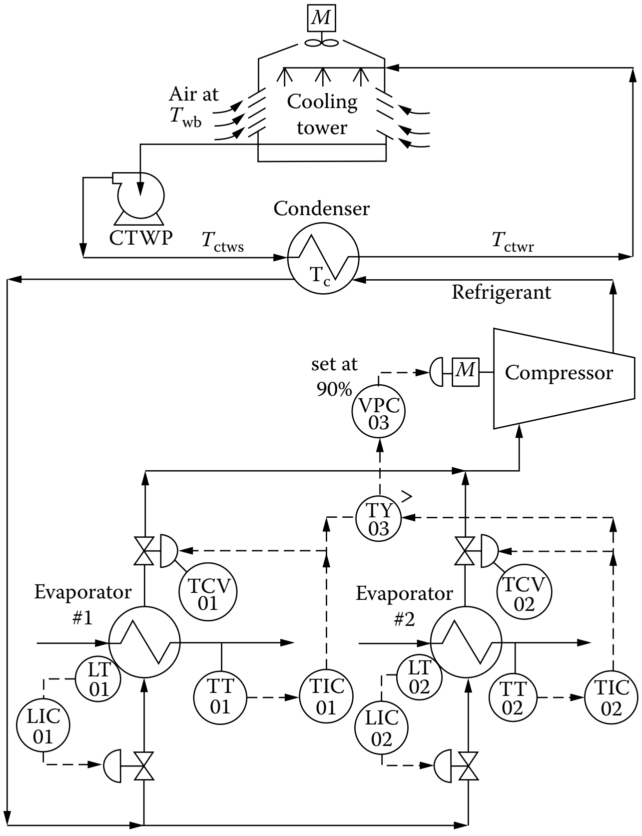

FIG. 8.13z

When a chiller is serving a number of users, the speed of the chiller can be automatically modulated so as to keep the temperature control valve of the most demanding user at 90% opening.

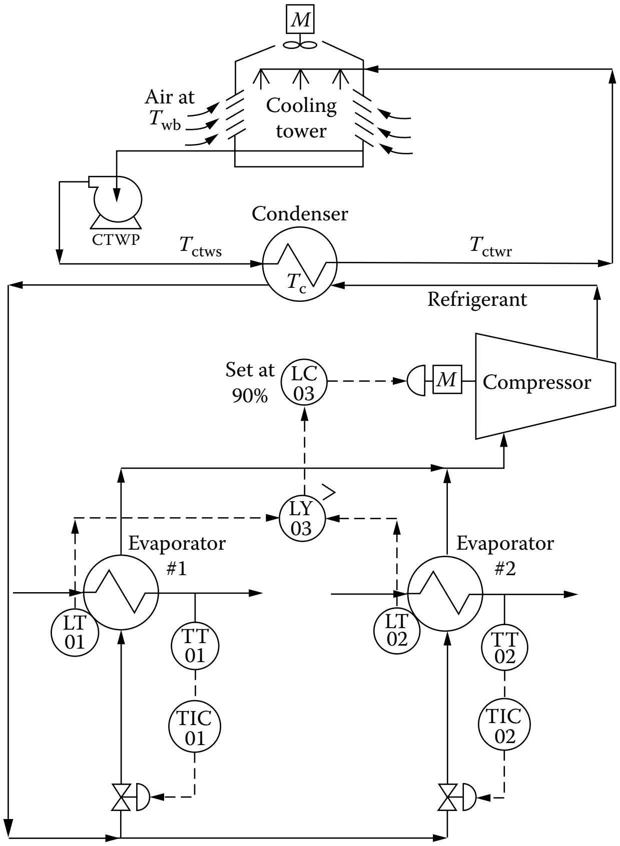

FIG. 8.13aa

The vapor-side control valves on multiple users can be eliminated by automatically adjusting the compressor speed, so as to keep the highest level in the evaporators at 90%. (Adapted from Reference 5.)

Eliminating the Vapor-Side Valves Figure 8.13aa illustrates a control system in which the vapor-side control valves have been eliminated. This advantage of the illustrated configuration must be balanced against a number of disadvantages. In the illustrated system, the heat transfer area is modulated and is exposed to boiling, and the user with the highest load will have the highest refrigerant level.

LY-03 selects the most flooded evaporator for control by LC-03, which, when the level rises above 90%, increases the speed of the compressor and lowers it when the level is below 90%.

This method of load following has some drawbacks. One problem is that the heat transfer surfaces within the evaporators are not fully utilized. Another difficulty is that the relationship between level and heat transfer area can be confused by foaming, which keeps the tubes wet even when the level has dropped.[5] For these reasons, tuning of such control system can be difficult, necessitating the sacrifice of responsiveness for stability.

Therefore, if responsiveness is critical, it is better to keep the refrigerant level constant and manipulate the evaporating pressure, as shown in Figure 8.13z.

RETROFIT OPTIMIZATION

In new plants it is easy to install variable-speed pumps, to provide the thermal capacity required for chiller cycling, or to locate chillers and cooling towers at the same elevation and near each other so that the cooling tower water pumping costs will be minimized. In existing plants, one has to accept the inherent design limitations and the system must be optimized without major changes to the equipment. Even with those limitations, one can still produce savings up to 50%,[3] but certain precautions are needed.

In optimizing existing chillers, it is important to give careful consideration to the constraints of low evaporator temperature, economizer flooding, steam governor rangeability, surge, and piping/valving limitations.

Surge Protection

A detailed discussion of surge controls is given in this chapter under Compressor Controls. Therefore, here it should suffice to just mention that surge occurs at low loads when not enough refrigerant is circulated. A surge condition can cause violent vibration and damage.

Old chillers might not have automatic surge controls and have only vibration sensors for shutdown. If the chillers will operate at low loads, it is necessary to add an antisurge control loop. Surge protection is always provided at the expense of efficiency. To bring the machine out of surge, the refrigerant flow must be artificially increased if there is no real load on the machine. The only way to provide this increase in flow is to add artificial and wasteful loads (for example, hot gas or hot water bypasses).

Therefore, it is much more economical either to cycle a large chiller or to operate a small one than to meet low loads by running the machine near its surge limit.

Low Evaporator Temperature

Low temperatures can occur in the evaporator when an old chiller is optimized—for example, when one that has been designed for operation at 75°F (23.9°C) condenser water is run in the winter using 45 or 50°F (7.2 or 10°C) condenser water. This phenomenon is exactly the opposite of surge, because it occurs when refrigerant is being vaporized at an excessively high rate. Such vaporization occurs because the chiller is able to pump twice the tonnage for which it was designed as a result of the low compressor discharge pressure.

In such a situation, the evaporator heat transfer area becomes the limiting factor. Furthermore, the only way to increase heat flow is to increase the temperature differential across the evaporator tubes. This shows up as a gradual lowering of refrigerant temperature in the evaporator until it reaches 32°F (0°C), at which point the machine shuts down to protect against ice formation.

There are two ways to prevent this phenomenon from occurring in existing chillers. The first is to increase the evaporator heat transfer area (a major equipment modification). The second is to prevent the refrigerant temperature in the evaporator from dropping below 33°F (0.6°C) by not allowing the cooling tower water to cool the condenser to its own temperature. The latter solution requires only the addition of a temperature control loop (Figure 8.13bb). This prevents the chiller from taking full advantage of the available cold water from the cooling tower by throttling its flow rate, thereby causing its temperature to increase.

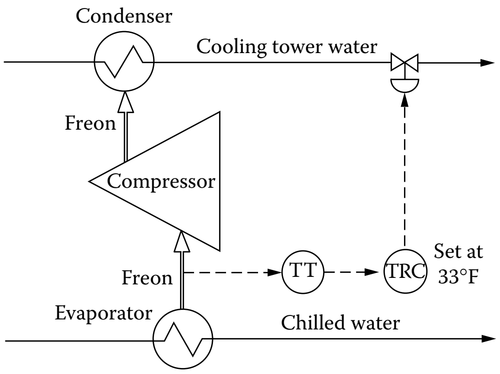

FIG. 8.13bb
Protection against evaporator freeze-up can be provided by the evaporator temperature controller throttling the cooling tower water flow.[4]

Economizer and Steam Governor

In existing chillers, the sizing of the economizer level control valves (LCV-1 and LCV-2 in Figure 8.13cc) is often based on an assumption. This assumption is that the refrigerant vapor pressure in the condenser ($P3$) is constant and corresponds to a condenser water temperature of 75 or 85°F (23.9 or 29.4°C). Naturally, when such units are operated with 45 or 50°F (7.2 or 10°C) condenser water, $P3$ is much reduced, as is the available pressure differential across LCV-1 and LCV-2.

If this occurs—when the freon circulation rate is high—the control valves will be unable to provide the necessary flow rate, and flooding of the economizer will occur, because the flow is higher and the ΔP is lower than was the basis of valve sizing. The solution is to install larger valves, preferably external, and throttle them using controllers with proportional and integral control modes.

The proportional control mode alone cannot maintain the set point as load changes. The addition of the integral mode is necessary to eliminate the offset. This is important in machines that were not initially designed for optimized, low-temperature condenser water operation, because otherwise the liquid refrigerant that overflows from the flooded evaporator can damage the compressor.

To optimize a steam-turbine-driven compressor, one must be able to modulate its rotational velocity over a reasonably wide range. This is not possible with old, existing machines, if they are provided with quick-opening steam governor valves. When such governors are throttled, a slight increase in lift from the fully closed position results in a substantial

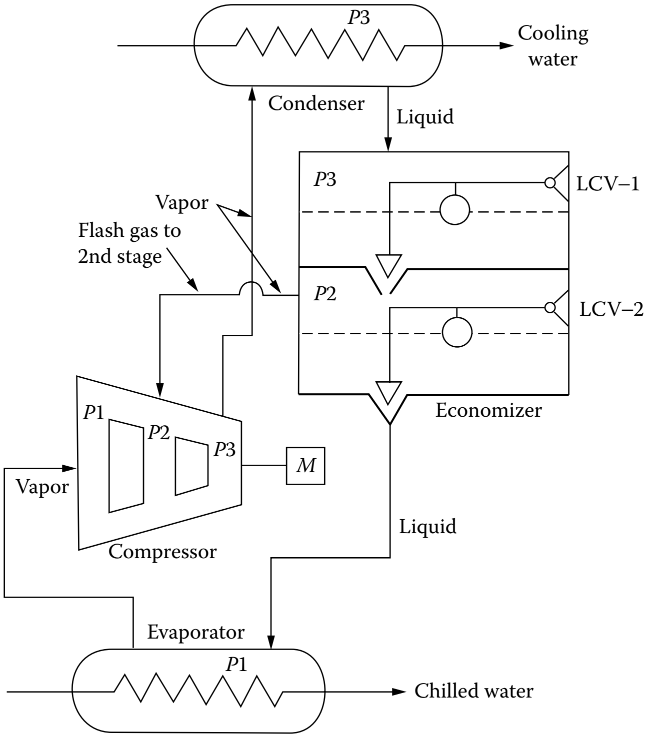

FIG. 8.13cc
To protect against economizer flooding, the internal valves (LCV-1 and LCV-2) can be supplemented with larger external valves.

steam flow and therefore a substantial rotational velocity. Consequently, the valves become unstable and noisy.

The characteristics of the steam governor valves can be changed from quick-opening to linear at minimal cost. The linear characteristics and the desired wide rangeability can be obtained by welding two rings with V-notches to the seats of the existing steam governor valves. This is shown in Figure 8.13dd.

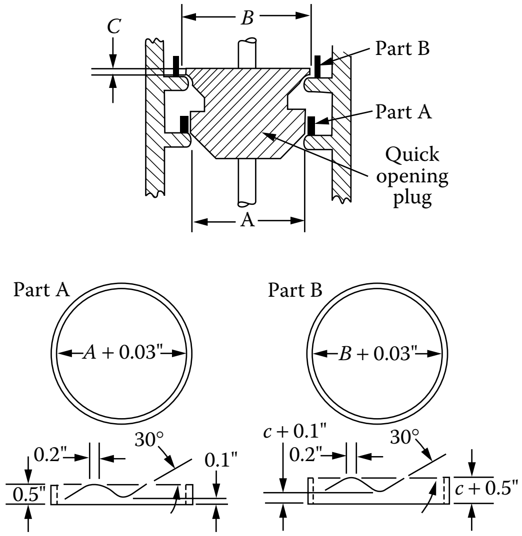

FIG. 8.13dd
A double-seated steam governor valve can be rebuilt to provide the required rangeability for optimized variable-speed service, if two notched rings are installed in the valve seat to modify its characteristics.[4]

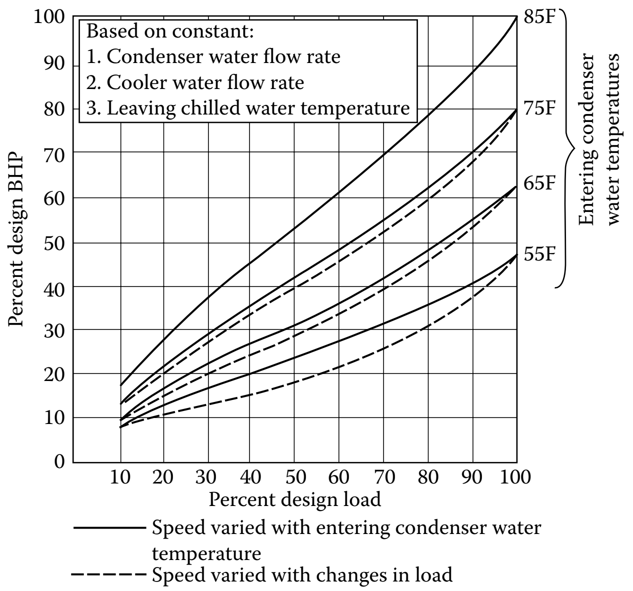

FIG. 8.13ee
The actual power consumption of a variable-speed compressor is reduced by lowering either condenser water temperature or the loading (speed). (Adapted from Reference 9.)

CONCLUSIONS

The goals of chiller optimization include:

- Minimizing the temperature difference across the chiller by minimizing the cooling tower water temperature and maximizing the chilled water temperature
- Minimizing pumping costs by transporting only as much water as is required to meet the load and by using variable-speed pumping
- Minimizing cooling tower operating costs by approach optimization
- Operating chillers at the load at which their efficiency is the highest and by meeting partial loads with part-time operation at maximum efficiency
- Making coolant when least expensive, if night storage is available
- Making load allocation on the basis of maximizing operating efficiency
- Initiating maintenance if a drop in efficiency is detected

As shown in Figure 8.13ee, when using variable-speed compressors, either a reduction in speed or a reduction in condenser water temperature will reduce the power consumption. For example, when the design load is 50% and the condenser water temperature is 55°F, the power consumption can be less than 20%. This compares with 53% if guide vanes are used on a constant-speed machine operating with 85°F condenser water.

The operating costs of chiller stations that operate throughout the year and are located in the northern regions can be cut in half[3] if the potentials of all of the optimization strategies that were discussed in this section are fully exploited. The payback period on investment for chiller optimization controls is usually under 1 year.

With the availability of inexpensive solid-state sensors and microprocessors, it is possible to incorporate all the optimization strategies in a single chiller controller. Such multivariable control software makes it possible to replace the uncoordinated control of flows and temperatures with optimized load following that always corresponds to the lowest possible cost of operation.

8.14 Clean-Room Controls and Optimization

B. G. LIPTÁK (1985, 1995, 2005)

INTRODUCTION

Clean-rooms are used for experimental studies of a wide variety. Testing and analysis laboratories, used in the medical, military, and processing industries, are all designed to operate as clean-rooms. The control and optimization of clean-rooms, therefore, is an important subject to many industries.

The traditional method of maintaining air cleanliness is by filtering. Standard HEPA filters are capable of removing up to 99.97% of impurities at 0.3 micrometers, while ULPA filters are efficient up to 99.9995% at 12 micrometers. In this section, besides filtering, other air cleanliness control methods will also be discussed.

The production of semiconductors is one of several processes that require a clean-room environment. Optimization of the clean-room control system will drastically reduce both the energy cost of operation and the cost associated with the manufacturing of off-spec products, because plant productivity is maximized if drafts are eliminated in the clean work aisle. This is because drafts can stir up the dust in the workstation area, and if the dust settles on the product, production losses result.

SEMICONDUCTOR MANUFACTURING

The process, or production area of a typical semiconductor manufacturing laboratory is between 100,000 and 200,000 ft^2 (9,290 and 18,580 m^2). The market value of the daily production from this relatively small area is well over $1 million. Plant productivity is increased if the following conditions are maintained in the process area:

1. No drafts (+0.02 in. H_2O ±0.005 in. H_2O, or 5 Pa ±1.3 Pa)
2. No temperature gradients (72°F ±1°F, or 22°C ±0.6°C)
3. No humidity gradients (35% RH ±3%)
4. No airflow variations (60 air changes/hr ±5%)

Therefore, the goal is to continuously maintain these conditions through the accurate control of these parameters. The secondary goal is to conserve energy. The sensors and control loop configurations required to meet both of these goals will be described in this section.

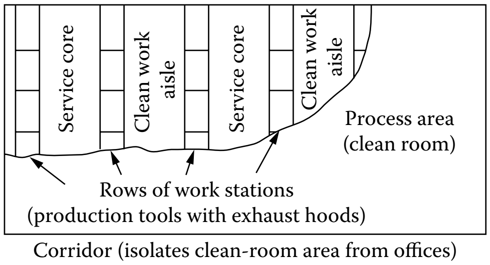

FIG. 8.14a
The configuration of a semiconductor manufacturing clean-room with rows of workstations and a corridor surrounding the whole area.

In order to prevent contamination through air infiltration from the surrounding spaces, the pressure in the clean-room must be higher than that of the rest of the building. As shown in Figure 8.14a, the clean-room is surrounded by a perimeter corridor. In order to protect against the in-leakage of dirty air from the corridor, the clean-room pressure is controlled above it.

The clean-room is made up of rows of workstations. These rows are also referred to as zones. A typical semiconductor producing plant has approximately 200 workstations, which are also called subzones. Each subzone faces the clean work aisle, and behind it is the service core.

Subzone Optimization

As shown in Figure 8.14b, air is supplied to the subzone through filters located in the ceiling in front of the workstation. The total flow and the temperature of this air supply are both controlled. The evacuated exhaust air header is connected to the lower hood section of the workstation. It pulls in all the air and chemical fumes that are generated in the workstation and safely exhausts them into the atmosphere.

In order to make sure that none of the toxic fumes will spill into the work aisle, clean air must enter the workstation at a velocity of about 75 fpm (0.38 m/s). The air that is not pulled in by the exhaust system enters the service core, where some of it is recirculated back into the workstation by a local fan. The rest of the air is returned from the service core by the return air header. A damper in this header (RAR-1) is modulated to control the pressure (DPS-1) in the clean work aisle.

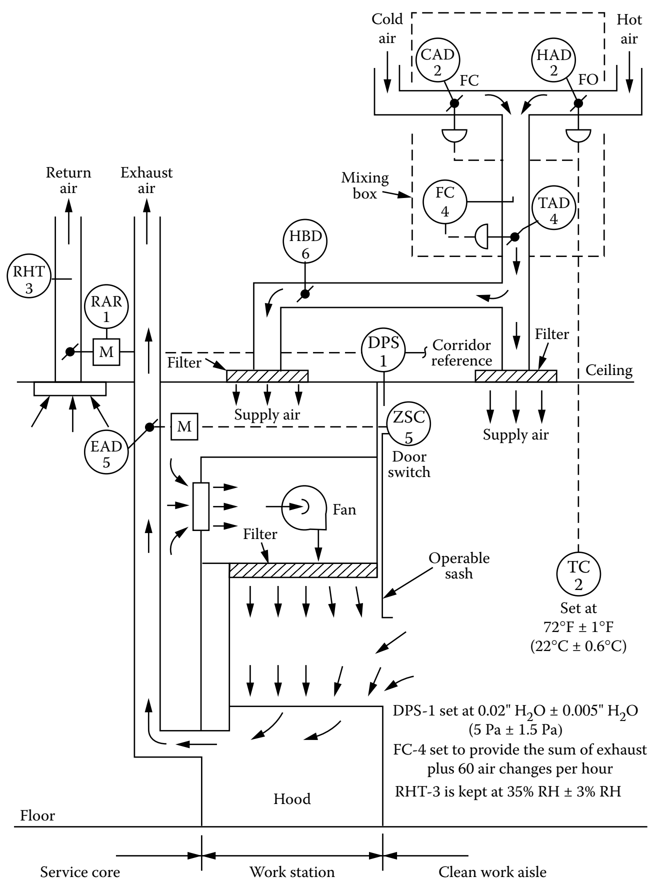

FIG. 8.14b

Workstation controls maintain comfort while guaranteeing that all toxic chemical fumes are removed from the work area.

The filter shown in Figure 8.14b can be a standard HEPA filter, which is efficient up to 99.97% at 0.3 micrometers, or it can be an ULPA filter, which is efficient up to 99.9995% at 12 micrometers.

Pressure Controls The pressure in the corridor is the reference for the clean-room pressure controller DPS-1 in Figure 8.14b. This controller is set to maintain a few hundredths of an inch of positive pressure relative to the corridor. The better the quality of building construction, the higher this set point can be, but even with the lowest quality buildings, a setting of approximately 0.02 in. H_2O (5 Pa) can easily be maintained.

At such near-atmospheric pressures, air behaves as if it were incompressible, so the pressure control loop shown in Figure 8.14b is both fast and stable. When the loop is energized, DPS-1 quickly rotates the return air control damper (RAR-1) until the preset differential is reached. At that point, the electric motor stops rotating the damper, and it stays at its last opening. This position will remain unaltered as long as the air balance in the area remains the same:

$$\begin{aligned}\text{return airflow} = \text{supply airflow} - (&\text{exhaust airflow}\\ &+ \text{pressurization loss})\end{aligned} \tag{8.14(1)}$$

When this airflow balance is altered (for example, as a result of a change in exhaust airflow), it will cause a change in the space pressure, and DPS-1 will respond by modifying the opening of RAR-1.

Elimination of Drafts Plant productivity is maximized if drafts are eliminated in the clean work aisle. Drafts would stir up the dust in this area, which in turn would settle on the product and cause production losses. In order to eliminate drafts, the pressure at each workstation must be controlled at the same value. Doing so eliminates the pressure differentials between stations and therefore prevents drafts. When a DPS-1 unit is provided to control the pressure at each workstation, the result is a uniform pressure profile throughout the clean-room.

PDS-1 usually controls the pressure in the clean work aisle on the "process" side of the workstation. Yet, it is important to make sure that all points, including the service aisle, are under positive pressure. Because the local circulating fan within the workstation draws the air in from the service core and discharges it into the clean work aisle, the pressure in the service core will always be lower than that on the process side (see Figure 8.14b). On the other hand, it is possible for localized vacuum zones to evolve in the service core. This could cause contamination by allowing air infiltration into the service core. To prevent this from happening, several solutions have been proposed.

One possibility is to have DPS-1 control the service core pressure. This is not recommended, because a draft-free process area can be guaranteed only if there are no pressure gradients on the work aisle side; this can only be achieved by locating the DPS-1 units on the work aisle side of the workstations.

Another possibility is to leave the pressure controls on the work aisle side but raise the set point of DPS-1 until all the service cores in the plant are also at a positive pressure. This solution cannot be universally recommended either, because the quality of building construction might not be high enough to allow operation at elevated space pressures. The pressurization loss in badly sealed buildings can make it impossible to reach the elevated space pressure.

Yet another solution is to install a second DPS controller, which would maintain the service core pressure by throttling the damper HBD-6. This solution will give satisfactory performance but will also increase the cost of the control system by the addition of a few hundred control loops (one per workstation).

A more economical solution is shown in Figure 8.14b. Here, a hand-operated bypass damper (HBD-6) is manually set during initial balancing. This solution is reasonable for most applications, because the effect of the workstation fan is not a variable, and therefore a constant setting of HBD-6 should compensate for it.

Temperature Controls The temperature at each workstation is controlled by a separate thermostat, TC-2 in Figure 8.14b.

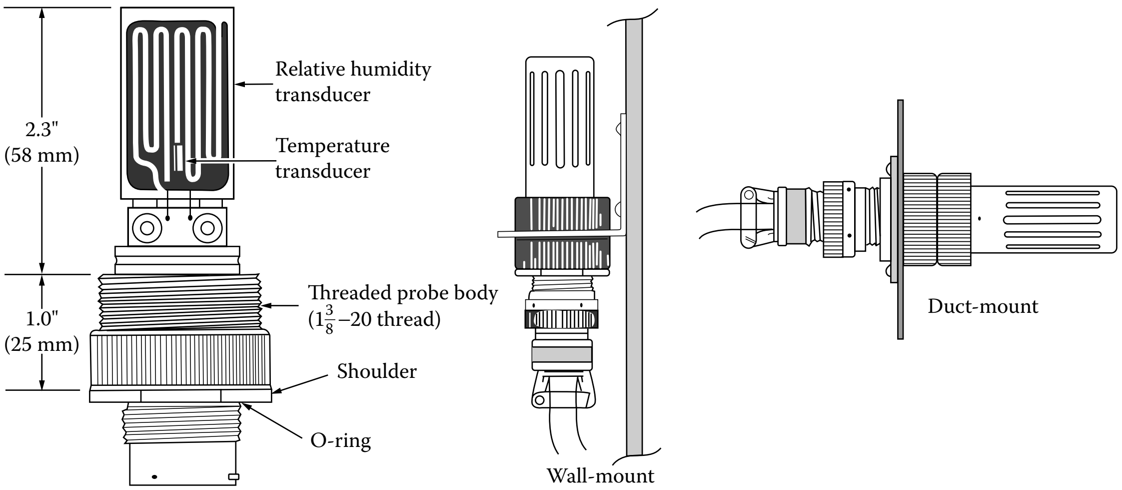

FIG. 8.14c
Polystyrene surface conductivity humidity element. (Courtesy of General Eastern.)

This temperature control adjusts the ratio of cold air to hot air within the supply air mixing box to maintain the space temperature.

Unfortunately, conventional thermostats cannot be used if the temperature gradients within the clean-room are to be kept within ±1°F of 72°F (–0.6°C of 22°C). Conventional thermostats cannot meet this requirement for either measurement accuracy or control quality. Even after individual calibration, it is unreasonable to expect an error of less than ±2 or 3°F (±1 or 1.7°C) in the overall loop performance if HVAC-quality thermostats are used. Part of the reason for this is the fact that the "offset" cannot be eliminated in plain proportional controllers such as thermostats (Section 7.9).

Thus, in order for the thermostat to move its output from the mid-scale value (50–50% mixing of cold and hot air), an error in room temperature must first develop. This error is the permanent offset. The size of this offset error for TC-2 in Figure 8.14b for the condition of maximum cooling can be determined as follows:

$$\text{offset error} = \frac{\text{spring range of CAD}}{2(\text{thermostat gain})} \qquad \mathbf{8.14(2)}$$

Assuming that CAD-2 has an 8–13 PSIG (55–90 kPa) spring (a spring range of 5 PSI, or 34.5 kPa) and that TC-2 is provided with a maximum gain of 2.5 psi/°F (31 kPa/°C), the offset error is 1°F (0.6°C). Under these conditions, the space temperature must permanently rise to 73°F (22.8°C) before CAD-2 can be fully opened. The offset error will increase as the spring range increases or as the thermostat gain is reduced. Sensor and set-point dial error are always additional to the offset error.

Therefore, in order to control the clean-room temperature within ±1°F (±0.6°C), it is necessary to use an RTD-type or a semiconductor transistor-type temperature sensor and a proportional-plus-integral controller, which will eliminate the offset error. This can be most economically accomplished through the use of microprocessor-based shared controllers that communicate with the sensors over a pair of telephone wires that serve as a data highway.

Humidity Controls The relative humidity sensors are located in the return air stream (RHT-3). In order to keep the relative humidity in the clean-room within 35% RH ±3% RH, it is important to select a sensor with an error lower than ±3% RH. The repeatability of most relative humidity sensors (see Section 8.32 in the first volume of this handbook) is approximately ±1% RH.

Figure 8.14c illustrates the polystyrene surface conductivity-type humidity element. These units are available for duct mounting and can be used for clean-room control applications if they are individually calibrated for operation at or around 35% RH. Without such individual calibration, they will not perform satisfactorily, because their off-the-shelf inaccuracy, or error, is approximately ±5% RH.

The controller associated with RHT-3 is not shown in Figure 8.14b, because relative humidity is not controlled at the workstation (subzone) level but at the zone level (as mentioned earlier, a zone is a row of workstations). The control action is based on the relative humidity reading in the combined return air stream from all workstations within that zone.

Flow Controls The proper selection of the mixing box serving each workstation is of critical importance. Each mixing box serves the dual purpose of providing accurate control of the total air supply to the subzone and of modulating the ratio of "cold" and "hot" air to satisfy requirements of the space thermostat TC-2.

The total air supply flow to the subzone should equal 60 air changes per hour plus the exhaust rate from subzone. This total air supply rate must be controlled within ±5% of actual flow by FC-4, over a flow range of 3:1. The rangeability of 3:1 is required because as processes change, their associated exhaust requirements will also change substantially.

FC-4 in Figure 8.14b can be set manually, but this setting must change every time a new tool is added to or removed from the subzone. The setting of FC-4 must be done by individual in-place calibration against a portable hot wire anemometer reference (Sections 2.2 and 2.13 in Volume 1). Settings based on the adjustments of the mixing box alone (without an anemometer reference) will not provide the required accuracy.

Some of the mixing box designs available on the market are not acceptable for this application. Such unacceptable designs include the following:

- "Pressure-dependent" designs, in which the total flow will change with air supply pressure. Only "pressure-independent" designs can be considered, because both the cold and the hot air supply pressures to the mixing box will vary over some controlled minimum.
- Low rangeability designs. A 3:1 rangeability with an accuracy of ±5% of *actual* flow is required.
- Selector or override designs. In these designs either flow or temperature is controlling on a selective basis. Such override designs will periodically disregard the requirements of TC-2 and will thus induce upsets, cycling, or both.

If the mixing box is selected to meet the aforementioned criteria, both airflow and space temperature can be accurately controlled.

Optimization of the Zones

Each row of workstations shown in Figure 8.14a is called a zone, and each zone is served by a cold deck (CD), a hot deck (HD), and a return air (RA) subheader. These subheaders are frequently referred to as *fingers*. The control devices serving the individual workstation (subzones) will be able to perform their assigned control tasks only if the "zone finger" conditions make it possible for them to do so.

For example, RAR-1 in Figure 8.14b will be able to control the subzone pressure as long as the ΔP across the damper is high enough to remove all the return air without requiring the damper to open fully. As long as the dampers are throttling (neither fully open nor completely closed), DPS-1 in Figure 8.14b is in control.

PIC-7 in Figure 8.14d is provided to control the vacuum in the RA finger and thereby to maintain the required ΔP across RAR-1. PIC-7 is a nonlinear controller with a fairly wide neutral band. This protects the CD finger temperature (TIC-6 set point) from being changed until a sustained and substantial change takes place in the detected RA pressure.

Similarly, the mixing box in Figure 8.14b will be able to control subzone supply flow and temperature as long as its dampers are not forced to take up extreme positions. Once a damper is fully open, the associated control loop is out of control. Therefore, the purpose of the damper position controllers (DPCs) in Figure 8.14d is to prevent the corresponding dampers from having to open fully.

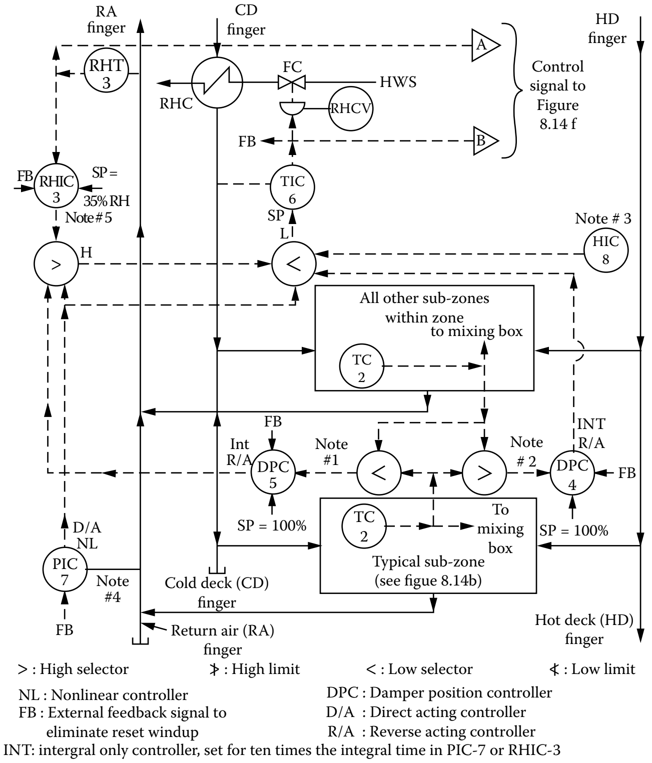

FIG. 8.14d

Typical zone control system that is under envelope control. Note 1: This is the opening of the most-open hot air damper. HAD-2 (shown in Figure 8.14b) which is fully open when the TC-2 output is minimum. Note 2: This is the opening of the most-open cold air damper. CAD-2 (shown in Figure 8.14b) is fully open when the TC-2 output is maximum. Note 3: HIC-8 sets the maximum limit for the CD temperature at approximately 70°F (21°C). Note 4: As vacuum increases (and pressure decreases), the output of PIC-7 also increases. Note 5: The controller action is D/A in summer, R/A in winter.

Lastly, the relative humidity in the return air must also be controlled within acceptable limits. Therefore, at the zone level there are five controlled, or limit variables but only one manipulated variable:

Limit or Controlled Variables	*Manipulated Variable*
RA pressure	TIC-6 set point
RA relative humidity	
Max. CAD opening	
Max. HAD opening	
Max. TIC-6 set point	

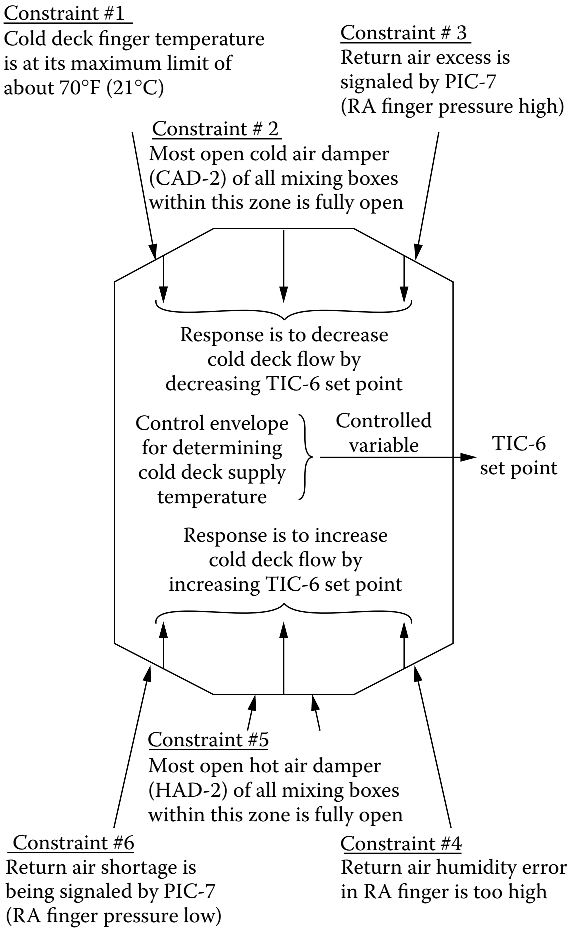

FIG. 8.14e

For optimized control of the cold deck temperature, a constraint envelope-based control system can be used.

Figure 8.14d shows the control loop configuration required to accomplish the aforementioned goals. It should be noted that dynamic lead/lag elements are not shown and that this loop can be implemented in either hardware or software.

Envelope Optimization Whenever the number of control variables exceeds the number of available manipulated variables, it is necessary to apply multivariable envelope control. This means that the available manipulated variable (TIC-6 set point) is not assigned to serve a single task but is selectively controlled to keep many variables within acceptable limits—within the "control envelope" shown in Figure 8.14e.

By adjusting the set point of TIC-6, it is possible to change the cooling capacity represented by each unit of CD air. Because the same cooling can be accomplished by using less air at lower temperatures or by using more air at higher temperatures, the overall material balance can be maintained by manipulating the set point of the heat balance controls.

Return air humidity can similarly be affected by modulating the TIC-6 set point, because when this set point is increased, more CD air will be needed to accomplish the required cooling. Increasing the ratio of humidity-controlled CD air in the zone supply (HD humidity is uncontrolled) also brings the zone closer to the desired 35% RH set point.

In this envelope control system, the following conditions will cause an increase in the TIC-6 set point:

- Return air shortage detected by a drop in the RA finger pressure (increase in the detected vacuum) measured by PIC-7. An increase in the TIC-6 set point will increase the CD demand (opens all CAD-2 dampers in Figure 8.14b), which in turn lowers the HD and, therefore, the RA demand.
- Hot air damper in mixing box (HAD-2 in Figure 8.14b) is near to being fully open. This, too, necessitates the aforementioned action to reduce HD demand.
- RA humidity does not match the RHIC-3 set point. This condition also necessitates an increase in the proportion of the CD air in the zone supply. Because the moisture content of the CD air is controlled, an increase in its proportion in the total supply will help control the RH in the zone.

On the other hand, the following conditions will require a decrease in the TIC-6 set point:

- Return air excess detected by a rise in RA finger pressure (drop in the detected vacuum) measured by PIC-7.
- Cold air damper in mixing box (CAD-2 in Figure 8.14b) is fully open.
- CD finger temperature exceeds 70°F (21°C). This limit is needed to keep the CD always cooler than the HD.

Plantwide Optimization

In conventionally controlled semiconductor plants, both the temperature and the humidity of the main CD supply air are fixed. This can severely restrict the performance of such systems, because as soon as a damper or a valve is fully open (or closed), the conventional system is out of control.

The optimized control system described here does not suffer from such limitations, because it automatically adjusts both the main CD supply temperature and the humidity so as to follow the load smoothly and continuously, never allowing the valves or dampers to lose control by fully opening or closing. The net result is not only increased productivity but also reduced operating costs.

A semiconductor production plant might consist of two dozen zones. Each of the zones can be controlled as shown in Figure 8.14d. The total load represented by all the zones is followed by the controls shown in Figure 8.14f. The overall control system is hierarchical in its structure: The subzone controls in Figure 8.14b are assisted by the zone controls in

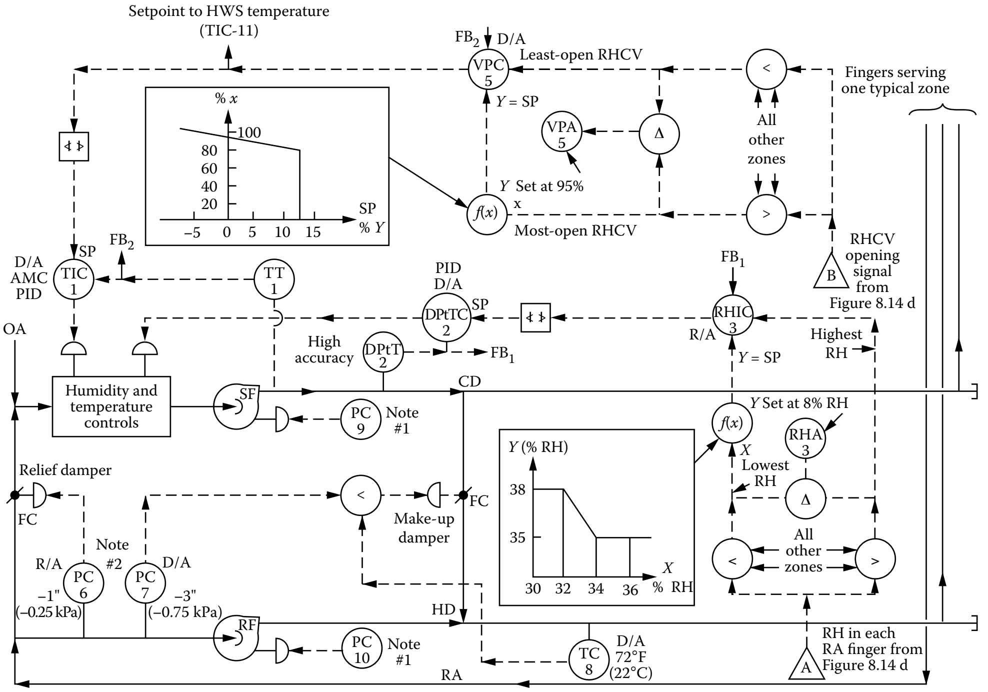

FIG. 8.14f

The plantwide control system handles the total load, the sum of the loads of all the zones in an optimized manner. Symbols: AMC = Controller with positions for automatic-manual-cascade modes of operation. DPtIC = Dew point controller. INT = Controller with integral control action only. Its setting is to be 10 times the integral time setting of the associated process controller(s). PID = Controller with proportional, integral, and derivative control modes. VPC = Valve position controller. Note 1: This pressure controller keeps the lowest of all finger pressures at a value above some minimum. It modulates the fan volume or speed and starts extra fan units to meet the load. When the load drops, the unnecessary fans are stopped by flow (not pressure) control. Note 2: If the pressure rises above −1 in. H_2O (−0.25 kPa), the relief damper starts to open, and if the pressure drops below −3 in. H_2O (−0.75 kPa), the makeup damper opens. This opening is limited by TC-8, which prevents the HD temperature from dropping below 72° (22°C). Between the settings of PC-6 and PC-7, both dampers are tightly closed and the suction pressure floats.

Figure 8.14d, and the plantwide controls in Figure 8.14f guarantee that the zone controllers can perform their tasks.

The interconnection among the levels of the hierarchy is established through the various valve and damper position controllers (VPCs and DPCs). These guarantee that no throttling device, such as mixing boxes or RHC valves, anywhere in this plant will ever be allowed to reach an extreme position. Whenever a control valve or a damper is approaching the point of losing control (nearing full opening), the load-following control system at the next higher level modifies the air or water supply conditions so that the valve or damper in question will not need to open fully. The hierarchical control scheme is depicted in Figure 8.14g.

The overall plantwide control system shown in Figure 8.14f can be viewed as a flexible combination of material balance and heat/humidity balance controls. Through the load-following optimization of the set points of TIC-1 and TIC-11, the heat balance controls are used to assist in maintaining the material balance around the plant. For example, if the material balance requires an increase in airflow and the heat balance requires a reduction in the heat input to the space, both requirements will be met by admitting more air at a lower temperature.

Material Balance Controls The plantwide material balance is based on pressure control. PC-9 and PC-10 modulate the variable-volume fans so as to maintain a minimum supply pressure in each of the CD and HD fingers. The suction side

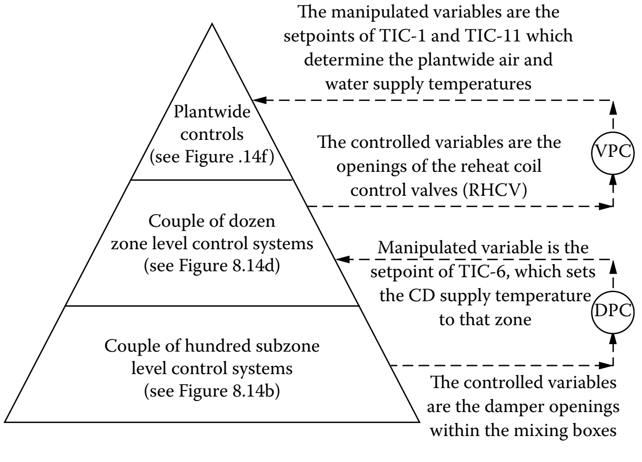

FIG. 8.14g

The overall control architecture in a semiconductor manufacturing plant is hierarchical in structure.

of the CD supply fan station is open to the outside and will draw as much outside air as the load demands (Figure 8.14f).

The suction pressure of the HD supply fan station is an indication of the balance between RA availability and HD demand. This balance is maintained by PIC-7 in Figure 8.14d, at the zone level. Because this controller manipulates a heat transfer system (RHCV), it must be tuned for slow, gradual action. This being the case, it will not be capable of responding to sudden upsets or to emergency conditions, such as the need to purge smoke or chemicals.

Such sudden upsets in material balance are corrected by PC-6 and PC-7 in Figure 8.14f. PC-6 will open a relief damper if the suction pressure is high (vacuum is low), and PC-7 will open a makeup damper if it is low (vacuum is high). In between these limits, both dampers will remain closed and the suction pressure will be allowed to float.

Heat Balance Controls Heat balance also requires a multivariable envelope control system (similar to that shown in Figure 8.14e), because the number of controlled variables exceeds the number of available manipulated variables. Therefore, the plantwide air and water supply temperature set points (TIC-1 and TIC-11) are not adjusted as a function of a single consideration but are selectively modulated to keep several variables within acceptable limits inside the control envelope (Figure 8.14e).

By adjusting the set points of TIC-1 and TIC-11, it is possible to adjust the cooling capacity represented by each unit of CD supply air and the heating capacity of each unit of hot water. This then provides not only for load-following control but also for minimization of the operating costs. Cost reductions are accomplished by minimizing the HWS temperature and by minimizing the amount of simultaneous cooling and reheating of the CD air.

This control envelope is so configured that the following conditions will decrease the TIC set points (both TIC-1 and TIC-11):

1. The least-open RHCV is approaching full closure.
2. CD supply temperature is at its maximum limit.

On the other hand, the following conditions will require an increase in the TIC set points:

1. The most-open RHCV is approaching full opening.
2. The CD supply temperature is at its minimum limit.

The set point of VPC-5 in Figure 8.14f is produced by a function generator, $f(x)$. The dual purposes of this loop are 1) to prevent any of the reheat coil control valves (RHCVs) from fully opening and thereby losing control, and 2) to force the least-open RHCV toward a minimum opening, so as to minimize wasteful overlap between cooling and reheat. All this is done while keeping any of the RHCVs from fully closing as long as possible.

These purposes are accomplished by $f(x)$, which keeps the least-open valve at approximately 12% opening as long as the most-open valve is less than 90% open. If this 90% opening is exceeded, $f(x)$ prevents the most-open valve from fully opening. It does so by lowering the set point of VPC-5, which in turn will increase the set points of the TICs.

Increasing the set point of TIC-1 reduces the load on the most-open RHCV, whereas increasing the TIC-11 set point increases the heating capacity at the reheat coil. Through this method of load-following and through the modulation of main supply air and water temperatures, all zones in the plant will be kept under stable control if the loads are similar in each zone.

Mechanical Design Limitations All control systems — including this one—will lose control when the design limits of the associated mechanical equipment are reached or if the dissimilarity in load distribution is greater than that which was anticipated by the mechanical design. Therefore, if a condition ever arises in which one zone requires large amounts of cooling (associated RHCV closed) while at the same time some other zone requires its finger reheat coil valve to be fully open, then the control system cannot control both.

In such a case, the control system must decide which condition it is to correct. The control system in Figure 8.14f is so configured that it will give first priority to preventing the RHCV valve from fully opening. Therefore, if as a result of mechanical design errors or because of the misoperation of the plant there is no CD supply temperature that can keep all valves from fully closing or from fully opening, then the control system will allow some RHCV valves to close while preventing all of them from fully opening.

Whenever such a condition is approaching (that is, when the difference between the opening of the most-open and the least-open valves reaches 95%), a valve position alarm (VPA-5) is actuated. This allows the operator to check the causes of such excessively dissimilar loads between the zones and to take corrective action by revising processes, relocating tools, modifying air supply ducts, or adding or removing mixing boxes.

By keeping all RHCV valves from being nearly closed, this control system simultaneously accomplishes the following goals:

1. Eliminates unstable (cycling) valve operation by not allowing valves to operate nearly closed
2. Minimizes pumping costs by minimizing pressure losses through throttling valves
3. Minimizes heat pump operating costs by minimizing the required hot water temperature
4. Provides a means of detecting and thereby smoothly following the variations in the plantwide load

Humidity Controls At the zone level, the RA humidity is controlled by RHIC-3 in Figure 8.14d. In addition, the dew point of the main CD air supply must be modulated. The main CD supply temperature is already being modulated to follow the load. This is accomplished by measuring the relative humidity in all RA fingers (RHT-3 in Figure 8.14d) and selecting the one finger that is farthest away from the control target of 35% RH.

The control system is similar to the TIC set point optimization loop discussed earlier. The first elements in the loop are the selectors shown in Figure 8.14f. They pick out the return air fingers with the highest and the lowest relative humidity readings. The purpose of the loop is to "herd" all RH transmitter readings in such a direction that both the highest and the lowest readings will fall within the acceptable control gap limits of 35% ±3% RH. This is accomplished by sending the highest reading to RHIC-3 in Figure 8.14f as its measurement and also sending the lowest reading to this RHIC-3 as its modified set point.

A humidity change in either direction can be recognized and corrected through this herding technique. The set point of RHIC-3 is produced by the function generator, $f(x)$. Its dual purposes are to prevent the most humid RA finger from exceeding 38% RH and to keep the driest RA finger humidity from dropping below 32% RH, as long as this can be accomplished without violating the first goal.

These purposes are accomplished by keeping the set point of RHC-3 at 35% as long as the driest finger reads 34% RH or more. If it drops below that value, the set point is raised to the limit of 38% RH in order to overcome this low-humidity condition, without allowing excessive humidity in the return air of some other zone.

This control strategy and the RHIC-3 controller in Figure 8.14d will automatically respond to seasonal changes and will give good RH control as long as the loads in the various zones are similar. If the humidity loads are substantially dissimilar, this control system is also subject to mechanical equipment limitations. In other words, the mechanical equipment is so configured that addition or removal of moisture is possible only at the main air supply to the CD. Consequently, if some zones are moisture-generating and others require humidification, this control system can respond to only one of these needs.

Therefore, if the lowest RH reading is below 32% while the highest is already at 38%, the low-humidity condition will be left uncontrolled, and the high-humidity zone will be controlled to prevent it from exceeding the 38% RH upper limit. Allowing the minimum limit to be temporarily violated while maintaining control on the upper limit is a logical and safe response to humidity load dissimilarities between zones. It is safe because the intermixing of the return airs will allow self-control of the building by transferring moisture from zones with excess humidity to ones with humidity deficiency.

Whenever the difference between minimum and maximum humidity readings reaches 8% RH, the RHA-3 alarm is actuated. This will alert operators that substantial moisture load dissimilarities exist so that they can seek out and eliminate the causes.

Exhaust Air Controls The exhaust air controls at the subzone level are shown in Figure 8.14b. At this level, the control element is a two-position damper, EAD-5. When the workstation is functioning, its operable sash is open. This condition is detected by the door position limit switch, ZSC-5, which in that case fully opens the two-position damper. When the workstation is out of service, its operable sash is closed, and therefore the door switch closes EAD-5 to its minimum position.

This minimum damper position still provides sufficient air exhaust flow from the workstation to guarantee the face velocity needed for operator safety. In other words, when the sash is closed, the air will enter the workstation over a smaller area; therefore, less exhaust airflow is required to provide the air inflow velocity that is needed to keep the chemical fumes from leaking out. Through this technique, the safety of operation is unaffected, and operating costs are lowered because less outside air needs to be conditioned if the exhaust airflow is lowered.

In order for EAD-5 to maintain the required exhaust air flow accurately, it is necessary to keep the vacuum in the exhaust air collection ductwork at a constant value. This pressure control loop is depicted in Figure 8.14h. In each zone exhaust finger, the PC-1 shown in Figure 8.14h keeps the vacuum constant by throttling the EAD-1 damper as required.

In order for these dampers to stay in control while the exhaust airflow varies, it is important to keep them from fully opening. This is accomplished first by identifying the most-open finger damper (low selector) and then by comparing its opening with the set point of the damper position controller, DPC-2.

The task of this controller is to limit the opening of the most-open EAD-1 to 80% and to increase the vacuum in the main EA header if this opening would otherwise exceed 80%. Therefore, if the measurement of DPC-2 exceeds 80%, the vacuum set point of PC-3 is increased (pressure setting lowered). This in turn will increase the operating level of the exhaust fan station (EAF).

The limits on the set point of DPC-2 will prevent mechanical damage, such as collapsing of the ducts as a result of excessive vacuum or manual misoperation. The reasons for integral action and external feedback are the same as in the case of all other damper and valve position controllers discussed earlier.

Figure 8.14h also shows a glycol-circulating heat recovery loop that can be used as shown to preheat the entering outside air or that can be used as a heat source to a heat pump in the winter (not shown). In either case, the operating cost of the plant in the winter is lowered by recovering the heat content of the air before it is exhausted.

The discharging of chemical vapors into the atmosphere is regulated by pollution considerations. The usual approach is to remove most of the chemicals by adsorption and scrubbing prior to exhaustion of the air. An added measure of safety is provided by exhausting the air at high velocity, so

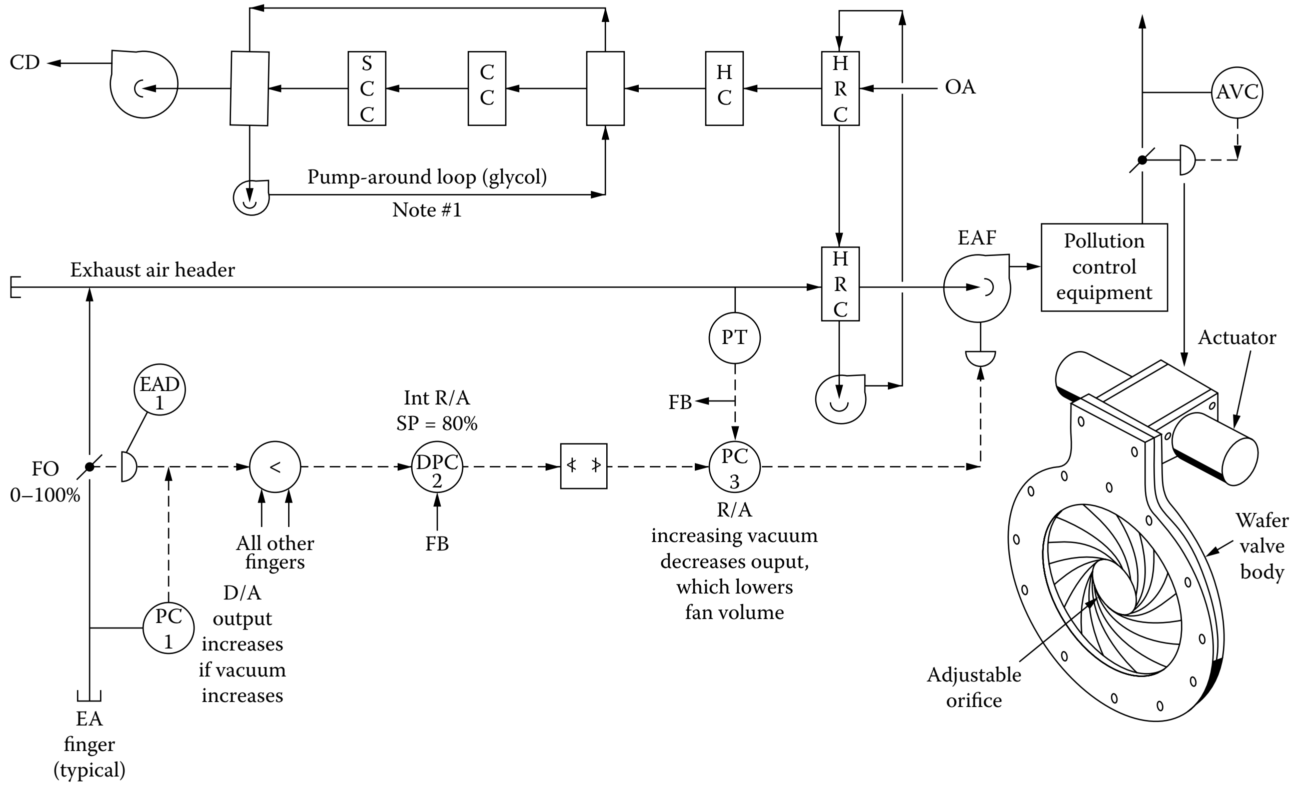

FIG. 8.14h

Exhaust air optimization controls are used to keep the vacuum in the exhaust air collection ductwork at a constant value and to maximize heat recovery. Note 1: When the need for dehumidification in the summer results in excessive overcooling of the CD air supply, and therefore in increased demand for reheat at the CD fingers, the pump-around economizer loop is started to lower operating cost. It also increases efficiency by reducing the degree of overcooling, thereby lowering the need for reheat.

as to obtain good dispersion in the atmosphere. Because the volume of air being exhausted varies, an air velocity controller (AVC in Figure 8.14h) is used to maintain the velocity of discharge constant. This is accomplished by modulation of a variable orifice iris damper, also illustrated in Figure 8.14h.

CONCLUSIONS

The productivity of semiconductor manufacturing plants can be greatly increased and the operating costs can be lowered through the control and optimization methods described in this section and by such added control system features as:

- Low leakage dampers (0.5 CFM/ft^2 at 4 in. H_2O ΔP, or 2.5 1/s/m^2 at 1 kPa ΔP)
- Accurate airflow metering for material balance and pressurization loss control
- Pump-around economizers (see Figure 8.14h)

The initial cost of the previously described control system is not higher than the cost of conventional systems, because the added expense of more accurate sensors is balanced by the reduced installation cost of distributed shared controls. Therefore, the benefit of increased productivity is a result not of higher initial investment but of better control system design.

It should be emphasized that the described load-following optimization envelope control strategy is far from being typical of today's practices in the semiconductor manufacturing industry. In fact, it has never been fully implemented, and many plants are still operated under conventional HVAC controls.

Therefore, the conclusion that yields will increase and operating costs will drop when such improved control systems are installed is an assumption. This appears to be supported by the results of partial system implementations that the author implemented at IBM plants and by the experiences in other industries but will remain an assumption until a semiconductor manufacturing plant that includes all the features of such modern controls is in operation.

INTRODUCTION

The transportation of vapors and gases is an important portion of the total operating cost of processing plants. The optimization of this unit operation can substantially lower the total operating cost of the plant. The goal of this section is to describe the strategies available to increase the safety and energy efficiency in these systems. Prior to the discussion of state-of-the-art advanced controls, the basic equipment and the conventional control strategies will be described.

Three types of compressors will be discussed: rotary, reciprocating, and centrifugal compressors. The emphasis will be on the centrifugal units, whose load, surge, and override controls will be described in some detail. Multiple compressor installations will also be described.

Compressors are gas transportation machines that perform the function of increasing the gas pressure by confinement or by kinetic energy conversion. Methods of capacity control for the principal types of compressors are listed in Table 8.15a. The method of control to be used is a function of process requirements, type of the driver, and cost considerations.

TABLE 8.15a
Capacity Control Methods Used on the Different Compressor Types

Compressor Type	*Capacity Control Method*
Centrifugal	Suction throttling Discharge throttling Variable inlet guide vanes Speed control
Rotary	Bypassing Speed control
Reciprocating	On/off control Constant-speed unloading Speed control Speed control and unloading

Because the driver constitutes half of the cost of the compressor installation, careful selection must be made in order to ensure trouble-free performance. Variable speed control can be accomplished by the use of steam turbines, gas turbines, or gasoline or diesel engines. Electric motors are well suited for both constant- and variable-speed applications.

The flow and discharge pressure ranges of the various compressor designs are shown in Figure 8.15b.

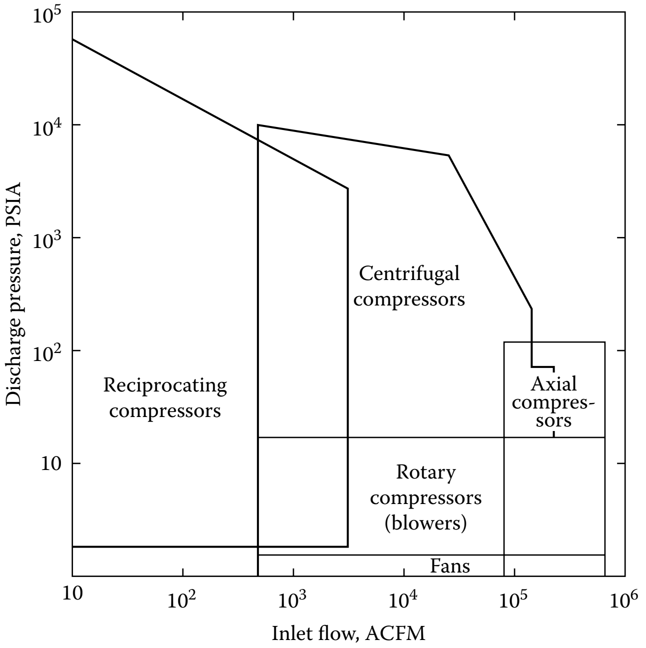

FIG. 8.15b
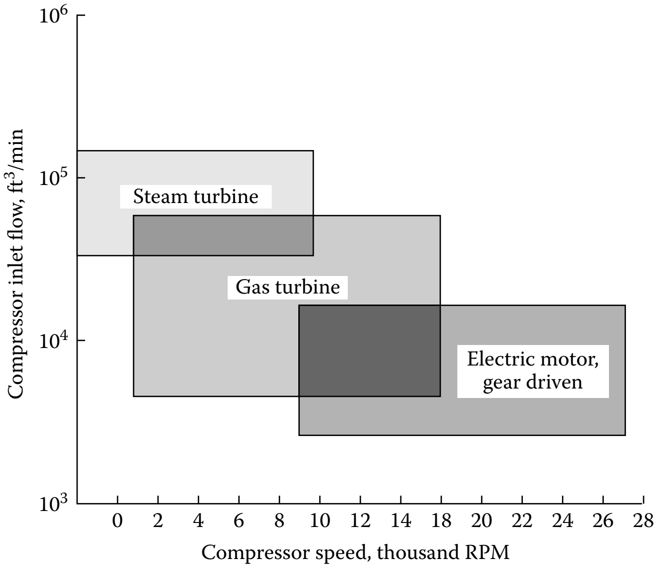
The range of flow capacities and discharge pressures that the different compressor designs can handle.[1]



Speed Governor Classification

Governor class	*Regulation*	*Variation*
A	10%	¾%
B	6%	½%
C	4%	¼%
D	½%	¼%

FIG. 8.15c
The speed and flow capacity ranges of standard compressor drives (top) and the classification of speed governors (bottom).

The operating ranges of the most popular drives are shown in Figure 8.15c. Also given in the lower part of the figure is the definition of some two-speed governors. Regulation error is the percentage of the difference in speed between the speed at zero power output and at the rated output. Variation error is the percentage variation that can be expected around the speed set point.

CENTRIFUGAL COMPRESSORS

The Compression Process

The centrifugal compressor is a machine that converts the momentum of gas into a pressure head.

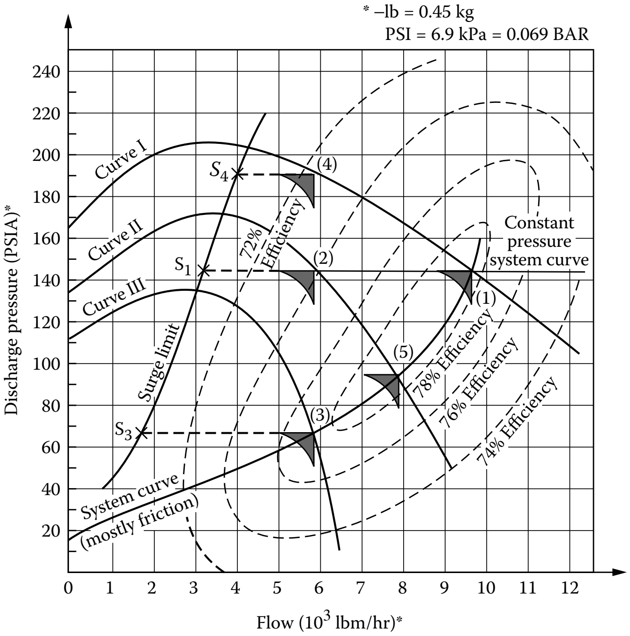
$$H = \frac{\tau\omega}{w} = \frac{n}{n-1} ZRT_I, \qquad [(P_D/P_I)^{\frac{n}{n-1}} - 1] \qquad \mathbf{8.15(1)}$$

Equation 8.15(1) is the basis for plotting the compressor curves and for understanding the operation of capacity controls. The nomenclature for the symbols in the equation is as follows:

h = differential head (ft or m)
H = polytrophic compressor head (ft or m)
$K_{1,2,3}$ = flow constant
m = mass flow (lb/hr or kg/hr) = $c\sqrt{h\zeta}$
n = polytrophic coefficient
P_D = discharge pressure (psia or Pa)
P_I = inlet pressure (psia or Pa)
Q = volume flow rate (ACFH or m^3/hr) = $c\sqrt{h\zeta}$
R = gas constant
T_1 = inlet temperature
u = rotor tip speed (ft/s or m/s)
W = weight flow (lbm/hr or kg/hr)
Z = gas compressibility factor
τ = motor torque (ft lb_f or J)
ψ = head coefficient
ω = angular velocity (radians/hr)
ζ = density of gas (lb/ft^3 or kg/m^3)

Characteristic Curves

In Equation 8.15(1), the pressure ratio (P_D/P_I) varies inversely with mass flow (W). For a compressor running at constant speed (ω), constant inlet temperature (T_1), constant molecular weight (implicit in R), and constant n, τ, and Z, the discharge pressure may be plotted against weight flow as in Figure 8.15d



*For SI units see Section A.1

FIG. 8.15d
The operating point is located where the centrifugal compressor curves cross the system curve of the process. The system curve can be a constant pressure one (horizontal line), a mostly friction one, or any other.

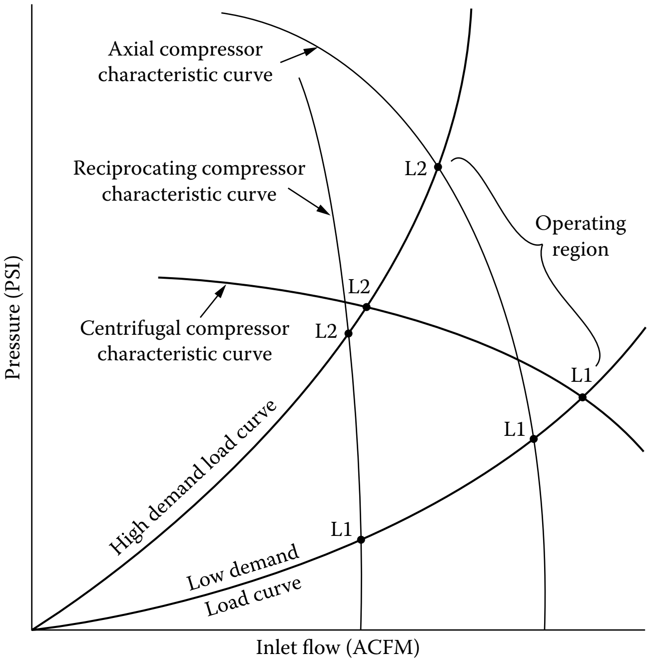


FIG. 8.15e
The characteristic curve of the axial compressor is steep, while that of the centrifugal compressor is flat. (Adapted from Reference 1.)

(curve I). The design point (1) is located in the maximum efficiency range at design flow and pressure.

Positive-displacement compressors pressurize gases through confinement. Dynamic compressors pressurize them by acceleration. The axial compressor moves the gas parallel to the shaft. In the case of the centrifugal compressor, the gas receives a radial thrust toward the wall of the casing where it is discharged.

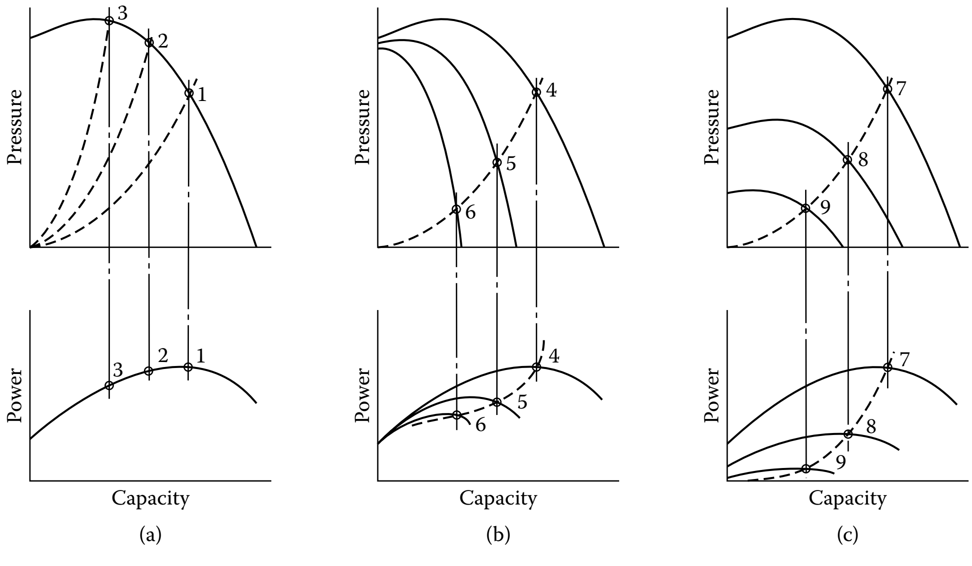
The axial compressor is better suited for constant flow applications, whereas the centrifugal design is more applicable for constant pressure applications. This is because the characteristic curve of the axial design is steep, and that of the centrifugal design is flat (Figure 8.15e). The characteristic curve of a compressor plots its discharge pressure as a function of flow, and the load curve relates the system pressure to the system flow. The operating points (*L*1 or *L*2 in Figure 8.15e) are the intersections of these curves. The normal operating region falls between the low and the high demand load curves in Figure 8.15e.

Axial compressors are more efficient; centrifugal ones are better suited for dirty or corrosive services.

Compressor Throttling

Compressor loading can be reduced by throttling a discharge or a suction valve, by modulating a prerotation vane, or by reducing the speed. As is shown in Figure 8.15f, discharge throttling is the least energy efficient and speed modulation is the most energy efficient method of turndown. Suction throttling is a little more efficient and gives a little better turndown than discharge throttling, but it is still a means of wasting that transporting energy that should not have been introduced in the first place.

Guide vane positioning, which provides prerotation or counter-rotation to the gas, is not as efficient as speed modulation, but it does provide the greatest turndown. As is shown in Figure 8.15f, speed control is the most efficient, as small



(a) (b) (c)

FIG. 8.15f
The efficiencies of discharge throttling (left), suction throttling (center), and variable speed control (right).

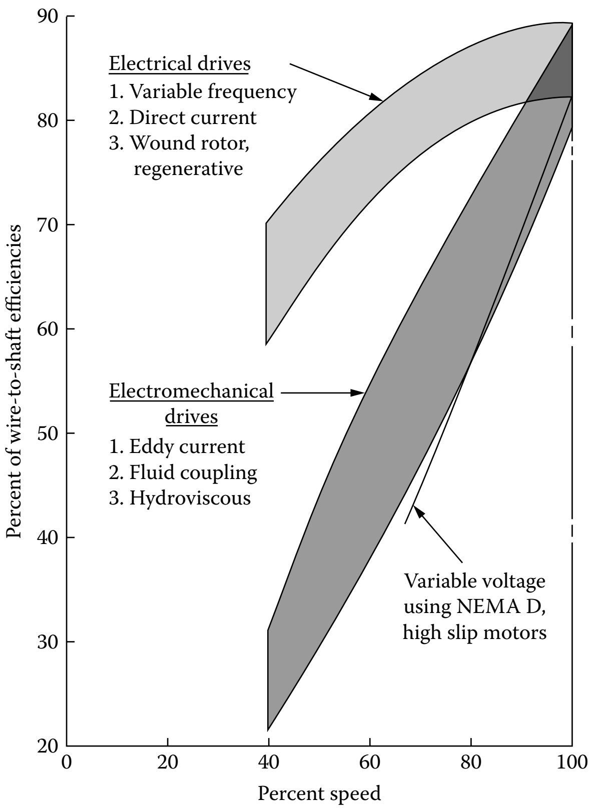


FIG. 8.15g
Wire-to-shaft efficiencies of electrical drives (top) are higher than those of the electromechanical drives.[2]

speed reductions result in large power savings because of the cubic relationship between speed and power.

If the discharge pressure is constant, flow tends to vary linearly with speed. If the discharge head is allowed to vary, it will change with the square of flow and, therefore, with the square of speed as well. This square relationship between speed and pressure tends to limit the speed range of compressors to the upper 30% of their range.[3]

Constant-speed steam turbine governors can be converted into variable-speed governors by revising the quick-opening characteristics of the steam valve into a linear one. The efficiency of variable-speed drives varies substantially with their design (Figure 8.15g). Electric governors tend to eliminate the dead bands that are present in mechanical designs. They also require less maintenance because of the elimination of mechanical parts. Electric governors also give better turndowns and are quicker and simpler to interface with surge or computer controls.

The error in following the load increases as the speed of process disturbances increase or as the speed control loop speed is reduced. Therefore, it is desirable to make the speed loop response as fast as possible. On turbines, this goal is served by the use of hydraulic actuators, and the motor response is usually increased by the use of tachometer feedback.

For the purposes of the control systems shown in this chapter, it will be assumed that the compressor throughput is controlled through speed modulation with tachometer feedback.

Suction Throttling One can control the capacity of a centrifugal compressor by throttling a control valve in the suction line, thereby altering the inlet pressure (P_I). From Equation 8.15(1) it can be seen that the discharge pressure will be altered for a given flow when P_I is changed, and a new compressor curve will be generated. This is illustrated in Figure 8.15d (curves II and III).

Consider first that the compressor is operating at its normal inlet pressure (following curve I) and is intersecting the "constant pressure system" curve at point (1) with a design flow of 9600 lbm/hr (4320 kg/hr) at a discharge pressure of 144 psia (1 MPa) and 78% efficiency. If it is desired to change the flow to 5900 lbm/hr (2655 kg/hr) while maintaining the same discharge pressure, it would be necessary to shift the compressor from curve I to curve II.

The new intersection with the "constant pressure system" curve is at the new operating point (2), at 74% efficiency. In order to shift from curve I to curve II, one must change the discharge pressure of 190 psia (1.3 MPa) at the 5900 lbm/hr (2655 kg/hr) flow on curve I to 144 psia (1 MPa) on curve II. If the pressure ratio is 10 (P_D/P_I), then it would be necessary to throttle the suction by only $\Delta P_I = 46/10 = 4.6$ psi (32 kPa) to achieve this shift.

It is also important to consider how close the operating point (2) is to the surge line. The surge line represents the low-flow limit for the compressor, below which its operation will become unstable as a result of momentary flow reversals. Methods of surge control will be discussed later in this section. At point (2) the flow is 5900 lbm/hr (2655 kg/hr), and at the surge limit (S_1) it is 3200 lbm/hr (1440 kg/hr). Thus, the compressor is operating at 5900/3200 = 184% of surge flow. This may be compared with curve I at point (1), where prior to suction throttling the machine was operating at 9600/3200 = 300% of surge flow.

The same method of suction throttling may be applied in a "mostly friction system" also shown in Figure 8.15d. In order to reduce the flow from 9600 lbm/hr (4320 kg/hr) to 5900 lbm/hr (2655 kg/hr), it is necessary to alter the compressor curve from curve II to III, so that the intersection with the "mostly friction system curve" is at the new operating point (3), at 77% efficiency.

In order to do this, one must change the discharge pressure from 190 psia (1.3 MPa—on curve I) to 68 psia (0.5 MPa—on curve III). Thus, $\Delta P_D = 190 - 68 = 122$ psi (0.8 MPa), and the amount of inlet pressure throttling for a machine with a compression ratio of 10 is $\Delta P_I = 122/10 = 12.2$ psi (84 kPa). The corresponding surge flow is at 1700 lbm/hr (765 kg/hr), which means that the compressor is operating at 5900/1700 = 347% of surge flow. Therefore,

TABLE 8.15h

Compressor Performance Parameters as a Function of Throttling Method

	Control Valve ΔP(PSI)	*Compressor Efficiency*	*Operation Above Surge By*
Suction throttling "constant pressure system"	4.6	74%	184%
Suction throttling "mostly friction system"	12.2	77%	347%
Discharge throttling "mostly friction system"	122	72%	148%

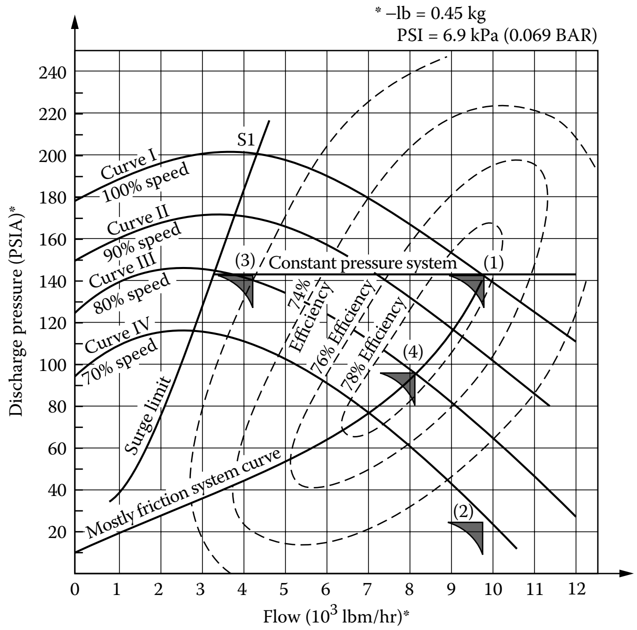
surge is less likely in a "mostly friction system" than in a "constant-pressure system" under suction throttling control.

Discharge Throttling A control valve on the discharge of the centrifugal compressor may also be used to control its capacity. In Figure 8.15d, if the flow is to be reduced from 9600 lbm/hr (4320 kg/hr) at point (1) to 5900 lbm/hr (2655 kg/hr), the compressor must follow curve I and therefore operate at point (4), at 190 psia (1.3 MPa) discharge pressure and 72% efficiency. However, the "mostly friction system" curve at this capacity requires only 68 psia (0.5 MPa) and the rest of the pressure is wasted through the discharge control valve. The surge flow (at S_4) is 4000 lbm/hr (1800 kg/hr), and the compressor is therefore operating at 5900/4000 = 148% of surge. Thus, surge is more likely to occur in a mostly friction system when discharge throttling is used than when suction throttling is used.

Table 8.15h compares the valve pressure drops, efficiencies, and surge margins of suction and discharge throttling.

Inlet Guide Vanes This method of control uses a set of adjustable guide vanes on the inlet to one or more of the compressor stages. By prerotation or counter-rotation of the gas stream relative to the impeller rotation, the stage is unloaded or loaded, thus lowering or raising the discharge head. The effect is similar to suction throttling as illustrated in Figure 8.15d (curves II and III), but less power is wasted because pressure is not throttled directly. Also, the control is two-directional, since it may be used to raise as well as to lower the band. It is more complex and expensive than throttling valves but may save 10 to 15% on power and is well suited for use on constant-speed machines in applications involving wide flow variations.

The guide vane effect on flow is more pronounced in constant discharge pressure systems. This can be seen in Figure 8.15d (curve II), where the intersection with the "constant pressure system" at point (2) represents a flow change from the normal design point (1) of 9600 − 5900 = 3700 lbm/hr (1665 kg/hr). The intersection with the "mostly friction system" at point (5) represents a flow change of only 9600 − 7800 = 1800 lbm/hr (810 kg/hr).



*For SI units see Section A.1

FIG. 8.15i

Control of centrifugal compressor capacity by speed variation.

Variable Speed The pressure ratio developed by a centrifugal compressor is related to the tip speed in the following manner:

$$\psi u^2/2g = \frac{ZRT_I}{(n-1/n)}[(P_D/P_I)^{(n-1/n)} - 1] \qquad \mathbf{8.15(2)}$$

From this relation the variation of discharge pressure with speed may be plotted for various percentages of design speed, as shown in Figure 8.15i. The obvious advantage of speed control from a process viewpoint is that both suction and discharge pressures can be specified independently of the flow.

The normal flow is shown at point (1) for 9700 lbm/hr (4365 kg/hr) at 142 psia (0.98 MPa). If the same flow is desired at a discharge pressure of 25 psia (173 kPa), the speed is reduced to 70% of design, shown at point (2). In order to achieve the same result through suction throttling with a pressure ratio of 10:1, the pressure drop across the valve would have to be (142 – 25)/10 = 11.7 psi (81 kPa), with the attendant waste of power, as a result of throttling. This is in contrast with a power saving accomplished with speed control, because power input is reduced as the square of the speed.

One disadvantage of speed control is apparent in constant-pressure systems, in which the change in capacity may be overlay sensitive to relatively small speed changes. This is shown at point (3), where a 20% speed change gives a flow change of (9600 − 4300)/9600 = 55%. The effect is less pronounced in a "mostly friction system," in which the flow change that results from a 20% speed change at point (4) is (9600 − 8100)/9600 = 16%.

Surge Control

The design of compressor control systems is not complete without consideration of surge control, because it affects the stability of the machine. Surging begins at the positively sloped section of the compressor curve. In Figure 8.15i this occurs at S_1 on the 100% speed curve at 4400 lbm/hr (1980 kg/hr). If the flow never drops below this limit, that will ensure safe operation for all speeds, but some power will be wasted at speeds below 100% because the surge limit decreases at reduced speed.

Even for a compressor running at a constant speed, the surge point changes as the thermodynamic properties vary at the inlet. This is shown in Figure 8.15j. Although inaccurate control of the surge point can put the compressor into deep surge, a conservatively set surge point results in useless recycling and wasted energy.

Various schemes to control surge are outlined in the following paragraphs. These include:

1. Compressor pressure rise ($\Delta P = P_D - P_I$) vs. differential across suction flow meter (h)
2. Pressure ratio (P_D/P_I) vs. actual volumetric flow (Q)
3. Break horsepower vs. mass flow (m)
4. Pressure ratio (P_D/P_I) vs. Mach number squared
5. Incipient surge
6. Surge spike detection

The Phenomenon of Surge In axial or centrifugal compressors, the phenomenon of momentary flow reversal is called surge. During surging, the compressor discharge pressure drops off and then is reestablished on a fast cycle. This cycling, or surging, can vary in intensity from an audible rattle to a violent shock. Intense surges are capable of causing complete destruction of compressor parts, such as blades and seals.

The characteristic curves of compressors are such that at each speed they reach a maximum discharge pressure as the flow drops (Figure 8.15k). A line connecting these points (*A* to *F*) is the surge line. If flow is further reduced, the pressure generated by the compressor drops below that which is already existing in the pipe, and momentary flow reversals occur. The frequency of these oscillations is between 0.5 and 10 Hz. The surge frequency of most compressor installations in the processing industries is slightly less than 1 Hz.[5] Surge is usually preceded by a stall condition, which is caused by localized flow oscillations around the rotor at frequencies of 50–100 Hz.

FIG. 8.15j

Discharge pressure generated and break horsepower used at various suction flows by a typical centrifugal compressor, under five different operating conditions.

At the beginning of surge, the total flow drops off within 0.05 seconds, and then it starts cycling rapidly at a period of less than 2 sec.[1] This period is usually shorter than that of the flow control loop, which controls the capacity of the compressor. If the flow cycles occur faster than the control loop can respond to them, this cycling will pass through undetected as uncontrollable noise. Therefore, fast sensors and instruments are essential for this loop.

As is shown in Figure 8.15k, the surge line is a parabolic curve on a plot of pressure rise (discharge pressure minus suction pressure) vs. flow. This function shows as increasing nonlinearity as the compression ratio increases. If the surge line is plotted as *Pd* − *Pi* vs. the square of flow (orifice differential = *h*), it becomes a straight line (Figure 8.15l) if the compression ratio is low (less than 4:1).

On a plot of ΔP vs. volumetric flow (Q), the following changes will reduce the safety margin between the operating

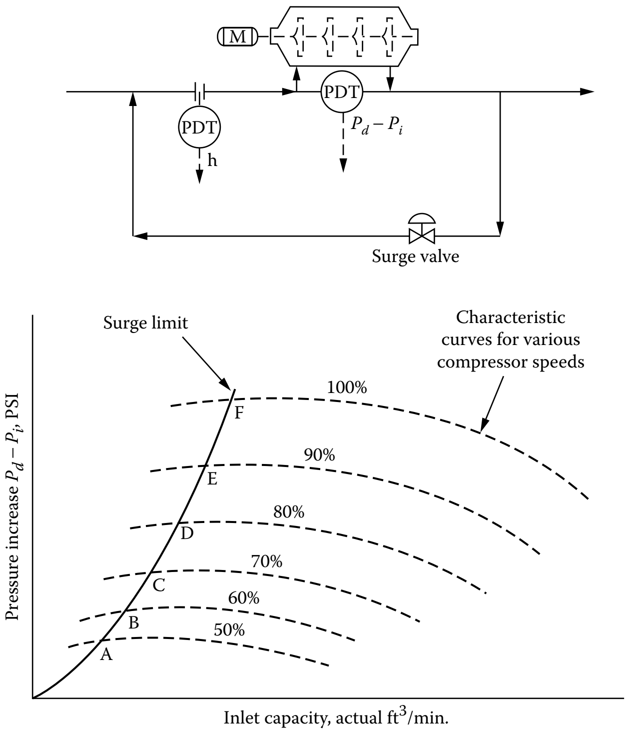

FIG. 8.15k

The location of the surge control valve (top) and the parabolic surge line of a speed-controlled centrifugal compressor (bottom).[4]

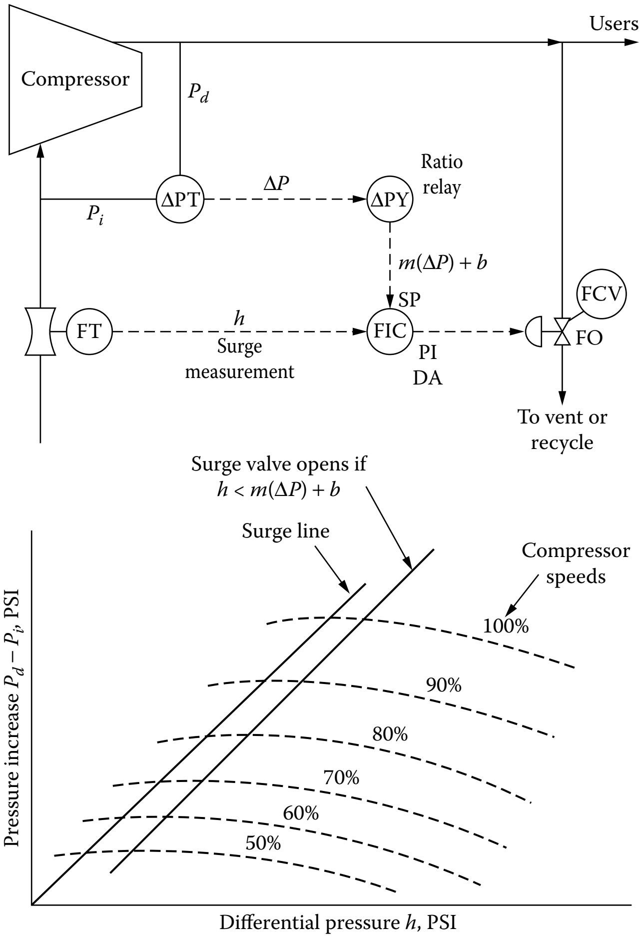

FIG. 8.15l

On a plot of ΔP vs. h, the surge curve becomes a straight line. (Adapted from Reference 4.)

point and the surge line: 1) a decrease in suction pressure; 2) an increase in suction temperature; 3) a decrease in molecular weight; 4) a decrease in specific heat ratio. These conditions will also increase the probability of surge (Figure 8.15k).

On a plot of ΔP vs. h (Figure 8.15l), these effects are most favorable. A decrease in suction pressure moves the surge line in the safe direction, temperature has no effect, and the effect of the other variables is also less pronounced. Therefore, although the ΔP vs. h plot is accurate only at low compression ratios, it does have the advantage of being independent from the effects of composition and temperature changes. However, suction pressure should be included in the model in order to be exact; most ΔP vs. h plots disregard it.

Variations in the Surge Curve Figure 8.15k shows the surge and speed characteristic curves of a centrifugal compressor; Figure 8.15m shows these curves for an axial compressor. The characteristic curves of the axial compressor are steeper, which makes it better for constant-flow services. The centrifugal design is better for constant pressure control.

The effect of guide vane throttling is also shown for both centrifugal and axial compressors (Figure 8.15n). As can be seen, the shape of the surge curve varies with the type of equipment used. The surge curve of speed-controlled centrifugal compressors bends up (Figure 8.15k), whereas for axial (Figure 8.15m) and vane-controlled machines (Figure 8.15n), the surge lines bend over. It is this negative slope of the axial compressor's surge curve that makes it sensitive to speed variations, because an increase in speed at constant flow can quickly bring the unit into surge.

As can be seen from the above information, the shape of the surge curve varies with compression ratio and with equipment design. It should also be noted that in case of multistage compressors, the surge line is discontinuous. If the compressor characteristics are as shown in Figure 8.15o, the addition of a compressor stage causes a break point in the surge curve. With more stages, more break points would also be added, and the resulting net effect is a surge curve that bends over instead of bending up, as does the surge curve for the single-stage compressor in Figure 8.15k.

Figure 8.15o also shows the choke curve. This curve connects the points at which the compressor characteristic lines become vertical. Below this curve, flow will stay constant

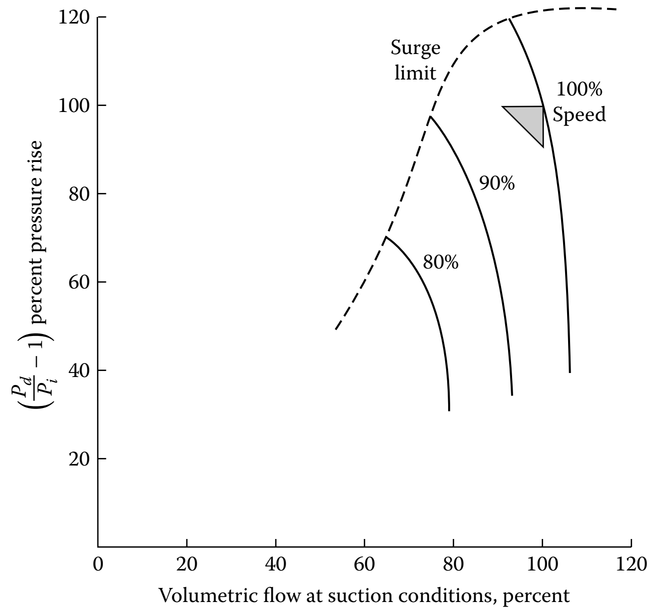

FIG. 8.15m
The surge line for an axial compressor is steep at low flows and flat at high flows.[3]

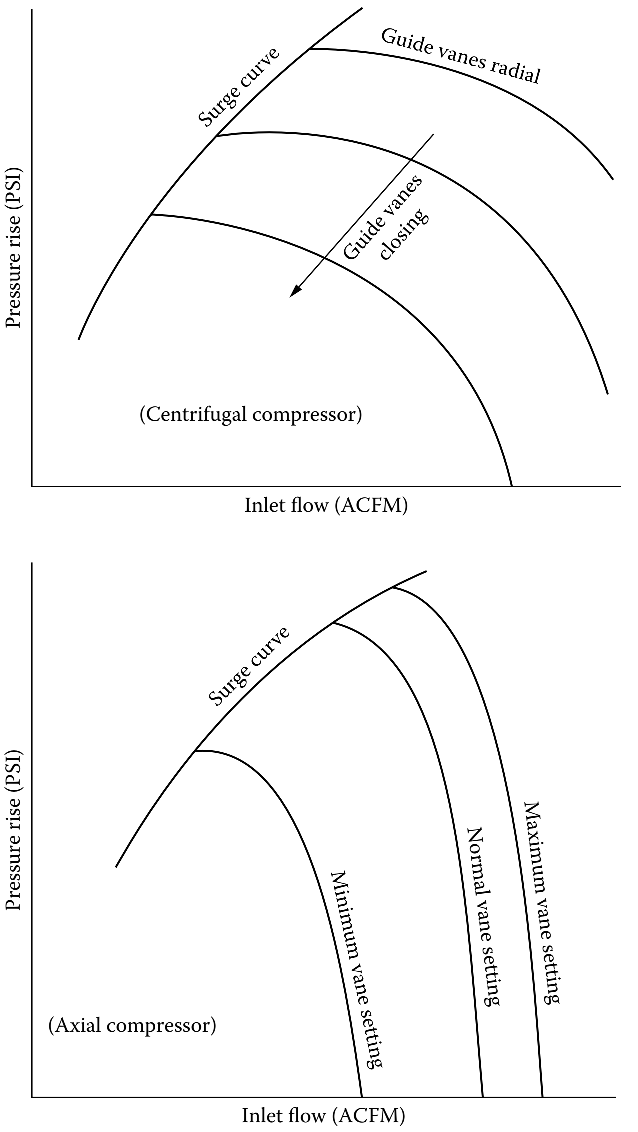

FIG. 8.15n
When guide vanes are used for throttling, both the centrifugal and the axial compressor's surge curve bends over.[1]

even if pressure varies, as long as the compressor is at a constant speed.[1] As speed is reduced, the surge and choke lines intersect. Below this intersection, the traditional methods of surge protection (venting, recycling) are ineffective; only a quick raising of the compressor speed can bring the machine out of surge.

This is similar to the situation when the compressor is being started up. As the operating point is moving on the load curve (Figure 8.15p), it must pass through the unstable region on the left of the surge curve as fast as possible in order to avoid damage from vibration.

Flow Measurement The two critical components of a surge control loop are the flow sensor and the surge valve. Both must be fast, accurate, and reliable.

Flow oscillations under surge conditions occur on a cycle of little more than a second. The flow transmitter should be fast enough to detect these. The time constants of various transmitter designs are as follows:[1]

Pneumatic with damping: Up to 16 sec
Electronic *d/p*: 0.2–1.7 sec
Diffused silicone *d/p*: Down to 0.005 sec

Only the diffused silicone-type sensor design is fast enough to follow the precipitous flow drop that occurs at the beginning of surge or the oscillations during surge. Measurement noise is another serious concern, because it necessitates a greater margin between the surge and the control lines. Noise can be minimized by the use of 20 pipe diameters of upstream and 5 diameters of downstream straight runs around the streamlined flow tube-type sensor. Noise will also be reduced if the low-pressure tap of the *d/p* cell is connected to a piezometric ring in the venturi-type flow tube (Figure 8.15q). The addition of straightening vanes will also contribute to the reduction of noise.

Antisurge control usually requires a flow sensor on the suction side of the compressor. If good, noise-free flow measurement cannot be obtained on that side, a corrected discharge side differential pressure reading (*hd*) can be substituted. Equation 8.15(3) can be used to obtain the suction side differential pressure (*hs*) from readings of (*hd*) and the suction plus discharge pressures and temperatures (*Ps*, *Pd*, *Ts*, and *Td*):

$$hs = hd(Pd/Ps)(Ts/Td) \qquad \mathbf{8.15(3)}$$

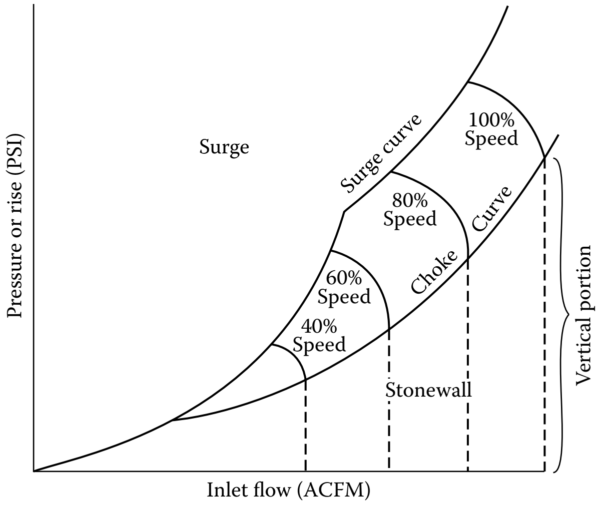

FIG. 8.15o
With multistage compressors, operation must be confined to the area between the surge and choke curves.[1]

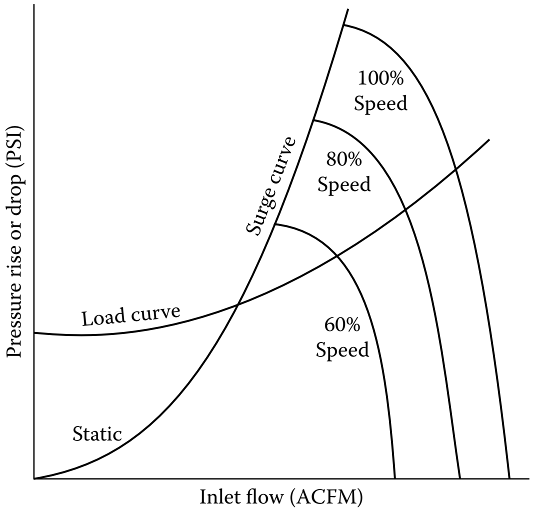

FIG. 8.15p
The speed and surge curves are both characteristics of the compressor, while the load curve is a function of the process load.[1]

Some of the performance characteristics of a number of flow tubes and flow nozzles are given in Table 8.15r.

Surge Control Valves Surge valves are usually fail-open, linear valves that are tuned for fast and precise throttling. Because the valve is the weak link in the total surge protection system, and because testing and maintenance cannot be done on-line if only one valve is used, total redundancy is recommended. Each of the two parallel surge valves should be sized for the full flow of the compressor but for only 70% of the discharge pressure. This pressure reduction is caused by the flow reversals during surge.

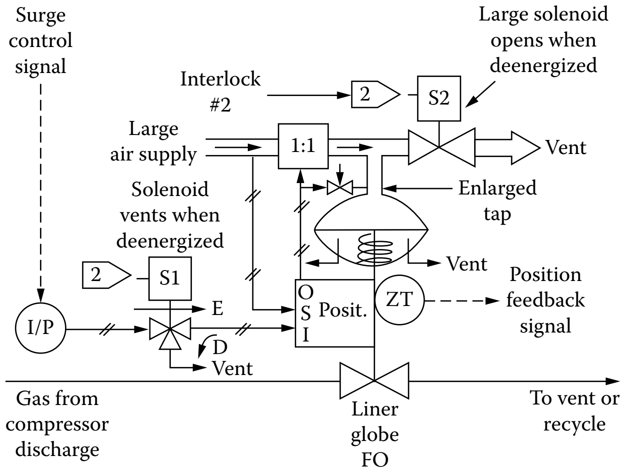

FIG. 8.15s
A well-designed surge control valve will have a positioner, a large air supply with a one-to-one booster repeater with bypass, vent solenoids, and position feedback. (Adapted from Reference 1.)

Globe valves (Section 6.19) are preferred to rotary designs because of hysteresis and breakaway torque considerations. Boosters (Figure 8.15s) can cut the sum of prestroke dead time and full-scale stroking to under 1 sec. Actually, valves as large as 18 in. have been made to throttle to any position in under a half-second.[1]

Digital valves (Section 6.18) are even faster: They can stroke in 0.1 sec without any overshoot. Their limitations are in the plugging of the smaller ports and in the difficulty of inspecting them.

Positioners are frequently required to reduce hysteresis (packing friction), dead band (boosters), disc flutter (butterfly valves), and overshoot; they are also often needed just to provide the higher air pressure required by piston actuators.

Figure 8.15s shows some of the main components of a surge control valve.[1] The electronic control signal is converted to a pneumatic one by the I/P converter, and this pneumatic signal is sent to the positioner through a three-way solenoid ($S1$). The output signal from the positioner is sent simultaneously into a booster relay (1:1) and an adjustable bypass. The output from the booster relay is connected by short- and large-diameter tubes to the valve actuator with an enlarged pressure tap and to the large venting solenoid ($S2$). Some of the operational features of the system are as described below.

When interlock #2 is de-energized, requiring instantaneous full opening of the surge valve (because of discharge line blockage or other reasons), $S1$ vents the positioner inlet and $S2$ vents the actuator top-work. Because $S2$ is large, air removal is fast and the valve opens quickly. On return to normal, both solenoids are energized. This closes $S2$ and opens $S1$ to the control signal.

Depending on the size or restriction in the line from $S1$, air might enter the system more slowly and the valve might close more slowly than it opened. Such fast-opening, slow-closing designs can respond to the first precipitous drop in flow and thus can prevent the second surge cycle from developing. It is important not to slow the speed of valve opening too much, because quick throttling is still required.

The valve must also respond quickly to the control signal and throttle quickly in either direction. In order to speed up the air movement into and out of the actuator, the vent and signal ports on the actuator are both drilled out, an air booster is installed, and a large-capacity path is established between the booster and the actuator. In order to reduce the dead band of the 1:1 booster, it is advisable to use a signal range of 6–30 PSIG instead of the usual 3–15 PSIG.

The bypass needle valve around the booster in Figure 8.15s is required because without it the volume on the outlet of the positioner would be much smaller than on the outlet of the booster. This would allow the positioner to change the input to the booster faster than the booster could change its output, resulting in a limit cycle. This limit cycle is eliminated by the addition of the adjustable bypass.

All surge valves should be throttle-tested before shipment. It is also desirable to monitor the surge valve opening through the use of a position transmitter.

Surge Control Curves As was shown in Figure 8.15l, a parabolic surge curve with a positive slope will appear as a straight line on a ΔP vs. h plot. The purpose of surge control is to establish a surge control line to the right of the actual surge line, so that corrective action can be taken before the machine goes into surge. Such a control system is shown in Figure 8.15t.

The biased surge control line is implemented through a biased ratio relay (ΔPY), which generates the set point for FIC as follows:

$$\mathrm{SP} = m(\Delta P) + b \qquad \mathbf{8.15(4)}$$

where

SP = desired value of h in inches H_2O
m = slope of the surge line at the operating point
ΔP = compressor pressure rise in psi
b = bias of the surge set point in inches H_2O

The offset between the surge and the control lines should be as small as possible for maximum efficiency, but it must be large enough to give time to correct upsets without violating the surge line.[6] The slower the upsets and the faster the control loop, the less offset is required for safe operation. In a good design, the bias b is about 10%, but in bad ones, as disturbances get faster or instrument slower, it can grow to 20%.

A second line of defense is the backup interlock FSL. It is normally inactive, as the value of h is normally above the FIC set point SP. When the surge controller FIC is not fast enough to correct a disturbance, h will drop below SP. FSL

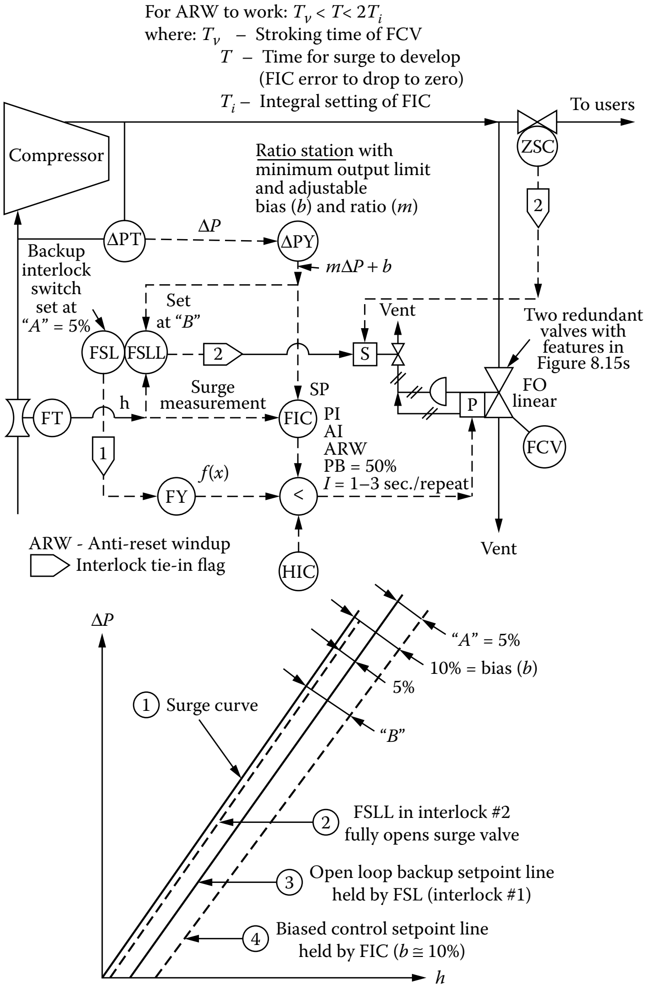

FIG. 8.15t

The surge control system (top) and the surge margin settings for controller set point and interlocks (bottom) for compressors operating at low compression ratios. (Adapted from Reference 1.)

is set to actuate when h has fallen 5% below SP, and at that point it fully opens the surge valve through interlock #1.

The shape of the control and backup lines shown in Figure 8.15t is applicable only when the surge curve is parabolic. As was shown in the surge curves in Figures 8.15m, 8.15n, and 8.15o, the surge curves can also be linear or have negative slopes and discontinuities. If the surge line is not parabolic, the following techniques can be considered for generating the surge control lines.

If the surge curve is linear, the signal *h* should be replaced by a signal representing flow. This can be obtained by adding a square root extractor to the FT in Figure 8.15t. If the surge curve bends down, the use of two square root extractors in series[1] can be used to approximate its shape.

On multistage machines with high compression ratios, it might be necessary to substitute a signal characterizer for ΔPY in Figure 8.15t. On variable vane designs, it has been proposed that the flowmeter differential (*h*) could be corrected to be a function of actual vane position to better approximate the surge curve[3] (see Figure 8.15u). If a flowmeter differential cannot be obtained from either the suction or the discharge side of the compressor, the surge curve can also be approximated on the basis of speed, power, or vane position measurements.[3]

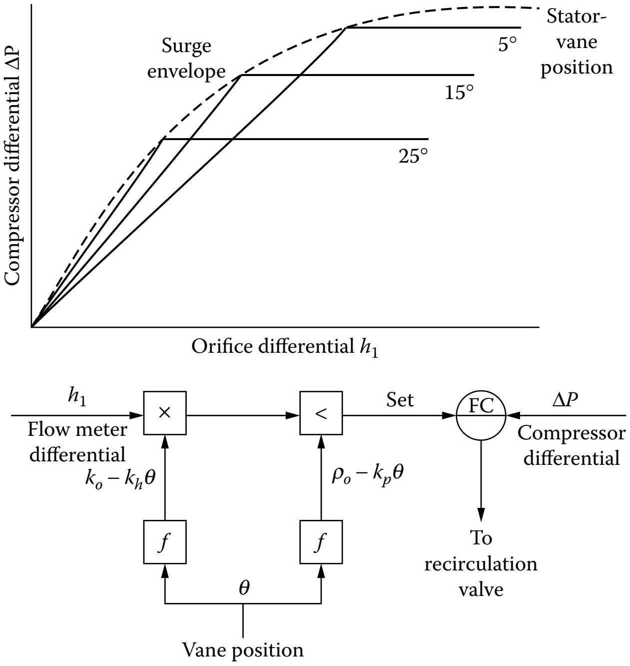

FIG. 8.15u

If the surge line of the compressor bends over, the control loop should measure both the flow meter differential and the vane position. (Adapted from Reference 3.)

The Surge Flow Controller The surge controller (FIC) in Figure 8.15t is a direct-acting controller with proportional and integral action and with antireset windup (AWR) features. It is a flow controller with a remote set point and a narrower proportional band than would be used for flow control alone. In a well-tuned surge controller, both the proportional band (PB) and the integral settings must be minimized (PB ~ 50%, 1–3 sec/repeat). With this level of responsiveness, the FIC set point can be less than 10% from the surge curve, as shown in Figure 8.15t.

Under normal conditions, the actual flow (*h*) is much higher than the surge control limit (SP), and therefore the integral mode of the FIC has a tendency to wind up on its positive error toward a saturated maximum output. If this was allowed to happen, the controller could not respond to a surge condition (a quick drop in *h*), because it would first need to develop a negative error equal to that which caused the saturation.

The aim of an antireset windup feature in this controller is to hold the FIC output under normal conditions at around

105%, so that the valve is closed but the signal is just lingering above the 100% mark without saturation.

As soon as *h* starts dropping toward the set point, the valve should start to open, and it should reach full opening before the set point is reached. As soon as *h* starts dropping, the proportional contribution to the FIC output decreases. If the approach is slow, the increase in the reset contribution will be greater than the decrease caused by the proportional contribution. Therefore, if *h* does not drop to SP, the valve slowly returns to the closed position. The effect of the internal feedback in the FIC is to activate the integral action only when the valve is not closed, while keeping the proportional action operational all the time.

The main goal of a feedback surge controller is to protect the machine from going into surge. Once the compressor is in surge, the FIC is not likely to be able to bring it out of it, because the surge oscillations are too fast for the controller to keep up with them. This is why backup systems are needed.

The surge controller is usually electronic, and the more recent installations tend to be microprocessor-based. Such digital units can memorize complex, nonlinear surge curves and can also provide adaptive gain, which is a means of increasing controller gain as the operating point approaches the surge curve. In digital controllers, it is desirable to set the sample time at about one quarter of the period of surge oscillation, or at 0.3 sec, whichever is shorter. If a flow-derivative backup control (Figure 8.15v) is used, the sample time must be 0.05 sec or less, because if it is slower, the backup system would miss the precipitous drop in flow as surge is beginning.

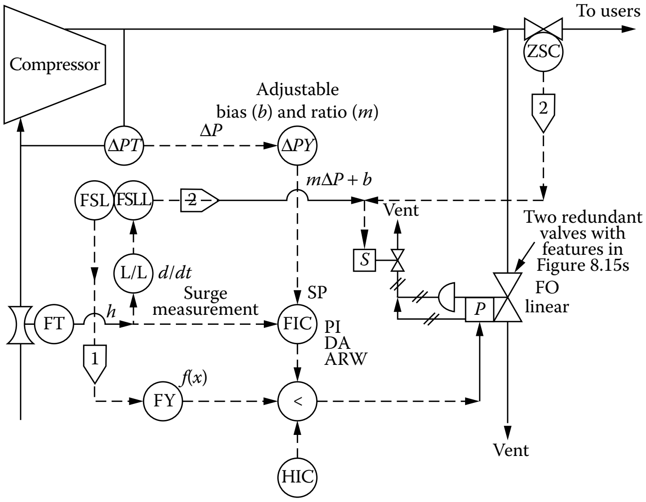

FIG. 8.15v
In this configuration the interlock backup (FSLL) is triggered by measuring the rate of flow change (L/L). If this is done by a digital control system, the sample time must be 0.05 sec or less. (Adapted from Reference 1.)

Tuning the Controller The *closed loop ultimate oscillation* method cannot be used for tuning the surge loop, because there is a danger of this oscillation triggering the start of surge. The *open loop reaction curve* technique of tuning is used with both the surge and the throughput controller in manual. The output of each controller is changed by 10%, and the resulting measurement response is analyzed on a high-speed recorder, yielding the time constant and the dead time of the process (Figure 8.15w).

The tuning settings of the surge controller can be tested by first increasing the bias (*b* in Figure 8.15t) until the surge valve opens and then analyzing the loop response. The FIC must be so tuned that its overshoot is less than the distance between the FSL and FIC set points (*A* in Figure 8.15t). The throughput controller should be kept in automatic while the surge controller is tested so that interaction problems will be noted. Once the surge controller is tuned, it should not be switched to manual but should remain always in automatic.

The antireset windup feature is not effective on slow disturbances, because the integral contribution that increases the FIC output outweighs the proportional contribution that lowers it; thus, the valve stays closed until the surge line is crossed. In order for the ARW to be effective, the time for the controller error to drop from its initial value to zero (*T*) must fall within two limits. It must be slower than the stroking time of the surge valve (*Tv*), but it must be faster than two integral times of the controller:[1]

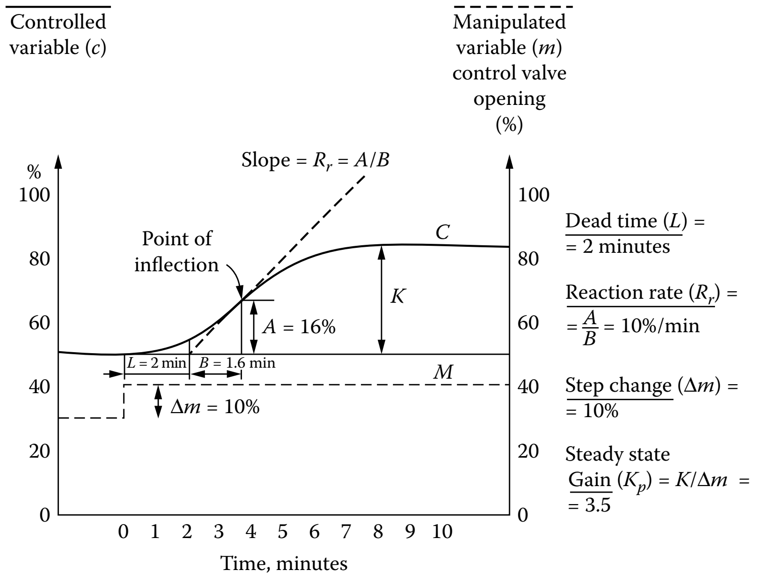
$$Tv < T < 2Ti \qquad \textbf{8.15(5)}$$

If the above requirement cannot be satisfied—because, for example, one of the potential disturbances is a slow closing discharge valve—an "anticipator" control loop should be added (Figure 8.15z).

Surge Protection Backup The purpose of the FIC in Figure 8.15t was to protect the compressor from going into surge. The feedback surge controller is usually not fast enough to bring the machine out of surge once it has developed, because the surge oscillations are too fast for this controller. Yet even with the best feedback surge controller design, the machine will go into surge.

This can be intentionally initiated to verify the surge curve, it can be caused by errors or shifts in the surge curve as the unit ages, and it can occur because of misoperation or failure of either the controller or downstream block and check valves. For these reasons, a second line of defense—a backup system—is required in addition to the surge FIC.

The backup system usually consists of two subsystems, identified as interlocks #1 and #2 in Figure 8.15t. In interlock #2, FSLL detects conditions that will cause the complete stopping of all forward flow from the compressor; when such a condition is detected, FSLL instantaneously and fully opens



Recommended Ziegler-Nichols settings (noninteracting)

Settings / Type of controller	Proportional	Integral (min/repeats)	Derivative
Proportional	$100\, R_r L/\Delta m = 200\%$	–	–
PI controller	$111\, R_r L/\Delta m = 222\%$	$3.33\, L = 6.66$	–
PID controller	$83\, R_r L/\Delta m = 166\%$	$2\, L = 4.0$	$0.5\, L = 1.0$

FIG. 8.15w
An example of open loop tuning where the settings are determined on the basis of the dead time (L) and reaction rate (R_r) of the controlled process.

the surge valve. One such condition in Figure 8.15t is signaled by a closed position limit switch (ZSC) on the block valve.

Interlock #1 in Figure 8.15t provides open-loop backup as follows: The FSL detects an approach to surge that is closer than the FIC set point; when it detects such a condition, it takes corrective action. Under normal conditions, FSL senses an *h* value that is higher than SP, meaning that the operating point is to the right of curve ④. As surge approaches, the operating point crosses the control line (curve 4) as *h* drops below SP. The FSL is set to actuate interlock #1 when *h* has crossed curve ③. This occurs when the flow has dropped below the FIC set point by the amount "*A*" (usually 5%).

When interlock #1 is actuated, it triggers the signal generator FY to drop its output signal to zero and then, when the operating point has returned to the right of curve ③, gradually increase it back to 100%. When the FY output drops to zero, the low signal selector (in the output of the FIC) will select it and send it to the valve. This causes the surge valve to open fully in less than a second, followed by a slow closure according to the program in the signal generator FY. As the FY output rises, it will reach the output of the FIC, at which point control is returned from the backup system to the feedback controller.

This type of backup is called the *operating point method.* Its advantage is that it takes corrective action *before* the surge curve (curve ①) is reached. Its disadvantages are that it is not usable on multistage machines or on systems with recycle and that the protection it provides is lost if Δ*PY* in Figure 8.15t fails by dropping its output to zero. For this reason, it is desirable to provide a minimum limit on the output of Δ*PY.*

The manual loader input (HIC) to the low-signal selector is used during start-up. Because its output passes through the low selector, it can increase but cannot decrease the valve opening.

Flow-Derivative Backup The difference between the operating point technique of backup (Figure 8.15t) and the flow-derivative method (Figure 8.15v) is that the first method acts before the surge curve is reached, whereas the second is activated by the beginning of surge. Because flow drops off very quickly at the beginning of surge, the instruments that measure the rate of this drop must be very fast.

If implemented digitally, the sample time of the flow derivative loop must be 0.05 sec or less in order not to miss the initial drop in flow. The lead-lag station (*L/L*) that detects the rate of flow reduction is adjusted so that the lag setting will filter out noise and the lead setting will give a large output when the flow drops.

The function of interlock #1 is the same as was described in connection with Figure 8.15t. When FSL detects the drop in flow, it causes the signal generator (FY) output to drop to zero, fully opening the valve within a second. If this action succeeds in arresting the surge, the signal generator output slowly rises and control is returned to the feedback FIC.

If interlock #1 does not succeed in bringing the machine out of surge, then after a preset number of oscillations FSLL is actuated. This triggers interlock #2, which keeps the surge valve fully open until surge oscillations stop.

The flow derivation method of backup has the advantage of providing protection even if the compressor pressure-rise instruments (ΔPT, ΔPY) fail, but it also has the disadvantage of not being usable when the flow signal is noisy.

Optimized Adaptations of Surge Curve The surge curve shifts with wear and with operating conditions. Figure 8.15x describes a surge control loop that recognizes such shifts and automatically adapts to the new curve. The adaptation subroutine consists of two segments, the set point adaptation section (blocks ① to ⑥) and the output backup section (blocks ⑦ to ⑪).

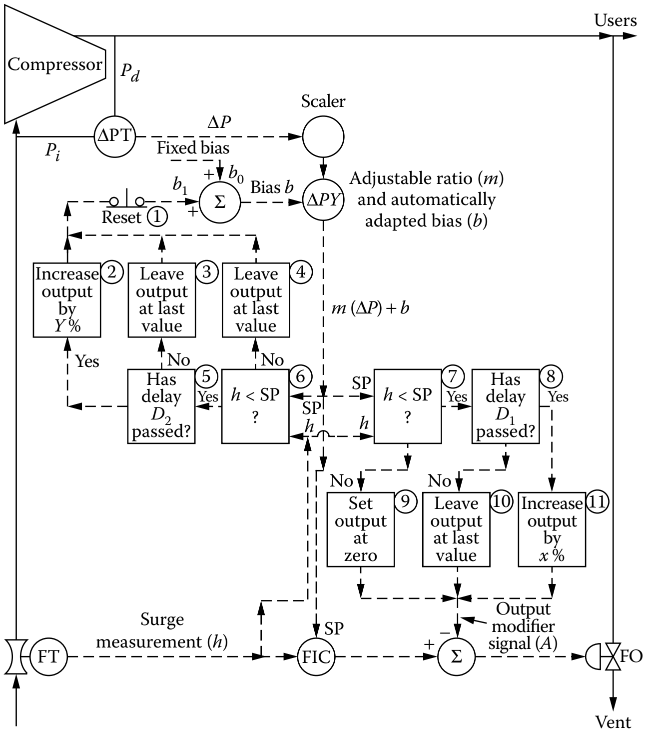


FIG. 8.15x
This control system recognizes changes in the surge curve and adapts the surge controller to the new curve. (Adapted from Reference 1, describing U.S. Patent 856,302, owned by Naum Staroselsky.)

The purpose of the output backup section is to recognize the approach of a surge condition that the feedback controller (FIC) was unable to arrest and to correct such a condition when it occurs. As long as the surge measurement (*h*) is not below the set point (SP), no corrective action is needed, and therefore blocks ⑦ and ⑨ will set the FIC output modifier signal (*A*) to zero. Once *h* is below SP, the operating point is to the left of curve ④ in Figure 8.15t, and the output of block ⑦ in Figure 8.15x is switched to "Yes."

Next, block ⑧ checks if the adjustable time delay D1—having typical values of 0.3 to 0.8 sec[1]—has passed. If it has not, signal *A* remains at its last value. If D1 has passed, *A* is increased by an increment *X*. Typical values of the *X* increment range from 15 to 30%.[1] As *A* is subtracted from the FIC output signal, this backup loop will open up the surge valve at a speed of 15–30% per 0.3–0.8 sec. When *h* is restored to above set point, the signal *A* is slowly returned to zero, allowing the surge valve to reclose.

The purpose of the set point adaptation loop (blocks ① to ⑥) is to recognize shifts in the surge curve and, as a response, to move the control line ④ in Figure 8.15t to the right by increasing to total bias *b* of the ratio relay ΔPY. The logic of blocks ② to ⑥ is similar to that described for blocks ⑦ to ⑪, except that the resulting variable bias signal (b_1) is added to the fixed bias (b_0) to arrive at the adapted new bias (*b*). The speed of set point adaptation does not need to be as fast as the opening of the surge valve. Therefore, the time delay D2 tends to be longer than D1, and the increment *Y* is smaller than *X*. The purpose of the reset button in block ① is to provide a means for the operator to reset the b_1 signal back to zero.

Override Controls

Figures 8.15t and 8.15v show backup and overrides implemented by a low-signal selector on the outlet of the feedback FIC. Figure 8.15y shows some additional overrides that might

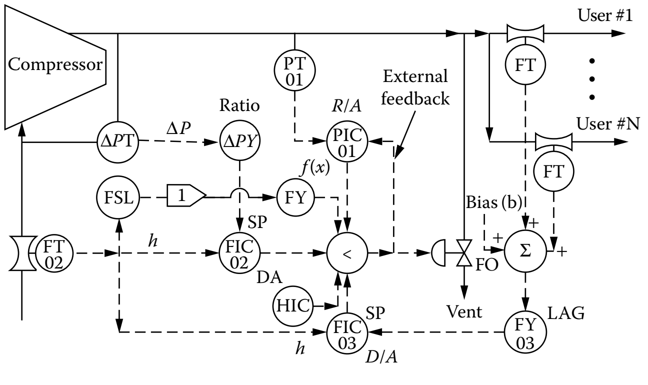

FIG. 8.15y
The low-signal selector provides this control system with a high-pressure (PIC-01) and a user shutdown (FIC-03) override. (Adapted from Reference 1.)

be desirable in some installations. Under normal conditions all override signals are above 100%, and they leave the feedback FIC in control. Sending the override signals through the low-signal selector guarantees that they can only increase the opening of the surge valve, not decrease it.

The high-pressure override controller (PIC-01 in Figure 8.15y) protects downstream equipment from overpressure damage. Normally its measurement is far below its set point, and therefore its output signal is high. In order to prevent reset windup, external feedback is used.

The other override loop (FIC-03) guarantees that the shutdown of a user or a sudden change in user demand will not upset the mass balance (balance between inlet and outlet flow) around the compressor. This is an important feature, because without it the resulting domino effects could shut down other users or the whole plant.

In Figure 8.15y, when a user is shut down, FT-03 detects the drop in total flow within milliseconds, if a fast flow transmitter is used. This drop in flow reduces the measurement signal (*h*) to FIC-03, while its set point is still unaltered because of the lag (FY-03). Therefore, the surge valve is opened to maintain the mass balance. As FY-03 slowly lowers the set point to the new user flow rate (plus bias), FIC-03 recloses the valve. The bias *b* is used to keep the set point of FIC-03 above its measurement, thus keeping the surge valve closed when conditions are normal.

Figure 8.15z illustrates another method of maintaining mass balance as users are suddenly turned off. The velocity limiter (VY-03) limits the rate at which the surge signal (*h*) can be lowered. If the surge signal drops off suddenly, the VY-03 output remains high and, through the high signal selector, keeps the surge controller set point up. This opens the surge valve to maintain the mass balance until it is reclosed by the limiter. This method is called an *anticipator algorithm,* because it opens the surge valve sooner than the time when the operating point (*h*) would otherwise drop to the set point, computed by the ratio station (ΔPY).

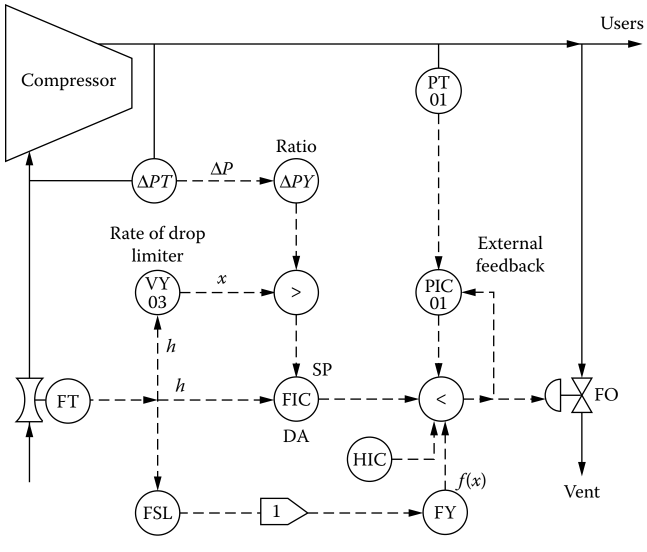

FIG. 8.15z
The velocity limiter serves to protect against sudden load changes by temporarily opening the surge vent valve when the load is quickly dropping.[7] This is achieved by providing VY-03, which, in case of a sudden drop in h, does not immediately lower x and therefore it (x) is selected by the high selector as the set point.

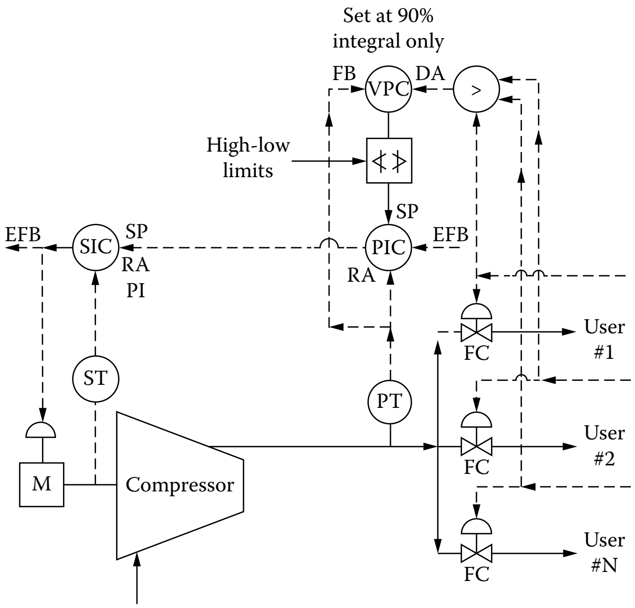

FIG. 8.15aa
By keeping the compressor's discharge pressure just high enough so that even the most open user valve does not open beyond 90%, the needs of all users are satisfied with a minimum investment of energy.

Optimized Load-Following

When a compressor is supplying gas to several parallel users, the goal of optimization is to satisfy all users with the minimum investment of energy. The minimum required header pressure is found by the valve position controller (VPC) in Figure 8.15aa. It compares the highest user valve opening (that identifies the needs of the most demanding user) with a set point of 90%, and if even the most open valve is not yet 90% open, it lowers the header pressure set point.

This supply-demand matching strategy not only minimizes the use of compressor power but also protects the users from being undersupplied, because it protects any and all supply valves from the need to open fully. On the other hand, as the VPC causes the user valves to open farther, these valves not only reduce their pressure drops but also become more stable.

The VPC is an integral-only controller, with its integral time set for about 10 times that of the PIC. This guarantees

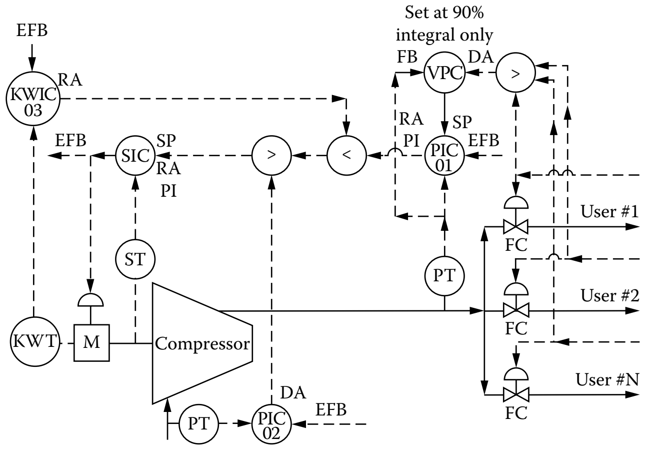

FIG. 8.15bb
Protective overrides can be added to optimized load-following controls, so that the system is protected against excessively low pressures on the suction side of the compressor or from overloading the compressor's motor drive.

that the VPC will act more slowly than all the user controllers, thus giving stable control even if the user valves are unstable. The external feedback (FB in Figure 8.15aa) protects the VPC from reset windup when its output is limited or when the PIC has been switched to manual.

In addition to following the load, it is also necessary to protect the equipment. In Figure 8.15bb, one protective override prevents the development of excessively low suction pressures (PIC-02), which could result in drawing oil into the compressor. The other override (KWIC-03) protects from overloading the drive motor and thereby tripping the circuit breaker.

In order to prevent reset windup when the controller output is blocked from affecting the SIC set point, external feedback (EFB) is provided for all three controllers. This arrangement is typical for all selective or selective-cascade control systems.

Interaction and Decoupling

Both the load and the surge control loops are shown in Figure 8.15cc. The manipulated variable of both of these loops is the compressor throughput. Under normal conditions, there is no problem of interaction; because the surge loop is inactive, its valve is closed.

Under abnormal conditions, when point "*A*" in Figure 8.15dd is reached, FIC-02 quickly opens the surge valve, which causes the discharge pressure to drop off as the flow increases. PIC-01 responds by increasing the vane setting or speed of the machine.

The faster the PIC-01 loop instrumentation is in Figure 8.15cc and the higher its gain (the narrower the proportional band), the larger and faster will be the increase in the speed of the compressor. If the load curve is steeper than the surge curve (as in Figure 8.15dd), the action of PIC-01 will bring the operating point closer to the surge line. In this case, a conflict exists between the two loops, because as FIC-02 acts to correct an approaching surge situation, PIC-01 responds by worsening it. The better tuned (narrower proportional band) and faster (electronic or hydraulic speed governors) the PIC-01

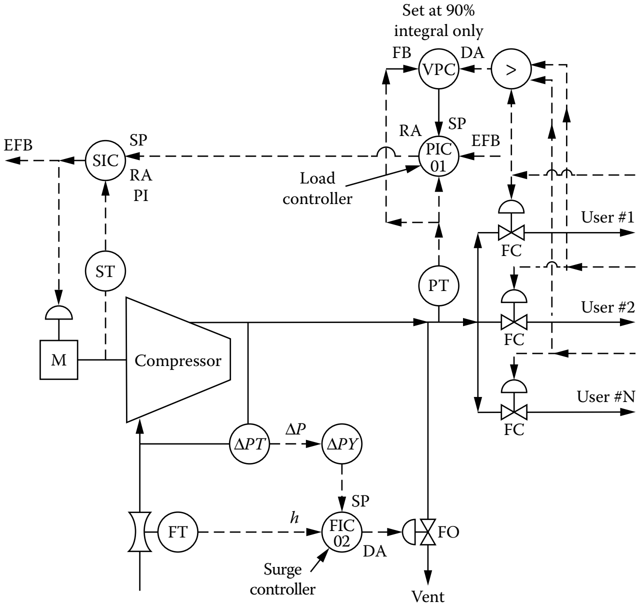

FIG. 8.15cc
The load controller (PIC-01) and surge controller (FIC-02) both affect the compressor throughput.

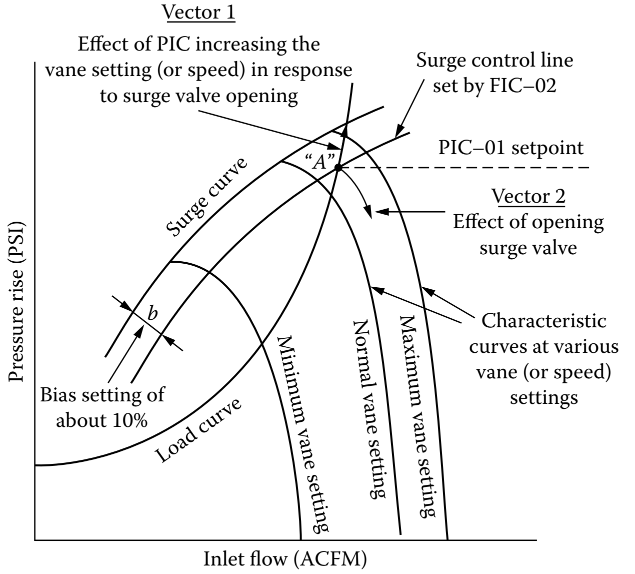

FIG. 8.15dd
If the load curve is steeper than the surge curve and if the controlled variable is pressure, the load and surge control loops will fight each other. (Adapted from Reference 1.)

TABLE 8.15ee
Type of Interactions between Load and Surge Controller

Controlled Variable	*Load Curve Steeper than Surge Curve*	*Nature of Interaction*
Pressure	Yes	Conflict
	No	Assist
Flow	Yes	Assist
	No	Conflict

TABLE 8.15ff
The Nature of the Interaction as a Function of the RG Value

RG Value	*Effect of Other Loop*
0 to 1.0	Assists the primary loop
Above 1.0	Conflicts with the primary loop
Below 0	Conflict that also reverses the action of primary loops

loop is, the more dangerous is its effect of worsening the approach of surge.

The throughput controller (PIC-01 in Figure 8.15cc) moves the operating point on the path of the load curve. The surge controller (FIC-02 in Figure 8.15cc) moves the operating point on the path of the characteristic curve of the compressor at constant speed. If the characteristic curve is steep, the action of the surge controller will cause a substantial upset in the discharge pressure controlled by PIC-01 (Figure 8.15cc). If the load curve is flat, the effect of the pressure controller on the surge controller will be the greatest.

If the throughput is under flow control, the opposite effects will be observed. The effect of the surge controller on the flow controller will be the greatest when the characteristic curves of the compressor are flat, and the effect of the flow controller on the surge controller will be greatest when the load curve is steep.

As shown in Table 8.15ee, whether the loops will assist or conflict with each other, both the relative slopes of the load and surge curves and the variable selected for process control need to be considered.

As both loops try to position the operating point on the compressor map, the resulting interaction can cause the type of inverse response that was described in Figure 8.15dd, or it can cause oscillation and noise. The oscillating interaction is worst if the proportional bands and time constants or periods of oscillation are similar for the two loops. Therefore, if tight control is of no serious importance, one method of reducing interactions is to reduce the response (widen the proportional band) of the load controller. Similarly, the use of slower actuators (such as pneumatic ones) to control compressor throughput will also reduce interaction, but at the cost of less responsive overall load control.

Relative Gain In evaluating the degree of conflict and interaction between the load and surge loops, it is desirable to calculate the relative gain between the two loops. The relative gain is the ratio between the open-loop gain when the other loop is in manual, divided by the open-loop gain when the other loop is in automatic. The open-loop gain of PIC-01 (Figure 8.15cc) is the ratio of the change in its output to a change in its input that caused it. Therefore, if a 1% increase in pressure results in a 0.5% decrease in compressor speed, the open-loop gain is said to be –0.5. Assuming that the open-loop gain of PIC-01 is –0.5 when FIC-02 is in manual and the switching of FIC-02 into automatic causes the PIC-01 loop gain to drop to –0.25, the relative gain is 0.5/0.25 = 2. Table 8.15ff lists the correct interpretations of the relative gain (RG) values.

If the calculated relative gain values are put in a 2-by-2 matrix, the best pairing of controlled and manipulated variables is selected by choosing those that will give the least amount of conflict. These are the RG values between 0.75 and 1.5, preferably close to 1.0. The regions of inhibition, reinforcement, and reversal are shown in Figure 8.15gg.

Decoupling Decoupling is the means of reducing the interaction between the surge and the load control loops. If the goal of decoupling is to maintain good pressure control even during a surge episode, the system shown in Figure 8.15hh can be used. In this system, as the antisurge controller opens the vent valve, a feedforward signal (X) simultaneously increases the speed of the compressor in proportion. The negative sign at the summing device is necessary because the surge valve fails to open. If the two vectors shown in Figure 8.15dd are correctly weighed in the summer, the end

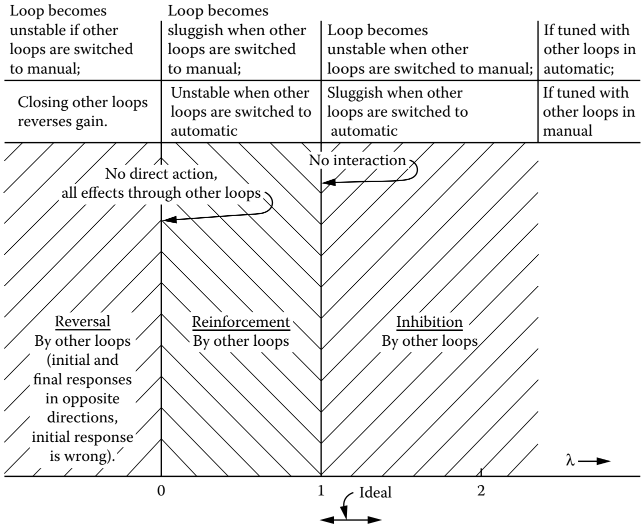

FIG. 8.15gg
The relative gain spectrum.

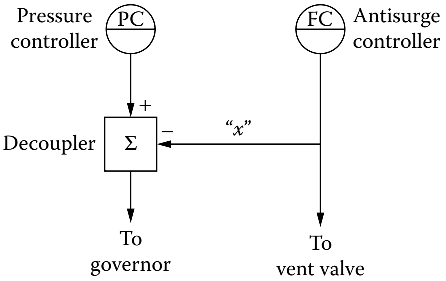

FIG. 8.15hh
The compressor discharge pressure can be kept unaffected by a surge episode, if the opening of the surge vent valve is converted into a proportional increase in speed setting of the governor.[3]

result of their summation will be a horizontal vector to the right, and PIC-01 will stay on set point.

On the other hand, if the main goal of decoupling is to temporarily reduce the size of vector #1 in Figure 8.15dd so that it will not contribute to the worsening of the surge condition, then the half-decoupling configuration shown in Figure 8.15ii can be considered. Here the decoupling summer also receives a feedforward signal (X) corresponding to the opening of the surge valve, but it acts to slow down (not speed up) the machine.

As the output of FIC-02 drops, the compressor speed is temporarily lowered, because the added value of X is reduced. This brings the operating point farther away from the surge line, as shown in Figure 8.15dd. The lagged signal Y later on eliminates this bias, because when its time constant has been reached, the values of X and Y will be equal and will cancel each other. Therefore, this decoupler will serve to temporarily desensitize a fast and tightly turned PIC-01 loop, which otherwise might worsen the situation by overreacting to a drop in pressure when the vent valve opens.

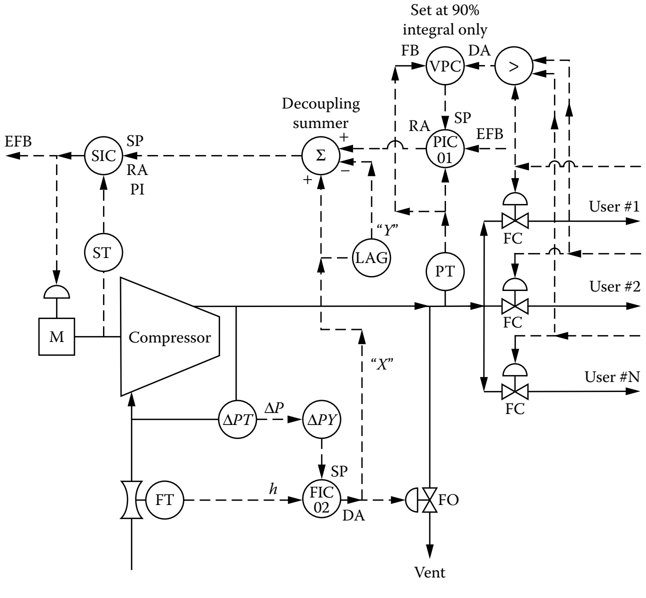

FIG. 8.15ii
The interaction between surge and load control loops can also be decoupled by temporarily reducing the speed of the compressor simultaneously with the opening of the surge valve. (Adapted from Reference 1.)

Multiple Compressor Systems

Compressors can be connected in series to increase their discharge pressure (compression ratio) or they can be connected in parallel to increase their flow capacity. Series compressors on the same shaft can usually be protected by a single antisurge control system.

When driven by different shafts, they require separate antisurge systems, although an overall surge bypass valve can be common to all surge controllers through the use of a low-signal selector.[3] This eliminates the interaction that otherwise would occur between surge valves, as the opening of a bypass around one stage not only would increase the flow through the higher stages but would also decrease it through the lower ones. In some installations, this interaction has been found to be of less serious consequence than the time delay caused by the use of a single overall bypass surge valve, which cannot quickly increase flow in the upper stages.[1] In such installations it is best to duplicate the complete surge controls around each compressor in series.

If streams are extracted or injected between the compressors, which are in series and their flows are not equal, a control loop needs to be added to keep both compressors away from their surge lines by automatically distributing among them the total required compression ratio. Such a control system is shown in Figure 8.15jj.

In this system, PIC-01 controls the total discharge pressure by adjusting the speed of compressor #1. The speed of

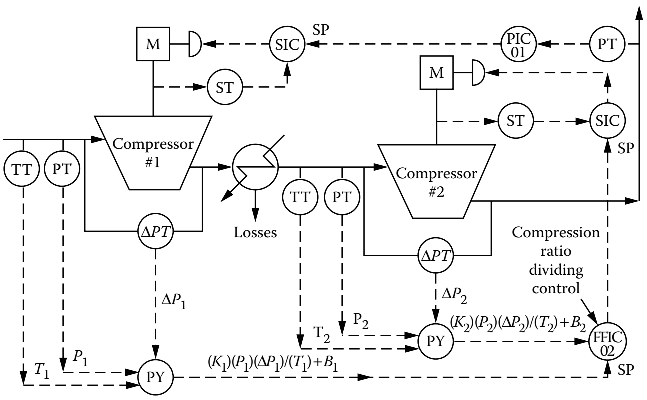

FIG. 8.15jj
When two compressors operate in series, one can be dedicated to maintain the total discharge pressure (PIC-01) from the pair, while the speed of the other can be manipulated to keep them at equal distance from their surge curves. This is achieved by FFIC-02 controlling the distribution of the total compression ratio between them. (Adapted from Reference 1.)

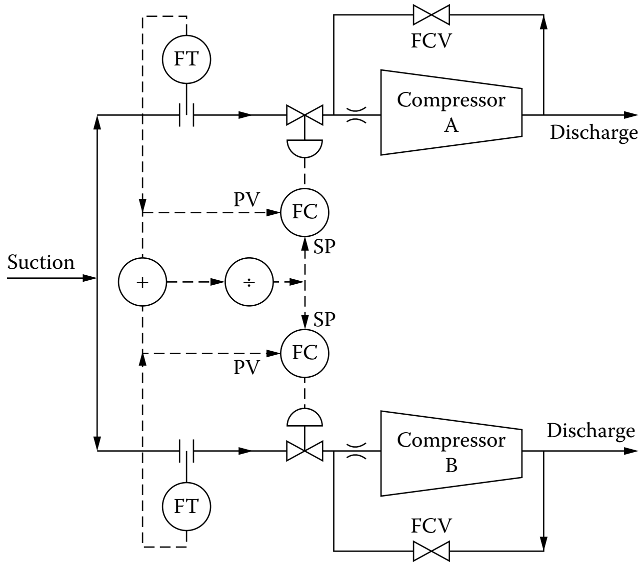

FIG. 8.15kk
When operating multiple compressors in parallel, the total flow (load) can be so distributed among the machines that one is fully loaded and the other handles the variations in demand.

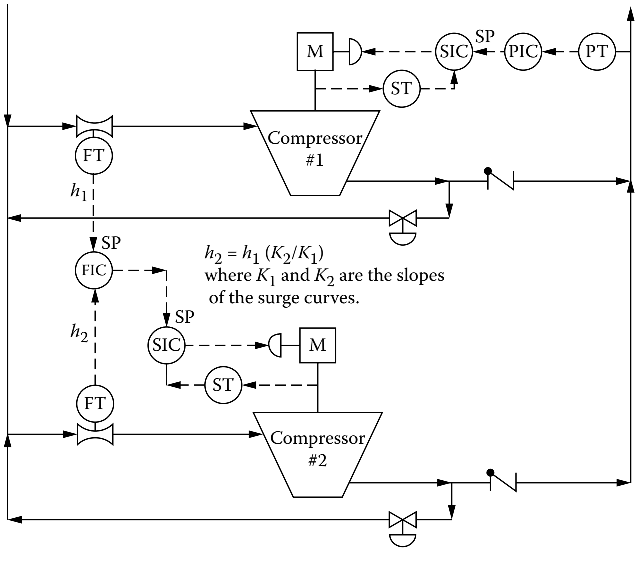

FIG. 8.15ll
Two parallel compressors can be so loaded as to keep both of them at equal distance from their surge curves. (Adapted from Reference 1.)

compressor #2 is set by FFIC-02; both compressors are thus kept at equal distances from their respective surge lines. This is accomplished by maintaining the following equality:

$$(K_1(P_1)(\Delta P_1)/(T_1)) + B_1 = (K_2(P_2)(\Delta P_2)/(T_2)) + B_2 \quad \mathbf{8.15(6)}$$

In this equation, K is the slope and B is the bias of the surge set points of the respective compressors.

Parallel Control of Compressors Controlling two or more compressors operating in parallel and having identical characteristics would be relatively simple. It is very difficult, if not impossible, to find two compressors having identical performance characteristics. Slight variations in flow can cause one compressor to be fully loaded. The parallel machine then has useless recycle. The control scheme shown in Figure 8.15kk alleviates that problem. Typically, care is exercised to ensure that the suction valve that receives the lower flow is kept 100% open. This prevents both suction valves from going fully closed to balance the flow. For an example of flow balancing controls, see Figure 8.17e.

Figure 8.15ll illustrates how two compressors can be proportionally loaded and unloaded, while keeping their operating points at equal distance from the surge curve. The lead compressor (#1 in Figure 8.15ll) is selected either as the larger unit or as the one that is closer to the surge curve when the load rises or is further from it when the load drops.

In Figure 8.15ll it is assumed that the compressors were so chosen that their ratio of bias to slope (b/K) of the surge set point is equal. In that case,

$$h_2 = h_1(K_2/K_1) \quad \mathbf{8.15(7)}$$

where h is the flow meter differential and K is the surge set point slope of the respective compressors.

Because of age, wear, or design differences, no two compressors are identical. A change in load will not affect them equally and each should therefore be provided with its own antisurge system.

Another reason for individual surge protection is that check valves are used to prevent backflow into idle compressors. Therefore, the only way to start up an idle unit is to let it build up its discharge head while its surge valve is partially open. If this is not done and the unit is started against the head of the operating compressors, it will surge immediately. The reason why the surge valve is usually not opened fully during start-up is to protect the motor from overloading.

Improper distribution of the load is prevented by measuring the total load (summer #9 in Figure 8.15mm) and assigning an adjustable percentage of it to each compressor by adjusting the set points of FFIC-01 and FFIC-02.

Optimization of Efficiency The load distribution can be computer-optimized by calculating compressor efficiencies (in units of flow per unit power) and loading the units in the order of their efficiencies. The same goal can be achieved if the operator manually adjusts the ratio settings of FFIC-01 and -02.

In the control system of Figure 8.15mm, the pressure controller (PIC-01) directly sets the set points of SIC-01 and -02 while the balancing controllers (FIC-01 and -02) slowly bias those settings. This is a more stable and responsive configuration than a pressure-flow cascade, because the time constants of the two loops are similar.

The output of PIC-01 must be corrected as compressors are started or stopped. One method of handling this is illustrated

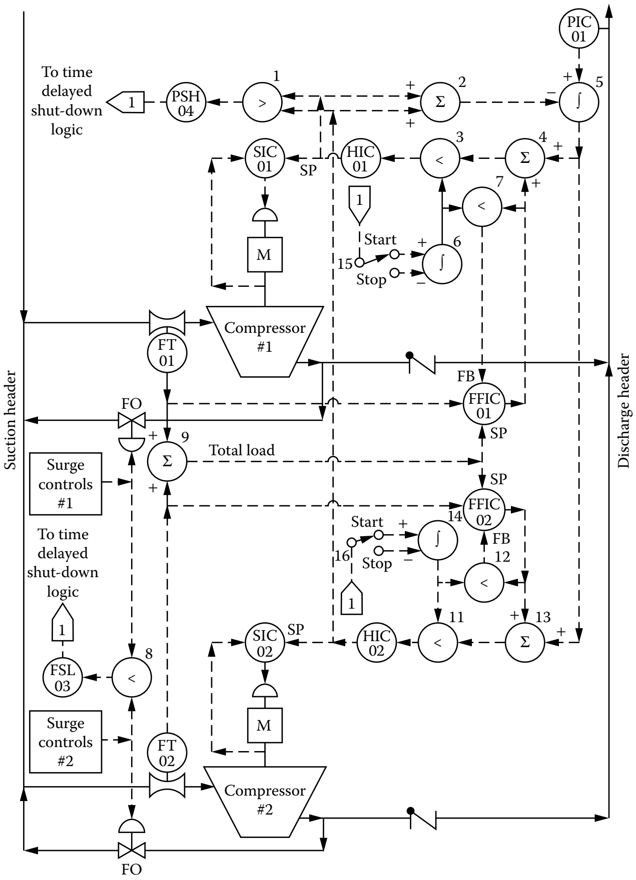

FIG. 8.15mm

A flow-balancing bias can be superimposed on direct pressure control. This control system can distribute the load between the two machines in the order of their efficiencies. (Adapted from Reference 3.)

in Figure 8.15mm. Here a high-speed integrator (item #5) is used on the summed speed signals to ensure a correspondence between the PIC output signal and the number of compressors (and their loading) used. The integrator responds in a fraction of a second and therefore does not degrade the speed of response of the PIC loop.

Figure 8.15mm also illustrates the automatic starting and stopping of individual compressors as the load varies. When the total flow can be handled by a single compressor or when any of the surge valves open, FSL-03 triggers the shutdown logic interlock circuit #1 after a time delay.

Operation with an open surge valve would be highly inefficient, because the recirculated gas is redistributed among all the operating units. When a compressor is to be stopped, item #15 (or #16) is switched to the stop position, causing the integrator #6 (or #14) to drive down until it overrides the control signal in low selector #3 (or #11) and reduces the speed until the unit is stopped.

Automatic starting of an additional compressor is also initiated by interlock #1 when PSH-04 signals that one of the compressors has reached full speed. When a compressor is to be started, interlock #1 switches item #15 (or #16) to the start position, causing the integrator #6 (or #14) to drive up (by applying supply voltage to the integrator) until PIC-01 takes over control through the low selector #3 (or #11). The integrator output will continue to rise and then will stay at maximum, so as not to interfere with the operation of the control loop.

The ratio flow controllers (FFIC-01 and -02) are protected from reset windup by receiving an external feedback signal through the low selector #7 (or #12), which selects the lower of the FFIC output and the ramp signal.

Interlock #1 is also provided with "rotating sequencer" logic, which serves to equalize run times between machines and protects the same machine from being started and stopped frequently. A simple approximation of these goals is achieved if the machine that operated the longest is stopped and the one that was idle the longest is started.

If only one of the compressors is variable-speed, the PIC-01 output signal can be used in a split-range manner. For example, if there were five compressors of equal capacity, switches would be set to start an additional constant-speed unit as the output signal rises above 20, 40, 60, and 80% of its full range. The speed setting of the one variable-speed compressor is obtained by subtracting from the PIC output the sum of the flows developed by the constant-speed machines and multiplying the remainder by 5. The gain of 5 is the result of the capacity ratio between that of the individual compressor and the total.

Multi-Inlet Compressor Control

These compressors most often are refrigeration compressors. The main problem here is to keep the process temperatures, which are controlled by the evaporators, within tolerable limits. This is achieved by controlling the vapor temperature (by quenching) in a feedforward manner, based upon the amount of recycle flow or recycle valve position. A typical control scheme to control a three-inlet compressor is shown in Figure 8.15nn.

Installation

A check valve in the discharge line as close to the compressor as possible will protect it from surges. On motor-driven compressors, it is helpful to close the suction valve during starting to prevent overload of the motor. After the unit is operating, it should be brought to stable operating range as soon as possible to prevent overheating.

The recycle valve control should be fast opening and slow closing to come out of surge quickly and then stabilize the flow. The transmitter ranges should be such that the recycle valve is able to open in a reasonable amount of time with reasonable proportional and integral control constants of the antisurge controller. The importance of proper controller tuning cannot be underestimated. Typical settings are PB = 50%, I = 1–3 sec/repeat.

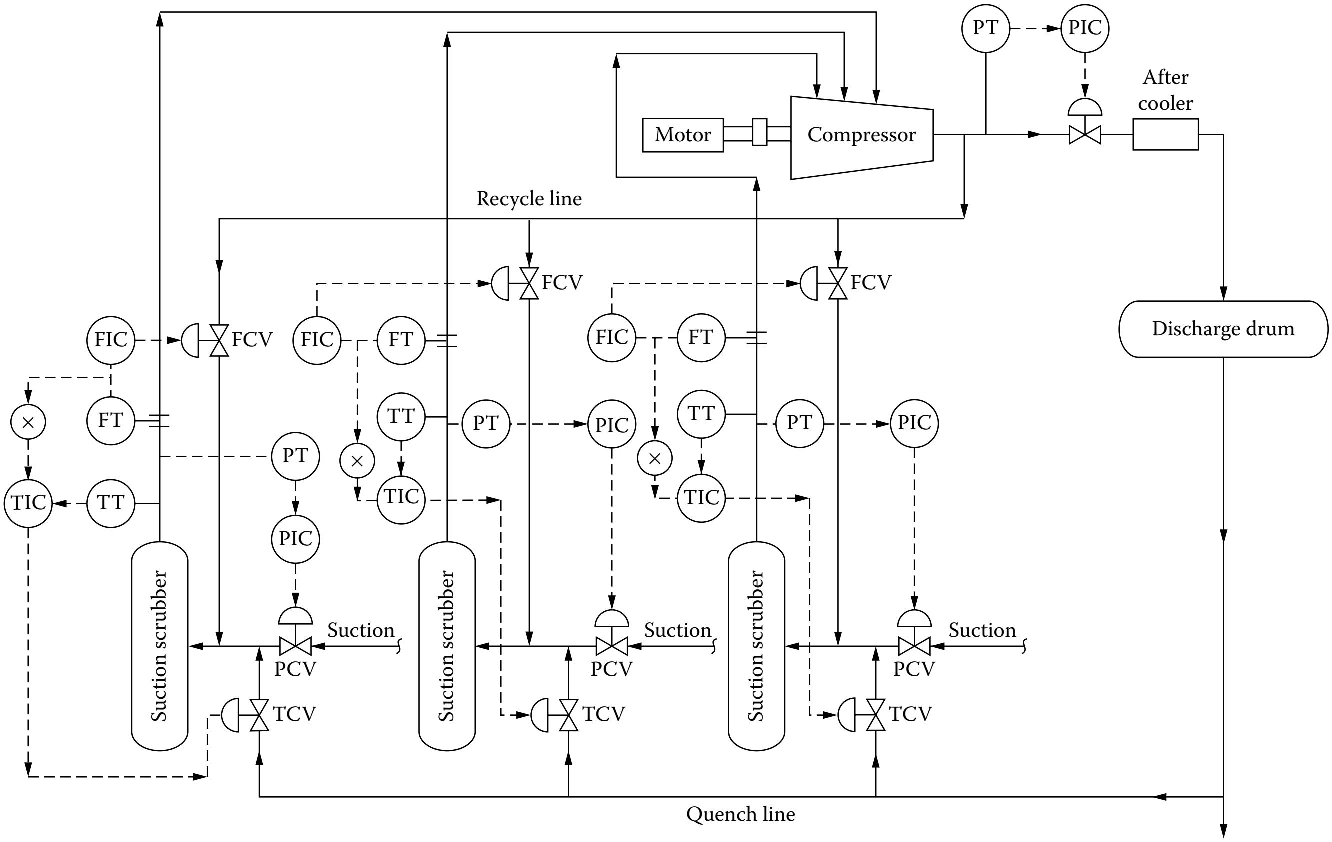

FIG. 8.15nn
Control strategy for a multiple inlet compressor.

Lube and Seal Systems A typical lube oil system is shown in Figure 8.15oo. Dual pumps are provided to ensure the uninterrupted flow of oil to the compressor bearings and seals. Panel alarms on low oil level, low oil pressure (or flow), and high oil temperature are provided. A head tank provides oil for coasting down in case of a power failure.

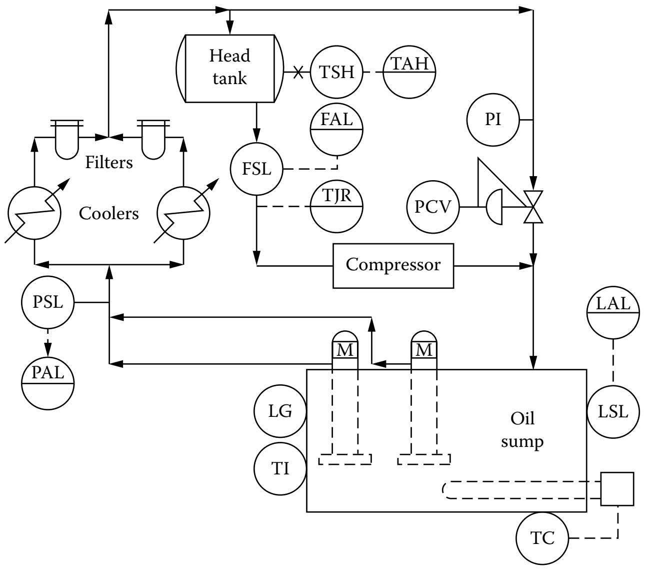

FIG. 8.15oo
Lube oil controls for the compressor's bearings and seals.

The design of these systems is critical, because failure of the oil supply could mean a shutdown of the entire process. In cases in which the process gas cannot be allowed to contact the oil, an inert gas seal system may be used. This is shown in Figure 8.15pp for a centrifugal compressor with balanced seals.

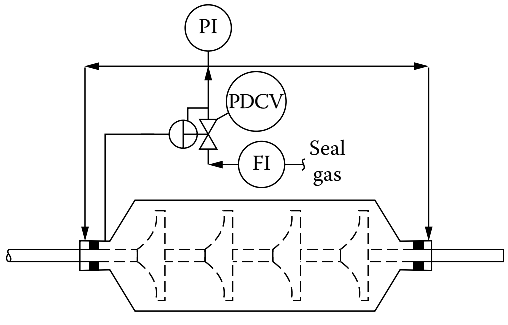

FIG. 8.15pp
Balanced seal controls on a centrifugal compressor.

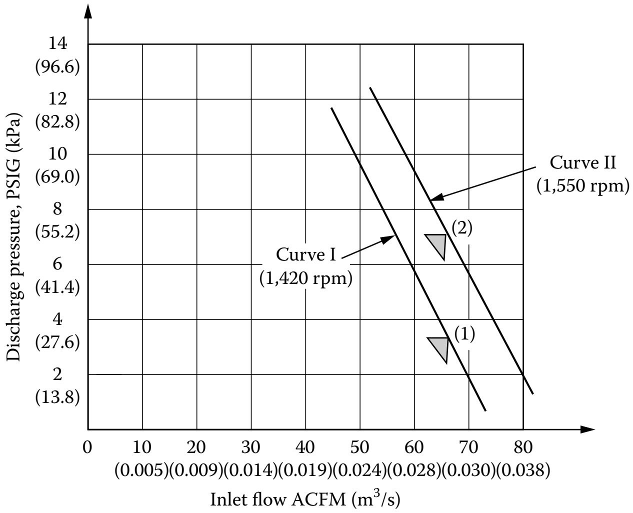

FIG. 8.15qq

The rotary compressor is a positive displacement machine. At constant inlet flow, the discharge pressure rises if the speed is increased, while at constant speed, the flow drops as the discharge pressure rises.

ROTARY COMPRESSORS, BLOWERS

The rotary compressor is essentially a constant-displacement, variable-discharge pressure machine. Common designs include the helical-screw, the lobe, the sliding vane, and the liquid ring types. The characteristic curves for a lobe-type unit are shown in Figure 8.15qq. As shown by curves I and II, the inlet flow varies linearly with the speed of this positive-displacement machine.

The small decrease in capacity at constant speed with an increase in pressure is a result of gas slippage through impeller clearances. It is necessary to compensate for this by small speed adjustments as the discharge pressure varies. For example, when the compressor is operating at point 1, it delivers the design volume of 66 ACFM (1.9 m^3/m) and 3.5 PSIG (24 kPa). In order for the same flow to be maintained when the discharge pressure is 7 PSIG (48 kPa), the speed must be increased from 1420 rpm to 1500 rpm at point 2 by the flow controller in the discharge line.

In addition to speed variation, the discharge flow can also be adjusted by throttling the suction, the bypass, or the vent line from the rotary blower. Vent throttling of the excess gas is shown in Figure 8.15rr in a process where the discharge is throttled by a temperature controller. This can be a dryer application, where the temperature of the outlet gas is controlled to prevent product degradation and to provide the proper product dryness. In other systems, instead of venting, the gas is returned to the suction of the blower under pressure control.

An important application of the liquid ring rotary compressor is in vacuum service. The suction pressure is often the independent variable and is controlled by bleeding gas into the suction on pressure control. This is shown in Figure 8.15ss, where suction pressure control is used on a rotary filter, maintaining the proper drainage of liquor from the cake on the drum.

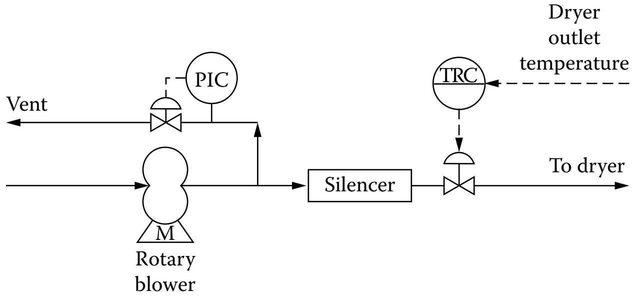

FIG. 8.15rr

The blower discharge pressure can be controlled by venting the excess gas that is not required by the process.

The optimization of rotary compressors will be discussed later, together with that of reciprocating compressors.

RECIPROCATING COMPRESSORS

The reciprocating compressor is a constant-volume, variable-discharge pressure machine. A typical compressor curve is shown in Figure 8.15tt, for constant-speed operation. The curve shows no variation in volumetric efficiency in the design pressure range, which may vary by 8 PSIG (53.6 kPa) from unloaded to fully loaded.

The volumetric inefficiency is a result of the clearance between piston end and cylinder end on the discharge stroke. The gas that is not discharged reexpands on the suction stroke, thus reducing the intake volume.

The relationship of speed to capacity is a direct ratio, because the compressor is a displacement-type machine. The

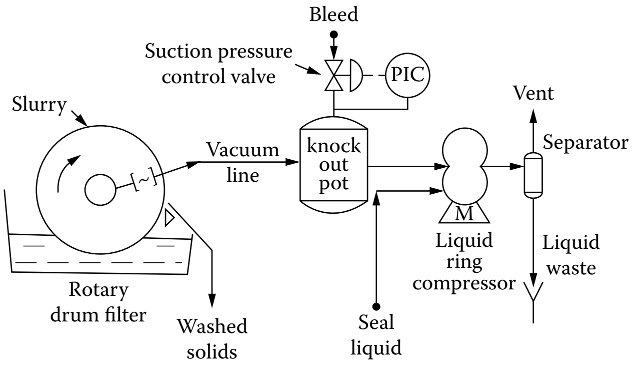

FIG. 8.15ss

The suction pressure control of a liquid ring-type rotary compressor is illustrated here.

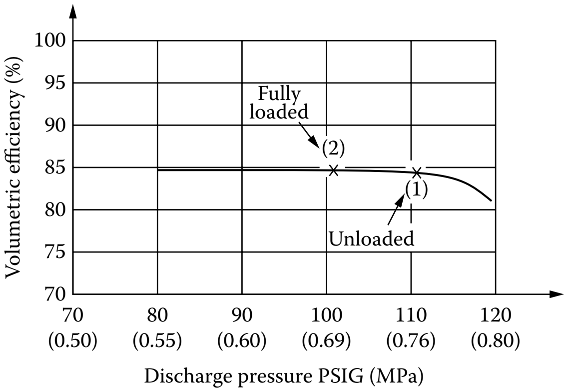

FIG. 8.15tt
Reciprocating compressor curve.

typical normal turndown with gasoline or diesel engine drivers is 50% of maximum speed, in order to maintain the torque within acceptable limits.

On/Off Control

For intermittent demand, where the compressor would waste power if run continuously, the capacity can be controlled by starting and stopping the motor. This can be done manually or by the use of pressure switches. Typical switch settings are on at 140 PSIG (1 MPa), off at 175 PSIG (1.2 MPa). This type of control would suffice for processes in which the continuous usage is less than 50% of capacity, as shown in Figure 8.15uu, where an air mix blender uses a rapid series of high-pressure air blasts when the mixer becomes full. The high-pressure air for this purpose is stored in the receiver.

Constant-Speed Unloading

In this type of control, the driver operates continuously, at constant speed, and one varies the capacity in discrete steps by holding suction valves open on the discharge stroke or opening clearance pockets in the cylinder. The most common schemes are three- and five-step unloading techniques. The larger number of steps saves horsepower because it more closely matches the compressor output to the demand.

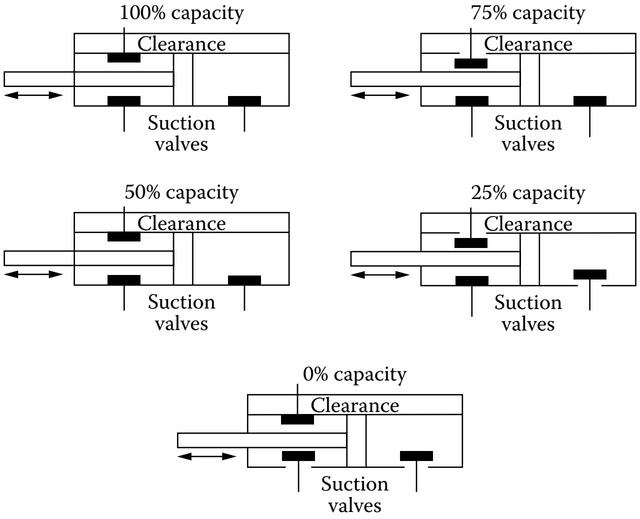

FIG. 8.15vv
The five steps in a constant-speed, positive displacement compressor with five-step unloading.

In three-step unloading, capacity increments are 100, 50, or 0% of maximum flow. This method of unloading is accomplished by the use of valve unloading in the double-acting piston. At 100%, both suction valves are closed during the discharge stroke. At 50%, one suction valve is open on the discharge stroke, wasting half the capacity of the machine. At 0%, both suction valves are held open on the discharge stroke, wasting total machine capacity.

For five-step unloading, a clearance pocket is used in addition to suction valve control. The capacity can be 100, 75, 50, 25, or 0% of maximum flow. This is shown in Figure 8.15vv. At 100%, both suction valves and the clearance pocket are closed. At 75%, only the clearance pocket is open. At 50%, only one suction valve is open on the discharge stroke. At 25%, one suction valve and the clearance pocket are open. At 0%, both suction valves are opened during the discharge stroke.

The use of step unloading is most common when the driver is inherently a constant-speed machine (Figure 8.15ww),

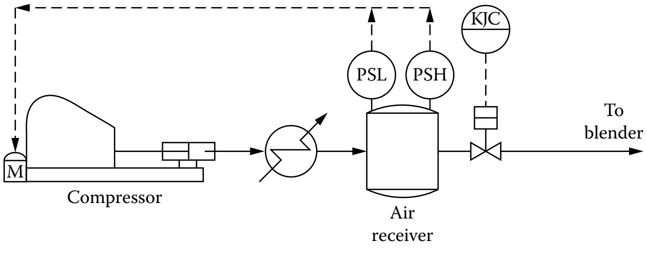

FIG. 8.15uu
On/off control of a reciprocating compressor.

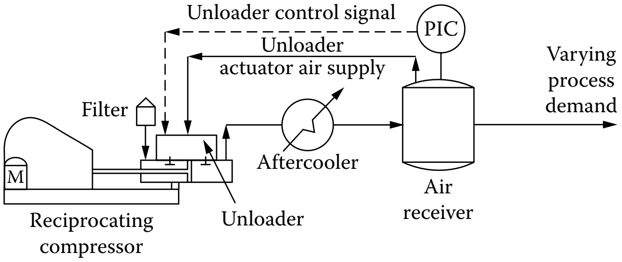

FIG. 8.15ww
Constant-speed capacity control of a reciprocating compressor, provided with pneumatic unloading.

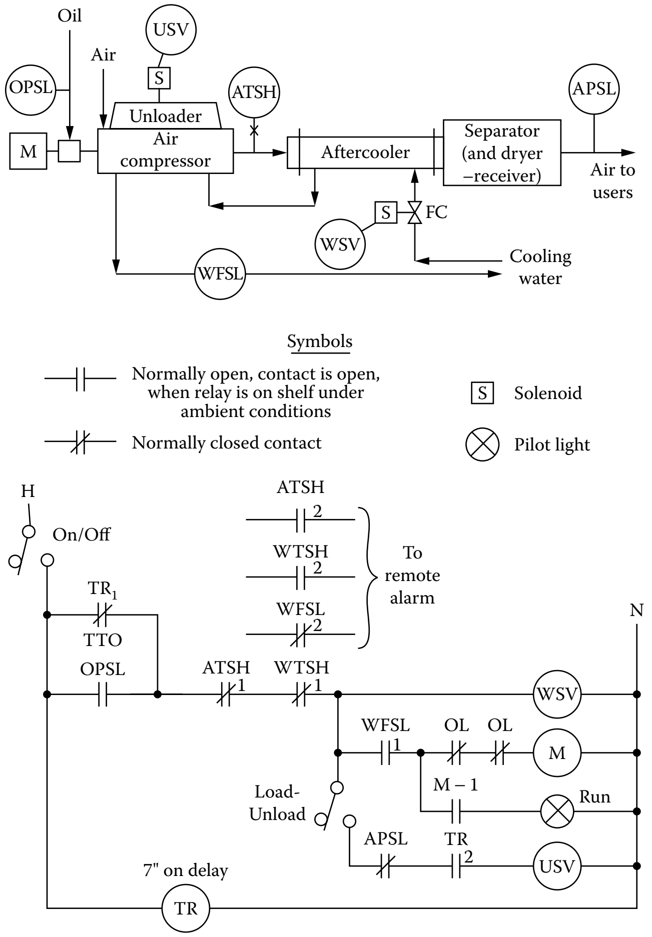

FIG. 8.15xx
The layout and control logic of a typical stand-alone air compressor.[2]

such as an electric motor. The pressure controller signal from the air receiver operates a solenoid valve in the unloader mechanism. The action of the solenoid valve directs the power air to lift the suction valve or to open the clearance port, or both.

For three-step unloading, two pressure switches can be used. The first switch loads the compressor to 50% if the pressure falls slightly below its design level, and the second switch loads the compressor to 100% if the pressure falls below the setting of the first switch.

For five-step unloading, a pressure controller is usually substituted for the four pressure switches otherwise required, and the range between unloading steps is reduced to not more than 2 PSI (13.8 kPa) deviation from the design level, keeping the minimum pressure within 8 PSI (55 kPa) of design. In cases in which exact pressure conditions must be met, a throttling valve is installed, which bypasses the gas from the discharge to the suction of the compressor. This device smoothes out pressure fluctuations and, in some cases, eliminates the need for a gas receiver in this service. This can prove economical in high-pressure services above 500 PSIG (3.45 MPa), in which vessel costs become significant.

The Stand-Alone Air Compressor

Abbreviations and Terminology

APSL Low air pressure switch with contact that closes as pressure drops below setting.

ATA Air temperature alarm, actuated on high temperature.

ATSH High air temperature switch with two contacts.

ATSH-1 First contact of ATSH is normally closed; it opens on high temperature.

ATSH-2 Second contact of ATSH is normally open; it closes on high temperature.

H Fused, 120 V, hot power supply of the stand-alone compressor control circuit.

HO Fused, 120 V, hot power supply of the integrated remote controls.

M Motor.

N Neutral wire of the stand-alone compressor control circuit.

NO Neutral wire of the integrated remote control system.

OFF DELAY This type of time delay introduces a delaying action when the relay is de-energized. A 2 min off-delay means that for the first 2 min period after de-energization, the relay contacts will remain as if the relay was energized. When the delay expires, the contacts will switch to their de-energized state.

ON DELAY This type of time delay introduces a delaying action when the relay is energized. A 3 sec on-delay means that for the first 3 sec after it is energized, the relay contacts will remain as if the relay was still de-energized. When the delay expires, the contacts will switch to their energized state.

TR Time delay relay. The delay time setting is marked next to it.

TTC Time to close action. This contact is open, then the TR relay is de-energized. This contact stays open when the TR relay is de-energized until the delay time setting expires. Then it closes.

TTO Time to open action. This contact is closed when the TR relay is de-energized. This contact stays closed when the TR relay is energized until the delay time setting expires. Then it opens.

USV Unloading solenoid. The compressor is loaded when this solenoid is energized.

WFA Water flow alarm. This alarm is energized if the flow drops below the minimum allowable.

WFSL Low water flow switch, with two contacts.

WFSL-1 This contact opens on low flow.

WFSL-2 This contact closes on low flow.

WSV Cooling water solenoid valve, opens when energized.

WTA Water temperature alarm, energized on high temperature.
WTSH High water temperature switch, with two contacts.
WTSH-1 This contact opens on high temperature.
WTSH-2 This contact closes on high temperature.

Operation A typical air compressor, together with the controls that are normally provided by its manufacturer, is shown in Figure 8.15xx.

Such a stand-alone compressor usually operates as follows: When the operator turns the control switch to "On," this will energize the time delay (TR) and will open the water solenoid valve (WSV) if neither the air temperature (ATSH) nor the cooling water temperature (WTSH) is high.

After 7 sec, TR-1 opens. Assuming that this time delay was sufficient for the oil pressure to build up, the opening of TR-1 will have no effect, because OPSL will have closed in the meantime.

If the opening of WSV resulted in a cooling water flow greater than the minimum setting of the low water flow switch, then WFSL closes and the compressor motor (M) is started. Whenever the motor is on, the associated "Run" pilot light is energized. This signals to the operator that oil (OPSL), water (WTSH, WFSL), and air (ATSH) conditions are all acceptable and, therefore, the unit can be loaded.

When the operator turns the other control switch to "Load," the TR-2 contact is already closed because the 7 sec have passed. Therefore, the APSL contact will determine the status of the machine. If the demand for air at the users is high, the pressure at APSL will drop, which in turn will cause the APSL contact to close and the compressor to load. As a result of loading the compressor, the pressure will rise until it exceeds the control gap of APSL, causing its contact to reopen and the machine to unload.

The compressor continues to load and unload automatically as a function of plant demand. As the demand rises, the loaded portion of the cycle will also rise. Once the load reaches the full capacity of the compressor, the unit stops cycling and stays in the loaded state continuously. If the demand rises beyond the capacity of this compressor, it is necessary to start another one. The following paragraphs describe how this is done automatically, requiring no operator participation.

If at any time during operation the cooling water flow (WFSL) drops too low, the motor will stop. If either water or air temperature rises to a high valve, this condition not only will stop the motor but will also close the water solenoid valve (WSV).

The above three conditions (WFSL, WTSH, ATSH) will also initiate remote alarms, as shown in Figure 8.15xx, to advise the operator of the possible need for maintenance. If the oil pressure drops below the setting of OPSL, it will also cause the stoppage of the motor and the closure of WSV, but after such an occurrence, the compressor will not be allowed to restart automatically when the oil pressure returns to normal. In order to restart the machine, the operator will have to go out to the unit and reset the system by turning the control switch to "Off" and then to "On" again to repeat the complete start-up procedure.

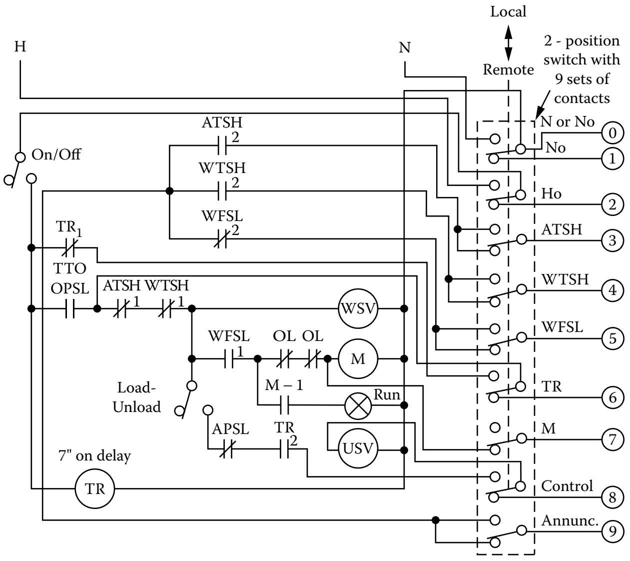

FIG. 8.15yy
The local/remote switch is wired to allow stand-alone or integrated compressor operation.[2]

Local/Remote Switch The first step in integrating several compressors into a single system is the addition of a local/remote switch at each machine. As shown in Figure 8.15yy, when this switch is turned to "Local," the compressor operates in the stand-alone mode, as was described in connection with Figure 8.15xx. When this switch is turned to "Remote," the compressor becomes a part of the integrated plantwide system, consisting of several compressors.

As shown in Figure 8.15yy, this two-position switch has nine sets of contacts and is mounted near the compressor. It can be installed in a few hours, and once installed, the compressor can again be operated in the "Local" mode. Only ten wires need to be run from each compressor to the remote controls. These ten wires serve the following functions:

#0 The working neutral, N in local, No in the remote mode of operation
#1 The common neutral (No) of the integrated controls
#2 The common hot (Ho) of the integrated controls
#3 The high air temperature (ATSH) alarm
#4 The high water temperature (WTSH) alarm
#5 The low water flow (WFSL) alarm
#6 The 7 sec time delay (TR) of the integrated controls
#7 The motor (M) status indication

#8 The load/unload control signal from the remote system

#9 The common hot for the remote annunciator (Annunc.)

When integrating several compressors into a single system, it is advisable to number these ten wires in a consistent manner, such as:

Compressor #1	Wire #10 to #19
Compressor #2	Wire #20 to #29
Compressor #3	Wire #30 to #39, and so on

In this system, the first digit of the wire number indicates the compressor, and the second digit describes the function of the wire. Immediately knowing, for example, that wire number 45 comes from compressor #4 and serves to signal a low water flow condition on that machine simplifies checkout and start-up.

Annunciator Of the ten wires from each of the compressors, six are used for remote alarming. Figure 8.15zz shows a remote annunciator for two compressors. This alarm system can be expanded to serve any number of compressors.

The position of the local/remote switch in Figure 8.15yy does not affect the operation of the annunciator. It provides the following remote indications for each compressor:

"Run" light
High air temperature light
High water temperature light
Low water flow light
Audible alarm bell with silencer
Alarm reset buttons

The only time these circuits are deactivated is when the associated compressor is off.

Lead-Lag Selector As plants grow, their compressed air requirements also tend to increase. As a result of such evolutionary growth, many existing plants are served by several uncoordinated compressor stations. When, because of space limitations, the new compressors are installed in different locations, the manual operation of such systems becomes not only inefficient but also unsafe.

The steps involved in integrating such stand-alone compressor stations into an automatically operating, load-following single system are described here. In such integrated systems, the identity of the "lead" and "lag" compressors, or the ones requiring maintenance ("Off"), can all be quickly and conveniently altered, while the system continues to efficiently meet the total demand for air. Thus, air supply shortage or interruption is eliminated, together with the need for continuous operator's attention.

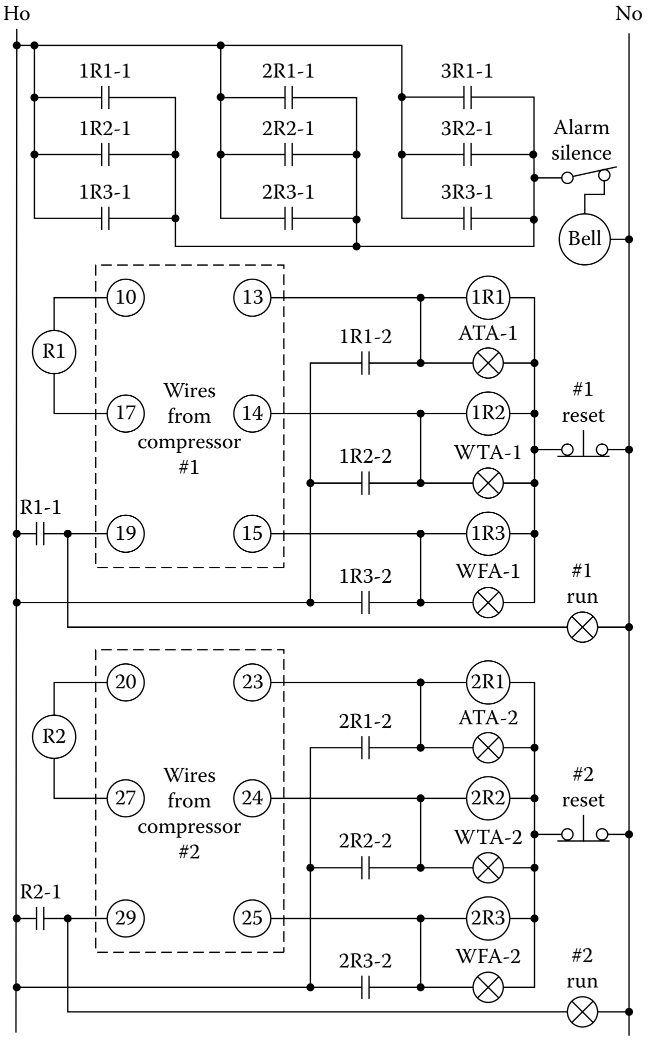

FIG. 8.15zz
The wiring requirements for an annunciator serving two compressors.[2]

When it is desirable to combine two compressors into an integrated lead-lag station, all that needs to be added are two pressure switches, as shown in Figure 8.15aaa.

APSL-A is the lead and APSL-B is the lag control pressure switch. To maintain a 75 psig air supply at the individual users, these normally closed pressure switches can be set as shown in Table 8.15bbb.

With the above settings, the system performance will be as shown in Table 8.15ccc.

When two stand-alone compressors are integrated into such a lead-lag system, only five wires need to be brought from each compressor to the lead-lag switch, shown in Figure 8.15ddd. Turning this single switch automatically reverses the lead-lag relationship between the two compressors. In addition to the two-position lead-lag switch, running lights are also provided; they show whether either or both compressors are unloaded (standby) or loaded.

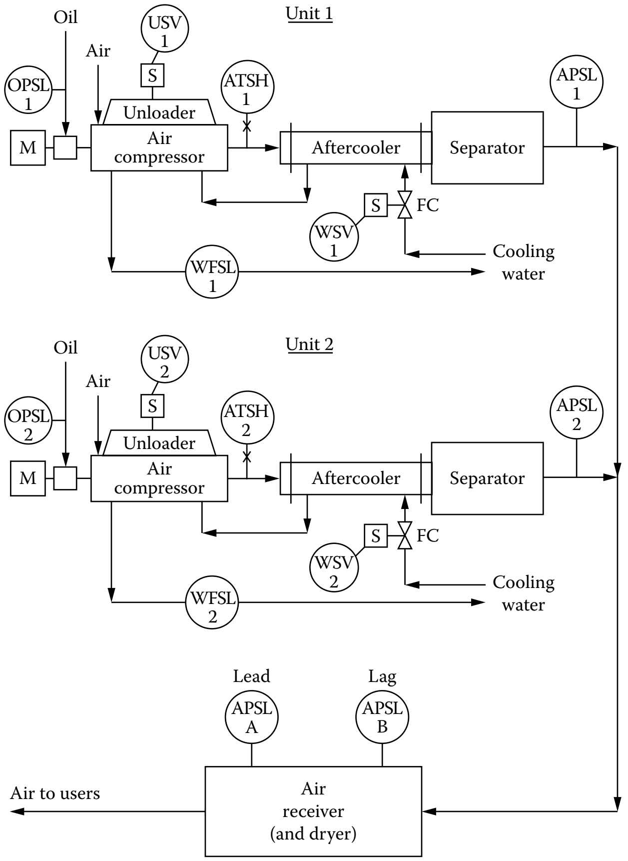

FIG. 8.15aaa

By adding two pressure switches (APSL-A and APSL-B), two compressors can be integrated into a single system.[2]

TABLE 8.15bbb

Set Pressures and Differential Gaps for Integrating the Controls of Two Compressors

Pressure Control Switch	*Pressure Below which Switch Will Close (psig)*	*Differential Gap (psi)*
ASPL-A	90	10
ASPL-B	85	10

As the demand for air increases, the lead machine will load and unload to meet that demand. If the lead machine is continuously loaded and the demand is still rising, the lag compressor will be started automatically. The interlocks provided are as follows:

The on-time delays 2TR and 3TR in Figure 8.15ddd are provided for stabilizing purposes only. They guarantee that a system configuration (or reconfiguration) will be recognized only if it is maintained for at least 3 sec. Responses to quick changes are thus eliminated.

The on-time delays ITR and 4TR are provided to give time for the oil pressure to build up in the system. If after 7 sec the oil pressure is not yet established, and therefore OPSL in Figure 8.15xx is still open, the contacts ITR-1 and 4TR-1 in Figure 8.15ddd will open and the corresponding compressor will be stopped.

The off-time delay 5TR guarantees that the lag machine will not be cycled on and off too frequently. Once started, the lag compressor will not be turned off (but will be kept on standby) until the off delay of 2 min has passed.

Off Selector Three stand-alone compressors can be combined into an integrated load-following single system, by the

TABLE 8.15ccc

System Performance when ASPL-A Is Set to Close at 90 psig, APSL-B Is Set to Close at 85 psig, and the Differential Gap Is Set at 10 psid

Pressure in Air Receiver (psig)	*APSL-A Contact*	*APSL-B Contact*	*Lead Compressor*	*Lag Compressor*
Over 100	Open	Open	Off	Off
100	Open	Open	Off	Off
95	Open	Open	Off	Off
90	Closed	Open	On	Off
85	Closed	Closed	On	On
80	Closed	Closed	On	On
85	Closed	Closed	On	On
90	Closed	Closed	On	On
95	Closed	Open	On	Off
100	Open	Open	Off	Off

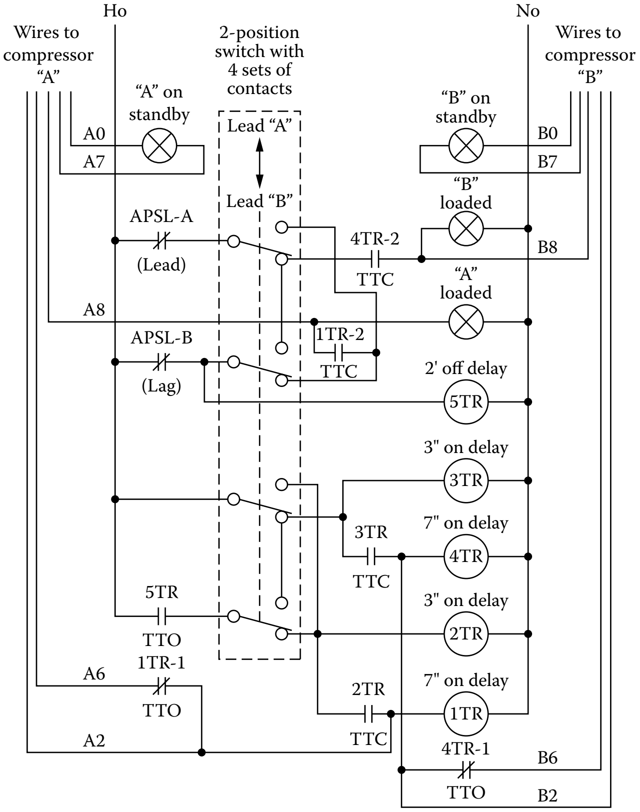

FIG. 8.15ddd

The wiring of a lead-lag selector switch that can automatically reverse the lead-lag relationship between two compressors.[2]

addition of a three-position "off" selector switch, illustrated in Figure 8.15eee. With the addition of the off-selector, any of the compressors can be selected for load, lag, or off duties, just by turning these conveniently located switches.

Depending on the position of the off selector, the identities of Compressors A and B in Figure 8.15ddd will be as follows:

Selected Off	*Compressor A*	*Compressor B*
1	3	2
2	1	3
3	1	2

For an integrated three-compressor system, only 30 wires need to be run if the remote annunciator is included. Without remote alarms, only 15 wires are needed (5 per compressor). The front face of a remote control cabinet of a three-compressor lead-lag system is illustrated in Figure 8.15fff.

Large Systems From the building blocks discussed in the previous paragraphs, an integrated remote controller can be configured for every compressor combination. Figure 8.15ggg

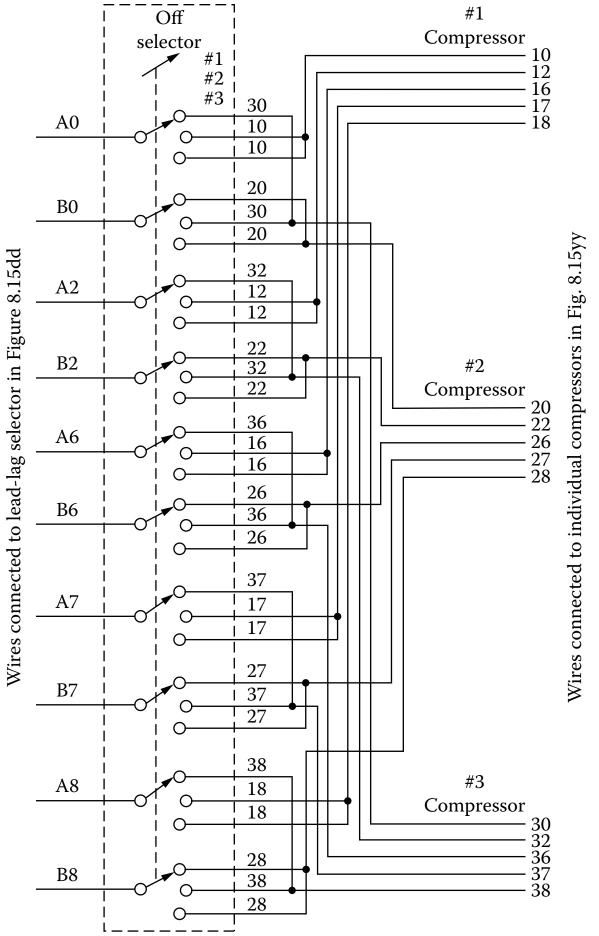

FIG. 8.15eee

The wiring of an "off" selector switch that can be used to identify the common spare compressor, or the compressor that is undergoing maintenance from among a set of three compressors.[2]

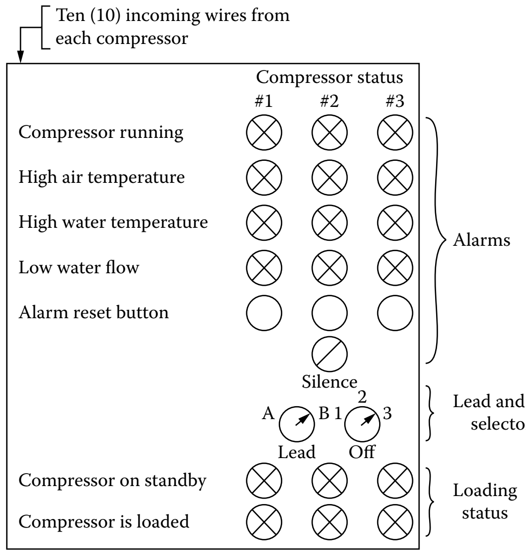

FIG. 8.15fff

The faceplate of the control panel that can be used to operate an integrated three-compressor system.[2]

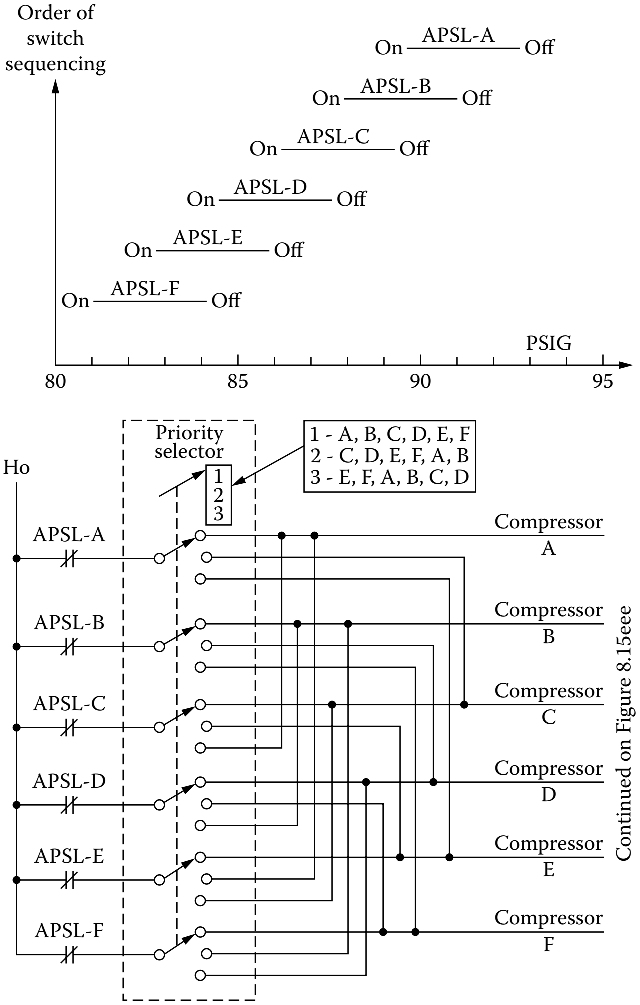

FIG. 8.15ggg

In large, multiple-compressor systems, a priority selector can be used to change the order of priorities of the compressors within the system.[2]

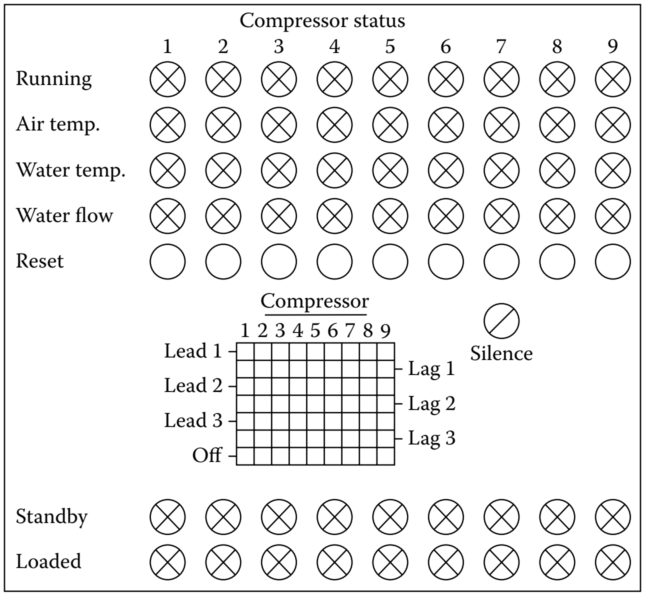

FIG. 8.15hhh

A control cabinet can provide full flexibility in remote control for an integrated nine-compressor system. Such a mechanically interlocked pushbutton station or its microprocessor controlled digital equivalent can be so designed that only one button can be pressed in each column or row, except in the bottom one. In the bottom row any or all buttons can be simultaneously pressed.[2]

illustrates how six stand-alone compressors might be integrated into a single load-following system.

As the system pressure drops below 90 psig, APSL-A closes, starting the first compressor. As the load rises, causing the system pressure to drop further, more switches will close, until at 80 PSIG all six switches will be closed and all six compressors will be running.

The "priority selector" shown in Figure 8.15ggg is provided for the convenient reconfiguration of compressor sequencing. When the selector is in position #1, as the load increases, the compressors will be started in the A, B, C, D, E, F order. When switched to position #2, the sequence becomes C, D, E, F, A, B. In position #3, the sequence is E, F, A, B, C, D.

If a system consists of nine compressors, and full flexibility in integrated remote control is desired, the faceplate of a control cabinet might look like Figure 8.15hhh. With this system, the operator can set the lead, lag, or off status for all nine compressors and can also select the order in which they are to come on.

Wired or Digital Bus From the previous discussion it can be seen that the building-block approach to compressor control system design is very flexible. Any number of stand-alone compressors can be integrated into automatic load-following control systems, with complete flexibility for priority, lead-lag, or off selection. The logic blocks described can be implemented either in hardware or in software. All wires and terminals can be prenumbered to minimize installation errors.

The potential benefits of compressor control system integration are listed below:

1. Unattended, automatic operation relieves operators for other tasks.
2. Automatic load-following eliminates the possibility of accidents caused by the loss of the air supply.
3. Because the supply and the demand are continuously and automatically matched, the energy cost of operation is minimized.

If priority or lead-lag switching is under computer control, this would also make the digital implementation of the system more desirable. On the other hand, if a dedicated, hard-wired system is preferred, because it is more familiar

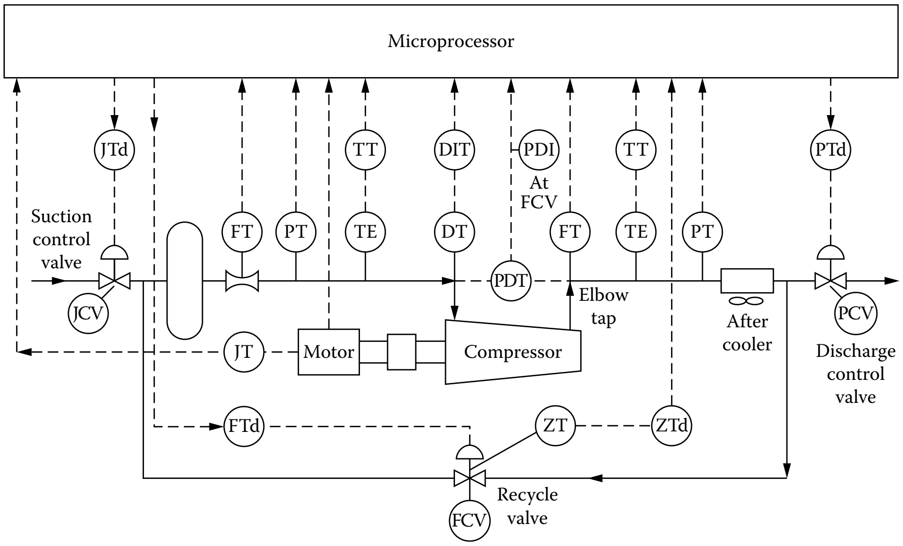

FIG. 8.15iii

A digital unit controller that is connected to the compressor I/O by a digital bus is well suited for both compressor optimization and for integrating the compressor controls into the total control system of the plant.

to the average operator, hardware implementation can be the proper choice.

CONCLUSIONS

As was shown in Figures 8.15g and 8.15j, the energy cost of operating a single centrifugal compressor at 60% average loading can be cut in half if optimized variable-speed control is applied. In the case of multiple compressor systems, similar savings can be obtained by the use of optimized load-following and supply-demand matching control strategies.

The full automation of compressor stations — including automatic start-up and shutdown — not only will reduce operating cost but will also increase operating safety as human errors are eliminated. Figure 8.15iii illustrates the use of a microprocessor-based digital unit controller. Such units can be provided with all the features that were discussed in this section in the form of software algorithms. Such digital systems provide flexibility by allowing changes in validity checks, alteration of limit stops, or reconfiguration of control loops.

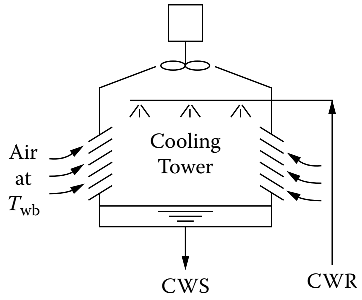
8.16 Cooling Tower Control

B. G. LIPTÁK (1985, 1995, 2005)



Flow sheet symbol

Types of Designs:	a) Mechanical draft towers a1. Induced (fan at air outlet) cross-flow a2. Induced counter-flow a3. Forced (fan at air inlet) cross-flow a4. Forced counter-flow b) Natural draft towers c) Evaporative condensers
Water Losses:	Blowdown: –0.5 to 3.0% of circulated flow rate Evaporation: –1% for each 12.5°F (7°C) of cooling range Drift*:* 0.02% to 0.1% of circulated flow rate
Fan Types:	Induced and forced draft fans, axial-flow propellers
Heat Load:	BTU = 500(gpm)(water ΔT)
Approach:	5 to 10°F (2.8 to 5.6°C) for mechanical draft 20°F (11°C) for evaporative condensers
Fan Power Savings at Reduced Speeds:	50% at 80% speed 85% at 50% speed
Costs:	Initial investment: \$25 to \$40 per gpm of capacity Energy cost of operation: 0.01 BHP/gpm, or about \$6 to \$10 per year per gpm

INTRODUCTION

This section is devoted to the discussion of the control of cooling towers, while the next section deals with their optimization. Other related sections in this chapter describe the control and optimization of HVAC systems and of chillers.

Cooling towers are water-to-air heat exchangers that are used to discharge waste heat into the atmosphere. Their cost of operation is a function of the water and air transportation costs. In conventional cooling towers, the air and water flows are often constant. In optimized cooling towers the water and air flows are variable and are adjusted as a function of the load.

In this section the types of cooling tower design are described and the various techniques of load-following capacity controls are discussed. Cooling tower winterizing and blowdown controls are also covered.

DEFINITIONS

In order to make the discussion of the control aspects of cooling towers completely clear, first some related terms will be defined:[1]

APPROACH The difference between the wet-bulb temperature of the entering ambient air and of the leaving water temperature from the tower. The approach is a function of cooling tower capacity; a large cooling tower will produce a closer approach (colder leaving water) for a given heat load, flow rate, and entering air condition (Figure 8.16a). (Units: °F or °C.)

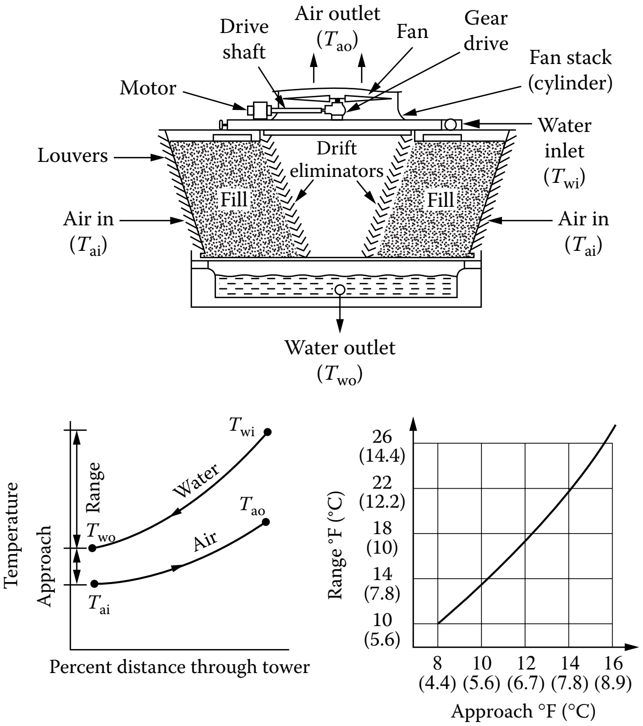


FIG. 8.16a

The mechanical cooling tower is a water-to-air heat exchanger. A direct relationship exists between water and air temperatures in a counterflow cooling tower. An increase in range will cause an increase in approach, if all other conditions remain unaltered.

BAY The area between two bents of lines of framing members; usually longitudinal.

BENT A line of structural framework composed of columns, girts, or ties; a bent may incorporate diagonal bracing members; usually transverse.

BLOWDOWN Water discharged to control concentration of impurities in circulated water. (Units: percentage of circulation rate.)

BRAKE HORSEPOWER (BHP) The actual power output of an engine or motor.

COLD WATER BASIN A storage device underlying the tower to receive the cold water from the tower and direct its flow to the pump suction line or sump.

COUNTERFLOW COOLING TOWER A cooling tower in which air flows in the opposite direction to the fall of water through the cooling tower.

CROSS-FLOW COOLING TOWER A cooling tower in which the direction of the airflow through the fill is perpendicular to the plane of the falling water.

DEW-POINT TEMPERATURE (TDP) The temperature at which condensation begins, if air is cooled under constant pressure (see Figure 8.16b).

DOUBLE-FLOW COOLING TOWER A cross-flow tower with two fill sections and one plenum chamber that is common to both fill sections.

DRIFT The water loss due to liquid droplets entrained and removed by the exhaust air. Usually under 0.2% of circulated water flow rate.

DRIFT ELIMINATOR An assembly constructed of wood or honeycomb materials that serves to remove entrained moisture from the discharged air.

DRY-BULB TEMPERATURE (TDB) The air temperature measured by a normal thermometer (see Figure 8.16b).

EVAPORATION LOSS Water evaporated from the circulating water into the atmosphere in the cooling process. (Unit: percentage of total GMP.)

FAN-DRIVE OUTPUT Actual power output (BHP) of drive to shaft.

$$\mathrm{BHP} = \frac{(\text{motor efficiency})(\text{amps})(\text{volts})(\text{power factor})1.73}{746} \tag{8.16(1)}$$

FAN PITCH The angle that a fan blade makes with the plane of rotation. (Unit: degrees from horizontal.)

FAN STACK (CYLINDER) Cylindrical or modified cylindrical structure in which the fan operates. Fan cylinders are used on both induced draft and forced draft axial-flow propeller-type fans.

FILLING That part of an evaporative tower consisting of splash bars, vertical sheets of various configurations, or honeycomb assemblies that are placed within the tower to effect heat and mass transfer between the circulating water and the air flowing through the tower.

FORCED DRAFT COOLING TOWER A type of mechanical draft cooling tower in which one or more fans are located at the air inlet to force air into the tower.

HEAT LOAD The heat removed from the circulating water within the tower. Heat load may be calculated from the range and the circulating water flow. (Unit: BTU per hour = gpm 500 [$T_{ctwr} - T_{ctws}$].)

LIQUID GAS RATIO (L/G) Mass ratio of water to airflow rates through the tower. (Units: lb/lb or kg/kg.)

LOUVERS Assemblies installed on the air inlet faces of a tower to eliminate water splash-out.

MAKEUP Water added to replace loss by evaporation, drift, blowdown, and leakage. (Unit: percentage of circulation rate.)

MECHANICAL DRAFT COOLING TOWER A tower through which air movement is effected by one or more fans. There are two general types of such towers: those that use forced draft with fans located at the air inlet and those that use induced draft with fans located at the air exhaust.

NATURAL DRAFT WATER COOLING TOWER (AIR MOVEMENTS) A cooling tower in which air movement is essentially dependent upon the difference in density between the entering air and internal air. As the heat of the

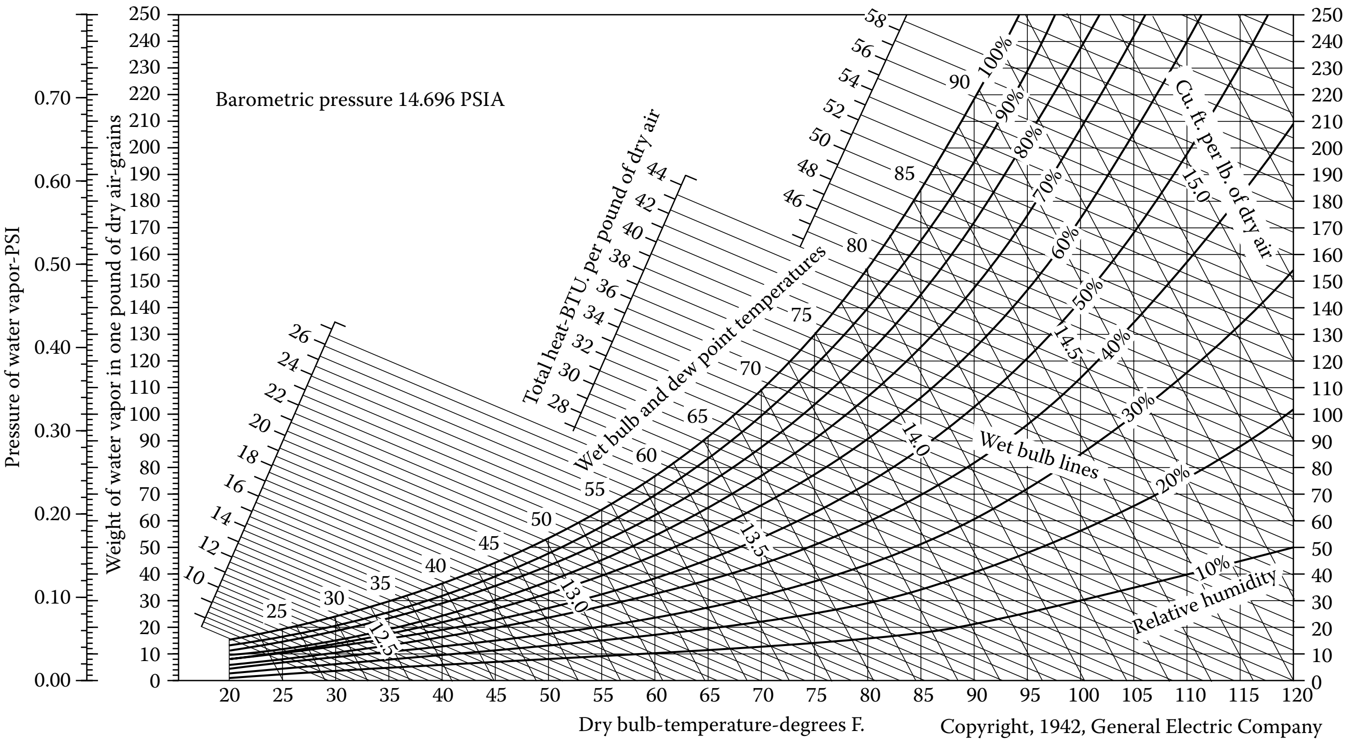

FIG. 8.16b

The psychrometric chart describes the following properties of air: Water vapor pressure, weight of water per pound of air, dry-bulb temperature, wet-bulb temperature, heat content per pound of air, volume per pound of air. The dew point temperature is the wet-bulb temperature when the relative humidity is 100%.

water is transferred to the air passing through the tower, the warmed air tends to rise and draw in fresh air at the base of the tower.

NOMINAL TONNAGE One nominal ton corresponds to the transfer of 15,000 BTU/hr (4.4 kW) when water is cooled from 95 to 85°F (35 to 29.4°C) by ambient air having a wet-bulb temperature of 78°F (25.6°C) and when the water circulation rate is 3 gpm (11.3 lpm) per ton.

PERFORMANCE The measure of a cooling tower's ability to cool water. Usually expressed in gallons per minute cooled from a specified hot water temperature to a specified cold water temperature with specific wet-bulb temperature. Typical performance curves for a cooling tower are shown in Figure 8.16c. This is a "7500 gpm at 105-85-78" tower, meaning that it will cool 7500 gpm of water from 105 to 85°F when the ambient wet-bulb temperature is 78°F.

PLENUM The enclosed space between the eliminators and the fan stack in induced draft towers, or the enclosed space between the fan and the filling in forced draft towers.

POWER FACTOR The ratio of true power (watts) to the apparent power (amps × volts).

PSYCHROMETER An instrument used primarily to measure the wet-bulb temperature.

RANGE (COOLING RANGE) The difference between the temperatures of water inlet and outlet, as shown in Figure 8.16a. For a system operating in a steady state, the range is the same as the average water temperature rise through the process loads. Accordingly, the range is determined by the heat load and water flow rate, not by the size or capability of the cooling tower. On the other hand, the range does affect the approach, and as the range increases, a corresponding increase in the approach will occur if all other factors remain unaltered (see Figure 8.16a).

RISER Piping that connects the circulating water supply line from the level of the base of the tower or the supply header to the tower inlet connection.

SPEED REDUCER A device for changing the speed of the driver in order to arrive at the desired fan speed.

STANDARD AIR Dry air having a density of 0.075 lb/ft^3 at 70°F and 29.92 in. Hg.

STORY The vertical dimension or area between two lines of horizontal framework ties, girts, joists, or beams. In wood frame structures, the story will vary from 5 to 7 ft (about 2 m) in height.

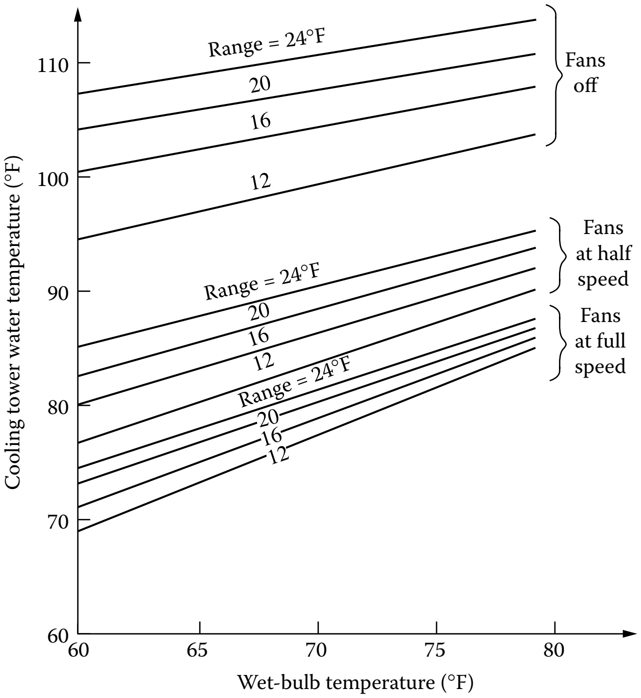

FIG. 8.16c

Cooling tower performance curves give the temperature of the generated cooling water as a function of the wet-bulb temperature of the air, the fan speed, and the range (the difference between the inlet and outlet temperatures of the tower water).

SUMP (BASIN) Lowest portion of the basin to which cold circulating water flows: usually the point of suction connection.

TONNAGE *See* Nominal Tonnage.

TOTAL PUMPING HEAD The total head of water, measured above the basin curb, required to deliver the circulating water through the distribution system.

TOWER PUMPING HEAD Same as the total pumping head minus the friction loss in the riser. It can be expressed as the total pressure at the centerline of the inlet pipe plus the vertical distance between the inlet centerline and the basin curb.

WATER LOADING Water flow divided by effective horizontal wetted area of the tower. (Unit: gpm/ft^2 or m^3/hr · m^2.)

WET-BULB TEMPERATURE (TWB) If a thermometer bulb is covered by a wet, water-absorbing substance and is exposed to air, evaporation will cool the bulb to the wet-bulb temperature of the surrounding air. This is the temperature read by a psychrometer. If the air is saturated with water, the wet-bulb, dry-bulb, and dew-point temperatures will all be the same. Otherwise, the wet-bulb temperature is higher than the dew-point temperature but lower than the dry-bulb temperature (see Figure 8.16b).

THE COOLING PROCESS

In a cooling tower, heat and mass transfer processes combine to cool the water. The mass transfer due to evaporation does consume water, but the amount of loss is only about 5% of the water requirements for equivalent once-through cooling by river water.

Cooling towers are capable of cooling within 5–10°F (2.8–5.6°C) of the ambient wet-bulb temperature. The larger the cooling tower for a given set of water and airflow rates, the smaller this approach will be. The mass transfer contribution to the total cooling is illustrated in the simplified psychrometric chart in Figure 8.16d.

Points A and D illustrate the conditions in which the ambient air might enter. After it transferred heat and absorbed mass from the evaporating water, the air leaves in a saturated condition described to point B. The total heat transferred in terms of the difference between entering and leaving enthalpies ($h_B - h_A$) is the same for both the AB and the DB processes.

The AC component of the AB vector represents the heat transfer component (sensible air heating), and the CB vector represents the evaporative mass transfer component (latent air heating). If the air enters at condition D, the two component vectors do not complement each other, because only one of them heats the air (EB). Therefore, the total vector DB results from the latent heating (EB) and sensible cooling (DE) of the air.

In terms of the water side of the DB process, the water is being sensibly heated by the air and cooled by evaporation. Therefore, as long as the entering air is not saturated, it is possible to cool the water with air that is warmer than the water.

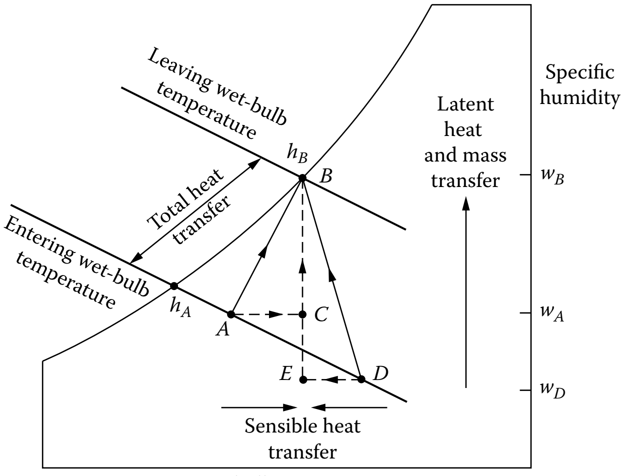

FIG. 8.16d

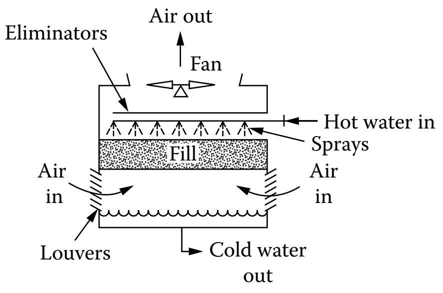
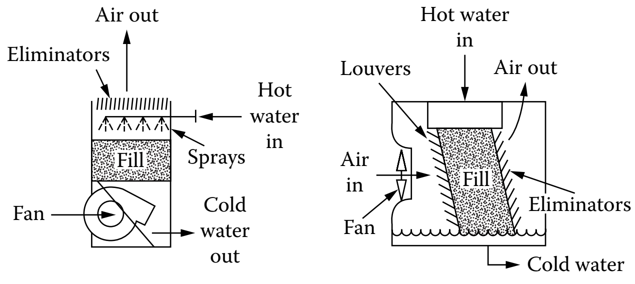
Heat and mass transfer processes combine to cool water. Total cooling is the sum of the latent cooling caused by the evaporation of water and the sensible heat transfer, which can either add to or reduce the latent cooling as a function of the relative temperatures of the entering air and water.[2]

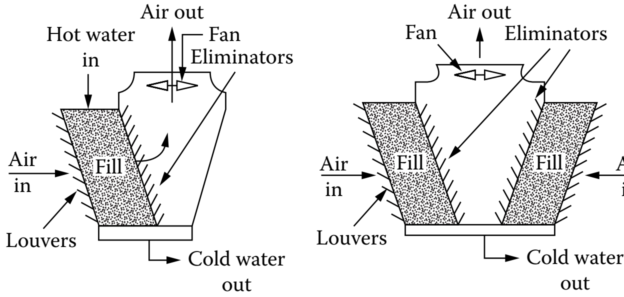


Induced-draft counterflow



Forced-draft counterflow

Force-draft crossflow



Induced-draft crossflow (single air entry)

Induced-draft crossflow (double air entry)

FIG. 8.16e

Mechanical draft cooling towers are distinguished by the location of the air fan (forced or induced draft), by the direction of the air flow (cross- or counterflow), and by the nature of the air entrance (single or double entry).[2]

MECHANICAL DRAFT COOLING TOWERS

The basic mechanical draft cooling tower designs are described in Figure 8.16e. For operational purposes, tower characteristic curves for various wet-bulb temperatures, cooling ranges, and approaches can be plotted against the water flow to airflow ratio in accordance with following equation:

$$\frac{KaV}{L} \sim \frac{(L)^n}{(G)} \qquad \textbf{8.16(2)}$$

where

K = overall unit of conductance, mass transfer between saturated air at mass water temperature, and main air stream: lb per hour (ft^2)(lb/lb)

a = area of water interface per unit volume of tower: ft^2 per ft^3

V = active tower volume per unit area: ft^3 per ft^2

L = mass water flow rate: lb per hour

G = airflow rate: lb dry air per hour

n = experimental coefficient: varies from -0.35 to -1.1 and has an average value of -0.55 to -0.65

Characteristic Curves

From the characteristic curves of the cooling tower it is possible to determine tower capability, effect of wet-bulb temperature, cooling range, water circulation, and air delivery, as shown in Figure 8.16f. The ratio KaV/L is determined from test data on hot water and cold water, wet-bulb temperature, and the ratio of the water flow to the airflow.

For air conditioning applications the thermal capability of cooling towers is usually stated in terms of nominal tonnage. This tonnage is defined as the heat dissipation of 15,000 BTU/h (4.4 kW) per condenser ton (kW) and a water circulation rate of 3 gpm/ton (0.054 l/s per kW) cooled from 95 to 85°F (35 to 29.4°C) at 78°F (25.6°C) wet-bulb temperature.

It may be noted that the subject tower would be capable of handling a greater heat load (flow rate) when operating in

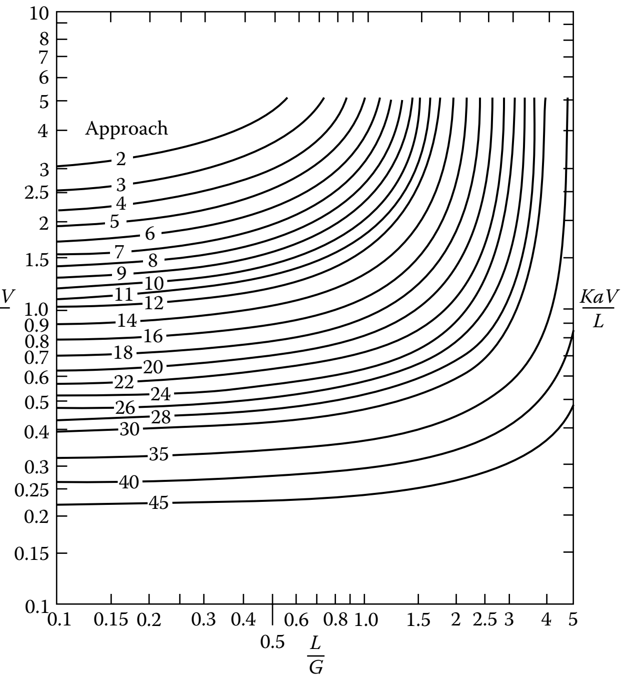


FIG. 8.16f

Characteristic curves of cooling towers (based on 64°F [17.8°C] air wet-bulb temperature and 18°F [10°C] cooling water temperature drop range).

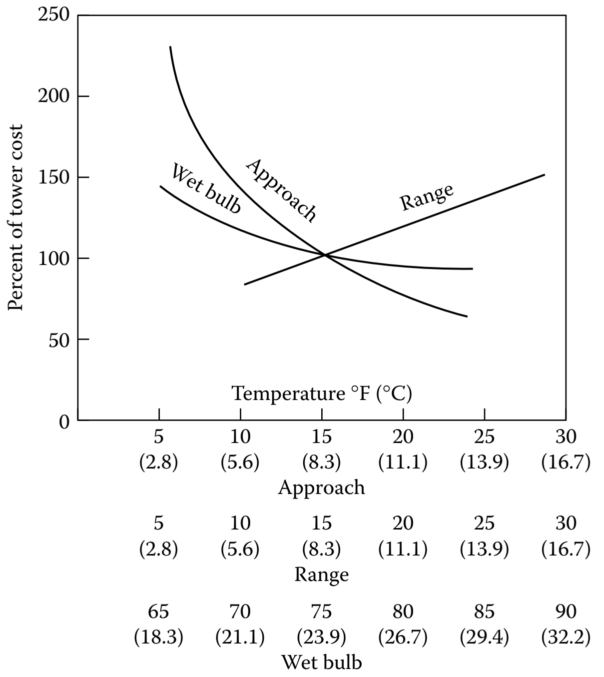

FIG. 8.16g

The smaller the cooling tower (the lower the initial investment), the higher will be the operating cost. If the tower cost is considered to be 100 when it is sized for an approach and a range of 15°F when the wet bulb is 75°F, the data in this figure give the comparative cooling tower costs for a range of other sizing basis. (Courtesy of Foster Wheeler Corp.)

a lower ambient wet-bulb region. For operation at other flow rates, tower manufacturers usually provide performance curves covering a range of at least 2 to 5 gpm per nominal ton (0.036 to 0.09 lps/kW).

The initial investment required for a cooling tower is essentially a function of the required water flow rate, but this cost is also influenced by the design criteria for approach, range, and wet-bulb. As shown in Figure 8.16g, cost tends to increase with range and tends to decrease with a rise in approach or wet-bulb. The initial investment is about \$25–\$40 per gpm of tower capacity, whereas the energy cost of operation is approximately 0.01 BHP/gpm, or about \$6–\$10 per year per gpm. This means that the cost of operation reaches the cost of initial investment in 5–10 years, depending on energy costs.

CONTROLS

On HVAC-type applications, the cooling tower controls usually consist of on/off or sequential load controls, safety interlocks, and blowdown and winter operation controls. In industrial applications, the controls tend to be continuous and are usually controlling sophisticated, variable-speed fans (Figure 8.16h) as discussed in the next section.

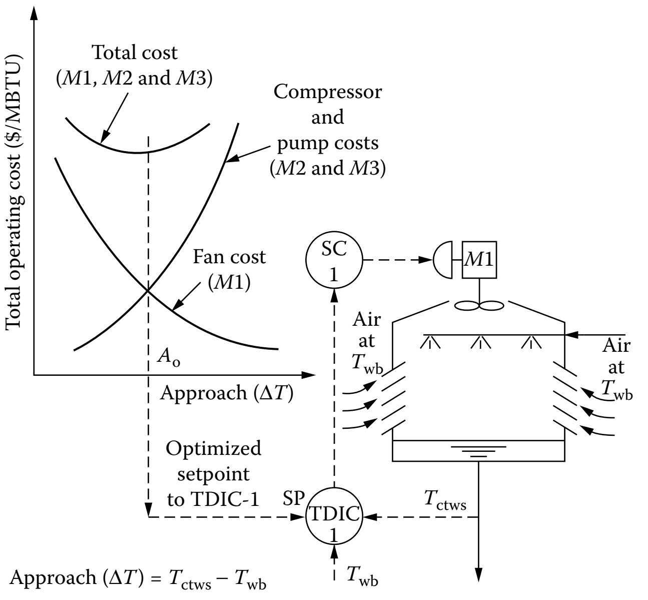

FIG. 8.16h

In order to minimize the total cost of operation, the speed of the cooling tower's air fan can be so throttled so that the optimum approach (the approach corresponding to the minimum cost of operation) is maintained.

Load Controls

The cooling tower is an air-to-water heat exchanger. The controlled variables are the supply and return water temperatures, while the manipulated variables are the air and water flow rates. Manipulation of these flow rates can be continuous, through the use of variable-speed fans and pumps, or can be incremental, through the cycling of single- or multiple-speed units.

If the controlled variable is the temperature of the water supplied by the cooling tower and the manipulated variable is the fan speed, a change in cooling load will result in a change in the operating level of the fans. If the fans are single-speed devices, the airflow rate is changed by cycling the fan units on or off as a function of load. This is illustrated in Figure 8.16i and can be done by simple sequencers or by more sophisticated digital systems.

In most locations, the need to operate all fans at full speed is required for only a few thousand hours every year. Fans running at half speed consume approximately one-seventh of the design air horsepower but produce over 50% of the design air rate (cooling effect). Therefore in 98% of the cases, two-speed motors are a wise investment for minimizing operating costs.

Operating Interlocks

Figure 8.16j describes a simple fan starter. A three-position "hand/off/automatic" switch controls the fan. When the switch is placed in "automatic" (contacts 3 and 4 connected),

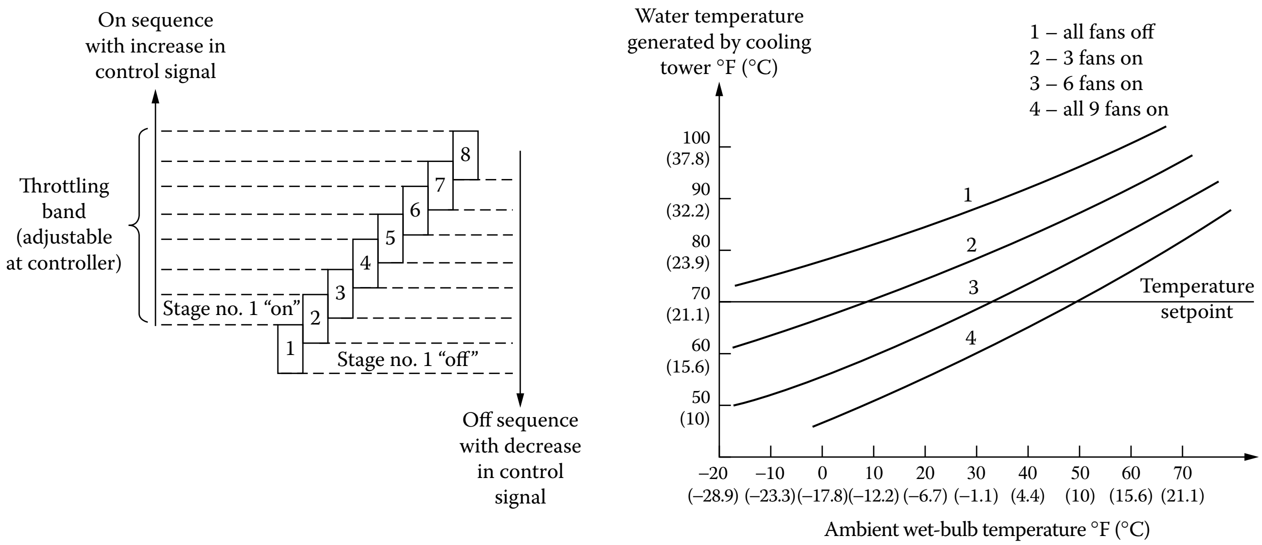

FIG. 8.16i

Illustrations of load-following control accomplished by fan cycling. The figure on the left illustrates how the output signal from the approach controller (TDIC-1 in Fig. 8.16h) sequences the fan stages on and off as a function of the load. The figure on the right shows the effect of fan cycling on a nine-cell tower that is designed for a full capacity of 160,000 gpm (608,000 l/m) water loading with an 84°F (29°C) inlet and 70°F (21°C) outlet temperature, operating at 50% load.[3]

the status of the interlock contact *I* determines whether or not the circuit is energized and the fan is on.

The sequencing of this contact *I* is described in Figure 8.16i. The purpose of the auxiliary motor contact *M* is to energize the running light *R* whenever the fan motor is on. The parallel hot lead to contact 6 allows the operator to check quickly to see whether the light has burned out.

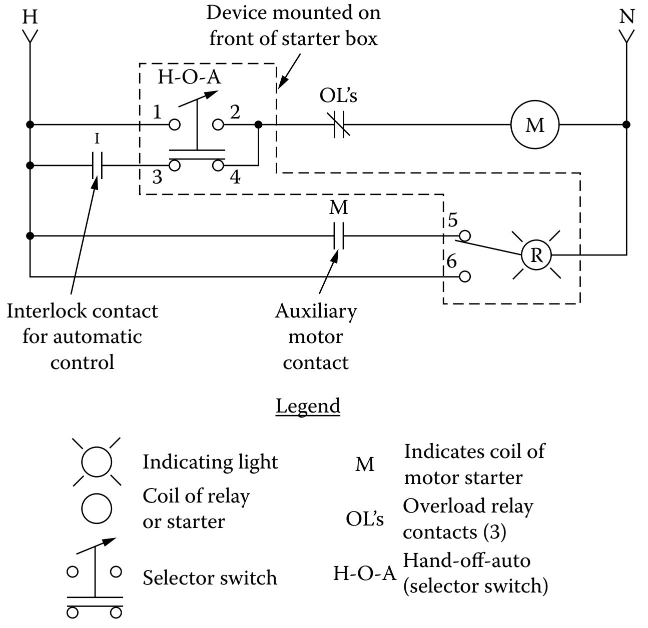

FIG. 8.16j

The wiring diagram of a simple fan starter circuit, manually controlled by a three-position (hand-off-automatic) switch.

The amount of interlocking is usually greater than that shown in Figure 8.16j. Some of the additional interlock options are described in the paragraphs below.

Safety Interlocks

Most fan controls include some safety overrides in addition to the overload (OL) contacts shown in Figure 8.16j. These overrides might stop the fan if fire, smoke, or excessive vibration is detected. They usually also provide a contact for remote alarming.

Most fan controls also include a reset button that must be pressed after a safety shut-down condition is cleared before the fan can be restarted.

When a group of starters is supplied from a common feeder, it may be necessary to make sure that the starters are not overloaded by the inrush currents of simultaneously started units. If this feature is desired, a 25 sec time delay is usually provided to prevent other fans from starting until that time has passed.

Larger fans should be protected from overheating caused by too frequent starting and stopping. This protection can be provided by a 0–30 min time delay guaranteeing that the fan will not be cycled at a frequency faster than the delay time setting.

When two-speed fans are used, added interlocks are frequently provided. One interlock might guarantee that even if the operator starts the fan to operate at high speed, it will operate for 0–30 sec in low before advancing automatically to high. This makes the transition from off to high speed more gradual.

Another interlock might guarantee that when the fan is switched from high to low, it will be off the high speed for 0 to 30 sec before the low-speed drive is engaged. This will give time for the fan to slow before the low gears are engaged.

When the fan can also be operated in reverse, further interlocks are needed. One interlock should guarantee that the fan is off for 0–2 min before a change in the direction of rotation can take place. This gives time for the fan to come to rest before making a change in direction. Another interlock will guarantee that the fan can operate only at slow speed in the reverse mode and that reverse operation cannot last more than 0–30 min. This limitation is desirable because when the fan is in reverse in the winter, ice tends to build up on the blades and the gears can wear excessively.

If the same fans can be controlled from several locations, interlocks are needed to resolve the potential problems with conflicting requests. One method is to provide an interlock that determines the location that is in control. This can be a simple local/remote switch or a more complicated system.

When many locations are involved, conflicts are resolved by interlocks that either establish priorities between control locations or select the lowest, highest, safest, or other specified choice from the control requests. In installations with multiple control centers, it is essential that feedback be provided so that the operator is always aware not only of the actual status of all fans but also of any conflicting requests that are possibly coming from other operators or computers.

EVAPORATIVE CONDENSERS

The evaporative condenser is a special cooling tower type, shown in Figure 8.16k. In this unit the induced air and sprayed water flow concurrently downward, and the process vapors travel upwards inside the multipass condenser tubes. A pressure controller (PIC) modulates the amount of cooling, so that it will match the load. The continuous water spray on that makes the tube surfaces wet, improves heat transfer and maintains tube temperatures.

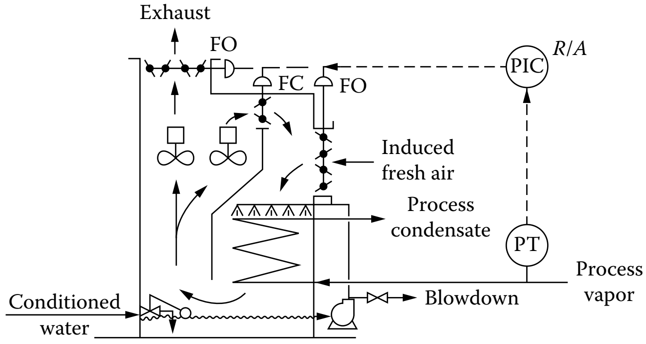

FIG. 8.16k
In evaporative condensers, the pressure of the process vapors can be controlled by modulating the proportion of the humid air, which is recirculated. (Adapted from Reference 4.)

The approach of these cooling towers is around 20°F (11°C), and the wet-bulb temperatures of the cooling air can be varied by the recirculation of humid (or saturated) air. The resulting condensing temperatures are lower than the condensers, which are cooled by dry air. The higher heat capacity and lower resistance to heat transfer make these units more efficient than the dry-air coolers.

The turndown capability of these units is also very high, because the fresh-air flow can be reduced all the way to zero. Both the exhaust and the fresh air dampers can be closed while the recirculation damper simultaneously opens to maintain the internal air flow rate constant. As more humid air is recirculated, the internal wet-bulb temperature rises and the heat flow drops off. In Figure 8.16k the heat flow is effectively linear with fresh-air flow.[4]

SECONDARY CONTROLS

In addition to the previously discussed load controls and safety interlocks, controls are also needed for winter operation, water quality, and blowdown controls and other miscellaneous purposes.

Winter Operation

In case of a power failure during subfreezing weather, the tower basin should be electrically heated and should be provided with an emergency draining system. Another method of freeze protection is to provide bypass circulation illustrated in Figure 8.16l. In this system, a thermostat (TSL) detects the outlet temperature of the cooling tower water, and

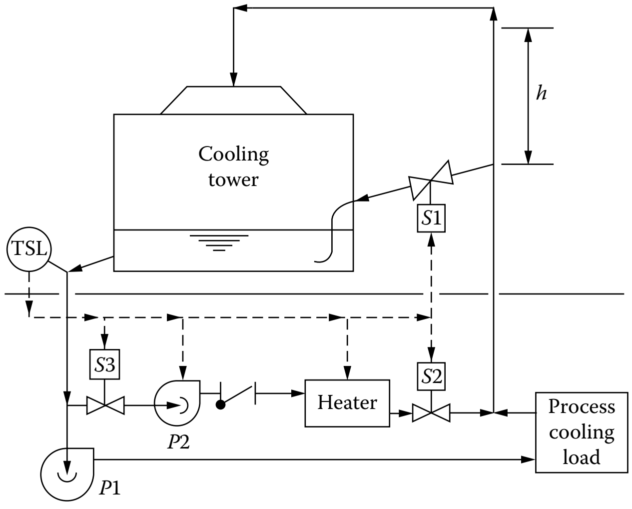

FIG. 8.16l
Protection against freezing can be provided in the winter by starting a bypass pump if the temperature drops to near freezing (TSL) and by sending this bypassed water through a heater and then back to the tower.

when it drops below 40°F (4.4°C), the bypass circulation (located in a protected indoor area) is started. This circulation is terminated when the water temperature rises to approximately 45°F (7.2°C).

The thermostat is wired to open the solenoids *S*1, *S*2, and *S*3 first and then to start the circulating pump (*P*2), which usually is a small, $^1/_4$ or $^1/_3$ hp (186.5 or 248.7 W) unit. The bypass line containing solenoid *S*1 is sized to handle the flow capacity of *P*2, with a pressure drop that is less than the height of the riser pipe (*h*). This makes sure that when *P*1 is off, no water will reach the top of the column.

In the northern regions, in addition to the *S*1 bypass shown in Figure 8.16l, there is a full-size bypass (not shown in Figure 8.16l). When the main (P1) pump is started in the winter, this full bypass is opened; it does not allow the water to be sent to the top of the tower until its temperature is approximately 70°F (21°C). Once the water reaches that temperature, the bypass is closed because the water is warm enough to be sent to the top of the tower without danger of freezing. As the water temperature rises further, fans are turned on to provide added cooling.

When open cooling towers are operated at freezing temperatures, the induced draft fans must be reversed periodically in order to deice the air intakes. The need for deicing can be determined through visual observation, through remote closed-circuit TV inspection, or by comparing the load and ambient conditions to past operating experience, as have already been discussed under interlocks.

All exposed pipes that will contain water when the tower is down should be protected by electric tape or cable tracing and by insulation. The sump either should be drainable to an indoor auxiliary sump or should be provided with auxiliary steam or electric heating.

Closed cooling towers should either operate on antifreeze solutions or be provided with supplemental heat and tracing. If the second method is used, the system must be drained if power failure occurs.

Blowdown Controls

The average water loss by blowdown is 0.5–3.0% of the circulating water rate. The loss is a function of the initial quality of the water and the amount and concentration of the dissolved natural solids and chemicals added for protection against corrosion or build-up of scale on the heat transfer surfaces. Because the cooling tower is a highly effective air scrubber, it continuously accumulates the solid content of the ambient air on its wet surfaces, which are then washed off by the circulated water.

The “normal” condition of the circulated water can be defined arbitrarily as:

pH	6–8
Chloride as NaCl	under 750 ppm
Total dissolved solids	under 1500 ppm

The blowdown requirement can be determined as follows:

$$B = \frac{([E+D]/N) - D}{1-(1/N)} \qquad \mathbf{8.16(3)}$$

where

B = blowdown in percentage (typically, for *N* = 2, 0.9%; for *N* = 3, 0.4%; for *N* = 4, 0.24%)
E = evaporation in percentages (typically 1% for each 12.5°F [7°C] of cooling range)
D = drift in percentage (typically 0.1%)
N = number of concentration relative to initial water quality

Problems and Solutions In cooling towers, the major causes for concern are delignification, which is the loss of the binding agent of the cellulose. It is caused by the use of oxidizing biocides, such as chlorine. It can also be caused by excessive bicarbonate alkalinity; biological growth, which can clog the nozzles and foul the heat exchange equipment; corrosion of the metal components (this corrosion should be less than 3 mils per year without pitting); general fouling by a combination of silt, clay, oil, metal oxides, calcium and magnesium salts, organic compounds, and other chemical products that can cause reduced heat transfer and enhanced corrosion; and scaling by crystallization and precipitation of salts or oxides (mainly calcium carbonate and magnesium silicate) on surfaces.

The treatment techniques to prevent these conditions from occurring are listed in Table 8.16m. The blowdown must meet the water quality standards for the accepting stream and must not be unreasonably expensive. It is also possible to make the water system a closed-cycle system (no blowdown) by ion-exchange treatment.

Miscellaneous Controls

The minimum basin level is maintained by float-type, makeup level control valves. The maximum basin level is guaranteed by overflow nozzles, which are sized to handle the total system flow. In critical systems, additional safety is provided by the use of high/low level alarm switches.

Torque and vibration detectors can be used to safeguard the operational safety of the fans and of the fan drives. Low-temperature alarm switches can also be furnished as warning devices signaling the failure of the freeze protection controls.

The need for flow balancing among multiple cells is another reason for using additional valves and controls. (Advanced water distribution controls will be discussed in the next section.) In conventional systems, the warm water is usually returned to the multicell system through a single riser, and a manifold is provided at the top of the tower for water distribution to the individual cells. Balancing valves should be installed to guarantee equal flow to each operating cell. If two-speed fans are used, further economy can be gained by lowering the water flow when the fan is switched to low speed. It is also advisable to install equalizer lines

TABLE 8.16m
Potential Cooling Tower Problems and their Solutions

Problem	*Factors*	*Causative Agents*	*Corrective Treatments*
Wood deterioration	Microbiological Chemical	Cellulolytic fungi Chlorine	Fungicides Acids
Biological growths	Temperature Nutrients pH Inocula	Bacteria Fungi Algae	Chlorine Chlorine donors Organic sulfurs Quatenary ammonia
General fouling	Suspended solids Water Velocity Temperature Contaminants Metal oxides	Silt Oil	Polyelectrolytes Polyacrylates Lignosulfonates Polyphosphates
Corrosion	Aeration pH Temperature Dissolved solids Galvanic couples	Oxygen Carbon dioxide Chloride	Chromate Zinc Polyphosphate Tannins Lignins Synthetic organic compounds
Scaling	Calcium Alkalinity Temperature pH	Calcium carbonate Calcium sulfate Magnesium silicate Ferric hydroxide	Phosphonates Polyphosphates Acid Polyelectrolytes

between tower sumps to eliminate imbalances caused by variation in flow or pipe layouts.

Another reason for considering the use of two-speed fans is to have the ability to lower the associated noise level at night or during periods of low load. Switching to low speed will usually lower the noise level by approximately 15 dB.

CONCLUSIONS

One of the least understood and most neglected unit operations in the processing industries is the cooling tower. Its pumps are frequently constant speed with three-way or bypass valves used to circulate the excess water. This excess should not have been pumped in the first place, because the process does not require it.

Meeting a variable load with a constant supply by wasting the excess is also frequently practiced in fan operation. In some installations, fan speeds cannot be changed at all; in others, they can be changed only manually, which can require seasonal adjustments in some extreme cases.

As the rating of the tower fans and pumps usually adds up to several hundred horsepower, their yearly operating cost is in the hundreds of thousands of dollars. As optimization can cut this in half, the added costs for controls are justified. This is the subject of the next section.

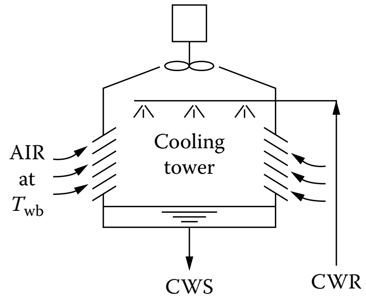
8.17 Cooling Tower Optimization

B. G. LIPTÁK (1985, 1995, 2005)



Flow sheet symbol

Savings through Optimization:	A 20% reduction in either air or water flow will result in a 50% reduction in fan or pump operating costs. A 50% speed reduction cuts operating cost by 85%.
Water Losses:	Blowdown:- 0.5 to 3.0% of circulated flow rate Evaporation: 1% for each 12.5°F (7°C) of cooling range Drift*:* 0.02% to 0.1% of circulated flow rate
Heat Load:	BTU = 500 (gpm)(water ΔT)
Approach:	5 to 10°F (2.8 to 5.6°C) for mechanical draft 20°F (11°C) for evaporative condensers
Costs:	Initial investment: $25 to $40 per gpm of capacity Energy cost of operation: 0.01 BHP/gpm, or about $6 to $10 per year per gpm.

INTRODUCTION

The plant's demand for cooling water determines the load on the cooling tower. The most efficient way of meeting this variable demand is to use variable-speed water pumps (Figure 8.17a). As the cooling tower is a water-to-air heat exchanger, when a drop in load causes the water flow rate to drop, the air flow on the other side of this exchanger can also be reduced.

In optimized cooling towers, the water and air flows are both controlled by variable-speed devices. The goal of cooling tower optimization is to maximize the amount of heat discharged into

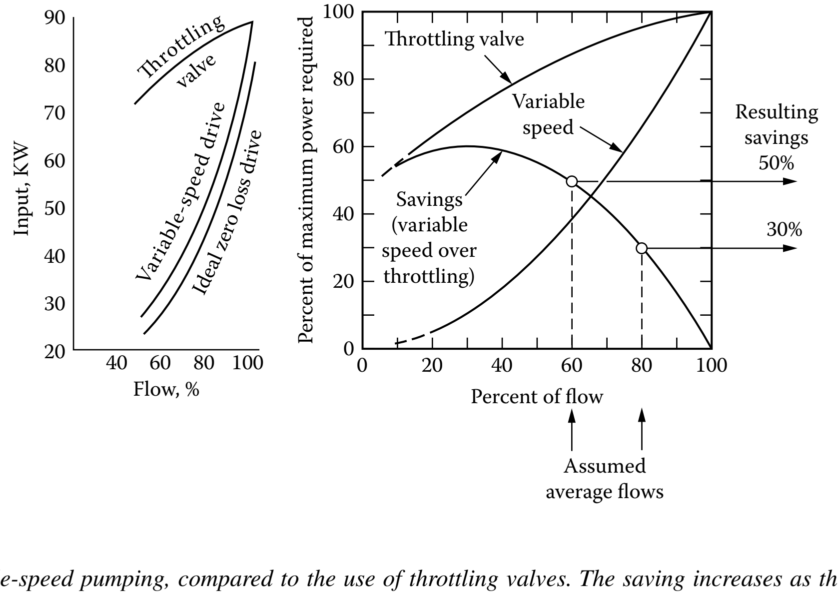


FIG. 8.17a
The savings due to variable-speed pumping, compared to the use of throttling valves. The saving increases as the flow rate drops.

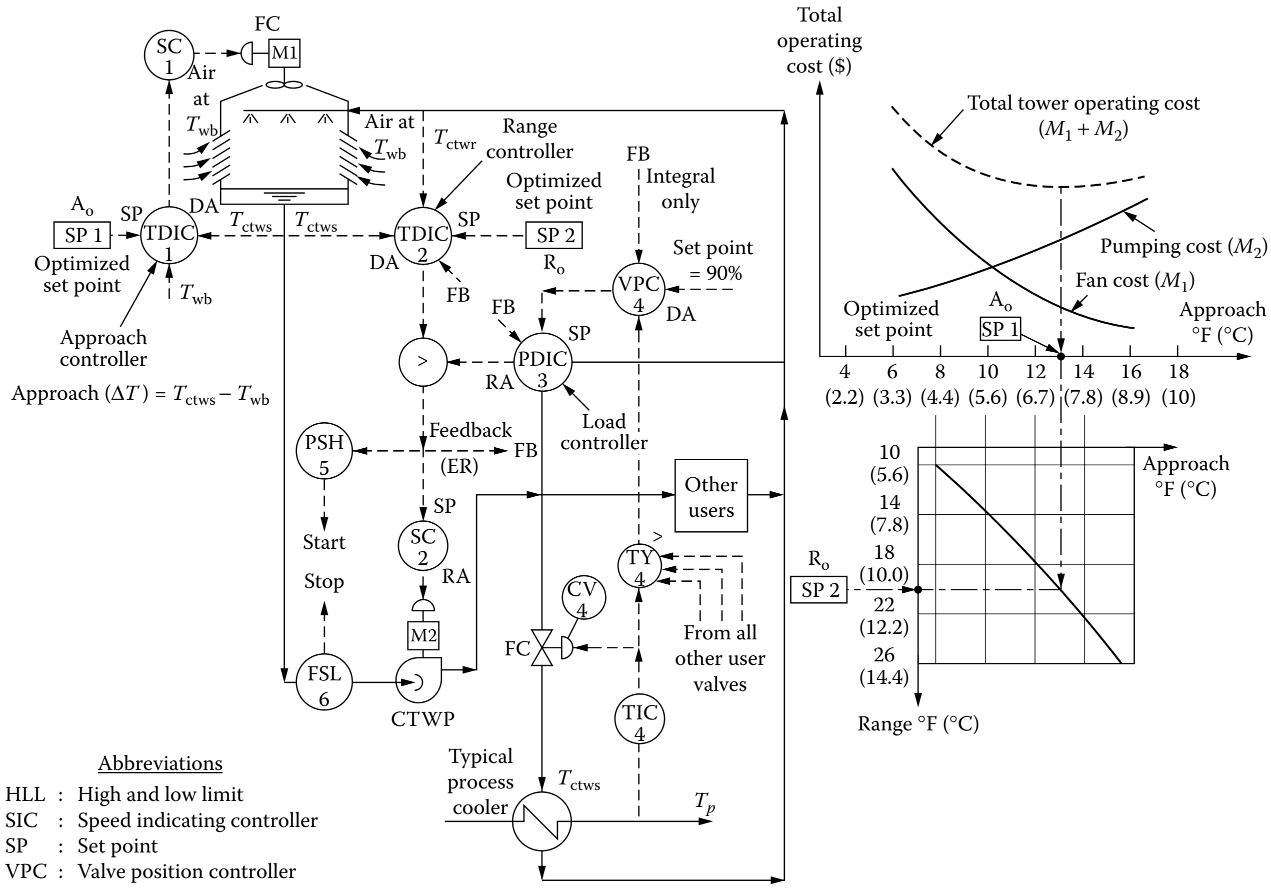

FIG. 8.17b

Optimization minimizes the unit cost of cooling by minimizing the operating speeds of both the cooling tower fans and pumps.

the atmosphere per unit of operating cost invested. The optimization strategies discussed in this section are applicable not only to standard mechanical draft cooling towers but to evaporative condensers and natural draft cooling towers.

The optimization of cooling towers as parts of chiller systems has been discussed in Section 8.13. The discussion here will concentrate on cooling systems, where the cooling water from the cooling towers is not used to generate chilled water but is pumped directly to cool the process.

MINIMIZING OPERATING COST

The cost of fan operation can be reduced by allowing the cooling tower water temperature (T_{ctws} in Figure 8.17b) to rise, thereby increasing the approach ($T_{ctws} - T_{wb}$) at which the tower operates. As shown in Figure 8.16c, the approach can be increased to a point at which the fans are off and their operating cost is zero. Under most load conditions, however, this would not produce a low enough cooling water temperature for the process.

The Optimum Approach

As shown in Figure 8.17b, as the approach, and therefore T_{ctws}, rises, the temperature difference across all process coolers ($T_p - T_{ctws}$) is reduced. This will cause the process temperature (T_p) to rise and its controller (TIC-4) to further open the coolant valve, CV-4. In order to reduce the process temperature, more and more water must be pumped. Therefore, an increase in approach will result in an increase in water transportation, and consequently the pumping costs will rise.

If the actual total operating cost is plotted against the approach (as in the right side of Figure 8.17b), the fan costs tend to drop and the pumping costs tend to rise with an increase in approach. If the operating cost of some of the users is also affected by cooling water temperature (this was the case when the water is used in chiller condensers, as in Figure 8.17c), then the total cost model should also consider that effect. Once a total operating cost curve is obtained, the optimum approach can be found by looking for the minimum point on that curve.

Cost Curves

The data for the cost curves are empirically collected and are continually updated through the actual measurement of fan and pump operating costs. Consequently, for any combination of load and ambient conditions there is a reliable prediction

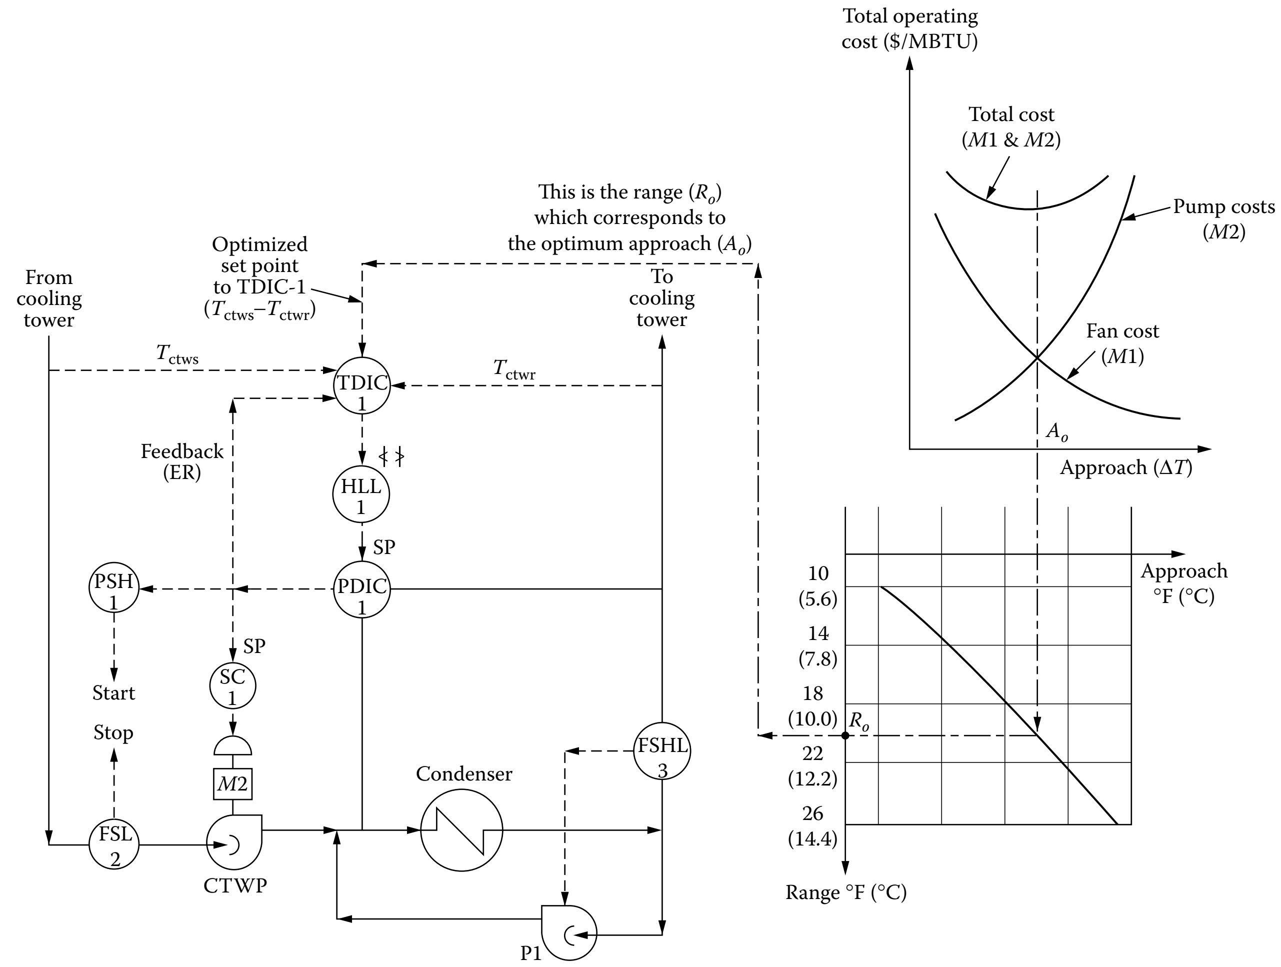

FIG. 8.17c

Total operating cost can be minimized by TDIC-1 controlling the range of the cooling tower (the difference between the return and supply temperatures) at the value that corresponds to the minimum cost of operation.

of optimum approach setting (A_o in Figure 8.17c). Once the initial prediction is set, that setting can be refined by adjusting it in 0.5°F increments, if the total operating cost is lowered by such adjustments.

As is also shown in the right side of Figure 8.17b, there is an empirical relationship between the values of approach and range, if all other conditions remain unaltered. Therefore, if the optimum value of approach (SP-1-A_o) has been determined, the corresponding optimum range value (SP-2-R_o) under the prevailing load conditions can be obtained from this curve. This is how the optimized set points (SP-1 and SP-2) of the approach and range controllers are determined and updated.

Supply Temperature Optimization

As shown in Figure 8.17b, an optimization control loop is required in order to maintain the cooling tower water supply continuously at an economical minimum temperature. This minimum temperature is a function of the wet-bulb temperature of the atmospheric air. The cooling tower cannot generate a water temperature that is as low as the ambient wet-bulb but it can approach it (hence the term "approach").

As is shown in Figure 8.17b, as the approach increases, the cost of operating the cooling tower fans drops, but the cost of pumping increases. The optimum approach is the one that will result in a minimum total cost operation. In Figure 8.17b, this ΔT is the set point of TDIC-1. This optimum approach A_o will increase if the load on the cooling tower increases or if the ambient wet-bulb temperature decreases.

If the cooling tower fans are centrifugal units or if the blade pitch is variable, the optimum approach can be obtained by continuous throttling. If the tower fans are two-speed or single-speed units, the output of TDIC-1 will incrementally start and stop the fan units in order to maintain the optimum approach, as was described in Figure 8.16i.

Return Temperature Optimization

Figure 8.17b also shows the controls needed for optimizing the return water temperature. TDIC-2 is the range controller, which is set by the optimized set point of SP-2. This is the range value corresponding to the optimum approach (R_o). TDIC-2 throttles the water circulation rate in order to maintain the range at its optimum value. The output of TDIC-2 sets the speed of the cooling tower water circulating pump, if none of the process user valves are nearly full open. This is guaranteed by PDIC-3.

The outputs of both TDIC-2 and PDIC-3 are sent to a high-signal selector, which guarantees that when one of the user valves is nearly full open and therefore nearly out of control, the needs of the users take priority over range control. The load is detected by PDIC-3, and if its output is higher than that of the range controller (TDIC-2), it will be selected to set the pump speed. This load-following optimization loop guarantees that all cooling water users in the plant will always be satisfied while the range is being optimized.

This is done by selecting (with TY-4) the set point of PDIC-3 so that if the most-open cooling water valve opening is less than 90%, the PDIC-3 set point is decreased; however, if the valve opening exceeds 90%, the PDIC-3 set point is increased.

In this way, a condition is maintained that allows all users to obtain more cooling (by further opening their supply valves) if needed, while the differential pressure of the water is continuously optimized. The VPC-4 set point of 90% is adjustable. Lowering it gives a wider safety margin, which might be required if some of the cooling processes served are very critical. Increasing the set point maximizes energy conservation at the expense of the safety margin.

Benefits of Optimization

An additional benefit of this load-following optimization strategy is that because all cooling water valves in the plant are opened up as the water ΔP across the users is minimized, valve cycling is reduced and pumping costs are lowered. The reduction in pumping costs is a direct result of the opening of all cooling water valves, which reduces the pressure drop across them. A side benefit of opening the valves is that valve cycling is eliminated when the valve openings are moved away from the unstable region near the closed position.[1]

In order for the control system in Figure 8.18b to be stable, it is necessary to use an integral-only controller for VPC-4, with an integral time that is tenfold that of the integral setting of PDIC-3. This control mode selection is needed to allow the optimization loop to be stable when the valve opening measurement signal that is selected by TY-4 is either cycling or noisy.

A high limit setting on the output of VPC-4 (not shown in Figure 8.17b) is also recommended to make sure that it will not drive the cooling water pressure to unsafe or undesirably high values. Because this limit can block the VPC-4 output from affecting the pump speed, it is necessary to protect against reset windup in VPC-4. This is done through the external feedback signal (FB), which protects the controllers TDIC-2, PDIC-3, and VPC-4 from reset windup.

A side benefit of the optimization system shown in Figure 8.17b is that it brings attention to design errors. For example, if PDIC-3 is in control most of the time, that shows that the control valves and water pipes are undersized in the plant. Similarly, if TY-4 consistently selects the same user valve, it shows that the water supply to that user is undersized. When such design errors are corrected, either by adding local booster pumps or by replacing undersized valves and pipes, control will automatically return to TDIC-2.

Therefore, in a well-designed water distribution network, the range optimizer TDIC-2 will be in control most of the time and PDIC-3 will override it only during process upsets that cause excessive cooling loads. Thus, PDIC-3 should operate as a safety override that becomes active only under emergency conditions and guarantees that no user will ever run out of cooling water.

Starting Additional Pumps

When the cooling tower water pump station consists of several pumps, only one of which is variable-speed, additional pump increments are started when PSH-5 signals that the pump speed controller (SC-2) set point is at its maximum. When the load is dropping, the excess pump increments can be stopped on the basis of flow, detected by FSL-6. In order to eliminate pump cycling, the excess pumping increment is only turned off when the actual total flow corresponds to less than 90% of the capacity of the remaining pumps.

The load-following optimization system described in Figure 8.17b will float the total flow rate from the cooling tower to achieve maximum overall economy.

Return Water Distribution and Balancing

In cases where a large number of cooling tower cells are available to receive the returning cooling water, it is also desirable to automatically distribute the water flows to the various cells as a function of the operation of their associated fans. In other words, the water flows to all cells whose fans are at high speed should be equal and high. Similarly, the water flows to cells whose fans are operating at low speeds should receive water at equal low flow rates. Cells with their fans off should receive water at equal minimum flow rates.

The normal water flow rate ranges from 2 gpm to 5 gpm per ton when the fan is at full speed. Figure 8.17d illustrates the relationship between water flow and water temperature (T_{ctws}) or approach. Under the illustrated conditions, a 20% increase in water flow rate will increase the approach from 7 to 9°F, while a 20% decrease in flow will reduce it from 7 to 5°F.

Water distribution balancing is often done manually, but it can also be done automatically, as shown in Figure 8.17e. Here, the total flow is used as the set point of the ratio flow controllers (FFICs). If the ratio settings are the same, the total

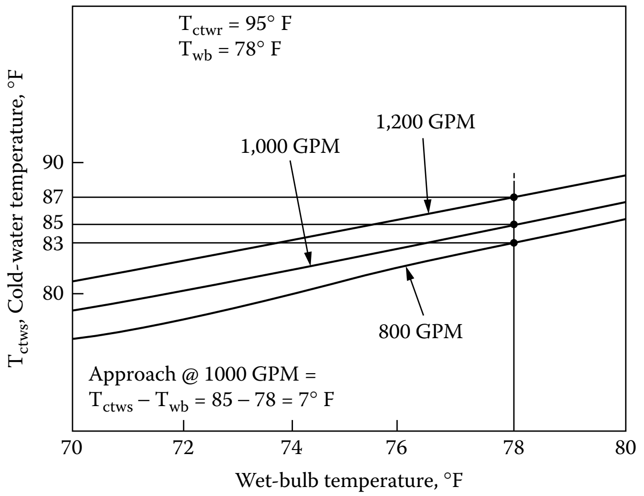

FIG. 8.17d

This figure shows the characteristic curves of a particular cooling tower that, when receiving a return water flow rate of 1000 gpm/cell at a temperature of 95°F and air at a wet-bulb temperature of 78°F, will generate a supply water temperature of 85°F (approach of 7°F and range of 10°F). In this case, if the demand for cold water rises to 1200 gpm/cell, the cold water temperature generated by the tower will rise by 2°F, while if the flow drops to 800 gpm/cell, it drops by 2°F. (From Reference 2.)

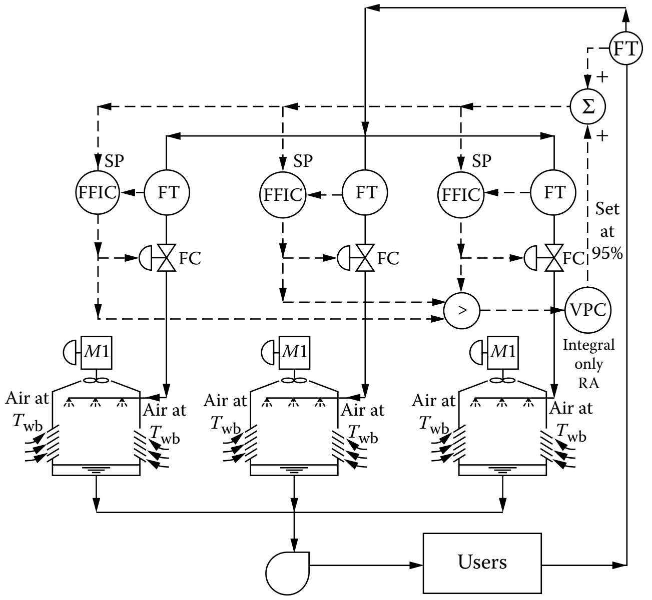

FIG. 8.17e

The distribution of the return water among several cooling tower cells can satisfy the dual goals of sending a preset percentage to each and to do that at a minimum pumping cost. The second goal is served by the valve position controller (VPC), which increases the measurement of all flow ratio controllers (FFICs) until the most open valve opens to 90%.

flow is equally distributed. The ratio settings can be changed manually or automatically to reflect changes in fan speeds. Naturally, the total of the ratio settings must always be 1. Therefore, if one ratio setting is changed, all others should also be modified. This, too, can be done automatically.

The purpose of the control system in Figure 8.17e is not only to distribute the returning water between the cells correctly but also to make sure that this is done at minimum cost. The cost in this case is the energy cost of pumping, which will be minimum when the pressure drop through the distribution control valves is minimum.

The valve position controller (VPC) in Figure 8.17e serves to keep this pressure drop to a minimum. It does that because as long as even the most open valve is not nearly fully open, the VPC adds a positive bias to all the set point signals of all the flow ratio controllers (FFICs). As a result, all valves will open and keep opening until the most open valve reaches the desired 90 or 95% opening. This technique provides correct flow distribution, while keeping the cost of pumping at a minimum.

When cells are manually balanced, it is not unusual to find all balancing valves throttled. It is also often the case that the same water flow is being sent to the tower cells, no matter if their fan is on or off. Both of these conditions will increase operating costs. The savings from automatic balancing can more than justify the control instruments required.

CONCLUSIONS

Cooling towers are simple devices, and possibly for that reason, their optimization is often neglected. Yet, the motors of the cooling tower fans and pumps in a plant can add up to many hundreds of horsepower. The operation of these motors can cost several hundred thousand dollars each year. That operating cost can be cut in half by optimization. Optimization is achieved by meeting the variable cooling load of the plant by the minimum water and air flows that are needed. Optimization also can include the cost-effective balancing of the distribution of the returning water among the tower cells.

A desirable side effect of optimization is the automatic indication of design defects in pipe and valve sizing and the increased level of safety, by making sure that no process cooling load is ever neglected.

INTRODUCTION

This section describes the control of industrial crystallizers. Crystallization requires supersaturation, which can be achieved by cooling, evaporation, vacuum cooling, dilution, and chemical reaction. The control of multiple-effect crystallizers is also covered.

Crystallization is a widely used technique in the process industry and is used for the purpose of purification and separation of substances, as well as for the production of good-quality crystals. It is a practical method to obtain concentrated chemical substances in particulate solid form that have desirable properties such as good flow characteristics, handling convenience, suitability for packaging, and pleasant appearance.

Crystallization can be carried out from solution, vapor, or melt. Here, only solution crystallization is discussed. The most commonly used methods for creating supersaturation in the solution phase include cooling, evaporation, vacuum cooling, dilution, or chemical reaction. The choice of the method depends on the solubility of the solute, feed solution composition, product specifications, and other engineering considerations.

Most crystallizers in industrial use operate on a continuous basis, but batch and semibatch crystallizers are also widely used to produce fine chemicals and special-effect high-added-value materials such as pharmaceuticals, pigment, agrochemicals, or catalysts.

This section is devoted to the subject of controlling basic continuous crystallizers. It will describe the basic crystallization techniques, while focusing on the measurement and control practices used in this industry.

THE CRYSTALLIZATION PROCESS

The fundamental driving force for crystallization is the difference in chemical potential between the crystallization substance in the solid and liquid phases, but the common engineering practice is to use supersaturation as the driving force of concentration. The crystallization process has three basic steps: (1) generation of supersaturation, (2) formation of nuclei, and (3) growth of nuclei into crystals.

Supersaturation is usually expressed as the supersaturation ratio

$$S = \frac{c}{c'} \qquad \textbf{8.18(1)}$$

or the concentration difference

$$\Delta c = c - c' \qquad \textbf{8.18(2)}$$

where

c = concentration of the crystallizing substance in the solution
c' = equilibrium concentration (solubility) of the crystallizing substance in the solution

In most cases, the solubility c' of a solute increases with the increase of temperature, but there are a few exceptions to this rule. The concept of supersolubility and the existence of the metastable zone are useful in understanding the behavior of the crystallization process. Figure 8.18a shows a temperature-solubility plot for a typical salt; the plot is divided into three zones: (1) stable under saturated zone, where crystallization is not possible; (2) metastable (supersaturated) zone between the solubility and supersolubility, where spontaneous crystallization is not possible; and (3) labile (supersaturated) zone, where spontaneous crystallization is probable.

The rate of nucleation and the crystal growth rate are controlled by supersaturation. The ideal process would be a stepwise procedure, but nucleation (i.e., formation of new crystals), because of the secondary nucleation, cannot be eliminated in a growing mass of crystals. The influence of supersaturation on nucleation and growth rates is shown in Figure 8.18b. Whereas the dependence of growth rate on supersaturation is linear or moderately nonlinear, the nucleation rate increases exponentially with supersaturation.

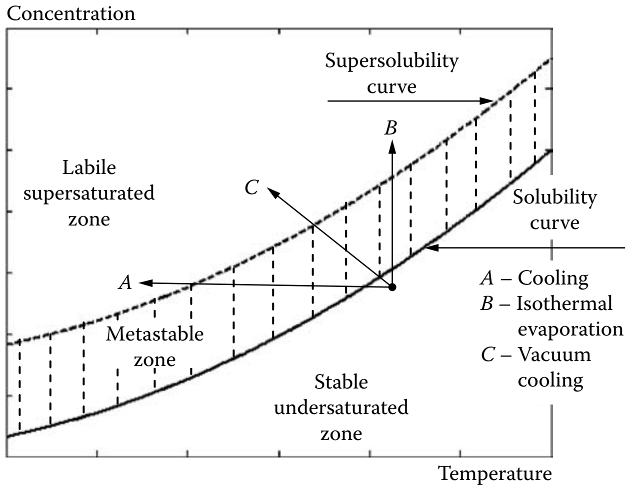

FIG. 8.18a
The zones of saturation and solubility plots and the methods by which the state of supersaturation can be achieved.

Figure 8.18b shows three regions of supersaturation, corresponding, in principle, to the zones in Figure 8.18a: (1) metastable, where nucleation is very low and growth predominates; (2) intermediate, where nucleation becomes larger, but growth is still significant; and (3) labile, where nucleation predominates.

Crystal Size Distribution

Industrial crystallizers usually yield a crystalline product that has a wide crystal size distribution (CSD). This CSD affects the behavior of the product in succeeding operations such as filtration, drying, transport, and storage, and is also defined by customer specifications. Because very small crystals are difficult to filtrate, dry, or handle, crystallizer design and control usually are directed toward reasonably large crystals by minimizing nucleation.

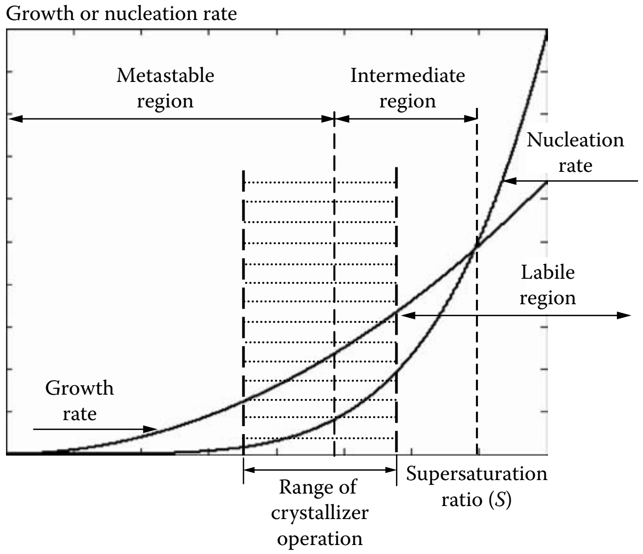

FIG. 8.18b
The influence of level of supersaturation on nucleation and the crystal growth.

Usual industrial practice involves sufficiently low supersaturation to minimize supersaturation while being adequate for reasonable growth. At the same time, among others in the pharmaceutical industry, there is also an increasing need to produce high specific-surface micro particles. Therefore, because the desirable properties of the crystalline product may change within wide limits, the main purpose is to control the crystal size distribution.

The CSD, determined by the rates of nucleation and growth, is influenced by the supersaturation, thus control of supersaturation becomes the basic element of crystallizer system control. Unfortunately, the workable degree of supersaturation is usually 0.5–1% so that it is so small that it is hard to measure directly. Besides, the on-line measurement of CSD, although it is also possible by laser diffraction, is restricted to slurries that contain solids at low concentration. As a consequence, the vast majority of crystallizers use indirect means of control.

An important exception to this rule is sugar, in the case of which the level of supersaturation can be greater than usual in industrial crystallizers, and correlations can be used to measure supersaturation directly. Estimations of sugar supersolubilities are based on these empirical correlations.

Degrees of Freedom

To define the maximum number of controllers, we consider the degrees of freedom for a crystallization system. The variables are

1. Temperature and flow of the process fluid
2. Temperature and flow of the cooling or heating medium
3. Level of supersaturation
4. Ratio of mother liquor to crystals, which can be changed by varying recycles of mother liquor to feed stream
5. Removal and dissolution rate of fine crystals

The first principles-based governing equations are

1. Energy balance equation
2. Mass balance equation for the crystallizing substance
3. Balance equation for fines

Because the system has seven variables and three equations, it has four degrees of freedom. Thus, the maximum number of automatic controllers permissible in a crystallizer system, without overdefining it, is four. The exceptions are the dilution and reaction crystallizers, where the flow of the diluent and ratio of reactants form additional degrees of freedom.

The amount of fines can be estimated by using density measurement. In crystallization operations, the density sensor (differential pressure or any other type), which gives an indication of the amount of crystals in the crystal slurry, appears to be an important instrument. This measurement is based on the fact that the density of the clear liquor is constant. Hence, the measurement of the differential pressure between two points in the vessel is a measure of the amount of crystals in the suspension, because any change in density is caused by a change in the amount of crystals in the crystal slurry.

EVAPORATIVE CRYSTALLIZERS

This type of crystallizer produces supersaturation and, hence, crystals, by loss of solvents induced by one of the three methods: (1) indirect heating, (2) submerged combustion, and (3) spray evaporation. The first two are the dominant types and will be discussed here.

Indirectly Heated Crystallizers

Circulating-magma crystallizers with indirect heating are by far the most important type of crystallizers in use today: The forced-circulation (FC) and the draft-tube baffle (DTB) designs belong to this class.

A typical FC crystallizer is shown in Figure 8.18c. In this design the feed is introduced into the recirculation loop. The critical design parameters in FC crystallizers are the internal recirculation rate and velocity, the crystallizer hold volume, and the speed of the circulating pump. At internal circulation less than the optimum, excessive flashing can occur at the boiling surface, causing a high level of supersaturation. If this supersaturation cannot be reduced by deposition of the solute because of the lack of adequate crystal surface area in the suspension, intensive nucleation will occur, producing a large amount of fines and causing build-up of solids on the walls of the crystallizer.

In general, recirculation rates aim at restricting the flashing at the crystallizer walls or at other boiling surfaces to approximately 1.7–4.5°C (3–8°F) whereas a magma-density range of 15–25% is typical, even though the exact optimum depends on the particular crystal system.

Various designs of crystallizers are available, but the approaches of controlling the processes are similar. A possible control system is shown in Figure 8.18c where four control loops are involved:

1. Feed clear liquor is fed on level control to a feed tank. Here it is mixed with the mother liquor from the centrifuge of the crystalline product.
2. The mixed liquor is fed to the suction side of the crystallizer recirculating pump. This feed is adjusted by a level controller. (For methods of protecting the level sensor from plugging and material build-up, refer to Chapter 3 of the first volume of this handbook.)
3. The steam flow to the heat exchanger is on flow control. Once the steam rate is fixed, the production rate is also fixed, provided that the feed composition does not change.
4. Temperature control in the vessel may be achieved by controlling the evaporator chamber pressure by an air bleed.

Refinements to this basic system are possible, as an interlock between the steam and circulating pump, or the addition of a density recorder. The magma density can also be used for control, rather than just for monitoring. In the control configuration shown in Figure 8.18d, the density controller

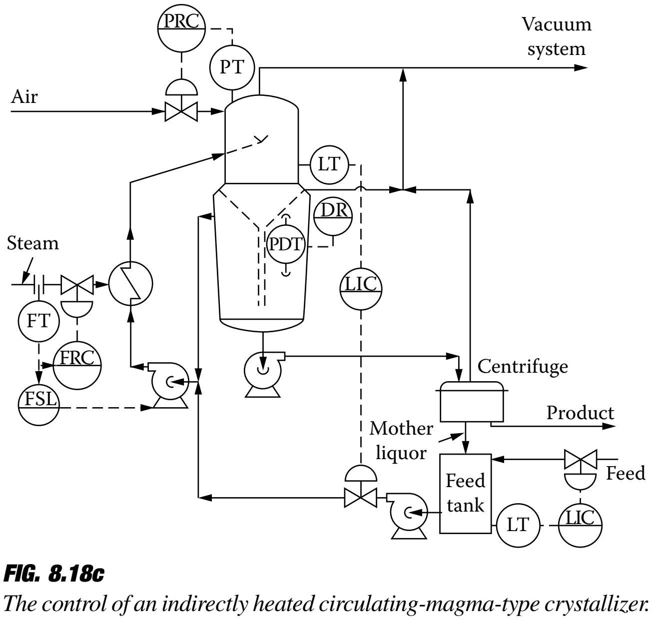

FIG. 8.18c

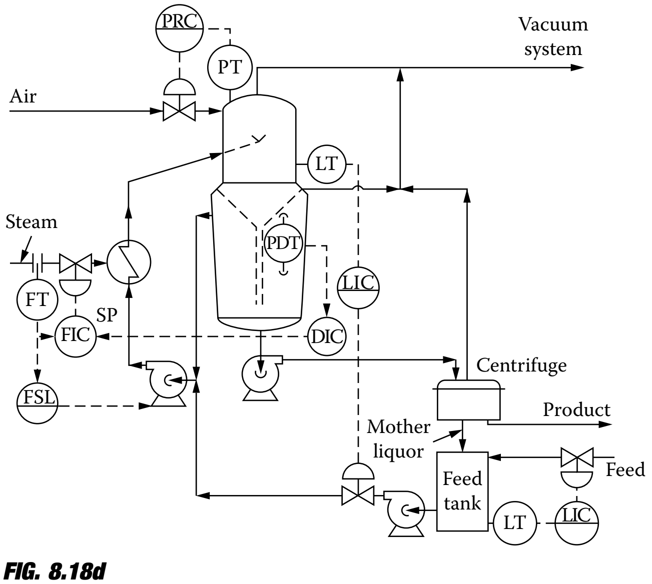

FIG. 8.18d
Cascade control of crystal concentration (measured by density) by throttling heat input.

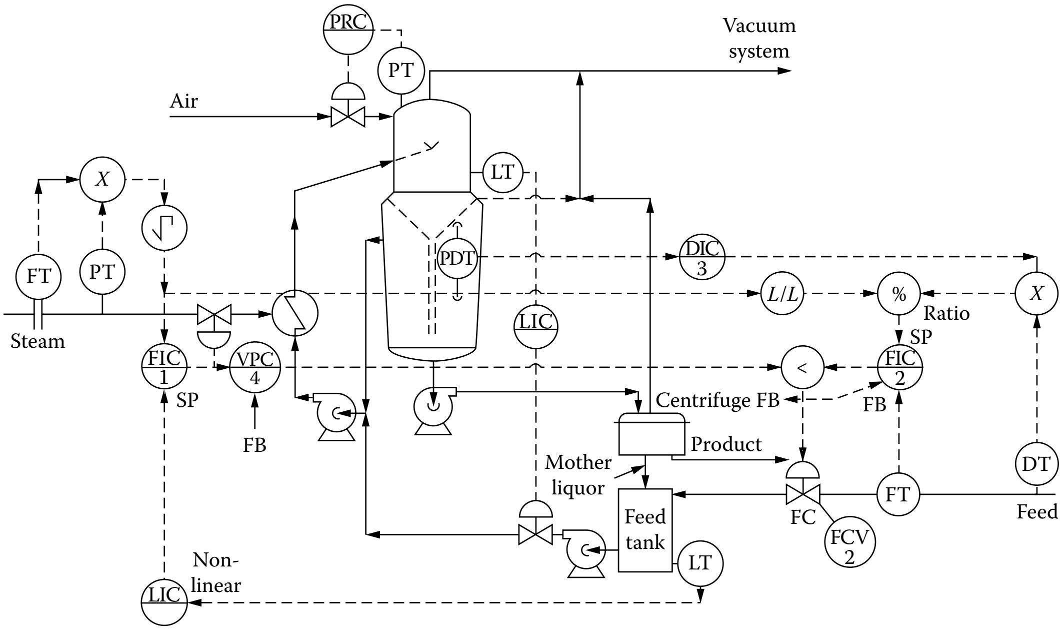

FIG. 8.18e
In this control system, feedforward, dynamic compensation and selective control of the feed are added to the basic controls of a circulating-magma crystallizer.

serves as the cascade master of the steam flow controller, and it varies the heat input in order to keep the crystal concentration constant.

Advanced Controls

Figure 8.18e illustrates how a number of additional features and flexibilities can be incorporated into the controls of a circulating-magma crystallizer. In this configuration the steam flow is measured and controlled on a mass basis (FIC-1) so that it might be directly related to the feed flow (FIC-2). The density of the feed stream is used to estimate the concentration of the solute. It can also be used to signal the need to increase the steam-to-feed ratio in a feedforward whenever the solvent content of the feed stream rises, i.e., when it becomes more dilute. The steam-to-feed ratio is trimmed by the feedback controller DIC-3 so as to guarantee consistent product concentration in the crystallizer.

In Figure 8.18e, in order to take full advantage of the surge capacity of the feed tank, its level is not held constant but is allowed to float up and down. This level variation slowly adjusts the steam flow rate (FIC-1), which in turn changes the feed flow set point, and thereby keeps the feed tank level within limits.

The lead-lag relay (L/L) provides dynamic compensation for the time constants of the process. The valve position controller (VPC-4) serves to guarantee that the crystallizer will not be starved for steam. Therefore, whenever the steam valve opening approaches 100%, the low-signal selector on the feed valve (FCV-2) blocks the control signal from FIC-2 and allows VPC-4 to reduce the feed flow as required to match the availability of the steam. Because VPC-4 and FIC-2 control the FCV-2 valve in a selective manner, they are both provided with external feedback (FB) to make sure that their integrals will not wind up when the other controller is manipulating the valve.

Draft-Tube Baffle Crystallizer

The draft-tube baffle produces larger crystals than the FC crystallizers under equivalent conditions. It consists of a closed vessel with an inner baffle forming a partitioned settling area, inside which a tapered vertical-draft tube surrounds the agitator, which enters from the top or the bottom. The agitator is of the axial-flow type and operates at low speeds. If additional classification of the crystals is desired, an elutriating leg can be fitted to the bottom cone. The draft tube is centered by support vanes to prevent body swirl and to minimize turbulence in the circulating magma. Supersaturation may be generated by either evaporation, cooling, or vacuum cooling.

The baffle controls the crystal size by permitting the separation of unwanted fine crystals. Figure 8.18f shows the control of the crystal size distribution in a draft-tube baffle-type crystallizer using fines removal and their dissolution.

Multiple-Effect Operation

Evaporative crystallizers are often used as multiple-effect systems, because such configurations improve the product size distribution because of the narrow residence time distributions. Different strategies can be employed to improve the product CSD. A successful strategy is, for instance, to permit nucleation in the first stage and only growth in the subsequent

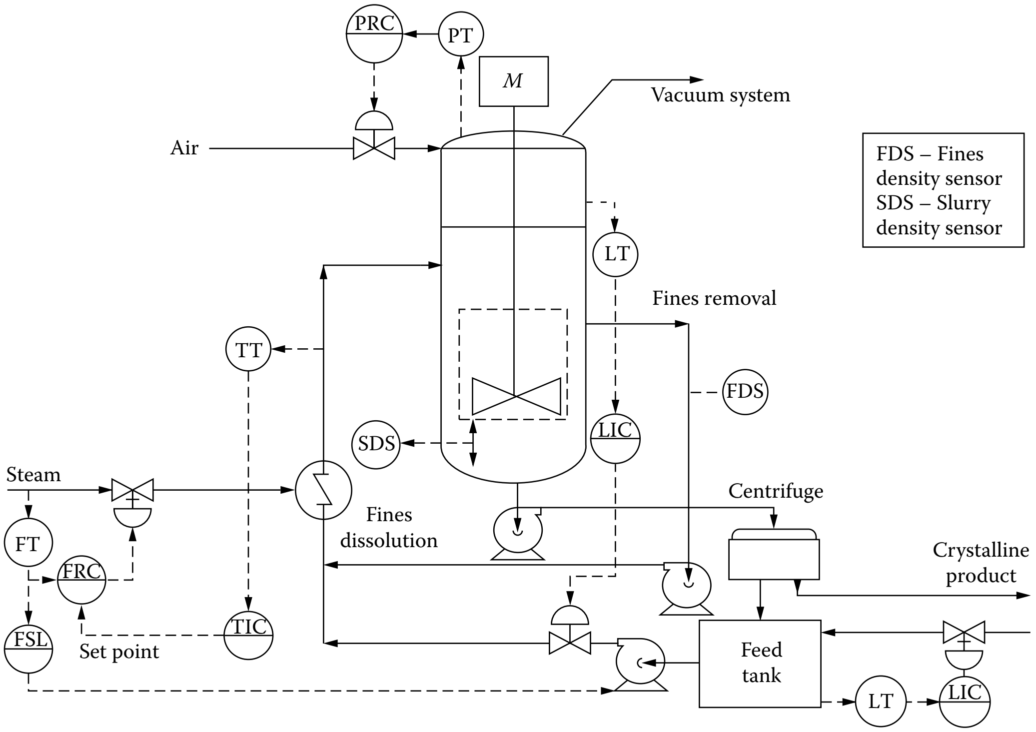

FIG. 8.18f
The crystal size in a draft-tube-type baffle crystallizer can be controlled by removing and redissolving the fines.

stages. A simplified control scheme on a triple-effect unit is shown in Figure 8.18g.

This complex system has three important features:

1. Level in each unit is an important process variable, because it determines the residence time. Level is usually controlled by throttling the makeup of the mixed liquor.
2. Steam flow to the first unit is usually on flow control.
3. Feed enters the feed tank on level control, where it is mixed with the mother liquor from the centrifuge of the crystalline product. Temperature control in the last unit is obtained by pressure control of the air bleed.

In these control systems, density recorders can also be used. If boiling point elevation is sufficiently large, the detected density can also be used to directly control the effluent liquor concentration, as was the case in Figure 8.18e.

Submerged-Combustion Crystallizers

Submerged-combustion crystallizers are used on corrosive applications or in cases where the salts have inverted solubility. One possible control configuration is shown in Figure 8.18h. Here, the clear liquor is fed under flow control, while the burner fuel gas can be under either flow or pressure control, in which case a bypass controls the flow of combustion air to the burner.

In developing the overall control system, both auxiliaries and safety interlocks must be included and designed to meet the requirements of the Fire Insurance Association (FIA).

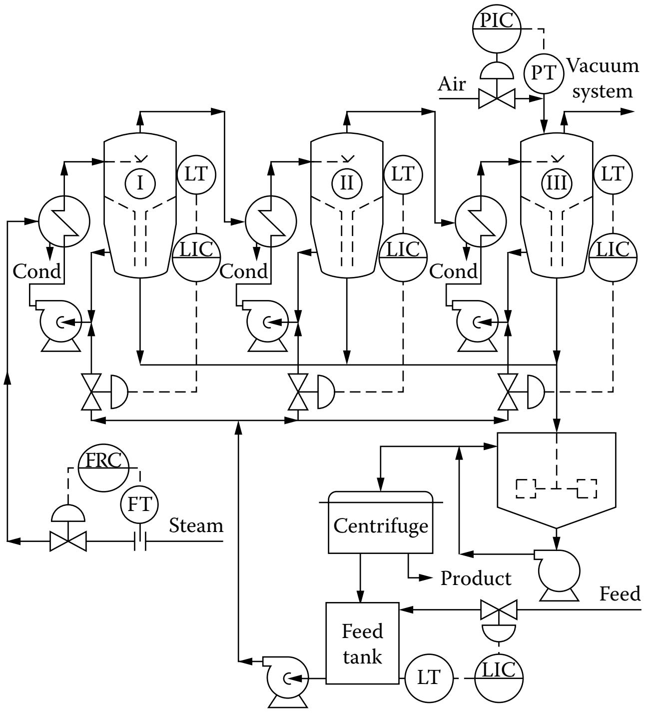

FIG. 8.18g
The basic controls of a three-effect crystallizer.

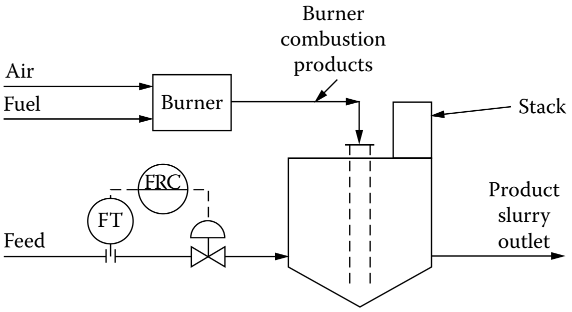

FIG. 8.18h
Submerged combustion-type evaporator crystallizer.

COOLING CRYSTALLIZERS

In principle, cooling crystallizers operate at atmospheric pressure, and their heat is transferred to a cooling medium or to air by either indirect or direct contact.

There are many types of cooling crystallizers, but the majority falls into three categories: (1) controlled-growth magma crystallizers, (2) classifying crystallizers, and (3) direct-contact crystallizers.

Controlled-Growth Magma Crystallizers

A variety of cradle crystallizers and scraped-surface units belong to this category. The cradle types are used in small applications and involve little instrumental control. The various scraped-surface crystallizers are used in crystallization from high-viscosity liquors or in open-tank crystallizers, as coolers to induce nucleation. Two designs of controlled-growth magma crystallizers and their controls are shown in Figures 8.18i and 8.18j. In Figure 8.18i an evaporating refrigerant cools the shell of the unit, while the crystallization process takes place in the tubes. Usually several scraped-surface tubes are used in series.

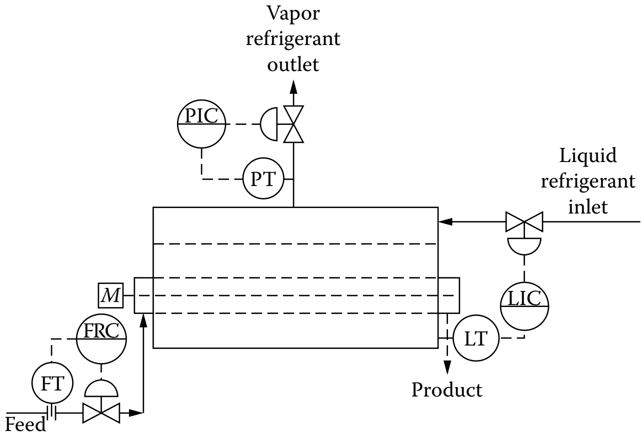

FIG. 8.18i
The basic controls of a refrigerant-cooled crystallizer.

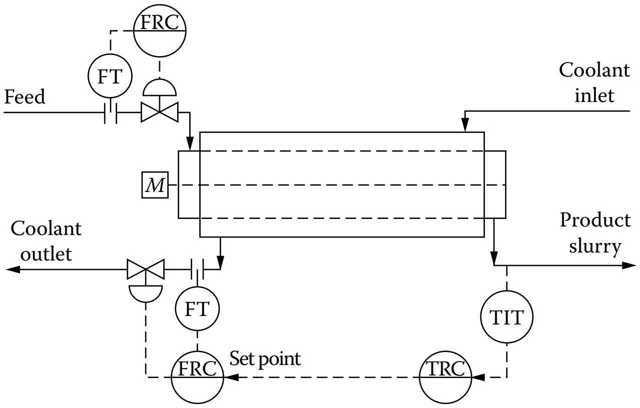

FIG. 8.18j
The controls of a cooling crystallizer that is cooled by a liquid coolant.

The control system operation is as follows:

1. Clear liquor is fed under flow control. Because the residence time in the tubes is large and because it is required in order to obtain the required crystal size, product quality-based feedback control from the product outlet is not practical. Yet, in some applications, feedback control with dead-time compensation has been applied.
2. In Figure 8.18i, liquid refrigerant enters under level control and leaves the system as a vapor under pressure control. In other applications, the refrigerant liquid is introduced under flow control provided by a metering pump. Both two- and three-mode controllers have been used to provide pressure control.

In other cooling crystallizer applications, liquid coolant is used as the heat transfer fluid. Figure 8.18j illustrates the control system of such a unit, where the cooling fluid flow is controlled in cascade by the outlet temperature of the product slurry.

Classifying Crystallizers

In the Oslo “Krystal” cooling crystallizer the supersaturation is generated entirely by cooling. In this design the feed is introduced into a circulating loop, which is also being cooled. The control configuration for a cooling-type classifying crystallizer is shown in Figure 8.18k.

The functions of the control loops are as follows:

1. Flow control of feed liquor is provided to maintain constant throughput.
2. Flow of coolant is controlled in cascade to maintain the outlet temperature of the process fluid at the outlet of the heat exchanger. One refinement is to interlock the coolant flow with the circulation pump motor.

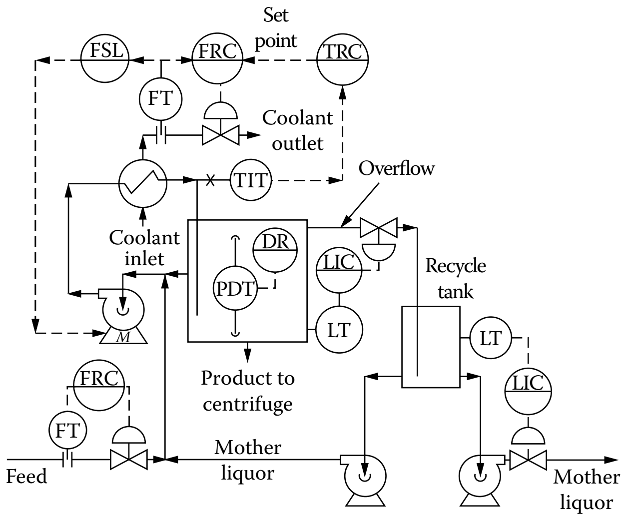

FIG. 8.18k
The controls of a classifying crystallizer with external circulation for cooling.

3. Overflow from the crystallizer is on level control. Differential pressure-type level measurement is acceptable for this application.
4. Mother liquor outflow from the recycle vessel is on level control.

Figure 8.18l illustrates a design that improves the crystal size distribution of the product by providing external classification in a cooling crystallizer. Here, the cooling occurs through a jacket under cascade control. The undersize fraction of crystals leaving the hydrocyclone with the mother liquor is returned to the crystallizer. Such operational configuration is very effective to control the size of the crystals, but it also has a tendency to cause steady-state oscillation. To minimize such oscillations requires more sophisticated control systems.

Direct-Contact Crystallizers

In such units, the coolant is an evaporating refrigerant or brine, and it is in direct contact with the process slurry. Basic control methods are similar to those in controlled-growth crystallizers (Figure 8.18i). These involve constant feed rate and flow controls of the evaporating refrigerant, based on process fluid outlet temperature or on tank level.

VACUUM CRYSTALLIZERS

In vacuum crystallizers, heat input to produce adiabatic evaporation comes entirely from the sensible heat of the feed liquor and from the heat of crystallization of the crystalline product. Thus, supersaturation is generated by a combination of cooling and concentrating the liquor. The forced-circulation and draft-tube baffle crystallizer designs are both used in this operation mode.

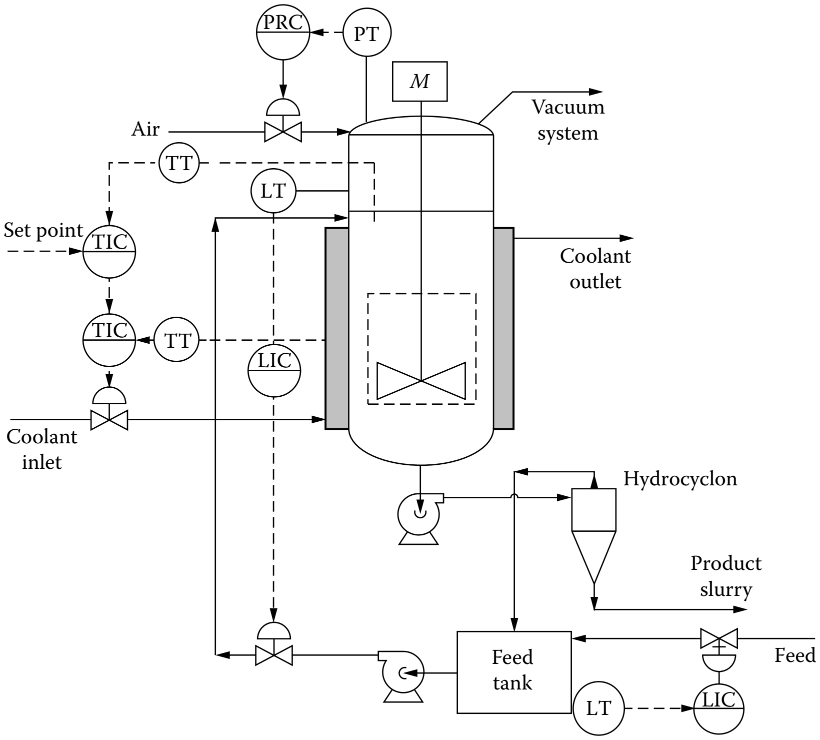

FIG. 8.18l
The controls of a jacketed cooling crystallizer with classified product removal.

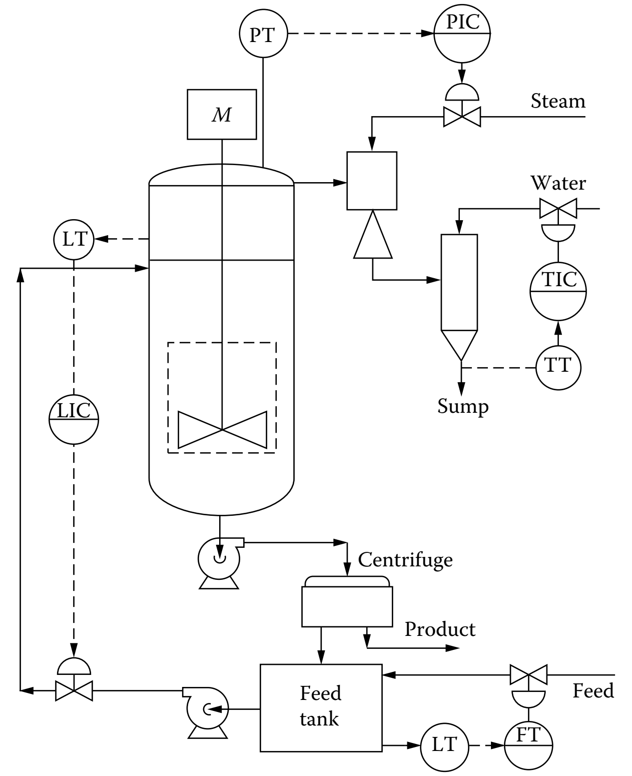

FIG. 8.18m
Draft-tube-type baffle crystallizer, provided with vacuum control and mother liquor recirculation.

The control strategy for a draft-tube baffle crystallizer with vacuum cooling is shown in Figure 8.18m. Here, the vacuum is on control with steam jet ejector. Air bleed is on pressure control, and both the steam and water supplies are on automatic control, which allows achieving the minimum cost of utilities.

Another control configuration is shown in Figure 8.18n. Here, the vacuum in the crystallizer is maintained by throttling the coolant outlet. This vacuum indirectly controls the process temperature.

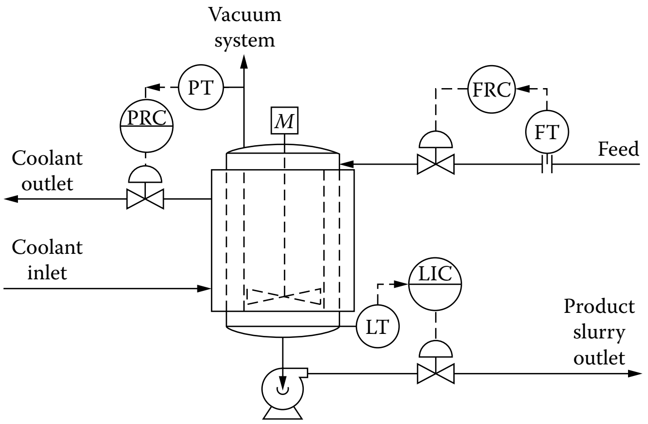

FIG. 8.18n
Draft-tube baffle crystallizer with combination of cooling and vacuum control.

The control system consists of (1) feed flow control, (2) product removal control based on level measurement, and (3) temperature control accomplished indirectly by manipulation of jacket coolant. Use of suspension density recorder and other refinements can also be used.

REACTION CRYSTALLIZERS

In reaction crystallizers, crystallization is associated with a chemical reaction that usually produces the solute directly. Chemical reactions between two components, however, may also produce some diluents, in turn causing “salting-out.” In a reaction crystallizer, once the reaction mixture is saturated with respect to the crystallizing substance, the reaction rate would determine the rate of supersaturation. In some cases, the heat of exothermic reaction may be used in evaporating the solvent, thereby producing additional supersaturation during the course crystallization.

A control configuration for a reaction crystallizer is shown in Figure 8.18o, where one of the reactants is fed into the crystallizer in the gaseous phase while the second reactant is fed in the form of aqueous solution. Here, the aqueous solution feed is on flow control, the total liquid feed is on level control, while the gaseous reactant is added on pH-cascaded control. The pH metering lines should be continuously flushed when this system is used.

In the case when both reactants A and B are liquids, they can be charged into the crystallizer under ratio control to maintain either the stoichiometric or any other predetermined ratio of these reactants. As shown in Figure 8.18p, the total

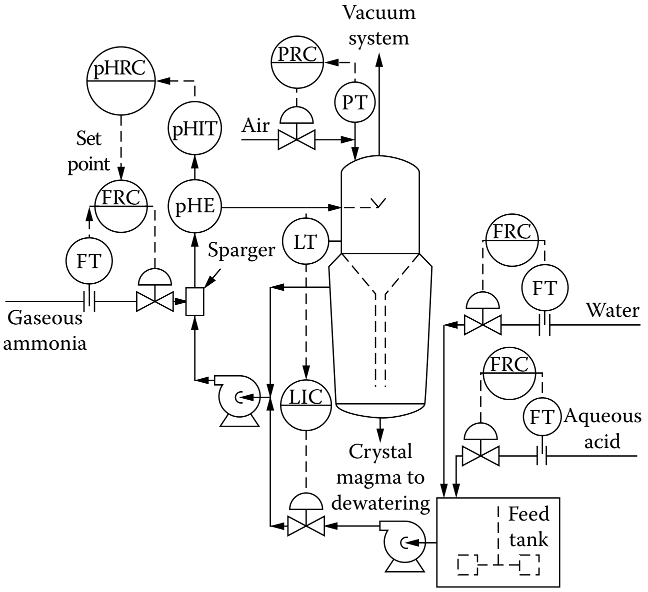

FIG. 8.18o
The controls of a reaction crystallizer that is utilizing both gaseous and liquid reactants.

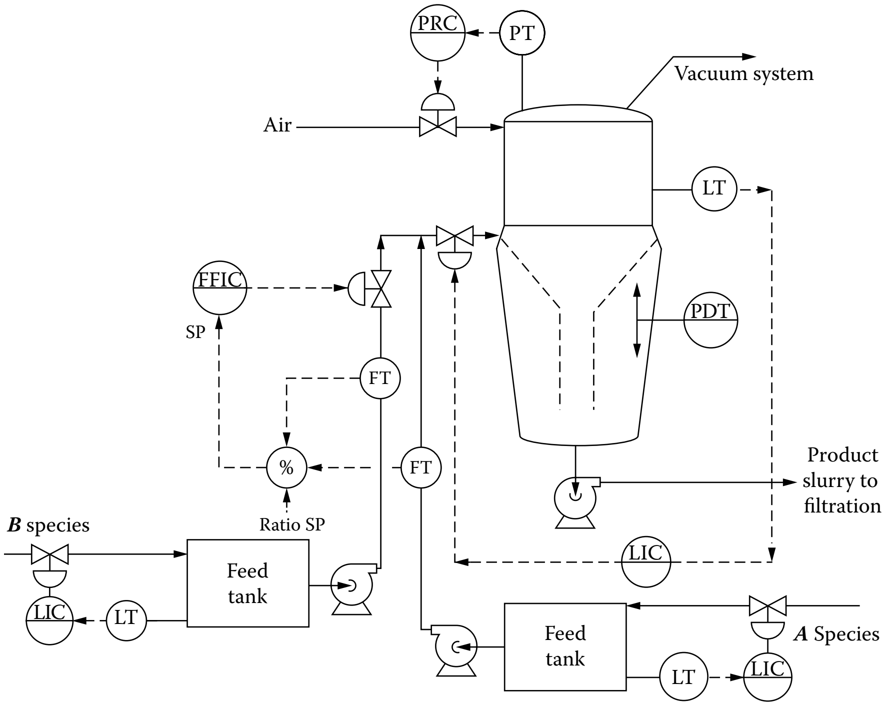

FIG. 8.18p
Reaction crystallizer controls provide ratio control of the reactants A and B.

flow into the reactor crystallizer can be on level control and the temperature can be controlled by bleeding in air to adjust the pressure.

AUXILIARY EQUIPMENT

The control requirements of crystallizers are also a function of the equipment associated with them. There are four subsystems whose control should be considered in particular:

1. The feed system, including the feed liquor, recycle, and wash streams.
2. Vacuum control to maintain predetermined pressure in the system as a common means of crystallizer temperature control.
3. Dewatering system control. This includes filters or centrifuges.
4. In the case of external classification equipment, in order to improve the crystal size distribution of the product, hydrocyclones, vibrating screens, and other external classification devices can be used.

CONCLUSIONS

In this section some of the common methods of crystallizer control have been outlined. In the crystallization process, because of the phase changes and because of the dispersed nature of the crystalline product, strong interactions exist between the process variables. Because of the complex, multiple-input/multiple-output nature of this process, the control system development should be based on a step-by-step analysis.

Pilot plant studies are often recommended, because small variations in the feed liquor compositions can have tremendous influence upon nucleation and crystal growth. Also, minor differences in operating conditions can produce crystals showing significantly different properties. The developer of a control system should take these factors into consideration.

INTRODUCTION

Distillation is the most common class of separation processes and one of the better understood unit operations. It is an energy-separating-agent equilibrium process that uses the difference in relative volatility, or differences in boiling points, of the components to be separated. It is the most widely used method of separation in the process industries. The distillation process will most often be the choice of separation unless the following conditions exist:

- Thermal damage can occur to the product.
- A separation factor is too close to unity.
- Extreme conditions of temperature or pressure are needed.
- Economic value of products is low relative to energy costs.

Control involves the manipulation of the material and energy balances in the distillation equipment to affect product composition and purity. Difficulties arise because of the multitude of potential variable interactions and disturbances that can exist in single-column fractionators and in the process that the column is a part of.

Even seemingly identical columns will exhibit great diversity of operation in the field. Therefore, this section will not attempt to provide control strategies that can be applied to columns in a "cookbook" fashion. Instead, discussion will begin with a basic description of the distillation process and equipment, followed by techniques used to derive a mathematical column model.

The presentation in this section will then describe methods to evaluate interactions and alternative control strategies; control models used for some product quality, pressure, and feed flow control strategies; and finally some common feedforward advanced regulatory control strategies commonly used in the regulation of fractionators.

The goal of this section is to provide the process control engineer with the tools necessary to design unique control strategies that will match the specific requirements of distillation columns.

General Considerations

Distillation separates a mixture by taking advantage of the difference in the composition of a liquid and that of the vapor formed from that liquid. In the processing industries, distillation is widely used to isolate and purify volatile materials. Thus, good process control of the distillation process is vital to maximize the production of satisfactory purity end products.

Although engineers often speak of controlling a distillation tower, many of the instruments actually are used to control the auxiliary equipment associated with the tower. For this reason, the equipment used in distillation will be discussed.

DISTILLATION EQUIPMENT

There are some basic variations to the distillation process. One such basic difference is between continuous and batch distillation. The main difference between these processes is that in continuous distillation the feed concentration is relatively constant, while in batch distillation it is rich in light components at the beginning and lean in light components at the end. While batch distillation is also described in this section, the emphasis is on the continuous processes.

Another basic difference is in the way the condenser heat is handled. The more common approach is to reject that heat into the cooling water and thereby waste it. This necessitates the use of "pay heat" at the reboiler, which usually is a large part of the total operating cost of the column. An alternate approach, also discussed in this section, is "vapor recompression" (Figure 8.19a), in which the heat taken out by the condenser is reused at the reboiler after a heat pump (compressor) elevates its temperature. While vapor recompression controls are also discussed in this section, the emphasis is on the traditional air- or water-cooled condenser designs.

The Column

The primary piece of distillation equipment is the main tower. Other terms for this piece of equipment are *column* and *fractionator*, and all three terms are used interchangeably. The tower, column, or fractionator has two purposes: First, it separates a feed into a vapor portion that ascends the column and a liquid portion that descends; second, it achieves intimate mixing between the two countercurrent flowing phases. The purpose of the mixing is to get an effective transfer of the more volatile components into the ascending vapor and corresponding transfer of the less volatile components into the descending liquid. The other equipment associated with the column is shown schematically in Figure 8.19b.

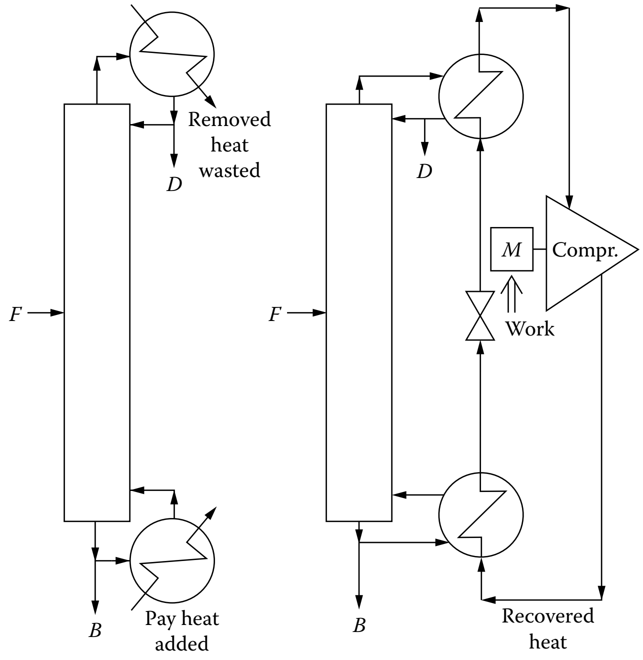

FIG. 8.19a
In contrast with conventional distillation, the vapor recompression system uses recovered heat.

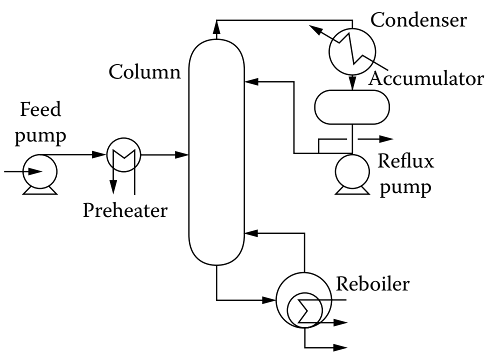

FIG. 8.19b
Distillation equipment.

In continuous distillation, the feed is introduced continuously into the side of the distillation column. If the feed is all liquid, the temperature at which it first starts to boil is called the *bubble point*. If the feed is all vapor, the temperature at which it first starts to condense is called the *dew point*. The feed entering the column is normally operated in a temperature range that is intermediate to the two extremes of dew point and bubble point. However, some optimization strategies may call for designs where the feed is either superheated or subcooled. For effective separation of the feed, it is important that both vapor and liquid phases exist throughout the column.

The separation of phases is accomplished by differences in vapor pressure, with the lighter vapor rising to the top of the column and the heavier liquid flowing to the bottom. The portion of the column above the feed is called the *rectifying* section and below the feed is called the *stripping* section.

Packing and Trays The intimate mixing is obtained by one or more of several methods. A simple method is to fill the column with lumps of an inert material, or *packing*, that will provide surface for the contacting of vapor and liquid. Another effective way is to use a number of horizontal plates, or *trays*, which cause the ascending vapor to be bubbled through the descending liquid (Figure 8.19c).

Tray designs are numerous and varied.[1] Tray designs include bubble cap plate unit, valve, sieve plate, tunnel, dual-flow, chimney, disc-and-donut, turbogrid trays, v-grid, Perform-Kontakt, Haselden baffle tray, Kittel trays, and other specialty-type units. Dualflo® trays, Flexitray®, Varioflex®, Bi-Frac®, Max-Frac®, NYE Trays®, Superfrac® trays, Super-Flux® trays, and Ultra-Frac® trays are specialty registered tray designs from different manufacturers that are variations of the aforementioned tray designs. Bubble caps

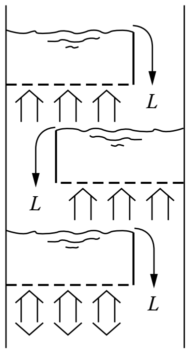

FIG. 8.19c
Intimate contact and therefore equilibrium is obtained as the vapor bubbles ascend through the liquid held up on each tray, as the liquid descends down the column.

and sieve trays are the most common designs used in distillation applications.

Many different types of packings are available.[2] They are normally classified as random or stacked. Random packings are those that are dumped into the containing shell. Raschig rings, Berl saddles, Intalox saddles, and Pall rings are the most common random packings and come in various sizes from $^1/_2$ to $3^1/_2$ in (1.25 to 9 cm).

Stacked packings, also known as grid or stacked packing, include large-sized Raschig rings and Lessing rings. Packings generally give lower pressure drops at the cost of higher installation costs. They are made of ceramic, plastic, or metal, depending upon the type of packing and the intended application. Other packings such as Maspac®, HyPak®, Tellerette®, IMTP® FLEXIPAC® KATAMAX®: FLEXIGRID®-2, -3, and -4, and KOCH-GLITSCH GRID® EF-25A are specialty registered packings from different manufacturers that are just variations of the aforementioned packings.

When deciding between the use of trays and packing, the following factors should be considered:[3]

- Because of liquid dispersion difficulties in packed towers, the design of plate towers is considerably more reliable and requires less safety factor when the ratio of liquid mass velocity to gas mass velocity is low.
- Towers using trays can be designed to handle wider ranges of liquid rates without flooding.
- Towers using trays are more accessible for cleaning.
- Towers using trays are preferred if interstage cooling or heating is needed because of lower installation costs of delivery piping.
- Towers using trays have a lower total dry weight, though total weight with liquid hold-up is probably equal.
- Towers using trays are preferred when large temperature changes are expected because of thermal expansion or when contraction may crush packing.
- Design information for towers using trays is generally more readily available and more reliable.
- Packed towers are cheaper and easier to construct than plate towers if highly corrosive fluid must be handled.
- Diameters of packed towers are generally designed to be less than 4 ft, while plate tower diameters are designed to be more than 2ft.
- Packed towers are preferred if the liquids have a large tendency to foam.
- The amount of liquid hold-up is considerably less in packed towers.
- The pressure drop through packed towers may be less than for plate towers performing the same service, making packed towers desirable for vacuum distillation.

Thus, generally, trays work better in applications requiring high flow, such as those encountered in high-pressure distillation columns, such as depropanizers, debutanizers, xylene purification columns, and the like. Packing works best at lower flow parameters, as the low-pressure drop of structured packing makes it very attractive for use in vacuum columns or ethylbenzene recycle columns of styrene plants.

The contacting between the vapor and liquid in a single-stage contacting device will not produce total equilibrium. The relationship between ideal and actual performance is the efficiency that translates the number of ideal separation stages into actual finite stages that must be used to accomplish the desired final separation. Efficiency varies, not only with the type of mixing method used (e.g., packing or trays), but also with fluid rates, fluid properties, column diameter, and operating pressure.

The influence of plate efficiency in the operation of the distillation tower becomes important in the control of the overhead composition. Because plate efficiencies increase with increased vapor velocities, the influence of the reflux-to-feed ratio on overhead composition becomes a nonlinear relationship.

Dynamics Dynamic considerations due to liquid hold-up on the trays comes into play when discussing distillation control. Because the liquid on each tray must overflow its weir and work its way down the column due to tray or packing hydraulics, this change will not be seen at the bottoms of the tower until some time has passed. The exact dynamics depend on column size, type of tray, number of trays, and tray spacing. The hold-up at each tray as shown in Figure 8.19c can be modeled by the LaPlace transform of the form

$$KG(s) = \frac{K}{(T_1 s + 1)} \tag{8.19(1)}$$

where

KG(s) = transfer function
K = system gain
T_1 = time constant
S = LaPlace transfer operator

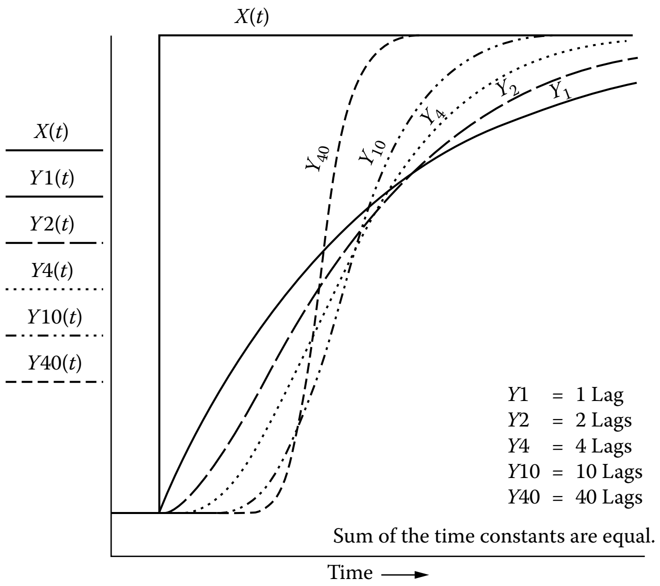

FIG. 8.19d
Response of nth-order lags to unit step change.

These lags are cumulative as the liquid passes each tray on its way down the column. Thus, a 30-tray column could be approximated by 30 first-order exponential lags in series of approximately the same time constant.

$$KG(s) = \frac{K}{(T_1 s + 1)^n} \quad \textbf{8.19(2)}$$

where
$n = 30$ for a 30-tray column

Figure 8.19d shows the response of nth order lags to a unit step change. The effect of increasing the number of lags in series is to increase the apparent dead time and increase the response curve slope. Thus, the liquid traffic within the distillation process is often approximated by using a second-order lag plus dead time as modeled by the LaPlace transform:

$$KG(s) = \frac{Ke^{-ts}}{(T_1 s + 1)(T_2 s + 1)} \quad \textbf{8.19(3)}$$

where
$e = e$ of log to the base e
$\phi =$ dead time
T_1, $T_2 =$ time constants

Condensers

The overhead vapor leaving the column is sent to a condenser and is collected as a liquid in a receiver, or accumulator. A part of the accumulated liquid is returned to the column as reflux. The remainder is withdrawn as overhead product or distillate. In many cases, complete condensation is not accomplished. In that case, the condensers are called partial condensers. In this instance, a vapor product is normally withdrawn as well as a liquid product.

A total condenser is usually designed for accumulator pressures up to 215 psia (1.48 MPa) at an operating temperature of 120°F (49°C).[4] A partial condenser is used from 215 psia to 365 psia (1.48 to 2.52 MPa), and a refrigerant coolant is used for the overhead condenser if the pressure is greater than 365 psia (2.52 MPa).

Common condensers include fin fans and water coolers. However, in order to improve efficiency of heat recovery, heat exchange with another process stream is often performed.

Propane is the most common refrigerant used. A pressure drop of 5 psia (34.4 KPa) across the condenser is often assumed if no measurements are available. The condenser and accumulator are the key pieces of equipment with respect to controlling pressure in the column.

Reboilers

The liquid leaving the bottom of the column is reheated in a reboiler. A reboiler is a special heat exchanger that provides the heat necessary for distillation. Part of the column bottoms liquid is vaporized and the vapors are injected back into the column as boil-up. The remaining liquid is withdrawn as a bottom product or as residue.

As shown in Figure 8.19e, reboilers come in widely varying designs. They can be internal, but most are external to the column. They can use natural or forced circulation.

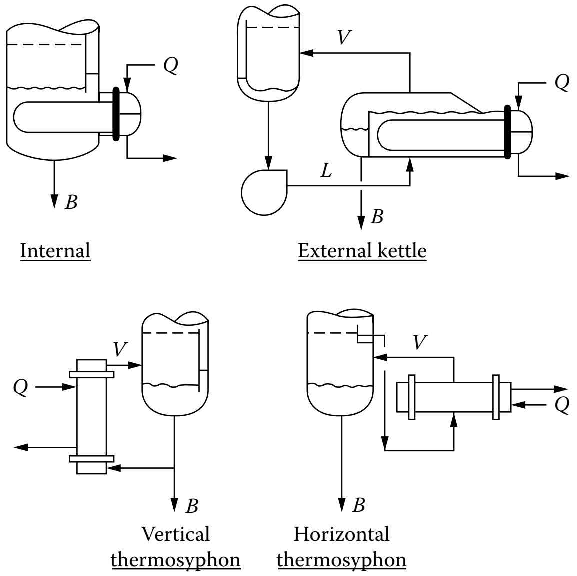

FIG. 8.19e
Reboiler design variations. External kettle reboilers often use forced circulation (pump), while the thermosyphon designs depend on natural circulation. The horizontal thermosyphon reboiler takes its liquid from the bottom tray, while the others take it from the column bottoms.

The kettle reboiler is the most common external forced circulation design.

Vertical and horizontal thermosiphon reboilers operate by natural circulation. In these, flow is induced by the hydrostatic pressure imbalance between the liquid inside the tower and the two-phase mixture in the reboiler tubes. In forced circulation reboilers, a pump is used to ensure circulation of the liquid past the heat transfer surface. Reboilers may be designed so that boiling occurs inside vertical tubes, inside horizontal tubes, or on the shell side.

A newer development in reboiler design is the concept self-cleaning shell-and-tube heat exchangers for applications where heat exchange surfaces are prone to fouling by the process fluid. Common heat sources include hot oil, steam, or fuel gas (fired reboilers). Cases where simple heat exchange with another process stream is used for efficiency of heat recovery are common. Thus, the choice of instrumentation to control heat addition to the tower depends upon the type of reboiler used.

Interheaters/Intercoolers

In some cases, additional vapor or liquid is withdrawn from the column at points above or below the point at which the feed enters. All or a portion of this sidestream can be used as intermediate product. Sometimes, economical column design dictates that the sidestream be cooled and returned to the column to furnish localized reflux. The equipment that does this is called a sidestream cooler, or intercooler. Multiproduct fractionators often have these intercoolers in a pump-around stream.

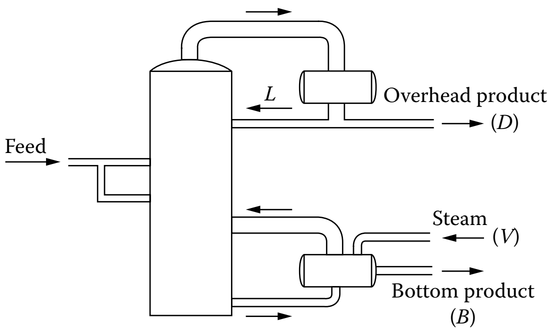
At other times, localized heat is required. Then, some of the liquid in the column is removed and passed through a sidestream reboiler, or interheater, before being returned to the column. Interheaters are usually utilized in cryogenic demethanizers.

Often the feed is preheated before entering the column. Common preheat mediums include the bottoms product or low-pressure steam. Preheating is often a convenient method to recover heat that would otherwise be wasted.

Column Variables

Controlling a fractionator requires the identifying of the controlled, manipulated, and load variables (Figure 8.19f). Controlled variables are those variables that must be maintained at a precise value to satisfy column objectives. These normally include product compositions, column temperatures, column pressure, and tower and accumulator levels.

Manipulated variables are those variables that can be changed in order to maintain the controlled variables at their desired values. Common examples include reflux flow, coolant flow, heating medium flow, and product flows. Load variables are those variables that provide disturbances to the column. Common examples include feed flow rate and feed composition. Other common disturbances are steam header pressure, feed enthalpy, environmental conditions (e.g., rain, barometric pressure, and ambient temperature), and coolant temperature.



Apparent variables:	Independent variables
C_1 = overhead temperature	2
C_2 = overhead pressure	
C_3 = overhead composition	
C_4 = overhead flow rate	1
u_1 = bottom temperature	2
u_2 = bottom pressure	
u_3 = bottom composition	
u_4 = bottom flow rate	1
u_5 = feed temperature	2
u_6 = feed pressure	
u_7 = feed composition	
u_8 = feed per cent vapor	1
u_9 = feed flow rate	1
m = steam flow rate (heat input)	1
	11

FIG. 8.19f
In a binary distillation process the number of independent variables is eleven (11) and the number of defining equations is two (2). Therefore, the number of degrees of freedom is nine (9), which is the maximum number of automatic controllers that can be used on such a process.

To handle these disturbances, column controls can be so designed as to make the column insensitive to these disturbances, or secondary controls can be designed to eliminate the disturbances. It is also important to evaluate the expected magnitude and duration of the likely disturbances, so that proper control system scaling and tuning can be achieved.

Feedforward controls are designed to compensate for these disturbance variables and are discussed later in this section. There are other advanced control or optimization methods that can be designed to compensate for these disturbance variables. They are discussed in Section 8.21.

Pairing of Variables The variables that should be controlled are usually obvious. They are normally identified when process objectives are defined and understood. Load variables are also easily identified. But identification of the manipulated variables can be more difficult. The general guidelines for identifying which manipulated variables to associate with which controlled variables are

- Manipulate the stream that has the greatest influence on the associated controlled variable.
- Manipulate the smaller stream if two streams have the same effect on the controlled variable.
- Manipulate the stream that has the most nearly linear correlation with the controlled variable.
- Manipulate the stream that is least sensitive to ambient conditions.
- Manipulate the stream least likely to cause interaction problems.

Unfortunately, the decision on pairing controlled and manipulated variables is complicated by the fact that the above rules may sometimes result in conflicting recommendations. Section 8.20 provides information on relative gain calculations, which can help to optimize the pairing of controlled and manipulated variables. Once the pairings are completed, the equations are then solved for the manipulated variables in terms of the controlled and load variables. In that form, the equations are the mathematical representations of the control systems.

MODELING AND CONTROL EQUATIONS

The primary application of instruments in distillation is to control the product purity, and secondarily, to minimize upsets to the unit caused by a change in process inputs. The instruments calculate the effects of the input changes and determine the corrective action needed to counteract them. The control actions are implemented by direct manipulation of the final control elements or by alteration of the set points of lower level controllers.

A careful analysis of limits and operating constraints is essential to the successful control of distillation columns. If the system is not designed to provide limit checks and overrides to handle operating limits, frequent operator intervention will be required during upsets. This is likely to result in a lack of confidence in the control system and will cause the operators to remove the column from automatic control more often than necessary, thereby not only reducing the effectiveness of the system, but also reducing safety.

The first step in the design of a good control system is the derivation of a process model. Knowing the defining equations, the manipulated variables can be selected, and the operating equations for the control system can be developed. The instrumentation is then selected for the correct solution of these equations.

The final control system can be relatively simple or can be a complex, interacting, multicomponent, computer-based system. In the discussion that follows, the procedures for designing distillation controls is followed by examples of the more common applications in distillation column control. A more detailed discussion of alternative strategies and advanced distillation column controls will be presented in Section 8.21.

Steady-State Model

The first step in the design of a control system must be the development of a process model. Frequently omitted in simple distillation columns, this step is essential to minimize the need for field reconfiguration of control strategies. Even with easily reconfigurable process automation systems (PASs), the development of the model is essential to fully understanding the process.

The model defines the process with equations developed from the material and energy balances of the unit. A common simplifying assumption is that all components of the feed have equal heats of vaporization, which leads to the assumption of equimolal overflow. Most shortcut fractionation calculations are based upon this underlying assumption.

The model is kept simple by the use of one basic rule: The degrees of freedom limit the number of controlled variables (product compositions) specified in the equations, as was illustrated in connection with Figure 8.19f. Some of the variables that can be manipulated to control a column are shown in Figure 8.19g.

Material Balance For example, for a given feed rate only one degree of freedom is available for material balance control. If overhead product (distillate) is a manipulated variable (controlled directly to maintain composition), then the bottom product cannot be independent but must be manipulated to close the overall material balance according to the following equations:

$$F = D + B \qquad \textbf{8.19(4)}$$

$$\text{Accumulation} = \text{Inflow} - \text{Outflow} \qquad \textbf{8.19(5)}$$

$$\text{Accumulation} = F - (D + B) \qquad \textbf{8.19(6)}$$

Because accumulation is zero at steady state, B is dependent upon F and D, as expressed by Equation 8.19(4):

$$B = F - D \qquad \textbf{8.19(7)}$$

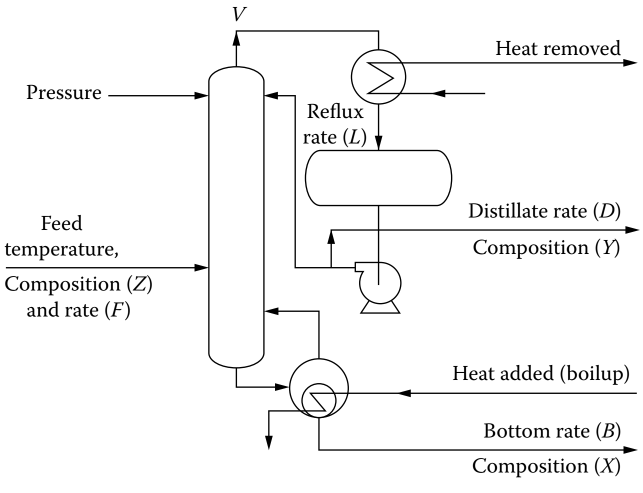


FIG. 8.19g
Variables that fix the distillation operation.

or if the bottoms product is the manipulated variable:

$$D = F - B \qquad \textbf{8.19(8)}$$

where:

F = feed rate (the inflow)
D = overhead rate (an outflow)
B = bottoms rate (an outflow)

If the compositions of the feed, distillate product, and bottoms product are known, then the component material balance can be solved:

$$100 = \%LLK_D + \%LK_D + \%HK_D \qquad \textbf{8.19(9)}$$

$$D \times \%LLK_D = F \times \%LLK_F \qquad \textbf{8.19(10)}$$

$$F \times \%LK_F = D \times \%LK_D + B \times \%LK_B \qquad \textbf{8.19(11)}$$

where:

$\%LLK_F$ = lighter than light key in the feed (mol%)
$\%LK_F$ = light key in the feed (mol%)
$\%LLK_D$ = lighter than light key in the distillate product (mol%)
$\%LK_D$ = light key in the distillate product (mol%)
$\%HK_D$ = heavy key in the distillate product (mol%)
$\%LK_B$ = light key in the bottoms product (mol%)

In the most general case, the feed might have four components, having the concentrations of LLK_F, LK_F, HK_F, and HHK_F. Three of these components appear in each of the bottom and overhead products. The separation of the column is fixed by specifying the heavy key component in the overhead product $\overline{HK}_D$ and the concentration of the light key component in the bottom product $\overline{LK}_B$.

Equations 8.19(9) to 8.19(11) assume no heavier than heavy key is found in the distillate and that no lighter than light key is found in the bottoms. Rearranging Equation 8.19(11) gives

$$\%LK_D = (F \bullet \%LK_F - B \bullet \%LK_B)/D \qquad \textbf{8.19(12)}$$

Substituting Equation 8.19(8) into Equations 8.19(10) and 8.19(12) gives

$$\%LLK_D = (F \bullet \%LLK_F)/(F - B) \qquad \textbf{8.19(13)}$$

$$\%LK_D = (F \bullet \%LK_F - B \bullet \%LK_B)/(F - B) \qquad \textbf{8.19(14)}$$

Substituting Equations 8.19(13) and 8.19(14) into Equation 8.19(9) to eliminate $\%LLK_D$ and $\%LK_D$:

$$B/F = \frac{(100 - \%HK_D - \%LLK_F - \%LK_F)}{(100 - \%HK_D - \%LK_B)} \qquad \textbf{8.19(15)}$$

For a given feed composition and desired product compositions, only one bottoms-to-feed ratio, B/F (product split), will satisfy the overall and component material balances. By fixing the bottoms flow, the distillate flow will be fixed. However, fixing a value of product split does not fix either the distillate or bottoms composition because many combinations of $\%LLK_F$, $\%LK_F$, $\%LK_B$, and $\%HK_D$ could yield the same value of B/F.

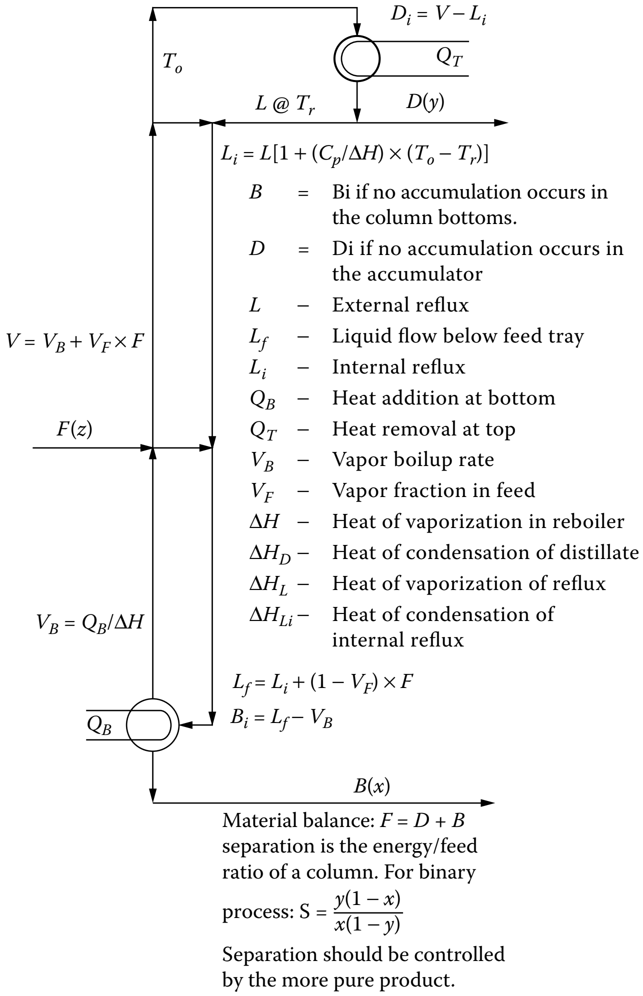

FIG. 8.19h
Energy balance equations can be used to describe the steady-state heat flow model of a distillation column.

Energy Balance The energy balance and the separation obtained are closely related. Conceptually, product composition control can be thought of as a problem of the rate of heat addition Q_B at the bottom of the fractionator and the rate of heat removal Q_T at the top of the column. A series of energy balances produces additional equations. Figure 8.19h shows a steady-state internal model of these equations.[5]

The vapor boil-up rate V_B equals the heat Q_B added by the reboiler divided by the heat of vaporization (ΔH) of the bottoms product:

$$V_B = Q_B/\Delta H \qquad \textbf{8.19(16)}$$

The vapor rate V above the feed tray equals the vapor boil-up rate plus the vapor entering with the feed (feed rate

F times vapor fraction V_F, provided the feed is neither subcooled nor superheated):

$$V = V_B + F \times V_F \qquad \textbf{8.19(17)}$$

The internal reflux rate, that is, the liquid at the top tray of the column is derived by a heat balance around the top of the tower. Assuming a steady-state heat balance where the heat into the tower equals the heat out:

$$\begin{aligned} &D \times (\Delta H_D + C_{p_D} \times T_t) + L_I \times (\Delta H_{L_I} + C_{p_{R_I}} \times T_t) \\ &\quad + L \times (C_{p_L} \times T_r) = D \times (\Delta H_D + C_{p_D} \times T_o) \\ &\quad + L \times (\Delta H_L + C_{p_L} \times T_o) + L_I \times (C_{p_{L_I}} \times T_t) \end{aligned} \qquad \textbf{8.19(18)}$$

where

C_p = specific heat

T_o = overhead vapor temperature (vapor at its dew point)

L = external reflux

T_r = external reflux temperature

L_I = internal reflux

T_t = top tray temperature (liquid at its bubble point)

Equation 8.19(18) reduces to:

$$\begin{aligned} &D \times C_{p_D} \times (T_t - T_o) + L_I \times \Delta H_{L_I} - L \times \Delta H_L \\ &\quad + L \times C_{p_L} \times (T_r - T_o) = 0 \end{aligned} \qquad \textbf{8.19(19)}$$

Making a simplifying assumption that the tray temperature equals overhead vapor temperature (i.e., the dew point of the vapor equals the bubble point of the liquid; $T_t = T_o$) produces:

$$L_I \times \Delta H_{L_I} = L \times \Delta H_L + L \times C_{p_L} \times (T_o - T_r) \qquad \textbf{8.19(20)}$$

or

$$\frac{L_i}{L} = \frac{\Delta H_L}{\Delta H_{L_i}} \cdot \left[\left(1.0 + \frac{C_{p_L}}{\Delta H_L} \cdot (T_o - T_r) \right) \right] \qquad \textbf{8.19(21)}$$

resulting in the equation

$$L_{pI}/L = K_2 \times [1 + K_1 \times (T_{po} - T_{pr})] \qquad \textbf{8.19(22)}$$

If a total condenser is employed, the composition of the internal reflux and external reflux are the same, i.e., $\Delta H_{L_I} = \Delta H_L$, so the constant $K_2 = 1.0$. Thus,

$$L = \frac{L_I}{[1 + K_1(T_O - T_r)]} \qquad \textbf{8.19(23)}$$

or

$$z_I = L \times [1 + K_1 \times \Delta T] \qquad \textbf{8.19(24)}$$

Note: This equation is valid for whatever units are used for C_{p_L} or ΔH_L. Because specific heat and heat of vaporization are nearly always in mass units, care must be taken to account for density differences whenever volume units are being used by the control equation. Also, C_{p_L} and ΔH_L should be calculated near the existing pressure and temperature of the external reflux.

The liquid rate, L_F, below the feed tray equals the internal reflux plus the liquid in the feed:

$$L_F = L_I + (1 - V_F) \times F \qquad \textbf{8.19(25)}$$

The distillate rate, D, equals the vapor rate, V, above the feed tray minus the internal reflux:

$$D = V - L_I \qquad \textbf{8.19(26)}$$

The bottoms rate, B, equals the liquid rate, L, minus the boil-up, V_B:

$$B = L - V_B \qquad \textbf{8.19(27)}$$

The criterion for separation is the ratio of reflux (L) to distillate (D) flows vs. the ratio of boil-up (V) to bottoms (B) flow rates. Manipulating reflux affects separation equally as well as manipulating boil-up, albeit in opposite directions. Consequently, only one degree of freedom exists to control separation. Thus, for a two-product tower, two equations define the process. One is an equation describing separation, and the other is an equation for material balance.

Dynamic Model

Because the tower doesn't always operate at steady state, it is essential to also account for the dynamics of the process. This necessitates extending the steady-state internal flow model and requires additional considerations. Figure 8.19i shows the internal flow model that includes dynamics.[6]

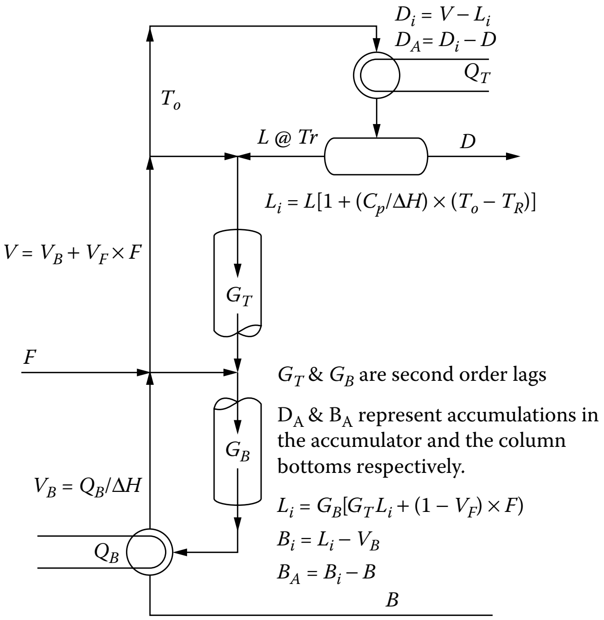

FIG. 8.19i
Dynamic internal flow model.

Because a change in the reflux rate must work its way down the column due to tray or packing hydraulics, this change will not be seen at the reboiler until some time has passed. The holdup at each tray has previously been modeled by the LaPlace transform of Equation 8.19(1). This Laplace transform can be converted to a simple first-order exponential lag equation of the form, which describes the response to a step change in input:

$$L_{\text{lag}} = L\,(1 - e^{-t}) \qquad \textbf{8.19(28)}$$

where

L is the liquid incoming to the tray

L_{lag} is the liquid leaving the tray

t is the time constant

These lags are cumulative as the liquid passes each tray on its way down the column. However, implementation of multiple first-order lags is impractical. Fortunately, it can be shown that multiple lags in series can be approximated by a dead time and a second-order exponential lag as shown by the LaPlace transform of Equation 8.19(3). For this reason, two dynamic terms (G_T and G_B) are included in Figure 8.19i. Equation 8.19(25) is then rewritten as

$$L = G_B[G_T L_I + (1 - V_F) \times F] \qquad \textbf{8.19(29)}$$

where

$G_B = \phi_1\,(1 - e^{-t1})\,(1 - e^{-t2})$

$G_T = \phi_2\,(1 - e^{-t3})\,(1 - e^{-t4})$

ϕ_1 and ϕ_2 are the dead times

G_B and G_T are the solution to the LaPlace transform of Equation 8.19(3).

Changes in boil-up rates are observed at the condenser in a matter of seconds. Normally, no dynamic terms are necessary for vapor streams, as the value of use of computing resources to that of the benefits by compensating for the dynamics is negligible.

The liquid inventory in the condenser or associated accumulator will change during unsteady-state actions. In the unsteady state, the difference $D_I - D$ is the rate of accumulation of material in the accumulator. Similarly for the liquid inventory at the bottom of the tower (the kettle), the difference $B_I - B$ is the rate of accumulation:

$$D_A = D_{II} - D \qquad \textbf{8.19(30)}$$

$$B_A = B_I - B \qquad \textbf{8.19(31)}$$

where

D_A is the accumulation in the overhead accumulator

B_A is the accumulation in the tower bottoms

Separation Equations

The control of product compositions for a fractionator is primarily a matter of control of the internal flows. In considering product separation, the degree of separation and the orientation of separation are important. The degree of separation is

$$\text{Degree of Separation} = \ln_e \frac{(\%LK_D \times \%HK_B)}{(\%HK_D \times \%LK_B)} \qquad \textbf{8.19(32)}$$

while the orientation of separation for a given degree of separation is defined as

$$\text{Orientation of Separation} = \frac{\%HK_D}{\%LK_B} \qquad \textbf{8.19(33)}$$

The relationship between x (the light key component) and the energy balance was developed by Shinskey[7] as a function of separation S:

$$S = \frac{y(1-x)}{x(1-y)} \qquad \textbf{8.19(34)}$$

where

x = mole fraction of the key light component the distillate ($\%LK_D$)

y = mole fraction of the key light component in the bottoms, (LK_B)

The relationship between separation (S) and the ratio of boil-up to feed (V/F) over a reasonable operating range is

$$V/F = a + bS \qquad \textbf{8.19(35)}$$

where a and b are functions of the relative volatility, the number of trays, the feed composition, and the minimum V/F. The control system therefore computes V based on the equation:

$$V = F\left[a + b\left(\frac{y(1-x)}{x(1-y)}\right)\right] \qquad \textbf{8.19(36)}$$

Because y is held constant, the bottom composition controller adjusts the value of the parenthetical expression if an error should appear in x. Let $V/F = y(1 - x)/(1 - y)$, and the control equation becomes:

$$V = F(a + b[V/F])/x \qquad \textbf{8.19(37)}$$

where $[V/F]$ = the desired ratio of boil-up to feed.

Figure 8.19j illustrates four of the most common basic controls for the flows and levels of a two-product fractionator, where it is assumed that feed flow and tower pressure are held constant. A different set of the above control equations for controlling internal product flow rates will apply, depending upon the configuration of instrumentation used.

Scaling

The form of the control system equations influences the computing functions required. Boolean operands, such as high and low selectors, and dynamic functions, such as dead times, lead, and lag function, are also used. Most process automation systems have these basic computing function blocks. Implementation in a distributed control system (DCS), programmable

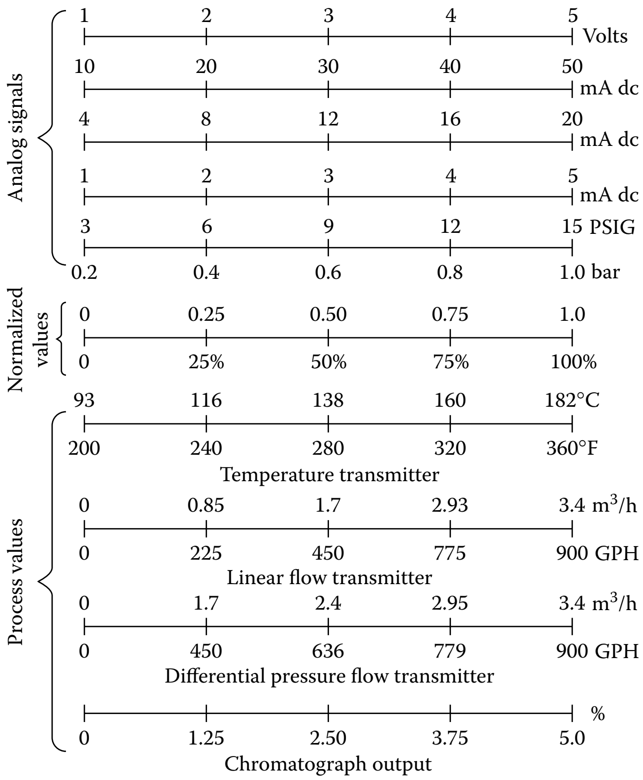

FIG. 8.19k

Common analog signals and their relationship to process variables.

logic controller (PLC), or multivariable digital controllers is vendor-specific.

The terms of the equations are sometimes scaled because most analog instruments and some PAS systems act on normalized numbers (0–100%) rather than on actual process values. With digital instrumentation and today's process automation systems, those occurrences are rare. The calculations become easier for those systems operating in engineering units.

Analog, and many digital, transmitters also operate on normalized values of the process variables. That is, the measurement signal will vary from 0 to 100% as the process variable shifts from 0 to its maximum value. Figure 8.19k illustrates the relationship among the various forms of analog signals and some typical process measurements.

The actual value of a process measurement is found by multiplying the analog signal by the calibrated full-scale value (*meter factor*) of the process variable. In the examples of Figure 8.19k, the temperature, represented by a 75% analog signal, is 320°F (160°C), the linear flow is 775 gph (2.93 m^3/h), the output of the differential pressure transmitter (flow squared) is 779 gph (2.95 m^3/h), and the composition is 3.75%.

Example As an example, let us review a flow ratio system in which the load stream, L, has the range of 0 to 1000 gpm (0 to 3.79 m^3/h); the manipulated stream, M, has a range of 0 to 700 gpm (0 to 2.65 m^3/h); and the ratio range, R, is 0 to 0.8 ($R = M/L$).

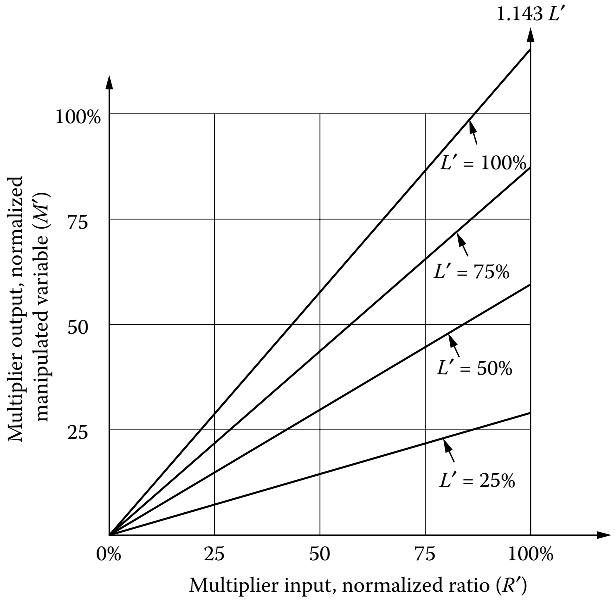

FIG. 8.19l

Multiplier output for the solution of Equation 8.19 (39).

$$700M' = (1000L')(0.80R') \qquad \mathbf{8.19(38)}$$

Reducing to the lowest form,

$$M' = 1.143(L')(R') \qquad \mathbf{8.19(39)}$$

The number 1.143 is the scaling factor. M' is plotted as a function of L' and R' in Figure 8.19l.

In applications such as the constant separation system, exact scaling is not critical. Exact scaling is when scaling constants must be used as calculated from instrument spans. The alternative is flexible scaling, where exact ranges are not needed but some arbitrary range is used to allow internal calculations to remain within range.

The flexible scaling cannot be used (1) when compensation for feed composition is part of the model, (2) when narrow spans must be used for reasons of stability, and (3) when transmitter calibrations are inconsistent with material balance ratios. Exact scaling techniques must be used for these cases.

MULTIPLE COMPONENT DISTILLATION

With binary mixtures, only two products are removed in the distillation column. However, most separations involve multiple components. Even then, most distillations remove only two liquid products. In other applications a vapor product is removed, or multiple liquid products are drawn from the tower. Sometimes only one product is withdrawn at a time.

Columns with Sidedraw

Having a sidestream product in addition to the overhead and bottom products adds a degree of freedom to a control system. The source of this extra degree of freedom can be seen from the overall material balance equation:

$$F = D + C + B \tag{8.19(40)}$$

where C is the sidestream flow rate. Two of the product streams can be manipulated for control purposes, and the material balance can still be closed by the third product stream.

The presence of this added degree of freedom makes the careful analysis of the process even more essential to avoid mismatching of the manipulated and controlled variables. As in the case of the previously discussed columns, the development of a control system for sidedraw applications also involves developing the process model and determining the relationship among the several controlled and manipulated variables.

In this case, for a constant feed rate and column pressure, five degrees of freedom exist: three composition specifications and two levels that can manipulate three product flows, and two heat balances (V and L). Several possible combinations of variables are available and should be explored.

The possible combinations of manipulated variables for the column in which the bottom composition and the sidestream composition must be controlled are

Distillate and sidestream flows
Distillate and bottom flows
Distillate flow and heat input
Sidestream and bottom flows
Sidestream flow and heat input
Bottom flow and heat input

Similarly, the possible combinations of manipulated variables for the column in which the distillate composition and the sidestream composition must be controlled are:

Distillate and sidestream flows
Distillate and bottom flows
Distillate flow and heat input
Sidestream and bottom flows
Sidestream flow and reflux
Bottom flow and reflux

The equations are

$$D = F\left[\frac{z_1 - c_1}{y_1 - c_1}\right] \tag{8.19(41)}$$

$$C = F\left[\frac{z_2 - x_2}{c_2 - x_2}\right] \tag{8.19(42)}$$

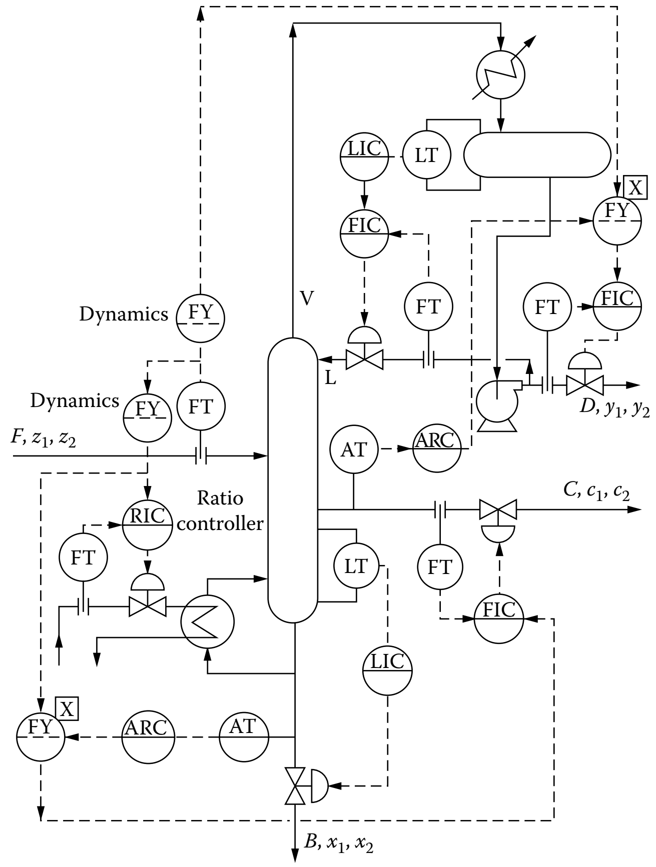

FIG. 8.19m
Control of composition in two product streams with a sidedraw.

The symbols z_1, y_1, and c_1 refer to the concentrations in the feed, distillate, and sidestream of the component under control in the sidestream. The concentrations of the key component in the bottom are respectively expressed by z_2, x_2, and c_2 for the feed, the bottoms, and the sidestream.

The resulting control system is shown in Figure 8.19m. Note that in this configuration the ratio of heat input to feed (and, therefore, boil-up to feed) is held constant. Separate dynamic elements are used for the distillate loop and for the heat input and sidestream loops.

Multiproduct Fractionators

Multiproduct fractionators are most common in the refining industry where multicomponent streams are separated into many fractions. Examples of multiproduct fractionators are crude towers, vacuum towers, and fluidized catalytic cracking unit (FCCU) main fractionators.

Product quality controls are used to adjust local column temperatures and sidedraw flow rates to control distillate properties related to the product specifications. An example is true boiling point (TBP) cut points. TBP cut points approximate the composition of a hydrocarbon mixture and are numerically similar to the American Society for Testing and

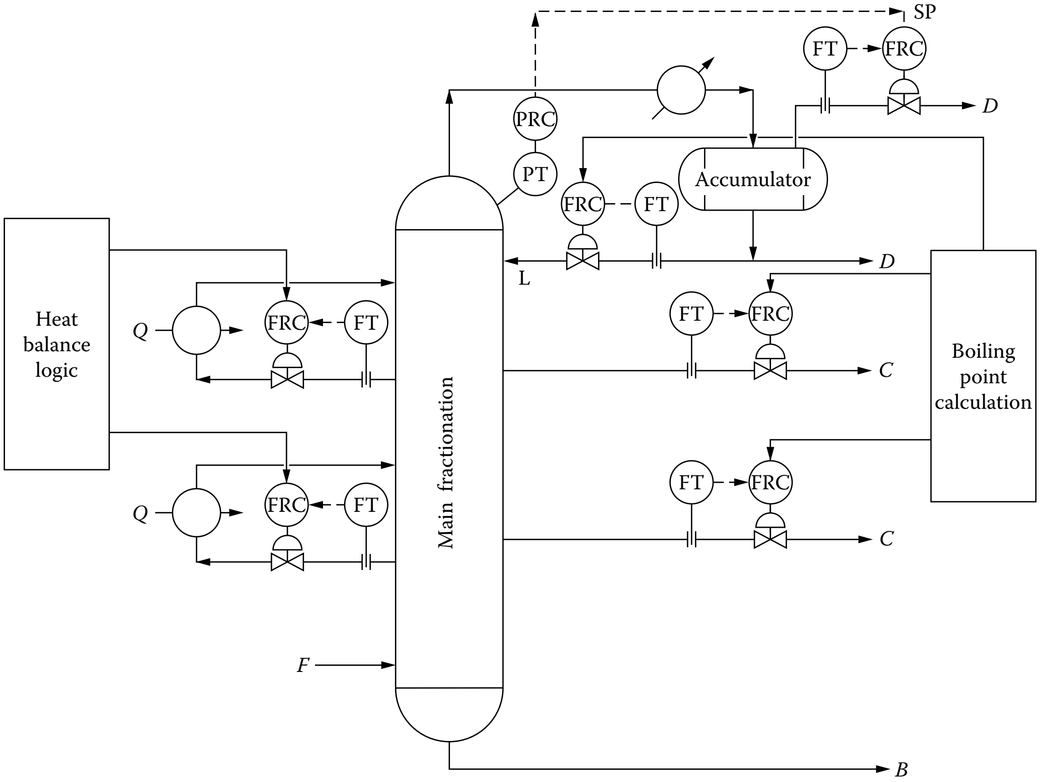

FIG. 8.19n
Control of product flows and pump-around refluxes.

Materials' (ASTM's) 95%. The ASTM laboratory distillate evaluation method is the standard used in the petroleum refining industry for determining the value (composition) of the distillation products.

A computer is required to calculate the product boiling point specification, such as 95% boiling point or TBP cut point on the basis of local temperature, pressure, steam flow, and reflux data. Local reflux is derived from internal liquid and vapor flows, as discussed previously, and the remaining variables are measured.

Boiling point analyzers can be used to provide the measurement signals. If there is no analyzer, the calculated boiling points can be used by themselves, or if there is one, they can be used as a fast inner loop with analyzer trim. Because of the volume of liquid/vapor loads within most multiproduct fractionators, the manipulated variables that provide the greatest sensitivity and the quickest response are generally the product flows.

Adjustment of reflux flows, as shown in Figure 8.19n, is an example of a heat balance control. The goal is to maximize heat exchange to feed, subject to certain limits[8] (limits and constraints are discussed as part of the subject of the optimization of distillation towers in Section 8.21). The task of maximizing the heating of the feed often simplifies to recovering heat at the highest possible temperature, which means recovering it as low as possible in the column.

Superfractionators

The term *superfractionator* is applied to towers that are physically large. These distillation units separate streams having their light and heavy key relative volatilities quite close to each other. Included in this classification are deisobutanizers, which separate isobutane from normal butane; propylene splitters, which separate propane from propylene; ethylbenzene towers, which separate ethylbenzene from xylene; and xylene splitters, which separate para- and ortho-xylene from meta-xylene.

Sometimes, the number of trays and subsequent height make it necessary to physically divide these towers into two or even three sections. Superfractionators have tremendous internal vapor-liquid rates in order to achieve the separation. Reflux-to-distillate ratios are very high, as are vapor-to-bottoms ratios.

A large pressure drop through the tower also exists. Long dead times and lag times are experienced before any response is seen to feed rate or reflux changes. Generally, distillate compositions of superfractionators have to be controlled with material balance equations due to the lack of sensitivity of response.

Batch Distillation

In batch distillation (see Figure 8.19o), an initial charge of liquid is fed to a vessel, and the distillation process is initiated

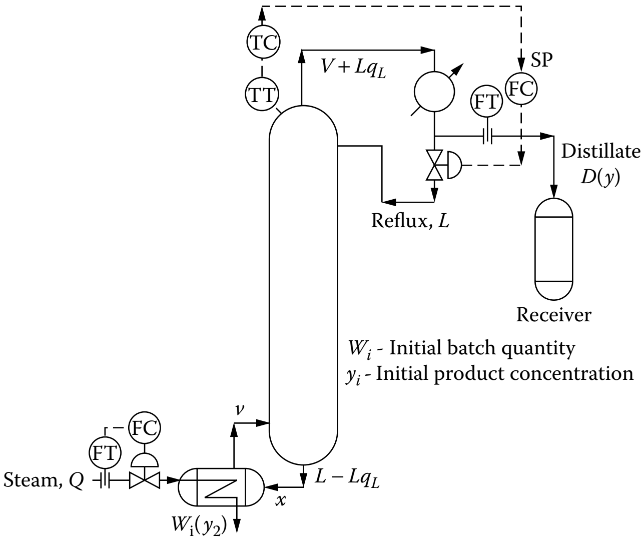

FIG. 8.19o
Batch distillation.

by turning on the heating and cooling systems. During the distillation process, the initial charge in the vessel continually depletes while building up the overhead product in the distillate receiver.

Batch distillations are more common in smaller, multiproduct plants where the various products can only be manufactured at different times, and where a number of different mixtures may be handled in the same equipment. Equation 8.19(43) is the basic equation that describes this operation:

$$W = W_i - Dt \qquad \textbf{8.19(43)}$$

where

W = amount remaining in the bottoms
W_i = the initial charge
D = distillate rate
t = time period of operation

The basic objective of the control system of this type of separation is to keep the composition of the distillate constant. Other goals include keeping the distillate flow constant or maximizing the total distillate production. The main goal of a batch distillation is to produce a product of specified composition at minimum cost. This often means that operating time must be reduced to some minimum while product purity or recovery is maintained within acceptable limits.

If product removal is too fast, separation and the quantity of the product are reduced. Conversely, if the product is withdrawn to maintain separation, its withdrawal rate is reduced and operating time is increased. However, the set point to a composition controller can be programmed so that the average composition of the product will still be within specifications while withdrawal rate is maximized.[9]

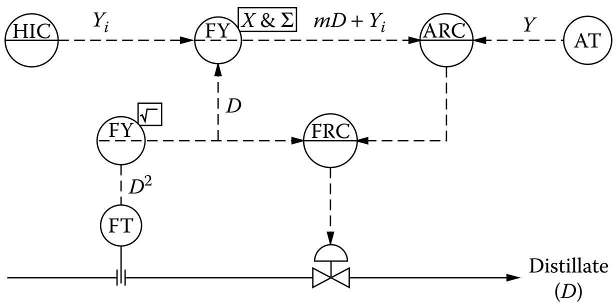

FIG. 8.19p
Control system for batch distillation.

Figure 8.19p shows the control system that will accomplish this when the vapor rate from the batch column is maintained constant. The equation describing this operation is:

$$Y = mD + y_i \qquad \textbf{8.19(44)}$$

where

y = the fraction of key component in the product
m = the rate of change of y with respect to the distillate (D)
y_i = the initial concentration of the product

The only adjustment required is the correct setting of m. The higher its value, the faster y will change and the smaller will be the quantity of material recovered.

CONTROL OBJECTIVES AND STRATEGIES

Operating objectives include the composition specifications for the top and bottom product streams. Other objectives can include increasing throughput, enhancing column stability, and operating against equipment constraints. Yet other considerations include what product composition is considered most important to maintain during disturbances, what are acceptable variations in product specifications, and what are relative economic values of the product streams and cost of energy used in the separation.[10]

The column operating objectives are ultimately governed by economic benefits that are measurable, significant, and achievable.[11] Economics of individual fractionators may continually change throughout the life of the plant. Prices and costs may determine that energy savings are important at one particular time but that recovery is more important at some other time.

The economic benefits of fractionator control include shifting of less profitable components into more profitable products, energy conservation, and increased throughput. Other benefits arise, including minimum disturbances propagated to downstream units, minimum rework or recycle of off-spec products, and more consistent product quality. Thus, a given column's operating economics and, therefore, its objectives may change with time.

When minimization of fractionator utilities is an objective, the following guidelines are recommended:

- Implement control to achieve composition control on all products of the fractionator
- Operate the fractionator to produce minimum overseparation
- Ascertain that the reduction in energy usage is reflected in the energy inflow to the production complex
- Minimize energy waste from blending of overseparated products

Alternative Control Strategies

Many choices confront the design engineer when selecting the control variables for a column. The first decision involves configuration of the top or bottom control loops, which directly determines product compositions. Once these strategies are tentatively determined, the control strategies for the remaining variables (e.g., pressure or levels) become easier to select.

Pairings of controlled and manipulated variables are normally made according to the single-input single-output (SISO) method. Multivariable control, where multiple-input and multiple-output (MIMO) variables are paired, are discussed in Section 8.21. In these multivariable strategies, although a controlled variable can be affected by several manipulated variables, only one manipulated variable is used to directly affect the controlled variable. The minimum number of controlled variables for a fractionator tower is four. These include:

Controlled Variables	*Manipulated Variables*
Overhead composition	Reflux flow
Bottoms composition	Reboiler heating media flow
Accumulator level	Distillate flow
Bottoms level	Bottoms flow

This allows for 24 possible configurations (4 factorial). Of course, most towers include pressure as a controlled variable, with condenser flow or vapor bypass as a manipulated variable. Additional manipulated variables can include feed flow and enthalpy. If a tower includes a sidedraw stream, another control pair is added to the possible combinations.

In fact, additional control variables increase the number of possible control configurations factorially (e.g., six variables produce 720 possible configurations).

The pairing of controlled and manipulated variables can follow three general control structures: energy balance control, material balance control, and ratio control.[12] Energy balance control uses reflux and reboiler heating media flow to control compositions, thus fixing the energy inputs.

Material balance control uses the distillate and bottoms product flows to control compositions, thus fixing the overall material balance. Ratio control utilizes a ratio of any two flow rates at each end of the column. The two common examples of ratio control are the control of reflux-to-distillate ratio and the boil-up-to-bottoms ratio. These control configurations perform quite differently depending upon the fractionator characteristics.

CONTROL LOOP INTERACTION

The selection of which product composition to control (or both, if control of both can be controlled) and the decision on which variables will give better control can be aided by calculation of a relative gain array. The concept of relative gain[13,14] provides a measure of the interaction that can be expected between control loops. This subject is covered in more detail in Chapter 2 in Section 2.12 and in Section 8.20. The concept may be used to find the control configurations that will have the least amount of interaction. Therefore, relative gain analysis should be considered the first step in evaluating alternative composition control strategies.

In addition, some pairings can be made heuristically from operating experience and on the basis of a general understanding of column dynamics (Table 8.19q).

The following are general rules used to reject some possible control pairings:[15,16]

1. Overhead composition and bottoms composition should not both be controlled with material balance equations if the objective is to control product specifications at both ends of the fractionator.

Because of lack of dynamic response the following loops should not be paired:

1. Accumulator level should not be controlled with reboiler heat if the reboiler is a furnace.
2. Bottoms level should not be controlled with reboiler heat if the reboiler is a furnace.
3. Bottoms level should not be controlled with distillate flow.
4. Accumulator level should not be controlled with bottoms product flow.
5. Overhead composition should not be controlled with bottoms product flow.
6. Bottoms composition should not be controlled with distillate flow.
7. Bottoms level should not be controlled with reflux flow.
8. Bottoms composition should not be controlled with reflux flow if the number of trays is greater than a minimum limit (approximately 20).
9. Bottoms level should not be controlled with reboiler heat if the diameter of the column is greater than a minimum limit (approximately 15–20 ft (4.5–6 m), indicating a high volume of liquid in the bottoms).

TABLE 8.19q
Dynamic Response and Sensitivity Limitations on the Pairing of Distillation Control Variables[4]
(Both compositions should not be controlled by material balance (B,D) if both specifications are important)

Controlled Variable / *Manipulated Variable*	*Distillate Flow (D)*	*Bottoms Product Flow (B)*	*Vaporization Rate (V) or Heat Input at Reboiler (O)*	*Reflux Flow Rate (L)*
Composition of Overhead Product (AC_y)	OK if $L/D \geqq 6$ Note 3		Notes 1 and 2	Note 2
Composition of Bottoms Product (AC_x)		Note 3	Notes 1 and 2	OK if trays $\leqq 20$
Accumulator Level (LC_a)	OK if $L/D \leqq 6$		Not good with furnace OK if $V/B \geqq 3$	OK if $L/D \geqq 0.5$
Bottoms Level (LC_b)		OK if $V/B \leqq 3$	Not good if furnace is used OK if diameter at bottom $\leqq 20$ ft	

Notes: 1. Control that concentration (x or y) which has the shorter residence time by throttling vapor flow (v).
2. More pure product should control separation (energy).
3. Less pure product should control material balance.
4. When controlling both x and y, the only choices for possible pairings are:
  a. Control y by D and x by V.
  b. Control y by D and x by L.
  c. Control y by L and x by V.
  d. Control y by B and x by L.

Of these, choice *d* is not recommended because *a* y/B combination is not responsive dynamically.

10. Accumulator level should not be controlled with reboiler heat if the control objective is to maintain overhead product specification and the V/B ratio is less than a minimum limit (approximately 3).

Because of lack of sensitivity, these loops should not be paired:

1. Overhead composition should not be controlled with reflux flow if the reflux ratio (L/D) is less than a minimum value (approximately 6).
2. Accumulator level should not be controlled with distillate flow if the reflux ratio (L/D) is less than a maximum value (approximately 6).
3. Accumulator level should not be controlled with reflux flow if the reflux ratio (L/D) is less than a maximum value (approximately 0.5).
4. Bottoms composition should not be controlled with sidedraw flow if the sidedraw is a vapor phase.
5. Overhead composition should not be controlled with sidedraw flow if the sidedraw is a liquid phase.
6. Bottoms composition should not be controlled with sidedraw flow if the sidedraw is a liquid phase and the sidedraw tray number is greater than a minimum number (approximately 20).
7. Sidedraw composition should not be controlled with reflux or distillate flow if the difference between the total number of trays and the number of the sidestream tray is greater than a minimum value (approximately 20).
8. Bottoms level should not be controlled with sidedraw flow if the difference between the bottoms and the number of the sidestream tray is greater than a minimum value (approximately 100).
9. Bottoms level should not be controlled with bottoms flow if the V/B ratio is greater than a minimum limit (approximately 3).

Choices for controlling product compositions include (1) controlling top or bottom composition only (generally suitable for constant separation conditions, where specifications for one product are loose or where effective feedforward/feedback systems can be designed to compensate for load changes) and (2) controlling of both product compositions (minimizes energy use and provides tight specification top and bottom products for columns in which the problems of interaction are small).

These choices can be broken down further into considerations such as manipulation of distillate-boil-up, *DV* configuration (generally suitable for high reflux columns) or manipulation of reflux-boil-up, *LV* configuration (generally suitable for low reflux columns), and so forth.

Further considerations include the use of decoupling control schemes (can present practical problems, such as insensitive control, operating problems, and high sensitivity to errors) and the use of temperature measurements to infer composition or analyzers to measure composition directly (generally an economic decision based on how well a temperature-sensitive control point can be determined and the costs of analyzer hardware and maintenance). These choices are based on operating objectives of the column, expected disturbance variables, and the degree of control loop interaction.

PRODUCT QUALITY CONTROL

Conceptually, product control is a problem of making precise adjustments to the rate of heat addition and the rate of heat removal from the tower. Heat removal determines the internal reflux flow rate, and the internal reflux as measured on the top tray is a direct reflection of the composition of the distillate. Heat added determines the internal vapor rate. These internal vapor and liquid flow rates determine the circulation rate, which in turn determines the degree of separation between two key components.

Once interaction of the various variable pairings has been established, and the column's operating objectives and disturbance variables are considered, the primary composition control loops of the column can be selected. Measurement of these control variables can be either direct or inferred.

Inferring Composition from Temperature

If the cost of on-line analyzer hardware and maintenance is prohibitive, or if backup is desired in case of analyzer failure or maintenance, and because the results of laboratory analysis take too long to be usable for effective control, temperature measurement often can be used to infer composition.

Because distillation separates materials according to their difference in vapor pressures, and because vapor pressure is a temperature-controlled function, temperature measurement has historically been used to indicate composition. This presumes that the column pressure remains constant, or that the temperature measurement is compensated for pressure changes, and that feed composition is constant. Then, any change in composition within a column will be detected as a temperature change.

The best point to locate the temperature sensor cannot be established from generalizations. The important consideration is to measure the temperature on a tray that strongly reflects the changes in composition. When composition of the bottom product is important, it is desirable to maintain a constant temperature in the lower section. This can be done by letting the temperature measurement manipulate the reboiler steam supply by resetting the steam flow controller set point (Figure 8.19r).

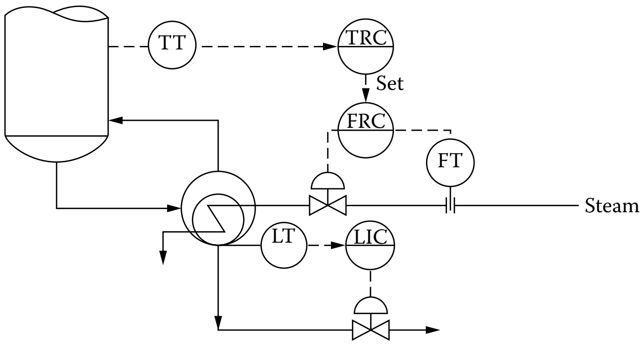

FIG. 8.19r
In this configuration the reboiler heat input is throttled by a temperature controller to keep the bottoms product composition constant.

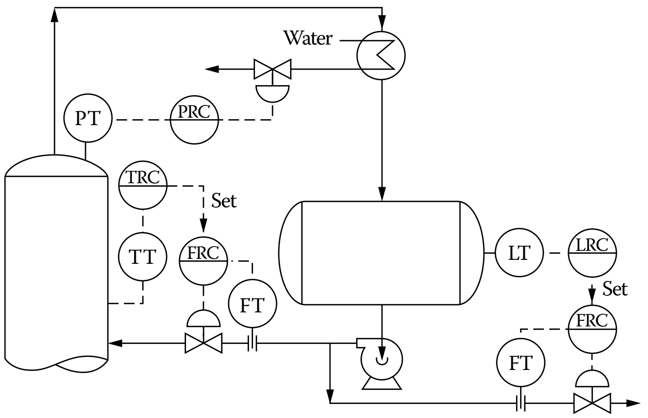

FIG. 8.19s
If overhead composition is to be controlled, the reflux flow to the column is throttled by a temperature controller.

When composition of the distillate is more important, it is desirable to maintain a constant temperature in the upper section, as in Figure 8.19s. In this configuration the sensing point for column pressure control should be located near the temperature control point. Keeping the sensor locations close to each other helps to fix the relation between temperature and composition at this particular point.

If column temperature profiles caused by small positive and negative changes in manipulated variables, such as a ±1% change in distillate flow (Figure 8.19t), can be generated, the

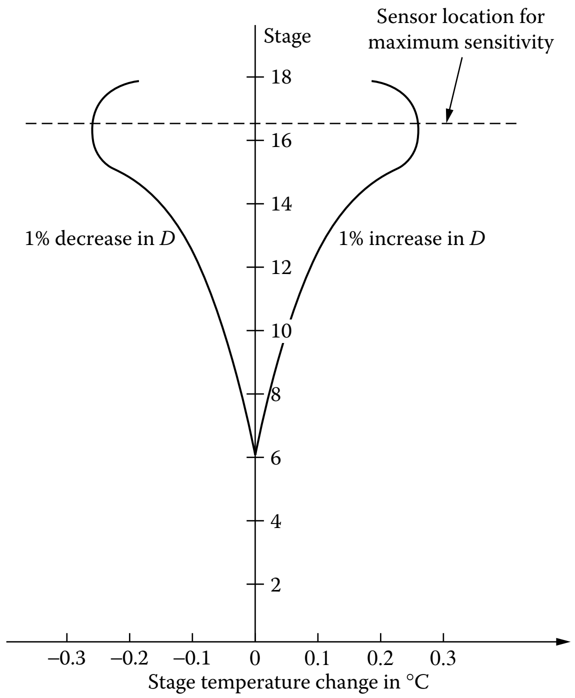

FIG. 8.19t
Example of column temperature profiles resulting from a 1% increase and from a 1% decrease in distillate flow.

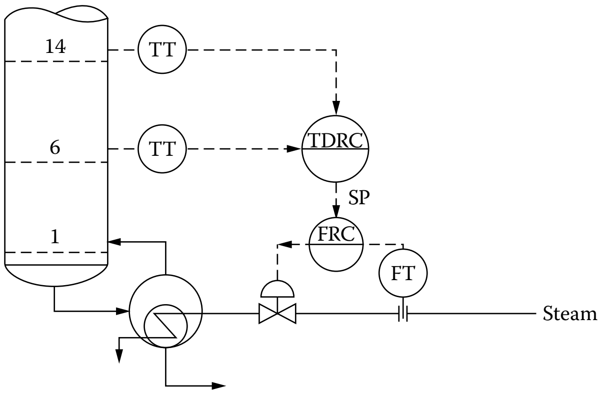

FIG. 8.19u
Heat input controlled by temperature difference.

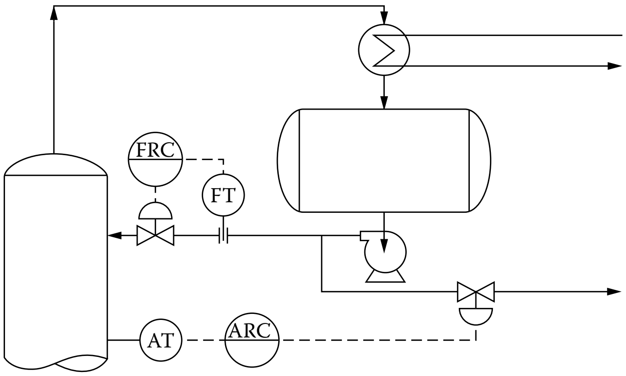

FIG. 8.119v
Distillate withdrawal controlled by chromatograph.

following criteria may be helpful in selecting sensor locations:[17] (1) The sensitivity of the temperature-manipulated variable pairing should be in the range of 0.1 to 0.5°C/% and (2) equal temperature changes should result when increasing and when decreasing the manipulated variable.

For a two-product fractionator, distillation temperature is an indication of composition only when column pressure remains constant or if the temperature measurement is pressure-compensated. When separation by distillation is sought between two compounds having relatively close vapor pressures, temperature measurement, as an indication of composition, is not satisfactory.

Fixing two temperatures in a column is equivalent to fixing one temperature and the pressure. Thus, by controlling two temperatures, or a temperature difference, the effect of pressure variations can be eliminated. The assumption used here is that the vapor pressure curves for the two components have constant slopes.

Controlling two temperatures is not equivalent to controlling a temperature difference. A plot of temperature difference vs. bottom product composition exhibits a maximum. Thus, for some temperature differences below the maximum it is possible to get two different product compositions.

Separation of normal butane and isobutane (in the absence of other components, such as pentanes and heavier substances) can be accomplished very well by using temperature difference control. Figure 8.19u illustrates how the heat input to such a column can be controlled by a temperature difference controller.

Control by Analyzers

Analytical or composition control is a way to sidestep the problems of temperature control. Although additional investment is needed for the analytical equipment, savings from improved operation usually results. Several types of instruments are available for composition analysis. Of these, the gas chromatograph is the most versatile and most widely used. (For details, refer to Chapter 8 of Volume 1 of this handbook.)

Once, the time required for a chromatographic analysis (several minutes) was a great barrier to its use for automatic control. Since then, the equipment has been enhanced so that analyses can now be made in less than 5 min, and in many cases for low-volatility hydrocarbons, the analysis can be made continuous.

With careful handling, the under 5 min sampling rate will permit closed-loop distillate control. In fact, fractionators are successfully controlled with cycle times as long as 7–10 min by applying dead time compensation algorithms.

Light ends fractionators have been satisfactorily controlled by the use of chromatography. Figure 8.19v illustrates the controls of a superfractionator designed to separate isobutane and normal butane. In this case, the chromatograph continuously analyzes a sample from one of the intermediate trays, and this measurement is used by the analyzer controller to modulate the product draw-off valve.

Overhead and bottoms analyzers typically measure the loss of a valuable product or the presence of impurities. Impurity components are chosen because small concentration variations can be measured more precisely and with better repeatability, and can provide a more sensitive measure of separation. For example, the change of an impurity from 1.0 to 1.1% can be measured with greater precision than a change of the major component from 99 to 98.9%.

When composition analyzers are used in feedback control, several configurations can be considered. These include 1) direct control of a manipulated variable, 2) cascade control adjusting the set point of a slave temperature controller, and 3) analysis control in parallel with temperature control in a selective control configuration. The configuration used depends on the control objective, sensitivity of control, and analysis dead time.

Direct Control by Analyzers Analyzer controllers in a feedback configuration can be considered when the dead time of each analysis update is less than the response time of the

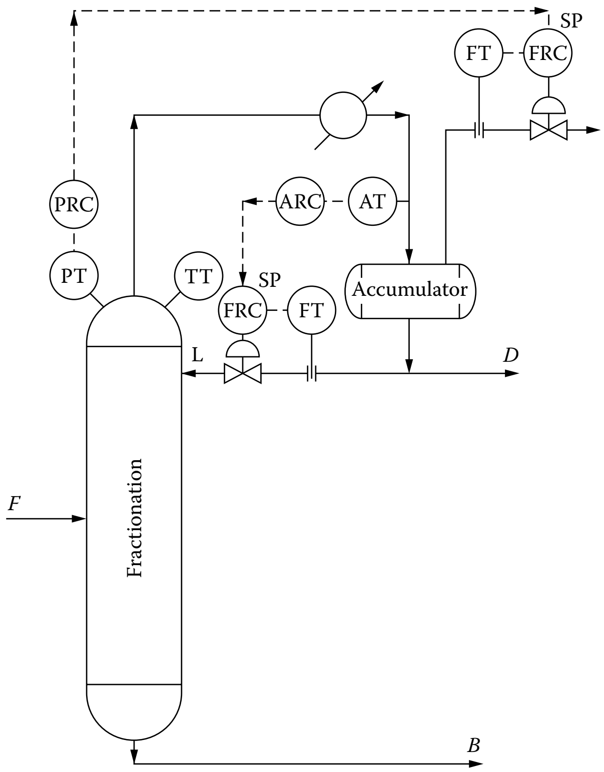

FIG. 8.19w
Direct control of overhead product composition by an analyzer controller (ARC) throttling the set point of a reflux flow controller (FRC).

process. Because it is the control of the composition of the product, which is often the objective, direct control by an analyzer controller would seem to be better than indirect control by temperature.

The composition controller provides feedback correction in response to feed composition changes, pressure variations, and variations in tower efficiencies. Figure 8.19w shows the configuration of a control system, in which a chromatograph analyzes a liquid sample from the condenser rundown line.

A sample probe gathers the liquid sample and the sampling system conditions and vaporizes the liquid sample to provide a representative vapor sample to the chromatograph. The analyzer controller (ARC) uses the chromatographic measurement to manipulate the reflux flow by adjusting the set point to the reflux flow controller (FRC).

Smith Predictor Often the analyzer is so slow that it introduces a significant delay time that degrades the controllability of the process. In that case, some type of dead time compensation is used (see Section 2.19 in Chapter 2). A Smith predictor compensator can serve to model the process to predict what the analyzer measurement should be between analysis updates. When the actual measurement is completed, the model's prediction is compared to the actual measurement and the input to the controller is biased by the difference.

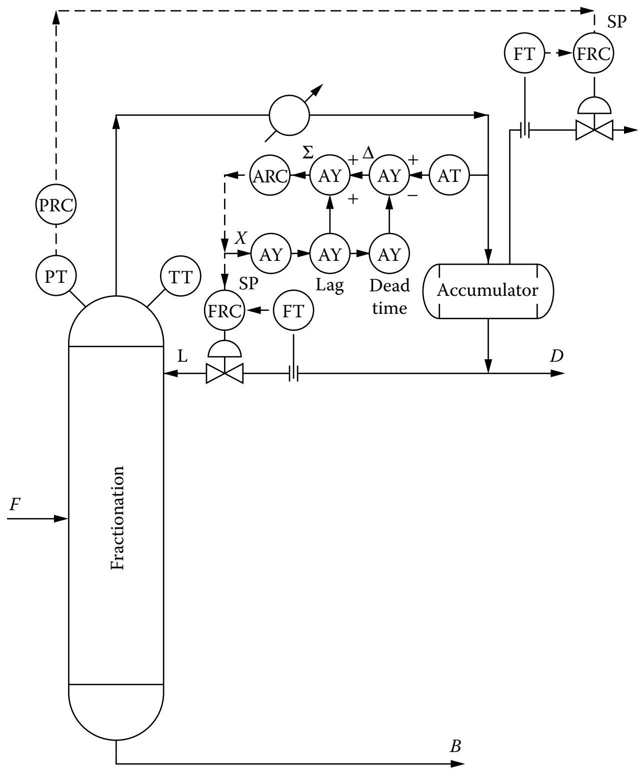

FIG. 8.19x
Analyzer controller with dead-time compensation cascaded to reflux flow control.

Figure 8.19x shows the same configuration as did Figure 8.19w except that the analyzer controller is equipped with a first-order Smith predictor that provides dead time compensation.

In Figure 8.19x, the multiplier, lag, and dead time calculations (*AY*) provide the predicted analysis. (The lag represents the first-order process.) This predicted response is subtracted from the actual measurement to give a differential of the actual process from its own model. This delta is added to the model without dead time to provide a modified pseudomeasurement to the analyzer controller. Thus, the analyzer measurement, which has a significant dead time due to sampling and cycle times, provides a trim to the predicted measurement of the model.

Triple Cascade and Selective Control Analyzer control cascaded to temperature control can be used when stable temperature on a particular tray is desired and the tower operates at a constant, maintainable, and controllable pressure. An example is cascading the analyzer controller to the overhead temperature of a tower, which in turn is cascaded to the reflux flow rate. Because temperature is an indicator of composition at this pressure, the analyzer controller only serves as a trim correcting for variations in feed composition. Figure 8.19y shows this triple cascade configuration of an analyzer controller setting the temperature controller setting the reflux flow controller.

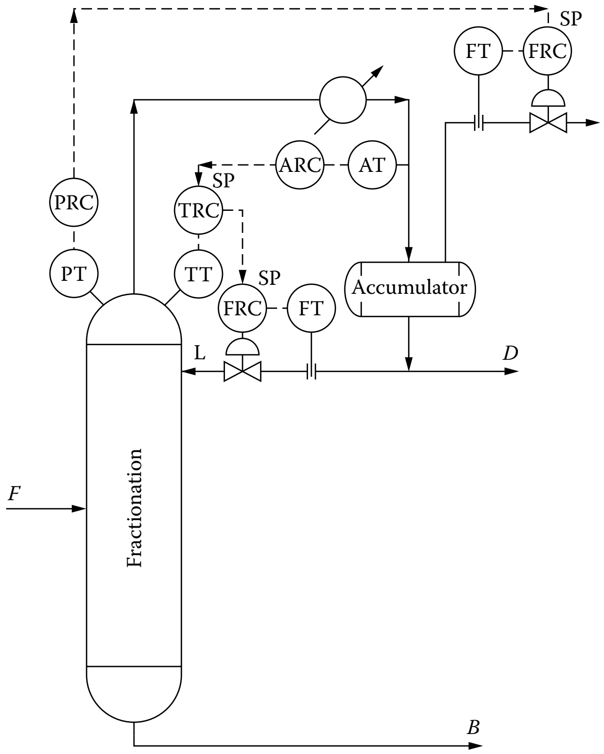

FIG. 8.19y
Triple cascade configuration of overhead composition control.

Analyzer controls can be used in a high or low select configuration in combination with temperature when a high or low limit based on temperature is important. The temperature controller is a constraint controller (see Section 2.28 in Chapter 2 for details) serving to prevent the temperature from exceeding a limit.

An example of using this control configuration is the control of the bottoms of an absorber stripper. Here, the temperature should not exceed a certain value, as no additional stripping of the light component in the bottoms of the column could be accomplished. Even though an analyzer controller may call for more heat, this heat would only increase the bottoms temperature of the recycled oil to the absorber without removing the impurity, thereby reducing the absorption capability at the absorber.

Figure 8.19z depicts an analyzer controller in a low select configuration with the temperature constraint controller.

Note that both cascade and selective control configurations require external feedback to protect them from reset windup. Figure 8.19aa illustrates how the external feedback (EF) is applied to the master controller in a cascade configuration (TIC) and to both controllers (FIC and PIC) in a selective control configuration. For more details on external feedback, refer to Section 2.28 in Chapter 2.

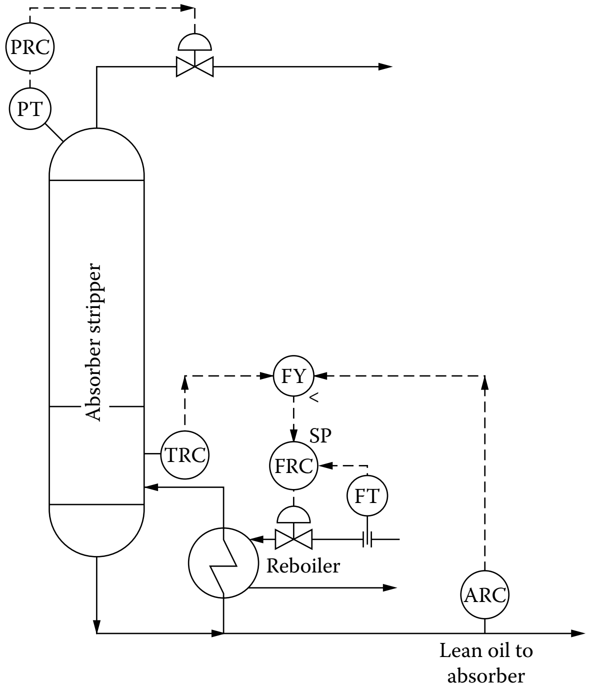

FIG. 8.19z
Analyzer control in a low select configuration with a temperature constraint controller.

Fractionator Trains A controller may use as its measurement the analysis of a single component, or may use the ratio of two components. A ratio (e.g., ethane-to-propane, C_2/C_3) is often used when the fractionator is not the final step in the separation sequence.[18] This often occurs in a natural gas liquids separation train where a de-ethanizer, a depropanizer, a debutanizer, and a deisobutanizer (butane splitter) produce the products ethane, propane, butane, isobutane, and gasoline as shown in Figure 8.19bb.

Specifications for the primary overhead products may include limitations on the amount of both light and heavy impurities. For example, the propane product from the overhead of the depropanizer would have limitations on ethane as well as isobutane. The problem is that the light impurity (lighter than light key) cannot be controlled in the tower that produces that product. Rather, it must be controlled in an upstream tower.

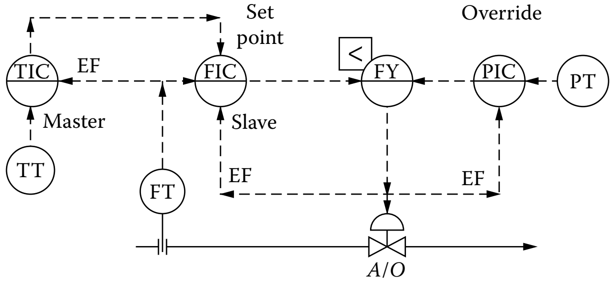

FIG. 8.19aa
In a cascade configuration the external feedback signal (EF) is the slave measurement, while in selective control configurations, it is the signal that is throttling the control valve.

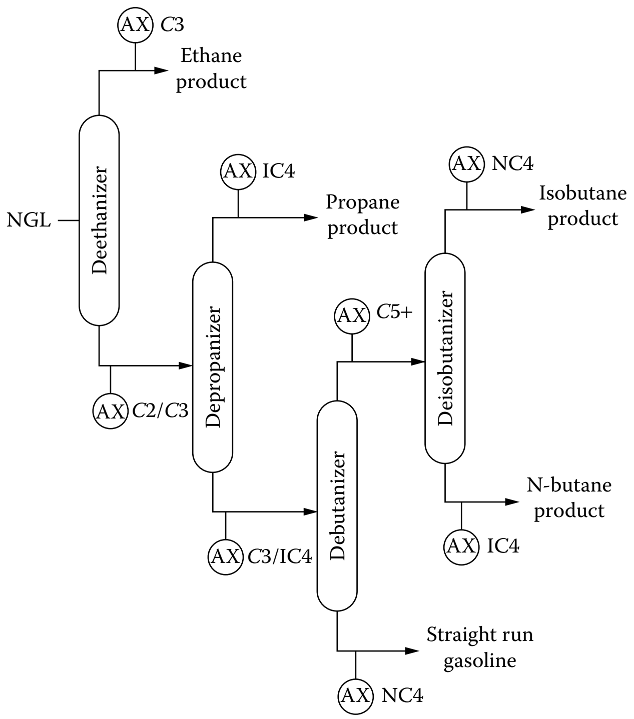

FIG. 8.19bb
Analyzer placement in a fractionator train.

The lighter than light key specification in the distillate of the downstream tower can be controlled more easily by controlling the ratio in the bottoms of the upstream tower. That is, the ethane content in the propane product (depropanizer distillate) is maintained by controlling the C_2/C_3 ratio in the bottoms of the de-ethanizer. Measuring the C_2/C_3 ratio in the bottoms requires an additional analyzer but eliminates the dead time of obtaining the concentration in the overhead of a downstream tower.

A feed analyzer is sometimes included as a part of feedforward control. The feed analysis is used in predicting internal reflux/overhead flow and bottoms/heat input. However, when feed composition changes slowly or when results from the analyzer cannot be obtained faster than the dynamics of the tower, this analyzer is omitted and the burden is placed on feedback control from the product analyzers.

In practice, a feed analyzer is the exception rather than the rule. Its use is mainly when the analyzer is already in place, because it is controlling an upstream tower. For example, the NGL separation train in Figure 8.19bb has a deethanizer bottoms analyzer that could also be considered the depropanizer feed analyzer.

Analyzer Selection The choice of analyzer control depends upon the analytical equipment available and on the type of separation desired. Each type of separation requires a compromise between the controllability and the delay of the control system. For example, the NGL train (Figure 8.19bb) was studied to determine the best analyzer system. In the depropanizer (where isobutane was to be measured in the presence of ethane, propane, and normal butane) and in the deisobutanizer (where isobutane was to be measured in the presence of normal butane and isopentane), an infrared analysis was to be preferred.

However, in the debutanizer the goal was to measure the combined isopentane plus normal pentane concentrations in the presence of isobutane and normal butane to control the butane-pentane separation. Here, investigation revealed that gas chromatography provides the best solution.

Some boiling point analyzers are reliable enough to be used for on-line control (see Section 8.50 in Chapter 8 in Volume 1 of this handbook). Normally, cut points between overhead products and side-cuts are maintained by temperature controllers. These controllers generally influence reflux rate or product draws to achieve the desired results. Laboratory distillation results are used to adjust the set points to the temperature controllers. This method of control, however, is cyclical because of the time lags involved in temperature control.

To avoid exceeding the target cut points and to meet required product specifications, the cut point is set below specification. This results in downgrading the more valuable product to the stream of lesser value. This downgrading can be minimized through the use of on-line boiling point analyzers. Justification of a boiling point analyzer depends upon the value of the products, how much downgrading is occurring, and the cost of analyzer maintenance. Figure 8.19cc illustrates an end-point analyzer.

Viscosity is another property that can be measured continuously to give faster control corrections. In vacuum distillation, the viscosimeter monitors each of the streams for which viscosity is a specification. Any deviation from the desired viscosity is corrected by a change in the set point of the control loop involved.

Deviation from the desired viscosity and the subsequent downgrading of the product can occur because of frequent variations in tower operating conditions and feed composition. In addition to normal operation, the use of a viscosity analyzer minimizes downgrading during major upsets and large feed compositions changes. With such an arrangement, low viscosity vacuum bottoms can be detected quickly and diverted to recoverable feed for profitable reprocessing.

Once again, profitability determination requires a thorough analysis of column operation and an assessment of the engineering, operating, and maintenance capabilities at the location where this type of control is to be implemented.

Many other analytical instruments are being moved out of the laboratory and into the processing area. Mobile units containing several different kinds of analyzers can be used to learn the best place to locate on-stream analyzers. In cases in which permanent analyzers cannot be justified, the mobile unit is connected to the process long enough to find the best operating conditions. Then, the mobile unit can be moved elsewhere.

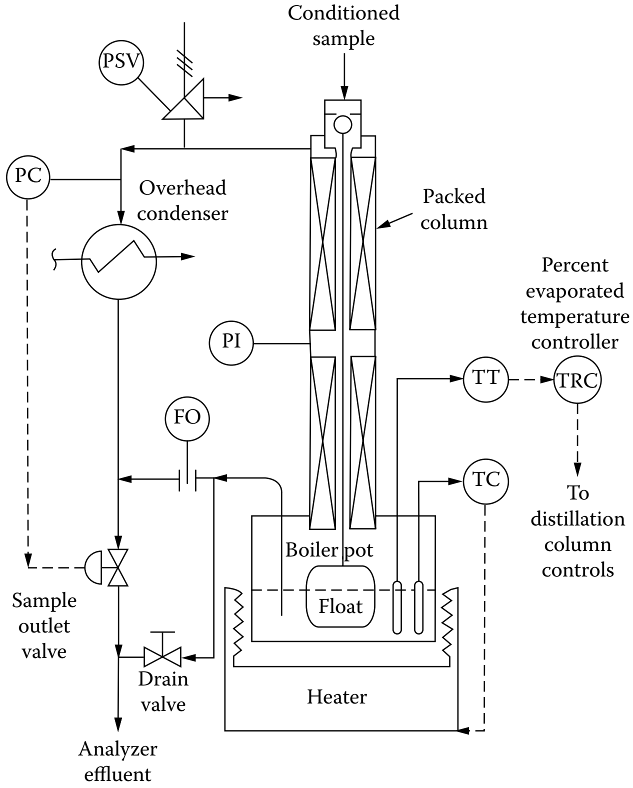

FIG. 8.19cc
The end-point distillation analyzer is a miniature version of the process column.

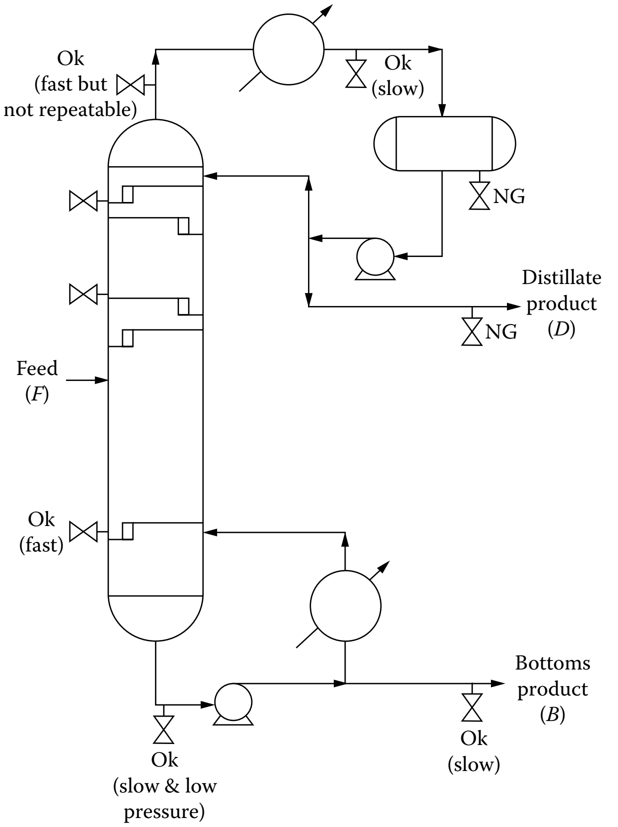

FIG. 8.19dd
The choices of sampling point locations for analyzers used in distillation column control.

Sampling Proper sampling of material in a column is necessary if analyzers are to control effectively. A poor sampling system often is responsible for the unsatisfactory performance of plant analyzers. For details on sampling system design, refer to Chapter 8, Section 8.2, in Volume 1 of this handbook.

The sampling points for composition analysis should be at, or very near, the column terminals for the following reasons: (1) freedom from ambiguity in the correlation of sample composition with terminal composition, and (2) improved control loop behavior as a result of reduction of transport lag (dead time) and of the time constants (lags) describing the sampling point's compositional behavior. This assumes that the controller applies its manipulation at the same terminal (steam or reflux) where the controlled variable is measured.

The factors favoring moving the point of sampling nearer to the feed entry point are (1) improved terminal composition behavior as a result of earlier recognition of composition transients as they proceed from the feed entry toward the column terminals, and (2) less stringent analytical requirements as a result of (a) analyzing the control component at a higher concentration and over a wider range, and (b) simplifying the multicomponent mixture, because nonkey components tend to exhibit constant composition zones in the column.

Figure 8.19dd shows some of the typical sample locations of a distillation tower. Most analyzers are designed to accept a clean, dry, noncorrosive sample at low temperatures, pressures, and flow rates. Such conditions seldom exist in the process, so the sampling system must be designed and operated to overcome the difference between the conditions in the process and the conditions required by the analyzer.

The sample system must provide a current and representative sample of the stream being analyzed. It must transport the sample from the sample point to the analyzer with a minimum of transport lag (preferably less than 30 sec and definitely not greater than 1 min). Transportation times are minimized using high flow rate bypass streams taken from the process sample point and returned to the process at a lower pressure. The sample system must condition the sample to remove traces of foreign materials through filtering, maintain pressure and temperature, and maintain or change phase for introduction into the analyzer.

For chromatographs, liquid sample points are generally preferred (Figure 8.19ee). This is because vapor streams have historically not provided representative samples. Vapor samples do not tend to produce repeatable values as consistently and reliably[19] because of condensation at the sample probe and in the sample lines when hydrocarbons of high boiling

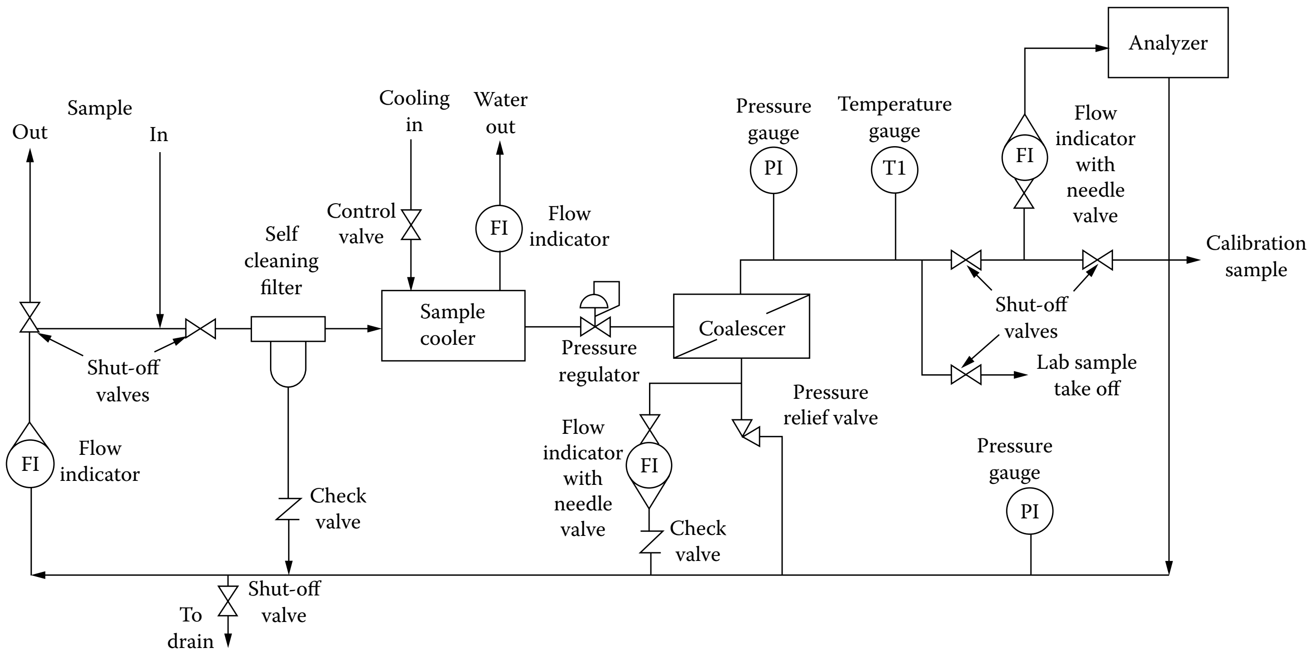

FIG. 8.19ee
Sampling system for a liquid product in a refinery application.

points are present in the sample. When the sample lines are long, some separation between components can also occur. However, vapor samples can be used when warranted and if the proper care can be taken.

A satisfactory point for measuring bottoms product composition is at the point of highest pressure. This approach will ensure a representative sample and will provide the pressure drop to return the sample bypass. The point of highest pressure is generally immediately after the product pump. However, if liquid holdup in the reboiler and kettle is large, a long lag is introduced, which slows the transient response of the measurement and control system. Alternative sample points such as a bottoms tray or seal pan may be used, but may require extra expense for the sample system.

A satisfactory sample-point location for measuring the distillate is the outlet liquid of the overhead vapor condenser. Sampling the overhead accumulator liquid after the reflux or distillate pump should be avoided because of the tremendous process lag it introduces. Sampling the overhead vapor reduces the process lag of sampling after the condenser if a repeatable, representative sample can be obtained.

PRESSURE CONTROL

Most distillation columns are operated under constant pressure. However, floating-pressure operation can have advantages in many processes. One reason for the resistance to the use of floating-pressure control is based on the fact that temperature is sensitive to pressure changes, and therefore, it requires pressure compensation if the pressure varies. As analyzers are increasingly replacing temperature-based controls, the argument favoring constant pressure operation is also lessening. However, even when temperature control is used, the temperature measurements can be compensated for pressure variations.

The primary advantage of floating-pressure control is the ability to operate at the minimum column pressure within the constraints of the system. Lower pressure reduces the volatility of distillation components, thereby reducing the heat input required to effect a given separation. Other advantages include increased reboiler capacity and reduced reboiler fouling due to lower tower temperatures.

In the following paragraphs, floating-pressure control strategies will be described for the following conditions: (1) liquid distillate withdrawn when noncondensables are present, (2) vapor distillate withdrawn when noncondensables are present, and (3) liquid distillate withdrawn when the amount of noncondensables is negligible.

Liquid Distillate and Inerts

In some separation processes the problem of pressure control is complicated by the presence of large percentages of inert gases. The noncondensables must be removed, or they will accumulate and blanket off the condensing surface, thereby causing loss of column pressure control.

The simplest method of handling this problem is to bleed off a fixed amount of gases and vapors to a lower pressure unit, such as to an absorption tower, if one is present in the system.

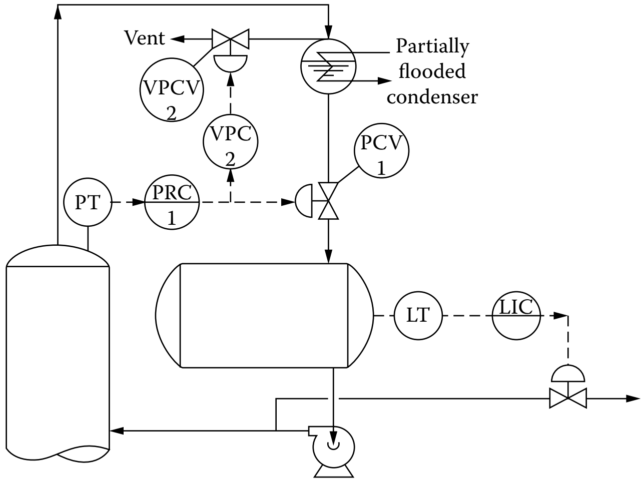

FIG. 8.19ff
Column pressure control with inerts present.

If an absorber is not present, it is possible to install a vent condenser to recover the condensable vapors from this purge stream. Often in refinery applications such noncondensables go to the fuel gas system or to flare.

It is recommended that the fixed continuous purge be used whenever economically possible; however, when this is not permitted, it is possible to modulate the purge stream. This might be desirable when the amount of inerts is subject to wide variations over time.

As the noncondensables build up in the condenser, the pressure controller will tend to open the control valve (PCV-1 in Figure 8.19ff) to maintain the proper rate of condensation. The controller signal that is throttling PCV-1 could also be used to start opening the purge control valve (VPCV-2), when the opening of PCV-1 reaches some preset limit. This can be done by means of a calibrated valve positioner or by using a valve position controller (VPC-2) in Figure 8.19ff.

Vapor Distillate and Inerts

In the case where the distillate is in the vapor phase and inerts are present, the overhead product is removed under pressure control as shown in Part A of Figure 8.19gg. In this configuration the system pressure will quickly respond to changes in the distillate vapor flow. In this control system a level controller is installed on the overhead receiver to regulate the cooling water to the condenser, so that it will condense only enough condensate to provide the column with reflux.

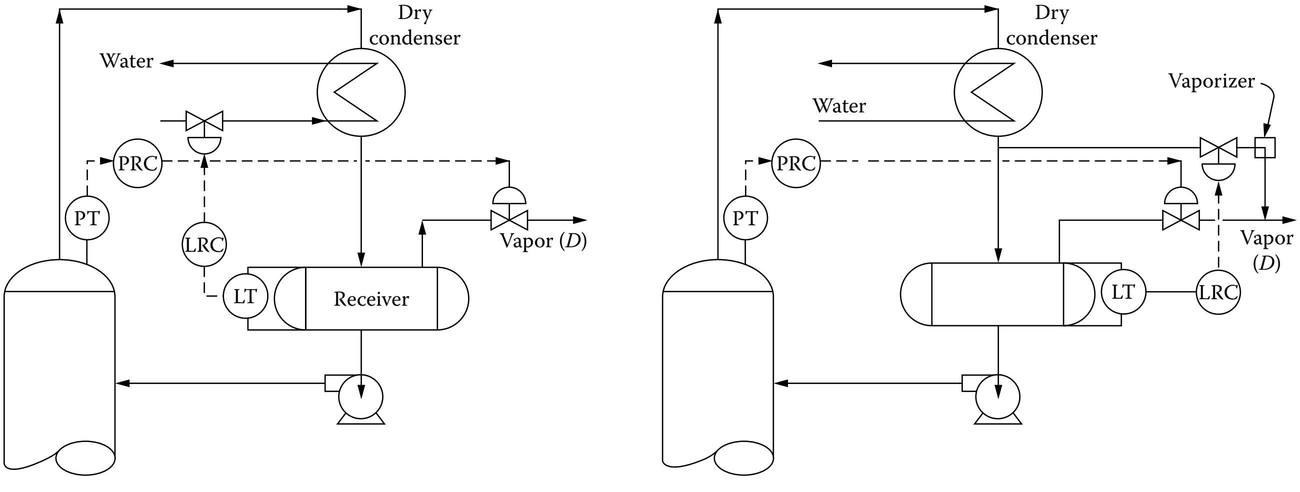
This control system will operate properly only if the condenser is designed to provide a short residence time for the coolant, which will minimize the level control time lag. If this is not the case, the cooling water flow should be maintained at a constant rate.

In this case (Part B in Figure 8.19gg), the level controller can regulate the flow of condensate through a small vaporizer and mix it with the vapor from the pressure control valve.

If the cooling water has fouling tendencies, it is preferable to use the control system shown in Figure 8.19hh, where a pressure controller regulates a vapor bypass around the condenser.

Liquid Distillate with Negligible Inerts

In distillation processes where the distillate is in the liquid phase and the amount of inerts is negligible, the column pressure is usually controlled by modulating the rate of condensation in the condenser. The method of controlling the



A. Variable water flow

B. Constant water flow

FIG. 8.19gg
Column pressure control when the distillate is in the vapor phase and contains inerts for variable (A) and constant condenser water flow configurations (B).

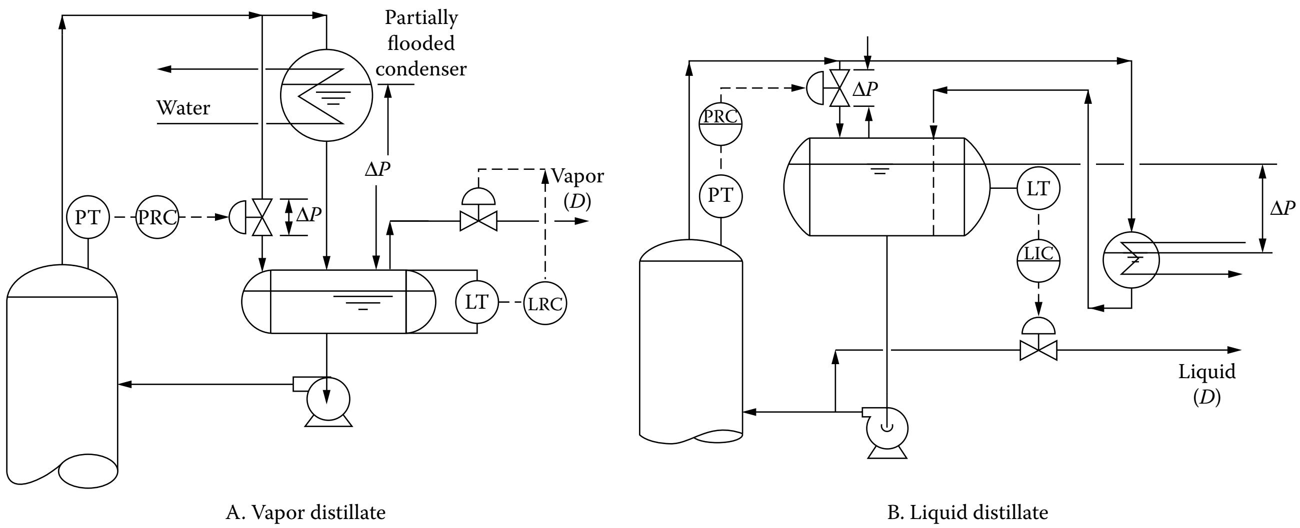


FIG. 8.19hh
Column pressure controlled by hot gas bypass throttling in case of vapor (A) and liquid (B) distillate processes.

rate of condensation depends upon the mechanical construction of the condensing equipment.

Controlling the Cooling Water Flow Figure 8.19ii describes a control configuration where the column pressure is controlled by throttling the cooling water flow from the condenser. This method of control is recommended only when the cooling water is treated with chemicals that prevent the fouling of the tubes in the event of high temperature rise across the condenser tubes. In such configuration, the maintenance costs are low, because the control valve is on the water side and the control performance is acceptable, provided the condenser is properly designed.

The best condenser for this service is a bundle-type unit with the cooling water flowing through the tubes. This water should be flowing at a rate of more than 4.5 ft/s (1.35 m/s), and the water should have a residence time of less than 45 sec. The shorter the residence time of the water, the better will be the quality of control obtained, owing to the decrease in dead time or lag in the system.

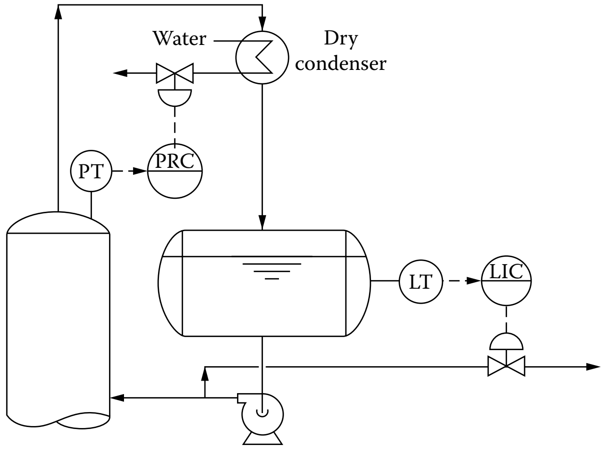

FIG. 8.19ii
Column pressure control by throttling condenser water.

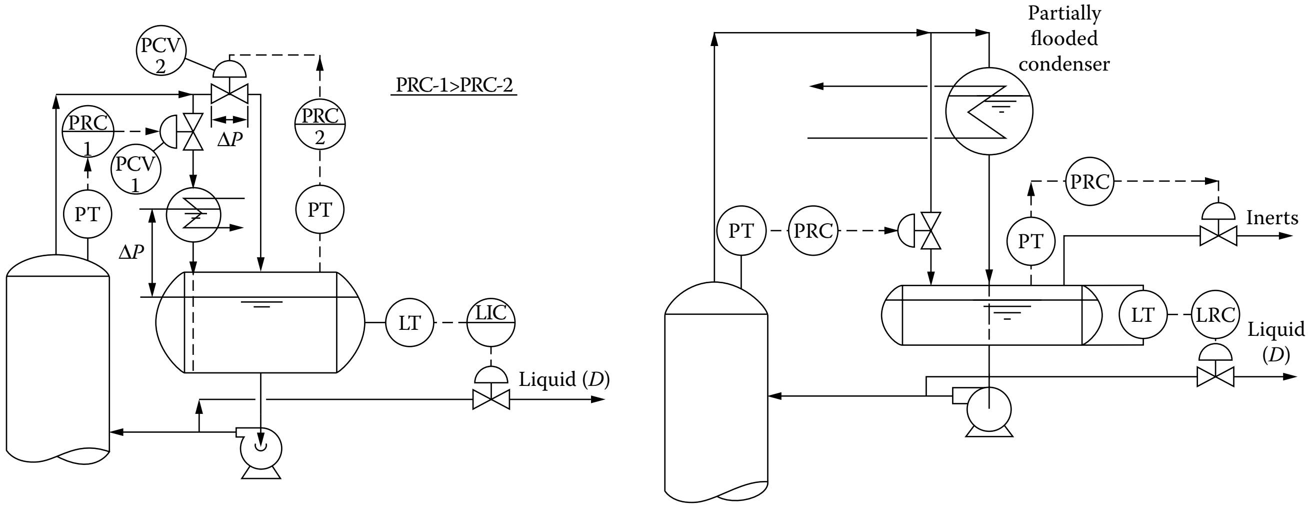
With a properly designed condenser, the pressure controller needs only proportional control, because a narrow throttling range is sufficient. However, as the residence time of the water increases, the time lag of the system will increase, and consequently the controller will require a wider throttling range and will need automatic reset to compensate for the load changes.

The control obtained by using a wide proportional band is not satisfactory for precision distillation columns because of the length of time required for the system to recover from an upset. Also, the dead time varies with load, and therefore the integral setting of the PRC should be set to match the variation in residence time.

Therefore, it is unacceptable to use this control system on a condenser box with submerged tube sections, because there would be a large time lag in the system due to the large volume of water in the box. It would require the passage of a significant amount of time before a change in water flow rate would change the temperature of the water in the box and finally would affect the rate of condensation.

Controlling the Condensate Flow To reduce such unfavorable time lags, it becomes necessary to use a different type of control system, one that permits the water flow rate to remain constant and controls the amount of surface exposed to the condensing vapors. This is done by modulating the flow of condensate from the condenser.

When the column pressure is dropping, this condensate throttling valve reduces the condensate flow, causing it to



A. No inerts

B. With inerts

FIG. 8.19jj
High-speed column pressure control.

build up and flood more tube surface and, consequently, to reduce the condensing surface exposed to the vapors. Thereby, the condensing rate is reduced, and the pressure in the column rises. In such designs, a vent valve should be installed to purge the noncondensables from the top of the condenser if it is expected that noncondensables could build up and blanket the condensing surface.

Control of Hot Vapor Bypass A third possible control configuration for applications with liquid distillate containing negligible inerts is used when the condenser is located below the receiver. This is frequently done to make the condenser available for servicing and to save on steel work. It is usual practice to elevate the bottom of the accumulator 10–15 ft (3–4.5 m) above the suction of the pump in order to provide a positive suction head on the pump.

In this type of installation the control valve is placed in a bypass of the vapor line to the accumulator (see Figure 8.19hh, Part B). When this valve is open, it equalizes the pressure between the vapor line and the receiver, causing the condensing surface to become flooded with condensate because of the 10–15 ft of head in the condensate line from the condenser back to the receiver.

The flooding of the condensing surface causes the pressure to build up because of the decrease in the rate of condensation. Under normal operating conditions, the subcooling that the condensate receives in the condenser is sufficient to reduce the vapor pressure in the receiver. The difference in pressure permits the condensate to flow up the 10–15 ft of pipe between the condenser and the accumulator.

A modification of this latter system controls the pressure in the accumulator by throttling the condenser bypass flow (Figure 8.19jj, Part A). The column pressure is maintained by throttling the flow of vapor through the condenser. Controlling the rate of flow through the condenser provides faster pressure regulation for the column.

Part A of Figure 8.19jj shows the operation if there are no inerts, as follows: If column pressure rises, PRC-1 opens PCV-1. This increases the vapor pressure in the condenser, which pushes some of the condensate out of it and increases the condensing surface area exposed to the vapors. Therefore, the rate of condensation is increased, and thereby the column pressure is lowered back to the set point of PRC-1.

At this higher rate of condensation, the pressure drop (ΔP) across PCV-2 is also reduced (the valve opens). If the column pressure drops, the opposite sequence occurs: PCV-1 closes and the flooding of the condenser increases, reducing the rate of condensation and increasing the pressure drop (ΔP) across PCV-2 by slightly closing it. The setting of PRC-1 must always be above that of PRC-2.

The most common pressure control configuration is shown in Part B of Figure 8.19jj. Here, the column pressure controller is throttling the hot vapor bypass, as was the case in Part A of Figure 8.19hh, but in addition a second pressure controller is utilized on the accumulator. This PRC is set at about 5 PSIG below the required tower pressure and is used to vent the inert gases that may build up in the system.

Vacuum Systems

For some liquid mixtures, the temperature required to vaporize the feed would need to be so high that decomposition would result. To avoid this, it is necessary to operate the column at pressures below atmospheric. Steam jet ejectors are often used to create vacuum in distillation systems. These

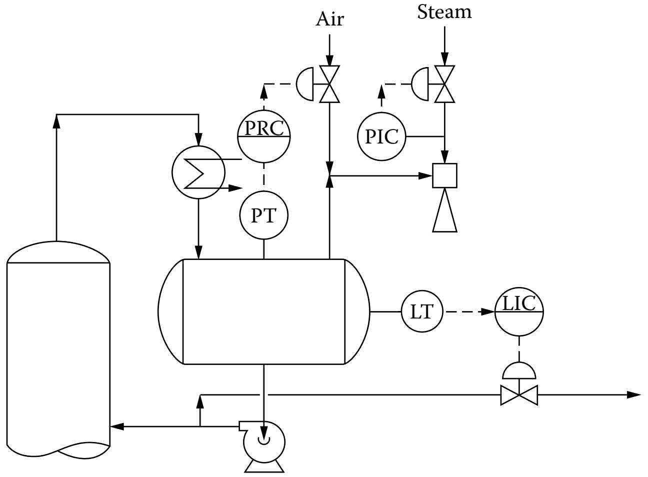


FIG. 8.19kk
Vacuum column pressure control.

can be used singly or in stages, when a wide range of vacuum conditions are required. The acceptance of steam jet ejectors is due to their having no moving parts and requiring very little maintenance.

Most ejectors are designed for a fixed capacity and work best at one steam condition. Increasing the steam pressure above the design point will not usually increase the capacity of the ejector; instead, it will sometimes decrease the capacity because of the choking effect of the excess steam in the diffuser throat.

Steam pressure below a critical value for a jet will cause the ejector operation to be unstable. Therefore, it is recommended that a pressure controller be installed on the steam to keep it at the optimum pressure required by the ejector.

The recommended control system for pressure control in vacuum distillation applications is shown in Figure 8.19kk. Here, a controlled rate of air or gas is bled into the vacuum line just ahead of the ejector. Closing this bleed valve makes the maximum capacity of the ejector available to handle any surges or upsets in the process load. A control valve regulates the amount of bleed air used to maintain the pressure on the reflux accumulator. Using the pressure of the accumulator for control involves less time lag than if the column pressure were used as the control variable.

Because ejectors are fixed capacity, the variable load is met by air bleed into the system. At low loads this represents a substantial waste of steam. Therefore, if substantial load variations are expected, operating costs can be lowered by installing a larger and a smaller ejector. This makes it possible to automatically switch to the small unit when the load drops off, thereby reducing the steam demand.

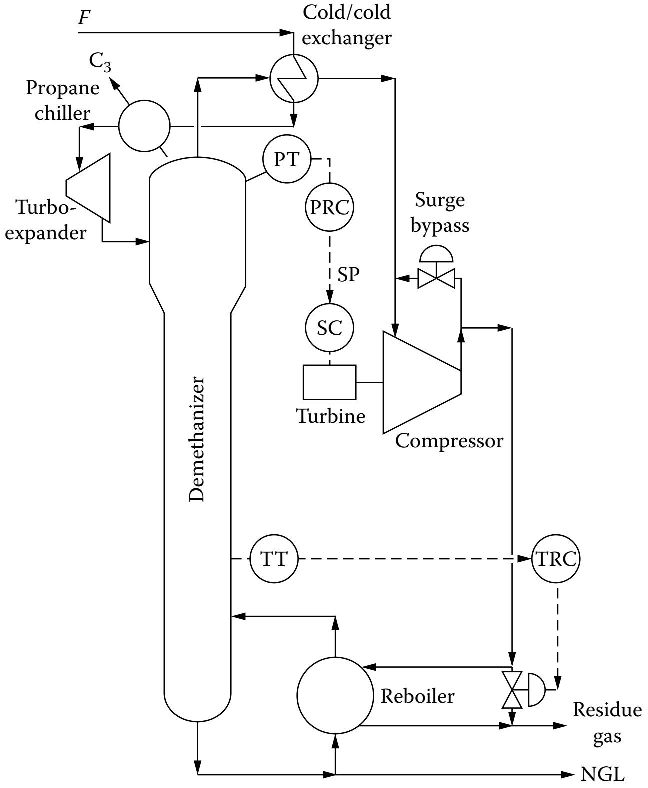

FIG. 8.19ll
Vapor recompression pressure control.

Vapor Recompression

Vapor recompression is another means of improving energy efficiency of the operation. The overhead vapor from the distillation column is compressed to a pressure where its condensation temperature is greater than the boiling point is at the pressure of the tower bottoms. The heat of condensation of the overhead can then be used as the source of heat for reboiling the bottoms.

This scheme is known as vapor recompression. It is used fairly often when the distillation involves a relatively close-boiling mixture, and the boiling points of the top and bottom products are similar. In cryogenic demethanization processes, illustrated in Figure 8.18ll, the column pressure is controlled by the throttling of the speed of the recompression compressors.

The heat of condensation of the overhead is also used as the heat for the reboilers in propylene fractionators. Figure 8.19mm shows the pressure controls needed for the operation of this vapor recompression via the heat pump on this particular tower.

FCCU main fractionators and crude towers make use of compressors to “draw” vapors from the tower because operation is essentially at atmospheric pressures. The pressure control system used in this case is shown in Figure 8.19nn. In this configuration, the tower pressure is maintained by controlling the speed of the compressor. This is accomplished by the manipulation of the steam used to drive the compressor turbine.

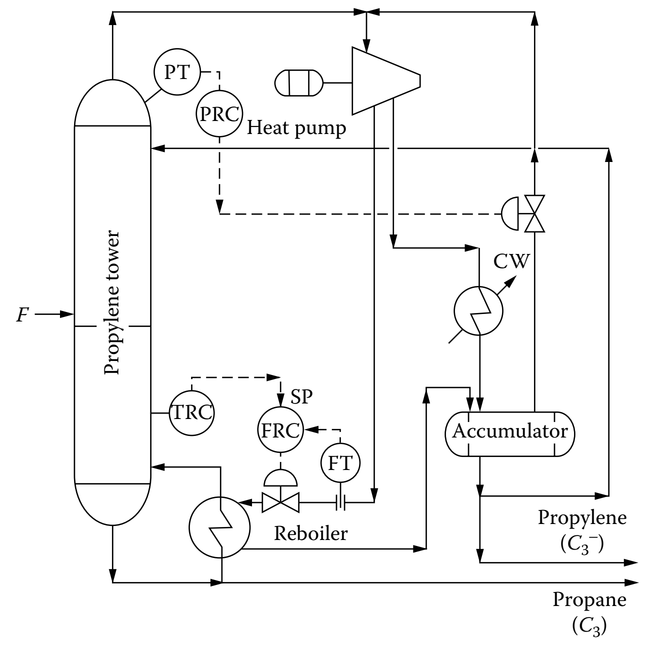

FIG. 8.19mm
Propylene tower vapor recompression pressure control.

FEED CONTROLS

One of the best means of stabilizing the operation of almost any continuous-flow-process, including distillation, is to hold the flow rates and operating temperatures constant. Therefore, whenever possible, a flow controller should be used on the feed to maintain a constant rate of flow.

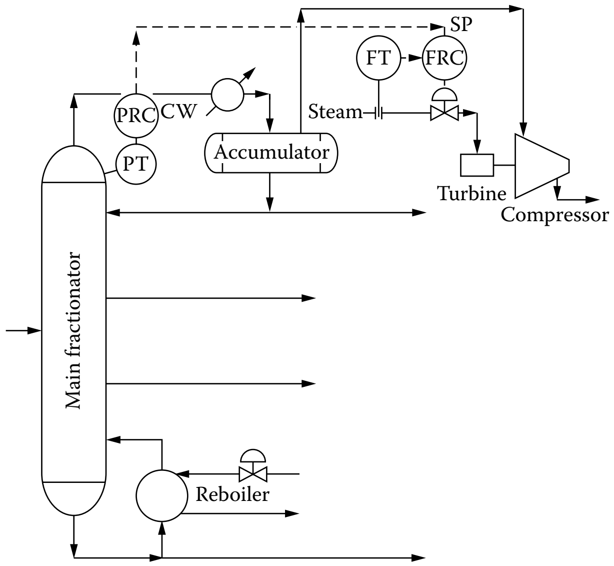

FIG. 8.19nn
Main fractionator pressure control.

Feed Flow Control

A flow controller in the feed line can maintain a constant flow rate. In some instances, the feed pump of a distillation unit is a steam-driven pump instead of an electrically driven one. In this case, the controller modulates the steam to the driver.

Feed composition has a great influence upon the operation of a distillation unit. Unfortunately, feed composition is seldom subject to adjustment. For this reason, it is necessary to make changes elsewhere in the operation of the column in order to compensate for the variations in feed composition. The corrective steps are discussed later. The discussion below assumes a constant feed composition.

Variable Column Feed

Having constant feed conditions simplifies the amount of control required to achieve stable operation. However, the distillate product is often fed to a second column. Then, any changes that occur in the first column are reflected in the quantity and composition of the feed to the second. If the feed flow to the column is controlled by a liquid level controller of the previous column, that controller can be tuned with a low gain, so that the level can swing over a wide range without drastically upsetting the flow of product.

Nevertheless, the second column will receive a varying flow of feed if it is linked to the first column. One way to iron out temporary variations caused by liquid level changes is to cascade the level to a flow controller in the product lines. Flow controllers also serve to smooth out the pressure fluctuations caused by the distillate/reflux pump.

With variable feed rates and variable feed compositions, cascade controls are justified. If the feed rate and composition are relatively constant, resetting the major control loop manually is sometimes adequate. In other cases the flow controller is arranged as the cascade slave of the level controller (Figure 8.19oo). The control algorithm for the level controller in Figure 8.19oo is usually selected to be nonlinear to allow the level to float in the surge tank without changing the FRC set point, which would upset the feed to the next column.

Therefore, the nonlinear controller is so configured that as long as the level in the surge tank is between 25 and 75%,

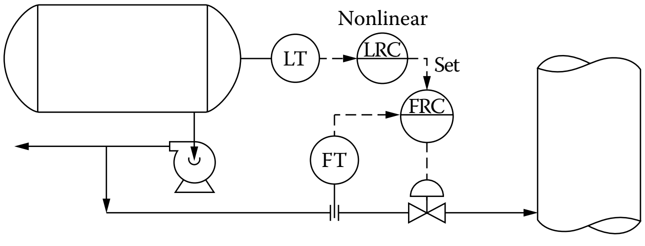

FIG. 8.19oo
Feed flow to the next column is kept relatively constant by the use of a nonlinear level controller (LRC) on the surge tank acting as the cascade master of the slave flow controller (FRC).

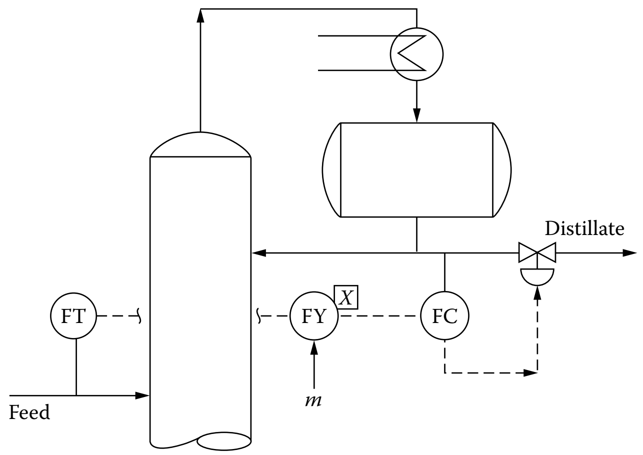

FIG. 8.19pp
Feedforward control minimizes feed rate disturbances.

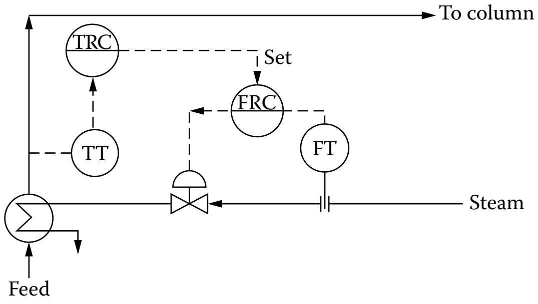

FIG. 8.19qq
The use of a temperature-flow cascade loop improves the column feed temperature controls provided by a preheater.

the set point to the FRC remains constant. This will allow the surge tank to fulfill its purpose and smooth out the load variations between the related processes. If the level drops below 25% or rises above 75%, the FRC set point is reduced or increased respectively to protect it from draining or flooding the tank.

If feed rate disturbances must be accepted by the column, a feedforward control system as shown in Figure 8.19pp can be used to minimize the impact of these disturbances.[10] The ratio, *m*, is selected by performance of a simple material balance around the column. Changing the product flow in proportion to the feed flow minimizes internal column transients and, thus, the quantity of off-spec material during recovery.

The value of *m*, however, is accurate only for one feed composition and will have to be readjusted either manually or automatically for different feed compositions. Dynamic compensation, which will be discussed in more detail in Section 8.21, is also recommended here.

Another method of minimizing feed rate disturbances is to use adaptive tuning or other nonlinear level control techniques (see Section 2.36 in Chapter 2) on the level controller. The key is to allow the accumulator, or the tower kettle, to utilize its capacity to accommodate transient material balance accumulations and act as a "surge drum" to minimize feed flow changes to the next unit.

Feed Temperature Control

The thermal condition of the feed determines how much additional heat must be added to the column by the reboiler. For efficient separation, it usually is desirable to have the feed preheated to its bubble point when it enters the column. Unless the feed comes directly from some preceding distillation step, an outside source of heat is required to achieve that.

Steam may be used to heat the feed, and a thermocouple inside a thermowell can detect the temperature inside the feed line. In this configuration, the temperature of the feed leaving this preheater controls the steam flow into the preheater. In such a cascade configuration, the temperature master is usually a three-mode controller. On start-up, the initially large correction provided by rate action of this three-mode controller helps to get the unit lined out faster. A full discussion of the advantages of cascade loops is provided in Section 2.6 in Chapter 2. Figure 8.19qq describes such a control system on a preheater application.

An alternate feed preheating configuration is to use an economizer on the feed stream. An economizer is a heat exchanger designed to take advantage of the waste heat to preheat the feed. Often, if the bottoms product is just sent to storage, it must be cooled anyway. Therefore, exchanging its heat content with the feed stream accomplishes both the objective of feed preheating and that of product cooling.

Two control configurations are common. If heat from the bottoms product stream is not sufficient, a second exchanger using steam is also installed to augment the heating of the feed, and on this second exchanger, a temperature control system like that previously shown in Figure 8.19qq is used. If the available bottoms product heat is more than sufficient, temperature control is achieved by manipulation of a bypass valve around the economizer, as shown in Figure 8.19rr.

Constant temperature feed does not necessarily mean constant feed quality. If feed composition varies, its bubble point also varies. It is common practice to set the temperature control at a point that is equivalent to the bubble point of the heaviest feed. As the feed becomes lighter, some of it will vaporize, but this variation can be handled by subsequent controls.

FEEDFORWARD CONTROLS

This section discusses the basic single-input–single-output feedback control loops, serving to control the product qualities, feed rate and temperature, and tower pressure. Such feedback systems are capable of compensating for deviations and disturbances only after they have occurred and have been

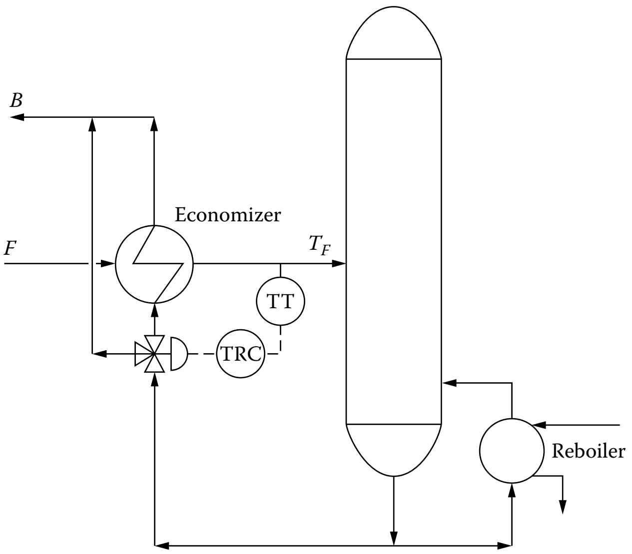

FIG. 8.19rr
The heat content of the bottoms products can be utilized to preheat the feed to the column in an economizer preheater.

detected. When using these simple control schemes, the operators are required to manually adjust the set point of these SISO loops in response to changing plant conditions as they occur. This approach is usually sufficient to keep the distillation column in operation, but it is not sufficient to achieve optimal performance.

As will be discussed in Section 8.21 in more detail, feedforward strategies attempt to compensate for process disturbances in the shortest time possible by accounting for process dynamics, dead times, time delays, and loop interactions.[1] The benefits of better control are:[11]

- Increased throughput
- Increased product recovery
- Energy conservation
- Reduced disturbances to other processing units
- Minimum rework or recycle of off-spec products
- Reduced operating personnel
- Increased plant flexibility

It has been reported that feedforward-based product composition control of distillation can give energy savings of 5–15%.[5]

While feedback-based basic distillation controls only aim at running the processing unit at current conditions, the objective of feedforward control is not only to do that, but also to account for conditions that can be anticipated. The challenge is to utilize the technique, the tools, and available resources to design unique feedforward control strategies that will match the specific objectives for the distillation columns. The choice between any of these control techniques depends upon factors such as preference and familiarity, complexity, degree of compensation, hardware for application, and number of variables monitored and controlled by a single strategy.

Often, additional instrumentation is not necessary when building upon basic feedback control designs to implement feedforward control. However, in many cases, if key measurements are not available and are needed for the feedforward calculation or compensation, the installation of new in-line sensors is also required.

Unlike basic feedback control, where much of the control could be implemented by simple analog control devices, feedforward control strategies generally require more sophisticated level computing systems. In this section, the common applications of feedback-based distillation column controls are discussed. Section 8.21 will discuss feedforward, model-based, and other advanced control systems, including optimization.

CONCLUSIONS

This section deals with some of the more basic control configurations for distillation towers. Section 8.20 describes the calculation of relative gains and Section 8.21 is devoted to the more advanced and optimized control strategies. The separation between these three areas is not very sharp, and some overlap does exist.

In this section, the control strategies for some of the more common distillation problems have been described. Although many other system configurations can exist, they usually are combinations of those presented. Control strategies today are no longer hardware dependent. Most modern microprocessor-based systems are designed with control function modules to execute a variety of the basic strategies that were discussed in this section. Multivariable unit operations controllers of both the model-predictive and the model-free variety are also slowly becoming available and will be discussed in Section 8.21.

It is important to emphasize that control by feedback methods alone cannot approach the quality of control possible by predictive (feedforward) techniques. This is true even though it is likely that the predictive control equations may need to be updated by feedback. In effect, predictive control tends to substantially reduce the size of the errors that are left to be handled by feedback. Further discussion of feedforward strategies and of other techniques for optimization are provided in more detail in Section 8.21.

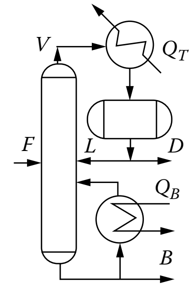
8.20 Distillation: Calculations of Relative Gains

L. A. KANE (1985) **S. OCHIAI** (1995) **S. OCHIAI, F. G. SHINSKEY** (2005)



Flow sheet symbol

INTRODUCTION

A distillation column has anywhere from four to six control loops, which need to be optimally configured if the column is to be stable and meet its performance objectives. Four single loops can be configured in 24 different ways, five single loops in 120 different ways, and six loops in 720 different ways. Some of these configurations can be ruled out on the basis of impossible dynamic response—for example, one would not attempt to control column base level by manipulating the flow of distillate product.

But even after eliminating those from consideration, many possibilities remain. Furthermore, a simple configuration of single loops may not be as effective in controlling product compositions as one that manipulates a logical combination of variables, such as reflux-to-distillate ratio. Logical mathematical combinations of manipulated variables expand the possible number of configurations manyfold.

It has also been observed that a configuration that successfully controls one column will not necessarily be successful on another, requiring each column to be considered on its own merits. Because of the complexity of the configuration problem, and the unique requirements of each individual column, a methodology is required for matching the configuration to the column. That methodology is relative gain analysis (RGA). The basics of RGA are described in detail in Section 2.25. Here, RGA is specially adapted to the particular multivariable control problem represented by distillation columns.

In addition, from the numerical values of relative gains, the open-loop gains are readily calculated. The open-loop gains can help control engineers to conduct plant tests to collect transient responses of distillation columns that are required to implement so-called advanced process control (APC).

RGA FOR DISTILLATION

Each product leaving a distillation column may have the concentration of one of its components controlled. Most columns have two products—distillate and bottom—but many also have a sidestream as well, and the composition loops tend to interact with each other. There are usually three other loops on a column: liquid levels in the base and in the reflux accumulator, and column pressure. (A column operating with a flooded condenser may also have a flooded accumulator, thereby eliminating one level loop.)

All of the economic value in operating a column, however, resides in the composition of its products. There is no inherent value in controlling liquid level or pressure more precisely; therefore, their control should be considered secondary to controlling product compositions. In fact, the configuration of the level loops especially should be based on what will provide the best composition control, and not the best level control. They must function, obviously, or product compositions cannot be controlled, but they must be subservient to the composition loops.

In this light, level and pressure loops should be arbitrarily assigned in such a way as to minimize the interaction among the composition loops. They are faster than the composition loops by an order of magnitude or more, and so cannot be upset by the composition controllers. In the definition of relative gain, the open-loop gain of a pair of manipulated and controlled variables with all other loops open is divided by what it would be with all loops closed. But in a distillation column, the level and pressure loops are always closed, so considering what the compositions would do with level and pressure loops open has no significance.

Two-by-Two Subsets

The interaction between the composition loops is of utmost importance because they are the slowest loops on the column and similar in dynamic response, and have the most economic significance. In a two-product column, the interaction exists between the key impurities in the distillate and bottom products. The controllable key component in the distillate is the heavy key, and in the bottom it is the light key, the column separating the light from the heavy key.

Petroleum fractionators are named after their light key, such as depropanizer, debutanizer, or deisobutanizer.

Each sidestream withdrawn from a column adds a manipulated variable — its flow — and therefore a controlled variable—another composition. However, manipulation of the smallest of the product streams in a single-sidestream column can be arbitrarily assigned to one of the composition loops in a logical procedure described later. This leaves the remaining two composition loops to be configured on the basis of relative gain.

The advantage of limiting consideration to two interacting loops is that only one relative gain needs to be calculated. In Section 2.25, it was explained that relative gain arrays consist of pure numbers whose rows and columns add up to 1.0. A two-by-two array then consists of diagonal elements having values of λ and off-diagonal elements having values of $1 - \lambda$:

$$\Lambda_{12} = \begin{array}{ccc} & m_1 & m_2 \\ y & \lambda_{y1} & 1-\lambda_{y1} \\ x & 1-\lambda_{y1} & \lambda_{y1} \end{array} \qquad \textbf{8.20(1)}$$

For a distillation column, y is the distillate-composition variable, x is the bottom-composition variable, m_1 and m_2 are the manipulated variables selected to control them, and Λ_{12} identifies the two-by-two array that applies those manipulated variables to composition control. Because $\lambda_{x2} = \lambda_{y1}$, the latter alone is enough to identify the entire array, and will be used as such throughout this section, in the form $\lambda_{y1}(\Lambda_{12})$. In practice, λ_{y1} can have different values depending on the choice of the second manipulated variable—for example, $\lambda_{y1}(\Lambda_{12})$ will not equal $\lambda_{y1}(\Lambda_{13})$.

Choice of Manipulated Variables

Figure 8.20a shows a two-product distillation column, identifying all streams and controlled variables. The five controlled variables are the levels in the reflux accumulator and column base, pressure, and the composition of distillate and bottom streams (often sensed as tray temperatures).

The five manipulated variables are distillate flow D, bottom flow B, reflux flow L, vapor boil-up V (as heat input Q_B), and heat removal Q_T. (Feed rate F is an independent variable.) Almost without exception, column pressure is controlled by heat removal to close the heat balance, as condenser cooling tends to be quite variable and difficult to measure. This leaves D, B, L, and V as flows that can be manipulated for composition control, although D and B are not independent of each other, for the overall material balance requires that

$$F = D + B \qquad \textbf{8.20(2)}$$

Two flow ratios are also possibilities as manipulated variables: reflux ratio L/D and boil-up ratio V/B. (Another possibility exists in L/B, but because these streams are at opposite ends of the column, their coordination presents serious dynamic problems, and so this ratio is not used.) A material balance across the reflux accumulator gives

$$V = L + D \qquad \textbf{8.20(3)}$$

which renders the ratios D/V and L/V dependent on L/D.

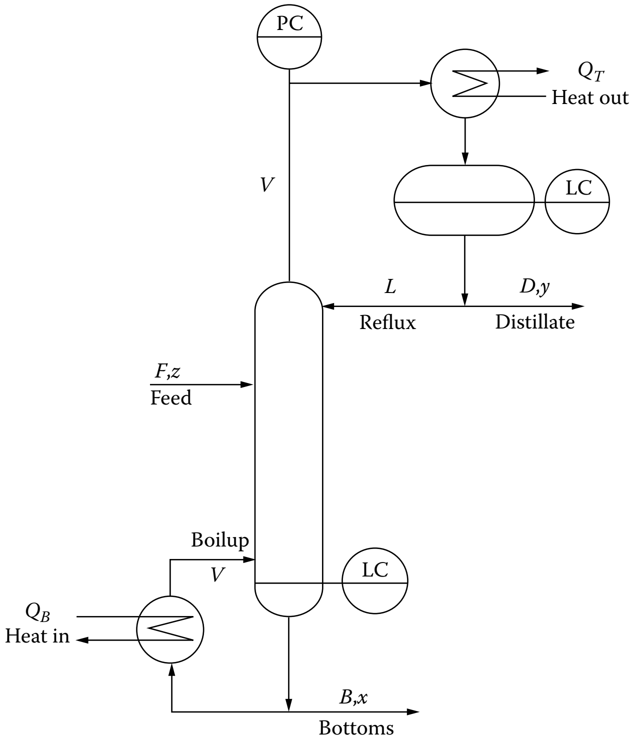


FIG. 8.20a
A typical distillation column has five manipulated and five controlled variables.

So, the independent manipulated variables that can be used for controlling product compositions are D or B, L, V, L/D, and V/B. Only those variables located at the top of the column can be manipulated successfully to control top composition y, and are listed as choices for m_y; those located at the bottom can be manipulated successfully to control bottom composition x, and are listed as choices for m_x. The choices can be displayed in a table such as Table 8.20b.

Each of the Λ terms in the table represents a two-by-two relative gain array. Note that there are only eight, because that in the upper left corner representing $\Lambda_{D/F,B/F}$ would be an array of ±∞, flow rates D and B being dependent on each other. So, there are basically eight different ways to control a two-product column, and therefore eight different two-by-two relative gain arrays.

Finally, each two-by-two array can be represented by a single relative gain number, so each space in the table needs only one number (rather than four) to identify its array. The

TABLE 8.20b
Table of Independent Relative Gain Arrays for Two-Product Distillation

m_y/m_x	D	L	L/D
B	—	Λ_{LB}	$\Lambda_{L/D,B}$
V	Λ_{DV}	Λ_{LV}	$\Lambda_{L/D,V}$
V/B	$\Lambda_{D,V/B}$	$\Lambda_{L,V/B}$	$\Lambda_{L/D,V/B}$

complementary numbers in the off-diagonal elements of each two-by-two array are not useful. For example, in the Λ_{LV} array, the diagonal elements λ_{yL} and λ_{xV} are useful pairs, whereas λ_{yV} and λ_{xL} will have negative values, and their loops are not dynamically viable.

COLUMN MODEL

The method of partial derivatives described in Section 2.25 under Equation 2.25(13) will be used to extract the relative gains. But this requires a differentiable column model. For this purpose, the column model described in Reference 1 is used, as expanded for multicomponent mixtures in Reference 2.

Material Balance

The model begins with the overall material balance of Equation 8.20(2) and continues with a component balance:

$$Fz_i = Dy_i + Bx_i \qquad 8.20(4)$$

where flow rates are in mols/hr, z represents the composition of the feed with all compositions in mol fraction, and subscript i refers to any particular component. When these two equations are combined, we have a single relationship between the two product compositions and the fractional product flow rates:

$$\frac{z_i - x_i}{y_i - x_i} = \frac{D}{F} = 1 - \frac{B}{F} \qquad 8.20(5)$$

Separation

A second relationship is required to reach a solution, and it is derived from the Fenske equation,[3] used for estimating the minimum number of trays required to separate a mixture at total reflux:

$$\frac{y_i/y_j}{x_i/x_j} = \alpha_{ij}^{nE} \qquad 8.20(6)$$

where i and j are any two components in a volatile mixture and α_{ij} is their relative volatility, n is the number of trays and E their fractional efficiency, so that nE is the number of theoretical trays. This relationship can be extended to operating conditions other than total reflux, and applied to the separation of the light l and heavy h key components:

$$\frac{y_l/y_h}{x_l/x_h} = S \qquad 8.20(7)$$

In Reference 1, the separation factor S is related to α^{nE}, and also to the reflux ratio L/D and the light components z in the feed:

$$S = \left(\frac{\alpha}{\sqrt{1 + D/Lz}} \right)^{nE} \qquad 8.20(8)$$

where α is the average relative volatility between the key components across the column.

This model is tractable for a feed stream having four components: the light and heavy keys, a lighter key ll, and a heavier key hh. The lighter is defined as exiting entirely with the distillate and the heavier as exiting entirely with the bottom product; each product stream then contains three components. In the expression above, $z = z_l + z_{ll}$.

To find the product compositions for any given set of feed conditions, distillate, and reflux flow rates, the following quadratic equation must be solved:

$$y_h = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \qquad 8.20(9)$$

where
$$a = (S-1)D/F$$
$$b = Sz_l - (S-1)(D/F - z_{ll}) + z_h$$
$$c = -z_h(1 - Fz_{ll}/D)$$

After solving for y_h, then

$$x_h = \frac{z_h - y_h D/F}{1 - D/F} \qquad 8.20(10)$$

After the heavy-key components in the products are determined, the others are readily calculated from the material balance and separation factor:

$$y_{ll} = \frac{z_{ll}}{D/F} \qquad 8.20(11)$$

$$y_l = 1 - y_h - y_{ll} \qquad 8.20(12)$$

$$x_l = \frac{x_h y_l}{S y_h} \qquad 8.20(13)$$

$$x_{hh} = 1 - x_h - x_l \qquad 8.20(14)$$

Operating Curves

We are primarily interested in controlling the key impurities, which are the heavy key in the distillate y_h and the light key in the bottom x_l. It is revealing to plot these two controlled variables against each other while holding selected manipulated variables constant. A set of such operating curves is shown in Figure 8.20c for a column separating a feed consisting of 1.2% lighter-than-light key, 38.0% light key, 47.0% heavy key, and 13.8% heavier-than-heavy key in 24 theoretical trays. The distillate is to be controlled at 1.5% heavy key and the bottoms at 0.3% light key; the reflux ratio (L/D) is 2.6 and α is 2.11.

The focal point of the curves (where they all cross) is the given set of controlled key impurities. Holding any one of the manipulated variables constant and changing one of the others will move both compositions along the path representing the variable held constant.

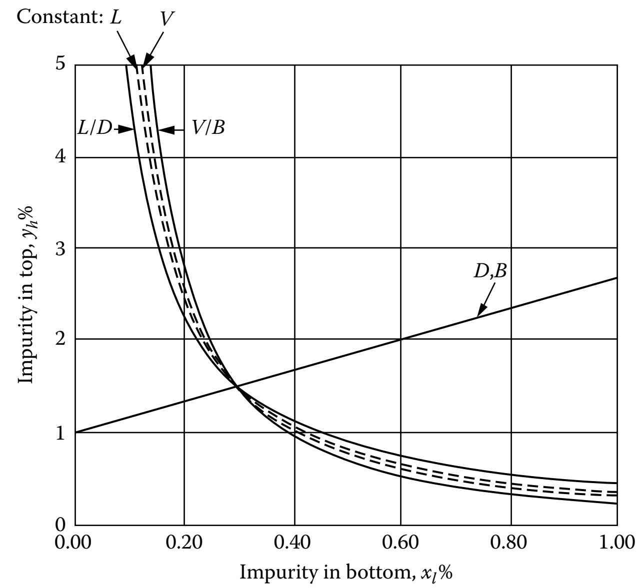

FIG. 8.20c
Each curve shows the relationship between top and bottom composition when that particular manipulated variable is held constant.

For example, if distillate (and hence bottom) flow is held constant and either reflux or boil-up is increased, both product impurities will decrease, moving along the straight line to the left. If reflux were held constant and distillate flow increased, compositions would move upward to the left along the curve represented by constant L, y_h increasing sharply and x_l decreasing to a smaller extent. (Recognize that feed rate is considered constant in this plot, or that L, V, D, and B are held in constant ratio to F.)

The material-balance line where B and D are held constant is given by Equation 8.20(5).

The line in the figure has a positive slope because y_h is plotted against x_l, whereas the Equation 8.20(5) uses the same component in distillate and bottoms. The slope of the material-balance line is always opposite in sign to that of the four hyperbolic curves. The curves are plotted by iterating D/F and calculating y_h and x_l with each of the other manipulated variables held constant.

Observe how closely spaced the four curves are, particularly the two representing constant reflux L and constant boil-up V, which are always the closest together. The curves representing constant reflux ratio and constant boil-up ratio are always on the outside of the envelope. The particular separation described in this example is considered mild. For columns making purer products, or with more trays or a higher reflux ratio, the curves are even more tightly packed. As will be seen later, this increases loop interaction.

Some information can be gleaned from the curves themselves. If they are widely spaced, interaction is slight and almost any control system will work satisfactorily. At the other extreme, if they are tightly packed, a material-balance control system manipulating one or the other product flow must be used if control over both compositions is to be attained, and any of the other manipulated variables can be used with it. Finally, the slope of the material-balance line is instructive. If it is nearly horizontal, then holding distillate flow constant (in ratio to feed rate) will tend to regulate distillate composition; if it is nearly vertical, then holding bottom flow constant (in ratio to feed rate) will tend to regulate bottom composition. In these cases, pairing manipulated and controlled variables is intuitive. For all other cases, however, relative gains should be calculated.

RELATIVE GAIN CALCULATIONS

The relative gains for controlling two compositions in a distillation column is a function of the ratio of the two slopes of the selected operating curves at the focal point:

$$\lambda_{y1} = \frac{1}{1 - \dfrac{(\partial y/\partial x)_2}{(\partial y/\partial x)_2}} \qquad \textbf{8.20(15)}$$

In this expression, the slope of the curve representing a constant manipulated variable m_1, proposed to control top composition, is divided by the slope of the curve representing a constant manipulated variable m_2, proposed to control bottom composition. If either the first approaches zero, or the second approaches infinity, the relative gain will approach 1.0—a favorable but unlikely result in distillation. If the two slopes have opposite signs—in which case one of the manipulated variables would have to be a product flow—the denominator will exceed unity and the relative gain will therefore fall in the range of 0–1. If the two slopes have the same sign—a nonmaterial-balance system—the resulting relative gains will lie outside of the 0–1 range.

Slope Calculations

The slope of the material-balance line is the partial derivative of Equation 8.20(5):

$$\left.\frac{\partial y_i}{\partial x_i}\right|_{D/F} = -\frac{y_i - z_i}{z_i - x_i} = -\frac{B}{D} \qquad \textbf{8.20(16)}$$

However, it needs to be placed in terms of the key impurities. At constant D/F, the partials of the key components have opposite signs: $\partial y_h = -\partial y_l$. Therefore,

$$\left.\frac{\partial y_h}{\partial x_l}\right|_{D/F} = \frac{y_l - z_l}{z_l - x_l} = \frac{B}{D} = \delta \qquad \textbf{8.20(17)}$$

It is given the designation δ because it will appear again in the formulas for the other slopes, which are much more complex.

The slope of the constant-reflux-ratio curve is given the designation σ because it, too, will be part of later formulas:

$$\left.\frac{\partial y_h}{\partial x_l}\right|_{L/D} = \frac{(1-x_{hh})y_l y_h}{(1-y_{ll})x_h x_l} = \sigma \qquad \textbf{8.20(18)}$$

The slope of the constant-reflux curve is a combination of δ, σ, and another term designated ε:

$$\varepsilon = \frac{nEy_l y_h}{2[1+(z_l+z_{ll})L/D](y_l-x_l)} \qquad \textbf{8.20(19)}$$

$$\left.\frac{\partial y_h}{\partial x_l}\right|_{L/F} = \frac{\sigma-\delta\varepsilon}{1-\varepsilon} \qquad \textbf{8.20(20)}$$

The slope of the constant-boil-up curve is similar:

$$\left.\frac{\partial y_h}{\partial x_l}\right|_{V/F} = \frac{\sigma-\delta\varepsilon(1+D/L)}{1-\varepsilon(1+D/L)} \qquad \textbf{8.20(21)}$$

Finally, the slope of the constant-boil-up ratio curve is another extension of these:

$$\left.\frac{\partial y_h}{\partial x_l}\right|_{V/B} = \frac{\sigma-\delta\varepsilon(1+D/L)(\delta-1)}{1-\varepsilon(1+D/L)(\delta-1)/\delta} \qquad \textbf{8.20(22)}$$

Because of the common factors spread throughout the formulas, it is not surprising that the operating curves always fall in the same sequence.

Table of Relative Gains

Using the format given in Table 8.20b, the relative gains will be displayed for the column described by the operating curves of Figure 8.20c.

Again, each of the numbers represents the diagonal pair in a two-by-two array. For example, 0.793 is the relative gain when distillate flow is assigned to control its own composition and boil-up is assigned to control bottom composition.

The off-diagonal pair in each array is not useful and so is not displayed. The numbers in the first row and first column always fall in the 0–1 range because they are the result of material-balance configurations. The other four numbers are always >1; the opposite pairs in these arrays are negative and therefore not useful.

Interpreting the Results

From the set of eight possible relative gains, there will be two on either side of the ideal value of 1.0—one higher and one lower. For relative gains in the 0–1 range, the worst case of interaction would be represented by 0.5, because configurations having lower numbers should be rejected by the designer. In general, relative gains are >0.5 for a less-pure product controlled by its own flow and a more-pure product controlled by one of the other manipulated variables. In the above example, distillate is less pure and is more favorably controlled by its own flow (relative gain of approximately 0.8 vs. 0.2).

TABLE 8.20d
Table of Independent Relative Gain Arrays for the Column of Figure 8.20c

m_y/m_x	D	L	L/D
B	—	0.125	0.236
V	0.793	21.02	6.408
V/B	0.813	6.400	3.963

Of the set of relative gains >1, the higher the number, the worse the interaction. Relative gains in the 1–10 range are controllable, but configurations having numbers >10 should be rejected. For composition loops on a distillation column, relative gain values of 0.5 and 10 give about equivalent levels of interaction.[4]

High relative gain values pose additional problems, however, one of which is increased sensitivity to disturbances associated with high *steady-state* gains. Consider the case for the *LV* subset in Table 8.20d, whose relative gain is 21. Relative gain in a two-by-two system is defined as the ratio of one open-loop gain with the other loop open (i.e., in terms of the other manipulated variable) to the open-loop gain with the other loop closed (i.e., in terms of the other controlled variable). The diagonal elements of Λ_{LV} are

$$\lambda_{xV} = \lambda_{yL} = \frac{(\partial x/\partial V)_L}{(\partial x/\partial V)_y} = 21.0 \qquad \textbf{8.20(23)}$$

However, if reflux ratio were chosen instead of reflux to control top composition, then we would be working with the elements of $\Lambda_{L/D,V}$:

$$\lambda_{xV} = \lambda_{yL/D} = \frac{(\partial x/\partial V)_{L/D}}{(\partial x/\partial V)_y} = 6.41 \qquad \textbf{8.20(24)}$$

Now the denominators in these two expressions are identical because the bottom-composition loop is unchanged, but its steady-state gain is different—it is a function of the configuration chosen for the top loop! Reconfiguring the top-composition loop from manipulating reflux to manipulating reflux ratio actually lowers the steady-state gain of the bottom-composition loop by a factor of 21/6.4 or approximately 3.3.

This allows a 3.3-fold reduction in the proportional band (increase in gain) of the bottom-composition controller, with an accompanying 3.3-fold decrease in peak deviation and integrated error following any disturbance to the column. This improvement has been witnessed following reconfiguration of the control-system structure on distillation columns.

Another reason to avoid configurations having high relative gains is the difficulty in applying decoupling to them. Reference 5 estimates the minimum error in a decoupler that would force the decoupled relative gain of the two loops to infinity—where all control is lost. For a relative gain of 21, the error in the decoupler—that is, its failure to match the parameters of the column perfectly—would have to be only 2.5% to produce a decoupled relative gain of infinity.

This "ill-conditioning" of the basic regulatory control structure has led to the failure of some multivariable predictive controllers to successfully decouple their processes.[5]

The lowest of the relative gains >1 is always the combination of controlling y with reflux ratio and x with boil-up ratio. In the example given in Table 8.20d, the relative gain of 3.96 should give acceptable control, significantly better than the other choices of 6.4. This is also the most complex control system, but has the advantage of built-in feedforward control.

Following an increase in liquid feed, the base level will start to rise, causing the level controller to increase bottom flow and boil-up in their existing ratio. The increased boil-up will raise column pressure and/or level in the reflux drum, causing the pressure or level controller to increase reflux and distillate flows in their ratio. Therefore, all four streams will have increased in ratio to the feed rate, at the right time, without a feedforward calculation having been made. The dynamic balance is achieved without a dynamic compensator required to model the hydraulics of the column below the feed tray.

The material-balance choices have distillate flow manipulated to control its own composition, with relative gains of about 0.8. Performance of these systems will be comparable to the 3.96 relative gain, but they require feedforward control in the way of distillate flow set in ratio to feed rate. To achieve equivalent dynamic response, changes in distillate flow must be converted into opposite changes in reflux flow as follows:

$$L = m_L - kD \qquad \textbf{8.20(25)}$$

where m_L is the output of the level controller on the reflux drum (or the pressure controller if the drum and condenser are flooded). Coefficient k has at least the value of L/D, and can be increased further to speed the response of the top-composition loop.

SIDESTREAM COLUMNS

Each sidestream adds a degree of freedom—a manipulated variable that can be used to control either its own composition or the concentration of an off-key impurity in one of the other products. This treatise will focus on single-sidestream columns as being the most common. The method can also be extended to some columns having two sidestreams, but it is not intended for those having multiple sidestreams, such as crude-oil fractionators.

The problem of assigning control loops to a single-sidestream column can be reduced to the simpler problem of interaction in a two-product column by deductive logic. Most single-sidestream columns will have one product flow that is much smaller than the other two, and it should be placed under material-balance control, as described for three different classes of column described below.

Pasteurization Columns

A pasteurization column has a main product withdrawn a few trays from the top, with a small stream taken overhead, usually as a vapor. An ethylene fractionator operates this way, its major product—ethylene—being withdrawn as a liquid sidestream whose lighter impurity, methane, is purged as a vapor overhead. Control-loop assignment for this column begins by using methane-product flow to control the methane content of the ethylene sidestream. This is an obvious choice, because whatever methane in the feed that is not withdrawn from the top will exit with the ethylene stream—none goes out the bottom.

With this loop assigned, relative gains may be calculated for controlling the heavy key (ethane) in the ethylene product and the light key (ethylene) in the bottom product, as if it were a two-product column. In the slope calculations, use the number of trays between the sidestream and the bottom as n, and the ratio of internal reflux (below the sidestream) to the sidestream flow, as the reflux ratio.

Nonmaterial-balance relative gains for ethylene fractionators tend to be very high, often over 1000, due to a low relative volatility and high product purities. As a result, a material-balance control system is needed, manipulating either the sidestream flow to control its own quality or bottoms flow to control its own composition, depending on the set of relative gains in the 0–1 range. An example is given in Reference 6.

Heavy-Ends Columns

The opposite of a pasteurization column is the heavy-ends column, where a major product is withdrawn as a sidestream vapor a few trays above the bottom. A small stream of heavy ends is taken from the bottom as a liquid to limit their concentration in the vapor product. The top section of the column is normal.

Here again, logic dictates that the flow of the smallest stream—the bottom—should be used to control the heavier impurity in the sidestream. This reduces the problem to one of interaction between the sidestream and distillate composition loops, and their relative gains can be used to select the best manipulated variables. The slope calculations should use the number of trays between the vapor sidestream and the top of the column—no other modifications are necessary.

Small Sidestreams

When a sidestream is the smallest of the flows, it is being used to withdraw a middle-boiling contaminant in the feed. Boiling between the major products, this substance is so volatile that it vaporizes before reaching the bottom, and yet condenses before reaching the top. If it is not intentionally removed as a sidestream, it will accumulate until it occupies most of the trays in the column, thereby reducing the separation between the main products.

This loop assignment is straightforward—sidestream flow is manipulated to control either its own composition or the middle-key impurity in the nearer major product. Then the interaction between the major products is treated in the same way as any two-product column.

An ethanol-water column has two liquid sidestreams—ethanol leaving a few trays below the top, and fusel oil (higher alcohols) withdrawn a few trays above the bottom. A small stream of heads (aldehydes) is removed from the top, and water from the bottom. This is essentially a pasteurization column in that a major product (ethanol) is taken as an upper sidestream.

Heads flow determines the aldehyde content in the ethanol product. Because the ethanol content in the water leaving the bottom is in the parts-per-million range, and the sidestream is not very concentrated, relative gains for material-balance control are typically in the 0.95–0.99 range. The preferred configuration then has ethanol flow controlling its own water content (proof), and boil-up controlling the trace level of ethanol in the water leaving the column base. A small stream of fusel oil is withdrawn to control its own water content—it is typically subcooled and decanted, with the aqueous phase returned to the column.

OPEN-LOOP GAINS IN TERMS OF RELATIVE GAINS

During the last 10 years process control software, advanced process control has been extensively used in the process industries including computer control of distillation columns operation. To develop control systems for distillation columns with it, dynamic characteristics of the column operations have to be identified by intentionally changing inputs to obtain responses of the outputs.

Based on the data of the inputs and outputs, the dynamic models of the columns are developed by using a part of the APC software. The size of an input change must be large enough to produce the sufficient change of the outputs that are clearly above the noise level. However, the input change should not be too large to cause the column upsets that are not only costly but also prolong the test periods. Without theoretical values of eventual changes of the outputs responding to a given input, a trial-and-error approach tends to require excessive time for model building for the APC usage. This aspect is particularly significant for distillation in which time constants are long compared with most "unit operations."

In addition, for most "self-regulating" processes, in which a step change in an input produces outputs that approach some fixed steady-state values, open-loop gains are readily calculated.[7] This is another reason why it is significant to calculate open-loop gains for distillation operations.

As stated above, to obtain the theoretical values of eventual changes of the outputs, we pay attentions to open-loop gains. An open-loop gain is a numerator in the definition of a relative gain; therefore, it is readily expressed in terms of a relative gain. As an example, let the distillation column shown in Figure 8.20a represent a methanol recovery column whose steady-state condition is given in Table 8.20e.

In Table 8.20e, a steady-state condition of a methanol recovery column, which fits to Figure 8.20a in its configuration, is illustrated. However, the performance of the column represented by this figure is different from that treated earlier in Figure 8.20c and Table 8.20b.

Using the definition of relative gain as it was defined in Equations 2.25(1) and 2.25(2) in Section 2.25, Relative Gain Calculations, open-loop gain $\partial y/\partial\, m_1|m_2$ is the sensitivity of y to m_1, whereas the $m_2 - x$ loop is open (control valve opening is constant) and the two level loops are closed (in automatic, and therefore maintaining their set points). Instead of computing the open-loop gains on the basis of their definitions, they will be readily calculated from the relative gains $\lambda_{yD}(\Lambda_{DV})$ and $\lambda_{yL}(\Lambda_{LV})$ by the formulas in Figure 8.20f.

Because the equation

$$\Delta D = -\,\Delta B \qquad \textbf{8.20(26)}$$

holds, derivatives with respect to B are not included in the figure.

Reducing Matrix Models to 2 × 2 Subsets

As described earlier in the paragraph titled RGA for Distillation, we set up 2 × 2 subsets that set x and y against possible

Where

$$\lambda_{yD} = \lambda_{yD}(\Lambda_{DV}) \qquad \textbf{8.20 (45)}$$

$$\lambda_{yL} = \lambda_{yL}(\Lambda_{LV}) \qquad \textbf{8.20 (46)}$$

$$\begin{bmatrix} — & -3.7 & -3.6 \\ 0.079 & — & -3.6 \\ 0.079 & 3.7 & — \end{bmatrix} \qquad \begin{bmatrix} — & -0.858 & 0.862 \\ -0.0036 & — & 0.862 \\ 0.0036 & 0.858 & — \end{bmatrix}$$

Matrices of Calculated Open Loop Gains
for Example #2

FIG. 8.20f

Open-loop gain matrices: y vs. m_i, left, Equation 8.20(43); x vs. m_i, right, 8.20(44). Top row of matrices give the defining equations, the middle row provides the formulas for calculation, and the bottom row gives the results for Example 2.

pairs of manipulated variables. The open-loop gains (numerators) for the pairs in these matrices are then evaluated with only the other composition controller in manual. For example, the subset that assigns m_1 and m_2 to control y and x is denoted by

$$\Lambda_{m_1m_2} = \begin{array}{c|cc} & m_1 & m_2 \\ \hline y & \lambda_{ym_1} & \lambda_{ym_2} \\ x & \lambda_{xm_1} & \lambda_{xm_2} \end{array} \qquad \textbf{8.20(27)}$$

By using similar notations as employed in Equation 2.25(1) in Section 2.25, Relative Gain Calculations, the modified relative gain for controlling y by manipulating m_1 is given by

$$\lambda_{ym_1}(\Lambda_{m_1m_2}) = \frac{\left.\frac{\partial y}{\partial m_1}\right|_{m_2} \text{(level loops closed and } m_2 - x \text{ loop open)}}{\left.\frac{\partial y}{\partial m_1}\right|_{x} \text{(level loops and } m_2 - x \text{ loop closed)}} \qquad \textbf{8.20(28)}$$

Simplified Model for Separation

To compute the relative gains, separation (S) defined in Equation 8.20(7) is used. With notation $y_l = y$, $y_h = 1 - y$,

$x_l = x$, and $x_h = 1 - x$, separation is expressed as

$$S = \frac{y(1-x)}{x(1-y)} \qquad \textbf{8.20(29)}$$

The separation may be thought of as the molar ratio of the light component to the heavy component in the distillate, $y/(1 - y)$, divided by the same ratio, $x/(1 - x)$ in the bottom product.

To keep this discussion and the following discussions more comprehensive, the following equation is used to represent separation:

$$V/F = \beta(\ln S) \qquad \textbf{8.20(30)}$$

where F is the feed flow rate to the column and β is a constant. This representation, outlined by Shinskey[8] in the 1970s, states that the separation is a function of vapor flow rate V. The constant β may be thought of as a factor that determines the separation in terms of the vapor flow rate for a given feed rate. For a given column, β can be obtained by dividing an observed V/F by the natural logarithm of the calculated separation.

The equation does not have the feature as the one that would be derived from Equation 8.20(8). However, the relative gains derived from Equations 8.20(29) and 8.20(30) are simpler and easier to use. Simplification is justified because our objective here is to estimate open-loop gains for the purpose that was described earlier.

Formulas for Relative Gain

Relative gain $\lambda_{yD}(\Lambda_{DV})$ is calculated from Equation 8.20(28) by computing the partial derivatives:

$$\lambda_{yD}(\Lambda_{DV}) = \frac{\partial y/\partial D|V}{\partial y/\partial D|x} = \frac{\partial y/\partial (D/F)|V}{\partial y/\partial (D/F)|x} \qquad \textbf{8.20(31)}$$

According to Equation 8.20(30), in which it is assumed that only V and S are variables, the numerator of the first equation is equal to $\partial y/\partial D|S$. Equations 8.20(29) and 8.20(31), together with material and component balance equations

$$F = D + B \qquad \textbf{8.20(32)}$$

$$Fz = Dy + Bx \qquad \textbf{8.20(33)}$$

will lead to:[9]

$$\lambda_{yD}(\Lambda_{DV}) = \frac{1}{1 + \dfrac{(y-z)x(1-x)}{(z-x)y(1-y)}} \qquad \textbf{8.20(34)}$$

where z is molar fraction of the light component in the feed. As described, the relative gain array has the number in every row and column summing to 1.0. Therefore,

$$\Lambda_{DV} = \begin{array}{c|cc} & D & V \\ \hline y & \lambda_{yD}(\Lambda_{DV}) & 1-\lambda_{yD}(\Lambda_{DV}) \\ c & 1-\lambda_{yD}(\Lambda_{DV}) & \lambda_{yD}(\Lambda_{DV}) \end{array} \qquad \textbf{8.20(35)}$$

Similarly, relative gain array Λ_{LV} can be written as

$$\Lambda_{LV} = \begin{array}{c|cc} & L & V \\ \hline y & \lambda_{yL}(\Lambda_{LV}) & 1-\lambda_{yL}(\Lambda_{LV}) \\ x & 1-\lambda_{yL}(\Lambda_{LV}) & \lambda_{yL}(\Lambda_{LV}) \end{array} \qquad \textbf{8.20(36)}$$

In the same way Equation 8.20(34) was derived, the value of $\lambda_{yL}(\Lambda_{LV})$ can be determined as

$$\lambda_{yL}(\Lambda_{LV}) = \left[1 + \frac{\beta(y-x)^2}{y(1-y)(z-x)}\right]\lambda_{yD}(\Lambda_{DV}) \qquad \textbf{8.20(37)}$$

Relative gain array for Λ_{DL}, which (as it was described previously) is equal to Λ_{BL}, is given by Equation 8.20(38):

$$\Lambda_{DL} = \begin{array}{c|cc} & D & L \\ \hline y & \lambda_{yD}(\Lambda_{DL}) & 1-\lambda_{yD}(\Lambda_{DL}) \\ x & 1-\lambda_{yD}(\Lambda_{DL}) & \lambda_{yD}(\Lambda_{DL}) \end{array} \qquad \textbf{8.20(38)}$$

Equations 8.20(34) and 8.20(37) will be used to obtain numerical values of matrices for open-loop gains y vs. m_i, which are contained in Equations 8.20(43) and 8.20(44) in Figure 8.20f.

Example 1

In Table 8.20e, pertinent steady-state conditions for a methanol recovery column[10] are shown. As illustrated in Table 8.20e, the column separates methanol from a methanol-formaldehyde-water mixture. Methanol is the light component and its molar fraction in the feed is z.

For simplicity, formaldehyde and water will be lumped as a heavy component whose "combined" molar fraction in the feed is $1 - z$. The same applies to the distillate and bottom products listed in Table 8.20e. By substituting the values of x, y, and z from Table 8.20e into Equation 8.20(34), and from Equations 8.20(35), 8.20(36), and 8.20(38), the relative gain arrays Λ_{DV}, Λ_{LV}, and Λ_{BL} are

$$\Lambda_{DV} = \begin{array}{c|cc} & D & V \\ \hline y & 0.165 & 0.835 \\ x & 0.835 & 0.165 \end{array} \qquad \textbf{8.20(39)}$$

$$\Lambda_{LV} = \begin{array}{c|cc} & L & V \\ \hline y & 39.6 & -38.6 \\ x & -38.6 & 39.6 \end{array} \qquad \textbf{8.20(40)}$$

$$\Lambda_{DL} = \Lambda_{BL} = \begin{array}{c|cc} & B(or\,D) & L \\ \hline y & 0.162 & 0.838 \\ x & 0.838 & 0.162 \end{array} \qquad \textbf{8.20(41)}$$

With reference to Equation 8.20(41),

$$\lambda_{yL}(\Lambda_{BL}) = \lambda_{xB}(\Lambda_{BL}) = 0.838 \qquad \textbf{8.20(42)}$$

Equations 8.20(43) to 8.20(46) are given in Figure 8.20f.

Open-Loop Gains

The open-loop gains, which are the numerators of the definition of the relative gains, should be considered. Open-loop gain $\partial y/\partial m_1|m_2$ is the sensitivity of y to m_1, while the $m_2 - x$ loop is open (control valve opening is constant) and the two level loops are closed (in automatic, and therefore maintaining their set points). Even when the relative gains are used in selecting the pairing of the controlled and manipulated variables, the designer should make sure that the open-loop gains are not too small. Instead of computing the open-loop gains on the basis of their definitions, they are readily calculated from the relative gains $\lambda_{yD}(\Lambda_{DV})$ and $\lambda_{yL}(\Lambda_{LV})$ by the formulas in Figure 8.20f.[10] Because Equation 8.20(26) holds, derivatives with respect to B are not included in the figure.

Example 2

If, for the distillation process of the previous example, the top product composition were more important than the bottom, the designer might use open-loop gains instead of relative gains to select variable pairing. The open-loop gains listed below have been calculated from the equations in the left-side matrices in Figure 8.20f. From Equation 8.20(43) in the figure,

$$\left.\frac{\partial y}{\partial (D/F)}\right|_v = -\left.\frac{\partial y}{\partial (L/F)}\right|_v = -3.7 \qquad \textbf{8.20(47)}$$

This equation means that for a fixed vapor flow rate V, or approximately for a fixed flow rate of the heating medium to the base reboiler (Q_B), an incremental increase in distillate-to-feed-flow ratio (or corresponding decrease of reflux-to-feed-flow ratio) will decrease the molar fraction of methanol in the top product by a factor of 3.7. Similarly, for a fixed reflux flow rate L, from Equation 8.20(43) in Figure 8.20f,

$$\left.\frac{\partial y}{\partial (D/F)}\right|_L = \left.\frac{\partial y}{\partial (V/F)}\right|_L = -3.6 \qquad \textbf{8.20(48)}$$

and for a fixed top product flow, from Equation 8.20(43),

$$\left.\frac{\partial y}{\partial (V/F)}\right|_D = \left.\frac{\partial y}{\partial (L/F)}\right|_D = 0.079 \qquad \textbf{8.20(49)}$$

The absolute values of the open-loop gains in Equations 8.20(47) and 8.20(48) are about the same, whereas that of Equation 8.20(49) is much smaller. Therefore, only control actions corresponding to Equations 8.20(47) and 8.20(48) should be considered. Based on this and on the preference for material-balance control[8] over energy balance, the recommended choice of pairing the controlled and manipulated variables as shown in Figure 8.20g might be obvious to many readers.

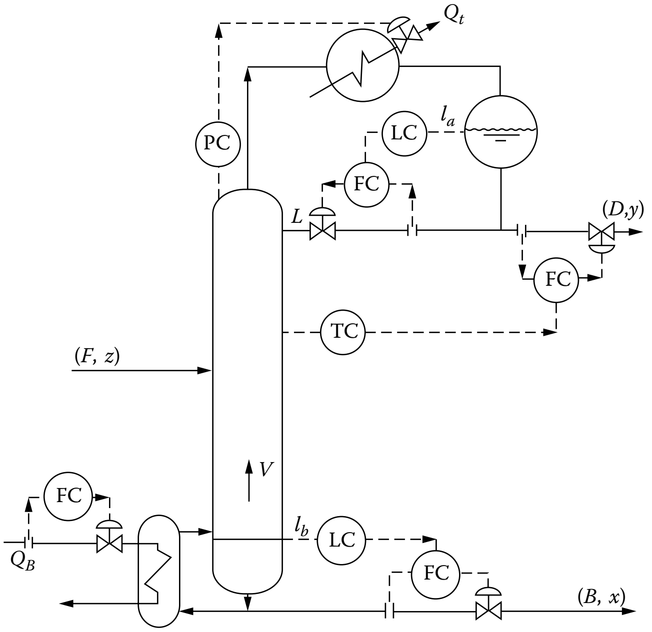

FIG. 8.20g
Pairing of controlled variables with manipulated variables as selected in Example 2.

A step-by step approach for arriving at the same conclusion is given in Reference 10.

CONCLUSIONS

A distillation column has anywhere from four to six control loops, which need to be optimally configured if the column is to be stable and meet its performance objectives. Four single loops can be configured in 24 different ways, and logical mathematical combinations of manipulated variables expand the possible number of configurations manyfold.

Because of the complexity of the configuration problem, and the unique requirements of each individual column, a methodology is required for matching the configuration to the column. That methodology is relative gain analysis. The basics of RGA, described in detail in Section 2.25, were specially adapted in this section to the particular multivariable control problem represented by distillation columns.

In addition, from numerical values of relative gains, open-loop gains were also readily calculated. The open-loop gains will help control engineers to conduct plant tests to effectively collect transient responses of distillation columns that are required to implement so-called advanced process control.

NOMENCLATURE

B	Bottom product flow rate
D	Distillate flow rate
E	Tray efficiency

F	Feed flow rate
h	Suffix indicating heavy key component
hh	Suffix indicating heavier key component
k	Coefficient defined in the descriptions that follow Equation 8.20(25)
L	Reflux flow rate
l	Suffix indicating light key component
ll	Suffix indicating lighter key component
l_a	Liquid level in overhead receiver
l_b	Liquid level in column base
m_i	Manipulated variable
m_L	Output of level controller on the reflux drum (or output of pressure controller if the drum and condenser are flooded)
n	Number of trays
P	Column pressure
Q_B	Heat input rate to base reboiler
Q_T	Heat removal rate at overhead condenser
S	Separation
V	Vapor flow rate
x	Molar fraction of light component in bottom product
y	Molar fraction of light component in distillate
z	Molar fraction of light component in feed

GREEK LETTERS

α	Average relative volatility between the key components across the column
β	Positive constant defined by descriptions that follow Equation 8.20(30)
∂	Partial derivative
δ	Constant defined in Equation 8.20(17)
Δ	Deviation from a steady-state condition
ε	Constant defined by Equation 8.20(19)
Λ	Relative gain array
λ	Relative gain
σ	Slope of constant-reflux-ratio curve defined by Equation 8.20(18)

INTRODUCTION

Section 8.19 described the basic, single-input single-output (SISO) distillation control systems. These simple control schemes do keep the operation stable, but they cannot optimize it and they do necessitate that the operator, as plant conditions change, periodically readjust the set points of these SISO loops.

In Section 8.20, it was noted that a two-product distillation tower has five controlled and five manipulated variables. Because pressure is usually controlled to close the heat balance and the two levels are controlled to close the material balance around the column, eight configurations are possible to control product compositions (Table 8.20b). Interaction always exists between the material and energy balances in a distillation column. Section 8.20 describes how the interaction between the two composition control loops can be minimized by calculating the eight corresponding relative gain (RG) values and selecting the pairing, which gives an RG closest to 1.0.

Control of distillation towers involves the manipulation of the material and energy balances in the distillation equipment to affect the composition of the products. This section builds upon the previous two, while focusing on optimization and on the use of multivariable advanced process controls (APC).[1] In today's competitive market, it is necessary to push equipment to operating limits to maximize production rate or minimize the energy cost of production.

Advanced process controls are usually distinguished from regulatory SISO controls by being multivariable in nature (multiple input/multiple output) and by utilizing some model of the process. The APC products on today's market can be distinguished on the basis of their approach to modeling the process. They can be grouped into three categories: The *white box* models apply to well understood processes, such as distillation, where theoretical dynamic models of the process can be derived based on mass, energy, and momentum balances of the process.

The *fuzzy logic* and *black box* models are used for processes that are poorly understood or when it is acceptable to use a complete mechanistic empirical model constructed solely from *a priori* knowledge. Because of the well-understood nature of distillation, this section will give emphasis to the white box approach to modeling.

The goal of this section is to provide instrument engineers with the tools necessary to design *unique* advanced control strategies that will match the requirements of the specific distillation columns they encounter. The section will first discuss the various APC control strategies, and after that it will describe a variety of optimization schemes. After a listing of APC-related definitions, the discussion of APC in distillation will first discuss the black box and the fuzzy logic techniques, which are less applicable to this well-understood process. After this brief treatment, a more detailed discussion of the development of the white box models will be presented.

Definitions

ARTIFICIAL NEURAL NETWORKS (ANN): ANNs can learn complex functional relations by generalizing from a limited amount of training data; hence, they can thus serve as black box models of nonlinear, multivariable static and dynamic systems and can be trained by the input/output data of these systems. ANNs attempt to mimic the structures and processes of biological neural systems. They provide powerful analysis properties such as complex processing of large input/output information arrays, representing complicated nonlinear associations among data, and the ability to generalize or form concepts-theory.

BLACK BOX MODEL: *See* EMPIRICAL MODEL.

EMPIRICAL MODEL: This type of model can be used for processes for which no physical insight is available or used. This model structure belongs to families that are known to have good flexibility and have been "successful in the past." The parameters of the models are identified based on measurement data. A complete mechanistic model is constructed from *a priori* knowledge.

FUZZY LOGIC MODELING: This type of model is used for processes that are not fully understood. It is a linguistically interpretable rule-based model that is based on the available expert knowledge and measured data.

MODEL-BASED CONTROL (MBC): In model-based control, a process model is used to make control decisions. The controller uses this model of the process to calculate a value for the manipulated variable, which should make the controlled variable behave in the desired way. The "inverse" nomenclature arises from how the model is used. In a normal modeling approach, one specifies the process input, and the model predicts the process output response. By contrast, MBC determines the process input (manipulated variable) that will cause a desired process output response (controlled variable value) to occur. This is the model inverse.

MODEL PREDICTIVE CONTROL (MPC): is a model-based control technique that uses process output prediction and calculates consecutive controller moves in order to satisfy control objectives.

OPEN-LOOP GAIN: The steady-state gain of a control loop when the other control loop(s) is (are) in manual. (Their control valve opening is constant.)

RELATIVE GAIN: RG is the ratio of the steady-state gain of the loop with other loops in manual, divided by the steady-state gain of the loop when the other loops are in automatic.

RELATIVE GAIN ARRAY: A matrix of dimensionless gain ratios giving one RG value for each pairing of manipulated and controlled variables.

WHITE BOX MODELING: This type of modeling is feasible if a good understanding of the process exists. In such cases, the dynamic models are derived based on mass, energy, and momentum balances of the process.

ADVANCED PROCESS CONTROL

Fuzzy logic- and black box-type model-free expert systems can be compared to the behavior of tennis players. The players do not necessarily understand Newton's laws of motion or the aerodynamic principles that determine the behavior of a tennis ball, but they have simply memorized the results of a large number of past responses. This is also the basis of human learning. All the neural network software packages on the market mimic this method of learning.

Neural networks, fuzzy logic, and statistical process control are all such methods, which can be used without the need for knowing the mathematical model of the process. The major difference between fuzzy logic and neural networks is that the latter can only be trained by data, but not with reasoning. Fuzzy logic is superior from this perspective, because it can be modified both in terms of the gain (importance) and also in terms of the functions of its inputs.

The main limitations of all model-free expert systems is their long learning period (which can be compared to the growing up of a child) and the fact that their knowledge is based solely on past events. Consequently, they are not prepared to handle new situations, and therefore if the process changes, they require retraining, because they are not well suited to anticipation.

Model-based control, model predictive control, and internal model control (IMC) are all based on white box modeling and are all suited for the optimization of such unit processes that are well understood, such as heat transfer or distillation. Their performance is superior to that of the model-free systems (fuzzy logic and black box), because they are capable of anticipation and, thereby, can respond to new situations. In this sense their performance is similar to that of feedforward control systems, while the model-free systems behave in a feedback manner only.

In this section, the APC control strategies that are based on fuzzy logic and black box models will be discussed first. This discussion will be followed by a more in-depth explanation of the white box model-based controls.

The Goals of APC Advanced control strategies attempt to compensate for process deviations in the shortest time possible by accounting for process dynamics, dead times, time delays, and loop interactions. The benefits of better control are:[2]

- Increased throughput
- Increased product recovery
- Energy conservation
- Reduced disturbances to other processing units
- Minimum rework or recycle of off-spec products
- Reduced operating personnel
- Increased plant flexibility

For example, good product composition control of distillation towers can save 5–15% of the energy required to achieve the required separation.[3]

The goal of basic distillation controls is to keep the unit running. The objective of advanced control is to keep it running at maximum profitability. The techniques available to implement advanced control include feedforward control; optimization, including constraint control; and model-based and multivariable control (MVC).

The challenge is to utilize the technique, the tools, and the available resources to design *unique* advanced control strategies that will match the specific objectives for the distillation columns. The choice between any of these control techniques depends upon factors such as preference and familiarity, complexity of scheme, degree of optimization, hardware for application, and number of variables monitored and controlled by single strategy.

Often, additional instrumentation is not needed when implementing advanced controls by building upon basic control designs. However, in many cases, new measurements are needed for calculation or compensation in order to implement an advanced control strategy. These must be retrofitted to the process.

Unlike basic distillation control, in which much of the control can be implemented by analog control systems, advanced control strategies usually require the use of higher-level computing systems. Optimization programs and model-based controls require large amounts of computing power. It is for this reason that APC control systems can be distributed over a variety of control equipment types in some kind of hierarchical or distributed fashion.

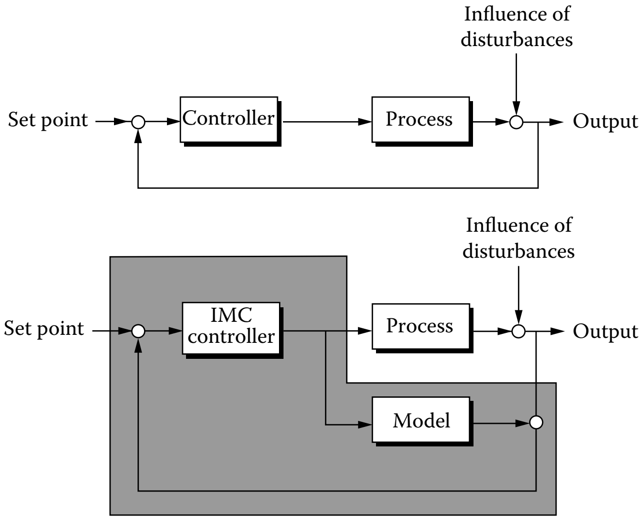

FIG. 8.21a
The configuration of a PID control loop (top) and an internal model controller loop (bottom).

Model-Based Control

The strategies presented in Sections 8.19 and 8.20 implement distillation control using PID controllers. Efforts have been made to improve PID performance by considering the dynamic nature of the fractionator, the nonlinearity of the system, and the decoupling of interactions.

Model-based controls have been gaining increasing popularity and have been discussed in detail in Sections 2.13 to 2.18 in Chapter 2. These use alternatives to the PID algorithms such as the internal model controller,[12] model algorithmic control,[13] dynamic matrix control,[14] and neural controllers.[15] Process model-based control uses an approximate process model directly for control in order to overcome the coupling effects in the distillation tower.

Most of these methods are nonlinear, all are predictive, and many are multiple–input multiple-output (MIMO). All depend upon the availability of some process model. Once a process model has been established, it is possible to build the inverse of that model, which can be used as a controller. In that sense, the PID controller is a linear inverse model of a single loop.

All control design is basically a model-based activity. This is true even with the PID controller, which uses first- and second-order lag approximations of the process to determine tuning parameters. An alternative to the PID controller is a linear model built into the controller. A simple model-based controller is the internal model controller. The difference between the PID and IMC controller is shown in Figure 8.21a.

Note that the IMC looks like it has the same structure as a Smith predictor in Figure 8.19x in Section 8.19. The difference is that the process model is explicitly an internal part of the controller model in the IMC. For a first-order system with dead time, a Smith predictor (Figure 8.19x) with a PI controller is equivalent to an IMC.

Nonlinear approximate models include algebraic representation of the McCabe-Theile diagram for both rectifying and stripping sections, short-cut fractionator calculations, and others.[16] These methods require the power of a computer to solve the equations. A number of control strategies also exist once the process model is known. For dual composition control, one method is the generic model control (GMC),[17] whose control law is described by the following equations:

$$y_{ss} = y_o + K_{1,1}(y_{sp} - y_o) + K_{2,1}\int (y_{sp} - y_o)\,dt \qquad \textbf{8.21(1)}$$

$$x_{ss} = x_o + K_{1,2}(x_{sp} - x_o) + K_{2,2}\int (x_{sp} - x_o)\,dt \qquad \textbf{8.21(2)}$$

where

x_{sp} and y_{sp} = the target set points for bottoms and overhead products
x_{ss} and y_{ss} = the specifications for bottoms and overhead products
x_o and y_o = the current compositions
K = tunable parameters for disturbance rejection

For example, if $K_{1,2} = 2.5$, $K_{2,2} = 0$, $x_{sp} = 2\%$, and $x_o = 1\%$, then $x_{ss} = 3.5\%$. x_{ss} is then used in the process model as the basis to compute *V*/*B* or any other output (manipulated) variable. Because the same action can be performed for y_{ss} with y_{ss} being substituted into a process model equation, such as *D*/*L*, the model-based control can be multivariable, handling nonlinearity, disturbances, and coupling, by tuning the *K* values.

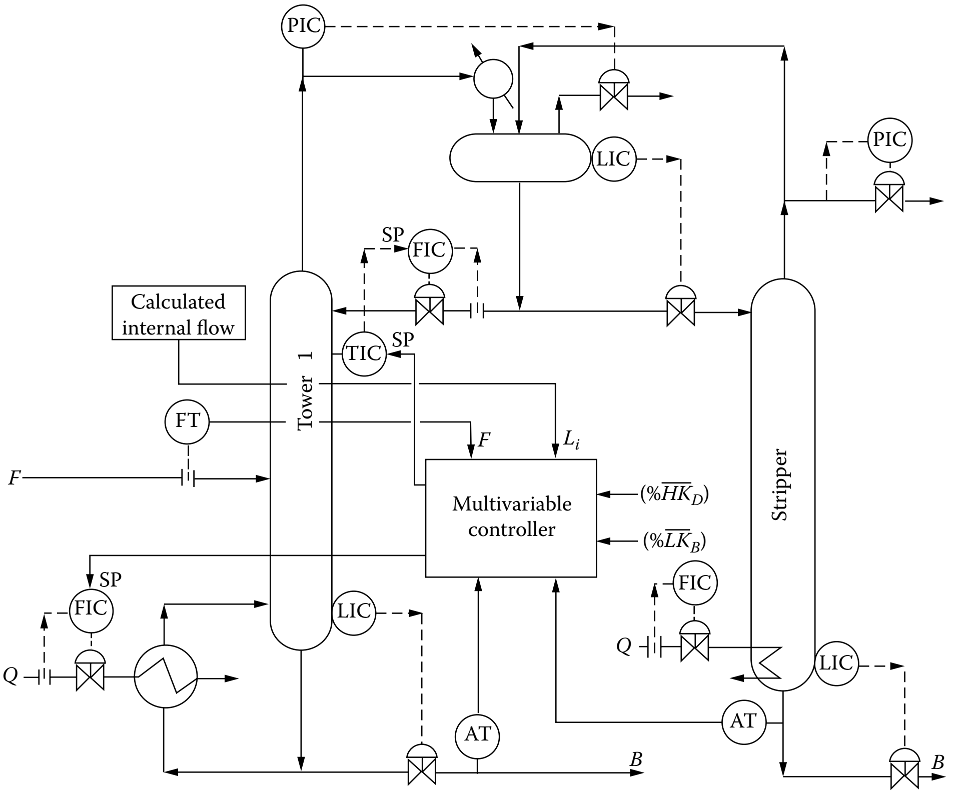

FIG. 8.21b
Fractionator control using a multivariable controller.

Multivariable Control

Multivariable control is a technique that services multiple-input, multiple-output algorithms simultaneously as opposed to the single-input, single-output ones. MVC is particularly well suited for highly interactive multivariable fractionators, where several control loops need to be decoupled. In general, the more difficult the process, the greater are the benefits of multivariable control. Multivariable control techniques can take safety constraints, process lags, and economic optimization factors all into consideration.

Like the model-based controller, the MVC-type controller is a predictive controller that uses information from the past plus dynamic models of the process to predict future behavior. Based upon predicted responses, the controller plans future moves to manipulated variables that will minimize the errors in each dependent controlled variable (Figure 8.21b).

The control diagram shown in Figure 8.21b illustrates an application of a multivariable controller. In the example, two products and an impurity stream are separated using two towers. The objective is to control the composition of both products. The two composition control loops are coupled so that when any single control action is taken to control one composition, that action also affects the other composition.

In this example, the controlled variables are the two product compositions as measured by process analyzers. Feed flow rate is a disturbance variable. The steam to the first column and the temperature at the top of that column are the manipulated variables. A constraint variable is an internal flow as calculated from other tower temperatures and flows.

The multivariable controller will take the appropriate steps to control both compositions, subject to the calculated constraint, by adjusting the two manipulated variables while accounting for the dead time caused by the stripper.

The identification and command (IDCOM)[13] method is a type of multivariable model algorithmic control. It is based on a process impulse response, which utilizes a predictive heuristic scenario technique to calculate the manipulated variable. The technique is to use a dynamic model to determine future values of the controlled variables. These calculated future values are compared to a desired reference set point trajectory. The manipulated variables are then adjusted to force future controlled variable values to follow the desired reference trajectories.

The technique of multivariable control requires the development of dynamic models based upon fractionator testing and data collection. Multivariable control applies the dynamic models and historical information to predict future fractionator characteristics. Predicted fractionator responses result in planned controller actions on the manipulated variables to minimize error for the dependent controlled variable, while considering constraints in the present and the future.

This controller is similar to a PID controller, except that the multivariable controller accepts several controlled variable set points and load variable measurements and, subject to constraints, outputs several manipulated variables.

All multivariable techniques require some sort of process model. Differences between various multivariable techniques lie in their calculation of internal models (whether nonlinear or linear), their method of predicting the future, their method of constraint handling, and their method for minimizing the controller's error.

Multivariable control may be considered to be an "overkill" and at worst a poor controller, if simpler techniques are adequate. However, for towers that are subject to constraints, towers that have severe interactions, and towers with complex configurations, multivariable control can be a valuable tool.

Dynamic Matrix Control

A multivariable predictive controller is based on dynamic matrix control.[14] DMC is a predictive control technique that uses a set of linear differential equations to describe the process. The DMC method is based upon a process step response and calculates manipulated variable moves via an inverse model. Coefficients for the linear equations describing the process dynamics are determined by process testing. A series of tests are conducted whereby a manipulated or load variable is perturbed and the dynamic response of all controlled variables is observed. This identification procedure is time-consuming and requires local expertise because of the experimentation involved. Once the models are obtained, the controller design can be designed.

The least-squares approach is taken to minimize the error of the controlled variables from their set points. Weighting constants scale controlled variable errors and influence which controlled variables are allowed to deviate from their set points if a constraint is encountered. The controller considers constraints in its plan for both present and future moves in each manipulated variable. Other factors affecting the response of the DMC controller are parameters that govern the relative amount of movement in the manipulated variables and the rate at which errors are reduced. This is analogous to the tuning parameters in a PID controller.

Artificial Neural Networks

As was discussed in detail in Section 2.18 in Chapter 2, one of the tools used in building internal models is the Artificial Neural Network, which can usually be applied under human supervision or integrated with expert or fuzzy logic systems. Figure 8.21c shows a three-layer, back-propagation ANN that serves to predict the manipulated variables of a column. Such predictive ANN models can be valuable, because they overcome the limitations of analyzers, which include both availability and dead time.

The process model's knowledge is stored in the ANN by the way the processing elements (nodes) are connected and the importance that is assigned to each node (weight). The ANN is "trained" by example, and therefore it contains the adaptive mechanism for learning from examples and to adjust its parameters based on the knowledge that is gained through this process of adaptation. During the "training" of these networks, the weights are adjusted until the output of the ANN matches that of the real process. Naturally, these networks do need "maintenance," because process conditions change, and when they do, the network requires retraining. The hidden layers help the network to generalize and even to memorize.

The ANN is capable to learn input/output relationships and inverse relationships, and hence it is useful in building internal model control based on the ANN-constructed plant models and their inverses. In a neural controller (Figure 8.21d), the ANN is used in calculating the control signal.

Neural Control The PID controller is the basic feedback mechanism for correcting errors between the current condition (measurement) and what is desired (set point). The PID assumes a linear process. Adaptive control and other techniques are used when nonlinearities are encountered (see Section 2.19 in Chapter 2). However, because of the structure of neural networks with their distributed representation, the neural controller promises the ability of adaptation, learning, and generalization to nonlinear problems.[18]

In the single-input, single-output configuration, instead of utilizing the basic PID equation, the network builds an internal nonlinear model, relating the controlled and corresponding manipulated variable. It builds this model by learning or "training" from a data set of known measurements and process responses. Often, a primary disturbance variable is included in this model. The dynamic response is recorded for the training data set. This makes the neural controller more useful and more robust than the standard PID.

These controllers most often use the back-propagation method of training to relate controlled, manipulated, and load variables (see Section 2.18 in Chapter 2). Figure 8.21c illustrates the simple back-propagation neural network used to create the nonlinear model.

Because the neural network paradigm can accommodate multiple inputs and multiple outputs, an entire fractionator model can be built into a single controller. The neural controller can be thought of in the same terms as model-based control algorithms, whereby the neural network is used to obtain the inverse of the process model. A back-propagation network can be trained to obtain the inverse model by considering load and controlled variables in its input vector and manipulated variables in its output vector. An example of a neural network controller on a distillation tower control application is shown in Figure 8.21e.

Building the Neural Model To build such a model, all inputs and outputs must first be normalized based upon expected minimum and maximum values and are presented to the network as the training set. All weights and processing element offsets are initially set to small random values. A recursive algorithm starting at the output processing elements

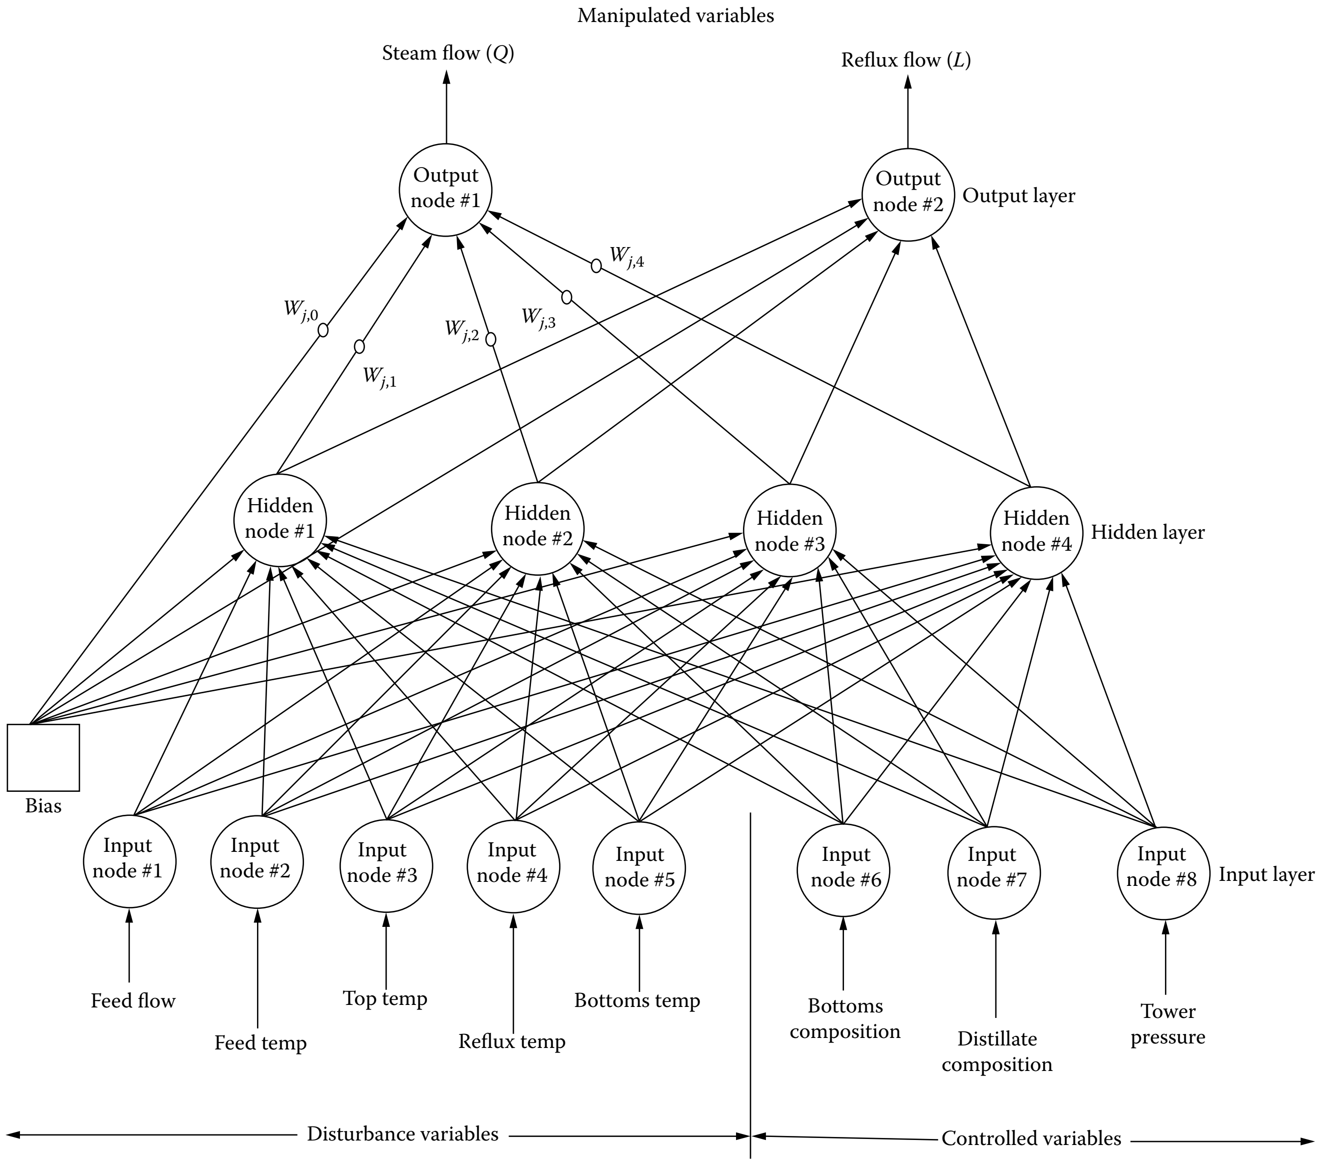

FIG. 8.21c
Back-propagation neural network.

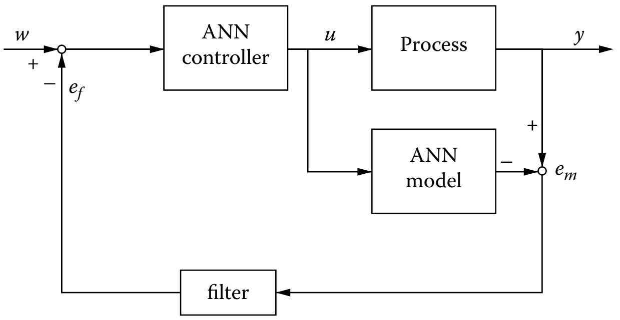

FIG. 8.21d
The configuration of artificial neural network (ANN) being used as an internal model controller (IMC).

is used and repeated until the input processing elements are reached. The weights are adjusted by

$$W_{ij}(t+1) = W_{ij}(t) + \eta \delta_j x_i \tag{8.21(3)}$$

where

W_{ij} (t) = the weight from hidden node i or from an input to node j at time t
x_i = either the output of node i or is an input
η = a gain term
δ_j = an error term for node j

The error term is

$$\delta_j = dE/dx_j \tag{8.21(4)}$$

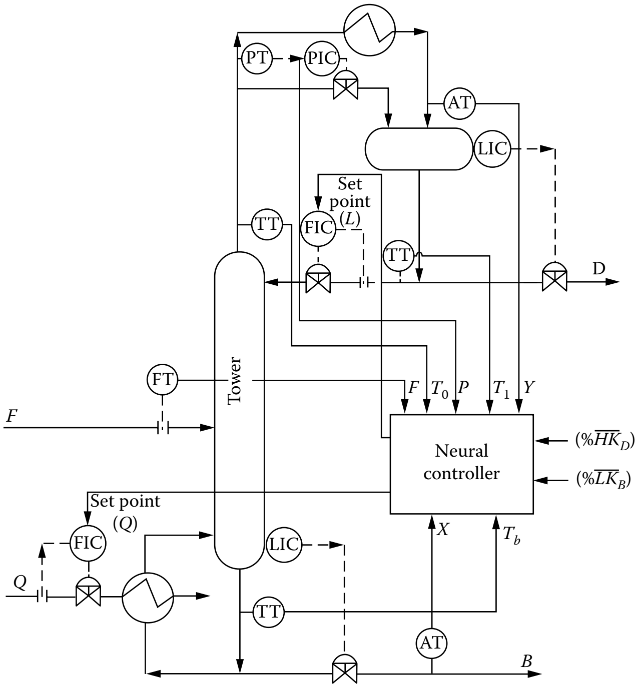

FIG. 8.21e
Fractionator control using a back-propagation neutral network.

where E is the difference between the desired output and the actual output.

A transfer function (also known as a squashing function) is applied to the weighted sum of the normalized inputs at each processing element to calculate each processing element's output. An often-used transfer function known as the sigmoid is

$$f(x) = 1/(1 + e^{-x})^{-1} \qquad \textbf{8.21(5)}$$

giving

$$dE/dx_j = x_j(1 - x_j) \qquad \textbf{8.21(6)}$$

If node j is an output node, then

$$\delta_j = y_i(1 - y_i)(d_j - v_i) \qquad \textbf{8.21(7)}$$

where d_j is the desired output of node j and y_i is the actual output.

If node j is a hidden node, then:

$$\delta_j = x_j(1 - x_j)\Sigma\delta_k w_{jk} \qquad \textbf{8.21(8)}$$

where k is over all nodes in the layers before node j.

Convergence is sometimes faster if a momentum term is added and weight changes are smoothed by a filter:

$$W_{ij}(t+1) = W_{ij}(t) + \eta\delta_j x_i + \alpha[W_{ij}(t) - W_{ij}(t-1)] \qquad \textbf{8.21(9)}$$

where $0 < \alpha < 1$.

As with any gradient descent method, back-propagation could find a local minimum instead of the global minimum. The momentum term is designed to help the training algorithm overcome the small valleys of local minima.

The learning procedures require that the change in weights be proportional to rate of change of error with respect to changes in weights. The constant of proportionality is called the learning rate, η (or learning coefficient). The larger the value of η, the faster the learning rate. Convergence is reached when the root mean square (RMS) error reaches a defined threshold value.

By using the same historical data required for the multivariable controller, the network can be trained and a nonlinear internal model can be created. In fact, the single neural controller is just a subset of the overall network used to build the entire fractionator model.

During the recall mode of operation, the network responds to the current values of the load and of the controlled variables by adjusting all manipulated variables accordingly. Each node sums the values of its weighted inputs and applies a transfer function. Thus, each output is attained by

$$I_j = \Sigma W_{ji}x_i \qquad \textbf{8.21(10)}$$

$$y_j = 1/(1 + e^{-Ij})^{-1} \qquad \textbf{8.21(11)}$$

The network's ability to do the prediction of the dynamics of the fractionator improves as more data become available for training. This approach assumes no explicit feedforward or feedback control actions because the control is totally integrated as part of the internally generated model (Figure 8.21e).

Thus, the neural controller can be considered a specific type of nonlinear, multivariable, model-based control algorithm. Instead of creating the nonlinear process model with explicit equations that are dependent upon various sets of assumptions (such as equimolal overflow, constant relative volatilities at differing conditions, and constant efficiencies), the neural controller builds its own process model from actual tower operation.

Because the neural controller is an empirical model as opposed to a theoretical model, it is susceptible to errors if operated outside the conditions of the training set. Data for the training set need to be continually gathered and the network retrained whenever novel conditions occur in order to increase the robustness of the neural controller throughout its life of operation.

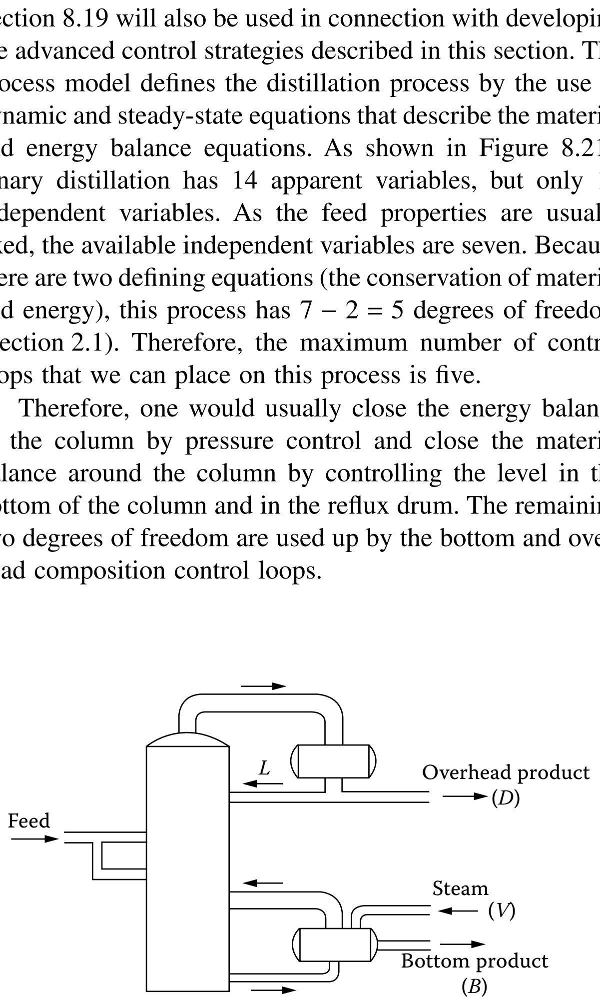
SISO CONTROL ADVANCES

Before proceeding to the subject of distillation optimization, some of the advances in single-input, single-output control strategies will be reviewed. These generally PID-based strategies involve the development of a process model and the use of feedforward and supervisory control techniques to achieve better control quality and localized optimization goals.

Process Model

The process model equations that were developed in Section 8.19 will also be used in connection with developing the advanced control strategies described in this section. The process model defines the distillation process by the use of dynamic and steady-state equations that describe the material and energy balance equations. As shown in Figure 8.21f, binary distillation has 14 apparent variables, but only 11 independent variables. As the feed properties are usually fixed, the available independent variables are seven. Because there are two defining equations (the conservation of material and energy), this process has 7 − 2 = 5 degrees of freedom (Section 2.1). Therefore, the maximum number of control loops that we can place on this process is five.

Therefore, one would usually close the energy balance of the column by pressure control and close the material balance around the column by controlling the level in the bottom of the column and in the reflux drum. The remaining two degrees of freedom are used up by the bottom and overhead composition control loops.



Apparent variables:		Independent variables
c_1	= Overhead temperature	2
c_2	= Overhead pressure	
c_3	= Overhead composition	
c_4	= Overhead flow rate	1
u_1	= Bottom temperature	2
u_2	= Bottom pressure	
u_3	= Bottom composition	
u_4	= Bottom flow rate	1
u_5	= Feed temperature	2
u_6	= Feed pressure	
u_7	= Feed composition	
u_8	= Feed percent vapor	1
u_9	= Feed flow rate	1
m	= Steam flow rate (heat input)	1
		11

FIG. 8.21f
A binary distillation process has five degrees of freedom, and therefore five of its process variables can be independently controlled: one pressure, two levels, and two compositions.

Control Equations Listed below are some of the key material and energy balance equations that define the distillation model, as they have been developed in Section 8.19:

$$F = D + B \tag{8.21(12)}$$

If the feed flow is uncontrolled, B is dependent upon F and D:

$$B = F - D \tag{8.21(13)}$$

or if the bottoms product is the manipulated variable:

$$D = F - B \tag{8.21(14)}$$

where
F = feed rate (the inflow)
D = overhead rate (an outflow)
B = bottoms rate (an outflow)

If the compositions of the feed, distillate product, and bottoms product are all known, then the component materials balance can be solved:

$$B/F = \frac{(100 - \%HK_D - \%LLK_F - \%LK_F)}{(100 - \%HK_D - \%LK_B)} \tag{8.21(15)}$$

For a given feed composition and desired product compositions, only one bottoms-to-feed ratio, *B*/*F* (product split), will satisfy both the overall and the component material balances.

A series of energy balances produce additional equations. The vapor boil-up rate V_B equals the heat Q_B added by the reboiler divided by the heat of vaporization (ΔH) of the bottoms product:

$$V_B = Q_B/\Delta H \tag{8.21(16)}$$

The vapor rate V above the feed tray equals the vapor boil-up rate plus the vapor entering with the feed (feed rate F times vapor fraction V_F, provided the feed is neither subcooled nor superheated):

$$V = V_B + (F)(V_F) \tag{8.21(17)}$$

The internal reflux rate (L_i), or the liquid at the top tray, of the column is derived by a heat balance around the top of the tower. If a total condenser is employed, this gives the equations:

$$L = \frac{L_i}{[1 + K_1(T_o - T_r)]} \tag{8.21(18)}$$

or

$$L_i = (L) \cdot [1 + (K_r)(\Delta T)] \qquad \textbf{8.21(19)}$$

The liquid rate, L_f, below the feed tray equals the internal reflux plus the liquid in the feed:

$$L_f = L_i + (1 - V_F)(F) \qquad \textbf{8.21(20)}$$

The distillate rate, D, equals the vapor rate, V, minus the internal reflux:

$$D = V - L_i \qquad \textbf{8.21(21)}$$

The bottoms rate, B, equals the liquid rate, L_f, minus the boil-up, V_B:

$$B = L_f - V_B \qquad \textbf{8.21(22)}$$

The criterion for separation is the ratio of reflux (L) to distillate (D) vs. the ratio of boil-up (V) to bottoms (B). Manipulating reflux affects separation equally as well as manipulating boil-up, albeit in opposite directions. Thus, for a two-product tower, two equations define the process: One is an equation describing separation and the other is an equation for material balance.

During the unsteady state of upsets, the process model must account for the dynamics of the process. This extends the steady-state internal flow model and requires additional consideration. For this reason two dynamic terms, G_T and G_B, are included, which provides a dynamic model for the tower based on its dead time and second-order lag, giving

$$L = G_B[G_T L_i + (1 - V_F) \cdot F] \qquad \textbf{8.21 (23)}$$

where

$$G_B = ta\,(1 - e^{-t_1})(1 - e^{-t_2})$$

$$G_T = tb\,(1 - e^{-t_3})(1 - e^{-t_4})$$

where
ta, tb = dead times

Scaling When using process models, it is very important that the measurements be correctly represented, that all I/O values be properly scaled. This was less of a challenge in the analog age, when a 9 PSIG or a 12 mA signal always meant 50%, no matter which supplier, industry, or continent was involved. This is not necessarily the case in the present digital age, with its multiple protocols and the need for interfacing translators when connecting them.

Scaling (the conversion from engineering units to fractions or percentages) is required in order to make the various transmitter signals meaningful to the DCS, PLC, or other central control system. A simple example of this type of conversion has already been given for zero-based signals in connection with Figure 8.19l in Section 8.19. In this section scaling will be illustrated on more complex systems, involving several nonzero-based transmitter signals.

The value of a transmitted signal in engineering units can be obtained from the normalized (scaled) transmitter signal and from the zero and range of the transmitter as follows:

$$\text{measurement in engineering units} = \text{zero} + \text{range (\% signal)} \qquad \textbf{8.21(24)}$$

Inversely, the percentage transmitter signal (scaled equivalent) corresponding to an engineering measurement can be obtained as

$$\text{\% signal} = \frac{\text{measurement in engineering units} - \text{zero}}{\text{range}} \qquad \textbf{8.21(25)}$$

Most DCS and other electronic controllers require that all signals conform to 0–100%. As mentioned previously, scaling is done to convert engineering unit inputs and outputs into normalized values that these DCS and electronic systems can use. Figure 8.21g shows how the internal reflux rate of a distillation column is calculated.

The calculation for internal reflux is given by the equation below:

$$L_I = L.[1 + (CP/\Delta H)\Delta T\,] \qquad \textbf{8.21(26)}$$

The subtracter is scaled first. Assuming $\Delta T_{\max}$ of 50°F (27.8°C), the span of T_o between 150°F and 250°F (65.6°C and 121°C), and the span of T_r between 125°F and 225°F (51.7°C and 107°C), the equation for the subtracter is written first in engineering units as

$$\Delta T = T_o - T_r \qquad \textbf{8.21(27)}$$

Now, converting from engineering to scaled units and denoting the scaled transmitter signal values as T_o' and T_r', the scaled equivalent of Equation 8.21(27) is

$$0 + 50\,\Delta T' = (150 + 100\,T_o') - (125 + 100\,T_r') \qquad \textbf{8.21(28)}$$

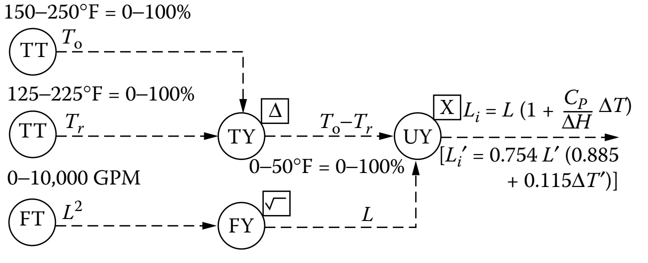


FIG. 8.21g
The steps in the calculation required to determine the internal reflux flow rate of a distillation column.

This reduces to the scaled equations:

$$\Delta T' = 2(T_o' - T_r' + 0.25) \qquad \mathbf{8.21(29)}$$

If the following assumptions are made:

$L_{I\,\max} = 15{,}000$ gpm ($0.95\ m^3/s$)
$L_{\max} = 10{,}000$ gpm ($0.63\ m^3/s$)
$Cp = 0.65$ BTU/lb°F (0.65 kcal/kg°C)
$\Delta H = 250$ BTU/lb (450 kcal/kg)

the equation for the multiplier then becomes

$$L_i' = \frac{10{,}000L'}{15{,}000}\left[1+\left(\frac{0.65}{250}\right)50\,\Delta T'\right] \qquad \mathbf{8.21(30)}$$

Equation 8.21(30) then reduces to

$$L_i' = 0.667L'(1 + 0.13\Delta T') \qquad \mathbf{8.21(31)}$$

When $\Delta T'$ is zero, the internal reflux equals 0.667 times the external reflux. The number 1 within the parentheses, therefore, sets the minimum internal reflux. When $\Delta T'$ is 100%, the ratio of internal reflux to external reflux is at a maximum.

The expression within the parentheses must be normalized. This is done by dividing both terms by the total numerical value, that is 1.13. To preserve the equality, the coefficient of L' is multiplied by 1.13. The scaled equation becomes

$$L_i' = 0.754L'(0.885 + 0.115\,\Delta T') \qquad \mathbf{8.21(32)}$$

Internal reflux systems are designed to compensate for changes outside the column, such as reflux temperature that is affected by ambient conditions. It should be understood that a change within the column can introduce positive feedback. Figure 8.21h shows a typical internal reflux application and its response to an upset within the column. The control system reacts in the same way to an increase in overhead vapor temperature and to a decrease in reflux liquid temperature, but the required control actions are in the opposite direction.

FEEDFORWARD SYSTEMS

Feedforward controls represented the first steps on the road towards multivariable model-based process control. They were first applied in well-understood processes such as heat transfer and distillation, where the material and heat balance equations made it possible to predict and anticipate the consequences of the process outputs to changes in the inputs, before they had time to evolve.

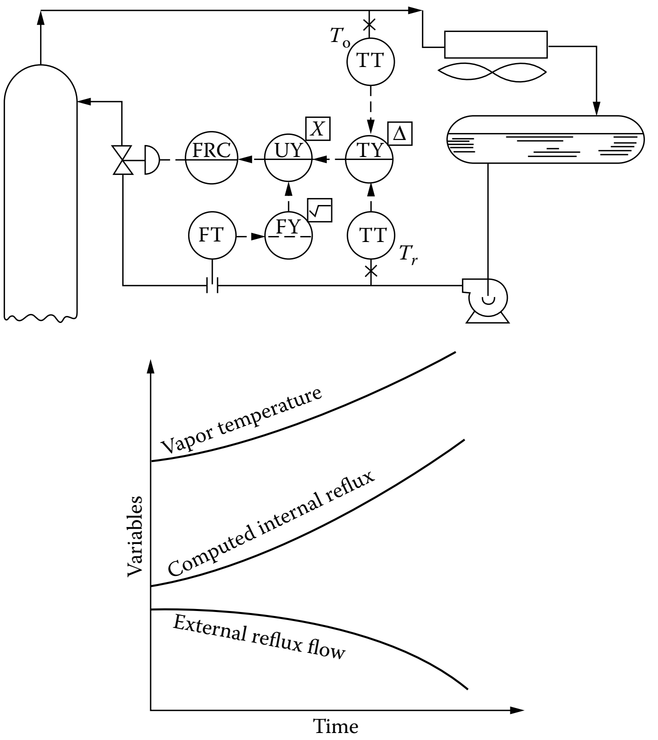

FIG. 8.21h
Response of internal reflux control system to an increase in the concentration of heavy components in the overhead vapors.

Feedforward control techniques react to variations in disturbance variables, predict the disturbance's effects, and take corrective action before the tower is significantly affected. Feedback control attempts to maintain the set point of a controlled variable by measuring its value at the outlet of the tower. In most cases, a combination of feedforward and feedback techniques can correct process deviations in the shortest time. This correction is accomplished by considering process dynamics (dead times and time lags), the nonlinearities between separation efficiency and column loading, loop interactions, and process measurements.

The types of disturbances that feedforward control is most often used to compensate for include (1) feed flow rate, (2) ambient temperature (top and reflux temperatures), and (3) reflux flow rate. Other variables that can be compensated for, but to a lesser degree include the disturbances are (4) tower pressure, (5) feed composition, (6) feed temperature or enthalpy, and (7) reboiler heat. The application of feedforward techniques involves the use of the models and equations described in Section 8.19, but dynamically tuned to approximate the response of the distillation tower.

Literally dozens of different feedforward control strategies have been proposed for distillation column control, and many of the more successful ones will be described and analyzed in this section. While feedforward control is common, it cannot be considered to be a universal solution for all columns.

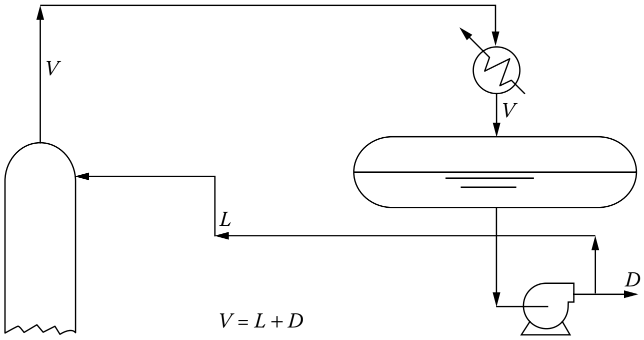

FIG. 8.21i
Reflux accumulator material balance.

Flow Control of Distillate

The column interactions that otherwise might necessitate the use of an internal reflux control system can be eliminated in some cases when the flow of distillate product draw-off is controlled and reflux is put under accumulator level control. This is a slower system than one in which flow controls the reflux, and its response is not always adequate. If necessary, the response can be speeded up by reduction of the accumulator lag.[4]

The steady-state material balance around the accumulator (Figure 8.21i) is expressed by

$$V = L + D \qquad \textbf{8.21(33)}$$

where
- V = boil-up (vapor rate)
- L = reflux rate
- D = distillate rate

To overcome the accumulator lag, the reflux rate, L, must be manipulated in direct response to a change in distillate rate, D, rather than by waiting for the response of a level controller. If V is constant (k), Equation 8.21(33) can be solved for L, which is the manipulated variable in this part of the system.

$$L = k - D \qquad \textbf{8.21(34)}$$

For this equation to be satisfied, L must be decreased one unit for every unit D is increased, and vice versa.

If V is indeed constant and both the computations and the flow manipulations are perfectly accurate, no level controller is needed. If these conditions cannot be met, a trimming function is introduced. The system equation becomes

$$L = m - KD \qquad \textbf{8.21(35)}$$

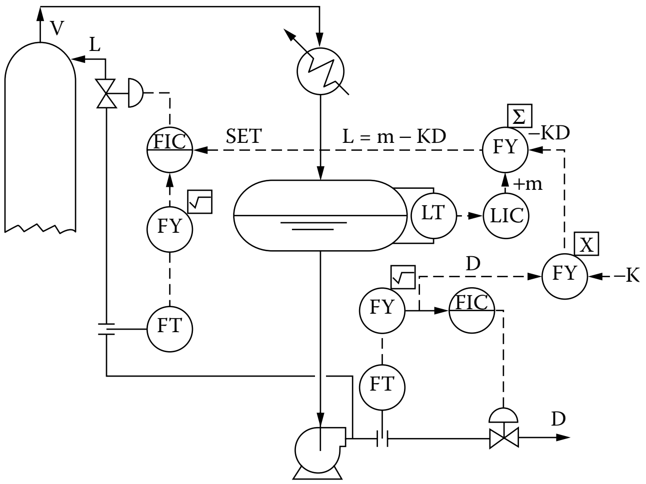

FIG. 8.21j
Reflux rate control system for overcoming accumulator lag.

where m is the output of the level controller and K is an adjustable coefficient. The resulting control system is shown in Figure 8.21j.

The range of coefficient K should be broad enough to allow scaling and adjustment to be done during commissioning. The level controller trims the computation, the scaling and the value of K but do not alter the steady-state value of external reflux, L, because these factors affect the transient response only. The response of the reflux flow to changes in distillate for several values of K is given in Figure 8.21k. The full-scale values of reflux, L_{max}, and distillate, D_{max}, flows in this case are 1000 gpm (3.79 m^3/min) and 500 gpm (1.89 m^3/min), respectively.

When $K = 0$, the reflux is adjusted by the level controller. In other cases, the reflux flow is immediately altered by some percentage for a change in distillate, and the level controller forces the balance of the change. The response is a first-order lag.

If $K = 0.5$, the reflux flow is changed to the exact new steady-state value, because K equals the ratio of D_{max}/L_{max}, and therefore the computation is exact; the lead equals the lag and the net effect is no dynamic contribution. If $K = 1.0$,

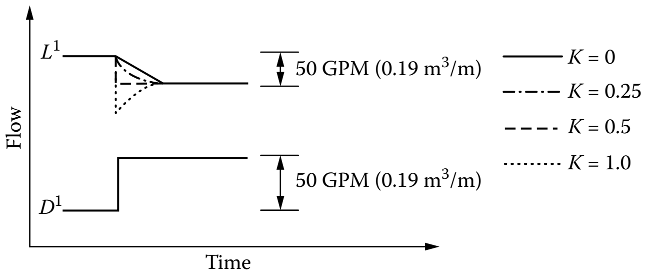

FIG. 8.21k
Reflux response as function of K.

the initial response is a first-order lead-lag function. In this case, the reflux is greater than required for the new steady state, and the level controller eventually corrects the flow.

The value of K does not change the steady-state flow. It affects the transient response only, and therefore it can be used to adjust the dynamics of the loop. The greater the value of K, the faster the response. Care must be taken to prevent increasing the response to the point of instability. A rule of thumb is

$$K_{\max} = 1.5(D_{\max}/L_{\max}) \qquad \textbf{8.21(36)}$$

Therefore, in this example, K should not be set greater than 0.75.

In some implementations, the range of adjustability of K is limited, and scaling is necessary. For the values used in the illustration (reflux full scale value equals 1000 gpm and distillate full scale equals 500 gpm), Equation 8.21(35) becomes

$$1000L' = 1000m' - 500KD' \qquad \textbf{8.21(37)}$$

where L' and D' are the normalized values of L and D. The maximum value of m is equal to the maximum value of L, because the level controller by itself can cause the level control valve to open fully.

The scaled equation is

$$L' = m' - 0.5KD' \qquad \textbf{8.21(38)}$$

K must be adjustable over a range of ±10% for satisfactory tuning flexibility.

Flow Control of Bottoms

Similarly to the feedforward systems described for distillate flow control, a similar system can be used on control the column bottom flows, if the bottom product is flow controlled and the bottoms level is maintained by manipulation of the heat input or boil-up (V). The equation for that system is

$$V = m - KB \qquad \textbf{8.21(39)}$$

where V is the boil-up, B is the bottom product flow, m is the output of the bottoms level controller, and K is the same kind of adjustable coefficient as in Equation 8.21(38).

Another commonly used model for feedforward compensation involves the bottoms-to-feed ratio (B/F). The bottoms product draw, ratioed with the feed rate, is a function of the overhead and bottoms composition targets at a given feed composition. The implementation of the bottoms-to-feed ratio control usually requires dynamic (dead time and lag) compensation of the feed rate. The dynamically compensated (lagged) feed rate, F_L, is then multiplied by the desired bottoms-to-feed ratio to obtain the target for bottoms flow rate.

$$B = (B/F)(F_L) \qquad \textbf{8.21(40)}$$

so that

$$V = m - K(B/F)(F_L) \qquad \textbf{8.21(41)}$$

Because these models are only approximations of the real process, inaccuracies do exist. For this reason, the bottoms-to-feed ratio target obtained by the feedforward calculation should be trimmed by analysis-based feedback control. In the majority of feedforward applications, their purpose is not to replace feedback but to minimize the amount of work that the feedback part of the loop has to do. This requires that the advanced control must be able to measure and quantify the disturbance, then react before the fractionator separation can be upset in the first place.

Constant Separation

A distillation column operating under constant separation conditions has one fewer degree of freedom than others, because its energy-to-feed ratio is constant. At a given separation, for each concentration of the key component in the distillate, a corresponding concentration exists in the bottoms.

In other words, for a constant-feed composition, holding the concentration of a component constant in one product stream fixes it in the other.[4] Figure 8.21l shows an example of a constant separation feedforward system in which distillate is the manipulated variable.

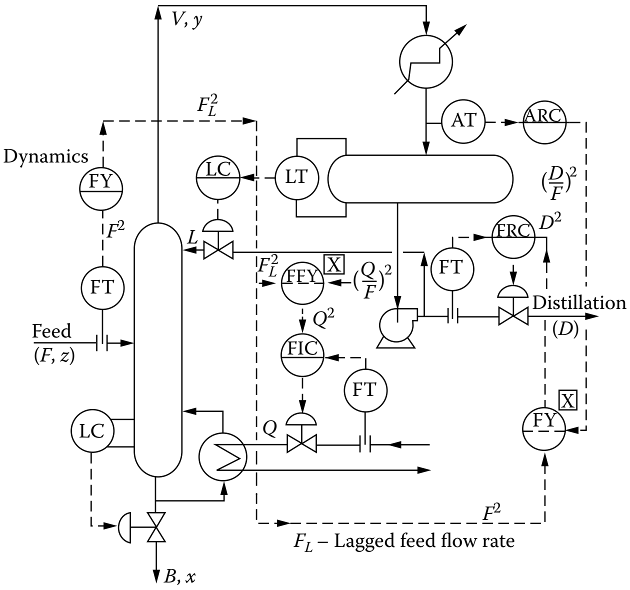

FIG. 8.21l
Feedforward distillation control system with constant separation.

A material balance on the light key component gives

$$Fz = Dy + Bx = Dy + (F - D)x \tag{8.21(42)}$$

$$D = F\left(\frac{z-x}{y-x}\right) = F\left(\frac{D}{F}\right) \tag{8.21(43)}$$

If the flow measurements are of the differential pressure type, then:

$$D^2 = F^2\left(\frac{z-x}{y-x}\right)^2 = F^2\left(\frac{D}{F}\right)^2 \tag{8.21(44)}$$

Because boil-up must change in proportion to feed rate, a second feedforward loop is obtained for setting heat input:

$$Q = F(Q/F) \quad or \quad Q^2 = F^2[Q/F]^2 \tag{8.21(45)}$$

where

z, y, x = mole fraction of the key light component in feed, overheads, and bottoms, respectively
D/F = required distillate-to-feed ratio
Q/F = required energy-to-feed ratio

No scaling is required of this equation if an adjustable ratio is used for both D/F and Q/F.

Normal design practice for scaled systems calls for the output of the trim analyzer controller ARC to be at 50% when the design or normal distillate-to-feed ratio is required. If the gain of the multiplier is set at 2, the output tracks the load when this normal distillate-to-feed ratio occurs.

In a linear system, the gain of the multiplier equals the scaling factor. In this system, however, the gain of the multiplier equals the square root of the scaling factor. When this rule is applied to the example, the scaled form of Equation 8.21(44) is

$$D^{2\prime} = 4.0(F^2)'[(D/F)^2]' \tag{8.21(46)}$$

where $D^{2\prime}$, $F^{2\prime}$, and $[(D/F)^2]'$ are the normalized values of the respective terms in Equation 8.21(44).

The block labeled "dynamics" in Figure 8.21l is a special module designed to influence the transient response. This is because the time response of the distillate to a feed rate change must be dynamically matched. The dynamic block is generally a dead time module and a lead-lag module in series. In the steady state, its output equals its input. Figure 8.21m illustrates the temporary modifications that various dynamic compensators can introduce to match the "dynamic personality" of the process. For a discussion of dead time compensation, refer to Section 2.9 in Chapter 2.

Maximum Recovery

In many distillations, one product is worth much more than the other, and the control system is designed to maximize the recovery of the more valuable stream. One such equation for this type of system is[4]

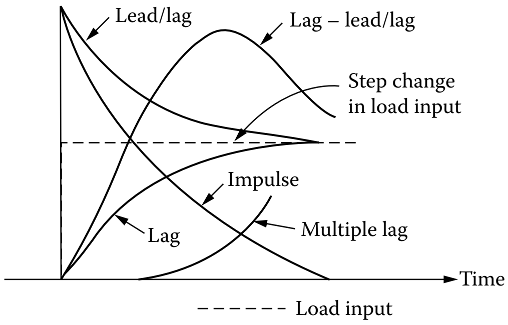

FIG. 8.21m
Dynamic compensators introduce temporary modifications into the value of their output signals which match the dynamic "personality" of the controlled process.

$$D = m(KF + K_2F^2) \tag{8.21(47)}$$

where

D = distillate rate
F = feed rate
K = adjustable coefficient
$K_2 = 1 - K$
m = feedback trim

This equation assumes that energy is free and that the distillate product is worth more than the bottoms. Distillate product flow is not linear with feed rate when boil-up is held constant. The control diagram for this maximum recovery system is shown in Figure 8.21n. Note that the distillate-to-reflux loop for accelerated response is also used. The summing block (FY-1) used to compute $(KF + K_2F^2)$ needs no special scaling.

The values of m can be computed from the feed composition. A typical range for m is 0.35–0.65. This is the output signal range of ARC-2, the feedback controller. Although the coefficients can be calculated in advance with reasonable accuracy, on-line adjustment is quite easy (these coefficients are accessible in most DCS and PLC systems), and the rigor of the calculations can be avoided.

If energy is not free and only one product composition needs to be controlled, then a linear relationship can be assumed. In this case, product flows will be directly proportional to feed rate when separation is fixed.

$$D = m_1(K_3F) \tag{8.21(48)}$$

or

$$B = m_2(K_4F) \tag{8.21(49)}$$

and

$$Q = m_3(K_5F) \tag{8.21(50)}$$

or

$$L = m_4(K_6F) \tag{8.21(51)}$$

where

D = distillate rate
B = bottoms flow rate
F = feed rate
Q = heat input rate
L = reflux rate
K_3, K_4, K_5, K_6 = adjustable coefficients
m_1, m_2, m_3, m_4 = feedback trim signals

Composition Control of Two Products

Because of the many variables that affect product composition, which are difficult to anticipate or control (e.g., feed composition), and because composition specifications for both products may be tight, some columns require better control than can be achieved by the previous constant separation strategy.

One method that can be used on some columns for achieving the required product specifications is to directly control the compositions of both products. One benefit of dual composition control is minimized energy consumption. However, it is difficult to implement dual composition control on many columns because of the severe interaction problems that may exist.

Also, with a given feed and tower design, it may not be possible to achieve two arbitrarily chosen product compositions.

An example of a feedforward dual-composition control model will be described here, after which a method for determining the degree of interaction, based on actual process data, will be discussed.

The control of distillate composition can still be done by manipulating distillate flow as required by

$$D = F\left(\frac{z-x}{y-x}\right) \tag{8.22(52)}$$

However, in order to also enforce composition control of the bottom product, an additional manipulated variable is needed. Another product stream cannot be independently manipulated without changing the accumulation in the column, which is not practical. The energy balance must, therefore, be adjusted to control bottoms composition x.

The relationship between x and the energy balance was developed by Shinskey,[5] for binary mixtures, as a function of separation S:

$$S = \frac{y(1-x)}{x(1-y)} \tag{8.21(53)}$$

For multicomponent mixtures separation is defined as:

$$S = \frac{y_L/x_L}{x_H/y_H} = \frac{y_L/x_H}{x_L/\,y_H} \tag{8.21(54)}$$

where the separation factor is the ratio of light to heavy key in the distillate divided by the same ratio in the bottoms product.

The relationship between separation (S) and the ratio of boil-up to feed (V/F) over a reasonable operating range is

$$V/F = a + bS \tag{8.21(55)}$$

where a and b are functions of the relative volatility, the number of trays, the feed composition, and the minimum V/F. The control system therefore computes V based on the equation for a binary mixture as

$$V = F\left(a + b\frac{y(1-x)}{x(1-y)}\right) \tag{8.21(56)}$$

Because y is held constant, the bottom composition controller adjusts the value of the parenthetical expression if an

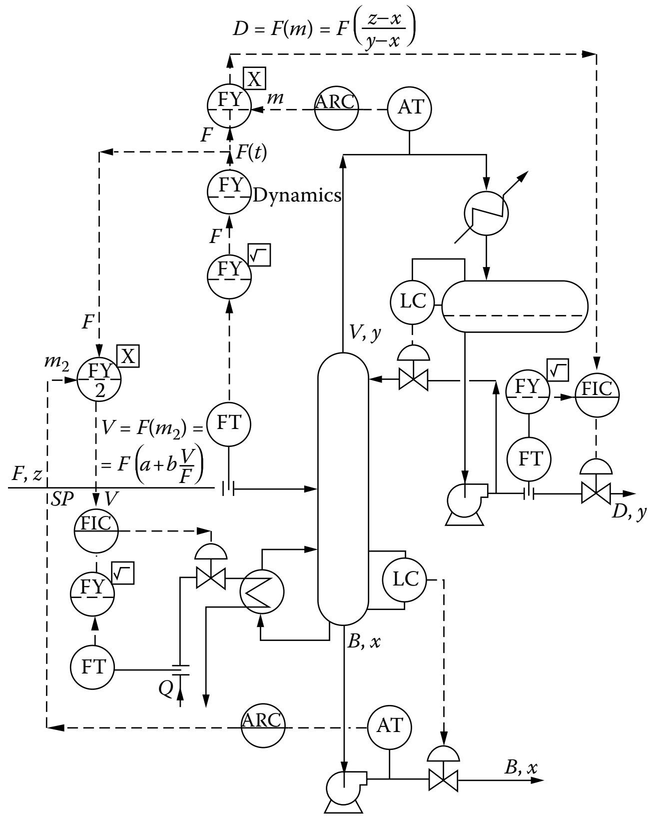

FIG. 8.21o
Feedforward control system provides closed-loop composition control of two product streams.

error should appear in x. Let $V/F = y(1 - x)/(1 - y)$, and the control equation becomes

$$V = F(a + b[V/F]) \qquad \textbf{8.21(57)}$$

where $[V/F]$ equals the desired ratio of boil-up to feed.

The system implementing Equation 8.21(52) is shown in Figure 8.21o. FY-1 and FY-2 are multipliers. The FY block labeled "dynamics" is a special block for dynamic compensation similar to the one described in Figure 8.21l and 8.21m.

Included in a and b are the relationship between boil-up (vapor rate), and energy flow (Q), and the minimum ratio of boil-up to feed. Equation 8.21(57) can therefore be written

$$Q = kF([V/F]_{\min} + [V/F]) \qquad \textbf{8.21(58)}$$

where k represents the proportionally constant.

Two Products with Interaction

Interaction always exists between the material and energy balances in a distillation column. In some columns, this interaction is not severe enough to impede closed-loop composition position control of the two product streams, but in others it is. The severity is a function of feed composition, product specification, and the pairing of manipulated and controlled variables.

Severe interactions frequency occur when the energy balance is manipulated by two independent composition controllers. A column in which reflux flow and steam flow are the manipulated variables is an example of a severely interacting column. The control system equations are

$$Q = kF([V/F]_{\min} + [V/F]) \qquad \textbf{8.21(59)}$$

$$L = F([L/F]) \qquad \textbf{8.21(60)}$$

where L is the reflux rate and $[L/F]$ is the desired reflux-to-feed ratio.

Note that in the control system described by these two equations, the rates of products leaving the column are dependent on two energy balance terms. Increasing heat input at the reboiler forces the composition controller that is resetting reflux flow to increase heat withdrawal, and the top and bottom composition controllers, therefore, "fight" each other. The only way to avoid this fighting is by preventing a change at one end of the column from upsetting the other end.

The heat input is changed when the bottom composition controller is upset. If the upset is because of a high concentration of light ends in the bottom product, heat is increased to adjust the separation being performed and to drive the extra light ends up and out the top. The top composition controller does not know how to split the increased vapor load, but it sees a measurement indicating an upset and responds to an increase in heat input by increasing the reflux flow. Theoretically, if the reflux rate is compensated for the change in heat input, the top composition controller upset can be avoided.

One can find the relationship between reflux L and heat input Q by solving Equations 8.21(59) and 8.21(60) for L in terms of Q. The resultant equation is of the form

$$L = k_1Q - k_2F \qquad \textbf{8.21(61)}$$

The values of k_1 and k_2 are found by deriving Equation 8.21(61) using actual process values of $[L/F]$, $[V/F]_{\min}$, and $[V/F]$.

The decoupling equation, Equation 8.21(61), replaces Equation 8.21(60) in the control model. The resulting system is shown in Figure 8.21p.

The system is now half-decoupled: A change in heat input will not upset the top temperature, because the decoupling loop adjusts the reflux independently of the top temperature (analysis) controller. However, the heat input is still coupled to reflux, because a change in reflux will still cause the bottom temperature controller to adjust steam flow. This degree of decoupling is enough to reduce the interaction approximately 20-fold. The two multipliers are scaled as described previously (under the paragraph Scaling), and the adder is tuned on-line.

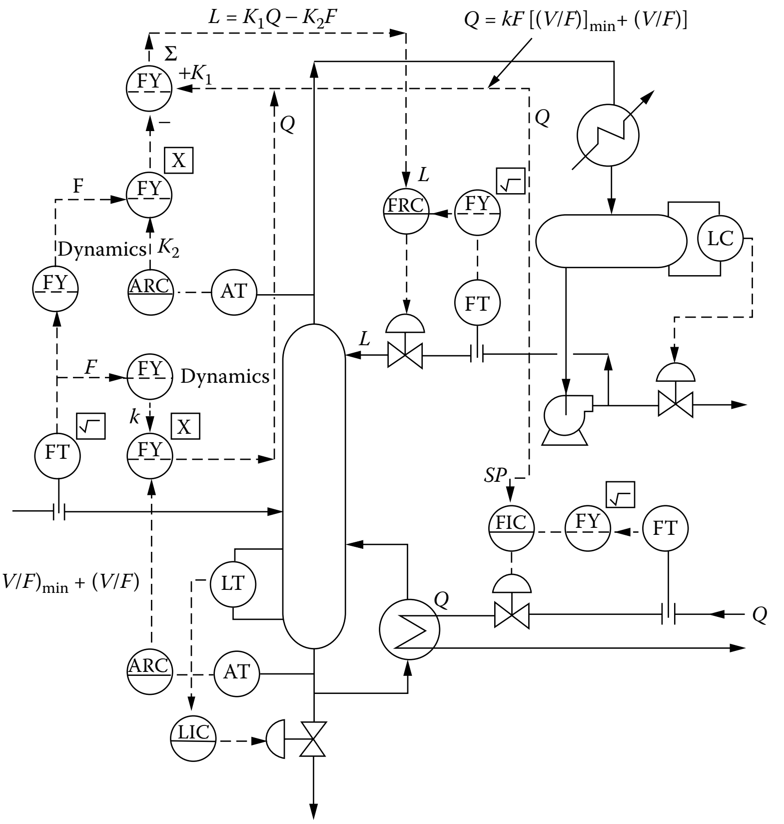

FIG. 8.21p
The decoupling of a distillation tower when the compositions of both products are being controlled.

Classical decoupling schemes,[6] however, often do not provide a solution to the problem of interaction because of practical problems encountered on real columns.[7,8] Decoupling systems that include overrides can drive to saturation when constraints are encountered. Most seriously, decouplers applied to systems with negative interaction (defined later) may have very little tolerance for errors in decoupler gains.

For this group, which always includes the interaction encountered in reflux and boil-up controls, small errors can transform a system that provides complete decoupling into one that provides no control at all. Because the proper decoupler gains depend on the process gains, which inevitably change with variations in feed rate, product specifications, and column characteristics, these systems require constant attention and adjustment beyond the ordinary capability of plant operating personnel.

The difficulties associated with the application of decoupling systems have prompted a re-examination of interaction itself. The problem may be postulated in two ways:

1. For a given column, is the interaction equally strong in each of the control structures available to the designer?
2. For a given control structure, will the interaction be equally strong in every column in which it is applied?

The stumbling block of loop assignment may in this way be converted into a stepping stone by providing the opportunity to select a control structure that will exhibit minimum interaction in any particular application.

Shinskey and Ryskamp have given consistent guidelines for assigning loops to minimize loop interaction. Shinskey[9] suggests that the controller assigned to the more pure product should manipulate separation. Ryskamp[10] suggests that the controller for the component with the shorter residence time should adjust vapor flow, and the controller for the component with the longer residence time should adjust the liquid/vapor ratio.

Feed Composition Compensation

Occasionally, changes in feed composition occur too fast to be handled by feedback control, and feedforward compensation for these changes is necessary (Figure 8.21q).

The basic material balance equation, Equation 8.21(62), already has a term, z, representing concentration of the key component in the feed:

$$D = F\left(\frac{z-x}{y-x}\right) \qquad \mathbf{8.21(62)}$$

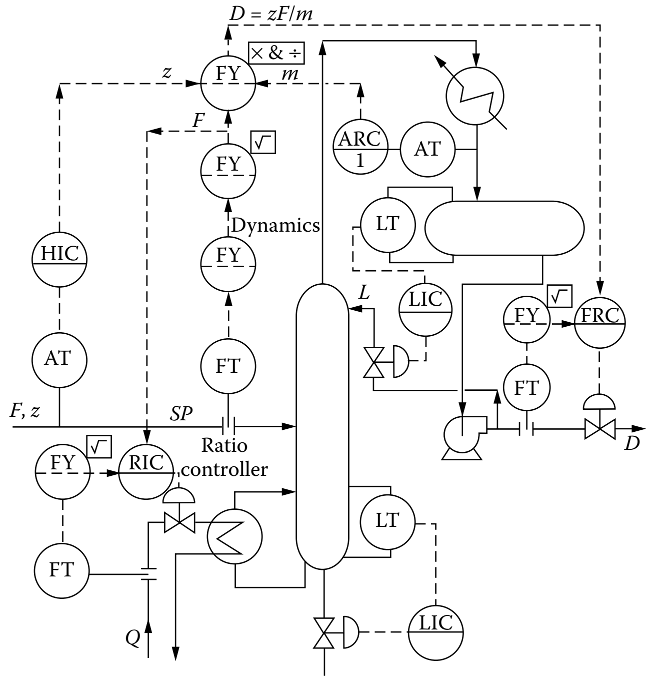

FIG. 8.21q
Feed composition measured and used to compute distillate flow.

When z is measured, the equation for distillate can be simplified to

$$D = zF/m \quad \textbf{8.21(63)}$$

where m is the output of the overhead analyzer feedback trim controller (ARC-1). The auto/manual station (HIC) is used in the event of analyzer failure. Dynamic compensation is placed on the flow feed signal only.

The control of the bottoms flow in Figure 8.21q is indirectly provided by the feedforward control of the reboiler heat input based on the (dynamically compensated) feed flow rate. If, instead of this approach, feedforward analyzer control of the bottoms flow is desired, Equation 8.21(64) can be utilized.

$$V = m - K(B/F)(F_L) \quad \textbf{8.21(64)}$$

where F_L is the dynamically compensated feed rate.

Substituting the B/F ratio:

$$B/F = \frac{(100 - \%HK_D - \%LLK_F - \%LK_F)}{(100 - \%HK_D - \%LK_B)} \quad \textbf{8.21(65)}$$

gives the feedforward expression for the vapor rate up the tower:

$$V = m - K\left[\frac{(100 - \%HK_D - \%LLK_F - \%LK_F)}{(100 - \%HK_D - \%LK_B)}\right]F_L \quad \textbf{8.21(66)}$$

SUPERVISORY CONTROL

On-line computer control can greatly enhance the profitability of the distillation process and data collection improvements, and increased flexibility can often justify computer control even if rigorous on-line optimization is not implemented. The optimization strategy can be implemented in the supervisory mode (recommendations to the operator) or in the automatic mode and can involve the whole plant or only particular subsystems of the total process.

The main computer control functions applied to distillation include engineering calculations, operating assistance, quality controls, and heat balance controls.[11] The primary engineering calculations are made from material and heat balances around column sections and include tray loadings, internal vapor flows, internal liquid flows, and heat duties. These calculations are helpful as operating guidelines and as inputs for on-line control. However, they are usually based on steady-state conditions, and therefore the input signals must be averaged to make the calculations.

Response, although normally fast enough for on-line control, may not be adequate if frequent, short-term disturbances must be handled. However, information gained from these types of calculations can often justify the computer system by providing better operating guidelines, even if it is not used for on-line control.

An example of a computerized control system that makes the operator's job easier is the balancing of the heater coil outlet temperature on furnaces (Figure 8.21r).

Other examples of computer controls include (1) the feedforward adjustments of products and pump-arounds on the basis of feed rates, (2) the control of the column's bottom level by throttling the feed preheater bypass flows, and (3) the control of overhead receiver level. Such control systems will be described in more detail later. Because many of these calculations result in the need for changing the set points of several controllers simultaneously, supervisory control can reduce the workload and the potential for human errors by the operator.

Product quality controls are enhanced if the computer adjusts the column temperature and side-draw flow rates to control product specification. Often computers are used to infer product specifications from local flows, temperatures, and pressures. Examples of these inferred calculations include true boiling point (TBP) cut points, ASTM 95% boiling points, Reid vapor pressure (RVP), octane, viscosity, freeze points, cloud points, and pour points.

These calculated measurements can be used in feedback controllers themselves or as a fast inner loop with an analyzer trim. The advantage of such model-based controls is that they can anticipate future events, because their outputs are not delayed by the process dead time and time lag. This results in tighter control.

Adjustment of pump-around reflux flows, as shown in Figure 8.21s, is an application example where the computer

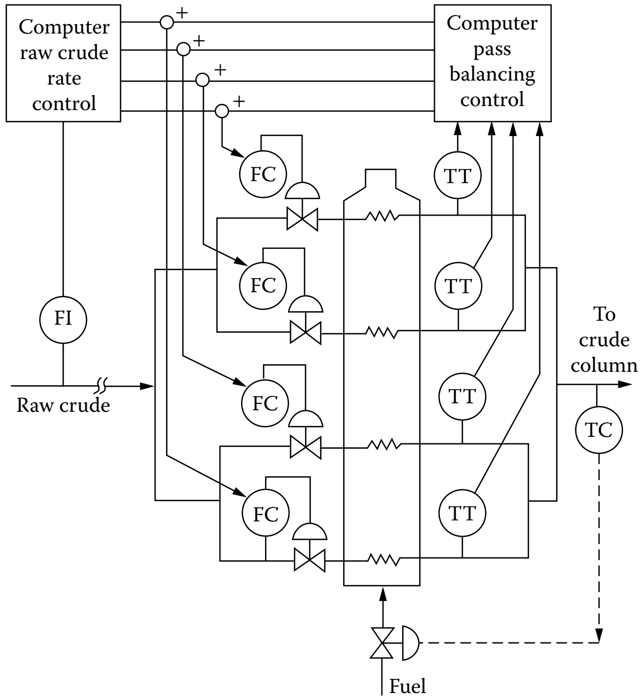

FIG. 8.21r
The balancing of heater coil charge rates in crude oil furnaces can be under computer control or supervision.

assists in heat balance control. The goal of such systems usually is to maximize the exchange of heat to feed, subject to certain limits,[19] which will be discussed in the subsection "Optimization."

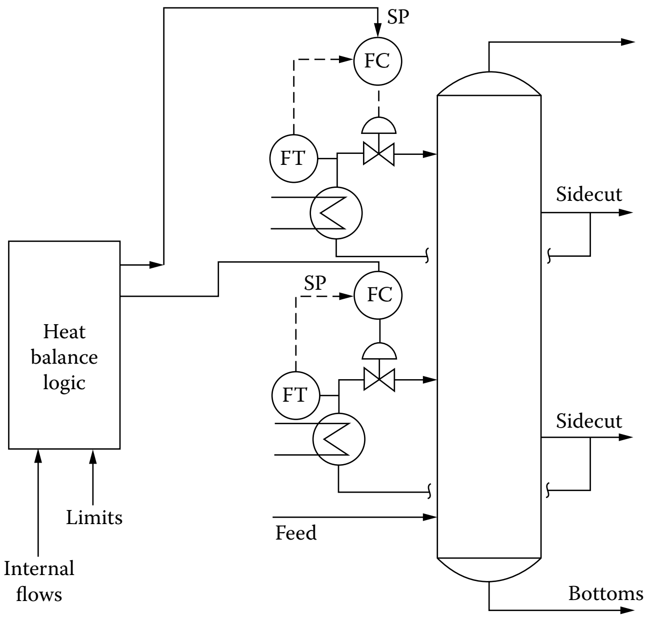

FIG. 8.21s
Computer adjustment of pumparound refluxes.

A careful analysis of the limits and operating constraints is essential, because if the system is not designed to provide limit checks and overrides to handle operating limits, frequent operator intervention will be required during upsets. This can cause a lack of confidence in the computer system, which can result in the column's being off computer control more than necessary.

The Total Model

It is possible to design a system to compensate for all load variables: feed rate, composition, enthalpy, reflux, and bottoms enthalpy. The goal of these systems is to overcome the problems associated with unfavorable interactions and to isolate the column from changes in ambient conditions. These problems can usually be solved by careful system analysis and variable pairing, thus avoiding complicated total energy and material balance control systems. The complexity of the total material and energy balance systems is made apparent by the list of equations required in the model:

Feed enthalpy balance
Bottoms enthalpy balance
Internal reflux computation
Reboiler heat balance
Overall material balance

Suboptimization

The following derivations will provide insight into the derivation and modeling of optimization equations and the handling of constraints. However, the reader is advised that every distillation column is unique; the examples given here are for illustrative purposes only and should not be considered to be suboptimal or optimal solutions for every column.

Optimization of a single distillation column normally implies a maximum profit operation, but to achieve maximum profit, the price of the column's products must be known. It is impossible to control every column in a system based on this criteria, because the prices of products for many columns are unknown. Product prices are often unknown because the products are feed streams to other units, whose operations would need to be taken into account to establish the column's product prices.

When product prices are unknown, it is possible to carry optimization only to the stage at which specified products can be produced for the least operating cost. This can be called an optimum with respect to the column involved, but only a suboptimum with respect to the system of which the column is a part.

When column product prices are known, complete economic optimization can be achieved. However, a number of different situations may still exist. If there is a limited market for the products, then the control problem is to establish the separation that results in a maximum profit rate. Such an optimum separation will be a function of all independent inputs to the column involved.

When an unlimited market exists for the products, and sufficient feedstock is available, the optimization problem becomes more difficult. Not only must the optimum separation be established, but also the value of feed must be determined. Optimization for this case results in operating the column at maximum loading or at maximum energy efficiency.

One of three possible constraints will be involved: Throughput will be limited by the overhead vapor condenser, the reboiler, or the column itself. In some cases, the constraint will change from time to time, depending upon product prices and other independent variables of the system. The design of optimal automatic control systems to single columns should follow three logical steps:

1. Design the basic controls to regulate basic functions, such as pressures, temperatures, levels, and flows
2. Configure the controls to regulate the main sources of heat inputs, including regulation of internal reflux flow rate, feed enthalpy, and reboiler heat flow rate
3. Apply controls to regulate the specified separation

A single column that is automated in this manner is called a suboptimized system. This suboptimum is defined as an operation that will produce close to the specified separation, whether or not that separation is ideal with regard to the total system of which the column is a part. If product purities are higher than specified, the operation cannot be considered suboptimum.

When a single column is automated through the suboptimum operation stage, it will still exhibit up to five degrees of freedom. As a basis for proceeding into the optimization phase, Figure 8.21t is presented as one example of a column automated through the suboptimization stage.

As shown in Figure 8.21t, the system used to regulate the separation is a predictive control system, similar to that described earlier. The function of the predictive control system is to manipulate the energy balance (reflux flow rate) and the material balance (bottom product flow rate) to give the specified separation. The equations derived for these manipulations are called the operating control equations.

Figure 8.21u is another example of suboptimization. Both figures achieve their goal of operating at suboptimum; the difference is mainly in their the basic controls. In the paragraphs below, the steady-state operating equations and the dynamics for bottom product and reflux will be described.

Bottoms Product Operating Equation The equation for predicting bottom product flow rate was derived in Section 8.19 as

$$B/F = \frac{(100 - \%HK_D - \%LLK_F - \%LK_F)}{(100 - \%HK_D - \%LK_B)} \qquad 8.21(67)$$

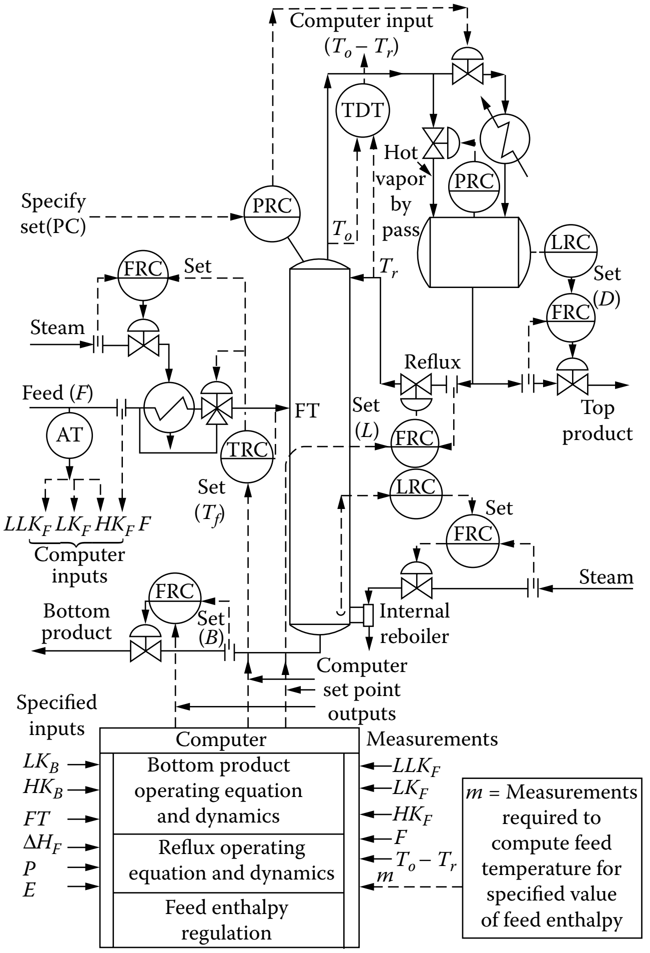

FIG. 8.21t
Distillation column automated through the suboptimization stage (to produce close to the specified separation.)

where

$\%LLK_F$ = lighter than light key in the feed (mol%)
$\%LK_F$ = light key in the feed (mol%) = z
$\%LLK_D$ = lighter than light key in the distillate product (mol%)
$\%LK_D$ = light key in the distillate product (mol%) = y
$\%HK_D$ = heavy key in the distillate product (mol%)
$\%LK_B$ = light key in the bottoms product (mol%) = x

Assuming that the composition in both ends of the tower are to be held at specification:

$$B/F = \frac{(100 - \%\overline{HK}_D - \%LLK_F - \%LK_F)}{(100 - \%\overline{HK}_D - \%\overline{LK}_B)} \qquad 8.21(68)$$

where

$\%\overline{HK}_D$ = specification of the heavy key in the distillate product (mol%)
$\%\overline{LK}_B$ = specification of the light key in the bottoms product (mol%) = x

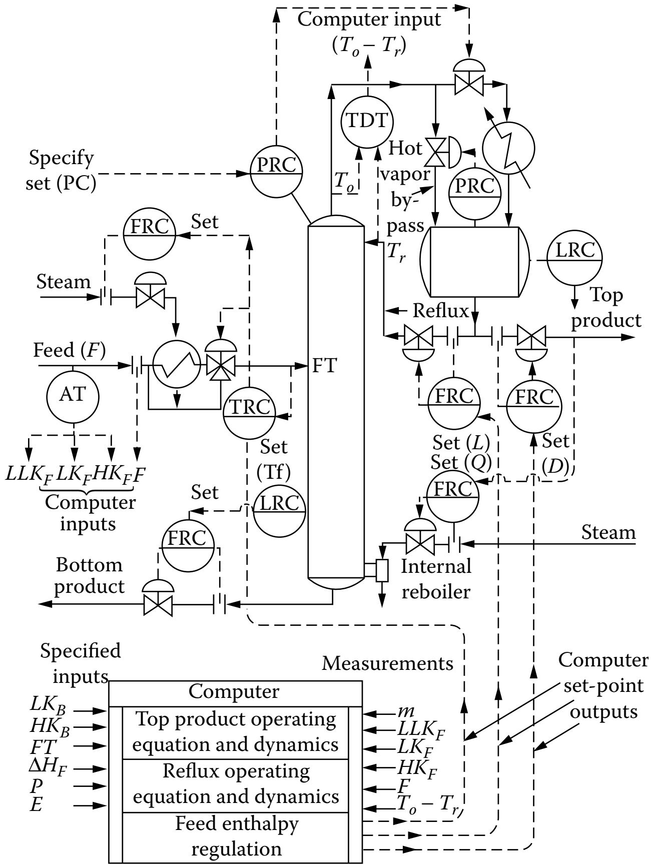

FIG. 8.21u

Alternative method of column automation through the suboptimization control stage.

Derivation of the internal reflux operating equation is more difficult. Typically, this equation is developed in two parts:

$$(L_i/F) = (L_i/F)t + (L_i/F)e \qquad \textbf{8.21(69)}$$

where

(L_i/F) = internal reflux to feed flow rate ratio required to give a specified separation
$(L_i/F)t$ = theoretical part of reflux operating equation
$(L_i/F)e$ = experimental part of reflux operating equation

The experimental part of this equation is necessary because the effect of loading on the overall separating efficiency (E) is normally unpredictable. Both parts of the reflux operating equation are functions of all independent inputs to the system. However, simplifications are normally considered for the experimental part, as follows:

$$(L_i/F)t = f_1[(LLK_F),(LK_F),(HK_F),(\bar{E}),(\overline{FT}),$$
$$(\overline{\Delta H}_F),(\bar{P}),(\%\overline{LK}_B),(\%\overline{HK}_D)] \qquad \textbf{8.21(70)}$$

$$(L_i/F)e = f_2(L_i) \qquad \textbf{8.21(71)}$$

where

$\bar{E}$ = specified constant average efficiency
$\overline{FT}$ = specified value of feed tray location
$\overline{\Delta H}_F$ = specified value of feed enthalpy
$\bar{P}$ = specified value of column pressure

The theoretical part of Equation 8.21(69) is normally developed by tray-to-tray runs of calculations performed by an off-line digital computer. A statistically designed set of runs is made, and the information thus obtained is curve-fitted to an assumed equation form.

Once the steady-state theoretical equation is developed and placed in service, the experimental part is determined by on-line tests. These tests involve operating the column at different loads to determine the correction required to $(L_i/F)t$ for the separation to be equal to that specified. Average overall efficiency $\bar{E}$ is set to make (L_i/F)t required to equal the actual L_i/F that exists. The loading tests are carried out under this condition.

Often plant tests are performed to determine L_i/F without consideration to the theoretical term. For a given distillate composition, the calculated internal reflux in Equation 8.21(72) is found for several different feed rates.

$$\frac{L_i}{L} = \frac{\Delta H_L}{\Delta H_{L_i}} \cdot \left[\left(1.0 + \frac{C_{p_L}}{\Delta H_L} \cdot (T_o - T_r)\right)\right] \qquad \textbf{8.21(72)}$$

The result often gives the relationship as shown in Figure 8.21v. Implementation of these curves is generally via a polynomial equation or segmented function curve.

Reflux Operating Equation Internal reflux controls were described in Figure 8.21h. One can approximate internal reflux flow rate of a distillation column by making a heat balance around the top tray. If that is done, the following equation is obtained:

$$(L_i) = LK_2[1 + K_1(T_o - T_r)] \qquad \textbf{8.21(73)}$$

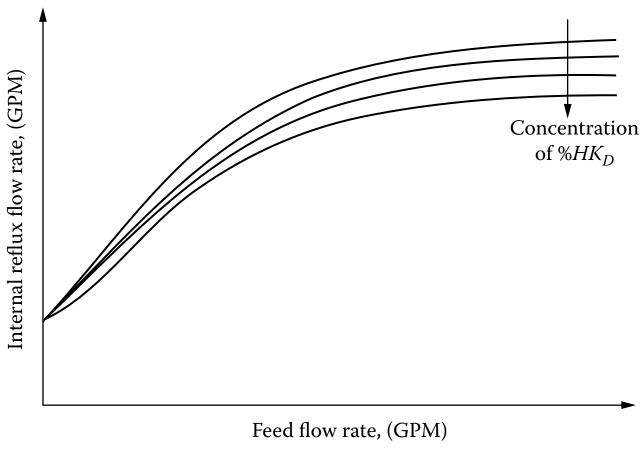

FIG. 8.21v

Relationship of internal reflux to feed at several distillate compositions.

Substitute this equation into Equation 8.21(69) to eliminate L_i:

$$(L/F) = \frac{[(L_i/F)_t + (L_i/F)_e]}{K_2[1 + K_1(T_o - T_r)]} \qquad \mathbf{8.21(74)}$$

where

L = external reflux flow rate

K_1 = ratio of specific heat to heat of vaporization of the external reflux

K_2 = ratio of heat of vaporization of external reflux to heat of vaporization of internal reflux

T_o = overhead vapor temperature

T_r = external reflux temperature

Dynamics Equations Equations 8.21(68) and 8.21(69) are steady-state equations. Applied without alteration, undesirable column response will result, especially for sudden feed flow rate changes. Feed composition changes are less severe than are feed flow rate changes and seldom require dynamic compensation.

Dynamic elements should compensate for feed flow rate changes in such a way that when the feed flow rate changes, the column's terminal stream flows should respond at the proper time, in the correct direction, and without overshoot. The simplest form of dynamics to meet these criteria involves dead time plus a second-order exponential lag response. The feed flow rate signal is passed through this dynamic element before being used in the operating equations to obtain the bottom product flow rate (B) and the reflux flow rate (L) set points. The transfer function for the dynamic element is

$$\frac{(F_L)}{(F)} = \frac{Ke^{-ts}}{(T_1 s + 1)(T_2 s + 1)} \qquad \mathbf{8.21(75)}$$

where

(F_L) = feed flow rate lagged

(F) = feed flow rate measured

t = dead time

T_1, T_2 = time constant

Using Equation 8.21(75), F is eliminated from the left side of Equations 8.21(68) and 8.21(69) to obtain the complete set of operating equations as used in Figure 8.21v. These equations become

$$B = F\left[\frac{Ke^{-ts}}{(T_1 s + 1)\,(T_2 s + 1)}\right]$$

$$\left[\frac{100 - (\%\overline{HK}_D) - (\%LLK_F) - (\%LK_F)}{100 - (\%\overline{HK}_D) - (\%\overline{LK}_B)}\right] \qquad \mathbf{8.21(76)}$$

$$L = F\left[\frac{Ke^{-ts}}{(T_1 s + 1)\,(T_2 s + 1)}\right]\left[\frac{(L_i/F)_t + (L_i/F)e}{K_2[1 + K_1(T_o - T_t)]}\right] \qquad \mathbf{8.21(77)}$$

where in functional form:

$$(L_i/F)_t + (L_i/F)_e = f_1[(LLK_F),(LK_F),(HK_F),(\bar{E}),(\overline{FT}),$$

$$(\overline{\Delta H}_F),\ (\bar{P}),(\%\overline{LK}_B),(\%\overline{HK}_D)] + f_2(L_i) \qquad \mathbf{8.21(78)}$$

Note that the bottoms and overhead dynamic constants, t, T_1, and T_2 in Equations 8.21(76) and 8.21(77), are not necessarily the same values.

Application of Equations 8.21(76), 8.21(77), and 8.21(78) will result in a suboptimized operation. This is an operation producing a performance close to the specified one. The control block diagram of Figure 8.21w illustrates the application of these equations.

Inspection of Equations 8.21(76) and 8.21(78) shows that the system still has five degrees of freedom. Therefore, feed tray location ($\overline{FT}$), feed enthalpy ($\overline{\Delta H}_F$), column pressure ($\bar{P}$), concentration of heavy key component in the top product ($\%\overline{HK}_D$), and concentration of light key component in the bottom product ($\%\overline{LK}_B$), must all be specified. Although tray efficiency is also included, it remains a fixed value, as explained earlier.

Local Optimum Variables

Feed enthalpy and column pressure are local optimization variables that can be manipulated to achieve two different objectives to increase profitability: minimizing utilities costs or maximizing throughput. Often, this type of optimization is implemented via valve position controllers. The purpose of valve position controllers is to drive the column to a constraint condition on either reboiler heat, condenser duty, or column loading.

Strategies to reduce utility costs include a valve position controller cascaded to pressure control. This is commonly referred to as "floating-pressure control." Strategies to increase throughput include valve position controller cascaded to feed flow rate. In both cases, the valve position controller will drive the manipulated variable to an equipment constraint.

Minimum Pressure Control Floating-pressure operation can often reduce energy consumption by providing minimum pressure operation within the constraints of the system. It is possible to operate a total condensing distillation column with no pressure control.[8] Although this provides for optimum operation at steady state, major problems could occur (e.g., flooding the column) during transient upsets. Flooding is caused by high vapor rates and can result in entrainment or foaming, or in preventing the liquid from flowing down the column. To prevent this, pressure control should be provided.

Most distillation columns are operated with constant pressure control. However, several advantages can be achieved

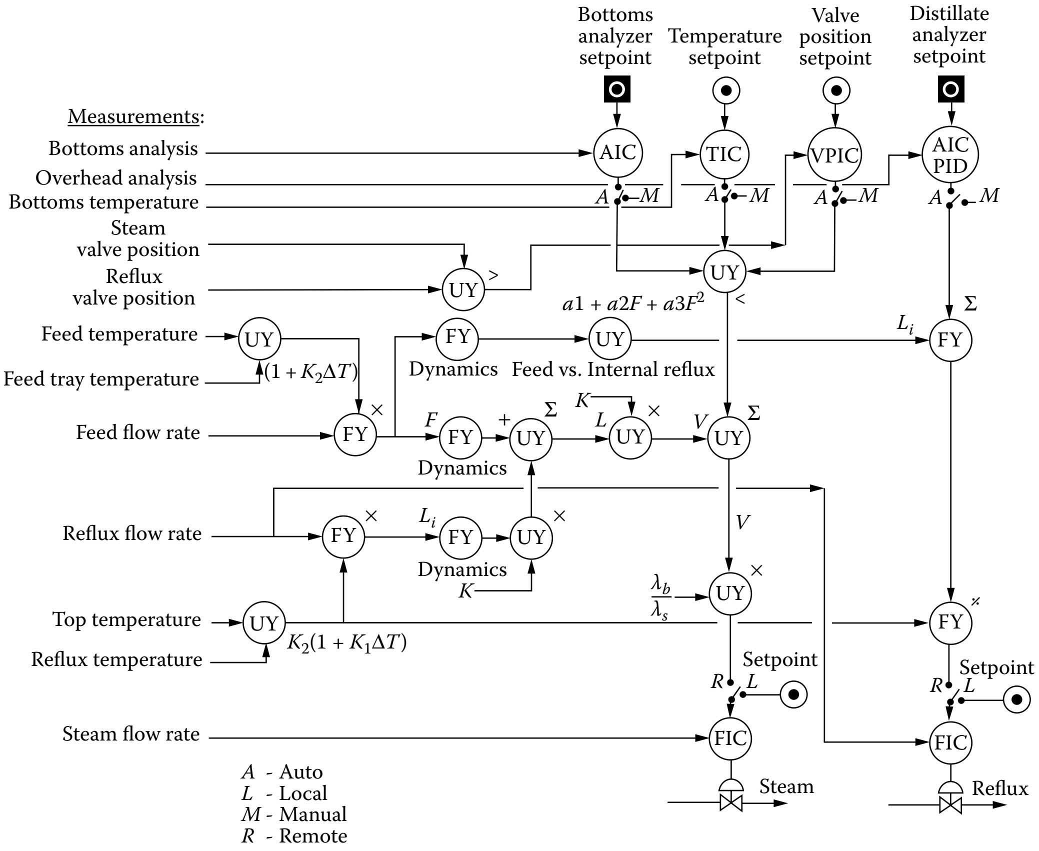

FIG. 8.21w

Fractionator control block diagram.

through minimizing operating pressure in most columns. Resistance to floating the pressure is largely due to the desire to use temperature measurements to indicate and control compositions. As analyzers are replacing temperature measurements, the traditional desire for constant pressure is also being removed. However, even when analyzers are not used, temperature measurements can be compensated for pressure variations.

Floating-pressure control allows the tower to operate with minimum pressure within the constraints of the system. Lower pressure increases the relative volatility of distillation components, thereby reducing the heat input required to effect a given separation. Other advantages include increased reboiler capacity and reduced reboiler fouling due to lower temperatures. Reducing pressure also affects other parameters, such as tray efficiencies and latent heats of vaporization. Some of these effects occur in opposite directions; therefore, floating-pressure control is desirable for some columns and not for others. The components being separated are the major determining factor.

Minimum pressure operation can be achieved by manual or automatic adjustment of the set point of the pressure controller to keep the condenser fully loaded at all times. However, to prevent upsets caused by rapid set point changes, the valve position control (VPC) scheme shown in Figure 8.21x is used.[8] The VPC adjusts the set point of the pressure controller. This maximizes cooling by holding the condenser control valve in the fully open or fully closed position, depending on whether the valve bypasses, throttles, or floods the condenser.

The pressure controller should incorporate proportional plus integral action to provide rapid response to upsets. The VPC should be an integral-only controller, so a rapid change in valve position will not produce a proportional change in the pressure set point. The integral time setting of the VPC should be approximately 10 times that of the overhead composition controller. In addition, it is common practice to limit the range within which the VPC can adjust the set point and to provide the external feedback shown in Figure 8.21x to eliminate reset windup when the VPC output reaches one of these limits. The setpoint for the VPC is given a value, such as 90%, so that the controller has a range in which to operate.

Partial condensers require a different approach to floating-pressure control because they are sensitive to cooling and accumulation of noncondensables. Typically, pressure in

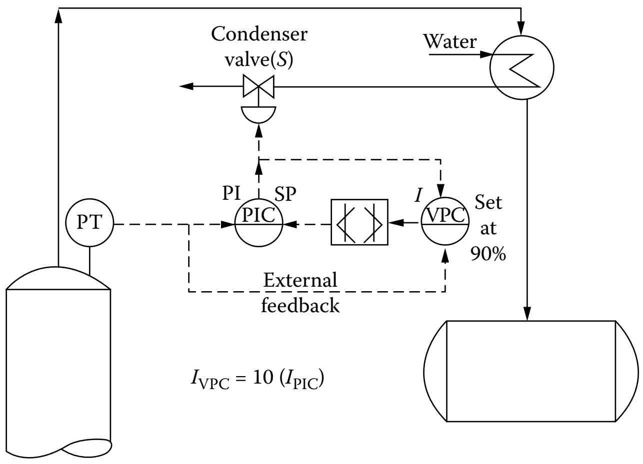

FIG. 8.21x
VPC provides floating-pressure control of total condenser.

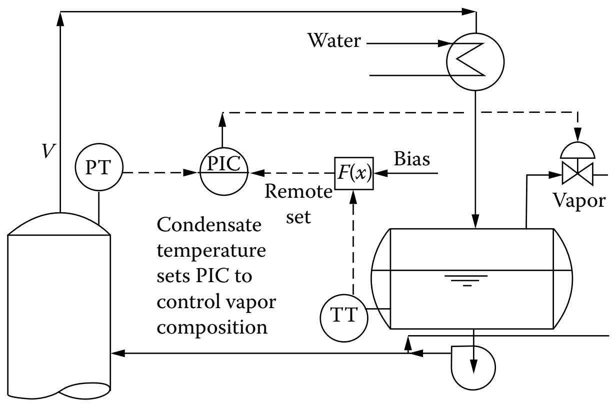

FIG. 8.21z
Floating-pressure control for a partial condenser with both liquid and vapor products.

these systems is controlled by addition or venting of inert gases. Though simple, this practice requires a source of inert gases, does not allow for steady-state optimum pressure operation, wastes overhead products that are vented with the noncondensables, and can create problems in downstream units through the addition of noncondensables.

Figure 8.21y shows a partial condensing system with no liquid product. Here, both level and pressure controllers are used to provide floating-pressure operation.^{8} The level controller acts as the VPC in the total condensing system to provide complete flooding (on the refrigerant side) in the long term, and the pressure controller handles short-term upsets.

When both liquid and vapor products are withdrawn, an additional control loop is required to control the composition of the vapor, as shown in Figure 8.21z. Here column pressure is controlled by vapor flow, but the set point must be adjusted for changes in accumulator (condenser) temperature.^{8} The temperature measurement is characterized to an equivalent vapor pressure representing the desired composition. A bias adjustment should be incorporated to readjust the relationship between pressure and temperature for desired changes in composition. This method completely eliminates the need for throttling the cooling water to the condenser.

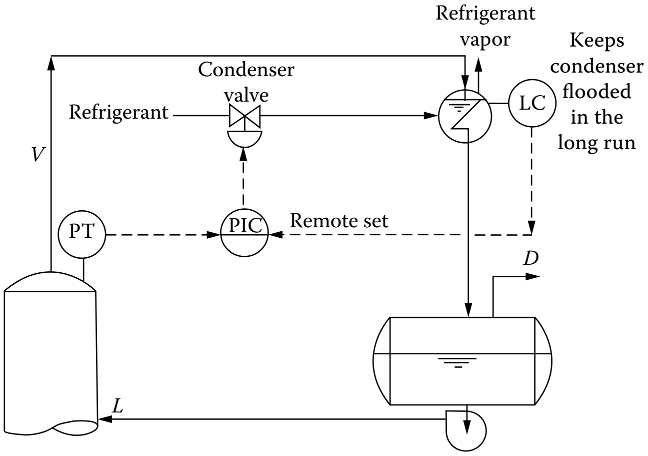

FIG. 8.21y
Floating-pressure control for a partial condenser with no liquid product.

It is important to realize that composition control must take precedence over pressure optimization. The pressure-valve position control loop response must be much slower than that of the composition control loops. Also, potential effects of pressure changes on upstream and downstream units must be considered. For example, if the pressure of an upstream tower provides the driving force to move product to a downstream tower, pressure minimization may not be practical. Fractionators using vapor recompression, such as a propylene splitter (Figure 8.19mm in Section 8.19) with a heat pump, may actually benefit from increasing pressure rather than reducing it.

Feed Maximization Control Where product demand and the availability of feedback is unlimited, increasing throughput maximizes profitability. In such installations, a valve position controller can be cascaded to the feed flow controller in order to increase the feed rate until an equipment constraint is reached. Figure 8.21aa illustrates a cascade configuration to

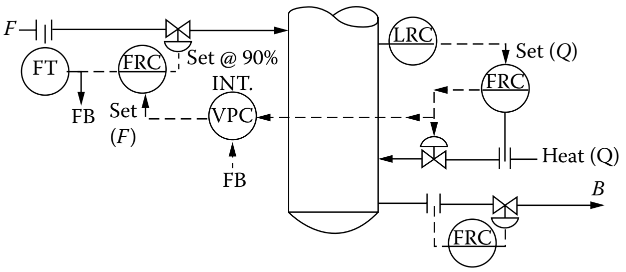

FIG. 8.21aa
Valve position control maximizes feed until a reboiler constraint is reached.

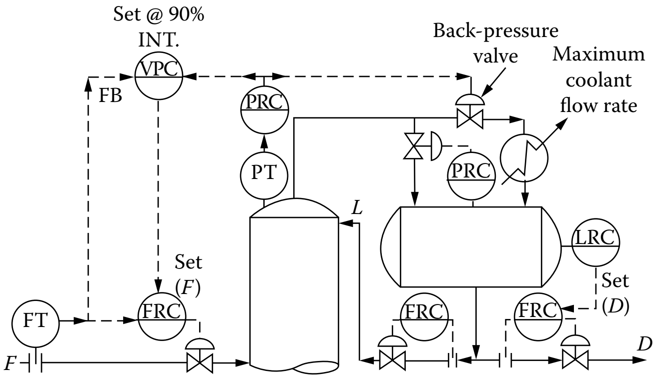

FIG. 8.21bb
Valve position control maximizing feed until a condenser constraint is reached.

keep the reboiler fully loaded. This strategy is particularly effective when the cost of reboiler heat is negligible, such as when waste steam is used that would be vented otherwise.

Likewise, if a condenser limit is involved, the opening of the column pressure control valve can be measured and the feed rate manipulated by a controller to maintain the back-pressure valve near open. Also, if a hot vapor bypass exists around the condenser, the opening of the bypass valve will also indicate the condenser load. These procedures are illustrated in Figure 8.21bb. Instead of minimizing pressure in order to reduce utility usage, here the objective is to maximize throughput.

The VPCs in Figures 8.21aa and 8.21bb are usually selected as integral-only controllers and are set at around 90% of valve stem lift, which on an equal-percentage valve corresponds to 70% of maximum flow. The integral setting of the VPC is slow, about 10 times the integral setting of the FRC, the set point of which the VPC adjusts in a cascade arrangement. In order to eliminate reset windup, the VPC is provided with external feedback from the slave transmitter.

In many cases, it is not known which single constraint will be encountered as feed is maximized. The critical constraint may vary over time. In such cases, a multiple constraint network is implemented.

Feed Enthalpy Control When an economizer is used to preheat the feed with the bottoms product (Figure 8.19rr), it is advantageous to maximize the amount of heat that is recovered from the bottoms product. In this case, the valve position controller (VPC) resetting the temperature controller as shown in Figure 8.21cc ensures that the flow in the bypass is kept at a minimum value. The tuning and feedback requirements of this VPC are similar to those of Figures 8.21x, 8.21aa, and 8.21bb.

Constant temperature feed does not necessarily mean constant feed quality. If feed composition varies, its bubble point also varies. It is common practice to set the temperature control at a point that is equivalent to the bubble point of the heaviest feed. As the feed becomes lighter, some of it will evaporate, but this variation can be handled by subsequent controls.

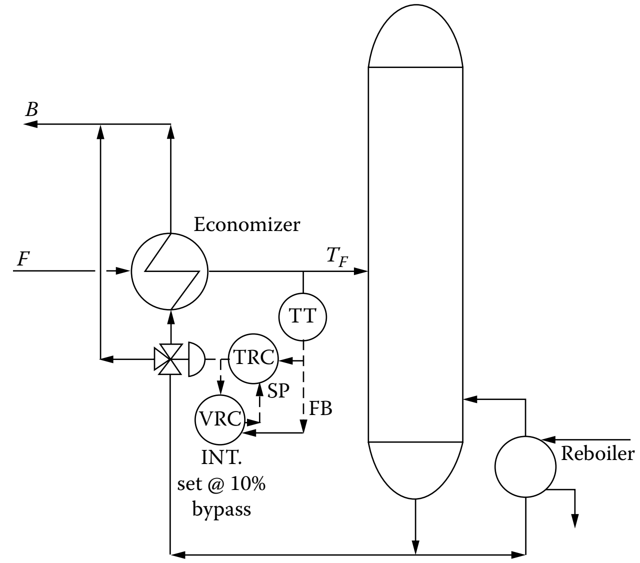

FIG. 8.21cc
Maximizing feed preheat through valve position control.

Control of feed enthalpy instead of temperature can be achieved provided the proper measurements are in place. Consider Figure 8.21dd, in which the cold feed at temperature T_f first passes through the bottoms-to-feed economizer, then through the steam preheater.

The feed may be partially vaporized as it leaves the economizer. In order to calculate the feed enthalpy as it enters

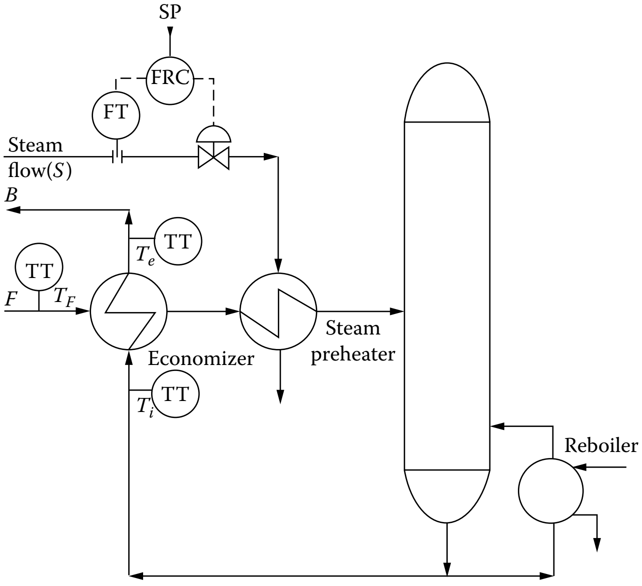

FIG. 8.21dd
Feed enthalpy control.

the column, the following heat balance can be written:

$$(F)(\Delta H_F) = (F)(C_{p_F})(T_f) + (B)(C_{p_B})(T_i - T_e) + (S)(\Delta H_{\text{stm}}) \qquad \textbf{8.21(79)}$$

where

ΔH_F = feed enthalpy as it enters the tower, BTU/lb (kcal/kg)
F = feed flow to preheater, lb/h (kg/h)
S = steam flow, lb/h (kg/h)
C_{p_F} = feed heat capacity, BTU/lb°F (kcal/kg°C)
T_f = feed temperature before preheaters,°F (°C)
B = bottoms flow to economizer, lb/h (kg/h)
C_{p_B} = bottoms heat capacity, BTU/lb (kcal/kg)
T_i = bottoms temperature to economizer,°F (°C)
T_e = bottoms temperature after economizer,°F (°C)
ΔH_{stm}= steam heat of vaporization minus condensate heat, BTU/lb°F (kcal/kg°C)

Rearranging Equation 8.21(79) gives

$$\Delta H_F = (C_{p_F})(T_f) + (B/F)(C_{p_B})(T_i - T_e) + (S)(\Delta H_{\text{stm}})/F \qquad \textbf{8.21(80)}$$

or, solving for the manipulated variable, the steam flow that will provide constant feed enthalpy is

$$S = [F(\Delta H_F - C_{p_F} T_f) - B(C_{p_B} \Delta T)]/\Delta H_{\text{stm}} \qquad \textbf{8.21(81)}$$

The primary effect of increasing feed enthalpy is to decrease vapor-liquid circulation below the feed tray relative to that above the feed tray. When feed preheat is less expensive than reboiler heat, or when the reboiler is the limiting constraint, maximum feed preheat is often optimal. When condenser capacity is limiting, or flooding is encountered above the feed tray, preheat is not desired.

OPTIMIZATION

Optimization implies maximum profit rate. An objective function is selected, and manipulated variables are chosen that will maximize or minimize that function. This is similar to the PID equation that is designed to minimize the error between the set point and measurement, but at a higher level. Optimization can be applied in several layers. Local optimization is the optimization of a single column. Normally, the goal of optimization of a single tower is to obtain minimum energy consumption or maximum throughput.

Unit optimization addresses several columns in series or parallel. It is concerned with the effective allocation of feedstocks and energy among the members of that system. Plantwide optimization involves coordinating the control of distillation units, furnaces, compressors, and so on to maximize profit from the entire operation. All lower-level control functions respond to set points received from higher-level optimizers.

If Product Prices are Unknown

Unless the prices of terminal products of a distillation column are known, it is impossible to maximize the profit rate for that column without taking into account all other aspects of the overall plant of which the column is a part. Thus, optimization for a single distillation column whose terminal product prices are unknown is a matter of producing specification products for minimum operating cost. Determining the optimum separation for the column requires optimizing the overall system of which the column is a part.

Optimization of a single column whose product prices are unknown involves determining the values for the location of the feed tray ($\overline{FT}$), for the feed enthal ($\overline{\Delta H}_F$), and for column pressure ($\bar{P}$) that result in minimum operating costs for whatever separation is specified. Any applicable mathematical approach can be used to establish values for ($\overline{FT}$), ($\overline{\Delta H}_F$), and ($\bar{P}$) that will result in minimum operating costs.

Assuming that Equations 8.21(76), 8.21(77), and 8.21(78) are available, it is a relatively simple matter to establish optimum values for these three variables that result in minimum operating costs. Because these variables have specific constraint values, one method involves a search technique. It is usually difficult to justify the search technique for on-line computer control. Therefore, a statistical design study can be made off-line on another computer that allows correlation of the variables with each of the three optimizing variables.

Theoretically, three equations in functional form describe the optimum for ($\overline{FT}$), ($\overline{\Delta H}_F$), and ($\bar{P}$)

$$(\overline{FT})_o = f_3[(\%LLK_F), (\%LK_F), (\%HK_F), (F), (\%\overline{HK}_D), (\%\overline{LK}_B)] \qquad \textbf{8.21(82)}$$

$$(\overline{\Delta H}_F)_o = f_4[(\%LLK_F), (\%LK_F), (\%HK_F), (F), (\%\overline{HK}_D), (\%\overline{LK}_B)] \qquad \textbf{8.21(83)}$$

$$(\bar{P})_o = f_5[(\%LLK_F), (\%LK_F), (\%HK_F), (F), (\%\overline{HK}_D), (\%\overline{LK}_B)] \qquad \textbf{8.21(84)}$$

In a majority of cases, the optimum for column pressure, ($\bar{P}$), will be the minimum value with constraints of the system. Normally, ($\bar{P}$) can be lowered until the condenser capacity is reached, or until liquid entrainment in the vapor on the trays is initiated.

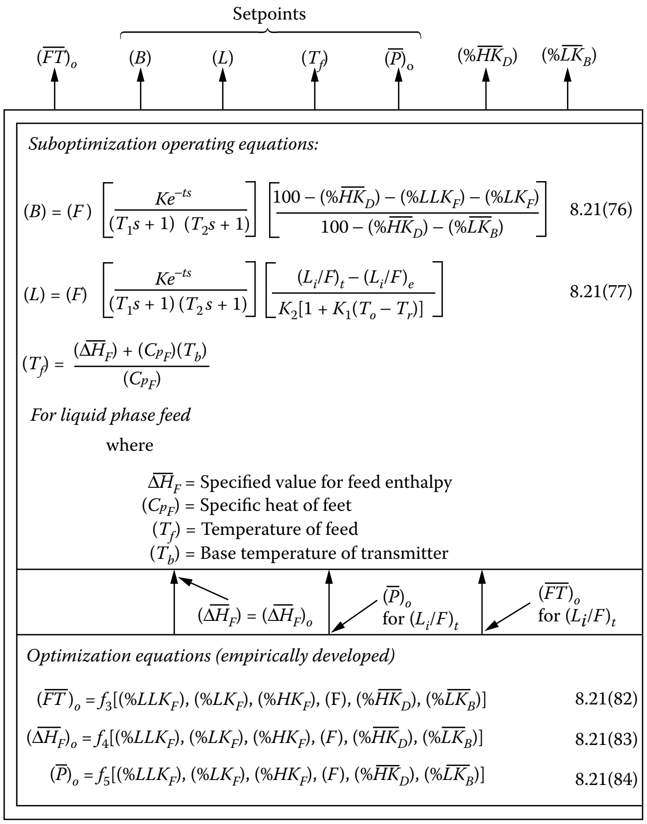

FIG. 8.21ee

Optimizing control for single column when product prices are unknown (criterion is to produce specification products for the least operating cost).

Figure 8.21ee illustrates all the control equations involved to optimize the operation of a column when product prices are unknown. Determination of column pressure is handled by the predictive control equation, Equation 8.21(84).

If Products Prices are Known

When terminal product prices for a single column are known, the column is optimized to obtain the specified separation for the least operating cost. The problem now is to determine values for the separation that will maximize profit rate. There are, however, a number of different situations that may exist, which will be covered below. Several general optimizing policies can be stated first. The purpose of these general policies is to reduce the number of variables involved in design of the optimizing control system.

Optimizing Policies

1. The optimum separation for a single distillation column can be determined independently of feed cost.
2. One condition resulting in optimized operation for a single distillation column is production of that product with the highest unit price at minimum specified purity.
3. The optimum separation to specify for a single distillation column is not a function of each terminal product price, but a function of the price difference between products.
4. When the individual components in the products of a single column have separate assigned prices, the optimum separation is not a function of all the component prices but it is a function of the price difference between the heavy key component in the top and bottom ($PHK_D - PHK_B$) and of the price difference between the light key component in the top and in the bottom products ($PLK_D - PLK_B$).

These policies are derived by the evaluation of the partial differential equations that describe the profit rate for a single column with respect to the specified separation, noted as $(\overline{LK}_D), (\overline{HK}_B)$.

Operating Constraints

When product prices for a distillation column are known, complete economic optimization almost always requires the operation to be against a constraint. If not against an operating constraint, the optimum will occur when the specified separation $(\overline{LK}_B), (\overline{HK}_D)$ is of such a value that incremental gain in product worth is equal to incremental gain in operating cost. Because the majority of cases will involve operating constraints, it is important to understand the principles involved.

Loading a distillation column is affected by the specified separation and by the existing feed rate. Loading is increased by specification of a better separation or by an increase in the feed rate at a constant separation. In general, both the feed rate and separation are involved as optimizing variables when an unlimited market exists for the products and when sufficient feedstock is available.

The operating constraints normally involve the capacities of (1) the condenser, (2) the reboiler, and (3) the column. As feed rate is increased, or an increased separation specified, one of these three constraints will be approached. The constraint encountered may also depend on prevailing external conditions, e.g., ambient conditions, steam pressure, and feed composition. The optimum may then be different depending upon these other conditions and the constraint first reached.

Condenser Constraint Capacity of a given condenser at maximum coolant flow rate is a function of the differential temperature between the overhead vapor and the coolant media. One useful approach to operating a column against the condenser constraint requires correlation of maximum vapor flow rate with this temperature difference. Such a correlation can be obtained by column testing. The information obtained by on-line tests is curve-fitted to some general form, such as in Equation 8.21(85):

$$(V_o)_{\max} = a_1 + a_2(\Delta T) + a_3(\Delta T)^2 \qquad \mathbf{8.21(85)}$$

where

$(V_o)_{\max}$ = maximum overhead vapor flow rate that will load the condenser maximally
ΔT = temperature difference between overhead vapor and coolant to the condenser
a_1, a_2, a_3 = coefficients

Values for feed rate and for the separation can be determined that will result in $(V_o)_{\max}$ to load the condenser. Column pressure and condenser fouling are also major variables that will affect overhead vapor temperature. For improved accuracy, the temperature of the overhead vapor can be modeled as a function of all independent variables in the system for use in the ΔT determination. This would result in a completely predictive system for loading the condenser. As the condenser becomes fouled, new coefficients must be established for Equation 8.21(85).

Reboiler Constraint Capacity of the reboiler at maximum flow rate of the heating media is a function of the temperature difference between the heating media in the reboiler tubes and the liquid being reboiled. Just as with the condenser, tests can be conducted to correlate maximum vapor flow rate out of the reboiler with temperature difference across the reboiler tubes.

Also, temperature of the reboiler can be expressed as a function of the column's independent inputs. Column pressure and reboiler fouling are major variables that will affect the temperature of the reboiler liquid. Generally, when using waste streams such as low pressure steam that would alternatively be vented, it is optimal to operate against a reboiler constraint.

Column Constraint The capacity of a given column is a function of liquid and vapor flow rates within the column as well as of the column pressure. Often, capacity is limited by entrainment of liquid by the vapor. At low internal liquid flow rates, a higher vapor flow rate can be used. Also, column capacity will be greater at higher pressures. If capacity is limited by entrainment, then loading can be increased at higher pressures. However, if column capacity is limited by the tray downcomers, internal liquid flow rate can be increased by lowering pressures. Therefore, the capacity-limiting parameter must be known.

Over a limited range, a linear relationship can be assumed between column pressure (P), liquid flow rate (L), and the maximum vapor rate ($V_{\max}$) that will initiate entrainment. Figure 8.21ff shows data that were obtained by column testing, because it is difficult to predict these effects.

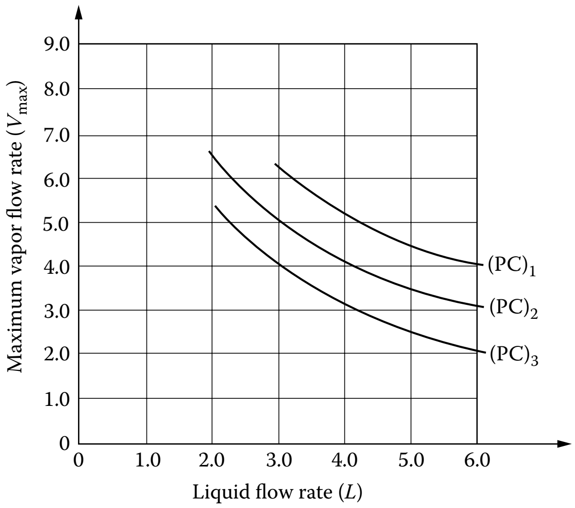

FIG. 8.21ff
Typical relationship between liquid flow rate (L) and the vapor flow rate ($V_{\max}$) that will initiate entrainment.

An equation can be developed from the test data to cover a limited range of liquid and vapor flow rates and pressure: Equation 8.21(86). This relationship can usually be considered linear.

$$V_{\max} = a_1 + a_2(L) + a_3(P) \qquad \mathbf{8.21(86)}$$

This equation is useful in predicting the values of feed flow rate and of the separation that will cause maximum vapor flow rate to exist. The use of these loading functions to optimize the operation of a column will be covered later in this section.

Limited Market and Feedstock

Assuming that the column is already equipped with the operating control functions given in Figure 8.21ee, the overall control system is illustrated in Figure 8.21gg. In order to keep the drawing clear, the basic controls are not shown here, but can be seen in Figure 8.21t.

This column is assumed to have four feed components having concentrations of LLK_F, LK_F, HK_F, and HHK_F. Three of these components appear in each product. The separation for the column is fixed by specification of the concentration of heavy key component in the top product ($\overline{HK}_D$) and the concentration of light key component in the bottom product ($\overline{LK}_B$).

The top and bottom products have unit prices of PD and PB, respectively. All the components in the feed that are

Inputs and outputs for computer control

With prices of the products (PD, PB) known, the problem is to find the separation (HK_D, LK_B) that will maximize profit rate.

lighter than the light key component, i.e., LLK_F components, will go to the top product, whereas all the components that are heavier than the heavy key component, i.e., HHK_F components, will go to the bottom product. Therefore, the operation of the column can do nothing about the distribution of these two components between the top and bottom products. $\overline{HK_D}$ will be the impurity component in the top, and $\overline{LK_B}$ the impurity component in the bottom.

The concentrations of these two components in the products can be fixed by specification of their values as inputs to the predictive controller. LK_D is the purity component in the top product, and HK_B is the purity component in the bottom. Sales specification for the two products usually state the minimum acceptable purities.

$$(HK_B) \geq (HK_B)_{ss} \qquad \textbf{8.21(87)}$$

$$(LK_D) \geq (LK_D)_{ss} \qquad \textbf{8.21(88)}$$

where $(HK_B)_{ss}$ and $(LK_D)_{ss}$ are minimum purity sales specifications.

Control Equations

Control equations for the heavy key in the top product and for the light key in the bottoms product will be developed first for the case in which the top product is considered to be more valuable and second for the case in which the bottom product is considered to be more valuable for a two-product fractionator.

Top Product Having Higher Value

As stated earlier, the general optimizing policy is that the product with the highest unit price must be produced at minimum specified purity. The heavy key component in the top product $(\overline{HK_D})$ is the control component. Its set point can be calculated as a function of feed component concentrations, minimum sales purity specification, $(LK_D)_{ss}$, and concentration of light key component in the bottom product $(\overline{LK_B})$.

Heavy Key in Top Product The following material balance equations are involved in determining the optimum value for the concentration of the heavy key in the top product, $(\overline{HK_D})_o$.

$$(\overline{HK_D})_o = 1.00 - (LK_D)_{ss} - LLK_D \qquad \textbf{8.21(89)}$$

$$(LLK_F)(F) = (LLK_D)(D) \qquad \textbf{8.21(90)}$$

$$D = (F - B) \qquad \textbf{8.21(91)}$$

$$B = F\left[\frac{(1-(\overline{HK_D})_o = [(LLK_F)+(LK_F)]}{1-(\overline{HK_D})_o-(\overline{LK_B})}\right] \qquad \textbf{8.21(92)}$$

In Equation 8.21(89), LLK_D is eliminated by use of Equation 8.21(90). D is eliminated by Equation 8.21(91), and B is eliminated by Equation 8.21(92). The following is obtained:

$$(\overline{HD_D})_o = \frac{\begin{array}{c}(LK_F)+(\overline{LK_B})[(LLK_F)-1]\\ -(LK_D)_{ss}[(LLK_F)+(LK_F)-(\overline{LK_B})]\end{array}}{(LK_F)-(\overline{LK_B})} \qquad \textbf{8.12(93)}$$

Light Key in Bottom Product Having obtained the value for optimum concentration of heavy key in the top product, the problem reduces to finding the value for optimum concentration of light key component in the bottom product, $(\overline{LK_B})_o$.

The maximum value that can be specified for LK_B to meet the minimum sales specification $(HK_B)_{ss}$ will be as follows:

$$(\overline{LK_B})_{\max} = \frac{\begin{array}{c}[1-(\overline{HK_D})_o][(LLK_F)+(LK_F)+(HK_F)+(HK_B)_{ss}]\\ -[(LLK_F)+(LK_F)][1-(\overline{HK_B})_{ss}]\end{array}}{(LK_F)-(\overline{HK_D})_o}$$

8.21(94)

This equation is derived by the same procedure that was used for Equation 8.21(94). As $\overline{LK_B}$ is lowered from its maximum value, the flow rate of the bottom product will decrease and the top product flow rate will increase. Because the top product is the highest unit price, profit will increase as is $\overline{LK_B}$ lowered. Also, operating costs will increase, because a better separation is being specified.

As $\overline{LK_B}$ is lowered further, one of two things will occur to establish $(\overline{LK_B})_o$ (the lowest value for LK_B). Either the change in operating cost will approach the change in profit rate, or the column will be loaded against an operating constraint. This constraint will be a condenser limit, a reboiler limit, or a column limit. Whichever occurs first will establish $(\overline{LK_B})_o$.

Assume, for example, that no constraints are involved. In that case, the value of the products will be given by

$$PW = (PD)(D) + (PB)(B) \qquad \mathbf{8.21(95)}$$

where PW is the total product worth rate, dollars/unit time. Eliminate B by

$$B = F - D \qquad \mathbf{8.21(96)}$$

to obtain

$$PW + (PD - PB)(D) + (PB)(F) \qquad \mathbf{8.21(97)}$$

Taking the partial derivative of this equation with respect to $\overline{LK_B}$, the following is obtained:

$$\frac{\partial(PW)}{\partial(\overline{LK_B})} = (PD - PB)\frac{\partial(D)}{\partial(\overline{LK_B})} \qquad \mathbf{8.21(98)}$$

Operating costs can be approximated closely by

$$(OC) = (CL_i)(L_i) \qquad \mathbf{8.21(99)}$$

where CL_i is the unit cost of operation per unit of internal reflux. Taking the partial derivative of this equation with respect to $\overline{LK_B}$, the following is obtained:

$$\frac{\partial(OC)}{\partial(\overline{LK_B})} = CL_i\frac{\partial(Li)}{\partial(\overline{LK_B})} \qquad \mathbf{8.21(100)}$$

When the change in operating cost is equal to the change in product worth, the value for $(\overline{LK_B})_o$ is determined.

$$(PD - PB)\left[\frac{\partial(D)}{\partial(\overline{LK_B})}\right] = CL_i\left[\frac{\partial(L_i)}{\partial(\overline{LK_B})}\right] \qquad \mathbf{8.21(101)}$$

Evaluation of this equation will yield a value for $(\overline{LK_B})_o$. D must be expressed in terms of the specified separation, the feed composition, and flow rate. L_i must be expressed in terms of the independent inputs to the system as used in the internal reflux control equation. The simultaneous solution of Equations 8.21(93) and 8.21(101) will yield optimum values for LK_B and HK_D: $(\overline{LK_B})_o, (\overline{HK_D})_o$. The total solution is indicated in Figure 8.21hh.

Bottom Product More Valuable

The general optimizing policy requires that the product with the highest unit price be produced at minimum specified purity.

Light Key in Bottom Product Because the bottom product must be produced at minimum purity, Equation 8.21(94) gives the optimum value for $\overline{LK_B}$. The optimum $\overline{LK_B}$ equals $(\overline{LK_B})_{\max}$. This, in turn, gives the minimum specified sales purity $(HK_B)_{ss}$.

Heavy Key in Top Product The maximum value for heavy key in the top product is given by Equation 8.21(93). As $\overline{HK_D}$ is reduced from its maximum allowable value, flow rate of the top product will decrease and flow rate of the bottom product will increase. Therefore, total worth of the products will increase together but with increased operating costs due to increased reflux required. The optimum value for $\overline{HK_D}$ will occur when an operating constraint is encountered or when the incremental gain in product worth is equal to the incremental gain in operating cost.

For this case, assume that the column approaches an operating constraint as $\overline{HK_D}$ is lowered. Let this constraint be flooding above the feed tray because of excessive entrainment of liquid in the vapor.

First, an equation needs to be developed for vapor flow rate above the feed tray in terms of variables that are contained in the bottom product and reflux operating equations. The loading equation is developed as follows:

$$L_i + D = V_t \qquad \mathbf{8.21(102)}$$

where

L_i = internal reflux flow rate
D = top product flow rate (distillate)
V_t = vapor flow rate above feed tray

V_t can have a maximum value as given by Equation 8.21(86), which is developed specifically for the column involved. Therefore, equate the right side of Equation 8.21(86) with the left side of Equation 8.21(102) to obtain

$$L_i + D = a_1 + a_2(L) + a_3(\bar{P}) \qquad \mathbf{8.21(103)}$$

where

a_1, a_2, a_3 = coefficients of experimental loading equation
L = liquid flow rate in column at the point at which flooding occurs
P = column pressure

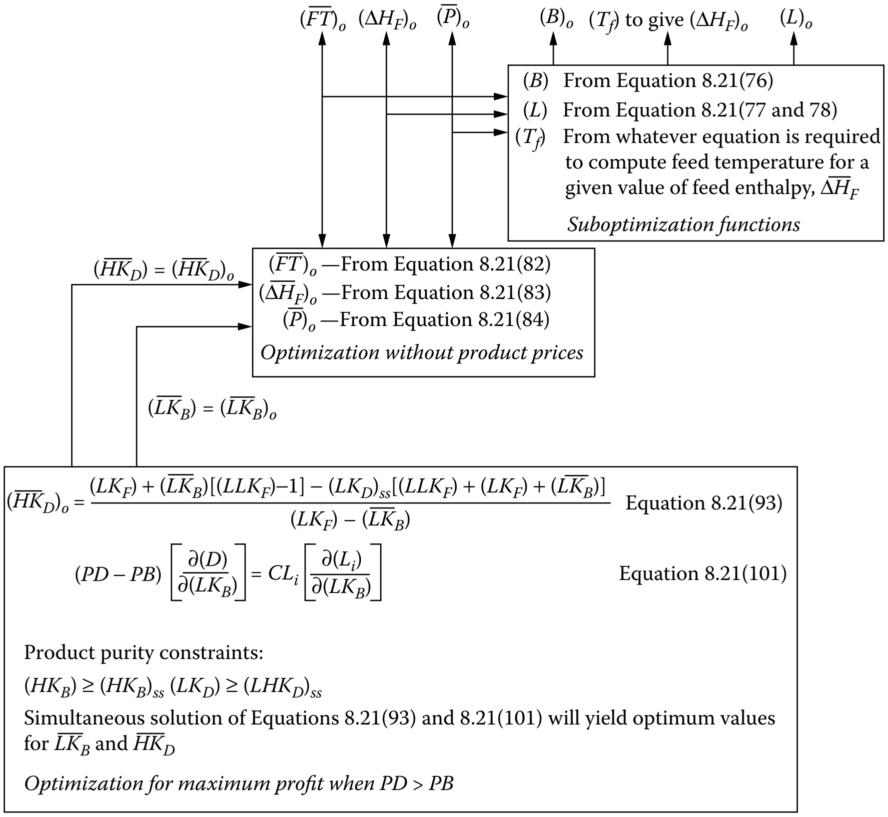

FIG. 8.21hh
Control hierarchy to maximize profit rate when operating constraints are involved.

For this case, L will equal L_i. Also, eliminate D by substituting $(F - B)$. Therefore, by substituting

$$L = L_i = \left[\frac{L_i}{F}\right]\mathrm{F} \qquad \textbf{8.21(104)}$$

and

$$B = \left[\frac{B}{F}\right]F \qquad \textbf{8.21(105)}$$

the following is obtained:

$$a_1 + a_3(\bar{P}) + \left[(a_2 - 1)\frac{L_i}{F} + \frac{B}{F} - 1\right]F = 0 \qquad \textbf{8.21(106)}$$

In this equation a_1, a_2, and a_3 are known from the experimental loading equation. $\bar{P}$ is specified, F is measured, and L_i/F and B/F are obtained from the operating control equations for reflux and bottom product flow rate.

It is now possible to find the optimum value for $\overline{HK}_D$. As $\overline{HK}_D$ is lowered from its maximum allowable value as given by Equation 8.21(93), the values for L_i/F and B/F will change. $\overline{HK}_D$ can be lowered until loading Equation 8.21(102) is equal to zero. Also, column pressure $\bar{P}$ can be raised to allow a greater loading that will result from a lower $\overline{HK}_D$. A point will be found at which maximum profit rate will exist.

The maximum limit for $\bar{P}$ will be determined by several factors. As $\bar{P}$ is increased, operating costs will also increase, because of the resulting smaller differential temperature at the reboiler. Therefore, one possible limit would be a reboiler (or operating cost) limit.

Another pressure limit will be set by the column pressure rating. Another limit for maximum $\bar{P}$ may be determined by requirements of upstream processing equipment. Yet another limit for maximum $\bar{P}$ could be loading of the downcomers between each tray. This comes about because at higher vapor densities, disengagements of vapor from the liquid becomes more difficult. Therefore, at some maximum pressure, density of the vapor can approach the point at which vapor will not have sufficient time to disengage from the liquid in the downcomers, and a condition known as downcomer flooding will occur.

Assume for the purpose of illustration that the maximum for $\bar{P}$ is set at the pressure rating of the column. Therefore, $\bar{P}$ will be set and left at this value.

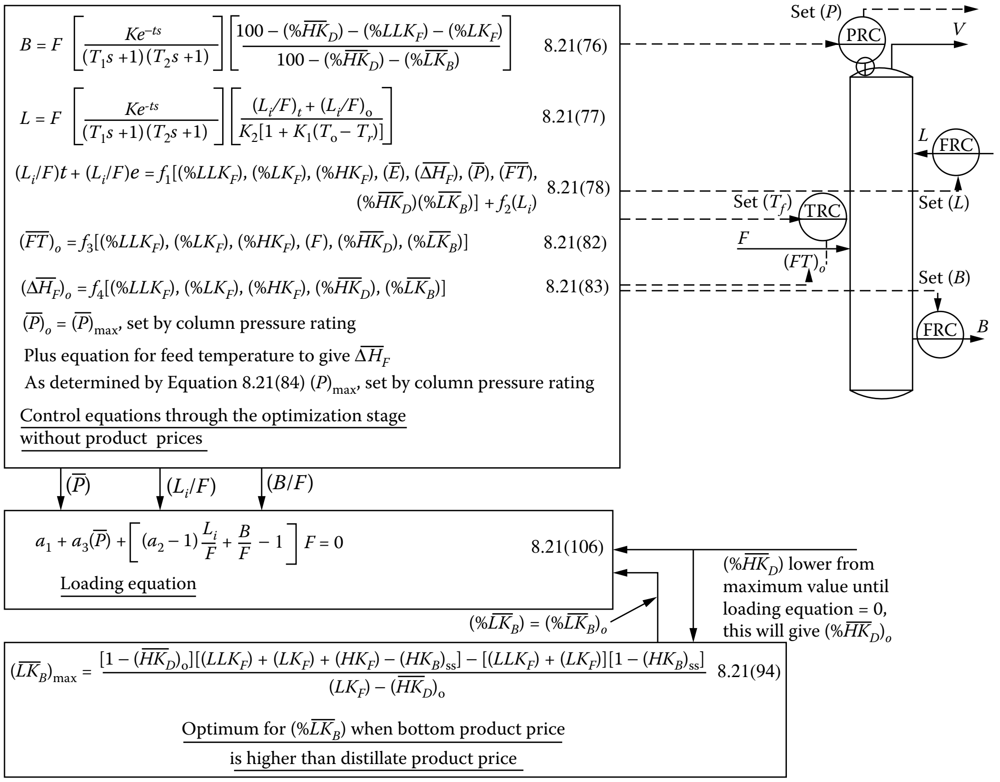

FIG. 8.21ii

System for maximizing profit rate when bottom product price is higher than top product price and when entrainment above the feed tray limits loading.

Figure 8.21ii shows the optimizing control system connected to a typical distillation column. Only part of the basic controls are shown for purpose of clarity. The basic controls are not show in this figure and can be assumed to be the same as shown in Figure 8.21t.

Unlimited Market and Feedstock

When an unlimited market exists for the products, the feed flow rate and separation resulting in maximum profit rate must be determined. Operation for a column under this condition will always be against an operating constraint. The following example assumes that the operating constraint is the overhead vapor condenser capacity.

In general, the overall optimization problem for this case is illustrated in Figure 8.21jj. Values must be determined for the optimum separation, $(\overline{HK}_D)_o, (\overline{LK}_B)_o$; feed flow rate, $(F)_o$; and column pressure, $(\overline{P})_o$, that will give maximum profit. One of the key component specifications, $\overline{HK}_D$ or $\overline{LK}_B$, can be easily determined from the general optimizing policies. Often, the incremental gain in recovery of the most valuable product will not exceed the incremental gain resulting from increasing feed flow rate. This means that both products operating at minimum purity will allow the largest quantity of feed to be charged for maximum profit rate.

Optimum Concentrations Both products must be produced at minimum purity to achieve the most profitable operation for this case. Therefore,

$$\overline{LK}_D = (\overline{LK}_D)_{ss} \qquad \textbf{8.21(107)}$$

$$\overline{HK}_B = (\overline{HK}_B)_{ss} \qquad \textbf{8.21(108)}$$

The concentration for each control component ($\overline{LK}_B$ and $\overline{HK}_D$) must be as follows to satisfy Equations 8.21(107) and 8.21(108):

$$(\overline{LK}_B)_o = (\overline{LK}_B)_{max} \qquad \textbf{8.21(109)}$$

$$(\overline{HK}_D)_o = (\overline{HK}_D)_{max} \qquad \textbf{8.21(110)}$$

$(\overline{HK}_D)_{max}$ and $(\overline{LK}_B)_{max}$ are given by Equations 8.21(93) and 8.21(94). The separation is optimized independently by column pressure $(\overline{P})$ and feed rate (F).

Loading Constraint As was previously explained, the overhead vapor condenser limits loading for this example. Column

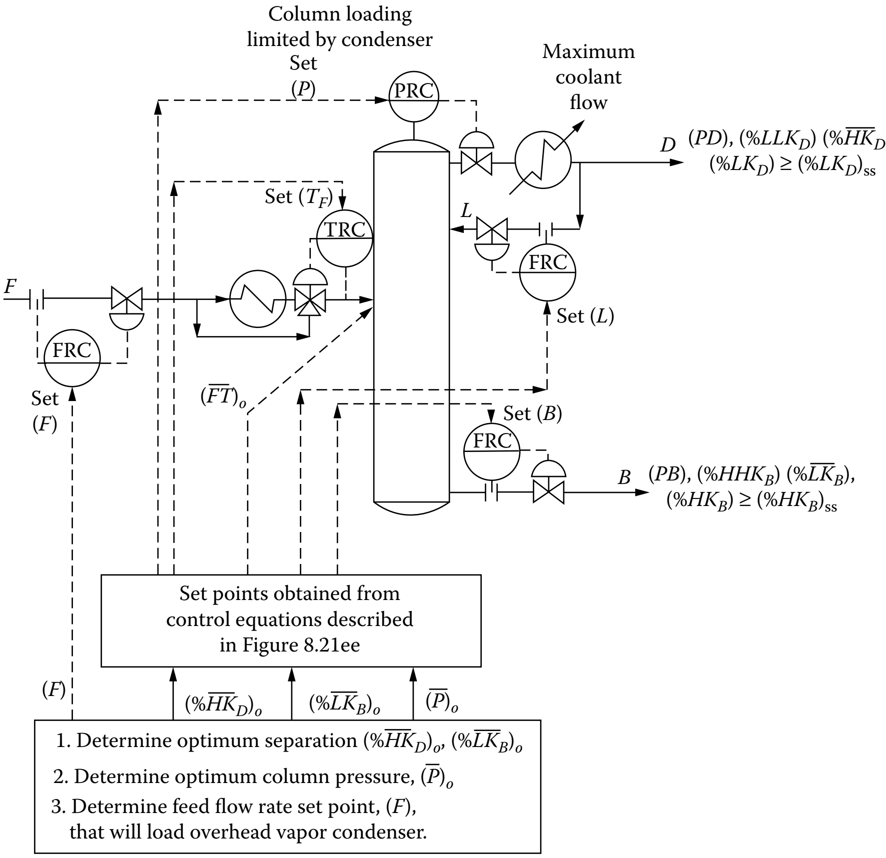

FIG. 8.21jj
When an unlimited market exists for the products and the product prices (PD, PB) are known, the optimum separation, the optimum column pressure, and the value for feed flow rate that will give maximum loading must be found.

pressure must, therefore, be operated at maximum in order to obtain maximum condensing capacity. (ΔT across the condenser tubes will be the largest at maximum column pressure, and therefore maximum condenser capacity will result.) The maximum pressure that can be used will be determined by one of the following five constraints, assuming operating costs do not become prohibitive before a physical constraint is reached:

1. Column downcomer capacity
2. Reboiler capacity
3. Upstream equipment pressure specifications
4. Pressure rating of the column shell
5. Fouling of the reboiler or condenser tubes

As column pressure is increased, the capacities of the reboiler and tower trays will be approached. Also, the pressure rating of the shell and of other processing equipment will be approached. The one of the five constraints that is approached first, as column pressure is raised, will set the operating pressure. Assume for the purpose of illustration that the shell pressure rating is the limit on column pressure. Pressure can, therefore, be set constant at the pressure rating of the column shell.

Optimum Feed Flow Rate After the optimum separation $(\overline{LK}_B)_o$ and $(\overline{HK}_D)_o$ and the optimum column operating pressure $(\overline{P})_o$ have been determined, the feed rate can be increased until the condenser capacity is approached. There are several ways that feed rate can be manipulated to maintain condenser loading. One very useful method involves a predictive control technique.

Overhead vapor flow rate can be expressed in terms of various independent inputs and terms obtained from the operating control equations. Development of the predictive control equation proceeds as follows:

$$V_o = D + L \qquad \textbf{8.21(111)}$$

where
V_o = vapor flow rate overhead
D = top product flow rate
L = external reflux flow rate

First, eliminate D by $D = F - B$. Now, the maximum overhead vapor flow rate will be given by Equation 8.21(85) and Equation 8.21(111) can be set equal.

$$a_1 + a_2(\Delta T) + a_3(\Delta T)^2 = L + F - B \qquad \textbf{8.21(112)}$$

or

$$F = a_1 + a_2(T_o - T_c) + a_3(T_o - T_c)^2 + B - L \qquad \textbf{8.21(113)}$$

where

a_1, a_2, a_3 = coefficients for condenser-loading equation that are determined by column tests
F = feed flow rate
T_o = overhead vapor temperature
T_c = temperature of coolant to overhead vapor condenser
B = bottom product flow rates from the output of operating control equation
L = reflux flow rates from the outputs of operating control equation

Temperature of the overhead vapor will be a function of all independent inputs to the system. However, column pressure is usually the main variable of concern. For this example let

$$T_o = f(\bar{P}) \qquad \textbf{8.21(114)}$$

where $f(\bar{P})$ is some function of column pressure.

In many cases $f(\bar{P})$ can be considered a linear function such as

$$f(\bar{p}) = d_1 + d_2(\bar{p}) \qquad \textbf{8.21(115)}$$

This equation can be determined off-line from correlation of data obtained from flash calculations at the average composition of the existing overhead vapor. If changes in composition of the overhead vapor affect temperature of the overhead vapor by a significant amount, then composition also has to be taken into account. Composition for the overhead vapor can be easily approximated from feed composition analysis. If Equation 8.21(113) is carried to this extent, then the feed flow rate can be predicted to keep the condenser against its maximum capacity. For the purpose of illustration here, T_o is assumed to be a function of column pressure only.

Eliminate T_o from Equation 8.21(113) by Equations 8.21(114) and 8.21(115) to obtain

$$a_1 + a_2[d_1 + d_2(\bar{P}) - T_c] + a_3[d_1 + d_2(\bar{P}) - T_c]^2\ B - L = F_{\max} \qquad \textbf{8.21(116)}$$

$\bar{P}$ and T_c are measured, and B and L are obtained from the operating equations' set point calculations. $F_{\max}$ will be the feed rate required to load the condenser for the particular values of $(\overline{HK_D})_o$ and $(\overline{LK_B})_o$.

Figure 8.21kk shows the overall optimizing control system. Only the necessary basic controls are shown. The other controls can be assumed to be as shown in Figure 8.21t.

Reboiler Limiting Let us now assume that loading is limited by the reboiler instead of the condenser. Optimum separation remains the same. However, now column pressure must be operated at a minimum value in order to gain maximum reboiler capacity. For this example, assume that minimum column pressure is set by the pressure requirements of downstream equipment. Therefore, column pressure is set at a constant value and will not be changed unless the pressure requirements of downstream equipment are changed.

Having achieved the optimum separation (minimum purity of products) and optimum column pressure, the feed rate can now be increased up to the maximum capacity of the reboiler. This, then, will represent the most profitable operation.

Again, manipulation of the feed flow rate can be handled by a predictive control technique. Liquid flow rate below the feed tray (L_f) is given by

$$L_f = L_i + F_i \qquad \textbf{8.21(117)}$$

where F_i is the internal feed flow rate.

$$F_i = F[1 + (K_F)(T_v - T_t)] \qquad \textbf{8.21(118)}$$

where

K_F = a constant equal to the specific heat of the feed divided by the heat of vaporization
T_v = temperature of vapor above the feed tray
T_f = temperature of feed at column entry

The vapor flow rate out of the reboiler is given by

$$V_B = L_f - B \qquad \textbf{8.21(119)}$$

Now, substitute Equation 8.21(118) into Equation 8.21(117) to eliminate F_i. Then, substitute Equation 8.21(117) into Equation 8.21(119) to eliminate L_f. The following is obtained:

$$V_B = L_i + F[1 + (K_F)(T_v - T_f)] - B \qquad \textbf{8.21(120)}$$

Next, substitute $(L_i/F)F$ for L_i, and $(B/F)F$ for B. Then solve for F to obtain

$$F = \frac{(V_B)_{\max}}{(L_i/F) + 1 + (K_F)(T_v - T_f) - (B/F)} \qquad \textbf{8.21(121)}$$

where

F = set point of feed flow controller
$(V_B)_{\max}$ = maximum reboiler heat input rate

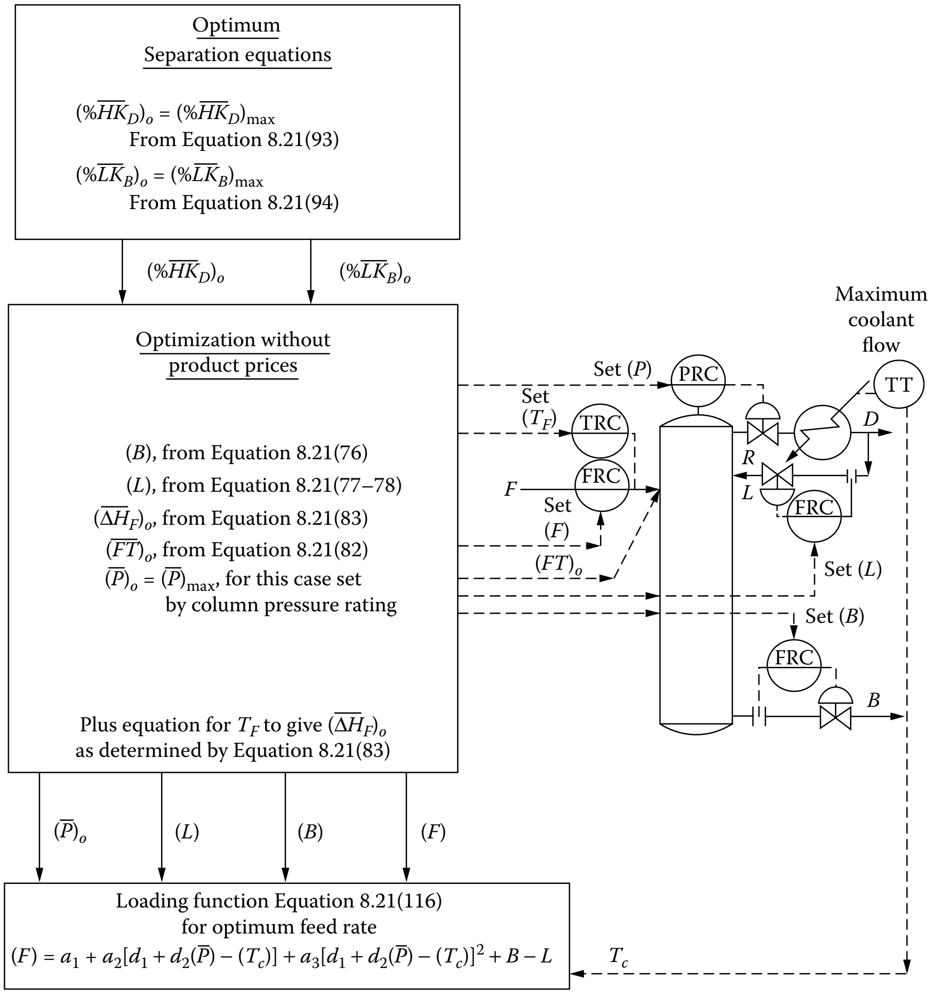

FIG. 8.21kk
Optimizing for maximum profit rate when unlimited market exists for the products and loading is limited by condenser capacity.

Equation 8.21(121) calculated that feed flow rate which is required to cause the vapor rate $(V_B)_{\max}$ to exist for all separations specified. L_i/F and B/F are obtained from the operating control equations used to achieve a suboptimum operation. T_v and T_f are measured.

Equation 8.21(121) is used by specifying $(V_B)_{\max}$ and then evaluating the column operation. After sufficient time for the column to stabilize, the reboiler valve position (output of reboiler heat flow controller) is observed. If, for example, the reboiler valve is 85% open, $(V_B)_{\max}$ can then be increased until the reboiler heat control valve is near its maximum opening, say, 95% open.

Enough room must be left to maintain control. $(V_B)_{\max}$ can be adjusted by the plant operator to maintain the reboiler valve near open or can be handled automatically by a valve-position-based feedback controller. Once $(V_B)_{\max}$ is established by experience, few adjustments will be required to maintain the column in a fully loaded condition. Adjustments to $(V_B)_{\max}$ will be required only as the heat transfer capability of the reboiler varies. The control scheme is illustrated in Figure 8.21ll.

CONCLUSIONS

Example solutions to some of the common distillation column optimizing problems have been given. Although many different situations can exist, they usually are combinations of those presented.

Optimization by feedback control methods cannot approach the quality of control obtained by predictive (feedforward) techniques. This is true even though the predictive control equations may require updating by feedback. In effect, predictive optimization control greatly attenuates any error that must be handled by feedback (updating).

The application of feedforward optimizing control forces development of mathematical models of the component parts

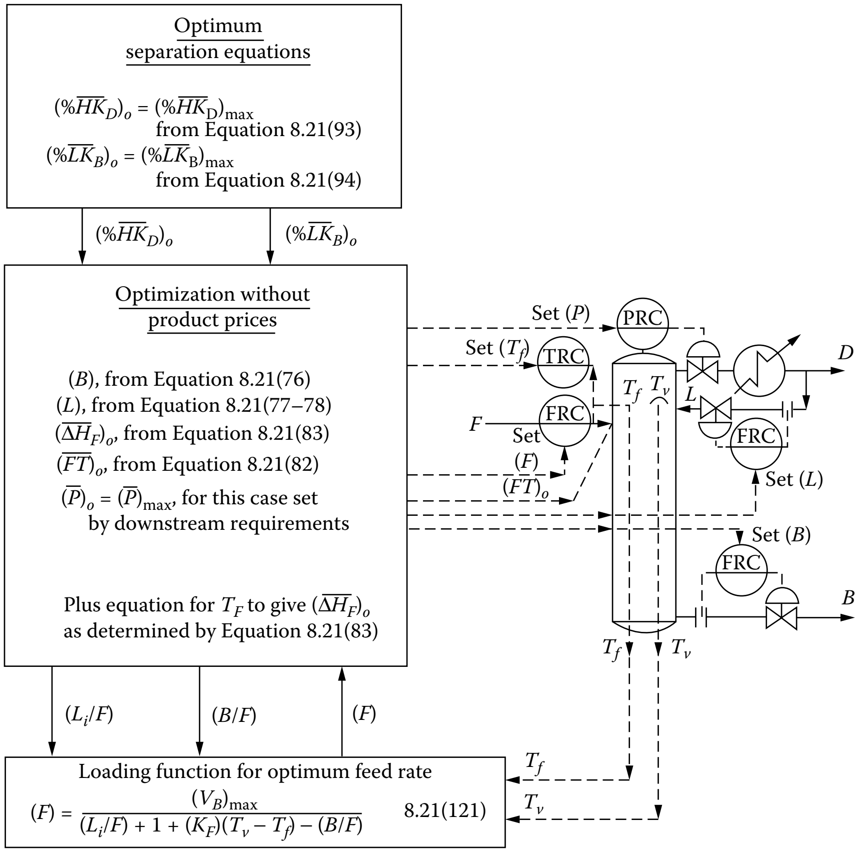

FIG. 8.21ll

Optimization of a distillation column when unlimited market exists for the products, prices of the products are known, and loading is limited by the reboiler.

of a process. The mathematical models developed for optimizing unit operations will eventually be required to extend optimization to include an entire plant complex.

The APC products most applicable to distillation modeling are the white box models, where the theoretical dynamic models are derived on the basis of the mass, energy, and momentum balances of the process. Fuzzy logic and black box models are used less often, as they are more applicable to processes that are poorly understood or when it is acceptable to use a complete mechanistic empirical model constructed solely from a priori knowledge.

Flow sheet symbol

INTRODUCTION

The equipment discussed in this section serves to dry solids. The process involves the removal of liquids, such as water or other solvents, by adding heat to vaporize them. The types of dryer designs discussed can be grouped into batch and continuous. They can be further subdivided on the basis of whether the dryer itself is heated (*nonadiabatic*) or unheated and the heat of vaporization is provided by preheated air (*adiabatic*).

Adiabatic dryers can be *co-current* (the solids and the drying air move in the same direction), *countercurrent* (hot air and solids move through the dryer in opposite directions), or *fluidized bed*. The control of each of these designs will be briefly discussed in this section.

The subject of dryers is so extensive that some limitations must be imposed on the discussion. Therefore:

1. The dryers and drying principles discussed will be limited to those related to the removal of a volatile solvent from a solid material. Such processes as the removal of a solvent from an air stream (air drying) or the removal of one solvent from another (drying of an organic solvent) will not be covered.
2. The solvent to be removed will be taken as water.
3. The heating medium used may be steam or the firing of a fuel.

ADIABATIC DRYING

The energy source for adiabatic drying is the sensible heat of a stream of air directed toward a bed or a stream of moist solids. Heat flows from the air to the solids, evaporating some of their moisture — in this respect, the governing force for drying is that of heat transfer. In this process the air is cooled, but its energy content (enthalpy) does not change, because the sensible heat loss equals the latent heat associated with its increased moisture content.

The Psychrometric Chart

Figure 8.22a is a psychrometric chart relating the absolute and relative humidity of air to its temperature and enthalpy. The vertical scale is absolute humidity in grains of moisture carried by a pound of dry air (1 lb is 7000 grains). Dry-bulb temperature is the horizontal scale.

The uppermost curve is the saturation limit — 100% relative humidity, the remaining curves representing lower levels of RH. The temperature of the air at 100% RH is also its dew point. Consider, for example, a hot summer day with a (dry-bulb) temperature of 85°F and a RH of 75%. The absolute humidity of the air would be about 137 grains/lb dry air, and its dew point would be about 76°F.

Such air might be used to dry lumber, for example, by heating it to 115°F. Point A on the psychrometric chart would then represent the condition of the heated air that is sent to the dryer — notice that its RH at that point is only 30%.

The scale in the center of the chart is marked in units of BTU/lb dry air total heat, or enthalpy. As the air passes through the adiabatic dryer, its enthalpy will remain at 50 BTU/lb, while it cools and evaporates moisture from the solids. The path it takes on the chart then follows a line of constant enthalpy sloping upward to the left toward point B, where it is exhausted from the dryer at 80%RH. These lines of constant enthalpy are also lines of constant wet-bulb temperature.

A wet-bulb thermometer's bulb is covered by a wick that is saturated with water. It is whirled in the air, or has a stream of air blown across it. The equilibrium temperature reached during this process is known as the wet-bulb temperature and can be used along with dry-bulb temperature to estimate RH, absolute humidity, and dew point from the chart. It is also a direct indication of enthalpy — note that the wet-bulb lines on the chart are also lines of constant enthalpy.

Wet-bulb temperature is particularly important in a drying operation, because the wet bulb is an analog of the solid material being dried. As moisture evaporates from the solid in an adiabatic dryer, its temperature approaches that of a wet-bulb thermometer in the same air, and it remains at that

FIG. 8.22a
Psychrometric chart.

temperature through most of the drying operation. Measuring the wet-bulb temperature in a dryer or even in the air entering a dryer is difficult, however, because the wick must be continuously supplied with just the right flow of water, and the wick is subject to plugging from dust and any dissolved solids in the water (Figure 8.22b).

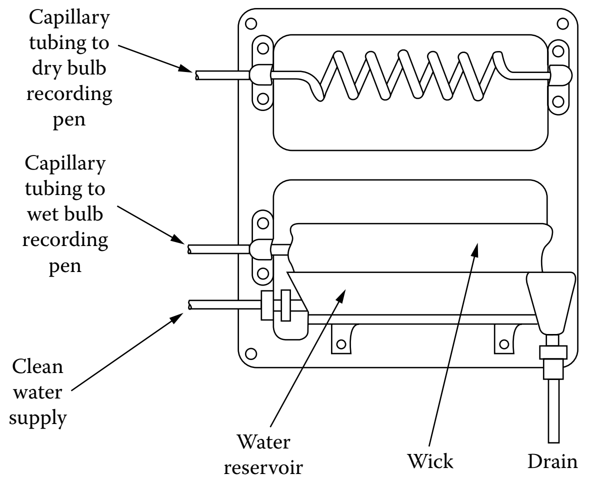

FIG. 8.22b
Wet-dry bulb hygrometer using filled system temperature sensors arranged for duct mounting.

As a result, wet-bulb temperature is rarely measured in situ, but can be calculated from other measurements such as dry-bulb and dew-point temperatures. The exception is in a lumber kiln, where conditions are relatively mild and dust-free.

Batch Drying

Many materials are dried in batches; for example, fine powders, which are later encapsulated into aspirin and other tablets. The drying is typically conducted in a fluid bed such as shown in Figure 8.22c.

A basket fitted with fine-mesh screens on bottom and top is charged with wet powder and wheeled into the dryer, where it is sealed in place. The exhaust fan is started, drawing air upward through the bed, fluidizing the wet powder. The air is heated by a steam coil to a controlled temperature before it contacts the solids.

Initially, the solids will be below the wet-bulb temperature of the heated air and will warm to that value within minutes, where evaporation will begin. The first water to be removed will be surface moisture, and it will be removed at a constant rate until the surface is partially dry. Migration of moisture from within the solids then progresses at a reduced rate. If drying is continued indefinitely, an equilibrium temperature will eventually be reached where no more moisture is removed.

When the product is later exposed to atmospheric conditions, the equilibrium will shift, however, and some moisture

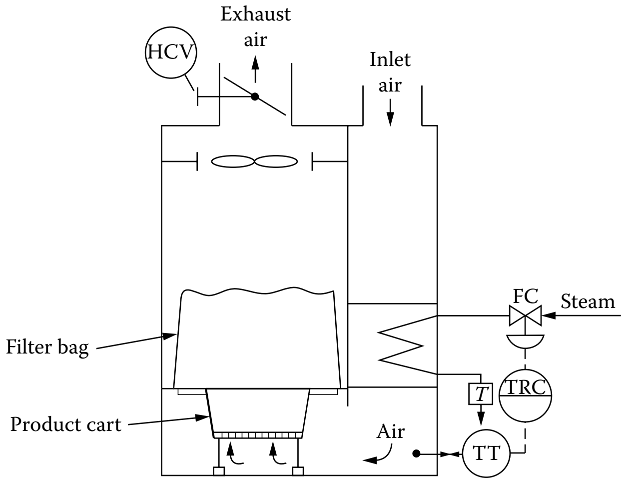

FIG. 8.22c
Batch fluid-bed dryer.

may be readsorbed from the air. A profile of moisture content against time for a typical batch dryer is given in Figure 8.22d.

The curve consists of four zones. Section A-B represents the period of preheating of the solid to the initial drying temperature; evaporation during this phase is slow. The next section, B-C, is a period of evaporation of surface moisture or moisture that migrates readily. The temperature near the surface of the solids during this time is the wet-bulb temperature of the air in contact with the product.

After the surface moisture has evaporated, the rate of evaporation drops off (section C-D). This reduction may be due in part to a case-hardening of the surface and in part to the long path necessary for the water to migrate to the surface. If the solid has water-of-crystallization, or bound water, the rate will then drop off even more, as shown in section D-E of the curve. At point E, equilibrium is established and the drying rate is zero.

Other curves are also useful for an understanding of dryer control requirements. The first of these, Figure 8.22f, represents the derivative of Figure 8.22e, that is, the variation in rate of drying as a function of time.

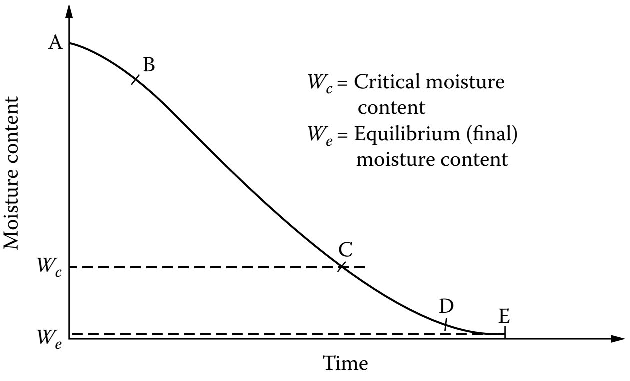

FIG. 8.22d
Typical batch drying curve.

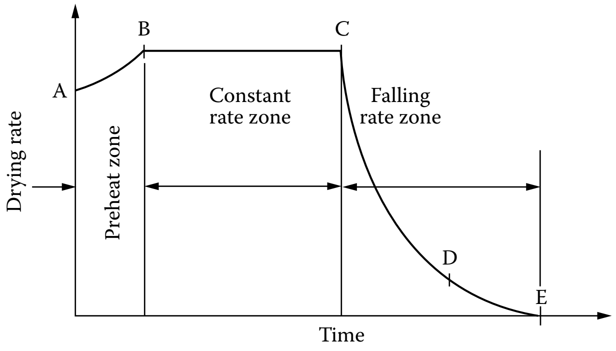

FIG. 8.22e
Rate of drying vs. time.

Another curve, Figure 8.22g, combines these two to relate the rate of drying to the moisture content of the solid.

In virtually all dryers, the desired moisture content of the product lies in the falling-rate zone, i.e., below its critical moisture content. In this zone, the moisture content of the product is proportional to the rate of drying, in fact, approximately linear with it, which gives the dryer a degree of self-regulation.

The lower the moisture content, the harder it is to remove. The relationship between rate of drying and driving force allows for moisture control without an on-line measurement.

It is common for operators of batch dryers to stop the operation when it is estimated that the product is close to its desired moisture content—on the basis of time or intuition—and sample it. The sample is typically placed in a loss-in-weight analyzer where it is weighed, dried thoroughly by

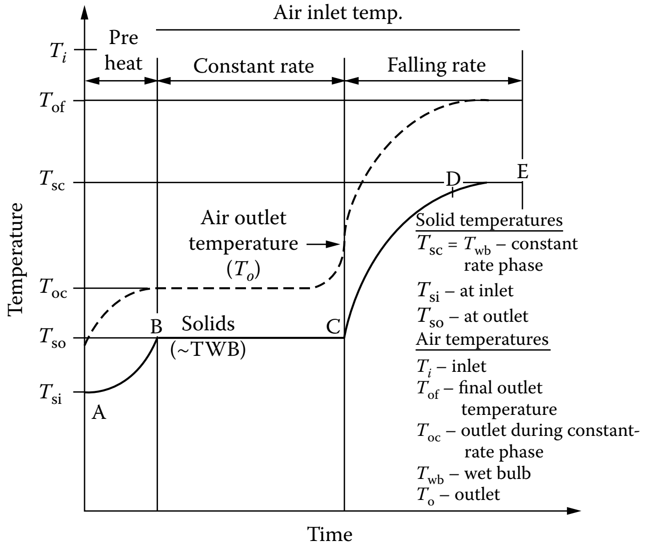

FIG. 8.22f
Product temperature rises in a batch dryer from T_{si} to T_{so} as it is heated by air, which enters at T_i and leaves at T_o.

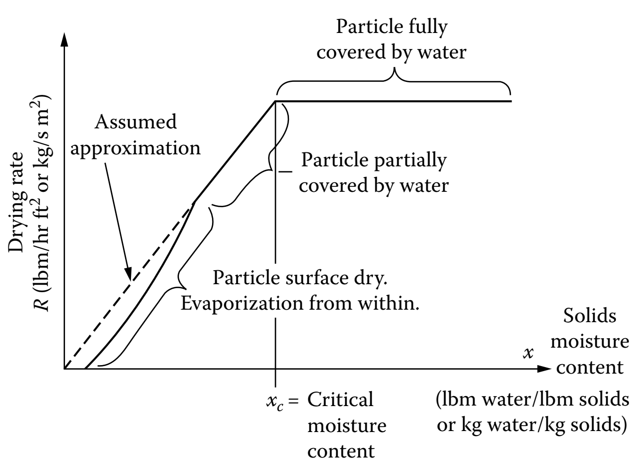

FIG. 8.22g
Drying rate versus moisture content.

infrared radiation, and weighed again, which takes a few minutes.

If the product moisture is still too high, the drying will be resumed for a time and the product sampled again. If the moisture is too low, the product may have to be sprayed with water and drying repeated. However, the conditions corresponding to the desired moisture can be estimated on-line, and the dryer can be automatically shut down when those conditions are met, avoiding unnecessary sampling and thereby saving time. To do this, a model of the drying process is needed.

Dryer Model

The rate of evaporation from a solid is proportional to its moisture content x (following the linear approximation) up to its critical moisture x_c. It is also proportional to the driving force, which is the temperature difference between the air and the solid, which is also the difference between the dry- and wet-bulb temperatures of the air, $T - T_w$:

$$dW = dAk(T - T_w)x/x_c \qquad \textbf{8.22(1)}$$

where dW is the water transferred from a solid particle of surface area dA to the air, and k is the mass-transfer coefficient. As the air passes through the bed, its temperature falls by evaporation:

$$-dT = dW\frac{H_v}{GC_p} \qquad \textbf{8.22(2)}$$

where H_v is the latent heat of evaporation, G is the mass flow of air, and C_p is its specific heat. Combining these two equations by eliminating dW, and integrating across the total area A of solids in the dryer, produces a relationship[1] between product moisture x and air temperatures:

$$x = \frac{x_c G C_p}{H_v k A}\ln\frac{T_i - T_w}{T_o - T_w} \qquad \textbf{8.22(3)}$$

where T_i is the inlet air temperature and T_o is its outlet temperature. Given a constant airflow and surface area, product moisture in the fluid bed is proportional to the ratio of the dry-to-wet-bulb temperature difference at the ends of the dryer. This relationship will be used to control product moisture in both batch and continuous adiabatic dryers.

MOISTURE CONTROL

Moisture Analyzers

On-line moisture analyzers are becoming more common in industry, and more reliable as well (Figure 8.22h). However, they are subject to a difficult environment—hot, humid, and dusty—and the material they are analyzing tends to have nonuniform properties within a product and quite-variable properties from product to product. Variable particle size and bulk density are particularly a hindrance to optical and electrical measurements.

Optical devices can only read surface moisture, while the internal amount in a lump of solids might be quite different; and a rough or irregular surface adds a high level of noise to the measurement. Devices based on loss in weight avoid the problem of variable density, but add sample-handling difficulties and are slow.

Even when an on-line measurement is found to be accurate and reliable, it is applied to a product that has already left the dryer. Most dryers are dominated by dead time, and so the analysis reflects a condition that is several minutes—perhaps even an hour—old.

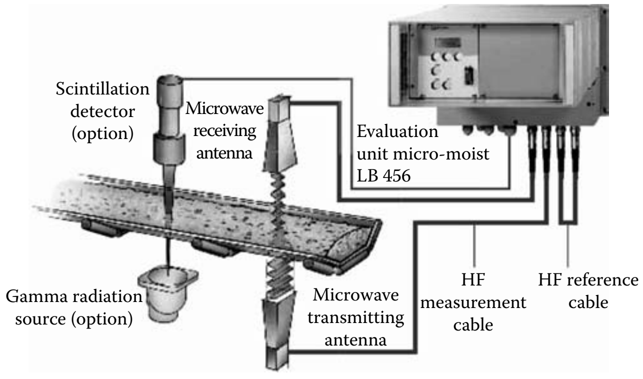

FIG. 8.22h
Noncontacting moisture analyzer can be provided with gamma radiation densitometer to compensate for variations in process density. (Courtesy of Berthold Technologies.)

By contrast, air temperatures respond readily to changing heat input and feed conditions, and if controlled, they can keep a product on specification before an analyzer can detect a significant variation. So, when an analyzer is used for control, it should set temperature in cascade and preferably be used to update an inferential model

Controlling Batch Dryers

The outlet-air temperature of a batch dryer is quite revealing of the process within. Figure 8.22i gives a typical time plot, relative to a constant inlet-air temperature at the top and a corresponding constant wet-bulb temperature at bottom. After a short preheat of the dryer and its contents, evaporation begins at a constant rate, with the outlet-air temperature settling at T_{oc}, not far above the wet-bulb temperature. After the product moisture has reached the critical value, falling-rate drying begins. This decrease in the rate of drying is reflected in a rise in outlet-air temperature, simultaneously increasing the driving force. Eventually, a temperature will be reached where the product moisture is at specification and the drying should be terminated—this is designated at T_{of} in Figure 8.22i.

To apply the fluid-bed dryer model, lump the constants of Equation 8.21(3) into a single constant K:

$$x = Kx_c \ln \frac{T_i - T_w}{T_o - T_w} \qquad \textbf{8.22(4)}$$

Wet-bulb temperature can be estimated from the measured value of T_{oc} by applying the model to the constant-rate period, setting $x = x_c$ and solving for T_w:

$$T_w = \frac{T_i - T_{\text{oc}}e^{1/K}}{1 - e^{1/K}} \qquad \textbf{8.22(5)}$$

where e is 2.718, the base of the natural logarithms. Once having estimated T_w, it can then be subsequently used in the same model to calculate T_{of}, which corresponds to the desired final moisture content x:

$$T_{\text{of}} = T_{\text{oc}} + C(T_i - T_{\text{oc}}) = CT_{\text{oc}} + (1 - C)T_i \qquad \textbf{8.22(6)}$$

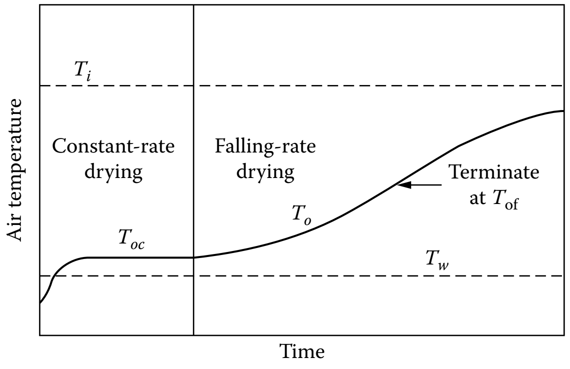

Fig. 8.22i
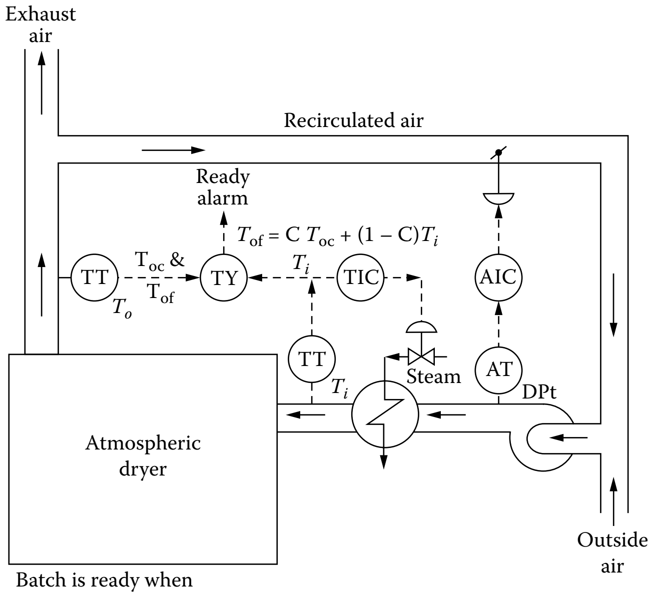
Product moisture should be on-specification at T_{of}.



Batch is ready when
$T_o > \text{C}\ T_{\text{oc}} + (1 - \text{C})T_i$
The smaller the constant "*C*" the drier the product will be.

FIG. 8.22j
Inferential control of a batch dryer with recirculated air.

The value of T_{oc} measured during constant-rate drying must be held in memory and used later to calculate T_{of}. When the actual measurement of T_o reaches the calculated value of T_{of}, drying should be terminated. Coefficient C is an adjustable constant, which includes the desired product moisture, batch size, and airflow. It must be determined for each product on-line. Once calibrated to a particular product, it should deliver consistent batch-to-batch moisture regardless of initial atmospheric humidity and inlet-air temperature; it is somewhat sensitive to batch size, however.

To keep inlet-air humidity from changing during the course of a run, some of the exhaust air can be recirculated under dew-point control, as shown in Figure 8.22j. At the beginning of a run, during constant-rate drying, the exhaust air will be cool and wet, and not useful for recirculation. But during falling-rate drying it becomes progressively warmer and dryer, and its recirculation under dew-point control can reduce steam consumption.

Lumber Kilns

A lumber kiln is a batch dryer where lumber is stacked in a manner that allows uniform airflow through it. Heated air circulates from one end of the kiln to the other, with the direction of flow reversed periodically for more uniform drying.

The wet-bulb temperature of the circulated air is controlled by opening an exhaust damper, which releases humid air and induces an equal flow of fresh air into the kiln. The rate of drying must be strictly limited to prevent cracking of the wood from stress caused by unequal moisture distribution.

At every reversal of flow, the temperature gradient in the kiln reverses. Temperatures at both ends of the kiln are compared in high and low selectors, with the higher selected as the inlet temperature T_i and the lower as the outlet temperature T_o. Rate of drying is limited by controlling $T_i - T_o$ with a steam valve on the air heater. T_i is also limited by a controller that is overriding the rate-of-drying controller through a low selector. These controllers are transferred to manual briefly after each flow reversal, until the temperatures settle at their new values.

Reference 2 describes the successful calculation of wood moisture using Equation 8.22(4) directly from measurements of inlet, outlet, and wet-bulb temperatures. Kx_c was adjusted to calibrate the model for each species and grade of wood, and drying was terminated when the calculated value of x reached the specification for that product. The use of the model resulted in a higher quality product, more batch-to-batch uniformity, and shorter batch times.

Continuous Fluid-Bed Dryers

The continuous fluid-bed dryer shown in Figure 8.22k uses a temperature controller on the air leaving the bed to manipulate the flow of steam to the air heater. A second controller maintains bed density by holding a constant differential pressure across it. In this dryer, rapid circulation of the solids means that the average moisture content in the bed is approximately the same as that of the product being discharged. As a consequence, the rate of drying is essentially that of the product.

The relationship between product moisture and air temperatures is then governed by Equation 8.22(4). An increase in either feed rate or moisture will lower the outlet-air temperature, causing the controller to increase steam flow to return it to set point. However, the addition of more heat to the air also raises its wet-bulb temperature, which narrows the temperature difference in the denominator of Equation 8.22(4), while raising the temperature difference in the numerator, thereby raising the level of moisture in the product. Therefore, controlling at a fixed temperature set point gives a product that is sensitive to variations in load as well as atmospheric humidity.

To provide load regulation and protection from humidity variations, the inferential model of Equation 8.22(4) can be applied. It requires a measurement of inlet-air temperature, which should be controlled in cascade from the outlet-air temperature controller. It also requires wet-bulb temperature, but this is not measurable under the conditions prevailing in the dryer—it must be calculated as a function of inlet-air temperature and humidity. The model is then inverted so that outlet-air temperature appears in the numerator, as that is the controlled variable. Outlet-air temperature is plotted as a function of inlet-air temperature for conditions of constant product moisture in Figure 8.22l, using the software in Reference 3.

Ambient temperature and dew point are entered into the program, along with fuel type in case of direct firing—this figure has no fuel input. The origin of the plot is the point where both inlet and outlet temperatures are equal to the ambient—here, 50°F.

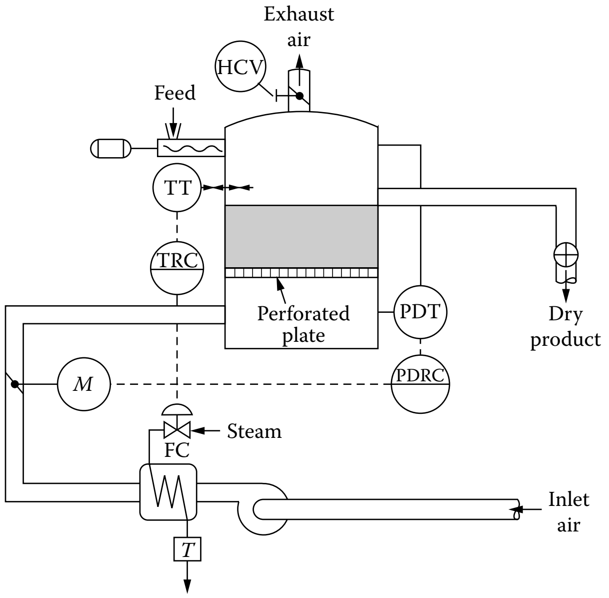


FIG. 8.22k
A continuous fluid-bed dryer with single-loop controls.

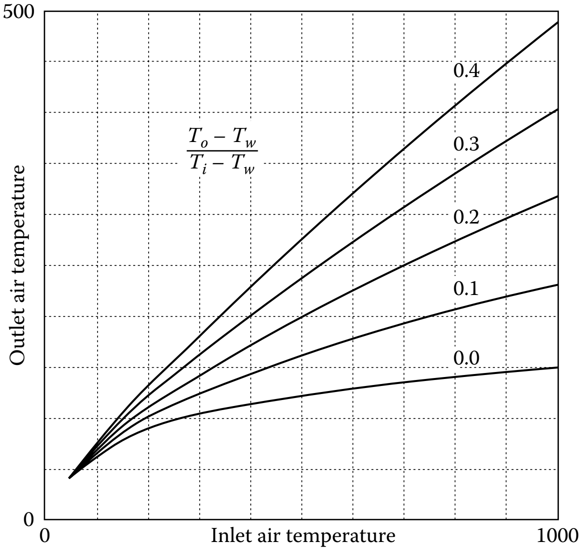

FIG. 8.22l
Each curve represents a contour of constant dryness; temperatures are in °F.

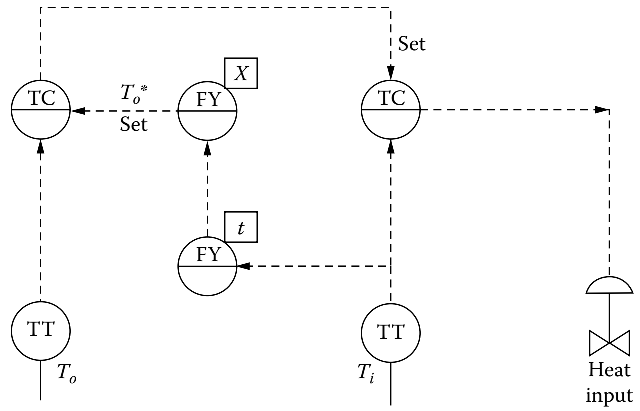

FIG. 8.22m
The inferential moisture control system has positive feedback.

The program then calculates the wet-bulb temperature for that air heated to each inlet temperature across the scale. (If the temperature is reached by combustion, then the water thus formed is added to the ambient humidity.) The wet-bulb temperature is plotted as the lowest contour, where the temperature ratio is 0. Each of the other curves is plotted by applying a different ratio, from 0.1 to 0.4, covering the conditions found in most dryers.

At a certain set of operating conditions, a fluid-bed dryer will be making on-specification product. A set of curves is plotted for that set of ambient temperature and dew point, and the inlet and outlet temperature coordinates corresponding to the desired product moisture are marked on the chart. A curve drawn through that point parallel to its neighbors then represents the locus of temperatures also producing that moisture content.

At higher temperatures and higher ratios, the curves are almost linear. Then, the model reduces to a simple matter of setting the outlet-air temperature set point T_o^* in ratio to inlet-air temperature T_i:

$$T_o^* = a + bT_i \qquad \textbf{8.22(7)}$$

where a and b are constants that give the best linear fit. However, a more accurate fit can be made by calculating wet-bulb temperature on-line and solving for T_o^* directly. A control system based on Equation 8.22(7) is shown in Figure 8.22m.

The indexing of the set point of the T_o controller forms a positive-feedback loop — a higher inlet temperature raises the outlet-temperature set point, which causes its controller to increase inlet temperature further. At the same time, the outlet-temperature measurement will also start to increase, and this is negative feedback. For a system having positive feedback to be stable, its gain must be lower and its dynamics slower than the negative feedback loop in the system.

The gains of all the curves in Figure 8.22l are 0.5 or less, compared to a negative-feedback gain of 1, so the system will not run away. But the loop will cycle if the positive feedback is not also slower. Therefore, a lag [*t*] is inserted in Figure 8.22m as a model of the dryer dynamics. This loop is very similar to the reset feedback loop in a PI or PID controller that has a positive feedback gain of 1.0 and a lag that represents the integral time. Therefore, the lag [t] in Figure 8.22m can be safely set at the same value as the integral time of the outlet-temperature controller.

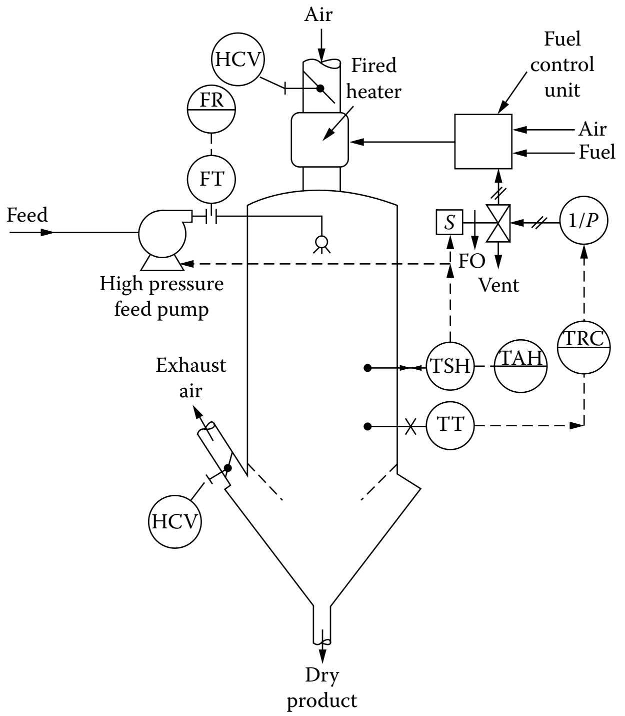

FIG. 8.22n
Spray dryer with single-loop controls.

Direct-Fired Dryers

Figure 8.22n shows a spray dryer whose air supply is heated by direct firing of a fuel. In an arrangement such as this, it is usually difficult to obtain a measurement of inlet-air temperature due to the radiation of the flame. However, given a constant airflow, air temperature should be proportional to the fuel flow. So, fuel flow is then used to index the outlet-temperature set point in the place of inlet-air temperature in Figure 8.22m. The relationship to fuel flow is not quite as accurate, but still preferable to operating at a constant set point.

The feed to a spray dryer is typically a thin slurry sprayed at high pressure through a bank of nozzles into a co-current stream of hot air. Residence time is very short, and granular product is withdrawn at the bottom of the dryer. When the model described in Figure 8.22l was originally applied to a spray dryer producing milk solids, it overcorrected—product moisture decreased following a load increase.[4] The gain factor b of about 0.23 in Equation 8.22(7) was subsequently decreased until the product moisture no longer varied with load—the final gain was 0.13.

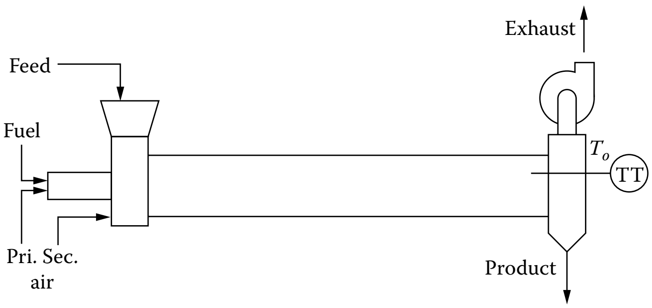

FIG. 8.22o
Ores are dried in a rotating kiln by direct firing of a fuel.

The reason for this discrepancy was discovered much later. The model used to develop the contours of Figure 8.22l was based on a constant feed moisture and variable feed rate. Within a fluid-bed dryer, the two load components produce the same effect on product moisture because of the complete back-mixing. But in a spray dryer, there is no back-mixing, so that the rate of drying varies through its length. In the particular dryer being studied, feed rate was maintained constant by pressure regulated at the nozzles, but its composition varied through a run. Wetter feed dries easier, and therefore requires less of a temperature rise to control product moisture than does an equivalent increase in feed rate.

Most common are rotary dryers, used for ores such as bauxite and gypsum, one of which is illustrated in Figure 8.22o. The center cylinder rotates slowly, conveying the solids through its length, which can be 100 ft or more. Airflow is co-current with the feed, induced by the exhaust fan. Primary air is mixed with the fuel for combustion, and a larger flow of secondary air is induced at the feed end. Inlet-air temperature cannot be measured and must be inferred from fuel flow.

There is also a problem measuring outlet-air temperature. Measurements made at an easy access point such as the suction of the exhaust fan can give temperatures below the wet-bulb—an impossibility in an adiabatic dryer. The low measurement is caused by the infiltration of ambient air through the rotary seals at the end of the dryer. To obtain an accurate measurement of outlet-air temperature requires the insertion of a resistance bulb into the rotating kiln upstream of the seal, as shown in the figure. It is best fastened under an angle-iron to protect it from falling rocks.

If a rotary dryer is exposed to feed-moisture changes, it will behave much like the spray dryer, and for the same reason. To discriminate between feed-rate and feed-moisture changes, a measurement of feed rate is required. This can be obtained by a mass-flow measurement on a conveyor feeding the dryer. On ore dryers fed by a bulldozer, feed rate may be estimated by the power load on the motor that rotates the dryer. The set point for outlet-air temperature then is calculated as

$$T_o^* = a + bF + cQ \qquad \mathbf{8.22(8)}$$

where F is feed rate and Q is the firing rate. If the feed rate is steady and the firing rate increases, the cause is an increase in feed moisture—hence coefficient c is the lower value found for the spray dryer above. If both F and Q increase, the load change is due to a rate increase—therefore, coefficient b in Equation 8.22(7) is equivalent to $b + c$ in Equation 8.22(8).

Countercurrent Dryers

Materials that have little heat sensitivity can be dried more efficiently by a countercurrent flow of air. Examples of these are sugar granulators, where the air is steam-heated, and carbon-black dryers, which are direct-fired. In these dryers, the temperature of the air leaving is unrelated to product moisture, because it is measured at the feed end. In the sugar granulator particularly, exit-air temperature reflects the temperature of the feed that is discharged hot from centrifuges. As a result, the models used for inferential control of fluid-bed and co-current adiabatic dryers do not apply when the flow pattern is countercurrent.

The best temperature to control in a countercurrent dryer is that of the product as it leaves. This can be difficult to measure, even in a sugar granulator where the product is clean, uniform, and freely flowing. Voids and dams easily form around any obstruction such as a temperature bulb. And the product temperature has much more dead time than air temperature. A reliable on-line analyzer is a real asset in controlling these dryers.

NONADIABATIC DRYERS

When heat is transferred to the solid through the walls of a dryer, enthalpy is added to the product, which raises the wet-bulb temperature of the surrounding air. An attempt to model this type of drying by estimating the internal wet-bulb temperature is difficult, because the airflow is often induced by natural draft and is neither measured nor controlled. A similar problem develops when air is recirculated within a dryer without control.

An example is a steam-tube dryer used for drying spent grain in distilleries. It is a rotating shell fitted with a bank of tubes containing condensing steam. The solids contact the tubes as the dryer rotates, and they flow at a downward slope against a natural draft of air. A rotating seal at the product end connects the steam to the tubes and draws the condensate out.

These dryers are conventionally controlled by regulating the steam pressure in the tubes. An increase in feed rate or moisture will wet more of the tube surface, thereby increasing the rate of heat transfer and condensing more steam, which the pressure regulator will then supply. However, a higher evaporative load will result in more wet-tube surface, thereby increasing the moisture content of the product.

An inferential control system was developed[5] that is similar to what was used successfully on adiabatic dryers—the

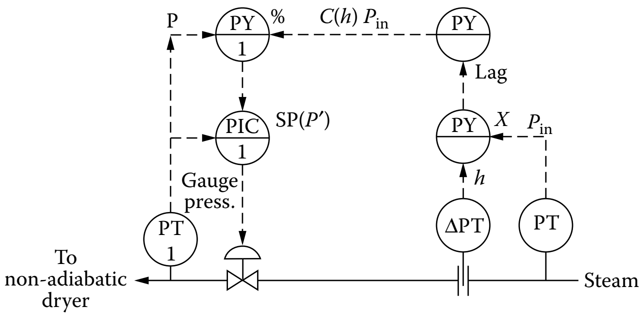

FIG. 8.22p
The ratio of the gauge pressure of the steam into the dryer (P) and the orifice differential corrected for supply pressure variations (ChP_{in}) can be adjusted to obtain the desired product dryness.

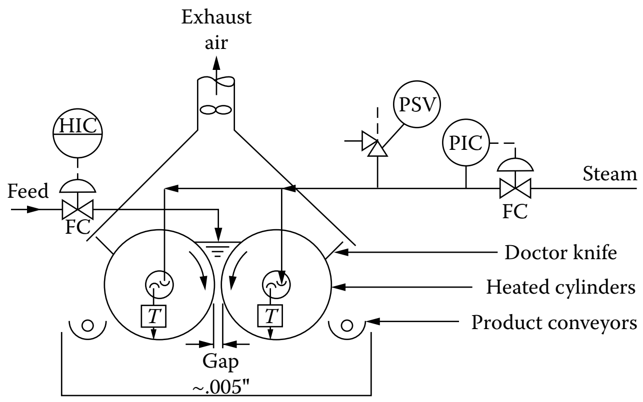

FIG. 8.22q
Double-drum dryer.

driving force for drying is increased in proportion to the evaporative load. Assuming that the moisture profile in the dryer is related to the overall heat-transfer coefficient, an attempt is made to keep that coefficient constant. Heat flow is linear with temperature difference:

$$Q = UA\Delta T \qquad \textbf{8.22(9)}$$

where U is the coefficient to be controlled, A the area of the tube surface, and ΔT the temperature difference between the solid and the steam. If steam flow increases due to a higher evaporative load, then ΔT should increase proportionately to keep U constant. This is accomplished by increasing steam pressure, as shown in Figure 8.22p.

The relationship needed between steam pressure and flow was found to be parabolic rather than linear. As a result, the differential pressure h measured across the steam orifice does not have its square root extracted before being used in the calculation. Compensation of the flow measurement for variations in supply pressure P_{in} was found to be necessary for accuracy. The pressure set point is calculated as

$$P^* = ChP_{\text{in}} \qquad \textbf{8.22(10)}$$

where C is a coefficient adjusted to make on-specification product.

Another nonadiabatic dryer that can be controlled in a similar way is the double-drum dryer shown in Figure 8.22q. Liquid is fed into the "valley" between the heated cylinders. The drums, rotating downward at the center, receive a coating of the liquid with the thickness depending upon the spacing between the rolls. The material must be dry by the time it rotates to the doctor knife, where it is cut off the roll.

The variables available for control are the speed of the cylinders, the spacing between them, the liquid level in the valley, and the steam pressure in the cylinders. The first two (speed and spacing) are usually adjusted manually. The liquid level is maintained by throttling the feed stream. Attempts to automatically control this level been thwarted by three difficulties: (1) The height of the level is only 6–9 in. (150–225 mm). (2) The liquid is constantly in a state of extreme agitation, bubbling, and boiling; and the liquid is highly concentrated and tends to plug conventional level sensors that depend on physical contact for measurement. (3) Frequently the control of feed is manual, indicated in the diagram by a manual loading station (HIC). In traditional applications, all of the other controls were on manual, and only the steam pressure was controlled automatically.

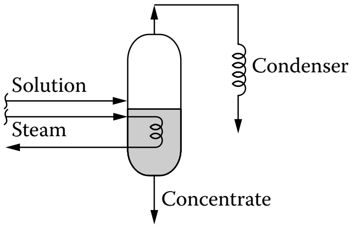
8.23 Evaporator Controls

T. J. MYRON (1972, 1985) **B. G. LIPTÁK** (1995, 2005)



Flow sheet symbol

INTRODUCTION

Evaporation is used in a number of unit operations. For example, one of the important steps in the operation of a chiller is the evaporation of the refrigerant, which usually occurs at low pressures. The controls of evaporators serving such heat pumps are described in Sections 8.12 and 8.13. If evaporation occurs at higher pressures, we refer to that unit process as vaporization or reboiling and the controls of those processes are described in Sections 8.19, 8.20, 8.21, and 8.27. The evaporation controls that are discussed in this section are for water-based near-atmospheric processes.

Evaporation is one of the oldest unit operations, dating back to the Middle Ages, when any available energy source was used to concentrate thin brine solutions in open tanks. As archaic as this technique is, it is still widely used during the early spring in northern New England when maple sugar sap is tapped and concentrated in open-fired pans.

Solar evaporation and bubbling hot gases through a solution are other examples of concentrating solutions. For our purposes, evaporation will be limited to concentrating aqueous solutions in a closed vessel or group of vessels in which the concentrated solution is the desired product and indirect heating (usually steam) is the energy source. Occasionally, the water vapor generated in the evaporator is the product of interest, such as in desalinization or in the production of boiler feed water. In other cases neither vapor nor concentrated discharge has any market value, as in nuclear wastes.

Evaporators can be arranged in forward-feed, reverse-feed, or parallel-feed configurations, with each stage being heated by the vapors of the previous stage. Evaporation is an energy-intensive process. Its efficiency can be improved by increasing the number of evaporators in series (effects), and some of the energy can be recovered by vapor recompression.

The product concentration can be measured by a variety of analyzers, including density, conductivity, refractive index, percent solids, turbidity, and boiling or freezing point analyzers, which are all discussed in Chapter 8 of the first volume of this handbook, *Process Measurement and Analysis*.

Evaporator Terminology

SINGLE-EFFECT EVAPORATION Single-effect evaporation occurs when a dilute solution is contacted only once with a heat source to produce a concentrated solution and an essentially pure water vapor discharge. The operation is shown schematically in Figure 8.23a.

MULTIPLE-EFFECT EVAPORATION Multiple-effect evaporations use the vapor generated in one effect as the energy source to an adjacent effect (Figure 8.23b). Double- and triple-effect evaporators are the most common; however, six-effect evaporation can be found in the paper industry, where kraft liquor is concentrated, and as many as 20 effects can be found in desalinization plants.

BOILING-POINT RISE This term expresses the difference (usually in °F) between the boiling point of a constant composition solution and the boiling point of pure water at the same pressure. For example, pure water boils at 212°F (100°C) at 1 atmosphere, and a 35% sodium hydroxide solution boils at about 250°F (121°C) at 1 atmosphere. The boiling-point

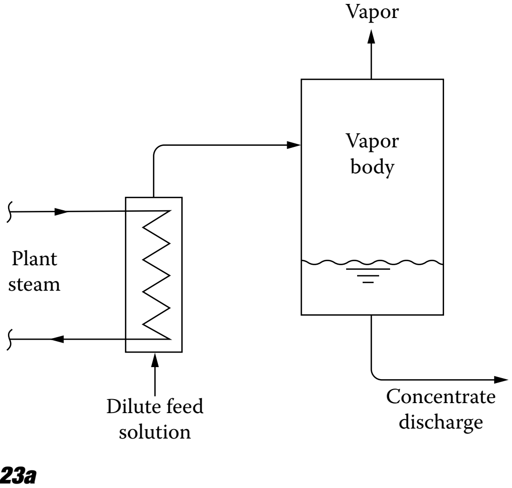


FIG. 8.23a
Single-effect evaporator.

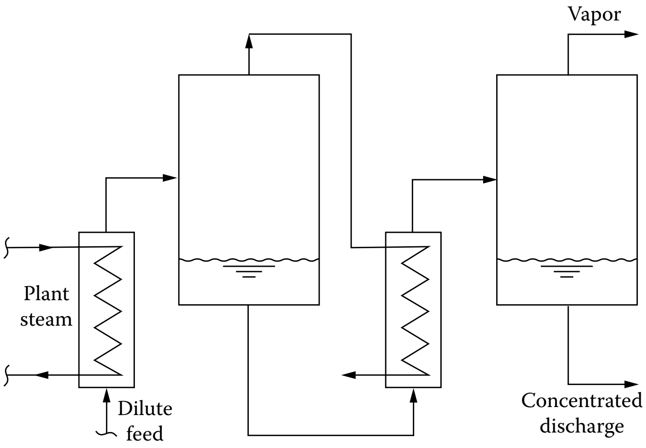

FIG. 8.23b
Multiple-effect evaporator.

rise is therefore 38°F (21°C). Figure 8.23c illustrates the features of a Dühring plot in which the boiling point of a given composition solution is plotted as a function of the boiling point of pure water.

ECONOMY This term is a measure of steam use and is expressed in pounds of vapor produced per pound of steam supplied to the evaporator train. For a well-designed evaporator system the economy will be about 10% less than the number of effects; thus, for a triple-effect evaporator the economy will be roughly 2.7.

CAPACITY The capacity for an evaporator is measured in terms of its evaporating capability, viz., pounds of vapor produced per unit time. The steam requirements for an evaporating train may be determined by dividing the capacity by the economy.

CO-CURRENT OPERATION The feed and steam follow parallel paths through the evaporator train.

COUNTERCURRENT OPERATION The feed and steam enter the evaporator train at opposite ends.

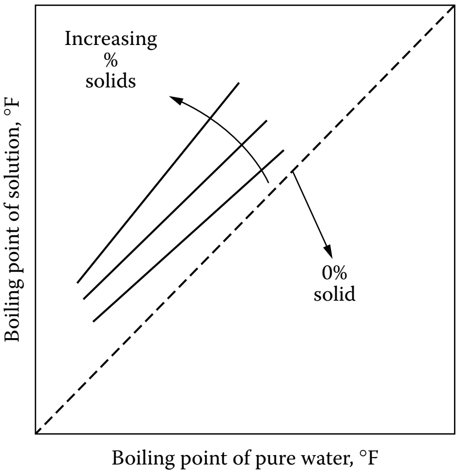

FIG. 8.23c
Dühring plot of boiling point rise.

EVAPORATOR MODELING

The Steady-State Model

Development of the steady-state model for an evaporator involves material and energy balances. A relationship between the feed density and percentage of solids is also required and is specific for a given process, whereas the material and energy balances are applicable to all evaporator processes. Figure 8.23d illustrates the double-effect evaporator from the standpoint of a material balance.

where

W_o = feed rate in lb (kg) per unit time
V_o = feed flow in gpm or lpm
V_1 = vapor flow from Effect I in lb (kg) per unit time
X_o = weight fraction solids in feed
W_1 = liquid flow rate leaving Effect I in lb (kg) per unit time
X_1 = weight fraction solids in W_1
V_2 = vapor flow from Effect II in lb (kg) per unit time
W_p = concentrated liquid product flow in lb (kg) per unit time
X_p = weight fraction of solids in product (the controlled variable)

Overall balance in Effect I:

$$W_o = V_1 + W_1 \quad \mathbf{8.23(1)}$$

Overall balance in Effect II:

$$W_1 = V_2 + W_p \quad \mathbf{8.23(2)}$$

Solid balance in Effect I:

$$W_oX_o = W_1X_1 \quad \mathbf{8.23(3)}$$

Solid balance in Effect II:

$$W_1X_1 = W_pX_p \quad \mathbf{8.23(4)}$$

Substituting Equation 8.23(2) in Equation 8.23(1):

$$W_o = V_1 + V_2 + W_p \quad \mathbf{8.23(5)}$$

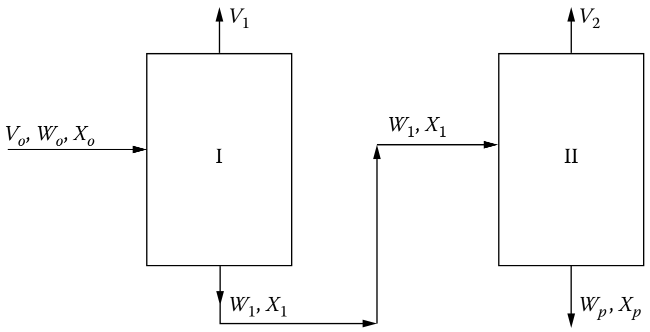

FIG. 8.23d
The material balance of a double-effect evaporator.

Combining Equations 8.23(3) and 8.23(4):

$$W_o X_o = W_p X_p \qquad \textbf{8.23(6)}$$

Solving Equation 8.23(6) for W_p and substituting in Equation 8.23(5) gives

$$W_o = V_1 + V_2 + \frac{W_o X_o}{X_p} \qquad \textbf{8.23(7)}$$

The W_o term of Equation 8.23(7) can be written in terms of volumetric flow (gallons per unit time) times density or specific gravity as follows:

$$W_o = V_o D_o = V_o D_w S_o \qquad \textbf{8.23(8)}$$

where

V_o = volumetric feed rate in gallons per unit time
D_o = fed density in lb per gallon
D_w = nominal density of water, 8.33 lb per gallon (1 kg/l)
S_o = specific gravity of feed

Substituting for W_o from Equation 8.23(8) in Equation 8.23(7) and combining terms,

$$V_o D_w S_o \left(1 - \frac{X_o}{X_p}\right) = V_1 + V_2 = V_t \qquad \textbf{8.23(9)}$$

where V_t = total vapor flow in lb per unit time.

The total vapor flow (V_t) is proportional to the energy supplied to the train (plant steam) and the proportionality constant is the economy (E) of the system, i.e.,

$$V_t = W_s E \qquad \textbf{8.23(10)}$$

where

W_s = steam flow in lbs steam per unit time
E = economy in lbs vapor per lb steam

Substituting for V_t in Equation 8.23(9):

$$V_o D_w S_o \left(1 - \frac{X_o}{X_p}\right) = W_s E \qquad \textbf{8.23(11)}$$

Equation 8.23(11) is the steady-state model of the process and includes all of the load variables (V_o and X_o), the manipulated variable (W_s), and the controlled variable (X_p). At this point the $W_s E$ portion of Equation 8.23(11) may be modified to include heat losses from the system and to include the fact that the feed may be subcooled. These are two forms of heat losses, because in either case a portion of the steam supplied is for purposes other than producing vapor. Typical values of effective heat losses vary from 3 to 5%. If, for example, a 5% heat loss is assumed, Equation 8.23(11) becomes

$$V_o D_w S_o \left(1 - \frac{X_o}{X_p}\right) = 0.95 W_s E \qquad \textbf{8.23(12)}$$

TABLE 8.23e
Weight Fraction and Specific Gravity Relationship

Solids Weight Fraction (X_o)	*Specific Gravity (S_o)*
0.08	1.0297
0.16	1.0633
0.24	1.0982

For an in-depth discussion relating to methods of computing the economy (E) of a particular evaporator system, see References 2 and 3.

The $S_o(1 - X_o/X_p)$ portion of Equation 8.23(11) is a function of the feed density, $f(D_o)$, i.e.,

$$f(D_o) = S_o \left(1 - \frac{X_o}{X_p}\right) \qquad \textbf{8.23(13)}$$

For each feed material a relationship between the density of the feed material and its solids weight fraction has usually been empirically determined by the plant or is available in the literature. See Reference 4 where the density equals percentage of solids relationship of 70 inorganic compounds is available.

Assume, for example, that a feed material (to be concentrated) has the solids–specific-gravity relationship shown in Table 8.23e.

If this feed material were to be concentrated so as to produce a product having a weight fraction of 50% ($X_p = 0.50$), the $f(D_o)$ relationship of Equation 8.23(13) could be generated as shown in Table 8.23f.

This body of data is plotted in Figure 8.23g. In all the cases investigated, the $f(D_o) = S_o$ relationship is a straight line having an intercept of 1.0, 1.0.

The $f(D_o)$ relationship can then be written in terms of the equation of a straight line: $y = mx + b$, i.e.,

$$f(D_o) = 1.0 + m(S_o - 1.0) \qquad \textbf{8.23(14)}$$

where m = slope of line.

TABLE 8.23f
Density to Weight Fraction Relationship

Solids Weight Fraction (X_o)	*Specific Gravity (S_o)*	$\left(1-\frac{X_o}{X_p}\right)$	$S_o\left(1-\frac{X_o}{X_p}\right) = \int(D_0)$
0	1.0000	1.0	1.0000
0.08	1.0297	0.840	0.865
0.16	1.0633	0.680	0.723
0.24	1.0982	0.520	0.571

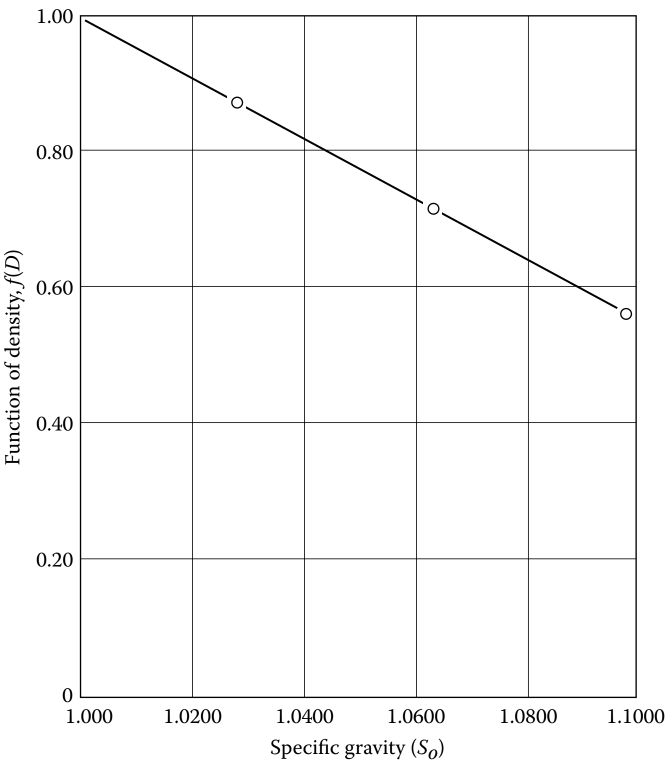

FIG. 8.23g
The straight-line relationship between density and specific gravity.

Using the data of Table 8.23f the value of m is determined as

$$m = \frac{1.000 - 0.571}{1.0000 - 1.0982} = -4.37 \qquad \textbf{8.23(15)}$$

therefore,

$$f(D_o) = 1.0 - 4.37(S_o - 1.0) \qquad \textbf{8.23(16)}$$

Substituting Equation 8.23(16) into Equation 8.23(11) and solving for the manipulated variable, steam flow, W_s:

$$W_s = \frac{V_o D_w f(D)}{E} \qquad \textbf{8.23(17)}$$

Therefore, W_s can be expressed as

$$W_s = \frac{V_o[1 - m(D-1)}{E} \qquad \textbf{8.23(18)}$$

If feed rate is manipulated in response to a variable steam flow and feed density, Equation 8.23(18) becomes

$$V_o = \frac{W_s E}{1 - m(D-1)} \qquad \textbf{8.23(19)}$$

Scaling and Normalizing

With the equation for the steady-state model defined, it can now be scaled and the digital or analog instrumentation specified. Scaling of computing instruments or software is necessary to ensure compatibility with input and output signals and is accomplished most effectively by normalizing, i.e., assigning values from 0 to 1.0 to all inputs and outputs. The procedure involves (1) writing the engineering equation to be solved, (2) writing a normalized equation for each variable in the engineering equation, and (3) substituting the normalized equivalent of each term in (2) into (1).

The first step of the procedure has already been done, because Equation 8.23(17) has already been written. To illustrate, let $V_o = 0$ to 600 gph (0 to 2.3 m^3/h), $W_s = 0$ to 2500 lb/hr (0 to 1125 kg/h), S_o = 1.000 to 1.1000, E = 1.8 lb vapor per lb of steam (1.8 kg vapor per kg of steam), and D_w = 8.33 lb/gallon (1 kg/l). The scaled equations for each input are

$$V_o = 600\,V_o' \qquad \textbf{8.23(20)}$$

$$W_s = 2500\,W_s' \qquad \textbf{8.23(21)}$$

$$S_o = 1.0000 + 0.10000 S_o' \qquad \textbf{8.23(22)}$$

where

V_o' = volumetric flow transmitter output, 0–1.0 or 0–100%
W_s'= steam flow transmitter output, 0–1.0 or 0–100%
S_o' = specific gravity transmitter output, 0–1.0 or 0–100%

The values of D_w and E need not be scaled, because they are constants. Because $f(D_o)$ is already on a 0 to 1.0 basis, the $f(D_o)$ term for the sake of completeness can be written

$$f(D_o) = 1.0 f(D_o)' \qquad \textbf{8.23(23)}$$

Operating on the $f(D_o)$ equation first, Equations 8.23(23) and 8.23(22) are substituted into Equation 8.23(16):

$$(D_o)' = 1.0 - 4.37 \times (1.0000 + 0.1000S_o - 1.0) \qquad \textbf{8.23(24)}$$

$$(D_o)' = 1.0 - 4.37S_o' \qquad \textbf{8.23(25)}$$

Substituting Equations 8.23(20), 8.23(21), and 8.23(25) into Equation 8.23(17) as well as the values of E and D_w,

$$2500W_s' = \frac{600(V_o')8.33(1.0 - 0.437S_o')}{1.8} \qquad \textbf{8.23(26)}$$

$$\begin{aligned} W_s' &= 1.11V_o'(1.0 - 0.437S_o') \\ &= 1.11V_o' f(D_o)' \end{aligned} \qquad \textbf{8.23(27)}$$

or if feed flow is the manipulated variable:

$$V_o' = \frac{W_s'}{1.11(1 - 0.437S_o')} \qquad \textbf{8.23(28)}$$

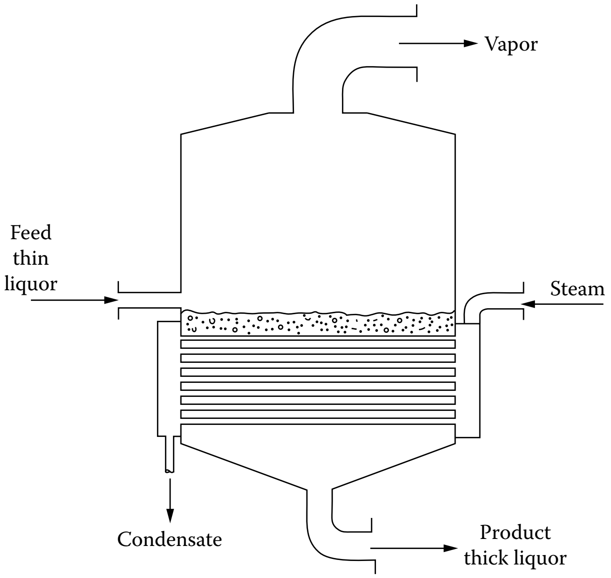

FIG. 8.23h
Horizontal-tube evaporator.

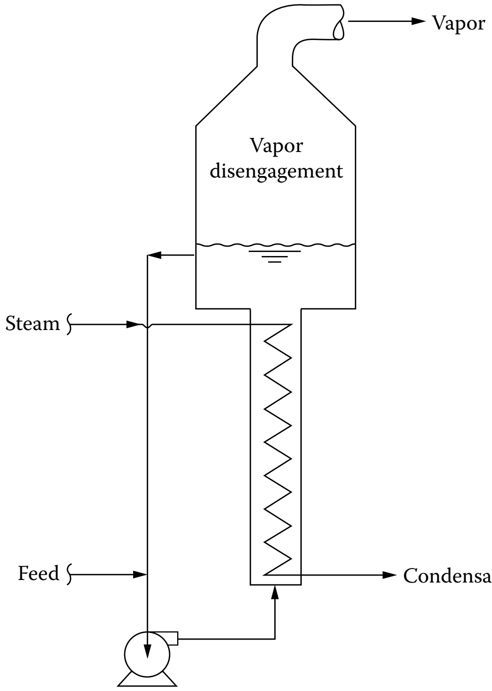

FIG. 8.23i
Forced-circulation evaporator.

EVAPORATOR DESIGNS

Six types of evaporators are used for most applications, and for the most part the length and orientation of the heating surfaces determine the name of the evaporator.

Horizontal-tube evaporators (Figure 8.23h) were among the earliest types. Today, they are limited to preparation of boiler feed water and, in special construction (at high cost), for small-volume evaporation of severely scaling liquids, such as hard water. In their standard form they are not suited to scaling or salting liquids and are best used in applications requiring low throughputs.

Forced-circulation evaporators (Figure 8.23i) are the most popular and have the widest applicability. Circulation of the liquor past the heating surfaces is assured by a pump, and consequently these evaporators are frequently external to the flash chamber so that actual boiling does not occur in the tubes, thus preventing salting and erosion. The external tube bundle also lends itself to easier cleaning and repair than the integral heater shown in the figure. Disadvantages include high cost, high residence time, and high operating costs due to the power requirements of the pump.

A short-tube vertical evaporator (Figure 8.23j) is common in the sugar industry for concentrating cane sugar juice. Liquor circulation through the heating element (tube bundle) is by natural circulation (thermal convection).

Because in the short-tube vertical evaporator the mother liquor flows through the tubes, they are much easier to clean than those shown in Figure 8.23h, in which the liquor is outside the tubes. Thus, this evaporator is suitable for mildly scaling applications in which low cost is important and cleaning or descaling must be conveniently handled. Level control is important — if the level drops below the tube ends, excessive scaling results. Ordinarily, the feed rate is controlled by evaporator level to keep the tubes full. The disadvantage of high residence time in the evaporator is compensated for by the low cost of the unit for a given evaporator load.

A long-tube vertical evaporator, or rising film concentrator (RFC), shown in Figure 8.23k, is in common use today,

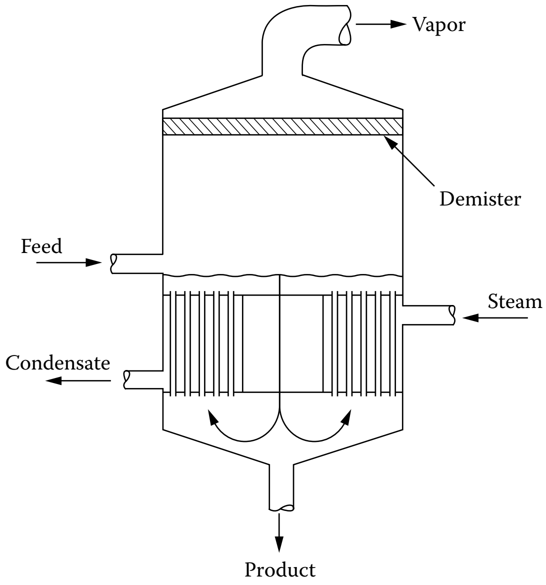

FIG. 8.23j
Short-tube vertical evaporator.

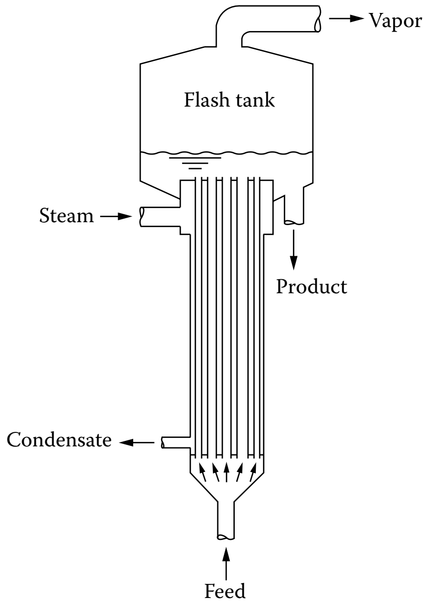

FIG. 8.23k
Long-tube vertical evaporator.

because its cost per unit of capacity is low. Typical applications include concentrating black liquor in the pulp and paper industry and corn syrup in the food industry.

Most of these evaporators are of the single-pass variety, with little or no internal recirculation. Thus, residence time is minimized. Level control is important in maintaining the liquid seal in the flash tank. The units are sensitive to changes in operating conditions, which is why many of them are difficult to control. They offer low cost per pound of water evaporated and have low holdup times but tend to be tall (20 to 50 ft, or 6 to 15 m), requiring more head room than other types.

A falling-film evaporator (Figure 8.23l) is commonly used with heat-sensitive materials. Physically, the evaporator looks like a long-tube vertical evaporator, except that the feed material descends by gravity along the inside of the heated tubes, which have large inside diameters (2 to 10 in., or 50 to 250 mm).

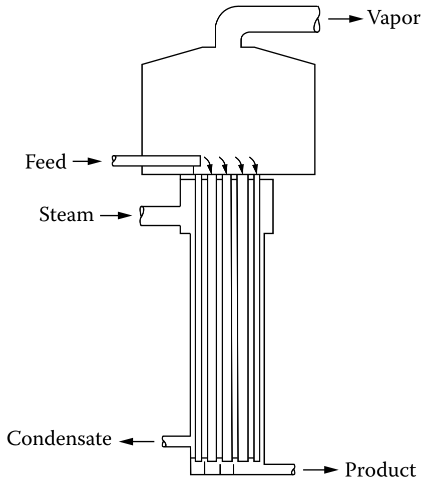

FIG. 8.23l
Falling-film vertical evaporator.

An agitated-film evaporator, like the falling-film evaporator, is commonly used for heat-sensitive and highly viscous materials. It consists of a single large-diameter tube with the material to be concentrated falling in a film down the inside, where a mechanical wiper spreads the film over the inside surface of the tube. Thus, a large heat-transfer coefficient can be obtained, particularly with highly viscous materials.

EVAPORATOR CONTROLS

In the following paragraphs the load variable will be assumed to be the flow rate and concentration of the feed stream. A later paragraph, Other Control Loops, will discuss the control of other variables, such as steam enthalpy, material balance, and absolute pressure controls.

The control systems to be considered in achieving final product concentration include (1) feedback, (2) cascade, and (3) feedforward, (4) auto-select, and (5) advanced controls. For ease of illustration, a double-effect, co-current flow evaporator will be used. Extension to more or fewer effects will not change the basic control system configuration.

The choice of the control system should be based on the needs and characteristics of the process. Evaporators as a process class tend to be capacious (mass and energy storage capability) and have significant dead time (30 sec or greater). If the major process loads (feed rate and feed density) are reasonably constant and the only corrections required are for variations in heat losses or tube fouling, feedback control will suffice.

If steam flow varies because of demands elsewhere in the plant, a cascade configuration will probably be the proper choice. If, however, the major load variables change rapidly and frequently, it is strongly suggested that feedforward in conjunction with feedback be considered.

Selective control can be superimposed on either control configuration, which will stay inactive until a limit is reached (such as running out of steam), at which point control is transferred to keep the operation (the demand for steam) under that limit. Advanced controls usually combine all the previous features and add to it a multivariable model-based predictive capability.

Feedback Control

A typical feedback control system (Figure 8.23m) consists of measuring the product concentration with a density sensor and controlling the amount of steam to the first effect by a three-mode controller. The internal material balance is maintained by level control on each effect. (A brief description of the various methods of measuring product density will be found at the end of this section; additional discussion regarding

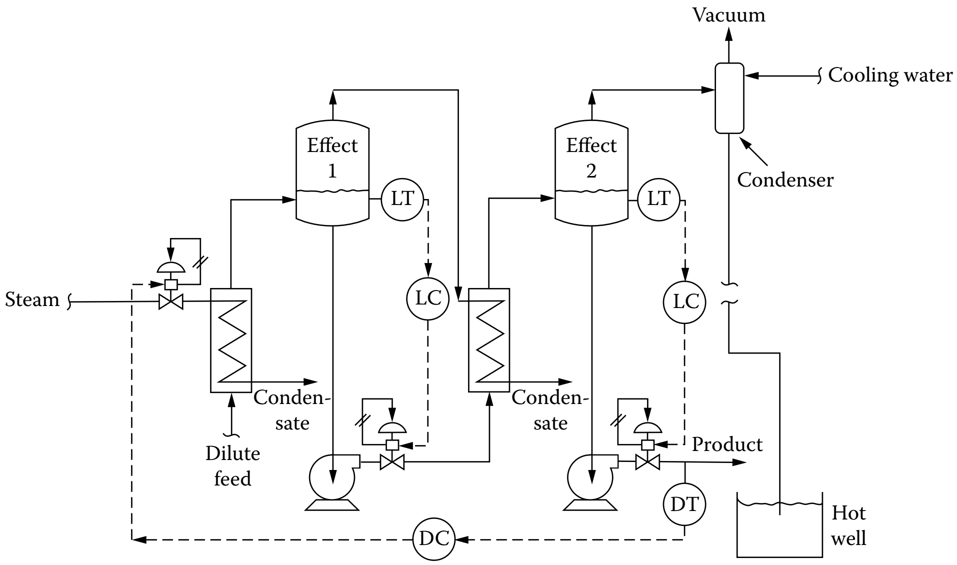

FIG. 8.23m
In a simple feedback control system the steam flow is directly throttled to keep the density of the product constant.

density measurement can be found in Chapter 6 of Volume 1 of this handbook, *Process Measurement and Analysis*.)

Ritter and associates[1] have modeled the control system configuration shown in Figure 8.23m and have found it to be very stable. They investigated other combinations of controlled and manipulated variables, which were less effective.

Cascade Control A typical cascade control system is illustrated in Figure 8.23n. This control system, like the feedback loop in Figure 8.23m, measures the product density and adjusts the heat input. The adjustment in this instance, however, is through a flow loop that is being set in cascade from the final density controller, an arrangement that is particularly effective when steam flow variations (outside of the evaporator) are frequent. It should be noted that with this arrangement the valve positioner is not required and can actually degrade the performance of the flow control loop. (For more information on cascade control see Section 2.6 in Chapter 2.)

Selective Control The selective control scheme shown in Figure 8.23o uses the previously described cascade configuration and adds to it the feature of protection against running

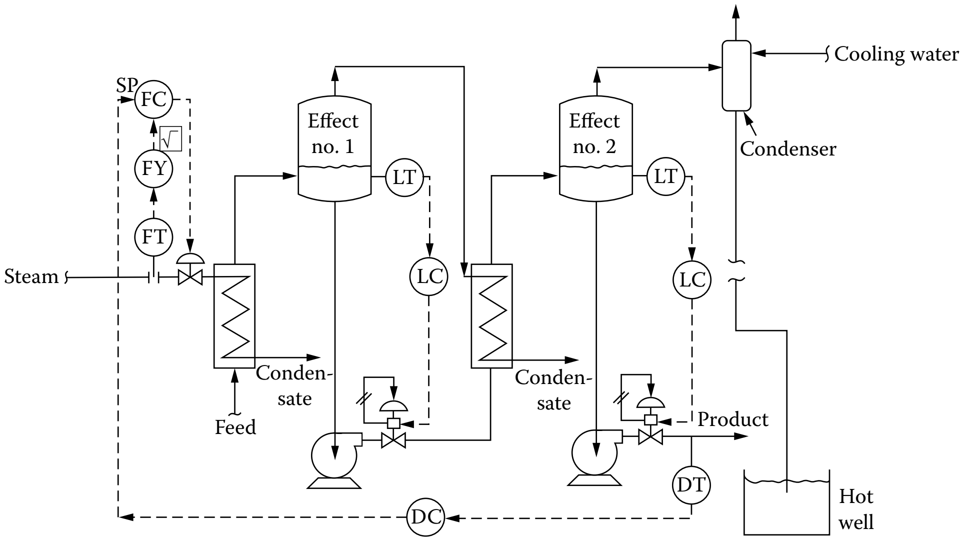

FIG. 8.23n
In the cascade version of a feedback control system the steam flow is controlled and the flow controller set point is adjusted to keep the density of the product constant.

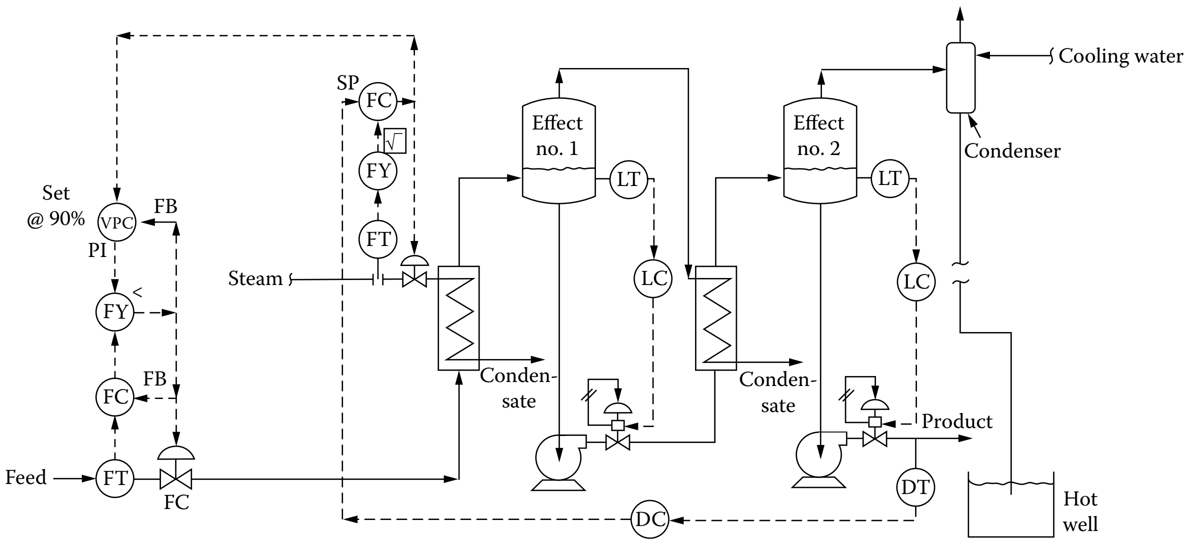

FIG. 8.23o
Valve position controller (VPC) cuts back the feed flow and thereby protects the system from running out of steam. The selective control scheme is protected from reset windup by external feedbacks.

out of steam. This feature is provided by the valve position controller (VPC), whose measurement is the steam valve opening and whose set point is about 90%. Therefore, as the feed gets too diluted and therefore requires more steam to concentrate, the steam valve opens. When it reaches 90% lift (which on an equal-percentage valve corresponds to 70% flow), the VPC output signal drops below that of the feed flow controller (FC), and therefore the low signal selector (FY) transfers the control of the feed valve to the VPC. During the period while the feed is diluted due to some upset, the VPC sets the feed flow rate to a value that corresponds to the allowable maximum opening of the steam valve.

The VPC is a PI controller with the integral mode dominating (as is the case in most valve position controllers). This allows it to operate smoothly even if the measurement signal (the steam valve opening) is noisy, as its output signal responds not so much to the error, but to the total area under the past error curve. Both controllers (FC and VPC) are provided with external feedback taken from the output of the low selector FY. This way the controller that is in control will have its output signal and its feedback signal at the same values and therefore will operate as a normal PI controller.

The controller that is not selected will operate as a proportional-only controller with a bias, where the bias is the external feedback signal. This guarantees that at the time of switchover the two outputs will be identical, and therefore the switchover will occur bumplessly (at the time of switchover the error in the idle controller has just reached zero, and therefore its output equals its external feedback signal).

Feedforward Control

In most evaporator applications the control of product density is constantly affected by variations in feed rate and feed density to the evaporator. In order to counter these load variations, the manipulated variable (steam flow) must attain a new operating level. In the pure feedback or cascade arrangements this new level was achieved by trial and error as performed by the feedback (final density) controller.

A control system able to react to these load variations when they occur (feed rate and feed density) rather than wait for them to pass through the process before initiating a corrective action would be ideal. This technique is termed *feedforward control*. (For an in-depth discussion of feedforward control, refer to Section 2.9 in Chapter 2.)

Figure 8.23p illustrates in block diagram form the features of a feedforward system. Feedforward controls utilize

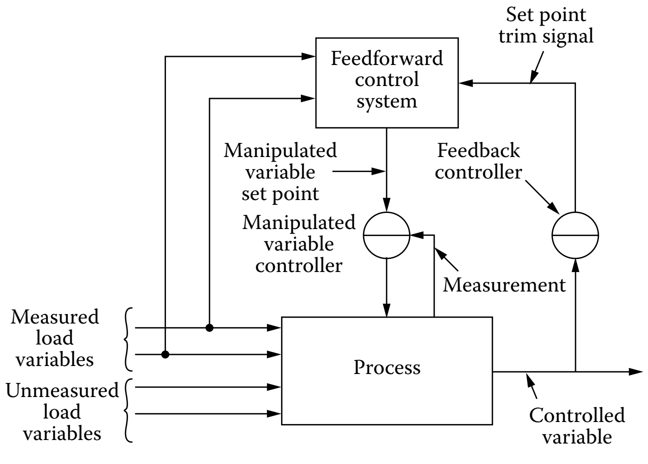

FIG. 8.23p
Feedforward system.

a simplified model of the controlled process. There are two types or classes of load variations — measured and unmeasured. The measured load signals are inputs to the feedforward control system, where they serve to compute the set point of the manipulated variable control loop as a function of the measured load variables.

The unmeasured load variables pass through the process, undetected by the feedforward system (disregarded in this simplified model), and cause an upset in the controlled variable. The output of the feedback loop then trims the calculated value of the set point to the correct operating level. In the limit, feedforward control would be capable of perfect control if all load variables could be defined, measured, and incorporated in the forward set point computation. This is what multivariable model predictive control provides, as will be discussed later.

At a practical level, then, the load variables are classified as either major or minor, and the effort is directed at developing a feedforward model that incorporates the major load variables, the manipulated variables, and the controlled variable. Such a relationship is termed the steady-state model of the process. Minor load variables are usually very slow to materialize and are hard to measure.

In terms of evaporators, minor load variations might be heat losses and tube fouling. Load variables such as these are usually easily handled by a feedback loop. The purpose of the feedback loop is to trim the forward calculation to compensate for the minor or unmeasured load variations. Without this feature the controlled variable would go off set point.

In addition to the two ingredients of a feedforward control system that have already been discussed, the steady-state model and feedback trim, there is a third ingredient. This third ingredient of a successful feedforward system application is dynamic compensation.

Dynamic compensation is required when a change in one of the major process loads also requires a change in the operating level of the manipulated variable. If the load and the manipulated variables enter the process at different locations, there usually will be an imbalance or inequality between the effects of the load and the manipulated variables on the controlled variable; i.e.,

$$\frac{\Delta \text{ controlled variable}}{\Delta \text{ load variable}} \neq \frac{\Delta \text{ controlled variable}}{\Delta \text{ manipulated variable}} \qquad \textbf{8.23(29)}$$

This imbalance manifests itself as a *transient* excursion of the controlled variable from set point. If the forward calculation is accurate, the controlled variable returns to set point once the new steady-state operating level is reached.

In terms of a co-current flow evaporator, an increase in feed rate will call for an increase in steam flow. Assuming that the level controls on each effect are properly tuned, the increased feed rate will rapidly appear at the end of the train, while the effect of the increased steam flow will take longer, because it has to overcome the thermal inertia of the process. Therefore, an increase in feed flow results in a transient decrease of the controlled variable (density), because the load variable passes through the process faster than the manipulated variable. This behavior is shown in Figure 8.23q.

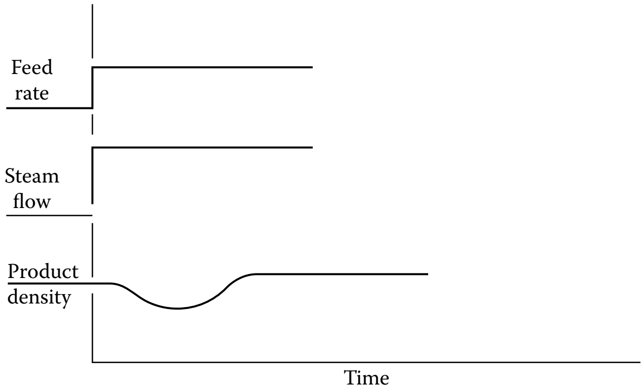

FIG. 8.23q
Load variable faster than manipulated variable.

The same sequence is seen in Figure 8.23r, except that this figure illustrates the case when the manipulated variable passes through the process faster than the load variable. Such behavior may occur in a countercurrent evaporator operation. This dynamic imbalance is normally corrected by inserting a dynamic element (lag, lead-lag, or a combination thereof) in at least one of the load measurements to the feedforward control system. Usually, dynamic compensation of that major load variable that can change in the severest manner (a step change) is all that is required. For evaporators this is usually the feed flow rate to the evaporator.

Feed density changes, although frequent, are usually more gradual, and the inclusion of a dynamic element for this variable is usually not warranted. In summary, the three ingredients of a well-designed feedforward system are (1) an accurate steady-state model, (2) properly set dynamic compensation, and (3) a correctly designed feedback trim, which corrects for the inaccuracy of the steady-state model.

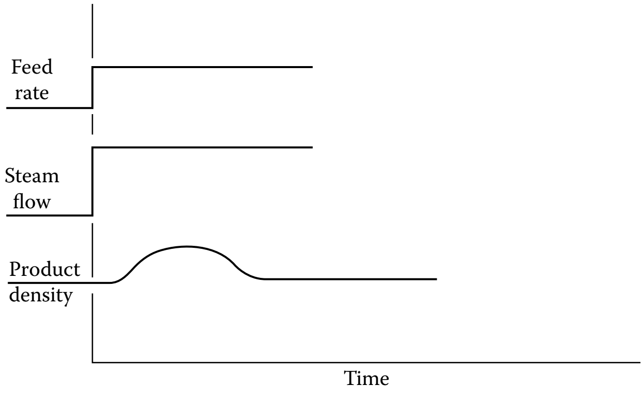

FIG. 8.23r
Manipulated variable faster than load variable.

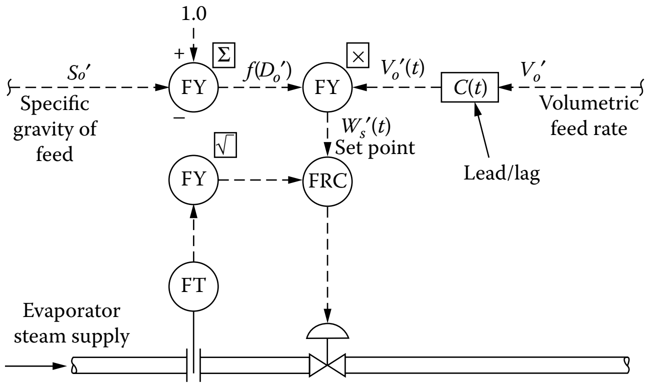

FIG. 8.23s
Implementation of the feedforward control loop for the case when the manipulated variable is steam flow, which is described in Equation 8.23(27), with first-order lag added for dynamic compensation.

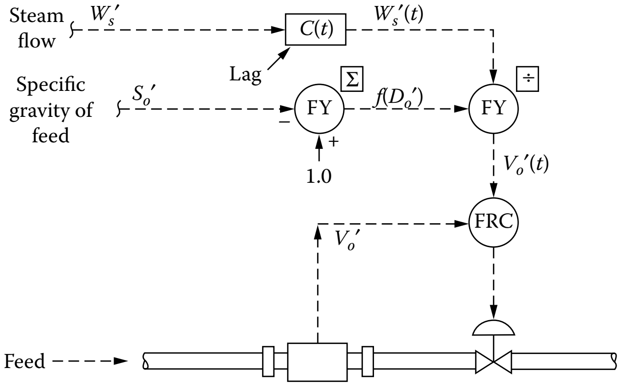

FIG. 8.23t
Implementation of the feedforward control loop for the case when the manipulated variable is feed flow, which is described in Equation 8.23(28), with first-order lag added for dynamic compensation.

Dynamic Compensation The dynamics of the co-current evaporator, in which steam is the manipulated variable, requires that a lead-lag dynamic element be incorporated in the system to compensate for the dynamic imbalance between feed rate and steam flow.

In the example, it was arbitrarily assumed that steam flow is the manipulated variable resulting in Equation 8.23(17). In some applications evaporators are run on waste steam, in which case the feed rate is proportionally adjusted to the available steam (Figure 8.23o), which makes feed the manipulated variable and steam the load variable.

Solving Equation 8.23(17) for feed rate,

$$V_o' = \frac{W_s E}{D_w(D)} \qquad \textbf{8.23(30)}$$

In this arrangement the dynamics do not change, but the manipulated variable advances through the process faster than the load variable, which requires a dynamic element having first-order lag characteristics. The instrument arrangement for the case where the manipulated variable is the steam supply was shown in Figure 8.23s.

The configuration where the manipulated variable is the feed flow is shown in Figure 8.23t and is based on Equation 8.23(28).

Feedback Trim of the Feedforward Loop As a general rule, feedback trim is incorporated into the control system *at the point at which the set point of the controlled variable appears*. For the evaporator the set point is the slope of the $f(D_o)$ relationship (Figure 8.23g). If the weight fraction of solids in the product (X_p) changes, the slope of the line changes too.

To this point the slope of the line (value of *m*) was assumed to be a constant (0.437), which value is incorporated into the summing relay or amplifier in Figures 8.23s and 8.23t. The instrumentation was scaled to make one grade of product, e.g., 50% solids. If a more or less concentrated product were desired, the gain term would have to be changed manually. In order to increase the flexibility of the control system, in Figure 8.23u a multiplier and a final product density control loop are added.

The controller output is now variable not only to permit changing the concentration of the product (slope adjust) but also to adjust the steam flow set point to compensate for the minor load variations, which up to this point were not considered.

The feedback trim for the case when steam is the manipulated variable is shown in Figure 8.23u. For the configuration where the manipulated variable is the feed flow, the product density controller will trim the value of the slope m, but in most other respects the feedforward-feedback configuration

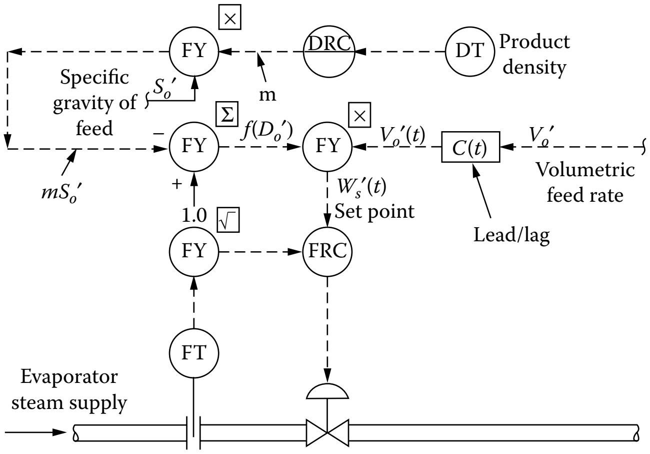

FIG. 8.23u
Feedforward control loop with feedback trimming of the slope m is shown for the case where steam is the manipulated variable.

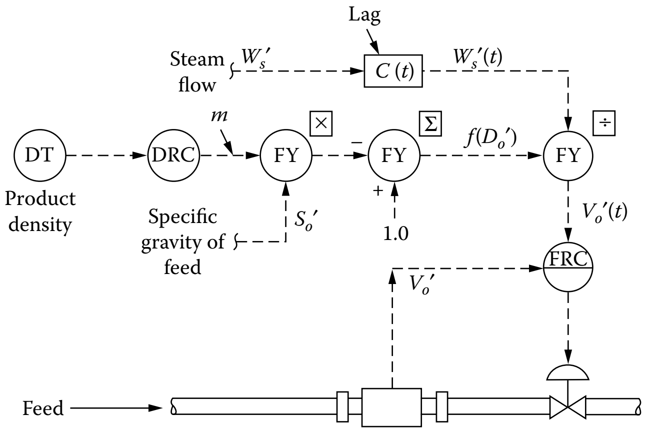

FIG. 8.23v
When feed flow is the manipulated variable, the feedforward signal based on steam flow is lagged while the product density controller trims the slope m in a feedback manner.

will be shown as in Figure 8.23v. The one exception is that the lead-lag dynamics is replaced with a simple lag.

Other Load Variables

Until this point it was assumed that the only load variables in an evaporation process are the feed flow rate and density. This is not the case, and in the next paragraphs, some of the other load variables and the controls they require will be considered.

Steam Enthalpy So far we have discussed only load changes related to feed density and feed flow rate and configured control loops to control the evaporator in response to these variations. One additional load variable that, if allowed to pass through the process, would upset the controlled variable (product density) is steam enthalpy.

In some applications the steam supply may be carefully controlled so that its energy content is uniform. In other applications substantial variations in steam enthalpy may occur. In order to correct for this, one must consider the factors that influence the energy content of the steam and design a control system that will protect the process from the changes in this load variable.

For saturated steam the energy content per unit weight is a function of the absolute pressure of the steam. If the flow of steam to the process is measured with an orifice meter, the mass flow of the steam is

$$W_s = K_1\sqrt{\frac{h}{v}} \qquad \textbf{8.23(31)}$$

where
W_s = steam flow in lb/hr (kg/hr)
h = differential head measurement in ft (m)
v = specific volume in cu. ft per lbm (m^3/kg)
K_1 = orifice coefficient dependent on the physical characteristics of the orifice

Therefore, the total energy to the system is

$$Q = W_s H_s \qquad \textbf{8.23(32)}$$

where
Q = energy to system per BTU per hour (J/hr)
W_s = steam flow in lb/hr (kg/hr)
H_s = heat of condensation in BTU per lb, or J/kg (enthalpy of saturated vapor minus enthalpy of saturated liquid)

Substituting Equation 8.23(31) into Equation 8.23(32) gives

$$Q = K_1\sqrt{\frac{(H_s)^2}{v}h} \qquad \textbf{8.23(33)}$$

For any particular application the steam pressure will vary around a normal operating pressure. To demonstrate the design of a control system to compensate for variations in the energy input into the process, assume that the steam pressure varies between 18 and 22 PSIA (124 and 152 kPa), with a normal operating value of 19.7 PSIA (135.9 kPa). The pressure transmitter has a range of 0–25 PSIA (0–172.5 kPa). These values of pressure variation and operating pressure are typical for a number of evaporator operations.

The value of the $(H_s)^2/v$ term appearing in Equation 8.23(33) will vary, depending on the steam pressure. Over a reasonably narrow range of pressures, the value of $(H_s)^2/v$ can be approximated by a straight line with the general form of

$$(H_s)^2/v = bP + a \qquad \textbf{8.23(34)}$$

where
P = absolute pressure in PSIA (Pa)
a and b = constants

Table 8.23w shows the typical values of H_s, v, $[(H_s)^2/v]'$, and P and P' selected for the specified range of pressures and for a case in which the steam is condensed at 1.5 PSIG.

$$\left(H_s^2/v\right)\text{ normal} = \frac{(970.7)^2}{20.4} = 46{,}208$$

Rewriting Equation 8.23(34) in scaled form:

$$\left(\frac{(H_s)^2}{v}\right)' = bP' + a \qquad \textbf{8.23(35)}$$

The designer can either linearize the data—using any two points from Table 8.23w—or can use a least squares computation to find the best straight line.

TABLE 8.23w

In a least square computation the following values of *a* and *b* constants of Equation 8.23(35) were obtained:

$$\left(\frac{(H_s)^2}{v}\right)' = bP' + a \qquad \textbf{8.23(36)}$$

where

$a = 0.085$

$b = 1.161$

Squaring Equation 8.23(33) and substituting in Equation 8.23(36):

$$(Q^2)' = (1.161\ P' + 0.085)hk_1 \qquad \textbf{8.23(37)}$$

The parenthetical portion of Equation 8.23(37) can be rewritten so as to make the sum of the two coefficients equal 1.0, which simplifies its implementation using conventional analog hardware. This is done by multiplying and dividing each term in the parentheses by the sum of the two coefficients.

$$(Q^2)' = 1.246\left(\frac{1.161P'}{1.246} + \frac{0.085}{1.246}\right)hk_1 \qquad \textbf{8.23(38)}$$

$$(Q^2)' = 1.246(0.932P' + 0.068)hk_1 \qquad \textbf{8.23(39)}$$

The instrumentation to implement Equation 8.23(39) is shown in Figure 8.23x.

Internal Material Balance The feedforward system described earlier imposes an external material balance as well as an internal material balance on the process. The internal balance is maintained by liquid level control on the discharge of each effect.

Analysis of the performance of level loops indicates that a narrow proportional band (<10%) can achieve stable control. However, because of the resonant nature of the level loop it can cause the process to oscillate at its natural frequency. Therefore, in most installations a much lower controller gain must be used (proportional bands 50 to 100%).[5]

Because of such wider proportional bands, the addition of the integral mode is required to help maintain the set point. A valve positioner and booster relay are also recommended to overcome the usual limit cycle characteristics of an integrating process and the nonlinear nature of valve hysteresis (Figure 8.23y).

Absolute Pressure The heat to evaporate water from the feed material is directly related to the boiling pressure of the material. In most multiple-effect evaporation each effect is held at a pressure less than atmospheric in order to keep boiling points below 212°F (100°C). The lowest pressure is in the effect closest to the condenser, with pressures increasing slightly in each effect away from the condenser.

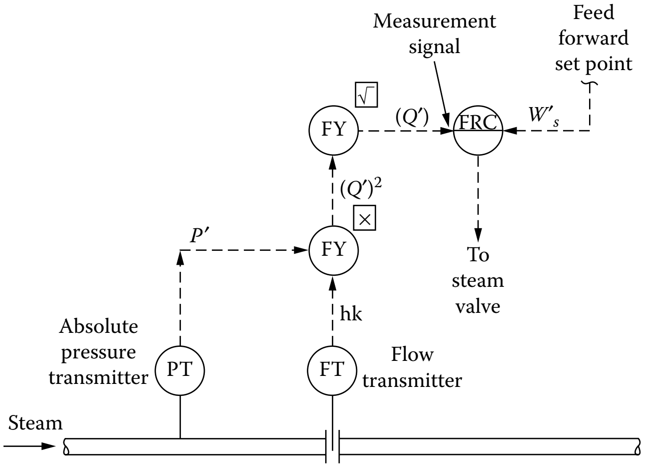

FIG. 8.23x
This control configuration compensates for variations in steam enthalpy by determining the heat input in terms of BTU/hr, based on the calculation required by Equation 8.23(39).

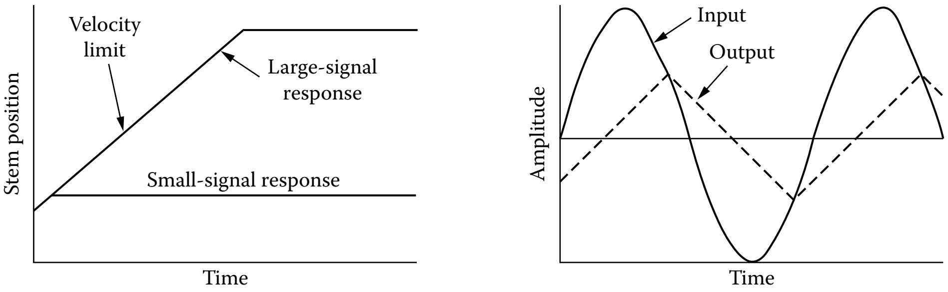

FIG. 8.23y
If a valve actuator cannot move as fast as the speed at which the control signal changes (velocity limited), a step change in the control signal (left) will result in a delayed straight-line response, while a sine wave in the control signal (right) will result in cycling.

The three possible methods of controlling the absolute pressure are (1) controlling the flow of water to the condenser, (2) bleeding air into the system with the water valve wide open, and (3) locating the control valve in the vapor draw-off line, manually setting the water flow rate and air bleeding as necessary.

Method 3 requires an extraordinarily large valve, because the vapor line may be 24 or 30 in. (600 or 750 mm) in diameter. Method 2 is uneconomical, because the expense of pumping the water offsets the savings realized by using a smaller valve on the air line. Method 1 represents the best compromise between cost and controllability, and therefore it is preferred (Figure 8.23z). (For more on condenser pressure control see Section 8.29.)

Auto-Select Controls

In many processes the final product is the result of a two-step operation. The first step produces an intermediate product that serves as the feed to a final concentrator. The aim is to ensure that the process is run at the maximum throughput consistent with the process limitations, an example of which is shown in Figure 8.23aa.

In this two-step evaporation process, three limitations are considered: (1) the steam availability to the intermediate concentrator can be reduced as a result of demands in other parts of the plant; (2) the steam availability to the final concentrator can be reduced as a result of demands in other parts of the plant; and (3) the final concentrator can accept feed only at or below a certain rate, and it is desired to run this part of the process at the rate set by its limits.

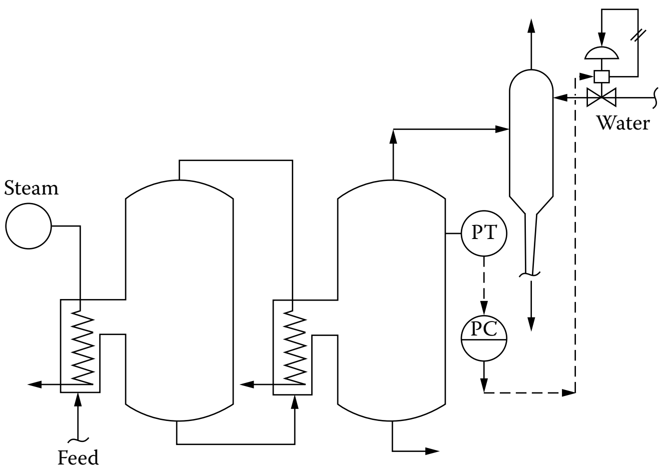

FIG. 8.23z
The recommended method of controlling the absolute pressure of evaporation is to throttle the water flow to the condenser.

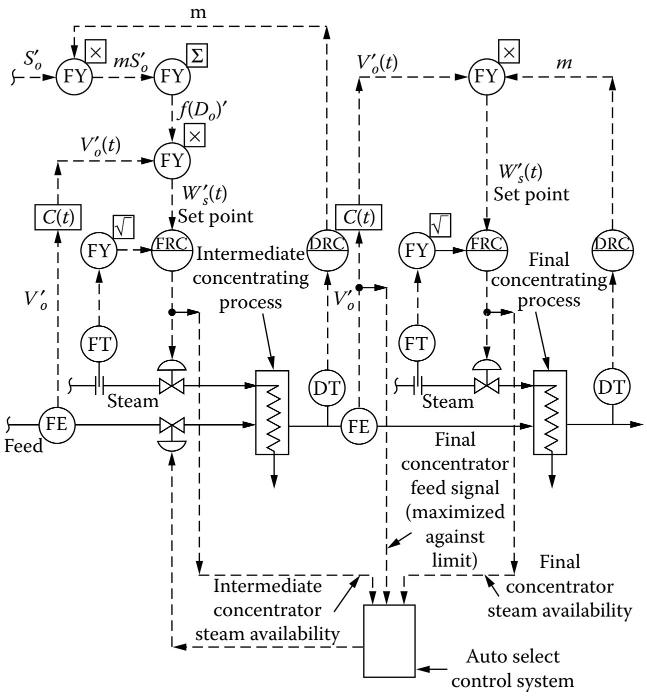

FIG. 8.23aa
This control system includes auto-select limits that consider the maximum feed rate to the final concentrator and the availability of steam in the plant.

Each part of the process has its own feedforward-feedback system. The intermediate concentrating process has the feedforward system shown in Figure 8.23u. The final concentrating process does not require feed density compensation, so that it is necessary only to establish the ratio of steam to feed and to adjust the ratio by feedback. The feed rate to the final concentrator is sent to the auto-select system that manipulates the feed to the intermediate process so as to maintain the final concentrator feed maximized at its set point limit.

Should either steam supply become deficient, the associated FRC output is selected to adjust the feed to the intermediate process. Thus, the process is always run at the maximum permissible rate consistent with the process limitation(s). (For more on auto-select control systems, see the explanation given in connection with Figure 8.23o.)

Trimming Controls

The system illustrated in Figure 8.23bb combines a number of advanced control features. These features include the selective control loop that was described in Figure 8.23o. This loop utilizes the valve position controller (VPC-4) to overrule the feed flow controller (FC-1) if the feed rate exceeds steam availability and requires the steam valve to open beyond 90%.

The feed flow rate is set by a nonlinear level controller (LC-12) on the feed tank. This tank provides surge capacity between the upstream equipment and the evaporator system. LC-12 is nonlinear, meaning that its output signal, which is the set point of FC-1, remains constant as long as the level in the tank is between 40 and 60%. This allows the evaporator loading to be stable, while production surges are averaged out in the feed tank. If the level gets above 60% or below 40%, the feed flow set point is slowly changed to match the new production rate.

The steam flow is measured on the basis of its heat content (enthalpy) as was explained in connection with Figure 8.23x. The set point of the steam flow controller (FRC-2) is obtained on a feedforward basis from the feed flow (FT-1).

Co-current evaporators usually respond faster to changes in feed flow than to steam flow. Therefore, the dynamic compensator in the feedforward loop (FY-11) is a dominant lead in Figure 8.23bb, just as it was in Figures 8.23s and 8.23u. If feed flow was manipulated in response to steam flow variations, the loop would require a dominant lag. (Countercurrent evaporators might respond faster to steam than to feed flow changes and, therefore, require different dynamic compensators.) A lead-lag compensator (FY-11) is usually provided with all feedforward systems and is adjusted as needed in the field.

The feedback trim in Figure 8.23bb is based on product density (DRC-6) and is configured similarly to the loop in Figure 8.23u. The steam flow set point is obtained in accordance with Equation 8.23(18), where E is the economy of the evaporator (the mass of vapor produced per unit mass of steam used).

If the product quality response to the changes in steam flow to the first effect (FRC-2) is too slow, the design engineer might speed up that response by adding a small trim heater to the last effect. Product quality responds faster to this trim heater, but it is more costly to add steam at this point, because the steam is used in only one effect, instead of passing through all.

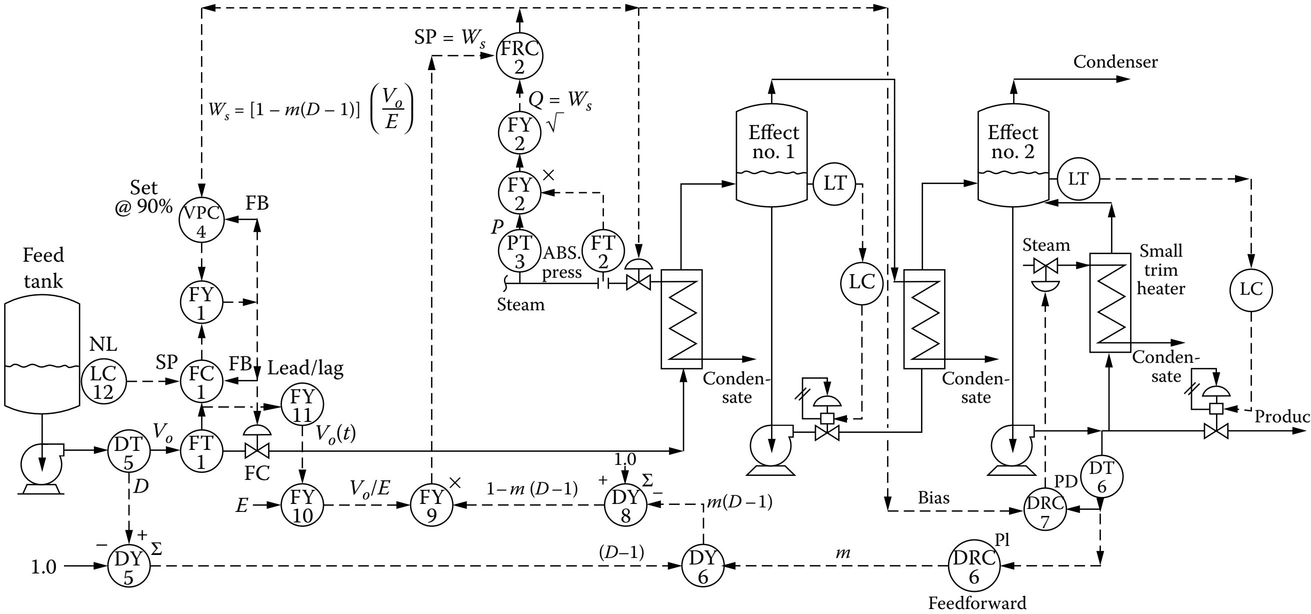

FIG. 8.23bb
Combined control system showing the discussed advanced control features plus controls of a trim heater on the last effect.

When a trim heater is used, as shown in Figure 8.23bb, the product density control is split between a proportional and integral controller (DRC-6), which controls the main steam flow, and a faster, proportional and derivative controller (DRC-7), which throttles the steam to the trim heater.

With feedforward control systems like the one shown in Figure 8.23bb, the control response is fast enough without a trim heater. Yet, if its better response can be economically justified, its controls should be coordinated with the primary steam controls. For this reason DRC-7 is biased by the main steam valve opening, so that they both move in the same direction.

Similar to the use of trim heaters, it is also possible to introduce a small stream of feed directly into the last effect. The use of this technique also improves the response of the system to variations in product quality but is also inefficient, as that stream of feed is exposed only to that one effect instead of to all. Trim controls were used prior to the introduction of feedforward controls, and in many cases the use of trim controls has been discontinued after the installation of feedforward controls.

PRODUCT DENSITY MEASUREMENT

Perhaps one of the most controversial issues in any evaporator control scheme is the method used to measure the product density. Common methods include (1) temperature difference, boiling-point rise; (2) conductivity; (3) differential pressure; (4) gamma gauge; (5) U-tube densitometer; (6) buoyancy float; (7) refractive index; and (8) oscillating Coriolis (see Chapter 6 in the first volume of this handbook).

Each method has its strengths and weaknesses (Table 8.23cc). In all cases, however, care must be taken to select a representative measurement location to eliminate

entrained air bubbles or excessive vibration, and the instrument must be mounted in an accessible location for cleaning and calibration. The relative location of the product density transmitter with respect to the final effect should also be considered. Long runs of process piping for transporting the product from the last effect to the density transmitter increase dead time, which in turn reduces the effectiveness of the control loop.

Boiling-Point Rise

Perhaps the most difficult and controversial method of product density measurement is by temperature difference or boiling-point rise. Dühring's rule states that a linear relationship exists between the boiling point of a solution and the boiling point of pure water at the same pressure. Thus, the temperature difference between the boiling point of the solution in an evaporator and the boiling point of water at the same pressure is a direct measurement of the concentration of the solution. Two problems in making this measurement are location of the temperature bulbs and controls of absolute pressure.

The temperature bulbs must be located so that the measured values are truly representative of the actual conditions. Ideally, the bulb measuring liquor temperature should be just at the surface of the boiling liquid. This location can change, unfortunately, if the operator decides to use more or less liquor in a particular effect. Many operators install the liquor bulb near the bottom of the pan, where it will always be covered, thus creating an error due to *head effects*, which must be compensated for in the calibration.

The vapor temperature bulb is installed in a condensing chamber in the vapor line. Hot condensate flashes over the bulb at an equilibrium temperature dictated by the pressure in the system. This temperature minus the liquid boiling temperature (compensated for head effects) is the temperature difference reflecting product concentration.

Changes in absolute pressure of the system alter not only the boiling point of the liquor but also the flashing temperature of the condensate in the condensing chamber. Unfortunately, the latter effect occurs much more rapidly than the former, resulting in transient errors in the system that may take a long time to resolve. Therefore, it is imperative that absolute pressure be controlled closely if temperature difference is to be a successful measure of product density. These systems are more effective when control of water rate to the condenser rather than an air-bleed system is used.

Conductivity

Electrolytic conductivity is a convenient measurement to use in relationships between specific conductance and product quality (concentration), such as in a caustic evaporator. For the conductivity of some aqueous liquids, refer to Figure 8.23dd. Problem areas include location of the conductivity cell so that product is not stagnant but is flowing past the electrodes; temperature limitations on the cell; cell plugging; and temperature compensation for variations in product temperature.

Differential Pressure

Measuring density by differential pressure is a frequently used technique. The flanged, extended diaphragm differential pressure transmitters are preferred for direct connection to the process (Figure 8.23ee); otherwise, lead lines to the transmitter could become plugged by process material solidifying in the lines. Differential pressure transmitters are more

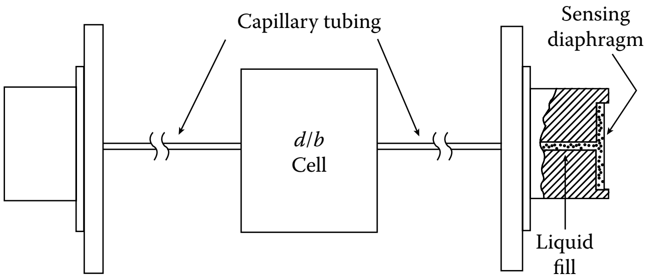

FIG. 8.23ee
d/p cell with extended chemical seal elements.

frequently used on feed density than on final product density measurements.

Gamma Gauge

This measurement is popular in the food industry because the measuring and sensing elements are not in contact with the process. It is very sensitive and not subject to plugging. Periodic calibration may be required because of decay due to the half-life of the source materials. Occasionally, air is entrained, especially in extremely viscous solutions. Therefore, the best sensor location is a flooded low point in the process piping.

U-Tube Densitometer

The U-tube densitometer, a beam-balance device, is also a final product density sensor. Solids can settle out in the measuring tube, causing calibration shifts or plugging.

Buoyancy Float

Primarily used for feed density detection, the buoyancy float can also be applied to product density if a suitable mounting location near the evaporator can be found. Because flow will affect the measurement, the float must be located where the fluid is almost stagnant or where flow can be controlled (by recycle) and its effects zeroed out. A Teflon-coated float helps reduce drag effects.

Oscillating Coriolis

When a Coriolis mass flowmeter (see Section 2.12 in Chapter 2 in the first volume of this handbook) is used for the measurement of feed flow, that same instrument can also provide a density reading for the feed. The error in these measurements is typically between 0.2 and 0.5% SG (0.002 to 0.005 g/cc).

CONCLUSIONS

The process of evaporation is well understood and easily modeled on the basis of mass and energy balance equations. For this reason, *white box*-type (see Section 2.10 in Chapter 2) multivariable models can be used to implement their advanced process control[3] (APC). When using APC-based unit operations controllers, the evaporators can be optimized to reach the criteria of maximized production, minimized energy consumption, or other goals.

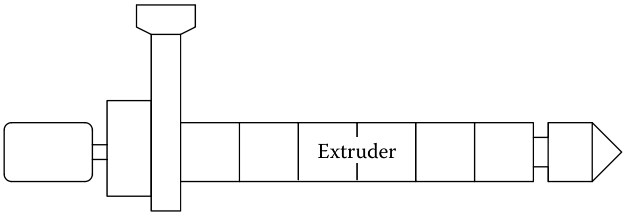
8.24 Extruder Controls

G. A. PETTIT (1972, 1985),

B. A. JENSEN (1995),

M. L. BERNS (2005)



Flow sheet symbol

INTRODUCTION

Integrated extrusion control requires more than controlling the extruder and associated equipment variables at appropriate set points. Extrusion control integrates all the functions an operator normally performs in the correct order at the proper time. This involves the complete integration of controlling, interlocking, sequencing, and scheduling of the extruder system with the other parts of the plant.

An equally important consideration in the automation effort is the interfacing to allow the operator or the higher level plantwide control system to retrieve the necessary data and to provide the means to control the operations of the equipment up- and downstream of the extruder.

Implementation of the various forms and levels of extruder automation is a continuing stepwise process. Achieving the benefits of extrusion automation is a matter of layering information functions and advanced supervisory strategies upon the basic regulatory and interlocking control strategies.

Extruder Production Rate

The extruder output flow is a function of the screw speed, plastic viscosity, screw leakage, pressure build-up, and so on. Assuming an uninterrupted resin supply and negligible screw overflight leakage, the relationship between the production rate of the extruder and the above listed factors is as follows:

$$Q = \frac{k_1 N - k_2 P}{\mu} \qquad \textbf{8.24(1)}$$

where

k_1 = constant, based on geometry of the last screw flight
N = screw speed
k_2 = constant, based on geometry of melting zone
P = pressure of the melt at the nose of the screw
μ = viscosity of plastic

Equation 8.24(1) shows that the output of the extruder is proportional to the speed of the screw and that an increase in output pressure reduces output flow rate.

Polymer Types and Characteristics

All lists of commercial polymers are incomplete owing to the rapid progress of polymer science and production. The common extruded products, such as polyethylene and polystyrene, extrude rather simply and are relatively stable, and their behavior is reasonably predictable.

Polymers in the vinyl chloride group are not so stable at extrusion temperatures. If not promptly removed from the process, they decompose, emitting hydrogen chloride gas, which is very corrosive to metal. Consequently, dies for vinyl chloride are commonly chrome-plated and designed to eliminate pockets or crevices where the material may become entrained and decompose.

An important characteristic of synthetic polymers that complicates their extrusion is sensitivity to shear rate, a phenomenon known as non-Newtonian behavior (Equation 8.24[1]). The relationship between apparent viscosity and shear rate is also dependent on temperature and must be considered when extruder controls are considered.[4] Certain polymers, such as polyvinyl chloride (PVC) and acrylonitrile-butadiene-styrene (ABS), are much more sensitive to shear rate than are more crystalline materials, such as nylon and acrylics. This is especially true if color pigment additives are used.

A wide variety of additives or fillers are available to reduce or eliminate various types of degradation (thermal, mechanical, chemical, environmental). Additives such as UV stabilizers, antioxidant, processing aids, flame retardants, lubricant concentrates, and impact modifiers are normally used in very small quantities. Other additives include reinforcing materials such as fiberglass and, of course, pigment additives for color. Fillers include mineral fillers, such as talc and $CaCO_3$ plus mica, which are added to improve physical properties and function as low-cost extenders.

COMPONENTS OF THE EXTRUDER SYSTEM

The extruder itself is the main component in an extrusion process. It is composed of a drive motor, gear box, screw, barrel zones, and die. On older systems, the screw drive motors are generally DC drives, while on newer systems

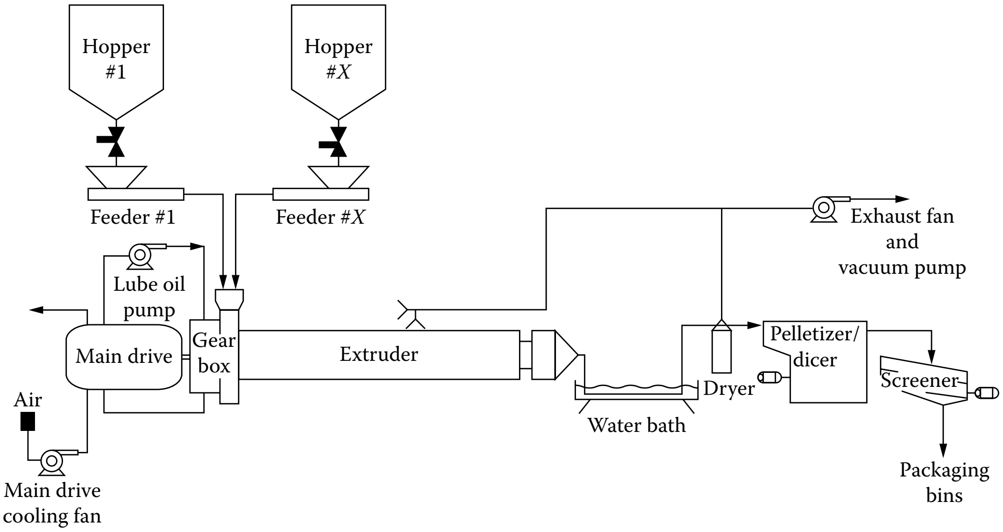


FIG. 8.24a
Extrusion flow diagram.

variable-frequency AC drives or open-loop vector-controlled AC drives are more often used (see Section 7.10 for details on variable-speed drives). The most important component in the compounding process is the screw-type extruder. In addition, an extruder system consists of several other pieces of equipment, including: blenders and feeders on the inlet of the extruder and coolers (water baths), pelletizers, tube cutter-pullers, shears, and stackers on its outlet side. In addition, the system includes such auxiliary equipment as fans and vacuum pumps.

An example of an equipment layout is shown in Figure 8.24a.

Blenders

The resin feed usually is blended with different additives such as pigments and fillers before it is fed into the extruder. The blenders can be volumetric and gravimetric. Both types consist of a resin station, one or more dosing stations, the mixer, and a controller.

The feed rate of a volumetric feeder typically ranges from 3 to 1500 ft^3/hr (0.085 to 42.5 m^3/h) and is determined by the gear ratio and the diameter of the metering screw. The associated microprocessor-based controller performs the following functions: 1) allows the operator to create, store, and recall recipes, 2) controls the running time of the dosing stations, 3) controls the running time of the agitator, 4) maintains the level of the material in each dosing station, 5) displays the status of the operation, and 6) warns the operator if abnormal conditions occur. Figure 8.24b provides a block diagram of the volumetric blender.

A gravimetric feeder measures the actual weight of each additive before loading it into the mixer. The rate of a gravimetric feeder typically ranges from 0.55 lb/hr to 16,500 lb/hr (0.25 kg/h to 7500 kg/h). A microprocessor-based controller performs the same control functions on a gravimetric blender as was described for the volumetric blender. Blender manufacturers use the same controllers for both types of feeders. Figure 8.24c provides a block diagram of the gravimetric blender.

Cooling System

When the molten extrudate exits the die, cooling is required to solidify the product. Different types of cooling systems are used, including: 1) water baths with vacuum sizing, which are used in pipe and tube manufacturing, 2) cooling rollers, which are used in sheet manufacturing, and 3) water baths, which are used in coating processes, including wire and cable covering.

The vacuum sizing tank system consists of the tank, which is under vacuum, a water reservoir, water, and vacuum pumps. The water pump circulates the water between the water reservoir and the vacuum tank through entrance and exit rings. The continuous circulation of the water ensures adequate cooling of the extrudate.

The molten extrudate enters the vacuum sizing tank through an entrance ring. The diameter of the entrance ring determines the size of the pipe or tube. The difference between the air pressure inside the tube or pipe and the vacuum outside it determines the inside diameter of the tube or pipe. The vacuum pressure in the tank can be controlled manually or automatically. (For a description of vacuum gauges and vacuum transducers, refer to the first volume of this handbook.)

When the extruded sheet leaves the die it passes through an air space of 3–10 ft (1–3 m). Here, additional cooling is

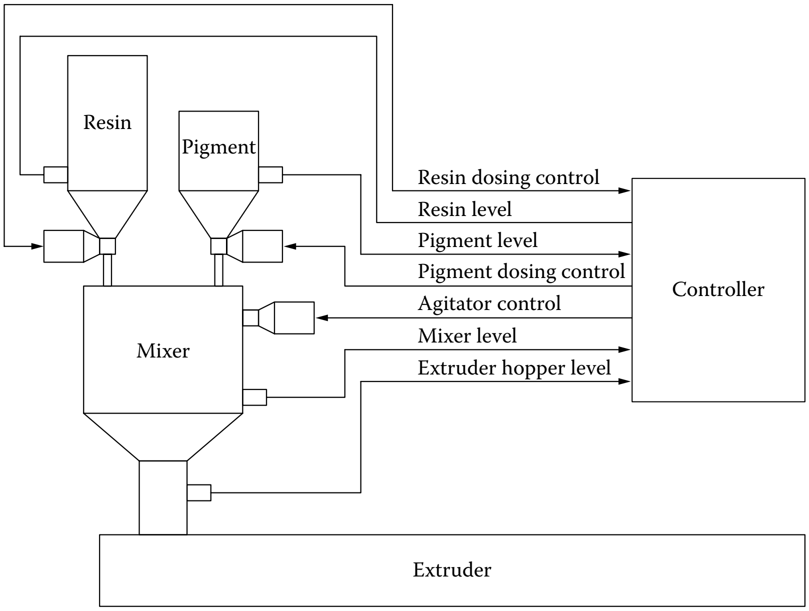

FIG. 8.24b
Block diagram of a volumetric blender and its controls.

provided by a set of cooling fans, which are placed above and below the sheet. In some applications, water-cooled rollers are also used to provide adequate cooling of the material.

When covered wires and cables are manufactured, they are cooled by passing through a cooling trough. To reduce the length of the trough and to maintain the high speed of production, it might be necessary to have several passages inside the trough.

Cutters

Depending upon the end product of the extrusion process, a cutting machine can be used to cut the extrudate strands into shorter lengths.

Pelletizers and Dicers Depending upon the type of the extrudate, a pelletizer, dicer, or some other kind of cutting machine is used to cut the strands into shorter lengths. Pelletizers

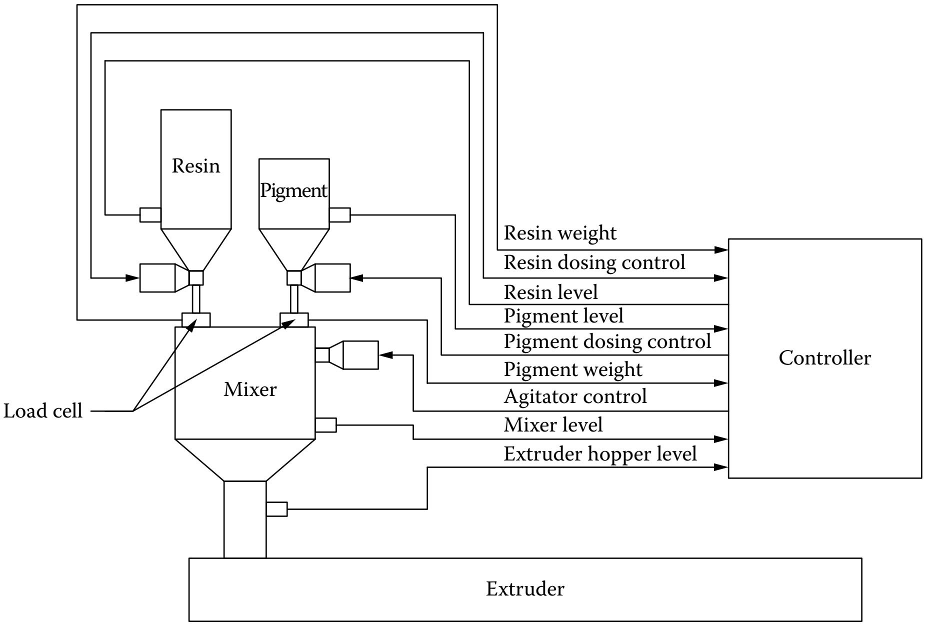

FIG. 8.24c
Block diagram of a gravimetric blender and its controls.

generally cut spaghetti-like strands into small pellets suitable for packaging in bags or boxes. Dicers are used to cut sheets into strips suitable to be wound up into rolls, or they can also be left flat.

Control of the pelletizers and dicers primarily involves the control of their speed so as to maintain the size of the pellets and the ratio of the pelletizer and feed speeds constant. The speed ratio is achieved by feedforward control of the pelletizer/dicer speed based upon the dynamically compensated master feed rate to the extruder.

Pullers-Cutters Cutter-pullers are used in the production of pipes and thin-wall tubes. As their name implies, they pull the extrudate through a vacuum sizer/cooler and cut the tube or pipe to the desired length. The speed of the puller is set by a slave controller to correspond to the speed of the extruder. Reciprocal movement of the cutting head is synchronized with the linear speed of the sleeve or pipe, and at a preset length, a blade cuts the sleeve and retracts. Then the cutting head moves back by the distance equal to the required tube or pipe length.

Auxiliary Equipment

Exhaust fans and vacuum pumps are some of the auxiliary equipment required to remove fumes from the extruder. Because during compounding a variety of gaseous by-products can form, special vent sections are provided in the extruder to allow the removal of these gases. Venting is also required to remove the vapors generated by moisture removal and devolatilizing. A decompression chamber is incorporated at the point of venting so that the process material does not extrude out through the vent port.

When the processing involves the sending of strands through a water bath, often these strands are sent through a vacuum system to dry them.

Screeners are used to sift pellets, ensuring common diameters and lengths.

EXTRUDER TYPES AND SUBSYSTEMS

Single-Screw Extruders

Single-screw extruders usually convert granular resin feeds into sheets, films, pellets, and shapes such as pipe. These extruders are described by their screw diameters (in inches or millimeters) and by their L/D ratio, L being the screw length and D the screw diameter.

Single-screw extruders are available in almost any size imaginable. Common sizes are $^5/_8$, $^3/_4$, 1, $1^1/_2$, $2^1/_2$, $3^1/_2$, $4^1/_2$, $5^1/_2$, 6, 8, 12, 15, and 20 in. (16, 19, 25, 37.5, 62.5, 87.5, 112.5, 132, 150, 200, 300, 380, and 500 mm). L/D ratios range from 5:1 to 48:1, with 20:1 to 30:1 being some of the common choices. The single-screw extruder is by far the most frequently used design; however, the twin-screw extruder is becoming even more popular.[1]

Twin-Screw Extruders

Machines using twin screws are generally large-volume production units used for resin pelletizing in petrochemical plants. They are equipped with various combinations of intermeshing and nonmeshing screws that can be either the co-rotating or the counter-rotating variety. The following types of processing can be performed in a single machine: 1) melting, 2) mixing and blending, 3) homogenizing, gelling, and dispersing, 4) reacting, 5) pumping, 6) compounding and formulation, 7) devolatilizing and degassing, and 8) drying.

Twin-screw machines are often melt-fed directly from polymerization reactors and perform multiple functions on the polymer prior to pelletizing and packaging it as a finished product. The twin-screw extruder is normally selected as the solution to many compounding and reactive extrusion tasks. Twin-screw extruders can be either intermeshing or nonintermeshing. Nonintermeshing extruders behave like two single-screw extruders with only minor interactions between the two screws.

A further subdivision of twin-screw types is the direction of rotation. Co-rotating extruders have both screws rotating in the same direction, and therefore the material is exchanged between the screws, while counter-rotating screws transport the process material through the extruder in a figure eight channel.

Compounding requires that the resin be melted and homogenized while incorporating additives or fillers at a given shear level. The key is the isolation of the high, medium, and low shear sections along the screw length, as well as the feeding of additives at the appropriate points. The advantages of twin screws include the capability for mixing, dispersion, and heat control in addition to efficient conveying.

Extruder Dies and Barrels

Die Types The shape and the ultimate use of the extruded product are defined by the die shape. Dies are broadly classified as follows:

1. Sheet dies for extruding flat sheets, up to 120 in. (3 m) wide and $^1/_2$ in. (12.5 mm) thick.
2. Shape dies for making pipe, gaskets, tubular products, and many other designs.
3. Blown film dies, using an annular orifice to form a thin-walled envelope. The diameter of the envelope is expanded with low-pressure air to roughly three times the annular orifice diameter to form a thin film. The process is used for films up to 5 mils thick (0.005 in., or 0.125 mm) at the upper limit.
4. Spinnerette dies for extrusion of single or multiple strands of polymer for textile products, rope, tire cord, or webbing.

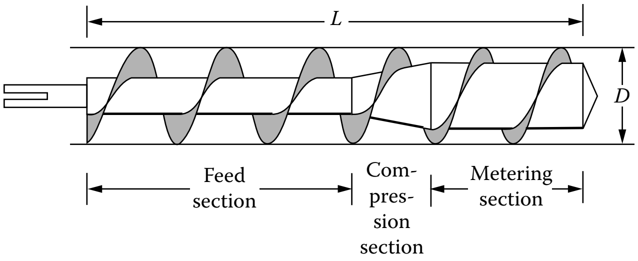

FIG. 8.24d
Typical extruder screw.

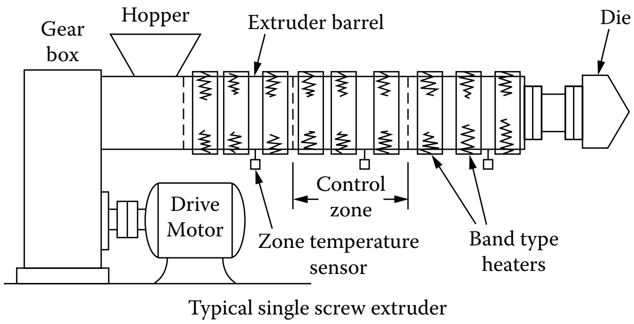

FIG. 8.24e
Single-screw extruder with band heaters.

5. Pelletizing dies for granular products in resin production, synthetic rubbers, and scrap reclaiming. These dies form multiple strands roughly $^1/_8$ in. (3.125 mm) in diameter. Rotating knives continuously cut the strands in short lengths, after which the pellets drop into water for cooling.
6. Cross-head dies for wire coating, in which the bare wire or cable enters the die and emerges coated with semimolten polymer. The wire enters and leaves the die at an angle of 90° to the extruder axis.

Many special configurations of extruder dies are used to produce composite films. In such designs, two polymers enter the die from two extruders and exit as a sheet. The top and bottom polymer layers are of different chemical composition so that one might obtain a film or sheet of two colors or to utilize the other desirable characteristics of both materials.

Dies for rigid foam production are similar to blown film dies. Special dies with moving parts can continuously extrude netting. Most dies require a short connecting pipelike piece, commonly called the adaptor, which connects to the extruder head. Also, twin-screw extruders require an additional special adaptor piece called an "eight-to-oh" (8/O) zone to convert the twin configuration (which physically looks like a figure eight lying on its side) to an output configuration of the adaptor (zero or the letter "O").

A typical extruder screw is shown in Figure 8.24d.

Barrels and Heater Rings The barrel of an extruder is usually divided into roughly 15–18 in. (375–450 mm) long temperature control zones. A $4^1/_2$ in. (112.5 mm) extruder, for example, may have four to six barrel zones. The number of zones depends upon the L/D ratio, the number of feed points for additives, and on the type of material being extruded; 4–6 zones is most common, but it is not unheard of to have 12–15 zones (Figure 8.24e).

Conventional temperature control loops include a power control device, temperature sensor, and heater for each zone. Adapter, 8/O, and die zones may all be provided with temperature controllers.

Extruders require large heater ratings to decrease heating time. A typical barrel zone electrical heater can be rated anywhere from 1.2 to 11 kW and greater. The size generally is determined by the type of feed, the screw type, and the resin feed location. External heating of the barrels can be provided by electric resistance heaters and by hot oil systems.

Band-type silicon control rectifier (SCR) resistance heaters are of two-piece construction to facilitate removal. Another type of electric heating is inductance heating, which is accomplished by coiling a copper wire about the barrel to induce an electromagnetic field. This technique is more responsive than resistance-type heating. The coil is energized with 60 cycle current and is usually controlled by contactors.

After extrusion has begun, heat is internally generated from the friction and shear of the rotating screw. This heat is a function of the square of the screw speed. The amount of heat generated is also influenced by screw design, head pressure, and resin viscosity. In some zones, the melt temperature may rise above accepted maximum, and barrel cooling is required.

Cooling Systems

The barrels are commonly cooled by fans (Figure 8.24f) or by a water-cooled jacket. Many extruders use aluminum heating shells with casting heaters of encased nichrome coiled

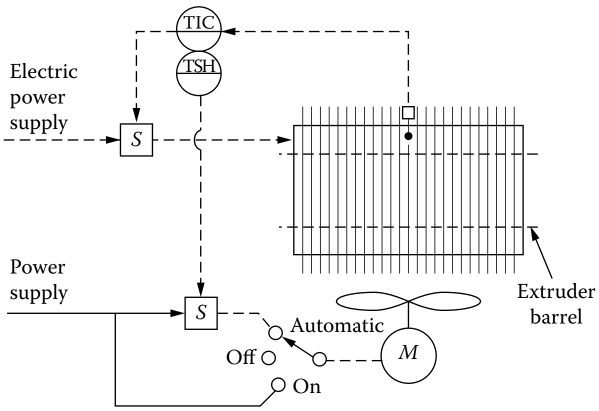

FIG. 8.24f
The extruder barrel is provided with fins and with temperature controls using electric heating and cooling by air fans.

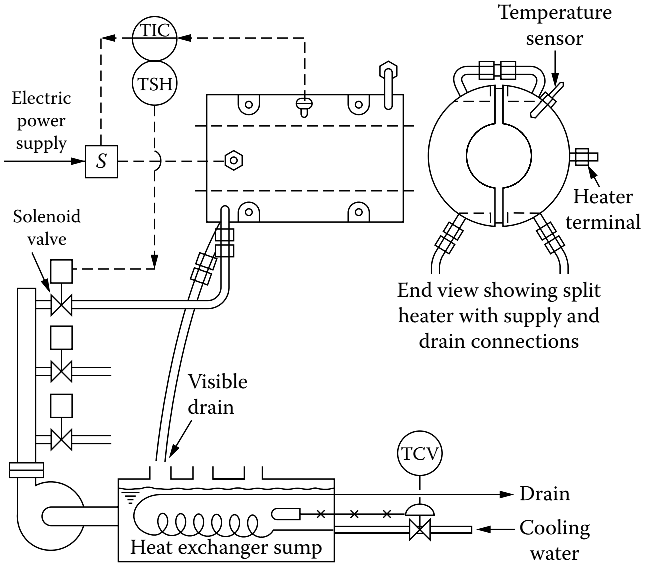

FIG. 8.24g
The extruder barrel is provided with fins and with temperature controls using electric heating and cooling by water.

throughout the aluminum jacket. The shells are constructed in two segments clamped together to surround the extruder barrel. Shells for fan cooling have fins cast to the outside surface to increase their surface area. Motor-driven fans or blowers are positioned directly below the zone, and when switched on by a high-temperature switch, they cool the barrel by forced convection. A zone fan on a $2^1/_2$ in. (62.5 mm) extruder can typically remove the equivalent of 5 kW per hour.

Water-cooled extruders are provided with aluminum shells with cast-in tubing as well as heaters. Treated water is continuously circulated through the coils by a common pump and heat exchanger (Figure 8.24g). Solenoid valves, regulated by the zone temperature controller, allow circulation to each zone in order to maintain the proper barrel zone temperature. The solenoid valves can be operated by an auxiliary high-temperature switch, which is part of the zone temperature controller. The switch is designed to operate in a time-proportioning manner with extra slow cycle rate and capability for very short pulses.

Water-cooling can be too effective compared with fan cooling. The cooling water is usually flashed into steam at most barrel temperatures used for processing thermoplastic materials. Some machine builders use compressed air to clear the water from the passages and to eliminate trapped fluid, which could cause erratic cooling.

Cooling water is often injected in very short pulses, which are followed by the immediate removal of the water to reduce cooling. Running the exchanger sump at higher temperatures also reduces the severity of water-cooling.

SENSORS, VARIABLES, AND THEIR CONTROL

Temperature Measurement

Accurate temperature measurement is very important for efficient extrusion and overall quality of the end product. The most common extruder temperature sensors are thermocouples (TCs) and resistance temperature detectors (RTDs). RTDs detect the change in their electrical resistance, which is proportional to their temperature, while thermocouples produce a millivoltage output, which is related to the temperature of the TC's junction.

A detailed discussion of all temperature sensors is provided in Chapter 4 of the first volume of this handbook.

Temperature Control

The zone temperature of extruders is usually controlled by time proportioning PID controllers. In such a control system, the on-time of the electric heater is modulated by the PID controller, while the total cycle period (usually 8–10 sec) remains fixed. In some systems each zone is provided with its own single-loop controller, while in others a programmable logic controller (PLC) executes the PID algorithms in sequence.

Time-proportioning control is less expensive than continuous modulation, because it allows the use of electromechanical or solid-state contactors. A block diagram of the time-proportioning controller is shown on Figure 8.24h.

Duration of on-time period of the final control element is a function of the continuous output of the PID controller. Therefore, if the output of the controller is 40% and the cycle period is 10 sec, then the on-time period of the solenoid or contactor is 4 sec. The output signal generated by the time-proportioning control system in response to a continuous PID controller output is illustrated in Figure 8.24i.

Temperature control is complicated by several factors. These include heating caused by the shearing action of the screw, changes in the feed rate, conduction of the heat along

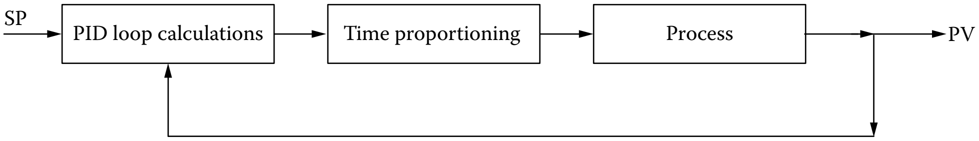

FIG. 8.24h
Block diagram of a time-proportioning controller.

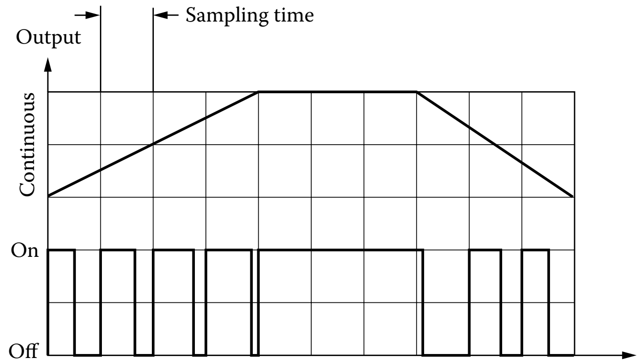

FIG. 8.24i
Illustration of the continuous output signal from a PID controller (top) and the corresponding output generated by a time-proportioning controller (bottom).

the barrel, and the difference between the process gains that exist during heating and during cooling. An increase in screw speed increases the shear in the screw channel and the mechanical work, which raises the resin temperature. At the same time an increase in screw speed and output flow rate reduces the amount of cooling, because the resin spends less time in contact with the same heat-transfer surface.

If the operating pressure is low, due to a low-resistance die size, the amount of frictional heat developed may not be sufficient to compensate for the decrease in conducted heat, and therefore, the resin temperature will drop as the screw speed increases. At higher pressures, the temperature may show an initial increase before dropping off. At still higher pressures (heavy screen packs or small dies), the same screw and operating conditions can result in an increased temperature with increasing screw speed, because the mechanical heating effect exceeds the decrease in conducted cooling.[2]

In some cases, as much as 80–100% of the heat produced throughout the extruder can be generated by screw shear alone. Effective temperature control requires accurate removal of heat as well as accurate application of the heat from the barrel heaters.

Zone temperature control is designed to maintain a constant temperature in each barrel, adaptor, and die zone to achieve a desired profile and thus guarantee the consistent melting of the extrudate. Feeding and compression zones are most effectively controlled at relatively constant temperatures, because under such conditions they will provide the optimum wall friction for efficient feeding.

Temperature can have a dramatic effect on both throughput and product quality. Good temperature control in the rear zones can increase the hourly output for some materials. On the other hand, some crystalline thermoplastics are relatively impervious to temperature variations of as much as 50°F.

Zone temperature is usually controlled either by single-loop PID control loops or by PLC-executed PID controls. However, the installation and maintenance of the RTD-, thermocouple-, or thermistor-type sensors is critical. (See Chapter 4 in the 4th edition of Volume 1 of this handbook.) The major problem is to maintain an optimal temperature profile, which is a function of the dynamics of heating, cooling, shear heat, and conduction. Adaptive tuning and the use of dead time PID control can improve performance.

Pressure Measurement

The accurate knowledge of extruder pressure is very important for efficient extrusion. Chapter 5 of the first volume of this handbook provides an in-depth description of all the available pressure sensors.

The commonly used extruder pressure sensors include grease-sealed gauges. These are direct-reading Bourdon tube gauges with a tube tip capillary for complete filling with high-temperature grease, usually silicone. The grease remains viscous at high temperatures and prevents the molten polymer from entering and solidifying in the gauge or piping. Disadvantages of this sensor include the need for periodic greasing and the occasional contamination of the product.

Force-balance transmitters provide a linear output signal that can be sent to digital or analog pressure indicators, recorders, and controllers. Their force-balance operating principle makes them less sensitive to process temperature variations.

Strain gauge-type pressure transducers are higher accuracy pressure sensors, and for that reason, they are widely used in extruder applications.

Pressure Control

Synthetic fiber processes frequently use an extruder to melt and transport nylon and polyesters to a bank of gear pumps feeding individual spinning die heads. The shear characteristics of these polymers are near-Newtonian and their viscosity is relatively constant at wide variations in shear rate. In such processes, the pressure is nearly proportional to screw speed, and therefore pressure can be controlled by the manipulation of the screw speed.

In contrast, PVC can be pumped through a restriction orifice at increasing rates without an increase in the pressure drop across the orifice, because its apparent viscosity decreases with increased pumping shear rate. In this case, the pressure cannot be controlled by the manipulation of the screw speed.

Figure 8.24j illustrates the control scheme used in fiber processes. Because some of the fiber spinning pumps frequently fail or are stopped intentionally, it is necessary that the pressure controller quickly respond to such events by immediately slowing the extruder screw to a new output rate determined by the number of constant volume pumps remaining in operation.

In the past, screw drive motors were generally DC drives or eddy current clutches. Today, these drives are being substituted by variable-frequency AC drives. These drives can

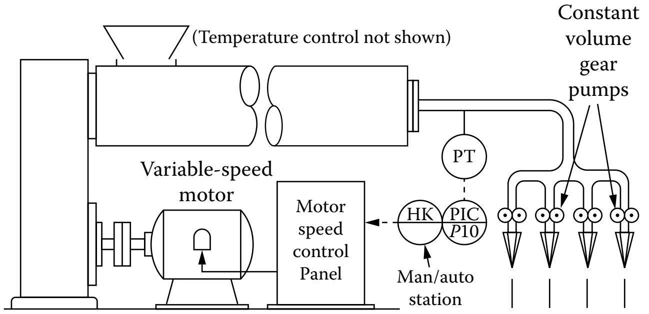

FIG. 8.24j
Extruder pressure control used in the production of synthetic fibers.

be modulated by either digital or analog control signals. The variable-frequency drives provide virtually instantaneous response, which is important to guarantee stable control.

Depending upon shear characteristics, die head pressure can remain uncontrolled or can be controlled by either feed rate or screw speed. Synthetic fiber processes frequently use an extruder to melt and transport nylon and polyesters to a bank of gear pumps feeding individual spinning die heads. The shear characteristics of these polyesters are near-Newtonian and, thus, have relatively constant viscosity at wide variations in shear rate. This characteristic is responsible for the discharge pressure being nearly proportional to screw speed, which is necessary for pressure control by the regulation of the screw speed.

In contrast, PVC can be pumped through a restricted orifice at increasing rates without an increase in back-pressure because its apparent viscosity drops with increased pumping shear rate. The pressure of such a process is nearly impossible to control by manipulating screw speed.

Film Thickness Control

Blown film, which is used in the production of tubular and flat film to 5 mils (0.125 mm) thickness, requires thickness measurement and control. Thickness can be adjusted by the speed of the take-up rolls if the thickness uniformly varies (in machine direction) across the film. Increasing the take-up speed reduces the film-gauge, while decreasing the speed increases its thickness (Figure 8.24k).

Thickness variations in die direction (across the width) can be measured, but most attempts to automate sheet die nip adjustments have been unsuccessful. Sheet dies extrude materials up to $^1/_2$ in. (12.5 mm) thick and 120 in. (3 m) wide.

Measurement of film thickness to 100 mils (2.5 mm) is made with radiation instruments (Figure 8.24l), using beta rays. Among design variations are scanning heads that measure and record thickness over the entire width of materials. Infrared, LVDT, laser, capacitance, ultrasonic, and mechanical devices have also been used. For details on these sensors, refer to Section 7.20 in Chapter 7 in the first volume of this handbook.

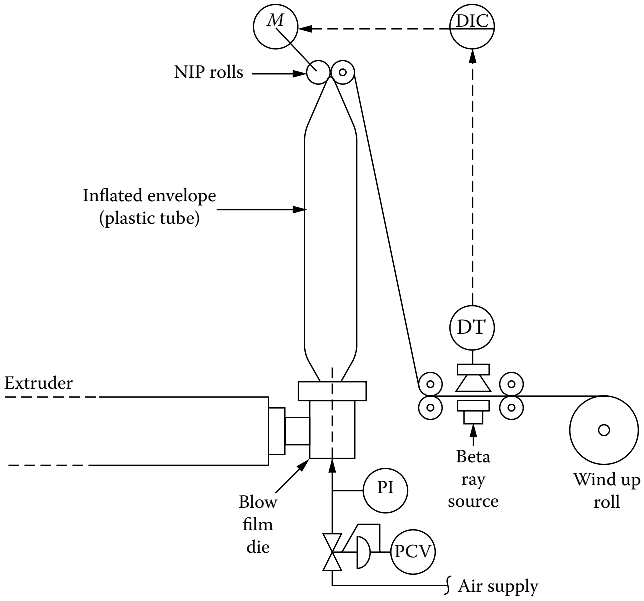

FIG. 8.24k
Film thickness control through nip roll speed manipulation.

Polymer viscosity variations of the feed constitute the most difficult aspect of extruder design, simulation, and control. The feed viscosity tends to have more influence on the extrusion process and on the dimensional quality of the pelletizing extruder output than all other variables. For the description of viscosity detectors, see Sections 8.62 to 8.64 in Chapter 8 in Volume 1 of this handbook.

In tube and pipe production lines, the outer diameter, wall thickness, and concentricity are determining factors of produce quality. Outer diameter is set by the entrance ring of

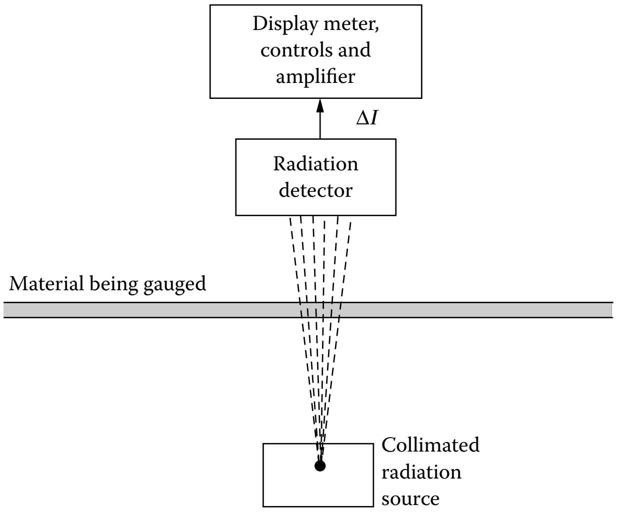

FIG. 8.24l
Radiation absorption gauge.

the water tank and can be slightly adjusted by the speed of the puller. Concentricity can be adjusted by controlling the vacuum inside the vacuum tank. Wall thickness can be adjusted by controlling extrusion speed.

EXTRUDER CONTROL SYSTEMS

The overall extrusion control system serves more than controlling the extruder and associated equipment at appropriate set points. Extrusion control should integrate all the functions that an operator normally performs into a control system that keeps the steps of the extrusion process in the correct order at the proper time. This includes the complete integration of controlling, interlocking, sequencing, and scheduling the extruder system with the other parts of the plant.[5]

An equally important consideration in the automation effort is the interfacing provided for the operator to retrieve data and to provide the means for control. Modern extruder control systems are based on programmable logic controllers or industrial computers to control temperatures and screw speeds. Using programmable logic controllers and networking offers systems that not only govern machine functions and parameters but also integrate them with upstream equipment, such as the feeders and mixers, and with downstream equipment, such as pelletizers, dryers, and conveyors.

Basic Control

Regulatory, discrete, and interlock controls are needed to operate an extrusion system. The typical basic control system consists of the several subsystems, including: 1) feeder mass flow rate control, 2) individual zone temperature control along the extruder barrel, 3) motor speed control, 4) die head pressure controls, and 5) auxiliary discrete devices for on/off operation of fans, pumps, pelletizers, and so on.

Mass flow rate control is designed to allow the operator to set the overall mass flow rate to the extruder. Feed rate control for blending is implemented by setting mass flow rate set points for each feeder, based upon the individual percentages determined by the recipe, and multiplied by the overall mass flow rate. For a detailed discussion of mass flow meter designs, see Sections 2.11 to 2.13 in Chapter 2 in the first volume of this handbook.

Main screw speed control is designed to maintain a reasonably consistent torque and specific energy of the extrudate at various feed rates. Implementation is based upon feedforward control from the master feed rate to the extruder screw speed, which is adjusted in a simple ratio. Extruders used in compounding tend to be run at top speed for extended periods and require only minor variations in RPM.

Interlocks build upon regulatory and discrete control functions in order to provide additional equipment and personnel protection in the case of hardware failure. The most common interlocks control the main drive motor, lube oil pump, feeders, feed hoppers, and pelletizers/dicers.

Advanced Control

Advanced controls include the cascade control of melt temperature, zone flux control, auto-tuning of temperature controllers, maximizing production, and extrudate quality control.

Melt Temperature Control The output melt temperature is a function of the internal shear energy (converted to heat energy) plus or minus the conducted heat (barrel cooling), depending on the operation. The temperature of the melt is as important, because it influences the output rate for quality extrusion. The cascade control to reset the zone controller set point achieves continuous temperature control of the melt. Figure 8.24m shows the arrangement for cascade feedback.[6]

One special feature is that the system allows only depression of the zone temperature controller set points, which is a safety consideration because of heat degradation and pressure build-up in polymer systems. A safety interlock with the extruder screw drive is usually incorporated in order to prevent both polymer freezing during shutdowns and drive damage at start-up.

Zone controllers provide both heating and cooling, and their set points are regulated by the melt controller. Each

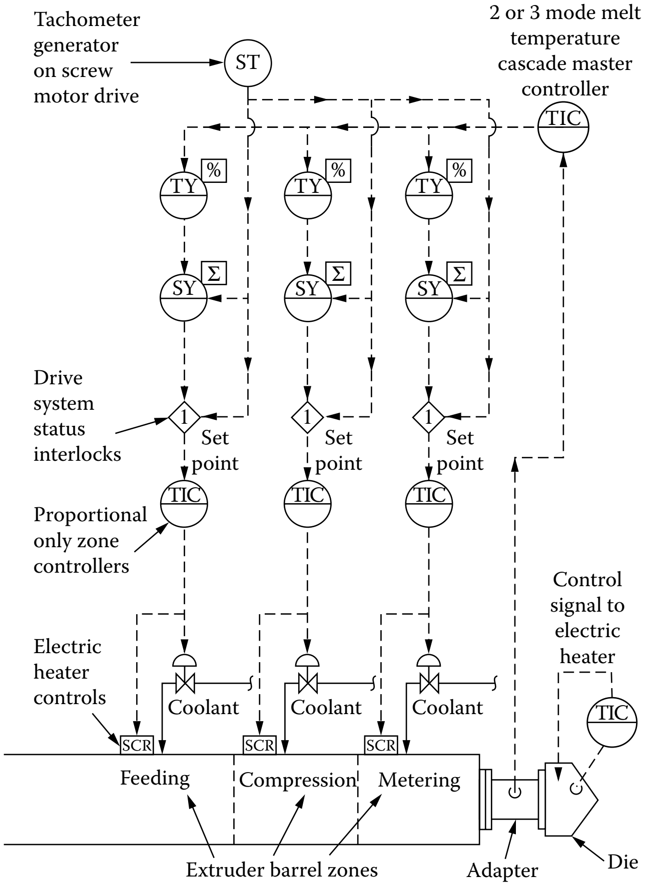

FIG. 8.24m
Melt temperature cascade system.

zone temperature set point can be adjusted individually to follow a certain percentage of the feedback cascade signal so that a preset program of zone depression will follow a definite barrel temperature zone profile curve. The extruder metering zones are capable of the greatest heat transfer and, therefore, receive the greatest percentage of feedback and most set point depression.

Feeding and compression zones are most effective at a relatively constant temperature to provide optimum wall friction for most efficient feedings; therefore, they usually receive a small percentage of the feedback signal. The melt controller must have proportional and integral control actions[7] with rate action being beneficial. Some cascade systems also incorporate a tachometer feedforward signal to supply set point depression proportional to screw speed. This function reduces temperature departures from the control point caused by screw speed drift or by intentional speed changes.

Flux Control Zone flux control is designed to maintain the desired temperature at all points throughout the extruder so that a consistent melt of the extrudate is achieved, which is the same objective as that of basic zone temperature control. Flux controllers are used to include feedforward control from feed rate and the drive motor screw.

Flux is defined as the heat per unit area in the extruder zone. It is the energy due to the heating elements, plus the energy due to the screw shear, minus the energy removed by cooling, and minus the energy required to heat and melt the resin. These factors must be dynamically compensated and applied to the measurement of the flux controller.

Both the motor and the feed energy terms provide feedforward responses to "load" disturbances. These disturbances are generally not significant during normal operation but become important during start-up and shutdown. This is because as the screw starts, the motor power begins to rise, which increases the flux controller's measurement. In response to this, the flux controller calls for a decrease in heat, resulting in a decrease in output to the heating element or an increase in the rate of cooling.

As feed is added to the extruder, the heat required to warm and melt the feed results in a decrease in the flux controller's measurement. In response to this, the flux controller's output increases, calling for more energy to be put into the zone. Therefore, the control algorithm must include dynamic terms, which have to be field-tuned. Figure 8.24n illustrates the control block diagram for zone flux control.

Auto-Tuning Maintaining the extruder barrel temperature profile is the most important factor in controlling the quality of the final product. Therefore, the temperature control loops must be tuned to ensure their optimal performance. Loop tuning is performed by initiating a small change of the set point (usually 10%) and adjusting the gain of the control loop to achieve the fastest response (see Figure 8.24o). For an in-depth discussion of PID controller tuning, refer to Section 2.35 in Chapter 2.

Most PLCs and microprocessor-based single-loop controllers have an auto-tuning feature that implement the Ziegler-Nichols method of tuning. Adaptive auto-tuning is designed to continually update the PID-type zone temperature controller's tuning constants in response to process gain variations caused by load variations. There are three methods of adaptive auto-tuning:

Programmed adaptive auto-tuning is based on automatic adjustment of the proportional gain as a function of changes in process dynamics. For example, the proportional gain of the controller can be affected by changes in the controlled variable, in the set point, and so on. The programmed adaptive algorithm can be set for independent gain adjustment using any combination of the process-related variables.

Model-based auto-tuning uses an internal model of the process to determine the optimal PID settings. In this case, the controller introduces step changes above and below the set point and observes reaction to these changes. The PID settings are then calculated according to predetermined criteria.

The *pattern recognition* method continuously examines the response of the process to naturally occurring disturbances such as set point or load changes. When the resulting error exceeds some threshold value (controller looks for peak values) and after several peaks (usually two or three), the controller determines the period of oscillation that is related to the dead time of the loop and, based on it, calculates the new PID tuning constants. See Chapter 2 for a general discussion of control theory and specifically for process modeling and controller tuning.

Maximized Feed Rate Control Figure 8.24p illustrates a master feed control system that is designed to maximize the throughput of resin to the extruder by increasing the feed rate until a constraint is reached. The master feed rate controller set point is constrained by the outputs of a number of limit controllers, which are sent to a select network. The output of the selector is the lowest of any of the constraint controllers.

The output of the low select then becomes one of two inputs into a high selector limit. The other input is the minimum feed rate setting of the extruder. The resulting output is the cascade master's feed rate set point for the feed hopper flow controllers. A set point for minimum feed rate is included in order to have a low limit clamp.

The constraint variables normally include the die head pressure, drive motor amps (or motor torque), extruder throat or chute level, maximum feed rate, and minimum feed rate. Many compounding extrusion processes can take advantage of a maximum feed rate control because of excess upstream storage capabilities. However, when feed to the extrusion system is from some other continuous process, this type of control may not be possible because of limited feedstock availability.

The ultimate test of the quality of any control system is the quality of the extrudate. Quality is affected by many

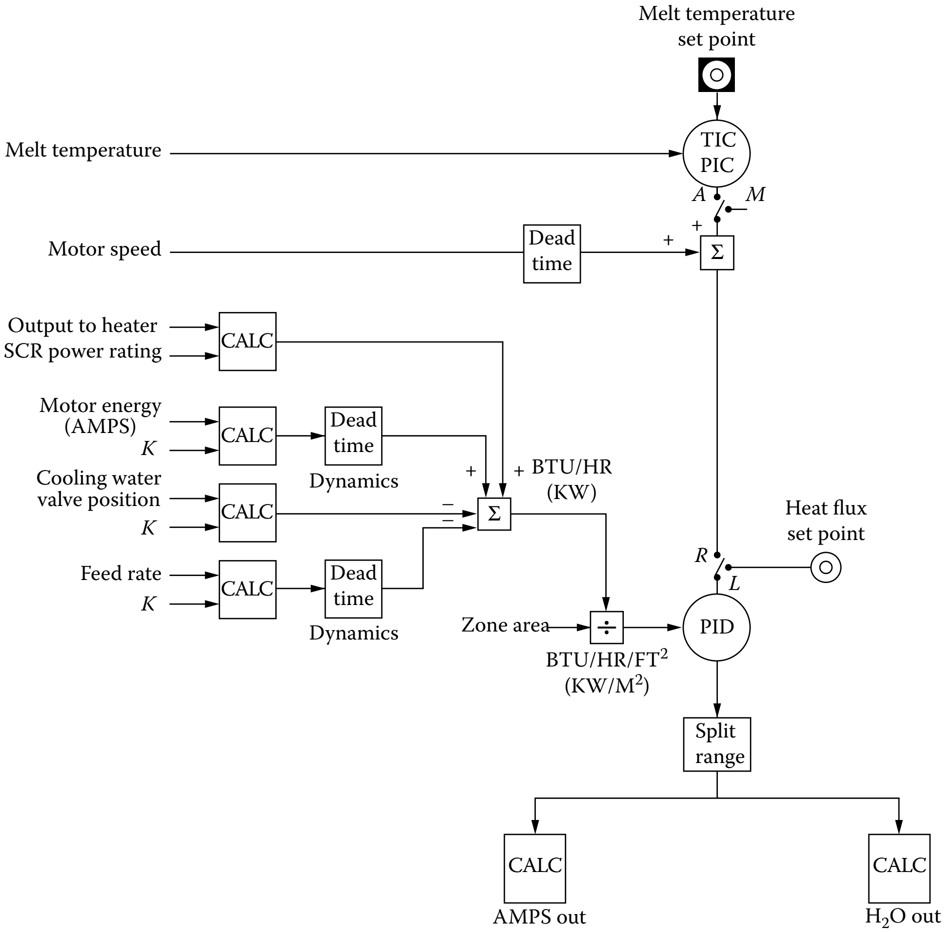

FIG. 8.24n
Heat flux control.

parameters, including feed mixing, barrel temperatures, melt temperatures, screw speed (shear rate), enthalpy (from external sources), pressure, and rheological conditions. On-line rheometers, machine vision analyzers, or other specialty instruments can be used to measure certain extrudate properties. They are becoming more numerous and more reliable.

Quality indicators measured by these instruments include such properties as melt flow index, viscosity, gels, color,

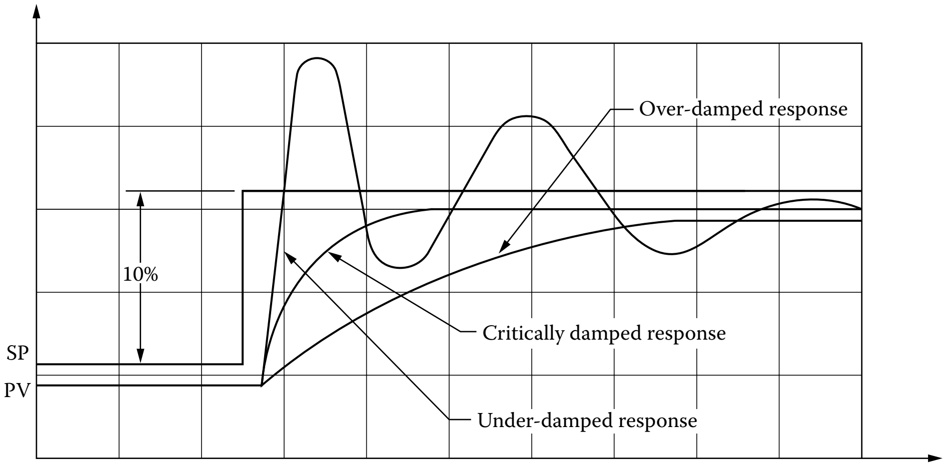

FIG. 8.24o
The response of a PID loop as a function of narrowing the proportional band (increasing the controller gain). The cycling curve corresponds to a high gain setting, the critically damped curve to the correct setting, while the overdamped curve to a low gain setting.

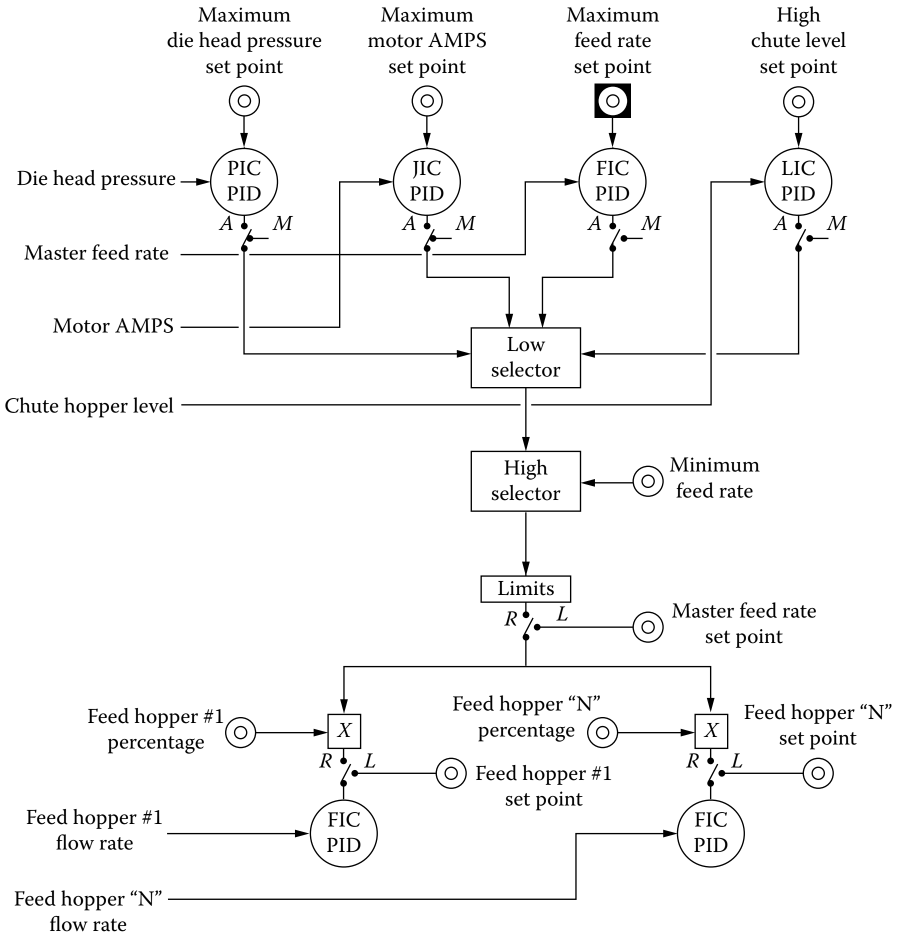

FIG. 8.24p
Optimized control system, serving to maximize the feed rate to the extruder while obeying limit constraints.

agglomerates, and excess ingredients, which are all described in Chapter 8 of Volume 1 of this handbook. A combination mass flowmeter and viscosity detector is illustrated in Figure 8.24q.

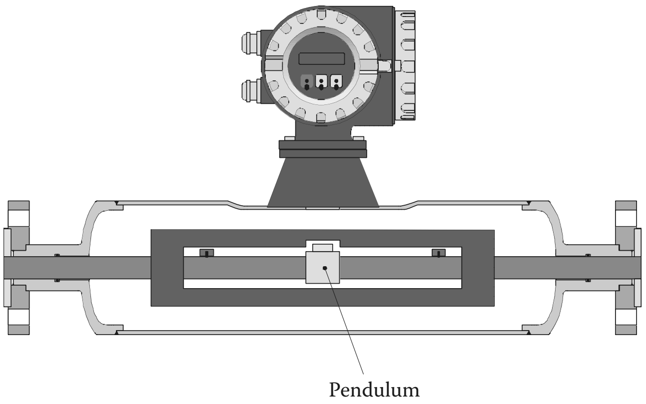

FIG. 8.24q
A pendulum mounted on a single Coriolis tube generates both torsional and lateral oscillations, which allow for the simultaneous measurements of mass flow and viscosity.

A measurable, repeatable value can be used as feedback to one of the above-listed quality-related parameters. Calculations determining extrudate properties can also be used. Choosing a manipulated variable from the above list is challenging because of the lack of sensitivity and the limited number of degrees of freedom available.

One method of controlling the quality of the extrudate is the manipulation of the feed ratio, i.e., the mixing of a particular feed resin with another resin of different properties while all other parameters are held constant. Model-based control or multivariable control can also be used to control extrudate quality, but in most polymer processes the majority of quality parameters of the feed can only be corrected at the reactor and not at the extruder.

The large dead time of the process can also render feedback control impractical.

Engineering Calculations Increased capabilities of modern digital controls allow engineering calculations to be displayed on the human-machine interfaces (HMIs) for the operator. The displayed variable trends include specific energy, extruder motor speed, torque, and current. Additional parameters such as actual zone temperatures and deviations, equipment run times, and other values are also displayed on auxiliary screens.

One such calculation is the physical property known as melt factor or melt flow index (MFI) of the extrudate. Another calculation could include viscosity or other indexing properties. The quality calculation is normally computed as a continuous on-line value. Because the laboratory result of the sample is not available until some time after the sample was taken, recording the current conditions allows a time-synchronized comparison of the laboratory result with the calculated value.

The process conditions are recorded at the time that the sample is taken. The conditions from which MFI is normally calculated are die pressure, melt temperature, and mass flow rate. However, feed mixing, screw speed, and rheological conditions are other nonmeasured parameters affecting extrudate properties.

Another useful calculation is specific energy of the extruder at the die head. The power input, whose units are horsepower (watts), is multiplied by an efficiency constant and by a constant conversion factor. This value is divided by the total feed rate to give a result in the units of hp/lb (kw/kg). This property relates to the shear rate and, thus, to the viscosity of the resin.

Torque and percent maximum torque are important operational parameters for the extruder. A linear relationship can be assumed to exist between the motor current (in amps) and screw speed (in RPM). A constant voltage is assumed, allowing power to be calculated from motor amps. Percent maximum torque is also calculated from the current and screw speed. The current torque measurement is divided by the maximum current rating and maximum drive speed, and is expressed in percent.

Equipment run-time numbers are generally of interest to maintenance personnel. The number of times the main drive motor has been started, the percentage up-time since initialization, total run time, and percentage up-time can be calculated for each extruder. The cutting time and the number of times each pelletizer/dicer has been started gives maintenance personnel information on when cutting blades should be sharpened or when the equipment should be overhauled.

Sequences Sequences are automated so that step-by-step procedures control the routine activities. Included in this category are heater/contactor check, heat-up, start-up, shutdown, and alarm disabling/enabling.

Heater/contactor checks provide the ability to test proper operation of the heater/contactors and extruder thermocouples, for those heating systems that are using electrical heating elements. A heater/contactor is suspected to be "bad" whenever the maximum output is sent to the zone and the expected amperage read back is not within a certain percentage of the expected value. The problem is either a bad contactor or bad heater legs.

Extruder heat-up provides the ability to heat the extruder to preset values in a series of steps and to display the duration of the heat-up. This results in a heat-up profile in accordance with the manufacturer's specifications in order to minimize thermal stress on the equipment.

Extruder start-up provides the ability to bring the extruder equipment on-line from a heat-up condition to preset values in a series of steps. The procedure checks system interlocks, starts auxiliary equipment, and ramps the extruder speed and feed rate to their preset recipe values. In addition, the appropriate alarms are enabled as the sequence progresses. Once the feed material is ready and a heat-up of the extruder has been performed, the extruder can be started up in an orderly stepwise manner.

Extruder shutdown sequencing provides the ability to bring the extruder equipment off-line from a running condition in a series of steps. The procedure turns off the feeders, decreases screw speed in a preset manner, ramps the pelletizer speed to a minimum value, and shuts down the main drive and auxiliary equipment. Appropriate alarms are inhibited as the sequence progresses. In addition, a "panic button" is normally provided for emergency shutdown. This button cuts all power to the line, resulting in immediate shutdown of the extrusion process in case of emergency.

The enabling and disabling of alarms is automated to reduce the frequency of unnecessary signals. Normally this function can be performed by the start-up and shutdown procedures. Whenever a unit is being started up, alarms need to be enabled to warn of abnormal occurrences during normal operating conditions. Similarly, when a unit is being shut down, certain alarms need to be disabled or inhibited to prevent alarms from actuating, because it is normal that during shutdown a number of alarm thresholds will be violated as equipment is being shut down.

Integrated Control

Management information control is a higher level automation activity. Timely information provided to engineers and management allows them to better evaluate performance and maintain consistency. Integrated control includes those additional steps that serve to optimize the overall utilization and performance of the extruders. Included in this category are line scheduling, lot history, recipe management, and statistical process control and statistical quality control (SPC and SQC).

Line scheduling provides the ability to optimize extruder availability. Optimizing extruder availability maximizes overall throughput. An individual extruder, chosen from a set of many extruders, may need to be made available to run a particular type of raw material to produce a certain grade of product. Factors affecting the scheduling of a single extruder line includes the amount of material to be run, availability of raw material, grade of material, color of material, size of extruder (screw diameter and number of barrel zones), extruder configuration (single or twin screw), and the availability of auxiliary equipment.

Lot history is a function that captures all the information associated with the process of extruding a resin product. This is analogous to batch tracking in a chemical plant. The information associated with extrusion of a resin product is normally categorized according to a lot number. Select process alarm information and process conditions are captured and stored as part of the production history on file. Quality standards within the batch industry mandate the reporting of all activity associated with a batch run.

Recipe management maintains a database of master recipes for various products, formulas, and procedures. Specific information for the extrusion equipment and extrusion lines that can perform the required operations are contained within the recipe. The recipe is selected and accessed according to the relationship of the material to be processed with a specific extruder line.

The recipe management function provides the ability to automate the start-up and normal operation of the extruder. Set points stored from previously run recipes and formulas are useful, because they store the relationship to the grade of materials that were processed in the past and can be inserted into the controllers for new runs on the same extruder and associated equipment. These set points include barrel zone temperatures, feed rates, and screw speed.

Statistical quality control provides a history of quality data for the extrudate. This process flags statistically improbable events in real time, evaluates process performance, and validates newly installed operating conditions. Various calculations and statistical tests can be made for each run. Real-time and historical graphs can then display these data to the operators and engineers as required.

CONCLUSIONS

During the last ten years digital control systems including programmable logic controllers have become more powerful. Today, even mid-size PLCs can perform complex calculations, including some modeling and floating-point mathematics. This allows extruder manufacturers to implement control systems with complex algorithms that include auto-tuning of temperature control and pressure control loops.

In addition, the human-machine interfaces allows storage of recipes and can display historical trends of many operating parameters. Because most mid-size PLCs have extensive networking capabilities, extruder manufacturers are able to offer integration with upstream equipment, such as feeders and mixers, and with downstream equipment, such as pelletizers, dryers, and conveyors.

System control and data acquisition (SCADA) packages provide plant management with production information that allows them to improve quality control, planning, and allocation of resources.

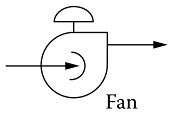
8.25 Fan Controls



Flow sheet symbol

B. G. LIPTÁK (1995, 2005)

INTRODUCTION

The transportation of gases and vapors is an important unit operation in all plants, particularly in the unit operations that involve the moving of large volumes of air, such as dryers, boilers, cooling towers, and HVAC systems. The reduction in the cost of air or gas transportation contributes to plant optimization. This section describes the automatic control of fans and provides some advice on how to operate them at minimum cost.

Fans transport large volumes (up to 1 million CFM) of gases at low pressures, usually at discharge pressures of a few inches of water to up to a couple of PSIG. For a detailed discussion of fan controls for HVAC, boiler, and cooling tower applications, refer to Sections 8.2, 8.6, 8.16, and 8.17. The emphasis of this section will be on the industrial application of fans.

FAN TYPES

Fan designs are classified into axial flow and radial (also called centrifugal) flow types, because of the difference between the nature of the flow through the blade passages. They move large volumes of air at relatively low pressures (in. H_2O), with the pressure-flow characteristics as shown in Figure 8.25a.

If the operating point is to the left of maximum pressure on the fan curve, and particularly if the fan pressure exceeds 10 in. H_2O, it is likely that pulsation and unstable operation will occur. This maximum point on the fan curve is referred to as the *surge point* or *pumping limit*. All fans must always operate to the right of the surge point.

Under low load conditions, the fan can be kept out of surge by artificially increasing the load by venting the gas that is not required by the process. The other possible way of eliminating surging is to substitute the use of dampers on the fan discharge as final control elements with blade pitch, speed, or vane control.

FAN CONTROLS

Fan Throttling

Figure 8.25b shows both fan curves and system curves. The system curves, the relationship between flow (velocity) and fan discharge pressure, in mostly friction transportation systems are parabolic. The operating point for the process is where the fan curve crosses the system curve (point *A* on Figure 8.25b).

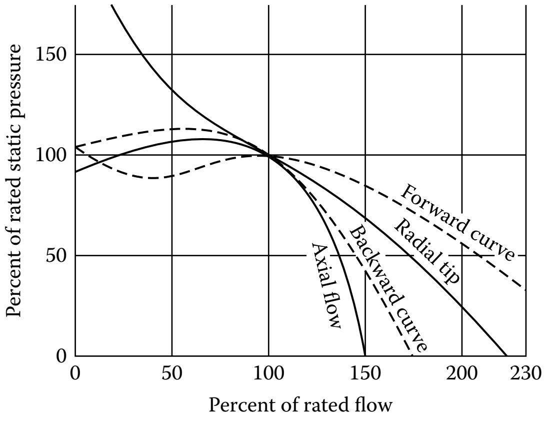


FIG. 8.25a
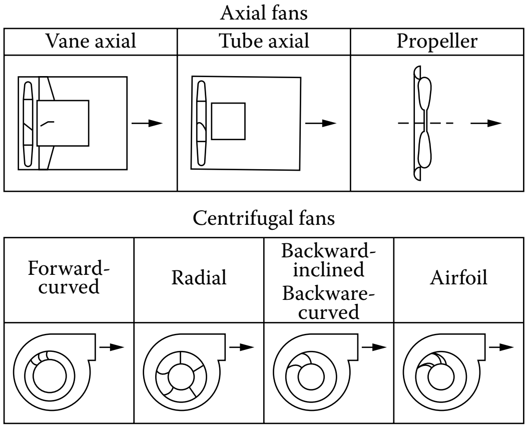
Different fan types exhibit different pressure-flow characteristics.[1]



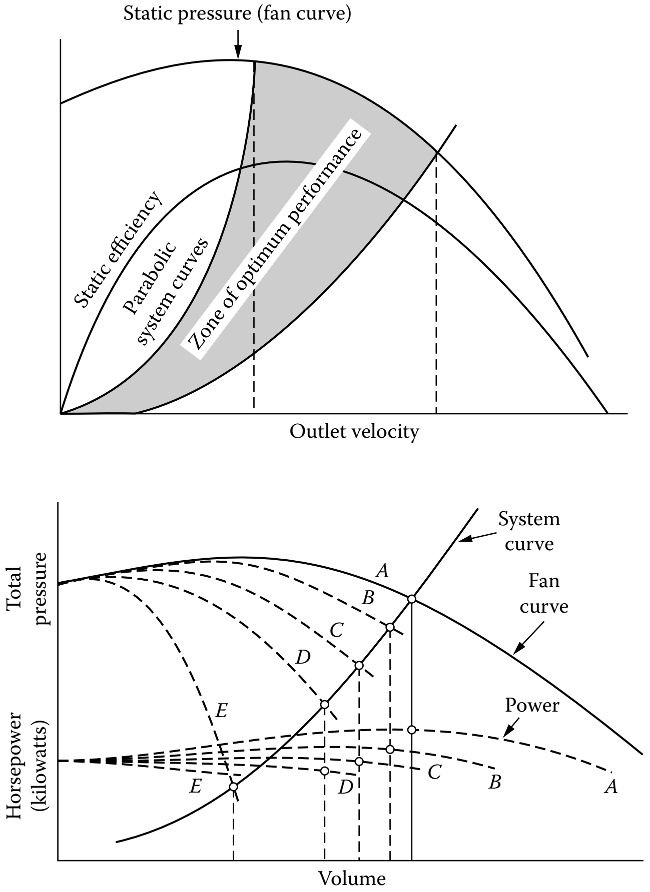


FIG. 8.25b
Upper curve shows optimum operating zone for fans; lower curves describe the effect of suction vane throttling on the fan curve.[1]

When the flow and pressure requirements of the process correspond to a point that is below the curve of the constant speed fan (points *B* to *E* in Figure 8.25b), one way to bring them together is to introduce an artificial source of pressure drop. In this figure, that source of pressure drop is a suction damper (a vane), which, as it is throttled, modifies the fan curve (from point *A* to *E*).

While the introduction of this artificial pressure drop does result in the wasting of transportation energy, its advantage is that this throttling shifts the surge point to the left and thereby, at lower flows, allows for stable operation.

Tube-axial fans are provided with adjustable pitch blades that permit the balancing of the fan to match the varying process load either automatically or by infrequent manual adjustments. Vane-axial fans are also available with controllable pitch blades (that is, pitch that can be varied while the fan is in operation) for use when frequent or continuous flow adjustment is needed. Throttling by varying the pitch angle retains high efficiencies over a wide range of conditions.

Figure 8.25c illustrates both the variable-blade pitch design and its performance curves. The efficiency is near maximum at zero blade pitch angle, and it drops off as the pitch angle is increased.

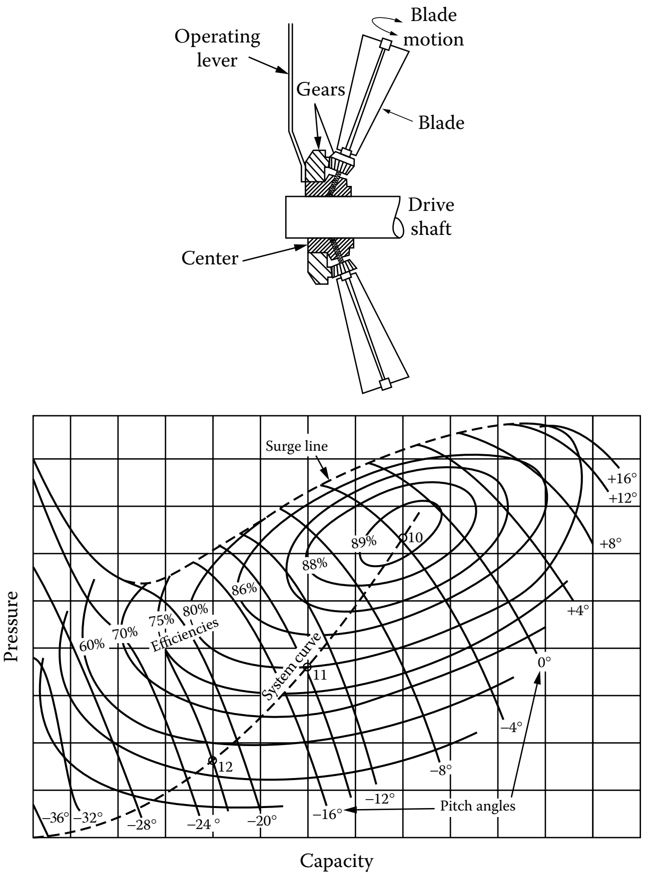

FIG. 8.25c
The design and characteristics of axial-flow fans with variable pitch control are described here. (Lower part is from Reference 2.)

From the standpoint of power consumption, the most desirable method of control is to vary the fan speed to match reduced process loads. If the load does not change too frequently, belt-driven fan drives can be considered. The speed in such designs is adjusted by changing the pulley on the drive motor of the fan. When the process load varies often or when continuous fan flow modulation is desired, electrical or hydraulic variable-speed motors are required.

Figure 8.25d illustrates both the fan curves and the power consumption of a variety of load controls on fans at partial loads. From the standpoint of noise, variable-speed is preferred to the variable-blade pitch design. On the other hand, both the variable-speed and the variable-pitch throttling designs are much quieter and more efficient than the discharge damper or suction vane throttling-type systems.

Safety Interlocks

All fans should be provided with safety interlocks, such as the ones illustrated in Figure 8.25e. In the illustrated design, interlock #1 will stop the fan if either excessively high pressure develops on its discharge side (PSH-02) or excessively high vacuums are detected on its suction side (PSL-03). Both of these pressure switches are protecting the ductwork from

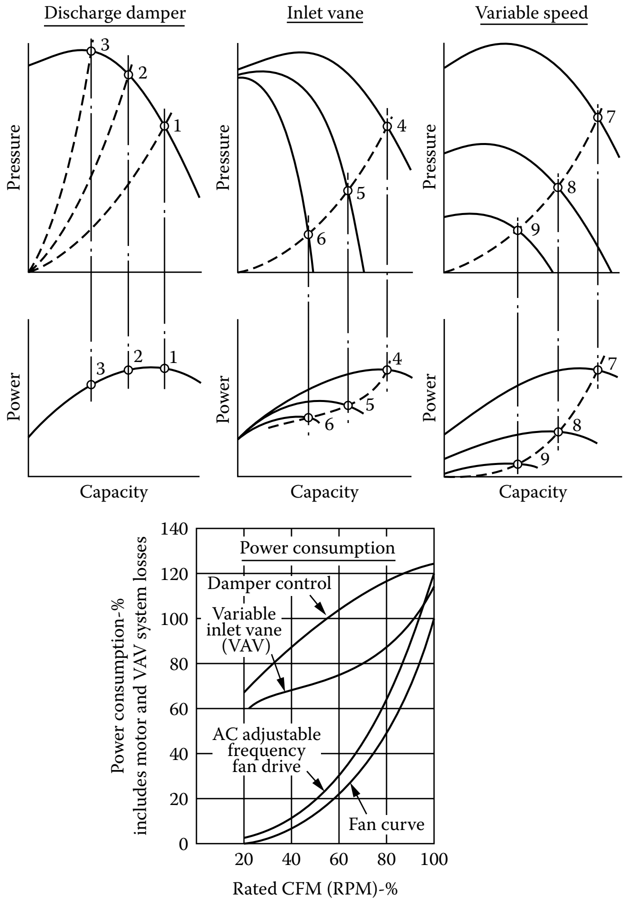

FIG. 8.25d
Turndown efficiency and energy conservation are directly related. (Upper part from Reference 2.)

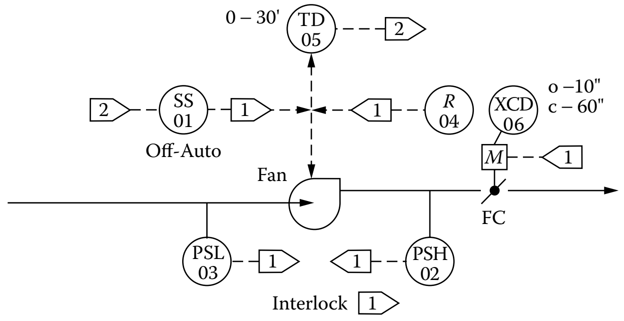
bursting (PSH) or from collapsing (PSL) due to the extreme pressure conditions. Both of these conditions can be caused by accidental blockage of the airflow.

Once the fan is shut down, it cannot be restarted until the reset button (R-04) is pressed. This gives the operator an opportunity to eliminate the cause of the abnormal pressure condition before restarting the fan. Whenever the fan is stopped, its discharge damper (XCD-06) is automatically closed to protect it from flow reversal, which can occur if several fans are connected in parallel. This discharge damper is designed for fast opening and slow closure, to make sure that it is always open when the fan is running.

The time delay (TD-05) guarantees that once the fan is started, it will run for a preset period, unless the safety interlocks turn it off. This protects the motor from overheating as a result of excessive on/off cycling. The fan cycling interlock (#2) is described below, in the paragraph titled Optimizing Multiple Fans.

Fan Controls in HVAC Applications

Air-handler controls are discussed in detail in Section 8.2. Therefore, here only the highlights will be mentioned of a fan configuration where supply fan(s) is/are transporting heat or cooling by sending conditioning air into a number of spaces (users), while return air fan(s) bring most of that air back for reheating or recooling. Figure 8.25f shows the fan controls of a variable-volume HVAC system.



Conditions				*Actions*		
SS-01	*PSH-02*	*PSL-03*	*R-04 (Reset)*	*Fan*	*XCD-06 (Damper)*	*TD-05 (Note #1)*
Off	—	—	—	Stop	Close	Time
Auto-On	High	—	—	Stop	Close	Time
		Low	—	Stop	Close	Time
	Not high	Not low	Not reset	Stop	Close	Time
			Reset	Run	Open	Reset to start

— = Any state or condition (don't care)
Note #1: Shut-down delay used in interlock 2

FIG. 8.25e
Illustration of the functioning of safety interlocks, which evaluate the state of suction and discharge pressures plus reset button status and, based on them, determine the fan, damper, and time delay status.

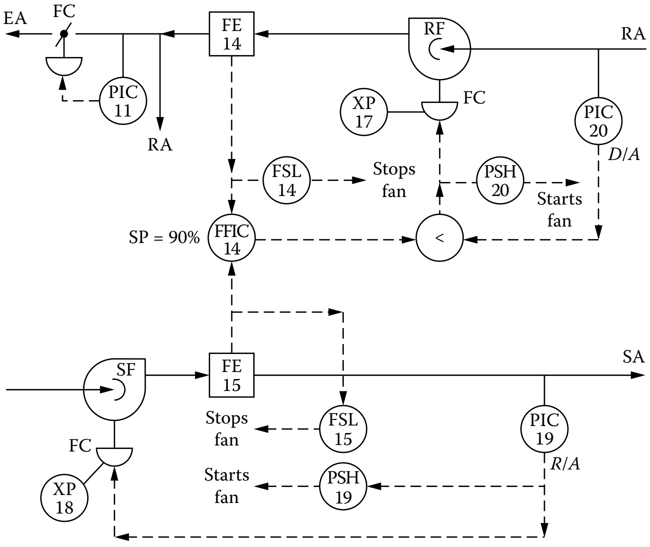


FIG. 8.25f
Variable-volume fan controls operate as shown here.

This configuration minimizes the operating cost by automatically maintaining the pressurization loss in the building at 10%, which is the usual minimum fresh air requirement in occupied spaces. This is achieved by setting the flow ratio controller FFIC-14 at 90%, meaning that the return fan station is modulated to return 90% of the air supplied to the zones.

PIC-20 is provided for dynamic balancing of the system. This is needed because the conditioned zones represent a rather large capacity, and therefore a change in supply airflow does not immediately result in a change in return flow. By overriding FFIC-14, PIC-20 prevents this ratio controller from increasing the return airflow faster than required and thereby prevents cycling or collapsing the suction ductwork by developing excessive levels of vacuum.

Parallel Fan Balancing

When two fans are operated in parallel, serving the same load, and one of them is idle, its damper should be closed in order to prevent recirculation from the operating fan. When one of the two fans is shut down or started up, it is important to simultaneously correct the damper position on the operating fan so that the supply pressure to the process will not be upset.

This goal can be achieved by installing a flow cascade loop as shown in Figure 8.25g. Here, the cascade master (FRC-104) compares the actual airflow being sent to the process with the airflow required, and if there is a difference, it changes its output signal, which is the set point to the cascade slave (FRC-103).

The measurement of FRC-103 is the sum of the damper position signals. Therefore, when one of the fans is shut down (and its damper is closed), the sum of the positions signal drops, while the set point of FRC-103 stays unaltered. Consequently, FRC-103 will quickly open the damper on the fan that remains in operation in order to keep the system balanced.

Optimizing Multiple Fans

The fan station is optimized when it is meeting the process demand for air or other gases at the lowest possible cost. The minimum cost of operation is achieved by first minimizing the number of fans that remain in operation and then by reducing the power consumption of these operating fans to the minimum. Figure 8.25h illustrates a control system that fulfills both of these goals. The lower part of the figure describes the control loops, while the operating fan curves are shown in the upper left and the interlock table in the upper right.

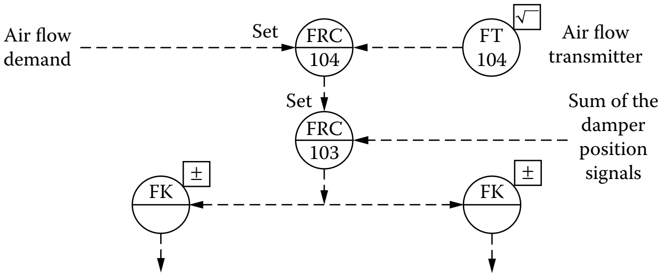

FIG. 8.25g
Flow to valve position cascade loop provides balancing controls for parallel fans.

The second fan is started and stopped in response to load variations according to the logic in the interlock table in the upper right of the figure. As the process demand increases, the speed of the operating fan (fan #1) is gradually increased. When its maximum speed is reached (point *A* on the fan curve) PSH-07 activates interlock #2 to start the second fan.

If the speed control signal were left unchanged when the second fan was started, an upset would occur, because the operating point instantaneously jumps from point *A* to *C*. In order to eliminate this temporary surge in discharge pressure (which otherwise could shut down the station), PY-07 is introduced. This is a signal generator, which, when actuated by interlock #2, drops its output to a value "*x*." The value of "*x*" corresponds to the required speed for the two-fan operation at point *A*.

The low-signal selector PY-09 immediately selects this signal *x* for control, and thereby, the upset is avoided. After actuation, the output signal of PY-07 slowly rises to full scale. As soon as it rises above the output of PIC-10, the low-signal selector (PY-09) disregards it and control is returned to PIC-10.

Once both fans are smoothly operating, the next control task is to stop the second fan when the load drops to the point where a single fan can meet it. This sequence is controlled by the low-flow switch FSL-08, which is set at 90% of the capacity of one fan (point *B* on the system curve). When the flow drops below the setting of FSL-08, interlock #2 is actuated to stop the second fan.

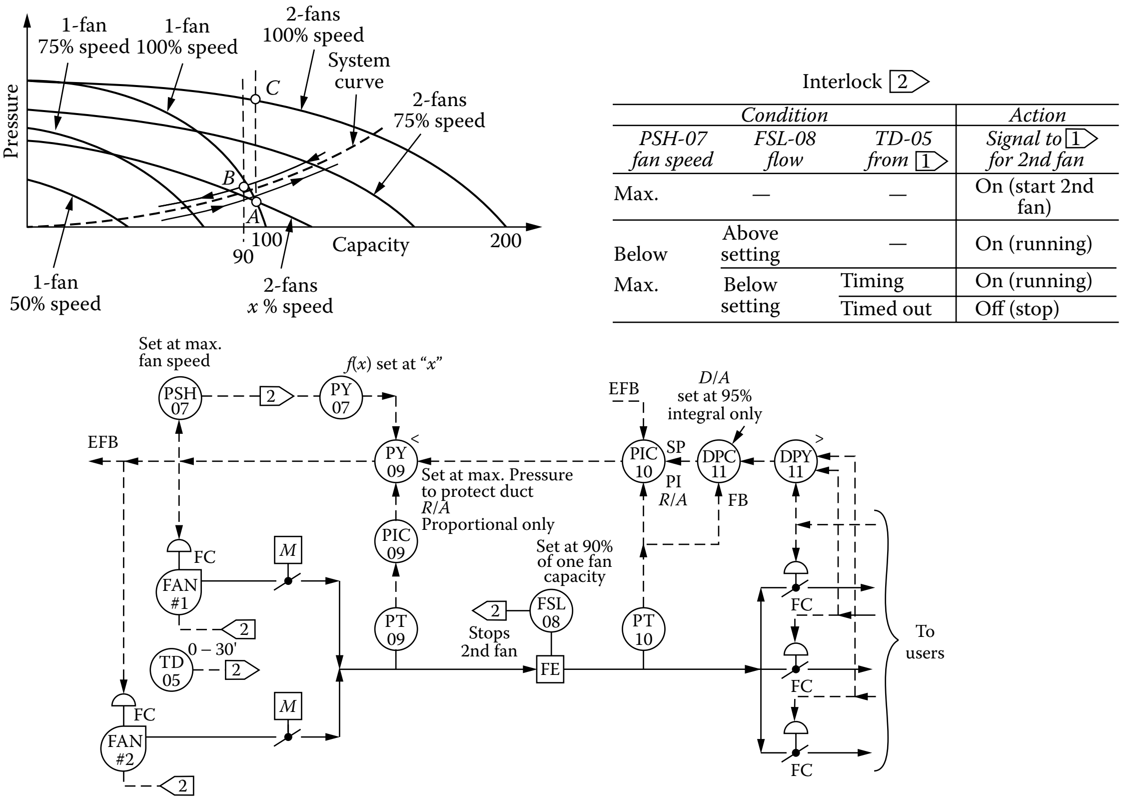
The stopping of the second fan is delayed until time delay TD-05 times out. This shutdown delay protects the fan from overheating due to excessive on/off cycling. Therefore, if TD-05 is set for, say, 20 min, the fan cannot be started more than three times an hour.

The fan cycling controls described here can be used to cycle any number of parallel fans. For each additional fan, another FSL-08 and PY-07 needs to be added. If n is the number of fans in operation, then FSL-08 is to be set for 90% of the capacity of $(n - 1)$ fans and PY-07 is to be set for "*x*" corresponding to the required speed of $(n + 1)$ fans at point *A*.

Optimizing the Discharge Pressure

The optimum discharge pressure is the minimum pressure that is still sufficient to satisfy all the users. This minimum pressure is found by observing the opening of the most-open damper. If even the most-open damper is not fully open, the supply pressure can be safely lowered, whereas if the most-open damper is fully open, the supply pressure must be raised. This supply-demand matching strategy not only minimizes the use of fan power but also protects the users from being undersupplied.

The optimization loop functions as follows: DPY-11 selects the opening of the most-open damper and sends its



Interlock [2>

		Timed out	Off (stop)

FIG. 8.25h

Optimized fan station controls include automatic fan cycling and a damper position to discharge pressure cascade loop to keep the most-open user supply damper at 90% opening.

opening as the measurement signal to the damper position controller DPC-11. If that signal is under 95%, this controller lowers the supply pressure set point, which in turn reduces the fan speed and opens all the load supply dampers until one has opened to 95%. Opening up all the dampers lowers the resistance to flow and saves fan power.

DPC-11 is an integral-only controller with an integral time (minutes/repeat), which is set to be 10 times that of the integral setting of PIC-10. This guarantees smooth, stable control, even if the dampers are unstable or cycling. The external feedback signal (EFB) protects the damper optimizer controller (DPC-11) from reset windup when PIC-10 is switched from the cascade configuration to manual set point.

PIC-10 is the load-following controller. It compares the optimized set point with the actual header pressure and adjusts the fan speed(s) or the blade pitch angle(s) of the fan(s). When its output signal reaches the maximum set on PSH-07, it starts another fan.

The role of PIC-09 is to provide overpressure protection at the fan discharge. Under normal conditions the fan discharge pressure is much below the set point of PIC-09, and its output is saturated at its maximum value. Therefore, under normal conditions PY-09 will select the output signal from PIC-10 for control. When the pressure limit set on PIC-09 is reached, it takes over control from PIC-10 and protects the ductwork from being damaged.

CONCLUSIONS

Fan optimization is an effective means to lowering the operating costs of plant operation. As can be seen from Figure 8.25d, if the average load is 60% of full capacity, the above-described optimization strategies can reduce the yearly operating cost to less than 50%.

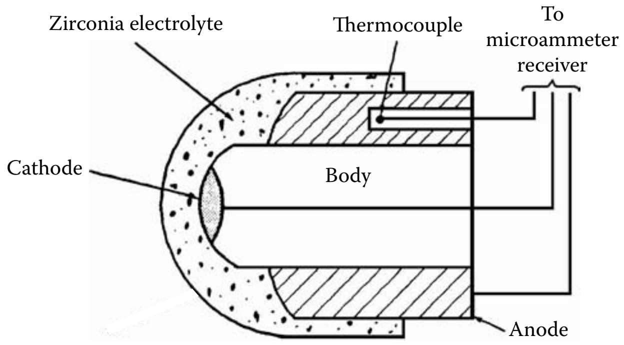

FIG. 8.26a
Galvanic cell design. Note: External heater not shown.

INTRODUCTION

Fuel cells are a means of converting chemical energy into electrical energy and, hence, to work. The term *fuel cell* describes a type of primary galvanic cell[1] using replaceable anode and cathode reagents. Conventional primary cells are limited by the ability to store reagents on the current-collecting plates. Fuel cells bypass this limitation by providing a continuous feed from an external reservoir.

In theory, almost 100% conversion efficiency is possible, as the energy conversion is via electrochemical reactions, bypassing the losses inherent in thermal conversion. In practice, however, other limitations, due to electrical losses and chemical concentration gradients, reduce the achievable performance to between 30 and 85% efficiency.

Any gaseous or liquid oxidizer and fuel can be used in a fuel cell system, but the preferred oxidizer is oxygen, as the exhaust in that case is relatively innocuous water and carbon dioxide.

The justifications for the use and development of fuel cell systems include a number of grounds. The most common is high efficiency, but low-temperature fuel cells are no more efficient than conventional steam systems and less efficient than some combined cycle systems that are now in service. However, fuel cell systems achieve this performance on a much smaller scale.

Efficiency and Pollution

An even more important benefit is the low emission achievable by the positive control of the reduction oxidation reactions, which eliminates some of the more undesirable pollutants from the exhaust streams. Fuel cells are also suitable for special-purpose applications where closed cycle operation is desired.

As the low-temperature fuel cell systems operate at temperatures too low for nitrogen oxides to form and because high-temperature fuel cells prevent the contact with nitrogen in atmospheric air (at least as far as the exhaust handling is considered), nitrogen oxide pollution is not a problem, and consequently ozone pollution from these units is also reduced.

Sulfur oxide emissions are also low, but it is still preferred to remove the sulfur at the source rather than from the exhaust. This is not an inherent advantage of fuel cells but rather an operational requirement and restriction for reforming fuel cells, as sulfur will poison the catalyst used in the process.

In the case of hydrogen-powered fuel cells, the above-mentioned advantages must be balanced with the consequences of the hydrogen production method used. If it is made by reforming of natural gas, that is a rather wasteful process if the carbon dioxide is vented and, therefore, the energy content of the carbon is not utilized.

Electrolytic[2] systems are cleaner but their power consumption and power generation are essentially the same (somewhat less), so unless renewable energy sources are used, their net efficiency and pollution reduction are very poor. A further problem with hydrogen fuel cells is losses while the hydrogen is in storage. Losses of up to 30% per month can be expected in automotive applications, because of leakage.

The alternative mode of operation is that of the fuel cell-operated storage battery. In this case, the fuel cell is run in reverse to generate hydrogen from the electrolysis of water. In this mode of operation, the fuel cell functions as a closed system and provides a battery with greatly increased storage capacity compared to batteries that store energy in solution or as a solid on the electrodes.

Low-temperature polymer electrolyte fuel cells are reliable in the regenerative mode. Solid oxide fuel cells have also shown promise of high efficiency due to a combination of their superior performance of the basic technology and their reduced cell voltage compared to the low-temperature fuel cells.

High-temperature solid oxide cells do not require the catalytic coatings used for the reforming fuel cell designs. Low-temperature polymer fuel cells are in service as oxygen generators in submarines around the world.

Fuel cell-based energy storage is not particularly efficient, and other options may be more effective on an industrial scale. For closed cycle applications, such as spacecraft and submarine vehicles, however, the combination of light weight, reasonable power density, and compact size of fuel

---

[1] In a galvanic cell (Figure 8.26a), no external voltage is applied to the cell, which consists of an electrolyte and two electrodes. For example, if the cathode is a noble metal, the anode is a base metal, and if the electrolyte is a zirconia oxide solution, which contains dissolved oxygen.

For the reactions that take place on the solid oxide fuel cell (SOFC) electrodes, refer to Equations 8.26(15) to 8.26(19).

As the cathode reduces an oxygen molecule into hydroxide, it releases four electrons, which causes a current flow. This flow is in proportion to the oxygen concentration in the electrolyte. As the current flows, the analyte diffuses and the cell is depolarized. The electrodes are consumed during this operation and require periodic replacement.

The minimum operating temperature is 752°F (400°C), the typical operating temperature is 1112°F (600°C) and the SOFC operating temperature is 1472°F to 1742°F (800°C to 950°C).

[2] An electrolytic cell is similar to a galvanic one, but it operates with an external voltage connected to its electrodes, and its electrodes are not consumed.

cells compares favorably to the equivalent battery-based systems with similar storage capacity.

An unfortunate aspect of the presently existing fuel cell systems is the difficulty in scaling up their designs. Often, the doubling of their power output also tends to double their complexity.

Historical Perspective

The oldest form of a fuel cell is the low-temperature Groves "gas battery" cell.[3] This cell was developed by Sir William Groves in 1839 and was based on the research work on water electrolysis by William Nicholson and Anthony Carlisle in 1800. It used fine-wire platinum electrodes encapsulated in glass tubes to demonstrate a reversible reaction. When a power supply was connected to the electrodes, this cell generated hydrogen and oxygen and then it became able to generate a current. The fact that it worked at all was an accident, resulting from the fact that Groves used the catalytic metal, platinum, for current collectors. Yet it formed the basis for what was to come.

The first attempt at a commercial fuel cell was a coal gas-driven fuel cell developed by Ludwig Mond and Charles Langer in 1889. This unit used a sulfuric acid electrolyte impregnated into a ceramic separator plate with perforated platinum electrodes. Coal gas is a mixture of hydrogen, methane, and carbon monoxide, and it is produced by injecting steam into a bed of coke at high temperatures and then scrubbing before being used. This 1889 coal gas-based fuel cell demonstrated that much more research was required before a viable product could be produced. This was the case because carbon monoxide rapidly poisons the platinum catalysts at low temperatures by binding to their surfaces. The other limitation was the need to remove the water generated by the oxidation reaction.

A theoretical basis for the fuel cells was provided in 1893 by Friedrich Wilhem Ostwald, who was a pioneer of electrochemistry. Based on experiments, he provided a solid basis for the further development in this field, because he determined the relationships between the electrodes, electrolytes, reducing and oxidizing agents, and anions and cations.

This was further investigated by Walter Herrmann Nernst (who in 1897 demonstrated an early yttrium-doped zirconia device in the form of the Nernst Lamp) and provided the theoretical basis for current research.

High-Temperature Designs

High-temperature fuel cells were first investigated by Emil Baur in Switzerland at Braunschweig and Zurich, up to the World War II, using metal oxide fuel cells with liquid silver electrodes. Their experiments with zirconium, yttria, cerium, lanthanum, and tungsten oxides laid the foundations for the current work on solid oxide fuel cells but were frustrated by problems caused by unwanted reactions that occurred with the calcium dopants. This led to a redirection of the development efforts towards molten salt fuel cells.

In parallel with Baur's experiments, Francis Thomas Bacon in 1939 was experimenting with nickel electrodes in high-pressure fuel cells. He used pressures above 200 atmospheres in demonstration fuel cells intended for submarine use. This led, in 1958, to the development of the alkali fuel cell stacks, which are capable of generating significant power levels.

This technology was the basis of the molten potassium hydroxide fuel cells built by Pratt and Whitney (now UTC Fuel Cells) in the mid-1960s for the Deep Submergence Rescue Vehicles of the military. Their "black" project is a counterpart of the Deep Submergence Search Vehicles project and the later of the Apollo spacecraft fuel cells. This in turn led to Lockheed's Deep Quest and to the current space shuttle systems.

The required high operating temperatures of phosphoric acid and of potassium hydroxide fuel cells made black start operation difficult. Another limitation was that in order to function reliably, these cells require exceptionally pure, carbon dioxide-free hydrogen fuel.

Polymer Technology

Polymer technology permitted General Electric to develop the next step in the development of the proton exchange membrane cells for the Gemini program. The benefits of high power-to-weight ratios outweighed the high costs of developing an essentially experimental system to an acceptable level of reliability. The project was helped by NASA's "cost is no object" philosophy of the time, and by the short operational durations that were dictated by the need to complete the dictated missions.

Even so, failures of the fuel cells curtailed all of the first flights in which they were used, from Gemini GT-2 to Gemini 7 (or over half the flights). The problems were finally ironed out, only by then the Apollo program had decided to switch to the older alkaline technology.

Therefore, anyone who is moving into the field of fuel cell development should not underestimate the difficulties, as a similar number of unexpected problems seem to occur in connection with each new design. New developments are in progress in a number of commercial organizations, with Ballard being the most commercially significant.

High cost and low reliability have dogged the implementation of fuel cells and still limit the existing projects from producing a commercially viable power generation system. Unjustified optimism has brought down more fuel cell devel-

---

[3] A battery is a device that converts chemical energy into electrical energy. A battery consists of two dissimilar substances (the two electrodes) and an electrolyte that acts chemically on the electrodes and functions as an ionic conductor for the transfer of electrons between the electrodes. The dry-cell battery of a flashlight consists of carbon and zinc. Wet-cell batteries are rechargeable and use liquid electrolytes such as a sulfuric acid solution, with the negative electrode being lead and the positive being lead coated by lead oxide.

The standard dry cell is manganese dioxide and zinc with a carbon electrode current collector and ammonium chloride electrolyte.

opment programs than any other cause. Adequate design and development budgets are also critical, and the costs are high.

PERFORMANCE AND DESIGNS

Electrical Performance

The potential voltage delivered by a fuel cell can be predicted by the Nernst equation:

$$E^N = E^0 - \frac{RT}{zF}\ln\left(\frac{a(\text{Reduction})}{a(\text{Oxidation})}\right) \qquad \textbf{8.26(1)}$$

E^N = normalized voltage (cell open circuit voltage)
E^0 = theoretical reversible voltage at reference conditions (°K)
R = universal gas constant = 8.314 472 (±0.000 015) Joules/mole/Kelvin = 8.314 472 · 10^7 erg/mole/Kelvin
T = absolute temperature in degrees Kelvin
F = Faraday constant = 96 485.3383(±0.0083) Coulomb mol^{-1}
Z = charge number of the electrode reaction = the number of moles of electrons involved in the reaction as written
$a(Reduction)$ = chemical activities on the reduction side of the equation (for gases, the partial pressure)
$a(Oxidation)$ = chemical activities on the oxidation side of the equation (for gases, the partial pressure)

Or as applied to common fuel cell applications:

$$E^N = E^0 - \frac{RT}{2F}\ln\left(\frac{[H_2O]}{[H_2][O_2]^{1/2}}\right) \text{ with } E^0 = 1.229\text{ V} \qquad \textbf{8.26(2)}$$

As can be seen from Equation 8.26(2) the cell voltage will be decreased by an increase in temperature and will be reduced as the reagents are consumed (if not replaced). Maintaining a high partial pressure of reagents will also improve the cell's stability as the load increases. Contamination with waste products will reduce the cell voltage, as will inert diluents that are not purged.

The cell voltage achieved at the load inputs is further reduced by the resistance of the electrolyte and by the resistance of the electrodes and connecting cabling. At high current rates and high temperatures, these losses caused by a high-temperature nickel cable can be significant.

The actual delivered voltages typically range from 1 to 0.6 V per cell. This voltage is a very good measure of cell efficiency, if the actual achieved output is compared with the one predicted by the Nernst Voltage.

In theory, the fuel cell fuel consumption can be predicted by the relationship that 1 mole of hydrogen gas yields 2 moles of electrons when ionized. This is equivalent to a charge of 2 × 96,485.3383 (±0.0083) Coulomb/mol or amp/sec/mol.

At 0°C 1 mole will fill 22.72 liters of space at standard atmospheric pressure. So, for a current draw of 1 amp the fuel cell will need to be receiving 0.1177 Ncm^3 per sec (7.062 Ncm^3 per min) at 100% efficiency. Considering the actual efficiencies of fuel cells, at least double this value (0.2355 cm^3) would, however, be more typical. This gas requirement does not seem to be much, but because each cell in a stack is consuming this much gas, the total volumetric feed requirement of the system rises rapidly.

Functional Requirements

Fuel cells are a means of converting chemical energy into electrical energy and, hence, to work. In theory, because fuel cells convert the energy in chemical bonds to electrical energy by means of a direct redox reaction, efficiencies should be able to approach 100% with minimal generation of unwanted reaction products.

Noise Similarly, because the basic fuel cell needs no mechanical drive, its operation is quiet and involves no frictional losses. These characteristics should make it acceptable to locate the generator near the final user, producing a more even distribution of the generation capacity.

These expectations necessitate that quiet-running auxiliaries be used to transport the reagents, particularly the fans and blowers that are used to transport the oxidizer, usually air (and for transporting and compressing the fuel in case of low pressure supplies, such as waste gas). In order to minimize the noise generated by the electrical systems, they should be well-potted to prevent their motion, which can be induced electrostatically or electromagnetically.

Blower noise can be reduced by providing variable-speed drives for the blowers and by careful duct design. In addition, the feathering of the blade edges and the use of noise-reducing enclosures are recommended, but should be so designed that it will not result in heat problems by overheating the blower drive.

Variable-speed control is also desirable, because it helps reduce the parasitic losses, if the drive is powered directly from the DC bus of the fuel cell, by avoiding conversion losses, but this requires a cell bus voltage consistent with the VSD AC bus voltage.

To reduce the electrically generated mechanical noise, the inductor and transformer windings should be carefully designed and the AC bus bars should be carefully secured. Some inverters that are used in conventional variable-speed drives can be exceptionally loud, as can the output filters needed for hazardous area certification.

Size and Reliability Fuel cell system size is important for mobile applications, and volumetric efficiency is even more critical. The volume of a 40 kW system today is about 10 m^3 with all its auxiliaries. This compares with 2 m^3 for a similar capacity diesel generator. Therefore, one goal of fuel cell research is to increase the power densities both in terms of volume and area of the unit.

Current state-of-the-art fuel cells are finally approaching the reliability levels that are acceptable for some applications. On the other hand, they are yet to live up to the expectation of a financially viable power generation, because of their low power efficiencies.

The cost per installed watt is still one to two orders of magnitude higher than that of the conventional technologies, and significant generation benefits are required to justify this added capital cost. The theoretical benefits include lower emissions, lower noise levels, and lower operating costs.

In reality, these benefits are undermined by the remaining unsolved problems. The advantage of lower emissions is undermined by the problems involved in generating and storing the hydrogen gas needed for the simplest (and so far most efficient) fuel cells. The advantage of low noise levels is limited by the limited availability and higher cost of the blowers. The advantages of higher power densities and lower operating costs are limited by the life expectations of both the control hardware and of fuel cell stacks, which today still result in low availability.

Recent U.S. military experience with phosphoric acid fuel cells resulted in under 1800 hours mean time between failure (MTBF) with an availability of 67%. This is comparable to the overall service intervals for diesel generators, and one fifth of the service interval for a typical gas turbine generation set.

All of these areas require further efforts by the developers to achieve a commercially viable product. Today, the typical system still requires servicing for the replacement of its scrubber packs every 3 to 4 days.

FUEL CELL TYPES AND FEATURES

Fuel cells fall into a number of distinct strains, each with its own advantages and disadvantages. Each cell type has a preferred feed stock (fuel) and operating regime, and in each of them a specific set of reactions take place, which affects the optimum operating conditions.

Fuel Cells Reactions

Low Temperature (Proton Exchange Membrane and Phosphoric Acid)

Anode Reaction: $2H_2 => 4H^+ + 4e^-$ **8.26(3)**

Cathode Reaction: $O_2 + 4H^+ + 4e^- => 2H_2O$ **8.26(4)**

Overall Cell Reaction: $2H_2 + O_2 => 2H_2O$ **8.26(5)**

(Note: These PEMFC cells are easily poisoned by carbon monoxide, which can form a complex on the surface of the platinum electrodes, because the fuel cell operating temperature is not high enough to oxidize it into carbon dioxide.)

Direct Methanol Conversion

Anode Reaction:

$2CH_3OH + 2H_2O => 2CO_2 + 12H^+ + 12e^-$ **8.26(6)**

Cathode Reaction: $3O_2 + 12H^+ + 12e^- => 6H_2O$ **8.26(7)**

Overall Cell Reaction:

$2CH_3OH + 3O_2 => 2CO_2 + 4H_2O$ **8.26(8)**

(Note: These cells have the same problems as the PEMFCs as far as carbon monoxide poisoning is concerned. They also have a limited ability to handle their own waste products, which leads to low efficiency and poor utilization of their fuel.)

Alkaline

Anode Reaction: $2H_2 + 4OH^- => 4H_2O + 4e^-$ **8.26(9)**

Cathode Reaction: $O_2 + 2H_2O + 4e^- => 4OH^-$ **8.26(10)**

Overall Cell Reaction: $2H_2 + O_2 => 2H_2O$ **8.26(11)**

(Note: This fuel cell design can be poisoned by carbon dioxide and carbon monoxide. Therefore, it is limited to fuels such as high purity gas or electrolytic hydrogen. It cannot use reformate from natural gas unless highly refined. If ambient air is used as oxidizer, it must be scrubbed.)

Molten Carbonate

Anode Reaction:

$2CO_3^{2-} + 2H_2 => 2H_2O + 2CO_2 + 4e^-$ **8.26(12)**

Cathode Reaction: $2CO_2 + O_2 + 4e^- => 2CO_3^{2-}$ **8.26(13)**

Overall Cell Reaction:

$4H_2(g) + O_2(g) + 2CO_2 => 2H_2O(g) + 2CO_2$ **8.26(14)**

(Note: This fuel cell requires a feed of highly concentrated carbon dioxide. This carbon dioxide can be recovered from the exhaust if the effort is felt worthwhile.)

Solid Oxide

Anode Reaction: $4H_2 + 2O^{2-} => 2H_2O + 4e^-$ **8.26(15)**

$2CO + 2O^{2-} => 2CO_2 + 4e^-$ **8.26(16)**

Cathode Reaction: $2O_2 + 4e^- => 2O^{2-}$ **8.26(17)**

Overall Cell Reaction: $2H_2 + O_2 => 2H_2O$ **8.26(18)**

$2CO + O_2 => 2CO_2$ **8.26(19)**

(Note: These solid oxide cells have some direct reforming ability when operating at their design conditions.)

TABLE 8.26b
Features and Characteristics of a Number of Fuel Cell Designs

	Fuel Cell Type	*PAFC*	*PEMFC*	*MBFC*	*DMFC*	*AFC*	*MCFC*	*SOFC*	*ZAFC*

Comments									

Notes:

(a) In reality, CO, with H_2O, shifts to H_2 and CO_2, and CH_4, with H_2O, reforms to H_2 and CO faster than reacting as a fuel at the electrode.

(b) A fuel in the internal reforming MCFC.

(c) Molten carbonate fuel cells, solid oxide fuel cells, and zinc air fuel cells all can consume complex hydrocarbons (C_xH_x).

(d) CO can strip nickel at high temperatures by forming $Ni(CO)_4$ gas.

(e) Microbiological fuel cells use bacteria to catalyze the conversion of carbohydrates to fuel, low efficiencies can be balanced against low fuel cost, including domestic sewage.

PAFC: phosphoric acid fuel cell
PEMFC: proton exchange membrane fuel cell/polymer electrolyte membrane fuel cell
MBFC: microbiological fuel cell
DMFC: direct methanol conversion fuel cell
AFC: alkaline fuel cell
MCFC: molten carbonate fuel cell
SOFC: solid oxide fuel cell
ZAFC: zinc air fuel cell

* The use of sulfur compounds was subject fo further testing.
Results are yet to be published.

Zinc Air

Anode Reactions:

$$CH_4 + H_2O \Rightarrow CO + 6H^+ + 6e^- \quad \textbf{8.26(20)}$$

$$2Zn + 2OH^- \Rightarrow 2ZnO + 2H^+ + 2e^- \quad \textbf{8.26(21)}$$

$$CO + ZnO \Rightarrow CO_2 + Zn \quad \textbf{8.26(22)}$$

$$\text{Cathode Reaction: } O_2 + 2H^+ + 2e^- \Rightarrow 2OH^- \quad \textbf{8.26(23)}$$

$$O_2 + 4H^+ + 4e^- \Rightarrow 2H_2O \quad \textbf{8.26(24)}$$

$$\text{Overall Cell Reaction: } CH_4 + 2O_2 \Rightarrow CO_2 + 2H_2O \quad \textbf{8.26(25)}$$

Fuel Cell Design Features

Fuel cells share a number of characteristics with heat exchangers. These include the fact that similar forces limit the transfer of heat as the ones that limit the transfer of ions. Also, the exchange of ions is dependent upon the available surface area in contact with the process fluids and by the resistance to transfer of energy through the separator material. The transfer of energy also depends upon the movement and mixing of the molecular components of the fluids on either side of the exchange surfaces.

A simple tubular design has been popular for solid oxide fuel cells, because it is easy to seal. On the other hand, because the surface area is a function of tube diameter, deducing the diameter of the tubes increases both the transfer area and the pressure drop through the smaller tubes. Also, it is hard to apply the current-collecting coatings to small-diameter tubes. For these reasons, tubular designs are very limited in terms of the ultimate achievable power densities.

Flat plate designs have, therefore, become the default standards for low-pressure services, as films are easy to fabricate, particularly if liquid or film electrolyte systems are involved.

In either design there are design limitations to the task of bringing turbulent reagent streams to the active surfaces. Reagent mixing can be enhanced by narrowing the passages between the electrodes or by placing obstructions into these streams to induce turbulence in the fluid flows. The downside of these solutions is that they both interfere with the fluid flow, and therefore they both increase pressure drop. In addition, if the dimensional tolerances cannot be accurately maintained or if the system model is not accurate, such obstructions can potentially interfere with the gas distribution between cells.

Sealing the flat-panel systems is not easy. Low-temperature systems can be sealed by elastomers or can have welded joints in the polymer membranes.

In high-temperature systems, a combination of thermal expansion and the poor adhesion of the conventional sealing materials must be considered. Solid oxide fuel cells have used metallic carriers to serve as both supports and current collectors, but thermal expansion differences between the ceramic electrolyte and metal carrier leads to leaks that are impossible to seal and can also shatter the cells. A newer solution is to use monolithic ceramic structures with ceramic glass seals. In such designs, the conductive glass links interconnect the cells into functioning stacks.

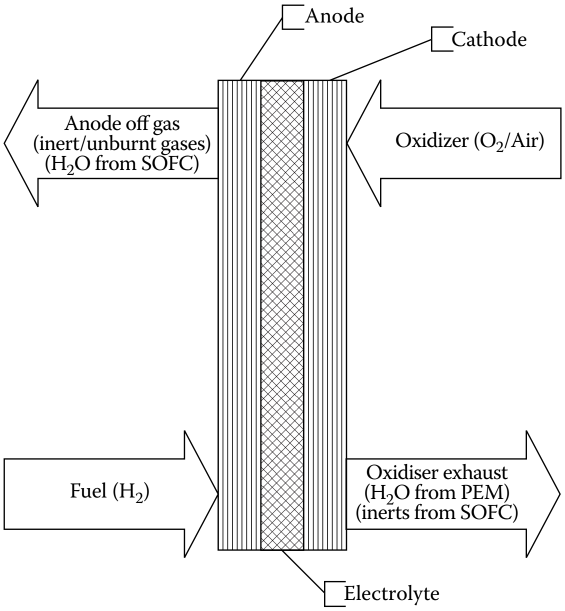

FIG. 8.26c
Illustration of one of the cells in a stack of solid oxide fuel cells (SOFCs) where the hydrogen fuel contacts the anode and the oxidizer acts on the anode surface. The overall reactions in this cell are described by Equations 8.28(18) and 8.26(19).

Single cells are rarely able to produce enough power as is required by commercial applications. The cells are therefore connected into batteries or stacks. Commercial stacks frequently have more than 100 and sometimes as many as 400 cells.

If the dimensional tolerances are not tightly controlled, a major limitation to balancing the fluid flows between the cells in the stack will result. Therefore, providing good control of the fuel and oxidizer flows in every cell (Figure 8.26c) increases both cost and size, which conflicts with the space constraints in commercial systems. If tight intercellular spacing is maintained to improve gas distribution and volumetric efficiency, small errors in the gaps, which can be due to the limitations in manufacturing tolerances, can produce large variations in the actual gas flows between the cells in a stack, which limits the effective stack efficiency as the most starved cell sets the current capacity.

FUEL CELL CONTROLS

Fuel cell control is conceptually simple. The fuel and oxidizer flows are regulated to ensure that the reagent flows match the required current generation, taking into account the cell efficiency factor.

At low levels of current generation and low volumetric efficiencies, simple diffusion is adequate to ensure that some current output is generated. This is the level of operation, achieved by the Groves gas battery, which is used by simple methanol cells. When higher power outputs are required, some type of control system is required to match the power generation with the power requirement of the process.

Oxidant and Fuel Flow Metering

In air breathing cells, the air flow can be maximized to ensure the availability of oxygen by maximizing its partial pressure. The partial pressure achieved is subject to maximum capacity limitations and to limitations imposed by losses due to heating in high-temperature cells and due to pumping losses in other cell types.

In the proton exchange-type cells this maximized air flow also sweeps the waste gases, principally water, away from the cathodes. In fuel cells running at high volumetric power levels, cold air bypass streams are provided to cool the cells if needed and to balance the temperatures between the cell stacks that are connected to a common manifold.

The fuel flows are generally metered more precisely, because of their generally higher costs, and are throttled to meet the current demand of the process being served. Fuel flow control in low-temperature cells is relatively simple. The control valves used are servomotor-driven quarter-turn valves (Chapter 6) and the flow sensors can be the type used on gas furnaces (Section 8.27).

In high-pressure systems, more expensive globe-type control valves (Section 6.19 in Chapter 6) are usually used with pneumatic or electric actuators.

Gas flow metering is relatively simple using thermal dispersion-type mass flow sensors (Figure 8.26d). These sensors provide reasonable accuracy (1–2% of full scale) and are relatively affordable (for details see Section 2.13 in Chapter 2 in the 4th edition of the first volume of this handbook). In the author's test, a bypass-type thermal dispersion meter with gas composition compensation was used (Yamatake CMS series).

The previously used flow sensor option in research fuel cells was the integrated circuitry-type differential sensors, which was limited by its low tolerance for water contamination. This was a serious limitation in reforming-type fuel cell applications, because there the presence of water is essential for the operation of the system, and no protection against water contamination was provided in the smaller and cheaper IC sensors.

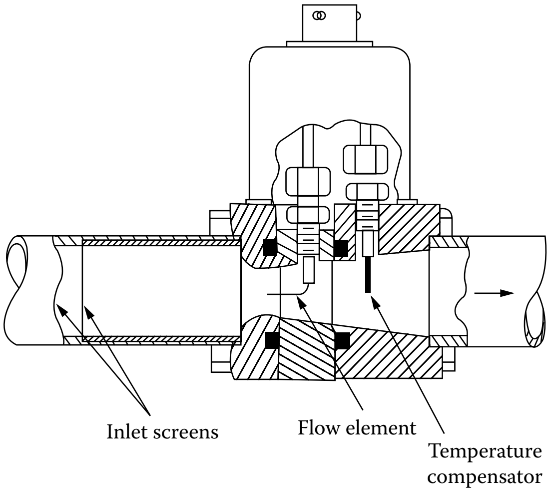

FIG. 8.26d
Venturi-type thermal mass flowmeter. (Courtesy TSI Inc.)

Spacecraft and High-Temperature Cell Applications The flow measurement tasks in spacecraft and similar closed circuit fuel cell applications are slightly different. This is because the oxygen content needs to be conserved with the same vigor as the hydrogen, and blowdowns are restricted to what is needed to maintain power output in the face of water fouling of the anode. As pure gases are used, partial pressure reductions are not a problem, other than for the production of wastewater. Therefore, constant supply pressures can be used, which greatly simplifies the control requirements, as the system becomes self-regulating on the demand side. In such applications, the waste can simply be blown down to a reservoir, based on time and current draw.

In high-temperature cells, special valve designs are required to handle the fuel gas, which is at up to 1000°C. These valves are used to balance the gas flows between stacks and for stack isolation to permit continued operation, when some of the stacks fail. In the automotive industry, for exhaust gas recirculation, such high-temperature valves are successfully operated with high-temperature servomotor drives. If these were available to fuel cell system integrators, they would solve many of the problems in high-temperature fuel controls.

Unfortunately, the major manufacturers of these devices (Mitsubishi and Hitachi) will not sell them to competing fuel cell manufacturers. This means that each fuel cell system designer has to reinvent the wheel each time a new system is designed, which is significantly raising the cost of complete systems.

Indirect Flow Detection In most fuel cells a measurement of the cell voltages (based on the stack voltages) will indicate if the fuel or air flow is inadequate, as the cell voltage will drop substantially. In large stacks (20 or more cells), this stack voltage-based measurement can be too insensitive to be of much use. On the other hand, the measurement of the voltages generated by the individual cells can be too complex to be economically viable. In case of low-voltage systems, cost is not a serious problem, and individual monitoring is possible for up to 40 cells using commercially available products.

In high-temperature SOFC cells, fuel utilization can also be measured by the oxygen content in the exhaust fuel gas. Using a zirconium oxygen probe (Figure 8.26e), the unused oxygen is drawn through the partially stabilized zirconia separator (partially stabilized zirconia is a mix of zirconia and 10–15% yttrium, which improves its thermal shock and impact resistance), which is balanced against the oxygen present in the fuel, which is measured by a second sensor. An overloaded individual cell will release excess oxygen into the fuel gas exhaust stream.

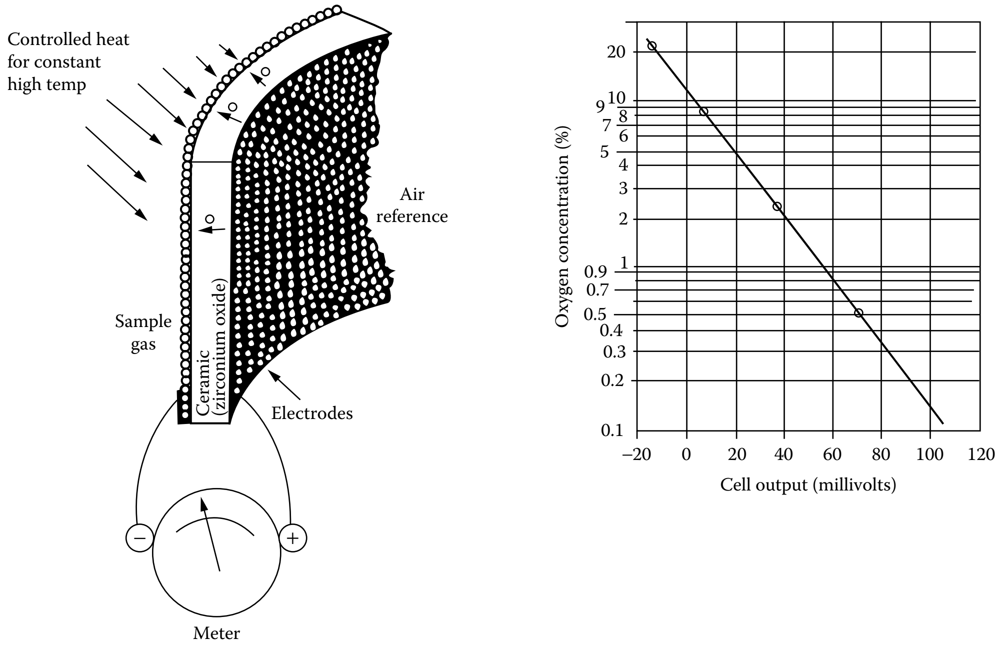

FIG. 8.26e

The flow of oxygen ions through the hot zirconium oxide electrolyte causes a voltage difference across the thickness of the element. (Courtesy of Ametek Inc.)

Both cell voltage and fuel oxygen content measurement respond to the worst cell in the stack. Erroneous readings can also occur if a cell is cracked, as this will result in the same reading as will an overloaded cell. In the case of overloading the fuel needs to be increased, while in the case of cracking the cell has to be isolated, so this reading is insufficient for accurate diagnosis.

Temperature monitoring of the stack exhaust is needed to resolve if the temperature rise is a consequence of cell overloading or of stack fire.

Both the cell voltage and the oxygen monitoring are negative correlations, because these measurements give an indication only when the utilization of oxygen drops. While this is useful information when the load is rising, the detection of falling load conditions require another mechanism to ensure that fuel is not being wasted. Therefore, as a means of checking, it is desirable to also measure the cell performance on the basis of a fuel cell model.

Feedback Control of Feed Flow In a load-following control system, as the demand for current falls, the fuel feed flow is reduced until a predetermined minimum value is reached or until a fuel deficit is detected. If the fuel flow cannot be raised when a fuel deficit is detected, the inverter drawing power from the cell stack will reduce the current draw. If the fuel cell system is connected to a grid that is also connected to a booster, this is not a problem, because more power can be drawn from the grid to make up the shortfall.

If the grid is isolated, it is necessary to shed some of the load on the cells by making up the shortfall from battery or other storage systems, such as capacitor banks, in the short term.

In multiple-stack installations it is important to control the performance of each stack separately to ensure that one stack cannot discharge into another. This is necessary because the manufacturing of identical stacks is just about impossible with the current means of manufacturing in the industry. This is particularly a problem for active anode SOFC and molten carbonate cell designs, because the oxygen drawn though the cell electrolyte can oxidize and destroy the catalytic ability of the cell.

To ensure that back feeds cannot occur, it is usual to design the stack electronics to act as a variable step-up DC/DC inverter with diode protection. In fuel cells, current flow always equals gas flow. In other words, whenever current is drawn, gas must also move from one place to another. With PEM cells, the current drawn results in moving of hydrogen to the oxidizer side, while in high-temperature cells, it results in moving oxygen into the fuel side.

If the reagents are not available to remove these flows, reagents can appear on the wrong side of the cell, which can cause adverse reactions or, in extreme cases, can cause cell fires and explosions. In isolated stack situations this is not a problem, but for installations connected to a grid or in multiple-stack installations, it can cause serious problems if reverse currents are permitted to flow.

Fuel cell control is relatively simple for one cell; the difficulties come when multiple cells need to be controlled in parallel. The control challenge is similar to controlling a single cylinder in a conventional engine, to controlling 24 cylinders in parallel; of course, no one has yet built a functioning 400 cylinder engine. Added to this challenge is the fact that because all cells are connected in series in a stack, the performance of the worst cell also determines the performance of the best cell.

Pressure Balancing and SOFC Problems Further concerns are the balancing of the inlet pressures on both sides of the cells to ensure that the maximum differential pressures are not violated. This is particularly a problem when thin film electrolytes are used in PEM cells or with some SOFC systems. The absolute pressures can, however, be raised quite high, as the strength of the outer casing is not limited by the requirement to enhance diffusion across a membrane, thereby potentially improving the power density of some fuel cell systems. This improvement has to be balanced against the energy cost of pressurizing the cell system. If fed from a high-pressure source like a gas bottle this cost is negligible at the consumer's end but can be significant at the source.

Solid oxide fuel cells have their own peculiar problems. Because of the elevated inlet gas temperatures, special materials are required to permit safe operation. This is because the chromium oxide films that are usually used are removed by the action of the high-temperature fuel gases and the steam, which cause accelerated corrosion and pitting.

Some of the protection techniques applied have been borrowed from the gas turbine industry, where the gas ducts had to be protected from the fuel supply. Commonly used materials are self-aluminizing steels, although alumina coatings have also been applied to Hastelloy and stainless steel to good effect, in a manner commonly used during the Second World War by the Junkers company in the production of the early jet engines. This technique utilizes the high-temperature strength of the material while bypassing its Achilles' heel.

Thermal Control

Temperature controls are used to override the power generation controls in fuel cells. The operating temperature of low-temperature cells can rise due to a combination of increased current draw, cell impedance, and elevated gas inlet temperatures from the external reformers to raise the temperature of the cell system. This can degrade electrolyte and can destroy the cell.

In high-temperature cells, this heating effect can be useful, because at low temperatures it will increase the load on a cold cell to raise its temperature and will reduce the load on hot stacks. Temperature controls are usually successful when a combination of heat exchanger bypasses and auxiliary heater controls are used to maintain the temperature of loaded cells.

Idling fuel cells will, however, require external supplements to maintain normal operating conditions. These supplements can be provided by either fired heaters or by external electrical heating. Efficient insulation is essential for all high-temperature cells.

A further issue for high-temperature fuel cells is the melting temperature and related vapor pressure of the current-collecting cabling. While most commercial high-temperature cable is nickel, its high resistance makes its use in fuel cell systems unwise and inefficient. Instead, solid silver cabling is used; however, the silver's vapor pressure limits its service to below 900°C, with an 850°C limit being more common. Recent developments in inexpensive cable insulation including ready availability of commercially produced silica and Nextel insulated thermocouple wiring simplifies the solving of the problems associated with sensor wiring. Therefore, this no longer is a serious problem.

CONTROL OF THE AUXILIARY SYSTEMS

Figure 8.26f describes a high-temperature fuel cell system that includes a number of auxiliary unit operations. The fuel treatment controls described in the following paragraphs include the scrubbers, humidifiers, and reformers. In addition, the controls of the exhaust systems, the inverters, and the required shutdown controls will also be covered.

Fuel Treatment Control

For all fuel cells, except those running on high purity hydrogen and similarly prepared fuels like methanol, some form of fuel treatment is required. The main problem with fuel supplies intended for conventional combustion systems is the presence of minor contaminants containing ash-making chemicals and sulfur compounds. In fuel cell applications, the sulfur compounds form corrosive substances that poison the catalysts in the reformer stages and the fuel cell itself.

Scrubber Controls Natural gas supplies can be a problem, as the hydrogen sulfide concentration in natural gas can reach 5.7 mg/m^3, and other sulfur compounds including mercaptan odorant (which typically contains 5 mg/m^3 sulfur) can total 50 mg/m^3 without violating industry standards. While these concentrations are low, they are sufficient to poison a fuel cell and the reformer stage within a short period if not scrubbed out.

Heavier oil supplies such as diesel (which can be used in solid oxide fuel cells) can also have a substantial sulfur content. Diesel oil received from third world refineries can contain as much as 10% of sulfur compounds due to lax regulation and cost pressures.

The most proven scrubbing technique to absorb sulfur compounds is to use a bed of sintered zinc oxide pellets that are heated to 300°C, but this requires a slipstream of hydrogen-rich gas to crack the more complex compounds to hydrogen sulfide. Iron oxides have also been used as absorption materials in similar installations. The saturated absorbent can then be either dumped (the usual option) or regenerated and recycled at a suitable facility.

This can result in a chicken-and-the-egg scenario at start-up, because hydrogen is needed for start-up but is not available until after start-up. This can be solved by either providing a bottle of hydrogen for start-up or a cold start-up system,

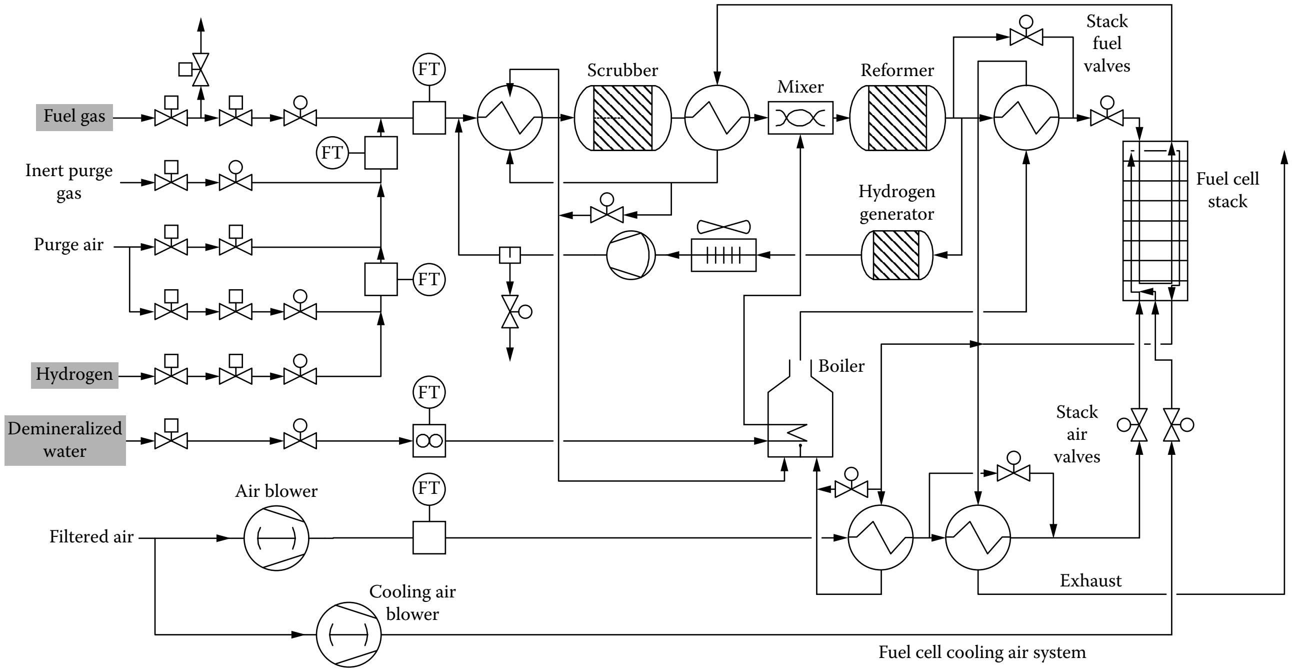

FIG. 8.26f
A simplified flow diagram of a high-temperature fuel cell system.

which is storing the hydrogen produced during the previous run.

The scrubber operation requires tight temperature control, because if the absorber is too hot, the sulfur is released, and if it is too cold the absorption process will not take place. Usually, electric heating is used to raise the bed temperature, and the heating is modulated on a feedforward basis as a function of the gas flow rate to prevent overheating or overcooling on load changes. The scrubbing process is not tolerant of water contamination, because it can cause the bed to collapse, if exposed for prolonged periods to high water vapor pressures or to condensation.

Alkaline fuel cells also require the removal of carbon oxides including carbon dioxide. The current carbon dioxide removal technology is, however, not suitable for use in mobile (or even compact) systems in long-term operation.

Humidification Controls After the scrubber (see Figure 8.26f), water vapor must be added to the scrubbed mix, in order for the shift reaction to properly function in the reformer. The shift reactions in low- and high-temperature cells are as follows:

$$\text{Low-Temperature Cell: } CH_4 + 2H_2O \Rightarrow CO_2 + 4H_2 \qquad \mathbf{8.26(26)}$$

$$\text{High-Temperature Cell: } 2CH_4 + 3H_2O \Rightarrow 2CO + 5H_2 \qquad \mathbf{8.26(27)}$$

In case of complex (saturated) hydrocarbons, the shift reaction is

$$2C_xH_{2x} + 2H_2O \Rightarrow 2xCO + 4H_2 \qquad \mathbf{8.26(28)}$$

The steam flow to the mixer is controlled on a mass flow ratio basis to the gas flow, considering the gas composition and the degree of reformation required.

For research applications, humidification can be controlled by bubbling the fuel gas through a water bath, the temperature of which is adjusted by the humidity controller and corrected for the system pressure. Such controls are similar to that used by the Carrier air-conditioning systems dating back to the early 20th century. For any system larger than a test bed, however, the bath system breaks down, as the bubble size generated by the available passive diffusers is too large for effective humidification in any reasonably sized bath.

Therefore, for larger humidification systems, steam generators are required (Figure 8.26f). These being low-pressure boilers, the steam must be superheated (up to 900°C) to minimize the thermal losses in high-temperature fuel cells. The steam produced by the boiler is mixed with the fuel stream by in-stream mixers ahead of the reformer. Mixing the gas with the highly superheated steam also assists with the heating of the fuel gas before it enters the reformer. The boiler itself must be designed for dry operation, as the bulk of the system will act as a superheater coil with no control of the heat flux.

Controlling the water feed to these boilers is a challenge in itself, as the flow rates are too low for most metering systems that are available at a reasonable price. For a 40 kW fuel cell system, the required water flow range is 0.25–10 gr/sec (see Chapter 2 in the first volume of this handbook for an in-depth discussion of low flow measurement).

In a particular application, paddlewheel flow meters have been made to function with adequate turndown in this range, but special linearization was required to accommodate for the nonlinear response at low flow. Thermal dispersion flow meters would also have been an option, but the price was too high for a commercially viable system.

Conventional control valves presented inadequate turndown (for high-turndown control valves, refer to Chapter 6), so in this particular installation pulsed and pulse-modulated solenoids were used, with the flow being averaged to match the required ratio to the fuel gas.

Limiting the outlet temperature both before and after the mixer is important to prevent flooding or forming slugs of water, which are then injected into the fuel stream. The boiler feedwater flow is also limited on the basis of low steam temperature and on the basis of an interlock that responds to the boiler casing temperature.

Some consideration has been given to the recycling of the water content of the exhaust but the carbon dioxide content makes this difficult in small systems sensitive to carbon monoxide and dioxide.

Reformer Controls All fuel sources other than hydrogen require some reformation to provide a hydrogen-rich gas feed to the fuel cells and the scrubber. Some fuel cells, such as the direct conversion methanol cell systems and to a more restricted extent the solid oxide fuel cells, use reforming catalysts on the cell surfaces.

However, in order to extract the most energy out of the feed stock, it is common practice to add a reformation stage using a water gas shift reaction to separate the hydrogen gas from the carbon backbone of the base fuel by a combined use of heat, steam, and catalyst. The reformer reaction requires temperatures higher than that of the scrubber stage. They are around 300–400°C for common iron/chrome catalysts but temperatures of over 500°C have also been found to be effective.

To reach such temperatures requires that the gas stream be further heated either by a heat exchanger that is using waste heat or by electric heating, which is also needed for start-up. Low-temperature reformer units operating at 160–250°C and using copper zinc oxide-based catalysts reduce the cooling requirements of the low-temperature fuel cells, but at the expense of the high risk of fire if the system is shut down incorrectly.

During start-up, the catalyst first has to be activated with hydrogen gas. This first requires a purge to strip the atmospheric oxygen and condensation from the beads (or carrier if used), and then heating to the operating temperature. The traditional means of purging is to use an inert blanketing gas for this purpose until the minimum activation temperature is reached.

A cheaper (at least in terms of inert gas) alternative is to heat up the system to 150°C by using air, at that point purging the condensate and then switching to fuel gas to purge the air while remaining below the autoignition temperature of the gas stream. This, however, requires additional valves in the fuel train to isolate the fuel from the air during normal operation and requires an explosionproof design of the complete fuel cell system.

Common reformer catalysts include iron/chromium complexes, nickel-based catalysts, vanadium/cobalt, and the very pyrophoric (but very effective) copper/zinc oxide-based catalysts. A more expensive option is platinum-based ceramic catalysts but care has to be taken to prevent carbon fouling, which will need to be burned off.

Recent developments have shown that this catalyst can withstand oxygen contents similar to normal air at 550°C and can operate at 400°C. This is an area of intense current research, with copper oxides showing great promise. Gold-based catalysts have also shown some recent promise, but their high cost will probably restrict their use to niche applications.

With either technique, once the minimum operating temperature is reached, hydrogen is introduced into the reformer to strip the oxide layer from the catalyst that has been made passive. As this is an endothermic reaction, extra heating is required. In addition, close control of the hydrogen flow is also required to ensure that even reduction is achieved. The hydrogen is usually supplied from gas bottles, but some attempts have also been made to use internal hydrogen generators to render the systems more self-contained and eliminate a potential fire hazard.

The hydrogen generators are simply miniature versions of the reformer. They are driven to higher temperatures and are not made passive on shutdown and can also be used to improve the performance of the slipstream to the scrubber in normal operation.

The slipstream needs to be stripped of water, which is generated by the shift reaction before being recycled. Both air- and water-cooled condensers have been used for this task with some success. The condensate can be removed by modified flameproof electric steam traps.

Low-temperature fuel cells require a further scrubber stage after the reformer to remove any carbon monoxide using platinum group metals, in combination with cobalt, silver, iron, copper, and molybdenum.

Exhaust Systems Controls

As most fuel cells do not produce complete conversion (other than hydrogen types), and most do vent unburned gas, some means of handling the waste fuel is required.

In proton exchange membrane-type cells, the hydrogen ions migrate to the oxidizer or cathode side of the cell, which results in a level of water or water vapor building up in the oxygen stream. This can greatly reduce the available reaction surface area and, therefore, must be flushed before that happens.

In hydrogen fuel cells of this type, the fuel stream is not contaminated with waste products and no exhaust is required. In methane- and methanol-powered PEM cells, reaction products from the fuel side eventually can poison the cell by limiting the maximum achievable efficiency, so the fuel stream has to be periodically purged.

In high-temperature SOFC cells the oxygen moves from the cathode to the anode side and reacts with both the hydrogen and carbon monoxide (and the anode material if a reverse bias is permitted to occur), generating water vapor on the fuel side of the cell requiring a continuous purge. The air side is depleted correspondingly and the resulting nitrogen-rich gas also needs to be purged before the low oxygen levels affect the cell output voltage.

Recycling of the waste fuel gas stream is possible in pure hydrogen-powered systems, if no contamination problems are present. This recycling in hydrogen-powered systems requires the removal of the water and recompression for injection to the intake stream.

Hydrocarbon fuel cells have the additional burden of carbon dioxide and monoxide accumulation. Their extraction is uneconomic in small installations; therefore, an afterburner is used to neutralize the exhaust stream and to extract the residual energy.

Either conventional burners or catalytic converters can be used in smaller systems. Their controls are the same as those of small heating units that are provided with pilot burners to ensure light off. In larger systems, one has the option of using small gas turbines to extract the energy remaining in the gas by generating electricity (at a slightly lower efficiency). Enough flammable components must remain in the gas stream to ensure that the combustor can maintain a stable flame.

With catalytic combustors, the opposite is the case, because when fuel-rich gases are vented in response to the shedding of the loads, the control of combustor temperature can become critical, requiring water sprays in extreme cases.

High-temperature systems can use the residual energy in the exhaust gases to heat the incoming feed gas to the operating temperature of the cell or to generate steam for humidification. This leaves considerable levels of available energy, which can be used for industrial and domestic heating or cooling by the use of absorption chillers. (For the controls of chillers, refer to Sections 8.12 and 8.13.) The downside of recovering the residual energy is that if the burners are run at too high a temperature, the NO_x emissions will no longer be low.

Inverter Controls

Because fuel cells produce direct current and the power distribution grid uses alternating current (for very good reasons), inverters are required to make the fuel cell-type generators compatible with the installed base of electrical consumers. The required technology for the inverters is the same as is used by the solar power industry, and the designs and requirements are frequently shared between the two industries. The solar power industry being more developed, it tends to lead the way, and therefore most specifications tend to refer to solar activities, but where a certification framework is required for fuel cells, most authorities will use the existing specifications written for the solar power systems.

For simple grid isolated systems, a simple electronic inverter that is similar in function to the converters used in variable-speed drives is used to drive the load. Some larger fuel cell systems also use this strategy to serve their internal loads of small blowers and other drives directly off the internal DC bus. More complex systems are required for interfaces to the distribution grid.

The simplest of these complex systems is the back-up power supply configuration, where an undervolt switch trips the fuel cell system into service on grid failure. In this case, frequency and voltage control are not critical, because the fuel system is transferred smoothly to the grid, when its voltage is zero.

The next level of complexity is when an uninterruptible power supply (UPS) is required, which is an extension of the conventional battery-backed UPSs. In this configuration, the mains power grid charges a battery bank in parallel with a fuel cell system, and the grid failure results in no interruption of the supply, because the battery bank gives time for the fuel cell system to ramp up.

The most difficult requirement is to provide a grid-connected inverter. Such an inverter must maintain the same frequency as the incoming grid and must detect the loss of the grid and respond to such an event either by isolating itself from the grid or tripping off-line. The usual means of detecting a grid disconnect or island situation is to have the output frequency periodically drift up or (more usually) down, because if the grid is in operation, the phase shift will be readily detectable. At 2 Hertz away from the nominal grid frequency the inverter will trip to island mode and either shut down (pending return of the mains supply), or disconnect itself from the grid.

The alternative method of detecting grid failure is by detecting the voltage deviation (either high or low) and set the inverter to trip if the voltage deviation moves outside a +10% or –6% deviation from nominal supply values. The purpose of doing this is to protect linesmen from possible back feeds from generation systems, which they may not be aware of, when they are isolating the main supply. This system must detect a grid link failure within 2 min. With multiple inverters driving the same load, one of the inverters has to be the frequency master in order for this test to function correctly, while the others are operated in load share mode.

Grid-connected inverters can either drive into the grid as a power supply or can supply some of a large load. The third option is to drive the main's current draw to zero, which requires a more delicate balance. The choice among these options depends upon the specifics of the local electricity supply and upon the receptiveness of the supply authority to generators that are not owned by them.

Base load fuel cells are, as yet, uncommon but will most likely comply with the requirements for conventional generator sets regarding frequency stability and load sharing modes of operation. No fuel cell system has as of yet demonstrated either the reliability or the power output needed for base load operation, except for the smallest and least critical operations.

Shutdown Control Requirements

The fuel cell's control system should also provide the controls for a safe shutdown. The emergency shutdown sequence starts with the isolation of the fuel gas supply and is continued with "inerting" of the fuel cell system to snuff out any fires that could be caused by leaks and to prevent the possibility of the fuel cell becoming an ignition source.

Conventionally, this is done by applying a nitrogen blanket, which is supplied from a high-capacity liquid nitrogen tank. High-temperature cells that are located in or near hazardous areas may require more drastic design features, such as using liquid CO_2 to cool the cell to below the auto-ignition temperature of 400°C (destroying the fuel cells in the process). This occurs in under 2 min and as such it complies with requirements for a fire suppression system and removes the need for the nitrogen supply.

A more normal shutdown sequence would first flush the fuel cell, reformer, and scrubber with nitrogen or carbon dioxide (if it is safe for the cell design). This step is followed by a slow bleed of air and nitrogen to repassivate the fuel cell and reformer under temperature control. If this is not done gradually the reformer can reach temperatures high enough to violate its containment (melt down) and become unrecoverable. The reformer performance does decrease after this treatment but over 90% of its capacity can be retained. Similar problems are present when reforming in the fuel cells themselves.

High-temperature fuel cells are governed by the same gas safety regulations as are fired heaters and boilers, because they also operate at above the auto-ignition temperature of the fuel gas. Some gas reformers are also in the same category. Therefore, double block and bleed arrangements are required for commercial systems in all but the smallest installations, and rapid removal of internal ignition sources is required after a forced shutdown, in addition to meeting the system purge requirements that are set in the relevant standards.

CONCLUSIONS

Further research is required to reduce the cost of instruments for all fuel cell systems. For example, a complex fuel cell system can require upwards of a hundred flow control valves. Even if the cost is only $200 for a typical low-cost commercial valve this cost can exceed the total cost of alternative generation equipment by a sizable margin. Transition to high-temperature fuel cells pushes the valve price up as special materials are required, yet low cost is critical for commercial viability and salability of fuel cells, if they are ever to move out of the laboratory and into general use.

Another source of problems are the thermal losses induced by instrumenting a typical high-temperature system. Thermocouple wiring and metallic capillary tubing to pressure and flow transducers can easily double the thermal losses of the system. Therefore, nonmetallic and thermally insulating sensor leads are required at reasonable costs for reliable operation at 1200°C. Today's costs of tens of thousands of dollars per point for using such commercial instruments as optical strain gauges and thermometry systems are totally unacceptable.

It is essential that in the field of fuel cell controls the instrumentation pricing changes from what is acceptable for research purposes to the sensor prices that car manufacturers are paying today. This is essential to the commercialization of the current generation of fuel cell technology. The reduction in price must also be matched with several orders of magnitude improvement in reliability. Such reliability today is available only in the current generation intelligent instrumentation (but at a cost that is unacceptable for commercial fuel cell systems).

The same reduction in pricing and increase in reliability are also needed for the auxiliary fuel cell equipment controls, from heat exchangers to the inlet gas train.

INTRODUCTION

The discussion that follows covers a wide range of process furnaces, including heaters, cracking furnaces, and reformers. Each type of furnace is described from a mechanical and process standpoint, in enough detail to make the recommended control strategies understandable. Examples are presented so that extrapolation can be made to services not specifically discussed in this section. The recommended control strategies are broken down into the following categories: 1) process controls, 2) fuel firing controls, and 3) safety controls.

In the first part of the section, general information is provided concerning the furnace and fired heater processes, their sensor and analyzer requirements, and their basic control requirements, including air preheat controls. In the second part of this section, specific control systems are described for start-up heaters, process heaters, and reforming and cracking furnaces (Figure 8.27a). The last part of this section discusses some of the more advanced control strategies that can be applied to furnace controls and optimization.

In furnaces and heaters, thermal energy is transferred to a process stream or feed in a controlled manner. The typical furnace, or heater (the terms will be used interchangeably), usually takes the form of a metal housing lined with an insulating refractory. The charge can enter as a liquid, gas, or two-phase mixture and may or may not be transformed to a different state by the energy supplied. In these types of furnaces, the charge can be carried through the furnace or heater continuously through metal tubes or can be batch-heated by leaving it stationary after it enters the furnace.

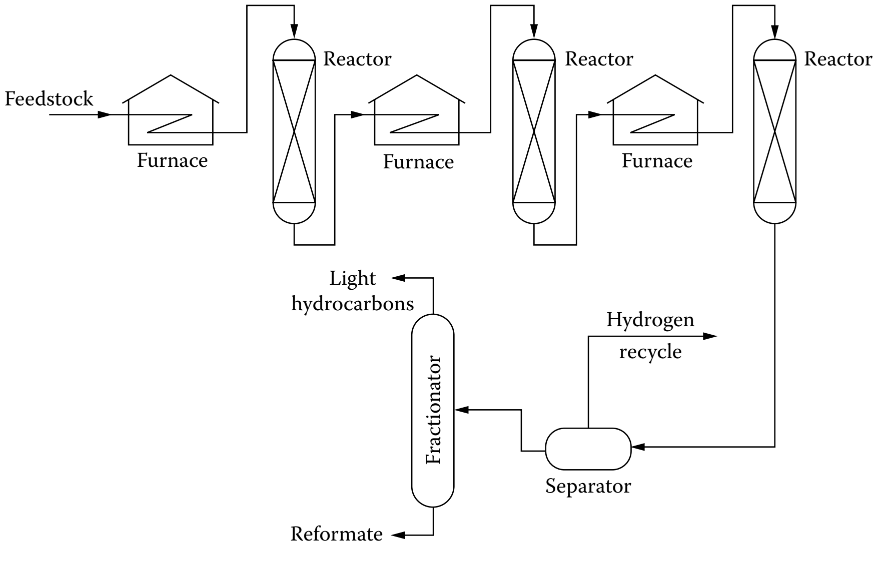

FIG. 8.27a
Illustration of a multistage reforming process.

The discussion in this section covers the controls of 1) refinery feed heaters and reboilers, 2) pyrolysis furnaces for ethylene production, and 3) steam reformers for hydrogen or synthetic gas production.

As will be seen later, the heat content of the hot flue gases leaving the furnace can be used to preheat process feed in a feed preheater or can preheat the boiler feedwater and generate process steam.

Controls for the more common types of process furnaces will first be described from a process standpoint. Next, the important process variables will be noted and the methods used to measure and control them will be outlined. The various types of firing controls applicable to the particular type of furnace will then be described. Finally, specific safety considerations and instrumentation will be presented.

As will be seen, the common control strategies include a feedback temperature/flow cascade loop, where the furnace outlet temperature adjusts the fuel flow into the fired furnace. The firing controls may use feedforward based on the feed flow rate in order to speed up the control system response to changes in feed flow rate.

Furnaces with long dead times or with highly interacting control loops tend to be unstable (Figure 8.27a). To overcome these problems, the use of mathematical analysis and process simulation may become a necessity. The control systems outlined have been empirically developed, and most of them are tried and reliable designs. In the more advanced control strategies, which are described in the last part of this section, process dynamics are also taken into full consideration.

GENERAL CONSIDERATIONS

The primary functions of furnace control systems are

1. To ensure that the charge receives the heat energy at the proper rate. In feed heater furnaces, the main controlled variable is the exit temperature of the charge.
2. To maintain efficient combustion of the fuel. Proper combustion of the fuel requires the regulation of the air-fuel ratio, and the control of the atomizing steam flow rate when fuel oil is burned. Other important controlled variables are draft and stack emissions of NO_x and of other pollutants.
3. To maintain the safety during all phases of furnace operation so as to prevent explosions or fires.

Standards Applicable to Furnace Controls

The ANSI, API, CFR, IEC, ISA, NFPA, and OSHA standards that are used to regulate furnace controls are listed at the end of this section, before the Bibliography.

In furnace operations, safety is a very important consideration. In the case of refinery furnaces, the potential sources of hazards include 1) fire or explosion caused by tube rupture. Such rupture can occur because of tube overheating due to feed flow loss or because of flame impingement; 2) explosion in the firebox caused by the loss of flame or by improper ignition or purge procedures; and 3) implosion of the furnace or refractory damage caused by high draft.

Furnace design and operation must follow OSHA's code of federal regulations: 40CFR1910.119, "Process Safety Management." The standard ANSI/ISA-84.01–1996, "Application of Safety Instrumemented Systems (SIS) for the Process Industries," must also be implemented, usually by applying independent PLCs for the control of firing shutdown sequences.

The required level of reliability must be determined by the analysis of the required Safety Integrity Level (SIL), described in the ISA Standard TR84.02-2002. The SIL level is established using process hazard analysis (PHA), which determines if dual- or triple-redundant PLCs must be used. An international companion standard that is also applicable in making this decision is IEC 61508, "Functional Safety–Safety-Related Systems." In addition, local codes and industry practices, usually set by the insurers of the plant, should also be consulted before controls are designed and installed.

The Combustion Process

To completely burn the combustible portion of any given fuel, an ideal quantity of oxygen and, therefore, an ideal quantity of air is required. Under real conditions, the inefficiencies in combustion require that some additional air be provided to ensure complete combustion. The quantity over and above the ideal (stoichiometric) amount of air is called the "excess air."

On a volumetric basis, air contains 0.21 oxygen and 0.79 nitrogen (on a mass basis 0.232 oxygen and 0.768 nitrogen). For example, in the combustion of methane (CH_4), the ideal amount of air required per pound is 4/0.232 = 17.24 lb, and in volumetric units, the volume of air required per cubic foot of methane is 2/021 = 9.52 ft^3.

The ratio of air supplied per pound of fuel (W_1) to the air theoretically required (W) is

$$(W_1/W) = \{3.02[N/(CO + CO_2)]\}/\{34.56[C/3 + H - O/8]\} \qquad \mathbf{8.27(1)}$$

Combustion Efficiency and Excess Air If we call "a" the ideal (minimum) amount of air required for complete combustion and we call "*xa*" the actual amount of air admitted, then "x – 1" is the excess coefficient. On a volumetric basis, the excess air requirement (E in %) can be calculated by

$$E = K[21/(21 - \%O_2) - 1] \times 100 \qquad \mathbf{8.27(2)}$$

where $K = 0.9$ for gas, 0.94 for oil, and 0.97 for coal.

Using the stack gas composition analyzer readings for carbon monoxide (CO), the air supply to the furnace can be adjusted to maintain the combustion efficiency at the optimum. Figure 8.6ttt in Section 8.6 shows the relationship between measured ppm concentration of CO in the stack gases and furnace efficiency.

The optimum percentage of excess oxygen is some percentage greater than what is theoretically needed for complete combustion. This margin is usually between 2 and 4% for most furnaces. For continuous emission monitoring system (CEMS) purposes, the pollutant concentrations are calculated with a reference basis of 3% O_2 on a dry basis.

The amount of carbon monoxide in the stack gases can be measured to determine the optimum set point for excess O_2 control. Elevated CO levels indicate that some of the fuel is unburned, which results in the waste of heat and the danger of potential explosion at high CO levels. In some installations, instead of continuously monitoring CO, only a one-time measurement is made to establish the crossover between the presence of excess oxygen and excess unburned fuel.

Combustion efficiency is usually defined in terms of heat input and output. In the case of furnaces, an energy balance around the unit must account for the total heat input and the total useful heat output. The difference is the total heat loss, as illustrated in Figure 8.6kkk in Section 8.6.

$$H_I = H_O + H_L \tag{8.27(3)}$$

where

H_I = heat input rate

H_O = heat output rate

H_L = heat loss rate

Furnace efficiency can be defined by one of the following three equations:

Input-output method:

$$EFF = 100 \cdot (H_O/H_I) \tag{8.27(4)}$$

Input-loss method:

$$EFF = 100 \cdot (1 - H_L/H_I) \tag{8.27(5)}$$

Output-loss method:

$$EFF = 100 \cdot [1/(1 + H_L/H_I)] \tag{8.27(6)}$$

Now, if these equations are expressed in terms of

Q = heat absorbed by fluid

W = fuel rate

I = heating value of fuel

L = total heat loss

Equations 8.27(4) to 8.27(6) become

$$EFF = Q/(W \cdot I) \cdot 100 \tag{8.27(7)}$$

$$EFF = 1 - L/I \cdot 100 \tag{8.27(8)}$$

$$EFF = Q/(Q + W \cdot L) \cdot 100 \tag{8.27(9)}$$

Although, in theory, any of these equations should produce the same results, experience has shown that the input-loss method [Equations 8.27(5) and 8.27(8)] produce the most reliable results, because the other methods are more sensitive to errors in process measurements.

Many furnaces burn gas preferentially and oil only as a standby. Emission compliance for NO_x is easier if gas fuel is being burned. However, some of the control systems described in this section are suited for combination firing (i.e., firing both gas and oil simultaneously).

Combustion Air Preheat With regard to furnaces, the overall efficiency is the ratio of the amount of heat absorbed by the process to the amount of heat liberated by the fuel. One of the major heat losses in a furnace is the heat lost up the stack in the form of hot flue gases. Therefore, much attention has been devoted to reducing the flue gas exit temperature as much as practical (to approximately 300°F, or 150°C).

A common method of reducing this waste is to add a combustion air preheater to the furnace. This device is a heat exchanger that transfers some of the heat from the hot flue gases to the cold combustion air, before it enters the burners (Figure 8.6ll in Section 8.6). Thus, the heat energy re-enters the furnace and is available for transfer to the process stream.

In addition to the combustion air preheater, it is usually necessary to add a forced draft fan to push the combustion air through the preheater (exchanger) instead of relying on natural draft. The instrumentation necessary to control this equipment is relatively simple. Figure 8.27b shows a typical combustion air preheat system.

In this control system, the forced draft fan is driven by a steam turbine drive, equipped with a variable-speed governor. A pressure controller (PIC-1) maintains the discharge pressure (and consequently the airflow) by manipulating the fan speed. A low-pressure alarm (PAL-1) is included to alert the operator of possible fan malfunction.

A trip interlock (FY-1) is provided to trip the forced draft fan to minimum speed in the event of failure of the induced draft fans. This precaution is necessary to prevent positive pressure in the hot combustion chamber, which could cause the hot gas or flames to blow out through the burner openings and other leaks in the furnace.

Temperature indicators TI-1, TI-2, TI-3, and TI-4 are provided on both streams in and out of the combustion air preheater to monitor the operation. Pressure measurements PI-1 and PI-2 are also included to allow the checking for excessive pressure drop across the unit.

Safety Considerations

As it is also discussed in the next paragraph, some 70% of furnace explosions occur during start-up or shutdown, where operator involvement is significant, while 21% of accidents were found to be caused by undocumented changes after commissioning.

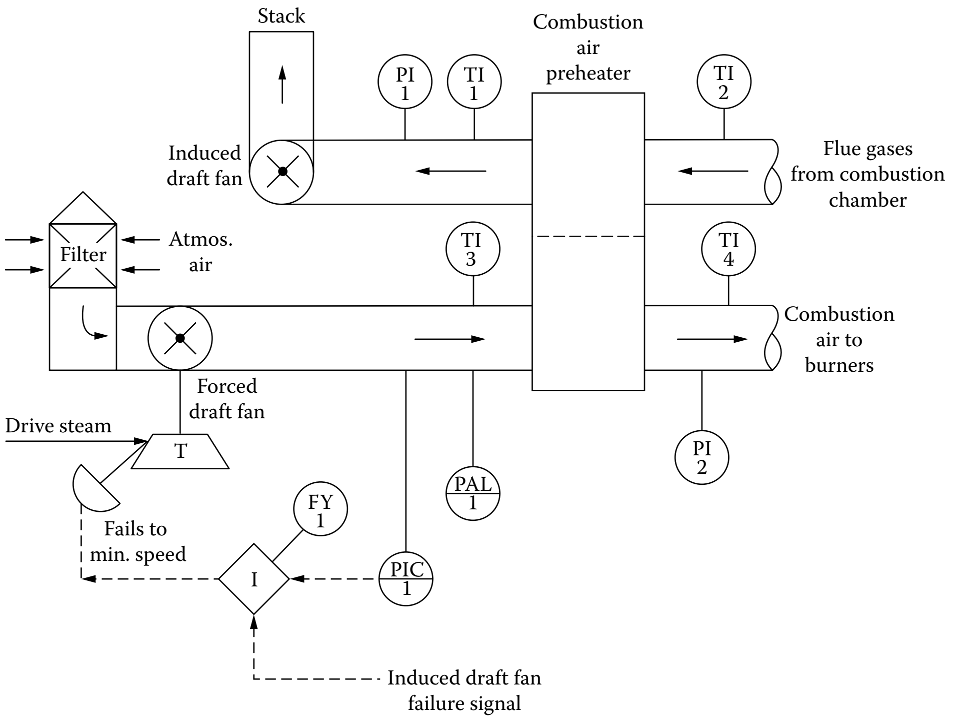

FIG. 8.27b
Combustion air preheat controls.

Fuel Gas Controls Figure 8.27c shows a typical fuel gas header, which can be branching off to several furnaces after the knockout pot. The relief valve shown should be piped to a relief header. For larger furnaces, the pressure control would be by a continuously throttling controller, rather than by a regulator.

The primary function of the furnace's safety system is to shut down the fuel supply if unsafe conditions evolve. In earlier furnace designs, the fuel control valve also served as the shut-off valve. This is no longer permissible, and separate, dedicated shut-off valves are required. Figure 8.27c illustrates a typical fuel gas regulating station with the safety shut-off valves left out and only their location being shown in the broken pipe line.

Figure 8.27d shows the safety shutdown valving usually used in the gas feed to a furnace. The top configuration is installed in the main gas line and consists of three on/off, tight shut-off, usually rotary ball valves. The dual shut-off

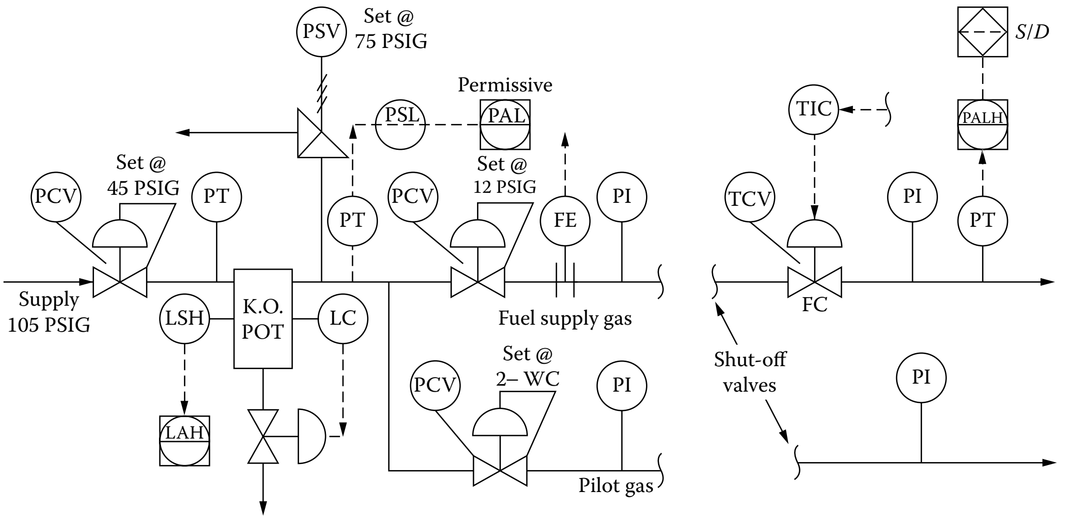

FIG. 8.27c
Fuel gas regulation station showing both the main gas supply line (top) and the pilot gas line (bottom). The locations of the safety shut-off valves are also shown in the broken pipe, but their actual configuration is separately illustrated in Figure 8.27d.

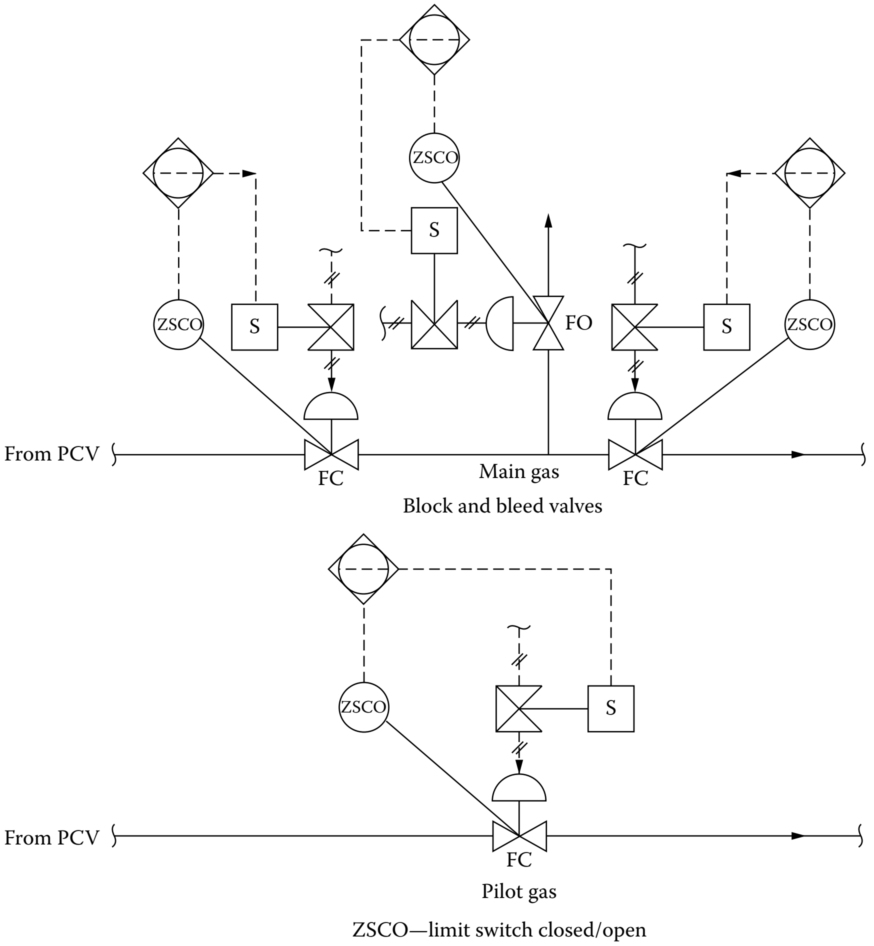

FIG. 8.27d

Safety shut-off valve configuration for the main gas (top) and the pilot gas (bottom) lines. Dual shut-off valves and a vent valve are used for the main, single shut-off valve for the pilot line.

valves are fail closed (FC), while the vent valve between them is fail open (FO). Therefore, when the shutdown interlocks are actuated, the two FC valves close, while the FO vent valve opens and vents the gas between the two FC valves, plus any leakage that might occur, to a safe location. The ZSCO (closed-open limit switches) provided on all three valves confirm to the controlling PLC that the interlock requirements have been performed.

The pilot gas line is usually provided with only a single shut-off valve with limit switch.

Safety Instrumented Systems SIS (formerly known as emergency shutdown system, or ESD) systems in general are discussed in detail in Sections 5.8 and 6.10. When designing a furnace control system, the designer should evaluate the following functional SIS requirements and clearly define the following:

- Define the safe state of the furnace (e.g., fuel shut-off, forced draft dampers open, and so on)
- Define the process variables, their normal operating range, and their limits
- Define the process outputs (conditions) and the actions required in response to them
- Considerations for manual shutdown
- Reset functions
- Actions on loss of power; UPS requirements
- Response time requirements for the SIS to bring the process to a safe state
- Operator interface criteria, including alarms and alarm responses
- Diagnostics; on-line and off-line testing
- Minimize nuisance trips while maintaining safety

As the final control elements in any SIS system are valves and dampers, their requirements should be defined by giving consideration to the following:

- Opening/closing speed
- Leakage
- Fire resistance–body and actuator
- Failure position

- Performance after staying in the same position for long periods
- Use separate shut-off and control valves
- Selection and correct sizing of solenoid valves and protecting them against plugging with bug screens
- Installing the solenoids between the valve positioner and the valve actuator
- Providing all shut-off valves with open-closed position detecting limit switches, which are wired to the SIS

The reliability of PLC-based SIS systems is increased by implementing them in redundant or triple-redundant (voting system) configurations, as far as their processors and power supplies are concerned. Important measurement and status input signals also are configured into 2 out of 3 voting systems, to avoid nuisance shutdowns caused by the failure of a single device or instrument. The shutdown output signals should also be redundant, and these redundant signals should originate on different I/O cards in the DCS or PLC systems.

The SIS safety and shutdown system is usually located on a PLC that is separate from the control equipment that directs the normal operation of the furnace. Such safety systems usually include a flame scanner. It is important to keep the air flowing through the firebox during a shutdown. In case of tube rupture, this may generate a lot of smoke, but it will protect the system from explosions that are caused by fuel-rich mixtures. Shutdowns are usually triggered by the following conditions:

- Low gas pressure: flame may go out and the resumption of gas flow can cause explosion
- High gas pressure: may blow flame away from burner
- Loss of flame, which can be detected by flame scanners
- High draft: may buckle furnace
- Low to zero draft: may push flames out
- Low feed flow: will cause tube overheating, coking, and eventual tube rupture
- Safety system failure: if PLC watchdog timer times out, this triggers hardwired fuel valve closure.

The emergency shutdown system software package within the PLC logic (also called the "problem solver") will cause the following actions as applicable:

- Fuel gas shutdown, with manual reset
- Pilot gas shutdown (not all furnaces)
- Opening of stack and fan dampers
- Ammonia injection shutdown–NH_3 valve, blowers (if the process includes them)

On furnaces with two induced air fans, dampers may be programmed to close if the fan is not running. The feed is usually shut down later manually when tubes have cooled off.

Guidelines for training can be found in OSHA Regulation 1910.119, which defines the requirements for safety systems-related training.

Procedures for on-line testing must also be established. Manual bypass switches should be available for each input that can initiate a shutdown so that the device can be tested periodically. If a bypass is open, that condition should also be indicated locally and alarmed in the central control room. In connection with testing of ESD systems, the ISA standard (S91.1-1995) should be followed, which lists the "Requirements for Functional Testing."

Purge Controls After a shutdown, the pilots must not be turned on and the furnace must not be reignited until all combustible gases are purged out. The purge cycle is initiated by the operator, who must not start the cycle timer in the safety PLC system until after the purge time has elapsed. At that point, the PLC unblocks the shut-off valves. A pilot flame detector is usually also part of the purge logic, and if no flame is detected after a few seconds, the purge will shut down and the cycle has to be restarted.

Large, PLC-controlled furnaces that are provided with emission abatement and monitoring systems are also provided with their own local control panel (Figure 8.27e), which is integrated into the total DCS- or PLC-based control system. Flow and draft indicators, alarms and shutdown bypass/test switches, and purge cycle controls are also often provided on these local panels. The purge-related pilot lights are usually designated as "purge on," "purge failed," or purge complete." After the purge is complete, the pilot burners can be ignited, and later the main gas control valve can also be opened.

Pollution Abatement

Furnace emissions must meet federal (EPA) and local air quality requirements. The applicable standards and guidelines include:

- ANSI/API 536, "NO_x Control for Fired Equipment in Refineries"
- 40CFR Part 60, "New Source Performance Standard" (section for oil refineries)
- 40CFR Part 61, "National Emissions Standards for Hazardous Pollutants"

Larger furnaces must be fitted with CEMS, which will be discussed in the next paragraph after NO_x controllers.

Gas- and oil-fired furnaces, operating at over 2800°F in their hot zones, typically produce about 100 ppm NO_x in their stack gas. EPA standards require that this concentration be reduced to 5 ppm or even 2.5 ppm. This can be achieved by several means:

- Use of cool-burning burners, with optimal air/fuel mixing nozzle design
- Use of flue gas recirculation, where part of the flue gas is returned into the firebox to cool the flame

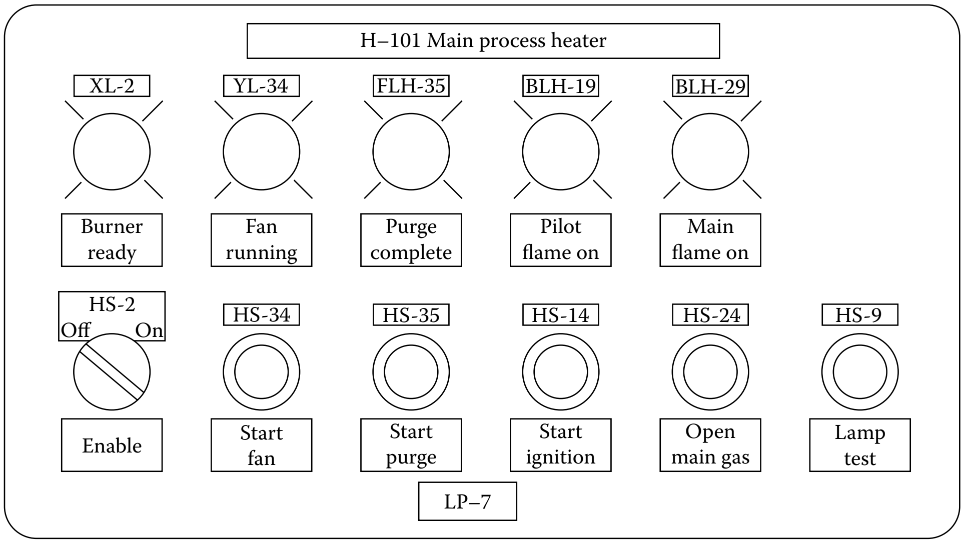

FIG. 8.27e

Local burner panel with status-indicating running lights and manual pushbuttons for purging and testing a typical furnace.

- Installation of catalytic converters between furnace and stack
- A combination of all above

Installing new burners and providing recirculation, by means of fans, can reduce NO_x to around 25 ppm. This still leaves the need for costly catalytic converters, which use vaporized ammonia to convert NO_x (mostly N_2O_3), according to Equation 8.27(10) as:

$$N_2O_3 + 2NH_3 = 2N_2 + 3H_2O \qquad \mathbf{8.27(10)}$$

To accomplish this conversion, because of the resistance of the selective catalytic reduction (SCR) catalyst bed, forced draft fans with control dampers are required. They must be installed on elevated platforms, making the installation expensive.

In the SCR process, by using a suitable catalyst, the NO_x reaction can be carried out at 300–400°C, a temperature normally available in a flue gas system. Figure 8.27f shows a schematic diagram of the SCR process. In this process at least 1% O_2 must be present in the flue gas, which is normally the case in boiler and furnace applications.

Using a movable injection lance is another effective means of reducing NO_x, CO, and volatile organic carbon (VOC), while improving thermal efficiency by optimizing the combustion process in boilers. The injection lance can be used with or without low NO_x burners.

These lances reduce NO_x emissions by 60–90% by injecting air, ammonia, or urea through retractable lances in the upper furnace. This creates turbulence and better mixing in the gas flow in addition to lowering the stoichiometric ratio of O_2. The lances are automatically retracted from the boiler on a regular basis and cleaned to remove the accumulated layers of soot and other depositions. Their costs are about 75% less than those of SCRs.

SCR Controls The controls of the SCR process are shown in Figure 8.27f. Here, from a storage tank, liquid ammonia is metered by a positive displacement pump or by Coriolis flowmeter to the ammonia vaporizer, which is heated by the dilution air. From the vaporizer, an array of small pipes takes the ammonia vapors to the distribution grid for injection at different elevations into the firebox.

Each pipe section in the distribution grid is provided with a balancing throttling valve, which serves to evenly distribute the vapors. The control valves in the major branches are controlled by the ammonia flow controller (FIC-1), which also controls the positive displacement ammonia pump. This controller measures the ammonia flow and in addition receives a feedback signal from a chemiluminescent NO_x analyzer transmitter and a feedforward signal, FT-1, the fuel gas flow transmitter, which detects the firing rate (gas flow) of the furnace or boiler.

FIC-1 also receives a trimming signal from the oxygen analyzer transmitter. It was found that increasing the amount of excess oxygen initially tends to increase the formation of NO_x, but further increases tend to decrease it due to flame cooling. The injection of ammonia is stopped by TSHL-1 (high-low temperature switch) when the converter temperature drops under 600°F, to prevent catalyst damage.

The NO_x Controller Figure 8.27g describes the ammonia controller (FIC-1 in Figure 8.27f) that is used as a cascade slave of AIC-1 to control the NO_x in a crude oil distillation heater furnace, which has a maximum gas firing rate of 8.5 MMSCFD. The figure also shows the various feedforward and trimming adjustments of the total control algorithm.

Feedforward is applied from the fuel gas flow transmitter (FT-1), which is the main determining factor in arriving at the set point of FIC-1. Oxygen content, detected by the transmitter AIT-2, serves to trim the fuel gas flow signal. Therefore,

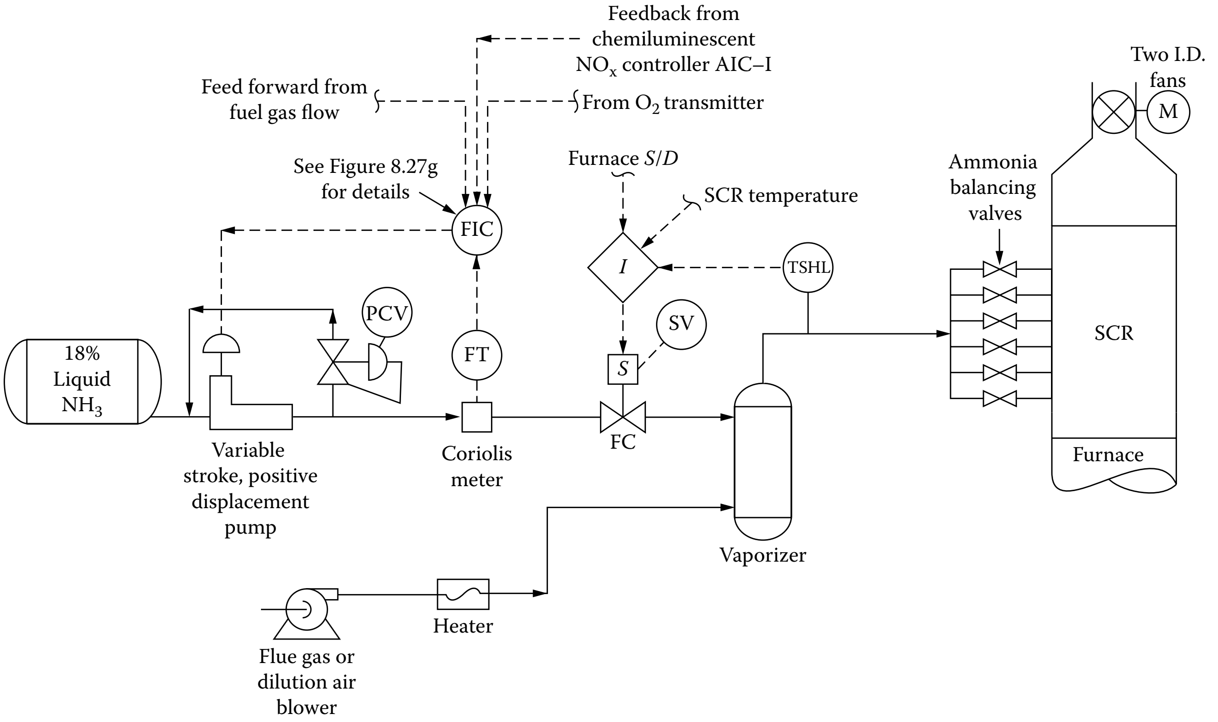

FIG. 8.27f
Control system for an SCR-type NO_x reduction system for the injection of ammonia.

changes in the output signals of FT-1 and AIT-2 will instantaneously change the set point of the ammonia flow controller, FIC-1. The basis for this relationship is that the NO_x production is proportional to both fuel flow and to excess oxygen, because the free nitrogen radicals—at over 2800°F—will seek out the extra oxygen and will combine with it.

The cascade master of the feedback portion of this control system is the NO_x controller, AIC-1. This loop is slow; its dead time can be 10 min, because the time lags from the NH_3 injection points to the stack and then through the sample line to the NO_x analyzer all add up before a measurement is obtained.

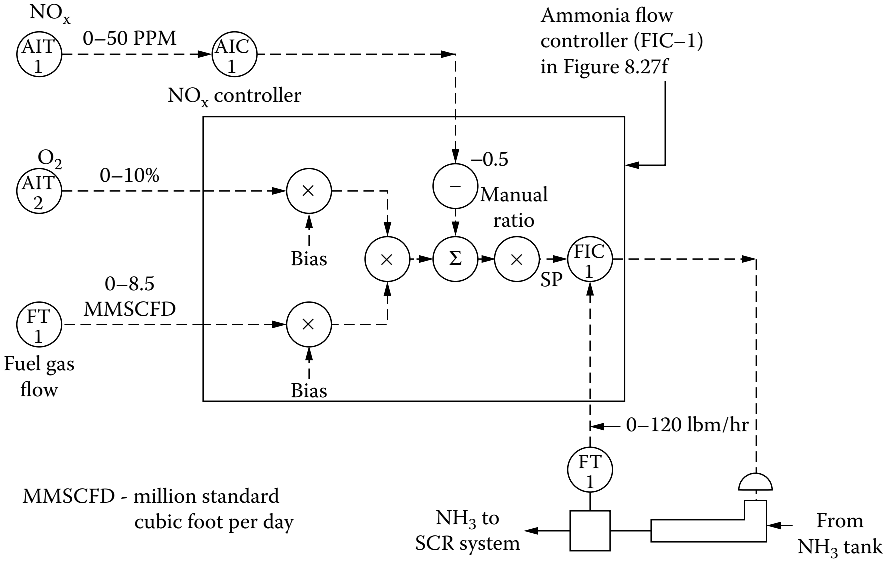

FIG. 8.27g
The configuration of the control algorithm of the ammonia controller (FIC-1 in Figure 8.27f) used to control the NO_x emissions of a furnace.

For the control algorithm shown in Figure 8.27g all measurement and control signals are scaled, so that the measurement output ranges of each transmitter or controller are converted to a 0–1 scale. For example, the output of the NO_x analyzer controller (AIC-1) is also 0–1, and when it is 50% (a value of +0.5), by subtracting −0.5, its influence on the set point of FIC-1 is eliminated. On the other hand, when the feedforward portion of this algorithm cannot correct for the changes in the SCR process, the feedback controller (AIC-1) will start moving its output away from 0.5 and will start correcting the FIC-1 set point.

Such an algorithm can be implemented either by a single-loop programmable controller or by the DCS system.

For a particular set of conditions, the following calculations can serve as an example of the operation of this control scheme:

At an average NO_x concentration of 110 ppm, the total unabated NO_x flow rate in the stack has been calculated to be 26.7 lbm/hr. The conversion of 1 mole of NO_x (Mw = 47) requires about 1 mole of NH_3 (Mw = 17). Thus, the rate at which pure ammonia should be added is 17/46 × 26.7 = 9.87 lbm/hr NH_3. Ammonia is received in 19% solution; consequently, this solution should be injected at a rate of 9.87/0.19 = 52 lbm/hr.

It was found that excess oxygen also contributes to NO_x formation and that up to 4% more NO_x is formed for each additional percentage of excess O_2 over the concentration of 2%. Because of draft limitations, the furnace in this example operates at a 5% excess oxygen level (3% over the 2% minimum). Therefore, 3 × 4% = 12% added NH_3 is required, which comes to 1.12(52) = 58.2 lbm/hr.

To measure the ammonia flow rate, a Coriolis meter with a range of 0–120 lbm/hr can be used, so that the 58.2 lbm/hr rate would approximately correspond to 50% of range.

The "manual ratio" correction factor applied to the set point of FIC-1 is available for the operator to correct for such differences as the calculated 58.2 lbm/hr and the 50% range of the flow meter.

Continuous Emission Monitoring Systems In order to comply with the requirements of the federal agencies (see "Standards and Guidelines" at the end of this section) and with local air quality district requirements, microprocessor-based, self-calibrating CEMS analyzers are used. The CEMS microprocessor calculates the pollutant concentrations reduced to 3% O_2 (as a measure of gas dilution) and provides rolling averages, peaks, their duration, and other records as required by the local agency. The CEMS is usually wired directly to the agency's computer. Emissions are referenced to the firing rate (gas flow) to provide the total mass of pollutants emitted.

For gas-fired heaters, the pollutant that is continuously monitored is only NO_x. In case of fuel oil-fired boilers and furnaces, SO_2 is also monitored. Other pollutants, such as CO, CO_2, and particles (opacity) are only checked periodically by portable instruments. EPA 40CFR60 provides specific criteria for CEMS.

Described here is a typical CEMS system used on a refinery furnace with selective catalytic reduction-based NO_x abatement controls.

The CEMS can utilize a zirconium oxide-based stack oxygen analyzer for firing controls and a chemiluminescent NO_x analyzer.

The CEMS provides NO_x readings (corrected to 3% O_2) and an O_2 signal for the ammonia injection controller (Figure 8.27g). The data collected by the CEMS is also used by the local air quality agency and by the plant monitoring system (PMS), using Equation 8.27(2). The O_2-corrected NO_x emission (E) is calculated on the basis of the actual measured concentration O_2 concentration (C).

If sampling-based analyzers are used (and not directly inserted probe-type analyzers), the components of CEMS systems can include:

- Stack sample probe, located usually $^2/_3$ up the stack (Figure 8.27h)
- Heated sample line with thermostat
- Sample conditioning cabinet with sample pump
- O_2 and NO_x analyzers
- Microprocessor with auto-calibration controller and solenoid valves
- Rack of calibration gas bottles

Sampling The stack sample probe is a stainless steel tube that extends into the stack and has a HastelloyC, 0.5-μ-size filter, a test and sample gas connection, and an electric heater with RTD. The sample line is heated to 300°F to keep moisture from condensing. An alternative method is to use a dilution extractive sample probe (Figure 8.27i). This method of sampling has the advantage of not requiring a heated sample line or a chiller/dryer.

In the standard sampling system, a sample conditioning cabinet is provided, where the sample is quickly chilled to knock out water without washing out the gases of interest. These components are usually followed by a gas dryer, then a bypass rotameter, which is used to control the sample gas flow rate to the NO_x analyzer.

A solenoid manifold is also provided, so that auto-calibration can be performed every 24 hours, by injecting zero and span gases. Sample system alarms are also provided to signal such conditions as high sample gas moisture content, low sample line temperature, and high condensate level.

NO_x Analyzer In the chemiluminescent NO_x analyzer, the reaction that takes place is described by Equation 8.27(11):

$$NO + O_3 \rightarrow NO_2 + \text{light @ } 0.6\text{–}3\mu \qquad \textbf{8.27(11)}$$

The intensity of light emission is proportional to the NO concentration in the sample. The chemiluminescence analyzer is usually provided with a catalytic converter to reduce the NO_x to the NO form and then uses its ozone generator to measure NO_x in the range of 0–50 ppm NO_x. The main components of this analyzer are shown in Figure 8.27j.

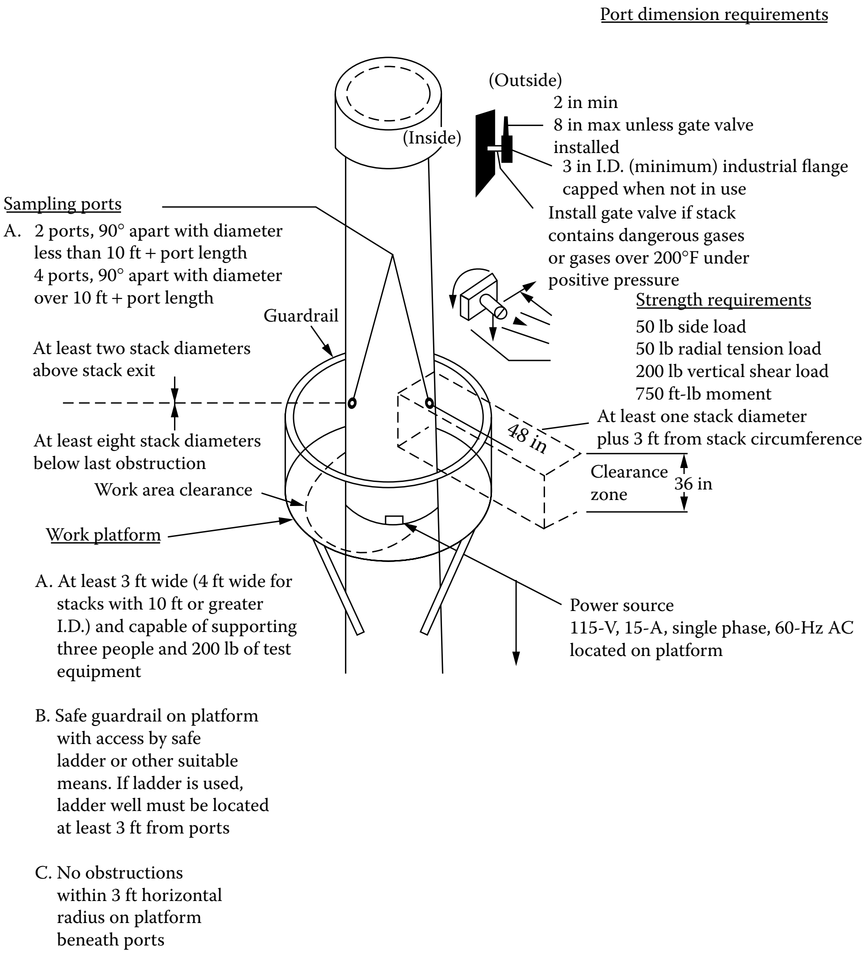

FIG. 8.27h
The location of a stack sampling probe.

Analyzers for Furnace Control

In addition to the analyzers discussed above, in connection with pollution abatement-related furnace analyzers, are the analyzers that are used in controlling the furnace's operation. These include oxygen analyzers, combustibles detectors, and fuel heating value (calorific) analyzers.

Oxygen and Excess Air Analyzers An oxygen analyzer is commonly used on furnaces to measure the oxygen content of the flue gas. From this information, the amount of excess air being delivered to the furnace can be computed. Keeping the excess air at a minimum results in conservation of heat, because the sensible heat content of the excess air is discharged into the atmosphere and is an outright heat loss.

The efficiency of combustion can be maximized by throttling the air of the furnace to maintain the oxygen content of flue gas at a desirable value. The analyzer is also tied to a low-oxygen alarm, which warns the operator if hazardous furnace atmospheres are developing.

The decision whether to install an oxygen analyzer is based on economic considerations, and energy efficiency usually justifies it. The cost of the analyzer and its upkeep must be balanced against the energy savings and increased safety. If the firing load or the type of fuel to the furnace often changes, the oxygen analyzer is a necessity from a safety standpoint alone.

The O_2 sensor can be a solid-state heated zirconium oxide probe that can be placed directly in the stack (Figure 8.27k). An instrument air purge connection is recommended for periodic blowing. At temperatures of over 600°F, these probes produce an open circuit voltage that is related to the partial pressure of oxygen in accordance with the Nernst Equation shown in Equation 8.27(12):

$$E = \frac{RT}{nF} \ln \frac{O_2\text{partial pressure in reference gas}}{O_2\text{partial pressure in sample gas}} \qquad \textbf{8.27(12)}$$

where

E = the open-circuit voltage developed
R = the universal gas constant
T = the temperature
n = the number of electrons transferred per molecule of oxygen
F = Faraday's constant

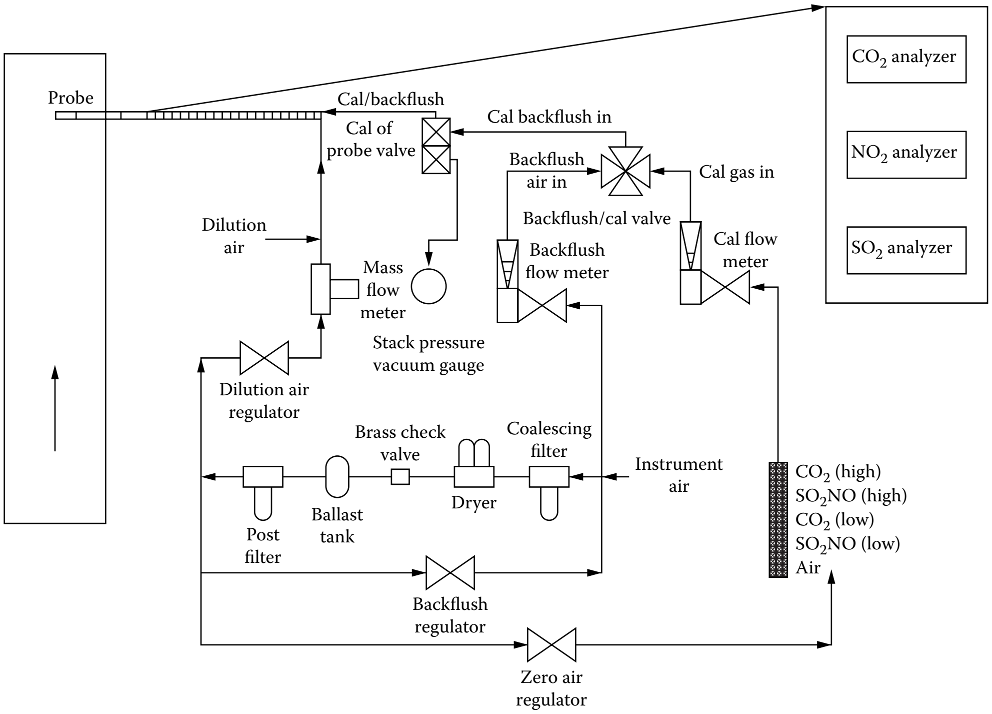

FIG. 8.27i
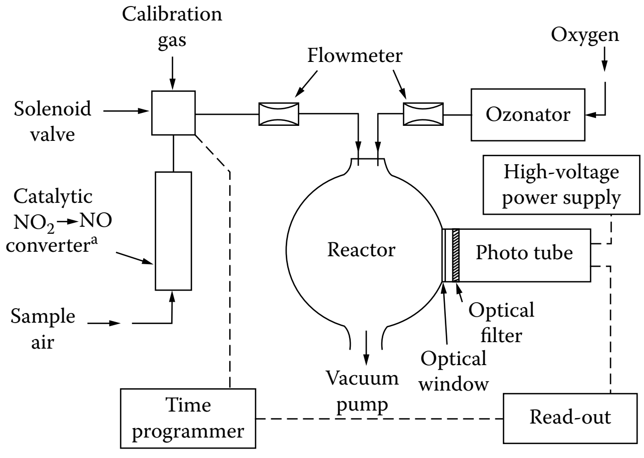
The components of a dilution-extractive sampling system.

Paramagnetic oxygen analyzers are less frequently used. They can be installed on the sides of fireboxes, to check for potentially explosive fuel-rich pockets. The sample gas is drawn to these analyzers by an air aspirator provided with a water seal.

Combustible Analyzers Combustible analyzers measure the amount of unburned fuel in the furnace flue gas (CH_4, CO); they are mostly used as portable instruments during emissions certification. For an in-depth discussion of combustible analyzers refer to Section 8.16 in Chapter 8 of the first volume of this handbook.



[a]Converter can be omitted if only NO is measured

FIG. 8.27j
Chemiluminescence nitric oxide analyzer.

The concentration of one combustible gas component, carbon monoxide, is sometimes used as a constraint variable in a “low select” configuration, in connection with the excess oxygen controller as described in connection with Figure 8.6bbbb in Section 8.6. The CO analyzer can be of the infrared type and can be installed to look “across the stack.”

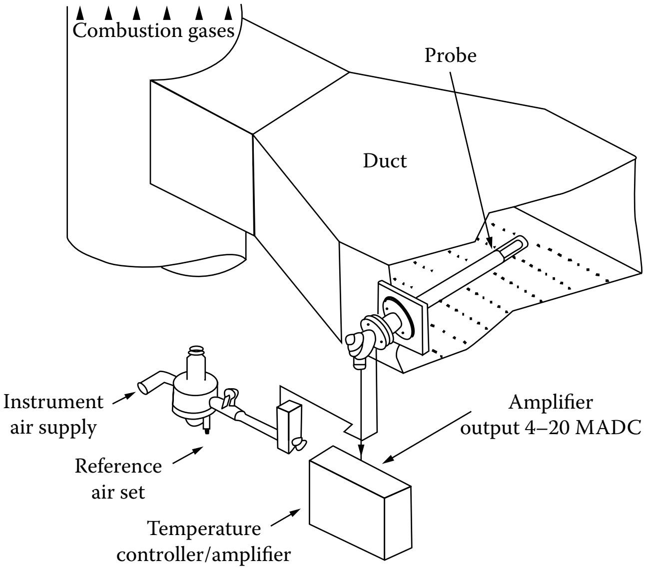


FIG. 8.27k
High-temperature, electrochemical, zirconium oxide-based oxygen analyzer probe.

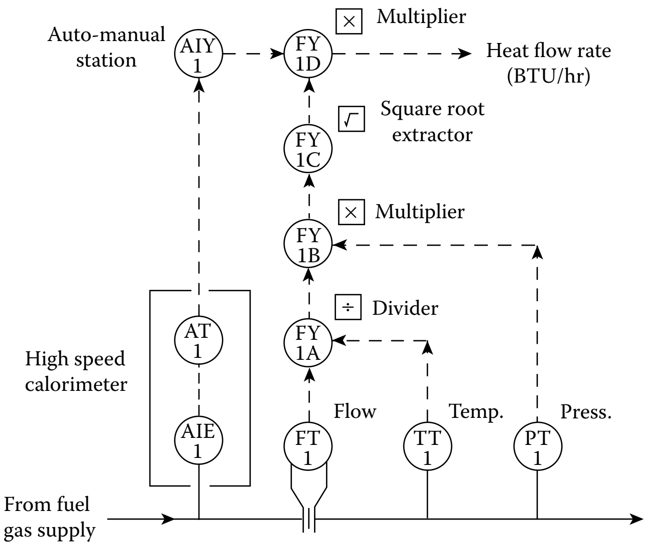

FIG. 8.27l
Heat flow rate detection loop.

NH_3 Analyzers Wet chemical NH_3 analyzers are used to detect the ammonia slip when selective catalytic reduction is applied for emission control. Excess ammonia in the flue gas is referred to as "ammonia slip" and must be avoided. NH_3 is difficult to sample because it is very easily dissolved in water. Experimental laser detectors, beaming across the stack, have been used as ammonia analyzers with some success.

Fuel Gas Heating Value When the refinery waste gas and utility gas are combined, the mixture resulting from their varying heating values will also have a varying heating value. BTU analyzers are used to measure the heat flow rate (Figure 8.27l) provided by the fuel being fed to the furnace (see Section 2.4 in Chapter 2 in Volume 1 of this handbook).

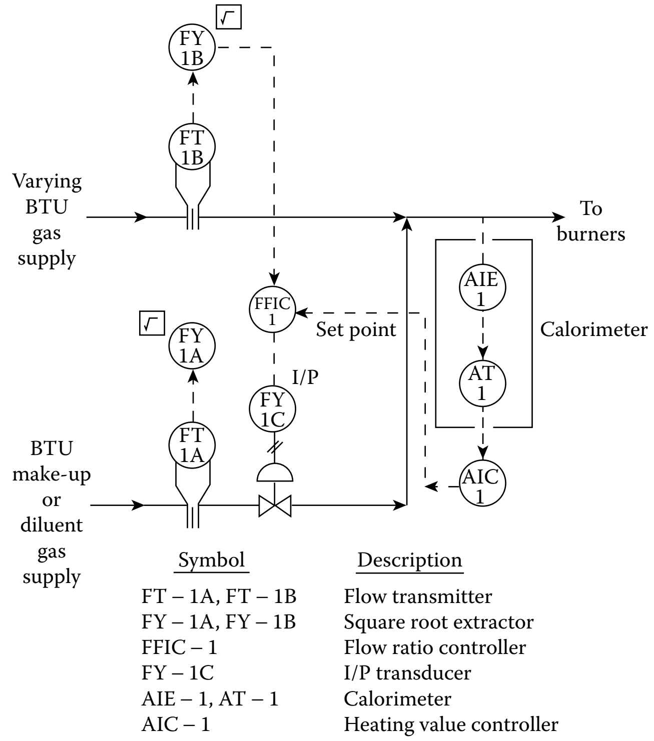
In order to stabilize furnace firing, the heating value of the fuel should be kept constant. This can be achieved by blending refinery gas with natural gas, propane, or some other supplemental fuel having a high and constant heating value. If the heating value of the total stream drops, more of the supplemental fuel is blended in.

This BTU instrument (calorimeter) can also serve as a safety device by actuating an alarm when the heating value of the fuel drops to the point where it cannot support combustion.

Both the blending of the fuels and the emergency shutdown controls can be automated (Figure 8.27m). In this control configuration, if the BTU analyzer detects a drop in the heating value, the fuel supply is shut down.

If the heating value of the two gases that are blended are known, but their ratio varies, the resulting variation in the total heating value can be compensated for by a gas blending system on the main fuel gas header.

Relatively inexpensive BTU analyzers are available for "sweet" gases. They operate by burning a sample stream of fuel and measure the oxygen concentration of the combustion products. The BTU measurement so obtained can be used in a feedforward manner, to compensate for the varying BTU content of the fuel values.



Symbol	Description
FT – 1A, FT – 1B	Flow transmitter
FY – 1A, FY – 1B	Square root extractor
FFIC – 1	Flow ratio controller
FY – 1C	I/P transducer
AIE – 1, AT – 1	Calorimeter
AIC – 1	Heating value controller

FIG. 8.27m
Control system to automatically maintain the heating value of mixed gas streams.

Figure 8.27n illustrates a fuel gas blending controller. The formula it uses to arrive at the total heating value of the blended stream is

$$HT = (F1H1 + F2H2)/ FT \qquad \textbf{8.27(13)}$$

where:

HT and FT are the total BTU content and total flow of the mixed fuel
H1 and F1 are the flow and the BTU content of fuel 1
H2 and F2 are the flow and the BTU content of fuel 2

Furnace Instrumentation

While the control hardware and software are constantly changing, today's furnaces in larger plants such as refineries are usually controlled by DCS systems, with independent PLCs used for safety shutdown. In case of some furnaces, PLCs with human-machine interfaces (HMIs) are also used in place of DCS systems, as are graphic software-supported PC displays located in the control room and in management offices. Smaller furnaces can be controlled by single-loop analog or digital PID controllers.

Both the DCS systems or the microprocessor-based unit controllers provide adaptive gain, auto-tuning, feedforward, and the capability of decoupling the interacting loops. Historical trends and temperature profiles can be graphically displayed,

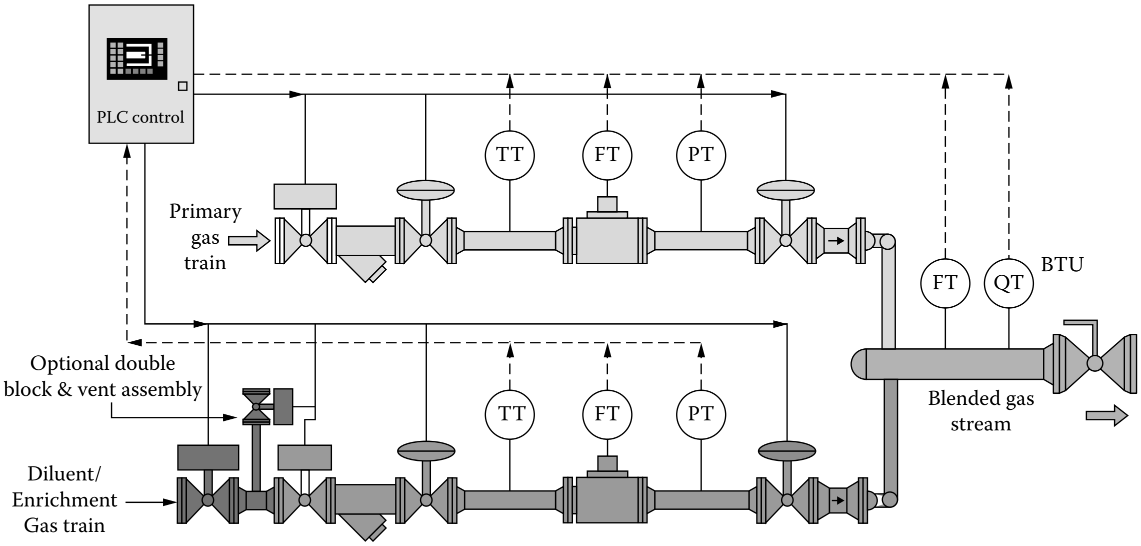


FIG. 8.27n
Pressure- and temperature-compensated fuel gas blending control system used when the BTUs of the blended streams are known, but their ratio varies. This typical controller also handles the safety shutdown interlocks.

and alarm conditions and status summaries can be shown on graphic displays with event printouts. Nuisance alarms can be eliminated by the use of smart alarm logic, and diagnostic messages can be generated for operating and maintenance information. All of these capabilities contribute to reducing the frequency of furnace shutdowns and increase its safety.

Transmitters and Valves Mostly 4–20 mA analog transmitters are used with the digital HART protocol superimposed over the analog signals to the DCS. In order to save on wiring costs, newer installations use Fieldbus networks, but their reliability for critical systems is still under evaluation.

Most field devices and their wiring need to be intrinsically safe or explosionproof, approved for Class 1 Div. 2 Gr. B, C, D. Intrinsically safe units are provided with current-limiting barriers. Most transmitters and I/P or E/P converters are provided with NEMA4X/7 explosionproof enclosures. For analyzers, purged enclosures are also used with proper safeguards (see ISA Standard S12.4).

Field instrumentation should not be located close to potential fire sources, such as on furnace walls. Their wiring should be routed from furnaces to junction boxes or from DCS I/O cabinets that are at a safe distance from potential fire sources, so that in case of a furnace fire, only the wiring to the junction boxes will need to be replaced.

Final control elements, such as control valves or dampers, should be selected so their gain variation will compensate for the variations in the process gain, with the goal being a constant loop gain over the range of the valve openings. Equal-percentage (gain increasing with load) valve characteristics should be used when the process gain drops as the load rises, in order to keep the loop gain at around 0.5.

Control valves should be provided with positioners, in order to overcome packing friction-caused hysteresis, but it is important to make sure that the positioner is faster than the controller that sets it. Newer E/P positioners also provide information on valve diagnostics such as packing problems.

Firing shutdown valves should always be separate from fuel control valves and be of the tight shut-off type with fire-resistant design. Usually, ball valves with steel seat rings are used for shut-off services. One should also consider the use of fireproof insulation of the valve actuators and of the air tanks on air-fail switch valves.

Flame Scanners Only some refinery furnaces are provided with flame scanners. Ultraviolet, visible, and infrared designs can be considered. Ultraviolet flame detectors measure the flicker of a flame in the UV band and are not blinded by the hot refractory (Figure 8.27o). Infrared sensors are able to

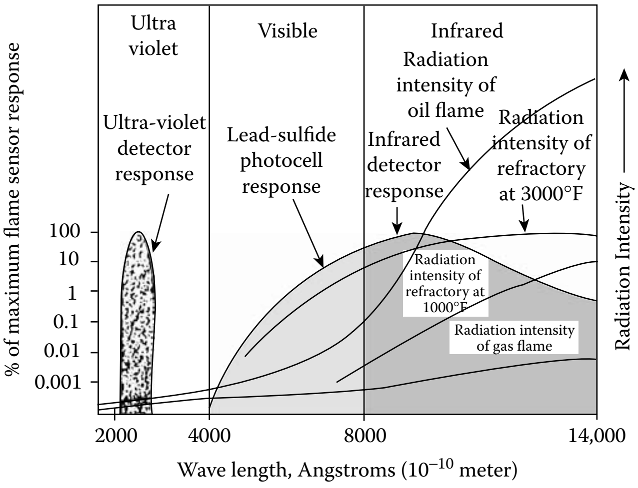

FIG. 8.27o
Applicable ranges of selected flame sensors and the range of hot refractors effect.

penetrate through the flame by-products such as smoke, atomized oil, or steam. Instrument air for purging and sometimes cooling water is also required for these sensors.

FURNACE TYPES

Start-Up Heaters

Start-up heaters are discussed here first because of their simplicity. These units are required at the start-up of a process unit, and their use lasts from a few hours to a few weeks. They are usually vertical, cylindrical units with vertical process tubes along the inner walls and with a single burner centered in the floor. Draft is normally by natural convection induced by a stack mounted on the top of the heater.

Processes that require start-up heaters include catalytic cracking units to heat up fluidized catalyst beds, ammonia units to heat up the ammonia converter catalysts, and fixed-bed gas-drying units to regenerate the dryer beds.

The start-up heater usually heats an intermediate stream, such as air or natural gas, which in turn heats another fluid or solid, such as a reactor catalyst. For example, the start-up heater for an ammonia unit is used to heat "synthesis gas" (primarily a mixture of hydrogen and nitrogen), which in turn is used to heat the catalyst bed in the ammonia converter to a temperature of 700°F (371°C).

The synthesis gas is recirculated through the catalyst bed, gradually bringing it up to operating temperature. After normal operation has begun, the exothermic nature of the ammonia synthesis reaction keeps the bed at a certain temperature, and the start-up heater can be shut down.

Process and Firing Controls The important variables are the flow and temperature of the "synthesis gas." Figure 8.27p shows the necessary controls for the operation of this unit. The flow of the cold synthesis gas is measured by the flow transmitter (FIT-1) and is indicated on a flow indicator (FI-1). The desired gas flow is manually adjusted by operating the hand valve (HV-1), while observing the local flow indicator (FIT-1). The effluent synthesis gas temperature is maintained by the temperature controller (TIC-1), which uses a thermocouple to measure the gas temperature and controls the flow of fuel gas by modulating the control valve TV-1.

The fuel gas firing rate is set by process temperature controller (TIC-1). The heater draft (i.e., negative pressure in the firebox) is produced by the stack; the operator sets it by observing the draft gauge (PI-1) and by manually adjusting the position of the stack damper. Once initially set, the damper is rarely adjusted again, unless the furnace conditions or loads change drastically.

Safety Controls Start-up heaters are usually controlled by simple PLCs or relay systems. Most start-up heaters have flame scanners. Their SIS system requirements have already been described in a previous paragraph.

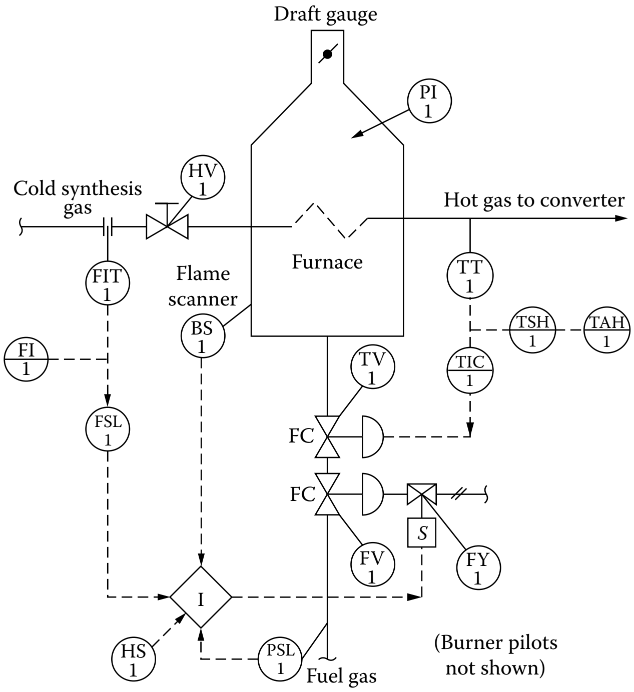

FIG. 8.27p
The controls of a start-up heater.

Fired Reboilers

The fired reboiler provides heat to a distillation tower by heating the tower bottoms and vaporizing a portion of it. Normally, a tower reboiler uses steam or another hot fluid as a source of heat, but where heat duties are great or where tower bottom temperatures must be high, a fired reboiler can be used. Depending upon its size, the reboiler may be of the vertical cylindrical type or the larger, conventional horizontal-type furnace.

The fired reboiler heats and vaporizes the tower bottoms as this liquid circulates by natural convection through the heater tubes. The coils are generously sized to ensure adequate circulation of the bottoms liquid. Temperature of the reboiler return fluid is generally used as the means of controlling the heat input to the tower, provided that the bottoms product material has a wide boiling-point range. Overheating the process fluid is a contingency that must be prevented, because most tower bottoms will coke or polymerize if they are subjected to excessive temperatures for some length of time.

Process and Firing Controls A common control scheme is shown in Figure 8.27q, which depicts the tower bottom along with the fired reboiler. It is usually not practical to measure the flow of tower bottoms to the reboiler, first, because the liquid is near equilibrium (near the flash point), and second, because it is usually of a fouling nature, tending to plug most flow elements.

Proper circulation of the fluid is provided in the careful hydraulic design of the interconnecting piping. An important variable is the reboiler return temperature, which is controlled by TRC-1 throttling the fuel gas control valve. The high-

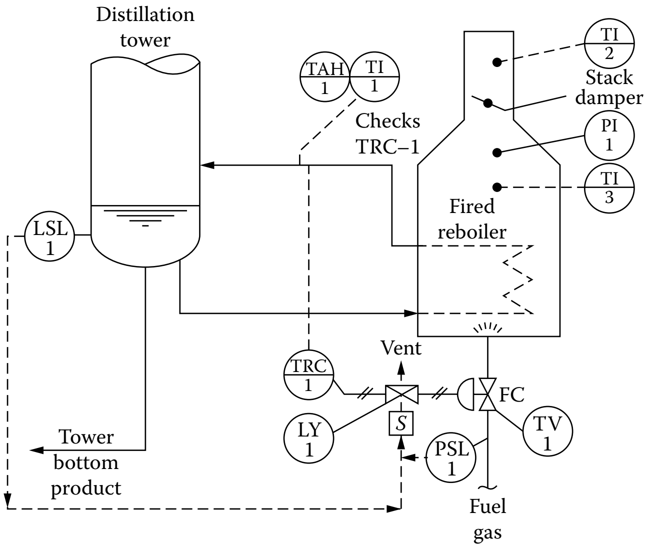

FIG. 8.27q
Fired reboiler controls.

temperature alarm (TAH-1) is provided to warn the operator if the process fluid reaches an excessive temperature.

The reboiler return temperature is actually an inferred indication of the percentage of vaporization. The sensitivity of TIC-1 depends upon the boiling-point range of tower bottoms. A wide boiling-point range provides adequate sensitivity. However, a narrow range does not control well. Often, for these cases, a differential pressure controller is used in place of the reboiler temperature to infer percentage of vaporization. A differential pressure controller (DPIC, not shown) offers increased sensitivity to firing for narrow-range boiling-point fluids.

The firing controls of fired reboilers are relatively simple and are similar to those of the start-up heater. The process temperature controller (TIC-1), or tower differential pressure controller, sets the set point of the gas pressure or flow controller. The fuel in this case is gas, but it could just as well be fuel oil. The furnace draft can be manually set by means of the operator throttling the stack damper while observing the draft gauge (PI-1). The stack temperature (TI-3) and the tube skin temperatures are monitored as checks for excessive temperatures that may develop during periods of heavy firing.

Safety Controls The major dangers in this type of furnace are caused by either the interruption of process fluid flow or by the stoppage of fuel. The loss of process fluid can occur if the liquid level in the tower bottom is lost. If this happens, flow will stop in the reboiler tubes, and a dangerous overheating of these tubes may result. To protect against this, the low-level switch (LSL-1) is wired to close the fuel gas valve (TV-1). For a more detailed description of the required shut-off safety system, refer to Figures 8.27c and 8.27d.

Process and Crude Oil Heaters, Vaporizers

The feed heater of a refinery crude unit is representative of this class of furnaces (Figure 8.27r). Crude oil, prior to distillation into the various petroleum fractions (gasoline, naphtha, gas oil, heavy fuel oil, and residual) in the "crude tower," must be heated to around 750°F and partially vaporized. The heating and vaporization are done in the crude heater furnace, which consists of a firebox with preheat coils and vaporizing coils.

Larger-duty heaters usually have multiple zones encompassing multiple passes, and they heat the oil inside the coils in the convection section of the furnace. This is the portion that does not see the flame but is exposed to the hot flue gases on their way to the stack. The vaporizing takes place at the end of each pass in the radiant section of the furnace (where

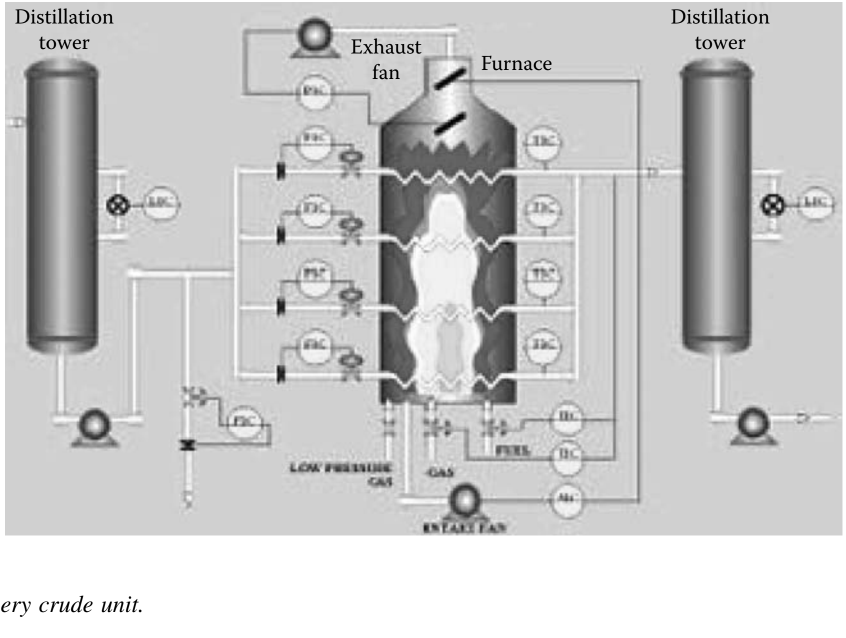

FIG. 8.27r
The feed heater of a refinery crude unit.

the coils are exposed to the flame and the luminous walls of the firebox). The partially vaporized effluent then enters the crude tower, where it is flashed and distilled into the desired "cuts."

Other process heaters that fall into this category are refinery vacuum tower preheaters, reformer heaters, hydrocracking heaters, FCCU feed heaters, and dewaxing unit furnaces. The control system presented is also applicable to these types of process heaters.

Process Controls The prime variables of this process that need to be controlled are

1. The flow of the feed flow to the unit
2. The proper splitting of the total flow into the parallel paths through the furnace, in order to prevent overheating of any one of the streams and to protect against its resultant coking
3. The correct amount of heat supplied to the process stream

Figure 8.27s shows the typical process controls for this type of furnace. The crude feed rate to the unit is set by the flow controller (FIC-4). This flow is split into the parallel paths of the furnace by adjustment of the manually set control valve openings by the hand indicating control (HIC) stations (HIC-1 through HIC-3).

The temperature indicators TI-1 through TI-3 (there may be several TIs on each pass) are periodically observed to determine if unbalanced temperatures are developing in any one of the passes. If such a trend develops, the flow through that pass is altered slightly to drive its temperature back toward the desired norm.

The outlet temperature controller (TIC-4) of the combined crude stream sets the firing rate through a cascade fuel flow or pressure controller (not shown).

However, the desired heat input into the feed stream can be more difficult to control, because the effluent of the furnace is partially vaporized and the feedstock varies in composition depending upon its source. If the feed were only heated and no vaporization took place, the control would require only that the effluent temperature be maintained. If complete vaporization and superheating occurred, this too could be handled by straight temperature control.

In the case of partial vaporization, combined with a variable-feed composition, effluent temperature control alone is not sufficient for reliable control. The composition and, hence, the boiling-point curve of the feed varies with time, and the required control temperature itself also varies. Therefore, additional information is required, and it is obtained from the distillation process, which is downstream of the furnace. By observing the product distribution from the fractionation, a need for changing the heat input can be determined.

Current practice is to achieve approximate control with a temperature controller (TIC-4) whose set point is periodically changed by the operator to account for feed variations. The operator depends both on experience and on the results in the fractionator (possibly a crude tower optimization strategy) to determine the proper temperature setting.

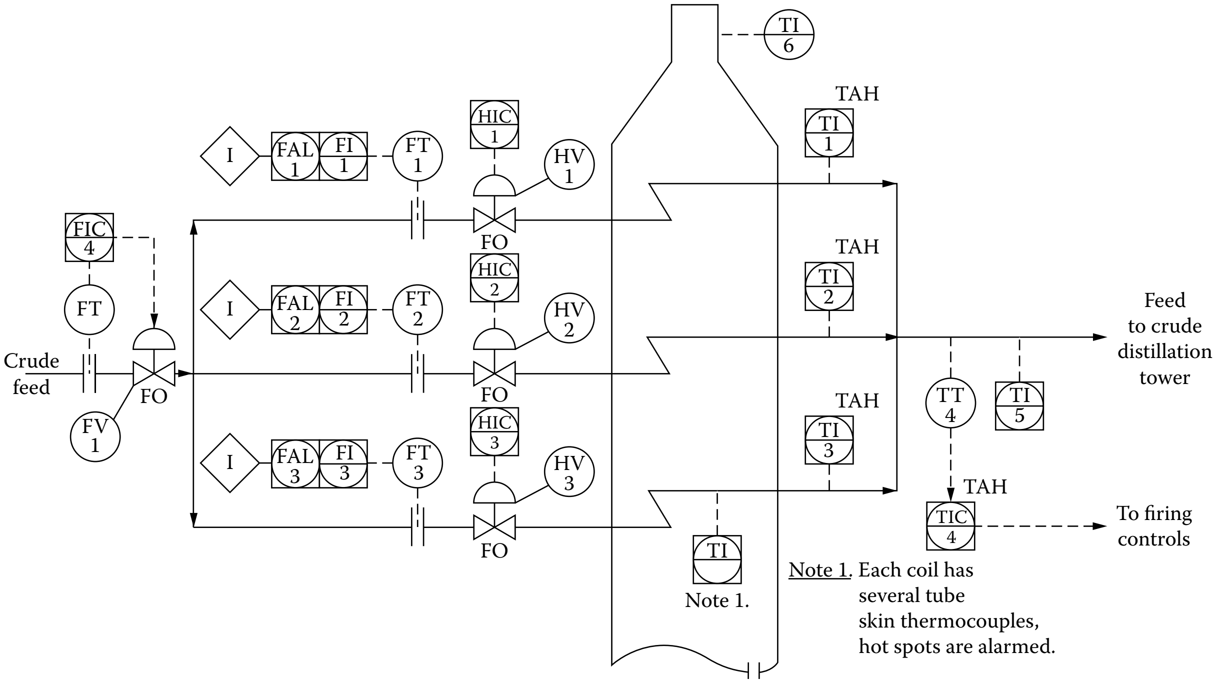

FIG. 8.27s
The controls of a crude heater-vaporizer, in which the flow distribution between the passes is manually adjusted.

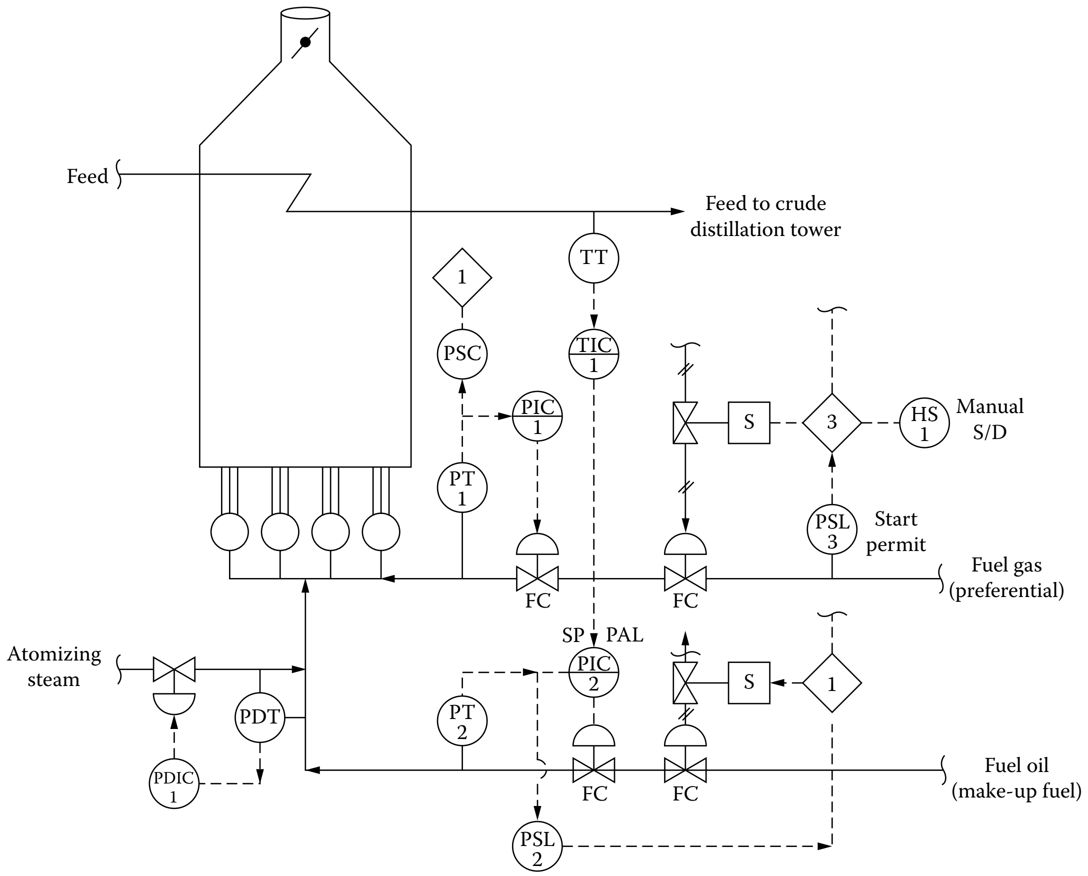

FIG.8.27t
The firing controls of a crude oil heater-vaporizer, in which fuel gas is the preferred fuel and oil is used as the make-up fuel.

Firing Controls

Figure 8.27t shows the firing controls for the furnace using fuel gas (or fuel oil as standby). The fuel gas headers serve many burners spaced equally along the floor of the firebox. The burners, being essentially fixed-diameter orifices, will pass more or less fuel depending on the header pressure. In the past, a pressure controller was often used in place of flow control. Because flow through an orifice is a function of the square root of the pressure, nonlinearity is eliminated by the use of pressure control.

Although fuel oil is the make-up fuel (trim medium), it must be available in sufficient quantity to take the whole load in the event of a fuel gas interruption. The temperature controller (TIC-1) varies the set point of the fuel oil header pressure controller (PIC-2) to satisfy process load requirements.

All burners have turndown ratio limitations. This is the ratio of minimum to maximum fuel burning capacity, which ratio is usually 3:1. Low pressure in the fuel oil header is indicative of the potential approach of a minimum firing condition. Consequently, the low-pressure switch (PSL-2 on PIC-2) is used to warn the unit operator when this situation arises. The operator then has the option of going out to the furnace and manually turning off some of the individual fuel oil burners or to reduce the fuel gas firing rate by lowering the set point of PIC-1. Either change will increase the fuel oil demand and, thus, bring the system back into a stable operating zone.

Newer installations use flow instead of pressure controllers (as shown in Figure 8.27u) on the fuel oil make-up to better control the heat balances. These controls are designed to meet a percentage of the total firing duty assigned to the hearth or floor burners to prevent furnace damage that can result from uneven firing. The percentage of the total firing duty that is assigned to the floor burners is a percentage that is recommended by the furnace manufacturer to protect metallurgy, reduce maintenance, and extend furnace life.

In Figure 8.27u, the effluent temperature controller (TIC-4 in Figure 8.27s) is the cascade master, and it adjusts the set point of FIC-5 to maintain the furnace effluent temperature. Cascading the TIC-4 to FIC-5 is beneficial in that the flow controller compensates for the disturbances (e.g., changes in fuel supply pressure) without allowing them to upset the effluent temperature, whereas the TIC-4 provides the correction required to correct the process for slower ambient changes.

Draft Control Furnace draft is normally maintained by free convection in the furnace (i.e., the stack produces a negative pressure in the firebox), and air is drawn in through louvers

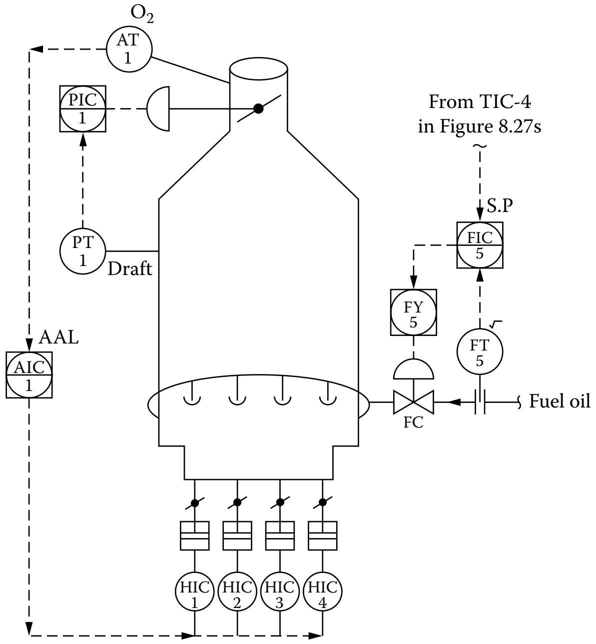

FIG. 8.27u
The firing controls of a crude oil heater-vaporizer with both stock and burner draft controls.

along the sides or bottom of the furnace. This is known as natural draft, because it is produced without mechanical means. Draft is controlled by pneumatically or motor-operated dampers in the stack.

Some furnaces use burner louvers with piston actuators for oxygen control (Figure 8.27u). Here, the overall furnace draft pressure is controlled by dampers in the stack, which are throttled by PIC-1, the draft controller, which strongly influences the O_2 content, because an increase in draft increases excess O_2. It is difficult to maintain the optimum (minimum) excess O_2 concentration in the flue gas without reaching dangerous pressure conditions at the furnace vault. Low excess O_2 and safe high arch/draft pressure limits are sometimes implemented in a duty constraint (cut-back) control configuration.

Damper characteristics are usually less than ideal, and linkages may stick. Installing powerful damper actuators will pay off in fuel savings. Newer furnaces with induced draft fans are usually provided with segmented damper blades, which have a near-linear characteristic. The nonlinearity of dampers can be compensated by using error-squared algorithms in their PID controllers.

Draft may violently oscillate, which can cause noise and furnace vibration. Therefore, measurement signal dampening is often required for PIC-1 in Figure 8.27u. The dampening filter should be so designed as to filter out fast pressure oscillations, but allow for the accurate measurement of all major pressure excursions in draft.

Changes in ambient temperatures, wind force and direction, or rain can also upset both the draft and the temperature controls. Draft controls set points should be selected with sufficient safety margins that a major storm will not cause the development of excessively low draft pressures.

If the furnace is large, or is provided with SCR NO_x abatement controls, forced draft fans that operate at positive pressures will serve the firebox. If the fans are located at the outlet of the combustion zone, they usually operate at below atmospheric pressures and are called induced draft fans. They usually are provided with variable-speed drives (VSDs).

Excess Oxygen Control The zirconium oxide stack oxygen analyzer (Figure 8.27k) that is used for combustion control can also be used to display the O_2 concentration next to the draft PIC (Figure 8.27u). This allows the operator to adjust the stack damper draft controller set point to keep the furnace pressure safely "on the negative side" and yet approach the optimum excess air concentration.

Attempts to reduce excess air by maintaining excess O_2 to 2–3% often fail, because of the draft limitations. Most furnace SIS systems are set to shut down if draft is out of limits for over 5 sec. The high-draft or low-pressure limit is usually set at any pressure below –1.0" W.C. (in order to prevent buckling of the steel or damaging the refractory lining). The high-pressure or low-draft limit is usually set at any pressure that is below 0" W.C., because overpressure could force the flames out and cause the burning of the sidings.

The sample tap (Figure 8.27h) serving the O_2 analyzer is often used to also bring a heated sample to the NO_x analyzer.

Safety Controls The primary sources of hazards in the operation of process heaters include the interruption of the charge flow, and the interruption of the fuel flow and resultant loss of flame. The reduction of crude charge rate below a minimum rate will result in overheating and possible tube rupture. Resumption of flow may cause hydrocarbon leakage into the firebox, with catastrophic results. The low-flow alarms (FAL-1, -2, or -3 in Figure 8.27s) alert the operator of this impending condition. If this happens, the operator has the option of correcting the fault or terminating the firing. If the instrument air supply fails, the control valves (FV-1 and HV-1 through HV-3) will fail open, thereby maintaining the flow through the furnace coils.

For the discussion of general safety requirements and the related PLC system design, refer to the earlier discussion on "Safety Instrumented Systems."

Reformer Furnaces

The purpose of a reformer in an ammonia plant is to produce hydrogen, which is used with nitrogen in the synthesis of ammonia (NH_3). Hydrogen is produced by reforming the hydrocarbon feed. This feed (usually methane or naphtha) is reformed with high-pressure steam, as shown in the reaction described in the equations below:

$$\underset{\text{(methane)}}{CH_4} + \underset{\text{(steam)}}{H_2O} = \underset{\text{(hydrogen)}}{3H_2} + \underset{\text{(carbon monoxide)}}{CO} \qquad \textbf{8.27(14)}$$

$$\text{General}: C_nH_{(2n+2)} + nH_2O = (2n+1)H_2 + nCO \qquad \textbf{8.27(15)}$$

The carbon monoxide is removed by further reaction later in the process. The reaction is endothermic (absorbs heat) and takes place at pressures of approximately 450 PSIG (3.10 MPa) and at temperatures of around 1500°F (815°C).

The reaction takes place as the feed gas and steam pass through tubes filled with a nickel catalyst, which is heated in the radiant section of the reformer furnace. Steam must be provided in excess of the reaction requirements to prevent the side reaction of coke formation on the catalyst. The coking of the catalyst deactivates it, requiring expensive replacement. To minimize coking, steam is usually supplied in a ratio of 3.5:1 by weight, relative to feed gas. Special precautions must be taken to maintain the excess steam at all times, because even a few seconds of interruption in the steam flow, while feed gas continues, can completely ruin the catalyst charge.

Process Controls The major controlled process variables are the feed gas flow, the reforming steam flow, and the temperature and composition of the effluent. As illustrated in Figure 8.27v, the feed gas flow is maintained by means of a pressure-compensated flow controller (FIC-1). Pressure compensation of flow corrects the measurement for fluctuations in feed gas pressure. The steam rate is maintained by means of FFC-2, and the ratio of steam to feed gas flow is continually monitored.

The ratio controller FFC-2 measures the ratio by dividing the gas flow signal from FT-1 with the steam flow signal from FT-2. If this ratio falls below the limit of approximately 3:1, a low flow ratio alarm (FAL) is sounded. If the ratio continues to fall below approximately 2.7:1, the feed gas is shut off by closing the valve (HV-1).

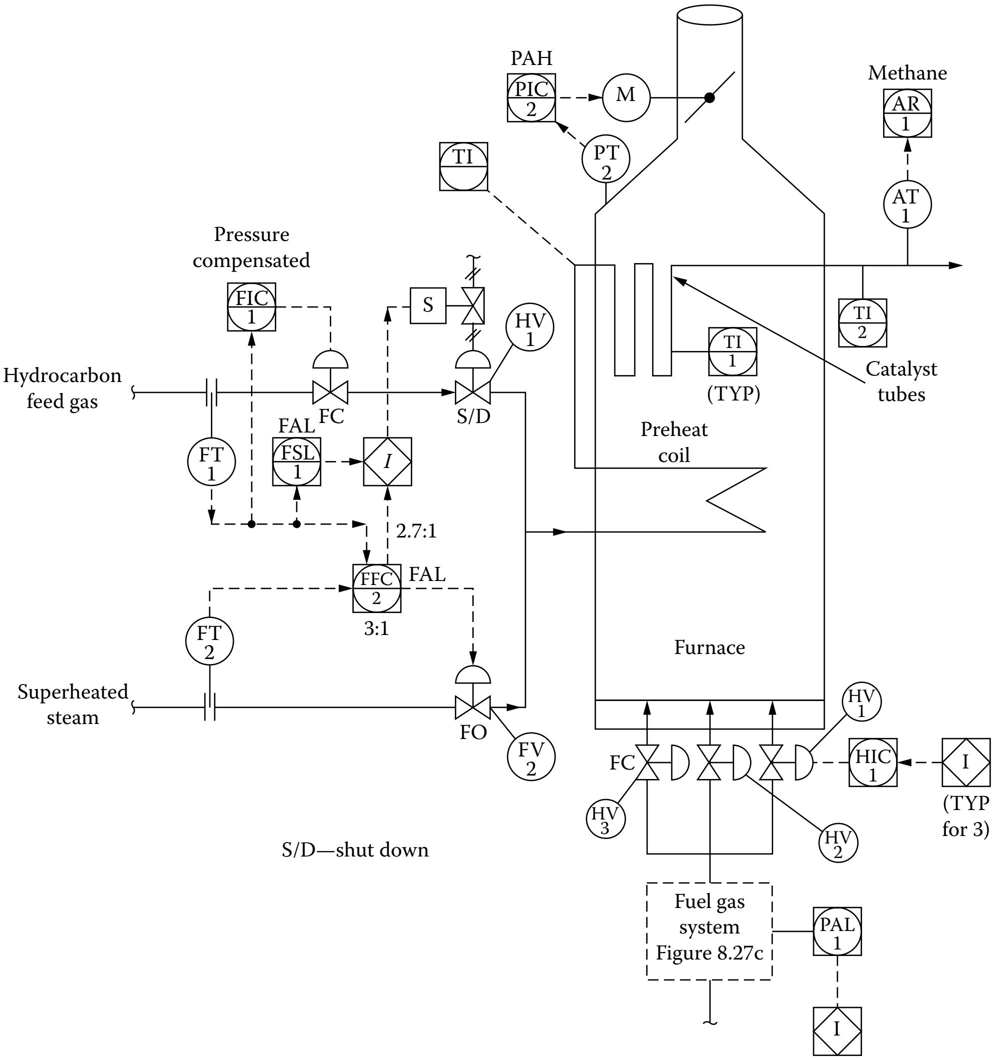

FIG. 8.27v
Reforming furnace process controls by manipulating the steam flow in ratio to the hydrocarbon feed.

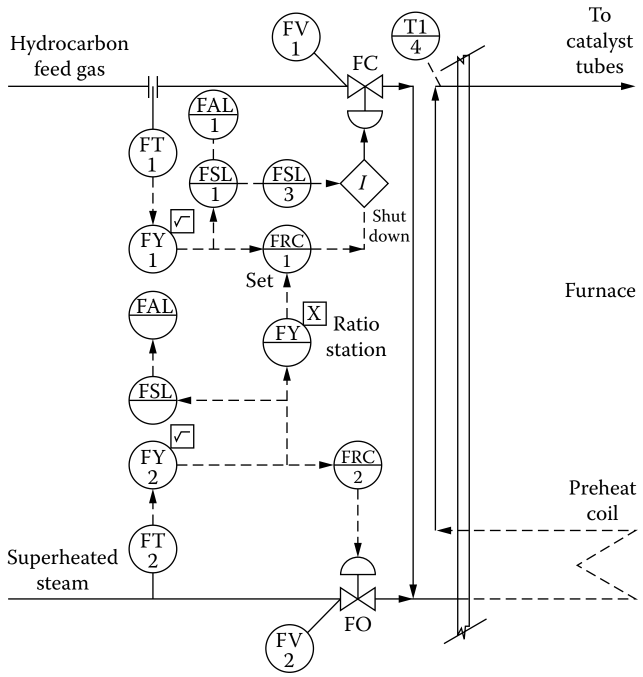

FIG. 8.27w
The reformer furnace control shown here (ratioing feed flow to the steam flow) is less stable than keeping the steam flow constant and ratioing the feed, as shown in Figure 8.27v.

If there is no separate shut-off valve (HV-1), the feed valve (FV-1) must be a quick-closing valve (4–5 sec for full closure) so that the flow of gas can be stopped almost instantly if the flow of reforming steam fails, thus protecting the reformer catalyst. If the shut-off valve HV-1 is used, but it is electric motor operated, FV-1 must also be a single-seated tight shut-off valve, to prevent leakage during the time while the electric-operated shut-off valve is closing.

An alternative to the controls shown in Figure 8.27v is illustrated in Figure 8.27w. Here, the steam flow is on straight flow control, and the hydrocarbon gas feed tracks the steam flow on ratio control. In theory, this appears to be an improvement over the previous control system, but in practice, the dynamics of the measurements and of the process make it less stable. The noise in the steam flow measurement and lags may result in cycling of the gas flow set point. Therefore, the integrated error in the gas flow obtained by the control strategy in Figure 8.27w can be considerably greater than when Figure 8.27v is implemented.

Manipulation of the steam instead of the feed gas is the most common method of alleviating this problem.

The effluent analyzer (AT-1 in Figure 8.27v) is used to determine reaction completion by measuring the methane (CH_4) content of the stream. Manipulating the profile of the furnace temperature can serve to achieve the desired degree of conversion.

This analyzer (AR-1) can be either an infrared or a chromatographic analyzer. The analysis is relatively simple, involving the measurement of 0–10% methane in a background of hydrogen and carbon monoxide. The only difficulty is the high water content in the stream, caused by the presence of excess steam used in the reaction. Therefore, water removal devices are required in the analyzer sampling system.

In newer DCS controls, the rates of competing reactions can be predicted so that the firebox and the optimum heat input profiles can be computed and set.

Firing Controls Firing of a reformer furnace, because of its massive design and great heat inertia, is often manually controlled. The furnace has approximately a dozen fuel headers with about 20 individual burners per header. Process temperature indicators TI-1 and TI-2 (on Figure 8.27v) are provided at the exit of the reaction tubes. These are constantly monitored, and periodic adjustment of firing is made by manipulation of the fuel header control valves (HV-1, HV-2, HV-3) in Figure 8.27v. The pressure upstream of the header control valves is controlled, so that once the valve stroke is set, fuel flow remains constant.

The fuel used is usually natural gas, with a small amount of purge gas from the NH_3 synthesis loop blended in.

Draft is usually maintained in these furnaces by a steam turbine-driven induced draft fan. The furnace draft (negative pressure) in the firebox is controlled by adjusting the fan speed. The pressure indicator controller (PIC-2) measures the pressure in the furnace (via PT-2) and controls the speed of the fan by adjusting the fan turbine governor to hold the furnace pressure at the desired setting. The draft points PI-1 through PI-4 are used to manually set the openings of the air inlet louvers, on the side of the furnace, to balance the drafts at various points in the furnace.

Safety Controls SIS controls are essentially the same as for the other furnaces described previously.

Upon instrument air failure, the gas feed valve (HV-1 in Figure 8.27v) closes to prevent coking the reformer catalyst. The fuel valves (HV-1, HV-2, and HV-3) close to stop firing during emergencies. The steam valve (FV-2 in Figure 8.27v) is a fail-open valve to maintain the flow of cooling steam through the furnace coils during such emergencies.

Cracking (Pyrolysis) Furnaces

An example of a cracking furnace is the ethylene pyrolysis furnace. Feedstock, which can vary from heavy gas oil, LPG, propane, to ethane, is preheated and vaporized in a preheat coil in the furnace and is then mixed with steam and cracked.

Steam is added to the feed in a fixed ratio to the hydrocarbon to reduce the partial pressure of the hydrocarbon feed. This tends to maximize the amount of olefins produced and to minimize the coke build-up in the coils.

The feed is heated to 1500°F (815°C) in the pyrolysis coils, which causes the cracking of the long chain hydrocarbons into shorter chain molecules and initiates the forming of such unsaturated (olefin) molecules as ethylene. The severity of cracking is dependent upon the temperature achieved and upon the residence time in the pyrolysis coils. Therefore, the distribution of furnace products is dependent upon the degree of firing and upon the temperature profile in the furnace. Effluent from the furnace is quickly quenched to prevent recombination of products into undesirable polymers.

Process Controls The important variables to be controlled in order to obtain the desired effluent product distribution are hydrocarbon feed flow, steam flow, coil temperatures, and firebox temperature. The firing controls discussed in connection with the previously discussed furnaces are also applicable here.

As shown in Figure 8.27x, the charge to the cracking furnace is determined by the flow controls on each of the individual passes rather than by total flow control. It is important to keep the flow through the coils constant, because coking causes a gradual build-up in the pressure drop through the coils and reduces both the flow and the heat transfer.

If the feed distribution were left purely to hydraulic splitting, the coking would start in one coil and reduce the flow through that coil, which in turn would cause overheating of that coil, producing even more coking. Eventually, the flow would be reduced to such a low rate that the overheating of the coil would cause its melting and rupture. The individual flow control valves serve to introduce variable pressure drops, which are adjusted to guarantee that all coils will coke at an almost equal rate.

The steam flow controllers (FIC-7 is shown as typical for all three) regulate the steam flow to match the total flow of hydrocarbon feed, controlled by FIC-4. The temperature controller (TIC-4) sets the firing controls by adjusting the total heat input to the process and brings the effluent temperature to the desired value.

The temperature indicator points (TI-1 through TI-6, as well as the tube skin temperature sensors) are monitored by the process operator to maintain a certain furnace temperature profile and, hence, a certain product distribution in the furnace effluent. The temperature relationships are accomplished by manually trimming burners at the required places in the firebox.

In order to determine whether the desired product specifications are being met, an analyzer is installed in the furnace effluent (AT-1). This analyzer is usually a chromatograph, though mass spectrometers could also be used, if the speed of response of this analysis was critical. This analyzer measures most of those components in the effluent stream that are lighter than butane.

This analysis is a difficult one, primarily because of the sample handling requirements. The sample has a high water content, and the water must be condensed and removed before the sample entrs the analyzer. The sample also has a

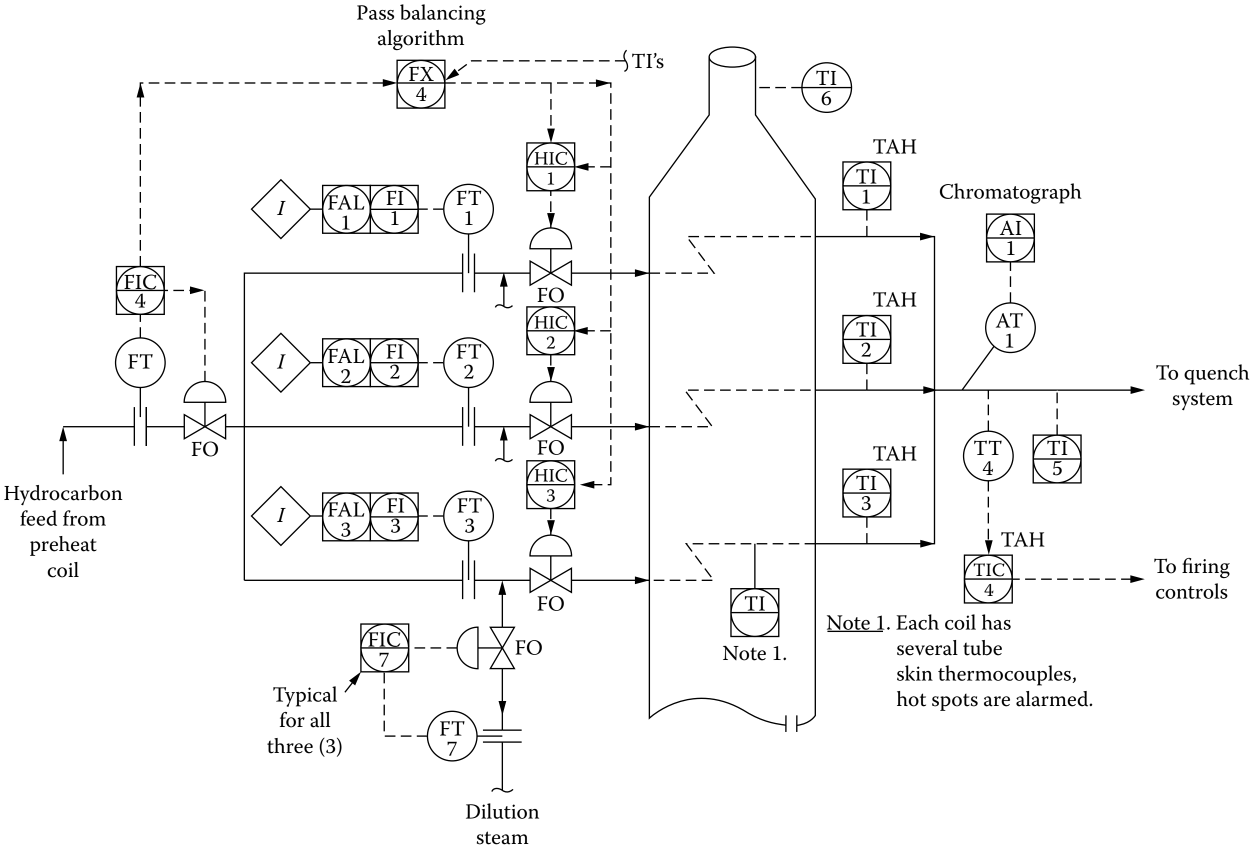

FIG. 8.27x
Pyrolysis furnace process controls.

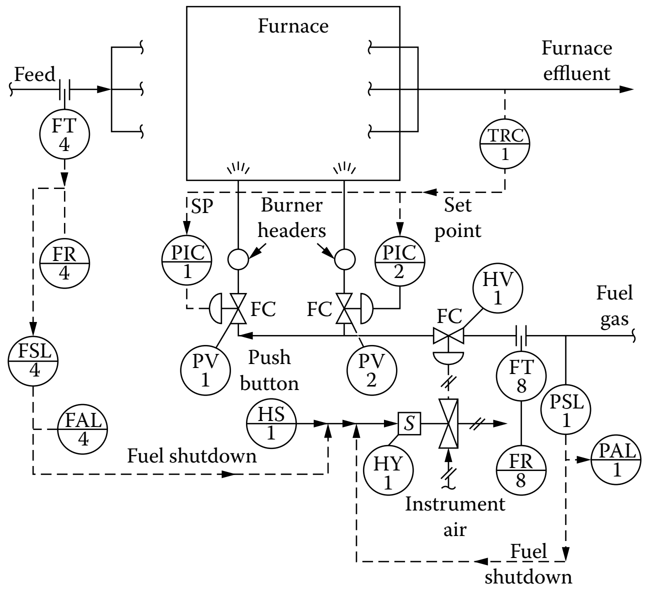

FIG. 8.27y
Pyrolysis furnace firing controls.

large amount of entrained coke and tars, which likewise must be eliminated (scrubbed out).

Safety Controls The major hazards in operating cracking furnaces are the interruption of the feed flow, the interruption of the fuel flow, coking of the individual coils, and the failure of the instrument air supply. Interruption of feed flow can result in a dangerous situation if firing is maintained at the normal rate, because the tubes are not designed for the excessive temperatures that result if charge is stopped or drastically reduced, and the danger of tube rupture is, therefore, pronounced.

The low-flow alarm (FAL-4, Figure 8.27y) is provided in the feed stream to warn of impending danger. Once it is verified that the danger is real, the vent solenoid valve (HY-1) can be tripped by the operation of the pushbutton (HS-1) that vents the diaphragm of the emergency valve (HV-1), shutting off the fuel gas. This shut-off can be automated, so that on a drop in the feed flow, a low-flow switch (FSL-4) automatically actuates the trip solenoid (HY-1), which cuts off the fuel flow.

Interruption of fuel flow will cause burner flameout, and resumption of fuel flow may result in a dangerous (fuel-rich) fuel/air mixture. To protect against such resumption of fuel flow, the low-pressure switch (PSL-1) is used in Figure 8.27y, which trips the emergency shut-off valve (HV-1) via the solenoid valve (HY-1). The solenoid valve is the manual reset type; therefore, once tripped it will reopen only if manually reset.

Excessive coking of an individual furnace coil can occur as a result of the restriction of the flow through it. This is a self-worsening effect and tends to cause dangerous overheating. The prevention of this situation is of prime concern. Should such a condition occur, it will be detected by the high-temperature alarms (TAH-1 through TAH-3 in Figure 8.27x) to warn the operator.

In response, the operator can increase the set point of the appropriate feed flow controller, thus forcing more fluid through the hot tube, thereby hoping to bring the temperature down. If this does not alleviate the condition, the operator has no alternative but to shut down the firing.

Failure of instrument air will result in failing all the control valves open, as in Figure 8.27x. The feed valves and the steam valves open on air failure to continue the flow through the furnace coils and, thereby, to prevent overheating and possible rupture of the coils.

ADVANCED CONTROLS

Advanced furnace controls include feedforward control based on feed rate, cross-limiting firing (Figure 8.6rr in Section 8.6), coil balancing (Figure 8.21r in Section 8.21), and optimization. Implementation of these control strategies is normally aided by expert system software, distributed control systems, single or dual loop programmable controllers, or dedicated microprocessor-based devices can also perform this type of control to a limited extent. An example of each type of control is presented in the next paragraphs. Control systems can include any combination of these advanced techniques.

Feedforward Control

In feedforward control, a simplified model of the process is used to predict the effect of disturbances before they reach and can upset the controlled variable. In contrast, feedback control must first detect an error in the controlled process variable before it can initiate a corrective action.

A simple example of feedforward control is given in Figure 8.27z. Here the feedback loop consists of the temper-

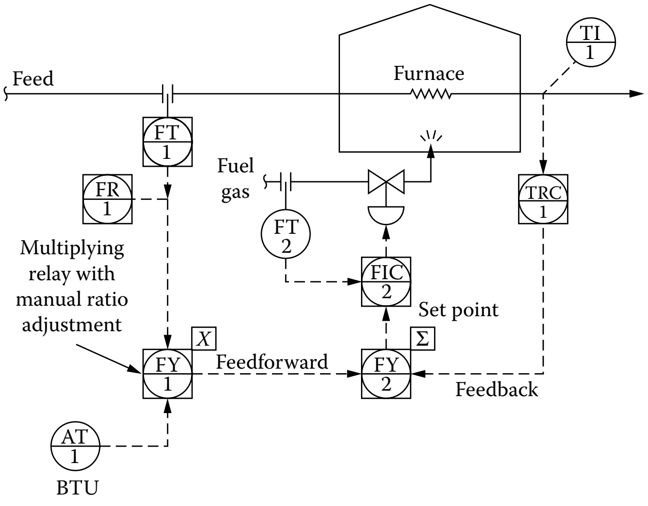

FIG. 8.27z
Feedforward adjustment of furnace firing rate can minimize upsets caused by feed flow changes.

ature controller (TIC-1) providing the set point for the fuel flow controller (FIC-1). When the feed flow to the furnace changes (this flow is an independent variable in this system), there is a need to change the rate of fuel firing.

The feedforward loop includes the feed flow transmitter (FT-1), which detects the change in feed flow rate, and this rate is multiplied by a constant in FY-1. This constant relates to the heating value of the fuel gas, and if a BTU analyzer (AT-1) is used, the correction can be automatically obtained. This multiplying block sets the relationship between a change in feed flow rate and the required corresponding change in fuel header pressure. This is an empirically determined value and can be field-adjusted.

Dynamics may be included (dead time, lead/lags) if warranted (this topic is discussed in full detail in Section 2.9 in Chapter 2). The response of the furnace to an increase in firing rate is often too slow, and therefore such controls are useful only when responding to step changes in feed flow rate.

The modified signal from FY-1 is then summed (FY-2) with the signal from the temperature controller output, thereby setting a new fuel gas flow rate via FIC-2. In effect, advance information is fed forward through FY-1 to the firing controller (FIC-2), indicating that a change in process load will require a change in firing rate shortly and that the firing rate, therefore, should begin to change.

Without the feedforward leg of the loop (FY-1 and FY-2), the required change in firing rate would take place much later, after the temperature controller (TRC-1) detects an error in the controlled variable (the effluent temperature of the furnace). If a constant ratio existed between feed flow and fuel gas flow, the temperature controller would not even be necessary, but with changing ambient and process conditions, this ratio changes with time. Thus, TRC-1 acts in the feedback path as a slow trim-controller, keeping the controlled variable at a desired value.

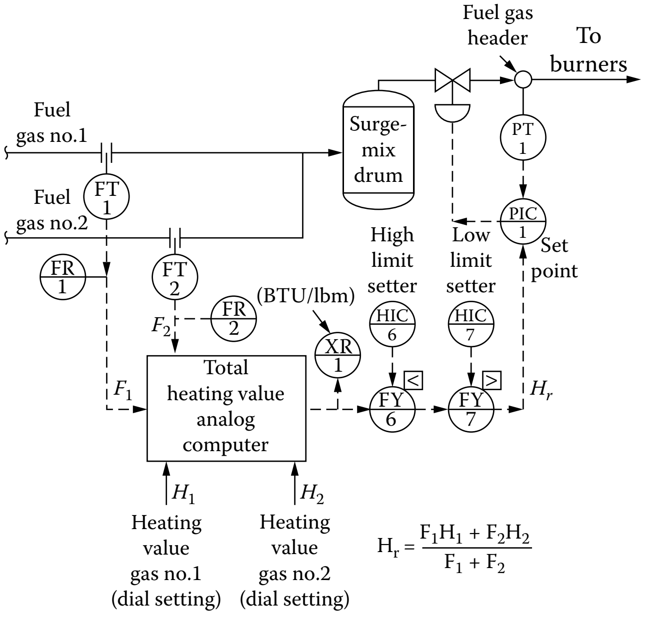

FIG. 8.27aa

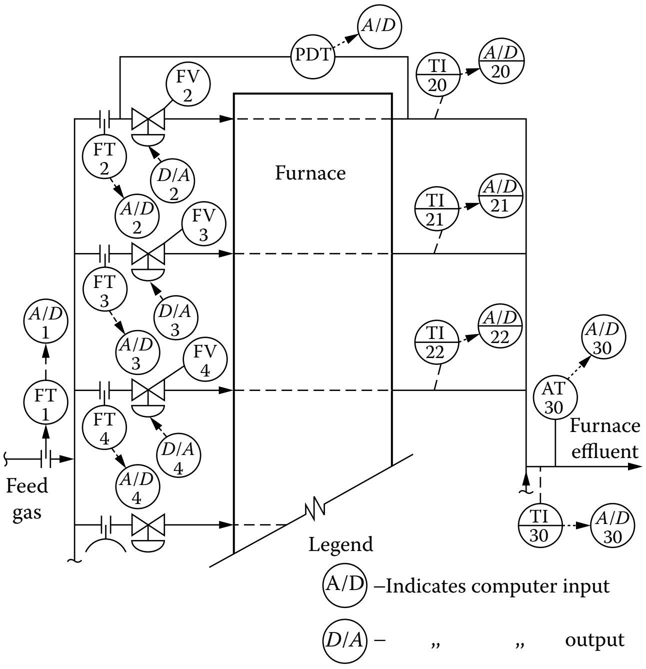

FIG. 8.27bb
The I/O requirements of a digitally controlled pyrolysis furnace.

Coil Balancing Control

One of the main considerations in a multipass furnace control is the proper splitting of feed among the parallel passes through the furnace. In a large ethylene plant, six to eight identical cracking furnaces may be present, each with from 10 to 20 parallel coils. Maintaining proper flow splits in these coils is a formidable task if done manually.

The objective is to maximize furnace energy utilization per unit of feed flow. In general, heat transfer efficiency is highest when the percentage of vaporization measurements in all the coils are equal. However, without a measurement of percentage of vaporization, the best that can be done is equalization of all the individual coil outlet temperatures.

Digital control of the total furnace circulation is implemented by feedback manipulation of all furnace coil flow rates. Figure 8.27bb shows an older computer control system. Here, the total feed flow (A/D-1) and the individual coil flows (A/D-2, -3, -4, etc.) are monitored by the DCS system, which calculates the proper valve settings based on these flows. The proper valve openings are sent by the DCS system (through the digital-to-analog converters (D/A-2, -3, -4, etc.), and the valves divide the total feed flow properly.

The total feed flow rate sets the total charge to the furnace. Each coil flow rate set point is calculated as the total furnace flow (minus the flow of all nonautomated coils), divided by the number of coils that are automatically controlled. This allows for coil balancing of at least a portion of the furnace, if some of the coils cannot be placed under automatic control due to defective instrumentation.

After start-up, the total flow will be divided equally among the passes, but as time progresses, coke builds up at different rates in the individual coils, causing outlet temperatures to vary from coil to coil. This control system keeps the coil effluent temperatures the same (within some tolerance) by adjusting the flows of the feeds through each coil. The DCS system does this by taking the effluent coil temperature information (A/D-20, -21, -22, etc.), comparing them with the desired temperatures, and modifying the "feed-splitting" computation to correct for deviations. The results of the computation are sent out to reposition the feed valves (FV-2, FV-3, FV-4, etc.).

Changes to the furnace charge rate are normally ramped, and their speed of change is limited to avoid rapid upsets in the furnace. Limit constraints, including a differential flow limit between each coil and the average coil flow, are normally included in the overall control algorithm to maintain safe flow rates in all coils, in order to prevent excessive coking or development of hot spots in the furnace.

Many additional optimization functions can be performed using much of the same input data. Some of these are "off-normal" alarms on feed flow, "off-normal" alarms on effluent temperatures, alarms to signal excessive pressure drops across coils, high coil-metal temperatures, and other scanning functions.

Cross-Limiting Firing

A cross-limiting firing control technique ensures that air is always in excess of the amount required to fully combust the fuel. This avoids hazardous (fuel-rich) combustible mixtures in the firebox. When an increase in firing rate is needed, cross-limiting firing controls first increase the airflow, and the fuel flow only after that. When a decrease in firing rate is desired, the strategy reduces fuel flow before reducing the airflow. This is performed through a combination of high- and low-select modules and dynamic exponential lag modules. A control block diagram of the cross-limiting firing circuit is shown in Figure 8.27cc.

The success of the cross-limiting firing is predicated on being able to measure or infer the air and fuel flow rates (see Table 8.6d in Section 8.6 for sensors). If the airflow is controlled only by damper position, this flow rate must be interpolated from the damper position. Also, fuel is often not metered, but only controlled by a pressure controller, so the

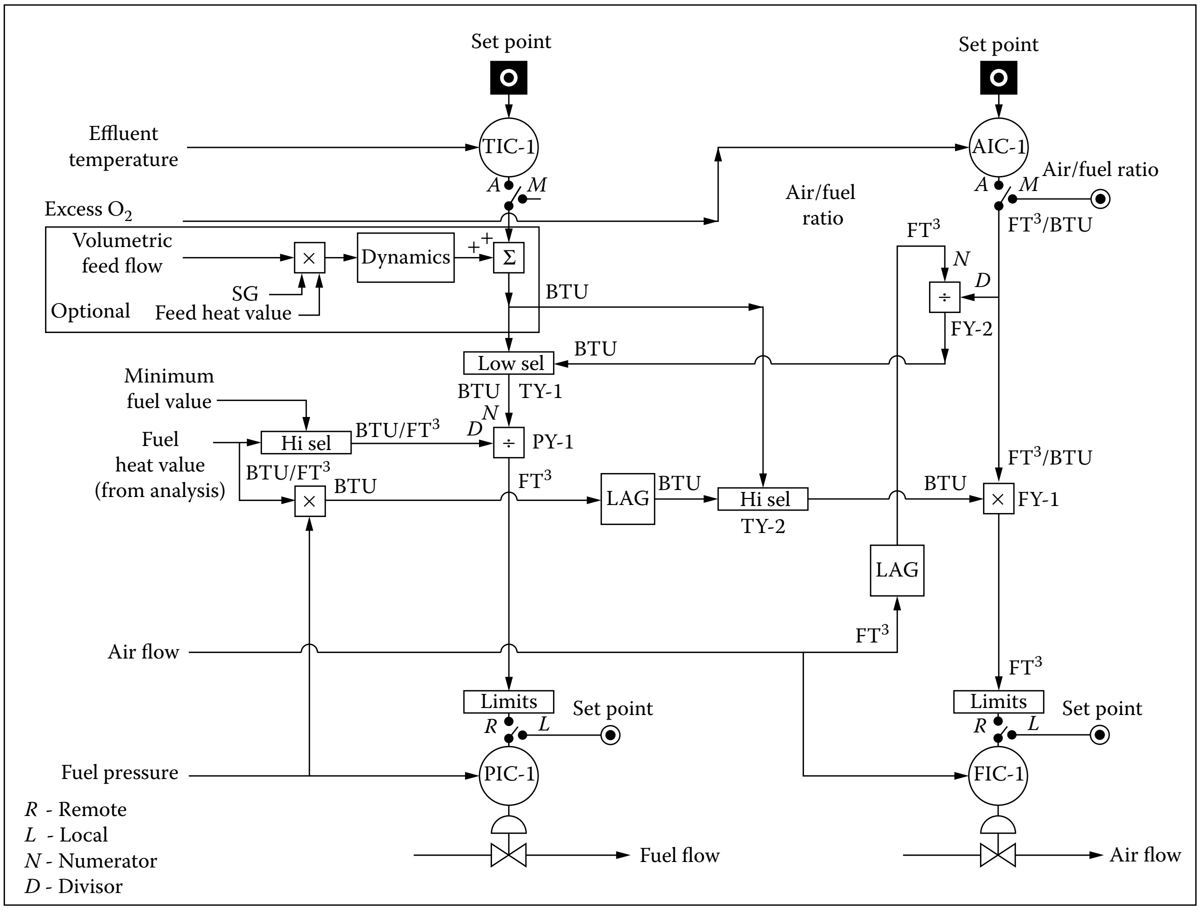

FIG. 8.27cc
Cross-limiting firing control block diagram.

header pressure must be converted into an approximation of flow rate. Such indirect methods of flow approximations are highly inaccurate and should no longer be used.

The cross-limiting firing system described in Figure 8.27cc works in the following manner: When the effluent temperature controller (TIC-1) calls for additional heat to be supplied by the furnace, the output of the controller increases. After feedforward adjustment, this signal goes to both a high- and a low-signal selector (TY-1 and TY-2).

At the high-signal selector, this rising signal will be greater than the signal representing current fuel flow (pressure). The high select (TY-2) will thus call for increased heat by increasing its output, and this increased signal will be multiplied by the current air/fuel ratio in FY-1. The output from this multiplier (FY-1) goes to the set point of the airflow controller (FIC-1). Therefore, the result of an increase in the output of TIC-1 is an immediate increase in the airflow controller set point.

At the low select (TY-1), the increasing TIC-1 output signal will not be chosen because it is greater than the signal supplied by the air/fuel ratio FY-2. The airflow measurement signal is sent through a lag block and is divided by the air/fuel ratio set point in FY-2, which produces the second input to the low selector. The immediate increase in air, which followed the rise in TIC-1 output, is thus lagged with a first-order lag block prior to the low select (TY-1), resulting in a gradual increase in fuel. Therefore, an increase in the firing rate (TIC-1 output) results in a fast increase in air and a slow increase in fuel flow.

When the firing demand drops due to a drop in the feed flow or in the temperature controller output, the reduced signal is sent to both the high and low selector modules (TY-1 and TY-2). The dropping signal is immediately passed through by the low selector (TY-1), resulting in an immediate decrease in the fuel flow set point.

However, at the high selector (TY-2), the decreased signal is blocked, because the lag element keeps the apparent flow of fuel higher. The result is a slow (first-order lagged) reduction in the flow of air. A change in the output of the excess air (or O_2) controller (AIC-1) goes through the low selector on the fuel flow (TY-1) in a similar manner. The output of the controller (AIC-1) is the air/fuel ratio setting for the furnace, which is multiplied by the signal from the high selector in FY-1. Therefore, the air/fuel ratio directly affects the airflow set point. This same air/fuel ratio is the divisor at the airflow in FY-2. The output of FY-2 is the second input to the low selector TY-1, which selects the fuel oil flow set point.

Severity Control

Using the ethylene cracking furnace in Figure 8.27bb as an example, an analyzer measuring the effluent stream composition (AT-30) also sends its measurement signal to the computer, where it is compared with the desired composition. Based on the difference between the two, the desired degree of fuel firing in various furnace zones can be computed.

These firing rates may be printed out as instructions to the operator or used to automatically manipulate the fuel valves, or fuel flow controller set points, thereby changing the heat flow pattern throughout the furnace and thus controlling the cracking operation.

Model-Based Control

Process models can relate the control variables of the radiant coil to operational parameters. Information on furnace operation includes hydrocarbon flow rate, steam-to-hydrocarbon ratio, coil outlet temperatures and pressure, severity of cracking, and fouling parameters. These parameters are used to develop interrelationships between independent and dependent variables.

Matrix calculations can be performed to change the manipulated variables so that the controlled variables are held at their set points. General-purpose computing modules are used to run these models and optimizers. For in-depth coverage of a variety of model-based control approaches, refer to Sections 2.13 to 2.18 in Chapter 2.

Two common applications of model-based control will be briefly discussed below.

Coil Outlet Temperature (COT) Matrix The individual COTs can be simultaneously controlled by solving an interaction matrix that relates the change in each coil temperature to the change in valve openings of the wall burners. The matrix coefficients determine the gains associated with each COT-firing zone pair.

Knowledge of furnace geometry and experimental data is employed to define the matrix. If the matrix accounts for only the steady-state character of the process, the dynamic nature must be handled by feedback trimming of the COT controllers.

It may be necessary to remove the excess degrees of freedom that result from having more wall burners than COT measurements. This can often be accomplished by interpolating the desired wall burner valve positions on the basis of the outputs of adjacent COT controllers.

Provisions should be made to disable controllers whose thermocouples have failed (burned out). The proper installation of tube surface-detecting thermocouples is shown in Figure 8.27dd.

Because of the harsh service, COT thermocouple (T/C) failure is a routine incident that the control strategy must handle. To detect the thermocouple burnout, it is necessary to detect the loop resistance of the installed thermocouple (Figure 8.27ee).

Dual or companion thermocouples can be connected to multiplexers and can be used to validate the COT measurements. When a COT controller is placed in manual, its output is forced to be equal to the average output of the COT controllers that are still controlling the process (the average of those controllers that are not in manual).

In this way, temperature control for the failed coil is still maintained to some extent, and responses are made to

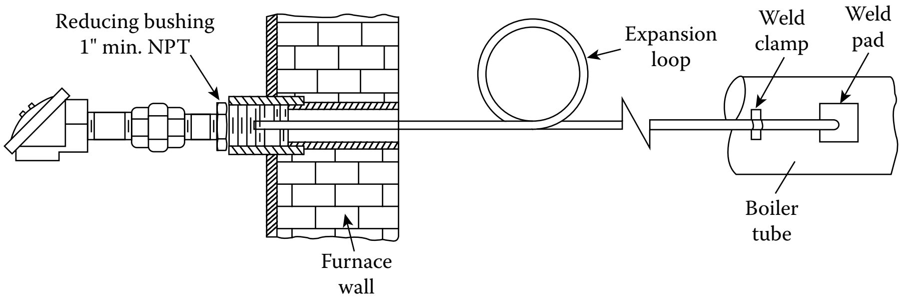

FIG. 8.27dd
The expansion loop allows for thermal expansion in furnace applications.

disturbances that are affecting all the coils. This approach has proven to be an effective solution whenever thermocouples are to be replaced on-line.

The use of a matrix algorithm alone does not necessarily guarantee an even firing pattern, because there is no feedback component in this strategy to correct for errors in the matrix model. Over time, as the effects of coking, air register adjustments, and burner fouling are better understood in a particular installation and when they are better quantified, solutions can be implemented by shifting the duty requirements between the firing zones in such a way as to equalize the bias station positions.

Optimizers Optimizers are used to calculate the required charge rates and the severity of cracking of ethylene furnaces, based upon financial or contractual criteria. The model-based program then simultaneously manipulates several independent variables to achieve these dependent control points.

The model solves simultaneous polynomial equations relating severity to charge rate, steam-to-hydrocarbon ratio, furnace effluent temperature, excess oxygen, and coil fouling rate in a matrix format. Outputs to local controllers or valves are then adjusted all at once.

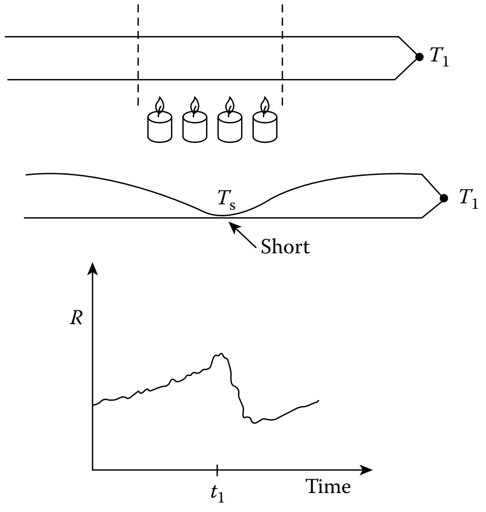

FIG. 8.27ee
Thermocouple burnout can be detected by measuring the resulting drop in thermocouple loop resistance.

CONCLUSIONS

The furnaces and control systems discussed in this section are representative of a wide spectrum of furnaces throughout the process industry. The strategies are valid whether implemented by older analog instrumentation or by more sophisticated DCS or PLC systems.

The control systems that were described in this section did not cover the specifics of advanced process control. For the subjects of optimization and modeling, the reader is referred to Sections 2.7 to 2.20, and for relative gain calculations or for decoupling of interactions to Sections 2.25 and 2.37 in Chapter 2. It should also be noted that the sections describing boiler controls (Section 8.6) and distillation controls (Sections 8.19 to 8.21) should also be studied, because there is a fair amount of overlap between these unit operations and furnace controls.

With the expansion of industrial facilities and with the use of larger furnace units on the one hand and with the increased availability of advanced process control (APC) on the other hand, the use of more advanced and model-based controls should be considered, while taking full advantage of the basic controls described in this section, to obtain more efficient and more profitable furnace operation.

8.28 Header-Supplied Distribution Control

S. BAIN AND B. G. LIPTÁK (2005)

INTRODUCTION

Distribution controls for gases and liquids have already been discussed in this volume in Section 2.23 (Ratio Control), Section 8.1 (Aeration Controls), Section 8.2 (HVAC Controls), Section 8.15 (Compressor Controls), and Section 8.17 (Cooling Tower Optimization). Similarly, the topics of gain compensation and control valve performance have been covered in detail in Chapters 2 and 6.

Yet, it is believed that it is worthwhile to combine in a single section the various control options and considerations that should be taken into account when designing and operating a distribution control system. This is the purpose of this section, which concentrates on controlling header-supplied distribution systems.

Terminology and Coverage

A *header* or a manifold is the pipe that interconnects the supply pumps or blowers with the user valves or other flow distribution elements of the process. A header is typically closed, but the control strategies outlined in this section also apply to open-conduit-type distribution applications. Control strategies will be described to coordinate both the supplying of gases and liquids from blowers and pumps into the distribution header, and the distribution of these materials among their users in the plant.

The main topics of this section will include the most-open valve (MOV)-based valve position control options and their improvements through feedforward and similar control strategies. The section will also discuss gain and hysteresis compensation, methods of failure and fault detection, energy conservation, and some specific applications.

VALVE POSITION CONTROL

Many of the control strategies described in this section are based on the MOV-based valve based valve position control (VPC) systems. The basic motivation for MOV control is to meet the requirements for gas or liquid supply to the process at a minimum of compressor or pump energy. By opening the user valves, the pressure drops and, therefore, the transportation energy requirement is reduced. Therefore, an MOV control system will open all the user valves until one of them approaches full opening. This way, all loads can be satisfied at minimum investment of transport energy.

The advantages of MOV control are not limited to energy savings; they also include the potential reduction for the need for valve maintenance caused by high pressure drop-based abrasion and cavitation. Operating safety can also be improved, because it is safer to work on and operate equipment at lower pressures. If the distributed process liquid is supplied by gravity from an elevated tank, the available maximum pressure drop can limit the maximum load to the most demanding user, and therefore by lowering the required pressure drop, this limit can be raised.

Another advantage of MOV control has to do with the positioning accuracy of control valves, which is about ± 1% of the valve stroke. This positioning error is a fixed quantity, which becomes a larger percentage of the operating stroke (and, therefore, of the flow through the valve) as the valve is throttled down. Therefore, if all valves are opened up, this positioning error will drop, because this error when the valve is 90% open is 1/90 = 1.1%, while with a 10% open valve it is 1/10 = 10%.

In this section the types of valve position control systems will be distinguished by numbers such as MOV1 and MOV2.

When the user valves are throttled on the basis of the flows they deliver, this configuration will be referred to as MOV1. In this case, the MOV1 controller not only controls the individual user flows, but as a consequence, it also controls the flow distribution among users and the total flow supplied to all users. This control strategy is illustrated in Figure 8.28a, where the individual user flows and, therefore, their share of the total flow are both controlled by the needs of the process. In this control configuration, the valve position controller (VPC) measures the total flow required and adjusts the compressor speed to match the demand with the supply, while keeping the discharge pressure at an optimum (minimum) value.

When only the flow distribution among the users is controlled, that configuration will be referred to as MOV2. As can be seen in Figure 8.28b, the flow control loops at the users control only the flow distribution, while the total amount of the flow is determined by pumping capacity. Therefore, in this configuration, the MOV2 controller has to allow the passage of all the flow the distribution header receives, and it only controls its distribution.

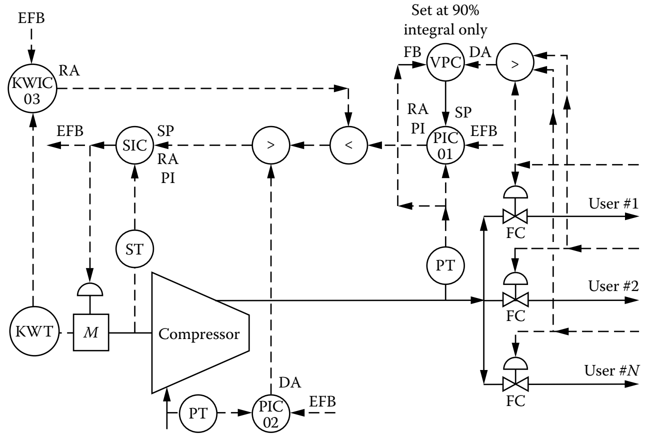

FIG. 8.28a

Illustration of the MOV1 control concept, where both the flows to the individual users and the total flow supplied to the header are controlled by the process demand.

The MOV1 and MOV2 control configurations are fundamentally different and are not interchangeable. They will be discussed in more detail below. Variations of the MOV controllers are many and are continuously evolving, because it makes good sense to automatically switch from controlling the system based on the opening of the MOV to temporarily controlling it by some other variable (pressure, level, or process analyzers), when that is desirable.

The Most-Open Valve

The extent to which the most-open valve should be allowed to open depends on the nature of the process, because the higher that percentage, the less safety margin is available to overcome a process upset. The set point of most valve position controllers is adjustable and is selected to be between 65 and 85%. The higher this set point, the higher the energy efficiency, but the lower the safety margin of operation.

One way to determine the desirable set point (MOVsp) is to make it flow-dependent. In other words, adjust the set point that is desired (say 75%), when the system flow is at the maximum value for which the process has been designed for (Q_d) as a function of the actual flow that is occurring (Q_a) at the time. A suitable relationship between flow and set point can be

$$\text{MOVsp} = 75\% \; (Q_a/Q_d)^k \qquad \textbf{8.28(1)}$$

where k is adjustable from 0 to 1.

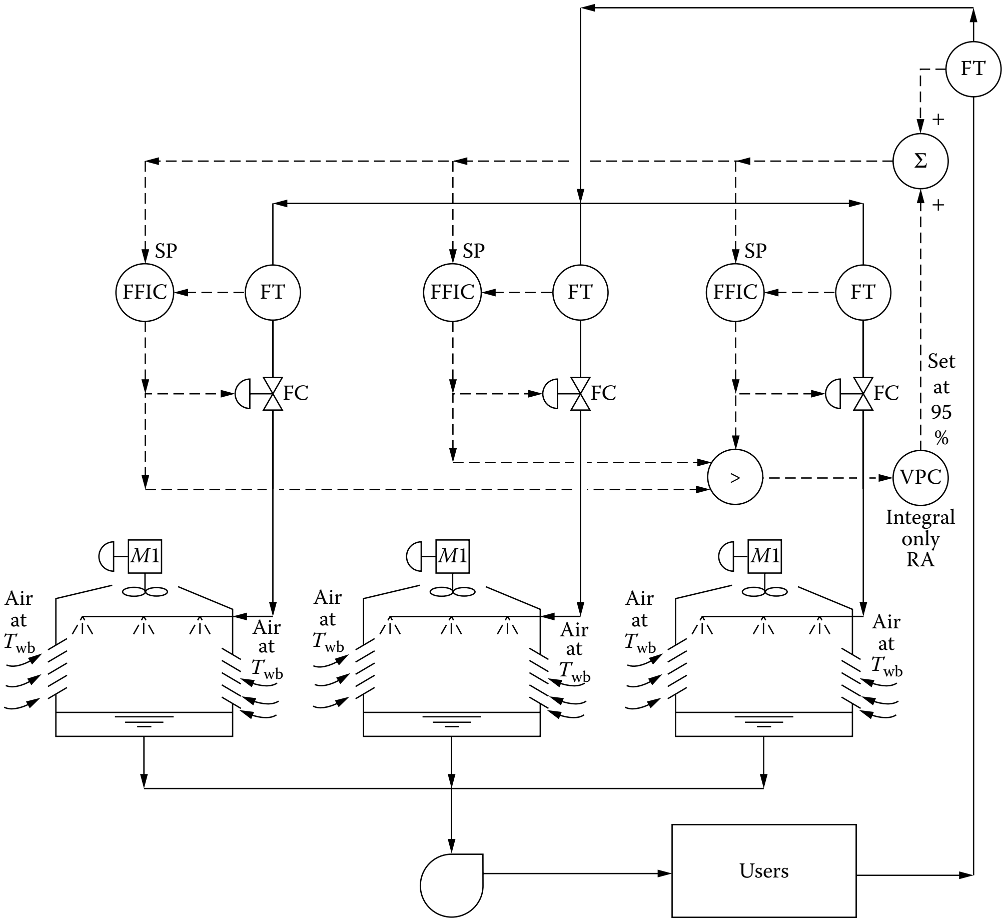

FIG. 8.28b

Water distribution can be controlled automatically while minimizing pumping costs.

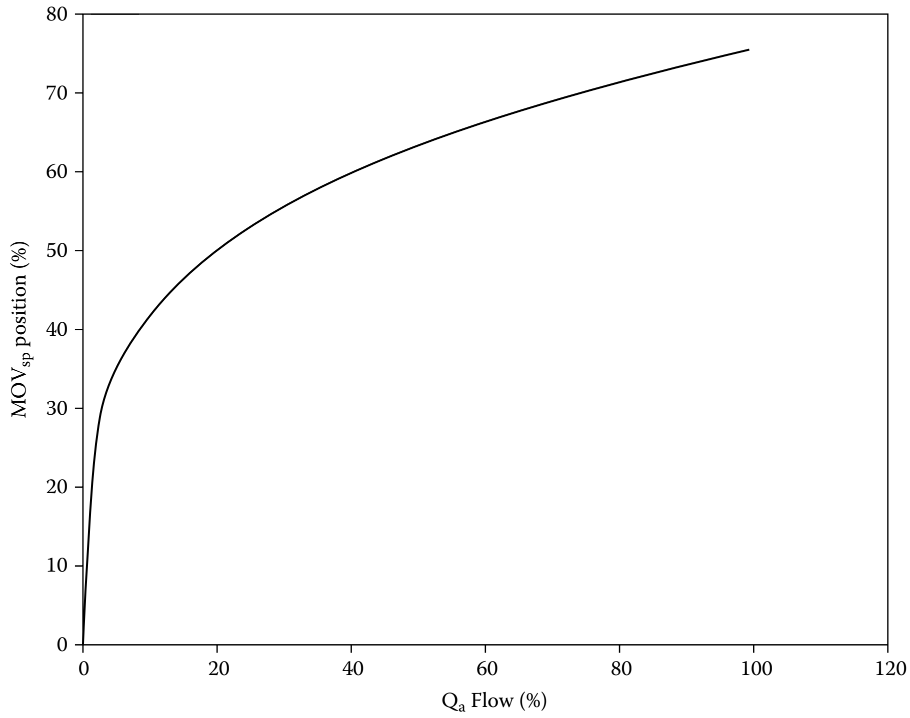

FIG. 8.28c

The relationship between MOVsp and actual system flow, if the value of k in Equation 8.28(1) is set at 0.25.

Figure 8.28c illustrates this relationship when k is selected to be 0.25. If Q_a is greater than Q_d the process is operating beyond its design maximum. The values of Q_a and Q_d can be based on flow through all the user valves or can be based on the flow through only the most-open valve (MOV). It is usually better to use the total system flow, because in that case Q_d is a constant, while if the flow through the selected MOV is used, Q_d has to be changed every time a new valve is selected as the controlling MOV.

In well-maintained systems that are operating with only a few valves, the MOV usually means the selection of a single valve, the one that is the most open. In processes that are not so well maintained (in HVAC or water treatment, where valves can be stuck in full open positions) or in processes involving the selection from among several hundred valves (fuel cells, aeration), selecting a single valve might not be the best. In these processes one might select the three, five, or even ten of the most-open valves and average their openings to arrive at the system MOV.

Energy Savings

A fluid distribution system that is controlled to maintain a traditional constant header pressure is likely to use considerably more energy than is necessary. One way to reduce the energy cost of fluid transportation is to minimize the pressure drops introduced by throttled control valves. This goal is served by valve position control that keeps the most-open valve nearly fully open.

The energy savings associated with using variable-speed or multistage blowers or pumps have been discussed in the sections dealing with compressor, fan, and pump optimization in this chapter. Figure 8.28d illustrates the energy savings potential of controlling the flow to a single user by variable-speed pumping instead of by throttling a control valve on the discharge of a constant-speed pump.

In most fluid distribution applications, the combination of MOV controllers throttling variable-speed supply devices can be expected to bring an energy savings of about 25% or more. Improvements, such as power factor correction or the use of high-efficiency motors, can also contribute significantly to energy reduction.

Similarly to pumping stations in liquid distribution systems, the operating energy costs of gas distribution systems can also be reduced by using variable-speed blower controls. Figure 8.28e compares the power consumption of constant-speed blowers that are throttled by suction or discharge dampers with the power consumption of variable-speed blowers as the load is reduced.

Companies that specialize in energy-related activities include Energy Strategies Corporation (ESCOR), which specializes in blower capacity control, such as adjustable-speed, inlet guide vane throttling and the control of discharge diffusers. H.V.-Turbo A/S (also known as Turblex), Helsingor,

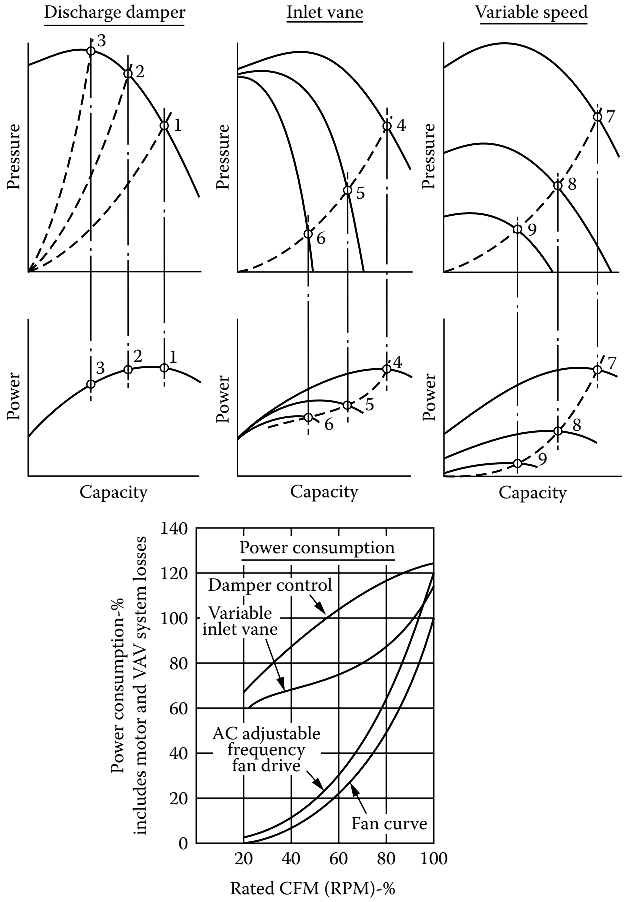

FIG. 8.28e
Operating power requirements of variable-speed blowers and compressors are less than those of constant-speed ones with suction or discharge dampers.

Denmark, is a supplier of high-performance blowers and supplies integrated control packages that can interface with other manufacturers' blowers as well.

Valve and Damper Gain

The gain of any device is its output divided by its input. For a linear (constant gain) control valve, the valve gain (G_v) is the maximum flow divided by the valve stroke in percentage (Fmax/100%).

When a control loop is tuned to provide quarter-amplitude damping, which is the typical goal (see Section 6.7), the controller gain (Gc = 100/% PB) is adjusted until the overall loop gain (the product of the gains of all the loop components) reaches 0.5. If a linear controller and a linear transmitter are used, their gains are constant. Therefore, if the process gain (G_p) is also constant, a linear (G_v = constant) valve is needed to keep the loop gain product constant at 0.5.

Valve or Damper Characteristics The inherent characteristics of a control valve or damper describes the relationship between the controller output signal and the flow through that valve. Some of the widely used inherent lift to flow rate relationships are the linear, equal-percentage, and quick-opening characteristics.

In equal-percentage valves, a unit change in lift will result in a change in flow rate, which is a fixed percentage of the flow rate at that lift. For example, each percentage increase in lift might increase the previously existing flow rate by 3%. Therefore, the theoretical gain of equal-percentage valves is directly proportional to the actual flow rate and increases as the flow rate increases. On a logarithmic chart

TABLE 8.28f
Valve Characteristics Selection Guide

Service	Valve ($\Delta p_{max}/\Delta p_{min}$) under 2:1	Valve ($\Delta p_{max}/\Delta p_{min}$) over 2:1but under 5:1
Orifice-type flow	Quick-opening	Linear
Flow	Linear	Equal %
Level	Linear	Equal %
Gas pressure	Linear	Equal %
Liquid pressure	Equal %	Equal %

the equal-percentage characteristic corresponds to a straight line having a slope that corresponds to a fixed percentage.

In quick-opening valves, the gain decreases with increasing flow rates. The inherent gain of linear valves is constant if the valve pressure drop is constant.

Table 8.28f lists the valve characteristics recommended for some of the most common control valve applications:

Gain Compensation The gain of any damper or valve can be measured at any opening by introducing a 1% step change in the valve stroke and measuring the resulting change of the flow through the valve [G_v = (flow change in units of % of Fmax)/(stroke change of 1% of full stroke)]. In computer-controlled systems, this gain characteristics determination can be performed automatically, and when such data are collected, compensation can be provided.

If it is desired that the apparent valve gain be constant (say $G_{va} = 1.0$), the compensator constant (C) is so selected that the product of the compensator constant and the inherent valve gain (G_{vi}) will be constant ($G_{va} = C \times G_{vi} = 1.0$). The results of a test performed on a 36-in. (900-mm) equal-percentage butterfly valve with a soft-start electric actuator, which was controlled over a digital network, are listed in Table 8.28g.

Modern control systems are provided with the automatic capability for loop component gain determination. Naturally, such tests should only be initiated after the valve stroke and flow sensors have been calibrated. The test to determine the actual, installed valve or damper characteristics should be performed during normal operation of the process, and therefore the data collection might require some time, such as running the program overnight.

It is also recommended that the characteristic curve be recorded when the device is opening and also when it is closing to check for hysteresis and repeat the test several times to establish its repeatability. Once the requirements for the compensator have been identified, one should fit a curve to the collected data. For example, the data in Table 8.28g corresponds to the curve shown in Figure 8.28h and is described by the equation below:

$$Q = -0.011x^2 + 2.036x + 3.094 \qquad \textbf{8.28(2)}$$

TABLE 8.28g
The Inherent Control Valve Characteristics Data Collected by Testing and Finding the Compensator Constant Values Required to Bring the Apparent Valve Gain to 1.0 throughout the Valve Stroke

Control Valve Stroke (x in percent)	% of Maximum Flow Measured (Q)	Inherent Control Valve Gain Measured (G_{vi})	Compensator Values at the Different Valve Openings
0	0		
5	7	1.93	0.519
10	25	1.82	0.551
15	35	1.71	0.586
20	44	1.60	0.627
30	57	1.38	0.727
40	68	1.16	0.865
50	76	0.936	1.068
60	83	0.716	1.397
70	88	0.496	2.016
80	93	0.276	3.623
90	97	0.056	17.86
100	100		

where:
Q is % of maximum flow
x is % of full stroke

To find the valve gain at any point on this curve, one needs to identify the slope of a tangent to the curve, which is the derivative of the valve characteristics. In other words, when using a second-order polynomial approximation for the valve characteristics, the gain equation will be first order, as expressed by the equation below.

$$G_{va} = -0.022x + 2.036 \qquad \textbf{8.28(3)}$$

In order to compensate for the inherent valve gain variation, at each valve opening, the inherent valve gain must be multiplied by the compensation constant C, in order to keep the apparent valve gain constant ($G_{va} = CG_{vi}$ = Constant). If the goal is to keep the apparent valve gain at 1.0, the equation for the compensator curve becomes

$$C = 1/(-0.022x + 2.036) \qquad \textbf{8.28(4)}$$

Hysteresis and Dead Band As was discussed in detail in Section 6.1, the response of the inner valve to a change in control signal is neither instantaneous nor direction-independent. When initiating a stem movement, it takes a finite amount of force to overcome the stem friction, and hysteresis represents the difference between the stem positions resulting from the same control signal when the valve is opening and when the valve is closing.

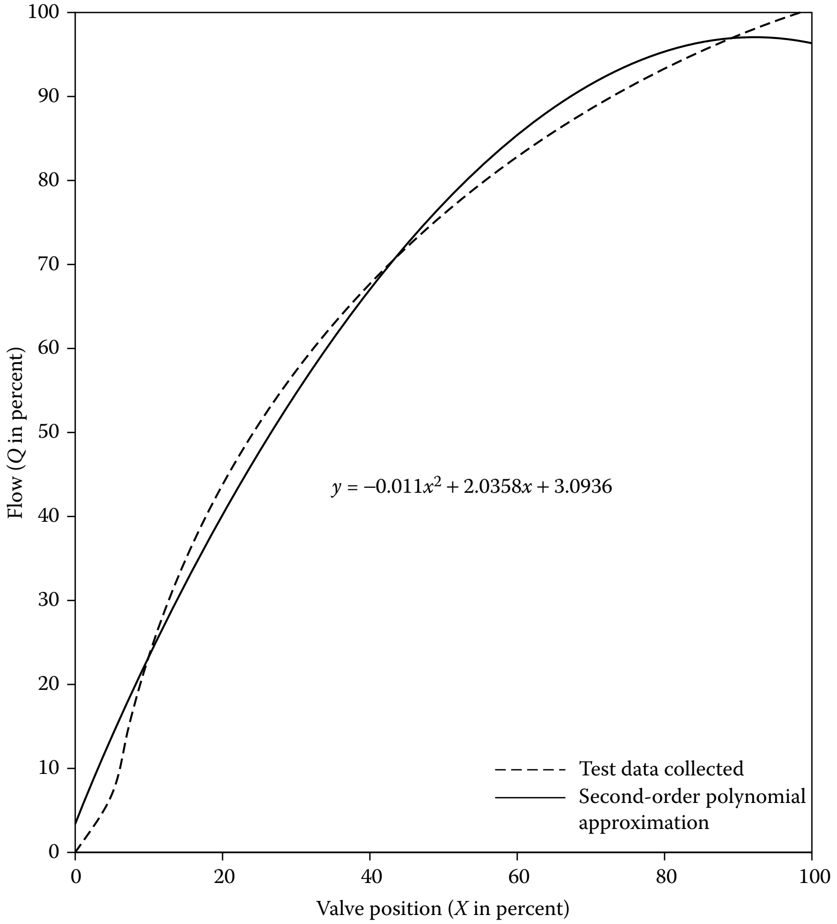

FIG. 8.28h
Fitting a polynomial approximation (———) to the test data collected (- - - - -).

Hysteresis also varies with use. In the case of new valves and dampers, it tends to be high and it tends to stabilize at some lower value after a fair amount of use, but later on, as the packing and other components wear out, it rises again. Hysteresis also varies with maintenance, such as lubrication.

For the above reasons, it is advisable that in critical applications the valve or damper hysteresis also be measured (usually by overnight or more extended automatic data collection). Once the hysteresis of the final control element is known, the compensation algorithm can be corrected by this expected value whenever the direction of stem movement reverses.

SUPPLY-DEMAND MATCHING VPC (MOV1)

As was illustrated in Figure 8.28a, the user valves serve to meet the needs of the process, while the MOV1-type valve position controller (VPC) modulates the total supply to the distribution header (pump or blower) to keep the most-open valve on set point. The set point of the controller sets the safety margin of the operation, because the closer it is to 100%, the less capability the most-open valve will have to respond to a sudden increase in process demand. Therefore, in critical processes, the set point can be as low as 65%, while in inconsequential processes, such as HVAC, it can be as high as 95%.

The header pressure is an indication of the supply-demand balance. If the demand is rising and the supply, therefore, is temporarily insufficient, the header pressure will drop until the supplying device (pump or blower) raises its capacity to match the demand. Inversely, if the demand drops, a temporary overpressure will develop in the distribution header. The time it takes for the system to respond to a change in demand is its speed of response, which can be improved by feedforward control (discussed later).

There are several analog and digital methods of implementing the control system described in Figure 8.28a. A digital and dedicated unit controller will be described below and will be referred to as a MOV1 controller.

MOV1 Controller Algorithm

The MOV1 controller described here is a digital unit controller that periodically identifies the most-open valve. The identity of this valve changes as the process loads vary. The measurement of the valve position controller is the opening of the most-open valve, while the set point of the MOV1 is adjustable. For illustrations of integrating MOV controllers into aeration process control systems, refer to Figures 8.1w and 8.1x in Section 8.1.

For example, if the set point is 80% and the identity of the MOV changes, such as when in the previous period *V*1 was the most-open valve at 80%, while in this period *V*2 is detected to be at 80.1% open, the MOV1 controller selects *V*2 for control. Because the valve opening of 80.1% is above its set point, it increases its capacity control output signal to the pump or blower that supplies the distribution header, which in turn increases the header pressure slightly to bring the new MOV back to set point.

Figure 8.28i shows the control schematic for a MOV1 controller that controls a gas distribution header (serving a number of process users) by throttling the suction control valves on "*n*" number of blowers. The user valves that the header serves are not shown, but their openings are listed on the top right of the figure.

This MOV1 controller algorithm includes a number of features: 1) It provides a feedforward approximation of the total demand of the users, by considering the openings of all user valves. 2) It determines the opening of the most-open valve (MOV) by measuring the average of the valve openings of the five most-open valves. This average then becomes the measurement of the valve position controller (VPC in Figure 8.28i). 3) The position controller VPC operates as the cascade master of the individual pressure controllers (PC), which all measure the header pressure, but control their own inlet control valves. 4) The current drawn by each blower is detected (IT) and controlled (IC) in such a manner so as to equalize them. This approximately equalizes the power consumption of the operating blowers.

Speed of Response and Failure Mode The speed at which the header pressure responds to an upset in the balance between supply and demand is a function of the process fluid and the volume of the header. When an incompressible fluid is being distributed, the response of the header pressure (PT) is fast, and therefore the amplitude and period of the pressure cycling can be limited.

In case of compressible fluids this is not the case, because an upset between supply and demand influences the header pressure (PT) very slowly. Therefore, if the demand changes, the supply does not only need to match the new demand, but also has to change the header pressure to a new value that is required to deliver the new demand. Because the pressure in the header has to rise (or fall) before flow through the control valves will increase (or decrease), a time delay is introduced. This is not the case with incompressible fluids, because if the header is full, whatever is pumped in at the supply end must instantaneously flow out at the delivery end, regardless of the header's volume.

One of the reasons for failure in a MOV1-type control system is the receiving of false user valve opening information. For example, if some failure causes a valve to fully open, it will become the controlling MOV and will cause the system to respond to a false measurement. An example of such a failure is when construction debris is lodged in a pipe bend or valve, restricting the flow.

When this occurs, the MOV1 algorithm will no longer operate at its optimum, but it will still continue to operate, because of two failure response features: One is the approximation of the sum of all valve openings and the averaging of the openings of the five most-open valves. The other is the limiting of the pressure controller (PC) set point values on each blower.

MOV Determination As it was already discussed, the most-open valve position is not necessarily determined as the opening of a single valve. When very large numbers of valves are involved or when some of the valves in the system can be stuck, failed, or manually controlled, it is better to use alternative methods that are selected to match the needs of the process.

For example, in Figure 8.28i, MOV is arrived at as the measurement of the average opening of the five most-open valves in the system, corrected for the total flow (average opening of all valves) in the system. An alternative approach could have been to determine MOV as the average opening of the most-open valves on each of the sub-branches of the distribution system.

It is also recommended to use the more conservative configurations (lower MOV, higher number of averaged valves) during commissioning, because it is more important to gain the trust of the operators than to save energy. In other words, first, the operator's suspicion of such "advanced" controls should be overcome.

After that, the operators should be trained to concentrate on equipment maintenance and on learning the "personality" of the process. They should also develop the habit to first remove the valve from the control algorithm before switching it to manual and, once maintenance is completed, to clear the latched fault switch to return the valve back into the system.

Optimization of the system should occur only after the full confidence of the operators has been gained. This control system also has built-in self-diagnostics capability, because it can be programmed to report any valve that does not move at all for longer periods of time, and can report valves that are cycling or are excessively open (90–100%).

DISTRIBUTION CONTROLLING VPC (MOV2)

As was illustrated in Figure 8.28b, the task of a MOV2 controller is only to distribute a flow that is determined by factors outside of its control. Examples include the distribution of cooling water returning from the plant among a number of cooling towers or chillers or the distribution of wastewater among treatment units.

The incoming wastewater is often received as gravity flow, which is dependable, but its head pressure is low and cannot be changed. In such applications, it is essential to minimize the pressure drop introduced by the distribution valves. In such

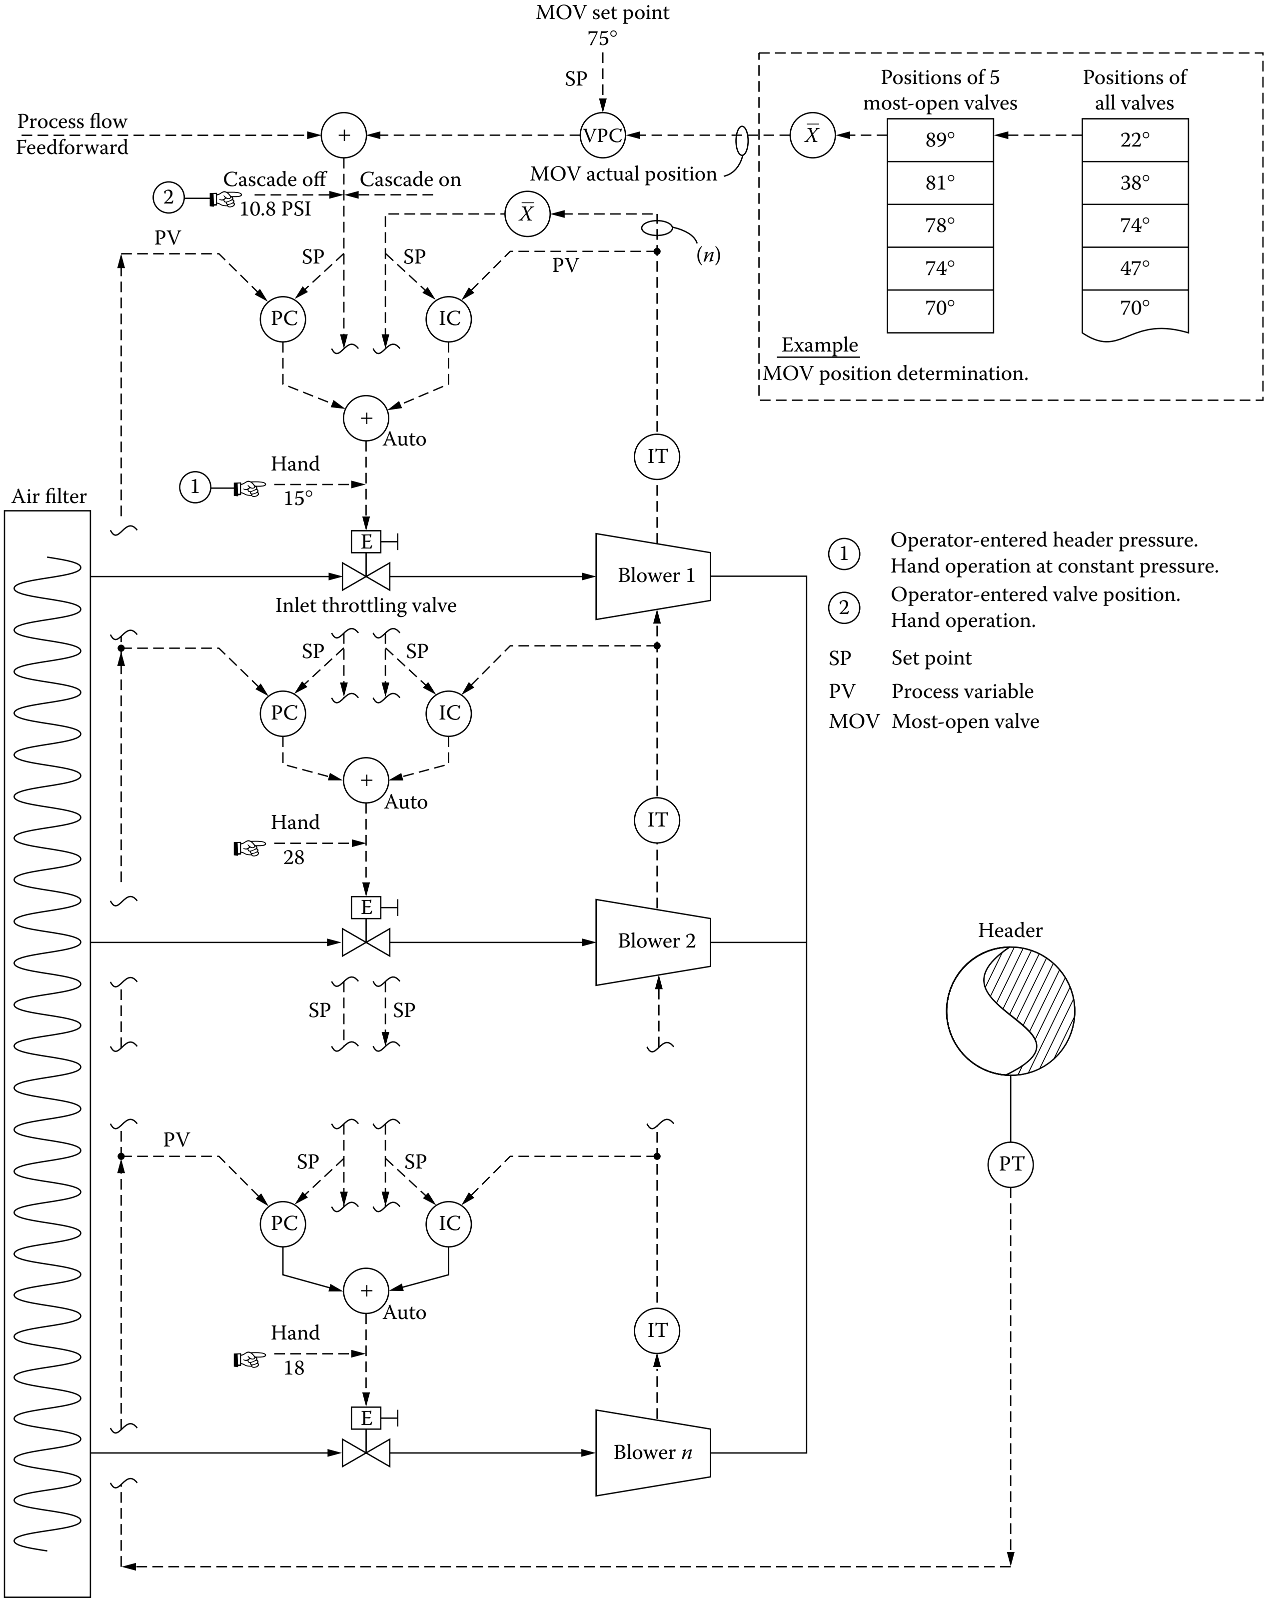

FIG. 8.28i

The structure of a particular unit operations controller (MOV1), serving to match the gas supplied into a distribution header by a number of blowers, to the demand represented by the process users on the header.

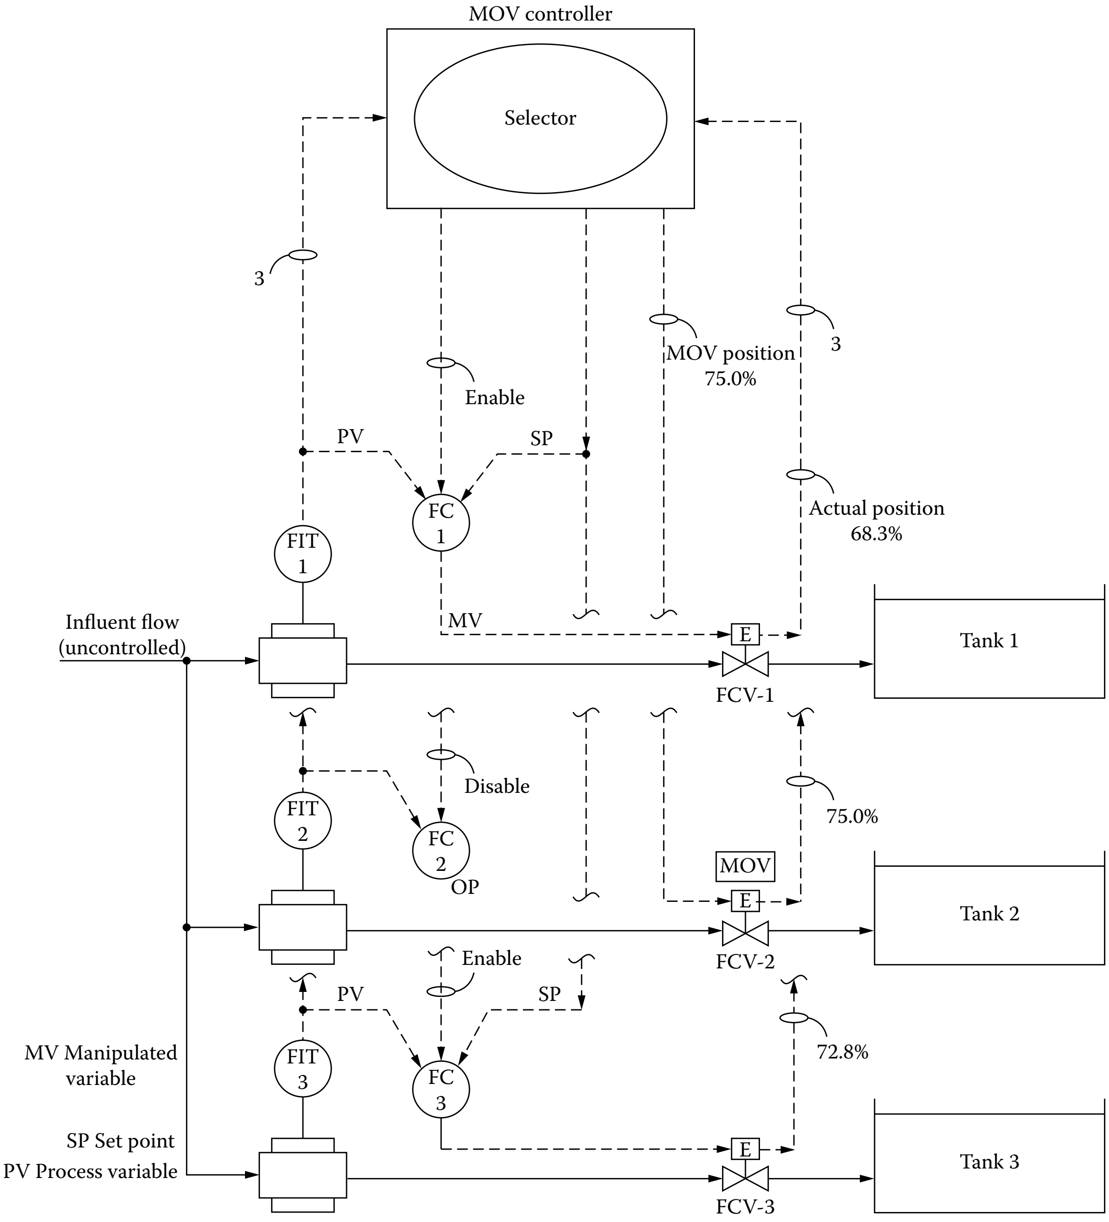

FIG. 8.28j
The structure of a particular unit operations controller (MOV2), serving to distribute an uncontrolled water stream among a number of receivers.

applications, the MOV2 controller serves to identify the most-open valve and compares that opening to its set point, which is the desired maximum opening of, say, 80%. The MOV2 controller also measures the flow through the selected MOV and, if the other users are of equal capacity, uses that flow as the set point for the other flow control loops that are throttling the other user valves. If the other users are of different capacities, the set point is sent through a ratio relay.

Example

If a MOV2 controller is set at 80%, its operation during a time when the identity of the most-open valve is changing is as follows: If FCV1 in Figure 8.28j is being controlled at 75% when FCV2 opens to 75.1% (possibly, because of an increase of pressure drop due to plugging in its piping), the measurement selection of MOV2 is switched to FCV2. As a consequence, the control of FCV2 is switched from its flow controller (FC-2 in Figure 8.28j) to the MOV controller, which keeps it at an opening of 75%. At the same time of this switching, the FVC-1 flow control valve is returned to be controlled by its own flow controller (FC-1).

If the tanks in Figure 8.28j are of different sizes or if they supply treatment facilities of different capacities, the set points of their flow controllers are sent through ratio relays that are set to reflect their capacity ratios.

Failure Modes and Applications

Once the MOV2 controller has positioned the valves to give the required flow distribution ratio, its valves should seldom move. In an MOV2 controller, a failure such as a blockage causes the blocked valve to open and become the MOV. The flow through the plugged valve will be low because of the blockage, yet that flow will then become the set point for the other valves so they will close. This will cause a backup and potentially an overflow on the influent side of the process.

For this reason and other maintenance-related reasons, it is desirable to provide the MOV2 controller with the means to turn off its controls, while equipment failure is being corrected.

MOV2 controllers are suitable for open-channel flow distribution applications. They are also suitable for distributing gases or liquids that are transported by pumps and blowers, including positive displacement types, because it is the pumps or blowers that control the flow; the valves only distribute it.

The MOV2 controllers can maintain other variables besides the opening of the most-open valve. If their measurement signal is switched from an MOV position to the back-pressure detector, it will maintain the back-pressure on the distribution system. Similarly, if the MOV2 measurement is switched to a level measurement signal from the supply tank of the distribution system, it will maintain that level. Needless to say, when the measurement is switched away from the MOV, the controller will abandon the control of the valve position.

Yet another option is to send the measurements of MOV, level, or pressure to a high-low limit envelope and allow the controlling active measurement to be selected on the basis of some predetermined process limit consideration.

The features of MOV controllers can be combined or control can be automatically switched from supply-demand matching (MOV1) to distribution (MOV2) control and back. It is also possible to automatically alter or select other process variables to temporarily replace the MOV measurement as the controlled variable or to combine the effect of some measurements in the set point as trimming variables.

DESIGN, START-UP, AND MAINTENANCE

For an in-depth discussion of the main components of distribution systems, such as the control of blowers, compressors, and pumps and for the dynamic characteristics of actuators, dampers, and valves, the reader is referred to the corresponding sections of this handbook. In addition to that, a few design recommendations that are specific to distribution system controls are listed here.

Actuators and Valves

Adjustable frequency drives (AFDs) are most often used, although DC and pneumatic actuators are also still in use. DC units tend to be high-maintenance items, while pneumatic units generally have high hysteresis. The actuators for the capacity controls of blowers should be fast and be provided with positioners. Electrohydraulic actuators, available from Acutrol or REXA, can meet this requirement.

Control

When designing load-sharing controls, it is preferred that they measure the power consumption rather than the speed in equalizing the power consumption of multiple variable-speed units. The set point of these power equalization controllers should be the average power consumption of the operating units. As shown in Figure 8.28i, the output of the power equalization controllers (IC) is then combined with the output signal of the capacity controller (PC).

When these two signals are combined, the capacity controller should maintain its primary role and the interaction between the two loops should be decoupled. For these reasons, the power controller output is often used only as a slow bias through a low-gain integrator.

When suction dampers or guide vane controls instead of variable-speed controls are used, reciprocal gain compensation is recommended, so that as the gain of the final control element increases (or decreases), the loop gain will stay constant.

One should also consider to modify the control algorithm such that when the blower is operating near its surge or overload lines, the gain of its capacity controller is temporarily reduced.

Operator Interface In many installations, it is desirable to suppress the measurement range of controllers by elevating the zero of the measurement signal. In such cases, the controller might consider, say, a header pressure reading of 70 kPa as 0 and 100 kPa as 100%. In such applications, it is desirable that on the operator's interface the actual header pressure be displayed with a range of 0–100 kPa, so that the operator can distinguish a true depressurized condition from a zero reading on the controller range with elevated zero.

Master Hand Controls If the distribution system consists of many valves and the restart sequence after a power failure is initiated manually, it is desirable to provide master controls for the restarting of all valves and other instruments by a single switch or other control device. In other applications, it might be convenient to approach this on a unit operation basis, so that a tank or other unit operation can be taken out or returned to automatic control by a single switch.

Blowers

When meeting the process load with two blowers, for smooth switching it is desirable to size them, so that at its maximum flow, one would deliver 110% of the sum of the minimum flows of two blowers. This requirement can bring the operation close to either the surge curve (see Figure 8.15i in Section 8.15) or the overload (choke) curve of these units.

During commissioning, the diffusers should be protected against overpressuring and from excessive temperatures. With no water pressure on the diffusers, the blower pressure can be sufficient to pop off or burst the diffusers. Membrane diffusers with PVC piping have a temperature limit of 70°C (160°F).

Fault Detection and Response

Distribution control system design should consider the response to power failure, sensor or actuator failure, valve plugging, and operator errors. The control system should also include the capability of both predicting and signaling the need for maintenance. Such self-diagnostics can be based on the comparison of valve opening and valve flow and also on the comparison between control signal and valve opening.

If such evaluation flags the need for valve maintenance, automatic checking could include the initiation of a 5 or 10% change in control signal and the checking if the valve opening changes in response to it. Similarly, such an automatic test can include checking if the flow has changed in response to the initiation of this temporary step change in the control signal.

Start-Up

The commissioning of distribution system controls is not very different from the start-up of any other unit operation. Commissioning should be started by leak and functional testing of all piping and equipment components. This should be followed by calibration, and when that is concluded, it should be continued by determining the values of multiplier, summer, bias, feedforward, and controller tuning constants.

In case of air distribution, it is desirable to provide the means for air venting, so that header controls can be tested without affecting the process.

When starting up in the winter, the plans for commissioning should take the low temperatures and the probability of ice formation into account.

CONCLUSIONS

The MOV1 controller is generally suited to applications where the flow can be controlled by the MOV1's valves. This is often the case, so that the MOV1 controller is widely used.

However, the MOV1 controller is usually not suitable for applications such as positive displacement (PD) pumps pumping incompressible liquid. In this situation there is nothing to compensate for inevitable differences between required and pumped flows. However, if the flow is compressible gas with PD blowers, the difference can be absorbed by a changing header pressure that the controls detect and correct. Or if the pumps or blowers are centrifugal types, then the changing header pressure shifts their operating points, which corrects the difference.

MOV1 controllers are not typically used with open-channel flow distribution, because usually the pressure in an open channel cannot be varied significantly. In an open channel, pressure equates directly to level, and an open channel suitable for variable pressures is likely to be uneconomical; a pipe is likely to be more suitable.

8.29 Heat Exchanger Control and Optimization

B. G. LIPTÁK (1970, 1985, 1995, 2005)

INTRODUCTION

The transfer of heat is one of the most basic and best understood unit operations of the processing industries. Heat can be transferred between the same phases (liquid to liquid, gas to gas), or phase change can occur on either the process side (in case of condensers, evaporators, and reboilers) or the utility side (in case of steam heater) of the heat exchanger. With the exception of evaporators, which are discussed in Section 8.23, the control and optimization of each of these systems will be discussed in this chapter.

The section is started with some general aspects, such as plantwide heat audits, heat exchanger safety, temperature measurement advances, tuning, and heat-transfer dynamics. Next, it describes the basic components and controls of liquid-to-liquid heat exchangers, steam heaters, condensers, reboilers, and vaporizers. The section is concluded by the description of more advanced control techniques, including override, cascade, feedforward, adaptive gain, model-based, and multipurpose systems.

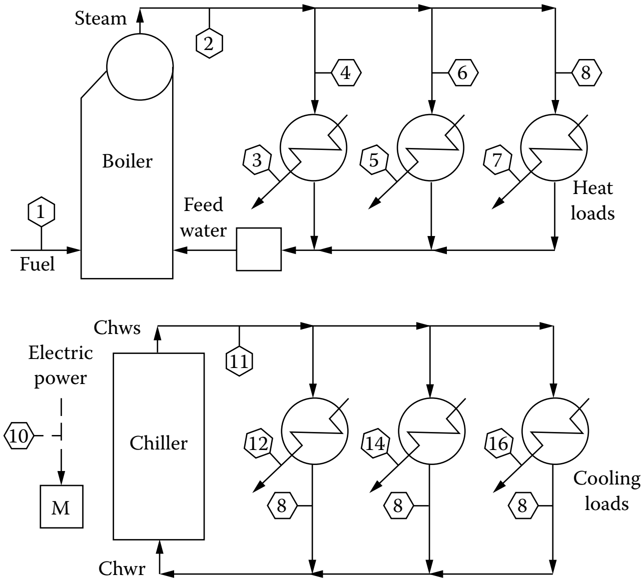

FIG. 8.29a
A plantwide energy audit can determine the useful portion of the energy that is represented by fuel consumed at the boiler(s) and by electric energy used by the chiller(s) that actually reaches the process.

GENERAL CONSIDERATIONS

In a processing plant, the heat exchanger as a unit operation is part of larger plantwide unit operations, serving the heating or cooling needs of all the processes in the plant. By the use of BTU flowmeters (Section 2.3 in Chapter 2 in the first volume of this handbook), one can obtain a plantwide energy audit (Figure 8.29a) and provide historical plots of both the total amounts of energy used and of the efficiency at which it was used. If the individual heat exchanger controls of the plant are optimized, such plantwide information can be useful in such decisions as when to clean heat-transfer surfaces or what the optimum cooling water temperature or steam supply pressure and superheat values are.

Temperature Detection and Transmission

Chapter 4 of the first volume of this handbook is devoted to the description of the capabilities of the various temperature detectors available. The vast majority of temperature measurements are made with either a thermocouple (TC) or a resistance temperature detector (RTD). Higher purity materials and improved manufacturing processes have provided sensors that more closely match theoretical curves and exhibit lower drift than sensors of the 1980s and the 1990s.

More advanced transmitters incorporate the ability to match the sensor to the transmitter to minimize this error. Typical accuracies are about ±0.4°F. For higher precision, at least one vendor offers a bath calibration technique that allows the transmitter to capture actual values output by the RTD or thermocouple at specific temperatures. This method provides system accuracies of about ±0.02°F (0.1°C) for RTDs and about ±2°F (1°C) for thermocouple measurements.

The array of intelligent temperature transmitters on the market seems almost endless. Some common features of the leading models are universal inputs from any TC, RTD, mV, resistance, or potentiometer; loop-powered with 0–20/4–20 mA output; digital outputs; and configuration with pushbuttons, PC software, or a handheld configurator. Choices must be made concerning the protocol required: HART, Foundation Fieldbus, Profibus, vendor proprietary, Ethernet, or just

4–20 mA. Some field locations will benefit from local indication, and this feature is optional with most manufacturers.

Direct connection of temperature sensors to input subsystems of DCSs or PLCs is an alternative to using a temperature transmitter for each measurement. This may sound like a way to cut costs. In actuality, on an installed basis, it is more expensive, far less accurate, and not as robust. The benefits of using transmitters include higher precision, sensor-transmitter systems calibrated to the range of interest, better RFI immunity and noise rejection, transmitter diagnostics, lower wiring costs, less expensive I/O cards, faster loop checks, and shorter start-ups.

Process Characteristics

Heat transfer is one of the best understood processes, and as such, it has good potentials for modeling and optimization. Before discussing the control of heat exchangers, the degrees of freedom, scaling, dynamics, and tuning of this unit operation will be briefly discussed.

Degrees of Freedom Chapter 2's Section 2.1, in connection with Figures 2.1r and 2.1s, provides a detailed discussion of the determination of the degrees of freedom of any process. The degrees of freedom of a process define the maximum number of independently acting automatic controllers that can be placed on a process.

Figure 8.29b shows a steam heater with its variables and defining parameters. The temperatures and flows are variables, and the specific and latent heats are parameters. The available degrees of freedom are determined by subtracting the number of system-defining equations from the number of process variables:

$$\text{degrees of freedom} = (\text{number of variables}) - (\text{number of equations}) \quad \mathbf{8.29(1)}$$

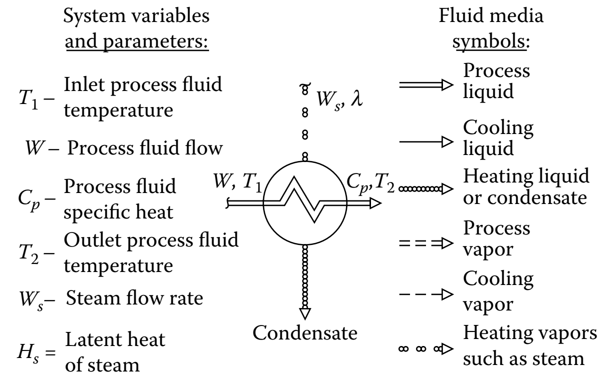

FIG. 8.29b
In a steam heater there are four process variables (two flows, two temperatures) and one defining equation (conservation of energy), hence the number of degrees of freedom of that process is three.[1]

In this case, there are four process variables and one defining equation, which is that of the conservation of energy, based on the first law of thermodynamics:

$$HsWs = C_pW(T_2 - T_1) \quad \mathbf{8.29(2)}$$

Therefore, this system has three degrees of freedom; thus, a maximum of three automatic controllers can be placed on it.

In a liquid-to-liquid heat exchanger, there are four temperature and two flow variables with still only one (conservation of energy) defining equation, resulting in five degrees of freedom:

$$C_pF(T_{h1} - T_{h2}) = C_{pc}F_c(T_{2c} - T_{1c}) \quad \mathbf{8.29(3)}$$

In a steam-heated reboiler or in a condenser cooled by a vaporizing refrigerant (assuming no superheating or supercooling), there are only two flow variables and one defining equation:

$$HsWs = H_1W_1 \quad \mathbf{8.29(4)}$$

In these cases there is only a single degree of freedom, and therefore on these processes only one automatic controller can be used.

In the majority of installations, fewer controllers are used than the available degrees of freedom, but every once in a while mistakes are made by using too many controllers and thereby overdefining the process.

Scaling, Gain, and Time Constant Scaling is the conversion from engineering units to fractions or percentages. For the scaling of a heat-transfer equation, a detailed example has been provided in connection with Figure 8.5r.

The steady-state gain of a heat-transfer process is the ratio of the percentage change in controlled temperature that result from a 1% change in the flow through the control valve that controls that temperature.

Because the heat-transfer surface of a heat exchanger is fixed, the more heat is to be transferred, the less efficient the process becomes and therefore the lower will be the process gain (*Gp*). Assuming that in the control loop the sensor gain (*Gs*) and the controller gain (*Gc*) are constant, a stable loop operation can be obtained if the control valve gain (*Gv*) rises with load, thereby compensating for the drop in the process gain and maintaining the loop gain constant. The gain product of a well-tuned control loop is about 0.5, as illustrated in Figure 8.29c.

The time constant of any process is the result of its capacitance and resistance. In case of a heat exchanger, the process outlet temperature is usually the controlled variable, and the flow rate of the heat-transfer fluid is the manipulated variable. The time constant of an exchanger is determined by the mass and the specific heat of the tube material, the mass flow and the specific heat of the process and utility streams, and their heat-transfer coefficients. A good approximation of

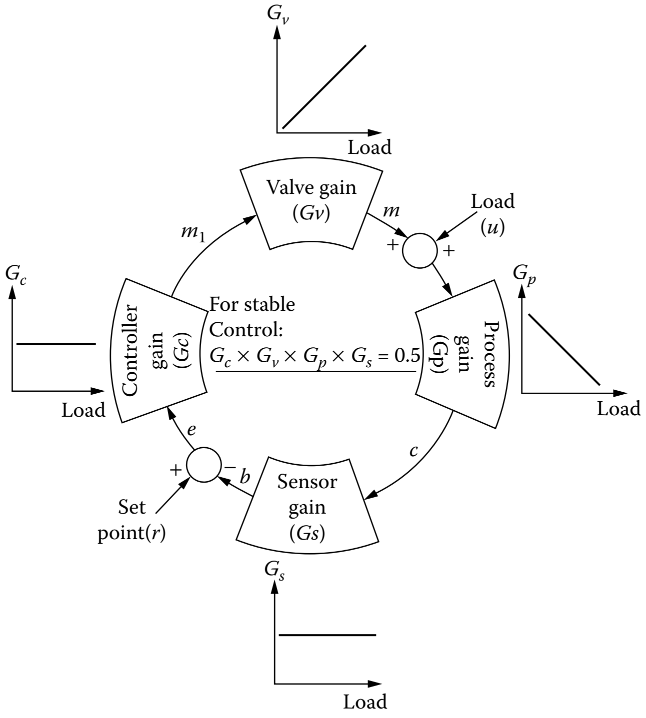

FIG. 8.29c
If the process gain varies with load, such as is the case of heat-transfer processes, the gain product of the loop can be held constant by using a valve whose gain variation with load will compensate for the process gain variation.

a heat exchanger's time constant can be obtained with the empirical formula:

$$\tau = K \frac{m_T \cdot C_{pT}}{F_w \cdot C_{pw} \cdot F_c \cdot C_{pc}} \qquad \textbf{8.29(5)}$$

where

τ = the time constant in seconds
K = 100 for English units, and 200 for SI units
m_T = the total mass of the tubes in lb (kg)
C_{pT} = the specific heat of the tube material in BTU/lb_m (kJ/kgK)
F_w = the flow rate of the warm stream in lb/sec (kg/sec)
C_{pw} = the specific heat of the warm fluid in BTU/lb_m (kJ/kgK)
F_c = the flow rate of the cold stream in lb/sec (kg/sec)
C_{pc} = the specific heat of the cold fluid in BTU/lb_m (kJ/kgK)

In process industry heat exchangers, the time constants are usually between 5 sec and 2 min.

Dead Time and Tuning Before the new flow rate or temperature of the heat-transfer fluid can start to have an impact on the heat balance, first it has to get to the heat-transfer surface of the exchanger. Therefore, dead time is also called transportation lag, because it is the time it takes for the heat-transfer fluid to transport (displace) the contents of the exchanger and its associated piping.

The dead time is the worst enemy of control, because until it has expired, a change in the heat-transfer fluid flow (or temperature) will not even start to have an observable effect on the process. For a heat exchanger, the dead time is usually between 1 and 30 sec. When the equipment is correctly designed, the dead time is much less than the time constant.

Tuning is discussed in detail in Sections 2.35 to 2.38 in Chapter 2 in this volume. The controller gain is adjusted so that the loop gain (the gain product of the loop components) will be around 0.5. In case of variable gain processes, such as heat transfer, one usually tries to compensate for the gain variations of the process by using a control valve characteristic that compensates for it. In case of the more critical processes, adaptive (Section 2.19) and model-based (Sections 2.13 to 2.18 in Chapter 2) controls can be used.

Control loops can be tuned by considering the dynamics of only the process (open-loop method) or evaluating the response of the complete loop (closed-loop method). Because the period of oscillation of all control loops (P) is some multiple (around 3.5 to 4.0) of their dead time, the integral and derivative settings of PID controllers are generally adjusted as a function of the dead time of the process.

For noninteracting control loops with zero dead time, the integral setting (minutes/repeat) is about 50% and the derivative is about 18% of the period of oscillation. As dead time rises, these percentages drop. If the dead time reaches 50% of the time constant, I = 40%, D = 16%, and if dead time equals the time constant, I = 33% and D = 13% of the period of oscillation. For a comparison of the various tuning criteria, refer to Table 2.35l, and for the load and set point responses of the various tuning methods, see Figures 2.35o, p, and q in Chapter 2.

As will be shown later, when tuning the feedforward portion of a control loop, one has to separately consider the steady-state portion of the heat-transfer process (flow times temperature difference) and its dynamic compensation. The dynamic compensation of the steady-state model by a lead/lag element is necessary, because the response is not instantaneous, but affected by both the dead time and the time constant of the process.

Safety

Heat exchangers are a class of process equipment requiring special relief considerations, because of the potential need for protection against thermal expansion, external fire, blocked outlet, and tube rupture cases.

Blocked-In Exchangers Heat exchangers frequently have valves located on both their inlet and outlet piping. When these valves are all closed, the exchanger is "blocked in." If the cold side of the heat exchanger can be blocked in, relief devices are installed to provide protection against thermal expansion of liquids in the exchanger. This is always done for the cold side of an exchanger where the liquid can be heated by the hot fluid on the other side, or can be heated by ambient temperature, while sitting with the inlet and outlet valves closed.

No relief device is necessary for the protection of either side of an exchanger that cannot be blocked in. In such installations it is assumed that the relief of the unit is taken care of by the relief device on the related tank or equipment.

Liquid Refrigerants When liquid refrigerants are used, a relief device should always be provided for the protection of the refrigerant side, if the refrigerant side can be blocked in and if the vapor pressure of the refrigerant can exceed the design pressure of the exchanger, when its temperature rises to that of the hot side.

A relief device should also be provided whenever the vapor pressure of the material flowing at 100°F (37.8°C) is greater than the design pressure of the exchanger. This recommendation is somewhat site-specific and is based on an assumed (maximum) ambient temperature of 100°F (37.8°C). This temperature should be modified according to the geographical areas involved.

Gas-Fired Tubular Heaters Direct gas-fired tubular heaters are always protected by relief valves on their tube side. The valve is normally sized for the design heat-transfer rating of the heater and must initially handle a fluid rate corresponding to the rate of thermal expansion in the tubes when they are blocked in.

When designing fired heaters, there should be no block valve on its outlet. This is because PRVs for high-temperature services exceeding 550°F are not available with dependable seat and seal materials.

Tube Rupture Consideration should be given to relief protection of low-pressure equipment in the event an exchanger tube should rupture because of corrosion or vibration or due to thermal shock. ASME Code, Section VIII, Division 1, Paragraph UG-133(d) requires such protection.

This consideration is particularly critical when the low-pressure side design pressure is less than the operating pressure on the high-pressure side. In terms of high- and low-pressure side design pressures, PRV protection against tube rupture is recommended, if the design pressure of the low-pressure side is less than 77% of the high-pressure side.

For advice on the sizing of PRVs to protect against overpressure caused by tube rupture, refer to Section 7.15 in Chapter 7 in the first volume of this handbook. The PRV that is to protect the exchanger should be located either directly on the exchanger, or very close to it.

BASIC CONTROLS

In the following paragraphs, the basic controls of liquid-liquid heat exchangers, steam heaters, condensers, vaporizers, and reboilers will be discussed. This will be followed by a description of more advanced controls for these unit operations.

Liquid-Liquid Heat Exchanger Controls

Figure 8.29d and Equations 8.29(7) and (8) illustrates that the total heat transferred (Q) from the hot process to the cold coolant fluid is dependent on the overall heat-transfer coefficient (U), the heat-transfer area (A), and the log mean temperature difference (ΔTm). Manipulation of any of these three variables can affect the total heat transfer.[2]

The dead time of a heat exchanger equals its volume divided by the flow rate through it. As process flow increases, the process dead time is reduced, while the loop gain is also decreased. If the controlled variable (Th_2 in Figure 8.29d) is differentiated with respect to the coolant flow (manipulated variable Fc), the steady-state gain of the process is

$$\frac{dTh_2}{dF_c} = \frac{C_{pc}}{F_h C_{ph}} \qquad \mathbf{8.29(6)}$$

where
C_{pc} is the specific heat of the cold fluid
C_{ph} is the specific heat of the hot fluid

If $C_{pc} = C_{ph}$, the steady-state gain equals $1/F_n$. Therefore, as the process flow (load) drops, the same amount of valve adjustment by TIC in Figure 8.29d will have more effect, because the process fluid will spend more time in the exchanger. As load is reduced, the exchanger becomes relatively oversized, and therefore, it becomes a faster and more effective heat-transfer device.

As a drop in load tends to increase the process gain — that is, tends to make the loop more sensitive and more prone to cycling — an increase in load does the opposite. As load rises,

$$Q = UA\Delta Tm = UA\,\frac{(Th_1 - Tc_2) - (Th_2 - Tc_1)}{\text{In}\,((Th_1 - Tc_2)/(Th_2 - Tc_1))} \qquad \mathbf{8.29(7)}$$

$$Q = Fh\;\; Cph\,(Th_1 - Th_2) = Fc\,Cpc\,(Tc_2 - Tc_1) \qquad \mathbf{8.29(8)}$$

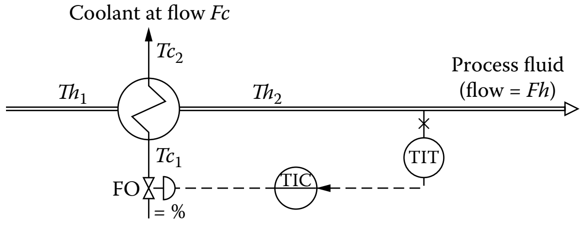

FIG. 8.29d
The feedback-type temperature control of a process cooler involves the control of a nonlinear and variable gain process.[1]

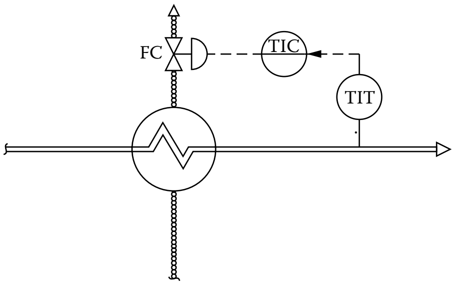

FIG. 8.29e

The feedback temperature controller of a process heater can throttle either the inlet or the outlet of the heating media on this nonlinear and variable gain process.[1]

the exchanger becomes less and less effective, more and more undersized; therefore, it takes more time for the TIC to make a correction. An increase in load thus will make the loop sluggish, as the residence and dead times are reduced and the process gain is lowered.

As the process gain of all heat exchangers varies with load, it would not be possible to tune the TIC in Figure 8.29d for more than one load, if all other loop gains remained constant, while the process gain varied. In order to minimize cycling, the TIC is usually tuned for the minimum load (maximum process gain). Therefore, if not automatically compensated, it can act sluggish at higher loads.

As the process gain drops with rising load, the total loop gain can be held relatively constant by introducing a loop component whose gain rises with load. Such an element is an equal-percentage valve, which can compensate for the variable gain process. This is a good solution if the temperature difference through the exchanger ($Th_1 - Th_2$) is constant.[3] If it is not constant, feedforward compensation of the gain is required, as will be discussed later.

Component Selection Figures 8.29d and 8.29e illustrate cooler and heater control systems with the control valve mounted on the exchanger inlet and outlet, respectively. From a control quality point of view, it makes little difference whether the control valve is upstream or downstream of the heater. The inlet side is usually preferred, because this allows the exchanger to operate at a lower pressure than that of the return header.

It is generally recommended that positioners be provided for these valves to minimize the effects of valve friction (hysteresis and dead band) effects. The use of equal-percentage valve characteristics is recommended, because it contributes to maintaining the control loop gain relatively constant under changing throughput conditions. Equal-percentage trims maintain a constant relationship between valve opening and temperature change (reflecting load variations).

In the majority of installations, a three-mode controller would be used for heat exchanger service. The use of the derivative or rate action is essential in slower (long time-lag) systems or when sudden changes in heat exchanger throughput are expected.

Because of the relatively slow nature of these control loops, the proportional band setting is usually wide to maintain stability (usually approaching 100%). This means that the valve will be fully stroked only as a result of a substantial deviation from the set point. It is for this reason that the integral control mode is required to correct for temperature offsets caused by process load changes. Other variables can give the appearance of load changes, such as inlet temperature and header pressure changes of the heat-transfer medium.

The Thermal Element The selection and location of the thermal element are also important. This element must be placed in a representative location, without increasing measurement time lag. In reference to Figure 8.29d, this would mean that the bulb should be located far enough from the exchanger for adequate mixing of the process fluid but close enough so that the introduced delay will not be substantial. If the process fluid velocity is 3 ft/s (0.9 m/s), then a 1 sec distance-velocity lag is introduced for each 3 ft (0.9 m) of pipe between the exchanger and the bulb.

This lag can be one of the factors that limits the dynamic performance of the system, but it is not the only thermal lag in the system. In order to change a temperature measurement, first heat must be transferred into the thermal bulb through its fixed area.

For example, a typical filled bulb might have an area of 0.02 ft^2 (0.0018 m^2) and the heat capacity of 0.005 BTU/°F (9.49 J/°C). If this bulb, which has a bare-bulb diameter of $^3/_8$ in. (9.375 mm), is immersed in a fluid having a heat-transfer coefficient of 60 BTU/h/°F/ft^2 (1.23 MJ/h/°C/m^2) and the process temperature is changed at a rate of 25°F/min (13.9°C/min), the dynamic lag can be calculated. To do so, first the amount of heat flowing into the sensor is determined:

$$\begin{aligned} q &= \text{(rate of temperature change) (bulb heat capacity)} \\ &= (25)(60)(0.005) = 7.5 \text{ BTU/h } (7.9 \text{ kJ/h}) \end{aligned} \qquad \mathbf{8.29(9)}$$

The dynamic measurement error is calculated by determining the temperature differential across the fluid film surrounding the bulb that is required to produce a heat flow of 7.2 BTU/h (7.9 kJ/h):

$$q = Ah\,\Delta T \qquad \mathbf{8.29(10)}$$

Therefore,

$$\Delta T = q/Ah = 7.5/(0.02)(60) = 6.25°\text{F } (3.47°\text{C}) \qquad \mathbf{8.29(11)}$$

If the rate of process temperature change is 25°F/min (14°C/min) and the dynamic error based on that rate is 6.25°F (3.47°C), the dynamic time lag is as follows:

$$t_o = 6.25/25 = 0.25 \text{ minutes} = 15 \text{ seconds} \qquad \mathbf{8.29(12)}$$

This lag can also be calculated as

$$t_o = \frac{\text{(bulb heat capacity)}}{\text{(bulb area)(heat-transfer coefficient)}} = \frac{60 \times 0.005}{0.02 \times 60}$$

$$= 0.25 \text{ minutes} \qquad \mathbf{8.29(13)}$$

Bulb time lags vary from a few seconds to minutes, depending on their mass, heat-transfer area, and the process fluid being detected. Measurement of gas temperatures at low velocity involves the longest time lags, and measuring water (or dilute solutions) at high velocity results in the shortest lags.

The addition to the sensor lag of a thermowell will further increase the total lag time, but in most industrial installations, thermowells are necessary for reasons of safety and maintenance. When they are used, it is important to eliminate any air gaps between the bulb and the socket.

One method of reducing time lag is by miniaturizing the sensing element. Conventional thermometers are not suitable for all temperature measurement applications. For example, the accurate detection of high-temperature gases (500 to 2000°C) at low velocities (3 to 5 ft/s) is a problem, even for thermocouples. This is because conductance through the lead wires and radiation both tend to alter the sensor temperature faster than the low velocity gas flow can resupply the lost heat. In such applications (fuel cell controls are prime examples), optical fiber thermometry is a good choice.

Thermocouples are usually not accurate enough for the precise measurement of temperature differences and are not fast enough to detect high-speed variations in temperature. RTDs can detect temperature differences of 10°F at a measurement error of ±0.04°F. If high-speed response is desired, thermistors or infrared detectors should be considered.

In the conventional control loop, the measurement lag is only part of the total time lag of the control loop. For example, an air heater might have a total lag of 15 min. Of this lag, 14 min represent the *process lag,* 50 sec the bulb lag, and 10 sec is the control valve's contribution to the total time lag.

Three-Way Valves The limits within which process temperature can be controlled are a function of the nature of load changes. In many installations, the process time lag in the heat exchanger is too great to allow for effective control during load changes. In such cases, it is possible to circumvent the dynamic characteristics of the exchanger by partially bypassing it and blending the warm process liquid with the cooled process fluid, as shown in Figure 8.29f. Increased speed of response and some cost savings are the main motivations for considering three-way valves in such services.

The bulb time lag discussed in the previous paragraph has an increased importance in system configurations, because this lag represents a much greater percentage of the total loop lag time than in the previously discussed two-way valve installations.

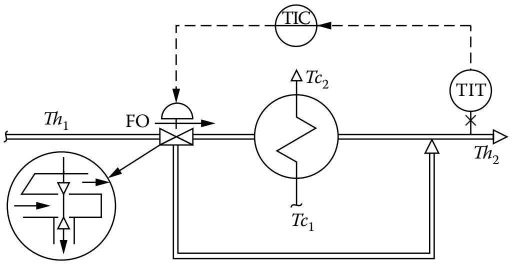

FIG. 8.29f
When a diverter valve is used to control a cooler, it does not eliminate nonlinearity, but it does speed the response and minimize fouling.[1]

The use of a three-way valve such as that shown in Figure 8.29f does not change the nonlinear nature of the heat exchanger, because the process gain will still vary with load, but the dynamic response of the loop will still be improved.

This is because the bypass will shorten the time delay between a change in valve position and the response at the temperature sensor. Another benefit from the use of a three-way valve on the process side is that the coolant is not throttled, which keeps the heat-transfer coefficient up while minimizing fouling. The disadvantages include increased pumping costs and lower temperature differences between supply and return water.

As illustrated in Figures 8.29f and 8.29g, either a diverter or a mixing valve can be used as a three-way valve. Stable operation of these valves is achieved by using flow to open valves in both cases. If a mixing valve is used for diverting service or if a diverting valve is used for mixing, the operation becomes unstable because of the "bathtub effect" (if the flow direction is reversed, the fluid itself will try to push the valve plugs closed). Therefore, it is not good enough just to install a three-way valve, but the selection (mixing or diverting design) has to match the particular service.

Three-way valves are unbalanced valve designs and are normally provided with linear ports. Their unbalanced nature places a limitation on the allowable shut-off pressure difference across the valve, and the linear ports eliminate the potential of them serving to compensate for the variable gain of the process.

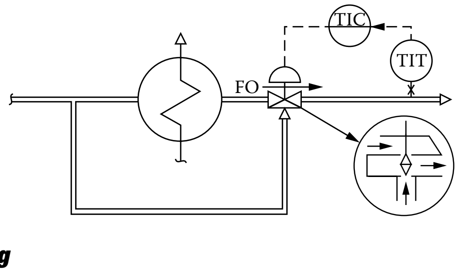

FIG. 8.29g
A mixing valve can be used to control the cooler. It has a flow to open inner valve for stability.[1]

Misalignment or distortion in a three-way control valve installation can cause binding, leakage at the seats, dead band, and packing friction. Such conditions commonly arise when three-way valves are used in high-temperature applications. This is because, having been installed at ambient conditions and rigidly connected at three flanges, the valve cannot accommodate pipeline expansion caused by high process temperatures, and therefore distortion results.

Similarly, in mixing applications, when the temperature difference between the two ports is substantial, the resulting differential expansion can also cause distortion. For these reasons, the use of three-way valves at temperatures above 500°F (260°C) or at differential temperatures exceeding 300°F (167°C) is not recommended.

The choice of three-way valve location is normally based on pressure and temperature considerations, with the upstream location (Figure 8.29f) usually being favored for reasons of uniformity of valve temperature. When the overriding consideration is the desire to operate the exchanger at a high pressure, the downstream location might be selected.

Cooling Water Conservation Figure 8.29h modifies the control systems shown earlier by adding a controller to serve cooling water conservation. The TIC-01 in Figure 8.29h is set at a relatively high value to maximize the outlet cooling water temperature, thereby minimizing the rate of cooling water usage.

When using this approach, one should be careful to make sure that the cooling water contains chemicals to prevent tube fouling under higher return water temperature conditions. If the cooling water supply is sufficient and the TIC-01 set point is properly selected, this system on the one hand will conserve water and, on the other, will also protect against excessively high outlet water temperature.

Unfortunately, this configuration will not yield stable control, because controlling temperature through manipulation of its own flow results in a limit cycle. The cause of this instability is that the output of TIC-01 affects the dead time of the process that it controls. This comes about because if TIC-01 detects a temperature rise, it opens its valve, causing a sudden drop in temperature as the process dead time is also reduced.

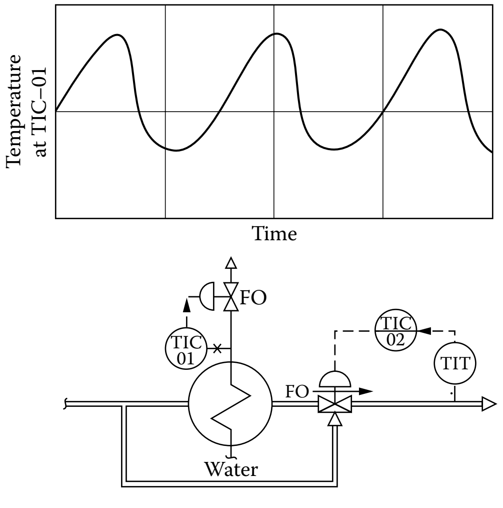

FIG. 8.29h
Conservation of cooling fluid is provided at the price of stability.[1]

As TIC-01 senses this sudden drop in temperature, it will close its valve, but because this also increases the process dead time, the resulting temperature will rise slowly.[4] This limit cycle, consisting of segments of slow rise and fast fall, will also affect the performance of TIC-02 through interaction between the loops. The amplitude of the cycle can be reduced by increasing the proportional band (reducing the gain) of TIC-01, which will also increase the period of oscillation.[4]

The only way to eliminate this oscillation altogether is to fix the process dead time. This can be done by the addition of a recirculating pump, which will return part of the heated water back to the inlet. As can be seen, there is no easy way to make this configuration stable, and for that reason, the best solution is to avoid its use.

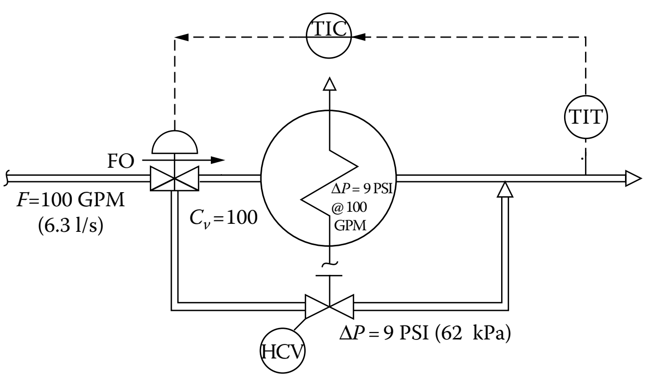

FIG. 8.29i
When three-way valves are used, it is recommended to install a manual balancing valve in the bypass.[1]

Balancing the Three-Way Valve When using three-way control valves, it is recommended that a manual balancing valve be installed in the exchanger bypass, as shown in Figure 8.29i. The opening of this valve should be so adjusted that its pressure drop equals that of the exchanger at normal load.

The resistance to flow in such installations will be maximum when one of the paths is closed and the other is fully open, whereas minimum resistance will be experienced when the valve divides the flow equally between the two paths. For example, if a diverting valve with $C_v = 100$ and process fluid flow rate of 100 gpm (6.3 l/s) has a 9 psi (6.21 kPa) pressure drop at full flow through either the exchanger or the balancing valve, the equivalent coefficient for the exchanger (or the balancing valve) is calculated as

$$C_e = \frac{\text{flow}}{\sqrt{\text{pressure drop}}} = \frac{100}{\sqrt{9}} = 33.3 \qquad \textbf{8.29(14)}$$

Therefore, in either extreme position (closed or full bypass), the total system resistance expressed in valve coefficient units is

$$\frac{1}{(C_t)^2} = \frac{1}{(C_v)^2} + \frac{1}{(C_e)^2} = \frac{1}{(100)^2} + \frac{1}{(33.3)^2} \qquad \mathbf{8.29(15)}$$

$$\therefore C_t = 31.7$$

When the valve divides the flow equally between the two paths, because of the linear characteristics of three-way valves, its coefficient at each port will be $C_v = 50$. The equivalent coefficient ($C_e = 33.3$) of the exchanger and balancing valve being unaffected, the total system resistance in valve coefficient units is $2C_t$:

$$\frac{1}{(C_t)^2} = \frac{1}{(C_v)^2} + \frac{1}{(C_e)^2} = \frac{1}{(50)^2} + \frac{1}{(33.3)^2} \qquad \mathbf{8.29(16)}$$

$$\therefore 2C_t = 55.6$$

If the total pressure drop through the system is calculated when the valve is in its extreme and when it is in its middle position, handling the same 100 gpm (6.3 l/s) flow, the following pressure drops are found:

$$\Delta P_{\text{extreme}} = \left(\frac{\text{flow}}{C_t}\right)^2 = \left(\frac{100}{31.7}\right)^2 = 10 \text{ PSI (69 kPa)} \qquad \mathbf{8.29(17)}$$

$$\Delta P_{\text{middle}} = \left(\frac{100}{55.6}\right)^2 = 3.25 \text{ PSI (22.4 kPa)} \qquad \mathbf{8.29(18)}$$

These results indicate that the system drop in one of the extreme positions is more than three times that of the pressure drop in the middle position.

Two Two-Way Valves Sometimes it is desirable to improve the system response speed, but three-way valves cannot be used. In such situations, the installation of two linear, two-way valves is a logical option.

As illustrated in Figure 8.29j, the two valves should have opposite failure positions, so that when one is open the other is closed, and at a 50% signal both are halfway open. The price of a three-way valve and its installation is about 65% that of two two-way valves.

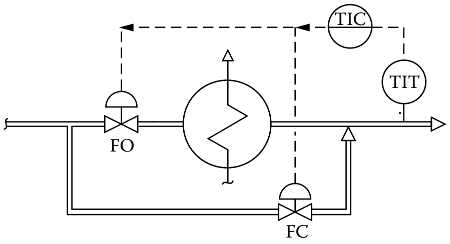

FIG. 8.29j
Exchanger bypass control by using two two-way valves.[1]

TABLE 8.29k
Merits of Two-Way vs. Three-Way Valves in Exchanger Bypass Installations

	One Three-Way Valve	*Two Single-Seated Two-Way Valves*	*Two Double-Ported Two-Way Valves*
Most economical	Yes		
Provides tight shut-off	Yes	Yes	
Applicable to service above 500°F (260°C)		Yes	Yes
Applicable to differential temperature service above 300°F (167°C)		Yes	Yes
Applicable to operation at high pressure and pressure differentials		Yes	Yes
Highest capacity for same valve size			Yes

On the other hand, the capacity of one three-way valve is only about 70% of the capacity of a double-ported two-way valve. This could mean that instead of one 10 in. (250 mm) three-way valve, two 8 in. (200 mm) double-ported two-way valves can be used, if the leakage of such valves (1–5% of full capacity) is acceptable. Therefore, if tight shut-off is required, only the three-way or the single-ported two-way valves can be considered, and their capacity is about the same.

The use of three-way valves is not recommended for high-temperature or high-pressure differential services. In addition, the hollow plug design of three-way valves also contributes to their limitations, because it makes these valves more sensitive to thermal expansion and more difficult to harden than are the solid plugs.

To summarize, bypass control is applied to circumvent the dynamic characteristics of heat exchangers, thus improving their controllability. Bypass control can be achieved by the use of either one three-way valve or two two-way valves. Table 8.29k summarizes the merits and drawbacks of using one or the other option.

Steam Heater Controls

The steam-heated exchanger shown in Figure 8.29l is also nonlinear. Its steady-state gain is the derivative of its outlet temperature with respect to steam flow,[2] having the dimension of °F(lb/h):

$$Kp = \frac{dT_2}{dFs} = \frac{\Delta Hs}{FCp} \qquad \mathbf{8.29(19)}$$

Therefore, its process gain varies inversely with flow. In a step response test, the outlet temperature (T_2) reaches 63.2%

$$Q = UA\Delta \mathrm{Tm} = UA\,\frac{(T_s - T_2) - (T_s - T_1)}{\ln((T_s - T_2)/(T_s - T_1))} \qquad \textbf{8.29(20)}$$

$$Q = F_s\,\Delta H_s = F\,C_P\,(T_2 - T_1)$$

Where Q = Heat-transfer rate
F_s = Steam mass flow
ΔH_s = Latent heat of vaporization
F = Feed rate
Cp = Heat capacity of feed
T_0 = Steam supply temperature
P_1 = Steam supply pressure
P_2 = Steam valve outlet pressure
P_s = Condensing pressure
T_1 = Inlet temperature
T_2 = Outlet temperature
ΔTm = Log mean temperature difference
T_s = Condensing steam temperature

F_s = 500 to 2500 lb/hr (227 kg/hr to 1134 kg/hr)
P_1 = 200 PSIA (1.38 MPa)

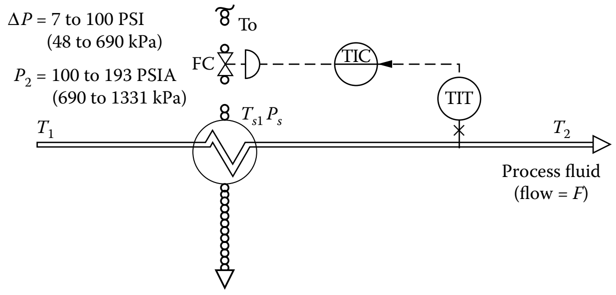

FIG. 8.29l
The feedback control of a steam-heated exchanger and its characteristic equations.[1]

of its final value after a time equivalent of its residence time, which is tube volume divided by flow. Therefore, its time constant, dead time, residence time, period of oscillation, and process gain all vary with flow. As flow (load) drops to 50%, the process gain is doubled.

Therefore, the TIC loops have a tendency to become unstable at low and sluggish at high loads. In order to eliminate cycling, these loops are often tuned at minimum load, resulting in sluggish response at higher loads. One way to compensate for the drop in process gain as the flow increases is to use an equal-percentage valve whose gain increases with load. This is sufficient if the temperature rise ($T_2 - T_1$) is constant. Otherwise, feedforward compensation is needed.

The use of equal-percentage valves is even more important in the case of steam heaters than with liquid-to-liquid exchangers, because the rangeability requirements of steam heaters is usually higher, because of the variations in condensing pressure (steam valve back-pressure) with changes in process load. This can be best visualized by an example.

In Figure 8.29l, both the high and the low load conditions are shown. When the steam flow demand is the greatest, the back-pressure is also the highest (P_2 = 193 PSIA, or 1331 kPa), leaving the lowest driving force (pressure drop) for the control valve (7 PSI, or 48 kPa). Sizing for high flow (2500 lb/h) and low pressure drop results in a large valve.

The back-pressure at low loads is only 100 PSIA (690 kPa), resulting in a pressure drop through the valve that is some 16 times greater (100 PSI, or 690 kPa) than at high loads. The ratio between the required valve coefficients for the high and low load conditions represents the rangeability that the valve has to furnish.

$$\text{rangeability} = S\,\frac{F_{s,\max}}{F_{s,\min}}\sqrt{\frac{[(P_1 - P_2)(P_1 + P_2)]_{\min}}{[(P_1 - P_2)(P_1 + P_2)]_{\max}}}$$

$$= 1.5 \times 5\sqrt{\frac{100 \times 300}{7 \times 393}} = 25.5 \qquad \textbf{8.29(21)}$$

The letter S with the numerical value of 1.5 in Equation 8.29(21) represents the safety factor that is applied in selecting the control valve. A rangeability requirement of this magnitude can create some control problems. One solution is to use a large and a small valve in parallel.

If this is not done, the control quality will suffer for two reasons: First, at low loads the valve will operate near to its clearance flow point (see Section 6.7), where the flow-vs.-lift curve changes abruptly, contributing to unstable or possibly on/off cycling of the valve. Second, for good control the system gain should not vary with changes in load, which an equal-percentage control valve can guarantee only if the control valve ΔP is not a function of load. This being the case, one way to guarantee constant system gain is to install a large and a small valve, both sized to maintain the same gain. The other option is to use an adaptive gain correction in the control algorithm, which is discussed later.

Minimum Condensing Pressure The condensing pressure is a function of load when the temperature is controlled by throttling the steam inlet. As long as the heat transfer area is constant, a reduction in load must result in the lowering of the log mean temperature difference across the exchanger. If T_2 is held constant by the TIC, this can occur only if the steam-side temperature (*Ts*) is lowered. The condensing temperature required can be calculated as follows:[5]

$$T_s = \left(\frac{T_1 + T_2}{2}\right)\left(1 - \frac{L}{100}\right) + \left(\frac{L}{100}\,\mathrm{To}\right) \qquad \textbf{8.29(22)}$$

where L is the load in percentage of maximum. The condensing pressure corresponding to the values of T_s can be plotted as a function of load. Once this pressure drops below the trap back-pressure plus trap differential, it is no longer sufficient to discharge the condensate, and therefore the condensate will start accumulating in the exchanger. As condensate accumulation progresses, more and more of the heat-transfer area will be covered up, resulting in a corresponding increase in condensing pressure.

When this pressure rises sufficiently to discharge the trap, the condensate is suddenly blown out and the effective heat-transfer surface of the exchanger increases instantaneously. This can result in cycling as the exchanger surface is covered and uncovered. In addition, noise and hammering can be

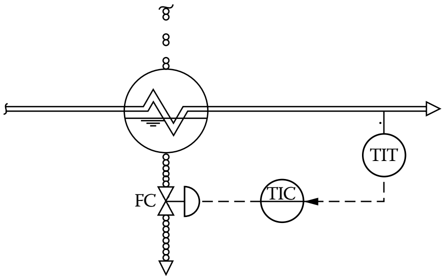

FIG. 8.29m
The problems associated with minimum condensing pressure and condensate removal can be eliminated by locating the control valve in the condensate line.[1]

caused as the steam bubbles collapse on contact with the accumulated cooler condensate. The methods to remedy this are several and are discussed in the following paragraphs.

Condensate Throttling Mounting the control valve in the condensate line, as shown in Figure 8.29m, is sometimes proposed as a solution to minimum condensing pressure problems. There also is a cost advantage to this configuration, because a small condensate valve costs less than a larger one for steam service.

On the surface this appears to be a convenient solution, because the throttling of the valve causes variations only in the condensate level inside the partially flooded heater and has no effect on the steam pressure, which stays constant. Therefore, condensate removal does not present a problem. Unfortunately, the control characteristics of this loop are not so favorable.

The response time of such a control configuration depends on both the load and exchanger geometry. Tests have shown that in such a system, correcting a load decrease takes about three times as long as correcting a load increase.[5] The response time to a 5% change in load is from a few seconds to a few minutes, whereas to a 50% change it can be from a few minutes to nearly an hour.[5]

When the load is decreasing, the valve is likely to close completely before the condensate builds up to a high enough level to match the new lower load with a reduced heat-transfer area. In this direction, the process is slow, because steam has to condense before the level can be affected. When the load increases, the process is fast, because just a small change in control valve opening is sufficient to discharge enough condensate to expose the heat-transfer surface area that is required to match the increased load.

With such "nonsymmetrical" process dynamics, control is bound to be poor. If the controller is tuned for the fast response speeds (corresponding to the increasing load direction), sluggish performance and overshoot can result when load is decreasing. If it is tuned for the slow part of the cycle, cycling can occur when the load rises. Therefore, the replacement of the steam trap with an equal-percentage control valve is usually not a good solution.

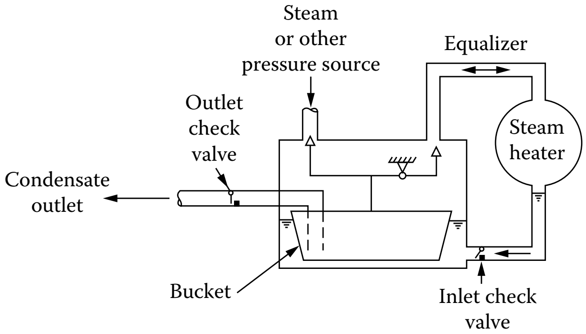

FIG. 8.29n
A lifting or pumping trap, shown here in its filling position, can help prevent condensate accumulation in heaters operating at low condensing pressures.[1]

Pumping Traps It is possible to use lifting traps to prevent condensate accumulation in heaters operating at low condensing pressures. This device is illustrated in Figure 8.29n and depends on an external pressure source for its energy.

The unit is shown in its filling position, in which the liquid head in the heater has opened the inlet check valve of the trap. Filling progresses until the condensate overflows into the bucket, which then sinks, closing the equalizer and opening the pressure source valve. As pressure builds in the trap, the inlet check valve is closed and the outlet valve opens when the pressure exceeds that of the condensate header.

The discharge cycle follows. In this cycle, the bucket is emptied. When the bucket is near empty, the buoyant force raises the bucket, which then closes off the steam valve and opens the equalizer. Once the pressure in the trap is lowered, the condensate outlet check valve is closed by the header back-pressure, and the inlet check is opened by the liquid head in the heater, which then is the beginning of another fill cycle.

The aforementioned pumping trap guarantees condensate removal regardless of the minimum condensing pressure in the heater. If such a trap is placed on the exchanger illustrated in Figure 8.29l, it will make temperature control possible even when the heater is under vacuum. Of course, this does not relieve the rangeability problems discussed earlier, and the use of two valves in parallel might still be necessary.

Level Controllers The control system in Figure 8.29l provided quick response but was unable to discharge its condensate at low loads. The system in Figure 8.29m eliminated the condensate problem, but at the price of worsening control response.

Because the low condensing pressure situation is a result of the combination of low load and high heat-transfer surface area, it is possible to prevent it from developing by reducing the heat-transfer area. One method of achieving this is shown in Figure 8.29o. Here, the steam trap has been replaced by a level control loop. With this instrumentation, it is possible to adjust the size of the heater by changing the level set point

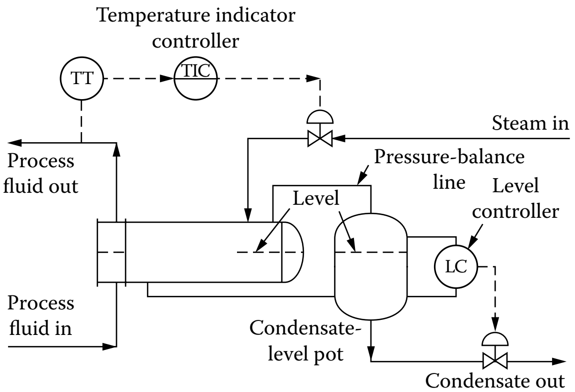

FIG. 8.29o
The use of two control loops can maintain sensitive temperature control without condensate removal problems.[5]

to match the process load. This technique gives good temperature control, if the level setting is correct and if there are no sudden load variations in the system.

As the required level is a function of the load, it can be adjusted automatically. This relieves the operator of the responsibility of manually changing the level controller set point whenever the load changes. More important, this also eliminates the potential for human error, which at low-level settings can result in condensate removal problems and at high levels can prevent temperature control.

Automatic adjustment of the level is illustrated in Figure 8.29p. Here the load is detected by the valve position controller (VPC) having a set point of, say, 50%. When the load rises, the steam valve opens beyond 50% and the VPC increases the active heat-transfer area in the heat exchanger by lowering the set point of the condensate level controller.

The VPC is an integral-only controller and, therefore, will not respond to measurement noise or valve cycling. The integral time is set to give slow floating action that is fast enough to respond to anticipated load changes. The external feedback protects the VPC from reset windup when the LIC is switched to local set point.

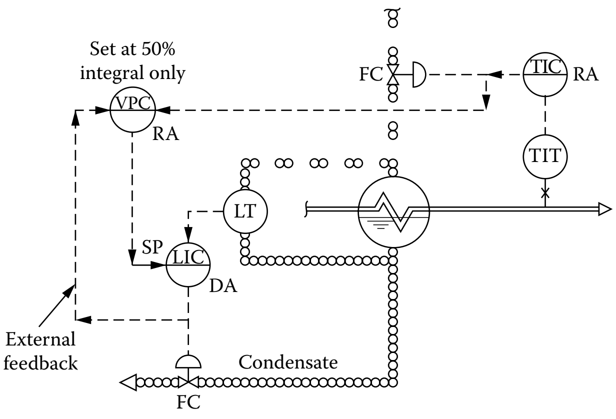

FIG. 8.29p
The level setpoint can be floated to match the load.[1]

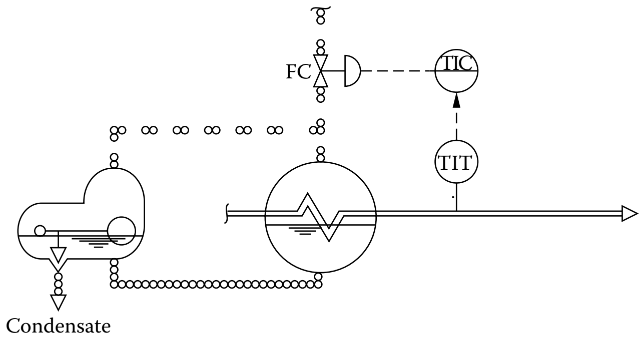

FIG. 8.29q
Continuous drainer traps can serve the same function as level controllers, but can handle only small variations in condensate level.[1]

In less critical applications, in which the cost of an extra level control loop cannot be justified, a continuous drainer trap such as the one shown in Figure 8.29q can serve the same purpose as the level control scheme just described. Its cost is substantially lower, but it is limited to the range within which its level setting can be varied. Another limitation is that its control point is offset by load variations. For this reason, continuous drainer traps are unlikely to be considered for installations on vertical heaters or on reboilers, where the range of level adjustment can be substantial.

Bypass Control Table 8.29k summarizes some of the features of three-way valve installations serving to circumvent the transient characteristics of coolers. Figure 8.29r shows the same concept applied to a steam heater. The advantages and limitations of this system are the same as discussed in connection with liquid-to-liquid exchangers, with the additional advantage that the bypass used has also created an additional degree of freedom.

Therefore, steam can now be throttled as a function of some other property. The logical decision is to adjust the

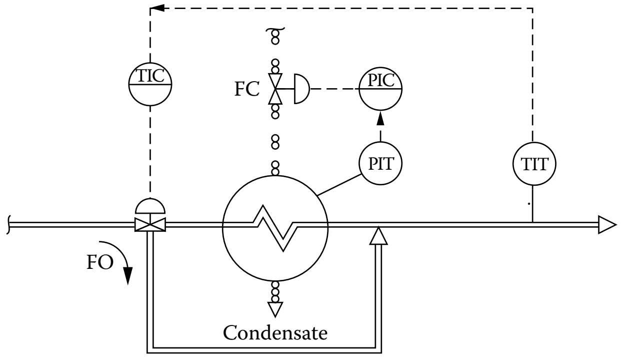

FIG. 8.29r
Bypass control of steam heater provides the added degree of freedom needed for independent control of condensing pressure.[1]

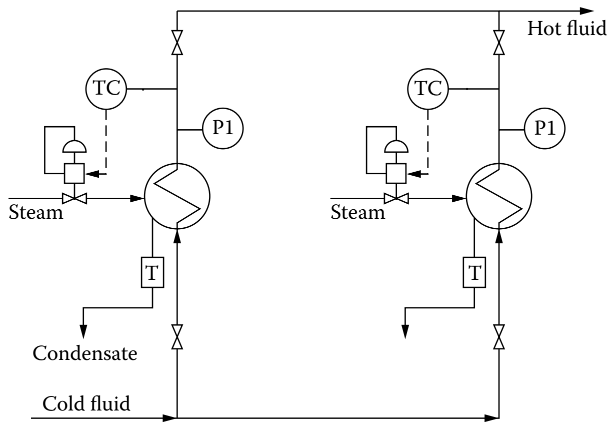

FIG. 8.29s
Parallel heaters operating close to the boiling point of the process fluid can experience serious interaction problems.[4]

steam feed so that it maintains the condensing pressure constant. This then eliminates problems associated with condensate removal. It is also important to realize that when all the process fluid flow is sent through the bypass, the stagnant exchanger contents will be exposed to steam heat, and therefore, unless protection is provided, it is possible to boil this liquid.

Interaction between Parallel Heaters If the process fluid is heated to a temperature approaching its boiling point, serious interaction can occur between parallel heaters (Figure 8.29s). The mechanism of developing this oscillation is as follows: A sudden drop in flow causes overheating and vaporization in one of the heaters. The vapor formation increases the back-pressure and further reduces the flow, eventually forcing all flow through the other "cold" exchanger, while the "hot" exchanger discharges slugs of liquid and vapor.

After a period of noise and vibration, when the "hot" exchanger has discharged all of its liquid, the back-pressure drops and flow is resumed, drawing feed from the "cold" exchanger. This causes the "cold" exchanger to overheat, and the cycle is repeated with the roles of the exchangers reversed.[4]

This type of interaction can be eliminated by distribution controls (Section 8.28). The control system used in making sure that the load is equally distributed between exchangers is the same as the system described for cooling tower balancing (Figure 8.17e).

Condenser Controls

Depending on whether the control of condensate temperature or of condensing pressure is of interest, the system shown in Figures 8.29t or 8.29u can be considered. Both of these systems operate by throttling the cooling water flow through the condenser, causing a potential for high-temperature rise that is acceptable only when the water is chemically treated against fouling.

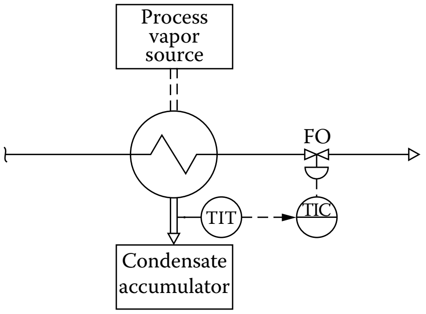

FIG. 8.29t
Condensate temperature control throttles the cooling water flow through the condenser.[1]

For good, sensitive control, the water velocity through the condenser should be such that its residence time does not exceed 1 min. Another rule of thumb is to keep the water velocity above 4.5 ft/s (1.35 m/s). This can be accomplished by the use of a small recirculating pump, such as P1 in Figure 8.13i. In this system, FSHL-3 detects the net forward velocity of the water. As long as it is under 4.5 ft/s, FSHL-3 will keep the recirculating pump running.

When it is not desirable to throttle the cooling water, the system illustrated in Figure 8.29v can be considered. Here, the exposed condenser surface is varied to control the rate of condensation. If noncondensables are present, a constant purge may be used to remove the inerts. The disadvantages of the nonsymmetrical response of such condensate level controls have already been described in connection with Figure 8.29m, and they are the main disadvantage of this design.

Because the heat-transfer efficiency is the highest when both the coolant flow and the heat-transfer area are at their maximums, the goal of optimization in Figure 8.29u is to open the coolant valve fully. In Figure 8.29v, the goal of optimization is to eliminate flooding. Both of these goals can be achieved by slowly lowering the PIC set point until the cooling capacity is fully utilized and none of it is wasted by throttling.

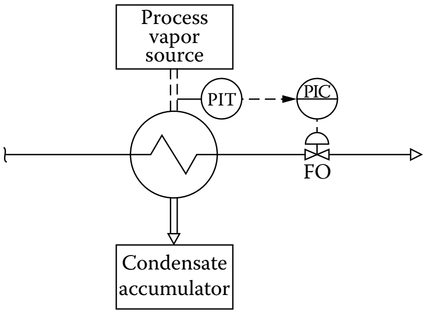

FIG. 8.29u
The cooling water flow through the condenser can be throttled to control pressure.[1]

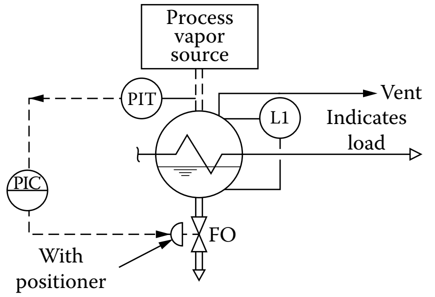

FIG. 8.29v
Condenser control can be achieved by changing the wetted surface area.[1]

The preferred method of condenser control is to vary the heat-transfer area through partial flooding.[2] In that case, the load is indicated by the condensate level (Figure 8.29v). The condensate is subcooled to differing degrees as a function of residence time. Therefore, condensate temperature cannot be used for control.

The controller on a partially flooded condenser can be tuned as a level controller, but because of the noise filtering effect of the system's heat capacity, derivative action can usually be added.[2] The addition of valve positioners is always helpful in improving the response and stability of the loop.

Distillation Condensers A variety of condenser designs is available for use on distillation towers. The disadvantage of air-cooled designs is that they are sensitive to ambient variations, particularly to rainfall. These units are throttled by manipulating their inlet louvers or by adjusting the blade pitch of their fans. If multispeed or variable-speed fans are available, the condenser rangeability can be increased while energy is saved.

When the condenser is water-cooled and its inlet pressure is controlled by partial flooding (Figure 8.29v), the main limitation is the response speed of the system, because a change in valve position does not immediately affect the heat-transfer area. The response speed is slower when the level needs to be increased and faster when it is to be decreased. The consequences of this "nonsymmetricity" have already been explained in connection with Figure 8.29m. In controlling distillation towers, the elimination of this nonsymmetricity is one of the important control goals.

The simplest method of handling this problem is to bleed off a fixed amount of gases and vapors to a lower-pressure unit, such as to an absorption tower, if such is available in the system. If an absorber is not present, it is possible to install a vent condenser to recover the condensable vapors from this purge stream.

It is recommended that the fixed continuous purge be used wherever economically possible; however, when this is not permitted, it is possible to modulate the purge stream. This might be desirable when the amount of inerts is subject to wide variations over time (Figure 8.19ff in Section 8.19).

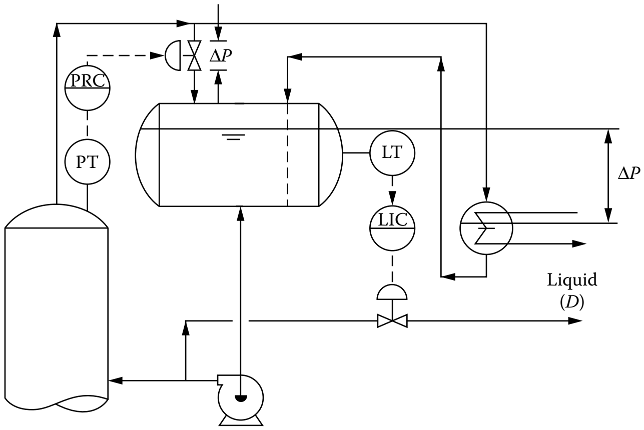

FIG. 8.29w
Condenser control by the throttling of hot gas bypass.

As the uncondensables build up, the pressure controller will tend to open the control valve (PCV-1) to maintain the proper rate of condensation. As shown in Figure 8.19ff, the signal that is opening this control valve can also be used to signal when the pressure control valve (PCV-1) is nearly fully open, and therefore purging is needed. In Figure 8.19ff, this is done by a valve position controller (VPC-2).

Condenser below Receiver Lowering the condenser below the accumulator not only reduces installation cost and makes maintenance more convenient but also eliminates the nonsymmetricity of the process. It is the usual practice to elevate the bottom of the accumulator 10 to 15 ft (3 to 4.5 m) above the suction of the pump in order to provide the required suction head.

In this type of installation, the control valve is placed in a bypass from the vapor line to the accumulator (see Figure 8.29w). When this valve is open, it equalizes the pressure between the vapor line and the receiver. This causes the condensing surface to become flooded with condensate because of the 10 to 15 ft of head that exists in the condensate line from the condenser to the receiver. The flooding of the condensing surface causes the pressure to build up because of the decrease in the active heat-transfer surface available.

Under normal operating conditions, the subcooling that the condensate receives in the condenser is sufficient to reduce the vapor pressure in the receiver. The difference in pressure permits the condensate to flow up the 10 to 15 ft of pipe between the condenser and the accumulator.

When the condensing pressure is to be reduced, the valve closes, resulting in an increase in the exposed condenser surface area. In order to expose more area, the condensate is transferred into the accumulator; this transfer can occur only if the accumulator vapor pressure has been sufficiently lowered by condensation. Therefore, the system speed in this direction is a function of the amount of supercooling of the condensate. Increased supercooling increases system response speed.

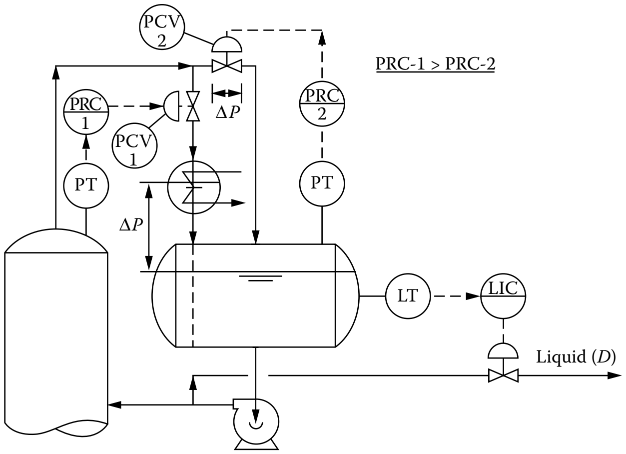

FIG. 8.29x
High-speed condenser control.

Based on these considerations, the unit might or might not be symmetrical in its dynamics. If high speed is desired and there are no inerts in the process vapors, the controls shown in Figure 8.29x can be considered. Here, the pressure is controlled in the accumulator by throttling the condenser bypass flow. The column pressure is maintained by throttling the flow of vapor through the condenser. Controlling the rate of flow through the condenser gives faster pressure regulation for the column.

When the condensing temperature of the process fluid is low, water is no longer an acceptable cooling medium and cooling by refrigerants is required. One standard technique of controlling a refrigerated condenser is illustrated in Figure 8.29y. Here, the heat-transfer area is set by the level control loop, and the operating temperature is maintained by the pressure controller.

When process load changes, it affects the rate of refrigerant vaporization, which is compensated for by level-controlled makeup. Usually the pressure and level settings are made manually, although there is no reason why these set points could not be automatically adjusted as a function of load. This can be done by placing a valve position controller on the PIC output signal. This VPC will detect an increase in load and will respond to it by lowering the LIC set point to increase the heat-transfer area, as was discussed in connection with Figure 8.29p.

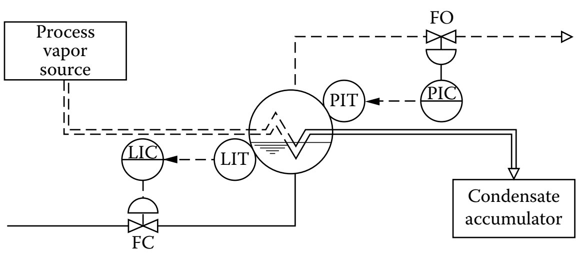

FIG. 8.29y
Condensers can be controlled using refrigerant coolants.[1]

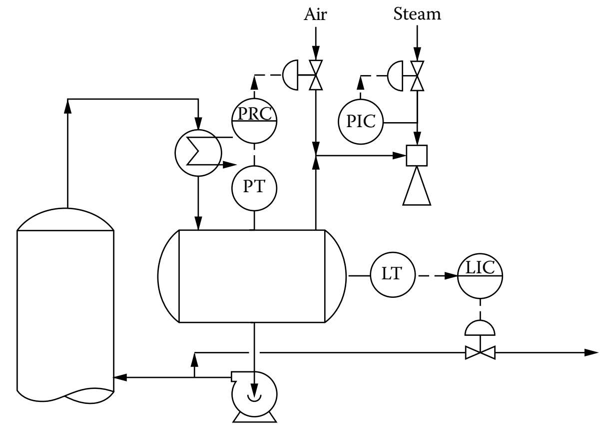

FIG. 8.29z
Typical control system for the operation of vacuum condensers.[1]

Vacuum Systems For some liquid mixtures, the temperature required to vaporize the feed would need to be so high that decomposition would result. To avoid this, it is necessary to operate at below atmospheric pressure. The common means for creating a vacuum is to use steam jet ejectors. These can be used singly or in stages to create a wide range of vacuum conditions. Their wide acceptance is due to their having no moving parts and requiring very little maintenance.

Most ejectors are fixed-capacity devices and work best at a single steam condition. Increasing the steam pressure above the design point will not usually increase the capacity of the ejector; as a matter of fact, it will sometimes decrease the capacity because of the choking effect of the excess steam in the diffuser throat.

Steam pressure below a critical value for a jet will cause the ejector operation to become unstable. Therefore, it is recommended that a pressure controller be installed on the steam inlet to maintain the optimum pressure required by the ejector.

The recommended control system for the operation of vacuum condensers is shown in Figure 8.29z. In this configuration, air or gas is bled into the vacuum line just ahead of the ejector. This makes the maximum capacity of the ejector available to handle any surges or upsets, but at low loads, this represents a substantial waste of steam. Therefore, for processes in which load variations are expected, the operating costs can be lowered by installing a larger and a smaller ejector. This makes it possible to switch to the small unit automatically when the load drops off, and thereby reduce steam demand.

A pressure controller (PRC) regulates the amount of bleed air used to maintain the pressure on the accumulator. Controlling the air bleed by the accumulator instead of the condenser inlet pressure reduces the time lag and, thereby, increases the sensitivity of the loop.

Reboilers and Vaporizers

As noted at the beginning of this chapter, when a steam-heated reboiler is used, only one degree of freedom is available

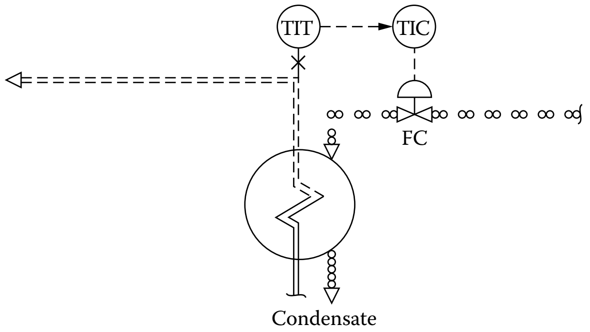

FIG. 8.29aa
Reboilers can be controlled by generating vapors at controlled temperatures.[1]

(Equation 8.29[4]); therefore, only one controller can be installed without overdefining the system. This one controller usually throttles the rate of steam addition. Minimum condensing pressure considerations are the same as have been discussed earlier in connection with liquid heaters.

Figures 8.29aa and 8.29bb show the two basic alternatives for controlling the reboiler. One is to generate the process vapors at a controlled superheat temperature, the other is to generate saturated process vapors at a constant rate by keeping the rate of heat input constant.

Naturally, there are other, more sophisticated reboiler control strategies, using composition, temperature difference, or derived variables as the means of control (see Section 8.21), but in their effects they are all similar to the systems shown in Figures 8.29aa and 8.29bb.

When several reboilers operate in parallel, it is important to balance the load distribution between them according to the type of control system, as was described in Figure 8.28b.

Fired Reboilers When heat duties are great and bottom temperatures are high, fired reboilers are used. The fired reboiler can vaporize the bottoms of a distillation tower as this liquid circulates by natural convection through the heater tubes. The coils are generously sized to ensure adequate circulation of the bottoms liquid. Overheating the process fluid is a contingency that must be guarded against, because most tower bottoms will coke or polymerize if under excessive temperatures for some length of time.

A common control scheme is shown in Figure 8.27q in Section 8.27. This figure depicts the tower bottom along with the fired reboiler. It is not usually practical to measure the flow of tower bottoms to the reboiler — first, because the liquid is near equilibrium (near the flash point), and second, because it is usually of a fouling nature, tending to plug most flow elements. Proper circulation of the fluid is provided for in the careful hydraulic design of the interconnecting piping.

The other important variable is the reboiler return temperature, which in Figure 8.27q is controlled by TRC-1's throttling of the fuel gas control valve (TV-1). The high-temperature alarm (TAH-1) is provided to warn the operator that the process fluid has suddenly reached an excessive temperature, indicating that manual adjustments are needed to cut back on the firing.

The furnace draft can be manually set by the operator, adjusting the stack damper while observing the draft gauge (PI-1), or it can be maintained automatically. The stack temperature (TI-2) and the firebox temperature (TI-3) are detected and can be alarmed to signal excessive temperatures that may develop during periods of heavy firing.

The major dangers in this type of furnace operation include the interruption of process fluid flow or the stoppage of fuel flow. The loss of process fluid can occur if the liquid level in the tower bottom is lost. If this happens, flow to the reboiler tubes will stop and a dangerous overheating of these tubes may result. To protect against this, the low-level switch (LSL-1) is wired to trip the solenoid valve (LY-1) that vents the diaphragm of the control valve (TV-1) to close the fuel valve.

A momentary loss of fuel can also be dangerous, because that can extinguish the flames, and on the resumption of fuel flow a dangerous air/fuel mixture can develop in the firebox. To prevent this occurrence, the low-pressure switch (PSL-1) also trips the solenoid (LY-1) if the fuel pressure is low, and that closes the fuel valve (TV-1). The solenoid valve (LY-1) should be of the manual reset type and should keep the valve (TV-1) closed even after the fuel pressure has been reestablished.

On loss of air supply, the fuel control valve (TV-1) should fail closed (FC), so that firing will be discontinued during such an emergency.

Fired Heaters and Vaporizers The unit feed heater of a crude oil refinery is representative of the class of furnaces that includes fired heaters and vaporizers. As was discussed in Section 8.27, crude oil, prior to distillation into the various petroleum fractions (gasoline, naphtha, gas oil, heavy fuel oil, and so forth) in the "crude tower" must be heated and partially vaporized. The heating and vaporization are done in the crude heater furnace, which consists of a firebox with preheating coils and vaporizing coils.

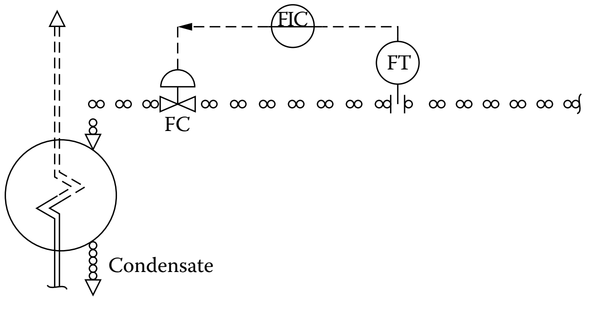

FIG. 8.29bb
BTU control sets the steam flow to reboilers.[1]

The heating is usually done in coils in the convection section of the furnace. The convection section is the portion of the coils that does not see the flame but that is exposed to the hot flue gases on their way to the stack. The vaporizing takes place at the end of each pass in the radiant section of the furnace (where the coils are exposed to the flame and the luminous walls of the firebox).

The partially vaporized effluent then enters the crude tower, where it flashes and is distilled into the desired "cuts." Other process heaters that fall into this category are refinery vacuum tower preheaters, reformer heaters, hydrocracker heaters, and dewaxing unit furnaces.

The prime control tasks in this process are

1. Flow control of feed to the unit
2. Proper splitting of flow into the parallel paths through the furnace to prevent overheating of any one stream, which could result in coking
3. Supplying the correct amount of heat to the crude tower

Figure 8.29cc shows the typical process controls for this type of furnace. The crude feed rate to the furnace is set by the flow controller (FRC-2). This flow can be split through the parallel paths of the furnace by remote manual adjustment of the control valves (HV-1 through HV-4) via the manual stations (HIC-1 through HIC-4) or can be distributed automatically.

In this manual control configuration, the operator manually adjusts (HIC-1 to HIC-4) the distribution valves to equalize the flows (FI-1 through FI-4). Naturally, this can also be done automatically by replacing the four flow indicators with four flow ratio controllers (FFIC-1 to FFIC-4) and sending the total flow transmitter signal (FT-2) as the set point to each.

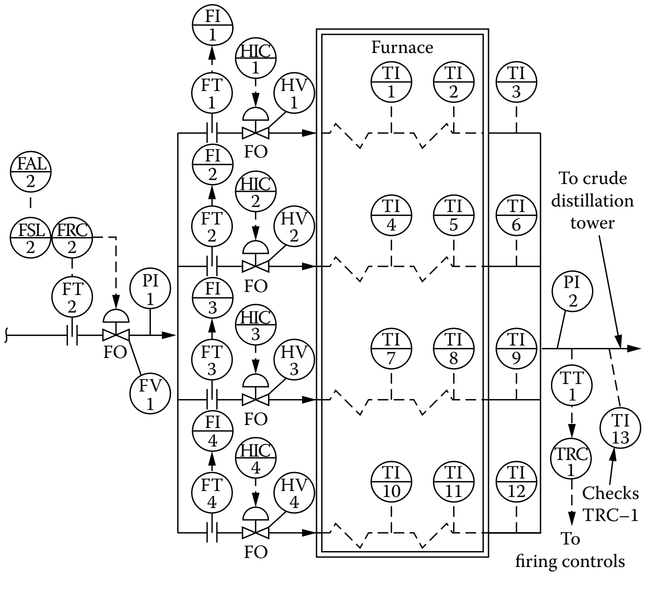

FIG. 8.29cc
Semiannual flow distribution controls of a fired vaporizer.

The temperature indicators TI-1 through TI-12 can be periodically observed to determine if there are any rising or falling trends in any one of the passes. If such a trend develops, the flow through that pass is altered slightly to drive the temperature back toward the norm. If a higher level of automation is desired, pass temperatures can act as cascade masters that will automatically adjust the set points of the flow ratio controllers (FFIC-1 to FFIC-4).

The desired heat output into the feed stream is more difficult to control, because the effluent of the furnace is partially vaporized and the feedstock varies in composition. If the feed were only heated, with no vaporization taking place, the control would require only that an effluent temperature be maintained. If complete vaporization and superheating occurred, this too could be handled well by straight temperature control.

But in the case of partial vaporization with a variable-feed composition, effluent temperature control alone (TRC-1 in Figure 8.29cc) is not a reliable approach. The composition and, hence, the boiling-point curve of the feed is not constant, and therefore required control temperature itself varies. Additional information is thus required and can be obtained from the distillation downstream of the furnace. By observing the product distribution from the fractionation, the need for a change in heat input can be determined.

Because this approach is slow and not precise, more accurate controls have been developed, using sophisticated instrumentation and special analyzers to measure feed composition and computers to optimize the mathematical model and thereby determine the required head input to the feed. Some of these control strategies are described in Section 8.27.

In older plants, the practice is to achieve approximate control with a temperature controller (TRC-1 in Figure 8.29cc). In that case the unit operator periodically changes the TIC set point to account for feed composition variations. The operator depends on experience and on the performance of the fractionator to determine the proper temperature setting. Naturally, in more advanced refineries (Section 8.21), all this is under computer control.

ADVANCED CONTROLS

In the paragraphs that follow, the more advanced heat-transfer controls will be described. These include the more traditional techniques of override, cascade, and feedforward controls and the more recent strategies of adaptive gain, model-based, and multipurpose strategies.

Override Controls

Override controls in general are discussed in Section 2.28 in Chapter 2. The purpose of override controls usually is to protect the operating equipment against unsafe or maintenance-intensive operation. An example of such a case is shown in Figure 8.29dd.

This control system should be considered when river water is being used for cooling and therefore the fouling of

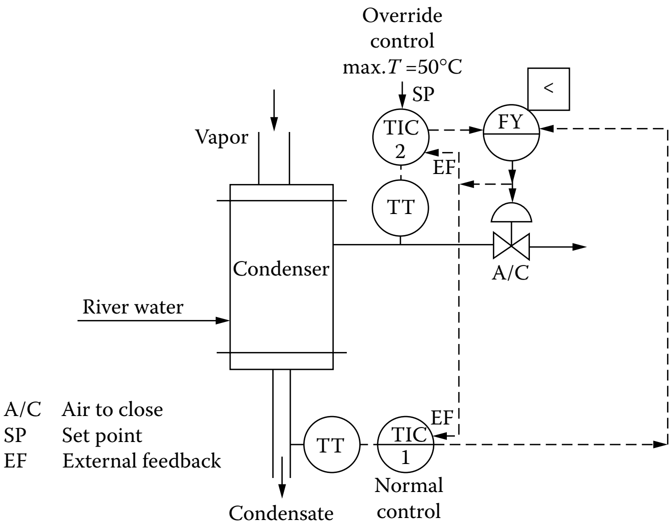

FIG. 8.29dd
When the river water outlet temperature rises to 50°C, the override controller (TIC-2) overrides the normal controller (TIC-1) and prevents the outlet temperature from rising beyond 50°C.

the heat-transfer surfaces tends to speed up when the water outlet temperature exceeds 50°C (122°F). In this configuration, normally the river water flow is throttled by TIC-1 to control the condensate temperature. However, if the cooling water temperature reaches 50°C (122°F), the high temperature override (TIC-2) takes over by increasing the cooling water flow and prevents this temperature from further rising. Naturally, during such override periods, the control of the condensate temperature will be abandoned, and having been left uncontrolled, it is likely to drop.

Similar override configurations can be utilized to prevent steam or process pressures from reaching undesirable limits. It is also possible to apply override controls in an envelope configuration, so that any of a number of limits (temperature, level, valve opening, and so on) can override the normal operation when their limits are reached.

Cascade Control

For a detailed discussion of all aspects of cascade control, refer to Section 2.6.

By definition, cascade loops consist of two controllers in series. In heat exchanger applications, the master detects the process temperature and the slave detects a variable that may upset the process temperature. A cascade loop controls a single temperature, and the cascade master adjusts the set point of the slave controller to assist in achieving this.

In order for a cascade loop to be successful, the slave must be much faster than the master. A rule of thumb is that the time constant of the primary controller should be ten times longer than that of the secondary, or that the period of oscillation of the primary should be three times that of the secondary.

Cascade loops are invariably installed to prevent outside disturbances from entering and upsetting the primary controlled variable. An example of such a disturbance is the steam pressure variation of a steam heater. The conventional single-controller system (see Figure 8.29l) cannot respond to a change in steam pressure until it has first upset the process temperature. In other words, an error in the detected temperature has to develop before corrective action can be taken.

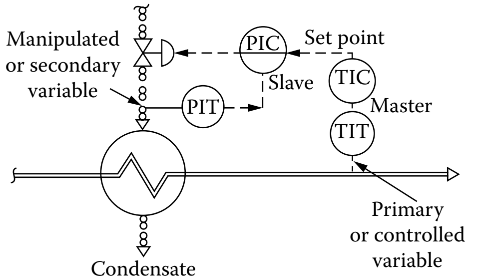

FIG. 8.29ee
A temperature-pressure cascade loop can eliminate the upsets caused by supply pressure variations in a steam heater.

The cascade loop, in contrast, responds immediately by anticipating an upset that would otherwise develop and corrects for the effect of pressure change before it can influence the process temperature (Figure 8.29ee).

The improvement in control quality is a function of relative speeds and time lags of the two loops. A slow primary (master) variable and a quickly responding secondary (slave) variable is a desirable combination for this type of control. If the slave can quickly correct the fast disturbances, they will not be allowed to enter the process and, therefore, will not upset the primary (master) variable.

One of the quickest and, therefore, best cascade slaves is the simple and inexpensive pressure regulator. Its air-loaded variety (Figure 8.29ff) is extremely fast and can correct for steam supply pressure or load variations almost instantaneously.

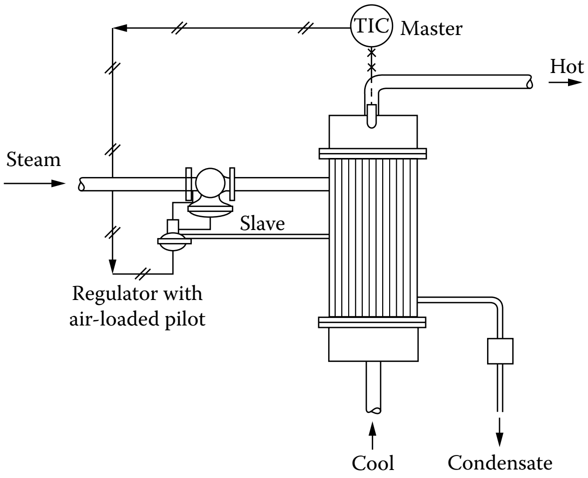

FIG. 8.29ff
One of the best cascade slaves is the pressure regulator.[6]

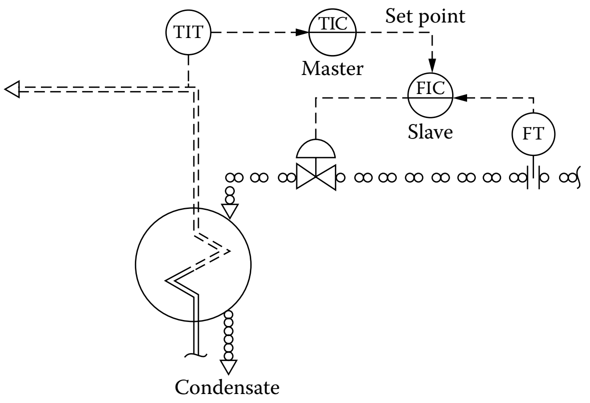

FIG. 8.29gg
Temperature-flow cascade loops are commonly used on steam reboilers.[1]

In Figure 8.29gg, the master controlled variable is temperature and the manipulated slave variable is the pressure or flow of steam. The primary variable (temperature) is slow, and the secondary (manipulated) variable is fast and capable of responding quickly to disturbances. Therefore, if disturbances occur (a sudden change in plant steam demand, for example) that are upsetting the manipulated variable (steam flow or pressure), these disturbances will be sensed immediately and corrective action will be taken by the secondary controller so that the primary variable (process temperature) will not be affected.

Feedforward Control

Feedback control involves the detection of the controlled variable (temperature) and the counteracting of its deviation from the set point by the adjustment of a manipulated variable (the flow of a heat transfer fluid). This mode of control necessitates that an upset occur in the controlled variable itself before correction can take place. Hence, the term "feedback" can imply a correction "back" in terms of time — a correction that occurs after an upset and should have taken place earlier, when the disturbance occurred.

Feedforward is a mode of control that responds to a disturbance instantaneously and compensates for the error that the disturbance would have otherwise caused later in the controlled variable.

Figure 8.29hh illustrates a steam heater under feedforward control. This control system consists of two main segments. The feedforward portion of the loop detects the major load variables (the flow and temperature of the entering process fluid) and calculates the required steam flow (W_s) as a function of these variables.

When the process flow increases, it should be matched with an equal increase in steam flow instantaneously. Because instantaneous response is not possible, the next best thing is to add more steam than needed as soon as possible. This goal of dynamic correction is served by the lead-lag element in the feedforward loop. The resulting improvement in control performance is illustrated in Figure 8.29ii.

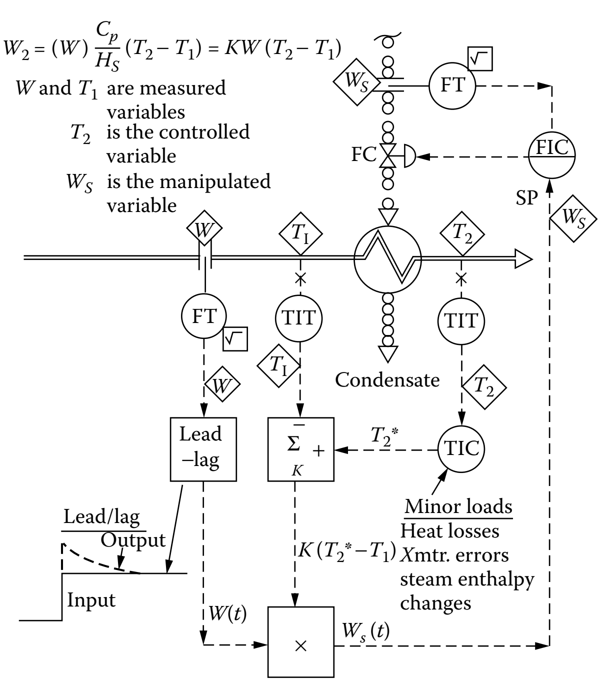

FIG. 8.29hh
In feedforward optimization of steam heaters, major load variations (T_1 and W) are corrected by the feedforward portion of the loop, leaving only the minor load variables for feedback correction.[1]

The feedback portion of the loop (TIC in Figure 8.29hh) has to do much less work in this configuration, as it only has to correct for minor load variables, such as heat losses to the atmosphere, steam enthalpy variations, and sensor errors. The feedback and feedforward portions of the loop complement each other. The feedforward portion is responsive, fast, and sophisticated, but inaccurate. The feedback portion is slower, but is capable of correcting the upsets caused by unknown or poorly understood load variations, and it is accurate.

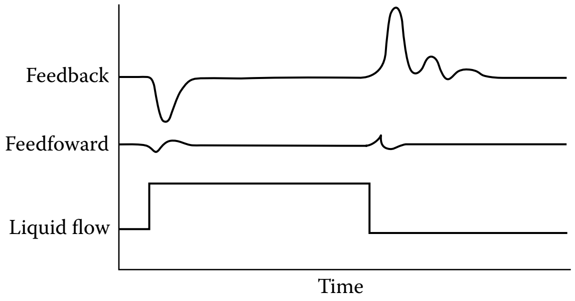

FIG. 8.29ii
Feedforward control is capable of reducing both the area and the duration of the load response transients.[2]

The design variations of feedforward loops, their dynamic compensation, and tuning are covered in more detail in Section 2.9 in Chapter 2.

Adaptive Gain As was already noted in connection with Figure 8.29l, the heat-transfer process is a variable gain process. The steady-state gain of a steam heater process is

$$dT_2/dW_s = \Delta Hs/WCp \qquad \textbf{8.29(23)}$$

Therefore, the process gain varies inversely with the process flow (W). If the temperature rise ($T_2 - T_1$) is also variable, even the use of an equal-percentage valve cannot correct for this nonlinearity in the process. In that case, the only way to keep the process gain constant is to use the feedforward system shown in Figure 8.29hh.

In the feedforward control system shown, a reduction in process flow causes a reduction in the gain of the multiplier, which cancels the increase in process gain because as the process gain varies inversely with flow, it causes the controller gain to vary directly with flow. Thus, the feedforward loop provides gain adaptation as a side benefit. The result is constant total loop gain and, therefore, stable loop behavior.

The feedforward concept described in Figure 8.29hh is not limited to steam heaters but can be used on all types of heat exchangers. The only modifications needed are the ones that are required to correctly reflect the heat balance equation corresponding to the particular heat-transfer unit.

The advantages of feedforward control are similar to those of cascade control, because in feedforward control also the load upsets or supply disturbances are corrected for before their effects are felt by the controlled variable. Feedforward control therefore contributes to stable dampened response to load changes and to fast recovery from upsets.

It is also possible to adapt the controller gain to vary directly with steam flow without using feedforward control. Equations 8.29(24) and 8.29(25) describe such a flow-adapted three-mode controller.

The equation for the flow-adapted three-mode controller is

$$m = K_c w\left(e + \frac{w}{T_i}\int e\,dt + \frac{T_d}{w}\frac{d}{dt}e\right) + b \qquad \textbf{8.29(24)}$$

where w is the fraction of full-scale flow, and K_c, T_i, and T_d are the proportional, integral, and derivative settings at full-scale flow. Equation 8.29(24) can be rewritten to reduce the adaptive terms to two:

$$m = K_c\left(we + \frac{w^2}{T_i}\int e\,dt + T_d\frac{d}{dt}e\right) + b \qquad \textbf{8.29(25)}$$

Model-Based Controls

All expert systems take advantage of the large memory and fast data manipulation capability of computers. There are hundreds of expert systems on the market today, and we should understand what they can and what they cannot do. Their common feature is that they all serve some form of optimization, while their distinguishing features are both in the type of optimization they perform and in their method used in performing it. From the perspective of their methods, one can distinguish model-based and model-free methods.

Model-based control (MBC), model predictive control (MPC), and internal model control (IMC) are all suited for the optimization of such unit processes that are well understood, such as heat transfer. Their performance is superior to that of the model-free systems, because they are capable of anticipation and, thereby, can respond to new situations. In this sense, their performance is similar to that of feedforward control systems, while the model-free systems behave in a feedback manner only.

For details on the nature and operation of the various model-based control systems refer to Sections 2.13 to 2.18 in Chapter 2.

Multipurpose Systems

To this point, the control of the isolated heat-transfer unit has been discussed. In the majority of critical installations, the purpose of such systems is not limited to the addition or removal of heat, but involves making use of both heating and cooling in order to maintain the process temperature constant. Such a task necessitates the application of multipurpose systems, incorporating many of the features that have been discussed individually earlier.

Figure 8.29jj, for example, depicts a design that uses hot oil as its heat source and water as the means of cooling, arranged in a recirculating system. The points made earlier in connection with three-way valves, cascade systems, and so forth also apply here, but a few additional considerations are worth noting.

Probably the most important single feature of this design is that it operates on a *split-range signal.* This means that when the process temperature is above the desired set point,

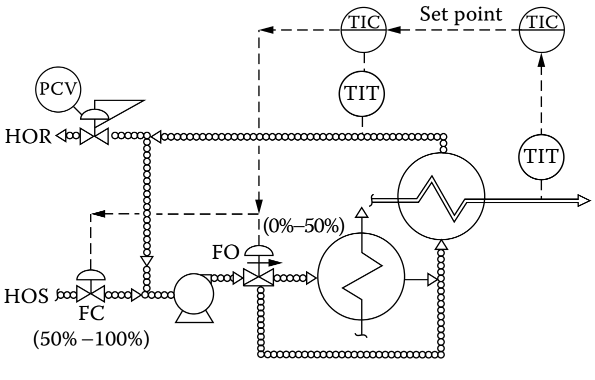

FIG. 8.29jj
This multipurpose temperature control system is capable of both adding and removing heat from the process fluid.[1]

the output signal to the valves will be reduced. When the value of this signal is between 50 and 100%, the three-way valve is fully open to the exchanger bypass, and the two-way hot oil supply valve is partially open.

If the reduction in the two-way valve opening is not sufficient to bring the process temperature down to set point, the signal will further decrease, thereby fully closing the two-way valve at a signal value of 50% and will begin to open the three-way valve to the cooler. At a 0% signal, the total cooling capacity of the system is applied to the recirculating oil stream, which at that time flows through the cooler without bypass.

The limitations of such a split-range operation include the following:

First, at a signal level near 50%, the system can be unstable and cycling. This is because at this point the three-way valve is just beginning to open to the cooler, and the system might receive alternating slugs of cooling and heating because of the limited rangeability of the valves. Such unstable operation occurs at loads that correspond to a flow rate between zero flow (which is not enough) and minimum flow (which is too much) at the particular load condition.

Second, when the signal is between 50 and 100%, the cooler shell side becomes a reservoir of cold oil. This upsets the control system twice: once when the three-way valve just opens to the cooler and once when the cold oil has been completely displaced and the oil outlet temperature from the cooler suddenly rises from that of the cooling water to some higher value.

Finally, most of these systems are nonsymmetrical in that the process dynamics (lags and responses) are different for the cooling and heating portions.

To remedy these problems, several steps can be considered. As was shown in Figure 8.29jj, a cascade loop can be used so that upsets and disturbances in the circulating oil loop will be prevented from upsetting the process temperature. In addition, a slight overlapping of the two valve positioners is desirable. This will offset the beginning of cooling and the termination of heating phases so that they will not both occur at 50%. The resulting sacrifice of heat energy can be justified by the improved control obtained.

To protect against the development of a cold oil reservoir in the cooler, a continuous low flow through this unit can be maintained.

The recirculating design shown in Figure 8.29jj is a flooded system. Therefore, when hot oil enters it, a corresponding volume of oil must be allowed to leave it. The pressure control valve (PCV) serves this function. The same purpose can be fulfilled by elevating the return header. The important consideration is that whatever means are used, the path of least resistance for the oil must be back to the pump suction, in order to keep it always flooded and, thereby, to prevent cavitation.

Most multipurpose systems represent a compromise of various degrees. Figure 8.29kk, for example, illustrates a design in which low cost and rapid response to load changes are the main considerations. These characteristics are provided by using the minimum amount of hardware and by circumventing the transient characteristics of the exchangers. The price paid for this compromise is the full use of utilities at all times and the development of hot and cold reservoirs. In addition, because the cascade slave (which detected the temperature of the heat-transfer fluid in Figure 8.29jj) is eliminated, all supply disturbances have to affect the process temperature before corrective action can be initiated.

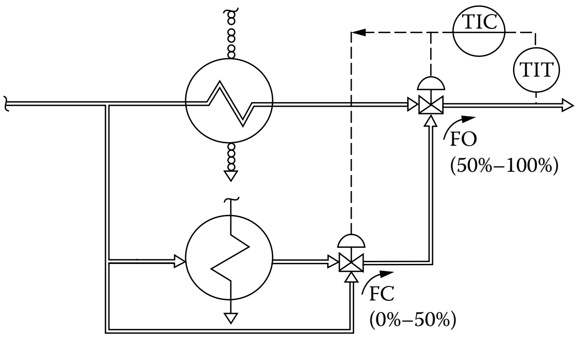

FIG. 8.29kk
This multipurpose temperature control system blends process streams at different temperatures.[1]

Other multipurpose heat-transfer systems are used in the control of jacketed chemical reactors. These can be single-purpose or double-purpose, or configured to operate with three or more different heat-transfer fluids, as was shown in Sections 8.8 to 8.11.

CONCLUSIONS

The temperature upset resulting from the sudden doubling of the load can be reduced by an order of magnitude through the use of feedforward control (Figure 8.29ii). Such a tenfold reduction in temperature error can make a great contribution to both safety and quality of production. Therefore, optimized or dynamically compensated feedforward heat exchanger controls are usually justified not on the basis of increased production or reduced energy costs, but on the basis of more stable, accurate, and responsive control.

Some of the considerations that the designer should consider are listed below:

The effect of supply disturbances on systems performance
The response speed of the system
Valve and sensor rangeability considerations
The quality of cooling water available
Potential problems due to nonsymmetrical dynamics
Potential problems caused by low minimum condensing pressures

In addition, it is always wise to consider the use of equal-percentage control valves furnished with positioners and to evaluate the advisability of using cascade, feedforward, or model-based advanced controls.

8.30 Inert Gas Blanketing Controls

D. S. NYCE, B. G. LIPTÁK (2005)

Applications:	Inerting systems are required for tanks containing flammable gases and vapors. Their goal is to keep the oxygen concentration in the vapor space of the tank below the minimum oxygen for combustion (MOC).
Range:	The MOC of most flammable gases and vapors is below between 5 and 12%; therefore, the setting of oxygen levels above 10% will not serve fire protection (Table 8.30e). Automatic inerting units can control the oxygen concentrations down to 0.1%.
Inaccuracy:	Automatic inerting systems can control the vapor space oxygen concentration within 0.1% of set point. The control system set point should be selected to provide a 30% safety margin below the MOC, because of the uneven mixing of the gases in the vapor space.
Reliability:	Inerting controls that do not include the measurement and control of oxygen may not be reliable. These systems, depending on the control of pressure or flow, provide no positive guarantee of safety and require long time periods of purging. Others are reliable but use a lot of inert gas.
Costs:	A manually operated combination of variable-area flowmeter and valve can be installed for less than \$200. A pressure control system costs \$500 to \$1000, depending on the required flow rate. An automatic system, with oxygen sensing and control, costs \$1000 to \$2000 for a single point of installation. The cost of multipoint systems adds about \$500 per channel.

INTRODUCTION

Inerting or inert gas blanketing is a fire- and explosion-prevention method that works by lowering the oxygen concentration of a flammable gas mixture. The technique is used to blanket the vapor space in tanks containing flammable process liquids, combustible dusts, fibers, and particulate solids. The applications for inerting systems include chemical reactor vessels, mixers, centrifuges, web coating lines, and mills. Although inert gas blanketing is also used to protect nonflammable process materials from discoloring or other forms of degradation, this section concentrates on inert gas blanketing (inerting) for the purpose of fire prevention.

In the process of inert blanketing, the vapor space of the tank is filled with inert gas in order to prevent fire and explosion. The term *inert gas* refers to any gas that will not support combustion. The inert gas most commonly used is nitrogen, although it is also possible to use CO_2, argon, or other gases that are oxygen deficient, such as steam, or the products of combustion.

Pollution and Personnel Safety

Many processes use volatile organic compounds (VOCs) as solvents that, when the vapor space of a storage tank is purged, are released to the atmosphere along with the inert gas exhaust. Therefore, the less inert gas is used in the process of inerting, the less VOCs will be lost to the atmosphere.

Minimizing VOC emissions is important for both safety and environmental reasons. As will be seen in the discussion below, the oxygen-based inerting systems are the best candidates for minimizing the use of inert gas and, therefore, also minimizing VOC emissions to the atmosphere.

A vapor space that has been purged by inert gas to obtain a low oxygen concentration, in order to prevent fires, also has too little oxygen for breathing. Therefore, plant operation should make sure that this does not result in a low-oxygen hazard to personnel.

Inert gas that is exhausted to the room normally has little effect on breathable air. A potential problem could arise, however, if an operator opens a hatch of an inerted vessel and leans into it for any reason. Therefore, alarms or interlocks must be provided to protect against such possibility.

THE COMBUSTION PROCESS

Combustion is a chemical oxidation process that occurs rapidly enough to produce heat and light in the form of a flame or glow. Combustion is called deflagration if the rate of propagation of the combustion zone is slower than the speed of sound in the unreacted medium.[1] If the propagation speed is greater than the speed of sound, it is called detonation. An explosion is the bursting of an enclosure due to internal pressure generated by a deflagration.

Inerting

An inerting system can prevent combustion of flammable materials in almost any sealed space by keeping the oxygen concentration below the level that could support the minimum oxygen for combustion (MOC). The most common application of inerting systems is to protect the vapor space (headspace) of a vessel containing a flammable liquid. The flammable liquid and the headspace in an agitated tank are shown in Figure 8.30a.

A flammable gas or vapor is one that will burn in air at normal temperatures and pressures, if it reaches a certain minimum concentration. Liquids can generate flammable vapors if they are above their flash point. The flash point of a liquid is its lowest temperature (at normal atmospheric pressure) at which the rate of evaporation is sufficient to form a combustible mixture near the liquid surface.

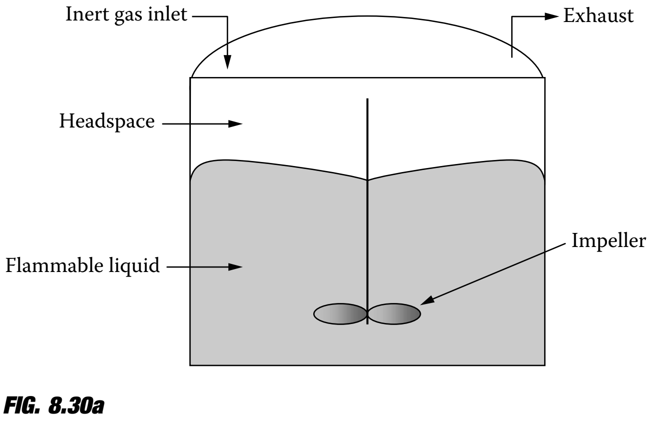

FIG. 8.30a
Fire protection is provided by introducing inert gas into the headspace of a mixing vessel that contains flammable liquids.

Alternatives to Inerting

For each flammable vapor or gas, there is a range of concentrations in air over which combustion is possible. This is the flammable range and is the range between the lower flammable limit (LFL) and the upper flammable limit (UFL)

Below the LFL, the gas concentration provides insufficient fuel to propagate a flame. Above the UFL, the gas concentration is too rich (not enough oxygen) to propagate a flame. If the gas concentration falls between the two limits, then it can be ignited and act as the fuel in a combustion process. In industrial applications, where process vessels contain flammable liquids at temperatures above their flash points, it is assumed that the vapor space can contain a flammable range of vapor concentrations. Therefore, fire prevention is necessary to ensure the safety of personnel and equipment.

As an alternative fire-prevention method to inerting systems, one can maintain the gas or vapor concentration above the UFL, where the flammable vapor concentration is too rich to support combustion (not enough oxygen). This is an acceptable method of prevention only in vessels that are normally sealed, with no entry of air allowed.

Another alternative method is to maintain the gas or vapor concentration below the LFL, where there is insufficient fuel concentration to support combustion. This is accomplished by purging with a nonflammable gas and can be used when the flow of flammable gas is low, or the flammable vapor is not being generated at a high rate during the normal operation of the process.

The Combustion Triangle

In order for combustion to take place, three requirements must be satisfied. These are the presence of a fuel, an oxidizer, and an ignition source (Figure 8.30b). In most cases (except with

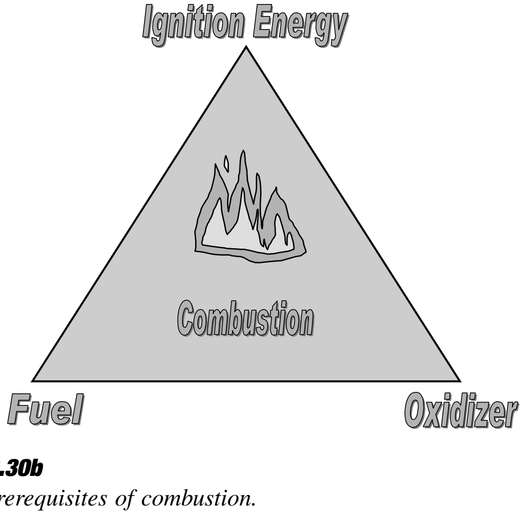

FIG. 8.30b
The prerequisites of combustion.

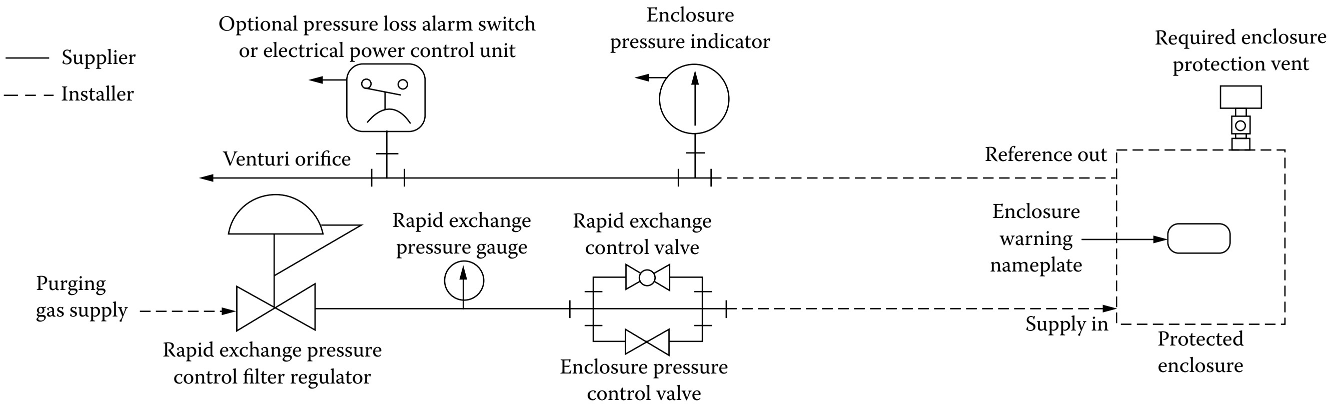

FIG. 8.30c

Packaged purge systems are marketed for Class 1 area and are provided with rapid exchange purging capability. (Courtesy of Bebco Industries.)

certain materials that contain their own oxidant), removing any one of these three prerequisites will prevent combustion.[2]

Fuel can be defined as a flammable gas or vapor within the combustible range of concentration, or a combustible fiber, dust, or other particulate material. This prerequisite of combustion is a given, so the design engineer must concentrate on the removal of at least one of the other two.

Common sources of ignition are electric sparks and heat. An electrical discharge can come from the opening of an electrical contact, a broken wire, or a discharge of static electricity. Heat can be generated by the process, by heaters, or by electrical faults.

The use of intrinsically safe (IS) electrical systems can eliminate some electrical ignition sources, but cannot protect against process-generated heat or static electricity discharge. Many industrial processes generate static electricity by mixing or agitating dielectric materials. For these reasons, the complete elimination of ignition sources, even when an IS electrical system is installed, is not always possible. Therefore, in many instances, the removal of the oxidizer by inert blanketing is the most practical means of fire and combustion protection.

The oxygen concentration of atmospheric air is about 20.9%, the remainder being mostly nitrogen. This percentage concentration remains the same over different pressures (and, therefore, different altitudes), although it is affected slightly by changes in relative humidity. If the air within the tank can be replaced with an inert gas, then the oxidizer prerequisite in the combustion triangle is removed. This is the goal of inert blanketing. A manual purge system is shown in Figure 8.30c.

Fibers, Dusts, and Particulate Solids Some dusts and finely divided powders, such as those of magnesium and zirconium, can deflagrate with no additional oxygen being present in the atmosphere. Therefore, their storage tanks cannot be protected by inerting.

Some magnesium or lithium compounds can react with nitrogen, and so argon is used as the inert gas supply for the gas blanket. Sometimes, fibers can continue to smolder after blanketing with inert gas, only to burst into flame when exposed to air later.

In addition, the mechanical difficulty of ensuring homogenous dispersion of an inerting gas throughout porous solid materials requires special attention. Inerting of the gas space above a process liquid contained in a vessel is a fairly straightforward process, but inerting of combustible fibers, dusts, and particulate solids requires a careful evaluation of the specific properties of the materials involved.

INERTING CONTROL SYSTEMS

Inert blanketing systems can be operated on pressure, flow, or oxygen control. Flow-controlled inerting is also called a "timed-volume" system, while oxygen-based inerting is often referred to as "automatic control."

Flow-Controlled Inerting

A *flow-based* inerting system is also called a *timed-volume* control system. It consists of a purge flowmeter in combination with a differential pressure regulator that acts as a self-contained flow regulator (Figure 8.30d). The inert gas flow through a standard purge flow controller is usually adjustable between 0.2 and 2 SCFH (6 and 60 slph). Over this 10:1 flow range, the flow control error is within 5% of full scale. The standard pressure and temperature ratings are 150–300 PSIG (1–2 MPa) and 212–572°F (100–300°C). The purge flowmeter can be obtained in much larger sizes to control higher flow rates as required.

At start-up, the required total initial charge of the inert gas is set to be about five times the volume of the vapor (dilution ratio[1] of 5) space of the vessel. This amount of inert gas, if introduced at a high enough velocity to create turbulent flow, will usually lower the oxygen concentration in the vapor space of the tank to under 0.5%. The purge flowmeter is

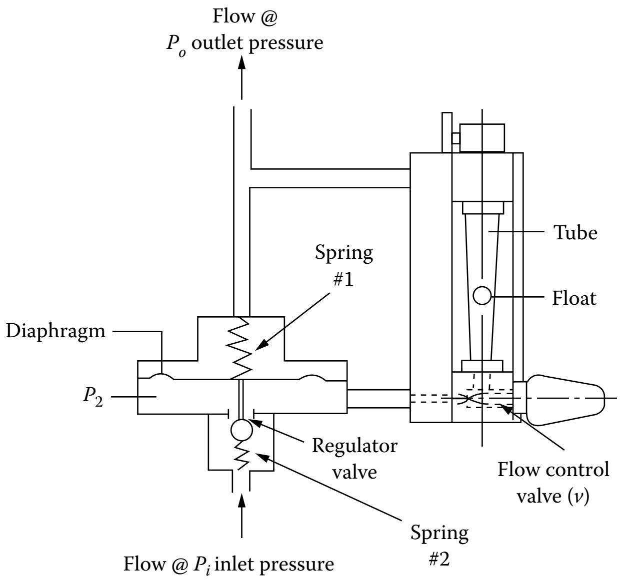

FIG. 8.30d

Purge flow regulator consisting of a glass tube rotameter, an inlet needle valve, and a differential pressure regulator. (Courtesy of Krone Inc.)

usually sized such that it will deliver this initial volume of inert gas into the tank's vapor space in an "initial purge time" of about 5 min.

When the inert blanketing system is manually operated, the operator is usually provided with an instruction sheet that is mounted next to the purge flowmeter. The first line on the instruction sheet gives the initial purge time period and the corresponding flow setting that the operator should use during start-up.

After the initial purge is completed, the purge flow rate is lowered to the continuously maintained rate that is required. This second flow rate is selected to make sure that the oxygen level in the vapor space will not reach the minimum oxygen for combustion level for the material in the tank.[1] If the start-up and the continuous purge rates are drastically different, a single purge meter might not be able to control both, and two purge meters have to be installed in parallel.

The continuous purge flow rate has to be set high enough to keep the oxygen concentration in the vapor space under MOC limits even during periods when a valve or a hatch has to be open to the atmosphere in order to add an ingredient or remove a product. Table 8.30e provides MOC values for a variety of flammable materials. For other material, consult Reference 1.

Flow-based inerting systems are usually used because of their simplicity and low installed cost. Their disadvantage is that the controlled variable (oxygen concentration in the vapor space) is only assumed, but not measured. Another disadvantage is their higher operating cost, because they tend to consume more inert gas than the other inerting systems.

TABLE 8.30e

MOC (Minimum Oxygen for Combustion) Values of Some Flammable Materials

Flammable Material	*MOC (%)*
Carbon monoxide	5.5
Gasoline	12.0
Hydrogen	5.0
Methane	12.0

Naturally, the manual mode of operation is only an option, not a necessity. Inert blanketing systems can also be controlled automatically. In that case, automatic on/off valves are required to start up the system, and timer controls are needed to automatically switch the purge flow rate set point from the start-up to the continuous rate.

Pressure-Controlled Inerting

Figure 8.30f illustrates the configuration of a pressure-controlled inerting control system. The start-up phase of the operation is the same as it was in the flow-controlled inerting system. During the start-up period, the purge valve is opened and the purge flowmeter is set for the initial purge rate. Once the initial purge time has expired and the vapor space of the vessel has been sufficiently diluted, the purge valve is closed.

After the purge valve has been closed, the pressure control valve (PCV) maintains the pressure in the vapor space at a safe value, determined by the design pressure of the tank and its associated equipment, including emergency and conservation vents.

Pressure-based inerting controls can reduce the inert gas consumption if the leakage rate is small because of tight vessel construction. If the tank operation is such that the inert gas flow needs to be drastically increased periodically (say, because of the need to open a hatch), the PCV has to be oversized, which can result in leakage and overpressuring during normal operation.

Similarly to the flow-based purge controls, the operation of the pressure-based inerting systems can also be automated by the use of a timer that operates an automated purge valve.

Oxygen-Controlled Inerting

While the pressure- or flow-based inerting systems indirectly lower the oxygen concentration of the vapor space, the measurement of oxygen is a direct and automatic method of keeping that concentration under the MOC limit. There are a number of methods of detecting oxygen concentration (see Section 8.42 in Chapter 8 in the first volume of this handbook), and once the measurement signal is available, it can be used in on/off or continuous control configurations.

The Oxygen Sensor In an oxygen-based automatic inerting system, the oxygen sensor is usually either the electrochemical

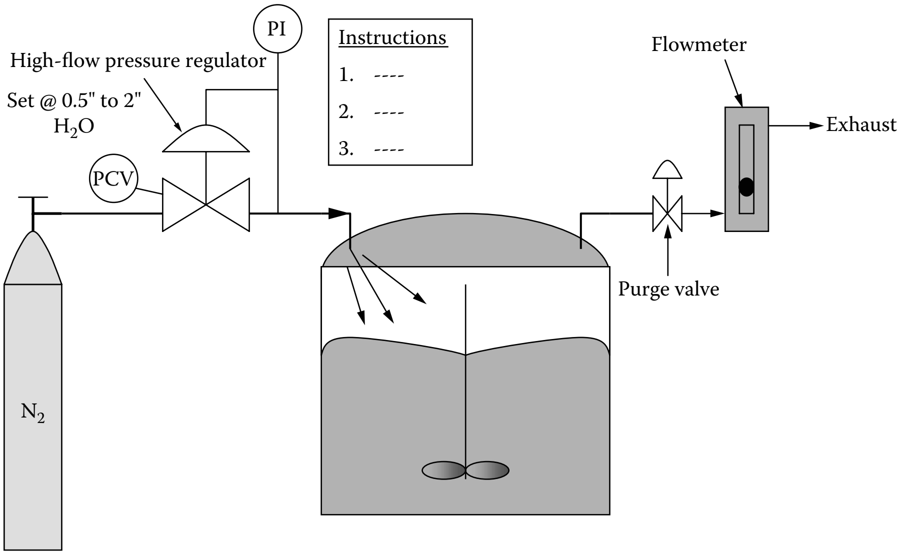

FIG. 8.30f
The main components of a pressure-based inert blanketing control system.

fuel cell-type design or the paramagnetic type. Fuel cells are small and relatively inexpensive, and can measure oxygen as a percentage by volume. They generate an output current by oxidizing an internal material, such as lead. Fuel cells also have an inherent true zero, i.e., no output is generated if no oxygen is present. The true zero means that no zero gas is needed for checking the calibration of the fuel cell.

All gas sensors should be routinely maintained so that their calibration is validated on a schedule. With an oxygen fuel cell, only a span gas is needed for calibration. Almost universally, fresh air is used to calibrate an oxygen fuel cell that reads in percent by volume. It can be adjusted to 20.9% in fresh air (ignoring the small changes that are due to changes in relative humidity). If using a membrane-type fuel cell that measures partial pressure, allowance may be made for changes in the atmospheric pressure.

For its measurement, the paramagnetic oxygen sensor relies on the force of alignment of oxygen molecules along the lines of flux in a strong magnetic field. In one design, this force generates a small motion that is measured through the use of a mirror, a light source, and a pair of optical sensors. Because a paramagnetic oxygen sensor measures the partial pressure due to oxygen, it is affected by atmospheric pressure, similarly to a membrane-type of fuel cell.

One limitation of paramagnetic oxygen analyzers is that a major repair is required if the sensing cell is damaged, and replacement is fairly expensive. In contrast, with a fuel cell, the sensing element is disposable and can be replaced at a nominal cost.

On/Off Oxygen Controls When the vapor space oxygen concentration is detected, there is no need to calculate the time required to complete the initial purge cycle during start-up, because the switching to the continuous mode of purging occurs automatically (Figure 8.30g).

At the beginning of a start-up cycle, the oxygen analyzer is likely to detect 20.9% oxygen (the concentration that is present in a normal atmosphere). Therefore, the solenoid valve on the inert gas supply line will open. As the inert gas displaces the vapors in the headspace of the vessel, the oxygen sensor will detect a steady decrease in the oxygen level.

When the oxygen level has dropped to the set point of the inerting controller, a green light goes on, indicating that it is safe to start up the process. During normal operation, the solenoid valve is cycled on and off as necessary to keep the oxygen level under control. (This system was invented by the author in the late 1970s.)

To reduce the amount of cycling, a dead band around the set point is provided in the on/off control switch. In normal operation, a red light illuminates when the solenoid is open and the oxygen level is being lowered to the set point during start-up. That light goes out and a green light comes on when the oxygen level is within the dead band of the set point's control range. A yellow light cycles on and off as the solenoid cycles on and off during normal operation.

Two control points are set by the user, depending on the MOC of the particular flammable materials present in the vessel. For example, if the published MOC of the stored liquid is 8.0%, the user might set the alarm point at 5.0% and the high and low control points (the control band) between 4.0 and 3.0%. With such settings, the solenoid valve will then open at or above 4.0%, and close at or below 3.0%.

This way, there is a safety margin between the MOC of 8.0% and the alarm point of 5.0%, while the minimum amount of inert gas is used. This control system also provides a continuous indication of the safety and operating status of the vessel.

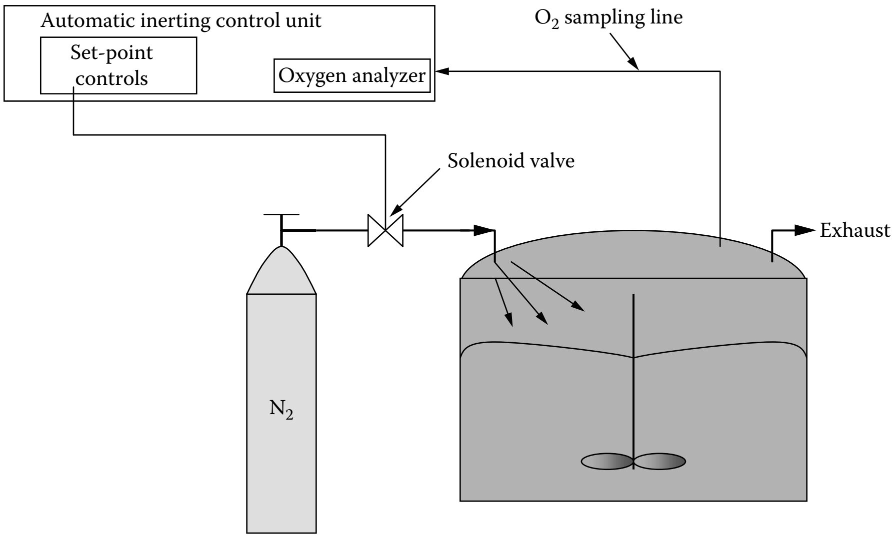

FIG. 8.30g
Automatic, oxygen-based, on/off inerting control system.

This oxygen-based on/off control system uses the least amount of inert gas and provides more safety than the flow- or pressure-based systems, because it directly detects the oxygen concentration. Its disadvantage is higher installed cost. The higher initial investment can usually be recovered through savings due to the reduction in inert gas usage.

COMPONENT DESIGN CONSIDERATIONS

The proper selection and installation of the purge control solenoid valves and of the purge flow rates deserve further discussion.

Do Not Use "Fail-Safe" Solenoids

On the surface it would appear that to select a fail-open solenoid valve (i.e., the valve is open when not energized) would guarantee safety, because it would open the inert gas flow to the protected vessel whenever power failed. In fact, such a design would mean that all of the solenoid valves on all of the inerted vessels would open up during a power failure.

This is undesirable if the inert gas supply system could not keep up with the demand and, therefore, no vessels would be adequately protected. Instead, the inert gas solenoid valves can be the energize-to-open design, and any failure (system or power) can require that the operation of the protected process be terminated until the problem is remedied.

The decision on the failure position of the solenoid should be based on the balance of the costs and consequences of the two solenoid failure options. Fail-closed solenoids can be used if the temporarily shutting down of the process is acceptable, while fail-open solenoids are the proper choice if providing a sufficiently high-capacity emergency inert gas supply system, which could supply all the failed open solenoids during periods of power failure, is feasible.

If fail-open solenoids are used (i.e., the valves open when energized), one area of concern is that the coil circuit wiring of a solenoid valve can open up (i.e., fail as an open circuit), while the controls are applying power to the valve circuit to open the valve when it is not. To protect against this, one can measure the current flow through the coil of the solenoid valve. This way, the solenoid valve will be reported to be energized only if current is flowing in its coil.

Purge Flow Rate Variation

In the flow-based inerting system, after the initial start-up purging cycle is completed, a continuous flow rate of purging is maintained. This rate must be large enough to maintain a low oxygen concentration even if the protected vessel has a substantial leak rate.

In addition, in case of an outdoor storage tank, on a hot and sunny summer day, the vapor temperature in the headspace will be quite high and will drop drastically during a thunderstorm. In that case, the tank will rapidly cool, reducing the gas volume, and tending to create a vacuum. If during such episodes outside air is drawn in, a hazardous condition can evolve.

The same applies to a process vessel from which the product is quickly discharged. During such episodes, it is necessary to quickly and safely break the vacuum by manually or preferably automatically switching to a higher capacity purge system.

The need for a variable flow rate is not a problem with a pressure-based or automatic systems, as long as the pressure-based system has a sufficiently high flow capacity. Similarly, the oxygen-based purge controls can also handle changes in purge flow demand as long as the inert gas supply and the size of the solenoid valve is sufficient.

CONCLUSIONS

The initial cost of flow- and pressure-based inerting systems is lower than that of oxygen-based ones. The flow- and pressure-based systems are indirect in the sense that they do not directly measure the oxygen content of the vapor space, and they also consume more inert gas and release more process vapors (including volatile organic compounds) into the atmosphere. Over the long run, when the operating costs of purge gas consumption are considered, oxygen-based systems can be less costly overall.

Each type of purging system requires routine maintenance to make sure that all valves and lines are clear and operational. In addition, an automatic system with oxygen concentration feedback requires maintenance of the gas sampling system and sensor. If an electrochemical fuel cell-type of oxygen sensor is used, it must be replaced once per year or when it fails to calibrate.

8.31 ORP Controls

D. M. GRAY (1985) **R. R. JAIN** (1995) **R. H. MEEKER, JR.** (2005)

INTRODUCTION

Oxidation-reduction potential (ORP) measurements are useful for the quantitative determination of ions, for monitoring chemical reactions, for determining the extent to which oxidizing or reducing reactions have taken place, and for determining the concentration of chemical species present. The ORP analyzer probes are described in Section 8.41 in Chapter 8 of the first volume of this handbook, *Process Measurement and Analysis*. While ORP measurements are somewhat similar to those of pH, the potential reading must be interpreted even more carefully for meaningful results.

In this section a description is given of the oxidation-reduction (redox) reactions and their control using oxidation-reduction potential measurement. ORP and pH instrumentation is compared and an example of titration curves is provided to serve the understanding of the ORP response. The pH electrode is an ORP sensor that is specific to hydrogen and has been designed to selectively develop a hydrogen ion activity-related potential.

Several major industrial applications for ORP control are described in this section, including cyanide oxidation, chrome reduction, sodium hypochlorite (bleach) production, and removal (scrubbing) of chlorine and chlorine dioxide from gaseous emissions. Both batch and continuous cyanide oxidation and chrome-reduction processes are discussed for waste treatment applications. The applications of bleaching of paper pulp and the treatment of swimming pool and spa water are also covered.

ORP AS A PROCESS VARIABLE

An oxidation-reduction reaction involves the transfer of electrons from one material (*oxidation*) to another (*reduction*). In industrial applications, oxidizing or reducing agents are used to promote the desired reaction. An example of such a reaction occurs between chromium and ferrous ions, as shown in Equation 8.31(1):

$$\mathrm{Cr}^{+6} + 3\mathrm{Fe}^{+2} \rightarrow \mathrm{Cr}^{+3} + 3\mathrm{Fe}^{+3} \qquad \textbf{8.31(1)}$$

In this process, the *reducing agent* (ferrous ion) donates electrons to the chromium, thus reducing chrome while the iron is oxidized.

The Nernst Equation

The measured electric potential developed by oxidation-reduction reactions is described by the Nernst equation:

$$E = E^0 - \frac{2.303RT}{nF}\log\frac{[\alpha_X]^x[\alpha_Y]^y[\alpha_Z]^z\ldots}{[\alpha_A]^a[\alpha_B]^b[\alpha_C]^c\ldots} \qquad \textbf{8.31(2)}$$

where

E = the developed potential (mV)

E^0 = the standard potential (mV)

R = the gas law constant (e.g., 1.987×10^{-3} kcal/mole°K, in SI units)

T = absolute temperature (e.g., 298°K, in SI units, for a reference temperature of 25°C)

n = number of electrons transferred in the reaction

F = Faraday constant (e.g., 23.06×10^{-3} kcal/mV, in SI units)

For a reaction written as a reduction equation:

$$aA + bB + cC + \cdots + ne^- = xX + yY + zZ + \cdots \qquad \textbf{8.31(3)}$$

$[\alpha_A]$, $[\alpha_B]$, $[\alpha_C]\ldots$, and $[\alpha_X]$, $[\alpha_Y]$, $[\alpha_Z]$, … are the *activities* of each respective ion (note, only ions, not neutral molecules, are counted in the equation); a, b, c, … and x, y, z, … are coefficients of the balanced chemical reaction.

Activity α is related to the molar concentration (e.g., moles/liter) as follows:

$$\alpha = \gamma[A] \qquad \textbf{8.31(4)}$$

where

α = the ionic activity

γ = the activity coefficient

$[A]$ = concentration of reactant A

Generally, the more ions there are in solution, the more difficult it is for the exchange of electrons to occur that results in development of an electric potential. The activity coefficient reflects this. Most solutions of interest are dilute enough that the activity coefficient is very close to unity, though this is not always the case. Fortunately, in most process control applications it is ionic activity (the tendency of a component to participate in a reaction) that is of most interest and not the absolute concentration of the ions.

With the constants for R, T, and F inserted and a reference temperature of 25°C assumed, Equation 8.31(2) can be written in a more commonly used form:

$$E = E^0 - \frac{59.16}{n}\log\frac{[\alpha_X]^x[\alpha_Y]^y[\alpha_Z]^z\ldots}{[\alpha_A]^a[\alpha_B]^b[\alpha_C]^c\ldots} \qquad \mathbf{8.31(5)}$$

The standard potential, E^0, is defined for any given half-cell reaction as the potential obtained when all ions or molecules in solution are at a concentration of 1 mole/liter and all gases are at a partial pressure of 1 atmosphere.[2] By convention, the standard potential is normally referenced to a temperature of 25°C and to the hydrogen ion/hydrogen (H^+/H_2) half-cell reaction ($E^0 = 0$ mV).

As indicated by Equations 8.31(2) and 8.31(5), ORP is dependent upon concentrations of all of the reactants involved. If any of the reactants are hydrogen (H^+) or hydroxide (OH^-) ions, then the ORP measurement is pH-dependent. This is evident by further refining the Nernst equation specifically for pH measurement:

$$E = E^0 - 0.198T_k \log\frac{1}{[\alpha_{H^+}]} \qquad \mathbf{8.31(6)}$$

and

$$\alpha_{H^+} = \gamma[H^+] \qquad \mathbf{8.31(7)}$$

The similarities between the ORP and pH measurements are evident in the fundamental principles upon which the measurements are based. It is helpful to realize the pH is just an ion-specific ORP sensor, where the measurement electrode has been designed to selectively develop a potential related to hydrogen ion activity. Similarly to hydrogen, other ion selective sensors can also be built.

Measurement

During the chemical reaction shown in Equation 8.31(1), an inert metal electrode is placed in contact with the solution and detects the solution's ability to accept or donate electrons. The resulting oxidation-reduction potential (redox potential) is directly related to the progress of the reaction. A ferrous reducing ion (Fe^{+2}) provides electrons and tends to make the electrode reading more negative. A chromium oxidizing ion (Cr^{+6}) accepts electrons and tends to make the electrode reading more positive. The resulting net electrode potential is related (logarithmically) to the ratio of concentrations of oxidizing and reducing ions in solution.

ORP is an extremely sensitive measurement of the degree of treatment provided by the reaction. However, it is generally impractical to relate this measurement to a definite concentration of a reaction component. This is due to the dependence of the measurement upon the concentration ratios of all oxidants and reductants. Interpretation of the measurement is further complicated because of its nonlinearity with respect to concentration, plus the detector's inaccuracy and the lack of temperature compensation.

The exact potential to ensure complete treatment can be calculated theoretically, but in practice is subject to variations in reference electrode potential, pH, the presence of other waste stream contaminants, temperature, purity of reagents, and so forth.[2] The target potential is usually determined empirically by testing the treated process flow for trace levels of the material to be eliminated or minimized. The optimum control point (ORP reading) occurs when just enough reagent has been added to complete the reaction. Approximate suggested control points are given later in this section, but should be verified on-line by testing the actual samples.

Instrumentation

The detectors used for ORP measurement are very similar to that used for pH measurement. The reference electrode is identical to the pH reference electrode. The measuring electrode, however, consists of a noble metal instead of a glass bulb. The noble metal electrode is usually made from platinum, gold, or nickel, but carbon may also be used. The noble metal electrode is subject not only to coating, but also to poisoning, which can result in sluggish or inaccurate measurement.

For this reason, it is advisable to use scrubber-type probe cleaners (Figure 8.31a) or retractable probes that in the retracted position can first be cleaned by a cleaning fluid and then can be recalibrated using a standard reference solution.

ORP measurement electrodes must be maintained to provide a very clean metal surface. Routine cleaning of electrodes with a soft cloth, dilute acids, or cleaning agents is needed often to promote fast response. The noble metal comprising the measurement electrode is often platinum or gold. It is important to carefully select the electrode material for compatibility with the process. For example, gold may actually have a greater tendency to corrode than platinum in some solutions; however, gold is generally more resistant to strong oxidizing agents than platinum.

Similarly, the composition and design of the reference electrode must be compatible. Incompatible reference electrode solutions can be quickly *poisoned* by the process fluid, rendering the measurement useless.

At a constant solution temperature of 25°C, the slope of pH measurement will be 59.16 mV per pH unit, so full scale would be approximately +414 to –414 mV for 0–14 pH.

Polarity of ORP measurements can be a source of confusion. Electrodes that measure pH produce a negative potential with upscale pH readings (because pH is defined as the *negative* log of the hydrogen ion concentration, and more hydrogen ion activity means a more acidic solution). Thus, the *reference electrode* connection of a pH instrument is the *positive* input.

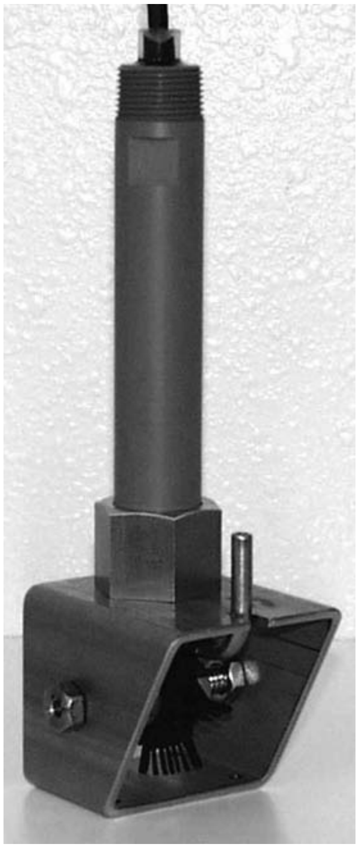

FIG. 8.31a
Scrubber-type probe cleaner. (Courtesy of Universal Analyzers Inc.)

Relative to the reference electrode, the more positive the potential of the ORP noble metal measurement electrode is, the greater the oxidizing environment of the solution in which it is placed, and conversely, the more negative, the more reducing the environment is. When ORP equipment is based on a pH instrument design, it may be necessary to connect the ORP electrode to the reference input and the reference electrode to the measuring terminal to achieve this response.

When sensor connectors are of the BNC style, this may not be practical. Some combination pH/ORP transmitters have a jumper or configuration selection that will swap the polarity internally or permit the mA output range to be reversed. The applications described in this section assume the ORP sensor readings indicate increasing potential with increasing oxidizing environment. This is the most common convention, consistent with most chemistry texts and standard potential tables.

Calibration

ORP instruments are calibrated like voltmeters, measuring absolute millivolts (mV), although a standardized (zero) adjustment is often available on instruments designed also for pH measurement.

TABLE 8.31b
ORP Values (in Millivolts) of Quinhydrone-Saturated pH Buffer Solutions (Using Saturated Silver–Silver Chloride Reference Electrode)

pH Buffer	*68°F (20°C)*	*77°F (25°C)*	*86°F (30°C)*
4.010	267	263	259
6.86	100	94	88
7.00	92	86	80
9.00	–26	–32	–39
9.18	–36	–43	–49

To verify operation of electrodes, it is useful to have a known ORP solution composition using quinhydrone and pH buffer solutions. These must be made up fresh to prevent air oxidation and deterioration. A quinhydrone reference solution prepared in a pH 4 buffer solution should read about 264 mV at 25°C with a platinum measurement electrode and silver–silver chloride (Ag/AgCl) reference electrode. With quinhydrone in a pH 7 buffer solution, the same-type electrodes should read about 87 mV at 25°C.

Quinhydrone-saturated pH buffers are used to establish known potentials as a check when a shift is detected (manually or automatically) in either the span or the potential. See Table 8.31b for ORP values in millivolts in quinhydrone-saturated pH buffer solutions at various temperatures.

A more stable ORP reference solution has been developed (also known as "Light's Solution"), consisting of 0.1 M ferrous ammonium sulfate, 0.1 M ammonium sulfate, and 1.0 M sulfuric acid. Its ORP is +476 mV when measured with a silver–silver chloride, saturated potassium chloride reference electrode.[3]

The ORP measurement is displayed in millivolts. Temperature compensation is not used because the compensation would be different for each reaction, making it impractical to produce a generally useful temperature correction as can be done with pH.

ORP CONTROL

The ORP control process (like pH control) requires that the control system designer understand the chemistry of the process that is to be controlled. In addition to vessel size, vessel geometry, agitation requirements (needed to guarantee uniform composition), and reagent delivery systems, solid removal problems must also be considered.

In cases where one or both of the half-reactions (redox reaction) involve hydrogen ions, ORP measurement becomes pH-dependent. The potential changes measured by the ORP electrode will vary with the redox ratio, but the redox ratio will vary with pH. Therefore, it becomes necessary to experimentally determine the control point, and both pH and ORP measurements are required to control the process.

As with pH, reliable ORP control requires vigorous mixing to ensure uniform composition throughout the reaction tank. For continuous control the tank should provide adequate retention time (filled tank volume divided by process flow rate), typically 10 min or more.[4]

ORP measurement in relation to concentration of reactants (and, therefore, reactant flowrate) produces a nonlinear response similar in shape to the familiar pH titration curve. This nonlinearity in the ORP titration curves can make PID control difficult. The degree of difficulty is a function of how tightly the ORP is to be controlled, where the operating point is on the ORP curve, and over what range of conditions should the ORP be controlled. If necessary, techniques used to improve pH control, such as characterization of the error, can also be applied in the control of ORP (see Section 8.32).

Complete treatment requires a slight excess of reagent and a control point that is slightly beyond the steep portion of the titration curve. Control in this plateau area, where process gain is relatively low, can be obtained by simple on/off control. Reagent feeders are typically metering pumps or solenoid valves. A needle valve in series with a solenoid valve can be used to set the reagent flow more accurately and to improve on/off control.

Chrome Waste Treatment

Chromates are used as corrosion inhibitors in cooling towers and in various metal finishing operations, including bright dip, conversion coating, and chrome plating. The resulting wastewater from rinse tanks, dumps, or cooling tower blowdown contains the toxic and soluble chromium ion (Cr^{+6}), which must be removed before discharge to comply with EPA regulations.

The most frequently used technique for chrome removal is a two-stage chemical treatment process. In the first stage, acid is added to lower the pH, and reducing agent is added to convert the chrome from soluble Cr^{+6} (toxic) to Cr^{+3} (nontoxic). In the second stage the wastewater is neutralized, forming insoluble chromium hydroxide, which can then be removed.

First Stage In the first stage, sulfuric acid is used to lower the pH to approximately 2.5 to speed up the reduction reaction and ensure complete treatment. The most commonly used reducing agents are sulfur dioxide, metabisulfite, and ferrous sulfate, but other reducers may also be used. The reducing agents react and form precipitates as shown in Table 8.31c.[5] Equation 8.31(8) describes the reduction reaction with chrome expressed as chromic acid, CrO_3, which has a +6 charge on the chromium. The reducing agent is expressed as sulfurous acid (H_2SO_3), generated by sulfites at low pH. The result is chromium sulfate, $Cr_2(SO_4)_3$, which has a +3 charge on the chromium.

$$2CrO_3 + 3H_2SO_3 \rightarrow Cr_2(SO_4)_3 + 3H_2O \qquad \mathbf{8.31(8)}$$

TABLE 8.31c
Chrome Reduction and Precipitation Reactions

Reducing Agent	*Reaction*
Ferrous sulfate ($FeSO_4$)	$2H_2CrO_4 + 6FeSO_4 + 6H_2SO_4 \rightarrow$ $Cr_2(SO_4)_3 + 3Fe_2(SO_4)_3 + 8H_2O$ $Cr_2(SO_4)_3 + 3Ca(OH)_2 \rightarrow$ $2Cr(OH)_3 + 3CaSO_4$
Sodium metabisulfite ($Na_2S_2O_5$)	$Na_2S_2O_5 + H_2O \rightarrow 2NaHSO_3$ $2H_2CrO_4 + 3NaHSO_3 + 3H_2SO_4 \rightarrow$ $Cr_2(SO_4)_3 + 3NaHSO_4 + 5H_2O$ $Cr_2(SO_4)_3 + 3Ca(OH)_2 \rightarrow$ $2Cr(OH)_3 + 3CaSO_4$
Sulfur dioxide (SO_2)	$SO_2 + H_2O \rightarrow H_2SO_3$ $2H_2CrO_4 + 3H_2SO_3 \rightarrow$ $Cr_2(SO_4)_3 + 5H_2O$ $Cr_2(SO_4)_3 + 3Ca(OH)_2 \rightarrow$ $2Cr(OH)_3 + 3CaSO_4$

Equation 8.31(8) describes the reaction if sulfur dioxide is the reducing agent.

As shown in Figure 8.31d, the first-stage reaction is monitored and controlled by independent control loops: acid addition by pH control and reducing agent addition by ORP control. Acid is added under pH control whenever the pH rises above 2.5. Reducing agent is added under ORP control whenever the ORP rises above approximately +250 mV. (Refer to Section 8.39 on water treatment for other control configurations.)

The ORP titration curve, Figure 8.31e, shows the entire millivolt range that is covered when Cr^{+6} chrome is treated in batches. With continuous treatment, however, operation is maintained in the completely reduced portion of the curve near the nominal +250 mV control point. The exact set point for a particular installation should be at a potential where all the Cr^{+6} has been reduced but without excess sulfite consumption, which is accompanied by the odor of sulfur dioxide.

To complete the chrome reduction reaction takes 10–15 min. The reaction time increases if pH is controlled at higher levels. Variations in pH also affect the measured ORP readings. Therefore, pH must be held constant to achieve consistent ORP control.

Second Stage The wastewater is neutralized to precipitate Cr^{+3} as insoluble chromium hydroxide, $Cr(OH)_3$, and also to the limits for pH, before the treated wastewater can be discharged. Sodium hydroxide or lime ($Ca(OH)_2$) is used to raise the pH to 7.5–8.5, as shown by the reaction in Equation 8.31(9):

$$Cr_2(SO_4)_3 + 6NaOH \rightarrow 3Na_2SO_4 + 2Cr(OH)_3 \qquad \mathbf{8.31(9)}$$

In the second stage, it is more difficult to provide good pH control than in the first, because the control point is closer to the sensitive region of the titration curve near neutrality.

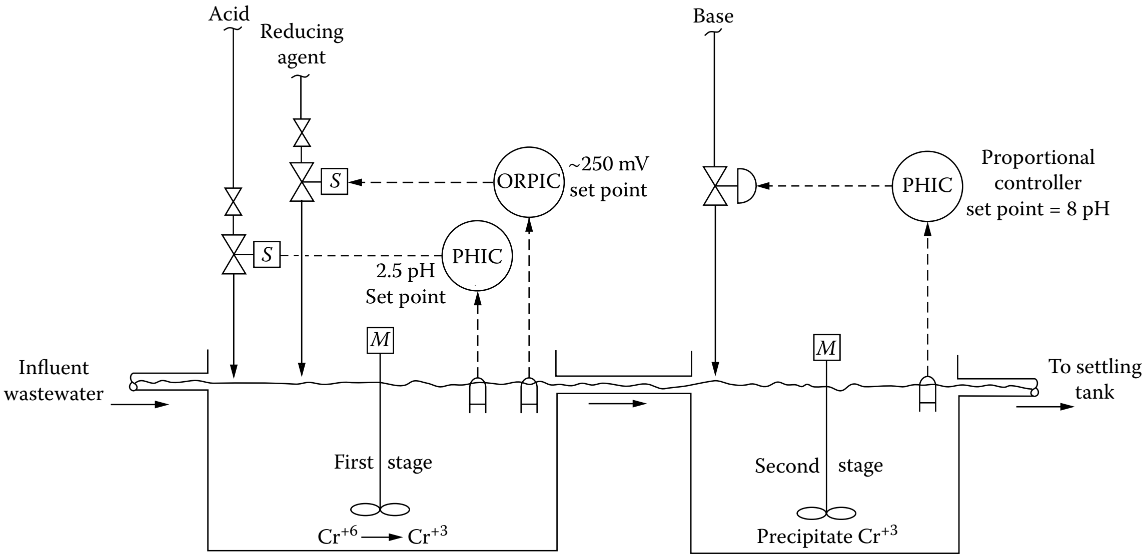

FIG. 8.31d
Continuous chrome treatment.

Although the second-stage reaction is fast, retention time of at least 10 min is usually needed for continuous treatment processes, in order to achieve stable operation. In this stage, the pH controller can be a proportional controller.

A subsequent settling tank or filter removes the suspended chromium hydroxide. Flocculating agents have been found helpful to assist in this separation.

Batch Chrome Treatment Figure 8.31f shows the arrangement for a batch chrome treatment process in which all steps are accomplished in a single tank using a pH and an ORP controller. The steps of the treatment are sequenced, so the pH set point may be changed as needed. In the first stage, acid is added to lower the pH to 2.5, then reducing agent is added to lower ORP to approximately +250 mV.

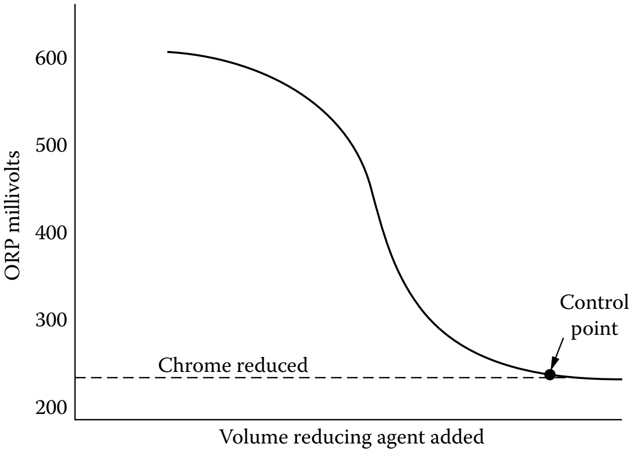

FIG. 8.31e
Chrome reduction titration curve.

After a few minutes have elapsed (ensuring complete reaction) and after a grab sample test for Cr^{+6} has been made, basic reagent is added in the second stage to raise pH to 8. A settling period then follows, or the batch is pumped into a separate tank or pond for settling.

Cyanide Waste Treatment

The metal-plating and metal-treating industries produce the largest amounts of cyanide waste. However, other industries also use cyanide compounds as intermediates. Cyanide solutions are used in plating baths for brass, copper, silver, gold, and zinc. The toxic rinse waters and dumps from these operations require destruction of the cyanide before discharge.

The most frequently used technique for cyanide destruction is a one- or two-state chemical treatment process. The first stage raises the pH and oxidizes cyanide to the less-toxic cyanate form. When required, the second stage neutralizes and further oxidizes cyanate to harmless bicarbonate and nitrogen. The neutralization also allows the metals to be precipitated and separated from the effluent.

First Stage Sodium hydroxide (NaOH) is generally used to raise the pH to approximately 11 to promote the oxidation reaction and ensure complete treatment. The oxidizing agent is generally chlorine (Cl_2) or sodium hypochlorite (NaOCl).

Alternately, oxidation reduction of cyanide wastes to less toxic by-products may be also be achieved by using ozone or hydrogen peroxide as oxidizing agents. The two-step chemical oxidation reaction between ozone and cyanide can be written as

$$CN^- + O_3 \rightarrow CNO^- + O_2 \qquad \mathbf{8.31(10)}$$

$$2CNO^- + H_2O + 3O_3 \rightarrow 2HCO_3 + N_2 + 3O_2 \qquad \mathbf{8.31(11)}$$

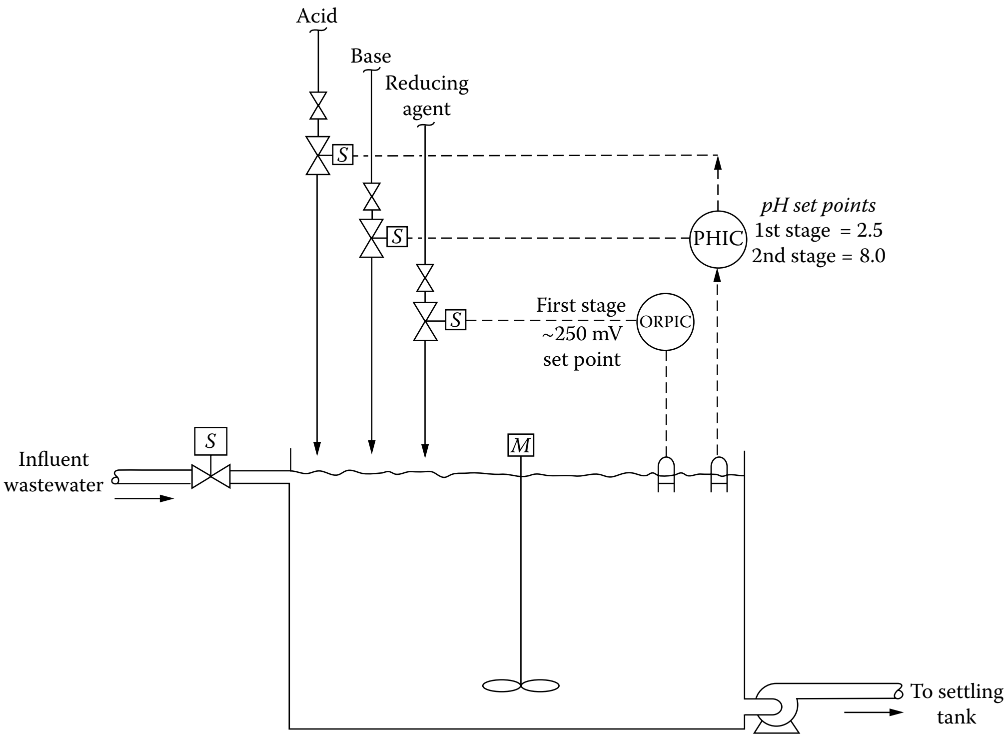

FIG. 8.31f
Batch chrome treatment.

A total ozone dosage of approximately 3–6 O_3/parts per million (ppm) CN is required for near-total cyanide destruction in industrial waste streams.

A one-stage process using hydrogen peroxide and formaldehyde effectively destroys free cyanide and precipitates zinc and cadmium metals in electroplating rinse waters. The chemistry of the destruction of free cyanide cannot be expressed in a simple sequence of reactions, because destruction involves more than one sequence. The monitoring of cyanide rinse water treatment by ORP measurement (using a gold wire electrode) is a useful diagnostic tool for indicating whether the proper quantities of treatment chemicals have been added.

The overall reaction for the first stage using sodium hypochlorite (NaOCl) is given here, with cyanide expressed in ionic form (CN^-), and the result expressed as sodium cyanate (NaCNO) and chloride ion (Cl^-):

$$NaCOCl + CN^- \rightarrow NaCNO + Cl^- \qquad \mathbf{8.31(12)}$$

For the case when the oxidizing agent is chlorine, refer to Section 8.39.

As shown in Figure 8.31g, the first-stage reduction is monitored and controlled by independent control loops: base addition by pH control and oxidizing agent addition by ORP control. The pH controller adds base whenever the pH falls below 11. The ORP controller adds oxidizing agent whenever the ORP falls below approximately +450 mV. A slightly different design is described in Section 8.39.

The ORP titration curve, Figure 8.31h, shows the entire millivolt rage that is covered when cyanide is treated in batches. With continuous treatment, however, operation is maintained in the oxidized, positive region of the curve near the +450 mV set point. The exact set point is determined empirically by measuring the potential when all the cyanide has been oxidized but no excess reagent is present. This point can be verified with a sensitive colorimetric test.

In this reaction, pH has a strong inverse effect on the ORP. Thus, pH must be closely controlled to achieve consistent ORP control, especially if hypochlorite is used as the oxidizing agent. Hypochlorite addition raises pH, which if left unchecked will lower the ORP, calling for additional hypochlorite and causing a runaway situation. To protect against this, the set point of the pH controller should be above the pH level at which hypochlorite has an influence. It is also necessary to move the ORP electrodes away from the hypochlorite addition point to prevent such interactions.

Gold ORP electrodes have been found to give more reliable measurement than platinum for this application.[6] Platinum may catalyze some additional reactions at its surface and is more subject to coating than is gold. The solubility of gold in cyanide solutions does not present a problem, because it is in contact primarily with cyanate. Any slight loss of gold actually serves to keep the electrode clean.

Second Stage In this stage, the wastewater is neutralized to promote additional oxidation as well as to meet discharge

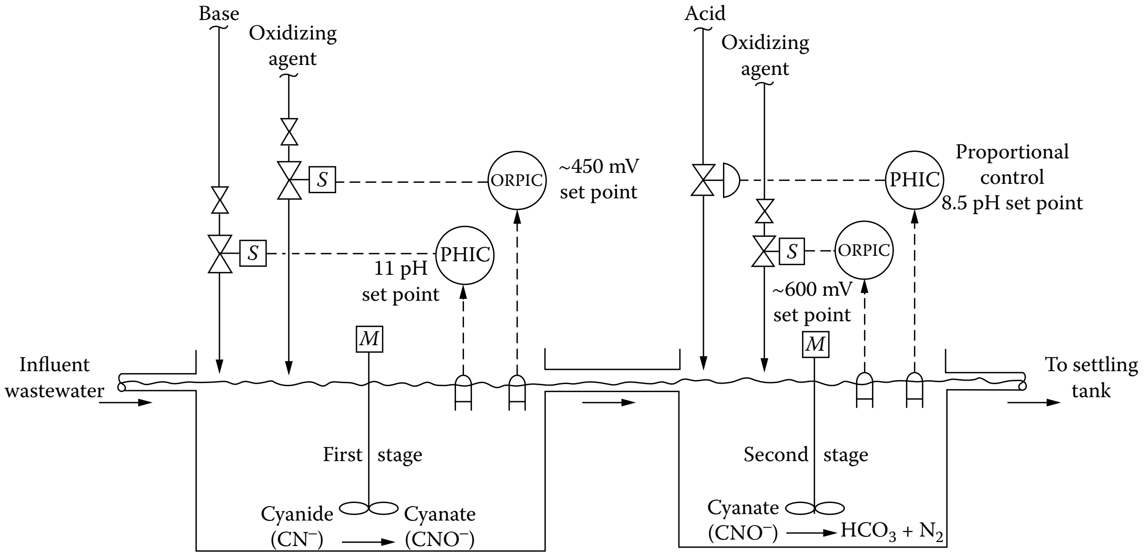

FIG. 8.31g
Continuous cyanide treatment.

pH limits. If the lowering of the pH is not required, that loop can be eliminated. Sulfuric acid is typically used to lower the pH to approximately 8.5, where the second oxidation occurs more rapidly. Acid addition must have a fail-safe design, because below neutrality (pH = 7) highly toxic hydrogen cyanide can be generated if the first-stage oxidation has not been completed.

Hypochlorite is added either in proportion to that added in the first stage or by separate ORP control to complete the oxidation to sodium bicarbonate ($NaHCO_3$), as shown by Equation 8.31(13):

$$2NaCNO + 3NaOCl + H_2O \rightarrow 2NaHCO_3 + N_2 + 3NaCl \qquad \textbf{8.31(13)}$$

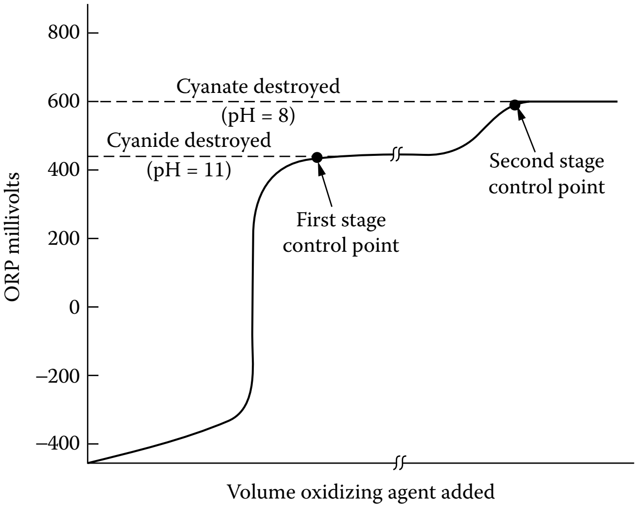

FIG. 8.31h
Cyanide oxidation titration curve.

ORP control in the second stage is very similar to that in the first, except that the control point is near +600 mV. In the second stage, pH control is more difficult than in the first, because the control point is closer to the sensitive region of neutrality. The pH controller can be proportional only.

A subsequent settling tank or filter can remove suspended metal hydroxides, although further treatment may be required.

Batch Cyanide Treatment Figure 8.31i shows the arrangement for batch cyanide treatment with all steps accomplished in a single tank, which is provided with one pH and one ORP controller. (Other control configurations are described in Section 8.39.)

In this control system, the steps are sequenced, changing the pH and ORP set points to obtain the required treatment, with the added assurance that treatment is complete before going on to the next step. Caustic is added to raise the pH to 11. Hypochlorite is added to raise the ORP to approximately +450 mV, simultaneously adding more caustic, as required, to maintain a pH of 11.

An interlock must be provided to prevent acid addition before the completion of oxidation of all cyanide to cyanate. Then acid can be added to neutralize the batch and further hypochlorite oxidation completes the cyanate-to-bicarbonate conversion. A settling period can be used to remove solids, or the batch can be pumped to another tank or pond for settling.

Sodium Hypochlorite Production

Sodium hypochlorite (NaOCl) is produced by reacting chlorine gas (Cl_2) and dilute sodium hydroxide (NaOH). Sodium hypochlorite is used both as an industrial and as a domestic

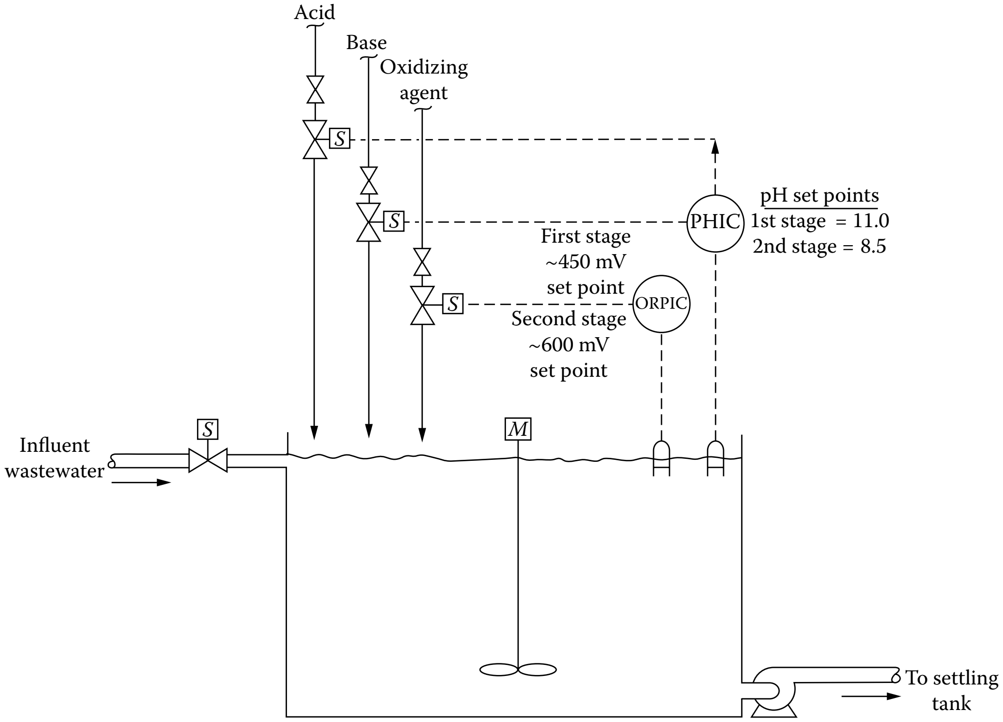

FIG. 8.31i
Batch cyanide treatment.

bleaching agent. For industrial use, it is normally produced on-site and has an available chlorine strength of 12–15%. For domestic use, as household chlorine bleach, the strength is typically 3–6% available chlorine.

ORP is used as a measure of the available chlorine in the final product. The control system of the NaOCl production process is shown in Figure 8.31j. Caustic soda solution (sodium hydroxide) at 5% concentration is admitted on level

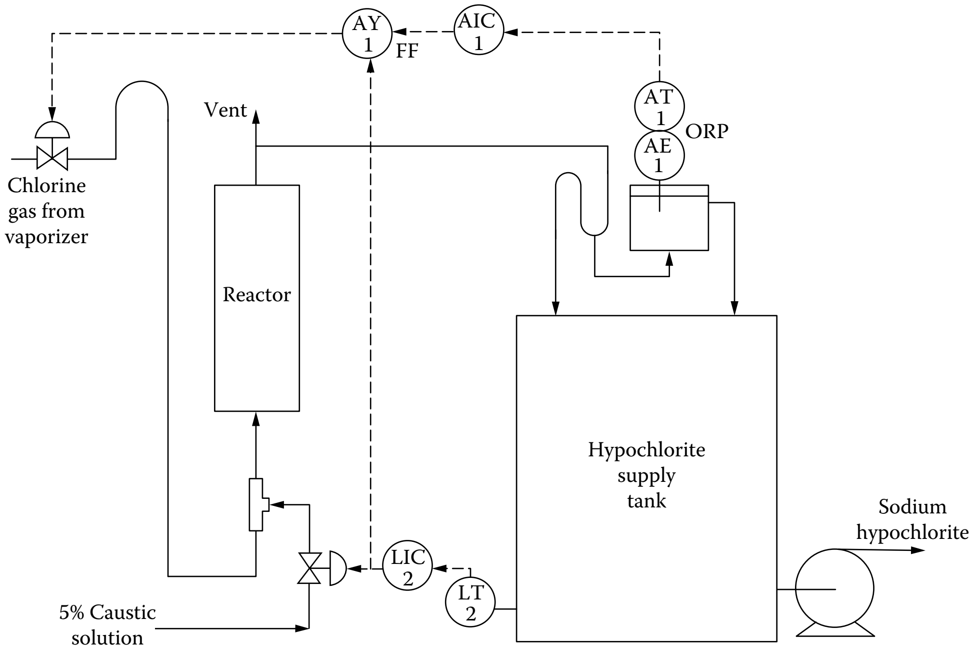

FIG. 8.31j
Control system for the continuous production of sodium hypochlorite.

control. This supply of caustic soda is normally diluted down from 50 to 5% concentration in two steps (not shown). The ORP controller throttles the ratio of the chlorine gas that is added to the flow of 5% caustic solution. The set point for the ORP controller will be somewhere between 500 and 750 mV, depending upon the initial caustic strength and the desired ratio of available chlorine to excess caustic.

On-site sodium hypochlorite production is common in pulp and paper mills, where it is used in the pulp bleaching process. However, the industry trend has been to move away from chlorine bleaching (elemental chlorine or sodium hypochlorite), in favor of chlorine dioxide, hydrogen peroxide, oxygen, and other bleaching agents, which are considered to be preferred from a pollution point of view.

Paper Pulp Bleaching

The pulp and paper industry uses strong oxidizing agents (commonly chlorine, chlorine dioxide, hydrogen peroxide, oxygen, and ozone) for bleaching and delignification of pulp. ORP has been applied both to control the pulp bleaching and the delignification process and as emission controls for chlorine (Cl_2) and chlorine dioxide (ClO_2) gases.

Bleaching and Delignification Control Bleaching and delignification are accomplished in several stages, with the residues of the bleaching operation extracted from the pulp in washers located between the stages. A traditional bleach plant sequence is chlorination ("*C*"), followed by caustic extraction ("*E*"), followed by hypochlorite bleaching ("*H*"), sometimes followed by caustic extraction ("*E*"), and finally, by treatment with chlorine dioxide ("*D*").

To eliminate chlorine, the CEHED or CEHD sequences have in many cases been replaced with DEDED, DED, or other variants that eliminate the *C* and *H* stages. ORP measurement can be used in the pulp discharge vat of the washer following the *D* stage to ensure the chlorine dioxide has been sufficiently rinsed from the pulp. Applying it to control actual chemical addition is more difficult.

Because a variety of organic compounds are oxidized, it is not possible to write exact equations for the pulp bleaching process. The critical control parameters for the bleaching and delignification process are brightness, kappa number (an indication of lignin remaining, or pulp purity), chemical residual, pH, temperature, pulp consistency, pulp flowrate, chemical flowrate, and retention time (determined by tower size and flowrate).

ORP can be used as an indication of the chemical residual. It is more apt to be useful for the measurement of lower concentrations of residuals, such as in the final stages or in the washers. Because ORP is so nonlinear over the potentially wide range of chemical concentrations in pulp bleaching, and because it can saturate at high residual levels, the preferred method of measurement has become the polarographic technique. Sensors based on polarography are now highly evolved for this application (see Sections 8.4, 8.42, and 8.43 in Chapter 8 in the first volume of this handbook).

Polarographic sensors can be located in the line a relatively short distance downstream from the point of chemical addition to rapidly measure how the reaction is proceeding and to be used in closed-loop control. While, in principle, ORP measurement could also be used, it has been found to be inadequate, because the ORP and reference electrodes require excessive maintenance in the harsh environment.

When ORP is used to control the dosage of bleaching (chemical flow), it is best used in combination with on-line brightness, pH, temperature, pulp consistency and flow, and chemical flow. Brightness, residual (ORP or polarographic), and chemical flow can be used to calculate a "compensated brightness" used to actually control chemical dosage (pH or consistency can also be part of the compensation). Controlling dosage on residual alone, as measured by ORP or a polarographic instrument, will tend to overbleach for certain process changes.[7]

It is also often necessary to independently control pH, depending upon the type of bleaching stage. In a ClO_2 bleaching stage, for example, pH must be kept below 3.5 for maximum effectiveness.

Chlorine/Chlorine Dioxide Scrubber Control A natural consequence of treating the pulp with strong oxidizing chemicals is the emission of noxious gases. Wet scrubbers are commonly used to "scrub" Cl_2 and ClO_2 from process gases prior to venting them to the environment. The most effective scrubbing media for this application are the white liquor or the weak wash, both of which contain large amounts of sodium hydroxide (NaOH) and sodium sulfide (Na_2S).[8]

The Cl_2 and ClO_2 gases rapidly oxidize the sulfides in the white liquor or weak wash to form chlorite (ClO_2^-) and chloride (Cl^-). A number of concurrent reactions are possible, the favored ones being:

$$8ClO_2 + 5Na_2S + 8NaOH \rightarrow 5Na_2SO_4 + 8NaCl + 4H_2O \quad \mathbf{8.31(14)}$$

$$4Cl_2 + Na_2S + 8NaOH \rightarrow Na_2SO_4 + 8NaCl + 4H_2O \quad \mathbf{8.31(15)}$$

The scrubber consists of a vertical packed tower. The scrubbing liquid is continuously circulated from the bottom to spray nozzles at the top (Figure 8.31k). Fresh scrubbing make-up solution is added under ORP control to maintain the required excess of reducing agent in the circulated liquid. A continuous overflow provides for changeover of liquid in the system.

The purpose of the double-headed positive displacement-type metering pump is to supply the required amount of scrubbing make-up solution to the scrubber, at the right concentration. The required dilution of the weak wash or white liquor is performed by manually adjusting the stroke of each head, thereby setting a constant ratio between these fluids and dilution water (usually condensate).

If there was no excess reductant remaining in the recirculated scrubber fluid, the concentrations of Cl_2 and ClO_2

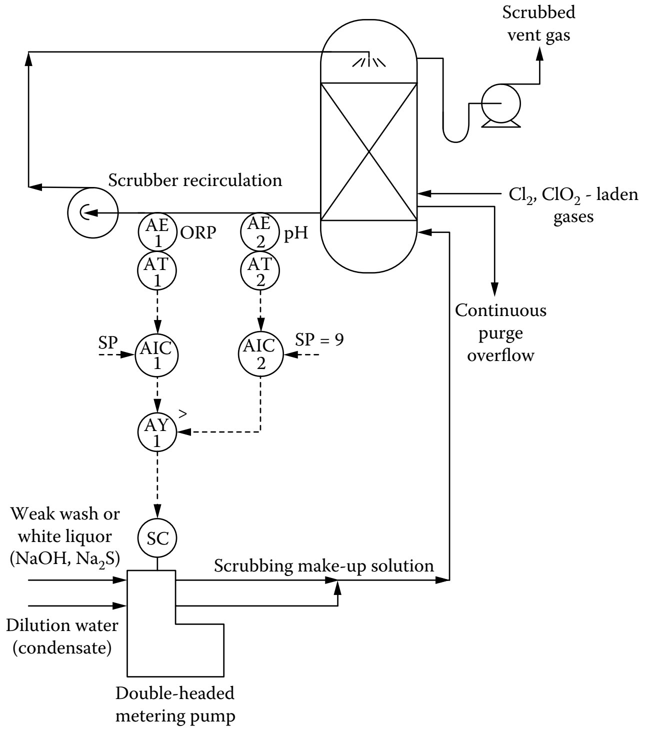

FIG. 8.31k
The control system for a chlorine/chlorine dioxide scrubber.

emissions in the vent gas will rise sharply. The object of the ORP control loop is to keep just enough excess reductant in the scrubbing fluid. The ORP set point would be in the reducing range, somewhere between –100 and –500 mV. For this process it is necessary to run emission tests and vary the ORP by varying fresh make-up to determine the operating point that results in design removal efficiency with only minimal excess chemical.

In scrubbers that use white liquor or weak wash that contains sodium sulfide (Na_2S), pH must be maintained above 7, because otherwise sulfur compounds will tend to form and deposit in the scrubber, increasing chemical consumption, decreasing removal efficiency, and causing plugging. Further, for liquor or weak wash containing sodium hydrosulfide (NaHS), pH must be maintained above 8.5 to avoid the formation of hydrogen sulfide (H_2S) gas.[8]

Consequently, the control system shown in Figure 8.31k includes a pH-based override controller. The output signal of this controller, through a high-signal selector (AY-1), overrides the ORP controller to ensure that enough white liquor or weak wash is added to keep the alkalinity at a pH of 9.0.

Other ORP Control Systems

There are numerous other industrial processes where it is important and useful to know the extent to which an oxidation-reduction reaction has proceeded or the extent to which an oxidizing or reducing environment is being maintained. Treatment of process cooling tower water and the indigo dyeing process (textiles) are two examples.

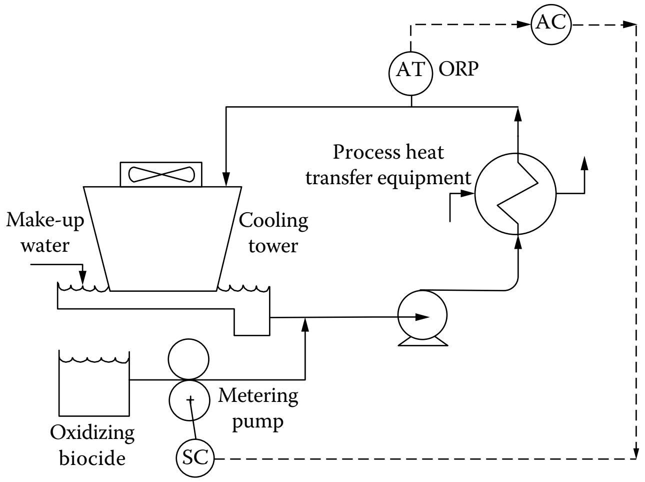

FIG. 8.31l
ORP-based control system for the control of biological growth in cooling towers.

Microbial Control in Cooling Towers Biocides are frequently used in cooling towers to control the growth of algae, bacteria, fungi, barnacles, and even clams and mussels in the water. Typical oxidizing microbiocides for this application are chlorine (Cl_2), bromine (Br_2), sodium hypochlorite (NaOCl), chlorine dioxide (ClO_2), and ozone (O_3). ORP-based continuous control of the addition of biocide helps to maintain effective treatment without wasting chemicals (Figure 8.31l). The desired range of ORP control is typically between 550 and 650 mV.

Indigo Dye Process[9] The process of dyeing cotton and cellulose fibers with indigo dye requires several additives to make the dye soluble in water. Sodium dithionite ($Na_2S_2O_4$) is added to the bath to reduce the dye (*leuco* form), and sodium hydroxide (NaOH) is added to form phenolates, which are water-soluble.

After the dye has been applied, it is reoxidized, fixing it into the fabric and making it once more insoluble (this can be done just by exposing it to air to dry). Control of the pH can be used to vary the behavior of the dye application (e.g., the degree of penetration) and, therefore, the final effect.

ORP is maintained in the range of –760 to –860 mV, to keep the indigo dye in its reduced (leuco) form for solubility. ORP can also be adjusted in and around this range to affect the final shade of the dyed fabric.

Swimming Pool and Spa Treatment ORP can provide a measure of sanitizer activity and water quality in swimming pools and spa water. In the United States many public pools and spas use ORP controllers for the automatic control of chlorine addition, but the controller readouts are usually labeled in parts per million of free chlorine instead of in units of ORP (mV).

When chlorine is introduced into the pool or spa water, it forms the active form of free chlorine, hypochlorous acid (HOCl), which is an excellent bactericide. The process of chlorine addition to water is described by the following equilibrium equation:

$$Cl_2(g) + H_2O \leftrightarrow HOCl(aq) + H^+(aq) + Cl^-(aq) \qquad \mathbf{8.31(16)}$$

The position of the equilibrium in the reaction shown in Equation 8.31(16) strongly depends upon the pH and the other reactions going on in the process of oxidizing and disinfecting. The HOCl is a fast-acting sanitizer (weak acid). Its concentration decreases very rapidly with increasing pH in the range of interest for pools and spas (pH 7–8).

For good bacteriological quality, it is essential to maintain a proper HOCl level in the water at all times. The recommended minimum ORP level should be controlled at between 650 and 750 mV. The ORP standards (650 or 750 mV) should apply to all sanitizers, including all forms of chlorine (with or without stabilizer) and bromine, as well as to systems using ozone or other sterilization methods.

The recommended chlorine control parameters are given in Table 8.31m.

Chemical controllers used in the pool and spa industry normally utilize an ORP sensor to monitor the sanitizer concentration, as well as a pH sensor to monitor the pH. The controller automatically turns the appropriate chemical feeders on and off as required to maintain the proper sanitizer and pH levels. This results in good water quality and elimination of chloramines and other undesirable by-products, as well as in savings in both chemical consumption and labor.

Cyanuric acid, used to stabilize chlorine against degradation by sunlight in outdoor pools, will tend to reduce the ORP (and, therefore, the chlorine effectiveness) at a given pH and free chlorine residual level. Above 50 ppm cyanuric acid, ORP controllers lose effectiveness, because additional chlorine called for by the ORP controller has a diminishing ability to increase free chlorine residual and, therefore, ORP. At about 70 ppm cyanuric acid, additional chlorine is reported to have no effect, and ORP control is rendered useless.[10]

TABLE 8.31m
Basic Control Parameters for the Treatment of Pool and Spa Waters

Parameters	*Recommended Control Levels*
pH	7.4–7.8
Free chlorine residual	Minimum free chlorine residual 0.4 ppm
Total chlorine residual	Maximum total chlorine residual should not exceed free chlorine by more than 0.5 ppm
ORP control standard	650 or 750 mV
Total alkalinity*	80–150 ppm
Calcium hardness	Above 140 ppm

**Note:* Total alkalinity times calcium hardness must equal 25,000–30,000 (this rule works when pH is 7.4–7.6 and temperature is 78–85°F).

ORP control can also be used for changing other oxidizers used in pool and spa water sanitation, such as bromine and ozone. Automated pool and spa water treatment systems represent a major advance in pool operation and maintenance. ORP standards for pool and spa sanitation have been recognized by the World Health Organization (WHO), the Centers for Disease Control and Prevention (CDC), the National Spa and Pool Association (NSPA), and a number of state and local health departments.[11]

CONCLUSIONS

ORP control is useful when the process to be controlled involves reduction and oxidation (redox) reactions. ORP measurement is best used to indicate the extent to which expected reactions have proceeded and to detect the relative strength of the oxidizing and reducing chemicals in the solution being measured.

Successful ORP measurement and control requires an understanding of the ORP measurement principles and of the chemistry that governs the process. ORP control can be highly nonlinear, and therefore the same techniques and strategies that are used in controlling highly nonlinear pH processes (Section 8.32) can also be used for ORP control.

8.32 pH Control

D. L. HOYLE (1985) **G. K. McMILLAN** (1995) **F. G. SHINSKEY** (2005)

Final Element Rangeability:	The rangeability requirement is extraordinary and depends upon the titration curve and on influent flow variability. Metering pumps are capable of 20:1 to 200:1, valves with positioners are capable of 50:1 or more, and a pair of split-ranged valves is capable of 1000:1 or more. For unbuffered titration, the pH variation (on either side of neutral) that valves can accommodate can be determined as the base 10 logarithm of the rangeability. For example, if rangeability is 1000:1 and the controllable pH variation is 3, it can be from pH 3–6 or 12–9.
Final Element Precision and Characteristics:	Requirement is exceptional and depends upon titration curve and desired control band. Electronically set metering pumps and valves with positioners have repeatability from 0.1 to 2.0%. Linear valve characteristics are generally preferred, and the use of smart digital positioners is recommended.
Control Loop Dynamics:	The effect of the extreme nonlinearity and sensitivity of a pH process is diminished by minimizing loop dynamic gain. To dampen oscillations, one needs ratios of loop dead time to time constant of less than 0.05, when controlling on the steep portion of the titration curve. Reagent delivery delay is often the largest source of loop dead time.
Design Considerations:	For proper mixing, process requires premixing of reagent with influent at the entrance of a well-mixed vessel. Close-coupled control valve with loop seal at the point of injection or water flush is needed to minimize reagent delivery delay. If the pH of the influent is more than three pH units away from the control band, or whenever the requirement for the final-element rangeability or sensitivity exceeds 1000:1, an additional neutralization stage is needed.
Reaction Tanks:	Liquid depth should equal diameter, retention time should not be less than 5 min (10–30 min for lime), and dead time should be less than 1/20th of the retention time. For strong acid-strong base neutralizations, one, two, or three tanks are recommended for influent pH limits of 4 to 10, 2 to 12, and 0 to 14, respectively. Influent should enter at top, and effluent should leave at the bottom.
Agitator Choices:	For tanks under 1000 gal (3780 1), use propeller-type agitators, and for larger volumes, axial-flow impellers are preferred. Flat-bladed radial flow impellers should be avoided. Acceptable impeller-to-tank diameter ratio is from 0.25 to 0.4. Peripheral speeds of 12 ft/s (3.6 m/s) for large tanks and 25 ft/s (7.5 m/s) for tanks with volumes less than 1000 gal (3780 1) are acceptable.
Mixing Equipment:	In-line mixer residence time should be less than 10 sec, and a well-mixed vessel residence time should be greater than 5 min. The vessel agitator should provide both a pumping rate greater than 20 times the throughput flow and a vessel turnover time of less than 1 min. Solid and gas reagents require a residence time greater than 20 times the batch dissolution time. Gas reagent injection needs a sparger designed to reduce bubble size and improve bubble distribution.
Set Point Location:	If the set point is located on the flat portion of the titration curve, this reduces the oscillation of the pH process. It also reduces control sensitivity and the requirement for control valve precision.

PH Sensor Location:	Insertion assemblies in pumped recirculation lines are preferred, because they can provide increased speed of response, decreased coating, improved accessibility, and auto on-line washing and calibration. If immersion sensor is used, it must be located in the mixed zone, directly before the discharge.
Continuous Control Techniques:	Nonlinear characterization is recommended for the feedback controller; self-tuning is helpful when the titration curve varies widely. Flow-based feedforward is effective when rapid upsets in flow are expected, while pH-based feedforward is rarely used, because it is effective only for neutralization applications having a single titration curve.

INTRODUCTION

This section begins with an explanation of the difficult nature of the pH process and of the various titration curves. Next, the process equipment used in neutralization facilities is described, including such topics as the selection of reagent delivery systems, mixing equipment, tank sizing, and other considerations. This is followed by a discussion of the special requirements of the pH controller and its tuning. The section is finished with an examination of the role of feedforward control.

TITRATION CURVES

The difficulty in controlling pH stems entirely from its nonlinear relationship to acid and base concentration in a solution. The slope of a single titration curve of pH vs. reagent delivery can vary over several orders of magnitude, and the set point where control is exercised is usually positioned in the steepest region of the curve. Because of this dominance, the nature of the titration curve will be the first topic to be considered in this section.

pH is the negative base-10 logarithm of the hydrogen-ion activity in g-ions/l in a solution. Hydrogen-ion *activity* is not quite the same as its *concentration,* but in dilute solutions, where pH is mostly controlled—especially wastewater—their difference is negligible.[1] For our purposes, then, the relationship will be expressed in terms of concentration, which appears in brackets:

$$\text{pH} = -\log[\text{H}^+] \quad [\text{H}^+] = 10^{-\text{pH}} \qquad \textbf{8.32(1)}$$

Water has a neutral pH of 7 at 25°C, at which point hydrogen and hydroxyl ions are in balance at 10^{-7} g-ions/l each:

$$[\text{H}^+][\text{OH}^-] = K_w = 10^{-14} \qquad \textbf{8.32(2)}$$

where K_w is the equilibrium constant of water. (It does change from 10^{-15} at 0°C to 10^{-12} at 100°C.) A tenfold increase in $[\text{H}^+]$ would lower the pH to 6, and a tenfold decrease would raise it to 8, where $[\text{OH}^-]$ would be at a concentration of 10^{-6} g-ion/l. One g-ion/l is considered a *Normal* solution and is designated 1.0 *N.* Control can be exercised over a pH of 0–7 in the acidic range and 7–14 in the basic range, or over a concentration range of 10^{-7} to 1.0 *N*:

Strong Agents

A strong agent is one that completely ionizes in aqueous solution. Two common strong agents are hydrogen chloride (HCl) and sodium hydroxide or caustic soda (NaOH). When dissolved in water, all of the H in HCl acts as the ion H^+, and all of the OH in NaOH acts as the OH^- ion. It is the ions that are reactive and are sensed by the pH electrode. A solution of 10^{-3} *N* HCl will then read pH 3, and a solution of 10^{-3} *N* NaOH will read pH 11. In any solution, the negative and positive charges must balance—for example,

$$[\text{Na}^+] + [\text{H}^+] = [\text{Cl}^-] + [\text{OH}^-] \qquad \textbf{8.32(3)}$$

Consider a neutralization reaction between these two agents, where HCl is added to water in a concentration of x_A and caustic to a concentration of x_B. All of the Cl^- comes from the HCl, and all of the Na^+ comes from the NaOH, so that the above charge balance becomes

$$x_B + [\text{H}^+] = x_A + [\text{OH}^-] \qquad \textbf{8.32(4)}$$

When the charge balance is combined with equilibrium Equation 8.32(2), the result is the strong-agent titration curve:

$$x_B - x_A = \frac{10^{-14}}{[\text{H}^+]} - [\text{H}^+] = 10^{\text{pH}-14} - 10^{-\text{pH}} \qquad \textbf{8.32(5)}$$

This relationship is plotted in Figure 8.32a, with the outer curve plotted against the bottom scale. Although the curve appears to be linear between pH 4 and 10, it is not— the inner curve, plotted against the expanded top scale, continues the logarithmic shape.

This is the titration curve when a strong acid is neutralized by a strong base; if a strong base were neutralized by a strong acid, the *x*-axis would be reversed to $x_A - x_B$, and the pH would fall. Another strong acid is nitric; sulfuric acid, while very corrosive, is not as strong, but may be considered so in the neutral pH range. Other strong bases are the hydroxides of potassium and lithium; calcium hydroxide is not as strong, and its pH is limited to about 12 by its low solubility, but in the neutral range it is essentially completely ionized.

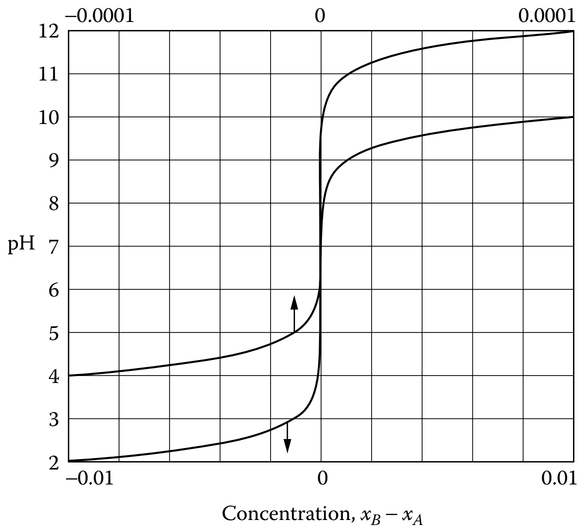

FIG. 8.32a
The strong-agent titration curve has the greatest gain variation of all.

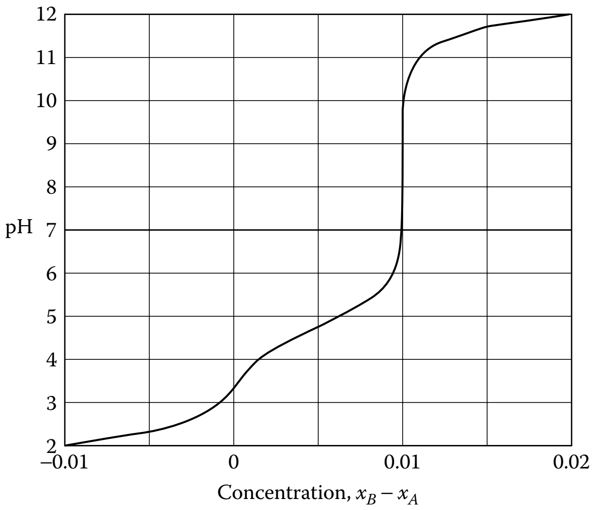

FIG. 8.32b
Acetic acid buffers the titration curve at about pH 4.75.

The difficulty the titration curve in Figure 8.32a presents to the pH controller can be estimated by comparing the size of the control target to the distance that the influent pH is from the target. For example, suppose the target specification that a wastewater must meet is a 6–8 pH and the influent entering the treatment plant is at pH 4.

This requires matching an influent concentration of 10^{-4} *N* with an accuracy of $\pm 10^{-6}$ *N*, or one part in 100 — difficult, but not impossible. However, if the influent pH were 2, then 100 times as much caustic would be required, but it must still be delivered with the same absolute precision, which amounts to control of 1 part in 10,000.

This level of accuracy is beyond the capability of controllers and valves especially, and so in the absence of buffering, multistage treatment would be required. Fortunately, most wastewater streams are buffered to some extent, and some are heavily buffered.

Buffering

Most acids and bases are weak and, therefore, only partially ionized. And most wastewater contains a small amount of carbon dioxide, which is also a weak acid, measured as alkalinity. Its presence greatly moderates the task of controlling pH in the neutral range. In fact, the bicarbonate ion is used as a buffer for stomach acid, as it tends to regulate pH around 7. Acids may have as many as three hydrogen atoms in their molecule, and they tend to be released as ions in different pH ranges. If a weak acid has but a single hydrogen atom, it affects the titration curve as follows:

$$x_B - x_A = 10^{\mathrm{pH}-14} - 10^{-\mathrm{pH}} + \frac{x_C}{1 + 10^{\mathrm{p}K_C - \mathrm{pH}}} \qquad \textbf{8.32(6)}$$

where x_C is the concentration of the weak acid and K_C is its ionization constant; pK_C is the negative base-10 logarithm of K_C and corresponds to the pH value where half of the acid is ionized. For example, the pK_C for acetic acid (vinegar) is 4.75. In this pH range, the titration curve is buffered by the weak acid, as shown in Figure 8.32b.

The curve was plotted for a concentration of $x_C = 0.01$ *N*. At that concentration of $x_B - x_A$, the weak acid is neutralized. The curve has been extended in both directions to show the effects of additional strong acid and base, because most wastewater includes both strong and weak agents to be treated.

Ammonia in water forms the weak base ammonium hydroxide, whose buffer point is pH 9.25, which just happens to be 14–4.75. Therefore, its titration curve is the mirror image of acetic acid's. Adding a strong acid to aqueous ammonia will lower the pH gradually through the range of 10.25–8.25, where it will begin to fall sharply and then continue to follow the strong-base curve.

Carbon dioxide in water forms the weak carbonic acid, which releases two hydrogen ions — its titration curve is described by

$$x_B - x_A = 10^{\mathrm{pH}-14} - 10^{-\mathrm{pH}} + \frac{x_C(1 + 0.5 \times 10^{\mathrm{p}K_2 - \mathrm{pH}})}{1 + 10^{\mathrm{p}K_2 - \mathrm{pH}}(1 + 10^{\mathrm{p}K_1 - \mathrm{pH}})}$$

8.32(7)

where $pK_1 = 6.35$ and $pK_2 = 10.25$. Its titration curve is plotted in Figure 8.32c for a concentration of $x_C = 0.0001$ *N*, which is one tenth of the horizontal scale. In other words, the initial pH of 3 is due to the presence of ten times as much strong acid.

This is typical for industrial wastewater, where strong agents need to be neutralized in the presence of much smaller

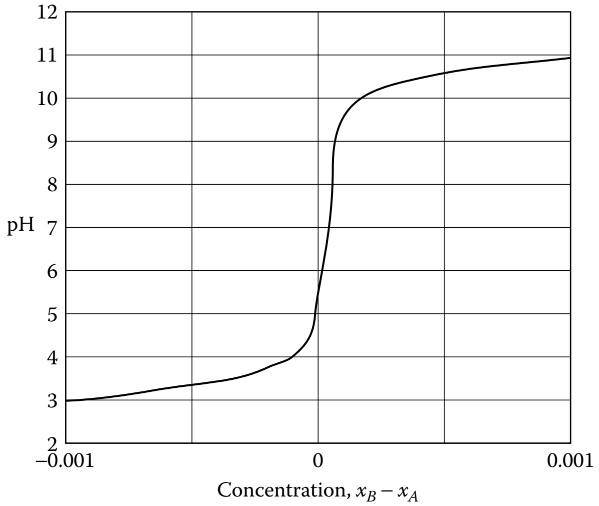

FIG. 8.32c
Carbon dioxide moderates the titration curve between pH 6 and 7.

concentrations of weak agents, principal among them being carbon dioxide. A normality of 0.0001 corresponds to an alkalinity of 5 ppm calcium carbonate, within the common range for surface water.

While the moderation of the curve in the range of pH 6–7 may not seem very noticeable, it is substantial compared with the strong-agent curve in Figure 8.32a. With that curve, neutralization from pH 3 to pH 6–8 required a caustic dosage accurate to ±1 part in 1000. For the curve in Figure 8.32c, the accuracy required is only ±1 part in 28, an improvement by a factor of 36.

Another measure of the effect of buffering is the gain of the titration curve at a set point of pH 7. The reagent valve needs to be sized for twice the anticipated demand. Given a wastewater at pH 3 or 11, the valve must be able to deliver a reagent concentration of 0.002 *N*.

In the absence of any buffering — as in treating distilled or deionized water — the steady-state open-loop gain, assuming a transmitter range of pH 2–12, would be about 420. In other words, a change in valve position of 0.01% could change the pH of the solution by 4.2% of scale, which is 0.42 pH.

The presence of carbon dioxide of as little as 10^{-5} *N*, which is very common in water supplies, lowers the gain to 75; at 0.0001 *N*, which is shown in Figure 8.32c, the gain is 11.4; and at 0.001 *N*, the gain is only 1.6. The lower gain both reduces the sensitivity of the solution pH to disturbances and allows a higher controller gain setting without causing cycling.

The presence of buffers is very common in industrial wastewaters. All cleaning agents are buffers: carbonates, silicates, phosphates, sulfonates, detergents, and surfactants. So are all organic acids and bases such as citric acid and amines. Most metal ions are also buffers, including iron, copper, chromium, cobalt, nickel, tin, zinc, cadmium, and aluminum. As a result, the pH of wastewater from metal-plating operations is very easy to control; regulation at pH 8–9 causes these metals to precipitate from solution as hydroxides.[2]

If the *principal* load on the pH loop is represented by a buffer, then variation in its concentration changes the gain of the curve and the load at the same time. An equal-percentage reagent valve, whose gain increases in direct proportion to flow delivered, can compensate for the gain reduction caused by increasing concentrations of the buffer.

This situation is unusual, however. The principal problem with the presence of buffers in wastewater is that they tend to come and go, while stronger agents remain. At any given time, a wastewater that is only lightly buffered may be mixed with the rinse from a cleaning operation. This changes the load and the gain of the curve, upsetting the controlled pH for some time, given the low gain of the controller — and then the buffer passes on. However, if the controller were tuned for the buffered condition, then after the buffer is gone — especially when the plant is idle on weekends — the loop will cycle until the buffer returns.

This is a problem when treating wastes from regenerating ion-exchange resin beds. Both anion and cation beds are used for treating boiler feedwater and ultrapure water used in manufacturing semiconductors. These beds are regenerated batchwise, acid for the cation bed and base for the anion bed, and the effluents from regeneration must be neutralized prior to disposal. The first effluent leaving a bed is highly buffered, with the buffering gradually declining toward the end of the procedure, making neutralization of this effluent on-line quite difficult. It is better to combine the anion and cation washings in a common tank where they neutralize each other, and then treat the mixture batchwise.

THE PROCESS

The acid-base reaction is considered to be zero-order — that is, it does not take any time or depend on the relative concentrations of the reactants. This would seem to eliminate the need for the kind of careful process design that goes into chemical reactors in general. However, the very difficult aspects of pH control cited above place other burdens on the design of the process.

Vessel sizing and layout are very important, as are mixing and reagent delivery. Experts in pH control have been known to enter a plant and completely redesign a vessel and its auxiliaries in order to achieve a control performance that was not possible with the original configuration. This is one process that *must* be designed for controllability, or it will have to be modified on-site to meet effluent specifications.

Vessel Design

A *static* mixer is a section of pipe fitted with vanes that provide intense *radial* mixing without longitudinal or backmixing — it is a plug-flow device. The step response of a static mixer is between that of 20 and 50 stirred tanks in series, as shown in Figure 8.10i — it is essentially dead time, and as such it has a dynamic gain of almost 1.0.

A step in reagent concentration at the inlet will emerge at the outlet one residence time later virtually unmitigated. As a result, a pH controller will have to face the full steady-state gain of the titration curve without any dynamic help. If the gain of the titration curve at set point is 10, for example, the controller proportional gain will have to be the order of 0.05 to provide a loop gain of 0.5 as required for damped stability.

A proportional gain of 0.05 is a proportional band of 2000% — rarely are controllers successful in such service — and a gain of 10 is considered moderate for a titration curve. As a consequence, pH control is rarely exercised across a static mixer, and then only when the process is heavily and consistently buffered, as in a fermentation process saturated with carbon dioxide, or when the set point is in a flat portion of the titration curve.

An example of the latter is the addition of sulfuric acid to a solution of sodium dichromate preparatory to its reduction to chromium ions by sulfur dioxide.[3] In the range of pH 2–3, where the set point is located, the slope of the titration curve is about 300 times lower than at pH 8.

Another problem with the static mixer is that its dead time varies inversely with flow. The dead time is essentially the residence time, which is its fixed volume V divided by the variable flow (F) through it — and at zero flow, the loop is open. This can be fixed, and the dynamics can be measurably improved as well, by the addition of a circulating pump.

A circulating pump, taking suction from the static mixer's outlet back to its inlet at rate F_a will reduce the dead time from V/F to $V/(F + F_a)$ and convert the balance of the residence time to a first-order lag.[4] A circulation ratio F_a/F of only 2:1 can reduce the dynamic gain of the static mixer from 1 to 0.26, and the ratio of 5:1 reduces it to 0.12. This allows a comparable increase in controller gain or reduction in proportional band.

Neutralizations should preferably be conducted in a back-mixed tank, with a minimum of 5 min of residence time. If the reagent contains a solid material such as lime, the residence time should be up to 20 min to allow the lime to dissolve. If not enough time is allowed in the controlled vessel, any solid particles of lime carried out will continue reacting and raise the final pH of the effluent beyond the control point. A similar dynamic is encountered when the reagent is a gas such as ammonia or carbon dioxide, which also takes time to dissolve.

The shape of the neutralization vessel is important. Ideally, the depth of liquid should be similar to its length and width, to minimize distance traveled for a given volume. A ditch or channel is the worst configuration, because it will be dead time-dominant like a static mixer. Given a ditch, baffle the entrance to create a square chamber where pH is controlled, and let the remainder of the ditch act as an attenuation basin.

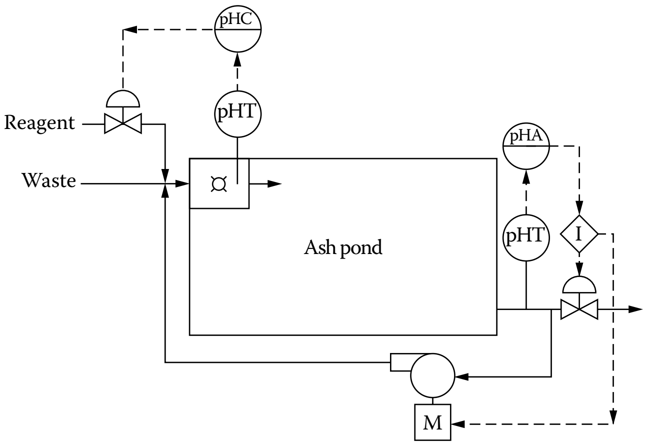

FIG. 8.32d
Ash pond control system, which recycles the pond's effluent until its pH is within specifications.

In some neutralization processes more than one vessel may be needed. If the waste alternates on both sides of pH 7, an upstream tank may allow for self-neutralization of some of the waste, thereby saving reagent. A downstream vessel is also useful to attenuate fluctuations in controlled pH, and may in fact be mandatory for impounding off-specification product. One such arrangement is shown in Figure 8.32d, for the treatment of fly-ash from a coal-fired power plant.

The waste is neutralized in a well-mixed corner of the ash pond where pH is controlled. It then overflows to the balance of the pond, which is unmixed, thereby allowing solids to settle. Hours later it emerges at the outfall, where its pH is again measured. If the effluent falls within specifications, it is discharged to the environment; if not, the discharge valve is closed and a recirculating pump started to return the wastewater for another round of treatment, as long as needed to bring it within specifications.

Mixing

Back-mixing is needed for uniformity of composition within the vessel, and a high velocity is required to minimize dead time between the point of entry and the point of discharge. Figure 8.32e shows two possible flow patterns in stirred tanks.

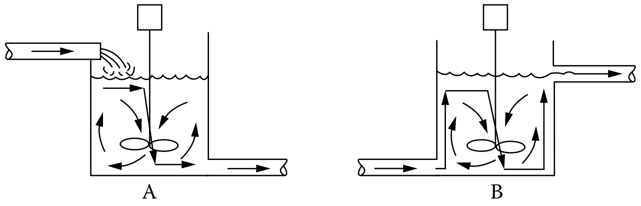

FIG. 8.32e
Flow patterns in stirred tanks. A. Recommended flow path. B. Undesirable flow path.

Reagent should be introduced — actually premixed — with the feed, and the pH should be measured at the vessel exit, but within the mixed zone. Then pattern A gives the shortest flow path, because mixers pump downwards (except those that intentionally aerate the vessel contents). Inflow entering the top of the vessel will be drawn to the bottom, where the pH is measured, whereas inflow entering at the bottom must flow up the side of the vessel first, doubling the dead time of the response of pH to reagent flow.

High-speed *axial* mixing is recommended, using a propeller or axial turbine, to minimize dead time. Low-speed radial mixers are intended to keep solids suspended and are not effective in this service, because they give excessive dead time. The step response for a typical back-mixed vessel is shown in Figure 8.10i. The ratio of dead time to residence time is essentially its dynamic gain.

In general, the degree of back-mixing can be defined in terms of the pumping capacity of an agitator with respect to the flow and volume of the neutralization vessel. In practice, however, this definition has limited usefulness because of variables such as agitator construction and blade pitch, baffling of the neutralization vessel, and placement of inlet piping and outlet measuring electrode. All influence the degree of back-mixing.

Experience shows that the best way to define back-mixing for control purposes is by the ratio of the neutralization vessel's dead time to residence time. A ratio of dead time to residence time equal to 0.05 is adequate for good control.

Figure 8.32f is a plot of tank size against agitator pumping capacity per unit volume on logarithmic coordinates. The family of curves shown for various dead times was developed from empirical data in tanks with capacities of 200, 1,000, 10,000, and 18,000 gal (756, 3,780, 37,800, and 68,040 l). They apply to baffled tanks of cubic shape, with the inlet at the surface and the outlet at the bottom on the opposite side of the tank. The ratio of impeller diameter to tank diameter varied from 0.25 to 0.4. Square pitch propellers at an average peripheral speed of 25 ft/s (7.5 m/s) were used in tanks up to 1,000 gal capacity. Axial-flow turbine impellers at an average peripheral speed of 12 ft/s (3.6 m/s) were used in the larger tanks.

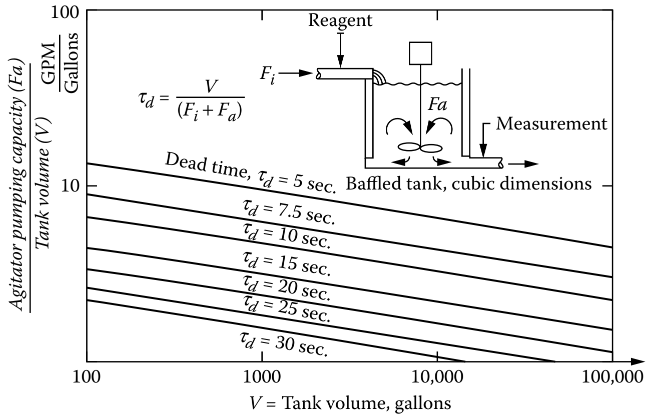

FIG. 8.32f
Dead time (τ_d) as a function of mixing intensity.

To be classified as a well-mixed vertical tank (by the standards of pH control applications), the liquid height should be between 100 and 150% of the vessel width or diameter. The vessel walls should have baffles to prevent liquid rotation, the agitation pattern should be axial, and the agitator pumping rate should be at least 20 times the influent flow rate. The agitation should be great enough to break the surface and pull down the inflow but not enough to cause air entrainment.

Reagent Demand

Titration curves produced from process samples in a laboratory are typically plotted as pH vs. milliliters of reagent, such as 0.01 *N* NaOH, used to treat a 50 ml sample. To convert this information into gal/min of industrial-strength reagent per 1000 gal/min of wastewater, one has to know the reagent concentration in normality. Table 8.32g provides that information for the most-common reagents.

To estimate the reagent requirement from a titration curve, consider the example where 10.2 ml of 0.01 *N* of NaOH was used to neutralize a 50 ml sample of wastewater. The original normality of the sample was then (10.2/50) 0.01 *N*, or 0.00204 *N*. If in the plant, a 10% NaOH reagent will be used, 1000 gal of waste will require 1000(0.00204) / 2.75 = 0.74 gallons of it.

A valve should be selected to deliver twice the maximum anticipated flow to allow for errors in the estimate, and to provide a margin for dynamic correction during recovery from load changes. A similar calculation should be made for the minimum anticipated load, to estimate the rangeability requirements of the system.

Reagent Rangeability

The rangeability needed in a given process is the ratio of the maximum required reagent flow to the minimum required.

TABLE 8.32g
Normalities of Common Reagents

Reagent	*Wt. %*	*Normality (N)*
HCl	32	10.17
	38	12.35
H_2SO_4	62.2 (50° Bé)	19.5
	77.7 (60° Bé)	27.2
	93.2 (66° Bé)	35.2
	98.0	36.0
NaOH	10	2.75
	25	7.93
	50	19.1
$Ca(OH)_2$	5	1.43
	10	2.86
	15	4.30

Metering pumps can be used for reagent delivery, but are of generally insufficient rangeability, typically on the order of 20:1, where *control valves* have rangeabilities of 35–100:1. The penalties for providing insufficient rangeability are two:

1. If the *maximum* reagent flow is insufficient for the largest plant load, the treated effluent will be off-specification—possibly well out of range. If the plant waste can be impounded as in Figure 8.32e, and enough capacity is available to weather the overload, this could be acceptable. But if not, the penalty may be severe.
2. If the *minimum* controllable flow the valve can provide is more than the minimum flow the plant requires, limit-cycling will result. This occurs because when the valve is shut, the small load will drive the pH away from set point, causing the controller to open the valve. However, when the minimum controllable flow is greater than needed to neutralize the current load, the pH will overshoot the set point, causing the controller to close the valve. This cycle will repeat, in a generally saw-tooth pattern, as long as the load remains below the throttling limit of the valve. If the amplitude of the cycle is within the acceptable pH limits, then the plant can live with it; a downstream vessel, even unmixed, will help attenuate the cycle.

Two valves in parallel can be sequenced to extend rangeability, but it must be done properly to be successful. Most importantly, they must not be open at the same time. This is because if the smaller of two sequenced valves is approaching full opening and the larger valve is then opened to its lowest controllable flow, the total flow delivered can almost double.

Therefore, the smaller valve must be closed when the larger is opened. Proper sequencing of valves differing in size by 20:1 or more must be done with equal-percentage characteristics, which are logarithmic, as plotted in Figure 8.32h.

The sequencing of the two valves in the figure produces essentially a single characteristic having a rangeability of almost 1000:1, with a small overlap in the center. The dots on the lines represent the calibration limits for the valve positioners. The smaller valve is throttling over the range of 0–52% of the control signal, and the larger valve from 48–100%. Logic on the control signal must switch one valve off and the other on when the controller output moves outside its range. Switching produces a small transient, but it lasts only for a second or so.

Because linear characteristics are needed for most pH loops, a curve characterizer is required between the controller output and the signal to the valve positioners. Its purpose is for the delivered flow to be linear with the controller output. Figure 8.32i describes the equal-percentage flow characteristic for 1000:1 rangeability, and a compensating hyperbolic characterizer of the form:

$$f(m) = \frac{m}{L + (1 - L)m/100} \qquad 8.32(8)$$

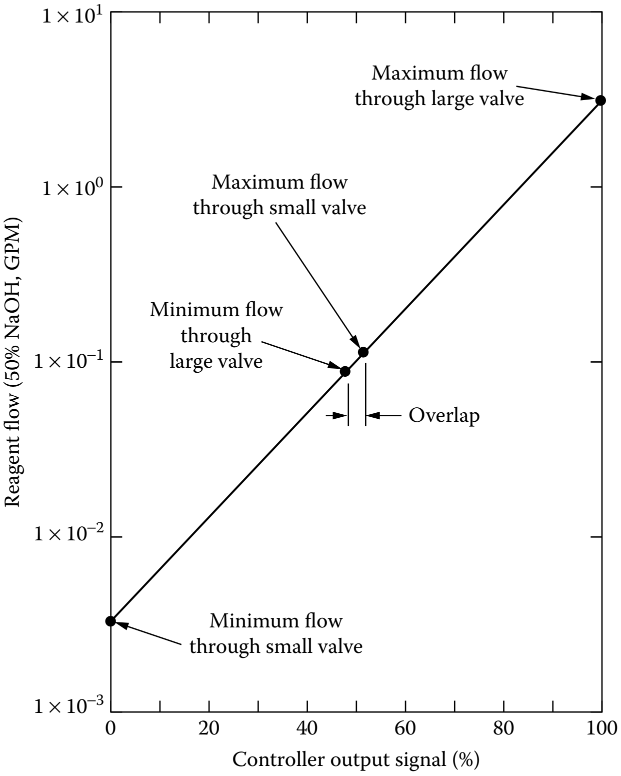

FIG. 8.32h
Reagent flow using sequenced valves.

where m is the controller output and L is the linearity of the characterizer; when $L = 1$, the function is linear. To compensate the 1000:1 equal-percentage valve in the figure, $L = 0.1$ and the compensation is adequate, as shown by the almost-linear combination of the two. Alternatively, an *x-y* function generator can be used.

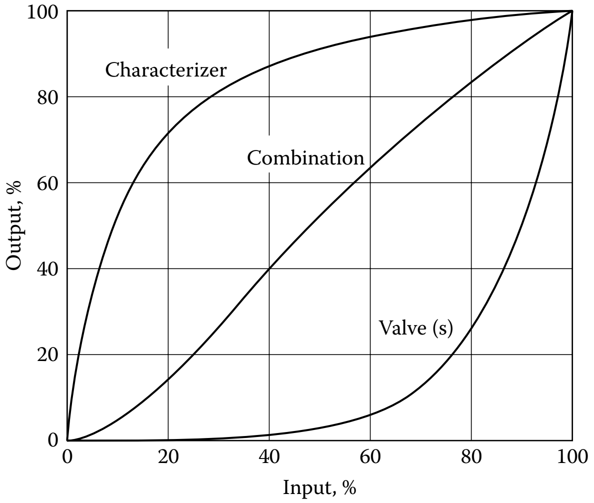

FIG. 8.32i
A hyperbolic characterizer can effectively compensate a 1000:1 equal-percentage valve.

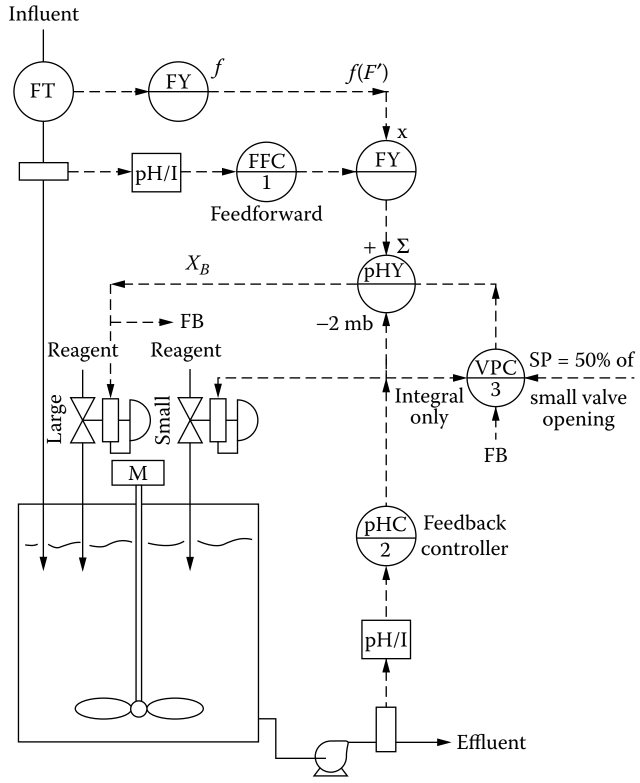

FIG. 8.32j
VPC-3 controlling the small valve opening at 50%. The feedforward portion of the control system is useful only if the relationship between influent pH and reagent demand is consistent, which usually is not the case.

Another, simpler, way to extend valve rangeability is through the use of a valve position controller (VPC) to drive the larger valve while the pH controller drives the smaller. The VPC compares the output of the pH controller to its own set point of 50%, and moves the larger valve to drive it slowly there by integral action. Short-term control is the function of the smaller valve, tending to return to 50% opening as long as the load is within the range of the larger valve. Figure 8.32j illustrates a VPC-based feedback control loop. The figure also shows feedforward trimming of that loop, which is not recommended unless the relationship between influent pH and reagent demand is consistent.

At times, the VPC will drive the larger valve closed, and this may bump the pH, as it will when suddenly opening to its minimum flow. This system may also not be fast enough to cope with load changes outside the range of the smaller valve.

When wastewater pH can vary on both sides of neutral, then acid and base valves must operate in sequence, the acid valve opening from 50 to 100% controller output, and the base valve opening from 50 to 0. Yet both valves must fail closed, and therefore the base valve requires a reverse-acting positioner.

Smart digital positioners are recommended on all valves used in pH control, whether sequenced or not. They combine speed with the elimination of dead band and can be individually characterized if necessary.

Reagent Piping

If reagent is simply dropped on the surface of the water in a tank, it will not be adequately dispersed into its contents, and the pH measurement will reflect this by randomly moving about. Premixing of the small flow of concentrated, viscous reagent with the much larger flow of water is essential for a steady pH reading. The reagent therefore should enter the vessel at the same point as the inflow, taking advantage of entrance hydraulics to provide premixing.

A major source of dead time in a pH loop is the movement of a small flow of dense reagent through the transfer line into the wastewater. When the reagent valve opens, flow into the mixed zone of the vessel should start immediately, and when it closes, flow should stop. The transfer line from the valve to the vessel must remain full at all times to accomplish this. The line should terminate in a loop seal, whether discharging on the surface, or through a dip tube into the bottom of the vessel (in the case where a bottom feed entry cannot be avoided).

Flushing of a transfer line with water is sometimes done, but is not recommended in two common cases. Concentrated sulfuric acid reagent is not corrosive, allowing cast iron and mild steel to be used for valves and piping. But when diluted with flush water, it attacks these materials vigorously. The other problem is with lime slurry. Flush water containing carbon dioxide will react with the lime at their point of contact to form a very hard scale of calcium carbonate, which will eventually plug the line and is very difficult to remove.

Lime is of very limited solubility and is, therefore, always administered as a slurry whose piping must be very carefully designed to avoid plugging — Figure 8.32k illustrates how it should be done. A level switch (LS) on the slurry tank is used

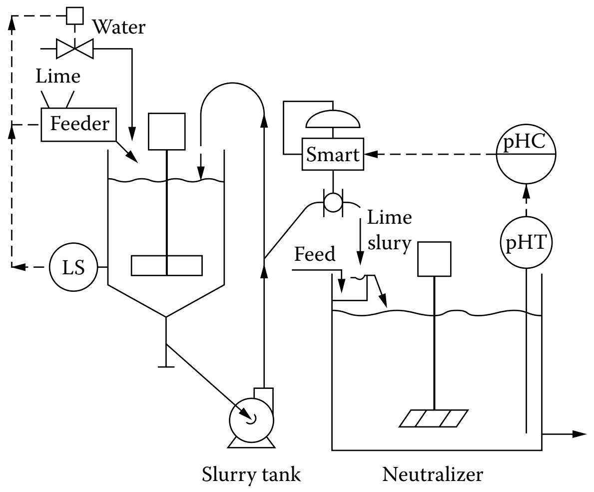

FIG. 8.32k
Control system for a lime-based neutralization process.

to turn on the solid-lime feeder and to simultaneously open the water valve when the level is low and to turn them off on high level, thereby adding the lime and water in consistent proportions.

The circulating pump is always running, keeping the slurry in constant motion. A ball-type control valve draws slurry from the top of its branch to the neutralization vessel, as needed. When closed, any solids in the branch will fall back downhill and away from the valve, avoiding plugging. Ball valves have an inherent equal-percentage characteristic, which must be linearized by a characterizer in their smart positioner.

Multiple Stages

Manipulating a reagent flow to within ±1% or 1 part in 100 is a reasonable expectation in a single well-designed treatment stage. This would take deionized water from pH 4 or 10 to 7±1, slightly buffered water from pH 3 or 11 to 7±1, and well-buffered wastewater from pH 2 or 12 to 6–9, a typical wastewater specification.

When the reagent demand is greater, or the buffering less, a single stage may not be enough. Effluent pH may cycle excessively simply due to valve imprecision. In this case, a second stage is needed, and in extreme cases of solutions at pH 0–1 or 13–14, a third stage. Each stage of treatment has its closed pH loop, which is capable of passing along a cycling load to the next stage.

Unfortunately, the worst type of load disturbance with which a feedback loop must contend is one that is cycling at its own period. To reduce this sensitivity to cyclic load changes, the individual pH loops should have different periods of oscillation. This is best achieved by sizing the stages progressively larger from feed to discharge, as shown in Figure 8.32l.

Each successive stage has a smaller valve, so failure of an upstream stage to control pH in an acceptable range could allow an overload to pass downstream where it cannot be handled. To protect against this possibility, the set points of upstream stages need to be properly positioned. For example, the first of three stages should control pH at 1 or 13, the second stage at 3 or 11, and the last stage at 7–8.

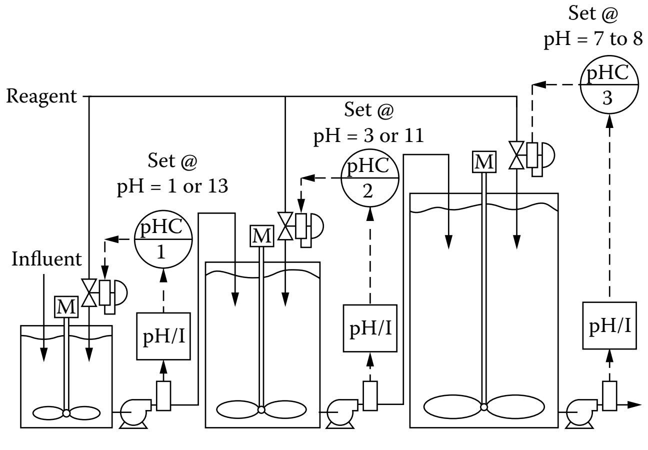

FIG. 8.32l
Classical three-stage pH control system.

THE CONTROL SYSTEM

If the process is well-designed, the control system can perform well with a simple structure. By contrast, even the most complex control system will not perform well or will be prone to failure and operator error if the plant is poorly designed. This applies to feedforward control, as well.

Feedforward adds complexity to the system and is prone to error — more in pH control than in any other process application — owing to the wide variability encountered in titration curves. For these reasons, only the simplest systems are described here.

Measuring pH

For a detailed discussion of pH detectors, refer to Section 8.48 in Chapter 8 in Volume 1 of this handbook.

The measurement of pH used for feedback control must be in the mixed zone, but directly before the exit, so that it truly represents the quality of the effluent. For the preferred flow pattern of top entry, bottom exit, this can mean locating the electrodes under several feet of liquid head.

In Figure 8.32k, this is avoided by locating the probes in the discharge of the transfer pumps. However, if flow were ever to completely stop, they would be in a dead space, causing the pH loop to be open. To avoid this problem, each electrode assembly should be located in a slipstream from the pump back to its tank.

Electrode assemblies have some strange failure modes. The reference electrode and the inside of the glass measuring electrode are both filled with solutions buffered to pH 7. As a result, a measured pH of 7 corresponds to 0 mV across the electrodes — unfortunately, so would a dead short. So a reading of pH 7 is not always good, because it can also be caused by a short circuit, or by a conduit full of water.

Remember that the electrical impedance of a glass electrode is in the order of 100 MΩ, and it only produces 59 mV per pH unit away from 7. Another source of error is a bias caused by contamination of the reference electrode, or by a ground current being rectified by it. Follow manufacturer's procedures for proper grounding, and frequently check electrode calibration against buffer solutions.

Electrodes can also become coated with scale, precipitates, tars, and biological growth. Coatings impede the free flow of ions between the sensitive surface of the glass and the solution at large, creating a dynamic lag that could be up to several minutes long. The effect is like a temperature sensor in a thermowell, but one that grows with time.

If the accumulation is slow, the electrodes may be removed periodically for chemical cleaning: Acids are effective if the

electrodes are in a predominately basic environment, and vice versa. If accumulation is rapid, ultrasonic cleaners are effective against most sources of fouling, and mechanical brushes are also used. A fluid velocity of 5–9 ft/s (2–3 m/s) past the electrodes will tend to keep them clean without excessive abrasion. See Table 8.32m for recommendations on cleaner selection.

The pH Characterizer

The only special feature used in PID controllers for pH is a nonlinear characterizer to help linearize the loop. Titration curves come in a wide variety of shapes, so there is no universal pH characterizer. However, there does not need to be — it is not necessary to match the curve over its entire length, because control is exercised mostly around set point.

Three classes of characterizers are presented here: matched, three-piece, and error-squared. The characterizer matched to the titration curve is the best option, but it is not realistic for most applications, principally because of the variability of the process curve. The three-piece characterizer consists of three straight lines, as shown in Figure 8.32n.

The error-squared curve is a parabolic function that has no adjustments; it is simply $f(e) = e|e|$. It is compared with a typical matched curve in Figure 8.32o.

The error-squared curve has zero gain at zero deviation, which can produce a small amount of offset. This is not a problem with wastewater, whose specification gives some latitude, e.g., pH 6–9. The three-piece function has an adjustable minimum gain, along with an adjustable width to the zone where that gain is applied; its gain outside that zone is 1.0. Other characterizers are feasible, but these have had the most extensive use.

Figure 8.32p plots the results of a simulated neutralization conducted in a stirred tank using the software of Reference 5. A solution containing 0.001 N HCl and 10^{-5} N CO_2 is being neutralized by NaOH, which gives a process gain of 75 at set point. The time scale is normalized to the residence time of the vessel.

With a *linear* PI controller, the 10% step-load change drives the pH from a set point of 7 beyond 9, where it remains for a full residence time before falling, followed by a large overshoot. If the specifications are pH 6–9, then they are violated in both directions.

The length of time required for recovery is critical, because it reduces the effectiveness of any attenuation vessel and can be detrimental to biological life downstream. The proportional band of the controller is 700%, set to provide (light) damping at set point; integral time is $0.32V/F$. The

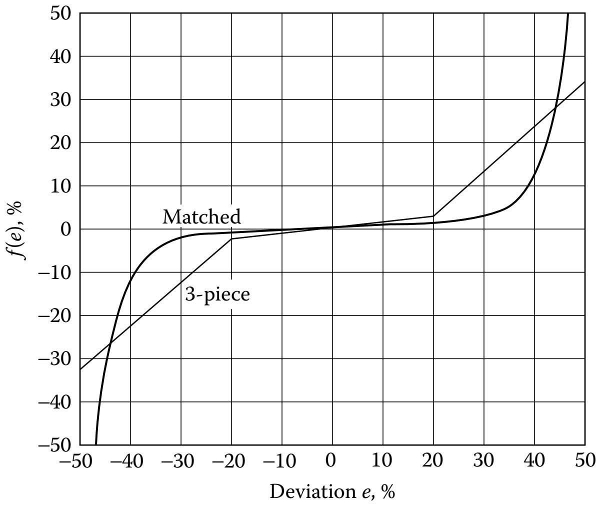

FIG. 8.32n
The three-piece curve has an adjustable low-gain zone.

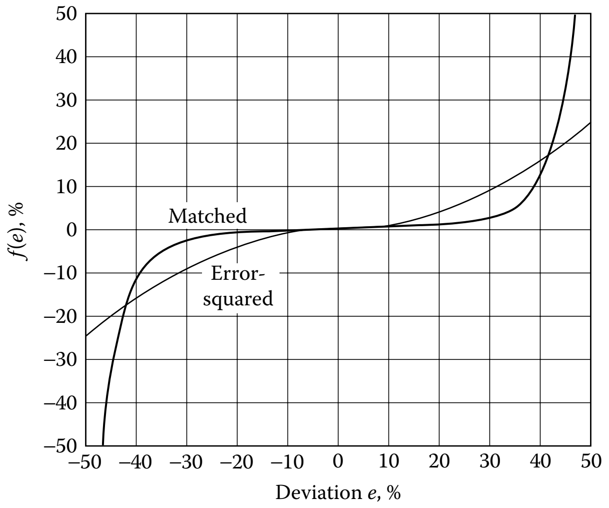

FIG. 8.32o

The matched curve is the most complex, the error-squared curve the simplest.

slow recovery is due to the low loop gain away from set point. Judging from this response, nonlinear compensation is needed to have any chance of satisfying specifications.

A characterizer *matched* to the pH curve across 200 points provides the best response. Because of its very low slope at set point, the controller's proportional band can be reduced to 12% (integral settings for all four controllers are the same). This provides the gain needed for rapid recovery from severe load changes.

Still, the time required to recover is much longer than the period of the cycle around set point. Due to the severely nonlinear nature of the process, even with matched characterization the loop will not behave like a linear loop having the same process dynamics.

The *three-piece* characterizer was given a zone width of ±1.5 pH units, where the gain is 0.10. The proportional band of the controller is 75%, which at set point gives the same gain as a linear controller at 750% band. It performs almost as well as the matched characterizer in this test, although it is a very crude approximation to the titration curve.

The crude fit means that the performance of the controller depends to some extent on the size of the load variations — deviations that lie just within the low-gain zone will not be corrected as quickly as those exceeding it. The width of the low-gain zone is the most effective adjustment and can be used to tune the loop to a particular titration curve. The gain in the zone can be left at 0.1 for most pH curves — it should not be set to 0, or the loop will limit-cycle between the two high-gain zones.

The error-squared characterizer is the least effective of the three, but has no adjustments to tune or points to match. It therefore can be considered as a compromise characterizer for pH control, keeping in mind that P, I, and D are more than enough adjustments for many technicians to tune.

PID Tuning

The tuning of pH controllers is based on the same technology as linear loops, which is described in Section 2.35 in Chapter 2 in great detail. But the extreme nonlinearity of the process makes some modifications necessary. After choosing a characterizer and its settings, the proportional band or gain needs to be adjusted so that the loop is damped at set point, but only lightly.

Several observations need to be made over time of the closed-loop behavior at set point, because as buffers leave the system, limit-cycling may develop — a very common observation in pH control. Limit-cycling may not be objectionable in some pH loops, providing that its amplitude is within the specification limits.

Where it can become costly is in a system where the controller manipulates acid and base valves in sequence. Then, the cycling could cause the controller to alternately add acid and base to the vessel, even with — in fact, especially with — no neutralization load or even any flow of water. To guard against this possibility, the air supplies of the reagent valves serving vessels with pumped flow should be shut off when the pump is stopped — closing both valves — and their controller should be transferred to manual. When the pump restarts, the controller can then resume where it left off.

The length of time required for pH to recover from a major load change, as shown in Figure 8.32p, limits the rate at which the controller can integrate without excessive overshoot. Too short an integral time causes overshoot, and it needs to be increased by a factor of two or more above its optimum value for a linear loop.

The derivative time needs to be optimized for the fastest part of the cycle, which occurs around set point. In this respect, its setting would be about the same as for a linear loop. A noisy pH measurement can preclude the use of derivative action completely, but the source of the noise is worth

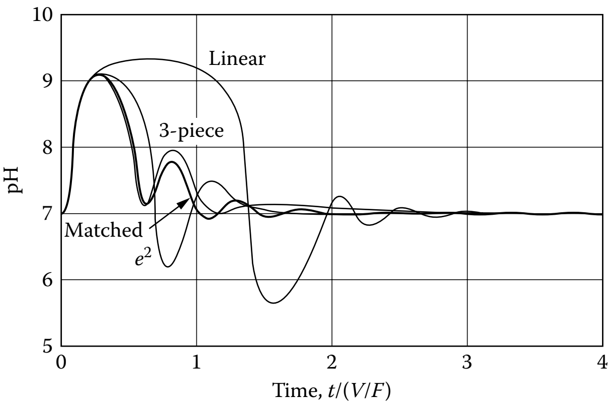

FIG. 8.32p

The response to a 10% step change in load is best with a characterizer matched to the pH curve. Other responses shown are those of "Linear" (linear PI controller), "three-piece" (three-piece characterization), and e^2 (error-squared characterization).

investigating and eliminating, because derivative is of great benefit in composition control, as it is able to substantially reduce the period of oscillation and, hence, the load recovery time.

Self-Tuning Control

Self-tuning controllers are useful whenever process parameters change substantially and frequently. If these variations can be associated with measurable quantities such as flow, then direct compensation should be applied.

An example would be the programming of the integral time of a pH controller on a static mixer to vary inversely with the measured flow, to compensate for dead time variation. When there is no measured variable that correlates to loop behavior, the only remedy is to change controller tuning based on that observed behavior. A device or software that does this is a self-tuning controller.

Given that a variable titration curve is changing the loop behavior, the proper compensation should be applied to the controller's characterizer. But this would require an on-line titration to be run periodically to determine the need for recharacterization. Unfortunately, this is not likely to be helpful, because an automatic titrator is a miniature pH control loop, with similar dynamics — therefore, the information it obtains is too late to be of much use. The first evidence of a change in the curve is likely to be the limit-cycling of the pH loop.

The best way to approach this problem with present technology is to tune the pH controller and to fit its characterizer as well as can be done for the existing or estimated worst-case conditions, and let self-tuning do the rest.

Commercial self-tuning PID controllers are available that observe loop behavior during upset conditions; calculate decay ratio, overshoot, and period of oscillation; and estimate the PID settings that will improve performance. A device that does this without intentionally disturbing the loop is the Foxboro EXACT controller.[6,7,8]

One danger of using a self-tuning controller is its tendency to adapt to unfavorable process changes, like a fouling electrode. It will continue to slow down the controller to accommodate the fouling, where the preferred remedy is to clean the electrodes.

Batch pH Control

The theory behind batch end-point control is covered under Chemical Reactors: Control and Optimization, in Section 8.10. In fact, a pH loop is used there to illustrate the concept. A vessel filled with a solution is held while its pH is adjusted by adding a reagent — there is no load because there is no flow into or out of the vessel. In that section, it was demonstrated that a proportional-only or proportional-derivative controller should be used, with a fixed output bias of zero, corresponding to the zero-load condition. In this way, the valve will be closed when the pH reaches set point.

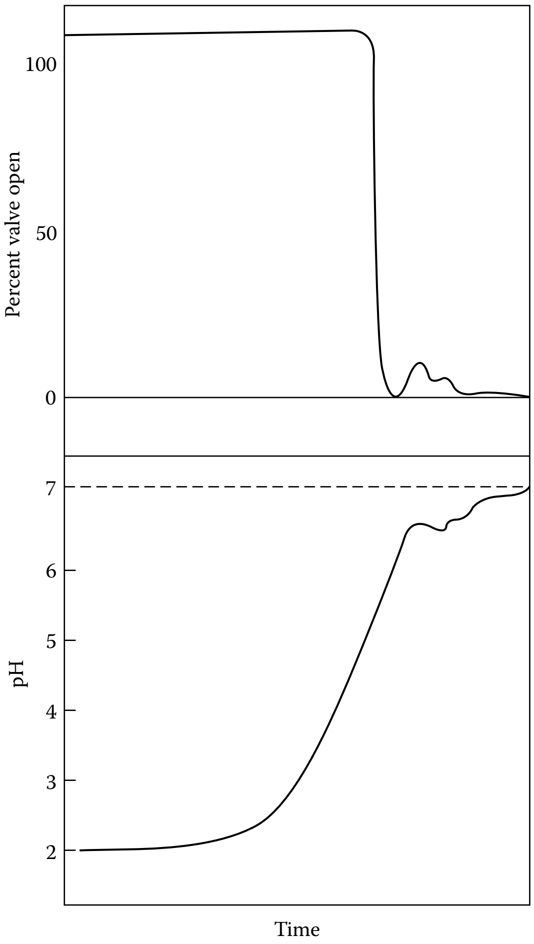

FIG. 8.32q
Measurement and valve opening behavior for a batch process.

The unique feature that a pH measurement brings to batch end-point control is the logarithmic titration curve. Compensation for this nonlinear feature is easily provided through the use of an equal-percentage reagent valve. The valve need not match the titration curve closely at all, for the only time the pH will be at the set point is at the end of the run, when the valve is closed.

So, the valve simply must deliver enough flow when wide open to give a reasonable processing time and throttle finely toward the end of the run, when the pH is on the steep portion of the curve. A record of pH and valve opening for a batch neutralization is shown in Figure 8.32q.

Observe how derivative action closes the valve before the set point is quite reached, resulting in an undershoot. This extends run time slightly, but that is preferred to using too little derivative action, which would result in a permanent overshoot.

Feedforward Control

When load disturbances are sudden and wide-ranging, feedforward control is recommended to reduce variations in the controlled variable, as described in detail in Chapter 2, Section 2.9:

Feedback and Feedforward Control. The method calculates from measurements of the load variable(s) where the manipulated variable needs to be positioned to maintain a dynamic balance in the process — in the case of pH control it is a material balance.

However, in the case of pH control the material balance must be extraordinarily precise — matches of reagent to load of 1 part in 1000 may be required. Equations have been presented at the beginning of this section to show the relationship between pH and the concentration of various agents, but they vary widely with the species and their concentrations. The problem is that all of the acids and bases must be neutralized, but that some are only partially ionized and sensed by the pH electrodes at any given pH. It is much like estimating the size of an iceberg from observing its tip, but with the relationship between the two being quite variable and even unknown.

Consider, for example, HCl in solution at pH 3.0 — its concentration would be 0.001 *N*, and it would require 0.001 *N* of caustic to neutralize it. Now look at Figure 8.32b, the titration curve for 0.01 *N* acetic acid. With no other agents in solution, its pH is about 3.5 — *higher* than that of the above HCl solution and, therefore, seemingly more neutral, yet it would take *10 times more* caustic to neutralize it.

In other words, if a feedforward signal from an influent pH measurement were to be used to estimate the flow of caustic reagent required for neutralization, the change in the influent from 0.001 *N* HCl to 0.01 *N* acetic acid would cause a miscalculation by a factor of –20!

In this light, feedforward is *not* recommended for pH control, unless there is a single species that must be treated, so that the relationship between influent pH and reagent demand is consistent. In wastewater treatment it is not. Feedforward from flow is much less of a problem — it amounts to a pH controller setting a ratio between measured inflow and manipulated reagent flow. But even this has its limitations. For example, in municipal wastewater treatment, the reagent dosage required for domestic waste is very different for stormwater. Yet in most municipalities, the two are mixed in varying proportions depending on the weather, causing the required dosage to vary widely.

8.33 Power Plant Controls: Cogeneration and Combined Cycle

J. E. JAMISON, B. G. LIPTÁK, A. ROHR (2005)

INTRODUCTION

The controls of the unit operations used in the power plants (boilers, heat recovery steam generators, compressor, turbines, combustion controls, cooling towers, and condensers) are discussed in detail in other sections of this chapter. Also, these mechanical packages, as purchased, are often already provided with their integral control systems. For these reasons, this section will give more emphasis to the description of the mechanical equipment, its features, possible combinations, operation, and start-up and shutdown procedures.

This section will describe processes that can substantially increase the efficiency of power generation. These processes include cogeneration, combined cycle generation, and the use of both techniques in combination. Cogeneration is a mode of operation when the plant produces both heat (steam or hot water) and electricity. In a combined cycle power plant, electricity is produced by two turbines, a gas and a steam turbine. The gas turbine is operated by the combustion products of the fuel (Brayton cycle), while the steam turbine (Rankine cycle) is operated by the steam generated by the heat content of the exhaust gases leaving the gas turbine.

The efficiency of a traditional power station, consisting of a fired boiler, full condensing steam turbine, and electric generator, can hardly reach 40%. The major losses occur in the steam condenser, which wastes more than 45% of the total thermal energy that is supplied to the plant. Therefore, when the total electric power generated is constant, the overall power plant efficiency can be improved by lowering the inlet steam quantity to the condenser.

COGENERATION

Cogeneration means that there are two marketable products: electricity and heat. The heat is usually in the form of steam, but sometimes as hot water. The heat is sold to process industries (paper mills, tire production plants, petrochemical plants, textile mills, desalination plants, sugar mills, and so on) or for civil applications (district heating), and thereby the latent heat of the steam is not wasted, but utilized.

In order to obtain a significant improvement in the overall plant efficiency, it is necessary that 1) The portion of the steam that can be sold is a high percentage of the steam being generated. 2) The demand for steam is continuous and steady. This means that seasonal users like sugar mills or district heating applications are not as good applications as are paper mills or tire production plants. 3) The steam user should be near the power plant (1000–5000 ft, or 300–1500 m), in order to reduce steam transportation and heat losses.

As a consequence, the large generation units normally are not suitable for cogeneration, because the exported steam would be only a small portion of the total that is generated, making the application unattractive. Also, the distance of the power station from the users would make the installation economically impractical.

In some cases, steam generation can be more critical than electricity production. This might require the installation of an auxiliary boiler to guarantee the continuous availability at least of the minimum steam supply that is required to protect against damage to the user's plant or production, or to avoid incurring expensive penalties.

The steam can be obtained from back-pressure steam turbines or from controlled/noncontrolled extraction in the IP or LP stage of the turbine, in an amount determined by the user. Some percentage (0–100% according to the application) of the steam is returned as condensate to the power plant.

The quantity of the returned condensate can impact the size of the demineralization unit and can require continuous checking of the quality of the returned condensate. If the condensate quality is unacceptable as boiler feedwater, it might be dumped to wastewater treatment or to the demineralization plant, if the pH, and/or conductivity, and/or TOC, and/or silica are beyond the acceptable limits. Before entering the thermal cycle of the boiler in the hot well of the steam turbine condenser, the returned condensate is mixed with the demineralized make-up water.

Cogeneration with Combined Cycles

Smaller combined cycle power plants (up to 60–100 MW) are particularly suitable for cogeneration, because they can be located very close to the thermal user or even within the fence of the industrial plant. Figure 8.33a is a simplified process flow diagram showing a combined cycle with cogeneration, in which some steam is sent to the associated industrial plant.

In many cases, the steam is generated at two pressure levels and the heat recovery steam generator (HRSG) is designed to serve the steam users. In some installations, if the HP or LP steam characteristics are suitable for the steam turbine, flexible operation is obtained by sending the excess steam to the turbine or by drawing steam from the turbine supply to meet the needs of the users in the plant.

Figure 8.33b shows a steam distribution control system where the steam generated by the HRSG is distributed to the steam users in the plant while sending the remaining low-pressure (LP) steam to the steam turbine. In the case when no steam is required by the steam users, PV-1 is fully open and PV-2 and PV-3 are closed.

The system status and operation is summed up in Table 8.33c. When, compared to the HRSG production, the users require only a small amount of steam, PIC-1 output is in the 50–100% range and throttles PV-1, and the PIC-2 output is in the 0–50% range and modulates PV-3 while PV-2 is closed. When the users' demand for steam rises further and, therefore, PIC-2 output rises above 50% (exceeding the steam availability from the HRSG), it throttles PV-2, while the low-signal selector PY-2 selects the under-50% output of PIC-1 to throttle PV-1 and PV-1 is closed. In this mode, the LP steam generated by the HRSG is supplemented by steam from the turbine.

The purpose of the low-signal selector PY-2 is to prevent the depressurization of the LP drum in case of high steam demand from the users. PV-2 and PV-3 operate on a split range, so that PV-2 starts opening only when the PIC-2 output has risen above 50%.

Cogeneration with Internal Combustion Engines

In case of smaller loads (e.g., hospitals or small district heating), when the required amount of heat is small and is at a low temperature, the required electric power can be generated with internal combustion engines. These engines can generate up to 1–2 MW. The heating medium is pressurized hot water that is close to its boiling point.

In this configuration, the heat is obtained by recovering it from the cooling circuit, lubricating oil, and flue gas of the engine, by means of heat exchangers.

COMBINED CYCLES

In a combined cycle power plant, electricity is produced by two turbines, a gas and a steam turbine. The gas turbine is operated by the combustion products of the fuel (Brayton cycle), while the steam turbine (Rankine cycle) is operated by the steam generated by the heat content of the exhaust gases leaving the gas turbine. The name *combined cycles* comes from the fact that the gas turbine operates according to the Brayton cycle and the steam system operates according to the Rankine cycle.

As shown in Figure 8.33d, the dual-shaft combined cycle plant consists of a gas turbine (GT) with its associated electric generator, a heat recovery steam generator (HRSG), a steam turbine (ST) with its associated condenser and electric generator, plus auxiliaries like a demineralization/polishing process, a fuel gas or fuel oil system, and a closed circuit cooling water system. The gas turbine (GT) exhausts into the heat recovery steam generator (HRSG) where the heat content of the flue gas produces steam, which is fed to the steam turbine (ST).

The combined cycles configuration is preferred for base load applications, i.e., to operate continuously at full power or very close to it, even though sometimes they can also be used to meet peak loads. When operating at base load (100% load) with no steam used for cogeneration, 3/4 of the generated electric power will be generated by the gas turbine (GT) and 1/4 by the steam turbine (ST), if aeroderivative turbines are used. When using heavy-duty turbines 2/3 of the electric power will be from the GT and 1/3 from the ST.

At partial loads on a heavy-duty GT, the ratio between the generated power from the two sources changes and can be 60% from the GT and 40% from the ST. Given a specific GT with its associated HRSG, at each load (generated MW) by the GT, there corresponds a certain (proportional) generated power by the ST, such that in steady state, the total generated power can be controlled by controlling the generated power of the GT.

During transients (either an increase or decrease of the total power), the ratio of the generated power between the GT and the ST can be different, because the GT has a much quicker dynamic response (seconds) than the HRSG and ST assembly (minutes). This fact has normally little impact on the operation of the power station, because a combined cycle is always operating in almost steady-state conditions.

If the load increase is large, it is possible that after a first step of a limited value (e.g., 5%), the rate of change in the GT needs to be limited to 2–5%/min. This is because the ST is unable to accept a sudden change in steam characteristics and quantity. The net heat rate for combined cycle units >150 MW is in the range of 5700–6800 BTU/kWh (6015–7175 kJ/kWh), while for 60 MW it is in the range of 6500–7000 BTU/kWh (6860–7385 kJ/kWh).

Single-Shaft Arrangements

In Europe it is quite popular to have a single-shaft arrangement for the rotating machinery, and this design is now also increasingly accepted in North America. This arrangement decreases the overall cost even though it decreases the flexibility of the plant. In this design, there is only one electric generator, driven by both the gas turbine and the steam turbine. This means that the electric power plant is simpler,

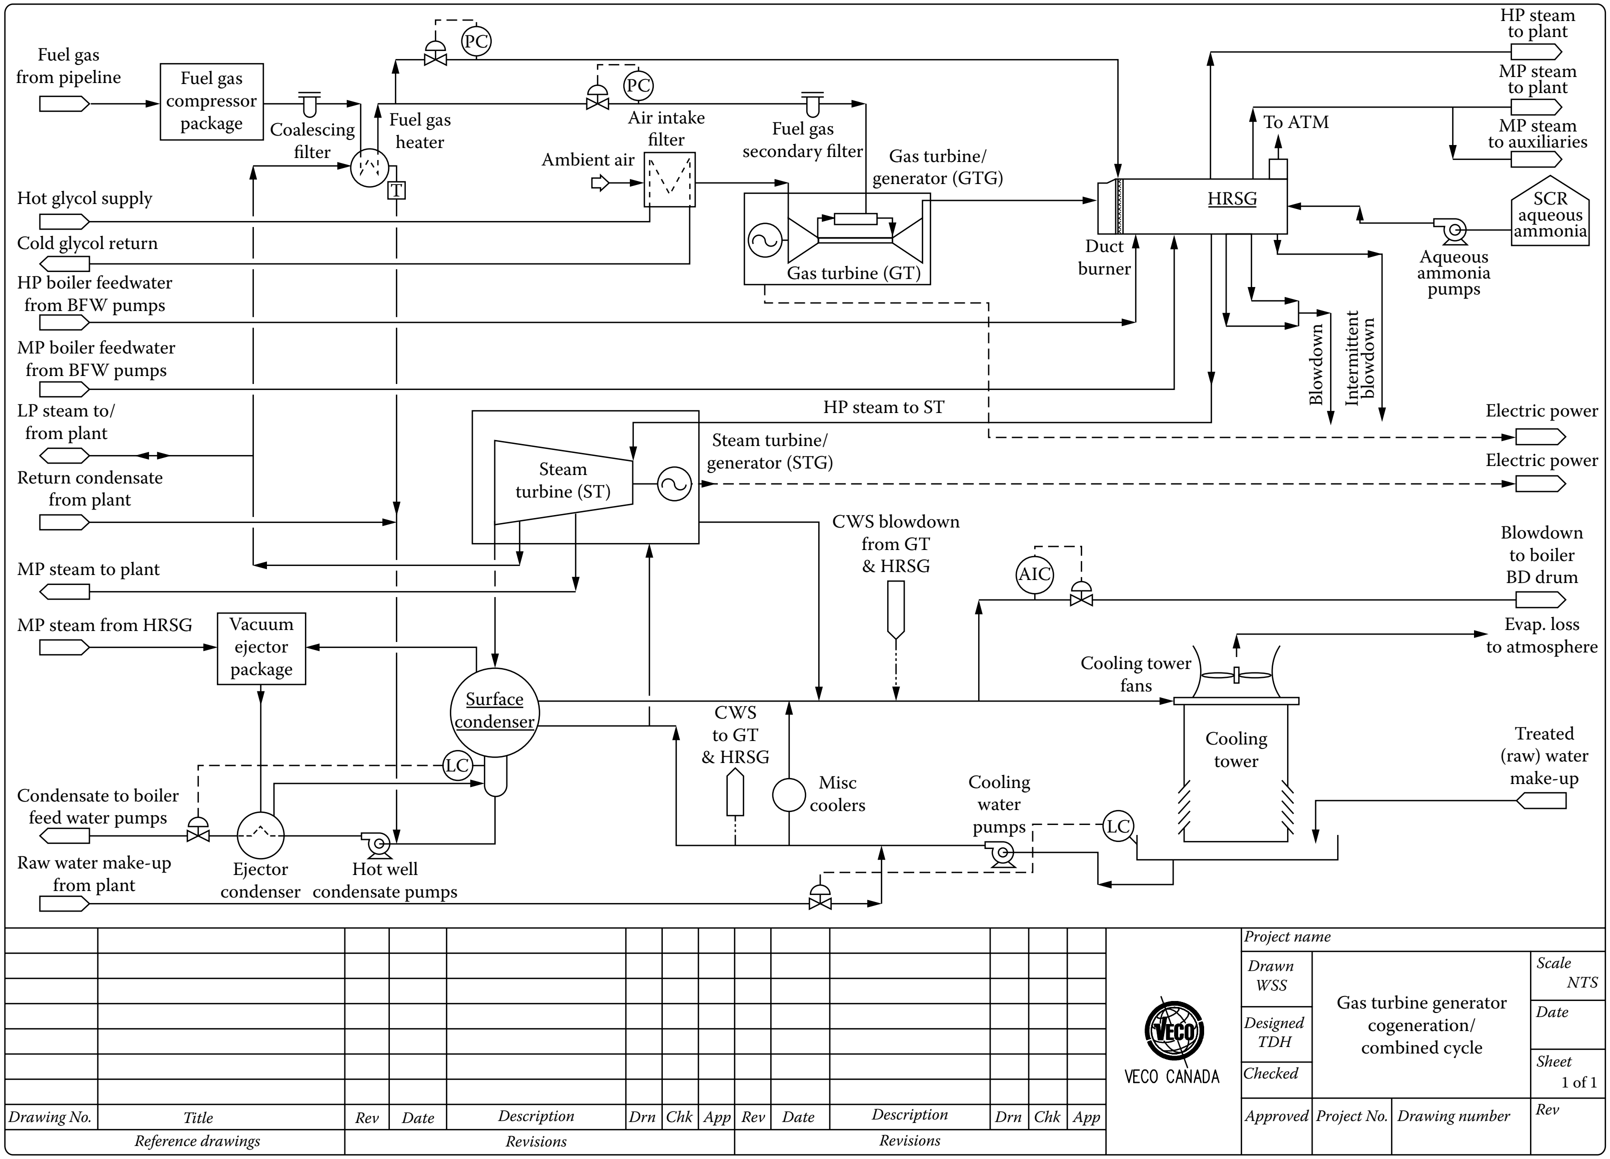

FIG. 8.33a

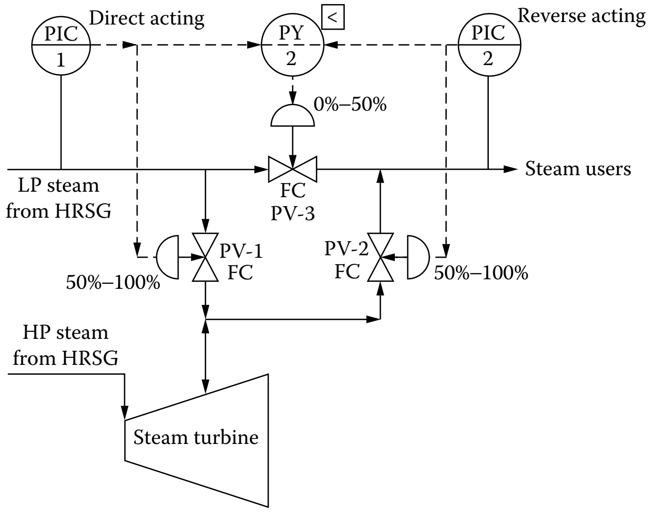

FIG. 8.33b
Control system used to distribute the steam generated by a heat recovery steam generator (HRSG) in such a way that the variable demand for steam can be met by either sending the excess to the steam turbine or by supplementing it from the steam turbine.

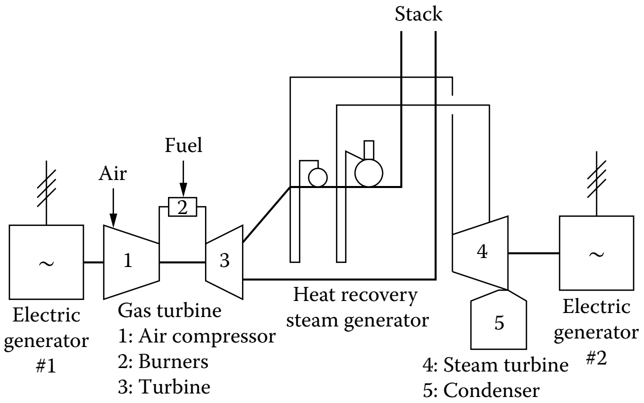

FIG. 8.33d
The main components of a dual-shaft combined cycle power plant.

because there is only one step-up transformer and one bay to connect to the grid.

There are two possible single-shaft configurations, shown in the top and bottom of Figure 8.33e: One is to locate the gas turbine and the electric generator at the two ends of the shaft (top) and the other is to locate the steam and gas turbines at the two ends of the shaft (bottom).

The configuration at the bottom requires a clutch or a special joint (e.g., SSS™) located between the generator and the ST. This is needed in order for the generator to be able to rotate during start, driven by the GT, with the ST stopped until the steam conditions are suitable for starting the ST with its own start-up procedure. If this joint is not used, an auxiliary boiler is needed or steam is derived from other HRSGs to supply steam to the seal glands and to the vacuum ejectors of the condenser, and at least a small amount to the ST.

The configuration on the top of Figure 8.33e always requires auxiliary steam for the vacuum system and for seal glands or from an auxiliary boiler or from other boilers available in the plant.

Alternative Configurations Sometimes, when an even number of GTs is used, it is possible to have two GTs/HRSGs

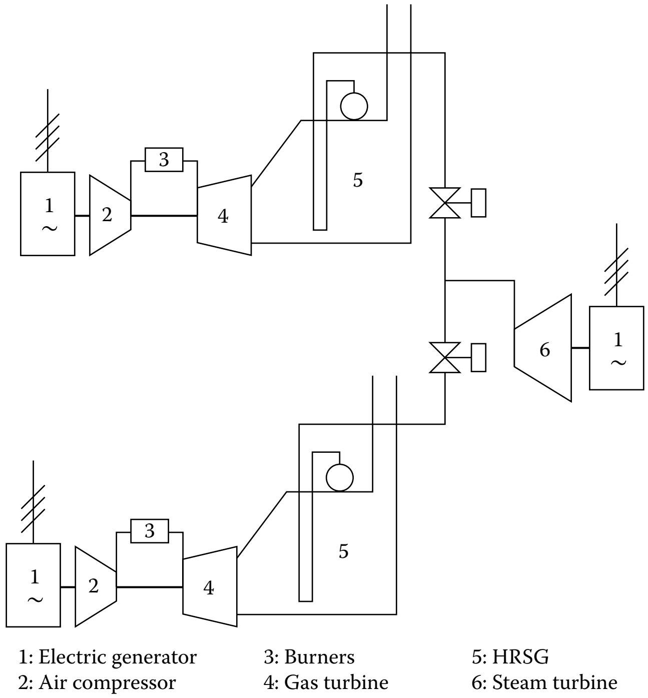

FIG. 8.33f
Power plant equipment configured in a 2 + 1 arrangement where two gas turbines and their two associated HRSGs are sending steam to the same steam turbine.

feeding only one ST. This configuration is known as 2 + 1. As a consequence, the electric generator/step-up transformer driven by the ST is roughly of the same power as the ones driven by the GT (Figure 8.33f). This simplification reduces the investment costs and reduces the electrical installation with the additional benefit of having similar electrical components. However, it is not rare that generators from different manufacturers are used because the GT supplier and the ST supplier could be different.

When aeroderivative GTs are used, sometimes a 3 +1 (i.e., three GT and one ST) configuration is used, with four identical generators. When only a GT is running, for instance during start up, the active HRSG is operating in a sliding pressure mode and the steam is delivered to the ST at about 65% of the normal pressure, with a minimum value of 50%. Sometimes, during the updating and modernization of existing power plants, the existing steam turbines can be reused. This involves a customized reconfiguration of the equipment in the plant as it is converted to operate in a combined cycle.

Main Equipment Blocks

Gas Turbine System The GT system consists of three main parts: the air compressor (axial type), the burners, and the turbine itself. The mechanical power generated by the turbine is partly (about 50%) used to drive the air compressor, so that the net generated power is the difference between the full-generated power and the power required by the air compressor.

The turbine types can either be "heavy duty" or "aeroderivative."

The heavy-duty design is of sturdy construction with the compressor running at the same speed as the turbine. The "aeroderivative" design is based on the design of aeronautical engines that have been modified for ground operation at continuous full load with no axial thrust. The turbine can be split into two parts, one rotating at the rated speed, and the other running at higher speed and driving the air compressor.

In general, these turbines are more delicate and more sensitive to changes in the fuel gas composition and to dirt deposited on the air compressor's blades, with subsequent decreases in the efficiency and in the generated power. The upper power for aeroderivative turbines is in the range of 40 MW at the shaft, but is expected to rise in the near future.

Gas Turbine Characteristics The characteristics of gas turbines are given at ISO conditions, which assumes no losses (i.e., no pressure drop in the inlet and outlet ducts), 59°F (15°C), 14.696 psia (101.325 kPa), 60% relative humidity. It is to be noted that the power generated by the turbine is highly dependent on air temperature. Starting from ISO conditions, roughly an increase of 35°F (20°C) of the inlet air temperature decreases the generated power by 10–13% and the efficiency by 3–5%, while a decrease of the air temperature of 20°F (11°C) increases the generated power by 6%.

In some instances, mainly for aeroderivative turbines, when the ambient temperature is high, the inlet air can be chilled before entering the air compressor to increase the throughput and efficiency. For heavy-duty GTs, the same effect can be obtained with so-called fog systems or wet compression.

The current generation of GTs has an efficiency of 33–38%, referred to as the low heating value of the fuel, when running in open cycle (i.e., exhausting to the atmosphere), thus approaching the overall efficiency of a traditional power station. The heat rate for heavy-duty turbines in sizes > 100 MW is in the range of 9,000–10,000 BTU/kWh (9,500–10,550 kJ/kWh), while for sizes of about 25 MW the heat rate is about 10,000–12,000 BTU/kWh (10,550–12,650 kJ/kWh). For aeroderivative turbines in sizes of about 40 MW, it is in the range of 8,200 BTUtu/kWh (8,650 kJ/kWh).

The GT is supplied as a package in which practically no custom tailoring is possible in the mechanical part because of the high development costs for the optimization of the blades and rotating speed(s) of the air compressor. The custom tailoring is limited to the extent of the supply for the auxiliaries, to the starting method, to the back-up fuel (if requested and feasible), to the voltages for the generator and auxiliary motors, to the cooling of the generator, to the available options for the governor, and so on. The turbine is optimized for operation at a power close to the base load (100% load) and has a turndown of approximately 100:55.

Temperature and Fuel Considerations The temperature in the combustion zone can be quite high [2280°F (1250°C) and even up to 2460°F (1350°C)] and is expected to increase even more with new developments in this technology (mainly due to the cooling of blades). This high temperature results in the nitrogen in the air combining with oxygen, with consequent production of NO_x concentrations that are well beyond the limits stated by almost all local regulations.

Additional nitrogen could be present in the fuel if it is obtained from coal gasification or from tail gas in some process industries. Hence, the need for NO_x abatement, which can be obtained in a wet process (by injecting steam or water into the combustion chamber) or by a dry method, with different flame configurations as a function of load. Nowadays, the latter solution is the preferred one even though it may involve flame instability at certain loads.

A dry method of NO_x reduction anticipates combustion with different flame shapes according to the load. Therefore, the flame shapes from the operating gas nozzles in a certain burner are different depending on the load. Changing from one shape to another involves flame instability, and therefore the loads corresponding to the change of flame shape should be avoided to prevent possible flame outage.

To limit the temperature in the combustion zone, a high excess air ratio is used, so that the oxygen content in the exhaust gas can reach 15%.

The preferred fuel is natural gas, but several types of turbines can accept either gas or liquid. For the dual-fuel-type designs, diesel oil is normally used as the back-up fuel. Some turbines can accept heavy oil as fuel, but the resulting emissions could exceed the limits stated in many states/countries. When liquid and gaseous fuels are used, the gas turbine should be equipped with a dual-fuel system, which is also needed when only gases are burnt, but these gases are characterized by much different "Wobbe Indexes."[1]

Operation The air compressors are very sensitive to pollution, particularly the aeroderivative machines. Thus, large intake filters are necessary. These filters should minimize the pressure loss and should be complete with cleaning systems and antifreeze protection. Depending on the type of turbine and air pollution, the air compressors need to be washed on-line every 8–48 hours, and washed off-line roughly every 1–3 months, when the power plant is out of service (Figure 8.33g). It is a desirable practice to perform the off-line compressor wash every time a long stop is required in order to improve the efficiency. The count down to the next washing is restarted after each wash-down.

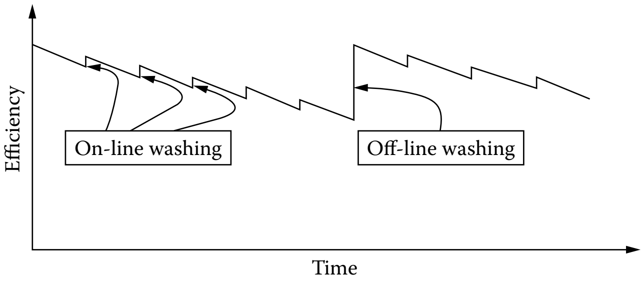

FIG. 8.33g
The gas turbine efficiency is slightly improved after each on-line wash, but periodic on-line wash is needed to return to full efficiency.

The GT is unable to start by itself and requires a launching motor, which can be electric or diesel, or use the electric generator as a motor, fed from the grid via a variable-frequency inverter, also called a static frequency converter (SFC). The starting system is selected according to the availability of the grid. If black starting (i.e., power is not available from the grid) is required, then a diesel engine or a diesel generator feeding an electric motor should be used.

When the GT runs at rated speed and without meeting any load, it is said to be at Full Speed No Load (FSNL). For many GTs this is a stable operating condition, at which the generated power is nil but the exhaust flow and temperature are still relatively high as compared with base-load conditions. For large turbines, the FSNL exhaust mass flow is in the range of 70% of the maximum flow at ISO conditions, and the temperature is roughly 50%, even though the available temperature drop in the HRSG is about 25% due to the increase of the temperature at the stack.

Some new turbines feature at FSNL an exhaust flow of approximately 60% of the nominal and a temperature about 65% of the nominal. The enthalpy per mass unit of flue gas at FSNL is greater than 45% of the one at base load, so that the total enthalpy transferred from the GT to the HRSG at FSNL exceeds 30% of base load and impacts on the start-up procedure of the HRSG. The FSNL-generated HP steam flow is in the range of 20% at a pressure in the range of 20–30%, a temperature (°F) of about 50%, with the superheating temperature in the range of 30%. With the new GTs the SH steam flow is roughly 30% at a temperature of 70% approximately. The fuel gas consumption at FSNL is about 25% of the consumption at base load.

Pollution and Safety At FSNL, the NO_x and CO contents can be beyond the limits accepted by the regulations, so that the FSNL condition can be accepted only as a transient to warm-up of the HRSG and the ST. When a turbine cannot run at FSNL, but needs to feed some load (about 20%), this situation is called minimum technical load. Similarly, at these conditions the emission limits could not be met.

A minimum environmental technical load (about 50–60%, depending on the GT and the local regulations) can be defined as well, where the GT emissions are in line with the regulations

---

[1] Wobbe index W is the ratio between the heating value H_s in standard volumetric units and the square root of the specific gravity G.

$$W = H_S/\sqrt{G} \qquad \textbf{8.33(1)}$$

or can be brought in line by means of selective catalytic reduction (SCR) in the HRSG, if present.

The GT is supplied with its own governor that takes care of all safety and control functions including antisurge control of the compressor, inlet guide vanes (IGVs) control, burner control, start-up and shutdown sequences, and excessive vibrations. For an I&C engineer, the GT is almost a black box interfaced with the overall plant DCS via a serial link (simple or redundant) and relatively few directly hardwired commands.

In several instances the old turbine governors had a standard set of information transmitted over the serial link, and only few could be custom-tailored. Out of the standard set of information, a certain amount was not needed for the specific plant and, therefore, was discarded in the GT governor or in the DCS.

All safety functions of the GT are performed by the turbine governor that normally has a 2oo3 (two out of three) or a 1oo2D (one out of two diagnostics) configuration, which are usually independent from the control functions. The control functions are performed in simple, redundant, or 2oo3 configurations that ensure the degree of safety and availability requirement, which should be consistent with the size and criticality of the plant. The safety functions are also performed in the control processors and are used as back-up for the safety functions performed by the dedicated processors.

The governors are provided with their own operator interface and with processors that store information on the behavior of the turbine, including the sequence of events leading to a shutdown. The governor includes comprehensive self-diagnostics that allow easy maintenance while the GT is running, while still keeping all of the protections active.

The GT runs in temperature control mode when it is at base load. When it is ramping up, it is in speed control, with the temperature of the first row of blades constraint limiting on the generated power.

The GT is normally enclosed in an acoustic cabinet, complete with ventilation, fire- and gas- detecting, and fire-fighting systems.

Steam Injection Gas Turbine (STIG™) When the power generated by the gas turbine (GT) is low (< 15 MW), the combined cycle configuration discussed earlier would be uneconomical. For such applications, small GTs have been developed that can accept the partial or total injection of the steam that is generated in the associated HRSG upstream from the turbine blades of the GT. This results in increasing the mass of the flue gas in the turbine and the generated power, without the need of a small steam turbine.

Part of the steam is injected in the burner chamber for NO_x abatement in a wet mode on a preferential basis. This type of turbine is suitable for small cogeneration plants requiring a variable quantity of steam, while the surplus is sent to the GT. The sizing of the demineralization plant should consider the large amount of demiwater wasted to the atmosphere.

Heat Recovery Steam Generator The HRSG receives the exhaust gases from the GT discharge. The exhaust gas, flowing in counterflow with respect to the steam/water coils, cools down by transferring heat to steam/water. The flue gas temperature at the stack is about 230°F (110°C), even though lower temperatures [200°F (93°C)] can be used if the fuel gas is very clean and sulfur-free. The HRSG is, therefore, similar to a heat exchanger in which the shell side carries the flue gas and the various sections of the tube side carry steam or water.

It has also the characteristics of a boiler because there are one or more steam drums, where the generated steam is separated from boiling water before entering the superheaters. The HRSG can be horizontal or vertical, according to the direction of flue gas path.

The horizontal ones have a horizontal path for the flue gas flow, and the steam/water tubes are vertical, normally with natural circulation in the evaporator(s). The vertical ones have a vertical path for the flue gas flow, and the steam/water tubes are horizontal, thus requiring assisted circulation in the evaporators, at least during the start-up period. The horizontal HRSGs are the most common, with the vertical ones mainly being limited to the revamping of existing boilers or to installations where space is very tight.

Pressure and Temperature Levels The HRSG can have one, two, or three pressure levels according to the size of the plant. For plant sizes of 200–400 MW per line, the pressure levels used are HP, IP, and LP (high pressure, intermediate or medium pressure, and low pressure). Plants down to 30–60 MW usually have two pressure levels (HP and LP), and smaller units only have one pressure level. Sometimes, with three pressure levels, the LP section produces the steam needed for deaeration only.

The following tube banks are used for each pressure level (starting from the GT discharge): 1) steam superheaters, 2) evaporator, and 3) economizer. When more pressure levels are used, the banks of the various levels can be intermingled as to maximize the heat exchange efficiency, taking into consideration the differential temperature between the flue gas at that point and the steam/water in the tubes. In large boilers, the two HP superheaters that are in series can be split in two to four parallel banks. In the large HRSGs the reheating coil for the IP steam can be derived from the steam turbine and mixed with the IP steam, which is generated in the HRSG.

The differential temperature between the exhaust from the GT and the HP superheated steam is called the "approach" temperature, and it is in the range of 50°F (30°C). The differential temperature between the flue gas at the outlet of the evaporator section (inlet for water) and the saturated steam temperature is called the "pinch point" and is approximately 15°F (8°C).

Starting from the turbine discharge, the HRSG casing is mechanically made of a diverging cone to reduce the velocity of the exhaust gases, plus a rectangular section (internally

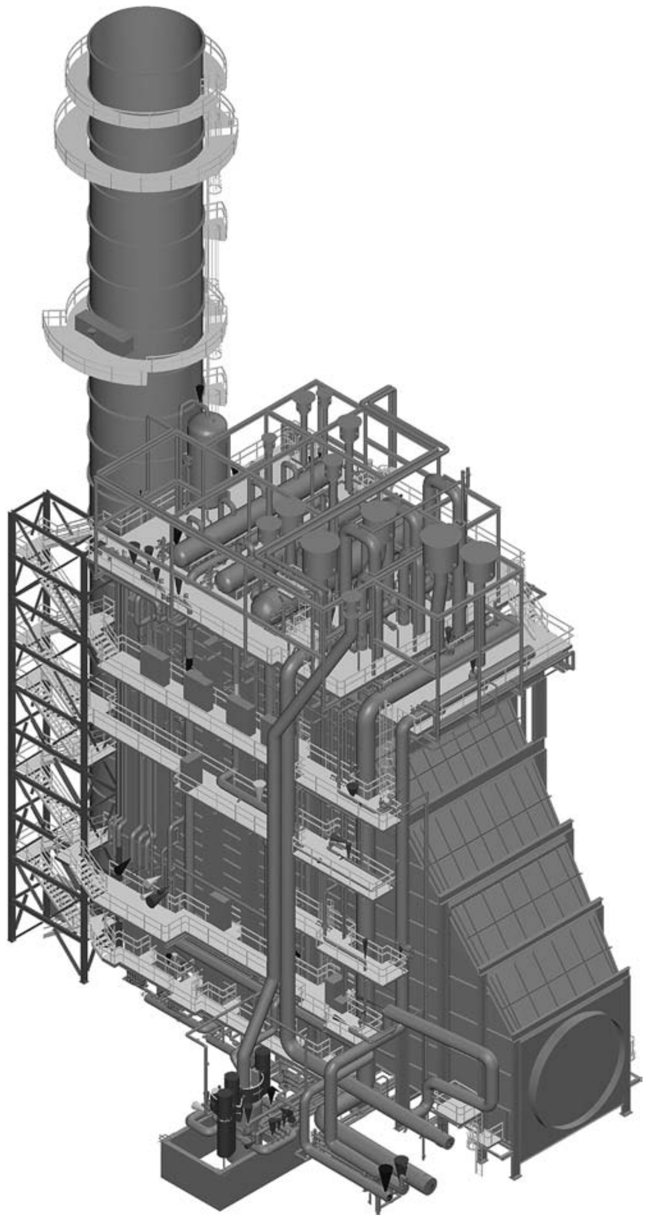

FIG. 8.33h

insulated and lined) housing the steam/water coils and the stack. Figure 8.33h shows a horizontal HRSG, with three pressure levels and integral deaerator.

Design Features In more recent times it has become a requirement to insert an empty module in the flue gas ducts of large HRSGs, which serves the possible future installation of a selective catalytic reduction unit for further NO_x abatement.

This empty module is installed in the expectation that in the future more stringent regulations will come into force. This empty module is positioned where the flue gas temperature is about 660–715°F (350–380°C).

Sometimes, a spool piece for future addition of an oxidation catalyst for CO abatement is included for the same purpose as the SCR and located in the same position. Nowadays in North America, almost all HRSGs are fitted with SCRs and occasionally with CO catalyst, while in Europe only provisions for SCRs are required.

In addition, many installations include a silencer in the stack or at least a dummy piece for the future installation of one. If the plant is to be operated in an intermittent mode (e.g., shut down overnight), a damper in the stack is required to protect against excessive cooling of the unit. The damper should be designed to fail open on high flue gas pressure, which failure position is normally obtained by counterweights, or with offset blades so the damper will open without the use of the actuator. Sometimes, actuators are included in order to have the maximum flexibility.

The pressure drop across the HRSG on the flue gas path is in the range of 8–15 in. (200–375 mm) water column. This pressure drop is the back-pressure of the GT and influences its generated power and efficiency by 1 and 2%, respectively.

The water/steam coils are helically finned on the outside to improve their heat exchange efficiency. In some cases, the HP superheater tubes can be nonfinned. Their construction material is carbon or alloy steel, as a function of the pressure/temperature rating required. The coldest coil (LP economizer or feedheater) can be stainless steel to protect it against corrosion on the inside, which might occur if the feedwater is not deaerated. If stainless steel is used, it will also protect against corrosion, which can be caused by acid condensation from the flue gas on the outside.

In some instances, for small plants where the GT exhaust temperature is relatively low, the HRSG can be designed to run dry (i.e., without damage if the water supply fails) in order to comply with some national regulations for unattended boilers.

The HRSGs are provided with a set of motor-operated valves that are installed in the steam and water lines. Each superheated steam line leaving the HRSG is provided with a shut-off valve and, in some cases, also an on/off bypass valve (mainly on HP) to intercept the steam to the user (turbine or industrial load).

The feedwater inlet lines to the economizers are also provided with on/off shut-off valves. Having these shut-off valves allows the “bottling in” of the HRSG by closing all inlet and outlet lines, thereby to keep the boiler pressurized when the shut-down period is expected to be short. Additional motor-operated valves are used to remotely and automatically operate the drains in the superheaters.

The HRSG also includes a pressurized blow-down tank and an atmospheric blow-off tank, and is also equipped with chemical injection pumps to keep the water and steam characteristics within the correct parameters required to maximize the life of the ST and the boiler itself. The HRSG is also equipped with nitrogen connections for purging (dry lay-up) to prevent corrosion in case of long shut-down periods.

Alternative Steam Generator Designs Other steam generator possibilities include an HRSG with the HP section only and a high rate of post-firing. In this case, the water/steam cycle is very similar to that of the standard fired boilers and utilizes water heaters to improve the overall efficiency. In such boilers, at some loads the efficiency can be higher than using a conventional HRSG.

Another possibility is the once-through steam generator OTSG), which is used mainly in combination with GTs in the capacity range of 40–50MW, although larger units are under development. These boilers, built with Incoloy 800 and 825 tube materials, operate without steam drums or blowdown systems and thus require a simplified control strategy.

Their flue gas flow is vertical upwards and the tubes are horizontal, thus allowing for a reduced footprint. These boilers feature the possibility of running dry (if required) and have very short start-up periods due to the thin wall of the tubes and to the missing steam drums. They are delivered in a few prefabricated pieces so that the field erection and installation takes place in a short period of time.

Steam Turbine Steam turbine controls are discussed in Section 8.38. The largest steam turbines today that can be fed by a single gas turbine/HRSG are in the range of 150 MW. Therefore, these steam turbines are still are relatively small for power generation. Only when one ST is fed by two HRSGs (in a 2 + 1 configuration[2]) can the steam turbine's rated power reach 250–300 MW.

The steam turbine is fed with HP superheated steam and is designed to also accept IP and LP steam from the HRSG and also to extract full steam flow at IP level in case of reheating. In addition, if the plant is cogenerative, suitable (controlled or noncontrolled) extractions shall be planned for. For example, if there is a requirement to feed thermal users with steam, it is possible to get this steam through one or more extractions (at the required pressures) from the steam turbine.

In many instances, the LP steam as generated in the LP steam drum has the correct pressure, but not in the required quantity. Therefore, there is a need to send steam from the LP section of the HRSG to the ST, or directly to the users, or to extract steam from the ST to comply with the demands of the users.

The vacuum condenser can be water- or air-cooled. The present trend is in favor of air-cooled condensers, particularly if the water availability is limited. The use of air-cooled vacuum condensers reduces the size of the cooling water towers required for the plant (still needed for cooling the rotating machinery) if closed circuit cooling is selected. This approach also eliminates the need for large flows of cooling water and the thermal pollution of rivers, lakes, or the sea, if open circuit cooling is used. The air-cooled condensers slightly decrease the efficiency of the steam turbine, mainly in hot climates.

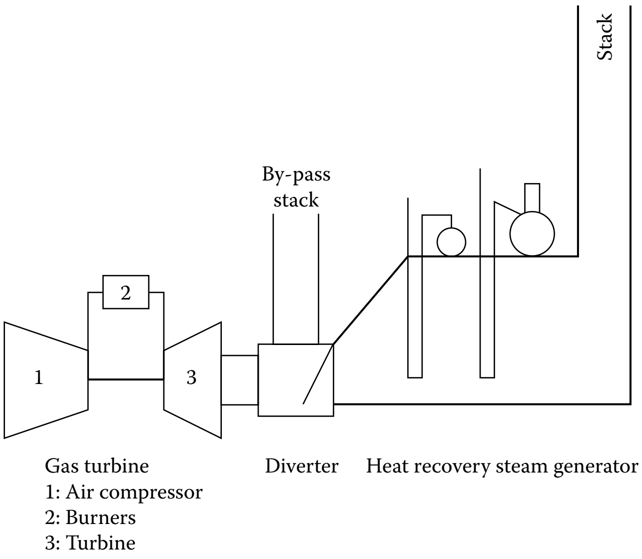

FIG. 8.33i
Diverter provides the flexibility to send the gas turbine exhaust gases to the HRSG or to the atmosphere.

When the plant is located in built-up areas, there might also be an atmospheric condenser that receives the steam that is vented during the start-up to decrease the noise level at the plant. The auxiliary circuits of the steam turbine are the lube oil, control fluid, and vacuum system for the condenser. The vacuum system can be equipped with steam ejectors or with liquid ring pumps (vacuum pumps), or a combination.

Bypass Stack and Diverter In some instances, when the electric power generation is a must, it should be possible to run the gas turbine in open cycle and exhaust the flue gas to the atmosphere instead of sending it to the HRSG, regardless of the overall efficiency (Figure 8.33i). This requires a bypass stack and a diverter that closes the path to the HRSG and opens it to the atmosphere through the bypass stack. The diverter is connected to the GT exhaust duct before the diverting cone of the HRSG, and this implies that the GT has to meet the plant emissions limits, as any SCR in the HRSG is also bypassed.

Throttling by the diverter could also be used to control steam generation in the HRSG. This configuration is rare and limited to STIG applications or to applications in which the steam is generated only for process use and the demand for it is low compared to the amount that could be generated, based on the prevailing demand for electricity (e.g., some desalination plants in the Gulf area).

The most important characteristic of a well-designed diverter is its ability to completely switch the flue gas from the bypass stack to HRSG, under all operating conditions. This requires a good seal, so that the GT exhausts fully to the HRSG without loss of efficiency due to leaking hot flue

---

[2] 2 +1 configuration means two GTs/HRSGs feed only one ST. For more details, see later under the heading "Alternative Configurations."

gas. For this purpose, seal fans are provided that blow air into the gap between the diverter blade and the wall.

Post-Firing (Supplementary Firing) In some cases, it is wise to boost the steam production by supplementary firing in the flue gas duct, at least on a temporary basis. This is possible because of the high oxygen content in the exhaust gas from the GT. The burners are normally in-duct burners located at the end of the diverging cone, upstream of the final HP superheater or between the final HP superheater and the IP reheater. They are fed preferably with natural gas in order to keep the emissions within the regulatory limits and to prevent fouling of the finned tubes.

They require pilot burners and ignitors and a burner management system (BMS). The thermal power delivered by the burners is normally capable of increasing the generated steam in the range of 10–30% so that the overall electric power generated by the GT/ST increases roughly by 5–10%. Post-firing decreases the overall efficiency of the plant but allows it to cover peak demand. It can also be advantageous when electricity can be sold at different prices as a function of the time of the day.

Supplementary firing is inhibited when the GT load is lower than a preset value, ranging between 50 and 80%. The latter value is typical for aeroderivative GTs. These limitations are due to several factors like exhaust flow distribution (not always available at reduced load), flame shape that is longer at reduced flows, and low exhaust temperature inducing increased firing to compensate for reduced energy in the GT exhaust. Allowing the post-firing to be active at lower GT loads could cause excessive temperatures that could damage the HRSG.

Fresh Air Firing (Complementary Firing) When a combined cycle is used for cogeneration, the availability of the steam supply can be very critical for the process and it can be requested that the steam be not used for any other purpose. This requirement can be met by using an auxiliary boiler as a back-up or by fresh air firing in the HRSG.

Fresh air firing requires a diverter to close the outlet duct from the GT, a fresh air fan, and in-duct burners in the diverging cone upstream of the final superheater. All of these system components should be sized to meet at least the minimum contractually guaranteed steam quantity and deliver it for industrial use, while still keeping a good distribution of gases in the flue gas path (Figure 8.33j). The flue gas quantity cannot be decreased too much with respect to the normal flow without impairing the heat transfer. The airflow is normally at least 70% of the flue gas flow at base load.

In this configuration, the HRSG behaves as a fired boiler even though the efficiency is much lower due to high excess air heat losses and a poor thermal cycle. The superheat temperature of the generated steam is usually not suitable for steam turbine supply and, therefore, has to be wasted to avoid damages.

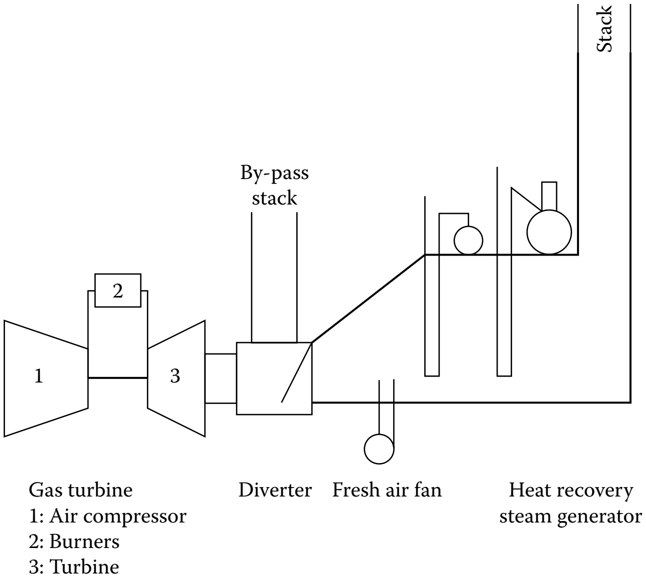

FIG. 8.33j
Equipment configuration when a fresh air fan is added to the combined cycle for complementary firing.

To reduce the pollutant emissions to the allowed limits, it is required to use flue gas recirculation (FGR).

Electric Generator The electric generator is a three-phase unit and can be air- or hydrogen-cooled. The excitation system is static and the voltage/cosφ control is obtained via the automatic voltage regulator (AVR) that is hardwired to the DCS or can be serially linked to the DCS, which is a less frequently used arrangement.

In large groups, at start-up the generator is fed with variable frequency and acts as the launching motor.

The lubricating system is normally common with the driver's system.

Auxiliary Systems

Steam and Water Cycle The steam and water cycle is dependent on the number of pressure levels of the HRSG. If the deaerator is integral with the LP steam drum, the LP drum has also the function of being the suction drum for the boiler feedwater (BFW) pumps that are working on a duty/standby basis. If there are HP and IP sections, the BFW pumps can be multiple-stage centrifugal pumps with an intermediate discharge for the IP section. Otherwise, the pumps have only a discharge nozzle for the HP section.

If required by the pump characteristics (and normally it is), an automatic minimum flow bypass should be installed on the HP discharge nozzle of the pump. It is preferable to use a four-way valve with the manual port used during pre-commissioning and commissioning to extend the life of the automatic port. Alternately, a flow control loop could be

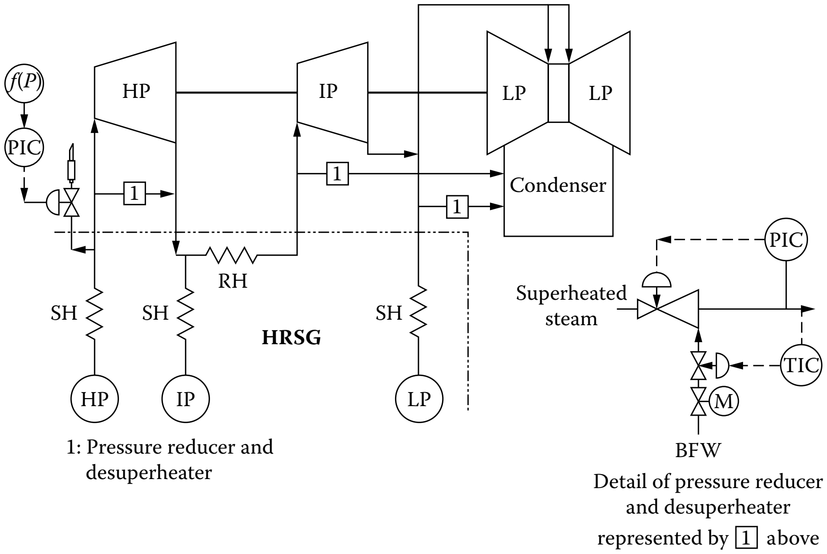

FIG. 8.33k
When high, intermediate, and low pressure (HP, IP, LP) steam turbines and plant users are combined with reheat and superheat (RH, SH) coils, bypasses containing pressure reducers and desuperheaters (1) need to be provided for start-up.

provided to maintain the water flow rate through the pump at a value that is above a preset minimum value and returning the unwanted flow to the suction drum (could also be the LP drum, in the case of an integral deaerator).

The superheated steam is conveyed to the steam turbine that should be bypassed during the start-up phase or in case of turbine shutdown or load rejection. A typical bypass arrangement is shown in Figure 8.33k.

The bypass arrangement includes 1) An HP bypass from HP header to IP header (cold reheat side if reheating is implemented) or LP header or condenser if only two pressure levels are required. 2) IP bypass from IP header (hot reheat side if reheating is implemented) to the condenser or to LP header (less frequently used arrangement). 3) LP by-pass from LP header to the condenser.

Each bypass requires a pressure reduction and desuperheating stage with boiler feedwater or condensate supplies at appropriate pressures so that the physical conditions of the reduced steam are fully compatible with the conditions of the downstream header.

In case of a 2 + 1 configuration, each HRSG has its own turbine bypass system installed upstream of the steam stop valves, so that the starting of the boilers can take place independently. Once the boilers are both on-line and paralleled on the steam header, these bypass valves are operated simultaneously, controlled by the steam header pressure and triggered by the steam turbine trip or load rejection.

An important decision to be made at an early stage of the design that affects the start-up procedure of the plant is how the steam lines are to be heated. It makes a difference if the HRSG starts with the steam stop valves closed or with the steam stop valves fully open and the steam intercepted by the ST admission valves. The latter configuration is preferred when long steam lines are used (e.g., in revamping old conventional power stations).

To keep the required steam purity, a small percentage (1–3%) of the water in the steam drums should be discharged to continuous blow-down and to discontinuous blow-off (as covered in more detail in Section 8.6 on boiler control). For large boilers there is a pressure blow-down tank into which the HP and IP steam drums drain. In addition an atmospheric blow-off tank is also provided to receive the water from the blow-down tank plus the drains from the LP drum and the blow-off from the HP and IP drums.

Small boilers only use one atmospheric tank. The water is cooled to an admissible temperature before dumping it to water treatment or collecting and sending it to the demineralization unit to minimize the quantity of the effluents.

AUXILIARY EQUIPMENT

Demineralization Plant

The water needed for filling the HRSG and as make-up water during normal operation is generated in a demineralization plant. The demineralization plant is usually controlled by its own PLC, which is serially interfaced with a redundant link to the DCS, but sometimes is controlled directly by the plant DCS system.

The demineralized water is stored in a tank that should be sized sufficiently large to provide water in case of disruption in the production. It should also store enough water to supply the quantity needed for pipe blowing in the precommissioning stage, without the need for waiting for the production of new water. This consideration can be the basis for sizing the demineralized water storage tank.

Fuel Gas System

The GT is best utilized when fuel gas, normally natural gas, is burned, because this is the cleanest available commercial fossil fuel and the one releasing the least amount of CO_2. Sometimes, natural gas is distributed at a pressure below that required by the GT, which normally requires 300–650 psig [20–45 bar(g)], as a function of its model.

If the available supply pressure is low, the addition of a compression station is required, which is normally composed of two reciprocating compressors or one centrifugal compressor. If two reciprocating compressors are used, one spares the other. They are followed by a multipurpose knock-out drum, serving the purposes of 1) pulsation damping, 2) residual liquid separation, and 3) surge tank duty to allow for switching the compressors without disrupting the gas supply to the GT.

In the case where the pressure of the natural gas is higher than required, it is necessary to provide a reducing station, which can require preheating with hot water or steam to prevent freezing caused by adiabatic expansion and to keep the gas above the dew point temperature. In this case electric heating or auxiliary hot water generators (boilers) could be required at least for the start-up phase, while during normal operation the heat from the HRSG is used.

The temperature decrease caused by the pressure reduction can be derived from pressure-enthalpy diagrams (see Reference 1 for pure methane). For this reason, the characteristic of the natural gas that is distributed in the grid is very similar to that of methane. As an example, a pressure reduction from 1000 psia (69 bara) at 60°F (16°C) to 435 psia (30 bara) would decrease the temperature to 30°F (–1°C). To obtain a gas at 435 psia (30 bara) and 95°F (35°C), the gas should be preheated to 122°F (50°C), with a heat delivery of 41 BTU/lb (95 kJ/kg) of gas.

The GT requires a very clean fuel gas, thus the gas at proper pressure needs to be further filtered in a location close to the GT. The line could be stainless steel downstream of the filters, to prevent any entrained rust from entering the GT. For safety reasons, servo-actuated double block and bleed valves should be installed upstream of the filters, and they should be independent from the valving supplied with the GT. In addition, the block valves should be fire-resistant.

A point to be checked with the GT manufacturer is the temperature at which the gas is delivered to the turbine. Some gas turbine manufacturers constrain the admissible temperature during the various stages of operations, with special regard to the start-up and shutdown conditions. Fuel gas heaters are usually fitted to the GTs in order to improve the efficiency of the GT cycle. Typically, the gas can be heated up to 365°F (185°C). The heating medium is hot water that is usually received from the IP economizer section of the HRSG, but sometimes from the condensate preheater.

In any case, it is essential that the water pressure be higher than the fuel gas pressure so any leakage that occurs will be water into gas and not vice versa. Some turbines are also very demanding in terms of the steadiness of the controlled gas pressure and its admissible rate of change (pulsation). These constraints impact on the gas system design and relevant instrumentation.

Liquid Fuel System

Some GTs can burn liquid fuel, even though this practice is decreasing because of emission constraints. However, in some countries this is still done. The use of liquid fuel requires careful discussion and agreement with the GT manufacturer on the features and characteristics of the fuel used. Some common requirements include 1) water shall be drained and shall not be fed to the turbine, 2) sediments shall not be pumped to the turbine, 3) the fuel shall be filtered to remove all particles that could clog the fuel injectors, and 4) the storage tank and lines shall be heated if the fuel is too viscous.

Also in the case of liquid fuels, the target is to obtain the cleanest possible fuel to extend the life of the turbine and to obtain a smooth operation. In particular, sodium, lithium, and vanadium should be eliminated, because they are highly corrosive to the GT blades at the combustion temperatures.

Closed Circuit Cooling Water

Water-cooled condensers, users like lube oil, control fluid, and bearings, all require cooling water. The cooling water can be supplied in two closed circuits, both being fed by the cooling tower. One circuit is for the water-cooled condensers and the other for all process coolers and other users (rotating machinery).

The cooling towers can be of modular design, equipped with double-speed air fans (see Sections 8.16 and 8.17). The water-cooled condenser can be cooled by river (seldom sea) water, which requires proper intake works and adequate design to prevent local overheating of the river (or sea). With a cooling water temperature rise of 18°F (10°C) in the condenser, the flow of cooling water is about 55 times the flow of the exhaust steam to be condensed.

If an air condenser is used, the closed-circuit cooling water system becomes much smaller, because the amount of water needed in the rest of the plant is a relatively small percentage of that needed for the water condenser. The air condenser is usually equipped with 2–20 double-speed fans, as a function of the steam flow that is to be condensed, to the required vacuum and to the ambient temperature. In other installations, variable-speed fans are used, which are provided with frequency converters capable of modulating their loading between 50 and 100%.

FIG. 8.33l
The control room of a power plant consisting of four 380 MW groups of generators, located at La Casella, Italy. (Courtesy of ENEL.)

CONTROL EQUIPMENT

Central Control Room

The control system in a combined cycle power plant having one generating group normally consists of a DCS system, provided with two operator stations, each with two CRTs, plus a keyboard, trackball or mouse, and printers.

When more groups are installed, each group can be equipped with three CRTs and possibly with large screens on the wall (Figure 8.33l). The operator stations can be PC-based in a client/server configuration. According to the size and criticality of the plant, the server can be simple or redundant. In general, the cost of controls is small in comparison to the mechanical equipment costs or the costs associated with plant shutdowns, loss of production, and expenses associated with restarting. For these reasons and for increased safety, usually redundant or voting systems are used.

The multiloop controllers are used in redundant or fault-tolerant configurations, and serial gateways should be provided to connect the GT and ST governors, the AVRs, the demineralization water plant, and possibly the electrical protections. In some instances, the ST governor can be part of the DCS itself with a dedicated redundant multiloop controller similar to the ones used to control the HRSG and the cycle. In other cases, the GT governor and the ST governor can be in separate hardware packages.

DCS and I/O Configuration Integration and properly designed interfacing between the DCS, PLC, and other digital control packages is essential. The serial links should be redundant to ensure the maximum operating continuity. If not all external devices are available with redundant links, it is recommended that they be provided. The system bus and the I/O buses should also be redundant, with the goal of guaranteeing the maximum uptime.

The number of continuous and discrete (on/off) I/O points used is in the range of 5000, and the discrete I/O outnumbers the analog. The input signals are often duplicated for control purposes or tripled in a voting system for safety functions, and this requires careful attention in point assignments to the input cards and of the input cards to the multiloop controllers (see Reference 2). If the sequence of events control function is carried out in the DCS, the appropriate input cards have to be correctly anticipated or a dedicated system must be installed and connected to the DCS via a serial link (see Reference 3).

In recent years, the connection of the plant DCS to the company intranet has become common practice, in order to allow for a remote overview of the plant's behavior and to remotely view the main operating parameters and to assist in correctly managing plant maintenance. However, no commands can be issued from the overview location.

When a company owns or operates several power production plants, this configuration allows for the gathering of information for further processing by management or by the engineering support team in real time. Adequate firewalls must be included to prevent unwanted access from hackers or the injection of viruses.

In a few cases, power plants are mechanically designed for operation from a remote location and are unattended. This means that the control room in the plant is equipped as if the plant were attended in order to allow for temporary operation mainly during precommissioning, commissioning, start-up, and tuning, and in case there is a plant upset.

Furthermore, there can be additional redundant links to other control room(s), located a few miles away. Of course, extensive additional information systems serve the goal of plant safety. These systems utilize the fire- and gas-detection and -protection systems and gate control, flooding, and so on. The fire-detection and fire-fighting system cabinets are located in the control room behind or to the sides of the operator's control desks, in order to allow for immediate response to any dangerous situation.

The software packages supplied with the DCS, in addition to the standard operating controls, also include such data sources as the steam tables, the sequence of event (SOE) module, post-trip review modules, and possibly the performance evaluators and stress evaluators.

Control Desks, Operator's Displays Operators find it very useful to have one CRT on the control desk directly connected to the GT governor and another one directly connected to the ST governor, in order to eliminate the transmission delays mainly during start-up and shutdown, or during plant upsets.

The control desk also houses the PC dedicated to continuous emission monitoring system (CEMS) plus the remote direct reading level gauges for the steam drums, where they are required by local regulations.

The engineering station can be located on the same control desk or in a separate room, according to the company policies and also as a function of the available space. It is, however, to be noted that the operations team is very small, has only a couple of operators per shift, a few other maintenance specialists, plus the plant manager. For example, in a power plant with four combined cycle units, the operating team is composed of two operators per shift, each running two units, and a common supervisor.

The control system is also used for the management of spare parts inventory and maintenance of both main machinery and the smart transmitters. The aim is to perform the maintenance on a predictive basis, i.e., when the behavior of a component shows a degradation that could result in a fault. In this case, the use of fieldbus technology connecting field devices is very useful, because of the large volume of diagnostic information to be processed and conveyed to maintenance engineers.

The control system sometimes also has the task of storing technical bulletins and documentation pertinent to the various components of the plant in order to facilitate the finding of information as required.

Monitoring and Control Loops

In a combined cycle power plant, these functions are quite simple and are similar to the boiler and the steam turbine controls that are covered in Sections 8.6 and 8.38 in this chapter. In contrast to boiler controls, HRSG controls do not have air/fuel ratio, steam pressure, furnace draft, and so on, so they are relatively simpler. In the paragraphs below, those measurements and controls will be discussed that are typical to combined cycle controls, or are different from the ones used on boilers and steam turbines.

Fuel Gas Heating Value The heating value of the gas delivered to the users is variable with time, and in several countries the heating bill reflects not only the quantity of fuel delivered, but also its higher heating value. The gas distributors provide average daily values of the upper heating value, which the users should check.

In addition to the commercial issues, this measurement, related to the lower heating value, is very important from an operational point of view, especially when the GT is the aeroderivative type. An increase in the fuel gas heating value increases the flame temperature and can overheat the first row of turbine blades, causing a sudden shutdown of the GT, if the firing rate is not decreased. The consequence of a shutdown is the loss of at least 1 hr of electric production, and if the plant is cogenerative, the steam production is also disrupted.

To prevent this kind of shutdown, a chromatograph or a calorimeter (or both) are installed on the fuel gas. For a detailed discussion of calorimeters and chromatographs, refer to Sections 8.8 and 8.12 of the first volume of this handbook, respectively. If the fuel gas heating value increases, the set point of the GT governor is automatically lowered to reduce the combustion temperature and, thereby, protect the system from a shutdown.

HRSG Start-Up Vent Valve The main purpose of this valve, which is installed downstream of the HP superheater (see item 1 in Figure 8.33k), is to control the pressure in the steam drum during start-up and to let it rise slowly so that the corresponding rate of rise in steam drum temperature will be acceptable. To perform this task, the HP vent valve works in combination with the ST bypass valves.

For large steam drums with a wall thickness > 4 in. (100 mm) operating at 1500 psi (100 bar) and over, the acceptable temperature gradient is 6–11°F/min (3–6°C/min), while for smaller drums operating at 900 psi (60 bar), the temperature gradient can be 15°F/min (8°C/min). The lower figures are used when the HRSG is subject to frequent starts and stops.

The problem that is typical of the HRSG is that during the start-up phase, the heat delivered to the HRSG is quite high even though the GT runs at its minimum capacity, i.e., at FSNL or minimum technical load. The start-up vent valve should be capable of operating with an upstream pressure from nil to the design pressure, with temperature varying from 212°F (100°C) to the superheated steam temperature at the nominal working pressure. The valve has critical pressure drop and should be designed to abate the noise pressure level down to 80–85 dB(a), according to most contractual specifications.

For the purpose of noise abatement, this valve cannot be considered as operating in emergency only, like safety valves, because it operates for long periods of time during all start-ups, and the start-ups can be relatively frequent, at least for the need of off-line washing the air compressor blades. For detailed information on control valve sizing and valve noise calculation, refer to Sections 6.14 and 6.15 of this volume.

Because this valve operates with both variable upstream pressure and variable flow, as a function of HRSG operation and of the requirement to keep the temperature gradient within the allowable limits, it is not easy to prepare sizing data of process conditions describing the pressurization operation in order to size the valve.

The sizing of this valve is dependent upon a number of factors, only one of which is the start-up condition.

It is possible that the plant should be designed to maintain the GT output in case of ST failure or in case of ST condenser failure. In this case, the valve should be sized for 100% unfired duty because the possible supplementary firing is shut down if the vent valve opens. If the plant can be started up by using the ST bypass valves only, because auxiliary steam is available to bring the condenser on-line, then this vent valve can be omitted. Experience has shown that this valve works properly to cope with the start-up needs, if it is sized for at least 30–35% of the boiler steam capacity at nominal conditions.

In some cases this valve can be a motor-operated (inching type) globe valve. An additional requirement for this valve often is to prevent the blowing of the safety valves that are protecting the drum and superheater coils from overpressuring in case of ST trip or load rejection. To be able to do this, the start-up vent valve should be fast opening (opening time of 2–3 sec) and stay open for about 5 sec until the ST bypass valves (if sized for 100% flow) can handle the upset caused by the ST trip.

If there are no ST bypass valves, as in smaller plants or process steam generators, the valve should be able to handle the full steam generating capacity. For high-pressure boilers, the flow can be split into two valves, one suitable for the controlling the start-up conditions up to a pressure of 30% of the nominal one, and the other, used for emergency only, to prevent the blowing of the safety valves. When operating at full pressure, the start-up valve is inhibited in order to prevent uncontrollable level upsets. Whatever valve size is selected, it is essential to consider the amount of make-up water required.

Steam Drum Level Control

The level control of the steam drum of an HRSG is very similar to that of fired boilers. Up to 30% of nominal steam flow, usually a single-element controller (level only as shown in Figure 8.6ww), is used. There have been cases where the level control of large HRSGs was stable, while its load was over 30% and the level was controlled with a single element controller.

Above 30%, the loop usually is bumplessly transferred to three-element control (water level, steam, and water flow as shown in Figure 8.6yy). The phrase *three-element* is used to define a mass balance between input and output flows to/from the steam drum, which are feedback-corrected by the level measurement. In more elaborate algorithms, more than three measurements can also be used.

The feedwater control valve can be located upstream or downstream of the economizer, as a function of the designs of the various HRSG manufacturers. Several HRSG manufacturers do not allow the economizer to steam, and therefore the control valve is installed downstream of the economizer. This solution is very effective in preventing steaming but imposes a higher design pressure on the economizer itself with the associated costs.

The valve in these installations is quite critical because it can be subject to flashing and cavitation. The installation of the control valve at ground level can help reduce this problem, provided the piping layout allows for it. Furthermore, during start-up, due to the water trapped in the economizer, an overpressure builds up, because the boiler feedwater valve is closed due to the minimal amount of steam generation in the steam drum, and the check valve on the BFW pump discharge is closed.

This overpressure needs to be relieved without opening the safety valve through an antiflash valve that should open on the pressure threshold. Some units are designed to maintain a minimum flow through the economizers to prevent this, and the excess water is dumped from the steam drums to a condensate-recovery system.

Some HRSG suppliers accept a little steaming in the economizer and install the control valve upstream of the economizer with an accurate heat-transfer design to reduce steaming during some transient conditions. The valve, in this case, is much less critical as it handles “cold” water without flashing or cavitation problems.

Mainly on the HP circuit, the BFW control valve sometimes requires a smaller valve in parallel for start-up. This start-up valve should be sized for a flow equal to approximately 20–35% of the nominal flow (in order to handle the water flow required during start-up). It should be sized to operate at a pressure drop that is much higher than the one during normal operation through the main control valve. This is because the flow is very low, the BFW pump is practically working at its shut-off pressure, while the friction losses in the line and coils are minimal, and the pressure in the steam drum is much lower than during normal operation.

As the power station can operate under several conditions, it is suggested that the suppliers who bid on the BFW control valve be provided with data on all the different operating conditions. This way they should be able to check the

performance of the proposed valve over the complete range of operating conditions (Table 8.33m). The valve body size is frequently determined not only on the basis of the required valve capacity (C_v), but also by considering the maximum acceptable flow velocity [approximately 30 ft/s (9 m/s)]. Additional information can be found in ISA standards (Reference 4).

Steam Temperature Control

Steam temperature is usually controlled with desuperheating valves installed between the first and second superheaters, similarly to the arrangement in regular boilers (Figure 8.33n). If the superheaters are split into more banks in parallel, good practice requires a desuperheating valve per each bank.

The control function is normally implemented by a cascade loop in which the master controller (TIC-111 in Figure 8.33n) senses the final steam temperature and the slave senses the temperature after the desuperheater, before the steam enters the second superheater. The set point of the slave controller has a low limit of roughly 28–30°F (15–16°C) above the saturation temperature obtained by characterizing the steam drum pressure to prevent moist steam in the second superheater, as well as poor temperature control.

The temperature used as the measurement of the slave controller (TT-112) should be located about 60 ft (20 m) downstream of the desuperheater to allow the water droplets to vaporize, which is necessary to obtain a correct measurement and to prevent mechanical damage to the protecting thermowell. Sometimes a feedforward action by steam flow is added (FY-102) to the control system.

Very often, the piping is also protected with internal sheathing to prevent erosion. If the thermal design is correct, in some operating conditions (mainly under base loading) the desuperheaters are not in operation, while in other operating conditions the desuperheating BFW flow can be highly variable. It is suggested that the suppliers who bid on the desuperheater be provided with data on all of the different operating conditions (Table 8.33o).

When a desuperheating valve is not in use, it is isolated by a pneumatically or electrically operated on/off valve that is installed upstream of the desuperheater in the BFW line. This valve is closed a few seconds after the desuperheating valve is closed (or when it is less than 2% open) and is opened

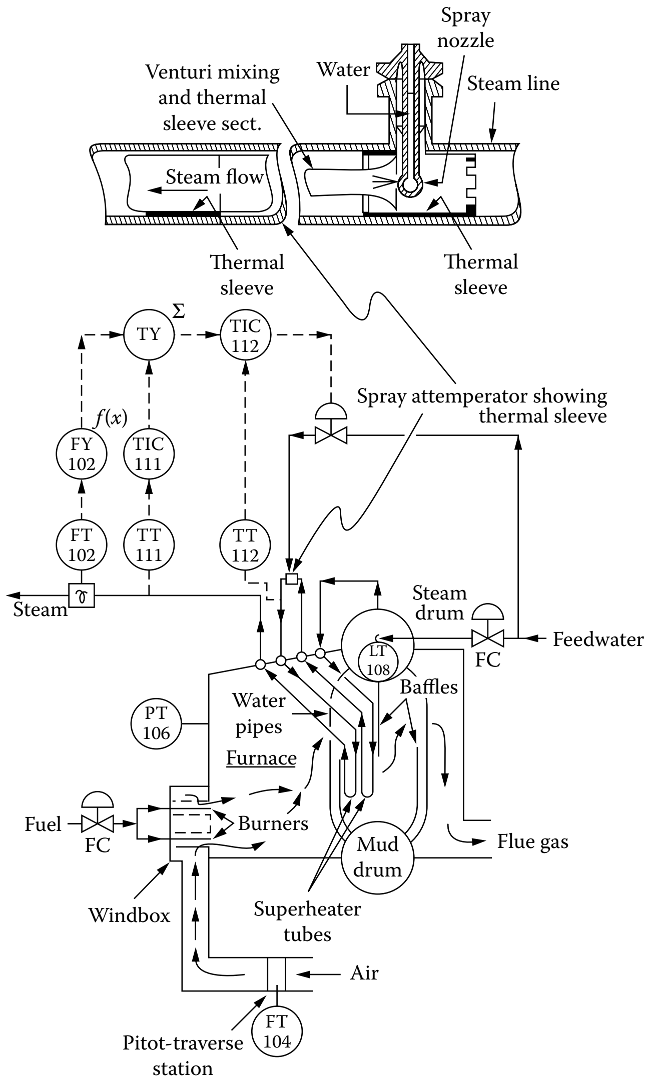

FIG. 8.33n

Cascade configuration for controlling the desuperheater control valve.

when control signal setting the desuperheater valve opening exceeds approximately 4%.

If the desuperheater is of the insertion type, its rating should be determined by considering the design pressure of the BFW and the design temperature of the steam. With today's high pressures [up to 3500 PSIG (241 barg)] and temperatures [up to 1075°F (580°C)], this is not always achievable. This creates serious problems when desuperheaters are selected. Additional information can be found in ISA standards (Reference 5).

Pegging Steam Control

Pegging steam is required to deaerate the boiler feedwater during start-up, when no low pressure (LP) steam is yet available and if no steam is available from an auxiliary boiler or from other HRSGs. The purpose of this control system is to start deaerating the boiler feedwater as soon as possible during start-up.

If the deaerating tower is located on top of the LP drum, then during normal operation, the steam needed for deaeration is generated in the LP drum. Under start-up conditions, the steam first becomes available in the HP section, then in the IP section, and finally in the LP section of the HRSG. If an auxiliary boiler is not available, in order to start degassing as early as possible, a connection can be made between the IP or HP drum and the deaerating head. In this connecting pipe, a motor-operated on/off valve and a throttling control valve are installed.

The control valve serves to reduce the HP or IP pressure to the LP level for the deaerator during start-up. Once the LP section is generating enough steam to be self-sufficient to ensure good deaeration, this start-up phase can be terminated. This happens when the pressure in the deaerator reaches a pressure of about 25 psia (1.7 bara). At this point, the pegging steam line is closed. This is done by closing both the control valve and the on/off isolating valve.

On fired units it is possible that pegging steam is also required during normal operation at high loads, because the LP section does not generate sufficient steam.

Condensate Preheater (Economizer) Temperature Control

This control system is unique to HRSGs and is not used on conventional fired boilers. Its dual purpose is to 1) prevent external condensation on the tubes of the preheater, which could cause external corrosion, and 2) obtain the correct inlet temperature to the deaerator.

The first objective is met by taking some of the hot condensate leaving the preheater and mixing it with the cold condensate entering the preheater (TIC-1 in Figure 8.33p). The hot condensate is recirculated by recirculation pumps, and the flow rate of recirculated hot condensate is throttled by TIC-1, which detects the temperature of the (mixed) condensate stream entering the preheater and keeps that temperature high enough to prevent external condensation.

The correct inlet temperature for the deaerator is obtained by mixing the hot condensate downstream of the preheater with cold condensate. This inlet temperature is maintained by TIC-2, which detects the mixed condensate's inlet temperature to the deaerator and is set a little lower [15°F (8°C)] than the boiling temperature. If large amounts of the hot condensate are recirculated by TIC-1, this could cause TIC-2 to lose control and cause a low temperature at the condensate inlet to the deaerator, thus the need for pegging steam.

A less sophisticated control configuration that has been used to remove sulfur from flue gas is shown in Figure 8.33q. Here, the cascade master TIC-2 maintains the required deaerator inlet temperature by modulating the set point of TIC-1, the slave controller. In this configuration, however, there is no positive protection of the preheater coil against condensation on its external surface.

In some HRSGs, block valves are provided so that the LP preheater can be temporarily valved off (isolated), if water leakage occurs.

If the fuel has a high sulfur content, the primary concern is to keep the inlet temperature of the condensate to the preheater above the dew point of flue gas by proper recirculation of some of the hot condensate.

Supplementary Firing Control

In some plants, the fuel flow to the burners is set manually by the load dispatcher, but errors can cause transient overfiring and overheating the superheater tubes. Therefore, a burner management system, complete with accessories such as flame scanners, purging, and cooling, shall be provided to ensure the boiler safety.

Supplementary firing should limited to a fraction of the GT load. The applicable safety codes in the area of the HRSG depend on the presence of fuel gas in the proximity. It is possible to reduce the area classification by a careful study of the piping layout and by the adoption of some precautions. These would include he use of double stuffing glands with bleeds in between the glands on the fuel gas valves. The intermediate bleeds from such valves are collected and vented to the atmosphere at safe location.

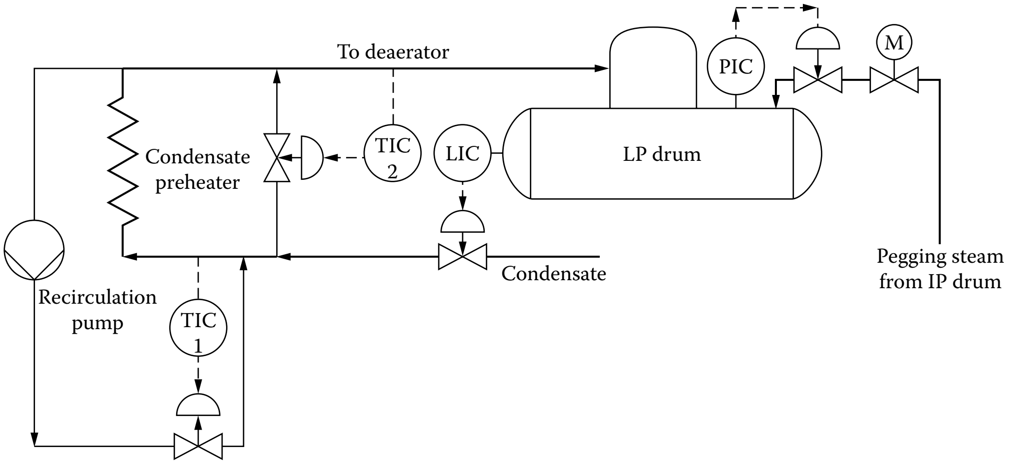

FIG. 8.33p
TIC-1 keeps the condensate preheater surface temperature high enough to prevent external condensation, while TIC-2 keeps the deaerator inlet temperature below the boiling point. Under certain conditions, the two loops can fight each other.

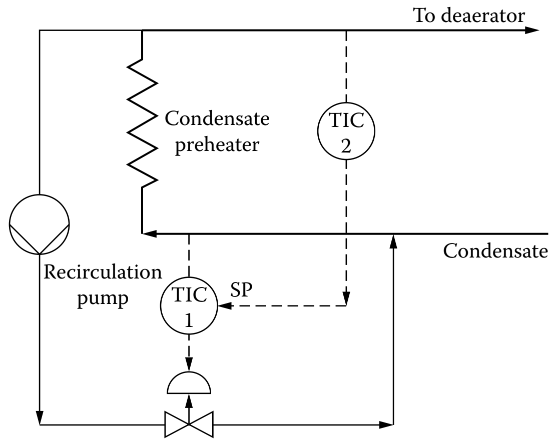

FIG. 8.33q
Cascade control of preheater does not give positive protection against flue gas condensation on the external surface of the preheater.

The firing could also pose some problems with emission control, especially at reduced GT loads, and may require the use of flue gas recirculation (FGR).

Steam Turbine Bypass Control

The bypass valves (Figure 8.33k) around the steam turbine (ST) are closed during normal operation and are throttling during the start-up, after an ST trip, or in the case of load rejection. A pressure controller PIC (with antireset windup) is throttling the bypass valve, so as to keep the upstream (inlet) pressures at the desired HP, IP, and LP settings and to make sure that they do not reach the settings of the corresponding safety valves.

In addition, the pressure control valves in the turbine bypasses should be provided with a quick-opening capability (a solenoid can be used on pneumatic valves) that will be triggered by an ST trip and remain open for a duration of approximately 5 sec.

When the boiler operates in sliding (floating) pressure, the set point of the bypass PICs should track the operating pressure to prevent sudden transients. In these conditions, the purpose of the bypass is to prevent the safety valves from blowing when the steam pressure suddenly increases due to a trip of the ST. Alternatively, if the valves have a hydraulic actuator capable of following the controller output with very little delay (a few seconds), the opening can be proportional to the steam flow prior to the ST trip, thus avoiding any pressure upset.

During start-up, after the vacuum has been established in the condenser, the set points of the bypass PICs are set to follow the acceptable heating curve of the steam drum until the steam turbine is warmed up and can handle the superheated (SH) steam. A desuperheater should be provided to reduce the steam temperature to the value that is compatible with the downstream steam conditions. This desuperheater can be integral with the pressure reducing valve or separate from it.

The bypass valves can be sized to pass partial or full flow at the operating pressure conditions. In combined cycle power plants, the bypass valves are normally sized to pass the full steam flow. If the HRSG can operate on sliding pressure, the sizing is still based on the maximum operating pressure and flow. During the operation in the sliding pressure mode, because the GT is not at base load, the pressure drop across the valve is reduced, and an ST trip can cause a rise in the upstream steam pressure, but always within the normal operating values.

If the plant configuration is 2 + 1 (Figure 8.33f), during plant start-up or if GT is out of service, only one GT and HRSG are feeding the ST. In such cases, the HP pressure is lower than the normal one even though the operating GT is running at base load. A trip of the ST under these conditions will cause a sudden opening of the bypass, and the pressure in the operating HRSG will rise up to a value close to the nominal operating pressure. Additional information can be found in ISA standards (Reference 6).

Load/Frequency Control

The purpose of this control system is to keep the frequency variations within preset limits when the load and the generated power are unbalanced. The system guarantees that each generator unit can automatically and autonomously participate in the frequency control by gradually modifying the generated power in order to keep the frequency constant.

This is completely true if the unit is running at partial loading and is somewhat less so as the loading approaches 95%. If the unit is running at base load, it can only decrease its load if the frequency is in excess of the nominal one but it cannot increase the load in the case of an underfrequency episode.

Due to the offset that is caused by the proportional-only mode of frequency regulation, even when the generated power is balanced with the load, there could still be an offset in the frequency that needs to be corrected. This correction is provided by an external controller (at grid level) that acts as a primary or master of a cascade control loop whose slave is the turbine governor. In such a case, a command is likely to be received from the grid dispatcher to vary the generated power of the units that have spare capacity, in order to restore the nominal frequency of the grid or the correct exchange of power with other grids.

The variation in total generating capacity is split between the GT and ST into 2/3 in the GT and 1/3 in the ST. This means that if the electric power generation should change by x MW, the total change almost immediately (within a few seconds) affects the GT, and then, a few minutes later, there will be an increasing contribution by the ST with simultaneous decreasing contribution by the GT. When the new steady state is reached, the contribution of the GT will be about

2/3x and the incremental power contribution of the ST will be about 1/3x.

Running Permissives

Each machine component is provided with its own internal safety instrumented functions (SIFs) that are defined and often implemented by the manufacturers, because they are inside their scope of responsibility for supply and are also proprietary systems.

As the components of the total plant are very much interconnected from both from the process and from the electrical perspective, it is necessary to provide reliable interconnections with the objective of minimizing the partial or total plant shutdowns that they can cause. These functional interconnections are very much dependent on the arrangement of the plant (single shaft or multiple shaft, 2 +1 configuration, and so on) and the response to the failure of all major pieces of equipment must be planned in advance. Therefore, it is good practice to prepare both a cause–effect table/matrix (sometimes called a shutdown key) and an overall diagram of running permissives, which are also useful to the plant operators during normal operation.

A steam turbine trip causes the sudden temporary opening of the bypass valves around the STs and possibly the opening of the HRSG vent valves (Figure 8.33k). This allows the plant to run at reduced electrical capacity with the GT only, yet retaining the possibility of restarting the ST if the causes for the trip can be quickly removed.

If the condenser is not available, the GT is forced to operate under FSNL condition and either vent valves on the HRSG are opened or the GT must be shut down. This choice is dependent on the design of start-up vents and on the availability of water, as was discussed earlier. If the HRSG is provided with a diverter, the possibility of exhausting the GT to the atmosphere should also be considered, particularly if it is expected that the restarting of the ST will be delayed beyond a certain time period.

An HRSG trip due to unsafe conditions (too low a level, or a "low-low" condition in the drums, or sometimes too high a temperature, or a "high-high" condition of the SH or RH steam) should either open the diverter (if such exists), or otherwise the GT should be shut down. If a high level condition is detected ("high-high"), the ST bypass system can be opened and the ST tripped. In the case of abnormal conditions in the post-firing (flame failure) section, only the burner trip should be considered.

A gas turbine trip causes the trip of the complete train, unless complementary firing is available in the HRSG. In this case, the ST should be tripped, the diverter should be switched, the air fan started, and the burners lit after purging, to avoid disruption of the steam being generated for industrial use.

An electric generator trip should cause the trip of the pertinent driving turbine or of the complete train, in case of single-shaft configuration. In some cases, if the fault is electric, it is possible to try to prevent the trip by opening the circuit breaker of the machine. This way, the GT can be kept in operation at FSNL, with the possible benefit of reducing the time to restart and of reducing the equivalent hours of GT operation.

A step-up transformer fault causes the trip of the pertinent generator, if it is directly connected, and also the opening of the line breaker. If there is a circuit breaker between the generator and the transformer, then it too is opened.

A fault in the bus bar system causes the isolation of the faulty bus bar, possibly without interfering with the generation set.

A fault in the grid causes the opening of the line breakers, the trip of the ST, and the running of the GT in "island mode" (or at minimum load sufficient to feed the pertinent loads in the power house). This kind of electric trip with sudden load loss is claimed to be tolerated by the GT, but sometimes keeping the GT in operation requires a time-consuming fine-tuning.

Safety Functions and Integrity Levels

The manufacturer-supplied GT and ST governors usually include the control and safety systems for the turbines. In fault-tolerant configurations containing a high level of diagnostics, they normally include separate processors at least for safety functions. However, detailed diagnostics are usually not provided by the GT manufacturers, and the safety integrity level (SIL) "capability" of the governors is not guaranteed, either, by their architecture alone. The attainment of the SIL capability also requires the proper selection of the sensors, wiring, final elements, maintenance, and testing.

The turbine suppliers are very reluctant to accept any modification or inclusion of additional functionality to their controls, even if it is strictly correlated with their supplied controls and is external to the GT. This is because the turbine package is provided with control functions inside the governor (designed around the turbine it protects). The supplied packages usually do include several architectures of the furnished control functions, from which the user can select.

Most safety-related controls that are required for turbines in a cycle with an unfired HRSG are furnished within the manufacturer's package. The unsafe conditions that are usually not covered are those of the levels in the steam drums of the HRSG and the fuel gas intercept valves to the GT.

Often the specifications call for a safety integrity level of 3 (SIL 3) for all SIFs, and this could be due to inadequate analysis. Such specifications could result in overengineering of the complete safety instrumented system (SIS) with its associated costs in maintenance, for the whole life cycle of the plant. For the proper selection of SIL levels, see References 7 and 8.

START-UPS AND SHUTDOWNS

Start-Up Procedures

The combined cycle power plants, even if they are operated at base load, are subject to starts and stops more frequently than other industrial plants or power plants. The frequency of start/stop requirements dramatically increases if the combined cycle operates in an intermittent way.

In order to operate the plants with reduced crews of operators, it is necessary to be able to implement a start-up procedure from the control room without people having to walk around the plant. Hence, all valves that need to be operated during the start-up should be motor-operated.

The main concern in starting up a combined cycle power plant is to avoid thermal stresses to the machinery that would shorten its life and produce unsafe conditions. This consideration results in extending the time for start-up, while economics would require that start-up take place in the minimum possible time and with minimum fuel consumption.

For the ST and the HRSG, different starting conditions can be defined depending on their status at the beginning of the start-up (i.e., if they are cold or hot). Of course, a cold start up requires a more cautious and longer procedure to avoid stressing the machinery. However, the cold and hot conditions are different for the HRSG and the ST, so that a start-up can be considered cold for one machine and hot for the other. For large HRSGs, a warm start-up condition is often considered.

Each manufacturer of the main plant equipment sets the requirements for its machine, and then it is up to the process design engineers to combine these requirements with their own to arrive at start-up procedures that will minimize the overall start-up time.

Sometimes, the normal start-up procedure needs to be modified to cope with the environmental constraints as dictated by local regulations. This could involve a long warming period at low load followed by a quick ramp-up, or starting with the GT at high load (even 70–80%) plus a lot of steam being bypassed to the condenser, in order to maintain the proper temperature gradient in the HRSG. This unusual situation can have an impact on the last stages of the ST and needs to be thoroughly investigated with the manufacturers in order to avoid dangerous operating conditions.

The start-up sequences are resident both in the DCS that acts as the overall coordinator, and in the turbine governors that are interfaced with the DCS. As previously mentioned, in several instances the governors are parts of the DCS.

Permissive Conditions The start-up can take place only if some permissive conditions are satisfied, such as the availability of instrument air, cooling water, demineralized water, fuel gas, and electricity to feed all motors (HV and LV) and the DCS. All these permissives should be listed in detail as prerequisites for the start-up procedure.

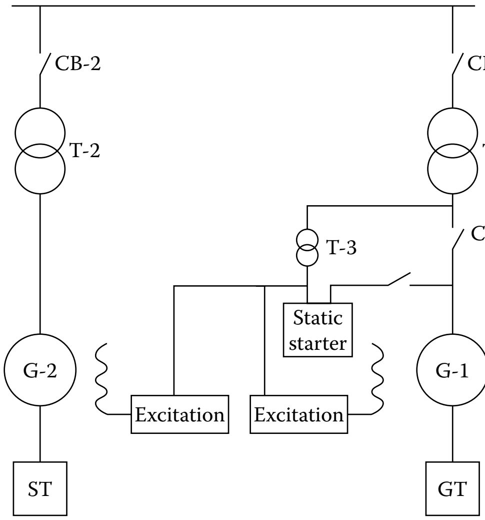

FIG. 8.33r
Simplified one-line electrical diagram of a dual-shaft power station of 250 MW capacity.

The document describing the overall sequence should start with the required position of all valves, status of all controllers (auto, manual, forced to XX value, and so on) and conditions of all pumps (running, standby, available/unavailable) at the beginning of the start-up procedure. The hot, warm, or cold condition of each machine should also be determined.

According to the mechanical and electrical configuration of the plant, the start-up procedure can vary to follow specific requirements. Therefore, each plant has to be designed individually. In other words, each plant is unique and its start-up procedure should also be developed to suit the unique requirements of the GT, HRSG, ST, and condenser manufacturers and, possibly, also of the electrical grid and plant operators. In the case of cogeneration, the requirements of the steam user operators should also be taken into account.

As an example, a typical cold start-up procedure is provided below for a unit designed for 250 MW, dual-shaft, unfired HRSG with three steam pressure levels, a water-cooled condenser, and a GT generator also acting as launching motor, in which the main steps correlating the different equipment are highlighted (Figure 8.33r). In this case, no black starting was required and no steam was available from an auxiliary boiler or other units.

Cold conditions mean that the boiler has an HP temperature lower than 212°F (100°C) and the first-stage metal temperature of the ST is less than 245°F (120°C). Some suppliers also recommend that the shafts of the turbines be cranked for few hours before starting up, with the lubrication system in operation.

For a power plant unit of this size, skin thermocouples are installed on the HP drum, on the final HP superheater, and on the IP reheater, mainly to monitor the metal temperature gradients during the start-up phases.

If all permissives are satisfied and the equipment is ready to be energized, the start-up sequence proceeds as follows:

The Start-Up Sequence

1. Close the line circuit breaker CB-1 in order to energize backwards to the gas turbine step-up transformer T-1 and the unit transformer T-3. The generator circuit breaker CB-3 is open.
2. On the operator's start-up command, the GT governor will put in operation the lube oil system, if it was not in operation because the turbine was cranking. For heavy-duty turbines a slow cranking (few rpm) is necessary for several hours before starting. The temperature of the lube oil shall be higher than the minimum required by the manufacturer.
3. The lubricating oil circuit of the steam turbine is put in operation as well as the jacking oil circuit of the generator.
4. The shaft turning gear of the steam turbine is started, unless it was already operating.
5. All cooling circuits are put in operation.
6. The level of the condensate storage tank is to be at a normal value.
7. The condenser hot well level is to be at a normal value.
8. The condensate extraction pumps are put into operation.
9. The LP drum level is filled to the required start-up value.
10. The IP and HP drums are filled to the required start-up level (minimum level).
11. The boiler blow-down system is started and put in auto; the sampling system is started as well.
12. One main boiler feedwater pump is started.
13. The steam turbine bypass system is prepared for automatic operation.
14. The HRSG configuration is set and checked.
15. The superheater drain valves are open and shall be kept open until a pressure of approximately 30 psig [2 bar(g)] is reached.
16. The steam line drains are open to warm up the piping and shall be kept open until the correct temperature has been obtained.
17. The boiler setup sequence is performed either automatically or manually, step by step. The automatic ramp-up sequence of the HRSG is selected for start.
18. The excitation system of the GT generator and the static starting system of the GT are energized.
19. The block and bleed valves on the fuel gas supply are put in operation in order to deliver fuel gas to the gas turbine inlet valve.
20. Under the control of the GT governor, the gas turbine is now ready to start, waiting for the start command from the operator that can be given through the DCS or directly via governor HMI.
21. When the correct lube oil pressure is established, the static starter will rotate the gas turbine and run it at a preset value without firing during the time needed for the proper purge of the turbine and of the HRSG. It should be noted that the purging time is longer on the combined cycle than on the open cycle, as the volume of the HRSG must be purged as well. The time for the purge (typically, 15–20 min) is calculated on the basis of five air changes with the airflow produced by the compressor running at launching motor speed.
22. At the end of the purge, the GT governor will light the burners, the static starting system will be switched off and the gas turbine will ramp up to the synchronization speed in 15–20 min (for heavy-duty GTs) or a couple of minutes (for aeroderivative GTs). The excitation system regulates the generated voltage to the correct value. The speed gradient of the gas turbine is controlled by the GT governor. The gas turbine is kept at full speed no load, exhausting to the HRSG with the generator disconnected from the grid. For some turbines, it is required that a minimum load be connected; in case the power station auxiliaries are not large enough, the paralleling of the GT generator to the grid shall be performed. Some turbines even at FSNL have an exhaust temperature higher than an acceptable value [usually 770°F (410°C)] for the HP superheater coils (abnormal thermal expansion due to very low steam flow), and therefore it is necessary to activate the exhaust temperature limitation function.
23. The HRSG will start steaming, and the pressure is controlled by actuating the vent valves so that the temperature gradient in the HP drum remains within the limit indicated on the relevant diagrams by the HRSG manufacturer for cold conditions in order to prevent stress to the pressure parts. The vent valves are initially kept at a minimum opening, then switched to automatic control with an automatic ramp of the controller set point. If the vacuum in the condenser can be obtained because some steam is available, the steam pressure is controlled by means of the turbine bypass valves.
24. The HRSG is kept at the warming up condition [HP 800 psig (55 barg), IP 300 psig (20 barg), LP 50 psig (3 barg), approximately] for at least 15 min, while the steam lines are preheated via the main stop bypass valves, line vents, and drains, or alternatively, with the main stop valves fully open.
25. As soon as the differential pressure across the main stop valves and the temperature of the steam lines are acceptable, the main stop valves of the HRSG are opened. If the start-up takes place with the stop valves fully open, this step is skipped.
26. The generated steam from HP or alternatively from IP is conveyed to pressurize the steam glands of the

steam turbine. If auxiliary steam is available, this step takes place much earlier.

27. The start-up ejector is started as soon as steam is available at suitable conditions and is operated until the condenser pressure reaches 4.5 psia [300 mbar(a)]. After that the main ejectors are started in order to reach the proper vacuum 0.4 psia [30 mbar(a)].
28. When the pressure in the condenser reaches 4 psia [280 mbar(a)], the turbine drains to the condenser are opened and the generated steam is desuperheated and dumped to the condenser. The pressure reducers (bypass valves and desuperheaters) in the main steam system are put in operation with an initial set point of approximately 870 psig [60 bar(g)] for the bypass from HP to the cold reheat (CRH), while 200 psig [14 bar(g)] or less is required for the bypass from the hot reheat (HRH) to the condenser and 45 psig [3 bar(g)] from LP to the condenser. The operation is performed by acting through the DCS, starting from the HP to the CRH bypass (sometimes this bypass is opened before the vacuum at the condenser is established in order to flush the RH coils) and ending with the IP and LP to the condenser.
29. At this point, the gas turbine is still running at FSNL (or at minimum load) and the HRSG (HP) stays at 870 psig [60 bar(g)] and 735°F (390°C).
30. When the correct control fluid pressures are established, the ST is started under control of the turbine governor. The turbine increases its velocity with a gradient defined by the governor and is gradually warmed up according to the sequence defined by the manufacturer. It is possible that the acceleration is increased in a range around the first critical velocity of the steam turbine and of the generator. When the turbine velocity is about 90% of the nominal speed, the excitation system will regulate the generated voltage to the correct value.
31. The steam lines' vents and drains are closed.
32. As soon as the steam turbine has warmed up to an acceptable point under control of the synchronizing equipment and on request of the operator, the gas turbine generator is put in parallel with the grid by closing the circuit breaker CB-3.
33. The GT governor ramps up the generated load at least to the minimum allowable working value (about 55%).
34. The gas turbine output is raised up at a rate of about 2%/min. This operation can be done either through the DCS or directly by the GT governor HMI.
35. Meanwhile, the set points of the pressure regulators of the bypass valves are gradually raised, so as to pressurize the boiler, always keeping in mind that the temperature gradient in the steam drums shall not exceed the value stated by the boiler manufacturer.
36. When the boiler reaches a load of 30% the level control is switched to three-element control with the normal operational set point.
37. Drains and chemical dosing system of the boiler are put into normal operation.
38. When the warm-up procedure of the ST is finished, the steam turbine generator is synchronized with the grid, and the circuit breaker CB-2 is closed.
39. The power plant is now ready for ramping up to nominal power; when pressure in the HP drum reaches 1150 psig [80 bar(g)], the ramp limitation for the gas turbine is increased to 5%/min.

The complete cold start-up procedure of such a group of equipment requires about 4–6 hr or even more because of the low acceptable gradients and of the suggested stabilizing time in the HRSG and ST heating. In practice, the GT remains at FSNL or at minimum load for almost the whole start-up period, except the last 1/2–3/4 hour.

The hot and warm start-ups differ from the cold one mainly because several steps in the early stage of the sequence can be skipped and because higher gradients are acceptable in the limits on temperature/pressure rise. On the other hand, some additional precautions must also be taken. For example, it is necessary to protect from the steam becoming cooler than the ST metal by synchronizing the GT and raising the load until a proper steam temperature is reached. It may be necessary to lower the pressure of the reheater (RH) by opening the bypass and possibly also the vent valve, because the bypass is sized to pass the full flow at nominal conditions.

As a result, for the group of equipment considered in the example, the hot or warm start-up time is shortened to 2–3 hr.

Short-Term Planned Stop

A planned shut-down of the complete unit has the purpose of stopping the operation of the group of equipment with minimum stress to the machinery. It is also a goal to keep the electrical system alive to the maximum extent, so as to be able to restart the plant as soon as possible, in the hot start-up conditions. It is advisable to verify with equipment suppliers if there are any process variable limits or constraints that must be obeyed to avoid damaging the equipment itself. In particular, there could be the temperature of the RH steam that should be lowered in a predetermined way to prevent abnormal axial elongation of the ST rotor.

Short Stop Sequence

1. Reduce the generated power with a predetermined gradient through the GT governor by reducing the fuel gas admitted to the gas turbine.
2. The GT governor starts the auxiliary lube oil pump of the GT unless lubrication is obtained by means of separate pumps.

3. Consequential to the reduced power generated in the gas turbine, the steam turbine reduces its generated power. It is necessary to decrease the pressure of the RH beyond the natural pressure decrease by assigning variable set points to the bypass and vents, based on pressure/power curves defined by the ST manufacturer.
4. When the power generated by the steam turbine is close to 30%, the steam turbine bypass valves are opened and shortly after the turbine is tripped. The circuit breaker CB-2 opens, actuated by the minimum load relay. The vacuum in the condenser and the steam to the glands should be maintained as long as possible, at least until the steam turbine is stopped and restarted under turning gear (a sudden inlet of fresh air inside the hot portion of the turbine might generate distortions and thermal stress both on rotor and casing).
5. Once the minimum allowable load is reached, the GT governor shuts the gas admission valves, opens the circuit breaker CB-3, and excludes the excitation circuit.
6. Close the block and open the bleed valves on fuel gas inlet to the gas turbine package.
7. Immediately after the turbines are stopped, the steam turbine jacking oil pump is automatically started and the turbine turning gear is put into service, keeping the AC lubrication oil pumps in service until the journal temperature is reduced to a value compatible with the babbit metal of the bearing.
8. The operator activates the automatic bottling procedure of the HRSG, by which all valves around the HRSG and the damper in the stack (if present) are closed. If the stop is very short, then a couple of minutes after the TG stops, a very slow depressurization procedure is activated by slightly opening the start-up vents, thus keeping the superheaters flushed as to prevent condensation.

At the end of the short planned stop, turbines of the power station are still hot and turning under the turning gear and the HRSG is still pressurized and hot, ready to start in the shortest possible time (a couple of hours).

Long-Term Planned Stop

The long-term planned stop of the complete power generating unit has the purpose of stopping the group of equipment with minimum stress to the machinery and to reach the cold conditions in the shortest time. This has to be done in a manner compatible with the allowable temperature gradients that are needed to perform maintenance by means of internal inspection of the HRSG, or maintenance of the steam turbine.

In case of the long-term stop, the short planned stop is modified by running the ST at minimum load to stabilize its temperature at low values. In addition to the steps listed for the short-term planned stop, the sequence required in this case is as listed below:

Long Stop Sequence

1. Open the vent valves.
2. Break the vacuum in the condenser and take out the sealing steam from the turbine gland, following ST manufacturer instructions.
3. When the pressure in the steam drums reaches about 30 psig [2 bar(g)], open the drain valves in the superheaters.
4. Bring the level in the steam drums to minimum value and close the BFW control valves.
5. Stop the BFW pumps, depending on the pressure in the steam drums.
6. The jacking pump and the lube oil pump of the ST must be kept in operation until the rotor is cold enough to be sure that the bearing shall not be damaged by temperature. This operation takes several days. Following manufacturer instructions, the ST turbine rotor shall be rotated under turning gear periodically to avoid unelastic permanent deformation. During this rotation, the oil system shall be in operation, jacking oil pumps included.

After such a stop the boiler needs cooling down before one can enter the flue gas side. This is accomplished by opening the inspection doors and allowing the air to circulate inside the casing. The boiler is, however, still full of water. If the inside of the steam drums is to be inspected, the blowdown valves should be opened to empty the steam drums. If the boiler must be completely emptied, it is done by also opening all the drains.

Emergency Shutdown

Depending on its cause, the emergency shutdown can be partial or total.

An example of a partial shutdown is a cause requiring the shutdown of the steam turbine. If the exhaust gas from the GT can be diverted to a bypass stack (Figure 8.33i) or if the generated steam is dumped to the condenser, the gas turbine can continue generating electric power, even though in an uneconomical manner.

A fault in the gas turbine or in the HRSG causes a complete stop of the power generating unit, unless a flue gas diverter exists and the fault is in the HRSG. A fault in the utilities can generate partial or total shutdown or lead to a runback of the gas turbine. The emergency shutdown can also be caused by the electric grid, resulting in partial or complete shutdown of the unit.

The operator can also initiate total or partial emergency shutdowns, but this operation should be avoided as much as possible to prevent stresses to the machinery. In terms of equipment life, an emergency shutdown of the GT is considered to be equivalent to at least 50 hours of operation and can exceed 150 hours, according to the formulas of some GT manufacturers. As a rule of thumb, for an emergency shutdown, the equivalent number of hours of operation is equal to the load percentage at the moment of the turbine trip (e.g., if the turbine trips at 75% of the load, the equivalent hours are 75).

A load rejection is accounted as 50% of the corresponding equivalent hours due to an emergency trip. If the causes for the shutdown are external to the generating set, its shutdown should be avoided as much as practical. This can be achieved by operating the gas turbine in an island mode, i.e., disconnected from the grid and feeding the electric loads of the power station only.

The operator can then decide whether to stop the gas turbine or to keep it in island operation. Sometimes, in the case of a sudden load rejection, the gas turbine is unable to go into the island mode of operation, because of the intervention of its overspeed protection interlocks.

PERFORMANCE TESTS

The performance tests are normally carried out in accordance with ANSI-ASME Performance Test Codes (PTCs), namely PTC 22 for Gas Turbines (Reference 9), PTC 4.4 for Gas Turbine Heat Recovery Steam Generators (Reference 10), and PTC 6 for Steam Turbines (Reference 11). For gas turbines see also ISO 2314 (Reference 12).

As part of the performance test, temperature measurements should be made in the HRSG inlet duct, as required by the code. These requirements call for a minimum of 24 temperature sensors in small ducts (up to 48 ft^2 in cross-sectional area). These thermocouples should be supported, mineral insulated, and provided with external stainless steel sheathing, and be without protecting wells.

The thermocouples should be located at the center of the individual areas of a grid, with the number of rows and columns selected according to the ANSI/ASME PTC 4.4. These thermocouples serve a temporary purpose and should be removed after the test is completed. The difference between temperature readings in the section of the flue gas duct can reach 15–20°F (8–12°C). A suitable method of temperature averaging has to be developed in order to correctly evaluate the performances of large units.

It is also necessary to test the BFW flow to the various steam drums (HP, IP, LP) of the HRSG, as the water flow measurement is more accurate than that of the steam flow. The steam flow, therefore, is measured as a reference. During the HRSG performance test, the blow-down valves and the sampling lines to the steam and water analyzers are closed.

The water flow measurement tends to be a little unstable even during steady-state operation, which is required for the performance test. It is, therefore, recommended to prepare a DCS screen page on which the various flows are totalized. This allows the operator to simultaneously start and stop all the totalizations, using software pushbuttons on the page (Table 8.33s).

TABLE 8.33s

Tabulation Allowing the Operator to Compare the Total Flows of Water and Steam In and Out of the Steam Drums

Service	*Total Flow*	*Units*	*Service*	*Total Flow*	*Units*
LP BFW	8 digits	Lbs	LP Steam	8 digits	Lbs
IP BFW	8 digits	Lbs	IP Steam	8 digits	Lbs
HP BFW	8 digits	Lbs	HP Steam	8 digits	Lbs
IP Dsh W	8 digits	Lbs			
HP Dsh W	8 digits	Lbs			
CURRENT TIME		PRESET DURATION		ELAPSED TIME	
hh/mm/ss		hh/mm/ss		hh/mm/ss	
RESET		START		STOP	
ν		ν		ν	

The totalized flows should cover 3- to 4-hr periods of flow integration as a minimum, because the corresponding ANSI standard (PTC4.4) requires that the test should last at least 2 hr. If there are reheat coils and the steam flow through them is not direcly measured, it should be calculated by mass balance around the steam drums.

CONCLUSIONS

In this section, the traditional basic controls used in power plants have been discussed. The potentials for optimizing these processes are somewhat limited, but should still be considered.

For example, when the plant is operated in an intermittent manner, the start-up period should be minimized. The corresponding savings in fuel and production can be substantial if during the design stage and during the subsequent tuning of the system in field, attention is focused on the goal of decreasing the start-up time. To reach this goal, the start-up sequences of the individual equipment should be well coordinated, and when necessary, some of the steps of the start-up sequence should be modified, postponed, or anticipated during commissioning.

Another potential for optimization is noise silencing. This is because if the steam venting during start-up is too noisy, it restricts the times at which the plant can be started up in built-up areas. This consideration can limit the acceptable time period and result in a need to put the power plant on-line well in advance of the required time.

In terms of the potentials for improving equipment efficiency through optimization, keeping the air compressor blades of the GT clean is an important goal. The frequency of the on-line washing required should be determined in the field, based on both the turbine characteristics and on environmental pollution. The off-line washing should be done when the GT performance drops substantially.

The goal of optimization can be served by evaluating the trade-off between the recovery in performance after a maintenance-related shutdown and the loss of production due to that plant shutdown. Computerized control systems can be useful in optimizing the maintenance practices of the plant.

ABBREVIATIONS

AVR	Automatic voltage regulator
bara	Bar absolute
BFW	Boiler feedwater
BMS	Burner management system
CEMS	Continuous emissions monitoring system
CRH	Cold reheat
CRT	Cathodic ray tube
DCS	Distributed control system
FGR	Flue gas recirculation
FSNL	Full speed no load
GT	Gas turbine
HP	High pressure
HRH	Hot reheat
HRSG	Heat recovery steam generator
HV	High voltage
IGV	Inlet guide vanes
IP	Intermediate pressure
KJ	Kilojoule
KW	Kilowatt
LP	Low pressure
LV	Low voltage
MP	Medium pressure
MW	Megawatt
PC	Personal computer
OTSG	Once through steam generator
RH	Reheater or reheated
SCR	Selective catalytic reduction
SFC	Static frequency converter
SH	Superheater or superheated
SIF	Safety instrumented function
SIL	Safety integrity level
SOE	Sequence of event recorder
ST	Steam turbine
STIG	Steam injection gas turbine
TOC	Total organic carbon
1oo2D	One out of two with diagnostic
2oo3	Two out of three

Flow sheet symbols

INTRODUCTION

This section describes the basic operation and controls of pumps and pumping stations, while the next section (8.35) concentrates on the optimization of the unit operation of pumping.

This section is divided into three main parts. The first provides a brief discussion of the processes into which the fluid is being transported by the pumps. The second part describes the types of pump designs, including centrifugal, rotary, and positive displacement designs and their basic methods of controls. The third part discusses some aspects of pumping system commissioning and operation.

The general discussion in this section is somewhat abbreviated, because related topics are also covered elsewhere in the handbook. Pumps, pumping stations, and metering pumps are also discussed in Section 7.4, and variable-speed drives in Section 7.10 in Chapter 7 of this volume. In addition, metering pumps are also covered in Section 2.14 in Chapter 2 in the first volume of this handbook.

Some of the pumping system-related terms, abbreviations, and conversion factors are described in Table 8.34a.

THE PROCESS

A pump is a liquid transportation device that must develop enough pressure to overcome the hydrostatic and frictional resistance of the process as it delivers the required fluid. These resistance components are unique characteristics of the process served and can be described by system curves. The system curve of a process relates the pressure (head) required and the amount of fluid flow that is being delivered.

System Curves

The characteristics of the system that is served by a pump or pumping station can be represented by a head-capacity

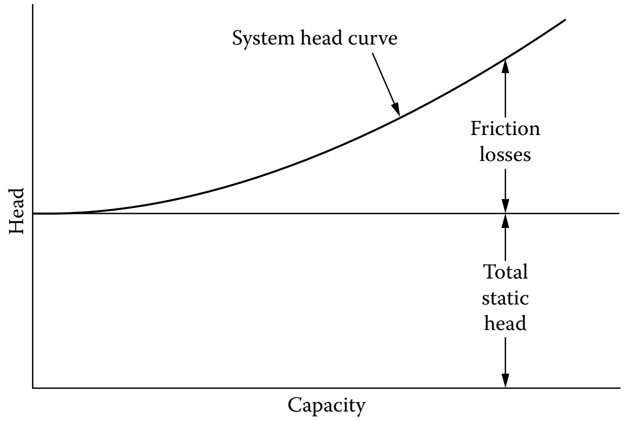

FIG. 8.34b
The system head curve is the sum of the static head and the friction losses that have to be overcome in order to pump liquid into the process.

system curve (Figure 8.34b). The head at any one flow capacity is the sum of the static and the friction heads. The static head does not vary with flow rate, as it is only a function of the elevation or back-pressure against which the pump is operating.

The friction losses are related to the square of flow and represent the resistance to the flow caused by pipe and equipment friction. A system curve tends to be flat when the piping is oversized and steep when the pipe headers are undersized. The friction losses also increase with the age of the plant. Therefore, the system curve for old piping tends to be steeper than for new piping.

A generalized equation describing the system curve of a process is given below:

$$P = H + F_f(Q^x) \qquad \textbf{8.34(1)}$$

where

P is the head pressure required to pump liquid into the process
H is the static or elevation head of the process
F_f is the friction factor of the process
Q is the flow rate of the incompressible fluid
x is an exponent that varies between 1.7 and 2.0, usually 2.0 is used

Static and Friction Pressures Constant static head (H) is the difference in pressure between the pump's intake and its discharge at zero flow, if the discharge piping is full. Usually it is measured between the pump's intake and the discharge side of its check valve, thereby correcting the measurement for any elevation differences between the two.

The constant static head can be the difference in elevation between the piping system's intake and discharge (corrected for liquid density if necessary). If the pump is discharging into a pressurized system such as a potable water distribution network or boiler, it will be the difference between the pump intake pressure and the system's pressure.

In any case, the constant discharge head is the pressure the pump works against when the piping system is full and pressurized, but there is no flow through the pumps' discharge pipes. As its name implies, it is comparatively constant. However, it may change, if for example the pump takes suction from a well and the well level drops, or if pumping to a water storage tower and the water level in the tower rises.

Therefore, the constant discharge head is constant only in relation to variations in one process variable: flow. If other process variables (pressure, temperature, density, level) change, it will be affected; it is not constant.

The friction pressure component in Equation 8.34(1) is the pressure that is lost due to friction between the liquid and the pipe. It includes losses from turbulence in bends and in the conversion of velocity pressure to static pressure in pipe expansions. However, for practical purposes they are combined into a single term.

The value of exponent x in Equation 8.24(1*)* is not critical. However, the controls can be improved by an accurate knowledge of the system curve, so the recommendation is to measure the value of x during commissioning.

Types of System Curves Figure 8.34c illustrates the system curves of three different types of processes. Curve 1 corresponds to the closed-loop circulation of a fluid in a horizontal plane. Here, there is no static head component at all, and the parabola that describes the system starts at zero.

Curve 2 is the system curve for a condenser water circulation network. Here, a limited amount of static head is present, because the pump must return the water to the top of the cooling tower. This curve also illustrates that the friction losses tend to increase when material builds up on the inside of the pipe, because it is no longer new. Curve 3 gives an example of a process dominated by static head. This is the case when feedwater is being pumped into a boiler drum. This curve is flat and is relatively insensitive to changes in system flow.

As will be discussed later in more detail, when the system curve is flat, there is little advantage to variable- or multiple-speed pumping, and the usual response to system flow variations is the stopping and starting of parallel pumps. Inversely, if the system curve is steep, substantial energy savings can be obtained from the use of booster, multiple-, or variable-speed pumps.

Open and Loop-Type Systems Hydraulic systems can be open (noncirculating) or loop-type, as illustrated in Figure 8.34d. Water supply and distribution systems in cities and buildings are typically open systems, whereas hot-and-chilled-water heating and cooling systems of plants are typically loop-type systems.

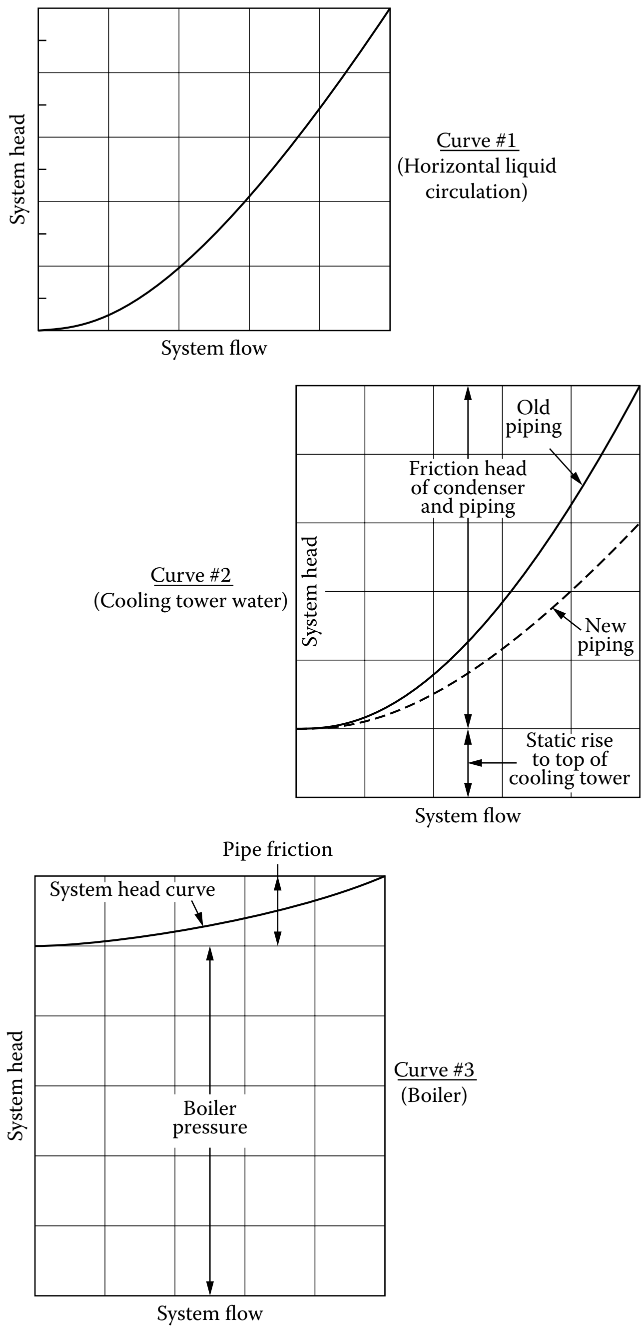

FIG. 8.34c
System curves vary as the static-head components change in various processes. (Adapted from Reference 1.)

Hydraulic systems must also be evaluated as to whether their flow is restricted or unrestricted. Restricted-flow systems are those that include valves that regulate the flow through the system. Hot-and-chilled-water systems, for example, are restricted-flow systems, because manual or automatic valves control their flow. Unrestricted-flow systems include sewage and stormwater lift stations as well as the pumping of municipal water into elevated storage tanks.

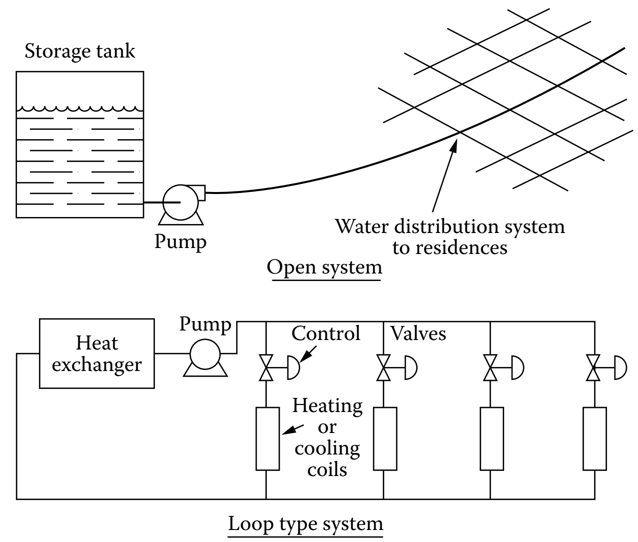

FIG. 8.34d
Pumping systems can be of the open or the loop type.

In actual systems, a single-system head curve may not exist. As illustrated in Figure 8.34e, what often exists is a system head band. This is because the distribution of active loads shifts the system curve within a wide band, as this figure shows.

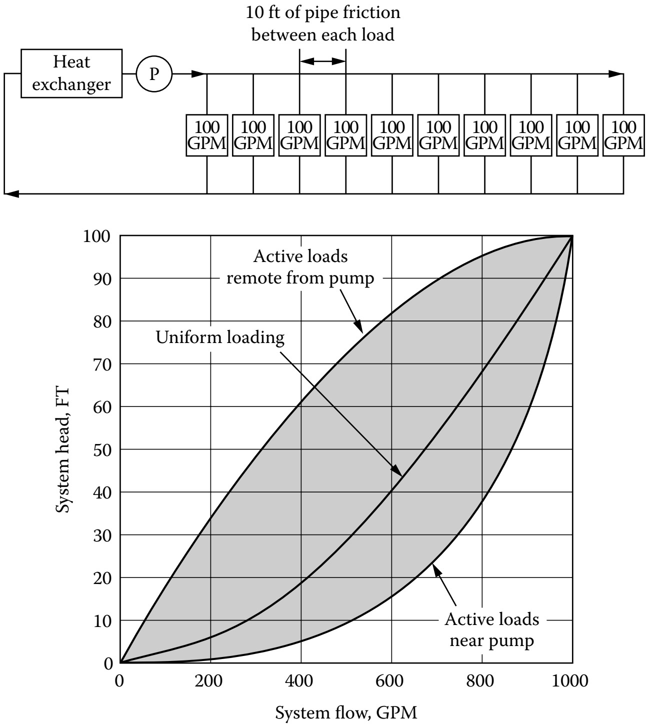

FIG. 8.34e
The system head drops when active loads are near the pump and it rises when the most remote loads are active.[4]

PUMP TYPES

There are many types of pumps; however, almost all flow is pumped by just two types: centrifugal pumps and reciprocating positive displacement (PD) pumps. As a result, this section will focus on these two types, and particularly on centrifugal pumps, which probably pump more flow than all other types combined.

Displacement and Centrifugal Designs

The two main pump designs are the positive displacement and centrifugal pumps. Vertical centrifugal units can pump water from depths up to 2000 ft (600 m), and horizontal units can transport process fluids from clear water to heavy sludge at rates up to 100,000 gpm (6.3 m^3/s). The centrifugal designs are of either the radial-flow or the axial-flow type.

Liquid enters the radial-flow designs in the center of the impeller and is thrown out by the centrifugal force into a spiral bowl. A number of impeller designs are illustrated in Figure 7.4b in Chapter 7. The axial-flow propeller pumps are designed to push rather than throw the fluid upward. Mixed-flow designs are a combination of the two.

In positive displacement pumps, a piston or plunger inside a cylinder is the driving element as it moves in reciprocating motion (Figures 7.4n and 7.4o). The stroke length and, thus, the volume delivered per stroke is adjustable within a 10:1 range. Rangeability can be increased to 100:1 by the addition of a variable-speed drive.

The plunger designs are capable of generating higher discharge pressures than the diaphragm types, because of the strength limitation of the diaphragm. The strain on the diaphragm is reduced if it is not attached directly to the plunger but is driven indirectly through the use of a hydraulic fluid. Because solids will still settle in the pump cavities, these designs are all limited to relatively clean services. For slurry service, the hose-type design is recommended. This design eliminates all the cavities, although the seating of the valves can still be a problem.

Pump Design Variations

If one attempted to give a more-or-less complete list of pump designs, the list would include the following:

Progressing cavity pumps are suitable for pumping liquids with entrained solids that would jam or abrade normal pump components, and liquids with low-shear requirements. The process industries use progressing cavity pumps for chemicals that may crystallize, polymers that need low-shear pumping, and liquids with some entrained solids. Progressing cavity pumps depend on the process liquid for lubrication, and they are easily damaged by low suction pressure. They behave like positive displacement pumps but are considerably less accurate than reciprocating pumps, and their accuracy deteriorates with use, to the 2–5% level.

Peristaltic pumps handle similar liquids as do the progressing cavity designs but are generally more economical in small (ml/s) sizes. The process industries use peristaltic pumps in real-time wet chemistry analyzers that depend on accurately metering small flows.

Gear, lobe, and vane pumps deliver a relatively constant flow at constant speed with large changes in discharge pressure and, therefore, approximate the characteristics of positive displacement pumps. These pumps cover the viscosity range from less than 1 centipoise up to 500,000 centipoises. The usual application of this type of pump is for viscous liquids and slurries that are beyond the capabilities of centrifugal pumps.

Rotary screw pumps are ideally suited for sludge and slurry services, and can safely pump high solids including live fish. A rotary screw pump design is also in development as an artificial heart. Rotary screw pumps behave similarly to centrifugal pumps.

In *lift pumps*, compressed gas, usually air, is blown into the bottom of a submerged updraft tube. The gas bubbles reduce the average density and, therefore, the hydrostatic head inside the tube. As the head is lower on the inside of the tube, the manometer effect induces the surrounding fluid to enter the updraft tube. This is a maintenance-free means of lifting large volumes of slurries over low elevations but is comparatively inefficient if one considers the compressor power required.

The Archimedes Screw is the earliest true pump and is still in use. An advantage of a screw is that it naturally changes its capacity to accommodate changing liquid levels without the complexity of a control system.

Air pumps use compressed air or steam to displace accumulated liquids from tanks (Figure 8.6llll).

Diffuser micropumps are generally specialized for use in small-scale work.

Pumps specialized for high-vacuum work, such as *diffusion and cryogenic pumps.*

CENTRIFUGAL PUMPS

Some centrifugal pumps use centrifugal force to throw liquid radially outward while others, such as propellers, use a screw-type action that results in axial flow. Between these two extremes, there is a whole continuum of impellers that change their pumping action from highly centrifugal radial to axial flow. The line separating centrifugal and axial-flow pumps is vague, and the behavior of these pumps is usually described by the same laws.

Figure 7.4b in Section 7.4 describes a number of impeller designs, including both radial and axial-flow types. Common characteristics of centrifugal pumps are high efficiency (over 90% in case of large pumps); they have only one moving part (the impeller with bearings); they deliver smooth, steady flow; they have a rangeability of about 4:1; and they are relatively insensitive to air-locking, but are susceptible to cavitation.

Vertical centrifugal pumps can lift water from depths of up to 2000 ft (600 m) and horizontal pumps can transport process fluids from clear water to heavy sludge at rates up to 100,000 gpm (6.6 m^2/s). The centrifugal pump is the most common type of process pump, but its application is limited to liquids with viscosities under 3000 centistokes.

Pump Curves

Figure 8.34f illustrates the typical pump curves of a single impeller pump.

Efficiency The typical range of pump efficiencies is from 60 to 85%. Pump efficiency is the ratio of the useful output power of the pump to its input power. Using the symbols defined in Table 8.34a, it is calculated (in both SI and US units) as follows:[2]

$$E_p = \frac{\text{pump output}}{P_i} = \frac{\text{SPQH}_t}{P_i} \text{ (SI units)} \qquad \textbf{8.34(2)}$$

$$E_p = \frac{\text{pump output}}{\text{bhp}} = \frac{\text{SPQH}_t}{\text{bhp} \times 550} \text{ (U.S. customary units)} \qquad \textbf{8.34(3)}$$

where

E_p = pump efficiency, dimensionless
P_i = power input, kW (kN·m/s)
SP = specific weight of water, lb/ft^3(kN/m^3)
Q = capacity, ft^3/s (m^3/s).
H_t = total dynamic head, ft (m)
bhp = brake horsepower
550 = conversion factor for horsepower to ft lb_f/s

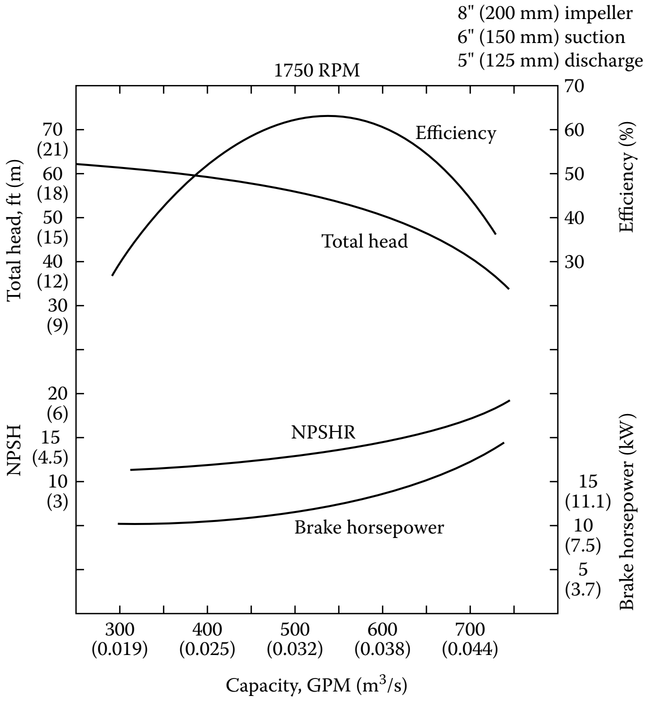

FIG. 8.34f
Typical characteristic curves of a single-impeller centrifugal pump.

Formulas Table 8.34g provides a summary of the more common formulas that can be used in connection with pumping calculations.

TABLE 8.34g
Common Formulas Used in Connection with Pumping Calculation[1]

Formula for	*Conventional Units*	*SI Units*
Head	H = psi × 2.31/SG* (ft)	H = kPa = 9.8023/SG* (m)
Output power	$P_o = Q_v \times H \times$ SG*/3960 (hp)	$P_o = Q_v \times H \times$ SG*/367 (kW)
Shaft power	$P_s = \frac{Q_v \times H \times SG^*}{39.6 \times E_p}$(hp)	$P_s = \frac{Q_v \times H \times SG^*}{3.67 \times E_p}$(kW)
Input power	$P_i - P_s \times 74.6/E_m$ (kW)	$P_i = P_s \times 100/E_m$ (kW)
Equipment efficiency, %	(Constant speed pumps) (Variable speed pumps)	$E_e = E_p \times E_m \times 10^{-2}$ $E_e = E_p \times E_m \times E_v \times 10^{-4}$
Utilization efficiency, %	Q_D = design flow Q_A = actual flow H_D = design head H_A = actual head	$E_u = \frac{Q_D \times H_D}{Q_A \times H_A} \times 100$
System Efficiency Index [see Eq. 8.34 (4)]		SEI = $E_e \times E_u \times 10^{-6}$

*SG = specific gravity

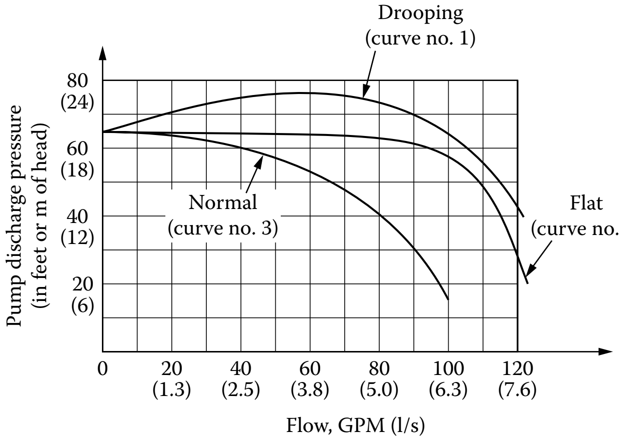

FIG. 8.34h
The centrifugal pump's curve can be drooping (1), flat (2), or normal (3).

Characteristic Pump Curves The head-capacity curve is the operating line for the pump at constant speed and impeller diameter. The characteristic curve of a pump describes the variation of its discharge pressure with volumetric flow. The discharge pressure is the total of the velocity and static pressures.

Three types of head-capacity curves are shown in Figure 8.34h, illustrating various relationships of capacity to discharge pressure. The capacity varies widely with changes in discharge pressure for all curves, but the shape of the curve determines the type of control that may be applied.

The shape of the head-capacity curve is an important consideration in pump selection. Curve 1 is referred as a *drooping* curve, curve 2 is called a *flat* curve, and curve 3 would be considered *normal*. For on/off switching control, curves 1 and 2 are satisfactory as long as the flow is above 100 gpm (6.3 l/s). Below this flow rate, curve 1 allows for two flows to correspond to the same head, and curve 2 may drop to zero flow to obtain a small head increase. Both are, therefore, unstable in this region. Curve 3 is stable for all flows and is best suited for throttling service in cases in which a wide range of flows is desired.

Matching the Pump(s) to the Process Figure 8.34i shows both the head-capacity curve of a centrifugal pump and the system curve of a process. When such a system is uncontrolled, the operating point of the system will be the point at which the pump and system curves cross each other.

If the process flow is controlled, a new system curve has to be artificially generated. This can be done 1) by generating a new system curve through the introduction of extra pressure drop in a control valve, or 2) by changing the pump curve through changing the pump speed. Figure 8.34j illustrates the case where a particular process flow is established by throttling a valve and, thereby, changing the unthrottled (solid) system curve into a throttled system curve (dotted).

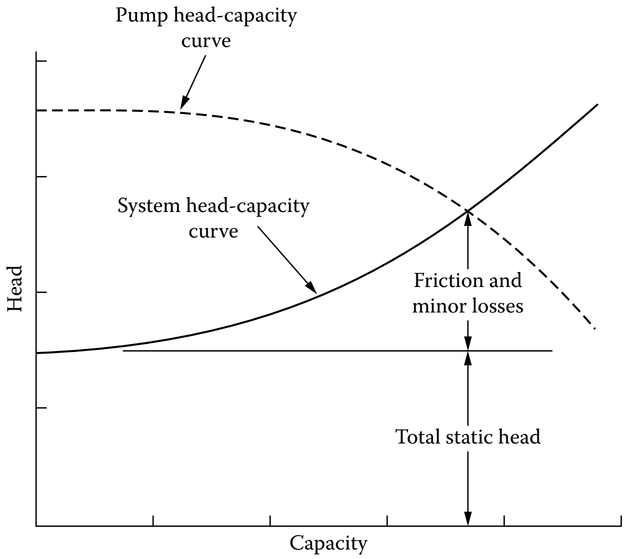

FIG. 8.34i
The system curve crosses the pump curve at the operating point.

Throttling with a control valve makes the apparent pump curve steeper, so that it will cross the system curve at the desired flow (operating point). This modification occurs at the cost of introducing an artificial pressure drop of ($H_p - H_s$), which burns up pumping energy and, therefore, reduces operating efficiency. In addition to that energy waste, the pump will also operate in a less-efficient region, as shown in Figure 8.34k by the throttled operating point #1 (72%) and the unthrottled operating point #2 (80%).

Adjusting the Pump Speed

The affinity laws describe the relationships among changes in speed, impeller diameter, and specific gravity. With a given impeller diameter and specific gravity, pump flow is linearly proportional to pump speed, pump discharge head relates to

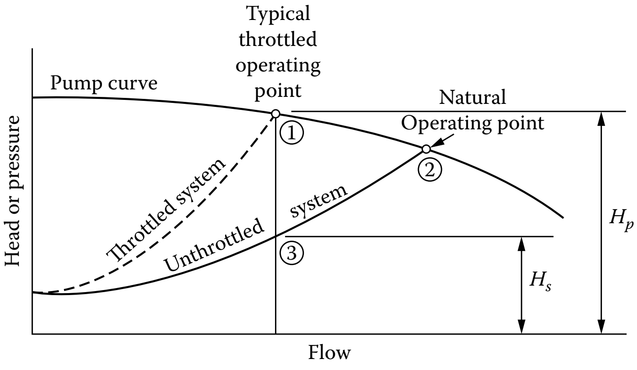

FIG. 8.34j
The addition of a control valve allows the control of flow at the cost of added pressure drop (wasted energy).

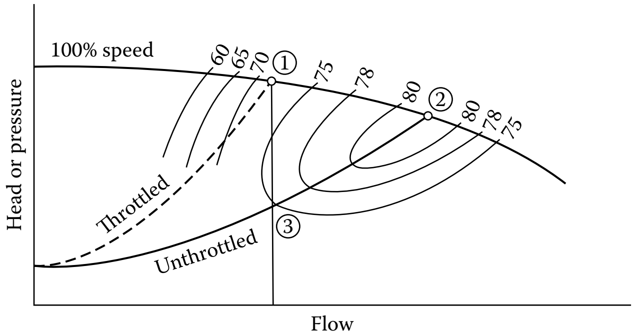

FIG. 8.34k
The throttled system not only wastes pumping energy through valve pressure drop but also operates at a less efficient point on the pump curve.

(approximately) the square of pump speed, and pump power consumption is proportional to the cube of pump speed.

As shown in Figure 8.34l, one can plot the system curves and the variable speed pump curves on a three-dimensional plot (a-pressure, b-flow, c-speed). On such a plot the system curves form one surface (surface A), and the pump curves form another characteristic surface (surface B). This then illustrates how the intersection of surfaces A and B is the operating line on which the variable-speed pump operates. (Section 8.35 will discuss the mathematical definition of the characteristic operating surfaces of pumps.)

Flow control via pump speed adjustment is less common than the use of throttling with valves, because most AC electric motors are constant-speed devices. If a turbine drive is considered, speed control is even more convenient. However, the advent of the pulse-width modulated (PWM) adjustable-speed drive with sensorless flux-vector control has brought adjustable-speed pumping into the mainstream of everyday applications.

In order to vary pump speeds with electric motors, one of the variable-speed drives described in Section 7.10 in Chapter 7 should be used. The efficiency curves (wire-to-shaft efficiencies) of the various variable-speed drives that are used on centrifugal pumps are shown in Figure 7.10z.

Variation of the pump speed generates a family of head-capacity curves, as shown in Figure 8.34m. If the impeller diameter is constant, the volumetric flow through the pump is proportional to its speed, and at reduced speeds, family of speed curves determines the flow rate (points 1, 2, or 3).

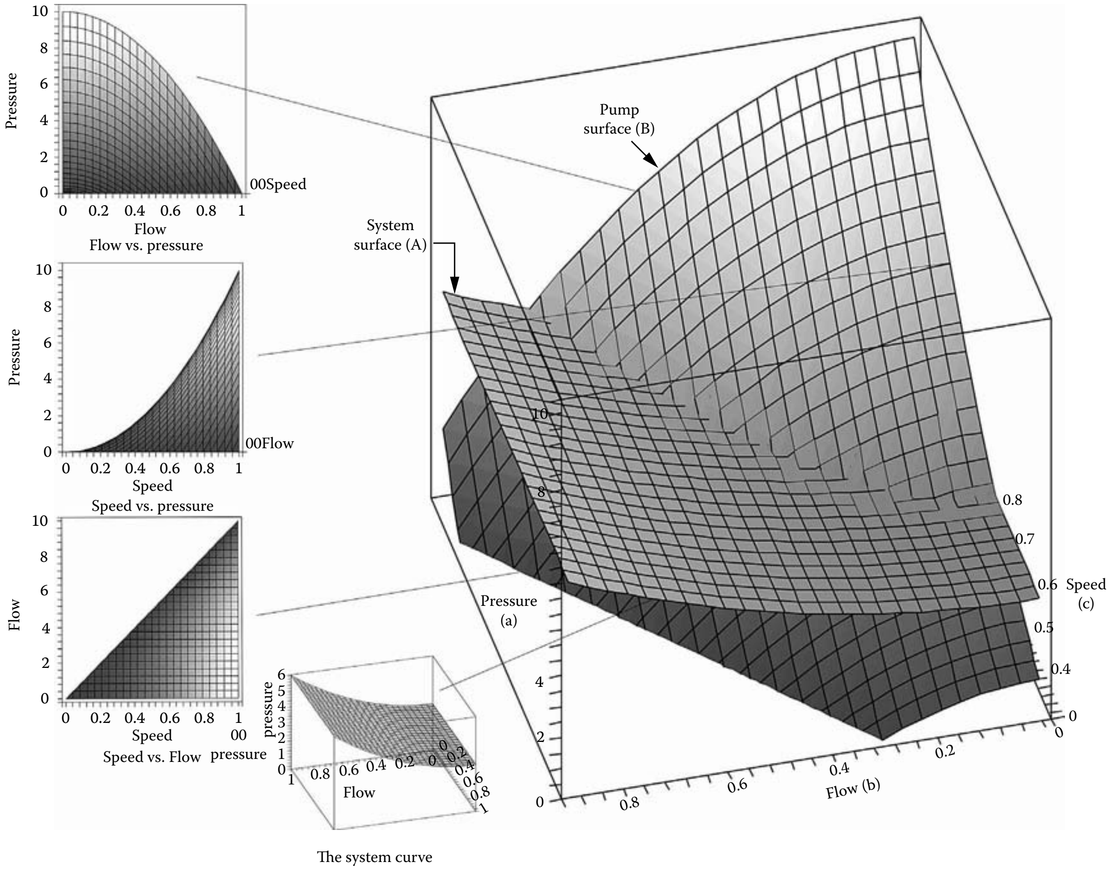

FIG. 8.34l
The variable-speed pump operates on the line where the surface formed by the system curves (A) intersects with the surface formed by the pump curves (B).

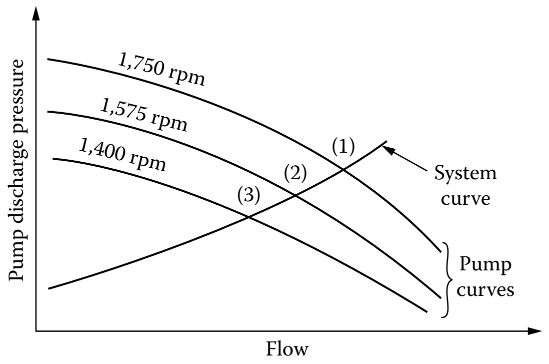

FIG. 8.34m
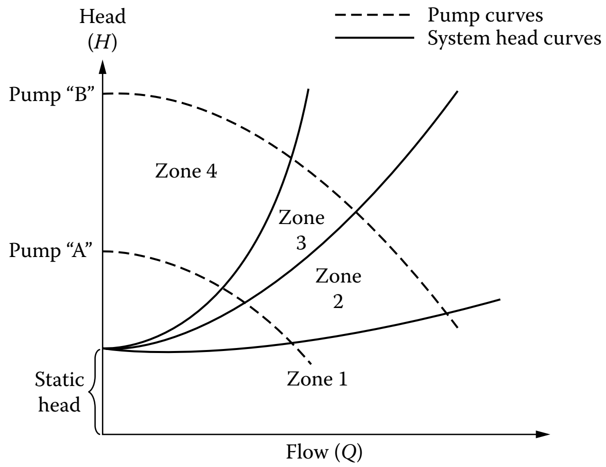
Variable-speed pump operation can be described by a family of head-capacity curves.

Because the area of peak pump efficiency falls on a parabolic path, speed throttling will usually not reduce the pump efficiency as much as valve throttling (Figure 8.34k). This increases the total energy savings obtained from pump speed control. As shown in Figure 8.34n, when the flow is reduced from F_1 to F_2, instead of wasting the excess pump head of $(P_1 - P_2)$ in pressure drop through a valve, that pump head is not introduced in the first place. Thereby, speed throttling saves the energy that valve throttling would have wasted.

When to Use Variable-Speed Pumps The shape of the system curve determines the saving potentials of using variable-speed pumps. As has been discussed, all system head curves are parabolas ($H \sim Q^2$), but they differ in the steepness of these curves and in the ratio of static head to friction drop. As shown in Figure 8.34o, the value of variable-speed pumping increases as the system head curve becomes steeper.

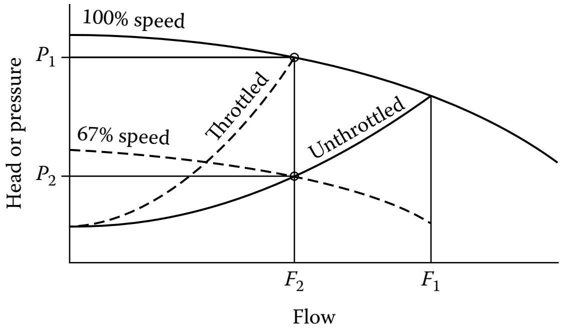
Studies indicate that in *mostly friction* systems (such as zone 4 in Figure 8.34o), the savings represented by variable-speed pumping will increase with reduced pump loading.[7] If, on the yearly average, the pumping system operates at not more than 80% of design capacity, the installation of variable-speed pumps can result in a payback period of approximately 3 years.



Zone	H_t/H_S	Pump sizes	Pump drives
1	< 1.2	Same	Constant
2	< 1.5	Various	Constant
3	< 2.0	Same	One variable
4	> 2.0	Various	All variable

FIG. 8.34o
Pumps and drives should be selected as a function of the steepness of the system curve.

The zones in Figure 8.34o are defined by the H_t/H_s ratio. The higher this number, the higher the zone number and the more justifiable is the use of variable-speed pumps. Figure 8.34p illustrates how the H_t/H_s ratio is calculated. The shaded areas identify the energy-saving potentials of variable-speed pumps. The values of H_t and H_s are identified on the basis of the average yearly flow rate (F_a) and determining its intersections with the pump and system curves. The larger the shaded area in Figure 8.34p, the higher the H_t/H_s ratio will be and, therefore, the shorter the payback for the use of variable-speed pumps is likely to be.



Speed, %	*Flow, %*	*Horsepower required, %*
100	100	100
90	90	73
80	80	51
70	70	34
60	60	22
50	50	13
40	40	6
30	30	3

FIG. 8.34n
Instead of wasting the unnecessarily introduced pump energy, speed is reduced so that such energy is not introduced in the first place.[6]

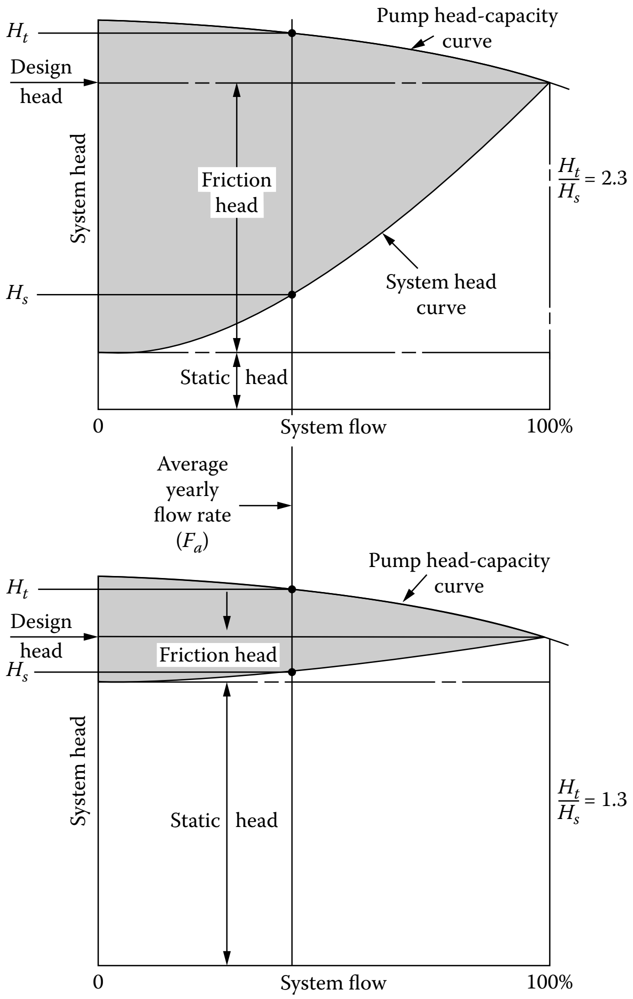


FIG. 8.34p
The higher the Ht/Hs ratio, the more justifiable is the use of variable-speed pumps.

Variable-Speed System Efficiencies The overall system efficiency index (SEI) of a variable-speed pump installation is determined as follows:

$$\text{SEI} = (E_p \times E_m \times E_v \times E_u)10^{-6} \qquad \textbf{8.34(4)}$$

where

E_p = the pump efficiency (%)
E_m = the motor efficiency (%)
E_v = the variable-speed drive efficiency (%)
E_u = the efficiency of utilization (%)

Figure 7.10z gave some typical wire-to-shaft efficiency values for variable-speed drives (E_v). The efficiencies of the variable-speed drives are represented as ranges, because each design has a different efficiency. Figure 8.34q provides some individual efficiency data for a number of variable-speed drive designs.

At 50% of rated speed, the variable-speed drive efficiency can be as low as 40% or as high as 70%, depending on the design selected. Naturally, the less efficient the variable-speed drive, the less expensive it is. Table 8.34r provides some cost information for variable-frequency induction motor drives.

The efficiency of utilization (E_u) is an indicator of the quality of the overall piping and equipment design. For example, in the piping distribution system illustrated in Figure 8.34s, Q_r might represent the required water flow and H_r the required pressure head to transport Q_r. Because three-way valves are used in this illustration, the actual flow (Q_a) is much higher than the required flow, and the head required to transport this actual flow (H_a) is also greater than what is required.

Therefore, the efficiency of utilization, which is defined in Equation 8.34(5), will also be rather low for the design described in Figure 8.34s.

$$E_u = \frac{Q_r H_r}{Q_a H_a} 100 \qquad \textbf{8.34(5)}$$

The numerical value of E_u can be accurately obtained only by testing. Once all four efficiencies are determined, they can be represented by a single system efficiency index curve (Figure 8.34t). By combining different pumps, motors, drives, and system designs, it is possible to arrive at a number of SEI curves. The relative advantages of different devices and designs can be evaluated quantitatively by comparing these curves.

Types of Variable-Speed Drives Section 7.10 in this volume provides a detailed description of the various variable-speed drive designs, their features including efficiencies, and costs. Table 8.34u provides a summary of some of the main features of these variable-speed drives.

Two-Speed Pumps Two-speed motors can be utilized on simple pumping systems in which accurate control of pump pressure is not necessary. Such motors should not be used in systems with high static head and low friction processes. On the other hand, for most friction systems, they can offer a reasonably efficient and inexpensive alternative to variable-speed pumping. As shown in Figure 8.34v, standard two-speed motors are available with speeds of 1750/1150 rpm (29/19 r/s), 1750/850 rpm (29/14 r/s), 1150/850 rpm (19/14 r/s), and 3500/1750 rpm (58/29 r/s).

Cavitation

Cavitation can be a severe problem; it can quickly destroy a pump. The cause of cavitation is that the pumped liquid flashes to vapor at one point in the impeller (where pressure is below the vapor pressure), and as the spinning impeller throws the liquid and vapor outward, the formed bubbles collapse as the pressure rises above the vapor pressure. When the collapsing bubbles come to the wall, they collide with extreme force. This gives rise to the characteristic sound of

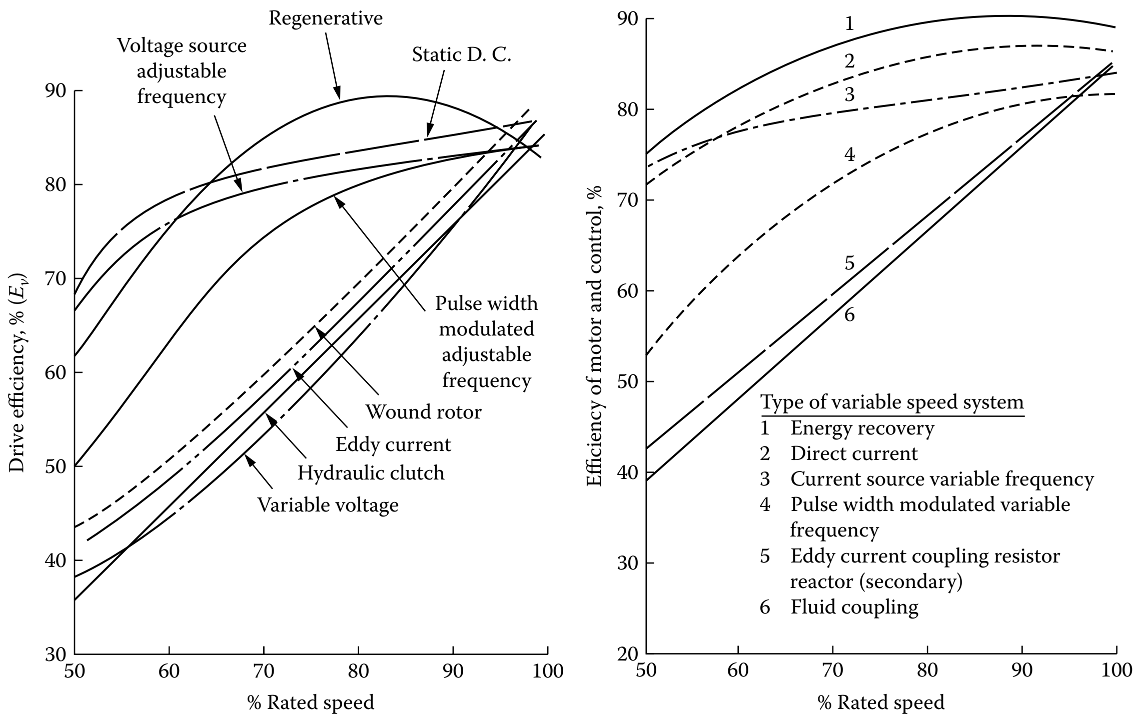

FIG. 8.34q
Variable-speed drives in the 100-HP and larger sizes offer a wide range of efficiencies.[9,10]

cavitation, and also to the consequent erosion, usually of the impeller.

For this reason, it is important to operate pumps only in their operating region where cavitation does not occur. Cavitation usually occurs when the pump is delivering high flow, but some pumps cavitate at low flow too, when liquid recirculating in the impeller passes through points of both low and high pressures (Figure 8.34w).

When one does not have reliable data on the locations of cavitation regions, it might be necessary to (very briefly) force the operating pump into cavitation intentionally. A practical way to force a pump to cavitate is to run it at or above design speed and then to restrict its intake gradually. Cavitation has a very characteristic and memorable sound that has been described as rocks rolling around inside the pump, or hammering on the impeller.

If a pump cavitates, one might try to eliminate or minimize the cavitation by improving inlet conditions. Just as restricting the inlet will force a pump into cavitation, so removing restrictions will often stop cavitation. Reducing the flow range of the pump usually helps also. If the pump cavitates at high flows, try to avoid those flows, possibly by starting a second pump sooner. If cavitation occurs at low flows, one might turn off the pump at low flows, based on some on/off flow control strategy.

Some impellers can accept a part, called an *inducer*, that reduces the pump's susceptibility to cavitation. An extreme option is to inject a compressible gas into the impeller. This reduces pump efficiency and capacity, but it can eliminate cavitation, because the gas acts as a spring inside the liquid, absorbing the drastic localized pressure changes, and so avoiding the pressure extremes that the pure liquid would experience.

However, cavitation is mainly a design concern and should be dealt with during design by ensuring that ample pressure is available around the impeller.

TABLE 8.34r
2004 Cost of Variable-Frequency Induction Motor Drives

Power Rating	*PWM Including Reactor*	*Current-Fed ASCI*
10 hp (7.5 kW)	$1,700	
20 hp (15 kW)	$2,500	
50 hp (37 kW)	$5,300	
100 hp (75 kW)	$7,500	$8,000
200 hp (150 kW)	$11,000	$12,000
500 hp (375 kW)		$18,000
1000 hp (750 kW)		$32,000

Note: The reactor price adds 50–90% to the base price of the variable-frequency drive electronics.

Net Positive Suction Head

When liquids are being pumped, it is important to keep the pressure in the suction line above the vapor pressure of the

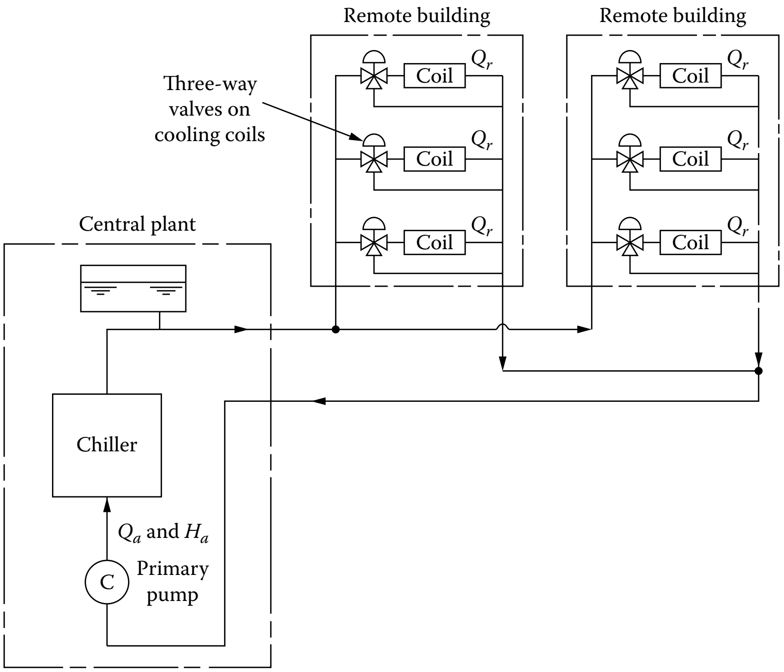

FIG. 8.34s
The efficiency of utilization of this design is low, because the water that is bypassing the coils is being circulated unnecessarily.[11]

fluid. The available head measured at the pump suction is called the *net positive suction head* (NPSH).

A pump at sea level that is pumping 60°F water, which has a vapor pressure of $h_{vp} = 0.6$ ft, and that is operating under a barometric pressure of 33.9 ft, has an available NPSH (NPSHA) of $33.9 - 0.6 = 33.3$ ft. If the impeller centerline is 3.4 ft below the surface elevation of the water being pumped and if the friction losses in the intake piping is 5.3 ft W.C, the NPSHA is $33.9 - 0.6 + 3.4 - 5.3 = 31.4$ ft. As shown in Figure 8.34x, the NPSHA increases with barometric

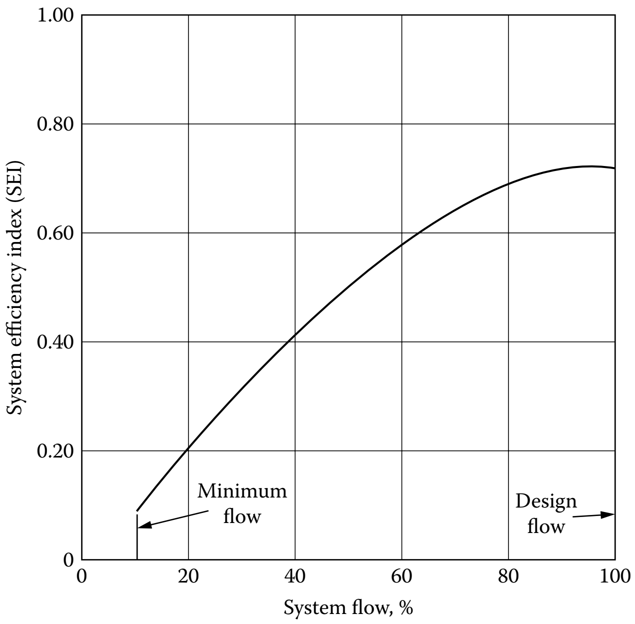

FIG. 8.34t
Overall system efficiency index (SEI) curves describe the total pumping efficiency as a function of load.[1]

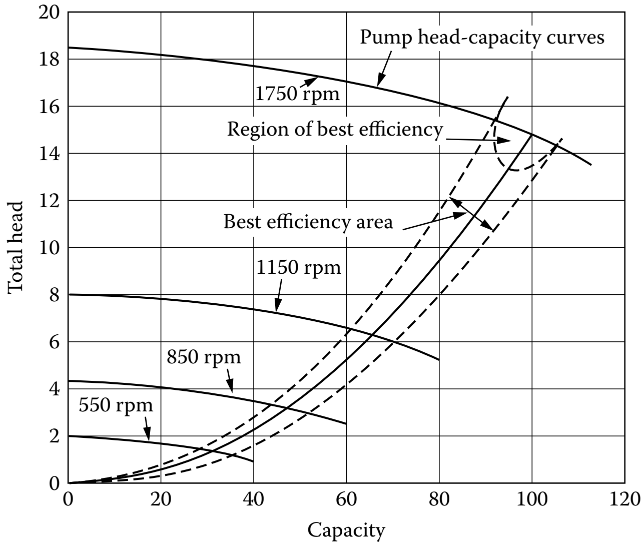

FIG. 8.34v
Several speed combinations are available in two-speed pumps.[1]

pressure and with static head, and it decreases as vapor pressure, friction, or entrance losses rise.

Figure 8.34x also illustrates the difference between *available* and *required* NPSH (NPSHA and NPSHR). Available NPSHA is the characteristic of the process and represents the difference between the existing absolute suction head and the vapor pressure at the process temperature. The required NPSHR, on the other hand, is a function of the pump design (Figure 8.34f). It represents the minimum margin between suction head and vapor pressure at a particular capacity that is required for pump operation. If this minimum NPSHR is not available, the pump will fail to generate the required suction lift and the flow will stop.

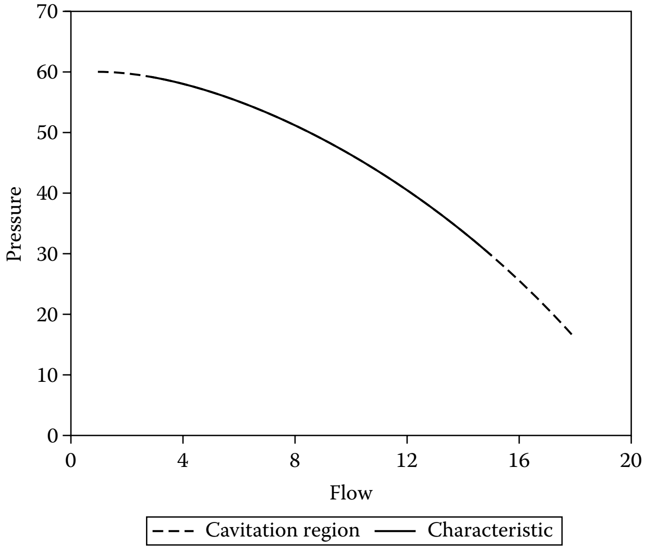

FIG. 8.34w
The dashed segments of the characteristic pump curve show the zones where the regions of cavitation might exist.

The *NPSHR* curve in Figure 8.34f describes the required amount of static head at the pump inlet required to avoid a discharge pressure from dropping more than 3% over the zero-cavitation condition (source of definition: ANSI/HI 9.6.1-1998, Paragraph 9.6.1.1). NPSHR is defined in absolute pressure, and typically for water at 0°C unless otherwise stated.

The available NPSH (the *NPSHA*) increases as 1) the barometric pressure increases, 2) the static pressure of the liquid at the entrance of the impeller, and 3) all other suction-side pressures increase. The NPSHA decreases as 1) the vapor pressure of the liquid increases, 2) friction or entrance losses rise, and 3) all other suction-side pressures decrease.

NPSH and Cavitation Traditionally, the NPSHR curve has been taken to define the onset of cavitation, and designers have concentrated on ensuring that the NPSHR is met under all operating conditions (Figure 8.34x). However, the accuracy of the NPSHR curve in defining the point when cavitation becomes significant is being questioned.

Indications are that cavitation actually begins sooner than previously believed. Allan Burdis (chairman of the Hydraulic Institute's NPSH Margin Committee) writes: "If you want to operate cavitation-free, you need NPSH margin ratios (NPSHA/NPSHR) of 4 to 5." Some evidence suggests that cavitation damage at NPSHA = NPSHR is actually less than the damage when the NPSHA is higher. The Hydraulic Institute's standard report reads: "There are studies that show the maximum cavitation damage can actually occur at NPSHA values that are twice the NPSHR or more for very high suction energy pumps."

Therefore, we might conclude that the science of cavitation prediction on the basis of NPSHA is still evolving, and if one wants to be positive, actual cavitation testing can be necessary.

Water Hammer

If a valve opening is suddenly reduced in a moving water column, this causes a pressure wave to travel in the opposite direction to the flow. When this pressure wave reaches a solid surface (elbow, tee, and so on), it is reflected and travels back to the valve. If, in the meantime, the valve has closed, a series of shocks, sounding like hammer blows, results. An example can illustrate this phenomenon.

Assume that 60°F (20°C) water is flowing at a velocity of 10 ft/s in a 3 in. Schedule 40 pipe, and a valve located 200 ft downstream is suddenly closed. The pressure rise and the minimum acceptable time for valve closure can be calculated. If the valve closes faster than this time limit, water hammer will result. In rigid pipe, the pressure rise (ΔP) is the product of water density (ρ in units of slugs/ft^3), the velocity of sound (c in units of ft/s), and the change in water

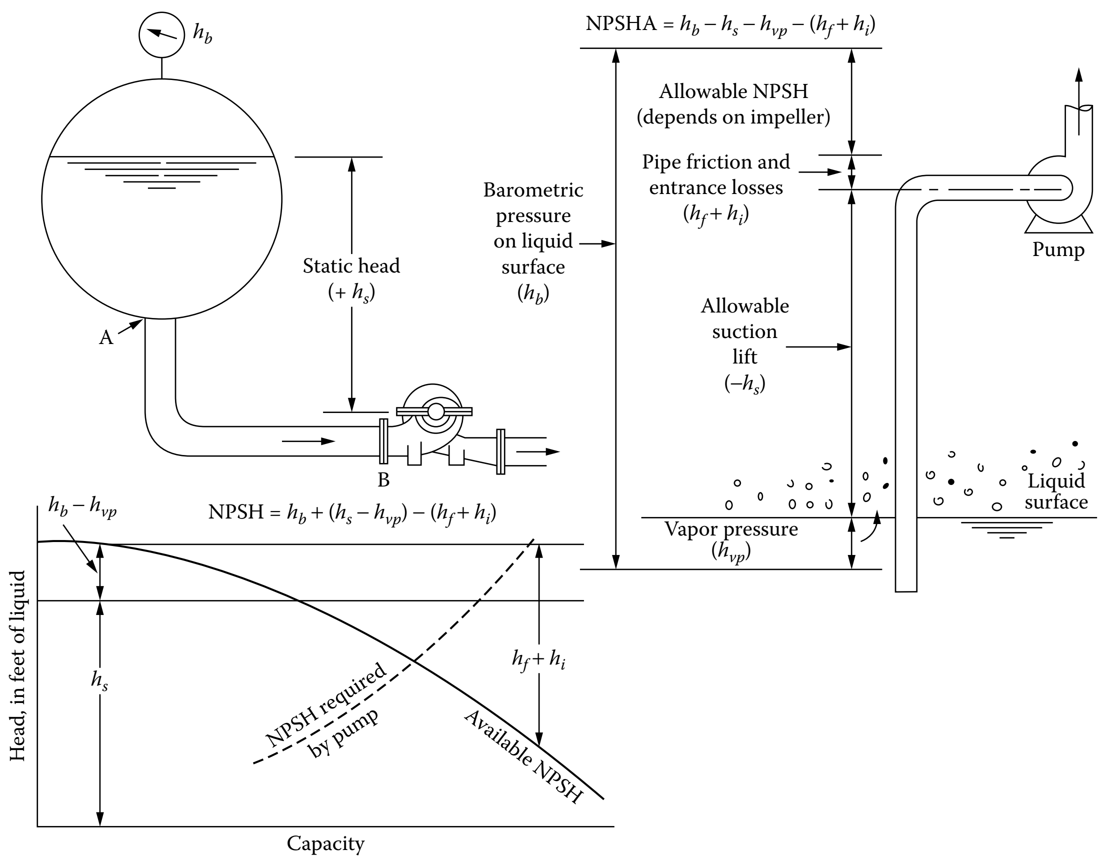

FIG. 8.34x
The available net positive suction head (NPSHA) increases with barometric pressure and static head, and decreases as vapor pressure, friction or entrance losses rise. (Adapted from Reference 3.)

velocity (ΔV in units of ft/s).[12] Therefore, the pressure rise can be calculated as follows:

$$\Delta P = -\rho c\,\Delta V = -(1.937)(4860)(-10)$$
$$= 94{,}138\ \text{lbf/ft}^2 = 653.8\ \text{PSI} \qquad \mathbf{8.34(6)}$$

In order to prevent water hammer, the valve closure time (t) must exceed the ratio of two pipe lengths ($2L$) divided by the speed of sound:

$$t = 2L/c = (2)(200)/4860 = 0.0823\ \text{seconds} \qquad \mathbf{8.34(7)}$$

Therefore, in this example, the valve closure should take more than 0.0823 sec.

The possible methods of preventing water hammer include (1) designing the system with low velocities, (2) using valves with slow closure rates, and (3) providing slow-closing bypasses around fast-closing valves, such as check valves.[15]

When water hammer is already present and the cause of it cannot be corrected, its symptoms can be treated (1) by adding air chambers, accumulators, or surge tanks; (2) by using surge suppressors, such as positively controlled relief valves; and (3) when water flows are split or combined, by using vacuum breakers to admit air and thereby cushion the shock resulting from the sudden opening or closing of the second split stream.

Pump Stations

When either the flow or the pressure requirements of the process are such that a single pump cannot meet them, pump stations consisting of two or more individual pumps have to be used. Multiple pumps operate in parallel and are used if the process flow rangeability exceeds the throttling capability of a single pump. Booster pumps are installed in series and are used to increase the total discharge pressure of the station.

Multiple Pumps in Parallel Individual centrifugal pumps have a rangeability of about 4:1, which can be obtained by either speed control or by discharge throttling. Pump turndown can be increased by 1) bypassing the unwanted flow, 2) turning the pump on and off, and 3) using multiple pumps.

When two or more pumps operate in parallel, the combined head-capacity curve is obtained by adding up their individual capacities at each discharge head, as illustrated in

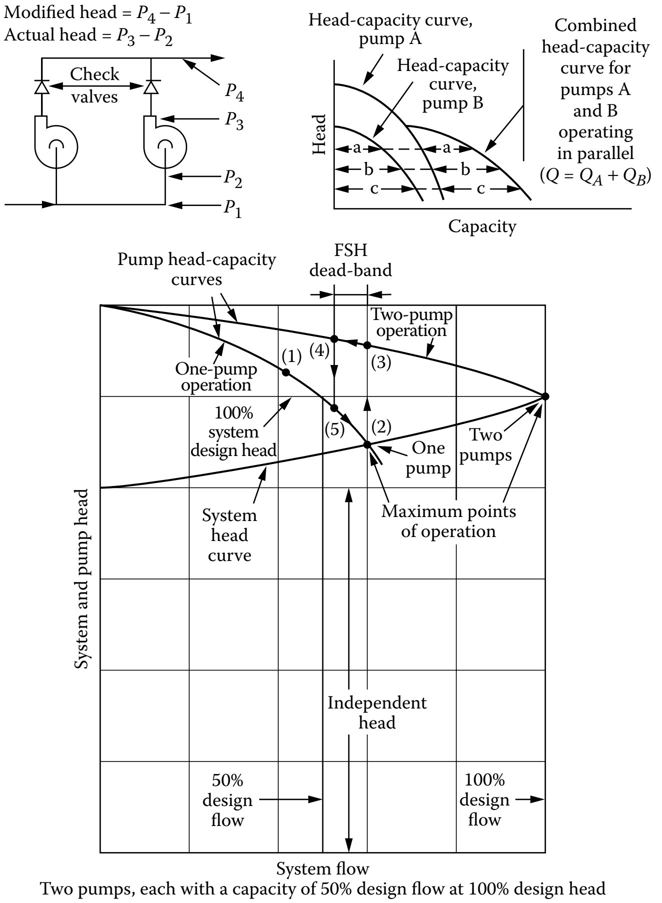

FIG. 8.34y

Pump turndown and rangeability can be increased by operating two or more pumps in parallel.

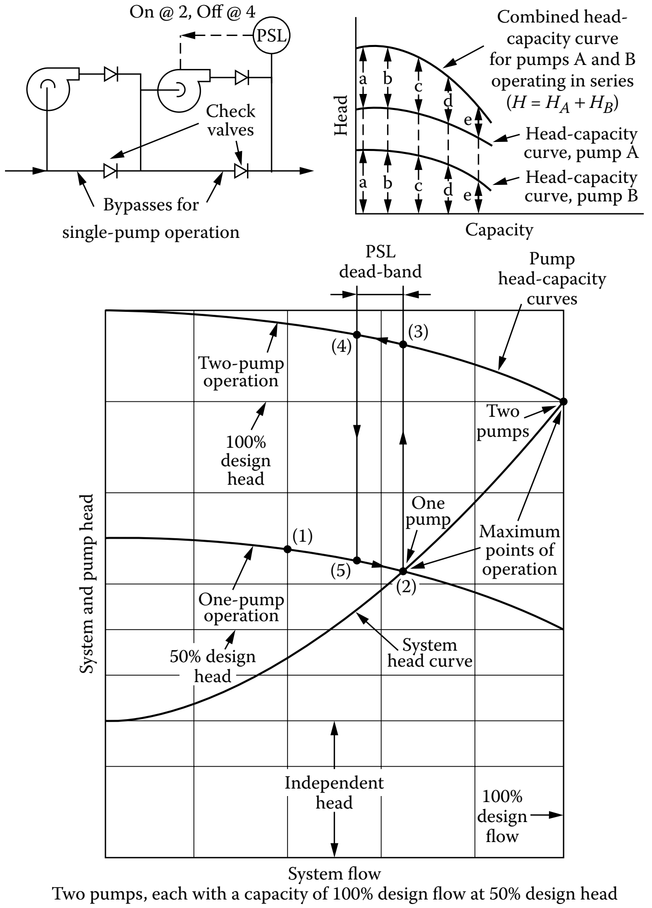

FIG. 8.34z

Multiple pumps in series are effective when the system head curve is steep. The two pumps illustrated by the lower graph are each capable of generating 100% design flow at 50% design head.[1,2]

Figure 8.34y. The total capacity of the pump station is found at the intersection of the combined head-capacity curve with the system head curve. This point also gives the head at which each of the pumps is operating.

If the selection is to be very accurate, the head-capacity curves should be modified by substituting the station losses (the friction losses at the suction and discharge of the individual pumps) so that the resulting "modified head" curve will represent the pump plus its valving and fittings.

When constant-speed pumps are used in parallel, the added increments of pumping can be started and stopped automatically on the basis of flow. As will be discussed later, a dead band is provided in these controls so that if a new pump is started at flow "*x*," the flow will have to drop to, say, "*x*–5%" before that increment is stopped.

Booster Pumps When two or more pumps operate in series the total head-capacity curve is obtained by summing up the pump heads at each capacity. When a booster pump is added to a main fed by several *parallel* pumps, the total head-capacity curve is obtained by adding the booster curve to the modified head of the parallel pumps at each capacity point.

Series pumping is most effective when the system head curve is steep, such as in Figure 8.34z. With such mostly friction loads, series pumping can substantially reduce the overpressure at low loads. Therefore, booster pumps or two-speed pumps can both be considered for the same kind of steep system curves. Multiple pumps in series are preferred from an operating cost point of view, but the capital cost investment of a single two-speed pump is lower.

When constant-speed pumps are used, the booster pump can be started and stopped automatically on the basis of pressure. In this case, an adjustable dead band is provided in the pressure switch. As an example, the normal operating point of the system can be point (1) in Figure 8.34z. As the load increases, the pump discharge head drops and when it reaches point (2) (the set point of the PSL), the booster pump is automatically started. As soon as the booster is on, the system operates at a point to the right of point (3) until the load drops off again.

The booster pump stays on as the load drops below point (3) until the PSL turns it off at point (4). At this point, the system is automatically returned to the single pump operation at point (5). The dead band in the PSL prevents the on/off cycling of the booster pump at any particular load. The width of the dead band is a compromise: As the band is narrowed, the probability of cycling increases, while the widening of the band results in extending the periods during which the booster is operated unnecessarily. If the pumps are identical, their running times can be equalized by alternating them, so that the pump with the higher running time will be the one that is stopped first.

POSITIVE DISPLACEMENT PUMPS

Reciprocating pumps, such as the piston and diaphragm types, deliver a fixed volume of fluid per stroke. The control of these pumps is based on changing the stroke length, changing the stroke speed, or varying the interval between strokes. In all cases, the discharge from these pumps is a pulsed flow, and for this reason they are not suited to control by throttling valves. In practice, the volume delivered per stroke is less than the full stroke displacement of the piston or diaphragm.

This hysteresis is a result of high discharge pressures or high viscosity of the fluid pumped. Under these conditions, the check valves do not seat instantaneously. A calibration chart must, therefore, be drawn for the pump under actual operating conditions. A weight tank or level-calibrated tank is usually the reference standard. Because the discharge is a pulsed flow (Figure 8.34aa), it must be totalized and divided by the time interval to get average flow rate for a particular speed and stroke setting.

Metering inaccuracy is approximately ±1% of the actual flow with manual adjustment and ±1.5% with automatic positioning. Methods of stroke and speed adjustment are covered in detail in Section 7.4 in Chapter 7, and other features of metering pumps are discussed in Section 2.14 in Chapter 2 in the first volume of this handbook.

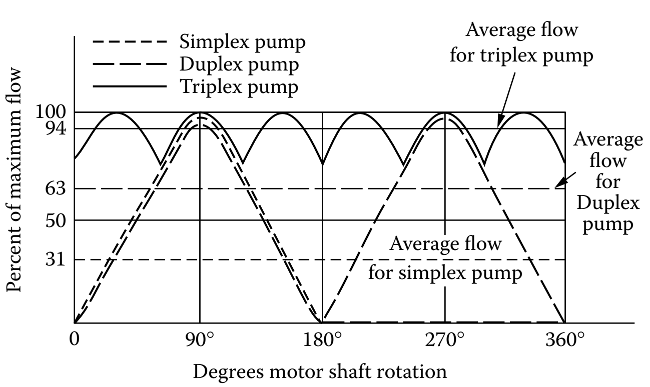

FIG. 8.34aa
Flow characteristics of simplex and multiple plunger pumps.

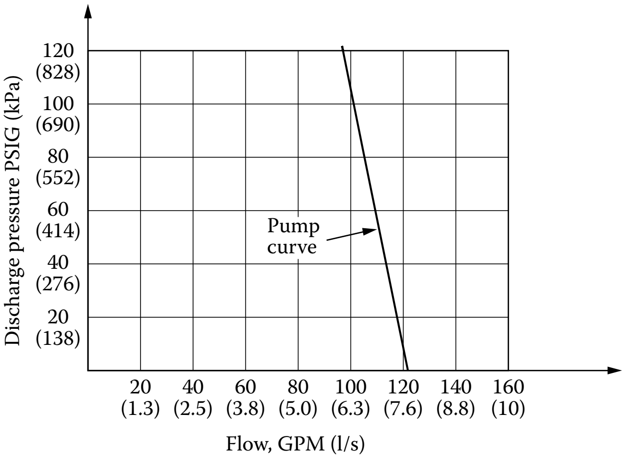

FIG. 8.34bb
The characteristic curve of a positive displacement (PD) pump operating at constant speed and stroke.

Reciprocating Pumps

Reciprocating pumps have a piston or plunger driving element inside a cylinder; the piston moves in and out, in a reciprocating motion (see Figures 7.4n and 7.4o). Liquid is sucked into the pump as the piston moves in, and is forced out as the piston moves out. The liquid flows through one-way valves on the intake to allow flow only into the pump, and on the discharge only to allow it out.

The reciprocating piston action results in each stroke displacing a positive, fixed volume of liquid almost regardless of pressure, hence the name. Figure 8.34bb shows a typical PD pump's flow-to-pressure characteristic. The main feature of this characteristic is that it is essentially constant-flow: The pressure varies greatly while the flow varies very little.

Many reciprocating PD pumps allow the stroke length to be adjusted, to change the pumping rate at constant speed, over a 10:1 range. Manufacturers offer higher stroke ranges, and theoretically they could adjust the stroke down to zero, but accuracy tends to decrease at low strokes, because of fixed losses such as valve leakage.

PD pumps normally develop higher pressures than centrifugal pumps, and their flow is generally unaffected by discharge pressure, which makes them well-suited to metering applications. They can handle higher viscosity liquids than centrifugal pumps, and they can also handle slurries, but they usually do not handle large entrained solids, as many centrifugal pumps can (Figure 8.34cc).

Liquid compressibility can become a consideration at extremely high pressures, so that volume flow (gpm, m^3/s) reduces slightly more than mass flow (lb/min, kg/s). PD pumps are usually considerably less efficient than centrifugal pumps except in high-head applications, so that large PD pumps are far less common than large centrifugal pumps.

Some PD pump assemblies have multiple pumps on a single shaft. This design is normally used to pump reagents

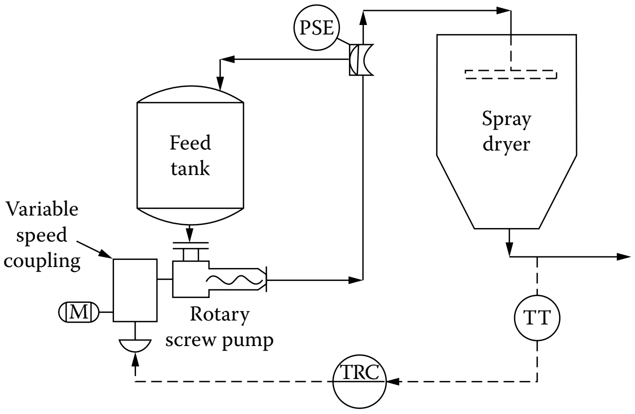

FIG. 8.34cc
When PD pumps are transporting slurries, it is advisable to use rupture discs to protect against the development of excessive discharge pressures.

or ingredients that need to be in a specific ratio. Operators adjust the individual pumps so that their volumes per stroke are precisely in the ratio required, then the pumps are driven by a common shaft so that they all run at the same speed and, thus, deliver flow in a specific ratio.

Because flow is essentially independent of pressure, PD pumps that operate against a closed discharge (closed isolation valve, blocked pipe, and so on) can develop very high discharge pressures that damage the equipment. For this reason, they often are provided with a pressure relief valve, or in applications with highly viscous liquids and slurries, possibly with a rupture disc to relieve the excessive pressures, back to the pump inlet or the intake source.

A PD pump's high pressure applies equally to the suction side of the pump. Vacuum pressure can damage a PD pump, although this is only common in progressing cavity pumps, where an internal vacuum pressure tends to delaminate the flexible stator seal from the rigid stator support. Vacuum pressure can also damage piping and flexible metal couplings.

NPSH and Cavitation It is important to keep the NPSH above 10 psia (69 kPa) or preferably above atmospheric. NPSH can be calculated as follows:

$$\text{NPSH} = P - P_v \pm P_h - \sqrt{\left(\frac{lvGN}{525}\right)^2 + \left(\frac{lvC}{980Gd^2}\right)^2} \qquad \textbf{8.34(8)}$$

where

P = feed tank pressure (psia)
P_v = liquid vapor pressure at pump inlet temperature (psia)
P_h = head of liquid above or below the pump center line (psid)
l = actual length of suction pipe (ft)
v = liquid velocity (ft/s)
G = liquid specific gravity
N = number of pump strokes per minute
C = viscosity (centipoise)
d = inside diameter of pipe (in)

Flow Rangeability Speed adjustment is also an effective method of adjusting a PD pump's output, again generally over a 10:1 range. One can combine both stroke and speed control to achieve rangeability to 100:1, and add on- to off-time (mark-to-space ratio) control to further extend that rangeability.

The PD pump's ability to operate over a wide rangeability may mean that only one pump is needed, which simplifies operation considerably. In process control, a PD pump's rangeability is important for chemical metering pumps, particularly those used for pH control, where the need for adjusting reagents to 1 part in 100, 1000, or more is not uncommon. Rangeability of a hundred to a thousand is seldom reliably achieved even with a PD pump, while it is impossible with centrifugal pumps having a rangeability of only 4:1 or 5:1.

Calibration A PD pump's check valves do not seat instantaneously, so accurate operation needs to be based on a calibration chart for the pump under actual operating conditions. Usually the reference standard for calibration is a calibration column or weigh tank that measures volume or mass. Calibrate the pump's flow by dividing the volume (or mass if using mass flow) by the time interval to get the average flow rate for a particular speed and stroke setting. Figure 8.34dd

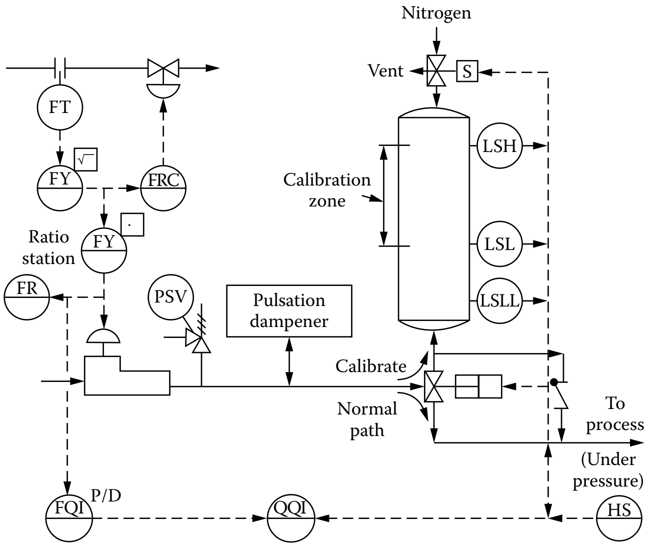

FIG. 8.34dd
Ratio and calibration controls for reciprocating pump. When level has reached LHS, the three-way valve returns to the "normal" path and nitrogen enters the tank to initiate discharge. When level drops to LSLL, discharge is terminated by venting off the nitrogen. Counter QQI is running while rising level is between LSL and LSH. Total count, when compared with known calibration volume, gives total error. Hand switch HS initiates calibration cycle by diverting the three-way valve to the "calibrate" path.

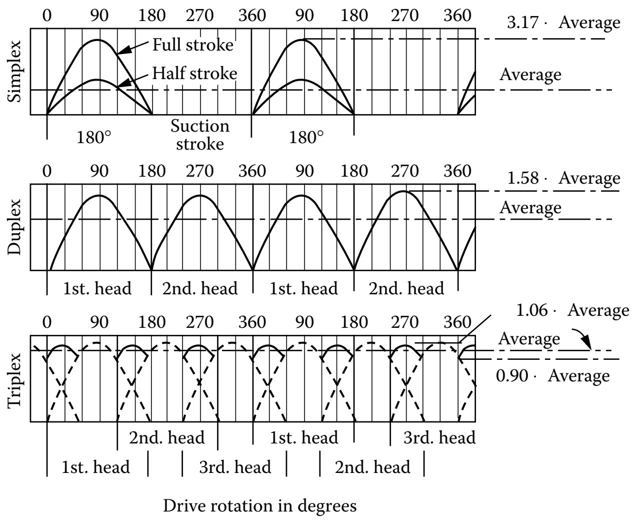

FIG. 8.34ee
Multiple pistons tend to dampen pressure fluctuations.

shows an automatic calibration facility that can be used for more advanced applications, or to calibrate the pump by hand periodically.

If the calibration is done on the suction side of the pump, this usually eliminates errors due to fluid compressibility, because close to the pump intake, the pressure is approximately constant.

Pulsating Flow As illustrated in Figure 8.34ee, the reciprocating pump produces a strongly pulsating flow.

One method of dampening pulsation is to use multiple cylinders, which, similarly to the way a car engine smoothes its pulsating thrust, smoothes out with multiple cylinders. The other option is to use pulsation dampeners, which are illustrated in Figure 7.4u in Chapter 7, Section 7.4.

Dampeners are usually connected into the piping near the pump discharge, and this is effective. However, performance can be improved by minimizing pipe friction losses between the discharge and the dampener, and introducing some friction in the line leading to the process user by a partially throttled valve to provide an acceptably smooth flow.

Valves Reciprocating PD pumps have check valves on their intake and discharge, and this adds several requirements that should be considered in the overall design.

It is necessary to ensure that the discharge pressure is always higher than the suction pressure. This can be guaranteed by placing a back-pressure regulator on the pump discharge, or possibly through the piping arrangement, as shown in Figures 7.4r and 7.4s in Chapter 7, Section 7.4. This is needed because otherwise the valves may open and allow flow through uncontrolled.

It is also recommended to orient the pump vertically, or near-vertically. The check valves are usually seated, at least partially by gravity, so their orientation is important. It is also desirable to strain or filter the pumped liquid to remove particles that may jam the valves, and ensure that the piping is scrupulously cleaned during and after installation.

Air-Locking and Cavitation When the purpose of a positive displacement pump is to meter the flow rate, certain precautions are needed. These include the removal of all entrained or dissolved gases, which otherwise can destroy metering accuracy. Figure 7.4t in Chapter 7, Section 7.4, shows how entrained gases can be returned to the supply tank.

PD pumps airlock comparatively easily: If a large bubble of gas accumulates between the intake and discharge valves, it can simply expand and contract through the pump strokes, and thereby stop the pumping action completely. This is a particular problem if pumping liquids that give off gas, such as sodium hypochlorite, which gives off chlorine; hydrogen peroxide, which gives off oxygen; or biological sludges, which give off methane, hydrogen sulphide, and other gases.

Therefore, one should ensure that the piping inherently intercepts and safely removes gases before they can enter the pump. If the removed gas is poisonous (chlorine and hydrogen sulfide), it must be piped to a safe location.

In the case of hydraulic diaphragm pumps, the gas bubble on either side of the diaphragm has the same effect. If the pump acts as though it is airlocked, but there is definitely no gas between the valves, there may be some on the hydraulics side of the diaphragm.

PD pumps are unaffected by cavitation, because no sudden collapse of the bubbles formed by cavitation is allowed. The piston strokes under complete control, the cavity (the bubble of vapor that is formed during cavitation) only collapses at the rate allowed by the piston. As a result, the destructive velocities that can be achieved by cavitation in a centrifugal pump do not occur in a PD pump.

Chemical Metering Pump Operation A major operational consideration that applies specifically to chemical metering pumps is the distance between the pump and the point where the pumped fluid enters the process. This results in dead time. Assume, for example, that this distance is 100 m and that the liquid's speed in the pipe is 0.33 m/s.

If the pump is transporting a constant dilution water flow, it will take 300 sec from the time when the dilution is changed to the time the new dilution reaches the process. Consequently, dead time limits the best achievable control, and it is always desirable to minimize it.

One method to minimize this dead time naturally is to reduce the distance between the point of control and the point of use. This may require a second pipe to carry the dilution liquid. If using this arrangement, consider running the chemical pipe inside the dilution pipe, to provide inherent secondary containment.

Another solution is to use feedforward based on a measurement that is in advance of the actual process requirement, by at least as much time as is the dead time.

Pacing the dilution or reagent flow to the chemical flow usually requires a separate metering pump, or possibly a flow control valve. If diluting or charging to a number of process users in a specific ratio, one can use fixed valves, such as needle valves, to ensure the correct distribution ratio to individual dilution points.

CONTROL OF PUMPS

Capacity control of pumps must recognize the incompressibility of liquids. For this reason, changes in the volumetric flow rate throughout the system occur simultaneously, and density is constant at constant temperature, regardless of pressure.

Pump capacity may be affected by (1) a control valve in the discharge of a pump, (2) one-off switching, (3) variation in the speed of the pump, or (4) stroke adjustment of PD pumps. Flow control by on/off switching provides only zero or full flow, whereas the other control methods provide adjustable flows in the system. The applicability of these four methods of capacity control is a function of the pump type, such as centrifugal, rotary, or reciprocating. The possible types of capacity controls for the various pumps are summarized in Table 8.34ff.

On/Off Control

On/off switching is the most common capacity control in use. It has many disadvantages such as flow surges that often hinder processing, high friction losses, and high electricity peak demand charges. However, on/off control is simple and can be economical, as its consequences do not require redesign to accommodate the limitations of on/off control.

Pumps that are controlled only by starting and stopping are said to be constant-speed (CS) pumps.

When pumping suspended solids or slurries, when the pump is stopped, a specific disadvantage of on/off control is that the solids may settle out of the liquid and may not go back into suspension when the pump starts again. This can cause plugging.

This can also happen if pumping entrained oil and grease: The grease will float and may stick to the top of the pipe. In these cases, an option is to keep the pump running: deliver flow through a circulating loop and control capacity with a pressure-controlled bypass back to the feed tank. For example, one can provide intermittent flow to feed a centrifuge by opening an on/off valve by a cycle timer. Such a loop is shown in Figure 8.7j. The pressure-controlled bypass shown in this figure allows the normal pump flow to be maintained in the loop, while the centrifuge feed valve is closed.

TABLE 8.34ff
Pump Control Methods

	Possible Types of Controls	
Method of Control	*On/Off*	*Throttling*
On/off switch	Centrifugal, rotary, or reciprocating	
Throttling control valve	Centrifugal or rotary	
Speed control	Centrifugal, rotary, or reciprocating	
Stroke adjustment	Reciprocating	

CS (on/off) pump operation is usually straightforward, except that the pump motor may overheat if it is started and stopped too frequently. Motors are usually rated for a maximum number of starts per hour (sph), because bringing the motor up to speed involves higher currents than keeping it at speed; perhaps ten times higher. Motor heating is proportional to current squared (I^2R), so the heating during start-up may be 100 times higher than normal.

Submersible pumps are usually rated for up to 15 sph, whereas large dry-pit pumps may be limited to 2–4 sph. Control systems must be designed to accommodate starts per hour limitations.

On/Off Level Control Figure 8.34gg illustrates the use of level switches for on/off pump control. The interlocks keep the tank level between the settings of LSH and LSL. In this illustration, the two-probe conductivity level switch operates a relay. When conductive liquid reaches the upper LSH probe, the relay closes contacts *H* and *I*. At this point the pump starts, and although the level then drops below the LSH probe, the pump keeps running because the holding contact (*H*) maintains the circuit.

When the level drops below the LSL probe, both the load (*I*) and the holding (*H*) contacts open, stopping the pump. When the level rises again, no action occurs when the LSL is contacted, because the holding contact is still open. However, when the level reaches the LSH, electrical contact is established, and the relay closes to repeat the pumping cycle.

The bottom portion of Figure 8.34gg shows a simple pump starter circuit that is controlled by the three-position hand-off-automatic switch. When the controls are in automatic (contacts 3 and 4 connected), the status of the interlock contact *I* determines whether the circuit is energized and whether the pump is on. The purpose of the auxiliary motor contact *M* is to energize the running light *R* while the pump motor is on. The parallel hot lead to contact 6 allows the operator to check quickly to see if the light has burned out.

The amount of interlocking provided for pumping systems is usually greater than that shown in Figure 8.34gg. In addition to the overload (OL) contacts shown in Figure 8.34gg, controls often include safety overrides. These usually detect excessive pressure or vibration, low flow, leaks (submersible pumps), or motor winding temperature, and these overrides usually energize remote alarms.

Most pump controls include a reset button that must be pressed after a safety shutdown condition is cleared and before the pump can be restarted. If the same pumps can be

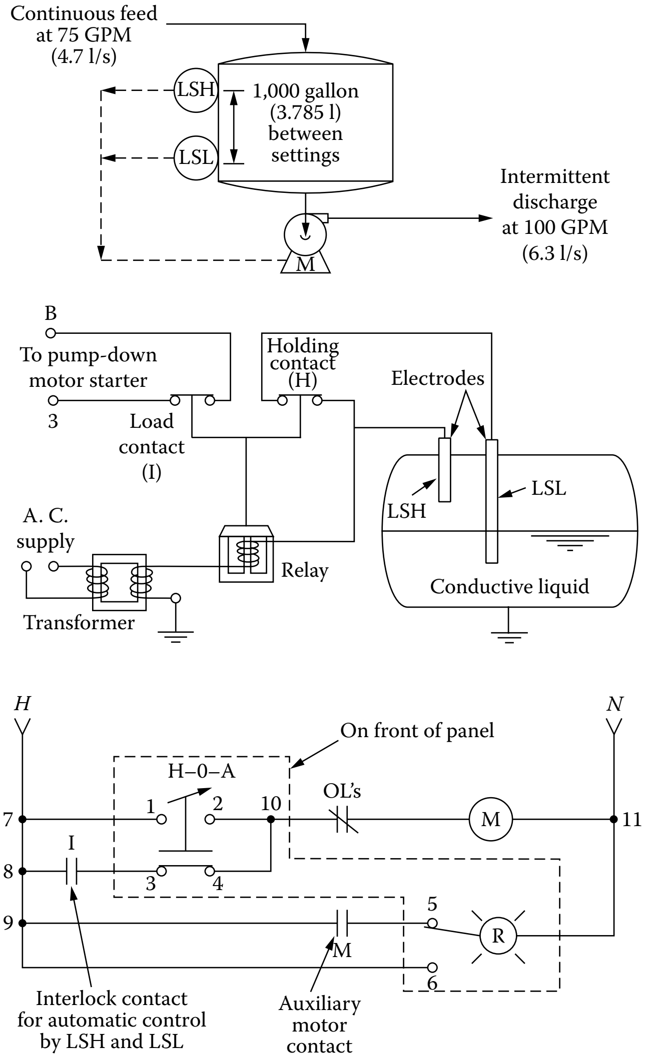

FIG. 8.34gg
On-off pump-down interlocks often utilize two-probe conductivity switches.

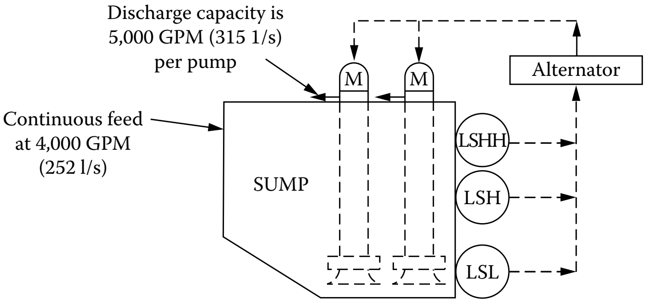

FIG. 8.34hh
On-off level control of dual pump station.

controlled from several locations, interlocks should be provided to resolve conflicting requests. One method is to provide an interlock to determine the location that is in control. This can be a simple local/remote switch or a more complicated system.

When many locations are involved, conflicts between requests are resolved by interlocks that establish priorities between control locations on the basis of selecting the lowest, highest, safest choice of pump operation. In such installations with multiple control centers, feedback should be provided, so the operators not only know the actual status of all pumps, but also are aware of any conflicting requests coming from the other operators or computers.

Multiple Speeds, Multiple Pumps When two-speed pumps are used, added interlocks are frequently provided. One interlock might guarantee that even if the operator starts the pump in high speed, it will operate for 0–30 sec in low before advancing automatically to high. This makes the transition from off to high speed more gradual. Another interlock might guarantee that when the pump is switched from high to low, it will be off the high speed for 0–30 sec before the low speed is engaged, to give time for the pump to slow down.

When several pumps are supplied from a common electrical feeder, it may be necessary to ensure that the feeder is not overloaded by the inrush current, when pumps are started simultaneously. If this feature is desired, a 0–30 sec time delay is usually provided between pump starts.

When two or more pumps are used, an alternator should be interposed between the level switches and the pump motors. The alternator places the pumps in service in an alternating sequence. Thus, if two pumps are used, each will have half as many starts per hour. However, while one pump is out of service, the other must pump all the flow so it will have the same sph as a single pump.

Alternation tends to equalize pump running hours and reduces starts per hour. In Figure 8.34hh, a cooling water return sump is illustrated. In this system, each pump is designed to handle the normal flow by itself, but both pumps operate together if abnormally high flows are required.

On/Off Flow Control Figures 8.34y and 8.34ii show a two-pump arrangement that responds to varying flow demands measured on the discharge side of the pumps. Pump I normally operates at point (1) (at 80 gpm and 36 ft, or 5 l/s and 10.8 m). When flow demand increases to 120 gpm (7.6 l/s), the head drops to 22 ft at point (2), and FSH starts pump II. The combined characteristic gives 120 gpm at 40 ft (7.6 l/s at 12 m) at point (3). In this control scheme, a wide range of flows is possible without serious loss of discharge pressure.

On/Off Pressure Control As was illustrated in Figure 8.34z, a pressure switch may be used to start a spare pump in order to maintain pressure in a critical service when the operating pump fails. In this case, a low pressure switch would actuate the spare pump, which is piped in parallel with the first pump.

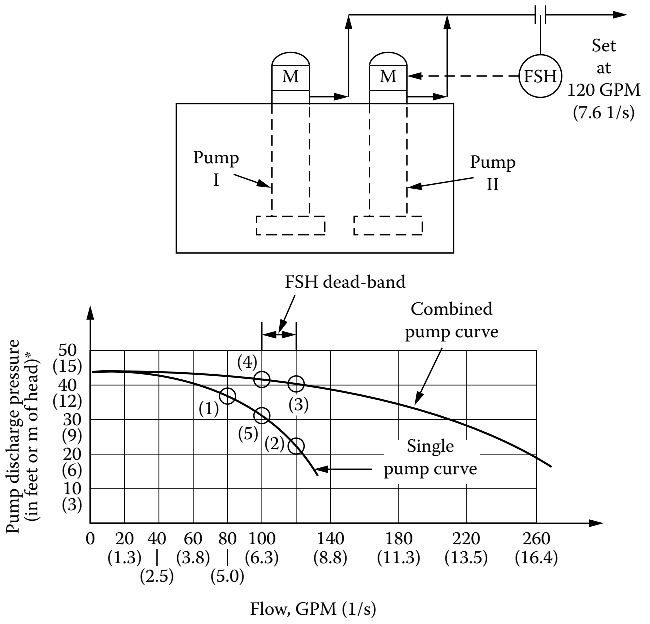

FIG. 8.34ii

On-off flow control can be used with parallel pumps.
**1.0 ft of water = 2.98kPa.*

A second possibility is to boost pressure, as shown in Figure 8.34jj. In this case, if pump I is normally operating at point (1), when the discharge pressure rises to 50 ft (15 m) at point (2), the flow is reduced from 53 to 20 gpm (3.3 to 1.3 l/s). At this point, the pressure switch (PSH) will start pump II and close the bypass valve. The system will now operate at point (3) on the combined characteristic curve, delivering 60 gpm at 50 ft (3.8 l/s at 15 m) pressure.

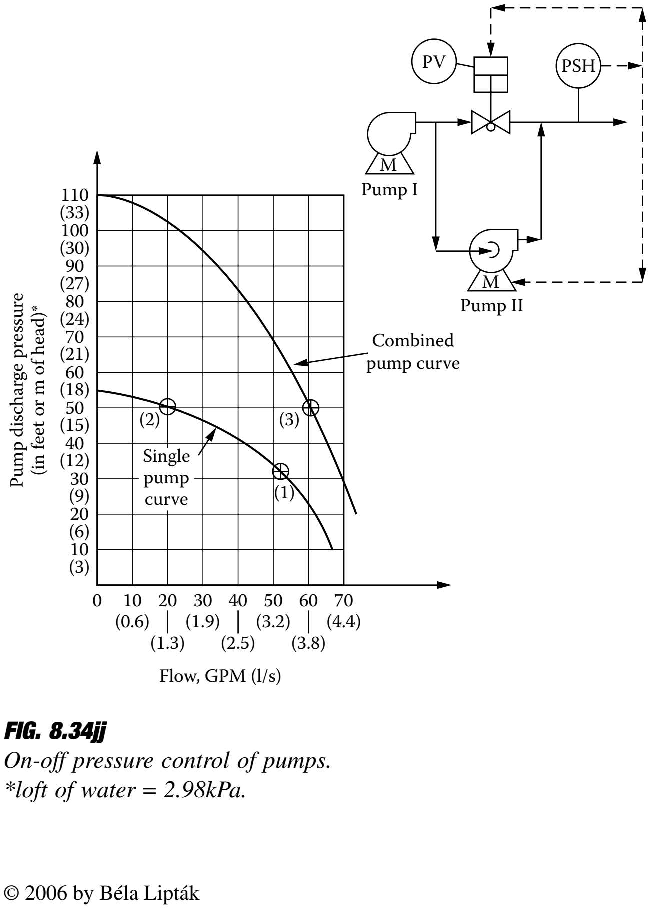

FIG. 8.34jj

On-off pressure control of pumps.
**loft of water = 2.98kPa.*

Using PLCs The previously described simple control strategies can be easily implemented in hardwired controls. With a programmable logic controller (PLC), it is easy to add many other features beyond what is practical in hardwire, such as to equalize the pump run times better, rather than just alternating when it is necessary to stop or start a pump. For example, it is simple to stop the running pump that has logged the most hours or start the pump that has the lower sph.

One can also program the PLC to flush the piping periodically by running both pumps together. If it has been a long time since both pumps ran together, and there is storage capacity available, one can initiate the running of both pumps by delaying the starting of one pump until more demand has accumulated and then run both pumps together. This strategy adds a pump start but is unlikely to result in an sph violation because it only happens if both pumps have not run together for some time.

If a pump has not run for several days because demand is low, and there is some liquid available to pump, it is recommended to run the pump regardless of demand, even if only for a few seconds. This strategy helps to keep the bearings lubricated and avoids developing flats on ball- or roller-bearings. It also adds starts, but again this only happens if demand is low, when starts are unlikely to be a consideration.

Starts per Hour Traditional SPH methods include the use of reduced-voltage or soft motor starters to increase the allowable number of SPH. Other design solutions include the providing of enough storage capacity in the system to accommodate the SPH limitation. One generally tries to avoid the technique of measuring the time between starts, and actively limit these starts, because this is an intrusive approach that is likely to interfere with process performance.

Reduced-voltage starters increase the allowable number of SPH, so they are a successful way of accommodating the sph limitation. However, when this means has been exhausted, the next step is to provide storage capacity. The sph limitation can be met by calculating the pumps' minimum cycle time (minimum start-to-start time), which is given by

$$\mathrm{MCT} = 4V/Q \qquad \mathbf{8.34(9)}$$

where

MCT is minimum cycle time in minutes
V is the available storage volume
Q is the design flow of the pump

Example: A 10,000 gpm pump is rated for up to four SPH. Find the working volume needed to ensure that the rating is not exceeded. Four SPH corresponds to an MCT of 15 min. Therefore,

$$V = \frac{15 \cdot 10{,}000}{4} = 37{,}500 \text{ gallons.}$$

Modulating Control

The flow from a pump or pumping station can be controlled by throttling either the forward flow or the bypass flow around the pump. Capacity control by valve throttling works essentially by throwing away what is not needed. The unnecessarily introduced pumping energy is wasted by either diverting the flow that is not needed through a bypass, or by restricting the pump discharge.

Pumps are usually powered by induction motors, which for a long time have been constant-speed devices. As a result, it was difficult or impractical to adjust pump speed, and alternative ways of controlling the pump's capacity were required. Modulating valves made CS pump capacity control practical, but they wasted energy. The development of reliable adjustable-speed (AS) induction motor drives has changed this situation, although modulating valves are still used.

Bypass Valves With a bypass valve, the pump delivers essentially a constant flow, and the bypass valve returns whatever the process does not need back to the pump inlet. The process determines by the opening of the flow control valve. For example, if the pump is supplying heating water to a reactor, when more heat is called for, the bypass valve is throttled to close, to increase heat to the reactor.

Bypass valves can work with both PD and centrifugal pumps, and they have other advantages, such as 1) When pumping slurries, greases, or mixtures that may separate, solidify, or coagulate, the bypass keeps the flow moving and so tends to keep the liquid homogeneous. 2) When pumping heating water, the water in the piping tends to lose heat. A bypass keeps the flow constant, which tends to ensure a consistent temperature to the process. 3) When pumping liquids with entrained gases, keeping the flow moving tends to avoid accumulation of larger gas bubbles that can airlock the system. 4) The heat gain in the pumped liquid stays constant. This is particularly important if pumping liquids near their vapor pressure.

Throttling Valves Throttling restricts the pump's discharge flow. When pumping incompressible (liquid) flow, throttle the discharge, but when gas (compressible) is transported, throttle the inlet. With a liquid, the problem with inlet throttling is that it causes cavitation, which cannot happen with a gas. With a gas, the advantage of inlet throttling is that the throttled gas expands into the blower at a reduced density (which reduces its power consumption). However, this cannot happen with an incompressible liquid — incompressible also implies inexpandable. So, the arrangement of liquid discharge throttling, and gas inlet throttling, makes the best of both possibilities.

Essentially, throttling changes the friction factor of the system curve. It works well with centrifugal pumps by shifting the pump's operating point, but does not with PD pumps because their characteristic curve is very steep (Figure 8.34bb), and therefore the discharge pressure just increases to force the positive displacement flow through the valve.

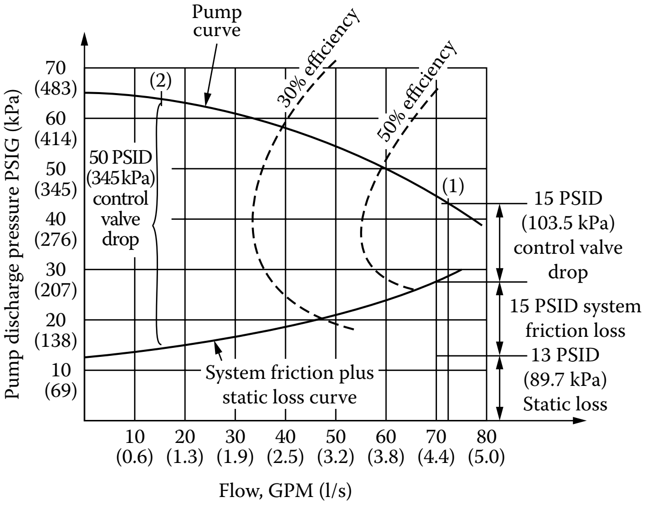

FIG. 8.34kk
Throttling control of centrifugal pump.

In Figure 8.34kk, design point (1) is near the maximum efficiency of the pump. Therefore, when throttling to point (2), the efficiency will drop.

For good controllability, the control valve should be sized to pass the design flow with a pressure drop equal to the system dynamic friction losses excluding the control valve but not less than 10 psi (70 kPa) minimum. (For more details on assigning sizing pressure drops to control valves, refer to Section 6.15 in Chapter 6.)

The control of flow by varying the pressure drop across the valve is illustrated in Figure 8.34kk. Here, when the flow is throttled from point (1) at 73 gpm (4.5 l/s) to point (2) at 15 gpm (0.95 l/s), the differential pressure across the control valve increases from 15 PSID (100 kPa) to 50 PSID (350 kPa).

However, one should be careful not to run the pump at flows low enough to overheat the liquid, or vaporize it, because vaporization can cause the pump to cavitate. One should use a heat balance on the pump to calculate the minimum flow needed through the pump to prevent vaporization. To be conservative, assume that all the motor's power is converted into heat. If this minimum flow was calculated to be 20 gpm (1.3 l/s), then size the PCV in the bypass to pass 20 gpm with a corresponding set pressure of 63 psi (435 kPa).

Figure 8.34ll shows a typical flow control loop with a pressure-controlled kick-back bypass. The rangeability of the control valve is assumed to be 25:1 (see Section 6.7). Thus, if the maximum flow required is 70 gpm (4.4 l/s) through the flow control valve, then the minimum controllable flow would be about 3 gpm (0.2 l/s). If control of lower flows is required, then install a second, smaller flow control valve in parallel with the first, and use it to control these lower flows.

Throttling Valves Waste Energy If there is no throttling valve in the system, a constant-speed pump will always operate at the intersection of its characteristic curve and the system

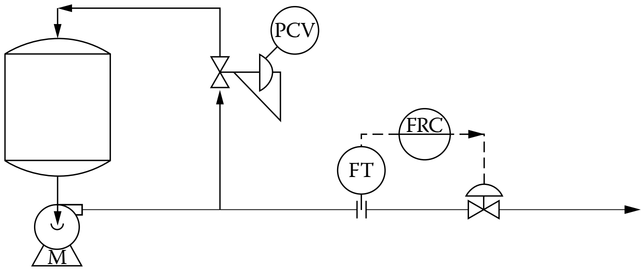

FIG. 8.34ll
Throttling control with pressure kickback.

curve. If the actual system curve has less slope than was designed for, the pump will deliver more flow than was intended. For example, in the case of the pump and system curves shown in Figure 8.34mm, the designers expected one system curve (solid line), but the actual system curve (dashed line) turned out to be flatter. Consequently, the actual operating point will be at point (2) instead of point (1), and therefore the actual flow will be higher, and the pressure lower, than the designers intended.

If a throttling valve on the pump discharge controls the flow, the pump will operate at point (1), and the valve will burn up the differential pressure between points (1) and (3). This drop represents wasted power:

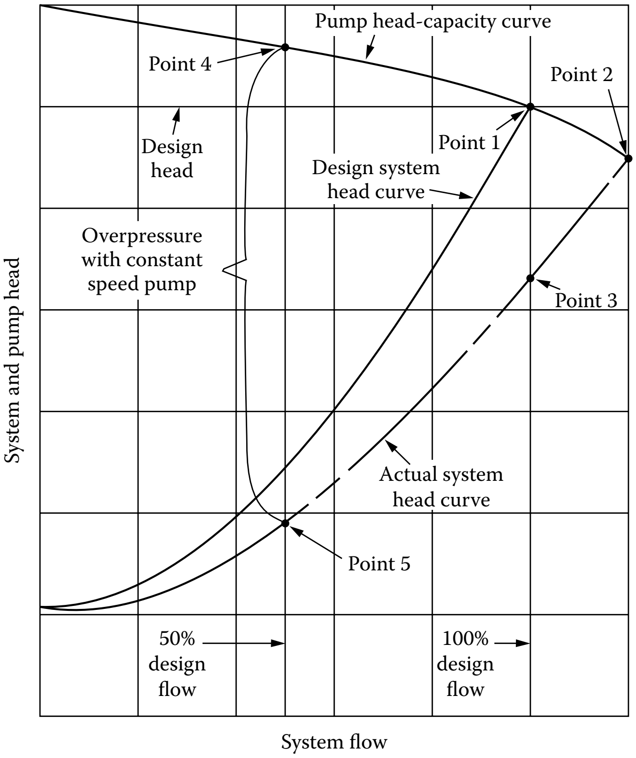

FIG. 8.34mm
Illustration of the consequence when the assumed and actual system curves are not the same.

$$Pw = p \cdot Q \qquad \textbf{8.34(10)}$$

where
Pw is the wasted power (watts, W)
p is the differential pressure across the valve (Pa)
Q is the flow through the valve (m^3/s)

If the valve throttles the flow to 50%, as in points (2) to (4), the energy wasted in the form of valve pressure drop increases, because it becomes the difference between points (4) and (5). This illustrates that throttling always wastes energy. In addition, throttling introduces another source of energy wastage, because it almost always also reduces the pump's efficiency (Figure 8.34k).

In Figure 8.34j, the useful pumping pressure is identified as H_s, and the actual pressure of the throttled system is given as H_p. The $(H_p - H_s)$ difference identifies the energy wasted through throttling. However, this is only part of the total waste, because moving the operating point from (2) to (1) also reduces the pump efficiency from 81 to 71%. As a result, not only is power lost to throttling, but power is also lost to reduced pump efficiency.

One can use Equation 8.34(10) to quantify the loss, by taking the example in Figure 8.34kk. If working with metric units, when the flow is throttled from point (1) at 4.5 l/s to point (2) at 0.95 l/s, the pressure across the valve increases from 100 kPa to 350 kPa. At point (1), the flow is 4.5 l/s (4.5×10^{-3} m^3/s) and required pressure is 190 kPa (4.5×10^3 Pa), giving a required power of

$$Pw = 4.5 \times 10^{-3} \cdot 190 \times 10^3 = 850 \text{ w}$$

However, the consumed power, including the valve's pressure drop, is

$$Pw = 4.5 \times 10^{-3} \cdot 290 \times 10^3 = 1300 \text{ w}$$

Therefore, the control's efficiency at point (1) is $\frac{850}{1300}$ = 65%

We can now compare that result with point (2), which has a flow of 0.95 l/s and required pressure of only 95 kPa, giving a required power of

$$Pw = 0.95 \times 10^{-3} \cdot 95 \times 10^3 = 90 \text{ w}$$

The consumed power, including the valve's pressure drop, is

$$Pw = 0.95 \times 10^{-3} \cdot 440 \times 10^3 = 420 \text{ w}$$

Therefore, the controls efficiency at point (2) is $\frac{90}{440}$ =20%

Figure 8.34kk does not provide the full pump efficiencies, but point (1)'s efficiency is likely to be about 60%, and point (2)'s about 15%. Including these values gives the overall efficiencies of 40% (65 × 60%) for point (1) and 3% (20× 15%) for point (2).

Capacity Control by Stroke Adjustment The flow generated by a PD pump is the product of the volume per stroke and the number of strokes per second. Therefore, one can adjust the PD pump flow by either adjusting the volume per stroke or the strokes per second (the speed). The volume of a piston is its area multiplied by the stroke length. Because the stroke length is readily adjustable, stroke control refers to the pump's flow adjustment method of modulating its stroke length.

The stroke can be adjusted by hand or automatically while the PD pump is operating at constant speed. Hand adjustments are currently more precise, usually rated at about 1% error, compared to 1.5% error when automatic adjustment is used. While manual setting is more accurate, automatic adjustment by closed-loop control will give better performance overall.

The range of flow control by stroke adjustment is 0–100%. However, in order to maintain accuracy, the practical range is 10–100% of maximum flow. The flow is related to stroke length through system calibration.

In chemical metering pump applications, it is often the case that the automatic controls modulate the pumps' speeds, while the operators adjust the strokes by hand. The reason for this technique is to use stroke adjustment to compensate for factors that are hard to measure and remain constant over long periods, such as the reagent concentration, that may change only from delivery to delivery. In such configurations, the feedback controls automatically adjust the speed to compensate for factors that change often and can be measured, such as the process flows or the reagent deterioration over time, possibly caused by temperature and so on.

Capacity Control by Speed Adjustment The cost of reliable and efficient adjustable-frequency drives (AFDs) has dropped rapidly in the past decade. As a result, adjustable-speed pumping is preferable today for both centrifugal and PD pumps. The main advantage of adjustable speed pumping is that it is efficient. It is efficient in two ways: 1) Rather than wasting energy (as do valves), speed control avoids introducing unnecessary energy in the first place, and 2) A modulating valve almost always moves the pump's operating point away from its best efficiency point (BEP). Speed control also moves the pump away from its BEP, but not nearly as much.

The basic concept is that a pump's speed controls its discharge flow: increase speed to deliver more flow, and reduce it to deliver less.

Multiple-Pump Controls

Distribution Controls From a control quality point of view, distribution controls have already been discussed in Section 2.23 in Chapter 2 and Section 8.28. Here, their description will be from the perspective of the performance of the pump station. The overall efficiency of the water distribution system, which was shown in Figure 8.34s, is described in Figure 8.34nn by curve 1.

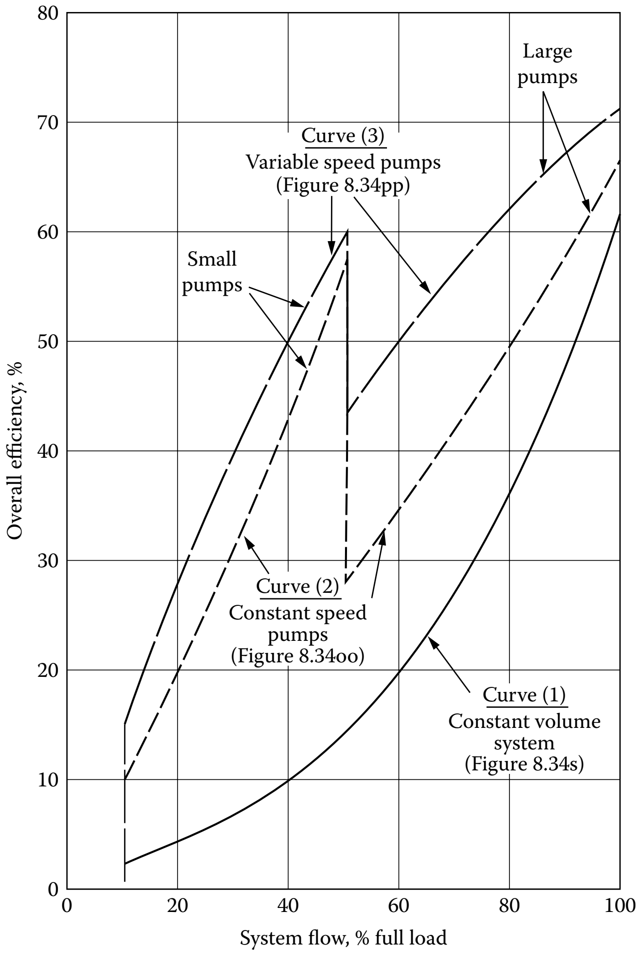

FIG. 8.34nn
Overall efficiency is maximum if two variable-speed pumps are used and is minimum with a constant volume installation.[4]

A substantial increase in efficiency (reduction in operating cost) can be obtained by replacing the three-way valves in Figure 8.34s with two-way ones and by replacing the single large pump with smaller ones. Figure 8.34oo shows such a system. Here, a small and a large primary pump are provided at the main supply point in the central plant, and a small and a large booster pump are furnished in each of the user buildings.

When the load is low, the small pumps are operating; when it is high, the large pumps take their place. The minimum flow requirements of the chiller are guaranteed by a bypass valve, and the chilled water makeup into the recirculating loop of each building is under temperature control (TC). The resulting improvement in overall efficiency is shown by curve 2 in Figure 8.34nn.

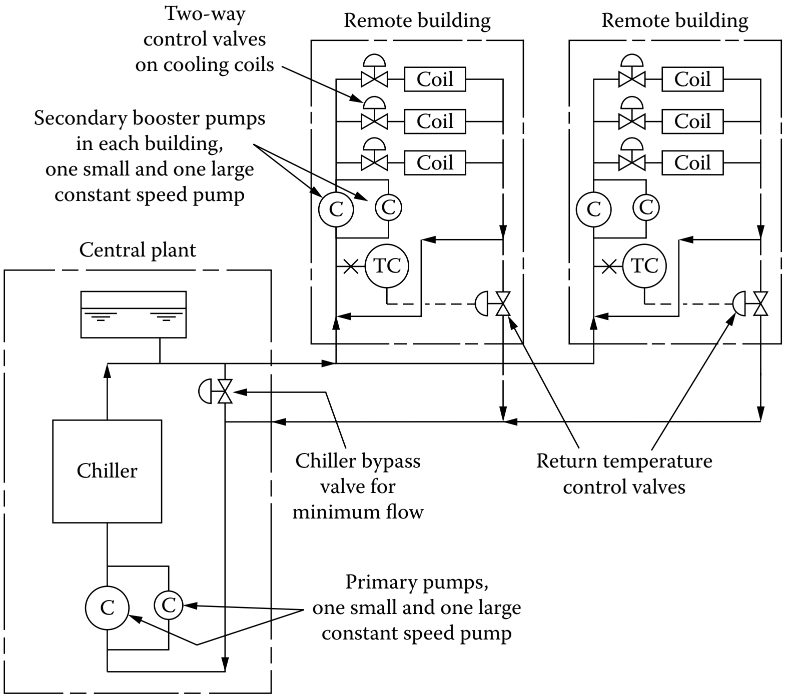

FIG. 8.34oo
Supply-demand matching can be achieved using constant-speed pumps of different sizes.[2]

The highest overall efficiency can be obtained through the use of variable-volume load-following. Figure 8.34pp illustrates such a system, utilizing variable-speed pumps in two sizes. In this system, all waste is eliminated except what is generated by the small minimum flow bypass around the chiller, which is guaranteed by a small constant-speed pump. The resulting increase in overall efficiency is illustrated by curve 3 in Figure 8.34nn.

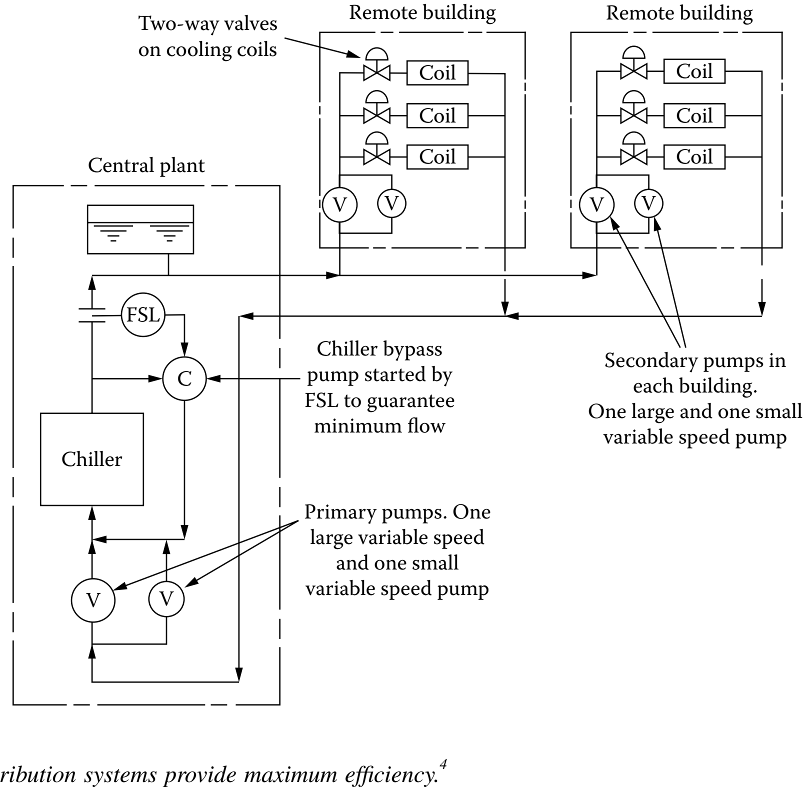

FIG. 8.34pp
Variable-volume water distribution systems provide maximum efficiency.[4]

Starting and Stopping Pumps When the running adjustable speed pumps are near their maximum speeds and when more flow is needed, the capacity of the pumping station must be increased by starting another pump. Similarly, when all pumps are at a low speed and less flow is needed, a pump must be stopped.

It is necessary to know the maximum pump speed a pump can run at and still deliver zero flow (called omega zero, ω_o), the pressure up to which the flow remains zero (shut-off pressure). This is the pressure that a starting pump must overcome before it can start delivering flow (superimposed back-pressure), and the flow delivered by an adjustable-speed centrifugal pump, which is running against the back-pressure, which is superimposed by the other operating pumps.

The subject of determining the above values for particular pumps and processes and to use these values in developing a detailed strategy for starting and stopping individual pumps is beyond the scope of this section, but if the reader needs such information, it can be found in Reference 15.

When to Start or Stop a Pump Accumulated running hours should be recorded on an elapsed time meter (ETM), because pumps are subject to wear while running, so recording their running hours can help distribute wear among them evenly, and it provides a guide to planned maintenance.

The time since the last stopping of the pump, called idle time, also should be recorded. During idle time, pump bearings lose lubrication, and they can be flattened out of round, so long idle periods are undesirable. Recording the idle time helps deal with this. A pump accumulates idle time while stopped, in the same way that it only accumulates running hours while running.

In critical applications consider always keeping an extra pump running at the same speed as the other pumps, so that if a pump fails it is only necessary to speed up the running pumps. One of the pumps should be stopped when the speed of the operating pumps has dropped to its low limit for over 30 sec.

The operator or the control system should initiate a start immediately when a running pump fails, unless a start is already in progress. A pump should also be started when the running AS pumps have been at their maximum speeds (ωm) for over 30 sec. Similarly, if an operating pump has traveled on its characteristic curve to the point where cavitation starts (Figure 8.34w), an additional pump should be started.

Start a pump if its idle time indicates that its bearings would benefit from being rotated. Preferably do this when the pumps are running around the middle of the speed range, so that a normal start or stop is unlikely to occur at the same time. Probably also stop another pump at the same time, to avoid a surge or having too much running capacity.

Selecting the Pump to Start or Stop When it is time to start a pump, start the AS pump that has accumulated the longest idle time. If all the AS pumps are running, start the CS pump that has the longest idle time. This strategy avoids accumulating idle time, consistent with not adding any extra starts.

When it is time to stop a pump, stop the running CS pump that has accumulated the most running hours. If all CS pumps are stopped, stop the AS pump that has accumulated the most running hours. This strategy tends to equalize the pumps' running hours, but it is not extremely successful because equalizing hours has the lowest priority—everything else takes precedence.

A highly successful strategy is to start the pump with fewest hours, stop the pump with the most hours. However, this can allow equipment to stand idle for long periods, particularly when other equipment is brought back into service after a long downtime.

Starting and Stopping When the pumps are of equal size and a pump is being started, accelerate it up to the omega zero speed (ω_0) quickly on its AFD's acceleration ramp. Then, gradually increase the flow through the starting pump, and reduce it through the running adjustable-speed pumps, until they are all running at the same speed and passing a similar flow. Similarly, when stopping, control the pump's deceleration down to ω_0, while accelerating up the running pumps. When the stopping pump reaches ω_0, stop it quickly.

When starting an AS pump, it is necessary to know how many AS pumps are running. Next, determine the starting pump's $\omega_{0.}$ If necessary, perhaps because as-commissioned pump measurements may not be available when the controls are configured, use the characteristic and system curves to estimate ω_0 against *n*. Start the pump and accelerate it up to ω_0 quickly.

When the starting pump reaches ω_0, start a timer, the *transition* timer, to bring the starting pump into action. Let the duration of the timer be *T* sec and the elapsed time since the start be *t* sec.

Depending on the system, the timer's duration may be faster or slower; it is usually not critical, provided it is slow enough that the pumps can follow the flow changes it requires, and fast enough to ensure it will have timed out before there is any need to start another pump.

While the transition timer is running ($0 < t < T$), calculate the starting pump's flow increase, and the running pumps' flow decrease, to pump the instantaneous flow required by the control loop output, *Q*, throughout the start transition. Then convert these flows to pump speeds, as follows:

When the transition timer has timed out ($t = T$), the starting pump has joined the running pumps.

Update the count of the number of running pumps, *n*.

When stopping an AS pump, the principles are the same as was for starting an AS pump, except in reverse: decelerate the stopping pump to ω_0 while accelerating the running pumps, so that total flow is controlled while it also transitions smoothly from the stopping pump to the running pumps.

CONCLUSIONS

This section covered the basics of pump control, while the next section will concentrate on the optimization of this unit operation. Pumping controls are a prime example of applications where it is essential to fully understand the personality of both the process and the pumping equipment used, before a successful control system can be designed.

Another unique characteristic of the pumping process is that over the life of the plant, the operating cost of a pump is much greater (sometimes a hundred times greater) than the first cost of the pumping equipment. It is for this reason that good process controls and optimization can have much higher returns when operating pumping stations than on other unit operations.

The goal of a well-designed pumping control system is good supply–demand matching, which will not only lower operating costs, but also reduce maintenance and cycling. The full automation of pumping stations — including automatic start-up and shutdown — not only will reduce operating costs but will also increase operating safety as human errors are eliminated.

8.35 Pump Optimization

S. BAIN AND B. G. LIPTÁK (2005)

INTRODUCTION

The previous section covered basic pump controls, while this section will concentrate on pumping system optimization. The savings resulting from pumping system optimization are greater than from most other unit operations, because pumping is a very energy-intensive operation. Over the lifetime of a pumping system, the operating cost is about a hundred times greater than the first cost of the pumping equipment. It is for this reason that optimization can have much higher returns here than on other unit operations.

Pump optimization includes the goal of introducing only the energy that is needed to transport the fluid, but no more. The elimination of energy waste and the providing of good supply–demand matching will not only lower operating costs, but will also reduce maintenance. The full optimization of pumping stations — including automatic start-up and shutdown — will not only reduce operating costs but will also eliminate human errors and increase operating safety.

Before starting on the optimization phase of designing a pumping station control system, the design engineer should make sure that power-factor correction, the use of high-efficiency motors, and operating against the lowest possible static and friction heads have been already implemented.

In this section, the subject of pump optimization will be first discussed without using a model. This discussion will focus on keeping throttling valves as open as possible, in order to minimize the waste of pumping energy.

In the later paragraphs of this section, a mathematical model of the pump's performance will be described. This model is stored in the digital memory of the control computer and can be used to predict and optimize future operation. By comparing the theoretical and the actual results, the model can also update itself automatically.

NOMENCLATURE

ω	Rotational speed. The instantaneous rotational speed the pump is running at. Typically in *rpm*.
ωd	The pump's design speed. Bearings, seals, and so on will probably not fail catastrophically immediately above this speed, but it is a guide.
ωo	The highest speed a pump can run at and still deliver zero flow.
Q	Flow; incompressible liquid flow.
P	Pressure; usually the pump's pressure gain.
Ff	Friction factor; used to calculate friction pressure loss in pipes.
N	The number of pumps that are running.
$c_1, c_2, \ldots$	Constants that describe a pump's characteristic curve.
CSH	Constant speed head.
Pw	Power absorbed by pump shaft or wire power. (The symbol for power is *P*, and for pressure is *p*, but the upper- and lowercase letters are similar, so to help distinguish them, this text uses *Pw* for power.)
$pw_1, pw_2 \ldots$	Constants that describe a pump's power curve.
$r_1, r_2 \ldots$	Constants that describe a pump's NPSHR curve.
$a, b, c, d \ldots$	General-purpose constants that are reused as needed without being redefined; their values are local to the expression being developed.
Ns	Specific speed

PUMP EQUATIONS

As the subject of pump and system curves has been covered in Section 8.34, here only a summary will be given, using the above-listed nomenclature.

Affinity 1, pump speed vs. flow:

$$Q_2 = Q_1 \cdot \frac{\omega_2}{\omega_1} \qquad \textbf{8.35(1)}$$

Affinity 2, pump speed vs. pressure:

$$p_2 = p_1 \cdot \left(\frac{\omega_2}{\omega_1}\right)^2 \qquad \textbf{8.35(2)}$$

Table 8.35a gives a summary of the affinity laws for both speed and impeller diameter:

The general form of the system curve is

$$p = CSH + Ff \cdot Q^x, \qquad \text{where} \qquad 1.7 < x \leq 2.0 \qquad \textbf{8.35(3)}$$

TABLE 8.35a
The Affinity Laws Describe the Relationships between Pump Impeller Speed and Diameter to the Resulting Fluid Flow, Pressure, and Power Consumption

Affinity Laws for Speed	*Affinity Laws for Diameter*
Flow ∝ Speed	Flow ∝ Diameter
Pressure ∝ Speed^2	Pressure ∝ Diameter^2
Power ∝ Speed^3	Power ∝ Diameter^3

Figure 8.35b graphically illustrates the mathematical expressions for the affinity laws and the system curve equation.

The pump's characteristics can be expressed as a continuous function (three-dimensional surface) of speed, flow, and pressure. Therefore,

$$p = a + b \cdot Q + c \cdot Q^2 + d \cdot Q^3 \qquad \mathbf{8.35(4)}$$

Characteristic pump surface equation:

$$p = c_1 \cdot \omega^2 + c_2 \cdot \omega \cdot Q + c_3 \cdot Q^2 + c_4 \cdot \frac{Q^3}{\omega} \qquad \mathbf{8.35(5)}$$

Similarly, the power consumption and the required net positive discharge head (NPSHR) of the pump can also be expressed in equation form.

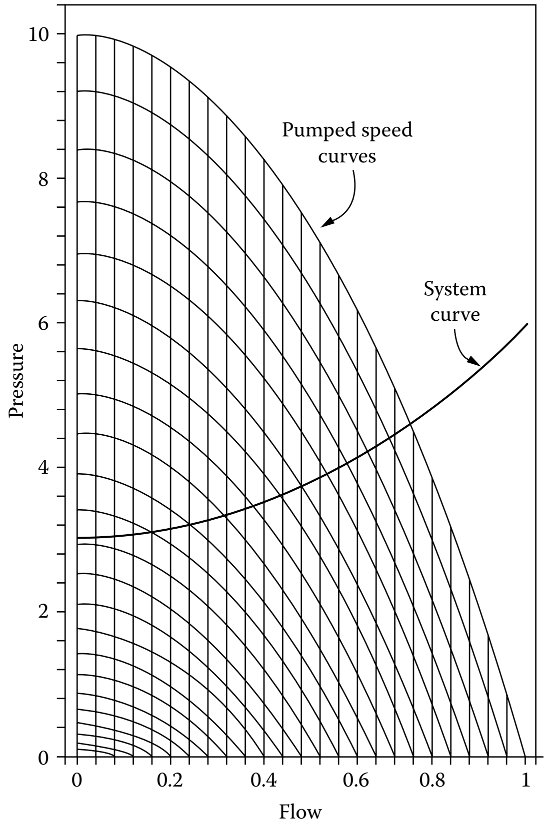

FIG. 8.35b
The system curve of the process is superimposed on a family of pump curves, corresponding to a variety of pump speeds.

The power consumption surface:

$$Pw = pw_1 \cdot \omega^3 + pw_2 \cdot \omega^2 \cdot Q + pw_3 \cdot \omega \cdot Q^2 + pw_4 \cdot Q^3 \cdots \qquad \mathbf{8.35(6)}$$

Equation describing the NPSHR surface:

$$\text{NPSHR} = r_1 \cdot \omega^2 + r_2 \cdot \omega \cdot Q + r_3 \cdot Q^2 + r_4 \cdot \frac{Q^3}{\omega} \cdots \qquad \mathbf{8.35(7)}$$

MODEL-FREE OPTIMIZATION

A pumping system is optimized when it meets the process demand for liquid transportation at minimum pumping cost and does that in a safe and stable manner. Once the equipment is installed, the equipment and piping is fixed and the potential for optimization is limited to selecting the best control system configuration. As an example, Figure 8.35c illustrates the optimization of a pump station consisting of a variable-speed and a constant-speed pump. (It was explained in connection with Figure 8.34o, in Section 8.34, that the use of only one variable-speed pump is the right selection if the static head of the system is between 50 and 67% of the total pump discharge head.)

In Figure 8.35c, PDIC-01 maintains a minimum of 10 psid (69 kPa) pressure difference between supply and return liquid pressures of each group of users. Therefore, if the control valve of any user opens up further, the flow will increase. On the other hand, if demand drops and, therefore, the pressure drop rises across all users, PDIC-01 will slow down the variable-speed pump to keep the differential from rising beyond 10 psid (69 kPa).

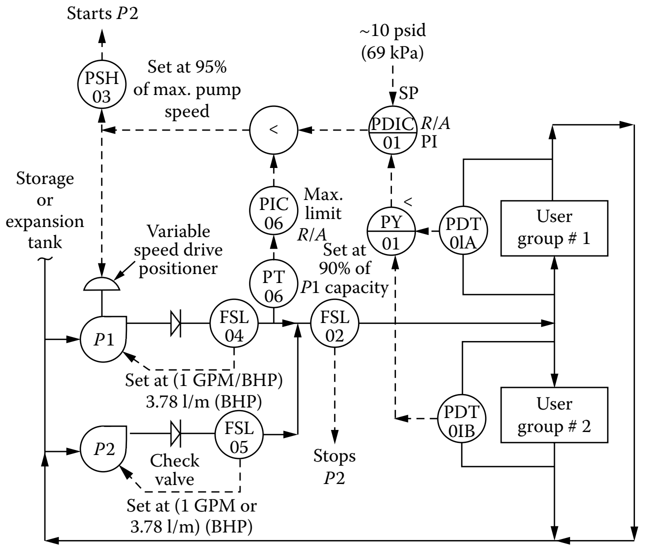

FIG. 8.35c
Optimization controls of a pump station consisting of a constant- and variable-speed pump.

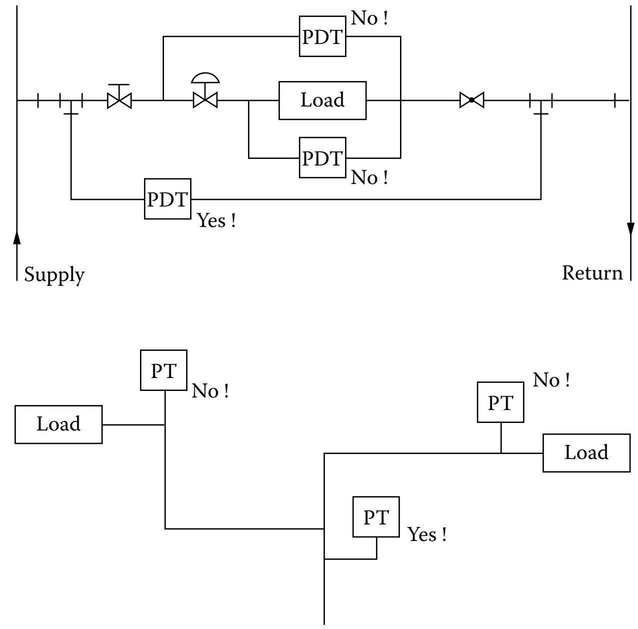

FIG. 8.35d
The pressure and differential pressure transmitters must be correctly located in the pipe distribution network.

When the variable-speed pump approaches its maximum speed, PSH-03 will automatically start the constant-speed pump (*P*2). When the load drops down to the set point of FSL-02, this second pump is stopped. One important recommendation to remember in connection with the operation of multiple-pump controls is that extra increments of pumps are started by pressure but stopped on flow.

FSL-04 and FSL-05 are safety devices that will protect the pumps from overheating or from going into low-flow cavitation. As long as the pump flow rate is greater than 1 gpm (3.78 l/m) for each pump break horsepower, the operation is usually safe from this perspective. If the flow rate drops below this limit, the pumps are stopped.

In Figure 8.35c, the pump speed is set to keep the pressure drop across the lowest user above some minimum limit. For this reason, it is important that the pressure drop across the users (PDT) be accurately detected. Figure 8.35d illustrates both the correct and the incorrect locations for the pressure-detection points in the system. The main consideration is that differential pressure transmitters should measure the head loss not only through the process load but also through the control valve, hand valves, and piping.

Similarly, as the lower part of Figure 8.35d shows, if the header supply pressure (instead of the pressure drop across the load) is to be controlled, the pressure transmitters should be located on main raisers or headers and should not be near major on/off loads.

Valve Position-Based Optimization

One of the best methods of finding the optimum pump discharge pressure is illustrated in Figure 8.35e. The optimum discharge pressure is selected as the one that will keep the most-open user valve at a 90% opening. As the pressure rises, all user valves close; as it drops, they will all open. Therefore, opening the most-open valve to 90% causes all others to be opened also. This keeps the pump discharge pressure and the use of pumping energy at a minimum.

As the valve position controller (VPC-02) lowers the set point of PC-01 and, thereby, opens the user valves, it not only minimizes the valve pressure drops but also reduces valve cycling and maintenance. This is because cycling is more likely to occur when the valve is nearly closed, and maintenance is higher when the pressure drop is high. The other important advantage of this control system is that no user can ever run out of coolant, because no user valve is ever allowed to reach 100% opening. This increases plant safety.

In order to make sure that the pressure controller (PC-01) set point is changed slowly and in a stable manner, the valve position controller (VPC-02) is provided with integral action only, and its integral time is set to be about 10 times that of PC-01. In order to prevent reset windup when the PC-01 is switched to manual or to local control from cascade, the valve position controller is also provided with an external feedback signal from PT-01.

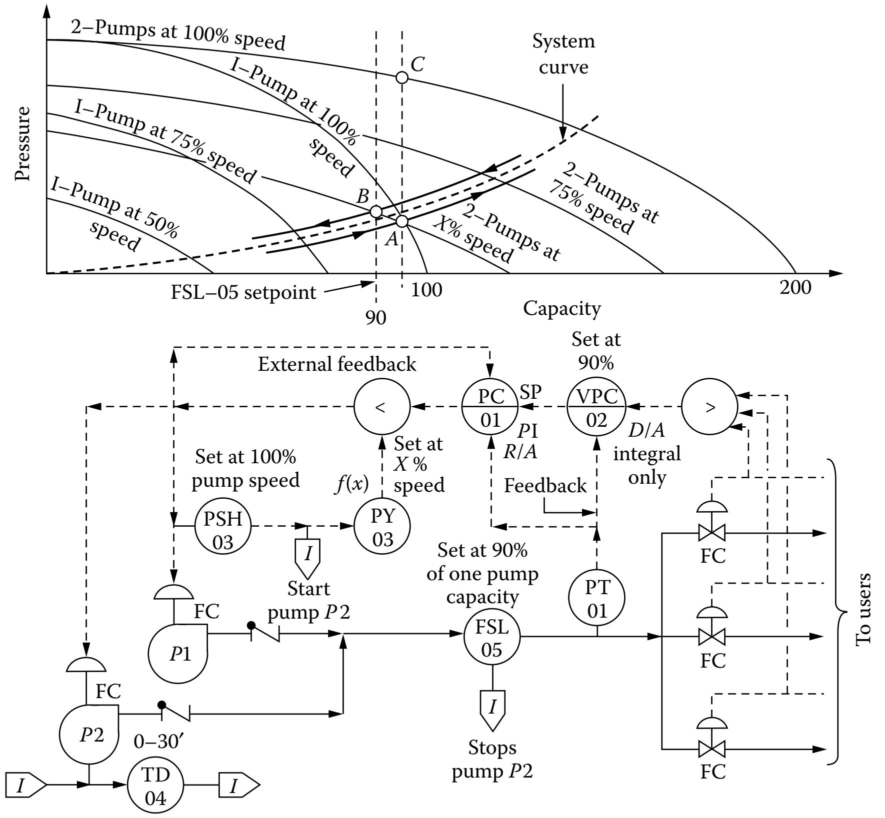
The pump station in Figure 8.35e consists of two variable-speed pumps. Their speed is set by PC-01. When only one pump is in operation and the PC-01 output approaches 100%, PSH-03 is actuated and the second pump is started, as shown by interlock #1 and the table at the bottom of Figure 8.35e. When both pumps are in operation and the flow drops to 90% of the capacity of a single pump, the second pump is stopped if this condition lasts longer than the setting of TD-04. The purpose of the time delay (TD-04) is to make sure that the pump is not started and stopped too often.

The top portion of Figure 8.35e shows the starting and stopping of the second pump on the pump and system curves. As the demand for water rises, the speed of the single operating pump increases until it reaches 100% at point *A*. Here, PSH-3 starts the second pump.

However, if the speed-control signal was unchanged when the second pump was started, an upset would occur, because the pressure and the corresponding pump speed of both pumps would instantaneously jump from point *A* to *C*. In order to eliminate this temporary surge in pressure, PY-03 is introduced. This is a signal generator that, upon actuation by interlock #1, drops its output to *x*. "*x*" corresponds to the required speed for the two-pump operation at point *A*.

Therefore, when interlock #1 is actuated, the low-signal selector immediately selects signal *x* for control, thereby avoiding the upset. After actuation, the output signal of PY-03 slowly rises to full scale. As soon as it rises above the output of PC-01, that signal is blocked by the low-signal selector and control is returned to PC-01.

Once both pumps are operating smoothly, the next control task is to stop the second pump when the load drops back to the point where it can be met by a single pump. This is



Interlock I

Condition			Action
Pump speed detected by PSH–03	Flow detected by FSL–05	Status of TD-04	Pump $P2$
At 100%	——	——	Start
Below 100%	Above 90%	——	Running
	Below 90%	Timing	Running
		Timed out	Stop

FIG. 8.35e

llustration of a control system that optimizes the energy consumption of a pumping station, consisting of two variable-speed pumps, by keeping the most-open user valve at near 90% opening.

controlled by the low-flow switch FSL-05, which is set at 90% of the flow capacity of one pump (point *B* on the systems curve).

The pump-cycling controls described here can be used for any number of pumps. For each additional pump, another PY and FSL must be added, but otherwise the system remains the same.

Optimization Alternatives

In fluid distribution systems in which the number of users served is large, Shinskey suggests a simpler system than the one described in Figure 8.35e. That control system is shown in Figure 8.35f. This control system configuration is based on the assumption that the terminal pressure will be kept constant if the pump discharge pressure is varied in proportion to the pressure drop across an orifice plate.

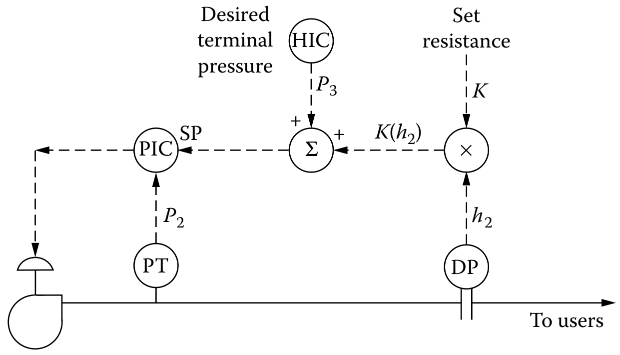


FIG. 8.35f

This control system keeps the terminal pressure of a mostly friction distribution system constant by varying it in proportion to the pressure drop across an orifice in the main header.

The pressure drop through an orifice varies in the same way as does the pressure drop in a mostly friction system. Therefore, if the orifice drop (h_2) is measured, this measurement can be related to the pipeline pressure losses by multiplying the drop by a set resistance ratio (K). Therefore, a set terminal pressure at the user can be maintained under variable load conditions by adjusting the pump speed, as shown in Figure 8.35f.

It is also advisable to continuously monitor the electric power consumption of all the pumps, so that empirical pump efficiency data will be always available and up to date. This will allow any load to be met with the most efficient pump or pump combination. In addition, the continuous monitoring of efficiency can also be used for maintenance scheduling purposes.

Calculating the Savings

The savings resulting from variable-speed pumping can be calculated at any operating point on the pump curve. Based on this information the relationship between the demand for flow and the power input required to meet that load can be plotted. Figure 8.35g shows these curves for both constant speed (control valve throttling)-type and variable-speed-type pumping systems. The difference between the two operating energy costs is the savings potential for optimization.

Once the saving curve shown in Figure 8.35g has been established, the next step is to determine the operating cycle. The operating cycle identifies the percentages of time when the load is 10%, 20%, etc., up to 100% (Figure 8.35h).

When both the savings and the operating curves are available, all that needs to be done is to incrementally calculate the savings as illustrated in Table 8.35i.

Knowing the total horsepower of the pumps and the cost of electricity makes it possible to convert the resulting percentages into yearly savings.

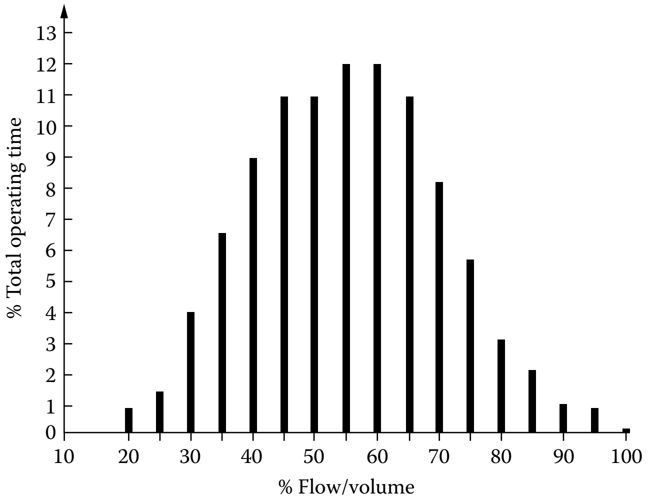

FIG. 8.35h
The pump operating cycle identifies the percentages of time when load is 10 percent, 20 percent, etc.

MODEL-BASED OPTIMIZATION

Equations 8.35(5) to 8.35(7) provide a model of a centrifugal pump that can run in a real-time controller. The basic concept is to add up the flows that are being pumped and then use the model of each of the pumps to calculate the power being consumed, if different pump combinations are used to meet that load. By the use of this model-predictive approach, the pump combination that consumes the least power can be identified and implemented.

Optimization of Pump Selection

A step-by-step optimization process involves the following steps:

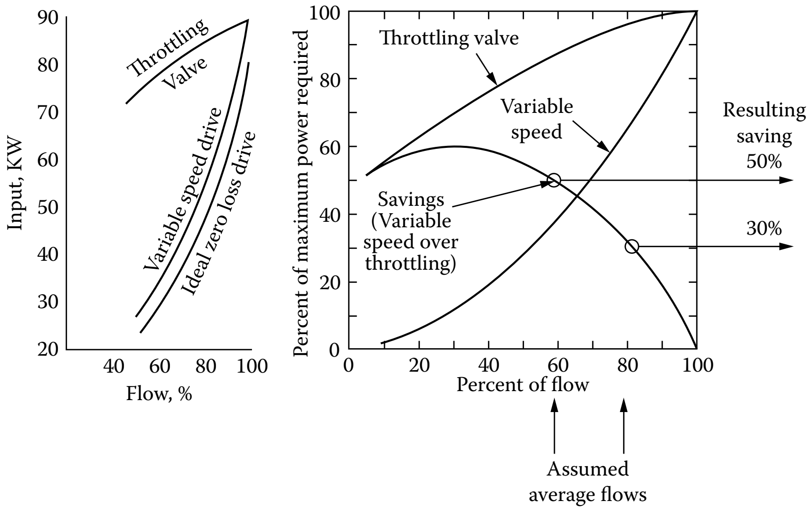

FIG. 8.35g
The savings generated by variable-speed pumping increase as the load drops off.

TABLE 8.35i
Illustration of Savings Calculation Based on Figures 8.35g and 8.35h.

% Flow	% of Time	% Savings	Total Savings (%)
Below 25	2.5	57	1.4
25–35	10	60	6.0
35–45	20	56	11.2
45–55	23	52	11.9
55–65	23	50	11.5
65–75	14	40	5.6
75–85	5.5	30	1.6
85–95	1.5	15	0.2
95–100	0.5	0	0.
	100%		49.4%

The first step is to measure the speed at which each pump is running and measure the pressure differential across each operating pump. Next, substitute the pressure and speed measurements into Equation 8.35(5) for each pump and calculate each pump flow. If individual flowmeters are available, it is advisable to cross-check these calculated flows against them. After this check, add the pump flows together to obtain the estimated total pump station flow.

The second step is to substitute the measured speed and the estimated flows into Equation 8.35(6) for each pump and calculate their power consumption. Sum up the powers to get the estimated pump station power consumption, and cross-check it against the actual power consumption, if installed power metering is available.

The third and last step is to assume that the required flow will be generated by a predetermined large variety of flow distributions among the pumps, and for each combination calculate the pump speed and the power consumption corresponding to the allocated flow. Compare the power requirements for each of the flow distributions and select the pump combination for operation that consumes least power.

The main advantage of having the pump models is speed (20+ combinations can be evaluated per second) and the ability to also automatically check for other criteria, such as NPSH availability. While much of this data can be condensed in look-up tables for manual use, such look-up tables can also be built into the controller, and it is not really necessary, because the digital controller can do the optimizing in real time and adapt to changing conditions.

The controller could also be programmed to find optimum pump selections. Such a heuristic solution would be more complicated than the controller described here, but it would configure itself to suit any set of pumps. See Section 2.18 in Chapter 2, Neural Networks, for more detail on this possibility.

Starting or Stopping Pumps

The strategy when starting or stopping pumps is to speed some up and slow others down smoothly during the *transition.* This smooth speed adjustment should always consider the speed limit represented by omega zero, which is the maximum pump speed that the pump can run at without delivering any flow, as was discussed in the previous section.

Therefore, when starting a pump, accelerate it up to ω_o quickly. Similarly, when stopping a pump, decelerate it from ω_o to zero quickly. This quick acceleration (and deceleration) does not cause flow surges because the pump does not deliver flow at speeds under ω_o.

In pump stations with pumps of different sizes, usually the optimum operation requires that one pump should stop at the same time as another starts. These pumps have different capacities, and after the transition the started pump will need to run at a different speed from the stopped one.

For a detailed description of the strategy to be used to optimize the selection, starting, and stopping of equal-sized and differing-sized pumps in a pumping station, the reader should study Reference 1.

CONCLUSIONS

Model-free pump station optimization, as described in the first part of this section, has been successfully used for decades. Model-based and neural network-based pump station optimization is relatively new and is expected to go through further development.

The adjustable-speed centrifugal pump optimization techniques described in this section will reduce the energy consumption of pumping stations by 12% or more, depending on the nature of the load served. They will also reduce pump wear commensurately.

Combined with surge-free pump starts and stops, and with their inherent predictive maintenance capability, these strategies can also improve the overall plant operation. In addition, they can eliminate the need for storage and can improve safety, if the particular storage volumes are hazardous in confined spaces.

Each model-based application can form a program shell that is reused, so that the development cost is amortized across many applications. Each implementation needs to be configured with specific pump curves and tuned for the specific application. However, this effort is insignificant compared to the initial cost of developing the program shell and the potential savings that can be obtained by these controls.

INTRODUCTION

Because of the high processing speeds involved and the increasingly stringent product quality specifications, modern automation systems can have a considerable impact on the profitability of a rolling mill operation. The high value of the strip produced means that short payback periods are often possible.

Multiple-drive systems for process lines are available using both analog and digital control techniques and are continually being advanced through the use of programmable digital hardware. These systems can use all available types of electrical drives and can be applied wherever speed is used for control of process variables.

Advanced mill setup models can generate actuator references for tandem and single-stand cold and temper mills rolling any combination of ferrous, aluminum, and brass alloys. The references calculated include interstand thickness and tensions, roll speeds, roll force, roll positions, work roll side shift, roll bending, and roll coolant flows. For continuous rolling mills, the model can calculate how to make a transition from the current coil conditions to those required for the new coil order.

Table 8.36a describes the features and characteristics of a typical rolling mill, which specification defines the equipment being controlled.

MULTIPLE DRIVES IN STRIP MANUFACTURING

The simplest application of two drives in a speed-controlled system is a conveyor line in which more than one set of rollers must handle a common strip of material. This strip can be a belt or a web of product, such as paper, plastic film, or foil. Roll and motor speeds must be maintained either at identical levels or at a constant ratio to allow for gearing differences.

Many process lines require the ability to vary and control speed relationships between machine sections. This ability is a key part of the process, regulating such things as stretch ratios of calendaring systems, proportions of various ingredients in a product, and printing synchronization. Regulation of some process variables is accomplished through coordination of drive speed as well as of torque.

TABLE 8.36a
Typical Rolling Mill Specification

Mill type..................................	1-2-3-4 reversing cold rolling mill
Material	Stainless steel, silicon steel, carton steel, nickel alloys
Strip width, maximum............	18 in. (457 mm)
Strip width minimum..................................	9 in. (230 mm)
Entry gauge maximum............	0.60 in. (1.5 mm)
Exit gauge minimum................	0.001 in. (0.025 mm)
Maximum coil size (winder).....	16 in. (406 mm) I.D./37 in. (940 mm) O.D.
Absolute coil weight.................	4,000 lb (1,820 kg)
Specific weight..........................	250 PIW (4.5 kg/mm)

Winder tension maximum................	9,000 lbs (4,050 kg) to 500 FPM (152 MPM)
Winder tension minimum................	140 lbs (64 kg)
Payoff mandrel diameter..................	16 in. (406 mm) nominal
Payoff/wind-on speed......................	400 FPM (122 MPM) @ 37 in.(940 mm) O.D. coil
Rewinder mandrel diameter..............	16 in. (406 mm) nominal
Payoff/wind-on tension.....................	3,000 lb (1,364 kg) max.@ 37 in.(940 mm) O.D. coil
Rewind payoff/rewinder speed.....	400 FPM(122 MPM) @ 37 in. (940 mm) O.D. coil
Rewind payoff/rewinder tension.......	1,100 lb (500 kg) max. @ 37 in.(940 mm) O.D. coil
Coolant system...................................	Mineral oil
Mill direction	Left to right

Multiple-drive systems are also used in advanced process control, in which speed is varied in response to changes in product properties, such as temperature or thickness. The refinement of process control computers has increased the potential applications of speed-controlled systems as effective control loops are developed for manufacturing lines.

Electrical Drive Systems

The techniques used for motor speed control in multiple systems include the eddy-current clutch, the DC static drive, and the AC variable-frequency drive.

Eddy-Current Drive

An eddy-current clutch drive applies variable voltage to a field coil, regulating the slip of an output rotor with respect to a constant-speed input rotor. The result is a smoothly operating unit with wide torque capability and simple, compact electronic controls. Its low efficiency, however, has limited its use to a few specialized applications.

DC Static Drives

The DC static converter is probably the most widely used speed control device. Because DC motor speed is proportional to voltage, and motor torque is proportional to current, the output of the system is easily regulated.

The available horsepower in these drives ranges from less than one to several thousand horsepower. Models currently on the market can give full output torque over the entire speed range with proper motor cooling. High efficiencies are obtained from the use of solid-state components, and speed regulation to 0.1% is available using conventional tachometers (for details on tachometers, refer to Section 7.19 in the first volume of this handbook).

The DC drive also lends itself to tension control because of its simple current-torque characteristic. It can also provide full negative, or braking, torque to a load when equipped with regenerative capability. One disadvantage of this type of drive is its poor power factor at low speeds. Installation of correction capacitors is sometimes required to avoid penalties from the utility. DC motors are also typically more expensive than corresponding induction motors (for details on tension and torque detectors, refer to Sections 7.21 and 7.25 in Chapter 7 in the first volume of this handbook).

AC Variable-Frequency Drives

AC variable-frequency drives are the beneficiary of many recent electronic advances. In these drives, the speed of the AC motor is proportional to the output frequency of the controller, with voltage varied in proportion. The development of power transistors and logic devices has enabled these drives to produce variable-frequency power compatible with virtually all AC motors up to 40 hp (30 kW).

In larger power ranges, silicon-controlled rectifier (SCR) choppers are used in place of transistors; efficiency deteriorates, however, because the power waveform is degraded. The AC transistorized drive has a high power factor (typically over 90%) and the ability to produce full motor torque over the entire speed range with proper motor cooling.

Variable-frequency drives are inherently self-regulating when used with synchronous motors. Speed regulation with induction motors depends on slip and is typically 20%. Closer regulation requires tachometer feedback.

Analog Multiple-Drive Systems

A conventional analog drive is speed-regulated through the comparison of a desired speed, represented by a reference voltage, with the actual speed, represented by a tachometer-generated voltage. The difference between the two speeds is the error used to raise or lower the actual drive power output to the proper level.

Speed coordination between two drives is easily implemented using the wide variety of amplifiers, multipliers, and meters developed for use with analog voltages. The techniques described here can be used with any of the basic drive types and are widely available.

Speed Control A typical speed control system is shown in Figure 8.36b. Here, the regulation of a metal foil rolling mill is illustrated, where one set of draw rolls are operating at a differential but constant speed ratio to the speed of another, prior set of rolls.

In the analog controls shown, the voltage used as a reference for the first, or lead, drive is fed into a potentiometer. The reference for the second drive is taken from the wiper of the pot, giving a reference that will vary with both the reference of the first drive and the wiper position. The ratio will be constant between the two drives for a given position. An amplifier is often used between the two drives to give the second drive the ability to go faster than the first as well as to prevent interaction between drives.

Additional amplifiers and control potentiometers enable the coordination of any number of drives. The system described in Figure 8.36b will maintain the desired speed ratios of the three sets of draw rolls as the process speed is changed. A variation often seen is a speed-follower system, in which the actual speed of a lead motor becomes the reference for the next drive or set of drives. This actual speed is generated by the lead motor tachometer.

Motor-operated reference potentiometers, acceleration control amplifiers, and upper and lower limit settings are usually incorporated into multiple-drive systems to give total control of reference voltages. The components used in these systems typically give accuracies of 5–0.1%, depending on their quality and complexity.

Dancer Tension and Speed Controls Winding and unwinding of a web of material, such as paper, is a common application of

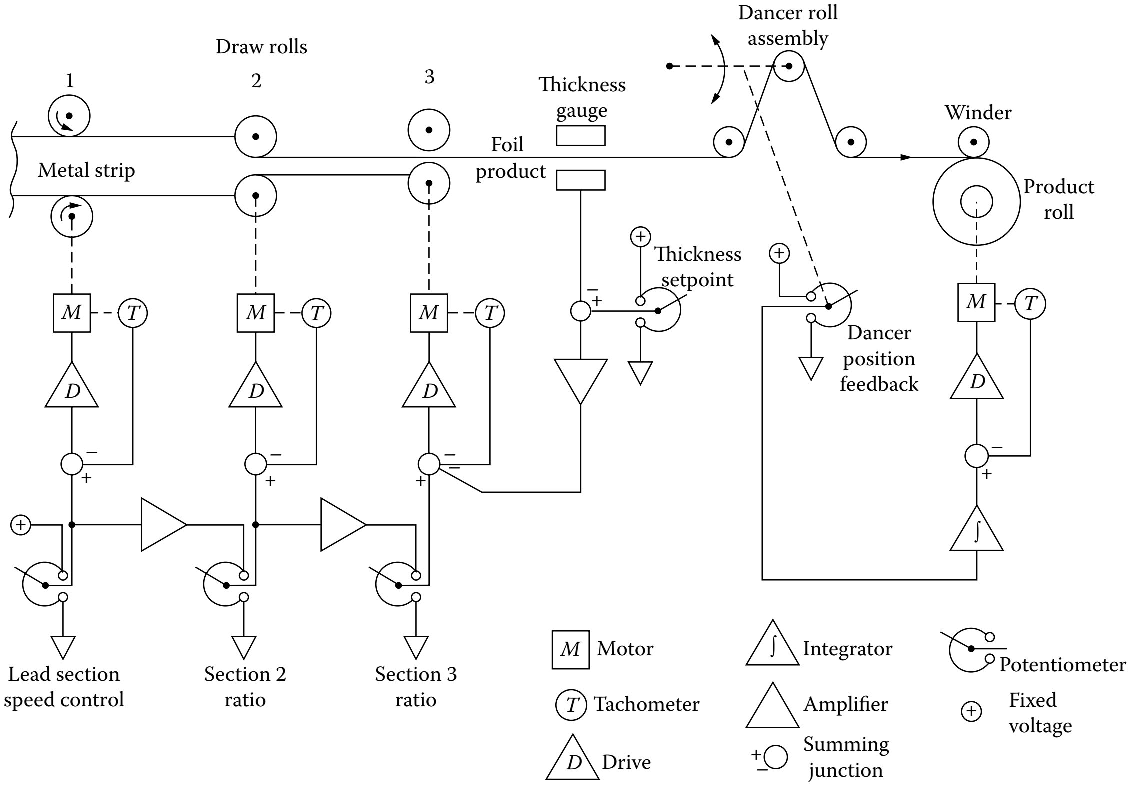

FIG. 8.36b
Analog speed-controlled process line metal foil rolling mill.

multiple drives. These systems often use movable rolls, called dancers, which accumulate a certain length of material and hold a preset tension on it. The dancer assembly is located between a constant-speed output roll and a roll of material being wound, as in Figure 8.36b.

As the diameter of the roll being wound increases, its rotational speed must decrease in order to maintain a constant surface speed. If the input speed to the assembly from the draw rolls has not changed, a gradual surface speed increase in the winder will pull the dancer down. Therefore, the dancer motion mechanically drives a feedback potentiometer, producing a voltage that is integrated and used to correct winder speed to the proper level.

Dancer systems can also be used in the same way between two machine rolls to maintain speed synchronization in a system with otherwise low accuracy. Slight changes in the speed of one section will raise or lower the dancer, which will produce a voltage correcting the speed error.

Thickness Control Analog systems can also be used for more complex process control. The foil thickness control loop shown in Figure 8.36b is an example of the control of two process variables in an interrelated system.

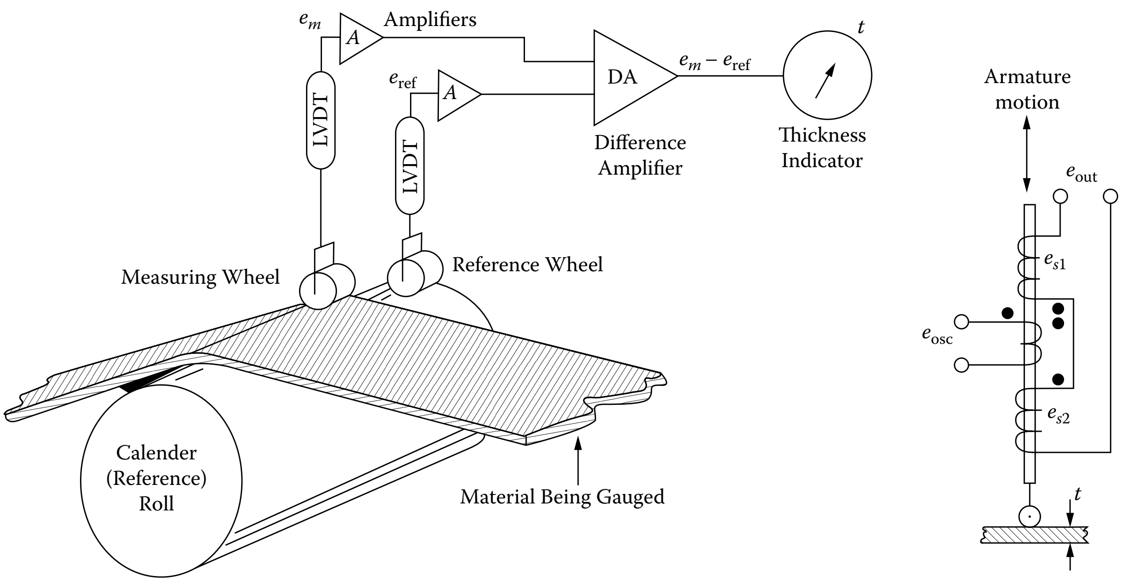
Figure 8.36c describes the operation of a linear variable differential transformer (LVDT)-type thickness gauge, while Table 8.36d provides a summary of the capabilities of a number of thickness detectors.

Digital Control Techniques

The availability of sophisticated and cost-effective digital equipment has greatly expanded the capability of process control systems. In many applications, digital signals are superior to analog signals, because of their precision and high noise immunity. Their processing by high-speed computers can also provide the basis of model-based advanced controls.

A digitally regulated drive and motor will typically be provided with a pulse generator as a feedback device. The pulse generator is driven by the motor and produces a frequency proportional to the motor speed. The speed reference for such a drive will be either a precision frequency or a numerical value. Systems using a frequency reference often include a phase-locked loop for comparison of the reference and actual speeds. These systems can also use up–down counters to detect any build-up in speed error.

Systems using a numerical reference compare the desired speed with the number of pulses generated by the feedback device in a given period; this allows numerical treatment of any speed error and great flexibility in processing the correction. Digital systems typically operate with zero average



$t = k(e_m - e_{ref})$
t = Thickness (mm)
k = Calibration constant (mm/Volt)
e_m = Output of measuring LVDT (Volt)
e_{ref} = Output of reference LVDT (Volt)

$e_{out} = e_{s2} - e_{s1}$
e_{osc} = Output signal of LVDT (Volt)

speed error, meaning that no speed difference is allowed to accumulate.

Two or more motor drives are easily coordinated with digital references. Analog components (which are less accurate) are replaced by thumbwheel switches and microprocessor-based computation, as illustrated in Figure 8.36e. Numerical speed ratios can be set and used precisely, and synchronization is held exactly, because no pulses are lost. The history of the

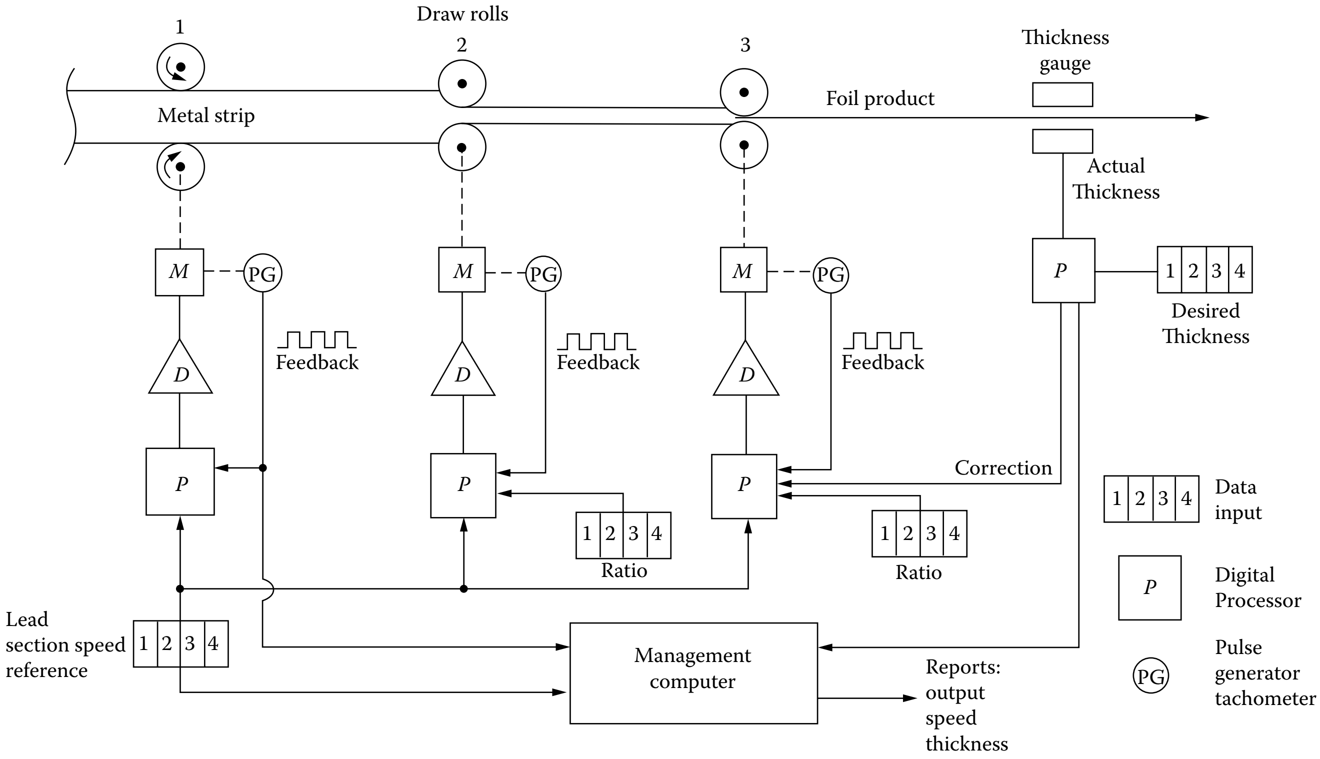

FIG. 8.36e
Digital rolling mill controls.

speed of the machine is always available for subsequent correction.

Thickness Controls The computation capability of a digital system allows complex functions to be easily implemented. An example is the control of the thickness of a strip of metal being drawn to a given gauge between sets of rollers, shown in Figure 8.36e. A thickness-measuring device outputs a number representing the actual gauge of the product, which is then compared with the desired gauge, and in case of an error, a correction signal is fed to the speed control of the draw rolls.

An increase in the speed of the last roll will reduce the thickness of the product foil, because the input rate has not changed; a decrease in the speed of the last roll will increase its thickness. Limits are set upon the maximum and minimum speeds and their rates of change. Tuning of the control system is simplified for the operator by the parameters being entered numerically.

Advanced Thickness Control In more advanced control systems, the noninteractive tension and thickness/extension and tension controls ensure the consistently high performance for any combination of mill type, product range, and operating practice.

A variation of feedback and feedforward control algorithms in combination with a variety of thickness gauges and mass flow thickness controls can optimize the performance of the available mill actuators.

Roll eccentricity compensation (REC) and different tension control strategies can be employed for threading and rolling in conventional tandem mills. The controls can also utilize speed-dependent actuator references generated by the setup calculation. The control systems usually include current overload protection, rounding of acceleration ramps and separate speed ramps for threading and tailout. A dynamic order change function is usually also available for continuous rolling mills.

Advanced Modeling An advanced mill setup model includes comprehensive sequences of calculations that involve the derivation of actuator references and schedule-dependent control system gains appropriate for the particular application.

One application might involve a thick product where the mill setup may aim to achieve the correct thickness on the coil head end as it is threaded with minimal out-of-tolerance lengths. In this case, the setup calculation can be made to achieve the target thickness on the coil head end and at thread speed with minimal yield losses.

In another case, it might not be possible to roll the head end to the target thickness until tension is established on each side of the stands. In such a case, two separate sets of mill actuator references are required for the threading operation. First, a short length of strip will be rolled that is thicker than desired due to the lack of front tension while the head end is produced, even with increased back tension.

Once the head end is coiled, the mill can achieve target thickness at thread speed with acceptable flatness. For this situation, the threading setup calculation must sacrifice a controlled length of out-of-tolerance material until tension is established and then the correct thread speed, roll gap, and roll bending references are applied to achieve the desired thickness reduction on each stand.

Operator Interfaces State-of-the-art digital control systems also improve the operator access to the system, because changes can be initiated directly through a keyboard or a video display using easily learned commands. Operator interfaces include mimic displays, performance monitoring, diagnostics, alarms, and screens to interact with the setup functions and dynamic controls.

Operator interfaces can be implemented on PCs using Windows NT and connected via an Ethernet TCP/IP network. The screens usually update rapidly, and the package is sufficiently flexible that the client's engineering staff can reconfigure screens where that becomes necessary.

Management Support Digital techniques in speed control also allow the monitoring of all other functions of a production process. As shown in Figure 8.36e, the information gathered about speed and thickness can be stored and used to generate reports. This can be used to inform both the equipment operators and management of the quantity and quality of the foil being produced.

The precise control of motor speed has thus led to accurate information that is vital to production management.

8.37 Separation Controls, Air

M. H. MACCONNELL (2005)

INTRODUCTION

This section will focus on the different processes and associated control strategies that are used in the air separation processes. The nominal composition of air is provided in Table 8.37a.[1] Air separation processes primarily produce oxygen, nitrogen, or argon in either the gas or the liquid phase. This section includes discussions of process controls that are associated with three air separation technology areas: membrane, adsorption, and cryogenic distillation in the manufacture of oxygen, nitrogen, and argon.

The typical product purities and production rates of the three highlighted technologies are provided in Table 8.37b. Production volume, product mix, and product purity determine the design of the individual air separation facilities. From a production volume point of view, oxygen is the most significant product.

Oxygen is the third-most-produced industrial chemical in the world today; the majority of the production plants use cryogenic air separation facilities.[2] The consumption of oxygen by market is illustrated in Table 8.37c.[3]

ADSORPTION TECHNOLOGY

The Process

The adsorption technologies used are either the vacuum swing adsorption (VSA) or the pressure swing adsorption (PSA) process. In either case, the principle of operation involves creating physical conditions in a vessel that permit an adsorbent material that is packed in the vessel to temporarily remove or adsorb the impurities of interest. Once the adsorbent bed is full, the physical conditions in the vessel

are switched to a different state to permit the initiation of desorption of the impurities from the adsorbent bed.

Adsorption processes depend on the affinity of certain natural and synthetic materials to preferentially adsorb the nitrogen or the oxygen molecules. Zeolites, for example, are aluminosilicates that have nonuniform electric fields in their void spaces that cause preferential adsorption of polar molecules relative to nonpolar ones. For this reason, when air is passed through the zeolite, nitrogen is more strongly adsorbed than are oxygen or argon molecules.

As air passes through the bed, nitrogen is retained and an oxygen-rich stream is produced in the vessel. Carbon molecular sieves can also be used as the air separation media. In carbon molecular sieves, the pore sizes are approximately the same size as the air molecules. Because oxygen molecules are smaller than nitrogen molecules, the oxygen molecules diffuse more quickly into the pores than do the nitrogen molecules. This is a kinetic adsorption process. In short, carbon molecular sieves are selective for oxygen, and zeolites are selective for nitrogen.

Control of the Adsorption Process

Typically, programmable logic controllers (PLCs) are used to control the VSA or PSA units. Analog, on/off, and timer functions are all utilized to control product purity, to operate the compressor and regeneration valves, and ultimately to obtain maximum productivity and efficiency.

Locating the Adsorbate Front If the position of the adsorbate front and the associated mass-transfer zone along the axial length of the adsorber is known, it can be very useful, because it determines the composition and ultimate product purity as well as the required timing of the regeneration step.

Because of the temperature and pressure variations in this process, the commercially available oxygen sensors are not useable for direct on-line measurement. Therefore, the operating parameters are established mathematically from pilot studies that infer the composition on the basis of energy balances and axially distributed temperature and pressure measurements.[4] After the product leaves the unit, its quality is analyzed to ensure that product specifications are met. This analysis is also used to determine regeneration valve timing based on the pilot scale-up process and operating experience.

Vacuum Swing Adsorption

Vacuum swing adsorption is principally used in the generation of oxygen gas in the purity range of 90–93%. Manufacturers of VSA units provide adsorbent materials that adsorb nitrogen at atmospheric and slightly elevated pressures. This permits generation of an enriched oxygen stream that can be accumulated in a receiver. Depending on the amount of adsorbent, the bed will be allowed to continue adsorption of nitrogen for a fixed period of time until it is nearly saturated. After this, the beds are switched to vacuum, and the desorption of nitrogen occurs and the nitrogen is vented.

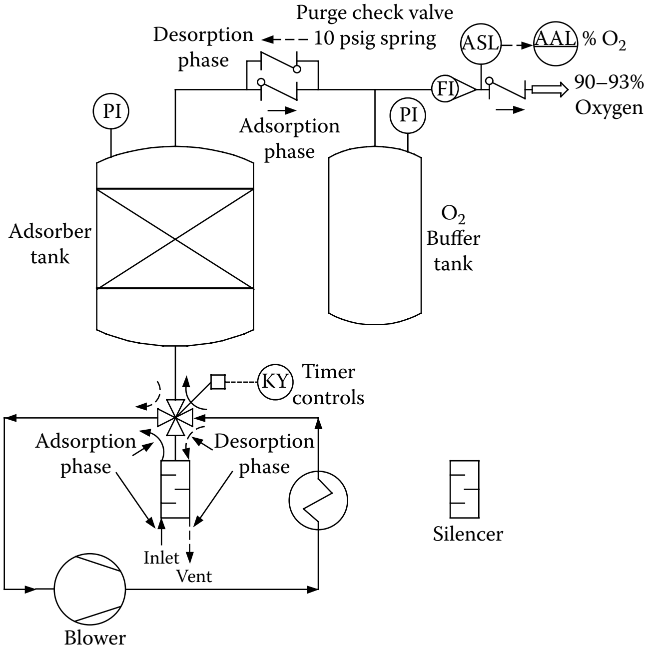

FIG. 8.37d
Components and controls of a small-scale vacuum swing adsorption unit. (Courtesy of Air Products and Chemicals, Inc.)

In a small-scale VSA oxygen generator, a timer (KY in Figure 8.37d) controls the blower that, during the desorption phase, generates the vacuum in the adsorber bed, causing the nitrogen, moisture, and other contaminants to be desorbed and vented. When the vacuum level in the adsorber bed is low enough, the adsorber vessel is purged with oxygen to sweep the remaining nitrogen from the vessel. This purge continues for a timed period, after which the automatic four-way valve returns the system into the adsorption phase, and the blower pushes fresh air into the adsorber bed.

When the pressure in the adsorber bed exceeds the pressure in the oxygen storage tank, oxygen will start flowing into the storage tank and will continue to do so until the feed timer times out and the cycle starts over again. This process is depicted in Figure 8.37d.

Paramagnetic oxygen analyzers (single or redundant) are typically used to continuously monitor the product quality and to alarm (AAL on Figure 8.37d) and initiate automatic interlocks to trip the equipment (which protects the customer by switching the oxygen supply to a backup), if purity falls below the 93–95% range. Larger-scale VSA units operate in a similar manner.

Pressure Swing Adsorption

The PSA technology utilizes co-adsorption, a phenomenon where both nitrogen and oxygen are adsorbed, but they are

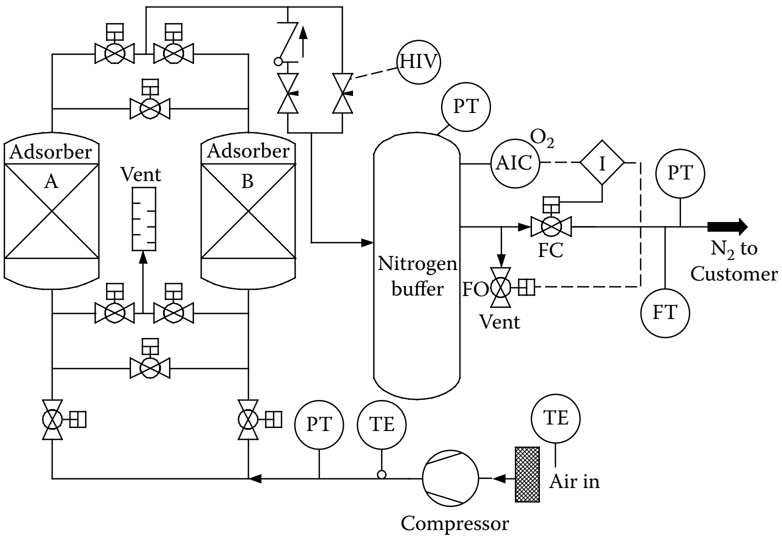

FIG. 8.37e

Process and instrumentation diagram of a pressure swing adsorption-type nitrogen generator. (Courtesy of Air Products and Chemicals, Inc.)

adsorbed at different rates. The process utilizes a two-tank (or tower) arrangement (see Figure 8.37e) in which two primary processing steps, adsorption and transfer, are performed. Unlike a desiccant-type adsorber that removes essentially all of the target molecules, the PSA carbon molecular sieve (CMS) takes advantage of the difference in adsorption rates (kinetic adsorption) to achieve the separation objectives.

The production rate of the PSA process can be limited by the adsorptive capacity of the adsorber, or when the bed is very cold, by the rate of desorption of oxygen from the carbon molecular sieve. The PSA units are often installed out of doors and need to be retuned for winter and summer operations, if ambient temperature conditions are substantially different.

A simplistic explanation of this temperature sensitivity is that hot molecules vibrate faster than cold molecules and, therefore, do not adsorb as readily into the carbon pores when hot. When the beds are cold, the opposite occurs, and therefore, it takes longer for the molecules to desorb from the carbon pores.

Design Considerations The carbon in the CMS is typically an extruded pellet approximately 2 mm in diameter and 1 cm in length. The carbon in the CMS bed is soft and can easily be pulverized into dust by agitation. Therefore, the bed must not be agitated.

If the carbon pellets turn to dust and the dust is vented, this is uneconomical because the CMS is relatively expensive and because the carbon dust shortens the life of the valve seats. Therefore, PSA vessel sizing and gas flow controls must guarantee that the gas velocity through the PSA unit is low, on the order of 1–5 ft/s. The product purity is a function of the gas velocity, the timing cycle of the tower, and the CMS selectivity grade. The sizing of the PSA vessel should also consider the required production rate and the CMS efficiency rating.

In a PSA-type nitrogen generator, it is also important to control the air-to-nitrogen ratio. If the nitrogen product has to be 0.5% pure, an air-to-nitrogen ratio of 3:1 is acceptable, whereas if high-purity (5–10 parts per million [ppm] O_2) nitrogen product is required, the ratio of air to nitrogen should be around 5:1.

The PSA vent dump volume largely impacts the air-to-nitrogen ratio. It is sometimes possible to increase efficiency by using a little more air or cycling the beds faster.

Process Measurements The product purity is generally measured with fuel cell-based electrochemical oxygen analyzers (for a detailed description of the different oxygen analyzers and their features, see Section 8.42 in Chapter 4 in the first volume of this handbook). For critical applications, it is often appropriate to install two oxygen analyzers in parallel to provide redundancy and improved reliability.

Given that the PSA units are subject to wide ambient temperature variation, it is important that the oxygen analyzer be provided with good temperature compensation. The PSA unit should always be provided with the capability for remote monitoring of the process conditions and of the product quality. Because many of the PSA units are located in remote locations, the remote monitoring of PSA installations is also used to dispatch maintenance crews from a central location as needed.

As shown in Figure 8.37e, the analog measurements typically include the measurement of product composition, product flow rate, compressor discharge (feed) pressure and temperature, N_2 supply pressure to the customer, product

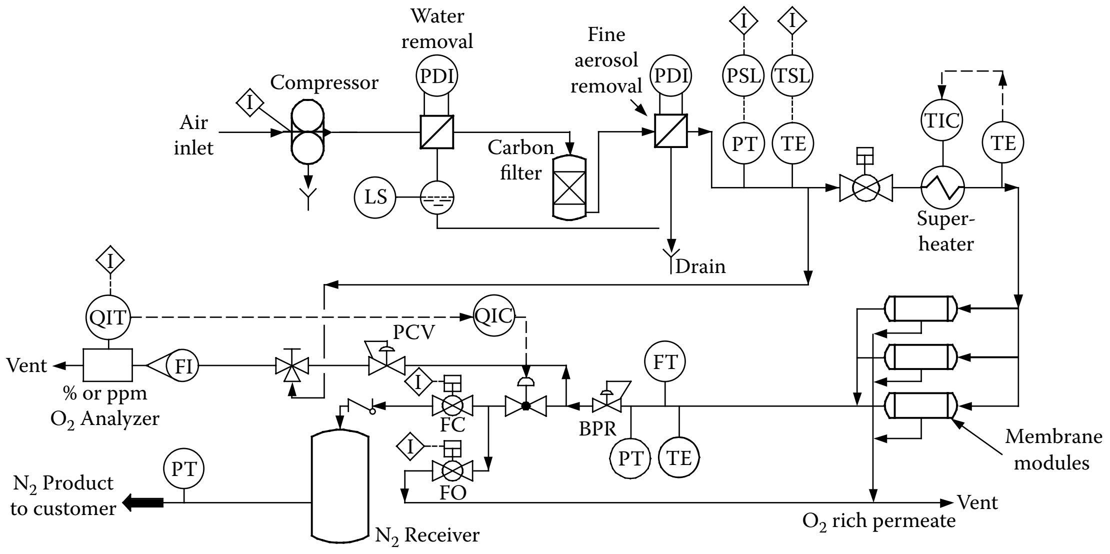

FIG. 8.37f

Process and instrumentation diagram of a pressure membrane-type nitrogen generator. (Courtesy of Air Products and Chemicals, Inc.)

buffer tank pressure, and ambient temperature. A number of on/off status measurements are also made to monitor valve positions and compressor status.

Programmable logic controllers are used to control the adsorption–desorption cycle of the plant, which essentially involves opening and closing the eight or so on/off valves on a time cycle sequence. These valves are either ball or butterfly valves, depending on the line size. The valve actuators are typically double-acting air cylinders, except for the fail closed (FC) nitrogen product valve and the fail open (FO) nitrogen product vent valve, which are spring-loaded to provide the required safe failure positions in the event of a product quality excursion or unit shutdown.

MEMBRANE AIR SEPARATION

Membrane systems are used for the continuous separation of components in mixed gas streams. The production volume and the achievable purity are generally lower than from adsorption or cryogenic processes. The most commonly used membrane systems are in the production of nitrogen, although membrane separation is also used in gas drying applications where water molecules permeate very quickly through the membrane material.

The predominance of nitrogen generators as membrane separators is because the smaller size of the oxygen molecules guarantees the superior permeability of oxygen through the membranes. As a result of this difference in permeability, membrane systems can only be used to produce oxygen in a concentration range of 25–50%, whereas 99.9% nitrogen purity is achievable.

Process Description

The membrane separation process starts with an air compressor (typically, an oil-flooded screw design) that compresses air to 100–200 psig (Figure 8.37f). The moisture and aerosols are removed from the compressed air by a carbon filter, and then it is superheated to prevent any condensation in the membrane modules. The superheated gas passes through a bank of parallel membranes, where oxygen permeates through to the low-pressure side of the membrane and is either vented or recycled.

One or two electrochemical gas oxygen analyzers (QIT in Figure 8.37f) continuously sample the high-pressure nitrogen product as it leaves the membrane modules. The product quality is controlled by the manipulation of the product flow control valve that is feeding the accumulation vessel. If the oxygen concentration in the product exceeds the allowable limits, the FC on/off valve on the receiver inlet trips closed and the FO on/off valve vents the product, until purity is reestablished. A back-pressure regulator (BPR) on the membrane system outlet prevents drawing more product than is available at the specified purity.

Flux and Selectivity

The membrane separation process is based on the difference in permeation or diffusion rates of nitrogen and oxygen molecules through a polymeric membrane that separates the high- and the low-pressure streams. Flux and selectivity are the two properties that bear directly on system design.

Flux determines the membrane surface area, and for a given gas, flux is a function of the partial pressure difference and inversely of the membrane thickness. In addition, each type of membrane material has a characteristic proportionality constant called permeability. Selectivity is the ratio of the permeability of the gases that are to be separated. In other words, permeability is the ratio of the speeds at which the respective gases diffuse through the membrane.

Membrane System Sizing

Sizing of the membrane system is based primarily on two parameters: the length of the membranes in each module and the number of modules installed in parallel. For a given amount of flow, the length of the membrane modules tends to determine the purity of the product. In general terms, the product purity is a function of the flow rate through the modules, while the number of parallel modules determines the volumetric production capacity.

The efficiency of a particular membrane module is a measure of the amount of nitrogen produced from a unit of air consumed. The efficiency and production capacity depend on the overall permeability and selectivity of the membranes, because there is always a certain amount of nitrogen that is lost with the oxygen. Therefore, a given membrane combination will produce a known amount of nitrogen product of a specific purity, if the unit is operating normally.

Physical Description The membranes are hollow polymeric fibers. The diameter of the fibers is on the order of some hundreds of microns. The fibers are composed of any of a number of polymers, including polysulfones, polycarbonates, and polyimides. The fibers are bundled together in a fashion similar to that of a shell and tube heat exchanger The bundle of fibers of specified length is effectively sealed on both ends to tube sheets.

During operation, the higher-pressure air passes through the inside of the fibers, and oxygen is permeated to the outside (the shell side). The entire membrane adsorption system is packaged in a cabinet with operator controls conveniently located on the front panel. Cabinets are normally installed indoors at the customer location.

CRYOGENIC AIR SEPARATION

The term *cryogenic* refers to any material or process that operates at very low temperatures, typically below 120°K (–243°F, or –153°C). The use of distillation to separate air into its component is a mature technology. The use of cryogenic engineering in the liquefaction of air was initially used at the beginning of the 20th century.

Cryogenic processes produce oxygen, nitrogen, argon, and other rare gases from atmospheric air. The selection from among these processes and cycles depends on the product volume, phase, and purity requirements as well as on the capital cost and energy consumption constraints.

An advantage of cryogenic over adsorption processes is their ability to coproduce oxygen, nitrogen, and argon as well as their ability to liquefy a portion of the total output. Storage of liquefied product in vacuum-insulated tanks serves as backup for gaseous product systems during outages or for the liquid filling of truck trailers for merchant sales.

This section will describe the low-pressure (LP) cycle and the associated process controls in a typical operation. Cryogenic processes utilize the same distillation principles as do higher temperature processes, except that the distillation equipment, heat exchangers, and associated piping are located inside an insulated enclosure referred to as a cold box or can, depending on whether the enclosure is rectangular or cylindrical in shape, respectively.

Front-End Air Purification

The cryogenic air separation process consists of two main operations. The first is the front-end purification of the air feed before it is sent to distillation. This step is described in Figure 8.37g. Once the air is purified, the air stream is split in two and both streams are sent to the cryogenic distillation (cold box) operation, which is shown in Figure 8.37h. The main heat exchanger is shown on both figures, completely on Figure 8.37h and partially on Figure 8.37g.

Feed Air Preparation The most commonly used process for the production of oxygen and/or nitrogen is the low pressure or double column cycle. In this process, the main feed air is compressed to a range of 60–200 psia, the heat of compression is removed by a cooler, and the high boiling impurities (H_2O, CO_2, N_2O, and certain hydrocarbons) are removed by an adsorption system (Figure 8.37g).

The purified air is divided into two streams, one of which is compressed with a booster compressor (shown on Figure 8.37h, which is a continuation of Figure 8.37g) to a range of 100–1200 psia. Both feed air streams are cooled in the main heat exchanger (schematically shown in both Figures 8.37g and 8.37h) by indirect heat exchange with cryogenic return streams.

Reversing Heat Exchangers Prior to 1980, most air separation plants used reversing main heat exchangers to remove the high boiling impurities such as moisture and carbon dioxide (CO_2) from the feed air. In these early plants, the moisture and CO_2 in the feed air to the cold box were allowed to freeze in the main heat exchanger that was cooled by the counterflow of cryogenic gas.

This accumulation was allowed to continue for a set time period or until the exchanger began to increase its pressure drop or began to lose some of its heat-transfer capability. At that point, the flow direction through the exchanger was reversed, and dry, CO_2-free waste gas was sent through it to purge the accumulated impurities to an atmospheric vent.

The reversing heat exchangers were very large and tended to require substantial maintenance due to leaks, which were caused by frequent and severe temperature cycling. Moreover, unlike the type of front-end adsorber systems shown in Figure 8.37g, the reversing exchanger also suffered from an

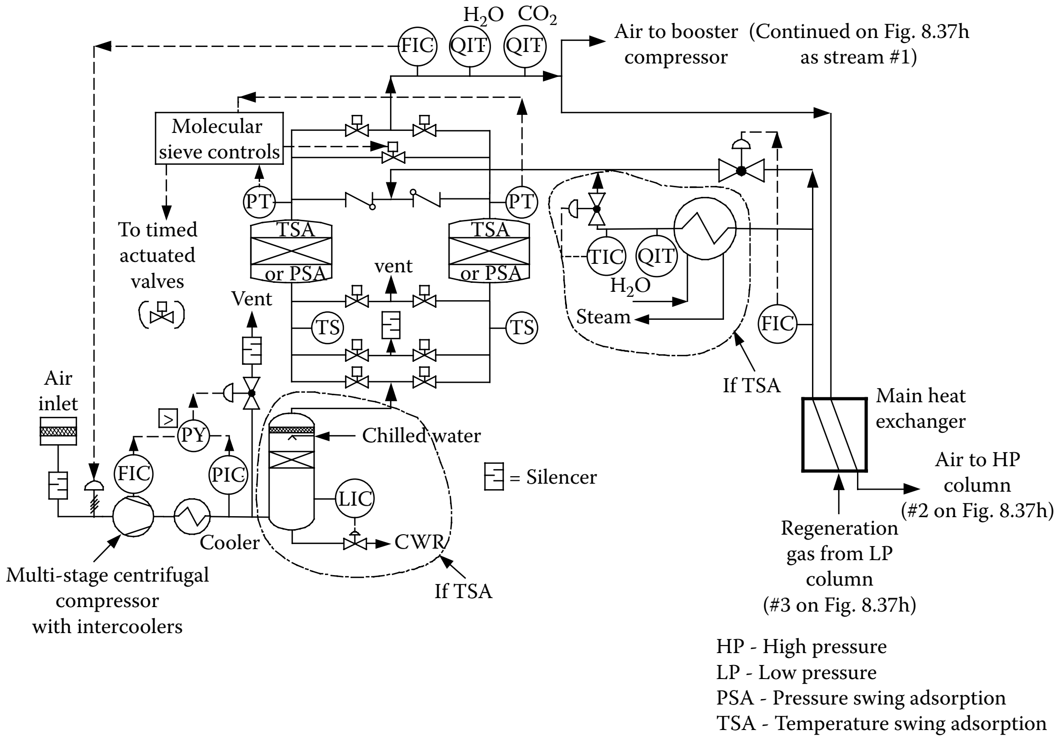

FIG. 8.37g
The equipment and main instrumentation used in the feed section of the cryogenic distillation process. (Courtesy of Air Products and Chemicals, Inc.)

inability to remove acetylene and other particular hydrocarbons, which could then concentrate in the liquid oxygen and, thereby, cause an unsafe condition, having the potential for energy release.

To address this safety concern, plants that use reversing heat exchangers continuously process all their liquid oxygen in the distillation system through adsorption beds to remove the hydrocarbons. The adsorbers are then periodically regenerated with nitrogen.

Feed Air Adsorption Systems Today, most cryogenic air separation plants are built with an adsorption system front end that features either temperature swing adsorption (TSA) or pressure swing adsorption (PSA), similar to the process illustrated in Figure 8.37g.

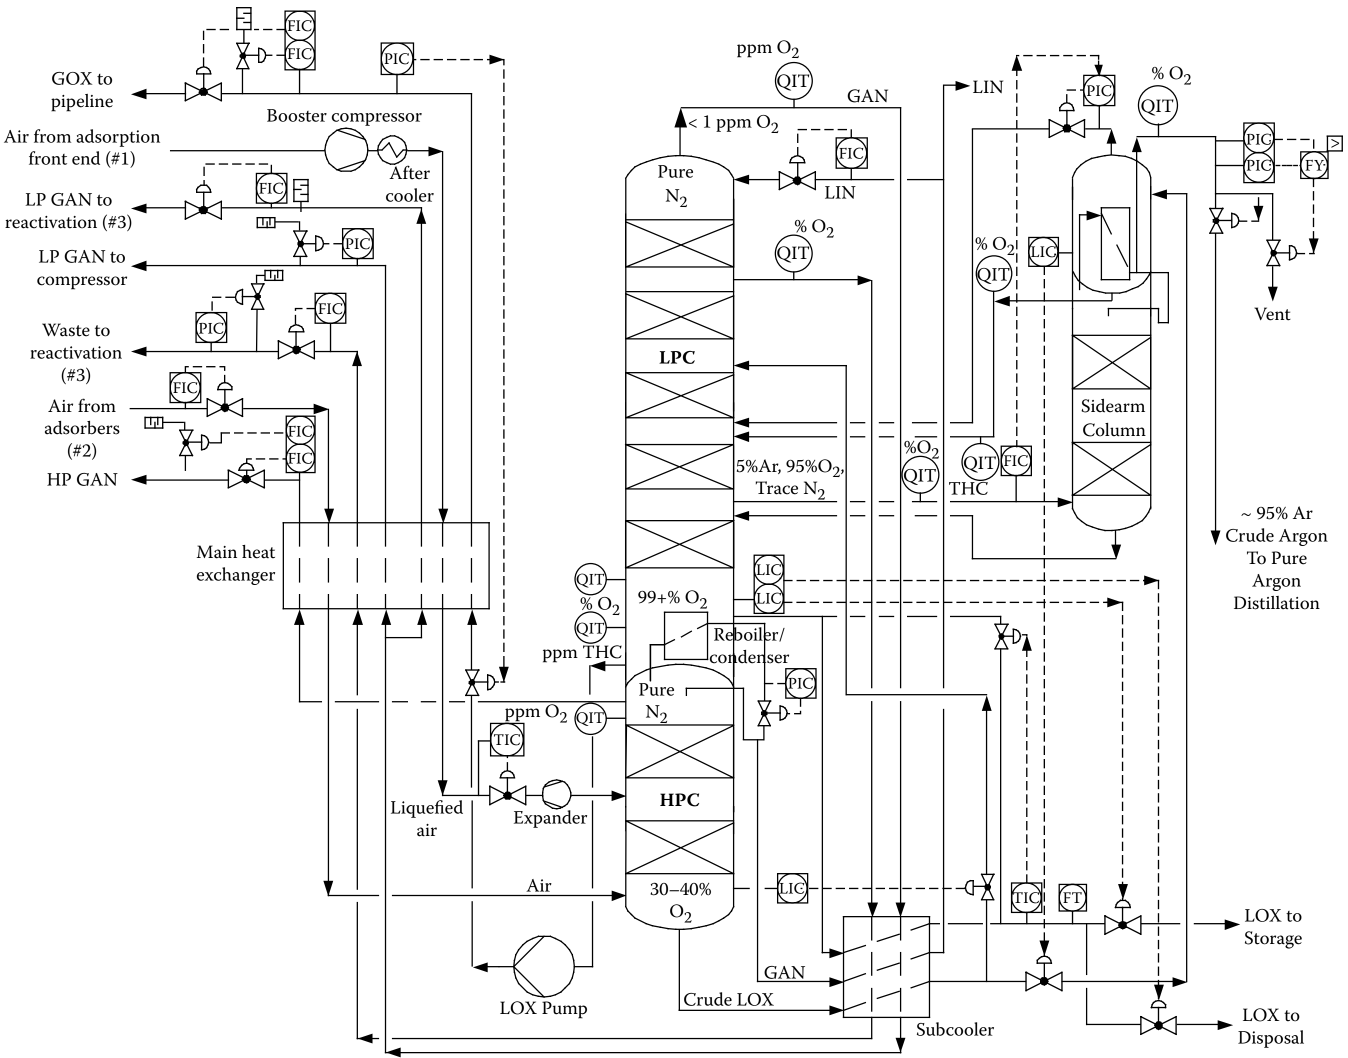
In either case, two or more vessels packed with alumina beads or with a molecular sieve are used, which packing has an affinity for high boiling impurities such as moisture, carbon dioxide, nitrous oxide, acetylene, and a number of other impurities. Removal of these impurities is critical, because if they freeze in the cryogenic section of the plant, they obstruct the flow passages.

Both the TSA and the PSA processes consist of two or more vessels packed with adsorbant beds. During operation, one vessel is on-line and is removing the impurities from the compressed feed air, while the other vessel is being regenerated by being purged with dry and CO_2-free waste gas, which is then vented to atmosphere. There are a number of operational differences between the two technologies that will be described in the paragraphs that follow.

Programmable control systems provide the required valve switching logic for the operation. This logic is based on a variety of process measurements and timing functions. Because the front-end system does not completely remove all impurities, the distillation system must be periodically shut down and defrosted. This defrosting operation is either scheduled on a preventive maintenance basis (typically 3–5 years) or scheduled sooner if dictated by deteriorating operating conditions such as increasing pressure drops across heat exchangers.

Temperature Swing Adsorption The TSA process consists of two or more vessels that are packed with a bed of adsorbant material. These vessels are switched from on-line to regeneration modes every 5 to 12 hr, depending on the design of the plant. While one vessel is on-line and is removing impurities from the compressed air feed, the other is being regenerated by a countercurrent purge flow of high-temperature dry and CO_2-free waste gas (stream #3 on Figure 8.37g).

The TSA waste gas heater uses whatever heat source is most economical. This could be low-pressure steam, electrical, or direct-fired natural gas heat. The TSA beds have greater affinity for adsorption when operated at lower temperatures. For this reason and to enhance removal efficiency, the compressed feed air is cooled with a direct contact after



GAN - Gaseous nitrogen
GO - Gaseous oxygen
HP - High pressure
HPC - High pressure column
LIN - Liquid nitrogen
LOX - Liquid oxygen
LP - Low pressure
LPC - Low pressure column

FIG. 8.37h

cooler (DCAC) that uses chilled water that is generated by the cooling effect of the excess cryogenic nitrogen waste gas that is not used to regenerate the beds. By operating at lower temperature, the impurity removal capacity is increased. This is because the required size of the TSA unit increases with water load, which in turn increases with air temperature.

Pressure Swing Adsorption The PSA process also consists of two or more vessels that are packed with a bed of adsorbant material. These vessels are also switched from on-line to regeneration modes but they are switched several times per hour, much more frequently than with TSA. While one vessel is on-line removing impurities from the feed air, the other is being regenerated by being purged with dry CO_2-free waste gas, which is then vented.

Comparison of TSA vs. PSA TSA adsorber beds are most commonly used in the newer air separation plants while PSA is considered a niche application that is most often used in smaller plants. The PSA process is sometimes favored if there is no economical heat source available for regenerating the TSA, such as low-pressure steam or natural gas.

The PSA does utilize a simpler, less capital-intensive compressor after cooler, as compared to the more expensive

DCAC, which is most often associated with TSA. The PSA process depends on pressure difference to separate impurities from the air and requires more regeneration gas than does TSA, which uses heat to regenerate.

Because the PSA process is often oversized to obtain the required capacity, PSA cycling can result in a variation in the feed airflow to distillation. Finally, TSA provides a secondary benefit if there are airborne contaminants that need to be scrubbed, because its DCAC tower does also provide scrubbing.

Cryogenic Distillation (Cold Box) Process

The equipment, piping, and basic instrumentation used in the cryogenic distillation (cold box) process is shown in Figure 8.37h. Here, the higher-pressure air from the booster compressor on Figure 8.37h is liquefied and fed through a Joule Thompson (JT)-type expander valve. In Figure 8.37h, the liquefied air stream is shown as a feed to the high-pressure column (HPC), but it could also be fed to either or both the HPC and LPC columns. Stream #2, the lower-pressure air stream, is shown as a feed gas to a point lower in the HPC.

Oxygen Production Figure 8.37h describes the design of the pumped liquid oxygen cycle, the "Pumped LOX" cycle. As the name implies, in a pumped LOX plant, the liquid oxygen (LOX) is pumped from the low-pressure column (LPC) sump to serve other process needs; this will be described in more detail later.

Oxygen is purified at the bottom of the LPC and is removed to storage either as gaseous oxygen (GOX) or LOX, depending on the customer requirements. The boiling point and relative volatility of argon is between that of nitrogen and oxygen. In the mid-section of the LPC column, the argon concentration is about 10%, and it is drawn off as feed to a sidearm column that produces crude argon.

All the oxygen, which enters with the gaseous air (stream #2 in Figure 8.37h), leaves in the bottoms from the high-pressure column as impure or crude LOX, in which the oxygen concentration is in the range of 30–40%. The crude LOX is flashed down to a lower pressure and is either fed to an intermediate stage in the low-pressure column, or if argon is to be recovered, it is used to operate the sidearm condenser and then fed to the low-pressure column as a more vapor-rich stream.

Nitrogen Production Nitrogen, having a greater relative volatility than oxygen, concentrates as it rises through the HPC. The vapor from the top of the column is condensed against boiling liquid oxygen in the reboiler/condenser. The condensed overhead is divided into a reflux stream that is returned to the HPC and a reflux stream that is sent to the top of the LPC.

Nitrogen is purified at the top of both the HPC and LPC, and this product can be extracted from either column overhead, depending on the process cycle, but is often withdrawn from the LPC overhead to prevent limiting the HPC reboiler/condenser of reflux.

Argon Product Argon is produced at the top of the sidearm column where impurities include oxygen at a range of 1 ppm to 4.0% and nitrogen at the ppm levels. If pure argon is required and the product from the sidearm column contains unacceptable oxygen levels (e.g., up to 4%), then oxygen is removed through additional purification steps. Pure argon is produced either directly from distillation or through a process that uses catalytic deoxidation of a crude argon stream.

Waste Gas The last remaining major process stream is the waste stream that is extracted from the upper portion of the LPC and contains principally nitrogen but also some small fractions of oxygen and argon, depending on the recovery characteristics of the plant. This purge stream provides refrigeration for the main heat exchanger and dry, CO_2-free regeneration gas for the reactivation of the front-end purifiers (stream #3 in Figures 8.37g and 8.37h).

CRYOGENIC INSTRUMENTATION

Severe-Service Control Valves

The LOX control valves or air JT valves often operate at pressure drop of 1000 psig or more, where flashing or cavitation normally occurs (Figure 6.1y in Chapter 6 describes some anticavitation valve designs). The valve seats in such severe services must be hardened, using such material as stellited trim. It is also desirable to keep the flow velocities as low as possible to reduce erosion of the valve trim and to minimize noise (see Section 6.14 in Chapter 6 for details).

Flashing and cavitation can cause severe erosion of the control valve trim, which can destroy the valve. It is for this reason that special valve designs are required for such services. These valves always require positioners.

The outlet area of severe-service valves should be maximized to better handle the expanding gas and to limit or prevent cavitation as much as possible. Design is complicated in multicomponent streams when flashing and cavitation process conditions exist. Still, one can properly specify and size control valves for cavitating service, while flashing is a consequence of process conditions and cannot be eliminated through valve selection or design.

Impulse and Sample Lines

All impulse or sample lines must include blow-down connections for periodic defrost operations. The impulse lines serving pressure transmitters, differential flow transmitters, and differential pressure level transmitters should be provided with liquid sealed legs inside the cold box. This design prevents large frost accumulations on the impulse lines and on the valves that are located outside the cold box, caused by the boiling of cryogenic liquid and freezing of ambient moisture.

On the other hand, continuously flowing cryogenic liquid samples to analyzers should not have seal loops, because these loops can cause the boiling of the sample inside the cold box and, thereby, cause the distilling of the sample, which makes it nonrepresentative.

The design of impulse and sample tubing/piping must also consider the stress caused by thermal expansion and contraction of cryogenic equipment, as well as the weight loads imposed by the insulation (typically perlite) that is packed in the cold box.

Flow Elements

Venturi and nozzle-type flowmeters (Section 2.29 in Chapter 2 in Volume 1) work well and are frequently used for the measurement of cryogenic liquid and gas flows. In some cases, cryogenic flows are approximated on the basis of the opening of control valves and of the pressure drop across them.

Outside the cold box, elbow meters (Section 2.29 in Chapter 2 in Volume 1) are occasionally used where line sizes are very large and where it is desired to minimize the pressure drop across the flow sensor, such as in the case of measuring TSA or PSA regeneration gas flows. The nominal 4:1 turndown capability of the differential flow devices is usually acceptable, because this rangeability exceeds the turndown requirement of the ASU plant itself.

The turndown capability of cryogenic liquid flow measurement applications is often limited by the flashing that occurs at low flows, as the control valve is throttled to the point where flashing starts. Nonetheless, smart transmitters can provide wider turndown than is possible with conventional differential pressure transmitters in flow measurement applications.

In order to increase plant efficiency, it is important that the instrumentation and control valves used will provide the required accuracy and rangeability. Inversely, if the control loop components are improperly specified or sized, they will not be able to accurately meet the controller set points, and this can cause sustained upsets.

Temperature Measurement

Temperature measurements are made by thermocouples and resistance temperature devices (RTDs). They are described in detail in Sections 4.10 and 4.13 of the first volume. They are provided with bar stock thermowells that are welded into the process lines and vessels as needed.

Thermocouple extension wire or RTD cables are run from the temperature element head to junction boxes on the outer face of the cold box.

Process Analysis in ASU

The three major purposes of using analyzers in an air separation plant are the monitoring and control of product quality, the performance of process control, and the continuous maintenance of process safety.

In a typical sampling system, the pressure of the sample drawn from the process is reduced, and this sample gas is sent to a remote analyzer panel. In order to lower the dead time of the measurement, bypass purge flow is provided around the analyzer. This also helps to minimize the impact of leaks in the sample line.

The sample system response time is computed from the sum of the sample and bypass flows, taking into account the transport system volume and pressure. The primary sample is taken from a tap that is situated in an ideal location, and sample stream-switching capability is provided at the analyzer panel, to use alternative samples taken from auxiliary sample taps, when necessary.

Product Quality Analysis Product quality analysis is required for the monitoring and control of the oxygen, nitrogen, and argon products of the plant.

The primary analytical method used for measuring the purity of the oxygen product is paramagnetic (Section 8.42 in Chapter 8 in Volume 1). The sensor in the paramagnetic analyzer is pressure-compensated and is either the dumbbell or the thermal wind variety. The specification for the oxygen product calls for 99% + purity, and the main impurity in this stream is argon.

The specification for the nitrogen product requires that its oxygen impurity be at the parts per million level. This is measured electrochemically by fuel cell, zirconium oxide, or Coulometric sensors (Section 8.42 in Chapter 8 in Volume 1).

The product specifications for the argon product limit the impurities of oxygen nitrogen and total hydrocarbon (THC) to trace amounts. The trace oxygen analysis is made by the same methods that are used for the measurement of trace oxygen in the nitrogen product.

The trace nitrogen in argon can be measured by either gas chromatography (Section 8.12 in Volume 1) or by spectrographic quartz plasma-type analyzers. THC is measured with a flame ionization detector (FID), and the results are reported as methane-equivalent THC.

Normally, all three products are analyzed for moisture (dew point or ppm), and this is typically done by analyzers having aluminum oxide or quartz crystal microbalance sensors (Section 8.33 in Chapter 8 in Volume 1).

Trace levels of carbon monoxide, hydrogen, helium, and neon are also present in atmospheric air. They are likely to pass through the HPC and concentrate in the nitrogen product and reflux. It is sometimes necessary to install a noncondensable purge on the condensing side of the LPC reboiler to purge these gases.

Similarly, small traces of krypton and xenon, which are present in ambient air, will also process through the system and concentrate in the LOX product in the HPC sump. These trace components can also be recovered and concentrated by specialized processes. The processing of krypton and xenon must also include the removal of hydrocarbons, because if they are allowed to concentrate in the oxygen, unsafe conditions can evolve.

Safety Analyzers For the purpose of safety, carbon dioxide and total hydrocarbons are measured in the ppm range or lower.

Samples are typically taken from the feed air supply to the plant and from the liquid oxygen streams. The trace carbon dioxide is typically measured with non-dispersive infrared (NDIR) methods that utilize the Luft principle or by gas filter correlation (GFC) methods (Section 8.27 in Volume 1).

Analysis of total hydrocarbon is typically performed using flame ionization detector analyzers, and the results are reported as methane equivalent hydrocarbon in ppm.

If thermal deoxidation units (Deoxo) are used to remove oxygen from crude argon, a safety analyzer is required to monitor the oxygen level in the crude argon feed to the Deoxo process to prevent high oxygen levels from causing unsafe thermal runaway of the catalytic bed. A paramagnetic or electrochemical method is used to monitor the percentage of oxygen in the feed to the Deoxo process.

Occasionally, safety analyzers are used to monitor for the unlikely situation where high levels of oxygen (> 21%) contaminate the waste gas stream used to purge the front-end adsorbers. Such monitoring can become necessary because adsorbers that are constructed of incompatible materials may present a risk of fire when exposed to enriched oxygen.

Finally, area monitors are used to analyze the air quality in occupied rooms to ensure that ventilation is adequate and to provide alarms if either an oxygen-depletion or an oxygen-enrichment condition is evolving, with the corresponding risk of asphyxiation or oxygen fire.

Process Control Analyzers

The product purity analyzers discussed earlier are also used in controlling the air separation process. The product purity or safety analyzers also trigger alarms and safety interlocks.

Other process control-related analytical loops include the control of excess hydrogen in the crude argon from the Deoxo process. The concentration of hydrogen is measured by thermal conductivity type analyzers (Section 8.57 in Chapter 8 in Volume 1).

Carbon dioxide in the feed air is measured after the front-end adsorption system and is monitored by NDIR-type analyzers (Section 8.9 in Chapter 8 in Volume 1).

Dew point is detected by aluminum oxide sensors (Section 8.33 in Chapter 8 in Volume 1) on the outlet of the TSA regeneration gas steam heat exchangers and compressor aftercoolers. In case a leak causes the dew point to rise, an alarm is actuated.

The hydrogen supply to the Deoxo systems is monitored for trace methane, because this methane is not removed by the Deoxo process or by argon distillation, and it would become an impurity in the pure argon product.

Nitrogen in the sidearm column feed is either inferred on the basis of LPC operating conditions or is directly measured by gas chromatography or by ion mobility spectrometers. The gas chromatograph first removes the oxygen and then chromatographically separates the nitrogen and argon for analysis. The ion mobility analyzers provide an effective method of nitrogen analysis in this mixed gas stream but have the disadvantage of using a radioactive source and therefore requiring special permits and are rarely used today.

REGULATORY AND FEEDFORWARD CONTROLS

The controls described in the following paragraphs refer to the subsystems of the process shown in Figures 8.37g and 8.37h. The control loops are not shown in detail, and the feedforward and logic/safety controls are not shown at all. Therefore, the reader is asked that for in-depth, detailed discussions of the related algorithms, dead times, time constants, and tuning, refer to Chapters 2 and 8, where they are discussed.

Both regulatory and advanced process controls are used to optimize the production of a specified product mix and to maintain product purity at minimum operating cost. In controlling the air separation processes, these control strategies have to be adapted to optimize production against purity and energy constraints, while also correcting disturbances that would upset the steady-state operation.

Regulatory controls serve to respond to upsets caused by feed airflow disturbances, which can be caused by upsets resulting from TSA or PSA regeneration or from diurnal variations in cooling water temperature, which can affect heat transfer. Advanced control technology is also used to provide load-following optimization strategies so as to ramp plant production in response to variations in customer gas demand.

Process control systems used to implement these objectives include large distributed control systems (DCSs), which are often linked to supervisory control computers for implementation of advanced controls by means of various forms of model predictive control (MPC).

In the following paragraphs, some specific control problems and solutions will be discussed.

Main Air Compressor Flow

As illustrated in Figure 8.37i, the compressed air is vented to provide the added throughput required to keep the main air compressor (MAC) out of surge. (See Section 8.15 for details on compressor control and optimization.)

The surge flow measurement is typically inferred from differential pressure measurement across the compressor stages. The surge line for the compressor is confirmed by surge tests. Some compressor suppliers do not use surge control, but only open the vent when a maximum operating pressure is reached. The level of control sophistication applied is a function of the relative importance to save energy by reducing the surge margin.

Stabilization of Pressure Surge

During regeneration of the front-end adsorbers, it is important to minimize the pressure surges, because these upsets have the potential of causing a disruption of the downstream distillation process, which in turn can disrupt the argon product

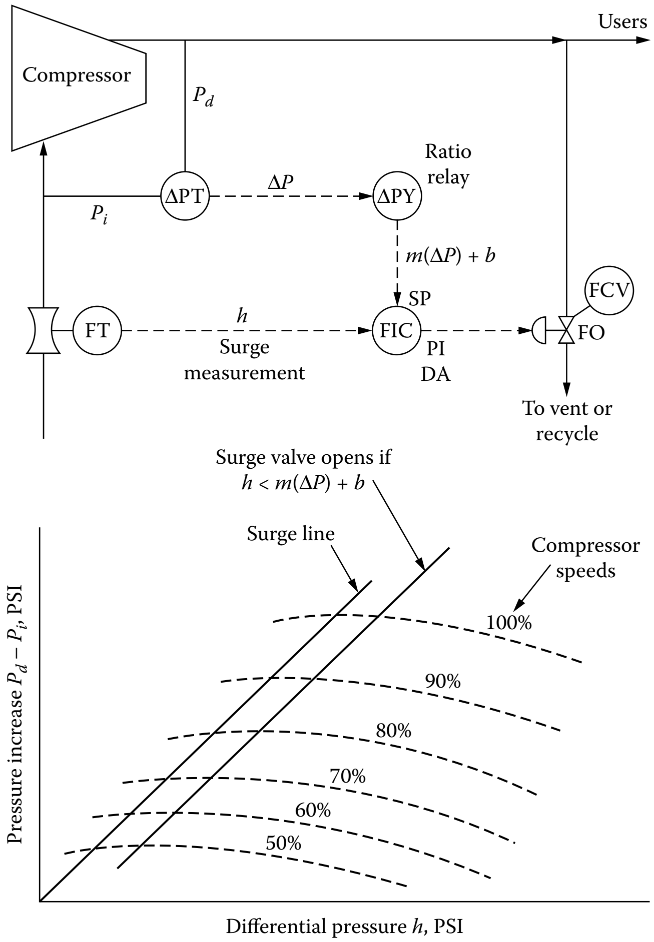

FIG. 8.37i

The flow across the compressor (h) is kept above the surge limit by venting, if the user demand is insufficient to keep it out of surge.

quality profile. Unlike the reversing exchangers that cycled multiple times per hour, the TSA adsorbers are regenerated only once in several hours.

If one has properly determined the process dead times and time constants, feedforward control can be used to attenuate these disturbances. The feedforward loop might include a ramping function to increase the main air compressor flow (the multistage centrifugal compressor in Figure 8.37g), in order to compensate for the increased airflow required when the off-line adsorber vessel is being pressurized after regeneration. After the regenerated unit is on-line and the beds are switched to regenerate the other adsorber vessel, the main air compressor flow is ramped back to its normal operating flow.

Sidearm Nitrogen Control

The feed flow disruption caused by adsorber regeneration is particularly important when argon is being produced, because the argon composition profile in the LPC is sensitive to feed flow, and feed flow upsets introduce a risk of excess nitrogen entering the sidearm column. Nitrogen impurity is normally in the low ppm range. Nitrogen excursions in excess of fractions of a percent in the sidearm column could vapor-lock the condenser and cause loss of vapor flow and reflux, resulting in the draining of the contents of the sidearm column into the LPC.

After a dumping episode, the reestablishing of oxygen purity in the LPC and also of the proper operation of the sidearm column can take many hours to complete. The challenge is in managing the sidearm column feed to maximize argon concentration while preventing too much nitrogen, which will cause the sidearm column to dump.

On the other hand, if the plant is operated conservatively with little or no nitrogen in the sidearm, argon will ultimately be lost in the waste and recovery will be lower than otherwise possible. Control of nitrogen in the sidearm is implemented by determination of composition in the sidearm or at a location several stages above the sidearm feed point by direct analytical measurement (see QIT in Figure 8.37h).

Operating personnel will tend to run the distillation column more conservatively to limit the nitrogen concentration in the sidearm to very low levels, but this also reduces recovery because incrementally more argon will be lost in the waste stream. Therefore, to maintain high argon recovery, the plant requires precise control of sidearm composition, and advanced control systems are capable of providing it.

Product Purity Control

In general, for a plant with a liquid product and a fixed air flow, the product purity is inversely related to the flow rate of product that is being removed from the plant. Therefore, product flow control is often used to control product purity. This control strategy is complicated by the fact that control loops often interact, necessitating feedforward control algorithms and model predictive control strategies for optimal load-following.

The performance of a load-following optimization system is dependent upon the maximum ramping rate of the air separation plant, the severity of demand changes, and the capacitance of the system. The objective is to minimize the venting of overproduction, while avoiding (minimizing) supplemental liquid vaporization, which makes up for production deficiencies.

Oxygen Recovery Controller

In steady-state operation, where the customer has specified a constant GOX production rate, the oxygen purity is a function of the oxygen recovery. The fixed GOX customer flow being the independent variable, the supplied airflow to the plant is the primary manipulated variable that impacts oxygen recovery.

Therefore, the oxygen purity controller (QIT at the bottom of LPC in Figure 8.37h) can act as a cascade master to manipulate the ratio of feed air to product flow. This manipulation affects the power consumption of the plant, and for a fixed number of distillation stages, increasing the feed airflow will improve the product purity. The control loop is configured as a triple cascade where the O_2 recovery controller (QIT, %O_2) is the cascade master of the purity controller (QIT, ppm THC), which is the cascade master of the feed flow controller (FIC on the compressor in Figure 8.37g).

Front-End Purity and Hydrocarbon Accumulation

Methane, ethane, propane, and to a certain extent ethylene are not adsorbed in the TSA or PSA-type front-end air purification processes. Acetylene, which is dangerous due to low solubility, is captured in the TSA or PSA molecular sieve. In addition, there are impurities that can accumulate and plug equipment, such as traces of CO_2 that slip through the front-end adsorbers.

Plugging increases the potential for accumulating local concentrations of hydrocarbons by blocking passages in the LOX sump reboiler/condenser section (bottom of HPC column in Figure 8.37h), which normally are continuously flushed by siphon action.

Trapped oxygen may create a localized concentration of hydrocarbons as a result of dry boiling in the blocked passages and may eventually leave a residue of pure hydrocarbon in a pure oxygen atmosphere that could potentially autoignite, with potentially severe consequences.

Normally, in a pumped LOX plant, it is the front-end CO_2 removal characteristics that determine the minimum amount of LOX that must be removed as a product or in a purge stream.

Hydrocarbon Concentration Factor

A hydrocarbon concentration factor can be determined on a material-balance basis by determining how much LOX is being removed from the LPC reboiler compared to the total oxygen in the air that is entering the system. In a pumped LOX plant, the concentration factor is approximately 5 because the entire oxygen product is leaving the column as a liquid. In a plant that produces gaseous oxygen, where most of the oxygen product is generated as GOX, with only a small amount as LOX being produced, the concentration factor might be in the range of 100–500.

Total hydrocarbon is continuously measured at several points in the plant. These include either the LPC sump (pure oxygen) or the crude liquid oxygen from the sidearm column condenser sump.

REFRIGERATION CONTROLS

In the early days of cryogenic air separation, the feed air was liquefied using a so-called “split cycle” that involved compressing the air to approximately 2000 psig and then cooling the compressed gas. After that, the cold gas was sent through an expander valve to cool it by the Joule Thompson effect. This expander valve is referred to as a Joule Thompson valve or JT valve.

Today, taking a portion of the air after it has been purified (stream #1 in Figure 8.37g), boosting the pressure with a booster compressor, cooling the stream, and then expanding it through a mechanical expander provides the refrigeration required for liquefaction.

Expander Configuration

The refrigeration required in oxygen plants to make up for the heat leak from the environment is provided by machinery that expands a portion of the feed airflow to the low-pressure column. The work done by the expander can be recovered as electrical power. The recovery can be achieved by using a generator-loaded expander, or by taking that portion of the feed that is to be expanded and first compressing it to a higher pressure by a compressor that is mounted on the same shaft as the expander. This machine is commonly referred to as a compander.

In a plant making GOX only, gaseous air would be taken from the TSA, cooled in the main heat exchanger, and expanded directly into the LP column. More refrigeration is needed if either some amount of liquid oxygen product is also needed or if the expander flow is starting to impact the oxygen recovery. In such a case, a compander can be used (instead of recovering the work as electricity), to boost that fraction of the air that is to be expanded. This way, a higher pressure ratio can be obtained across the expander.

Refrigeration Balance Controller

Refrigeration to the plant is typically controlled by manipulation of expander flow. Normally, an expander flow is so selected as to match the cooling needed to produce a little more than the minimum LOX production required. At a constant expander flow, the liquid oxygen sump level controller (LIC at bottom of HPC in Figure 8.37h) will provide steady-state operation.

Main Heat Exchanger Control

On a pumped LOX plant, high-pressure air from the booster compressor is condensed in the main heat exchanger, and the JT valve essentially controls the liquid level in the exchanger, while the booster compressor discharge pressure effectively controls the vapor inventory in the exchanger.

The oxygen in the feed to the plant is an independent variable based on customer oxygen flow requirements, and the booster compressor discharge pressure is held constant. By maintaining a constant discharge pressure, the molecules that condense in the exchanger are effectively offset by the oxygen molecules that are vaporized.

The liquid level measurement in the exchanger is difficult, particularly, because above the critical pressure, the vapor/liquid interface disappears. Knowledge of the liquid level is important, as this determines the available surface area for condensation as well as the magnitude of the temperature approach. The temperature approach translates into a pressure ratio between the high-pressure air and the oxygen that is boiling in the exchanger.

There are multiple complex positioning strategies for the temperature element of the temperature controller (TIC) that throttles the JT control valve. Proper tuning of this controller is also important to provide the required refrigeration.

ADVANCED CONTROL

There is no doubt that advanced controls can improve the plant efficiency, as well as argon recovery, over what is possible through regulatory controls alone. Advanced control systems can interface with the distributed control system using supervisory computers that are used for regulatory process control to assist in control and optimization. Advanced control systems, using model predictive control, can predict evolving conditions and, as such, can optimize the operation through model-based anticipation.

Without advanced control, the plant will still run reliably and will deliver good product, but operators tend to pick safe controller set points, which can be further away from operating or safety constraints than necessary. The safety margins used by the operator are usually a function of both their motivation and their experience/education. Therefore, while the plant will run reliably under manual operator control, its operation will not be optimized. Such unoptimized operation is likely to result in significant losses in argon recovery and is a significant increase in air compressor power consumption.

The advanced controls monitor the operating constraints while meeting the production target at minimum waste of either product or energy. In the air separation process, advanced controls can improve the production and purity of GOX, the sidearm feed composition, the flow and purity of argon, and the total cryogenic liquid production.

Characterizers to Compensate Process Nonlinearity

Nitrogen purity can be controlled by using the nitrogen purity controller as the cascade master of the airflow controller that sets the gaseous air feed flow to the HPC as its slave, if its set point is not already controlled by GOX purity. While linear response is assumed between the composition of the overhead product (GAN) and changes in boil-up and reflux ratio, these relationships are not linear over the whole range of the operation.

As the column approaches a state of operation that corresponds to minimum reflux and maximum recovery, it becomes difficult to recover any more nitrogen, and the bottom liquid (LOX) will approach equilibrium with the air feed. If, under these conditions, more nitrogen is taken off, the process gain drastically changes and product purity drops (oxygen impurity in the nitrogen rises).

In general terms, if the process gain varies with load, stability of the loop can only be maintained if the variation in the process gain is compensated, because stable control requires a stable gain product of the loop components of about 0.5 (Figure 8.37j). One way to achieve this is to remove the nonlinearity from the measurement (of nitrogen purity, in this specific case) by a compensator. Such characterizer can take the logarithm of the product quality signal, for example, to arrive at a constant loop gain.

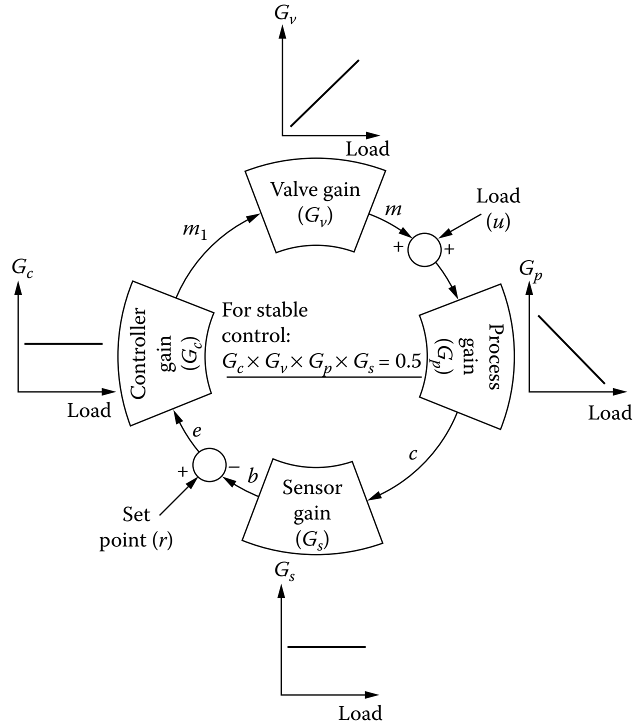

FIG. 8.37j
If the process gain varies with load, it is necessary to compensate for that nonlinearity. This can be done by characterizing the control valve (shown above) or can be done by characterizing the measurement.

Operating Close to Constraints

The most efficient plant operation is obtained if the process is run close to the limitations that are set by the equipment used, the available raw material and utility supplies, market conditions, product quality requirements, power consumption, and so on. If one focuses on the objective of minimizing energy consumption, then airflow should be reduced until the limitations set by the purity requirements of the product are approached. This is because an increase in airflow also increases the boil-up and reflux rates, which in turn results in higher product purity, but at a higher investment of energy.

The ratio of the power consumption and the production rate of a plant expresses its energy efficiency. Air separation plants can have six or more constraints that are alternately approached during operation. When a constraint is approached, the control system should load or unload the plant, as needed to maintain a margin from the constraint. The more constraints are approached at the same time, the more difficult the control challenge becomes, but selective control can handle that task.

Therefore, good plant design should eliminate the possibility of the plant operation being able to approach multiple constraints that require conflicting control responses. For example, no extra stages of distillation should be added in order to obtain better purity than the purity needed at near ideal recovery.

CONCLUSIONS

In this section, the process controls for air separation processes using adsorption, membrane, and cryogenic technologies have been discussed.

Cryogenic plants are the economic choice for most medium to large-scale oxygen and nitrogen production applications, because of their lower unit power consumption and economies of scale. They represent the only choice for argon production. LOX, LIN, and LAR facilities are available for backup and peak shaving to gaseous supply systems and are readily available on-site, using the same equipment that produces the gaseous products. This eliminates the need for add-on liquefiers or the use of supply contracts.

Adsorption systems for the production of oxygen can supply 85–95% oxygen and are best suited for applications requiring less than 100 tons per day production. Nitrogen-producing PSA and nitrogen membrane systems are economical for smaller scale production volumes and where the high purity products of cryogenic systems are not required.

ABBREVIATIONS

ASU	Air separation unit
CMS	Carbon molecular sieve
DCAC	Direct contact after cooler
Deoxo	Deoxidation unit
GFC	Gas filter correlation
GOX	Gaseous oxygen
HPC	High pressure column
JT	Joule Thompson
LAR	Liquid argon
LIN	Liquid nitrogen
LOX	Liquid oxygen
LPC	Low pressure column
MAC	Main air compressor
MPC	Model predictive control
NDIR	Non-dispersive infrared
ppmV	Volumetric parts per million
PSA	Pressure swing adsorption
THC	Total hydrocarbon
TPD	Tons per day
TSA	Temperature swing adsorption
VSA	Vacuum swing adsorption

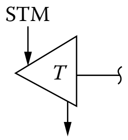
8.38 Steam Turbine Controls

E. J. FARMER (1985) **B. G. LIPTÁK** (1995, 2005)



Flow sheet symbol

INTRODUCTION

Steam turbines are used in the generation of electric power, particularly in combined cycle power stations (Section 8.33), and also as variable- or constant-speed drives (Section 7.10) for larger rotary equipment, such as compressors and pumps (Sections 8.15 and 8.34). Their controls are often integrated with the steam generator (Section 8.6), which can use fossil or nuclear fuel.

In the first part of this section, the nature and the operating principles of steam turbines will be discussed first. This will be followed by a description of the various types of turbine designs, efficiencies, and applications.

In the second part of this section, the control of steam turbines will be covered. This discussion will be started with the description of the traditional steam governors and basic regulatory turbine controls. The controls of pressure let-down and extraction turbine applications and the methods of eliminating interaction and decoupling will also be discussed. The section will also describe the steam turbine safety systems and will be concluded with a description of optimization and advanced controls.

The optimization strategies described will consider the nature of the installation, which might have the goal of maximized electric power production while meeting the steam demand of the plant or the goal of maximizing direct steam utilization.

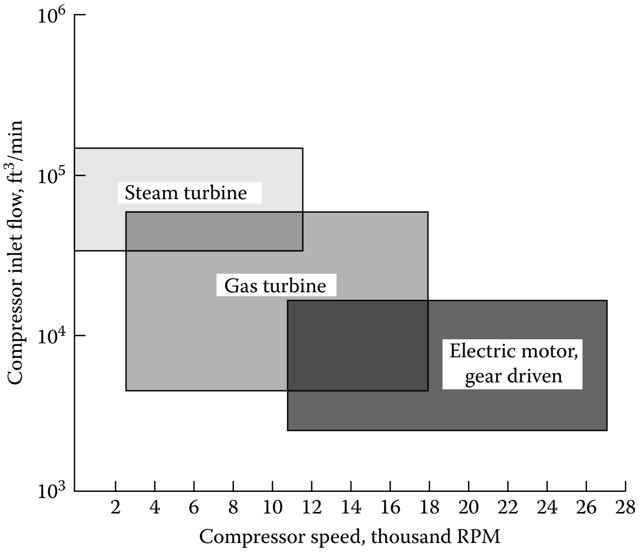
The discussion of advanced controls will cover the use of model-based predictive control and self-diagnostics for maintenance purposes. It will also touch upon thermal stress monitoring (TSM), turbine protection (TP), and monitoring/sequential control (MSC).

Characteristics

Steam turbines are energy conversion machines. They extract energy from the steam and convert it to work, which rotates the shaft of the turbine. Steam turbine sizes range from shaft output energies of a few kilowatts to well over 1000 megawatts, and there is no reason why still larger machines could not be built. No other prime mover can achieve the shaft output capability that is easily attained by large steam turbines.

Rotational speeds vary from approximately 1,800 to 14,000 rpm; this speed can be modulated over a wide range. Such variable-speed operation is an advantage, if the turbine is used to drive pumps or compressors. Figure 8.38a shows the relative operating ranges of different types of compressor drives. When provided with the appropriate speed governor, steam turbines can provide excellent speed stability, which is desirable when the turbine serves as the prime mover in electric generators.

In comparison to all other prime movers, steam turbines are very reliable. Their availability factors are high, and their maintenance costs are low. This is largely a result of the inherently balanced design that is completely free of



Speed governor classification

Governor class	*Regulation*	*Variation*
A	10%	¾%
B	6%	½%
C	4%	¼%
D	½%	¼%

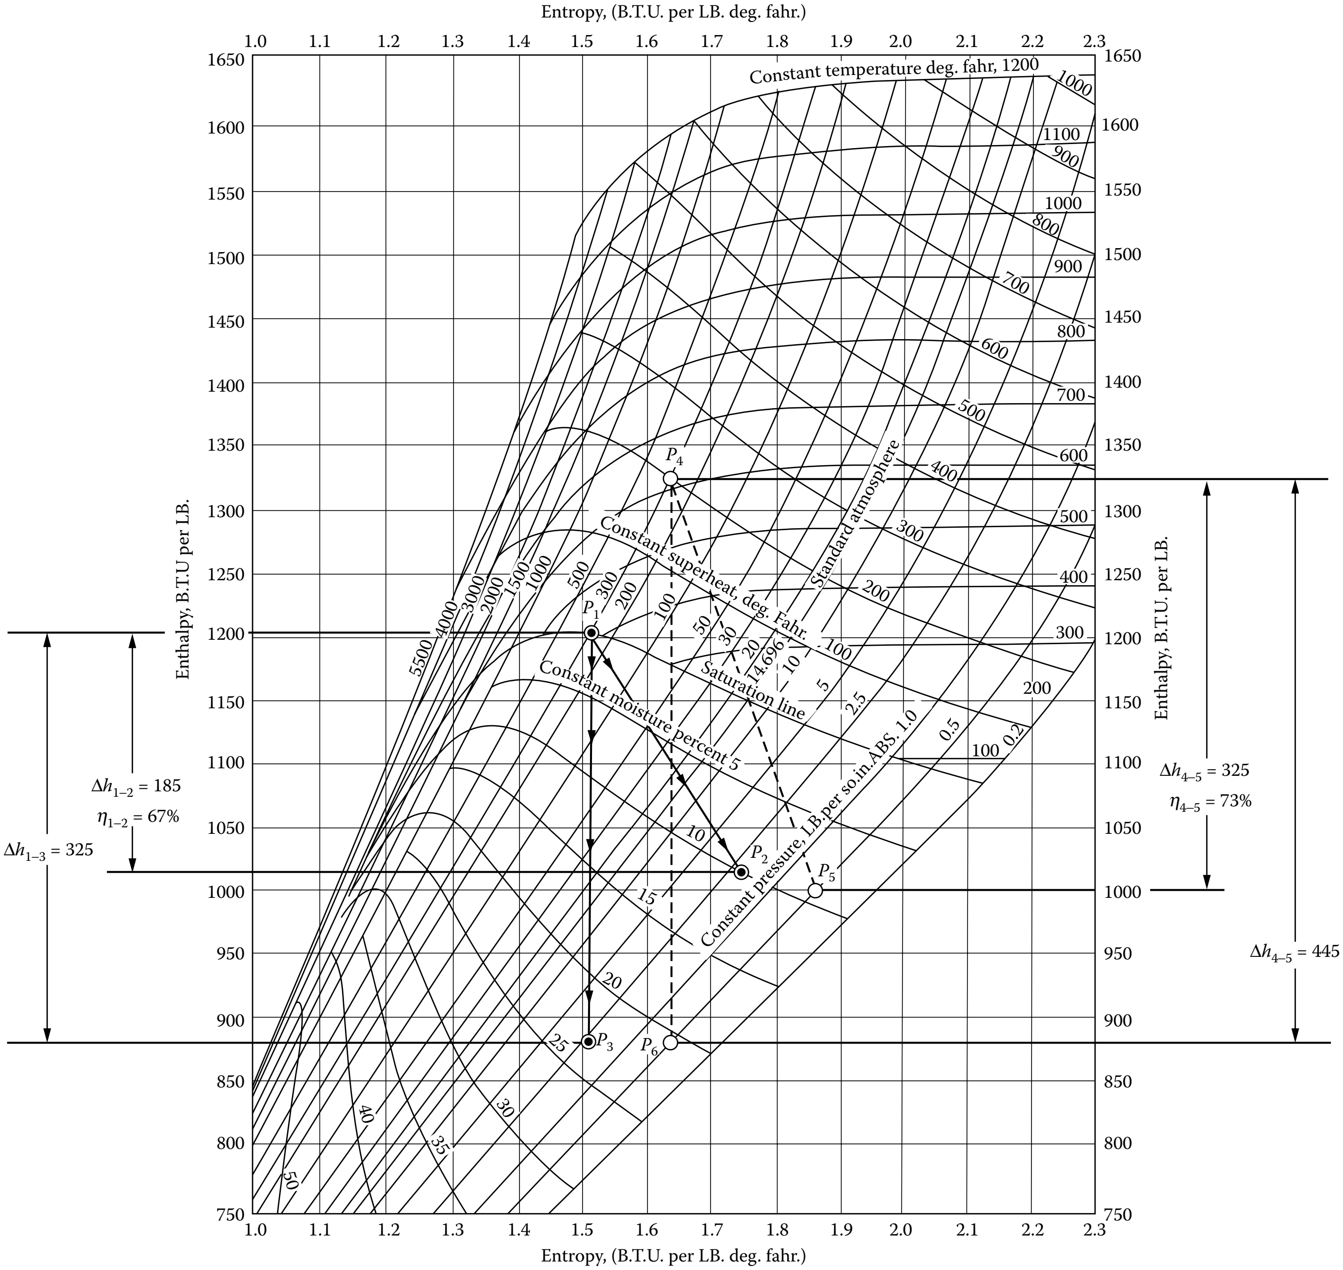

FIG. 8.38b
Mollier diagram showing performance of a steam turbine.

reciprocating or rubbing components (except, of course, for the bearings).

OPERATING PRINCIPLES

The amount of energy that the steam turbine extracts from the steam depends on the enthalpy drop across the machine. The enthalpy of the steam is a function of its temperature and pressure. Because the operating conditions of steam turbines are generally known in terms of inlet and outlet temperature and pressure, one can use a Mollier diagram as a graphic tool to determine the amount of energy available under a particular set of conditions (Figure 8.38b).

As an example, one might consider the case where the turbine inlet conditions correspond to point P_1 and the outlet conditions to point P_2 in Figure 8.38b. A line drawn between these two points is called the "expansion line" and represents the operation of the turbine as it is extracting energy from the steam. In actual operation, this line is not straight, and its shape does depend on the internal operation of the turbine.

In an ideal turbine, the steam would expand at a constant entropy (isentropically). The condition of the exhaust steam from an ideal machine that has no losses would correspond to point P_3 on Figure 8.38b. This P_3 point is found by drawing a vertical line from the inlet point P_1, down to the same exhaust pressure as the actual machine is operating at.

Steam Turbine Efficiency

If one refers to the change in enthalpy from P_1 to P_2 as Δh_{1-2} and to the change in enthalpy between P_1 and P_3 as Δh_{1-3}, one can use these quantities to calculate the turbine's efficiency and steam rate. The efficiency of the turbine, neglecting mechanical losses, is found by

$$\eta = \frac{\Delta h_{1-2}}{\Delta h_{1-3}} \qquad \textbf{8.38(1)}$$

The steam rate that an ideal machine would require to operate as theoretically predicted is called the theoretical steam rate, Q_T, and may be found as

$$Q_T = \frac{2545}{\Delta h_{1-3}} \frac{\text{lbm}}{\text{HP-hr}} \qquad \textbf{8.38(2)}$$

The actual steam rate, Q_A, is calculated by dividing the theoretical steam rate with the efficiency, hence,

$$Q_A = Q_T/\eta \frac{\text{lbm}}{\text{HP-hr}} \qquad \textbf{8.38(3)}$$

This somewhat simplified perspective of steam turbine performance can help the control engineer in both understanding and optimizing steam turbines.

In order to operate the turbine at maximum efficiency, the steam should leave the nozzles and impact on the turbine blades at sonic velocity. In order to maintain the nozzle jets at sonic velocity at partial loads, it is necessary to shut off some blocks of nozzles so that the active ones will receive approximately the same amount of steam all the time. The efficiency of steam turbines increases with size, with the superheat temperature of the steam, and with the level of vacuum at the turbine exhaust.

Example As shown in Figure 8.38b, if saturated steam enters the turbine at 300 psia and is exhausted at 2 psia, then from each pound of steam, 325 BTUs of energy can theoretically be recovered in an "ideal" turbine. If the actual expansion line is $P_1 - P_2$, the actual energy recovery is 185 BTUs per pound of steam, and therefore the efficiency of the installation is 67%.

In actual practice, turbines are not supplied with saturated steam. This is because condensation could cause turbine blade erosion due to the presence of water droplets at the high jet velocities, and also because much more energy can be recovered if the steam supply is superheated and if the exhaust pressure is reduced.

If, for example, the same 300 psia steam enters the turbine with 200°F superheat and is exhausted at 0.5 psia (instead of 2 psia), the theoretical energy recovery will rise to 445 BTUs per pound ($P_4 - P_6$). Under these operating conditions, the actual energy recovery will rise to 325 (from 185) BTUs per pound. This obviously represents a major improvement in the performance of the machine.

This improvement can also be expressed in terms of steaming rate. The steam rate of the turbine is the amount of steam needed to provide one horsepower-hour (hp-hr) of work, which is the equivalent of 2545 BTUs. If the actual operation of the steam turbine corresponds to $P_1 - P_2$ on Figure 8.38b, the steaming rate is 13.8 lb of steam per horsepower-hour, while if it corresponds to $P_4 - P_5$ it is only 7.8 lb of steam per horsepower-hour.

Advantages and Limitations

Even though the initial cost of steam turbines is usually higher than that of alternative prime movers, there are some benefits that can mitigate this cost difference. Especially in larger sizes, steam turbines are physically smaller than most other prime movers, consequently, they require less floor space. This can decrease the cost of the building in which they are to be installed.

Because the inherently balanced design of steam turbines produces considerably less vibration than do reciprocating machines, equipment foundations can also be considerably lighter. Because steam turbines are less likely to cause fires than are other prime movers, they also have an advantage in applications in locations where flammable materials are present.

In applications where the prime mover has to endure substantial overloads, the steam turbine also has an advantage. It can tolerate, without damage, such overloads that would severely shorten the service life of alternative prime movers, if they could tolerate them at all.

The optimization of steam turbine systems is well understood and more widely practiced than the power consumption optimization of alternatives such as electric motors and gas turbines. Less energy will usually be required for a steam turbine prime mover to drive a load than would be necessary if the size of a turbine driving an electrical generator were increased to provide the electric power to drive the same load with an electric motor.

Besides initial cost, the major disadvantage of steam turbines is their low tolerance for wet or contaminated steam. Wet steam can cause rapid erosion, and contaminants can cause fouling. Both will reduce the turbine's efficiency and will shorten its life. Steam quality monitoring is therefore an important requirement to maintain the reliability and to reduce the operating cost of steam turbines.

TABLE 8.38c
Performance Data for Condensing and Noncondensing Steam Turbines

Technical Data	*Units*	*Condensation Turbine*	*Back-Pressure Turbine*
Output	MW	5–120	5–120
rpm	min^{-1}	Up to 14,000	Up to 14,000

Discharge pressure	bar (psi)	Up to min. 0.02 (0.29)	Up to 40 (580)
Exhaust flow	M^3/s (ft^3/s)	Up to 1,300 (45,930)	—

TURBINE DESIGN CONFIGURATIONS

The energy source for steam turbines is the pressure difference between the supply and exhaust steam. The higher this pressure difference and the higher the superheat of the steam, the more work the turbine can do.

The two main categories are the condensing and the back-pressure turbines (Figure 8.38d). Table 8.38c provides a range of operating conditions and electrical power production rates for both types of steam turbines.

The exhaust pressure of a "condensing" turbine is usually subatmospheric, while that of a "noncondensing" or "back-pressure" turbine is greater than atmospheric. Condensing turbines are most often used for electric power generation, while back-pressure turbines are utilized in cogeneration power plants (Section 8.33), which simultaneously supply steam and electricity for the users.

Steam turbine installations can also be configured with more than one exhaust steam streams. A second, and sometimes even a third, outlet may be provided to allow the "extraction" of steam at different pressures (Figure 8.38e).

A rare combination of a mixed input and an extraction turbine is one in which steam can be removed when load conditions permit, or steam can be inducted when additional energy is necessary. This unit is usually referred to as *induction–extraction turbine.*

Application Configurations

A back-pressure turbine with its inlet connected to the plant's high-pressure header and its outlet supplying steam to an intermediate header is called a *topping turbine*, because it is

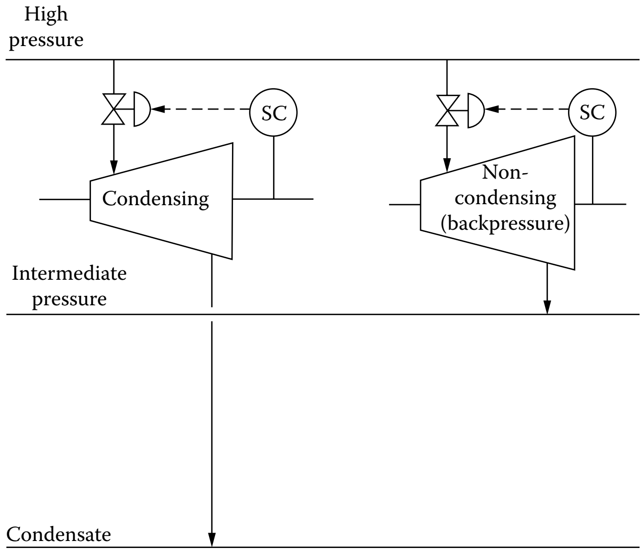

FIG. 8.38d
Typical installation of condensing- and backpressure-type steam turbines.

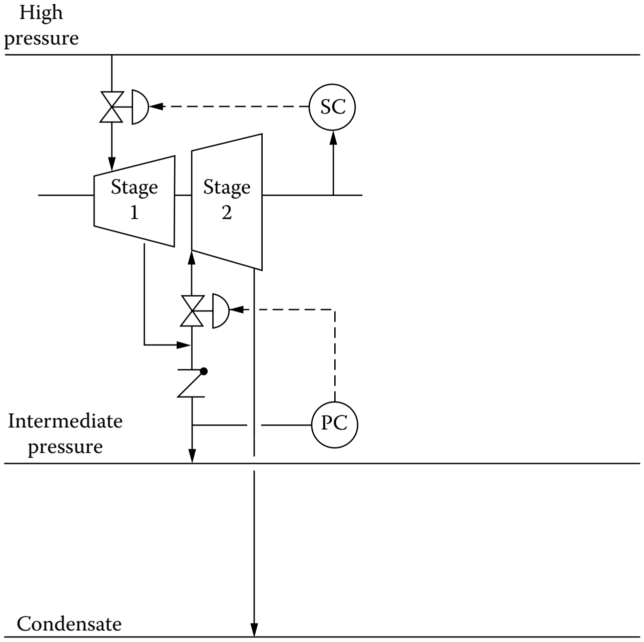

FIG. 8.38e
The extraction turbine generates as much intermediate pressure steam as required by the plant, while taking as much high-pressure steam from its supply header to meet the load by maintaining its shaft speed constant.

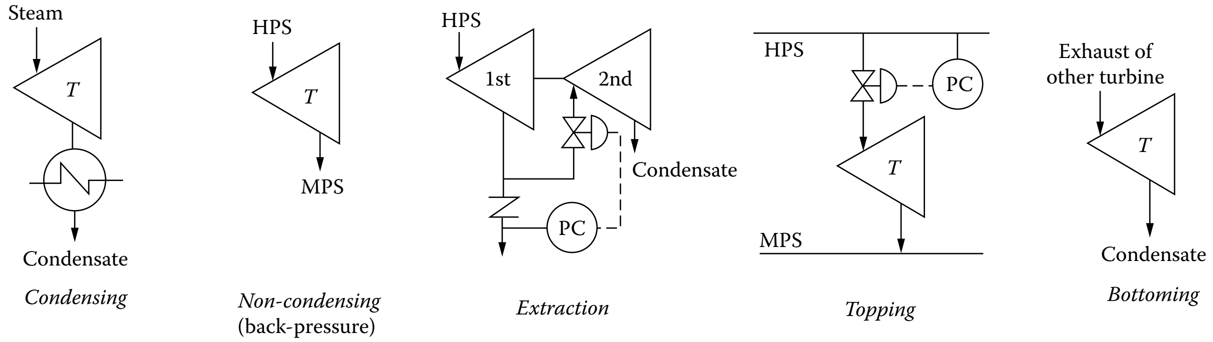

FIG. 8.38f
Terminology used to describe various steam turbine installations.

using steam from the "top" of the plant's thermodynamic cycle.

Similarly, a turbine installed between the noncondensed exhaust of another turbine and the condensate system of the plant is called a *bottoming turbine*. A topping turbine could also be described as a noncondensing or back-pressure unit, and a bottoming turbine as merely a condensing turbine. Figure 8.38f describes the main variations of turbine configurations.

The terms "topping" and "bottoming" as generally used describe turbines that are designed to work over unusual ranges of pressures. For example, a bottoming turbine is unusual in that it is generally designed for operating at a very low inlet pressure, and hence the term "bottoming" is more descriptive than the more generic term of "condensing."

Steam turbines can also be classified according to the purpose of their installation. If a turbine's purpose is to generate electricity, it might be called a "generator drive," while if its purpose is to drive a pump or compressor, it can be called a "mechanical drive."

Internal Design Configurations

From an internal design perspective, the steam turbine is either an "impulse"- or a "reaction"-type design. In the United States, almost all turbine designs are of the axial flow variety, and only a small number are the tangential flow variety. In Europe, a significant number of turbines are the radial flow design.

The steam turbine can also be single-stage or multistage; if multistage and as a function of the number of parallel exhaust stages, one would refer to the turbines as single-flow, double-flow, and so forth.

The casing and shaft arrangement is also an important way of categorizing turbines. In a single casing machine, there is a single casing and one shaft. In a "tandem" design, there are two or more casings connected end to end by a shaft. In "cross-compound" configurations, there are two or more casings connected by multiple shafts.

As can be seen from the above, a turbine can be described on the basis of at least three methods of classification.

STEAM TURBINE GOVERNORS

There are two broad categories of steam turbine controls: "safety systems" and "process systems." Both will be described in the paragraphs that follow. Safety systems are intended to eliminate or, at least, to minimize the possibility of damage to the machine or the hazard to operators. Process control systems serve to control the operation of the machine, so as to follow the load in a stable and efficient manner.

The Governor Valve

One valve, the governor valve, is common to all turbine applications. This is the valve between the main steam supply and the turbine. This valve is the primary means of controlling the unit. When the demand for energy from the turbine is changed, it is the opening of this valve that changes to match the new demand by introducing a new supply of steam energy. The energy supply and demand is matched when the turbine speed is constant.

If the supply valve is too far open, the turbine will run at a speed above that desired. If the valve is too far closed, the turbine will slow down. In essence, the governor valve controls the flow of steam, generally measured in pounds per hour, into the turbine with the assumption that inlet and outlet conditions are constant. When that is the case and the shaft speed is constant, there is a balance between the steam flow and the shaft horsepower.

Some of the steam turbines can only be operated at constant speed because the characteristics of their steam supply valves (the governor valves) are not suited for throttling, because of their quick-opening characteristics. A quick-opening valve plug (Figures 6.19a and 6.19f) is like the plug of a bathtub in which a slight lift results in nearly maximum flow.

By changing that characteristic, a constant-speed turbine can be changed into a variable-speed one. Figure 8.38g illustrates how, by welding into the governor seat a characterizing ring, the initially quick-opening characteristic can be altered and the turbine can be changed to operate at variable speed.

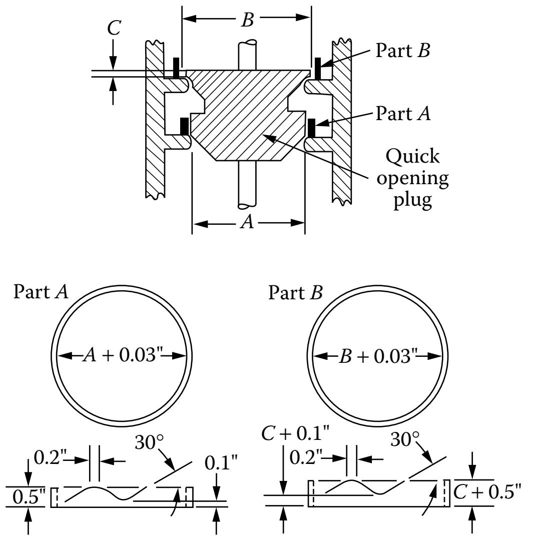

FIG. 8.38g
A double-seated steam governor valve can be rebuilt for optimized variable-speed service. The notched rings provide the necessary rangeability.

The Early Speed Governors

The speed of the turbine is controlled by the "governor." Governors can be mechanical, hydraulic, and electrical. They all include a pilot valve, or a more sophisticated controller, which modulates the turbine's inlet valve in order to keep the shaft speed on set point.

Mechanical governors have been developed from James Watt's original flyball governor shown in Figure 8.38h. The assembly consisted of two weights on the end of short arms, with a hinge in the center to allow vertical motion of each. By gearing to the shaft of the turbine, the assembly was made to rotate. As the shaft speed increased, the weights lifted up toward horizontal.

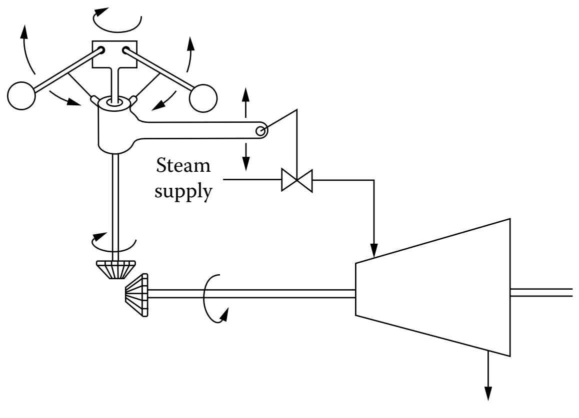

FIG. 8.38h
Schematic representation of flyball governor. As shaft changes speed, rotating fly balls move up and down. Linkage then controls steam supply valve to regulate steam rate. If shaft speed is too fast, balls move up, raising linkage, which then closes down the inlet valve. If shaft speed is too slow, balls drop, lowering collar and opening the inlet valve.

A linkage controlled the throttling valve by admitting less steam as the weights rose and more as they fell. This system was the beginning of automatic machine control and is still used almost unchanged in some modern mechanical governors.

Hydraulic Droop Governors

In hydraulic governors, the shaft speed is generally detected by a flyball, but instead of a direct mechanical linkage between the position of the flyballs and the control valve, a hydraulic system is used to amplify the force generated by the flyball position. The amplification feature improves control sensitivity, because very small changes in flyball position, corresponding to small changes in shaft speed, are sufficient to produce effective control actions. In addition to amplification, the signal can also be characterized as needed for stability.

Two types of governors are distinguished: In the "isochronous" design, the objective is to maintain the speed of shaft rotation constant regardless of load, while in the "droop" design, the speed of the machine is deliberately decreased as load increases (Figure 8.38i). The droop governor is a proportional-only controller, which cannot change its output control signal without first developing an error. This "offset" phenomena was explained in connection with Figure 2.2e in Chapter 2. The terms "offset" and "droop" are interchangeable.

On an increase in speed, the flyballs of a droop governor move out, which raises the stem on the pilot valve. This movement is opposed by the spring. Pressure is applied from the pilot valve to the top of the actuator; the bottom of the actuator drains to the sump through the pilot valve. This decreases the throttle setting. As the linkage moves down, the spring force increases and the force provided by the flyballs is exactly opposed. This moves the pilot valve back to the null position, which maintains the new lower speed.

Droop governors can be an advantage in some applications. For example, if two steam turbines are used to drive two electric generators that are electrically connected in parallel, the droop characteristic will allow the generators to share the total load, whereas isochronous governors would not.

If both generators were to run at exactly the same speed, the division of load between them would depend only on the electrical characteristics of the generators. If they were not precisely identical, which is always the case, the division of load between them would be unequal. If the speeds were not perfectly matched, one might carry all of the load.

A droop governor, however, would cause the one turbine with the heavier load to tend to slow down. When the load carried by the first generator matched that of the other unit and began to surpass it, the first unit would slow down. An

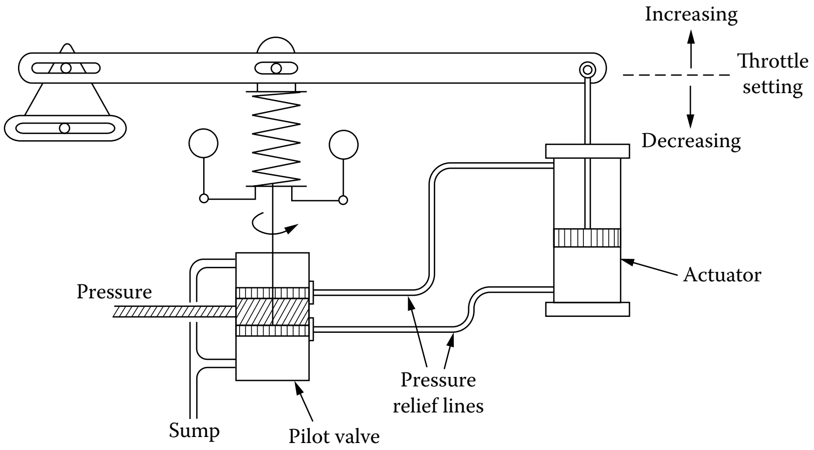

FIG. 8.38i
The design of a droop governor.

equilibrium would be quickly established with each unit carrying a share of the load.

The problems requiring compensation generally include instability that occurs during speed changes. In high-gain control systems, buffering is used to minimize instability. In this case, the governor introduces droop on all speed changes and controls the rate at which the temporary droop characteristic is removed. In this way, speed transitions can smoothly be made. The droop due to buffering can be built into a governor whether the device is a droop type or not.

Electronic Governors

Electronic governors perform the same functions as their mechanical-hydraulic counterparts, but in a somewhat different way. The flyballs are replaced by an electronic tachometer input that is usually generated by a magnetic sensor. The sensor can be triggered when the teeth of a gear connected to the machine's shaft pass by it (Figure 8.38j).

The varying reluctance of the magnetic circuit is used to generate a periodic function with a frequency proportional to the rotational speed of the shaft. The control valve is most often throttled hydraulically, although its actuator can also be electronic or pneumatic. The characteristics of the controller are determined by its transfer function, which usually provides similar performance as that of the earlier designs.

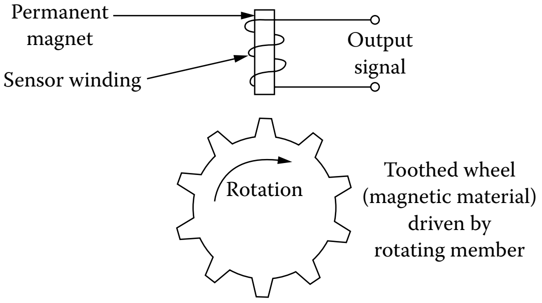

FIG. 8.38j
Schematic of an induction-type speed sensor.

The main difference is that a wider range of features can be built into a single unit, and the same design can be easily adapted to a variety of applications. For example, in addition to speed control, the governor can maintain either the inlet or the exhaust pressure or can control or manipulate other process conditions. Further, it can automatically parallel generator sets, provide overspeed protection, and monitor other machine safety devices so a shutdown can be effected in the event of an unsafe condition. Electronic governors provide versatility rather than improved performance.

Advanced Governors

Advanced control systems perform speed control, load control, steam pressure control, valve testing, remote control, and turbine protection. Normal operation, in addition to speed, load, and steam pressure modulating control, also includes valve testing and remote control (autodispatch, autosynchronizer, and so on). Even the advanced controls usually operate the high-pressure and low-pressure valves through the existing electrohydraulic controls of the turbine.

Further information on steam turbine performance and speed control can be found in API Standard 611, "General-Purpose Steam Turbines for Refinery Services," API Standard 612, "Special-Purpose Steam Turbines for Refinery Services," NEMA Standard SM21, "Multistage Steam Turbines for Mechanical Drive Service" (Table 8.38k), and NEMA Standard SM22, "Single-Stage Turbines for Mechanical Drive Systems." Performance objectives of governors are covered in NEMA Standard SM22-3.13.

Governor systems are classified as A, B, C, or D, depending on performance objectives. Table 8.38k summarizes the basis for these classifications.

TABLE 8.38k
Governor Classification and Performance per NEMA SM21

Class	Speed, Range, %[a]	Maximum Speed Regulation, %[b]	Maximum Speed Variation, ±%[c]	Maximum Speed Rise, %[d]	Trip Speed Setting, %[e]
A	10, 20, 30, 50, 65	10	0.75	13	115
B	10, 20, 30, 50, 65, 80	6	0.50	7	110
C	10, 20, 30, 50, 65, 80	4	0.25	7	110
D	10, 30, 50, 65, 80, 85, 90	0.5	0.25	7	110

[a] Governor may be adjusted to produce any speed within this percentage of rate speed.
[b] Maximum speed regulation from no load to full load.
[c] Maximum speed variation when operation is at constant load.
[d] Maximum overspeed that can occur under any operating conditions.
[e] Proper overspeed trip setting to coordinate with governor maximum speed rise.

CONTROLS AND OPTIMIZATION

A number of control systems will be described here in an order of increasing sophistication. These will include the controls for pressure let-down and extraction turbine controls. Controls systems will also be described for the decoupling of interaction between control loops and for optimization purposes.

The Basic Turbine Controller

The simplest application is one in which a turbine is used to operate a mechanical load at constant speed. Here, steam is supplied from a header and is condensed in the turbine (Figure 8.38l). In this case, the speed controller (governor) senses the shaft speed and manipulates the steam supply valve to keep the speed on set point.

Variations in load, caused by either shaft loading or variations in supply header pressure, affect the balance between the energy supplied to the turbine from the steam system and the work removed from the turbine's shaft. If more energy is available than is being used, the shaft will speed up. The governor will detect this increase in speed and act to eliminate it. Its means of doing so is to reduce the energy supplied to the turbine by closing the supply valve.

If the net change in the energy balance were negative, the shaft would slow down and the governor would respond by opening the supply valve.

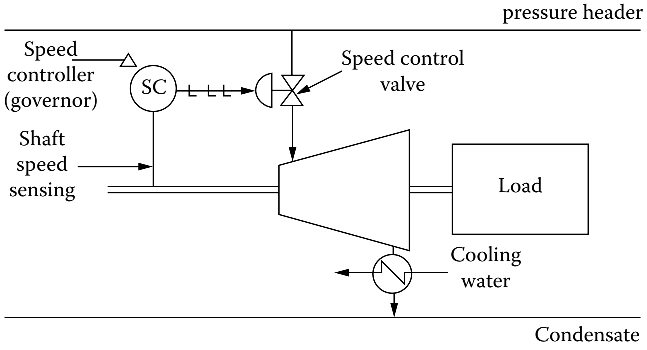

FIG. 8.38l
Simple mechanical drive.

Pressure Let-Down Control

A noncondensing turbine is generally less expensive to buy and to operate than a condensing one, because the energy is extracted from the steam while it has a higher enthalpy, and hence, it has a smaller volume per unit of energy. This has the desirable effect of reducing the size of the turbine and, frequently, also increasing its efficiency.

Because plants usually have a requirement for low-pressure steam for various loads, such as heating, the low-pressure steam generated by noncondensing turbines can often be used to advantage. (Figure 8.33b illustrated the control system to be used if the plant also has a requirement for high-pressure steam, and therefore total HP steam must be shared between the HP steam users and the steam turbine.)

In designing any let-down steam turbine controls, it is important to evaluate the relative amounts of the exhaust steam flow from the turbine and the demand for low pressure steam in the plant and make sure that one has considered all possible combinations.

Optimized Electricity Recovery For example, if the plant's demand for low-pressure steam is variable, it is desirable to send that variable amount of steam through a let-down turbine and to recover its energy content in the form of electricity. On the other hand, one should not send more high-pressure steam to the turbine than the amount of low-pressure steam demanded by the process. These two goals can be converted into two control loops as shown in Figure 8.38m.

In this control configuration, the pressure controller (PC) serves to make sure that all low-pressure steam users in the plant are always satisfied, because if the LP steam pressure

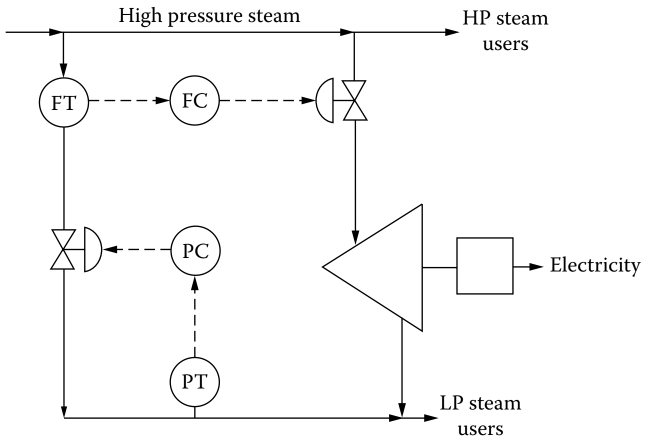

FIG. 8.38m
This control system will follow the variable low-pressure steam demand, while sending most of the HP steam through the turbine to convert its energy content into electricity.

drops, it opens up the turbine bypass to the HP steam header. If the LP steam users cannot tolerate superheating of their steam supply, the bypass has to be provided with a desuperheater.

The task of the flow controller (FC) is to make sure that whatever happens to be the LP steam demand of the plant, it is satisfied mostly by exhaust steam, from which the excess energy has already been recovered in the form of electricity. The flow controller does that by keeping the flow in the bypass at some minimum rate and increasing the HP flow to the turbine as soon as the bypass flow starts to increase.

The control configuration in Figure 8.38m can only be used when the load on the turbine is not determined by the process, but is freely variable, such as in plants where the excess steam energy is utilized for the cogeneration of electricity. While energy conservation dictates that the flow through pressure let-down line be minimized, control dynamics suggest that it should not be completely eliminated. This is because the speed of response of a let-down valve is much faster than that of a turbine. Therefore, the sensitive control of the LP steam pressure is provided by the let-down pressure controller, while the bulk of the steam passes through the turbine and is used to make electricity.

Under the discussion of extraction turbine controls in a later paragraph, Figure 8.38r describes the control configuration required if the LP load of the plant can exceed the full capacity of the turbine or when the demand for LP steam can drop below the steam flow from the let-down section of the turbine.

Valve Position-Based Optimization It was noted in connection with Figure 8.38m that if the low-pressure header is supplied by just throttling the high-pressure steam through a control valve, a considerable amount of energy is lost. It was shown that if the LP steam is supplied by a noncondensing turbine, much less energy is lost. In that configuration, the low-pressure header is supplied preferentially by the steam turbine.

Figure 8.38n illustrates the control system for an installation where the flow controller (FC) sets the turbine's speed controller and the objective is to maintain shaft speed relatively constant. In such a case, the amount of LP steam available from the turbine depends on its load. Therefore, if LP demand exceeds the turbine's ability to supply it, additional steam has to be supplied through the pressure let-down valve in the turbine's bypass. This bypass valve is controlled by the LP header pressure controller (PC).

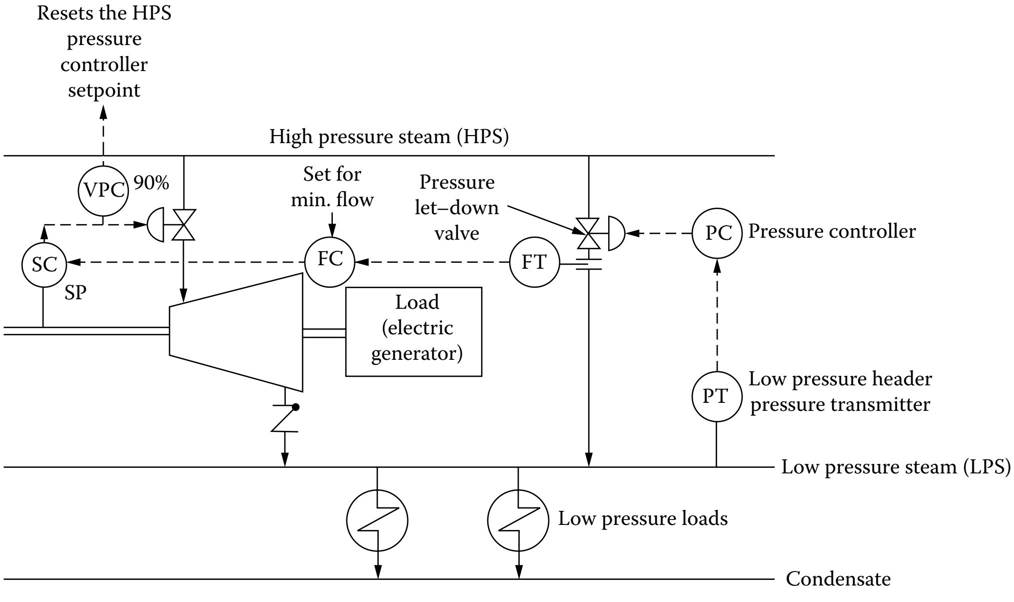

FIG. 8.38n
Back-pressure turbine control system for the generation of LP steam, provided with valve position-based optimizer.

If the only user of high-pressure steam in the plant is the turbine shown in Figure 8.38n, then the HPS pressure controller (not shown) set point can be adjusted to keep the steam governor valve always nearly open (90%). This is done by an integral-only valve position controller (VPC) that reduces the HPS pressure controller set point whenever the governor valve is less than, say, 90% open.

As the HPS supply pressure is reduced, more HP steam will be needed to meet the same electric load on the turbine, and therefore, the governor valve will open. This control strategy, which keeps the governor valve nearly open, is an optimization strategy, because the same load is being met with less pressure drop through the governor valve, and therefore it is being met at a higher efficiency.

The flow controller in the turbine bypass, as was explained in connection with Figure 8.38m, serves to make sure that most of the steam is sent through the turbine. Therefore, whenever excessive amounts of steam pass through the let-down valve, the flow controller (FC) increases the speed set point and thereby increases the amount of steam passing through the turbine.

Extraction Turbine Control

In addition to the governor valve, in extraction turbines, a second "valve" is required. It controls the steam flow rate that is extracted from the first stage of the turbine and is sent to the second stage. The extraction rate can be controlled to keep the pressure of the LP header constant, but it can also be a function of shaft speed, or a combination of the two.

If the turbine incorporates the controls as a built-in feature, the turbine is referred to as an "automatic-extraction" type. Such turbines are generally designed to deliver 100% shaft power and to provide extraction steam only if the load requirements permit. This is the most common type of extraction machine.

Extraction turbines may be visualized as two-stage units from which steam can be removed at a pressure between that of the supply and that of the exhaust. When the demand for work (load) on the turbine is small, the high-pressure stage may be adequate to meet the "work load," and consequently, a large amount of extraction steam may be available to supply the low-pressure header. As work load increases, the second stage becomes necessary to meet the demand for added work and begins to compete for the steam previously being extracted. The control system must allow for this to occur, if meeting the work load is the first priority.

At least a minimal amount of steam must be maintained through the second stage to prevent overheating. This requirement may necessitate limiting extraction, but it can also require the maintaining of a specific second-stage discharge pressure. These requirements are given in the manufacturer's operating specifications.

LPS Demand Exceeding First-Stage Exhaust Figure 8.38o shows an extraction turbine in a pressure let-down application.

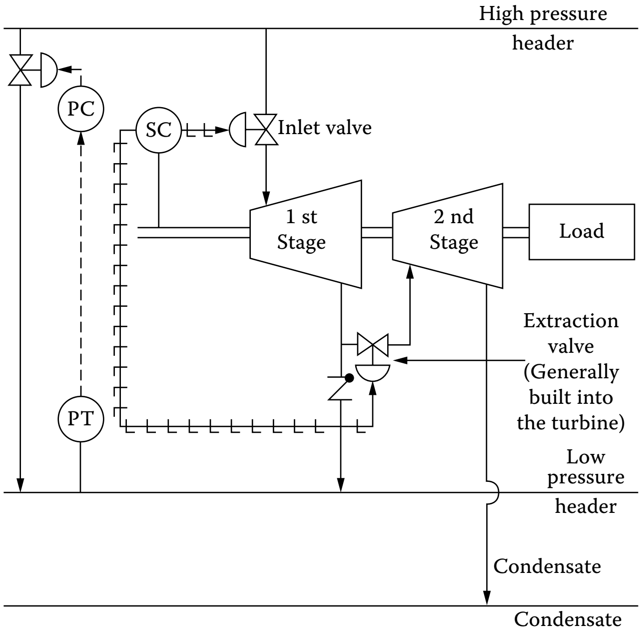

FIG. 8.38o
The controls of an extraction turbine in a pressure let-down application, where the demand for LPS always exceeds the steam available from the interstage of the turbine.

In this example, the exhaust of the first stage is used to supply a low-pressure header, while the second stage is condensing. The speed controller (governor) is arranged by hydraulic or mechanical linkage to close (or nearly close) the extraction valve, if the turbine speed can be maintained by the governor throttling the HP steam supply valve to the first stage (the steam inlet valve).

If speed cannot be maintained by the first stage alone, the extraction valve starts to open, admitting more steam to the second (condensing) stage and, consequently, starving the low-pressure header. When the available extraction steam is insufficient, similarly to the arrangement in the previous figures, a pressure-controlled bypass valve is used to maintain the pressure in the low-pressure header.

LPS Demand Less Than First-Stage Exhaust So far, it has been assumed that the low-pressure header can use all the steam that is available from the turbine. If this is not the case — if the interstage steam supply is in excess of the low-pressure header's requirements — the excess steam must be condensed or vented to protect from overpressuring the LPS header. Figure 8.38p illustrates the controls that will protect against either unnecessary condensing or wasting treated water by venting the steam.

In this control configuration, if the low-pressure header does not need the steam, the HP steam supply flow to the first stage of the turbine is reduced. Because this reduces the energy available from the first stage, the extraction valve is opened to the condensing stage to supply the additional horsepower required to maintain shaft speed. The main

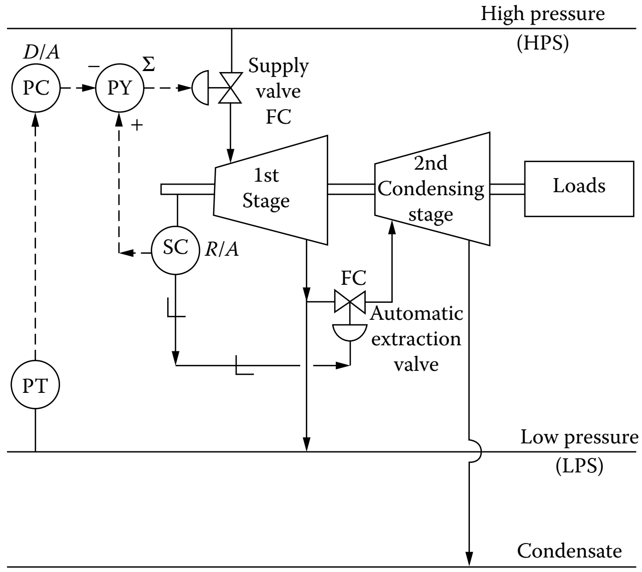

FIG. 8.38p
The controls of an extraction turbine in a pressure let-down application, where the demand for LPS is always less than the steam available from the interstage of the turbine.

difference with the controls in Figure 8.38o is that the pressure controller (PC) that maintains the pressure in the LPS header does not modulate a bypass valve, because there is no bypass. Instead, it reduces the HP steam supply to the turbine if the LPS pressure rises, by sending a negative bias to the summing relay (PY).

The speed controller (SC) in this configuration controls the extraction valve to maintain the shaft speed. The speed controller's output to the HPS supply valve is sent to the positive input of a summing relay (PY). In the absence of a signal from the PC to the negative input of PY, this scheme would operate the same way as the controls in Figure 8.38o.

The pressure controller on the LPS header in Figure 8.38p is direct-acting, so its output will increase when the LPS header pressure rises. This increasing control signal will be subtracted from the speed controller's output and will cause the FC inlet valve to close slightly. This, in turn, will cause the turbine to slow down.

As the shaft speed drops, the speed controller will attempt to open the inlet valve by increasing its output signal, but the change will again be resisted by the pressure controller. As speed falls off, the reverse-acting speed controller will open the extraction valve. As a consequence, the pressure in the LPS header will decrease. This will cause the pressure controller to reduce its output, which in turn will slightly open the HPS supply valve, which will increase the shaft speed, and therefore, the speed controller will close the extraction valve somewhat. Eventually, after much interaction, a new equilibrium will be achieved.

Improving the Control Dynamics The dynamics of the pressure control system in Figure 8.38p is dependent on the dynamics of the turbine's extraction control system. The characteristic of the extraction valve is often not suitable for throttling control and can be improved by use of a characterizing positioner.

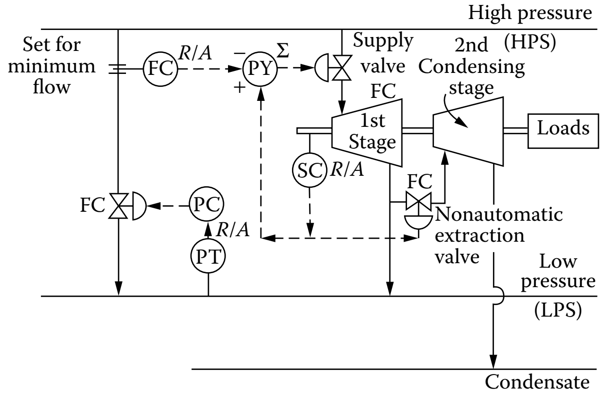

FIG. 8.38q
The addition of a pressure-controlled let-down line increases the speed of response, while the flow controller minimizes the energy waste through that line.

Another method of improving the dynamic response of the control system in Figure 8.38p is to provide a pressure let-down bypass line, as shown in Figure 8.38q. Here, the pressure controller (PC) provides the sensitivity required for quick response, while the flow controller (FC) keeps the flow in the bypass line at a minimum, as it slowly opens the HPS supply valve to the turbine whenever the flow in the bypass line exceeds its set point.

Flexibility by Controller Sequencing If the relative sizes of the work load on the turbine and the user's demand for LPS are unpredictable, the previously described control systems will not work. Figure 8.38r illustrates a control strategy that utilizes controller set-point sequencing to allow optimized and stable operation under any combination of relative load sizes.

If the demand for LPS exceeds the amount of exhaust steam available, the control system shown in Figure 8.38r will operate in a similar manner as did the control system in Figure 8.38o, by the pressure controller (PC) providing the additional steam through the pressure let-down bypass line. The main difference between the two control systems is the addition of the optimizing controller FC-3, which is set at a bypass flow rate slightly exceeding the set point of FC-1.

Therefore, if the pressure controller (PC) opens the bypass and the let-down flow rate exceeds the set point of FC-1, the previously inactive (saturated) FC-3 becomes active and starts cutting back the LPS steam flow to the boiler feed water preheater and, thereby, reduces the plant's demand for LPS. This is an energy-efficient response because the energy recovered from the LPS supplied to the feedwater preheater is less than the energy content of the HP steam that is needed to produce that LPS.

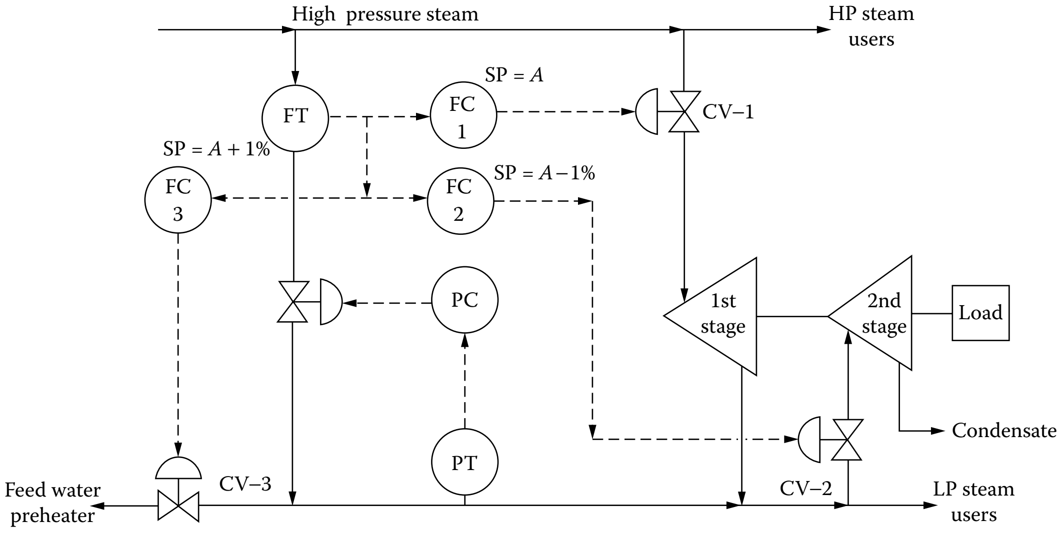

FIG. 8.38r
This control system is both flexible and optimized: FC-1 keeps the bypass flow to a minimum, while FC-3 reduces the LPS demand if it exceeds the work load on the turbine, and FC-3 makes more steam energy available to the turbine if the LPS demand is below the work load.

If the relative loads are reversed and the LPS availability exceeds the demand for LPS, this will cause the pressure in the LPS header to rise and the pressure controller (PC) to reduce down the bypass flow. When this let-down flow drops below the set point of FC-1, the previously inactive (saturated) FC-2 becomes active and admits that part of the LP steam that is not needed in the LPS header into the second, condensing stage of the turbine.

Any number of such bypass flow controllers can be used to sequentially respond to changes in the relative sizes of the work and LP steam loads. These controllers should be provided by integral action only, so that they will be saturated (and their control valves closed) until their set points are reached.

Decoupling the Interaction If the turbine is a nonautomatic extraction type, and therefore one can send a control signal to the extraction valve (as was the case in Figure 8.38r), the interaction between the pressure and turbine speed controllers can be decoupled. In the control system configuration shown in Figure 8.38s, a drop in the speed of the shaft opens both the inlet and the extraction valves, and an increase in shaft speed closes both of them.

In this control system, when the LPS header pressure rises, the pressure controller (PC) output rises, and therefore the PY-1 output drops and the supply valve closes. At the same time, the increase in the PC output increases the output of PY-2, which opens the extraction valve. When the LPS header pressure drops, the opposite is the response: The supply valve opens and the extraction valve closes.

If the weighing of the combining algorithms (PY-1 and PY-2) is correct (if they properly consider features of the valves and the time constants of the loop components), the response to changing pressure conditions, the supply, and extraction valves will complement each other.

Therefore, if the control model is properly tuned and the gains of the summers PY-1 and PY-2 are properly set, there will be no interaction between speed and pressure control,

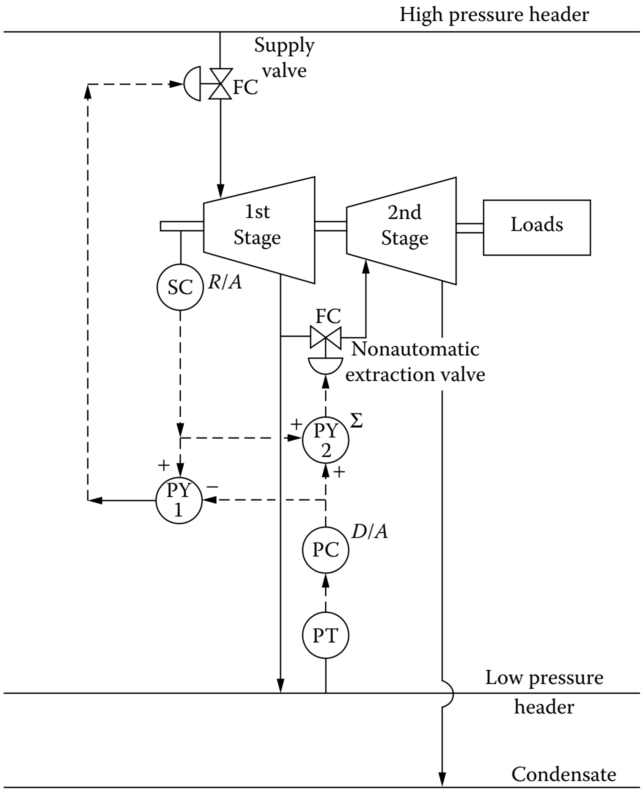

FIG. 8.38s
One way to eliminate interaction between flow and pressure loops is to allow the pressure controller to throttle both the supply and the extraction valves.

and the speed control will not be adversely affected by the responses to pressure disturbances, and vice versa. The speed of the response of this system can also improved by the addition of bypass let-down controls be shown in Figure 8.38q. On the other hand, if the speed of response of the turbine is sufficient to respond to pressure variations, the let-down station (shown in Figure 8.38q) can be eliminated.

An intriguing aspect of this control configuration is the possibility of eliminating the need to throttle steam completely, if the turbine's operating capacity sufficiently matches the low-pressure header's demand for LPS. In that case the supply valve is kept fully open, as was the case in the control configuration shown in Figure 8.38n, and the pressure controls of the LPS header determine the distribution of the extracted steam between the turbine's second stage and the LPS header. Obviously, this configuration is only viable if the size and characteristics of the turbine are properly selected.

SAFETY CONTROLS

The turbine protection system protects the turbine from overspeeding, monitors all critical turbine parameters, and trips the turbine if a condition exists that could cause equipment damage. Thermal stress monitoring performs the calculations needed to determine thermal conditions of the turbine and safe parameters for control operation. It also provides the operator with information on rotor thermal stress (acceleration and load rates, and maximum allowable initial load pick-up).

The main safety control element on a turbine is the steam supply valve. This safety valve can be a separate on/off valve, or the shut-off function can be incorporated into the controls of the steam supply valve that is used for speed control. Taking the turbine off-line is accomplished by closing this valve. Consequently, the safety control system should be so designed as to require that all interlocks be satisfied before this valve is allowed to open.

As shown in Figure 8.38t, the safety interlocks usually include the safety response to lube oil failure, high bearing temperature, overspeed, and vibration. Lube oil is generally monitored by a pressure switch in the case of pressure lubrication systems or by a level switch in nonpressure systems. If the lube oil failure switch is not satisfied, the turbine shutoff valve is closed.

The sudden loss of load will cause the turbine to overspeed. This can happen in mechanical drive applications, but it is a more common occurrence in electrical generator drives. Abnormal electrical conditions in a distribution system can

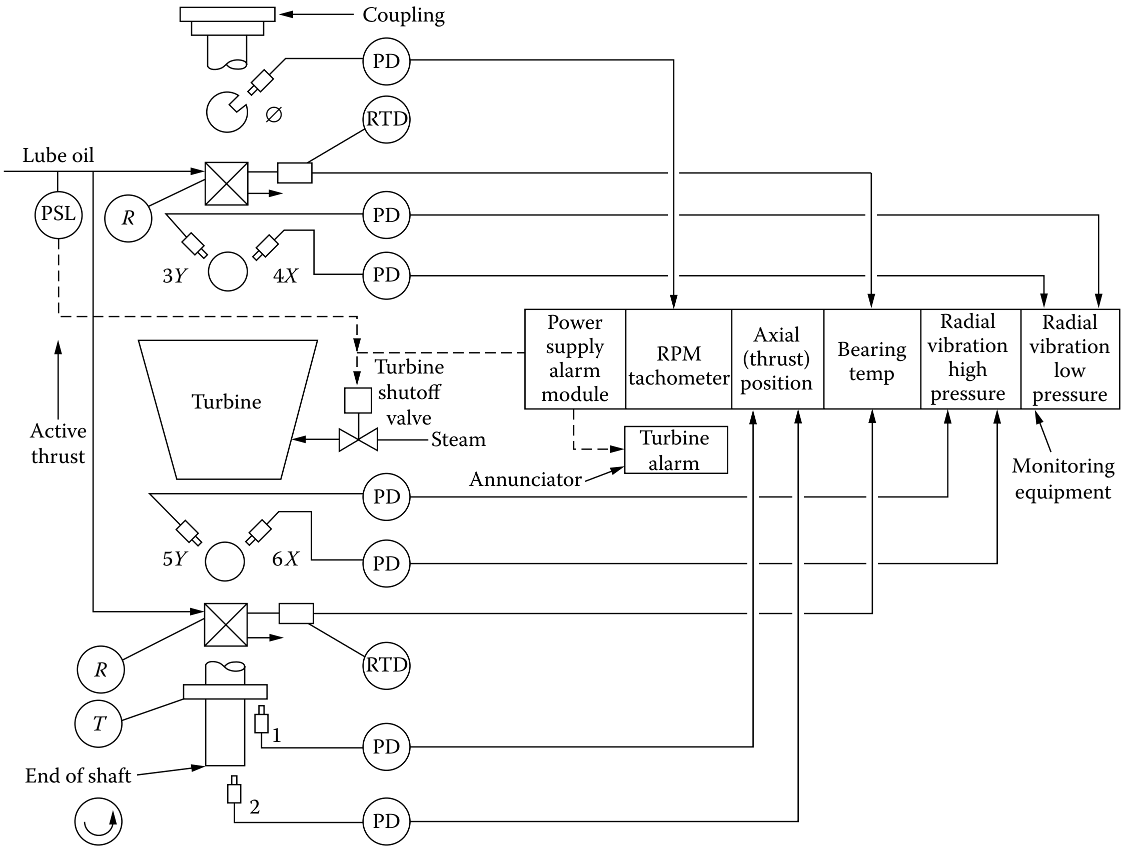

FIG. 8.38t

Turbine "health-monitoring" system. PD: Position detector, proximity sensor. (Adapted from Figure C-1 of American Petroleum Institute Standard 670, Noncontacting Vibration and Axial Position Monitoring System.)

cause protective devices to separate the generator from the system. In that case, a generator that may have been supplying megawatts of power and, consequently, megawatts of load to its prime mover can suddenly disappear, leaving only a small demand for energy that will serve to overcome the friction of its bearing and the windage on its moving parts.

When this occurs, if the control system is not fast enough to reduce the steam supply to the turbine, it will overspeed. This condition can be detected by a variety of devices, such as centrifugal switches, electronic tachometers, or strain-detecting devices installed on or near such components of the machine that are affected by the overspeed condition.

Bearing temperature is an additional indication if lubrication is functioning properly. It is also a way of detecting the deterioration in bearings before complete mechanical failure. Mechanical wear accelerates as a result of improper lubrication or because of mechanical stresses that cause deformation of the bearing's component parts. In either case, the bearing begins to dissipate abnormally large amounts of energy, which in turn results in heating.

Consequently, a sudden rise in bearing temperature is generally an indication of incipient failure. It is important to quickly stop the machine when a potential bearing failure is detected. This is because some turbine designs maintain very small clearances between stationary and rotating parts. If the bearing deforms, it may mean the total destruction of the machine.

Especially on larger machines, a stationary vibration-monitoring system is usually installed. Such a system generally consists of accelerometers or proximity sensors located radially in each bearing and axially on the end of the shaft or the thrust collar. Two sensors positioned at right angles are typically used in bearings.

Electronic monitoring equipment is used to measure the acceleration or displacement that occurs at each monitoring point. The monitoring equipment generally incorporates an "alarm" setting, which is intended to warn an operator of an impending problem, and a "danger" setting, which is intended to shut the machine down. In many instances, a vibration-initiated shutdown can prevent major damage in situations in which, without prompt action, equipment could be lost.

Sequential Controls

In power generating installations, the monitoring and sequential controls serve to automatically bring the turbine from turning gear to generator grid synchronization. These controls evaluate such parameters as bearing temperatures and vibration, water detection, and differential expansion. The control package advises the operator on current turbine status and provides recommended actions.

Vibration monitoring equipment is covered extensively in Section 7.22 in Chapter 7 of the first volume of this handbook.

CONCLUSIONS

Steam turbines are versatile energy conversion devices that, in addition to powering a variety of mechanical loads, can do an excellent job of extracting energy that might otherwise be wasted from a plant's thermodynamic cycle. They provide opportunities for process improvements and energy savings. Therefore, their application should be carefully and insightfully considered. The controls of the high-pressure and low-pressure steam admission valves most often are implemented through the existing (furnished electrohydraulic) turbine controls.

Advanced controls include the features of redundant control, on-line tuning, field-proven hardware, and remote operator displays, including custom graphics, report generation, and on-line, systemwide integration. There usually are four separate and redundant control packages, which perform operator automatic control (OAC), thermal stress monitoring, sequential control, and turbine protection functions.

As has been discussed in this section, OAC control includes speed, load, and steam pressure modulating control, as well as valve testing and remote control operation (autodispatch, autosynchronizer, and process interface).

8.39 Wastewater Treatment Controls

A. J. BAKER (1970, 1985) **B. G. LIPTÁK** (1995, 2005) **S. E. GAERTNER** (2005)

INTRODUCTION

This section concentrates on the description of the controls used in industrial wastewater treatment. It also covers, but in less detail, the controls used in municipal wastewater and cooling water treatment processes. The controls of water supply plants, including water softening and purification, are covered in Section 8.40.

In the United States, the operations of all water treatment plants are directed by the Federal Water Pollution Act. Together with its amendments, it is known as the Clean Water Act (CWA). Water treatment plants can be privately or publicly owned. Private treatment plants can discharge into publicly owned treatment works (POTWs) if they have the proper permits.

The goal of the water treatment plants is to remove organic matter and to reduce the water's nitrogen content to less than 20 mg/l in all forms. The water quality targets for the treated plant discharge usually include BOD concentration under 5 mg/l, suspended solids concentration under 3 mg/l, PO_4 under 0.05 mg/l, and NO_3 under 10 mg/l. If the plant discharge is for golf course use, the allowable BOD concentration is under 10 mg/l and the suspended solids concentration is under 12 mg/l.

The coverage of this section overlaps with a number of other sections in this chapter. These are:

Section 8.1, Aeration and DO Controls, Section 8.31, ORP Controls, and Section 8.32, pH Control. It is recommended to the reader that for an in-depth coverage of the control strategies available for dissolved oxygen (DO), oxidation-reduction potential (ORP), and pH control and optimization, they also refer to the above sections.

Lastly, the reader is reminded that the various sensors and analyzers used in the wastewater treatment processes are all covered in the first volume of this handbook. Their section numbers are as follows:

8.2	Analyzer Sampling, Process Samples
8.6	Biometers
8.7	BOD, COD, and TOD Sensors
8.11	Chlorine
8.15	Colorimeters
8.23	Fiber-Optic Probes
8.28	Ion-Selective Electrodes
8.36	Nitrate, Ammonia, and Total Nitrogen
8.38	Odor Detection
8.39	Oil in or on Water
8.41	Oxidation-Reduction Potential (ORP)
8.43	Oxygen in Liquids (Dissolved Oxygen)
8.45	Ozone in Water
8.48	pH Measurement
8.49	Phosphorus Analyzer
8.54	Streaming Current or Particle Charge Analyzer
8.58	Total Carbon Analyzers
8.60	Turbidity, Sludge, and Suspended Solids
8.65	Water Quality Monitoring
8.66	Wet Chemistry and Auto-Titrator Analyzers

General Considerations

Some of the processes used in the treatment of wastewater are not well suited to automatic process control. This is because many continuous analyzers are not reliable enough for the control of such processes as coagulation and flocculation of water or the biological treatment of wastewater. These processes are, for the most part, an art, not a science, still requiring some human judgment to determine chemical application rates and process control parameters.

The measurements that are reliable and in wide use are pH, oxidation-reduction potential, residual chlorine, and flow rate. Other water properties that are measured to assist the operator in controlling the system are conductivity, alkalinity, temperature, suspended solids, dissolved oxygen, and color. Figure 8.39a illustrates the design of the sampling system used when measurements obtained by inserting the sensors directly into the process are not reliable.

Water and wastewater treatment consists of unit operations that may be classed as mechanical, chemical, biological, and any combinations of these. The mechanical operations most often consist of screening, filtration, and separation by gravity.

Industrial Wastewater Treatment

Environmental regulations restrict the discharges of chlorine, heavy metals, arsenic, cyanides, biological pollutants, and excessively acidic or basic water. These regulations are

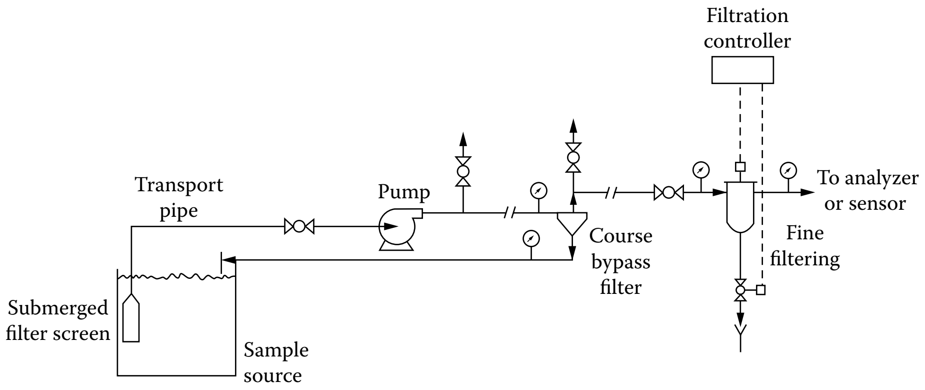

FIG. 8.39a
Schematic of a typical sample transport system.

included in the Clean Water Act and its amendments, including the effluent limitations and pretreatment standards for centralized waste treatment (CWT) facilities.

The majority of industrial wastewater treatment processes are continuous rather than batch-type operations. In the discussion that follows, the control of the following types of water treatment processes will be described: (1) chemical oxidation, (2) chemical reduction, (3) neutralization, (4) precipitation/flocculation/filtration, and (5) biological control by chlorination.

CHEMICAL OXIDATION

Wastewater is treated by chemical oxidation when the contaminant can be destroyed, its chemical properties altered, or its physical form changed. Examples of chemicals that can be destroyed are cyanides and phenol. Sulfides can be oxidized to sulfates, thus changing their characteristics completely. Iron and manganese can be oxidized from the soluble ferrous or manganous state to the insoluble ferric or manganic state, respectively, permitting their removal by sedimentation.

Strong oxidants, such as chlorine, chlorine dioxide, ozone, and potassium permanganate, are used. Chlorine is preferred when it can be used because it is the least expensive and is readily available. Ozone is a strong second choice and is now favored because its excess converts to oxygen, while the excess chlorine could react with industrial waste to produce cancer-causing substances.

The time required for these reactions to proceed to completion is usually pH-dependent. Most often, either residual oxidant or ORP measurement is used to control these processes.

Cyanide Destruction Process

Oxidation-reduction implies a reversible reaction. For a detailed discussion of ORP-based controls, refer to Section 8.31. Because these reactions are carried to completion and are not reversible, the term is misleading. In practice, control is by what may be called "electrode potential readings." An illustration is the oxidation of cyanide into cyanate with chlorine, according to the following reaction:

$$\begin{array}{ll} \mathrm{2Cl_2} & \text{Chlorine} \\ + & \\ \mathrm{4NaOH} & \text{Sodium hydroxide} \\ + & \\ \mathrm{2NaCN} & \text{Sodium cyanide} \\ \downarrow & \\ \mathrm{2NaCNO} & \text{Sodium cyanate} \\ + & \\ \mathrm{4NaCl} & \text{Sodium chloride} \\ + & \\ \mathrm{2H_2O} & \text{Water} \end{array} \qquad \mathbf{8.39(1)}$$

The electrode potential of the cyanide waste solution will be on the order of –200 to – 400 mV. After sufficient chlorine has been applied to complete the reaction described in Equation 8.39(1), the electrode potential will be on the order of +300 to +450 mV. The potential value will not increase until *all* cyanide has been oxidized. Control of pH is essential, with the minimum being about 8.5. The reaction rate increases as the pH rises.

Complete oxidation (the complete destruction of cyanide) is a two-step reaction. The first step is oxidation to the cyanate level described in Equation 8.39(1). The endpoint of

TABLE 8.39b
Set Points and Operating Parameters of the Two-Stage Cyanide Destruction Process

	Process Stages	
Parameters and Set Points	*First Stage: Cyanide to Cyanate*	*Second Stage: Destruction of Cyanate*
pH set point	10–12	8.5–9.5
Reaction time (minutes)	5	45
ORP (mv) set point	+300 to +450	+600 to +750
Maximum concentration of cyanide (cyanate) that can be treated	1000 mg/l	1000 mg/l

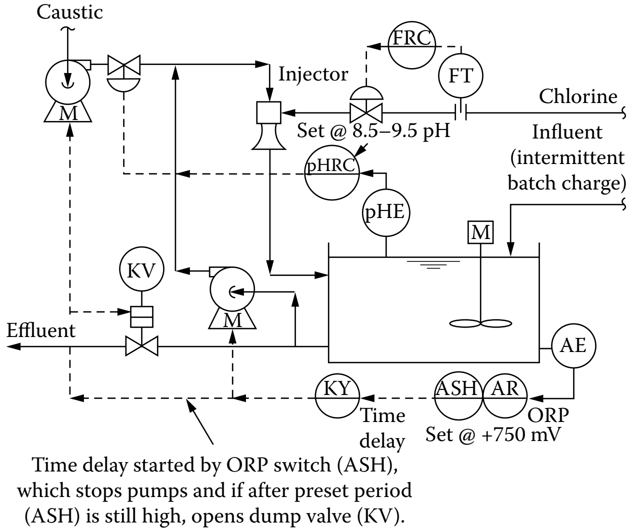
the second-stage reaction is at an electrode potential of about +600 to +750 mV. The overall reaction is

$5Cl_2$ Chlorine
+
$10NaOH$ Sodium hydroxide
+
$2NaCN$ Sodium cyanide
$\downarrow$ **8.39(2)**
$2NaHCO_3$ Sodium bicarbonate
+
N_2 Nitrogen
+
$4H_2O$ Water

Cyanide destruction is the only chemical oxidation reactions that takes place in two steps, as described in Table 8.39b.

Batch Cyanide Control Because of the complexity of a two-stage process, the toxicity of cyanide, and the rigid requirements on waste discharge, a batch-type treatment is often recommended. Such a batch type control system has already been described in Figure 8.31i, and a slightly different one is shown in Figure 8.39c.

In Figure 8.29a, chlorine is charged at a constant flow rate (FRC), while caustic is being added under pH control to maintain the batch pH at about 8.5–9.5. When the ORP set point of +750 mV is reached, the high ORP switch (ASH) actuates a delay timer (KY) and the chemical feed systems are shut down.



Time delay started by ORP switch (ASH), which stops pumps and if after preset period (ASH) is still high, opens dump valve (KV).

FIG. 8.39c
Batch oxidation of cyanide waste with chlorine.

If, after a 30-min delay, the ORP of the tank contents is still at or above the +750 mV set point, the batch is discharged (by opening KV). If further reaction has been taking place during the delay period and the ORP potential value has dropped below the set point, the system is reactivated and the cycle is repeated. When this batch approach is used, additional, usually duplicate, storage tanks are required to receive the incoming waste while the batch tank is used for treatment.

Continuous Cyanide Control As was shown in Figure 8.31g, the continuous flow-through cyanide destruction control systems have the advantage of requiring less space, but this advantage is often offset by the capital cost of the additional equipment that is required.

In the control system configuration shown in Figure 8.39d, the two steps in the cyanide destruction process are separated. In the first step, the ORP controller set point is approximately +300 mV, and this ARC controls the addition of chlorine to oxidize the cyanide into cyanate. The pH in the first-stage tank is controlled by the pHRC at approximately 10 by throttling the caustic flow into the recycled effluent into the injector.

The reaction time of this first-stage process is on the order of 5 minutes. The set point for the chlorine flow controller (FRC) that charges the chlorine into the second-stage tank is ratioed (FY) to the chlorine flow into the first stage. The caustic requirement of the second stage is dependent solely on the chlorine flow rate (pH control is not necessary), and therefore the same chlorine flow signal can be ratioed (FY) to generate the set point for the caustic feed flow controller (FRC).

The ORP detector (AE) is provided to signal process failure and to actuate alarms or initiate emergency actions, if the potential level drops below approximately +750 mV.

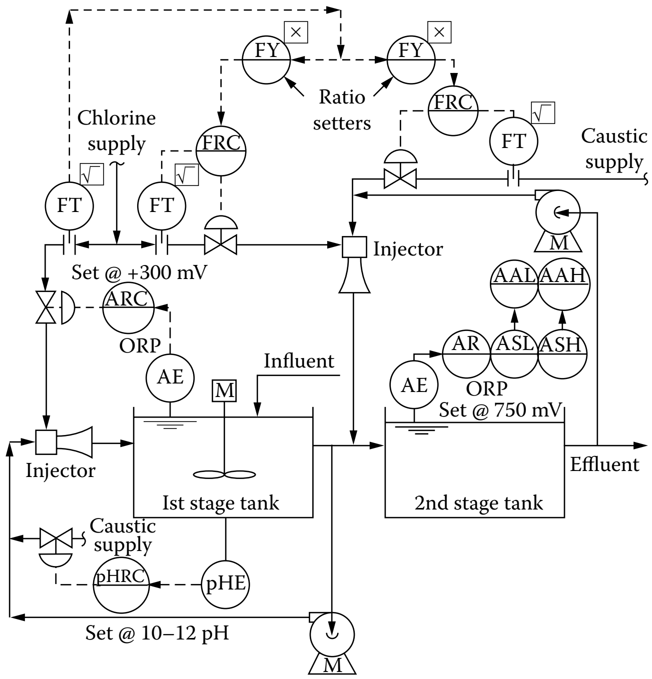


FIG. 8.39d
Continuous oxidation of cyanide waste with chlorine. Influent here has continuous constant flow rate and variable quality.

One might note that in the control system described in Figure 8.31g, an ORP controller (ORPIC) was used to charge the chlorine into the second stage. It is debatable if that is necessary, because the ratioing accuracy available between the first-stage chlorine flow rate and secondary addition (which is approximately 1:1) is, in most cases, sufficiently high. The probability is that the system shown in Figure 8.39d might apply a little more chlorine than is actually required.

In the cyanide destruction process, fixed flow rates are preferred, because they will provide constant reaction times. Residual chlorine analyzers are seldom used in this process, because the metal ions usually present in the waste interfere with their accurate operation. They are used in processes in which the presence of excess residual chlorine indicates a completed reaction. In such processes the set point is usually 1 mg/l or less.

Chlorinator, Sulfonator, and other Controls Figure 8.39e describes the main components of the feeders that can be used in chemical oxidation operations to charge chlorine, sulfur dioxide, or carbon dioxide.

The chlorinator shown in the figure has two operators, two control valves that can be throttled. One is operated in a feedforward mode (PVC) and responds to changes in the influent flow rate. The other control valve (FV) is throttled in a feedback configuration by the effluent quality controller (ARC), which can be detecting ORP, pH, residual chlorine, or other related indicators.

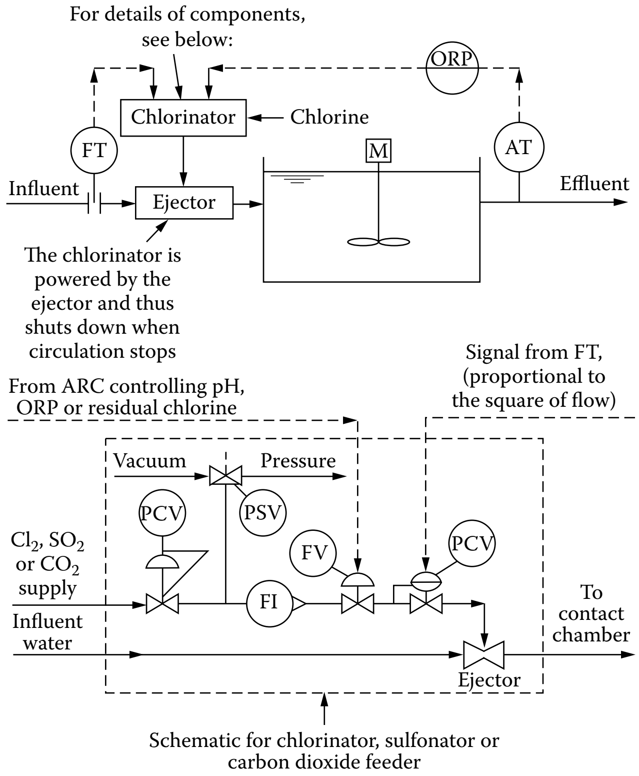

FIG. 8.39e
The lower part of this figure shows the main components of a gas feeder, such as a chlorinator. The top part of the figure shows how a chlorinator is integrated into a chemical oxidation control system.

Most reactions are completed within 5 min, and except for cyanide treatment, most all other chemical oxidation operations are carried out simultaneously with other unit operations, such as coagulation and precipitation, which govern the pH value. Thus, whereas the pH value affects the rate of reaction, it is seldom controlled solely to serve the oxidation process.

Cyanide Destruction by Ozonation The oxidation of cyanide to cyanate by ozonation is extremely fast and is carried out at a pH of 9 to 10.

$$CN^- + O_3 \rightarrow CNO^- + O_2 \qquad \mathbf{8.39(3)}$$

The further reaction to cyanates is much slower and can be accelerated by the addition of copper (2+) salt catalysts. Figure 8.39f illustrates how cyanide oxidation by ozone can be controlled, using either a stirred reactor or a packed or sieve plate tower.

Chlorination is a better developed and more frequently utilized process than ozonation. On the other hand, ozone is faster and more powerful as an oxidizing agent and requires smaller holding and reaction tanks. Chlorine gas is also

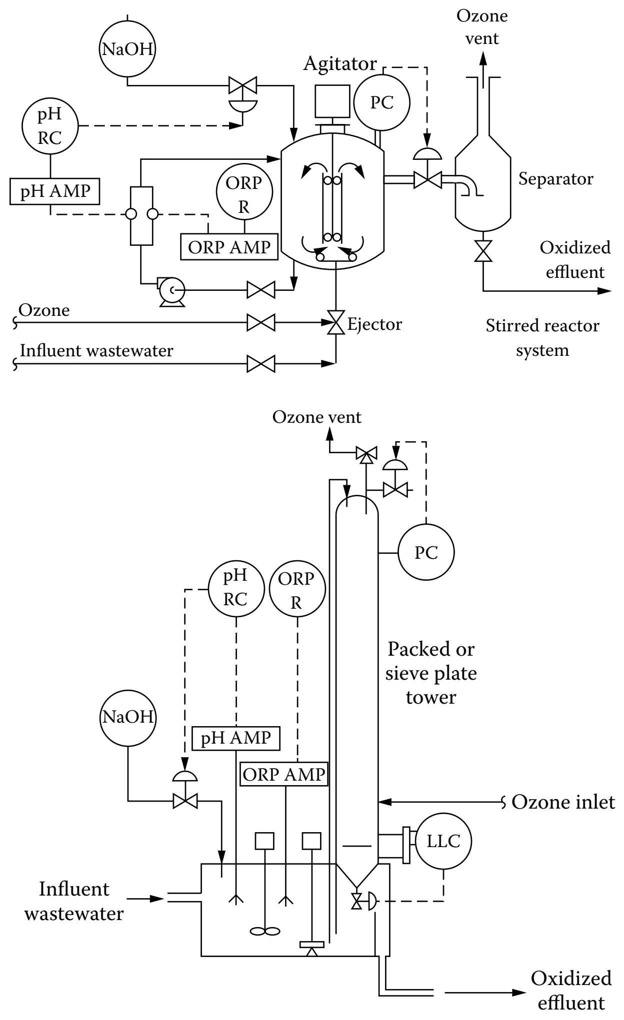

FIG. 8.39f

Control systems for the oxidation of cyanide by ozone, utilizing a stirred reactor (top) or a packed or sieve plate tower (bottom).

hazardous. In order to remove 1 lb of cyanide, one usually requires 2.7 to 6.8 lb of chlorine gas or 1.8 to 4.6 lb of ozone.

CHEMICAL REDUCTION

Wastewater treatment by chemical reduction is quite similar to chemical oxidation. Commonly used reductants are sulfur dioxide and its sodium salts, such as sulfite, bisulfite, and metabisulfite. Ferrous iron salts are infrequently used. Typical examples are reduction of hexavalent chromium, dechlorination, and deoxygenation. Table 8.39g lists some of the reduction and precipitation reactions that take place in the process of chrome treatment.

TABLE 8.39g

Chrome Reduction and Precipitation Reactions

Reducing Agent	*Reaction*
Ferrous sulfate ($FeSO_4$)	$2H_2CrO_4 + 6FeSO_4 + 6H_2SO_4 \rightarrow$ $Cr_2(SO_4)_3 + 3Fe_2(SO_4)_3 + 8H_2O$ $Cr_2(SO_4)_3 + 3Ca(OH)_2 \rightarrow$ $2Cr(OH)_3 + 3CaSO_4$
Sodium metabisulfite ($Na_2S_2O_5$)	$Na_2S_2O_5 + H_2O \rightarrow 2NaHSO_3$ $2H_2CrO_4 + 3NaHSO_3 + 3H_2SO_4 \rightarrow$ $Cr_2(SO_4)_3 + 3NaHSO_4 + 5H_2O$ $Cr_2(SO_4)_3 + 3Ca(OH)_2 \rightarrow$ $2Cr(OH)_3 + 3CaSO_4$
Sulfur dioxide (SO_2)	$SO_2 + H_2O \rightarrow H_2SO_3$ $2H_2CrO_4 + 3H_2SO_3 \rightarrow$ $Cr_2(SO_4)_3 + 5H_2O$ $Cr_2(SO_4)_3 + 3Ca(OH)_2 \rightarrow$ $2Cr(OH)_3 + 3CaSO_4$

Reduction of Hexavalent Chromium

The ORP-based controls of the reduction of highly toxic hexavalent chromium into the innocuous trivalent form has already been discussed in some detail in Section 8.31. If the reducing agent is sulfur dioxide, the following reaction takes place:

$$\begin{array}{ll} 3SO_2 & \text{Sulfur dioxide} \\ + & \\ 2H_2CrO_4 & \text{Chromic acid} \\ \downarrow & \\ Cr_2(SO_4)_3 & \text{Chromic sulfate} \\ + & \\ 2H_2O & \text{Water} \end{array} \qquad \textbf{8.39(4)}$$

Most hexavalent chrome wastes are acidic, but because the rate of reaction is much faster at very low pH values, pH control is essential. Sulfuric acid is preferred because it is cheaper than other mineral acids. The set point of the pH controller is approximately 2.

Similarly to the treatment of cyanide, the chrome reduction reaction is not reversible, either. As shown in Figure 8.39h, the control of sulfur dioxide addition is by electrode potential level, using ORP instrumentation. The potential level of hexavalent chromium is +700 to +1000 mV, whereas that of the reduced trivalent chrome is +200 to +400 mV. The set point on the ORP controller is approximately +300 mV.

The illustrated batch treatment of chrome is controlled at a pH of 2 by feedback control of the acid addition (pHRC), while the sulfur dioxide addition is under ORP control (ARC), which feedback loop is set at 300 mV The reaction time is about 10 min at a pH of 2, and it drops to 5 min if the pH is reduced to 1.5. The control system used in continuous chrome treatment is shown in Figure 8.31d.

The trivalent chromic sulfate is removed from solution by subsequent raising of the pH to 8, at which point it will precipitate as chromic hydroxide (see Figure 8.31d). The control system for this step can be identical with the one used in Figure 8.39v.

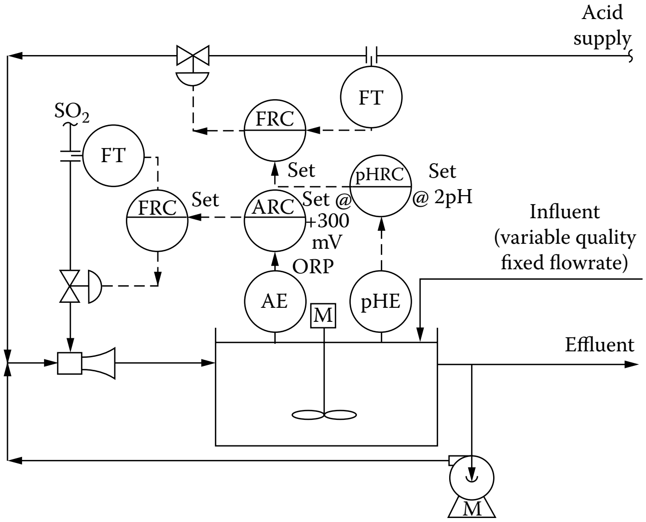

FIG. 8.39h
Batch reduction of chromium waste using sulfur oxide as the reducing agent.

Other Reduction Processes

In dechlorination or deoxygenation controls, the reducing agent is usually added in proportion to the oxidant concentration but by maintaining a slight excess. In most cases, a slight excess of reducing agent is not detrimental. The pH value is not critical and can be determined by corrosion control considerations.

Dechlorination to a fixed residual value is controlled, as illustrated in Figure 8.39e, except that sulfur dioxide is used instead of chlorine.

NEUTRALIZATION CONTROLS

For a detailed discussion of pH control, please refer to Section 8.32. It should be emphasized that pH is a measure of hydrogen ion activity and not acid concentration. A weak sulfuric acid solution will have a low pH value because of the high degree of hydrogen ion activity (disassociation), whereas some strong organic acids may show a pH value as high as 3 or 4.

Strong alkalis react quickly and efficiently to neutralize strong acids. The simplicity of this fact is misleading in its consequences. Acid neutralization is a common requirement in wastewater treatment, but few operations can be as complex. The information needed for the proper design of neutralization systems includes (1) flow rate and range of flow variations; (2) titratable acid content and variations in acid concentration; (3) rate of reaction; and (4) discharge requirements for suspended solids, dissolved solids, and pH range.

Figure 8.39i shows the pH values corresponding to the mixtures of a strong acid and a strong base. The slope of this pH curve near neutrality (pH = 7) is so great that there is no likelihood of controlling such a system. Fortunately, plant effluents usually contain weak acids or bases that are neutralized by strong reagents. (The dotted pH curve shows that these are much easier processes to control.)

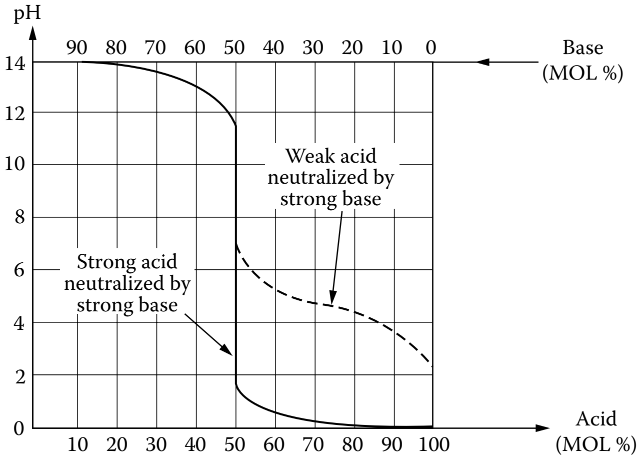

FIG. 8.39i
pH curve of strong acid neutralized by strong base (solid line) and of weak acid neutralized by strong base (dashed line).

The slope of the pH curve is affected by the ionization constants of the acid and base involved and by buffering. Buffering compounds are those that contain no hydrogen or hydroxyl ions but are capable of suppressing the release of these ions from other solutes and, thereby, affect the solution acidity or alkalinity.

Neutralization control of wastewater is difficult because their acid or base contents can vary by several decades and because as the type or amount of buffering of acid (or base) varies, it changes the applicable pH curve. In some plants, the flow rate of the wastewater is also highly variable and the effluent itself can change from acidic to basic, in which case two reagents are required.

Equalization Tanks

An equalizing basin should be installed ahead of the neutralizing system whenever possible. This will tend to level out fluctuations in the wastewater flow and concentration. This point cannot be overemphasized, because the lack of such a basin has been the cause of many failures. Pumping from an equalizing basin at a constant rate eliminates the need for high rangeability flow rate instrumentation. This, in combination with reduced variations in base or acid content, reduces the reagent feed range requirements.

The obvious disadvantage is in the capital cost for large basins. Most systems are designed with as large an equalization tank as possible according to the available space. Any equalization that can be installed will pay some dividends.

In sizing the reagent equipment, the maximum capacity of the alkali feed system should be determined on the basis of the maximum acidic wastewater concentration and

	pH	Hydrogen ion activity gr mols/liter	Hydroxyl ion activity gr mols/liter
Acidic	0	1	0.00000000000001

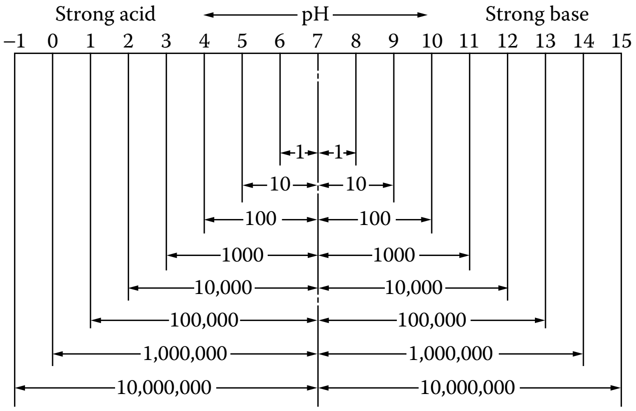
	10	0.0000000001	0.0001
	11	0.00000000001	0.001
	12	0.000000000001	0.01
	13	0.0000000000001	0.1
	14	0.00000000000001	1



Graph of reagent demand. Reagent addition units are 10^{-6} mols/liter.

FIG. 8.39j
The logarithmic nature of pH.

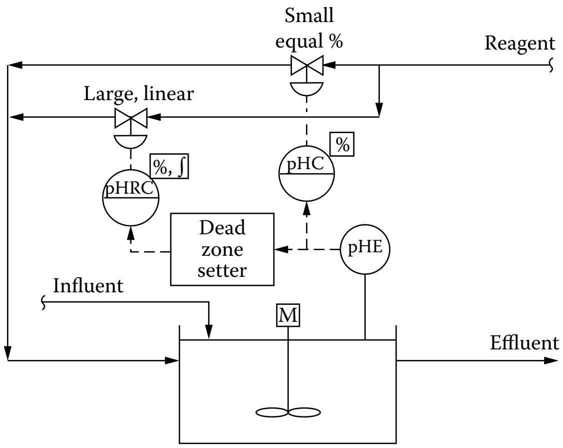


FIG. 8.39k
For accurate neutralization, the required high rangeability is provided by parallel control valves.

maximum flow rate. The minimum flow and minimum acid concentration determines the minimum capacity requirement of the reagent feed system.

Valve Rangeability Required As shown in Figure 8.39j, the reagent demand to neutralize a unit of wastewater increases tenfold every time its pH changes by a single unit. In other words, neutralizing a unit of wastewater at a pH of 3 will take 1000 times more reagent than would an effluent at a pH of 6.

As a consequence, a regent addition rangeability of several hundred to one or more may be required. This is accomplished by the use of two or more control valves in parallel, as has already been discussed in detail in connection with Figure 8.32h.

As shown in Figure 8.39k, the smaller valve has equal percentage characteristics and is throttled by a proportional only controller (pHC). This is desirable to match the pH characteristics near neutrality with that of the valve. If the pH measurement moves outside a preset and narrow "dead zone," this causes the second controller (pHRC) to make an adjustment in the opening of the large linear valve, thereby compensating for load changes. This second controller is provided with two control modes, with the integral action serving to bring the system back to set point after a load change.

A valve position control-based method of using multiple valves in a feedback-trimmed feedforward neutralization system was shown in Figure 8.32j in Section 8.32.

Sequenced Valves A wider reagent delivery capability can be obtained by using the sequenced valve approach where the controller output can be switched to either valve by a pressure switch (PS) or its electronic equivalent. With sequenced controls, only one valve at a time is operating, while the other is closed. In this way, the overall characteristics of a pair of equal-percentage valves are still equal percentage, which is represented by a straight line on a semilog plot.

Figure 8.39l illustrates various combinations of different pairs of sequenced valves. On such sequenced valves, positioners must be used because each valve must be calibrated to stroke over only a portion of the controller output signal range.

Table 8.39m lists the various flow rangeabilities for some of the valve pairs in Figure 8.39l, assuming a constant pressure drop across the valves (equivalent to 9.5 ft, or 2.85 m, of 66° Be sulfuric acid) and assuming an individual valve rangeability of 35:1. For the four valves, the valve capacity coefficients ($c_v s$) are 1.13, 0.14, 0.08, and 0.04, respectively, for CV-1, 2, 3, and 4.

The overlap between each valve pair becomes smaller as the rangeability increases. The pressure switch to transfer the valves can be set anywhere in the overlap region, because in this region the process loads can be satisfied by either valve.

Reaction Rates and Tank Sizing It is essential that reaction rates be determined so that suitable reaction tank sizes (residence time) can be calculated. Once the reaction rates are

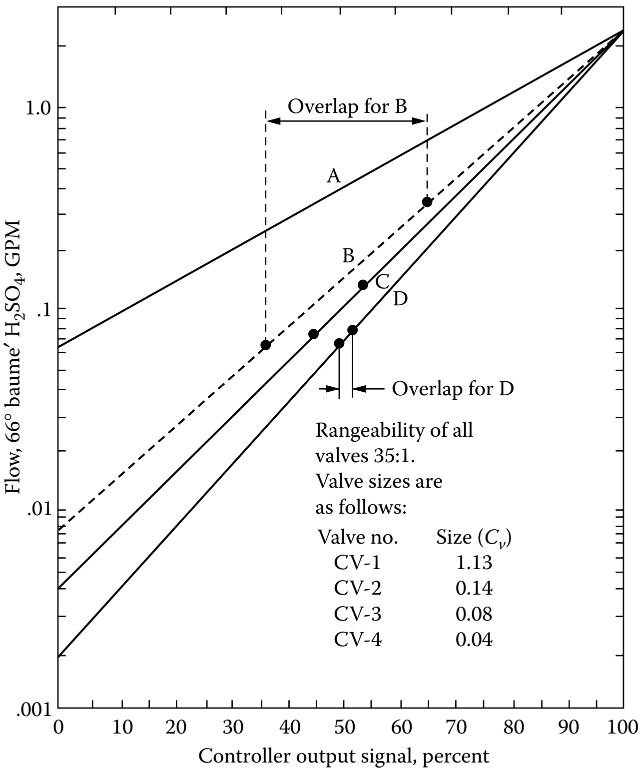

FIG. 8.39l
Delivery capability for various valve pairs.
Key: A = CV-1 alone; B = CV-1 + CV-2; C = CV-1 + CV-3; D = CV-1 + CV-4.

known, one can determine the residence time required to make sure that the reaction has time to go to completion. One obtains these rates by first determining the total amount of alkali (in case of an acid waste) that is required to neutralize a sample of the wastewater and then adding this amount to a second samp1e in a single dose.

Plotting the pH of that sample show the pH rise as a function of time (Figure 8.39n). The reaction vessel volume should provide at least 50% more holding time than the time it took for the sample to reach neutrality.

TABLE 8.39m
Reagent Delivery Turndown (Rangeability) for Sequenced Pairs of Equal-Percentage Valves

Valve Pair	*Line on Figure 8.22hh*	*Turndown*	*Log Turndown**	*Valve Positioner Calibration(s) (%)*

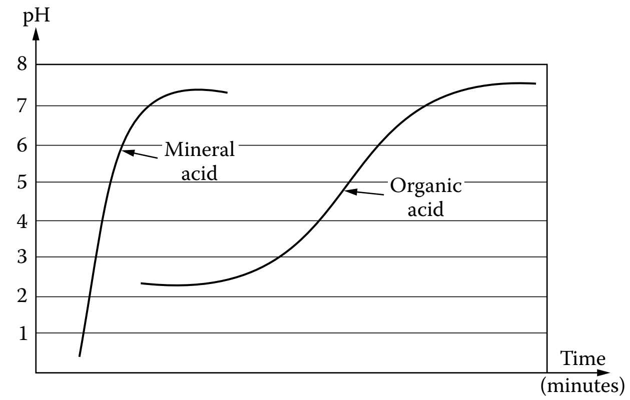

FIG. 8.39n
Acid neutralization reaction rates.

The ideal aim is obtain sufficient equalization to provide a homogeneous wastewater pH at a constant flow rate. To neutralize such a system, a lime feeder operating at a preset constant rate would suffice. Unfortunately, this seldom occurs, and provision must be made for reagent throttling.

Single Reagent Control

Figure 8.39o illustrates a system that can handle changes in both the flow and the acid concentration in the wastewater. In this equipment configuration, the equalization tank is followed by three treatment tanks, and to each of these tanks, the lime slurry feeding controls have identical capacities.

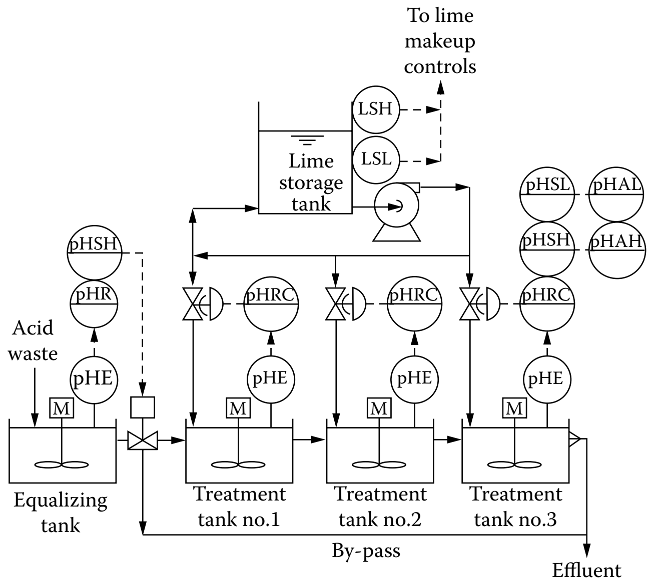

FIG. 8.39o
Simple acidic wastewater neutralization system with a 30:1 rangeability.

Assuming a 10:1 range for each lime slurry control valve, the range of the system is 30:1. Thus, it can handle any combination of flow and acid concentration within that range.

The three pH controllers are set at the same set point of usually between pH 6 and 8. At periods of low flow, or when the acid content is low, treatment tank number 1 can handle the entire neutralization load. Under other conditions, all three tanks may be required, with the first one or two satisfying a major portion of the reagent requirement and the third serving a "polishing," or final trim, function.

Each tank in this system should be sized for a minimum of 50% of the total retention time determined at maximum flow rate. Where mixtures of acids are involved, the maximum time (not average) must be used. Figure 8.39o also has a provision for the occasional case when the incoming wastewater is self-neutralizing and the treatment system can be bypassed.

High maintenance costs of pH electrodes have been reported when lime is used as the reagent, because of the formation of calcium sulfate coatings on the electrodes. For the designs of retractable and self-cleaning pH detectors, refer to Section 8.48 in Chapter 8 of the first volume of this handbook.

Two Reagent Control Systems

In some plants, the wastewater can be either acidic or basic. Figure 8.39p illustrates the two-sided feedback control system required to neutralize such wastewaters. Although only one valve for each side is shown, it would be possible to have a sequenced pair for one side of neutrality and a single valve for the other, or a sequenced pair for both sides.

Because this is a feedback control system, load changes cannot be frequent or severe in order for this system to give acceptable performance. For those applications in which load changes are frequent and severe, a combination feedforward-feedback should be considered, such as the system shown in Figure 8.32j in Section 8.32.

If sequencing is used, the reagent delivery system will have a high gain characteristic, because the stroking of the pair (moving from closed to open) is accomplished with only half the controller output signal, thereby doubling their gain (making them twice as sensitive). The valve gain will vary with the turndown, and a characterizer will be required for each set of sequenced valves to provide constant loop gain.

Ratio Control

Ratio control of pH can be effective when the process flow rate is the major load variable, and the objective is to meet increased flow with a corresponding increase in reagent. Because the errors in flow measurements and because reagent concentration may vary, a means for on-line ratio adjustment must be provided.

Figure 8.39q illustrates a ratio control system in which the reagent set point is changed proportionally to changes in wastewater flow. A feedback signal supplied by the feedback controller (pHC) also adjusts the reagent flow set point proportionally to a nonlinear function of the deviation between desired and actual effluent pH.

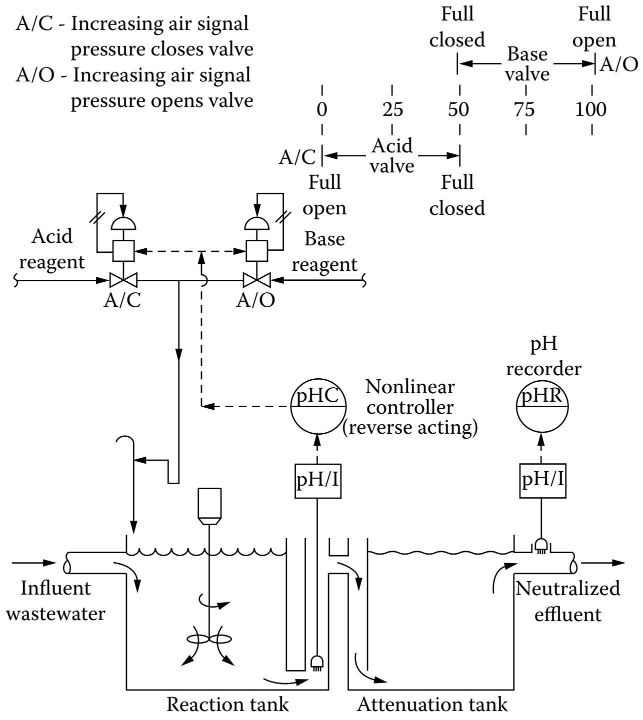

FIG. 8.39p
Two-sided feedback control of pH.

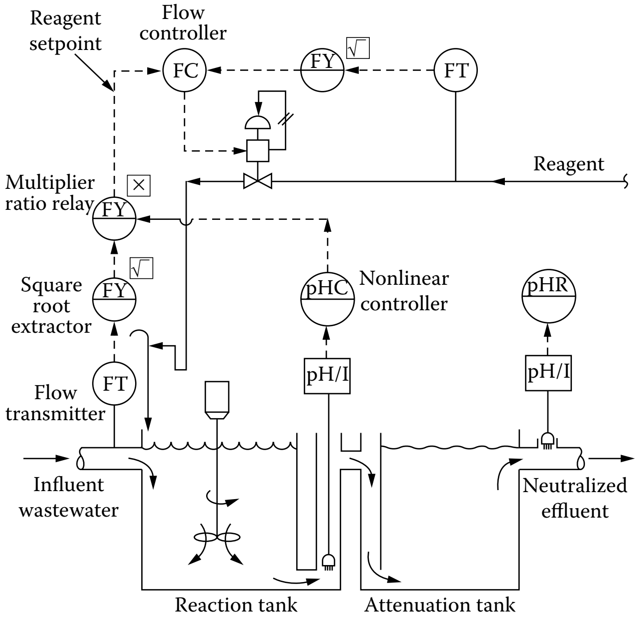

FIG. 8.39q
In this control system, the reagent flow is ratioed in a feedforward manner to the influent wastewater flow, whose ratio is feedback-trimmed by the pH controller.

Note that the rangeability of the ratio system is limited by that of the flowmeters, typically 4:1 for orifice meters to 30:1 for some turbine meters.

Cascade Control

Cascade control as applied to pH control systems can take two forms. In addition to the usual condition in which the output of one controller serves as the set point to another controller, it is also possible to have two vessels arranged in series, each with its own control system. The latter arrangement is referred to as *cascaded residences.*

The conventional cascade control system is shown in Figure 8.39r, wherein the output of controller pHC-1 is the set point of the slave, or secondary controller, pHC-2. This arrangement is particularly useful when lime is the reagent, because of the finite reaction time between the acid and reagent. The set point of pHC-2 may have to be lower than the desired pH of the final effluent, because the materials are still reacting with each other after they have left the first tank. If the set point pHC-2 is too high, the pH of the final stream will be greater than desired. When flocculation is to be carried out downstream of the pH treatment facility, stable pH values can be extremely important.

A delicate balance must be struck in this type of system with respect to the size of the first vessel. A long residence time in the first tank ensures long contact time between reagents, thereby producing an effluent pH that is close to the desired value, but at the same time it may result in a sluggish control loop around this vessel. For efficient cascade control, response of the inner loop (control loop around the first tank) must be fast.

The other control loop (pHC-2), sometimes referred to as the master, or primary, control loop, is usually tuned so as to be less responsive than the inner loop. The tuning of pHC-1 will be a result of the dead time (a delay between a change in reagent flow and the time when its effect is first felt), capacity, and process characteristics.

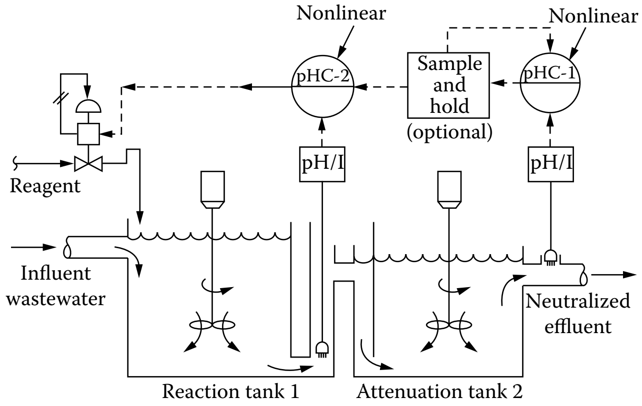

FIG. 8.39r
Cascade control of pH.

When this part of the process is dominated by dead time, the technique of sample data control may be useful in stabilizing the control system by a sample and hold device. This device may be a timer that automatically switches the controller between automatic and manual modes of operation (see Figure 2.2q in Chapter 2). This can allow the controller to be in automatic for a fraction (x) of the cycle time (t) and then can switch it to a fixed-output, manual condition for the rest of the cycle $(1 - x)t$.

Feedforward Control

In those systems in which equalizing basins or other averaging techniques cannot be applied and accurate pH control is required, control by feedback alone is insufficient, and feedforward schemes can be considered. It should be kept in mind, that feedforward based on influent pH is only recommended *if only a single specie in the wastewater must be neutralized*, because if there are several species, the relationship between influent pH and reagent demand cannot be predicted.

A feedforward control system is dedicated to initiating corrective action as soon as changes occur in process load. The corrective action is implemented using a control system that is essentially a mathematical model of the process. For example, the amount of base required to neutralize an acid can be predicted using the following formula:

$$\log(B) = \log(K) + \log(F) + (7 - \text{pHi}) \qquad \textbf{8.39(5)}$$

where

B is the base in normal equivalents
F is flow rate
K is a constant specific to the chemical reaction
pHi is the pH value of the influent

Ordinarily, the inclusion in the model of each and every load to which the process is subjected is neither possible nor economically justifiable. This means that a feedback control loop (usually containing the nonlinear controller for pH applications) is required in conjunction with the feedforward system. The function of the feedback controller is to trim and correct for minor inaccuracies in the feedforward model.

Feedback–Feedforward Combination Control Figure 8.39s describes a feedback-trimmed feedforward neutralization control system, using three control valves for high rangeability. In this system, the control signal to the reagent valves (X_b) is the sum of the characterized flow signal $f(F')$ of the influent wastewater and the output of the feedforward pH controller (pHC-1). Therefore, the total output signal to the sequenced pair of valves (X_B) becomes the sum given in Equation 8.39(6), minus twice the feedback controller's (pHC-2) output:

$$X_B = f(F') + \text{feedforward output} - 2(\text{feedback output}) \qquad \textbf{8.39(6)}$$

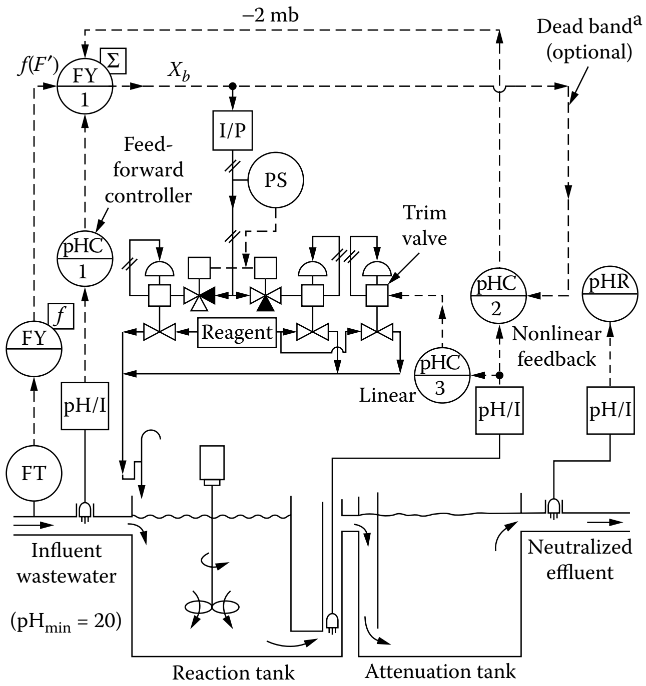

FIG. 8.39s
High rangeability feedback-trimmed feedforward pH control system utilizing three control valves, which are so configured that only one is throttling at any one time.

If the total rangeability of the pair of sequenced valves is 1500:1 and if the minimum expected influent pH is 2.0, then the maximum controllable influent pH value is pH(max) = 2.0 + log(1500) = 5.2 pH. Therefore, in this control configuration, when the influent pH rises to over 5.2, both sequenced valves will be completely closed and the linear feedback controller (pHC-3) will throttle the trimming valve. Figure 8.39t describes the operating ranges of the three valves and their total rangeability in terms of reagent flow.

The nature of a neutralization system is such that the process gain (slope of the pH curve) is likely to be the highest at set point (around pH = 7) and it decreases as the deviation from set point increases. To compensate for this inverse relationship between process gain and deviation, the feedback controller that is trimming the feedforward model (pHC-2) should be a nonlinear one, with its gain varying (increasing) with deviation.

With this controller, the greater the deviation from set point, the larger the controller's correction, but this does not create an unstable condition, because at high deviations the process gain is low. In the control system shown in Figure 8.39s, the feedback control signal (mb), which is trimming the feedforward signals in summer FY-1, is generated by the nonlinear pHC-3 controller. This controller can be provided with a dead band around its set point, so that it does not change its output until its measurement moves outside that gap.

Figure 8.39u illustrates a similar feedforward–feedback neutralization control system, where the expected rangeability

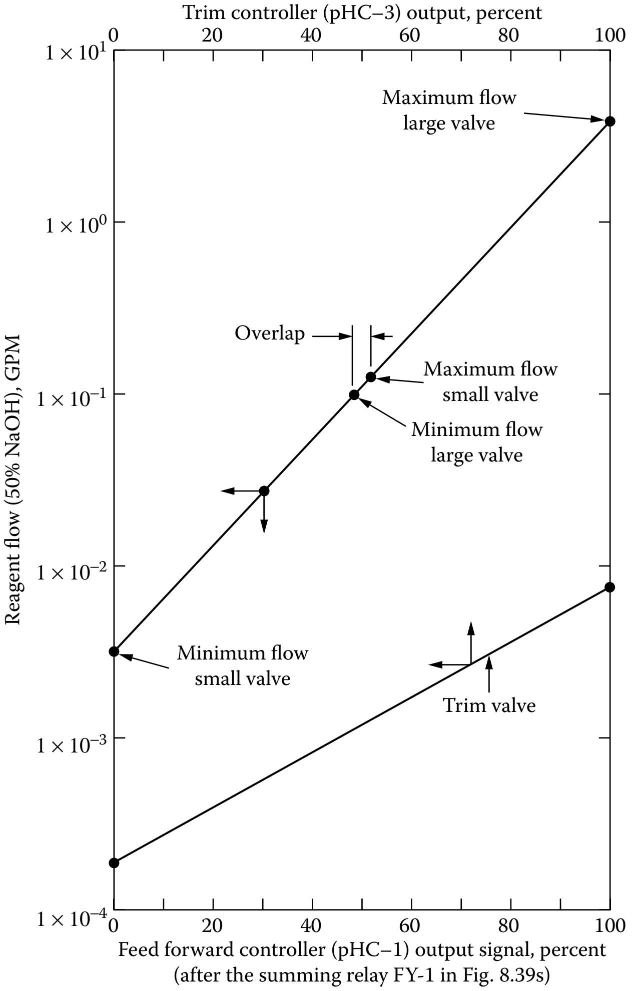

FIG. 8.39t
When the influent pH is below 5.2, the sequenced large and small valves throttle the reagent (top line). When the influent pH rises above 5.2, only the trim valve is modulated (bottom line)

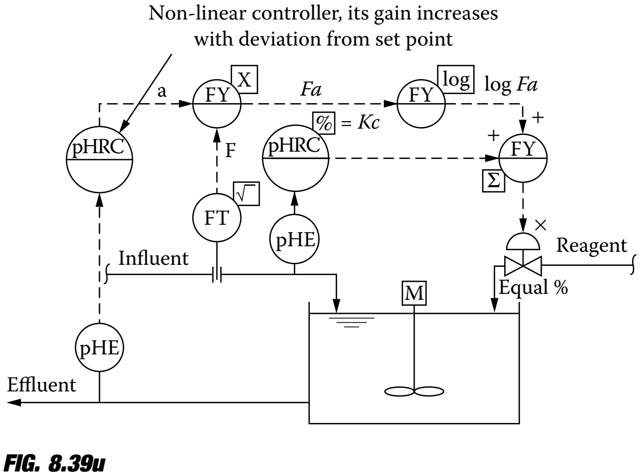

FIG. 8.39u
Low rangeability feedback-trimmed feedforward neutralization control system.

requirement of the reagent is low enough to be met with a single control valve. Here, the reagent valve opening (x) is calculated as follows:

$$X = Kc(\text{setpoint-measurement}) + \log(F.a) \qquad \mathbf{8.39(7)}$$

where

X is the valve position signal to an equal-percentage reagent valve
Kc is the gain of the proportional-only feedforward controller
F is the influent flow
a is the output signal of the nonlinear feedback controller

In this control system, the opening of the equal-percentage reagent valve is obtained by the summing of the feedforward pH controller's output signal with the logarithm of the product of the influent flow (F) and the output of the nonlinear feedback controller (a).

PRECIPITATION AND FILTERING

Precipitation is the creation of insoluble materials by chemical reactions that can then be removed through subsequent liquid-solids separation. Typical of these operations is the removal of sulfates, removal of trivalent chromium, and softening of water with lime. Iron and manganese are removed by a variation of this process, following the treatment discussed earlier in connection with the chemical oxidation process.

Lime Softening

The process of water softening and its controls are discussed in detail in Section 8.40. Figure 8.39v shows a precipitation control system that can be used for the precipitation of calcium carbonate in the process of water softening or for the precipitation of other insoluble crystals.

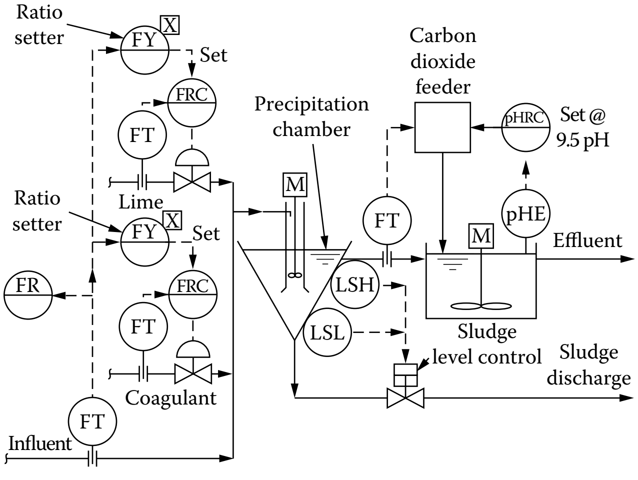

FIG. 8.39v
Calcium carbonate precipitation control system. (For the details of the gas feeder refer to Figure 8.39e.)

In this process, *crystal seeding* involves the acceleration of crystal formation by the presence of previously precipitated crystals. This is accomplished in practice by passing the water being treated through a "sludge blanket" in an upflow precipitation chamber, shown schematically in Figure 8.39v. The resulting crystals are hard, dense, and discrete; therefore, they separate readily.

When colloidal suspended material is also to be removed, which would be the case where surface waters are softened, a coagulant of aluminum, iron salts, or polymers is also added to precipitate the colloids. Dosage is variable, depending on the quantity of suspended material. Application of both coagulant and calcium hydroxide is controlled by flow-ratio modulation.

The resulting sludge, consisting of calcium carbonate, aluminum, or iron hydroxides, and the precipitated colloidal material are discharged to waste continuously. An automatic sludge-level control system is used in Figure 8.39v to keep the sludge level within an optimum range of operation.

Water softened by the excess lime treatment is saturated with calcium carbonate and, therefore, is unstable. Stability is achieved by addition of carbon dioxide to convert a portion of the carbonates into bicarbonate. This process is suited to automatic pH control as shown in Figure 8.39v. The carbon dioxide feeder has two operators; one is controlled in feedforward by the influent flow rate and the other in feedback by effluent pH control (pHRC). The set point is on the order of 9.5 pH.

Fouling of the electrodes is likely to occur as a result of precipitation of crystallized calcium carbonate. Daily maintenance may be expected, unless automated cleaners are used (Figure 8.39w). The farther downstream (from the point of carbon dioxide application) the electrodes can be placed, consistent with acceptable loop time delays, the less will be the maintenance requirement.

Hydroxyde Precipitation

Precipitation is the process used to remove soluble metal ions from solutions as hydroxydes. The process is pH controlled. By raising the pH with lime or sodium hydroxide, the corresponding metallic oxide precipitates out. Figure 8.39x shows the solubility curves of some heavy-metal hydroxides as a function of the pH of the solution.

As can be seen in Figure 8.39x, copper at a pH of 6 will start precipitating from the solution at a concentration of about 20 mg/l, while if the pH is raised to 8, its solubility drops to 0.05 mg/l.

Several metals such as chromium and zinc are amphoteric, being soluble at both alkaline and acidic conditions.

As can be seen in Figure 8.39x, chromium is least soluble in the range of pH 7.5 to 8.0. It is for this reason that in the second stage of chrome treatment in Figure 8.31d, the set point of the pHIC is 8 pH. For a detailed discussion of chrome treatment, refer to Section 8.31 or to the earlier paragraph in this section in connection with Figure 8.39h.

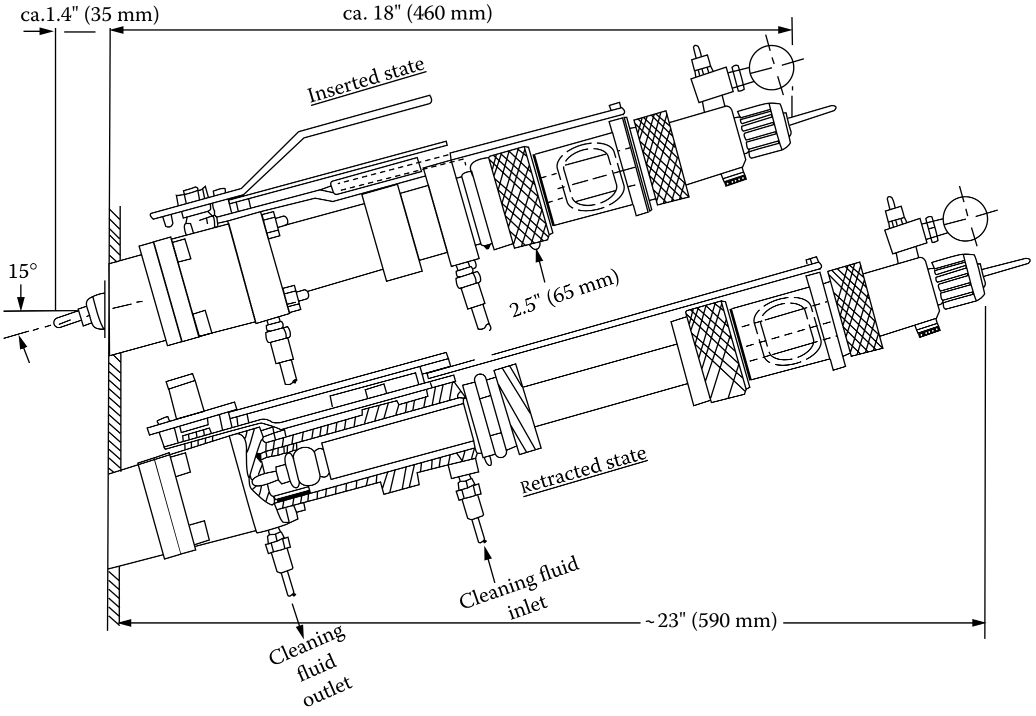

FIG. 8.39w
Self-cleaning, retractable pH probe installation.

Filtering

The solids suspended in the wastewater, including the particles generated by precipitation, can be removed by filtration. A large variety of filter designs are available, including diatomite, microstrainers, gravity, pressure, deep-bed, multilayered, cartridge, moving bed, and membrane. (See Section 7.33 in Chapter 7 of the second edition of the *Environmental Engineers' Handbook* for more details.)

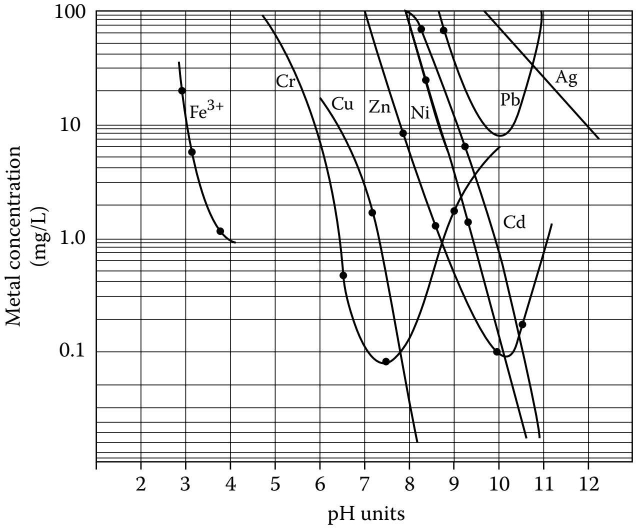

FIG. 8.39x
Solubility curves of a number of metal hydroxides at various concentrations as a function of the pH of the solution. (Courtesy of Hoffland Environmental Inc.)

Figure 8.39y illustrates the design of a multilayered filter, having a flat under-drain deck with long-stem nozzles for washing with backwash and air.

Figure 8.39z describes a deep-bed, pressure type, granular filter that is in forward flow operation. *Forward flow* refers to the state of filtering, while *back flow* refers to the backwashing or wash cycle during which the collected solids are removed and the filter is prepared for another filtering cycle.

Polishing filtration packages are usually designed in duplex configurations. In such designs, under normal "pump down" operation, while one filter is active, the other is being backwashed. The system is operated in its "normal" mode, when the level in the feed buffer tank is within its allowable high and low limits. In this mode, while one filter is filtering the wastewater from the large buffer tank and, after filtering, discharges it to drain, the other filter is being backwashed. The backwash cycle can either be initiated on the basis of the total flow that has passed through the filter or on the basis of the pressure drop that has built up across the filter.

The operation is automatically reconfigured as a function of the level in the large buffering feed tank. If the level in the buffer tank reaches a high level, the normal "pump down" mode of operation is switched to a "dual pump down" mode. In this mode, both filters are operating in their filtering mode, and the discharges of both filters are being sent to drain.

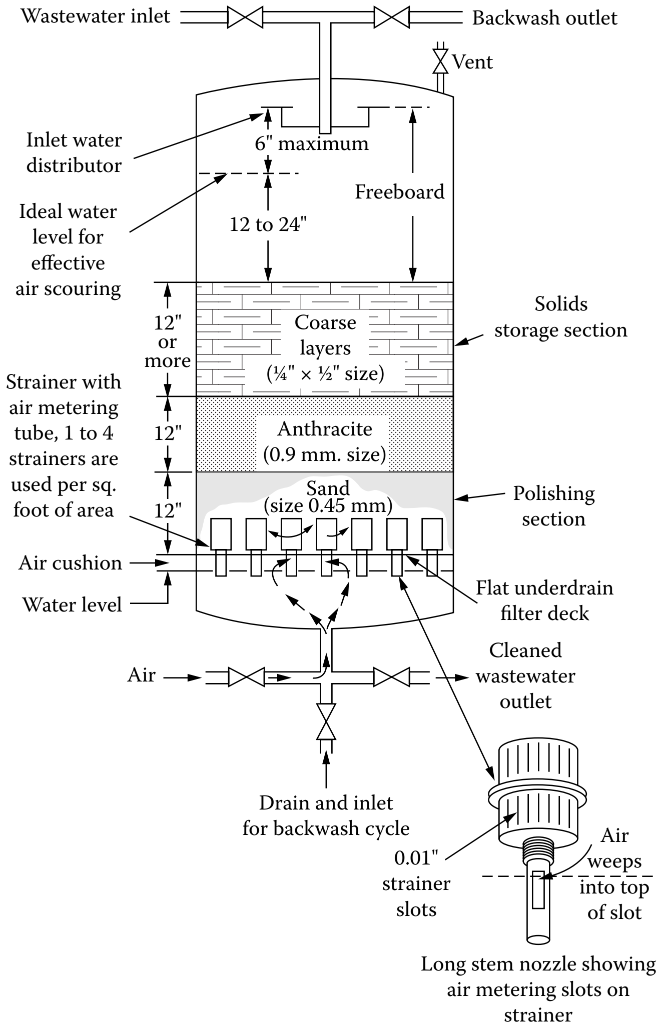

FIG. 8.39y
Construction of a multilayered filter.

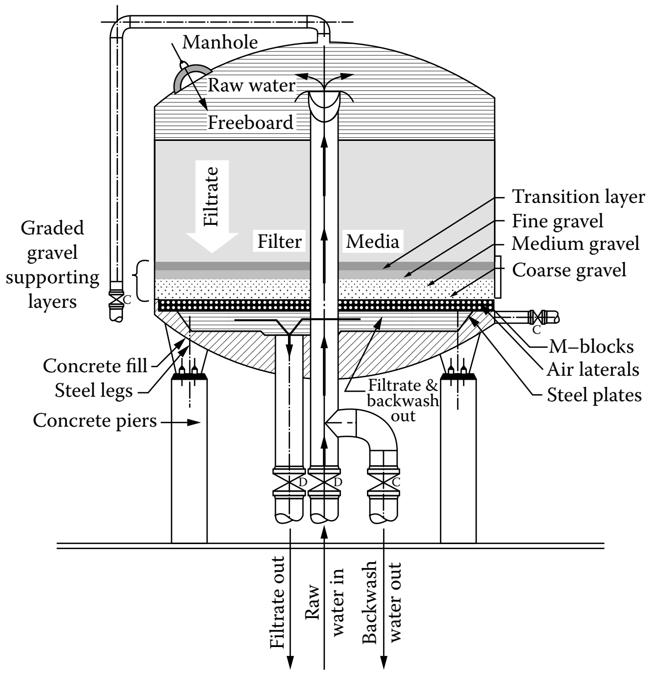

FIG. 8.39z
Construction of a deep-bed granular filter.

The buffer feed tank has three level probes, detecting high, normal, and low levels. If, after a "dual pump down" episode, the level drops to the "normal" probe, the system is returned to the single filter pump down mode and the inactive filter is backwashed. If the level in the buffer feed tank drops further and reaches the low level probe, the filtered wastewater will no longer be drained, but is returned into the holding tank.

Superfilters The required purity of nuclear power plant boiler feed water, in terms of conductivity, is 0.05 microSiemens. The total organic carbon (TOC) content of such feedwaters must be under 50 ppb. Such purity can only be obtained by membrane filtration. These designs are discussed under Tertiary Water Treatment in a later paragraph in this section.

In order to prevent corrosion, oxygen scavengers such as hydrazin are also added to boiler feedwater.

CHLORINATION

Nearly every wastewater treatment process uses chlorination, although drinking water chlorination is being phased out in favor of ozonation. Chlorination may be used either to reduce the possibility of pathogenic bacterial contamination of the receiving water or to prevent biological growth from interfering with other processes. Control of biological slimes that interfere with heat exchange in cooling water systems is often accomplished with chlorine, but also with biocides.

Chlorine is a strong oxidant with many other uses, as were described earlier in connection with chemical oxidation. It is a very effective bactericidal agent readily available at reasonable cost. Its effectiveness has been proved by over 75 years of use.

Several factors contribute to the complexity of chlorination for biological control. These include that the materials in the water that can be chemically oxidized cause an immediate reduction of the available active chlorine into an ineffective chloride form. Therefore, sufficient chlorine must be added to the water to account for this reaction and, in addition, to provide a residual amount, reserving sufficient chlorine for subsequent reactions. The amount of chlorine involved in the initial reduction is called *chlorine demand*. A dosage greater than this amount provides excess chlorine, which is called *residual chlorine.*

When nitrogenous material, particularly ammonia, is present in the water, the residual chlorine will be altered. Two kinds of residual chlorine are recognized: (1) free residual is that remaining after the destruction with chlorine of ammonia or of certain organic nitrogen compounds; (2) combined residual is produced by the reaction of chlorine with natural or added ammonia or with certain organic nitrogen compounds.

Because these two compounds (free residual chlorine and combined residual chlorine) are completely different in their ability to control bacterial organisms, it is important to differentiate which of the two forms of chlorine are involved in a process. Laboratory methods are available for both the measurement and the differentiation among these two.

Continuous analyzers (see Section 8.11 in Chapter 8 in the first volume of this handbook) suitable for control are also available to measure either the level of free residual chlorine or the level of total residual chlorine, meaning the combination of the two when both are present.

The presence of residual chlorine in water does not ensure either disinfection nor biological control. A bacteriological analysis requires several hours, or even days. Through years of experience, it has been determined that measurement of residual chlorine can be a suitable inferential indicator of the effectiveness of biological control. For this reason, such processes are suitably controlled by analysis of residual chlorine.

An example of a typical control system used in the disinfection of wastewater is shown schematically in Figure 8.39aa. The chemical feed system for applying chlorine must be of sufficient capacity both to satisfy the chlorine demand of the waste and to provide sufficient residual after the contact time that is required for the disinfection action has passed. Typical of this for wastewater treatment would be a chlorine demand of 5 mg/l.

Another important factor is that the amount of residual chlorine will decline with time. There is no assurance that the initial residual concentration will persist for the length of time required for the disinfection to be accomplished. Yet, it is important that residual chlorine be present during this entire period. Typical design basis is to size the contact chamber for 30 min retention at maximum flow.

Local regulations usually require that there be a minimum of 1 mg/l of available chlorine at the end of this contact time. It is not uncommon for flows to vary over a range of 6:1. To account for these variations and for the continuing chemical reactions, the control system must automatically control the residual after a short (approximately 5 min) fixed contact time. This is accomplished by building the 5 min retention time into the sampling system.

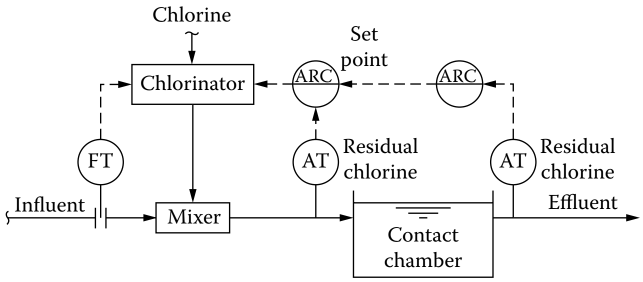

FIG. 8.39aa
Illustration of chlorination-based disinfection controls used when both the flow rate and the quality of the wastewater influent is variable. For the details of the chlorinator, refer to Figure 8.39e.

Feedback control of residual chlorine, in conjunction with flow-proportioning feedforward correction (Figure 8.39aa), establishes a constant residual value at the inlet of the contact chamber. Because of the variable rate at which residual decay occurs, assurance that the residual at the exit of the contact tank is maintained at a minimum value requires a second analyzer. This cascade master adjusts the set point of its slave, the inlet residual chlorine controller, as required.

The amount of residual chlorine decay varies widely as a result of variations in temperature, quality of wastewater, and detection times. It may vary from a minimum of 0.5 to 5 mg/l. To maintain an effluent residual of 1 mg/l, the set point on the controller for the chlorinator may be anywhere from 1.5 to 6 mg/l.

Chlorination of wastewater for disinfection is unique in that it is usually the final process unit prior to discharge. For this reason, detection time is provided as a part of the process. For most other biological control applications, other subsequent unit operations provide sufficient contact time, and the residual decay can be reasonably well predicted.

MUNICIPAL WASTEWATER TREATMENT

As shown in Figure 8.39bb, the conventional household sewage treatment process consists of pretreatment, primary settling, aeration, final clarification, and disinfection steps.

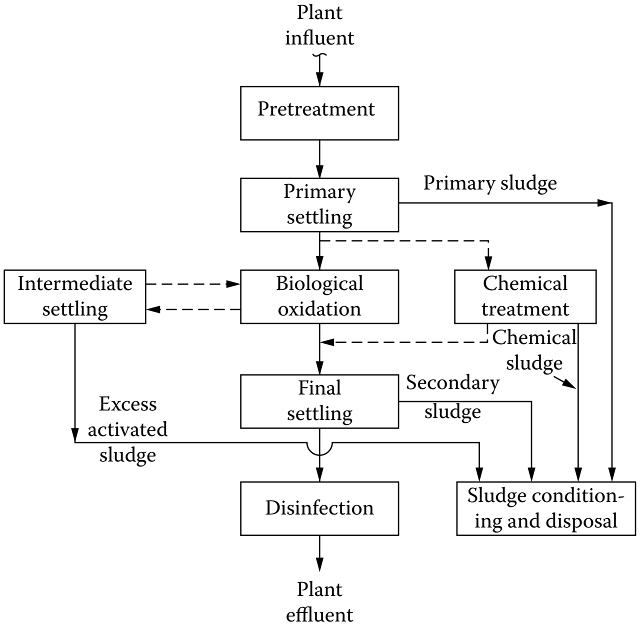

FIG. 8.39bb
The basic stages of municipal wastewater treatment.

Pretreatment equipment includes screens, grinders, skimmers, grit chambers, flow equalization, and primary settling. Traveling grates are also used to remove large debris. Plugging is detected by level differential across the grate. Older systems use bubbler tubes with d/p transmitters for this measurement; newer ones use noncontact ultrasonic level transmitters.

The second step usually is biological oxidation, which can be done either in aeration tanks or in aeration ponds. The aeration process is controlled by dissolved oxygen (DO) analyzers. See Section 8.43 in Chapter 8 of Volume 1 of this handbook for the description of the submersed platinum electrodes operating under diffusing Teflon membranes that are used for this measurement. The biological oxidation step is usually combined with chemical treatment and intermediate settling, which respectively produce chemical and excess activated sludge.

The aerated water is allowed to settle in a settling tank, which is also referred to as a clarifier or a thickener. Figure 8.39cc illustrates a circular basin-type clarifier. Other designs include horizontal flow, solids contact, and inclined surface versions. RF capacitance probes and ultrasonic sludge interface detectors are both often used to detect the sludge blanket level in the clarifier (Sections 3.3 and 3.20 in Chapter 3 Volume 1). The settled sludge is pumped to sludge digester or sludge conditioning units.

Microwave-type density sensors are often used to detect the consistency of the secondary sludge from the final settling tank (see Chapter 6 in the first volume of this handbook). The purpose of the sludge density measurement is to make sure that the secondary sludge that is being pumped to sludge conditioning or sludge digestion is thick enough in its solids content.

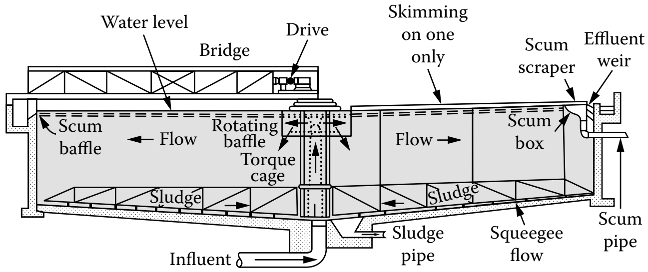

FIG. 8.39cc
Circular basin-type clarifier design.

Either prior to, after, or in parallel with biological oxidation, treatment chemicals such as ferrous chloride or soluble polymers are added to cause flocculation. Figure 8.39dd describes a combined coagulation and settling apparatus used for such dual purposes.

The flocculant and coagulant chemicals are usually added by metering pumps, having either variable-stroke or variable-speed adjustments. The flocculant flow through these pumps is ratioed to the sewage influent flow, so that the chemical dosage is maintained constant. The sewage influent flow is usually measured by a magnetic flowmeter (Figure 8.39ee) if a pipe is used. In open channels, Parshall flume or ultrasonic flow detectors are used (see Chapter 2 in Volume 1 of this handbook).

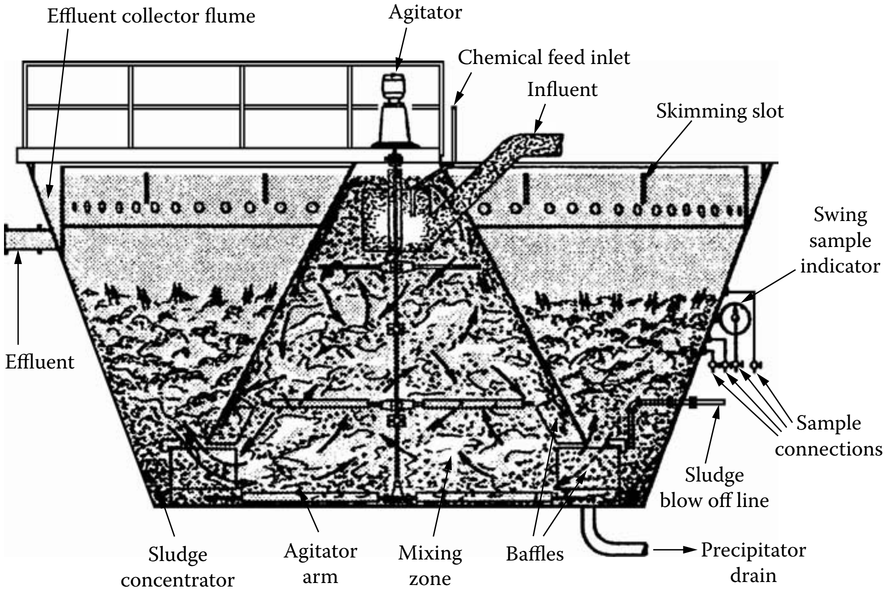

FIG. 8.39dd
Apparatus for the combined processes of coagulation and settling.

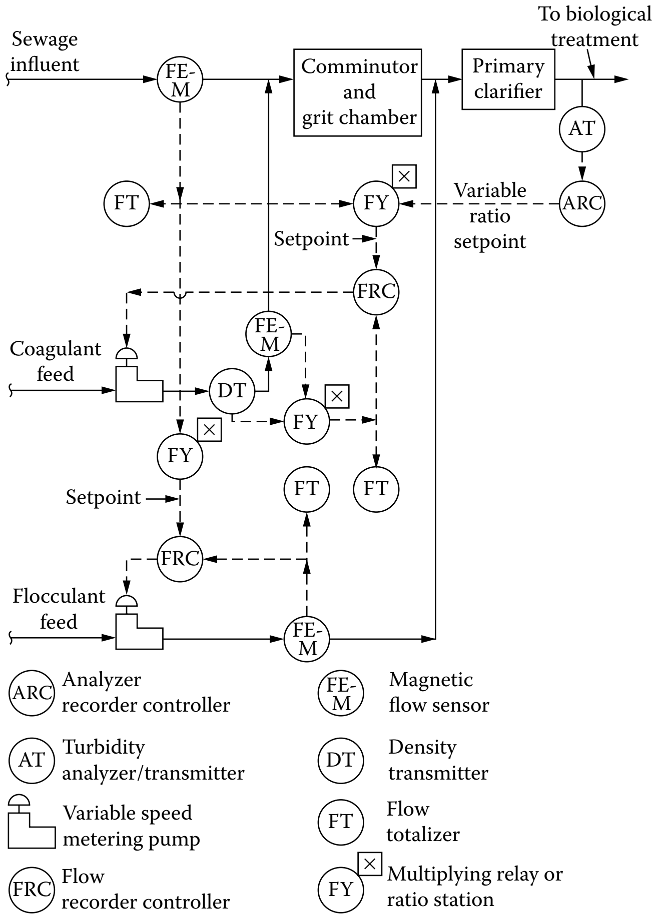

FIG. 8.39ee
Control system for automatic flocculant and coagulant additions.

The coagulant flow is also ratioed to the sewage influent, and the ratio is modulated by the cascade master (ARC in Figure 8.39ee), which keeps the turbidity level of the clarifier effluent constant. If the pH is under 7.5, caustic solution is also added under pH control by a positive displacement pump, because good flocculation requires that the pH in the tank exceed 7.5.

Final settling is usually followed by disinfection and filtration steps, which were discussed in connection with Figures 8.39y and 8.39z. The sand filters are backwashed either on the basis of time or on the basis of totalized flow through them. The clarity of the filtered water is monitored by light-scattering turbidity detectors (see Section 8.60 in Volume 1 of this handbook).

Disinfection While ultrafiltration removes quantities of pathogens, other methods of filtration require disinfection, either by UV radiation, chlorination, or ozonation, mainly to remove coliform bacteria. While coliform tests are lab based, most water treatment plants also use refelometric turbidity meters to bring the purity to 0.06 turbidity units. Chlorination is controlled by residual chlorine analyzers. They measure free chlorine or total chlorine (which includes, e.g., NH_2Cl).

Tertiary Wastewater Treatment

Tertiary treatment is used for the water reclamation where the purification process is followed by disinfection. Membrane filtration separates the influent into two streams. The stream that has passed through a semipermeable membrane will have less solids than the one that did not. The designs used include reverse osmosis (RO), nano-filtration (NF), ultrafiltration (UF), and microfiltration (MF), which is the separation of submicron particulates from dissolved material.

Reverse osmosis uses hollow filter membranes to route ions into one side and pure water into the other side of the membrane. Pumps generate the RO pressure, which usually exceeds 900 psig. In the RO process pH is monitored to prevent the precipitation of alkaline salts and the water purity is detected by conductivity and ion selective electrodes (see Sections 8.17 and 8.28 in Chapter 8 in the first volume of this handbook).

Nano-filtration separates monovalent salts from multivalent and uncharged organic molecules. NF is used for desalting and for concentrating dyes.

Ultrafiltration is used in paper mill, oily, and latex effluent streams. It can also be used as a pretreatment to ion exchange to prevent particulate fouling of the resin bed.

Microfiltration uses ceramic and polymeric membranes for processing liquids in the pharmaceutical and chemical industries, as well as for separating wastewater effluents.

Deionization Ion exchange is mostly used to soften water by the removal of calcium and magnesium. These units can remove not only water hardness, but also other mineral salts and silica. They can provide 2 ppb purity. Ion exchange purified water can be further cleaned by reverse osmosis, combined with ultrafiltration.

Ion exchangers are vessels filled with resins that are saturated with Na+ during regeneration by a salt solution. When the cycle is switched to deionization, the resin captures Ca++ and Mg++ while releasing Na+. When Na+ is exhausted, the resin is backwashed (Figure 8.39ff). During the first phase of regeneration, Ca++ and Mg++ are purged to waste.

The sequencing of the run, regeneration, purge, and backwash phases of the operating cycle are usually PLC controlled, and these phases are started either on the basis of elapsed time or because a conductivity sensor indicates an ion-breakthrough.

When the removal of Cl^- or sulfate is also required, mixed-bed ion exchangers are used that contain both anionic and cationic resins. The anionic resins are regenerated by HCl, which saturates the H+ ions. Conductivity sensors are used to initiate the regeneration of the exhausted unit while switching the water to the stand-by unit.

The sludge from the settling and treatment steps is usually dewatered in rotary filters and is then dried for disposal as soil supplement or is sent to aerobic or anaerobic digesters for fermentation. The H_2S in the generated digester gases is usually monitored by infrared analyzers (see Section 8.26 in Chapter 8 in Volume 1 of this handbook).

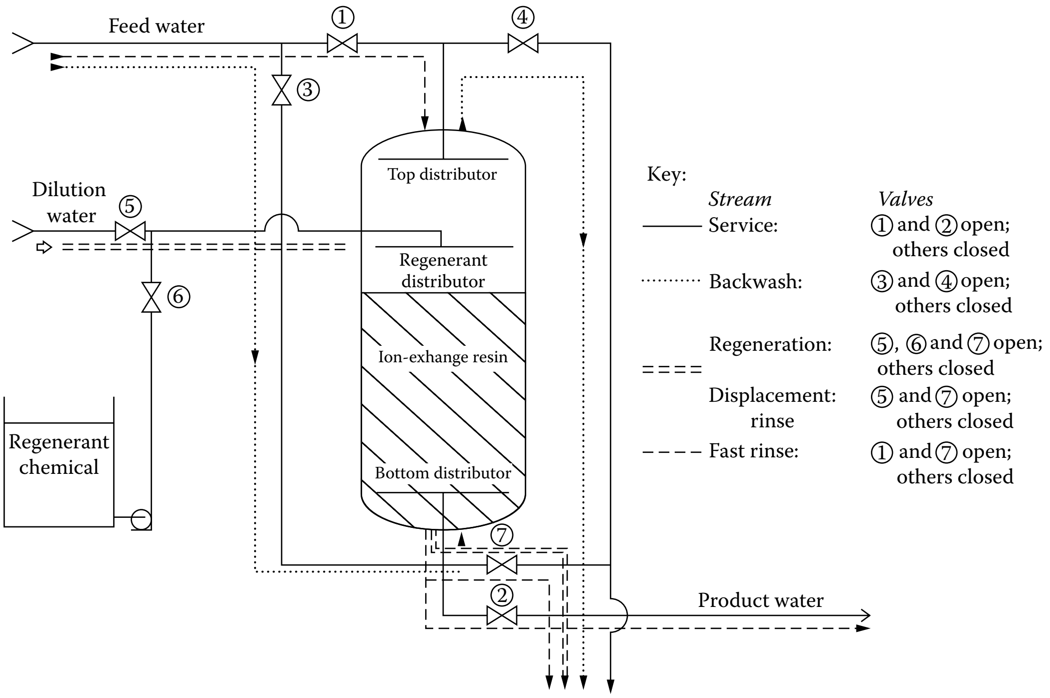

FIG. 8.39ff

Simplified ion-exchange operations cycle. The water used for backwash, dilution water, or displacement rinse can be feed water, softened water, decationized water, or DI water depending on the ion-exchange resin used and the quality of water produced in the service cycle. (Reprinted with permission from Owens, 1985, p. 89.)

Safety

If the treatment plant is in a closed building, the air in the building has to be monitored for toxic H_2S, for combustibles in explosive concentrations, and for oxygen deficiency. The low-oxygen alarm is usually set at 19.5% of oxygen in the air. Combustibles can be detected either by infrared sensors or by catalytic combustion detectors (for details see Section 8.16 in Chapter 8 in Volume 1 of this handbook).

The safety monitoring sensors actuate both local and central alarms. Figure 8.39gg illustrates the remote head-type safety monitoring installation.

In remote and unattended installations, radio transmission in the 920 MHz band is used. The radios can receive both analog and on/off contact signals, and their receivers can transmit them to SCADA, PLC, or PC devices, using Ethernet or Modbus protocols.

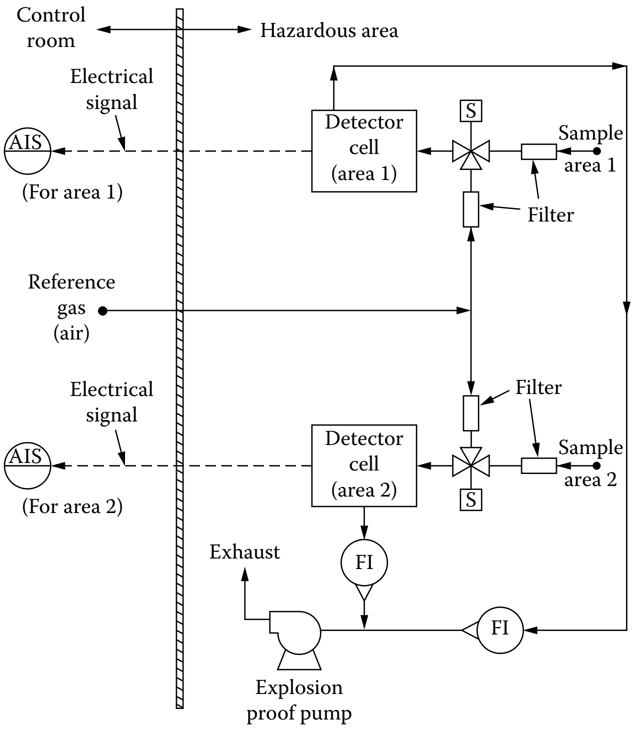

FIG. 8.39gg

Safety monitoring installation using remote detector cells located in the monitored area.

COOLING WATER TREATMENT

For a detailed discussion of cooling tower controls and optimization, refer to Sections 8.16 and 8.17.

Cooling systems can be once-through, cooling tower, or closed-loop cooling systems. Most power plants and refineries use cooling towers with water recirculation, but evaporation losses will cause concentration of scaling compounds such as calcium and magnesium carbonates. Also, biological

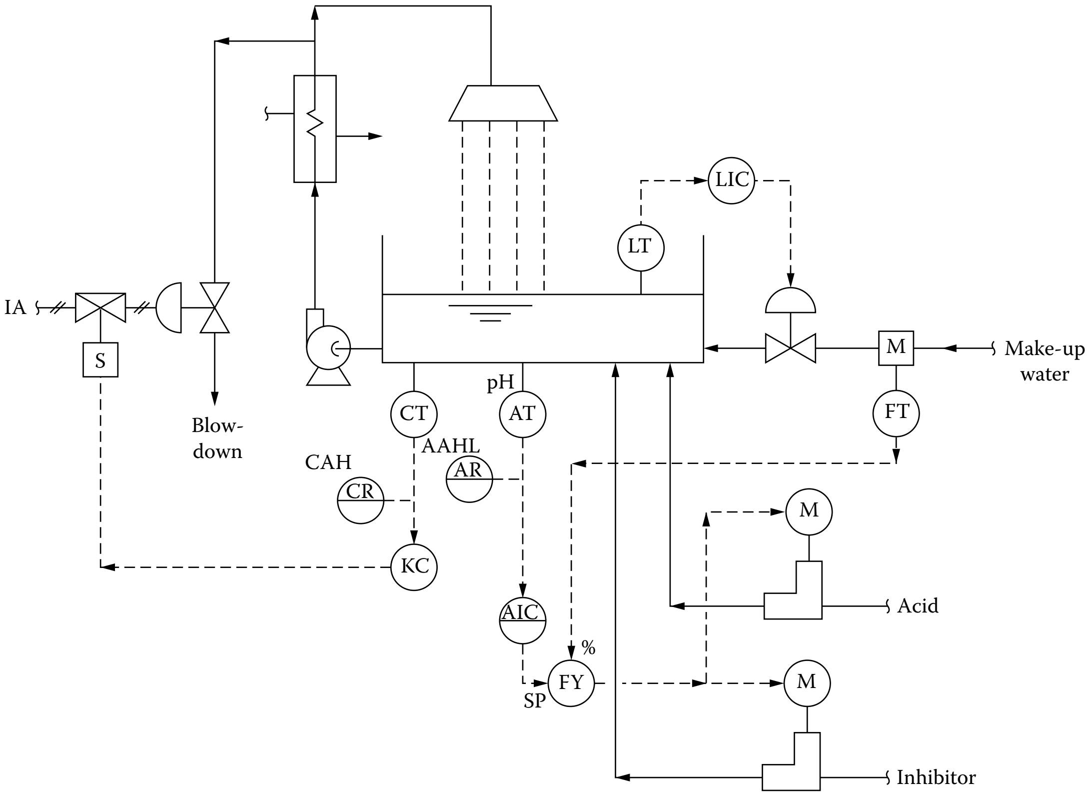

FIG. 8.39hh
Cooling tower water treatment controls. CT: Conductivity transmitter; KC: Intermittent timer.

fouling (algae, slimes) of water pipes and heat exchangers needs to be prevented by using chlorine, chlorine/bromine, or biocides. Sometimes, shock treatment is used, i.e., the periodic introduction of high chlorine concentrations.

Figure 8.39hh describes part of a control system for treating the water in the cooling tower basin.

Some of the considerations in connection with that system are:

- Make-up water needs to be treated with biocides or with chlorine, and these additives should be ratioed to the make-up flow rate. A water meter with totalizer can start an on/off timer, which will start and stop a positive displacement-type, variable-stroke chemical feed pump (interlock not shown in Figure 8.39hh). Periodic biocide shock treatment is normally done manually.
- Make-up water may need pH adjustment (to 7.2–7.6) by injecting an acid (or sometimes caustic). Sulfuric acid is used to destroy scaling bicarbonates of calcium.
- The pH in the basin is monitored and is used to control (AIC in Figure 8.39hh) the acid (caustic) feed rate, which is also proportioned to the make-up water flow rate.
- Conductivity is measured in the basin and used to adjust the blowdown rate. Blowdown may be continuous, using a control valve, or intermittent (as shown in Figure 8.39hh), using an on/off valve.
- Corrosion inhibitors and antiscalants can be mixed in with the acid in the acid feed tank or can be added under the same controls as the acid, as shown in Figure 8.39hh.

The cooling tower's water chemistry can be upset by wind, rain, or drifting spores. Some microorganisms also generate corrosive gases. The treatment process (as was explained in detail in Sections 8.16) has long time constants and dead times. For these and many other reasons, advanced controls (Section 8.17), including statistical process control (Section 2.34 in Chapter 2), can be considered.

Because cooling towers are unattended, upsets detected by the pH and conductivity meters are set to trigger remote alarms, by radio or using a telephone dialer.

CONCLUSIONS

Most wastewater treatment systems are designed for continuous operation, using several process units. Many of the processes consist of chemical treatment. Some of the features of automated effluent and water treatment systems are summarized in Table 8.39ii. The natural laws governing chemical

8.40 Water Supply Plant Controls

P. Y. KESKAR (2005)

Reviewed by B. G. Lipták (2005)

INTRODUCTION

This section describes some of the control strategies and instrumentation systems that can be used in the treatment of raw water in the preparation of drinking water supplies. The described control systems correspond to applications in which PLC-based controls were used. This is not intended to suggest that a PLC-type of control hardware is preferred for these types of applications, but only that the author's experience was based on that type of hardware. The last paragraph of this section provides a brief discussion of some of the PLC limitations of the PID loops described in this section.

The previous section, Section 8.39, discussed wastewater treatment controls. Because some of the unit processes are utilized in both types of plants, there is some overlap between the coverage of these two sections, and it is recommended to review both.

This section will describe the controls of conventional water treatment plants, which perform lime softening, filtration, and chlorine- or ozone-based disinfection. The section will also describe the control of water treatment plants using reverse osmosis or submerged ultrafiltration membrane technologies. Examples of actual treatment plants will also be described by flow diagrams.

CONVENTIONAL WATER TREATMENT PLANTS

Figure 8.40a shows a simplified block diagram of the unit processes involved in a typical groundwater treatment plant, where raw water is pumped from wells into the treatment units that perform lime softening. In this step, the lime for softening (LS) and the polymer (PO) that assists in the coagulation are added by metering pumps.

The coagulated calcium carbonate and colloids, which were used in the water softening step, settle down as chemical sludge (CHS). This sludge is periodically discharged into the washwater recovery and sludge handling unit process by a blow-down pump station.

The softened water (FI in Figure 8.40a) flows into the filter influent channel, where carbon dioxide is added to stabilize it and to bring the alkalinity of the water down to 9.5 pH. The pH-adjusted water is filtered in a series of filtration steps, and the filtered and treated water (FE) is sent to a clear well for transferring into ground storage tanks. A disinfectant chlorine solution (CS) is added in the softening, in the filtration, and again in the clear well steps. A high-service pumping station pumps the water from the ground storage tanks (FW) into the water distribution system.

Filters are periodically backwashed and air scoured to clean the filter media. The backwash water from the filters is drained (BWD) to the washwater recovery process. The washwater recovered from the washwater recovery process is recycled (BWR) back to the treatment units, and the sludge (DWS) is pumped to vacuum filters for dewatering and disposal.

The sludge thickener also receives sludge (DWS) from the washwater recovery basin. Sludge pumps transfer the sludge from the washwater recovery basin to the sludge thickener (see Figure 8.39cc). The thickener decant is received in the decant pump station, where the water is pumped back to the treatment units, and the sludge is pumped to the vacuum filter for dewatering and disposal.

The paragraphs that follow will describe the major unit processes and their associated controls.

Filtration Hardware and Controls

The clarified and softened water from treatment units enters the filter influent channel common to several filters (FI in Figure 8.40a). Here, the water passes through the filter media for the removal of suspended solids from the water such as silt, clay, colloidal particles, and microorganisms.

Filtration removes disinfection-resistant microorganisms and colloidal particles that can cause growth and deposition in piping and can alter the taste of water. Figure 8.40b illustrates a typical filtration process and its related controls. In this configuration, the filter effluent and backwash flows, the filter differential pressure, the influent level, and turbidity are continuously measured, and the effluent flow is continuously throttled.

Signals from all valves and instruments are connected to a local control panel that houses a remote I/O rack. On/off sequencing valves receive open/close commands from the PLC, and their status is reported to the PLC. The controls shown in Figure 8.40b can be typical for various numbers of filters.

PLC Configuration

Figure 8.40c illustrates the configuration of the PLC equipment used in the filtration process that was described in Figure 8.40b. The system consists of a redundant PLC housed

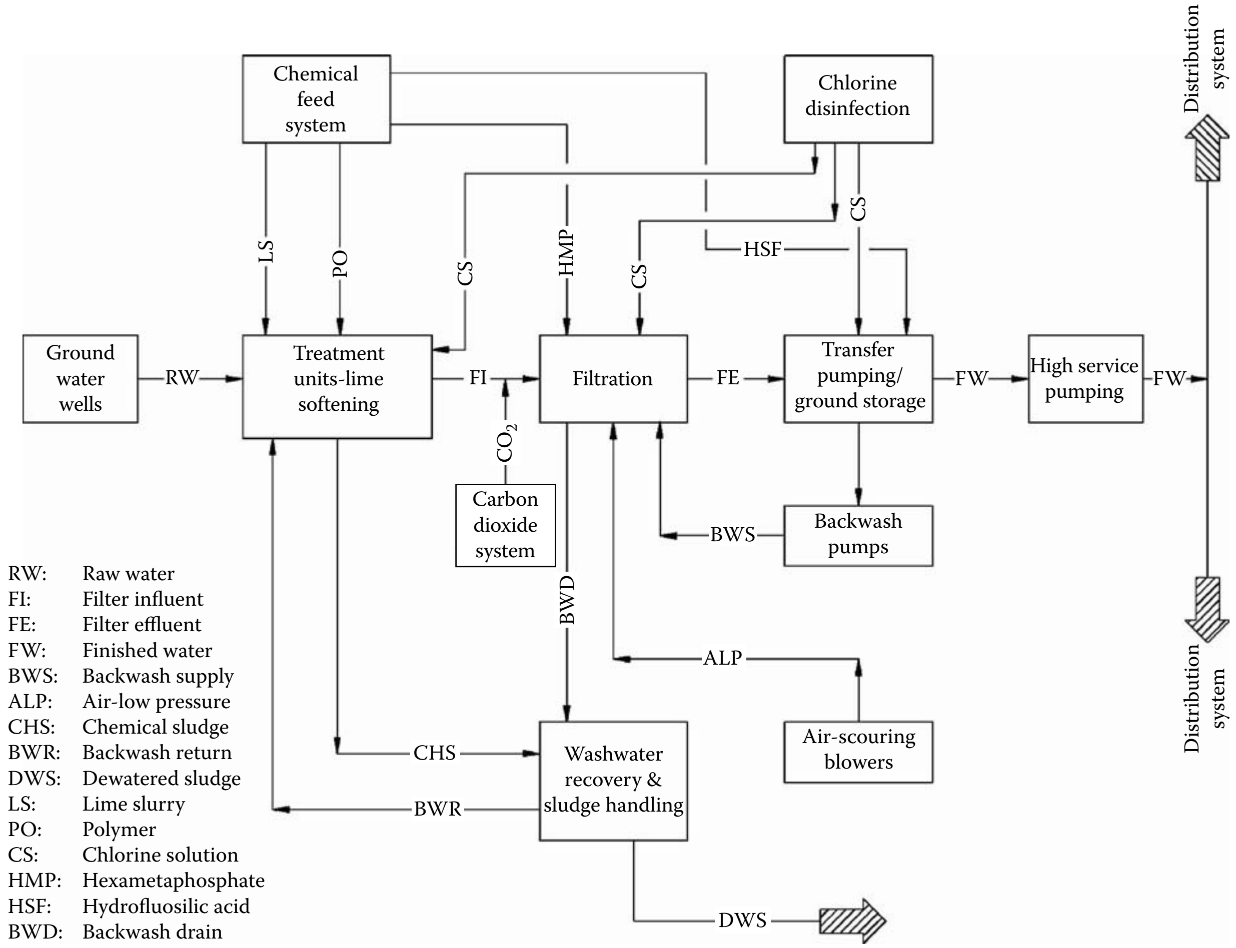

FIG. 8.40a
Block diagram of the unit processes of a drinking water supply plant that uses groundwater as its source of water.

in a main control panel, MCP-1. The redundant PLC communicates with eight remote I/O racks over a self-healing fiber-optic data link. Each remote I/O rack is housed in a local control panel (LCP) and receives I/O from a pair of filters. Thus, the system controls a total of 16 filters via eight I/O racks. One local I/O rack is installed in the main panel to receive common signals related to backwash pumps and air-scouring blowers.

Logic for sequencing of backwash and filter effluent valve control for each filter is resident in the main redundant PLC. The main PLC communicates with the plant computer system via fiber-optic Ethernet links. This allows the plant computer system HMI to display dynamic displays for all filters and to perform SCADA functions like changing set points. The main PLC panel MCP-1 also includes an industrial PC-based operator interface (OI-P) that allows monitoring and control of all filters as well as balance of the plant unit processes via the Ethernet link to the plant computer system. Each local panel has a local operator interface (OI-F) that allows monitoring and local manual control of each pair of filters from the dedicated panel. Other filters can also be monitored from each local operator interface (OI-F).

Filter Control and Sequencing The control and backwash sequencing logic associated with Figure 8.40b is typical of PLC-based constant-rate filtration installations, where the level in the filter is controlled by modulating the effluent flow control. The operating states of the filter include “auto filtration” (Modes 1 and 2) and “backwash.”

When a filter is in its “Auto Filtration” mode, the PLC controls the opening of the effluent valve (FCV-X-3 in Figure 8.40b) as a function of the level in the filter. If the level is very low, a low–low alarm is actuated and the effluent valve closes.

If the level (LIT-X-9) is to be kept between $L_{\min}$ and $L_{\max}$ (say, 7.0 and 8.0 ft) and the filter flow rate is adjustable between $F_{\min}$ and $F_{\max}$ (say, 1.0 and 2.0 million gal per day, or MGD), in *Mode 1 (gap control)* the PLC would set the effluent flow as follows: If level is at or below $L_{\min}$, the flow is set at $F_{\min}$ and stays there until the level reaches $L_{\max}$. At that point, the PLC switches the flow set point to $F_{\max}$, which remains there until the level drops back to $L_{\min}$.

In *Mode 2 (level-proportional),* if the actual level is $x\%$ above $L_{\min}$ (for example, at 7.6 ft, the value of $x = 60\%$), the PLC adjusts the flow set point to $F_{\min}(100 + x)$, or to 1.6 MGD.

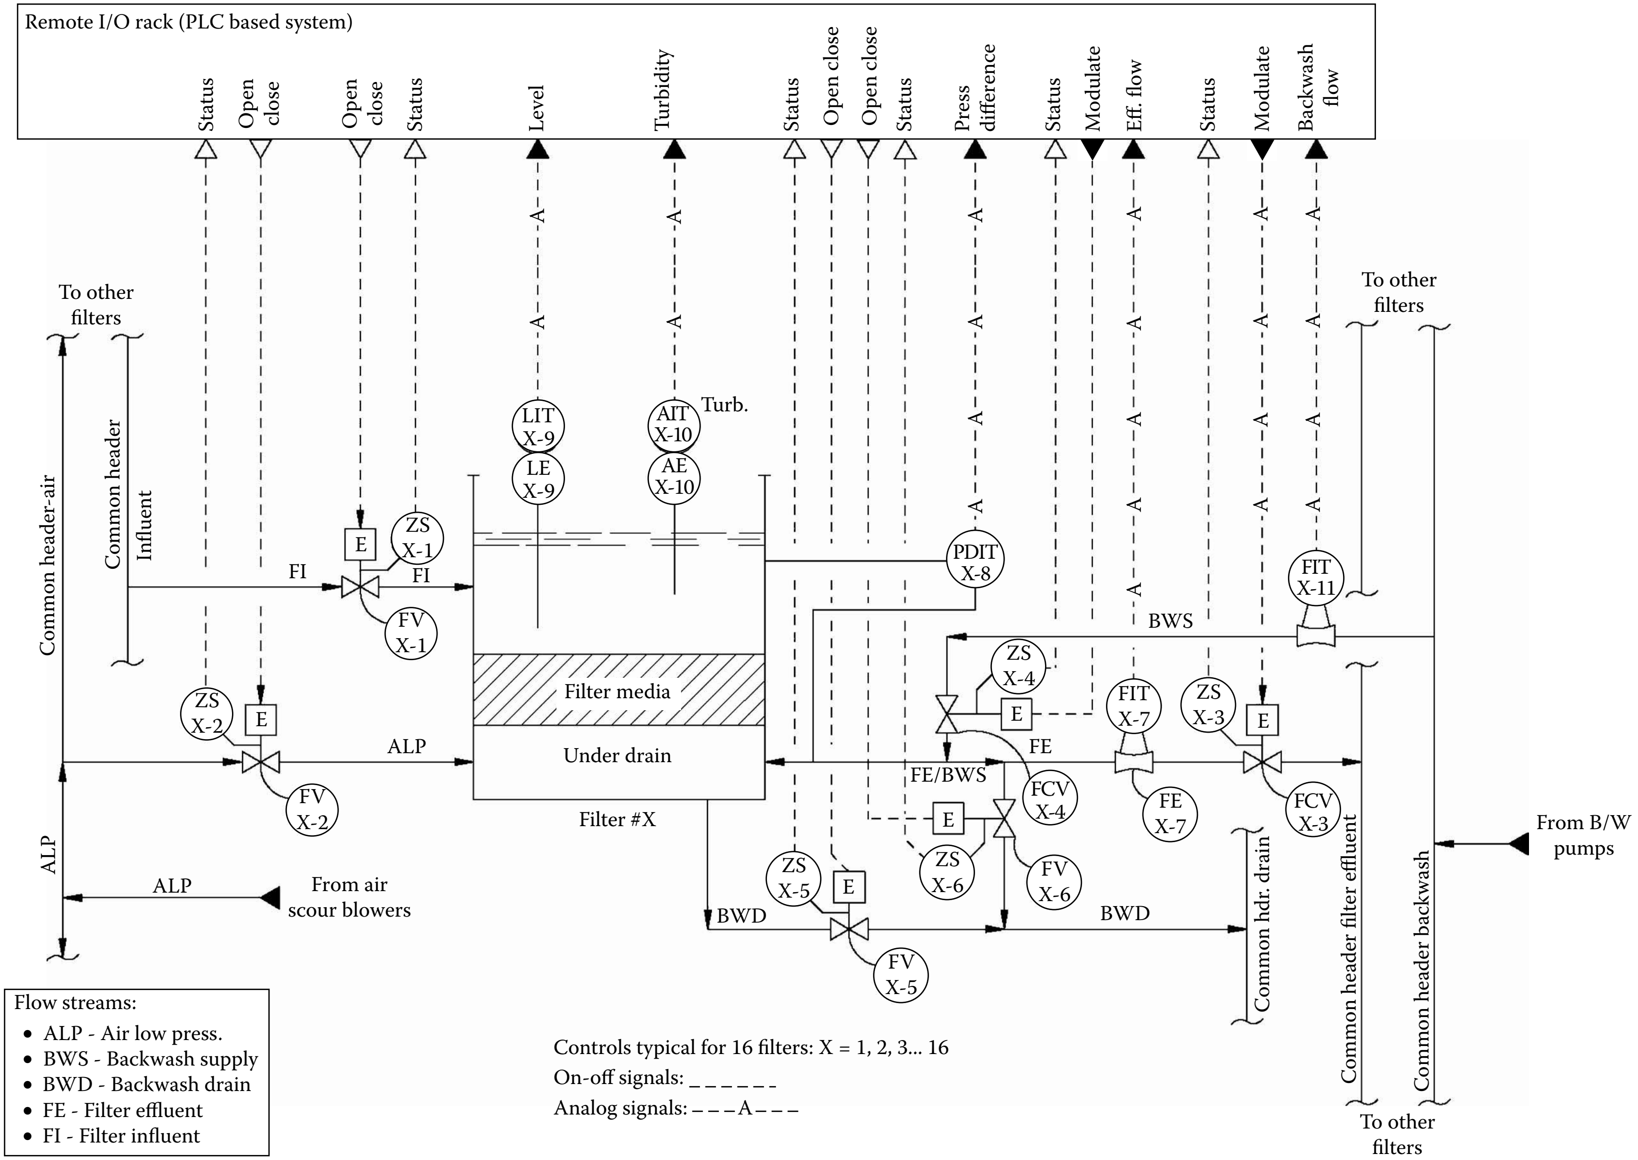

FIG. 8.40b
The sensors and valving of one of 16 filters having PLC-based sequencing controls.

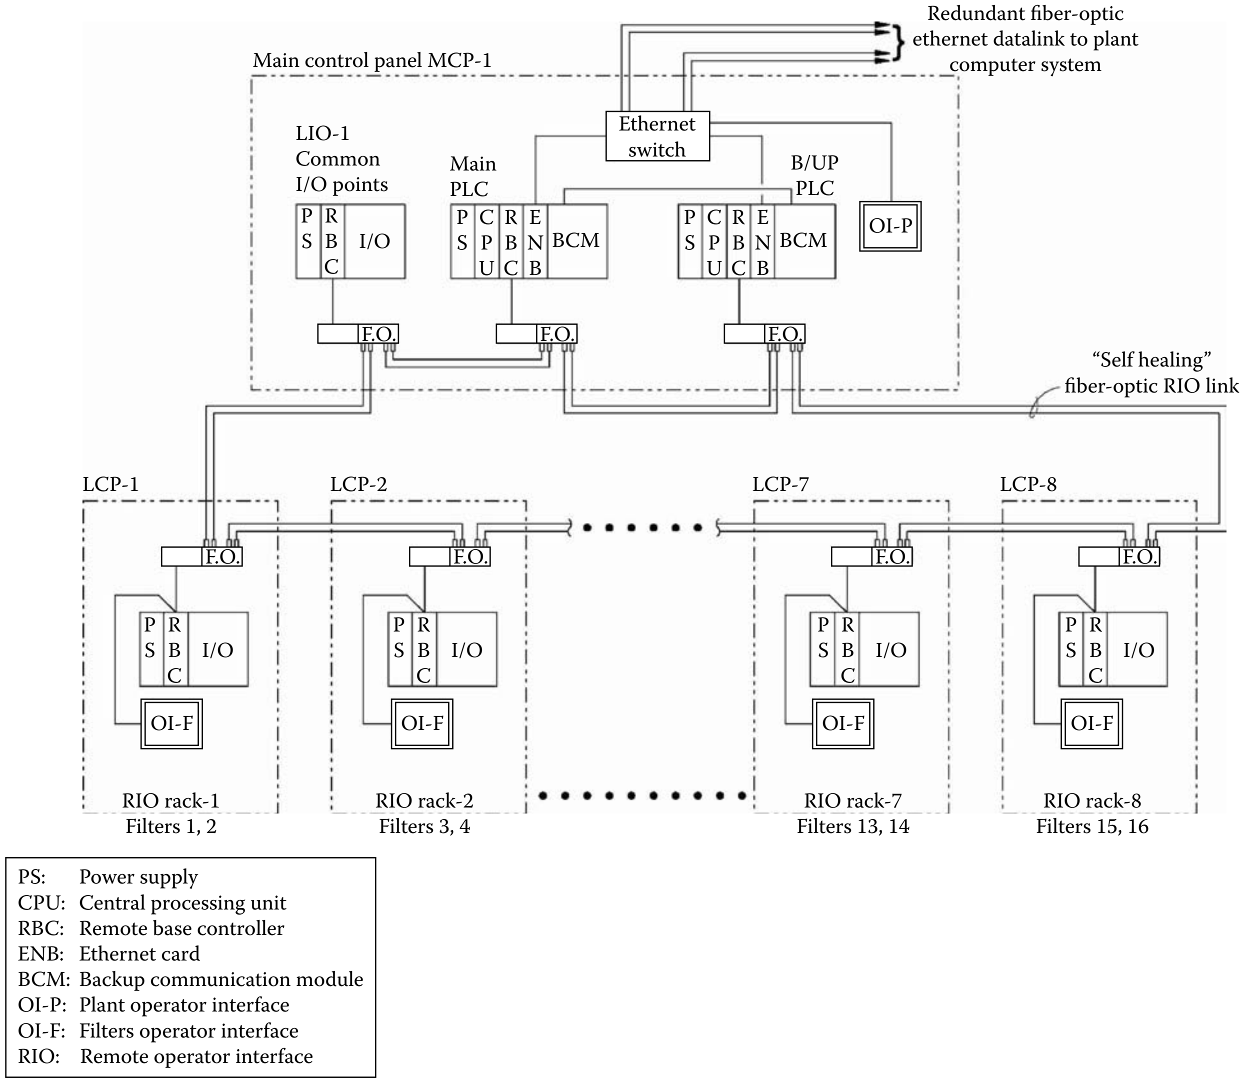

FIG. 8.40c

PLC main and subpanels are connected by "self-healing" fiber-optic links and with redundant FO Ethernet links to the plant computer.

If the effluent valve opening reaches 90% during the auto filtration phase, this initiates an alarm condition, indicating that the pressure available for valve differential is becoming insufficient, probably because the drop across the filter bed is high (PDIT-X-8 in Figure 8.40b). Under such conditions, the operator might initiate a backwash cycle.

Backwash Cycle The sequence of the backwash cycle can be initiated either manually by the operator or automatically by the PLC. The PLC controls the operation of a number of filters (for example, 16) and will allow only one filter to be backwashed at a time.

Automatic backwash is initiated by the PLC, if the preset limits are exceeded on any of the following process variables (Figure 8.40b): level (LIT-X-9), turbidity (AIT-X-10), pressure drop across filter media bed (PDIT-X-8), or when the total run time reaches a preset limit. Table 8.40d lists the steps that occur in a sequence during the automatic backwashing of a filter.

Transfer Pumping and Ground Storage

As shown in Figure 8.40a, the filtered effluent (FE) flows into a clear well, where it is further disinfected by a chlorine solution (CS) until the required residual chlorine concentration is reached in the finished water (FW). For detailed discussions of chlorination controls, refer to Sections 8.31 and 8.39.

Transfer pumps are used to pump the finished water from the clear well to the ground storage tanks, before it is sent into the water distribution system. The transfer pumping station consists of both constant- and variable-speed pumps and is operated under level control. For a detailed discussion

TABLE 8.40d
Definitions of the Steps in the Auto-Backwash Sequence

Step No.	*Description*
0	Out of service
1	Filtration
2	Washwater recovery basin not at high level
3	Close influent valve (FV-X-1)
4	Open drain valve at Falling Level 1 (FV-X-5)
5	Close effluent valve at Falling Level 2 (FCV-X-3)
6	Wait for preset time
7	Start air scour blower
8	Open air supply valve FV-X-2
9	Air scour at preset airflow for preset time
10	Enable washwater control valve (FCV-X-4)
11	Start backwash pump
12	Backwash at low rate with air scour
13	Open air vent valve at Rising Level 3 and close air supply valve (NOTE 2)
14	Stop air scour blower
15	Backwash at mid-rate for preset time (NOTE 1)
16	Backwash at high-rate for preset time (NOTE 1)
17	Backwash at mid-rate for preset time (NOTE 1)
18	Backwash at low rate for preset time (NOTE 1)
19	Close washwater control valve (FCV-X-4)
20	Stop backwash pump
21	Wait for preset time
22	Close drain valve (FV-X-5)
23	Open influent valve (FV-X-1)
24	Open filter-to-waste valve at Rising Level 4
25	Close filter-to-waste valve after preset time (FV-X-6)
26	Select standby/in filtration mode
27	Filter back in filtration

Notes:

1. Low, medium, and high backwash flow rates are set by a flow control algorithm, which detects the actual measured flow (FIT-X-11), changes the flow set point as required and modulates the control valve (FCV-X-4) to meet these set point settings.
2. The blowers are positive displacement (PD) blowers; therefore, the vent valve at the blower discharge header must be opened before closing the air scour valve FV-X-2.
3. All valve positions are confirmed via limit switches before advancing to next step.

of pump station control and optimization, refer to Sections 8.34 and 8.35.

High-Service Pumping

The finished water from the storage tanks is pumped into the distribution system by the high-service pumping station, which consists of both variable- and constant-speed pumps. The flow and residual chlorine concentration in the distribution header is continuously monitored, while the pressure is controlled.

The high-service pumps are controlled and sequenced to maintain the pressure in the distribution header within a ±2 psi band around the desired pressure set point. A PID algorithm is provided in the PLC to modulate the variable-speed pumps to maintain this pressure set point.

In order to properly design a pumping station, one needs to develop reliable system curves for the process, obtain the characteristic curves of the individual pumps, and identify such operating constraints as the surge lines. Based on such information, static and dynamic models can be developed and used to simulate pump station operation using a variety of alternate pump combinations and strategies, before they are implemented.

The key to success is using reliable data to obtain the correct system and pump curves for all possible combinations of load conditions. The goal is to avoid overdesigning, which can cause excessive pump cycling, pressure fluctuation, and waste of pumping energy, yet provide all the capacity that is needed to meet present and future loads. For a detailed discussing of pump station control and optimization, refer to Sections 8.34 and 8.35.

OZONATED WATER TREATMENT

The conventional water treatment system shown in Figure 8.40a utilizes disinfection steps using chlorine. Figure 8.40e describes the configuration of the equipment in a water supply plant where ozone is used for disinfection.

The plant that is illustrated has two ozone generators, each supplying a common header, which takes the ozone to two ozone contactors. Each contactor supply line serves five ozone diffusers, which mix the ozone with the raw water received from sedimentation basins. The ozonated water effluent (OZW) from the contactors is sent for filtration to the biologically activated carbon (BAC) media filters. The excess ozone (OZA) that accumulates above the water surface in each of the contactors is removed and destructed.

Each ozone generator includes a power supply for the generation of high-amplitude, high-frequency voltage, which is applied to the electrodes in the ozone generator, which ionizes the oxygen-rich air (GOX) supplied to the ozone generator. The frequency of the power supply unit output is modulated to vary the rate of ozone production. An ozone production turndown of 10:1 can be achieved by varying the frequency from 1000 to 100 Hz.

In another method of ozone production, the frequency is kept constant and the ozone production rate is adjusted by varying the amplitude of the voltage. The ozone production rate can be modulated either in proportion to the raw water flow rate (feedforward) or to maintain the desired ozone

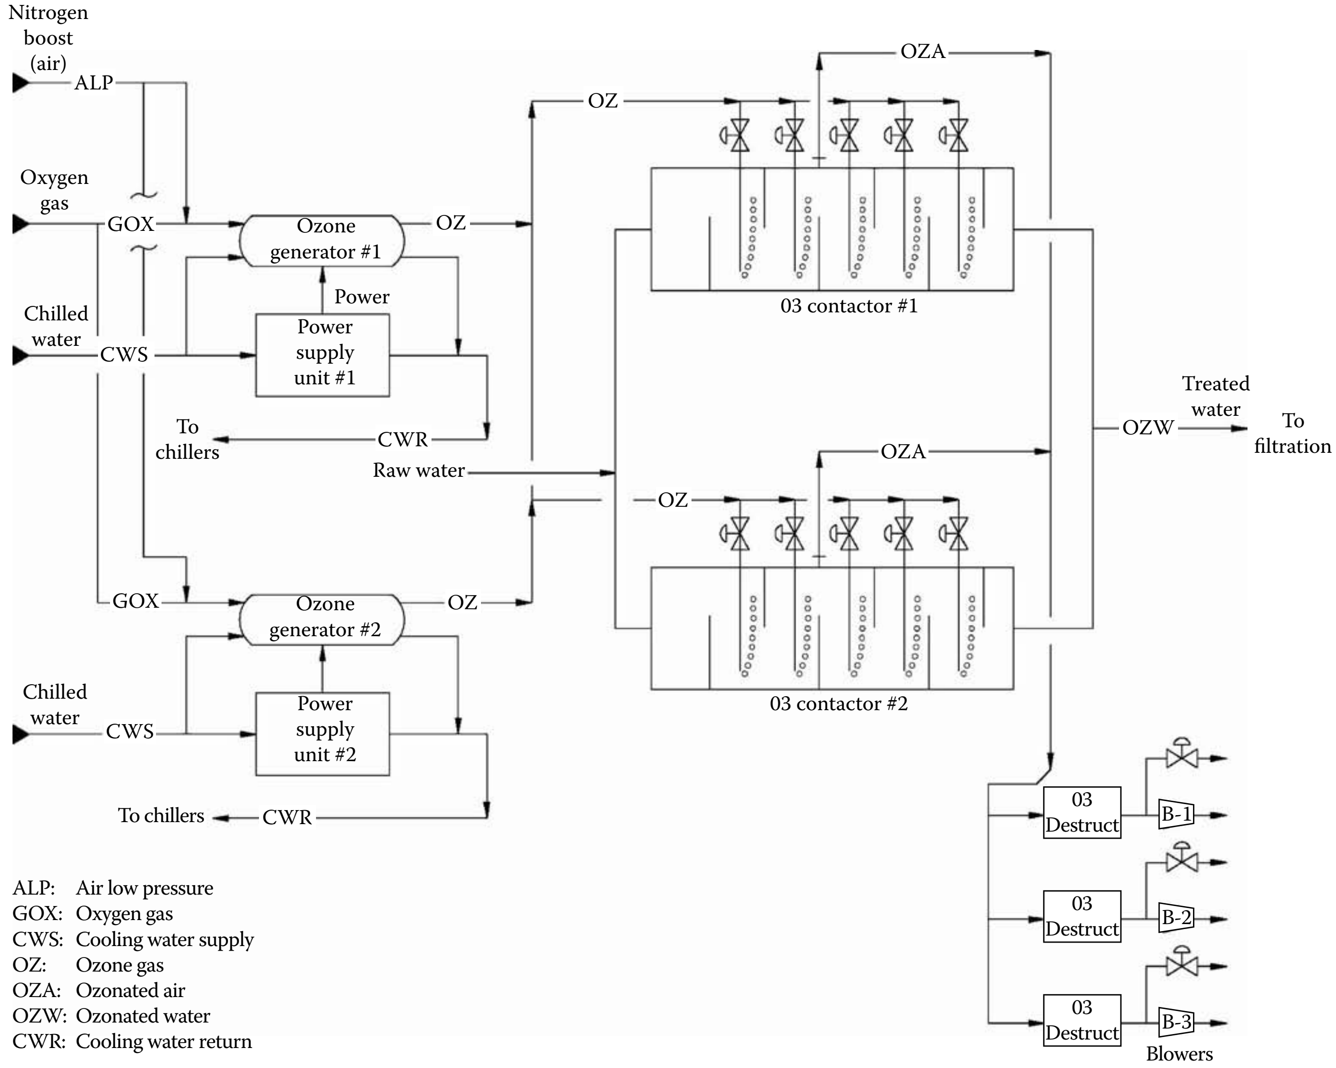

FIG. 8.40e

The configuration of the unit processes in a drinking water supply plant, where ozone is utilized as the disinfectant.

concentration in the water effluent (feedback). In either case, the control signal modulates the power supply inverter circuits.

As shown on Figure 8.40e, both the power supply units and the ozone generators generate significant amount of heat. Chillers and cooling water circulation pumps are provided to remove this heat and to cool this equipment to the desired operating temperature.

Ozone Generator Controls

Figure 8.40f illustrates how a PLC system might approximate, by a series of simple calculations, the operation of a cascade control loop. In this case, the cascade master is the ozone pressure to the contactors (PIC-1-2) and the cascade slave is the oxygen flow (FIC-1-1) into the ozone generator.

As illustrated in Figure 8.40f, the oxygen supply to the ozone generator can be under either "pressure" or "flow" control. The operator can select (FY-1-1-2) the output of either the pressure controller (PIC-1-1) or the flow controller (FIC-1-1) to modulate the oxygen supply valve PCV-1-1. Depending on that selection, either the pressure or the flow in the oxygen supply header will be held on set point by the corresponding PID algorithm in the PLC.

The set point for the oxygen supply pressure controller is set by the operator.

Calculating the Slave Flow Controller Set Point In the following six steps, a sequence of simple mathematical calculations will be described. This procedure illustrates how PLC-based systems can approximate the operation of cascade control systems.

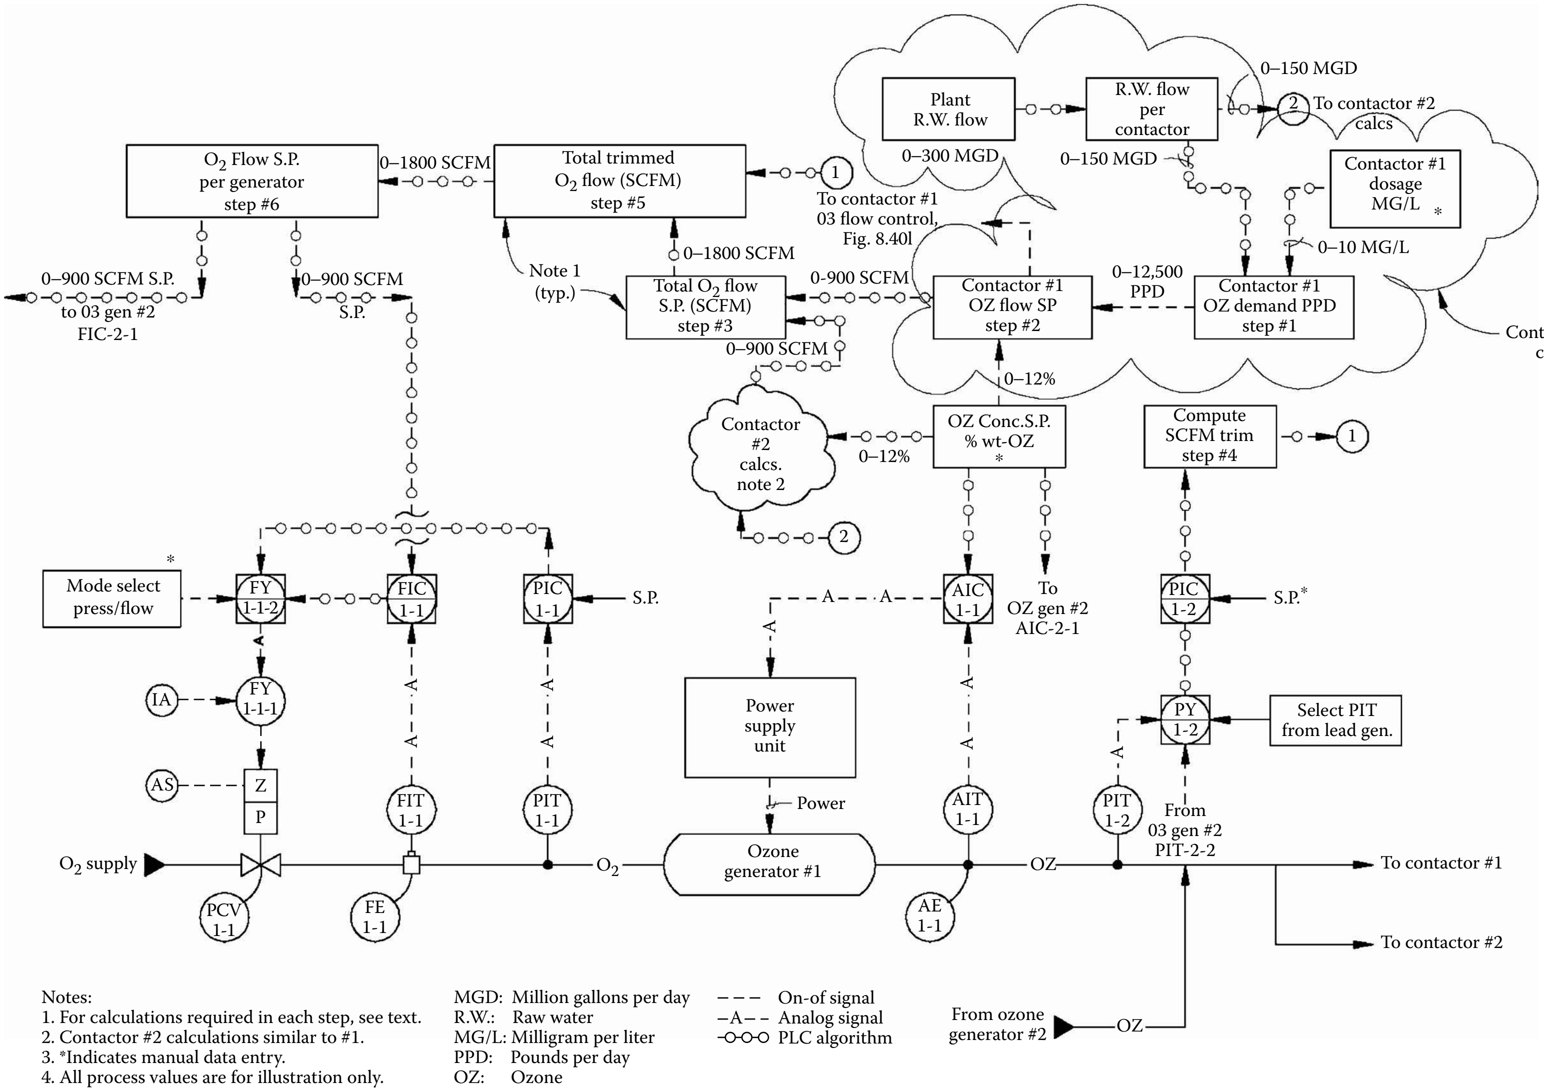

FIG. 8.40f

Ozone concentration is controlled by modulating the frequency of the power supply, while the oxygen feed rate is throttled either on the basis of holding the inlet or the discharge pressure of the generator constant.

The set point of the oxygen flow controller to the ozone generator is calculated on the basis of raw water flow, ozone dosage requirement, and ozone concentration measured in the effluent as follows:

STEP 1: $\text{PPD} = \text{RWF} \times \text{Dosage} \times 8.34$ **8.40(1)**

where

PPD is pounds per day of ozone demand in Contactor 1
RWF is raw water flow per contactor in million gallons per day (mgd)
Dosage is the required ozone dosage in mg/liter

STEP 2: $O_3\,\text{Flow\#1} = [(\text{PPD})/(O_3\%\ \text{wt} \times .083 \times 1440)] \times 100$ **8.40(2)**

where

O_3 Flow#1 is the O_3 flow set point in SCFM for the flow into Contactor 1
O_3% wt is the set point for the ozone concentration in percentage by weight
Note: The ozone flow S.P. for Contactor 2 is calculated the same way as for Contactor 1.

STEP 3: $\text{Total } O_2 \text{ Flow} = O_3\,\text{Flow\#1} + O_3\,\text{Flow\#2}$ **8.40(3)**

where

Total O_2 Flow is the set point for FIC-1-1 in SCFM.

STEP #4: $O_2 \text{ Flow Trim} = [(\text{PIC-1-2 output})/100] \times \text{Trim Range} - (\text{Trim Range}/2)$ **8.40(4)**

where

O_2 Flow Trim is the set point trimming signal in SCFM, received from PIC-1-2.
Trim Range is (−100 SCFM to +100 SCFM) = 200 SCFM.
PIC-1-2 output is the percentage output signal of the ozone generator discharge pressure controller PIC-1-2. This controller algorithm in the PLC detects the ozone pressure of the lead ozone generator (PIT-1-2 or PIT-2-2) and compares that reading to an operator-entered pressure set point.

STEP #5: Total Trimmed O_2 Flow S.P. $= \text{Total } O_2 \text{ Flow (Step \#3)} + O_2 \text{ Flow Trim (Step \#4)}$ **8.40(5)**

where

All flow set points and trim are in SCFM.

STEP #6: O_2 Flow S.P. per generator $= \text{Total Trimmed } O_2 \text{ Flow S.P. (Step \#5)}/2$ **8.40(6)**

Ozone Concentration Control Loop AIC-1-1 in Figure 8.40f controls the percentage concentration of ozone by weight in the ozone generator discharge stream. This controller receives its measurement signal from the ozone analyzer AIT-1-1 and maintains the ozone concentration at the operator-entered set point (percentage) by modulating the output frequency of the inverter part of the power supply unit.

Ozone Flow Distribution Control

Figure 8.40g describes the ozone flow distribution control loops. The set point for the ozone flow to Contactor 1 is calculated by using Equation 8.40(2), described in Steps #1 and #2 earlier. This total ozone flow is distributed among five diffuser tubes in Contactor 1.

Each ozone feeding tube is provided with its own flow transmitter, controller, and control valve. A predetermined percentage of the total ozone flow is sent as the set point of the flow controller of each ozone diffuser tube. The percentages can be changed by the operator; they are provided in a lookup table, and their total must add up to 100%.

Control of Ozone Destruction

As was noted in connection with Figure 8.40e, the excess ozone that accumulates above the water surface in the contactors is exhausted through ozone destructors, which heat it and, by the use of a catalyst, reconvert it back to oxygen.

Each ozone destructor is provided with a continuously running exhaust blower, which maintains a slightly negative pressure within the ozone contactor. A single pressure controller (PIC-4 in Figure 8.40h) maintains a slight vacuum, which is measured at the outlet of the “lead” contactor (PIT-1-4-1 or 2-4-1) and modulates all three vacuum breaker valves (FCVs).

In the destructor, the ozone is preheated to a preset temperature and is converted back to oxygen by a catalyst. An SCR-based solid-state controller controls the heater by changing the SCR firing angle to control the amount of heat generated.

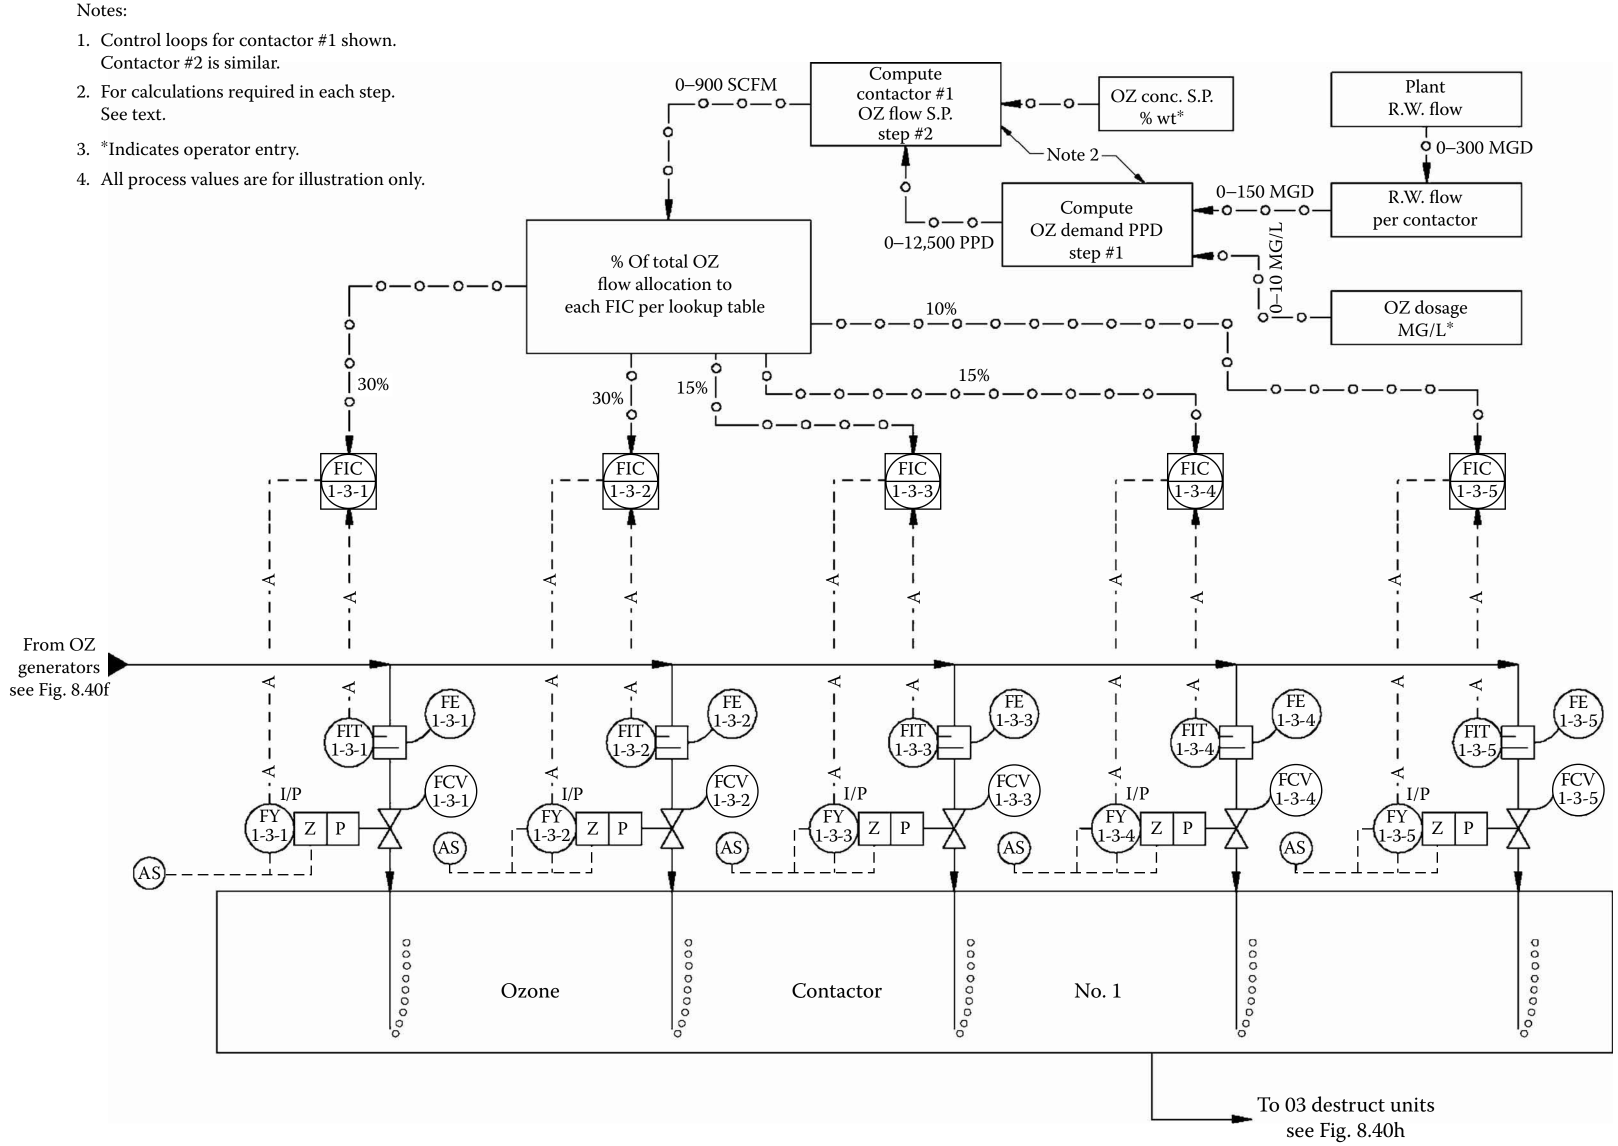
The ozone destructors must be on and running properly before any ozone gas is generated.

Ozone Generator Start-Up Sequencing

The PLC logic also includes an ozone generator automatic sequencer, which initiates and carries out the system start-up and shutdown in a safe manner. Certain prerequisite conditions must be satisfied before an automatic start-up or shutdown sequence can be initiated.

Prior to initiating the automatic start-up sequence of an ozone generator, the following major prerequisites must be satisfied: 1) At least one of the two oxygen supply valves of the two ozone generators (PCV-1-1 or PCV-2-1 in Figure 8.40f) must be in automatic control. 2) At least one of the two ozone generators must be in automatic and ready for operation. 3) At least one of the two contactor trains must be enabled and ready for operation. 4) Emergency stop has not been actuated.

When all of the above prerequisites are satisfied, the “Ready” status is displayed and a run command can be



Notes:

2. For calculations required in each step. See text.
3. *Indicates operator entry.
4. All process values are for illustration only.

FIG. 8.40g

Ozone flow controls for distributing the gas among five diffuser tubes.

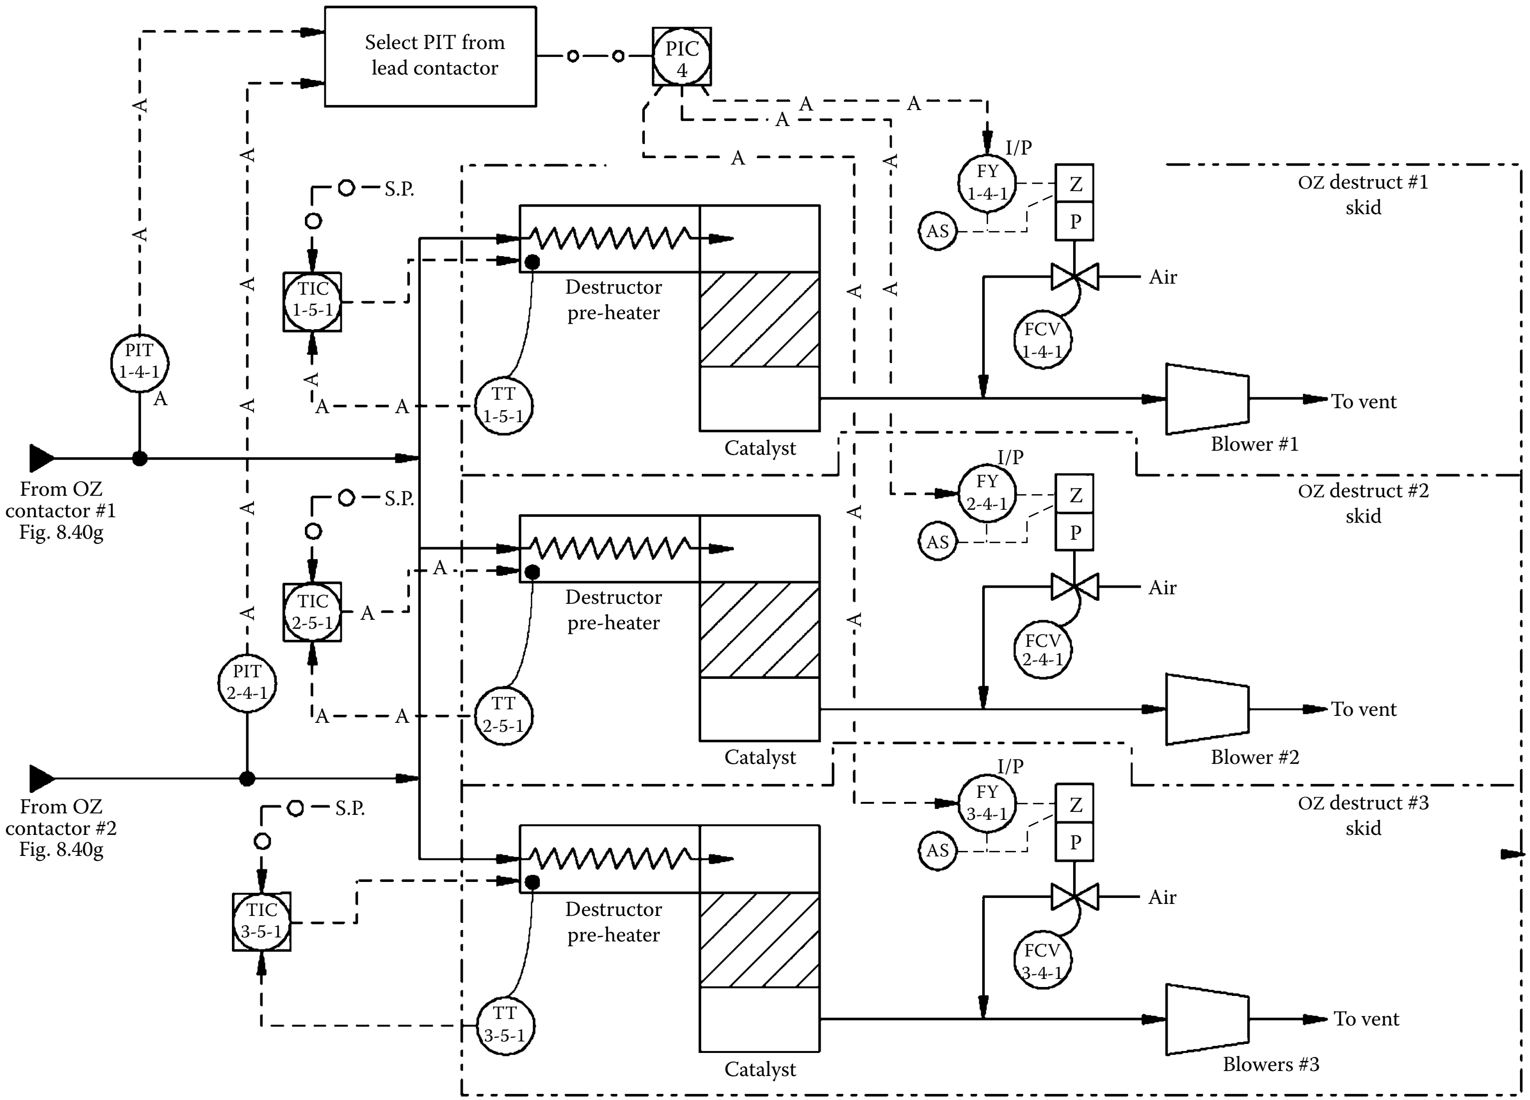

FIG. 8.40h
The ozone is preheated and its vacuum pressure is controlled by throttling FCV valves that admit air into the suction of the blowers.

TABLE 8.40i
Steps in the Ozone Generator Start-Up and Shutdown Sequence

Step 0 — System off, idling. System ready. System run command issued.
Step 1 — Start cooling water pump.
Step 2 — Start chiller.
Step 3 — Start boost air.
Step 4 — Start destruct unit and enable controls.
Step 5 — Open oxygen valves.
Step 6 — Enable ozone flow control loops.
Step 7 — Start ozone generator purge.
Step 8 — Start generator, enable generator control loops.
Step 9 — Enable contactor flow controls, system running.
**Issue system stop command.
Step 10 — Stop generator, disable control loops, purge.
Step 11 — Stop purge.
Step 12 — Disable ozone flow controls.
Step 13 — Close oxygen valves, wait, destructor purge.
Step 14 — Stop destructor.
Step 15 — Stop boost air.
Stop 16 — Stop chiller.
Step 17 — Stop cooling water pump.

issued. Once a run command is issued, the system sequencer goes through a series of steps to start the system. Automatic shutdown is similarly sequenced. The major start-up and shutdown steps in the sequence are listed in Table 8.40i.

As each step is taken in Table 8.40i, the actions of the previous step are verified and confirmed before the current step is initiated.

PLC Hardware

Figure 8.40j shows the hardware of a typical PLC-based control system for ozone generation and disinfection. The control components include a main control panel (MCP) that houses a redundant PLC, a local I/O rack, and an operator interface (industrial PC).

Each generator has a dedicated control panel, OGCP-1 and OGCP-2, housing a PLC, I/O modules, and an operator interface. Each ozone generator is controlled by its PLC with all related sensors connected to the PLC I/O modules. The chillers, contactors, destructors, oxygen flow controls, and overall sequencing is controlled by the redundant PLC part of the main control panel, and the local I/O rack in the main panel receives all signals related to everything else except the ozone generators.

The operator interfaces in each of the panels allow local control and monitoring of the system. The main redundant PLCs, the two generator PLCs, and the three operator interfaces communicate over a high-speed peer-to-peer data link.

The main redundant PLC communicates with the overall water plant computer system via fiber-optic Ethernet links. The Ethernet communication allows SCADA functions from the central control room.

REVERSE OSMOSIS-BASED WATER TREATMENT

A water treatment plant utilizing the reverse osmosis (RO) process includes a raw water pretreatment section, an RO membrane train section, and a post-treatment with transfer pumping subsystem.

Raw Water and Pretreatment

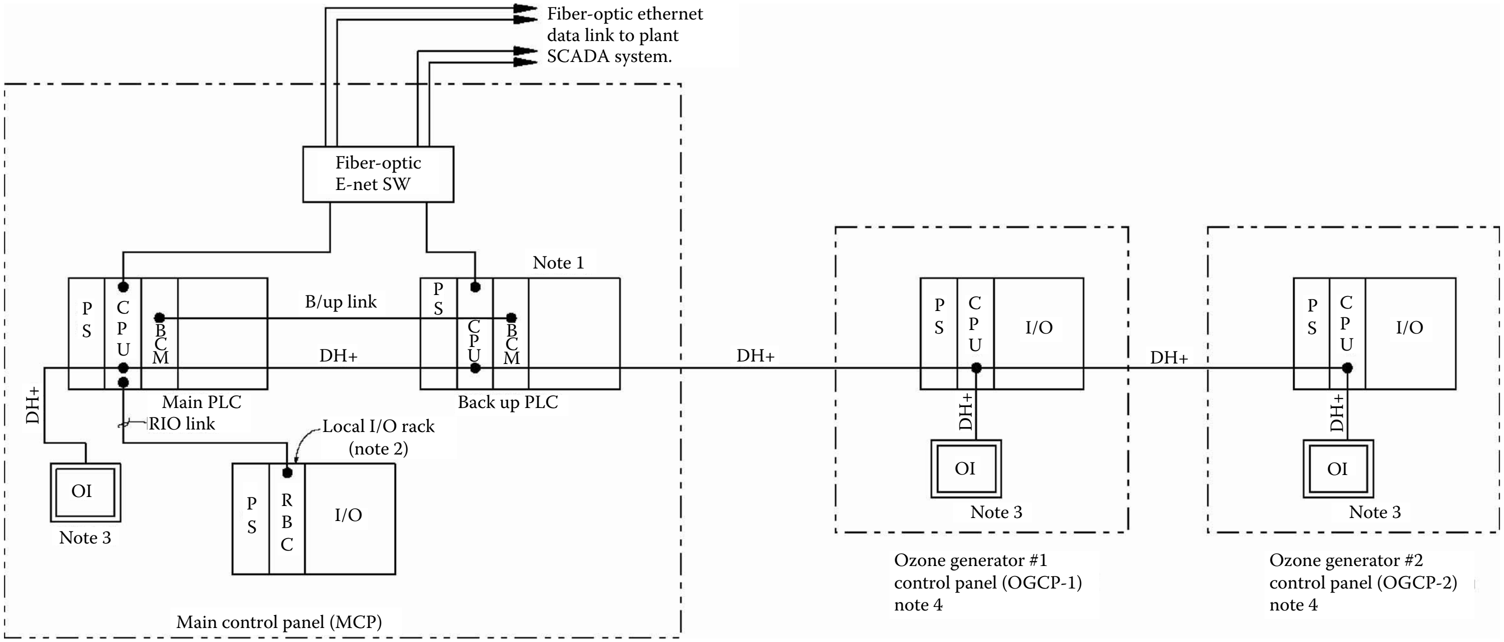
As shown in Figure 8.40k, this subsystem consists of the raw water wells from which the raw water is pumped into the membrane trains, after chemical pretreatment and filtering. Chemical pretreatment consists of the injection of acid for pH control and of scale inhibitor, which prevents scaling inside the membranes.

The starting/stopping and the adjustment of the speed of the raw water well pumps is automatically controlled to maintain the cartridge filter effluent pressure (PT-1-2-2 in Figur 8.40k) and a "well pump sequencer." The following data is manually entered into the pump sequencer: well number, pump number, the order in which pumps should be started, target speed, target flow, maximum flow, and well water conductivity. The real-time data used by the pump sequencer includes the pump status (on/off), actual speeds, flows, and well levels.

Based on the well levels, water conductivity and other process parameters, the operator manually selects the target speeds and flows for each pump and enters this data in the pump sequencer, which then becomes part of the PLC logic. The operator also enters the pump-starting priority (1–8) in the sequencer logic.

In the automatic mode, the well pumps automatically start to maintain the cartridge filter effluent (CFE) pressure in their predetermined sequence and operate at speeds determined by the pump sequencer. As the pressure rises, the pumps are automatically stopped in reverse order, determined by the sequencer. If a pump is switched into the manual mode, it can be started and stopped manually, and its speed can be set by the operator.

Acid and Scale Inhibitor Controls As shown in Figure 8.40k, acid is injected into the raw water, upstream of the mixer and cartridge filters, and after the sulfuric acid has been mixed with the raw water, the resulting pH is measured downstream of the mixer (AIT-1-5). The stroke of the acid metering pump is adjusted as a function of the raw water flow (FT-1-1) using a look-up table. The speed of the acid pump is set by the pH controller, AIC-1-5.



PS:	Power supply
CPU:	Central processing unit-PLC
BCM:	Backup module
RBC:	Remote base communication module
OI:	Operator interface
DH$^+$:	High speed datahiway, peer to peer link

Notes:

1. Redundant PLC with hot backup.
2. Local I/O rack receives signals from ozone destruct units, chillers & other auxiliary equipment.
3. Operator interface is touch screen, industrial environmentally hardened personal computer.
4. Each ozone generator includes a dedicated PLC communicating with main PLC via DH$^+$.

FIG. 8.40j

PLC hardware configuration used for the ozone generation and disinfection processes.

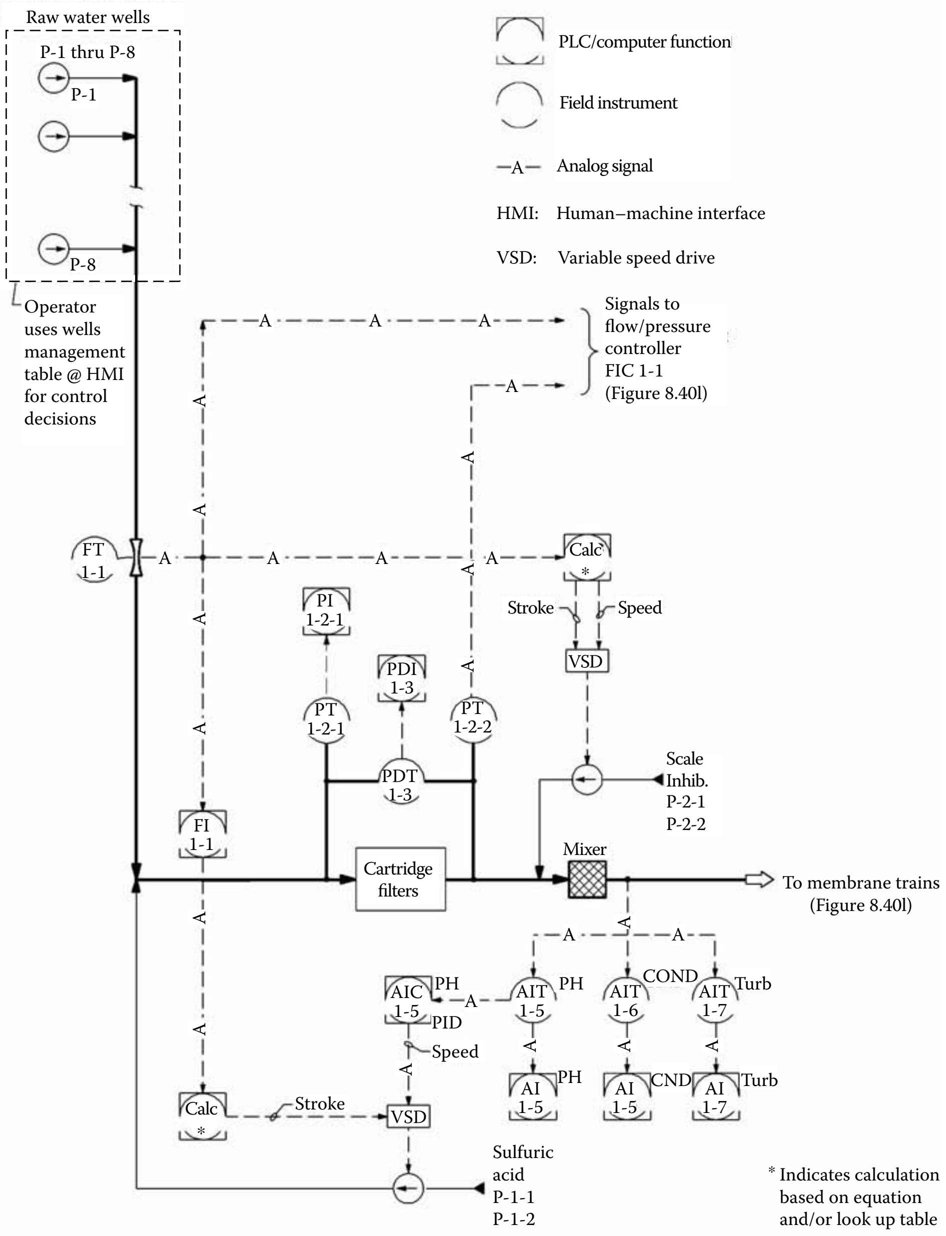


FIG. 8.40k
Raw water pretreatment controls.

The scale inhibitor metering pump is controlled to keep the scale inhibitor concentration (mg/l) in the raw water constant. Here, too, the stroke position of the metering pump is adjusted as a function of the raw water flow (FT-1-1) using a look-up table. The speed of the scaling inhibitor pump is determined by the PLC, using Equation 8.40(7):

$$\%\ \text{speed} = [\ (F \times D \times Ki)/(\#\ \text{of Pumps} \times \%\ \text{Stroke})\ ] \times 100 \tag{8.40(7)}$$

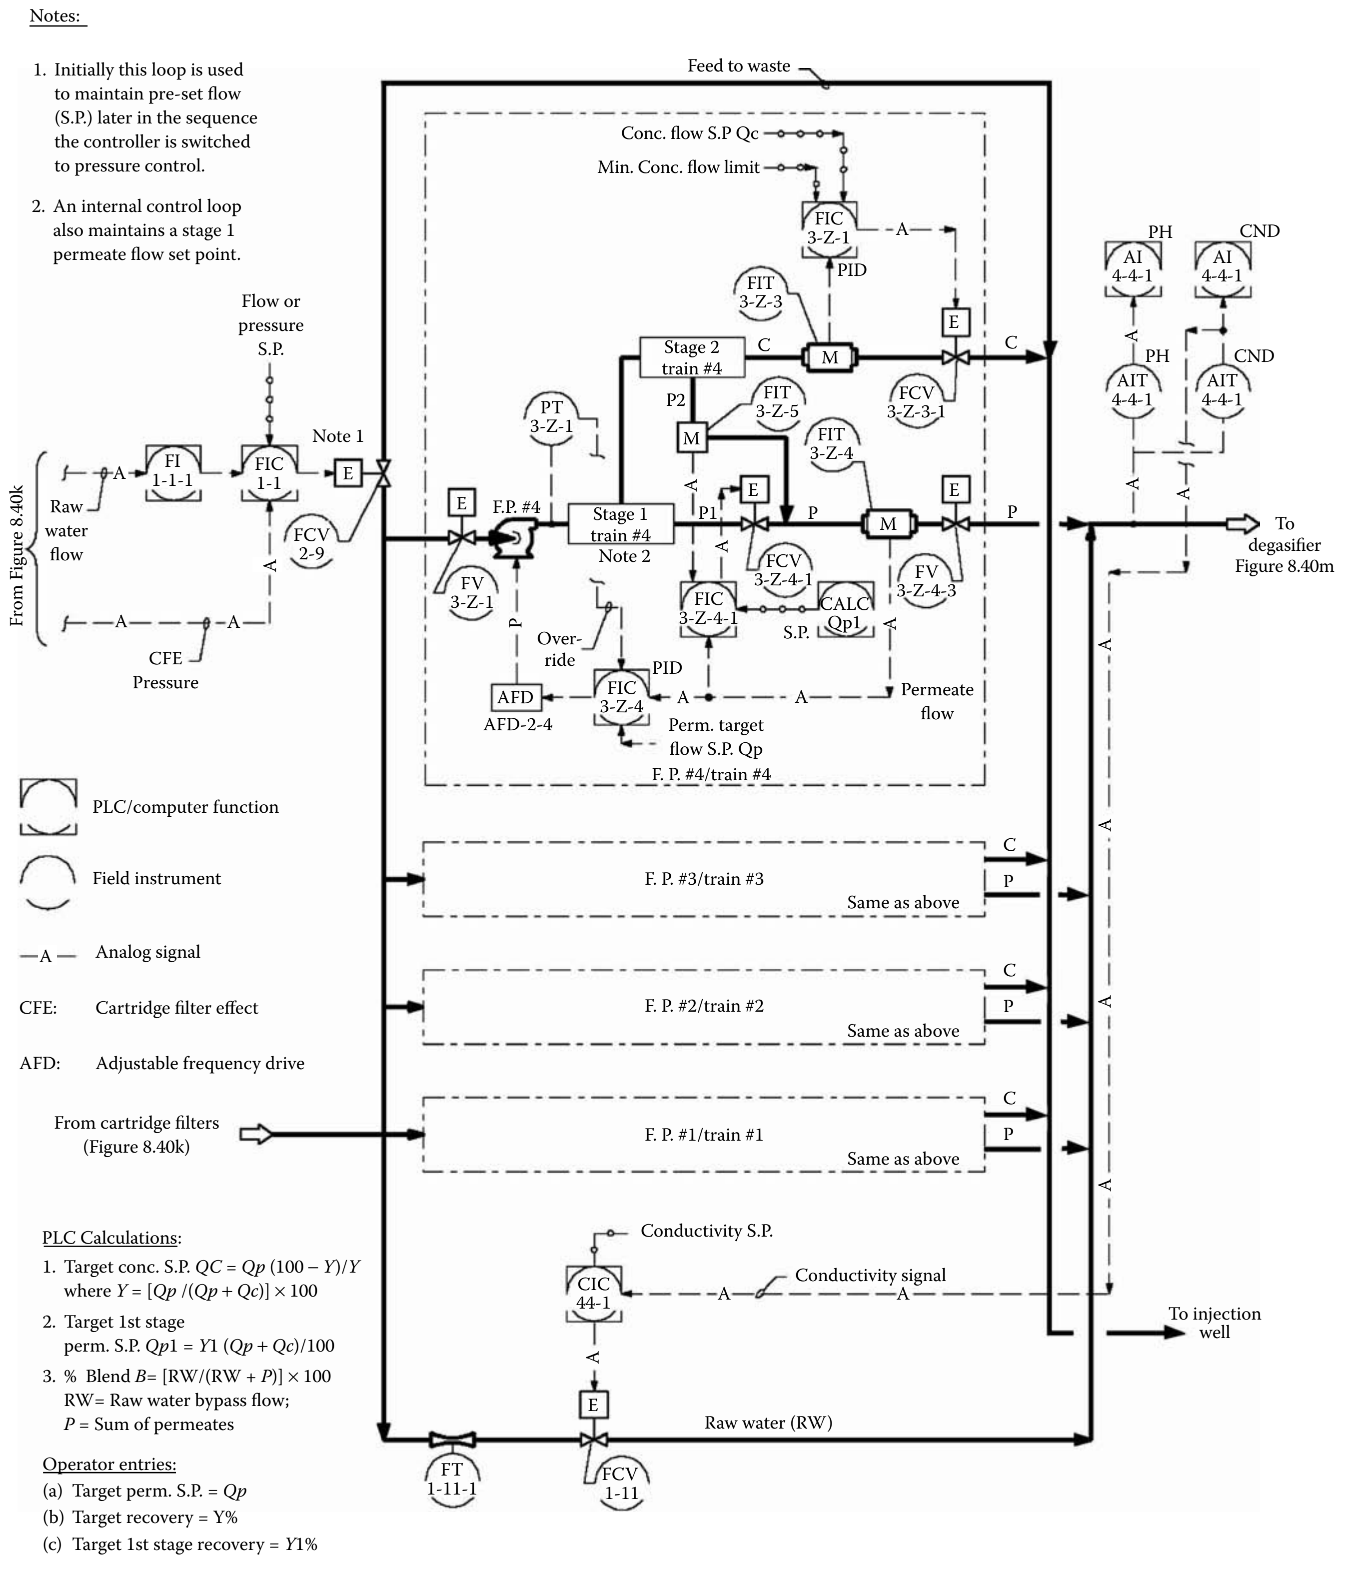
where

F is the raw water flow in mgd
D is the desired inhibitor dose in mg/l
Ki is a constant; in this case, its numerical value is 0.0092

The conductivity and turbidity of the conditioned water feed to the membrane trains is displayed for the operators. The water is allowed to reach the membranes only, if the water quality is within acceptable limits. Any excursions are alarmed, and in extreme conditions, trains can be automatically shut down.

R.O. Membrane Train Controls

Figure 8.40l illustrates a membrane train configuration, where there are four trains working in parallel. Conditioned water from the pretreatment system is received through a common header that supplies the membrane feed pumps.



Notes:

1. Initially this loop is used to maintain pre-set flow (S.P.) later in the sequence the controller is switched to pressure control.
2. An internal control loop also maintains a stage 1 permeate flow set point.

PLC Calculations:

1. Target conc. S.P. $QC = Qp\,(100 - Y)/Y$ where $Y = [Qp/(Qp + Qc)] \times 100$
2. Target 1st stage perm. S.P. $Qp1 = Y1\,(Qp + Qc)/100$
3. % Blend $B = [\mathrm{RW}/(\mathrm{RW} + P)] \times 100$
   RW= Raw water bypass flow;
   P = Sum of permeates

Operator entries:

(a) Target perm. S.P. = Qp
(b) Target recovery = Y%
(c) Target 1st stage recovery = $Y1$%

FIG. 8.40l
The control loops of a number of parallel trains of reverse osmosis membrane unit include the pressure and flow controls of the water supply, the individual concentrate and permeate flows, and the bypass flows to waste and for blending.

Each variable-speed membrane feed pump feeds conditioned water to the corresponding train.

The permeate flow from each train is taken by a common header to a degasifier and, after that, into a clear well. Concentrate from each train is taken by a common header for dumping into injection well. Each train consists of two stages. In Figure 8.40l, the overall permeate and concentrate flows are designated as "*P*" and "*C*," respectively. Stage 1 and Stage 2 permeate flows are designated as *P*1 and *P*2, respectively.

A common feed-to-waste bypass allows the conditioned water to be sent to waste into an injection well by control valve FCV-2-9 during initial start-up or during normal operation, should a high-pressure condition arise. Another bypass allows raw water to be blended into the permeate by control valve FCV-1-11 under conductivity control.

Concentrate and Permeate Flow Controls The target percentage of overall water recovery (Y) can be calculated by Equation 8.40(8). The values of Y, Q_P, and Q_{CMIN} are all entered by the operator into the PLC:

$$Y = [Q_P/(Q_P + Q_C)] \times 100 \qquad \textbf{8.40(8)}$$

where

Y is the target percentage of overall water recovery
Q_P is the target set point for the overall permeate flow
Q_C is the target set point for the overall concentrate flow
Q_{cMIN} is the minimum acceptable overall concentrate flow

The set point for the overall concentrate flow (Q_C) is calculated by Equation 8.40(9) as follows:

$$Q_C = Q_P\,(100 - Y)/Y \qquad \textbf{8.40(9)}$$

where

Y is the recovery in percentage (%)

If $Q_C \Lleftarrow Q_{CMIN}$ then Q_{CMIN} is used as the overall concentrate flow set point.

The overall permeate flow set point Q_P is maintained by FIC-3-Z-4, which is controlling the speed of the variable-speed feed pump. If, during operation, a high-pressure condition is detected (PT-3-Z-1), the output of FIC-3-Z-4 is frozen and an alarm is sounded.

The overall concentrate flow set point Q_C is maintained by FIC-3-Z-1, which throttles FCV-3-Z-3-1. If, during operation, the concentrate flow drops below a minimum preset value, the output of FIC-3-Z-1 is frozen and an alarm is sounded.

First-Stage Permeate Flow Control The set point for the permeate flow rate through the first stage (Q_{P1}) is calculated by Equation 8.40(10):

$$Q_{P1} = Y_1\,(Q_P + Q_C)/100 \qquad \textbf{8.40(10)}$$

where

Y_1 is the target percentage of the first-stage recovery, which is entered by the operator
Q_P and Q_C are overall permeate and concentrate flow set points, respectively

The first-stage permeate flow (FSPF) is calculated as the difference between the overall permeate flow (FIT-3-Z-4) and second-stage permeate flow (FIT-3-Z-5).

$$\text{FSPF} = [(\text{FIT-3-Z-4}) - (\text{FIT-3-Z-5})] \qquad \textbf{8.40(11)}$$

In Figure 8.40l, the flow controller FIC-3-Z-4-1 keeps the permeate flow through the first stage at the set point that was calculated in Equation 8.40(10).

Feed-to-Waste Flow Control During the initial start-up of a train, the raw water has to be bypassed into the injection well until the quality of the conditioned raw water meets all water quality requirements. Therefore, during the initial start-up, FIC-1-1 controls valve FCV-2-9 to keep the bypass flow equal to one train's rated flow. The raw water flow transmitter (FT-1-1 in Figure 8.40k) provides the measurement signal for this control loop.

Later in the start-up sequence, once the conditioned raw water meets the quality requirements, FIC-1-1 is switched to control the pressure detected by PT-1-2-2 in Figure 8.40k. When operating in this configuration, the bypass is used for overpressure relief only, and because the normal pressure is very much below the pressure set point of FIC-1-1, the feed-to-waste valve is closed during normal operation.

Raw Water Blend Control This control loop at the bottom of Figure 8.40l serves to blend the permeate product with conditioned (bypassed) raw water, in order to keep the conductivity of the blend that is being sent to the clear well constant. The conductivity of the permeate/raw water blend (detected by AIT-4-4-1 in Figure 8.40l) is controlled by CIC-4-4-1, which determines the blend percentage (B) by modulating the raw water bypass flow (RW). The PLC determines the blend ratio by using Equation 8.40(12) as follows:

$$B = [(\text{RW})/(\text{RW} + P)] \times 100 \qquad \textbf{8.40(12)}$$

where

B is the percentage blend that is calculated
RW is the raw water bypass flow, measured by FT-1-11-1
P is the sum of the permeate flows of all running trains

If the calculated bypass blend (B) is more than or equal to a preset maximum (say, 15%) then the CIC-4-4-1 controller's output is frozen, the bypass valve remains in its last position, and an alarm is sounded. Even during automatic operation, the operator always has the option of switching the controller in manual and modifying the bypass flow to maintain a blend ratio.

Pumping and Post-Treatment Controls

Figure 8.40m describes the process of transfer pumping and post-chemical treatment applied prior to the water being sent to storage tanks for distribution.

The blended permeate from the membrane trains is sent into the clear well via the degasifier. In the degasifier, hydrogen sulfide (H_2S) gas is removed from the water and passed through an odor control scrubber system, where the odor is eliminated before the cleaned gas stream is released to the atmosphere.

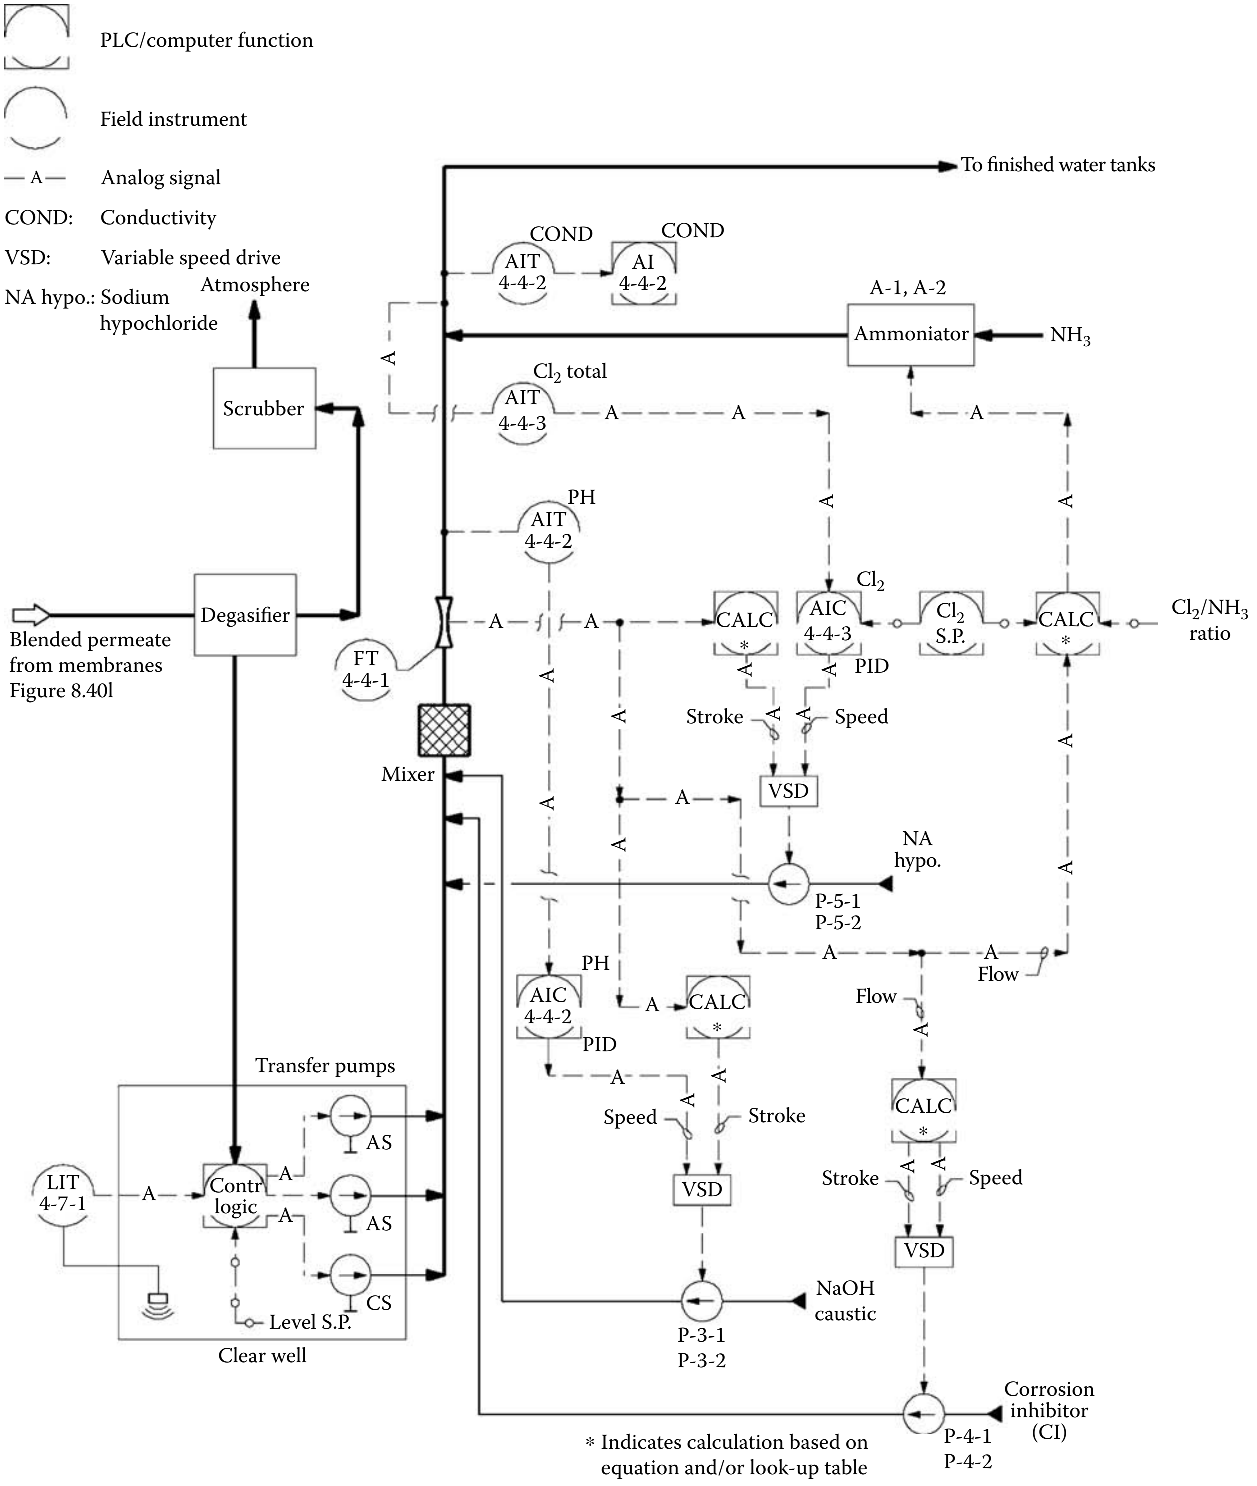


FIG. 8.40m

Transfer pumping and post-treatment controls include the adjusting of the injection rates of pH, residual chlorine, corrosion inhibitor, and ammonia controls.

The water from the clear well is pumped into storage tanks by the transfer pumps. A combination of variable- and constant-speed pumps are operated under level control in the clear well (LIT-4-7-1 in Figure 8.40m). The speed of the variable-speed pump(s) is modulated to maintain the level in the clear well level within a preset band.

The blended permeate from the clear well must be chemically treated before being transferred to the storage tanks. Therefore, the pH of the blended permeate is adjusted to bring it between the limits of 7.5–8.5 pH by the addition of sodium hydroxide (caustic) to the water line.

Similarly, sodium hypochlorite is added to maintain the required chlorine concentration (mg/l) for disinfection. Lastly, a corrosion inhibitor is also added to provide protection against corrosion. All three chemicals are added upstream to the inline mixer to guarantee thorough mixing.

Metering pumps are used to inject the above-mentioned chemicals. The strokes of all metering pumps are controlled according to the values stored in a look-up table to match the additive injection rate to the actual water flow rate (FT-4-4-1 in Figure 8.40m).

Additive Controls Both residual chlorine and pH are measured on-line, downstream of the mixer. The speed of the caustic metering pump is adjusted by AIC-4-4-2, which keeps the finished water pH between 7.5 and 8.5. The speed of the sodium hypochlorite pump is controlled by AIC-4-4-3, which maintains the required total chlorine concentration (mg/l) on set point.

The speed of the corrosion inhibitor pump is controlled in a similar manner as was described for the scale inhibitor metering pump on Figure 8.40k by Equation 8.40(7). Finally, ammonia is added to the finished water to maintain the chlorine-to-ammonia ratio in a range of 3 to 5. Equation 8.40(13) describes how the required feed rate of ammonia is calculated:

$$NH_3 \text{ Feed Rate} = [F \times \text{Hypochlorite Dose} \times 8.34]/\text{Ratio} \qquad \textbf{8.40(13)}$$

where

NH_3 Feed Rate is in lb/day

F is the flow rate of finished water (FT-4-4-1) in mgd

Hypochlorite Dose is in mg/l

Ratio is in the range from 3 to 5 and is entered by the operator

Sequence of Operation Controls

For the reverse osmosis train of equipment, the sequence of operation includes both manually initiated prerequisite steps and automatic steps. Several of the steps are subdivided into mini-sequences. The total reverse osmosis process is subdivided into some ten major sequence steps, listed in Table 8.40n.

TABLE 8.40n
Major Sequence Steps in the RO Treatment Process

Post Chemical Feed
Transfer Pumping/Degasifier/Scrubber
Pretreatment Chemical System
Raw Water Well Management and Automatic Sequence
Train Start-Up Check Lists
First Train Start-up
Subsequent Train Start-up
Automatic/Manual Train Shutdown
Plant Power Failure Scenarios
Train Flush Sequences

Before initiating an automatic train start-up, the operators use two types of checklists, which are displayed on the HMI screens. These are regular and train-specific checklists. The first general checklist display allows operators to verify pump selection, manual valve positions, and selector switch positions for the auxiliary subsystems, e.g., chemical systems, transfer pumping, and scrubber.

The second, train-specific checklist display allows operators to verify major valve positions, feed pump switch positions, controller modes, and manually entered set-point and target values. The automatic train start-up cannot be initiated unless all boxes in the checklists are checked and the correct manual data entries are made.

Start-Up and Shutdown Sequences In the train start-up sequences, there are two types of prerequisite interlocks. The permanent interlocks are active all the time, while the initial condition interlocks are active only during start-up.

Permanent prerequisite interlocks are safety interlocks that must be in place all the time, e.g., feed pump suction and train inlet valves must be open before starting a feed pump, or chemical injection valve must be open before starting a chemical pump.

Initial conditions are the prerequisites required only during the initial start-up, and these conditions can change once the train is in operation. As an example, such initial conditions are the start-up positions of such valves in Figure 8.40l as the raw water bypass valve (FCV-2-9), raw water blend valve (FCV-1-11), and train concentrate valves (FCV-3-Z-3-1).

The logic sequences for "first" train start-up are different from the logic sequences used for "subsequent" train start-up.

Train shutdown sequences can be either automatically initiated by process upsets or manually initiated by operators because of maintenance functions, such as for membrane cleaning or following alarm conditions. Membrane cleaning operation is a completely manual process that is performed by the operators with the aid of a local field panel.

Plant power failure scenarios are included in the sequence of operation. Control strategies are developed for situations when the power failure is only at the raw water wells and not at the plant or vice versa.

Nonoperating trains must be "flushed" every 24 hours and also after each power failure of significant duration. Flush sequences can be initiated automatically, for trains that are not in operation, or manually, based on operator commands.

ULTRAFILTRATION-BASED WATER TREATMENT

For certain types of raw waters, submerged ultrafiltration membranes can be used instead of conventional lime softening water treatment. Ultrafiltration membranes can be substituted for the processing steps of direct filtration, settled water treatment, TOC and color removal, and taste and odor removal, and for pretreatment of the raw water prior to reverse osmosis-based filtration.

Transmembrane Pressure

Equation 8.40(14) can be used to calculate the transmembrane pressure (TMP) difference:

$$\mathrm{TMP} = \mathrm{PP} + K \times [(A + B) - \mathrm{WL}] \qquad \mathbf{8.40(14)}$$

where (referring to Figure 8.40o)

PP is the permeate pressure in psi

A is the elevation of the pressure transmitter above the top of the membranes, in inches

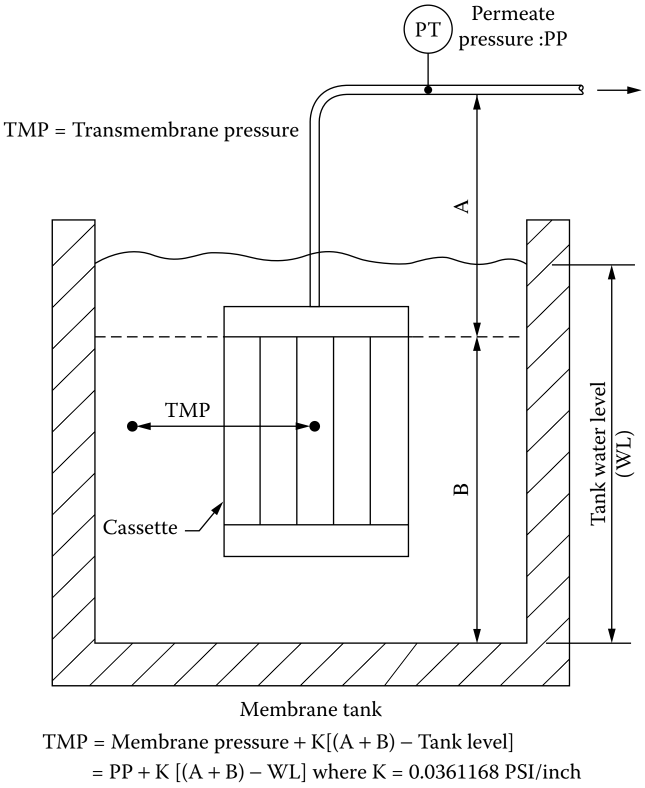

FIG. 8.40o

Illustration for defining the transmembrane pressure (TMP). (Courtesy of ZENON Environmental Inc.)

B is the distance between the top of the membranes and the bottom of the membrane tank, in inches

K is the conversion factor to convert pressure from in. H_2O to psi (0.0361168 psi/inch)

WL is the water level in the tank in inches

The TMP is negative when the unit is in production. During backwashing and cleaning, the TMP value is positive.

Control Loops

Figure 8.40p describes the ultrafiltration process and its controls.

When an ultrafiltration train is to be started up, the state of the train with the highest starting priority is changed from the "standby state" to "backwash operation state." During the backwashing operation, the backpulse pumps under flow control (FIC-6 in Figure 8.40p) start pumping permeate into the membranes for a short, preset time period. During the backwash cycle, FIC-6 maintains the required flow rate by modulating the speed of the backpulse pumps.

Permeate Pump and TMP Controls After being backwashed, the state of the train is changed to the "production state." At the beginning of production, the speed of the permeate pump is held constant by the control logic for a preset period. When that time has passed, the control of the speed of the permeate pump is transferred to be set by the output of a low-signal selector.

This selector compares the output signal of the clear well level controller (LIC-2), divided by the number of operating trains (N) and the output of the transmembrane pressure difference controller (PDC-1), and admits the lower of the two to adjust the speed of the permeate pump. Operating the permeate pump at a lower speed prevents overpressuring and reduces membrane fouling.

The flow controller (LIC-2) and the TMP pressure controller (PDC-1) loops selectively control the permeate pump speed through the low-signal selector. The output of LIC-2 is divided by the number of operating trains to arrive at the flow requirement of the individual train. If the membranes become fouled or if the TMP rises for other reasons, the low-signal selector selects the TMP controller (PDC-1) output to set the pump speed.

Membrane Tank and Clear Well Level Control Water from the distribution channel is fed into the membrane tanks under level control (LIC-1). The water level in the membrane tanks is held by the controller above the top of the cassette troughs.

At the beginning of the backwash cycle, the backwash drain valve (FCV-7) opens and drains out the water from above and in the backwash channel. At the end of the backwash cycle, FCV-7 closes and the train returns to the production state.

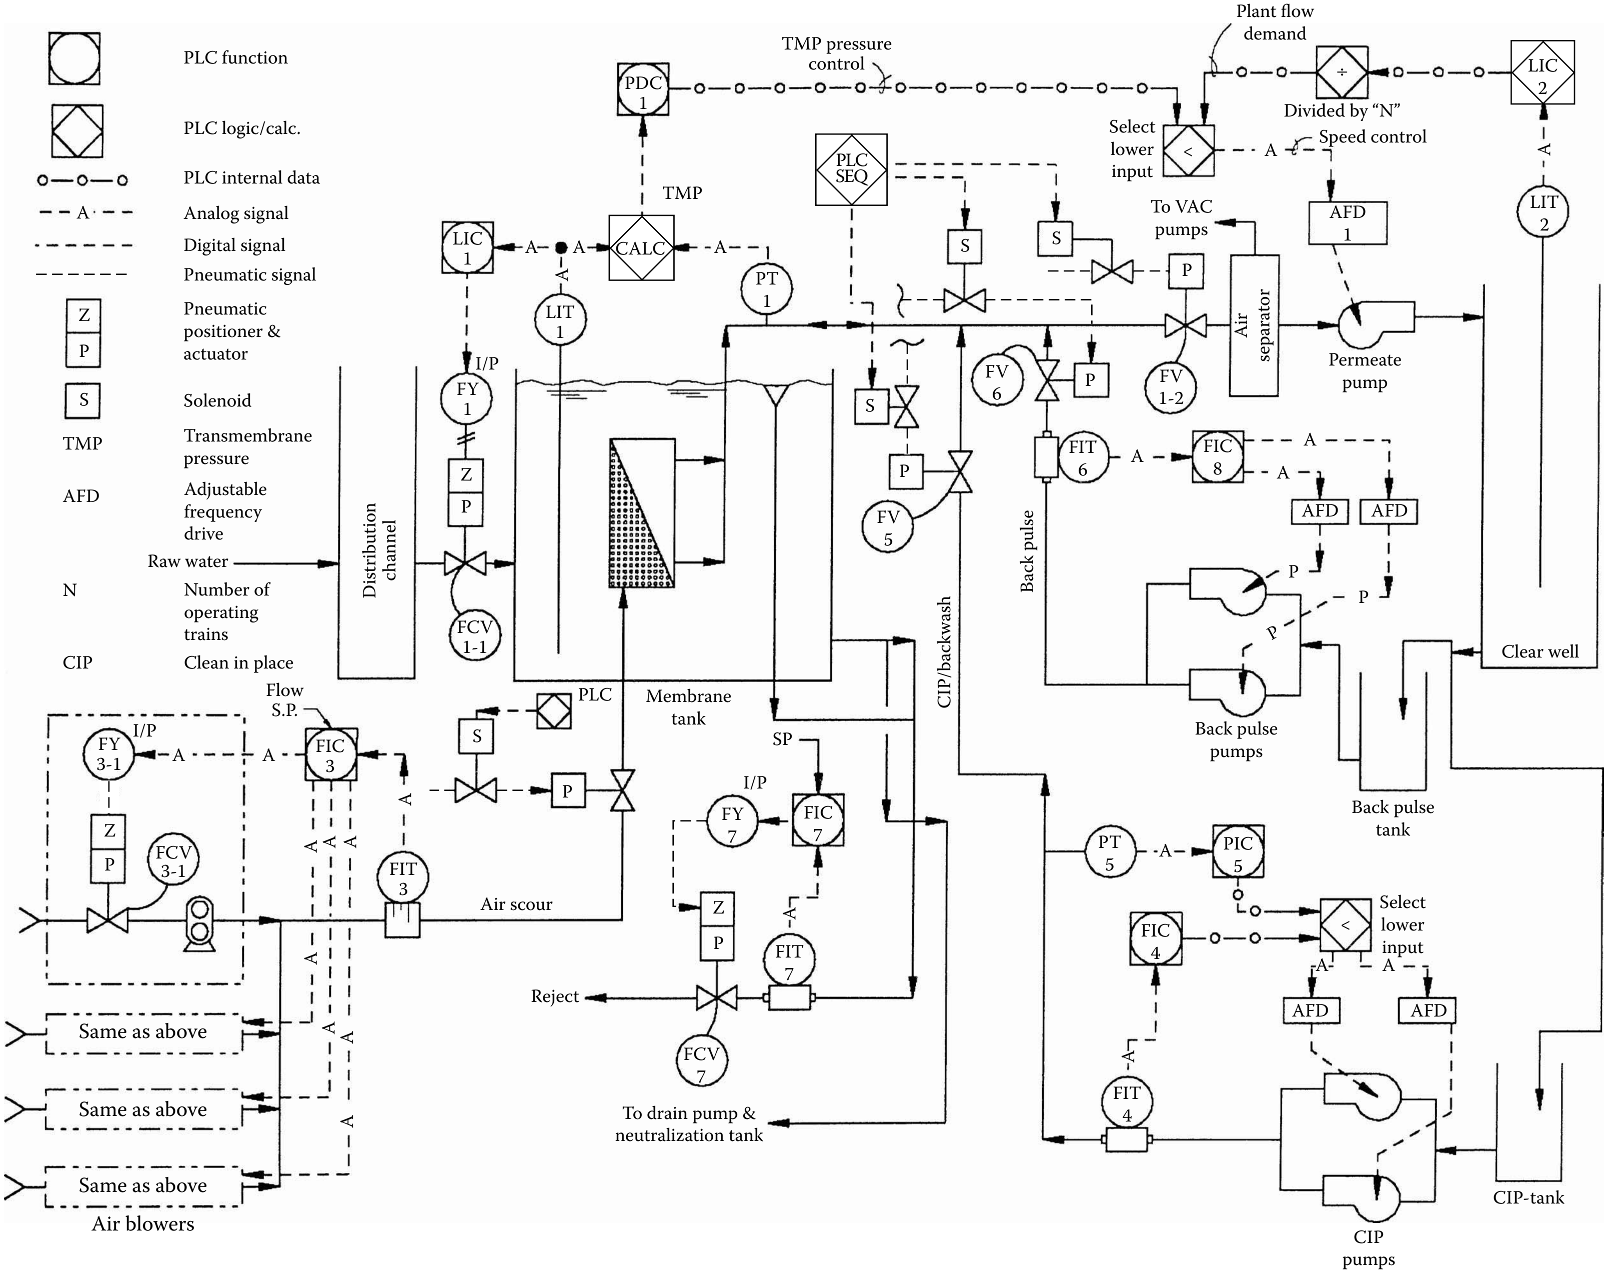

FIG. 8.40p
Ultrafiltration process controls include the selective control of the production rate by adjusting the permeate pump speed, using the lower of the PDC-1 and LIC-2 outputs. The CIP pumps are on overpressure protected selective flow control (FIC-4, PIC-5); the backpulse pumps, air scour, and reject streams are on straight flow control. (Courtesy of ZENON Environmental Inc.)

The total demand for permeate water that is to be produced by the trains of treatment plant is controlled by the clear well level controller (LIC-2). This demand is divided evenly between the operating trains. The instantaneous actual flow from the membranes is set higher than this net flow demand, in order to allow for the time when the trains are not producing water (i.e., during backwash), and to consider the water that is wasted during backwash.

The flow set point can also be entered manually for each train. The operator can set the net production flow rate for each train on the HMI. The control system will maintain the operator-entered production flow rate or the automatically set production flow rate, so long as they do not result in a trans-membrane pressure difference that exceeds the maximum allowed by PDC-1.

Air Scour Flow Control The flow controller, FIC-3, maintains a preset airflow for the scouring of the membranes. Air scouring is required during the backwash and the clean in place (CIP) maintenance cycles. The flow controller (FIC-3) throttles the inlet valves on the operating air blowers. The number of the blowers in operation is a function of the airflow controller set point.

If, because of blower malfunction, the required airflow cannot be maintained, a low-flow alarm is actuated and one or more trains are shut down. This control strategy has been described in Section 8.1.

CIP and Reject Flow Controls The clean in place control loops maintain a preset flow during maintenance cleaning operations. The flow controller (FIC-4) sets the speed of the CIP pump, while the pressure controller (PIC-5) provides standby overpressure protection. As long as the pressure is safely below the PIC-5 set point, the pump speed is set to maintain the required flow. If the pressure exceeds the set point of PIC-5, its output is selected by the low-signal selector, and pressure control takes over the control of the pump speed.

FIC-7 maintains the reject flow rate during the backwash cycle.

For a detailed discussion of all the control strategies and logic sequences that can be programmed in a PLC, the reader is referred to the references at the end of this section.

PLC IMPLEMENTATION OF PID LOOPS

While PLCs are ideally suited for logical and sequential on/off control tasks, when used on PID applications, one should clearly understand their characteristics. It should be understood that when these algorithms are implemented digitally, what used to be integration in the analog world becomes summation, and what used to be time differential becomes difference. The scan period of digital systems is usually fixed at around 0.5 sec or is selectable for each loop from 0.1, 0.2, 0.5, 1.0, 5.0, 10, or 30 sec.

As a digital system looks at the measurements only intermittently, it increases the dead time of the loop by two "scan periods" (the time it takes to return to that measurement), and it makes its algorithm calculations on the basis of the "present" and the "previous" error. This might not be a limitation on slow processes, but can be on fast ones.

There are two basic types of digital algorithms in use. One is called positional. This means that the full output signal to the valve is recalculated every time the measurement is looked at (Equation 8.40(15)).

$$m = K_c\left(e + \frac{1}{T_i}\sum_{o}^{n} e\,\Delta t + \frac{T_d}{\Delta t}\Delta e\right) + b \qquad \textbf{8.40(15)}$$

where

Δt is the scan period

Δe is the change between the previous and the present value of the error

$\sum_o^n e$ is the sum of all previous errors between time zero and time n

The PID algorithm used in this section is called a velocity algorithm. In this case, the value of the previous output signal (m) to the valve is held in memory, and only the required change in that output signal is calculated (Equation 8.40(16)).

$$\Delta m = K_c\left(\Delta e + \frac{1}{T_i}\sum_{o}^{n} e\,\Delta t + \frac{T_d}{\Delta t}\Delta(\Delta e)\right) \qquad \textbf{8.40(16)}$$

where

$\Delta(\Delta e)$ is the change in the error between the previous and the present scan period

The positional algorithm is preferred when the measurement is noisy (flow, for example), because it works with the error and not the change in the error when calculating its proportional correction. Velocity algorithms have the advantages of bumpless transfer and less reset windup, and they are better suited for controlling servomotor-driven devices. Their main limitations include noise sensitivity, likelihood to oscillate, and lack of an internal reference.

In-Line Mixer Controls

In this section, additives are mixed into water streams under the feedback control of analyzers. Because agitated vessels are expensive, simple devices such as in-line mixers are often considered for composition control systems. Properly applied, these devices can be effective, but careful attention to the following design criteria is required: reagent delivery hysteresis, loop gain, and neutralization stage interaction.

In case of pH control, an in-line mixer will control influent streams entering between 4 and 10 pH, and between pH

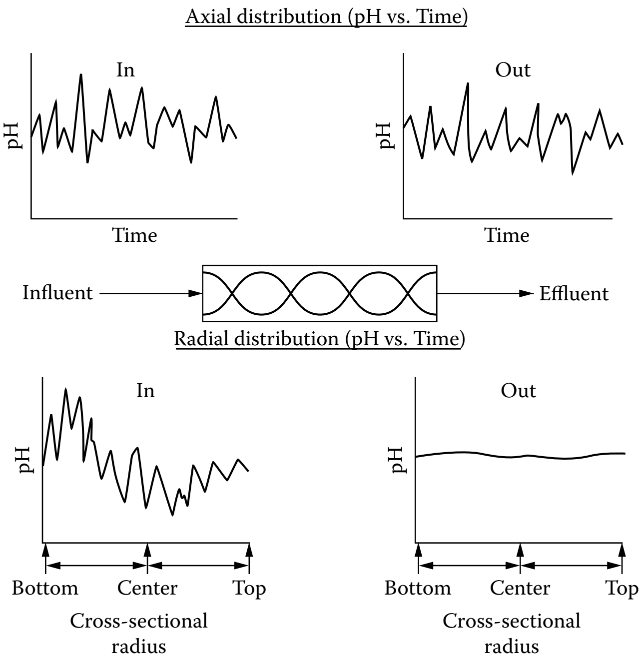

FIG. 8.40q
Axially, the fast disturbances pass through the static mixers, because they provide no back-mixing. This process is dominated by dead time.

6 and 8. The response will always be oscillatory following a disturbance.

An in-line mixer can be a dynamic mixer such as centrifugal pump or a baffled section of pipe called a static mixer. The static mixer provides radial mixing but little back-mixing. It can be considered to be a plug flow process *dominated by dead time.* Disturbances and noise pass through the mixer unattenuated. With such a mixer, the controller response to fast disturbances and noise is no *response at all*, because any corrective action will arrive too late and will create yet another disturbance (Figure 8.40q).

For this reason, a filter is often used on the pH measurement, introducing the largest time constant in the loop to attenuate the type of noise shown in Figure 8.40q. The response to a step change in load of an inline mixer is relatively slow and therefore, when a new train is started up or shut down, upsets are likely to occur.

The advantage of the in-line system is its small dead time loop period and recovery time. Disturbances that have ramp time or time constant greater than that of the in-line mix dead time will reduce the peak error, because the peak error approximates the deviation reached during 150% of the dead time. Averaging tanks downstream from the mixer will attenuate the oscillations that pass through the mixer, and attenuation tanks upstream will slow down concentration upsets. Similarly, valve or set point velocity limits will slow down flow upsets sufficiently to make the use of in-line mixers an attractive economic alternative to well-mixed vessels for even those applications with difficult titration curves.

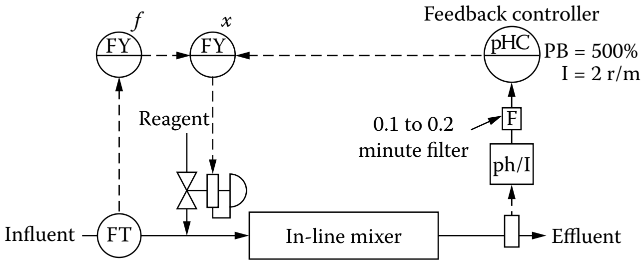

FIG. 8.40r
Flow-based feedforward correction can correct for the sudden changes in influent flow as trains are turned on or off. The reagent should be injected right before the mixer, the sensor should be located at about 10 diameters from the mixer, and its measurement should be filtered.

Filtering and Feedforward In this section, the influents are pumped, and the reagent and influent are both liquids. For pH control, the acceptable control band is greater than 0.5 pH, and an in-line mixer system becomes a low-cost option for continuous pH control. Originally, in-line mixers were relegated to installations with set points on a relatively flat portion of the titration curve. This is no longer the case.

When the set point is on a steep section of the titration curve, a digital filter with a time constant of 0.1–0.2 min can average the severe oscillations sufficiently to provide good control. This technique allowed the in-line mixing method to be used in a wide variety of applications and provided considerable cost savings.

Flow-based feedforward as shown in Figure 8.40r will substantially improve the performance of mixer-based analytical controls. In mixer controls the feedback controller gain is only 0.1–0.2, and the integral (reset) setting varies from two to four repeats per minute while the digital filter is set at 0.2 to 0.1 min. For in-line mixer systems, it is not important to add adaptive gain for flow-based feedforward, because it is a mostly dead time process and the controller gain is already detuned due to measurement noise.

The neutralization reaction is instantaneous once the ions are in intimate contact. The reagents should be injected as close to the mixer inlet as possible, and the measuring electrodes should be located about 10 pipe diameters downstream from the mixer as a compromise between the need to get a more uniform flow profile and the desire to minimize transportation delay.

Override and Selective Control

There are several loops in this section, where the normally operating flow control system is provided with a pressure-based override on a selective basis. In case of such overrides, a pressure controller can take command of a manipulative variable from a flow controller when the pressure would otherwise exceed the equipment limits. Whereas interlocks shut down equipment to avoid exceeding a limit, overrides

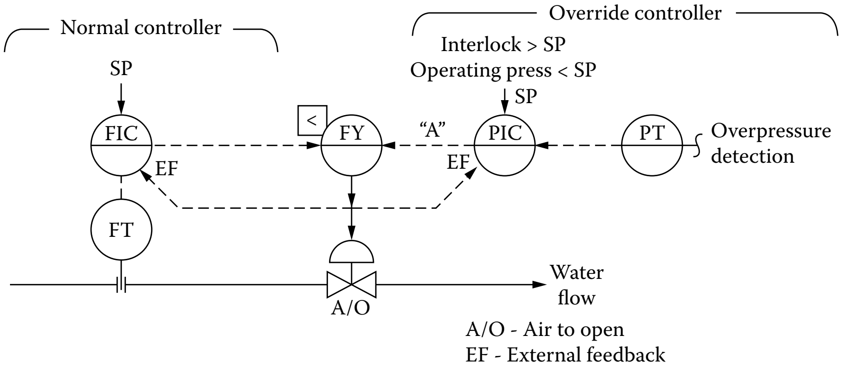

FIG. 8.40s
Flow control with pressure override requires external feedback (EF) to prevent reset windup in the idle controller.

"back off" from the desired operating set points so that the interlock trip point is not reached. Thus, equipment is kept running although perhaps at a suboptimal level.

The signal selectors facilitate the switching from one controller to another. Very often, overrides are preferable to interlocking when safety is not an issue. However, in most applications the overrides should be backed up by interlocks. The definition of overrides can therefore be stated as follows:

"Controllers that remain inactive until a constraint is about to be exceeded, at which point they take over control of the manipulated variable from the normal controller through a selector and, thereby, prevent the exceeding of that constraint."

Figure 8.40s shows a simple override control loop in which the normal controller (FIC) and override controller (PIC) outputs are both fed to a low-signal selector. The override controller set point (in this case, pressure) is set at a maximum value somewhere above the normal operating pressure but below the interlock point. As long as the pressure set point is not exceeded, the output of the override controller "A" is blocked by the low selector and cannot reach the flow control valve.

When the water pressure exceeds the override set point, the controller output decreases and eventually will become lower than the normal controller output and, therefore, will start to throttle the valve to satisfy the override set point. PID control algorithms require "external reset feedback" to avoid integrating the error, i.e., "reset windup," when their outputs are overridden.

CONCLUSIONS

Over the years, water plant controls have become more complex and more automated. The section described some of the PLC-based controls that can be used in conventional water supply treatment plants and in ozone disinfection-, reverse osmosis-, and ultrafiltration-based raw water treatment processes.

The emphasis on PLC-based controls is not intended to suggest that a PLC-type of control hardware is preferred for these types of applications. The treatment in this section reflects the author's experience with a specific application and the type of control hardware that was used in that application.

8.41 Well-Supplied Underground Gas Storage Controls

B. G. LIPTÁK (2005) **G. SZECSŐ** (2005)

INTRODUCTION

This section describes the controls of an actual underground natural gas storage system and the associated distribution network that supplies the nation of Hungary with natural gas. This large operating facility takes the gas from several natural geographic layers of sandstone, pressurizes it to 1450 psig (100 bars), and stores it in a spongy, underground sandstone formation (Figure 8.41a). This underground storage layer is about 3000 ft below the ground, it is about 300 ft thick, and it is penetrated by hundreds of natural gas wells, grouped in two distinct regions, referred to as the Northern and the Southern sites.

The storage facility is operated in two cycles. During the winter, it is in its production cycle (PRC), during which the natural gas is removed from storage and is distributed to the users at between 725 and 870 psig (50 and 60 bars) pressure. The pressure difference of 1450 to 870 psig is used up as pressure

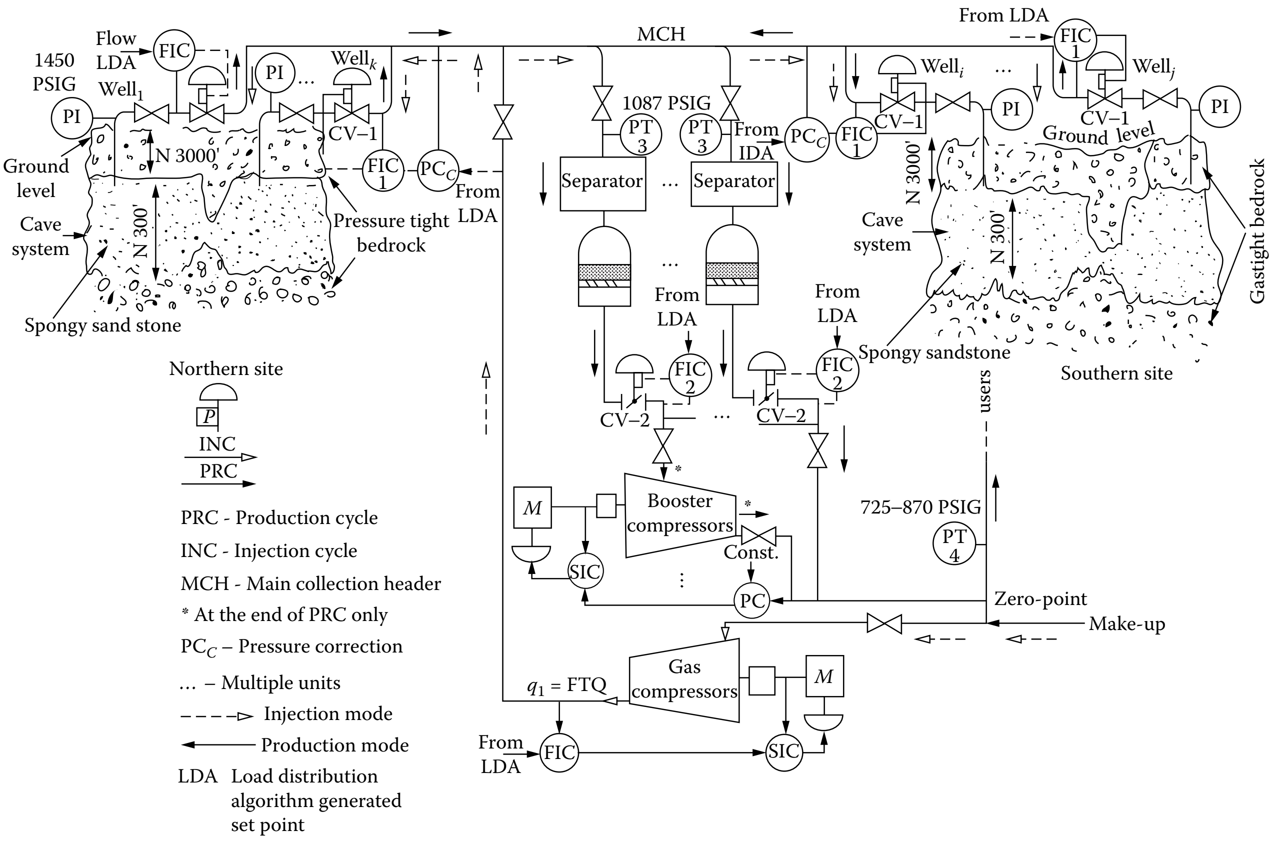

FIG. 8.41a
Schematic representation of an underground natural gas storage facility. It supplies a nationwide natural gas distribution system in the winter, when it is operated in its production mode (PRC). The actual facility consists of 100+ wells, a number of dryers, compressors, and the associated network of piping. Each well connects to a storage area of spongy sandstone. In order not to damage the underground geological formations, the differential pressure between storage areas served by the neighboring one should be minimized.

drop through the well flow control valves (CV-1s in Figure 8.41a), the dryer flow control valves (CV-2s), the dryers, and the connecting system piping. At the end of the production cycle, a booster compressor station can serve to remove the remaining low-pressure gas from storage.

After the production cycle of the winter, the depleted wells are refilled during the injection cycle (INC) of the summer. During this cycle, compressor stations deliver fresh natural gas, obtained from domestic gas containing sandstone layers in the area (and from gas supplied mainly by Russia), into this underground gas storage (UGS) system. Figure 8.41a schematically describes the overall UGS system.

The reader is reminded that the controls for the various unit operations that are utilized in this system are discussed in more detail in the following sections: Section 8.15, Compressor Control and Optimization, Section 8.22, Dryer Controls, and Section 8.28, Header Pressure Control. It should also be kept in mind that what is being described is an operating system that has evolved from a manually controlled process that has been in opreation for nearly a decade.

THE PROCESS

Over millions of years, hermetically sealed multiple hydrocarbon gas layers evolved in the sandstone under Hungary. This region used to be the sea bottom of the ancient Pannon Sea. The natural gas in these layers is extracted and stored in a pressurized artificial storage layer to serve as the gas energy supply of the nation. The shape of the storage layer is elliptical, about 300 ft thick, and is situated about 3000 ft below the surface.

The gas is collected by hundreds of wells, which are grouped at two gas-collecting stations (Northern and Southern sites). The wells are periodically discharged (production mode of operation) and then refilled (injection mode of operation). Piping is provided among the wells and stations, serving the purposes of flow and pressure control. The two stations are also connected by one large-diameter pipe.

At one of these stations, the natural gas is dried and conditioned during the PRC so as to be suited for long-distance transportation. During the reinjection cycle, the natural gas is distributed for reinjection in order to refill the wells during the INC. The whole system is comprised of more than 100 gas wells.

The UGS system therefore consists of the Southern and Northern sites and the above-ground plants, which include the distribution pipelines, separators, dryers, and compressors. The gas supply is divided 60 to 40% between the Southern and the Northern sites, where the majority of above-ground equipment is also located. All gas wells and the above-ground facilities been designed for 1450 psig (100 bars) operation. The gas distribution network is designed for 870 psig (60 bars). If the adequate conditions exist then the above-mentioned two systems will be connected to each other.

The underground gas storage system has two modes of operations, which mostly depend on the seasons. The control system in both modes of operation has to provide protection for the natural geological formations and the sandstone storage, while providing continuous operation either in the injection or the production mode of the underground storage system.

The Operating Modes

The two modes of operation are referred to as the pressure correction control method (PCCM) and the load distribution algorithm (LDA). In both cycles, unique algorithms perform the controls of the process. Digital controls (DCS) are used to implement the algorithms that generate the control signals to the manipulated variables.

Basically, the system has a start-up mode, TWM1 (Technological Working Method #1), during which the controls start the process and supervise the changing operating set points (OP), and TWM2, which stabilizes the operating points (OP) and maintains it in the steady state. During the start-up phase (TWM1), the gas supply to the nationwide distribution network is not stable or tightly controlled. Table 8.41b gives a summary of the two modes of operation.

Injection Cycle

In this mode of operation, single automatic stage flow control (SASFC) is provided with the control loop in automatic (ACM) for the individual gas wells in order to optimize the operation of the whole group of wells. In this mode of operation, the load distribution algorithm (LDA) provides the flow set points for the flow controllers on the individual wells.

TABLE 8.41b
The Two Modes of Operation of the Underground Gas Storage System

Operating Modes (Cycles)	*During the Injection Cycle (INC)*	*During the Production Cycle (PRC)*
Start-up mode: Technological Working Method #1 (TWM1)	Starting process and groups of compressors. Supervising the operating set points (OP).	Starting process for operation in the production cycle (PRC). Supervising the operating set points (OP).
Normal operating mode: Technological Working Method #2 (TWM2)	Stabilizing the operating set points (OP). Supervising gas distribution among wells.	Stabilizing the operating set points (OP). Producing required gas quantity at the required outlet pressure.

During the start-up mode of the INC, the flow into the individual wells is limited by the maximum flows that are allowed for each well. These limits are used in initiating the emergency stoppage of the compressors or the changes of OPs.

One of the goals of the control system is to have the pressure in the main collection header (MCH) approximately approach the average pressure of the underground gas storage (UGS) system in order to minimize the energy consumption of the compressors. This is achieved by the use of weighing factors (WFs), so that the load distribution will be proportional to the capacities of the individual wells.

The compressors are manually controlled, and it is important that the manual changes that modify the injected total gas flow set point do not upset the stable operation of the cascade flow control on the individual wells. When the compressors are restarted after a power failure, they are protected against overpressure.

All other control and safety functions, including control mode switching and emergency responses, are the same as used during the PRC, which is described below.

Production Cycle

In this mode of operation, single automatic stage flow control (SASFC) set points are provided for the single flow loops on the individual wells and also for the wells that are provided with LDA cascaded flow control. The LDA serves to guarantee that the total gas produced matches the total demand. The flow set points of the individual gas wells are set according to their WFs with minimal actuator actions.

During the operation of the system, it is necessary to limit the pressure drop across the control valve (CV-1 in Figure 8.41h) between the wells and the MCH and also on the dryers (CV-2 on Figure 8.41k) to 290 psid.

When the production OP is steady, it is the goal to limit the error between the actual and the desired flow (*Q*) to ±1%. It is desirable to keep the control system operable even if the measurement errors of the ultrasonic flowmeters on the gas wells (F^w in Figures 8.41h, j, and k) increased or if deep groundwater interfered with their operation.

It is also desirable that the upset caused by the manual starting of the booster compressor station should not interfere with the operation of the other control loops.

MODELING AND SIMULATION

The simulation of the operation of the total system requires the modeling of the individual equipment components, which are listed in Table 8.41c.

The overall system model is composed of several submodels. The first submodel is the model of the individual wells (GGW1, GGW2, and so on), which includes the models of the valves, sensors, and their PI controllers. The typical operating conditions of a well are listed in Table 8.41d.

TABLE 8.41c
Submodels Are Required of Each System Component in Order to Model the Total System

System Component	*Function*
Control valve (CV-1)	Control valve with positioner* and its programmable characteristic curve, which controls the gas flow from each individual well
Butterfly valve (CV-2)	Butterfly valve with positioner* to control the flow through the dryers
Flowmeter (F^w and F^d)	A sonic, gas flow-measuring block with programmable timing from 5 to 60 readings
Main collection header (MCH)	The model for the main collection header is a block that is a nonconcentrated and nonlinear, long-distance pipe model
Dryer	The model representing a dryer block with variable capacity
Well group	The model of three groups of gas wells
Dryer group	The model for a group of dryers
Controller (PID)	Proportional and integral control** algorithms for the flow controls of the gas wells and the dryers
Load	A variable load change model for the zero point

* Generally we do not use positioners on flow control valves, because flow is a fast process and the positioner cannot keep up with it, which results in detuning of the controller and in limit-cycling and hunting.

** In cascade configurations, external reset is required to protect against integral windup, when the loop is switched from cascade to manual or direct slave control.

The other three submodels are that of the MCH, the group of dryers (GD), and the simulated load change (LC). While the model of the gas wells (GGW1, GGW2, and so on) can use real, dynamically measured data, the other three

TABLE 8.41d
Typical Operating Conditions Used in Modeling the Wells

Parameters	*Conditions*
Gas temperature	$T = 50°F$
Set point (reference signal) change	$\Delta q = 1310$ yd^3/h
Set point (work point) at steady state	$qst = 3270$ yd^3/h
Average system pressure	943 psig
Sampling time of flow detection	15 sec*
PI controller tuning parameters**	PB = 150%, Integral time = 120s/repeat

* The sampling time on flow loops should be much shorter than 15 sec. Also, because of their noisy nature only positional algorithms should be used.

** These tuning parameters can be improved (PB narrowed, integral time shortened), if the valve positioner is eliminated.

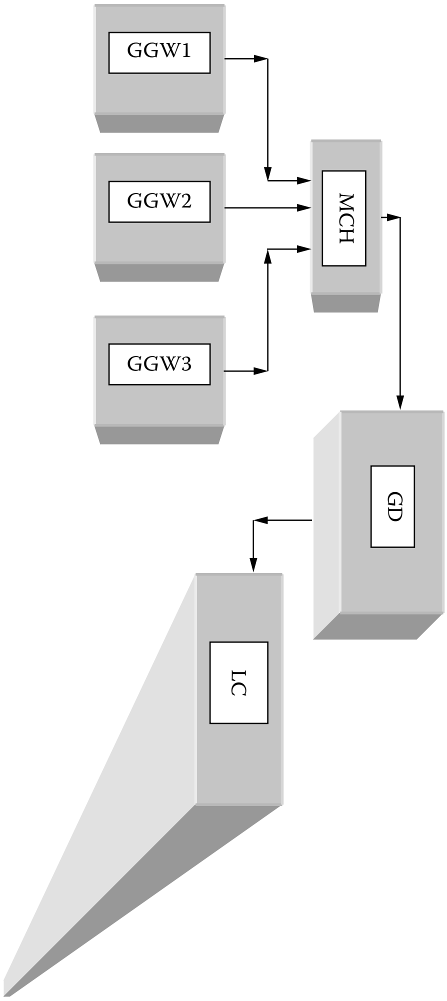

FIG. 8.41e
Functional block diagram of an integrated gas storage model, where GGW1–GGW3 are the submodels of the gas wells, MCH is the submodel of the main collecting header, and GD is the submodel of a group of dryers and represents a simulated load change (LC).

submodels utilize only statically measured inputs. Figure 8.41e illustrates the relationship of these submodels within the total model of the gas storage system model.

In order to decrease dynamic and static deviation, nonlinear control needs to be used. Capacity of the gas well has a long-term (monthly) and a short-term (hourly) characteristic. In either case, the pressure drop across the control valve (CV-1 in Figure 8.41h) affects the dynamics of the flow control loop. For this reason, adaptive control is desired to adapt the tuning of the loop to the changing inlet pressure to the valve. The effect of the variations in outlet pressure can be minimized by pressure compensation.

GENERAL CONTROL CONSIDERATIONS

The quality of control can only be as good as the sensors, the control valves, and the control algorithms used. Therefore, it is desirable to carefully consider their requirements.

Sensor Selection

It is important that when two flowmeters operate in series, such as the flow sensors at the wells (F^w in Figure 8.41h) and at the dryers (F^d in Figure 8.41i), they be calibrated together, so that they will give the same readings at the same flow rates.

It is also important that the sampling time of the flow sensors be short enough so that their contribution to the flow control loop dead time is minimum, because otherwise the flow control loop will cycle. It is also important that only smart, self-diagnosing sensors be used, and only those suppliers be considered that have substantial experience with natural gas service applications. As can be seen from Table 8.41f, the number of ultrasonic flowmeter suppliers is large, but as of this writing the most experienced are Daniel and Instromet.

Control Valve Selection

The proper selection of control valves is equally important. On fast loops such as flow control loops, the use of positioners is rather questionable, because in effect the positioner is the cascade slave of the flow controller, and therefore its time constant should be one tenth of its master, and such high-speed positioners are seldom available.

A controlled process can be considered “fast” if its period of oscillation is less than three times that of the positioned valve. In such situations, the positioned valve is one of the slowest components in the loop, and therefore it slows the loop down (limits the open-loop gain of the loop and lengthens its period of oscillation). In such cases the loop without a positioner can be tuned more tightly (for higher gain and more repeats/minute); such a loop responds better without a positioner. It might also be noted that after a new steady state is reached, the positioned installation can provide more noisy control because of the hunting and limit cycling of the positioner, if it cannot keep up with the process.

Some will argue that all loops can be controlled using positioned valves if the controllers are sufficiently “detuned.” This is true, but “detuning” means that the controller is made less effective (due to a reduction in the amount of proportional and integral correction), which is undesirable.

Controller Algorithms

On fast and noisy processes such as on flow loops, positional digital algorithms are preferred (see Section 2.4 in Chapter 2). It is also recommended that the sampling time of the flow loops should be short, because the sample period is pure dead time. Therefore, for example, if a set point change can occur faster than several sampling periods, the loop will be upset. Consequently, if large set-point changes are anticipated and fast loop response is required, one should increase the sampling frequency.

It is also important that when a cascade configuration is used, the controller be provided with external reset, so that its integral mode will not wind up when its output signal is

blocked from reaching the control valve, because the loop has been switched to manual.

Lastly, one should keep the total loop gain constant, because the proper tuning of the controller cannot be maintained if the loop gain varies. Therefore, if the control valve gain is not constant, which is the case with all valves except the linear ones, valve compensators should be used. This is also the case with butterfly valves.

Pressure Correction

In the following paragraphs, three control loop configurations will be described for controlling the flow from the individual wells: 1) cascaded total flow master setting individual flow loops as its slaves, 2) combination flow/pressure cascade master, and 3) combination cascade master based on flow and pressure correction from the main collection header.

Pressure correction of the flow control loop can improve the quality of flow control both in terms of accuracy and in terms of reducing the size of the upsets caused by sudden load changes. A method of pressure correction will be described in the following paragraphs that can also be useful in keeping the pressure drop across the dryers constant and in keeping the total natural gas flow from the facility constant.

Different control algorithms will be described for use when the load is increasing or decreasing and to achieve bumpless transfer between the manual and automatic modes of controller operation. Figure 8.41g illustrates the response

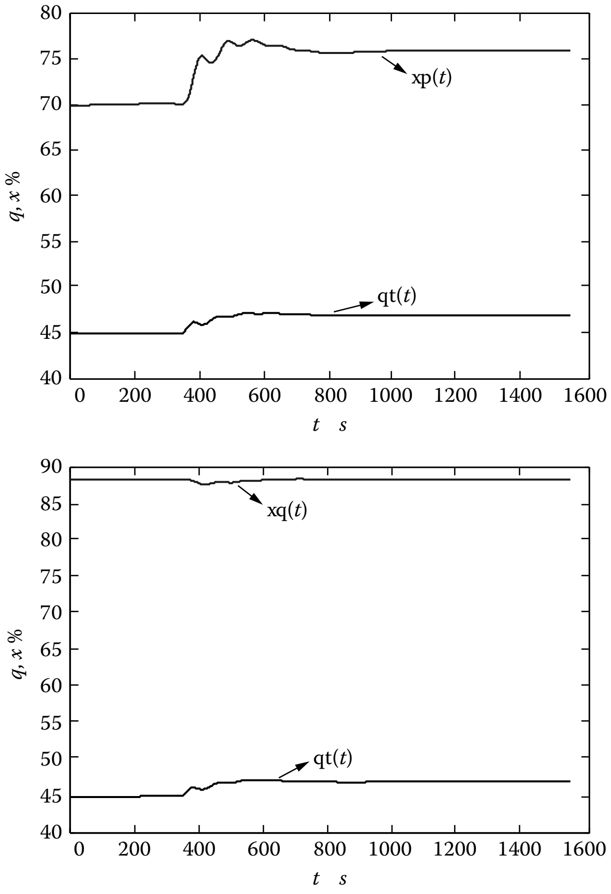

FIG. 8.41g
The response of the pressure-corrected natural gas flow control loop to a sudden change in set point.

of a pressure-corrected flow control system when responding to sudden change in the required flow rate.

CONTROLLING THE INJECTION CYCLE

After the winter season, the exhausted wells must be recharged. This is done by switching the system to the INC, which is shown by the dashed arrows in Figure 8.41a. During the injection cycle, the exhausted storage wells are recharged by natural gas that is lifted by compressors from other layers of the sandstone deposits of the region and from Russian gas imports. The compressors pressurize an MCH, from which the gas is distributed to the individual wells that need recharging. The pressure in the MCH is a function of the flow rate of gas delivered by the compressors and the permeability (the rate at which the spongy sandstone in the wells can absorb the gas).

The wells in the more porous sandstone layers can receive and store the gas faster. These are called “soft wells.” The less porous formations can accept the gas only at a slower rate. These are called “hard wells.” The control task is to refill the underground storage system, while on the one hand using a minimum amount of compression energy and on the other hand protecting the underground geological formations from damage, caused by excessive pressure differences between the wells serving neighboring storage areas.

If one based the operation only on the permeability of the “soft” wells, the MCH pressure could be relatively low and much compression energy would be saved, but the speed of recharging the “hard” wells would suffer. If the MCH pressure was maintained at a level that keeps the rate of recharging of the “hard” wells efficient, compression energy consumption would be high, and much compression energy would be burned up as pressure drops in the gas valves serving the “soft” wells. In addition, the pressure differences between soft and hard wells could cause damage to the geologic formations.

The task of the control system in the reinjection mode (INC) is to find a reasonable compromise.

Prestart-Up Settings

The operator manually initiates either the start-up mode (TWM1) or the operating mode (TWM2) of the control system. Prior to start-up, the operator should enter the following constants:

ETMI	The expected total mass of the gas that is to be stored, in m^3/h
ALSW	The amount of gas that can be admitted into each well, in m^3/h
IWFW	The initial weighing factor for each well
FRSS	The slope at which the total flow rate can change, in (m^3/h)/h
MVSM	The rate at which a single well’s control valve signal can change in %/h
MDPH	The maximum pressure difference between the average well pressures (p^w in Figure 8.41h) and the pressure in the main collection header (P_c in Figure 8.41k) in bars
DFSWi	The direction of flow that can be measurement or production
AFSW	A flag indicating if the particular well is active or on standby
CMW	The control mode for the flow controllers on the individual wells
MVLS	The low-signal limit for the control signal to the valve (CV-1 in Figure 8.41h) in %
MVHS	The high-signal limit for the control signal to the valve (CV-1 in Figure 8.41h) in %

START-UP MODE

The start-up mode (TWM1) is used: 1) during the initialization of the INC when the compressors are being started, 2)

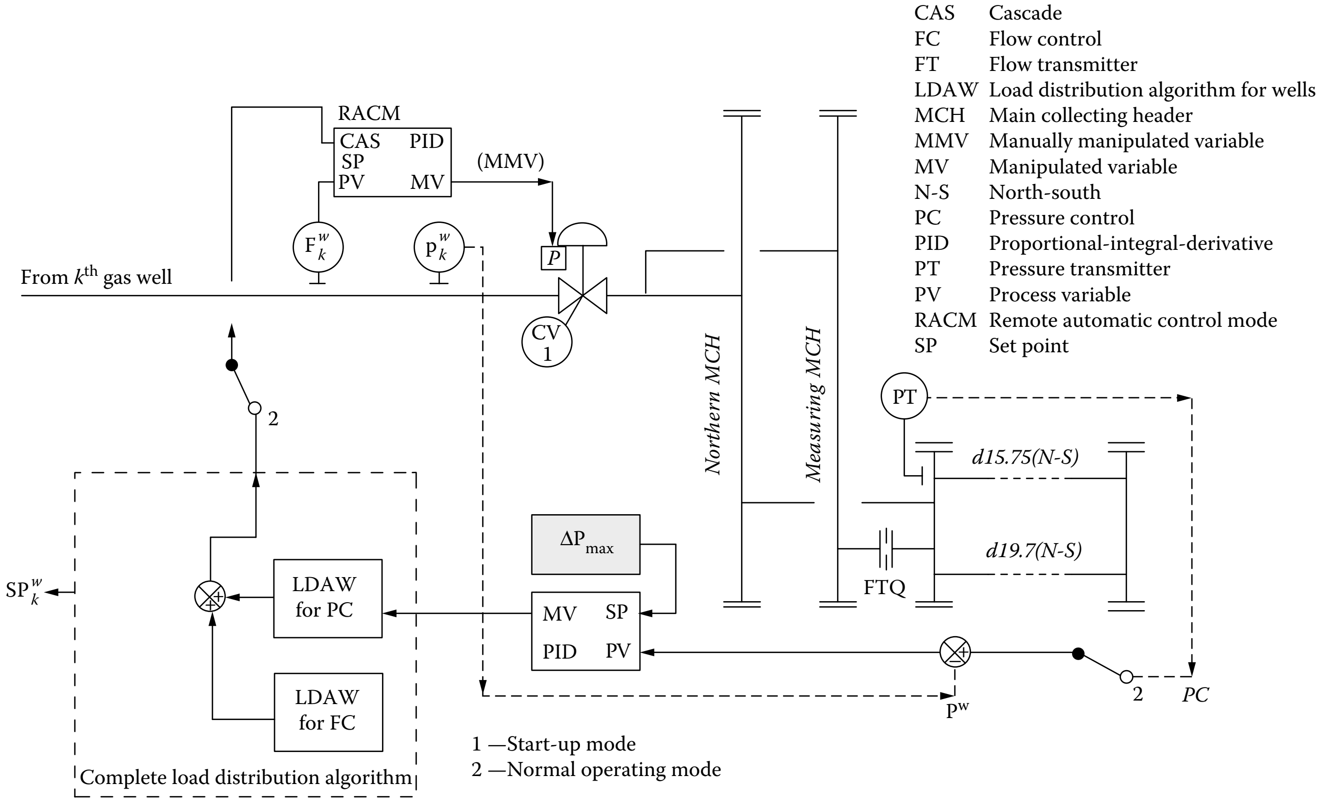

FIG. 8.41h

The flow control loop on each well is cascaded to properly distribute the total flow and to keep the pressure drop across the control valve (CV-1) under a maximum limit.

when the flow distribution among the compressors is being changed, 3) in case of problems that necessitate that the operator initiate manual corrections, 4) prior to the activation of the safety controls to protect against the development of overpressure at the end of the injection operation (INC), and 5) during upsets that result in fast changing (high-transient) operating conditions.

At the beginning of the start-up operation the control valves (CV-1 in Figure 8.41h) are totally opened and the active wells imbibe (absorb) the gas according to their natural permittivity (the rate at which gas can be absorbed). When the flow rate reaches its maximum limit, which is set for each particular well, the flow controller is activated and maintains its set point at that limit. This maximum flow stage of operation continues as long as the compressors can meet the demand by lifting the required quantity of gas.

The pressure that is developed in the MCH is a function of the permittivity of the "soft" gas wells. When the compressors can no longer meet the demand for gas, the pressure in MCH drops and the remaining gas is charged to the soft permittivity gas wells. These remaining gas quantities (lent values) are delivered at flow rates that are controlled at a maximum limit for each well.

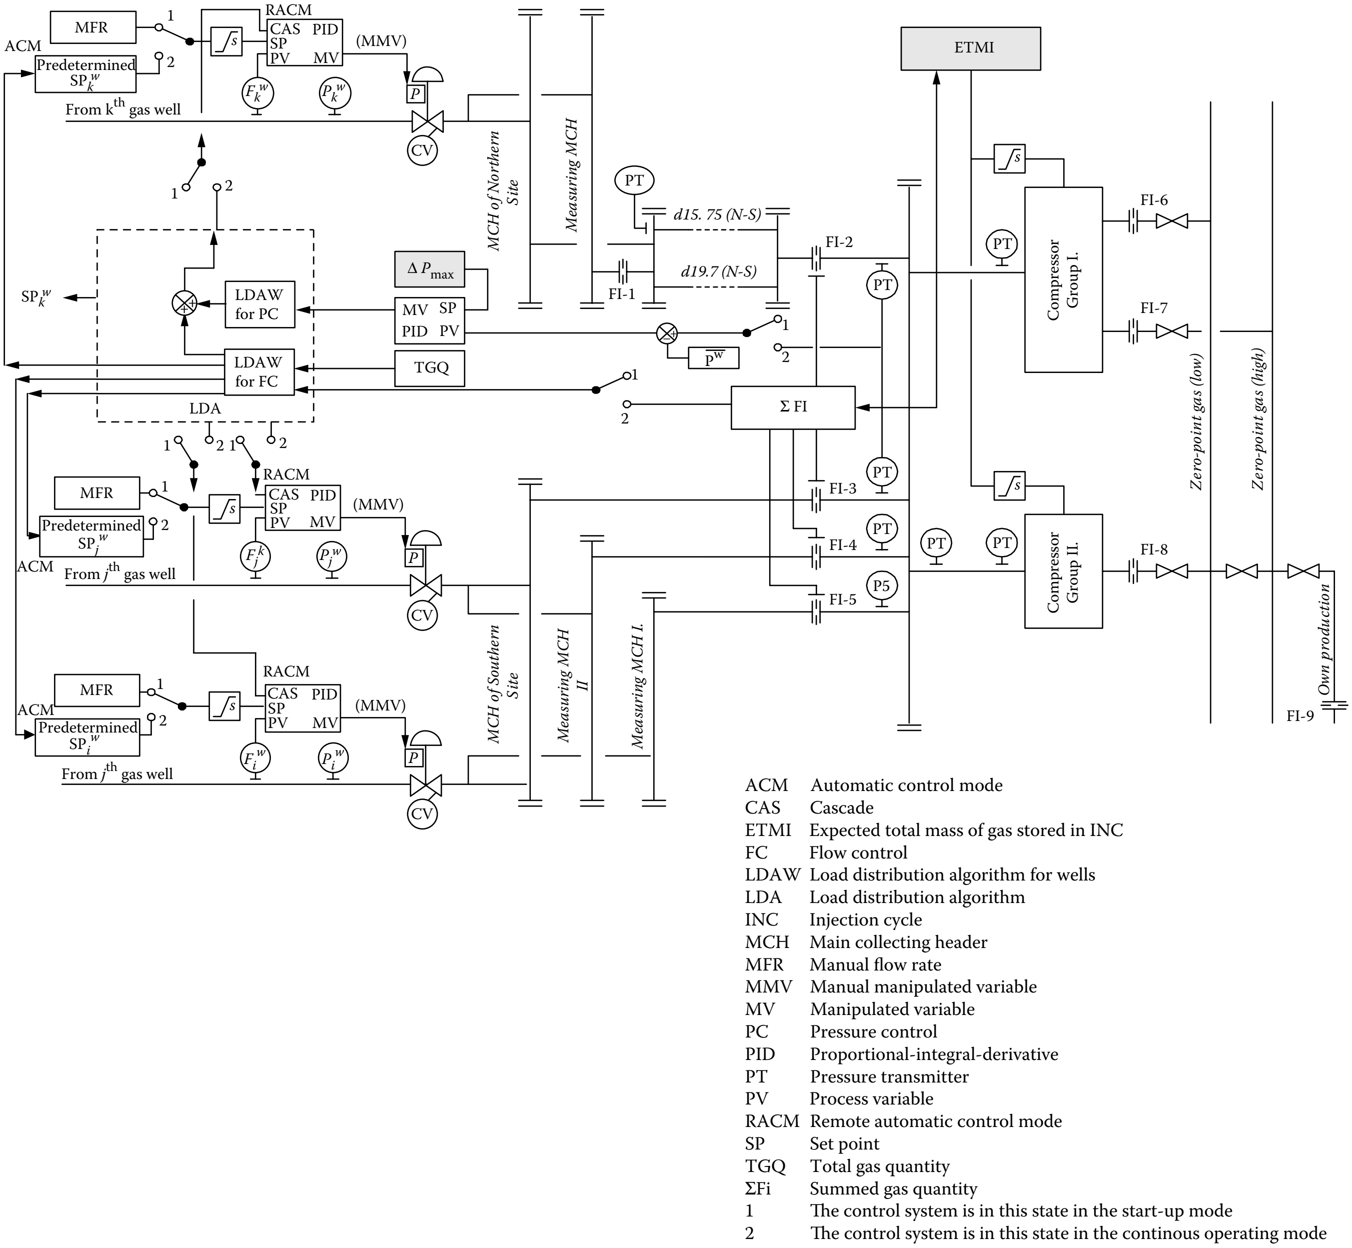
During the reinjection cycle (INC), the pressure in the storage wells is increased, while the actual amount of gas stored is a function of the permittivity of the individual wells. The storage pressures obtained in the individual wells will be different because of the differing permittivity of the wells, but this pressure difference must not be excessive, because the pressure differences between underground storage layers can damage the geological structures.

The requirements for energy-efficient operation of the compressors is different if they are serving hard or soft permittivity wells. In case of hard permittivity wells, the compressors can efficiently charge them at maximum flow rates, but if soft permittivity wells are also served, the pressure loss across their control valves will be large, which represents a waste of energy. In case of the soft permittivity gas wells, the minimum level of compressor operation (minimum lifting energy) is insufficient to develop the pressure required for the wells to efficiently absorb (imbibe) the gas.

The overall control system and equipment used during the INC of this underground gas storage facility is shown in Figure 8.41i.

Operator Actions in the Start-Up Mode

After the parameters that were listed in the previous paragraph have been specified, the system is placed in the start-up mode (TWM1) and is started up in manual, under the supervision of



ACM	Automatic control mode
CAS	Cascade
ETMI	Expected total mass of gas stored in INC
FC	Flow control
LDAW	Load distribution algorithm for wells
LDA	Load distribution algorithm
INC	Injection cycle
MCH	Main collecting header
MFR	Manual flow rate
MMV	Manual manipulated variable
MV	Manipulated variable
PC	Pressure control
PID	Proportional-integral-derivative
PT	Pressure transmitter
PV	Process variable
RACM	Remote automatic control mode
SP	Set point
TGQ	Total gas quantity
ΣFi	Summed gas quantity
1	The control system is in this state in the start-up mode
2	The control system is in this state in the continous operating mode

FIG. 8.41i
The equipment and control system used in the reinjection of natural gas into underground storage.

the operator. The start-up sequence involves the switching of all controllers to the manual mode and setting their output signals (manipulated variable signals to the control valves) to their low limit values (MVLS).

All flow control loops on all wells (AFSWi) are activated. Compressor groups are loaded up at a rate that is less than the rate allowed (TDTR) for reaching stable state of the system. When the flows have stabilized, the operator switches the controllers to automatic and specifies the maximum total flow rate limit for the facility. The operator also adjusts the set point of the flow controller to the admissible load (AL for INC) and switches the controllers to automatic.

The operator checks the rate and stability of the flows into the active wells, while isolating the nonoperative gas wells. The initial flow rate that was set by the operator (AL) is overridden by the LDA, as the set points of the flow controllers are automatically modified. At this point, the local or remote automatic control mode of the flow controllers is switched to cascade control, which provides pressure correction, and the control system is switched from the start-up mode (TMW1) to the production mode (TWM2). When in the production mode, the total gas flow is distributed between the wells according to the weighing factors of the individual wells.

Normal Operating Mode

In the normal operating mode of the injection phase (TWM2), the set point of the individual flow controllers on the individual wells is provided as shown in Figure 8.41h. The charging rate into the wells can be manually determined by the operator, can be automatically maintained as a preset portion of the total flow, or can be adjusted in a cascade manner to also consider the compressor discharge pressure and the openings of the operating control valves. The goal of the control system is to match the rate of natural gas supply generated by the compressors with the rate at which the operating well can accept that flow and to do that without either wasting compressor energy or creating unsafe overpressure conditions.

Artificially determined weighing factors are used to describe the permittivity of each well. The operator can choose to switch the system into the normal mode (TWM2), if the following conditions exist: The injected total gas flow rate is stable, the starting of the compressors or the changing of their loading been completed, and the distribution of the total gas flow among the wells can be handled by making small changes in the set points of the corresponding flow controllers.

In the normal mode of operation, the flow rate set points of the wells are determined by distribution of the total gas flow in proportion to WF of the wells. The flow set points are redistributed if the total injected or supplied quantity of gas changes. The change in the total flow rate has to exceed the limits of a dead zone (dead band) before automatic redistribution is initiated, but the operator can also initiate this redistribution.

Pressure Correction and Flow Balancing The total flow generated by the compressors is detected by orifice plates (FI-1 in Figure 8.41i), while the flow received by the active wells is the sum of the active ultrasonic flow sensors (F^w in Figures 8.41h and i). If the two flows are not the same, the imbalance will change the pressure in the MCH, and to avoid that, the total flow has to be redistributed among the active wells. Equation 8.41(1) describes how the individual flow set point is calculated for a particular well, in order to keep the pressure in the MCH (the reserve pressure in the main collection header) constant.

$$\mathrm{SP}_i^w = F_i^{\min} + \left[\sum_{i=1}^{n} F_i^{\text{injected}} \mathrm{SC} \left(\frac{\sum_{i=1}^{m} F_i^{ns}}{\sum_{i=1}^{m} F_i^{\text{injected}}} \right) - \sum_{i=1}^{k} F_i^{\text{man}} - \sum_{i=1}^{l} F_i^{\text{man, aut, cas}} \right] \frac{\mathrm{WF}_i}{\sum_{i=1}^{m} \mathrm{WF}_i} \qquad \mathbf{8.41(1)}$$

During reinjection (INC), constant pressure in the MCH indicates a balance between the supply and demand for gas, because the gas quantity lifted by the compressors matches the amount of the injected gas mass.

If more gas is lifted by the compressors than the amount of gas pressed into the wells, the pressure of the MCH will increase. When this occurs, the pressure correction cascade algorithm in Figure 8.41h will increase the set points of the flow controllers on the wells that can safely accept more gas.

If the mass of gas lifted by the compressors is less than the amount pressed into the wells, the pressure in the MCH decreases and the control valves serving the soft permittivity wells will not receive enough gas, so they will fully open. When this happens, the operator will switch the system to the PCCM if the flow into the soft permittivity wells is higher than maximum allowed. In this case, the pressure correction controls (PCC) will lower the automatic and cascade set points of the flow control loops of the “soft” wells and redistribute the total flow. If the flow through the fully opened valves falls below their minimum limit for the soft permittivity gas wells, the redistribution process will stop.

Because of flow sensor errors and other considerations, the total gas quantity (TGQ in Figures 8.41a and h) is calculated as follows:

$$q_2 = v q_1 \mathrm{SC} \qquad \mathbf{8.41(2)}$$

where

q_2 is the total gas flow (TGQ) that is measured by ultrasonic flow sensors

v is the average deviation ($q_1 - q_2$) of the previous sampling period

q_1 is the total gas flow (TGQ) that is measured by an orifice-type detector

SC is a system constant

In order to minimize the power consumption of the compressors, the pressure in the main collection header should be minimized. When this minimized pressure is stabilized, the flows into the active wells will differ, as soft permittivity gas wells can accept more and hard ones can take less flow. Consequently, the soft permittivity gas wells will not receive all the flow they could take, and their control valves will fully open (100%).

Once a control valve is fully open, it is out of control and cannot maintain the flow set point requested by the LDA. Under these conditions a new, experience-based flow set point is applied to these soft permittivity wells as their maximum flow rate (MTSP). If the flow into a soft permittivity gas well exceeds this MTSP, the total flow is redistributed among the active wells to maintain it. The goal of this redistribution is the deactivation of the hard permittivity gas wells. The redistribution procedure modifies the set points of the flow controllers according to the following relationship:

$$\mathrm{SP}_i^k = \mathrm{SP}_i^{k-1} - \left(\sum_{i=1}^{n} \mathrm{SP}_i^{\mathrm{AUT+CAS}} - \sum_{i=1}^{n} \mathrm{F}_i^{\mathrm{AUT+CAS}} \right) \frac{1}{2} \frac{\mathrm{WF}_i}{\sum_{i=1}^{n} \mathrm{WF}_i} \qquad \mathbf{8.41(3)}$$

The redistribution procedure based on Equation 8.41(3) is executed every 15 min, until the actual flow into the soft permittivity gas well drops below MTSP.

Manual, Automatic, and Cascade Control Modes

The flow control loop can be in manual (MCM), local automatic (LACM), and remote cascade (RACM). When the controller is in manual, the control valve (CV-1) is manually throttled by the operator. This is the case if the ultrasonic flow sensor (F^w) is out of service. This is referred to as the manual control mode (MCM).

The controller is in local automatic (LACM) at the beginning of both the start-up and the continuous operating modes or when load changes occur. In the start-up phase (TWM1), the set points of the controllers are set to a maximum value that corresponds to the admissible load of the particular well (ALSW). In the continuous operating phase (TWM2), the flow controller set point is determined on the basis of the weighing factor (WF) that is assigned to the particular well by the load distribution algorithm (LDA). This set point is also limited, so that the LDA cannot move the set point higher than the allowable maximum for the particular well. The operator can manually modify this set point when necessary.

The flow controller is in cascade or remote automatic (RACM) when the pressure correction mode is active. In all control modes, the rate of change of the flow measurement signal is limited until the steady state is reached. When in the continuous operating mode (TWM2), the set point of the flow controller is adjusted to protect against overpressuring the system.

Controlling Valve Pressure Drops

In the reinjection mode of operation (INC), the energy consumption of the compressors rises as the pressure differential across the control valves rises. The higher this differential, the more energy is wasted. In such distribution control systems, it is recommended to use valve position-based optimization, which is described in detail in connection with Figure 8.15dd in Section 8.15.

As the system is started up in the reinjection mode (TWM1), the pressure in the MCH is minimum, and therefore the valve pressure drops are also low. During this phase of operation, if the flow controller set point is limited to its maximum flow rate, the differential pressure between that of the MCH and the average pressure at the side of the gas wells will not be excessive.

During the continuous mode of operation (TWM2) the pressure drop across the control valves is limited to a programmed value (dPmax). The development of an overpressure in the MCH can be eliminated by sending more gas to the best permittivity gas wells. This cascade controller configuration for the best permittivity wells is shown in the lower part of Figure 8.41h. The set point of these controllers can be calculated by the following equation:

$$\mathrm{SPi}^{\mathrm{CAS}} = \mathrm{SPi}^{\mathrm{FLOW}} + \mathrm{MV}^{\mathrm{PRES}}(\mathrm{Fi}^{\mathrm{MAX}} - \mathrm{SPi}^{\mathrm{FLOW}}) \times \mathrm{MV}_{\mathrm{max}}^{\mathrm{PRESS}} \qquad \mathbf{8.41(4)}$$

The cascade controller shown in Figure 8.41h serves to lower the pressure in the MCH by increasing the set points of the flow controllers serving the high permeability wells, according to Equation 8.41(4). This nonlinear algorithm stabilizes the MCH pressure at a level that is below the allowable maximum. These algorithms can also respond to fast pressure transients, because they do not contain any ramp functions that would limit the rate of rise of their measurements.

Protecting the Compressors

If the discharge pressure or the rate of change of the discharge pressure of any compressor exceeds its predetermined limit, the control system is automatically switched back into its start-up mode (TWM1). The system is also switched automatically to the start-up mode if the control valves on half of the operating wells exceed their 90% opening.

Alarm signals are actuated if the tale gas flow of the gas well that is under pressure-corrected cascade control reaches its maximum limit. Another condition that initiates a warning signal is when the flow rate to half of the active wells exceeds their predetermined maximum admissible load settings (MVAL). Another element in the safety logic of this control system is that if the opening of a valve exceeds 80%, it cannot be switched to cascade. In that case, the operator has the option of either activating new wells or switching controls of that well to the start-up mode (TWM1).

Additional safety-related logic steps include the stopping of compressors if, after activating the start-up mode (TWM1), the total lifted gas quantity (TGQ) is less than 25%. After the compressors are returned to stable operation at their expected OPs, the system can be returned to the operating mode (TWM2). The control system will automatically switch to the start-up mode (TWM1) if the discharge pressure or its rate of rise exceeds a preadjusted maximum limit value.

CONTROLLING PRODUCTION CYCLE

The natural gas that was compressed into the underground storage facility during the summer months is used up in the winter. Therefore, as the heating season approaches, the gas wells are switched from the injection (INC) to the production

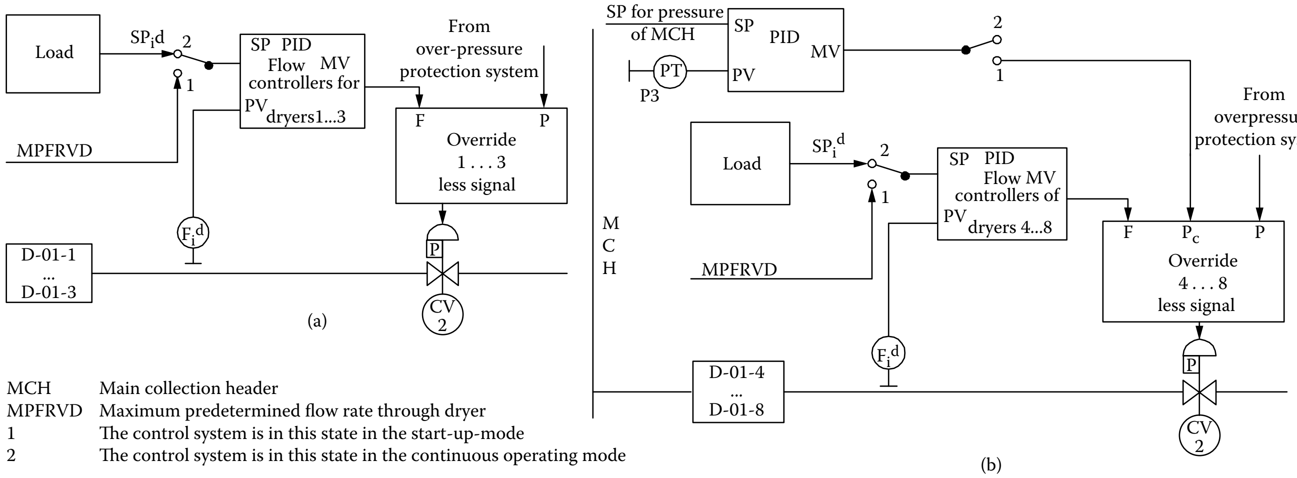


FIG. 8.41j
Dryer flow control algorithms for low- and high-capacity dryers. Note that the high-capacity dryers (b on the right of the figure), when in their start-up mode, are provided with a pressure override, which controls the pressure in the main collection header (MCH).

(PRC) mode. In this mode of operation the gas that is stored at about 1450 psig (100 bars) in the wells is admitted under flow control into the main collection header (MCH in Figures 8.41a, j, and k). This header is held at 1087 psig (75 bars) and supplies the large- and small-capacity dryers (Figure 8.41j).

The gas flow through the individual dryers is under flow control. The set points of the individual flow controllers (FIC-2 in Figure 8.41a) are adjusted so that, on the one hand, their total flow matches the total demand of the users. On the other hand, these set points are corrected to keep the pressure in the MCH (PT-3 in Figure 8.41a) at 1087 psig, while keeping the "zero point" pressure (the pressure at the beginning of the distribution header, detected by PT-4 in Figure 8.41a) below its high limit of 870 psig (60 bars).

Start-Up

After the START command, the flow controllers on the individual gas wells receive their set points on the basis of the LDA and move to that point at a preset rate (FRS). After the pressure of the MCH has stabilized, the required (expected) total gas flow (ETMP) is sent through the dryers in a distribution set by the operator.

In the start-up mode (TWM1) of the production cycle (PRC), the flow control loops on each active well are switched to their local automatic modes (LACM), and their set points are automatically established according to Equation 8.41(5) as follows:

$$SP_i^w = \left(Q_{\text{total}}^{\text{prescribed}} - \sum Q_i^{\text{manual}}\right)\frac{WF_i}{\sum_{i=1}^n WF_i} \qquad \mathbf{8.41(5)}$$

where

SP_i^w is the set point of the flow controller on the individual well
WF_i is the weighing factor for each individual well, which determines its share of the total flow required

The set points of the flow controllers are gradually increased according to the rate determined by a preprogrammed length of transient time (TDTR), which sets the new value of this set point, determining its slope. Similarly, the task of the control valves downstream of the dryers (CV-2 in Figures 8.41a, j, and k) is to maintain the pressure in the main collection header at a pressure of 1087 psig (75 bars). This is necessary in order to provide a steady pressure drop across the dryers. At the same time, the flow rate through the individual dryers is set to its predetermined maximum flow rate, and override controls are actuated if that limit is exceeded.

Pressure Correction During the production cycle, it is necessary to apply pressure correction to the MCH in order to maintain a constant pressure drop across the dryers, but this goal is subordinated to the necessity of meeting the total user's demand for conditioned gas.

The gas flow from the individual wells will be constant if the pressure in the MCH is stable, because this keeps the pressure drop across the well flow control valves (CV-1 in Figures 8.41a and j) constant. It is desirable to keep the MCH pressure relatively high, because that provides the driving force for high production rate. This relatively high pressure can be maintained as long as the pressure in all the active gas wells is greater than the pressure in the MCH.

Continuous Operation

After start-up, the system is switched into continuous operation (TWM2), during which the supply from this UGS must match the gas demand of the countrywide distribution network. The actual total gas flow (TGQ) obtained during start-up (TWM1) is usually not equal to the expected total (EFRD). In order to correctly match the supply to the demand and, thereby, stabilize the pressure in the main collection header, the control system has to be switched into its continuous operating mode (TWM2).

Before changeover, the operator must set the allowable set-point ramp rate for the dryers (SPR) and the admissible or required load or production rate for each dryer (AL). The pressure controllers (PCc in Figure 8.41a) that control the pressure in the MCH are configured as the cascade masters of the well flow controllers that are assigned to pressure correction. Also before changeover to the continuous production mode (TWM2), the individual well flow controllers must be in automatic and should be delivering the gas flows matching their set points. See Figure 8.41j for a schematic description of the two algorithms used for dryer flow controllers.

In the continuous mode of operation (TWM2), the system automatically performs the following functions: It calculates the total gas flow that the UGS should produce (ETMP). The operator then sets the set points of the dryer flow controllers based on this total required flow, using the LDA to make sure that each dryer is assigned the right flow. When the load demand is changing, the algorithm revises its recommended set points, which are then modified by the operator.

In determining the set points for the individual dryer flow controllers, the control system limits that value to the maximum flow rate that is allowable through the particular dryer (MFRD). If the calculated set point is below the MFRD of the dryer, the operator is not allowed to modify that setting. The dryer flow set point is calculated as follows:

$$\mathrm{SP}_i^d = \left(\mathrm{ETMP} - \sum_{i=1}^{n} \mathrm{MPFD}_i \right) \frac{\mathrm{MVAL}_i}{\sum_{i=1}^{n} \mathrm{MVAL}_i} \qquad \mathbf{8.41(6)}$$

where

SP_i^d is the set point for the particular dryer

ETMP is the required (expected) total amount of gas to be produced

MPFD_i is the predetermined maximum flow rate that the particular dryer can handle

MVAL_i is the maximum value of the flow that a particular well can produce

If some of the dryers are already operating at their maximum (MPFD), the required total production (ETMP) must be met by setting the flow controllers on the other dryers, in accordance with Equation 8.41(6).

Switching the Operating Modes When the operation is stable, the operator can switch the system back into the start-up mode (TWM1), but the normal mode of operation is continuous (TWM2). When the system is in the continuous mode, the set point of the flow controllers on the individual wells is cascaded for pressure correction (PCCM), while the flow controllers on the dryers are in their automatic flow control mode.

Switching between operating modes should be bumpless, and the pressure in the MCH should be controlled by pressure correction (PCCM). The set points of the dryer flow controllers remain the same as existed before the mode change. If the operator changes the set-point values, the rate of change is limited by the slope that is predetermined for each dryer (FRSD).

Control Modes and Loops

Figure 8.41k describes the equipment and controls used in the production mode of operation. The main components of this system include the wells that supply the gas; the MCH, which collects and transports the gas to the dryers; and the header, which takes the gas to the users. The demand for the gas is determined by the users, while the supply is a function of the gas flows from the operating wells. If the supply and demand are out of balance, the pressure in the MCH will change.

The control system described in Figure 8.41k serves to match the supply to the demand, while protecting the component subsystems (wells, dryers) from sudden upsets or from overpressure conditions. Because both the accuracy and the rangeability of the flow sensors are limited, pressure correction is used to maintain the balance between gas supply and demand.

Controlling the Wells

If the ultrasonic flowmeter that is serving the flow control loop of a particular well fails, the loop is switched to manual. Under this condition, the flow is estimated on the basis of control valve pressure drop and opening.

The well flow control valve (CV-1 in Figure 8.41a and k) is switched to the local automatic mode (LACM) whenever sudden upsets are experienced or when the operation mode is being switched between the start-up (TWM1) and continuous (TWM2) operating modes of operation. In this case, the flow controller set point is provided by the LDA, but can be modified by the operator. When the set point is being changed, the rate of change is limited. Minimum and maximum flow limits are also provided for each well.

When the well is in continuous operation (TWM2), pressure correction is applied to the flow controller's set point (PCCM). If a controller is in its remote automatic mode (RACM), the operator is not allowed to modify its set point.

EFRVD	Expected flow rate value through dryer
ETMP	Expected total mass produced
LACM	Local automatic control mode
LDAD	Load distribution algorithm for dryers
LDAW	Load distribution algorithm for wells
MPFRVD	Maximun predetermined flow rate value through the dryer
1	The control system is in this state in the start-up mode
2	The control system is in this state in the continuous operarting mode

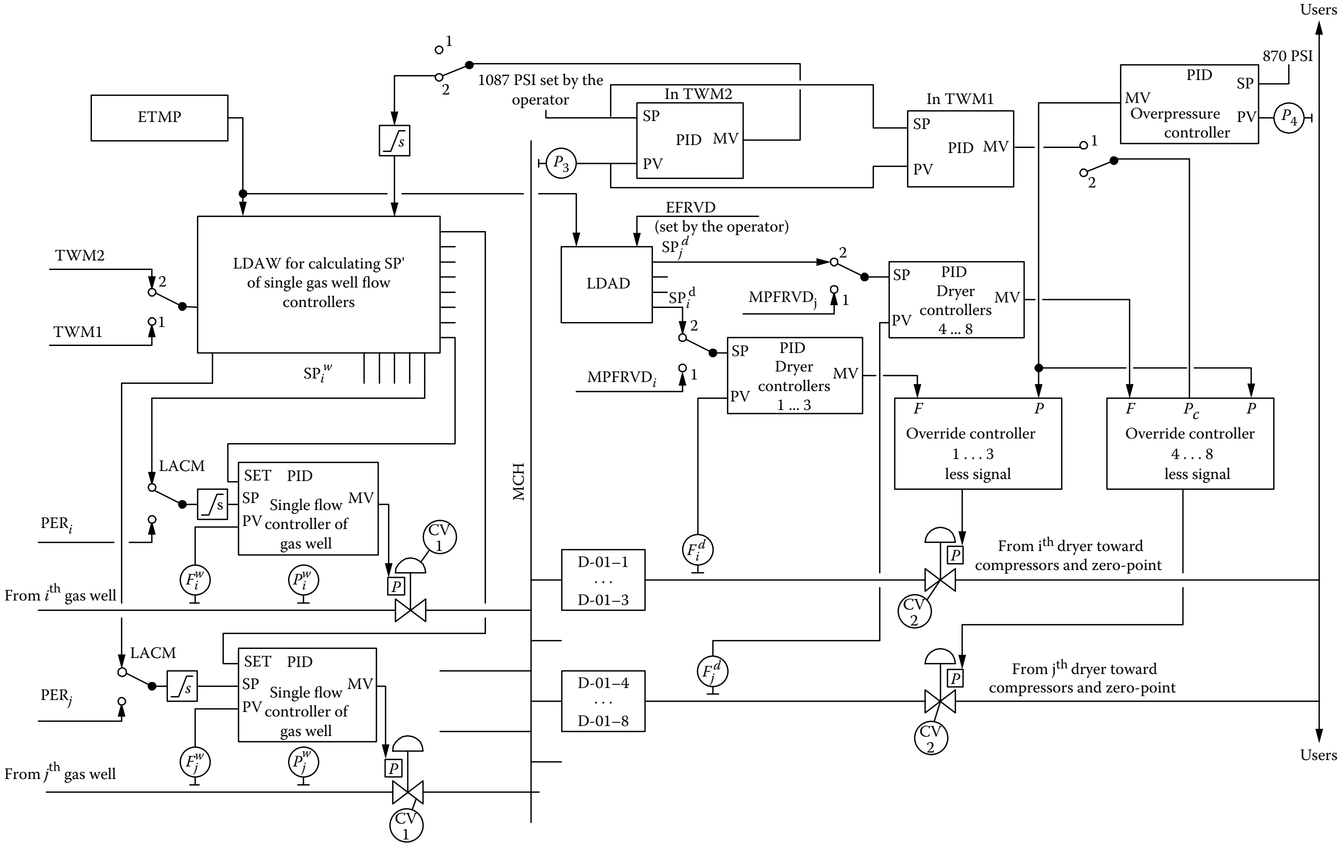

FIG. 8.41k

The overall control system of an underground gas storage facility, operating in its continuous-production mode (PRC).

Dryer Controls As shown on the left side of Figure 8.41j, the three small-capacity dryers are under flow control during start-up (TWM1). In this mode, the operator adjusts the dryer flow controller set point, using the LDA as a reference. When the total flow demanded by the users changes, the set points of the active dryer controllers are recalculated, based on the predetermined flow rate of the total system (PFRU). In addition to flow control, the dryer control loops are also provided with overpressure protection, as shown on the left side of Figure 8.41j.

The right side of Figure 8.41j illustrates the controls used on the five high-capacity dryers. In the start-up mode (TWM1), their controls are in the PCCM, but their set point cannot exceed the maximum flow (MPFD) set by the operator. In the continuous mode of operation (TWM2), the operation of these high-capacity dryers is similar to that of the small-capacity dryers. Therefore, they are operated in the PCCM in order to maintain the pressure in the MCH at the setting specified by the operator.

Pressure Correction In the start-up mode (TWM1), the set points of the control loops on the high-capacity dryers have to satisfy several considerations. They have to be under the maximum flow allowed for the particular dryer. In addition, they have to be pressure corrected. The pressure correction considers the pressure in the MCH (P_3 in the figures) and the pressure at the start of the supply header serving the users, which point is also called the “zero point” (P_4 in the figures).

In the continuous operating mode (TWM2), the flow controllers of the active wells develop a relatively steady pressure in the MCH. The FICs on the wells are in their RACMs, and their set points are adjusted by the operator. If the control valves (CV-1 in the figures) on half of the active the wells are more than 80% open, the operator is warned to lower the pressure in the MCH by reducing the set points of the FICs on the wells.

Warning the Operator Usually, the load redistribution is recommended to be done per Equation 8.41(3). When this is not feasible, the control system advises the operator if the flow set point from a particular well is no longer available for pressure correction. The operator is also advised by the control system if the maximum or minimum allowable flow limit is reached for a particular well. The control system also warns the operator if any well control valve has opened beyond 80% or if the flow through them is outside allowable limits. When the demand for gas cannot otherwise be met, the operator must activate new, previously passive wells.

Normally, the control system keeps the total flow from the wells that are under pressure-corrected control within the minimum and maximum tale flow limits (mCC and MCC). If the flow from the wells that are controlled in the PCCM reaches the preset limit for maximum tale flow (MCC), the control system must warn the operator.

The control system also warns the operator if any well control loop with a pressure-corrected set point (PCCM) opens its control valve to more than 80%.

Controlling the Pressure at "Zero Point" The "zero-point" pressure is the pressure at the beginning of the header that serves the users (P_4 in Figures 8.41a and k). This supply pressure to the users is not controlled directly, as it is the consequence of the balance between the gas supply and demand. Therefore, it is allowed to float between 725 and 870 psig (50 to 60 bars).

At the beginning of the PRC, the outlet pressure of the active wells is about 1450 psig (100 bars), and under such conditions, overpressure conditions can arise. As shown in Figure 8.41k, the overpressure protection control loop is set at 870 psig (60 bars), and if the zero-point pressure reaches that level, the controller will start to throttle down the dryer flow control valves (CV-2). A high-pressure alarm is also provided.

Just as the pressure in the main collection header is a function of the balance between the total flows of the wells and the dryers, the zero-point pressure is an indication of the balance between the flow supplied by the dryers and the flow demanded by the users. In more sophisticated control systems, feedforward control can be used on the basis of the gas demand, so that the system does not wait until a pressure upset is caused by the supply–demand imbalance, but eliminates it as soon as it occurs.

THE TOTAL CONTROL SYSTEM

The control system is so designed that it has to be switched into the start-up mode whenever the OP for the overall facility is changed or when upsets occur. In that mode (TWM1), the individual wells are on straight flow control. The LDA is used to distribute the total gas production (ETMI), according to the WFs of the individual wells.

Because of the limited reliability of the flow sensors under changing flow conditions, the total gas flow obtained from the wells (ETMI) is not accurately known during start-up. Once the flows have stabilized, the system is switched into the continuous operating mode (TWM2). In this mode, when the operating point for the whole system (OP) changes, the pressure of the main collection header (MCH) reflects that change, and the automatic pressure correction (PCCM) adjusts the flow set points at the individual wells.

As shown in Figures 8.41j and k, the control system is reconfigured as the operating mode is switched from start-up (TWM1) to continuous (TWM2). In the figures these modes are indicated by the numbers 1 and 2.

Existing DCS Hardware

The control hardware consists of two fiber-optic bus-connected DCS units. The first DCS contains the controls for the well side of the total UGS, ten field control stations (FCS), four human interface stations (HIS), three operator consoles, one PLC serving data acquisition, another PLC for safety controls, and a number of ultrasonic flowmeters.

The second DCS controls the gas conditioning and drying process. It is provided with two field and two operator consoles.

All the FCSs, including their controllers, digital and analog I/O, CPU, power, and communication boards, are redundant. The HISs consist of an industrial computer with hard disc, 21 in. monitor, trackball, and keyboard.

CONCLUSIONS AND COMMENTS

The goal of the existing control system is to accurately meet the demand for natural gas of the users while minimizing upsets or disturbances. This task is made more difficult by the changing conditions in the wells during both charging (INC) and discharging (PRC) of the wells. An added source of difficulty is the low accuracy and unreliability of the flow sensors. In addition, the capacity and safety limitations of both the wells and the dryers cannot be violated and is desired to minimize the energy cost and maintenance of the operation.

One of the tools used to achieve these goals is to apply pressure correction to the flow controllers at both the wells and the dryers. Another tool is to use the pressure drop ratio ($\Delta p/p_1$) and the control valve openings to estimate the flows passing through them.

The reader might notice that the control system described in this section is one that probably evolved from a manually operated facility; it is still operating with unreliable sensors when water is present in the gas and control valves that have no direct stroke position detectors. Under these conditions, it

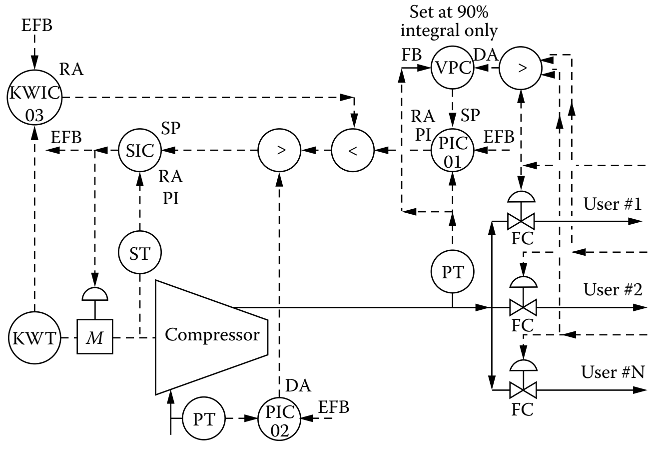

FIG. 8.41l
Optimized load-following controls satisfy the users at minimum energy cost while providing protection against low suction pressure and against overloading the compressor drive.

is not surprising that the addition of DCS controls resulted only in a semimanual mode of operation, with the DCS system serving to correct for the inadequacy of the in-line hardware and fulfilling only supervisory functions.

If the controls of a new gas storage facility were being designed today, in addition to the improvements in the sensors, one would use more model predictive feedforward, and adaptive controls. In the PRC, such feedforward controls would be based on supply-demand balancing. This is because the pressure in the MCH is a function of the balance between the total flow from the wells and the total flow to the dryers. Similarly, the zero-point pressure is an indication of the balance between the total flow from the dryers and the total flow demanded by the users. Consequently, in a modern and automated control system, feedforward control would be based on the gas demand, so that the system does not have to wait until a pressure upset is caused by the imbalance between supply and demand imbalance, but can eliminate it as soon as it occurs.

Similarly, in the reinjection mode (INC), the goal is to refill the wells as quickly as possible without causing damage to them and to do that at a minimum energy cost at the compressors. In this mode, the users are the wells, the suppliers are the compressors, and supply–demand control at minimum energy consumption can be provided by feedforward-based valve position control (Figure 8.41l).

A.1 International System of Units

B. G. LIPTÁK

The decimal system of units was conceived in the 16th century when there was a great confusion and jumble of units of weights and measures. It was not until 1790, however, that the French National Assembly requested the French Academy of Sciences to work out a system of units suitable for adoption by the entire world. This system, based on the metre (meter) as a unit of length and the gram as a unit of mass, was adopted as a practical measure to benefit industry and commerce. Physicists soon realized its advantages and it was adopted also in scientific and technical circles. The importance of the regulation of weights and measures was recognized in Article 1, Section 8, when the U.S. Constitution was written in 1787, but the metric system was not legalized in this country until 1866. In 1893, the international meter and kilogram became the accepted standards of length and mass in the United States, both for metric and customary weights and measures. The tables of conversion factors presented in the following pages are intended to serve two purposes:

1. To express the definitions of miscellaneous units of measure as exact numeral multiples of coherent "metric" units. Relationships that are exact in terms of the base unit are followed by an asterisk. Relationships that are not followed by an asterisk are either the results of physical measurements or are only approximate.
2. To provide multiplying factors for converting expressions of measurements given by numbers and miscellaneous units to corresponding new numbers and metric units.

Conversion factors are presented for ready adaptation to computer readout and electronic data transmission. The factors are written as a number equal to or greater than 1 and less than 10 with six or fewer decimal places. This number is followed by the letter E (for exponent), a plus or minus symbol, and two digits that indicate the power of 10 by which the number must be multiplied to obtain the correct value. For example:

$$3.523\,907 \text{ E} - 02 \text{ is } 3.523\,907 \times 10^{-2}$$

or

$$0.035\,239\,07$$

Similarly,

$$3.386\,389 \text{ E} + 03 \text{ is } 3.386\,389 \times 10^{3}$$

or

$$3\,386.389$$

An asterisk (*) after the sixth decimal place indicates that the conversion factor is exact and that all subsequent digits are zero.

When a figure is to be rounded to fewer digits than the total number available, the procedure should be as follows:

1. When the first digit discarded is less than 5, the last digit retained should not be changed. For example, 3.463 25, if rounded to four digits, would be 3.463; if rounded to three digits, 3.46.
2. When the first digit discarded is greater than 5 or if it is a 5 followed by at least one digit other than 0, the last figure retained should be increased by one unit. For example, 8.376 52, if rounded to four digits, would be 8.377; if rounded to three digits, 8.38.
3. When the first digit discarded is exactly 5, followed only by zeros, the last digit retained should be rounded upward if it is an odd number, but no adjustment made if it is an even number. For example, 4.365, when rounded to three digits, becomes 4.36. The number 4.355 would also round to the same value, 4.36, if rounded to three digits.

Where fewer than six decimal places is shown, more precision is not warranted.

[a] Since 1893, the U.S. basis of length measurement has been derived from metric standards. In 1959, a small refinement was made in the definition of the yard to resolve discrepancies both in this country and abroad, which changed its length from 3600/3937 m to 0.9144 m exactly. This resulted in the new value being shorter by two parts in a million.

At the same time it was decided that any data in feet derived from and published as a result of geodetic surveys within the United States would remain with the old standard (1 ft = 1200/3937 m) until further decision. This foot is named the U.S. survey foot.

As a result, all U.S. land measurements in U.S. customary units will relate to the meter by the old standard. All the conversion factors in these tables for units referenced to this footnote are based on the U.S. survey foot, rather than the international foot.

Conversion factors for the land measures given below may be determined from the following relationships:

1 league = 3 miles (exactly)
1 rod = 16$^1/_2$ feet (exactly)
1 section = 1 square mile (exactly)
1 township = 36 square miles (exactly)
1 chain = 66 feet (exactly)

[c] The SI unit of thermodynamic temperature is the kelvin (K), and this unit is properly used for expressing thermodynamic temperature and temperature intervals. Wide use is also made of the degree Celsius (°C), which is the SI unit for expressing Celsius temperature and temperature intervals. The Celsius scale (formerly called Centigrade) is related directly to thermodynamic temperature (kelvins) as follows:

1. The temperature interval one degree Celsius equals one kelvin exactly.
2. Celsius temperature (t) is related to thermodynamic temperature (T) by the equation $t = T - T_0$, where $T_0 = 273.15$ K by definition.

[f] In 1964 the General Conference on Weights and Measures adopted the name liter as a special name for decimeter. Prior to this decision the liter differed slightly (previous value, 1.000028 dm^3) and in expression of precision volume measurement this fact must be kept in mind.

TABLE A.2I

Pressure Head Conversion

The center column, marked "Known," may be used either for head in feet or for pressure in pounds per square inch—when used as head, the corresponding pressure is found in the column at the left designated as "Pressure Wanted"; when used as pressure, the corresponding head is found in the column at the right designated as "Head Wanted." For example, a 10-foot head has a pressure of 4.33 pounds per square inch, and a 10-pound pressure has a head of 23.094 feet. By moving the decimal place, quantities larger than 100 may be used.

Pressure Wanted lb. per sq. in.	*Known Pressure or Head*	*Head Wanted ft.* H_2O	*Pressure Wanted lb. per sq. in.*	*Known Pressure or Head*	*Head Wanted ft.* H_2O	*Pressure Wanted lb. per sq. in.*	*Known Pressure or Head*	*Head Wanted ft.* H_2O	*Pressure Wanted lb. per sq. in.*	*Known Pressure or Head*	*Head Wanted ft.* H_2O

The viscosity is often expressed in terms of viscosimeters other than the Saybolt Universal. The formulas for the various viscosimeters are given opposite.

If viscosity is given at any two temperatures, the viscosity at any other temperature can be obtained by plotting the viscosity against temperature in degrees Fahrenheit on special Log paper. The points for a given oil lie in a straight line.

$$\text{Kinematic viscosity} = \frac{\text{absolute viscosity}}{\text{specific gravity}}$$

$$\text{Redwood } K = 26t - \frac{180}{t}(\text{British})$$

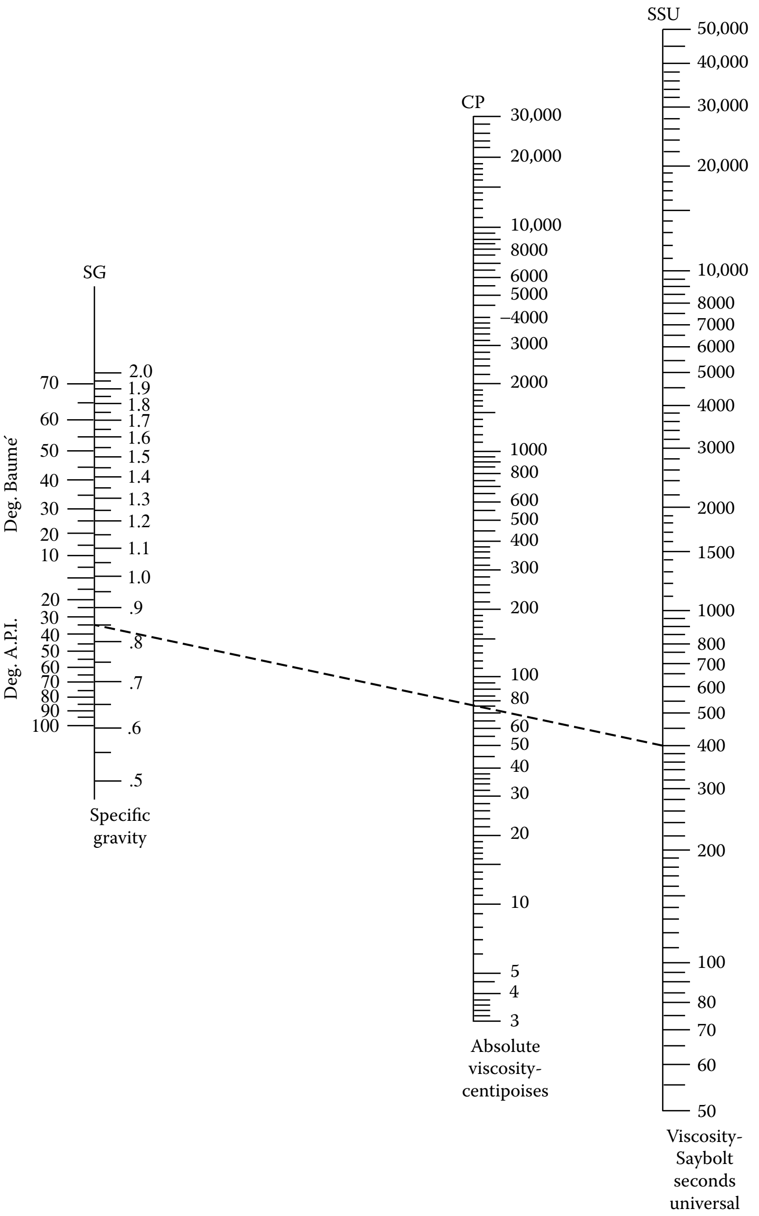
$$\text{Redwood Admiralty } K = 2.7t - \frac{20}{t}(\text{British})$$

$$\text{Saybolt Universal } K = .22t - \frac{195}{t}(\text{American})$$

$$\text{Saybolt Furol } K = 2.2t - \frac{184}{t}(\text{American})$$

$$\text{Engler } K = .147t - \frac{374}{t}(\text{German})$$

TABLE A.2q
Viscosity Conversion Chart



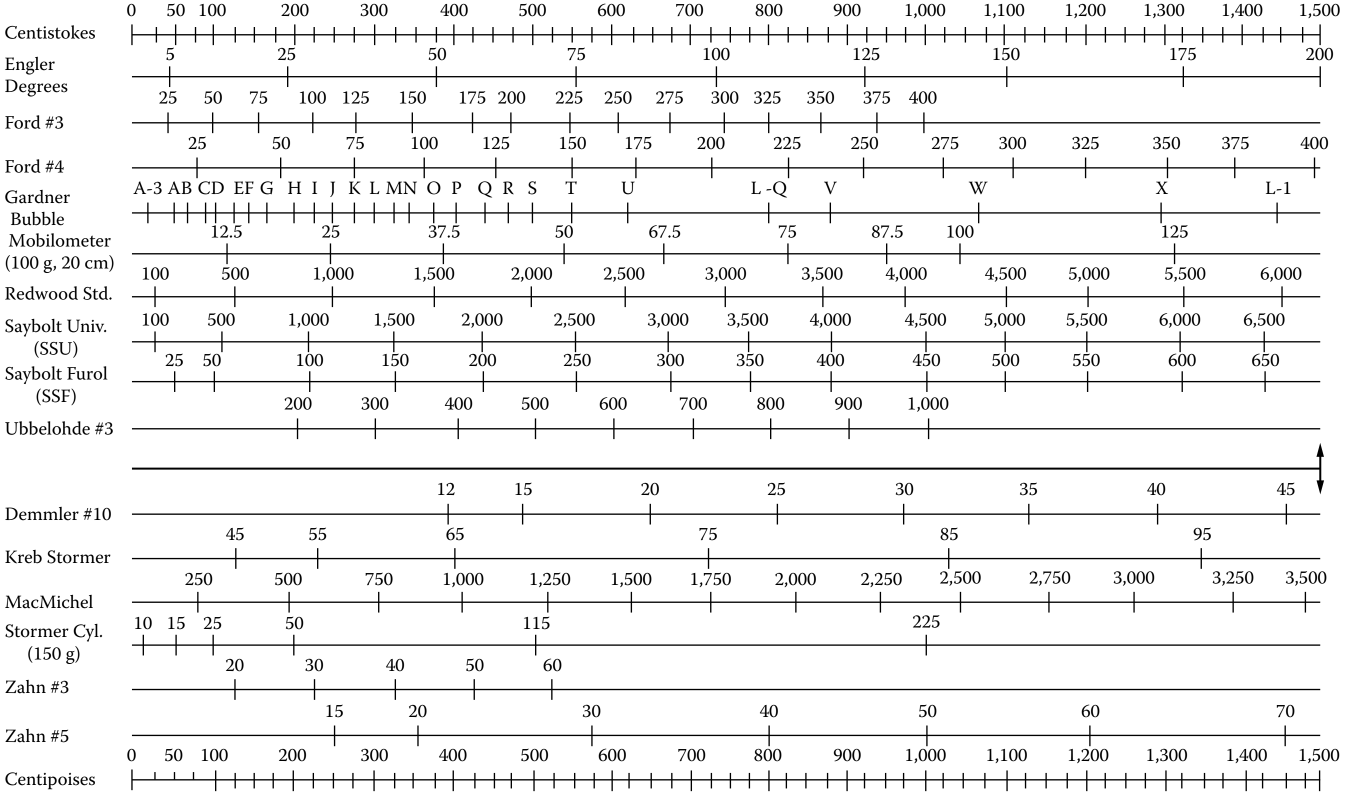
This chart enables the direct conversion of a viscosity in centipoises to a SSU viscosity. As an example, suppose the liquid under consideration has a specific gravity of .85 and a viscosity of 75 centipoises. To determine the viscosity in SSU, lay a straight edge between 75 on the cp scale and .85 on the G scale. The viscosity in SSU can be read directly on the SSU scale. In this instance, the SSU viscosity is 400 (see dotted line).

If the viscosity value is given in centistokes (kinematic viscosity), it can be used directly on the viscosity correction nomograph. The relationship between the absolute viscosity and the kinematic viscosity is expressed by the following formula:

Centipoises = Centistokes × Specific Gravity

TABLE A.2r

Approximate Viscosity Conversion Chart



Note: Scales in lower section read directly in centipoises. Those above read in centistokes (to convert into centipoises, multiply by liquid specific gravity).

A.4 Composition of Metallic and Other Materials

B. G. LIPTÁK

TABLE A.4
Composition of Metallic and Other Materials

No.	Material	Manufacturer	Composition or Description
		Metals	
17	Aluminum		
19	Aloyco-20	Alloy Steel Products Co.	Fe; 19–21 Cr; 28–30 Ni; 4.0–4.5 Cu; 2.5–3.0 Mo; 1.5 max. Si; 0.65–0.85 Mn; 0.07 max. C
19a	720 Alloy	General Plate	20 Mn; 20 Ni; Cu
54–60	Brass		Various commercial grades ranging 60–65 Cu; 35–40 Zn; 0.5–3.0 Pb
63	Brass, red		85 Cu; 15 Zn
66	Bronze, comm.		90 Cu; 10 Zn
73	Bronze, phosphor, 5% A		94.8–95.5 Cu; 4.3–5 Sn; P
74	Bronze, phosphor, 8% C		Cu; 7–9 Sn; 0.03–0.25 P
75	Bronze, phosphor 10% D		89.5–90 Cu; 10–10.5 Sn; P
76	Bronze, phosphor, spec. free cutting		88 Cu; 4 Zn; 4 Sn; 4 Pb
81	CA-FA20	Cooper Alloy	Fe; 19–21 Cr; 28–30 Ni; 3.5 Mo; 4–4.5 Cu; 0.07 max. C
82	CA-MM	Cooper Alloy	67 Ni; 30 Cu; 1.4 Fe; 0.1 Si; 0.15 C
86	Cast iron		Ordinary unalloyed cast iron
88	Chlorimet 2	Duriron Co.	63 Ni; 32 Mo; 3 max. Fe; 0.15 max. C; 1 Si; 1 Mn
89	Chlorimet 3	Duriron Co.	60 Ni; 18 Mo; 18 Cr; 2 Fe; 0.07 max. C; 1 Si; 1 Mn
111	Copper		99.9+ Cu
112	Copper, Be		97.5 Cu; 2.15 Be; 0.35 Ni
119	Corrosiron	Pacific Fdry.	Fe; 14.5 Si
140	Durichlor	Duriron Co.	Fe; 0.85 C; 14.5 Si; 3 Mo; 0.35 Mn
141	Durimet 20	Duriron Co.	Fe; 20 Cr; 29 Ni; 0.07 max. C; 2 Mo; 4 Cu; 1 Si
142	Durimet T	Duriron Co.	Fe; 19 Cr; 22 Ni; 0.07 max. C; 2 Mo; 1 Cu; 1 Si
143	Duriron	Duriron Co.	Fe; 0.80 C; 14.5 Si; 0.35 Mn
148	Everdur 1000	Amer. Brass	94.9 Cu; 4 Si; 1.1 Mn
149	Everdur 1010	Amer. Brass	95.8 Cu; 3.1 Si; 1.1 Mn
150	Everdur 1015	Amer. Brass	98.25 Cu; 1.5 Si; 0.25 Mn
156	Gold		99.99 Au
156a	Green gold		75% Au; 25% Ag
159	Hastelloy A	Haynes Stellite	Ni; 17–21 Mo; 17–21 Fe
160	Hastelloy B	Haynes Stellite	Ni; 24–32 Mo; 3–7 Fe; 0.02–0.12 C
161	Hastelloy C	Haynes Stellite	Ni; 14–19 Mo; 4–8 Fe; 0.04–0.15 C; 12–16 Cr; 3–5.5 W
162	Hastelloy D	Haynes Stellite	Ni; 8–11 Si; 2–5 Cu; 1 max. Al
163	Stellite 1	Haynes Stellite	Co; 28–34 Cr; 11–15 W

TABLE A.4 Continued
Composition of Metallic and Other Materials

No.	Material	Manufacturer	Composition or Description
165	Stellite 6	Haynes Stellite	Co; 25–31 Cr; 3–6 W
184	Inconel	Int'l Nickel	79.5 Ni; 13 Cr; 6.5 Fe; 0.08 C; 0.2 Cu; 0.25 Mn
191	Lead		99.9 + Pb
192	Lead, antimonial		94 Pb; 6 Sb
193	Lead, antimonial		Pb; 4–12 Sb
196	Lead, chemical		99.93 Pb; 0.06 Cu

TABLE A.4 Continued

Composition of Metallic and Other Materials

No.	Material	Manufacturer	Composition or Description
		Plastics	
700	Ace Saran	American Hard Rubber	Vinylidene chloride
710	Geon	B. F. Goodrich	Polyvinyl chloride
711	Haveg 41	Haveg Corp.	Phenolic-asbestos
712	Haveg 43	Haveg Corp.	Phenolic-graphite
713	Haveg 60	Haveg Corp.	Furan-asbestos
714	Haveg 63	Haveg Corp.	Furan-graphite
715	Heresite M 66	Heresite & Chem. Co.	Transparent molding powder
716	Heresite MF 66	Heresite & Chem. Co.	Black molding powder
717a	Kel-F	M. W. Kellogg	Polymerized trifluoroethylene
718	Koroseal	B. F. Goodrich	Plasticized polyvinyl chloride
731	Nylon FM-101	E. I. du Pont	Injection, compression and extrusion moldings (tubing, sheeting, wire covering, gasketing)
731a	Plastisol		Polyvinyl chloride
735	Polythene	E.I. du Pont	Polyethylene
740	Saran	Dow Chemical	Vinyl chloride-vinylidene chloride copolymer
740a	Sirvene	Chicago Rawhide	Synthetic rubber
742	Teflon	E.I. du Pont	Polymerized tetrafluoroethylene
746	Tygon	U.S. Stoneware	Synthetic compounds
		Rubber	
800	Ace Hard Rubber	American Hard Rubber	Vulcanized rubber
805	Butyl (GR-I)	Stanco Distributors	Solid copolymer of isobutylene and isoprene
820	Hycar (GR-A)	B. F. Goodrich	Nitrile type synthetic rubber
829	Neoprene	E. I. du Pont	Polymer of chloroprene
836	Natural (soft)		
837	Natural (hard)		
838	GR-S (soft)		
839	GR-S (hard)		
853	Thiokol (GR-P)	Thiokol Corp.

A.6 Friction Loss in Pipes

B. G. LIPTÁK

Friction loss moduli for laminar flow are shown by the 45° lines in the upper left-hand portion of each chart. Moduli for turbulent flow are shown by the steeper curves in the lower right-hand portion. Both of these regions represent stable states of flow. A diagonal line separates the regions of laminar and turbulent flow and represents the critical zone, a region in which it is difficult to predict the state of flow and, hence, the friction loss. The critical zone usually represents a region of unstable flow. The critical zone line gives approximate moduli on the high side for this region of unstable flow.

The bottom scale of each chart represents flow in gallons per minute, GPM. An auxiliary top scale shows the average velocity in the pipe in feet per second. Read vertically from the GPM scale to find the corresponding velocity in feet per second. The vertical scales, labeled "Friction Loss Modulus for 100 Feet of Pipe," represent values of the ratio:

$$M = \frac{\Delta p}{SG}$$

where

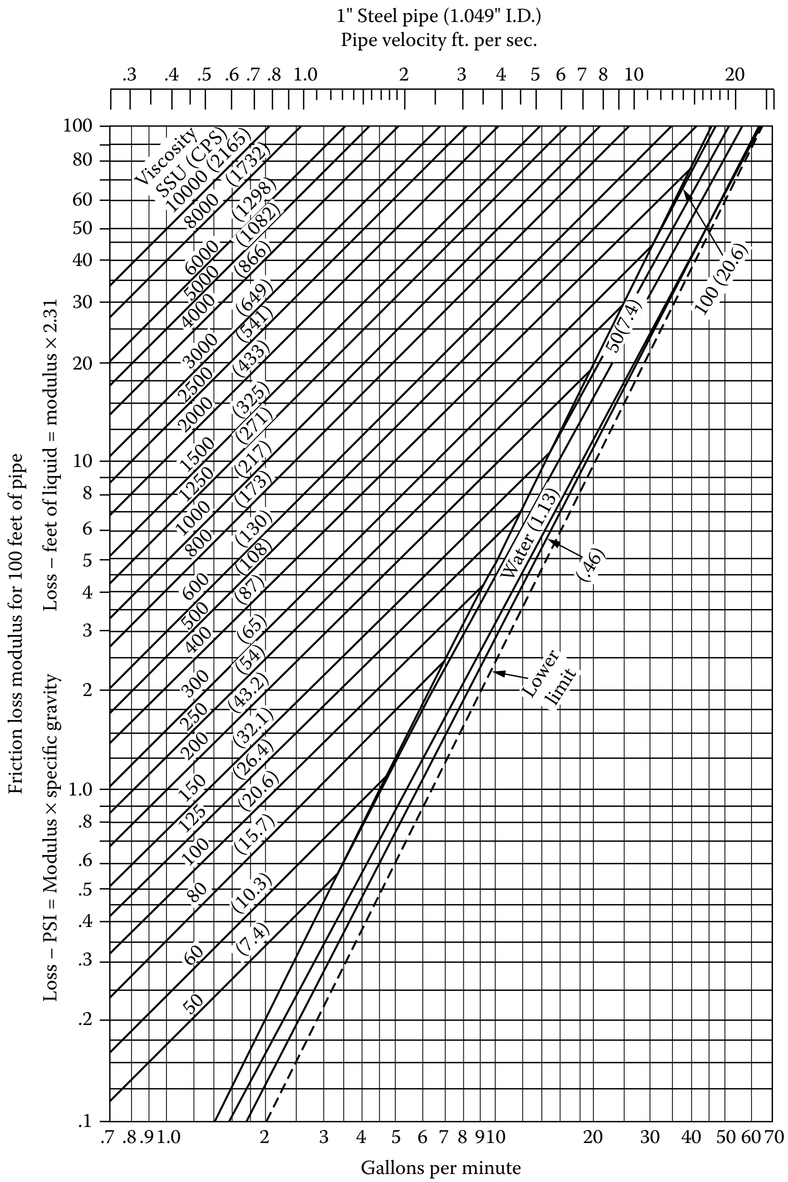
M = friction loss modulus for 100 feet (30 m) of pipe
Δp = pressure loss in pounds per square inch per 100 feet of pipe
SG = specific gravity of fluid at 60°F (15.6°C)

The loss due to pipe friction may be obtained as follows:

$$\Delta p = M \times SG$$

To use the charts, proceed as follows:

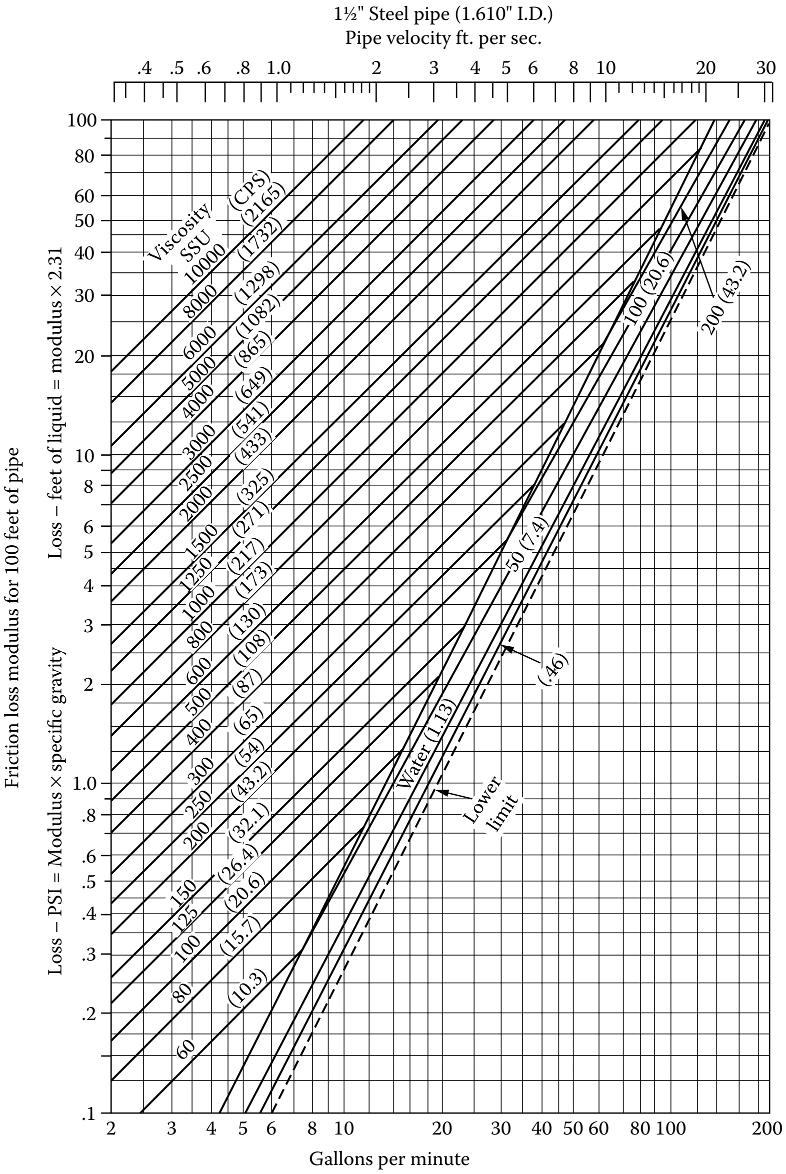
1. Select the chart for the size of pipe in question.
2. Follow the vertical line representing the flow in GPM to its intersection with the desired viscosity curve, and read the modulus at the left.
3. If the vertical line representing the flow in GPM does not intersect the viscosity line in either turbulent or laminar flow, use the intersection with the critical zone line.
4. Compute the friction loss in pressure drop from the equation above.



Loss – lbs. per sq. in. = modulus × specific gravity
Loss – feet of liquid = modulus × 2.31

*For SI units see Section A.1.

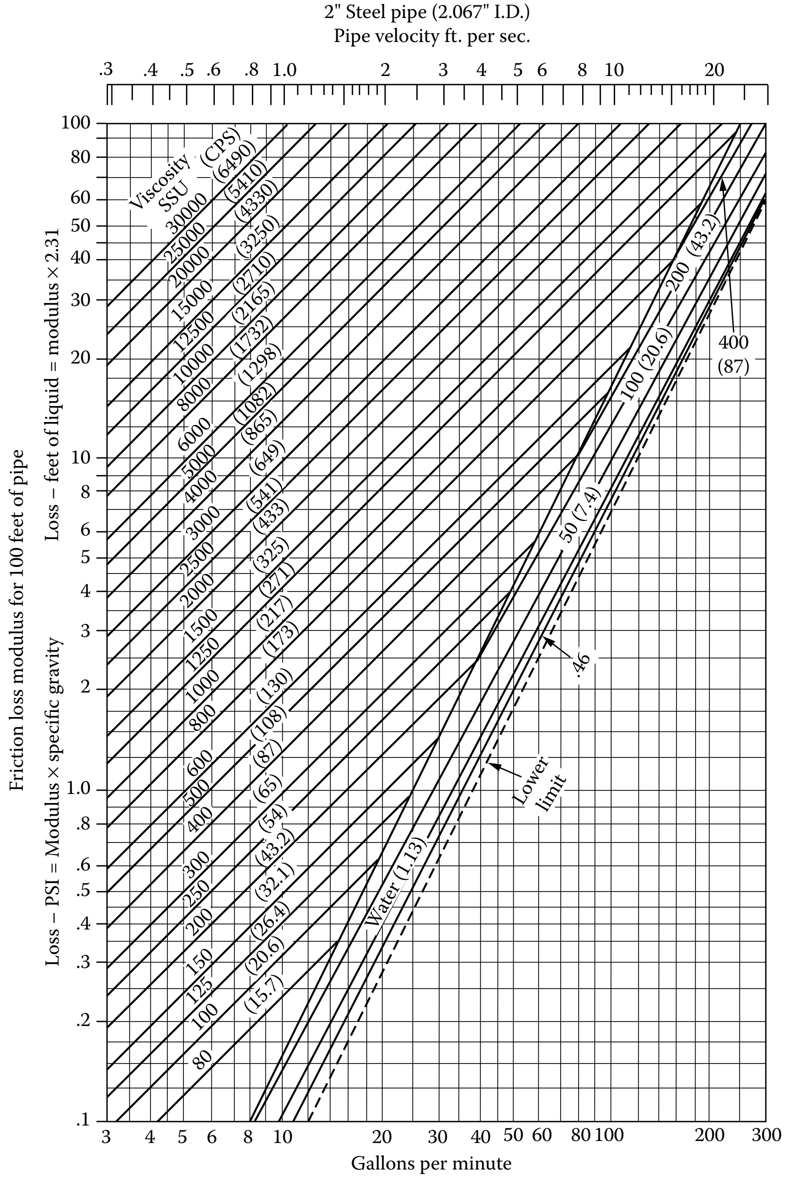
FIG. A.6a
*Friction loss modulus for 100 ft of 1″ steel pipe.**



Loss – lbs. per sq. in. = modulus × specific gravity
Loss – feet of liquid = modulus × 2.31

*For SI units see Section A.1.

FIG. A.6b
*Friction loss modulus for 100 ft of 1½″ steel pipe.**

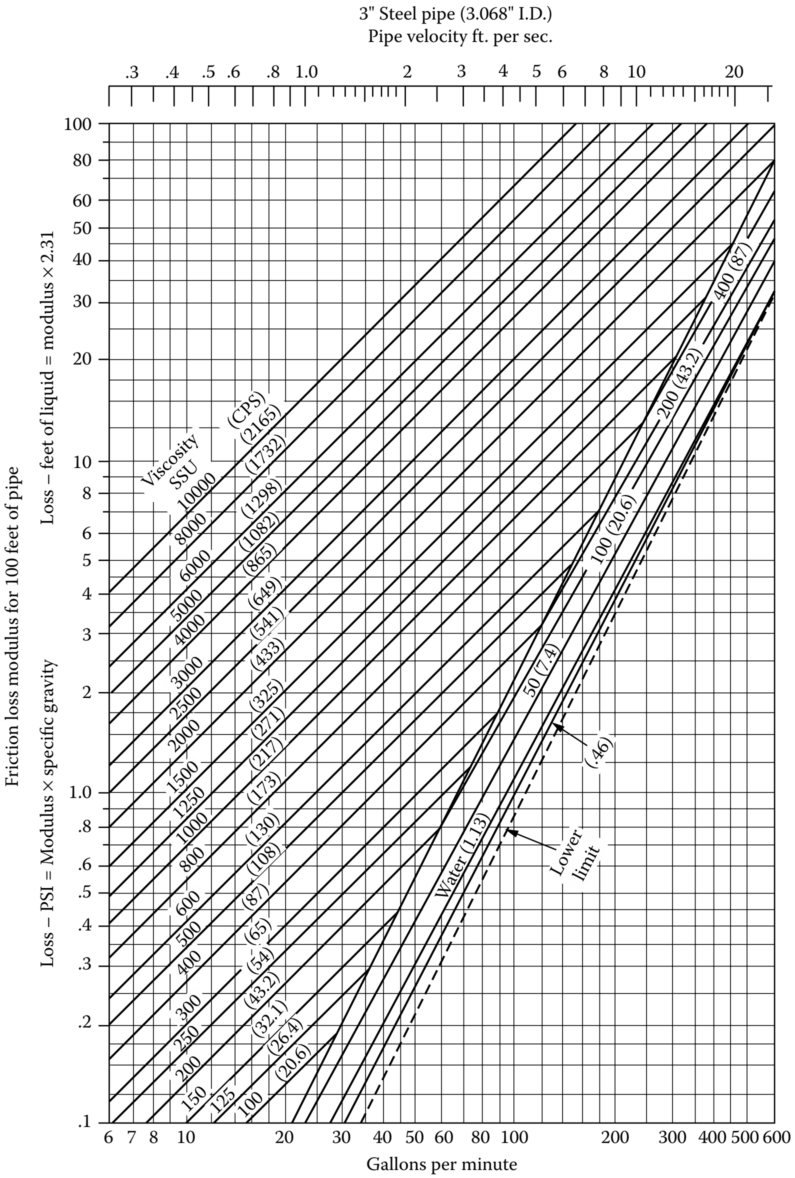


Loss – lbs. per sq. in. = modulus × specific gravity
Loss – feet of liquid = modulus × 2.31

*For SI units see Section A.1.

FIG. A.6c

*Friction loss modulus for 100 ft of 2″ steel pipe.**

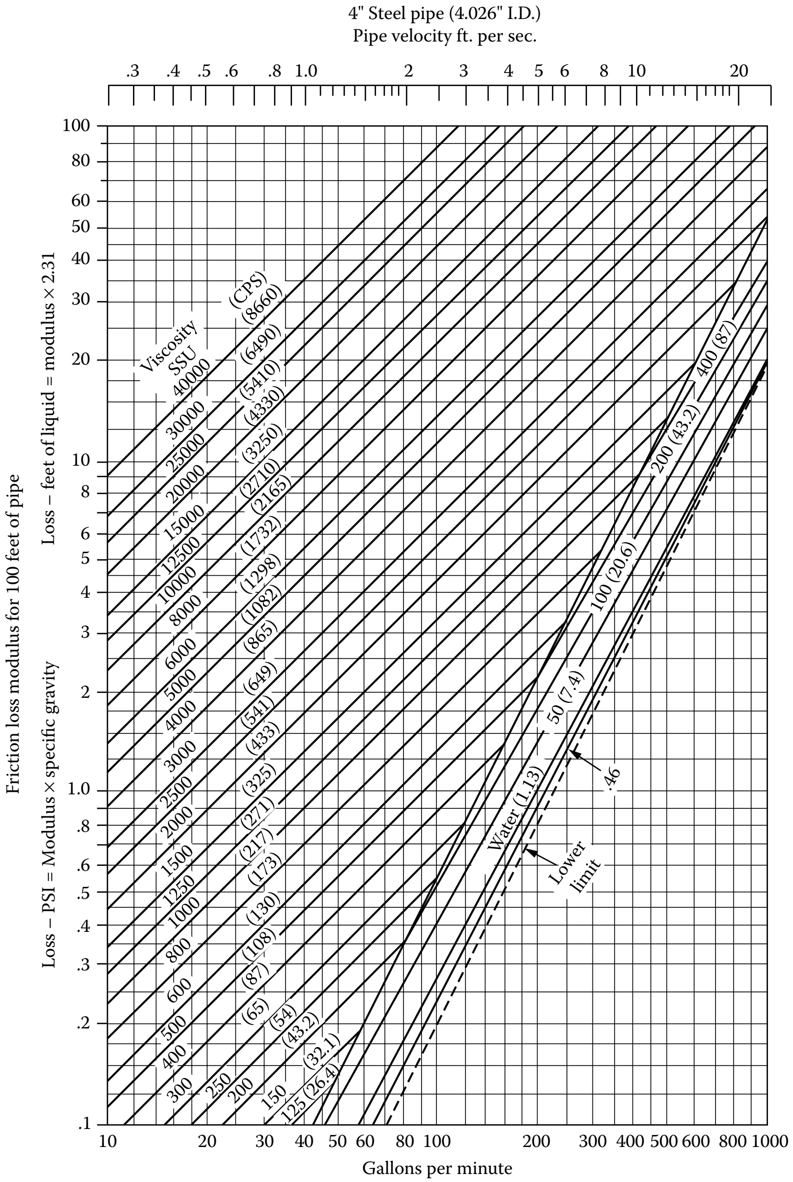


Loss – lbs. per sq. in. = modulus × specific gravity
Loss – feet of liquid = modulus × 2.31

*For SI units see Section A.1.

FIG. A.6d

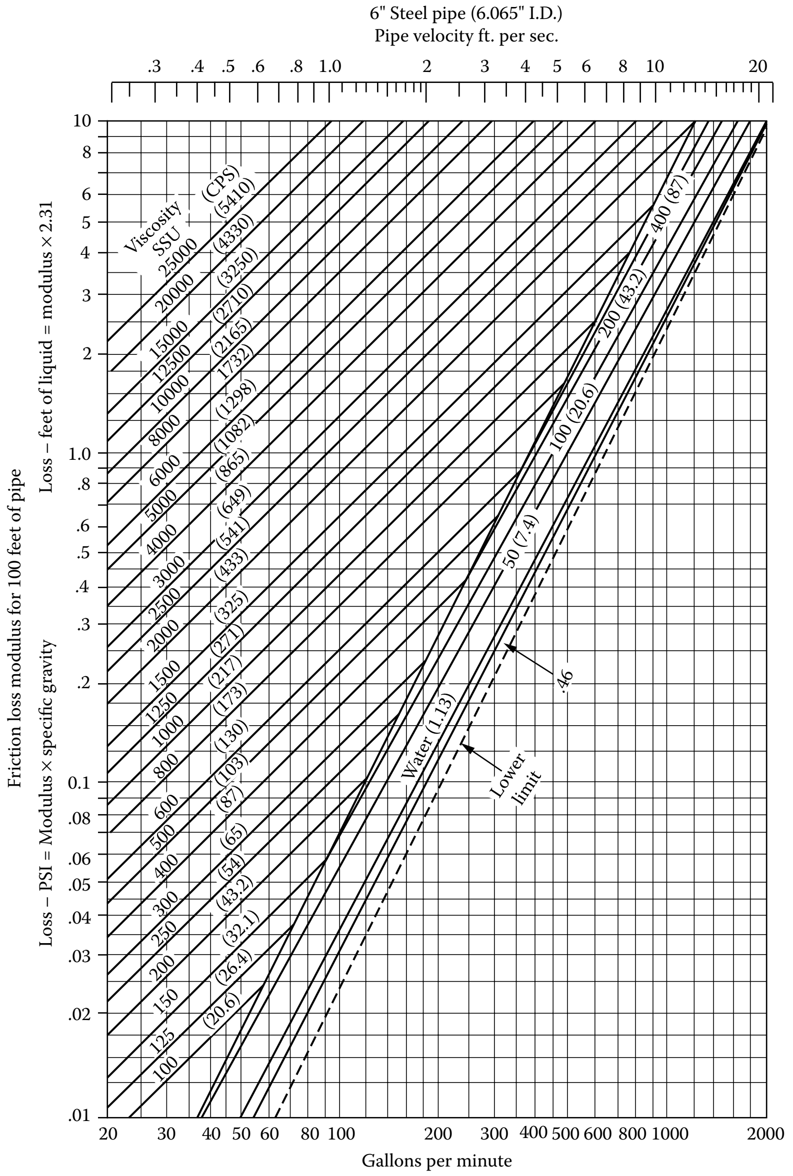
*Friction loss modulus for 100 ft of 3″ steel pipe.**



Loss – lbs. per sq. in. = modulus × specific gravity
Loss – feet of liquid = modulus × 2.31

*For SI units see Section A.1.

FIG. A.6e
*Friction loss modulus for 100 ft of 4″ steel pipe.**



Loss – lbs. per sq. in. = modulus × specific gravity
Loss – feet of liquid = modulus × 2.31

*For SI units see Section A.1.

FIG. A.6f
*Friction loss modulus for 100 ft of 6″ steel pipe.**

A.9 Directory of "Lost" Companies

W. H. BOYES WITH S. EDVI (2005)

Between 1990 and 2005, the instrumentation, systems and automation industries were the subject of significant, not to say massive, change. Not only was this change of a technical nature, with significant advances in many product areas, but also this period has been one of consolidation among supplier companies who furnish instruments and control systems. It appears that this consolidation will continue for the foreseeable future.

Identified in this appendix are over 100 companies whose name, ownership, or product line changed significantly over the period from 1990 to 2005. This list is not complete, and the authors believe that there are perhaps as many as 50 more companies, most outside North America, whose names have also changed in the same fashion.

This turmoil among suppliers has had a significant effect on the ability of Instrument Engineers to find familiar products, and locate companies for service of existing installed equipment. For example, the Fischer & Porter Company, a well-known name in 1990, ceased to exist as a marque in 2002. The company itself was purchased by Elsag BV, and merged with Bailey Controls to form Bailey-Fischer-Porter. Later, Elsag sold the combined companies to ABB, who elected to drop both trade names in favor of ABB Process Instrumentation. So, an Instrument Engineer whose company installed Fischer & Porter instrumentation or control systems in the early 1990s may now find it impossible to easily find information, manuals, and source spare parts and service for Fischer & Porter systems. Fischer & Porter, as you will see in the table below, is far from the only example of this problem. The authors therefore provide this information as a public service to the profession.

Prior Name	Intermediate, If Any	2005
Advanced Pollution Instrumentation Inc.		Teledyne Instruments - API
AEG Automation Systems		Cegelec
AEG Schneider Automation	Groupe Schneider/Schneider Electric	Schneider Automation
AGEMA Infrared Systems		FLIR Systems Inc.
Altek Calibrators		Transmation
American Sigma		American Sigma div. of Danaher
Ametek McCrometer	Ketema-McCrometer	McCrometer div. of Danaher
Amscor	Fluid Data; ThermoONIX	ThermoElectron Measurement and Control
Anatel	Anatel Div. of Danaher	Pacific Scientific Instruments div. of Danaher
Anchor Darling		Flowserve Corporation
Applied Automation Inc	Elsag-Bailey	ABB Process Automation (much of AAI was sold to Siemens)
Aquamatic Inc.	Osmonics, Inc.	GE Infrastructure Sensing
ARCOM Control Systems		Spectris PLC
Argus	Invensys Flow Control	Flowserve Corporation
Arthur Technology		Respirometry Plus
ASAP Software	Xycom Automation/Pro-face America div. of Digital-Japan	Schneider Electric
Ashcroft-Heise		Ashcroft-Heise div. of Dresser Industries Instruments
Astro	Hach Co.	Hach div. of Danaher
Atomac		Flowserve Corporation
Automax		Flowserve Corporation
Azonix		Crane Co.
BTG	BTG Spectris	Spectris PLC BTG div.
B/W Controls	Ametek Patriot Sensors	Ametek Automation & Process Technology
Baan Software	Invensys	SSA Global Technologies
Badger Meter Ultrasonic div.		Badger Eastech Inc.
Bailey Controls	Elsag-Bailey	ABB Process Automation
Barber-Coleman	Eurotherm	Invensys
Battig		Flowserve Corporation
Bebco		Pepperl+Fuchs
Beta Products	Hathaway-Beta and Beta Calibrators div. Hathaway Process Instrumentation Corp.	Martell Electronics
Bettis Actuators & Controls		Emerson Process Measurement
Bindicator	Aaliant	Venture Meas. Div. of Danaher
Biosynergy Inc		Biosynergy Inc div. of America Clinical Laboratory
Brooks Instruments	Rosemount-Brooks	Emerson Process management (no longer a div. only a trademark)
Bruel & Kjaer	B&K div. Of Fairey Group	B&K div of Spectris PLC
Edmond Buhler GMBH	Buhler Montec	Buhler Montec div. of Danaher
CSI	Emerson CSI	Emerson Process Management
Cannonbear Technologies	TN Technologies; ThermoMeasureTech	ThermoElectron Measurement and Control
Celtek	Bindicator Celtek, Aaliant	Venture Meas. div. of Danaher
Chessell	Eurotherm	Invensys
Chino Works Ltd.		Chino Corporation

Prior Name	Intermediate, If Any	2005
Combustion Engineering		ABB Process Automation
Danfoss Flow Control	Siemens Danfoss	Siemens
Daniel Industries	Rosemount	Emerson Process Measurement, Daniel div.
Detector Electronics Corp		Det-Tronics
DeZurik Valve Corp.	DeZurik Div. Of SPX	SPX Process Equipment
Dietrich Standard (Annubar)	Rosemount	Emerson Process Measurement, Dietrich div.
Direct Measurement Corp.	DMC	FMC Energy Systems Group
Dolch Computer Co.	Dolch Kontron	Kontron Inc.
Drexelbrook Eng. Co.		Ametek Drexelbrook
Druck Inc.	GE Druck	GE Infrastructure Sensing
DuPont Process Instruments		Ametek Process Instruments Div.
Durco		Flowserve Corporation
Eastech Controls	Neptune Eastech	Badger Eastech Inc.
Eckhardt	Siebe	Invensys
Edward Valve	Invensys Flow Control	Flowserve Corporation
Elsag-Bailey		ABB Process Automation
Elcon Inc.		Pepperl+Fuchs
Eurcontrol	BTG	Spectris div. of Fairey
Ever Ready Thermometer Company		Apogent Technologies Co.
Fairey Group PLC	Purchased Spectris	Spectris PLC
Fenwal		Kidde-Fenwal
Fischer and Porter Co.	Elsag-Bailey	ABB Process Automation
Fischer and Porter Co. (chlorination div. only)		Capital Controls Co. div. of Severn Trent
Fisher Controls Inc.	Fisher-Rosemount Inc.	Emerson Process Measurement
Flow Research	Polysonics	ThermoElectron Measurement and Control
Fluenta AB		Roxar Flow Measurement
Fluid Data Inc.	Thermo ONIX	Thermo Electron Measurement and Control
Forma Scientific Co.		Forma Scientific Co. div. of Thermo Electron
Foxboro	Siebe	Invensys
FTS Systems Inc.		FTS Kinetics
Gas Measuring Technology		RMG Group - Germany
Gemco Controls	Ametek Patriot Sensors	Ametek Automation & Process Technology
GEMS Sensors	IMO-Delaval Gems	GEMS-Danaher
General Eastern Inc.	GE General Eastern	GE Infrastructure Sensing
GE Kaye Instruments	GE Kaye Instruments div. of GE Industrial Systems	GE Infrastructure Sensing
Gestra	Invensys Flow Control	Flowserve Corporation
Gilbarco		Gilbarco div. of Danaher
Great Lakes Instruments	GLI-Viridor/Danaher-GLI	Hach div. Danaher
Griffith Industrial		Winters Instrumentation
Groupe Schneider	Schneider Electric	Schneider Automation
HBM	HBM div. Of Fairey Group	Spectris PLC
Hach Chemical Co.	Hach Inc.	Hach div. of Danaher
Hart Scientific	Hart Scientific div. of Fluke	Hart Scientific div. of Danaher Electronic Test and Measurement
Hartmann and Braun	Elsag-Bailey	ABB Process Automation

Prior Name	Intermediate, If Any	2005
Hastings Instrument Co.	Teledyne Hastings	Teledyne Instruments Group- Hastings
Heinrichs Messtechnik		Bopp and Reuther
Heise Instruments		Ashcroft-Heise div. of Dresser Industries Instruments
Helicoid Instruments		Helicoid Instruments div. of Bristol Babcock
Hewlett Packard	HP Instruments	Agilent Technologies
Hiac-Royco	Pacific Scientific Inc.	Pacific Scientific Instrumentation div. of Danaher
Honeywell Control Valve div.	DeZurik Corp.	SPX Process Equipment
Hydrolab Inc.	Hydrolab div. of Danaher	Hach div. of Danaher
Hyprotech	Aspen Technology HYSIS and OTS div.	Honeywell Unisym
Hyprotech AXSYS	Aspen Technology	Bentley Systems Inc.
InLine Measurements		Honeywell Inc.
Innovative Sensors Inc.	ISI	Endress+Hauser
Intellution	Emerson Process Management	GE Fanuc Automation
Invalco Inc (Smith Meters)	FMC Invalco	FMC Energy Systems Group
IRCON Inc.	IRCON div of Fairey Group	Spectris PLC
ISA Instruments	Solartron ISA	Solartron ISA div. of Roxboro
ISCO Environmental		Recently sold to Teledyne Instrument Group
John Fluke Company	Fluke Inc.	Fluke div. of Danaher Electronic Test and Measurement
Fluke Inc. (networks and communications only)	Fluke Networks Inc.	Fluke Networks div. of Danaher Electronic Test and Measurement
Joseph Kaye Co.		GE Kaye Instruments
Kammer		Flowserve Corporation
Kay-Ray	Rosemount-Kay-Ray; ThermoMeasureTech	ThermoElectron Measurement and Control
KDG Mobrey Ltd.	KDG Mobrey Ltd. div. of Solartron/div. of Roxboro	Mobrey Measurements div. of Emerson Process Mgt.
Kent Meter Co.	Kent Taylor	ABB Process Automation
Kistler-Morse	(ultrasonics to American Sigma)/Kistler-Morse div. of Danaher	Venture Meas. Div. of Danaher
Kollmorgen	Kollmorgen div. of Danaher	Dahaher Motion- General Purpose Systems
Lakewood Instruments	Fisher-Rosemount Inc.; Osmonics Inc.; GE Osmonics	GE Infrastructure Sensing
Lear Siegler Measurement Systems	Bowthorpe plc	Spirent plc
Leeds and Northrop Inc.	Honeywell AIC	Honeywell Inc.
Leeds and Northrup Inc. (DCS only)		ICS
Leeman Labs Inc.		Teledyne Instruments Leeman Labs
Lighthammer, Inc.		SAP
Limitorque	Invensys Flow Control	Flowserve Corporation
Liquid Metronics Inc.	LMI	Milton Roy Flow Controls, LMI div.
Loveland Controls Ltd.	Love Controls	Dwyer Instruments
Lumidor Safety Products	Invivo Corporation Zellweger Analytical	Honeywell Inc.
M & J Valves Inc.		SPX Process Equipment
MagneTEK	Ametek Patriot Sensors	Ametek Automation & Process Technology
Maihak		Sick Maihak
Malvern Instruments		Spectris PLC

Prior Name	Intermediate, If Any	2005
Markal Co.		LA-CO /Markal
Marsh Instruments		Desco Inc.
Marshalltown Instruments		Desco Inc.
Masoneilan	Masoneilan div. of Dresser	Masoneilan div. of Dresser Flow Control
Mass Evolution		Brechbüehler AG
McCANNA	Invensys Flow Control	Flowserve Corporation
MDA Scientific	Zellweger Analytics	Honeywell Inc.
Measurex		Honeywell Inc.
Mercoid		Mercoid div. of Dwyer Instruments Ltd.
Merlin Gerin	Groupe Schneider	Schneider Automation
Micro Motion Inc.		Micro Motion Inc. div. of Emerson Process Measurement
MicroSwitch Inc.	Honeywell MicroSwitch	Pepperl+Fuchs
Milltronics	Siemens Milltronics	Siemens
Modicon (Gould Modicon)	Groupe Schneider	Schneider Automation
Monitek Technologies		Monitek Technologies div. of Martisa Inc.
Monitor Labs		Teledyne Monitor Labs
Montedoro-Whitney Corp.	Badger Meter Ultrasonic div.	Badger Eastech Inc.
Moore Industries Inc.		Moore Industries-International, Inc.
Moore Products Co.	Siemens Moore	Siemens
Moore Products — flow and pressure transmitter line only	MycroSensor Technologies Inc.	Prime Measurement Inc.
MTI		Agilent Technologies
MultiFluid International		Roxar Flow Measurement
NAF	Invensys Flow Control	Flowserve Corporation
NDC Infrared Engineering		Spectris PLC
Nametre Inc.		Nametre div. of Metrisa Inc.
Naval Oy	Invensys Flow Control	Flowserve Corporation
Neotronics		Zellweger Analytics
Neptune Meter Co.	Neptune Schlumberger	Actaris
Neptune-Hersey	Hersey Meter Div., Aaliant	Venture Meas. div. of Danaher
Neslab Instruments Inc.	Thermo Electron	ThermoNeslab
Newport Electronics		Newport div. Omega Eng.
Noble Alloy Valve, Inc. (NAV)		Flowserve Corporation
Nordstrom Audco	Invensys Flow Control	Flowserve Corporation
Norriseal		Norriseal a Dover Resources Company
NovaSensor	Lucas Novasensor	GE Infrastructure Sensing
Osmonics	GE Osmonics	GE Infrastructure Sensing
Pacific Scientific ATC	Pacific Scientific div. of Danaher	Danaher Motion, General Purpose Systems
Panalarm		Panalarm div. of Ametek Inc.
Panametrics Inc	GE Panametrics	GE Infrastructure Sensing
Patriot Sensors Inc.	Ametek Patriot Sensors	Ametek Automation & Process Technology
Penny and Giles Ltd.	TRENDview	Honeywell
PID	Sequencia	Rockwell Automation
PMV	Invensys Flow Control	Flowserve Corporation
Polymetron		Hach div. of Danaher
Powers Process Controls		Moore Industries-International Inc.
Profimatics	Honeywell Inc.	KBC Advanced Technologies plc

Prior Name	Intermediate, If Any	2005
Promac Inc.	Hathaway Beta	Martell Electronics
Red Lion Controls Inc.	Redlion div. Fairey Group	Redlion div. Spectris PLC
Robertshaw Controls		Robertshaw Controls div. of Invensys
Rochester Instrument Systems	RIS	Ametek Inc.
Rosemount Inc.	Fisher-Rosemount Inc.	Emerson Process Measurement
Ruska Inc.	Druck Ruska; GE Ruska	GE Infrastructure Sensing
Saab Level Control	Rosemount Saab	Emerson Process Management
Schmidt Armaturen	Invensys Flow Control	Flowserve Corporation
Seaflow Inc.		Seametrics Inc.
Serck Audco	Invensys Flow Control	Flowserve Corporation
Sereg Vannes		Flowserve Corporation
Servomex		Servomex div. Spectris PLC
Setpoint		Aspen Technology
Setra		Setra div. of Danaher
Sieger	Zellweger Analytics	Honeywell
Siemens Electronic Personal Dosimetry div.	Siemens EPD	Environmental Instruments div.
Sievers Instruments		Ionics Instrument Business Group
Signet Scientific Company	George Fischer Signet	GF Signet Inc.
Smith Meters		Smith Meters a FMC Energy Systems Business
Solartron Analytical		Solartron div. of Roxboro
Square D	Groupe Schneider	Schneider Automation
Steeplechase Software	Schneider	Entivity
Taylor Instruments	Combustion Engineering/Sybron Corp.	ABB Process Automation
TBI	TBI-Bailey; Bailey-Fischer & Porter	ABB Process Automation
Telemechanique	Groupe Schneider	Schneider Automation
Tempil		Tempil div. of Illinois Tool Worka Inc. (ITW)
Tenny Engineering Inc. (bankrupt 2000)	Tenny Environmental	Tenny Environmental div. of Lunaire Ltd.
Texas Nuclear Corp	TN Technologies; ThermoMeasureTech	ThermoElectron Measurement Products
Thermometrics		GE Infrastructure Sensing
Thornton Instruments		Mettler-Toledo Thornton
Tracor	Tracor Westronics	ThermoFinnegan Austin
Trend Instruments		Wika
Triconex	Siebe	Invensys
Tytronics Inc.		Tytronics div. of Metrisa Inc.
UES	Neptune Schlumberger	Liquidated the division — out of business
UFM Vortex meter only		Asahi-America Inc.
Valtek	Durco International	Flowserve Corporation
Varec div. of Emerson	Whessoe Varec	Endress+Hauser
Veeder-Root		Veeder-Root div. of Danaher
Vogt	Invensys Flow Control	Flowserve Corporation
Water Specialties	McCrometer-Water Specialties	McCrometer div. of Danaher
Weksler Instruments Corp.		Weksler Instruments Corp div. of Dresser Industries Instruments
Western Research Div. of Bow Valley Resources Ltd.	BOVAR	Ametek Process Instruments

Prior Name	Intermediate, If Any	2005
Westinghouse Process Control		Westinghouse Process Control div. of Emerson Process Management
Westronics Inc.	Tracor Westronics; ThermoWestronics	ThermoElectron Measurement Systems
Wonderware Inc.	Siebe Wonderware	Wonderware div. of Invensys
Worcester Valve	Invensys Flow Control	Flowserve Corporation
Xomox	Emerson	Crane Corp.
Zellweger Analytics		Honeywell Inc.

A.10 ISA Standards

B. G. LIPTÁK (2005)

The latest standards and related technical publications available from the Instrument Society of America (ISA):

1-55617-531-0 — Standards Library for Measurement and Control (ISA)
12.00.01 — Electrical Apparatus for Use in Hazardous Locations (ISA)
12.01.01 — Electrical Instruments in Hazardous (Classified) Locations (ISA)
12.02.01 — Electrical Apparatus for use in Hazardous Locations (ISA)
12.10 — Area Classification in Hazardous (Classified) Dust Locations (ISA)
12.12 — Nonincendive Electrical Equipment for Hazardous Locations (ISA)
12.13-1 — Performance Requirements, Combustible Gas Detectors (ISA)
12.16.01 — Electrical Apparatus for Use in Hazardous Locations (ISA)
12.22.01 — Electrical Apparatus for Use in Hazardous Locations (ISA)
12.23.01 — Electrical Apparatus for Use in Hazardous Locations (ISA)
12.25.01 — Electrical Apparatus for Use Hazardous Locations (ISA)
12.26.01 — Electrical Apparatus for Use in Hazardous Locations (ISA)
18.1 — Annunciator Sequences and Specifications (ISA)
20 — Process Measurement, Instruments, Primary Elements, Valves (ISA)
26 — Dynamic Response Testing of Process Control Instrumentation (ISA)
37.1 — Electrical Transducer Nomenclature and Terminology (ISA)
37.10 — Piezoelectric Pressure and Sound-Pressure Transducers: Specs (ISA)
37.12 — Potentiometric Displacement Transducers: Specs, Tests (ISA)
37.3 — Strain Gage Pressure Transducers: Specs, Tests (ISA)
37.6 — Potentiometric Pressure Transducers: Specs, Tests (ISA)
37.8 — Specifications and Tests for Strain Gage Force Transducers (ISA)
5.1 — Instrumentation Symbols and Identification (ISA)
5.2 — Binary Logic Diagrams For Process Operations (ISA)
5.3 — Graphic Symbols for Distributed Control/Shared Display Systems (ISA)
5.4 — Instrument Loop Diagrams (ISA)
5.5 — Graphic Symbols for Process Displays (ISA)
50.02.2 — Fieldbus Standard for Use in Industrial Control Systems (ISA)
50.02.3 — Fieldbus Standard for Use in Industrial Control Systems (ISA)
50.02.4 — Fieldbus Standard for Use in Industrial Control Systems (ISA)
50.02.5 — Fieldbus Standard for Use in Industrial Control Systems (ISA)
50.02.6 — Fieldbus Standard for Use in Industrial Control Systems (ISA)
51.1 — Process Instrumentation Terminology (ISA)
67.01 — Transducer and Transmitter Installation for Nuclear Safety (ISA)
67.02.01 — Nuclear Safety Instrument Sensing Line Piping, Tubing (ISA)
67.03 — Light Water Reactor Coolant Pressure Boundary Leak Detection (ISA)
67.04.01 — Setpoints for Nuclear Safety-Related Instrumentation (ISA)
67.06 — Response Time Testing of Nuclear Safety Instrument Channels (ISA)
67.14.01 — Certification of Instrumentation and Control Technicians (ISA)
71.01 — Environmental Conditions Process Measurement, Control Systems (ISA)
71.02 — Environmental Conditions Process Measurement, Control Systems (ISA)
71.03 — Environmental Conditions Process Measurement, Control Systems (ISA)
71.04 — Environmental Conditions Process Measurement, Control Systems (ISA)
72.01 — PROWAY-LAN Industrial Data Highway (ISA)
72.02 — Manufacturing Message Specification: Companion Standard (ISA)
75.01.01 — Flow Equations for Sizing Control Valves (ISA)
75.02 — Control Valve Capacity Test Procedures (ISA)
75.03 — Integral Flanged Globe-Style Control Valve Bodies (ISA)
75.04 — Dimensions for Flangeless Control Valves (ISA)

75.05 — Control Valve Terminology (ISA)
75.11 — Inherent Flow Characteristics, Rangeability of Control Valves (ISA)
75.12 — Socket Weld-, Screwed-End Globe-Style Control Valves (ISA)
75.13 — Method of Evaluating the Performance of Positioners (ISA)
75.14 — Dimensions for Buttweld-End Globe-Style Control Valves (ISA)
75.15 — Dimensions for Buttweld-End Globe-Style Control Valves (ISA)
75.16 — Dimensions for Flanged Globe-Style Control Valve Bodies (ISA)
75.17 — Control Valve Aerodynamic Noise Prediction (ISA)
75.19 — Hydrostatic Testing of Control Valves (ISA)
75.22 — Dimensions for Flanged Globe-Style Angle Control Valve Bodies (ISA)
77.13.01 — Fossil Fuel Power Plant Steam Turbine Bypass System (ISA)
77.20 — Fossil Fuel Power Plant Simulators – Functional Requirements (ISA)
77.41 — Fossil Fuel Power Plant Boiler Combustion Controls (ISA)
77.42.01 — Fossil Fuel Power Plant Feedwater Control System (ISA)
77.43 — Fossil Fuel Power Plant Unit/Plant Demand Development (ISA)
77.44 — Fossil Fuel Plant Steam Temperature Control System (ISA)
77.70 — Fossil Fuel Power Plant Instrument Piping Installation (ISA)
82.02.01 — Safety Standard for Electrical and Electronic Equipment (ISA)
82.02.02 — Safety Requirements for Electrical Equipment (ISA)
82.02.04 — Safety Requirements for Electrical Equipment (ISA)
82.03 — Safety Standard for Electrical and Electronic Equipment (ISA)
84.01 — Safety Instrumented Systems for the Process Industries (ISA)
88.01 — Batch Control: Models and Terminology (ISA)
91.01 — Identification of Emergency Shutdown Systems and Controls (ISA)
92.0.01 — Toxic Gas-Detection Instruments: Hydrogen Sulfide (ISA)
92.02.01-1 — Carbon Monoxide Detection Instruments (ISA)
92.03.01 — Ammonia Detection Instruments (25–500 ppm) (ISA)
92.04.01-1 — Detecting Oxygen-Deficient/Oxygen-Enriched Atmospheres (ISA) 93.00.01 – External Leakage of Manual and Automated On-Off Valves (ISA)
95.00.01 — Enterprise-Control System Integration (ISA)
95.00.02 — Enterprise-Control System Integration (ISA)
REWIC03 — Management of the Development of Critical Computer Systems (ISA) MC96.1 – Temperature Measurement Thermocouples (ISA)
RA8425 — Standards Library for Automation and Control 2003, CD (ISA)
REWIC01 — Programmable Logic Controllers in Safety-Related Systems (ISA)
REWIC02 — Achieiving Safety in Distributed Systems (ISA)
REWIC03 — Development of Critical Computer Systems (ISA)
RP12.13-2 — Combustible Gas Detection Instruments (ISA)
RP12.2.02 — Intrinsic Safety Control Drawings (ISA)
RP12.4 — Pressurized Enclosures (ISA)
RP12.6 — Wiring Practices for Hazardous Locations Instrumentation (ISA)
RP16.1,2,3 — Indicating Variable Area Meters (Rotameters) (ISA)
RP16.4 — Extension-Type Variable Area Meters (Rotameters) (ISA)
RP16.5 — Glass Tube Variable Area Meters (Rotameters) (ISA)
RP16.6 — Calibration of Variable Area Meters (Rotameters) (ISA)
RP2.1 — Manometer Tables (ISA)
RP31.1 — Turbine Flowmeters: Specification, Installation, Calibration (ISA)
RP42.1 — Nomenclature for Instrument Tube Fittings (ISA)
50.1 — Analog Signals for Electronic Industrial Process Instruments (ISA)
RP52.1 — Recommended Environments for Standards Laboratories (ISA)
RP60.1 — Control Center Facilities (ISA)
RP60.11 — Crating, Shipping, and Handling for Control Centers (ISA)
RP60.2 — Control Center Design Guide and Terminology (ISA)
RP60.3 — Human Engineering for Control Centers (ISA)
RP60.4 — Documentation for Control Centers (ISA)
RP60.6 — Nameplates, Labels, and Tags for Control Centers (ISA)
RP60.8 — Electrical Guide for Control Centers (ISA)
RP60.9 — ISA-RP60.9-1981 – Piping Guide for Control Centers (ISA)
RP67.04.02 — Setpoints for Nuclear Safety-Related Instrumentation (ISA)
RP74.01 — Continuous-Belt Weighbridge Scales (ISA)
RP75.21 — Process Data Presentation for Control Valves (ISA)
RP75.23 — Considerations for Evaluating Control Valve Cavitation (ISA)
RP76.0.01 — Analyzer System Inspection and Acceptance (ISA)
RP92.0.02 — Toxic Gas-Detection Instrument: Hydrogen Sulfide (ISA)

RP92.02.02 — Carbon Monoxide Detection Instruments (ISA)

RP92.03.02 — Ammonia Detection: Installation, Operation, Maintenance (ISA)

RP92.06.02 — Chlorine Detection: Installation, Operation, Maintenance (ISA)

TR12.06.01 — Electrical Equipment in Hazardous Locations (ISA)

TR12.13.01 — Flammability of Combustible Gases, Vapors (ISA)

TR12.13.02 — Fire, Explosion Accidents in the Chemical, Mining, Fuel (ISA)

TR12.2 — Intrinsically Safe System Assessment: the Entity Concept (ISA)

TR12.24.01 — Classification of Locations for Electrical Installations (ISA)

TR50.02-9 — Fieldbus Standard for Use in Industrial Control Systems (ISA)

TR67.04.08 — Setpoints for Sequenced Actions (ISA)

TR75.04.01 — Control Valve Position Stability (ISA)

TR77.60.04 — Fossil Fuel Power Plant Human-Machine Interface (ISA)

TR77.81.05 — Interfaces for CEMS Relative Accuracy Test Audit Data (ISA)

TR88.0.03 — Possible Recipe Procedure Presentation Formats (ISA)

TR92.06.03 — Feasibility of Chlorine Detection Instrument Testing (ISA)
