The operation of direct-connected large-case controllers is the same as that of large-case receiver controllers. The pen or pointer arm, instead of being actuated by pressure from a process transmitter, is actuated by its own built-in process pressure detector. The cross sections of some of the measuring elements that are available with large-case controllers are shown in Figure 3.1v.

These include sensors for the detection of pressure, absolute pressure, draft, vacuum, differential pressure, liquid level, and filled systems for temperature measurement. Basic electrical measurements involved in thermocouples, resistance bulbs, radiation pyrometers, and pH probes are accommodated in the potentiometer versions of large-case pneumatic controllers.

As with the large-case receiver controller, the direct-connected ones are also available with remote set point adjustment for cascade and ratio control applications.

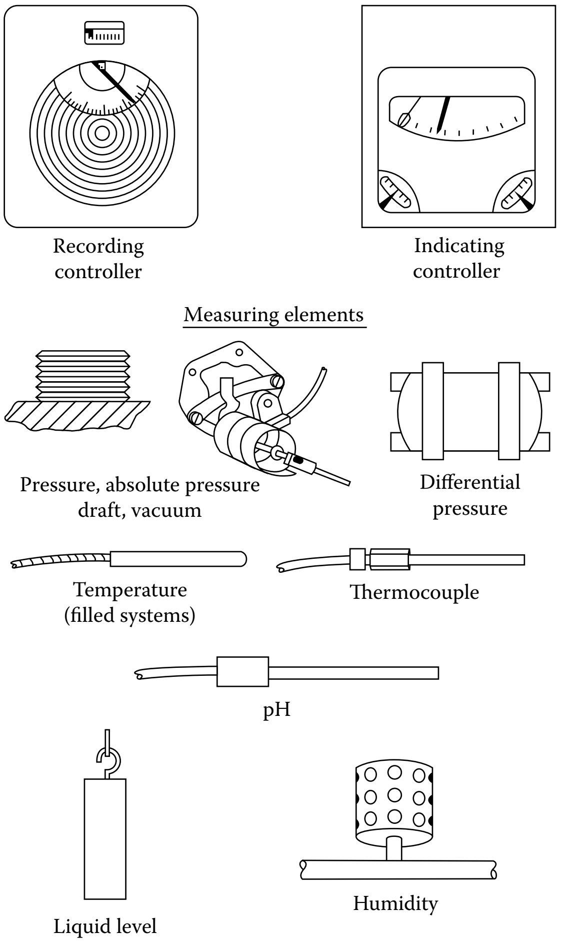

FIG. 3.1v
Direct-connected large-case recording and indicating controllers can be provided with a variety of direct sensors, including the shown measuring elements.

FIELD-MOUNTED CONTROLLERS

Direct-Connected

Direct-connected controllers mounted in the field are smaller than the large-case instruments. They usually have weatherproof cases and are available in both indicating and blind designs. They can be pipe-mounted, mounted directly on a valve or surface, or flush-mounted on a local panel. They include their own measuring elements. Figure 3.1w shows some typical types and mounting arrangements.

These units are the least expensive pneumatic controllers, and they are expected to be less accurate than the previously discussed designs are. They find use in small local installations and as local field loops in larger plants. Every plant has some noncritical loops that do not require auto–manual switching or the displaying of their controlled variable or access to their set point from the control room. These units are used as local pressure, temperature, and level regulators.

These field-mounted controllers can be had with on/off, differential gap, proportional, reset, and derivative modes of control. Their principles of operation are similar to that discussed in connection with Figures 3.1a and 3.1w.

Receiver-Type

Some field-mounted local controllers receive a signal from a transmitter rather than having their own measuring element. Such controllers are used if the measurement must be transmitted to the control board for recording, alarm, or indication, but the controller is local. Field-mounted receiver controllers are shown in Figures 3.1c and 3.1d. Remote adjustment of set point is also an option with these controllers.

Pneumatic with Electronic Detectors

The temperature controller illustrated in Figure 3.1x, receives a temperature measurement signal from either a thermocouple or a resistance temperature detector (RTD). These indicating pneumatic controllers provide the accuracy, convenience, and range of electrical temperature sensing but without the need for external electrical power. A built-in generator accepts a conventional pneumatic pressure source and produces electrical power for the controller.

The controller compares the process temperature signal with an operator-adjustable set point and delivers a pneumatic control signal to a final control element, which then moves the process temperature towards the set point. Process temperature

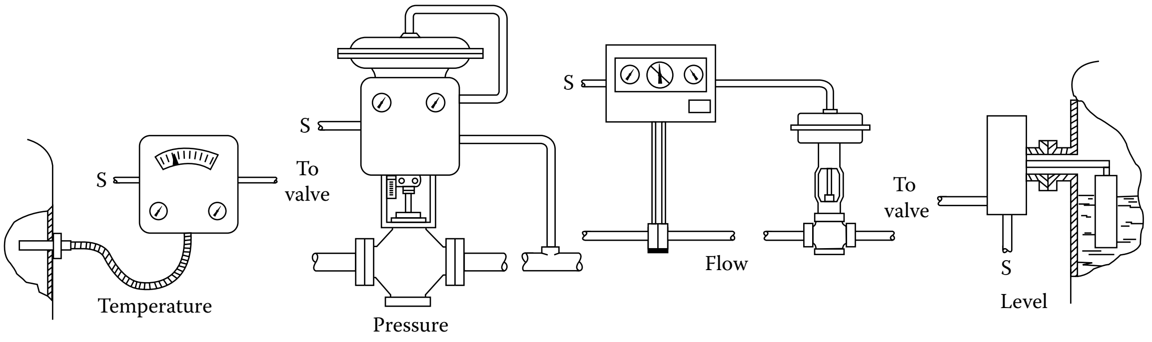

FIG. 3.1w

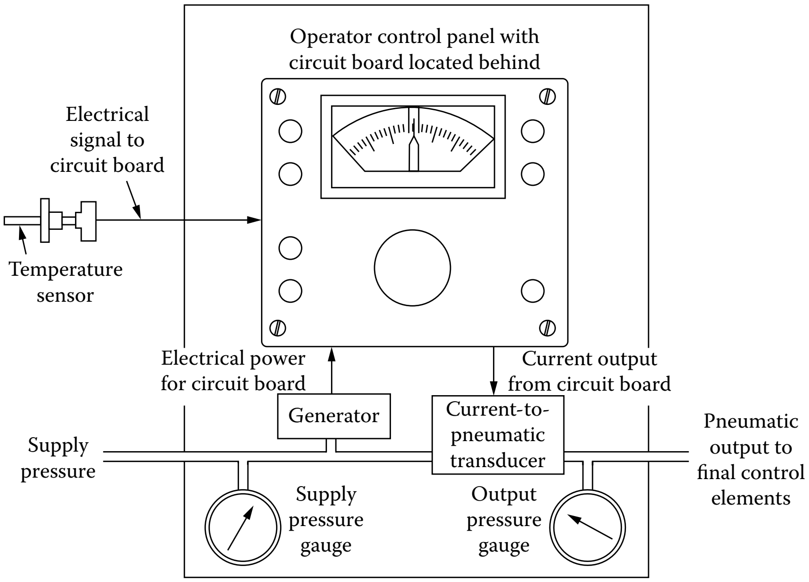

FIG. 3.1x
Pneumatic controller with electronic temperature sensor.

and set point are both indicated on this controller. These controllers are available with PI and PID control modes and with or without bumpless and balanceless auto/manual switching.

In some designs, the air supply is also used to generate the required electric power for the unit and therefore, the maximum "instantaneous" air supply requirement could reach 80 SCFH (2.3 normal m^3/hr), while the maximum "steady state" air consumption is only 35 SCFH (1.0 normal m^3/hr).

In this controller, a thermocouple or RTD temperature sensor signal is applied to the circuit board, which electrically compares the signal with the set point value and acts on the error with its proportional, reset, and rate control modes to restore the process temperature to the set point value.

SPECIAL PNEUMATIC CONTROLLERS

Connections for Digital Highways

Figure 3.1y illustrates a pneumatic controller, which is provided with microprocessor-based digital highway communication modules for integration into distributed control systems (Figure 3.1y). By thus making it possible to communicate over a data highway, pneumatic controls were made compatible with distributed systems.

The serial communications module reports, upon command, the current value of the set point, process variable, and valve output and the operating mode that the station is in. The communications module can also receive and execute commands, which can change set points or outputs or operating modes. Miniature transducers convert the pneumatic signals to electric, from which the signals are then converted to digital. The serial link operates at 19.2 kilobaud.

The first data highways were introduced in the late 1970s. Fieldbus is an architecture that provides a communication link between all instruments and all computers using a standard interface. Several manufacturers have entered the fieldbus technology market. However, the Internet seriously threatens the fieldbus market, because Web-based communication between instruments and computers may eventually lead to the replacement of some fieldbus components.

Special Controls

Feedforward, ratio, cascade, and other loop configurations can be easily implemented with pneumatic hardware. Two of the popular control configurations involve selective and batch

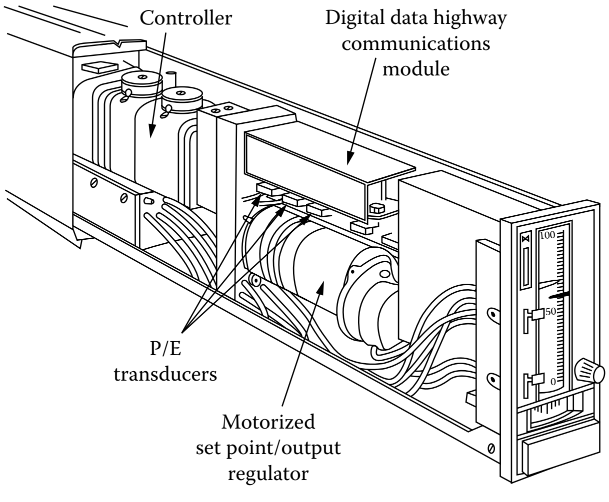

FIG. 3.1y

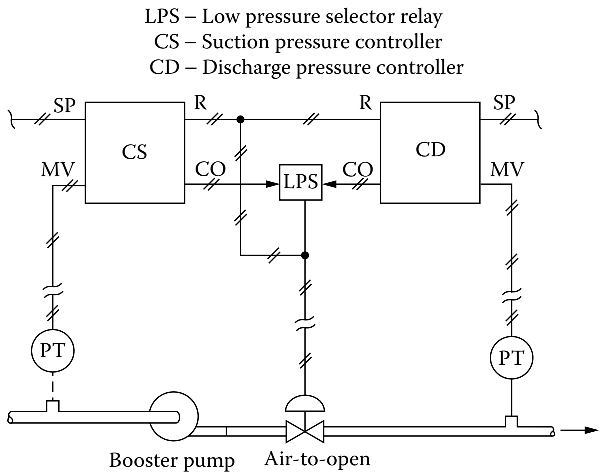

FIG. 3.1z
Automatic override or selector control circuit on pipeline booster pump.

control. Controllers are sometimes packaged specially for these applications.

Selective Control With automatic selector control, also called override or limit control, two or more control loops are connected to a common valve. In this configuration, when the conditions are normal, the normal controller has command of the valve. However, if some abnormal condition arises, one of the other loops can automatically take over control to keep the plant operation within safe limits.

Unlike safety shutdown systems, here the plant is kept in operation, although its production rate might be cut back as much as necessary to stay within safe limits. When the abnormal condition abates, the normal loop resumes control. Figure 3.1z shows a control system that can be used on a booster pump station that is serving a transcontinental pipeline.

Under normal conditions the discharge pressure of the pump is being controlled. If the suction pressure gets too low, however, as would be the case if the booster pump upstream failed or if a line rupture occurred, the discharge controller would open the valve wide, which would lower the suction pressure beyond safe limits, causing cavitation, which could seriously damage the pump.

To protect against this, a suction pressure controller is added, which is set to the low safe limit, and a low-pressure selector is installed on the two controller outlets. Since the control valve is air-to-open, the low selector chooses the output of that controller, which is asking for the valve to be less open. Under normal conditions, when the suction pressure is adequate, the output of the discharge pressure controller will be the lower and hence, it will throttle the valve. If suction pressure drops to the set point of the suction pressure controller, it automatically takes over control.

A key requirement for correct implementation of this system is to provide both controllers with a live reset feedback from the valve pressure. In this way the controlling unit has its reset acting normally while the standby controller is prevented from saturating or winding up. This way, when either controller takes over, its reset will exactly match the pressure of the signal reaching the valve at the instant of switchover.

Batch Control Figure 3.1aa shows a control system for batch pressure control. Batch control is special because when a batch is completed and the manual valve is closed while the controller is in automatic, the reset mode of the controller will keep integrating the error until the controller saturates (winds up).

At the next startup, if the controller is PI only, or if it is a PID controller but its derivative mode is interacting with the proportional and reset actions (Figures 3.1a and 3.1c), the controller output will stay saturated until the error changes sign. Therefore, the controller will stay inactive until the process measurement crosses over set point. This will result in a considerable overshoot.

One solution is to add the antireset windup relay shown in Figure 3.1aa. This is simply a throttling relay set to operate at 15 PSIG (1 bar), which corresponds to the wide-open position of the control valve. As long as the controller output is below

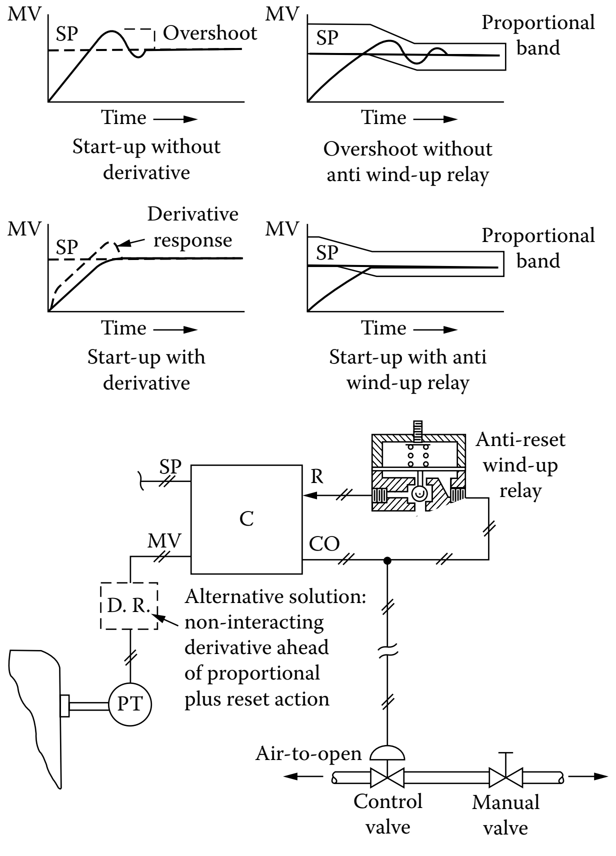

FIG. 3.1aa
Alternative circuits for eliminating over-peaking during startup of batch processes.

15 PSIG, the relay transmits the output to the reset feedback connection of the controller and the reset acts normally.

If the output goes above 15 PSIG, the relay begins exhausting the reset feedback line until the output pressure drops to 15 PSIG. Thus it does not affect control except when the system is shut down. At that time it lowers the reset pressure to whatever value it has to be in order to limit its output to 15 PSIG. This allows the proportional action to be active during startup so that it can prevent overshoot. How effective the antireset windup protection is depends upon the quality of the tuning of the controller.

An alternative solution to reset windup on batch applications is to use either a separate derivative unit or a controller with a built-in derivative unit ahead of the proportional-plus-integral sections. This way the derivative unit's output crosses over the set point sooner than the variable itself does, and this starts the reset to unwind, which is in time to prevent overshoot.

The effectiveness of this circuit also depends upon proper tuning. Too little derivative allows some overshoot; too much causes initial undershoot.

3.2 Controllers—Electronic

P. M. B. SILVA GIRÃO (2005)

Types:	Analog, digital.
Applications:	Single-loop or multi-loop; single or multi-variable.
Control Modes:	Analog: Manual, two-step (on/off), multi-step, proportional (P, throttling), integral (I, reset), derivative (D, rate), cascade, selective, feed forward, limiting, ratio and adaptive. Digital: all types listed for analog, plus multi-variable interactive, model based, neural and fuzzy logic.
Input Ranges:	4 to 20 mA (most common), 0 to 20 mA, 0 to 10 V, 2 to 10 V.
Typical Output Range:	4 to 20 mA.
Displays:	Set point, controlled (process) variable, manipulated (output) variable, deviation, alarms, limits.
Typical Front Panel Size:	1/32 DIN (1.89 in. × 0.95 in. [48 mm × 24 mm]), 1/16 DIN (1.89 in. × 1.89 in. [48 mm × 48 mm]), 1/8 DIN (1.89 in. × 3.78 in. [48 mm × 96 mm]), 1/4 DIN (3.78 in. × 3.78 in. [96 mm × 96 mm]).
Supply:	AC: 24, 120, 230 V. DC: 12 V.
Inaccuracy:	Analog: 0.5 to 1% of span; Digital: from under 0.1 to 0.5% of span (zero < 0.2%; gain < 0.1%).
Costs:	*On/off controllers (switches):* The simplest versions of both analog and digital units can be obtained for $100. HVAC quality direct-connected controllers range from $200 to $500. Process control quality analog PID controllers are in the range of $1000 to $1500, and microprocessor-based local digital controllers, with more options than their analog counterparts are in the $1000 to $2000 range.
Direct Signal Processor (DSP) Controller Capabilities:	Can be programmed for almost anything, including linearization, compensation for valve and actuator characteristics, a variety of control modes (including batch control), and a variety of algorithms, both linear and nonlinear, self-tuning and self-optimization.

INTRODUCTION

In this handbook, electronic controllers are discussed in three chapters, and there is some overlap between them. Chapter 2 is devoted to control theory; it discusses a number of software packages that include control algorithms. This chapter concentrates on local controllers. Chapter 4 covers control room equipment, including a variety of electronic controllers and DCS systems. Because electronic controllers can be mounted in either the control room or locally out in the field (properly protected), they are discussed in both Chapters 3 and 4.

Electronic controllers entered the market in the late 1950s using vacuum tube technology. In the beginning, the process variable and the controller output signals were both voltage signals, but they were not immune to noise. In addition, if the signal were to drive several series loads, it would degrade. Because current signals provide better accuracy, the 4- to 20-mA signal was adopted as standard. In the 1960s and 1970s, the performance of electronic analog controllers increased due to the use of solid-state electronics.

Digital control systems using mainframe computers were considered since the mid-1950s and early 1960s. However, it was the introduction of the microprocessor in the 1980s that boosted the use of digital process and today one can say that digital electronic controllers dominate the process controller market. The microprocessor allowed the implementation of more sophisticated and better-performing control algorithms and led to the production of controllers whose configuration and tuning can be easily changed or adapted to different applications.

The microprocessor has also contributed decisively to the development of new control approaches, such as DCS, which is discussed in Chapter 4; PLCs, which are covered in Chapter 5; and digital networks, which are the topic of Volume 3 of this handbook.

An electronic controller can be an ac- or dc-powered device whose inputs (set point and measurement [controlled process variable]) and output (manipulated variable) are electric signals. When the controller is manipulating the opening of an air-operated valve, its electronic output signal is converted to an air signal by an I/P or V/P (current-to-air or voltage-to-air) converter. A typical electronic control loop configuration is shown in Figure 3.2a.

Electronic controllers can be analog or digital. Analog controllers are real-time devices that operate on continuous analog signals. The operation of digital controllers is software-based and implements control algorithms, which are very fast but still are intermittent devices in comparison to their analog counterparts. Analog electronic controllers are cheaper than their digital counterparts when the control requirements are small (e.g., single control loop and simple on/off or plain proportional control algorithms).

Digital controllers are more complex because they need (1) to convert analog input signals to digital ones before they can be processed and then to convert the digital output signals back to analog and (2) because digital controls and displays are usually more expensive. In spite of the relative costs favoring analog designs when the control requirements are minimal, the trend is clearly in favor of the digital design, not only because of its flexibility, superior performance, and communications

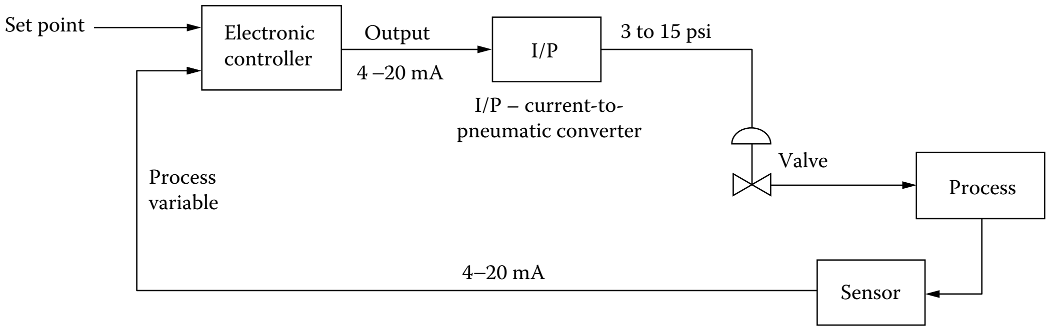

FIG. 3.2a
The main components of an electronic process control loop with a pneumatically operated control valve, which necessitates the use of a current-to-air (I/P) converter.

abilities, but also because of its relative economy in case of large control systems.

ANALOG ELECTRONIC CONTROLLERS

Today, analog electronic controllers are solid-state electronic instruments using operational amplifiers. The amplifiers have high gain, high input impedance, very low offset, and high common-mode rejection. When mounted locally, they must be protected against the environment, and they require special care in selecting the controller's components and packaging.

The majority of analog electronic controllers are used to implement the less sophisticated control algorithms (on/off, P, PI, PID, cascade, ratio, etc.) usually in single control loops that are measuring only one process variable. Sometimes, they are also used as backup (for computer failure) of critical loops in systems that are controlled by multi-loop digital controllers.

As shown in Figure 3.2a, an analog electronic controller receives the controlled process variable from a 4- to 20-mA electronic transmitter, compares that signal to its set point and generates a 4- to 20-mA output based on its control algorithm. This signal is converted into a 3- to 15-PSIG pneumatic signal if the manipulated element is an air- operated throttling valve.

Analog On/Off Switch

Figure 3.2b shows the block diagram of an analog based on/off electronic switch. (For a discussion of regular field mounted on/off switches refer to Volume 1 of this handbook and for panel- or console-mounted switches, see Chapter 4 in this volume.)

In Figure 3.2b, the 4- to 20-mA to voltage conversion is achieved by inserting a resistor into the current loop. The isolation amplifier serves to provide the separation between the transmission loop and the on/off controller electronics. The voltage switch provides the means for switching from direct to reverse action. In the direct mode, the in- and outputs move in the same direction, while in the reverse mode an increase in the controlled variable (input) results in a drop in the manipulated variable (output).

In Figure 3.2b, the hysteresis of the voltage comparator (Schmitt trigger type) provides an adjustable dead band to reduce the duty or rate cycle. Voltages at the switch inputs and comparator's output can be used to monitor set point, controlled variable, and manipulated variable values. The set point may be provided either (1) locally using a dc power supply and a voltage divider, or (2) by the output of another controller (cascade control) or (3) by a remote source.

For the manual control of the loop, the input of the voltage to a 4- to 20-mA converter must be disconnected from the comparator output and connected to the remote and adjustable dc supply (e.g., a power supply and a adjustable voltage divider).

Analog PID Controller

PID control algorithms are used on processes with multiple capacities and large and/or fast-changing loads. The output of the PID controller (E_o), which is also called the manipulated variable (m), is a function of the difference between the controlled variable and the set point or error (e). The classical

I/V – current (4–20 mA)-to-voltage converter
V/I – voltage-to-current (4–20 mA) converter

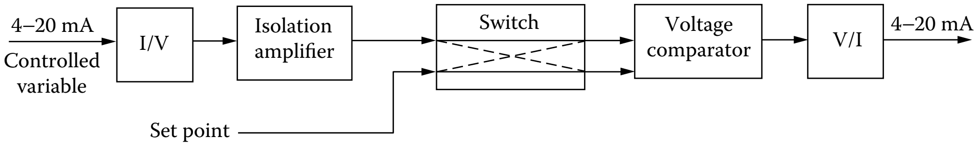

FIG. 3.2b
ON/OFF analog electronic controller.

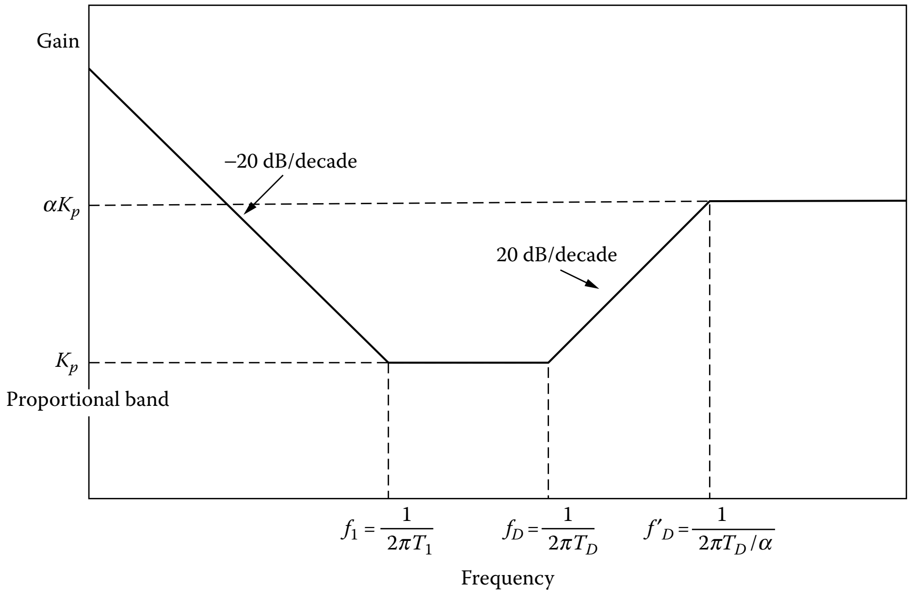

FIG. 3.2c
Bode representation of the PID controller algorithm corresponding to Equation 3.2(3).

differential equation relating the two is:

$$m = E_o = K_P e + K_D \frac{de}{dt} + K_I \int e\,dt \qquad 3.2(1)$$

where K_P is the proportional gain, K_D the derivative time, and $1/K_I$ the integral time. The transfer function $G(s)$, which relates E_o with e in the frequency domain, is obtained by Laplace transformation of Equation 3.2(1) yielding:

$$G(s) = K_P\left(1 + T_D s + \frac{1}{T_I s}\right) \qquad 3.2(2)$$

where $T_D = K_D/K_P$ and $T_I = K_P/K_I$. Most analog electronic PID algorithms are not this noninteracting variety in the time domain but rather in the frequency domain:

$$G(s) = K_P\left(\frac{1 + T_I s}{T_I s}\right)\left(\frac{1 + T_D s}{1 + (T_D/\alpha)s}\right) \qquad 3.2(3)$$

where $K_P = 100/\mathrm{PB}$, (PB is proportional band), $T_D = K_D/K_P$ is a rate (derivative) time, $T_I = K_P/K_I$ is a reset (integral) time, and α is the derivative gain, usually between 5 and 20, that ensures that the output does not change significantly in response to electrical noise (incomplete derivative controller). The Bode frequency-response of this equation is presented in Figure 3.2c.

PID Components Figure 3.2d shows one possible implementation of a PID analog electronic controller. In this figure, IA is a very-high-input impedance amplifier that amplifies the difference between the controlled (process) variable and the set point. If the controlled variable and the set point are equal, the output of the IA (the error, e) is equal to the reference voltage. The same objective can be obtained with an operational amplifier in a difference configuration, but because the voltage that is to be amplified is floating, the

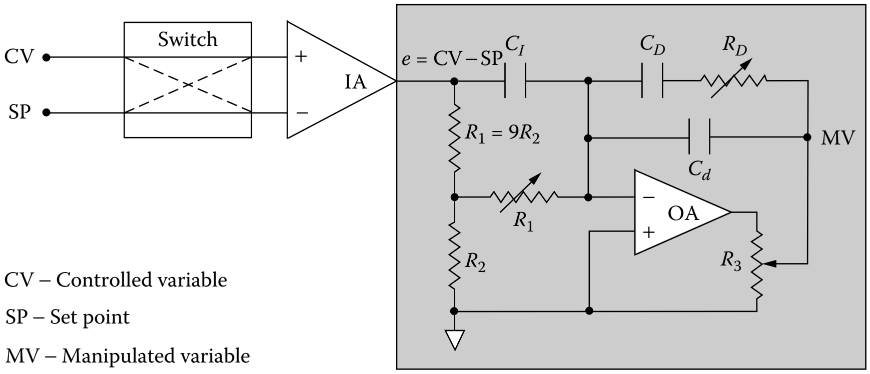

FIG. 3.2d
PID analog electronic controller circuitry including an error amplification stage.

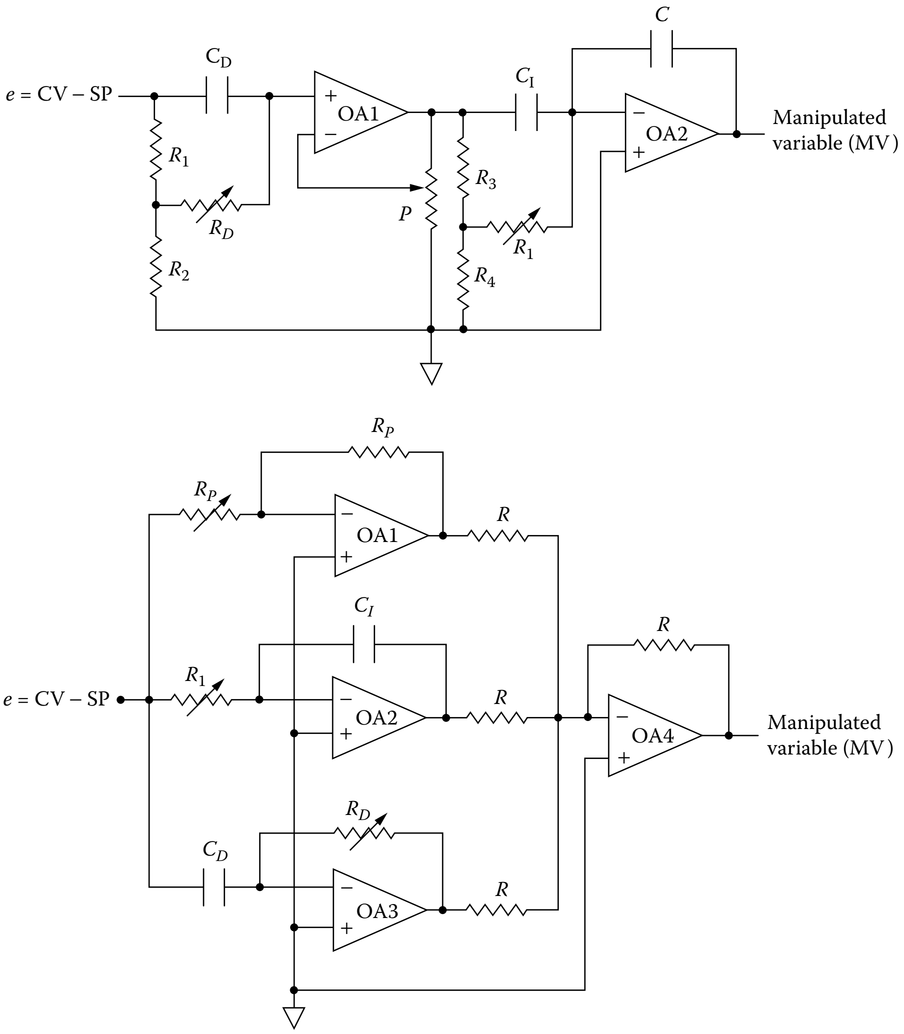

FIG. 3.2e

Operational blocks of two PID controller algorithms corresponding to Equation 3.2(3) (top) and Equation 3.2(1) (bottom).

higher common-mode rejection ratio of instrumentation amplifiers suits this application better.

The switch is in front of the instrumentation amplifier and serves to implement the direct or reverse action of the controller. As shown in Figure 3.2b but not in Figure 3.2d, a current-to-voltage converter and an isolation amplifier would complete the path of the controlled variable to the switch input.

OA is a very high-impedance operational amplifier. The transfer function of this amplifier configuration conforms to Equation 3.2(3). $R_I C_I$ define the reset time constant that determines f_I on the Bode plot of Figure 3.2c. R_1 and R_2 divide the error voltage by 10 so that R_1 is 1/10 of the value required to obtain the same time constant if this voltage divider were not used. The rate time constant of the controller is set by the combination of R_D, C_D, and C_d.

These components determine the lead or lag at f_D and f_d on the Bode diagram of Figure 3.2c. The voltage divider R_3 adjusts the feedback voltage (proportional-band adjustment), the minimum feedback voltage corresponding to the highest gain. Voltage-to-4- to 20-mA conversion, not shown in Figure 3.2d, is usually implemented by feeding the output voltage to a current amplifier.

Figure 3.2e shows two circuits that can also be used instead of the one inside the shaded box of Figure 3.2d for PID analog electronic controller implementation. The top one also implements Equation 3.2(3) while the one on the bottom implements Equation 3.2(1).

Both controllers, which are described in Figures 3.2d and 3.2e, implement PID algorithms that act on the deviation or error. As it is discussed in more detail in Chapter 2, there are several other options as a function of the controlled process. Figure 3.2f shows an algorithm implementation where the derivative mode acts on the measurement (derivative-in-front PID), which tends to speed up the return to set point in some processes.

Displays and Communications In an analog electronic controller the values of set point, controlled variable, deviation, and manipulated variable are represented by the amplitudes of slowly varying electric voltages. Indicating dc analog voltmeters

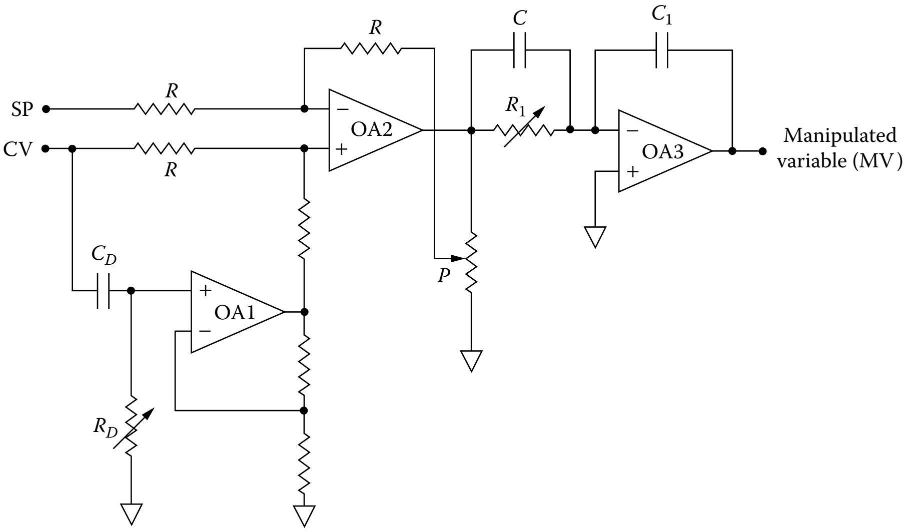

FIG. 3.2f

Operational block of a PID analog electronic controller where the derivative mode acts on the measurement instead of the error.

(e.g., D'Arsonval type) with scales graduated either in units of the process variable or more often in percentage of the span are used for monitoring these values. Abnormal conditions are signaled by voltage- or current-operated sound alarms. Even in analog controllers, the low price of numeric, alphanumeric, and bar graph displays and of their respective circuit drivers favors their use.

One feature that is common in today's analog electronic controllers is the capability for digital interfacing. Interfacing circuits and boards for serial communication, such as RS485, are quite inexpensive, available from different vendors, and fairly easy to incorporate in the controller. As already mentioned, this feature is decisive when the controller is to be integrated into a distributed or supervised control system.

Reset Windup Any controller that has an integral mode will saturate when a deviation between the controlled variable and the set point persists. This is because the reset capacitor in the controller will continue to charge so long as the error exists. This phenomenon is called integral or reset windup and is important in process phases during which the controller is switched to manual. This is the case, for example, after startup, where the controller can saturate its output before it is switched into automatic. Problems resulting from reset windup can be minimized by including circuitry that limits the output voltage of the reset amplifier.

Automatic-to-Manual Switching The manipulated variable (controller output) should stay constant while switching from the automatic to the manual mode of operation and vice versa, because any sudden change in this signal will upset (bump) the process.

One possible way to obtain bumpless transfer is to use a switch that is controlled by voltage transition and is enabled by pressing the front panel button, which commutates only if a comparator circuit detects that the output voltage of the manual operation block crosses the controller output voltage. In this design, if the output of the manual operation block changes very quickly, a bump may still occur.

To avoid this problem, slewing buttons (step-up, step-down) are used for manual adjustment. Controllers provided with automatic commutation means are sometimes called procedureless controllers.

Stability In analog electronic controllers the feedback amplifiers and feedback networks must be carefully designed to ensure that the controller is stable under all operating conditions. Drift due to component leakage is also a problem to overcome. Currents even as low as some nanoamperes can still produce significant output drift due to the extremely large time constants and very high input impedance of the amplifiers. Thus, it is important to carefully select not only the components of the operational amplifier but also the design of the circuit's layout.

DIGITAL ELECTRONIC CONTROLLERS

Computers of medium and large size are used in process control, while local digital controllers are mainly microprocessor based. Initially, microprocessor-based controllers were developed to control more than one loop, which reduced the per-loop cost. Nowadays, however, the price of microprocessors has dropped to a level that allows their usage in both multi-loop and single-loop controllers.

Other processing structures available to support the implementation of digital controllers are programmable logic devices (PLDs), namely, field-programmable gate arrays (FPGAs). Control algorithms such as PID can be implemented in FPGAs.[1] Nevertheless, FPGA-based digital process controllers are still rare because in many aspects they are outperformed by microprocessor-based controllers.

Performance

Digital controllers outperform analog controllers in several aspects. The accuracy of a digital controller is mainly dependent on the performance of the analog-to-digital (A/D) and the digital-to-analog (D/A) converters it incorporates. Thermal, drift, nonlinearity, and hysteresis errors are minimized in digital controllers, which result in errors of 0.1% or less of the span.

The sophistication and number of available control algorithms and number and topology of control loops and special functions (alarm, totalizing, display) that can be implemented with digital controllers, and the low cost or minimal additional hardware required to do so, are factors in favor of this type of controller. Digital controllers with such options are usually less expensive than the equivalent analog controllers.

Communication Capabilities

Digital techniques allow more information to be transmitted faster and with fewer errors than does analog communication. In addition, a digital controller can easily communicate with a digital computer.

The expected lifetime of local electronic controllers is typically 10 years. Integrated circuits (ICs) are the basis of electronic controllers and, due to the fast rate of development in this domain, some ICs become obsolete in a few years or even less. This is particularly true with digital components that support digital controllers. On the other hand, local controllers operate sometimes in harsh environments.

Microprocessor-Based Controllers

For many years, the name microprocessor was associated with a digital system composed of a central processor unit (CPU), memory, and input/output. The term microprocessor was introduced in 1972 by Intel to designate a large-scale integrated (LSI) circuit with the central processor unit functions of a computer implemented by Intel.

Following Intel's terminology, the microprocessor is viewed as central processor unit and the expression *microprocessor-based controller* refers to any digital electronic controller that is implemented around a CPU. This terminology applies to all digital process controllers, programmable logic controllers (PLCs), micro-controllers, and microcomputers. DCS systems are discussed in Chapter 4 and PLCs in Chapter 5 of this handbook. Here we concentrate on microcontroller—and microcomputer-based electronic controllers that can be mounted locally in the plant.

Operation

In contrast to analog controllers, which operate continuously, digital controllers implement their control algorithms in a batch mode. The CPU, which is the heart of the digital controller, operates sequentially in cycles. The cycles include the steps of process data collection and preprocessing (e.g., linearization), if necessary, calculation of the new value of the manipulated variable, and checking for alarm functions and limits before the new value of the manipulated variable is returned to the analog domain.

The displays are also updated during each cycle. This requires the calculation of engineering values of the controlled variable and the set point, the calculation of other process parameters, and the actualization of the display. This cycle of procedures repeats at rates from 0.05 to 0.5 s, typically 0.1 s. In other words, the process is evaluated and the output of the controller is updated 10 times per second.

This means that a digital controller with a single CPU is not in touch with the process except in the instants of sampling. Thus, the controller is not aware of all events that occur during the cycle. Therefore, all events that need to be continuously monitored must be latched by dedicated hardware for later processing. The communications between the controller and other instruments are handled either by using the time when the CPU is idle between the end of one cycle and the beginning of the next or on an interrupt basis.

Hardware

Microprocessor-based process controllers are data acquisition and processing systems with analog output capabilities. Figure 3.2g shows a block diagram of such a controller. It consists of an analog-to-digital conversion block, a digital-to-analog conversion block, a micro-processing block, a display and controls section, and a communications port. The micro-processing block includes not only the processing element (CPU) but also the memory. Memory used for program storage is of the read-only type (ROM); memory for temporary data storage is of the random-access type (RAM). In addition, the controller has two output ports, one of the serial type for communications and another of the parallel type with individually addressable lines.

The conditioning and analog-to-digital conversion block of the controller provides the processor with the set point and controlled variable values for the control algorithm. The conditioning part of the block provides the interfacing between the controller's input signals and the analog-to-digital conversion section and thus its design depends on both.

The remaining components include an analog multiplexer, a programmable-gain amplifier, a sample-and-hold and an analog-to-digital converter (ADC). The CPU controls these components. The ADC must be chosen taking into account the accuracy and resolutions required for the controller and the conversion rate used.

For ADCs, two good choices are the dual-slope and the successive approximation designs. The first is of the averaging type and thus is less influenced by noise while the second can be implemented using the controller's CPU and few additional components.

Sensors with frequency output (e.g., measurand range converted into a 10- to 50-kHz frequency range) are becoming more and more popular, and some microprocessor-based

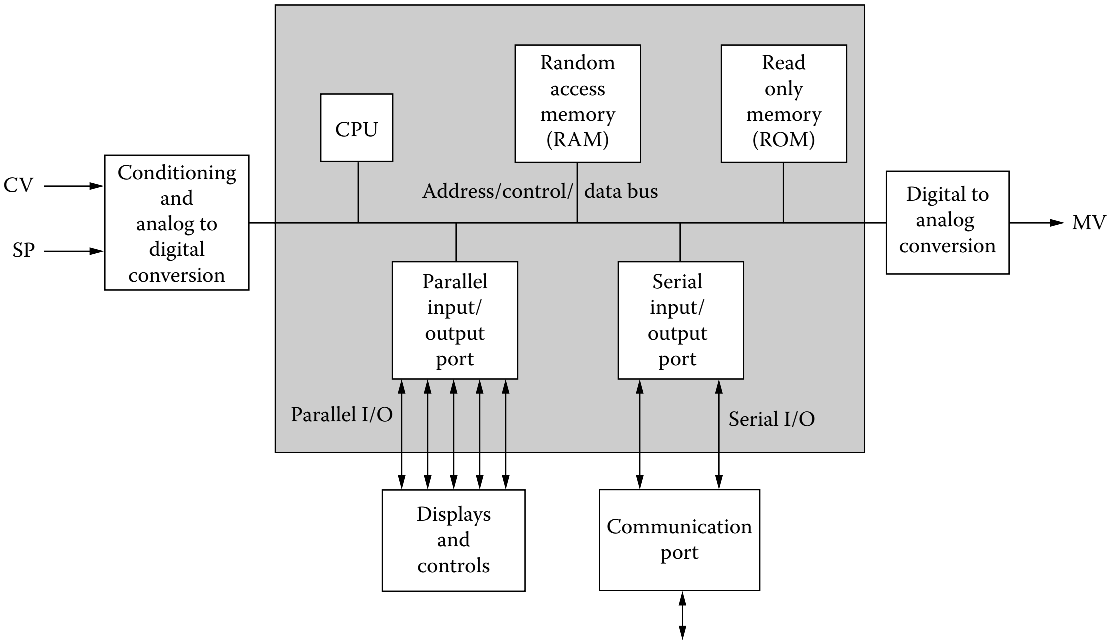

FIG. 3.2g
Typical hardware block diagram of a microprocessor-based process controller.

controllers are able to directly interface with them. In this case, the analog-to-digital conversion is easier because it depends on pulse counting, and thus the analog-to-digital conversion block is not required.

The function of the digital-to-analog conversion (DAC) block is to convert the calculated value of the manipulated variable into a dc voltage or current. DACs use an R-2R resistor ladder network whose natural output is a current. Some manufacturers also offer digital controllers with air pressure output.[2]

Displays and Communications Digital displays with either a bar graph and a digital readout that provide the variable values in engineering units are both good choices since they allow fast reading of values and also fast detection of abnormal conditions.

For adjusting digital controllers, switches, pushbuttons, keyboards, and joysticks are the natural replacements for potentiometers because they are more accurate to input data and easier to read. Figure 3.2h shows the face plates of three microprocessor-based controllers, which all have these types of displays. As a rule, displays and controls are connected to the parallel port of the processing block.

Communication between the controller and other systems is in serial formats to minimize wiring. The serial port of the processing block interfaces the processor buses, but the remaining of the transmission and communication channel can and is implemented in several different ways, some standardized others not, which makes interconnection of equipment from different manufacturers difficult if not impossible.

It is true that several manufacturers offer controllers that are compatible with standard hardware interfaces. Unfortunately, most suppliers provide only the minimum information a user needs to establish communication with other equipment. What is even worse is that in many cases the user has to configure or even has to program the equipment (e.g., computer) to code and decode the commands and data communicated by the controller.

The diversity of solutions is undesirable for users, but to date the definition and general acceptance of a single standard has been resisted by manufacturers. The existence of several fieldbuses is another example of lack of standardization. Nevertheless, some attempts have been made to standardize communications in control systems. The IEEE 1451 series of standards[3] is a good example, but it has had little success to date.

Micro-Controllers and Backup Power In the micro-processing block in Figure 3.2g, the CPU and the other components are separately shown. This corresponds to the architecture of a microcomputer. When the CPU, memory, and I/O are integrated into one circuit chip, the processor unit is called a micro-controller.

Microcomputers and micro-controllers differ also in other aspects. Microcomputers run at higher clock rates, have larger memory blocks, and are easier to program. For these reasons, microcomputers are presently better suited for process control applications. Nevertheless micro-controllers, which were initially designed to operate as embedded systems, are growing in complexity and functionality.

Some micro-controllers today can not only perform as a microcomputer but can also include, in the single chip, a variety of additional functions. These include analog-to-digital and digital-to-analog conversion, memory arrays, both of RAM

FIG. 3.2h
Front panel view of microprocessor-based controllers: temperature (upper left), general-purpose single-loop or cascade (bottom) and multi-loop (Courtesy of Foxboro Co. and Smar International.)

and of electrical alterable or erasable programmable read only memory (EAPROM, EEPROM), of reasonable sizes and advanced input/output capabilities (e.g., "high" power signal handling). Micro-controllers are inexpensive (less than $10) and thus potentially interesting as hardware support for digital process controllers.

Some processes require control modes and algorithms involving a heavy arithmetic workload and thus fast memory access or heavy data transfer. In those cases, the processing block must use special processors called digital signal processors (DSPs).

The operating parameters of a digital controller are entered by the operator and must be stored in the memory. It is good practice to provide backup power, so that the stored data are not lost and do not need to be reloaded after a power interruption (nonvolatile memory).

Possible solutions are: (1) incorporation of a long-life or rechargeable battery in the controller to maintain power to the RAM during loss of primary power, (2) use of EAPROMs or EEPROMs for parameter storage. Since the number of write/erase cycles in EAPROMs and EEPROMs is limited, the lifetime of this last solution may prove to be incompatible with the expected lifetime of the controller.

Software

The standard control algorithm for process control still is the PID algorithm. Its velocity algorithm is:

$$u_{n\Delta t} = u_{(n-1)\Delta t} + K_P \left(\begin{array}{l} (e_{n\Delta t} - e_{(n-1)\Delta t}) + \dfrac{\Delta t}{T_I} e_{n\Delta t} \\ + \dfrac{T_D}{\Delta t}(e_{n\Delta t} - 2e_{(n-1)\Delta t} + e_{(n-2)\Delta t}) \end{array} \right) \tag{3.2(4)}$$

where $u_{n\Delta t}$ is the controller's output in sampling instant $n\Delta t$ (current value); $u_{(n-1)\Delta t}$ is the controller's output value in sampling instant $(n-1)\Delta t$ (previous value); $e_{n\Delta t}$, $e_{(n-1)\Delta t}$, and $e_{(n-2)\Delta t}$ are deviations at sampling instants $n\Delta t$, $(n-1)\Delta t$ and $(n-2)\Delta t$, respectively; K_P, T_I, and T_D are the proportional gain, integral, and derivative times, respectively; and Δt is the time interval between samples.

In the velocity algorithm, integral is replaced by addition, and the simplification leads to a requirement of calculating only the change that has occurred in the error since the last sampling; the change in error is weighted by the appropriate constants.

The performance of a microprocessor-based controller naturally depends on its hardware. Nevertheless, it is the software component that ultimately dictates the controller's capabilities. The controller's cost reflects this. The same hardware may support controllers with different specifications and different prices.

General-purpose digital controllers are designed to meet the expectations of a broad spectrum of users rather than fully exploiting the capabilities of the hardware. Direct signal processor (DSP)-based controllers, for instance, can be programmed for almost anything, including linearization, compensation for valve and actuator characteristics, a variety of control modes (including batch control), and a variety of algorithms, both linear and nonlinear, self-tuning and self-optimization. Many of these features do not require the computation power of a DSP and can be easily implemented with basic processing hardware.

The suitability of a microprocessor-based controller for a specific application depends not only on the algorithms it contains, but also on their implementation and parameter adjustment capabilities. Since most controllers have no or just some extremely restricted reprogramming capabilities, the user should study their capabilities before purchasing. This is particularly the case with batch process control, where the control algorithm is usually dependent on several variables.

CONCLUSIONS

Local electronic controllers were described in this section. Some of these controller designs are similar to the ones that are located in central control rooms. Because the control room equipment is covered in Chapter 4, it is not discussed here in detail. Therefore, the reader is encouraged to also review the sections titled: Annunciators and Alarms, CRT Displays, Digital Readouts, Indicators, Analog Displays, Switches, Pushbuttons, Keyboards, and Touch Screen Display in Chapter 4.

INTRODUCTION

A wide variety of converters are used in process control. This section provides only a partial overview of these devices. For more details on the individual categories, it is recommended to review the specific sections that deal with them.

In Volume 1 (*Measurement*) of this handbook, the TC and RTD converters are discussed in Chapter 4 and the various pressure repeaters and pressure scanners are covered in Chapter 5. In this volume (*Process Control*), the current-to-air (I/P) converters are also discussed under control valves in Chapter 6, and the DCS-related analog-to-digital (A/D) or digital-to-analog (D/A) converters are covered in Chapter 4.

When interfacing different digital devices, they too require conversion, as the digital information can be coded differently and the communications can follow different formats. These topics are also addressed in Chapter 4 of this volume and also in Volume 3, which is devoted to software.

PNEUMATIC CONVERTERS AND DAMPENERS

In the sense that they convert a process pressure into a standard output air signal, all pneumatic pressure transmitters

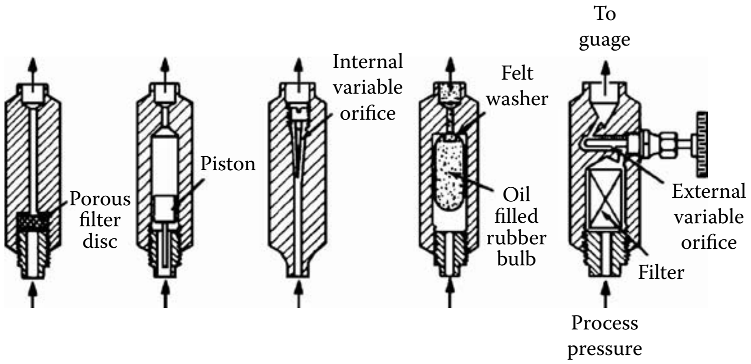

FIG. 3.3a
Pulsation dampener design variations.

(covered in Chapter 5 of Volume 1) are converters. Similarly, the various pneumatic pressure boosters and multiplying and reversing relays are also converters and are discussed in Chapter 6 of this volume.

Pulsation Dampeners

Pressure systems, both pneumatic and liquid-filled ones, transmit process noise very rapidly. A good example is the output of a reciprocating compressor or positive displacement pump. In order to obtain precise measurements when the process pressure is pulsating, it is necessary to dampen the pressure pulses by restricting the flow passages. Some of the various types of snubbers and pulsation dampeners are illustrated in Figure 3.3a.

One design consists of a fitting with a corrosion-resistant porous metal filter disc. By the use of such a device, the equilibrium reading on the outlet is delayed by about 10 seconds. Another snubber design depends for its damping action on a small piston in the inlet fitting, which rises and falls with pressure impulses and thereby absorbs shock and surge. Still another snubber design uses the adjustable restriction created by a micro-valve in the inlet fitting to damp pulsation. This differs from a needle valve in two important ways: the filler consists of stainless steel wool to prevent plugging, and it does not quite shut off. This is to prevent “shutting-in” a false reading.

Other forms of pulsation or noise dampening can be obtained by using dashpots in motion balance devices or by restricting the flow between bellows in fluid-filled devices. For further information on snubbers and pulsation dampeners refer to Chapter 5 in Volume 1 (*Measurement*) of this handbook.

DIGITAL CONVERTERS

Analog-to-digital and digital-to-analog converters are covered in Chapter 4 of this volume, where I/O devices are also discussed. Analog–to–on/off and digital–to–on/off logic devices, such as monitor switches, relays, and counters, are also discussed in Chapter 5.

ANALOG CONVERTERS

Pneumatic-to-Electronic Converters

The pneumatic-to-electronic transducer is used wherever pneumatic signals must be converted to electronic signals for any of the following reasons:

1. Connecting existing pneumatic plants to computers
2. Transmission over large distances
3. Input to an electronic logger
4. Input to telemetering equipment
5. Instrument air not available at the receiver controller

In principle, any of the electronic pressure transmitters could be used, but in practice, special, improved-accuracy devices are used. The air signals are at low pressure levels (3 to 15 PSIG or 0.2 to 1.0 bar), and many of the standard pressure detectors are not sensitive or not linear enough at these pressures.

A P/I transducer should be at least 1/2% of full-scale accurate and preferably 1/4% to preserve the integrity of the initial signal. Since the total error is the square root of the mean squares of the individual component errors, the greater the precision of the P/I transducer the better the signal.

Because of this need for higher accuracy, most P/I transducers use a bellows input and a motion balance sensor. A typical high-quality P/E converter is shown in Figure 3.3b.

Pneumatic-to-electronic converters are also discussed in Chapter 4 of this volume and in Chapter 5 of Volume 1 (*Measurement*).

Current-to-Air Converters

Electropneumatic transmitters are also referred to as converters and transducers. They are important because they form

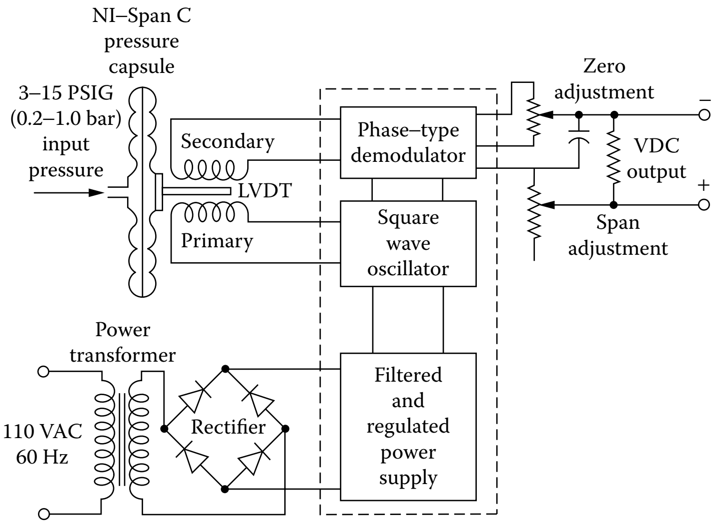

FIG. 3.3b
Pneumatic-to-electronic converter.

the link between electrical measurements in a pneumatic control system. They also convert electronic controller outputs into air pressure signals for the operation of pneumatic control valves. (These devices are also discussed in Chapter 6.)

Figure 3.3c illustrates one of these converter designs and also lists the various electric devices with which it can be combined. The input is usually a DC current in the range of 1 to 5, 4 to 20, or 10 to 50 milliamperes. An Alnico permanent magnet creates a field that passes through the steel body of the transmitter and across a small air gap to the pole piece. A multi-turn, flexure-mounted voice coil is suspended in the air gap. The input current flows through the coil creating an electromagnetic force that tends to repel the coil and thus converts the current signal into a mechanical force.

Since the total force obtainable in a typical voice coil motor with such small current inputs is only on the order of some ounces, a different approach, namely, the use of a reaction nozzle, is employed to convert the force into a pneumatic output

Types of inputs
1. Thermocouple amplifier
2. Resistance bulb amplifier
3. Speed detector amplifier
4. Radiation detector amplifier
5. pH amplifier
6. AC current or power converter
7. Magnetic flowmeter amplifier
8. Electronic controller output

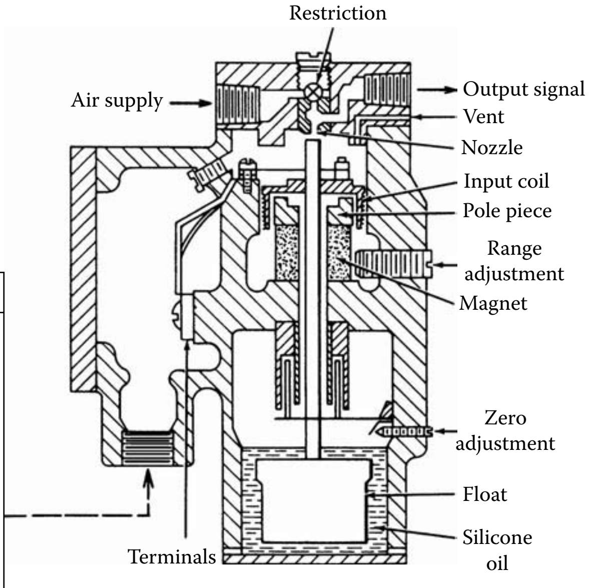

FIG. 3.3c
Electric-to-pneumatic transducers or transmitters can have a variety of input sources.

pressure. In this circuit, the supply air flows through a restriction and out the detector nozzle. The reaction to the air jet as it impinges against the nozzle seat supplies the counterbalancing force to the voice coil motor. The nozzle backpressure is the transmitted output pressure.

To make the transmitter insensitive to vibration, the voice coil is integrally mounted to a float submerged in silicone oil. The float is sized so that its buoyant force equals the weight of the assembly, reducing the net force to zero.

The zero of the transmitter is adjusted by changing the force on a leaf-spring. Span is adjusted by turning the range-adjusting screw, which changes the gap between the screw and the magnet, thus shunting some of the magnetic field away from the pole piece.

Millivolt-to-Current Converters

Millivolt-to-current converters are widely used in the measurement of temperature, using thermocouples or other millivolt-generating sensing elements. They are also utilized in converting the output signals of analyzers into higher-level transmission signals. A typical millivolt-to-current converter is illustrated in block diagram form in Figure 3.3d.

When these devices are used to convert thermocouple signals, they are also referred to as temperature transmitters (See Chapter 4 in Volume 1). In the mid-1960s several companies developed miniaturized converters for local mounting in the thermocouple head, which is mounted directly on the thermowell (Figure 3.3e). These devices have been discussed in more detail in Section 4.13 of the Measurement volume of this handbook.

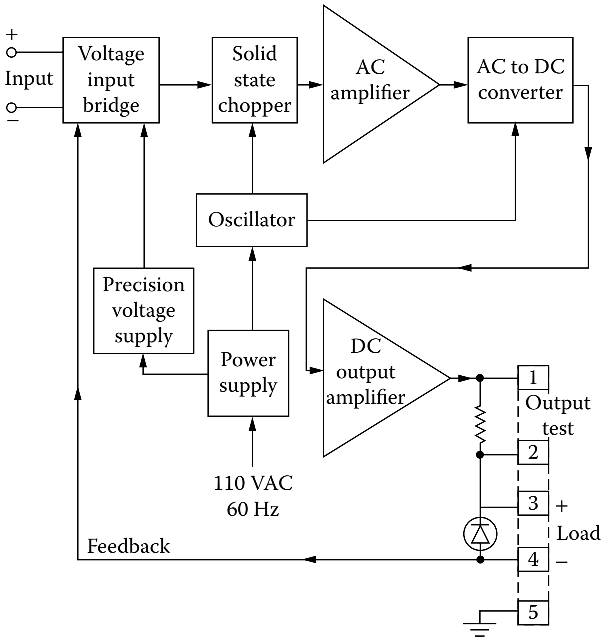

FIG. 3.3d
The block diagram of a millivolt-to-current converter.

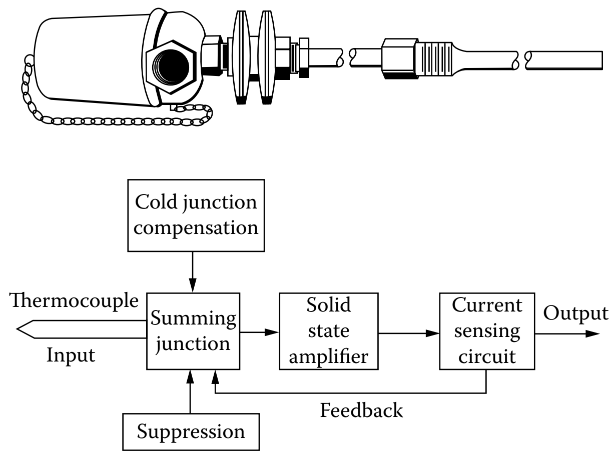

FIG. 3.3e
Thermocouple-to-current converter, which is mounted directly on the thermowell.

Voltage-to-Current Converters

Converters are also available for the conversion of higher than millivolt voltages into transmission signals (Figure 3.3f). These usually consist of voltage dividers (and rectifiers if necessary) to reduce voltages to a level compatible with the receivers.

Current-to-Current Converters

Current-to-current transducers are available to convert AC signals to DC (or DC to AC). They also serve to amplify or reduce the current levels as necessary. They are sometimes used in the power industry, but not too widely because other methods are capable of receiving and handling higher current levels.

Levels of alternating current can be changed, when necessary, by current transformers. A common signal level in the power industry is 0 to 5 amperes. Direct currents are re-ranged by putting a series resistor (low ohms) in the circuit and reading the voltage drop across it.

A milliampere converter for AC to DC is shown in Figure 3.3g. This Figure shows three separate devices: a current transformer, an AC-to-DC milliampere converter, and a current-to-air converter. The function of the transformer is to scale down the current to the range normally used for direct AC metering. The AC/DC converter makes this signal compatible with the

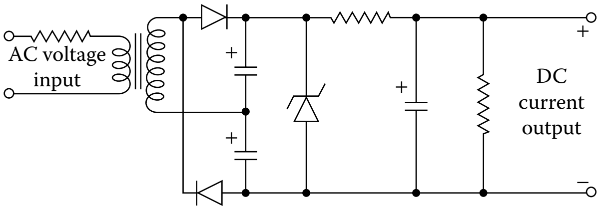

FIG. 3.3f
Solid-state voltage-to-current converter.

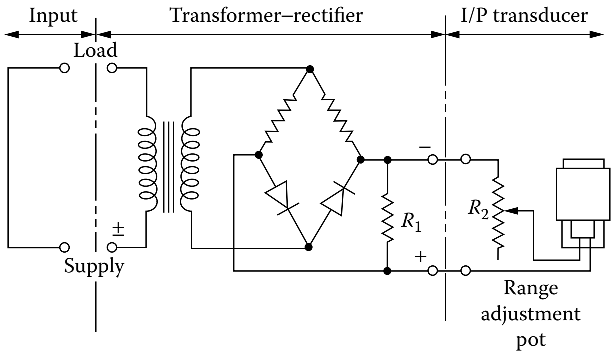

FIG. 3.3g
AC-to-DC milliampere converter with integral I/P transducer.

usual DC milliampere transmission systems. DC to DC "converters" are sometimes used for isolation of electrical circuits, such as in intrinsically safe systems. In such installations they are usually called current repeaters or barrier repeaters.

Resistance-to-Current Converters

Resistance measurements are common in temperature measurements and also in resistance or strain gauge sensors. The circuits used are similar to those of millivolt-to-current converters except that the front end is a resistance bridge instead of a voltage bridge (Figure 3.3h).

The strain gauge bridge, a special form of resistance element, is described in Sections 5.7 and 7.25 of the *Process Measurement* volume of this handbook. The strain gauge elements may take the place of two of the resistors in the resistance bridge shown in Figure 3.3h.

ELECTRONIC NOISE REJECTION

It is a general consensus that the analog electronic signal leads should be twisted pairs, and that they should be run in metallic conduit or be shielded. Less generally agreed upon is a recommendation that these conduits or shielded bundles of wiring be isolated from high-power wiring to motors, but this too is followed in most cases.

DC signals of 4 to 20 or 10 to 50 milliamperes can be run in the same conduit with telephone wires, low-voltage DC signals, and/or thermocouple leads. They should not be run in the same conduit or in the same shielded bundle with alarm signals or power wiring.

AC signals (which are much less common) should be run in twisted pairs, with each pair shielded, and then in conduit or shielded bundles. Some common-mode noise rejection is built into the instruments, but this is not sufficient if computers are being used or if higher-level spikes from motor loads are experienced.

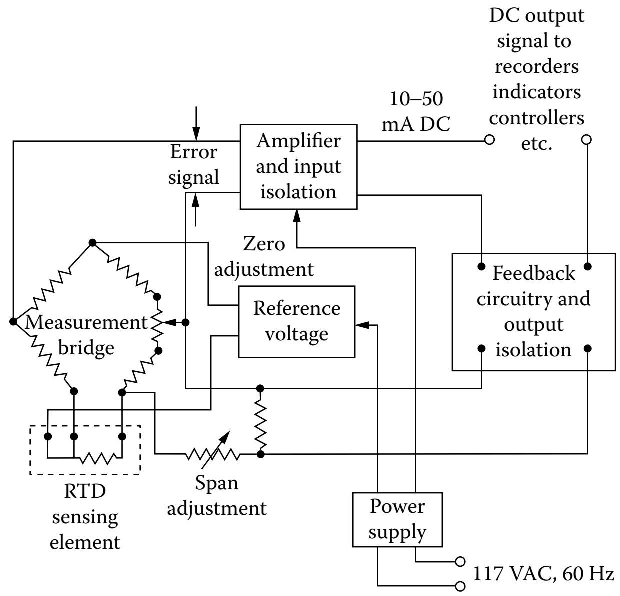

FIG. 3.3h
Resistance-to-current converter.

The various methods of conditioning digital signals, and the subject of computer-compatible wiring practices in general, are covered in Section 1.8 of this volume.

INTRODUCTION

In our digital age, most computing and timing functions are done in software. Volume 3 of this handbook is devoted to the description of such and many other software packages. The topics discussed in this section are from the analog age when mathematical and time function generators were still dedicated hardware components. Computing functions were performed by pneumatic and analog electronic relays, while timing and sequencing was controlled by programmers. Some of the common relay functions and their symbols are listed in Table 3.4a.

From the controller's viewpoint automation is, in effect, a set of computing and timing elements that carry out the mathematical operations required to implement a control scheme. Summation, subtraction, multiplication, division, raising to a power, extracting the root, integration, and differentiation are important examples of such computing operations. Popular timing functions include lag elements, time function generators, ramp and hold programmers, event sequencers, and profile programmers. Both timing and computing functions are still available as stand-alone products or in combinations that add up to a complete controller.

MATHEMATICAL FUNCTIONS

Most control systems require that the controller perform some sort of mathematical calculation before a control action is initiated. These calculations involve algebra as well as integral and differential calculus. The popular computing elements perform summations, subtractions, multiplication, division, raising to a power, extracting roots, and specific types of differentiation and integration. In the discussion that follows, these analog computing relays are grouped into pneumatic and electronic categories.

PNEUMATIC RELAYS

In some existing plants, pneumatic computing relays are still used because of their simplicity, reliability, and safety advantages when used in processes with high fire and explosion potentials.

Multiplying and Dividing Relays

In the force bridge multiplier-divider shown in Figure 3.4b, input pressures act on bellows in chambers *A*, *B*, and *D*. The output is a feedback pressure in chamber *C*. The bridge consists of two weigh-beams that pivot on a common movable fulcrum, with each beam operating a separate feedback loop. Any unbalance in moments on the left-hand beam causes a movement of the fulcrum position until a moment-balance is restored. An unbalance in moments on the right-hand beam results in a change in output pressure until balance is restored.

TABLE 3.4a
*Relay Functions and Their Symbols**

Symbol	*Function*	
1-0 or ON-OFF	Automatically connect, disconnect, or transfer one or more circuits, provided that this is not the first such device in a loop. (See Note 13 in Table 1.4b)	
Σ or ADD	Add or totalize (add and subtract), with two or more inputs.	
Δ or DIFF	Subtract (with two or more inputs)	
±	Bias (single input)	
AVG.	Average	
% or 1 : 3 or 2 : 1 (typical)	Gain or attenuate (input:output), with single input	
	Multiple (two or more inputs)	
÷	Divide (two or more inputs)	
$\sqrt{\ }$ or SQ. RT.	Extract square root	
x^n or $x^{1/n}$	Raise to power	
f(*x*)	Characterize	
1 : 1	Boost	
> or HIGHEST (Measured Variable)	High-select. Select highest (higher) measured variable (not signal, unless so noted).	
< or LOWEST (Measured Variable)	Low-select. Select lowest (lower) measured variable (not signal, unless so noted).	
REV.	Reverse	
	Convert	
a. E/P or P/I (typical)	For input/output sequences of the following:	
	Designation	Signal
	E	Voltage
	H	Hydraulic
	I	Current (electrical)
	O	Electromagnetic or sonic
	P	Pneumatic
	R	Resistance (electrical)
b. A/D or D/A	For input/output sequences of the following:	
	A	Analog
	D	Digital
∫	Integrate (time integral)	
D or *d*/*dt*	Derivative or rate	
I/D	Inverse derivative	

Note: The use of a box enclosing a symbol is optional. The box is intended to avoid confusion by setting off the symbol from other markings on a diagram.

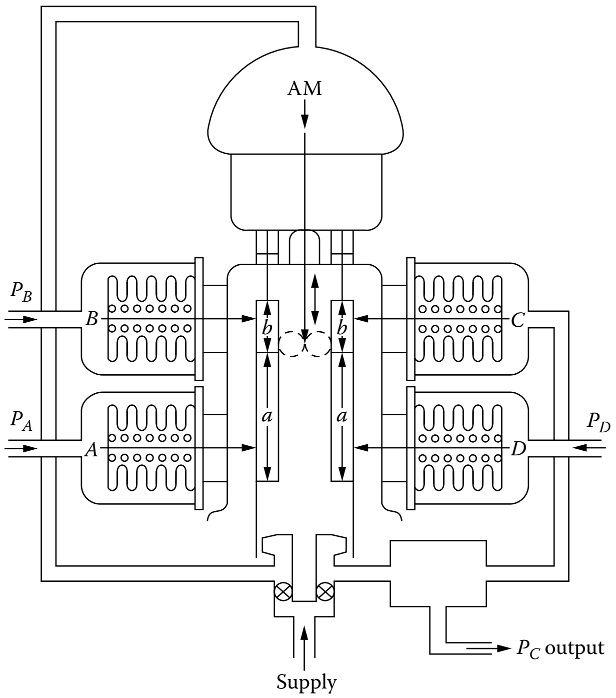

FIG. 3.4b
Multiplying and dividing relay, utilizing a pneumatic force bridge.

The equations that characterize the force bridge operation with respect to each subunit diaphragm in the unit shown in Figure 3.4b can be conveniently reduced to:

$$C = \frac{B \times D}{A} \qquad \textbf{3.4(1)}$$

Multiplication results when the two input variables are connected to chambers *B* and *D*. Division results when the dividend is connected to either chambers *B* or *D*, with the divisor connected to *A*. Simultaneous multiplication and division results when *B*, *D*, and *A* chambers are used.

The significant advantage of a cam-actuated multiplying and dividing relay is that it can operate with practically any type of nonlinear function that can be cut on a cam. These can include logarithmic functions, as in pH measurement, and computation in narrow, suppressed ranges of measurement, which results in good resolution.

The pure multiplier-divider in Figure 3.4c, when used for temperature and pressure compensation, for example, uses input signals proportional to the total absolute temperature and pressure range, starting with zero. Since the usable temperature and pressure range might be a small percentage of the total measurement range, the results might lack precision.

In Figure 3.4c, input pressure P_1 and output P_0 act on double-diaphragm capsules, and the net resultant force in each is in the direction of the larger area diaphragm. Input P_1 creates force *Y*, which pulls the baffle, pivoted at *A*, away from the nozzle. Output pressure P_0 creates force *X*, which moves the baffle closer to the nozzle. The θ input/output relationship is a function of the angle of the nozzle beam.

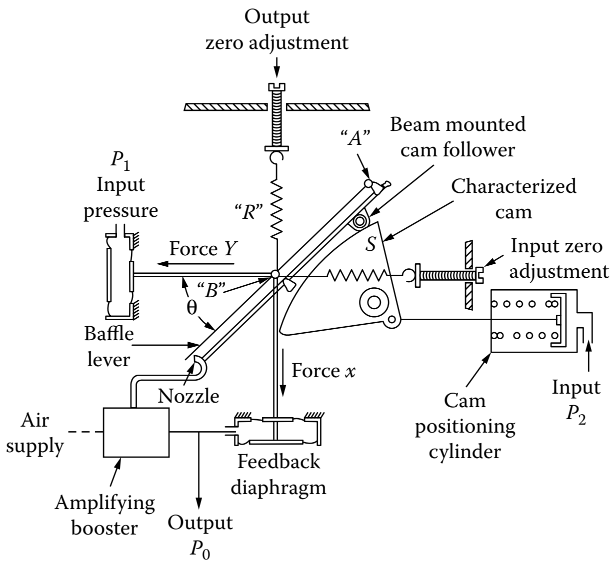

FIG. 3.4c
Multiplying and dividing relay characterized by a pneumatic cam.

When angle θ is 45 degrees, the relationship is 1 : 1. This can also be considered the multiplication factor or gain, *K*. At larger angles, *K* is greater than 1, and at smaller angles, smaller than 1. The multiplicand P_2 acts on the cam-positioning cylinder and thereby changes the nozzle beam angle in accordance with the cam characteristic. The zero adjusting springs subtract the 3-PSI (0.2-bar) zero from P_1 and set a 3-PSI (0.2-bar) zero on the output, respectively.

Adding, Subtracting, and Inverting Relays

In the force balance arithmetic computing relay, Figure 3.4d, a signal pressure in chamber *A* acts downward on a diaphragm with unit effective area. A signal in chamber *B* also acts downward on an annular diaphragm configuration, likewise having an effective area of unity. Signal pressures in chambers *C* and *D* similarly act upward on unit effective diaphragm areas. Any unbalance in forces moves the diaphragm assembly with its integral nozzle seat. The change in nozzle seat clearance changes the nozzle backpressure and hence, changes the output pressure, which is fed back into chamber *D* until force balance is restored. The following equation describes the operation of the relay:

$$T = A + B - C \pm K \qquad \textbf{3.4(2)}$$

K is the spring constant. It is adjustable to give an equivalent bias of ±15 PSI (1.24 bar).

The relay in Figure 3.4e is a modification of Figure 3.4d in that it incorporates additional input chambers and output feedback chambers. It can be used to add and/or average up to nine inputs. Figure 3.4e is an averaging relay for five inputs. The averaging feature keeps all signals in the same

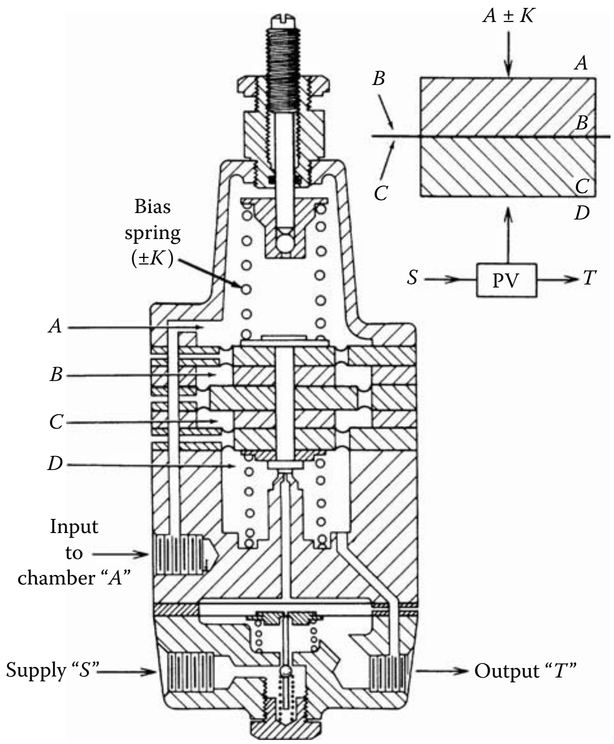

FIG. 3.4d
Pneumatic, adding, subtracting, inverting, and biasing relay.

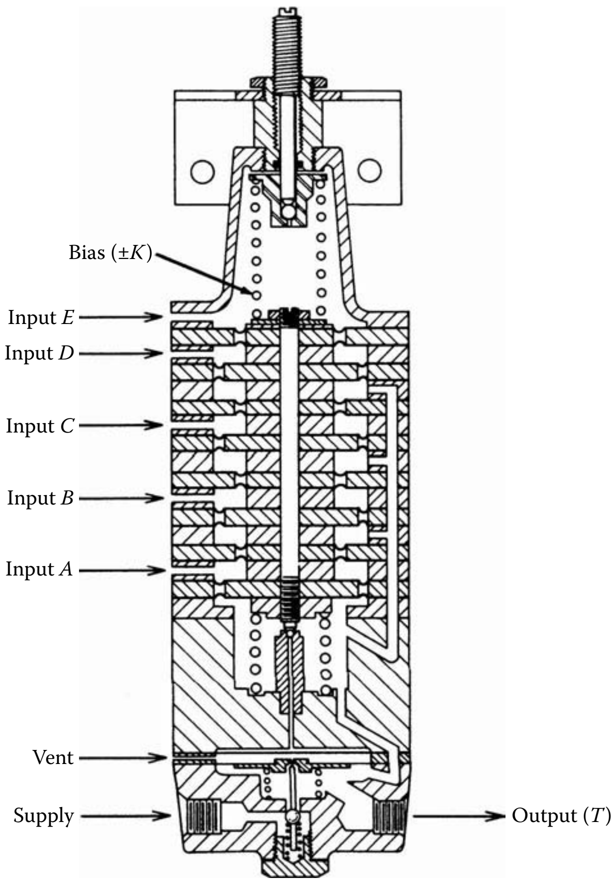

FIG. 3.4e
Multi-input averaging relay.

standard 3- to 15-PSIG (0.2- to 1.0-bar) range. Its characteristic equation is:

$$T = \frac{A + B + C + D + E}{5} \pm K \qquad \textbf{3.4(3)}$$

The relay shown in Figure 3.4d provides inverting or reversing action by setting the loading of the bias spring to a maximum and by connecting the input to subtracting chamber C. If the bias is set at +18 PSIG (1.2 bar), then a 3- to 15-PSIG (0.2- to 1.0-bar) signal in chamber C results in a 15- to 3-PSIG (1.0- to 0.2-bar) output. The equation describing this operation is:

$$T = K - C \qquad \textbf{3.4(4)}$$

Differentiating Relay

A differentiating relay produces an output proportional to the rate of change of the input. Figure 3.4f shows an ideal pneumatic differentiating relay. The relay is basically similar in construction to the relay shown in Figure 3.4d, except that the annular effective diaphragm area between chambers *B* and *C* is more than ten times the effective area of the small diaphragms between chambers *A* and *B*—giving a gain of greater than ten. The input signal is transmitted unrestricted to chamber *B* and passes to chamber *C* through an adjustable restriction. When the input is steady, the forces resulting from pressures in *B* and *C* chambers cancel each other, so that the output equals the zero-spring setting (usually mid-scale, 9 PSIG [0.6 bar] if both positive and negative rates are to be measured).

If the input pressure changes, a differential develops across the restriction. The relay transmits an output proportional to this differential. For accurate results, this differential must be directly proportional to the rate of change of input. Using a needle valve that produces laminar flow provides a linearly proportional volumetric flow, but the differential developed across the needle valve is a function of the mass flow, which varies with static pressure because of compressibility. This compressibility error is approximately ±15%. The effect can be fully compensated, however, by the addition of a variable volume to chamber *C*, the restricted chamber. As the static pressure increases, tending to make the differential smaller because of higher mass flow rate, the volume increases proportionately to maintain a constant differential. The needle valve setting determines the rate time constant.

The compensated relay is not a standard piece of hardware. In most cases, a noncompensated differentiating relay is satisfactory.

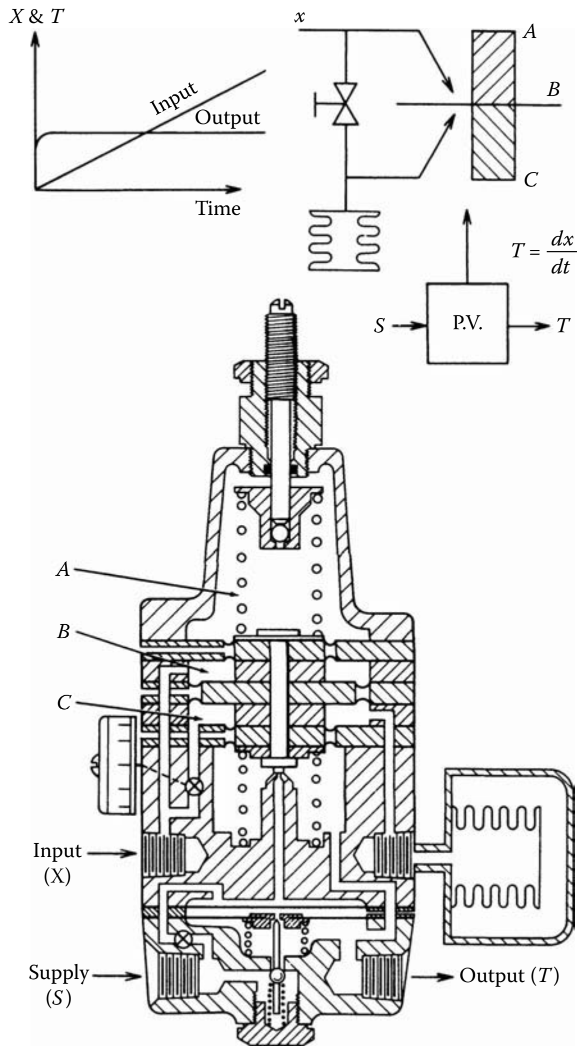

FIG. 3.4f
Differentiating relay.

Scaling and Proportioning Relays

Scaling, or proportioning, involves multiplication by a constant. Several approaches are available:

1. Special fixed-ratio relays
2. Pressure transmitters
3. Proportional controllers
4. Adjustable ratio relays

The fixed-ratio scaler is the simplest if the correct ratio is available and if adjustability and exact ratio are unnecessary. Figure 3.4g shows such a relay. The input pressure is connected to the top chamber and acts on the upper diaphragm. Output acts upward on the small bottom diaphragm. The gain is a function of the relative effective areas of the large and small diaphragms as determined by the dimensions of the diaphragm ring. The bottom spring applies a negative bias to the input and the adjustable top spring allows exact zero setting. The operating equation is:

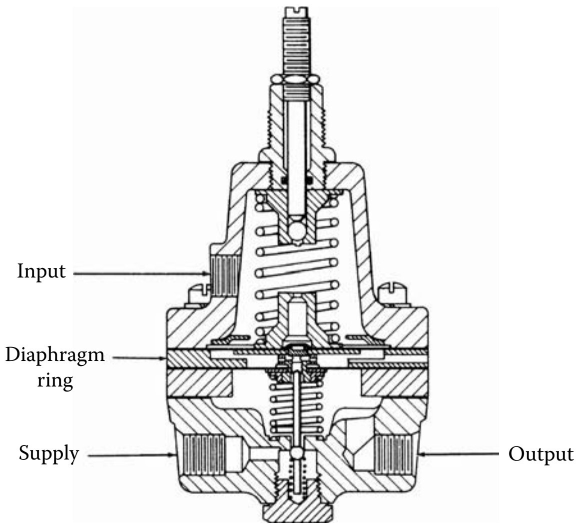

FIG. 3.4g
Fixed-ratio amplifying relay.

$$T = AP_1 + K \qquad \textbf{3.4(5)}$$

where A is the gain constant and K is the spring setting.

Where the scaling must be exact and does not have to be adjusted periodically, pressure transmitters are an economical, reliable, and accurate choice. Where the scaling factor must be modified occasionally, conventional ratio relays, which often consist of the proportioning section of a controller, are commonly used.

Integrating Relay

Integration, the reverse of differentiation, essentially involves measurement of accumulated pressure resulting from a flow that is proportional to the offset (from some chosen reference) of the input variable. Figure 3.4h shows an ideal integration relay. The input signal loads chamber *B*. The output, it should be noted, is the accumulated pressure in chamber A, *not* the booster pilot output.

The input signal determines the pressure differential across the needle valve. As in the case of the differentiation relay, with laminar flow across the needle valve, the volumetric flow is directly related to the differential. The mass flow, however, which determines the accumulated pressure, still varies with the static pressure because of compressibility. This effect is also compensated by connecting a variable volume to chamber *A*. The needle valve sets the proportionality constant of the integrator.

Neither the compensated differentiating relay nor the compensated integrator is available as standard hardware. Usually, the noncompensated relay (actually a proportional-speed floating controller) is satisfactory.

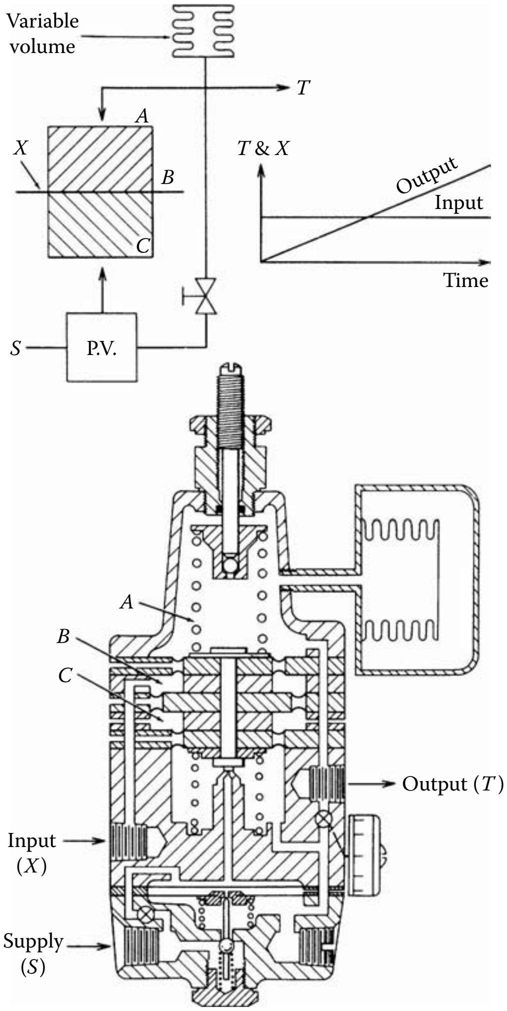

FIG. 3.4h
Integrating relay.

Square Root Extractor Relay

Square root extraction is commonly required to linearize signals from differential pressure-type flow transmitters. The force bridge, Figure 3.4b, provides square root extraction when the output is connected in common to the *A* and *C* chambers, giving the equation:

$$C^2 = B \times D \qquad \textbf{3.4(6)}$$

Other solutions are based on:

1. Use of a cam-characterized function generator
2. A geometric relationship, namely, change in cosine compared with the change in included angle, for smaller angular displacements (Figure 3.4i)

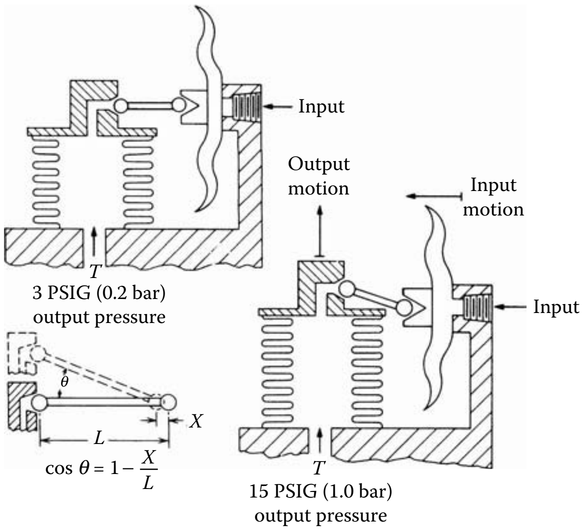

FIG. 3.4i
Square root extractor.

Starting with the input and output at 3 PSIG (0.2 bar), an increase in input causes the floating pilot link to restrict the pilot nozzle. This increases the output pressure and moves the output feedback bellows upward until balance is restored. Since the length of the floating link is fixed, the angular displacement produced by movement of the output bellows follows the relationship:

$$\cos\theta = 1 - \frac{X}{L} \qquad \textbf{3.4(7)}$$

A plot of the angle θ (output displacement) versus X (input displacement) in this equation shows the relationship to be virtually an exact square root for small angular motion.

High- and Low-Pressure Selector and Limiter

Selector relays are used in override systems. The high- pressure selector relay compares two pressures and transmits the higher of the two in its full value. In Figure 3.4j, the two input pressures act against a free-floating flapper disk. The differential pressure across the flapper always results in closure of the low-pressure port.

In the low-pressure selector, Figure 3.4k, if input *A* is less than input *B*, the diaphragm assembly throttles the pilot

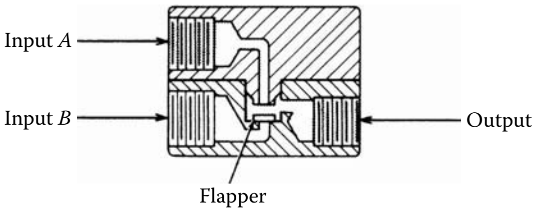

FIG. 3.4j
High-pressure selector relay.

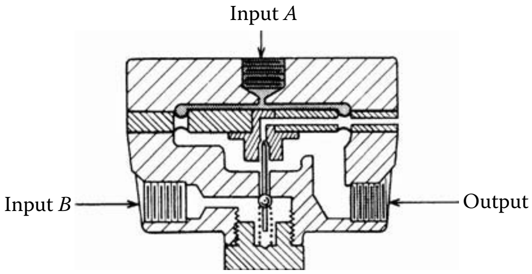

FIG. 3.4k
Low-pressure selector relay.

plunger to make the output equal to input A (the conventional action of a 1 : 1 booster relay). If input B is less than A, the supply seat of the pilot plunger is wide open so that pressure B is transmitted in its full value.

By connecting a set reference pressure into one of the ports of the high-pressure selector, a low-limit relay results. Conversely, by connecting a set reference pressure into the low-pressure selector, a high-limit relay results. Limit relays are available with the reference-setting regulator built into the relay.

ELECTRONIC COMPUTING ELEMENTS

Although electronic instrumentation is based on large-scale integrated circuits, computing functions based on discrete component operational amplifier, i.e., op amp, are still available. In addition, op amp concepts are at the heart of all the current and future electronic computing elements. Therefore, it is appropriate to review the electronic computing functions within their op amp context.

Multiplying and Dividing

In Figure 3.4l, inputs e_1 and e_2 are multiplied in the diode bridge. Conduction of the diodes in the bridge is dependent upon the relative magnitude of the inputs with respect to the constant slope of the sawtooth input. The output of the diode bridge is a trapezoid, the area of which can be calculated by the following equation:

$$\text{area} = e_1 e_2 \tan\theta \qquad \mathbf{3.4(8)}$$

The angle θ is established by the constant slope of the sawtooth, and thus

$$\text{area} = K e_1 e_2 \qquad \mathbf{3.4(9)}$$

The output voltage, e_0, is amplified and filtered to a DC signal, and its voltage level will therefore be proportional to the area and, consequently, to the product of e_1 and e_2.

Adding another diode bridge to the multiplier circuit produces a multiplier/divider (Figure 3.4m). The input to the amplifier is the output difference from the two bridge networks.

$$e_0 = A(Ke_1e_2 - Ke_3e_0) \qquad \mathbf{3.4(10)}$$

where A = gain of the amplifier. Rearranging the equation yields:

$$e_1e_2 = \frac{e_0}{AK} + e_3e_0 \qquad \mathbf{3.4(11)}$$

The term e_0/AK is very small if the amplifier gain is high, and thus

$$e_0 = \frac{e_1e_2}{e_3} \qquad \mathbf{3.4(12)}$$

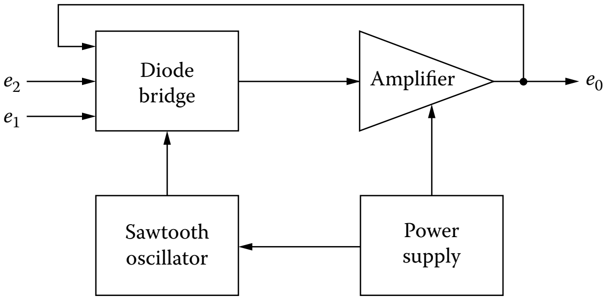

FIG. 3.4l
Multiplier.

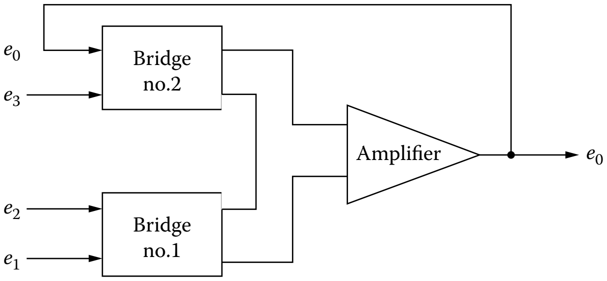

FIG. 3.4m
Multiplier-divider.

Adding, Subtracting, and Inverting

In Figure 3.4n, the two input potentials e_1 and e_2 are compared in the multiple comparator, which produces a proportional output to the amplifier. The current paths of the two inputs can be the same or opposite, resulting in either an adding or subtracting circuit, respectively.

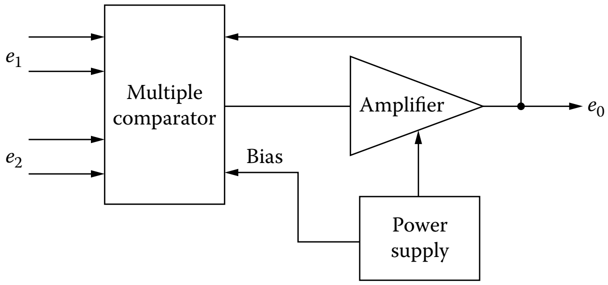

FIG. 3.4n
Adder, subtracter, and inverter.

Inverting is accomplished by biasing the comparator to produce maximum output with no input. Applying a reverse input (i.e., a reverse current input with respect to bias current) causes the output to decrease with increasing input. The feedback signal is such that the amplifier acts as a unity gain network.

Differentiating

The input amplifier in Figure 3.4o is a capacitor-coupled so that only the rate of change of the input signal is seen by the amplifier. Two diodes in the feedback of the amplifier allow its output to go positive or negative (depending on the direction of the rate of change) by an amount equal to the forward drop across the diodes (only a few tenths of a volt). The output amplifier inverts and amplifies this signal by its open-loop gain.

A small positive feedback is applied to the last amplifier to prevent output from "chattering" at the diodes' switching point.

Integrating

The first amplifier in Figure 3.4p, a simple inverting type, performs the integration function as the charge accumulates across the capacitor of the RC (resistor-capacitor) network. The second amplifier is an inverting, general-purpose type, which relates the output directly to the input.

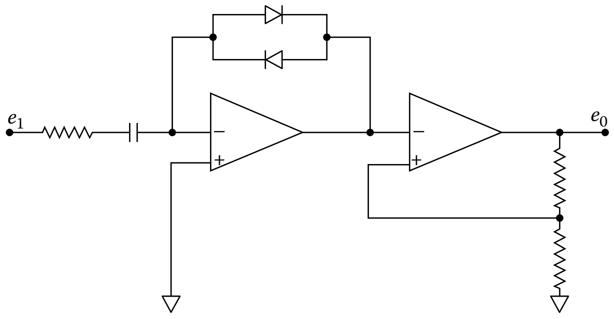

FIG. 3.4o
Differentiator.

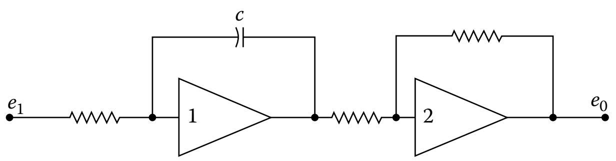

FIG. 3.4p
Integrator.

Scaling and Proportioning

Simple electronic scaling or proportioning involves combining a voltage divider circuit with an amplifier. The voltage divider circuit is connected to either the input or output side, depending upon whether the gain is to be greater or less than unity.

In Figure 3.4q, the amplifier comes to balance when Δe_i equals zero. Since the voltage divider is on the output, only a portion of the amplifier output is fed back to counterbalance the input voltage. Therefore, the output will rise above e_1, resulting in gains greater than one. The operation can be expressed as:

$$e_0 = e_1 \frac{(R_1 + R_2)}{R_1} \tag{3.4(13)}$$

An electronic scaler with a gain of less than one is constructed by a simple alteration of the circuit shown in Figure 3.4q. The voltage divider is moved from the amplifier output and placed across the e_1 input. If the signal from the middle of the voltage divider is fed to the amplifier's "+" terminal, then the resulting gain will be less than one. This can be expressed as:

$$e_0 = e_1 \frac{R_2}{R_1 + R_2} \tag{3.4(14)}$$

Square Root Extracting

The square root converter combines a DC amplifier with a negative feedback diode network. As current into the amplifier increases, the amplifier gain decreases with decreased feedback resistance in the diode network. The gain typically varies according to seven straight line segments that approximate a square root function. This is accomplished by having seven diode-resistance

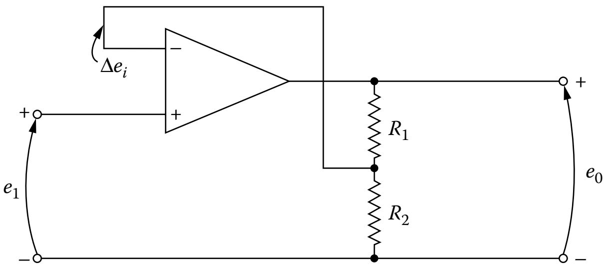

FIG. 3.4q
Scaler with gain greater than one.

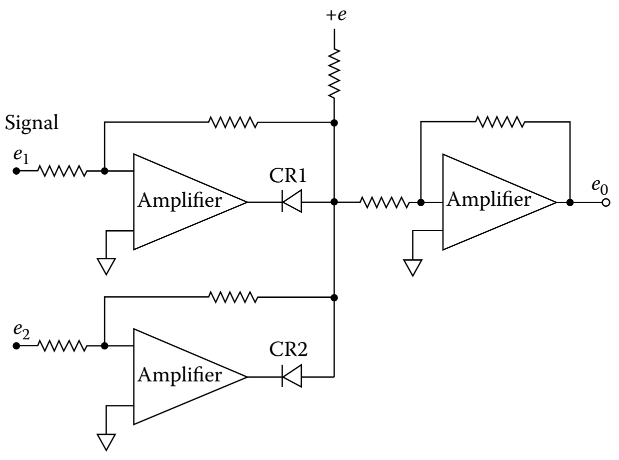

FIG. 3.4r
High-voltage selector.

paths in the feedback network automatically parallel each other with increasing input. The output stabilizes when the diode network modified feedback counterbalances the input.

High- and Low-Voltage Selector and Limiter

The higher of the two positive inputs in Figure 3.4r causes a higher negative potential at the cathode of one of the diodes (CR1 or CR2). The forward bias of this diode passes the higher input and reverse-biases the other diode to isolate the lower input. Thus if signal e_1 drops below signal e_2, CR2 is forward-biased to pass signal e_2 and CR1 is reverse-biased to isolate signal e_1.

All the amplifiers are unity gain inverter types. Substituting a fixed input for one of the variables produces a low-limit relay. To obtain a low-voltage selector, the diodes shown in Figure 3.4r are inverted and a negative supply is used. Thus, the least positive input forward-biases one of the diodes (by the least negative potential applied to the anodes of the diodes). This automatically reverse-biases the other diode and isolates the higher input from the output.

TIMING ELEMENTS

Common technologies for time management devices include discrete analog and digital circuits, microprocessor-based time functions, and pneumatic timing devices. Each of these choices may offer an advantage over the other, depending on the type of timing operation and process application of interest. These timing options are discussed below and also in Chapter 5, where the emphasis is on digital software-based systems.

Here the timing elements are grouped for convenience into analog, digital, and microprocessor categories. In most process applications digital and microprocessor-based timing functions provide the same accuracy as their analog equivalents. Analog timing elements are still used in some cases because of historic, maintenance, and process environment reasons, that is, people have used them in the past and are comfortable with them, technical support personnel needed to repair them are available in the plant, and they function well under various harsh plant operating conditions. All of the analog time functions discussed here are also available as digital or microprocessor-based units.

Analog Timing Operations

A simple but highly useful time function generator is the first-order lag function. In many industrial control schemes, motors and other loads must be energized in a time sequence provided by a lag function. First-order time functions are also used in controllers that provide reset and rate actions. Although a first-order time function is certainly available as a digital circuit or as a microprocessor-based unit, it can also be implemented in its analog or pneumatic versions.

Electronic Time Delay Analog first-order lag circuits are common and are often used to generate delay times on applications involving the starting of motors. Such circuits are simple variable resistance and capacitance circuits that provide output voltages as a function of time as set by the values of the two variable circuit components. The integral equation that describes this type of circuit is as given in Equation 3.4(15):

$$V(t) = \mathrm{IR}(1 - e^{-\tau/\mathrm{RC}}) \qquad \textbf{3.4(15)}$$

Voltages from circuits that follow Equation 3.4(15) vary exponentially with time. Thus, a motor starter that is monitoring $V(t)$ will not respond until the voltage reaches a level it recognizes. The time delay that it takes for the voltage input signal to the motor to go from zero volts to the starter's trigger voltage is controlled by the actual values of R and C, which are selected for the specific motor application.

Pneumatic Time Delay The equivalent RC circuit in its pneumatic form is usually described by Equation 3.4(16):

$$\tau dP_i/dt + P_i = P_0 \qquad \textbf{3.4(16)}$$

The solution of this differential equation with respect to $P_i(t)$, which is the input pressure as a function of time, gives a pressure–time profile similar to the shape of the voltage–time profile obtained from the solution of Equation 3.4(15).

The construction of a pneumatic system that follows Equation 3.4(16) is not difficult. The input air signal is fed to a laminar flow throttling device and a small-capacity single-port storage tank. The time delay in the output pressure signal is a function of the storage tank size and the restriction in the throttling device.

As with its analog circuit counterpart, a pneumatic time lag device must be able to vary the time constant, τ, over a range from 5 seconds to about 20 minutes. On commercially available units, the resistance and capacity parameters are designed such that τ has an adjustable range from 5 to 300 seconds for each capacity. Therefore, a four-equal-capacity parallel system would allow an adjustable range from 20 seconds to 20 minutes.

Digital Timing Operations

This subject is discussed in more detail in Volume 3 and in Chapter 5 of this volume.

The main distinction between the analog and digital worlds is the concept of a discrete event. For timing elements, the disadvantages of a discrete, i.e., digital- or microprocessor-based, timing function becomes significant in a control application only when the time between output signal updates is long; if the circuit does not quickly update the output signal to the process heater, then the ramp profile will have a lot of fluctuation in it.

All of the timing functions are available as digital- or microprocessor-based products. Their selection depends on several constraints. First, the selected timing circuit must update its control signals at least twice as fast as the process can change the value of the process variable that is being controlled. Second, the selected timing element should be able to survive the chemical and mechanical environment it is to be subjected to. Finally, the product must function properly despite electrical noise.

Microprocessor Timing Functions When compared to the older technologies, one major difference is the convenience with which additional control functions can be included with the microprocessor-based system. On the other hand it is desirable to make sure that the unit meets government and industry safety standards for the expected application. These include fire and explosion standards in hazardous environments. Second, will it meet the mechanical vibration and electrical requirements for the environment in which it will be installed? Third, do the input signal conditions required and the output signal characteristics delivered by the unit match the needs of the application?

PROGRAMMERS

Step Programmers

A step programmer is a process sequencer that does not have a practical analog circuit equivalent.

Step programmers are used for on/off event sequencing, a subject that is discussed in more detail in Chapter 5 under the topics of PLCs and logic elements. These step programmers do not provide an analog output. A typical design consists of a perforated drum (Figure 3.4s). Each perforation represents a step in one channel. Drums are available with from 30 to 100 steps and from 16 to 93 channels. Inserting a nylon plug into a hole results in a switch actuation on the corresponding step and channel. The stepping can be initiated by a remote sensor switch, counter, timer, or pushbutton.

These units are easily programmed and can replace complex logic and interlock circuits. They can not only replace such systems but can eliminate the need for their custom design and construction as well.

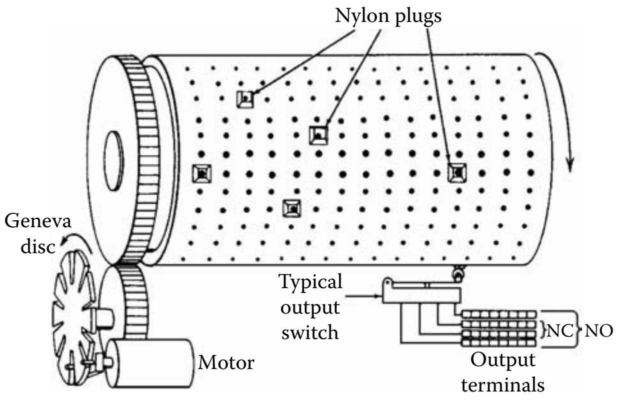

FIG. 3.4s
Drum programmer for on/off event sequencing.

Related to the step programmer is the multi-channel cam timer in which a number of individually adjustable cams are mounted on a single drive shaft and provide event-sequencing control.

Profile Programmers

There are three types of process profile programmers that use the same basic time function control mechanisms. Although the cam-type, the belt-type, and the electrostatic-line-type programmers have different mechanical operating principles, they fundamentally perform the same process control function. Each uses a tracing element that follows the movement of a rotating cam, belt, or electrostatic line. Each has a motion detection subsystem that converts the tracing element movements into a predetermined time-dependent control signal. The time dependence of the control signal depends on the shape, cut, or position of the programmer's cam, belt, or electrostatic line.

Cam Programmer Figure 3.4t shows the general layout for a cam-driven profile programmer. The cams of the cam-type programmers can be driven by pneumatic or electric motor drives that move the set-point index. This motion in the tracing element in turn generates a time-dependent standard, i.e., 3 to 15 PSIG, 4 to 20 mA DC, etc., output signal. The cams can be

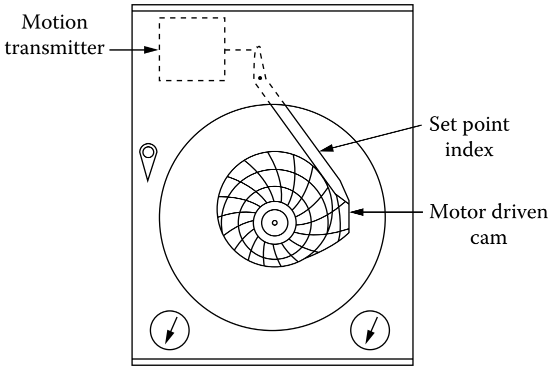

FIG. 3.4t
Cam-type programmer.

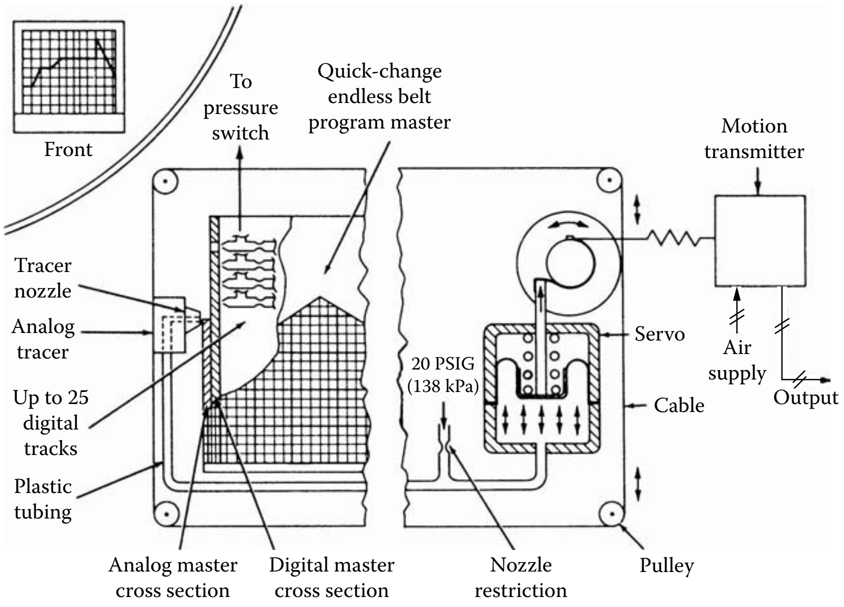

FIG. 3.4u
Pneumatic profile tracer programmer with synchronized on/off sequence control switches.

made of plastic or metallic materials. Traditionally, cam programmers have incorporated an integral controller, a sensor element, and a circular chart recorder in the same package.

Cam programmers are used only on batch processes for the following reasons.

- The making of the new cams and changing them is not a simple matter.
- The cam rise is limited for mechanical reasons to about a 50-degree cam rotation for full-scale movement of the tracing element.
- Although graphic lines are scribed onto the cam surface to facilitate cutting the cam to the desired shape, these coordinates are curvilinear. It is more difficult to lay out the cam design for cutting with such coordinates than it is to program a device that uses rectilinear coordinates, such as a belt programmer.

Belt Programmers Figure 3.4u illustrates an early belt-type profile programmer with pneumatic output. This specific unit was housed in a 6 in. by 6 in. recorder case. The time profile program was stored on a laminated, endless-belt plastic master. It combines an analog set-point program with up to 25 synchronizes digital tracks for operation of logic circuits, auxiliary equipment, solenoid valves, lights, etc. There is no limit to the slope the programmer can follow—even slopes of 90 degrees can be accommodated.

Since the master program can be quickly changed, these programmers were often used where the program does require periodic change and where accurate reproduction of the program is essential, as in textile dyeing processes. The complete program is stored on the master, thus eliminating the need for having an operator make various program settings for each change and therefore eliminating the chance for human error in setting the program. These programmers are accurate to within 1/4% of full scale, which makes them applicable when accuracy is one of the critical requirements of the operation.

The endless belt master can be made up by plotting the desired analog program on the rectilinear chart and cutting the top portion away with scissors. The second layer serves as a backing and is also used to program the synchronized digital tracks. At any point of the program where a switch action is desired, a hole can be punched in with a conductor's punch. The back of the analog program has a pressure-sensitive adhesive that joins the two sections. A splice finishes the makeup of the master.

In operation, a motor drives the master program. A cable-mounted tracer nozzle senses the step on the analog program profile. The backpressure of the nozzle actuates a servo which, through the cable drive, keeps the tracer following the profile. Operating from the same servo drive is an accurate force-balance-type motion detector. Sensing the back side of the digital master are a series of vertically aligned nozzles. Normally, their backpressure is high, since the master baffles the nozzles. However, if a punched hole presents itself, the backpressure of that particular nozzle drops to zero, actuating the connected pressure switch.

Line Follower Programmers Electric line and edge follower programmers will perform with less than ±1/4% error. In the electrostatic line follower design, Figure 3.4v, the desired program curve is etched into a chart with a conductive surface, dividing it into two electrically isolated surfaces. These surfaces are energized by oppositely phased AC voltages, which establish a gradient across the gap. A noncontacting probe is used to sense the electrostatic fields developed by the surfaces. It energizes a

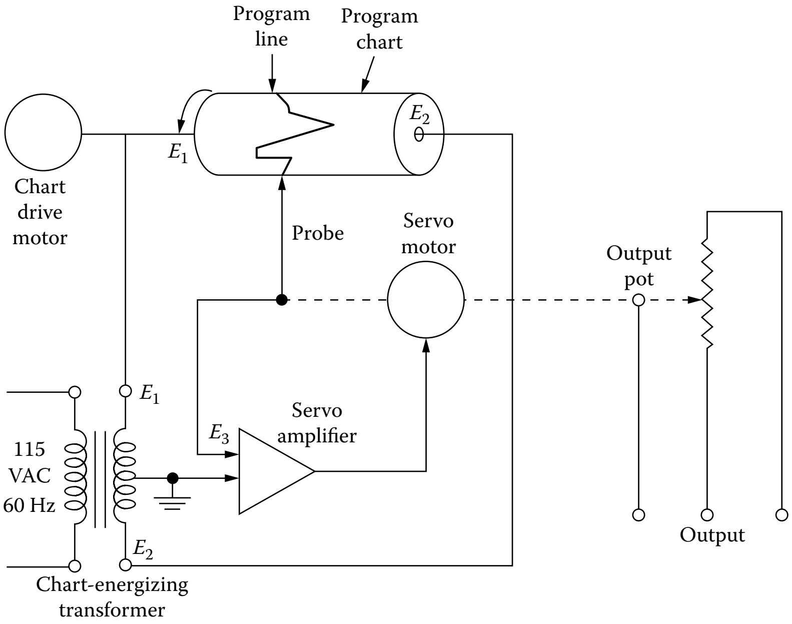

FIG. 3.4v
Electrostatic line follower programmer.

servo amplifier, which keeps the probe at zero potential as it tracks the line. Attached to the servo drive is the wiper of a potentiometer with its output proportional to line position.

The photoelectric line follower type functions to keep the line centered between two slightly overlapping pickup heads. The detector must be manually set over the line at startup, and slope rate is limited by the speed of the follower mechanism. The photoelectric edge programmer is a common variation of the electrostatic line programmer. This type of programmer has a higher slope rate limit than does the line programmer. The edge detection system is basically a photocell detector attached to the tracing element. Line and edge programmers include digital control tracks as common additional features.

Adjustable Ramp-and-Hold Programmers For such batch processes in which the controlled variable must rise at a controlled rate, then hold at some preset value and, possibly, fall at a controlled rate, programmers such as that in Figure 3.4w are often preferable to cam types. This is particularly the case if the program must be changed periodically.

These too are usually packaged as large-case circular chart recorders. In this type of programmer the set-point index is driven by a constant-speed motor. The rate of rise is set by adjustment of an interrupter timer, which makes contact for a set percentage of the basic timer cycle time. The movement of the index is therefore actually in steps, but the steps are so small that the operation is, for all practical purposes, continuous. The set-point rises until it coincides with the hold point index, at which point the hold timer is energized while the interrupter timer is deenergized. Controlled cooling rate requires driving the set-point index in reverse. This type of programmer can come complete with a controller and a direct sensing element.

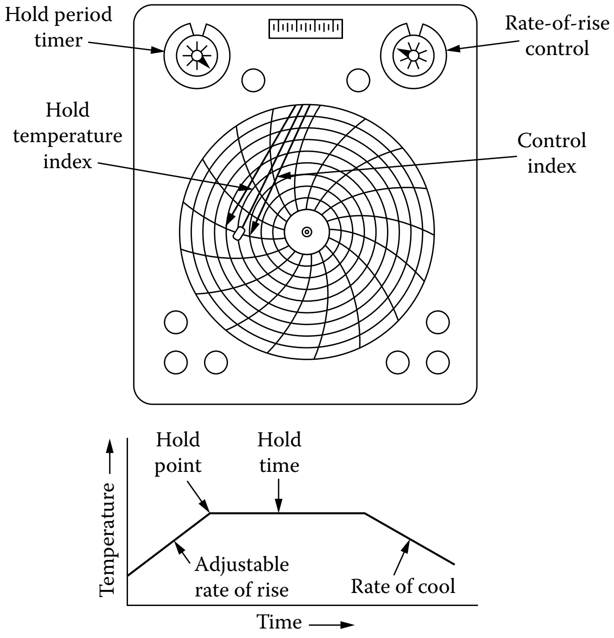

FIG. 3.4w
Adjustable ramp-and-hold programmer.

INTRODUCTION

Telemetry is a process of gathering information from remote locations. The data obtained from field instruments is transmitted to a convenient location for processing and recording purposes. Telemetry can be performed by different methods: electromagnetic, optical, electrical, sonic, Internet, etc. Recently, radio frequency (RF) and microwave telemetry methods have been used extensively. This section largely concentrates on wireless telemetry systems. However, the use of optical fiber systems allows the measurement of broad bandwidth and provides high immunity to noise and interference. Here, telemetry and telemetry systems that are based on electrical and electromagnetic principles are covered.

Electrical telemetry methods can be divided into groups depending on the transmission methods that they use. There are two basic types: wire telemetry and wireless telemetry. Wire telemetry uses wire transmission utilizing coaxial cables, twisted wire pairs, telephone systems, common communication buses, or similar communication means. It offers simple and inexpensive solutions for data flow and networking of devices. It is extensively used where the basic infrastructure and wiring systems already exist, as in the case of electric power lines that can be used as wire telemetry carriers.

Wireless telemetry is somewhat more complex as it requires radio frequency transmitters and receivers. Despite the complexity, it is widely used because it can transmit information over longer distances without wires from normally inaccessible areas. It can also operate at high speeds and can have the capacity to transmit several parallel channels of information at the same time. The applications of other wireless telemetry methods such as ultrasound and infrared radiation are limited to certain environments, such as marine telemetry.

Telemetry systems can operate repeatedly without any adjustments and calibrations under widely ranging environmental conditions, such as high-temperature and high-pressure situations. Telemetry is extensively used in space exploration and military applications for telemeasurements of distant variables or telecommandment of actuators and controllers.

Some land-mobile vehicles, such as passenger and cargo trains, also use telemetry systems, either wireless or by using some of the existing power distribution networks to transmit data to a central station. In medical applications, the use of telemetry increases the quality of life of patients, giving them mobility while still being monitored. Several medical applications are based on implanting a sensor in a patient and transmitting the data to be further analyzed and processed either by radio or by adapted telephone lines. In industrial applications, fiber optic communications are used in hazardous and electrically noisy environments.

The design and methodology required for a fully functional telemetry system depends on the application requirements and the environmental characteristics. From the applications point of view, telemetry can be grouped into four main categories: telemetry in medical and life sciences, industrial telemetry, space telemetry, and others. Application examples are provided at the end of this section.

BASIC TELEMETRY CONCEPTS

Classical Configuration

A telemetry system consists of many components, as illustrated in Figure 3.5a. The main components are:

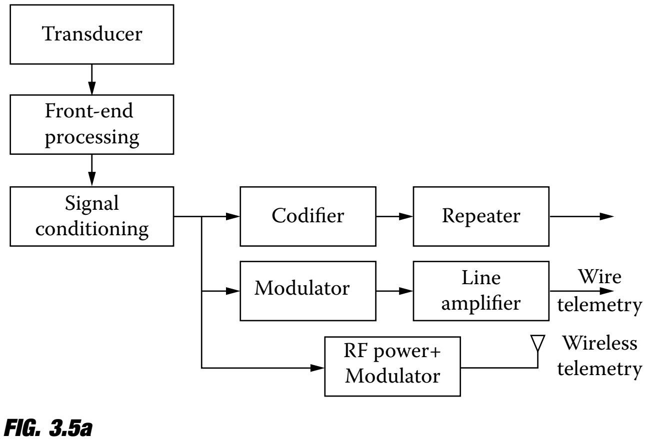

FIG. 3.5a
Basic components of a telemetry system.

1. Sensors and transducers, which convert physical variables into electrical signals for processing
2. Preconditioning circuits, which serve to amplify the low-level signals, limit their bandwidth, and realize impedance matching of inputs and outputs
3. A main signal processing unit for further signal conditioning
4. A sub-carrier oscillator, whose signal is modulated by the output of the transducer
5. A coding circuit, which can be a digital encoder or an analog or digital modulator, and which serves to prepare the signal to match the characteristics of transmission channel
6. A radio transmitter for wireless telemetry, modulated by the composite signal
7. An impedance line adapter in case of wire transmission, to match the input impedance of the line to the output impedance of the circuits
8. For wireless communication, a transmitting antenna
9. Dedicated or general computer and/or microprocessor systems with supporting peripherals

The receiving end of the telemetry system consists of similar modules. In the case of wireless telemetry, these modules are:

1. A receiving antenna suitably designed to operate in the radio frequency band of interest
2. A radio receiver with a suitable demodulation circuitry
3. Demodulation circuits for each of the transmitted channels in case of multiple transmissions
4. Computers and/or microprocessor systems with supporting peripherals

Both in wire or wireless telemetry, the transmitted signals can be analog or digital. The digital systems send data digitally as a finite set of symbols, each representing one of the possible values of the signals at the time of sampling. In case of wire telemetry, the antenna and the radio receiver are substituted by a generic front-end circuit to amplify and process the signals.

The effective communication distance in a wireless system is limited by the power radiated by the transmitting antenna, the receiver's sensitivity, and the bandwidth of the radio frequency signal. As the bandwidth increases, the contribution of noise to the total signal also increases, and consequently more transmitted power is needed to maintain the same signal-to-noise ratio. This is one of the main limitations of wireless telemetry systems.

In some applications, the transmission is done on base band, after the conditioning circuits. The advantage of base-band telemetry systems is their simplicity, although because of the base-band transmission, they are normally limited to only one channel at low speeds. The base-band concept will be explained in detail in the following sections.

Recent Trends

Nowadays, many instruments use intelligent sensors that include not only the sensor but also the signal processors and telemetric communication capabilities in a single chip. These units are appearing in the marketplace as pressure sensors and accelerometers, bio-sensors, chemical sensors, optical sensors, magnetic sensors, environmental sensors, and so on. Some of these sensors are manufactured with RF transceivers, neural network, neural processors, vision systems, and intelligent parallel processors.

Recently, due to advances in wireless communication technology and intelligent sensors, a new class of devices, called wireless sensors, is finding extensive applications. These small sensor devices integrate micro-sensing and actuation with on-board processing and wireless communication capabilities. In many applications, due to low cost and small size, a large number of sensors can be deployed. These sensors are capable of organizing themselves into multi-hop wireless networks in environmental monitoring, surveillance, and scientific data gathering applications.

In parallel with the rapid developments in the hardware aspects of modern sensors, some new standardized techniques are emerging for intelligent sensors such as the support software and robust communications and networking components. This is making a revolutionary contribution in the development and applications of telemetry. For instance, the IEEE-1451 is a set of standards that define interfaces, network-based data acquisition, and control of sensors. This subject will be revisited later in this section.

Apart from the intelligent and sophisticated sensors, the communications capabilities of many modern electronic instruments are enhancing the widening of their application possibilities. Modern instruments have two levels of communications. The first is communication at the sensor level, which is mainly realized by intelligent sensors. The second is at the device level. At the device level, the communication takes place in wire, wireless, infrared, and sonic forms.

In the implementation of wireless communications of today's instruments and sensors, the "Bluetooth" technology and Near-Field Communication protocols are gaining wider acceptance. Particularly, Bluetooth is considered to be a low-cost and short-range wireless technology to provide communication functionality, ranging from short length wire replacements to wide area networks. As the number of products incorporating technology such as the Bluetooth increases, the development of various types of instruments for many new applications gains momentum.

OPERATING PRINCIPLES AND TYPES

Telemetry can be analog or digital. Nowadays, mostly digital telemetry is used because of ease in data transmission and handling. As far as operating principles are concerned, telemetry can be divided into two main categories: base-band

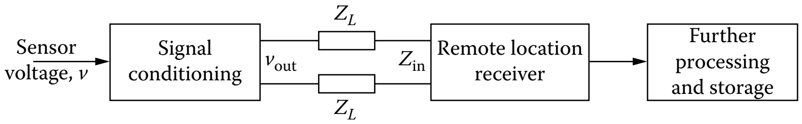

FIG. 3.5b
A voltage-based telemetry system.

telemetry and multiple-channel telemetry. These methods will be explained next, and appropriate comments will be made for their analog and digital applications.

Base-Band Telemetry

Base-band telemetry uses a wire line to communicate the signals obtained from the sensors and transducer to some remote location. There are two basic types: amplitude-based telemetry and frequency-based telemetry.

Amplitude-Based Telemetry Amplitude-based telemetry is extensively used in industry for short-distance signal transmission. In this system, the signal from the transducer is amplified, normally to a voltage level between 1 and 15 V, and is sent to the receiver through a line consisting of two wires. Figure 3.5b shows a simple voltage-based telemetry system. The permissible distance for transmission depends on the resistance of the line, the input resistance for the receiver, and the electrical noise of the environment.

The limitation on the transmission distance due to noise and impedance of the line can be partially overcome by using current signals instead of voltages, as is shown in Figure 3.5c. The basic theory is that unlike voltage, the current is not affected by noise. In addition, the drop in voltage caused by the wire resistance does not affect the transmitted signal.

However, this system requires an additional step of voltage-to-current conversion. At the receiver end, the signal is converted to voltage by using a suitable resistor. The most common method used in industry is the 4- to 20-mA current transmission. In this configuration, zero voltage corresponds to and is transmitted as a 4 mA current value, while the highest voltage is transmitted as 20 mA. Other standard current ranges are 0 to 5, 0 to 20, 1 to 50, 1 to 5, and 2 to 10 mA.

Frequency-Based Telemetry Similarly to amplitude-based telemetry, frequency-based telemetry is also often used in industry for short-distance signal transmission. Frequency-based telemetry, shown in Figure 3.3d, is known to provide higher immunity to noise. In this method, the signals obtained from the measurements are converted to frequencies by voltage-to-frequency converters. A frequency-to-voltage converter puts signals back to the voltage form at the receiving end. A special form of frequency-based telemetry is pulse telemetry in which the modulating signals are in the form of a train of pulses, which will be explained in detail in the forthcoming paragraphs.

Multiple-Channel Telemetry

Most processes require the measurement of multiple physical variables, thus requiring special methods for handling the signals. In multiple-channel applications, the use of base-band telemetry is not economical, as it would require building a different system for each channel. Instead, multiple-channel telemetry can be configured by sharing a common transmission channel (Figure 3.5e) and by using suitable multiplexing techniques.

The multiplexing can be realized by frequency division multiplexing (FDM) or time division multiplexing (TDM). In frequency division multiplexing, different channels are assigned to different spectrum bands. In time division multiplexing (TDM), the information of different channels is transmitted sequentially.

Frequency Division Multiplexing Frequency division multiplexing (Figure 3.5f) makes use of modulations of signals from each channel onto sinusoidal signals of different frequencies. The sinusoidal signals are called sub-carriers. Each modulated signal is then sent through a low-pass filter to ensure that the bandwidth limits are observed.

After the filtering stage, all the modulated signals are fed into a common summing block, producing what is known as the base-band signal. The base-band signal is then modulated by a carrier signal whose frequency and amplitude depend on the characteristics of the transmission. The carrier signal is then fed into a transmission wire or into an antenna in the case of wireless systems.

At the receiver end, the transmitted signal is detected and demodulated to separate each sub-carrier signal. This is done by feeding the signal into a bank of parallel pass-band filters.

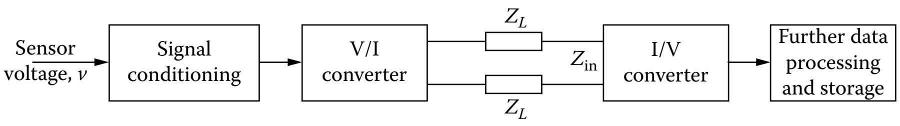

FIG. 3.5c
A current-based telemetry system.

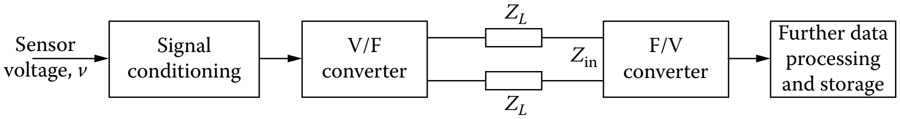

FIG. 3.5d
A frequency-based telemetry system.

Each channel is further demodulated to recover the original measurement signals. One problem with FDM systems is the cross-talk between channels. Cross-talk can be minimized by having a guard band between the spectrums of two contiguous channels. The guard band can be increased to decrease the cross-talk, but then the effective bandwidth also increases. The effective bandwidth is the sum of the bandwidth of all channels, plus the sum of all the guard bands.

The frequency and energy level of the carrier cannot be arbitrary; hence, international agreements on the use of the electromagnetic spectrum must be complied with. There are national organizations as well as international consortiums (e.g., International Consortium on Telemetry Spectrum, ICTS) to regulate the use of the electromagnetic frequency spectrum. The problem of allocation of the telemetry spectrum is common to many nations, whether telemetry is used in support of national defense, the commercial aerospace industry, or space applications.

In the United States, the Federal Communications Commission (FCC) is the body that regulates the allocation of frequencies for various communication services. For informational purposes, the most commonly used telemetry frequency bands and their intended use are shown in Table 3.5g. The allocation of bands is a process subject to change from time to time.

There are three basic techniques of modulation for FDM: amplitude modulation (AM), frequency modulation (FM), and phase modulation (PM). Combinations of these modulation techniques are also used—FM/FM, FM/PM, or AM/FM.

Amplitude Modulation Amplitude modulation makes use of the amplitude of a sub-carrier signal that changes in accordance with the value of the measured channel. The resulting signal can be expressed by:

$$v(t) = A_c\,[1 + m(t)]\cos(\omega_c t) \qquad \textbf{3.5(1)}$$

where A_c is the amplitude of the carrier, $m(t)$ the modulating signal, and ω_c the frequency of the carrier.

AM has limitations, particularly due to efficiency. It is possible to overcome some of the limitations by using modulation techniques, such as Double Side Band (DSB), Single Side Band (SSB), and Compatible Single Side Band (CSSB) techniques.

Frequency Modulation Frequency modulation and phase modulation techniques are by far the most common modulation scheme used in FDM telemetry systems. These modulations are inherently nonlinear. For example, the angle modulation can be expressed as:

$$v(t) = A\cos[\omega_c t + \phi(t)] \qquad \textbf{3.5(2)}$$

where $\phi(t)$ carries the information on the signals from the transducers.

The value of the instantaneous frequency can be expressed as:

$$f = \frac{1}{2\pi}\frac{d}{dt}[\omega_c t + \phi(t)] = \frac{\omega_c}{2\pi} + \frac{\mathrm{d}}{dt}\phi(t) \qquad \textbf{3.5(3)}$$

From these equations, it can be seen that the signal $v(t)$ is modulated in frequency. This expression can further be modified in terms of frequency deviation (f_m) and modulation index (β). The frequency deviation is defined as the maximum departure of the instantaneous frequency from the carrier frequency, and the modulation index is defined as the maximum phase deviation. Now this equation can be expressed as:

$$f = \frac{\omega_c}{2\pi} + \frac{\beta_m}{2\pi}\cos(\omega_m t) = f_c + \beta f_m \cos(\omega_m t) \qquad \textbf{3.5(4)}$$

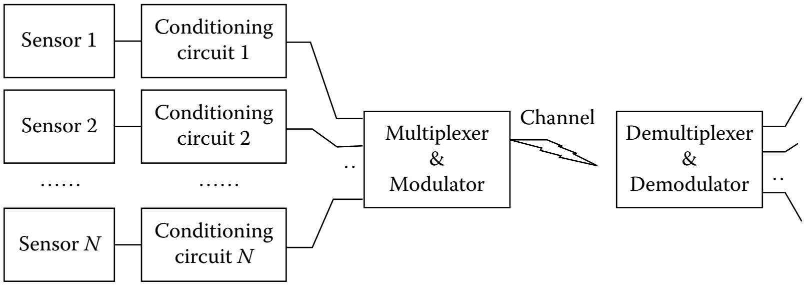

FIG. 3.5e
Block diagram of a multiple-channel telemetry system.

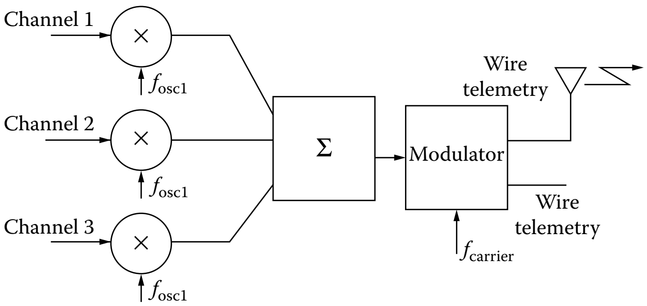

FIG. 3.5f
Frequency division multiplexing (FDM) block diagram.

The maximum frequency deviation is defined as Δf and is given by

$$\Delta f = \beta f_m \qquad \textbf{3.5(5)}$$

Therefore, we can express the equation for the frequency modulated signal as:

$$v(t) = A\cos\left[\omega_c t + \frac{\Delta f}{f_m}\sin(\omega_m t)\right] \qquad \textbf{3.5(6)}$$

The previous equation shows that the instantaneous frequency, f, lies in the range $f_c \pm \Delta f$. A practical rule states that the bandwidth of an FM modulated signal is twice the sum of the maximum frequency deviation and the modulating frequency.

TABLE 3.5g
Frequency Band Allocation for Telemetry in the United States

Frequency Band	*Uses*
72 to 76 MHz	Biotelemetry
88 to 108 MHz	Educational
154 to 174 MHz	Industry
174 to 216 MHz	Biotelemetry
216 to 222 MHz	Multiple purpose
450 to 470 MHz	General
458 to 468 MHz	Biotelemetry
512 to 566 MHz	Biotelemetry
1427 to 1435 MHz	Fixed (land mobiles services, telemetering, and telecommand)
1435 to 1535 MHz	Aeronautical (L-Band)
2200 to 2290 MHz	Mobile (S-Band)
2310 to 2360 MHz	Terrestrial sound broadcasting
2360 to 2390 MHz	Telemetry flight testing

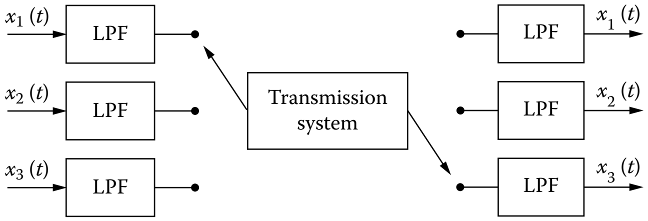

FIG. 3.5h
Block diagram of a time division multiplexing (TDM) system.

Time Division Multiplexing Time division multiplexing (TDM) is a transmission technique that divides the time in different slots and assigns one slot to each measurement channel. The entire transmission bandwidth is assigned to the assigned channel during transmission. The measurement channels are sequentially sampled by a digital switch for a period of time (T). For M measurement channels the period between two consecutive pulses is $T_s/M = 1/M f_s$, where T_s is the sampling period.

At the receiver end, the original signals are recovered by separating the digital signals into different channels by synchronized demultiplexers and by low-pass filtering. Figure 3.5h shows a basic block diagram for an FDM system.

TDM systems have a number of advantages over the FDM. In FDM, sub-carrier modulators and demodulators are required for each channel, while TDM systems need only one set of multiplexer at the transmitter and one set of demultiplexer at the receiver. The TDM signals are resistant to cross-talk. However, in TDM systems, the separation between channels depends on the sampling method adopted. Since, in practice, it is impossible to produce perfectly square pulses without rise and fall times, it is then necessary to provide time guards between pulses, similar to the band guards in FDM.

Time Division Multiplexing can be achieved by either digital or analog methods, as explained below.

Pulse Code Modulation Pulse code modulation (PCM) is a digital technique in which the measured signal is represented by a group of codified digital pulses. Figure 3.5i shows the basic elements of a PCM telemetry system. Two variations of PCM that are commonly used are Delta Modulation (DM) and Differential Pulse Code Modulation (DPCM).

PCM systems transmit data as a serial stream of digital words. An encoder converts the input data into a serial data

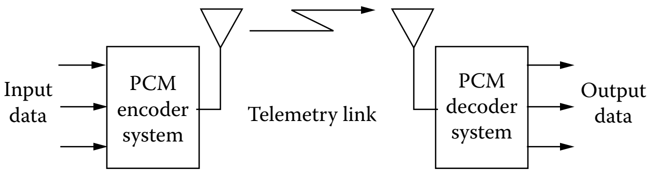

FIG. 3.5i
Block diagram of a pulse code modulation (PCM) telemetry link.

format suitable for transmission. At the receiving end, a decoder converts the serial data back into individual output data signals. The PCM encoder samples the input data and inserts the data words into a PCM frame. Words are assigned specific locations in the PCM frame so the decoder can recover the data samples corresponding to each input signal.

The simplest PCM frame consists of a frame synchronization word followed by a string of data words. The frame repeats continually to provide new data samples as the input data changes.

Pulse Amplitude Modulation *Pulse Amplitude Modulation* (*PAM*) is an analog method along with two other methods, *Pulse Duration Modulation* (*PDM*) and *Pulse Position Modulation* (*PPM*). In PAM, the waveforms are realized from unipolar, nonrectangular pulses whose amplitudes are proportional to values of samples.

Similarly, PDM is made from unipolar, rectangular pulses whose duration or widths depend on the values of samples. PPM is closely related to PDM, in which the information to be transmitted resides on the time location of the pulses rather than in the pulses themselves. The common characteristics of these modulation techniques are:

1. The modulated signal spectrum has strong low-frequency content, particularly near the sampling frequency.
2. There is a need to avoid overlaying of consecutive pulses.
3. The original signals can be reconstructed by using suitable filters after demultiplexing.

TELEMETRY PROTOCOLS, STANDARDS, AND NETWORKS

Telemetry is basically a form of communication of information obtained from measurement devices, which can be termed nodes. Information flow between nodes, individual instruments, and computers is regulated by protocols, as will be explained here.

Protocols and Standards

According to the IEEE (Institute of Electrical and Electronics Engineers), a *protocol* is defined as "a set of conventions or rules that must be adhered to by both communicating parties to ensure that information being exchanged between two parties is received and interpreted correctly." In general, communication protocols are defined by the following:

- *ISO reference model layers:* physical, datalink, network, transport, session, presentation and application layers
- *Network topology:* star, ring, or bus (tree) and so on
- *Data communication modes:* simplex, half-duplex, or duplex
- *Data transmission modes:* synchronous or asynchronous
- *Data rate supported:* several bps (bits per second) to several Gbps, depending on both oscillator frequency and transmission medium
- *Transmission medium supported:* twisted pair, coaxial cable, optical, RF, or microwave, etc.
- *Data format:* mainly based on data transmission modes and individual protocol specifications
- *Error detection methods:* parity, block sum check, or CRC (cyclic redundancy check).
- *Error control methods:* echo checking, automatic repeat request (ARQ), sequence number I, etc.

Generally, telemetry systems are subgrouped together to operate in nodes by the help of communication protocols, micro-controllers, and microprocessors. At the grassroots of this networking lie the fieldbus for industrial systems and other communication protocols developed by vendors to enable reliable and fast data communications among nodes, computers, and individual sensors. Volume 3 of this handbook is devoted to this subject.

Manufacturers offer a bewildering range of buses and protocols, but all protocols comply with the ISO reference model. Some of the typical protocols used in telemetry are: IEC 60870-5 series protocols, ISO 9506, IEC 62056, Bluetooth, and IEEE 802.11.

ISO Reference Model ISO reference model layout for the protocols is shown in Table 3.5j. The reference model has seven layers, of which each is an independent functional unit. Each layer uses functions from the layer below and provides functions for the layer above. The lowest three layers are network-dependent layers; the highest three layers are network- independent layers (application-oriented); and the middle layer (transport layer) is the interface between the two.

All digital devices need to obey the ISO reference model when communicating with each other. In some applications, some of the seven layers of the ISO reference model may be omitted, as in the cases of many fieldbuses.

Bluetooth *Bluetooth* is a protocol based on the ISO reference model; it is used in digital telemetry systems. Initially, Bluetooth was mainly aimed at bringing short-distance wireless interfaces to consumer products on a large scale. As the number of products incorporating Bluetooth wireless technology increased, the development of various types of instruments for a diverse range of applications became widespread.

However, Bluetooth did not escape competition. ExtremeTech reports that Sony and Philips have agreed to jointly work on "Near-Field Communication," a potential competitor to Bluetooth in the short-range personal area network (PAN) market. Also, the IEEE just recently adopted and approved

TABLE 3.5j

1	Physical	Electrical, mechanical and packaging specifications. Functional control of data circuits.	ISO/IEEE802.4, phase Coherent Carrier, Broadband 10 Mbs, etc.

the Bluetooth protocol under its WPAN standards, the IEEE-802 series of protocols.

Many Bluetooth products are appearing on the marketplace, from the chip level to sophisticated devices. On the chip level, a typical example of Bluetooth products is an under-$5 chipset from Texas Instruments. It provides up to 1 Mbps for fast data transmission.

On the device level, Sony has introduced in Europe and Japan the ultra-compact fixed lens DSC-FX77 camera with a built-in Bluetooth communication protocol. Many chip-level products target Bluetooth specifications. Point-to-multipoint applications consisting of a base-band controller with flash memory, a reference crystal, and an RFCMOS (radio frequency complementary metal-oxide semiconductor) transceiver.

In some cases a two-chip approach is chosen to ensure a good level of performance and reliability in RF-intensive environments. The architecture is based on independent silicon optimization with digital circuits in standard CMOS and analog parts in BiCMOS (bipolar metal oxide semiconductor) or RFCMOS, enabling cost and size reduction.

IEEE 802.11 The *IEEE 802.11* is a high-bandwidth standard for transfer of large amounts of data; it is extensively used in telemetry systems. It handles spread-spectrum and high-data bursts easily. The IEEE 802.11b standard is supported by three chips compared to two chips or the single-chip solution of Bluetooth. 802.11b is designed as a communication channel to host processors running TCP/IP (transmission central protocol/internet protocol). The encryption length is 64 bits.

IEEE-1451 The *IEEE-1451* standard aims to make it easy to create solutions using existing networking technologies, standardized connections, and common software architectures. The standard allows application software, field network, and transducer decisions to be made independently. It offers flexibility to choose the products and vendors that are most appropriate for a particular application.

As an example, Bluetooth finds wide applications in wireless smart sensor and transducer networks. Interfacing of IEEE-1451 Smart Transducer nodes to a Bluetooth network is gaining momentum. This involves a detailed study of the network communication models specified for smart transducer communication as well as the Bluetooth protocol stack.

CCSDS There are many software packages supporting telemetry applications. Many of these packages are application-specific, tailored for particular applications. An example of such packages is *CCSDS* (Consultative Committee for

Space Data Systems). CCSDS is a telemetry and telecom software library that provides a reference implementation of the international protocol standard for the transmission and reception of data in radio communications with spacecraft.

This library supports the full set of uplink and downlink virtual channels. It has a frame-acceptance and -reporting mechanism (FARM) that supports a sliding window specified within the standard. The library has been written in the C programming language for execution on various computers running the SunOS4, SunOS5, AIX, and VxWorks operating systems.

MLS-STD-1553 The *MLS-STD-1553* standard addresses the acquisition of all the traffic flowing on MIL-STD-1553–type data buses for telemetry and recording purposes. Up to eight data buses within a single system can be used. Constraints such as RF bandwidth and recording times are defined.

As the application of telemetry widens, many forms of supporting hardware and software appear in the marketplace offered by different vendors and organizations. Although most of these products are supported by the existing standards, in some cases new standards appear in lieu of new developments.

Networks

The network is an essential element of telemetry systems. A network includes many instruments, controllers, microprocessors, and computers. The hardware architectures of a network can be centralized, decentralized, hierarchical, or distributed. Many different network topologies exist, as illustrated in Figure 3.5k.

The group arrangement of telemetry systems results in many advantages. For example in message sharing, because all the nodes are connected together by one single transmission medium, nodes can demand information from another node to implement strategies, for setting and resetting, for alarms, and so on. Also, due to the simple data transmission medium and the node configuration, any problem from sensors or transmissions can be isolated, thus helping maintenance without affecting the performance of the network.

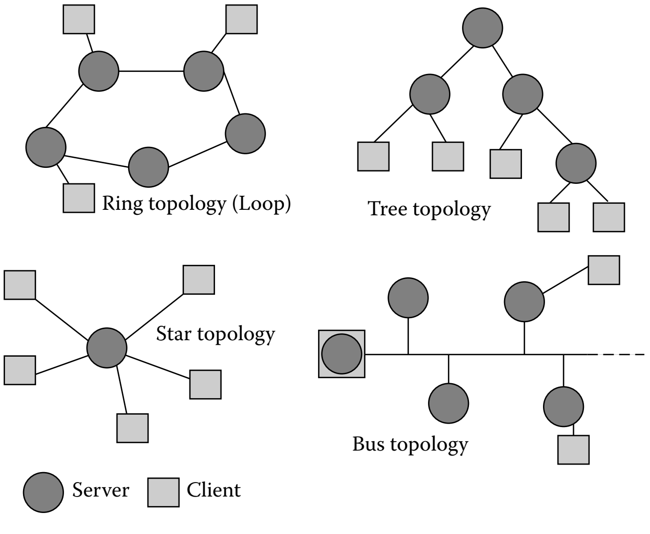

FIG. 3.5k
Common network configurations.

Telemetry Equipment and Hardware

As stated previously, a telemetry system consists of a collection of components such as computers, micro-controllers, wire and wireless transmitters and receivers, transceivers, repeaters, receivers/decoders, sensors, actuators, measurement instruments, controllers, signal converters, plug-and-play components, and protocol converters. Most of these components can be bought off the shelf or can be designed from their basic components. A list of the manufacturers and suppliers of telemetry systems and components is provided on the first page of this section.

If a system is to be designed from the basic principles, there are many single-chip RF transceivers available. A typical example is the LMX3162 from National Instruments. This transceiver is a 48-pin 7 mm × 7 mm × 1.4 mm monolithic device operating at 2.45 GHz wireless systems. It contains phase locked loop (PLL) transmit and receive functions. The 1.3 GHz PLL is shared between transmit and receive sections. The transmitter includes frequency doublers and a high frequency buffer. The receiver consists of a 2.5-GHz low noise mixer, an intermediate frequency (IF) amplifier, a high-gain limiting amplifier, a frequency discriminator, a received signal strength indicator (RSSI), and an analog DC compensation loop. The circuit has on-chip voltage regulation, which allows the use of supply voltages ranging from 3.0 to 5.5 V. Such chips are extensively used in personal wireless communication systems/networks (PCS/PCN), and wireless local area networks (WLANs).

If the data need to be transmitted for long distances in which transmitter and receivers are out of range, wireless bridges and repeaters can be employed. Wireless bridges and repeaters provide long-range point-to-point or point-to-multipoint links. Some of these devices use direct sequence spread spectrum (DSSS) radio technology operating at typical frequencies (i.e., 2.4 GHz). Data may be transmitted at speeds up to 11 Mbps. These bridges comply with standards such as IEEE-802.11b, connecting one or more remote sites to a central server or Internet connection.

On the other hand, industrial plug-and-play or long-range wireless communication devices are offered by many companies such as Microwave Data Systems, Inc. Typical products provide point-to-point and point-to-multipoint communication of data with frequencies from 200 MHz to 2.4 GHz and speeds up to 8 Mbps. Such devices are used for health monitoring and other civil, military, and industrial applications. Networks of low-cost wireless sensors enable monitoring of large civil structures with a large number of sensing nodes.

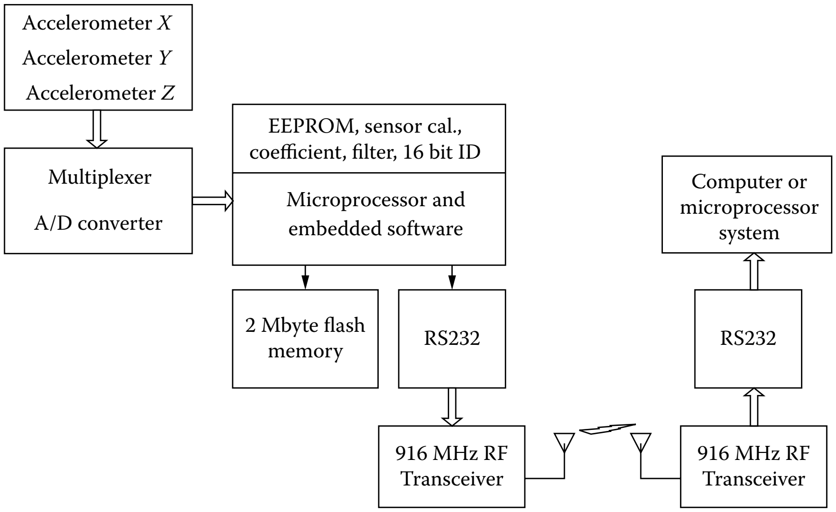

FIG. 3.5l
An intelligent accelerometer sensor equipped with telemetric features.

A typical single-unit data logging transceiver is a wireless data communications device that can serve multichannel sensor arrays to a remote data acquisition system hosted by a computer or a microprocessor. The frequency of transmission is 916 MHz, narrow-band. The RF communication link operates with 19,200 baud, and the device is capable of triggering a sample to be logged (typically from 30 m), or requested data to be transmitted.

A typical application of wireless data logging on a triaxial MEM accelerometer is illustrated in Figure 3.5l. These accelerometers have flash memory (typically 2 to 8 Mbytes). The nodes in the wireless networks may be assigned with 16-bit address lengths, hence are able to connect with thousands of multi-channel sensor clusters. They are powered by 3.1- to 9-V lithium ion AA-size batteries. They draw about 10 mA and contain 10- or 12-bit A/D converters. The dimensions of the total package are 25 mm × 40 mm × 7 mm.

Sensor Networks

Nowadays, geographically distributed sensors can be networked as distributed sensor networks (DSN). The networking requires intelligent sensors that may obey some form of a hierarchical structure.

In recent years, an IEEE-1451 compatible interface between the Internet/Ethernet serial port websensors has been developed. These sensors have direct Internet address. The interface is realized in IEEE-451 Network Capable Application Processors (NCAP). The NCAP connects the Internet through Ethernet. NCAP is a communication board capable of receiving and sending information using standard TCP/IP format. The sensor data are formatted to and from the serial port by one of the followings, RS232, RS485, TII, Microlan/1-wire, Esbus, or I^2C.

The future of sensors will probably be shaped by how they interface into the network to share information. Nevertheless, the importance of sensor networks has been understood by many vendors; hence, the vendors promote proprietary solutions to connect smart sensors into TCP/IP-based networks. As was explained earlier, developments are taking place at both low-level interfaces and at high-level interfaces.

TELEMETRY APPLICATIONS

Telemetry finds a wide range of applications in medicine and life sciences, in industry, in the military, in space exploration, and in other fields.

Medical and Life Science Applications

In recent years, medicine and life sciences have benefited considerably from the use of telemetry techniques. Telemetry has proven to be particularly important in those situations where it is desirable to leave the subjects in a relatively normal physiological and psychological state with minimum interference with their normal pattern of activities. It finds extensive applications in remote locations, where health and safety are the prime concerns. For example, for humans working in hazardous environments, the telemetry of their vital signs is a way to ensure their safety.

Medical Telemetry Medical telemetry is used to detect the regular and/or irregular functioning of the human body. A patient's vital signs, such as electrocardiogram (ECG) waveforms, are monitored continuously and the information is transmitted to a central station for observation and recording. Often wireless telemetry is selected to free patients from being bedridden, thus giving them freedom to move about.

Over the past several years, manufacturers have made tremendous strides in improving the design and functionality of

(1) Bed side monitor (2) handheld transmitters (3) base station

FIG. 3.5m
A telemetric patient monitoring system. (Courtesy of Nihon Kohden Corporation, www.nihonkohden.com)

telemetry systems, allowing more acute patients to become ambulatory during recovery. These systems are now capable of monitoring several different parameters, from ECG waveforms, arrhythmias, and heart rate to pulse oximetry and other vital signs.

Many medical telemetry systems consist of a small digital transmitter worn by the patient, a set of sensors for gathering patient vital signs, a distributed transmitter, and receiving systems. Displays, controls, and recordings are often controlled from a central computer, which is located at the nursing station, where telemetry units dedicated to the diagnosis and treatment of life-threatening illnesses are also located.

A telemetric nurse-based biomedical instrumentation system is illustrated in Figure 3.5m, where (1) shows the telemetry bedside monitor of a patient. It has a 7-inch CRT screen with two waveforms. Vital signs can be graphically or tabularly displayed. The vital signs of patients, such as electrocardiogram (ECG) waveforms, and data can be transmitted, normally wireless, to a remote station for observation and recording.

In Figure 3.5m (2), a patient transmitter for a wireless bedside monitor is illustrated. The base station, in Figure 3.5m (3), can monitor waveforms, data, trends and alarms of up to eight telemetry patients. It has dual-antenna diversity reception, 100-arrhythmia event memory, and a vital signs list.

The use of wireless medical telemetry systems is on the rise worldwide despite a growing problem with electromagnetic overcrowding on the airwaves. Different countries approach congestion of the airwaves in different ways. Some countries assign less crowded regions of the electromagnetic spectrum to telemetry services while others concentrate on the development of modulation and compression techniques to limit bandwidths.

In the United States, the Federal Communications Commission (FCC) is the agency responsible for assigning portions of the electromagnetic spectrum to users other than the federal government. The FCC has issued new rules for medical telemetry in which it assigns portions of the spectrum to telemetry services to operate on an interference-protected basis. In this approach, hospitals will have reasonable assurance that the next generation of medical telemetry devices will operate in this expanded spectrum with minimal interference.

One application of telemetry is the cardiac pacemaker. A bidirectional telemetry process is initiated by the cardiologist when a special signal is sent to the pacemaker. Each pacemaker that is carried by a patient has a different identification code set by the cardiologist before implantation. The typical data from the pacemaker include voltage, impedance, and current consumption of the battery; battery charge level; voltage and current levels; and width, rate, and energy of pulses to record the electrical activity of the heart. All this information can be read and interrogated.

In many cases, especially for patients who are located in rural or isolated areas, monitoring of physiological parameters by wireless transmission is not possible. In these cases, public telephone networks are used for telemetry purposes; the data obtained from the patient is transmitted over telephone lines. However, this approach needs careful attention since the transmission of multiple physiological channels can be problematic in terms of recovering useful information due to frequency band limitations of telephone lines. In this telemetry, speech and data are transmitted simultaneously. This requires an increase in bandwidth, which is achieved by suitable processing devices.

Life Sciences and Bio-Telemetry Telemetry is extensively used in diverse range of life science applications. Telemetry systems equipped with radio transmitters implanted or attached to marine and land animals allow the study of their biological functions and behavior without disturbing their normal way of living. Implanted transmitters have been used to study animals. The transmitter surgically implanted in the body of the animal supplies valuable information on animals' survival patterns.

In life science applications, the range of the transmitter of the telemeter is an important parameter. The range can be from a few centimeters in laboratory experiments to several miles for tracking wildlife. Another critical parameter is the selection of the sensors and transducers that can accurately sense the desired range and at the same time can be protected from corrosion and harmful body fluids. The operating temperature of the sensor can vary from sub-freezing temperatures in the North to the temperature of the deserts. Temperature is important because the life of the batteries powering the telemetry system is largely dependent on the operating temperature.

Figure 3.5n illustrates an implantable sensor/telemetry transmitter to measure the temperature, gross motor activity,

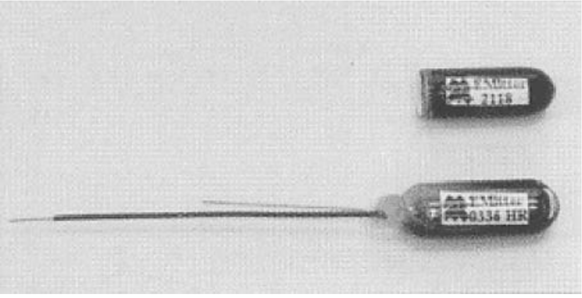

FIG. 3.5n

and heart rate of an animal. This sensor/transmitter arrangement does not require a battery.

Industrial Telemetry

Telemetry is extensively used in industrial applications. Industrial telemetry enables the automatic and remote monitoring and recording of process variables. By using telemetry, operational efficiencies and safety can be improved. Some applications include oil and gas operations, medical equipment, utilities production and consumption, and intelligent transportation systems.

There are many different types of industrial telemetry systems, since they are offered by a diverse range of vendors competing for the same market. SCADA, which is discussed below, is an example of a well-established telemetry system.

Modern industrial systems use computers, remote terminal units (RTUs), programmable telemetry controllers (PTCs), and so on. PTCs consist of modular intelligent units that can handle multiple inputs (typically 128 I/O) for networking purposes. Remote terminal units can handle virtually thousands of digital and analog inputs and outputs. Some RTUs support local, public switched telephone networks (PSTN), private wire (PW) systems, leased lines (LL), and radio communications.

SCADA Systems SCADA stands for *System Control and Data Acquisition.* SCADA consists of a collection of computers, sensors, and other equipment interfaced by telemetry to monitor and control processes. The uses of SCADA systems are endless as they are only limited by the designer's imagination. Some typical applications include high- and low-voltage power distributions, broadcasting stations, and environmental measurements.

An example of SCADA applications is in water management. Water conservation is critical not only in drought-stricken areas but everywhere, as water is becoming a limited resource due to increases in consumption. Application of SCADA systems enables the remote and effective monitoring and controlling of water levels.

Another application of SCADA in industry is digital pager alarming systems. If an unusual situation occurs in a process, the SCADA system can alert key personnel by sending messages to their pagers. SCADA systems also archive information and generate reports and graphs that are critical to processes.

An important advantage of SCADA systems is that the existing sensors in an application can be incorporated into the overall SCADA system. In doing so, the SCADA system simply adds a new level of intelligence and provides additional capabilities to the existing controls in the plant. In addition to lowering the cost of implementing new technological solutions in existing plants, it can also help to centralize the controls to a central commanding post. SCADA systems can be equipped with alarms so that if one of the subsystems fails, corrective actions can be taken without delay.

FIG. 3.5o
A wireless bridge for SCADA. (Courtesy of Industrial Control Links, Inc., www.iclinks.com)

Figure 3.5o illustrates a ScadaBridge Wireless Remote Terminal Unit (RTU). Such units combine the traditional remote I/O functions of an RTU with a built-in Spread Spectrum radio, thus lowering cost and simplifying installation and support. This particular device serves as a "standard" Modbus Slave RTU in a radio-based SCADA system, or as a wireless I/O bridge that "mirrors" analog and digital signals between two remote locations, providing radio capabilities to non-radio enabled process equipment. The ScadaBridge is "plug-and-play" compatible with SCADA/DCS software packages such as WonderWare, FIX, FactoryLink and Labview — and with PLCs and process controllers.

Space Telemetry

The need to control and gather information from objects put into space is one of the earliest applications of telemetry systems. In the U.S., the current industrial and commercial telemetry standards are largely derived from the telemetry of missiles and other unmanned space objects. Today, telemetry finds extensive applications in space exploration and military use.

In manned space flights, telemetry is used to detect the potential onset of distress and take the necessary precautions. The astronaut's EKG, blood pressure, respiratory rhythm, and other life functions are monitored continuously and telemetered to earth. During the first manned landing on the moon, the voices of the astronauts were combined with 900 other signals, some of them physiological parameters from the astronauts. These complex signals transmitted to Earth, at about 2.2 GHz, were picked up by the ground station in California and relayed to the space flight center in Houston. The different signals were separated and human physiological parameters were extracted as the command ship orbited around the moon.

There are numerous satellite systems around the Earth relying on telemetry systems for spacecraft management. Onboard, they have a Telemetry, Tracking and Command (TT&C) system that supports the daily functioning of the spacecraft. The functions of the TT&C system are numerous. It monitors the performance of satellite subsystems, transmits the data to satellite control centers, supports the determination of orbital parameters, and performs control functions issued by the command center.

The information received from the satellites is used for operational and failure diagnostic purposes. The commonly monitored parameters include voltages, currents, and temperatures of

FIG. 3.5p
Typical space telemetry equipment. (Courtesy of Acroamatics Telemetry Systems, www.acroam.com)

all the major subsystems; the switch status of communication transponders; the pressure in propulsion tanks; and the outputs from altitude sensors.

In modern satellite systems, distributed telemetry systems in modular forms are favored. In this configuration, digital encoders are located in each satellite subsystem and the data from each encoder are sent to a central encoder via a common, time-shared bus. This method reduces the number of wire connections and improves the reliability of the whole telemetry system. Modular design also permits the easy expansion of the initial design and facilitates easy testing during the satellite assembly phase.

Typical space telemetry data processing equipment is shown in Figure 3.5p. This data processor is a virtual machine environment (VME) based system using open architecture and operating systems. It is used in applications where extensive real-time processing of single to multiple streams in complex formats is required. It is capable of real-time data display and recordings.

Other Applications

Apart from medical, life sciences, industrial, and space applications, telemeters are used in many novel applications. For example, vibrations and additional stresses of power lines due to wind and snow can be monitored to prevent fatigue and failure. In this case, the telemetry systems are used as a watchdog before a problem occurs. Some of the telemetry applications are listed below, but such applications are limited only by the imagination of the designer:

- Determination of levels and flow rates of rivers and lakes
- Computer and other equipment fault information systems
- Vending machines connected to mobile phones
- Electric meters interrogated for billing purposes
- Water and gas flow meters monitored for billing and fault diagnosis
- Personal security systems, etc.

Flow sheet symbols

Range:

Temperature: Thermocouples can measure as low as –518°F (–270°C) with a K, E, or T-type thermocouple, and as high as 4200°F (2300°C) with a Nanmac model HTP tungsten/rhenium (W/Re) thermocouple. Platinum RTDs can measure from –328 to 1112°F (–200 to 600°C) with Tegam model 8693 probe.

Pressure: Absolute, gauge, and differential pressures. Fullscale ranges from 0.1 in. H_2O (25 Pa) (with Druck model LPM 1000), to 200,000 PSI (1,380 MPa) with Omegadyne model PX91.

Flow: Virtually unlimited. Orifice size can be varied for use with DP cell, electromagnetic induction, paddle, thermal conductivity, etc.; can vary pipe size.

Level: Maximum level is unlimited with bubbler or differential pressure. Radar up to 114 ft (35 m) with Solartron/Mobrey model MRL 700, magnetostrictive up to 100 ft (30.6 m) with MTS Temposonics flexible Level Plus™.

Motion: Full scale ranges from 0.020 in. (0.5 mm) with Schaevitz LVDT model LBB, to over 20 ft (6 m) with MTS Temposonics magnetostrictive models.

Inaccuracy: Fully compensated transmitters are available with error as little as 0.1% of full range over their operating temperature range. Lower cost devices are normally 0.25 to 1%. Transmitters with especially high or low full scale ranges may have errors of 2% or more.

Costs: Process control pressure, flow, and level transmitters in common full-scale ranges cost $500 to $2000. Temperature and motion sensors are typically less than $500. Replacement RTDs and thermocouples are $25 to $100.

TRANSMITTER CONFIGURATIONS

Industrial products and processes, commercial products, and automotive products all have requirements to access data that indicate physical parameters either continuously or on demand. Since industrial process control is the target of this work, attention in this chapter is concentrated on the measurement of temperature, pressure, flow, level, and motion. Although many industrial processes require additional measurements, those listed are the most common. To facilitate a closed-loop control system, information from the process must be obtained before a controller can determine what action may be required by a control element. Some popular names for the sensing devices that provide the information are sensors, transducers, and/or transmitters. Other names are also used, but we will define these three for the purposes of this chapter on transmitters.

> A *sensor* is an input device that provides a usable output in response to the input measurand.[1] A sensor is also

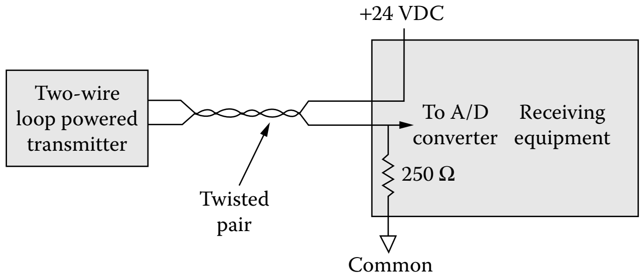

FIG. 3.6a
Wiring configuration of a two-wire, loop-powered 4- to 20-mA transmitter.

> commonly called a sensing element, primary sensor, or primary detector. The *measurand* is the physical parameter to be measured.
>
> An *input transducer* produces an electrical output that is representative of the input measurand. Its output is conditioned and ready for use by the receiving electronics.[1] (The terms "input transducer" and "transducer" can be used interchangeably.)

The receiving electronics can be an indicator, controller, computer, PLC, etc. The term "transmitter," as commonly used with industrial process control instrumentation, has a more narrow definition than those of a sensor or transducer:

> A *transmitter* is a transducer that responds to a measured variable by means of a sensing element and converts it to a standardized transmission signal that is a function only of the measured variable.[2]

Transmitters can have any of several electrical connection schemes. The most common and easiest to use is the two-wire, loop-powered configuration. This is generally the basic configuration assumed by engineers for industrial process control systems when digital communication is not required. As shown in Figure 3.6a, only two wires are used to accommodate both power to the transmitter and output signal from the transmitter.

The loop current is usually 4 to 20 mA, but 1 to 5 and 10 to 50 mA have been used. Important calibration parameters with a current loop are zero, full scale, and span. With the 4- to 20-mA range, the loop current is normally 4 mA when the measurand is at *zero*, and 20 mA when the measurand is at *full scale*. The difference between zero and full scale, 16 mA, is called the *span*. Thus, the span corresponds to the indicated range of the measurand.

When considering a motion transmitter, for example, the range of the measurand could be 0.0 to 100.0 mm, corresponding to a 4- to 20-mA loop current (output span is then 16 mA); the output *scaling factor* is 0.16 mA/mm (which is 100 mm/16 mA).

Two-Wire Loops

The main advantage of a two-wire loop is that it minimizes the number of wires needed to run both power and signal. The use of a current loop to send the signal also has the advantages of reduced sensitivity to electrical noise and to loading effects. The electrical noise is reduced because the two wires are run as a twisted pair, ensuring that each of the two wires receives the same vector of energy from noise sources, such as electromagnetic fields due to a changing current in a nearby conductor or electric motor. Since the receiving electronics connected to the transmitter is designed to ignore common-mode signals, the resulting common-mode electrical noise is ignored.

The sensitivity to loading effects is reduced because the current in the twisted pair is not affected by the added resistance of long cable runs. A long cable or other series resistance will cause a greater voltage drop but does not affect the current level as long as enough voltage compliance is available in the circuit to supply the signal current. The circuit compliance to handle a given voltage drop from additional loop devices depends on the transmitter output circuit and on the power supply voltage.

The typical power supply for industrial transmitters is 24 VDC. If 6 volts, for example, are needed to power the transmitter and its output circuit, then 18 volts of compliance remain to allow for wire resistance, load resistance, voltage drops across intrinsic safety (IS) barriers and remote displays, etc. Where the current loop signal is connected to the main receiving equipment or data acquisition system, a precision load resistor of 250 ohms is normally connected. This converts the 4- to 20-mA current signal into a 1- to 5-volt signal, since it is standard practice to configure the analog-to-digital converter of the receiving equipment as a voltage-sensing input.

Three- and Four-Wire Loops

In contrast to the two-wire current-loop configuration, some current-loop devices require a three- or four-wire connection, as shown in Figure 3.6b. These are not loop powered and

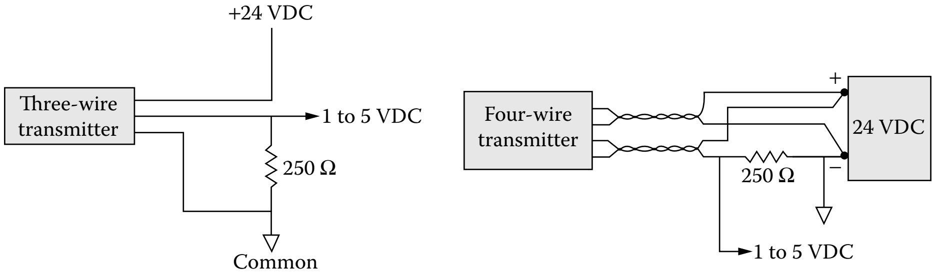

FIG. 3.6b
Three-wire (left) and four-wire (right) current-loop configurations.

therefore have a separate means for providing power by adding one or two more wires.

In a four-wire configuration, the current-loop wires can be a twisted pair, and the power supply wires a separate twisted pair. This preserves the ability to reject electrical and magnetic common-mode interference.

This is not so effective in a three-wire configuration due to the common connection for the return current path. Typically, though, when an instrumentation engineer specifies a current-loop transmitter for industrial process control, it is assumed that a two-wire, loop-powered 4- to 20-mA device is intended. Other data signals may also be impressed upon the same wire pair, or alternatively, various digital communication techniques can be used instead of a current loop. These are described in Section 4.16, which covers field boses and network protocols.

MEASURED VARIABLES

Although almost any type of transducer can be configured as a transmitter, the most common types for industrial process control comprise measurands of temperature, pressure, flow, level, and motion. These are presented here with an explanation of principle of operation. Transmitters for measuring other parameters will have the same possibilities for connection and communication methods, with the main differences being in the sensing element design.

Temperature

A temperature transmitter can utilize a sensing element based on a solid state device (voltage or current output), or thermistor (resistance change) sensing element, but most use either a thermocouple (TC) or resistance temperature device (RTD). Since they are the most popular, thermocouple and RTD-based temperature transmitters are presented here. Thermocouples and RTDs for use with temperature transmitters are available from many sources and will have similar characteristics if ordering the same type.

Thermocouples Thermocouples are one of the most widely used devices for measuring temperature where the temperature probe can contact the body to be measured. They are simple and relatively easy to fabricate. A thermocouple half-circuit is formed by the joining of two dissimilar metals together, usually by welding the tips of the two wires. The point of contact between the two wires is called a thermocouple junction. The metal used for each wire can be a pure element or an alloy.

A voltage potential is developed that can be measured in millivolts across the wire ends opposite the junction. The amplitude of the voltage depends on the difference in electronegativity between the two metals and the difference in temperature between the junction and the other ends of the thermocouple wires. A complete thermocouple measuring circuit includes two junctions. The pair of wires leading back to a voltmeter can be the same metal or alloy as each other, shown in Figure 3.6c.

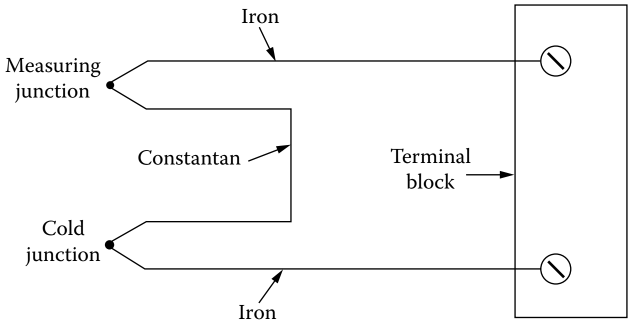

FIG. 3.6c
The measuring and the cold junctions of a thermocouple-type temperature detection circuit.

One junction is the reference, theoretically held at 0°C and called the cold junction. The other junction is incorporated into the measuring probe. Letters such as J, K, and T are used to indicate the metals used. Standard tables list the output voltage generated vs. temperature and thermocouple type, assuming that the cold junction is held at 0°C. (For such tables and much more, refer to Section 4.13 in Volume 1 of this handbook.)

Temperature transmitters do not actually incorporate a “cold” junction but simulate it through the use of an electrical circuit and a special terminal block to accept the thermocouple (TC) extension wires. The terminal block is arranged so that the two terminals will remain at a temperature equal to each other. This provision is needed in order to prevent the introduction of additional thermocouples at the extension wire connection points from affecting accuracy. In the electronic circuit, the cold junction simulator adjusts the zero point for the given thermocouple type, while the gain of an amplifier adjusts the sensitivity or span. In addition, a linearizing circuit is incorporated to improve the accuracy over the full operating range. The most popular thermocouple types are J, K, E, and T, with ranges and conductors as listed in Table 3.6d.

For a tabulation of inaccuracy, repeatability, ambient temperature, and supply voltage effects on a variety of pressure and temperature transmitters, refer to Table 3.6e.

TABLE 3.6d
The Most Common Thermocouple Types, Their Ranges, and Conductors Used

Thermocouple Type	*Conductors Used*	*Temperature Range*
J	Iron-Constantan	–210 to 1200°C
K	Chromel-Alumel	–270 to 1372°C
E	Chromel-Constantan	–270 to 1000°C
T	Copper-Constantan	–270 to 400°C

motion balance	0.5%	0.1%	1.0%	0.1%
RTD-Based TT (platinum)	0.15%	0.05%	0.75%	0.02%
TC-Based TT	0.1% or 5 microV	0.05%	See below	0.02%

Ambient error sources include 1) reference junction error of 40 microvolt maximum, 2) span error of 0.5%, and 3) zero error of 0.5%.

PT = Pressure Transmitter; TT = Temperature Transmitter.

RTDs Most RTDs are made with a platinum resistance element and calibrated to have a nominal resistance at 0°C of either 100 or 1000 ohms, although other resistances are available. (For a detailed description of RTDs refer to Section 4.10 in Volume 1 of this handbook).

The resistive element can be made from wire coiled onto a nonconductive form or can be a film deposited onto a nonconductive substrate. The form or substrate is usually made of a ceramic material. The element resistance increases as temperature increases. A constant current is applied, and the voltage drop across the element is measured. The current must be kept low enough so that the power dissipation is not sufficient to appreciably heat the RTD.

If the copper extension wires are long, the resistance reading can be corrupted by the resistance change of the wires due to ambient temperature changes. To prevent this, a four-wire circuit called a Kelvin connection can be used, as shown in Figure 3.6f.

In the four-wire configuration, the current is applied through one pair of wires, and the voltage is measured by the other pair of wires. There is minimal current in the voltage-sensing pair, thus avoiding a voltage drop and preserving the accuracy of the RTD resistance reading. Table 3.6g shows the performance data for standard “smart” RTD transmitters.

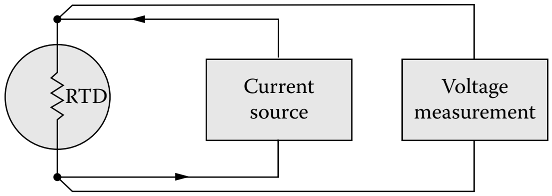

FIG. 3.6f

The four-wire circuit, which is also called the Kelvin sensing circuit, that is used in RTD thermometry.

When using any type of contact probe for the measurement of temperature, it is important to note that this technique does not work well in vacuum. The sensing area (usually the tip) of the temperature probe must touch a thermally conductive medium. Air is acceptable as a thermally conductive

Span Shift/6 mo.	± 0.1%	± 0.4%	0.18°F (0.1°C)	0.18°F (0.1°C)
Supply Voltage Variation	± 0.2% or 0.02°F (0.01°C)		—	(0.005%)/Volt
Ambient Effect (100°F or 55°C)	± 0.75%		Included above	± 0.1%

*When two values are given the error is the higher of the two. When % is given it refers to % of span or % of calibrated span, except if %R is shown, which means % of actual reading.

medium for measuring relatively slow temperature changes, but heat is not conducted in a vacuum. A vacuum chamber is heated by radiation (or conduction through some other medium, such as the chamber walls), so another sensing method should be used in vacuum. One example of a preferred method would be to aim an infrared detector at an interior surface.

Pressure

Industrial pressure transmitters measure fluid pressure, either gas or liquid, while using any of several types of sensing elements. (For a detailed discussion of all the pressure sensors used in the processing industry, refer to Chapter 5 in Volume 1 of this handbook.)

The most popular pressure sensors are the strain gauge, LVDT, capacitive, resonant wire, and inductive or variable reluctance types.

Strain Gauges Strain gauges can be wire, bonded or unbonded foil, thin film, or semiconductor. In any of these types, the resistance varies with strain, although capacitance- and inductance-based gauges have also been built. Figure 3.6h provides a pictorial representation of a bonded foil-type strain gauge and a diffused semiconductor type.

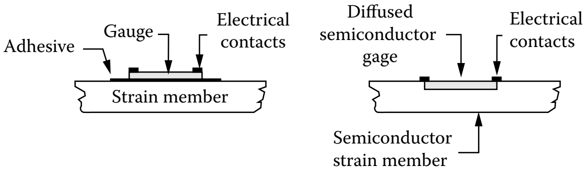

FIG. 3.6h

Strain gauge configurations: bonded foil (left) and diffused semiconductor (right).

In the bonded-foil gauge, the adhesive also provides electrical insulation from the strain member. Due to its small size and relatively low cost, a diffused semiconductor sensing element is the most common strain gauge implementation. Since an adhesive is not required, it is easier to manufacture than the bonded type, but has an intrinsic temperature sensitivity that results in both strong zero and span shifts. Accordingly, effective means for temperature compensation must be employed.

The compensation scheme usually corrects for nonlinearity of the sensing element in addition to correcting temperature errors. A diffused semiconductor strain gauge pressure transmitter can be designed so that the fluid directly wets the semiconductor diaphragm if the measured media are noncorrosive, but an isolation diaphragm of stainless steel or other metal is usually used to ensure compatibility with various measured media. The space between the metal diaphragm and the semiconductor sensing element is filled with a liquid (usually a degassed silicone oil) to transmit the pressure from the diaphragm to the sensing element.

With pressure transmitters utilizing LVDT, capacitive, inductive, or variable reluctance sensing elements, a pressure-sensing metal diaphragm, capsule, or bourdon tube is exposed to the pressure. The diaphragm, capsule, or bourdon tube converts the pressure into motion. Then the motion is measured

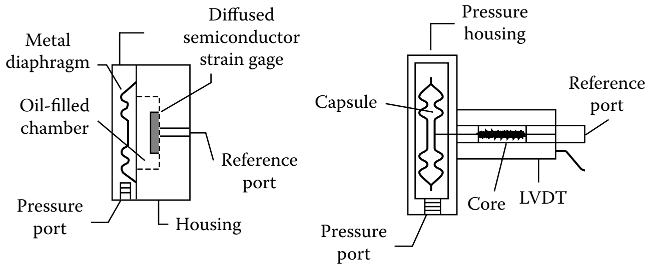

FIG. 3.6i
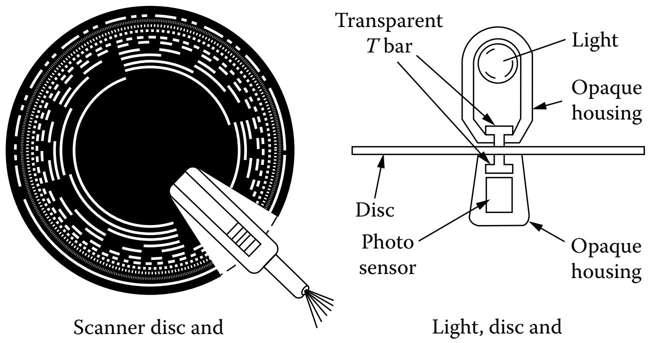
Mechanical pressure sensor configurations: diffused semiconductor strain gauge (left) and LVDT with pressure capsule (right).

and converted into an electronic signal by the sensing element and associated electronics module. Figure 3.6i shows some representative configurations for pressure sensing.

LVDT The diffused semiconductor strain gauge was shown in Figure 3.6h. A pictorial representation of an LVDT (linear variable differential transformer) is shown in Figure 3.6j. An LVDT normally comprises three coils of wire, arranged in a line as shown. The center coil is the primary and is driven by an AC waveform, usually a sine wave at a frequency of 500 Hz to 10 kHz. The circuit generating the drive for the primary coil and receiving the signal from the secondaries is called a signal conditioner. A ferromagnetic core is positioned within the bore of the bobbin on which the coils are wound.

The two secondaries are connected in series so their voltages subtract. When the core is centered, the voltage of each secondary has the same amplitude but opposite polarity, so the output voltage is approximately zero. As the core moves one way or the other, the output becomes more positive or negative respective to the direction. In order to produce this bipolar output, a demodulating circuit must be used to change the output voltage of the secondaries to DC.

There are many circuits to do this, and so they are not shown here, but they can be passive or synchronous. A passive demodulator uses diodes, capacitors, and resistors and does not rely on the phase of the primary voltage. Synchronous demodulators use semiconductor switches that conduct with a timing depending on the phase of the primary.



Scanner disc and photocells

Light, disc and photocell assembly

FIG. 3.6k
Photoelectric encoder transducer.

A synchronous demodulator has better performance than a passive one when the cable to the LVDT is longer than a few inches from its signal conditioner.

Photoelectric Transducers Figure 3.6k shows a typical schematic of a photoelectric transducer where the position of the photocoder is proportional to the motion of a primary sensing element. Light from the source shines through perforations in the shutter to energize photoelectric cells. The output of these cells is scanned and the pulses are amplified to produce a digital signal or they are rectified to produce a DC analog signal.

Capacitive Transducers Figure 3.6l shows a capacitance-type pressure or differential pressure transducer, which is of the motion-balance type. Positioned between two fixed capacitor plates is a highly prestressed thin metal diaphragm. This forms the separation between two gas-tight enclosures that are connected to the process. The difference in pressure between the two chambers produces a force that causes the diaphragm to move closer to the fixed capacitor plate of the low-pressure chamber. The transducer is excited by a 10-kHz voltage with an amplitude proportional to the difference in pressure.

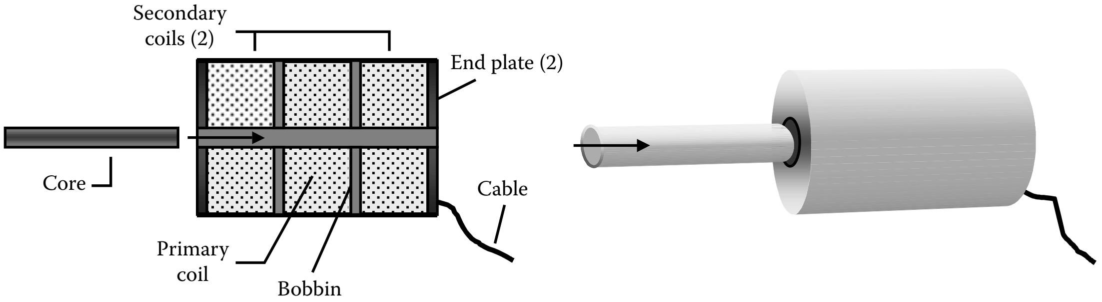


FIG. 3.6j
Cutaway view of an LVDT-type pressure sensor (left), and the outside view of the same sensor showing the core as it is about to enter the bore (right).

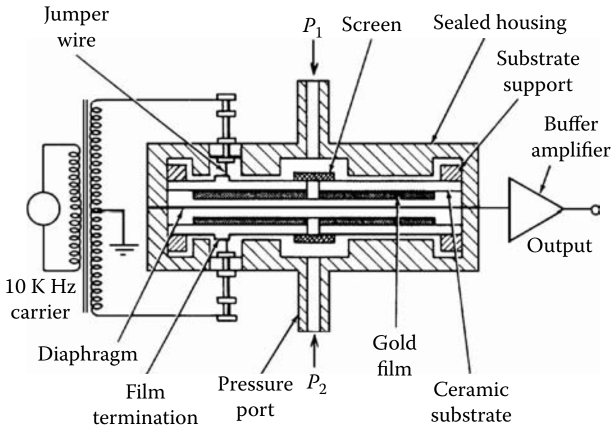

FIG. 3.6l
Capacitance pressure transmitter.

In some designs, the transducer is filled with an inert fluid (usually silicone oil) to prevent contamination of the capacitor plates or transducer interior by the process fluid or gas. A metal barrier diaphragm keeps the fill fluid in the transducer and the process out of the transducer.

Capacitive Semiconductor Transducers The capacitive semiconductor transducer is very similar to the metallic capacitance transducer except that the sensing diaphragm is micromachined from silicon instead of metal. Figure 3.6m shows a silicon capacitive cell. The semiconductor transducer has almost no hysteresis and has excellent elasticity. The sensing diaphragm is sealed between two rigid plates to complete the capacitor cell. Silicon is normally sealed with low-melting-point glass to create a hermetic seal, instead of being welded like the metallic cell.

Potentiometric Transmitters Figure 3.6n shows a potentiometer (resistance) driven by a bourdon tube in a manner similar to the movement of a pressure gauge. Rotation due to a pressure change turns the shaft of a precision potentiometer, and the change in resistance is proportional to the process pressure.

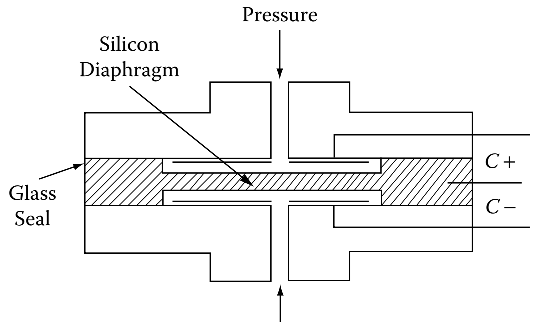

FIG. 3.6m
Silicon capacitive cell.

Pressure Measurement Types Pressure measurements can be gauge, absolute, or differential. A pressure-sensing diaphragm, for example, has two sides. To measure gauge pressure (PSIG), one side (the reference port) is exposed to the ambient atmospheric pressure, and the other side (the measuring port) is exposed to the measurand. Thus, the measurement is made relative to the ambient pressure.

The reference port may or may not be accessible to the user. To measure absolute pressure (PSIA), the reference port is sealed off while containing a vacuum. To measure differential pressure (PSID), both ports are connected by the user and the pressure difference is indicated. A pressure transmitter specially designed to accept a wide common mode pressure range and high overpressure is called a DP cell.

Flow

Flow transmitters are widely used in all types of process control applications. (For a detailed discussion of the various flow detectors, refer to Chapter 5 in Volume 1 of this handbook.)

Airflow is measured to monitor and control the performance of fans and dampers. Liquid flow is measured to control boilers, chillers, heat exchangers, and the supply of liquid components and final product. Common methods employ measuring the pressure drop across a section of pipe, duct, orifice plate, venturi, or pitot, as well as direct methods using a paddle, thermal conductivity, vortex shedding, or turbine.

A paddle-type flow transmitter is shown in Figure 3.6o. The paddle, which is positioned in the flow stream, receives increasing force as the flow increases. This force can be measured by a strain gauge, or the paddle can be allowed to move with the force and then measured by a motion sensor.

Process flow transmitters utilizing a pressure drop combine a standard pressure transmitter with a pressure drop–generating element that is placed in line with the flow. Some of these are depicted in Figure 3.6o. When a fluid flows through an orifice, a pressure differential develops across the two sides of the orifice. The amount of pressure drop varies as the square of the flow rate, so a square root function is added within the transmitter or within the data acquisition system to return a linear output reading vs. flow rate.

In a pitot arrangement, a port perpendicular to the flow measures a reference pressure, and a port angled into the flow measures a pressure that increases with increased flow due to the impact pressure of the fluid. A venturi arrangement provides a more linear change in pressure vs. flow rate and provides less obstruction of flow than would an orifice.

Pitot turbine meters are inserted into the flow to detect its velocity, while full flow turbine meters are more accurate because the full flow passes through the turbine blades. Turbine meters can measure the flow rate by detecting the RPM developed. In this case a small magnet in the impeller can induce voltage pulses into a nearby pickup coil. The pulse rate then represents the flow rate.

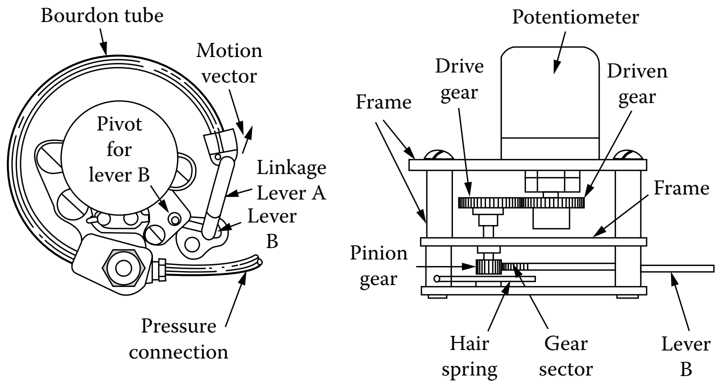

FIG. 3.6n
Potentiometric transmitter.

When using thermal conductivity to measure flow, a reference temperature sensor (nonheated) on the upstream side provides a reading that is subtracted from the heated temperature sensor. The temperature difference decreases with increased flow.

Flow transmitters can also detect the speed of sound in the measured fluid, electromagnetic induction, and the float position of rotameters. To measure fluid flow depending on the speed of sound in a medium (the fluid), a sonic wave is caused to propagate in the fluid along the path of the flow to be measured. With zero flow, a known amount of time will elapse as the wave travels from the sender to the receiver. This time will increase as the flow velocity in the opposite direction to that of the waves rises or will decrease if they travel in the same direction. The amount of time measured indicates the flow rate. This varying rate of wave propagation due to the relative difference in velocity between the sender and the medium is called the Doppler effect.

When using electromagnetic induction (called the Faraday effect) to measure the flow of electrically conductive liquids, the fluid flows in a magnetic field. Electrodes that are electrically insulated from the pipe pick up a voltage potential with a magnitude depending on the flow rate.

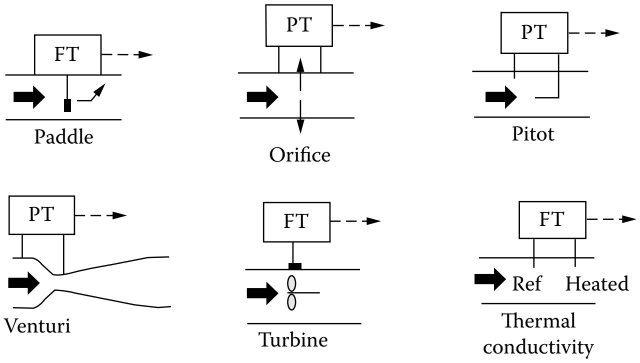

FIG. 3.6o
Six flow transmitter designs, each operating on a different working principle.

Rotameters can be instrumented with magnetic, inductive, optical, or other sensors so that the position of the float within the measuring tube is measured. If a rotameter with a glass measuring tube is used, local visual indication is also available.

Level

Transmitters for measuring liquid level are commonly used for process control, but also for inventory control and custody transfer. (For a detailed discussion of this topic, refer to Chapter 3 of Volume 1 of this handbook.) Level measurement for solids is not as accurate or reliable, due to the nonuniform settling that often occurs.

A liquid level measuring range can be less than 1 meter for a small reaction vessel, or may be more than 60 ft (20 meters) for a petroleum storage vessel. The highest accuracy can be obtained by using a contact method, such as a liquid level float measured by a magnetostrictive transmitter. Sometimes a contact method is not suitable due to the sticky nature of the product being measured, such as tar. Noncontact measurements can be made with transmitters employing radar or ultrasonic waves.

A simple but always popular way to indicate liquid level is through the use of a sight glass, but this typically provides no electronic output for use by automated equipment.

A variation of a sight gauge uses a closed metal pipe that houses a float containing a permanent magnet. As the float follows the liquid level in the vessel, the float position is detected by an externally mounted magnetostrictive transmitter. The transmitter then provides an accurate electronic reading of the level. Several level transmitter designs are shown in Figure 3.6p.

A simple and popular system for measuring liquid level in vessels open to atmospheric pressure is the bubbler shown in Figure 3.6p. Here, a small amount of airflow is introduced into a tube that extends down to the tank level from which the head measurement is to be made. Bubbles slowly escaping from the tube end ensure that the entire tube is full of air at the same pressure as at the bottom end of the tube. A gauge pressure transmitter measures the air pressure and thus indicates the liquid head.

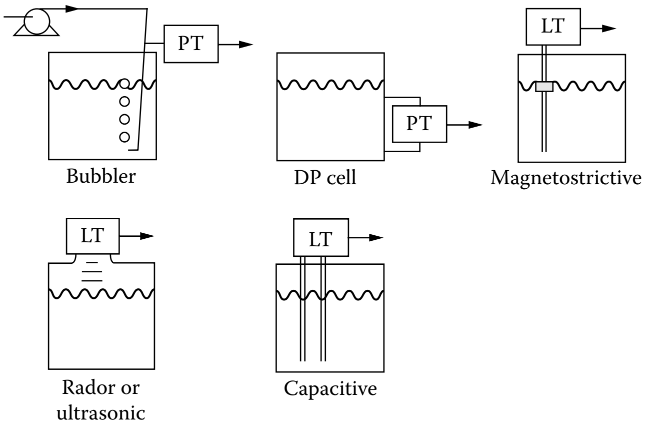

FIG. 3.6p
A number of level transmitter designs.

A differential pressure transmitter can also be connected to pressure taps at different elevations that have a known distance between them. This configuration allows the detection of level if the liquid density is known and that measurement is independent of vessel pressure. This installation has an advantage over the bubbler in that the level can be determined when the vessel is pressurized at various amounts of pressure during normal operations.

A magnetostrictive level transmitter can have a flexible probe, which is easy to carry up a ladder to the top of a large vessel. The probe tip is attached to the vessel bottom by a magnet, weight, or clamp. A float rides on the liquid level. A second float can be weighted to sink through oil, for example, and float on the layer of water near the vessel bottom. This allows measurement of the amount of water, and the amount of oil is the top float position minus the water float position.

These sensors can measure with high resolution. Inside each float is mounted a permanent magnet. The probe contains a magnetostrictive wire, called the waveguide, in which current pulses are periodically introduced. The interaction of the magnetic field from the current pulse with the magnetic fields from the float magnets generates sonic waves in the waveguide at the location of each float. The sonic waves travel to the transmitter end of the waveguide at a velocity depending on the waveguide material.

When a current pulse is introduced into the waveguide, a timer is started. When a sonic wave is detected at the end of the waveguide, the timer is stopped. The measured time indicates the position of the float, and thus the liquid level. If more than one float is used, then multiple timers are used.

In a capacitance-level probe, the relative permittivity (also called the dielectric constant) of the measured medium must be substantially different from the surrounding environment. The probe responds with a variable capacitance, depending on how much of the probe length is submerged or adjacent to the measured medium.

Motion

Popular transducers used in motion transmitters include the LVDT, magnetostriction, and inductive types. The LVDT is good for relatively short strokes but becomes less accurate and more expensive with measuring lengths over a few inches. Magnetostrictive linear motion transmitters are highly accurate and available with lengths of less than a foot, to well over 20 feet. Inductive types are practical for lengths of up to a few feet.

A simple LVDT is constructed with three coils of wire wound onto a bobbin. A ferromagnetic core passes within the bore through the center of the bobbin. The center coil is the primary and is powered from a stable with an AC source, as shown in Figure 3.6q.

The two secondaries are typically connected in series bucking, so the voltages subtract. Synchronous demodulation is also used (with semiconductor switches instead of diodes) for better performance. As the core moves within the bore, the output voltage becomes more positive with movement in one direction and more negative with movement in the other direction. The output voltage vs. input position is relatively linear, in the range of 0.1 to 0.5%.

A magnetostrictive linear position transducer operates as was described earlier. Instead of mounting within floats, the magnet assemblies have means to mount to the member to be measured. They are called position magnets.

At one time, it was not thought possible to operate a magnetostrictive transducer with the low power needed for a

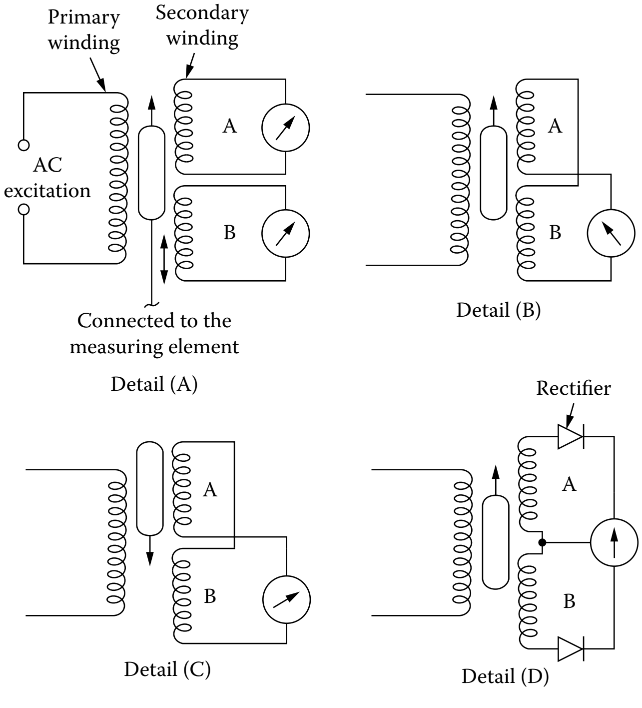

FIG. 3.6q
Linear variable differential transformer.

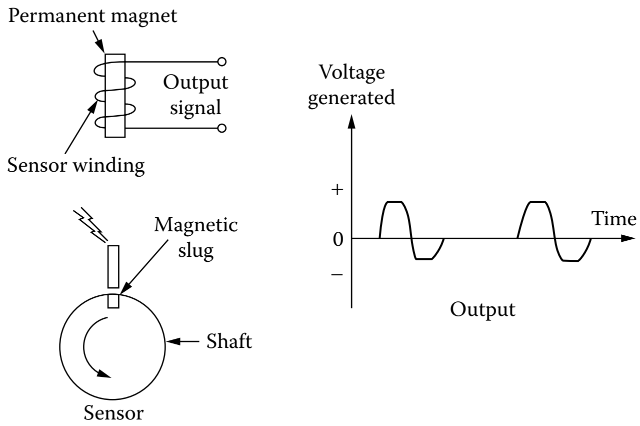

FIG. 3.6r
Magnetic tachometer sensor.

two-wire transmitter. This problem was solved in 1990, and several companies now offer motion transmitters based on this technology.[3] Magnetostrictive linear position transmitters can have a nonlinearity of less than 0.01%.

Inductive motion transducers are constructed similarly to LVDTs, but as few as one coil may be used. As the core moves farther into the coil, the inductance increases. Then, the inductance can be converted into a signal voltage by using an oscillator and measuring the inductive reactance. The nonlinearity error is in the range of 0.2 to 0.5%.

The AC tachometer is an example of a device that generates variable frequency signals for transmission. Here a magnetic slug, gear tooth, key in a shaft, or other device is counted as pulses created in a coil (Figure 3.6r). When the magnetic slug comes across the face of the coil, a voltage is generated in one direction as it leaves.

These pulses are a direct measurement of the speed of shaft rotation. When counting gear teeth where the space between them is similar to the width of the teeth, a smooth AC signal without wide gaps between pulses is generated. The design of the sensor probe has to be made with knowledge of the tooth shape, size, etc., so that good waveforms can be generated for easy measurement.

IMPORTANT FEATURES

Inaccuracy

The basic performance criteria that define the error limitations of a transmitter are contained in a specification called the static error band. This includes the combined effect of nonlinearity, hysteresis, and repeatability. The next group of errors are contributed by calibration error, temperature-induced errors, and line/load regulation. There are many additional performance criteria that can be specified, but they typically are related to the specific type of transmitter, so they will not be presented here.

Nonlinearity *Nonlinearity* is expressed as a percent of full range output (%FRO) and is determined from the maximum difference between a datum on the output vs. measurand plot and a best straight line (BSL) drawn through the data. Nonlinearity error can be specified in several different ways, including independent, zero based, and terminal based.

With independent nonlinearity, the BSL does not have to go through the origin or any particular datum. It can be found using a computer program with an iterative process, adjusting the slope and intercept of a straight-line equation until the errors are minimized. A more popular way to find an independent BSL, while avoiding an iterative process, is to use a least-squares approximation.

This function is available on most calculators and spreadsheet programs. It provides a BSL approximating that achievable with iteration but less perfectly if there are any strong irregularities in the data. The least-squares approximation is the most commonly used method because it can be directly calculated.

In zero-based nonlinearity error specifications, the straight line goes through the origin, but the full-scale point is adjusted (changing the slope of the line) to minimize the error. This is used when it is most important to have an accurate zero indication.

A terminal-based BSL is drawn through both the origin and the full-scale datum. This normally produces the highest nonlinearity error number for a given device but may be preferred when no manual or automated adjustments are possible after installation.

Hysteresis *Hysteresis* in a process transmitter is the maximum difference between readings taken at the same measurand with upscale and downscale approaches to the readings. It is due to inelastic qualities of the sensing element, friction, and backlash. When linkages are used to connect the measurand to the sensing element, hysteresis can be increased. A related property is called deadband, which is the range through which the measurand may be varied by reversing direction without producing an observable response in the output signal.

Repeatability *Repeatability* is the difference between consecutive readings taken at the same measurand, approaching from the same direction, other conditions remaining constant. As long as the repeatability error is low, an intelligent system can reduce the errors from other sources by using the known characteristics of those errors and compensating accordingly.

Zero Suppression and Elevation

There may be some measurement values that are of no interest in a transmitter installation for process control, even though that range falls within the operating range of the transmitter. In some cases it will be desirable to ignore this unimportant area in order to improve the readability within the range of interest.

If, for example, a temperature transmitter is rated for a range of 0 to 1000°C but readings of less than 200°C are of no interest, a *zero suppression of 20%* can be used. Then the 4.0 to 20.0 mA output signal would correspond to a temperature range of 200 to 1000°C, yielding a higher sensitivity (in mA/°C).

Conversely, if the same transmitter were set instead for a *20% zero elevation,* a 7.2- to 20.0-mA output signal would correspond to a temperature range of 0 to 1000°C (the lower end of the current range would be increased by 20% of the 16-mA span). Zero elevation may be used in order to match the output signal current to that expected by another piece of equipment.

Turndown

When one part of a process operates in the 90- to 100-PSIG range, while another part operates within a 15- to 20-PSIG range, an engineer might specify the installation of two different pressure transmitters, each having the appropriate full-scale range.

Ordering the transmitters and then stocking spare parts can become a logistical problem in a processing plant where hundreds of pressure transmitters are installed. A preferred method is to specify a pressure transducer that can provide the required accuracy over several ranges.

This can be done in the cited case if the transducer is designed to operate over a full range of 0 to 100 PSIG but also can be readjusted (turned down) to read accurately at 20 PSIG. In order to do this effectively, the sensing element used in the transmitter must be highly accurate, so that the resulting accuracy after turndown will still be adequate to provide the needed performance.

The ratio of the highest full scale to the least full scale that can still deliver the rated accuracy is called the turndown ratio. Turndown ratios of 10 are common, but some up to more than 100 are also available. This feature can be used with any type of process transmitter and is commonly used with pressure transmitters.

External Calibration

In older equipment, it was often required that the instrument cover be removed to facilitate calibration or other adjustment. For explosion-proof equipment, this required a safety tag and appropriate means to ensure safety during the operation, often meaning that the process had to be shut down completely.

Many modern transmitters allow for calibration without removing the instrument cover. Some have zero and span adjustments under a nameplate, which is easily slid to the side to provide the access. This provides the convenience of allowing adjustment while the only tool needed is a screwdriver.

Some transmitters have provision for the use of a handheld calibrator that plugs into an electrical connector or uses magnetic or optical coupling to enable the digital connection. This method has more flexibility but requires the often-proprietary handheld calibrator.

Still others, such as those using the HART protocol, provide means for uploading or downloading information digitally over the same pair of wires operating the 4- to 20-mA signal. Digital communications will be discussed later in this section.

Intrinsic Safety

When the transmitter will be used in a hazardous location, where flammable or explosive gases, vapors, fibers, or powders may be present, a protection method must be employed. Popular methods include mounting the transmitter within an explosion-proof housing, in a purge cabinet, or as part of an intrinsically safe system.

In an explosion-proof housing, it is possible that the enclosed atmosphere may burn or explode, but the resulting pressure is withstood by the strength of the housing. A flame path allows the high-pressure gas to escape while being cooled. This prevents ignition of the external atmosphere and bleeds away the pressure so the worker is not injured when the housing cover is subsequently removed.

When the transmitter is mounted in a purge cabinet, fresh air flows through the cabinet at a sufficient rate to prevent the buildup of a flammable mixture. Both explosion-proof and purged equipment relies on the installation method to provide the safety features. Intrinsically safe installations, however, require the transmitter itself to be designed within specific safety criteria.

A transmitter can be installed into an intrinsically safe system through the use of an approved safety barrier device. In the U.S., the approval agency is usually Factory Mutual (FM) or Underwriters Laboratories (UL) but can be one of the other smaller agencies if acceptable under local regulations where the equipment will be installed. The safety barrier is installed in the safe area (typically, the control room), in series with the wiring between the safe area and the hazardous area (the process).

The safety barrier limits the electrical current and voltage to levels that are too low to provide energy sufficient to ignite the type of hazardous materials expected to be present. In addition, the transmitter must be designed so that there is no energy storage, arcing, or hotspot sufficient to cause ignition. The specific requirements are listed in the National Electrical Code, and the publications of FM, UL, and NFPA (National Fire Protection Agency).

DIGITAL COMMUNICATION

As described earlier, the 4- to 20 mA two-wire current loop is the assumed standard for analog communication for industrial process control. In addition, there are several popular methods for digital communication from process transmitters. Some of these are HART, CAN, and PROFIBUS.

These and other digital networks and buses are described in full detail in Volume 3 of this handbook.

The HART (highway addressable remote transmitter) protocol was originally developed by Rosemount in 1986. It is now owned by the HART Communication Foundation. It utilizes a standard current loop installation, but allows digital signals to be impressed onto the same pair of wires. The digital signals do not affect other equipment that may be using the 4- to 20-mA signal.

The digital words are placed on the lines using a frequency shift keying (FSK) method according to the Bell 202 telephone standard. A logical zero is 2200 Hz, and a logical one is 1200 Hz. This allows information to be sent from the transmitter to the receiving equipment, as well as allowing the receiving equipment to send signals to the transmitter for calibration, configuration, etc. It is also possible to disable the current loop signal, if desired, and use only the digital communications. Since it uses Bell 202 FSK, it is a relatively slow communication method.

CAN was introduced by Robert Bosch, GmbH in 1986 and originally intended for automotive use. It stands for controller area network and is a much higher-speed system than HART, but it uses a different hardware layer. Power is provided by one pair of wires, and bidirectional signals are sent and received on a second pair.

CAN is a bus system and several devices can be connected to the same sets of wires. It can operate in a master–slave mode, or in a mode where any device can take the bus when needed. Bus contention is solved by a priority level assigned to each device. A popular implementation of CAN is called DeviceNet.

PROFIBUS is an open digital communication system that uses application profiles, thus receiving the PROFI part of its name. The profiles are provided by manufacturers and users to define performance and other features of the device. These profiles are downloaded by the connected equipment to interpret how to interface with the device.

The hardware interface is by an RS 485 connection, using two wires for bidirectional signals. Another pair of wires is used for power. There are several different implementations of PROFIBUS that provide tradeoffs among baud rate, power consumption, transmission distance, fiber optic, and intrinsic safety.

There are many other protocols for digital communications with transmitters and industrial instrumentation. The most popular ones change over time, and new ones are added. The reader can also investigate Foundation Fieldbus, MODBUS, IEEE 1451, and Ethernet, which are all described in detail in Volume 3 of this handbook.

TRANSMITTER SELECTION

In addition to selecting the proper range and accuracy rating for a transmitter installation, it is important to keep in mind a few additional criteria for proper selection. The materials of construction of the transducer elements that will contact the process must be specified to avoid corrosion by or contamination of the measured media.

Sometimes, one must use a transmitter design with a robust housing. For example, it is common for technicians to use pressure transmitters mounted to vessel walls as steps while climbing up to perform routine maintenance and inspection duties.

When the transmitter will be exposed to wide changes in temperature during normal operation, the temperature sensitivity specification of the transmitter may become the most important specification regarding total accuracy of the system.

Many communication protocols are now in common use. Consideration must be given to the cost of providing the hardware connection (wiring) as well as the suitability for providing the desired information. A HART device may communicate more slowly than a CAN device but can use existing current loop wiring.

When using intrinsic safety barriers in a 4- to 20-mA current loop, make sure that the sum of voltage drops for the transmitter, readout devices, IS barriers, and load resistor add to less than the power supply voltage available for the loop.

Intelligent Transmitters

Although Section 3.10 in this chapter deals with smart transmitters in detail, they should also be mentioned in connection with digital communications. The main contribution of the addition of a microprocessor to the transmitter has been the ability to calibrate the unit over a much wider range than the actual span needed for the particular application. This resulted in much increased rangeability without sacrificing accuracy because by memorizing the temperature and pressure effects on zero and span the smart transmitter can automatically correct for these variations, and therefore the performance of the unit is only a function of repeatability, linearity, and hysteresis.

In addition to lower error and higher rangeability, the smart transmitters are also more flexible. Because their calibration curve is in the microprocessor's memory, one can electronically change the zero and the span of the transmitter through the keyboard of a portable terminal (Figure 3.6s), and the microprocessor will automatically match the minimum and maximum output signals to the newly set measurement inputs without affecting instrument calibration.

Desirable Features Checklist

The most desirable features are high resolution, accuracy, rangeability, reliability, and low cost. In order to meet these requirements, a transmitter should be designed to have the following features:

1. Small size and weight for easy installation and maintenance.
2. Rugged design to withstand the industrial environment.

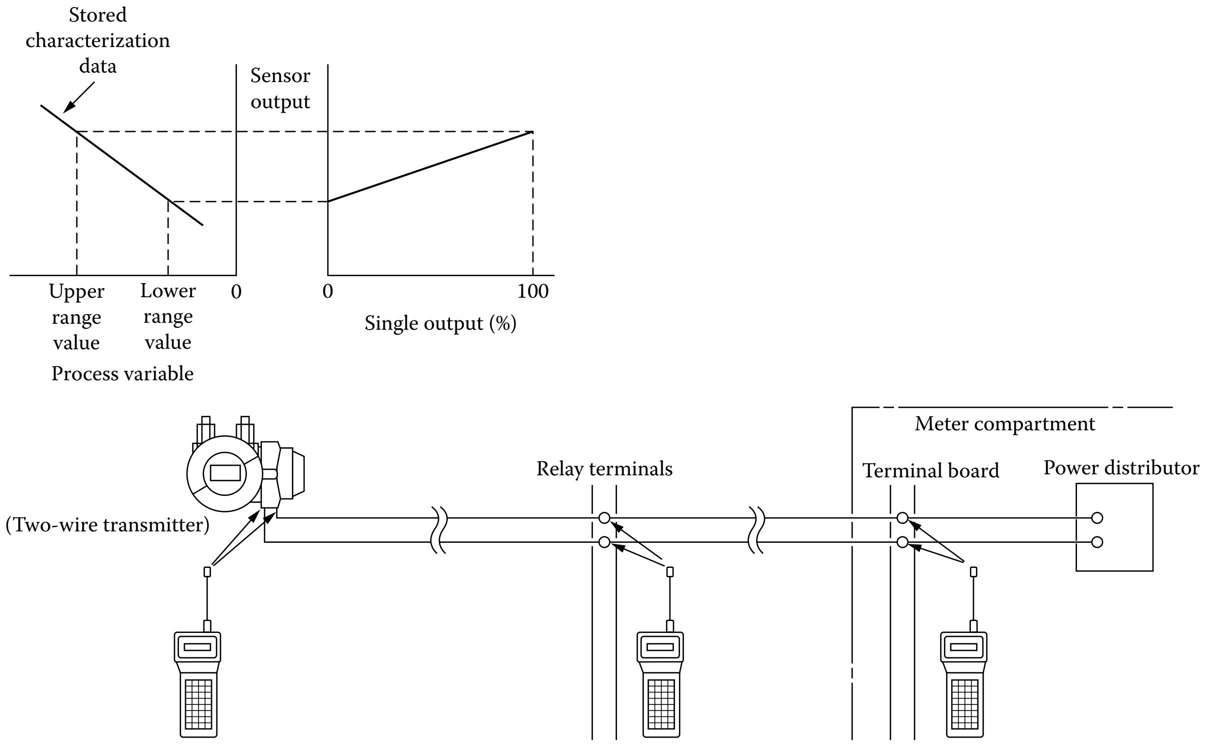

FIG. 3.6s
Portable terminal can be used to re-range transmitters from a number of locations. (Courtesy of Yokogawa Electric Corp.)

3. Minimum dependence on environmental conditions for accuracy; this requires good temperature stability, resistance to barometric change, weatherproofing, etc.
4. No need for adjustment due to load or line resistance variations.
5. No potential hazard to personnel or equipment in explosive atmospheres. Low-voltage operation with limited current capacity assists in eliminating these problems. By definition, intrinsically safe equipment provides all three kinds of protection.
6. Convenient and accurate field calibration and maintenance. In electrical transmitters this usually means conveniently located test terminals. In explosion-proof designs, calibration should be possible without opening the housing.
7. Capacity to operate during voltage dips and power outages. Generally, this is accomplished elsewhere in the control system.
8. Minimum number of transmission and power wires. In most systems installed today, the transmitter is powered from the receiver over the same wires that are used for transmission.
9. Output compatible with both measuring and controlling instruments.
10. Optional local indication of output signal.
11. Circuitry designed to facilitate troubleshooting and maintenance. Most systems today are solid state (no tubes) and are mounted on circuit boards or are encapsulated. Plug-in components make fast repairs easy, but encapsulated modules are considered to be throwaway items.

Ability to be integrated into DCS systems and, in the case of smart transmitters, to communicate over the data highway provided with the particular system.

Flow sheet symbol

Costs: Transmitters are in the $2500 to $4500 range. Microprocessor-based temperature transmitter with PID included is $5000 to $6000. Same unit with 2, 4, 6, or 8 channels is about $15,000. Wand probe $1000 with tip to $2500 for spectra-caliper probe; fiber-optic spectrophotometer systems range from $2000 to $20,000.

The topic of this section is fiber-optic transmitters, but there is a fair amount of overlap between this subject and related ones in the three volumes of this set of handbooks. In the first volume Section 4.5 covers fiber-optic temperature transmitters and Section 8.23 discusses fiber-optic probes. In the third volume of this handbook, the subject of fiber-optic networks and cables is discussed in Section 4.18, which also covers the topics of installation, inspection, and testing.

INTRODUCTION

Optical fibers are commonly used in communications because they cost less than copper due to their multiple pathways and because of their good distance and high bandwidth capabilities. Although such characteristics are valuable in most applications, the overwhelming reason for using fiber optics in industrial communications is their immunity to electromagnetic interference (EMI).

Today, few plants can operate without extensive data processing and control. Sensors, solenoids, switches, motors, and pumps are all monitored and controlled by computers and programmable logic controllers. These devices are interconnected by communication cables, which used to be made of copper wire. Often, the copper cables perform adequately. But as data rates increase, the data signals are frequently interrupted by electrical interference. When these interruptions can be very expensive, it is vital to control such interference.[1,2]

Industrial transmitter signals are subject to many sources of electrical noise. Most plants move large quantities of product at high speeds, which requires large electric motors to operate conveyors and pumps. These large electrical loads create electromagnetic waves and ground surges. In addition, many plants are composed of several structures, which usually means separate power distribution systems, resulting in differences in ground potential. Finally, the communication cables between structures tend to attract lightning strikes. These are some of the reasons why alternates to electrical transmitters are being considered.

FIBER OPTICS BASICS

Almost all data processing and control systems use digital signals. The distinguishing feature of fiber optics is that the digital signals are optical pulses rather than electrical. Except under the most intense conditions, light is unaffected by electrical fields; therefore, it is an ideal medium for data transmission in automatic process control. Optical fibers conduct light in a manner similar to the way wires conduct electricity. The physical laws are different, but the results are quite similar. A typical optical fiber is shown in Figure 3.7a.

The center of the fiber is called the core. It conducts the light, similarly to the conductor in a wire. The outer part of the fiber is called the cladding. It keeps the light in the core, similar to the insulator on a wire. Outside the cladding is a protective polymeric coating that gives the fiber greater mechanical strength and endurance.

Both the core and the cladding will pass light, but they have different densities. When the light passes from a higher- to a lower-density material, it changes speed, which in turn changes its direction. This is called *refraction.* This change of direction is a function of 1) the light velocity difference in the two materials (*refractive index*) and 2) the angle at which the light approaches one medium from the other (*angle of incidence*). As the angle of incidence increases, the angle of refraction also rises until the *critical angle* is reached. At this angle, the light is reflected back into the originating medium and does not enter the other medium at all (Figure 3.7b).

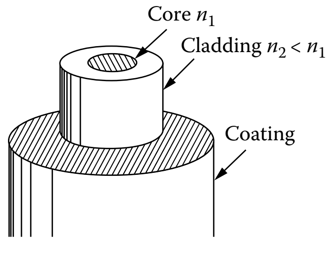

FIG. 3.7a
Optical fiber construction.

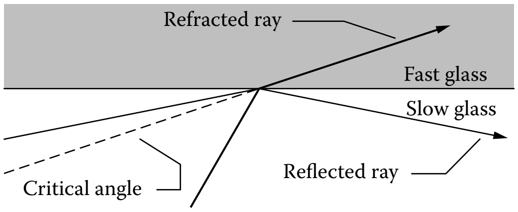

FIG. 3.7b
Refracted and reflected light rays and the critical angle.

Both the cladding and the core are transparent. For cladding with a lower index of refraction than the core, light within the cone will be totally reflected back into the core. The greater the difference between the indexes of refraction of the core (n_1) and the cladding (n_2), the larger is the cone of light (theta) that the fiber will handle. The size of this cone of light is called the numeric aperture (*NA*); it is calculated by Equation 3.7(1) and is shown in Figure 3.7c.

$$\mathrm{NA} = \sin\theta = \sqrt{n_1^2 - n_2^2} \qquad n_2 < n_1 \qquad \mathbf{3.7(1)}$$

Numeric aperture is one of the most important parameters in a fiber-optic system. If light enters the fiber core at an angle greater than the critical, it will be reflected at the core-cladding boundary back into the core and will travel down the core in a zigzag pattern. When this is achieved (Figure 3.7d), the light signal stays within the core of the fiber and travels down to the end of the cable, where a receiver converts the light into an electrical signal.

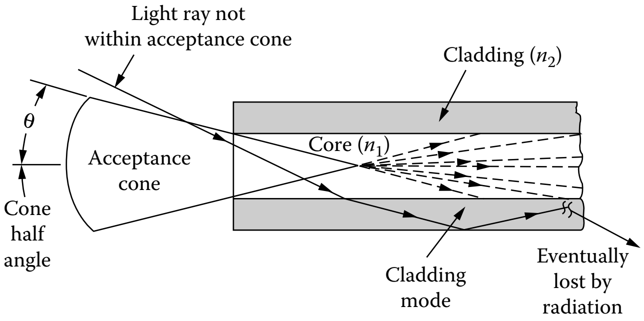

FIG. 3.7c
In order for the light to be fully reflected, its entering angle must be within the "acceptance cone." If the angle exceeds the critical, some of the light will be refracted and lost.

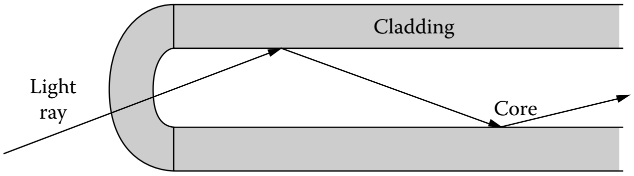

FIG. 3.7d
If the light entered at an angle exceeding the critical, it will travel down the optical fiber without attenuation.

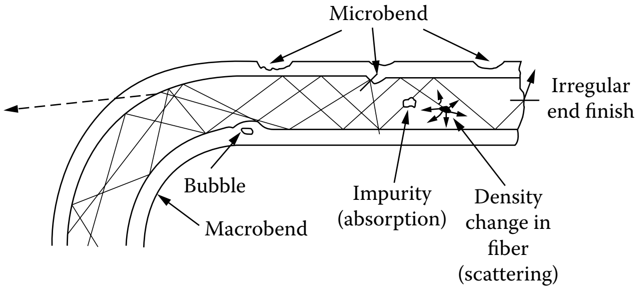

FIG. 3.7e
The sources of light attenuation include macro-bends, micro-bends, bubbles, impurities, fiber density variations, and irregular end finish. (Courtesy of 3M Company.)

All optical fibers are subject to a number of sources of light attenuation. These sources are shown in Figure 3.7e. In industrial applications, the most important causes of light attenuation are macro-bends and dirt. As is shown later in this section, a large numeric aperture helps reduce these effects.

SYSTEM COMPONENTS

The fiber-optic system consists of the transmitter, the cable, and the receiver (Figure 3.7f). The sensor associated with a fiber-optic transmitter can be a temperature probe (Section 4.5 in Volume 1) or a variety of other probe designs (Section 8.23 in Volume 1). The fiber-optic transmitter contains a driver and a light source, and it converts the measured process variable signals into light signals. The driver converts a standard electrical signal to a digital pulse that modulates the light. The light source is an LED (light emitting diode) or a laser, which is turned on and off by the driver.

The data are transmitted in a digital form over the optical fiber by turning the light on to signal 1s and turning it off to signal 0s. The frequency of light is seldom varied because it is less expensive to install more fibers. Because most communications are two-way, most fiber cables are used in pairs, with

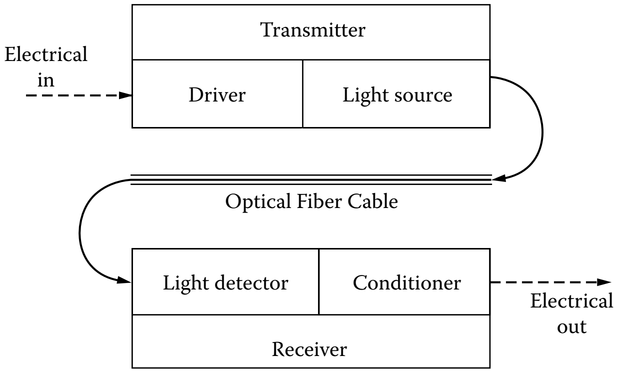

FIG. 3.7f
The three main components of a fiber-optic system are the transmitter, the cable, and the receiver.

one carrying the signal from the transmitter to the receiver and the other carrying another signal back to the transmitter.

The receiver is the interface, which converts the light signal back to an electrical one. It consists of a light detector and a conditioning circuit. The optical-to-current converter is usually a photodiode. The conditioning circuit checks that each bit of information is a binary 1 or 0 and amplifies the signal from the light detector. After that the binary signal is converted to the form required by the control system.

Fiber Sizes and Properties

There are many standard sizes of optical fibers. Sizes are specified in microns by stating the diameter of the core and the diameter of cladding. Standard sizes are 9/125, 50/125, 62.5/125, 85/125, 100/140, and 200/230. All these fibers, including the 200/230 fiber, have been standardized in IEC 793–2 Ammendment 1, "Optical Fibers," Part 2: Product Specifications, Issue 1991–04. The most widely used sizes are 9/125, 62.5/125, and 200/230. Their relative sizes are shown in Figure 3.7g.

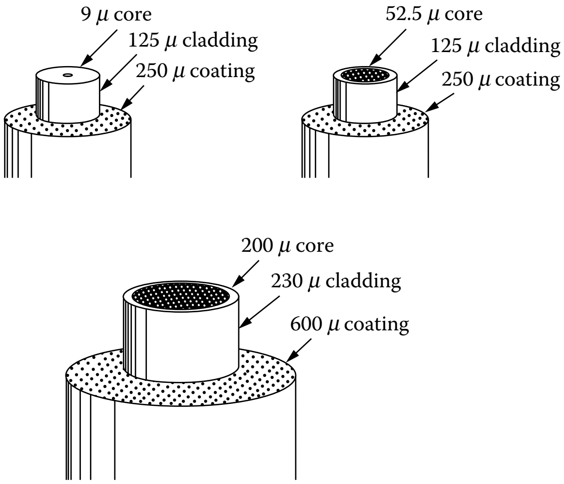

FIG. 3.7g
Sizes of the most widely used optical fibers. (Courtesy of 3M Company.)

When installing an optical fiber network, choosing the fiber size is mostly a matter of balancing the requirements for communications performance and ease of installation and maintenance. Table 3.7h lists the fiber sizes, numeric apertures, most common applications, data rates, and connector installation times.

Generally speaking, fibers with smaller cores tend to have smaller attenuations and larger bandwidths, which are required for their long-distance applications. Fibers with larger cores tend to have larger numeric apertures and greater tolerance to dirt or bending, and the time to install their connectors is faster.

Step index fibers have a constant index of refraction from the center of the core to the edge of the cladding and then a single step down to the index of refraction of the cladding. Graded index fibers have a smooth downward gradation of index of refraction from the center of the core to the edge of the cladding. Step index fibers collect twice as much light as graded index fibers do.[3] This factor is called coupling efficiency. These factors are shown in Figure 3.7i.

Single- and Multi-Mode Fibers

The "mode" is the light path followed by the light as it travels down a fiber. If the light travels straight at the axis of the core, because the core diameter is so small (8 or 9 microns) that the light has only one path, it is called a *single-mode* design. In single-mode fibers the light travels a shorter distance and therefore reaches the receiver sooner. Single-path fibers are not much used in the process industry, because their termination and connection are difficult due to their smallness. Their main applications are in long distance (up to 75-mile) communications at very high bandwidth (10-Gbps) applications.

In *multi-mode* designs, the light is reflected off the core-cladding interface and travels in a zigzag as shown in Figure 3.7j. Here, the different modes cause the rectangular light pulse to spread out, a phenomenon called *dispersion.* The multi-mode fiber has a 50- to 200-μm diameter, which causes dispersion and limits the allowable transmission distance and bandwidth. On the other hand, because of its larger

TABLE 3.7h
Optical Fiber Characteristics as a Function of Their Sizes

Size	*NA*	*Application*	*Data Rate*	*Connector Installation*
9/125	0.14 to 0.16	Telephony	1 to 2 Gbps	40 to 50 minutes
50/125	0.20 to 0.23	Data communications	125 Mbps	15 to 30 minutes
62.5/125	0.27 to 0.29	Data communications	125 Mbps	15 to 30 minutes
85/125	—	Substantially obsolete		
100/140	—	Substantially obsolete		
200/230	0.37 to 0.39	Factory automation	20 Mbps	4 to 5 minutes

*Gbps = 10^9 bits/sec, Mbps = 10^6 bits/sec, each one and zero is called a bit, and a binary number of eight bits is called a byte.

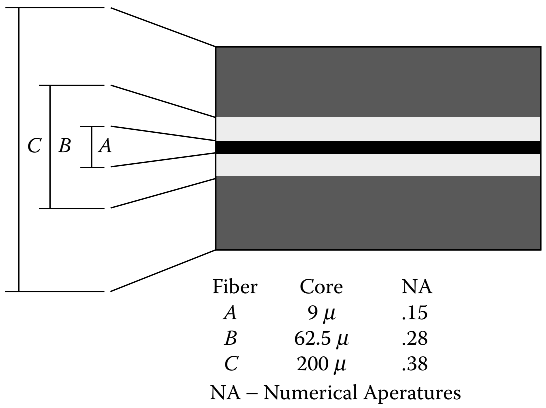

FIG. 3.7i
Fiber size and acceptance cone. (Courtesy of 3M Company.)

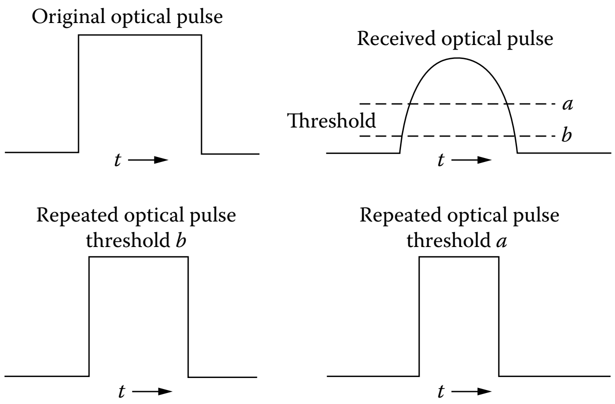

FIG. 3.7k
Pulse width distortion increases as the threshold rises, but so does noise immunity. (Courtesy of 3M Company.)

diameter, termination is easier and the light source is less expensive. The multi-mode fibers used in industry can handle 200-Mbps data rates over distances up to about 1 mile. The most common core-cladding diameter for multi-mode is 62.5/125 μm.

Pulse Width Distortion

In programmable logic controller installations, a common application is to have one master controller with a number of remote input/output (slave) modules. (PLC system design is discussed fully in Chapter 5 of this handbook.) In one common layout, the remote I/O simply taps onto the copper cable. When a fiber-optic system is used, each remote I/O repeats the signal. This means that a remote I/O string of 20 units would thus have 19 repeaters.

Pulse repetition is an important aspect of digital signal transmission. The receiver must be able to identify the point at which the signal has risen sufficiently above the noise to be certain that the leading edge of a pulse has arrived. It must also be able to determine when the signal has fallen enough to be certain that the trailing edge of the pulse has arrived.

Then a new, repeated pulse is placed between these two event times. As shown in Figure 3.7k, if the edges of the received pulse have dispersed from their original square shape, different threshold levels will result in different pulse widths. This is called pulse width distortion.

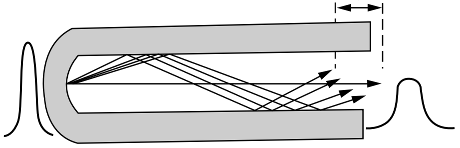

FIG. 3.7j
Modal dispersion and distortion of the optical pulse in a multi-mode fiber.

Although exaggerated in this example, it can be readily seen that a chain of many repeaters can distort the pulse sufficiently to cause communication errors. Many PLCs can tolerate 20% pulse width distortion. If each repeater causes 1% distortion, the maximum number of repeaters is 20. Clearly, pulse width distortion must be kept small.

Fiber Selection

There is no one perfect fiber for all applications. Tradeoffs and compromises must be made for each application. Table 3.7l lists the some of the primary fiber selection criteria. The 200/230 fiber was specifically designed for factory automation applications, while the 62.5/125 μm size is popular for industrial process control applications.

There are substantial differences between factory automation and other data communications applications; the most important difference is that the installation and maintenance in a factory are usually done by onsite personnel, primarily because interruptions in a factory can be very expensive and thus repairs must be performed immediately.

TABLE 3.7l
Fiber Selection Criteria

Fiber Size (μm)	*9/125*	*62.5/125*	*200/230*
Longest distance between repeaters	>3 km	<3 km	<2 km
Greatest bandwidth at longest distance	>1 GHz	<200 MHz	<10 MHz
Environmental tolerance	Very clean	Clean	Dirty
Installation and maintenance skill	Expert	Specialist	Electrician

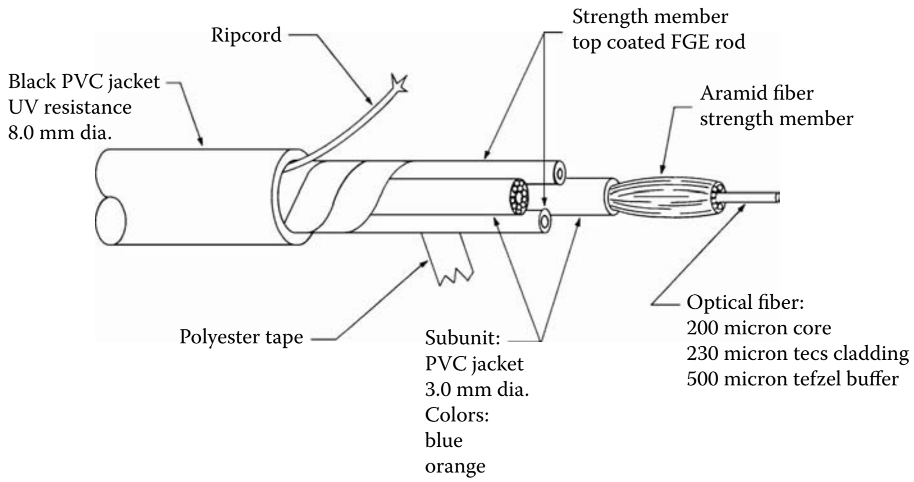

FIG. 3.7m
Tight buffer fiber-optic cable. (Courtesy of Belden Div. Cooper Ind.)

Other reasons for using onsite personnel for maintenance relate to proprietary processes, safety considerations, and union rules.

Onsite personnel usually are electricians by training, and most of their daily work is with large-gauge power and communications wiring. The work site is often cramped, dimly lit, hot or cold, and dirty: a catwalk is a typical example of these conditions.

Fiber-Optic Cable

Two basic types of fiber-optic cable constructions exist: tight buffer and loose tube. Selecting the cable construction depends on the application.[8]

Indoor and short-distance outdoor applications use a tight buffer construction, shown in Figures 3.7m and 3.7n. This construction supports the fiber and therefore usually has greater crush and impact resistance, suitable for cable tray applications. Also, it usually has strength members for each fiber, and connectors can be attached directly. Tight buffer construction cables can be obtained for flame-retardant, aerial, and cable tray installations.

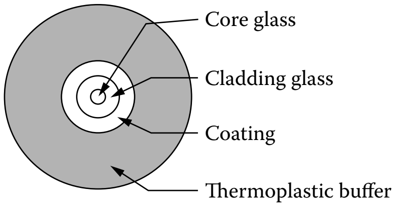

FIG. 3.7n
Cross-section of a tight-buffered cable.

Long-distance outdoor applications typically use a loose tube construction, shown in Figures 3.7o and 3.7p. In the loose tube construction, the fiber is loosely laid inside a plastic tube, which is usually filled with a water-repellent gel. This construction insulates the fiber from stresses on the cable such as thermal expansion and contraction. It usually has less attenuation in outdoor, long-distance applications. Loose

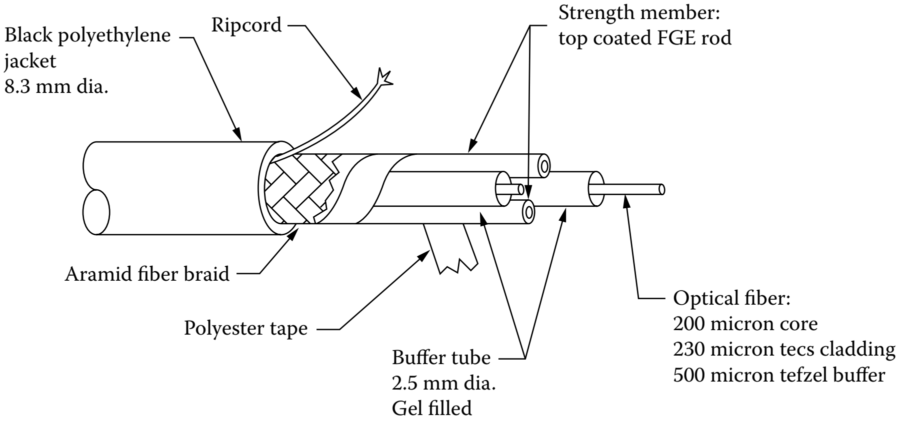

FIG. 3.7o
Loose tube fiber-optic cable. (Courtesy of Belden Div. Cooper Ind.)

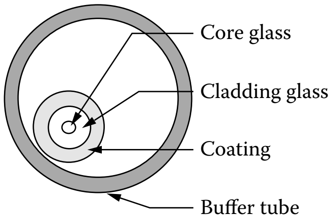

FIG. 3.7p
Cross-section of a loose-tube fiber optic cable.

tube construction cables can be obtained for aerial, conduit, and buried installations. This construction lacks strength members on each fiber and consequently requires accessories to attach connectors.

Fiber-Optic Connectors

Since fiber-optic communications first became practical in the early 1980s, at least six connector designs have come into standard usage. Some of these designs are shown in Figures 3.7q and 3.7r:

The SMA, ST, and SC connectors are commonly used in data communications and are the principal candidates for industrial applications.
ST is a steel bayonet-style connector that is most widely used in industrial plants.
SC is a plastic rectangular connector that is officially recommended to replace the ST style.
MT-RJ is a duplex-style connector that contains both transmit and receive fibers in a single, small form-factor connector.
VF-45 is a competing duplex-style connector that also contains transmit and receive fibers in a single connector similar to an RJ-45 phone jack.
The biconic, FC, and D4 connectors were designed for long-distance telephony and are rarely used in data communications.

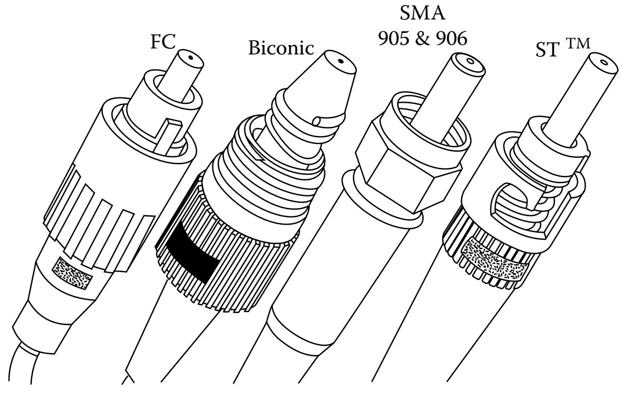

FIG. 3.7q
Fiber-optic connectors. (Courtesy of GTE Products Corp.)

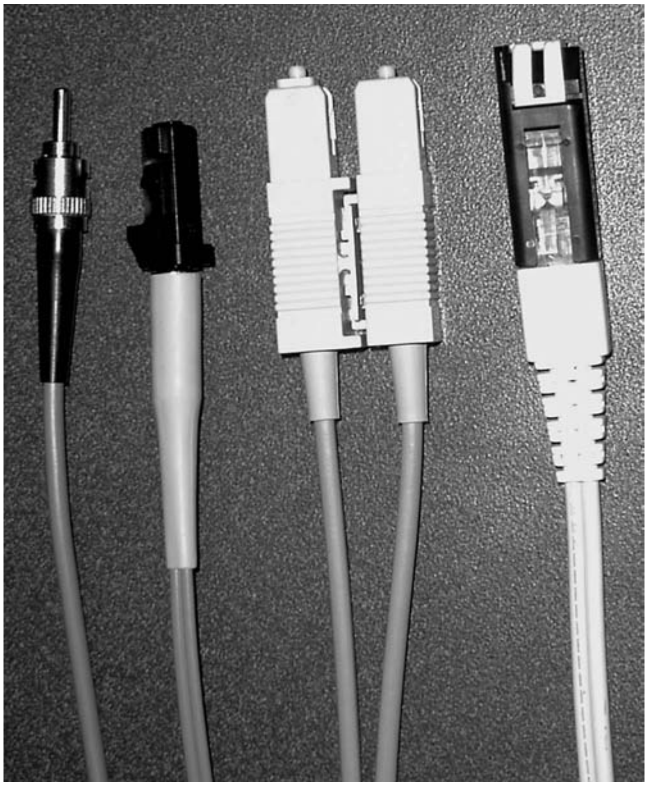

FIG. 3.7r
ST, MT-RJ, SC, and VF-45 fiber-optic connectors.

The typical method of mounting connectors on the other fibers uses adhesives and polishing. These techniques require substantial training and experience to be achieved in the installation times shown in Table 3.7h.[5] Further, they require at least 2 square feet of work space to lay out the equipment.

Each of these connector designs has advantages and disadvantages; no single design is the best for all applications. The automated factory and process control environment is quite different from the office or telephone-related environment. The SMA connector was designed with a dirty environment in mind, and its performance in industrial applications has made it one of the common connectors. Connector design selection criteria are summarized in Table 3.7s.[6]

Attaching the Connectors For 200/230 fiber, the combination of large core and thin cladding allows the use of connectors that can be installed with simple tools. Their crimp-and-cleave operation requires no adhesive and no polishing. It takes less than 5 minutes to install a connector, including the time to prepare the cable. All the installation operations are handheld and do not require work space to lay out equipment.[7]

There are basically two methods of attaching the connectors to the end of each fiber. One is the splicing of factory-made pigtails. These are short cable segments that have factory-finished fiber-optic connectors on one end and are not terminated

TABLE 3.7s
Connector Design Selection Criteria

	Unit	*SMA*	*ST*	*SC*
Maximum clearance (ferrule to receptacle)	μ	28	17	10
Loss due to 10-μ particle on ferrule side				
62.5/125 fiber	DB	0.35	0.70	1.00
200/230 fiber	DB	0.06	0.10	Not available
Loss due to 20-μ particle on fiber core				
62.5/125 fiber	DB	1.03	1.03	1.03
200/230 fiber	DB	0.10	0.10	Not available

at the other end. The unterminated end is field spliced to a cable needing termination. If loose-tube fiber is being used, pigtail splicing is the fastest way to terminate a cable.

The other method of attaching connectors is field connectorization. In this case the connectors are directly attached to the fiber. Consequently there is no splice and no need for a splice tray. This method is less expensive than buying preconnectorized pigtails, but it requires that the installer learn how to cleave, polish, and fasten connectors. The techniques of field connectorization include three easily learned methods: the use of crimp, epoxy, and hot-melt.

RECEIVERS AND TRANSMITTERS

Receivers are integrated packages containing both the light detector and signal amplifier circuit. Detectors for optical fibers are almost exclusively semiconductor diodes, either PIN or avalanche design. Avalanche diodes are commonly used with 9/125 fiber. PIN diodes are commonly used with 62.5/125 and 200/230 fiber due to their lower cost, wider temperature range, and greater stability. An example is shown in Figure 3.7t.

Light sources for optical fibers are almost exclusively semiconductor light-emitting diodes and lasers. Lasers are commonly used with 9/125 fiber. Light-emitting diodes (LEDs) are commonly used with 62.5/125 and 200/230 fiber for their lower cost, wider temperature range, and longer lifetimes. Transmitters are similar to the detector shown in Figure 3.7t, but with the emitter integrated circuit (IC) replacing the detector IC. The light from a typical LED is imaged into a spot 100 to 250 microns in diameter with a numeric aperture of .31 to .49.[4]

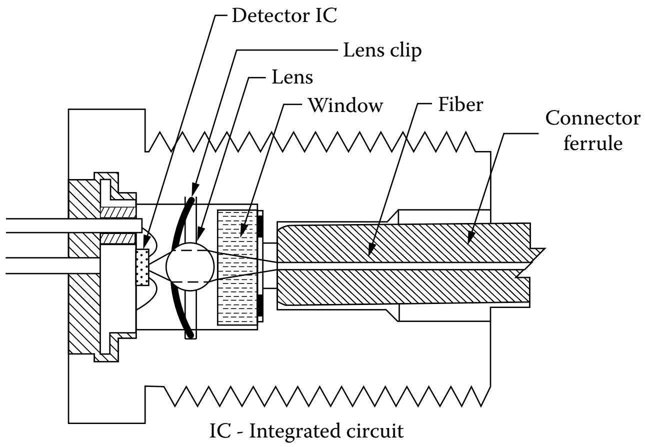

FIG. 3.7t
Fiber-optic receiver. (Courtesy of Hewlett-Packard Co.)

For large-core fibers, the core is about as big as the spot of light at the window of the LED, so very little light spills over into the cladding and is lost. For uniform brightness, the light collection efficiency is proportional to the area of the core.

For large numeric aperture fibers, the maximum ray from the LED is about the maximum ray the fiber can capture, so very little light is lost. For uniform angular distribution, light collection efficiency is proportional to the square of the numeric aperture.

Modems

In its simplest form, a modem translates the communication signals from one kind of device into the signals for another kind of device. The basic principles of electronic transmission were described in Section 3.6. The most common form of modem is one that converts the digital electrical RS-232 communication signals from a personal computer into the analog electrical signals required for the telephone network. Thus, modems allow use of the telephone network for long-distance communications between computers.

In the case of fiber-optic modems, the operation is somewhat similar. For industrial communications, digital computers, programmable logic controllers (PLCs), and their remote I/O drops often need to communicate over optical fiber. Thus, the fiber-optic modem converts digital electrical signals into digital optical signals to be transmitted by optical fibers.

In its simplest form, a PLC modem converts each electrical pulse into an equivalent optical pulse. There is no sampling or multiplexing of the pulse; thus, no change in the pulse-to-pulse timing occurs. The attached PLCs and remote I/O drops operate exactly as if they were linked by their ordinary cabling. The major difference is that they experience virtually no electrical noise — radio frequency interference, ground loops, lightning surges, and so forth — so they have virtually no errors, outages, or downtime due to interrupted communications.

Modem Selection Criteria

Until recently, PLC modems were designed as single-purpose devices. However, increased use of optical fiber networks, advances in fiber-optic technology, and advances in PLC communication technology have resulted in changing requirements for new modems.

Even more difficult were changing requirements for modems that were already installed. For example, a simple point-to-point link would need to be extended, thereby requiring one or more of the modems to become a repeater. Another example is that the fiber-optic link would need to be extended and a longer distance needed, thereby requiring higher-power transmitters and/or more sensitive receivers. Yet another example is the need to add fault tolerance to an existing noise-immune fiber-optic network.

A modular fiber-optic modem's capabilities can be tailor-made to the original application, yet additional capabilities can be added later if the application changes. However, if it were not properly designed, such a modem could be hard to install in the first place and hard to upgrade thereafter. In selecting modular modems, it is important to consider the following:

Standardization—The modem must support all the standard PLCs. Even though some of the signaling methods are proprietary, the modem must function with them. Many plants use more than one brand of PLC yet need the benefits of fiber optics throughout the plant. The modem must be transparent to the electrical signaling by the attached devices. Specifically, design circuitry must minimize pulse width distortion.

Compactness—PLCs and modems are usually mounted together in racks or cabinets. Space is usually at a premium, especially vertical space.

Robustness—In factory automation and process control, the environment is often hostile: wide temperature swings, vibration, dust and dirt, oil mist, and corrosive vapors are among the perils. The modem design must have proven field reliability.

Ease of use—Selecting the modem modules to fit common user requirements must be simple and trouble-free. A simple step-by-step process with a few choices would be best. The actual installation should be as simple as "plug-in and play."

Upgradeability—Upgrading existing modules should be a simple matter of replacing the old with the new. There should be no further adjustments necessary. Adding new capabilities should be a simple matter of plugging the new module into an empty space. This is especially true when adding fault tolerance to an existing network.

Modularity—The main functions of optical communication, electrical communication, and power supply must be in separate modules so that each can be changed without the cost of changing the others.

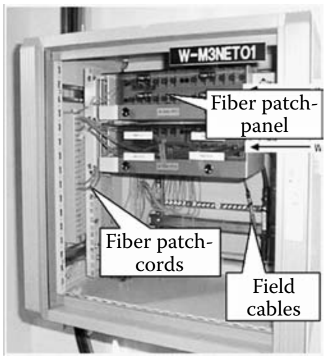

FIG. 3.7u
Wall-mounted cabinet with terminal tray and patch panel.

INSTALLATION AND TESTING

Cabinets

It is recommended that each plant design and standardize its communication cabinets, where all field cabling is terminated and where splices and connectors are protected. Usually, two cabinet sizes are used, a full-size, freestanding cabinet and a smaller wall-mounted one (Figure 3.7u).

Fiber cables usually are brought to the back of the cabinet and are terminated on the fiber patch panels in the rear. One should never connect the fiber cables from the field directly to any electrical device. Patch cords are used to make the connections between the field cables and the electronics. For future expansion, at least 30% spare capacity should be provided in each cable and in each cabinet.

Most of the wear and tear on fiber-optic cables occurs at the end points. One should be careful in avoiding the risk of cutting back the field cables for repair until they become too short and the whole cable has to be reinstalled.

Splicing

The ends of the cable can be terminated by connectors, which are metal or plastic fasteners (Figures 3.7q and 3.7r) used to mate two fibers or to attach fibers to equipment. The other means of termination is by splices, which are permanent connections between two fibers made by welding them in an electric arc (fusion splicing) or aligning them and gluing them together (mechanical splicing).

Fiber termination is the most critical part of the installation process because most failures occur there and because the greatest losses occur at terminations. Cables are run continuously from area cabinet to area cabinet because that results in the least attenuation (signal loss) and are patched through the patch panels, which makes cable numbering easier to follow. The two methods of splicing, mechanical and fusion, both provide excellent long-term reliability when the splices are protected by splice closures.

Fusion Splicing Fusion splicing uses an electric fusion splicer, which is easy to operate. Here, the cables to be connected are fused together with a high-voltage electrical arc. For single-mode splicing, fusion splicing is preferred because this connection results in lower losses. The disadvantage is that the fusion splice machine that is required costs from $20,000 to $40,000.

Mechanical Splicing In this type of splicing the two cable ends are first aligned to a common centerline, thereby aligning their cores. The ends are butted together and permanently secured by adhesive or other means. For multi-mode fiber, this is an effective and easy method. It requires only a few special tools and is ideal for performing emergency field splices. On the other hand, it can be expensive if many splices need to be made.

Pull Strength and Bending Radius

Manufacturers of fiber-optic cables will specify two stress values that must not be exceeded. The higher value is the installation or short-term stress limit, which must be observed while pulling the cable around stationary objects, such as corners, ducts, and conduits. The lower stress limit applies during operation and is called the long-term static or operating load limit. Neither should be exceeded.

Bending fiber-optic cables can seriously affect their performance because it causes increased attenuation of the optical signal in the bends. The minimum bend radius recommended by the manufacturers also has two limit values. The higher value is associated with temporary bending during installation, while the lower limit applies for final training. Naturally, these limits change with cable size, construction, and application.

In addition, repeated impact causing crushing forces must also be avoided, and much heavier power cables should not be placed on unarmored fiber-optic ones. Also, the fiber-optic cable should not be spun off the spool end because that will put a twist in the cable for every turn of the spool. Instead, the cable should be rolled off the spool.

Testing

After the cables are installed, the integrity and performance of the cable system is tested. Visual testing uses 30 to 100 magnification power to inspect the end surface of the connector, which should be smooth, polished, and free of scratches. Only defects that affect the fiber core are a problem. Scratches that affect only the cladding or chipping of the glass outside the cladding will have no effect on the ability of the connector to couple light in the core.

Attenuation Testing Here a light source of known strength is injected into the cable, and the resulting strength is measured at the other end. The optical power loss is measured in decibels (dB) and is a good overall indication of the quality of splices, connectors, and cable. Attenuation is increased by badly finished connectors, tight bends, and excessive strain on the cables. No installation should be accepted without attenuation testing in both directions.

Figure 3.7v shows the main components used in attenuation testing. The optical light source provides the input light at a set wavelength. The launch cables or test jumpers are short fiber-optic cables that connect the light source and the optical power meter to the cable system under test. The optical power meter is set to the same wavelength as that of the light source and contains a photodiode detector and a meter that indicates the amount of signal loss in the cable system. In case of Figure 3.7v, that loss is 21.7 dBm. Such losses are compared to the budgeted design loss, and unacceptable losses are rectified.

Optical Time Domain Reflectometers (OTDR) When superior information is desired about the cable, and it is necessary to know the type of flaw and the location of the flaw along the cable, Optical time domain reflectometers (OTDRs) are used. The OTDR works by injecting a light pulse into one end of the fiber and by detecting the reflected light that is reflected back to the OTDR from any imperfections along

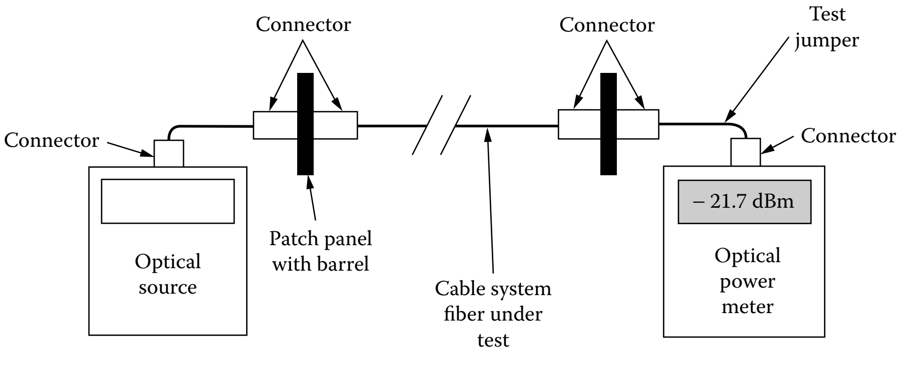

FIG. 3.7v
Attenuation in fiber-optic cables is tested by connecting a light source to one end and an optical power meter to the other end of the cable under test.

the cable. Because of the high cost of OTDRs, their use is limited to testing long-distance cable runs.

CONCLUSIONS

Fiber-optic networks are increasingly used in factory automation and process control applications. These applications have some similarities and significant differences from other fiber-optic data communications networks. These differences affect the criteria for selecting a fiber-optic supplier. The following should be considered:

Experience—No university teaches industrial fiber networking. All the knowledge must be learned from real-world field experience. A supplier should be able to perform network designs and have a strong working knowledge of product specifications and their system compatibility.

Standards conformance—Networks are a utility, similar to the electric power or telephone system. The network must support any connected device. Thus the supplier must use standard fiber, use standard connectors, and support standard industrial communication protocols used by the major equipment suppliers.

Field support—Lightning will strike. Forklift trucks will ram columns. Welders will cut cables. A fiber-optic supplier must have field support personnel readily available to consult or to travel to a field location to assist in disaster recovery. Support is also needed to confirm network layout, product selection, and installation practices.

Full system offering—Especially for an initial fiber-optic network installation, one-stop shopping for all the components in the system and an end-to-end warranty is important for a successful installation. Most factory and process plant communication managers do not want to become experts in fiber-optic technology. They want a network that is painless to install, operate, and maintain so they can concentrate on their own business—manufacturing products.

Supplier selection is an important task. The above criteria must be carefully considered and the supplier's ability to meet them must be carefully evaluated. A mistake in supplier selection can be very expensive and time-consuming to correct.[9]

INTRODUCTION

The transmitter senses a process variable and generates an output whose steady-state value varies only as a predetermined function of the process variable. The sensor can be an integral part of the transmitter, as in the case of a direct-connected pressure transmitter, or can be a separate part, as in the case of a thermocouple-actuated temperature transmitter.

Electronic, fiber-optic, self-checking, smart, and multivariable transmitters are discussed in other sections of this chapter. The design of traditional pneumatic transmitters has not changed much during the last couple of decades. For this reason, the material that follows is little changed from the section that was prepared by C. L. Mamzic 20 years ago.

HISTORY

A pneumatic transmitter is a device that senses some process variable and translates the measured value into an air pressure that is transmitted to various receiver devices for indication, recording, alarm, and control. Pneumatic controllers date back to the end of the 19th century. Pneumatic transmitters, however, did not make their appearance until the late 1930s—some 25 years after electric telemetering had become an established practice.

Before pneumatic transmitters were introduced, controllers were all direct connected, i.e., they contained a measuring element that was connected to the process. This meant that the controllers and control boards had to be located close to the process.

Pneumatic transmitters were first developed as an alternative to expensive explosion-proof electric transmitters for use in medium-range signal transmission systems in refineries and chemical plants. It was quickly recognized that transmitters offered many advantages over the use of direct-connected controllers, recorders, and indicators, such as safety, economy, and convenience. Transmitters eliminate the need for connecting flammable, corrosive, toxic, and pressurized fluids into the control room.

Furthermore, since controls can be located remotely, centralized control rooms become practical and such elements as long, gas-filled, temperature-sensing bulbs with expensive armored capillary and with attendant ambient temperature errors and sensing lags become unnecessary. As a result, the process variable could be conveniently indicated, recorded, and controlled on relatively inexpensive standardized receiver devices. Once introduced, transmitters caught on quickly, and when miniature pneumatic controls were introduced in 1948, the concept was based on the use of pneumatic transmitters in all remotely controlled loops.

GENERAL FEATURES

Signal Ranges

At first, each supplier settled on its own standard transmitter output range. Generally, the span was selected to be compatible with commonly available pressure sensors and in some cases with the then commonly used operating ranges of pneumatic valve actuators. Too high a pressure would have placed extra demands on the piping and air supply system, whereas too small a span would have meant a sacrifice in resolution or accuracy.

Also, the minimum pressure had to be some value above 0 PSIG (0 bar), since the nozzle backpressure in a transmitter does not (theoretically) drop to atmospheric. In fact, the closer the nozzle backpressure approaches zero, the more critical the seating and the greater the change in baffle clearance per increment of output becomes. This, in turn, results in greater error due to hysteresis and nonlinearity. Using a "live" zero provides an added benefit in that if a transmitter failed, the reading would drop below zero on the scale and give immediate evidence of failure.

Originally, ranges such as 2 to 14, 3 to 18, and 3 to 27 PSIG (0.13 to 0.93, 0.2 to 1.2, and 0.2 to 1.8 bar) were used. The benefits from complete standardization became obvious, and by 1950 a 3- to 15-PSIG (0.2- to 1-bar) range was fast becoming the accepted standard. The 3- to 27-PSIG (0.2- to 1.8-bar) range had been used mostly in power plants and combustion-control systems, and it continued to be used as one of the standard ranges. Formal recognition of standard ranges appeared in 1958 with the issuance of SAMA (Scientific Apparatus Makers Association) Standard RC2-11958. Three ranges were listed as standard: 3 to 15, 3 to 27, and 6 to 48 PSIG (0.2 to 1, 0.2 to 1.8 and 0.4 to 3.2 bar). Today, however, 3 to 15 PSIG (0.2 to 1.0 bar) is overwhelmingly the most accepted.

Baffle-Nozzle Error Detector

The heart of practically all pneumatic transmitters and controllers is a baffle-nozzle–type error detector (Figure 3.8a). The circuit consists of a restriction, detecting nozzle, connecting chamber, and baffle. The baffle is effective as long as the clearance is within one-fourth of the inside diameter of the nozzle. Beyond this clearance, the annular escape area is greater than the area of the nozzle itself, and the baffle no longer provides a restrictive effect.

The restriction must be small enough with respect to the nozzle so that when the baffle is wide open, the resultant nozzle backpressure will be practically atmospheric. The restriction size also determines the continuous air consumption of the circuit, and for that reason it should be kept small.

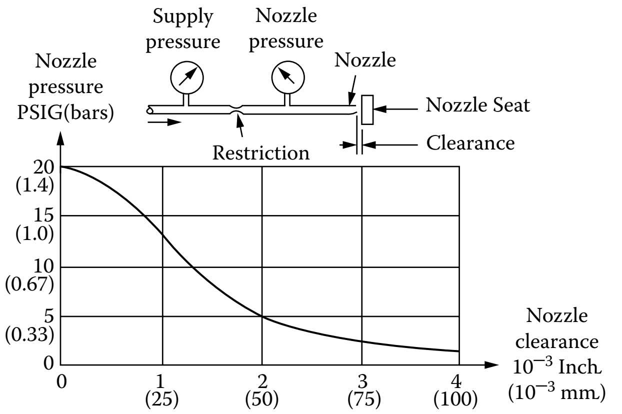

FIG. 3.8a
The relationship between nozzle seat clearance and nozzle backpressure.

On the other hand, the restriction cannot be too small because then it could clog easily with dirt or foreign matter that can be present in the supply air.

Conversely, the nozzle should be large enough to give the proper minimum backpressure but not so large that the corresponding clearance change for full-scale operation becomes so small as to require near-perfect seating. With this in mind, a typical restriction size might be 0.012 in. (0.3 mm) ID and nozzle size 0.050 in. (1.3 mm) ID. For such a general configuration, a plot of nozzle backpressure versus baffle clearance is given in Figure 3.8a.

Pneumatic detector circuits also take some other forms, some of which will be covered in the descriptions of individual transmitter types. The emphasis in this section is on the functioning of the pneumatic transmitter circuitry, since application and measurement details are covered in the *Process Measurement* volume of this handbook. It is not possible to cover all varieties of pneumatic transmitters, but the ones selected are typical and cover the basic types, so that collectively, they represent a good cross-section of the various design features that are available.

FORCE-BALANCE DEVICES

One-to-One Repeaters

The force-balance principle is commonly used in pneumatic transmitters. A very basic 1 : 1 force-balance transmitter is shown in Figure 3.8b. Other repeater designs are discussed in connection with level and pressure detectors in the *Process Measurement* volume of this handbook.

In Figure 3.8b the process pressure acts downward on the flexible diaphragm, and the force resulting therefrom is counterbalanced by the force of nozzle backpressure acting upward on the diaphragm. Air, at a supply pressure slightly higher than the maximum process pressure to be measured, flows through the restriction to the underside of the diaphragm and bleeds through the nozzle to atmosphere. At equilibrium, the nozzle seat clearance is such that the flow of air in the nozzle is equal to the continuous flow through the restriction. If the process pressure increases, the diaphragm closes (baffles) off the nozzle, causing the backpressure to increase until a new equilibrium is achieved. If the process pressure drops, the diaphragm moves away from the nozzle, causing the backpressure to drop until equilibrium is reestablished. Since nozzle backpressure is directly related to process pressure, the signal can be used remotely for indication, recording, or control.

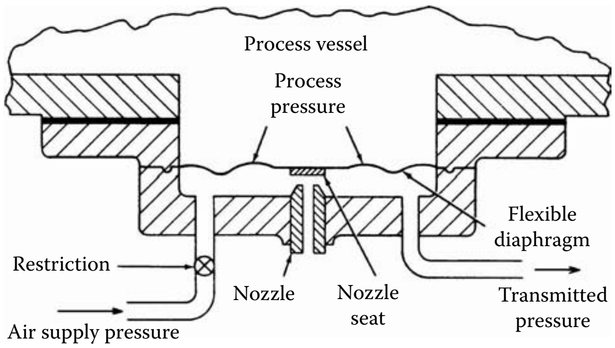

FIG. 3.8b
Simplified drawing of a 1:1 force-balance pressure transmitter with direct nozzle circuit.

Volume Booster Though such a transmitter is accurate, it has some limitations. Namely, since all the air must flow through the restriction, the speed of response will be slow, particularly if there is much volume in the output side of the circuit. Also, a leak in the output side will cause an error or even make the unit completely inoperative. Figure 3.8c shows

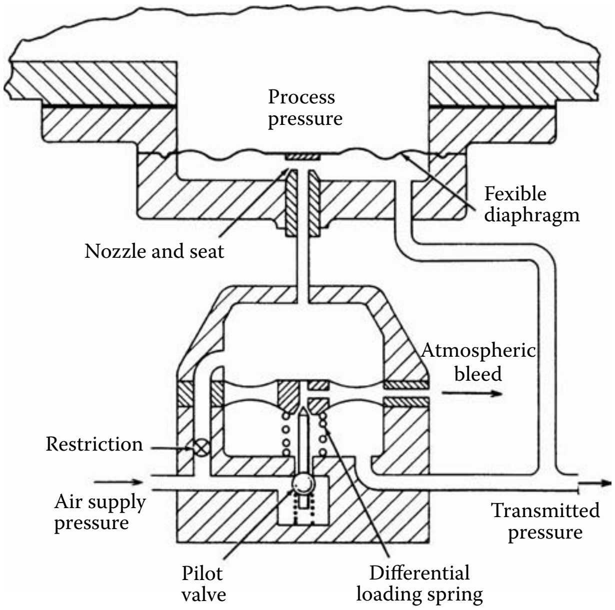

FIG. 3.8c
One-to-one force-balance pressure transmitter with volume booster and constant differential nozzle circuit.

essentially the same repeater as did Figure 3.8b, but with refinements. This system employs a volume booster that has considerable air-handling capacity, so that it speeds up the response, minimizes transmission lag, and copes with leakage.

In addition, it provides a constant pressure drop across the nozzle regardless of the level of operation. This improves accuracy with regard to linearity and hysteresis as the total diaphragm travel is lessened, and the relationship of nozzle seat position to nozzle backpressure is more linear than that of the direct nozzle circuit in Figure 3.8b.

The booster contains an exhaust diaphragm assembly consisting of two diaphragms that move integrally and that provide a bleed to atmosphere. On the underside of the diaphragm is a differential spring, which at balance exerts a force equivalent to 3 PSID (0.2 bar) acting on the diaphragm. Therefore, the nozzle backpressure that acts above the exhaust diaphragm is always nominally 3 PSI (0.2 bar) higher than the transmitted pressure. Since the nozzle bleeds into the transmitted pressure, the pressure drop across the nozzle is *always constant* regardless of output pressure. As in Figure 3.8b, the air pressure on the underside of the transmitter diaphragm counterbalances the process pressure.

If the process pressure increases, the diaphragm moves the seat closer to the nozzle, increasing the nozzle backpressure. This moves the exhaust diaphragm downward, closing off the exhaust port as it contacts the pilot valve, and moves the pilot valve downward to open the supply port. The result is an increase in transmitted pressure until the transmitted pressure, which is fed back to the underside of the diaphragm, equals the process pressure. A decrease in process pressure causes the nozzle backpressure to drop, and the exhaust diaphragm moves upward so that the pilot valve closes off the supply port while the diaphragm opens the exhaust port, causing the transmitted pressure to drop until equilibrium is established. At balance, there is a continuous flow of air passing through the restriction, the detection nozzle, and out to atmosphere via the exhaust diaphragm.

Membrane d/p Cells

Transmitters developed for the detection of very low pressure differentials (Figure 3.8d) detect by pressure balance across a membrane, which has a negligible mass and practically no movement. The output signal (Po) of the membrane d/p cell is related to the pressure difference between the high-pressure (Ph) and the low-pressure (Pl) inputs but is amplified by 1000 times or more. The membrane d/p cell is continuously purged and is capable of detecting down to a range of 0 to 0.01 in. H_2O (0 to 0.25 mm H_2O) differential.

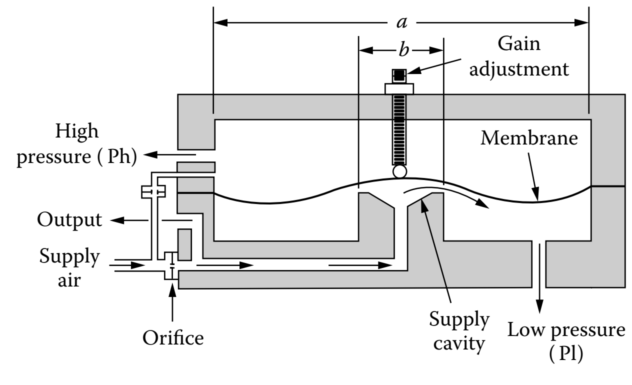

FIG. 3.8d
Membrane type low d/p transmitter. (Courtesy of Brandt Industries Inc.)

Advantages Since the membrane does not move or displace during measurement, the valve has no moving or mechanical parts to wear or contribute to hysteresis. Thus, the device will accurately sense very low pressures at its input ports, while being insensitive to shock, vibration, and mechanical problems normally associated with high-mass pressure-sensing devices. It consumes less than $^1/_5$ the amount of instrument air of a traditional d/p cell.

Because this transmitter does not have bellows or diaphragms that must fill with air, it responds much faster to an input change than any other device measuring pressure changes at very low levels. This means that in an application measuring turbulent air or gas flow, the transmitter will exhibit a higher output than manometers or similar devices would because it will respond to true average flow, which has short-term peaks not "seen" by a manometer or mechanical device.

This transmitter is not "wetted" by the process, but rather continuously purges the high and low ports with a low flow of air. This prevents the entrance of water, dirt, or process gases into the sensitive measurement cavities of the transmitter. As a result of this constant purge, some backpressure or resistance to flow in the connecting tubing, will develop. Therefore, this tubing must never be blocked, and corrections must be made for the pressure drop in the connecting tube.

Operation Referring to Figure 3.8d, supply air enters through an orifice. When there is no pressure difference between the high and low ports, the membrane does not exert a force on the supply cavity, and output pressure does not appear at the output port. If the output is dead-ended, all the supply flow is relieved through the ports.

When a difference exists between the high and low ports, the membrane exerts a force on the supply cavity, which also appears at the output port. This pressure is a function of the gain, which is a function of dimensions *a* and *b*. When the pressure in the supply cavity satisfies the gain equation, supply air flows out of the supply cavity into the low port. At this point, the valve is in equilibrium. If the applied pressures decrease, the reverse occurs. The valve has a stable gain and no measurable hysteresis; therefore, the valves can be cascaded (output of one fed into the input of the next valve) for very high total gains.

Pressure Balance Membrane technology is based upon pressure-balance theory rather than force balance or diaphragm displacement. By definition, the membrane is virtually mass free and will not support a bending moment.

Movement is limited to billionths of an inch (millionths of a millimeter).

A membrane-type differential pressure transmitter utilizes three high-gain amplifiers, each with a specific gain according to the required span of the transmitter (Figure 3.8e). The first stage senses the input differential pressure to be measured, which may be as low as 0 to 0.01 in. W.C. (0 to 2.5 Pa) full scale. It amplifies this pressure, and its output is conveyed to the second-stage valve, which amplifies the signal further and conveys it to the third stage. This third stage amplifies the signal by a small amount, but its primary purpose is to provide "driving" power to supply a standard 3- to 15-PSIG (0.2- to 1.0-bar) transmitter output.

Pressure Transmitter

The applications for pressure repeaters are limited. The more common transmitter is one that converts the measured process variable range into a standard 3- to 15-PSIG (0.2- to 1.0-bar) output pressure signal (Figure 3.8f). It operates on a principle of force balance, or more precisely, on a principle of moment balance.

Process pressure acts on the input bellows and applies a force on the balancing beam, which rotates on the flexure pivot. A change in input pressure results in a moment that is counterbalanced by an equivalent change in moment as output pressure changes in the feedback bellows. An increase in process pressure rotates the beam counterclockwise and moves the nozzle seat closer to the nozzle, increasing the backpressure and booster output until the moments come into balance. The biasing spring ensures sufficient counterclockwise moment on the balancing beam so that, even with zero process pressure, it is

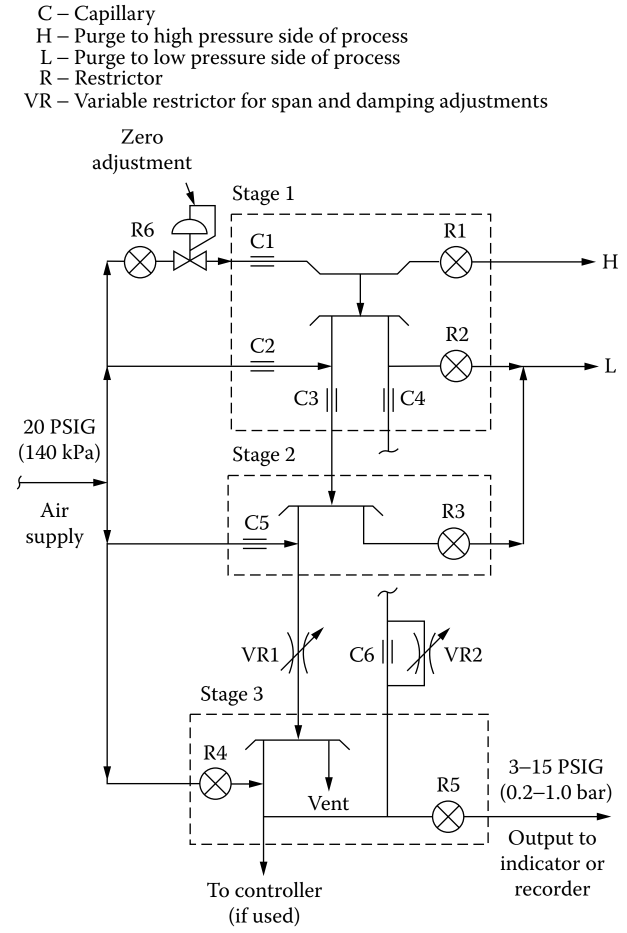

FIG. 3.8e
Membrane-type differential pressure transmitter.

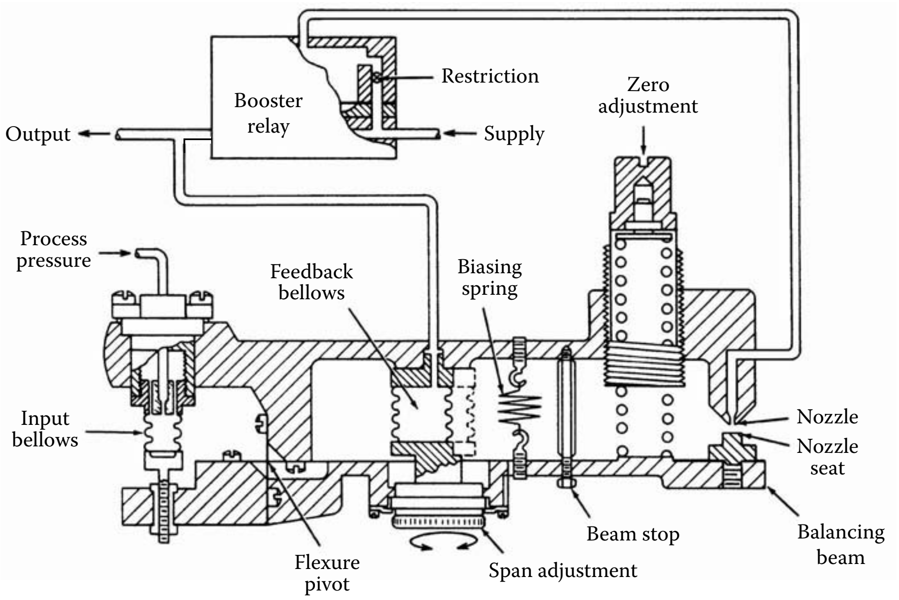

FIG. 3.8f
Force-balance pressure transmitter with variable range.

possible to set the output at 3 PSIG (0.2 bar) by adjusting the compression of the zero spring. Added compression of the zero spring gives an elevated zero, or range suppression.

The feedback bellows is eccentrically mounted on a rotatable seat. Rotating the assembly changes the moment arm, hence the span. The span is basically a function of the relative ratio of effective areas of the input bellows and the feedback bellows. The booster relay is an amplifying type that minimizes total nozzle clearance and improves accuracy.

MOTION-BALANCE TRANSMITTERS

The pressure transmitter in Figure 3.8g consists of a pressure measuring element and a motion transmitter. Instead of a conventional baffle-nozzle, this transmitter employs an annular orifice with a variable restrictor called the wire pilot. Supply air passes through the fixed restriction into the follow-up bellows and out the detector nozzle. The wire pilot throttles the exhaust from the nozzle. It has a sharply tapered step so that when the large-diameter wire restricts the orifice, the backpressure rises to a maximum, and when the small diameter is effective the backpressure drops to atmospheric. At balance, therefore, the follow-up bellows move to position the detector nozzle in line with the tapered step of the wire pilot.

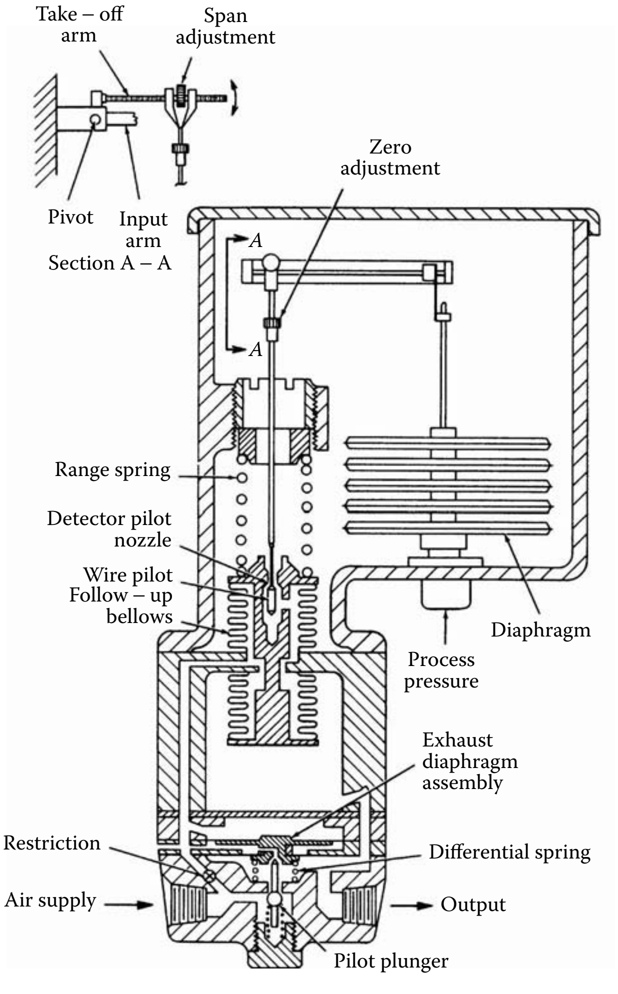

FIG. 3.8g
Motion-balance-type pressure transmitter.

Process pressure acts on the measuring diaphragm. An increase in process pressure moves the diaphragm upward, which, via the U-shaped linkage, moves the wire pilot upward. The wire pilot restricts the annular orifice and the backpressure increases. The two bellows that make up the follow-up bellows system have the same area and are connected rigidly by a center post so that nozzle backpressure has no effect on movement of the bellows assembly. The nozzle backpressure is connected to the top of the exhaust diaphragm assembly.

This is an amplifying-type diaphragm assembly since the upper diaphragm has six times the effective area of the lower. Therefore, as the nozzle backpressure increases, the output increases in a 6:1 ratio. The output feeds back to the underside of the follow-up bellows and pushes it upward. Upward motion is resisted by the range spring. The spring constant is such that a 12-PSIG (0.8-bar) change on the follow-up bellows moves the bellows assembly through the nominal full-scale travel of the wire pilot.

Zero is adjusted by setting the initial operating position of the wire pilot. Span is adjusted by varying the radius of the takeoff arm shown in section A-A. The total force required to operate such a transmitter is only 2 grams. Therefore, any type of primary element can be used with it—from low-force draft elements to various types of high-pressure elements. The basic range is determined by the spring rate of the measuring element.

TRANSMITTERS GROUPED BY MEASURED VARIABLE

Differential Pressure Transmitter

A typical force-balance differential pressure transmitter is shown in Figure 3.8h. The high and low pressures act on opposite sides of a diaphragm capsule, and the resulting pressure differential exerts a force on the force bar. The force bar pivots on the diaphragm seal. The external end of the force bar pulls on one end of the range rod. The range rod, with its integral flapper, pivots about the range wheel. A feedback bellows acts on the opposite side of the range rod. A change in differential results in a changed flapper position, which alters the nozzle backpressure, relay output, and feedback force until all moments come to balance.

Zero is adjusted by adjusting the zero spring tension. Span is adjusted by moving the range wheel, which changes the relative input/output moment arm ratio.

Since the output of the transmitters is linearly proportional to pressure differential, if the unit were used on an orifice-type measurement, the flow would have to be read on a square root calibrated scale.

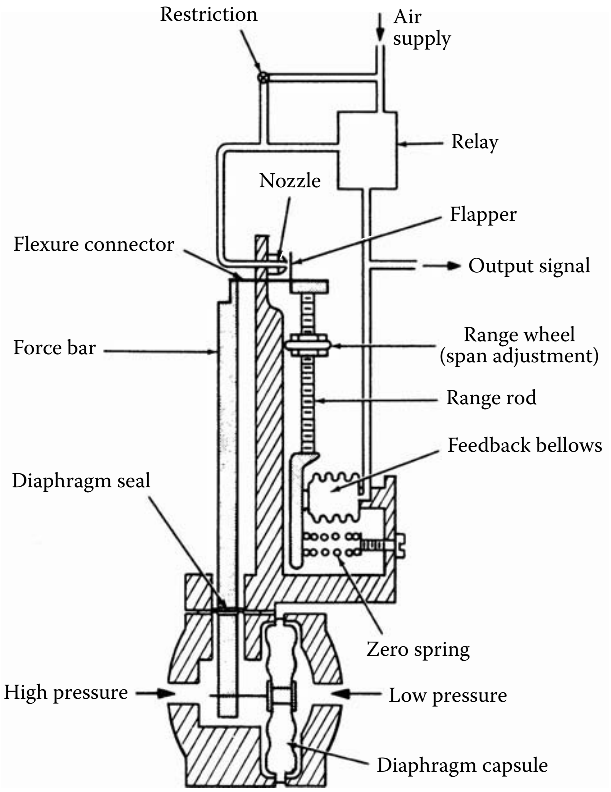

FIG. 3.8h
Force-balance–type differential pressure transmitter.

Square Root–Extracting d/p Transmitter

Differential pressure elements, such as in Figure 3.8i, provide a motion output. A motion transmitter, as in Figure 3.8g, could be used with such a meter to give an output linearly proportional to the differential. However, the motion transmitter shown in Figure 3.8i converts linear motion of the meter into a square root–related output so that orifice-type flow can be read on a linear scale.

Linear signals are preferred when flows are added, subtracted, or averaged and when other analog computing and characterizing requirements exist. They are often specified in order to give better readability and control rangeability.

The meter in Figure 3.8i consists of a high- and a low-pressure bellows joined by a common center shaft. The differential causes the bellows to move a linearly proportional amount depending upon the total spring rate of the range spring, the bellows, and torque tube. Movement of the bellows twists the torque tube, causing rotation of the torque tube shaft. It is this motion that actuates the transmitter. The bellows are filled with liquid (usually ethylene glycol), and as the bellows move, liquid is transferred from one bellows to the other via the pulsation dampener needle valve. If the normal differential pressure range is exceeded, the bellows move until an O-ring on the center shaft seals off the liquid in the bellows. The pressure can then build up to the body rating of the meter without damaging the unit.

The torque tube rotates the lever connector of the motion transmitter. A floating pilot link is socketed in the connector at one end and baffles off the detector nozzle at the other. The transmitter is calibrated so that at zero differential the output is at 3 PSIG (0.2 bar) and the pilot link is horizontal. An increase in differential rotates the connector counterclockwise. This restricts the nozzle and causes a buildup in transmitted pressure, which in turn acts on the large bellows, moving it downward until equilibrium is attained.

Since the pilot link has a fixed length and because the nozzle clearance is constant for all practical purposes, the pilot nozzle must be moved downward according to the cosine law. This means that at minimum input with link horizontal, there must be considerable motion of the pilot nozzle as compared with the lever connector, and therefore the gain is practically infinite. As the included angle increases, considerably less nozzle travel is required to offset lever connector motion. For small angles, the relationship is almost exactly square root.

Another transmitter having the same function employs a varying spring rate with travel. This is accomplished by picking up added leaf springs as the travel increases.

Variable Area Flow Transmitter

When a variable area flowmeter is used as a primary flow-measuring device, the float position is magnetically detected. The motion of the magnetic follower mechanism then is converted into a 3- to 15-PSIG (0.2- to 1.0-bar) signal. (Volume 1 of this handbook contains a detailed discussion of the operation of rotameters.)

In Figure 3.8j, a permanent magnet is embedded either in the float or in an extension of the float. A magnetic steel helix, which is supported in an aluminum cylinder, is mounted between bearings. The leading edge of the helix is constantly attracted to the magnet. The vertical position of the float results in a corresponding radial position of the helix.

A cam is attached to the helix follower assembly. A pneumatic circuit consisting of a transmitting and a receiving nozzle detects the cam profile. The receiving nozzle pressure serves the same function as nozzle backpressure in a conventional baffle-nozzle circuit. When the cam does not interrupt the flow from the transmitting to the receiving nozzle, the receiver pressure is at maximum. When it is fully interrupted, the receiver pressure is 0 PSIG (Pa). At balance, the detector system is throttled by following the cam profile.

As the float rises, the cam rotates in a direction of decreasing displacement. As the cam edge moves away from the detector nozzles, the increasing receiver nozzle pressure acts on the relay and results in an increase in transmitted pressure. The transmitted pressure acts on the feedback capsule and moves the flexure-mounted detector nozzles toward the cam edge until equilibrium is established. The spring rate of the range spring is set so that a 12-PSI (0.8-bar) change in output is required to track the full displacement of the cam.

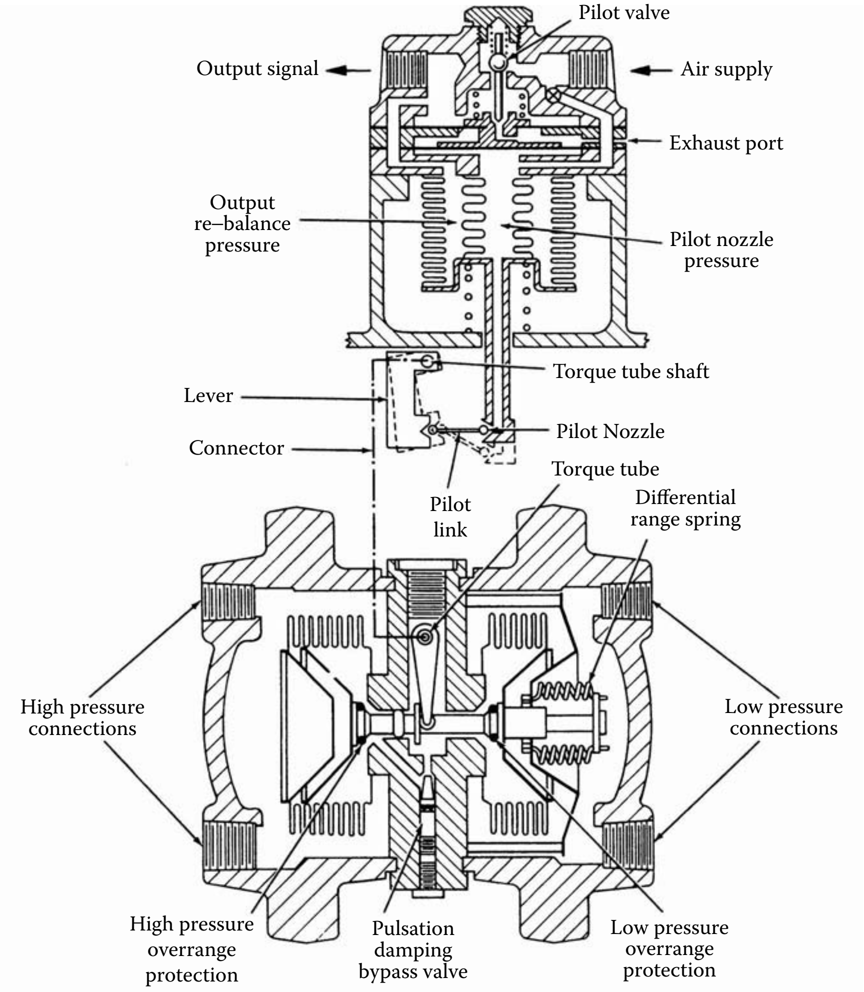

FIG. 3.8i
Linear flowmeter consisting of a combination of differential meter and square root–extracting motion transmitter.

Span is adjusted by turning a screw that takes up coils in the range spring, thus changing its spring rate. Zero is set by adjusting a second screw that sets the initial spring tension.

Filled Bulb Temperature Transmitter

Pneumatic temperature transmitters are almost exclusively the force-balance types. Figure 3.8k shows a transmitter with a sealed, gas-filled bulb (Class III system). (A detailed discussion of filled thermal systems can be found in Chapter 4 of the *Process Measurement* volume of this handbook.).

Except for a negligible volume of gas in the thermal system bellows and in the connecting capillary, practically all the fill gas is in the bulb. The volume of the thermal system is constant, and as the bulb senses the process temperature, the pressure of the fill gas varies according to the gas laws. The fill gas pressure creates a force downward on the thermal system bellows. This force acts through the thrust rod and is counterbalanced by the force resulting from transmitted air pressure acting upward on the transmitter bellows.

An increase in process temperature increases fill gas pressure, which pushes down on the thrust rod baffling off the nozzle. The consequent increase in nozzle backpressure pushes the exhaust diaphragm and pilot plunger down, closing the exhaust seat and opening the supply port until the increase in transmitted pressure acting on the transmission bellows results in force balance.

The temperature range is a function of the initial fill pressure (the higher the pressure, the narrower the span) and the ratio of the effective areas of the thermal system and transmission bellows. The zero spring acts counter to the thermal system and establishes the low end of the measured temperature range.

Buoyancy Transmitter (Level or Density)

Figure 3.8l illustrates a motion-balance buoyancy transmitter. (A more detailed discussion of displacement type level instruments is presented in Chapter 3 of the *Process Measurement* volume of this handbook.) Changes in level directly affect the net weight of the float as the float displaces the liquid.

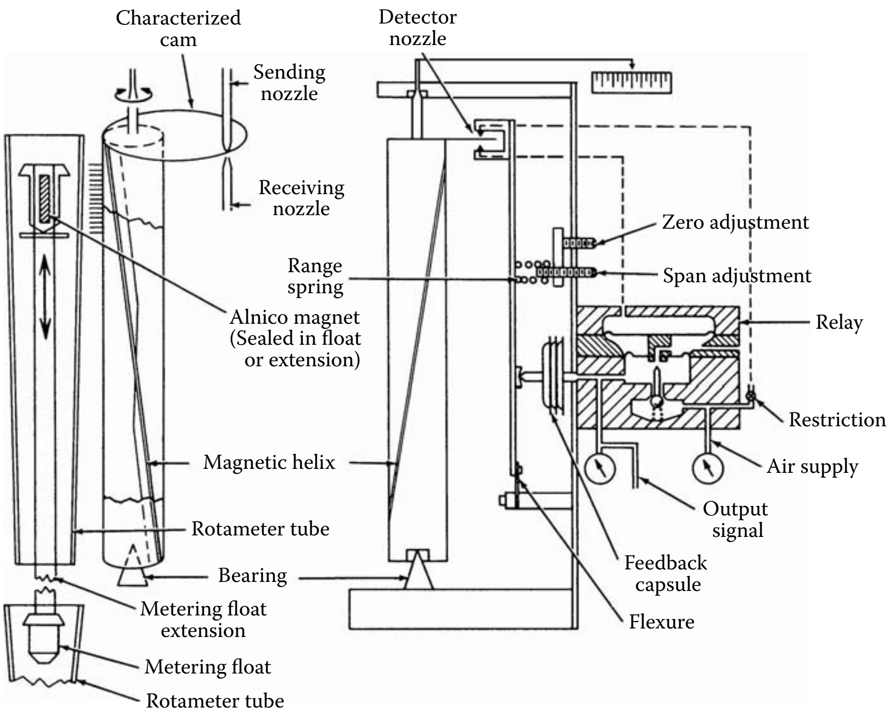

FIG. 3.8j
Rotameter transmitter with magnetic take-out and pneumatic cam follower mechanism.

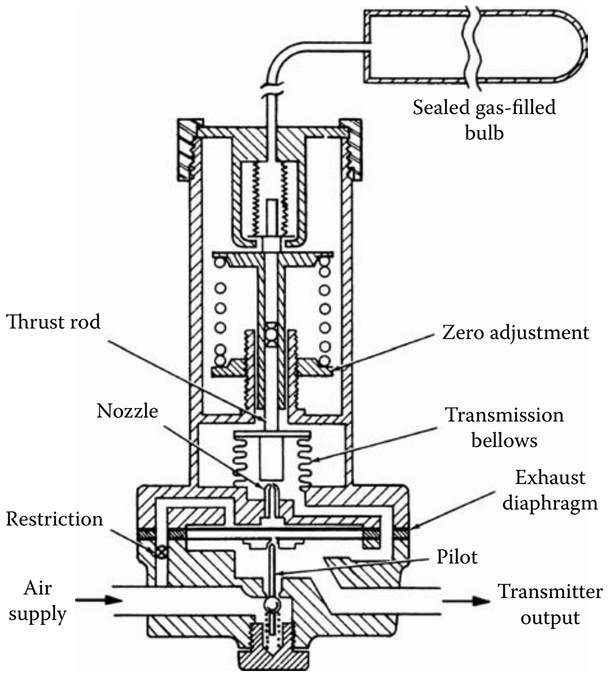

FIG. 3.8k
Filled bulb–type force-balance temperature transmitter.

The float lever is connected to a torque tube. As the torque tube twists, it rotates a center shaft to which the flapper is attached.

Supply air flows through a restriction to the top of the booster relay and through a small tube inside the bourdon to the detecting nozzle. The booster relay, which is amplifying with a 3:1 ratio, provides an output pressure, a portion of which is fed back to the bourdon via a three-way valve. The three-way valve provides for span adjustment. If its plunger is moved up, closing off the exhaust seat, full transmitted pressure feeds back to the bourdon.

The result is that when the level rises and moves the flapper closer to the nozzle, the consequent increase in transmitted pressure makes the bourdon move away from the nozzle (negative feedback) so that total flapper travel and hence measuring range is large. Adjusting the three-way valve in its other extreme position where it closes off transmitted pressure results in practically on/off action at the nozzle, representing the narrowest range of measurement. Normally the three-way valve is adjusted somewhere between these limits. By rotating the bourdon tube with respect to the flapper, the zero is changed.

Buoyancy transmitters can be used to measure density or specific gravity as well as level and level interface. Force-balance designs are also available.

Force Transmitter

Force transmitters can serve as load cells in weighing applications or in the measurement of variables such as web tensions. The transmitter in Figure 3.8m operates on a force-balance principle. (For a more detailed discussion of pneumatic load cells refer to Section 7.25 in the *Process Measurement* volume.)

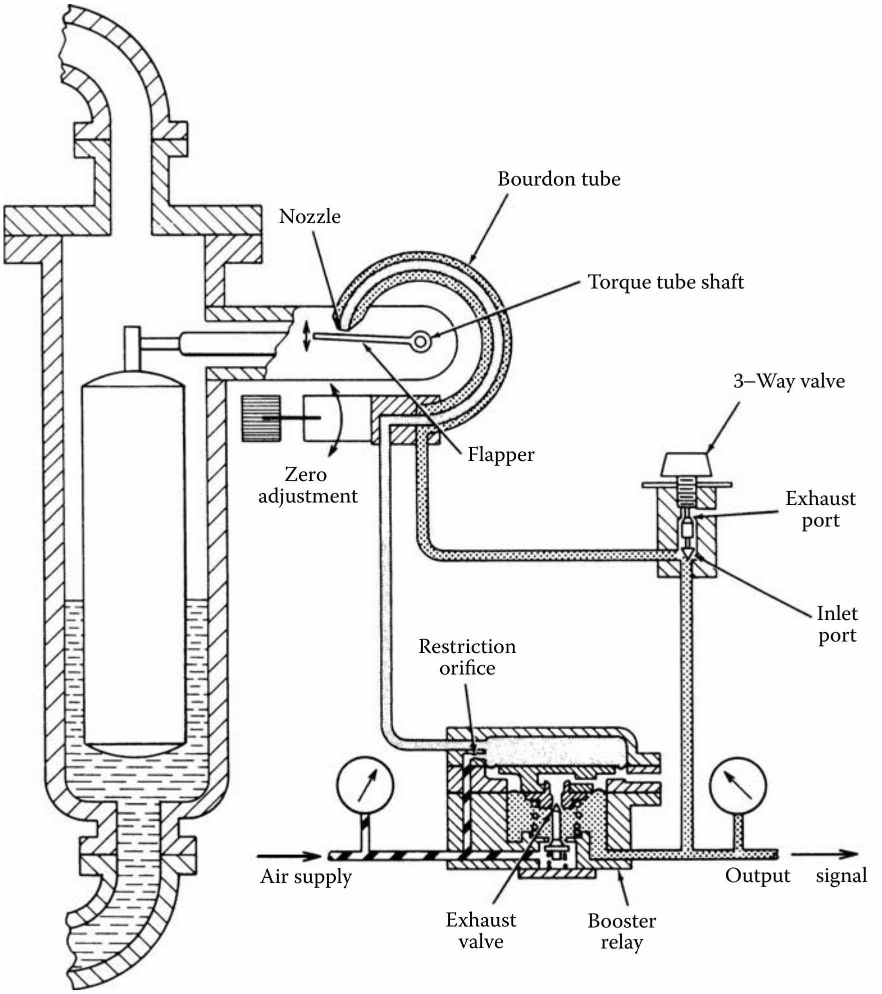

FIG. 3.8l
Level transmitter with torque tube–type spring and pneumatic follower system.

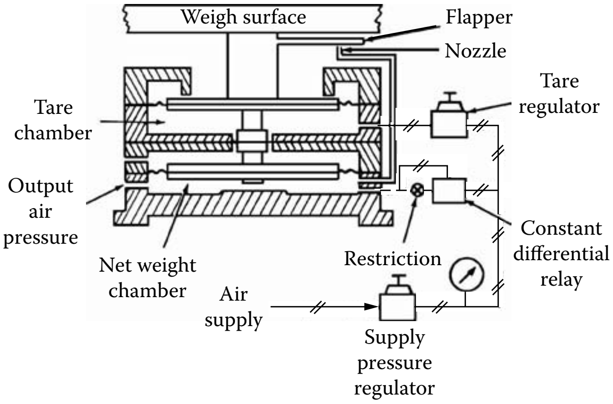

FIG. 3.8m
Force-balance weight transmitter.

Pressure from the tare regulator acts upward on the top diaphragm and is set to counterbalance the fixed weight of a hopper or tank and support structure. The net weight in the tank is counterbalanced by the output air pressure, which is acting under the bottom diaphragm. Air flows from supply through a constant differential relay, which maintains a relatively constant flow across a restriction and into the net weight chamber. The net weight chamber is connected to the detector nozzle. The nozzle baffle is attached to the supporting platform. If net weight increases, the platform and flapper move down, baffling off the nozzle and causing the backpressure to increase until force-balance is restored.

Smaller pneumatic force transmitters are also available. For stabilizing potentially noisy systems, some of these designs incorporate hydraulic pulsation dampening.

Motion Transmitter

A variety of approaches are used to detect motion. Some of these are described in Sections 7.14 and 7.19 of Volume 1, the *Process Measurement* volume of this handbook.

A motion balance transmitter as shown in Figure 3.8g can be adapted to measure total motions from $^1/_8$ in. (3 mm) to approximately 1 in. (25 mm). This design is particularly useful where only a low force is available. Ordinary pressure

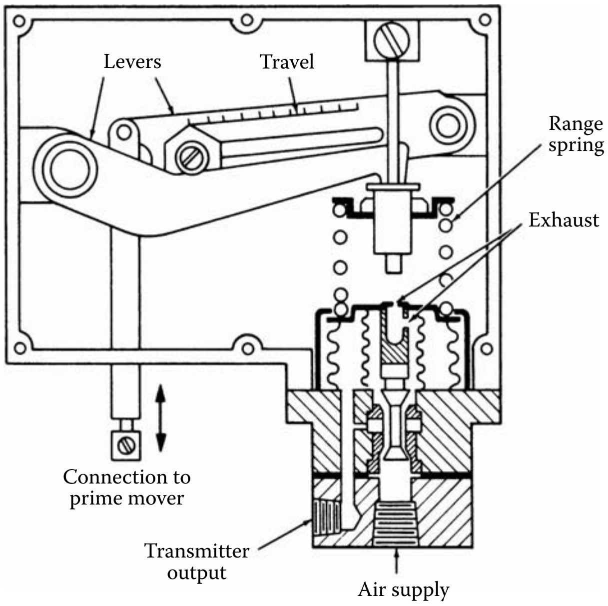

FIG. 3.8n
Valve positioner connected to serve as a position transmitter.

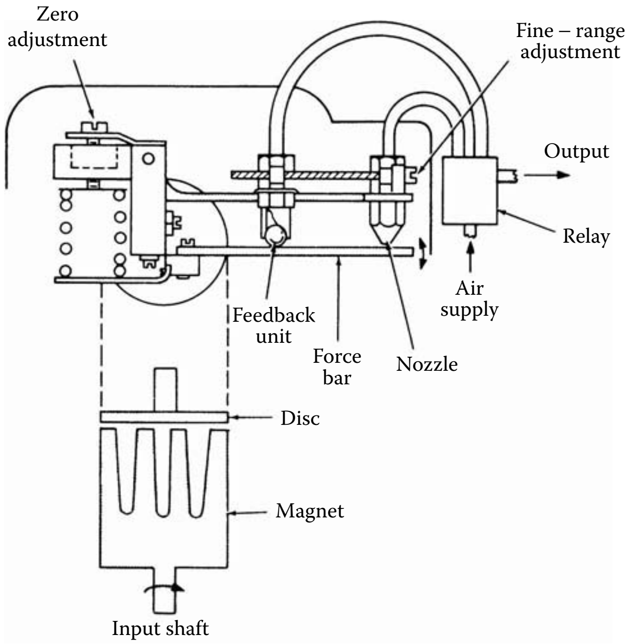

FIG. 3.8o
Pneumatic, force-balance–type speed transmitter.

regulators can also be adapted as motion transmitters by substituting a sliding thrust rod for the lead screw that normally adjusts the pressure-setting spring.

The most common approach, however, is to use a valve positioner and, in effect, reverse its functioning. This way, instead of controlling position or motion, it will transmit a signal that is proportional to position or motion. Figure 3.8n shows a valve positioner that is connected as a motion transmitter. The pilot valve is reverse-acting, and the output feeds back into what is normally the input bellows.

If in Figure 3.8n the prime mover pulls the connector downward, the parallel lever system pushes down and compresses the range spring. This opens the supply port and closes off the exhaust port of the three-way pilot, causing the output to increase. The output applies an upward pressure on the outer bellows to counteract the increase in spring force. A roll-type contact point establishes the gain of the lever system. Hence, its adjustment determines the span of measurement.

Speed Transmitter

In Figure 3.8o, a prime mover drives an input shaft that carries a multi-pole permanent magnet. The combination of magnetomotive pull and rotation of the magnet tends to turn the disc on its flexure pivot. The torque on the flexure is proportional to input shaft speed. Attached to the flexure is a radial force bar that doubles as a flapper and as a rebalancing lever. Output pressure feeds back to a ball-type piston, and the derived force counterbalances the input torque.

As speed increases, an increase in counterclockwise torque results. This moves the flapper toward the nozzle. The relay amplifies the nozzle backpressure change, which serves as the output and as the feedback to the ball piston. The pressure increases until the feedback moment balances the input torque.

Pneumatic speed transmitters are also obtained by combining an electrical speed detector–amplifer combination with an electric-to-pneumatic converter. A typical detector is one that integrates the rate of magnetic pulses generated as gear teeth cut across the field of a magnetic pick-up head, illustrated in Figure 3.8p. (This design is explained in more detail in Section 7.19 of the *Process Measurement* volume.)

TRANSMISSION LAG

With pneumatic transmitters, there is a transmission lag that increases with the length of transmission tubing.

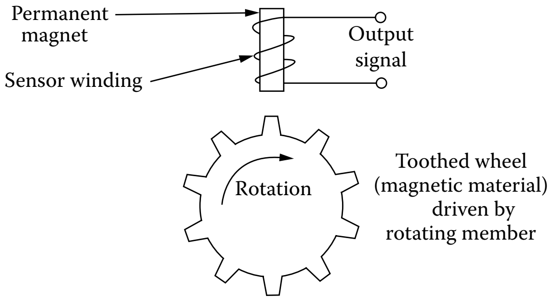

FIG. 3.8p
Schematic of an induction-type speed sensor.

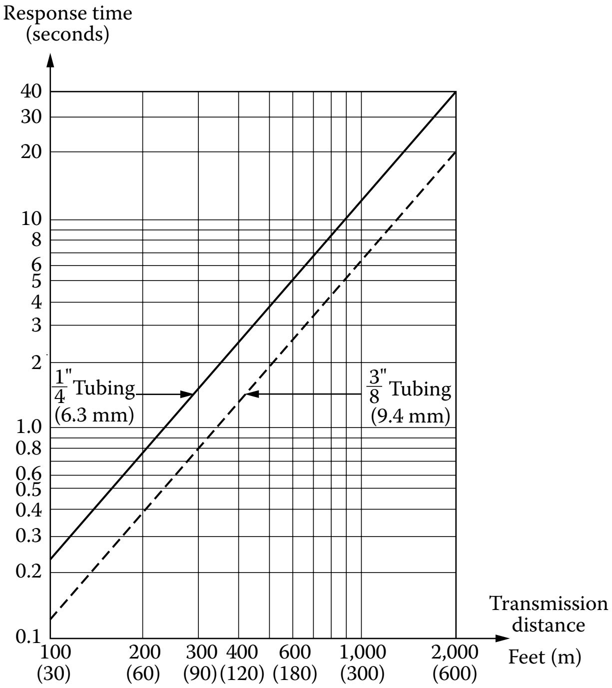

FIG. 3.8q
Response time (time for 63.2% of the complete response) versus transmission distance.

The transmission lag is described as the time that is required to obtain 63.2% of a step input. The 63.2% figure defines the time constant in first-order systems, but since transmission systems do not behave as first-order systems, the figure cannot be so interpreted. Nevertheless, it does serve as an arbitrary benchmark for comparison.

A plot of response time versus transmission distance for 1/4 and 3/8 in. (6.3 and 9.4 mm) tubing is given in Figure 3.8q. Response is faster with 3/8 in. tubing, but 1/4 in. tubing is more often used. At 300 ft (90 m), for example, the response time for 1/4 in. tubing is 1.5 seconds, and for 3/8 in. tubing, it is 0.8 seconds.

The effect of transmission distance on pneumatic control is discussed in more detail in Sections 1.4 and 3.1 of this volume.

3.9 Transmitters: Self-Checking and Self-Validating

J. BERGE (2005)

Communications Infrastructure (Permanently Connected):	Transmitters with 4- to 20-mA output shall conform to NAMUR NE-43 HART handheld such as the Smar HPC301 (about U.S. $1000) Foundation™ fieldbus host such as Smar SYSTEM302 (from U.S. $4000)
Costs (Typical base prices for pressure transmitters):	Microprocessor-based 4 to 20 mA, such as SMAR LD290, U.S. $500 HART, such as SMAR LD301, U.S. $700 *Foundation Fieldbus, such as SMAR LD302, U.S. $800*
Suppliers:	Refer to Sections 3.6, 3.7, and 3.8 in this volume and to Volume 1 of this handbook.

INTRODUCTION

Self-diagnostics are of great importance for both operation and maintenance. Self-diagnostics are important because the reliability of the measurements is essential for proper control. Control and alarm systems using invalid inputs are a safety hazard. Measurement validation is therefore paramount. Indications of invalid measurements can be used to shut down the loop or to activate backup systems.

Conventional and more sophisticated software tools such as statistical process control (Section 2.34), model-based predictive control (Section 2.14), and optimization (Section 2.20) should all work only with validated data and must know whether a measurement is invalid.

Until recently only two types of maintenance strategies were used in the processing industry: reactive maintenance (its response is usually too late) and preventive maintenance (too early). Both are costly and ineffective. The recommended maintenance scheme is a proactive one, which responds to the actual device status.

Such condition-based maintenance strategies rely on self-diagnostics to report on the health of field instruments to an asset management software system. Self-diagnostics detect and immediately signal the failure of a device. Diagnostics in conjunction with appropriate means of communication and advanced software tools permit remote troubleshooting.

Measurement validation is also critical in the proper operation of safety control systems. This requirement resulted in a trend that because switches provide no diagnostics, low-cost transmitters are taking their place in critical applications, where self-diagnostics are used.

LEVELS OF DIAGNOSTIC INFORMATION

Self-validation methods vary by both the type of measurement and by the supplier involved. In the past, most transmitters only had a single "general failure" indication for all faults. Today's transmitters, however, increasingly provide detailed diagnostics. The level of diagnostics available varies greatly by manufacturer.

Indeed, some transmitters are equipped to provide diagnostics that go down to the chip level, even if repair can only be performed at the board level. Because component level repairs are currently rare and are subject to approval from both a certification agency and the manufacturer, for most practical purposes, board-level diagnostics are sufficient.

Transmitters have diagnostics for the transmitter itself, i.e., the main circuit board, as well as diagnostics for its sensor or sensors. Transmitters can be categorized into two groups with respect to the sensor: those with integral sensors such as most pressure, flow, and level transmitters, and those with external sensors such as most temperature, pH, conductivity, etc. Devices without microprocessors have no diagnostics at all.

How Diagnostics Are Performed

Self-diagnostics of transmitters are active when the power supply is on. When this is the case, the integrity of data in the different nonvolatile memories is checked to ensure that they have not been corrupted (Figure 3.9a). Memory checks are also performed periodically while the device is in operation. Other diagnostics include consistency of configuration and calibration. If a device is in simulation mode, this is also reported by the diagnostics software.

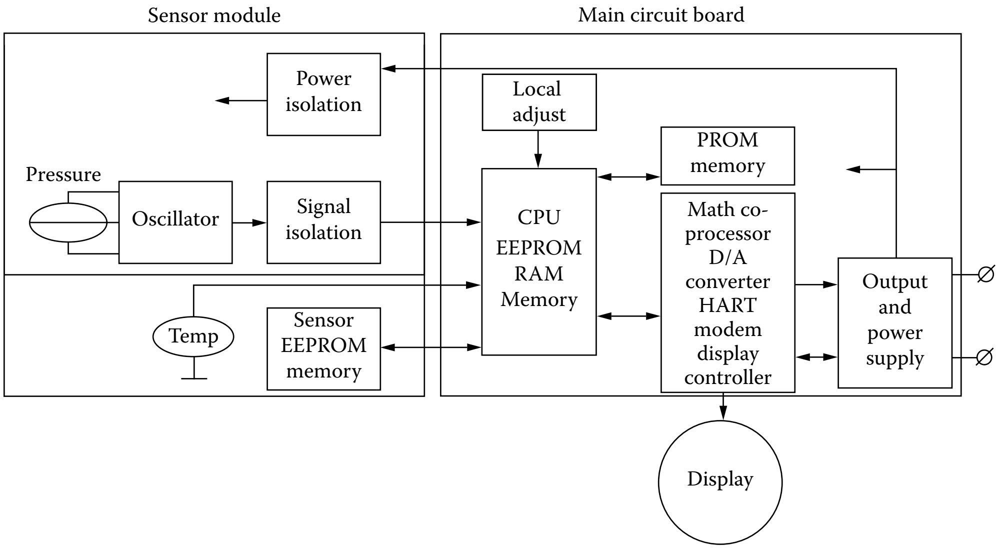

FIG. 3.9a
Diagnostics are performed by CPU firmware in conjunction with sensor's application specific integrated chips (ASIC).

Many types of device failures can manifest themselves in similar ways and it may not be possible to distinguish among them. Moreover, a failure of the main circuit board often results in the failure of a local display and communication channel, thereby making easy diagnostics impossible. Therefore, the user may not know exactly what is wrong with the sensor module. However, it suffices to know that the main circuit and not just the sensor module has failed because the main circuit has to be replaced in either case. Detailed analysis can be performed once the faulty circuit board has been replaced.

Transmitters with Integral Sensors Transmitters with integral sensors continuously check the sensor signal and compare it to expected readings to detect abnormal conditions based on manufacturer experience with the particular measurement method used. Pressure, level, and flow transmitters are all available with integral sensors. In order to allow for easier repair, the sensor is usually detachable from the main circuit board (Figure 3.9b).

The device or its sensor module provides temperature monitoring for temperature compensation of the measurement in addition to registering the violation of temperature limits. If a low limit is violated, this can be used to alert operators that the process fluid may be solidified or frozen and therefore the operation of the heat tracing system should be checked. Similarly, if a high-temperature limit is violated, it is desirable to check whether the sensor has been affected, degrading its accuracy or requiring recalibration. Such condition monitoring is required for proactive maintenance, which can ensure that small transmitter problems are corrected before they can cause large plant problems.

The symptoms of several types of sensor failures are similar and may not be distinguishable. For example, the leaking of pressure sensor diaphragms caused by corrosion

FIG. 3.9b
Pressure sensor module contains application specific integrated chips (ASIC) that handle diagnostics. (Courtesy of SMAR.)

may result in the same symptoms as some other type of sensor failure. In this case, the user may not know exactly what is wrong, but it suffices to know that the problem is with the sensor module and not the main circuit board and therefore the sensor has to be replaced. Detailed analysis can be performed after the faulty sensor has been removed. What is most important is to know that it was indeed a genuine sensor failure and not some kind of process upset or blocked impulse line that created the indication of failure.

Transmitters with External Sensors Transmitters utilizing external sensors include temperature, pH, and conductivity as well as several other types. A self-diagnosing transmitter periodically checks the external sensor to determine its health as well as checking the integrity of the wiring. A variety of tests can be performed, depending on the measurements and on the type of the primary sensor.

For example, in the case of thermocouple-type (TC) temperature sensors, the test may involve the sending of current through the leads to verify the continuity of the wires and to detect "burn-out" of the TC junction. Another test is to check the plausibility of the cold-junction temperature sensor reading.

For an RTD (Resistance Temperature Detector) sensor, the transmitter may measure the resistance of the individual sensor wires because excessive resistance can signify poor or wrong connections. Furthermore, the transmitter may contain internal comparison circuits, which can detect drift in its own internal secondary measurement circuitry.

More expensive but also more comprehensive diagnostics can be provided if two temperature sensor elements are used. If their readings excessively deviate from each other, that is used as an indication of failure.

pH is a notoriously difficult measurement and is perhaps one of the best examples where good use can be made of measurement validation. A modern pH transmitter (Figure 3.9c) continuously monitors both the measurement and the reference electrodes to detect mechanical damage of the sensor, contamination or blockage of the diaphragm, and aging or defects in the cabling. As a means to support proactive maintenance, the transmitter may even include a timer that alerts the operator when it is time to recalibrate. Furthermore, the transmitter may contain internal gain check to detect drift in its own internal secondary measurement circuitry.

FIG. 3.9c
Self-checking pH transmitter. (Courtesy of Mettler-Toledo.)

DIAGNOSTICS TRANSMISSION

The output signal of a transmitter can indicate its own health and the validity of its measurement. In case of analog transmitters, if the output is outside the normal operating range, that usually signals some type of failure. Intelligent transmitter communication indicates the status by using codes and parameters.

Analog Transmitters

Transmitters without microprocessors have practically no real diagnostics capability. However, thermocouple temperature transmitters may still have a "pull-up" resistor that prevents the input from floating in case of thermocouple burnout, which otherwise can drive the output to either of the following extremes: above 20 or below 4 mA.

Other analog transmitters work in a similar fashion. This scheme of protection is available for "live zero" signals such as 4 mA or 1 V, but for "dead zero" (zero-based) signals, the scheme does not work because it is usually not possible to go below 0 mA or 0 V. In these cases, an output that is below 1% is usually considered to be a failure indication.

Microprocessor-Based Transmitters

Microprocessor-based transmitters with 4- to 20-mA output and with or without highway addressable remote transducers (HART) have sensor diagnostics and can manipulate their outputs intelligently.

The NAMUR NE-43 (Normen-Arbeitsgemeinschaft für Meß-und Regulungstechnik in der Chemischen Industrie) standard defines the signal levels that indicate the health of instruments (Figure 3.9d).

To indicate that the measurement is "Good," the transmitter uses a signal in the range 4 to 20 mA. The wider range of 3.8 to 20.5 mA indicates that the measurement is outside the set range but probably still useful. This status may be considered "Uncertain." If the signal is between 3.6 and 3.8 mA or between 20.5 and 21 mA, the transmitter is "Bad." So, when the signal rises higher (20.5 to 21 mA) or drops lower (3.6 to 3.8 mA), a set of user-defined safety actions should be initiated.

HART Transmitters HART (highway addressable remote transducer) transmitters are smart instruments (see Section 4.11 in Volume 3 of this handbook) that provide slow digital communication in addition to their simultaneous 4- to 20-mA analog signals. The device status is included in all their communication responses.

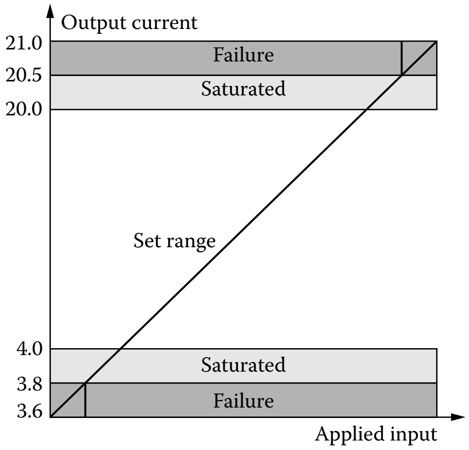

FIG. 3.9d
A failure indication recommendation by a German standard, NAMUR NE-43 (Normen-Arbeitsgemeinschaft für Meß-und Regulungstechnik in der Chemischen Industrie).

Because HART is relatively slow, the control loops rely on the 4- to 20-mA analog signal for control. Therefore, in most installations the HART communication capability is only utilized occasionally, by connecting a handheld tool. Therefore, in most plants the HART device rarely communicates the measurement validity digitally. Consequently, when the HART communication is not continuous it is even more important that the control system should detect any fault indication by the analog signal from the transmitter and bring it to the attention of the operator (Table 3.9e).

TABLE 3.9e
Descriptions of HART Errors

Error	*Description*
Field Device Malfunction	The device has failed. The measurement is invalid.
Configuration Changed	The device configuration has been changed, possibly affecting the measurement.
Cold Start	The device has restarted.
More Status Available	Additional detail status about the device health or measurement validity is available.
Analog Output Current Fixed	The device is in simulation mode. Output does not reflect measurement.
Analog Output Saturated	The output is out of range. The output does not reflect the measurement.
Nonprimary Variable Out of Limits	Auxiliary measurement, e.g., sensor temperature, is out of range. The measurement may be uncertain.
Primary Variable Out of Limits	The measurement is out of range. The output does not reflect the actual value.

However, in such control systems where the communication is "always on" and continuously polls the transmitters, a faulty sensor is reported instantly. In order to provide this mode of operation, it is necessary that the DCS/PLC systems use input modules with HART communication or an auxiliary HART multiplexer.

Foundation Fieldbus Transmitters Foundation Fieldbus transmitters are intelligent instruments (see Section 4.12 in Volume 3 of this handbook) with pure digital communication. Fieldbus communication is "always on." The health of the device and the validity of the measurement are continuously communicated. The extensive diagnostics capabilities and the ability to effectively report the health and measurement validity of the transmitted data are among the primary reasons for choosing Fieldbus.

In addition to the diagnostic and validity information listed in Table 3.9f, every transducer block has detailed diagnostic

TABLE 3.9f
Diagnostics and Validity Information Provided by Fieldbus Transmitters

Parameter	Description
*.status	All input and output parameters, including the measurement, as well as some contained parameters have a status associated with the value (see Table 3.9g)
BLOCK_ERR	All blocks have a summary of faults. In the resource block, this parameter reflects the health of the device as a whole. In the AI block, it represents the associated measurement (see Table 3.9h).
XD_ERROR	All transducer blocks have more detailed information about the fault.
MODE_BLK	All blocks have a mode. If the actual mode of the resource block does not match the target mode, this is an indication of some sort of problem with the device as a whole. If the actual mode of a transducer block does not match the target mode, this is an indication of a problem with the associated measurement.
RS_STATE	The resource block indicates the overall health of the device. If it is "failure," the memory or other hardware has a fault.

TABLE 3.9g
Fieldbus Measurement Status Attributes and Their Descriptions

Status Attribute	*Description*		
Quality	The validity of the measurement value may be Good, Bad, or Uncertain. There are two forms of Good; the one associated with measurements is "Good (Noncascade)."		
Substatus	Additional details hinting why the quality is Bad or Uncertain. For Good it contains alarm summary or other information used by the internal workings of the block.		
	Bad	Nonspecific	
		Configuration error	Some parameter is incorrectly configured.
		Not connected	Input is not linked.
		Device failure	Output has failed.
		Sensor failure	Sensor has failed.
		No communication—last usable value	Input is not being received. The value remains since last communication.
		No communication—with no usable value	Input is not being received. No earlier value is available.
		Out of Service	The block is out of service.
	Uncertain	Nonspecific	
		Last Usable Value	Input is disconnected. The value remains since earlier on.
		Substitute	The value is entered manually
		Initial Value	Value entered while in out-of-service mode.
		Sensor Conversion Not Accurate	Out of range or the sensor may have fouled.
		Engineering Unit Range Violation	Out of range.
		Subnormal	Auxiliary or redundant sensors have failed or are not in agreement
Limit condition	The limit condition for the value may be either High, Low, Constant, or none at all. High, low, and constant mean that the measurement does not represent the actual value, e.g., due to over range.		

parameters that are specific for the particular transmitter type, technology, and manufacturer.

The BLOCK_ERR parameter is found in all Foundation Fieldbus function blocks. It gives a summary of all faults in the device (Table 3.9h).

DIAGNOSTIC INFORMATION DISPLAYS

The fact that a transmitter failed or that it needs attention must be indicated both locally and in the control room in order to bring this information to the operator's attention. Fieldbus and HART configuration tools allow for effective management of failures, as was discussed in Section 1.6 of the first volume of this handbook.

The local indicator on the transmitter can display status, such as Bad, and can provide direct failure messages, such as sensor "burnout," both textually (Figure 3.9i) and symbolically (Figure 3.9j).

Health indication is very helpful for troubleshooting in the field. For this reason it is a good idea to use transmitters that are provided with local digital displays.

Usually, the operator in the control room is the first to notice that invalid measurements or transmitter failures have occurred. In order for the total process of transmitter self-checking and validation to be fully effective, the chain, consisting of failure detection in the transmitter, transmission of that information to the control system, and its presentation for the operators, must be fully integrated (Figure 3.9k).

In addition to the displaying of the status on the faceplate, any Uncertain or Bad status should also be logged and alarmed. Once operators detect an invalid measurement they can initiate the process that will determine the actual cause.

OPC (Object link embedding for Process Control) is a key technology serving to get data to the operator's workstations in the control room. This software architecture was described in Section 5.4 of the third volume of this handbook. It is recommended to use OPC in conjunction with HART or Foundation Fieldbus.

Portable and Handheld Displays

On the displays of handheld tools, technicians can see the detailed diagnostics of the transmitter. In the case of HART

TABLE 3.9h

Types and Descriptions of Universal Fieldbus Errors

Error	*Description*
Block configuration error	One or more parameters are wrongly configured, preventing the block from operating properly. The measurement may be invalid.
Link configuration error	One or more of the links for the block are wrongly configured.
Simulate is active (enabled)	For the resource block this means that simulation is permitted for the transmitter inputs. In an analog input it means that the input is actually being simulated and does not represent the actual measurement.
In Local Override (LO) mode	The block is in local override mode.
Device fault state is forced	"Fail safe" is forced in the device.
Device needs maintenance soon	The predictive diagnostics in the device indicates that it may soon be in need of service. The device may e.g., require calibration, cleaning, or some other service.
Input failure	The measurement has failed. The measurement may not be valid.
Output failure	The output has failed.
Memory failure	The device has a problem with one or more of its memories.
Lost static data	The device has lost its configuration. The measurement may be affected.
Lost nonvolatile data	The device has lost its configuration. The measurement may be affected.
Readback check failed	The actual output may not match the desired output.
Device needs maintenance now	The predictive diagnostics in the device indicates that is now in need of immediate service. The device may e.g., require calibration, cleaning, or some other service.
Powering up	The device is starting up
In Out-of-Service (OOS) mode	The mode of the block is set Out-of-Service.
Others	Additional device-specific status is available in other parameters.

systems, the portable handheld tool is brought out into the field and is connected at the transmitter (Figure 3.9l).

In a Fieldbus system the technician can "drill down" into the transmitter the detailed diagnostics information that can be helpful in the troubleshooting effort. Because the communication in Fieldbus systems is "always on," there is no need to locate and connect a handheld tool to obtain the diagnostics; they are available from the engineering station at any time (Figure 3.9m).

FOUNDATION Fieldbus transmitters are provided with more diagnostics, and the information provided is easier to access from the control room. These extensive diagnostics and the effective reporting of measurement validity are primary reasons for choosing Fieldbus.

FIG. 3.9m
The transmitter diagnostics information, which is presented on a Fieldbus software-supported display.

To effectively manage large numbers of installed transmitters and other instruments, the Fieldbus and HART network infrastructure should be complemented with powerful online plant asset management (OPAM) software (Figure 3.9n).

If the asset management software is Web-based, the maintenance system can securely be connected to the enterprise-wide intranet or the public Internet using appropriate firewalls and other means of protection. This permits diagnostics to be carried out from just about anywhere where it is possible to establish an Internet connection. For example, experts can access it from their homes, or access can be granted to the manufacturer's support center.

ACTING ON THE DIAGNOSTIC DATA

It is not possible to control a process if the transmitted information is invalid or Bad. However, it may be possible to maintain control while using uncertain measurements, such as readings that are slightly out of range. In general, plant safety is improved if transmitter self-diagnostics are utilized to improve the validity of measurements.

Failsafe and Alarm Actions

Even the simplest analog control loop can be designed to fail safely. For example, in case of level control, a failsafe transmitter will generate a high analog output (say 21 mA), if the sensor fails. Therefore, the controller or alarm system will interpret a 21-mA signal the same as if the tank is overfilled and thus will automatically close the filling valve.

Sophisticated DCS and PLC may interpret NAMUR NE-43 signal levels and thus determine if signal quality is Good, Uncertain, or Bad.

HART communication is too slow for closed-loop control or shutdown interlocks and therefore both controls and alarms utilize 4- to 20-mA analog signals.

Converters exist that can tap the HART communication from the signal lines and can activate relays in case of failure. Such relays can tie to control systems, which do not communicate HART but do need to know the transmitter status.

In a Fieldbus-based control system, safe loop action is part of the IEC 61804-1 function block diagram language for building control strategies, which is an integral part of the FOUNDATION Fieldbus system architecture. Values communicated between function blocks, such as from an analog input (AI) block in a transmitter to a PID block in a control valve positioner, are accompanied by their status.

A "Bad" measurement status from the transmitter can automatically switch the loop to a manual mode of operation or optionally, the PID control block can bring the control valve to its predetermined safe position (Figure 3.9o).

An advantage of the Fieldbus function block language is that the interlocks are built into the control blocks. Therefore there is no need to configure and validate additional logic to implement the interlocks. Moreover, because Fieldbus is a standard, the interlocks work across all devices conforming

to the standard. Therefore it is advisable to use transmitters, valve positioners, and central controllers that are based on the FOUNDATION fieldbus blocks rather than using proprietary languages. This can ensure that the measurement validity and other status information is propagated throughout the control strategy and not lost along the way.

Within the fieldbus PID block it is possible to set whether the status "Uncertain" shall be treated as "Good" or as "Bad." This makes it possible to be selective when balancing production availability against plant safety on a loop-by-loop basis. For loops that require high availability, an uncertain status is configured as good, thus permitting control to continue under such conditions. For loops where safety is the primary concern, the uncertain status can be treated as bad, thus shutting the loop down.

3.10 Transmitters: Smart, Multivariable, and Fieldbus

J. BERGE (2005)

Communications Infrastructure (Permanently Connected):	Transmitters with 4- to 20-mA output shall conform to NAMUR NE-43 HART handheld such as the Smar HPC301 (about U.S. $1000) Foundation™ fieldbus host such as Smar SYSTEM302 (from U.S. $4000)
Costs (Typical base prices for pressure transmitters):	Microprocessor-based 4- to 20-mA, such as SMAR LD290, US$ 500 HART, such as SMAR LD301, U.S. $700 Foundation fieldbus, such as SMAR LD302, U.S. $800
Suppliers:	Refer to Sections 3.6, 3.7, and 3.8 in this volume and to Volume 1 of this handbook.

INTRODUCTION

Transmitters are referred to as “analog,” “microprocessor based,” “intelligent,” “smart,” “fieldbus,” etc. depending on the technology used.

An “analog” transmitter has no microprocessor and therefore its linearization, temperature compensation, and diagnostics are rudimentary. An analog transmitter is configured by switches and jumpers and adjusted using potentiometers.

A “microprocessor-based” transmitter is capable of much more sophisticated linearization, temperature compensation, and diagnostics. However, a microprocessor-based transmitter still only has an analog output, such as 4- to 20-mA, and therefore only transmits rudimentary diagnostics. A microprocessor-based transmitter is configured from the local display and buttons.

An “intelligent” transmitter too has a microprocessor, but it also has digital communication capability, which permits remote diagnostics and configuration.

A “smart” transmitter is an intelligent transmitter that has analog output but that also permits simultaneous digital communication. The HART protocol is a typical example. Not all intelligent transmitters are smart because some do not provide simultaneous digital communication and analog output, as the analog output is disrupted while communicating digitally.

A “fieldbus” transmitter has only digital communication. Today, the same supplier often markets microprocessor-based, smart, and fieldbus transmitters that are externally identical but differ in their internal electronics and software (Figure 3.10a). In general, a smart or fieldbus transmitter consists of the sensor or input circuitry, the microprocessor, the communication block and, in the case of smart transmitters, an analog output (Figure 3.10b)

OPERATION AND PERFORMANCE

Analog circuits are subject to drift over time and are affected by ambient temperature variations. Moreover, there is no obvious way to check whether or not an analog signal is invalid because signal distortion just changes one valid value to another valid value, as all signal levels are valid. For example,

FIG. 3.10a
Microprocessor-based, smart, fieldbus, or Profibus-PA transmitters can be externally identical and differ only in the electronics and software used. (Courtesy of SMAR.)

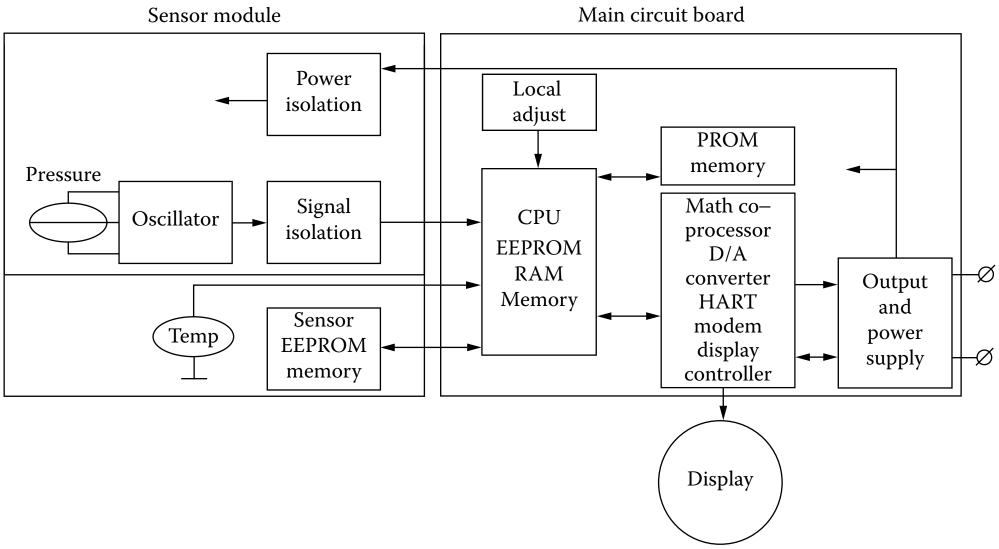

FIG. 3.10b
Smart pressure transmitter with auxiliary cold junction temperature. (Courtesy of SMAR.)

a signal that should be 5 V may vary between 4.85 and 5.15 V due to noise, but there is no way to tell the value is true because 4.85 or 5.15 V are also valid signals.

Similarly, if, because the supply voltage is insufficient, a signal that should be 19 mA is limited to 18 mA, there is no way to tell that a distortion has occurred because 18 mA is also a valid signal. Distorted or limited signal values cannot be detected in analog circuitry because these signals cannot be distinguished from the genuine process measurements.

For these reasons, there is a trend to obtain greater accuracy and stability in transmitters by eliminating more and more analog components in the measurement circuitry and aiming to convert it to a completely digital system that has digital sensors, processing, and communication.

Digital Sensors

In smart and fieldbus transmitters the sensor is usually digital. Keeping the sensor signal digital from the very beginning provides for more precise signal processing and lowers noise pickup and signal degradation.

The signal from a digital sensor gives the value of the measurement as a function of frequency or time. Such time-based functions do not depend on the signal amplitude. For example, a capacitance-type pressure sensing element can be a part of an oscillatory circuit with a frequency output. Similarly, an ultrasonic flow meter detects the time of flight. Other digital sensors operate on frequency phase-shift.

Timers in the microprocessor easily measure frequency and duration using precise crystal clocks. In such direct digital measurements there is no need for an A/D converter, which also eliminates the conversion error and lowers inaccuracy by eliminating quantization error.

In earlier “semismart transmitter” designs with analog sensors, the outputs from resistive strain gauges or piezo or conventional capacitance sensors were first converted to a voltage before being converted to the digital format. Most of these transmitter designs have been replaced by digital sensing.

When the detector is inherently analog, such as in case of some temperature sensors, A/D converters are required, and their resolution determines the accuracy of the conversion.

Sensor Compensation and Characterization

Firmware in the microprocessor provides a variety of functions, including sensor temperature chatacterization and linearization, communication, self-diagnostics and sensor diagnostics, as well as flow totalization, PID control capability, and other functions depending on type of the transmitter.

No sensor has perfect linearity or temperature stability. It is for that reason that the microprocessor must characterize and compensate the sensor signal. For external sensors such as thermocouples and RTD (Resistance Temperature Detectors), the relation between detected and sensor output is well established. In these cases, standard tables or polynomials are used to convert the thermocouple’s millivolt or the RTD’s ohm signals to temperature in the transmitter firmware. Similarly, the temperature effect on a pH sensor is well understood, and its compensation is preprogrammed in a pH transmitter.

The characteristics of many pressure and flow transmitters are not predetermined but must be obtained by testing. In case of these units, all sensors are tested in the factor by exposing them to their operating range of inputs at different temperatures (Figure 3.10c).

The test data obtained are used to compute the characterization coefficients that are unique to the particular sensor, and these coefficients are stored in the memory of the sensor module. When the power supply is turned on, the transmitter loads these characterization coefficients from the sensor module into

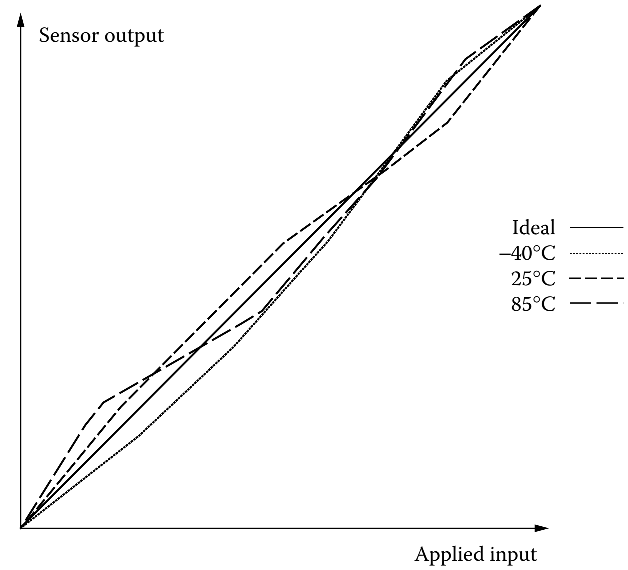

FIG. 3.10c
Exaggerated illustration of sensor characterization test results.

its characterization algorithm. The goal of this procedure is a temperature-compensated and linear measurement.

Because the sensor characterization coefficients, along with other pertinent information such as sensor serial number, range, and materials of construction, are stored in the sensor module itself, when the sensor is replaced the new characterization coefficients are automatically loaded into the microprocessor.

By reducing the measurement error, it becomes possible to increase the rangeability of smart transmitters and provide turndowns, sometimes as high as 120:1, while still keeping the error within acceptable limits. The increased turndown makes the transmitter suitable to a wider range of applications. Two of the main limitations to accuracy is the hysteresis and the thermal hysteresis of the sensor because these cannot be corrected.

Multivariable and Inferential Sensors

Once the signals of individual sensors have been characterized, they can be combined in a multivariable transmitters to compute such process variables as density or concentration (Figure 3.10d). Multivariable transmitters perform several measurements and use these to obtain an inferential reading of a single property and generate a single 4- to 20-mA output. For example, a multivariable transmitter may measure density and process temperature in order to compute concentration or density based on the Brix or API tables.

Similarly, a multivariable transmitter may measure the differential pressure drop across and orifice plate, static line pressure, and process temperature in order to compute either standard volumetric flow or mass flow. Such a transmitter also has auxiliary sensors to compensate the differential pressure and static pressure sensors for temperature effect before they are used in the AGA (American Gas Association) equations to compute standard volumetric gas flow or in the AIChE (American Institute of Chemical Engineers) equations to compute mass flow for gas or liquid flows. (These equations can be found in Volume 1 of this handbook.)

FIG. 3.10d
Multivariable transmitter for the detection of density. (Courtesy of SMAR.)

Other multivariable transmitter applications include the use of multichannel temperature transmitters in order to obtain differential, average, minimum, or maximum temperature readings. A multichannel transmitter is connected to several sensors that are installed in various points in the process piping and equipment.

In addition to multivariable transmitters, particularly in the case of FOUNDATION fieldbus, transmitters can also perform calculations such as flow totalization and PID control. These capabilities are also present in some smart transmitters.

Some transmitters can also perform process linearization such as the use of hydrostatic tank gauging (HTG) lookup tables to relate the level in cylindrical, spherical, and odd-shaped tanks to volume. Fieldbus transmitters, particularly those supporting instantiable function blocks, may also support signal selection, limiting, and arithmetics. Today, it is up to the system design engineer to decide whether the above-mentioned calculations should be performed in the field instruments or in the central computers.

HART Communication

Digital communication such as HART and FOUNDATION fieldbus permits remote monitoring, diagnostics, configuration, and calibration. In the case of fieldbus networks, the digital communication can also be used to perform closed-loop control.

In digital transmission there are only two valid states for the signal (zero and one). Therefore, a large amount of interference is required to distort the signal by changing one to the other. This makes the digital signal very robust. In addition, error detection techniques are provided to detect errors due to noise. Errors due to D/A conversion are eliminated by not requiring such conversions at all.

HART transmitter communicates at 1200 bit/s, which is too slow for closed-loop control but adequate for the technician to perform interrogation using a handheld tool. In order to guarantee fast loop response, in most applications the analog 4- to 20-mA signal is used for control (see Section 4.11 in Volume 3 of this handbook). HART transmitters are typically wired in a point-to-point fashion. Multi-dropping up to 15 transmitters on the same pair of wires is possible but is rarely used as it is slow and not well supported in control systems.

Fieldbus Transmitters

FOUNDATION fieldbus transmitters use the H1 version of fieldbus communicaton at 31.25 kbit/s, which is fast enough for closed-loop control. This speed eliminates the need for using analog signals (see Section 4.12 in Volume 3 of this handbook).

Typically 12 to 16 devices, which can be a mix of types and suppliers, are multi-dropped on the same pair of wires. Fieldbus is much more than a digital equivalent of 4- to 20-mA transmission. Fieldbus can be used in place of Distributed Control Systems (DCS) because the devices in the field can also perform the control functions. This reduces the controller and I/O-subsystem complexity because the majority of controls tend to be simple monitoring and basic control functions, computation, or logic, which all can be done in the field instruments.

Fieldbus transmits the measurement status information along with the sensor's reading. The status information includes measurement quality and limit condition information. The measurement quality is usually stated as Good, totally Bad, or Uncertain, e.g., having an error of not exceeding a few percent. Other function blocks use this measurement quality information to automatically initiate safety steps or to exclude that measurement when doing selection or calculating an average.

Smart and fieldbus transmitters use their auxiliary sensors to provide temperature and static pressure compensation of the primary sensor's reading. Such compensated smart transmitters still have only one output because the other measurements only serve to detect the existing conditions under which the primary sensor operates.

BENEFITS OF ADVANCED TRANSMITTERS

Many benefits resulted from the use of digital circuitry, microprocessors, and digital communications in smart and fieldbus transmitters. These include greater accuracy and stability, lower temperature sensitivity, greater flexibility due to higher turndown ratio, remote parameterization, calibration, diagnostics, and monitoring. Online diagnostics also improve plant safety.

Savings

Savings can be achieved in both capital expenditures (CAPEX) and operational expenditures (OPEX). Because fieldbus is a system architecture and not just a 4- to 20-mA replacement, fieldbus savings exceed the savings associated with transmitters because they also improve the operation of the process.

Although a smart transmitter costs about $100 more than its analog counterpart, the savings in commissioning expenses due to quicker parameterization and loop checking result in a lower installed cost for a smart transmitter.

Maintenance costs are also reduced because of the easier and faster diagnostics. In addition, the monitoring of ambient conditions allows plants to switch to a proactive maintenance program. In general, effort and resources required for maintenance are low in comparison with those of analog instruments.

If "always on" communication is used, the ability to perform remote diagnostics and other functions can reduce the number of required field trips as the causes of trouble can often be determined from the control room. For example, it is possible to determine that loss of control is caused not by transmitter failure but by a process upset, and thus one can avoid unnecessary maintenance. Also, because failures can be pinpointed more accurately, repairs tend to be faster. In addition, the availability of user-friendly handheld tools will make calibration easier and faster, while improved calibration will improve the performance of the transmitter.

Improved diagnostics guarantee that failures can be detected and corrected faster so that production can get back online sooner, thus reducing downtime. By monitoring sensor temperature, it is possible to protect against overheating- or freezing-related failures. By monitoring the health of the transmitters, it is possible to schedule maintenance shutdowns so that many instruments are simultaneously maintained, rather than experiencing several unexpected shutdowns due to surprise instrument malfunctions. In comparison with analog transmitters, the resources required for maintenance are also lower.

More accurate measurements result in better product quality, lower risk of off-spec product, and reduced costs of disposal or rework. Higher accuracy measurement also allow

FIG. 3.10e
HART to current converter. (Courtesy of SMAR.)

one to keep set points closer to values corresponding to maximum production efficiency.

Installation and Commissioning

Smart transmitters are usually loop powered and are wired the same way as their analog counterparts are. One should make sure that a typically 250-ohm shunt resistor for the minimum current loop load is installed. That resistor is usually already provided on the input of the controllers, I/O-modules, recorders, or indicators.

As was described in Section 4.11 of Volume 3 of this handbook, because HART operates in a frequency range that is above the registered range of most process instrumentation, smart transmitters are completely compatible with analog instrumentation. Naturally, in order to guarantee intrinsically safe operation, special safety barriers are required.

Because the smart multivariable transmitters provide only a single analog output, only the calculated inferential measurement is available in the control room; the multivariable inputs, such as temperature, are not. However, HART-to-current converters are available, which use HART communication to interrogate multivariable transmitters and generate 4- to 20-mA signals based on their digital inputs (Figure 3.10e).

Using a HART-to-current converter with one or three outputs, it is possible to send all the process measurement signals to the control system even if it does not communicate HART.

Fieldbus transmitters connect using H1 wiring based on the IEC 61158-2 type 1 standard. Fieldbus transmitters are wired in parallel, just like other fieldbus devices (see Section 4.12 in Volume 3 of this handbook). Note that power supply impedances are required for regular installations, and special safety barriers are required to provide intrinsic safety (see Section 2.2 in Volume 3 of this handbook). For fieldbus systems, transmitters with low power consumption should be selected so that more devices, longer wires, and reduced numbers of safety barriers can be used.

6–TAG – Smar –DT301
7–TAG – Smar –FY301

FIG. 3.10f
Handheld tools can be used to identify which HART transmitters are connected to a bus.

By using handheld tools, one can remotely detect which transmitters are connected (Figure 3.10f).

It is also possible to check a loop by switching the transmitter into the simulation mode and setting its output current to any value in the 4- to 20-mA range, independent of the measurement. This makes it possible to verify the reading at the workstations and on the panel.

When a fieldbus transmitter is connected to a HSE (High Speed Ethernet) linking device or to a proprietary interface module, this will be automatically detected and shown in the live list on the configuration tool (Figure 3.10g).

Parameterization

The term "parameterization" implies the process of setting the operating parameters, such as the range of the transmitter.

Analog transmitters are configured by using switches or jumpers in order to select sensor type as well as elevation and suppression. These are finely adjusted using potentiometers. To get square root extraction it is necessary to change the

circuit board. Smart and fieldbus transmitters can be parameterized from a handheld tool or by the use of software by keying in the desired sensor type, range, transfer function, etc.

Because the sensor and input circuitry errors are absolute, the percentage error gets worse as the span is reduced. This limits the transmitter's turndown, particularly those that use low-resolution A/D converters. Most smart transmitters maintain their nominal accuracy even if their span is turned down by a ratio of 10:1. When the spans are reduced further (greater turndown), the accuracy becomes progressively worse.

Unfortunately, many transmitter manufacturers do not state this clearly, but it is always the case. Therefore, transmitters should be specified by stating their minimum and maximum span requirement and the maximum allowable error limit (inaccuracy), in units of percent of span, which must hold anywhere within that range. The minimum span limit prevents the inadvertent setting of an excessively small span, resulting in gross errors. Some transmitters may permit turndowns as high as 400:1, but the corresponding error can become very high.

Perhaps the most important setting for a smart transmitter is its range, i.e., the process variable measurements corresponding to the outputs of 4 and 20 mA (0 and 100% of scale). The range can be set remotely without requiring an input just by keying in the desired range value (Figure 3.10h). While this is possible, it is not always desirable. In case of level loops, for example, it might be desirable to "zero" the transmitter by bringing the actual process level to an elevation that should be treated as zero and use the corresponding transmitter output as the "zero" for the loop. The HART protocol supports both methods of setting the range, which should not be confused with calibration trim.

Because fieldbus communicates the measured process variable values in engineering units, it is often not necessary to set a range in the transmitter. When the transmitter measures 5080 mmH_2O, it can transmit that value. On the other hand, range needs to be set in the transmitter for inferential measurement applications, such as when using a differential pressure transmitter on an orifice-type flow element (Figure 3.10i).

For fieldbus, instead of setting the range in the transmitter, it is often set in the controller by adjusting a scale in the PID control function block.

Integration into DCS and PLC Systems

Smart and fieldbus transmitters provide new capabilities but also place new requirements on the control system software and networks. Most DCS and PLC systems that are in use today were designed when analog transmitters with single outputs were used. Today, there is a tremendous increase in diagnostic and other data, which the existing control system networks and software are not able to manage.

Smart transmitters can be connected into traditional DCS and PLC systems or to single station controllers by

their 4- to 20-mA output signals, in which case they are configured by handheld tools. However, in order to fully benefit from smart instruments, the communication channels must be "always on," meaning a permanent HART communication connection. This can either be achieved by using a separate multiplexer, which is a gateway, in parallel with the analog I/O-subsystem that communicates with the smart transmitters and links to the host computers, which are using a faster protocol and media such as Modbus or Profibus. A neater alternative is a system where HART communication is built into the AI module.

Fieldbus is a system architecture in itself, complete with field-level networking (H1) and host-level networking (HSE), as well as a graphical function block programming language to build the control strategy. Fieldbus transmitters sit on the H1 network that connects to the HSE network through standard linking devices. However, some systems still use a proprietary host-level network and controllers and connect to H1 fieldbus through interface modules.

Although many controller and system manufacturers also make transmitters, none of them make all the different kinds of transmitters used in the processing industries, and none of them are best in all categories. Therefore, there is always a need to mix and match transmitters from different suppliers in the overall control system.

When equipment from different suppliers is combined, interoperability becomes an issue. It should not be confused with interchangeability. Interoperability is the ability of different equipment to work together, allowing a single configuration tool to be used for all brands of transmitters. Control loop integration when using smart transmitters is easy because smart transmitters use the universally accepted, but functionally limited, 4- to 20-mA signal.

Building Control Loops

The FOUNDATION fieldbus technology includes not only a communication protocol but also a graphical programming language for building control strategies. This language is based on function blocks and includes an AI block, which is the principal block in a transmitter. Since many function blocks are standardized, especially in terms of their input and output parameters as well as the way they are linked and executed, a fieldbus transmitter can easily operate in a control loop with devices from other manufacturers.

For a fieldbus configuration tool to interact with a fieldbus transmitter, it is necessary for the standard Device Description (DD) and capabilities files to have been loaded. These files are provided by the transmitter manufacturer and contain all the information the host software requires in order to access all the features and capabilities the transmitter manufacturer has put into the transmitter and arranged logically to reflect typical use of the instrument.

However, some systems do require additional proprietary files for each device type, but in these cases, they must be obtained from the systems manufacturer and may not support all kinds of devices. Because fieldbus devices are very sophisticated and extremely rich in features, there is essentially no way a configuration tool can work in a meaningful way without the DD files.

HART also uses DD, and it is implemented in universal handhelds that can be used to fully configure any HART transmitter. However, HART functionality is divided into groups of commands. Universal commands are supported by all HART devices, and most support common practice commands. Therefore a handheld tool and PC software or even a smart calibrator can access many functions in a HART transmitter even without using DD.

J. A. GUMP (1972, 1985) **B. G. LIPTÁK** (1995, 2005)
E. M. MARSZAL (2005)

Types:

A. Audiovisual Annunciators: integral, remote, and semigraphic systems with audible and visual display and electromechanical (relay) or solid-state (semiconductor) designs
B. Recording Annunciators: integral, solid-state systems with recorded printout
C. Bargraphs
D. Vocal Annunciators: integral, solid-state systems with audible command message

Cost per Alarm Point:

Integral cabinet costs $75 to $175; remote system, $125 to $250; semigraphic system, $125 to $250; recording annunciator or annunciator with communications will add about 30% to the cost per point. These figures are budgetary in nature (± 20%), and a number of variables can affect the price. These factors include system size, window size, number of alarm points per board, field contact voltages, type of lamp, communications options, and required certifications (e.g., Class I, Div. 2, etc.).

In addition to this section, safety alarm systems are discussed in several other parts of this handbook, particularly in connection with DCS and CRT systems in Chapter 4 and PLCs in Chapter 5. The subject of process alarm management is separately covered in Section 1.6. This section concentrates on dedicated, conventional annunciators and other alarm devices.

INTRODUCTION

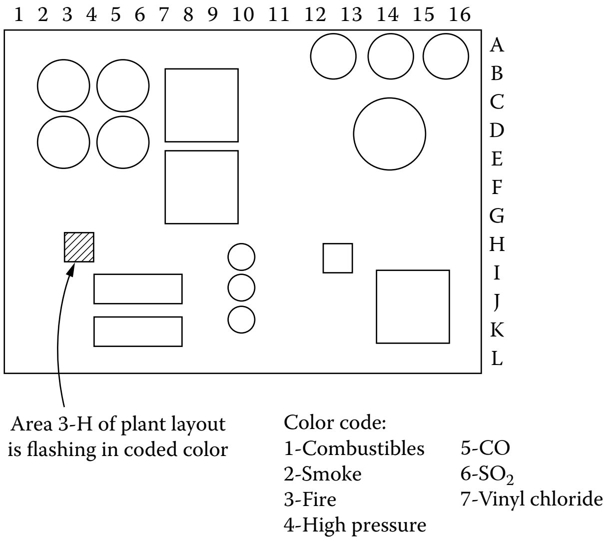
The purpose of an alarm system (annunciator) is to bring attention to an abnormal or unsafe operating condition in the plant. Traditional annunciators used discrete alarm modules for this purpose. These dedicated hardware units are diminishing in numbers yet are still used in installations where simplicity is desired or where separation from the basic process control system is required for safety reasons.

In some installations where traditional units have been replaced by PLC- or DCS-based annunciators, the recognition of and response to alarm conditions have deteriorated because on computer screens they are not very visible and can go unnoticed. In addition, because of the low incremental cost of adding new alarm points, excessive numbers of alarms been configured. Because of the floods of alarms, an important new component of safety system design is alarm rationalization and alarm management (Section 1.6).

It is possible to connect conventional annunciators as front-end devices to DCS systems through various communication links. There is a wide variety of such links available, ranging from serial links employing MODBUS protocol to Ethernet links utilizing Object Linking and Embedding (OLE) for Process Control (OPC). This hybrid solution adds the visibility, reliability, and built-in redundancy of dedicated annunciators to the flexibility and record-keeping convenience of DCS-based systems.

More sophisticated annunciator designs can incorporate bargraph-type displays, color computer graphics, and event-recording or data-logging systems. Much of the new development in annunciator system designs involves enhanced methods of communication and reporting. As a consequence, annunciator status can be logged and used for tasks such as alarm management and abnormal event analysis.

Graphic displays can be dynamic, where flow in pipes is shown by actual movement, and CRT displays can concentrate large amounts of information into a single display. Figure 4.1a illustrates such a display, where the CRT displays



Area 3-H of plant layout is flashing in coded color

FIG. 4.1a
The overall safety status of the plant can be displayed on a single CRT.

the plot plan of the plant as the background. Such a plot plan can be separated into small square segments, so that if an unsafe condition is detected in a particular segment, the corresponding square can start flashing in the color that corresponds to the type of safety problem detected. This type of annunciator display is easily and quickly comprehended and can provide a summary report on a large number of safety conditions in an efficient manner.

HISTORY

The term "drop" was initially applied to individual annunciator points, from which we may infer that annunciator systems developed from paging systems of the type used in hospitals and from call systems used in business establishments to summon individuals when their services are needed. These systems consisted of solenoid-operated nameplates that dropped when deenergized. The drops were grouped at a central location and were energized by pressing an electrical pushbutton in the location requiring service. The system also included an audible signal to sound the alert.

Similar systems were used for fire and burglar alarms. The drops were operated either by manual switches or by trouble contacts that monitored thermal and security conditions in various building locations. The use of these systems in the chemical processing industry was a logical development when alarm switches became available.

This development, however, was preceded by explosion-proof, single-station annunciators that were designed to operate in the petroleum and organic chemical process plants constructed immediately before, during, and after World War II. They were usually installed on control panels located either outdoors near the process unit or in local control houses. A drop-type system could not be used in these locations because they were electrically hazardous.

By the late 1940s, centralized control rooms were introduced. Drop-type annunciators were suited for these general-purpose central control rooms. However, more compact, reliable, and flexible annunciators were subsequently introduced.

In the early 1950s, the plug-in relay annunciator was developed. Instead of utilizing solenoid-operated drops, it used electrical annunciator circuits with small telephone-type relays to operate alarm lights and to sound a horn when abnormal conditions occurred. The alarm lights installed in the front of the annunciator cabinets were either the bull's-eye type or backlighted nameplate designs.

The annunciators were compact, reliable, and because of the hermetically sealed relay logic modules, they could also be mounted in certain hazardous areas in addition to the general-purpose control rooms. In order to be mounted in Class 1 explosion-proof areas, they required purging (Figure 4.1b). Miniaturization of instruments and the use of graphic control panels initiated the development of remote annunciator systems, consisting of a remotely mounted relay cabinet connected to alarm lights installed at appropriate points in the graphic or semigraphic diagram.

Solid-state annunciator systems with semiconductor logic modules were developed in the late 1950s. These permitted additional miniaturization and lowered both the operating power requirements and the amount of heat generated. The semigraphic annunciator was introduced in the late 1960s and fully utilized the high-density capabilities of solid-state logic. It has permitted the designs of very compact and flexible semigraphic displays in control centers.

With the spread of digital communication networks and microprocessor-based smart instruments, the number of alarm points increased, their management as a function of importance (Section 1.6) became a separate field, and their displays were further miniaturized. These days, with the greater availability and reliability of integrated circuit logic components, alarms can be displayed on handheld tools in the field, on computer screens at workstations, or on CRTs in DCS systems.

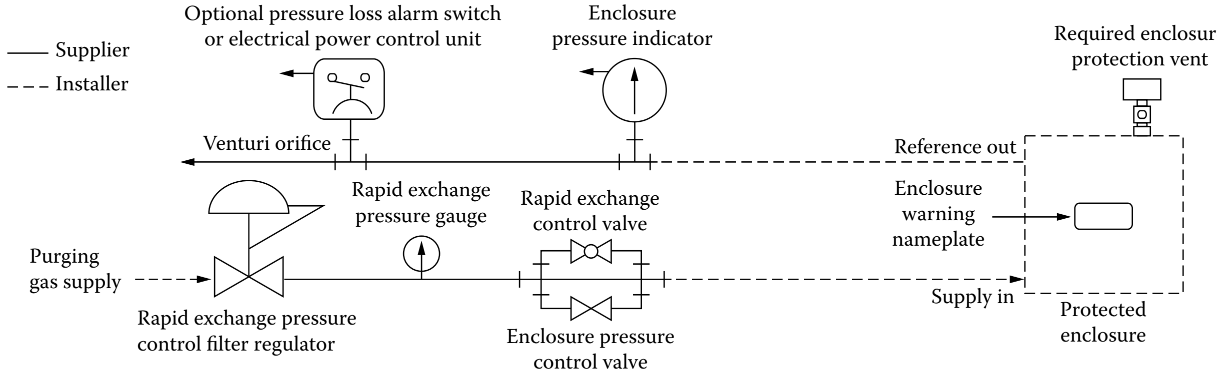


FIG. 4.1b
Local annunciators were available in explosion-proof designs or were mounted in air-purged enclosures when mounted in Class 1 areas. (Courtesy of Bebco Industries.)

PRINCIPLES OF OPERATION

The annunciator system consists of multiple alarm points. Each alarm circuit includes a trouble contact (alarm switch), a logic module, and a visual indicator (Figure 4.1c). The individual alarm points are operated from a common power supply and share a number of annunciator system components, including an audible signal generator (horn), a flasher, and acknowledge and test pushbuttons. In normal operation the annunciator system and individual alarm points are quiescent.

The trouble contact is an alarm switch that monitors a particular process variable and is actuated when the variable exceeds preset limits. In electrical annunciator systems it is normally a switch contact that closes (makes) or opens (breaks) the electrical circuit to the logic module and thereby initiates the alarm condition. In the alert state, the annunciator turns on the visual indicator of the particular alarm point, the audible signal, and the flasher for the system. The visual indicator is usually a backlighted nameplate engraved with an inscription to identify the variable and the abnormal condition, but it can also be a bull's-eye light with a nameplate. The audible signal can be a horn, a buzzer, or a bell.

The flasher is common to all individual alarm points and interrupts the circuit to the visual indicator as that point goes into the alert condition. This causes the light to continue to flash intermittently until either the abnormal condition returns to normal or is acknowledged by the operator.

The horn acknowledgment pushbutton is provided with a momentary contact: when it is operated, it changes the logic module circuit to silence the audible signal, stop the flasher, and turn the visual indicator on "steady." When the abnormal condition is corrected, the trouble contact returns to normal, and the visual indicator is automatically turned off.

The lamp test pushbutton with its momentary contact tests for burned-out lamps in the visual indicators. When activated, the pushbutton closes a common circuit (bus) to each visual indicator in the annunciator system, turning on those lamps that are not already on as result of an abnormal operating condition.

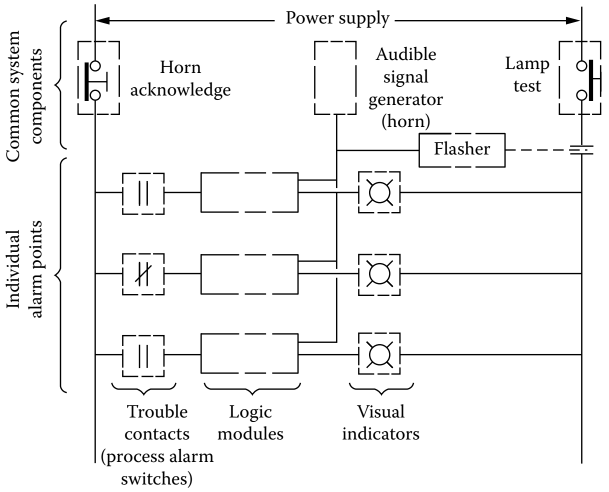

FIG. 4.1c
The main components of a traditional annunciator system.

Operating Sequences

A wide variety of sequences are available to define the operation of an individual alarm point in the normal, alert, acknowledged, and return-to-normal stages in the annunciator sequence. The five most commonly used annunciator sequences are shown in Table 4.1d, identified by the original code designation of the Instrumentation, Systems, and Automation Society (ISA). These sequences were specified by the ISA-recommended practice RP-18.1, which has since been revised and updated into standard ISA 18.1.

Because the old sequence designations are still used in some plants, some of their more common versions are listed in Table 4.1d and also described below. The sequence designations of the present standard ISA 18.1 will also be discussed below.

The Old ISA Sequence Designations ISA Sequence 1B, also referred to as flashing sequence A, is the one most frequently used. The alert condition of an alarm point results in a flashing visual indication and an audible signal. The visual indication turns off automatically when the monitored process variable returns to normal.

ISA Sequence 1D (often referred to as a dim sequence) is identical to Sequence 1B except that ordinarily the visual indicator is dim rather than off. A dimmer unit, common to the system, is required. Because all visual indicators are always turned on—for dim (normal), flashing (alert), or steady (acknowledged)—the feature for detecting lamp failure is unnecessary.

ISA Sequence 2A (commonly referred to as a ring-back sequence) differs from Sequence 1B in that following acknowledgment the return-to-normal condition produces a dim flashing and an audible signal. An additional momentary contact reset pushbutton is required for this sequence. Pushing the reset button after the monitored variable has returned to normal turns off the dim flashing light and silences the audible signal. This sequence is applied when the operator must know if normal operating conditions have been restored.

ISA Sequence 2C is like Sequence 1B except that the system must be reset manually after operation has returned to normal in order to turn off the visual indicator. This sequence is also referred to as a manual reset sequence and, like Sequence 2A, requires an additional momentary contact reset pushbutton. Sequence 2C is used when it is desirable to keep the visual indicator on (after the horn has been silenced by the acknowledgment pushbutton) even though the trouble contact has returned to normal.

ISA Sequence 4A, also known as the first-out sequence, is designed to identify the first of a number of interrelated

TABLE 4.1d
The Old ISA Designations of Annunciator Sequences

ISA Code for the Sequence	*Annunciator Condition*	*Process Variable Condition (Trouble Contact)*	*Visual Indicator*	*Audible Signal*	*Use Frequency*
IB	Normal	Normal	Off	Off	55%
	Alert	Abnormal	Flashing	On	
	Acknowledged	Abnormal	On	Off	
	Normal again	Normal	Off	Off	
	Test	Normal	On	Off	
ID	Normal	Normal	Dim	Off	1%
	Alert	Abnormal	Flashing	On	
	Acknowledged	Abnormal	On	Off	
	Normal again	Normal	Dim	Off	
2A	Normal	Normal	Off	Off	4%
	Alert	Abnormal	Flashing	On	
	Acknowledged	Abnormal	On	Off	
	Return to normal	Normal	Dim flashing	On	
	Reset	Normal	Off	Off	
	Test	Normal	On	Off	
2C	Normal	Normal	Off	Off	5%
	Alert	Abnormal	Flashing	On	
	Acknowledged	Abnormal	On	Off	
	Return to normal	Normal	On	Off	
	Reset	Normal	Off	Off

4A	Normal	Normal	Off	Off	28%
	Alert	Abnormal			
	Initial		Flashing	On	
	Subsequent		On	Off	
	Acknowledged	Abnormal			
	Initial		On	Off	
	Subsequent		On	Off	
	Normal again	Normal	Off	Off	
	Test	Normal	On	Off	
All others					7%

variables that have exceeded normal operating limits. An off-normal condition in any one of a group of process variables will cause some or all of the remaining conditions in the group to become abnormal. The first alarm causes flashing, and all subsequent points in the group turn on the steady light only. This sequence monitors interrelated variables. The visual indication is turned off automatically when conditions return to normal after acknowledgment.

The New ISA Sequence Designations In the updated annunciator standard ISA 18.1, the sequence designations are different, as shown in Table 4.1e. The most widely used sequence, the basic flashing sequence, is now designated as sequence A. The sequence designations in ISA 18.1 use the following letter codes:

A = Automatic Reset
M = Manual Reset
R = Ringback
F = First-out

Therefore, using the ISA 18.1 sequence designations A-13 means that the annunciator has automatic reset and is provided with Option 13, which suggests the presence of a dim lamp monitor. For definitions of less frequently used sequences, refer to ISA 18.1.

TABLE 4.1e

The New ISA Designations of Annunciator Sequences as Defined by ISA Standard ISA 18.1

Sequence	*Signal Device*	*Normal*	*Alert*	*Condition-sensing Returns to Normal Before Acknowledge*	*Acknowledge*	*Condition-sensing Returns to Normal*	*Return to Normal Reset*	*Remarks*
A	Visual	Off	Flash	Flash	On	Off	—	Flasher memory
	Audible	Off	On	On	Off	Off	—	
A-5	Visual	Off	On	On	On	Off	—	Memory
	Audible	Off	On	On	Off	Off	—	
A-4	Visual	Off	Flash	Off	On	Off	—	Flasher
	Audible	Off	On	Off	Off	Off	—	
A-4-5	Visual	Off	On	Off	On	Off	—	
	Audible	Off	On	Off	Off	Off	—	
A-13	Visual	Dim	Flash	Flash	On	Dim	—	Memory—flasher
	Audible	Off	On	On	Off	Off	—	Continuous lamp test

Optional Operating Features Annunciator sequences may be initiated by alarm switch trouble contacts that are either open or closed during normal operations. These are referred to as normally open (NO) and normally closed (NC) sequences, respectively, and the ability to use the same logic module for either type of trouble contact is called an *NO-NC option.* It is important because some alarm switches are available with either an NO or an NC contact but not with both, and therefore without the NO-NC option in the logic module two types of logic modules would be required. The logic module is converted for use with either form of contact by a switch or wire jumper connection.

The relationship between the NO and NC sequences required in the logic module to match the various trouble contacts and analog measurement signal actions is shown in Figure 4.1f. A high alarm in a normally closed annunciator system requires a normally closed trouble contact operated by a direct-acting analog input.

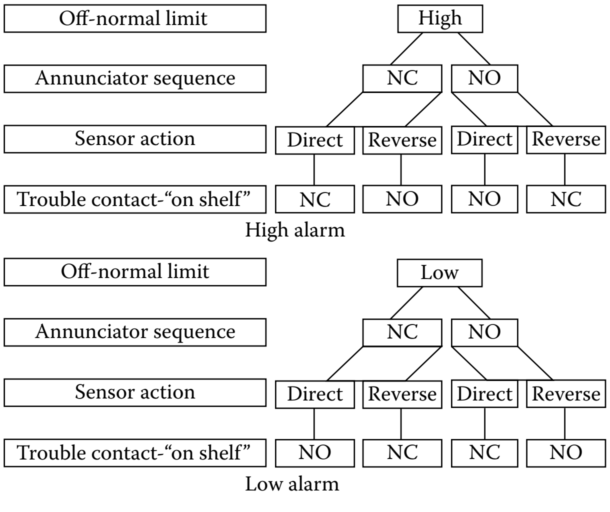

FIG. 4.1f

Logic trees for the NO and NC annunciator sequences.

If an increase in the measured variable results in an increased output signal, the detector is direct acting; if the output signal is reduced, it is a reverse-acting sensor. If the trouble contacts in all alarm switches in the plant are standardized such that normal operating conditions will cause all trouble contacts to be NC (or NO), the required annunciator sequence is also NC (or NO), and Figure 3.1f need not be consulted.

Annunciator systems are fail safe or self-policing if they initiate an alarm when the logic module fails because of relay coil burnout. The feature is standard for most NO and NC annunciator sequences; annunciators using NC trouble contacts are also fail safe against failures in the trouble contact circuit.

The lock-in option locks in the alert condition initiated by a momentary alarm until the horn acknowledgment button is pushed, preventing loss of a transient alarm condition until the operator can identify it. The logic module is usually changed from lock-in to non-lock-in operation by either addition of a wire jumper or operation of a switch. The lock-in feature is useful for monitoring unstable or fluctuating process variables.

Test and Repeater Features The test feature in a standard annunciator serves only to test for burned-out lamps in the visual indicators. The operational test feature provides a test of the complete annunciator system, including logic modules, lamps, flasher, audible signal, and acknowledgment circuits. The operational test circuit usually requires an additional momentary contact pushbutton, which can replace the regular lamp test pushbutton.

The logic module of relay-type annunciators may have spare (electrically isolated) auxiliary contacts that can operate shutdown and interlock systems when alarm conditions occur. The auxiliary contacts are wired to terminal blocks in the annunciator cabinet for connection to external circuitry.

Repeater lights may be located away from the common logic module and serve to alert operators in other areas. Annunciator cabinet terminals for connecting these repeater lights in parallel with the annunciator visual indicator are available.

It may also be desirable to actuate a horn in more than one location. The electrical load of multiple audible signals requires an interposing relay, called a horn-isolating relay, operated by the logic modules. This relay has contacts of adequate capacity to operate multiple audible signals. Horn-isolating relays may be installed either in the annunciator cabinet or in a separate assembly.

Annunciator systems can be used for several operational sequences without changing system wiring, and many logic modules can supply more than one operational sequence. This multiple sequence capability is sometimes useful when the sequence has not yet been determined.

ANNUNCIATOR TYPES

The audiovisual annunciator can be packaged as an integral, remote, or semigraphic annunciator.

Integral Annunciator

The integral annunciator, a cabinet containing a group of individual annunciator points wired to terminal blocks for connection to external trouble contacts, power supply, horn and acknowledge and test pushbuttons, is the most economical of the various packaging methods available in terms of cost per point. It is also the simplest and cheapest to install.

Two methods of packaging integral annunciators are illustrated in Figure 4.1g. In the nonmodular type, plug-in logic modules are installed inside the cabinet and connected to alarm windows on the cabinet door through an interconnecting wiring harness; in the modular type, individual plug-in alarm point assemblies of logic module and visual indicator are grouped together.

The nonmodular and modular cabinet styles are both designed for flush panel mounting with the logic modules and visual indicators accessible from the front. Electrical terminals for the external circuitry are located in the rear of the cabinet and are accessible from the back.

Integral annunciators are used on nongraphic and on semigraphic control panels in which physical association of the visual indicators with a specific location in the graphic

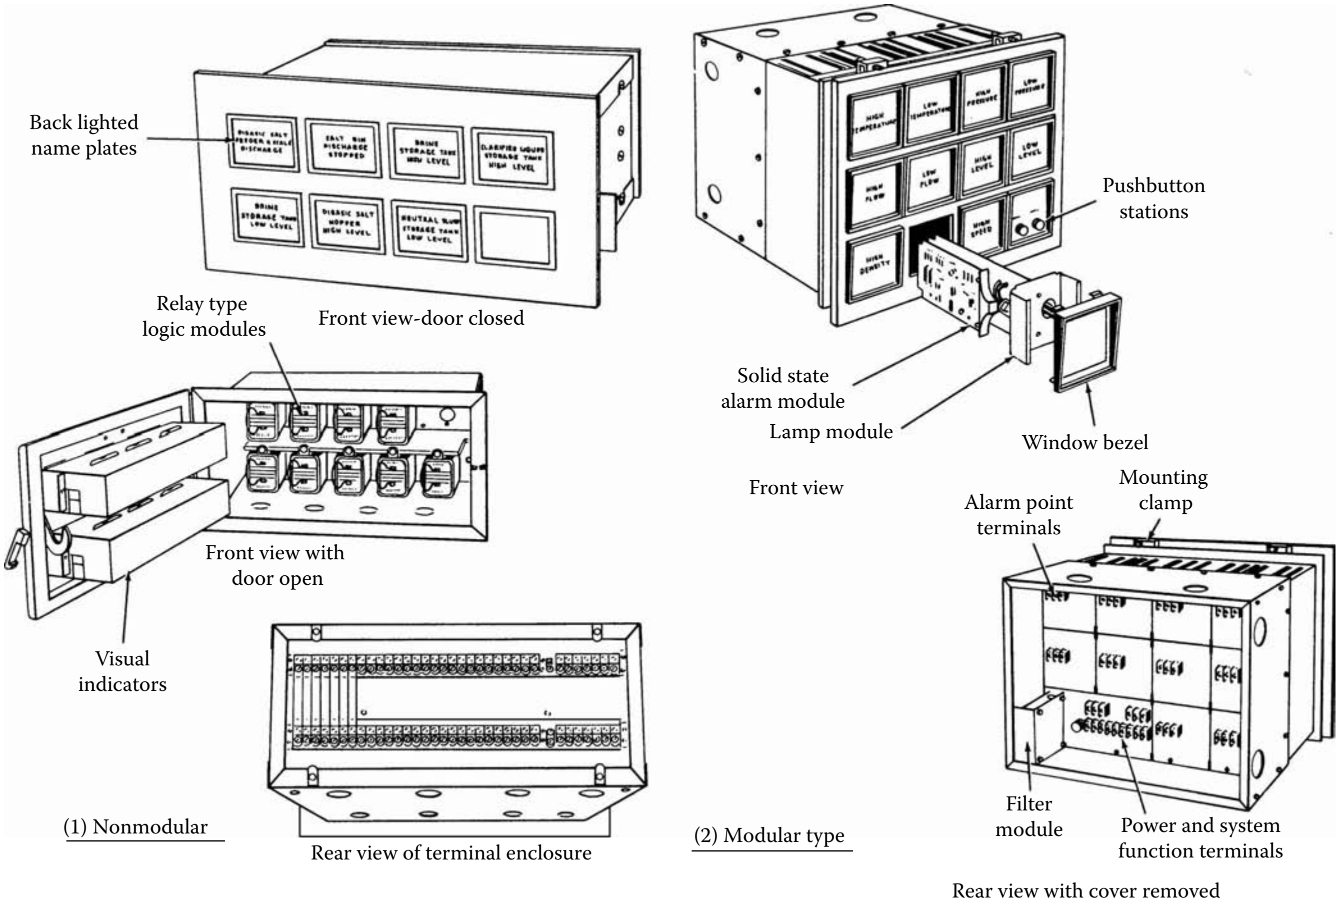

FIG. 4.1g
Integral annunciator cabinets are available in modular (right) and nonmodular (left) construction.

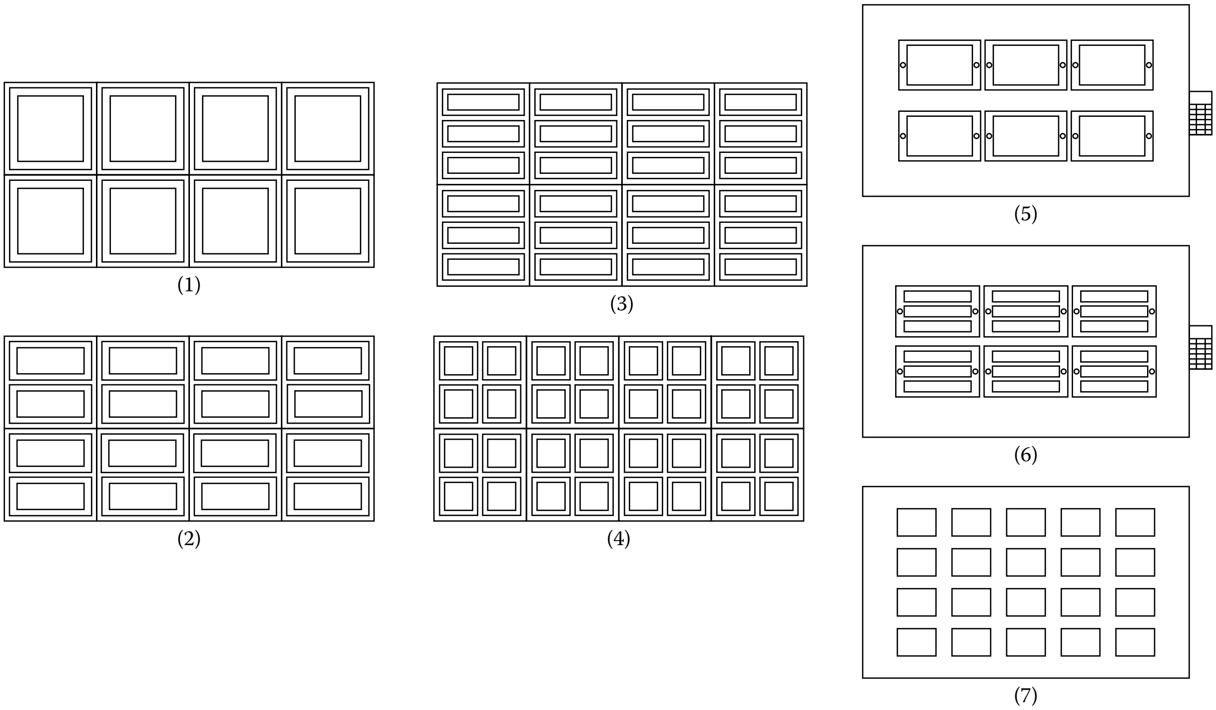

FIG. 4.1h
Integral annunciator window configurations. 1. Modular single-point annunciator. 2. Modular double-point annunciator. 3. Modular triple-point annunciator. 4. Modular quadruple-point annunciator. 5. Nonmodular single-point. 6. Nonmodular triple-point. 7. Nonmodular single-point with small nameplate.

process flow diagram is not required. Integral annunciator cabinets occupy more front but less rear panel space than the equivalent remote designs. The electrical terminals are in a general-purpose enclosure at the rear of the cabinet, and trouble contacts can be wired directly to them, thus eliminating the need for and resultant costs of intermediate terminal blocks for trouble contact wiring.

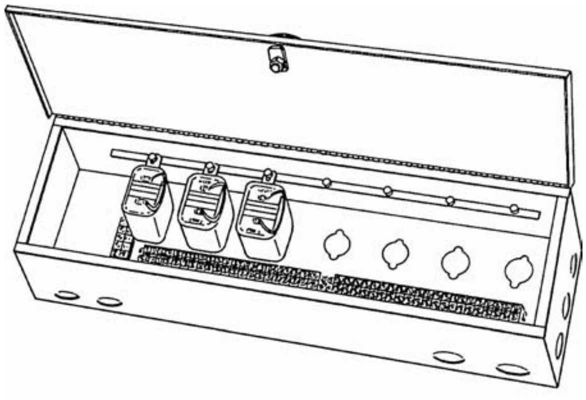
An advantage of the modular-type cabinet is that it can be expanded by enlargement of the panel cutout and by the addition of modular alarm point assemblies. Nonmodular cabinets cannot be expanded, and new cabinets must be installed to house additional alarm points. Consequently, one should include more spare points when specifying the cabinet size for a nonmodular system. The modular cabinet is also more compact, takes up less panel space, and has a greater visual display area per point than the nonmodular design.

Figure 4.1h illustrates various configurations of visual indicators that can be supplied with integral annunciator cabinets. Many of these groupings are also available in single-unit assemblies for remote annunciator systems.

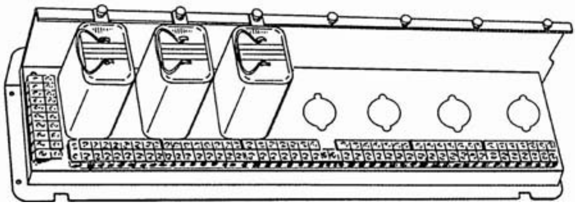
Remote Annunciator

The remote annunciator differs from the integral annunciator in that the visual indicators are remote from the cabinet or chassis containing the logic modules. Remote annunciators were developed to allow the visual indicators to be placed in their actual process location in the graphic flow diagram.

They are used with full and semigraphic control panels and in nongraphic applications in which an integral annunciator cabinet may require too much front panel space. Figure 4.1i



(1) Chassis with general purpose enclosure



(2) Chassis

FIG. 4.1i
General purpose, remote annunciator cabinets.

illustrates a remote annunciator chassis with optional cabinet enclosure. The chassis contains spare positions for plug-in logic modules and a system flasher. Auxiliary system modules, such as horn-isolating relays, may also be plugged into the logic module chassis positions.

The chassis and cabinet enclosure are designed for wall or surface mounting behind the control panel. Each chassis position has terminal points for connecting the visual indicator and trouble contact. In addition, the chassis has a system terminal block for connecting electrical power, horn, flasher, and acknowledge and test pushbuttons.

The disadvantages of remote annunciators include higher equipment and installation costs and an increased requirement for back panel space. In addition, the wiring connections from field trouble contacts must be made to intermediate terminal blocks rather than directly to the cabinet terminals, as with the integral annunciator.

These terminal blocks, the terminal enclosure, and the required wiring result in higher installation costs and extra space requirements. Finally, the remote annunciator is difficult to change, and modification costs of remote systems are substantially higher than those of the integral type, partially because spare visual indicators cannot be installed initially.

Semigraphic Annunciator

The semigraphic annunciator developed in the late 1960s combines some of the advantages of the integral annunciator with the flexibility to locate visual indicators at appropriate points in a graphic flow diagram. Figure 4.1j illustrates a semigraphic annunciator.

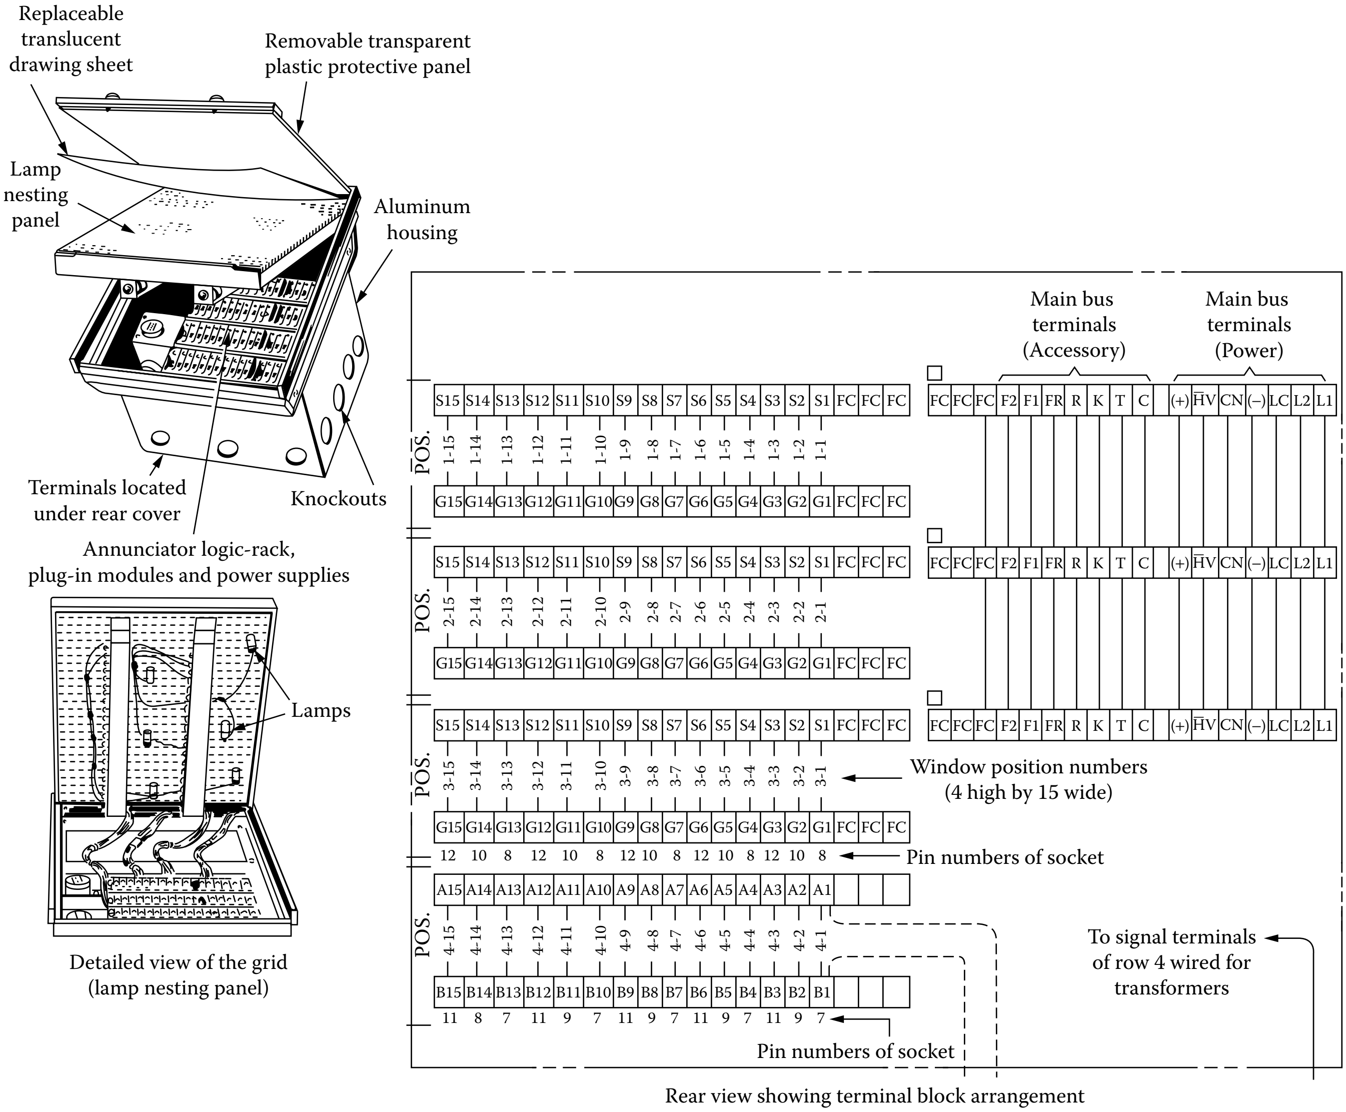


FIG. 4.1j
Construction of a typical semigraphic annunciator, showing the plug-in modules,the lamp nesting panel, and the arrangement of the terminal blocks on the rear of the unit.

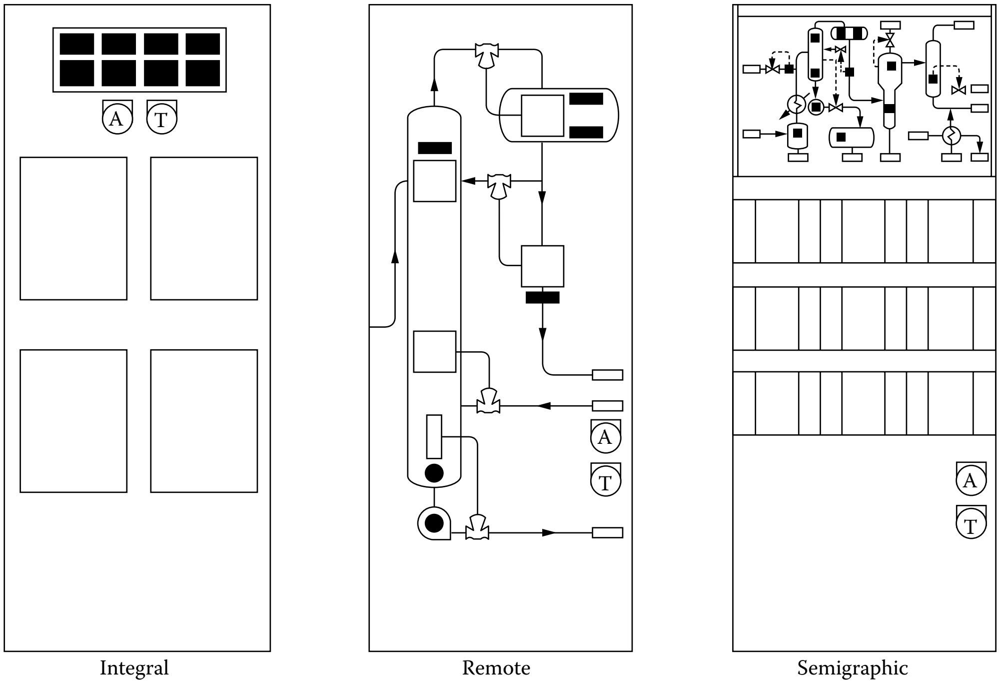

FIG. 4.1k
Control panels with integral, remote, and semigraphic annunciators.

It consists of a cabinet containing annunciator logic modules wired to visual indicators placed in a 3/4-inch (18.75-mm) lamp insertion matrix grid forming the cabinet front. The semigraphic display is placed between the lamp grid and a transparent protective cover plate, and the visual indicators are positioned to backlight alarm name plates located in the graphic display.

The protective cover and lamp grid are either hinged or removable to provide access to the logic module and lamp assemblies. The lamp assemblies are connected to intermediate terminals located behind the lamp grid, and the terminals in turn are connected to the logic modules. Terminal points for trouble contact wiring are in the back of the cabinet.

The semigraphic annunciator is flexible, and changes in the annunciator system, graphic display, and related panel modifications can be made easily and cheaply. It is practical to prepare the graphic displays in the drafting room or model shop, thus protecting proprietary process information of a confidential nature.

The graphic display has little or no effect on completing either the annunciator or the control panel because it can be installed on site or at any time. The semigraphic annunciator has a high density of 40 alarm points per linear foot (0.3 m) and a solid-state rather than relay-type logic design. Power supplies are self-contained in the semigraphic annunciator cabinet.

Front panel layouts illustrating integral, remote, and semigraphic annunciators are shown in Figure 4.1k. Integral systems similar to the one shown at the left in the figure are normally specified on nongraphic control panels. The graphic panel in the center contains a remote annunciator with backlighted nameplates (shaded rectangles) and pilot lights (shaded circles) for visual indication. The remote system may also be used with miniature lamps in a semigraphic display similar to the one shown at the right.

Recording Annunciators

Solid-state, high-speed, recording annunciators are available to amend or substitute a printed record of abnormal events for only visual and/or audible alarms. These systems print out a record of the events and identify the variable, the time at which the alarm occurs, and the time at which the system returns to normal. They can also discriminate among a number of almost simultaneous events and print them out in the time sequence in which they occurred. A number of optional features, including secondary printers at remote locations, supplementary visual indication, and computer interfacing, are also available. The typical unit consists of logic, control, and printer sections.

The input status is continuously scanned. If a change in the trouble contacts has occurred since the preceding scan cycle, the central control places the exact time, the alarm point identification, and the new status of the trouble contact (normal or abnormal) into the memory and initiates the operation of the output control unit (Figure 4.1l).

The output control unit accepts the stored information and transfers it to the printer, which logs the event. Following this, the memory is automatically cleared of the data and is ready to accept new information. In addition to or in place of the printer (if a permanent record is not required), a CRT display can serve as the event readout. Trouble contacts are

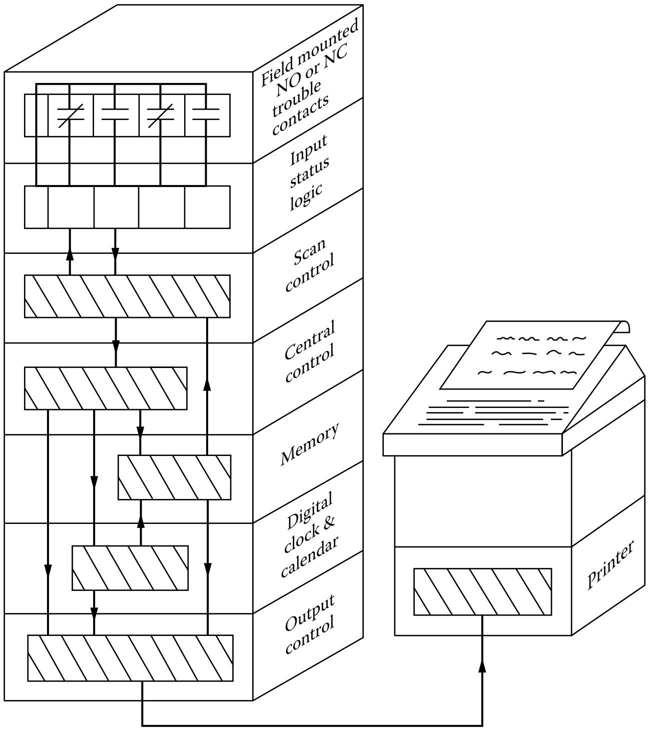

FIG. 4.1l
Functional block diagram of a digital, recording annunciator with its printer, which can be replaced by a CRT.

connected to terminal points in the logic cabinet, and a cable connects the cabinet and the printer.

A recording annunciator can perform more sophisticated monitoring than an audiovisual annunciator and is correspondingly more expensive on a per-point basis. System cost per point decreases as the system size increases. Higher equipment cost, however, is offset in part by savings in control panel space and in installation costs. Recording annunciators are frequently used by the electrical power generating industry but may be applied to advantage in any industrial process that must monitor large numbers of operating variables and analyze abnormal events efficiently.

Vocal Annunciators

Vocal annunciators are unique in the type of abnormal audible message they produce. The audible output is a verbal message identifying and describing the abnormal condition when it occurs and repeating the message until the operator acknowledges the difficulty. The system continuously scans the trouble contacts, and when an abnormality is found, it turns on a flashing visual indicator and selects the optional proper verbal message for broadcast.

The visual indicator is turned off by the system when the point returns to normal. The control unit also arranges the messages to be broadcast in the order in which the difficulties occur. In the event of multiple alarms, the second message is played only after the first has been acknowledged. The flashing visual indicator for each point, however, turns on when the point becomes abnormal. The verbal message may be broadcast simultaneously in the control room and related operating areas, thus permitting personnel at the operating unit to correct the problem immediately.

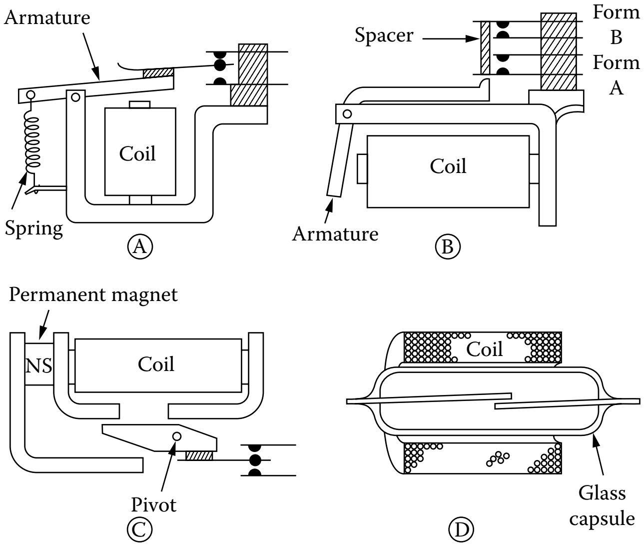

FIG. 4.1m
Standard electro-mechanical relay structures include: A) the clapper-type, B) the phone-type, C) the balanced-force, and D) the Reed relay.

Relay-Type Annunciators

The basic element of this annunciator is an electrical relay wired to provide the logic functions required to operate a particular sequence. Figure 4.1m illustrates some of the basic relay designs.

At least two relays per logic module are necessary for most sequences. The relays are installed and wired in a plug-in assembly, which is the logic module for a single alarm point. The plug-in module assembly is usually hermetically sealed in an inert atmosphere to prolong the life of the relay contact. The sealing also makes the logic module acceptable in certain hazardous electrical areas.

Figure 4.1n is a semischematic electrical circuit for a remote system with sequence operation according to old ISA Sequence 1B (new Sequence A): Two logic modules are shown; one is in normally closed operation and the other is in normally open operation. The remote visual indicators for each alarm point, the horn, the flasher, and the acknowledge and test pushbuttons common to the system are also shown. Each logic module has two relays, A and B, shown in their deenergized state according to normal electrical convention. The operation of these circuits during the various stages of sequence operation is as follows:

Normal The trouble contact of the NC alarm point is wired in series with the A relay coil at point terminals H and NC. In the normal condition, the trouble contact is closed, relays

Operational sequence

Condition	Trouble contact	Signal lamps	Audible signal	"A" relay	"B" relay
Normal	Normal	Off	Off	Energized	Energized
Alert	Abnormal	Flashing	On	Deenergized	Energized
Audible silenced (acknowledged)	Abnormal	Steady–on	Off	Deenergized	Deenergized
Normal again	Normal	Off	Off	Energized	Energized
Lamp test	Normal	Steady–on	Off	Energized	Energized

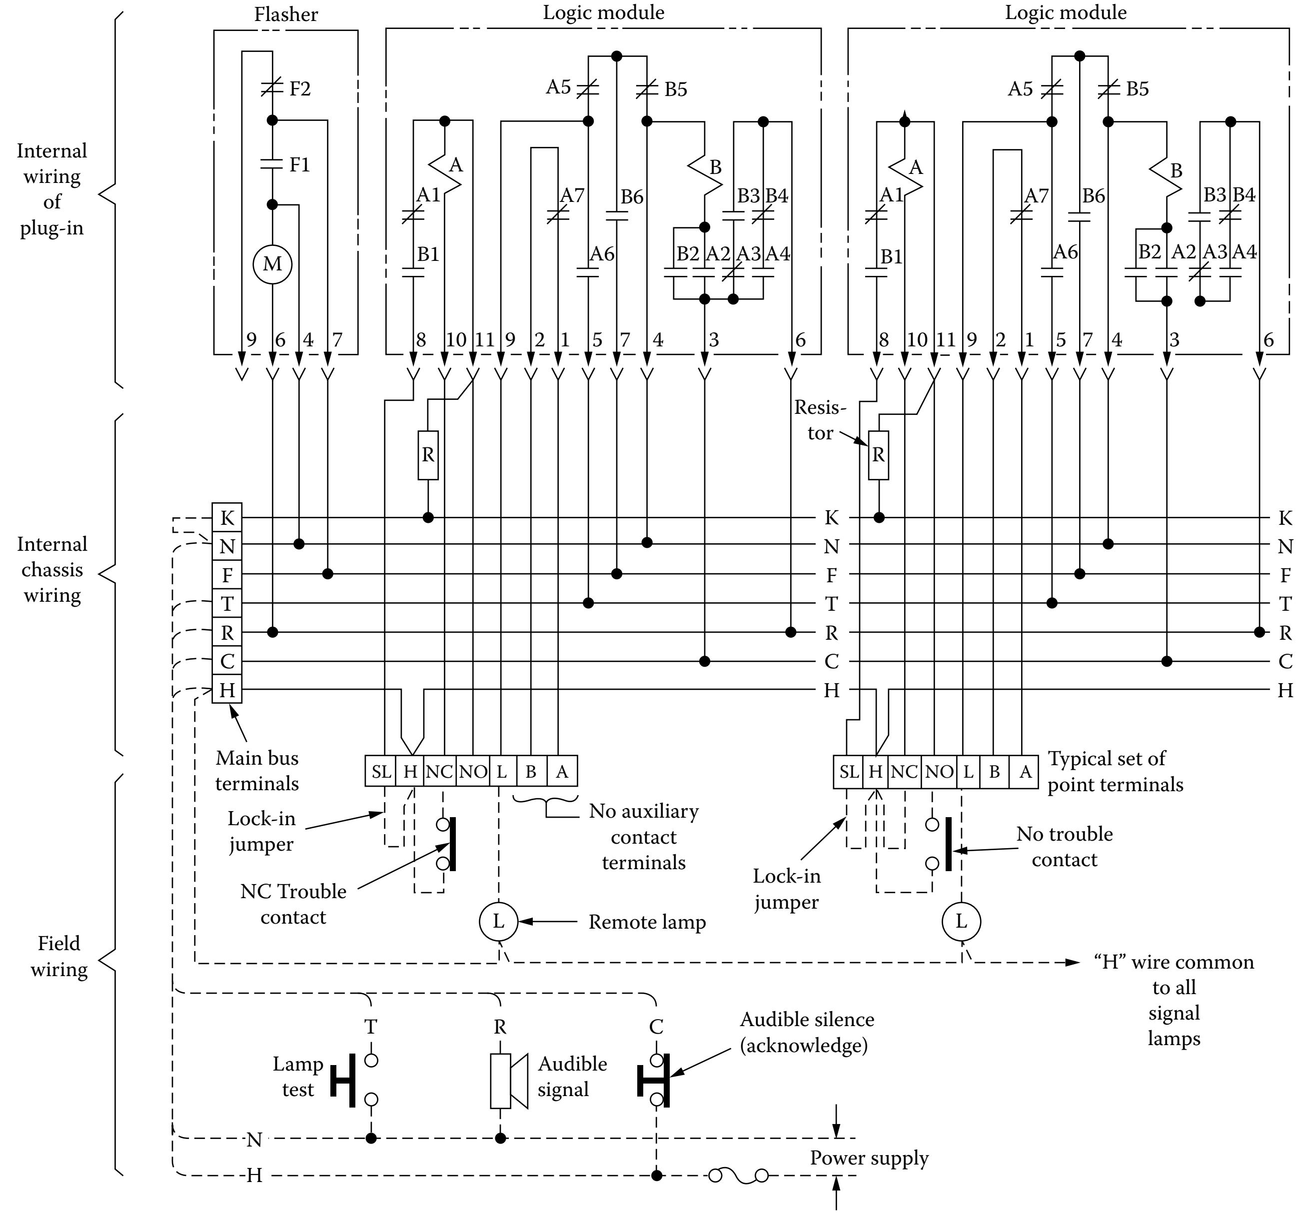

FIG. 4.1n
Semischematic diagram of a relay-type annunciator designed for ISA new sequence A (old sequence 1B), which sequences are described in Tables 4.1d and 4.1e.

A and B are energized, and all A and B relay contacts are in the state opposite that shown.

Relay A is energized from power source H through the closed trouble contract, relay coil A, resistor R, terminal K, and jumper to the neutral side of the line N. Relay B is also energized from H through the normally closed acknowledge pushbutton to terminal C, closed contact A2, and relay coil B, to N. Relay B is locked in by its own contact B2, which closes when relay B is energized. The visual indicator is turned off by open contact A5. The audible signal and the flasher motor are turned off by open contacts A3 and B4 in the same circuit.

Alert The trouble contact opens, deenergizing relay A and returning all *A* relay contacts to the state shown in Figure 4.1n. The visual indicator is turned on, flashing through circuit H, lamp filament, terminal *L*, closed contacts A5 and B6, bus F, and flasher contact F1, to N. The flasher motor is driven through circuit C, closed contacts A3 and B3, R bus, and the flasher motor to N, and the audible signal is turned on by the same circuit.

Acknowledged Relay B is deenergized by operating (opening) the momentary contact horn acknowledgment pushbutton and is locked out by open contact A2. All B relay contacts are returned to the state shown in Figure 4.1n. The visual indicator is turned on steady through closed contact *B*5 to *N* and is disconnected from flasher contact F1 by open contact B6. The flasher motor and audible signal are turned off by the horn acknowledgment pushbutton and remain off as a result of open contact B3.

Normal Again When the variable condition returns to normal, the trouble contact closes to energize relay A, the visual indicator is turned off by open contact A5, relay B is energized by closed contact A2, and all circuits are again in the state described under normal.

Lamp Test The lamp test circuit operates the visual indicators of only those alarm points that are in the normal condition. The circuit is completed through power source H, lamp filament, terminal L, closed contact A6, bus T, and normally open momentary contact lamp test pushbutton, to N. Closing the lamp test pushbutton to N completes the circuit and lights the visual indicators. Alarm points that are in the off-normal condition (either alert or acknowledged) do not operate because their A relays are deenergized and the A6 contact is open. The visual indicators of these abnormal alarm points are already turned on (either flashing or steady) through the operation of the alarm sequence.

Lock-In The lock-in feature operates to prevent an annunciator alert condition (caused by a momentary alarm) from returning to normal until the horn acknowledgment button is pushed. Point terminals H and SL are jumpered to provide the lock-in feature (see Figure 4.1n). When the trouble contact opens, the A relay is deenergized, and power source H is applied to the N side of the relay through closed contacts A1 and B1.

The power is dissipated through resistor R, terminal K, and jumper to N. If the trouble contact returns to normal, relay A will remain deenergized because potential H is on both sides of the coil. If the acknowledgment button is pushed before the trouble contact closes again, relay B will be deenergized, opening contact B1 and the lock-in circuit, thus permitting the system to return automatically to normal when the trouble contact closes.

If the acknowledgment button is pushed after the trouble contact has reclosed, contact B1 opens momentarily, allowing the A relay to reenergize. Contact A1 opens, and the circuits are reestablished in their normal operating state.

Operational Test Full operational test is incorporated in the annunciator sequence shown by replacement of the jumper connection between main bus terminals K and N with a normally closed momentary contact pushbutton, which when pushed opens all annunciator circuits, thus initiating the alert condition of all alarm points in the normal condition.

Auxiliary Contacts Normally closed contact A7 connected to point terminals A and B is available for auxiliary control functions.

Relay Fail-Safe Feature Two parallel circuits, one consisting of closed contact A3 and open contact B3 and the other of open contact A4 and closed contact B4, operate an alert signal when there is a failure of either the A or the B relay coil. A failure of the former initiates a normal alert in the same way as the trouble contact. A failure of the B relay turns on the audible signal through closed contacts A4 and B4.

Normally Open Trouble Contacts The annunciator sequence and features described for NC trouble contacts operate in essentially the same way when NO contacts are used. In the NO system, however, the trouble contact is wired in parallel with the A relay coil to point terminals H and NO, and a wire jumper is installed between point terminals H and NC. Normally, the trouble contact is open and the A relay is energized from terminals H and jumper to terminal NC. In the alert condition, the trouble contact closes to deenergize the A relay by applying power source H to the N side of the relay.

Electromechanical relays are available for use with a variety of AC and DC voltages, but 120 AC, 50 to 60 Hz, and 125 DC are the most popular. Power consumption of the logic modules is normally less than 10 voltamperes (AC) and 10 watts (DC). Special low-drain and no-drain logic modules are available; these consume no power during normal operation. Visual indicators consume different amounts of power, depending on the type. Small bull's-eye lights and backlighted nameplates use approximately 3 watts, whereas large units require 6 to 12 watts, depending on whether one or two lamps are used.

Electromechanical annunciator systems are reliable and may be used at normal atmospheric pressures and ambient temperatures in the 0 to 110°F (–17.8 to 43.3°C) range. They are not position sensitive. They will generate a substantial amount of heat during plant shutdown when a large number of points are askew, and therefore power should be disconnected during these periods. The principal disadvantages of the relay-type annunciator are size, power consumption, and heat generation.

Solid-State Annunciators

A solid-state logic module consists of transistors, diodes, resistors, and capacitors soldered to the copper conductor network of a printed circuit board supplying the required annunciator logic functions. The modules terminate in a plug-in printed circuit connector for insertion into an annunciator chassis; they may also contain mechanical switching or patching devices to provide lock-in and NO-NC options.

Figure 4.1o is a semischematic electrical circuit for a remote system with ISA Sequence 1B. The logic module shown is in normally closed operation. Remote lamps for two points and a flasher-audible module, speaker, and acknowledge and test pushbuttons common to a system are also included. Switch S1 is the NO-NC option switch and is shown in the NC operating position. Switch S2 is the lock-in option switch and is shown in the lock-in position. The following description uses negative logic, i.e., a high equals a negative voltage, whereas a low is approximately 0 volts.

Normal The trouble contact of the NC alarm point is connected to an input filter circuit consisting of resistors R13 and R50 and capacitor C1. This provides transient signal suppression as well as voltage dropping. The slide switch S1 connects the trouble contact and filter network to resistor-R14. In this state transistor T1 is conducting, causing the full negative voltage to be dropped across resistor R17, resulting in a low voltage at the bottom end of resistor R20. Transistors T2 and T3 are the active elements of the input memory and are roughly equivalent to the A relay of an electromechanical module (see Figure 4.1n).

The base of T2 has four inputs, including resistor R20, either directly from the trouble contact in NO operation or from the collector of T1 in NC operation; resistor R19 with a locking signal from the alarm memory transistor T5; resistor R28 and capacitor C2, which form a regenerative feedback from T3; and resistor R15 from the test circuit. The base of T3 has one input, resistor R29 from the collector of T2. In normal operation, all four inputs to the base of T2 are low, T2 is not conducting, and T3 is conducting. Conversely, when a high signal is present at any one of the four inputs to the base of T2, T2 conducts and T3 turns off.

Transistors T4 and T5 are the active elements of the alarm memory and are approximately equivalent to the B relay of an electromechanical module. T4 and T5 together with bias resistors R30 and R33 and cross-coupling resistors R31 and R32 form a bi-stable (flip-flop). In normal operation T4 is off and T5 conducts. The upper end of capacitor C4 is connected to the collector T2. When T2 is off, its collector is at a high and capacitor C4 will change from top to bottom, minus to plus. Transistor T7 is a high-capacity lamp amplifier and T6 is its preamplifier. In normal operation the base of T6 is high and T6 is on, T7 is off, and the visual indicator is off.

Before completion of the description of the normal condition, the operation of the flasher-audible module in Figure 4.1o will be described. The module has two oscillators. The first is a 3-Hz unit generating a signal that is amplified and supplied to the logic modules through the Fl bus. The second is a 700-Hz oscillator generating a signal that is amplified and supplied to the audible signal through the R bus.

The audible signal is a permanent magnet-type transducer (speaker) that converts the electrical energy into sound. Initiated by an audio oscillator, the active elements of which are transistors T1 and T2, these transistors together with passive components (capacitors C1 and C2 and diodes D3 and D4) form an unstable multivibrator when an input is present on the FR bus. In the normal conditions there is no FR signal, the voltage necessary to turn on transistor T1 is missing, and the oscillator will not operate. This is the normal, or quiescent, condition.

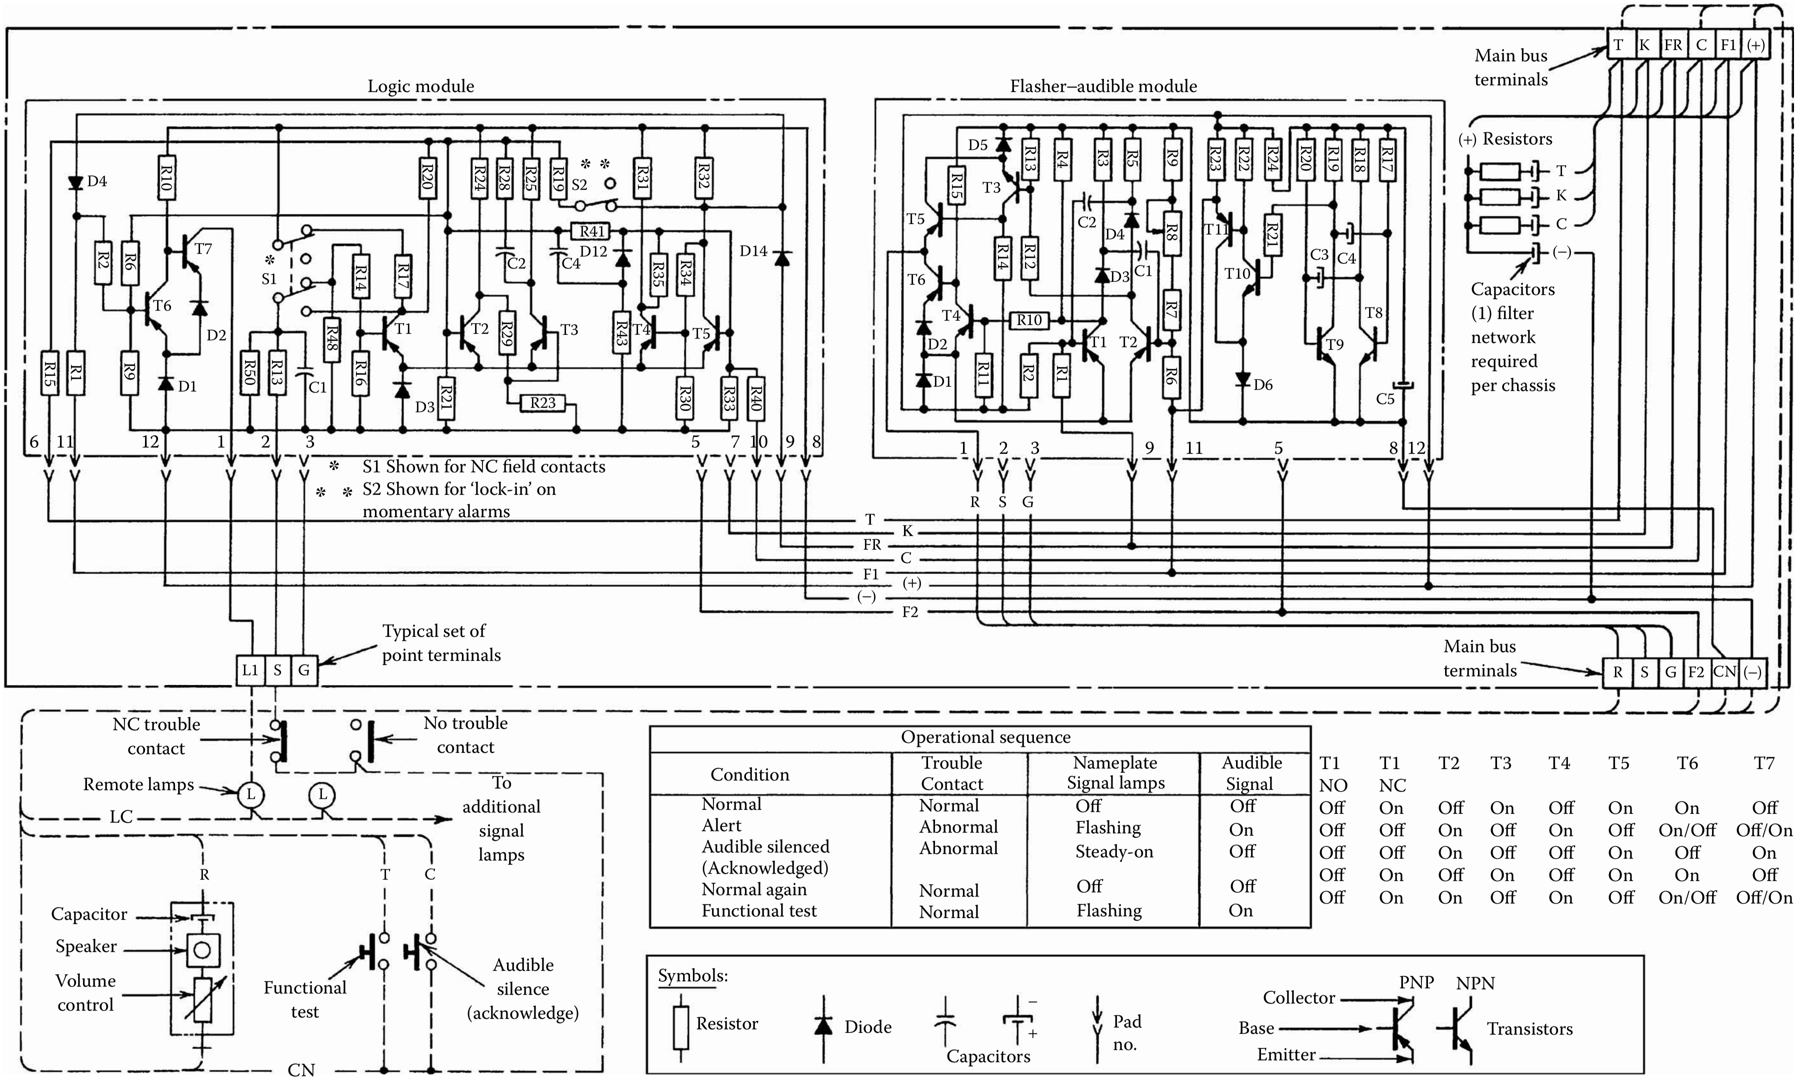
Alert The trouble contact opens and the base of T1 becomes low, turning off T1. This action produces a high on the base of T2 through R20, which turns on T2 and turns off T3. The negative end of C4 is clamped to common through T2, causing a positive pulse at the base of T5 through diode D12, turning T5 off and T4 on. With T2 conducting, the base of T6 becomes low through resistor R6, and with T5 off the clamp on the flasher signal is removed through diode D4 at the junction of R1 and R2. The flasher source provides an alternating high and low voltage at the Fl bus, which turns T6 on and off, which in turn turns T7 and the light off and on.

The flasher signal is generated by transistors T8 and T9, which are the active elements of an unstable multivibrator used as an on/off signal to the output driver stage. Resistor R24 and capacitor C6 decouple the oscillator from the power lines so that its frequency is not affected by that of the other oscillators. The output driver stage consists of transistors T10 and T11, a switching inverter, and an emitter follower stage, which produces an alternating high and low voltage of F1 bus through R23. Transistor T11 is a high-current transistor capable of driving a multiple lamp load.

The audible signal is initiated by a high on the FR bus, which turns on an audio oscillator, the elements of which are transistors T1 and T2. The audio oscillator output is amplified in an audio amplifier stage composed of transistors T3, T4, T5, and T6 connected in two pairs—one T3 and T5; the other T4 and T6.

The input components to the stage from the audio oscillator are opposite each other, i.e., whenever one is high (negative voltage) the other is low (near zero), causing only one pair of transistors to conduct at a time. When T5 is off, T6 is on and the capacitor is discharged. This alternating action causes an alternating current to flow in the speaker coil, giving an audible signal.

Acknowledged A negative voltage is applied to the base of T5 through resistor R40 by closing the acknowledge pushbutton. This turns T5 on and T4 off, and the FR bus becomes



Operational sequence			
Condition	Trouble Contact	Nameplate Signal lamps	Audible Signal
Normal	Normal	Off	Off
Alert	Abnormal	Flashing	On
Audible silenced (Acknowledged)	Abnormal	Steady-on	Off
Normal again	Normal	Off	Off
Functional test	Normal	Flashing	On

T1 NO	T1 NC	T2	T3	T4	T5	T6	T7
Off	On	Off	On	Off	On	On	Off
Off	Off	On	Off	On	Off	On/Off	Off/On
Off	Off	On	Off	Off	On	Off	On
Off	On	Off	On	Off	On	On	Off
Off	On	On	Off	On	Off	On/Off	Off/On

FIG. 4.1o
Semischematic diagram of a solid-state annunciator designed for ISA new sequence A (old sequence 1B), which sequences are described in Tables 4.1d and 4.1e.

low, thus silencing the audible signal. When the point is acknowledged, T5 conducts; this restores the clamp at R1 and R2, which removes the flash source voltage. T6 is off all the time, T7 is on all the time, and the light is on steady.

Normal Again When the variable condition returns to normal, the trouble contact closes and the base of T1 becomes high, turning T1 on. This produces a low on the base of T2, which turns T2 off and T3 on. All circuits are again in the state described under the normal condition.

Lamp Test No separate lamp test is normally provided. One initiates a full operational test by pushing the test button, which applies an alternate input signal through resistor R15 to the base of transistor T2. This turns T2 on, initiating a full operational test of the system as already described.

Lock-In The lock-in feature is provided by a switch S2. If the switch is in the lock-in position (see Figure 4.1o), when T5 turns off (on the alarm condition), a high at the collector of T5 is coupled to the base of T2 through R19, which keeps T2 turned on even if the trouble contact returns to normal. Transistor T5 will remain off and keep T2 turned on until the acknowledgment button is pushed.

If the switch is in the non-lock-in position, the circuit between the collector of T5 and the base of T2 is open; therefore, T2 will turn off if the trouble contact returns to normal before acknowledgment and return all circuits to normal.

Operational Test See description under lamp test.

Auxiliary Contacts Auxiliary contacts are not supplied as part of the logic module. Adapter assemblies consisting of relays operated by the semiconductor logic, however, are available.

Relay Fail-Safe Feature Not available in solid-state circuits.

Normally Open Trouble Contacts The annunciator sequence and features already explained for NC trouble contacts operate in essentially the same way for NO contacts. The NO-NC option switch bypasses inverter stage transistor T1. When the contact closes on an abnormal condition, it turns on T2 though R20 and the sequence operation proceeds exactly as described for the NC operation.

Solid-state annunciators are for use with DC voltages ranging from 12 to 125 DC. Power consumption of the logic modules ordinarily is less than 5 watts. Visual indicators consume different amounts of power, depending on the type. Bull's-eye lights use approximately 1 watt, whereas back-lighted nameplates use from 1 to 6 watts, depending on the number and wattage of lamps.

Solid-state annunciators are very reliable and are not position sensitive. They offer the advantages of compactness, low power consumption, and little heat generation, factors that make them particularly useful in large integral annunciators. The per-point cost of solid-state systems is slightly higher than that of their relay-type equivalent, due to the cost of power supplies and interfacing accessories that may be required with solid-state systems. The cost of the logic modules, visual indicators, and cabinets themselves is not excessive. Integrated circuit components using recently developed microcircuits will most likely reduce size, power consumption, and heat dissipation of annunciator systems.

ANNUNCIATOR CABINETS

Annunciator systems are installed in areas ranging from general purpose to hazardous. Annunciator cabinets are installed indoors and outdoors in a variety of dusty, moisture-laden, and other adverse environments. Industrial annunciator cabinets are usually designed for general-purpose, dry indoor use. Special cabinets and enclosures are used in hazardous, moist, and outdoor locations.

Hazardous Area Designs

The requirements of Class 1, Division 2 hazardous locations as defined in Article 500 of the National Electric Code (NEC) are satisfied by the visual indicators and logic modules (either relay or solid state) of most annunciator systems. A manually operated or door-interlocked power disconnect switch is used with annunciator cabinets in those locations to turn off power when logic modules are relamped or changed.

Annunciator equipment for Class 1, Division 1 areas is installed in cast steel or aluminum housings approved for the hazardous environment. The housings are expensive to purchase and install. These annunciators are available in both integral and remote configurations. The remote type is generally wired to explosion-proof bull's-eye lights. Annunciator power must be disconnected either manually or automatically before the enclosures are opened to prevent an accidental arc or spark when logic modules are relamped or changed.

One can weatherproof annunciator cabinets installed in either general-purpose or hazardous areas (class 1, division 2) either by housing them in a suitable enclosure or by covering the exposed cabinet front with a weatherproof door. Housings that comply with class 1, division 1 requirements are also weatherproof. Figure 4.1p illustrates several weatherproof and hazardous-area enclosures. For the design of purging systems, refer to Figure 4.1b.

Intrinsically Safe Designs

Annunciators are classified as intrinsically safe if they are designed to keep the energy level at the trouble contact below that necessary to generate a hot arc or spark. Care must also be taken in installing the system to place wiring so as to prevent a high-energy arc or spark at the trouble contact caused by accidental short circuit or mechanical damage. Thus, general-purpose trouble contacts may be used with

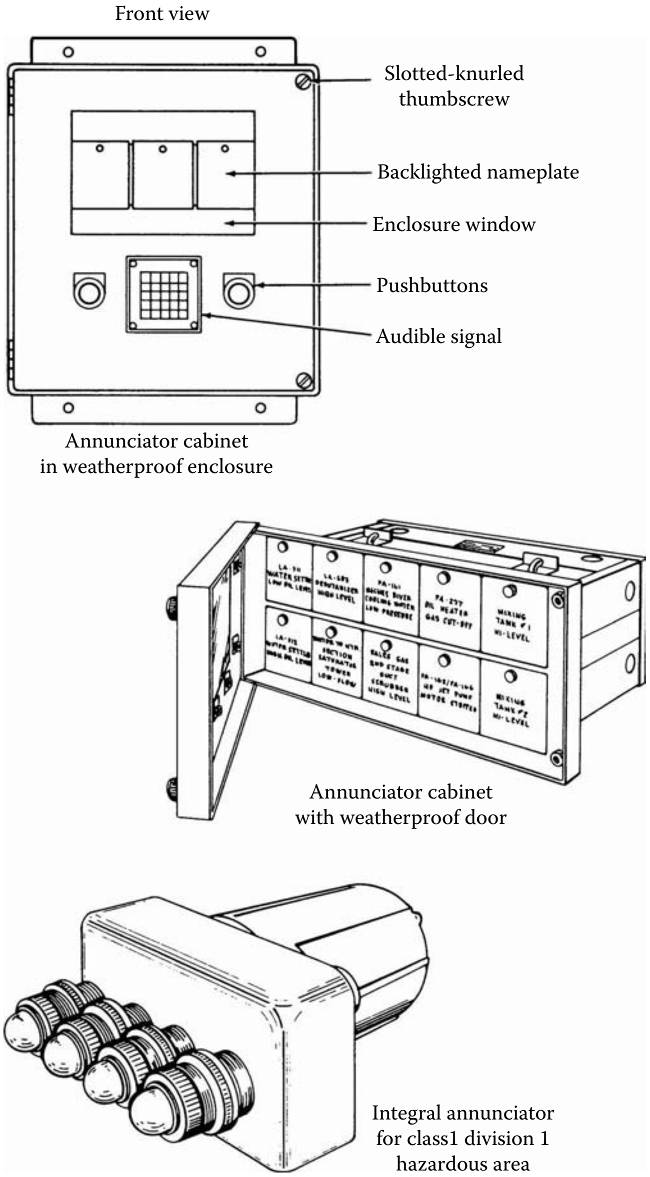


FIG. 4.1p
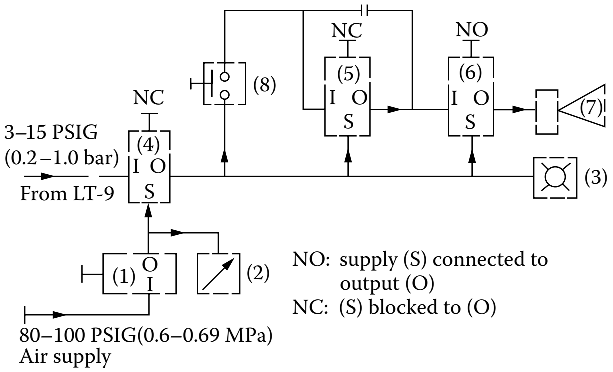
Annunciator enclosures for weatherproof and hazardous areas.

intrinsically safe annunciator systems even though they are installed in a hazardous area.

The annunciator logic modules and visual indicators, however, must conform to the electrical classification of the area in which they are installed. (For more on intrinsically safe designs, see Section 7.2 in Volume 1 of this handbook.)

PNEUMATIC ANNUNCIATORS

Pneumatic annunciators consist of air-operated equivalents of the trouble contact, logic module, and visual indicator stages of an electrical annunciator system. A single-point system furnishing high tank level monitoring is shown in Figure 4.1q.



Condition	Relay (4)	Relay (5)	Relay (6)	Horn (7)	Indicator (3)
Normal	Closed	Closed	Open	Off	Off
Alert	Open	Closed	Open	On	On
Acknowledge	Open	Open	Closed	Off	On
Normal again	Closed	Closed	Open	Off	Off

FIG. 4.1q
The tubing configuration and components of a pneumatic annunciator circuit.

Power supply to the system is instrument air at 80 to 100 PSIG (0.6 to 0.69 MPa), which is reduced to the required operating pressure by pressure regulator (1). The operating pressure is indicated on pressure gauge (2). A 3 to 15 PSIG (0.2 to 1.0 bar), an analog input signal from a direct-acting level transmitter (LT-9) enters high-pressure limit relay (4), which is normally closed and set to open when the high level limit is exceeded. When this happens (alert condition), an input at supply pressure from (4) turns on a pneumatic visual indicator (3), and a normally open high-pressure limit relay (6) allows supply air flow to air horn (7), turning it on. Simultaneously, the air output from (4) enters normally closed high-pressure limit relay (5) and momentary contact pushbutton (8), which is a normally open acknowledgment pushbutton for the system. In the alert condition, the pneumatic indicator and horn are both on.

One acknowledges the alert condition by pushing button (2), closing it, and thereby opening high-pressure limit relay (5). Supply air pressure from (5) closes high-pressure limit relay (6), which cuts off the operating air to the horn, thereby turning it off. Simultaneously, operating air pressure from (5) is fed back to the inlet of (5).

The feedback pressure locks up (5) so that it will not close when the acknowledgment pushbutton (8) is released. In the acknowledged condition, the pneumatic indicator is on and the horn is off. The system returns to normal when the 3- to 15-PSIG (0.2- to 1.0-bar) analog input falls below the setpoint. This closes high-pressure limit relay (4) which turns off the pneumatic indicator (3). It also closes high-pressure limit relay (5) by venting the lock-in circuit through relay (4).

Pneumatic annunciators are used when one or two alarm points are needed but electrical power is not readily available and in hazardous electrical areas where an electrical annunciator might not be practical. Pneumatic annunciators require a substantial amount of installation space and are expensive to manufacture.

Flow sheet symbols

Costs:	The cost of conventional panels ranges from \$2000 to \$8000 per linear foot (\$6000 to \$25,000 per meter) depending on type and concentration of instruments and graphics. The costs of the instruments mounted on the panel are not included in these figures. For estimating the cost of distributed control systems (DCS), the cost of workstations ranges from \$15,000 to \$30,000 depending on the number of displays, computers, and input devices. These costs do not include the expenses associated with the integration of hardware with software. Refer to the later sections of this chapter for a more detailed treatment of DCS costs.
Note:	Because many process units are constructed by members of building trade unions, prefabricated control boards will not be permitted on the site unless they have labels certifying that they were constructed by members of the required unions. The required labels are United Association of Journeymen and Apprentices of the Plumbing and Pipe Fitting Industry of the United States and Canada (UA) and International Brotherhood of Electrical Workers (IBEW).

INTRODUCTION

The operator should be the focal point of any control room design because operators are the real experts on the daily operation of the plant. In the traditional control room the control panel was the operator's window on the process, through which the operator judged how the process was doing and based on that information, determined the way to control it. The operator makes hundreds of decisions every day as problems with supply materials and equipment operation develop or when schedules change, tests and reports are needed, etc.

In traditional control rooms (Figure 4.2a), the operators adapted the control panel to their needs by attaching notes to the various instruments or by marking critical conditions and the proper responses to them. This was easily done because the instruments associated with the various unit processes were mounted on the panel in logical clusters. In DCS-based systems one must be careful to provide the operator with the same logical convenience for alarm handling, status display review, and navigation. Particular care is required to make start-up and shut-down controls convenient and not to force operators to move between various interface systems to do their jobs.

This section describes the design of both conventional and DCS-based control rooms and a variety of traditional panel designs that were used in connection with analog and pneumatic control systems. DCS-based control rooms are also discussed, but more briefly because the details of many aspects of DCS systems are discussed in other sections of this chapter and the reader is therefore advised to also refer to those sections.

The design, wiring, and tubing of conventional control panels are discussed in this section. ISA, The Instrumentation, Systems, and Automation Society, has prepared a number of standards and recommended practices on the design of both traditional and DCS-based control centers. These are recommended reading for those who are responsible for the detailed design of such facilities. The documents that have been prepared include the following:

RP60.1-1990	Control Center (CC) Facilities
RP60.2-1995	CC Design Guide and Terminology
RP60.3-1985	Human Engineering for Control Centers (updated in 1985)
RP60.4-1990	Documentation for Control Centers
RP60.6-1984	Nameplates, Labels and Tags for Control Centers (updated in 1984)
RP60.8-1978	Electrical Guide for Control Centers
RP60.9-1981	Piping Guide for Control Centers
RP60.1-1991	Crating, Shipping and Handling of CC

For other ISA standards and recommended practices refer to http://www.isa.org.

TRADITIONAL CONTROL ROOMS

Conventional control panels often consist of several sections, each corresponding to a different processing step or unit operation (Figure 4.2b). The control room itself must be so designed that only those operations necessary for the control of the plant are performed there. The operators must not be distracted by unassociated functions. The room should have limited access and should not act as a passageway. Equipment must be arranged in such a way that unauthorized personnel cannot tamper with the instruments or with the auxiliaries mounted close by. Figure 4.2c shows a traditional control room layout for analog instruments.

In the control room, air conditioning and room pressurization must be provided. Aside from ensuring operator comfort, maintaining a constant ambient temperature at the instruments will also minimize signal drift. Room pressurization is used where the plant atmosphere is explosive or flammable. The control room is pressurized by admitting into it fresh and clean air from a safe area. This permits the reduction of the area

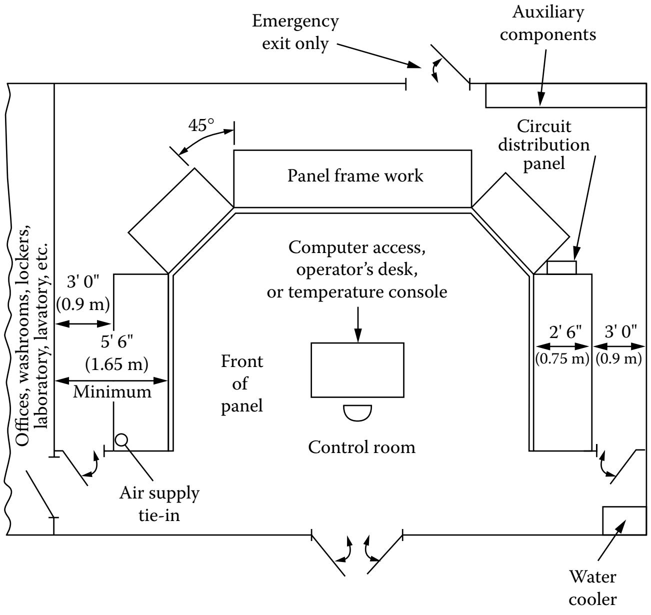

FIG. 4.2c
Traditional control room layout.

classification from either "hazardous" or "semihazardous" to unclassified, with commensurate savings in instrument and installation costs. (Section 7.2 in the *Process Measurement* volume of this handbook gives details on area classification.)

The illumination in the control room must be of a level consistent with close work. The lighting intensity of the panel should average 75 foot-candles (807 lx) across its face. The back of the panel area should be lighted to 30 foot-candles (322.8 lx). The lighting system should be designed to minimize reflections on instrument cases, and point sources of light should be avoided. Continuous fluorescent lighting, placed behind egg crate-type ceiling fixtures, will give adequate light and will minimize annoying highlights.

The most advantageous ratio of panel length to control room area is obtained by bending the panel to a U shape. Right-angled bends of the panel, as opposed to 45-degree bends, should be avoided. The slightly increased panel length that could be gained by the use of right angles is negated by the interference to opening instrument doors or withdrawing the chassis. Also, operators can monitor a greater length of panel if it bends around them.

CONTROL ROOMS FOR DCS SYSTEMS

The upgrading of traditional control rooms is discussed in the next section, while other aspects of DCS-based and other digital control systems are covered in other sections of this volume.

In physical appearance the control equipment used in DCS systems is similar to modern office equipment. CRT-based consoles, keyboards, printers, and personal computers are some of the basic high-visibility components in these control centers. The design of these workstations is modular and can be configured to match the number of operators and other features of the particular plant (Figures 4.2d and 4.2e).

DCS-based control rooms require significantly less space than did traditional control rooms. On the other hand, DCS-based control rooms do require additional rooms for auxiliary equipment and other purposes. These rooms should be located adjacent to the control room itself (Figure 4.2f). In these rooms computer-type floors are used to allow for the routing of the cables between units.

A well-designed control center of this type requires a significant amount of advance planning. The input/output (I/O) and peripheral equipment cabinets are usually located in rooms adjacent to the control center. These adjacent rooms also include the central processing units (CPUs) and their supporting gear.

The overall control house might consist of two rooms (Figure 4.2f), one for the control room operators and the other for the auxiliary equipment, or might consist of several rooms, as shown in Figure 4.2g. In either configuration it is recommended to provide adequate spare cabinet space and display area to accommodate later plant enlargement.

TRADITIONAL CONTROL PANELS

There are three basic shapes of control panels—straight, breakfront, and console. Each type has an accompanying family of variations. The dimensions shown in the various illustrations are only typical, and instrument heights and spacing must be adjusted to suit the particular manufacturer and application.

Flat Panels

The flat panel shown in Figure 4.2h is the least expensive, the easiest to construct, and the simplest to design. The straight, vertical plane of the panel allows an orderly layout of tubing, electrical ductwork, and miscellaneous equipment. Instruments and auxiliary components can be arranged so that all are accessible for maintenance and calibration. The lower row of instruments is approximately 3 feet 3 inches (0.975 m) from the floor and should be used to mount recording or indicating instruments only because this low elevation is rather inconvenient for controller operation. In this layout a maximum of four horizontal rows of miniature instruments (recorders and controllers) can be used, which is less than with some of the breakfront console configurations.

Breakfront Panels

Breakfront panels allow greater use of the front face of the board because the instruments located in the lower rows are swung upward to a convenient height (Figure 4.2i). The top portion of the panel is swung downward to an angle normal to the line of sight, allowing better visibility. The additional rows obtained with this layout tend to reduce the overall panel length requirement. However, the higher the instrument density, the less room is left for maintenance and for the mounting of auxiliary components in the back of the panel.

Consoles

Consoles are aesthetically pleasing to most people. They are often used with high-density instrumentation in control rooms of limited size. Normally, their length is a function of operator responsibility and convenience. Usually there is one operator

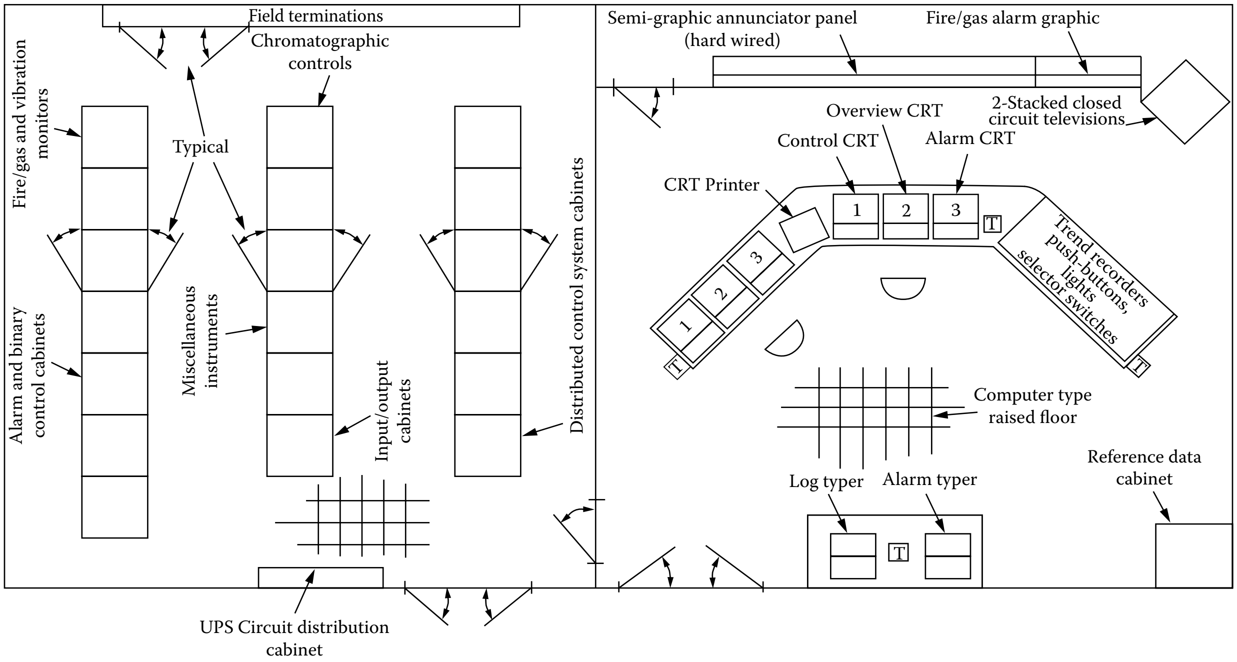

FIG. 4.2f
Typical control house arrangement for distributed control instrumentation.

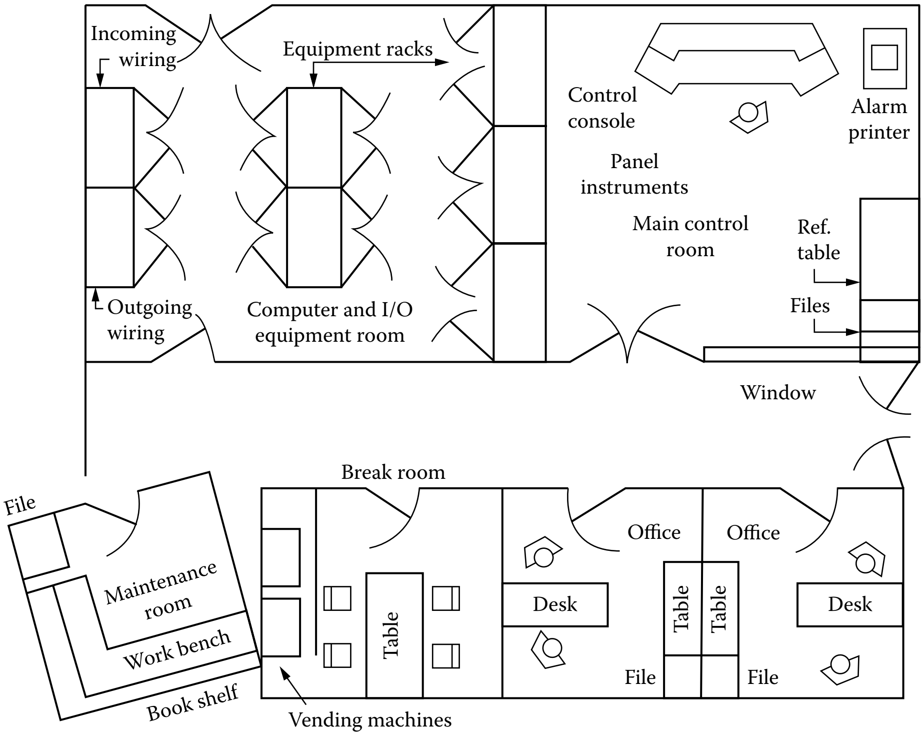

FIG. 4.2g
The ideal control house layout can be arrived at by trying a variety of configurations using 20:1 scale cutouts of the required equipment.[1]

per console and one console per operator. The lengths vary from 4 to 12 feet (1.2 to 3.6 m).

Auxiliary equipment, such as transducers and pressure switches, can be installed inside the console cabinet, but the arrangements of flush-mounted instruments, as shown in Figure 4.2j, severely limit the available free space in the back of the console. Performing instrument maintenance within the consoles can therefore become a real problem.

Consoles are often coupled with a conventional flat "backup" panel, which contains the larger instruments and auxiliary components. Because the average operator is less than 5 feet 9 inches (1.7 m) tall, the "see over" console should not rise above 5 feet 0 inches (1.5 m). This will allow the operator to see the backup panel over the top of the console.

TRADITIONAL FRONT PANEL LAYOUTS

Analog instrument sizes and shapes include the large-case conventional type (nominally 18 inches wide by 24 inches high [450 mm wide by 600 mm high]), the miniature type (nominally 6 inches square [150 mm square]), and the high-density type (2 inches wide by 6 inches high [50 mm wide by 150 mm high]). The same considerations that determined the panel type often also determined the selection of the instrument size.

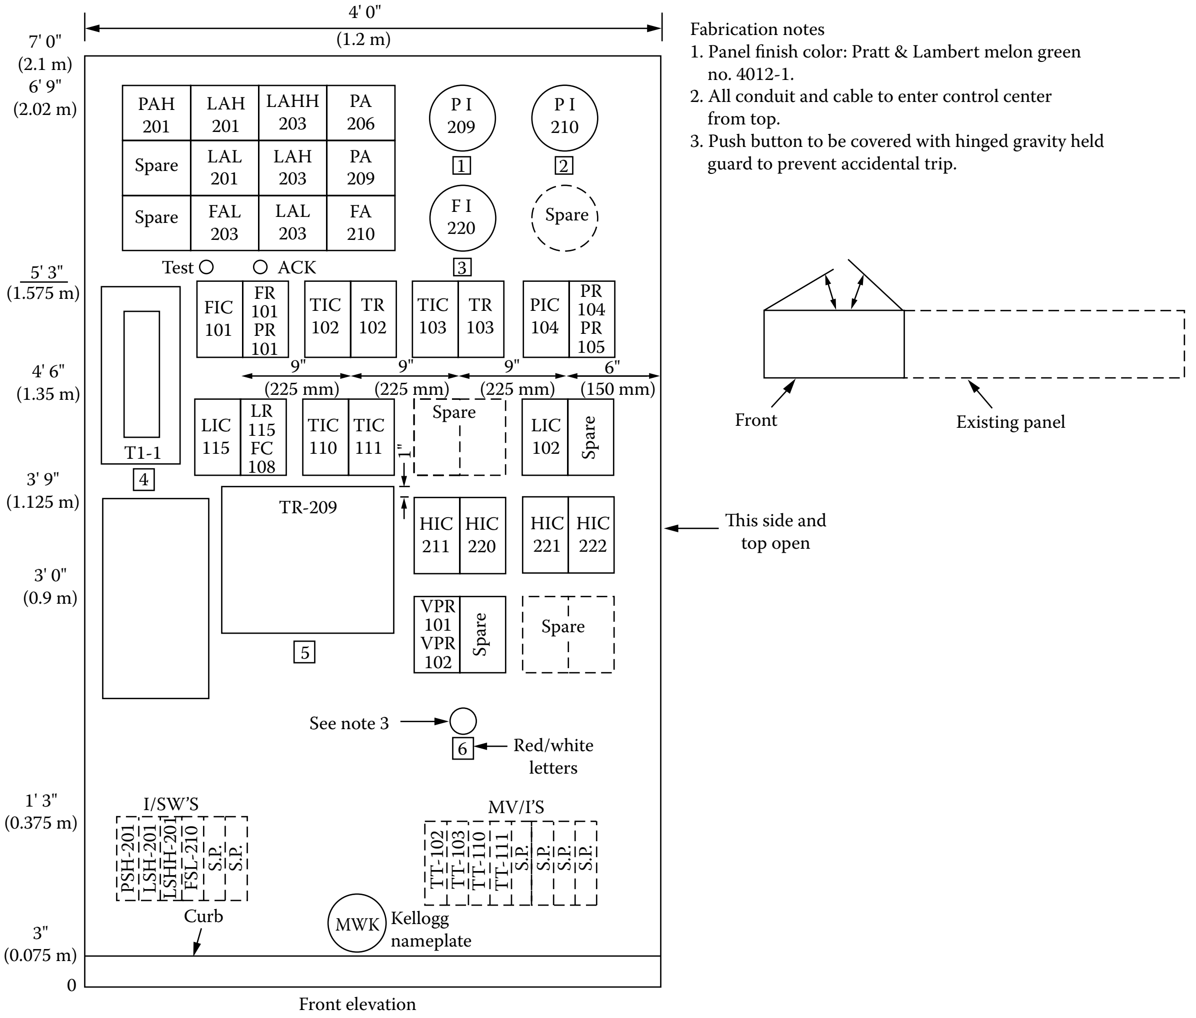
Large-Case Instruments

Today, seldom seen are the large-case, conventional instruments, which were installed on old panels, mounted two rows high (Figure 4.2k). They did not permit a great deal of flexibility in layout, but they were rugged and suitable for almost any outdoor location as local control stations. The control systems for most of these applications were simple with few instrument components.

Miniature Instruments

Prior to the digital age and DCS systems, miniature instruments were the most widely used process control devices. Relative to large-case instruments, they allowed a moderate reduction in panel length (Figure 4.2l). They were used for most indoor installations. These devices can be used in almost all configurations of flat panel, breakfront, or console designs, but there are some mounting angle limitations that should be kept in mind when the panel is designed.

For estimating the length of control panels, a horizontal spacing of 9 in. (225 mm) between vertical center lines of miniature instruments was used. Ten to 12 inches may be used between horizontal center lines. Instrument manufacturers have not fully standardized the overall dimensions, cutouts, connection locations, and so forth. Therefore, the manufacturer's spacing and installation recommendations for each instrument had to be checked and followed.



Fabrication notes
1. Panel finish color: Pratt & Lambert melon green no. 4012-1.
2. All conduit and cable to enter control center from top.
3. Push button to be covered with hinged gravity held guard to prevent accidental trip.

FIG. 4.2h
Typical flat control panel layout.

High-Density Instruments

There are several designs of high-density-type miniature instruments available on the market. They may be mounted in groupings to suit a particular processing unit, as shown in Figure 4.2m, or in long rows to condense panel length, as illustrated in Figure 4.2n.

This type of instrument layout requires additional space on the rear of the panel for auxiliary equipment. Additional devices can also be mounted on the wall behind the panel or in a peripheral equipment room remote from the panel. High-density instruments tend to have a longer chassis, requiring about 6 additional inches in panel depth. Some of these instruments require amplifiers or converters, which must be mounted in close proximity to the primary instrument.

Some high-density instrument lines did not include a similarly sized recorder. In these cases, a standard miniature strip chart recorder (6 by 6 inches, or 150 by 150 mm) was utilized (Figure 4.2l). In some cases, instead of permanently installed recorders, trend recorders were used to reduce the overall recorder requirements.

Graphic Panels

A graphic control panel depicts a simplified flow diagram of the processing unit and describes its control philosophy. Prior to DCS systems, the most common material used for this depiction was colored plastic or melamine. The lines and symbols were affixed to a removable steel, aluminum, or plastic plate.

The extra expense of a graphic panel was justified with the following reasons:

1. To enable the panel operator to visualize a complex process flow pattern
2. To make a sophisticated control philosophy with complex interrelationships between variables understandable

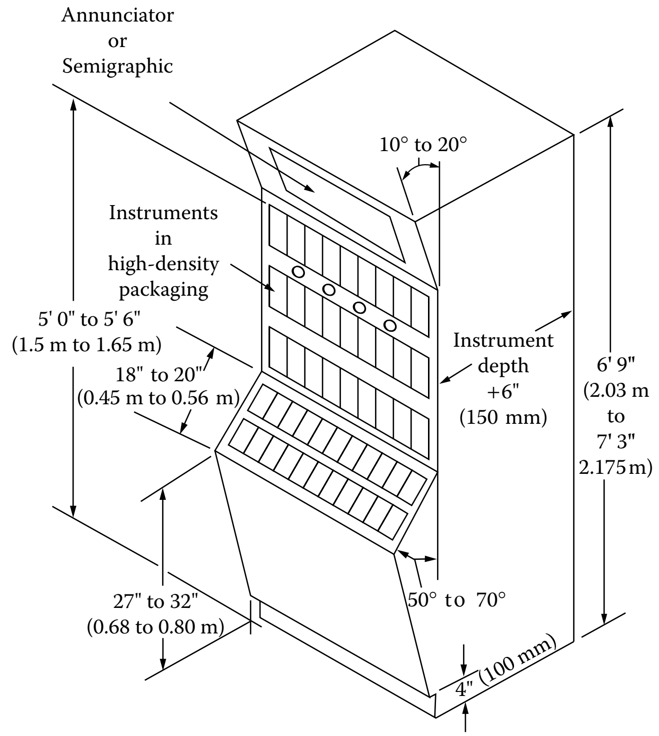


FIG. 4.2i
Breakfront console design.

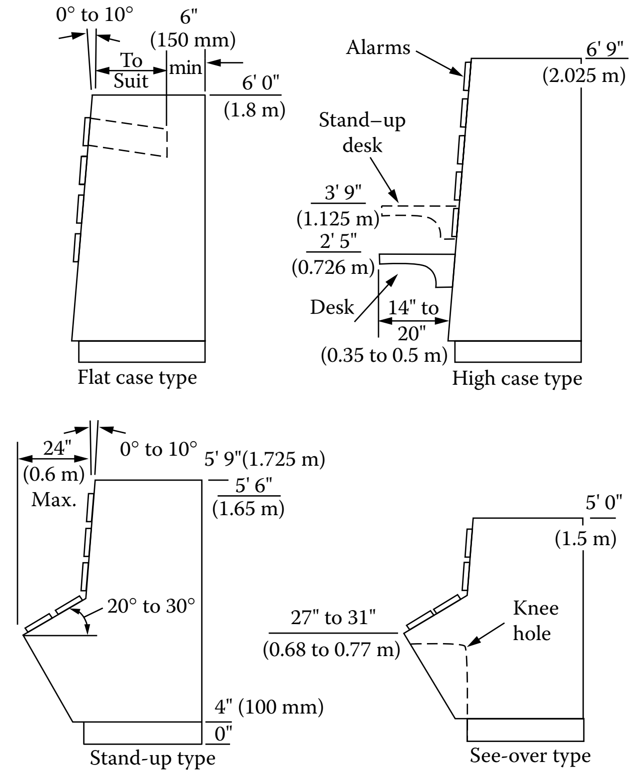

FIG. 4.2j

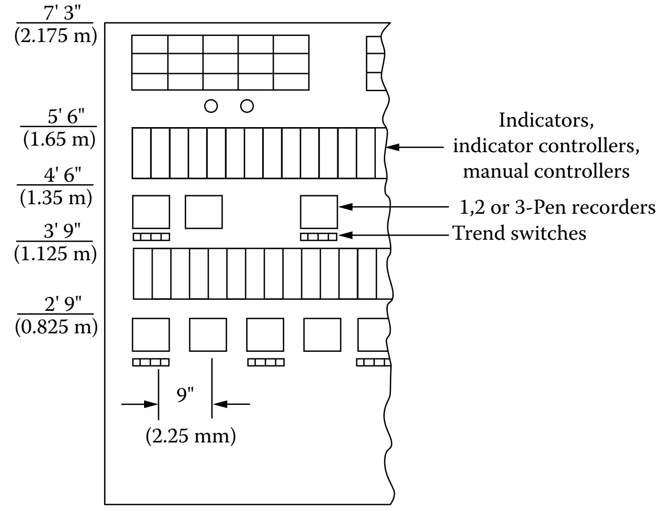

FIG. 4.2l
Panel layout for miniature analog instruments.

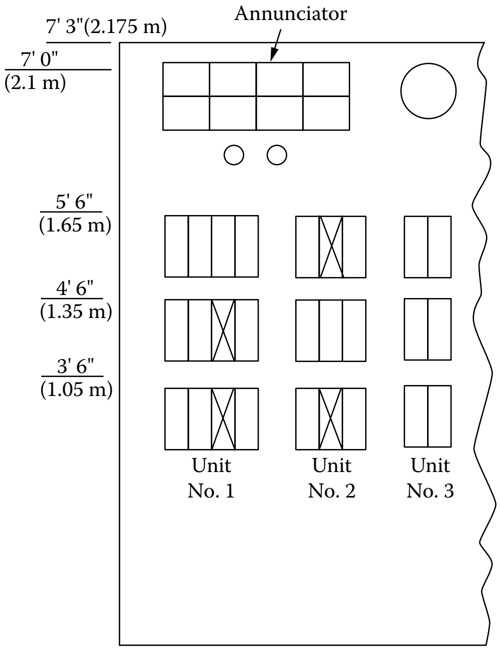

FIG. 4.2m
Miniature analog instruments in a grouped layout.

3. For the training of new operators
4. For aesthetic enhancement of the control room (a motivation seldom admitted but frequently present)

Although the shapes or dimensions for equipment symbols were not standardized, there were some agreements in the adoption of some common symbols for graphic layout purposes, such as the ones shown in Figure 4.2o. Here, the dimensions shown are typical and can be adjusted to suit individual requirements, as long as they are consistent throughout the panel. Symbols representing equipment, such as furnaces, vessels, drums, pumps, and compressors, are usually shown in silhouette. Internals are shown only when necessary to ensure complete understanding of equipment functions.

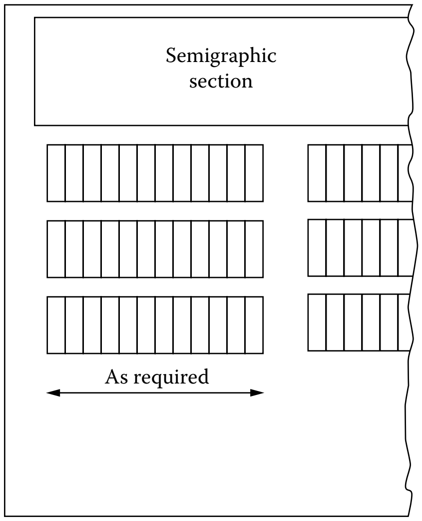

FIG. 4.2n
Semigraphic panel with high-density layout.

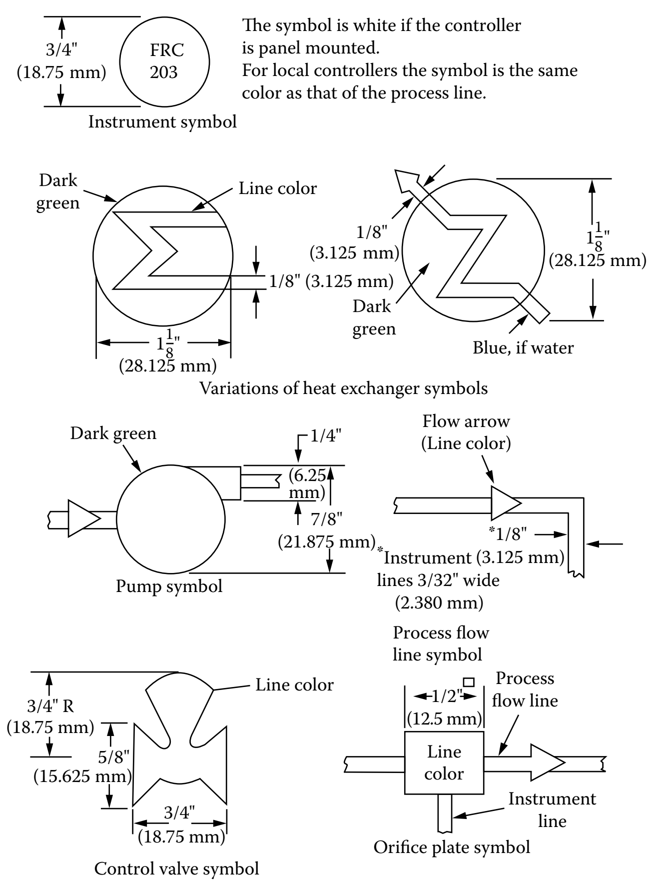

FIG. 4.2o
Symbols used on graphic panels.

In general, the graphic display showed the process flow from left to right in a step-by-step sequence, where fresh feed enters from the left and the product stream exits to the right. Only the process streams and those utilities that are required for clarifying unit operations were normally shown. Similarly, only the most important local instrumentation was depicted.

The flow diagrams were laid out with horizontal and vertical lines. The pattern and its density was as consistent as possible. Vessels usually encompassed the middle three fifths of the graphic section, with a common bottom line whenever practical. Equipment in similar service often occupied similar positions. For example, reflux drums would be aligned along the upper three-fifths division line, while reboilers would rest atop the lower two-fifths line, and so forth. This leaves the top and bottom fifths of the panel for long horizontal lines. The graphic diagram was designed so that as few lines as possible would cross each other. Where a crossing was necessary, the horizontal line was broken.

Semigraphic Panels Semigraphic panels were either flat or of the breakfront type. The top portion of the panel was occupied by a flow diagram of the process (Figures 4.2p).

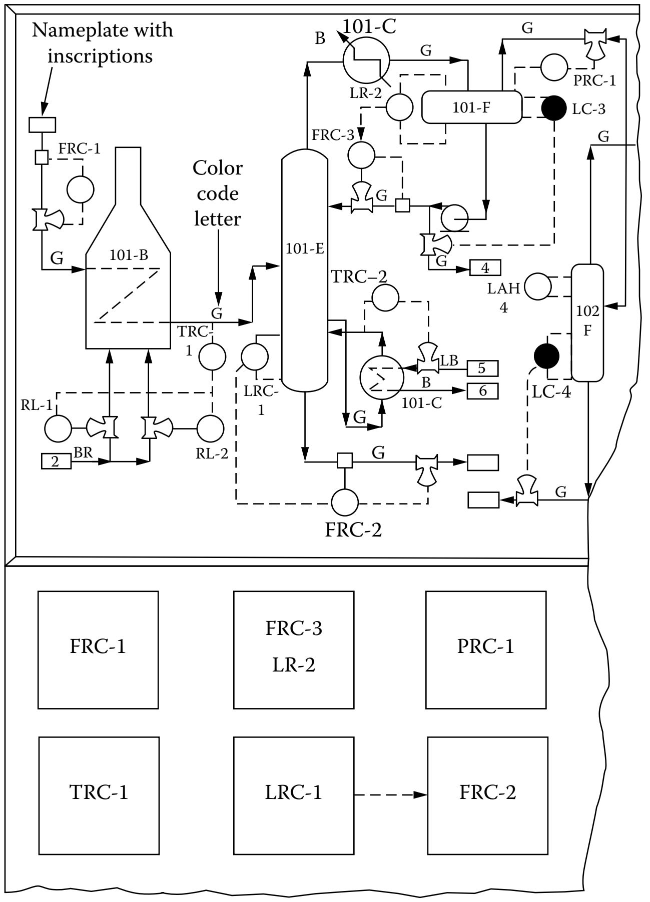

FIG. 4.2p
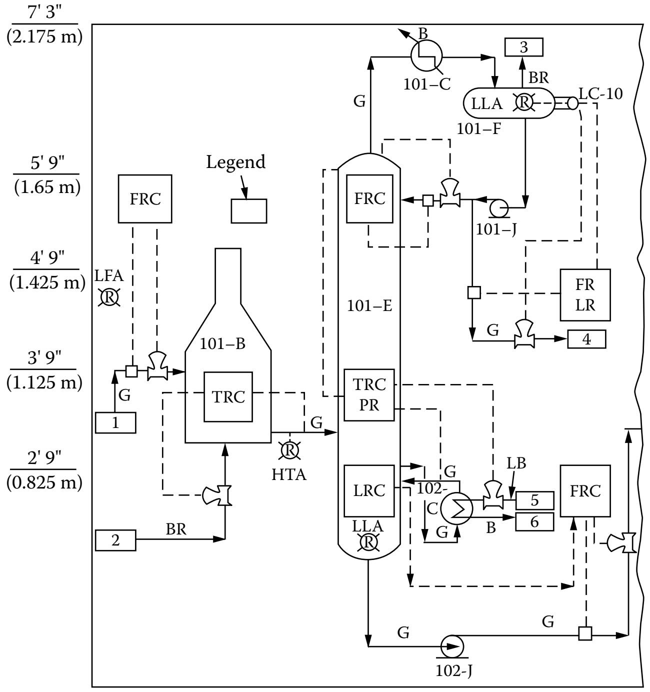
Partial front view of semigraphic panel with miniature instruments.



Legend
G – Process line (green)
BR – Vent or fuel gas (brown)
LB – Steam (light blue)
B – Water (blue)
S – Instrument line (silver)
No. – Nameplate with inscription

FIG. 4.2q
Full graphic panel with miniature instruments incorporated into the graphics.

The location of each instrument was so selected that it was installed directly underneath its corresponding symbol in the graphic diagram (or as close to this point as was feasible). The instrument item number was clearly noted in both locations. In some instances, alarm or running lights were also installed within the graphic section in the appropriate locations. The instrument density was reduced when using this type of panel because of the desirability of locating the instruments in relative proximity to their graphic symbols.

Full Graphic Panels In this design, the graphics cover the complete front face of the control panel, as shown in Figure 4.2q. On these panels the instruments were positioned at the points that corresponded to their location in the process. As in all other panels, the instruments were aligned in horizontal and vertical rows for ease in conduit, duct, and tube layout. The instrument density for this type of panel is extremely low and can vary from one to three instruments per linear foot of board length. This low density significantly extends the overall length of the panel.

Graphic Panel Constructions In addition to the glued-on plastic-type graphic panels, other designs exist. If there is a likelihood of process changes, the degree of difficulty in making changes to the graphic diagram should be considered. The aforementioned plastic strips are relatively easy to change. If the lines and symbols are painted on the panel, changes can be made easily when the panel is new, but as the paint ages and fades, colors become difficult to match.

A flow diagram can also be drawn full scale on reproducible paper and placed in a semigraphic frame. It may be held in place and protected with a glass or clear rigid plastic cover. This method of graphic presentation is simple to change by revising the drawing master and acquiring a new print. If this type of panel is made in only black and white, it is not as aesthetically pleasing as other types.

Another method of graphic process display is by the use of automatic slide projectors. This system uses a rear-projection-type, translucent screen. In order to gain the necessary focal length distance, a set of mirrors is strategically placed on the rear of the panel. This approach to graphics allows a great deal of flexibility. As many slides can be prepared as desired, showing the process or instrument systems or subsystems in color and in as much detail as is deemed necessary. Slides can be prepared to give instructions for emergency procedures, unit operating parameters, and optimum set points for various product choices.

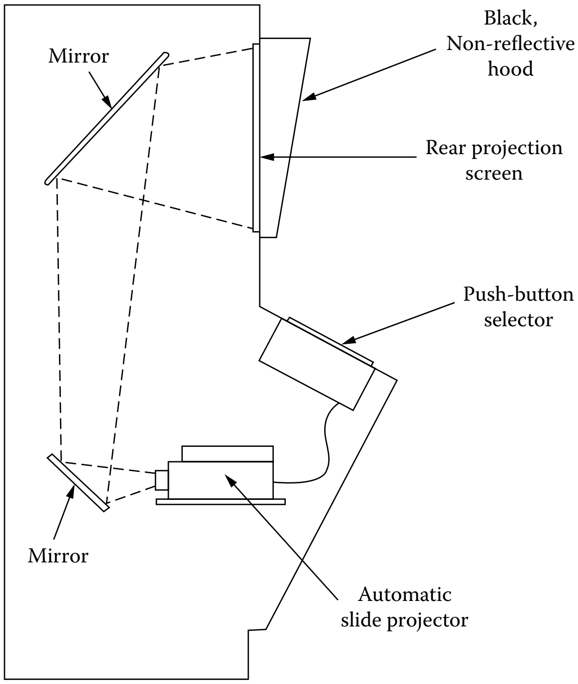


FIG. 4.2r
Breakfront console with rear projection system for graphic presentation.

One serious drawback to the system is that the bright light in the control room tends to "wash out" the image and reduce legibility. Therefore, the lighting level must be reduced, and the fixtures must be so located as to minimize reflections on the screen. In addition, the screen should be furnished with a black shield to reduce side lighting (Figure 4.2r).

Yet another type of graphic panel design uses the back-engraving of a sheet of clear plastic. The plastic lines are then filled with the selected colors. This type of panel is easy to maintain because only the smooth surface is exposed. Changes can be made by reengraving and by refilling. This is extremely difficult, and even when it is expertly done, telltale signs of the change remain.

The front-engraved and enamel-filled graphic line-work allows vivid coloring and sharp lines, making this panel one of the most impressive and pleasing to the eye. It is not feasible to make changes on this panel, and maintenance is somewhat more difficult, since the engraved lines tend to fill with dust.

Back-of-Panel Layout

In order for the overall panel design to be well executed, sufficient attention must be given to the back-of-panel arrangement. It must be verified that there is sufficient room to run the conduits, ductworks, air headers, tube leads, and so forth. There must also be enough room to mount the various switches, relays, converters, amplifiers, and other auxiliary components. A back-of-panel profile will sometimes assist in this (Figure 4.2s). Auxiliary equipment must be located such that its connecting wiring or tubing does not obstruct the maintenance or calibration of, and accessibility to, the other instruments.

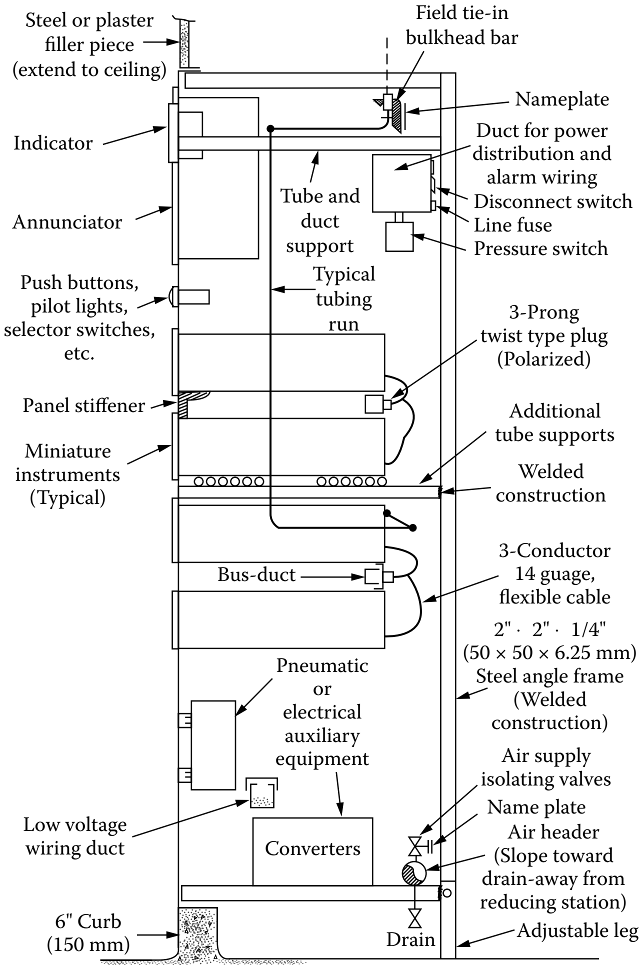

FIG. 4.2s
Back of panel arrangement for miniature analog instrumentation.

Panel Materials of Construction

The materials used most frequently for the construction of panel boards are steel and various plastics. Materials less frequently used are stainless steel, aluminum, and fiberglass.

Steel The advantages of steel are as follows:

1. *Strength.* At instrument cutouts, where the panel is weakened, steel requires less stiffening than do other materials. Steel stands up better to the cantilever effect of the deep bezel-supported, flush-mounted instruments.
2. *Ease of construction.* Holes can be drilled or flame-cut. Auxiliary equipment supports can be welded at any point. Bend-backs on straight panels and the breakfront shapes add significantly to panel stiffness.
3. *Safety.* When grounded, the panels offer an excellent path to ground if an instrument chassis or case

becomes energized as a result of a short circuit or mistermination.

4. *Attractive finish.* Long lengths can be finished in any color or hue desired, without visible seams.
5. *Ready availability.* Sheet steel of good quality and with a minimum of surface pitting is readily available.

Disadvantages of steel panels include the following:

1. *High susceptibility to corrosion.* In corrosive atmospheres, the finish is only as durable as the paint.
2. *Difficulty in adding cutouts.* Once the panel has been constructed and instruments are installed, cutting the steel to accommodate new instruments scatters steel particles that may interfere with the mechanical or electrical operation of the surrounding instruments.

Plastics The plastics available for panel boards are all melamines: Formica, Peonite, Micarta, Textolite, and so forth. They are used either as sheets 1/2 in. (12.5 mm) in thickness or as laminates. The cores of the laminates are materials such as aluminum, flakeboard, steel, or plywood.

Plastic panels, like those of steel, have both favorable and unfavorable aspects:

1. *Great durability.* The finish is very resistant to scratching and heat.
2. *Availability in colors.* Sheets come in many colors, but if the desired color is not in stock, delivery can be delayed. A color may vary slightly from one run at the factory to the next.
3. *Seam required every 4 feet (1.2 m).* This is true regardless of panel length because sheets are usually 4 by 8 feet (1.2 by 2.4 m).
4. *Steel frame required.* The plastic panel must be bolted to a skeletal steel frame for support.
5. *Routing of holes may be necessary.* Many switches, pilot lights and other flush-mounted instruments are designed for a 3/8-in. (9.36-mm) maximum panel thickness. Solid Formica and some laminates will require routing in the back of the panel, around the cutout for bezel-locking rings or locknuts, because of their thickness.

PANEL SPECIFICATIONS

In addition to the drawings and diagrams described earlier, a written specification covering other important aspects of panel manufacturing must be developed. This specification is the document that precisely instructs the panel manufacturer as to design options and the materials to be used to fulfill the contract.

A panel specification should include a delineation of at least the following requirements:

1. *General.* Definition of the design drawing specification and codes furnished by the purchaser that the panel manufacturer is to follow.
2. *Engineering.* Description of the extent and type of engineering drawings to be developed by the panel manufacturer, including whether "as-built" drawings are required. It also includes the number of prints and reproducible masters required and the approval or review requirements for preliminary designs.
3. *Construction.* Description of the type of panels and their fabrication. This includes National Electric Code (NEC) area classification, ambient conditions, and similar requirements.
4. *Design.* Specification of methods of installing wiring and piping systems. This includes a listing of materials of construction for wire, pipe, tubing, ducts, nameplate inscriptions, and so forth.
5. *Materials.* Complete description of all materials to be used. A generic description is usually sufficient.
6. *Cost.* The specification should direct the bidder to delineate various costs so that additions and deletions to the contract can be negotiated more easily. A Quotation form (such as is shown in Figure 4.2t), which is completed by the control center manufacturer, should be included with the bid.
7. *Inspection.* Delineation of the number and types of inspections planned, which may include preliminary inspections during specific stages of construction. This section of the specification should also describe the extent of inspection required, such as visual, point-to-point checks or functional testing.
8. *Shipping.* Specification of the type of conveyance used to ship the panel to the plant site, type of crating, and protection requirements.
9. *Guarantees.* Conditions under which a panel or equipment may be rejected and the length of time during which the panel is covered by the manufacturer's warranty.

HUMAN ENGINEERING

Human engineering or ergonomics has already been discussed in full detail in Section 1.5, so it is only briefly covered here. Ergonomics has proved invaluable in the design of all panels and consoles.

Figure 4.2u describes the reach of 95% of the people in the United States when conveniently operating controls. Median heights and reaches of people from other nations should be used if the control center is to be used in another country.

Studies performed in nuclear energy power plant control rooms have shown that psychological as well as physical considerations are important. Many of the rules listed below are obvious, yet they are often overlooked:

1. Indicating lights and pushbuttons should be colored so that their relative importance is immediately recognized: i.e., green = go or safe, red = danger or stop, yellow = caution or slow.

5. NO DEVIATIONS ARE PERMITTED FROM THIS FORM WITHOUT THE PERMISSION OF M. W. KELLOGG. HOWEVER, A MULTIPLIER MAY BE ADDED TO ADJUST PRICES FOR VARIOUS STAGES OF CONSTRUCTION.

FIG. 4.2t

Quotation form, which the bidder is to complete and attach to the control panel bid package.

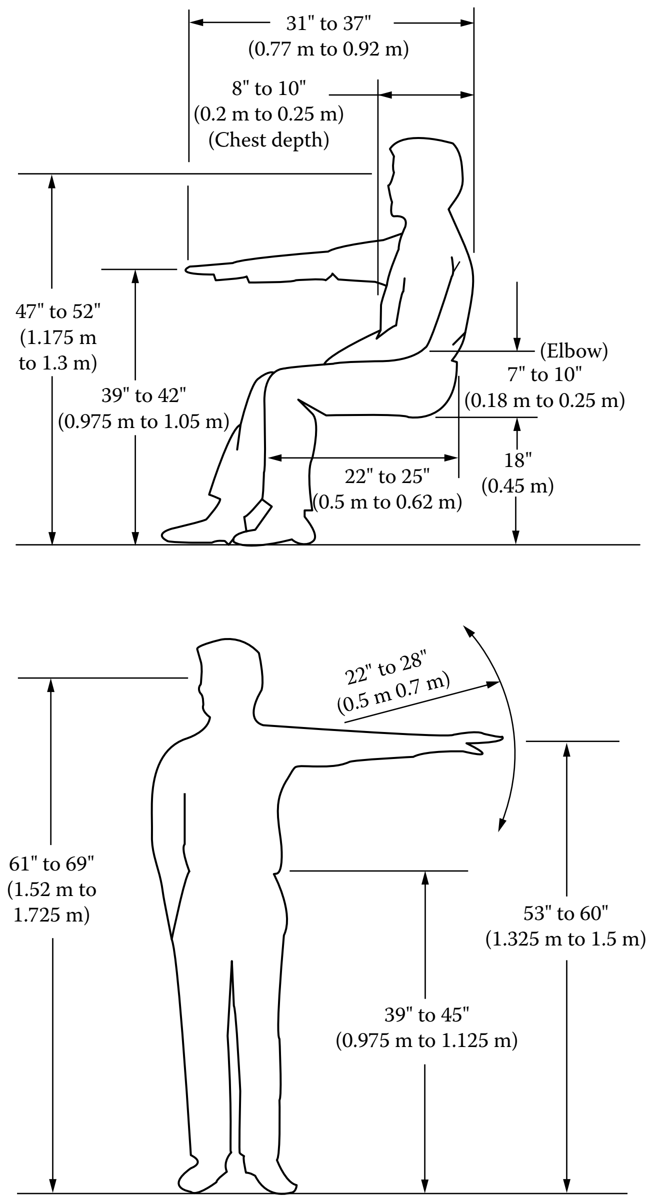

FIG. 4.2u
Anthropometric figures. The mid-range of these dimensions should cover the 95th to 5th percentiles of American operators.

2. Indicating scales, selector switches, and other instruments should push in or up, rotate clockwise, or slide to the right for the "increase" or "on" setting. The opposite position should result in "decrease" or "off" settings.
3. The style of emergency operating devices should reviewed. Emergency trips must be designed so that they are easy and fast to operate, but they should also be located and designed to prevent accidental trips.

Other less obvious ideas include the following:

1. *Annunciator horns.* These can be set to increase in pitch or to go on and off with increasing frequency as the emergency increases in severity.
2. *Annunciator lights.* These can be made to flash brighter and at a higher frequency.
3. *Instrument arrangement.* Instruments should be located in a panel or CRT display as though they were in a graphic panel, that is, following the process from left to right. They should be grouped in logical sets. For example, a distillation column instrument arrangement would have the column feed to the left, the overhead pressure instrument high, the reflux drum instruments high and to the right, and a reboiler instrument low and to the right. It is not possible to follow these recommendations exactly in all cases, but the devices should be located in these relative positions. Additionally, these instruments should be separated from the next column or other unit operation by a space or a line.

A key rule of human engineering is that the operator must be allowed to concentrate on running the plant. Distractions such as performing a complicated or confusing instrument procedure should not take the operator's attention away from this primary responsibility. The primary goal of the control center design is to make plant operation convenient.

PANEL TUBING AND WIRING

Tubing

Most panel manufacturers used to stock an acceptable line of industrial-grade tubing, pipe, and fittings. One of the most commonly used tubing materials behind the panel was copper. It is relatively resistant to corrosion, readily available, and rigid enough to require only a minimum of support, yet it is sufficiently ductile to bend to precise measurements. It is available with a tightly extruded PVC sheath for corrosive atmospheres, and with cadmium or tin plating for damp locations. Commonly used sizes are 1/4 in. (6.25 mm) OD with 0.030 in. (0.75 mm) wall thickness, ASTM B68.

Another commonly used tubing material is aluminum (1/4 in. [6.25 mm] OD with 0.032 in. [0.8 mm] wall thickness), federal specification WWT-700/4c. Aluminum tubing offers good resistance to chloride- or ammonia-containing atmospheres. It is somewhat softer to work with than copper and requires significantly more support. It has a tendency to harden, which makes it particularly susceptible to vibration failures. This tubing is also available with a PVC sheath.

The most frequently used plastic tubing material is polyethylene. This tubing should be of a material that has undergone environmental stress testing in accordance with ASTM D1693. Although polyethylene is markedly less expensive than metallic tubes, additional costs are incurred because it requires an extensive support network, which consists of plastic, slotted, or sheet metal ducting. The ducting should extend to within 1 or 2 inches of the connected instrument. Unsupported lengths are to be avoided because the plastic tubing has a tendency to kink and because it is almost impossible to

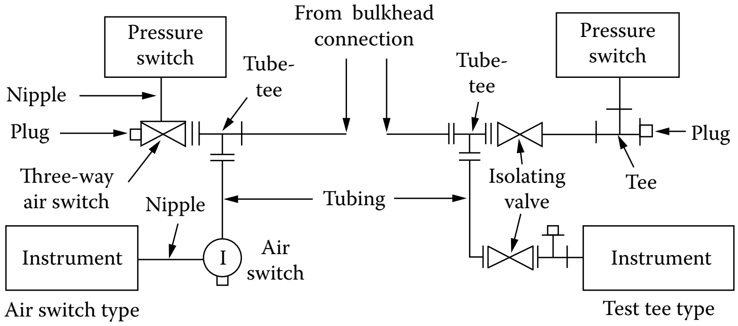

FIG. 4.2v
Test or calibration connections for pneumatic instruments.

run this soft tubing neatly. Tubing may be color coded to conform to the ISA recommended practice ISA RP-7.2. Common sizes are 1/4 in. (6.25 mm) OD, 0.040 in. (1 mm) wall thickness.

Other tubing materials are available, such as stainless steel, nylon, polyvinyl, rubber, and glass, but they are not used as frequently as the aforementioned three materials.

Fittings

Fittings are available for all tubing materials. For control panel applications standard compression-type tube fittings were used rather than flared, soldered, or other specialty types. Pipe material should be seamless red brass, threaded in accordance with USAS B.2.1 and soldered or brazed. The fittings should be rated to at least 125 PSIG (865 kPa). Air supply isolating valves should be either the straight-line needle type or the packless diaphragm two-way type.

The panel air supply should consist of two sets of parallel-piped reducing valves and filters. Each should be sized and manifolded so that either set can supply the total panel requirements. In general, 0.5 SCFM (0.014 m^3/m) of air flow per air user is sufficient. The main air header must be sized so that the pressure drop to the farthest instrument is under 1 PSID (6.9 kPa).

The use of a plugged tee and isolating valve or a three-way switch allows for calibration of instruments or components without disconnecting them or losing the measurement signal to other loop components (Figure 4.2v). The isolating valve need be used only when the measurement signal is branching to another instrument or when the instrument is not furnished with an integral spring-loaded air cutoff valve, as in plug-in type devices. The location of the instrument air supply tie-in to the board is usually noted on the panel drawings, as depicted in Figure 4.2w.

The pneumatic signal lead tie-in location usually requires only a general description since there is enough flexibility in the tubing installation for adjustment. Notes such as “top of panel” or “bottom of panel” are usually sufficient.

Each tubing termination for field leads should be identified with the tag number of the instrument it serves and its function. For example, FRC-10-V could indicate that the field lead terminates at the control calve of FRC-10, whereas FRC-10-T would mean that the air signal tube is received from the so-identified flow transmitter.

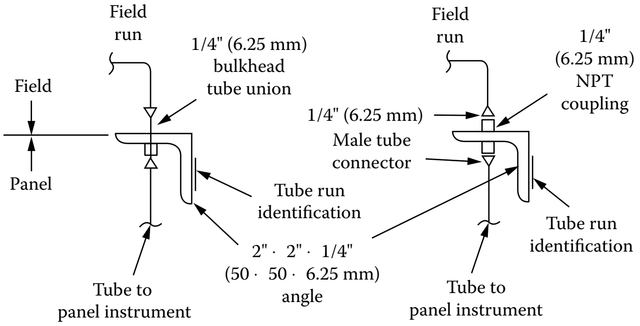

FIG. 4.2w
Typical field tie-ins to pneumatic panels.

There are several different types of interface connections on the panel, some of which are shown in Figure 4.2w. To allow for future changes or additions, at least 10% additional tie-in points should be provided.

Panel Wiring

The first step in deciding what equipment to use is to determine the nature and the degree of hazard. The National Electrical Code[*] describes hazardous locations by class, group, and division.

The class defines the physical form of the combustible material mixed with air:

Class I: Combustible material in the form of a gas or vapor
Class II: Combustible material in the form of a dust
Class III: Combustible material in the form of a fiber, such as textile flyings

The group subdivides the class:

---

[*] NFPA 70, ANSI/NFPA-70 National Electrical Code. Canadian equivalent: CSA Standard C22.1 Canadian Electrical Code Part 1.

Group A: Atmospheres containing acetylene
Group B: Atmospheres containing hydrogen, gases, or vapors of equivalent hazard, such as manufactured gas
Group C: Atmospheres containing ethyl ether vapors, ethylene, or cyclopropane
Group D: Atmospheres containing gasoline, hexane, naphta, benzene, butane, propane, alcohol, acetone, benzol, lacquer, solvent vapors, or natural gas
Group E: Atmospheres containing metal dust, including aluminum, magnesium, and their commercial alloys or other metals with similar hazardous characteristics
Group F: Atmospheres containing carbon black, coal, or coke dust
Group G: Atmospheres containing flour starch or grain dusts

The division defines the probability that an explosive mixture is present. For instance, a hazardous mixture is normally present in a Division 1 area but will be only accidentally present in a Division 2 area.

In addition to knowing the area classifications, one should also be aware of the National Electrical Manufacturers Association (NEMA) terminology for classifying equipment enclosures:

NEMA 1 General-purpose
NEMA 2 Drip-tight
NEMA 3 Weatherproof
NEMA 4 Watertight
NEMA 5 Dust-tight
NEMA 6 Submersible
NEMA 7 Hazardous (Class I, Groups A, B, C, or D)
NEMA 8 Hazardous (Class I, Groups A, B, C or D) — oil-immersed
NEMA 9 Hazardous (Class II, Groups E, F, or G)
NEMA 10 Explosion proof—Bureau of Mines
NEMA 11 Acid- and fume-resistant, oil-immersed
NEMA 12 Industrial

Most panels are enclosed by or parallel to a wall, with a door on either or both ends to limit unauthorized access. Under such conditions and when the area is general-purpose and nonhazardous (see Figure 4.2c), it is permitted to reduce the mechanical protection requirements for the wiring. Electronic transmission, power, and signal wiring need not be enclosed in conduit or in thin-walled metallic tubing.

All of the wiring may be run in a sheet metal or slotted plastic duct. The insulated wire may be run exposed, from the duct to the instrument, an inch or two (25 to 50 mm) without the necessity for a conduit nipple. Bare or exposed terminals, however, are not permitted.

Panels installed in hazardous or semihazardous areas must be installed in strict adherence to the National Electrical Code requirements. Because the code does not allow much flexibility in these cases, this discussion will be limited to the nonhazardous applications, in which the designer has some flexibility. For requirements in hazardous locations, refer to Section 7.2 in the *Process Measurement* volume of this handbook.

Power Distribution Instrument power supplies should be taken from a reliable source, with automatic switchover capability to an alternate power supply, which is to be used upon failure of the main source. The two typical standby power supplies are a separate supply bus (fed from batteries or from a different source) and a steam- or gasoline-powered generator. A detailed coverage of backup power supply systems is given in Section 4.23.

To reduce the cross-sectional area of the power feeders, it is often expedient to mount a three-phase (440-, 208-, and 120-volt) transformer directly in the control house. Then only a 440-volt power supply is provided from the switch gear to the transformer (Figure 4.2x).

A conventional lighting-type circuit breaker panel may be installed on the back of the panel to provide the necessary circuit distribution. This permits the panel manufacturer to install the complete system and significantly reduces field tie-in time. Breakers (sized to trip above 15 amperes) and AWG #14 wire gauge are generally used. Three-wire power circuits having hot, grounded neutral, and ground leads are frequently used.

To avoid the possibility of overloading, circuits should be lightly loaded to approximately half their rated capacity or to a maximum of 850 volt-amperes.

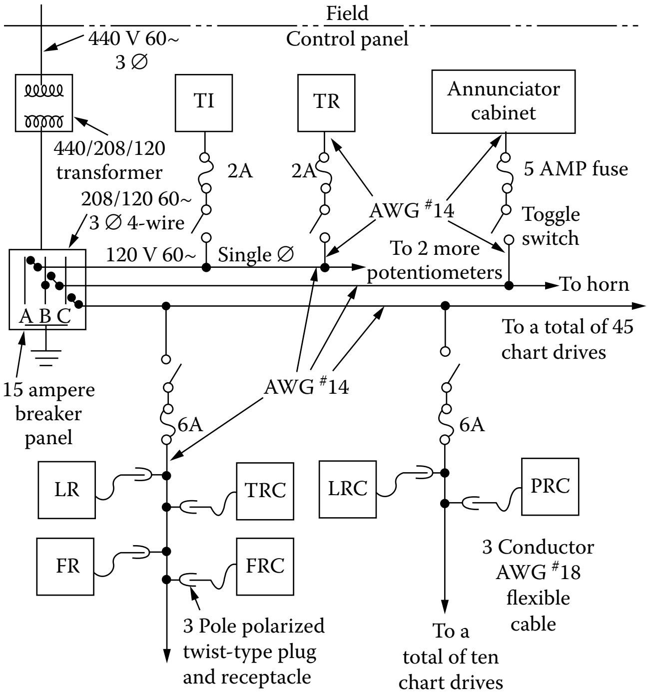

FIG. 4.2x
Typical power distribution system.

Fuses The following groups of instruments will keep the load of 15-ampere circuits within acceptable limits:

4 Potentiometer-type temperature instruments
1 Annunciator cabinet with horn
2 Analyzer circuits (900 volt-amperes maximum)
45 Miniature (pneumatic) recorder chart drives
5 Miscellaneous auxiliary components, at 800 volt-amperes maximum
10 Electronic instrument loops (500 volt-amperes maximum)
2 Emergency trip circuits

Secondary subcircuits must be used so that a short or ground at one instrument does not rip out the 15-ampere circuit breaker but only the associated fuse and so that each instrument (or group) can be isolated for maintenance or replacement. This isolation is accomplished with a fused disconnect device. The fuses must be coordinated so that it is not possible for that 15-ampere breaker to trip before a fuse blows. The fuse must also blow before a significant voltage dip occurs. An exception to the individual fusing isolation rule is chart drive power to pneumatic instrumentation. Here, ten drives (or some similar number) may be connected to one common fuse. A three-pronged, polarized, twist-type plug can serve as disconnect.

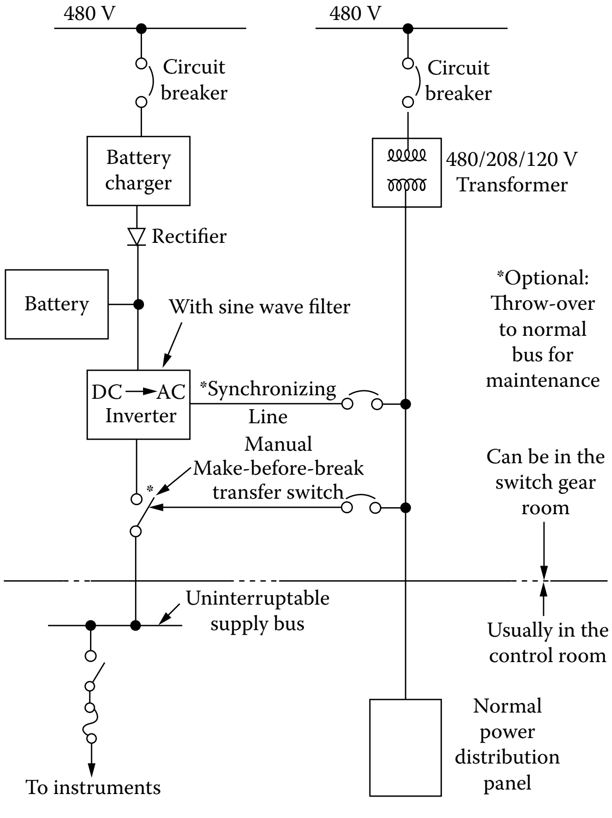

FIG. 4.2y
Battery backup type standby power supply system.

When instruments are internally fused, that fuse may be utilized, but the instrument circuits must be checked to verify that the fuse protects the complete chassis and not just a single critical component.

Battery Backup Several factors must be considered in deciding whether a standby power supply is required. These are as follows:

1. The power source that is used has a history of failures with duration of up to one half hour.
2. The unit uses normally energized solenoids or relays that must be manually reset.
3. There is a flame safety system.
4. The process is extremely fast-acting with electronic controllers in critical services, in which a dip in power supply could send the unit into uncontrollable cycling.
5. The process control system is computerized.

A typical uninterruptable power supply (UPS) is shown in Figure 4.2y, having a battery backup system. This system consists of a battery charger, a bank of batteries, and an inverter. One of the main advantages of this system is that the AC power input phase does not have to be synchronized with the output phase. The instruments are normally powered directly through this system. Upon failure of the mains, the batteries (which have been floating on the charging current) start feeding the inverter.

The battery ampere-hour capacity should be sized using one or more of the following considerations:

1. Length of time of average power outage × 1.5
2. Length of time plant will remain operable after power mains fail × 1.5
3. Length of time it takes to switch to alternative power supply × 2
4. Length of time the functioning of instruments will be required to bring about an orderly shutdown

The charger must be sized so that it can simultaneously operate the unit and recharge the battery system after a discharge. A recharge time of 8 hours is reasonable. Circuit breakers and fuses downstream of the inverter must be sized and coordinated so that the available current will trip them out before a significant voltage disturbance could occur.

Isolation Transformers Digital equipment is usually very susceptible to spikes in its power supply. The UPS system will filter out spikes from the main power source. If equipment other than the digital system is connected to the UPS bus, an isolating transformer should be used. A transformer that will filter a 50-volt peak and is furnished with a Faraday shield will often be adequate. The actual instrument manufacturer's recommendations must govern the final choice of specifications.

Grounding Each instrument case, control panel, auxiliary cabinet, and instrument system must be safely wired to the control house ground. Low-level instrumentation and DDC equipment require their own separate grounding net. A 1-ohm resistance to ground is usually a safe number. Here again, the individual equipment manufacturer's recommendations must be followed.

Wiring and Terminal Identifications Most analog electronic control loops are of the "two-wire" type. This means that the locally mounted transmitter or control element does not require a separate power supply but takes its actuating energy from the signal wires. Therefore, the installation requires only a two-conductor cable for each transmitter or final control element. To simplify field wiring and minimize overall field installation costs, auxiliary components are usually mounted on the back of the panel. In this way the complex interconnecting wiring is installed by the panel manufacturer.

For flexibility in making loop changes and additions, one method of installation is to use a centralized terminal block for each complete instrument loop on the back of the panel. In this system, each transmission and control loop is assigned a set number of terminals in the field tie-in junction box. Each group of terminals is identically marked, and the terminal marking strip carries the instrument loop number. Each component of the loop is then wired to this terminal, as shown in Figure 4.2z. Spare terminals should also be included for future instruments and components.

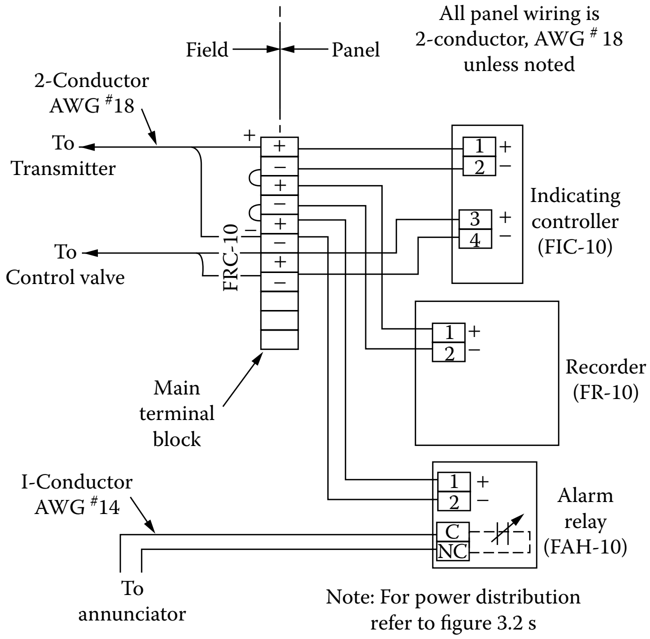
Terminal strips are available with white plastic or painted marking surfaces, suitable for penciling in identification. At all electronic instrument field tie-ins, the junction blocks should be identified with the instrument loop number, its function, and its polarity in the following manner; FRC-10-T(+) FRC-10-T(–). All other terminals should be identified similarly, except that they are marked with the instrument terminal designation instead of the polarity. For equipment such as relays, switches, and other components without terminal designations, the terminal should duplicate the identification shown in the wiring diagrams, such as SV-10-VS (SV-1) or annunciator A (S1-1).

Wire identification data should duplicate the information shown on the terminal marking strips: instrument item number, function, and polarity. Function and polarity identification may be replaced with color-coded wire insulation. To be effective, the color code must be simple and consistent. A typical color code recommendation is given in Table 4.2aa.

In addition to the color coding, the wire may be identified with the instrument item number by means of a preprinted marker tape or by a plastic sleeve. The sleeves either are sized to a snug fit over the wire insulation or are of the shrink type.

Wire terminations should be made with crush-type wire lugs. Special lugs are available for solid wire. A good lug to use is flanged spade lug. This type combines the ease of installation of a spade lug with flanges that hold the lug in place if the terminal screw becomes loose.

Where wires are run within a duct, it need not be laced. Although it gives a neater appearance, lacing is time-consuming and is a nuisance when wires must be frequently added or rerouted.



Note: For power distribution refer to figure 3.2 s

FIG. 4.2z
Typical wiring diagram for an electronic instrument loop.

TABLE 4.2aa
Wiring Color Code Used on Control Panels

Color of Wire Insulation	*AC Service (120-volt, 60-cycle Supply Using AWG #14 wires)*	*DC Service (Low Voltage Using 2-conductor AWG #18 wires)*
Black	"A" phase — hot	Positive power, transmission or control signal
Red	"B" phase — hot	Negative power or control
Blue	"C" phase — hot	—
White	Neutral	Negative transmission signal
Brown	Annunciator common (II)	Annunciator signal
Orange	Annunciator signal	Annunciator signal
Green	Ground	Ground
Gray	Miscellaneous interconnections and jumpers	

CONTROL CENTER INSPECTION

A complete panel inspection at the manufacturer's plant will usually pay dividends in ease of installation, field tie-ins, loop checkouts, and in a smoother plant start-up with fewer field man-hours expended.

The control center designer, familiar with the overall instrumentation and operating philosophy of the unit, can visually inspect and functionally check a control panel most expeditiously. Together with a pipe-fitter and an electrician, the designer can locate piping errors or wiring mis-terminations in a fraction of the time that it would take in the field.

Each panel has its own peculiarities. The following examples may be useful as a guide for formulating a checklist for inspection:

1. Panel construction dimensions should be evaluated, for example:
   a. Overall dimensions
   b. Thickness of panel
   c. Size of framing
2. Construction materials to be assessed include:
   a. Panel and framing material
   b. Panel finish (e.g., smooth, unblemished, correct color)
   c. Piping materials (copper, brass, PVC, etc.): sizes, correct valves, fittings, and so forth
   d. Wiring, proper wire gauge, type, and insulation
   e. Hardware (acceptable industrial grade, rated equal to or better than service requirements)
3. A properly designed panel will have the following construction features:
   a. The finish and appearance of the overall panel will be workmanlike.
   b. All instruments and equipment will be properly aligned.
   c. Tubing, piping, and wiring will be neatly laid out and adequately supported and will not interfere with instrument maintenance.
   d. All equipment will be rigidly mounted.
   e. The back-of-panel auxiliaries and miscellaneous hardware will be properly identified by item numbers.
   f. All field tie-ins will be identified.
4. The following rules regarding instrumentation should also be followed:
   a. All instruments should be installed in their proper location on the panel.
   b. Correct instruments should be furnished and installed including the charts, scales, model or type numbers, and instrument nameplate inscriptions.
5. Preliminary checks are performed as follows:
   a. Power distribution is checked using these steps:
      i. Verify that no one is working on the panel.
      ii. Check that the panel is securely grounded.
      iii. Put all disconnect switches and circuit breakers in the "off" position.
      iv. Pull all polarized plugs.
      v. With a high resistance (light or other) across the input terminals, energize the panel.
      vi. If the light dims, find and remove the ground or short circuit.
      vii. Energize each circuit and check each power supply subcircuit sequentially. Deenergize the circuit after checking and before energizing the next one.
      viii. Check for proper voltage.
   b. Air supply is checked using the following steps:
      i. Close all instrument air supply isolating valves.
      ii. Close reducing station gate valves.
      iii. Connect clean, dry air supply to the panel at the specified pressure.
      iv. Open reducing station blocks and check downstream air pressure of each reducing station (set at 20 PSIG, or 138 kPa).
      v. Blow down the filters and the header drain valves.
      vi. Increase the header pressure until the relief valve pops.
      vii. Individual air supplies may be checked as each loop is operated.
      viii. Bubble-test the main air header connections for leakage.
6. Functional tests may include the following examinations, which should be performed in the order listed:
   a. Assessment of pneumatic instruments:
      i. Simulate the input signal at the bulkhead fitting with a 3- to 15-PSIG (21- to 104-kPa) regulator.
      ii. Attach a 0- to 30-PSIG (0- to 207-kPa) gauge to controlled output at the bulkhead.
      iii. Turn on the air supply.
      iv. Verify that the bulkhead and air supply nameplates are correctly inscribed.
      v. Vary the input signal and watch the output gauge for proper response.
   b. Evaluation of alarm and 120-volt control circuits:
      i. "Jumper" the input terminals one at a time to verify that the correct annunciator light flashes. The horn may be disconnected after the first alarm checkout.
      ii. Energize the relay circuits on the panel by simulating the input signals.
      iii. Connect a pilot light to the output terminals of outgoing signals actuating remote solenoid valve or relay. Be sure to verify output voltage so that pilot lamp will match.

   - iv. As each item is checked, verify the tagging of equipment and of field tie-ins.
   - v. Energize all chart drives, place mark on roller, and check after 1 hour for movement.
- c. Assessment of analog electronic instruments:
   - i. Energize the loop for checking and deenergize when checked.
   - ii. Simulate the input signals at field tie-in points. Check input signal type, level, and voltage. This is particularly important for special instruments.
   - iii. Put proper resistance across output terminals.
   - iv. As each instrument is checked, verify the identification of equipment and of field tie-in terminals.

DCS or other digital instrumentation is checked as follows:

1. Simulate the proper field input signal at the I/O cabinet.
2. Add resistance across output terminals at the I/O cabinet.
3. Check the CRT for proper response.
4. Verify that all incoming square roots have been converted to linear signals within the distributed system.
5. Verify that all control algorithms and PID settings are correct.
6. Check the groupings to ensure that each loop appears in the proper place.
7. As each loop is checked, verify that the I/O terminals are correct.

If the inspector is unable to stay at the shop and verify that all mis-terminations and errors have been corrected prior to panel shipment, then a “punch list” is prepared. One copy is left with the panel manufacturer, another is kept as a record, and a third copy is sent to the field so that the panel can be checked upon arrival at the job site.

After a proper panel inspection there should be no difficulty in hooking up the field tie-ins. Any problems in the loop checkout and calibration will most likely be external to the panel. This will significantly ease the troubleshooting in the field.

PANEL SHIPMENT

A panel should be handled as little as possible because the chance of damage is much higher during loading and unloading and when the device is in motion on the carrier.

When the panel is to be shipped by truck and installed immediately upon arrival at the job site, only skids with a light framework holding a tarpulin are necessary. To save time and handling, the panel should travel via an air ride van. The van should be “exclusive,” that is, reserved for transportation of the panel. This will ensure a direct route to the plant, without stopovers at trucking terminals, and will reduce handling. The van should also be furnished with a removable top so that the panel can be lifted out.

If the panel cannot be installed immediately and must be stored at the plant site, heavier crating is required and a thicker plastic sheeting should be used. Because time is not critical and the panel is better protected, an exclusive van need not be used in this case. Shipment by train, although less expensive for long distances, requires additional handling and moving. Some trains are also severely jostled during make-up and routing.

When shipped by boat, the panel should be sent as below-decks cargo. The panel crating must be especially heavy and must be cushioned within the case. The wrapping should effectively seal out the salt air. Prior to sealing, the voids inside the wrapping should be liberally loaded with a dessicant, such as silica gel. Heavy, impregnated, water-resistant paper or 5-mil-thick polyethylene can be used for wrapping. All seams should be covered with waterproof tape. When possible, smaller shipping units should be used to ease handling. All panel equipment must be securely braced.

Air freight does not require any particular crating or wrapping other than that required for a nonexclusive van. The particular airline must be contacted and questioned regarding weight and overall size limitations for each panel and crate. The plant site airport may also be checked to verify that it is capable of receiving the type of airplane required for the shipment.

CONCLUSIONS

Control center designs need not be limited to the basic examples discussed in this section. There is no limit to the number of design variations. Each center may be formulated of new and different shapes specifically conceived and adapted to its own unique application.

The multiplicity of design parameters is such that drawings and specifications cannot cover every particular feature. The only reasonable way to ensure the development of the exact control panel desired is by close cooperation of the panel manufacturer and the panel user.

4.3 Control Center Upgrading

B. J. GEDDES (2002)*

Cost:	Workstation costs range from $10,000 to $30,000 depending on the number of flat panel displays, video display units, computers, and input devices. Where new screens replace analog instruments in a conventional panel, cost is typically $5,000 per screen. The above costs do not include hardware/software integration.

As process plants age, owners must consider a variety of asset life cycle management issues, including instrument and control (I&C) system obsolescence. Plants constructed prior to the early 1970s were predominantly supplied with analog instruments and controls, either electronic or pneumatic.

It is likely that the vendors who supplied these original analog systems no longer provide parts or services to keep them running. As computer chips and information systems became available through the advent of the information age, instrument and control system vendors found innovative ways to apply this digital technology across their product lines. Systems and components are now smaller, more reliable, and fault tolerant, and they can perform multiple functions that were previously spread across multiple, discrete components.

Today, process engineers are presented with a variety of digital components and systems ranging from transmitters, switches, relays, breakers, controllers, recorders, indicators, video displays, distributed control systems, fieldbuses, and networks to connect them all together. The control system vendor may supply any or all of these new components and systems as replacements for the original equipment.

Digital information and control technology offers a variety of entry points in the analog process plant. The entire plant can be upgraded at once in one outage, or the owner and designer can choose to upgrade one system or component at a time. The technology is flexible enough to consider any upgrade path, which almost always has an effect on the control room.

The designer has two basic choices:

1. Building a New Control Room—If the plant is still operating, but has excessive cost or obsolescence problems in the I&C system or in the control room, then a new control center (building) may be economically justified. A new control center will be built as close as possible to the old control room or control center, so operations and maintenance tasks that require proximity to plant equipment can be maintained. This option also has the advantage of allowing construction to proceed while the plant is operating.
2. Upgrading the Control Room as Required (Phased Approach)—If the plant can still meet its business goals safely and effectively, and obsolescence is not yet a significant safety, reliability, or cost issue, then the designer can select an upgrade path for the plant on a system-by-system basis that accounts for time-to-obsolescence. System upgrades can be performed while the plant is in production, or during routine maintenance outages. Over time, the control room will have the same basic layout as that supplied during original construction, but the panels and furniture will be configured with modern technology where it is needed. Original indications and controls that are not obsolete and can still be easily maintained may remain as-is, but they will be reintegrated in a hybrid

---

[*] This section been reprinted with minor additions and changes, from Volume 3 of the *Instrument Engineers' Handbook*, which is titled: "Process Software and Digital Networks."

analog/digital design with modern human machine interfaces.

Designers must consider the impact on the control room when applying new technology in any part of the plant. Even a seemingly innocuous plant change can impact the control room. For example, a digital, fieldbus-compatible process transmitter may offer a local upgrade path for a given plant system. But this transmitter now supplies much more information than the original 4–20 mA DC transmitter, and it should be applied in the context of a total plant architecture that will impact the control room as it evolves.

It is critical to see beyond the immediate needs of the plant. Plant owners will naturally tend to apply funding and resources to the I&C systems that cause the most trouble and stop until the next acute need arises. Acute system problems usually have a significant impact on plant safety or production, and the designer owes a more proactive and comprehensive approach to the owners.

BASELINE EVALUATION

The goal of the baseline evaluation is to ensure the upgraded control room still functions well within the original plant. The functional allocations between humans and machines should be well understood and documented. Operations and maintenance tasks should be understood and documented, and information zones should be mapped and correlated with these tasks. More importantly, the baseline will also ensure that the control room operating staff's sense of how the plant is designed and operated will be maintained with the modified or new control room.

The designer must first understand how and why the original control room is designed the way it is, then understand the basic operating philosophy of the control room staff. The operating philosophy can be defined as the set of rules and procedures matched with the set of roles and responsibilities of operating staff resources that are applied during all modes of operation, including normal, abnormal, and emergency operations. Operating staff (control room supervisors, control room operators, and system operators) roles and responsibilities in an existing plant are based on the functional allocations between humans and machines, which then determine the tasks assigned to humans in all phases of plant operations.

The baseline evaluation should begin with an evaluation of the basic design of the existing plant information and control systems by reviewing loop diagrams, schematics, wiring diagrams, and panel layout/cutout drawings. Figure 4.3a represents an architectural perspective for the analog I&C systems and components in a typical older process plant. Each set of systems and components can be categorized by its basic function.

The cloud at the bottom of Figure 4.3a comprises the basic sensors such as pressure, temperature, flow, level, and

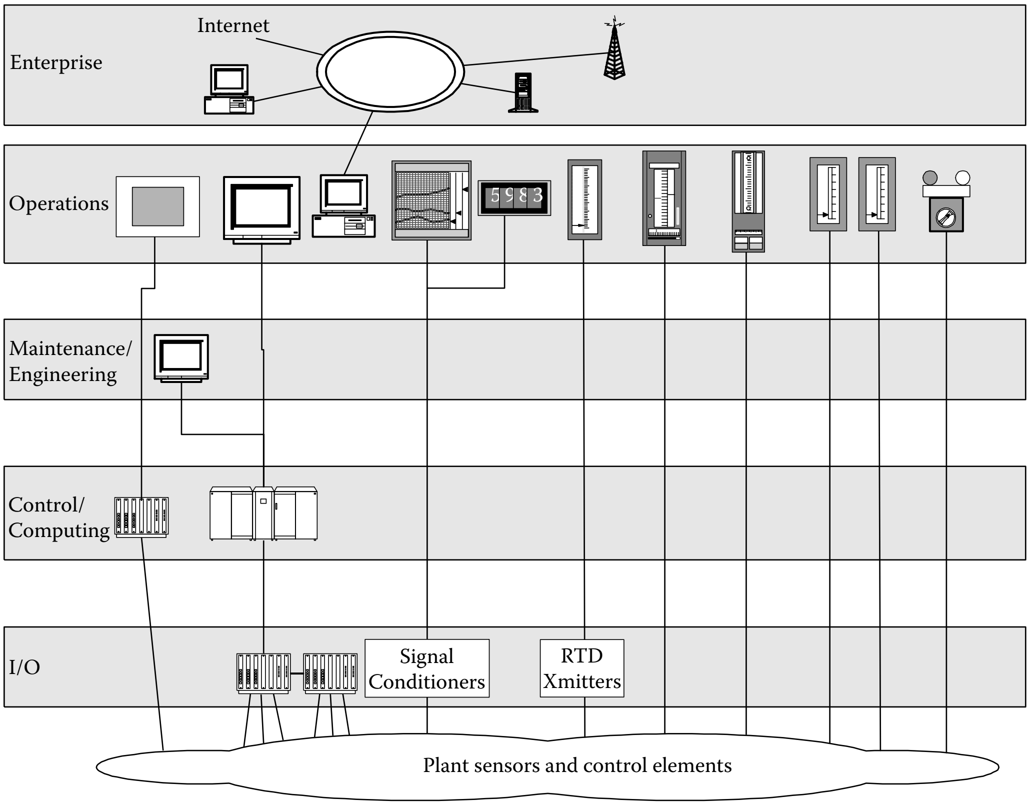

FIG. 4.3a
Analog I&C architecture.

position switches, various measurement elements, and analog process transmitters. It also represents final control elements such as motor control centers, motor-operated valves, air-operated valves, dampers, and machines. This population of sensors and control elements usually numbers in the thousands for large process plants.

The input/output (I/O) layer just above the cloud at the bottom of Figure 4.3a represents the basic I/O systems that may be used by what few digital platforms are employed, such as a mainframe plant process computer.

The mainframe computer, in the control/computing layer, typically runs a real-time database program for those plant variables that need to be stored and retrieved in group displays or reports, or used as input data for complex performance calculations. The number of data points assigned to the plant process computer may number in the thousands, but its role is limited to information-only applications.

The maintenance layer represents any interfaces made available to maintenance and engineering. The only interfaces that are available to maintenance and engineering in the analog plant are confined to the one or two computers that may be used in specialized applications.

The operations layer represents the devices used by the plant operator, and it can be seen that the majority of the devices in Figure 4.3a are in this layer. These devices include trend recorders, digital indicators, vertical and horizontal meters, a variety of hand switches, single-loop controllers, lamps, and annunciator light boxes. By inspection, most of the analog plant sensors in Figure 4.3a terminate directly on these devices used by the operators. Any maintenance required on these analog loops will usually take the affected devices out of service and result in a negative impact on the operation of the plant due to disruptions and loss of information and control.

Finally, the enterprise layer illustrates the basic plant or company enterprise where information technology (IT) systems are deployed. Operators may have a company PC at their disposal in the control room for retrieving enterprise information such as drawings or accounting data, or sending and receiving e-mails. This PC is only connected to the office local-area network (LAN) and is not used directly to operate or maintain the plant.

Changing any component in the lower layers of Figure 4.3a can impact the operations layer, and vice versa. For example, the plant may need to upgrade a set of plant sensors due to obsolescence. The signals from the old sensors were processed by the mainframe computer. The new sensors require a new software code to properly acquire and convert their signals to the engineering units required by the operator. The new software cannot run on the old mainframe computer, so a new computing platform is needed in the form of a server, which comes with a client software package for use on a PC or workstation in the control room. The server can also be integrated with a DCS (distributed control system). Now we have a complete system upgrade that affects every functional layer in Figure 4.3a, with significant control room impact.

FIG. 4.3b
Analog control room.

ORIGINAL DESIGN PERSPECTIVE

Figure 4.3b shows an older control room, typical of power plants and other process plants designed and built between the late 1960s and the early 1980s. The majority of the indications and controls are from original construction and are almost all analog instruments. Some plant systems have been upgraded since original construction, but only on an as-needed, system-specific basis. No serious consideration has been given yet to a total control room modernization effort.

The operator interfaces are typically located on “stand-up” control panels and are used by control room operators during normal and emergency operations. Desks are provided for senior control room operators and control room supervisors, with telephone and radio equipment and terminals connected to a mainframe plant process computer. The panels are laid out by major plant functions such as electrical systems, cooling water systems, major machine controls (e.g., turbine/generators or compressors), reactor controls, and emergency systems.

On each panel, indications and controls are grouped by specific plant systems or functions. For example, Figure 4.3c shows a feedwater control system panel from the same control room shown in Figure 4.3b. Annunciator windows are on the top plane of the panel. Feedwater heater level indications are grouped on the left-hand side of the vertical plane. Steam generator temperature and level indications are grouped on the right-hand side. Across the bottom planes are indications and controls associated with the control elements for feed pump turbines, condensate pumps, and various valve position indications and controllers. Groups of instruments and controls are bordered or separated by a thick black demarcation line called “zone banding.”

Each group of instruments and controls can be associated with a set of operator tasks for each mode of plant operation (start-up, normal, shutdown, and emergency operations).

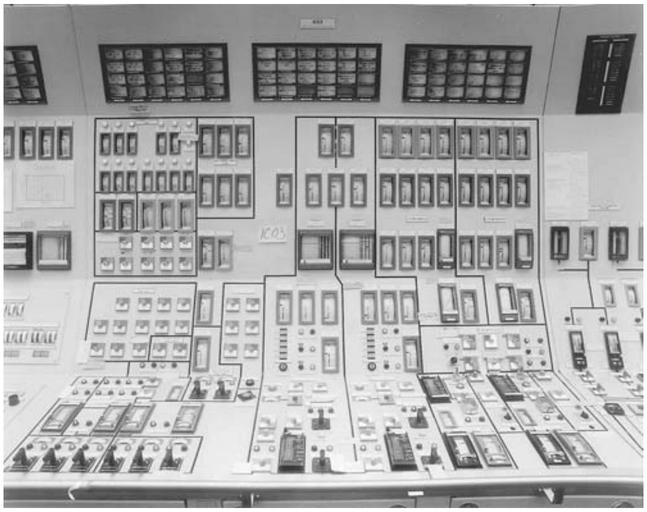

FIG. 4.3c
Analog control panel.

Written procedures describe operator actions required for responses to various alarms or during various controlled transients. Operators are trained in a full-scale simulator for various operating modes and equipment failure scenarios, and they are trained to perform periodic visual scans, or surveillances, of each group of indications and controls either close up or from a “total control room” perspective. The baseline evaluation should capture all of these operator tasks and their associations with each group of indications and controls.

INFORMATION ZONES AND TASK ANALYSIS

Perhaps the most significant design aspect of an older, analog control room is that all plant indications and controls are in discrete locations on the panels. Most plant variables are only readable from one instrument in a “fixed position” on a panel, and plant system variables are grouped in “information zones” where operators are trained to look for patterns in the indications to detect, diagnose, and maintain or mitigate various plant conditions. The information zone human–machine interface (HMI) design concept is a very strong paradigm for operators, and should not be significantly modified or corrupted unless a new control room is built, complete with a new task analysis, operating procedures, and operator retraining and qualification program. In the phased approach, information zones are kept intact as each zone is upgraded over time.

Each information zone is associated with a set of operator tasks, which should be studied and evaluated using simulators or mockups. Tasks will vary with modes of plant operation. Most operator tasks in a continuous process plant will be associated with surveillance of the process systems. During routine surveillances, an operator will visually scan the control panels looking for patterns in the indications and alarms that indicate plant systems are operating within specifications. Some manual manipulations of multichannel meters or displays may be required.

In an upset mode, such as a sensor or equipment failure, or a trip of a major plant machine or the plant itself, an operator’s task loading will shift dramatically, and will be focused on key plant variables and controls. Alarms will be prioritized by the operator per procedures and training plans, and the event will be diagnosed and mitigated through the cognitive strengths of the human operator. The HMI will be designed to accommodate this shift in task loading with an emphasis on decision making.

Once the task evaluation is captured, operating experience should be evaluated. Operating logs and event reports should be reviewed for positive or negative trends in plant or human performance. Operators should be interviewed to see if there are any HMI issues that need to be improved or corrected. Are there any recurring situations where operators are tasked with too many simultaneous inputs requiring concurrent actions? How do operators prioritize their actions under these scenarios? Are there any operator tasks where there is a deficiency in available information, such as resolution, timeliness, or readability? Are there any indications and controls that are too difficult to read or understand, or are simply not available under certain conditions where they are required for an operator task?

If an operating experience review indicates deficiencies, event scenario walkthroughs should be conducted in a full-scale simulator if one is available. If a full-scale simulator is not available, a full-scale mockup of the control room should be built. At first, a mockup of the old control room might seem like a waste of time, but it can support an engineering analysis of the strengths and weaknesses of the old control room without disturbing plant operations, and it can support experimentation and evaluation of new design concepts as they are integrated in the original control room if the phased approach is used.

Figure 4.3d shows a 1/8 scale mockup of the same control system panel shown in Figure 4.3c. It was made by reviewing photographs and layout and cutout drawings of the panel, then making a scale template of each plane on a personal computer using Visio™, a commercial graphics software package. Objects for each type of control panel device (recorders, indicators, controllers, etc.) were made and stored in a Visio stencil, then applied to the scale template using a “drag and drop” technique. Each panel was printed on a color printer or plotter, spray-glued to a piece of cardboard, then cut out and assembled using a hot glue gun. The total cost of the software and materials for this mockup was less than $100.

The engineering and technician time invested in building the object library, or stencil, and preparing this first panel was over 100 hours, but subsequent panels take less time and the library is now available for finishing a mockup of the entire control room. This mockup was prepared at full scale in the computer, then printed at 1/8 scale for this version. The same Visio files can be printed at full scale on

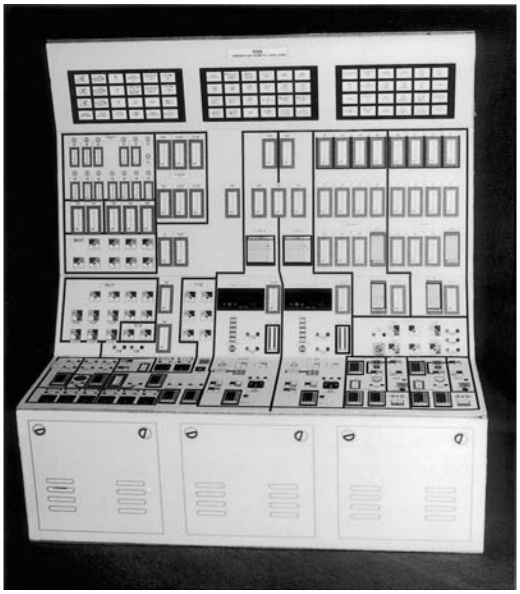

FIG. 4.3d
Panel mockup.

an engineering plotter, and applied to a full-scale plywood mockup, which is useful for walkthroughs with operators.

Finally, the baseline evaluation should examine all of the operating and maintenance costs associated with the original I&C systems in the plant. If an older, analog plant is expected to have a long operating life, many if not all of the I&C systems will need to be replaced. These replacement activities will be necessary to maintain continued plant operation, to take advantage of current technology, to improve plant availability, and to facilitate further reductions in operating and maintenance costs.

The most significant economic driver is usually obsolescence, which can be changed from a liability to an asset in considering control room upgrades. When obsolescence is considered in aggregate, a strong economic case for an integrated, modern control room can be made. A system should be considered obsolete when any of the following criteria are met.

1. The system will not meet the operational demands required of it during all phases of plant operation, including normal, abnormal, offline, online, and emergency situations.
2. The parts manufacturer has formally announced that it will no longer directly support the system or component, or will require a significant increase in component cost to continue support.
3. The system or component will not interface with new components that are required in other systems. It is virtually assured that if the operational life of a process plant is extended, all system components will require some form of major component replacement.
4. The system or component cannot support plant operations that are desired by the business plans.

Once the baseline evaluation is completed, the plant owner and the designer will have an accurate assessment of the functional, performance, and economic state of the plant I&C systems and, in particular, the control room. Goals and objectives can be clearly described, and upgrade options can be estimated and undergo a total cost–benefit analysis.

BUILDING A NEW CONTROL ROOM

Building a new control room all at once allows the full potential of modern I&C systems to be immediately realized in an older process plant. A new control room in this context means the complete retirement and replacement of the original analog panels, I&C systems and HMI components with new digital systems, using a DCS or PLC (programmable logic controller) platform. The replacement systems may be installed in the original room, or may be installed in a new building or otherwise spare plant location.

If the plant can no longer meet its business goals safely and effectively because of control system degradation and obsolescence, it probably needs a major overhaul, and an entirely new control room may be in order. If a plant is being overhauled for a major capital upgrade (new reactors, boilers, compressors, turbine generators, or other major machinery), it will probably include a new process or machine control system. The designer can engineer a new control house and demolish or retire the old one in place, or gut and rebuild the existing control room. The new control room should be implemented with a workstation/console arrangement designed to maximize safety, quality, reliability, and productivity with a heavy emphasis on human engineering.

The decision to build an entirely new control room all at once has profound implications for the entire process plant. The designer can demolish the old control room by removing all components and structures, including panels and furniture, leaving floor and ceiling slabs and four bare walls, with field cables pulled back or left coiled near their penetrations.

Using this approach, an analog control room is replaced with a fundamentally new “glass control room,” or one that consists of video display units (VDU) located on operator workstations or consoles and can also include one or more large displays. The control system cabinets will typically be located in a computer room or cable spreading room adjacent, above, or below the new control room, with data communications interfaces serving the consoles and workstations.

The ISO 11064 standards (Parts 1 through 8) offer a sound methodology in the design of a new control room. Their emphasis is on the design of a new control room in the context of a new plant, but they also describe design processes that can be used in designing a new control room as a retrofit in an existing facility.

Using a standard design methodology, as shown in Figure 4.3e, will improve safety, quality, and reliability when applying modern digital system technology. The roles and responsibilities of operators and machines can be modified

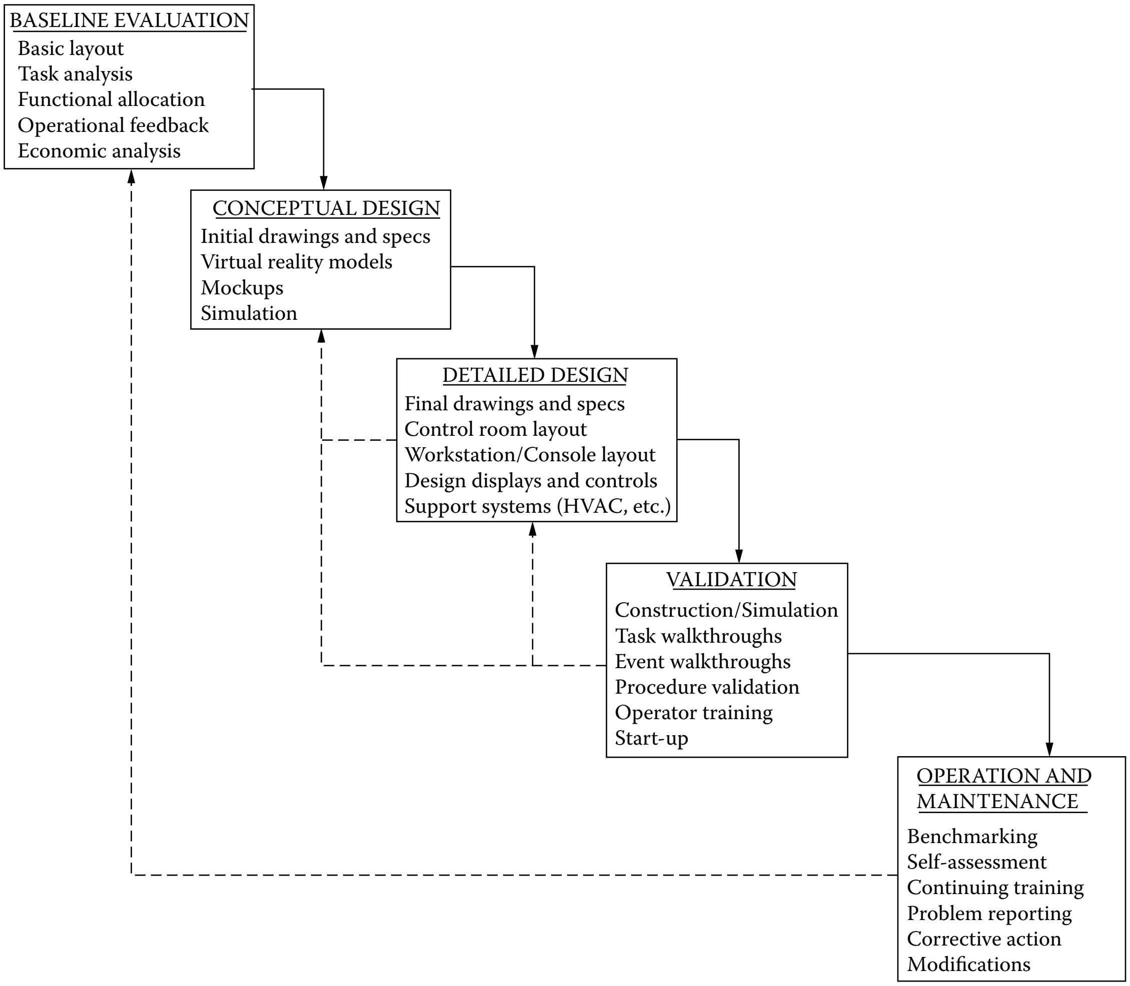

FIG. 4.3e
General design process for new control rooms.

and tasks and functions reallocated to achieve a higher performance standard. An increased reliance on automation can significantly alter the role of operators by reducing their task to vigilance over a constant process, while also greatly expanding their role during system upsets to one of corrective action through cognition, diagnosis, and appropriate manual responses. If a new control room is under consideration, particular attention has to be paid to ensuring that any changes in roles and responsibilities of machines and operators from the old control room to the new one continue to meet or exceed the goals and objectives outlined in the baseline evaluation. Without a careful design process, unintended functions can be created with potentially negative consequences.

Basic ergonomic principles should be applied in the design of control rooms. Ergonomic design principles include:

- Use a human-centered design approach. Design for basic physical limitations, but also emphasize human cognitive strengths such as perceptual, problem-solving, and decision-making abilities.
- Improve design through iteration. Repeat design evaluations until functional and performance goals are achieved.
- Start with the baseline evaluation performed on the original control room, and revise through each design iteration.
- Design error-tolerant systems. Allow for human error, and provide interlocks, alarms, and overrides where appropriate.
- Ensure user participation. The most knowledgeable asset on the design team can be the control room operator. Add system and process engineers, ergonomists, architects, and industrial designers to form an interdisciplinary design team.

TECHNOLOGY ADVANCES

Technology advancements in recent years have enabled a state-of-the-art approach to control room design. Compact workstations, large display panels, soft controls, fixed and selectable displays, advanced alarm systems, and computerized procedure systems greatly enhance safety, reliability, and efficiency.

A modern control room includes compact workstations, a safety console for plants that require one, and furniture and rest areas. A large display panel (LDP) can also be provided. Key features that support the ability of the operating crew to maintain efficient and safe plant operation include:

- Full-function workstations supporting direct plant control and monitoring by one or more system operators
- An identical workstation supporting normal monitoring and crew coordination functions of a control room supervisor and serving as a backup to the operator workstations
- An LDP providing overall plant operational and safety assessment
- A safety console (for those industries with safety requirements) providing control capability for all safety-related components independent of the workstations supporting safe plant shutdown even in the event of complete workstation failure

Advantages of this control room layout, shown in Figure 4.3f, include enhanced communication between operators, operational facilities for all expected crew members, good visibility of the LDP, ease of accommodating design and job allocation changes, and convenient access and egress routes. Layouts will vary depending on the number of systems in the process plant that are monitored and controlled in a main control room. If a site has multiple process plants that are independent islands, but still controlled from one central control room, then the control room layout may employ multiple sets of compact workstations, depending on operator and supervisory tasking.

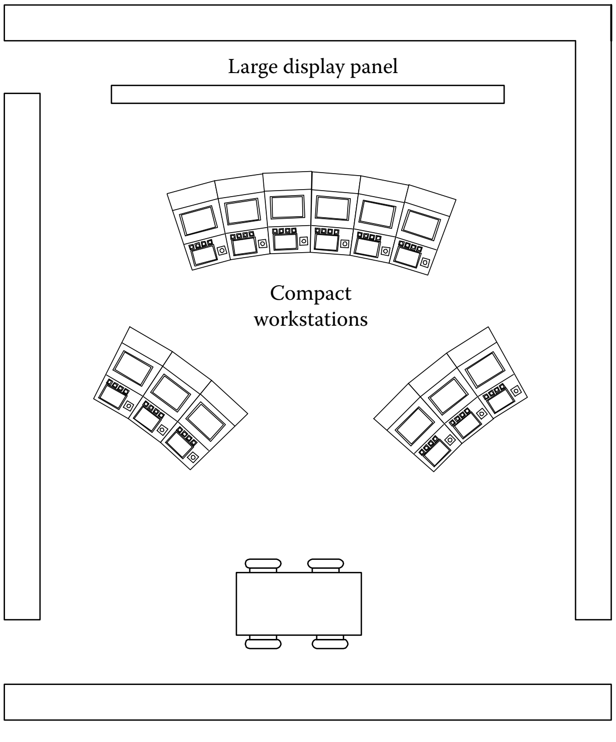

FIG. 4.3f
Sample control room layout.

The LDP is a wall-mounted overview display, which includes static and dynamic elements. High-resolution, tiled projection systems are available today with seamless borders between tiles. The fixed display section of the LDP provides continuous, parallel display of key alarm, component, system, and parameter information. This complements the workstation HMI with a spatially dedicated graphical depiction of the plant. A variable display section allows operators to display pertinent information selectively to support crew coordination. A sample LDP design is shown in Figure 4.3g.

Each main control room workstation provides devices for access to all information and controls necessary for one person to monitor and control all processes associated with plant operation and safety. This includes both safety and nonsafety systems. A sample workstation layout is illustrated in Figure 4.3h. Each workstation contains the following:

- One alarm VDU with trackball user interface
- Multiple VDUs supporting process monitoring or electronic procedures with trackball user interface
- Multiple flat panel displays used as soft controllers for process and component control; each works in conjunction with one VDU, using a touch-sensitive user interface
- Dedicated, diverse push buttons for manual safety system actuation
- Laydown area for logs, drawings, backup paper procedures, etc.

The major advantages of the compact workstation approach are its (1) operational and design flexibility, (2) compactness and simplicity, (3) ability to accommodate changes cost-effectively, and (4) provision of an enhanced integrated environment for a computerized procedure system (CPS) and operator aids.

Workstations should allow simultaneous access to plant information through selectable displays on multiple VDUs per workstation. A wide variety of display formats should support system mimics, major plant functions or conditions, technical data sheets, trends and graphical information, and application program access. All are designed to support specific operator functions. Multiple methods should be provided for convenient access to the display set, including navigational access through menus, direct access through format chaining from other displays (or alarms and procedures), and a dedicated mechanism such as function buttons or voice entry. A major function of the VDU displays is to provide a soft control link allowing the operator quickly to select a

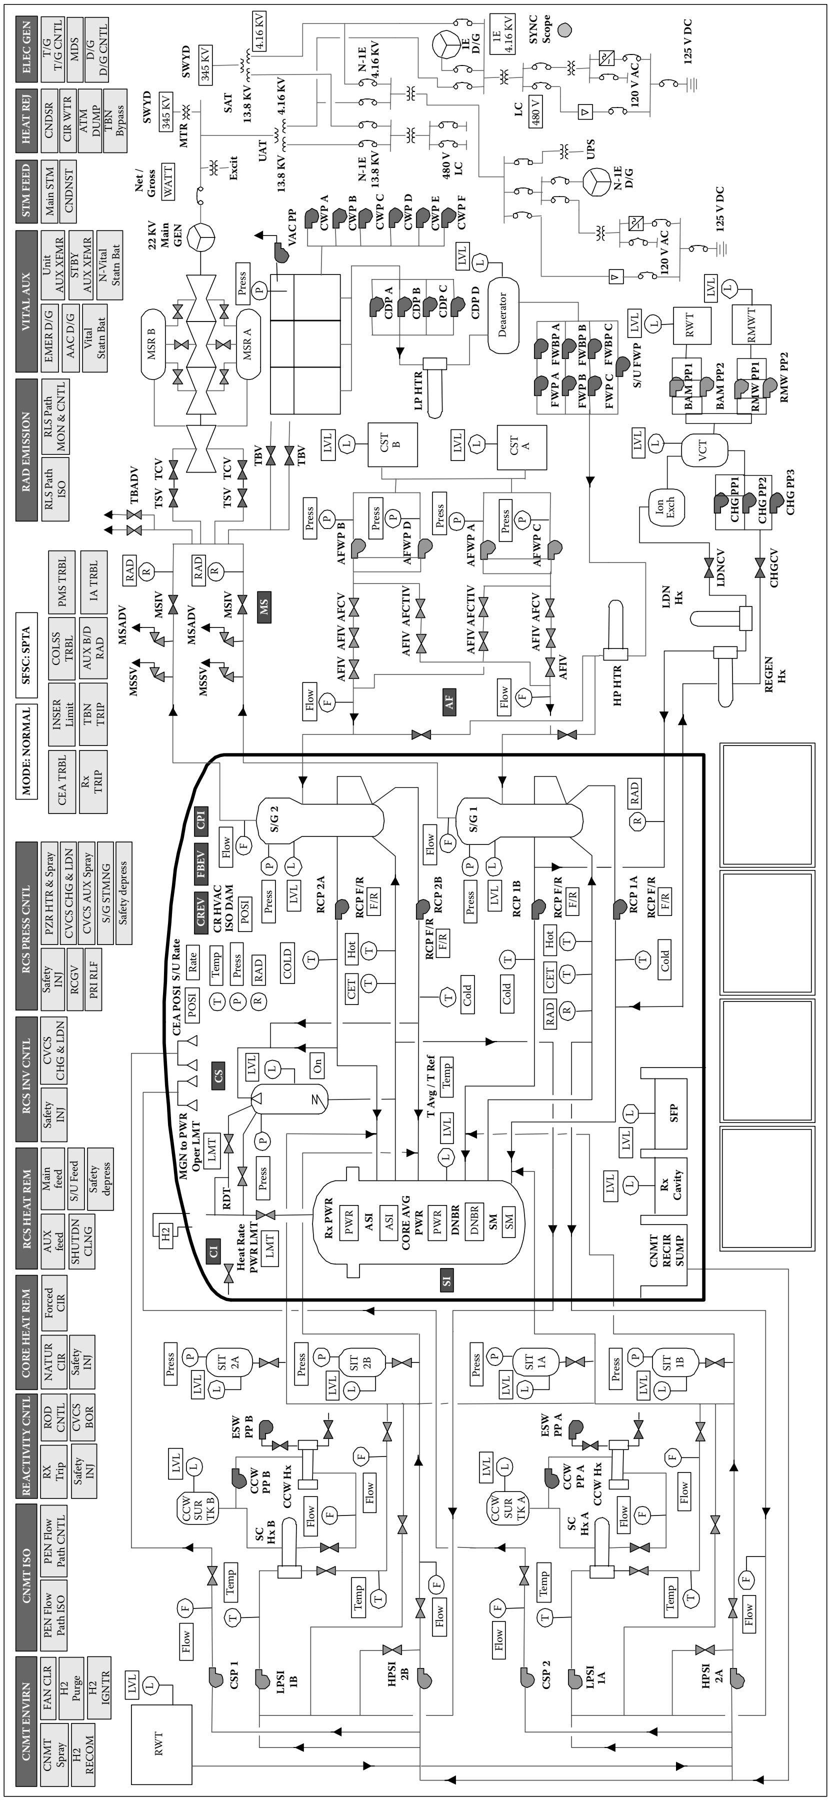

FIG. 4.3g
Large display panel. (Courtesy of Westinghouse–CENP & KEPRI.)

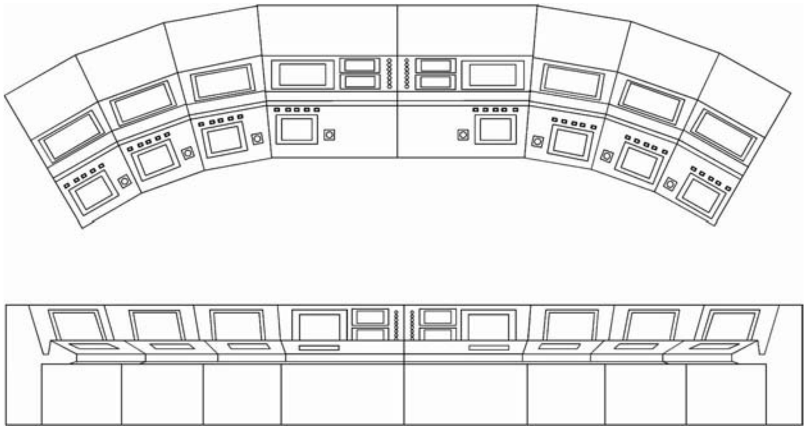

FIG. 4.3h
Typical workstation design. (Courtesy of Westinghouse–CENP & KEPRI.)

component or process control on the soft controllers directly from display pages.

"Soft controls" should utilize flat panel displays to emulate the physical switches and manual/auto stations that populate conventional plant control panels. Use of software-based control allows a standard interface device to assume the role of numerous physical devices. This has the advantage of allowing operator access to all plant controls from a single workstation, design flexibility, the ability to accommodate changes easily, and simplification of hardware procurement and maintenance. Various design concepts can support control of multiple safety and nonsafety divisions from the same workstation device, while maintaining the single-failure-proof reliability of conventional channel separation and independence to support safety system requirements such as those called out in IEEE-603 (1998) "Standard Criteria for Safety Systems for Nuclear Power Generating Stations" and ISA 84.01 (1996) "Application of Safety Instrumented Systems for the Process Industries."

An advanced alarm system can be provided to improve the annunciation process, by incorporating methodologies that:

- Reduce the total number of alarms with which the operator must cope
- Distinguish between true process deviations and sensor failures
- Minimize the occurrence of "nuisance" alarms
- Prioritize the relative importance of alarms so the operator can focus on the most critical alarm conditions first while deferring less critical alarm conditions
- Determine the impact of alarms on plant operations and distinguish these from lower-level system alarms

Highest priority alarms, such as those for critical functions, are presented in fixed locations on the LDP. All alarms are presented in list form on a dedicated workstation VDU as well as through relevant locations in the VDU display hierarchy.

COMPUTERIZED PROCEDURE SYSTEMS

Computerized procedure systems (CPSs) are another significant technology development in modern control rooms, which take advantage of state-of-the-art technology to provide benefits in the human–machine and control room integration areas (Figure 4.3i).

The purposes of an online, data-driven, cathode ray tube (CRT)-based CPS are the following:

- To guide the user step by step through the procedures by monitoring the appropriate plant data, by processing the data and by identifying the recommended course of action.
- To provide the parallel information necessary to allow the user to assess other plant conditions that may require attention, such as, for example, notes, cautions, and foldout page items.

The computer monitors and evaluates large amounts of information quickly and efficiently. Procedure information is online and is updated essentially continuously. Hence, the operator becomes more vigilant because a large amount of procedurally required information is immediately available. The operator's mental loading is reduced because all required procedural information is displayed, including, for example, the status of the current high level step.

The human user's primary role in a CPS environment is to monitor the progression through the plant procedures while maintaining a clear picture of plant state, to take control actions on the control board when they are required and to watch for unsafe plant conditions. The user should retain both authority and responsibility for plant operation. A CPS is user paced, that is, the system should not advance to a procedure step, a note, caution, or foldout page item, or a procedure unless instructed to do so by the user.

FIG. 4.3i
Computerized procedure system. (Courtesy of Westinghouse–CENP.)

A CPS can operate on a two-CRT workstation such that the required procedural information always appears on the first screen and supporting or supplementary procedural information appears on the second screen. Access to the supporting information should be through pull-down menus located along the top of the main screen.

The benefits of a CPS include:

- The computer and the operator complement each other for a more accurate implementation of the procedures, resulting in enhanced situation assessment by the operator.
- The system simultaneously monitors multiple plant parameters.
- The system brings all procedural information to one location.
- The system provides detailed record-keeping capability of the procedure execution.

PHASED APPROACH

A phased approach to upgrading the control room may be economically attractive. In this approach, it is important to recognize whatever design and operating constraints may be in place. The control room to be upgraded is assumed to be in service, and should continue to meet the business goals set by the owner.

The entire control room can be upgraded in phases, over time, according to whatever drivers are selected. The scope and schedule of each phase is optimized when it is consistent with the overall cost–benefit analysis of the entire upgrade, which may take years. If obsolescence issues are not acute, but are slowly accumulating, and the plant is running safely and meeting business objectives, then upgrades can be applied to individual systems or groups of systems while the plant is running or during routine maintenance outages.

If a phased approach is used, then a long-range strategic I&C modernization plan should be developed before any system or component upgrades can significantly impact the control room. Failure to do so will not have any impact on a particular system upgrade, but in the overall scheme, it can increase the total cost of the finished control room. The long-range plan will provide a conceptual design for the finished plant and control room, and it will provide a scope, schedule, and budget for each phase so that they are scheduled in the most cost-beneficial sequence. Each phase will account for the set of systems and components that should be upgraded, taking into account time-to-obsolescence and grouping of systems and components so duplication or rework on later phases is avoided. Obsolescence can be successfully applied in arguing for a comprehensive upgrade plan. Not all the original analog I&C systems will become acutely obsolete at the same time.

In the original analog control room, a unique treatment of indications and controls for each plant system was the norm. Panels were typically designed to support collections of meters, recorders, switches, and controllers grouped by plant system. It is important to avoid unique upgrades for each plant system. If unique digital solutions are applied over time, the result will be a muddled set of DCS, PLC, and other operator interfaces in the control room. All the operational goals of the plant upgrades will not only go unfulfilled but will worsen when realized in total.

Figure 4.3j illustrates the modernized plant. The functional layers are still the same, but there is a significant change in the technology applied in each layer. Figure 4.3j can be considered a hybrid digital/analog plant. The left side of this figure shows digital systems; the right side shows the original analog components. As more plant systems are upgraded, more of Figure 4.3j becomes digital. Hardware and software diversity may be applied for safety systems in each layer where required by regulatory agencies.

The key point in Figure 4.3j is that new I&C systems are expandable horizontally in this perspective, using a building-block approach that applies DCS or PLC technology linked by network communications technology, such as Ethernet, fieldbus, or any other standard that is supported by the manufacturer. This point is essential for implementing a cost-effective phased control room upgrade, where systems are expanded until obsolescence issues are resolved and modernization goals are realized.

The I/O layer employs subracks that can be field-mounted or mounted in cabinets or panels in the control room. The location of the new subracks depends on a number of factors, such as communication constraints (distance, bandwidth, number of allowable nodes) and the impact on cable costs. To optimize cable costs, the best place to mount I/O subracks is within reach of the field cables that were originally terminated on or near the old analog devices.

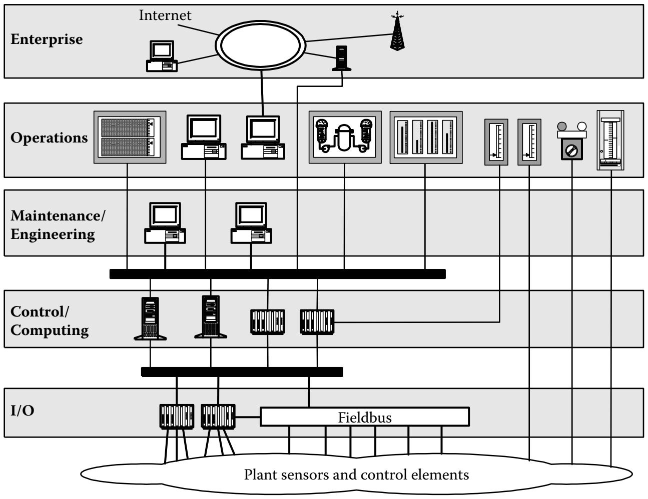

FIG. 4.3j
Hybrid I&C architecture.

The control/computing layer employs DCS or PLC processors or a combination of both. Equipment selection should allow data archiving and computational servers to be added to this functional layer and integrated into the whole control and computing platform system. Hardware and software integration can be expensive and time-consuming, so it should be consistent with one set of standards.

Note that original control room meters can still be used with a new DCS/PLC platform using the new I/O subsystems. This design feature is useful when an entire process system is upgraded, where video display units cannot replace every system switch, light, meter, or annunciator. For example, a small-scale DCS can replace a turbine/generator electrohydraulic control (EHC) system with one or two main VDUs in the place of the original operator interface and still allow connections to original devices in other locations. If all original EHC interface devices in this example are scheduled for replacement with VDUs, the potential exists for other plant systems to be caught up in the EHC upgrade simply because the new VDUs take up more panel space than the original meters and switches.

If any special applications are required, such as a data archiving agent or any plant performance calculation packages, plan ahead and select a DCS/PLC hardware and software platform that can support the special application hardware and software. Pay close attention to database integration issues, because a central database is the strength of a DCS. If an original plant data acquisition system can be connected to a new DCS and the data integrated into the central database, then it will be possible to display and archive the data seamlessly, transparent to the operator, without a new front end for those data points.

Network communications is utilized between all layers. The network topology is optimized for cost and connectivity options, and the first phase of the modernization effort should be carefully designed so that future phases are accounted for with at least 100% spare connectivity. Spare connectivity should support copper and fiber media options. When pulling new fiber-optic cables, select termination locations that support the long-range plan, and pull as many fibers as possible in each cable run (limited by budget or raceway fill).

The operations layer in Figure 4.3j is the most constrained layer in the phased upgrade approach. This layer is constrained by the physical layout and fundamental design of the existing control room. For example, the breakfront panels shown in Figure 4.3b are designed for a standing operator, and indications and controls are laid out by groups associated with major plant system functions. HMI resources such as flat panel displays have to be designed so that the basic information zones of the control panels can remain intact. If a particular information zone contains vertical meters and trend recorders, then flat panel displays should be sized to fill that zone (with redundancy if possible), and the DCS or PLC system should be

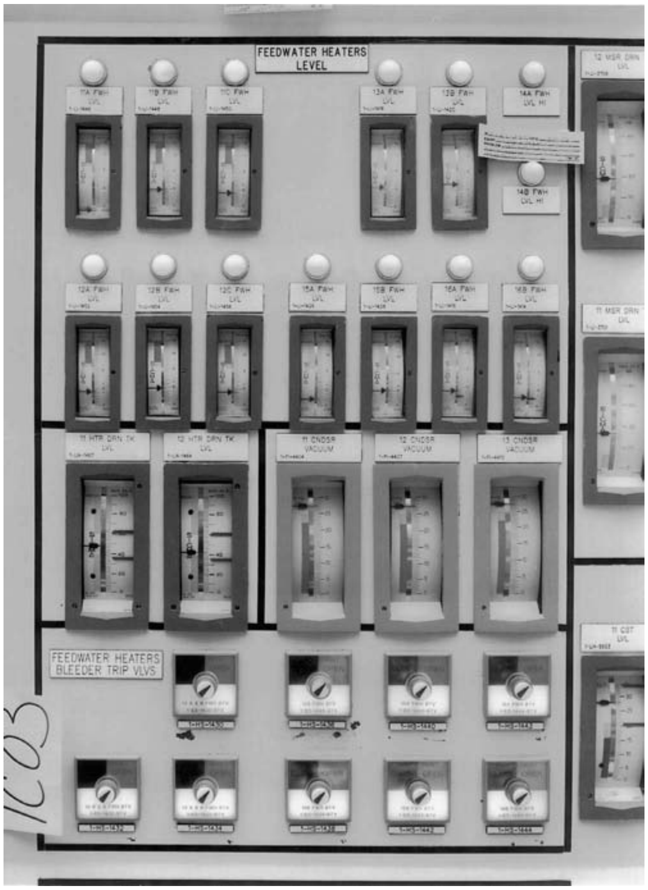

FIG. 4.3k
Feedwater heater indicators and controls.

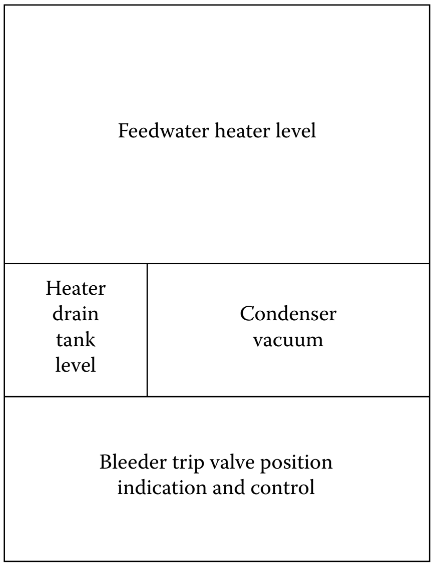

FIG. 4.3l
Feedwater heater information zone.

programmed with a display page that carries the same information with the same readability of the replaced components.

Figure 4.3k is a good example of some information zones on the control room panel shown in Figure 4.3c. Shown here are four zones. The zone on top is a group of feedwater heater level indicators. The middle-left zone is a pair of heater drain tank level indicators while the middle-right zone consists of three condenser vacuum indicators. The bottom zone is a set of indicating hand switches that indicate and control valve position. All of these instruments are connected to obsolete transmitters in the field, which are being upgraded using fieldbus technology. New controllers are being installed, and an integrated display can be connected to the system for use by operators in the control room. The original indicators in Figure 4.3k can be maintained as-is using analog and digital I/O points connected to the controller I/O subrack, but this upgrade provides a point of entry into the control room for a modern HMI interface, which is inevitable given the I&C obsolescence issues in the plant. The feedwater heater system is a good pilot project for this technology, where its information zone remains intact using flat panel displays.

Note the size of the meters in Figure 4.3k. The character size, color, luminosity, and arrangement are designed to allow readability from 15 ft away, where the control room supervisor sits. This is a firm constraint for the system, because operator tasking is designed to allow one control room supervisor to stand back and take in all of the control panel indications simultaneously from a central location in the control room, while an operator can stand close to these indicators and manipulate them manually.

The information zone "map" for these instruments is shown in Figure 4.3l. The information is of relatively low density. These parameters are used by control room operators during normal operations, including start-up and shutdown. The operators' task during normal operations is to monitor these variables during routine watch-standing operations. Their task during alarm conditions is to diagnose the cause of the alarm and verify automatic control actions have taken place and/or to take manual action as required by written procedures, so that the system parameters are returned within normal operating limits.

Figure 4.3m shows the same information zone in a modern display example, which can also be applied in a mockup (any scale). This figure shows two flat panel displays, designed for installation in the place of the original instruments. The concept is to program each flat panel with a "default page" that arranges the same variables in a similar fashion to the original arrangement, with font sizes as large as or larger than the characters on the original meters. Because this is a redundant design, each flat panel can be set to display any other page in the display hierarchy.

This design maintains the same readability and operator tasking as the original design, while offering powerful new interfaces to the operator. The control room supervisor can continue to stand back and take in all indications during normal and emergency operations, while the control room operator can manually page through the various display pages

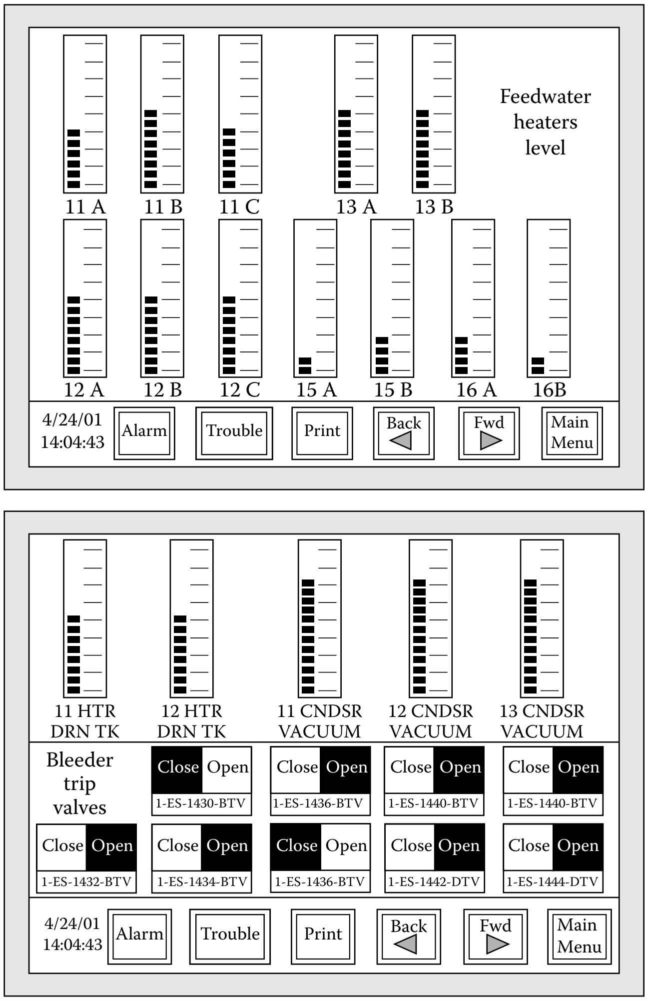

FIG. 4.3m
Upgraded feedwater heater displays.

available on the flat panel using a touch or trackball interface. Also, applying DCS technology for this interface supports additional flat panels or VDUs in other parts of the control room, such as an auxiliary panel or on the control room supervisor's desk. Although the default page is designed to be simple and readable consistent with the original panel design and operator tasking, the system also supports a full range of object-oriented graphic displays, event logs, archives, alarm management, and testing provisions.

Maintaining the original information zone design concept is only the start of any control room upgrade effort. Improvements in safety, reliability, readability, and a reduction in the potential for operator error should also be goals of the project. The use of a digital DCS or PLC platform enables the realization of these additional goals. Variations in colors, fonts, reverse video, and flashing objects are available with digital technology. New systems can detect an alarm on a failed channel (out of range high or low). Also, technology developments such as automatic alarm prioritization and computerized procedures may be implemented in a new system such as this one.

The feedwater heater displays in the above example are a starting point for the entire panel in Figure 4.3c. As more channels of information are added to the DCS/PLC system, more displays can be added to the same panel, or larger displays can be installed with more information available per display.

PLANNING AHEAD

The first phase in a phased control room upgrade project should prove that the overall conceptual design for the control room can be implemented safely and effectively. Once it is proven that the upgraded system has a positive impact on control room operations with improved reliability and cost-effectiveness, then the system can be expanded to all systems in the control room. The pilot approach allows training of engineers, technicians, and operators to commence without a massive undertaking, and valuable lessons learned can be applied to all disciplines on future phases (design, procurement, start-up, and operations and maintenance). The key is to purchase a digital I&C platform that can be applied on a smaller-scale project then expanded into the rest of the I&C systems in the plant.

HMI STANDARDS

It is essential that the long-range plan account for the impact on the operator, and that an HMI standard be applied consistently from start to finish. Flat panels, video display units, workstations, and consoles should be uniformly designed, and software should be standardized so that all system indications and controls are seamless and transparent in a common interface style. If an operator has to move to a specific piece of HMI hardware for each plant system or point-and-click on different icons for each plant system, then the opportunity to improve safety and reliability while reducing operating costs is diminished. The only exception to this rule is when diverse indications and actuations are required, such as for manual safety system actuations (e.g., reactor trip).

HMI attributes such as color codes, abbreviations, fonts, graphic elements, display sizes, and readability should all be consistent. A human-factors engineering (HFE) program should develop standards and procedures that will be coupled with an operator and maintenance technician training program, consistent with the long-range plan.

While the goals of a control room upgrade are to eliminate obsolescence, reduce maintenance and operating costs, and improve safety and reliability, the basic control room panel and furniture layouts and operating and maintenance procedures will be constrained throughout the phased approach. However, the control room panels and furniture can still be altered in a local sense. It is acceptable to introduce different HMI methods in clearly distinct contexts. For example, it is acceptable to add modern soft controls

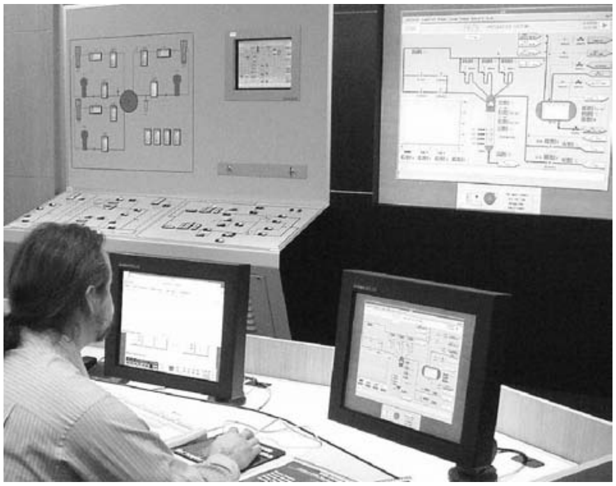

FIG. 4.3n
Demonstration control room. (Courtesy of Westinghouse Electric Company.)

techniques into conventional control rooms for distinct operations such as water treatment. As operators become familiar with the new HMI, the designer can be confident they will accept transitioning to the modern HMI for more critical systems. At any point in this transition process, it is important to ensure that operators are within the same HMI context (conventional or soft) for any particular plant system.

Figure 4.3n illustrates design concepts for panels, furniture, and a large display that can be evaluated for use in any analog control room. Panels can be modified and still mix manual controls, analog meters, and flat panel displays. Furniture can be modified to mount flat panels on arms that can be manipulated to suit operator tasks. For example, if an operator needs a line of sight to the control panels during routine operations, then the flat panel can swing out of the way. If an alarm requires some diagnosis, then the operator can swing the flat panel back into view and perform a specific task, or use it in combination with the large display panel in a supervisory role.

Gross design problems in the control room should not be applied as constraints in the phased approach. For example, if a critical process variable is indicated on one panel and controlled on another in a way that does not allow the operator to observe and control the process simultaneously within acceptable HFE practice, even if the operator has learned to work around the problem, then the control and indication should be colocated in the new interface. This is a good example of how a VDU in each information zone can resolve old design issues.

MAINTAINABILITY

Improved maintainability of the plant and control systems in particular should be a significant goal of a control room upgrade. Information and control systems should be purchased with diagnostic aids and functions that support the ability to store short-term, local data logs and the ability to off-load data to archival systems. In addition to normal process information, there should be pages of information related to process events (warnings and alarms), diagnostic events (system and component faults), and maintenance information. This information should enable an operator to detect and mitigate an event immediately, and call the maintenance department to investigate, troubleshoot, and perform corrective actions if necessary. Corrective actions should be more timely and effective on the control system itself as well as on plant equipment.

Networks allow multiple video displays in and around the control room. When an analog plant was constrained to field- or panel-mounted indications and controls, the only data available to the maintenance or engineering department were real-time data in the control room, or sparse, historical data by way of manual operator logs. Intermittent problems were usually very difficult to repeat, diagnose, and correct. A control room upgrade should fill this void in the maintenance and engineering departments. Displays should be set aside for these departments in or adjacent to the control room, with secure access. Control system access should be controlled first by physical security, then by password security.

Maintenance and engineering displays should provide enough data to understand a plant process event or a control system event. Digital inputs and outputs should be captured in a sequence of events (SOE) log. Maintenance and engineering displays should also allow users to navigate all available information and settings on the system, including the ability to change settings, start and stop programs or tasks, and run system diagnostics in an offline mode. Modes should be controlled by password and/or key switch inputs to the system.

Displays on the main control panels should be limited to information and controls that are related only to normal and emergency plant processes. Physical security should limit access to operator displays to qualified plant operators only.

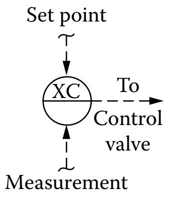
4.4 Controllers—Electronic Analog and Digital

J. E. TALBOT (1970, 1985) **B. G. LIPTÁK** (1995, 2005)



Flow sheet symbol

Types:	A1. HVAC quality and or 1/8 Deutsche Institut fuer Normung (DIN) case for direct RTD, TC, mV, or mA DC service. Can be analog or microprocessor-based A2. Process control quality electronic analog controller for 4 to 20 mA DC service B. Digital, microprocessor-based (“smart”), configurable controllers
Standard Input/Outputs:	A. 4- to 20-mA DC B. No standard
Other Input/Outputs:	A. 1 to 5, 10 to 50 mA DC; 1 to 5, 0 to 10 V DC; ±2 mA DC; ±10 V DC B. Binary, binary-coded decimal, or American Standard Code for Information Interchange (ASCII) data with communication formats per RS232, RS422, RS485, and IEEE488 in addition to TC and resistance temperature detector (RTD) inputs and analog I/O
Repeatability:	A. 0.25 to 0.5 %; A2 designs give better repeatability B. 0.1 to 0.5 %
Inaccuracy:	A. Generally around 1%; can be better with A2 designs and is worst with A1 designs B. Generally 0.1% on input (except TC and RTD, which are 1°F or 0.5°C), set point, alarm, calculations, and displays, except for bar graphs, which are 2%. Outputs to valves are 0.5% and mode settings are about 5% inaccurate. A 55°F (30°C) ambient temperature change will cause an error of 0.1% in local set points and 0.5% in remote set points, and an error of 0.5% in analog inputs and valve outputs. The error due to humidity variations or to a 10% change in supply voltage is about 0.1%. While the different error sources can be additive, it is also possible to limit the overall system error to less than 0.1%.
Control Modes:	A. Manual, on/off, proportional, integral, PI, PD, PID B. Same as analog plus error squared, sample and hold, ratio, linearization, arithmetical and logical operations, counter-timer-selector or limiter functions, external feedback, feedforward compensation including lead/lag, and many other software options
Control Mode Adjustment Ranges (Standard):	A. Gain = 0.1 to 50, proportional band (PB) = 2% to 1000%, integral = 0.04 to 100 repeats/minute, derivative = 0.01 to 20 minutes B. Gain = 0 to 128, PB = 0.8% to unlimited, integral = 0 to 293 repeats/minute, derivative = 0 to 895 minutes
Displays:	A. Analog indications of process variable, set-point, output, deviation, and balance B. Hybrid display of above data in digital and bar graph form plus a variety of status displays including lights and letter code abbreviations
Costs:	A. Direct TC, mV, RTD input controllers in 1/4 or 1/8 DIN case can be obtained for $500 or less; process control quality electronic PID controllers range from $1000 to $2500 B. $1500 to $7500; the higher-cost units can handle more loops and can be provided with I/O for both logical status and multi-loop control

INTRODUCTION

This section describes on/off, direct-connected, and transmitter-based controllers of both the analog and the digital types. In the first part of this section, the discussion of electronic controllers begins a description of on/off and direct-connected analog controllers. This is followed by a more detailed treatment of transmitter-based analog control (Figure 4.4a), which is followed by a description of the features and capabilities of digital controllers.

Analog vs. Digital Controllers

As of this writing analog controllers are still more familiar to plant operators and maintenance personnel, and even to some engineers, than are their digital counterparts, and therefore require less time to specify or to program. Analog controllers can also be less expensive, although some low-cost microprocessor-based controllers are also available (Type A1 in the Feature Summary at the front of this section).

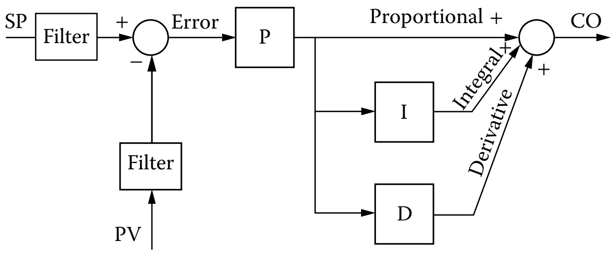

FIG. 4.4a
Configuration of a transmitter-based analog PID loop (PV = Process Variable, CO = Controller Output).

Analog controllers are also not only dedicated and hard-wired but are continuous devices, while microprocessor-based controllers, even when dedicated and hard-wired, are still intermittent units in the sense that they do not look at their inputs continuously, but on a 0.05- to 0.5-second time cycle. Analog controllers do not require the use of analog-to-digital (A/D) and digital-to-analog (D/A) converters. Another advantage of analog controllers is that they are easily interfaced with any other analog control system, due to their standardized signal level of 4- to 20-mA DC. In contrast, the interfacing of digital controllers of different suppliers can require the use of interface cards.

The advantages of digital controllers are also many. Their accuracy and stability are fundamentally unlimited. Error sources such as hysteresis, nonlinearity, or thermal drift do not exist in a digital system. In addition, the digital systems are capable of more sophisticated calculations and algorithms without recalibration (see Figure 4.4b showing a model-based feedback controller). Digital controllers can also be easily and quickly reconfigured without requiring any change in hardware. They can provide more information to the operator on their displays and can transmit data to other

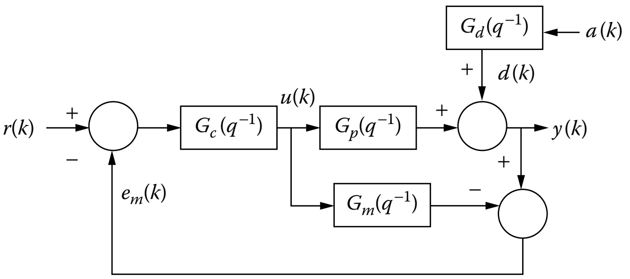

FIG. 4.4b
The configuration of a model-based feedback controller.

digital devices faster and more accurately than analog systems can.

Digital systems can reduce wiring costs and control room sizes and are also less subject to drift, which occurs in analog devices due to component leakage. Digital controllers can also include such functions as alarm, square root extraction, timing, sequencing, totalization, and specialized displays, which in analog configurations would require separate components.

The Controller's Function

Most industrial processes require that certain variables, such as flow, temperature, level, and pressure, remain at or near some reference value, called a set point. The device that serves to maintain a process variable value at the set point is called a controller. The controller looks at a signal that represents the actual value of the process variable, compares this signal to the set point, and acts on the process to minimize any difference between these two signals.

Any simple process control loop (Figure 4.4c) contains the equivalent of a sensor, transmitter, control element (usually a valve), and controller. The sensor measures the actual value of the process variable. The transmitter amplifies this sensed signal and transforms it into a form suitable for sending to the controller. The controller really has two inputs: a measurement signal and a set-point signal. The set point can also be internally generated. The controller subtracts the two input signals and thereby produces a deviation or error signal.

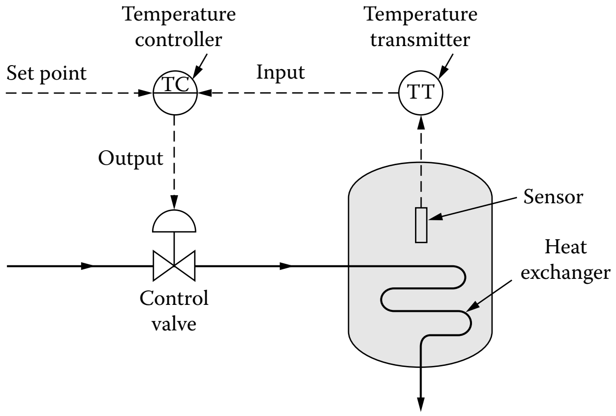

FIG. 4.4c
Standard temperature control loop.

Additional hardware or software is provided in the controller to act on this deviation or error signal and thereby to generate the controller's output. For the various control algorithms, including PID, refer to the sections in Chapter 2. The controller output then typically sets the position of a pneumatic or electrical final control element or control valve in a direction to decrease the error.

Although the function of the controller is easy to define, it may be implemented in many different ways. For example, the controller may work on pneumatic, fluidic, electric, magnetic, mechanical, or electronic principles, or on combinations of these. This section, however, will confine itself primarily to electronic controllers.

The general nature of their inputs, outputs, and control modes makes controllers applicable to a wide variety of process control situations. The same controller may control flow in a pipe, which responds nearly instantly to valve movements, or control a temperature in a distillation column, which often takes hours to respond to disturbances. Any process variable is a candidate for remote control as long as it can be converted to a transmitter signal. The process control engineer must choose and tune the control modes to fit the dynamics of the variable to be controlled (see Chapter 2).

Feature Checklist

The following is a summary of the relevant features that an instrument engineer must consider when picking a controller:

Control mode selection
Input and output ranges (including set point)
Output load resistance range
Emergency service provisions
Maintenance accessibility and convenience
Panel readability and accuracy
Control repeatability and accuracy
Tuning ranges and resolution
Electrical classification
Power requirements; need for regulation
Mounting flexibility and density
Switches for local/remote set point, direct/reverse action, and manual/automatic operation
Balancing procedures and accuracy
Alarm modules and lights
Output limits
Antiwindup
Computer compatibility

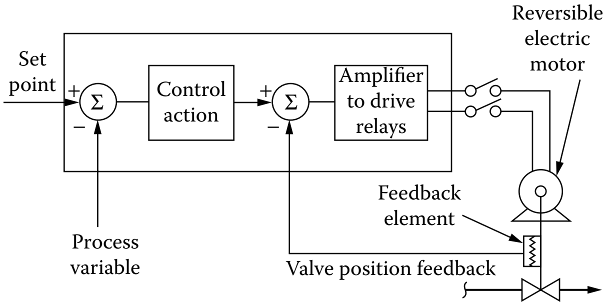

FIG. 4.4d
Electronic positioner controller with relay outputs.

ON/OFF AND DIRECT-CONNECTED CONTROLLERS

On/Off Relay Outputs

A common example of an electronic controller with relay outputs is the positioner controller (Figure 4.4d). Here the controller energizes one of two relays to operate an electric motor in either direction. The motor drives some final element to a desired position. A feedback signal from the final element tells the controller when the desired position has been reached.

Essentially, the controller acts as a master controller in a cascade system, where the relays, motor, final element, and feedback signal constitute the slave loop, and the master controller generates the set point for the slave by conventional control action.

A meter–relay combination provides an extremely simple way of implementing two- and three-position, high-gain control. Basically, the input signal, such as a thermocouple, drives a galvanometer's pointer to indicate temperature. Another pointer (or index) is manually set to the desired temperature on the same indicating scale. The idea is to operate a relay or a silicon controlled rectifier (SCR) when the two pointers are in the same position.

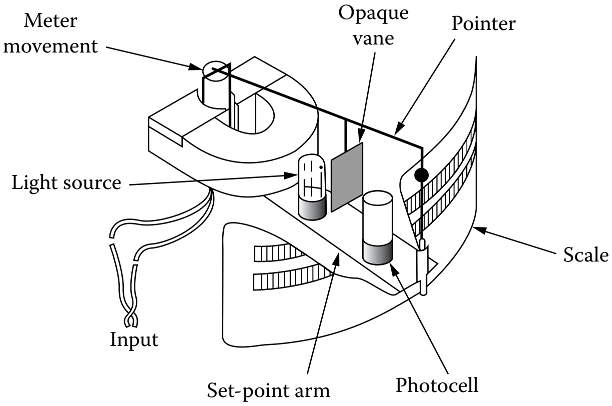

FIG. 4.4e
Optical meter relay.

Optical Relays The system shown in Figure 4.4e optically senses the correspondence of the two pointers. The set-point arm carries a small photocell and light source. As long as light strikes the photocell, amplified current energizes the relay to supply power to a load. When the indicated temperature reaches the set-point temperature, a vane on the indicating pointer breaks the light beam, and the relay drops out.

Some meter relays are equipped with two set-point arms and relays to give three-position control. In a meter with an SCR output, the vane can be shaped to provide some degree of proportional control over a narrow temperature band. The optical system avoids any interaction between the process and set-point pointers, as would be present in mechanical or magnetic systems. Obviously the idea can be extended to other displays where the variable is indicated by a pointer's position. For example, it has been applied to electronic circular and strip-chart recorders.

Electronic Relays Meters can also be purchased with built-in electronic amplifiers to boost the input signal, as in Figure 4.4f. In one meter–relay package of this type, the meter's set-point arm wipes a resistance element. This resistance element, connected as a voltage divider, provides a voltage reference signal, which is compared to the amplified input. The deviation, after further amplification, drives a transistor that operates a control relay. The meter and resistance element can be encapsulated in an inert atmosphere if the device must be installed in a relatively hostile environment.

Direct-Connected Controllers

A wide variety of controllers on the market are tailored to specific kinds of control by specialized input or output schemes, or both. The most common examples by far are electronic temperature controllers for driving electric heaters and motor speed controllers. The temperature controllers are designed to directly accept inputs from sensors like thermocouples, resistance bulbs, or thermistors. Their outputs may drive relays or contactors, silicon-controlled rectifiers (SCRs), or saturable reactors.

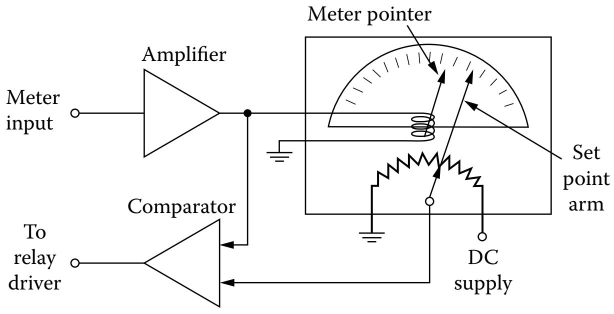

FIG. 4.4f
Meter-relay package with electronic input and output circuits.

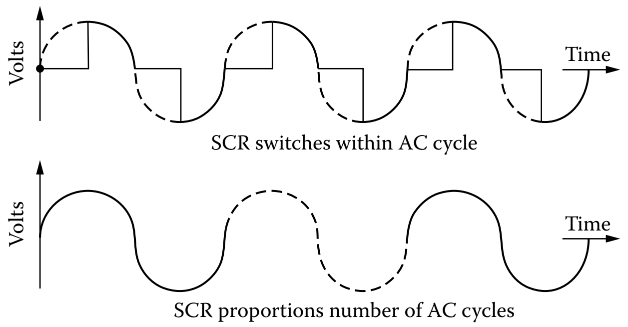

FIG. 4.4g
Two SCR switching techniques that are used for driving electrical heaters.

Since the sensor connects directly to the controller, the input signal lines handle very low power levels and the lines are kept short to avoid interference from other sources. In these designs the input circuit is usually for a particular kind of sensor and a certain range of temperature. Common thermocouple inputs include iron-constantan, copper-constantan, chromel-alumel, and platinum/rhodium-platinum pairs. The controller's input circuit compensates for variations in the thermocouple's cold junction temperature.

Resistance bulb and thermistor inputs generally feed into resistance bridge circuits.

As in all feedback controllers, the input circuit compares the incoming signal with a reference or set-point signal, and control circuitry acts on the resulting deviation. The form of control ranges from simple two- (on/off) or three-position (high-low-off) control to sophisticated three-mode control. Some manufacturers offer three-mode control on one set-point position and on/off control on another.

Time-Proportioning Control Proportioning, however, is generally on a time basis, called time-proportional control. Here the output is driven full on or off, but the control signal varies the percentage of on-to-off time in some duty cycle, such as 10 seconds. The *average* power level determines the load temperature. This kind of control applies to both relay and SCR outputs. However, the SCR is capable of faster switching than the relay, permitting proportioning periods of a fraction of a second and thereby giving smoother control.

Some controllers trigger the SCR to chop up each AC cycle; in others the SCR proportions the number of AC cycles that are on and off in a certain period (Figure 4.4g). Available SCRs can handle loads up to 300 kW in three line phases.

ANALOG CONTROLLERS

An electronic process controller consists of six basic parts or sections: input, control, output, display, switching, and power supply (Figure 4.4h). The input section comprises the hardware for generating the set-point signal, for accepting and conditioning the process signal, and for comparing the two signals to produce a deviation signal. The heart of the control section is generally a chopper-stabilized AC amplifier that acts on the deviation signal. Associated circuitry amplifies, integrates, and differentiates the deviation signal to produce an output with the necessary proportional gain, integral (reset), or derivative (rate) control actions. (In some controllers the derivative circuit acts on the process signal rather than the deviation signal.)

The controller's output has two forms: automatic and manual. When in the manual mode, the controller's output remains at a steady level, often dependent on the shaft position of a potentiometer. Switching and balancing hardware on the front panel selects the automatic or manual output. In some cases the source of the manual output is the control amplifier (modified by switching), while in other cases the source is entirely separate, requiring only the operation of a power supply.

The display section on the front panel carries information about the set point, process variable value, deviation, and controller output. The front panel also contains mechanisms for switching between manual and automatic modes and for adjusting the value of the set-point input and the manual output. A secondary indication, balance, allows the operator to equalize the manual and automatic outputs before transferring from the automatic to the manual mode.

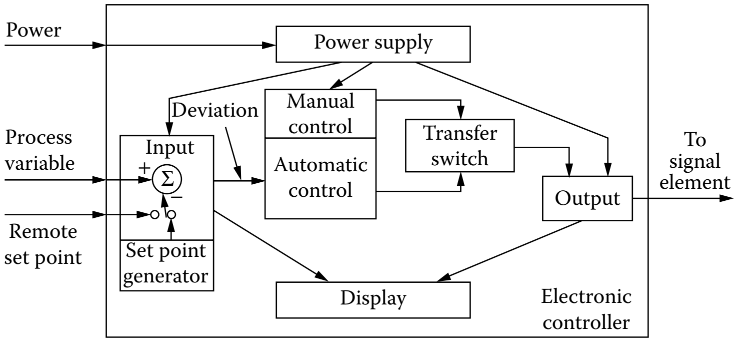

FIG. 4.4h
The basic components of a controller.

The power supply section serves to transform the incoming AC line voltage to the proper DC levels to operate the other controller sections. Some controller power supplies also serve to energize instrumentation external to the controller. For example, the controller may power the transmitter in the same loop. In other cases the power supply itself may be external to the controller, energizing many controllers and other instruments.

In addition to these basic parts, the controller may have various special optional or standard features. Some examples include alarms, feedforward inputs, output limits, and batching aids (described later).

Input Variations

Input and output signals for analog electronic controllers have more-or-less been standardized, through general usage, to three ranges: 1- to 5-, 4- to 20-, and 10- to 50-mA DC, with 4 to 20 by far the most common. Nearly all the controllers on the market will accommodate at least one of these standard input signals. Many offer all three, either as standard or optional features. On the output side, the manufacturers generally offer only one of the signals, the most popular being 4- to 20-mA Dc.

The use of a DC current amplifier for transmitting signals over great distances has one primary advantage over a voltage signal: small resistance that develops in the line (from switches and terminal connections and from the line itself) do not alter the signal value. Once the input signal reaches the controller, it is generally sent across a suitable resistor to produce a voltage that matches the working voltage range of the controller's amplifier.

The signal's live zero aids in troubleshooting since it differentiates between the real signal zero and a shorted or grounded conductor. Besides these three signal ranges, some manufacturers offer uncommon inputs such as 1- to 5- and 0- to 10-V DC, and outputs such as 1- to 5-V DC; centered-zero signals (±10 V DC and ±2 mA DC). Direct TC, RTD, or mV signals are also available.

Set-Point Variations The controller's set-point input is either internally (local) or externally (remote) generated. Manufacturers generally provide a switch to let the user choose between the two, but other suppliers require the user to choose between two different models. In some electronic controllers the two signals can be displayed and "nulled" to equalize them before transferring from one to another. It is also possible, but more costly, to have the unused signal automatically track the other, so that the two are always equal.

If the remote and local set-point signals are not equal before transfer, the controller will see a sudden set-point change. The output will therefore also change abruptly, unnecessarily disturbing or "bumping" the process.

The local set-point is often merely the output of a voltage divider that is connected to the set-point adjustment and display mechanism. The divider consists of either a multi-turn variable resistor (potentiometer) or a large fixed circular slide-wire with wiper. The divider's output is compared to the voltage drop produced by the process input signal, yielding a deviation signal that corresponds to the difference between the two.

The remote set-point signal must have the same range as the process input signal. Manufacturers provide terminals at the back of the controller to accept this signal. Common examples in which a remote set-point signal comes into play are the cascade and ratio control systems (Figure 4.4i).

In the cascade system the source of the set-point signal is the output of another controller, called the primary, or master, controller. The controller that accepts this remote set point is the secondary, or slave, controller. Another common source of remote set point is a function generator or a programmer, set up to make the controlled variable follow a prescribed pattern (Section 3.4).

Blending systems are a form of ratio control. Here the set-point signal is really a second process variable from a flow transmitter. The controlled stream is forced to follow the flow rate of the uncontrolled (or wild) stream in some adjustable proportion (ratio). So the signal from the flow transmitter on the wild stream serves as a remote set point. The means for adjusting the desired ratio between the two streams is usually incorporated in the front panel of the controller, making it a special model. Calibrated ratios generally run from 0.3 to 3.0.

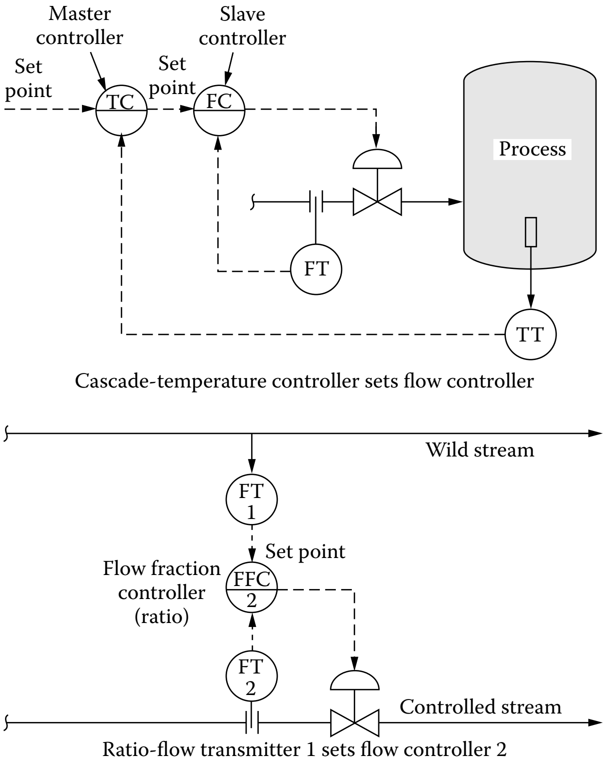

FIG. 4.4i
Cascade and ratio control systems.

An optional feature pertaining to a remote set point is a servo system (motorized set point) that makes the set-point display mechanism track the remote set-point value. Otherwise the display should be blanked or marked in some way because it corresponds to the local rather than remote set point. In some controllers the set point is displayed on a galvanometer, and then the above comments do not apply. Motorized set points often find application in supervisory control systems where the remote set-point source is a computer.

Control Modes

The controller must deal with processes having wide ranges of dynamic characteristics. Adjustable control modes provide the needed flexibility. These modes act on the error signal, producing changes in controller output to compensate for process disturbances that have affected the controlled variable. Electronic hardware modules provide one or more of the following control actions, which are discussed in detail in Chapter 2:

1. Proportional gain
2. Proportional gain plus integral (reset)
3. Proportional gain plus derivative (rate)
4. Proportional gain plus integral plus derivative
5. Integral (proportional speed floating)

The control action with the most widespread use is proportional gain plus integral. Only a few manufacturers offer proportional gain alone, and even fewer offer pure integral.

In most cases the manufacturer provides one basic controller that has all three modes. In that case the user can switch off the unneeded mode(s). In other designs, the user can pick from a variety of models, depending on desired modes, fast or slow integral rates, fast or slow derivative rates, and other options. The choice depends on the dynamics of the process to be controlled.

The proportional mode varies the controller output in proportion to changes in the error. High gains mean that the controller output varies greatly for small changes in deviation from set point. Extremely high gains result in nearly on/off control. In processes requiring relatively low gains, the importance of the integral mode increases because at low proportional gains the controller will be satisfied even though the controlled variable and the set point are relatively far apart (offset). The integral mode continues to drive the output until the deviation goes to zero.

The derivative mode is a refinement that produces an output component proportional to the rate of change of either the deviation or the process input signal. Its effect is to anticipate changes in the process variable under control. Figure 4.4j shows a simplified circuit for implementing three-mode control.

The advantage of having the derivative mode act on the process input rather than on the deviation is that the controller does not respond directly to a set-point change. If it acts on the deviation, the derivative component of the output depends, for example, on how fast the operator turns the set-point knob. Of course one could always switch to manual before making a set-point change and then switch back to automatic. A few manufacturers can provide both kinds of derivatives as optional designs, but most offer only one or the other.

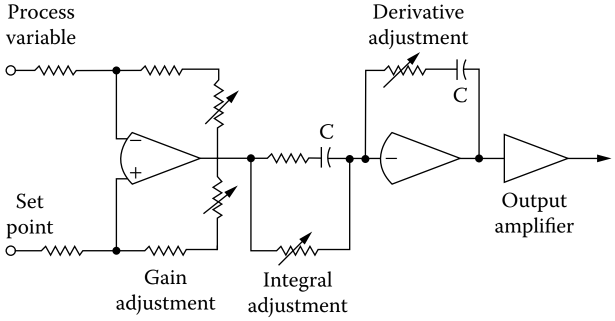

FIG. 4.4j
Three-mode control circuit.

Tuning As was discussed in Chapter 2, the adjustments of each control mode allow the operator to tune the controller so it will match the process dynamics. Continuous or multiposition knobs are provided, usually inside the controller case. These knobs are calibrated in units of the corresponding control mode. Typical ranges and units are:

1. Proportional gain, 0.1 to 50 (proportional band 1000 to 2%)
2. Integral, 0.04 to 100 repeats per minute
3. Derivative, 0.01 to 20 minutes

Higher and lower values for each mode are available, depending on the manufacturer. The term proportional band (PB) is also used; it is related inversely to proportional gain:

$$\text{PB} = \frac{100}{\text{proportional gain}}\% \qquad \textbf{4.4(1)}$$

One repeat per minute means that the integral mode will ramp the output up or down, repeating the proportional action that corresponds to a particular deviation every minute. Ramping continues until the deviation is zero. A derivative setting of 1 minute means that the controller output should satisfy a new set of operating conditions 1 minute sooner than it would without the derivative mode.

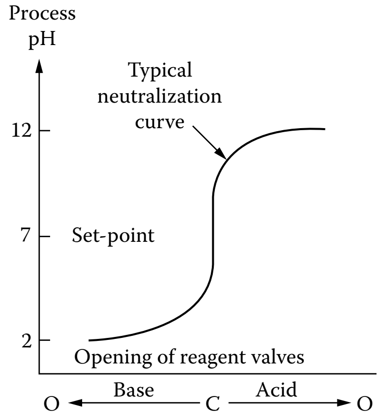
Many manufacturers also have scaling switches or jumpers that multiply the effects of the integral and derivative modes by factors of 2 or 10. Also, the ability to switch the derivative and integral modes completely out of the control circuit is an aid for troubleshooting and calibrating.

The direction of the control action depends on the set point and the process variable input. Direct control means that as the process variable increases, the controller output also increases. Reverse control means that the controller output responds in a direction opposite to that of the process variable. A direct-reverse switch in the controller allows the operator to reverse the controller action. If the derivative action is on the process measurement rather than the error, at the time of switching, this connection must also be reversed.

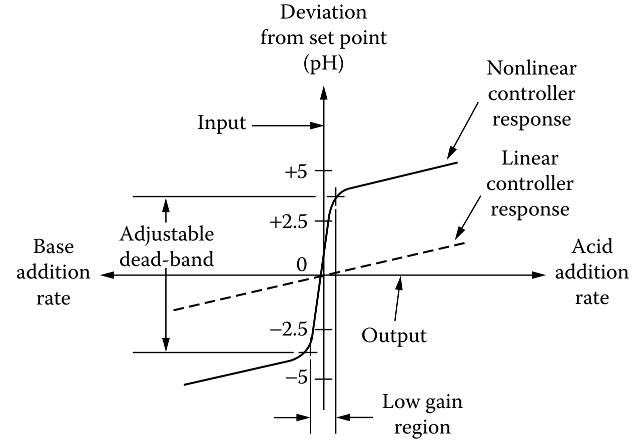
Some circuit designs permit changes in the control settings while the controller is operating in automatic, without disturbing the output. Sometimes only the proportional gain can be so adjusted, without having an effect on the output. Otherwise, the controller must be switched to manual before changing the settings. Usually the settings are somewhat interacting, meaning that a change in one affects the value of another. However, certain controllers incorporate features such as separate amplifiers for each mode to eliminate or minimize this interaction. These controllers have an advantage when tuning is critical.

Although the process controllers have standard output signal ranges, limitations on the maximum load resistance in the output circuit vary by manufacturer. The load resistance is the sum of the series resistance of all the devices driven by the controller's output current. Typically, the output current drives a converter that connects to a diaphragm-actuated control valve. These varying load requirements among manufacturers complicate matters somewhat if the user wants to buy parts of the control loop from different manufacturers.

A sampling of actual specifications for maximum load resistance includes 75, 500, 600, 800, 1500, and 3000 ohms. Higher maximums, of course, give the user greater flexibility. A few manufacturers require a minimum load resistance as well. At least one vendor asks the user to adjust the load resistance in the output circuit to an exact value, which is a severe limitation.



The nonlinear process of neutralization



Nonlinear controller response

FIG. 4.4k
The nonlinear controller response required for the control of a nonlinear acid-base neutralization process.

Nonlinear Controllers

If the process tends to be sensitive (fast) at certain measurement values, while at other measurement values it is sluggish (slow to respond), then that process is nonlinear. A nonlinear process can be properly controlled only by a nonlinear controller. In order to arrive at a uniform loop gain at all measurement values, it is necessary to change the controller gain from high to low as the process measurement moves from its sluggish region to a more sensitive zone.

The best known of the nonlinear processes is acid-base neutralization, which is sensitive in the region near neutrality and therefore requires a low controller gain in that region. Figure 4.4k illustrates this nonlinear process together with the nonlinear controller response it requires. This controller has an adjustable nonlinear relationship between measurement and output, with low gain surrounding the set point and with normal gain outside of this band. The width of the "dead band" (band of low gain) is usually adjustable both manually and remotely from 0 to ±30% of the measurement range, and its gain relative to the normal gain of the controller is adjustable manually from 0.02 to 0.2. If the dead band is set at zero, the result is a linear controller, illustrated by the dotted line in Figure 4.4k.

The standard control modes of proportional, reset, and derivative are superimposed on the nonlinear function. For example, if the normal gain is set at 2 and the minimum gain within the dead zone is 0.2, then the effective gain inside that zone will be 0.04. This means that while the process measurement is inside the dead band, a 25% change in measurement will result in only a 1% change in controller output, due to the proportional mode response.

The width of the dead band can be adjusted manually or automatically in direct or reverse proportion to an external signal. For example, the control valve gain can increase as the valve opens. Widening the controller's dead band can compensate for the increase in loop gain.

Nonlinear controllers can also be used to allow the levels to float in surge tanks, while preventing the tanks from flooding or draining. The goal of such a loop is to keep the controlled flow reasonably constant while allowing it to be smoothly modified when necessary.

A nonlinear controller can also be used to filter out the noise or pulsations from flow loops, while permitting effective control over major disturbances. In order to eliminate valve cycling during normal operation, the dead band should equal the band of noise or pulsation. When used for flow control, the nonlinear controller gain inside the dead band should *not* be set at very low values because this could cause regenerative oscillation.

Special Features

Manufacturers usually offer special features, either optional or standard, to enhance the convenience and usefulness of controllers. The most common features involve alarm modules and output limits in some form. Electronic alarms can be set up on either the process measurement, the deviation, or both, depending on the supplier. Also, they can be actuated on either the high or low side of the alarm point. Some controllers have panel lights for connecting to the alarm contacts as well as terminal connections for external alarms such as lights, bells, horns, or buzzers.

Nearly all manufacturers of electronic controllers limit the high side of the output current range to the maximum standard value. Often a zener diode arrangement serves to clamp the current at this value. Some manufacturers go a step further and place a fixed limit on the low end of the range. Still others offer adjustable output limits on both ends. Output limits serve only to constrain the range of the manipulated variable (valve stroke).

Antireset Windup Certain limits can prevent a phenomenon called reset (integral) windup (discussed in detail in Chapter 2). Windup occurs if the deviation persists longer than it takes for the integral mode to drive the control amplifier to saturation. This might occur, for example, at the beginning of a batch process, if the controller input signal is temporarily lost, or if a large disturbance occurs in either the set point or the measurement.

Only when the deviation changes sign (process variable value crosses set point) does the integral action reverse direction. So the process variable will most likely overshoot the set point by a large margin.

If the limit acts in the feedback section of the control amplifier's integral circuit, the controller output will immediately begin to drive in the opposite direction as soon as the process signal crosses the set point. This approach is commonly referred to as *antireset windup.* On the other hand, if the limit acts directly on the output as discussed earlier, it essentially diverts excess current coming from the control amplifier, and therefore the output will remain at a high value for some time after the process crosses the set point. The output limit will simply divert less and less excess current. This extends the time that the output remains at a saturated value, aggravating the overshoot due to windup. Antireset windup circuits are usually offered only to eliminate saturated output currents at the high end of the signal range.

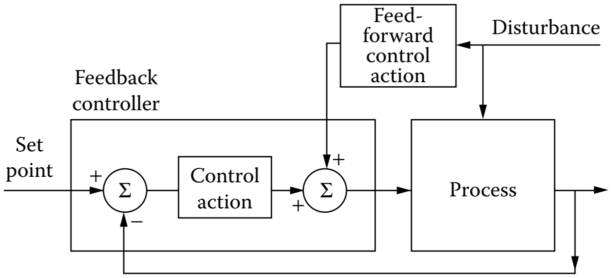


FIG. 4.4l
Electronic controller configuration in a feedforward application.

A few manufacturers go so far as to provide special batch controller models to minimize reset windup. Here, special circuit modifications actually begin to drive the output out of saturation *before* the process variable value crosses the set point. Reset windup can be avoided in batch applications if the operator equalizes the process variable value and set point in the manual mode before switching from manual to automatic operation.

Feedforward and Special Features Another powerful control configuration is feedforward. In these controllers, a feedforward input signal influences the value of the controller output. Feedforward control (covered in detail in Chapter 2) assumes that the user knows exactly how much the control valve (or other final element) should change to compensate for the changes in the feedforwarded process input variable (Figure 4.4l).

This relieves the controller of compensating for this particular process disturbance by normal feedback control. A few manufacturers offer gain and bias modules for conditioning the feedforward signal before it sums with the controller output signal. A direct and reverse switch is necessary to match the feedforward signal to the controller action.

Other special features offered by various manufacturers include:

Communication jack. Lets signal wires between the controller and transmitter serve also as an audio communication link; an AC carrier system does not disrupt the DC process variable signal. This eases calibration and troubleshooting of the control loop.

Trend record. Provides jacks or pins for patching a recorder to the process variable input signals available in voltage form in the controller.

Output tracking. Locks the controller output to a remote signal. This feature is useful, for example, when an electronic controller backs up a computer control installation.

Process retransmission. Converts a process current signal to a low-impedance voltage signal for distribution to other parts of the control panel. Other devices can then be connected in parallel to this signal without loading down the controller input signal.

Special input modules. Extract square root, select inputs, accept resistance inputs, excite strain gages, convert pulse inputs, integrate, isolate, condition, and limit inputs. Some manufacturers offer many more options than others.

Battery backup. Automatically takes over when regular power mains fail.

Displays

As mentioned earlier, the controller's front panel indicates four basic signals: set point, process variable, error deviation, and controller output. The deviation meter sometimes doubles as a balance meter for equalizing the manual and automatic signals or local and remote set-point signals when the operator wants to switch from automatic to manual output. The front panel has one small meter to show the controller output. The forms of display for the other three basic variables differ among manufacturers and sometimes differ among models by the same manufacturer. Controllers without any panel displays are called blind controllers.

The majority of process controllers merge the set point, deviation, and process variable indications into one display (Figure 4.4m). This display consists essentially of a deviation meter movement combined with a long steel tape or drum scale behind the meter's pointer. The scale length ranges from 6 to 10 in. (150 to 250 mm), depending on the manufacturer. Only a portion of this scale shows, but the tape or drum can be moved so that the scale value corresponding to the desired set point rests exactly at the center of the display, marked by a hairline or a transparent green band. If used, the green band masks the red pointer for small deviations. For larger deviations, the red pointer peeks glaringly from behind the band to alert the operator.

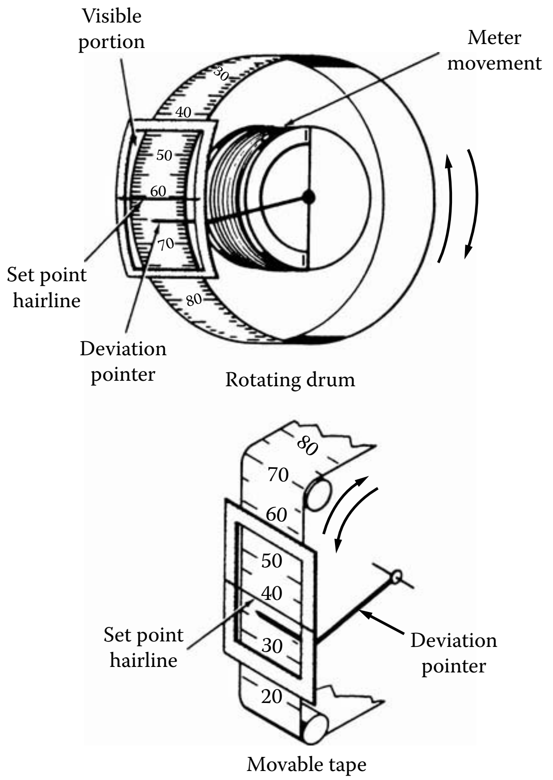

FIG. 4.4m
Process variable, set point, and error can all be shown on expanded scale displays.

The deviation meter movement corresponds to the visible part of the scale. For example, if 50% of the scale shows, the deviation movement is ±25 % of full scale. So the pointer indicates the process variable value as long as it is on scale, the hairline at the center gives the set-point value, and the distance between the hairline and pointer indicates the deviation.

The mechanical set-point scale movement also drives components for generating the corresponding electrical set-point signal. Commonly, the scale movement drives a multi-turn potentiometer. In some controllers, a wiper attached to a movable scale drum contacts a large fixed circular slide-wire connected as a voltage divider. Either design should avoid gearing between the set-point drive and electrical components; otherwise, backlash would destroy their one-to-one correspondence.

Controllers that have a large deviation display with a long, expanded scale offer high resolution and readability of each signal value. Of course, the deviation must be on scale to be able to read the process value at all. Also, the electrical and mechanical set-point values must be calibrated carefully or the process reading will be inaccurate.

In controllers without this kind of display, some compromise is usually made in the indication of set point, deviation, and process variable value. It is impractical and confusing to put a display for each of these signals on the controller's narrow face. The set point must be displayed, but either the process variable or deviation display can be sacrificed without great loss, since one is implied by the other once the set point is known.

The set point is either read out directly on a meter or mechanically displayed with a calibrated dial and index arrangement (Figure 4.4n). Sometimes the process variable and set-point value are shown with two pointers on a single scale. This lets the operator easily compare the two for estimating the deviation. In another case it is the process value that must be estimated from markings that relate the deviation meter readings to a calibrated set-point dial.

One way to circumvent the limited space on the controller's front panel is to have one meter serve to indicate more than one variable. The operator then must position a switch to choose the variable he or she wants to read. One manufacturer indicates five basic controller signals (including a balance indication) with one meter. To avoid confusion, a set of switches inside the case determines the direction of meter movement for different switch positions so that the meter movement always drives upscale.

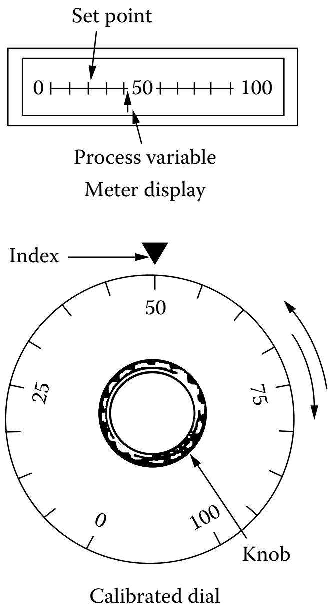

FIG. 4.4n
Conventional set-point setting knob and display.

The controller's output meter shows either the manual or the automatic output signal, depending on the transfer switch position. Interchangeable tags at the side of the meter remind the operator of the valve positions (open or closed) for the extreme controller outputs. In certain controllers the output meter can be physically inverted so that the pointer always drives upscale as a valve opens. Occasionally the output meter may act as a deviation meter to null the automatic and manual outputs before transfer.

The front panel may also contain alarm light displays. These are often connected to alarm modules behind the panel that monitor deviation or process variable input. Some lights may merely run to an external connection at the rear of the controller. The position and form of the lights vary greatly. One manufacturer backlights legend plates. Another backlights the top and bottom of the deviation meter to show high and low deviation. In one case, deviation alarm lights replace the deviation meter itself. A few manufacturers provide a small standard panel light to indicate whether the local or remote set point is implemented.

Balancing Methods

All electronic controllers have a switch on the front panel for transferring between automatic and manual outputs. The switch takes many forms, including lever, toggle, rotary, and pushbutton. It is often important to balance the two output signals before transferring from automatic to manual to avoid a sudden change in controller output that might disturb or "bump" the process. Controllers that feature "bumpless transfer" have some provision for balancing the two output signals just before switching.

No balancing is necessary when switching from manual to automatic output because the unused automatic controller signal takes the same value of (or tracks) the output when the controller is in the manual mode. So the operator merely switches from manual to automatic and need not be concerned with balancing procedures. However, if a deviation exists between process and set-point values at the time of transfer, the integral action in the controller (if present) will immediately begin to drive the controller in a direction to eliminate this deviation. For large deviations the integral action will often produce a controller output change fast enough to bump the process.

This balance-less, bumpless transfer from manual to automatic output depends on a modified integral circuit to make the automatic signal track the manual output. So the integral function must be present if balance-less transfer is desired.

Nearly all manufacturers require a balancing procedure for bumpless transfer when the controller is switched from automatic to manual output. The transfer switch has a balance position to accommodate this procedure. In the balance position, the controller retains its automatic output, but the functions of the display meters change. The automatic and manual output signals usually feed to either side of a deviation meter. This allows the operator to equalize the two signals by adjusting the manual output until the meter reads zero at mid-scale.

This nulling method has a high sensitivity for accurate balancing. Usually the large deviation meter, if present, serves to compare the output signals, but some manufacturers connect the output meter as a deviation meter for the controller's balance state. At least one supplier places a small separate deviation meter on the panel that always shows the condition of balance.

Still other manufacturers provide a momentary pushbutton on the front panel that, when depressed, connects the manual signal to the output meter in place of the automatic signal. To balance the two signals, the operator repeatedly presses the button while adjusting the manual output. When the pointer on the output meter remains motionless, the two signals should be about equal.

A unique design features balance-less, bumpless transfer in both directions. This means that the unused output signal tracks the other signal at all times. In this case the control amplifier is switched into a simple integrator configuration when the operator transfers from automatic to manual mode. This circuit holds the latest value of the automatic output as a manual output.

To change the manual value, the operator throws a momentary switch that introduces a DC input signal to the integrator circuit input. This causes the output to ramp up or down, depending on whether the input signal is positive or negative. So the operator jogs the manual output to the desired value. The control amplifier also holds the latest manual output signal at the instant the operator switches back to automatic operation, but integral action begins immediately to eliminate any existing deviation between the set point and process variable values.

Mounting

Miniature electronic controllers are designed for panel mounting in a relatively clean and safe environment such as a control room. The room should be free from corrosive vapors and excessive vibration. A few controllers can work at ambient temperatures from 0 to 130°F (0 to 72°C), but others are more restricted. Some models can be mounted in areas designated by the National Electrical Code as Class 1, Group C, Division 2. These areas require that equipment have no open sparking contacts but do not require the instruments to have explosion-proof cases. In these designs the manufacturers provide hermetically sealed on/off power switches to avoid open sparking.

The controller's small frontal size allows many controllers to be installed in a small panel space, which is called a high-density configuration. The controller's depth (over 20 in. or 500 mm) and weight (often over 15 lb or 6.8 kg) usually require additional support at the rear of the panel for multiple mountings. The controllers can usually be mounted in multiple arrays in four different ways, as shown in Figure 4.4o. They can be in individual adjacent panel cutouts, side by side in a single large panel cutout, in large cases or packs that accept some multiple of controller chassis, or on shelves that accept some number of individual controller cases.

The mounting approach depends on the particular manufacturer, but some companies offer more flexibility than others. A few require individual panel cutouts for each controller. This increases panel fabrication costs. When the controllers are placed side by side in a single cutout, the manufacturer may offer outside trims to frame the installation. The company will also suggest ways to support the back ends.

Packs sometimes have both vertical and horizontal capacity, while shelves are limited to horizontal mountings. Some horizontal packs may be specified for any number of controllers, but others are limited either by a maximum number or by certain multiples of controllers. Mounting in packs or shelves generally simplifies power and signal connections. Controllers designed for 1/2 and 1/8 DIN cases are lighter and require less panel space.

If the panel tilts too far from the vertical, the controller may not operate properly. For example, one manufacturer specifies a maximum of 60-degree panel tilt, and another stops at 75-degree tilt from the vertical. Still others say that the controller works in any position. But some companion products, such as recorders, have limitations on their mounting positions.

In all these electronic controllers, the chassis slides partway out of the case without interrupting the control signal. A retractable plug connects the chassis with all the necessary power, signal input, and signal output leads. This permits tuning, calibration, and realignment, while the controller operates in place. In a few controllers, the panel display section can be mounted in a location different from that containing the control and output circuitry.

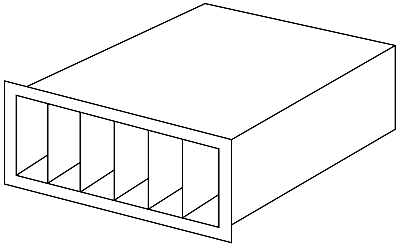
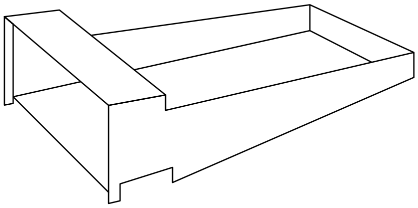
Single cutout–side by side



Pack for controller chassis



Shelf for controller cases

FIG. 4.4o
Alternate methods for the panel mounting of miniature instruments.

Although the controller is mounted in a relatively safe area (the control room), its signal must eventually go into the field to operate some final element, such as a control valve. Some control systems have been approved by either Factory Mutual or by Underwriters Laboratories as intrinsically safe for hazardous field areas (see Section 7.2 in the *Measurement* volume of this handbook). This means that the output signal in the field cannot release sufficient electrical or thermal energy, under defined normal or abnormal conditions, to ignite a specific hazardous atmospheric mixture.

Special barrier circuits and energy limiters, sometimes with zener diodes (Figure 4.4p), limit the output signal energy, even if the full voltage of the power main is somehow connected to the signal lines. Some suppliers put the barrier in the controller case; others prefer to place a barrier at the location where the signal lines leave the control room. Also, distinct mechanical separation of energy levels in the controller will add to its intrinsically safe properties.

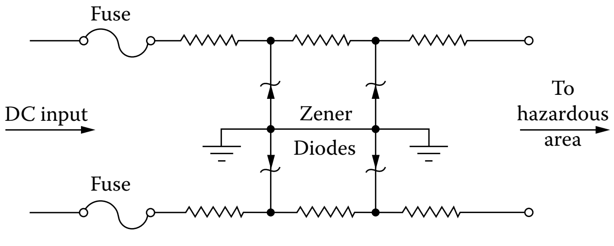


FIG. 4.4p
Barrier circuit approved in Great Britain.

Servicing

The electronic controller frequently is the first to receive the blame for loop malfunctions because its panel tends to give the first indication that something is wrong. Before removing the controller, however, the user should check other loop components and the operation of main plant equipment and should also make sure that the controller output is not shorted to ground in the field.

If the controller is at fault, the course of action depends on the manufacturer's provisions for emergency servicing. In many cases the manual section of the controller will continue to work, so the operator can set the controller output at a desired DC current value. But the instrument maintenance technician must somehow remove the automatic section to troubleshoot it. The following items highlight the basic approaches taken by manufacturers:

1. Manual and automatic sections are completely independent, plug-in modules. One may be removed without affecting the other. They may even have separate power supplies to ease testing of the faulty unit. Sometimes only the automatic section is removable for emergency servicing.
2. An adjustable plug-in power module takes the place of manual output when the controller is removed from its case.
3. A battery-operated or auxiliary manual station replaces the controller to hold output current. In some cases the substitution can be made without interrupting the signal to the process and (by a balancing procedure) without abruptly changing (bumping) the value of the controller output signal.

A few manufacturers make no provisions for emergency servicing. The faulty unit must simply be replaced regardless of signal interruption and output bumping.

Once the controller or its automatic section is in the shop, the technician can try to isolate the trouble by hooking up suitable input signals and a dummy load to the controller, closing a mock control loop. Some suppliers offer a jig that plugs into the controller to simulate a closed loop. Terminals are provided for input signals and for monitoring the deviation and output signals. Most companies at least provide easily accessible test pins or jacks for checking and calibrating key controller signals. Instruction manuals contain guides and schematics for diagnosing the fault from the symptoms. Multimeters used for voltage signal measurements should have at least 20,000 ohms-per-volt sensitivity.

The best buy is the controller that requires little maintenance and can be quickly replaced and repaired when it does need servicing. All electronic controllers will perform satisfactorily in a control loop, at least in the short run. But those that frequently break down may result in costly process downtime, a factor that tends to override any differences in initial controller purchase and installation costs. Highly modular controller designs and circuit accessibility simplify maintenance. Rugged, high-quality, solid-state circuit designs along with dust-tight encapsulation of key parts, including meter displays, help to prevent controller breakdowns. Silicon transistors are more rugged and reliable than those made of germanium. Much depends on the quality control practices implemented by the particular supplier.

DIGITAL ELECTRONIC CONTROLLERS

Later sections in this chapter will cover a variety of DCS and other computer-based digital control systems. Here our focus in on the first generations of microprocessor-based digital controllers (see Figure 4.4q).

Advantages and Disadvantages

The main disadvantage of microprocessor-based shared controllers is an inherent consequence of their being shared among several control loops. This shared nature results in a potential problem of reduced overall system reliability because "many eggs are placed in one basket."

Single-loop digital controllers have overcome this limitation because they can be dedicated to serve only a single output, while retaining most of the capabilities of shared digital controllers. This gives the instrument engineer a very powerful and flexible tool for fully distributed optimal process control because all control loops can be configured and reconfigured to any desired level of sophistication while using the same controller.

Because the control functions are in software, all the control hardware can be purchased and installed before the control system itself is finalized, or an existing control system can be reconfigured without adding or revising any hardware or wiring.

The capabilities of single-loop digital controllers are very similar to the shared controllers also discussed in other sections of this chapter, and therefore they will be discussed here only briefly, emphasizing those features that are not available in analog controllers.

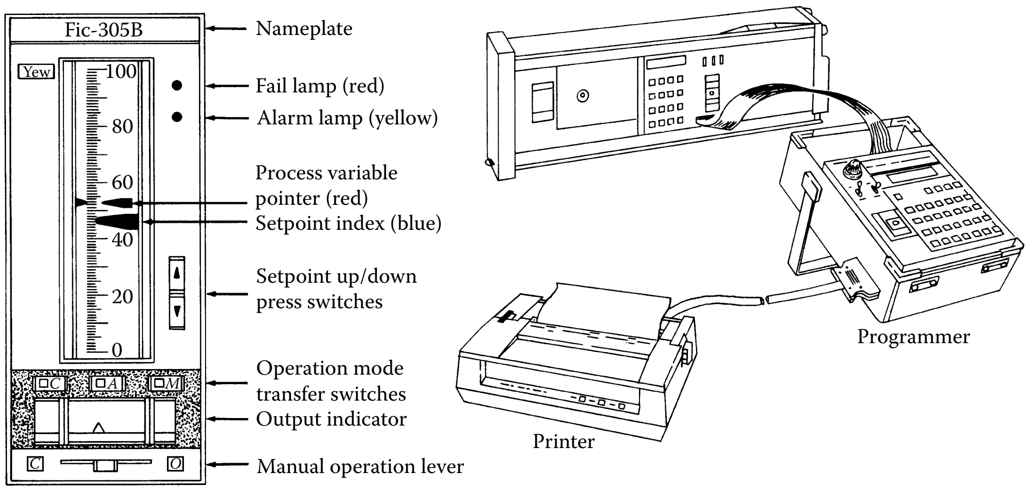

FIG. 4.4q
The faceplates of earlier digital controllers resembled the analog faceplate, and the units were programmed by separate programmers. (Courtesy of Yokogawa Corp.)

Hardware Components

A typical digital controller consists of a D/A and A/D converter, a microprocessor, a display, and control sections, in addition to communications ports (Figure 4.4r). The microprocessor section includes the computational element, the read-only memory (ROM) for program storage, and the operating or random-access memory (RAM).

The A/D converters on the input must have high resolution and high noise tolerance, which can be obtained from voltage-to-frequency converters with counters or from dual-slope integrators. Some controllers operate on pulse train inputs, where the frequency indicates the value of the input. The D/A converters are usually implemented from resistor ladder networks.

The microprocessor calculates the engineering equivalents of set-point, measurement, and output signals and operates the display. The cycle time of the microprocessor varies from 0.05 to 0.5 seconds. During this cycle the controller is not aware of alarm or other conditions that might have evolved until the processor again comes around to evaluate the condition that has become abnormal.

Communications with other instruments are usually handled on an interrupt basis. As digital controllers process data in this "batch" manner, the sequence usually starts with reading all the inputs, linearizing them, and checking them for alarms. This is usually followed by calculating the control algorithm, which can be velocity or a positional configuration (for the actual PID algorithms see Section 2.4 in Chapter 2), and only after that are the displays updated and the other communications outputted.

The potentiometers that are used on analog controllers to set the various alarm points, tuning constants, etc., are replaced by switch matrices, pushbuttons, or keyboards and are retained in RAM on the digital controllers. Provisions are required to retain this memory when the power supply fails,

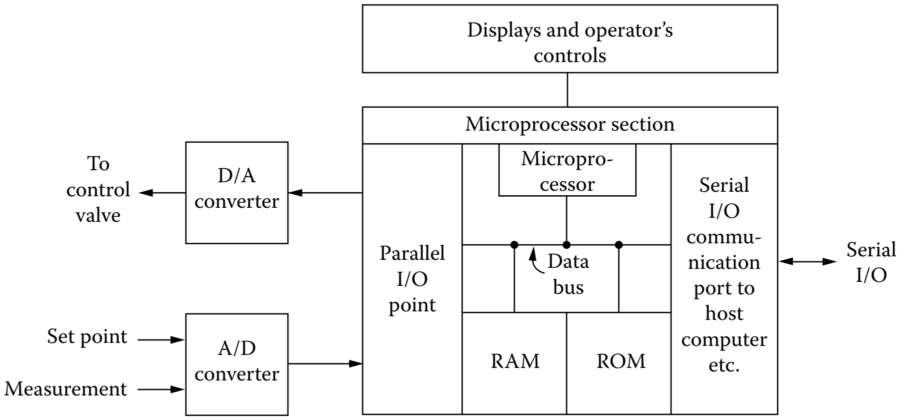

FIG. 4.4r
Block diagram of the hardware components of a typical digital controller.

so that these parameters will not need to be reentered after the power interruption. This is usually accomplished by the use of rechargeable, long-life batteries.

The communication formats used with other digital equipment have not been standardized (RS232, RS422, RS485, IEEE488, etc., may be used), and the coding of the data also varies from manufacturer to manufacturer, using systems such as ASCII, binary, and binary coded decimal. Therefore, special provisions can be needed before digital instruments can be interconnected. International standardization of digital protocols is much needed but is progressing rather slowly. (See Volume 3 of this handbook.)

These communication formats are usually serial in nature to minimize the wiring requirements, they can be unidirectional (single wire) or bi-directional (two conductors), and their data rates vary from kilobauds to several megabauds. In setting up communications with a host computer, the user usually needs to perform programming to code and decode the data communicated by the computer.

Software Capability

A library of control algorithms is available, including many of the more sophisticated functions such as lead-lag, feedforward, dead time compensation, program pattern control, sample and hold, inverse derivative, gap control, auto select or limit functions, error squared, PID, and multiple inputs and/or outputs for cascade, ratio, or batch control. Many designs are able to handle just about all the different types of input signals (including low-level RTD and TC-type measurements with table lookup) and are able to generate any of the various outputs.

Signals can be linearized, pressure- or temperature-compensated, converted to any engineering unit, totalized, time delayed, or arithmetically manipulated.

TABLE 4.4s
*Programming an Auto-Manual PID Controller by Answering a Series of Questions**

Step No.	*Description*	*Parameter*	*Value*
1.	Engineering Units 0% value	EU 0%	–99999 to 99999 (E.U.)
2.	Engineering Units 100% value	EU 100%	–99999 to 99999 (E.U.)
3.	Gain	GAIN	0 to 128
5.	Reset	RESET	0 to 293 (repeats/minute)
6.	Rate	RATE	0 to 895 (minutes)
8.	Process variable filter time constant	PV FTIM	0 to 1.8 (minutes)
9.	Reverse control action	REV ACT?	YES or NO
10.	Increase closes	INC CLO?	YES or NO
11.	Alarm A trip point	ALM A TR	0 to 136% of E.U. span (E.U.)
12.	Alarm B trip point	ALM B TR	−16 to 136% of E.U. span (E.U.)
13.	Alarm C trip point	ALM C TR	−16 to 136% of E.U. span (E.U.)
14.	Alarm dead band	ALM DBND	0 to 136% of E.U. span (E.U.)
16.	Setpoint low limit	SP LO LM	−13.97 to 113.97% of E.U. span (E.U.)
17.	Setpoint high limit	SP HI LM	−13.97 to 113.97% of E.U. Sspan (E.U.)
18.	Valve output low limit	VO LO LM	−13.97 to 113.97(%)
19.	Valve output high limit	VO HI LM	−13.97 to 113.97(%)
20.	Antireset windup low limit	ARW LO LM	−13.97 to 113.97(%)
21.	Antireset windup high limit	ARW HI LM	−13.97 to 113.97(%)
22.	Feedforward gain	FF GAIN	0 to 1
23.	Feedforward reverse action	FF REV?	YES or NO
24.	Feedforward filter time constant	FF FTIM	0 to 112 (minutes)
25.	Track filter time constant	TK FTIM	0 to 112 (minutes)
28.	Restart mode	RST MD	1 to 5
29.	Restart valve output	RST VO	−13.97 to 113.97(%)
30.	Restart set point	RST SP	−13.97 to 113.97% of E.U. span (E.U.)

The logic interlocks associated with the loop can also be implemented because many single-loop digital controller designs have both continuous and sequential control features, utilizing all the basic logic functions. These functions are in addition to the standard alarm features.

Programming and Capabilities The programming of a particular controller is usually done by sequentially entering the answers to a number of questions (Table 4.4s). In this example, the process control engineer would, in response to the first question, identify the engineering units of the controlled variable and would indicate the reading that the controller should consider as a 0% reading.

In step 2, the full span (upper range limit = 100%) value would be similarly identified, and in step 3, the gain (proportional band) setting would be entered. As the engineer goes through these steps, the control algorithm and related features are all specified and the controller is ready to take control. In most PID configurations one can vary the basic algorithm (velocity, positional, sample-and-hold, error squared, noninteracting, external-reset, derivative and/or proportional, acting on measurement instead of error, nonlinear, etc.)

In addition to configuring the control algorithm (Table 4.4s), one might also provide linearization functions (such as square root extraction, TC, RTD, or irregularly shaped tanks), counting or totalization, batching, or other types of logic and safety interlock functions. Some digital controllers also offer multivariable control or self-tuning and self-optimizing capability.

In general, digital controllers are much more flexible in tailoring the controller to the particular application than are analog units. Table 4.4t gives a summary of the capabilities of a particular single-loop programmable controller.

TABLE 4.4t
*Features and Capabilities of a Programmable Single-Loop Digital Controller**

Item	*Specifications*	
Control	Loop	Single PID loop Cascade loop Autoselector loop Two PID loops
	Control Types	Nonlinear PID control Feedforward control Batch PID control Sample-and-hold PI
	Self-tuning	
	SVF (Set Variable Filter)	
Signal Computation	Four-function math, square root, selector, limiter, characterizer alarms, first-order lag, derivative, dead time, velocity, moving average, timer, program set unit, counter, pulse output, logical calculations, comparison, branch, subprogram, switch, stack-register operations	
Control period	0.05 sec, 0.1 sec	
User program	Main program and subprogram, 200 steps total	
Analog signals	Inputs	5 points (1- to 5-V DC; direct input (mV/RTD/pulse etc.) possible for one point)
	Outputs	3 points (1- to 5-V DC; two 4- to 20-mA)
Status signals	Inputs Outputs	6 points (user-selectable as inputs or outputs)
Communications	Communicates with DCS or via RS-485) PC

Faceplates and Programmers

Loop configuration and programming are usually done through pushbutton operations. The problem of maintenance and spare parts storage is minimized by the complete interchangeability between units. Single-loop controllers can be integrated into large systems through data bus communications between them (networks and buses are covered in Volume 3 of this handbook), and they can also be connected to CRTs for display purposes.

The data highway can also be used to provide a communication link for the plantwide optimizing computer, which can reset the individual loops as required. Such remote signals can not only modify set points, but can also initiate auto/manual transfer, disable displays for information security, switch set points between local and remote sources, change controller actions, etc. In addition, some of the more advanced units also provide self-calibrating, self-diagnostics, and self-tuning functions.

Evolution of Faceplate Designs The earlier designs of digital controllers attempted to imitate the appearance of analog controller faceplates (Figure 4.4q) in order to gain better operator acceptance. For programming these early digital controllers a separate programmer unit was also required, and this device had to be reconnected whenever reprogramming was needed.

Later, in many designs the D’Arsonval meter movement was replaced by digital displays using gas discharge, light emitting diode (LED), or liquid crystal bar graphs. These “quantitized” images convey the innate value of the variable, similarly to analog displays, but have the added capability of flashing to gain the attention to the operator.

Figure 4.4u illustrates the faceplate of a more recent digital controller design in which bar graphs are augmented with digital readouts and the display itself is a bitmap LCD. The programming of most of the more recent digital controllers can be performed through a keyboard, which is integral with the controller. Some of the older designs still require separate plug-in programmers or can be integrated into a DCS system and programmed through the keyboard of the central console, as discussed in later sections of this chapter.

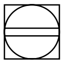
4.5 CRT Displays

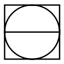
N. O. CROMWELL,
D. D. RUSSELL (1972, 1985)

B. G. LIPTÁK (1995, 2005)

General symbol for recorder or printer. "XX" designates the measured variable and modifier. The letter K is substituted for R to indicate control station.



An auxiliary operator's interface device for distributed control, normally panel-mounted with an analog faceplate. Normally not mounted on main operator console. Can be a backup controller or manual station.



Distributed control/shared display for an indicator/controller/recorder or alarm point, usually for a video display. Access is limited to the communication link.

This is a computer symbol, usually a video display, normally accessible to the operator, which is an indicator controller/recorder or alarm point in a distributed control scheme.

Flow sheet symbols

Designs:	Monoaccelerator and postdeflection accelerator (PDA) tubes
Types:	Storage tubes, character generation tubes, refreshed raster (TV) scan or refreshed X-Y position designs
Operating Voltages:	3 to 4 kV for monoaccelerator and 10 to 14 kV for PDA designs
Screen Size:	Standard sizes are 14, 17, 19, 20, and 21 inches, but units are available from 6× 8 in. (150 × 200 mm) to 23 × 30 in. (575 × 750 mm).
Refresh Rate:	40 to 60 Hz
Character Capability:	500 to 4800 characters
Characters per Line:	64 to 128 characters
Number of Character Lines:	12 to 74 lines
Character Set:	64 to 96 characters
Vector Modes:	Relative or absolute, or both
Vector Capability:	500 to 5000 per frame
Cost:	$3,000 to $10,000, higher for multiple CRT workstations

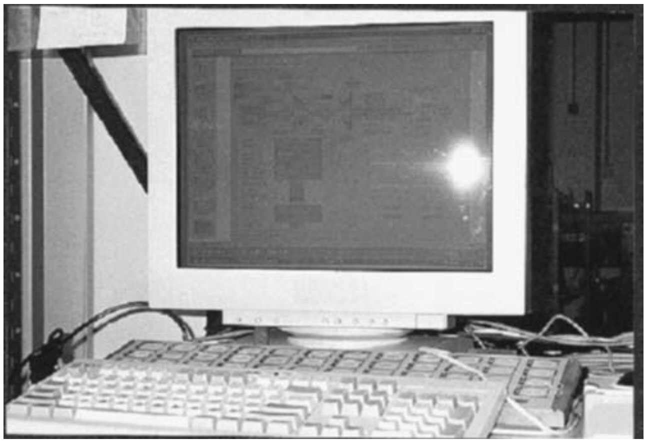

FIG. 4.5a
Workstation with single CRT and keyboard.

INTRODUCTION

The cathode ray tube (CRT) has become an important component in all workstations, DCS-based process control systems, and other human-machine interfaces (HMI). The various workstation, HMI, and control center designs have been discussed in detail in Chapter 3 of Volume 3 of this handbook. DCS systems in general and DCS graphics in particular are discussed in this chapter. The topic of this section is the CRT tube itself.

The CRT tube belongs to the family of emissive displays. Another main family of displays is the passive displays, such as liquid crystal devices. Other emissive displays include incandescent lamps, gas discharge lamps, electroluminescent devices (such as LEDs), and cathodoluminescent displays, including vacuum fluorescent devices.

The first CRT tubes were used on oscilloscopes and in industrial television applications. When, in the 1970s, large and reliable color tubes became available, the CRT tube became the prime means of process display in DCS systems (Figure 4.5a). Compared to the "nonvideo" type displays, its main advantage is its compatibility with computers and with digital electronics. The CRT can serve as an indicator, recorder, alarm, monitor, or logger; it also can provide instructions, display trends, or store data. Most DCS systems (Figures 4.5b and 4.5c) utilize several CRT displays.

DISPLAY OPTIONS

Some of the available display categories are also shown in Section 4.6. In addition, other types of displays can provide management with status reports, provide diagnostic displays to assist plant personnel in their troubleshooting efforts, provide coordinated and high-resolution bar graphs for analog readings, or display status or alarm conditions on a display whose background is a diagrammatic overview of the plot plan of the plant. Figure 4.5d shows such alarm displays.

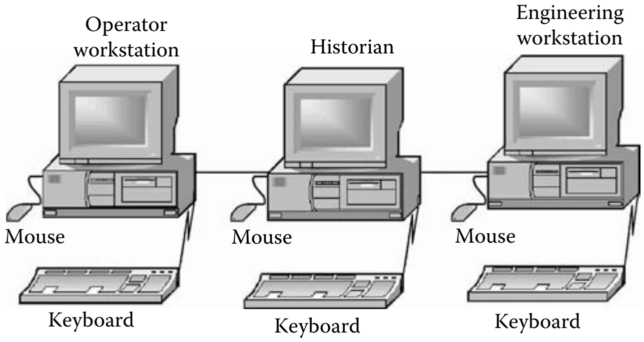

FIG. 4.5b
Intelligent workstations allow for each station to perform its own task while sharing the same database.

When such a display is used to report the safety status of the plant, the nature of the problem is identified by the color of a flashing square (Figure 4.1a), while the location is made obvious by the plot plan of the plant in the background. These types of displays are quickly and easily comprehended and thus are useful for conveying safety-related information. Such displays are often used in addition to, but not in place of, conventional annunciators.

In some applications it is useful that CRTs can generate three-dimensional displays that can be rotated and viewed from all sides. The CRT display can be used in the graph mode, interrelating two or more variables with each other (*X*–*Y* recorder) or with time.

As larger and more complex plants are built with central control rooms containing greater numbers of instruments, the man–process communication problems grow. When digital computer control was first applied in the process industry, alphanumeric control panels were used in addition to the conventional analog instrumentation displays. With these systems the user was able to display and manipulate the control loop parameters (usually, however, only singly).

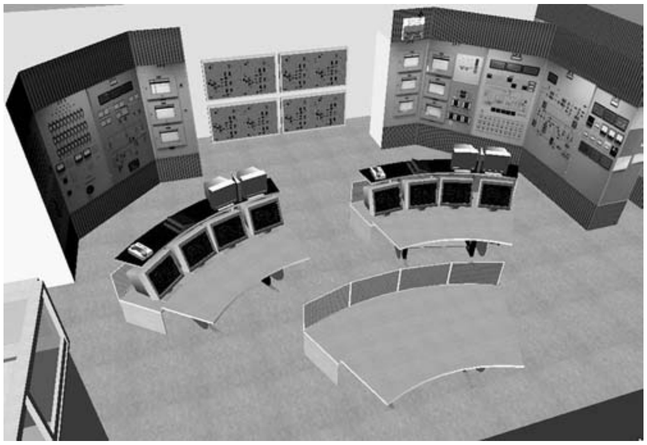

FIG. 4.5c
New workstations are often added to existing control rooms with analog instrumentation.

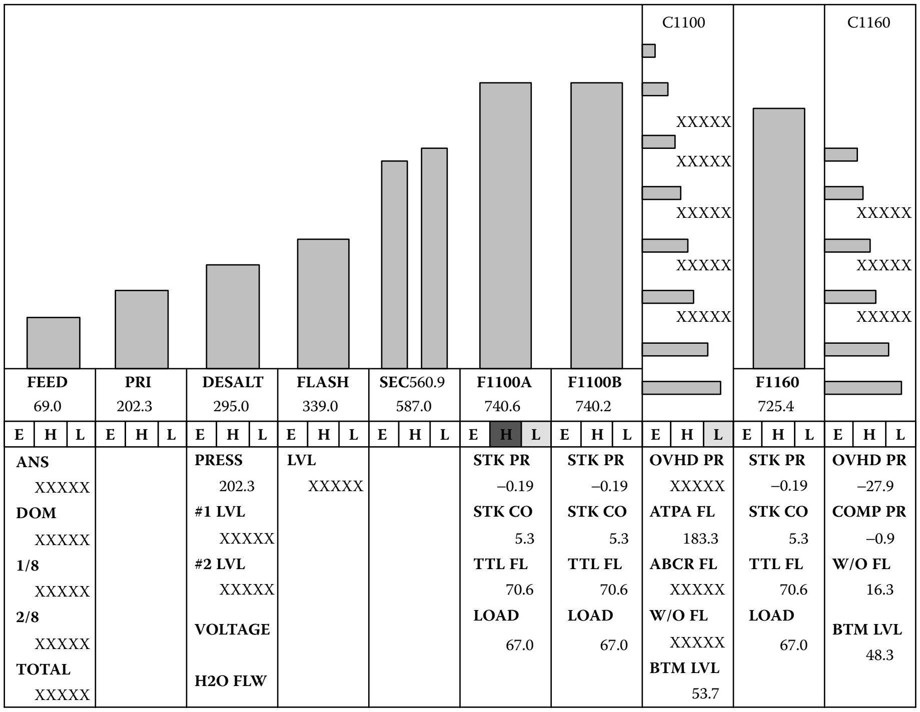

FIG. 4.5d
Integrated CRT display of alarm status overview.

More recently, the man–process communication requirement has been expanded to include not only the needs of the process operator but also all communication between the process and plant personnel. Table 4.5e defines seven levels of communication in a process plant involving process operating, engineering, programming, and management personnel. A process operator, for example, would use information from levels 1 and 3, an instrument engineer would require information from level 2, and a systems engineer would require information from level 4. A manager needs information from level 7.

TABLE 4.5e
Communication Levels in a Process Plant

Level 1:	*Emergency Indicators and Alarms*	Includes both indicators and safety alarms that warn of impending difficulty; assists operator either in moving process to a safe operating point or in shutting it down.
Level 2:	*Component Diagnosis and Maintenance*	Includes information required to diagnose plant and computer system component failure; makes maintenance checks and assists maintenance personnel in finding the corresponding faults.
Level 3:	*Process Operation Information*	Includes all information required by operating personnel to keep the plant running safely and as close to economic optimum as possible.
Level 4:	*Process Evaluation and Diagnosis*	Includes all information needed to determine how well the process is operating, to investigate potential technical or efficiency problems, and to diagnose rapidly complex process failures when they occur.
Level 5:	*Process Supervision Information*	Includes plant parameters that affect overall economy and efficiency; e.g., information on current schedules, feedstock availability and quality, utility usage, and product qualities and costs required to make day-to-day or minute-by-minute adjustments of operating conditions to achieve optimum plant operation.
Level 6:	*System Maintenance and Improvement Information*	Includes program information needed to derive the most from the computer system and to make online system modifications as better operating methods are developed by plant personnel.
Level 7:	*Process Accounting and Scheduling*	Includes information on quantities of production, feedstock supplies, shipping, and labor to assist in establishing production schedules.

THE TOTAL SYSTEM

Although there are multichannel bar graph instruments utilizing CRTs for displaying analog inputs, most CRTs are used in DCS-controlled plants and are operated by digital logic devices. An overall block diagram of a typical digital control system is shown in Figure 4.5f.

The CRT hardware is contained in the two consoles and consists of a CRT display, a keyboard (containing alphanumeric, functional, and cursor control keys), alarm light switches, a refresh memory, an alphanumeric character generator and format control, and associated control logic. A vector generator can be supplied (optional) for graphic displays. Figure 4.5g illustrates the interconnections within the CRT hardware components.

The digital computer memory stores the operating system and data lists. An auxiliary bulk storage device (drum or disk) is sometimes used to store additional programs and data files, and the computer uses a priority interrupt scheme and two bidirectional information channels for communication with other devices. One of these channels, commonly referred to

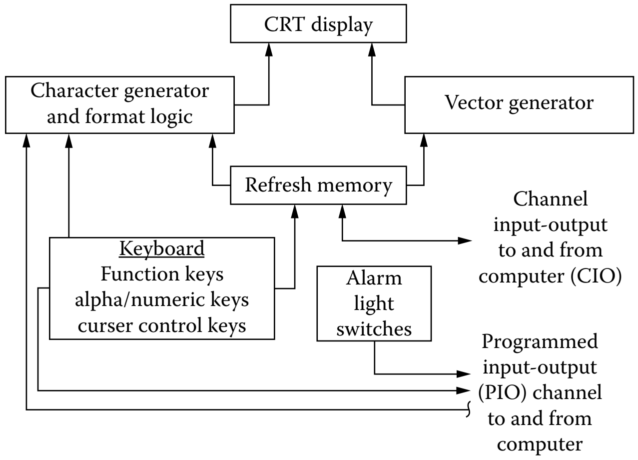

FIG. 4.5g
The roles and interconnections within the CRT hardware components.

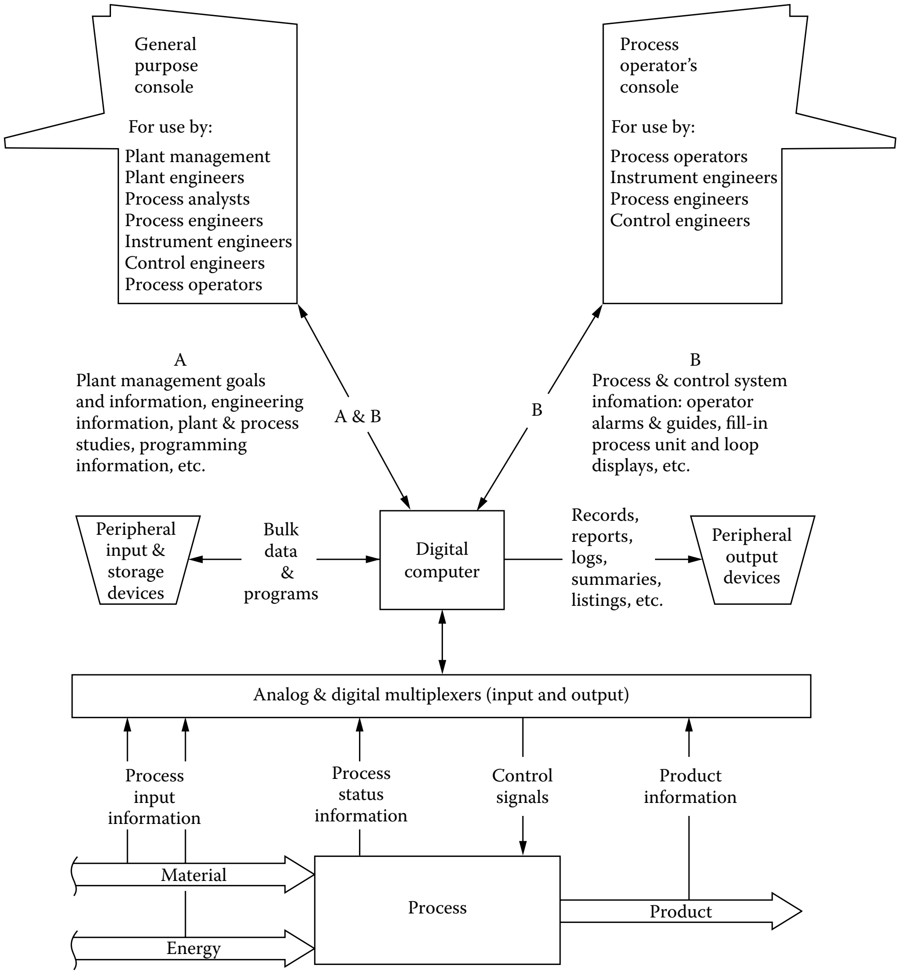

FIG. 4.5f
The components of a plantwide computer control system with CRT display.

as the programmed input–output (PIO) channel, transfers control information and single data words to and from a specified register (usually an accumulator) in the computer. The second channel transfers multiple words or blocks of data to and from the computer memory and is usually referred to as the direct memory access (DMA) channel, or simply the channel input–output (CIO).

The process control program requires a list of control tasks to be performed at specified intervals. These tasks include acquiring process data through analog and digital inputs and computation of appropriate control or alarm actions, or both, based on the input data. The task list contains the necessary data for the process control programs to carry out the desired control operations. These data include input and output addresses, constants, point names, digital status information, and current input–output values. This task list is called the *process database* and is the prime source of process data for display.

Servicing console data transmission requests from programs operating in the central processing unit and handling console keyboard interrupt requests are functions of the real-time executive system. Programs performing tasks requiring data to or from a process display console pass their requests for service to the real-time executive function programs. The calling programs receive acknowledgment of successful completion of the requested operation or indicators describing an aberrant condition.

Data Display Options

Cathode ray tubes can display large amounts of information and can be selective in displaying only relevant parameters or complex relationships between parameters. By fully exploiting the alphanumeric and graphic capabilities, the CRT is more efficient and economical than other methods of data display.

Several choices of CRT implementation include a storage tube display, a raster (TV) scan display, and a random *X–Y* positioned, refreshed display. What follows is a description of the random *X–Y* positioned, refreshed display.

X-Y Positioned Displays The size of the usable display area, and hence the size of the CRT, is determined primarily by the size of the character, the number of characters per line, and the number of lines required. A secondary consideration is the required amount of graphic display. A typical display of a process plant unit is shown in Figure 4.5h. As discussed in Section 4.15, in order that this display be legible from a distance of 5 to 10 feet, the character height should be between 3/8 and 1/4 in. (9 and 6.3 mm).

To display the information shown in Figure 4.5h, a character format of 80 to 96 characters per line and 20 to 30 lines are required. These characteristics dictate a diagonal measurement on the CRT of at least 19 or 21 in. (475 or 525 mm). The body of data necessary to initiate a display of the type shown in Figure 4.5h includes:

1. The names of the blocks or loops, or both, to be displayed
2. The format of the display
3. For each block in the display:
    a. The symbolic references to values in the block record, e.g., MEAS (measurement), ABS (absolute)

b. For each symbolic block reference value, its relative or absolute display address
c. Whether or not the value is to be updated in real time, whether or not the operator is to be allowed to modify the value, and how many characters are to be displayed

The mixed display of alphanumeric characters and graphics shown in Figure 4.5i would also fit comfortably on a 21 in. (525 mm) CRT.

Operator Interaction Operator interaction with a process display consists of manipulating the blocks displayed, e.g., changing a block from ON to OFF, and of entering new numerical data, e.g., changing a set point.

Figure 4.5h shows a process display. In the column labeled "set point" there is (for each block) a numerical value, and directly under the value a line of underscores that shows the operator where a new value for the set point is to be entered. The cursor is moved to the underscore field and the new value is entered, using the numerical keys. The underscores are unprotected characters and can be overwritten from the keyboard.

The operator may then either move the cursor to other underscores and enter more data or press the ENTER key, which causes an interrupt to occur in the CPU. In response to the interrupt a program is called for execution that will service the operator's console. The program will in this case read the unprotected characters in the display memory and attempt to modify the appropriate values in the process database block records.

The functional key service program uses data supplied by the display initiator to determine the set of data that goes with the blocks on display. Appropriate visual feedback to the operator is obtained by overwriting the existing value (the one above the entered value) with the new value and restoring the data entry area to unprotected underscores. Should the new value be unacceptable, the underscores are not restored and the offending value may be set to blink. An error diagnostic message may also be displayed.

The operator may accomplish block state changes by pointing the cursor to the block name and pressing one of the measurement and control status function keys. These keys have been appropriately labeled control on, control off, and so forth (see Figure 4.5i). The same interrupt response takes place as already described.

Interrupt Response The program responding to operator requests for service must be able to activate and deactivate function keys. Also, the interrupt-causing keys must be identified. Activating and identifying keys is performed by a key mask table for each console keyboard. It contains the code for each key that is currently active. An active key is one that has been put in the table by the program servicing the console.

Thus, the servicing program can at any time determine the function keys that the operator may legitimately use. The key mask table is used by the console-interrupt-handler segment of the real-time executive to determine whether the servicing program has to be called.

Multiple Workstations If many consoles are operating concurrently, the servicing program attends to each as requests occur. There need be only one servicing program. The information that it requires for each console that has a currently active process display includes:

1. The total number of unprotected characters on display
2. A sequential list of the block name and symbolic value name for each data entry field
3. The length of each data entry field and the display address of its related protected value
4. Access to the same data as the display update program

This set of data is needed to ensure that visual feedback for every requested state change is available. If visual feedback is not possible, the requested state change is erroneous, and an appropriate diagnostic measure is displayed.

Components of a CRT Display In a block diagram of a typical CRT display unit (Figure 4.5j), electromagnetic deflection and low-voltage electrostatic focus maintain display quality at all locations on the CRT screen. P-31 phosphor (green) is usually preferred over P-1 phosphor (white) because it is more durable. The block of input data to the display unit shown in Figure 4.5j (X and Y position data and

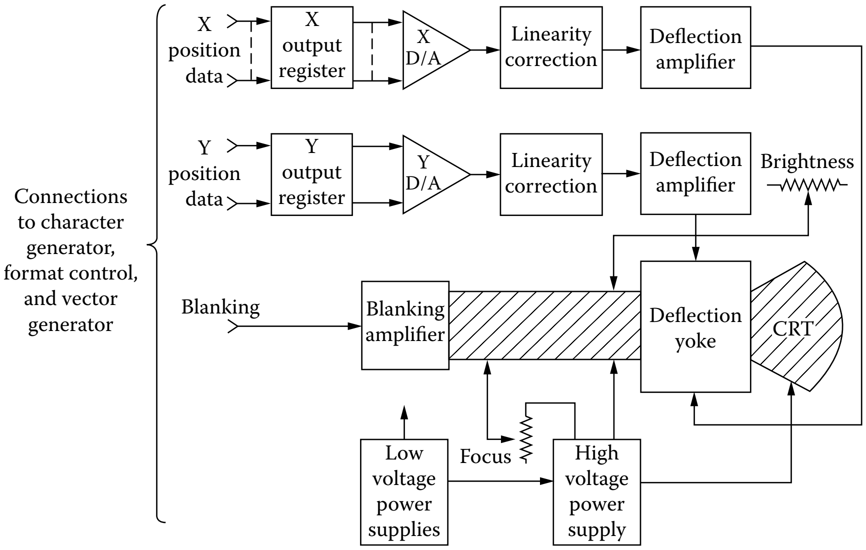

FIG. 4.5j
CRT display components.

blanking) is supplied by a character generator, format control, or vector generator. The data are digital in nature.

The body of *X* and *Y* position data is loaded into output registers connected to high-speed, digital-to-analog (D/A) converters, the output of which drives a linearity corrector and deflection amplifier. The linearity corrector compensates for geometrical distortion in the CRT, and the deflection amplifier must be capable of furnishing as much as 5 amperes of current to the deflection yoke. The blanking amplifier provides a signal to turn the electron beam in the CRT either on or off.

The information supplied to the CRT display unit must be continually repeated or refreshed. So that flickering or a "swimming" effect does not occur on the display screen, the refresh rate should be synchronous with the power line frequency—ordinarily 60 (or 50) Hz.

Keyboard

When a CRT display is used in process control, a pointer, or cursor, is required to indicate the parameter upon which the action is to occur. Cursors (see Figure 4.5h) are manipulated from a keyboard so that they are beneath the line, value, or character to be selected for the next operation.

Cursor Control Cursor control keys (Figure 4.5k) include the four arrow keys (←, →, ↑, ↓) for movement in one of the four primary directions. In addition there is a FAST key to increase the rate of movement, a HOME key to return the cursor to the upper left corner of the CRT screen, and a JUMP key, which will be subsequently explained together with the "protect" feature. The position of the cursor can also be controlled or questioned from the computer.

It is often undesirable to enable a user to modify values or characters on the CRT screen. A "protect" feature protects characters specified by a program in the digital computer from being modified. This feature might be implemented by a bit associated with each character, such that when it is set to a "1" state, the character can be modified only by the computer, not directly by the user. This feature also enables the computer to read selectively only unprotected information in the refresh memory.

The cursor control JUMP key allows the cursor to move from a current position to the next unprotected character following a protected one, thus bypassing (protected) characters that cannot be changed by the user—a very useful feature in a fill-in-the-blanks operation.

A "blink" feature permits individual characters displayed on the CRT to be blinked on and off several times per minute; this is useful for special conditions such as alarm indication. This too is controlled by a bit associated with each character in the refresh memory. Supplying solid, dashed, and dotted lines is useful for graphic displays. For example, a solid line and a dashed line might differentiate between a measurement and a set point when trend information is displayed.

Alphanumeric Keys Alphanumeric keys (see Figure 4.5k) modify or make additions to the display on the CRT screen. Entries can be made only into unprotected locations and are themselves unprotected. The operations are performed by the hardware associated with the CRT and require no response from the computer. The keys resemble those commonly found on a typewriter.

When they are depressed, a code (usually USASCII-8) corresponding to the key legend is entered into a refresh memory location corresponding to one directly above the cursor on the CRT screen, and the cursor is incremented by one location. With the key code entered into the refresh memory, the character is displayed at the corresponding location on the CRT screen.

A depression of the SPACE bar (key) causes a space (blank) character to be entered into the refresh memory and the cursor

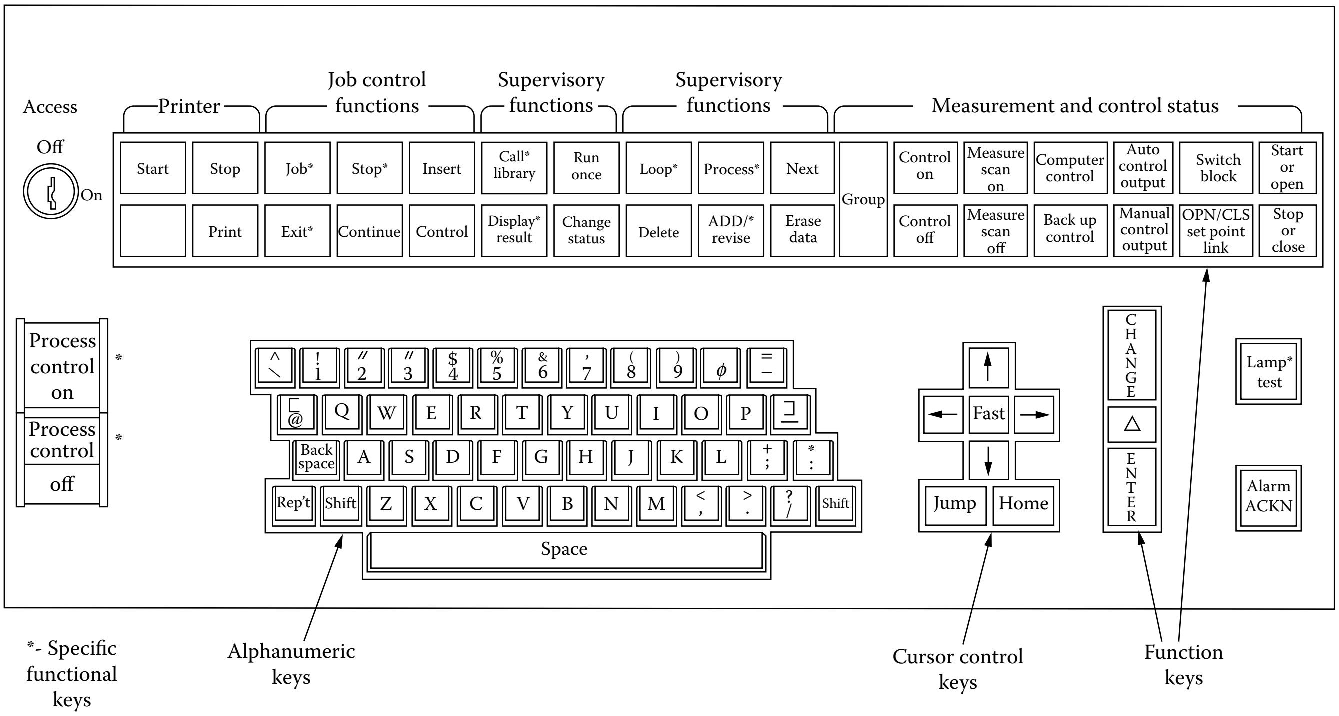

FIG. 4.5k
General-purpose keyboard adapted for process control.

to be incremented by one location. A BACKSPACE key, when depressed, causes a space character to be entered into the refresh memory and the cursor to be decreased by one location. By depression of the repeat key and a character key, the normal operation of the character key is repeated at a predetermined rate.

The function keys (see Figure 4.5k) request a specific action of the digital computer. When a function key is depressed, a priority interrupt signal is sent to the computer. The computer reads a code on the PIO channel corresponding to the depressed key and executes the request, which might be to place all the control loops displayed on the CRT on manual control or to show a directory of the display library on the CRT. In other words, each key requests a unique function that is programmed in the computer.

Alarm Light Switches Alarm light switches operate very much like function keys, with one notable exception—the former are lighted pushbutton switches whose light is controlled either from the computer or by an external (field) contact closure. When depressed, the buttons primarily request new displays; when lighted, they indicate alarm conditions associated with the corresponding display. Depressing an alarm light switch causes a hardware action identical to a function key depression, when the computer program detects conditions that should turn an alarm light on the PIO channel. By setting a unique bit to 1 or 0, one can turn the light on or off, respectively.

DISPLAY CAPABILITIES

Refresh Memory

The refresh memory stores information (in coded form) displayed on the CRT screen. Since the duration of the CRT phosphor is several hundred microseconds, the displayed information must be regenerated and displayed at a nominal rate of 60 times per second. The refresh memory may consist of magnetic or acoustic delay lines, semiconductor shift registers, magnetic cores, magnetic disk or drum, or semiconductor memory cells.

The particular size, organization, and bit coding can vary. It can furnish information to a computer or to a character and vector generator. It can also accept information from a computer and a keyboard.

For example, a refresh memory associated with a 2000 alphanumeric character display (80 characters per line, 25 lines) or with a display having 3000 in. (76 m) of vectors (straight line segments for graphic displays) may consist of semiconductor memory cells, which are organized into 2000 words, with each word containing 12 bits of information. For display generation, each word is sequentially accessed and sent either to a character generator or to a vector generator. For a memory word that stores a character code, the bit structure shown in Figure 4.5l might be used.

The mode bits differentiate among characters and several types of vectors. For example, when the mode bits are

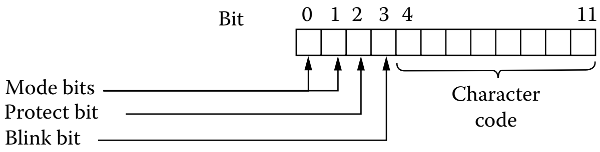

FIG. 4.5l
Bit structure for character code.

logical 00, the word is defined as containing alphanumeric character information. The protect bit determines whether or not the character code can be changed from the keyboard or selectively accessed from the computer. The blink bit determines whether or not the character will blink. The character code defines the alphanumeric character (usually in USASCII code) that will be accessed from this memory location and displayed by the character generator.

If the mode bits of a memory word are logical 10 or 11, the current word and the word in the next memory location are defined as containing either relative or absolute vector information, respectively. A relative vector is a straight line; its origin is the current beam position on the CRT screen and its endpoint is defined as a change in X and Y position with respect to this origin.

An absolute vector is a straight line. Its origin is the current beam position on the CRT screen and its end point is defined as an X and Y position in a fixed grid with the grid origin of $X = 0$ and $Y = 0$ at the lower left corner of the CRT screen. The bit structure in Figure 4.5m might be used to define a vector.

If the mode bits (in word 1) are logical 10, the two words define a relative vector, and therefore the X displacement contains a ΔX value and the Y displacement contains a ΔY value. If the mode bits are logical 11, the two words define an absolute vector, and therefore the X displacement contains an X value and the Y displacement contains a Y value. The line type determines whether the vector to be generated will be a solid, dashed, dotted, or invisible line (blanked movement).

Character and Format Control

Alphanumeric characters may be generated by means of several techniques. Analog stroke, "race-track," character mask scanning, and read-only memory character generation are a few examples. The following example is based on read-only memories.

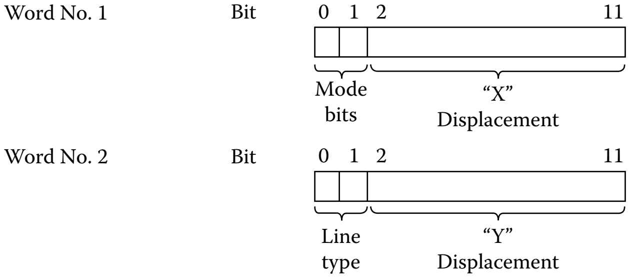

FIG. 4.5m
Bit structure for vector code.

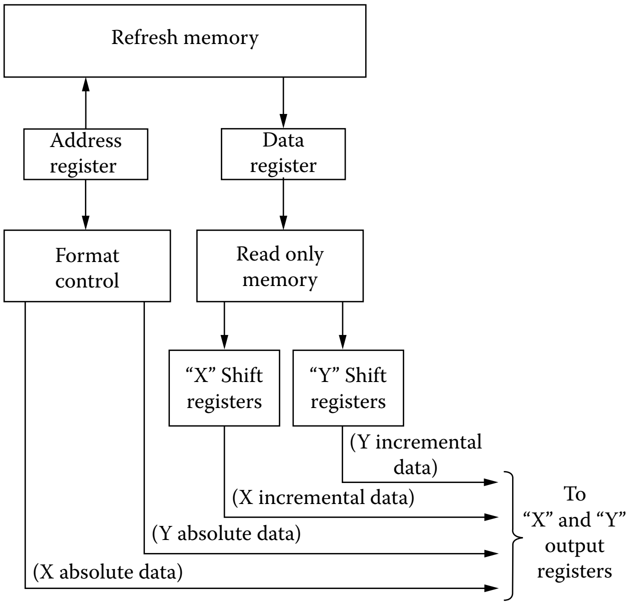

FIG. 4.5n
The logic of generating characters and controlling the format.

Figure 4.5n illustrates a character generator and format control logic. Since there are 2000 memory locations containing character codes for each of 2000 character positions on the CRT screen, the value contained in the refresh memory address register (Figure 4.5n) must be unique for each character position.

The refresh memory is accessed at the location specified by the contents of the address register, and data are loaded into the data register from this location. The format control accepts the contents of the address register as an input and generates absolute values of X and Y data, which positions the CRT beam to the starting position of the appropriate character location on the CRT screen.

The contents of the data register are then used as an address for the read-only memory, and the body of X and Y data is accessed and loaded into the appropriate shift registers (see Figure 4.5n). As the information is shifted out of these registers bit by bit, it is decoded and sent to the X and Y output registers (see Figure 4.5j). This mass of decoded data causes the output registers to increment (or count) up or down, which in turn causes the appropriate character (specified by the contents of the data register) to be written on the CRT screen.

Vector Generator

Vectors are straight line segments used to construct graphic displays. Typical methods of vector generation use analog ramp generators, binary rate multipliers, or digital arithmetic units. The example to be described uses digital arithmetic units.

The vector generator receives data from the refresh memory (see Figures 4.5m and 4.5n) and based on this body of data provides incremental data to the X and Y output registers (see Figure 4.5j).

When the vector generator receives the X and Y displacement information from the refresh memory, if the vector was specified as a relative vector, the information will consist of a ΔX and a ΔY value. The vector generator operates directly on this body of data. If the information received from the refresh memory has been specified as an absolute vector, an auxiliary operation of computing ΔX and ΔY will occur, by subtraction of the current beam coordinates (X and Y values) from those obtained from the refresh memory.

The operation (algorithm) of the vector generator is such that an incremental step (or movement) is made to minimize the value of ΔX and ΔY. A new value of ΔX and ΔY is then computed, and another incremental step is made to minimize the value of ΔX and ΔY. This process is repeated until the computed values of ΔX and ΔY are both zero. The result is a best fit to the desired straight line segment displayed on the CRT screen. The solid, dashed, or dotted lines are generated by turning the CRT beam on or off (blanking) at desired intervals.

Display Initiation

Process display initiation comprises a chain of events that begins with an operator key action and ends when the selected display has been transmitted to the console refresh memory and real-time update has commenced. From the operator's point of view, one or more key actions are required to fetch a display. From the point of view of program or software, these key actions identify what the operator wants to see.

The operator must have a method of observing both the process variables and the response to actions taken by the control programs in the computer. The operator also needs to be notified of alarm conditions and requires a method of communicating directives to the process control program.

To accomplish these objectives the process display programs must allow the operator to:

1. Initiate process data display requests, which will be updated to reflect process variable changes
2. Manipulate reference values and states (on/off or automatic-manual) of block or loop records in the process database
3. Terminate a process display
4. Request other relevant programs, such as directories or plant efficiency calculations
5. Respond directly to an alarm

Function Keys Inherent in each of the operations just mentioned is the process display console keyboard. Considerations of key sequence include:

1. How much data must be entered from memory
2. How many keystrokes are required to achieve a display response
3. How many keystrokes are required to recover from a data entry error
4. How many operator decisions (choices) are required to proceed through a desired sequence

The function keys (see Figure 4.5k) may be divided and arranged in groups as shown. From the point of view of software, the keys are also arranged by purpose. Keys supplying a constant response can be grouped by key code. All other keys are conditioned response keys. It is useful to think of these two groups as specific (constant-response) keys and conditional (sequence-dependent) keys. Alarm key lights are specific keys. Conditional keys manipulate process reference values, control states, and select data from a recipe.

Specific functional keys are indicated by an asterisk in Figure 4.5k; all other keys are conditional. Although in general it is desirable to minimize key operations that serve to initiate process displays, it does not always follow that every action that an operator might take should have minimum key activity. On one hand, operations such as modification of numerical values may require visual verification before entry into the process database is attempted. On the other hand, state changes of process data blocks or loops should require minimum key actions. Thus, the design of operator key activity and key sequencing must be related to the display tasks and to the keyboard design.

Key Sequencing The key sequence for any operation may be constructed as follows: First a specific key is used. This produces a fixed (by key code) visual response. Operator data are entered by the alphanumeric keys followed by a conditional key. The alphanumeric keys transmit data only to the display memory rather than to the central processing unit (CPU). The cursor is manipulated by the operator to enter data at appropriate display locations. Key sequence diagrams are useful in planning process display–process operator interaction.

Figures 4.5o and 4.5p show two typical sequences. The alarm key sequence (Figure 4.5o) is used when an alarm key light comes on owing to a process upset. The operator presses the key, initiating a process unit display (see Figure 4.5h). The process loop display sequence (Figure 4.5p) requires entry of data before the loop to be displayed can be selected.

The sequence begins with a specific key operation (loop key) and continues through entry of data (Figure 4.5q) and initiation of loop display (see Figure 4.5i). These examples are initiating sequences. Operator interaction with a live loop or process display is a continuation of the techniques described, using conditional keys.

Format Construction Display formats consist of the fixed or static information (column titles, headings, operator instructions, and recipes) and the address for each piece of data to be retrieved from the process database, displayed, and appropriately updated on the display. Static format data may be conveniently separated from the process database-related information, allowing independent modification of titles and headings.

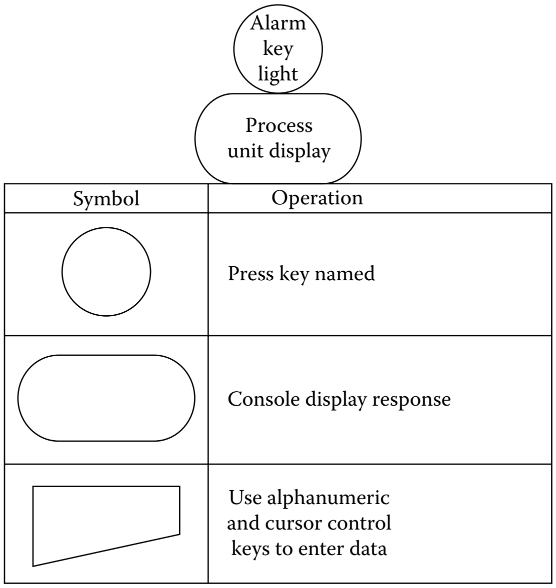

FIG. 4.5o
Alarm key sequence: When a process upset causes an alarm key light to actuate, the operator presses it, which in turn initiates the process display shown in Figure 4.5h.

The references to process database information should be symbolic. Usually, the process database is referenced by block or loop name, which points to a complete set of measurement and control data about one process control input or output or both. Within this set of data the references to particular information, such as a set point or measurement, should be symbolic.

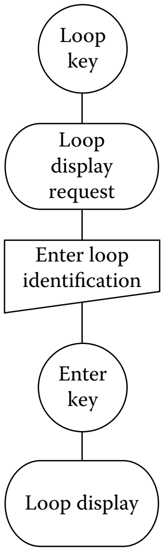

FIG. 4.5p
Process loop display sequence: before the loop display in Figure 4.5i can be displayed, the operation of the loop key is required.

Symbolic references to data items in each block record simplify the display-initiating program. The references are passed as arguments to a subroutine set that locates the appropriate item and performs internal-to-external format conversions.

Process Data Retrieval The CRT-based process display allows considerable flexibility about what process data are to be shown. Various special-purpose displays may be constructed

to suit individual processes and operating policies. Individual blocks or a single piece of information for several loops (Figure 4.5r), groups of connected blocks (a control loop—see Figure 4.5i) or sets of data related to process unit performance (see Figure 4.5h) may be displayed.

If each of these displays is considered a standard type, one may then construct displays using different sets of block or loop names for each process unit display, the format of which will remain constant—the block or set of loop data, or both, is changed to reflect the set of names chosen. Each set of blocks or loops is referred to by a identity code.

Process Data Display Process unit displays may be automatically shown in response to an alarm key action by construction of a list of alarm key codes and association of a "process unit display" identity code with each. The identity code retrieves the list of block or loop names to be displayed. At the same time that the name list is retrieved, the identity of the format (both the fixed part and the database-related part) is also retrieved. Thus, a process unit display identity is used to point to a predefined display format and a set of process data.

Propagation and Termination

The display-initiating program retrieves the appropriate data for building the display and supplies real-time display control and functional key service data through files or lists to the respective programs. The updating program is responsible for maintaining the displayed measurements and other values in a current or real-time state. The functional key service program is responsible for all operator-requested modifications of the data display. Typically, these changes are of two types: data entry or value manipulation, and state changes (e.g., on/off or automatic/manual).

In Figures 4.5h, 4.5i, and 4.5r, unprotected underscores define the appropriate areas for data entry for the operator. All other data displayed are protected and cannot be modified or changed by the operator at the console. The display-initiating program also must set a flag or bit in each block record requiring update; this bit or flag is referred to as the display capture bit.

Data Capture and Routing In display propagation the values shown are changed to reflect the variations in the controlled process. Measurements, alarm states, internally modified set points, and reference values are examples of data requiring continuous updating. Update frequency may be other than the normal processing interval, which is inconvenient and requires additional program logic.

If the update frequency is the same as the processing (scan) interval, the process control program may be constructed to examine the data capture bit in each block record. When the bit is on, the block record data are set aside in a temporary display file or list. When the process control program has completed its tasks for the current interval, it calls on the display update program for execution. It should be noted that display update is called on only when data have been captured for update.

The display update program finds the block record in the display file or list and with the display control information assembled by the display initiator converts the appropriate mass of data in the captured block record to external format and transmits it to the display.

Typically, for each block record the display update program includes:

1. Block name
2. Display console number if more than one
3. Symbolic data names for all items to be updated
4. Display memory address (where the data are to be displayed)

Terminating the Display After observation and manipulation, the operator indicates that the operation is complete by requesting another display by a specific function key or alarm key light, or both. The console-interrupt-handler segment of the real-time executive determines whether process display termination is necessary by keeping track of real-time update

TABLE 4.5s
Comparison between a 13.5-in. Passive Matrix LCD (PMLCD) and Active Matrix LCD (AMLCD) and a 15-in. CRT Monitor

Display Type	*Viewing Angle*	*Contrast Ratio*	*Response Speed*	*Brightness (foot-lamberts)*	*Power Consumption (watts)*	*Life*
PMLCD	49 to 100 degrees	40:1	300 ms	70 to 90	45	60K hours
AMLCD	>140 degrees	140:1	25 ms	70 to 90	50	60K hours
CRT	>190 degrees	300:1	n/a	220 to 270	180	4 to 5 years

operations on a console-by-console basis. If the current display on a console is not being updated in real time, termination is unnecessary; the requested program is responsible for clearing the display.

The process display termination program determines which blocks in the process database were being "captured" for display on the console and resets or stops their ensuing capture and display by resetting the display capture bit in the block record. The program also purges the data files supplied by the display initiation to the update program. When termination is complete, the operator-requested function is allowed to proceed. If many process displays on many consoles are being updated in real time, the termination must take care not to terminate capture of blocks that are being displayed on other consoles.

CONCLUSIONS

For a detailed discussion of a number of new developments in the field of graphic displays, please refer to Section 4.15. For a comparison between the features and capabilities of a CRT monitor and two LCD monitor designs, refer to Table 4.5s.

INTRODUCTION

This section gives a bird's eye view of where we stand in utilizing the distributed control systems (DCS) in the process control field. This section is followed in this chapter by more detailed discussions of fieldbus and network protocols (Section 4.16) and the various aspects of DCS design, installation and start-up.

Before going into the specifics of the progress made and problems remaining in the field of DCS-based control, I would like to illustrate the general trend through two examples.

In the 1970s I designed the controls of the new IBM headquarters so that the building would be self-heating and without chimney effect. The building had 43 floors and the control room was in the third basement. During startup, communication was an immense task. Just visualize that you have experienced a "hang-up" of the herding-optimization scheme because of a sticking control valve on the top floor and you constantly need information from the control room in the third basement. Well, in respect of the ease of communications, tremendous progress been made.

Today, one can plug in a PC laptop or use a wireless hand tool (see Figure 4.6a) and one can have instant access to all the data, displays and intelligence that reside anywhere in a DCS network. This capability, in combination with the self-tuning, self-diagnosing, and optimizing features, makes startup and operation much more efficient.

Operator training for startup, operation and shutdown can also be simplified because of the process simulator. If the simulation model integrates the process and its control system, so that it can train the operators without risking the consequences of learning while the plant is running, everybody benefits.

FIG. 4.6a
Mobile communication system can provide interface capability for roving operators. (Courtesy of Iconics.)

But this is only part of the picture. On the other side of the coin are the problems associated with the fact that some DCS vendors are selling their "violin" without strings (software is extra) and expect the users to put on these strings (prepare the control algorithm, faceplate, and graphic displays) on their own. In addition to these hidden costs due to "outsourcing," the problems include lack of standardization due to the competing vendors' commercial interests and limited connectivity.

If one reads a bid that lists the costs as "hardware with software license," one might think that the operating software is included. Sometimes it is not, only its license. Similarly, when one reads that an analyzer or an optimization or simulation package needs "layering" or is in the "8th layer," that can mean the software has not been integrated into the total system and to do so is an extra.

In this section, I will concentrate on three areas: First, I will talk about connectivity system integration to obtain good communications among the components of the total process control system of the plant. After that I will discuss the various new and advanced control algorithms and strategies, and finally I will give some data and advice on the costs of DCS.

CONNECTIVITY AND INTEGRATION

Automation is the only means of making American industry globally competitive, while tariffs are lifted to guarantee free trade. The only way to eliminate unemployment is to fully automate our industries and to make sure that the children of the blue-collar steel workers of Pennsylvania grow up to be well-educated process control engineers, computer programmers, intelligent device designers, and optimization specialists. This will take education, and the contents of this handbook should help in providing that education.

At present, 90% of industrial production is still controlled by analog systems, but modern control systems of newly built plants consist of intelligent and self-diagnosing field instruments (sensors, valves, motors, safety devices) and a number of data highways or network buses, which serve to integrate these field devices with the DCS workstations (serving control/operation, engineering/historian, maintenance), the plant/enterprise-wide network serving business functions, and external PCs serving process modeling and simulation functions (Figure 4.6b).

The trend seems to be that HART is becoming the standard for interfacing with analog systems and Ethernet is handling most office solutions. SCADA serves to combine field and control data to provide the operator with an overall view of the plant.

Protocol is the language computers speak. If two black boxes in a refinery do not speak the same language, the consequences can be serious. Yet the commercial goal of

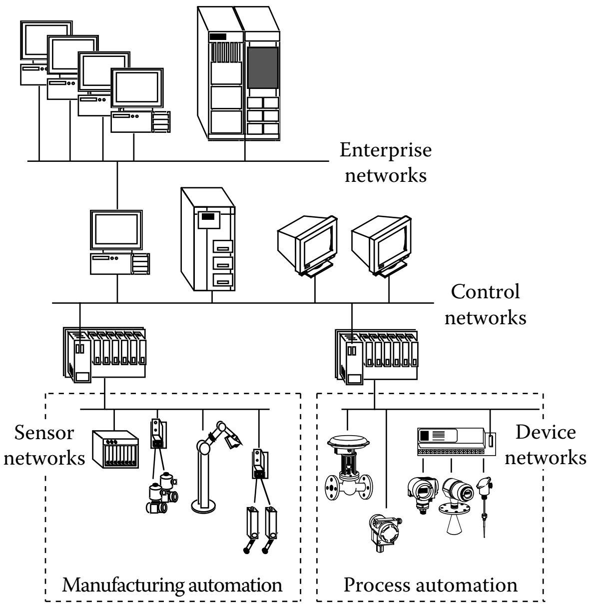

FIG. 4.6b
Connectivity requires that the intelligent devices of the sensor and device networks be provided with unlimited two-way communications not only with DCS workstations connected to the control network but also with sophisticated (external) process simulation models.[1]

creating captive markets is strong, and IEC has standardized on eight protocols (Table 4.16i).

While there is no common DCS fieldbus protocol, all protocols use Ethernet at the physical and TCP/IP at the Internet layer. MODBUS TCP is used to interface the different DCS protocols.

The layers of the communication pyramid are defined several ways. As described in Figure 4.16c, OSI defines seven (7) layers, #1 being the physical and #7 the application layer (with #8 being used by some to refer to the "unintegrated" components). The IEC-61512 standard also lists seven levels, but they base them on physical size: 1) control module, 2) equipment, 3) unit, 4) process cell, 5) area, 6) site, and 7) enterprise. In the everyday language of process control, usually four layers are discussed in the automation pyramid: Here, #1 is the level of sensors and actuators in the field, #2 is control, #3 is operations, and #4 is the level of business administration.

When one is designing the overall control system of a new plant or when one is updating the control system of an existing facility, there is a tendency to make a quick I/O count and, based on that preliminary information, to obtain bids and select the DCS supplier. This is the wrong approach because it will result in endless extras and delays.

Organizing the Project

Field Instrument Integration In a new plant, the first step should be to specify all the sensors, transmitters, control valve actuators, positioners, local controllers, electric motors, solenoid valves, and all other microprocessor-operated devices in the field that need to communicate information to or receive commands from the DCS system over the networks.

When the project consists of additions to an existing plant, all the interfacing between the existing and new facilities must also be specified (Figure 4.10a). The three types of interfaces most often used are object linking and embedding (OLE), serial-to-highway gateway and serial-to-serial port. Because digital transmitters, smart analyzers, digital actuators, and motor starters utilize a variety of communication protocols, the manufacturers provide interface cards to the common buses. Such cards are available for HART, DeviceNet, Foundation Fieldbus, AS-inetface, Profibus, Modbus, or AB's Data Highway Plus.

This integration is not as simple as one might think because there is no international standardization and some smart field devices are proprietary, or cards can be mixed up. Another roadblock to DCS system integration is that manufacturers implement the same task in different manners. For example, the controller status is described by some manufacturers by using two parameters: Auto/Manual and Remote/Local, while others use a single parameter: Manual/Auto/ Cascade/Remote-Cascade/Remote-Out.

Safety Integration The second step is to specify the network requirements in terms of the needs for physical layer redundancy and also in terms of the number and type of network levels required (Figure 4.6c). It is at this point, where the type of safety instrumented system (SIS) is selected for the plant and it is decided whether the plant's SIS and the control systems will be separated (Figures 4.10e and 4.10f) and, if they will be separate, what kind of interfacing will be used. If safety and control will not be separated, decisions are required on prioritizing, redundancies, hard wiring, etc.

Some suppliers provide redundancy by building two of everything in the system as standard; others provide redundancy on an optional basis for power supplies, data highways, traffic directors, remote controller electronics, and workstation video terminals. Yet others provide one for one, one for four, or one for eight backup of controller file cards. In addition to the backup method, there are also differences to backup diagnostics and method of switchover, which can be automatic or manual.

Maintenance and Simulation Integration The third step is to specify the requirements for interfacing between maintenance and control systems and to decide on the optimization, simulation, training and commissioning tools that will be used and therefore need to be integrated into the total plant automation package.

When it comes to process simulation, the process modeling software packages can be very large and might reside in separate PCs or might even be obtained from the Internet (Figure 4.6c). Therefore, it is essential that the communication

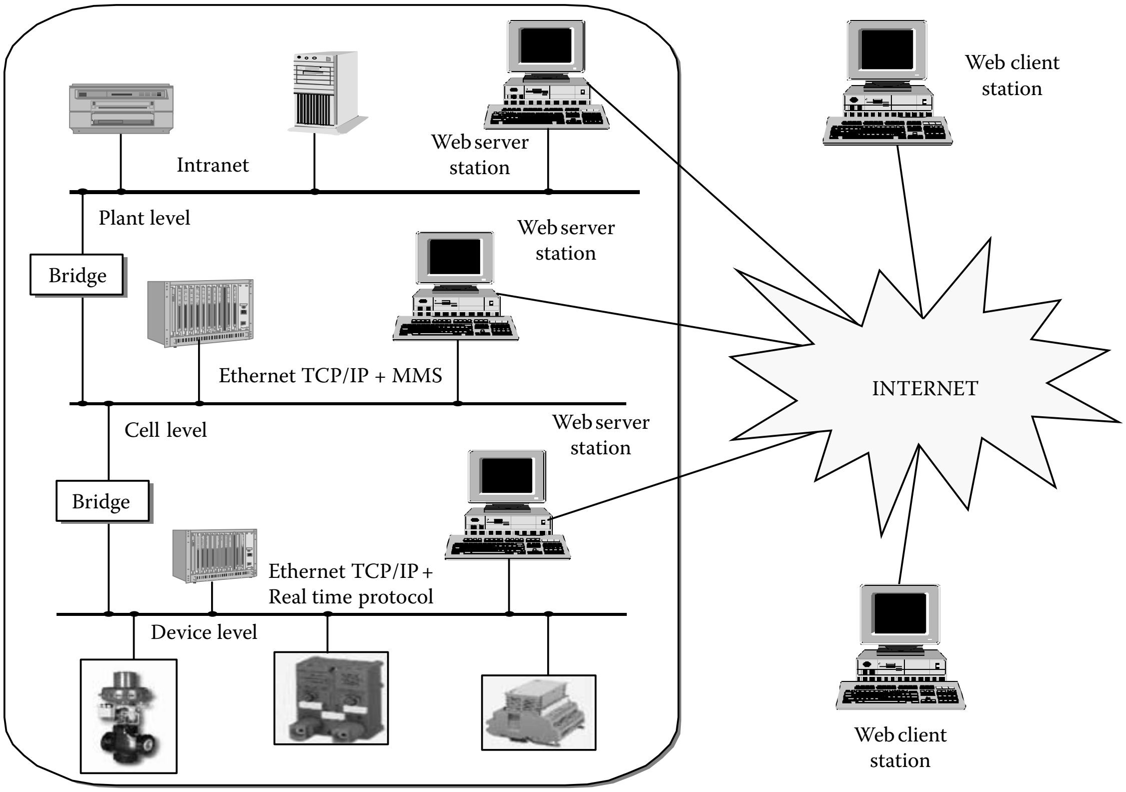

FIG. 4.6c
It is important to integrate the DCS system with intelligent instruments at the device level and provide communication bridges both between the networks and with process-specific dynamic models used for simulation and training.[2]

bus network be able to interface with them and to handle the information flow without interrupting the control functions.

Network and Bus Integration The fourth step is to select the network to be used. Profibus is supported by Siemens, Endress & Hauser, Yokogawa, Rosemount, Invensys, and ABB; Fieldbus Foundation is supported by Emerson, Honeywell, and Telemechanique; while Controller Area Network (CAN)/DeviceNet is supported by Allen-Bradley, Modicon, Numatics, and ProLog.

The major DCS manufacturers accepted the IEC1158-2 fieldbus standard for integrating their systems by providing the means of communication between them. IEC-61804 specifies function block interfaces between technologies, while others can be integrated "proxy" function blocks, which can "map" the data from the systems of the "other" suppliers. The digital communication of these devices should be specified to include not only the requirements of control but also those of self-diagnostics, maintenance, and safety. MODBUS interfacing can be used to integrate existing and new DCS systems.

In this fourth step the user should evaluate which bus network is best capable of meeting the requirements of the previously listed three steps. For the capabilities and features of some of the above-mentioned networks, refer to Table 4.6d.

TABLE 4.6d
Features and Characteristics of Some Field Automation Networks[3]

Network Name	*Type of Protocol*	*Speed*	*Type of Wiring*	*Bus Power*
PROFIBUS-DP	Master/slave and token passing	12 Mbps	UTP	No
PROFIBUS-PA	Master/slave	31,250 bps	STP	Yes
Foundation Fieldbus H1	Arbitrated	31,250 bps	STP	Yes
Foundation Fieldbus HSE	Arbitrated	100 Mbps	UTP	No[a]
DeviceNet	Master/slave	500 Kbps	UUP(2) or flat	Yes
AS-interface	Master/slave	500 Kbps	Flat	Yes
ControlNet	Timed slot	5 Mbps	CATV coaxial	No
Interbus	Slot-ring	500 Kbps	UTP	No

[a] IEEE802.3af will define power from switch.

UTP = unshielded twisted pair, STP = shielded twisted pair, UUP = unshielded untwisted pair, FSK = frequency shift keying, HSE = high-speed Ethernet, CATV = community antenna television (cable).

Selecting the DCS Supplier The fifth and final step in this process of designing a plant control system is to send out the whole automation package for bids. Only DCS suppliers who support the selected network should be invited to bid (for the supplier's web addresses, refer to the Feature Summary at the beginning of this section).

In the specifications, it is essential to list all the intelligent field devices and external systems that must be integrated into the total control system. The bid specification should require the DCS supplier to include all that is needed, both in terms of hardware and in terms of supporting software to integrate the external devices and systems into the overall control system. Similarly, it is essential to clearly specify what software packages (advanced control, maintenance, graphics, simulation, and training tools) must be included in the bid.

In terms of the required graphics, the bid package should state which of the three IEC 61131-3-approved graphic control languages are to be used. The specification should also list the displays (graphic, detail, faceplate, alarm and event summary, trend, tuning, diagnostic, and report), which the DCS supplier is responsible for preparing, and the types of dynamic elements (dynamos), background colors, and aliases that are to be used.

The specification should also state the division of responsibilities between the user, engineering firm, system integrator, and DCS supplier for advanced control, graphics or other software development, simulation, training, and commissioning. In the area of commissioning, the DCS supplier's responsibilities should be clearly stated in connection with training, preliminary checkout, fieldbus testing, safety system and advanced control testing, startup, and controller tuning.

If the above outlined procedure is followed, the extras and delays will be fewer. If they are not and if the DCS supplier is selected before its scope is clearly specified, the consequence could not only be a doubling of the initial bid, but could also cause construction delays, startup problems, and reduced safety.

The Future

It will take a couple of decades, but it is hoped that the day will come when the proprietary networks have disappeared and there is only one worldwide communication network standard. It is hoped that the time is not too far off when all digital devices can connect to all networks and all software packages can be "embedded" into any DCS systems.

From the experience with the PC and the Internet, we can see that if it is in the interest of suppliers, we can quickly arrive at global standardization and any software package can be "embedded" into all PCs. What is needed to bring about global standardization in the process control field is commercial pressure by the users. Professional societies and user groups can play an important role in speeding up this development.

CONTROL ADVANCES

Murphy's second law is that one cannot control a process without understanding it. Others will argue that no computer will ever beat the world champion in bridge or chess because the programmers are not as good at bridge or chess as these champions. There is much validity to these views, yet it is also true that computers need not be limited by the knowledge of the programmers but can be provided with the ability to learn. After all, once even Einstein was only a baby and knew absolutely nothing. Yet, through some process of neural fuzzy logic, he managed to build a pretty good model of the world we live in and learned much more than just to speak and walk.

The purpose of this writing is not to predict the future but only to give a bird's-eye view of where we stand in the field of process control. I will first discuss the progress made in the configuration of PID control algorithms and in their autotuning, both in the "on demand" mode and in the self-tuning or adaptive mode. Next, I will mention the Smith predictor and discuss the various non-PID based model predictive control (MPC) schemes, including the Dahlin variety and adaptive model controllers (AMC). I will conclude this discussion by describing the operation of the fuzzy logic and artificial neural networks (ANN).

Basic PID Algorithms

The main advantage of the computer is the speed and convenience with which one can select and change the best choice of a PID algorithm to match the dynamics of the controlled process. Figure 4.6e shows some of the basic PID configurations from which the DCS system can select the best choice either automatically or with the operator's approval. In this figure, configuration 1 is the basic ISA PID algorithm, where all three modes (P, proportional; I, integral; and D, derivative) act on the error, which is the difference between the process variable (PV) and the set point (SP).

Configuration 2 is a better selection when it is desirable to reduce the frequency of changes to the controller's output. This algorithm is applied either to increase the life expectancy of the control valve or in "herding" control, where the error is considered to be zero as long as it is inside a predetermined dead zone or gap.

Configurations 3 and 4 give different options on which control modes should act on the error and which on the process variable only. In my view, with the exception of cascade slaves, 3 should be used for all controllers that have a derivative mode because there is no advantage to D acting on SP changes. If one wants to completely eliminate the overshoot on set point changes, 4 should be used, where both D and P act on PV only.

If the set point of a loop is changed frequently, it is recommended to filter the set point as in configuration 5. This will reduce the overshoot while allowing the use of a narrower P-band. In configuration 6 the controller responds to

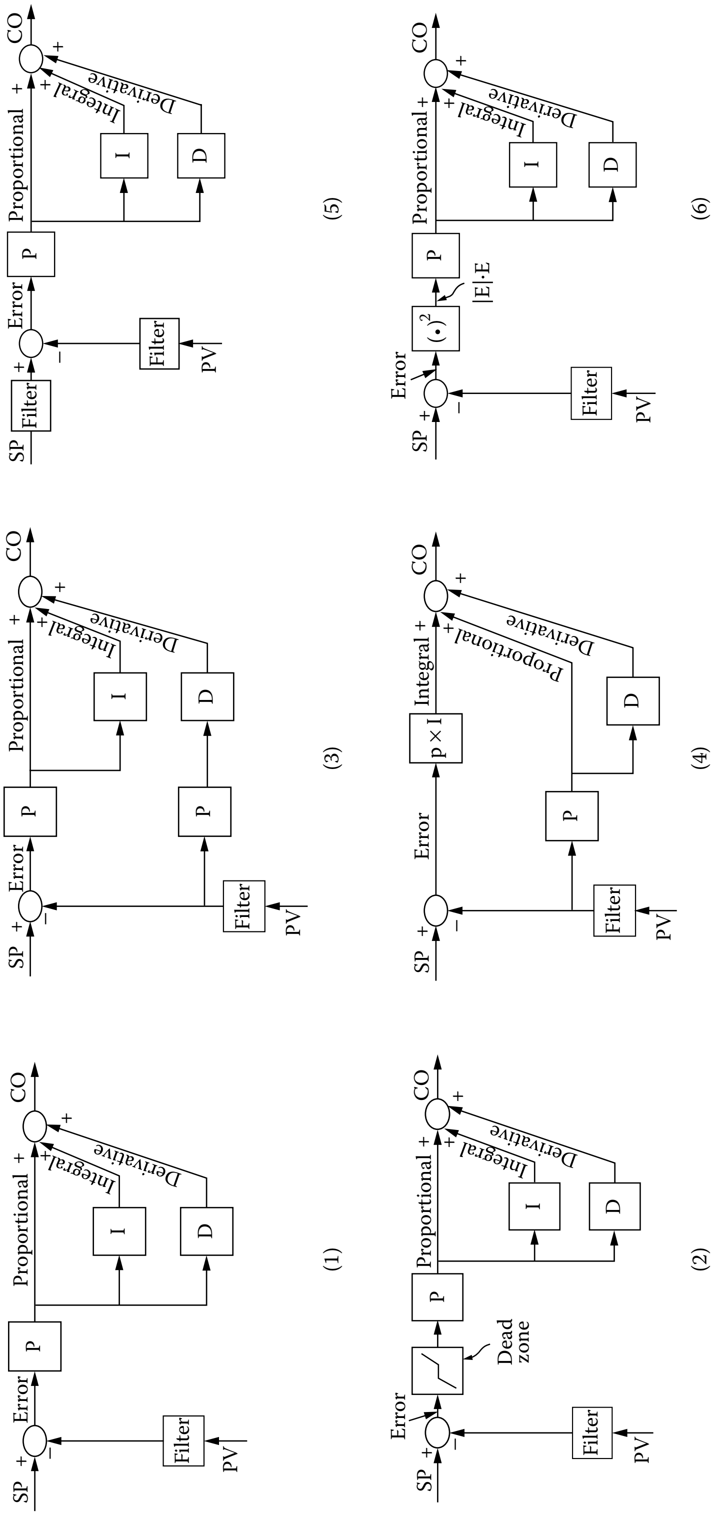

FIG. 4.6e
The basic PID algorithms include the 1) ISA, 2) dead band, 3) D on PV, 4) D and P on PV, 5) SP filtering, 6) error squared, and 7) integral squared.[4]

the square of the error, which is desirable on surge level control, where we want stable operation in near the steady state, but aggressive correction of large errors. In configuration 7 only the integral is squared, which is good on variable dead time processes.

Naturally, there are many variations on these basic themes. For example, if the controller output can be blocked, such as in selective or in cascade configurations, the integral action should act not on the output but on some external signal, such as the opening of the valve. This is called external reset. In other cases, such as on extremely fast flow loops, one might use inverse derivative to stabilize the loop.

Auto-Tuning

Once the appropriate PID algorithm is selected for the particular process, the next task is to tune the controller to match the dynamics (gain, time constant, and dead time) of the process. The various PID algorithms are described in full detail in Section 2.3 and the equations to be used to tune them are defined in Sections 2.35 to 2.37. Section 2.38 explains how the loops are optimized and tuned by computers.

There is an inherent contradiction between the goal of tuning, which is to keep the controlled variable constant, and the method by which the tuner must learn the dynamics of the process, which is to intentionally upset the controlled variable. Finding an acceptable balance between these considerations is the criterion for a good self-tuning controller.

Self-tuning or auto-tuning can be done either on demand, where it is initiated by the operator, or automatically. In “on-demand” tuning, it is up to the operator to decide when the loop needs retuning, but once that decision is made, the DCS system performs the retuning automatically. If “adaptive” tuning is used, the DCS system is programmed to initiate an automatic retuning cycle after changes in set point or when significant noise or upsets are experienced.

Tuning on Demand This method of tuning involves the switching of the controller to manual, while maintaining its output signal to the manipulated variable (control valve) as it was before the switching. After switching to manual, a small increase (1 to 3%) step change is made in the output signal, then it is held and after that a step change is made down (Figure 4.7b), and this sequence is repeated in an oscillatory manner.

The above-described oscillatory step changes in the manipulated variable cause a sinusoidal response in the controlled variable. This response is analyzed by the DCS system to determine the ultimate gain, ultimate period, dead time, time constant, etc. of the process. For an explanation of the determination of ultimate gain and time period, refer to Figures 2.38c and 2.38i in Chapter 2.

Once the process dynamics are determined, the operator can input the kind of tuning rules to be used (Section 2.35) and the DCS software will use the corresponding equations to calculate the corresponding controller settings.

This oscillatory method of open-loop tuning usually gives acceptable results on self-regulating or integrating processes to obtain the initial controller settings during plant startup. Because such open-loop tests disregard the dynamics of the controller itself and because they tend to be rather inaccurate when the measurement is noisy, it is advisable to retune the loop using a closed-loop method (Section 2.35) after startup.

Adaptive Tuning Different DCS suppliers use different methods to continuously and automatically adjust the tuning constants of the control algorithm in response to changes in the dynamics of the process. Similarly, they use different methods of injecting excitation into the loops prior to detecting the process response. These excitations can be small changes to the set point or to the controller output, and they can occur either in the manual or the automatic (open or closed) modes.

The adaptation cycles continue until the controlled variable response is sufficiently excited for analysis. Adaptation of feedback and feedforward portions of loops can be done separately or in combination. Once the process dynamics or the total loop dynamics are identified and, based on those, the tuning constants for standard PID can be calculated (1 in Figure 4.6e), the adaptive tuning controls can proceed to select the most appropriate control algorithm and switch to it.

While theoretically this sounds fine, in reality, we have a long way to go before adaptive tuning and automated control algorithm switching on the basis of self-diagnostics will be fully developed. This is because on process control applications, the presently used DCS systems have a tendency to remodel continuously. This is due to the compromises made between the size of the excitations applied vs. the effects of noise, hysteresis, valve sticking, and nonlinearity in our control loops.

Model-Based Control Algorithms

Chapter 2 of this volume discusses a number of control strategies (Sections 2.13, 2.14, 2.17, and 2.19), where the controller is loaded with the model of the process and therefore it can compare the response of the real process to that of the model and act on the difference similarly to how a PID controller acts on the measurement error.

Smith Predictor On processes with long dead times, this method of control gives good set-point response without overshoot, while it is only slightly better than regular PID on responding to load disturbances. It operates by comparing the controlled variable from a model of the process, which

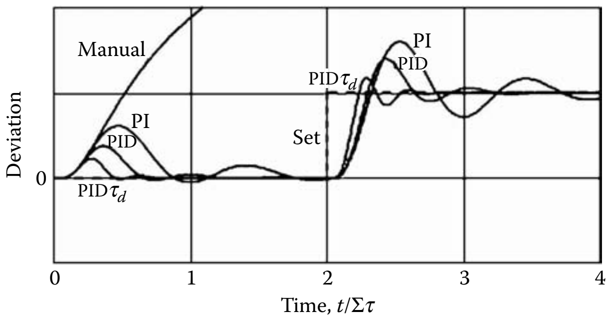

FIG. 4.6f

The response of the $PID_{\tau d}$ *controller to load and set point changes is superior to those of both the conventional PI and PID controllers.*[5]

does not have dead time with the controlled variable measurement from the real process.

Shinskey[5] has shown that the regular $PID_{\tau d}$ controller (which is easier to tune than the Smith predictor) can give similar performance under some conditions. Figure 4.6f shows the improvement provided by the interacting $PID_{\tau d}$ controller, compared with regular PI and PID control.

Model Predictive Control (MPC) These controllers, where the controller model is the inverse of the dynamic process model, are called by different names, including internal model controllers (IMC) and lambda, Dahlin, or pole cancellation controllers. From most DCS suppliers, only small MPC packages (eight inputs by eight outputs) can be embedded; larger models have to be external. As to who calls what, an MPC application varies. Some DCS suppliers consider such simple tasks as set-point limiting, rate of change limiting of controller output, or the application of high and low constraint limits as MPC.

Most larger MPC controllers have to be external (layered) and integrated into the DCS system. If the process model is very accurate (usually it is not) and if the dynamics of the process do not change (usually they do with load variations), MPC performance will be superior to PID. In most cases the process dynamics do change with load changes, and in such cases the MPC response will be sluggish unless the model itself is updated (adapted) periodically.

When the MPC model is used in a simulator, it is possible to see the actual process response before it happens. The ability to be used for operator training and the ability to adjust the speed of execution are some of the advantages of MPC. One of its limitations is the high cost of developing an accurate process model that will self-adapt to the changing dynamics of the process.

Fuzzy Logic What a good operator does is hard to describe by a mathematical equation. It is for this reason that very complex processes (say the landing of a helicopter) cannot be easily controlled by conventional means and are often left to be controlled manually. This is because operators aggregate a variety of data and combine them into strategies that cannot be integrated into a single control law.

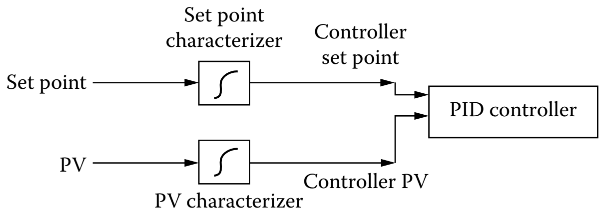

FIG. 4.6g

If the nonlinearity is known and does not change with time, conventional controls can be used if a characterizer is applied to both the set point and the measurement (PV) signals.[6] *(Courtesy of ExperTune Inc.)*

One reason why conventional controls cannot be used on some processes is that they are nonlinear. If the nonlinearity is accurately known and does not change with load or time, conventional PID controls can be used after the measurement and set point are both characterized (Figure 4.6g). When this is not possible, one of the options to consider is fuzzy logic.

The first step in developing a fuzzy model is to talk with the plant engineers and operators and learn about the process variables that have an influence (positive or negative) on the controlled variable and to approximate the size of their influence by some weighing factors. What is required for fuzzy logic to work is that the process be controllable in the manual mode by an operator and that great quantities of data be available to show how that manual control is achieved (see Section 2.31 for details).

Based on all the data, rules are established to determine the controller output on the basis of a number of input functions, and each of these functions is scaled to describe its relative influence on the total output.

ANN Control Artificial neural networks (ANN) are explained in some detail in Section 2.18. They are similar to fuzzy logic controllers to the extent that the mathematical model that relates their inputs to their outputs need not be known. The main difference is that an ANN can only be "trained"; the gains of its functions cannot be changed, they are fixed.

Some successful applications of back-propagation type ANN control involve the prediction of pH values in stirred tanks and the prediction of product boiling points in distillation processes. ANN has shown its ability to learn the dynamics of a process well if sufficient amounts of training data are available.

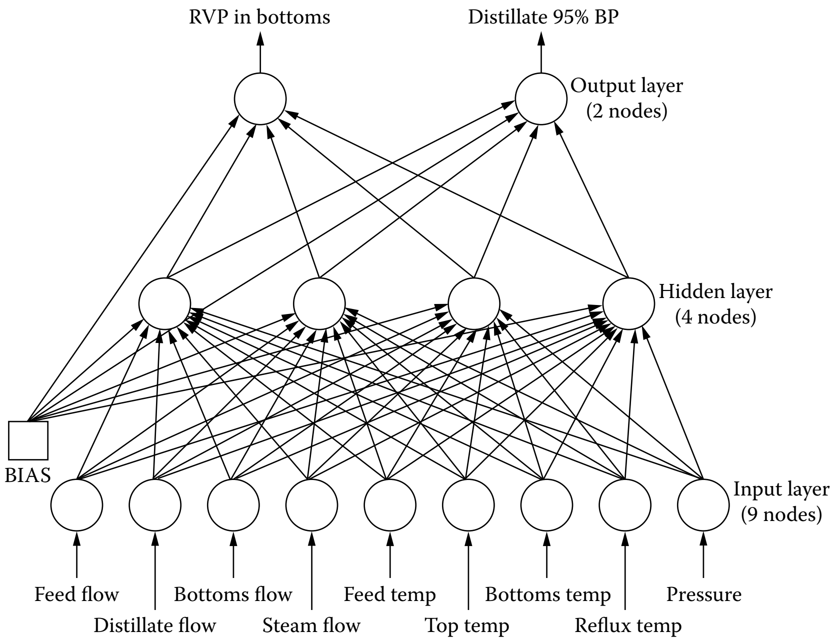

FIG. 4.6h
A three-layered ANN can predict the Reid vapor pressure (RVP) of the bottom product and the 95% boiling point of the distillate.

An example of a three-layer ANN network is illustrated in Figure 4.6h. Here the goal is to control the Reid vapor pressure of the bottom products and the 95% boiling point of the distillate without measuring it directly. Instead, a variety of other properties are measured (nine input nodes) and, based on large amounts of past historical data, the actual real-time values of the two controlled variables are detected. Between the in- and output layers in this example there are four additional nodes in a hidden layer and bias.

The main advantage of ANN is the ability to predict the controlled variables when otherwise they are either unmeasurable online or the analyzers (online or in the laboratory) take too long to analyze the sample. The ANN model can have more than three layers and more than nine inputs. The smaller ANN applications can be embedded in most DCS systems, while the larger ones are usually interfaced to the DCS from an external eighth layer.

DCS Bid Package

When specifying the control system, it is important to obtain both the PID and the control algorithm library from each of the bidding DCS suppliers (Tables 4.6i and 4.6j). At the time of analyzing the bids, it is equally important to check whether all the costs associated with the building and embedding the control algorithms are included. These costs should also cover the associated graphics and faceplate preparation for the required PID. Advanced control costs also should be included and fully guaranteed, because otherwise startup problems can result.

COSTS

When it comes to DCS-based total control systems, one has to be careful with implementing the traditional bidding process (Figure 4.6k). This is because the expenses associated with the previously discussed interfacing and integrating problems and the costs of special software requirements for control, simulation, and optimization can sometimes exceed the total hardware and labor cost of the project.

Table 4.6l gives the costs associated with a small control system addition consisting of one analyzer, seven transmitters, some thermocouples, and three computer supported touch-screen monitors. In this $100,000 project, the installation labor cost was only 10% and the software cost was only 20%. These percentages can be so small only if no custom software is used and if most of the sensor/transmitter installation, commissioning, operator training, and startup is performed by the user. If that is not the case and some advanced control algorithms, custom graphics, and training or simulation is required from the DCS supplier, the cost can easily double.

Table 4.14n describes the hardware cost of a medium-size DCS project with a fieldbus and about 200 analog and 1,000 on/off I/O. The hardware cost of this project (including licensed software) is $250,000. What is not so obvious from that hardware list is that very little software is included. Yet, if some of the I/O is from intelligent field devices, which need to be integrated (layered) into the total system, and if advanced controls, process simulation, and operator's training are needed, the installed final cost can approach a million dollars.

It is the software and labor costs that often determine the total DCS project cost. In order to control these costs, it is essential to fully specify all the interfacing and all the custom software requirements of the project and obtain the initial bid on that basis. This means that all field components of the system, including intelligent field devices, must be selected and their interfacing included in the DCS bid package before bids are obtained. Similarly all the interfacing and software support for the required advanced controls, process simulation, and operator's training must also be specified before bids are obtained. If this is not done, substantial delays and extras will result.

CONCLUSIONS

Figure 4.6m illustrates a DCS workstation, the end result of a long and difficult design effort. Designing a good process control system takes a lot of effort. The tools of process control — the DCS and PLC systems, and the network buses, sensor, and valves — are like the instruments in an orchestra. The engineer who designed the control strategy is the composer, and his job is to make sure that the instruments of the

orchestra are fully coordinated to produce smooth and optimized control.

Another important aspect to remember is that in the absence of strong and competent user associations, the (natural) commercial interests of suppliers tend to conflict with standardization. When the system supplier says that this or that optimization or other software package needs to be layered (referring to the eighth layer of the ISO model protocol), the resulting problems and expenses of integration can be substantial. The difficulty in integrating systems that were not designed to "speak the same language" is like flying an airplane with pilots who do not speak the same language.

It should also be remembered that DCS costs have not dropped. The case is that the costs of unconfigured hardware have dropped, but total system costs have risen. The

limitations of new software do not end with their connectivity and their hidden costs; an added serious source of problems is that they are only as good as the programmer who configured them, and the Greg Shinskeys of this world do not do programming.

INTRODUCTION

The computational requirements of software products for advanced control have traditionally limited their implementation. For that reason, their associated software resided either in a host computer or in dedicated control units that were external to the basic DCS package and were “layered” onto the plant’s control system. This situation is changing, as some of the more advanced software packages can be embedded in the basic DCS system.

Recent advances in the processing power available within some DCS control systems have allowed them to include some advanced control capability. These embedded software packages include:

- Performance monitoring
- Loop tuning
- Fuzzy logic control
- Model predictive control
- Neural network-based variable estimation
- Control simulation

Most of the successful advanced control applications, such as MPC, that are in use today are used on high-throughput processes, where the savings justify the high cost of developing, installing, and maintaining these layered control applications. This new generation of advanced control is often designed so that the average process engineer can use these features with the same level of confidence as he or she used the more traditional controls. Fuzzy logic control, model predictive control, and property estimation may be implemented as a function block that can be assigned to execute in the standard redundant controllers.

This operating environment has improved security and performance in comparison to the traditional approach of leaving the advanced controls outside of the basic control system, which is referred to as “layering.” For this embedded implementation, the engineering tools for the configuration and troubleshooting of traditional control may also be used with these advanced software blocks.

Also, the standard dynamos of these blocks support operator displays that include advanced controls without the need to map parameters. Thus, the engineer and the operator can have consistent interfaces to both the advanced and the traditional control applications.

Embedding advanced control applications has many other advantages as well. Probably the most important is that the advanced control application software runs inside the embedded controllers where the applications can fully participate in controller redundancy, alarming, configuration downloads, and online upgrades. This also means that all parameter references are managed by the runtime and the configuration system, and such terms as “Mode” and “Status” have meanings consistent with the terminology of other software packages in the system. To the operator and other operations personnel, the advanced control applications are largely invisible — they are just other function blocks and parameters.

PERFORMANCE MONITORING

The maximum production rate and efficiency of a plant are determined by the process design and the capacity of the equipment used. However, many plants never reach the production capacity that is inherent in the plant design and equipment. In addition, there usually is little time to study the process operation to determine whether it could be improved because attention is concentrated on maintenance and on abnormal conditions that can become major sources of process disturbances.

To improve on this situation, some distributed control systems are now designed to support automatic and continuous monitoring and detection of abnormal operation of control and field devices. When control is based on the Foundation fieldbus architecture, the status associated with each function block output gives a direct indication of the quality of the measurement of control signal. Also, the actual and normal mode attributes of these blocks may be used to determine whether a function block is operating in its designed mode. Thus, by continuously monitoring the status and mode supported by fieldbus function blocks, it is possible to automatically determine the following abnormal conditions in control and input-output (I/O) function blocks:

- A condition exists that could be reducing the accuracy of the measurement.
- Control effectiveness is limited by a downstream condition.
- The block is not running in its designed mode of operation.

Based on the inherent accuracy of the sensor and its maximum error, it is possible to compute a variability index that compares the actual performance to the best achievable. These calculations can be built into the control and I/O function blocks to support control analysis. By this approach, the control performance of even the fastest processes can be evaluated.

Within the control system, the status and mode values are automatically processed to determine the percent of time when an abnormal condition existed during the current and previous hour, shift, or day. If this percentage exceeds a preset limit, then the condition is flagged as abnormal and the module containing the function block will show up in the monitoring interface. An example of an abnormal condition monitoring interface is shown in Figure 4.7a.

CONTROLLER TUNING

Loop tuning can be done either when needed (on demand) or continuously by adaptive tuning. On-demand tuning is initiated by the operating personnel. Continuous adaptive tuning is performed automatically after set-point changes or significant disturbances, or when noise is experienced. On-demand tuning is often used during startup to obtain approximate tuning constants during the initial commissioning of a control system. Adaptive tuning corrects the tuning in response to changes in process dynamics.

On-Demand Tuning

One of the most successful techniques for providing on-demand tuning is based on using the relay oscillation tuning method to identify the process ultimate gain and ultimate period. (For a detailed discussion of tuning by computer, refer to Section 2.38 and for an explanation of the determination of ultimate process gain and ultimate time period, see Figures 2.38c and 2.38i in that section.)

This "relay oscillation" tuning method can be used on both self-regulating and integrating processes but is not suited for pure dead time processes, which require sample and hold control. Once the ultimate gain and ultimate time period of a loop are known, the tuning rules (see Sections 2.35 to 2.38) may be automatically applied to obtain the initial controller settings.

The relay oscillation technique of tuning is performed in an open loop under two-state control. Each time the controlled variable (process output) crosses the set point or initial value of the controlled variable, the relay is switched. Relay action causes the loop to oscillate at its ultimate period, T_u. The ultimate gain, K_u, is determined as the ratio between the amplitude of the two-state controller output and the amplitude of the oscillations in the controlled variable.

Upon completion of the relay oscillation test, the autotuner calculates the ultimate gain, ultimate period, dead time, time constant, static gain, and integrating gain of the process. The user can input the type of process (only self-regulating or integrating), the type of tuning rules to use, and perhaps an additional tuning factor such as the closed-loop time constant. The tuning rules are then applied and the calculated settings are provided for the controller, as illustrated in Figure 4.7b.

Adaptive Tuning

Adaptive tuning can be used to tune both feedback and feedforward controllers. There are two ways to design an adaptive PID controller: direct and indirect or identifier based. An identifier-based approach is advantageous when model switching and parameter interpolation are used. In this case a set of models is available together with a switching strategy among them, and parameter interpolation is based on the integrated squared error assigned to every value of the model parameter.

The adaptation cycle continues through a declared number of scans or until there is enough excitation on the inputs. As soon as a model has been updated, controller redesign takes place based on the updated model parameters. Adaptation can proceed for the whole model or separately for the feedback or feedforward portions of the model. The external excitations can be injected into the feedback loop automatically. The applied excitations can be a small change of the set point or controller output in either the Manual or in the Automatic modes.

Since the process model obtained is first-order plus dead time, any tuning rules can be used, including applied, typically lambda or IMC tuning. A general adaptive PID controller structure with model parameter interpolation is shown in Figure 4.7c.

FUZZY LOGIC CONTROL

Many industrial processes operated by humans cannot be automated using conventional control techniques since the

performance of these controllers is often inferior to that of the operators. One of the reasons is that linear controllers, which are commonly used in conventional control, are not appropriate for the control of nonlinear processes.

Another reason is that humans aggregate various kinds of information and combine control strategies, which cannot be integrated into a single analytic control law. The underlying principle of knowledge-based (expert) control is to capture and implement experience and knowledge available from experts (e.g., process operators).

One would usually consider fuzzy logic control only after all attempts at controlling the process by optimized PID

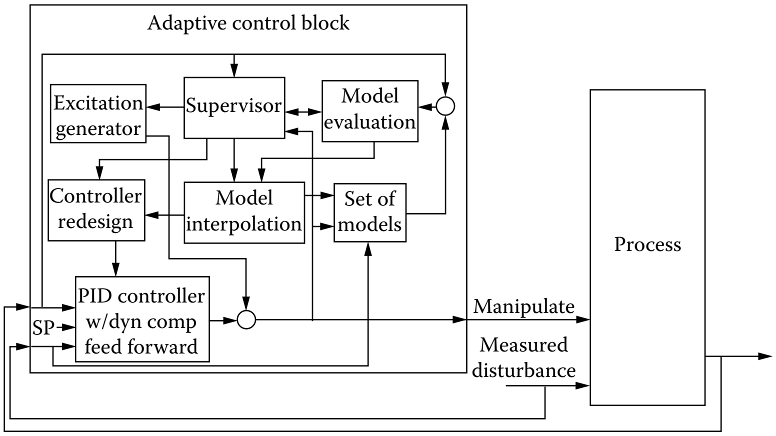

FIG. 4.7c
The configuration of the blocks of software in an adaptive PID controller, which includes both feedback and feedforward parts.

controllers have failed. Because fuzzy logic control requires exhaustive amounts of process data, the other essential requirement is that the process be somehow manually controllable. For a detailed discussion of fuzzy logic control, refer to Section 2.31.

The concept of fuzzy logic originated in 1965 when Lofti Zadeh of the University of California at Berkeley proposed what he called "fuzzy set theory." Theoretically, fuzzy logic-based controllers can provide significant performance improvements over conventional PID-based controllers. The nonlinearity introduced in the fuzzy PID controller can reduce overshoot significantly without compromising disturbance rejection capability, but fuzzy logic has not been widely adopted in the process industries.

One reason is that the tuning is difficult since no standard guidelines exist for the establishment of membership function scaling. To address this issue, many manufacturers provide preengineered versions of fuzzy control that require little user input to commission. In addition, manual tuning may be substituted by relay-based automatic tuning. Such controllers can be used as nonlinear single-loop replacements for conventional PID controllers.

Fuzzy logic controllers combine the concept of membership functions with *rule inference* (see Section 2.31 for definitions and detailed explanations). The rules are used to determine a controller output based on the input membership functions. Tuning is accomplished through adjustment of the scaling associated with the membership functions. Figure 4.7d illustrates the software block components of a fuzzy logic controller that has already been defined.

The fuzzy logic controller in many cases provides increased performance and improved response with little or no overshoot relative to PID control. According to some sources, the improvement can range from 20% on the basis of integral of absolute error (IAE) to almost 50% for integral of absolute error multiplied by time.

MODEL PREDICTIVE CONTROL

In internal model controllers (IMC), MPC, and pole-cancellation, lambda, and Dahlin controllers, the model used by the controller is based on the controlled process (see Sections 2.13, 2.14, 2.17, and 2.19 for details). (Editor's note: According to some users, the MPC model relates to the inverse of the process model. Therefore, when the process dynamics are unchanged (set point changes), these controllers are effective; if the model is exactly known, they are better than PID. Therefore, people use them, *when the process cannot tolerate set-point overshoots*. Their main limitation is their sluggish response to changes in process dynamics (process load changes). In some applications it is the response to load upsets that is critical.)

Since the introduction of MPC in the 1980s until 2004, over 5000 plant sites have utilized this technology. Modern DCS software packages include embedded MPC control for small applications (models of eight inputs by eight outputs in size) as well as larger applications, which traditionally were handled externally to the DCS (layered MPC). Fast execution rates and ease of use in commissioning allow the new embedded MPC control to be used where previously only traditional control techniques based on PID control had been applied. Improvements in the user interface and in the tools for commissioning and operating the MPC allow some experienced process or control engineers to apply this technology without the assistance of outside experts.

FIG. 4.7d
Application of preengineered fuzzy control.

In some simple MPC applications, the controller configuration might consist of only a few parameters. Examples of such parameters include:

- Controlled variable — Set-point limits
- Manipulated variable — Maximum rate of change, controller output limits
- Constraint parameter — Constraint high and low limits

The MPC controller is based on a dynamic model of the process. Traditionally, the dynamic model of the process is determined by manual manipulation of the control valve openings (process inputs). When the model is small enough for embedded MPCcontrol, automated testing of the process is provided as part of the MPC engineering tools.

Once data on the dynamics of the process is collected, the process model and controller the MPC, can be generated automatically. Both the step response of the MPC model and of the actual process can be displayed. An example of the overview step response model and a detail of an individual output response for a particular input are shown in Figure 4.7e.

MPC identification tools compare the measured process variables with those calculated based on the model, if the manipulated variables to both the model and the actual process are the same. This comparison may be displayed in different formats to allow the user to determine how good the model is, i.e., how closely the model dynamics match those of the actual process.

A simulated environment is used to evaluate the control response to both set-point and load changes before the MPC control is commissioned. Using the model of the process for simulation, it is possible to see the actual process response in advance of real time. Similarly, on very fast processes, the ability to simulate the control and process response slower than real time can also be valuable. The ability to adjust the speed of execution allows the control response to be quickly verified for a variety of operating conditions. Figure 4.7f illustrates the testing of the MPC model by viewing the simulated controlled variable response of the MPCmodel to a change in the manipulated variable.

Once the MPC control has been tested offline using simulation, then the control can be commissioned.

(Editor’s note: If the process model accurately reflects the process, the control response to set-point changes is likely to be good. The response to load disturbances is usually poorer if the load disturbances result in substantial changes in process dynamics; in such cases, adaptive control should be considered as a possibly better option.)

NEURAL NETWORK APPLICATIONS

Artificial neural networks (ANNs) can learn complex functional relations by generalizing from a limited amount of training data. Hence they can thus serve as black-box models

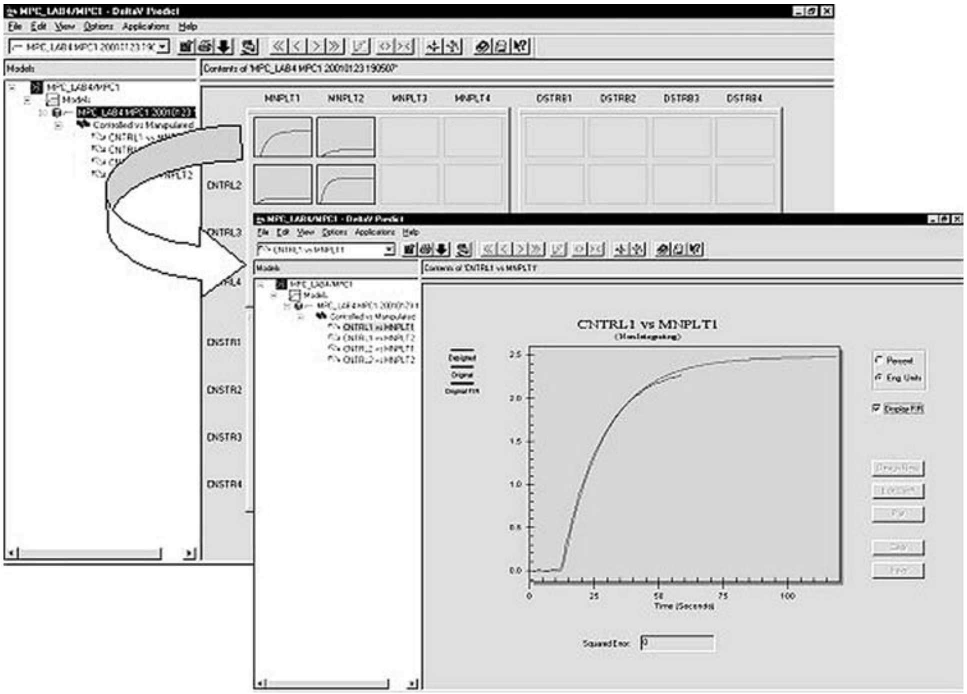

FIG. 4.7e

The step response of an accurate MPC model and of the actual process can be very similar if the process load is the same as it was at the time when the model was developed.

of nonlinear, multivariable static and dynamic systems and can be trained by the input–output data of these systems. Applications that are suitable for ANN solutions and the detailed theory of ANN are discussed in Section 2.18.

ANN is similar to fuzzy logic in that the mathematical model that relates the inputs and the outputs of the model does not need to be known. To use ANN, it is sufficient to know the behavior or response of the model. The main difference between fuzzy logic for property estimation and ANN is that the gains and functions cannot be modified in ANN; they can only be “trained” with data.

The use of estimated process variables can improve control and monitoring when critical measurements are only available through laboratory analysis**.** The intermittent laboratory analysis results can be used as inputs to provide online inferred or estimated variable values when actual analytical readings are not available. Neural networks are often used for process variable estimation even if the inferring relationships are nonlinear. ANN provides a nonlinear model of a process, which uses those input variables that indirectly influence the composition that is intermittently detected by laboratory analysis.

After a neural network has been commissioned, the offline laboratory analysis is still required to correct for unmeasured disturbances and changes in the process. Without this correction, the prediction provided by the model of the neural network will drift away from the true measurement value as time passes. For example, the laboratory analysis may be used as an input to the ANN model to obtain automatic adaptation of its prediction in response to changes in process.

Modern tools embedded in DCS control systems have reduced the complexity of designing and training neural networks. ANN can be integrated as a function block into a distributed control system and that block can be configured similary to other function blocks. The tools provided to train the neural network take into account the dynamic nature of the processes for which a neural network is developed.

Once a potential application for a neural network is identified, the first step in the ANN development is to configure the function block. For example, as a first step in configuring the ANN block, the user may browse the past history of the process to identify the variables that tend to influence composition and use them as function block parameters. As actual laboratory analysis takes place, the results are provided to the ANN model for updating the model of that analytical variable that is being estimated by ANN (Figure 4.7g).

Once the neural network block is configured and downloaded, all measurements used in the ANN block are assigned to a historian for collection. After a sufficient amount of process data have been collected, the operator can graphically view the historic data and make corrections by adding/removing inputs. Once the input data have been screened, the ANN model can be generated. During this generation process, the dynamics of the input delays and output sensitivity to every input are calculated. To help the user determine the accuracy of the neural

FIG. 4.7g
Neural networks can be used to estimate analytical laboratory measurements on the basis of the past history of such readings by sending the associated laboratory readings to the ANN block. Later composition measurements from the laboratory are used to update the ANN model.

network, the value calculated by the neural network may be compared to the lab analysis, as illustrated in Figure 4.7h.

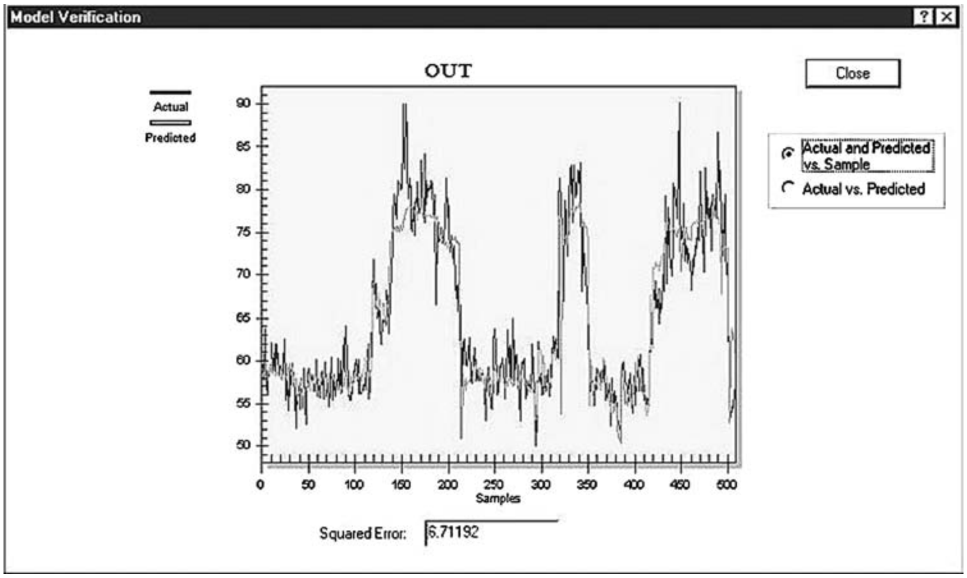
PROCESS AND CONTROL SIMULATION

Process simulation packages are used to train operators prior to plant startup; they are also used to examine the dynamic response and performance of a process during operation, and finally, they are used to prepare the operators for complex and critical shutdown procedures.

The cost of developing the simulation software rises exponentially with the required accuracy of the process model. Yet, it is desirable that the model reflect not only the process dynamics but also the operation of the actually implemented control system and that it incorporate the simulation of process upsets to train the operators in a real-time setting. It is also important that the keyboard, strokes, sequences, mouse, and touch screen used during simulation be identical to the actual ones.

Some commercial systems allow all features of the process control system to be executed on a single PC platform or distributed between multiple computers. This high-fidelity process control simulation capability may be used to check out control system logic and operator interface as well as to train operators on the continuous and discrete control, diagnostic, and alarming under a variety of conditions.

The software and the associated configuration of a control system may be designed to be used in multiple operating environments without change. When this approach is taken,



● Actual and Predicted vs. Sample

it is possible to distribute control system functionality in a variety of ways without needing to reengineer the software or reconfigure the associated applications.

All features of the control system can be combined on a single platform or distributed between multiple PCs to support configuration and dynamic checkout of the controls and interface associated with a process control system, as illustrated in Figure 4.7i.

When a control system utilizes the Fieldbus Foundation function block architecture, a SIMULATE parameter is available in each I/O function block. Through this parameter, a value and status may be provided to I/O function blocks to simulate the field measurement or actuator in the control system.

This capability may be used to check out control logic and operator displays. Also, where the control systems support

the object linking and embedding (OLE) interface for processing control (OPC), the process simulation package may write the simulated value and status. This capability, combined with the ability to redistribute control functionality without reconfiguration, provides a strong foundation for the integration of high-fidelity simulation with control system simulation in a single or multi-PC environment.

Depending on the modeling rigors and computing resources, the process simulation can potentially run faster or slower than real time. To allow the control simulation to match the process simulation execution, the control system executes function blocks faster or slower. In addition, a trainer or an application may coordinate the execution of control and process simulation. An example interface for such coordination is shown in Figure 4.7j.

CONCLUSION

Modern distributed control systems can provide embedded advanced control solutions. The DCS system supports the advanced control capability similarly to the support provided for the traditional control tools. Among the major advances in DCS system designs are the easy-to-use engineering and commissioning tools.

4.8 DCS: Installation and Commissioning

T. L. BLEVINS, M. NIXON (2005)

Installation Costs:	Based on the local labor market, costs vary widely. If the prevailing labor rates are not known, union halls and engineering contractors in the area can help. Instrument installation requires high-skilled tradesmen, some training and good supervision, which can range from 15 to 30% of labor costs.
Fieldbus Costs:	Installation and commissioning costs are reduced by 20 to 50% because fieldbus devices can identify themselves, require fewer terminations, and can be managed remotely.

INTRODUCTION

The installation and commissioning of a distributed control system impact the cost and schedule of a new plant or the expansion of an existing plant. Also, the work done during this part of construction can have a long-term impact on the plant operation and system reliability. The steps associated with installation and commissioning are much the same whether the control system is provided for new plant construction or as an upgrade to an existing system. However, the implementation details of installation and commissioning are dependent on the technology incorporated in the control system, for example, fieldbus vs. traditional actuators. Also, in some cases the manner in which the implementation is done will be dependent on the design of the control system and field equipment. Thus, the steps advised in this section may be used as a guideline in examining the detailed requirements at each key step of installation and commissioning.

In most cases the system configuration is completed before installation begins. Even if the system hardware is not available, modern control systems allow the complete system configuration and execute simulation including input-output (I/O). Using this capability, the control logic, alarm setup, and operator displays may be checked out in advance.

Also, using process and control simulation, it is possible to train plant operators on the system interface, the value of which will much depend on the quality of the process model. Thus, all efforts should be made that by the time the system is ready to install, the operators are familiar with the control system and the operator interface. Also, there should be good confidence that the system configuration is complete except for the I/O assignment, which must be verified during installation using the actual field devices.

Commissioning and startup will benefit if the design is well documented, particularly in the area of electrical and instrument (E&I) drawings and supervision, and if the commissioning team is well trained and the operators are experienced on the particular process. It is particularly important that the various software packages used in the intelligent workstations be fully understood and that the communication between intelligent devices from different manufacturers, including analyzers, be fully tested.

INSTALLATION

System installation is of prime importance for personnel safety and system availability. The steps involved in the installation of a distributed control system include the following:

- Power and grounding
- System assembly
- Heating, ventilating, and air conditioning (HVAC) and heat tracing
- Field wiring and checkout
- Bus installation

During control system installation, multiple steps are executed in parallel to reduce the time required for installation. The teams assembled for electrical and instrumentation checkout work closely with the engineering firm responsible for system design and documentation. Work during installation acts as further training for the operators as they participate in the control system checkout and correction of any problems found in the installation. During commissioning, the loop sheets, piping and instrumentation diagrams (P&IDs), and documents showing further details on the installation will be marked up. Where the changes impact the system configuration, these will also be noted and implemented so installation may be verified.

Power and Grounding

If a process is critical to plant operation and process interruptions must be minimized, secondary power sources should be included in the plant design. Electrical noise effects can be minimized by using isolated AC power sources, grounding at single points, minimizing undue influence on signal wiring from stray magnetic fields, and selecting appropriate cables and pathways, including adequate separation. Proper earth grounding is important to user safety and efficient operation of a control system. Installation methods to obtain good power and grounding are defined by industry-accepted standards.[1] A typical ground network is shown in Figure 4.8a.

During the installation, checks should be done to ensure the quality of the power and ground for the control system. This will include verifying the voltage levels, designed load on isolation transformer, and noise level.

System Assembly

In many cases the components of the distributed control system are shipped directly to the construction site for assembly. The control system may be designed to allow controller, I/O, and associated wire trays to be wall mounted, see Figure 4.8b.

Also, specific varieties of enclosures are used when the control system is installed in harsh environmental conditions. System assembly should follow manufacturer guidelines on heating considerations and device placement in the enclosure. In particular, placement of the enclosure or equipment on a wall should take into account the space needed to service, remove, or replace components. During installation, the temperature in the enclosure or room in which the equipment is mounted should be monitored to ensure proper dissipation of internal heat.

System cabinets and components assembled during installation should be labeled for quick identification during

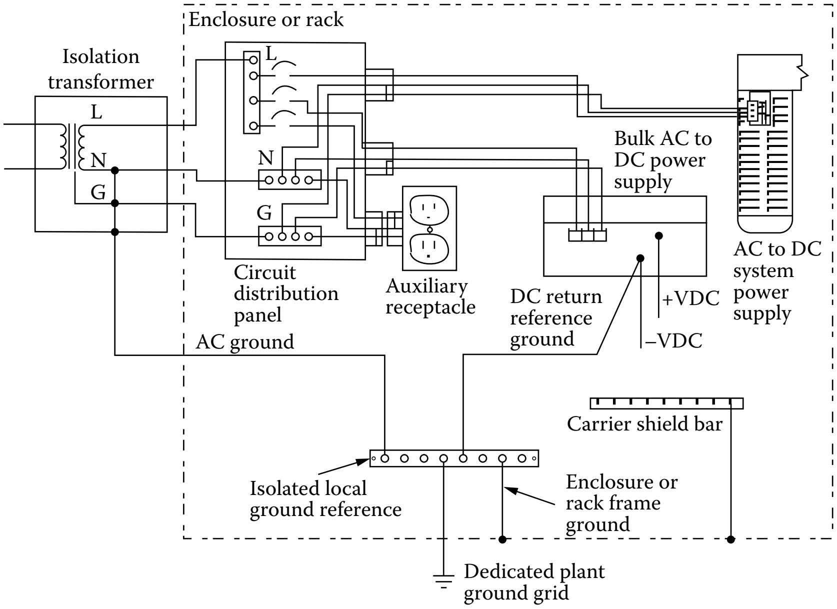

FIG. 4.8a
Typical, single-point ground network for a single enclosure.

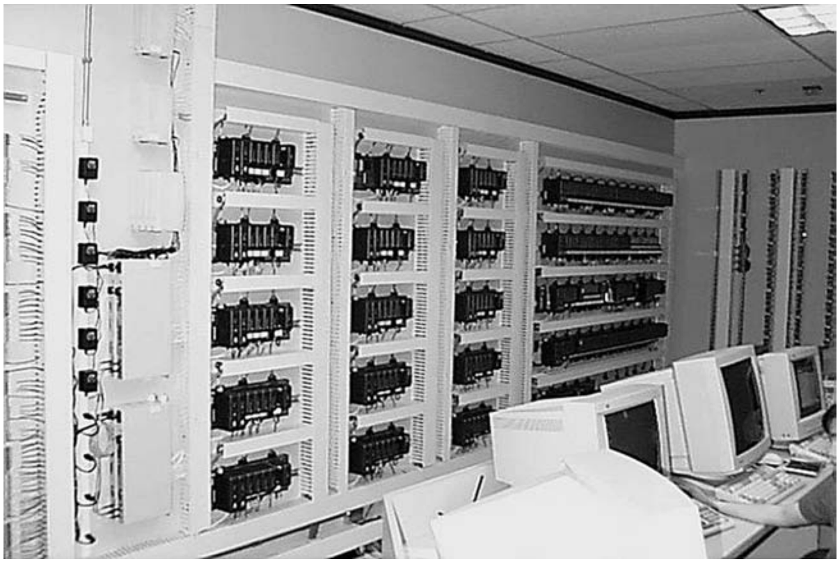

FIG. 4.8b
Example of an installation utilizing wall mounting of I/O, wire trays, and other system components.

installation. Once the system is fully assembled, the correct operation with the plant configuration should be verified. Any system problems should be addressed to avoid delays in using the system for I/O checkout.

HVAC and Heat Tracing

Environmental conditions can affect the operation of electronic equipment. Temperature, humidity, dust (including carbon), and corrosive vapors can cause gradual performance degradation, intermittent failures, and malfunctions.

To ensure maximum system efficiency and reliability, the air conditioning system including air filtering or scrubbers, if required, should be fully in place before the control system is installed. During installation, care should be taken to avoid open doors to the process, which could allow contaminates to enter the rack room or control room area. All environmental conditions must be maintained in accordance with the manufacturer's recommendations.

Where controllers are to be mounted in the field, care should be taken to ensure that enclosures remain closed and that any purge air or heat tracing required to maintain environmental conditions are in correct working order.

The standard described in Reference 2 defines the environment for control system operation. Such conditions include ambient temperature, relative humidity, and electromagnetic interference.

Field Wiring and Checkout

Field wiring should be properly installed to negate electromagnetic interference (EMI) and other electrical noise that can adversely affect the instruments controlling the process. Signal cabling should be kept away from AC power lines, transformers, rotating electrical equipment, or other high-power machinery to reduce the possibility of electromagnetic interference being induced on analog and discrete signals. Industry standards[3] describe noise identification and recommended wiring practices.

After field wiring is installed, continuity checks should be made from the field device to the I/O terminal strip. In addition, electrical isolation checks should be performed between the signal and ground wiring.

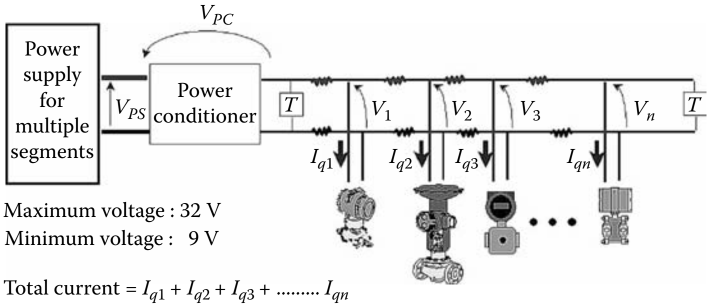
Injecting a signal at the transmitter end and observing the measured value at the operator screen may check the operation of traditional transmitter wiring. For traditional valves, the specified valve position should be verified in the field to ensure the software setting for increase open/close is correctly set to deliver implied value position.

As part of the instrument checkout, it should be verified that the alarm setting and the configured control setting match those specified on the loop sheet. Also, as part of the control checkout, the operation of the control after power failure or system download should be verified.

Bus Installation

To achieve optimum system operation, digital I/O bus systems, such as AS-Interface, DeviceNet, Foundation Fieldbus, and Profibus, must be properly installed. Otherwise, EMI and other electrical noise can adversely affect the capabilities of the instruments controlling the process.

Once a bus wiring is installed, its operation should be verified before commissioning. Most manufacturers provide a verification checklist that includes such things as a measuring of cable voltage and current capacity and verifying of



Maximum voltage : 32 V
Minimum voltage : 9 V

Total current = $I_{q1} + I_{q2} + I_{q3} + \dots\dots\dots I_{qn}$

Maximum current limited by the power conditioner.
Example : 400 mA

FIG. 4.8c
Voltage and current limits of fieldbus installation.

terminators on each end of the segment (Figure 4.8c). After these checks, each fieldbus device may be quickly commissioned and its operation status determined at the operator station using the device diagnostics.

Installing HART Networks

The HART signal is a modulated analog signal, and HART communication is designed to be compatible with existing or new 4- to 20-mA analog process control systems. The HART signaling occurs in a separate frequency band from the 4- to 20-mA analog signal and therefore, in most cases, does not interfere with the operation of the analog control loop. While HART uses modems designed for analog telephone networks and therefore is forgiving, the capacitance of the wire does limit the maximum allowable cable lengths (Table 4.8d).[4]

Depending on the type of transmitter, final control element, or handheld tool used, the HART signal is modulated by varying the loop current or by directly modulating the voltage of the power supply into the loop, as shown in Figure 4.8e.

On a three-wire or multi-drop transmitter loop the current sense resistor is 250 ohms. For DCS, final control elements and handheld tools, the power supply voltage drop is used as the HART signal. For impedance and other requirements of the process control system installation to guarantee reliable HART operation, refer to Table 4.8f.

TABLE 4.8d
Allowable Cable Lengths for 1.02 mm (#18 AWG) Shielded Twisted-Pair Cable[4]

	Cable Capacitance, pf/m			
No. Devices	*65*	*95*	*160*	*225*
1	2769 m	2000 m	1292 m	985 m
5	2462 m	1815 m	1138 m	892 m
10	2154 m	1600 m	1015 m	769 m
15	1846 m	1415 m	892 m	708 m

COMMISSIONING

The commissioning of the control system occurs once process construction is complete. Often this work is staged to each process area or piece of major equipment to be commissioned. The steps involved in the commissioning of a distributed control system generally include the following:

- Training and preliminary checkout
- Fieldbus testing
- Process startup
- Tuning process control loops
- Safety systems
- Advanced control

The plant operators play a key role in commissioning. During this phase of the startup, the engineering firm that designed the plant, the E&I contractor, plant engineering, the operators, and equipment suppliers work as a team to find and correct any process or instrumentation problems. Control loop commissioning early in the startup plays an important part in getting the plant to a sustainable level of operation. Any mistakes in system configuration should be corrected during commissioning and reflected in the final documentation of the system. In some cases, these configuration changes are automatically traced to allow the time and person who made the change to be documented.

Training and Preliminary Checkout

Training is important, particularly if digital communication systems are used and the E&I contractor and/or the commissioning team has no experience in troubleshooting a fieldbus system. In that case, they have to learn unfamiliar definitions, understand unfamiliar drawings, devise check procedures, and devise configuration software and the approach to troubleshooting a communication network. Training is the only way to overcome the defensiveness of the inexperienced, which in the long run will save a lot of rework. On some critical processes, it is

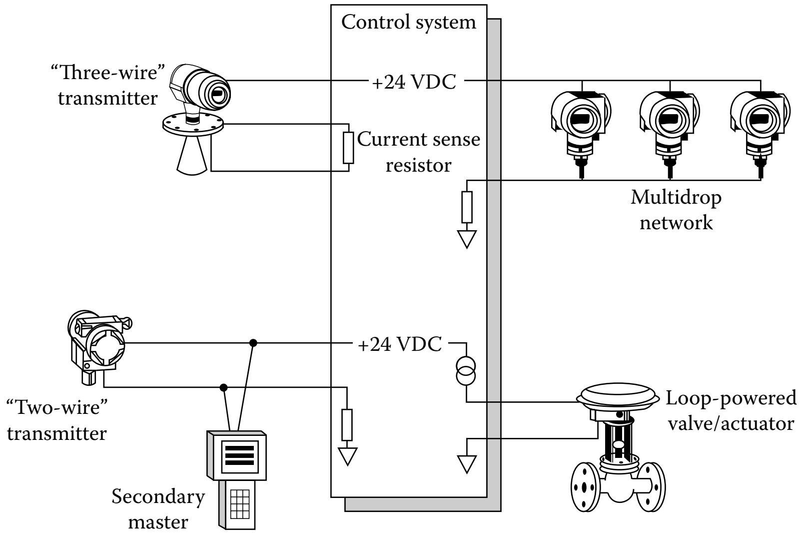


FIG. 4.8e
For multi-drop networks and three-wire transmitters, the loop current (for other devices, the voltage of the power supply) is modulated in a HART installation.[4]

possible to initially test the system using water as the process fluid. During this time, initial loop tuning constants should be determined, and control loop operation and interlock or permissive limit functioning should be verified. Such testing may reveal process or control problems that can be corrected before startup.

Fieldbus Testing

The testing of fieldbus-based process control systems is done in three steps. The first level of testing is called bus segment testing. This testing requires specialized equipment and troubleshooting skills and serves to check the physical installation of the system, including power supplies, terminations, and wire lengths. Prior to starting the testing, it is advisable to identify a qualified contact at each hardware vendor whose field device is part of the system, so that when (not if, when) integration issues requiring expertise arise, one knows whom to call.

The second step is to confirm that the field devices are correctly wired and addressed, their I/O is functioning, and they are communicating on the bus. If some of the field devices perform control or logic functions based on the application software, these too should be checked. When final control elements or other field devices are supposed to provide such information as on/off status and fault or diagnostic information using a data map, which must be unmapped by the other devices on the bus, data-map testing is also part of this second step. The third and last step is operational testing, which confirms that the bus and the PLC, DCS, and other devices that are connected to it are capable of operating as a unit and performing the required control and logic functions. The operational test should also include the checking of cycle times and the testing of all backup systems, data server connections, and bus redundancy.

TABLE 4.8f
Installation Requirements of a HART Network[4]

A network must have at least one, typically only one, low impedance device. Total loop resistance must be between 170 and 600 Ω.
A network must have no more than one device varying the 4–20 mA signal.
Only one secondary device is allowed.
Cable run lengths to 3000 m for single-pair cable and 1500 m for multiconductor cables are typical. Actual length depends on the number of multidropped field devices and the quality of the cable used (see Table 4.8d).
Low capacitance shielded twisted pair cable is recommended. However, HART has been successfully used over poor quality, unshielded wiring. Do not replace wiring until HART communication has been attempted.
Linear power supplies should be used.
HART is compatible with intrinsic safety (IS) rules and HART communicates across most IS barriers. In general, zener diode barriers are acceptable as they do not prevent two-way communication. However, isolating barriers must be HART compatible (i.e., some isolating barriers support one-way communication only).

Process Startup

The startup of a process requires that a person, such as the chief operator, together with a process engineer who is fully familiar with the process and the control system, are both present to coordinate the start-up activities. During the initial phase of a startup, the production rate is usually low and process limitations may dictate that operating conditions be gradually ramped while the process control loops are in manual. During this phase, it is possible to once again verify the operation of the process I/O and the associated field measurements and actuators.

If the quality of prior testing was inferior, at the time of control system startup it is possible that a safety subsystem or control interlock will initiate false trips or that interlocks may hamper the startup. In such cases the source of the problem should be addressed rather than attempting to bypass the input that initiated the trip or interlock.

For this reason, fieldbus devices are designed to allow I/O simulation to be enabled only if a physical key is present on the device. Similar protection is provided in many process control systems through the administration of system security that requires a certain level of authorization to change a critical parameter.

Commissioning of Control Loops

During startup, the process control loops may be commissioned once the process loads reach normal operation and therefore the controller set point and dynamics are close to normal. Before switching any loop to automatic or initiating self-tuning in the automatic mode, it is essential to check the response of the final control element. Therefore, before switching to on-demand tuning, it should be checked that the final control element responds to a change in the controller output when initiated in the manual mode.

Also, such a test may be used to verify that the PID Direct/Reverse setting is correct. Similarly, it is advisable to verify that the final control elements are not sticking and that their hysteresis is not excessive.

Advanced control tools for process and control monitoring are available to determine which loops have been commissioned and have performed as expected. Information collected on control utilization and variability index may be used to determine which loops may need to be closely examined to detect why the loop is unstable, is noisy, does not hold its set point, or is not being used as designed.

Advanced Control

Only after a process has been successfully started up, base loops fully commissioned, and production fully established, is it possible to commission the advanced control features of the system used for process control. A key step in commissioning various optimized, multi-variable or model-based control (MBC) systems is to make sure that the process variable measurements used are reliable and repeatable. Similarly, it is important to verify that the speed of response, characteristics, and dead time of the final control elements are all acceptable for proper loop performance.

CONCLUSION

Long-term reliability of DCS systems may be improved by paying attention to the power and grounding, environmental, and field installation requirements. Industrial standards or manufacturer's guidelines exist for such purposes. Advanced control tools such as on-demand self-tuning and process and control monitoring can be used to quickly commission the control loops and to identify loops that require closer examination.

INTRODUCTION

The adoption of the IEC1158-2 fieldbus standard by the major DCS manufacturers has ushered in the next generation of control and automation products and systems. Based on this standard, fieldbus capability may be integrated into a DCS system to provide:

- Advanced functions added to field instruments
- Expanded view for the operator
- Reduced wiring and installation costs
- Reduced I/O equipment by one-half or more
- Increased information flow to enable automation of engineering, maintenance, and support functions

Similarly, the Ethernet and OPC industry standard have provided DCS manufacturers with a standard means to access information in a process control system. Through the active use of control system data in a plant information system, the operation benefits that may be achieved are:

- Improvement in production scheduling
- Better inventory control
- Consolidation of maintenance- and operation-related information from multiple sites

However, the integration of networks and fieldbus has presented DCS manufacturers with many technical and commercial challenges. Many DCS systems on the market today were designed before the creation of these standards for bus and network integration. Also, the integration of bus technology is complicated by the fact that the IEC1158 standard covers eight fieldbus architectures. Each of these fieldbus architectures differs significantly in physical interface, communication protocol, and the way information is modeled within the field device.

Several approaches have been taken by DCS manufacturers on the integration of buses and network technology. The manner in which this is done can influence the engineering effort that is required to implement and maintain such interfaces.

Figure 4.9a illustrates the control and automation communication network of an industrial plant, which connects the components of the total system.[1] The device-level fieldbuses connect the process control sensors, the final control actuators, and their controllers. The cell-level fieldbuses coordinate, trend, monitor, calibrate, and reconfigure the process controllers, while at the plant level, the overall production strategy is planned. At the device level, a variety of standards of real-time protocols exists.

BUS INTEGRATION

(Editor's note: A single, internationally accepted fieldbus protocol has not yet evolved. As shown by the listing of standards A to G above, there are a variety of technologies and interfaces

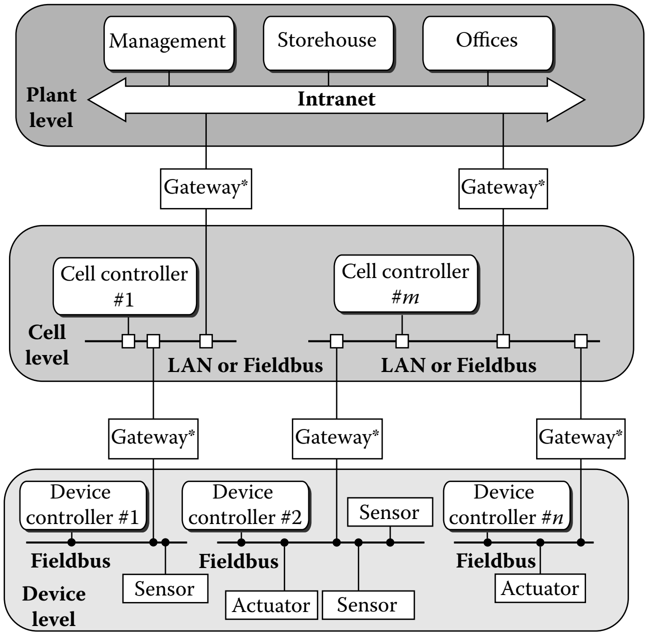

FIG. 4.9a
*The three levels of communication networks used in the automation of industrial plants are 1) the device level, 2) the cell level, and 3) the plant level.[1] *Sometimes not required (see Figure 4.9g).*

that serve the communication among intelligent field devices. Some users refer to this state as a “digital Babel” because in addition to these listed major protocols, a number of proprietary protocols also exist.

Some proprietary networks were designed for specific purposes and therefore lack flexibility in equipment selection and command capabilities. Some were introduced to integrate bus architectures with older DCS architectures. Such linking devices might connect fieldbuses on one side and MODBUS and/or 4-20ma interfaces on the other side. This style of interface tends to be limited by bandwidth, parameter type matching, and, in some cases, the meaning of the parameter value itself.

While much progress has been made, the goal of international standardization is yet to be reached. Today, for example, the digital representation of a 0% or a 50% measurement or the indication of the manual-automatic-cascade status of a controller is still not identical within the various protocols.)

The bus design largely determines the types of devices and applications that may be effectively addressed to implement an application. For example, the Profibus™, AS-Interface, and DeviceNet bus technologies are optimized for fast access of discrete information and best address applications such as motor control and discrete part manufacturing.

Conversely, buses such as Foundation Fieldbus® and Profibus PA address the specific requirements associated with continuous control applications. As such, bus technologies were initially integrated into older DCS as subsystems to address dedicated applications such as motor control interfacing.

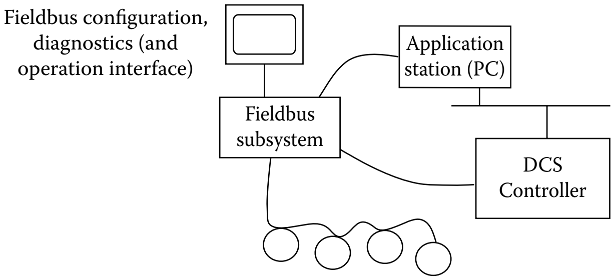

FIG. 4.9b
Integration of open fieldbus subsystems into a traditional DCS.

In such cases, the manufacturer of the fieldbus subsystem was different from that of the DCS supplier. Where such fieldbus subsystems are integrated with the DCS, this is typically done utilizing a serial interface to the DCS controller or interface station, as illustrated in Figure 4.9b.

The integration of fieldbuses often limit the effective use of fieldbus technology because of the differences in design as summarized below:

- Different engineering interfaces must be used to configure and diagnose operation problems.
- It is necessary to engineer how fieldbus system information will be mapped into the DCS controller. Any change in the DCS or fieldbus system may impact this design.
- One interface is not available to view the control and monitoring functions that are split between the DCS and the fieldbus devices. This can complicate engineering, commissioning, and troubleshooting of the control system.

DCS Fieldbus Support

Because of the limitations associated with the integration of fieldbus as separate subsystems, most modern DCS systems provide native support for a number of fieldbus technologies. Such support typically consists of standard interface cards that may be used with DCS controllers. These cards are designed to support the physical and communication interface associated with each fieldbus technology.

In taking this approach traditional I/O can be intermixed on an I/O card basis with standard device buses such as AS-Interface bus, Profibus DP, DeviceNet, Foundation Fieldbus, and HART. Furthermore, the same configuration, diagnostic, and operator interface techniques can be used to configure the system, enabling users to match bus technologies to application requirements.

Field Networks

Field networks reside at the device level (Figure 4.9a), below a PLC, DCS, or other host controller. They serve to replace point-to-point wiring of sensors, actuators, and other I/O devices with an open, multi-drop, bus-type wiring scheme. Sensors, actuators, and other devices formerly hardwired to the host or remote I/O racks now become nodes on a device-level network.

Fieldbuses can be of three categories, depending on the application requirements and device types. These three categories are at the bit, byte, and block levels and are sometimes referred to as sensor-bus, device-bus, and fieldbus, respectively.

Sensor-Bus Sensor-bus networks tend to be driven by the need to move a small number of bits very fast between devices and controllers. Many discrete devices need to transmit only one or perhaps a few bits of information. Examples are proximity switches, pushbuttons, and motor starters. A sensor-bus network can meet this need and transmit bit-level messages to the controller.

Often an I/O brick, such as AS-Interface, which allows several sensors or actuators to be attached to one node, is used in sensor-bus networks, thus distributing the already low interface cost across several physical devices. This also results in a lower node count relative to the number of physical devices. Given the small message size and limited diagnostics, reduced wiring costs are the primary benefit of using sensor-bus networks.

AS-Interface, or Actuator Sensor Interface, is a bit-level network that was introduced in late 1994. Along with Profibus-DP and WorldFIP-I/O, AS-Interface is one of the four technologies included in EN 50254 (High Efficiency Buses for Industrial Automation). Gateways are available for the connection of AS-Interface networks to Profibus-DP, DeviceNet, and ModBus.

Device-Bus Device-bus networks have message capacities ranging from several bytes to over 200 bytes. Device-bus networks are designed to meet the communication needs of higher-level devices. The device-bus networks are typically employed where more information is transferred or where diagnostics are required.

Profibus, or PROFIBUS, was a German national standard for digital communication at the fieldbus level, and is now a European standard as part 3 of EN50170. It is also one of the parts of IEC61508. DP, short for decentralized peripherals, was designed to optimize the network throughput to meet the networking requirements at the device-net level. Profibus-DP is an RS-485-based protocol. Applications range from material handling to control of paper and packaging machines.

Since its 1994 launch by Allen-Bradley, the DeviceNet technology has been turned over to the independent Open DeviceNet Vendor Association (ODVA). DeviceNet offers master/slave and peer-to-peer capabilities with devices from a number of vendors. The goal of DeviceNet is to provide a low-cost communications link eliminating expensive hard wired I/O. The communication profile for DeviceNet is shown in Figure 4.9c.

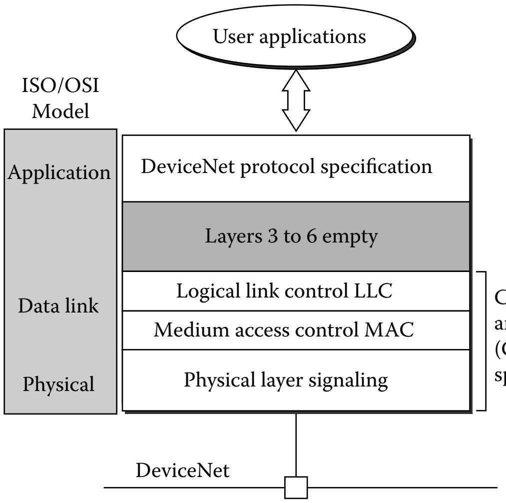

FIG. 4.9c
DeviceNet communication profile.[2]

Fieldbus Fieldbus networks are designed to provide highly reliable bidirectional communications between "smart" sensors and actuators and a control system in time-critical applications. Fieldbus messages contain the readings of several floating point process variables all sampled at the same time and their respective status.

One of the main objectives for fieldbus is to become the digital replacement for analog 4- to 20-mA transmission of process variables in the process industries. Examples of implemented low-speed fieldbus networks include Foundation Fieldbus H1 and Profibus-PA. Due to the differing requirements for process versus discrete installations, fieldbus networks typically have slower transmission rates than device-bus or sensor-bus networks. Another key differentiator is the addition of a user layer, or layer 8, on top of the typical three-layer communications stack. The user layer portion of Foundation Fieldbus includes standard and open function blocks that can be used to implement distributed field control systems.

Fieldbus Devices

Fieldbus devices used in manufacturing automation may in some cases support a limited number of parameters associated with basic measurement or actuator functions. Fieldbus devices designed for use in the process industries may support numerous parameters for diagnostics, measurement, calculation, and control functions. For either type of field device, the manufacturer must provide information that may be used in the DCS to automatically locate information within the field device.

To address this requirement, an Electronic Device Description (EDD) language has been defined by the IEC 61804 standard. This description method allows the DCS to use devices based on different technologies and platforms. The

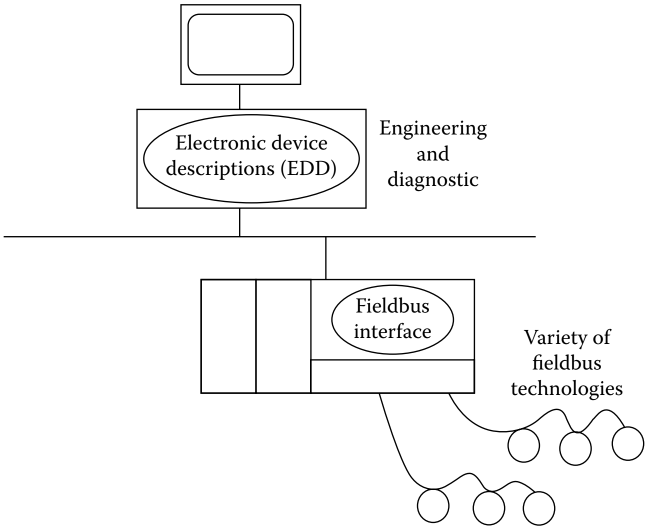

FIG. 4.9d
Native DCS integration of fieldbus technology.

IEC 61804 standard contains profile conformance statements for numerous technologies including PROFIBUS and Foundation Fieldbus. A modern DCS system that fully integrates fieldbus devices is illustrated in Figure 4.9d.

Function Blocks

A block of parameters for measurement, control, and calculation functions may be represented in process control systems as function blocks. The IEC61804 defined the abstract architecture and basic set of function blocks parameters that can be implemented, for example, in field devices or DCS controllers.

Applications within the DCS to system engineering, operation interface, and maintenance have to interact with the function blocks. Functions defined for a function block in the conceptual model are not necessarily mapped one-to-one to the parameters included in a field device. In such cases, these functions can be mapped to a proxy if a device does not support the same capability as included in the DCS.

The IEC 61804 specification may be used in a DCS to give a consistent function block interface for the different technologies. Fieldbus devices that do not support function blocks such as those based on AS-Interface, Profibus DP, and DeviceNet may be brought into the DCS using the concept of a proxy. Through a proxy, function block capability may be provided in the controller for the measurement or actuator value provided by a device.

To the user, these proxy function blocks may be configured for monitoring and calculation application in the same manner as the function blocks supported by the DCS. For these cases, the advanced signal processing and alarming that would normally be done by function blocks in the fieldbus device are done instead in the controller. Some differences in the dynamics associated with the signal processing exist, but in many cases they will have no impact on the application. An application example that utilizes proxy function blocks to provide a consistent interface to AS-Interface and Profibus DP devices is shown in Figure 4.9e.

NETWORK INTEGRATION

Some of the initial DCS systems installed in process control provided little or no support for the integration to plantwide networks. When such support was provided by the DCS manufacturer, the interface may have used a common, low-speed physical interface, e.g., IEEE485. However, the protocol associated with the interface in most cases was proprietary to the manufacturer. Information access was often based on the manner in which data were organized within the DCS. Thus, custom applications were required to access information in the DCS and to save this information in a database that could be accessed by other applications (Figure 4.9f).

The cost of implementing and maintaining proprietary interfaces for network access limited their use in early DCS applications. However, the common adaptation of Ethernet technology in the early 1990s for plantwide local area networks (LANs) helped to create a demand for better integration and exchange of information for production planning, remote diagnostics, and monitoring.

Modern DCS systems are designed to support plantwide access to real-time DCS information to support business planning and remote system monitoring. To provide an open interface, this capability is typically based on international and industry standards. In most cases, these will consist of support for:

- OPC to allow plant information to be accessed in a consistent manner
- Ethernet physical communication layer for high performance at low cost
- Internet connection support for remote access to plant information
- Wireless fidelity (WIFI) access within the plant to operation data
- Modern operating system, such as Microsoft XP and .Net framework, to provide extensible markup language (XML) data exchange and support for Terminal Server Capability

These technologies may be combined in a modern control system to address information access requirements. Also, manufacturers of older DCS architecture may offer increased capability by adding interfaces based on these technologies. For either case, the network integration is illustrated in Figure 4.9g.

Through the use of OPC and XML technology, a common means of information access is provided within the control system at remote locations. The capabilities of modern operating systems such as Microsoft XP allow the same interface to be utilized to display real-time information.

The advent of wireless communication standards, such as IEEE 802.11b, WIFI (which is defined by IEEE 802.116), and the use of inexpensive handheld devices based on this technology is being quickly adopted. This technology allows real-time data and configuration information within the control system to be accessed throughout the plant. In such an environment, strict implementation of security to authenticate user access to the control system is crucial to maintain system

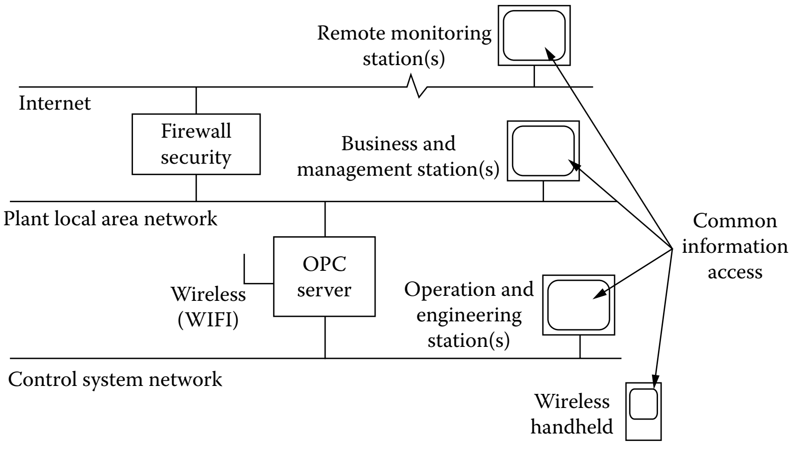

FIG. 4.9g
Present-day method of network integration.

security. Also, any provision that the plant makes for Internet access to the control system usually includes some kind of firewall, a secured connection, and in some cases, data encryption. Virtual private network (VPN) connections are often used to provide a high level of security.

Ethernet routers and switches may be incorporated into the communication system to limit information. Routers and switches are also used to ensure that when plant information is accessed via the LAN or remote applications, then it has no impact on control system communication and data updates at the operator interface.

Plant network interfaces are being used for a wide range of applications including material and resource planning, maintenance, scheduling, remote access, and many other applications. As plant networks become more prevalent, a fundamental shift is occurring in how manufacturers approach production automation.

Historically, the focus was on individual unit operations; the process unit definition and associated equipment defined the overall system architecture. The user definition for the process unit instrumentation determined the plant automation strategy. The expected benefits related primarily to improved unit repeatability and reductions in head count—goals narrowly focused on localized operational improvement.

Recent Integration Trends

In recent years, the needs of the manufacturing industry have changed. Minimizing the total time from conceptual development of a process through implementation and startup is necessary to ensure maximum return on research and development investment. The pressure of competition limits the supplier's ability to increase price. In conjunction with price constraints, increasing regulatory compliance, reporting requirements, and growing raw material costs are also squeezing profitability.

In response, automation users and suppliers have developed an expanded approach, called Manufacturing Execution Systems (MES), for production automation systems. The premise of MES is simple:

- Provide open information exchange across manufacturing production and business planning systems.
- Provide integrated real-time manufacturing applications.

MES has great potential. By integrating today's sophisticated enterprise resource planning systems with real-time production data, process plant managers can now more easily schedule production, manage raw materials, and optimize equipment use. Closing the "information gap" is key for achieving an agile manufacturing environment.

In practice, however, MES systems have been anything but simple. To date, MES solutions have required a significant investment in additional hardware, software, and application engineering. Essentially, users have been required to implement an additional system layer on top of existing systems in order to support the information routing and numerous interfaces required across functional areas. As may be expected, initial user adoption of MES has been slow due to the added cost, complexity, and inflexibility of this approach.

Another area where plant networks are improving is in the area of maintenance. The performance of the processing industries improves by the integration and automation of operation and maintenance functions. A key element in this integration is the quality and availability of maintenance and process data. It is for this reason that most suppliers are integrating their computerized maintenance management systems (CMMS) with their process control products.

Foxboro, for example, integrated its MAXIMO and Invensys' Avantis with its I/A DCS. Similarly, Honeywell integrated its EHM into both MAXIMO and SAP, Emerson's AMS is interfaced with MAXIMO, Wonderware's InTouch was integrated with Avantis, etc.

In the various maintenance packages, alerts are initiated by vibration monitoring (CSi and Bentley Navada), corrosion detection, equipment performance monitoring, production monitoring, and many types of detectors and are routed back into the DCS systems using Internet-based services such as Web services, XML, and SOAP.

Modern DCS systems treat these alerts just like other alarms. They can be prioritized, acknowledged, used to drive animations in process graphics, and combined with control strategies. More advanced features such as combining their alerts with process conditions are being created and presented as "Smart Tags" or "Smart Process Objects."

Plant networks will continue to play an important role picking up features from Web service architectures as they evolve. Standards bodies such as OPC recognize this and are busy developing the next level of interfaces.

CONCLUSIONS

Modern process control systems support a variety of field devices that are based on different fieldbus technologies. These systems use Electronic Device Descriptions and proxies to provide the user with a common interface to all field devices. Information within the control system can be accessed in a common fashion for operations and engineering. Also, control system information may be accessed through local area networks and the Internet. For any network connection to the Internet, protection should be provided by the DCS manufacturer and the plant network to ensure the security of such access.

INTRODUCTION

The reinstrumentation of an existing process or the construction of a new plant often involves interfacing to intelligent external devices or subsystems. For example, the safety system that protects a critical piece of equipment may be an integral part of and is provided by the equipment manufacturer.

Devices as a motor starter may include embedded logic, diagnostics, and support for digital communications to access this added information. When an existing plant is being expanded, the process control system selected for the expansion may not be the same as that used in the existing plant. To provide safe and efficient plant operation, it is important to fully integrate these external devices and subsystems into the new control system.

Integration provides the plant operator with a single window interface into all functions of the complete process. Related process information may be included in the operator displays. This way, the operator is provided with consistent presentation of process alarming and trending and consistent means of changing set points or modes of operation. This makes it possible to provide a single login and span of control.

EXISTING SYSTEMS

When a new plant area is added or expanded, the operators often need to know the conditions in the existing plant section in order to maintain a coordinated operation. Similarly, the operators of the existing plant will also need to have feedback from the new process area to enable them to make decisions on how best to run the balance of the plant. In most cases, only a small fraction of the information in either system must be communicated to support such coordination between process areas or plant sections.

Three techniques that have been successfully used to support the exchange of such information serving plant integration (Figure 4.10a) are:

1. OPC interface
2. Serial interface to highway gateway
3. Serial interface to serial port

A fourth technique is to hardwire the measurement signals to more than one system. This method is not illustrated here, although it is often used when only a small number of signals are involved in the interface.

MODBUS Interface

MODBUS, a specialized network for use with other open networks, was developed for use on the Modicon Company proprietary network. MODBUS can be implemented over any transmission medium but is most often seen on RS-232 and less often on RS-422 or RS-485. It is a serial transmission technique that uses master/slave arbitration and is discussed in detail in Volume 3 of this handbook. MODBUS can transfer 300 registers per second at 9.6 kB and can communicate

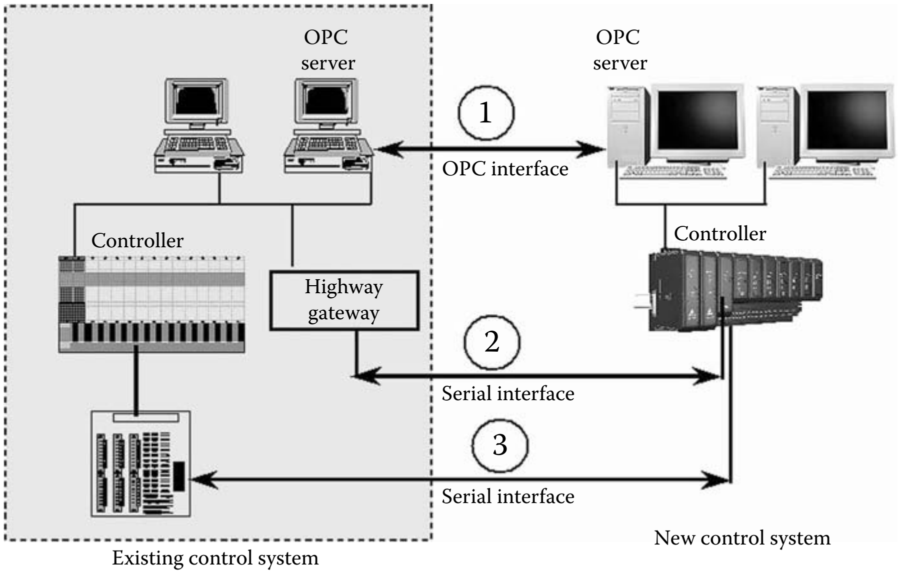

FIG. 4.10a
Three methods of integration of an existing DCS system and a new control system can be obtained by the use of three types of interfacing: 1) OPC interface, 2) serial interface to highway gateway, or 3) serial interface to serial port.

in half-duplex style with up to 247 slaves. MODBUS Plus is an RS-485 based, peer-to-peer network protocol that transmits at a rate of 1 mB.

Many new and existing DCS systems include a hardware interface that utilizes a common communication protocol such as MODBUS block transfer of information from other devices. In some cases, this serial interface may be redundant to improve system availability. If such interface exists, it may be the least expensive method of exchanging information between the systems.

MODBUS is a popular method for moving data values between systems, but if the updating frequency cannot be longer than 1 second, it can handle only a few hundred signals. It is an application layer messaging protocol, positioned at level 7 of the open system interconnection (OSI) model, which provides client/server communication between devices connected on different types of buses or networks. MODBUS support is provided across both serial and transmission protocol/Internet protocol (TCP/IP) networks, as illustrated in Figure 4.10b.

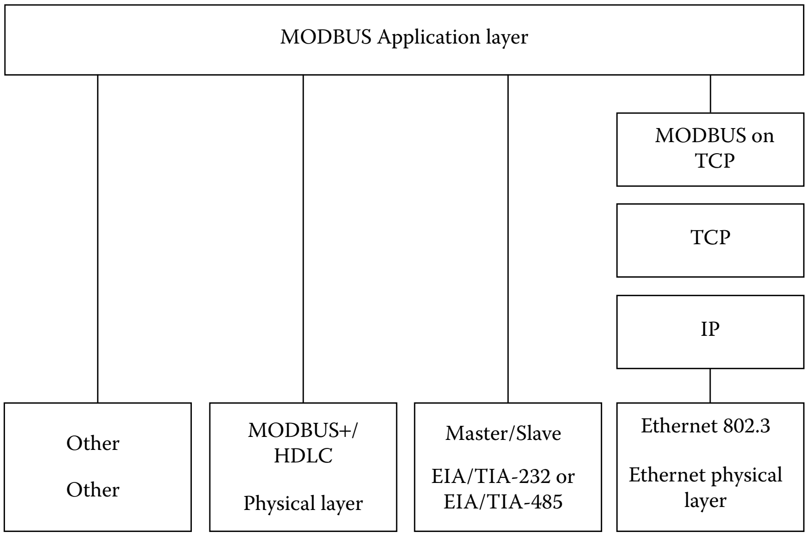

FIG. 4.10b
Integration of existing and new DCS systems using MODBUS interfacing.

Support for MODBUS continues to be strong. Most vendors have built-in support for master/slave stacks over serial and/or TCP/IP. The Internet community can access MODBUS at a reserved system port 502 on the TCP/IP stack.

Some manufacturers may also provide a gateway device that can be used to interface to external systems. These devices are often provided to connect different revisions of equipment from the same manufacturer. Thus, such interfaces may rely on a proprietary communication protocol and limit the types of information that may be accessed through this interface.

OPC Interface

OPC (OLE for Process Control, where OLE stands for Object Link Embedding) is based on Microsoft Windows COM (Component Object Model) architecture. OPC was developed by the OPC Foundation and provides standard software interface to hardware databases.[1] The three basic types of servers it provides are for 1) data access, 2) alarm and events access and 3) historical data access, as shown in Figure 4.10c.

Most modern process control systems support information exchange based on the OPC Foundation's Data Access Specification Version 3.0, March 2003. This process industry standard was created through a collaborative effort of leading automation suppliers and Microsoft. The specification defines a standard set of objects, interfaces, and methods that facilitate data interoperability. Many manufacturers offer OPC servers that may be added to older DCS systems. Where such capability exists, it is to exchange a large number of readings between control systems.

On the other hand, the OPC approach has several disadvantages. One is that the addition of the OPC servers may be more costly than using a serial interface (Figure 4.10a). These interfaces tend to be time consuming to configure—often requiring duplicate configuration to map parameters from one system to another. The interfaces also tend to lack basic features such as holding last value on configuration download, upload, and integrated parameter security. Also, such an interface often is not redundant and thus should be used only where temporary loss of communication will not impair plant operations.

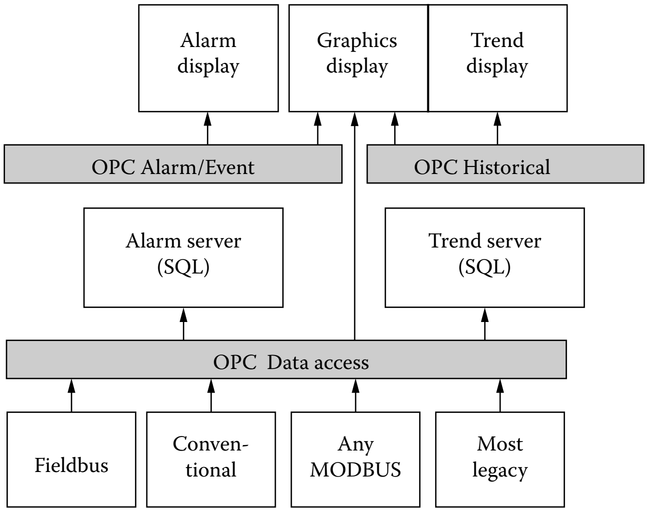

FIG. 4.10c
The three types of OPC servers are: 1) DA, data access, 2) A&E, alarm and events, and 3) HAD, historical data access.[1]

The latest OPC standardization efforts are making important improvements to the data model, in integrating data sources such as alarms, and in supporting a much more capable Web Service Style interface.

One of the biggest challenges in DCS system integration is the fact that each control implementation may represent control parameters in a different manner. Take for example the representation of the operating mode of a controller. Some control systems implement the control mode as two separate parameters, i.e., local/remote and auto/manual, while other systems represent the control mode as a single parameter, i.e., manual/auto/cascade/remote-cascade/remote-out.

Where such differences exist, the basic calculation features of the "old" controller can be used to create a proxy in the "new" controller to map these parameters to their equivalent representation in the new control system.

Looking ahead, several developments are underway that promise to make the integration easier. Perhaps the most significant of these is again OPC. The OPC standardization efforts, recognizing the importance of extensible markup language (XML), software componentization, and Web services, are moving forward with new standards that combine existing data models on top of new service frameworks.

For example, real-time, alarms and events, and history models are being combined. Once combined, a single client will be able to browse to locate the data of interest, subscribe, and then retrieve real-time data, alarms, and events, as well as history. These newer models also address problems related to consistent naming and consistent use of the status/quality attribute.

Consistent/standardized naming would allow clients to reconcile the naming differences between systems — the same OPC path would always refer to the same data. The standardization would also define how status is assigned. OPC servers would be expected to use a consistent status when communicating and receiving data from devices. Uniformity in the assignment of status by OPC servers would improve the consistency of clients.

Other standardization efforts, including the Fieldbus High-Speed Ethernet and PROFIBUS PA, are extending the reach of device networks. These standards provide capabilities to integrate devices across much higher-speed networks.

MOTOR CONTROLS

Analog measurements and actuator signals represent only a fraction of the total inputs and outputs of process control systems. The remaining inputs and outputs are discrete. They

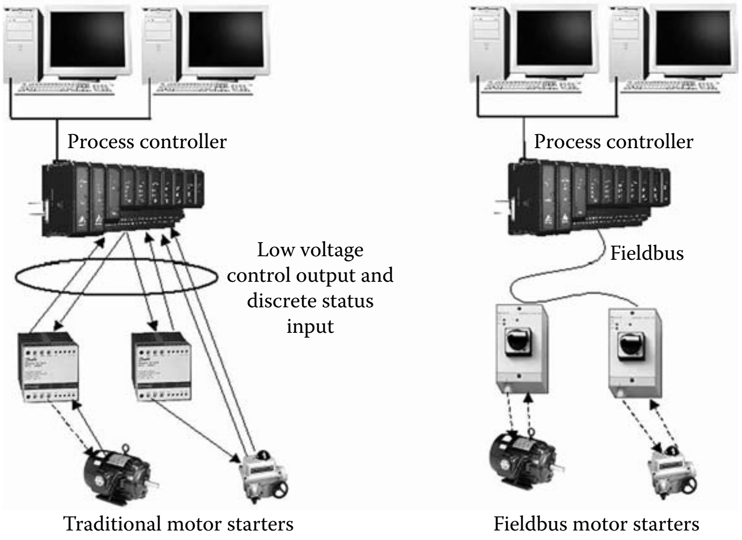

FIG. 4.10d
Traditional and fieldbus-based interfacing of motor starters.

often are associated with motor control, position sensing, and the operation of on/off valves.

The motor control interface for a DCS system often consists of low-voltage discrete outputs from a controller wired to motor starters. Controller feedback of the motor start relay status (M contact) and associated conditions are provided through discrete inputs. The installation cost of this approach may be quite high because of the requirement for the installation and checkout of the large number of wires. Also, diagnostic information that may be available locally at the motor starter may not be remotely accessible, or may be too costly to access as discrete inputs.

Significant advances have been made in motor starter designs that allow more compact packaging. New fault diagnostic capability is also often available for the detection of power loss, sensor input circuit short and phase imbalance, phase currents, full-load current, and thermal capacity for easy troubleshooting and quick restarting.

Also, most manufacturers provide integrated add-on communication interfaces for the motor starter and local input hand-off-auto selectors and pushbuttons. For many applications, this can reduce the quantity of wiring plus simplify connections and thus can reduce installation and maintenance costs, as illustrated in Figure 4.10d.

Fieldbus Interface

The fieldbus communication interface with motor control equipment is often specific to the manufacturer. Some of the most popular intelligent motor starters offer either Profibus DP, AS-Interface, or DeviceNet communication. Thus, modern process control systems are often designed to support a variety of communication interfaces.

The logic associated with motor start, stop, interlocks, and permissive constraints is typically implemented in the process controller. Such logic may have been designed and implemented using ladder logic. However, it is possible to standardize motor control logic as a function block. One example of this is the Device Control block as defined by the Fieldbus Foundation Function Block Application Process Specification, Part 3. A variety of applications including single- and multiple-speed motors with permissives and interlocks may be addressed using this the Device Control block.

Integrating devices such as motor starters with control systems has become considerably easier with standards such as Fieldbus and Profibus. More recent standards such as FDT/DTM (see below) are further simplifying the integration of device configuration and operation by defining a common parameterization format. Together, the Field Device Tool (FDT) and Device Type Manager (DTM) provide a configuration front-end and driver-like back-end, similar to printer drivers today, to support the configuration and communication interfaces to devices.

SAFETY SYSTEMS

Safety instrumented systems (SIS) is responsible for taking the process to a safe state when predetermined conditions are violated. The safety system includes the hardware, software, and all field equipment necessary to perform the desired operations to reach a safe state. Because of the critical role these systems play in plant operation, their design and implementation are normally based on accepted standards, such as IEC 61508, IEC 61511, and ANSI/ISA 84.01. In such designs, the process control system is typically separated from the

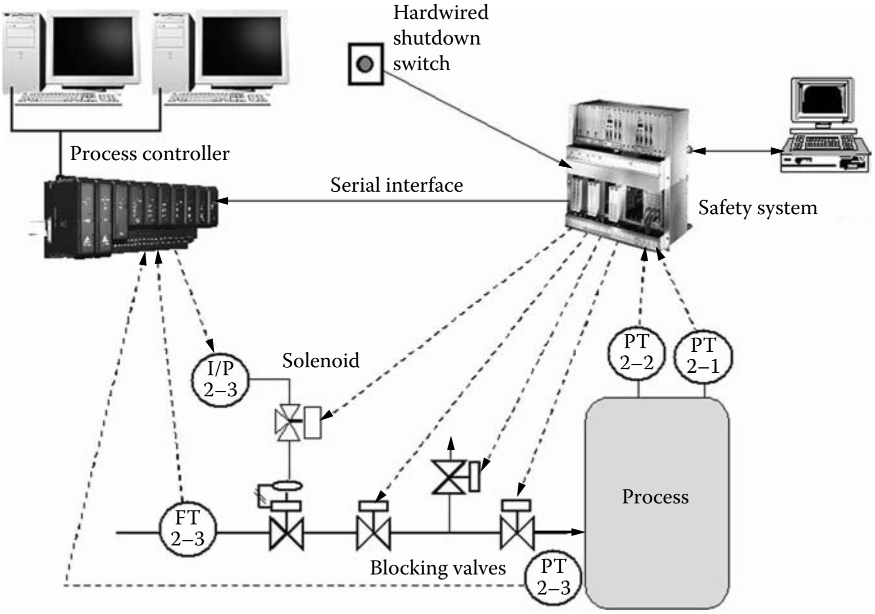

FIG. 4.10e
The integration of the safety instrumented system (SIS) into the overall process control system.

SIS (Figure 4.10e) to avoid the need for all process control systems to meet SIS requirements.

As it is illustrated in this example, the process input signals to the safety system are separate and independent from those used by the process control system. The outputs of the safety system are also designed to act independently from the process control system. For example, a solenoid valve may be placed into the air tube between the I/P converter and the control valve actuator.

In this configuration, when the SIS system requires that the solenoid be energized, it will cause the control valve to take up a safe position, i.e., open or closed. Also, the safety system output may activate blocking on/off valves that stop or divert process streams from their normal flow-paths, regardless of the signals received from the process control system.

As the safety system overrides the normal operation of the throttling control valves of the process control system and prevents the controllers from returning their controlled variables to set point, the integral action is likely to saturate the controller's output. The consequence of this is that when the SIS system returns to normal, the control loop output is still saturated and is not ready to take control.

To avoid any upsets this could cause, when the safety system returns to normal, it also provides a status input to the process control system. If the process control system has maintained or memorized the controller output that existed before the SIS episode, that output value can be automatically set to provide smooth recovery.

The safety system status may be simply provided to the process control system as a discrete input. However, a serial link is typically used to provide status and other information concerning the safety system. Through this link, such information as first-out indication of the cause of action, status of blocking valves, flame sensor indication, etc., may be communicated to the process control system and included in the operator interface.

Operator requests such as "initiate shutdown" or "reset the safety system" may also be added to the operator interface and communicated to the safety system. However, even if this capability is provided, an independent hardwired interface is normally required for the operator to manually initiate shutdown.

To reduce the effort required to integrate information from a safety system into the process control, some process control system manufacturers offer special controllers designed for the execution of safety system logic. Alternatively, independent hardware components may be added to a standard controller for the execution of the SIS logic as illustrated in Figure 4.10f.

When a manufacturer provides SIS controller support as part of the process control system, information and alarms from the SIS controller are available for use in the operator interface without the need to map such information. Also, this approach may allow the same tools that were used to engineer the control system to also be used for the configuration and checkout of the SIS system. Using a common set of tools allows the user to easily integrate parameter access, alarming, history collection, span of control, diagnostics, and security. Advanced features such as configuration audit trail and authorization can also be provided.

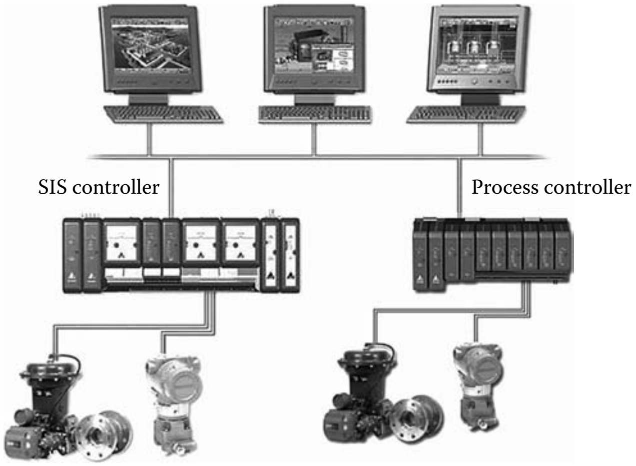

FIG. 4.10f
The system configuration if SIS controller support is available in the process control system.

CONCLUSIONS

Modern process control systems support a variety of communication interfaces. These may be used to integrate information from intelligent external devices, subsystems, and existing DCS systems into the total process control system of the plant. Where the products of several manufacturers are used, it may be necessary to implement proxies in the controller, which can be used to map the information from these "other" suppliers to its equivalent representation in the total control system of the plant.

INTRODUCTION

From an industrial process control standpoint, an abnormal condition develops when the process deviates significantly from the “normal” and acceptable operating range. In pragmatic terms, the “abnormal” that one must manage is a deviation that will lead to financial losses. The challenge of abnormal condition management is to provide the operating team with tools that will enable them to avoid or minimize the impact of abnormal conditions. This is not an insignificant undertaking, but it is one that stabilizes operations and has dramatic financial rewards.

This section will provide a conceptual overview of abnormal condition management and will highlight key considerations in a formal abnormal condition management program focusing on design elements for control room layout, operator training systems, alarm systems, and the graphical operator’s interface to the control system.

ABNORMAL CONDITION MANAGEMENT

To manage anything, one must first understand its basic nature. From an industrial process control standpoint, an abnormal condition can be defined as the condition that develops when the process deviates significantly from the “normal” acceptable mode of operation. In pragmatic terms, the “abnormal” that one must manage is a deviation that will lead to unsafe

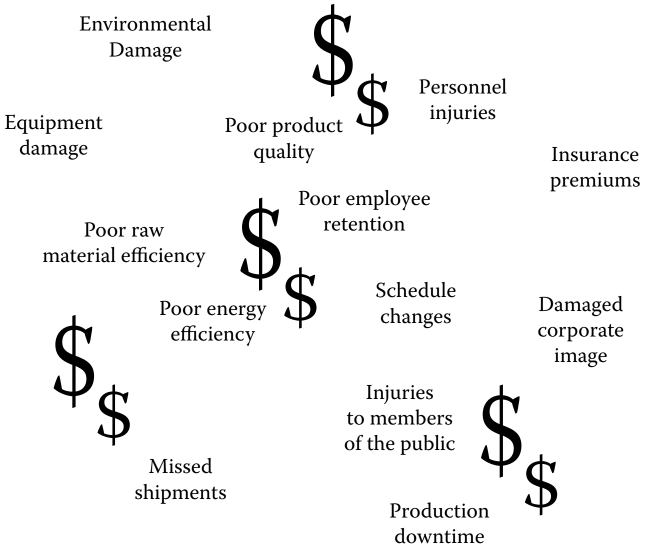

FIG. 4.11a
Types of losses that can be caused by abnormal conditions.

conditions or losses. Figure 4.11a shows a sampling of losses that can be caused by abnormal conditions, including losses in efficiency, quality, production, or equipment or environmental damage, personnel injuries, and other softer issues.

The preventable losses to the U.S. economy are estimated at several billion dollars annually. Recognition of this led to the formation of the Abnormal Situation Management (ASM) Consortium^{TM}, a group managed by Honeywell and composed of several manufacturing companies, universities, and other organizations performing research and development focused on developing technologies to aid in abnormal management. The consortium has published several guidelines and documents for use by member companies. Additional information can be found at www.asmconsortium.com.

Types of Control

In most industrial processes, the operator no longer initiates the majority of the steps of the operation. The days of (local- and panel-mounted) single-loop controllers whose performance was orchestrated by human operators is largely gone. Distributed control systems (DCSs) are generally financially attractive to implement and have become quite common.

Control schemes have become quite robust and generally require little operator intervention. The trend in staff downsizing has resulted in ever-fewer operators managing an increasing number of loops. In the days of the panel-mounted single-loop controller, the entire span of control for an operator was generally mounted within his or her sight. Alarms and annunciators were mounted on the control panel. The action required to intervene was generally visually apparent and in close proximity.

With the advent of the DCS and optimizing control systems, the interactions between control loops became less apparent in the new operating graphics. Today, a single line of text in the alarm summary can be all the information that is provided to the operator. The degree to which the operator understands the process provides the context that leads to the decisions about intervention. In case of a significant upset it is common that the operator will be overwhelmed or "flooded" with hundreds or even thousands of alarms, signaling a variety of abnormal conditions. This sudden flood of information is hard to handle.

The newer types of controllers tend to also diminish the likelihood that the operator will understand all the details of the control algorithm and its interactions. As control systems are becoming more complicated and more robust, an unfortunate result is that abnormal conditions that occur are increasingly difficult for the operator to recognize and respond to in a manual mode.

Figure 4.11b shows a pyramid of a typical control system. Moving up the pyramid, profitability and on-stream reliability increases, but the complexity of the control strategy rises and therefore the role and the understanding of the operator can diminish. When the control strategy is very complex, no matter how well the operators are trained, they cannot fully understand all the possible interactions and consequences. One of the challenges of abnormal conditions management is to provide tools to the operations team to bridge this gap in understanding.

Need for Operator Intervention

With all of the capabilities of current technology, one might question why operator intervention is needed at all. The reason is Murphy's Law—anything that can happen, will. For this reason, human operators are required to reason and adapt their knowledge of the process and develop a response plan to any situation. While adaptive controls and optimization technologies are emerging and are useful in obtaining ever-higher levels of automation, it is still probable that human operators will be needed when systems fail.

An analysis of the root causes of abnormal conditions and incidents suggests that in some 40% of the cases, operators have played a role in causing the accidents. Figure 4.11c recaps the general findings of varied studies[1] performed to determine the root causes of incidents that have prompted significant losses.

PSYCHOLOGICAL BASIS FOR INTERVENTION

To work out how to best enable the operating team in the management of abnormal conditions, it is useful to understand the basic steps of cognitive processing. There are numerous models for the psychology of operations, notably that of Swain and Guttman, who suggest a three-step model of Orienting, Evaluating, and Acting. These steps are key elements in the Human Intervention Framework developed by the Abnormal Situation Management Consortium. Figure 4.11d

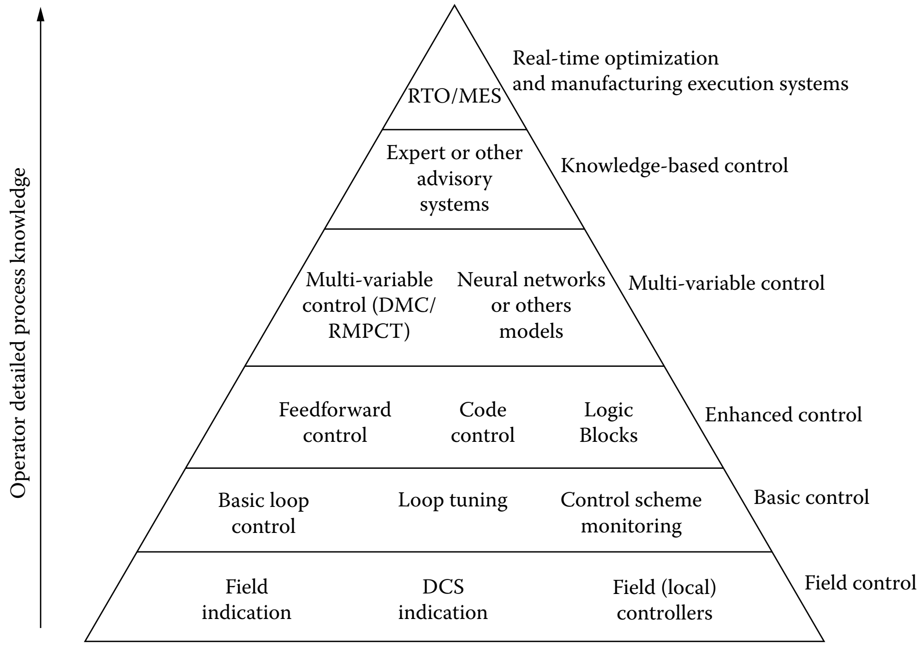

FIG. 4.11b
An approximate pyramid of the elements of an advanced control system.

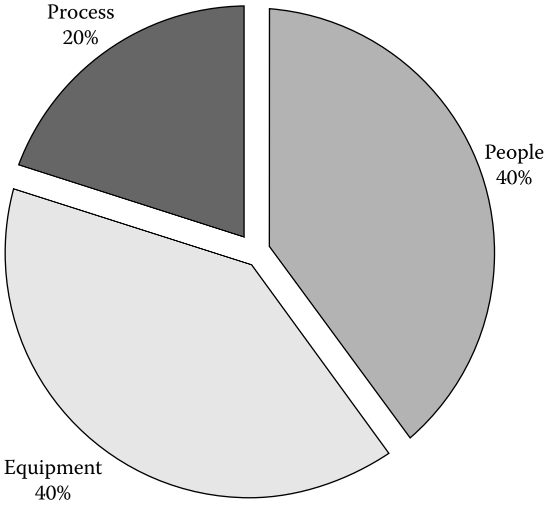

FIG. 4.11c
Root causes of industrial upsets and accidents.

proposes a simple sequential model of Detect, Sort/Select, Plan/Act, and Monitor.

Detect Phase

Tools for the Detect Phase of operator intervention should be focused on ensuring that the operator is aware of conditions in his or her span of control. There are several elements that are critical to successfully managing the operator's awareness of process conditions, including the design of the control room environment, the alarm system, and the graphical user interface (GUI).

It is very important to remember that operators have human physical and mental limits that can be exceeded in abnormal conditions. Thus, it is important to factor these limits into the design of critical systems. Also, advanced detection tools exist that can aid the operator by helping to detect abnormal conditions early and give the operations team additional time to avert an upset or loss.

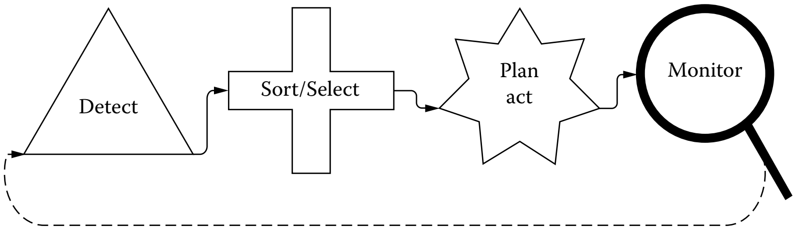

FIG. 4.11d
Sequential model for operator intervention in case of an upset.

Sort/Select and Monitor Phases

Tools for the Sort/Select and Monitor phases of operator intervention should be focused on ensuring that the operator will draw the correct conclusions regarding the state of the process. Key elements include Operator Training Systems, Advanced GUI Design, and Advanced Alarm System handling. Fundamentally, any clues regarding the root causes of upsets and any prevailing interactions should be presented and managed in these systems. One other important consideration is Additional Operator Information Needs. Systems should be assessed to ensure that any information relevant to diagnosing abnormal conditions should be presented to the operator if feasible.

Plan/Act Phase

Tools for the Plan/Act phase of operator intervention should focus on ensuring that whatever action taken is the correct one. Key elements here include:

- Graphics showing the entire span of control
- Contextual information displayed on key graphics (including advice on response)
- Appropriate update rates that show the impact of operator moves

Several other factors can impact the ability of people to perform effectively in a plant environment. These include personal factors such as knowledge, skills, motivation, and personality, and group factors such as the working environment, organizational structure, and work hours. Psychological and work process factors like availability of procedures, communications within the organization, work methods, control display relationships, and task criticality also have a profound effect on an operator's performance.[1]

Response Time

The time available for operators to respond is a primary requirement. Industrial processes are dynamic, and the pace of change during an abnormal condition, particularly once it has been detected, can be quite rapid. Varied studies have repeatedly suggested that the less the time available to respond, the more likely that the correct response will not be found.[2]

TABLE 4.11e
Probability of Failure to Respond[2]

Time Available (Minutes)	*Probability of Failure*
1	~1
10	0.5
20	0.1
30	0.01
60	0.001

In the stress of the moment, it is likely that the operator will not process all available information, but will act when a theory of the state of the process makes sense. Operators generally look for patterns in the behavior of the process. Once a pattern is recognized, then it becomes "reality" until an accumulation of data might prove it otherwise.

In fact, as soon as a pattern is selected, the operator focus will shift from understanding the upset to monitoring intervention activities. The focus will not shift back to a search for general system understanding until it becomes clear that the intervention is not improving the situation or *several* new alarms do not match the pattern selected. Thus it becomes critical to provide support in identifying the root cause of a given condition.

Planning the Intervention

Once the problem has been identified, the key issue becomes one of planning and executing the appropriate intervention. Any known responses should be designed into the automatic control system. If the response cannot be automated, then the operator should be instructed to make the required changes. Any advice that can be concisely presented may speed up the intervention process. If there is no pattern that can be diagnosed automatically, then the interface to the control system should be designed so that the process state and critical interactions are visually apparent.

It is important to remember that the abnormal conditions will generally be complex and will result from a series of consequences rather than one single event. Belke[3] performed a review of chemical industry accidents looking for common causes and found that major disasters are often preceded by a series of smaller accidents, near-misses, and other known precursors.

Plants are routinely run "blind" with failed instruments. And, at times, "without a safety net" because shutdown devices are bypassed. The decision to continue operating under these conditions is a critical one because a new event or failure combined with the existing failures is often simply too much for the operators to overcome in the time available to intervene.

Types of Operations

Finally, it is also important to note that the type and quantity of operator interventions needed are functions of the type of operation. Figure 4.11f shows a proposed model for the types or modes of operation. The first type of operation is under Optimal Operations, where the process is operating at peak efficiency and quality.

Optimal Operations is considered to be a subset of Normal Operations. Normal Operations can have some efficiency and quality losses, recognizing a range of operations that is considered acceptable. As the magnitude of losses increases, the type of operation becomes Upset Operations. This mode of operation might incur some minor equipment damage.

As the problem escalates, the mode of operation can shift into Emergency Operations. Emergency Operations has more

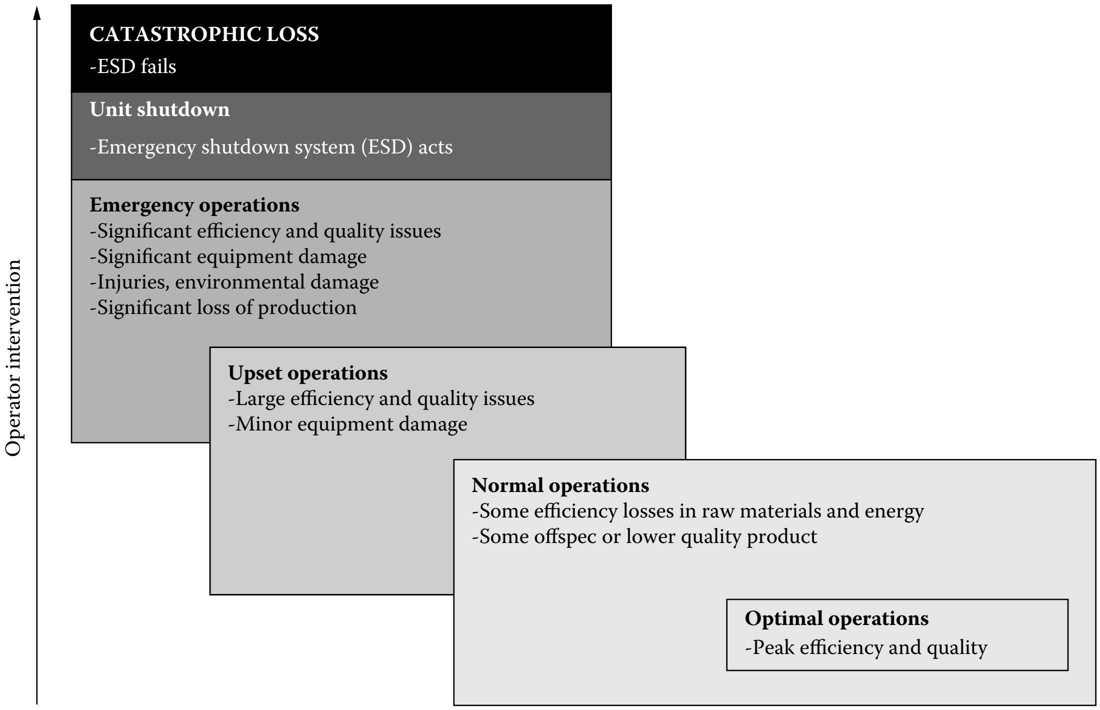

FIG. 4.11f
Model for defining the types of prevailing states of operation.

significant losses in efficiency, quality, and equipment damage. Also possible are injuries, environmental damage, and loss of production. The model also includes an escalation into Unit Shutdown and, with a failure of the Emergency Shutdown Systems, an escalation into a Catastrophic Loss.

As the type of operation changes, the operator also has different primary active goals. While safety is generally the primary goal of all types of operations, it is not the most active goal during, for example, Optimal Operations. During Normal Operations, operators can, in theory and in fact, undertake a variety of tasks that are not directly related to "operating" the plant.

It is common for operators to undertake personal training or to support projects during these relatively quiet times. However, as an abnormal condition develops, the operator becomes fully engaged in operating. The pace and magnitude of intervention generally accelerate. Table 4.11g summarizes the most common active goals and types of operator intervention during the different types of operations.

So, as the time available to respond drops and the likelihood of successful intervention diminishes, the need for operator intervention increases, as does the magnitude of the likely losses if the intervention is not successful.

MANAGING ABNORMAL CONDITIONS

There are certainly as many approaches to managing abnormal conditions as there are causes for the upsets themselves. Perhaps the most prominent and effective lines of defense

TABLE 4.11g
Overview of Operator Intervention and Goals

Type of Operation	*Operation's Active Goals*	*Major Type of Intervention*
Optimal	Exceed targets for production, efficiency and quality	Process monitoring (minor SP and OP changes)
Normal	Move to Optimal Operations	Process optimization (small SP and OP changes)
Upset	Return to Normal Operations	Process stability (large SP and OP changes)
Emergency	Ensure safety, stabilize unit (if possible)	Process safety (major SP and OP changes)
Shutdown	Secure unit, prepare for restart (if possible)	Process safety (major SP and OP changes); interact with ESD system
Catastrophic Loss	Secure unit for safety, minimize losses (if possible)	Emergency containment, field isolation

SP: set point; OP: output.

are in the control schemes and in the design of the emergency shutdown systems. Care should be and is taken in the design of these systems. However, the following ancillary systems can also be useful in the management of abnormal conditions and care should be taken in their design:

- Control rooms
- Operator training programs
- Alarm systems
- Graphical user interfaces (GUI)
- Advanced condition detection and advice systems

Control Room Design

Early control rooms were not much more than glorified umbrellas designed to do little more than provide shelter for equipment and operators. The early equipment was reasonably impervious to the elements, so the designs were not complicated and operators got little extra consideration. As the control equipment became more advanced and environmental requirements were added, the control rooms generally became actual buildings requiring architectural design support.

Over time, safety considerations have became more prominent, so it is relatively common today to have blast-proof buildings with advanced environmental controls. In fact, a specialty within the field of architecture eventually emerged, focused specifically on control center design. Additionally, reliance on video display terminals for process control system interactions with operators makes the ergonomics of workstation and console design critical. A detailed discussion of the design and upgrading of control centers is provided in Sections 4.1 and 4.2 in this chapter.

It is important to remember, however, the needs of the operating team during abnormal conditions and to factor those needs into the final control center design. The control room is the communications center for operations. Varied types of people need to interact with the workstation operators. But these groups of people also need to interact among themselves, as is illustrated in Figure 4.11h.

Thus, it is important to provide meeting facilities and entryways in such a way that they do not disturb the workstation operators. In abnormal conditions, the traditional control center design with its direct entry into the console area and its limited space often hinders operator performance.

The following key design specifications have been proven effective in designing for the management of abnormal conditions:[4]

1. Control center arrangements (focused on different types of rooms)
2. Control room layout (including usable space, furniture, maintenance access, storage, entrance and exits)
3. Workstation layout and dimensions (including communication systems)
4. Displays and controls design

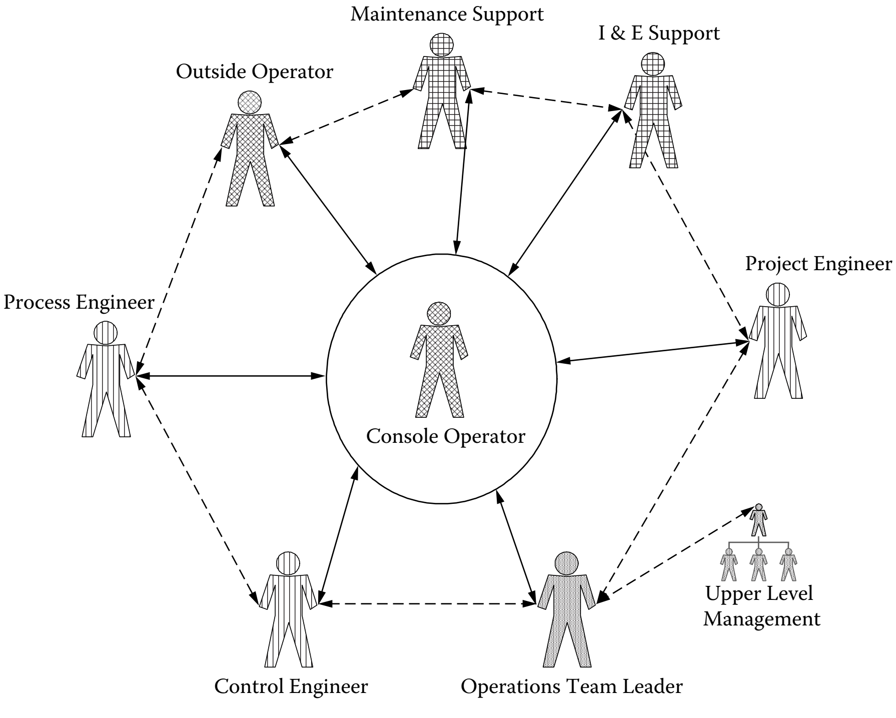

FIG. 4.11h
The required communication interactions in a control center.

5. Environmental design (including air quality, lighting, noise, static, electromagnetic field, hearing clarity)
6. Operational and managerial requirements (practices and organizational policies)

Summarizing, care should be taken in the design and retrofit of existing control rooms to address the communication and ergonomics needs of the operating team. Efficient designs can be effective in dramatically improving operator response to abnormal conditions.

Operator Training

Formal operator training programs, for the most part, evolved from programs designed to meet the first governmental training regulations. The early programs were largely on-the-job training (OJT) systems that were largely modeled after the traditional apprenticeship system. Programs today commonly have a mix of OJT, classroom lectures, and computer-based training (CBT) systems (some of which are programmed to adapt to the student's pace and success).

Increasingly, training simulators have also been developed to simulate the operation of varied industrial processes, with varied degrees of process model fidelity. The simulators are generally either a generic training module at moderate cost or a high-fidelity model of that actual process unit at generally very high cost. These high-fidelity simulators allow operators to operate the plant offline in simulation mode, but with the same look and feel of the actual plant. The simulators can be used for operator training, as well as to verify process engineering and process control designs.

Progressively more companies that are focused on achieving manufacturing or operational excellence have acknowledged the need for structured training in preparing for emergency operations. This is because there is no time to review emergency operating procedures or to call for engineering support during an emergency. By the time an emergency arises, the operators must already have a series of possible response plans internalized or "unless special care is given to developing and maintaining the operator's abnormal operations skills, such as through simulator-based training, he will have difficulty fulfilling his role effectively once an abnormal event occurs."[5]

New regulations have also spurred an emerging approach to training systems based on operator competency, where the specific skills and knowledge for a given job are documented and the operator is assessed against these requirements. Many companies have augmented this approach with a tiered training curriculum as seen in Figure 4.11i.

The number and specifics of the tiers vary from company to company, depending on the work process design at each location. The example in Figure 4.11i shows that all site field operators complete the first three tiers, while all console operators complete Tier 4 and, for the unit process they operate, would complete two additional tiers that would be unique to their specific jobs. From an abnormal condition management perspective, it is useful to consider possible abnormal conditions at each of the tiers, so that the operator would know how to respond to major site risks and sitewide upsets, as well as the specific risks within the process unit and his or her specific job tasks.

One effective way to document much of this is through periodic process hazards analysis reviews. Fundamentally, it is important to train operators in the response to abnormal conditions or upsets either through OJT discussions, classroom training, CBT reviews of past events, or the use of process simulators. This training, periodically refreshed, is a first line of knowledge that can be critical in avoiding or managing abnormal conditions.

Alarm System Design

As was discussed earlier, the financial losses due to upsets are varied and many. More functional alarm systems can help

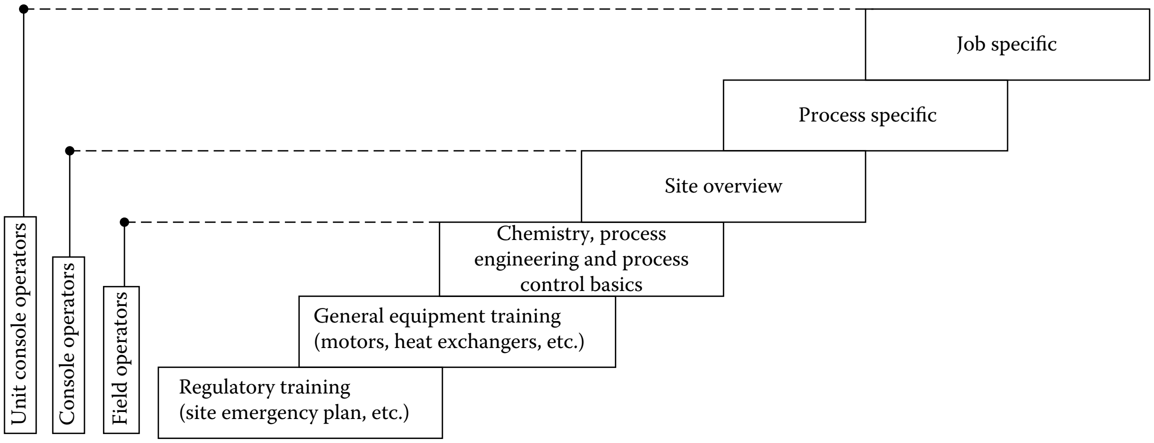

FIG. 4.11i
Illustration of a tiered approached to operator training.

minimize losses in several ways by:

1. Avoiding overloads in upsets
2. Decreasing trips and downtime
3. Decreasing losses in efficiency
4. Identifying areas for improvements in instrumentation, operations, and/or control

It has been observed that severe upsets can corrupt DCS database files, requiring involved rebuilding of these databases. A corrupt database can result in inaccurate alarm system displays, providing the operator with an inaccurate image of the process. The possibility of inaccurate alarming could justify an alarm management evaluation project.

Perhaps the most commonly referenced guideline for the design and use of alarm systems is the Engineering Equipment and Materials Users Association (EEMUA) guideline entitled "Alarm Systems, a Guide to Design, Management and Procurement." The guideline provides a comprehensive look at the design and procurement of alarm systems and the assessment of alarm system performance.

Additionally, the ISA SP18 committee started work in 2004 on a new ISA standard (ISA-18.00.02), tentatively titled "Alarm Systems Management and Design Guide." The Abnormal Situation Management Consortium published a guideline titled "Effective Alarm Management Practices" in 2004.

The following ten-step process, as depicted in Figure 4.11j, is recommended for managing an alarm system performance improvement project:[6]

1. Set alarm system objectives
2. Set an alarm philosophy
3. Set an alarm interface standard
4. Set up the standard approaches
5. Set up the collection infrastructure
6. Set goals and measures
7. Perform alarm analysis
8. Perform alarm rationalization (as needed)
9. Implement improvements
10. Repeat the process

Alarm System Objectives As with any course of action, setting clear objectives is critical to success. Example objectives include the elimination or optimization of:

- Chattering alarms, i.e., alarms that rapidly cycle in and out of the alarm state, causing a large load for both the DCS system and the operators.
- Nuisance event-based alarms, i.e., alarms that are just expected steps in routine procedures or sequence of events.
- Duplicate alarms, i.e., alarms that detect and annunciate both a high and a high–high process variable condition. These alarms eclipse one another and essentially are duplicated entries in the alarm system.
- Stale alarms, i.e., alarms that have been in their alarm condition for a protracted period and do not need to remain in the active alarm summary.
- Disabled or inhibited alarms, i.e., alarms whose annunciation is not enabled, indicating a potential problem in the alarm design.
- Operator alarm changes. Frequent changes by the operator indicate a potential problem in the alarm design.
- Other operator actions, e.g., changes to outputs or set points, that might indicate areas for improvement in instrumentation, process design, or process control.

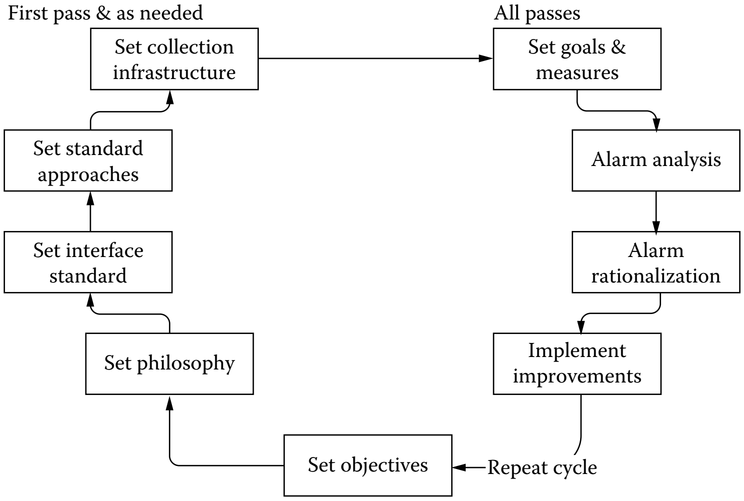

FIG. 4.11j
Steps required in an alarm system performance improvement project.[6]

- Controls not in Normal Mode, if the process is not controlled in the normal mode, that might also indicate potential areas for improvement in instrumentation, process design, or process control.

Alarm Philosophy Setting an alarm philosophy can be difficult, since the varied stakeholders have disparate needs and generally strong opinions. The needs of most of the alarm systems tend to meet a variety of different needs. From a process safety standpoint, it is vital to start and end with operators. The alarm system should primarily be an Operations tool.

It is also important to ensure that Operations is aware of the limitations of the DCS, such as the bandwidth limits that cannot be exceeded, because systems can be overburdened to the point of being unreliable in an upset. The alarm practices could easily be different for every DCS system at a given site, though some level of common ground is useful. Examples of common philosophy include:

- Stipulate that annunciated alarms *require* an operator action. If no action is needed, then it is *not* an alarm.
  - While it can be useful to alarm a variety of items for operator information (e.g., alarms to alert the operator that a sequence program has moved from one step to another), it is important to remember that the primary goal of the alarm system is process safety. Overloading the system with message-type information can make it fail to perform during emergency operations.
- Reserve emergency alarms for true emergencies. (*Note:* Emergency is defined as the highest DCS alarm priority, recognizing that different DCS vendors have different naming conventions.)
  - It is very useful to have a sound and color reserved for true emergencies that require critical responses from the Operations team. Deciding which alarms warrant emergency could be based on, e.g., time to respond or potential impact severity.
  - It is vital to ensure that the operator response is not diluted with too frequent emergency alarms. True emergencies should be rare occurrences.
- All alarm types need a defined rationale and response.
  - A good first step at improvement can be setting the rationale for the emergency alarms in the system. However, every alarm type should have a defined meaning and expected operator response. It is important that the operations team understand and internalize the meaning of the different types of alarms. Recommendations on how to proceed with defining the rationale will be discussed under standard approaches below.
  - In general, three levels of alarms are considered sufficient. A proliferation of alarm types makes color and sound coding difficult and success at internalizing operator understanding unlikely.
  - Several publications recommend certain ratios of alarm types by priority, including the EEMUA guideline. Such ratios are illustrated in Figure 4.11k:
    - — *Emergency* alarms should represent true emergencies requiring immediate operator intervention and be less than 3 to 5% of the total configured alarms in the system.
    - — The *High* alarm priority should represent upsets that are likely to move the process into emergency operations, requiring timely operator intervention. This category should be no more than a third of the remaining alarms or a maximum of roughly 30%.

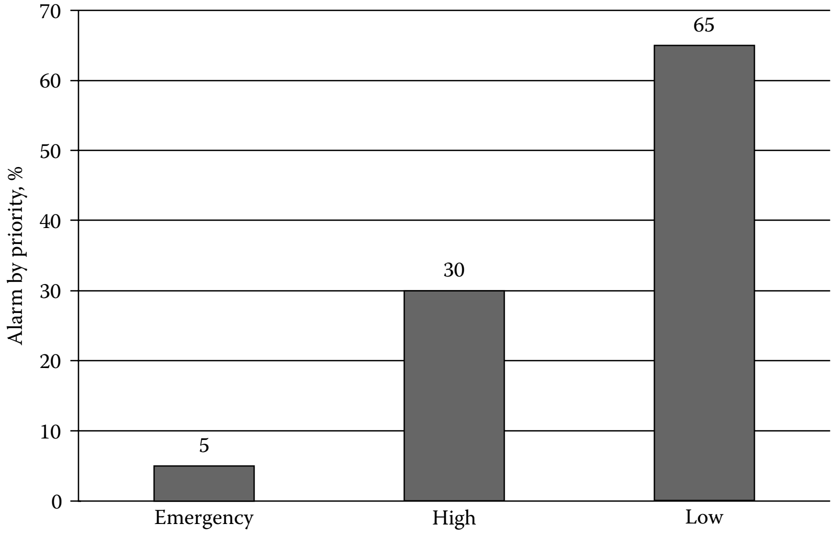

FIG. 4.11k
Recommended alarm priority ratios of low, high, and emergency alarms.

    — The *Low* alarm priority represents the balance of the annunciated alarms and should sound as the operation is moving from normal into upset conditions, requiring operator action, but generally not with great urgency.
- Operator training operations will be provided for all deleted alarms.
    - At first glance, this might seem more of a step in the project process than a true philosophy element. However, it is important to understand that operators have an internal mental model of the process and that a missing alarm will be assumed not active and actions will be taken consistent with that assumption. Thus, removing alarms can have serious consequences if the operators are not adequately trained.

Interface Standards Rapid visual identification of alarm conditions can be an important part of an effective alarm system. Thus it is important that alarms have a standard visual and audible presentation format.

Some example elements of an interface standard include:

- Alarm presentation is consistent
- Alarm presentation is redundant (e.g., by color and symbol to ensure that it is prominent and insensitive to loss of color in the display or to colorblind operators).
- Red and yellow are reserved for alarms *only.*
    - This can be hard to initially sell to the operations team that is accustomed to red used for tripped equipment, but generally once implemented, operators grow to appreciate the value of reserving the color for alarms. One effective means of differentiating tripped versus running equipment is the use of hollow symbols for tripped and filled for running.
- Ensure that the alarm enable state status is redundantly apparent on the graphic, in color and with a coded symbol, e.g., INH for inhibited alarms or DIS for disabled.
- Ensure that the operator is aware of critical code execution status on affected controls (e.g., if code acts on a given controller and it is not functioning, ensure that a visual message or symbol is present on the operating graphic).

Standard Approaches Alarm management projects can be daunting to undertake. There are, however, four things that can make the projects more likely to be successful:

1. Get strong management support and charter a cross-functional team that includes representation of all areas of the operations team.
2. Start with Basic Alarms Cleanup, which will generally show initial improvement.
3. Consider the use of commercial software, which will save time in setup and ensure that someone else will manage any needed updates to keep in synch with the DCS database structures.
    a. Most DCS vendors have some form of alarm management software.
    b. Other commercial packages that are available were listed at the beginning of this section.
    c. If commercial packages are not feasible, consider automation of key reports to ensure that the analysis is ready whenever time is available to work on improvement.
4. Find a specific area of concern to the stakeholders and work on that in parallel with the rest of the general project. Success at resolving a key stakeholder worry will help build enthusiasm.

Improvement projects can be most effectively managed when the engineering decisions are made at the beginning and then used as templates for specific applications. The most common solutions are:

- Database management
- Group alarming
- Alarm "silencing"
- Alarm analysis
- Alarm rationalization

Database management should be designed to run in an automated manner, providing a periodic audit of the DCS, including:

- Disabled or inhibited alarms
- Changes since last audit

Group alarming can be used where a process upset results in numerous alarm conditions, which the operator does not need to be aware of:

- For example, eliminate alarms when a given section of the plant is down and secured. Include logic to test for down and secure. Perform a safety review indicating which alarms are not needed when down and secure. Visual indication of the true state of all alarms should be available at the user interface.
- A second example of alarm grouping is to take all of the noncritical alarms in one area of the process into a single alarm. This can dramatically improve the clutter of stale or standing alarms (defined as the alarms that remain on and standing in the alarm summary). Standing alarms can be a significant issue during upsets as an additional information load that the operator has to sort through to understand the state of the process.

Alarm "silencing" can be an effective temporary tool. Consider the automation of alarm "silencing," where the operator

TABLE 4.11l
Types of Alarm System Analyses

Alarms per time period (minutes, hours, days, shift, etc.)
Time in alarm (both event and cumulative over the period)
Time between new alarms
Duplicate alarms (query for alarms with *xxx)
Alarm annunciation not enabled
Operator changes to: alarm parameters, controller mode, etc.
Time not in normal mode
Time to acknowledge
Time in alarm (time to return from alarm)
Sorting: by area, unit, priority, unit and priority, operating shift, day or night, etc.

is allowed to inhibit the audible annunciation of alarms until the next shift change. This can eliminate the stress of an alarm that is malfunctioning and chattering on and off with high frequency or any other temporary condition. It can also help manage standing alarms due to instrumentation problems.

Such an automation step would reintroduce the alarms after shift change (checking for a lack of abnormal condition) or on operator demand. This would eliminate the possibility that the alarms could be left in their inhibited state for a long period of time.

Alarm analysis is the bulk of the effort needed in an alarm management program. A variety of analyses can be useful, as listed in Table 4.11l. The most important data are the number of alarms per operator per time period, the number of chattering alarms, and the number of standing or stale alarms.[6]

Alarm rationalization is the formal process for setting alarm priorities. The alarm philosophy will define the meaning and calculation methods for alarm priorities. The most common approaches involve the consideration of the time available to intervene and correct the situation and the potential magnitude of impact (type of injuries and equipment or environmental damage). There are varied commercial software packages available to assist in the documentation and calculation of priorities.

Rationalization is the process for applying the alarm priority to individual alarms. It is perhaps simplest to do this rationalization as part of the periodic process hazard analysis (PHA). Alarm rationalization can be a time-consuming process, though detailed review is likely to be only needed on such parts of the process that can lead to emergency operations and should be identified as part of the PHA cycle.

Alarm Collection Infrastructure Most DCS systems are designed to manage a rolling buffer of alarm information and have no standard means to store a continuous stream of alarm information. Alarm understanding is generally improved with a review of operator changes, which is also generally stored on a rolling buffer. A wide variety of options are available for the collection of alarm information, from custom to commercial applications:

- DCS vendors are starting to offer optional packages.
- Data historian companies generally offer optional tools.
- Most DCS systems can stream this information to a “system printer,” which can be directed to a virtual file system.
- The system printer can also be replaced with a connected personal computer, running terminal/modem software managing the data or directly to varied third-party applications.

The most critical issue is to make the data readily available to all users and to automate as much as possible. The most effective improvement programs make the alarm information available to the entire operations team on their desktops so that access to data is not a roadblock to improvement.

Goals and Measures Alarm Management is never complete; monitoring the performance of the system is a never-ending task. Thus it is important to set intermediate improvement goals and minimum performance limits on key performance targets. Management commitment to the goals will help make the process of Alarm Management become a way of life.

Common problems beyond simple redesign of alarm systems include:

- Noncritical digital indicators failing/failed
- Field switches that need new set points due to process changes
- Noncritical loops with chronic performance issues
- Critical loops in need of maintenance
- Different modes of plant operation needing different alarm trip points

Graphical User Interface

The graphical user interface can be designed in several ways to support the operators during upsets. Key issues to consider include:

- View of span of control
- Navigation design
- Dedicated displays for abnormal conditions
- Dedicated displays for task support
- Basic display design guidelines

View of Span of Control In modern digital control systems, the full span of control for an operator is often not shown on a single screen. In an abnormal operating condition, this lack of the “full picture” can lead to errors in judgment. Thus it is recommended that an operating graphic be designed that clearly shows the entire operator span of control. In order to manage graphic throughput constraints, alarm grouping techniques or alarm counts by area can be used to manage the information needs for this process overview display.

Navigation Design Navigation design can be critical because it directly impacts the time to understanding and ultimate action. Key considerations include:

- Display every loop in the unit on at least one operator graphic.
- Keep the number of operator graphics to a minimum.
- Keep the navigation scheme fairly simple and flat.
  - Most companies have display design guidelines that limit the depth and breadth of the graphics hierarchy. There has been significant research into "menuing" and navigation design. A simple rule of thumb is that every loop should be visible within no more than three navigation moves. Graphics for critical loops should be accessible with one move.

Dedicated Displays for Abnormal Conditions Dedicated displays for special tasks and abnormal conditions can be very effective. However, care must be taken to either use the same type of layout as used in the normal operating graphic or have periodic training sessions that include the actual use of the dedicated displays. It can be very effective to display context-sensitive information. Examples include:

- Information about interlocks; include details on permissive and bypasses that are available as required.
- Conditional advice embedded in the graphics that displays only when logic tests are true (or only at high intensity when true).
- Sections of the graphic dedicated for the display of information relevant to the actions of the operator.

Dedicated Displays for Task Support Where there are specific tasks that are more prone to generate abnormal conditions, it can be valuable to perform a process mapping of the task and to then generate specific operating graphics to support the effort. Additional automation ideas are likely to be generated as part of this process mapping. There is an emerging field of specialty in procedure automation and verification, partially driven by OSHA 1910.119 and partially by initiatives like abnormal situation management.

Basic Display Design There are some basic design guidelines that can be effective in designing operating graphics that perform well under abnormal conditions. Perhaps the most important considerations are those concerned with the basic ergonomics of the operator, ensuring that the pace of information delivery matches reasonable human capabilities. Key considerations include:

- The display refresh rate is appropriate. Just because the DCS can refresh the graphic every 1/10 of a second does not mean that this speed is needed. The speed of refreshing the graphic should be based on the actual response time of the process, thus reducing the information load on the operator and on the system.
- Error avoidance techniques should be implemented.
  - Require a double confirmation on critical steps.
  - Redisplay the requested action in the verification, if appropriate.
  - Enforce high and low limits of change on typed entries.
- Design the graphic to ensure that the equipment and piping fade into the background. While the graphic represents the process of, for example, a distillation tower, the valves, pumps, and instruments are more important than the tower or its trays.
- Detailed information should be available, but only on operator demand. Do not clutter the operating graphic with all the information that might ever be needed, but the tag numbers and shutdown limits provide methods to display, etc.
- The direction of flow and the overall layout should be consistent with the actual process.
- Reserve red and yellow for alarms only. It is also prudent to keep the number of other colors to a minimum and apply the meaning of these colors consistently. It can be very effective to make all process equipment gray and all text some other dull color. This makes the red and yellow for alarms very prominent.
- Consider colorblindness and contact in the design of the graphics.

Advanced Detection and Advice A key goal of abnormal condition management is to ensure that the operator gets the correct information at the correct time to be able to make the required corrective action.

Advanced detection and advice systems strive to provide real-time alerts and dynamic advice to the operator. Technologies that support this include knowledge-based systems (e.g., expert systems), model-based systems, data-driven approaches (e.g., statistical process control, Six Sigma, and neural networks), and engineering process control.[7]

Research into abnormal condition management, especially with the ASM Consortium, is currently striving to create a collaborative technology that will further enable the generation and delivery of this advice. Much of this is presented in contextual-based graphics within the DCS or in a technology-specific interface on a non-DCS computing platform. One useful presentation aid is that of the polar star, which provides a multi-dimensional image of "normal" operating conditions for key controllers or properties and a real-time view of the process in the same format.

Providing more time to orient the operator with early detection and dynamic real-time advice can be a very effective means of averting abnormal conditions or of minimizing their impact.

CONCLUSIONS

Abnormal conditions cost the U.S. economy billions of dollars every year. The keys to the management of abnormal conditions are the use of complex control and emergency shutdown systems, as well as early detection systems, comprehensive operator training, performant alarm systems, dynamic well-designed user interfaces, and advanced operator advice systems.

No one of these elements is the magic bullet to solve the problem; rather, they form a basis for context and understanding for the operations team. In reality, the problem is never solved; it is a continuous work process for operations, requiring vigilance and unremitting improvement.

ACKNOWLEDGMENTS

INTRODUCTION

Graphical standards for defining control and calculation were in common use long before the introduction of the DCS. However, early digital control systems were limited by computer, software, and interface technology in supporting graphic control languages and in implementing process control and simulation graphics. With the introduction of the IEC 61131-3 standard in the early 90s, most manufacturers began to provide general support for control graphics.

The IEC 61131-3 standard is in its third edition and defines four control languages for process control and manufacturing automation. Three of these languages use graphical representation of the control, as follows:

- Function block—Allows both continuous and discrete control to be represented by reusable blocks of functionality. The information flow between blocks is by wiring between the function block input and output connections.
- Sequential function chart—Defines calculation and control where the logic evaluation is done in a sequential manner and may follow different paths depending on the operating conditions. Such capability is often required in the sequential controls of batch processes.
- Ladder diagram—Allows discrete logic to be implemented as rungs of contact, coils, and function blocks. It has been utilized in discrete control and in motor control interlock and permissive logic applications.

Major equipment manufacturers and organizations of Foundation Fieldbus and Profibus have supported the use of function blocks for control in the process industry. Many of the fieldbus devices utilized in the process industry today are based on the function block specifications defined by these industry sponsored organizations.

The IEC 61804 international standard for process industry function blocks has adopted much of the function block architecture of Foundation Fieldbus and Profibus. Modern control systems are based on this standard for function block representation. The IEC 61804 standard also defines a migration path that allows older systems and field devices to be used in a consistent fashion within these systems.

The release of batch control standard ANSI/ISA-88.01-1995, Batch Control Part 1: Models and Terminology, led to revolutionary advances in the way factories design, implement, and integrate flexible, modular batch processes. The standard made it possible to design better processes by combining recipes with equipment control in a standardized manner.

Safety logic functions are also being integrated into the DCS systems. Doing so will greatly simplify the configuration and support for safety instrumented control strategies. Improved graphic displays contribute to better control of both continuous and batch processes.

FUNCTION BLOCK REPRESENTATION

Control definitions based on function block representations are very common, providing graphic displays for continuous and batch-type processes. Much of this acceptance is based on the fact that common components that have been traditionally used for process control such as feedback controllers, computing elements, and interface stations can each be represented by function blocks. For example, the analog PID controllers and their interfaces on the central control panel can, along with their associated field input and outputs, be represented as function blocks.

The IEC 61131-3 made a significant contribution in standardizing the graphical representations of measurement, control, and calculations by function blocks. This standard specifies that any independent function which, when executed, yields one or more values may be represented as a block. Multiple, named instances of a function block can be created. Each instance must have an associated identifier (instance name) and defined input and output data structure. All the values of the output variables and the necessary internal variables must persist from one execution of the function block to the next.

A function block instance is graphically represented as a block with the function block name inside the block and the instance name above the block. Any values that are required for the associated calculation must be shown as input connections on the left-hand side of the block. The size of the block may vary depending on the number of inputs and outputs. Formal input and output parameter names must be shown respectively at the inside left and right side of the block.

Measurement and actuator access associated with Input and Output function blocks may not be explicitly shown since they are accessed in a proprietary fashion. For example, the graphical function block representation of the activation of a solenoid (DO function block) based on the logic OR of the contact status of two limit switches (using two DI function blocks) is shown in Figure 4.12a.

Standard for Process Control

The foundation for function block implementation has been further extended by the IEC 61804-2 Function Block standard for Process Control. In particular, this standard requires that function block implementations conform to the following:

- Function block inputs and outputs include both a value and status attribute. The quality associated with a function block input value is indicated by its status. The status of calculated function block outputs is based on the status of the block's inputs and on the block mode.
- All function blocks associated with a control function will support a mode parameter. The mode parameter allows the source of the block setpoint and outputs to be explicitly selected by a plant operator.
- Configuration values used in the block algorithm, operating targets, and calculation results may be defined as contained parameter and do not need to be shown as input connections—as defined in IEC 61131-3. The majority of parameters associated with process industry function blocks fall into this category.

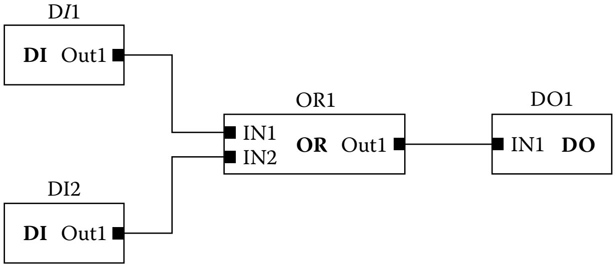

FIG. 4.12a

Block diagram representation of "or" logic, utilizing discrete I/O: The status of two digital inputs (DI) from two limit switches is evaluated by the logic block OR, which sets a digital output (DO) to a solenoid, which will be energized if either of the two limit switches is closed.

Function Block Modes

The IEC 61804 standard defines the mode parameter used in control blocks. The allowed target mode values of a block are defined by the permitted mode attributes of the mode parameter. Thus, the modes available for controlling a block may vary with each block instance. To help an operator select the normal mode of operation from those available, a normal mode attribute is provide in the mode variable. This attribute may be used by a human interface application to help guide the operator in setting the operation mode of a block.

The values assigned to the permitted mode attribute are selected from those defined by the block designer. They are assigned during block configuration to meet the specific requirements of a function block application. Interface devices and temporary devices may use the permitted mode to limit operator changes in target mode. Field devices limit changes in target mode to those allowed by the permitted mode attribute. Once the actual mode is determined, the block execution progresses and the outputs are generated.

Figure 4.12b illustrates a block that contains a setpoint variable and an output variable whose values are determined by the mode variable. The target operating point of a control is determined by the setpoint variable. In addition to indicating how the algorithm is to execute, in this case, the mode also indicates the source for the block's setpoint variable and the destination for its output variable.

As shown in Figure 4.7b, the source of the setpoint or destination of the output variable value may be an input variable, the algorithm itself, a control application or a human interface application in an interface or temporary device.

The effect of the mode on the operation of the function block is as follows:

Out of service (O/S) mode—The block is not being evaluated. The output and set point are maintained at their last values.

Initialization manual (IMan) mode—The block output is being set in response to the status of the "back-calculation input variable."

Manual (Man) mode—The block output is not being calculated, although it may be limited. It is directly set by the operator through an interface device (*A*).

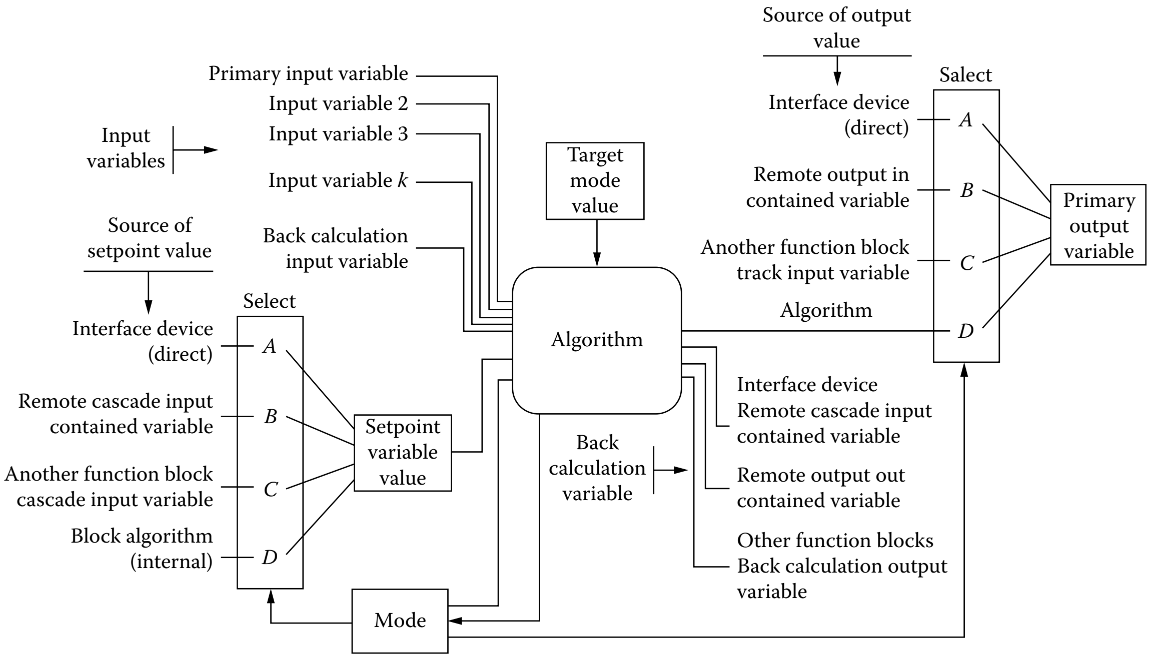

FIG. 4.12b
The internal structure of an algorithm block with mode-controlled set point and output parameters.

Local override (LO) mode—In the local override mode, the block output is being set to track the value of the tracked input parameter.

Automatic (Auto) mode—A local set point value is used by the normal block algorithm in determining the primary output value. The local setpoint value may be written to by an operator through an interface device.

Cascade (Cas) mode — A set point value supplied by another function block through the cascade input parameter (*C*) is used by the normal block algorithm in determining the primary output value (*D*).

Remote-Cascade (RCas) mode — The block setpoint is being set by a control application running on an interface device through the remote-cascade input variable (*B*). Based on this setpoint, the normal block algorithm determines the primary output value (*D*).

Remote-Output (ROut) mode—The block output is being set by a control application running on an interface device through the remote output variable.

Function Block Types

The architecture and basic parameters of function blocks are defined for measurement, calculation, and control. The standard allows DCS manufacturers to identify specific function blocks and to define how the requirement for status attribute will be achieved. Providers of control equipment may contribute by specifying additional features (named profiles) to the standard. The standard includes profiles for Foundation Fieldbus, Hart, and Profibus Organization.

The Foundation Fieldbus profile is used by many manufacturers of fieldbus devices. Many control systems have adopted the Foundation Fieldbus function block architecture and specific function blocks. In this architecture, 10 basic blocks are available to specify the basic control and measurement requirements:

- Discrete input (DI)
- Discrete output (DO)
- Analog input (AI)
- Analog output (AO)
- PID, PI, I control (PID)
- P, PD control (PD)
- Control selector (CS)
- Manual loader (ML)
- Bias/Gain station (BG)
- Ratio station (RA)
- PID

In addition, 19 advanced function blocks have been defined by the function block specification that provide pulse count input and pulse duration output, dynamic compensation of feedforward, characterization, integration, and discrete device control for motors and valve manifolds. Most control applications may be addressed using these blocks.

As a part of input block processing, the Foundation Fieldbus specification requires that checks be performed on associated hardware and software. The status of an output parameter is calculated by the block to give an explicit indication of the quality of the value — *Good, Uncertain,* or *Bad* — as shown in Figure 4.12c.

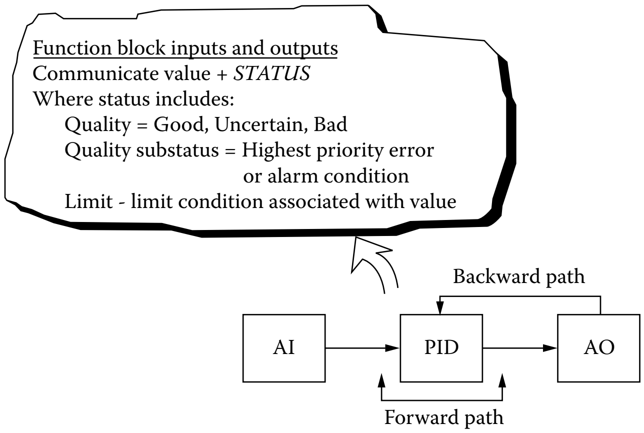

FIG. 4.12c

When a function block calculates an output value, status and substatus statements are also generated. The status statement indicates whether the quality of the output value is good, uncertain, or bad. The substatus statement indicates whether the value has reached a limit or alarm setting.

A substatus attribute indicates the primary condition, which determines the quality. Also, there is an indication in the status attribute whether the value has reached its high or low limit. When a block input or output parameter is accessed for viewing at an operator console, historian, or diagnostic tool, both the value and its associated status can be communicated. The quality information and its substatus may be useful in diagnosing the cause of a Bad or Uncertain measurement.

Quality is indicated by a substatus attribute. If the substatus indicates that the quality is Good, it can also provide additional information that may be needed for control or monitoring purposes. For example, if the substatus of an input block is Good, it will also give information on the status of alarms that are defined for that block.

As part of block definition, the processing and propagation of status is defined. To facilitate the use of status information, the representation and meaning of quality and its associated substatus have been defined in the Foundation Fieldbus specification.

SEQUENTIAL FUNCTION CHART (SFC)

The IEC 61131-3 standard defines the capabilities of the sequential function chart (SFC) that is used to determine the execution of control functions. The set of SFC execution control elements as defined by IEC 61131-3 was originally designed as a program organization unit for a PLC.

Many process control systems have adopted this graphical language as the primary means of sequential logic specification. Sequential evaluation of function blocks may be structured as sets of steps and transitions that are interconnected by directed links that use the SFC graphic language.

At any time the state of logic evaluation is defined by a set of active steps and by the values of the internal and external output parameters. The definition of these elements according to IEC 61131-3 is as follows:

Step—A situation in which the behavior of a program organization unit with respect to its inputs and outputs follows a set of rules defined by the associated actions of the step.

Transition—Represents the condition when control passes from one or more steps preceding the transition to one or more successor steps along the corresponding directed link. Each transition has an associated transition condition, which is the result of the evaluation of either a Boolean expression, a ladder diagram, or a network in the function block diagram language. When the transition condition is evaluated as TRUE, the transition is triggered and associated steps are enabled or disabled.

Action—Can be defined as a collection of networks in the function block diagram or by various other means such as a collection of rungs in the ladder diagram language. It is used to assign the result of an expression to a database item, which can be an SFC step.

A specific task may be represented graphically using steps, transitions, and actions. A sequence in an SFC is drawn as a series of steps and transitions. Steps are represented by boxes and transitions by vertical lines with crosses attached, as illustrated in Figure 4.12d.

Each step contains a set of actions that affect the process. At any given time, one or more of the steps and transitions can be active. Each time the SFC scans, the active steps and transitions are evaluated. When a transition evaluates as TRUE (for example, when a transition condition is met), the steps prior to the transition are made inactive and the step(s) following the transition become active. This way, the SFC can sequence through the various control states as defined by the SFC diagram.

Transitions allow single-stream or parallel execution of logic within the SFC. By using a sequence select divergence, divergent paths may be used to enter alternative sequences. To converge paths again, a sequence select convergence can

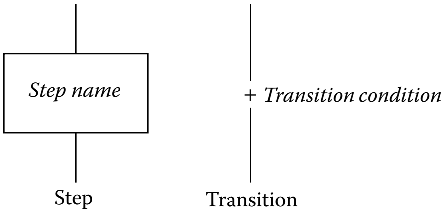

FIG. 4.12d

Representation of a step and of a transition, which are used in a sequential function chart (SFC) as sequentially numbered blocks.

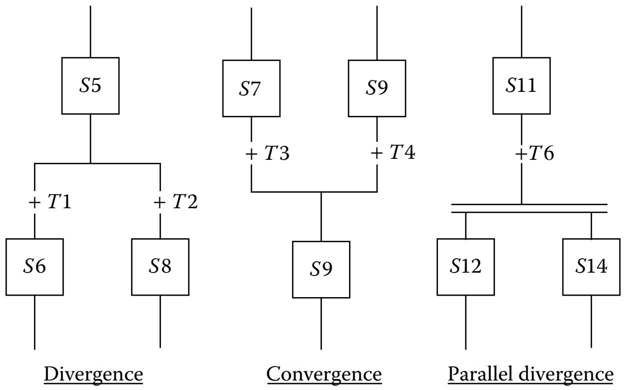

FIG. 4.12e
Examples of divergence and convergence paths in an SFC chart presentation.

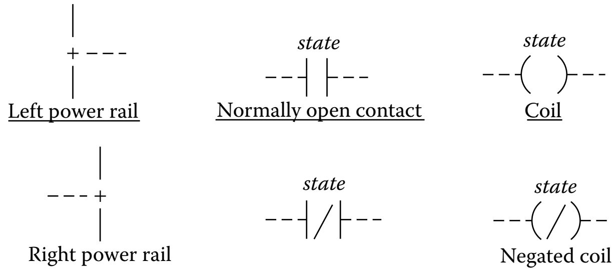

FIG. 4.12f
The component element symbols used in a ladder diagram include the left and right power rail and the contact and coil symbols.

also be graphically defined. Simultaneous or parallel sequences can be specified using parallel divergence. The graphic representation of divergent and convergent paths is illustrated in Figure 4.12e.

The logic associated with an action or the logic for a transition may be defined as an expression. Within IEC 61131-3, the semantics and syntax of structured text language (ST) may be used to define an expression. Expressions may also be used to provide information for process operators so that they can make control decisions.

LADDER DIAGRAMS

The ladder diagram as defined by IEC 61131-3 is utilized by many manufacturers of programmable controllers as their primary means of implementing discrete logic. By using this language, the PLC may test and modify data by means of standardized graphic symbols. These symbols are laid out in networks in a manner similar to "Rungs" of a relay ladder logic diagram.

As defined in IEC 61131-3, the ladder diagrams are bounded on the left and right by power rails. The state of the left rail is considered ON (powered) and no state is defined for the right rail. A horizontal link element is represented by a horizontal line and transmits the logical state (ON or OFF) of the element on its immediate left to the element on its immediate right. A vertical link element consists of a vertical line intersection of one or more horizontal link elements on each side. The state of the vertical element represents the inclusive OR of the ON states of the horizontal links on its left side. The state of the vertical link is copied to all of the attached horizontal links on its right.

Three basic elements that are used within the ladder diagram to express the implemented logic and calculations are:

Contact—Imparts the state of the horizontal link on its right side that is equal to the Boolean AND of the state of the horizontal link at its left side with the associated Boolean input, output, or variable. Four basic types of contacts are defined: normally open, normally closed, transition-sensing, and negative transition.

Coil—Copies the state of the link on its left to the link on its right without modification and stores an appropriate function of the state or transition of the left link into the associated Boolean variable. In addition to the basic coil and negated coil, various types of latched, retentive, and transition-sensing coils may also be used in the ladder diagram.

Function Block—At least one Boolean input and one Boolean output must be shown to allow for power flow through the block.

Examples of the graphical representation of a power rail, contact, and coil are illustrated in Figure 4.12f.

Within the ladder diagram, the network is evaluated in a top-to-bottom order. Figure 4.12g provides an example of how these basic elements may be combined to serve a motor control application.

Even though logic applications can be implemented by using ladder logic, many applications require too many elements to fully address the control and interface requirements of the system. For example, a motor control that includes features such as capturing first-out trip indication and includes

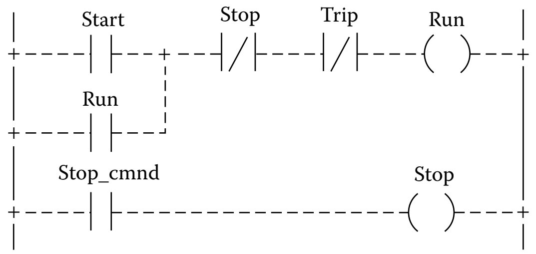

FIG. 4.12g
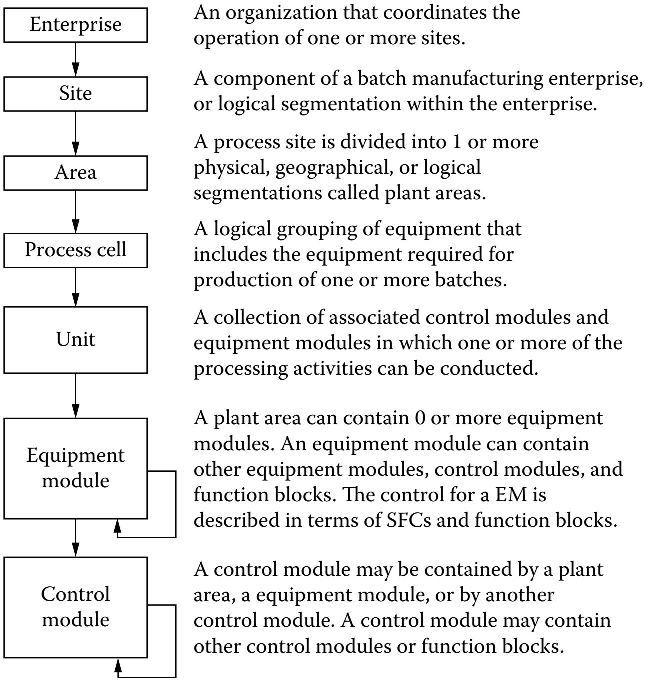
This motor control application illustrates how the component elements of a ladder diagram can be combined to serve a particular logic sequence.



An organization that coordinates the operation of one or more sites.

A component of a batch manufacturing enterprise, or logical segmentation within the enterprise.

A process site is divided into 1 or more physical, geographical, or logical segmentations called plant areas.

A logical grouping of equipment that includes the equipment required for production of one or more batches.

A collection of associated control modules and equipment modules in which one or more of the processing activities can be conducted.

A plant area can contain 0 or more equipment modules. An equipment module can contain other equipment modules, control modules, and function blocks. The control for a EM is described in terms of SFCs and function blocks.

A control module may be contained by a plant area, a equipment module, or by another control module. A control module may contain other control modules or function blocks.

FIG. 4.12h
ISA Standard S88 provides a basic structure for the hierarchical definition of batch controls.

permissive as well as interlocks in the control logic may require 50 or more elements and many rungs of logic.

This complicates the implementation and troubleshooting of logic interlocks in the field. Since a single function block can be designed to perform the same function in a standardized manner, many control system manufacturers provide a set of function blocks designed to address discrete applications in lieu of supporting the ladder diagram language.

BATCH S88

The ISA SP88 developed the S88 Standard to define batch control as a way to standardize recipe handling, equipment control, and the configuration of batch control systems so they fit together. The S88 Standard has served as the basis for almost all of the newer batch-oriented control systems on the market.

The S88 standard defined a hierarchy of modular control that supports reusable control components. The standard also provides for flexibility by allowing a recipe to determine the product-related characteristics of a process, while equipment control functions are embedded in the reusable modules.

Further, it defined and gave names to the modules that are in continuous and discrete control—referred to as "basic control" in the S88 standard. The standard also defines a layer of procedural controls that allows sequences of control actions to step a process through a recipe-defined procedure. Moreover, it defines the coordination controls, which keep all the other pieces of the system properly sorted.

Overall, the S88 Standard has provided an efficient means for collecting data in an understandable way from a process that, by its nature, is in a constantly changing state. S88 was adopted as an ANSII standard and has become an international standard (IEC61512-01).

The basic structure of the S88 standard is illustrated in Figure 4.12h.

SAFETY LOGIC

Safety systems and safety interlocks must be integrated into the overall process controls of the plant. Safety interlocks serve the protection and safety of operators, equipment, and the environment. Two major types of interlocks are used:

Failure interlocks—which are continuously active and usually serve to initiate equipment shutdowns
Permissive interlocks—which evaluate conditions in order to allow the starting or the continuation of actions

Several control languages have been used to implement safety instrumented control strategies. The most often used languages used are ladder logic, SFCs, and function blocks.

More recently there has been a move to embed safety features inside the DCS. Doing so leverages the configuration, diagnostics, alarming, history collection, and control capabilities of the DCS.

CONCLUSIONS

The IEC 61131-3 and IEC 61804-2 are graphical control language standards used in many modern control systems. The function block-type graphic language defined by IEC 61804-2 can be used in many measurement, calculation, control, and discrete logic applications.

For logic and interlock applications, the SFC-type control language defined by IEC 61131-3 may be effectively utilized. The ladder diagrams graphic language defined by IEC 61131-3 is supported by many PLC manufacturers for the graphic definition of their discrete logic. However, because it requires a large number of rungs for such applications as motor control, it can complicate the troubleshooting of the system. As a result, many control systems provide function blocks, which are designed to fully address such applications.

S88 has been widely adopted by the batch processing industries and is now part of most modern DCS systems. Similarly, the SIS safety control strategies are also embedded into some of the DCS systems.

INTRODUCTION

The operator's workstation is the area where operators follow the process and, if assisted by fast and accurate translation of raw data into useful animations, trends, and patterns, can make the required decisions and take the correct actions. As was shown in Figures 4.2d and 4.2e in Section 4.2, one continuously attended operator console is usually dedicated to each section of the plant.

The operator's console includes one or more cathode ray tube (CRT)/liquid crystal display (LCD) monitors (described in Section 4.5), a standard or custom keyboard, a sound card, speakers, and a pointing device such as a mouse, trackball, or touch screen. This operator interface either replaces, or in case of upgrading of existing plants (Figure 4.3f in Section 4.3) supplements, the control room panel, which was/is filled with single-case analog controllers, meters, and digital indicators.

In addition, the operator interface also replaces the previously panel-mounted start/stop pushbuttons and status indications, chart recorders, annunciators, and subsystem interfaces. In the early DCS systems, because of processor and memory limitations and because of lack of software, the operator interface displays consisted only of preformatted faceplates that provided measurement, alarm, and control. In modern DCS the faceplate-type displays have been replaced by graphic displays.

From the console the operators respond to alarms, adjust the operation of the process by changing set points or other parameters, "zoom in" on particular portions of the process for further details, and utilize specialized batch, advanced control, or business applications.

Here, the hardware and functions of the operator console are discussed first, followed by a more detailed description of the operator's graphics including both static and dynamic ones.

OPERATOR CONSOLE EQUIPMENT

The operator console is usually an Intel processor-based workstation with single or dual 19-in. (475-mm) or 21-in. (525-mm) monitors. Memory requirements vary from 256 Mbyte to 1 Gbyte or greater. Hard disks can be either SCSI or IDE and range from 10 to hundreds of Gbytes.

Peripherals include the two-button mouse, track ball, or touch screen with full duplex audio built into the motherboard. The allowable environmental operating ranges for the consoles are temperature 10 to 35°C (50 to 95°F), relative humidity 8 to 80% (noncondensing), vibration 0.25 G at 3 to 300 Hz for

FIG. 4.13a

a maximum of 15 minutes. A typical operator station is illustrated in Figure 4.13a.

Video Display

The process monitor, sometimes referred to as the operator's window into the process, is usually a 19-in. (475-mm) or 21-in. (525-mm) diagonal, multicolor CRT or LCD display. Some DCS systems offer smaller, mono-color screens for remote or dedicated functions. A few suppliers offer 25-in. (625-mm) diagonal screens for wall-mounted display, which are observable from the working area of the control room. The more common 19-in. (475-mm) and 21-in. (525-mm) monitors are for tabletop or console mounting.

Most suppliers depend on visible cursor control to define screen areas; some use light pens. Touch-sensitive screens (Section 4.22) are quite common. They give the operator the ability to call up, for example, a detail from a larger graphic display by touching the portion of the screen where the corresponding process is located.

One type of touch-sensitive screen uses a grid of conductive material that changes circuit capacitance when a crossing pair is touched. The material is embedded in a sandwich of transparent plastic. Another uses a grid of infrared light beams. Touching the screen breaks two crossing beams and triggers an appropriate response.

Flat tubes are seldom used because of cost and resolution limitations. Similarly, standard distributed control systems do not accept voice commands or talk back to the operator. The technology exists for both, and at the present rate of technological change, these features will be soon available.

The most difficult task at the console-based operations center is to effectively display on a limited screen area a complex plant operation, monitored by hundreds if not thousands of sensors. This task is made more difficult by the fact that a human being is capable of assimilating only a limited amount of information at one time. Because of these considerations there is a need for both "bird's-eye view" type overview displays, and for more details as contained in equipment graphic displays (Figure 4.13b). These displays tend to emulate the graphic panel of the traditional control room.

If the operator needs additional information concerning the operation of a particular control loop, detailed faceplate displays are also available (Figure 4.13h). Other displays provide graphs, trends, and information on dynamic responses. Most importantly, such features as hot links allow the operator to "zoom in" on specific problem areas by drilling into detailed information that concerns only that area.

Although providing useful displays for operators is a common goal of all DCS manufacturers, the solutions provided vary. Some suppliers give more emphasis to the keyboard in moving among the displays, effected by the use of dedicated function keys, addresses based on instrument tag numbers, addressing by group numbers, and function keys that are display dependent.

Display-dependent function keys relate directly to the display on the video screen: depressing the key selects the associated screen segment and expands its information content in the next display. Other techniques used in obtaining this kind of telescoping effect can include the use of auxiliary cursor positioning (mouse), touch-sensitive screens, light pens, pan-and-zoom joysticks, and some other more advanced and less developed techniques, such as voice actuation.

Keyboards

Both standard and custom-made keyboards are used. Standard keyboards tend to sit on a table top. Custom keyboards are often incorporated into the monitor housing or connected to the operator station by cable. The keys may be movable pushbuttons or they may be printed squares on a flexible membrane. The membrane-type keyboard is familiar to users of microwave ovens and pocket calculators. It has a cost advantage, besides permitting the design of imaginative keyboard layouts.

The switches operated by the keys may be sealed reed switches, Hall-effect switches that are operated by actuating a magnetically energized semiconductor, or capacitative switches that are operated by the motion of a plate at the end of a plunger, which increases the capacitative coupling between two other plates.

The membrane-type switch has a flexible, hermetically sealed covering. When the pattern of a key printed on the membrane is pressed, a conductive elastic sheet is pushed through an opening under the key picture, making contact with another conductive sheet beneath it.

Some custom keyboards are implemented as a touch screen/monitor combination. This approach provides considerable flexibility in arranging the key layout, choosing which keys to automate or script, and support. Usually a fourth display is dedicated for this style of usage.

Some keyboards use special function keys, which are programmable by the user. Others use a conventional typewriter keyboard combined with blocks of special-function keys whose purpose is predefined. Table 4.13c lists the functions that are commonly provided by keyboard keys.

TABLE 4.13c
Some of the Typical Key Functions Provided on DCS Keyboards

Standard typewriter keyboard:

- Numberpad: 0–9, + and –
- Cursor control: up, down, left, right, home
- Cluster
  - Alarm
    - Acknowledge
    - Defeat
    - Restore
- Trending
  - Trend time space
    - Increase
    - Decrease
    - Range limit adjust
      - Increase
      - Decrease
- Mode select
  - Automatic
  - Manual
  - Cascade
  - Computer
- Direct input keys (input number keyed from keypad)
  - Set point
    - Output
    - Bias
    - Ratio
  - Set-point trim—slow and fast entry
    - Raise
    - Lower
  - Output trim—slow and fast entry
    - Raise
    - Lower
  - Logic
    - On, Raise, Start, Reset
    - Off, Lower, Stop, Reverse
- Overview select
- Detail select
- Special function keys

Peripheral Devices

Operator stations can be customized by adding extra memory, disk drives, networking cards, monitors, printers, and in some cases, backup devices. Whereas in the past printers were standard accessories, today they also store events in structured or relational databases to provide better reports, responses to queries, and analysis. Some government agencies, such the Food and Drug Administration (FDA), require the storing and inclusion of all operator actions in the batch end report.

REMOTE AND WEB-BASED STATIONS

A number of vendors now offer remote access into their process as well as access to remote systems. The approaches seem to have been standardized; the two prominent ones are referred to by some suppliers as remote clients and Web pages.

Remote Clients

Remote Client access supports terminal services or remote desktop functionality. This capability allows full function operator workstations to be located remotely from the DCS. If it is used by engineers, they can operate and troubleshoot the DCS from their desktops with a direct local area network (LAN) connection or from remote locations using any of a variety of communications methods, including dial-up modems and virtual private network (VPN) connections. This capability is illustrated in Figure 4.13d.

The remote client is made up of two hardware components—a client computer and a server computer. The server computer provides information to the remote clients. The client computer can be any Windows-based computer or thin-client hardware capable of running the remote desktop

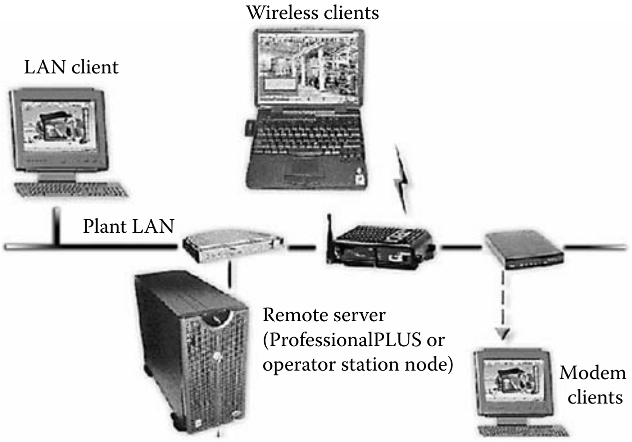

FIG. 4.13d
The control and access capability of the operator workstation can be made available remotely by wired or wireless means.

FIG. 4.13e
Example of a Web-style interface, the use of which is supported by some DCS suppliers. These displays can monitor process conditions and alarms and can also provide multivariable trend recordings.

connection software. Operator station software is not installed in this computer.

Web Pages

The widespread use and acceptance of the Web has led a number of vendors to fully integrate and support Web-style interfaces. Although security remains the key issue in this approach, at least one of the vendors, Honeywell, appears to have gone to great lengths to secure its Web services infrastructure.

Web pages and Web services offer a number of advantages. They include the ability to integrate more enterprise application content and make that content available to many users on their local or remote desktops. Examples include monitoring and analysis of process conditions, performance indicators, and alerts from devices and equipment. The use of Web pages is illustrated in Figure 4.13e.

OPERATOR GRAPHICS

A graphic operator interface shows the piping, instrumentation, and other equipment that is part of a unit operation of the process. The primary advantage of such an approach is that more information can be provided to the operator. However, the effectiveness of such interfaces depends a great deal on the accuracy and completeness of the graphic displays. Standardized display packages cannot provide that accuracy, while custom graphics require substantial investments of time from both the user and the vendor.

Modern distributed control systems include a variety of standard tools that can be used to create graphic operator displays. However, since the process equipment and associated field devices are unique to each plant and because most plants develop their own standard symbols and color schemes, the development of the graphic interface tends to be unique for each plant. The control system manufacturer does provide some tools and some guidance in the development of the graphic displays, but the actual work is usually done by the design engineering firm or the user.

The characteristics of the graphics systems vary with the needs of the users, but they all have to meet some basic requirements:

- The operator graphics must be highly reliable because process control operators cannot control the "process" without them. Their characteristics include:
  - *Must always be available.* In many cases, the application must be available for long periods of time (e.g., weeks, months, even years) without unplanned disruptions.
  - *Must be interacting.* Operator must always have the opportunity to "move on" to other displays and to get predictable responses to new directives even when previous requests take "too long" to complete or "everything is changing" due to a plant upset.
  - *Must be mistake-resistant.* Repeatable behaviors and user interaction features have to be provided to help reduce the possibility of high-cost "human errors," especially in high-stress situations.
- The graphics should provide extremely responsive interactions and fast call-up of process and historical information. This means that even large user-configured displays should be updated with live data from the DCS system within 1 second.

- The updating of data points, alarms, history, and dynamic graphic objects on the displays should occur in real time.
- The graphics should be suited for a dedicated (kiosk-style) operator environment and be resistant to programs or data on the workstation being damaged by users or people gaining access to unintended applications. The degree of restriction is usually user configurable so that the user can decide on access to the workstation.
- The graphics should interface with a wide range of user interface hardware features:
  - Two-, three-, or four-monitor video configurations
  - 4:3 (PC format) and 16:9 (HDTV format) aspect ratio monitors
  - Mouse + keyboard operation
  - Touch-screen operation
  - In newer systems, Tablet PC and PDA form factors and user input techniques
- The display graphics should provide the means for integration of operator tools/applications (e.g., batch, diagnostics, history viewing) with user-configurable displays (and user display logic) and also easy access to information related to display elements. These systems usually also provide easy access to auxiliary information sources (e.g., video feeds) and collaboration technologies (e.g., e-mail and instant messaging).
- The graphics should minimize the requirement for the operator to spend time in managing the windows and should allow the use of data sources not specifically engineered for use by the particular display.
- The display graphics must be provided with integrated user security and authentication facilities to support fast user switching and multi-user authentication for electronic signature requirements.
- The displays should provide a platform for improved information capture and analysis for operations staff. This usually includes features such as snapshot logs and the analyzing of alarm floods and history.

TYPES OF DISPLAYS

The operator station in the central control room functions somewhat like the cockpit of an airplane, where the pilot sits and observes all the information relevant to the performance of the plane. The operator of a DCS system depends on the video screen of the CRT/LCD for plant information. Because the preparation of the various graphic and faceplate displays for a particular DCS application is both expensive and time consuming, it is important that the responsibility for their preparation be clearly resolved before the purchase order is issued.

Each supplier has its own complement of lists, menus, and libraries (including measurement units and messages), which might include:

- Graphic displays
- Detail displays
- Faceplates
- Alarm summary displays
- Event summary display
- Trend displays
- Loop tuning displays
- Diagnostic displays
- Standard reports

The operator interface most often consists of overview, detail, faceplate, and trend displays. These will be discussed next.

Overview Graphic Displays

The graphic display of the whole plant provides a graphical and logical representation of the process, which makes it easier for operators to visualize what is happening. Overview displays are graphical displays with a lot of information to provide the operator with a "bird's eye view" of the process.

Such an overview display, as in Figure 4.13b, shows a section of the plant, with abnormal conditions animated (e.g., blinking) and/or colored (red). Additional animations are often provided to make the display more representative of the process. For example, a tank may be in the process of being filled, the agitator might be operating, etc.

The operator, looking at an overview display, can see at a glance the condition of all the loops and can quickly spot a process variable or piece of equipment that is out of control. The operator can also note trends or recognize patterns, even prior to the full development of their consequences.

On/off status can also be shown on an overview display. Discrete conditions (an open or closed switch, for example) can be shown as the presence or absence of a bar rising from the reference line. Sequential events can be displayed by displaying messages that change with the advance of the sequence.

If the overview display indicates an alarm condition the operator can, with a single keyboard stroke, easily call up a more detailed graphic display which shows the active alarm. If the operator wants still more detailed information, another keystroke can often be used to call up a faceplate and detailed display of the loop that generated the alarm.

Graphic Displays

Graphics are valuable training tools and help the operator in following plant conditions when a number of variables are changing. The graphic display capability of a DCS system allows for the creation of both overview and more detailed graphic displays.

Figure 4.13b illustrates the graphic display of a process that consists of three tanks. The graphic contains both process and control information, which is continuously updated in real time. On such a graphic, a pipeline downstream of a valve, for example, can become filled with color when the valve is opened or the symbol of the value can change color, say from black, when closed to green, which can indicate an open condition.

Some graphic displays are also capable of showing movement. For example, when liquid is flowing in a pipeline, when solids are traveling on a belt, when agitators are turning, or when fuel is burning in a combustion process, the associated movements are dynamically displayed. Obviously, this capability adds to both the cost and to the information content of the display.

Faceplate with Detailed Display

The detailed display is usually specific to a single loop or control function. Figure 4.13h illustrates a typical controller faceplate display. The bar graph in the faceplate display can show the controlled process variable, the set point, and the output. The transmitters or other sources from which these signals are received are also listed on the screen.

The display is identified with the tag number of the associated instrument; this tag number is also used in the DCS software to define the function. The tag number is added, using the keyboard like a typewriter to "fill in the blanks." The configuration of a function is done by moving a cursor to locations on the screen where values are to be entered and typing in the values on the keyboard.

In order to avoid errors or startup delays, it is advisable to make the preparation of the various graphic displays part of the DCS system supplier's scope.

Trend Displays

Analog strip chart recorders have been replaced by trend displays in DCS systems. They display the past values of the recorded process variable over a period of time. Some detailed graphic displays (see Figure 4.13e) include a real-time trend graph of the process variable covering the selectable period of the last 90 seconds, 1 hour, or 24 hours. In some displays, several trend graphs can be displayed at once, allowing comparison of the history of several variables. One supplier can accommodate up to four trends graphs in a single display.

Figure 4.13e also shows the trend display of several variables. This information is valuable to, for example, a foreman coming on shift who, by looking at these trends, can observe the recent patterns of operating history. It is also valuable to an operator after an upset has occurred because such trend recordings can help determine which condition was the cause and which were the consequences of an upset.

Trends can also display historical data records. This allows the operator to go back in time to find patterns or conditions that might have caused similar previous upsets.

STATIC GRAPHIC COMPONENTS

ANSI/ISA-S5.5-1985 is an American National Standard for Graphic Symbols for Process Displays. The stated purpose of this standard is to establish a system of graphic symbols for displays that are used by plant operators in the area of process measurement and control.

The goal of such standardization is to help operators comprehend the information that is conveyed through the displays and to provide uniformity throughout the process industries. The benefits of such standardization are a reduction in operator errors, faster training, and more accurate presentation of control systems. This standard is followed by many companies and is suitable for use in numerous industries.

However, the standard's two-dimensional line drawings are a mismatch with current commercial workstation technology, where some of the graphic displays are three-dimensional. Faster computers with graphics card accelerators and vector graphics are supported by most DCS vendors. High-definition visual display units, VDUs, are commonly available based on CRT or LCD technology that support 800 × 600 to 2048 × 1536 resolution. Object-oriented libraries or GDI software allow more complete three-dimensional representations of the process equipment.

Modern DCS systems include a graphic display editor and a comprehensive library of prebuilt display objects with professionally drawn three-dimensional representations of process equipment including pumps, valves, meters, piping, tanks, and other graphic objects.

Also, some systems may offer the capability to import graphics from a number of different sources including AutoCAD and Windows metafiles such as Visio vector drawings, as well as Windows Bitmap (.bmp) and Joint Photographic Experts Group (.jpg) image formats. These components may be used to create a realistic representation of the process with added dynamic information. An operator display created by using a library of three-dimensional components is illustrated in Figure 4.13f.

DYNAMIC ELEMENTS

If users decides to prepare the graphics on their own, detailed familiarity is required not only with the capabilities of the various DCS suppliers, but also with their software and the language they use, which might include such terms as "dynamos," "aliases," and "animation." Some of these terms will be discussed below.

Predefined objects such as knobs, dials, slide bars, and buttons are standard parts of any DCS graphic tool set and can be dynamically linked to information within the control system. Programmers call the workhorse of this linking process the dynamo (which has nothing to do with its "noncomputerize" meaning, the electric generator). The dynamo allows a particular field on the faceplate to be linked with a real-time reading and/or color that describes the state of the parameter associated with that field. In other words, "dynamo" in the language of the noncomputerese means the tool that is used to convert a field on a faceplate into a dynamic one.

A library of custom dynamos is typically provided by the DCS supplier; it can be used to access the actual real-time values of measurements, calculations, analog and control components, etc. Often these preengineered dynamos can be

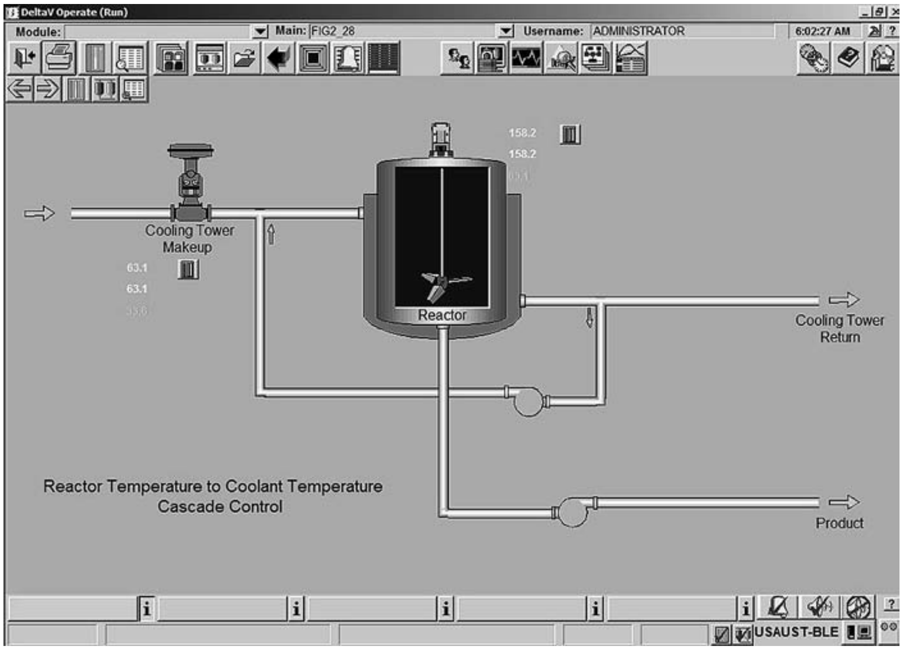

FIG. 4.13f
Some DCS systems offer the capability to import graphics, from which the experienced user can build the type of graphic display shown here.

customized to fit the specific needs and standard practices of the particular plant.

Dynamos

Standard dynamos typically include the key parameters associated with measurement and control functions. For example, a dynamo used to display a control loop may only display the controlled process variable, the set point, and the controller output. Therefore, the engineering units, for example, have to be added by the help of dynamos.

Process alarms associated with control loops can be shown in the dynamo by color change, such as changing the background color behind a number representing the value of a process variable.

Another use of color change can be to indicate that a loop is not in its designed/normal mode of operation. The ANSI/ISA-S5.5-1985 standard provides general guidelines for the use of colors in displays. Red, for example, is reserved to indicate an emergency situation such as the stopping of a motor or the actuation of a highest priority alarm. The predefined dynamos provided with a control system conform to this standard.

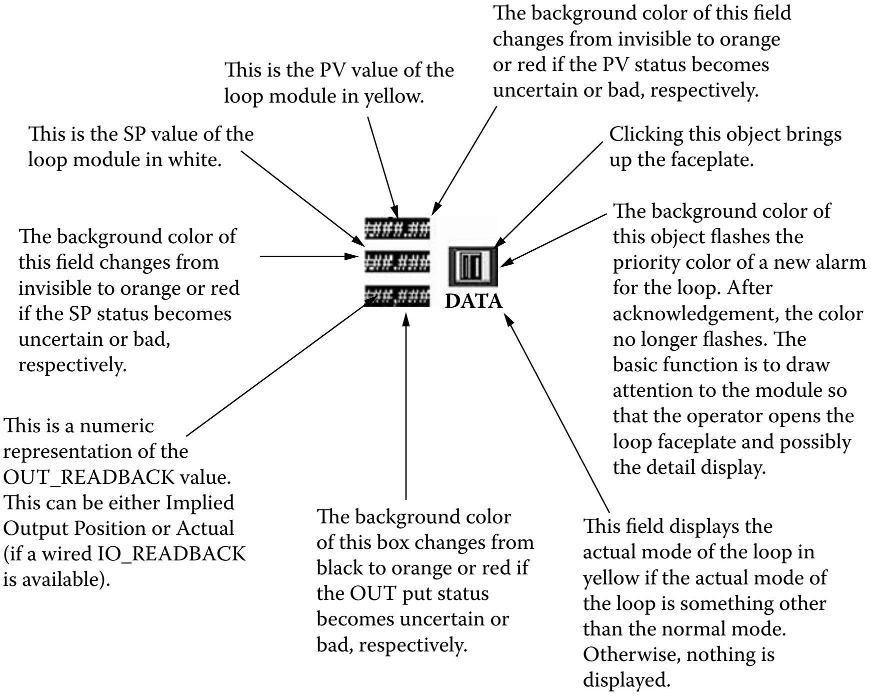
However, these guidelines may not match the traditions and past practices of the plant. In such cases, the colors used in dynamo templates can be modified to conform to the plant's standard. An example of a dynamo is illustrated in Figure 4.13g.

When the operator accesses a dynamo, a faceplate may be automatically presented providing further information on the parameter shown. For example, when a dynamo associated with a control loop is accessed, the faceplate presented to the operator may be used to modify the mode or change a set point or output. In addition, the capability may be provided to access further information, such as loop tuning, by selecting a detail display reference.

Parameters in a detail display, which can be changed by the operator, are determined by the system security. As shown in Figure 4.13g, in some designs, not all the parameter values are displayed all the time; instead, it is necessary for the operator to sequentially obtain them (by clicking) on a parameter-by-parameter basis. An example of a faceplate display with the associated detail display generated by accessing a control loop dynamo is shown in Figure 4.13h.

Just about any property in a display can be converted to a dynamic element and animated. A list of the more commonly used dynamic behaviors are:

- Text
- Visibility
- Scale
- Position
- Rotation
- Skew
- Enabled, disabled
- Stroke (pen size)
- Fill color
- Stroke color
- Gradient (both linear and radial)
- Font
- Font size
- Filter
- Images



This is the PV value of the loop module in yellow.

The background color of this field changes from invisible to orange or red if the PV status becomes uncertain or bad, respectively.

This is the SP value of the loop module in white.

Clicking this object brings up the faceplate.

The background color of this field changes from invisible to orange or red if the SP status becomes uncertain or bad, respectively.

The background color of this object flashes the priority color of a new alarm for the loop. After acknowledgement, the color no longer flashes. The basic function is to draw attention to the module so that the operator opens the loop faceplate and possibly the detail display.

This is a numeric representation of the OUT_READBACK value. This can be either Implied Output Position or Actual (if a wired IO_READBACK is available).

The background color of this box changes from black to orange or red if the OUT put status becomes uncertain or bad, respectively.

This field displays the actual mode of the loop in yellow if the actual mode of the loop is something other than the normal mode. Otherwise, nothing is displayed.

FIG. 4.13g
As can be seen from this example, the "dynamo" allows the programmer or the operator to link a particular field in the faceplate with a real-time reading and/or color that describes the state of the variable or parameter that is associated with that field.

Aliases

In order to speed up the tedious work involved in designing displays, some DCS manufacturers use "aliases." These software tools allow the designer to reuse previously designed displays or display segments and thereby eliminate the need for complete rebuilding of the displays for applications that are similar but are connected to different I/Os.

If the DCS system supports the use of aliases in the definition of similar pieces of equipment, the dynamic display components are usually designed to support dynamic referencing based on the piece of equipment selected for display. In such cases, preconfigured aliases and attributes are used in place of object tag or graphical attributes normally defined as part of the display object.

Thus, aliasing improves flexibility and reusability because display objects can be connected to different I/O points and can represent different graphical attributes, appearances, and security. Such capability can eliminate the need to completely

rebuild similar display objects. An example aliased substitution is shown in Figure 4.13i.

Another way to improve the reusability of displays, faceplates, dynamos, and similar equipment is through the use of class-based displays. With this technique the display designer can develop displays with dynamic or aliased references. For example, the user could base the references in a display against library- or class-based items (e.g., a Phase Class in a batch configuration). When the display is instantiated during runtime, the graphics engine would resolve references based on the object that the display is being opened against.

Display Access

The increased use of a mouse in the operator interface has changed the way operators accesses information within a graphic display. Displays are typically designed to support both horizontal (at the bottom of the display) and vertical (to the right of the display) toolbars. The control system typically provides default toolbars to support the following functions:

- Time and date display
- Alarm list with direct access to the display required to acknowledge the alarm
- Navigation to alarm summary, main menu, system status, last display, page back and forward, and print
- Alarm acknowledge and silencing

Figure 4.13j illustrates the operator display of one DCS supplier, showing scroll bars and navigational items that can be used by the operator.

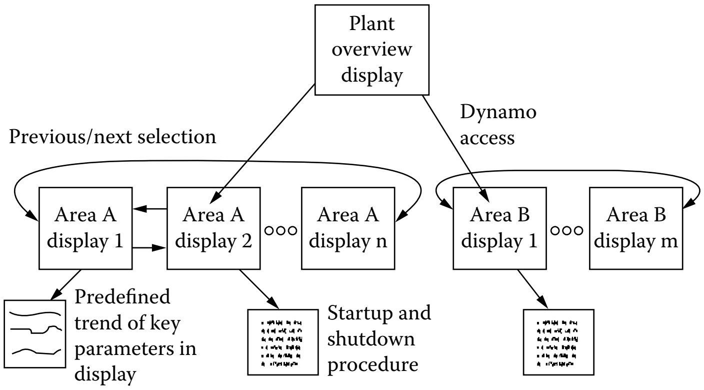

FIG. 4.13k
Example of the hierarchy for accessing information and trend for a display.

Using the page forward and page back feature of the toolbar, it is possible for an operator to access displays that contain information upstream or downstream of the displayed process. In addition, dynamos may be added for accessing another display. Through the use of these tools, it is possible to create a display hierarchy that allows, from an overview display, access to the key display in each process area.

Within the process area, it is possible to pan through the displays using a page forward/backward toolbar. Also, using a dynamo for display access and trend window access, it is possible to provide the operator with startup/shutdown information and trends of key parameters in a display, as well as in-context documentation, as illustrated in Figure 4.13k.

The graphics editor supported by the control system allows incorporation of animation into a graphic display. Using this capability, the static graphic component for process equipment may be modified to indicate the status of the equipment for example motor on or tripped. Also, animation may be used to represent dynamic data associated with the equipment such as showing the level of a tank using a filling technique or showing the status of an agitator by rotating the agitator to indicate that the agitator is on. In newer products, adding dynamics to the properties of controls (send-to-front, -back, send-forward, -backward) are used to show different information in the display based on the state of the process operation.

In some cases it is necessary to create a specialized display complete with user interface (UI) controls such as buttons, check boxes, or sliders. The user would also add behaviors to these specialized displays—the behaviors could be driven from parameters internal to the special display or from parameters in another display, the DCS, or some external source such as OPC. A designer creating such a display would in general keep all of the references unbound so that the specialized display could be activated in context from some other graphic item at run time.

PROCESS PERFORMANCE MONITORING

The graphic display capability may be used to create special displays, allowing easily monitoring of the status of critical equipment. Some examples of these types of applications are:

- First-out indication on a process shutdown
- Vibration monitoring
- Burner management
- Sootblower
- Safety system status

The associated displays are structured to summarize the information. In cases where moving equipment is involved, such as a sootblower, animation may be effective, allowing an operator to quickly access the operation.

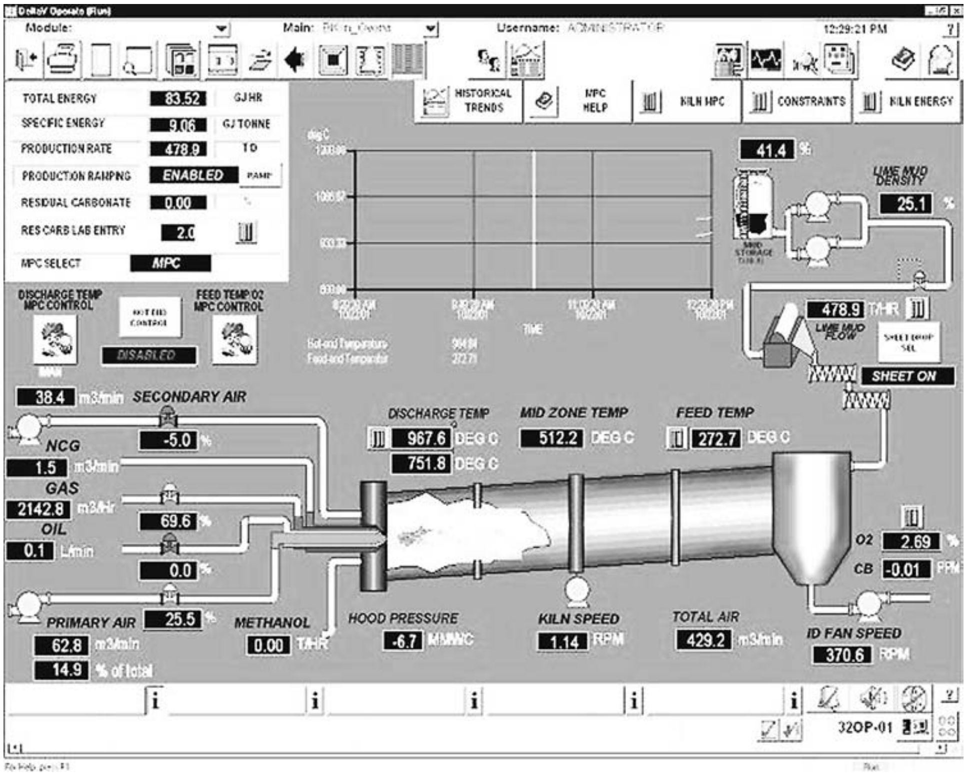
The calculation capability of most control systems is used to implement online calculation of operation cost, efficiency, and other performance indicators. This type of information may be easily incorporated into the operators' graphic display so that they can use this information to improve the process operation. An example of such types of calculations for a lime kiln operation is shown in Figure 4.13l.

PROCESS GRAPHIC DATA INTERFACES

A variety of data sources may be integrated into the process display graphics. The data may be sourced internal to the DCS from the runtime, historians (continuous, batch, event), and alarm services. The data may also be sourced externally from OPC, XML files, or even a hypertext transfer protocol (HTTP) browser. Supporting both internal and external data sources allows the operator displays to be used for a wider range of functions.

The ability to activate interfaces external to the operator graphics is a very powerful feature. Examples of this include calling up menus in context related to applications external to the graphics—for example, bringing up the menu to calibrate a device from the graphics system. This is illustrated in Figure 4.13m.

In special cases, the information may need to be displayed in a manner that is not supported by the control system. For example, some control systems do not support three-dimensional plotting of matrix values as is required



TOTAL ENERGY 83.52 GJ HR
SPECIFIC ENERGY 9.06 GJ TONNE

to show sheet gauging information. To address these special requirements, the graphics display may support terminal server client/server interface for accessing the subsystem.

CONCLUSION

The graphics capability of modern control systems allows construction of an effective operator interface. The graphic editors provided with the control systems are used to create custom graphic displays that represent the process equipment and the associated field measurements. Preengineered graphic components and dynamos are used to easily create the operator graphics. The display features may be used to create a display hierarchy that allows the operator to quickly access information in any part of the plant. Information from performance monitoring and from subsystems may be directly included in operator graphics or in some cases incorporated using terminal server technology.

Flow sheet symbol

Analog Inputs:	Single-ended (reference to signal common) or isolated, channel to ground — 600 V RMS Intrinsically safe (field circuit Class 1 Division 1, Zone 1, Zone 0) and redundancy options
Analog Input Ranges:	4 to 20 mA, 1 to 5 volts with optional digital communications (HART) Thermocouple, RTD Input resolution 12 bits (1 part in 4000) to 16 bits (1 part in 64,000)
Analog Outputs:	4 to 20 mA into a 700 ohm load Intrinsically safe (field circuit Class 1 Division 1, Zone 1, Zone 0) and redundancy options Resolution: 10 to 12 bits
Digital Inputs and Outputs:	24 or 48 volts DC; 120 or 230 volts AC; optically isolated Simplex or redundant
Fieldbus:	AS-Interface, DeviceNet, Foundation Fieldbus, Profibus
Other I/O Types:	RS232, RS422/485 half duplex, RS 422/485 full duplex serial communication ports, binary coded decimal (BCD), pulse count input, pulse duration output, sequence of events
Number of Loops of Control:	8 to 30,000
Display Interface:	CRT or LCD monitor, 19 in diagonal measure
Normal Operating Limits:	Temperature: 0 to 60°C Relative humidity: 5 to 95%, noncondensing Power supply: 115/220 VAC
Network:	IEEE 802.3 (Ethernet) 10BaseT or dual-speed 10/100BaseT network, depending on the hubs or switches; shielded twisted-pair cable connects each node to the hub or switch; maximum cable length from the hub/switch to a node is 100 m. For longer distances, use a fiber-optic solution.
Cycle Times:	Sample interval cycle times range from 0.02 to 0.2 sec/cycle for dedicated loop controllers and from 0.1 to 1 sec/cycle for multiloop unit operations controllers. Scan periods can be fixed or individually specified for each loop.
Partial List of DCS Suppliers:	ABB (www.abb.com) Emerson (www.EasyDeltaV.com) Honeywell (www.honeywell.com) Invensys (www.invensys.com) Siemens (www.siemens.com) Yokogawa (www.yokogawa.com/us)

INTRODUCTION

The instrumentation used to implement automatic process control has gone through an evolutionary process and is still evolving today. In the beginning, plants used local, large-case pneumatic controllers; these later became miniaturized and centralized onto control panels and consoles. Their appearance changed very little when analog electronic instruments were introduced. The first applications of process control computers resulted in a mix of the traditional analog and the newer direct digital control (DDC) equipment located in the same control room. This mix of equipment was not only cumbersome but also rather inflexible because the changing of control configurations necessitated changes in the routing of wires. This arrangement gave way in the 1970s to the distributed control system (DCS).

The DCS offered many advantages over its predecessors. For starters, the DCS distributed major control functions, such as controllers, I/O, operator stations, historians, and configuration stations onto different boxes. The key system functions were designed to be redundant. As such the DCS tended to support redundant data highways, redundant controllers, redundant I/O and I/O networks, and in some cases redundant fault-tolerant workstations. In such configurations, if any part of the DCS fails the plant can continue to operate.

Much of this change has been driven by the ever-increasing performance/price ratio of the associated hardware. The evolution of communication technology and of the supporting components has dramatically altered the fundamental structure of the control system. Communication technology such as Ethernet and TCP/UDP/IP combined with standards such as OPC allowed third-party applications to be integrated into the control system. Also, the general acceptance of object-oriented design, software component design, and supporting tools for implementation has facilitated the development of better user interfaces and the implementation of reusable software.

Major DCS suppliers introduced a new generation of process control systems based on these developments. These systems incorporate commercially available hardware, software, and communications. They fully integrate I/O Bus technology such as Fieldbus and Profibus into the system. Batch technology, advanced control, and safety system-oriented software packages are also being included as embedded technologies within the DCS system, although some suppliers might charge extra for some of that software.

These new systems are the foundation for the instrumentation and control implemented in new grass-roots plants. Also, because of the significant operational improvements, including such advanced features as abnormal situation prevention, which may be achieved with such systems, they are quickly replacing the early DCS systems.

More recently, some of the control functions have begun to move into the field. This move to further distribute control and functionality has opened the door to hybrid controllers available from most of the DCS suppliers.

These newer controllers are also being used as linking devices—interfacing with and integrating multiple I/O buses such as Fieldbus, DeviceNet, AS-Interface, HART, and conventional I/O into a single system, as is illustrated in Figure 4.14a.

DCS control, which has dominated the process control industry for years, has improved its performance and reliability. Over the years the DCS design has become more modular and, due to the reduction in the cost of its hardware, has penetrated even some of the smaller installations—especially where advanced capabilities such as alarm management, batch, and advanced control are needed. Installations consisting of only a single controller, one workstation, a bus arrangement such as AS-Interface and Fieldbus, and a small number of I/O are not uncommon.

A review of the nature of analog and DDC is useful in understanding why the DCS has been so successful.

Analog Control

Operators often receive large amounts of information concurrently. This information arrives in the form of alarms and value updates. The operator needs to be able to focus on critical information when an issue arrives, but at the same time, operators should be able to freely move about displays displaying the key aspects of their process. For these reasons, panel arrangements in the past proved to be unsatisfactory, particularly when handling a plant upset or emergency.

The DCS addressed these problems by assigning priorities to issues. Alarming features such as alarm prioritization, acknowledgement, suppression, and filtering play an important part in plant operations. Alarms are associated with control items so that a user in a single click can move from the alarm directly to the appropriate display or faceplate.

Analog instrument panel designs of the past consumed too much expensive space. Issues included recording instruments whose charts were filed in equally expensive storage locations, fixed instrument arrangements on the panel, and the fact that the panels do not easily permit the relocation of associated devices so that they can be observed as a unit. The requirement to run individual electric wiring from every transmitter and final control device to the control room also increased the cost of a project.

Other costs include the cost of real estate for the control room, the cost of the instrument panel, and the cost of utilities necessary to provide a clean and comfortable environment for the instruments. The DCS addressed this need by including trending directly into the operator workstations. Specific process conditions to be monitored were added directly into the displays. Other related items can be placed on the same trend or on a graphic display along with the trend.

More recently the cost of running individual pairs of wires from transmitters and to valves has been reduced by substituting the use of networks and I/O buses such as Fieldbus and Profibus.

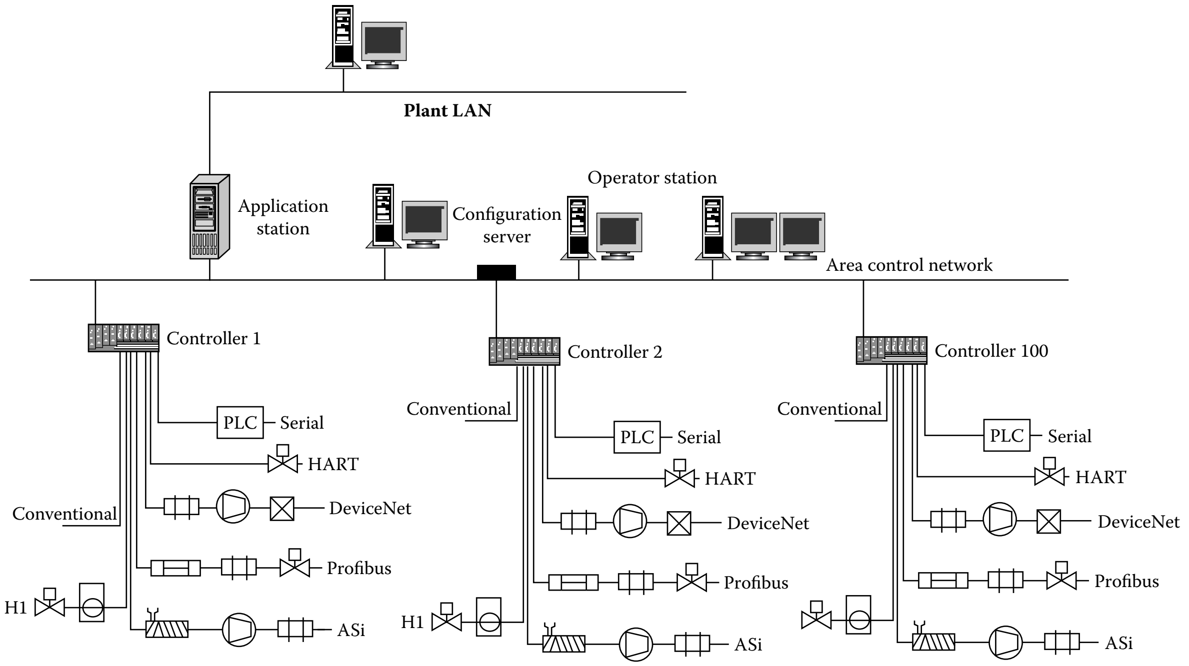

FIG. 4.14a
Current DCS topology integrating multiple I/O buses such as Fieldbus, DeviceNet, AS-Interface, HART, and conventional I/O into a single system.

DIRECT DIGITAL CONTROL

Direct digital control (DDC) and supervisory control of analog systems by computers are two other control options. In DDC a digital computer develops control signals that directly operate the control devices (DDC is rarely used in current DCS installations). In supervisory control, a digital computer generates signals used as reference (set-point) values for conventional analog controllers. Both options were offered by earlier generations of the DCS. Even with DCS systems this is still a problem to be reckoned with because each installation is different and requires a separate programming effort; however, the availability of standardized and tested DCS software packages for the more routine functions reduces this problem.

DISTRIBUTED CONTROL SYSTEM

The major components that make up a DCS process control system are illustrated in Figure 4.14b. The operator interface to the process is typically made up of standard off-the-shelf personal computers (PCs), standard keyboards, mice, and CRT or LCD monitors.

The use of custom keyboards and furniture for the operator interface is often not a viable option because of the associated cost and restrictions on operation. Initial fears that operators would not accept a standard keyboard and mouse have been proven wrong by successful installations on a variety of processes. To provide a wider view and range of control, dual or quad monitor arrangements are often included as part of the operator station.

Similarly, the speed, memory, and disk capacity of personal computers have proven sufficient to address the requirements of the engineering stations that are utilized for system configuration and diagnostics. Also, the price-performance of PCs has driven their adaptation as application stations for the integration of third-party software into the control system. Standard operating systems such as Windows NT and XP are often preferred because of the broad support available to manufacturers.

Equipment that the operator uses to monitor process conditions and to manipulate the set points of the process operation is located in a central control room or distributed on the plant floor close to the equipment. From these locations the operator can (1) view information transmitted from the processing area and displayed an operator display and (2) change control conditions from an input device. The controlling portions of the system, which are distributed at various locations throughout the process area, perform two functions at each location: the measurement of analog variable and discrete inputs and the generation of output signals to actuators that can change process conditions.

Input and output signals can be both analog and discrete. By means of electrical transmission, information is communicated between the central location and the remotely located controller locations. The communication path is either a cable from each remote location to the central station or a single

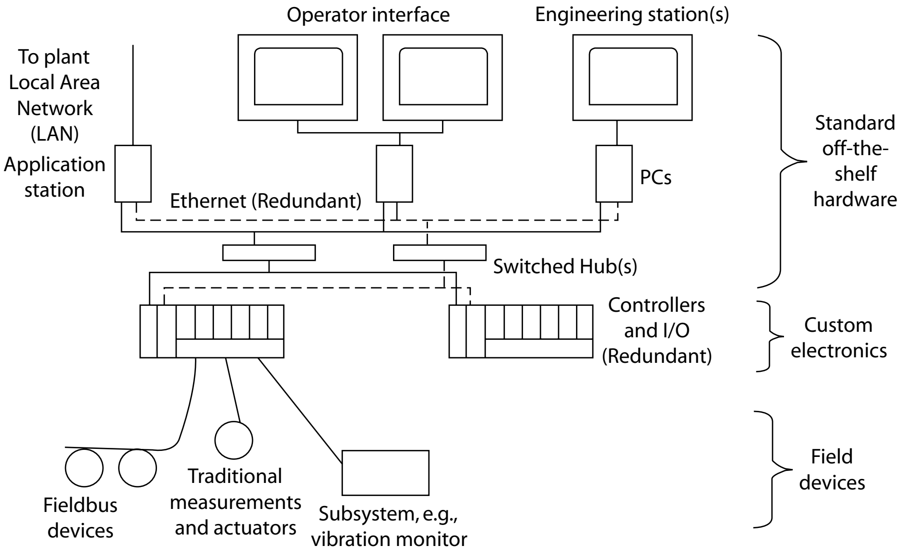

FIG. 4.14b
The components of a DCS system, shown from the perspective of its physical structure.

cable data highway interfacing all the remote stations. The cable in some cases can be a wireless connection via radio, microwave, or satellite.

Functional Components

Distributed control systems are made of several components including workstations, controllers, I/O cards, I/O buses, a control network, control technology, and software. The controllers are connected to field devices via analog, digital, or combined analog/digital buses. The field devices, such as valves, valve positioners, switches, and transmitters or direct sensors, are located in the field.

Smart field devices, if they are designed to conform the bus protocols for the I/O, can communicate on the buses while locally performing control calculations, alarming functions, and other control functions. Control strategies that reside in field-mounted controllers send their signals over the communication lines to the final control elements, which they control. The main components of a process control system are illustrated in Figure 4.14c.

Information from the field devices and the controller can be made available over a control network to the operator workstations, data historians, report generators, centralized databases, etc. These nodes run applications that enable the operator to perform a variety of operations. An operator may change settings, modify control modules within the controller or within the field devices, view the current state of the process, or access alarms that are generated by field devices and controllers. The system may support process simulation for the purpose of training personnel or testing the process control software, plus keep and update a configuration database.

DCS control systems are always sold as packages. Suppliers do not sell only the remote portions or only the centrally located portion. This is because the parts function together as a system; they must be completely integrated and tested as a system. Because the components of the system communicate over a shared data highway, no change is required to the wiring when the process and its control system are modified (Figure 4.14d).

DCS Control Network

The communication link from the controller and from the PCs supports the workstations for the operator, engineering, and applications of the DCS system. For process alarms and values needed by the operation, earlier DCS systems utilized customer communication interfaces. These have been replaced in most process control systems by less expensive Ethernet interfaces operating at communication rates of 10 or 100 Mbit.

With twisted pair wiring, the maximum distance between hub and workstations is limited, but this distance limitation can be overcome by using fiber-optic cables. For example, at a rate of 100 Mbit per second, the distance limitation for twisted pair of wiring is 300 ft (100 m), while with fiber-optic cable it is 6000 ft (2000 m). For the distance capabilities and relative features of various cable designs refer to Figure 4.14e and Table 4.14f.

Uncertainty in communications due to packet collisions can be eliminated by using full-duplex switches rather than hubs because each interface has its own channel on which to transmit. By designing the PC communication interface to utilize two Ethernet interface cards, it is possible to provide fully redundant communications.

As was shown in Figures 4.14b and 4.14c, the operators' console in the control room can be connected through a shared communications facility (e.g., area control network consisting of Ethernet hubs, switches, and CAT5 cable) to

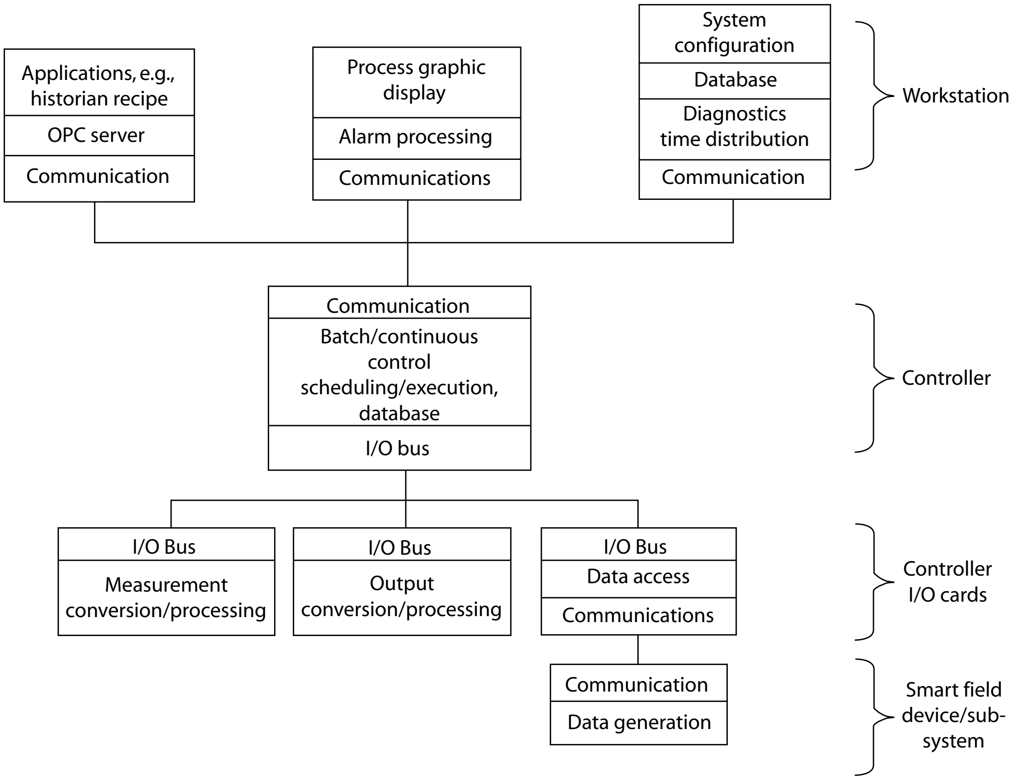

FIG. 4.14c
The main components of a DCS system, shown from the perspective of its main functional components.

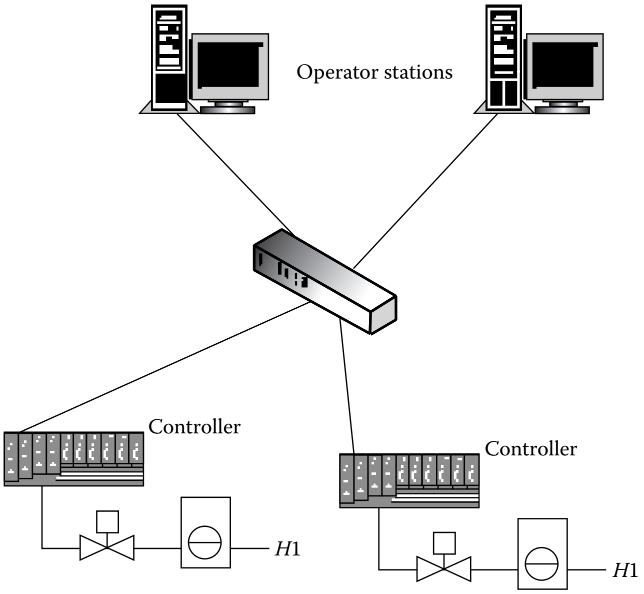

FIG. 4.14d
DCS communications are over area control network. In some cases switches may be used to manage the flow of traffic on specific network segments.

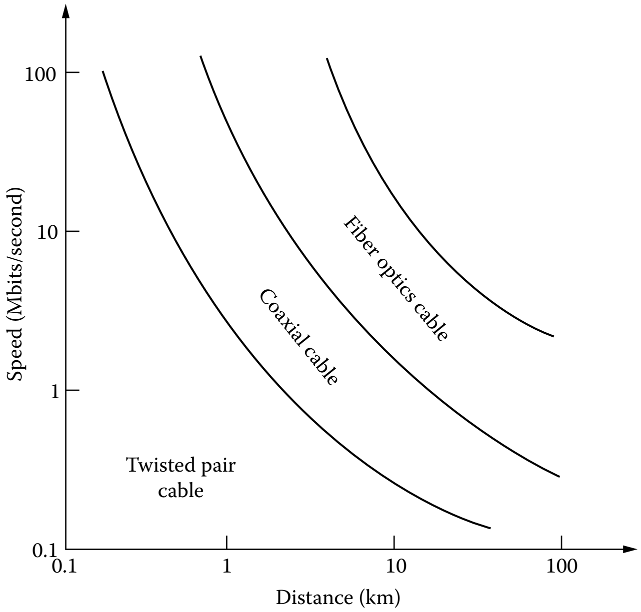

FIG. 4.14e
The capabilities of data highways made of twisted pairs, coaxial cables, or fiber-optic cables. (From M. P. Lukas, Distributed Control Systems, Van Nostrand Reinhold, 1986.)

TABLE 4.14f
*Relative Features of Different Data Highway Cables**

Feature	*Twisted Pair Cable*	*Coaxial Cable*	*Fiber-Optic Cable*
Relative cost of cable	Low	Higher than twisted pair	Multimode fiber cable comparable with twisted pair
Cost of connectors and supporting electronics	Low due to standardization	Low due to CATV standardization	Relatively high—offset by high performance
Noise immunity	Good if external shield used	Very good	Excellent—not susceptible to and does not generate electromagnetic interference
Standardization of components	High—with multiple sources	Promoted by CATV influences	Very little standardization or second sourcing
Ease of installation	Simple due to two-wire connection	Can be complicated when rigid cable type is used	Simple because of light weight and small size
Field repair	Requires simple solder repair only	Requires special splice fixture	Requires special skills and fixturing
Network types supported	Primarily ring networks	Either bus or ring networks	Almost solely ring networks
Suitability for rugged environments	Good, with reasonable cable construction	Good, but must protect alumium conductor from water or corrosive environment	Excellent—can survive high temperatures and other extreme environments

*From M. P. Lukas, *Distributed Control Systems,* Van Nostrand Reinhold, 1986. CATV: cable TV.

several distributed system components. These components can be located either in rooms adjacent to the control room or out in the field.

These distributed control units, which can be remotely located controllers, intelligent fieldbus devices, or remote I/O modules, can in some cases also provide a limited amount of display capability (low-level operator's interface, LLOI). An example of this is a local panel connected to a serial device using a MODBUS protocol.

A specific DCS for a particular plant is configured from standard building blocks marketed by most DCS suppliers. Figure 4.14b illustrates the categories of components that are available to configure various DCS systems. These components include the operator consoles in the central control room, controllers, I/O cards, communications components, and serial cards serving the interconnections with other digital systems such as PLCs and supervisory computers. The components also include bus cards interfacing to Fieldbus, Profibus, DeviceNet, AS-Interface, and other buses.

The process I/O signals are connected to I/O cards, which can fail. For all control loops that should continue functioning if the central processor or the data highway fails, the I/O should be directly connected to the location where the control is executing.

The preferred approach of control system layout is to keep all the I/O and all the associated controllers for a particular unit operation of the process (chemical reactor, distillation column, etc.) in the same physical controller. If this approach is implemented, the process will remain under control as long as the controller is functioning.

In critical applications, the controller and I/O modules can be made redundant.

Operator Console

The viewing applications, which may run on one or more operator workstations, receive data from the controller application via the control network and display this data to process control engineers, operators, or users of user interfaces, and may provide any of a number of different views, such as an operator's view, an engineer's view, and a technician's view.

Operator display applications are typically implemented on a systemwide basis in one or more of the workstations and provide preconfigured displays to the operator or maintenance people regarding the operating state of the control system or the devices within the plant. Alarm displays receive alarm signals generated by controllers or other devices within the process plant, control displays indicating the operating state of the controllers and other devices within the process plant, maintenance displays indicating the operating state of the devices within the process plant, etc.

These displays are generally preconfigured to display, in known manners, information or data received from the control modules or the devices within the process plant. Often displays are created through the use of objects that have a graphic that is associated with a physical or logical element and that is tied to the physical or logical element to receive data about the element. The object may animate the graphic on the display screen based on the received data to illustrate, for example, that a tank is half full or to illustrate the flow measured by a flow sensor.

Although the information needed for the displays is sent from the devices or configuration database within the process plant, that information is used only to provide a display to the user containing that information. As a result, all information and programming that is used to generate alarms, detect problems within the plant, etc., must be generated by and configured within the different devices associated with the plant, such as controllers and field devices, during configuration of the process plant control system.

Although error detection and other programming are useful for detecting conditions, errors, and alarms associated with control loops running on different controllers and problems within the individual devices, it is difficult to program the process plant to recognize system-level conditions or errors that must be detected by analyzing data from different devices within the process plant.

New control systems provide various levels of support for alarm management. In some cases control logic must be built into the control strategies. In other cases smart objects or agents are configured on top of the control strategy to detect abnormal conditions.

Core Architectural Components

The core architectural components of the DCS are:

- System configuration
- Communications
- Control
- Alarms and events
- Diagnostics
- Redundancy
- Historical data
- Security
- Integration

System Configuration Like any computer, distributed control equipment must be told what to do. Programming the process control system instructions is called configuring. There are several aspects to the configuration—the physical configuration and the control strategy configuration. These two activities are generally run in parallel and brought together as the project is engineered.

The configuration database enables users to create and modify control strategies and download these strategies via the control network to distributed controllers, consoles, and devices. Typically, the control strategies are made up of interconnected function blocks, sequential function charts (SFC), and equipment and units representations, which perform functions within the control scheme based on inputs and which provide outputs to other function blocks and/or I/O within the control scheme.

The configuration application also allows a designer to create or change operator interfaces, which are used by a viewing application to display data to an operator and to enable the operator to change settings within the process control system. Each controller and, in some cases, field devices too, stores and executes controller applications that run the control modules assigned and downloaded to implement actual process control functionality. The general configuration items are illustrated in Figure 4.14g.

For regulated and highly critical applications, such as those requiring Food and Drug Administration (FDA) certification, a record can be kept of any changes that are made to the control system configuration. Such an “audit trail” records all changes that were made, the names of people who made the changes, and the time and date when the changes were made. Provisions are also provided to automatically or manually undo any changes that are made in the control system.

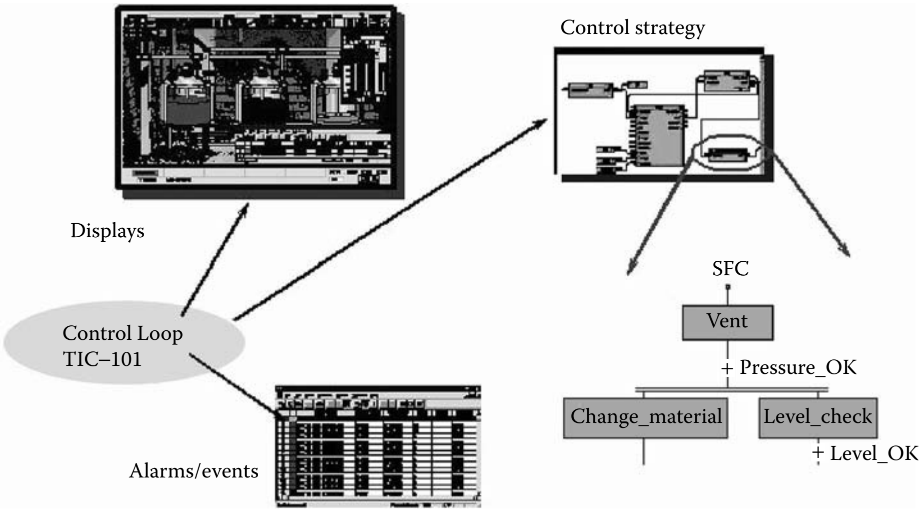

FIG. 4.14g
DCS system function configuration, showing the process display and a listing of alarms and other key events.

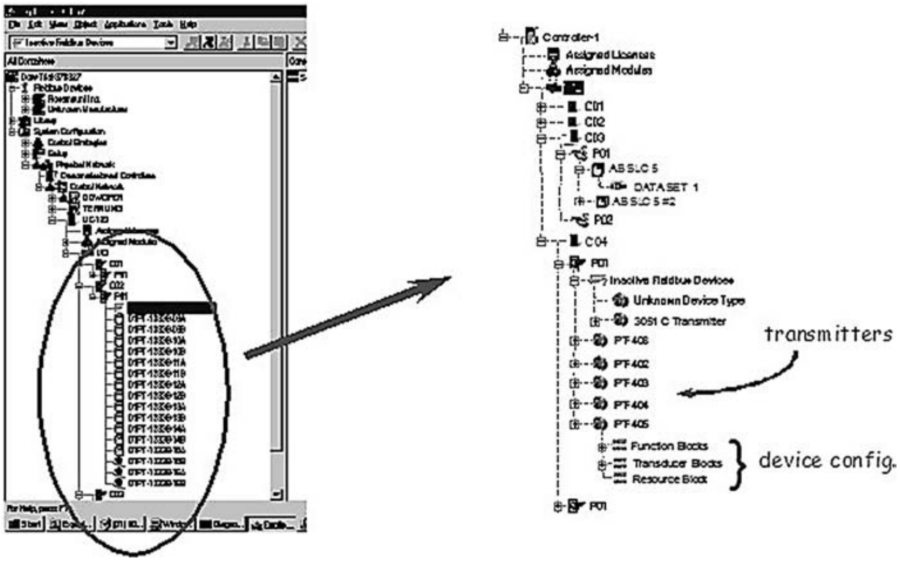

FIG. 4.14h
Physical configuration of nodes, cards, and other devices in the DCS system.

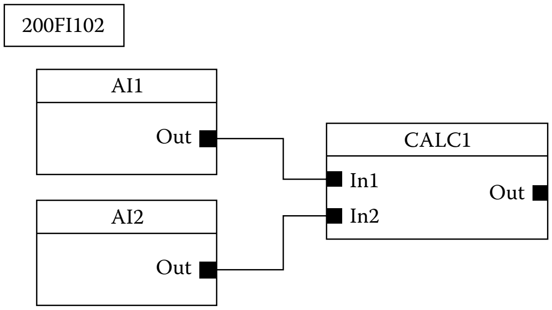

FIG. 4.14i
The configuration of a flow indicator module, with a tag number of 200FI102, is shown here, where two inputs (AI1 and AI2) are sent to calculation CALC1, which generates an output .

Physical Configuration The physical configuration requires configuring the nodes, cards, and devices. In many systems this activity is greatly simplified using auto-sense capabilities. The physical configuration of part of the system is illustrated in Figure 4.14h.

Logical or Control Strategies A distributed control system must have a consistent means of representing and referencing information. Ideally, such reference can be made independent of the physical device that holds this information. A common way to divide data within the control system is according to identifier tag numbers.

The S88 batch standard defines such logical grouping of measurement, calculation, or control as a module. When a control system follows this convention, then each module is assigned a tag that is unique within the control system. Based on this tag and the structure of the components in the module, it is possible for applications in the control system to reference any piece of information. For example, consider the module of an instrument with the tag number 200FI102 (which represents flow indicator No. 102 in area 200 of the plant). In the module a calculation identified as CALC1 is made using inputs AI1 and AI2 and generating an output as shown in Figure 4.14i.

Based on the module tag number and unique function block names within the module, the output of the calculation block is identified as 200FI102/CALC1/OUT.

DCS Systems support multiple control languages. The control languages include function block diagrams, sequential function charts, and structured text and may also include ladder diagrams and instruction lists. Some systems may be IEC 61131-3 compliant. Most control systems also include interlocking and batch capability — in most cases supporting S88. Some systems also support embedded advanced control and safety functions. The control strategies can often be mixed. Strategies can reference I/O as well as local and remote parameters.

An important feature of DCS systems is their ability under certain conditions to be upgraded online. In case of failure, most systems have extensive support for holding the last value, using a default value, or moving to some known state.

One of the features that make distributed control systems so powerful is their function library, which is available and can be used just by calling for it. This availability simplifies the task of the process control engineer, if he or she is familiar with the particular vendor's practices. Such a function library list of one supplier is shown in Table 4.14j.

What distinguishes some DCS suppliers from most PLC manufacturers and what distinguishes the various DCS suppliers from each other is the size and quality of the algorithm library that is embedded and freely available with their basic

TABLE 4.14j
Distributed Control Functions That Can Be Entered by Configuration

1. Highway definition — Assign names and addresses to the workstations and controllers that make up the DCS.
2. Configure reusable configuration components and store them in a configuration library.
3. Configure system level items such as enumeration sets, engineering units, and alarm priorities.
4. Configure loops, equipment, units, process cells, and areas. Make use of library as much as possible.
5. Bind inputs and outputs in control strategy to actual IO and devices in physical hierarchy.
6. Configure additional alarming.
7. Assign control strategies to controllers.
8. Configure historical values.
9. Download configuration into controllers, workstations, IO cards, and devices.
10. Tune parameters (gain, reset, sensitivity, ratio, etc.) and limits (alarm limits, output rate, etc.) for each control loop.
11. Check out sequences.
12. Check out first level of control strategy, displays, alarming.
13. Run water batches checking out critical loops. If this is a batch system, begin checking out phases.
14. Check out first level of control strategy, displays, alarming.

packages. When it comes to implementing some of the more advanced control strategies, it makes all the difference whether the algorithm library includes the algorithms that the particular project requires.

Some of these are analog inputs, sample and hold for dead time processes, dead band control for fast processes, set-point filtering, error squared, integral squared, dead time PID, set-point and process variable characterizers for nonlinear processes, decoupling of interactions, linear dynamic compensation of lead/lag blocks for feedforward, external feedback for antireset windup, self-tuning, and nonlinear adaptive controls, not to mention the more demanding algorithms for optimization, statistical process control, fuzzy logic, model-based optimization, sampled data control, sliding mode control, neural networks, and state-space controls.

Configuration of the control strategy often makes use of libraries of prebuilt control logic. The prebuilt control logic can be linked into final control strategies, in which case changes to the library can be automatically propagated to each control item. Alternatively, the prebuilt control logic can be embedded or unlinked so that individual control strategies are unaffected by changes in the library.

Batch and larger continuous projects, following the suggestions of S88, define strategies as a set of class-based items that can come together as a complete class-based strategy. If the required elements are offered by the DCS supplier, creating a control strategy from a class-based library can result in a significant set of configurations. Binding these configurations to actual I/O, loops, and equipment can become a “fill in the table” exercise.

Input/Output The requirements for redundancy and interfacing for I/O processing dictate that the process controller be of custom hardware design. Multiple processors are often used to address the communication and I/O processing and control execution. Also, a real-time operating system for embedded applications is often used to provide deterministic scheduling and execution of control. A large variety of I/O cards are normally provided to address a variety of field measurements and actuators:

Analog Input (isolated) 1 to 5 volt DC, 4 to 20 mA
Analog Output 4 to 20 mA
Isolated RTD input (2, 3, 4 wire) and Thermocouple Input (B, E, J, K, N, R, S, T)
Discrete Input 24 VDC, 120/230 VAC
Discrete Output 24 VDC, 120/230VAC
Pulse Count Input
Pulse Duration Output

Since digital transmitters and actuators that utilize a variety of communication protocols and physical interfaces are available, many manufacturers offer interfaces to the most common buses. Also, serial interface cards are often supported for interfacing to supporting systems. Examples of these communication interface cards are:

HART AI-Card, 4 to 20 mA
HART AO Card, 4 to 20 mA Series
DeviceNet (Baud rate 125 250 500 kbit/sec)
FOUNDATION Fieldbus
AS-Interface
Profibus DP Baud rate (9.6 19.2 93.75 187.5 500 1500 kbit/sec)
Serial Interface (MODBUS or Allen-Bradley’s Data Highway Plus protocol)

In addition, some manufacturers may offer I/O cards to meet special requirements. For example, sequence of events (SOE) input cards are used to capture process-upset events coming directly from devices in the field. Because events are captured and temporarily stored locally—on the SOE input card itself—faster recording for each of the channels on the card is possible. For example, events captured by an SOE input card are time stamped using a 1/4-millisecond resolution.

Input and output terminations are made at terminals that are either part of the electronic mounting frames or on separate terminal boards. In the latter case there will usually be a cable connection between the terminal board and the electronic controller file. Connections are usually made from the front of the cabinet. An alternate method is to use a separate termination cabinet, filled with rows of terminal strips. This requires extra wiring from the termination cabinet over to the terminals in the remote controller cabinet, but it has the advantage that field wiring can be completed before the distributed control housings are delivered and installed.

Conventional I/O Analog input and output signals will usually be carried on shielded, twisted pairs of copper wire. Digital inputs and outputs, either 120-volt AC or 24-volt DC, can be carried on twisted pairs, which do not, however, have to be shielded. Analog signals should never be run in proximity to alternating current wiring. The controller files operate almost universally on 1- to 5-volt signals, so the most common input is a 4- to 20-mA current signal, developing a 1- to 5-volt input across a 250-ohm resistor mounted on the input terminal board. Most distributed control systems can accept low-level signals from RTDs and thermocouples, performing the signal amplification in their input electronic circuitry. A few systems can accept pulse input with frequencies sufficiently high to allow signals from turbine flow meters to be used directly.

Most suppliers offer some conditioning of signals. Providing square root extraction, linearizing thermocouples, and resistance thermometers and dampening noisy inputs can be selected by configuration. Some input/output boards provide terminals with fused 24-volt DC power that can be used to supply a positive voltage to two-wire transmitters.

Separate terminal boards may also be supplied for digital input and output signals. Usually, optical isolation is provided. A DC input signal (or a rectified AC input signal) causes a light emitting diode (LED) in the isolating relay to be energized. A photoelectric device energized from the LED actuates a transistor in transistor–transistor logic (TTL) input circuitry to signal a digital input. A digital output signal is similarly isolated to actuate a transistor driver circuit for DC outputs or a triac for AC outputs. The solid-state relay from which the output is generated functions like a dry contact, and the output must be powered from a separate power source.

Diagnostics Integrated diagnostics is an important feature of the DCS. The diagnostics cover the hardware, redundancy, communications, control, and to some extent, the software that makes up the DCS.

Redundancy Redundancy is an important requirement for any critical process control application using DSC systems. These systems must have redundant communications, redundant controllers, redundant I/O cards, and redundant I/O communications. It is also possible to take redundant or preferably two out of three voting measurements and discard the defective or inaccurate one during control execution.

One advantage of redundancy is the ability to upgrade components online in the control system, but on critical processes this has to be very carefully planned so that safety will not be compromised.

Historical Data The DCS usually includes the ability to collect batch, continuous, and event data. A centrally defined history database is available for the storage of historical data. The value of any attribute, alarm or any control strategy, alert, or process condition can be recorded in the history database along with its status. In modern control systems the data values are collected as an integrated feature of the system. Events are collected and time-stamped at their source—in some cases down to a few millisecond resolution.

Users and layered applications can retrieve the batch, continuous, and event data in a time-ordered fashion. For security reasons values cannot be edited without leaving behind an audit trail.

Security Security is essential in process control. The DCS system must be able to limit the access to the various parts of the control system to authorized people only. This is done by user, plant area, and workstation. Layered applications have to form a session before they are allowed access into the system. There are several aspects to security as summarized below:

- *Authentication.* Access to the DCS for human users and layered applications users will be controlled through the use of password-protected user accounts.
- *User.* A human user of the DCS must have a user account on the system in order to gain access. All user accounts are named. User accounts have unique names within the scope of a site. All user accounts have a password, which must be provided in conjunction with the account name in order to start a DCS session.
- *Plant area security.* A user account can be permitted or denied access to make changes within zero or more plant areas within a site.

For each plant area where access is permitted, access can be restricted at runtime according to the classification of the runtime attribute data. For each plant area where access is permitted, the ability to make configuration changes can be restricted.

A user account can be permitted or denied access to view or modify user account and privilege information.

In some systems it is also possible to enable authorization. In these cases a user, or in some cases several users, will need to confirm by password the changing of certain parameters, starting/stopping a batch, etc.

Integration When a new plant area is added or expanded, the operators of the new area may need some information about the existing plant to provide a coordinated operation. Similarly, the operators of the existing plant may need to have feedback from the new process area in making decisions on how best to run the balance of the plant. In most cases, only a small fraction of the information in either system must be communicated to support such coordination between these areas. Several techniques are used to integrate systems.

The OPC Foundation has defined an industry standard for accessing information within a control system. Thus, many control systems provide OPC server capability in workstations designed for interfacing to the plant local area network (LAN).

OPC client applications in this station or on the network may access information using the path convention supported by the control system.

International Fieldbus Standards

The adoption of the IEC1158-2 Fieldbus standard by the major DCS manufacturers has ushered in the next generation of control and automation products and systems. Based on this standard, fieldbus capability may be integrated into a DCS system to provide:

- Advanced function added to field instruments
- Expanded view for the operator
- Reduced wiring and installation costs
- Reduced I/O equipment by one half or more
- Increased information flow to enable automation of engineering, maintenance, and support functions

Similarly, the Ethernet and OPC industry standards have provided DCS manufacturers a defined means for other applications to access information in a process control system. Through the active use of control system data in a plant information system, the operation benefits that may be achieved are:

- Improvement in production scheduling
- Better inventory control
- Consolidation of maintenance and operation information from multiple sites

DATA HIGHWAY DESIGNS

DCS systems today range in size from a single stand-alone laptop for the purpose of plant design and simulation to full-scale systems covering a whole plant. The systems come complete with integrated Web services for plant integration — often supporting a variety of open standards, such as OPC, for communicating with outside data sources.

Control Network

The communication infrastructure on the area control network supports the following:

- *Connections.* Connection between nodes in the system.
- *Unsolicited communications.* Transferring real-time information as data changes.
- *Synchronous and asynchronous read/writes.* Reads and writes block/don't block during the transaction.
- *Passthrough messages.* Transfer of hosted messages across control network to device, serial, or other network.
- *Configuration downloads.* Transfer of configuration from engineering node to controller and devices.
- *Auto-sensing.* Automatic detection of controllers, workstations, I/O cards, devices.
- *Diagnostics.* Diagnosis of system components, control strategies, etc.
- *Debugging.* Debugging of control strategies.
- *Directory services.* Location services to find nodes, cards, control strategies, devices, and other items in the system.
- *Online upgrades.* Upgrading a system that is in operation.
- *Hot/warm /cold restart.* Restarting a control strategy from backup.
- *Secure and unsecured access.* Security required to access information in the system.
- *Alarms and events.* Alarms and events are generated by the control strategy and system.
- *Device alerts.* Device alerts are generated by devices and equipment in the control system.
- *Time synchronization.* Time synchronized across nodes, devices, and sometimes I/O (e.g., sequence of events recording).

The data highway is the communication device that allows a distributed control system to live up to its name, permitting distribution of the controlling function throughout a large plant area. Data highways vary in length as a function of traffic capability and speed of transmission.

The most popular medium is Ethernet CAT5 cable. Several suppliers still offer twisted and shielded coax cables. In situations where noise is extensive, either fiber optics or wireless may be used—with fiberglass cable being the most prevalent. This is used most commonly for point-to-point connection between switches and hubs. Fiber optics is attractive for use as a data highway because it eliminates problems of electromagnetic and radio frequency interference, ground loops, and common mode voltages; it is safe in explosive or flammable environments; it can carry more information than copper conductors; it is inert to most chemicals; and it is lighter and easier to handle than coaxial cable. For more details on fiber-optic transmission refer to Section 3.7.

Ethernet Configuration

Hubs and switches can be used for 10 or 100 Mbit and even 1 Gbit per second networks. With Ethernet switches, each port auto-senses the speed of the attached workstation or controller and then operates at that speed. Standard DCS architectures operate at 100 Mbit per second speed.

Figure 4.14k illustrates a Class II repeater network where the maximum distance between workstation A and workstation B (the furthest points) can be up to 672.6 feet (205 meters) when up to two of the dual speed hubs are daisy-chained with twisted pair link segments. Each port on the switch can support up to 328 feet (100 meters) of twisted pair cable; however, only 672.6 feet (205 meters) is allowed end to end. This leaves 16.4 feet (5 meters) for the twisted pair link segment between the hubs.

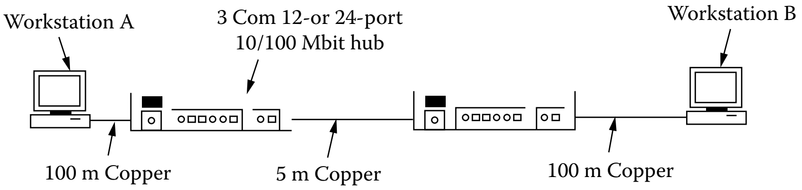

FIG. 4.14k

Ethernet-based control network switch configuration, where the maximum distance between workstations is up to 672.6 feet (205 meters). Each port on the switch can support up to 328 feet (100 meters), and 16.4 feet (5 meters) are allowed for the twisted pair link segment between the hubs.

An alternative is to use shorter-length cables (less than 328 feet [100 meters]) from workstation or controller to hub and allow a longer cable between hubs. Any combination will work as long as the total of all cable lengths does not exceed 672.6 feet (205 meters). It is a good practice to use a 16.4-foot (5-meter) or shorter cable between the hubs to avoid problems later if a new cable needs to be attached to the hub. This is to avoid a situation in which the 672.6-foot (205-meter) maximum length is exceeded because the length of the intra-repeater link is not known and an assumption is made that all ports can have a 328-foot (100-meter) cable.

ALARM MANAGEMENT

A critical part of the DCS is its integrated alarms and events system. The system provides configuration, monitoring, and notification of significant system states, acknowledgments, and priority calculations. Events represent significant changes in state for which some action is potentially required. An active state indicates that the condition that caused the event still exists. The acknowledge state of an event indicates whether an operator has provided acknowledgement that an event has occurred. In most systems event types can also be defined.

The event type specifies the message to be displayed to an operator for the various alarm states and the associated attributes whole value should be captured when an event of this type occurs. Event priorities can also be defined. An event priority type defines the priority of an event for each of its possible states.

Many DCS systems now also support device and equipment alerts. Like process alarms, alerts can have priority assigned to them, can be acknowledged, and convey information related to the condition that caused them. Unlike process alarms, however, these alerts are generated by the DCS hardware or devices and equipment external to the DCS.

Alarms and alerts are presented to the operators in alarm banners and summaries. Using these specialized interfaces, operators can quickly observe and respond to conditions. They typically use these specialized displays to navigate to a display where they can view additional details and take action as appropriate.

Operators can also suppress and filter alarms. Alarm suppression is typically used to temporarily remove alarms from the system for which some condition exists that the operator knows about (e.g., a piece of equipment has been shut down). Alarm filtering provides a way for the operator to view collections of alarms.

The following paragraphs describe alarm processing and alarm management and conclude with a discussion of higher-level applications built on top of the overall alarm processing and management system.

Alert Processing

In 1996 the SP50 committee finally finished its standards, including field-testing, and made the standards available in the form of a commercial product.

As part of SP50 alarms and events, collectively known as alerts, were included as part of the function block efforts of Foundation Fieldbus and IEC 61804. In these standards, alarms and alerts represent state changes within function block applications. Resources each have an alert notifier responsible for reporting their alert occurrences. Alerts objects are used to communicate the event to other devices.

An alert notifier examines the results of resource, transducer, and function block executions to determine whether any of a defined set of alert states has been entered. For alarms, both entering and exiting alarm conditions are defined as alert states. When an alert occurrence has been detected, the alert object builds a report message, referred to as an event notification, and publishes it onto the network. The time at which the alert state was detected is included as a time stamp in the alert message. The reporting of alerts may be individually suppressed.

A reply is required that confirms receipt of the notification. If the reply is not received within a time-out period, the alert may be retransmitted.

Alerts may also be acknowledged. Acknowledgment indicates that the alert has been processed by an interface device to satisfy operational interface requirements.

An alert notifier examines the results of function block executions to determine whether any of a defined set of alert states has been entered. When an alert occurrence has been detected, the alert notifier builds a report message, referred to as an event notification, and publishes it onto the network through the alert object.

Based on the type of alarm and event information, which may be reported by blocks contained in a resource, up to three classes of alerts may be defined in the resource:

1. *Analog alert.* Alert used to report alarms or events whose associated value is floating point
2. *Discrete alert.* Alert used to report alarms or events whose associated value is discrete
3. *Update alert.* Alert used to report a change in the static data of the block

A reply is required from one interface device that confirms receipt of the notification. If the reply is not received within a time-out period, the alert notifier will retransmit the notification. This method ensures that alert messages are not lost.

The following alarms are supported by Foundation Fieldbus devices:

0 = Discrete alarm
1 = High high alarm
2 = High alarm
3 = Low low alarm
4 = Low alarm
5 = Deviation high alarm
6 = Deviation low alarm
7 = Block alarm

Associated with each alarm is a time stamp that indicates the time when evaluation of the function block was started and a change in alarm state was detected that is unreported. The time-stamp value will be maintained constant until alert confirmation has been received, even if another change of state occurs. Also, the value of the associated parameter at the time the alert was detected is reported.

A function block must detect the alarm condition. The alarm must be transported to the responsible entity, e.g., interface device supporting human interface. The entity must confirm that the transport was successful. The alarm may require that a plant operator acknowledge that the alarm has been noticed, even if the condition has cleared.

Every occurrence of an alarm must be balanced by a notification that the alarm has cleared or that the same alarm has occurred again before the clear could be reported. An alarm will also be cleared in a device when 1) an alarm that is active is disabled or 2) a block containing an active alarm is placed in out-of-service mode. In these cases, specific alarm-clear messages should be generated, to allow remote alarm summaries to clear the alarm information for this block.

Each alarm and event parameter may have an associated priority parameter. The alert priority enumeration value is:

0 = The associated alert may clear when the priority is changed to 0, but it will never occur.
1 = The associated alert is not sent as a notification. If the priority is above 1, then the alert must be reported.
2 = Reserved for alerts that do not require the attention of a plant operator, e.g., diagnostic and system alerts. Block alarm, error alarm, and update events have a fixed priority of 2.
3 to 7 = Increasing higher priorities; advisory alarms.
8 to 15 = Increasing higher priority; critical alarms.

The alert object allows block alarms and events to be reported to a device responsible for alarm management.

The alert object contains information from an alarm or update event object, which is to be sent in the notification message. The alert object will be invoked by the alert notification task. If multiple alarms or event parameters are unreported, then the one with the highest priority or the oldest of equal priority will be selected by the alert notification task. The selected alert object is sent in a message at the first opportunity—less than the alert confirm time. If a confirmation from an interface device is not received by the alarm notification routine in the field device within a time determined by the resource block confirm time parameter, then the alert will be considered unreported so it may be considered for selection.

Figure 4.14l illustrates the transport of an alert.

Alarm Management Operator consoles maintain a list of active alarms in the system:

- Consoles register an interest in alarms/events (by plant area) in all other nodes in the system.
- The alarm state change events are routed to the software that maintains the active alarm list.
- Active alarms may be regenerated in order to build the active alarm list in workstations starting up, or when additional plant areas are required.
- In the background, alarms are resynchronized to keep the active alarm lists accurate (in particular, remove “dead” active alarm list items for alarm parameters/modules/nodes that are no longer out there and communicating (and did not get a message out before they went away).

Workstations select which alarms are eligible for inclusion in the workstation alarm list:

- Must be in workstation’s “alarm scope” (set of plant areas).
- Must be in current user’s “alarm scope” (set of plant areas that user has one or more security keys for).
- Area level alarm filtering (per workstation) must be set to enable alarms from that area.

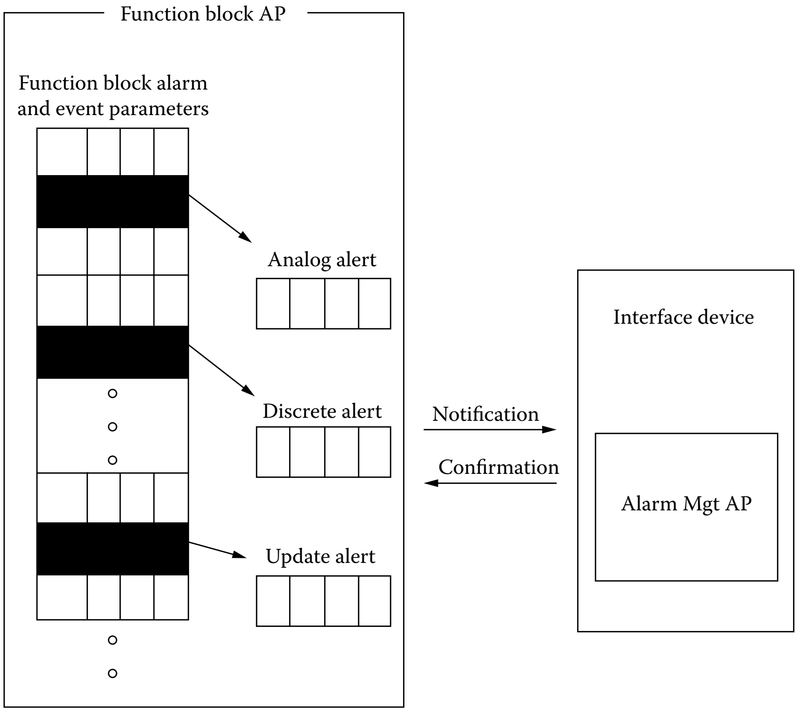

FIG. 4.14l
Alert event notification and confirmation.

- Unit level alarm filtering (per workstation) must be set so if the alarm is associated with a unit, that unit does not have the alarm turned off.

The workstation alarm list maintains the list in order of importance:

- Unack ahead of acked
  - Then: Higher priority ahead of lower priority
    - —Then: Condition still active ahead of condition cleared (latched)
      - —Then: more recent "went active" time ahead of older alarms

When alarms and alerts arrive at the operator console they are first classified. Alarms and alerts can be classified into process alarms, device/equipment alarms, and hardware alarms.

Process alarms cover "traditional" process alarms: HI, LO, HI-HI, LO-LO, DEV, etc. They are highly configurable:

- User-configurable alarm (parameter) names
- User-configurable alarm types (alarm words, category, message content)
- User-configurable alarm condition (with arbitrarily complex logic to arrive at the alarm condition)
- User-configurable priority
- Unlimited number per containing module

Device alarms are from instruments, transmitters, valves, and equipment attached to the DCS. Relatively little configuration is needed:

- Limited/fixed number of distinct alarms:
  - FAILED
  - MAINT
  - ADVISE
- Alarm conditions have "fixed" mapping to the alarms.
- User-configurable priority, and whether or not alarm should be enabled.

Hardware alarms are triggered by the hardware components of the DCS (controllers, I/O cards, remote I/O communication links, redundant hardware, etc.). Relatively little configuration is required.

Operators usually interact with the alarm system through alarm banners and alarm summary displays.

DCS ATTRIBUTES

The DCS has a number of advantages over other control approaches. If the client and design engineering firm are highly experienced, distributed control can reduce overall installation, configuration, and commissioning costs. Less wiring is required when information is transmitted over bus networks.

From the point of view of the operator, the interface with the process is improved. Integrated alarming and diagnostics substantially improve the operator's ability to identify the causes of upsets and to bring the process back under control.

Configuration capabilities allow for prebuilding portions of the control system configuration, which can be reused on other projects. There is great potential for extensive standardization of control systems.

The distributed control system is flexible and relatively easy to expand.

Reliability

Digital computers are more reliable today than when they were first introduced, but the possibility of failure of a single piece of electronic equipment causing the shutdown of an entire production facility still raises concerns that cannot be ignored. How does distributed control satisfy the requirement for continuous production?

Most suppliers subject their equipment to extensive periods of cycling at temperatures exceeding the extremes listed in equipment specifications. This weeds out the components most likely to fail. Failures of marginally operational parts will usually show up in the first few weeks of operation. Once past that period, electronic equipment seems to operate indefinitely, so long as limits of temperature and atmospheric cleanliness are observed. The advent of large-scale integration (LSI) has fostered this reliability. As size has been reduced, so has heat generation.

Nevertheless, failures will inevitably occur. Consequently, suppliers provide redundancy in their design, as well as backup. Some suppliers simply build two of everything and supply it as standard. Others offer redundancy on an optional basis. Power supplies, data highways, traffic directors, and remote controller electronics are important links in the communications chain and should be considered as candidates for redundancy. The operator station itself, with its video terminal, will not shut the system down if it fails, but it will leave the operator blind to the condition of the process, and so it is another candidate for redundancy.

There should be automatic transfer between redundant parts, so that if one fails the other takes over with no disturbance of the operation or output. At the same time, there must be some sort of alarm to alert the operator to the fact that a failure has occurred. How much redundancy is provided must depend on how much loss of production will cost. If continuous production is absolutely necessary, no expense cutting is justified.

Another form of redundancy, available from most suppliers, is controller backup. A complete modular file is mounted in the same remote location as others that are considered important enough to require backup protection. Some suppliers back up one complete set of electronics with another complete set, updating the database of the backup unit as that of the primary is changed. The two are cabled together, and on failure of the primary, the secondary takes over automatically.

Another supplier backs up eight controller files with a single backup file, and if any of the eight fails, its place will be taken by the backup unit. Still another supplier, in addition to supplying one-for-one backup, allows portions of the backup file to back up portions of the primary controller file, freeing the unused portions of the backup file for additional control tasks.

Mean Time between Failure

High availability is as important as reliability. Defining availability as the ratio of mean time between failure (MTBF) to mean time between failure plus mean time to repair (MTBF + MTTR), it is clear that a system will be most available when it is very reliable (high MTBF) and can be quickly repaired (low MTTR). Since distributed control equipment is highly modular and contains many printed circuit cards, time to repair can be very short if sufficient spare parts are available.

Most systems make good use of diagnostics; internal failures are reported on the CRT screen, indicating where in the system a failure has been detected and providing some clue to the cause. Substitution of printed circuit cards can often restore operation, and this can be done quickly by a service technician who knows where to look for the trouble and has spare parts for making the substitution. The failed card can then be returned to the supplier for replacement.

High-availability process control systems are essential in case of large continuous processes such as a cracking unit in a petroleum refinery. Such units can be designed to run with no shutdown for 5 to 6 years while running 24 hours a day 7 days a week. Some parts of the system can be made redundant so that automatic switchover might occur in case of a failure. Other parts of the system can be provided with automatic fault diagnosis and identification for rapid repair.

For such applications obviously one would hope and aim to design a system that allows the failed unit to be replaced while the process continues without interruption, but in the real world Murphy's Law often comes true.

The high diagnostic coverage and rapid replacement capabilities of the controller and I/O assemblies allow the user to decide how much redundancy is really needed for an application. A customer may choose to use simplex I/O and possibly even simplex controllers, where failure events are not significant as long as the failures are automatically diagnosed and reported and the repair steps are simple.

To address this, built-in diagnostics that identify the majority of assembly failures are provided by some suppliers. In addition, all of these assemblies are "hot pluggable" (a "computerize" buzzword for testing while in operation) so that an I/O assembly can be diagnosed and repaired efficiently. Some controllers are also able to check whether a new card is the proper type when replacement of a failed card is needed.

TABLE 4.14m
Sample Price List for DCS Components

	Description	*Price Range ($US)*	*Typical ($US)*
1.0	HARDWARE W/SOFTWARE LICENSE		
1.1	Control unit, w/carrier, power supply	5300 to 6600	5500
1.2	Redundant control units	11,700 to 14,300	13,000
1.2	Operator's console w/21" monitor (1200 I/O)	9,800 to 10,300	10,000
1.3	Engineer's station w/21" monitor (1200 I/O)	20,000 to 22,000	21,000
1.4	Analog input (AI) card, 8 channel w/HART	1400 to 1800	1500
1.5	Analog input (AI) card, 8 channel w/HART redundant	2500 to 3000	2800
1.6	Analog output, 4 to 20 mA, 8 channel w/HART	1700 to 1900	1800
1.7	Analog output, 4 to 20 mA, 8 channel w/HART, redundant	2700 to 3300	3000
1.7	Foundation Fieldbus interface card w/2 segments	2200 to 2900	2500
1.8	Discrete input, 24 Vdc, 8 channel	520 to 630	550
1.9	Discrete output, 24 Vdc, 8 channel	1000 to 1150	1100
1.10	Discrete input, 24 Vdc, 8 channel as fieldbus I/O	820 to 930	850
1.11	Discrete output, 24 Vdc, 8 channel as fieldbus I/O	1000 to 1150	1000
1.12	Discrete input, 24 Vdc, dry contact, 8 channel, redundant	1000 to 1200	1100
1.13	Discrete output, 24 Vdc, hi-side, 8 channel, redundant	1500 to 1700	1600
1.14	Carrier for 8 cards	600 to 800	700
1.15	Bulk power supply	900 to 1200	1000

Some manufacturers also have extensive diagnostics on their bus cards such as Fieldbus Foundation H1 Fieldbus IO cards and HART analog input and analog output cards. Some conventional cards, such as discrete input and output cards, also support automatic short-circuit and open-circuit detection on discrete sensors and actuators.

PRICING

Utilizing PCs and standard monitors and keyboards for operator and engineering stations and the use of standard Ethernet for communication have reduced the cost of DCS system hardware. Also, the introduction of fieldbus devices has dramatically impacted the cost and space required for controller I/O.

In the cost information provided here, the cost of services associated with system configuration, factory acceptance, installation, simulation, testing, commissioning and startup are not included. Similarly excluded is any software not embedded in the DCS supplier's standard package. This usually excludes control and simulation or modeling algorithms that are unique to the particular process, interfacing with software or hardware of other suppliers that the DCS vendor does not support with embedded software, and the configuration of most graphics that are specific to the particular project.

A sample price list for DCS hardware components is shown in Table 4.14m. This price list basically covers the cost of DCS control system hardware. Most of the software costs are not included in the list.

As an example, Table 4.14m lists the cost of the DCS hardware (and the licenses for some basic software) for a project that requires 256 analog and 961 on/off I/O as follows:

- 25% Fieldbus Analog (64 I/O—12 fieldbus devices per segment)
- 75% Non-Fieldbus I/O (192 I/O, redundancy for 5% of analog I/O)
- 10% Fieldbus Discrete (96 I/O—8 discrete fieldbus devices)
- 90% Non-Fieldbus Discrete (865 I/O, redundancy for 10% of discrete I/O)

Based on the above scope definition, the cost of the package has been estimated using typical list prices for the components, as shown in Table 4.14n.

After the hardware components of the DCS have been manufactured, the system must be integrated and made fully operational before it can be tested. If the user wants to have a complete estimate for the whole DCS project, including factory acceptance test and startup, it is advisable to include *all* the software development, integration, and training tasks in the initial specifications for the DCS bid package, when it is sent out for competitive bidding. Following system integration, a factory acceptance test (FAT) is normally conducted.

TABLE 4.14n
Cost Estimate for the System Described in the Text

	Description	*Quantity*	*Unit Price ($US)*	*Total ($US)*
1.	Redundant control units	3	13,000	39,000
2.	Operator's console	2	10,000	20,000
3.	Engineer's station	1	21,000	21,000
4.	Analog input (AI) card	12	1,500	18,000
5.	Analog input (AI) card, redundant	1	2,800	2,800
6.	Analog output, 4 to 20 mA	12	1,800	21,600
7.	Analog output, 4 to 20 mA, redundant	1	3,000	3,000
8.	Fieldbus interface	3	2,500	7,500
9.	Discrete input, 24 Vdc	65	550	35,750
10.	Discrete output, 24 Vdc	34	1,100	37,400
11.	Discrete input, 24 Vdc, fieldbus I/O	8	850	6,800
12.	Discrete output, 24 Vdc, fieldbus I/O	5	1,000	5,000
13.	Discrete input, 24 Vdc, redundant	8	1,100	8,800
14.	Discrete output, 24 Vdc, redundant	4	1,600	6,400
15.	Carrier for 8 cards	20	700	14,000
16.	Bulk power supply	1	1,000	1,000
				Total: 248,050

If an engineering firm or system integrator performs some of the software development, simulation, training, and commissioning tasks, the initial bid package should clearly define the areas of responsibilities that are to be met by the DCS supplier.

4.15 Digital Readouts and Graphic Displays

J. VENCZEL (1985) **B. G. LIPTÁK** (1995) **P. M. B. SILVA GIRÃO** (2005)

Types:	A. Mechanical and electrical counters B. Gaseous discharge displays C. Cathode ray tube displays (CRTs) D. Rear projection displays E. Light-emitting diode (LED) displays F. Liquid crystal displays (LCD) G. Vacuum fluorescent displays (VFD) H. Digital panel meters
Note:	In this feature summary, the letters A through H refer to the listed alphanumeric readout types.
Display Application:	A and H. Numeric B and G. Alphanumeric C, D, E, and F. Alphanumeric and symbols
Character Sizes:	A. 0.1 to 0.5 in. (2.5 to 12.5 mm) E and G. 0.1 to 4 in. (2.5 to 100 mm) and larger H. 0.1 to 6 in. (2.5 to 150 mm) and larger B and C. 0.3 to 2 in. (7.5 to 50 mm) D. 0.12 to 3.38 in. (3 to 84.5 mm) F. 0.3 to 6 in. (7.5 to 150 mm) and larger
Maximum Viewing Distance:	A. 30 feet (9.12 m) G and H. 50 feet (15 m) B and C. 100 feet (30 m) D. 150 feet (45 m) E and F. 200 feet (60 m) or more
Viewing Angle:	A, C, E, and F. 90° D. 100° B, G, H. 120°
Brightness in Foot-Lamberts:	A. A function of ambient lighting F. A function of ambient lighting or 75 (255 cd/m^2) H. A function of ambient lighting or 75 (255 cd/m^2) or 200 (680 cd/m^2) D. 75 (255 cd/m^2) C. 100 (340 cd/m^2) B. 150 (510 cd/m^2) E. 200 (680 cd/m^2) G. 300 (1020 cd/m^2)
Life:	D. 10,000 hours C. 30,000 hours A and B. 100,000 hours G. 300,000 hours E, F, and H. 500,000 hours
Operating Voltage:	E. 3 to 5 V DC D and F. 5 to 28 V DC H. 5 to 30 V DC or 45 to 270 V AC A. 0 to 115 V AC or V DC B. 100 to 300 V DC G. 15 to 40 V DC C. 3,000 to 15,000 V DC

Costs: Type A from $10 to $30; type B from $20 to $40; type C from $75 to $500; type D from $30 to $60; type E from $1 to $100, type F from $4 to $40; and type G from $10 to $30. When the display is built into digital panel meters, voltmeters, multimeters the cost ranges from $100 to $500 or more. Large-size, high-resolution state-of-the-art CRT, rear projection, LED, and LCD displays may reach the tens of thousands of dollars.

INTRODUCTION

The development of digital technology in the 1970s was followed by the increased use of digital or alphanumeric (a/n) displays. As pocket calculators became commonplace, light-emitting diode (LED) displays and liquid crystal displays (LCD) were produced in very large quantities. This led to increased research and development efforts and greatly reduced prices. The evolution of cheaper monolithic analog-to-digital (A/D) converters paved the way for the widespread use of digital voltmeters. This again opened up new markets for alphanumeric displays. The use of microprocessors only added to the popularity of digital readouts, and so the digital era has led to the obsolescence of analog art.

As their name implies, a/n readouts furnish alphabetical (letters or legends) and numerical (digital or numbers) information. Common examples are the television cathode ray tube and the automobile odometer. These readouts provide accurate, easily understood displays and require no operator interpretation because they present clear, concise legends or exact numerical values.

Versatility is the primary advantage of a/n readouts because they have the capability to display many different types of information. Some readouts display only numbers, whereas others display numbers, letters, and symbols. The contents of the display can be tailored to the type of variable being displayed. For example, the readout of a digital voltmeter or electronics calculator may accommodate the maximum value and the decimal point location. In a process control display the readout may include the loop name and tag number with the value of the variable being measured.

Automated process control, in particular of complex distributed processes, is increasingly computer based. This means that from the human–machine interface point of view, significant changes are taking place and will continue to do so. The amount of information that can be easily presented to an operator is extremely large and diversified, recommending the use of displays with graphics and image capabilities of the same types used in computer monitors (cathode-ray tubes, liquid crystal displays, and even plasma-based monitors). The information conveyed by such displays, although eventually appealing and complete is very demanding for the operator since (a) to obtain the required information on a process several levels of pull-down menus must be navigated, and (b) the quantity of information for the operator to process can harm an effective and prompt answer to abnormal situations.

In the context of process control, and as far as the human–machine interface is concerned, two distinct situations may occur:

1. Simple processes (e.g., single loop control, single or small number of process variables) requiring simple interfaces (small number of displayed quantities and alarms). In this instance, LED, LCD, and VFC displays or panel meters are used.
2. More complex processes, requiring a heavy interface with a large or very large quantity of information to be analyzed. The display is then assured by either CRTs or flat-panel displays, mainly of the LCD type.

In the present section, different types of digital readouts are discussed. Some of them, namely type B, are clearly of the past or marginally used but, at least for historical reasons, still justify some attention. Because the interface between an operator and the process(es) control system (human or man–machine interface) is being constantly enriched with information technology-based solutions, some references are made to the pertinent technologies.

HUMAN FACTORS

The design of a human–machine interface (including display and means of obtaining the presented information such as pushbuttons, up–down buttons, or touch screen controls), as detailed in Section 4.17, "Human-Machine Interface Evolution," must be carefully designed to reduce operator stress and to quickly provide the information required. Some important aspects to consider are:

1. Organization of the information on the display, including its consistency (where it is shown and how it is presented)
2. Type of data presentation (alphanumeric, graphics, etc.)
3. Colors and character size

The design is particularly critical when the information requires large displays, several displays or, as it is more common, a single monitor but several menus and windows. In this last case, the performance of the software used for data presentation is extremely important.

To transmit information efficiently, readouts must have sharp character resolution, which is a measure of the character image sharpness or clarity and relates directly to readability. Readability is the quality that allows an observer to perceive information with speed and accuracy and is a function of character style, proportions, height, contrast, color, and refresh rate.

Characters that are pleasing to the eye are generated by simple continuous lines. To aid in character recognition, critical details should be prominent, and special features such as openings or breaks should be readily apparent. Many a/n readouts use a matrix of dots or bar segments for character generation. Closely spaced dots are more legible and natural-looking, whereas bar segments usually form boxlike characters containing noticeable inter-segmented spaces. Character proportions should be predicated on a height-to-width ratio of roughly three to two. Line width should be approximately one-seventh of character height. Minimum spacing between characters should be two line widths, with approximately six line widths between words.

SIZE AND CONTRAST

A guideline for determining character height based on viewing distance is given in Table 4.15a. The heights can be modified slightly for high ambient illumination or high-brightness displays. A display mockup is recommended if a particular viewing distance is critical.

Contrast is the ratio between character image brightness and its background brightness when measured under normal ambient illumination. Acceptable ratios for a/n readouts are about five or ten to one. Assuming the background to be a typical control console surface with a brightness of 20 to 50 foot-lambert (ft-L), or 68 to 170 candela per square meter (cd/m^2), a nominal brightness range for readouts should be 100 to 500 ft-L (340 to 1700 cd/m^2). Contrast depends on ambient illumination. Consequently, locations near an outside window or directly under a lighting fixture may require a filter to prevent image washout or to reduce objectionable

TABLE 4.15a
Character Heights Based on Viewing Distance

Required Viewing Distance in Feet (m)	*Nominal Character Height in Inches (mm)*
2.3 (28 in. or 0.7 m)	0.12 (3)
5 (1.5)	0.18 (4.5)
10 (3)	0.25 (6.25)
15 (4.5)	0.31 (7.75)
20 (6)	0.38 (9.5)
30 (9)	0.50 (12.5)
40 (12)	0.68 (17)
50 (15)	0.75 (18.75)
65 (19.5)	1.38 (34.5)
100 (30)	2.00 (50)

reflections. An antireflective filter reduces reflections and improves contrast by passing proportionately more self-generated image light than reflected image background light.

The optimum readout colors are green and yellow because the eye is most sensitive to them (Figure 4.15b). Amber, red, and orange are the next best choices. A filter can be used to obtain a desired color. A red filter, for example, will pass only the red light of an incandescent readout while it absorbs all other colors. Several types of a/n readouts generate character images by addressing time-displaced current pulses to dots or segments. The number of times (per second) that the image is generated is called the refresh rate. Low refresh rates can result in lowered brightness and occasionally cause flicker.

Two additional human factors involve viewing angle and change or update rate. If the readout must be seen from several operator positions, it should have a viewing angle of approximately 120 degrees. Recessed characters are satisfactory only for direct viewing. The maximum readout update rate is twice per second if the operator is expected to read consecutive values. Numerical readouts are not recommended for determining rate of change, direction, or tracking.

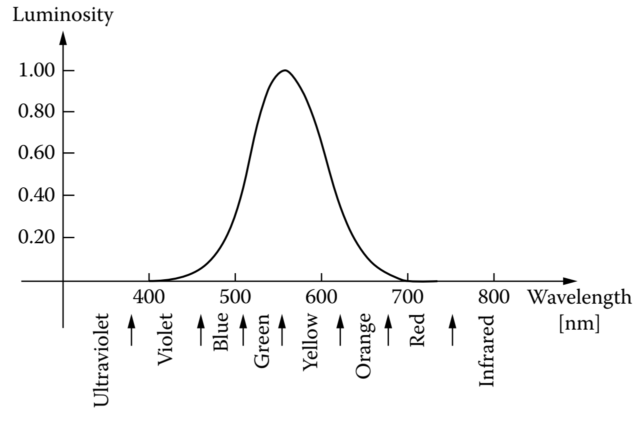

FIG. 4.15b
Luminosity as a function of wavelength. The National Bureau of Standards developed the above spectral-luminosity curve based on the findings of 52 experienced observers. The curve indicates that the eye responds to light between 380 and 760 nanometers, reaching maximum sensitivity at 555 nm in the yellow–green region.

APPLICATION NOTES

For critical readouts there should be a test function or switch to locate burned-out lamps or tubes or lost character portions. The loss of the horizontal center section of some matrix readouts, for example, can cause an operator to misread an integer as zero when eight is really intended. The readout bezel should be aesthetically pleasing and in contrast with the panel mounting surface.

Most a/n readouts require an electrical power supply to provide memory and to keep the readout continuously lighted. The readouts are updated or changed by a decoder driver that accepts binary coded decimal inputs. Readout modules containing standard decoder drivers with memory are preferred. Characteristics of common a/n readouts are listed in Table 4.15c, and a description of each type follows.

MECHANICAL AND ELECTRICAL COUNTERS

Mechanical and electrical counters (Figures 4.15d and 4.15e) are relatively simple and inexpensive devices that provide a cumulative count of sequential events. Usual configurations consist of a series of numbered wheels mounted on a common input shaft rotated by mechanical or electrical pulses. The numerical readout is visible through a window placed over the foremost row of digits. Digits should be as close as possible to the window to provide the maximum viewing angle and to eliminate shadows from ambient lighting. Internal lamps should be supplied if these counters are to be used in darkened areas.

The driver output and the counter input should be compatible. Mechanical counters are driven by mechanical rotation or oscillation of the input shaft. Rotation changes the readout through internal gearing, and oscillations use ratchet-pawl mechanisms. Electrical counters work similarly, except that a solenoid or an electromagnet actuates the input shaft. Counters operating with mechanically rotating inputs usually provide one or ten counts per complete rotation of the input shaft. Inputs can be either clockwise or counterclockwise; consequently, the count adds in one direction and subtracts in the other. Oscillating inputs provide one count per oscillation, and counting is in one direction only.

Electrical counters ordinarily supply one count per pulse and are available for AC or DC operation with a wide selection of voltage coils. Counters with two coils will add one count for a pulse through one coil and will subtract one count for a pulse through the other coil. Zero reset counters should be used for applications requiring a cumulative count

TABLE 4.15c
Alphanumeric Readout Characteristics

Type/Feature	*Method of Operation*	*Operating Characteristics*	*Typical Application*
Mechanical and electrical counters	Numbered wheels are rotated behind a viewing window.	Contain inherent memory; power required only to change display; usually illuminated by ambient light.	Digital clock; water meter; gasoline pump
Gas discharge displays	Shaped electrodes, in form of characters, ionize surrounding neon gas.	Require external memory and operate on high voltages (170 to 300 V DC).	Electronic calculators; electrical meters
Cathode ray tubes	Shaped electron beam is projected on phosphor screen.	Require character generation and memory circuitry; operate on very high voltages (3,000 to 15,000 V DC).	Computer-controlled displays
Rear projection displays	Miniature optical projectors containing incandescent lamps display images on viewing screen.	Require external memory; models are available for wide range of operating voltages.	Control-console displays, television monitors
Light-emitting diode displays	Semiconductor junction emits light when DC current is passed through it. Individual diodes make up dot or bar matrix.	External memory and drivers are required. Low-voltage, high-current operation (2 V, 15 mA per segment).	Electronic calculators, clocks, panel meters, computer-controlled displays
Liquid crystal displays	Transmissive technology. LCD does not generate light. It can be made to pass or block light by application of AC voltage.	External memory and AC drivers are required. Low-voltage, low-current operation (5 V, 1 $\mu A/cm^2$).	Digital watches, portable instrument displays, panel meters, computer monitors, computer-controlled displays
Vacuum fluorescent displays	A triode vacuum tube with phosphor-coated anodes. Variously shaped segments form matrix.	Medium-voltage (20 to 40 V), low-power device. External memory and drivers are required.	Clocks, calculators, and alphanumeric displays on instruments

between random times or events. A single knob depression for mechanical counters or pulse for electrical counters will set all wheels to zero, and a new count can be established.

GAS DISCHARGE DISPLAYS

The forerunners of this outdated group of displays were the so-called Nixie tubes (Figure 4.15f). The operation of these tubes is similar to that of neon lamps. A sealed glass tube contains a common anode and a stack of ten independent cathodes shaped like numbers. When a large negative voltage is applied to a selected cathode, the gas around it glows from being ionized and emits a yellow–orange light.

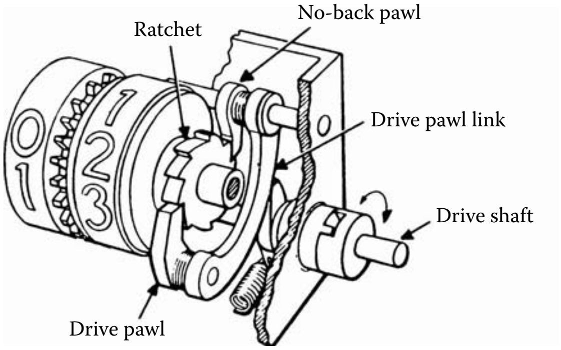

FIG. 4.15d
Mechanical counter.

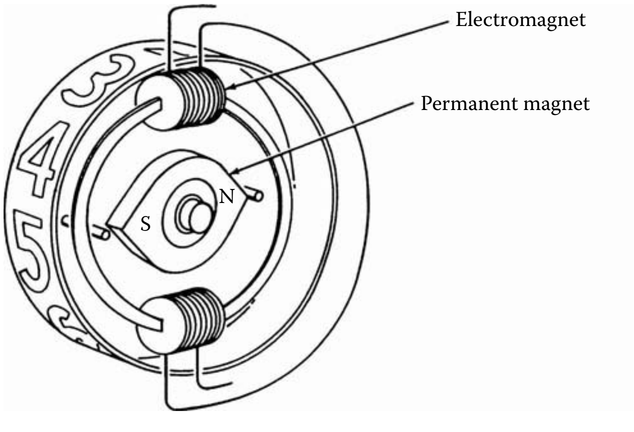

FIG. 4.15e
Electrical counter.

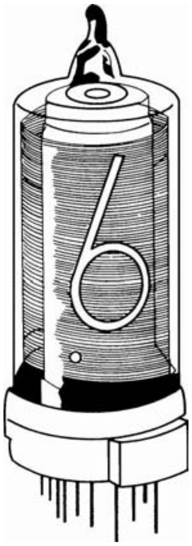

FIG. 4.15f
Gaseous discharge tube.

The gas in the tube is usually a mixture of neon and argon. A small amount of radioactive krypton and liquid mercury is added to the mixture to improve starting and to reduce cathode sputtering. These tubes were used up to the 1970s, when the planar-type matrix displays took over. These displays involve the same physical phenomenon as the Nixie tubes, except that the characters are made up of selectively lighted segments. The most common version is the seven-segment display, in which by using variable combinations of seven bar-shaped segments one can write all ten numbers and some other characters as well (Figure 4.15g).

The characters may be straight or slanted. The segments can be rectangular, mitered, or a combination of both with rounded corners (Figure 4.15h). For construction details, refer to Figure 4.15i. The whole assembly is placed in a flat, sealed glass container. The character segments are the cathodes and are located on the bottom of the glass enclosure. The anode is a fine metal mesh or a transparent tin oxide or indium coating on the inside surface of the cover glass. There are generally two or three characters to an envelope, with the connecting pins coming out on the rear side. A seal-off tube is located on the rear side for pumping the air out and inserting the gas mixture.

These devices are presently hard to find. They provide high brightness, good viewing angle, and 10,000 to 30,000 hours of operation and are moderately priced ($3 to $5 per digit). Among the disadvantages are the need for a high-voltage power supply (~180 V DC) and a high-voltage driving circuit.

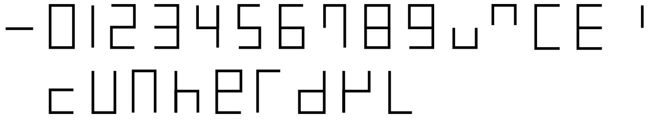

FIG. 4.15g
Some symbols available from the seven-segment character.

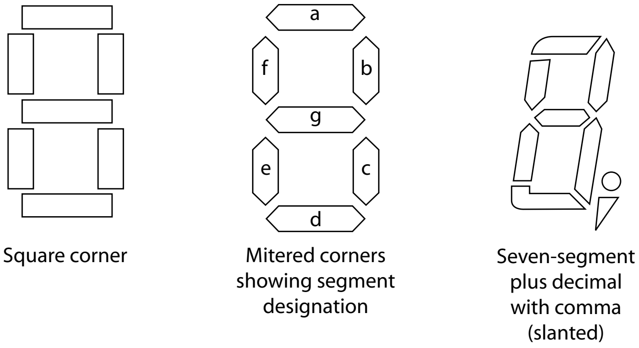

FIG. 4.15h
Typical character shape of seven-segment displays.

CATHODE RAY TUBE DISPLAYS

Cathode ray tube displays, commonly called CRTs, are discussed in detail in Section 4.5. CRT displays are versatile alphanumeric readouts. They are based on a cathode ray tube and from the outside they look like ordinary television sets. In effect, the operation is very similar to that of the display section of a television set. The characters may be drawn by a line raster that blanks and unblanks the beam or by X–Y writing, also known as stroke writing. A CRT is shown schematically in Figure 4.15j.

This type of display requires the most complicated support circuits. It requires a high-voltage power supply (3 to 15 kV), horizontal and vertical deflection circuits for raster generation, and a character generator. The raster generally consists of 525 horizontal lines or 1200 lines in high-resolution displays. Digital character generators can produce any types of characters previously defined and stored in semiconductor memories. CRT displays are complicated but can display a large amount of information. Typical uses are in computer terminals and airport departure–arrival displays.

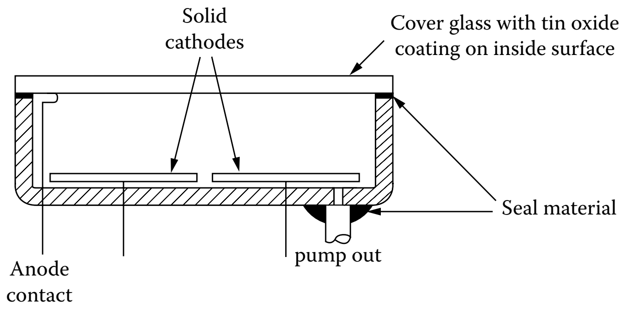

FIG. 4.15i
Cross-sectional view of a popular construction technique for the gas discharge display.

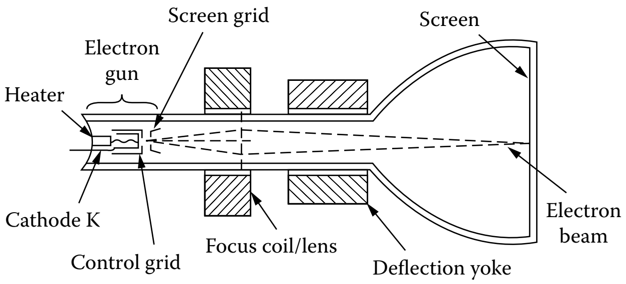

FIG. 4.15j
Basic CRT. The electron gun projects an electron beam on the screen that becomes luminous at the point of impact. The electromagnetic focus lens causes beam convergence, reducing spot size to usable dimensions.

The CRT, based on well-established principles and using commonly available materials, provides inexpensive, high-performance, true-color, stable, and high-resolution displays. However, CRT-based displays also have the drawbacks of high power consumption, divergence, and color variations across the viewing area. Their size and weight are also limitations (Figure 4.15k). For these reasons, the CRT is slowly but progressively being replaced by other technologies (e.g., LCD and plasma), particularly for mobile and/or large-size displays.

REAR PROJECTION DISPLAYS

Rear projection displays (Figure 4.15l) are miniature optical projectors stacked in cordwood fashion. They can display anything that can be put on film, including symbols, words, and colors. Twelve incandescent lamps at the rear of the display ordinarily illuminate the corresponding filmed messages, which are focused through a lens system and projected onto a single-plane, nonglare viewing screen. Rear projection displays exhibit excellent character resolution and readability and produce a very natural a/n readout appearance. They can be operated directly from electrical relays or from self-contained decoder drivers.

FIG. 4.15k
Twenty-inch Fast Scan Console Mount Monitor with touch screen capabilities. Dimensions: 17.62 in. (447.55 mm)(w) × 13.72 in. (348.48 mm) (h) × 20.35 in. (516.89 mm)(d); Weight: 50 lb (22.6 kg). (Courtesy of VarTech Systems Inc.)

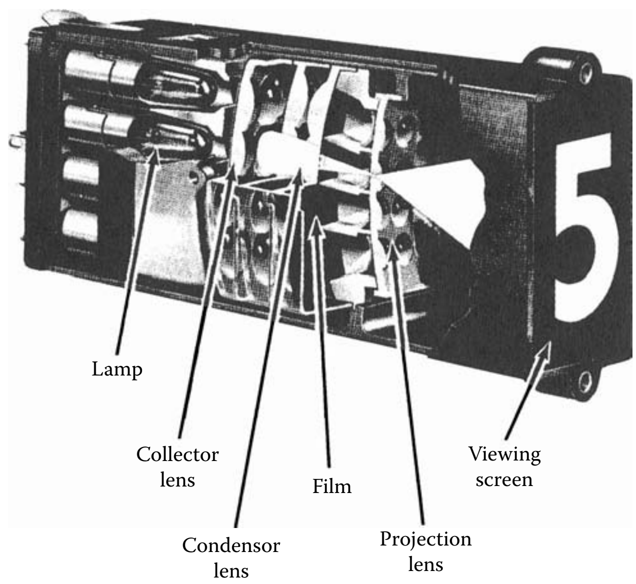

FIG. 4.15l
Rear projection readout.

Rear projection has recently experienced a strong technical development toward the implementation of performing rear projection monitor.[1] Nevertheless, the use of such monitors in process control rooms is insignificant because they cannot compete with CRT and LCD-based displays.

LIGHT-EMITTING DIODE DISPLAYS

Light-emitting diode (LED) displays have a wide variety of uses. They were developed in the 1970s, and by the end of that decade they could be found in all types of products, from watches and calculators to instruments, appliances, and point-of-sale advertising. Among their advantages are that they are inexpensive and easy to drive and have reasonable power requirements. The disadvantages include a reduced viewing angle for displays with magnifiers, and possible nonuniform segments for larger displays. They can be used as solid-state lamps, bar-segment displays, and dot-array displays.

Three colors are available for LED displays: red, yellow, and green. The red displays have the highest brightness and are the most widely used. The yellow is acceptable, and the green is the least legible. The sizes range from 0.1 to 0.8 in. (2.5 to 20 mm). As an example, Figure 4.15m shows a seven-segment digital LED display manufactured by Hewlett-Packard.

The most recent developments in LED technology are the introduction of the organic light-emitting diode (OLED) and the polymeric light-emitting diode (PLED) displays. Both types of displays are organized as matrices of pixels of OLEDs and PLEDs, respectively, formed on a thin film transistor (TFT) array.

An OLED is a device that sandwiches carbon-based films between two charged electrodes, one a metallic cathode and

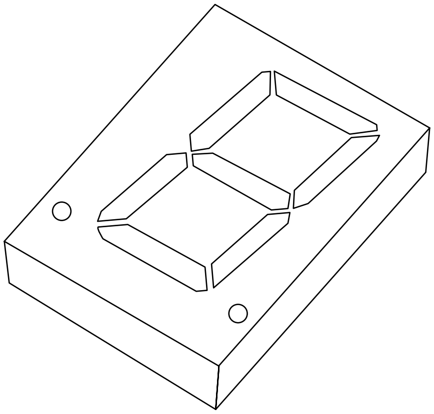

FIG. 4.15m

The HDSP-3400 Series are very large 20.32 mm (0.8 in.) GaAsP LED seven-segment displays. Designed for viewing distances up to 10 m (33 ft), these single-digit displays provide excellent readability in bright locations.

one a transparent anode, usually glass. The organic films consist of a hole-injection layer, a hole-transport layer, an emissive layer, and an electron-transport layer. When voltage is applied to the OLED cell, the injected positive and negative charges recombine in the emissive layer and create electroluminescent light. Invented by Eastman Kodak in the 1980s, the technology of OLED is brighter, thinner, faster, and lighter than LCDs, uses less power, offers higher contrast, and is cheaper to manufacture.

A PLED is created by sandwiching an undoped conjugated polymer between two proper electrodes at a short distance. The polymer emits light when exposed to electricity. It is a possible alternative to liquid crystal-based displays with the advantage of not requiring backlight. PLEDs enable full-spectrum color displays, are relatively inexpensive compared to other display technologies such as LCD or OLED, and require little power to emit a substantial amount of light.

LIQUID CRYSTAL DISPLAYS

The liquid crystal display (LCD) is an electronic readout that uses the unique characteristics of liquid crystals. This display technology is unique in that electrical energy is not converted to visible light, as with LEDs, gas discharge, and vacuum fluorescents; rather, the display modifies light. To create substantial contrast, the other display technologies require either considerable power (milliwatts per display element) or high voltage.

By taking advantage of unique characteristics of the liquid crystal materials, one can design LCDs to pass or block light. Only the orientation of the liquid crystal molecule must be altered in order for this effect to be created. This takes only microwatts of power per display element.

To understand the operation of an LCD and a twisted nematic liquid crystal display (TN LCD), refer to Figures 4.15n and 4.15o. The molecules in a liquid crystal display form a helix when viewed from the front to the back of the display cell. That is, the cigar-shaped molecules at the front of the cell may be oriented vertically and those at the rear horizontally. Those in the center are somewhere in between, forming a very orderly 90-degree helix. This 90-degree angle can be controlled exactly during construction.

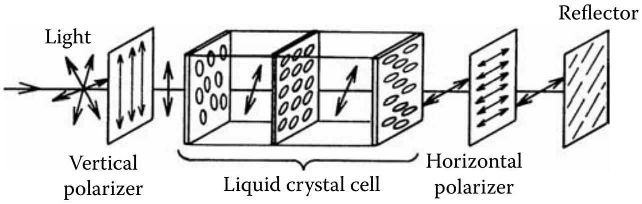

FIG. 4.15n

Field effect display unenergized between segments. (Courtesy of Fairchild Corp.)

The key to the operation of a liquid crystal display is polarized light. When scattered light is polarized (see Figure 4.15n) in the vertical plane and passed through the liquid crystal helix described previously, light is twisted, following the helical arrangement of the molecules. The light leaving the back of the display will be polarized in the horizontal direction. If a reflector is placed behind the display, the polarized light will return along its entry path, being twisted as it passes through the helix in the opposite direction.

If the helix of molecules is placed in an electric field, the molecules will align with the electric field, destroying the molecular helix. The polarized light entering the front of the liquid crystal cell will not be twisted but will emerge from the rear of the display polarized in the vertical plane. When vertically polarized light encounters the horizontally oriented rear polarizer, the light will be attenuated (see Figure 4.15o). If a reflector is present, no light will be reflected; the display would appear dark.

The construction of the LCD involves simple implementation of the operating principles (Figure 4.15p). The liquid crystal material is encapsulated in a glass "sandwich." The glass is coated with a transparent conductive material, usually indium-tin oxide, which is etched back to the preferred pattern.

Once the electrode has been formed, the inside surface must be treated to give the molecules a 90-degree twist, After this, the package is sealed with a small gap left between the

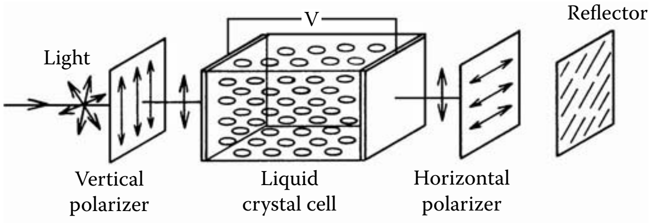

FIG. 4.15o

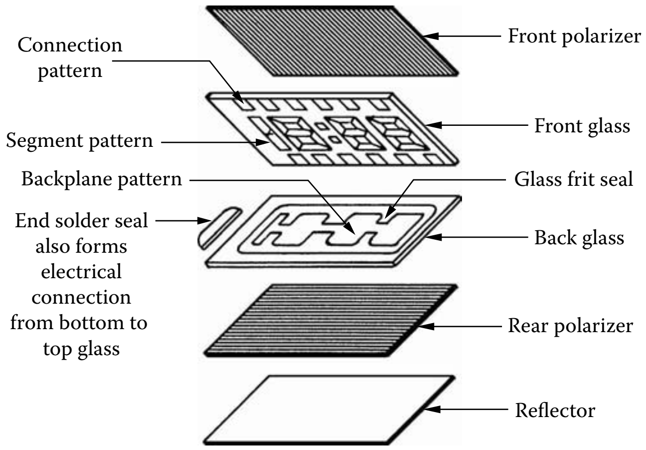

FIG. 4.15p
Liquid crystal cell structure. (Courtesy of Fairchild Corp.)

plates—generally 10 microns or less—for the liquid crystal material.

Liquid crystal displays are available in several configurations; reflective, transmissive, and transreflective. The choice of configuration depends on the lighting to be used. The reflective option includes a small reflector laminated on the rear of the display. This option gives the best performance and appearance in bright light. In a dark environment, however, the display has to be lighted from the front.

Liquid crystal technology was first applied to monochromatic numerical and alphanumeric displays. Its development was boosted by the television and computer monitor markets. The research involving materials and display construction is very active today. The available LCD panels can be divided into picture elements (pixels), which are arranged as a matrix. They fall into the categories of either passive matrix (PMLCD) or active matrix (AMLCD).

Passive Matrix Liquid Crystal Displays

One of the more common PMLCD designs is dual-scan twisted nematic (DSTN). The design includes several layers (Figure 4.15q):

1. A sheet of glass coated with metal oxide that operates as a grid of row and column electrodes, which pass the current needed to activate the screen elements.
2. An alignment layer made of a polymer of parallel grooves running across it to align the liquid crystal molecules in the appropriate direction and to provide a base on which the molecules are attached. This layer is repeated on another glass plate that also carries a number of spacer beads, which maintain a uniform distance between the two sheets of glass when they are placed together.
3. Polarizing layers applied to the outermost surfaces of each glass sheet to match the orientation of the alignment layers.

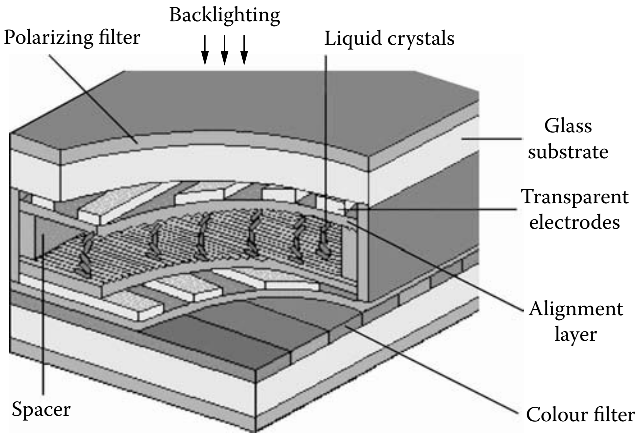

FIG. 4.15q
Passive matrix liquid crystal display (PMLCD) structure.

Backlighting is added, typically in the form of cold-cathode fluorescent tubes mounted along the top and bottom edges of the panel; the light from these is distributed across the panel using a plastic light guide or prism.

The image on the screen is created by this light as it passes through the layers of the panel. With no power applied across the LCD panel, light from the backlight is vertically polarized by the rear filter and refracted by the molecular chains in the liquid crystal so that it emerges from the horizontally polarized filter at the front. Applying a voltage realigns the crystals so that light cannot pass, producing a dark pixel. Color LCDs simply use additional red, green, and blue colored filters over three separate LCD elements to create a single multicolored pixel.

PMLCDs respond slowly, which causes smeared images and ghosting. Ghosting is when an area populated by pixels that are “on” causes a shadow on “off” pixels in the same rows and columns. Several solutions have been developed to overcome such problems, including the use of hybrid passive displays (HPD) and multiline addressing.

Full-color display requires intermediate levels of brightness between all-light and no-light passing through the crystals. The varying levels of brightness are achieved by changing the strength of the voltage applied to the crystals since liquid crystals untwist at a speed directly proportional to the strength of the voltage.

In contrast to full-color CRT displays that can provide 256 brightness levels (8-bit), PMLCDs offer only 64 different shades per element (6-bit), which means that using three elements per pixel, color PMLCDs deliver a maximum of 262,144 colors (18-bit). This compares with 16,777,216 colors (24-bit) of true-color CRT monitors. Figure 4.15r shows a small-size, low-cost, 64,000-color PMLCD, whose viewing angles are of 60° x-axis and 35° y-axis.

Active Matrix Liquid Crystal Displays

Thin film transistor (TFT) technology is presently used both in high-image-quality computer and process control monitors.

FIG. 4.15r
Seven and one-half inch color scan twisted nematic (STN) passive matrix LCD Module 640 × 480. Outline dimensions: 7.76 × 5.7 in. (197 × 145 mm); viewing area: 6.22 × 4.48 in. (158.00 × 113.75 mm). (Courtesy of Lumex, Inc.)

In a TFT screen, an extra matrix of transistors is connected to the LCD panel—one transistor for each color (RGB) of each pixel (Figure 4.15s). Transistor polarization controls the voltage applied across the liquid crystal element and thus the degree of twist and hence the intensity of the red, green, and blue elements of each pixel forming the image on the display. Thereby both slow response speed and ghosting of PMLCDs is eliminated.

A 640 × 480 color display AMLCD, such as the one shown in Figure 4.15r, would require 921,600 perfect transistors on a silicon wafer. In addition it would require an external driver circuitry, which justifies the higher prices of TFT LCDs compared to the passive LCDs. Similarly to PMLCDs, AMLCDs have also gone through several cycles of development to improve their viewing angles, response times, and contrast ratios. These developments involved in-plane switching (IPS), vertical-aligned (VA) systems, and multi-domain vertical-aligned (MVA) systems.

Table 4.15t shows the main characteristics of a 13.5-in. PMLCD and AMLCD and of a 15-in. CRT monitor. LCDs have advantages in terms of bulk, power consumption and flicker, but they are much more expensive, have poorer viewing angles, and are less accurate in their color reproduction.

The lower viewing angles of LCDs result from the fact they are transmissive systems that work by modulating the light that passes through the display, while CRTs are emissive. With emissive displays, there is a material that emits light at the front of the display, which is easily viewed from greater angles. In an LCD, in addition to the light, which is passing through the intended pixel, obliquely emitted light also passes through the adjacent pixels, causing color distortion.

Contrast ratio is a measure of how much brighter a pure white output is compared to a pure black output. The higher the contrast, the sharper the image and the purer the white will be. The contrast ratio of LCDs is lower than that of CRTs. Nevertheless, ratio values of 500:1 are currently available both in PMLCD and AMLCD displays.

Response time is the time it takes for each pixel to respond to the command it receives. Response time is a feature of LCDs because of the way they send their signal. Response time does not apply to CRTs because of the way they handle the display of information (an electron beam exciting phosphors). An AMLCD has a much faster response time than a PMLCD.

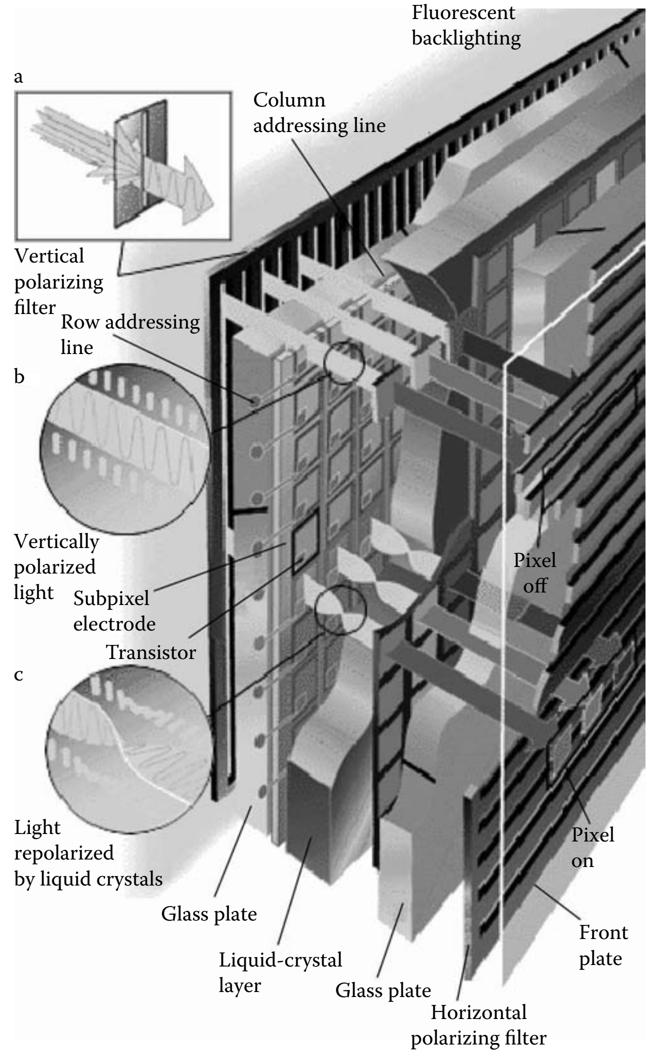

FIG. 4.15s
TFT active matrix liquid crystal display (TFT AMLCD) structure.

Brightness can be measured in different ways, but the higher the brightness number in Table 4.15t, the brighter the white display is.

Life-span value of an LCD is taken as the mean time before failure for the flat panel, which means that if it runs continuously it will have an average life of 60,000 hours before the light burns out. CRTs can last much longer, but while LCDs simply burn out, CRTs get dimmer as they age, and in practice, they do not have the ability to produce a standard luminance after around 30,000 hours of use.

While CRTs are capable of displaying a range of resolutions and can be scaled to fit the screen, an LCD panel has a fixed number of liquid crystal cells and can display only one resolution at full-screen size using one cell per pixel. Lower resolutions can be displayed by using only a portion of the screen or by using complex rescaling techniques. On

TABLE 4.15t
Comparison between a 13.5-in. Passive Matrix LCD (PMLCD) and Active Matrix LCD (AMLCD) and a 15-in. CRT Monitor

Display Type	*Viewing Angle (degrees)*	*Contrast Ratio*	*Response Speed (ms)*	*Brightness (cd/m^2)*	*Power Consumption (watts)*	*Life*
PMLCD	49 to 100	40:1	300	240 to 300	45	60 K hours
AMLCD	>140	140:1	25	240 to 300	50	60 K hours
CRT	>160	300:1	n/a	220 to 270	180	4–5 Years

the other hand, the ability to pivot the screen from a landscape to a portrait orientation is a feature of LCDs that is particularly suited to flat panels.

VACUUM FLUORESCENT DISPLAYS

The vacuum fluorescent (VF) display is based on the electronic tuning eye used in radio receivers up to the 1960s. The VF display consists of a vacuum tube triode with phosphor-coated anodes arranged in a planar configuration. It is widely used in digital alarm clocks and radios and as a digital display in automobiles. The typical color is a bright bluish green. The construction of the device is shown in Figures 4.15u and 4.15v, and a typical alphanumeric display is shown in Figure 4.15w.

The display is sealed in a flat glass enclosure. The anode segments, which represent the display elements, are located on the bottom. Each segment is connected to outside terminals sealed in the glass envelope. The anode segments are coated with phosphor material that emits visible light under electron bombardment. The grid is a fine mesh located between the filament (cathode) and the anode segments. The device requires a separate filament voltage, which may be AC or DC and ranges from 1.5 to 5 V. The anode voltage is typically between 12 and 40 V.

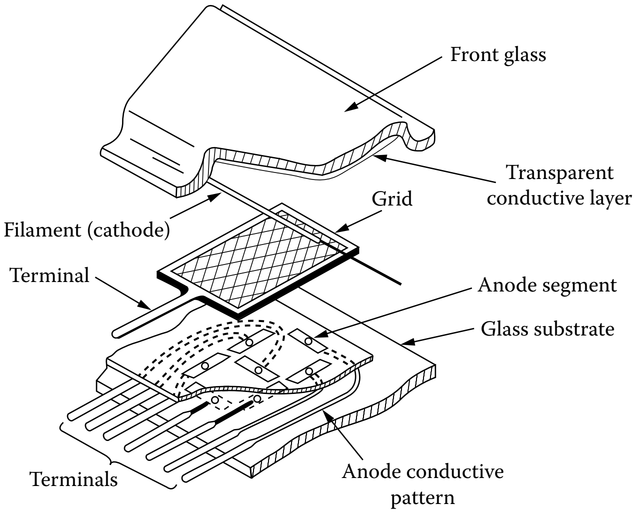

FIG. 4.15u
Construction of a vacuum fluorescent display. (Courtesy of Futaba Corp.)

The grid is used for turning on or blanking a whole digit for multiplexing purposes, whereas the combination of anode segments defines the character. One glass envelope generally contains several characters. The number of characters ranges from four to 40 or more. Displays with reduced graphic capabilities are available. Some modules have the same mounting hole location and have compatible interface with LCD devices, which means that such VF displays can replace LCDs with the advantages of lower power consumption, wider viewing angles, and higher brightness.

There are various numbers given in the literature for life expectancy or mean time between failures (MTBF), of a VF display. These numbers also depend on the definition of failure. Filament breakage is not a serious problem since it rarely happens. The phosphor coating will lose its effectiveness in time and this will result in lower brightness. Some manufacturers report VF devices with life spans of 300,000 hours.

In summary, the VF displays are adequately illuminated, have a wide viewing angle, and involve a medium-voltage, low-power operation. Their disadvantage is the low contrast at normal ambient lighting. This can be improved with green or blue filters, which also reduce distracting glare. These devices can be quite inexpensive, especially when purchased in large quantities.

NEW TRENDS IN GRAPHIC DISPLAYS

Several new static and dynamic display technologies are under development. These include organic LEDs (OLEDs); polymeric LEDs (PLEDs), which are also known as light-emitting polymers-based displays (LEPDs); plasma display panels (PDPs); field emission displays (FEDs); electroluminescent displays (ELDs); and digital light processor-based displays (DLPDs) for two-dimensional displays and holographic autostereoscopic display (HAD) for three-dimensional displays.

The required performance of the displaying devices depends on the applications. The more significant markets are television, computer monitors, and displays for small portable devices such as mobile phones. Other domains, such as medical imaging, are likely to benefit from the outcome of the ongoing research. A short reference to some of those technologies follows, even if they are not yet used in process control.

Plasma Displays

Plasma display panels (PDPs) are a fast-growing and very popular new generation of large-size displays.

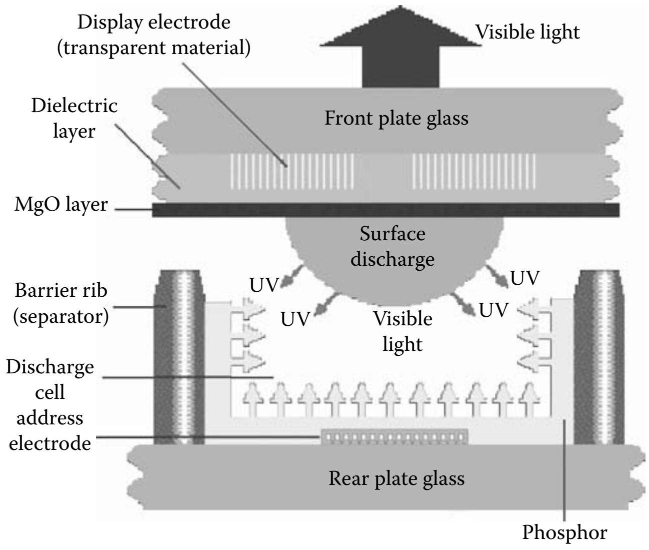

FIG. 4.15x
Plasma display panel structure and operating principle.

PDPs are based on multiple micro-discharges working on the same basic principles as fluorescent tubes. Plasma panels (Figure 4.15x) are arrays of cells, known as pixels, which are composed of three sub-pixels, corresponding to the colors red, green, and blue. Each cell has gas confined in the plasma state and electrodes that enable gas ionization under an electric field.

The UV rays that are created from this plasma gas excite the phosphors in each sub-pixel to produce colored light (red, green, or blue). Each sub-pixel is individually controlled by advanced electronics to produce over 16 million different colors. PDP technology is able to provide direct view displays with diagonals in the range 30 to 65 in., different resolutions, and viewing angles of more than 160°. Unlike projectors, they can be viewed under room-light or sunlight conditions. The main applications are public information displays and home cinema.

Table 4.15y summarizes the specifications of a 25-in. SXGA PDP released by a manufacturer that developed one of the several techniques presently available, an interlaced technique called alternate lighting of surfaces (ALiS).

Field Emission Displays

The field emission display (FED) (Figure 4.15z) is a promising flat panel display design that could replace both CRTs and LCDs. Similarly to CRTs, its operation is based on phosphors excited by electrons traveling in vacuum. The difference is in the electron emitters: instead of one electron gun, FEDs use millions of microscopically small electron-emitting cathodes that are matrix addressed. FEDs feature high brightness and

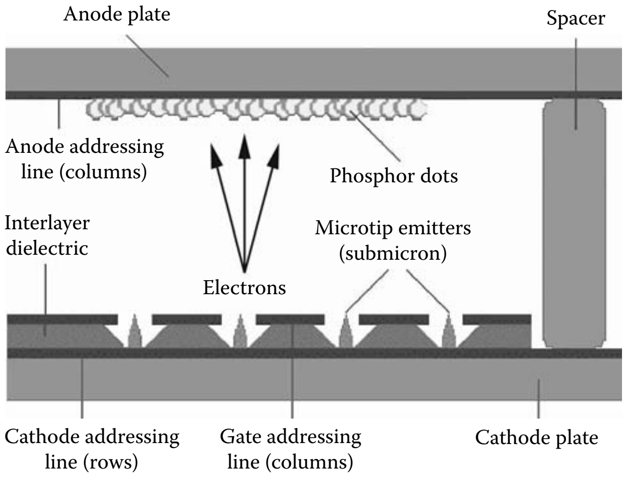

FIG. 4.15z
Field emission display structure and operating principle.

high efficiency, with a wide viewing angle, fast response time for video viewing, and perfect color quality. Actually, they are flat, thin, low-power CRTs.

Electroluminescent Displays

The operation of electroluminescent displays (ELDs) is based on the nonthermal conversion of electrical energy into luminous energy, the same principle as that of LEDs.[2] However, in ELDs light is generated in special materials when high-energy electrons that have been accelerated by an electric field impact on light-emitting centers (called activators).

Figure 4.15aa shows the schematic diagram of a thin-film electroluminescent display (TFELD) structure. The central layer is the thin film phosphor that emits light when a large electric field (on the order of some 1.5 MV/cm) is applied across it. Current limiting layers (the insulators) are needed on either side of the phosphor layer to protect it from the huge amount of dissipated energy if the phosphor were connected to the electrodes and a short circuit due to imperfection in the thin film would occur.

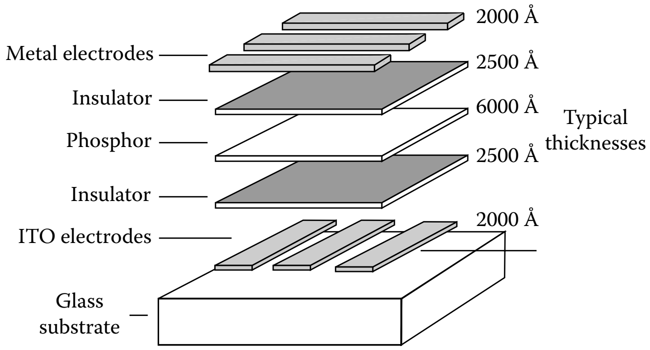

FIG. 4.15aa
Schematic diagram of a conventional thin film electroluminescent display (TFELD) structure.

The electrodes on the top and bottom of the device complete a basic capacitive structure. At least one set of these electrodes should be transparent, to permit viewing of the emitted light. Color displays have been demonstrated either using white or broadband phosphors and filters to produce a red–green–blue display or red, green and blue electroluminescent phosphors.

TFELDs have short response time and wide viewing angles (>160°) and are quite rugged, which makes them particularly attractive to produce high-information-content flat panel displays with the image quality of the CRT in portable applications requiring low weight and compact size.

4.16 Fieldbuses and Network Protocols

P. G. BERRIE (1995, 2005) **B. GUT** (1995) **K-P. LINDNER** (1995, 2005)

Partial List of Suppliers: (Most fieldbuses or control system communication systems that have reached the stage of international or industrial standard are supported by user groups who maintain Internet sites. These sites contain lists of products and suppliers. For the systems covered in this section these are as follows:)

AS-i (www.as-interface.com)
HART (www.hartcomm.org)
PROFIBUS (www.profibus.org)
FOUNDATION Fieldbus (www.fieldbus.org)
ControlNet (www.controlnet.com)
MODBUS (www.modbus.org)
Ethernet TCP/IP (www.industrialethernet.com)

INTRODUCTION

In the ten years since the publication of the third edition of the *Instrument Engineers' Handbook*, fieldbuses and network protocols have become a major point of interest in process automation. While it is true that conventional plants, i.e., plants using 4 to 20 mA or pneumatic equipment for the collection and distribution of control signals, still represent 90% of production capacity, the majority of new and extension projects are now utilizing fieldbus technology.[1] The last decade has also seen HART technology achieve the status of an industrial standard. Thanks to a comprehensive range of auxiliary equipment and its ability to provide communication between conventional 4 to 20 mA signals and DCS systems, it has become the major method of migration toward fieldbus-like networks.

There have also been considerable changes at higher levels, where the success of Ethernet office solutions has broken down the monopoly of proprietary systems in plant operation and management. At the moment there is no agreement between manufacturers on a common protocol—FOUNDATION Fieldbus HSE, PROFInet, and MODBUS TCP (also known as MODBUS TCP/IP) are just three examples—but all use the same Ethernet physical layer and Internet TCP/IP protocols, and so can run on the same network. In this respect MODBUS TCP is assuming the same role as HART at the field level as a practical means of linking controllers or remote I/Os interfacing to networks operating with a different protocol.

Such technological advances mean that information technology (IT) now plays a major role in the design and operation of plant networks. As a consequence, a number of computer models for the structuring, processing, or exchange of data in a plant network are in the process of becoming international standards.

At the other extreme, many users are uncertain of how to implement the new technology, and a quick look at one of the many fieldbus user forums reveals lively discussions on, e.g., how best to ground a fieldbus segment. It is beyond the scope of this section to go into depth on either of these subjects; however, it is the authors' intention to provide interested readers sufficient insight into the basics of networks and fieldbus protocols that they can pursue the various aspects in more depth by referring to the sources in the References and Bibliography at the end of this section.

COMMUNICATIONS HIERARCHY

Before discussing the basics of digital communication, it is useful to consider how a plant network is structured and what activities occur at the various levels. Figure 4.16a shows a so-called automation pyramid. In this case, it comprises four levels: field, control, operations, and enterprise, each of which is discussed below. The reader may be familiar with other versions of the pyramid with a different number of levels, but the basic hierarchy remains the same. It must be said that nowadays the division into "levels" is more a matter of convenience than reality.

Some of today's fieldbus devices are equipped with the capability to drive control loops, so that the difference between control and field level is becoming blurred. In addition, the term "pyramid" is also misleading. There might be more equipment at field level, but the enterprise level with its

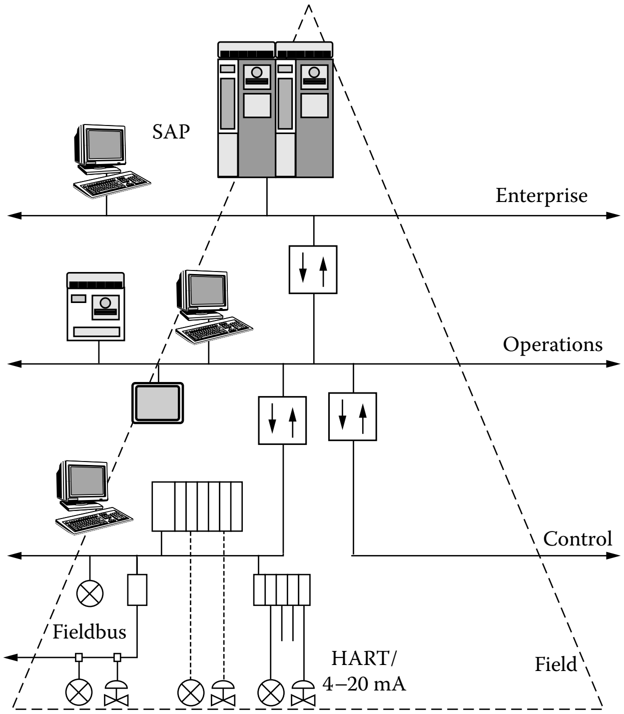

FIG. 4.16a
Automation pyramid.

business management programs is just as extensive, and the control level requires more programming effort. Nevertheless, the pyramid provides a simple overview of what should be attained by process automation, even if the realization may be somewhat different.

Field Level

The field level comprises the sensors and actuators that are required for the control of the processing plant. The sensors measure their process variables, i.e., temperature, pressure, level, flow, etc., and pass the signals up to the control level. There are two basic types of sensor:

- Limit switches signal one of two states: They detect whether the process variable that they are monitoring is in or out of limit. Conventional switches require the appropriate I/O card in the control system: relay, NPN, or PNP transistor circuit pulse frequency, NAMUR are examples. Fieldbus switches, e.g., PROFIBUS or AS-i, transmit a discrete digital signal, i.e., "0" or "1," directly over the fieldbus segment.
- Continuous measuring devices deliver a signal that is proportional to the process variable that they are monitoring. Conventional instruments deliver a standard current or voltage signal, often 4 to 20 mA, to an analog I/O card. Fieldbus sensors transmit an "analog output signal" — in reality a digital signal representing the current measured value — directly over the fieldbus segment.

The actuators receive signals from the controller in much the same way and perform a function, e.g., they start a pump when the signal changes state or close a valve in proportion to the magnitude of the control signal.

Control Level

At the control level, the signals from the sensors in the field are processed and the commands to the actuators are generated. The usual agent is a programmable logic controller (PLC), a process control system (PCS), or a distributed control system (DCS):

- A PLC uses simple ladder logic and provides real-time control. It executes its tasks in strict sequence by scanning the status of the analog and discrete inputs and generating appropriate output commands. The controller is programmed either directly through a console or from a remote engineering console — a personal computer — using the manufacturer's operating program.
- Process control systems are based either on mainframe computers or increasingly on personal computers or workstations. They differ from PLCs in that they are not bound to strict sequences and are capable of executing several tasks at once. A PC-based system cannot handle conventional signals, so these must be fed in via multiplexers or gateways on the control level bus. Since the information is already in the computer, they offer more possibilities for displaying the incoming signals.
- Distributed control systems: Modern process control systems are based on distributed intelligence. Here the control of the various parts of the plant is in the hands of several controllers or control systems. Each is responsible for its particular part and works autonomously. Each reports back to a central station based in the control room. Depending upon the network structure, the controllers may communicate over the control level network or be directly connected to the plant management level via Ethernet.

Operations Level

At the operations level we are no longer dealing with individual signals, but with the collection of plant data. It is also the last level at which intervention in the process is possible. Data are acquired directly from the field or via the controller by so-called SCADA programs (SCADA = supervisory control and data acquisition), giving the operator a schematic plant view on the monitor. Here, the operator can check all process values and take appropriate action when a value is out of limit. The signals are registered and stored in a daily log, alarm histories are archived, and trends are visualized. The performance of the plant is continuously monitored, analyzed, and optimized by specially adapted software. When necessary, recipes are changed.

This level also accommodates so-called asset management programs. These may operate independently of the control system, collecting fieldbus device process and status data at specific intervals rather than continuously. These programs usually allow configuration of the devices and may be linked to plant documentation, maintenance, and calibration scheduling programs. Asset management is a fast-developing area at the present moment, and the trend will be to marry both control and asset management into a single entity.

Enterprise Level

The enterprise level is where the information gained from the operations level flows into the business administration world, e.g., for production planning or ordering and billing of material. The enterprise level of a company network uses standard office networks and programs. A field device may signal the amount of liquid pumped in a day, but it cannot supply this information directly to a program at the enterprise level. Its data must first be processed and analyzed at the operations level, before being passed on through special software interfaces to the enterprise system.

Data Models

The communications hierarchy just described also forms a broad basis for two important standards that are concerned with the computer modeling of process industry networks. These are primarily concerned with the exchange of data throughout all levels of the factory, but are sufficiently well accepted that most major vendors base their engineering and enterprise tools on them. The oldest, the ISA S88 standard for batch control,[2] describes a more refined control hierarchy that splits the plant into operational units or parts thereof. This has been adopted by the International Electrotechnical Commission (IEC) in their IEC 61512 standard series,[3] and extended to include continuous processes, discrete processes, and inventory management. The structure is shown in Figure 4.16b.

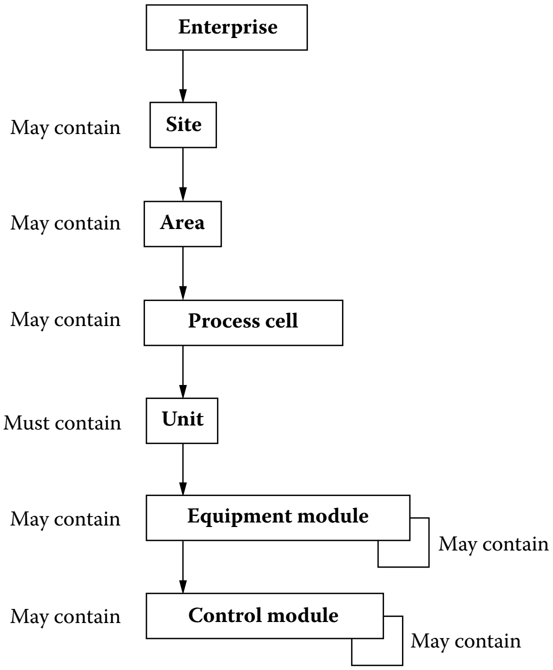

FIG. 4.16b
ISA S88/IEC 67512 model for process control.

Processes at the enterprise level and the exchange of data between it and the operations level are the subject of the ISA S95 standard.[4] Again, this is being adopted by the IEC as the IEC 62264 standard series.[5]

NETWORK BASICS

Digital communication between components at the top levels of control systems first became a serious proposition in the mid-1970s. System suppliers were quick to develop their own systems, a situation that repeated itself when field devices also began to talk a decade later. What was a fairly profitable operation for the vendor was a particularly expensive adventure for the user, who when wanting to use the best available components was faced with enormous programming costs for the integration. Not only did two systems speak different languages, there was also no common model for handling communication. Faced with this proliferation of proprietary solutions, the International Standards Organisation (ISO) took corrective action when it published the central pillar of all network standards, the so-called ISO-OSI reference model.

OSI Reference Model

The Open Systems Interconnection Model[6] was published in 1978 and aimed to bring uniformity and transparency into communication network standards. It defines a communication model that is applicable to all network devices, from mainframe computers operating at enterprise level to simple actuators in the field. It makes no physical specifications: rather, it provides a framework in which communications standards can be placed.

The OSI model splits the communication process into seven functional levels or "layers," see Figure 4.16c and Table 4.16d, each of which performs a clearly defined task. By defining the interfaces between contiguous layers, the model ensures the compatibility of all devices using a particular network protocol. It also simplifies the exchange of data between networks operating with different protocols. The application process that requests or receives transmissions is above Layer 7. This may be an enterprise system, an office program, a controller, a database, a SCADA program, a workstation, a sensor or actuator, etc. This so-called Layer 8 or "User Layer" is not part of the OSI standard.

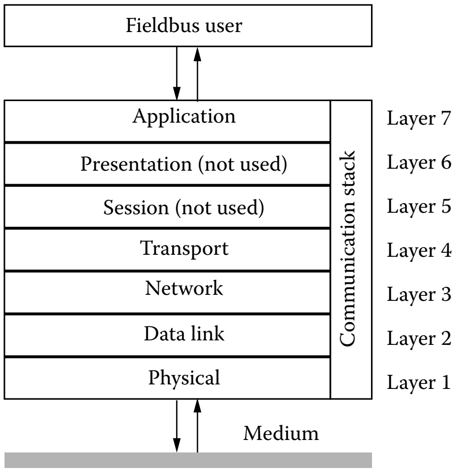

FIG. 4.16c
ISO-OSI communications model.

The seven layers can be divided into two functional groups:

- Layers 1 to 4 serve the network and are set the task of transporting data from one part of the network to another.
- Layers 5 to 7 serve the application and must present the data transported in an understandable form to the network user.

Since fieldbuses and control networks are much simpler than, say, the Internet, not all layers are required. Fieldbuses normally operate with Layers 1, 2, and 7 only; the devices on the bus receive their data from predefined controllers over so-called communication relationships. Since "Ethernet TCP/IP" is now found at control level, Layers 3 and 4 have also become relevant to process control networks. It can be seen from Table 4.16d that quite a number of standards of relevance to process control are already in place within the OSI framework. These together with other aspects of the physical network are discussed briefly in the next sections.

Physical Layer

The physical layer is concerned with how signals are placed on and carried over the network. The extent of standardization depends on the protocol used in the network. In some cases, a transmission standard only is specified; in others, the physical layer is completely defined including topology, transmission rate, connection pieces, cable length, cable type, etc. From a practical point of view, the most important aspects of the physical layer are the cable, the topology of the network, and the electronics residing in the fieldbus devices or control equipment that put the signal on the line.

Cabling The backbone of all networks is the transmission medium, i.e., the "cabling" that connects the devices. At field level this is usually copper cable, of which there are three main types, see Figure 4.16e. At higher levels it might be fiber optics or even "wireless":

- Unshielded Twisted Pairs (UTP). These comprise one or more twisted pairs of copper conductors within a protective jacket. UTP is used primarily in Ethernet networks. The cables are rated according to the

TABLE 4.16d
The Layers of the OSI Model

Layer	*Function*	*Task*	*Examples: Standards/Realizations for Fieldbuses*
Layer 7	Application	Provides the user with specific network commands and functions	Dynamic host configuration protocol (DHCP) Simple network time protocol (SNTP) Simple network management protocol (SNMP)
Layer 6	Presentation	Encodes the application layer data before forwarding them for transmission and decodes incoming data before forwarding them to the application layer	Not relevant to fieldbuses
Layer 5	Session	Synchronizes communication sessions between two applications	Not relevant to fieldbuses
Layer 4	Transport	Prepares the data string for transmission and ensures that it is reliably exchanged	Transmission control protocol (TCP) User datagram protocol (UDP)
Layer 3	Network	Selects the data route and ensures that the network is not overloaded	Internet protocol (IP)
Layer 2	Data link	Establishes and maintains connection between two participants	IEEE 802.2, Token passing IEEE 803.3, CMSA/CD IEC 61158/PROFIBUS PA: Master–slave IEC 61158/FF: Bus arbitration (LAS)
Layer 1	Physical	Puts the data on the physical medium and takes it off at its destination	EIA RS-232, EIA RS-422, EIA RS-485 IEC 61158-2 100BaseT (IEC 802.3u) 100BaseFX (ISO/IEC 9314-3)

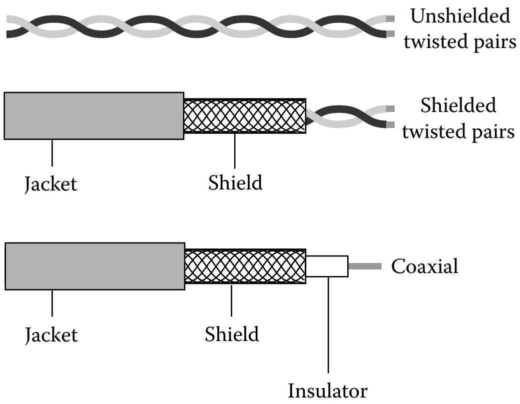

FIG. 4.16e
Copper cable types met in control applications.

EIA/TIA-568 standard,[7] whereby a Category 5 cable is recommended for transmission rates of 100 Mbit/s

- Shielded Twisted Pairs (STP). These are similar UTP cables, but the pairs are either shielded individually or share a common shield. The shield protects against electromagnetic interference. STP cables are recommended for fieldbuses: they are classed as Type A cables in the IEC 61158-2 physical layer standard.[8]
- Coaxial cable (Coax). This has a solid central conductor separated from an outer, tubular braided or foil conductor by an insulating medium, all within a protective jacket. The shield reduces electromagnetic interference and acts as the signal reference conductor. Coaxial cables are graded according to U.S. Military Standard MIL-C-17 with a RG (Radio Guide) number. In view of their expense, they are seldom found in the field, but might be used in computer systems operating at higher levels.
- Fiber-optic cables are specified as an alternative to copper cables in Ethernet (100BASE-FL), PROFIBUS DP, and FOUNDATION Fieldbus HSE. They are able to transmit at much higher rates and over much longer distances. Moreover, they are completely unaffected by electromagnetic interference and can be run into explosion hazardous areas without the need for barriers.
- Wireless at field level is still more of a dream than reality at the time of writing, but it has established itself within Internet applications as a means of connecting to remote networks.

For an overview of the connectors used in control systems and other aspects of the physical layer, the reader is referred to Barton.[9]

Topology The network topology describes the way in which the devices in the network are connected together. The basic topologies are star, ring, and bus: all other topologies are built from these basic elements. Figure 4.16f shows all three together with a so-called “tree” structure:

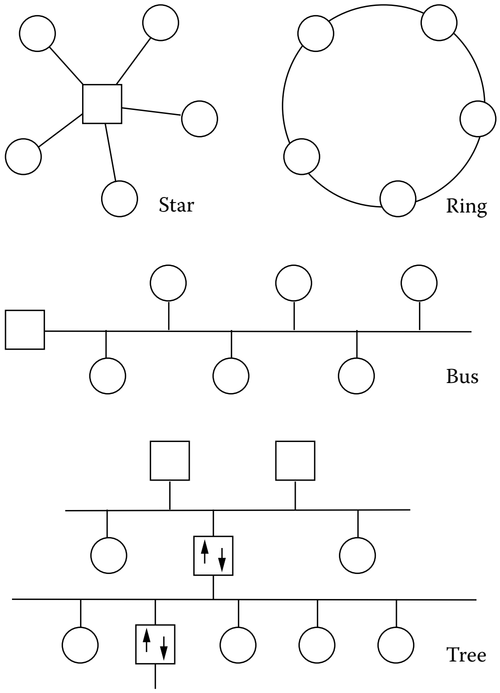

FIG. 4.16f
Network topologies.

- A star topology comprises a central device with point-to-point connections to all peripherals. The central device controls access to the network, and any data exchanged between peripherals must pass through it. If the central device fails, the network fails. The failure of individual lines is uncritical. The extent of the network is limited by the number of connections to the central controller. Shielded cable should be used. As transmission interface RS-232C is sufficient, however, in the classic star application, a computer system, this is now being displaced by the much faster universal serial bus (USB) interface.
- In a ring topology all devices are connected together in a physical ring. Decentralized control is required and access rights are passed from device to device. If a line fails the network fails, so bypass switches are required to avoid this. The number of participants is unlimited; however, the time it takes to circuit the ring sets a practical limit since this governs the response time of the system. The line must be interference free, i.e., coaxial or other reliable cable is required.
- In a bus topology all devices are connected either directly or via spurs to a single physical line. Both centralized and decentralized control is possible. Depending on control mode, line failure has the same consequences as in a star or ring. Failure of individual devices, however, does not affect the network function.

The number of participants is unlimited; however, the time taken to poll all devices sets a practical limit. The line must be interference free, i.e., coaxial or other reliable cable is required.

- A tree topology is basically a bus topology with branches or so-called "chicken feet," i.e., points where several devices are connected to one junction box. It is frequently met in PROFIBUS and FOUNDATION Fieldbus applications where a fieldbus operating at 31.75 kbit/s is connected to a high-speed bus via a link or coupling element.

Although, e.g., a bus or ring topology allows an unlimited number of participants, in practice, the associated communication protocols and transmission interfaces impose limits. The design of a network must also take into consideration other factors such as maximum cable length, grounding and, if power is taken from the cable, maximum allowable load. More information on designing FF and PROFIBUS segments can be found in Volume 3 of the *Instrument Engineers' Handbook*.[10]

Transmission Interfaces The digital signals produced by the devices are launched onto the network via a transmission interface. In order to communicate with each other, all the devices must use the same interface, and as such it will be part of any system or fieldbus specification. The transmission interfaces of interest to control networks are listed together with their attributes for copper cables in Table 4.16g.

It is beyond the scope of this section to go into detail about how the various interfaces work; however, it can be seen that the transmission standard itself often imposes conditions on the topology and protocol. Thus, RS-232 can only be used in a star topology with one device driving the communication. It should also be noted that the line lengths quoted are the maximum for the standard. The 1900 m quoted for IEC 61158-2 becomes 1000 m with an intrinsically safe bus, and the 1200 m copper for RS-485 shrinks to 100 m when the maximum rate of 12 Mbit/s is required. The other attributes in Table 4.16g together with a number of terms frequently met when transmission interfaces are discussed are found in Table 4.16h. Readers requiring detailed information are referred to Thompson.[11]

Data Link Layer

The data link layer provides the tools necessary for two or more devices to establish and remain in communication. It is responsible for fault-free transmission of bit streams over the network, calculating various cross-sums, and comparing them to so-called check bits. When a data packet is lost or faulty it may also have the responsibility for retransmitting the message. Another function of the data link layer is to add extra data frames to the bit stream that contain information about the transmitter and receiver, the priority of the message, and whether or not its receipt is to be acknowledged.

The data link layer is also responsible for media access, i.e., the controlled use and sharing of the network by the various devices connected to it. There are two distinct methods to regulate access:

- Centralized bus control (fixed master): the central bus master controls the access to the bus by the devices. Examples are the master–slave and the bus arbitrator models.
- Decentralized bus control (flying master): thanks to its intelligence, each device is in a position to control the bus itself when it wants to communicate. Two examples of decentralized bus control are the Token Passing model as per IEEE 802.2[12] and the CMSA/CD model as per IEEE 802.3.[13]

TABLE 4.16g
Characteristics of Transmission Interface Standards of Interest to Control Systems

Attributes	RS-232C	RS-422	RS-485	IEC 61158-2	100BaseTX
Max. devices	1 transmitter 1 receiver	1 transmitter 16 receivers	32 transmitters/ receivers	32 transmitters/ receivers	Limited only by address range[1]
Signal coding	±12 V pulses	Differential	Differential	Manchester II	8B6T
Topology	Star	Bus	Bus	Bus	Star
Max. line length[2]	15 m	1200 m	1200 m	1900 m	100 m
No. of lines	min. 3	4	2	2	4
Max. rate of transmission	19.2 kbit/s	10 Mbit/s	10 Mbit/s	37.5 kbit/s	100 Mbit/s
Communication mode	Duplex	Duplex	Half-duplex	Half-duplex	Duplex
Transmission type	Asynchronous	Asynchronous	Synchronous	Synchronous	Synchronous
Connectors	9- or 25-pin connectors	Not specified	Not specified	Not specified	RJ45 connectors

[1] A practical limit to the address range is given by the response time.

[2] Maximum possible allowed by the standard. Line length is dependent upon transmission rate and application.

TABLE 4.16h
Terms and Definitions Associated with a Transmission Interface

Attribute	Alternatives	Description
Transmission mode	Parallel transmission	Byte-by-byte transmission over a minimum of eight parallel lines. High transmission speeds, but expensive cables. Used by some buses for automated manufacturing.
	Serial transmission	Bit-by-bit transmission over a minimum of one line. The transmission time is dependent upon the length of the data string. Often used for fieldbuses.
Carrier mode	Baseband	Direct transmission of data without prior modulation.
	Broadband	Transmission of data by modulating the data on a high-frequency carrier signal. The data can then be simultaneously transmitted with other data modulated on a different carrier signal on the same transmission medium.
	Carrier signal	Frequency in a communications channel modulated to carry analog or digital signal information.
Signal transmission	Amplitude modulation	The amplitude of the data signal (“0” = low DC voltage or current, “1” = high DC voltage or current) causes a change in amplitude of a carrier signal, usually an alternating current.
	Frequency and/or phase modulation	The amplitude of the data signal causes a change in frequency or phase of a carrier signal, usually an alternating current.
Transmission type	Asynchronous transmission	Spontaneous transmission of data, requiring agreements on set sequences and types of information (protocol). Suitable for smaller blocks of data.
	Synchronous transmission	Transmission requiring that system clocks in both transmitter and receiver are in phase. It allows long data blocks to be transmitted efficiently and safely with a high proportion of useful data.
Communication mode	Half-duplex	In half-duplex communication, information flows in both directions. First one device transmits: after it has finished, the partner answers.
	Duplex	In duplex communication information can be simultaneously transmitted and received.
Transmission rate	1200 bit/s in steps to 100 MB/s	Indicates how many bits per second can be transmitted between the transmitter and receiver. All devices on a network must operate at the same transmission rate. The maximum rate is limited by the type of interface and transmission medium used.

At field and control level, it is often the case that two methods are used together, e.g., when several masters share the same backbone but communicate in a master–slave relationship with their field devices and other control equipment.

Communication Modes Communication modes include:

- *Master–slave.* In this method, one bus device is the master. The master alone possesses a continuous right to transmit. It polls (or addresses) each bus participant in turn, supplies it with data, and/or asks it to transmit its data, e.g., its measured value and status. To increase the efficiency, i.e., the amount of useful data to overheads, the protocol is kept as simple as possible. The security of the data depends upon the protocol structure and the error checking method used. MODBUS, PROFIBUS DP/PA, and AS-i are all protocols that use the master–slave method.
- *Bus arbitration.* In this method, every device on the network may transmit and receive data. The right to transmit is organized by a central controller, the so-called bus arbitrator. The arbitrator maintains a list containing the order in which and the length of time devices are allowed to transmit. The arbitrator works through the list, passing the right to transmit to each device in turn. If different scanning frequencies are required, the device can appear more than once in the table. It should be noted that although this is classified as centralized control, token passing is a central element. The method is used in the WorldFIP and FOUNDATION Fieldbus H1 protocols.
- *Token passing (token ring).* In this access method, the token, i.e., the right to transmit, is passed from device to device. This may be done on a master–slave or peer-to-peer basis. In the event of peer-to-peer passing, a so-called token ring is built, which may be real or logical. The passing sequence depends upon the application and is defined during the planning of the system. This method allows each device a fair share of the bus, since each is allowed to transmit within a preset period of time. The time taken to pass the token around the system determines the frequency of polling of the individual members. Token passing is used by FOUNDATION Fieldbus to ensure deterministic communication on the H1 layer.
- *Stochastic or random bus access.* There are several random access methods of which CSMA/CD is the most well known. CSMA/CD stands for Carrier Sense

Multiple Access with Collision Detection. All devices on the bus have the right to transmit. Each continually listens to (or senses) the bus. If this is free, then any of the devices can transmit its data. If several devices want to transmit simultaneously, a collision is detected and all withdraw. A random generator in each of the devices then determines the time interval that must elapse before it can attempt to transmit again. The CSMA/CD bus access method is specified in the Ethernet protocol and is used in office networks and the higher levels of automation systems. At field and control levels it has to be supported by a centralized access management method because there is no strict periodicity of scanning.

Communication Relationships Several types of communication relationships between devices may be supported by the bus protocol:

- *Client–server.* The client transmits a request to its server communication partner. When the requested action is executed and its confirmation is necessary, the server issues a response to the client. If the client is also a server to its communication partner, the relationship is said to be peer-to-peer. Otherwise it can be considered to be master–slave.
- *Publisher–subscriber.* All the devices sense the traffic on the bus continuously. The publisher broadcasts its data when it has the right to transmit. The subscribers to the data recognize that they are of interest to them and update their local copies. There is no direct confirmation of receipt. When communication is controlled by bus arbitrator, transfers can be scheduled on a precisely periodic basis. Publisher–subscriber is also known as the producer–consumer method.
- *Source–sink.* A source transmits when it detects a necessity to report, e.g., an event and has the right to do so. One or more sinks receive the (multicast) message, ensuring that the event is detected. One of the sinks is responsible for acknowledging the event via a separate client–server relationship.

Network Layer

The network layer is required neither by "H1" fieldbuses nor by Ethernet itself, which defines only the physical and data link layers. It is used by so-called "Industrial Ethernet" or "Ethernet TCP/IP" and by other industrial standards such as MODBUS TCP and FOUNDATION Fieldbus HSE.

The network layer is responsible for data routing. When the transport layer demands a connection between A and B with a specific capacity, it is the network layer that finds a suitable route. It must also make sure that the network is not overloaded. Where intermediate networks are to be used, the data must be stored before it is transferred from one network to another. The Internet protocol is of interest to process control:

- *Internet protocol* (*IP*). IP is the Internet's most basic protocol and is used to forward data packets. It is a datagram-oriented protocol that treats each data packet independently. This means that each packet contains complete addressing information. Packets can also be assigned priorities via a "type of service" field. IP has, however, no mechanisms to determine whether packets reach their destination. Furthermore, each packet has a "time to live" (TTL) field: when the TTL value reaches zero, the packet is discarded. The contents of a packet are not checked for transmission errors; only the IP header is checked. These functions are provided by such transport layer protocols as UDP (to a limited extent) and TCP. IP also provides several optional features, allowing a packet's sender to set requirements on the path it takes through the network (source routing), to trace the route a packet takes (record route), and to label packets with security features.

Transport Layer

The transport layer is responsible for the interference-free transport of data via the various routes and networks connecting any two communicating units. According to requirement, the transport layer sets up several logical channels and chops long information strings into small packets. On the receiving side, it reassembles the packets into the original string or, if the data are not received in sequence, attempts to place them in correct order. The transport layer also checks that the data packets have not been falsified during transport. Two protocols are of interest to process control:

- *Transmission control protocol (TCP).* The transmission control protocol runs on top of the Internet protocol, see above, and enables two hosts to establish a connection and exchange streams of data. TCP guarantees delivery of the data and also guarantees that the data packets are delivered in the same order as they were sent.

- *User datagram protocol (UDP).* The user datagram protocol also runs on top of IP. Unlike TCP it provides very few error recovery services. Instead it offers a direct means of sending data telegrams over an IP network. It is used primarily for broadcasting messages.

Application Layer

The application layer defines the services supported by the network, for instance, read and write commands, program management functions, network synchronization, addressing, up- and downloading of data, and virtual device images. It is not concerned with the actual carrying out of services, but rather with their presentation to the user so that the user can program the network. The procedures are then mapped onto the lower layers. In the full model, the application layer is connected to the lower layers through the presentation and session layers. In both fieldbuses and in Ethernet, these layers are bridged by special communication programs. Of the various protocols available to the application layer at least three find use in control applications:

- *Dynamic host configuration protocol (DHCP).* A protocol that automatically assigns IP addresses to devices on a network every time they connect to it. This means that a new device can be added to a network without the need to manually assign it a unique IP address.
- *Simple network time protocol (SNTP).* Simplified version of the Network Time Protocol (NTP), an Internet standard protocol that assures accurate synchronization of device clock times in a network. Running as a background client program on a computer, NTP sends periodic time requests to servers, obtaining server time stamps and using them to adjust the client's clock.
- *Simple network management protocol (SNMP).* The Internet standard protocol for network management software. It monitors devices on the network and gathers device performance data for management information databases.

FIELDBUS PROTOCOLS

Readers familiar with the history of digital communication in process control will know that work on standardizing an international fieldbus for the process industries was started in the late 1980s under the auspices of the ISO/ISA SP50 committee. Its feasibility was demonstrated by a multi-vendor demonstration at both ISA and Interkama exhibitions in 1989. Before the events occurred that caused to committee to become the scene of the so-called "fieldbus wars," it had been decided that a two-tier structure was best suited to the application. At fieldbus level, a bus with moderate transmission rates was to offer device power and be suitable for use in hazardous locations. This became known as H1—"Hunk 1," referring to the work package. "Hunk 2" was the control level requiring faster transmission rates, no bus power, and no requirement for use in hazardous locations.

The committee standardized the H1 physical layer in IEC 61158-2,[8] but there was no agreement on the data link and application layers or on the H2 bus. Company politics and various other factors caused the standardization to grind to a halt. Without going into further details, the result of this stand-off was emergence of the PROFIBUS standards and the setting up of the FOUNDATION Fieldbus. Enmity continued for several years until the IEC decided to publish both standards, plus a variety of proprietary systems that were prepared to open their specifications to the public, in the IEC 61158 set of standards,[14] see Table 4.16i.

At the same time, the FF standard was published as a European (EN) standard.[15] The decision was much criticized, but it has basically set up a situation where individual users can decide for themselves which fieldbus "flavor" they prefer.

TABLE 4.16i
Fieldbus Types Standardardized in IEC 61158: 2000–01

Type	*Protocol*
IEC 61158, Type 1	FOUNDATION Fieldbus H1
IEC 61158, Type 2	ControlNet
IEC 61158, Type 3	PROFIBUS DP/PA
IEC 61158, Type 4	P-Net
IEC 61158, Type 5	FOUNDATION Fieldbus HSE
IEC 61158, Type 6	SwiftNet
IEC 61158, Type 7	WorldFIP
IEC 61158, Type 8	Interbus

Note: The IEC 61158 standard itself currently comprises six parts that specify and define services for the physical, data link, and application layers. The types reference the parts that are relevant to the particular standard.

Although the idea of a single fieldbus is laudable, in practice there are also different demands at field level. In a typical production facility, there is a mixture of factory automation (e.g., filling and packaging) and process automation (e.g., batch and continuous control), which justifies the use of different protocols. In the following, those control and fieldbus protocols of interest to process control will be discussed. The various types of components used to build the networks are listed with a short description in Table 4.16j.

AS-i

AS-i (Actuator-Sensor interface) is a primarily a factory automation bus for simple binary sensor and actuators operating in safe areas. An overview of the principal technical data is given in Table 4.16k. AS-i is supported by a consortium of users and manufacturers, which is responsible for development and conformance testing.[16] Currently over 100 vendors offer AS-i devices or equipment.

Figure 4.16l shows a typical architecture. The AS-i bus is normally connected to a PLC or PC by using an appropriate interface card. It can also be connected to a control network by means of a gateway and multiplexer acting as a master. Power is supplied over the bus, and each participant can draw up to 100 mA at 24 VDC. A maximum of 8 A can be drawn.

AS-i is a cyclically operating system with a master–slave structure. In the standard configuration, the master interrogates all connected slaves in strict rotation and receives telegrams from them. The data structure is extremely simple: AS-i telegrams have four output bits that are used to control connected devices—to open a valve or close a switch. A slave answers immediately, returning four bits indicating that the function has been performed. A sensor, e.g., a level limit switch returns its current status. Alarm interrupts or similar event-controlled messages are not provided. The

TABLE 4.16j
Network Components

Component	*Standard*	*Description*
Bridge	Ethernet	Device that connects two local area networks (LANs) or two segments of the same LAN that use the same protocol.
Field device	General	Sensor or actuator attached to the process under control.
Frequency converter	General	Device on a network that serves to control motor drives, etc.
Gateway	General	Device on a network that serves as an entrance to another network. In addition to interfacing physical layer and protocols, a gateway may also scan and assemble data for forwarding as a single packet.
Host	Ethernet	Computer that is connected to a TCP/IP network, including the Internet. Each host has a unique IP address.
Hub	Ethernet	Common connection point for devices in a network with several ports. When a data packet arrives at one port, it is copied to the others so that all segments can see it.
I/O	General	Short for input/output. Device that transfers data, usually in the form of analog or discrete signals, to and from a controller.
Interface	General	Boundary across which two independent systems meet and act on or communicate with each other.
Link (PROFIBUS)	PROFIBUS	Device comprising a gateway and one or more segment couplers.
Linking device	FOUNDATION Fieldbus	Device serving as the interface between FOUNDATION Fieldbus H1 and HSE segments.
Modem	General	Device to enable transfer of digital data over analog telephone lines or cell telephone networks.
Multiplexer	General	Device that combines (multiplexes) several signals for transmission over a single medium. Often called a mux.
Port	General	Interface on a computer to which a device or network can be connected.
Programmable logic controller		Device using ladder or similar simple logic to provide real-time control.
Repeater	General	Device used to regenerate or replicate a signal.
Router	Ethernet	Device that forwards data packets along networks. Routers are located at gateways, i.e., the places where two or more networks connect.
Remote I/O	General	I/O device that is not an integral part of the controller but an independent entity residing within the network.
Segment coupler	PROFIBUS	Device comprising a signal coupler, a bus power unit, and a PROFIBUS DP/PA interface.
Switch	Ethernet	Device that filters and forwards data packets between LAN segments.
Switching hub	Ethernet	Short for port-switching hub, a special type of hub that forwards data packets to the appropriate port based on their address.

error detection is also much simplified and provides only moderate security.

Originally AS-i supported 31 slaves, whereby a slave could be an intelligent device or a so-called user module with 4 inputs and 4 outputs. The recently introduced Version 2.1

TABLE 4.16k
Principal Technical Data of AS-i

Property	*AS-i*
Standard	IEC 62026-2; EN 50295-2
Physical layer	AS-i specific, UTP
Length	Max. 100 m
Transmission rate	167 kbit/s
Bus access method	Central master slave
Participants	1 master, max. 31 slaves

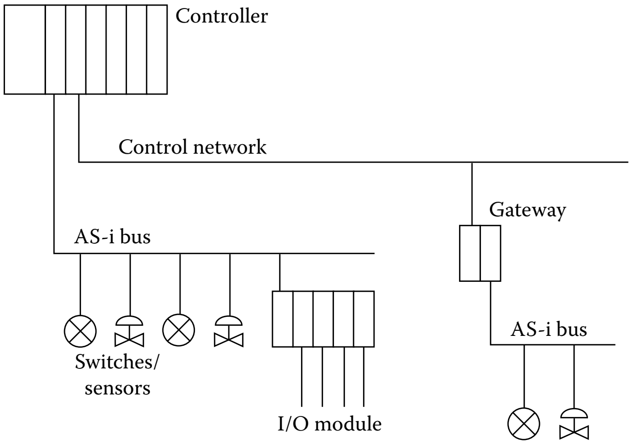

FIG. 4.16l
Typical AS-i architecture.

specification doubles the number of slaves to 62, while providing backwards compatibility with earlier devices and networks. The maximum cycle time of a fully loaded network is around 5 ms (double for Version 2.1). Version 2.1 also offers better diagnostics and a profile for analog signals. It is now possible to transmit analog signals such as temperature over 5 cycles for PID control.

HART

HART (Highway Addressable Remote Transmitter) is primarily a smart protocol; its information is transferred point-to-point by superimposing a digital signal on a standard 4 to 20 mA output. The protocol also allows for a multi-drop bus structure, however, at the expense of the conventional output. An overview of the principal technical data is given in Table 4.16m. More detailed information on HART is available in Volume 3 of this handbook.[17] HART is supported by the HART Communication Foundation,[18] an independent body of users and vendors who are responsible for development and conformity testing.

HART is a single master protocol, which for multi-drop applications allows a secondary master. This is the case when a master reading process data cyclically from the field devices and a terminal for device configuration (handheld or laptop) are connected to the same segment. As far as the coding of the data frames is concerned, HART uses a mixture of Layer 7 and Layer 2. Every data frame contains a command byte that determines the service to be performed (Layer 7) as well as the significance of the data for the data link layer (Layer 2). The command codes are divided into three classes: Universal, Common Practice, and Device Specific.

TABLE 4.16m
Principal Technical Data of HART

Property	*HART Point-to-Point*	*HART Multi-drop*
Standard	Industrial standard maintained by HART Communication Foundation	
Physical layer	Bell 202 FSK (Frequency Shift Keying) "0": 2200 Hz, "1": 1200 Hz	
Length	As for analog signals on UTP cable	Max. 1500 m with multi-core STP cable Max. 3000 m with two-core STP cable
Transmission rate	Digital information at 1200 bit/s with simultaneous analog transmission	1200 bit/s
Bus access method	For digital communication, master–slave with secondary master	Master–slave with secondary master
Participants	1 slave per connection	Max. 15 slaves with central power supply

All HART instruments must be able to process commands of the type universal. Common practice commands are not mandatory, but when they are implemented, the meaning of the commands must conform with the specification. In the case of device-specific commands, the same designations may have different meanings in different instruments. The data security in HART is ensured by the building of cross-sums, parity building in each frame, and an additional cross-summing of the parity bits.

In view of the fact that the protocol allows for device-specific commands, manufacturers must supply device description files (DDs) if their products are to be fully operable by a HART application. If no DD is available, operation is restricted to the basic parameters encompassed by the universal commands such as the writing of zero, span, and damping and the reading of process value and status.

Figure 4.16n shows typical ways in which HART devices are integrated into control system architectures:

- *Conventional.* Where digital communication is not of interest (except perhaps for device configuration via handheld terminal), HART devices are connected directly to analog or binary PLC cards via a point-to-point connection. Where the 4 to 20 mA device is loop-powered, the PLC provides the power.
- *Multiplexer.* If the HART digital signal is required, e.g., to configure the devices or monitor their readings from a workstation in the control network, a multiplexer may be used. This is often operated parallel to conventional point-to-point wiring. The multiplexer acts as HART master and scans each of the transmitters in turn, storing the measured values (and status information) in a buffer. The controller now accesses the buffer over the control network and reads the information it requires. The data

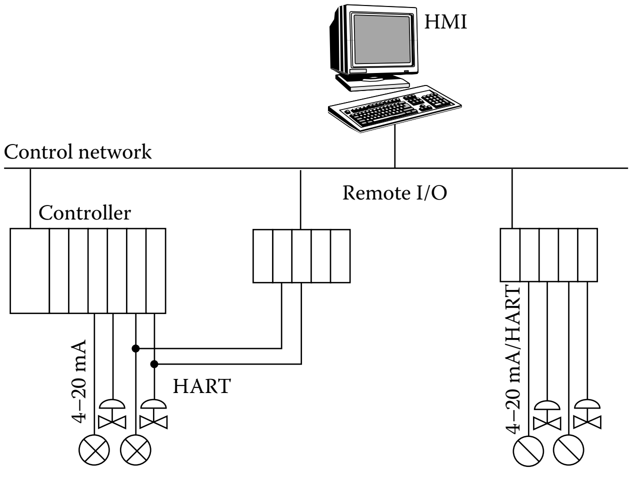

FIG. 4.16n
Typical HART architectures (not including multi-drop bus).

can also be accessed by a SCADA program, which is running in parallel to the controller on a workstation.

- *Remote I/O.* Remote I/Os are wired point to point and may provide loop power for 4 to 20 mA devices. Intelligent I/Os may also contain processing abilities, e.g., the ability to link signals from several sensors to produce a secondary process variable, e.g., density or mass, or be able to perform simple control actions such as closing a valve. Device information is collected by the controller or application software via the control network. Remote I/Os are often transparent, allowing direct configuration of the devices by an appropriate engineering tool.
- *Direct integration.* A recent development on the market is the introduction of controller I/O cards which also process the HART digital signal. This allows the controller to directly access the additional information provided by the devices.

It was mentioned at the start of the section that HART is extremely popular. It has sustained its popularity by successively enhancing its protocol with features that the users require. Where it has not been successful is to free itself from its origins as a protocol for pressure transmitters. This means that more complex devices such as flow transmitters and analyzers rely heavily on device-specific parameters for configuration to the detriment of interchangeability. In addition, the low transmission rate means that the time required for configuration is some 20-fold that of a standard fieldbus protocol.

PROFIBUS DP/PROFIBUS PA

PROFIBUS is an open fieldbus standard. It was developed in Germany and was published as national standard in 1992. European Standard EN 50170 followed roughly a year later.[19] The application profiles PROFIBUS DP (Decentralized Periphery) and PROFIBUS PA (Process Automation), which are used in process automation, are incorporated into the IEC 61158 standard published in 2000.[14]

An overview of the technical data is given in Table 4.16o. PROFIBUS is supported by an international network of PROFIBUS User Organizations, which are also responsible for the maintenance of the standards and certification and testing of the devices.[20] Readers requiring more detailed information on PROFIBUS are referred to Sections 4.13 and 4.14 in Volume 3 of this handbook.[10,21,22] Here they will find a full description of PROFIBUS DP and PROFIBUS PA, as well as information on how to design IEC 61158-2 segments (PROFIBUS PA).

TABLE 4.16o
Principal Technical Data of PROFIBUS PA and PROFIBUS DP Version DPV1

Property	*PROFIBUS PA*	*PROFIBUS DPV1*
Standard	DIN 19245 Part 4; EN 50170, Part 2; IEC–61158 Type 3	DIN 19245 Parts 1 to 3, Version DPV1; EN 50170, Part 2; IEC 61158 Type 3
Protocol	PROFIBUS DP	PROFIBUS DP
Physical layer	IEC 61158-2	RS-485 and/or fiber optics
Length	Max. 1900 m for safe and EEx ib areas Max. 1000 m for EEx ia	Up to 1200 m, depending upon transmission rate
Transmission rate	31.25 kbit/s	9600 bit/s to 12 Mbit/s
Bus access method	Handled from PROFIBUS-DP side	Master–slave with token passing
Participants	32 in safe areas, approx. 24 in EEx ib and approx. 10 in EEx ia	Per segment: max 32 Logical: max 126 (using repeaters), including max. 32 as masters

Figure 4.16p shows a typical PROFIBUS process automation network. It can be seen that PROFIBUS DP (Version DPV1) provides the H2 control network backbone and PROFIBUS PA the H1 fieldbus. Many systems comprise a programmable logic controller (PLC) and a personal or laptop computer equipped with a PROFIBUS DP card, on which the engineering tools are installed. All other devices, e.g., drives, valve positioners, and sensors, are slaves. They may be PROFIBUS DP or PROFIBUS PA devices:

- The PLC acts as a Class 1 master and communicates cyclically or acyclically with the slaves.
- The engineering tool acts as a Class 2 master and communicates acyclically with any device, either

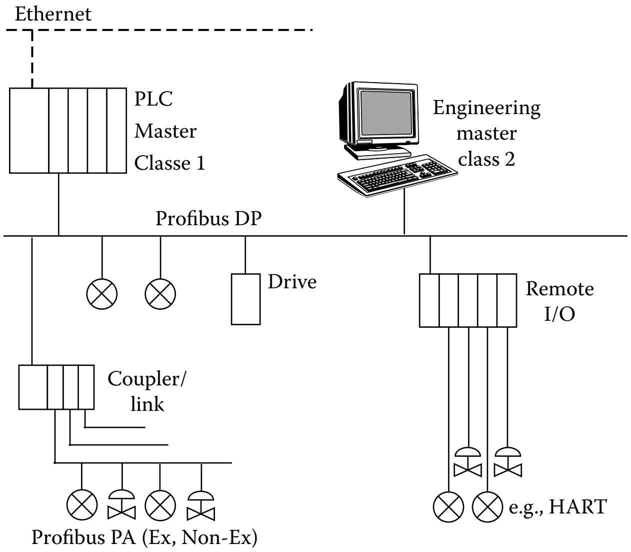

FIG. 4.16p
Typical PROFIBUS architecture.

according to its own schedule or at the request of the device.

- The medium is shared between the two masters by token passing.
- When a master has the right to transmit, it talks with its slaves in a master–slave relationship

The field devices, i.e., sensors and actuators, on the PROFIBUS PA segment communicate with a PROFIBUS DP master via a segment coupler or link:

- A segment coupler interfaces the RS-485 (PROFIBUS DP) and IEC 61158-2 (PROFIBUS PA) physical layers and provides (intrinsically safe) bus power: the same protocol is used throughout the network.
- A link comprises two or more segment couplers and acts as a slave on the PROFIBUS DP side and a master on the PROFIBUS PA side. It collects data cyclically from its slaves on the PROFIBUS PA segments and parcels them into a single telegram, which is sent to the PROFIBUS DP master. In acyclic communication a PROFIBUS DP master, it provides a direct connection with the PROFIBUS PA device addressed.

PROFIBUS PA supports the FISCO model (Fieldbus Intrinsically Safe COncept), so that for segments operating in explosion-hazardous areas, certification is required only for the individual components, not for the network as a whole.[23]

The PROFIBUS standard specifies that each device must contain a set of universal parameters. Mandatory parameters must always be present. Optional parameters are only present when required. Finally, manufacturer-specific parameters are used to realize device functions that are not in the standard profile. Certification ensures configuration compatibility between identical "device-types" manufactured by different manufacturers, e.g., pressure transmitters.

For devices that conform to the standard, these parameters are managed in block objects, e.g., resource, transducer, input, and output blocks. Manufacturers supply both device description files (DDs) for device configuration and device database files (GSMs) for system integration. Should these not be available, devices can still be operated, if not fully, by means of the profile parameters (mandatory and optional) for the particular device type.

Data are exchanged by means of standard telegrams. An "analog" value requires 5 bytes (4 bytes value, 1 byte status) and a discrete value 2 bytes (1 byte value, 1 byte status). A device may output more than one measured value; for instance, a Coriolis flow meter may offer up to 10 different outputs, i.e., a maximum of 50 bytes. When the segment is operated through a segment coupler, data exchange presents no restriction to segment size. For a link, however, there is an upper limit to the length of the telegram, often 244 bytes, but sometimes 122 bytes. This may reduce the number of devices connected to a segment to below the limits shown in Table 4.16o.

Another limiting factor is the current available to devices on the bus. FISCO devices typically draw less current than other intrinsically safe devices, but nevertheless, eight devices is often the maximum per segment for applications in explosion-hazardous areas.

Cycle times vary according to the number of devices in the network and the number of outputs being scanned. An estimate can be made as follows:

Total cycle time = Sum of the cycle times of the field devices + internal PLC cycle time + PROFIBUS DP system reaction time

The cycle time of the PLC is typically 100 ms, that of the devices typically 10 ms for one measured value and 1.5 ms for each additional measured value. The PROFIBUS DP system reaction time is dependent upon the number of slaves and the retry setting. Both are dependent upon the baud rate on the PROFIBUS DP side, which may range from 45.45 kbit/s to 12 Mbit/s depending upon the components used.

PROFIBUS has a large installed base covering a variety of applications in both factory and process automation all over the world. Although it is true to say that its stronghold is in Europe, it would be foolish to dismiss it as a European phenomenon. There are many important users to be found in North America, Southeast Asia, and South Africa. Its strengths lie in the amount of vendor support it has, its ability to use one protocol for factory and process automation, and last but not least, the ease with which it fits into PLC architectures.

FOUNDATION FIELDBUS

FOUNDATION Fieldbus is an open fieldbus standard to IEC 61158[14] and European Standard EN 50170[15] that was developed and is supported by the Fieldbus Foundation.[24] It has been designed to solve the measurement and control tasks associated with process automation, aiming to provide optimum communication between programmable logic controllers (PLCs) or process control systems (PCS) and the plant equipment operating on the field level. A detailed description is to be found in Volume 3 of this handbook.[25] The standard specifies two communication levels:

- HSE, on which traffic between controllers, computers, frequency converters, and other control equipment is handled
- H1, on which traffic between the process sensors and actuators is handled

HSE (High-Speed Ethernet) is the high-speed communication specification for the FOUNDATION Fieldbus. It provides a cost-effective, high-speed backbone by using standard Ethernet technology running at a fixed rate of 100 Mbit/second. FOUNDATION Fieldbus H1 provides low-speed communication for field instrumentation. The FOUNDATION

TABLE 4.16q
Overview of FOUNDATION Fieldbus H1 and HSE

Property	*FOUNDATION Fieldbus H1*	*FOUNDATION Fieldbus HSE*
Standard	EN 50170, Part 4; IEC 61158 Type 1	EN 50170, Part 4; IEC 61158 Type 5
Protocol	FOUNDATION Fieldbus	FOUNDATION Fieldbus
Physical layer	IEC 61158-2	100BaseTX, 100Base FX
Length	Max. 1900 m for safe and Ex ib areas Max. 1000 m for Ex ia	Up to to 100 m (copper) Approx. 2 km (fiber optics)
Transmission rate	31.25 kbit/s	100 Mbit/s
Bus access method	Bus arbitrator (Token passing)	CSMA/CD
Participants	32 in safe areas, approx. 10 in Ex ia	Logical: limited by address range only Practical: limited by response time

Fieldbus protocol is used for both HSE and H1 levels. Table 4.16q gives an overview of the main technical data.

The H1 physical layer (wiring and data transfer mechanism) is based on the international standard IEC 61158-2,[8] i.e., it is exactly the same as PROFIBUS PA. Originally, safety in hazardous areas foresaw only an Ex i or Ex d concept, but the FISCO model[23] was added to the specification in 2002. More information on design of H1 buses can be taken from the corresponding section in Volume 3 of this handbook.[10]

Figure 4.16r shows a typical architecture as foreseen by the specification:

- The process is run by one or more controllers connected to the HSE backbone. These may be separate entities or reside in the linking device. The engineering tool may be part of the system or may run on a separate workstation. Similarly, there may be a SCADA system running in parallel.
- FOUNDATION Fieldbus HSE handles the communication at the control level. Drives, remote I/Os and linking devices, etc., are connected to this bus. At this level the devices are externally powered and HSE ensures that data are quickly exchanged.
- FOUNDATION Fieldbus H1 is used at the field level. The linking device serves as interface to the HSE system. In addition, a power unit and conditioner are required to power the field devices over the bus. Depending upon power conditioner type, the H1 segment can be installed in safe or hazardous areas.

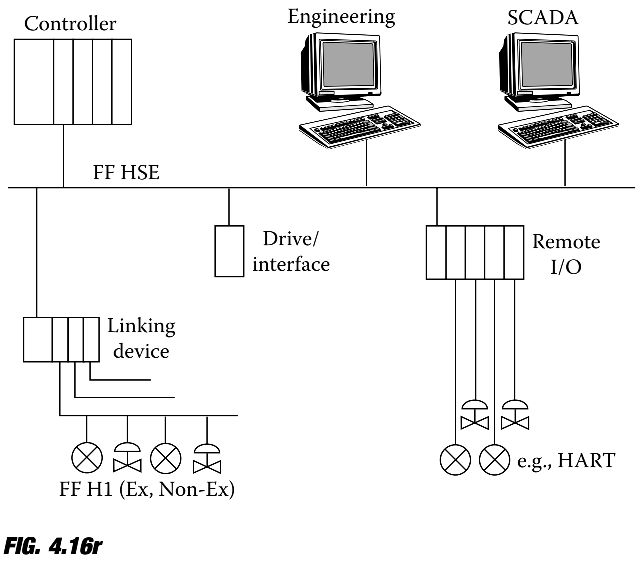

FIG. 4.16r
Typical FOUNDATION Fieldbus architecture.

In view of the fact that the HSE specification was published much later than the H1 specification, there are at least two alternatives to the above architecture:

- Connection via ControlNet: The field devices on the H1 bus are connected to the ControlNet network via a bridge (linking device), which in turn is connected to the ControlNet card of the controller.
- Connection via H1 card: The FOUNDATION Fieldbus H1 bus is connected directly to the controller or control system via a FOUNDATION Fieldbus H1 I/O card.

Access to the fieldbus is managed through a deterministic centralized bus scheduler called the link active scheduler (LAS). Fieldbus devices may be of two types: link masters or basic devices. A link master has LAS functionality; a basic device does not. Each fieldbus segment contains one LAS. It may also contain other link masters that are not active, but that can be called upon to become the LAS in the event of failure of the preferred device. All transmissions, whether scheduled or unscheduled, are instigated at the request of the LAS:

- Scheduled transmissions are used to cyclically transmit process values and control block I/O parameters. The LAS sends a compel data (CD) request at the scheduled time, and the device publishes its data on the bus.
- Unscheduled transmissions are made during the periods when the field devices are executing their function blocks or at the end of the CD schedule. The LAS temporarily gives device permission to transmit in a client–server or source–sink relationship, by sending a pass token message.

Table 4.16s gives more details of how the various communication methods are used.

Similar to PROFIBUS PA, FOUNDATION Fieldbus also manages device parameters in block objects, e.g., resource, transducer, input, and output blocks. It is unique, however, in

TABLE 4.16s
Types and Uses of Communication Relationships in FOUNDATION Fieldbus

Publisher/ Subscriber	*Client/Server*	*Report Distribution (Source–Sink)*
Scheduled	Unscheduled	Unscheduled
Used for publishing data	Used for operator messages	Used for event notification and trend reports
Sends parameters between blocks, e.g., the PV value to a PID control block and operator console	Set-point changes Mode changes Tuning changes Upload/download Alarm management Access display views Remote diagnostics	Sends process alarms to operator consoles Sends trend reports to data historians

TABLE 4.16t
Principal Technical Data for MODBUS

Property	*Serial MODBUS*	*MODBUS TCP*
Standard	Industrial standard	Industrial standard
Physical layer	Not specified, but usually RS-422, RS-485	10BaseTX, 100BaseTX
Length	1200 m at 19.2 kbit/s	100 m
Transmission rate	Max. 19.2 kbit/s	10/100 Mbit/s
Bus access method	Master–slave	CSMA/CD
Participants	1 master, max 247 slaves	Logical: limited by address range only Practical: limited by response time

specifying standard control blocks, e.g., PD, PID, Arithmetic, etc., that may be implemented in the field devices. Manufacturers supply both device description files (DDs) for device configuration and device database files (CFFs) for system integration. Unlike PROFIBUS, up to the time of writing FOUNDATION Fieldbus has not specified device profiles, so that generic operation of particular device types is not possible. Usually, the system engineering tool is used both to configure the network and set up the devices parameters.

The control cycle time depends upon the number of devices on the segment and the way in which the control loop has been configured. Although control block execution in a controller is quicker than in a field device, it involves a greater number of data transfers, each taking around 10 ms. In addition, unscheduled transmissions must be made to ensure the data flow within the system. On average, therefore, the full cycle (macrocycle) is 150 to 200% of the time it takes to execute the control itself. Typically this will be around 1 to 2 seconds. If the cycle time is unacceptable for the application at hand, it must be optimized by reducing the number of devices on the segment or changing the location of the function blocks.

FOUNDATION Fieldbus was later on the market than PROFIBUS and suffered from the late introduction of the HSE layer. As a result, support for high-level control equipment, i.e., drives, etc. is still weak. Initially, it suffered from interoperability problems because only devices and not host systems were tested for conformance. This has now been remedied, however, and the market has responded accordingly. FOUNDATION Fieldbus has strong support in North and South America as well as Southeast Asia and China. It is beginning to make an impact on Europe.

Its installed base is in traditional DCS industries such as oil and gas and pulp and paper, but it is also penetrating water and wastewater and chemicals. Although it offers control in the field, and many users see great potential in this functionality, most system vendors steer clear of such applications and use FF in a pure "master–slave" environment.[26]

MODBUS

MODBUS is a quasi-industrial standard developed some years ago by Gould-Modicon[26] and is a messaging service that may run on a variety of physical layers. Its two open versions are of interest here:

- Serial MODBUS, using RS-485 (or RS-422) as physical layer allows the connection of MODBUS devices to a PLC in a bus structure, whereby analog devices can be connected via gateways.
- MODBUS TCP (also known as MODBUS TCP/IP), using Ethernet as physical layer, allows the exchange of data between PLCs in different networks.

Table 4.16t summarizes the principal technical data. Figure 4.16u shows a typical system architecture.

The MODBUS protocol exchanges data in a master–slave relationship. Each slave has a unique address, and the data are identified by their location in the slave address register. Certain characteristics of the MODBUS protocol are fixed,

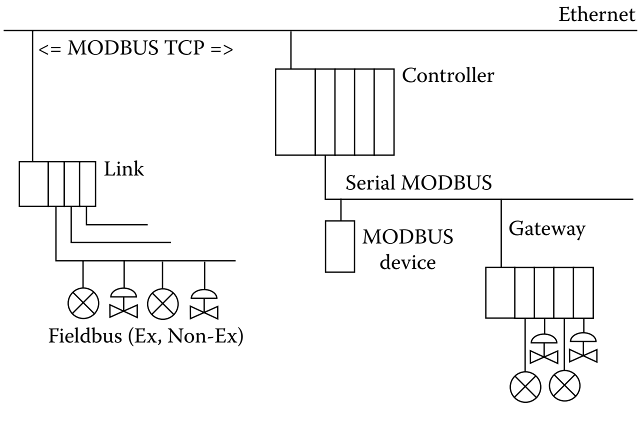

FIG. 4.16u
Typical MODBUS architecture.

such as the frame format, frame sequences, handling of communications errors, exception conditions, and the functions performed. Other characteristics are user selectable; these include transmission medium, baud rate, character parity, number of stop bits, and transmission modes (ASCII or RTU). The contents of the data carried by the protocol are also freely selectable, i.e., nothing is said about strings, integers, floating-point numbers, etc.

The MODBUS protocol controls the query and response cycle between master and slave devices. Only the master can initiate a transaction. A query and response may involve only a single slave, or it may be in the form of a broadcast, in which case the slaves do not answer. The query is contained in a frame that includes the address of the intended receiver, what this slave is to do, data needed to perform the action, and a means of checking for errors. The slave checks whether errors have occurred and performs the desired action. After the action is performed, the slave builds the response and returns it to the master. The master can send another message to any slave as soon as it receives a valid response or after a user-selected time interval. This "time-out" time has to be selected on the master device and depends on the slave response time.

The data can be exchanged in two transmission modes: ASCII (American Standard Code for Information Interchange) and RTU (Remote Terminal Unit). The major differences between them are the type of error check performed on the message and the number of characters used. MODBUS offers several read, write, and test functions, each identified by a code number. They are designed as control commands for sensors and actuators, e.g., coils, inputs, input registers, holding or output registers, diagnosis and test reports, programs, polling control, and reset. For MODBUS TCP the serial frame is simply inserted into the Ethernet data frame. In addition, not all codes are implemented (see Reference 27).

MODBUS has a large, worldwide, installed base. It remains popular because it is a very simple protocol that requires little programming effort to get it running. It enjoys extremely good support from system manufacturers both on the field and now on the control network side. The support for MODBUS TCP by manufacturers and users makes it a serious contender, alongside FOUNDATION Fieldbus HSE, to become the universal "Industrial Ethernet."

CONTROLNET

ControlNet is an open fieldbus standard to IEC 61158[14] that was developed as a proprietary protocol by Rockwell Automation. It is supported by the ControlNet User association.[29] Essentially, it is a control network that shares a common application protocol with DeviceNet[30] and Ethernet IP.[31] Its installed base is in factory automation, but like PROFIBUS DP it crosses the border to process automation. When used in the latter, FOUNDATION Fieldbus provides the H1 layer; the connection is made by a ControlNet/FF gateway that interfaces both physical layer and protocol. This solution may be short lived, however, since manufacturers are working on a full FOUNDATION Fieldbus solution for their controllers.

ControlNet is important because it has a large installed base in a broad range of applications in North America. Apart from isolated countries, however, it has no great significance for the rest of the world.

INDUSTRIAL ETHERNET

As mentioned in the introduction, Ethernet has become the dominant technology at the operations and in some cases the control network level. Detailed information and white papers are available at a number of company Web sites, e.g., References 31 and 32. A typical system architecture is shown in Figure 4.16v. Unlike PROFIBUS and FOUNDATION Fieldbus, it is not a designer solution for Process Automation; rather, it has been found to have a lot of characteristics required for the H2 layer: openness, inexpensive components, and support from major systems and software manufacturers.

Unfortunately, there is no "Industrial Ethernet" standard as such, although there is a supporting association.[33] Rather there is a collection of protocols that use the Ethernet physical layer, IP, and TCP. The most fully defined protocol is FOUNDATION Fieldbus HSE. MODBUS TCP is not a standard but is popular and in widespread use. Ethernet IP has some

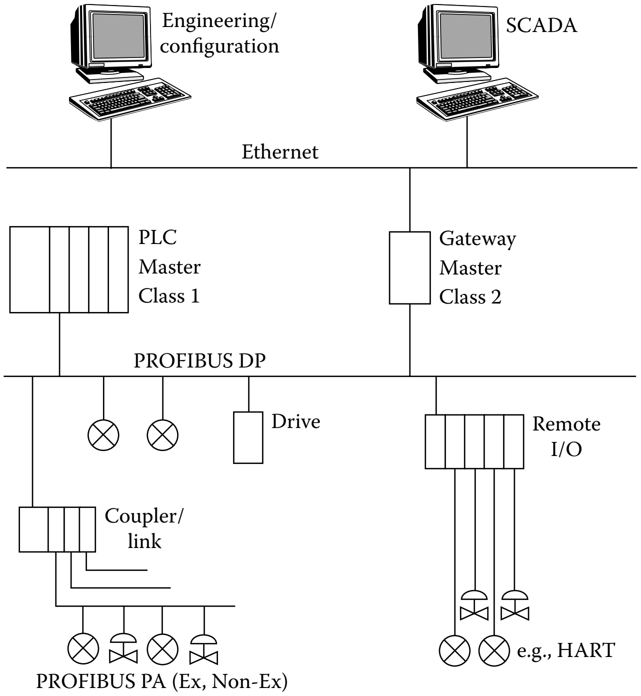

FIG. 4.16v
Typical Ethernet TCP/IP architecture using the example of PROFIBUS DP as control network.

support, and there are a number of proprietary systems with Ethernet TCP/IP backbones.

The protocols function by either packing their information in the Ethernet data frame or mapping proprietary applications on the TCP and IP protocols. Devices using different protocols cannot understand each other, but in some cases, e.g., with HSE and MODBUS TCP/IP, it is possible to use the same network to transport data. The matter is further complicated by the existence of two different Ethernet frames: devices receiving the wrong kind simply assume that a collision has occurred and reject the data. On the other hand, it is a fairly simple matter to map compatible systems, and for example, FF Function blocks for the interpretation of MODBUS data already exist, providing a excellent means of communication between FF and legacy systems.

Ethernet is accessed by means of the CSMA/CD method. This means that it is ideal for the transfer of non-time-critical information but requires an additional means of controlling medium access if it is to be used in deterministic control applications. Current equipment is usually capable of transmitting at 10 or 100 Mbit/s as required over 4-wire twisted pairs as well as fiber-optic cables. Commercial equipment is sufficiently rugged for a control room environment.

A frequently asked question is how long will it take Ethernet to penetrate the field. Four factors may have an influence:

- *Cost and availability of suitable chips.* This is probably a question of supply and demand; if there is a move toward Ethernet devices, the costs will decrease in inverse proportion to the numbers produced. In the long term, therefore, no hindrance will occur.
- *Information content and response times.* The standard TCP/IP frame has a minimum length of 72 bytes. Although the transmission of information across the network is fast, the protocol overhead increases the turnaround time and hence the response time of the system. At present, Ethernet is no match to a binary protocol such as AS-i, and in this case, would be definitely more expensive. The increase in transmission speed provides little advantage where process variables such as temperature and level are concerned, because the sensor response time places a lower limit on the polling interval.
- *(Intrinsic) powering of the devices.* Power supply over Ethernet is not an issue, but intrinsically safe power is. This is the main reason why IEC 61158-2 was developed for process automation. Any substitute must solve this problem before it can penetrate at field level. Since intrinsic power is not of interest to the home and office applications, it is unlikely that there will be much pressure in this direction.
- *Ruggedness.* Industrial connectors do exist, but other Ethernet equipment, such as cables and switches, is seldom designed for an industrial environment. An adaptation to, e.g., IP 67 or the equivalent NEMA rating would cut off the user from the benefits of a mass market and lead to a considerable increase in price.

Summing up, Ethernet at field level still seems far away, but devices operating in safe areas will be provided with Ethernet connections for integration at control level in the not-too-distant future. More information is contained in the recent ARC survey on the subject.[34]

NETWIDE DATA EXCHANGE

Where a process facility has a proprietary process control system installed, the problem of information exchange across the plant will have been solved by the system vendor. This is done, however, at the expense of freedom of choice regarding the sensors, actuators, and auxiliary equipment as well as flexibility in system design. Being locked into a particular system can also be expensive. Open systems, on the other hand, allow the user to choose the best devices and components or simply ensure that the best performance is being bought for the budget at hand.

For standard systems, data exchange between field devices and controllers is governed by the standard specification. There are many applications, e.g., a SCADA system or Microsoft Office program running on a personal computer connected to an Ethernet at the operations level, where information needs to be exchanged outside the bounds of the standard specification. This also applies when data from different systems operating with different protocols is to be gathered together at a single point.

Plantwide information exchange in an open system is often solved by the use of OPC servers. Since the support by Microsoft for XML, there is also considerable interest in this technology as a means of handling structured information in open networks. Finally, FDT/DTM, although still regarded skeptically by some parts of the I&C establishment, provides a protocol-independent technology for exchange of data for device configuration and asset management tasks. The paragraphs below describe these three technologies.

OPC Servers

OPC is a series of specifications based on basic PC standards and technology that provides open connectivity in industrial automation and enterprise systems. The standards are created, maintained, and adapted to new technologies by the OPC Foundation, a user group, which owns the technology and provides compliance testing.[35]

The original OPC standard, covering data access, was the result of collaboration between a consortium of system vendors and Microsoft. It defined a standard set of objects, interfaces, and methods that provided a simple means of ensuring interoperability of process and factory automation applications. This framework allowed a large number of software products to be developed that ensure seamless data exchange throughout the factory network.

Before the development of the OPC specification, a special driver had to be written if one application on a network, e.g., a controller, was to exchange data with another, e.g., a human-machine interface (HMI) application. Since no two controllers handled data in exactly the same way, an HMI supplier had to supply a driver for every controller on the market. In practice this did not happen, so users were restricted in their choice. By installing standardized OPC interfaces in both components, only one driver was required and data could be exchanged in a client (HMI)–server (controller) relationship. This technology is not restricted to controllers, however, and other control devices such as remote I/Os, gateways, FF linking devices, or even field devices can publish data in the same manner.

The benefit to users is flexibility and lower costs. Software components can be chosen on the basis of their features and performance rather than a need to connect to a particular device. Quality is improved since components are subject to independent testing. In addition, because a component is reused many times, it undergoes continuous improvement.

The original standard regulated the acquisition of process data, but it was quickly realized that other types of data could benefit from standardization. At the time of this writing, seven specifications have been completed or are in development, covering many aspects of data exchange, from data access, through alarm and event handling, to the exposure of XML data in field devices. Cooperation between the OPC and field device tool-joint interest group (FDT-JIG) in the field of device configuration and asset management standards has also been announced recently.

XML

XML stands for eXtensible Markup Language and is a text markup language that in functionality and simplicity lies somewhere between its parent SGML, which was standardized in the 1970s, and HTML. It is designed to carry structured textual information independent of style information. HTML differs, because style information, e.g., font and font size, is carried by predefined tags within the file. XML does not have predefined tags and uses a Document Type Definition (DTD) or an XML Schema to describe the data held in an XML file.

Readers familiar with DD technology will immediately recognize the similarities between the two technologies: a TXT file, DD or XML, carries the data and the Type Definition, Device or Document, respectively, interprets them.

Separating data content from the way in which it is displayed ensures that any change to one does not affect the other. This leads to several interesting applications in process automation:

- XML data can be published in HTML pages provided by a Web server and read by a local browser.
- XML data can be transmitted together with its DTD across the Internet or control network and read directly by, e.g., Microsoft Office programs such as Excel that support XML data exchange.
- An OPC server is capable of taking the XML data and storing it for use by a HMI or SCADA application.
- The simple nature of the file form means that it is easier to share data between different components within a system.
- The structured nature of the data means that it is easy to store them in files or databases. Storage and retrieval programs are easily written and generic applications can be used to display the data.

XML can also be used for exchange of data between control and enterprise systems as well as for business-to-business (B2B) applications. Thus, it is being considered as a data carrier in e-business applications and e-purchase based on the exchange of electronic data sheets. The latter foresees the automatic generation of a measuring point specification from an engineering tool and in response a corresponding device data sheet from an electronic catalogue. At each stage of the purchase process, data are added to the sheet, e.g., serial number, device attributes, so that on delivery of the physical device, its full electronic description can be loaded into the engineering or asset management system.

Finally, moves are afoot to bring XML into the field devices themselves. This would mean that eventually, all the parameters and information held within a fieldbus device would be structured in the same manner, with the same tags, independent of vendor and protocol. Only the communication across the network would be protocol dependent, and when the features of FDT technology are considered, even this will play a minor role in the future.

FDT/DTM

With digital communication, field devices must be integrated into the control system before they can be operated. To this end the manufacturer supplies a device description with each device, which tells the operating software which parameters the device contains and how incoming data are to be interpreted.

Unfortunately, device integration is seldom a matter of plug and play. Although device descriptions are standardized for HART, PROFIBUS, and FOUNDATION Fieldbus, it is often the case that additional data or proprietary formats are required for particular systems.

Quite detailed knowledge of the system is required if the device is to work properly the first time. Moreover, it is seldom that all device functionality can be integrated into the third-party system. Even when system and device vendors cooperate to optimize interoperability, updates to software can cause devices to fail because the updated device descriptions are not immediately available. In addition, although the device appears in a uniform environment, it may be totally different from the one described in the device operating manual.

This is essentially the same as the HMI/controller driver issue, which was solved by the OPC initiative. The prime mover in the case of FDT (field device tool) was the PROFIBUS User Organisation. The idea was to define a set of protocol-independent interface standards for the exchange of device configuration and later asset management data throughout the control network. Each intelligent device in the network is supplied with a so-called DTM, which contains both the parameters and the operating interface for full device configuration. The DTMs are programs that run in an FDT frame program. There are two types: Device DTMs for field devices and CommDTMs for communication devices, e.g., gateways or remote I/Os. Transparent communication devices requiring no configuration, e.g., couplers, require no DTM.

The standard ensures that all DTMs run in all FDT frame programs. Responsibility for the production of the DTM lies with the manufacturer, who together with the user has the guarantee that it will run in all systems that are FDT compliant. The DTM is generated from the existing HART, PROFIBUS, or FOUNDATION Fieldbus device descriptions (DD or EDD). This means that even if a manufacturer does not support the standard, DTMs can be obtained for its devices. An alternative, with restricted operability, is to use generic DTMs for a particular protocol. Since FDT essentially frees device operation from protocol-dependent factors, it also provides seamless data flow across networks in which different protocols are operating.

The year 2002 saw the establishment of the FDT-JIG,[36] which has now taken over the responsibility for developing, maintaining, and testing compliance to the standard. At the time of writing, over 30 companies worldwide are actively involved in the group, many with DTMs or FDT frame tools on the market. CommDTMs are available for Ethernet, PROFIBUS, and HART components; MODBUS may also be a possibility in the near future. Device DTMs are available for HART and PROFIBUS. The specification for FOUNDATION Fieldbus is complete; its feasibility was demonstrated at the ISA shows in 2002 and 2003, and products were shown at the Inter Kama 2005 show.

CONCLUSION

Having seen the progress made over the last 10 years in fieldbus technology, it would be appropriate at this point if the authors could look into the future. Unfortunately, this is not possible. There are, however, certain trends observable that will probably have a great influence on the control system of the future:

- Field devices are becoming increasingly important as a source of information for plant and enterprise asset management systems. The standards are already in position; vendors will adapt their systems to allow free flow of information from field to enterprise level.
- As plant and enterprise asset management grow in importance, the influence of information technology on control system design will increase. The databases behind the system will become standardized, and proprietary systems will move towards openness.
- As protocol-dependent factors are eliminated from the system database, the role of the protocol in control and asset management systems will be reduced. OPC, XML, and FDT are already eroding its influence; cooperation between them will eliminate it completely.
- Web technologies are beginning to appear in remote monitoring applications. The embedding of sequential or continuous control in “Plant Access Points” utilizing this technology will open a new era of “Microcontrol,” where size and control capability will be exactly matched to the task at hand.

There are, of course, a great number of other factors that can and will influence the development of both networks and the protocols that are used on them. Perhaps the future is different—but we will have to wait until the next edition of this handbook before we will know for certain.

INTRODUCTION

The devices that operators use to control process equipment have changed dramatically since the beginning of the digital age. In some cases the operator is surrounded with multiple human–machine interfaces that more closely resemble NASA's mission control center than the bench boards and instrument panels of the past. In other cases the operator control room is becoming less significant as operators are using handheld devices and Web pages to access the process information and control systems. However, we still see much of the information presented on digital displays with images of the control stations, pushbuttons, and trend charts resembling bench-board equipment used 50 years ago. Further, the digital displays are often installed and configured by technicians and system integrators without regard to supporting the operator's entire job, making the modern controls less intuitive than the bench-board controls were (Figure 4.13h). Notwithstanding these issues, the digital display HMI has allowed a single operator to monitor and control thousands of process control loops from a single station (Figure 4.5c). The latest advances in HMI technology using inexpensive hardware, thin-clients, handheld computers, and cell phone technology have freed the operator from confinement to a particular location for control and information systems. Understanding the evolution of the operator interface and the changing role of the operator in a plant allows suppliers to build a better HMI product, plant engineers to pick the best technology, and integrators to make the operator more effective and efficient.

The modern HMI is at the evolutional convergence of two different development paths. One development path is that of the operator console of the distributed control system (DCS). The other path is the development of the HMI for the programmable logic controller (PLC). This makes a chronological discussion of HMI evolution somewhat difficult without getting the reader confused about which HMI is being discussed. Therefore, this author will discuss the basic functions of an HMI and then attempt to describe the evolution of DCS and PLC human–machine interfaces separately. Toward the end of this section, once again the discussion of control rooms, operators, and the future will apply to all HMI systems.

FUNCTIONS OF THE CONTROL SYSTEM HMI

Operators have always had HMIs, with some of the oldest being the handle of a valve or the faceplate of a pneumatic controller. Although the term HMI can refer to any type of device that allows a person to manipulate a machine or process, the term as used in process and manufacturing usually refers to the display, computer, and software that serve the specific role as the operator's interface to a controller or control system. The same display, computer, and software used for another purpose do not make an HMI. An analogy is a taxi. A taxi is an automobile, boat, coach, or rickshaw that serves a specific function of transporting a customer from one location to another. Use the same vehicle in another function and it is not a taxi.

This section uses the term HMI to describe the computer hardware and software that allow interaction between the operator and the controls.

Many HMI product suites provide functionality beyond HMI. These system functionalities will be discussed, but we will always try to use a term other than HMI to describe these devices. Further clarification will be provided as necessary to describe specific HMI hardware, software, or a specific type of HMI. Table 4.17a is a quick reference of the specific "HMI" terms used in this section.

The operator interface to the plant process, whether bench-board devices or HMI, has four primary functions. The first function is to provide visualization of process parameters. The second function is to enable interaction or manipulation of the process or machine. Third, the interface is to provide alarms and event notification to the operator that some area of the process should be monitored more closely or that some type of corrective action is required. Finally, the fourth function of the operator interface is to provide a method, such as a trend chart, to allow the operator to understand where the process is going and how fast. Other uses of the operator interface should be secondary to these.

TABLE 4.17a
Definitions of HMI Terminology

Term	*Definition*
HMI	Human–machine interface. Computer hardware and software that allows operators to interface with the control system.
CRT HMI	Cathode ray tube HMI. The term is specifically used where there is a transition from hand stations to the HMI.
DCS HMI	Proprietary HMI from DCS vendors that is optimized to work with the DCS.
GUI	Graphical user interface. General computer term for software that allows graphical interaction with the computer.
Open HMI	HMI built on PC hardware and Windows operating system for general use. Not specific to any hardware.
Operator's window	Open HMI that incorporates information systems and controls.
PLC HMI	Proprietary HMI from PLC vendors that is optimized to work with the PLC.

Visualization and Control

The first two responsibilities of the HMI are to provide the operator with a view of the process and a way to control the process. The panel board was the operator's window to the process through the various control stations and the analog instruments before the digital age of controls. The controllers themselves were mechanical devices that mounted to the bench board or the control panel.

Most of the controller was hidden from view, and the part of the controller that was above the bench board for the operator to see and use was the controller faceplate. This faceplate displayed the process variable and provided access to change the mode, set point, or output to the loop. The controllers were mounted on the panel in logical clusters based on the process group. Figure 4.17b shows a power

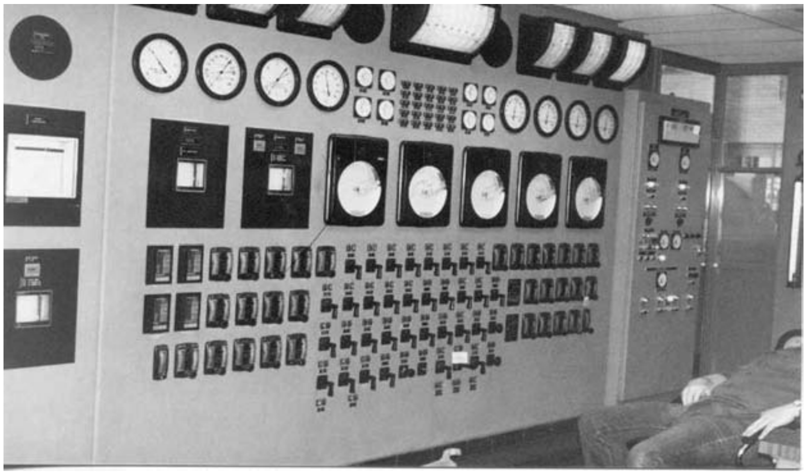

FIG. 4.17b
Power boiler control panel circa 1984, picture by Jim Mahoney. Nineteen hand stations are in the bottom center of the panel. Four are digital stations for a Bailey Net90 DCS, the other fifteen are pneumatic controllers.

FIG. 4.17c
Group display of hand-station faceplates on a Bailey Net90 HMI circa 1985. Photograph provided by Jim Mahoney.

boiler control panel with pneumatic controllers to the right and a few electronic trend units and DCS hand stations on the left.

The HMI provides the same functionality to monitor and control the process in a newer, highly customized, and constantly evolving package. The HMI makes it possible to increase the number of control loops and process information presented to the operator many times higher than could be mounted in a control panel. A configurable display also gives the ability to present the information to the operator in many and various ways. Figure 4.17c shows a very simplistic graphical operator interface with the controller hand stations implemented on the HMI.

Process Alarming

The third responsibility of the operator's HMI is generation, annunciation, and manipulation of process and system alarms. Prior to the digital control age, generation of the alarm was the sole function of a switch in the field to determine whether a process parameter such as a pressure or temperature exceeded specifications. A backlit light box with translucent window panels with the alarm written on the panel, called an annunciator, is the operator's indication of the alarm. The discrete alarms were wired from switches to the annunciator to provide a visual and audible alarm for serious process upsets or failures.

The annunciator allowed the operator to manipulate the alarm by silencing the audible portion or acknowledging the alarm. Alarming process parameters with an annunciator panel is very straightforward—install and calibrate the proper switch in the process, and wire the switch contact to a power source and to the annunciator panel. Of course, the alarms were expensive because of the required field installation of switches and wiring. Also, there was a finite amount of wall space in a control room to install annunciator panels, but on the positive side there were very few nuisance alarms.

The modern HMI generates process alarms from the analog process variable or a discrete input from the control system. The HMI displays, stores, and manages the alarms. Process switches are not needed to provide process alarms, and the number of alarms that can be generated is virtually unlimited. The modern HMI makes process alarms cheap and easy to implement, thus allowing engineers and managers to create nuisance alarms at an unprecedented rate.

Management of process alarms through silencing, acknowledging, and summarizing is now a primary function of the HMI. Advanced alarm management, organization, and analysis are distinguishing features among HMI products.

Trending

Long before the digital control system age, operators depended on pen recorders to tell then what the process was currently doing and also the trend of the process variable. Analog pen recorders were set up to record the process at variable rates to make the chart show the process trend for a certain number of previous hours. The resolution of the recorder was inversely proportional to the amount of time the recorder captured on paper. Getting the proper balance of time and resolution on the recorder was very important to helping the operator understand the direction and rate of change of the process. Recorder paper was changed as necessary and kept on file to enable process engineers and managers to look at the history of the control parameter.

The first digital display HMI immediately had provisions for keeping a history and the capability to provide the operator with trending to replace the chart recorder. The trending is very similar to the chart recorders—the data are collected at a rate that will balance resolution with the total trend time.

However, unlike with the chart recorder, the operator cannot change the paper and store an unlimited amount of process history.

Most of the control system and HMI companies abdicate the long-term historical systems to others, choosing instead to provide medium- to short-term trending for operators only. This decision is still reflected in many HMI products, where operator history and trending are an integral function of the HMI, but long-term history for management or regulatory compliance is not.

DCS CONSOLES

The first companies offering digital display operator consoles for process controls are the DCS companies, beginning with Honeywell in 1975 with the TDC 2000.[1] This was followed closely by several other major manufacturers of control products. The introduction of a graphical user interface (GUI) display as the operator HMI is a technology leap destined to change the way many industries operate. Yet many operators and some engineers feel more comfortable operating the process from a digital representation of their own older process controller faceplate than from a graphic of the process.

The faceplate is familiar to the operators, provides all of the detail about the controller and the control loop, and is easily implemented by engineers. The problem with using the faceplate from the HMI is that the operator often had a much better intuitive feel for finding the right controller and responding quickly to upsets with the bench-board controls as compared to navigating through various displays of screens to find the right controller.

Custom process graphics, or mimic displays, showing representations of pumps, motors, vessels, agitators, heaters, and other process equipment along with good overview displays and standards for navigation make controlling large processes from the HMI display much more intuitive for operators.

In 1983, Savannah Electric and Power Company bought a Bailey Net90 DCS to replace pneumatic boiler controls and, like many others, chose to only replace pneumatic controllers on the bench board with rows of digital hand stations connected to the DCS. Figure 4.17d shows digital hand stations for a Bailey Net90 mounted in a panel beside pneumatic controllers.

The Bailey OIU (operator interface unit) displaying process graphics and graphical representations of the hand station faceplates sits beside the operator bench board. The logic of the transition is that the operators are accustomed to controlling the process by controller faceplates, and process graphics are new and will take time to learn. The expense of redesigning the control room to make the HMI useful as the primary interface is also a large factor in a phased approach to introducing the HMI.

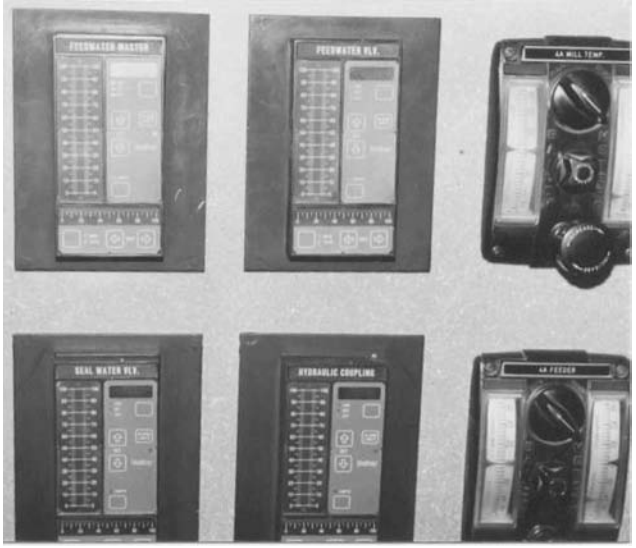

FIG. 4.17d
Four Bailey Net90 DCS hand stations mounted beside two pneumatic controllers, circa 1984. Photograph courtesy of Jim Mahoney.

At Savannah Electric, the HMI offers more information than the hand stations show, and the operator can sit in one position to control and monitor the boiler and auxiliaries. Eventually, the operators use the HMI as their primary control interface.

DCS Console Graphic Standards

The early DCS console was built specifically for a single control system. Controller faceplates were standard graphical objects that looked and functioned like bench-board hand stations. The most popular early displays were the faceplate, group, and area.[1] The faceplate is the graphical representation of the hand station with all of the process information and loop control. The group display is a display showing four to eight faceplates in a little less detail. The area display is an overview of many process variables that allows operators to quickly see whether the processes are stable. DCS mimic displays are the highly customized displays that operators like.

Mimic displays show graphical illustrations of the process with process information. Good mimic displays and good overview pages that show only the most pertinent information about large process areas make the operators more efficient. The HMI is so flexible and easy to change that companies quickly realized that they needed to adopt at least basic standards for building these custom displays to ensure consistency between engineers and projects.

Suddenly, industry and plant questions arose as to whether a red motor indicated the motor is energized or did it mean the motor is stopped? Does a green valve indicate open, closed, or deenergized? The standards that most companies adopted include object size, conditional colors, process colors, screen navigation, and screen density guidelines. Organizations such as the ISA developed standards for operator displays that include the items above and many more.[3]

The standard displays for most DCS operator consoles include:

- Process graphic displays
- Faceplates
- System diagnostic graphics
- Controller tuning pages
- A list or hierarchy of displays
- Alarm summary page
- Trending pages

Screen/Page Navigation and Item Selection Navigating between DCS displays on first- and second-generation systems and selecting the controllers on the display is highly customized with custom keyboards to make the operator efficient. Generally, the only "mouse" in the control room at this time (early to mid-1980s) was the real one that shorts out control loops while eating insulation off the cables. The common methods of screen navigation included:

- *Touch screen.* Touch the object to select it. This included paging objects.
- *Direct screen reference (DSR) numbers from one display to the next.* The DSR selected the display.
- *Direct screen reference (DSR) numbers from the display list.* Each display on the display list was assigned a DSR number. Selecting that DSR from the display list would take the operator to the display.
- *Configured forward and backward display keys.* Each display could have configured forward and backward displays to navigate logically.
- *Show detail keys.* Devices selected could bring up a detailed display of the object or controller.
- *Defined function keys.* Console keys that change to preconfigured display.
- *Trackballs.* The trackball was mounted in the custom keyboard and manipulated a pointing device on the display.

More vendors used a mouse or trackball and fewer use custom keyboards with later revisions of the DCS operator console, although the best operators swear they are more efficient with the older custom keyboards and DSRs on the display.

DCS HMI Redundancy

Many managers and engineers were worried about operating potentially dangerous processes through a computer when the DCS first arrived on the scene. DCS vendors worked hard on the technical issues of redundancy and selling the concept of the HMI to industries that liked the idea of direct manipulation of hand stations on controllers.

First-generation DCS consoles were built of a minicomputer and multiple workstations that were dumb terminals (thin-clients) of the computer. Installing at least two computers or sets of console electronics, and using two different power sources for the electronics and the operator terminals achieved a comfortable level of redundancy. See Figure 4.17e again for the "typical" DCS HMI arrangement. Notice in the diagram that the operator has two workstations from two different console electronics. If one power source fails, or one HMI computer fails, the operator loses only one workstation.

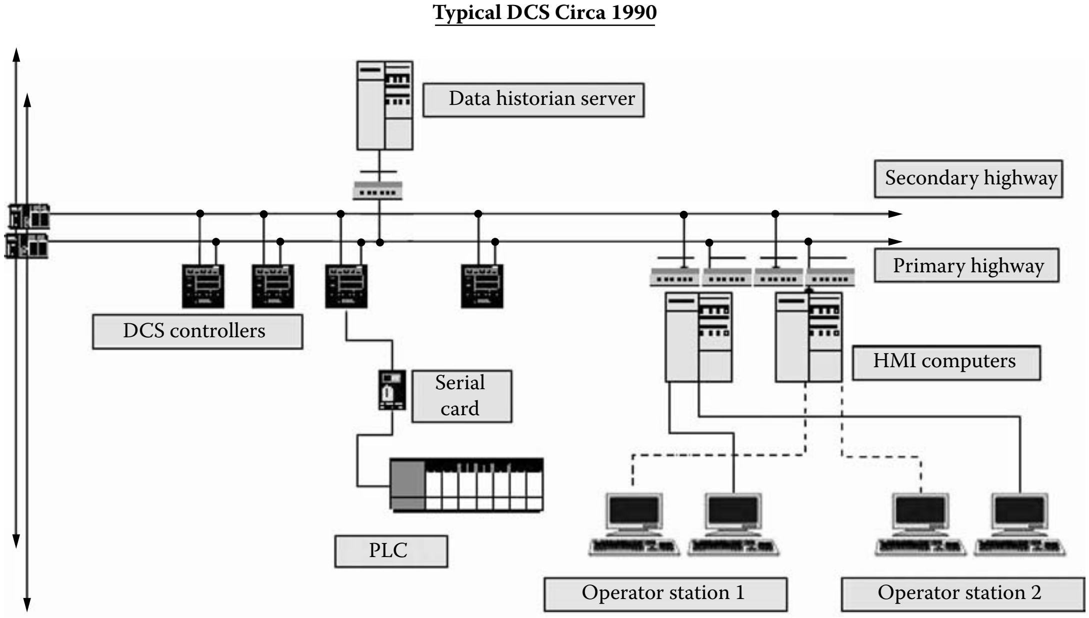

FIG. 4.17e
This is a typical DCS system from the early 1990s.

The first-generation consoles from vendors such as Fisher Controls and Bailey Controls could be configured with up to 2,500 points. Second-generation consoles could handle 10,000 points. The HMI had to provide operators with an efficient interface to the DCS with the number of displays and point count necessary for the application yet still refresh quickly. A common console specification demands a maximum screen update time of 5 seconds and a refresh rate of 3 seconds. The console is a very large part of the selection criteria for a DCS for many customers.

DCS HMI Chronological Evolution

1975–1985 The various HMI offerings use proprietary hardware and software and, like other systems of that generation, hardware and software are inseparable. Nowhere is this more evident than in the HMI keyboards. The keyboards contain rows and rows of special fixed keys to start, stop, open, and close the selected devices and acknowledge alarms and silence horns. The keyboards also have configurable keys for display navigation and special functions.

Finally, the HMI includes function keys that change function with each display to help make the operator more efficient. Each DCS vendor has different ideas and standards for their HMI, but all approach the operator interface as the total solution to replace the bench board. The DCS HMI includes cabinets with room for mounting push buttons or telephones, wedge-shape tabletops to mount between HMI consoles to curve the console, matching tabletops for writing surfaces, and even chairs.

1986–1995 Later generations of these proprietary HMI products show incredible integration with other components in the "system." Most DCS HMI products incorporate distributed alarming, console redundancy, and a common configuration database for controllers and consoles. System ease of use is a theme. One price for this tight integration of proprietary systems is that by the second or third generation of DCS offerings, communication problems exist between vintages. The first-generation HMI cannot always communicate with second- or third-generation controllers and third-generation HMI cannot always communicate with first- or second-generation controllers.

The proprietary HMI communicates only with the DCS controllers. A company that employees PLCs to do motor logic has to interface the PLC to the DCS at the controller level to have the DCS HMI stop and start the motor. Figure 4.17e shows a typical DCS interface to PLCs and historians. This adds greatly to the cost of the system and adds unnecessary load on the DCS highway just to give the operator access to the motor controls through the HMI.

1996–2002 This is generally the first generation of HMI from DCS vendors that is based on the Microsoft Windows™ operating system and uses commercial off-the-shelf hardware where possible to keep costs lower. Proprietary may not be the correct terminology to describe this generation of DCS HMI products, but they are very often highly optimized with their own proprietary DCS controllers and much less capable of working with other controllers.

This generation DCS HMI uses inexpensive PC equipment and operating systems familiar to their clients but is not generally marketed as an open system to other controllers. Many of the DCS companies have trouble building a console on the Windows operating system that is as functional or as reliable as their older consoles. DCS companies control access to competitors' controllers from their HMI, and open operator interfaces are not generally part of their strategy even when the DCS is built on open-system HMI software.

Emerson's Delta V hybrid DCS uses Intellution's Fix software as the basis for their DCS console. However, Emerson maintains a single DCS configuration database that requires a third-party controller to interface at the controller level rather than allowing the HMI to access the controller directly. Similarly, Moore Products APACS chooses to build their Windows NT console on Wonderware's InTouch HMI software

2003– Today, DCS vendors are on their second or third generation of Windows-based HMI consoles. The products are better, more reliable, and more open. The DCS consoles are competitive with open-system HMI software as far as features and interfacing capability. Thin-client capability, Web client operator stations, and handheld technology are all possible with many of the systems. The distinguishing factor for many of the DCS consoles is the same as with open-system HMI products and that is ease of configuration, reusable configuration objects, and migration of existing engineering work. The converging of features and capability between the DCS console and the independent open-system HMI that grew up from the PLC world is nearly complete.

THE OPEN HMI

Open HMI development was very different from that of the DCS HMI. Since the early PLC market was replacing relays and timers, it was utilized in many applications without an operator interface of any type or was connected to pushbuttons and lights. PLC systems were relatively inexpensive, so the HMI had to be inexpensive too. There was little market for an expensive operator interface, as in the DCS world. However, the major PLC manufacturers saw the immediate need for industrial operator interfaces that could replace the pushbuttons and lights and give more information to operators. But it was several small companies that developed HMI software for personal computer hardware that really vitalized open HMI development. A distinguishing factor in the development of the open HMI vs. the DCS console was that the open HMI is not an integral part of a proprietary control system.

Open HMI Display Standards

Open HMI software is extremely versatile, providing a cost-effective operator HMI to a stand-alone machine or a networked series of many operator stations for a large system of many controllers. That versatility works against the open HMI in terms of configuration standards. The open HMI software companies cannot foresee how the HMI will be used by the purchaser. The open HMI companies follow the Microsoft business model of supplying shrink-wrapped software for their customers to build into a functional HMI for their particular installation. The organization of process information and the configuration standards for the open HMI falls entirely to system integrators, engineers, and end users—with mixed results.

Information on the ergonomics of human factors such as position of the chair, screen glare, and others is abundant. There is less information readily available on specific guidelines to help engineers organize the information and build an effective HMI. The ISA has a document, ISA-TR77.60.04-1996, for fossil fuel plants that provides some guidelines that are common to all process industries. The problem is that many companies implementing medium to small projects never dedicate resources to human-factors engineering and establishing HMI standards.

Documentation

Documentation is defined in this section to include installation, configuration, backup, and change control documentation. Documentation is a weak point for the open HMI when compared to any proprietary system. The first weakness is that the hardware, software, network, and configuration are individual components from different companies. The engineers who install and configure the open HMI must provide the documentation for the HMI system. The open HMI software companies provide software documentation, configuration training, and configuration examples and tips to their users. The software company cannot know the system hardware or the configuration application, leaving the end user and engineer responsible for documentation of the system.

The second area of documentation weakness for the open HMI is the configuration backup and change control documentation. The DCS prescribed database backup procedures, and most of the configuration systems automatically documented database changes. The configuration backup of a PC file such as an HMI application is intuitively easy, but change control documentation is not. Third-party software products such as MDT's AutoSave and GE's Cimplicity Manager fill this void with software that limits access to the HMI or PLC configuration and maintains a log of the changes that are made to the HMI and PLC software packages.

Open HMI Evolution Chronology

1980s Early open or independent HMI products are written to operate on all of the various computers and workstations of the day on all of the various operating systems. It is the office PC, however, that provides the basic HMI capability in an inexpensive package. Microsoft releases the Windows 3.1 operating system for the PC in the 1980s, and with each successive release it is more apparent that Windows is the platform of choice for the open HMI. This is the time when many of the first computer-based HMI products such as Intellution, USData, and Wonderware began to fill a void in manufacturing control systems.

1990–1997 The PLC is now a very powerful logic controller capable of PID control and processor redundancy. The low price of the PLC and open HMI make them competitive in the process industry over most of the "mini-DCS" platforms that are available. Technology increases and low cost continue to bring the PLC and open HMI into larger service in the process industries and particularly in supervisory control and data acquisition (SCADA) applications. The open HMI continues increasing in functionality compared to the DCS HMI, although many of the major DCS players scoff at suggestions of an HMI based on an Intel PC running Windows.

Microsoft releases Windows NT 3.5 in 1994, Windows NT 3.51 in 1995, and Windows NT 4.0 in 1996.[4] Most of the open HMI companies upgrade their software to the current releases from Microsoft, and with each release come new features and arguably better stability. PLC companies release open HMI software products at this time to capitalize on the burgeoning market for HMI products.

Major DCS vendors stop scoffing at the suggestion of utilizing PC hardware and the Windows operating system toward the end of this time period and begin projects to create PC-based operator stations.

1997–2001 The major open HMI companies such as Intellution, Rockwell, and Wonderware continue to expand HMI functionality as computer hardware becomes more capable of providing statistical process control (SPC), recipe management, soft control capability, and a host of other capabilities.

The open HMI begins to look even more impressive for process systems when several of the leading HMI companies introduce software supporting client–server architecture and distributed alarming. The open HMI can act as a common, integrated HMI for all control systems at a plant. Figure 4.17f shows the open HMI accessing data from multiple tag servers.

Through acquisition and partnering the open HMI, companies also begin the drive to integrate their HMI with a suite of software products to provide better information to the entire corporation. Process data historians, execution systems, Web-enabled clients, downtime tracking systems,

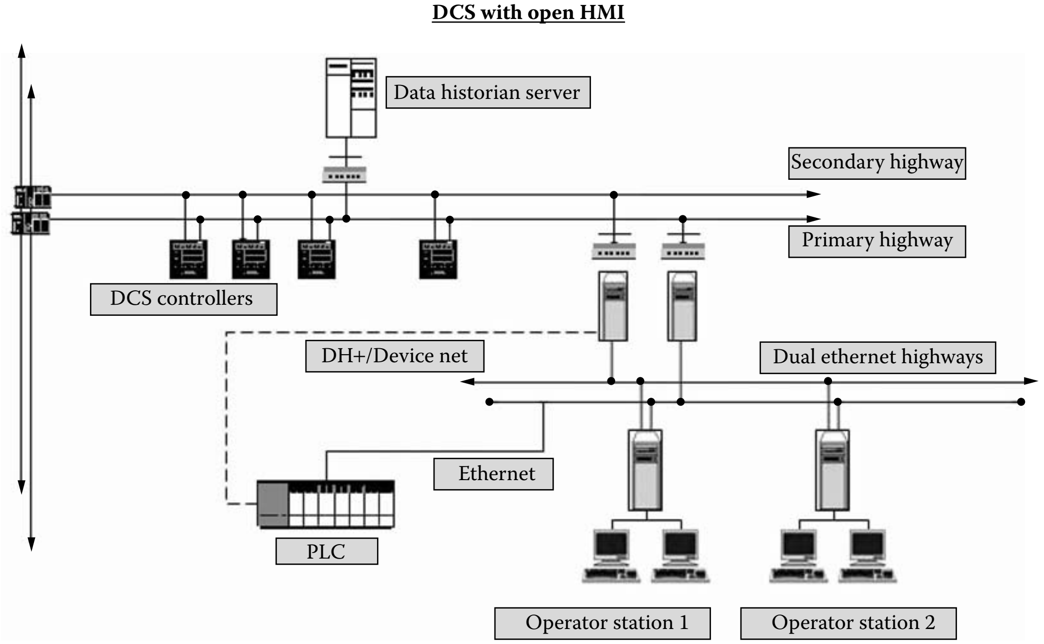

FIG. 4.17f
A DCS using Open HMIs. Note that the PLC has redundant communication directly to the HMI.

statistical quality control (SQC), and other systems are bundled with the large-system HMI providing a coordinated mid-level information system to just about any control or process information system. Rather than the HMI being an integral part of a control system like the DCS console, the open HMI is now part of a layer of plant-floor information systems above the control systems.

Larger automation companies purchase many of the independent HMI software companies during this time period.

2002 to Present Since about 2002, the development and capability of the DCS console and the open system HMI have virtually converged. The larger hardware-independent HMI products are as capable as the DCS consoles with functionality and are generally considered easier to use. DCS consoles are capable of interfacing to other controllers like open-system HMIs. The class distinction for new HMI products now appears to be between feature-rich HMI systems capable of running plants and those HMI products that are primarily designed to interface with a single controller.

Controller and PC hardware vendors are deploying Web servers in their components. The Quantum PLC from Schneider Electric and the WebOIT industrial CE computer from Advantech are examples of devices enabled with Web server capability. Any PC connected to the device via IP protocol can access the Web server using only a Web browser for device configuration of the PLC or even control in the process with the operator interface. Hundreds of HMI vendors, machine builders, and building automation companies are making low-cost products that are a single-window operator station into a single device.

The biggest and most sophisticated HMI systems also employ thin-client computing for operator interfaces. Full-function process control operator stations might use terminal services and thin-clients for operator stations while using a Web server providing an HMI for auxiliary operating or information-only stations. The future of HMI will include continued use of thin-client stations to control the cost of hardware and engineering time on configuration of the software.

Finally, vendors are working hard to make system configuration easy and highly reusable because these companies recognize that 60% of the cost of a process control or information system is in the engineering. The large open-system HMI companies are making their configuration systems object oriented. Configuration takes place in a separate environment where all devices within a plant, or even a company, are defined as objects within a common namespace.

Objects built within the configuration system are available to be copied and modified. The device object can then be attached to system objects and then deployed on a physical system component. The configuration system makes the appropriate connections at the physical device level. Adding, subtracting, or changing physical devices is now an easy configuration task by dropping the object into a different device.

EVOLUTION OF HMI ARCHITECTURE

The open HMI began as a single operator interface to a single PLC controller. In such a system, the HMI software contains the tag database and the graphical displays. In a system of multiple HMI machines, each one runs the controller I/O driver. All of the HMI machines initiate communication conversations with the controller. This is a fine arrangement for a small system but cannot support systems with many controllers

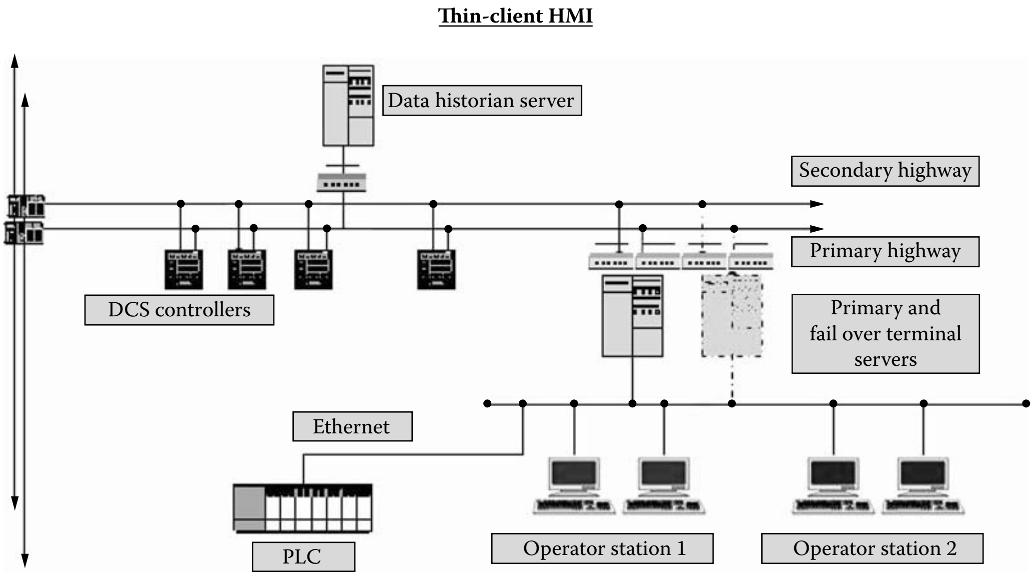

FIG. 4.17g
The architecture of thin-client open HMI on a traditional DCS.

and HMI machines. The answer is a client–server architecture and remote tag access in the HMI.

The client–server architecture for the open HMI was introduced in the mid to late 1990s. The server machine connects to the controller device or system. Multiple HMI machines act as clients accessing the tags in the one or more servers. The client–server architecture improved the ability of the open HMI to interface to multiple controllers and greatly opened the door for the HMI to become the operator's window to information from any source.

The cost of buying and maintaining the HMI hardware and software assets is high for large industrial plants. The client–server architecture described above still requires PC hardware and HMI software at both the client and server locations. The next major development in HMI architectural design is to reduce these costs by making the operator HMI a thin client. This architecture also requires upkeep of client software. The definition of a thin client is a client machine that displays the operator HMI displays without application software on the client.

The advantage of this architecture is the decreased cost of system management, increased system maintainability, and longer component life cycle since the thin client does little work. There are two types of thin client systems: thin clients that display and interface to an instance of an application on terminal server and thin clients that display information through a browser.

A terminal services thin client displays an HMI application session that is running in a Microsoft Terminal Server. The client box views and interfaces to the session through an Ethernet TCP/IP network. This HMI architecture, shown in Figure 4.17g, enables every thin client to have a full-functioned HMI that is very fast using either Microsoft Remote Desktop Protocol (RDP) or Citrix Independent Computing Architecture (ICA) protocol. This is an excellent way to enable wireless handheld computers.

Citrix MetaFrame software further enhances the architecture by allowing server farms and server load balancing. Most DCS operator stations of the 1970s, 1980s, and early 1990s were thin-client terminals displaying an instance of the program on the operator console computer. The operating system was likely UNIX or VME, and the client was called a dumb terminal, but the concept of the thin client is the same.

The second type of thin client is one that uses only an Internet browser to view the operator HMI from a Web server. Tim Donaldson, Marketing Manager for Iconics, an industrial automation software company, describes how their WebHMI functions (see Figure 4.17h):

> The Web publishing wizard publishes the graphics, trends, reports, and alarms to the Web server running WebHMI, Genesis32 software and Microsoft Personal Web Server or Microsoft Internet Information Server (IIS). WebHMI uses communication technology that supports routers, switches, firewalls, virtual private networks (VPN). Any client PC with an Internet browser can point to the desired Web page on the server and the HTML page will load all necessary components in the background providing a real-time OPC-enabled HMI.

The last architecture discussed in this section is the HMI application server. An HMI application server is built similar to the software application servers from companies such as Sun Microsystems, IBM, and Oracle. By the time of this printing, Wonderware, Adroit, and possibly other companies

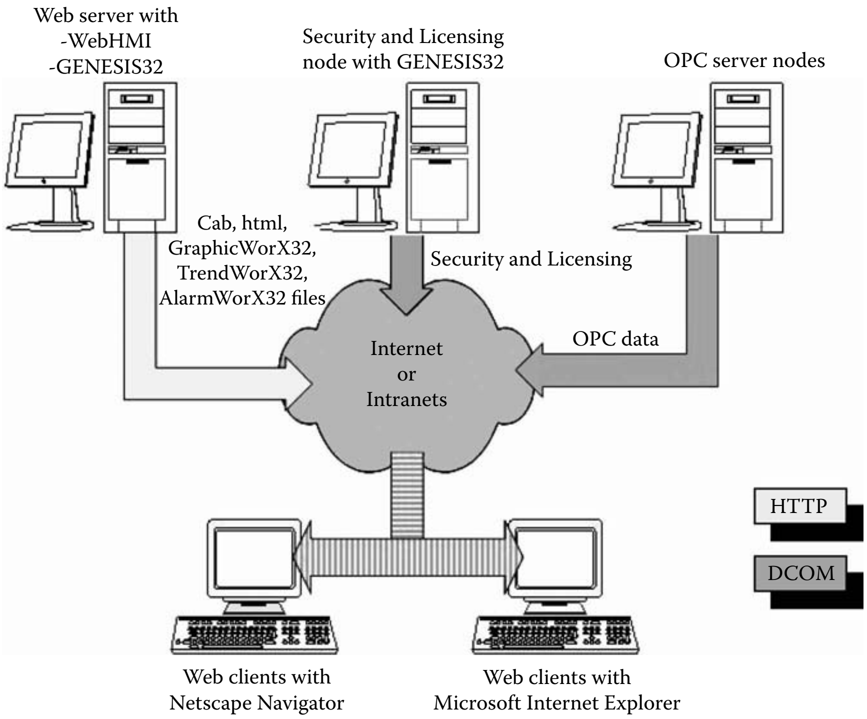

FIG. 4.17h
This diagram shows how the Web clients get information from the Web server and from the OPC server nodes.

have built their systems on this architecture, which once again radically will change the concept of the HMI.

The application server systems of which the author is aware are being built upon a Microsoft .NET framework and take full advantage of object configuration. Once an object is defined with all of its scripting, alarming, trending, and so on, it is then deployed in an application server creating an HMI engine. Application servers can be redundant. The distributed network of application servers perform all of the HMI work for gather control system information, scripting, alarming, trending, and the like. Since the full features of the HMI are being accomplished in the application server, the actual operator visualization is not doing much work. In many cases, the operator visualization may be accomplished in a .NET portal.

This architecture offers many advantages:

- In large systems, maintaining several application servers is much easier than maintaining hundreds of computers running HMI software.
- Implementing change is easier.
- Reducing licenses at every computer may reduce cost.
- HMI redundancy will be standardized.

Perhaps the best advantage of the application server architecture is that using a portal as the operator interface will further help to open the information that is available to present to the operator. The HMI engine will be only one of many application engines running in the plant. Other engines will include manufacturing execution system (MES) calculations such as downtime and overall equipment effectiveness (OEE), tracking, genealogy, statistical process control (SPC), and more. The HMI application server will sit on the plant network along side these other application servers all supplying real-time information to the operator interface.

EVOLUTION OF PLANT NETWORKING

One of the major technologies fueling HMI evolution is the plant information system networks that tie process control systems together. The DCS can be credited with introducing the plant communication network in many process companies. At the outset the DCS was meant to communicate with peer controllers and the HMI over a network highway, allowing the system to excel at SCADA, as well as grow with expanding system needs.

The early DCS network was easy (if expensive) to buy and easy to install because the DCS vendor sold all of the network components and prescribes every phase of the installation. The network was part of the DCS. Whether completely proprietary or an early adoption of IEEE standards, the DCS network provided the backbone for communication over long distances and a way to incrementally add to the existing control systems. The problem of the DCS network was that

FIG. 4.17i
Control room with pneumatic controllers, alarm annunciators, and pushbuttons, circa 1984. Photo provided by Jim Mahoney.

early DCS vendors did not foresee the vast amount of data that customers would pull across those early highways to higher-level systems.

PLCs commonly communicate on proprietary networks and fieldbus networks. PLC vendors and companies such as Woodhead SST build interface cards for the HMI to communicate on these various fieldbus highways. In the 1990s many process industries begin installing TCP/IP network systems for communication of personal computers. The inexpensive network equipment and IT support make them the *de facto* standard for all communication networks at the HMI level and above.

Development of industrial Ethernet networking equipment and widespread acceptance by equipment vendors is quickly making IP communication the standard down to the I/O level. This common and easy networking in process plants is a key factor in implementing large systems of open HMI operator stations.

EVOLUTION OF CONTROL ROOMS

The control rooms that predate the digital HMI have individual process controller devices for valves, vanes, dampers, and other process control equipment that allow operators to manipulate the controller output and set point. Push buttons and lights are the operator interfaces for discrete relay logic. Individual instrument gauges, thermometers, strip chart recorders, and sight glasses monitor process variables in the control room and in the field. Annunciator panels provide alarming and first-out indications.

The old operator panels of control devices, annunciator systems, telephones, and the operator's desk in the control room were part of an ergonomic design for the operator. See Figure 4.17i. Engineers designed the control panels for functionality during routine and emergency situations, as well as startup and shutdowns. Operators easily adapted the controls to their own needs by attaching notes to the instruments and using markers to indicate "sweet spots" of control or danger areas beside the controller. In a glance the operator could survey the control panel and easily recognize and respond to problems.

Unfortunately, some companies never duplicate the ergonomic functionality of the old control room when they install HMIs. An HMI designed by a system integrator sitting on a spare desk or mounted into a convenient panel board is not optimizing the operator of the process. Some managers believe that manufacturing processes run better when the operator is surrounded by human–machine interfaces that present a plethora of information and all controls at the operator's fingertips.

Capstone Technologies of Camas, Washington, designs displays that incorporate hundreds of process trends that surround the operator HMI. The concept is that operators do not need to understand each of the process variables trended, but they will begin to recognize anomalies in the trends and get others involved in diagnosing process issues before they create problems. Concepts and tools such as Capstone and others

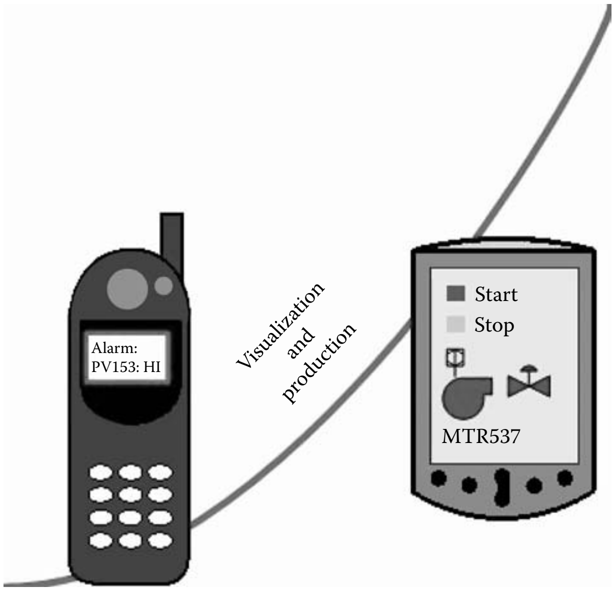

FIG. 4.17j
Mobile wireless communication devices provide interface capability for roving operators and maintenance personnel.

deliver require "maximizing operator butt time" which in turn requires that the HMI and auxiliary tools that the operator needs be designed to keep operators in front of their command stations.

Other managers believe that their industry or process is not conducive to bringing all information to the operator in a control room. Their operators are moving about the operating floor between several stations. Iconics is an industrial automation company that is at the forefront of providing flexibility of operator interfaces from control room to Web-based operator stations to handheld operator interfaces. The modern HMI can enable operators with a combination of handheld wireless devices, inexpensive Web-based HMI computers, and control room systems. See Figure 4.17j.

EVOLUTION OF THE PROCESS OPERATOR

The operator's job is more than to merely operate the process. The operator makes visual inspections of equipment, performs or coordinates chemical testing, and performs shutdown, lockout, and tagging of equipment. The operator implements manufacturing schedule changes and generates production reports and log sheets that describe operating conditions and show how the product was made. The operator reports productivity, dispatches support personnel, and coordinates problem resolution and maintenance activities. The operator makes thousands of individual decisions every day in reaction to material, system, and process equipment problems. The process operator is the conductor of the orchestra of people and systems that produce the product. The control system HMI must help the operator do this job more easily.

Operators are controlling and monitoring an ever-increasing number of process loops because of the capabilities of the modern HMI. Simultaneously with the increased process control responsibilities, many operators are also asked to perform tasks once accomplished by foremen such as coordinating product transitions, making shutdown and maintenance decisions about equipment, and monitoring product quality.

Many control rooms are an eclectic mess of HMI consoles, various information consoles, written logs and books, video monitors, chalkboards, and written notes because of the roles of the operator. The HMI must become a picture frame for the operator with a collage of control system objects, informational objects, and financial objects from many different systems arranged sensibly. The HMI will be the operator's window into the process, the production and maintenance schedules, and likely the customer's order.

The HMI will require increasing organization of the display of information to convey the real-time data, lab test data, historical information, maintenance information, tracking, and integration of video cameras. Pierce Rumph of Orion, CEM of Atlanta, has a hobby of studying the operator tasks and the HMI. Orion CEM, part of Emerson Process Management, is a leader in developing an HMI style guide that helps Pulp and Paper operators become process managers.[5]

Orion's CyberBAR style guide is a navigation bar that separates information above the bar from process interaction below the bar. The bar moves up or down depending on the information contained on the display. The CyberBAR is a navigational tool that uses icons for paging navigation and alarm notification. The CyberBAR also serves as an information bar calling up items such as diagnostics, trends, and SOPs. Figure 4.17k shows a display using the CyberBAR style guide.

The CyberBAR near the top of the display is showing navigation to information pages. The arrow shows where the operator has selected a flow loop on the display and the change zone is populated and ready to accept control inputs. Orion is also a leader in the use of audible messages from the HMI. Voice messages that notify the operator of alarms and console-activated sequences and audible feedback for motor starting and stopping keep the operator engaged with the process.

Unfortunately, navigational aids and intelligent audible signals are not sufficient for the process manager trying to manage a major crisis in a process area of thousands of points. Dynamic alarm management and intelligent alarming methods to enable better response to emergencies are necessary if the operator's process area continues to increase. Process alarms must be written smart to take advantage of alarm hierarchies to suppress minor alarms when a higher-level alarm for the same process group is active. Also, the operator's

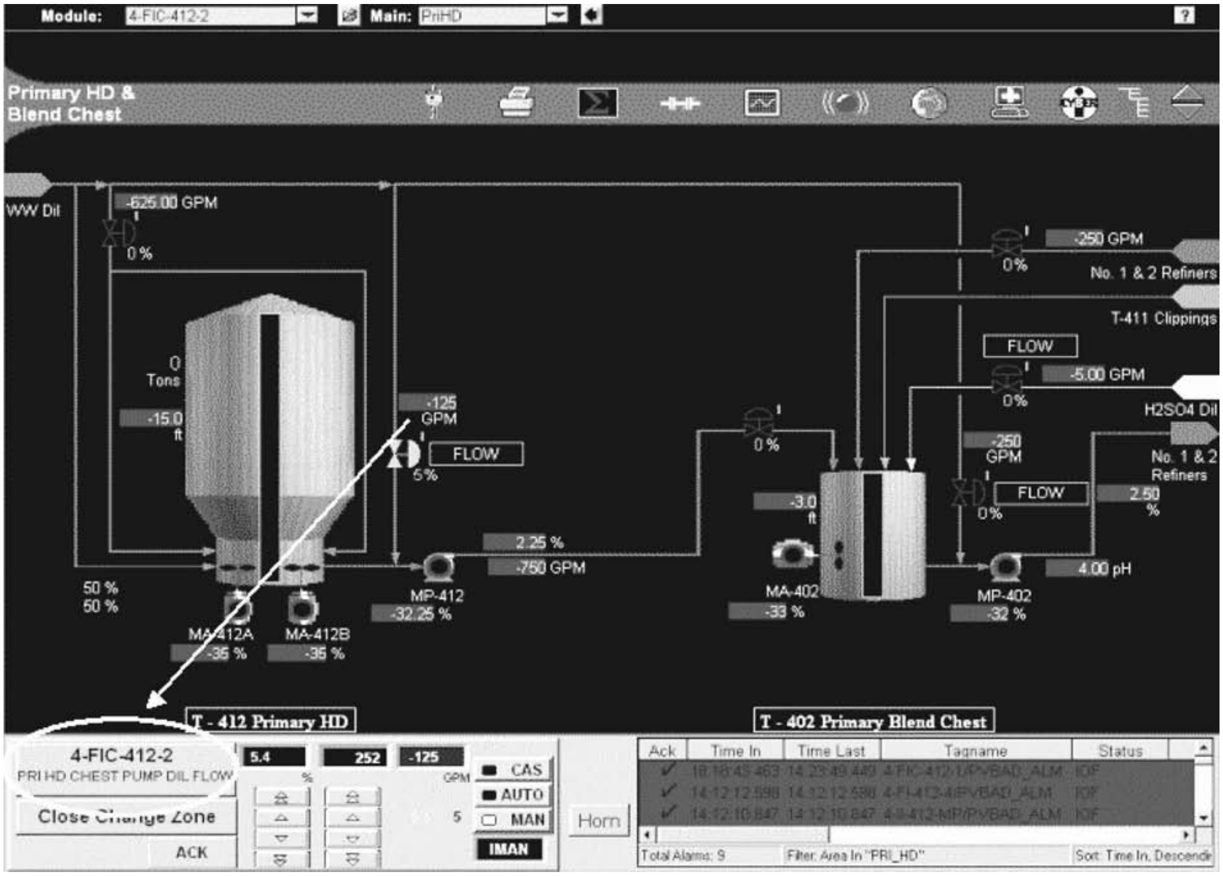

FIG. 4.17k
HMI graphic using Orion's CyberBAR display style guide. Selecting the flow on the graphic populates the change zone for operator entry. The CyberBAR near the top of the display is selected to navigate to information pages.

window must offer alarm disabling, silencing, and dynamic alarm level changes for various modes of operation for large highly sophisticated process industries. TiPS Incorporated of Georgetown, Texas has several products such as LogMate and ACE to help capture and analyze process alarms to reduce confusion during system upsets.

2005 AND BEYOND

Process control, the HMI, and the operator's job function will continue to evolve. The physical choices for providing the operator with a window into the process will continue to increase and will include HMI stations distributed around the plant, consolidated control rooms, personal human–machine interface devices such as handheld computers or cell phones, thin-client operator stations, and off-site human–machine interfaces.

Process industries such as pulp and paper, foundries, utilities, chemical production, and others are very capital intensive. Expensive process control equipment will not be replaced without a great return on investment, so existing controls will continue to be utilized for years, with new systems integrating with old components and plant support systems.

Three initiatives that may have a large impact on the process operator HMI through 2010 will be integration of data from any system into the HMI, widely distributed and mobile operator windows, and the remote-from-site HMI. These technologies can integrate into existing plant systems and utilize existing legacy systems, and they have the capacity to fundamentally change the way process systems are operated in the future.

Distributed and Mobile Control

Is a control room the best place for the operator to control the process? Or should the operator move about the process area?

The control room is a relatively new invention in manufacturing. Prior to the DCS, many processes were run from local panel boards. Coordination of the process control with the panel boards was very difficult, and the central control room increased the plant control quality by allowing for better coordination. The control systems are advanced enough that the control room is not needed to coordinate the control in some cases.

HMI technology is capable of distributing inexpensive operator stations throughout a process area so that an operator can easily walk around the process and still be very close to an HMI. The operator can also use wireless handheld computer technology or even cell phone technology to manage the process.

Remote Operation of the Plant

If your main operator is in a central control room 100 yards from the process today, why couldn't the operator be 100 miles from the process? Why not 1000 miles?

Control systems must be located within the propagation limits of the signal wiring and process lines without extraordinary expenses. However, there are virtually no longer limitations on distance away from the process for the HMI.

Thin-client HMIs and the Internet now enable an operator, or a backup "expert" operator, to be located anywhere in the world. The few technical limitations associated with remote operation of the plant today are dissolving, and future discussions about the location of operators will be philosophical.

The Future

Joey Rodems of InSource Solutions is a 10-year veteran sales consultant of HMI software. In that time the HMI has changed dramatically, but Mr. Rodems expects more and faster change.

> The need for mobile production workers to stay connected, combined with the explosion of new wireless digital personal communications devices, signals the eventual shift of traditional fixed location HMI terminals in many production environments to the production worker's secondary means of collaboration. Growing support for Web browsers, thin clients, smart phones, PDAs and tablet PCs is just the tip of the iceberg. Over the next 5-10 years look for SCADA's reach to extend beyond the HMI toward increasingly numerous and specialized personal communication devices. While these devices will provide a low-cost, natural and effective means of event-based communications, strategically positioned fixed location HMI terminals will provide rich analytical capabilities.

Human–machine interface is the subject of many research projects in private industry, governments, and academia. The work in virtual imaging is fascinating, but will it be relevant in process control? The work by NASA on changing HMI functionality associated with modes of operation[6] could have industrial applications one day. Audio-based interaction between humans and machines might prove to the greatest benefits for the industrial HMI in the near future.

Auditory messages can be sent in parallel with visual signals and can be spoken and received in hands-free operations providing unmatched flexibility by any other I/O method.[7] Engineers can implement auditory HMI in small phases to augment conventional control. The technology of audio HMI is only beginning and like most technology, it will be tested and refined in commercial applications long before it is introduced into industry.

However, the biggest gains in operational success associated with HMI may come not from the technology, but from the management and customization of HMI for the particular industry, process, and individual operator. Distributed HMI devices throughout the plant, personal HMI devices, ergonomically designed central control rooms, and perhaps auditory control can all be used with great success. Companies that implement or ignore the technology without a plan will probably achieve much less than will companies that have a plan for operating the plant and provide the right HMI tools to make it happen.

Increased priority on display design, information presentation, and operator interaction will provide a good return on investment. The process industries have more similarities in their needs than differences. This creates opportunities for toolkits from outside organizations and open HMI companies to increase the efficiency and standards of HMI displays.

Jim Mahoney, a Project Specialist with ABB Automation, has over 20 years' experience working with operator control system interfaces. He has migrated control rooms from pneumatic to digital, from first-generation HMI to the newest PC-based HMI. In a conversation about operator interfaces Jim said,

> The key to a good console is well-laid-out graphics that properly mimic the process, and ease in getting around the multitude of screens. A state-of-the-art console with lousy graphics does not help operators do their job and can actually be a major detriment.

Few experienced people will disagree with Mr. Mahoney, yet few realize that an HMI with mediocre displays helps make mediocre operators and an HMI with great displays helps make great operators.

Finally, remember the four fundamental functions of the HMI software—visualization, control, alarming, and trending—discussed at the beginning of this section? These functions were lumped together in software in the 1970s because of the available technology to produce an HMI at that time. A future generation of HMI could see each of these functions performed by different software or application servers and presented through a very thin operator's window that is also looking at business systems, maintenance systems, and the company stock price.

This section is devoted to the description of analog indicators. Digital displays are covered in Section 4.15, CRTs in Section 4.5, and human–machine interfaces of other types in Section 4.17. Analog indication can be based on the expansion of liquids in thermometers, on the movement of liquids in manometers (Figure 4.18a), on the motion of flexible elements used for the detection of pressure (Figure 4.18b), on the movement of an electric sensing mechanism, and on a variety of force and motion detection principles.

TERMINOLOGY

Indication implies a representation from which either an individually distinct state or a quantity can be inferred. In instrumentation, indication usually involves a measurement of a quantity to which a numerical value is attached. The magnitude of measurement is displayed on a graduated scale. A movable pointer indicates the magnitude on the scale.

Indicators can also display the existence of a condition without necessarily attaching a quantitative value to it. The same basic sensor elements can be used for such on/off indications or for recorders.

The term *gauge* is used for an instrument that only indicates. The suffix *-scope* refers to an instrument used for viewing only. An oscilloscope is an indicator; an oscillograph is a recorder. The oscillogram is the recording itself.

All of the aforementioned indicators are analog instruments. They vary one physical phenomenon to indicate another

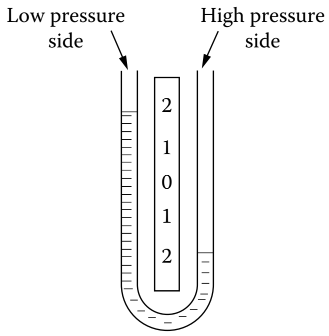

FIG. 4.18a
Differential pressure indicator utilizing a U-tube manometer.

one by analogy. One of the most widely used analog indicators is the liquid-in-glass thermometer, which uses the property of metallic media (such as mercury, mercury- thallium, or gallium) or of various organic liquids to expand under the influence of heat to indicate the temperature of another medium.

Other analog measuring methods include the following:

- One type of viscosity indicator uses the time required for a ball to sink from the surface of a liquid medium in a cylinder to the bottom as an analog measure of the viscosity of the liquid.
- The vapor-pressure thermometer indicates temperature by detecting the pressure of a filling liquid that is in equilibrium with its own vapor.
- The frequency of an alternating current can be indicated by the vibration of a reed in an instrument that contains several reeds, each tuned to a different frequency. The particular reed whose resonant frequency is closest to the current frequency swings with the greatest amplitude and indicates the frequency on an adjacent scale.

ELECTRICAL MOVEMENTS

Probably the most fundamental electrical movement is that of a dynamometer, consisting of two coils: one moving, the other stationary. When current flows through the coils, the resulting coil movement drives a pointer. This indicator can detect DC or AC (up to 200 Hz) current, voltage, or power, and the reading error can be as low as 0.1%.

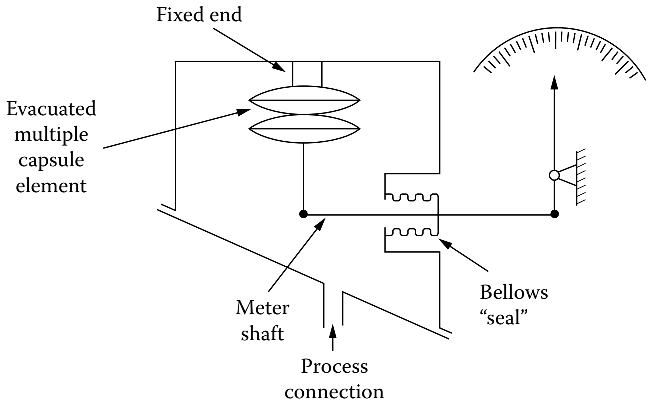

FIG. 4.18b
Motion balance absolute pressure indicator.

The D'Arsonval movement is the most sensitive of all movements. It consists of a fixed magnet and a moving coil, which moves in response to the field created by the magnet. This movement is inexpensive; it can detect DC or, if a rectifier is provided, AC (up to 10 kHz); and it requires only microwatts for operation. Its response is linear, and its error can be as low as 0.1%.

In the polarized iron movement the roles are reversed: the coil is fixed and the magnet is moving due to the field in the coil. Historically, this was the first inexpensive DC ammeter used, for example, in automobiles. The moving iron vane movement also consists of a fixed coil. Here the field generated by the fixed coil moves an iron vane. This is an inexpensive DC or AC (up to 125 Hz) indicator that requires a square-law scale, which is compressed at the low end.

For high AC or DC (over 10 volts) voltages and for applications where inaccuracies of 0.5 to 1% are acceptable, the electrostatic movement can be used. The response of this readout follows the square law, and the operation of the movement is based on the repulsion or attraction of charged electrodes. For a detailed discussion of all electrical sensors refer to Section 7.3 in Volume 1 of this handbook.

INDICATION OF MEASUREMENTS

Indications on a graduated scale require the relative motion of two elements. One of the two is a fixed reference. In most indicators, the scale is stationary and the indicating pointer moves. The indicating element may be a liquid column (Figure 4.18a), a float, a pointer, or a beam of light. The scale may be laid out on a straight line (Figure 4.18c) or arc (Figure 4.18d) or on a circular arc (Figure 4.18e).

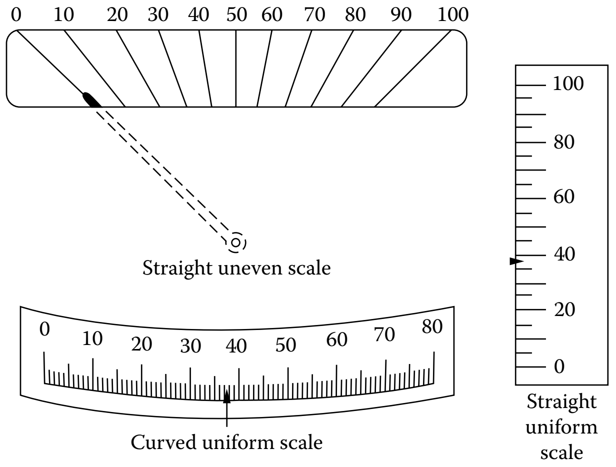

FIG. 4.18c
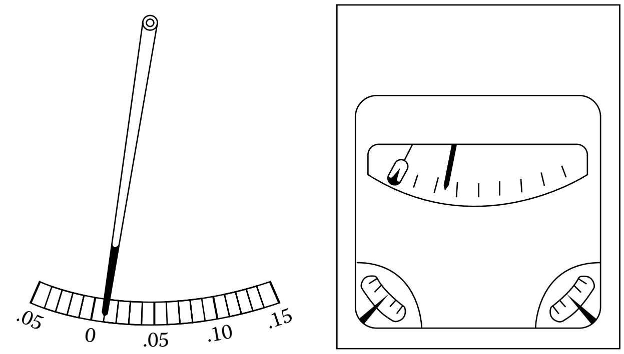
Straight and curved indicator scales.



Segmental uniform scale

Controller with segmental scale

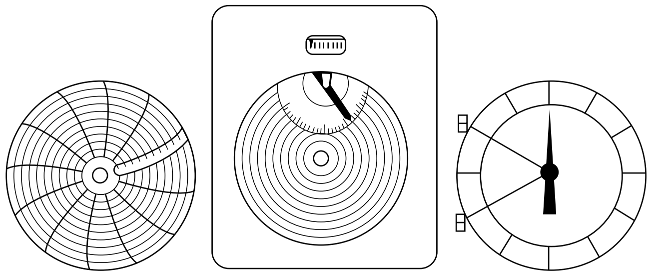
FIG. 4.18d
Segmental scale indicators.

The larger the radius, the better the readability. A scale of more than 180 degrees laid out on a circular disk is usually referred to as a dial. A scale is called uniform if the graduations on it are equidistant. The increments may also be different, reflecting other than a linear relationship. Flow meters utilizing orifice-type sensors often have square root scales; vapor-pressure thermometers have an uneven scale that becomes progressively wider. They are calibrated according to the individual filling medium.

Fixed-Scale Indicators

A liquid column moving in a transparent, usually cylindrical tube with a stationary scale on the tube forms the simplest fixed-scale indicator. Liquid-in-glass thermometers and manometers are examples of this type of indicator. Manometer and thermometer scales are often adjustable to allow recalibration, and the tubes are usually vertical.

One manometer type uses two tubes connected in the shape of a “u” (Figure 4.18a). If one leg of the “u” is bent on an angle, the device is called an inclined-tube manometer. For very low pressure difference measurements it offers the advantage of a longer, more accurately readable scale, stretched out by the reciprocal of the sine of the angle that the inclined leg forms with a horizontal line (Figure 4.18f). In some designs the inclined leg is provided with a logarithmic scale to stretch readings in the low range farther out.



Segmental scale on circular recorder

Circular recorder with concentric indication

Circular scale on circular recorder

FIG. 4.18e
Scales used on circular recorders.

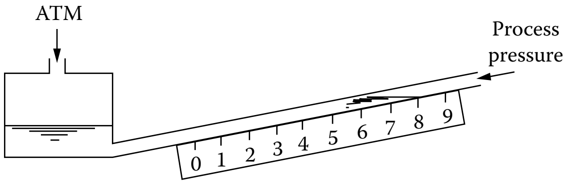


FIG. 4.18f
Inclined tube-type manometer indicator.

Readings in liquid columns are taken at the crest of the meniscus formed as a result of capillary attraction. Mercury forms a convex meniscus; most other liquids form a concave meniscus.

A plummet (or plumb bob) floating in a calibrated tapered tube is used in the variable-area-type flowmeter to indicate by its position the rate of flow through the tube (Figure 4.18g). The position of a plummet in a liquid inside a graduated transparent tube can be an indication of fluid density.

The pointer is the most commonly used moving reference for indication. The color of the pointer usually contrasts with the background for better readability. Pointers are frequently covered with luminescent materials to make readings in darkness possible. Transparent plastics are used if the pointer would otherwise obscure other indicators under it, e.g., when a totalizing counter is on the same dial.

Incandescent, fluorescent, or neon-edge lighting is also used to facilitate observation. To minimize the parallax or apparent displacement effects caused by the lens, knife-edge pointers are used. Also, mirrors are used in the same plane as the dial, and the readings are taken at an angle of observation where the pointer and mirror image coincide. Sometimes the dial is raised to pointer level. In another meter design, either a part of the rotatable scale or the pointer is optically projected onto a coated window, whereby parallax is completely eliminated.

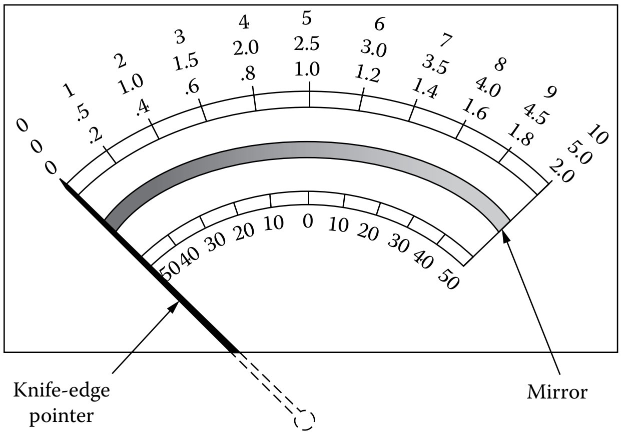

FIG. 4.18h
Multiple-scale indicator.

Indicating instruments usually read from left to right or clockwise. If negative values have to be read, as in vacuum indications, graduations progress from right to left. Compound gauges indicating pressure and vacuum have the zero point near the middle of the scale. When readings near zero are of lesser importance, suppressed-zero ranges are used with narrower graduations at the beginning of the scale followed by wider increments. There are scales with extended sections and scales with condensed sections. A multiple scale is illustrated in Figure 4.18h.

Thermometers are often provided with dual scales that indicate in both Fahrenheit and Celsius degrees. Pressure gauges usually have a circular scale of 270 angular degrees (Figure 4.18i). Precision gauges are made with 350-degree scales. Extending the pointer rotation to two turns covers a total of 660 degrees, resulting in a scale of 80 in. (2 m) in a gauge 16 in. (400 mm) in diameter. A light beam can be used as the movable reference, throwing a light spot on a scale. Readings in this case are taken at the center of the light spot.

Multiple-scale meters show different ranges of the same variable on concentric scales. A selector switch changes the range in such electrical indicators and shows the range of the scale on which the reading is to be taken.

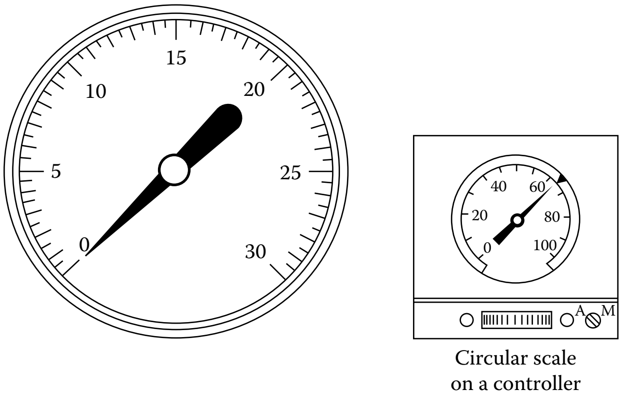

FIG. 4.18i
Circular gauge dials.

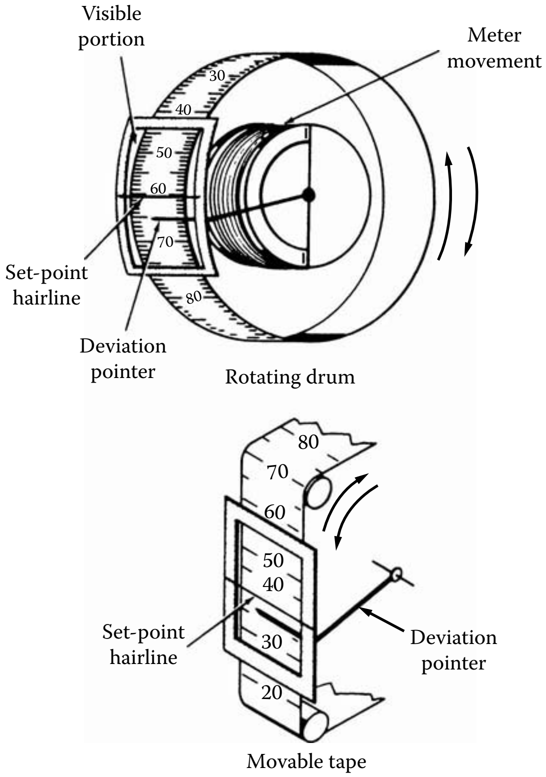

FIG. 4.18j
Movable scale indicator design.

Movable-Scale Indicators

The alternative to the moving pointer is the moving scale and fixed reference or index (Figure 4.18j). A dipstick with a scale engraved on it used for immersion measurements in a vessel is the simplest indicator in this category.

A large circular disk with graduations on its entire periphery, read at an index in 12 o'clock position, affords great precision in reading fine subdivisions (Figure 4.18k). The hydrometer is also in this category. The floating vertical scale projecting through the surface of a liquid shows the specific

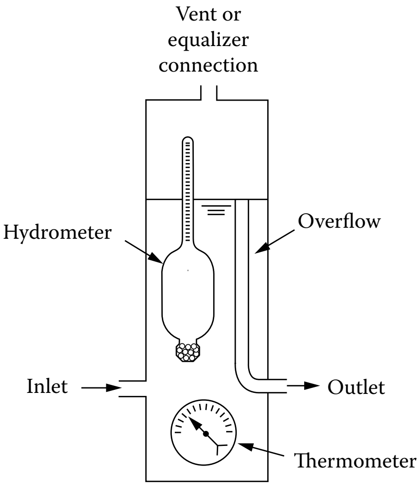

FIG. 4.18l
In-line hydrometer in rotameter housing.

gravity or density of the liquid as indicated by the surface of the liquid on the scale (Figure 4.18l).

One of the more special sorts of moving scale devices is the stroboscope-disk indicator. In these devices the exact value of the frequency to be measured is displayed in standing lanes resulting in a virtual image given by the coincidence of the velocity of the black and white lanes on the disc with the frequency of the impulse-type light lamp. If the frequency does not match the reference frequency, the displayed virtual image rotates to the right or left.

In one of the designs, the motor-driven disc is controlled by an AC reference frequency, which can be the power from the grid if this simple reference is acceptable. For higher precision the frequency of a quartz oscillator is used (Figure 4.18m).

The impulse-type light lamp (Glimm lamp, flash light, LED) is controlled by an amplifier from the power of the frequency to be measured. Slowly, the variable signals to be measured (or indicated) could function conversely.

PARAMETRIC INDICATION

A parametric indication tells only that a state exists, e.g., whether a fluid is flowing or static. For example, the precise level of water in a boiler may be less important than the knowledge of whether it is an adequate quantity.

Examples of indicators of states or conditions include the sight flow meter or the vane- or paddlewheel-type flow sensor, which allow the observer to see whether or not a fluid is moving. Similarly, a bubbler in which an air stream is passing through a narrow glass tube does not measure the air flow but only indicates that it is occurring.

In an electrical system, an indicator light is often used to show that an electric potential has reached a certain point. Similarly, a Geiger counter indicates radiation by clicking or blinking. Various other nonmetering analog indicators use color, which is easily distinguished by the human eye. Color changes are also used in instrumentation to indicate changes of state. Chemical conditions and reactions are often indicated by color. This is exemplified by the pH meter and by litmus paper.

The change that take place in the physical state of a compound can monitor approximate temperature. Solid waxes with various admixtures show the amount of heat absorbed by drooping in an oven. Color changes brought about by heat in certain materials are likewise used for approximate temperature indications.

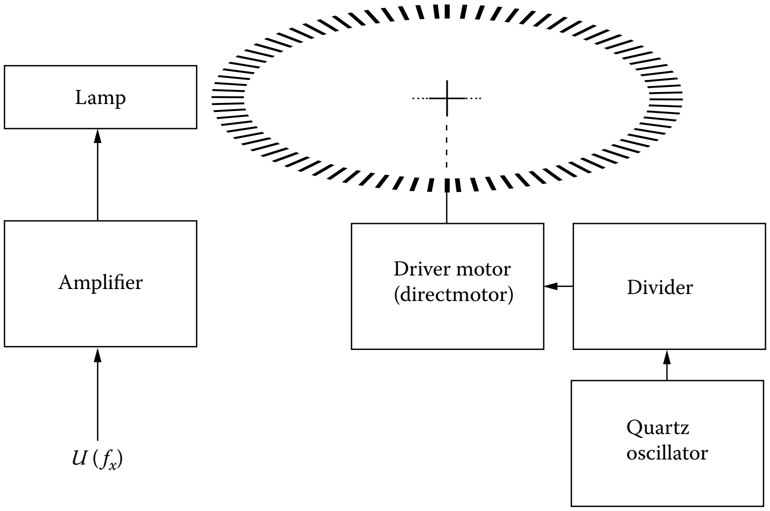

FIG. 4.18m

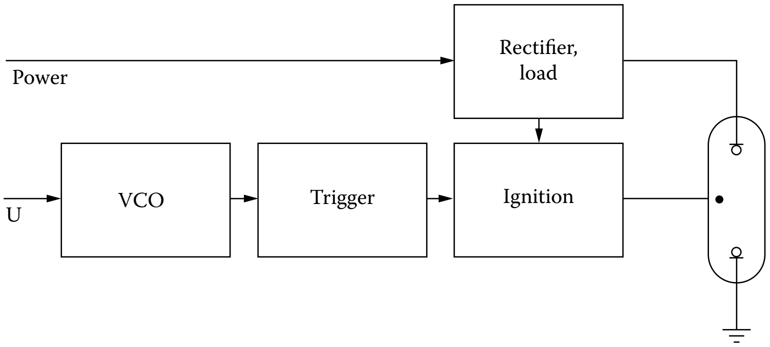

FIG. 4.18n
The variable frequency stroboscope-lamp.

DIGITAL INDICATORS

Digital indicators (Section 4.15) present the readout in numerical form. They are preferred, because fewer mistakes are made in reading a number than in deciphering an indication on a scale. Numerical readouts are also called for when a quantity is to be counted. Thus, counters usually present the result in figures even though an analog indication of the instantaneous value of a variable offers other advantages.

A speedometer is an analog indicator of an instantaneous rate of speed, whereas the mileage traveled is digitally shown on a counter.

In the case of flow meters, the flow rate is usually provided by analog indication (i.e., in units of the quantity flowing at a given instant per unit of time), but the total quantity is usually indicated numerically on a separate counter. To accomplish this, a somewhat complicated conversion by an integrator is required. A positive displacement meter indicates total flow and is generally provided with a digital readout.

Digital clocks and thermometers are easier to read than dial clocks and scale thermometers. The necessary analog-to-digital conversion is even simpler in electrical measurements. Digital meters are made for the readout of almost any variable. Voltmeters (including panel meters with gaseous numerical display devices); thermocouple thermometers; indicators of pressure, load, strain or torque; pH meters; oscilloscopes; and stroboscopes all have become available with digital displays. Digital displays are discussed in detail in Section 4.15.

Alarm switches can also be considered as a special group of the digital indicators. Their task is to detect faulty or dangerous conditions and draw attention to them. The simplest alarm device is a light bulb that signals the state or condition of a process. In other cases the frequency of a flashing light is used as an alarm indication, where higher frequencies can signal higher levels of danger.

The frequency of a stroboscope indicates voltage, as illustrated in Figure 4.18n. The input to the stroboscope enters a voltage-controlled oscillator (VCO), the frequency of which can be varied. The output of the VCO controls the flash tube through an ignition circuit.

ACOUSTIC INDICATORS

Acoustics is often used to indicate or signal to the operator the existence of some dangerous or undesirable condition. Acoustic information is usually provided in addition to visual and is in the form of ringing, beeping, or buzzing. Such combinations are used in annunciators (Section 4.1) and in other systems that manage abnormal conditions (Section 4.11).

These sounds can be produced electronically and can be made to be relaxing, harmonious, or polyphonic. Both the volume and the sound frequency can be used to provide

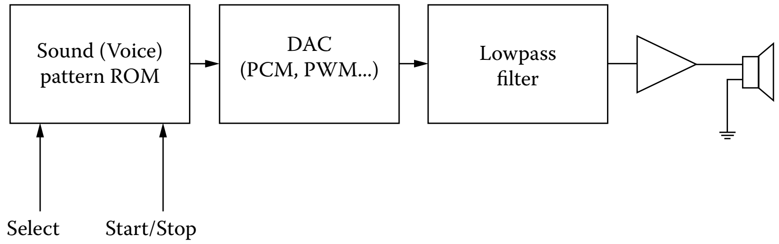

FIG 4.18o
The generation of machine sound.

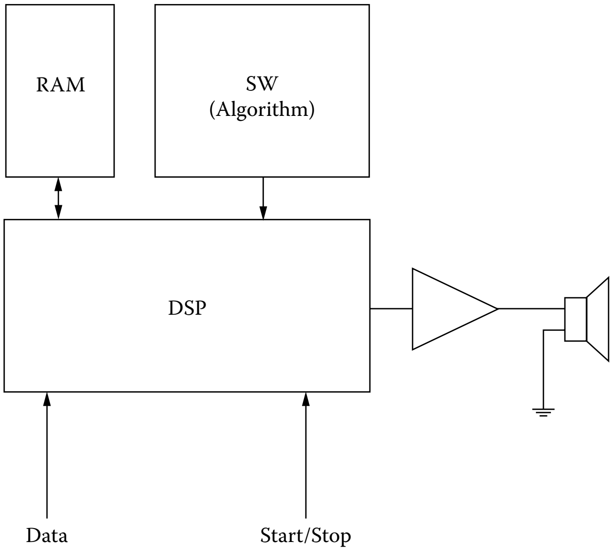

FIG. 4.18p
The synthetic generation of artificial sound.

information about the degree of danger. The choice of these sounds must be made very carefully, because if they are too monotonous or high pitched, they can irritate or stress the operators.

In addition to using sound to signal certain conditions, the human voice can also be used to indicate certain developments, state measured values, or describe the desired corrective actions. Such speech generators record a spoken text, then digitalize the recorded sound-pattern, breaking it down to units and writing it into a semiconductor memory (EEPROM, FLASH, NVRAM, ROM).

When generating the sound, first the digital units of the sample speech are read from the memory, then, by the help of an analog-to-digital converter (ADC) it is converted into a continuous signal. A low-pass filter can be used to reduce the quantity of quantum noises. Through this method one can obtain a device that can "utter" a few words or even a sentence. Such devices are available and are inexpensive in integrated circuit designs. (Figure 4.18o).

When the text is more complicated, speech synthesizers can be used, which can handle some basic grammatical rules, accents, and intonation of the language (Figure 4.18p). Such speech can be produced by a variety of algorithms in signal processors (DSP) or custom-made IC circuits.

The speech generators can be remotely controlled or supervised. In this case the speech generator can be connected to a regular or a cell phone. The input of the control unit is a driven order instruction that, with the meaning "what" and "whom," is transmitted to a particular phone with the desired message (Figure 4.18q). This way a particular operator can receive the message through the phone, in the form of a human voice (Section 1.7). There is also the possibility of interactive message reinforcement or message forwarding orders to other operators.

4.19 Lights

D. W. LEPORE R. A. WILLIAMSON (1985) **B. G. LIPTÁK** (1995, 2005)

Types:	A. Incandescent B. Neon C. Solid-state (LED); Software is also available for virtual instruments, including virtual LEDs. *Note:* In the summary below the letters A to C refer to the above-listed indicator light types.
Operating Power Ranges:	A. 1 to 120 V AC, V DC; 8 mA to 10 amps B. 105 to 250 V AC, 90 to 135 V DC; 0.3 to 12 mA C. 1 to 5 V DC; 10 to 100 mA
Color of Unfiltered Light:	A. White B. Orange C. Red
Relative Brightness:	A. 1.0, 1.0 B. 1.0, 0.5 C. 2.0, 2.0
Average Useful Life:	A. up to 50,000 hours B. up to 25,000 hours C. up to 100,000 hours
Application Limitations:	A. Shock and vibration can cause early failures and generate considerable heat. B. Require high voltages and current-limiting resistors; have relatively low light output. C. Expensive; brightness is high but total light output is low.
Cost:	A heavy-duty, push-to-test, oil-tight pilot light for panel mounting costs about $75 to $100.

INTRODUCTION

Alarm lights are also discussed in Section 4.1, as status indicators, and in Section 4.18 as components in HMI (human–machine interface) systems.

Lighted indicator lights can convey several types of information to the operator. These include binary information, in which an on/off or open/closed condition can be displayed by a lighted (on) or unlighted (off) indicator, and status information, in which normal or alarm (abnormal) conditions are

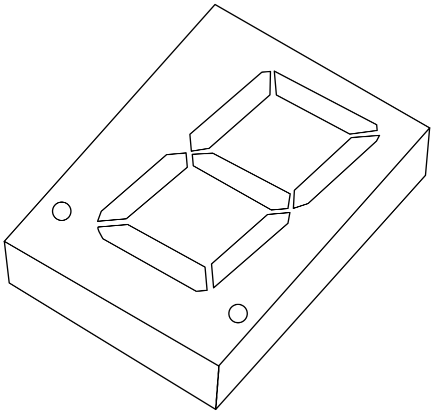

FIG. 4.19a
A seven-segment digital display, designed for good readability in brightly lit control centers. (Courtesy of Hewlett-Packard.)

expressed by legends, colors, and flashing or nonflashing indicators.

Lights can be incandescent, neon, solid state, or software-based virtual displays. The amount of information that can be displayed by a single light is directly proportional to the equipment being monitored and its size or complexity. The use of redundant indicators is not recommended because their use reduces the attention value of all light indicators, and confusion can result if large numbers of them are used.

Light-emitting diodes (LED) can not only be used as solid-state lamps, but also as bar segment (Figure 4.19a) or dot array displays in red, green, or yellow colors, in 0.1- to 1.0-in. (2.50- to 25-mm) sizes. Such indicators are not discussed here because they have already been covered under “Digital Readouts and Graphic Displays” earlier in this chapter (Section 4.15).

LIGHT SOURCE CHARACTERISTICS

The most common types of lighted indicators are incandescent, neon, and solid-state lamps. Figure 4.19b shows their spectral response curves. The relative response ordinate at 100 corresponds to the peak sensitivity of the human eye and to the peak wavelengths emitted by the lamps.

Standard vision, for example, is most sensitive at approximately 560 millimicrons, which is in the yellow and yellow–green band. The gallium arsenide phosphide (GaAsP) solid-state lamp peaks at a wavelength of 650 millimicrons, which is in the red and red–orange band. The curves in Figure 4.19b reflect the relative efficiencies of the light sources. The more efficient lights are the ones that have an output that nearly matches or falls within the standard vision curve. This output characteristic is approximated by both neon and the solid-state lamps. They are efficient because they convert most of their input power into light and emit little heat.

While LED cluster-type lights are more expensive and their total light output is less than that of incandescent lights, their life expectancy is much longer (up to 100,000 hours) and their energy consumption is less because their operating

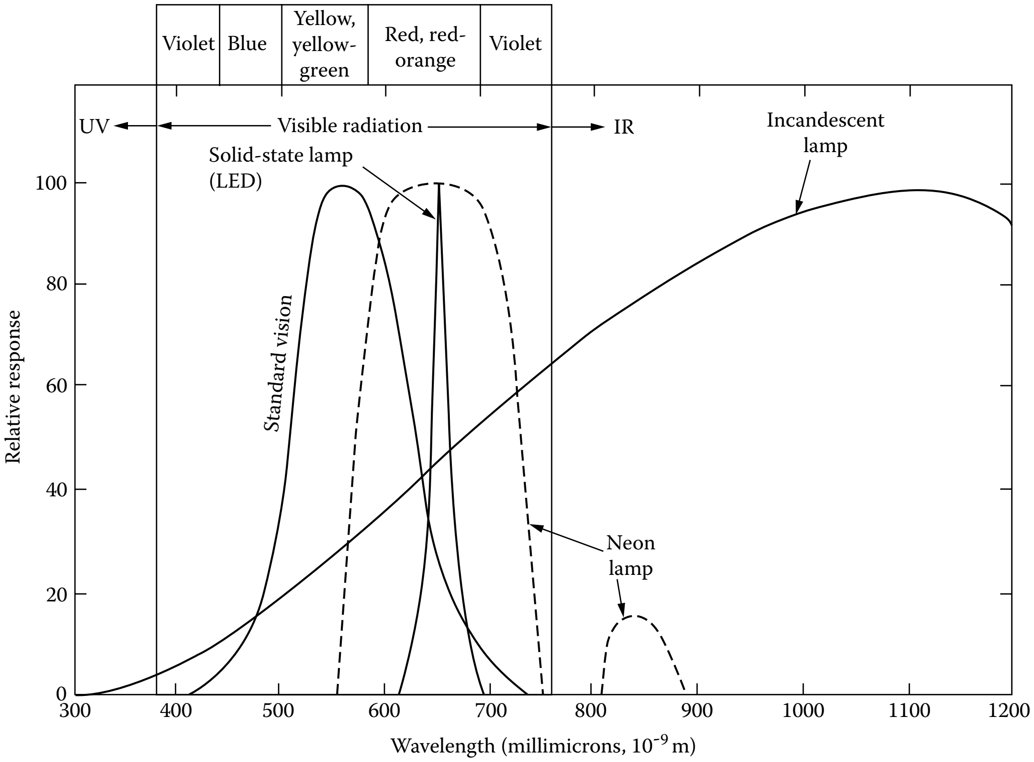

FIG. 4.19b
Spectral response curves of the human eye to various common lamp designs.

temperature is low. LEDs are also insensitive to vibration or shock and can be connected in an intrinsically safe manner. In addition, in the case of LEDs, defective bulbs can be identified (reduced luminescence) while the light is off.

Light Selection

Important human factors in the selection and use of lighted indicators are visibility and arrangement. To transmit information, the indicator must be clearly visible to the operator. Variables that affect visibility are location, brightness, contrast, color, size, and whether the indicator is flashing or nonflashing.

Critical indicators should be located within 30 degrees of the line of sight and should be at least twice as bright as the surface of the mounting panel. The use of dark panels is recommended because they furnish strong contrast to the indicator and reflect little light to the operator. When the ambient light levels are high, alarm legends should have dark characters imprinted on a light background. Inconsequential and routine messages should use the reverse combination.

Colors and Flashing

Colors can be powerful tools when properly used for lighted indicators. To avoid confusion, however, only a few colors should be used to code the different operating conditions.

General information should be lighted in white, while normal conditions should be green. For abnormal conditions or in cases where caution is required, amber (yellow with a reddish tint) is a good choice because it affords maximum visibility. Red color should be used only for critical alarms that require immediate operator response. The use of blue or green lenses should be kept to a minimum.

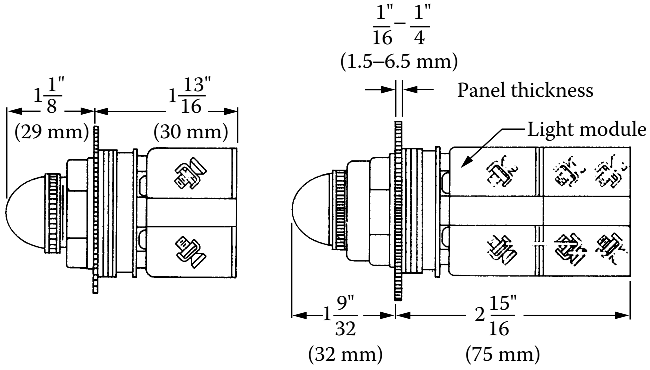
All lamps emit most strongly in the red and red–orange band. Consequently, much light is lost if it is filtered so as to appear blue or green. For important indicators, one should use the largest size that is compatible with the panel space.

Flashing greatly improves visibility, but its use should be limited to critical alarms. The rate of flashing should be 3 to 10 flashes per second with the "on" time approximately equaling the "off" time. Light indicators should be arranged according to a functional format. Indicators associated with a manual control device (pushbutton or switch) should be placed right above the control device.

It is best to locate related indicators on separate subpanels. Displays requiring sequential operator actions should be arranged in the normal reading pattern—from left to right or from top to bottom. Critical indicators should have dual lamp assemblies for additional reliability. A lamp check switch should be supplied to test for and to locate burned-out lamps for replacement.

Lenses and Operating Environments

The selected lenses should be diffusive and should eliminate glare or hot spots. The lens should also provide a wide angle of view (120 degrees minimum), and if side visibility is required, it should protrude over the mounting surface. The lens must be large enough to accommodate the required legends.



Standard pilot light

Push-to-test pilot light

FIG. 4.19c
Pilot lights for panel mounting. (Courtesy of Square-D Co.)

Legends are commonly produced by hot stamping, engraving, or photographic reproduction of transparencies. Ordinarily, hot stamping is the most economical, whereas photo-transparencies furnish the sharpest characters and are the most versatile.

Environmental parameters also affect the operation of indicator lights. Special designs are available for shock, vibration, or high-temperature applications. Rapid dissipation of heat is important if the indicator generates heat. Dripproof or watertight designs should be selected if the indicators are to operate in high humidity or corrosive atmospheres or if the lights will be placed on panels that are periodically washed down.

Figure 4.19c illustrates some heavy-duty oil-tight pilot lights designed for panel mounting applications. They are available in both standard and push-to-test versions.

Light Components

The main components of most indicator light assemblies (Figure 4.19d) include the lamp-holder, the lamp, and the lens. Panel light types are usually secured to a panel by a nut and a lock-washer. Cartridge models can be held in place by a speed-nut type friction clip. Snap-in lights are usually retained by expandable latching fingers. Power can be supplied through wire leads and solder, screw, or quick-connect terminals.

The heart of all lighted indicators is the lamp or light source itself. The three types (Figure 4.19e) of lamps in common use are incandescent, neon, and solid-state designs. The major parts of a lamp are the bulb (containing the light emitter) and the base. Lamps are also classified according to bulb shape and size and by the type of base.

Bulb shape and size are designated by a letter that describes the shape and by a number that gives the nominal diameter in eighths of an inch. For example, a T-1 lamp has a tubular-shaped bulb that is one eighth of an inch in diameter. Common bases are bayonet, screw, flanged, grooved, and bi-pin. Some

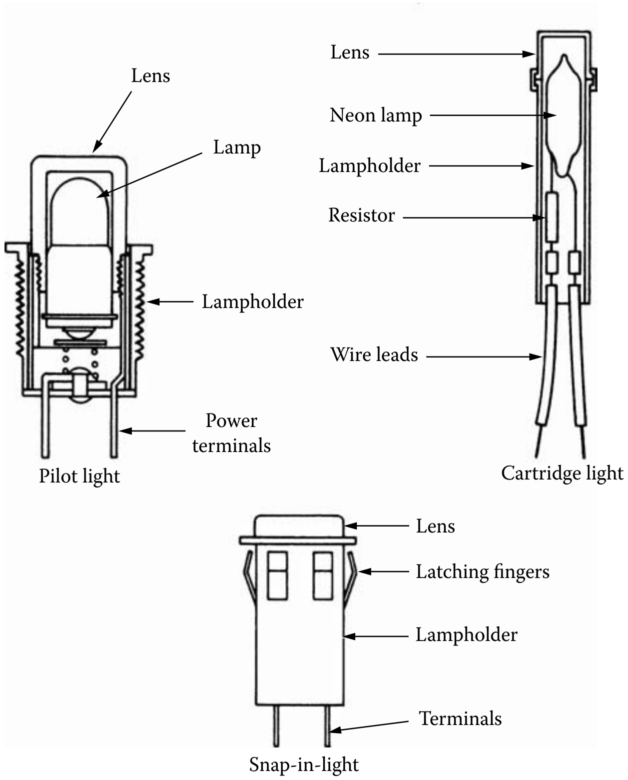


FIG. 4.19d
Indicator light assemblies.

lamps have no base at all and are only supplied with wire terminals.

LAMP TYPES

Incandescent Lamps

The incandescent lamp shown in Figure 4.19e consists of a coiled tungsten filament mounted on two support wires in an evacuated glass envelope. When current is passed through the filament, its resistance causes it to glow and to emit both light and heat. In Figure 4.19b it can be seen that only about one third of the radiation emitted from this lamp is in the visible band (white light), while the rest is in the infrared band (heat). This means that approximately two thirds of the input power is emitted as heat.

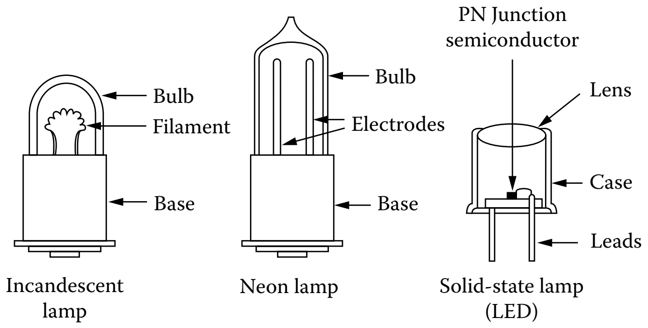

FIG. 4.19e
Common lamps.

If large quantities of incandescent lamps are to be operated continuously and mounted closely together, special allowance for adequate heat dissipation is necessary.

If the lamp is likely to experience shock and vibration, a low-voltage, high-current design should be used because it has stronger filaments. Lamps of 6 volts or less usually have short, thick filaments, whereas lamps of more than 6 volts generally have longer and thinner filaments. In all cases, however, the lamp should be tested under simulated operating conditions.

Incandescent lamps can operate from 1 to 120 volts AC or DC. Current drain will be from 10 milliamperes to 10 amperes. Figure 4.19f shows the relationship of the applied voltage, lamp life, current, and light output. Variations in applied voltage have a drastic effect on lamp life. It is common practice to improve life and sacrifice some light by operating the lamp at slightly below rated voltage. For example, a 6-volt lamp operated at 5 volts will have roughly eight times the normal life and will still provide 60% of normal light.

Over-voltage results in nearly the opposite effect: A 6-volt lamp operated at 7 volts will have only about one sixth of its normal life and will provide one and one half times the normal light. Therefore, controlling applied voltage is very important.

Space permitting, a large lamp is preferred to a small one because its cost will be lower and its life and reliability higher. The larger lamp will also emit less heat than the smaller one of equal light output because the former has more surface area and its filament operates at a lower temperature.

Neon Lamps

The neon lamp shown in Figure 4.19e consists of two closely spaced electrodes mounted in a glass envelope filled with neon gas. When sufficient voltage is applied across the electrodes, the gas ionizes, conducts a current, and emits light and heat. All neon lamps require a current-limiting resistor in series with the lamp to guarantee the designed life and light characteristics, an example of which is the cartridge light in Figure 4.19d.

The orange light emitted by this lamp is easily seen because a large portion of it falls within the standard vision curve (see Figure 4.19b). Since most of its emitted radiation is in the visible band, little heat is emitted. An important consideration, however, is that although the neon lamp is an efficient light source, its total light output is low. A clear or lightly diffusing lens should be used with it so that only a small portion of the light is absorbed.

Neon lamps are very satisfactory for use under conditions of severe shock and vibration. The rugged mechanical construction avoids the use of the fragile filament of the incandescent lamp. Neon lamps will operate only on high voltages

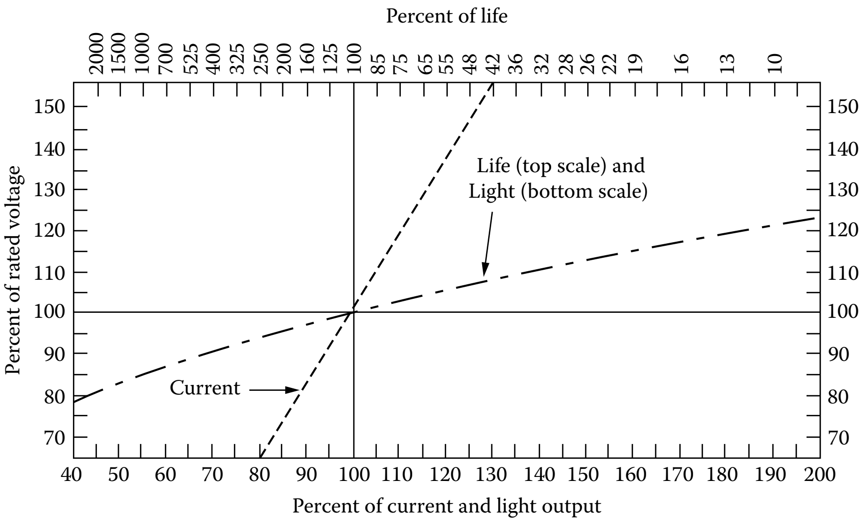

FIG. 4.19f
Incandescent lamp characteristics.

and commonly run directly from standard 120 or 240 volt AC line voltages. Because of the high voltage, they require little current and power.

Solid-State Lamps (LEDs)

The solid-state lamp shown in Figure 4.19e is commonly called a light-emitting diode (LED), and it is a valuable byproduct of semiconductor technology. It is basically a P–N junction diode mounted in a hermetically sealed case with a lens opening at one end.

Light is produced at the junction of P and N materials by two steps. First, a low-voltage DC source increases the energy level of electrons on one side of the junction. In order to maintain equilibrium, the electrons must return to their original state. Therefore, they cross the junction and give off their excess energy as light and heat.

The light output of the popular gallium arsenide phosphide LED (see Figure 4.19b) has a very narrow bandwidth centered in the red band. These lamps are very efficient and have an exceptionally long life but are small and have low light output.

The electrical characteristics of the LED are similar to those of the silicon diode. They are compatible with integrated circuits and operate directly from low-level logic circuits. Solid-state lamps, like neon lamps, perform satisfactorily under shock and vibration.

Virtual Lights

Virtual displays can be programmed to resemble all the familiar analog instruments, including running lights. The Microsoft Visual Basic programming language is popular in depicting virtual instruments. This language is popular because it is easy for third-party vendors to develop products that their customers can use with their Visual Basic programs. The virtual LED displays can mimic the functions of stand-alone LEDs.

CHECKLIST

1. Determine operating voltage.
2. Select lamp type and size.
3. Select lens for type, color, size, and shape. The last two features should be large enough to hold the necessary legends.
4. Select a lamp holder that is compatible with both lamp and lens. Also consider the allowable panel space and the methods of mounting and providing electrical connections.
5. Test the indicator under simulated operating conditions.

CONCLUSIONS

The possible uses of indicator lights to display information are limited only by the designer's imagination. There is usually one particular combination of lamp, lens, and lamp holder that is best suited for an application. Incandescent lamps are preferred for most applications because they are available in the widest range of light output, sizes, and voltages. The low light output of both neon and solid-state lamps limits their use to on/off indicators.

Amber lenses should be widely used because they absorb little lamp light and because amber is the most visible of all colors. Snap-in lamp-holders should be used wherever possible because they require no mounting hardware and take little assembly time.

4.20 Recorders, Oscillographs, Loggers, Tape Recorders

F. D. MARTON (1970) **G. F. ERK** (1985) **B. G. LIPTÁK** (1995)
P. M. B. SILVA GIRÃO (2005)

Types of Designs and Movements:	1. Portable or laboratory, bench-top or flatbed 2. Strip-chart 3. Multipoint 4. Circular chart 5. *X–Y* recorder 6. Oscillograph/paperless recorder (light beam recorder) 7. Tape recorder 8. Loggers 9. Charts and accessories
Sensor mechanisms:	A. Potentiometric B. Galvanometric C. Linear array recorder
Costs:	A portable drum chart recorder for temperature or humidity costs $500. A portable 2.375-in. (60-mm) strip-chart recorder for event, mA, mV, V DC, V AC, or thermocouple inputs costs from $400 to $650. A 4-in. (102-mm) portable circular chart recorder is available with 2% full-scale error for temperature ($250), pressure ($350), or temperature and humidity ($500). An 8-in. (203-mm) portable, circular chart recorder with 0.75% full-scale error for temperature or 4 to 20 mA costs $750. A 12-in. (305-mm) digital circular chart recorder for direct temperature, 4 to 20 mA, or voltage costs from $1000 for one channel up to $2000 for four channels. A programmable 4-in. (102-mm) folding strip-chart recorder for millivolts, volts, or direct temperature with 0.5% error outfitted with one pen costs $1250; with two pens $1700; and with three pens $2200. A portable bench-top flatbed recorder with a 10-in. (254-mm) chart and 0.35% full scale error can be obtained with mV and V input for one ($1000), two ($1500), three ($2200), or four ($3100) channels; built-in RS-232C interface adds $500. *X-Y* recorder/plotters with 0.25% error and RS-232C and IEEE-488 interface cost about $4000; 24-point, 10-in. (254-mm) strip-chart potentiometers range from $4000 to $7000, depending on features. A data logger for eight channels costs around $100 and for 96 channels about $12,000. Paperless recorders cost from $650 to $4000 or more.

INTRODUCTION

The recording of events, trends, or variables is an important part of process control. With the increase of computer-based process control and information digitized and displayed mainly in cathode-ray tubes (CRTs) and liquid crystal-based displays (LCDs), temporary recordings are often made using the computer's memory and permanent recordings are made using a mass-storage unit (e.g., hard disk, CD, tape).

When information on paper is required, the easiest and cheapest way is to use printers connected to the computer. This type of solution is surely the state of the art and probably seen in control rooms of distributed control systems. Nevertheless, both for local and for less complex applications, other means of variable recording for event and trends detection are used.

Information can be recorded either in analog or digital format. In the first case the quantity to be recorded is continuous in time and the recorder (analog type) must have the bandwidth required for reproduction without distortion. Digital recording uses sampled data and the information recorded corresponds to discrete values of time (digital recorders). Some recorders, called hybrid, are of the analog type insofar as printing is concerned but also output data in digital format. Both digital and hybrid recorders operate under microprocessor control, and features presently available include remote operation through instrumentation interfaces (e.g., IEEE488, Fieldbus).

This section describes the various recorder designs; printers are covered in Sections 4.17, "Human–Machine Interface Evolution," and 4.24, "Workstation Designs and Features"; CRTs are discussed in Section 4.5, "CRT Displays."

Recorders can be classified according to their measurement signals (electronic, electrical, pneumatic, thermal), according to their sensor mechanism (potentiometric, open loop, galvanometric, linear array), according to their application (portable, laboratory, flatbed, benchtop, industrial, panel-mounted), according to the type of chart used (strip roll, fanfold, circular, multipoint, *X–Y* plotter), or according to the recording technique applied (pressure, electrostatic, light beam, ink, electric, thermographic). The discussion below begins with descriptions of the most widely used sensing mechanisms.

SENSOR MECHANISMS

Practically all the indicator movements that have been discussed in Section 4.18, "Indicators, Analog Displays" can also be used to operate analog recorders. Here only the most widely used designs — the galvanometric (including light-beam),

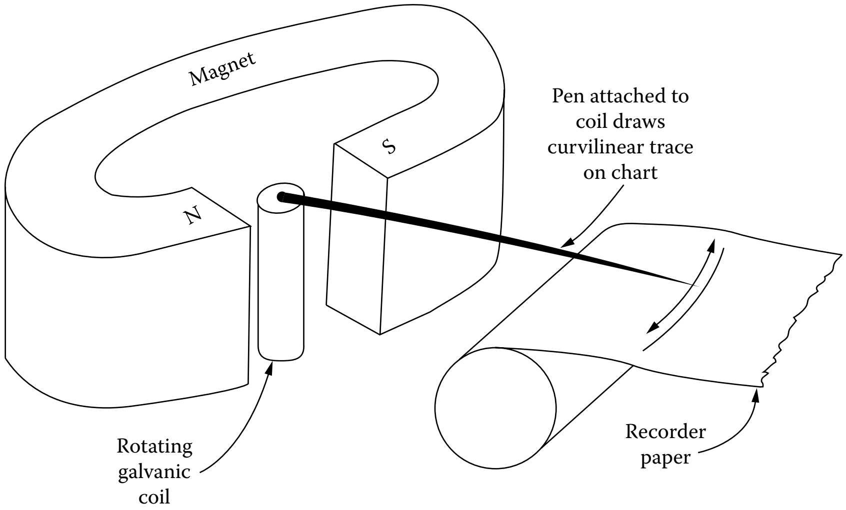

FIG. 4.20a
The recorder pen of a galvanometer can be connected directly to the rotating armature.

potentiometric, open loop, and linear array type recorders—will be described.

Galvanometric Recorders

Figure 4.20a illustrates a direct-writing galvanometer on which the pen is connected to the armature of the galvanometer and therefore rotates with the rotating-coil or moving-iron type armature. The writing system can use carbon transfer, thermal, pressure, electro-discharge, ink, or ink-jet methods. The error sources in galvanometers include linearity, tangential error, drift, and hysteresis. The torque capability of galvanometers limits their frequency response to about 100 Hz in a 10 mm (0.4 in.) wide channel. Multichannel recorders can be obtained by placing several galvanometers side by side. Galvanometers are relatively inexpensive, require little maintenance, and are suited for operation in extreme temperature (high or low) and humidity environments. Nevertheless, they are seldom used today.

Light-Beam Recorders (Oscillographs)

When the armature of the galvanometer is used to rotate a mirror, the unit is called a light-beam-type recorder (Figure 4.20b). As a change occurs in the electric measurement signal, which travels through the coil, this change causes the mirror to rotate. The main components include a light source (usually ultraviolet), the galvanometer with a rotating mirror, an optical system, and a light-sensitive recording chart. A recorder that has several channels, using several galvanometers, can record several measurements simultaneously.

When ultraviolet-sensitive recording film or paper is used, a permanent record is obtained instantaneously, without a need for any further processing. A galvanometer (oscillograph) with several channels can print numbers on the edge of the record to identify the corresponding channels. The light-beam-type galvanometer has a much higher frequency response (up to 25,000 Hz) than does the direct recording galvanometer (under 1000 Hz).

Recorders based on the above-mentioned principles are also rarely seen in use today. In present usage the word “oscillograph” refers mainly to an instrument that incorporates the functions of an oscilloscope and of a printer and, less commonly, to paperless recorders.

Potentiometric Recorders

Today, most analog recorders are of the potentiometric type. Figure 4.20c illustrates a servo-operated null-balance potentiometric recorder. Here the amplifier drives the balancing servomotor (usually a DC motor), which is mechanically connected to the writing pen and the feedback slide-wire. Because there is no current flow when the unit is in balance, load resistance variations or lead-wire resistances have no effect. This allows the sensor to be located a long distance from the recorder.

Potentiometers are sensitive down to the microvolt level and are accurate to within 0.25% of span. Because most process variables can be detected in terms of micro- or millivolt signals, potentiometers can be used to record most variables. When used with a null-balancing bridge input, it can measure resistance, inductance, and capacitance, in addition to electromotive force (emf).

The main limitations of potentiometric recorders are cost and speed of response. The inertia inherent in the recording system limits conventional null-balance recorders to a full-scale pen travel of about 0.5 seconds. Although at low frequencies (few Hz), the potentiometric recorder is the most accurate unit available, its speed of response is a limitation. If the belts, pulleys, gears, and rotary servomotors of a conventional potentiometer are replaced by a high-speed servo (the armature of this servomotor moves back and forth as a shuttle), the speed of response can be increased by a factor of 2 to about 0.2 seconds and hysteresis can be reduced.

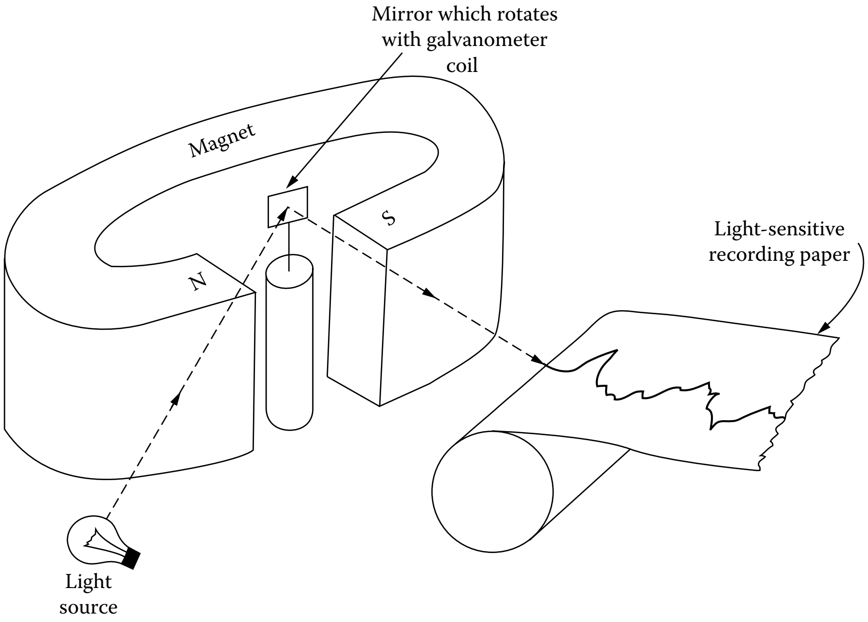

FIG. 4.20b
A recorder design in which a mirror is connected to the rotating armature of the galvanometer and a UV light detects the mirror position is often called a light-beam-type or oscillograph-type recorder.

Open Loop Recorders

In digital recorders, signals to be plotted are digitized. The mechanisms that actuate the writing element(s) are then usually driven not by DC servomotors but by step-motors. The drivers are microprocessor controlled and the system operates in open loop. In a typical arrangement, a step-motor produces paper movement in one direction and one or several step-motors actuate the writing elements in an orthogonal direction. This setup permits the representation not only of time-varying quantities but also an *X–Y* plot if the paper is allowed to move in either sense. In fast-responding strip-chart digital recorders the paper can be alternatively actuated by a DC motor.

Linear Array Recorders

In these recorders the recorder pen has been replaced by a fixed (nonmoving) array of small recording elements. The recorder chart moves under this linear array of “stylii,” each one of which corresponds to a particular measurement value to be recorded. If a 0.25% resolution is desired, a 0 to 100% range will be incremented among 400 fixed stylii, each of

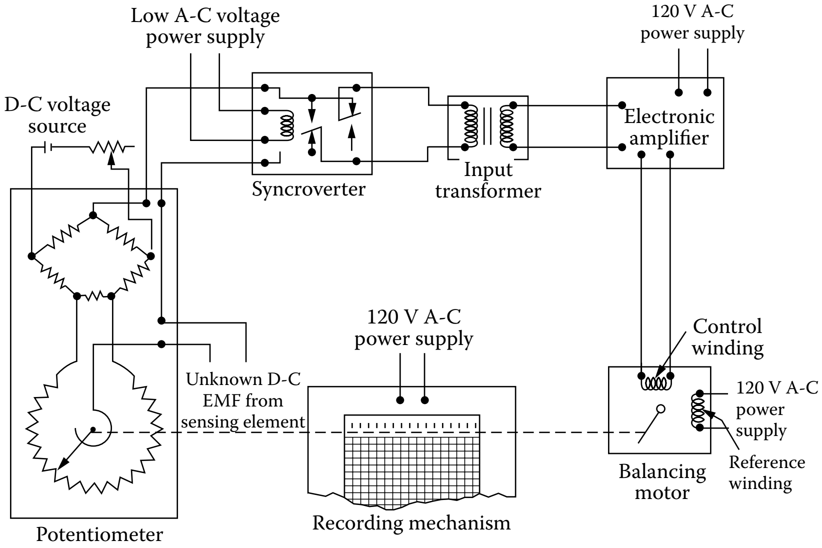

FIG. 4.20c
One of the traditional potentiometric recorder designs.

which represents a particular measurement signal increment. Every print cycle the drivers select the stylii to be activated to print a dot pattern forming the alphanumerics, grids, and signal traces. As this process is repeated every cycle, a continuous recording results.

The main advantage of linear array recorders is the absence of moving parts (other than the paper). The array elements can be thermal or electrostatic. When thermal elements are used, the paper is coated with a thin film of thermoreactive material on a substrate. When electrostatic elements are used, the chart paper is dielectric; in addition to the paper, a liquid toner is required.

The records resulting from the electrostatic technique last longer and require less energy than do thermally obtained recordings. Paper costs are similar for the two methods: about 5 to 10 cents per foot of paper. The maximum width of the print ranges from 10 to 15 in. (254 to 314 mm), chart speeds range from 1 mm/hr to 0.5 m/sec, and the printing speed can approach 2000 lines per second.

RECORDING METHODS

There are many ways of leaving a mark on a chart, including the various ink-writing systems and the inkless methods of thermographic, electric, pressure, light-beam, and electrostatic marking.

Ink-Writing Systems

The early pen-and-ink recorders used bucket, V, fiber-tipped, or ballpoint pens and pressurized or gravimetric capillary-type feeding systems. Refilling was performed by the use of disposable ink cartridges, and maintenance was performed by the use of replacement pen assemblies. In high-speed oscillographs either pressurized inking systems are used (requiring special coated paper) or high-cost ink-jet hardware is installed.

Impact printing initially used a carbon ribbon and later slow-drying inks stored in porous pads; when the pointer mechanism presses down, it leaves a single-color or multicolored mark. More recently, the pointer has been replaced with a traveling print wheel, which is engraved with numbers or symbols that identify the variables being recorded. This type of marking is used on most multipoint strip chart recorders, which are usually provided with an 11-in. (279-mm) chart and can simultaneously record about 20 variables.

Inkless Systems

Thermographic recorders use a heated stylus that melts or chemically changes the heat-sensitive coating on the paper. In the linear array version, some 420 fixed thermal-printing elements (stylii) can be used on a 4.5-in. (114-mm) paper chart. Each element is capable of generating some 100 dots per inch (4/mm). When used with up to six channels as a multipoint recorder, the channels are identified by different letter characters, while the date and time are periodically printed onto the recording.

Pressure-type recorders were one of the earliest designs, in which a sharpened stylus was used to remove smoke or other special coating from the chart, thereby exposing a contrasting color underneath.

In electric recorders an electric discharge generated by the stylus etches the record into an aluminum coating on a black paper, thereby exposing the black substrate.

The light-beam-type recorder is illustrated in Figure 4.20b. In this recorder a photosensitive paper or film is used to record the location where the high-intensity light impinges on the chart. In order to eliminate the effects of ambient light, ultraviolet sources rather than visible light sources have been used. If a programmable light gate array is used to record directly on ultraviolet (UV)-sensitive paper, the error contributions of linearity, beam deflection, tangential error, inertia, and overshoot can be reduced.

In the electrostatic recorder, there is an imaging head with some 1000 wire elements, spaced at 4/mm, giving a total length of 10 in. (254 mm). As the recording chart moves over the image head, a negative voltage is applied to selected wires while positive voltage is applied to “shoes” on the other side, giving a positive point charge to the paper chart at the activated points. Next the chart proceeds to the toner head, where negatively charged ink particles adhere to the charged points on the paper. Following this step a vacuum knife removes the excess toner particles, and when the remaining particles are exposed to air, they permanently bond to the paper.

Paperless Systems

Paperless recorders (Figure 4.20d) are multichannel data acquisition systems that present the information on a display similar to a computer monitor, usually of the LCD type. Some of them have also paper printing and permanent data storage capabilities. They are light-beam-type recorders, much like digital sampling oscilloscopes (DSOs), but as they are acquisition systems they can also be considered data loggers. Thus, paperless recorders can be found in suppliers identified both by 6 and 8 on the partial list of suppliers at the beginning of this section.

CHARTS AND COORDINATES

The process variable actuates a recording mechanism, such as a pen, that moves across a chart. The chart moves constantly with time. These two motions produce an analog record of variable versus time. Any point on the continuous plot obtained in this manner can be identified by two values, called coordinates. Many coordinate systems are in use, with the Cartesian coordinates most widely used in industry. If the reference lines are straight and cross each other at right angles, they are called rectilinear coordinates. If at least one of the reference lines is an arc of a circle, the coordinates are curvilinear.

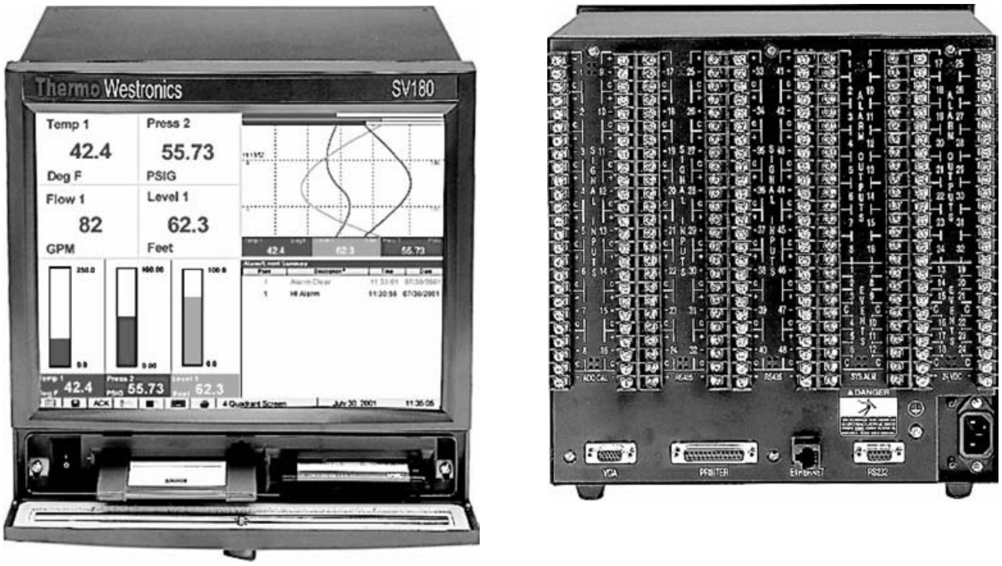

FIG. 4.20d
Front and rear views of a touch-screen paperless recorder with input/output handling and communications capabilities, as well as flexible data storage options. (Courtesy of Thermo Electron Corporation.)

The shape of the chart provides a primary means of classification into (1) circular charts and (2) rectangular charts, in sheet or strip form. Strip charts can be torn off and can be stored in rolls or folded in Z folds. Strip chart lengths vary from 100 to 250 feet (30.5 to 76.2 m).

Circular Chart Recorders

Circular chart recorders are still used because they are simple and, consequently, low priced. Chart speeds are a uniform number of revolutions per unit time. Chart drives making one revolution in 24 hours are standard, but instruments are also equipped with drives of 15 minutes; 1, 4, 8, 12, or 48 hours; and 7, 8, or 28 days per revolution.

The best applications for portable circular chart recorders are temperature or humidity recordings used in heating and ventilating systems.

The circular chart recorders shown in Figure 4.20e produce concentric circles crossed by circular arcs whose center, when the pen crosses the arc, is the same as that of the recording arm. The tangents at the intersection points of the two curves should be as near to a right angle as possible for best readability. The concentric circles form the scale on which the variable is read. The “time arcs” divide the

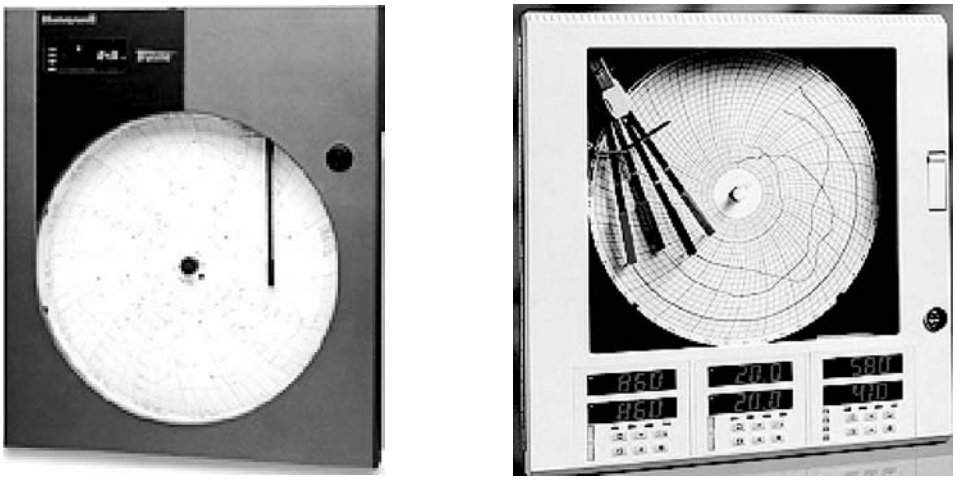

FIG. 4.20e
Circular chart recorder. (Courtesy of Honeywell Industrial Measurement and Control and Omega Engineering, Inc.)

full circles into appropriate uniform intervals of the total period.

Chart diameters vary from 3 in. (75 mm), 4 in. (100 mm), and 8 in. (200 mm) to up to 12 in. (300 mm). Circular charts offer the advantage of a flat surface. Special features, such as automatic chart changers, allow collection of daily records in a continual manner. Contacts can also be mounted in the pen mechanism for alarms on preset high or low signal conditions. One of the limitations of circular chart recorders is that the recording of more than two variables on one chart poses design problems.

Strip-Chart Recorders

Strip-chart recorders are characterized by the uniform linear motion of the paper either horizontally (Figure 4.20f) or vertically (Figure 4.20g). The measurement lines can be straight or curved, furnishing either rectilinear (Figure 4.20g) or curvilinear recordings.

The curvilinear method uses very simple linkage geometry and offers better readability than is obtained with circular charts. Figure 4.20h shows a two-pen recorder (second from left) and a recorder controller. Whereas the two-pen recorder records two independent variables, the recorder controller accepts one sensor signal, compares that signal with a manually operated set point, and provides a signal output for closing a control loop by actuating a final control element.

Strip-chart recorders are available in several standardized sizes, including 4-in. (Figure 4.20i), 6-in., and 11-in. (102-mm, 152-mm, and 279-mm) charts. The standard miniature strip-chart recorder is used either in the wide (6 by 6 in. or 152 by 152 mm) or in the narrow format (3 by 6 in. or 76 by 152 mm). Chart speeds are available from 1 in./hr to 30 in./min in adjustable increments (1.0 in. or 25.4 mm). These strip-chart recorders are available with up to three pens and with up to two alarm contacts per pen. The accuracy of recording is usually within 0.5 to 1% of span.

Multiple Recorders

When several variables are to be recorded on the same chart, such as several temperatures from thermocouples in various locations, multiple recorders are used. Circular chart recordersmay handle only up to four variables, whereas strip-chart recorders handle as many as 24 to 36 measurements. To identify each variable, symbol or numerical coding or color printing is used, as well as full digital alphanumeric printouts on the chart margin.

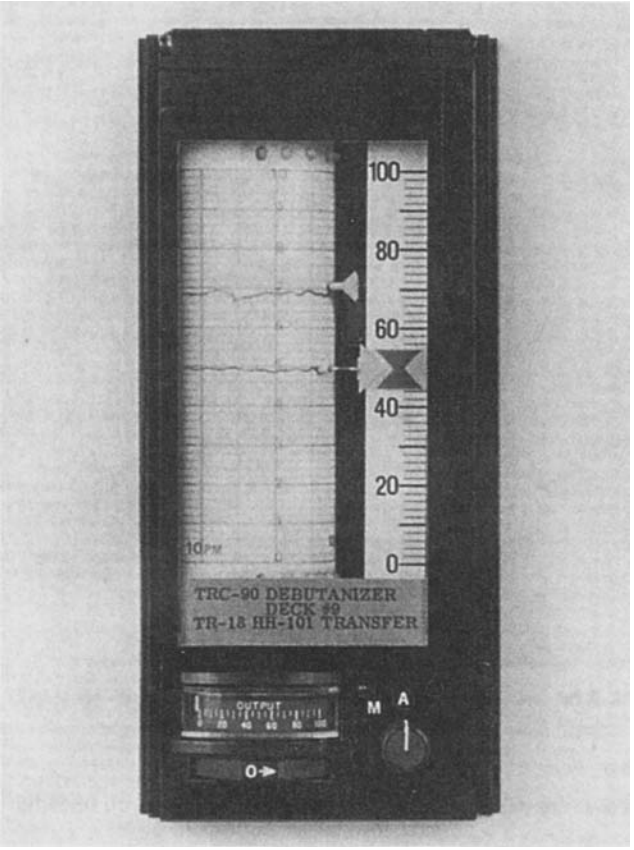

FIG. 4.20f
Horizontal strip-chart recorder.

With the advent of microprocessor technology, multivariable recorders became available. These allow recording of a multitude of variables, such as flow and the associated temperature and pressure. Likewise, for comparison of several variables on the same time scale without line crossing or overlapping, multichannel recorders are available.

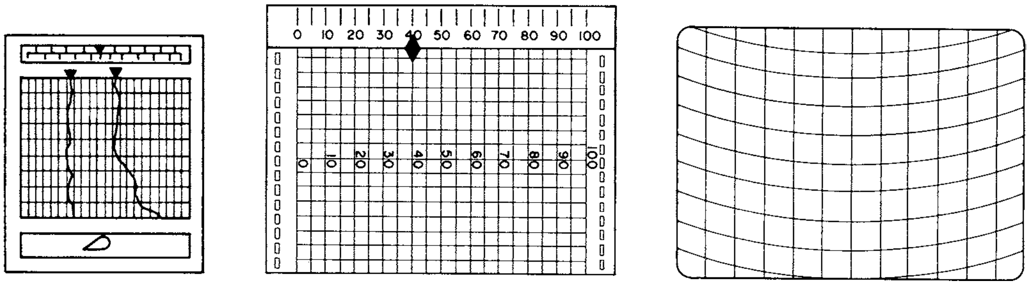

FIG. 4.20g
Strip-chart recorders with vertical movement.

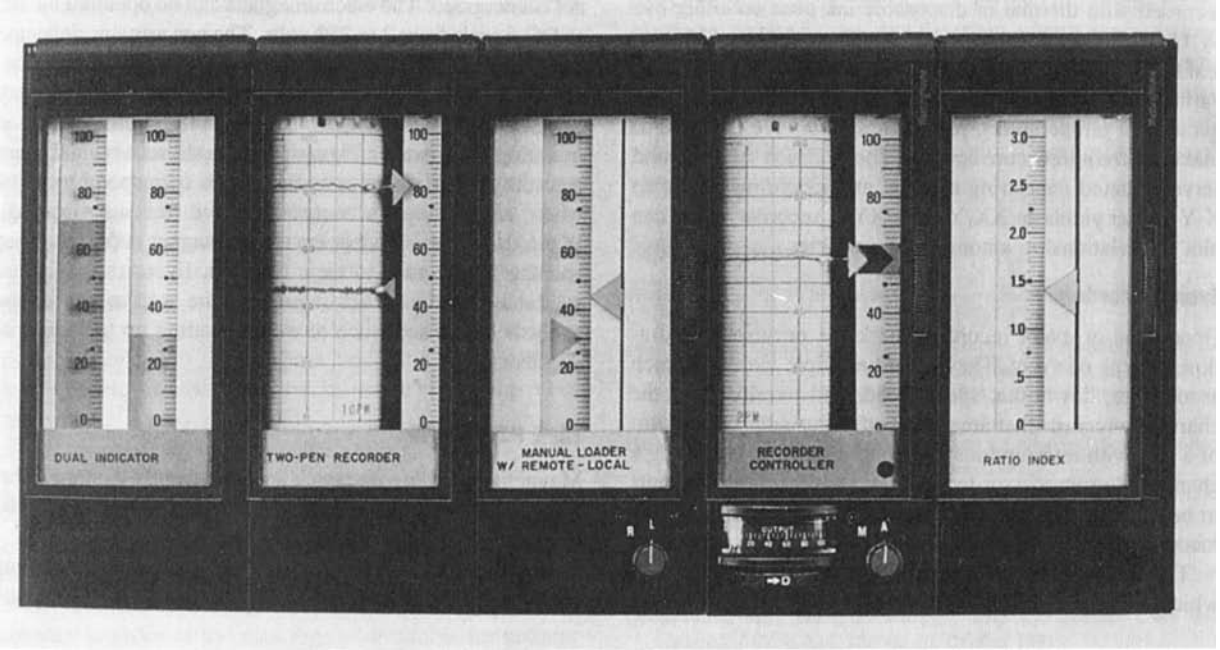

FIG. 4.20h
Two-pen recorder and recorder controller.

Figure 4.20j shows the cut-out requirements and the front dimensions of typical 6-in. and 11-in. (152-mm and 279-mm) multipoint strip-chart recorders. With the addition of microprocessors, high-speed hybrid recorders became available with up to 30 recording channels.

Inputs can be DC volts or millivolts, thermocouples, and resistance temperature detectors. On these units the digital measurement data are printed on the left margin of the chart in up to six colors. The basic accuracy of these units is 0.25% of span. Most hybrid recorders are provided with a keyboard on the front panel, which allows for the programming of chart speed, alarm set points, full scale range, and other features.

FIG. 4.20i

X–Y Recorders

X–Y recorders plot two variables simultaneously, such as stress versus strain or temperature versus pressure. Either the chart is stationary and the scriber is moved along both the abscissa and the ordinate by the two signals, or the chart is moved in one direction while the stylus slides on an arm in the other direction.

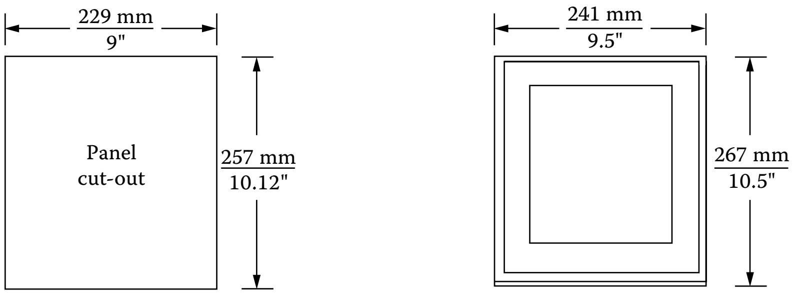
The signals entering the function plotter can be analog or digital. Digital signals require transducers to obtain an analog plot. Likewise, digital records can be provided with analog-to-digital conversion and conventional digital printout.

There are also combination function plotters, called X–Y–Z_1 recorders. Some allow the pen to be driven along either axis at a constant speed, thus making recordings of X versus Y, Y versus T (time), and X versus T possible. Recorders with three independent servo systems allow the recording of two variables against a third.

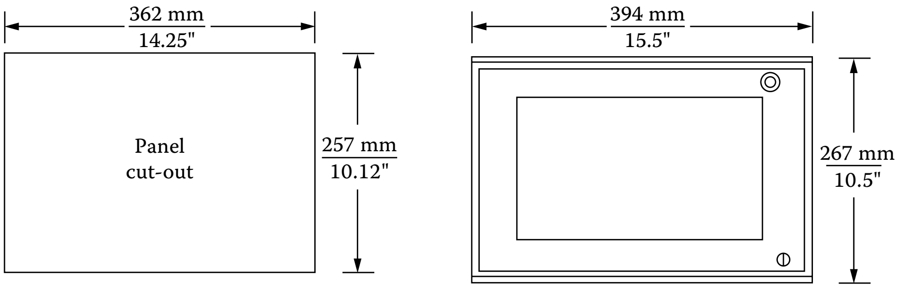
X–Y recorders usually have flat beds with measurements ranging from $8^1/_2$ by 11 in. (216.5 by 279 mm) to 45 by 60 in. (1143 by 1524 mm). Some record on drums. Recorders that print from the back or on a glass screen do not obstruct visual observation.

X–Y plotters can be connected to computers using either RS-232C (serial) or IEEE-488 (parallel) ports and can send or receive data with 0.02 mm resolution. Data are most often recorded with thermal or disposable ink pens on either $8^1/_2$ by 11 in. (216 by 279 mm) or 11 by 17 in. (279 by 432 mm) leaf or roll paper.

When the X–Y recorder is used to measure variables other than voltage (for example, current, frequency, or temperature),



6" (150 mm) strip chart



11" (275 mm) strip chart

FIG. 4.20j
Panel cutout and front dimensions of multipoint strip-chart recorders. (Courtesy of Honeywell Industrial Measurement and Control.)

plug-in amplifiers are installed to make the required conversions. The addition of a second servo-actuated measuring element and recording pen to an X–Y plotter yields an X–X_1–Y or an X–Y–Y_1 recorder that can plot the relationship among three variables.

Event Recorders

Operations or event recorders mark the occurrence, duration, or type of event. They record multiple incidents, such as on-time, downtime, speed, load, and overload, on the chart. The records that are produced are usually in the form of a bar, with interruptions in a continuous line indicating a change. Microprocessor technology allows scores of points to be scanned every millisecond, with high-speed printouts made for the events that occur.

The classic event recorder is a simple instrument (Figure 4.20k) in which the pen is deflected when the associated electromagnet is energized. The electromagnets can be operated by AC or DC signals from 2 to 250 volts. The pen remains deflected until the associated electromagnet is deenergized. The resulting recording shows not only that an event has occurred, but also its time, duration, and possible consequences in initiating other events.

Figure 4.20k also shows a typical event recording chart where open rectangles correspond to times when electromagnets were energized (events occurred). When the event is ended, the electromagnet is deenergized and the pens return to their baseline. Event recorders are available with up to 128 inputs and are well suited for the analysis of the sequence of events leading up to industrial accidents.

TAPE RECORDING

Today, permanent storage of information, either in analog or digital formats, uses different technologies such as battery-operated random access memories, magnetic discs, tapes, and compact optical discs (CDs). In process control, magnetic recording on tape is frequently used either for analog or digital form signals.

Videotape recording is similar to magnetic tape recording with the additional feature of reproducing both picture and sound. Industrial application is found in closed-circuit television monitoring.

Magnetic tape recording is done by magnetizing fine iron oxide particles, which are coated onto a polyester plastic tape. The data can be recorded by fixed heads on multitrack longitudinal recordings in analog or pulse-code-modulated (PCM) form, or the data can be recorded by helical scan techniques, which record analog or digital data in VHS, Beta, or R-DAT formats. For process-control-related recording the multi-track fixed-head recording has been the most popular. On a 0.5 in. videocassette tape, usually no more than 24 recording tracks are available. Helical scanning reduces this track width of 25 mils to about 2 mils and thereby allows a track density of about 250 tracks per 0.5 in. in the VHS format.

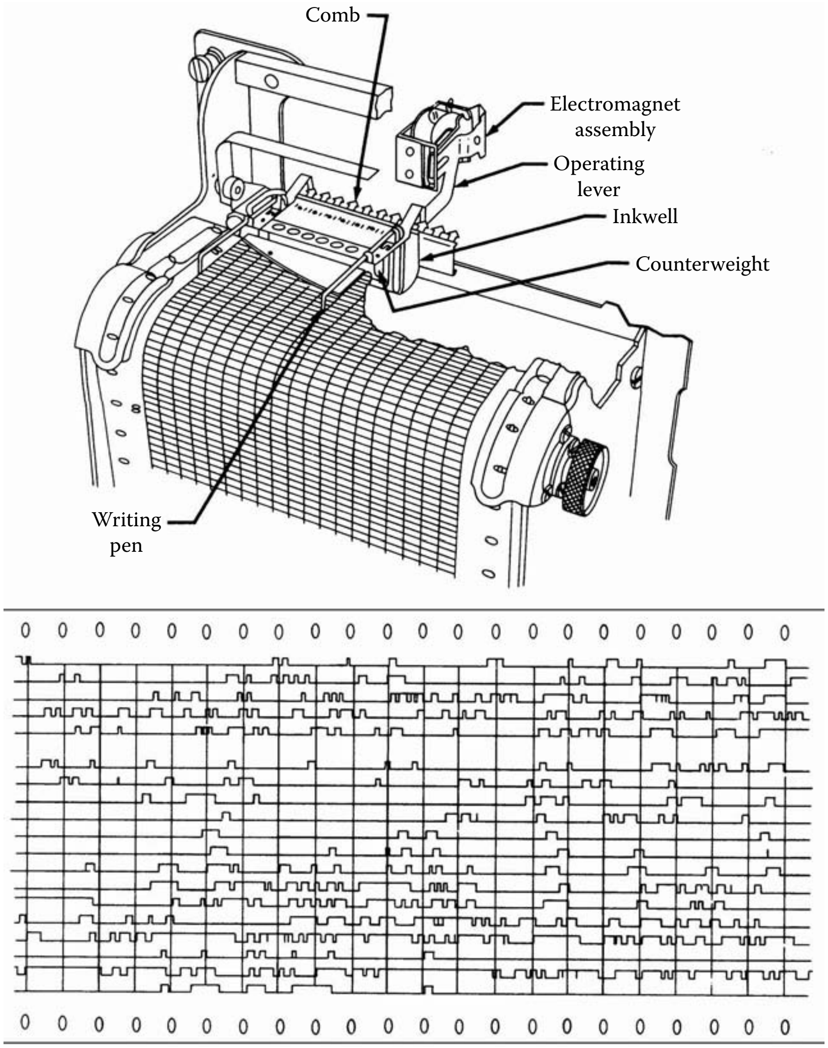


FIG. 4.20k
The design of an event recorder and the appearance of a typical event record chart. (Courtesy of Esterline Angus Instrument Corp.)

DATA LOGGERS

Data loggers are electronic instruments that record measurements of different quantities such as temperature and relative humidity or events over time. They can be software packages loaded into personal computers, DCS systems, or other computing devices that serve to operate printers, but more often they are stand-alone battery-powered units that are equipped with a microprocessor, data storage, a printer and sensors.

Most data loggers utilize turn-key software on a personal computer to initiate the logger and view the collected data. High-speed recording is achieved by combining electronic readouts with electrostatic printing. Digital recorders can print as many as 1 million characters per minute on paper in digital form. For applications such as electric power generation, the high-speed digital recorder is the best choice.

Some stand-alone microprocessor-based data loggers, commonly called paperless recorders, record data in a processor's memory; they do not incorporate printing capabilities but are provided with a screen where charts are presented.

A low-cost solution to data logging is to use a personal computer to control the printer, which shows the trend of the process or the results of a test. Most data-logging systems are provided with capability both for front panel programming and for switch-selectable remote programming, implemented over RS-232C, IEEE-488 fieldbus connections from remote terminals. The logged data can be linearized or scaled; the data can be averaged by time or by groups; and up to four alarm set points can be programmed onto each channel being monitored.

The typical scanning capacity of stand-alone data loggers is up to 128 channels. These units are also provided with an automatic restart feature that functions after a power failure and with RS-232C and passive current loop ports for computer interconnection. Central data loggers are usually integrated into the total control system of the plant and consist not only of a complete data acquisition system but also of some control capability.

Stand-alone battery-operated data loggers are an interesting alternative to analog chart recorders because they are smaller, less expensive (base price and no consumables required), more accurate, and more reliable. On the other hand, because information is digitized, data analysis, presentation, and storage are simplified. The reduced size of some models allows their operation in areas inaccessible to other recording systems.

INTRODUCTION

In this section both the traditional and the more advanced manual switching elements are discussed. The traditional switches and pushbuttons are used to start and stop or open and close final control elements, while the more advanced microprocessor-based touch-panel keyboards are used in all types of information-handling systems and in computer interfaces. In keyboard-type applications, solid-state switching circuits operate either on the Hall effect or by using contact or capacitance-type membrane switches. Light-emitting diodes (LEDs) illuminate switching devices or provide status indication.

In selecting switching devices, one might consider such factors as the requirement for panel and display area. Other factors include the type of switching action required (SPST, SPDT, DPDT, momentary or maintained), contact ratings (from microamperes to 15 A, and from 5 V DC to 600 V AC, with 5 A at 125 V AC being a common industrial selection), service life (ranging from 1 million to 30 million operations), the type of terminations (quick-connect, screw, solder, push on) and the type of housing required (NEMA 1, 4, 7, etc.).

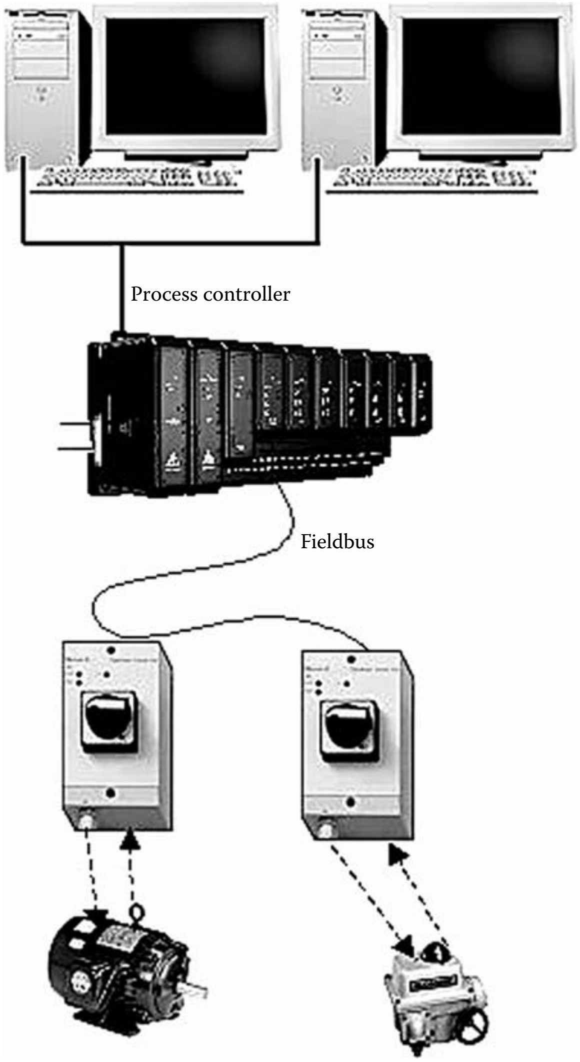
In the area of motor-starter designs, significant advances have been made. These days the packaging is more compact, and the motor starter includes some form of intelligence. The fault diagnostic capability usually includes the detection of power loss, short-circuit sensing, phase imbalance and phase current detection, full-load current, and thermal capacity. These features contribute to the ease of troubleshooting and quick restarting. Most motor-starter manufacturers also provide integrated interfaces for communication on the plant's bus network (Figure 4.12a), while the hand-off-auto switch or pushbuttons remain local, near the motor. This design reduces the amount of wiring and therefore the cost of installation, while the simplified connections and the self-diagnostic features tend to lower the cost of maintenance.

SWITCH DESIGNS AND OPERATION

A manual electric switch (Figure 4.21b) consists of the switching contacts, an actuator to bring them into proximity, terminals to connect the contacts to the conductor of an electric circuit, the insulating mounting provisions, and the enclosure, either separate from or integral to the mounting for contacts and terminal.

The gap between contacts is filled by air or by an inert gas. The control is operated by moving the contacts closer together until the applied voltage causes an electrostatic failure of the gap. The ensuing electron flow heats the cathode and cools the anode contact until molecular welding occurs, creating a continuous metallic path and completing the circuit.

Contact resistance is a measure of the degree to which the insulating gas remains between the contacts, preventing welding over their entire bearing area. It is directly proportional to contact pressure.



Fieldbus motor starters

FIG. 4.21a
Motor starter with local controls and fieldbus interfacing for self-diagnostics and automatic control.

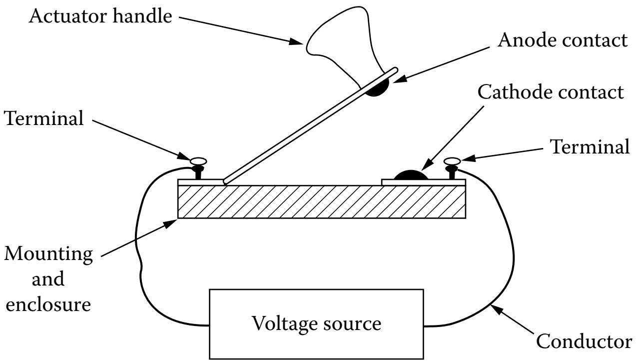


FIG. 4.21b
Operating elements of a manual switch.

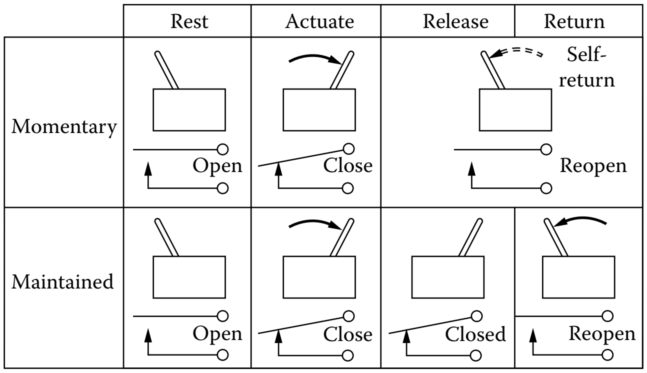

FIG. 4.21c
Basic switching actions.

Switching Action

Switching action refers to the positions assumed by the contact in response to actuator motion. The two basic types (Figure 4.21c) are momentary action, which provides one contact closure and subsequent reopening with one actuation, and maintained action, which requires separate actuation to transfer the contacts from one extreme position to another and back.

Other special types include:

1. Mechanical bail, which allows operation of only one control at a time, physically inhibiting depression of others. Automobile radio selectors are a typical example.
2. Electrical bail, which allows delayed or remote actuation, including sequencing of several controls. Solenoid operators frequently sequence rotary selectors or ganged pushbuttons.
3. Sequential action, which opens one contact set in a specified order in relation to other contacts in the same control. This type may involve simultaneous operation of several contact sets and repeated opening and closing of one contact set during one actuation.

Contact Arrangements

Switching capacity refers to the number, type, and arrangement of contacts and circuits within the control. Figure 4.21d contains the related terminology:

Normally open contacts (NO). The circuit is open (current does not flow) when the contacts are not actuated. Moving them to the other extreme position completes (closes) the circuit.

Normally closed contacts (NC). The circuit is complete when the switch is not operated. Moving the contacts opens the circuits, interrupting current flow.

Number of poles (P). The number of conductors in which current will be simultaneously interrupted by one operation of the switch.

Number of throws (T). The number of positions at which the contacts will provide complete circuits. Since contacts usually have only two extreme positions, switches are either single-throw or double-throw.

	Diagram	Operation	Features
SPST NO	 Form A	Make (pulse)	Pulses when actuator is depressed, but not when released.
SPST NC	 Form B	Break (pulse)	Same as Form A except opens circuit instead of closing it
SPDT NO/NC	 Form C	Break-make (transfer)	Provides complete circuits at both contact positions
SPDT NO/NC	 Form D	Make-before-break (Continuity transfer)	Momentary overlap of contacts provides circuit continuity
SPDT NO	 Form K	Center off (pulse)	Provides pulses in two conductors from one switch. Useful for "up, down" jogging.
DPST NO	 Form AA	Double make (Double pulse)	Interrupts current in two independent conductors of a circuit. Replaces two Form A switches.
DPDT NO/NC	 Form CC	Double break-double make (Double transfer)	Simultaneously operates two circuits. Several wiring possibilities. Replaces two Form C switches.

FIG. 4.21d
Switching contact configurations.

Switching Elements and Circuits

Switching circuits are classified as low energy or high energy. Low-energy circuits do not develop sufficient volt-amperes to break down insulating contaminant film (that may have built up on the contacts) by contact heating. Consequently, infrequent use degrades the controls in these circuits. Accordingly, reliable low-energy switching elements must maintain low contact resistance. Solutions include:

1. Wiping action under high contact pressures
2. Contact materials with high oxidation resistance
3. Hermetically sealed enclosures, either evacuated or filled with an inert atmosphere

High-energy circuits generate sufficient power to sustain an arc between contacts. Therefore, a reliable high-energy switching element must perform under very high contact temperatures. With these circuits, unlike low-energy circuits, frequent operation degrades reliability. Large contact areas, thick plating, and thermally conductive alloys combat high temperatures. Special features divert, vent, or extinguish the arc.

Switching elements are summarized in Figure 4.21e. Mechanical contactors either wipe the contacts over each other or strike them together. Wiping contacts move in a series of jerks, during which the contacts alternately weld and break loose. Striking contacts are either elastically or plastically deformed on impact.

Magnetic Reed Magnetic reed contacts are overlapping ferromagnetic beams, cantilevered from a glass tube filled with a dry inert gas. A small gap separates the overlapping

	Name	Diagram	Operation	Operating characteristics	Advantages and disadvantages	Applications
Mechanical contactors	Magnetic reed		Magnetic induction bends reeds. Striking contacts.	Actuation force independent of contact pressure. High contact pressure, fast precise timing. Excellent for low-energy circuits.	Hermetically sealed contacts. Bounce is problem, requires external compensating circuitry. Can be actuated by vibration. Requires shielding from external magnets. Long life, inexpensive.	Keyboard pushbutton, panel pushbutton, (integral).
	Snapaction		Leaf spring snapped. Over-center. Striking contacts.	Irreversible action no "teasing". Fast, precise, short, repeatable timing and travel. Best for simultaneous switching of many circuits with one actuator. High contact pressure, high actuation force.	Enclosed contacts. Suitable for low- or high-energy circuits. Relatively inexpensive. Very small sizes available.	Toggle, panel pushbutton (built-up), industrial pushbutton (medium and heavy duty).
	Wiping blade		Cantilever blade contact wipes past fixed spring contact.	Low contact pressure. Wiping cleans contacts, but wears away plating, timing and travel not precisely repeatable.	Hard silver plating used to resist abrasion, thus not generally suited to low energy use. Rotary is exception since infrequent use allows gold plating. Relatively inexpensive.	Integral panel pushbutton, rotary, industrial pushbutton (light duty).
Contactless	Integrated circuit		(Hall effect) Voltage is developed across edges of current—carrying conductor by magnetic induction.	Actuator force independent of switching action. Very fast switching, precise timing.	No contact bounce. Always-on bias voltage sometimes required. Excellent for repetitive, long-life use in low-energy circuits. Expensive, sealed.	Keyboard pushbutton.

FIG. 4.21e
Basic switching elements.

ends, and magnetic induction in the gap eventually overcomes their stiffness, bending them until they touch. The circuit is reopened by removal of the magnetic influence. Reed contacts provide:

1. High contact pressure with low actuator force, since the actuator does not directly move the contacts
2. Very fast response
3. Long life

Since the reeds are cantilevered springs, a major problem is contact bounce.

Snap-Action Snap-action switches are very rapidly struck together by an overcenter spring mechanism. They provide:

1. Irreversible switching, since the operator can do no more than start the switching action
2. Precise timing, including virtually simultaneous switching of many circuits with one actuator
3. Precise, consistently repeatable travel because there is only one moving part—the spring
4. High load capacity and long life, since arcing is limited by the very fast contact transfer time

Wiping Blade Wiping blade contacts employ a stiff, blade-shaped contactor that passes over spring-mounted stationary contacts under high pressure. Alternately, the moving blade is the spring, and the fixed contacts are stiff. The contacts are sometimes knurled to assist the wiping action. Hard silver plating alloys are required to resist wear, which generally restricts the use of wiping blade contacts to high-energy circuits.

Integrated Circuit Contact-less switches are useful in low-signal-level electronic circuits. The absence of contact bounce eliminates the need for external filtering circuits. Other advantages are virtually unlimited life, very fast switching, and freedom from the effects of contamination. Most contact-less switches employ semiconductors, which require an always-on bias voltage. This can be a disadvantage when compared with a mechanical switch.

Grades of Switching Devices

Table 4.21f summarizes the features of four types of manual control devices—pushbutton, toggle, rotary, and thumbwheel—all of which are available in several grades and types of construction:

Appliance-grade switches are not suitable for process control; they are low-cost devices designed for light, nonabusive environments in which precise timing and current control are not required, performance degradation is not critical during operating life, and exacting operator feedback is not necessary.

Commercial-grade switches are suitable for the control room. They provide consistent actuation and switching performance at specified reliability in average environments. Some degree of contact sealing is present, and corrosion-resistant contact materials are used. Actuation and switching mechanisms afford precise control of light-to-medium electrical loads.

Industrial-grade switches are specialized for local installation in harsh environments. Construction is rugged in order to accommodate abusive actuation and unusually heavy electrical loads. Actuators and contacts are sealed against liquid and solid contaminants, especially oil.

Military-grade switches are suitable for process control use but are usually overspecified in some areas and underspecified in others and carry a price premium.

Built-up construction uses separate housings for the actuator and the switching element. Circuit flexibility is the principal advantage, since switching modules can be ganged at will, although standard capacities are available. Disadvantages are unsealed interface between actuator and switch modules, back-of-panel volume, and price.

Integral construction combines the actuator and the switching element in a common housing. Advantages include satisfactory sealing and smaller overall dimensions. The major disadvantage is fixed switching capacity.

TYPES OF SWITCHING DEVICES

Pushbuttons

Pushbuttons provide the simplest, most naturally comfortable actuation motion. They alone accommodate extensive labeling without the use of separate nameplates. Disadvantages include a switching capacity that is lower than that found in other types because there are only two contact positions and lack of inherent indication of switching status (such as by handle position) other than lighting. Two methods of producing colored light are by transmission and by projection. Color selection has been discussed in Section 4.19.

Transmitted colors are produced by transmission of white light through colored button-lenses; they should be used whenever possible. Colors are intense, saturated, and uniformly distributed over the button; do not degrade from lamp heat; and can be read both from great distances and through wide viewing angles.

Projected colors are produced by projection of colored light on a white button-screen. The colored light is produced by transmission of white light through colored filters that slip over the lamps. Projected colors are weak, dilute, and easily overpowered by normal room ambient light; have restricted viewing distances and angles; and degrade as the colored filter is progressively destroyed by lamp heat.

TABLE 4.21f
Types and Characteristics of Electric Switches

	Pushbutton	*Toggle*	*Rotary*	*Thumbwheel*
Typical applications	Keyboard, motor, machine tool, instrument; best for pulsing; action dynamics match digital display	Computer data register; power on-off, test; "center off" type suitable for jog, adjustment about reference	Computer control panels, ammeter adjustment (potentiometer); action dynamics match fine analog adjustment	Encoded data entry to digital computing circuits; instrument settings; exact value setting
Advantages and disadvantages	Easiest, most comfortable operation; self-contained label flexibility	Least expensive 2,3 position selector; simple nonprecision operation, reflex action; best for actuation of multiple switches simultaneously	Most capacity in one control; selector available for 4+ positions in high-energy circuits; self-contained encoding optional; also mounting for components	Most capacity in least panel area; self-contained encoding, dial readout of value setting; single alphanumeric character-position or complete messages
Handles and feedback features	Integral handle, lighting very useful; no feedback from handle position	Integral, special "decorator" style available; handle position positive feedback (indicator) or status; no light or label except rocker (marginal)	Separate, many shapes and color options; label on skirts; no lighting	Integral; small tabs adjacent to indicator dial; same number as number of positions; lighting optional
Environmental protection	Sealed switch elements standard; sealed actuators optional; standard industrial grade	Enclosed switch elements standard; sealed actuator handle optional	Enclosed switch elements optional; sealed actuator shaft optional	Enclosed switch elements and actuator handle optional
Number of positions	1,2	2,3	2 to 24 (potentiometer)	8 to 16
Comparable cost, position	2.5	1.0	5.0	—
Ratings	0.5 to 60A @ 125 V AC or 30 V DC; 1A @ 600 V AC; 0.5A @ 600 V DC	20A @ 125 V AC 12A @ 30 V DC	0.3A @ 125 V AC 1A @ 30 V DC	0.13A @ 125 V AC or @125 V DC
Life	10 million operations	1 million operations	100,000 360° cycles	100,000 360° cycles
Mounting	Front or back of panel; printed wiring board	Back of panel; printed wiring board	Back of panel; printed wiring board	Front or back of panel; printed wiring board

Panel Pushbuttons A variety of integral and built-up configurations is available (Figure 4.21g), incorporating molded or metal housings, various force and travel options, and a wide range of lighted and unlighted buttons. Square and rectangular buttons are most easily mounted and provide the most labeling area. Labeling is accomplished by hot-stamping, engraving, two-shot molding, silk-screening, or by use of photographic film inserts. Panel pushbuttons are usually mounted in individual openings; built-up configurations mount from the front of the panel, using threaded bushings and lock nuts. Buttons and lamps in each configuration are accessible from the front of panel.

Each mounting method has definite panel thickness limits, which can, however, be circumvented by subassembly to a bracket that in turn mounts on the back of the panel. The buttons are available for both low-energy and high-energy circuits.

Industrial Pushbuttons These buttons are ruggedly made to withstand abusive environments and to resist abusive operation (Figure 4.21h). Compact and standard sizes are available, and both kinds use a built-up construction to accommodate custom switching for specific applications. Actuators and contacts are both liquid tight and dust tight, and contacts are available for three grades of duty:

1. Electronic (wiping action, gold plating)
2. Standard (wiping action, silver plating)
3. Heavy-duty (striking action, silver, silver alloy, or cadmium alloy plating)

Keyboard Pushbuttons These buttons are integral pushbuttons used in low-energy electronic circuits (Figure 4.21i). Force-travel characteristics are carefully designed for precise tactile feedback during repetitive, high-speed touch typing. Simplified, durable, low-cost actuator mechanisms and switching elements furnish a high degree of reliability for many operations.

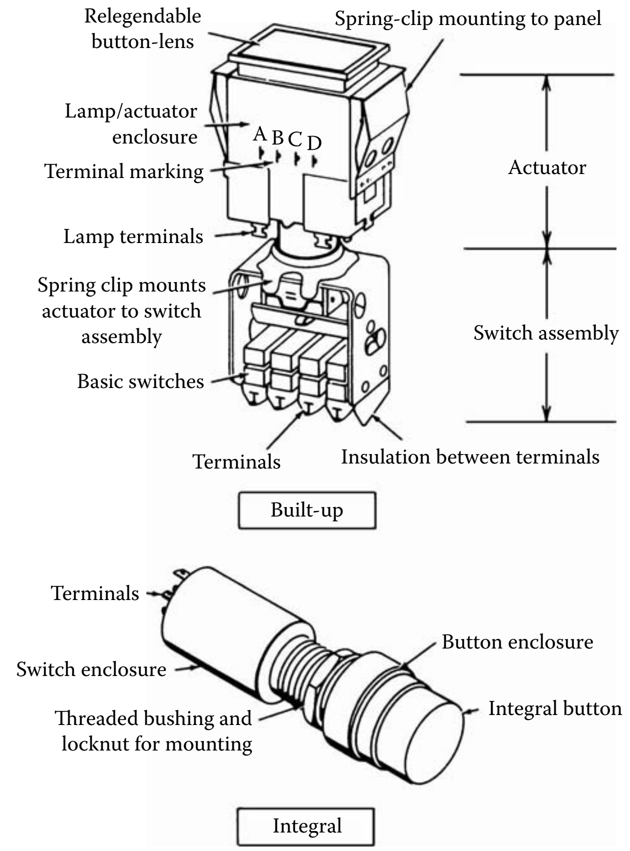

FIG. 4.21g
Panel pushbuttons.

Construction is as functional as possible for mass production, group mounting, and group connecting. Techniques include molded housings, two-shot molded buttons and labels, and printed wiring board mounting and connecting. Both assembled keyboards and a variety of standard and custom arrangements, encoding, operating forces, and buttons are available from most manufacturers of keyboard pushbuttons.

The inscriptions and function buttons of the keyboards are usually highly customized and reflect the purpose that the workstation serves (Figure 4.21j). This customized, process-specific design of keyboards makes the operator's work more efficient.

Hall-Effect Pushbuttons The early keyboard pushbutton designs used reed switches. In modern keyboards either the traditional Hall-effect plunger switches are applied or more modern membrane-type switches using either contact or capacitance-type sensors are employed. Hall-effect devices are snap-acting, solid-state sensors that consist of a generator and a trigger circuit integrated on a single silicon chip.

The Hall-effect chip (Figure 4.21k) detects both the strength and direction of the magnetic field and therefore generates a signal as the magnet attached to the plunger assembly passes the chip. The integrated circuit produces an analog control voltage, usually 0.4 V DC maximum at 4 milliamperes per output. The power supply is 5 V DC, and the rise or fall time of the signal is about 1 microsecond. The purpose of the trigger circuit is to convert this voltage into a digital output. Hall-effect pushbuttons are available with LED-type lighting, and one of their advantages is that they eliminate the problem of contact bounce.

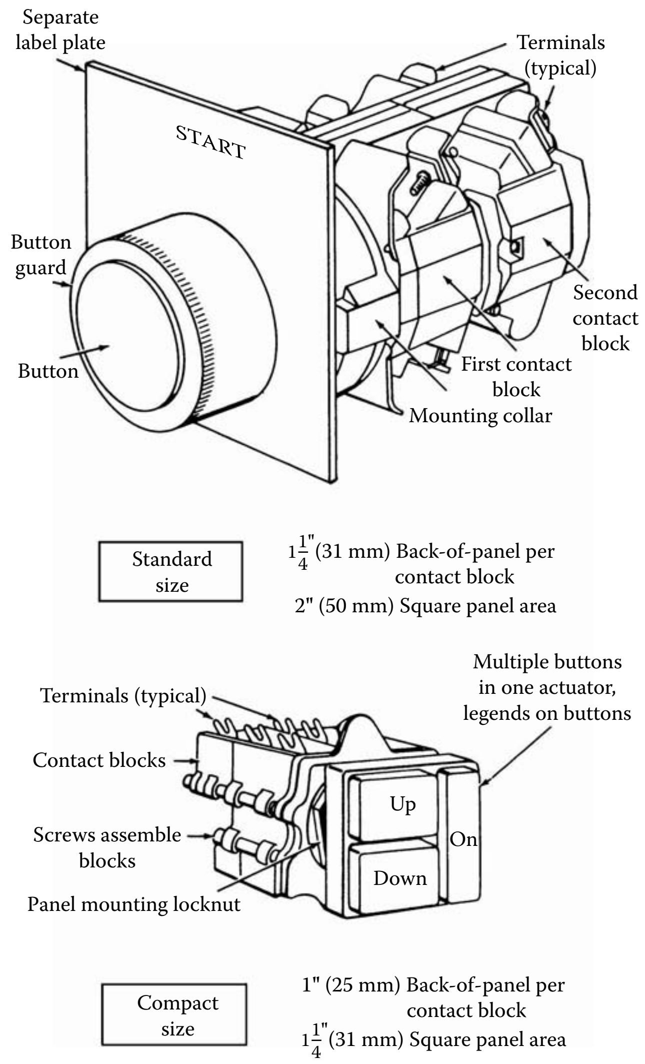

FIG. 4.21h
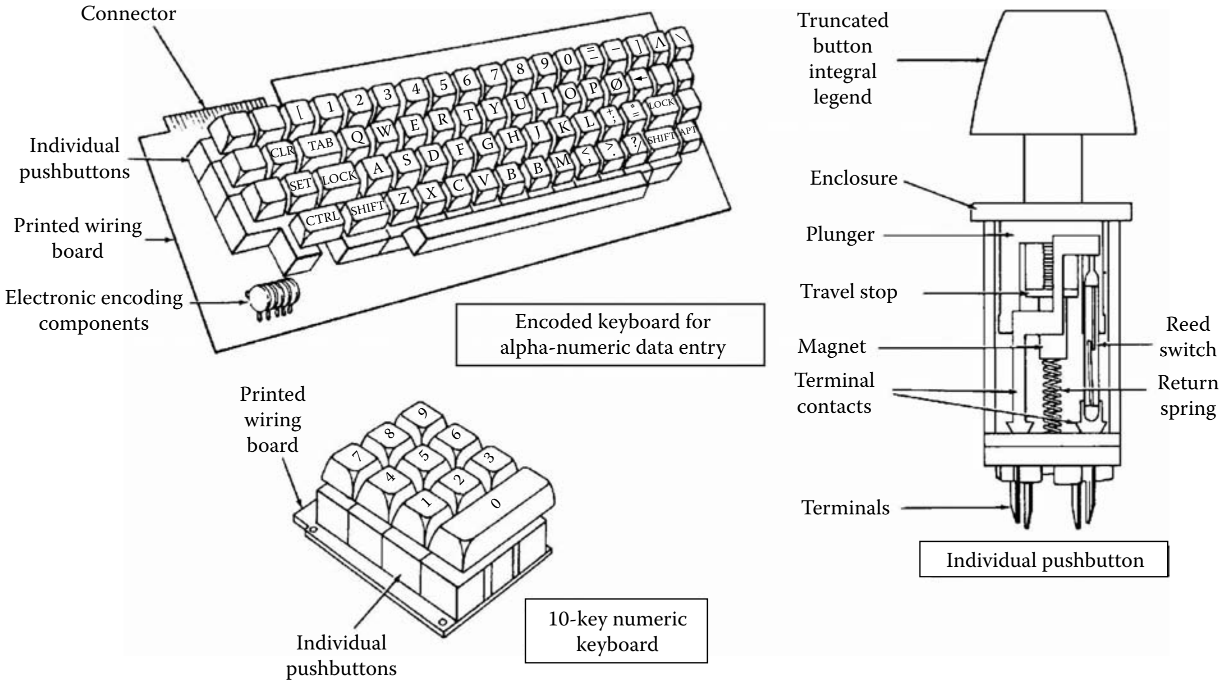
Industrial pushbuttons.

Membrane Pushbuttons Touch panels or membrane switches are inherently rugged and immune to dirty environments (Figure 4.21l). They are manufactured in a sandwich-like configuration with the circuit layers separated by spacers with holes for the actuation points. When force is applied at the actuation points, the membranes are flexed. In the contact design, a SPST-NO (Single-pole single-throw, normally open) circuit is closed, while in the capacitance design the drive pad approaches the sense pad, resulting in an increase in the variable capacitance, which triggers the detector circuit. The fixed capacitance between the float and sense pads is used as a reference. When the finger pressure is removed, a snap spring reopens the circuit and a compression spring self-returns the key top.



Encoded keyboard for alpha-numeric data entry

10-key numeric keyboard

Individual pushbutton

FIG. 4.21i
Keyboard pushbuttons.

The operating life of such keys is between 2 and 5 million operations, the key size is usually 0.5 by 0.5 in. (13 by 13 mm), and the key travel is 0.01 to 0.02 in. (0.25 to 0.5 mm).

The membrane switches are allowed to “breathe” through venting openings, so that the development of pressure differences across the membranes, due to the pressing of a key or because of altitude or temperature changes, will not affect performance.

The keys of various keyboards are wired in a matrix format. When a key is depressed, one sense circuit and one drive circuit are energized, and the unused circuits are automatically grounded, shielding the keyboard from electrical noise, which could generate erroneous code.

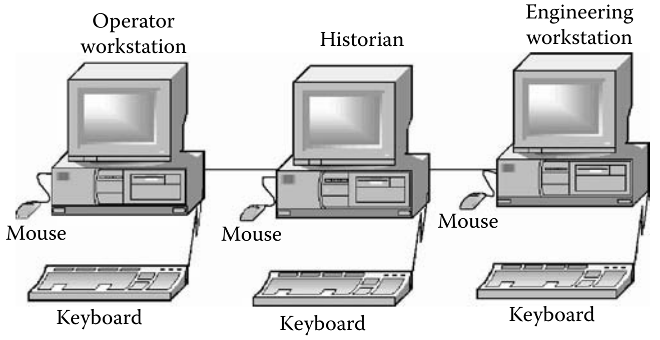


FIG. 4.21j
Custom keyboards are designed to fit the nature and purpose of the workstation.

Toggle Switches

Toggle switches are the cheapest two-position or three-position selectors for a large number of circuits of any level of complexity or energy, and integral and built-up configurations are available. A major advantage is positive indication

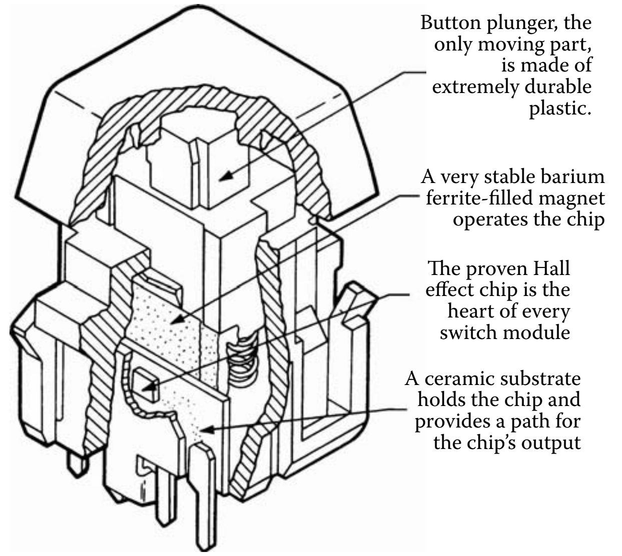

FIG. 4.21k
Solid state Hall-effect pushbutton design. (Courtesy of Pepperl + Fuchs Inc.)

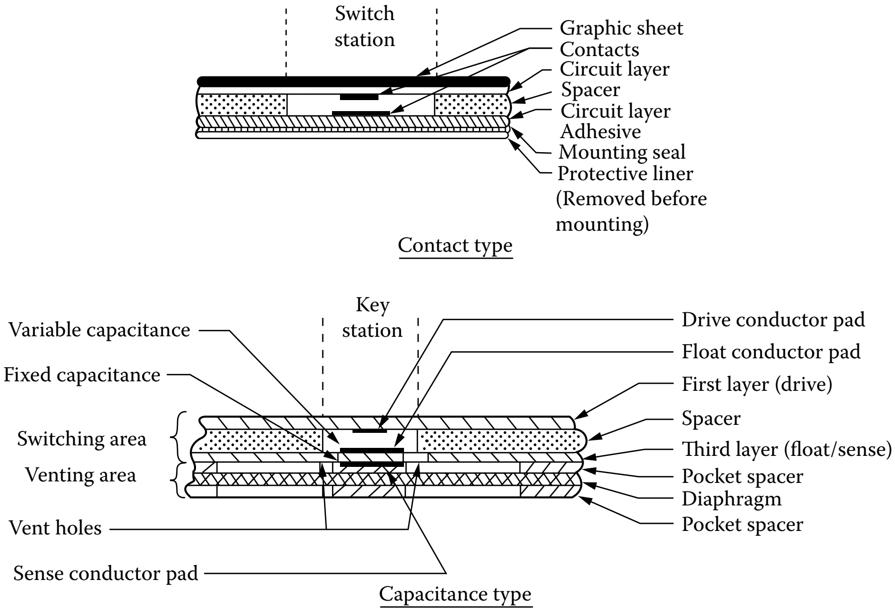

FIG. 4.21l
Membrane-type pushbutton designs. (Courtesy of Pepperl + Fuchs Inc.)

of switching status from handle position. The three basic handle configurations are lever, rocker, and thumbwheel.

The lever handle configuration (Figure 4.21m) is the most common and gives the most positive handle position indication. Careful consideration of length, shape, protrusion above the panel, and panel graphics design is required before the operator can capitalize on this advantage. A wide selection of shapes, sizes, colors, and trim hardware is available to create various front-of-panel appearances, accentuate handle positions, and safeguard against accidental actuation.

The rocker handle (see Figure 4.21m) combines positive handle indication with the operating simplicity of pushbuttons. Some space for labeling and lighting are also available, but both features are marginal owing to space limitations.

The thumbwheel handle (see Figure 4.21m) is occasionally used to reduce front-of-panel protrusion and to accommodate special actuation motion. The disadvantages of the thumbwheel handle are that handle position does not provide a positive indication of switch position and that control of travel and force is difficult since the finger moves in and out at the same time that it moves from side to side. The latter characteristic makes the handle especially awkward for use as an adjustment control about a spring-loaded "center off" position.

Rotary Switches

Rotary controls (Figure 4.21n) are selectors or adjustors for low-energy circuits and afford greater switching capacity in less volume than any other control does. Switching capacity is expanded by addition of switching modules, and a major advantage is that entire operational sequences can be contained on one control. The disadvantages of rotary controls are that operating force is increased with increased switching capacity and that there is no direct access to individual positions without actuation of intermediate positions.

Built-up construction is almost universal, either enclosed or open-frame. Mounting is either to printed wiring boards or back-of-panel, using standoffs or threaded bushings and lock-nuts. Switch modules consist of fixed contacts mounted on round printed wiring board decks. Each deck has a movable contactor attached to a common shaft. The printed wiring affords flexibility in contact arrangement, contact spacing, total rotational travel, switching action, and mounting of electronic components for self-contained encoding.

Users commonly abuse the inherent flexibility of these controls by packing too much switching capacity into one control, based on the rationale of saving the cost of another rotary switch. Angular spacing of contacts becomes so small, and operating force so high, that actuation is awkward and imprecise.

Very high contact pressures result and can mechanically damage contacts and the actuator mechanism. Considerable panel area is required to label a large number of positions. Large-diameter handles, although they decrease force, also consume panel area. The other extreme of excessively wide contact spacing causes awkward wrist and arm movements.

The guidelines generally accepted include:

1. Minimum angular spacing = 15°
2. Maximum angular spacing = 90°
3. Minimum positions = 4 in 360°
4. Better minimum = 4 in 240°

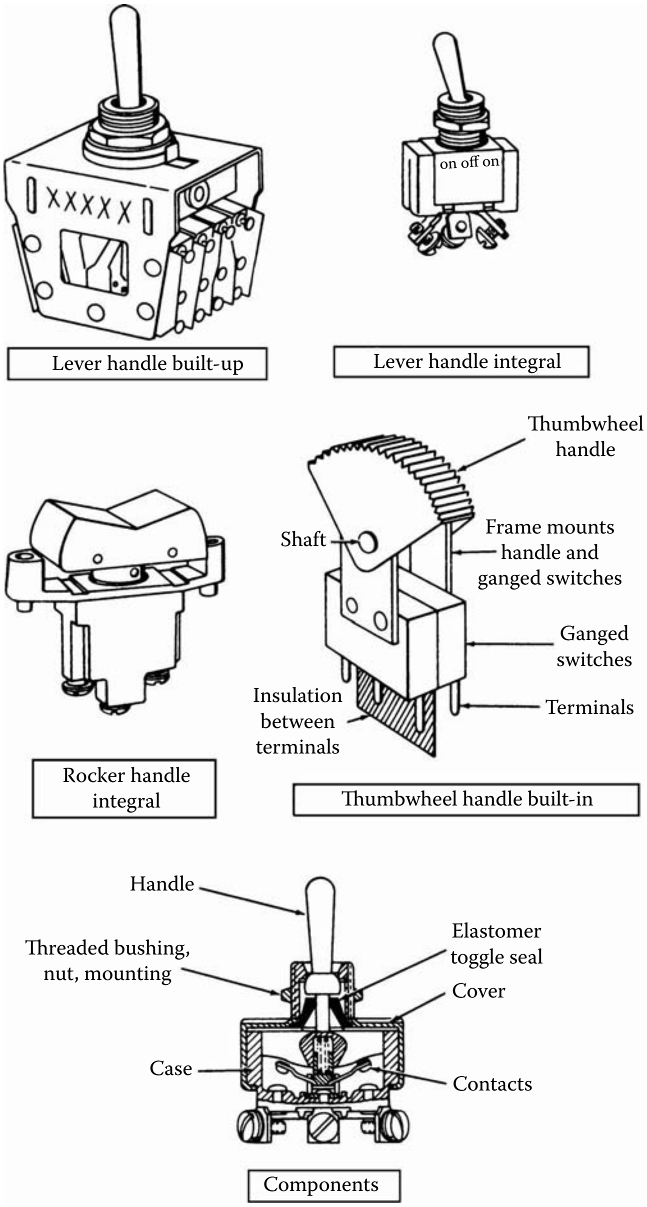

FIG. 4.21m
Toggle switches.

5. Maximum positions = 24 in 360°
6. Better maximum = 20 in 300°

Thumbwheel Switches

Thumbwheel switches (Figure 4.21o) are a form of rotary selector for encoded data entry to low-energy electronic circuits. Encoding is accomplished by internally mounted electronic components. Thumbwheels take up very little front-of-panel area owing to the parallel arrangement of contact disk, moving contactor and handle and self-contained indicator dials. Contact disks can be stacked horizontally to create controls of any size. Thus, thumbwheel switches can do the job of several rotaries, pushbuttons, or toggles and use considerably less panel space.

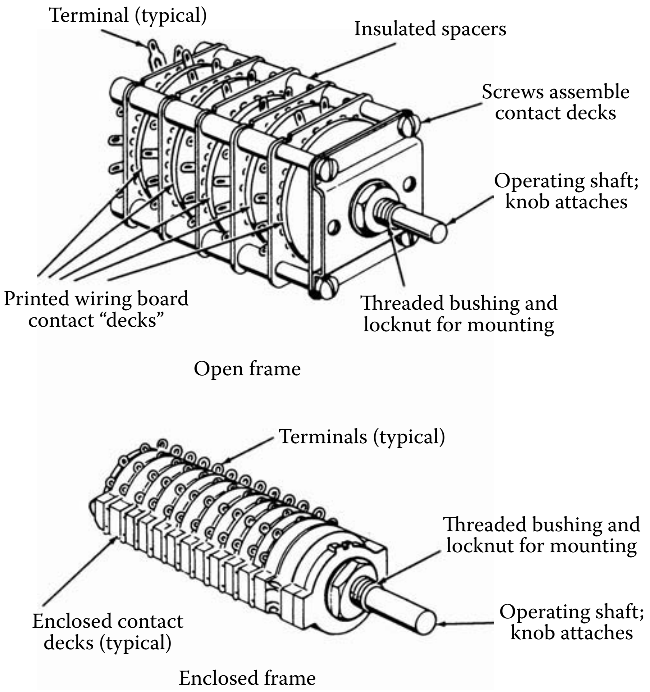

FIG. 4.21n
Rotary selectors.

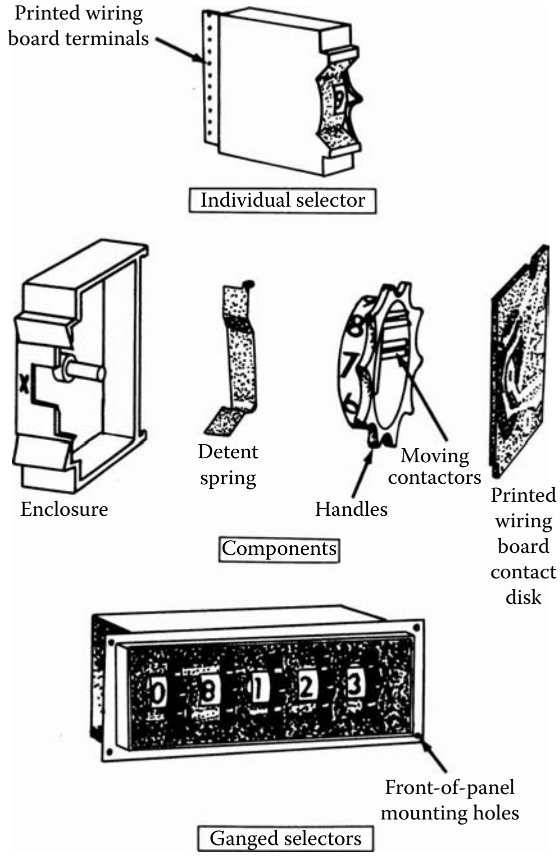

FIG. 4.21o
Thumbwheel selector.

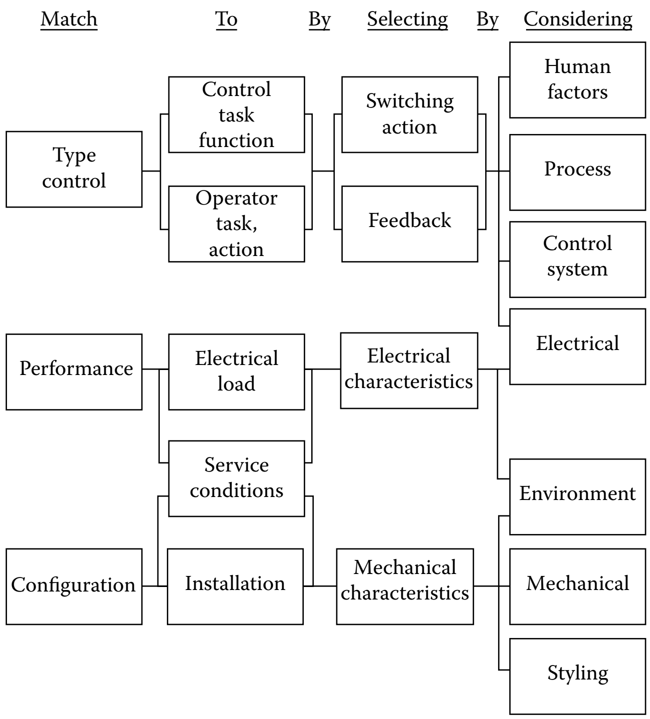

FIG. 4.21p
Selection procedure.

A major disadvantage of their use is that considerable concentration and dexterity are required for efficient operations. Also:

1. Actuator motion is usually opposite dial motion.
2. Handles are very small and must be poked at with fingertips.
3. Incremental spacing on the dial is small.
4. Horizontal spacing between handles is small.

APPLICATION AND SELECTION

The goal of the switch selection process (Figure 4.21p) is to provide the most direct link between operator and process by considering the following factors:

1. What is being controlled—the process
2. How it is being controlled—the type of control system
3. How the control is used—human factors
4. The service conditions—electrical, mechanical, and environmental

Process response to control action determines the operator's subsequent action. Important variables include time response, amplitude response, linearity, and damping.

Control system translation separates the process from the operator's control action and the operator from the process response. Important factors affecting selection of manual control involve:

1. Type of control—analog, digital
2. Resolution—proportional, derivative, integral, and combinations
3. Accuracy—physical losses through transmitters
4. Data processing errors—chop-off and round-off
5. Visual feedback—display resolution, speed, accuracy
6. Safety provisions

Human Factors

Basic to the human factors is mind–eye–hand coordination. Figure 4.21q depicts the role of this neural aptitude in manipulating controls. Its efficiency depends on how well the controls are matched to:

1. The control task and actions required to perform it
2. The workstation design
3. The displays associated with the controls

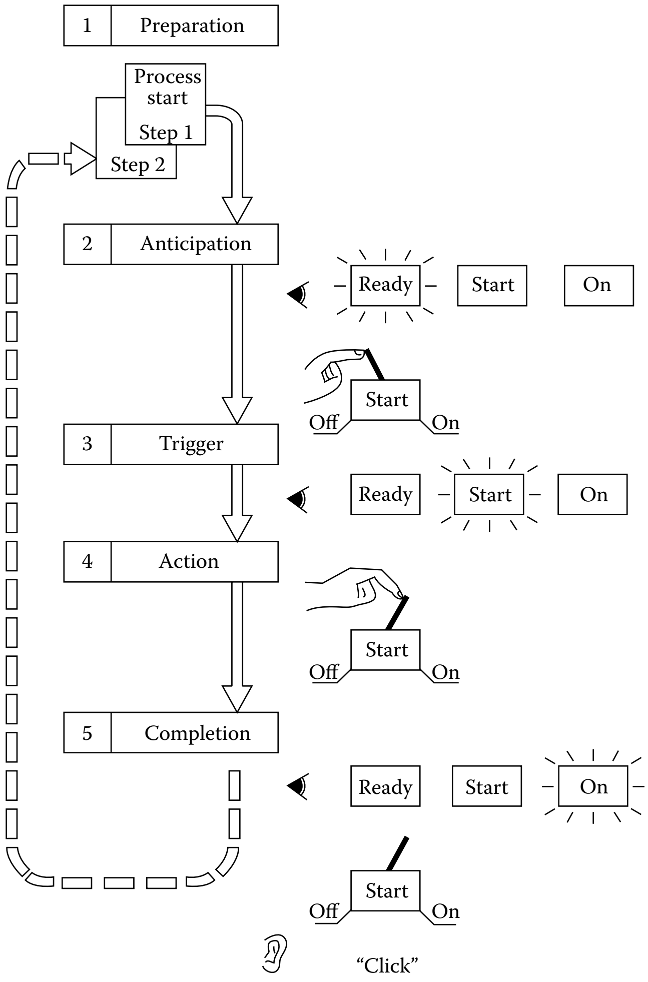

FIG. 4.21q
Mind–eye–hand coordination in control manipulation.

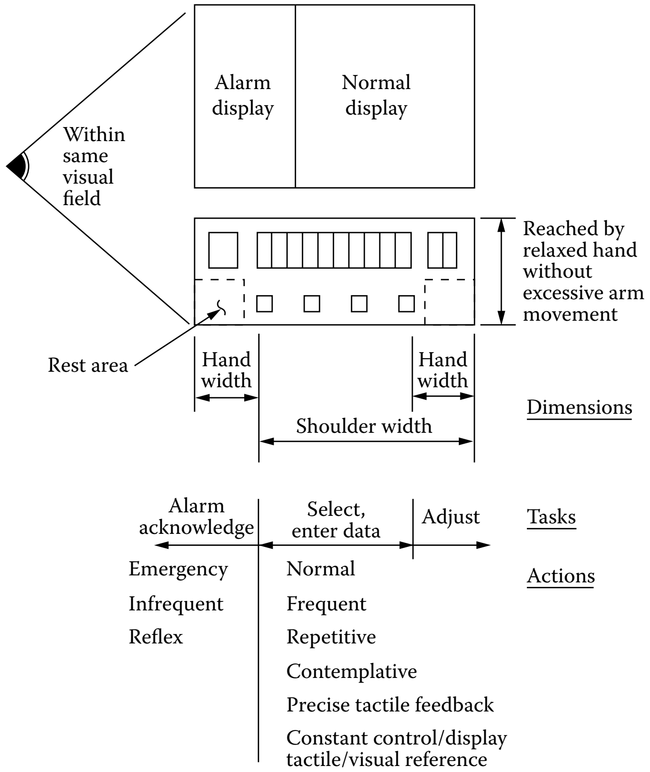

FIG. 4.21r
Workstation layout considerations.

Tasks (Figure 4.21r) are classified according to:

1. Selection of alternates: start, stop, automatic, and manual
2. Adjustment: gross, fine, fast, and slow
3. Tracking: adjustment about a moving reference
4. Data entry: setting values, loop address, and loading computer registers

Actions (see Figure 4.21r) required to perform these tasks may be either:

1. Sequential or simultaneous
2. Continuous or intermittent
3. Exact or approximate
4. Repetitive or different each time
5. Frequent or infrequent
6. Single-pulse or hold-down
7. Normal or emergency

The workstation design objective is to match the physical characteristics of controls and displays to the nature of the control task, the actions required to perform it, and the operator's capabilities.

Anthropometry and general arrangement are different depending on the operator's position (sitting, standing, stationary, or mobile). Figures 4.21s and 4.21t show proper physical relationships. The angles formed by hand, fingers, and controls affect the "feel" of the control.

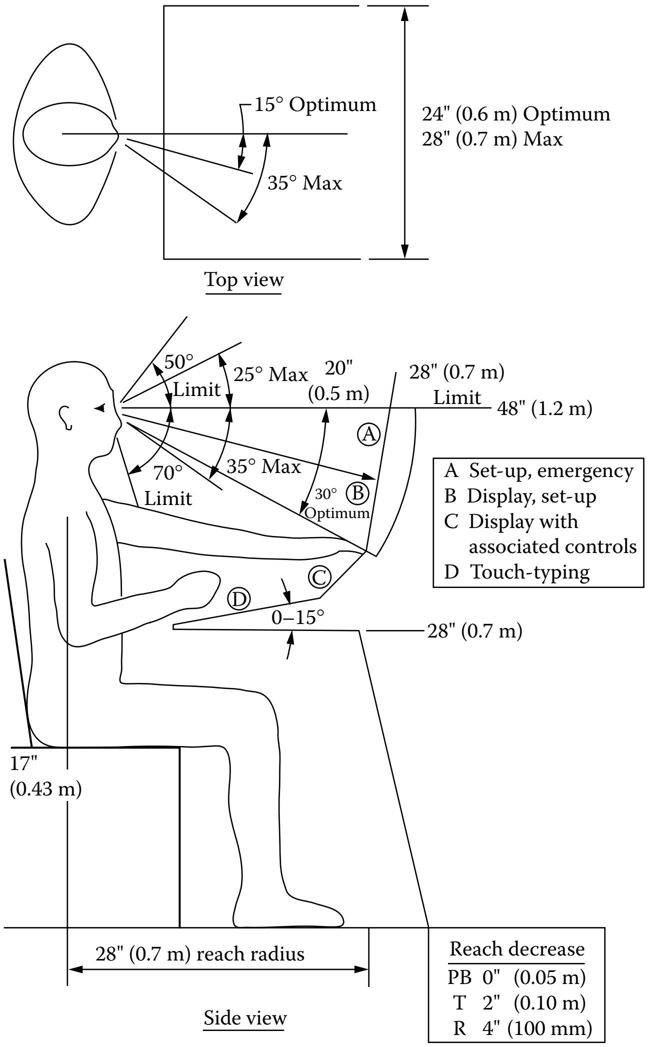

FIG. 4.21s
Hand and eye coordination considerations for an operator who is working in the sitting position.

The relaxed hand assumes natural angles that determine the most comfortable and strongest line of force (Figure 4.21u). Controls should be oriented and arranged so as to achieve these angles over the entire control panel. Compromises are necessary to reach extremities of the panel without inordinate body movement. Detailed arrangement should include the following considerations:

1. The same type of control should be placed differently for sitting and standing positions.
2. A sequence of time or order of use should be clearly depicted. The sequence should be maintained regardless of operator or panel orientations.
3. Workload should be distributed properly between left and right hands with consideration given to the fact that most people are nimbler with their right hand than with their left hand.

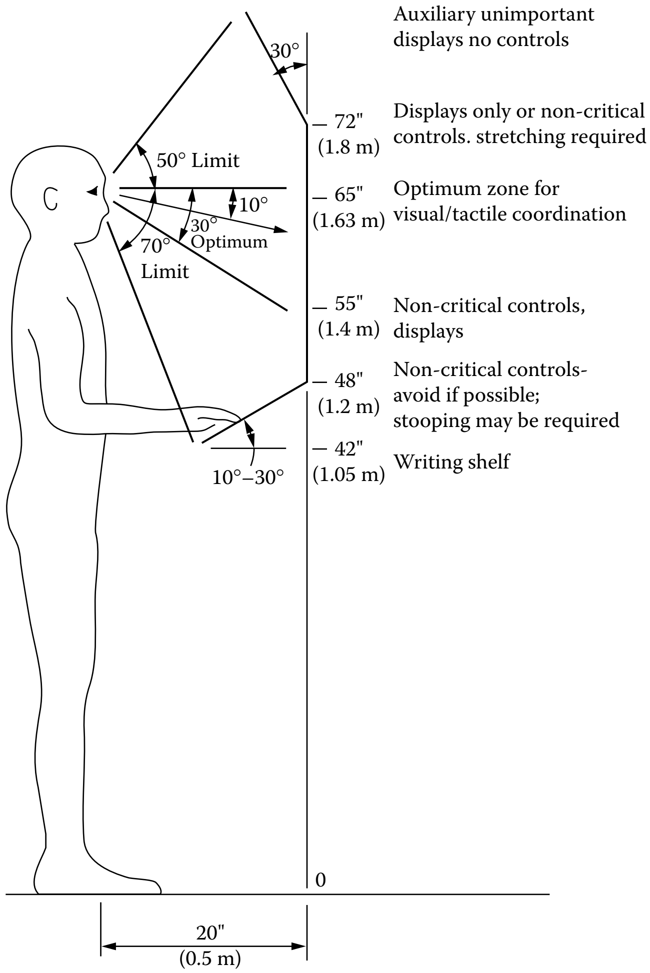

FIG. 4.21t

Hand and eye coordination considerations for an operator working in the standing position.

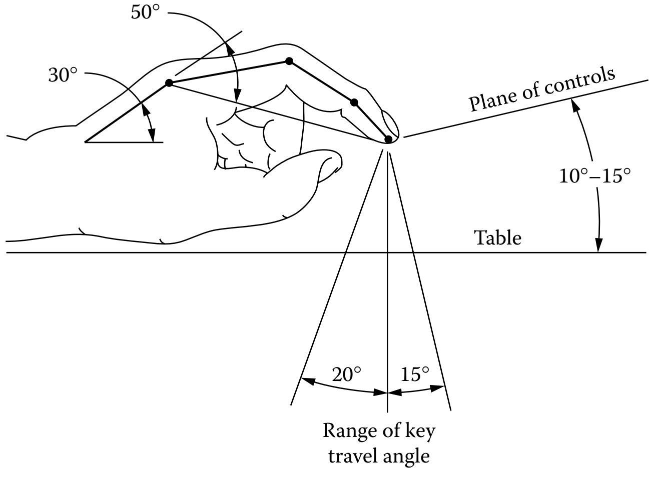

FIG. 4.21u

Natural hand and finger angles.

4. Related controls and displays should be clearly associated and located within the same visual field to minimize head and eye movement. Actuation of controls should not obscure related displays, labeling, or lighting.
5. Controls should be located below or to the left of the display for left-hand operation and below or to the right for right-hand operation.
6. Similar controls performing similar functions should operate in similar directions; similar controls performing dissimilar functions should operate in distinctly different directions.
7. Critical controls may require safeguards against accidental actuation by clothing, general body contact, and falling objects.

Display Movement

Control and display movement should be coordinated for direction, rate, accuracy, resolution, ratio, and linearity. Certain natural relationships are required by human habit patterns and reflexes (Figure 4.21v). Small, precise display adjustments require long-travel, low-force control motion. Short

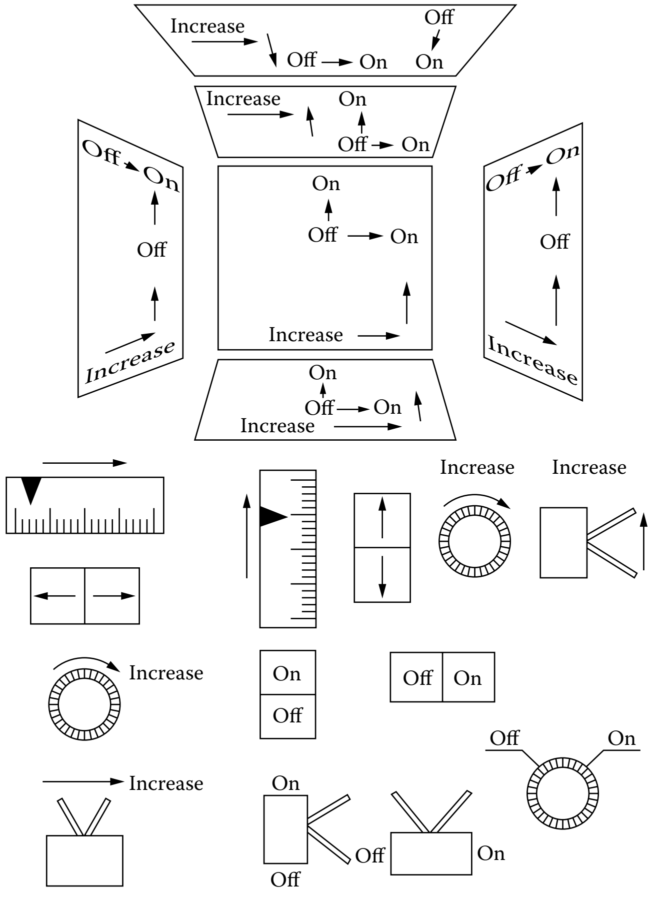

FIG. 4.21v

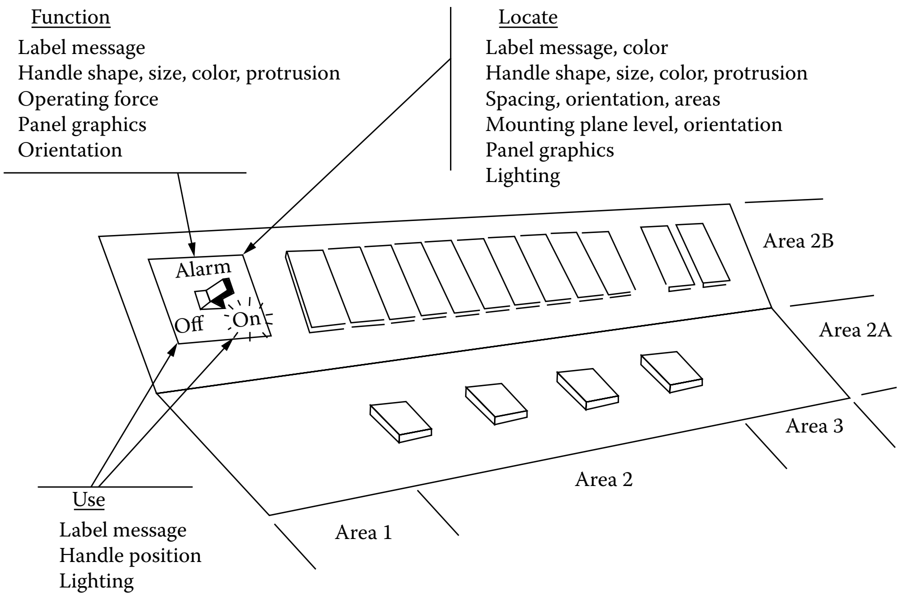
Natural relationships between the directions of motion.



Labeling guidelines

Too much information is as useless as too little
Be specific, concise, clear, but not elaborate
Avoid "engineering language," identify what is being controlled not the name of the control
Labels should be on controls whenever possible. When on panel, association with identified control should be obvious.
Adjacent labels should not create additional. "false" label
Place labels consistently above or below identified control
Orient labels horizontal to reading line-of-sight, avoid vertical, slanted, or curved orientations
Use capital letters, correlate size with viewing distance
Colors of labels should provide maximum contrast with label background

FIG. 4.21w
Guidelines for labeling and identification.

travel and low force should be used for fast displays. Pulse controls are well suited to incremental displays.

Analog displays are tracked or adjusted most efficiently by a rotary potentiometer or by a control with maintained "on" positions on either side of a spring-return center "off." Efficient identification of the control, its function, and its use is a keystone of efficient operation. Considerable care is required to achieve this seemingly commonplace goal. It is important to recognize that most identification techniques involve double duty and that redundancy of controls can both confuse the operator and lend a "busy" appearance to the panel (Figure 4.21w).

Control design should blend with the overall styling theme of the workstation. Handles and mounting hardware are available in a variety of shapes, sizes, textures, materials, labeling, and lighting (Figure 4.21x).

Error Prevention

Error prevention techniques are valuable in order to forestall simultaneous and missed actuations. Both activities are especially prevalent in repetitive, high-speed keyboard operation and can be traced to speed limits imposed by switching mechanisms, actuator mechanisms, and the scanning speed of external monitoring equipment.

Mechanical interlock inhibits two types of simultaneous actuations so that:

1. Two keys cannot be simultaneously depressed to the switching point.
2. A depressed key must be released before another can be depressed.

Electronic interlocks artificially increase the actuation speeds by delaying scanning of consecutive key outputs. "Two-key roll over" generates codes during depression of one key and release of another by blocking the second until

the first is released. "One-character memory" stores a character code until another is generated, erasing the first.

Tactile feedback in the form of a properly designed force-travel relationship is the best guarantee against missed actuations. Skilled operators develop a rhythm of depressing keys. They keep several steps ahead of their actual manipulation, counting on a change in their rhythm as a signal to stop. This change is usually the absence of a completion cue for an intended actuation. Completion is signified by a sudden increase in operating force near or at the end of travel. Supplementary audible or visual cues also occur at this point. The force-travel relationship shown in Figure 4.21y is generally regarded as desirable, is available in solenoid-assisted electric keyboards, and is closely approximated by some manual keyboard controls.

However, the curve shown in Figure 4.21z is the most economical (a simple linear spring) and therefore the most available. Tests have shown that poor force–travel relationship is a primary source of missed keystrokes in high-speed data entry.

Environmental variables affecting manipulation of controls include temperature, relative humidity, ambient illumination, and noise. Sweating may limit the amount of force the operator can apply, degrade dexterity, and cause fingers to slip off handles. Excessive light can mask lighted buttons, causing errors and loss of time and reducing safety. Noise detracts from concentration and may preclude audible feedback.

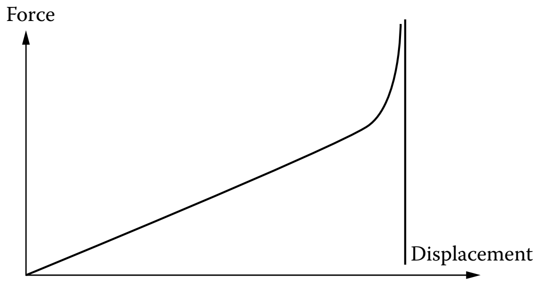

FIG. 4.21z
Force–travel relationships with linear spring feedback.

Electrical Rating and Performance Electrical performance of the control is determined by current and voltage ratings, contact bounce, switching sequence, and electrical interference from other equipment. Current rating measures resistance to welding of contacts. Underrated contacts either fail to open or do not open the required number of times during a specified interval. Current ratings are determined by contact configuration, plating materials, and transfer time.

Selection should account for potential overloads, which can exceed normal currents by as much as 30 times. Common sources of overload are:

1. Inrush starting currents of motors and tungsten-filament lamps
2. Relays and solenoid
3. Equipment malfunctions, such as short circuits and unstable power suppliers
4. Lightning

Voltage rating reflects resistance to arcing between contacts or terminals due to voltage surges. Ratings are determined by air gap spacing between contacts and between terminals and the insulation resistance of their mounting materials. Terminal spacing can cause a problem on subminiature switches, requiring supplementary insulating strips between terminals.

Low insulation resistance can cause voltage leakage to ground or excessive dissipation within the dielectric itself. High-impedance analog computing circuits are especially sensitive to these phenomena. Certain insulating materials support formation of conductive surface films by repeated arcing, leading to eventual flashover between contacts or terminals.

Alternating current resistive loads are easily interrupted because the cyclical current reversals prevent arcing caused by continuous current buildup across the contacts. However, high AC frequencies (400 Hz) can approach DC in this respect. Direct current ratings are usually lower than the ratings for AC service, and DC arcs tend to sustain themselves since the applied voltage does not reverse as it does with AC. Special arc suppression techniques are sometimes required and are incorporated either within the switch using surge cavities, vents, or magnets whose field opposes that generated by the arcing current or within external circuitry using resistors, capacitors, and rectifiers to reduce or surmount the arcing current.

Contact bounce occurs partially in all mechanical contactors. Reed contacts are especially vulnerable owing to their cantilevered spring construction. Snap-action contacts have little bounce since the over-center spring provides damping. Contactless keyboard switches, of course, are free from bounce. Bounce is equivalent to a sequence of contact openings and closings, the consequences of which are:

1. Reduced contact life
2. Generation of extraneous signals, which requires external filter circuitry
3. Radio frequency interference

The switching sequence should be chosen to minimize the circuit complexities that can occur during contact transfer. Make-before-break sequences furnish momentary contact overlaps—useful maneuvers when attempting simultaneous switching of several fast, low-inductance circuits with a multi-pole switch.

Mechanical Features

Mechanical features of electrical switches and of parent equipment that affect workstation design include:

1. Type of mounting (front-of-panel, back-of-panel, printed wiring board, individual, in groups, and vibration isolation)
2. Front-of-panel dimensions (spacing and size of openings)
3. Back-of-panel dimensions (spacing and access)
4. Access requirements (repair, replacement, maintenance, and rearrangement of lamps, handles, and wiring)
5. Wiring (terminal configuration and location)

Special precautions are occasionally required to preclude undesirable interaction between controls and parent equipment. Communications equipment operating at radio frequencies requires shielding from electrical noise generated by contact bounce. Reed switches must be shielded from heavy magnetic ferric materials (steel) and from magnetic fields stronger than their actuating magnet.

Environmental Considerations

Environmental factors pertinent to process control application include:

1. Temperature
2. Relative humidity
3. Contamination from gases, liquids, and solids
4. Barometric pressure
5. Vibration and shock

Most commercial and industrial electrical switches function within specification in environments that the operator can also withstand.

However, infrequently attended controls may be exposed to much more severe operating conditions. Electrical codes sometimes require low-energy circuits in hazardous locations, a circumstance that may necessitate intermediary isolation circuitry between control and controlled equipment, or sufficient air gap spacing to ensure potential differences below spark-generation levels.

The contact temperature is the sum of the room temperature, the rise within the parent equipment, and the rise within the switch. High temperatures accelerate contact corrosion. Unequal expansion of components can cause cracking and binding. Forced cooling may be required for densely spaced lighted pushbuttons that operate continuously.

Relative humidity and temperature cycling produce condensation. Moisture accelerates contact corrosion (decreasing current rating) and decreases insulation resistance (decreasing voltage rating). Contamination from moisture, salts, oils, corrosive gases, and solid matter degrades contacts and actuator mechanisms.

Contacts are protected by glass-to-metal or plastic seals or by inert atmospheres. Sealing can be done at the control panel, between the actuator and the contact mechanism, or within the contact enclosure. Controls should remain in their original packing materials until just before installation. Special materials, such as low-sulfur-content papers, retard contact corrosion during shipping and storage.

Vibration and shock can cause contact chatter, arcing, and outright structural failure of the contact mechanism and can affect the choice of operating force, handle shape, weight, and mounting method. Vibration damping is provided by snap-in spring mounting and the parent equipment structure. Orientation on the control panel should place handle travel at right angles to the vibration force. Barometric pressure affects the ability of air to extinguish arcs and dissipate heat. Current and voltage ratings must be reduced for use at high altitudes; hermetically sealed enclosures are occasionally needed for such atmospheric applications.

4.22 Touch-Screen Displays

BABAK KAMALI (2005)

Sizes:	From 12.1 in. to 19 in.
Costs:	Up to 15-in. monitors are under $1000 (CRT or LCD). Capacitive and resistive overlays are the cheapest ones. CRT displays are more expensive than LCD displays. 15-in. resistive or capacitive LCD is $400 to $500, CRT is $750 to $800. 15-in. surface acoustic-type LCD is $900 to $1000. Serial connectors are cheaper than USB connectors.
Partial List of Suppliers:	Elo TouchSystems Inc. (www.elotouch.com) 3M United States (www.3m.com) Touch International Inc. (www.touch-international.com) GVision Inc. (www.gvision-usa.com) Posiflex Inc. (www.posiflexusa.com)

INTRODUCTION

Touch screens are widely used in industrial applications that require accuracy, touch sensitivity, and durability. Today's computers come in many different shapes and sizes. Displays such as touch screens and single-board computers have made it possible to mount computers in locations as diverse as gas pumps and shopping carts. Touch-input devices fit over any size display and occupy little additional space, making them perfectly suited to the current trends in computers.

It is not only computers that have evolved over time, but the perception of them by the general public as well. These are the reasons that made touch technology so popular. In addition, the use of graphical icons and images makes the touch applications easy to understand, requiring little learning and no complicated instructions. There simply is no easier way to access a computer than by touching its screen. Pointing at an object is natural and intuitive for people all over the world because pointing transcends the barriers of language and culture.

TOUCH TECHNOLOGY

Advantages

Touch technology is especially beneficial if *space is critical.* If the available space is too limited for input devices such as a keyboard or mouse, touch technology is an excellent alternative. The traditional detached input devices are not suitable for use with handheld computers or personal digital assistants (PDAs).

In certain applications, such as during driving, *time is critical* because it is dangerous to divert one's eyes from the road. Touch screens eliminate the time needed for the operator to switch attention back and forth between a display and an input device, and the graphical target displays tend to minimize or eliminate the need for the operator to read any instructions.

Touch technology is also *accurate.* For example, an air traffic controller or a chemical plant operator can touch a radar image on a display rather than typing data to receive additional information on a particular aircraft or unit process.

Another advantage is that touch technology can provide a *simple interface* to an otherwise complex process. One example is a maintenance diagnostics computer. This type of computer, with a traditional interface, may be frustrating to mechanics with no prior computer experience and costly to their employers while they are learning to use it. Graphical touch interfaces can reduce or eliminate both the frustration and the learning curve by guiding the mechanics through the process with a series of touch-active menus. (In addition, many touch screens are impervious to grease and other substances that would damage a keyboard.)

Touch-Screen Designs

In order to select the touch technology that best fits the needs of a particular process control application, it is important to take a brief look at how each technology functions.

There are six basic types of operating principles in touch technology:

1. Capacitive overlay
2. Guided acoustic wave
3. Resistive overlay
4. Scanning infrared
5. Near field imaging (NFI)
6. Surface acoustic wave

Each type of touch technology has attributes that are desirable for specific applications.

All the touch screen designs are attached to a display unit, which can be a terminal, CRT, flat-panel display, static graphic, or combination of flat-panel display and static graphic. The differences between the technologies lie largely in the way the touch is detected and the method used to process the touch input. The next paragraphs describe the touch technologies that are available today.

Capacitive Overlay A capacitive overlay touch screen consists of a glass panel coated with a charge-storing thin coating. To activate the system, the operator must touch the overlay with a conductive stylus, such as a finger. Circuits located at the corners of the screen measure the capacitance and current flows resulting from the operator's touching the overlay and the current flows, which are proportional to the distance of the finger from the corners. The ratios of these current flows are used to locate the touch.

Capacitive touch screens are very durable and have a high clarity (Figure 4.22a). They are widely used, including industrial control applications.

Guided Acoustic Wave The guided acoustic wave design is based on transmitting acoustic waves through a glass overlay placed over the display's surface. Here a transducer is mounted at the edge of the glass and emits an acoustic wave. The wave packet travels along the reflector array and is redirected across the overlay to the reflecting edge, from which it returns to the array, where it is reflected back to the transducer. The first reflector will send a signal back first, then the second, and so on.

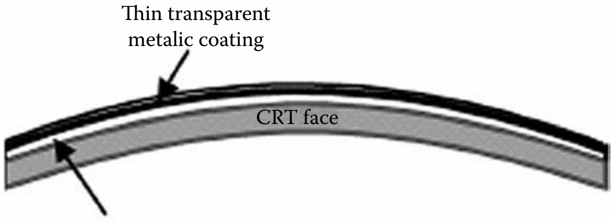

FIG. 4.22a
The design of a capacitive overlay screen.

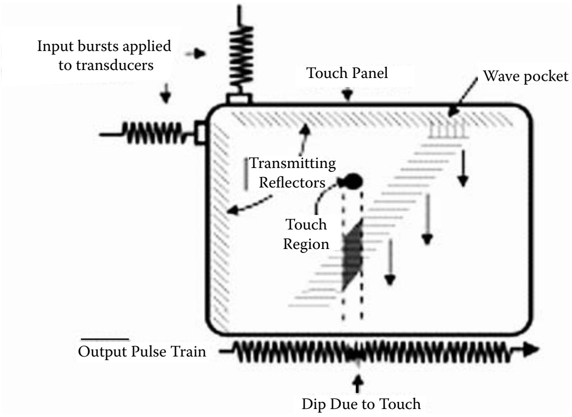

FIG. 4.22b
The guided acoustic wave touch screen design.

When a stylus such as a finger comes into contact with the wave, it attenuates its motion by absorbing part of the wave (Figure 4.22b). Control electronics detect the location of the dip in the wave amplitude, thus determining the location of the touch.

Resistive Overlay A resistive touch sensor consists of a glass or polyester panel that is coated with electrically conductive and resistive layers. The polyester layer has a similar metallic coating on the interior surface. The thin layers are separated by invisible separator dots.

An electrical current travels through the screen. When pressure is applied, the layers are pressed together, causing a change in the current flow, which is detected to locate the touch.

Such resistive touch screens are generally the most affordable. Although their clarity is less than of other touch-screen designs, resistive screens are very durable and are able to withstand a variety of harsh environments (Figure 4.22c). This screen design is recommended for control and automation systems, medical use, and more.

Scanning Infrared The scanning infrared (IR) design relies on the interruption of an IR light grid on the display screen. The touch frame or opto-matrix frame contains a row of IR-light emitting diodes (LEDs) and photo transistors, each mounted on the two opposite sides to create a grid of invisible infrared light. The frame assembly is comprised of printed wiring boards on which the opto-electronics are mounted and

FIG. 4.22c
The design of a resistive overlay touch screen.

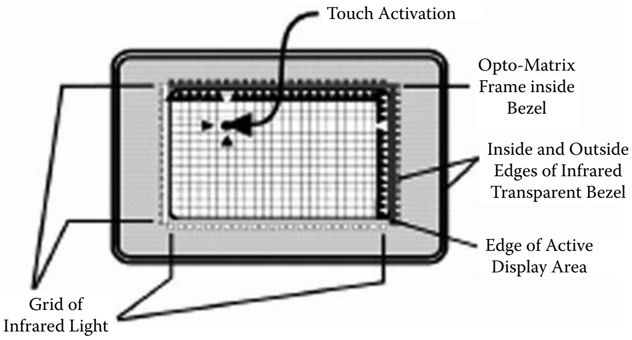

FIG. 4.22d
Scanning infrared touch-screen design.

is concealed behind an IR-transparent bezel. The bezel shields the opto-electronics from the operating environment while allowing the IR beams to pass through.

The IR controller sequentially pulses the LEDs to create a grid of IR light beams. When a stylus, such as a finger, enters the grid, it obstructs the beams (Figure 4.22d). One or more phototransistors detect the absence of light and transmit a signal that identifies the *x* and *y* coordinates of the pouch.

Surface Acoustic Wave The surface acoustic wave design is one of the most advanced touch-screen types. It is based on sending acoustic waves across a clear glass panel, which is provided with a series of transducers and reflectors. Since the speed of the wave is known and the size of the glass overlay is fixed, the first reflector will send the first signal back first, then the second, and so on.

When a stylus such as a finger comes into contact with the wave, it attenuates the wave motion by absorbing part of the wave. This is detected by the control electronics and determines the touch location (Figure 4.22e). This design is the most durable and provides the highest clarity because the panel is all glass and has no layers that could be worn. This technology is recommended for public information kiosks, computer-based training, or other high-traffic indoor environments.

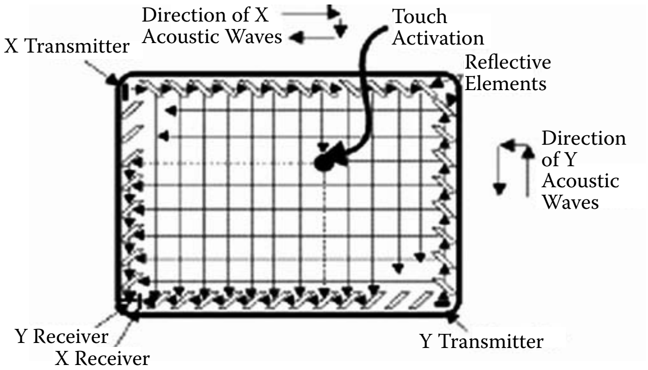

FIG. 4.22e
Surface acoustic wave touch-screen design.

Near Field Imaging (NFI) Near-field imaging (NFI) is based on a proprietary topology/imaging technology. The sensor layout is a piece of glass coated with a pattern of indium tin oxide (ITO) on the front and is completely ITO coated on its back side. The front of the sensor is optically laminated to a layer of passive glass, typically 0.043 in. thick.

An excitation waveform to the conductive sensor is supplied and generates an electrostatic field, which becomes the baseline. When a finger or other conductive stylus comes into contact with the sensor, a change occurs in the electrostatic field. The control electronics then subtract the change from the baseline and determine the peak imaging shape and location to establish the *x* and *y* coordinates of the touch location.

Simply put, in this design the screen itself is the sensor. NFI uses a sophisticated sensing circuit that can detect a conductive object—a finger or conductive stylus—through a layer of glass, as well as through gloves or other potential barriers (moisture, gels, paint, etc.). This is done with a high degree of accuracy using data acquisition and image processing techniques that generate a precise profile of the touch.

The NFI touch-screen sensor uses a transparent conductive film patterned with a proprietary topology applied to the base layer of glass. The front layer of glass is bonded over the base layer with an optical adhesive. An excitation waveform is supplied to the conductive layer by the controller to generate a low-strength electrostatic field in the front layer of glass. The near field is modulated by finger contact with the front layer on the glass, and a differential signal is created, making it possible to accurately resolve the electrostatic loading on the face of the screen.

The system firmware recognizes and decodes the location of the touch. The controller scans continuously until it receives signs of an impending touch. At this point it shifts into a different mode and subtracts the baseline associated with the conditions immediately preceding the touch. This way static and noise do not affect the image of the touch. The profile of the touch is constructed from a dynamic array of data points and is resolved to an actual touch point through continuous reimaging of the electrostatic field. Touch coordinates are fed back to the operating system as fully compliant Microsoft mouse coordinates.

Any long-term changes in the electrostatic image are compensated for, allowing the system to ignore unwanted loading effects from large or distant objects, such as hands or arms, and reject false touches. Sophisticated data acquisition and image processing techniques ensure that NFI can consistently and precisely control the associated equipment, yet it is sensitive enough to detect finger touches through gloves and work in the presence of moisture and other contaminants.

The sensor's glass construction provides superior optical performance and will continue to operate despite scratching, pitting, and other surface damage from abrasives, chemicals, or vandals (Figure 4.22f). NFI touch screens are reliably sealed for applications that require high pressure wash-down or for protection from contaminant-filled environments.

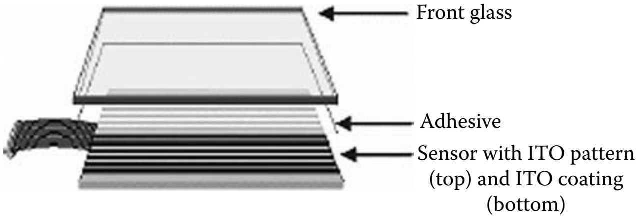

FIG. 4.22f
Near-field image (NFI) touch-screen design.

Evaluating Touch Technologies

Each touch-input technology has both advantages and disadvantages. These result both from the physical factors associated with the technology and from the ability of each design to withstand the environment of the particular application.

Physical Factors Factors to consider include: resolution, transmissivity, response time, stylus type, calibration, integration, and reliability. These factors are specified in Table 4.22h below for each of the touch-screen designs discussed.

The *resolution* of a touch screen refers either to the number of touch-active points or to the physical spacing between the adjacent touch coordinates. When considering the resolution of the touch system, it is important to keep in mind the intended application. For many applications, such as control panels, public access, or computer-based training, fine resolution is not required. In some other applications, such as signature verification, a very high touch-system resolution is desired.

Another variable to consider is image clarity or *transmissivity.* The display image can be affected by the placement of any material between the display image and the viewer's eye. All designs that require an overlay over the display screen (such as resistive, capacitive, surface acoustic wave, near-field imaging, and guided acoustic wave) result in some visual obstruction between the operator and the image on the screen. Transmissivity is defined as the percentage of the light generated by a display that passes through the coating or layered material.

Response time is another important consideration because the faster a touch screen system can respond to an input, the better that design is. Response time is defined as the time required to determine the location of the touch and to transmit that information to the host system. Several factors contribute to the total response time of the application, including the touch-system response time, the host's processing speed, access time to the host's electronics, and the processing time of the application software. Response times specified in Table 4.22g give the response time of the touch system only.

The *stylus type* that can be used is also a selection consideration. A stylus can be an object or an instrument used to activate the touch system and can include a finger, pen, gloved hand, etc.

Calibration is the process of adjusting the active area of a touch system by physically modifying the calibration parameters of the touch (i.e., adjusting potentiometers, setting EEROM parameters, etc.). Although all touch systems require an initial calibration during installation, only systems that are subject to drift (where touch targets gradually move away from the desired locations) require routine or periodic calibration. Capacitive and resistive overlay systems are subject to drift and require calibration, which generally consists of adjusting the offset and scaling parameters to make the touch area equal to, or greater in size, than the display image. Surface acoustic wave, scanning infrared, and guided acoustic wave designs are not subject to drift and do not require calibration after installation.

Integration is the process of attaching the touch system to the display. Invasive integration requires the disassembly of the display to attach the touch system. Typically, this type of integration results in voiding both the manufacturer's warranties and the Federal Communications Commission (FCC) certification. This type of integration requires from 15 to 90 minutes of a skilled technician. Noninvasive integration does not require disassembly of the display. This type of integration can be performed by unskilled people and usually takes less than 10 minutes.

Reliability of a touch system is the time or the number of touches it is expected to last before it fails. Touch systems with polyester or conductive coatings will fail after an anticipated number of touches, which will wear the coatings off. The reliability of other touch systems that do not wear by use is measured in *mean time between failures* (MTBF). This number is a function of the average life expectancy of the electronic components built into the touch system.

Environmental Factors The ability of the various touch-screen designs to withstand a variety of environmental conditions is summarized in Table 4.22h.

Sealability is the ability to seal a touch system (including display electronics) from dirt, liquids, etc. If the system is going to be located in an area where contaminants are present, sealability can be an important consideration. In environments such as surgical operating rooms, sealability is critical. All touch-screen designs can be sealed to meet NEMA 12, which only requires that a system be operational after accidental splashing or cleaning. Capacitive overlay, guided acoustic wave, resistive overlay, near-field imaging, and scanning infrared technologies can be sealed to also meet NEMA 4, which requires that the system continue to operate even after it has been exposed to a hose-down by water.

Durability is the ability to withstand millions of touches over many years and *resistance to vandalism* is the ability to resist defacement—scratching, breaking, theft, etc. Both are evaluated in Table 4.22h.

An excessive buildup of *dust, dirt, or other contaminants* can adversely affect the performance of some touch technologies. Capacitive overlay, scanning, infrared, and surface acoustic wave technologies will operate with low-to-moderate

TABLE 4.22g
*Touch System Comparison Chart 1**

Type of Design	*Resolution and Z-Axis*	*Transmissivity*	*Activation, Parallax and Response Time*	*Stylus Type*	*Sensor Drift and Calibration*	*Integration*	*Reliability*
Capacitive overlay	1024 × 1024 physical, no *z*-axis	85 to 92%	Tactile activation, no parallax, 15 to 25 ms	Requires conductive stylus; unable to simultaneously detect gloved and ungloved finger	Subject to drift; requires repetitive calibration	Invasive and noninvasive; optical bonding required for optimum display clarity	Sensor: 20 million touches per point; controller: > 186,000 hours MTBF**
Near-imaging	1024 × 1024 physical, no *z*-axis	85%	Tactile activation, parallax, 15 to 25 ms	Requires conductive stylus	Not subject to drift	Invasive	Sensor: unlimited. controller: >180,000 hours MTBF
Guided acoustic wave	21,904 points/square inch physical, plus *z*-axis	92%	Tactile activation, no parallax, 18 to 50 ms	Requires soft, energy-absorbing stylus	Not subject to drift	Invasive; optical bonding required for optimum display clarity	Sensor: unlimited; controller: >180,000 hours MTBF
Resistive overlay	256 × 256 to 4096 × 4096 physical, no *z*-axis	55 to 78%	Tactile activation, no parallax, 13 to 18 ms	No stylus limitation	Subject to drift; requires repetitive calibration	Invasive; optical bonding required for optimum display clarity	Sensor: 2 million touches per point; controller: 86,000 to 180,000 hours MTBF
Scanning infrared	0.25 in. physical, 0.125 in. logical, no *z*-axis	100%	Proximity activation, parallax, 18 to 40 ms	No stylus material limitation. Minimum stylus diameter 5/16 in.	Not subject to drift	Invasive and noninvasive	>138,000 hours MTBF
Surface acoustic wave	0.030 in. physical, plus *z*-axis	92%	Tactile activation, no parallax, 53 to 59 ms	Requires soft, energy-absorbing stylus	Not subject to drift	Invasive; optical bonding required for optimum display clarity	Sensor: 50 million touches per point; controller: 86,000 to 118,000 hours MTBF

TABLE 4.22h
*Touch System Comparison Chart 2**

Type of Design	*Durability/Resistance to Vandalism*	*NEMA Ratings, Moisture Resistance*	*Dust and Dirt Resistance*	*Chemical Resistance*	*Vibration and Shock Resistance*	*Ambient Light*	*Temperature, Humidity, and Altitude*
Capacitive overlay	Difficult to scratch; conductive layer is subject to wear; glass overlay is breakable	NEMA 12; NEMA 4	Will operate with moderate dust and dirt; excessive accumulation will affect performance	Not affected by general-purpose cleaning solutions	Tolerant of vibration; thick glass overlay moderately susceptible to shock	Unaffected by ambient light	0 to 70°C; 0 to 95% nonconducting humidity; 30,000 ft (9000 m)
Near-field imaging	Difficult to scratch; glass overlay is breakable	NEMA 12; NEMA 4	Not affected by dust and dirt	Not affected by general-purpose cleaning solutions	Tolerant of vibration and shock	Unaffected by ambient light	0 to 50°C; 0 to 95% nonconducting humidity; altitude not specified
Guided acoustic wave	Difficult to scratch; glass overlay is breakable	NEMA 12; NEMA 4	Not affected by dust and dirt	Not affected by general-purpose cleaning solutions	Tolerant of vibration; glass overlay susceptible to shock	Unaffected by ambient light	0 to 50°C; 0 to 95% nonconducting humidity; altitude not specified
Resistive overlay	Sensor is vulnerable to scratches and abrasion; glass overlay can be broken	NEMA 12; NEMA 4	Not affected by dust and dirt	Not affected by general-purpose cleaning solutions; chemicals that affect polyester should not be used	Tolerant of vibration; glass overlay susceptible to shock	Unaffected by ambient light	0 to 50°C; 0 to 95% nonconducting humidity; 15,000 ft (4500 m)
Scanning infrared	Not susceptible to scratching; no overlay to break; completely solid state; no exposed parts	NEMA 12; NEMA 4	Will operate with moderate dust and dirt; excessive accumulation may affect performance	Not affected by general-purpose cleaning solutions; chemicals that affect polycarbonates should not be used	Tolerant of vibration and shock	Varies by manufacturer	0 to 50°C; 0 to 95% nonconducting humidity; altitude not specified
Surface acoustic wave	Difficult to scratch; glass overlay is breakable	NEMA 12	Will operate with moderate dust and dirt; excessive accumulation may affect performance	Not affected by general-purpose cleaning solutions	Tolerant of vibration; glass overlay susceptible to shock	Unaffected by ambient light	0 to 50°C; 0 to 95% nonconducting humidity; altitude not specified

* Manufacturer's published data.

accumulations of dust, dirt, and other contaminants. Excessive levels will affect their performance. Guided acoustic wave, resistive overlay, and near-field imaging designs are not affected by dust, dirt, or other contaminants.

General-purpose cleaning solutions have no harmful effects on any of the touch-screen designs. However, some of the designs can be attacked by certain *chemicals*. A resistive overlay touch system has an exposed polyester overlay. Therefore, such design should not be used if chemicals that attack polyester will be used in the area. A scanning infrared touch system has exposed polycarbonate bezels. Therefore this design should not be used if chemicals that attack polycarbonate, such as petroleum-based chemicals, are going to be present in the area where the screen is to be located. More resistant materials are also available for the construction of special IR touch systems but are not widely used and therefore must be clearly specified.

Vibration and shock is an important consideration if the application is installed on a moving device or on equipment that is subject to significant vibration or shock.

Ambient light is the level of visible and invisible light in the operating area; most designs are not affected by it. On the other hand, some infrared designs are so packaged that they can be adversely affected. The levels of ambient light that are found in well-lit indoor environments do not present any problems.

The *temperature, humidity, and altitude* at which the touch screen is to operate have effects on the operation and durability of any touch system. Plastics and electronics are affected by temperature. Humidity enhances the corrosion of circuitry. Altitude affects the dissipation of the heat generated by functioning electrical circuitry. It is safe to say, however, that the impact of these environmental factors on touch systems will be less (or at least no greater) than their impact on the circuitry of the display or flat panel into which the touch system is integrated.

Specific data regarding the impact of these environmental factors is provided in Table 4.22h.

OVERALL SYSTEM DESIGN

The systems integrator must pay attention to the interrelated considerations of mechanical and physical attributes and also to programming considerations.

Mechanical Considerations

Display Selection Selecting the computer display is one of the major decisions affecting the cost of the complete touch system. Today, the display choices include both flat panels and CRTs. Flat-panel displays tend to present the fewest mechanical design concerns for touch systems, while CRTs typically require some degree of mechanical design compensation to correct for the curvature of the display surface. As a general rule, touch applications that require a large number of targets on a single screen should use a larger size display.

Touch System Integration Touch-system designers can choose between invasive and noninvasive integration options. An invasive integration typically requires that the display be disassembled. This is very time-consuming and may void the factory warranties of the display. Noninvasive integration requires very little time to assemble and will not affect the manufacturers' warranties. Maintenance is simplified as well.

Space Constraints Many touch systems are located in areas where space is limited. Flat panels require very little space, while CRTs tend to be bulky. The amount of physical space required for the touch system varies for the various touch screen designs. The type of integration method selected can also affect the amount of space required for the system. In general, invasive integration tends to require less space than noninvasive integration.

Environmental Factors Touch-systems are designed to operate under a wide range of environmental conditions. When designing a touch-based system, one should consider the sealability, durability, reliability, and vulnerability (to vandalism) of the system, as was discussed in connection with Table 4.22h.

Sealing Depending on the environmental conditions, the touch system may require different degrees of sealing. Applications that may require special consideration include industrial and process control applications and outdoor applications.

Physical Attributes

System Capabilities The system designer must match the application requirements to the capabilities of the touch-screen design. Factors to be considered include glare, transmissivity, resolution, stylus types, and aesthetics. For instance, systems that require high-quality graphics would gravitate toward those touch technologies with the best transmissivity and the least glare. Applications requiring handwriting recognition would need those technologies with the highest resolution.

Another consideration is the type of stylus that will be used in the specific application. Other factors to consider include the availability of features such as multiple operating and reporting modes, improved software resolution, fault tolerance, and diagnostics.

Touch systems can be programmed to detect multiple styli, calculate the size and center of the stylus, reject a stylus that is larger or smaller than the specified limits, or require that the stylus remain in the touch-active area for a specified amount of time before the touch is considered to be a valid hit.

Another operating feature available with some touch technologies is the capability to report a z-axis coordinate, which measures the amount of pressure applied to the sensor. Typically, the harder the user presses on the sensor, the higher the z-axis value. This z-axis coordinate is often used to emulate mouse button events. This is done by comparing the z-axis coordinate to the threshold value.

Programming Considerations

For each application, the programmer must consider the interaction or communication:

1. Between the touching operation and the user
2. Between system hardware units
3. Between the system software packages

Hardware Interface Options Touch systems are designed to interface with the host in a variety of different configurations.

One configuration involves communicating through serial ports, using the RS-232, the RS-422 or other protocols. Another configuration involves parallel communication via a bus standard. Examples include ISA/EISA, micro-channel, and PC/104™.

Another interface method uses the mouse port. In this method, the touch system is connected to the host computer's mouse port and uses either a standard mouse interface protocol or a proprietary touch-system interface protocol.

Another interface configuration involves the use of daisy-chained input devices, such as the Apple Desktop Bus™. Some vendors have chip sets available that can be added to the host's electronics and packaging. The chip sets typically contain all of the functions required to control and communicate with the touch system as well as the host's electronics. Touch vendors have proprietary software interface protocols unique to their touch systems. All of the touch vendors' software protocols report an x and y coordinate; some technologies permit the reporting of a z coordinate as well.

Software Interface Options In the *direct interface method,* the touch application communicates directly with the touch system using the proprietary interface protocol of the touch system.

Software drivers are available from touch vendors that assist the touch application developer in interfacing to the touch system. These drivers usually provide calibration and scaling support, plus they communicate with the touch system using the touch vendor's proprietary interface protocol and with the touch application via a simple application program interface (API).

An *authoring system* is a program that the application developer can use to create a touch application without writing programming code. Authoring systems either include direct support for the touch system or run under a graphical user interface (GUI), which provides support for the touch system. Hypercard™ for the Macintosh and Asymetrix Toolbook™ for the IBM PC™ are examples of such authoring systems.

Mouse emulator drivers that make the touch system appear to be a mouse to the application code are available from touch vendors. The driver emulates the standard Microsoft® Mouse driver protocol. With the touch system connected and the mouse emulator loaded, applications that use a mouse may be used with touch instead. Little or no modification of the application is required. If the application uses targets that are of sufficient size to be used with a mouse but are too small to be used with touch, the application would have to be modified to enlarge the targets for touch use.

Graphical user interfaces (GUIs) such as Apple Macintosh™ or Microsoft Windows™ are operating systems that use icons, pull-down menus, windows, etc., instead of keyboard-entered commands. GUIs typically support installable pointing device drivers. The touch vendor supplies the pointing device driver, which generates the pointing device event messages that are sent to the application. Applications are written to use these standard pointing device event messages, and are therefore independent of any particular pointing device, such as a mouse, touch system, graphics tablet, or other pointing devices.

The *touch user interface* application program is the interface between the user and the computer system. The application program presents displays, accepts user input, and takes action based on that input. The design and organization of the program are critical to the successful use of the touch system, especially when the end users are likely to be novices.

Interface Design Factors To maintain the natural simplicity of the touch interface and to lead the user easily through the program, the interface designer should be aware of the following factors:

Touch *target location* on the screen is determined by the relative importance of the target. Consistency must also be considered. The user will locate targets with greater speed and with less confusion or errors when targets of the same or similar function are consistently located in the same relative location on the screen.

The *number of targets* per screen should be limited to as few as possible, balanced by the difficulty of switching screens. Nesting and prioritizing relieve the need to crowd targets on the screen, hence reducing the potential for human error. In the case of menus, more items can be put on the screen. But if menus are nested too deeply, users will soon tire of searching through the menus. The use of graphic symbols (icons) for touch targets can be effective in helping the user in quickly identifying the targets.

The *size of targets* is limited by the stylus size. The number of errors can be reduced by increasing the size of the targets. When designing targets for finger activation, research has shown that few fingertips are more than 22 millimeters across. Each target should be surrounded with a guard band or dead zone, where touches are not recognized. Guard bands reduce the possibility of user confusion and frustration by eliminating the possibility of activating an adjacent target.

Touch activation mode refers to the behavior of the target when it is touched. Slides, switches, and buttons are typical variations of touch targets. A typical button target has three states: unarmed, armed, and activated. The simplest activation mode is the activation of the target whenever a finger is over the target. The target proceeds directly from the unarmed state to the activated state in much the same manner as a mouse pointer might activate by simply pointing to an area without clicking a button.

This method of activation is the least desirable because it is a one-step process that lacks a means of canceling the activation of a target. This makes unintended activation likely. A variation of this method is to activate the target when the finger is removed from the screen over the target. This activation mode is only slightly better, since it also means that there is no way of canceling the activation; the result can be inadvertent activation.

The most frequently used activation mode is to cause the target to go to the armed state whenever the finger is over the target. If the finger is over the target when it is withdrawn from the screen, the target is activated. If the finger moves away from the target before the finger is withdrawn from the screen, the target is not activated. This allows the user to cancel the selection.

Touch feedback is an integral part of most well-designed activation modes. The user must receive immediate feedback to know for certain when a target has been armed and/or activated. Highlighting, changing color, or depressing a chiseled button are all good visual feedback techniques for indicating that a touch target is armed or activated.

The screen should not be allowed to go blank, even if dummy screens must be designed to fill up the display screen. To the inexperienced user, a dark screen is a sure sign that the system has failed. Audio feedback is an appealing complement to visual feedback, with various tones or sounds being used to indicate the target activation state. This effect can be especially impressive on multimedia computers.

4.23 Uninterruptible Power and Voltage Supplies (UPS and UVS)

S. P. JACKSON (1970, 1985) **B. G. LIPTÁK** (1995, 2005)

Types:	The energy source of uninterruptible power supplies (UPS) can be batteries or engines. In uninterruptible voltage sources (UVS), capacitors allow the system to ride through an outage of several cycles.
Costs:	A UVS rated for 1500 VA costs around $2500. A UPS rated for 3 KW costs about $7500. For the costs of batteries, alternators, chargers, and inverters, refer to the Figures in the "System Components" paragraph of this section.

INTRODUCTION

After this introduction, the section will first give a general description of the features of uninterruptible voltage and power supplies (UVS and UPS), followed by a brief discussion of the requirements of buses and networks. This will be followed by a discussion of the classes of power failures that are likely to occur, the components of UPS and UVS systems, and the types of standby and redundant power supplies.

Electric power lines are commonly assumed to be perfectly reliable sources of constant voltage. This assumption is valid when complete source reliability, particularly on a short-term basis, is not important. Control and instrument engineers frequently make this assumption for power supply systems that do not satisfy this criterion. Obvious long-time power outages are fairly rare in modern power systems. Notable exceptions, however, have called attention to the complete spectrum of possibilities of power failure.

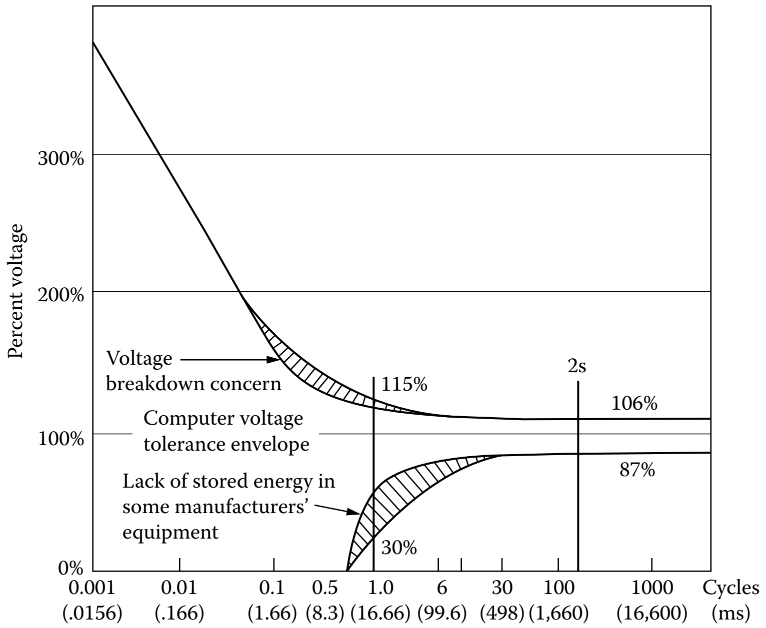

FIG. 4.23a
The safe operation area (SOA) of computers defined in terms of allowable input voltage variations and their duration. (Source: ANSI/IEEE Standard 446–1987.)

Voltage dips too short to be noticed by human senses can occur frequently during the lightning season on exposed suburban and rural power systems. These systems serve many industrial plants. In addition to the obvious power failures caused by weather, there are many transient variances resulting from electrical, mechanical, and human occurrences. A system designer who assumes a perfectly reliable power source is responsible for any loss of production and damage to machines and plant facilities resulting from power irregularities.

The trend in control system design is to use faster components operating on smaller signals. This results in increasing system sensitivity to line voltage variation and in particular to short transients. As control instrumentation technology advances, the need for standby power sources increases. Frequently, the cause of the transients that result in control or instrument circuit complications is not the lack of voltage alone. Phase shift, a change in frequency, inadequate transient response, and noise can be equally damaging. Therefore, an adequate standby power supply system must consider all types of power failure.

UNINTERRUPTIBLE VOLTAGE SOURCES (UVS)

The IEEE-446 standard defines the "Safe Operating Area" for computer-based equipment in terms of the power disturbances that are allowable. As the time duration of the disturbance increases, the allowable magnitude of the disturbances that can be tolerated diminishes (Figure 4.23a).

The purpose of uninterruptible voltage sources (UVS) or line conditioners is to provide protection against short-duration brownouts or outages by guaranteeing that the output voltage is not lost and its waveform remains stable for several cycles after utility loss. This "ride-through" time can extend to several cycles (Figure 4.23b) and can prevent processor crashes. As the ride-through capability is provided by programmable capacitors, it can be extended by the addition of capacitors.

UVS units are a little less expensive than the battery-based UPS units (to be discussed later) and are designed for the hostile environment of the factory floor. They regenerate new AC power in pure sine wave form and keep the output voltage and frequency within 3% of normal, even if the input voltage or frequency experiences wide variations. The ride-through capability enables the user to continue operation when the

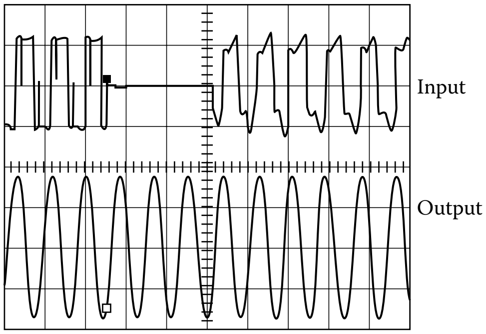

FIG. 4.23b

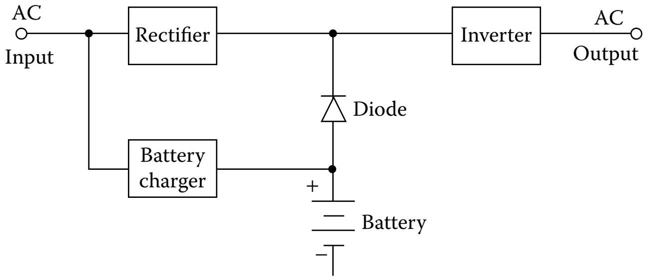

FIG. 4.23c
Standby system with battery charger redundancy.

outage is short or, when the duration of the outage is longer, to anticipate the loss of power in time to signal the processor to stop at a known state.

UNINTERRUPTIBLE POWER SUPPLY (UPS) FEATURES

Standby systems (UPS) can be quite complex. They involve the use of a number of components that may be of the static type, the electromechanical type, or some combination of both. The selection of the standby system and the components for it should be based upon the degree of integrity required of the application.

It is frequently possible to improve standby system reliability and to decrease cost. An example is that of the redundant input circuit shown in Figure 4.23c. By separating system functions, it is possible to purchase the component that does the precise job required.

Much attention has been focused on the problem of failure of the incoming power line. Although this is an important consideration, it is not the only consideration. Attention should also be given to the equipment constituting the standby power supply system. Should critical pieces of the standby equipment be less reliable than the incoming power line, failure will be more frequent, and little improvement will have been accomplished.

Also of importance is the load circuit. If a number of load branches are connected to the output of a standby power supply system, the failure of any one load may result in the failure of the remaining loads. Proper design of the load system will minimize or eliminate this possibility.

The importance of system redundancy cannot be overemphasized. Once designed, the system must be evaluated to determine its weakest link. The cost of redundant equipment may then be assessed in light of the importance of maintaining the load.

Table 4.23d summarizes the standby system classifications and lists the most commonly used components. Obviously, special arrangements may be found that extend some of the components into an additional classification. This table is intended as a means of outlining the discussion that follows.

TABLE 4.23d
Summary of Standby System Classifications and "Most Used" Component Parts

	Standby System Classification		
System Componet	*Multi-Cycle*	*Sub-Cycle*	*"No-Break" (Minimum Transient)*
Secondary power source	Engine-driven alternator or generator *starting* on primary source failure	Engine- or motor-driven alternator or generator *running* with flywheel	Battery
Inverter	Rotating or static	Rotating or static	Static
Bus transfer switches	Electromechanical	Static	Static

Various degrees of *redundancy* may be designed into the standby system. This redundancy may occur on the input side of the inverter, on the output side, or on both sides. A tabulation of components in a single- and a double-source redundant system is provided in Table 4.23e. Both input redundancy and output redundancy are included.

NETWORKS AND BUSES

Fieldbus devices work with supply voltages in the range of 9 to 32 V DC. The 9 V DC is a minimum and a margin of at least 1 V (a minimum of 10 V DC) is recommended to be maintained. The documentation of the bus segment should always show the minimum voltage, and a warning concerning additional loads should be posted on segments operating under 15 V.

TABLE 4.23e
Standby System Component Redundancy

Level of Redundancy	*Input Side*	*Output Side*
One source	Battery and battery charger	Inverter
One source with some equipment redundancy	Battery, battery charger, and rectifier	Inverter with transfer to line
Two sources	Battery, battery charger, and engine-driven generator	Inverter with transfer to alternate inverter
Two sources with some equipment redundancy	Battery, battery charger, rectifier, and engine-driven generator	Inverter with transfer to alternate inverter and then to line

If an ordinary power supply were used to power the fieldbus, it would absorb the communication signals on the cable, due to its attempt to maintain a constant voltage level. Fieldbus power supplies are therefore conditioned by placing an inductor between the power supply and the field cable,

TABLE 4.23f
Examples of Power Component Used in Foundation Fieldbus and PROFIBUS-PA Systems

Type	U_s	I_s	R_Q	*Remarks*
MTL 5053	18.4 V	80 mA	105 Ω	IS power supply with power conditioner and switchable terminator
MTL 5995	19.0 V	≤350 mA	<2 Ω	Non-IS power supply with power conditioner and switchable terminator
Relcom PCS-PC	$V_{input} - 5$ V	≤330 mA	—	Power conditioner
Relcom FCS-PCT	$V_{input} - 5$ V	≤330 mA	—	Power conditioner with terminator
Siemens 6ES7-157-0 AD00 0XA0	12.5 V	100 mA[a]	—	PROFIBUS segment coupler EE*x* [in] IIC
Siemens 6ES7-157-0 AC00 0XA0	19.0 V	400 mA[a]	—	PROFIBUS segment coupler for safe areas
Pepperl + Fuchs KFD2-BR-EX1.2PA.93	13.0 V	110 mA[a]	—	PROFIBUS segment coupler EE*x* [ia] IIC
Pepperl + Fuchs KFD2-BR-1PA.93	25.0 V	380 mA[a]	—	PROFIBUS segment coupler for safe areas

Note: Inclusion in this table does not imply a recommendation; other suppliers exist.

[a] The bus current has already been subtracted from these specifications.

and a resistor is added to the inductor to prevent ringing. The power conditioner might consist of a 50-ohm resistor and a 5-mH inductor in series. The fieldbus conditioning unit is normally installed at the start of the fieldbus segment and often contains a bus terminator. If the segment runs into an explosion-proof area, a barrier is also required. Table 4.23f gives some examples of conditioning unit components.

Several layers of UPS might be required in a plant-wide SCADA process control system. First, the clock and memory of all digital equipment, computers, and remote terminal units (RTUs) must be continuously supplied by power. A small dedicated battery with a life of several years can be used for this. Next, the critical sensors, transmitters, and RTU logic need to be supplied until normal power is restored. In some installations the requirement is for 35 days of UPS power.

POWER FAILURE CLASSIFICATIONS

Standby power systems can be characterized according to the time it takes to achieve full output from the standby power source after failure of the primary source. This transfer time might be as long as many cycles—for large electromechanical switching devices or for engine-driven alternators or generators that start up on failure of the primary source—or as short as fractions of a cycle—for some of the solid-state switching devices or for motor-alternator or generator sets with flywheels. Additionally, no-break systems are available.

Most early standby systems necessitated an interval during which there was no voltage to the load on transfer from the primary source to the standby source or on retransfer from the standby source to the primary source. As control and instrumentation circuits have become more critical, standby systems have been developed that include new techniques for transferring power sources such that essentially no transfer time occurs. For the most part, these no-break systems cost little more than those requiring a significant amount of time to transfer. In general, this characterization of the standby power system by transfer time is disappearing, since a large percentage of present standby systems are of the no-break variety.

Another means of characterizing standby systems is by type of failure. One's first thought is to protect the critical loads from failure of the commercial power line. A careful scrutiny into the system suggests that there also are other points worthy of consideration. Among these is the failure of standby power supply components and the failure of the load.

Source Failure

A very simple standby power system is shown in Figure 4.23g. It consists of an AC power line feeding a battery charger. The battery charger, in turn, floats a battery that provides power to the inverter. The inverter provides an AC output through a distribution panel to a number of loads. Should the AC line fail, the battery charger will cease to provide the current to the inverter. The current will then be provided by the battery that is floating on the system.

In this fashion, the inverter supplies the loads until such time as the AC line is reenergized, at which point the battery charger again provides the power for the inverter and for the loads and at the same time provides recharge current to the battery. Thus, the simple standby system of Figure 4.23g protects against a line failure since there is no cessation of power to the loads when the AC line fails.

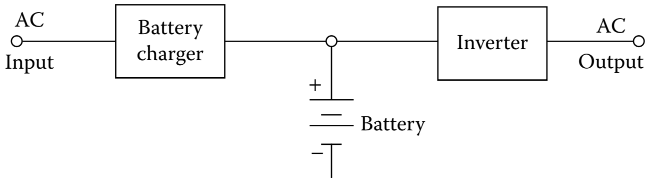

FIG. 4.23g
Basic AC standby system.

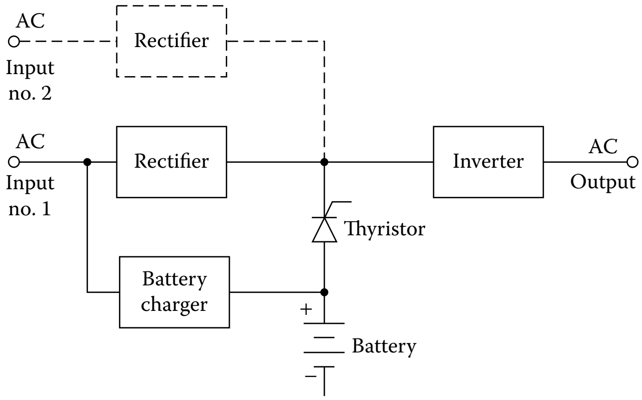

FIG. 4.23h
Standby system with multiple AC inputs.

A suggested improvement in the basic system is shown in Figure 4.23h. Because the functions of the battery charger are separated into (1) supplying steady-state running current to the inverter and (2) supplying recharge current to the battery, two rectifiers can be used. An unregulated rectifier is adequate to supply load current by means of the inverter. The battery charger rectifier must be regulated to ensure long battery life. Since the unregulated supply is less likely to fail, some additional reliability is gained. This can be seen when one considers the results of failure of the battery charger.

In the circuit of Figure 4.23g, should the battery charger fail, the system is no longer operable after the energy stored in the battery is consumed by the load. In the case of Figure 4.23c, however, should the battery charger fail, the system continues to function as long as the AC input is available. Should the AC input source fail, the system will continue to operate until the energy stored in the battery is consumed.

If, prior to this time, the AC input source is restored, the system continues to function properly but the battery charger is not capable of recharging the battery. While the system continues to operate properly, the battery charger may be repaired if it is possible to do so between the time that the failure of the battery charger is noticed and the next failure of the AC input source. Indeed, if nothing else can be done, it is generally possible to bypass the diode with some available resistance (even a light bulb) that will restore some energy to the battery. Even a small amount of battery capacity is ample for a number of short, transient outages.

In addition to the increased reliability of the two sources noted in Figure 4.23c, a lower cost for this system frequently results. This lower cost is attained because the unregulated rectifier in most cases is providing a larger current than the battery charger. Thus the rectifier capacity is greater than that of the battery charger. Since it is less expensive to buy unregulated power than to buy regulated power, it is possible under many circumstances to achieve a lower cost. This combination of lower cost and increased reliability is the optimum objective of the system designer.

The system of Figure 4.23c can be extended to include more than one AC source, as illustrated by Figure 4.23h. Alternative sources may include other AC lines and the output from engine-driven alternators, or, indeed, from any alternator regardless of the number of phases, the voltage, the frequency, or the variation in frequency.

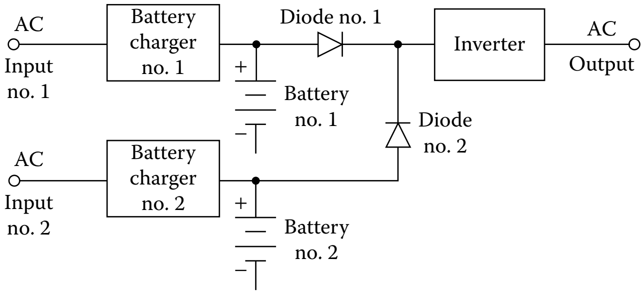

FIG. 4.23i
Standby system with multiple-input redundancy.

It may be desirable to "stagger" the input voltage ranges of the sources to favor one or another source. Since this "staggering" of sources results in an increase in input voltage variation over which the inverter must operate, a thyristor has been included to provide a dynamic switching of sources, minimizing the input voltage variation. The peak value of the alternative sources when rectified must be greater than the battery potential in order to "turn off" the thyristor.

The ultimate in input redundancy occurs with more than one complete power source. Shown in Figure 4.23i is a system with source, battery charger, and battery redundancy. It is also wise to separate the power feeds to the inverter. This system can be extended to any desired degree.

The systems of Figures 4.23c, g, h, and i offer a continuous source of power to a load without regard to the state of the AC input source as long as the standby source has sufficient energy to supply the load. The options noted provide any degree of redundancy desired for the standby power source. These figures show that this redundancy is adequate to ensure the most critical loads. The diagrams also make it clear that, should a failure occur in the inverter, the load source is no longer protected. Thus, our next concern must be the failure of equipment within the inverter block.

Equipment Failure (Inverter)

In many applications of standby power, the integrity of the line must be maintained in spite of equipment failure. Failure to preserve this integrity can result in loss of output, scrap material, plant damage, or loss of life. The degree of the protection necessary depends on the damage that can result. Process control computers are particularly important in plant operations because failure of the computer system results in an uncontrolled process. Loss may be sufficiently high to justify greater system redundancy.

The simplest form of output redundancy is illustrated by Figure 4.23j. A bypass switch is provided from the output of the inverter to the AC input line. In this diagram, and in many to follow, the symbol for an electromechanical switch (relay)

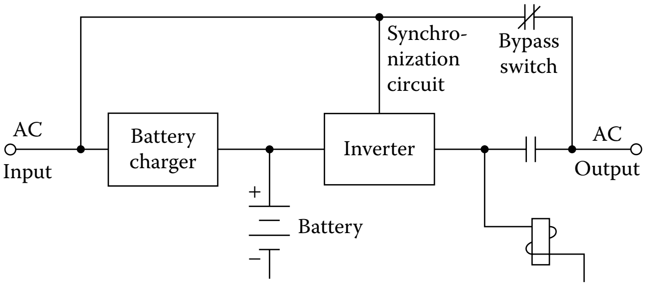

FIG. 4.23j
Output redundancy to AC input.

will be used. This symbol should be construed to include both static and electromechanical devices.

Two items are essential in the operation of the circuit of Figure 4.23j: a synchronization circuit and a means of sensing source failure. A synchronization circuit has been added to ensure that both the AC input and the inverter are in phase in order to minimize the switching transient. The switching device or devices have also been added, together with appropriate sensing circuitry.

At this point, it is easy to gloss over an essential discussion masked by the obviousness of the preceding remark. Consider for a moment the fact that both voltage waveforms must be of the same frequency and in phase. On failure of the input AC line, no transfer occurs since the output of the inverter is not impaired. In the event of a loss of output from the inverter, transfer to the AC source takes place. Retransfer to the inverter can occur when the inverter output is established and when synchronization of the outputs has been restored. The retransfer may occasion an output voltage transient, as well as the transfer, since stored energy in the filter or the inertia of the rotating alternator used in the inverter requires some time to bring up to full output current.

Note that the addition of the line synchronization capacity has increased the number of components in the inverter, thereby decreasing its reliability. The synchronization circuit must be carefully designed to eliminate any AC transients that may cause a failure in inverter output.

The point of detection of inverter output failure is instant. Sensing as early in the circuit as possible provides a better transfer since energy stored in the filter may be used to reduce the transient. Early detection of thyristor failure or of abnormal vibration is preferable to the simple detection of reduced output voltage.

Difficulties can occur in providing a sensing circuit that operates on an adjustable reduced output voltage level. If no delay is built into the sensing circuit, transfer can occur on line transients, causing frequent operation. If the normal delay is included in the retransfer circuit, no system redundancy occurs in the interval defined by the time of transfer and the delay before the retransfer.

To minimize transfers on simple line transients, which may be caused by sudden load demands, an integrating circuit may be inserted in the voltage level sensor. Although this eliminates the transfer resulting from short transients, it causes a greater output transient when a transfer is made because of equipment failure.

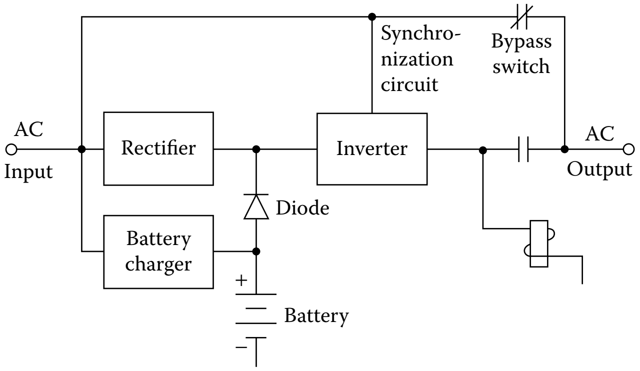

FIG. 4.23k
Input and output redundancy.

The difficulties noted strongly suggest that consideration be given to early failure detection. The importance of this portion of the standby power supply system cannot be overemphasized. It is wise to provide a double sensor system, which on either the failure of a component such as thyristor or on the failure of a bearing (resulting in abnormal vibration) will provide a delay, as well as an integrating sensor circuit and detecting the reduction of the output voltage.

Input and output redundancy is shown in Figure 4.23k. Any of the previously discussed redundant input schemes can be used.

With AC input redundancy, the integrity of the AC line must be considered. Naturally, if frequent line disturbances occur, little is achieved by such an arrangement. The only gain is the possibility of not having a line failure until something can be done to reestablish source redundancy.

The degree of redundancy can be improved if a backup inverter standby system is provided. Figure 4.23l illustrates this emergency power supply backing up an emergency power supply but with dual loads. Here, each inverter is capable of

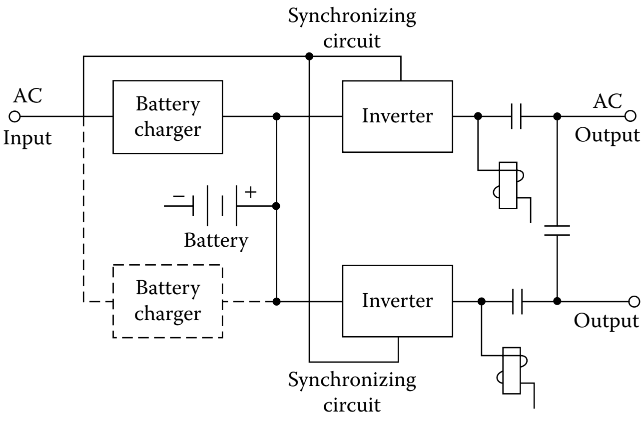

FIG. 4.23l
Redundancy with dual loads.

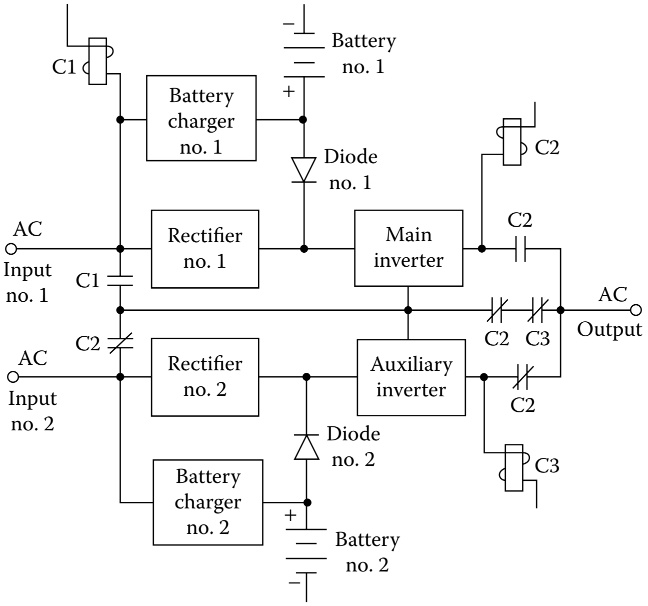

FIG. 4.23m
Threefold redundancy.

handling the full output capacity (both loads). On failure of either, the remaining unit assumes the full load. Momentary paralleling is possible to use the stored energy in the filter of the unit going off. As noted previously, this energy can help to minimize the transfer transient.

Complete input and output redundancy are diagrammed in Figure 4.23m. Battery, battery charger, rectifier, and inverters are repeated. Each is sized to handle the full load. Further redundancy is provided by the AC line. If the main set fails, the auxiliary set supplies the load. If it, in turn, fails before the main is repaired, the load is supplied by the line.

Common Bus Branch (Load) Failure

In addition to providing a means of transfer from the output of an inverter that has failed to an alternate power source, the transfer switch provides a means of clearing branch circuit fuses sufficiently fast to protect other loads from a faulted load. The inverter is frequently current-limited to provide a finite overload capability. Thus, on failure of one load, the current limit provides a known amount of current for opening the fuse in the faulted branch.

By referring to available fuse characteristics, one derives the information that a number of branches are required with even the fastest of available fuses in order to provide load clearing within one half cycle. By using a transfer switch, which allows the transfer of the load from the inverter output to the AC line, one can, in effect, increase the short-circuit current capability, thus providing a means of rapidly clearing the fuse in the branch circuit. After clearing the faulted branch, one can retransfer back to the inverter standby systems.

Ideally, a short circuit in one fused branch of an n-branch load, such as in Figure 4.23n, would have no effect upon the power supplied to the remaining branches. In reality, however, a fuse requires a finite amount of time to clear. If the power source is current-limited, the supply voltage will drop to a value near zero until the fault is cleared. Unless rapid opening of the fuse occurs, other loads will become inoperable.

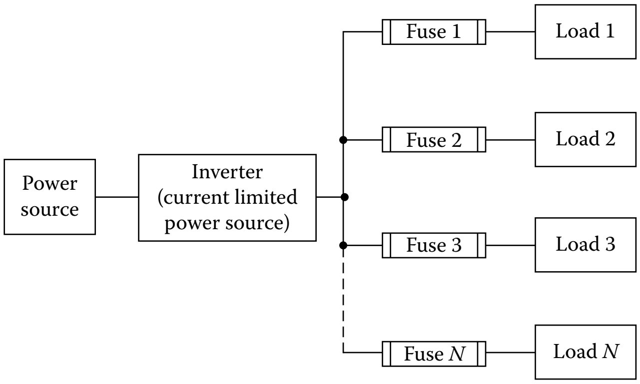

FIG. 4.23n
Inverter system, which is supplying N fused load branches.

Assuming, for any given supply output capacity, that all branches of an n-branch load consume nearly equal parts of the supply power, it follows that the larger the number of load branches, the smaller the average branch fuse rating. A 10 KVA power source, for example, may have five equally loaded (2 KVA) branches. Another 10 KVA supply may have ten equally loaded (1 KVA) branches. In the latter case, the average branch fuse has approximately one half the current rating of those in the former case.

In general, the larger the current capacity of a power source, the shorter the time required to clear a fuse in a short-circuited branch. Looking at the same relationship in a slightly different way, we can see that the smaller the fuse rating of a short-circuited branch, the less time required to clear it—assuming the short-circuited supply capacity remains constant.

The preceding two paragraphs lead to the generalization that the smaller the fraction of total supply capacity carried by a fused load branch, the smaller the time required to clear a branch fuse and the less serious the load power disturbance. Conversely, the larger the fraction of total capacity carried by each branch, the larger the fuses in each and the longer the time required to clear the fault.

Figure 4.23o demonstrates this generalization. Assuming that (1) all branches consume equal fractions of load power, (2) the source always current-limits at 15 amperes, and (3) the short-circuit load impedance is zero, fuse clearing time is shown as a function of the number of load branches. The graph illustrates these data for three different fuse "speeds."

A well-designed standby power supply system requires that consideration be given to all types of failure. The most often neglected area of consideration is the load bus system. Selection of the type of branch circuit protector must be coordinated with the short-circuit characteristic of the inverter as well as the requirements of the loads.

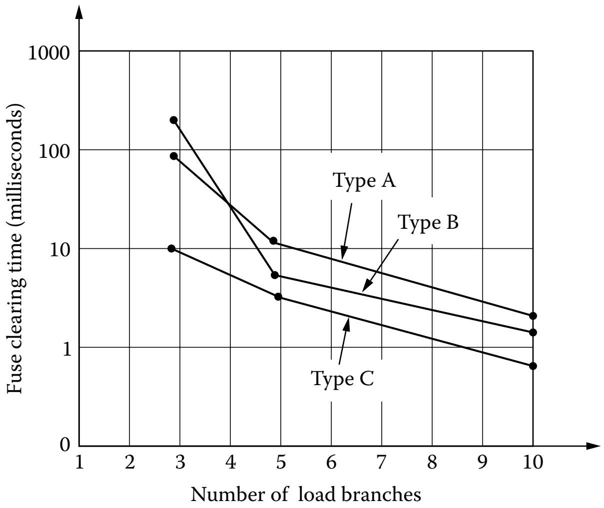

FIG. 4.23o
Fuse clearing time expressed as a function of the number of load branches.

SYSTEM COMPONENTS

It is frequently true that the characterization of the system itself is dependent on the components available for use in the system. For each system function, there are a number of components from which to choose. Arbitrary selection of any single component without regard to the others can result in an unworkable or, at best, an inefficient system.

Thus, the designer's problem is to choose a compatible set of components that will satisfy the requirements. Specifically, the designer seeks the optimum compatible set of components. In order to select the appropriate component for a given function, it is necessary to understand the characteristics of the components from which one must select.

Rotating Equipment

Rotating equipment may be subdivided into two general classes. The first class includes all devices operating from a source of electric power. This set includes motors and, because of their intimate relationship, alternators and generators. The other general category of rotating equipment includes those devices driven by engines that have the ability to operate from liquid or gaseous fuels.

The preceding discussion has not covered the nature of the equipment in the blocks. As an example, the battery charger could be a motor generator set with appropriate controls. The inverter could, of course, be a DC motor driving an alternator. The selection of these components is determined by economic considerations. The economics involve not only the initial cost, operating cost, and maintenance cost of the equipment itself but also an evaluation of the need for reliability based on the importance of the load.

If load failure results in a vacant lot characterized by a hole or by the need to repipe a plant because of the solidification of material that under normal circumstances would have been a usable product, the greatest possible reliability should be built into the standby power source. On the other hand, if the loss of power results in some annoyance but not in the loss of plant capacity or deterioration of product quality, then the ultimate in redundancy and reliability is not warranted.

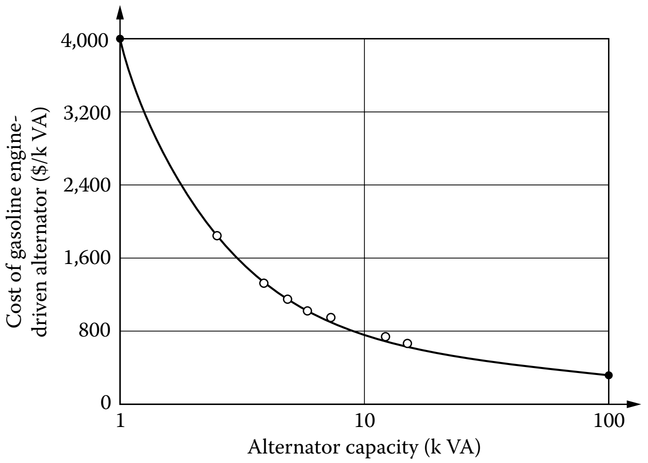

FIG. 4.23p
Cost of gasoline engine-driven alternators as a function of their capacity.

The costs of some standby power supply systems using engines are shown in Figure 4.23p. The engine has been proved to be a reliable device in many situations and in very adverse environments. Unfortunately, the engine itself is not the most frequent cause of failure. Most complaints of poor reliability of engine-driven sets can be traced to unreliable but necessary peripheral equipment, such as fuel pumps, cooling systems, and so forth. Care should therefore be exercised in the specification of all the engine system components.

Two typical standby power supply systems involving motors, generators, and alternators are shown in Figures 4.23q and 4.23r. In Figure 4.23q, the AC line provides power until it fails. On failure, the battery supplies power to the alternator, which, in turn, supplies the output voltage.

In Figure 4.23r, the AC motor has been replaced by a rectifier of the static variety. Now referring to Figure 4.23r and to Figure 4.23g, it is easy to see that the two are identical, with the motor–alternator set replacing the block marked "inverter." A system involving an engine is shown in Figure 4.23s.

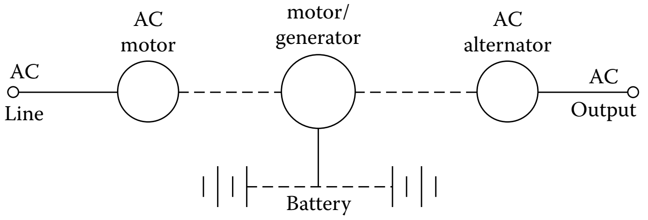

FIG. 4.23q
Standby power supply system consisting of AC motor, generator, and alternator.

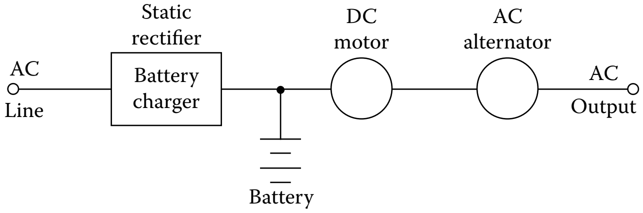

FIG. 4.23r
Standby power supply system utilizing a static rectifier.

Batteries

Three types of batteries are in general use for standby systems: lead antimony, lead calcium, and nickel cadmium. For their approximate costs refer to Figure 4.23t.

Lead Batteries The lead antimony and lead calcium are lead acid batteries deriving their name from the hardening material in the lead alloy. Both have approximately the same ampere-hour characteristics on discharge. The lead antimony construction costs less, requires more maintenance because of its higher internal losses, and evolves more hydrogen than the lead calcium. Life expectancies of 14 to 30 years are frequently quoted. The life depends on the construction of the plate and the plate thickness. It also depends in large measure on the care given the batteries in service.

Both types can operate over a temperature range of –10 to 110°F (–23 to 43°C). The lead calcium cell may be floated at 2.25 volts per cell without the necessity for equalizing charge or, at worst, with long periods between equalizations.

Nickel Cadmium Batteries Nickel cadmium batteries are the alkaline type. They differ from lead acid batteries in that they have a larger short-time current capability, higher cost, and lower volts per cell. Little hydrogen is generated by this cell, and frequent overcharge is recommended. Life expectancy and operating temperature range are similar to those of the lead acid types.

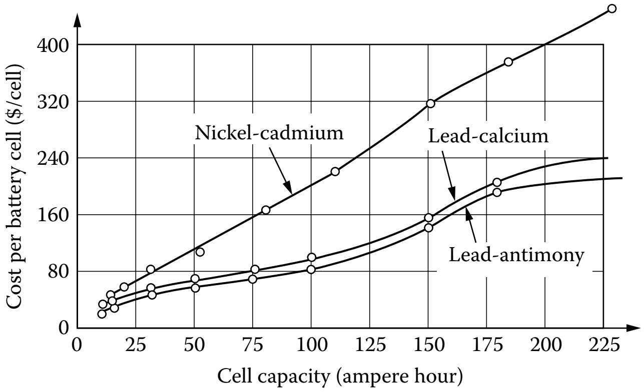

FIG. 4.23t
Battery cell unit costs as a function of battery type and capacity.

Battery Chargers The battery chargers generally used for standby systems are "float" chargers. Their cost is a function of the rated charging current and the float voltage as shown in Figure 4.23u. They are characterized by relatively constant output voltage to recharge the battery because their output current varies from almost zero to rated value. Beyond their rated current, output voltage drops rapidly with increased load current. This current limit protects the charger when applied to the battery in the discharge state.

Satisfactory battery life is dependent on the design and operation of the battery charger, and so are maintenance costs. The feedback techniques used to maintain the constant output voltage and current limit of battery chargers are well known and will not be discussed in detail. The rectifiers themselves may take the form of either a polycrystalline cell, such as selenium or copper oxide, or a monocrystalline cell, such as germanium or silicon. The trend is toward the silicon rectifier. Control devices include the magnetic amplifiers and thyristors.

Motor-generator battery chargers are also available for standby system recharging service. The use of motor generators in this application predates that of the drive-type rectifiers.

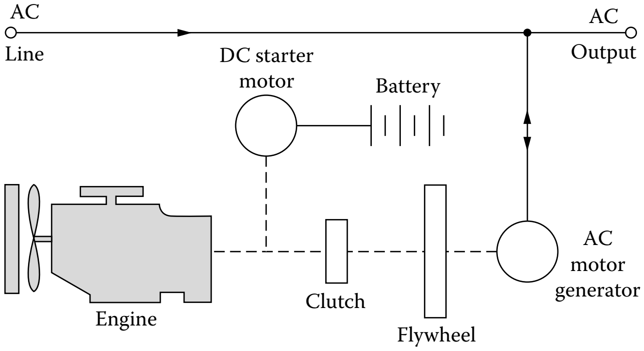

FIG. 4.23s
Standby power supply system using an internal combustion engine as the source of the power.

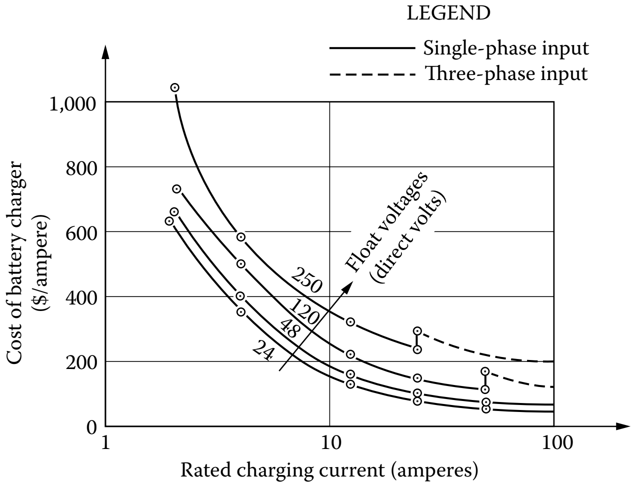

FIG. 4.23u
Battery charger costs as a function of their current and voltage ratings.

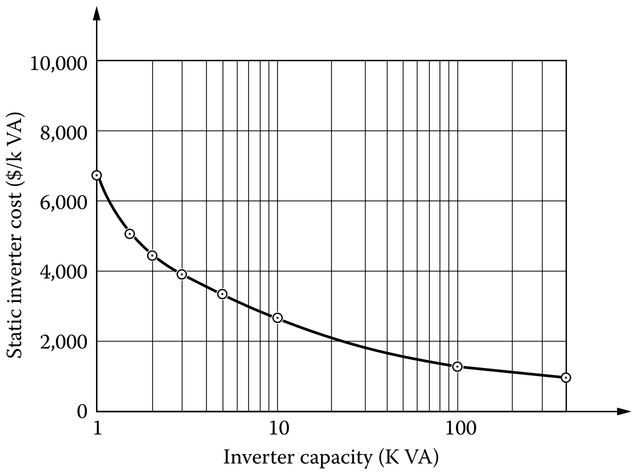

FIG. 4.23v
Static inverter costs as a function of its capacity.

Static Inverters

The static inverter used in a standby system tends to be the most complex piece of equipment in that system. The approximate costs of static inverters are given in Figure 4.23v, and a brief discussion of their operation is provided here.

Transistor inverters are the least expensive of the static inverters. Their principal area of usefulness is the low input voltage (24 direct volts and less) and low output capacity (500 volt-amperes and less) range. This type of inverter can operate at high frequency and can cease operation under dangerously high output current overloads. Figure 4.23w shows a typical circuit for the center-tap transistor inverter; N_1 and N_2 are feedback windings, R_1 is the feedback resistor, and R_2 is the starting resistor.

The operating cycle can be traced by assuming Q_1 closed and Q_2 open. Substantially all the supply voltage E appears across N_3 causing a change in flux level by Faraday's law:

$$\Delta\phi = \frac{10^8 Et}{N_3} \qquad \textbf{4.23(1)}$$

where

$\Delta\phi$ = change in flux level
N = turns in N_3 and N_4 coil (identical)
E = supply voltage (appearing across N_3)
t = time

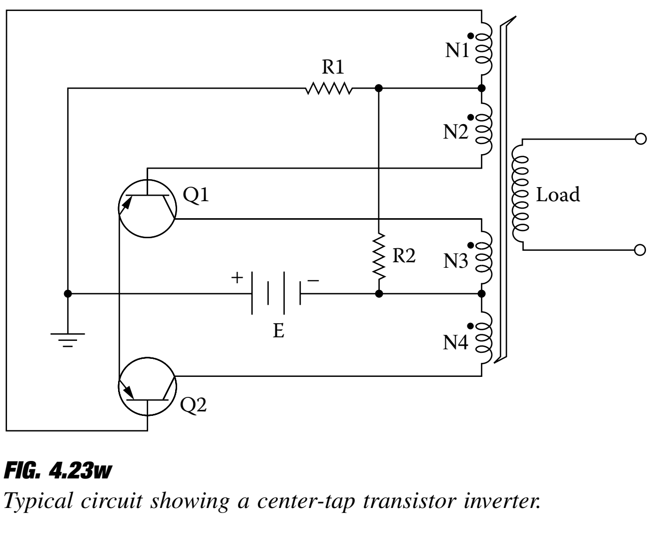

FIG. 4.23w
Typical circuit showing a center-tap transistor inverter.

Eventually the core saturates, requiring an increase in exciting current. To supply this increased collector current, the transistor must have an increased base current. This cannot be supplied because of the decreased coupling between N_2 and N_3 resulting from core saturation; thus, Q_1 begins to open, reducing exciting current. At this point, the change of flux reverses, reversing the coil voltage polarity. Q_2 is then turned on by N_1 and Q_1 is turned off by N_2. The half cycle begun in this fashion is similar to that described until a reversal occurs again, completing the cycle.

Starting resistor R_2 provides enough base bias current to allow exciting current to flow. Natural circuit imbalance ensures that only one transistor closes, thus starting the oscillator.

Should the load be short-circuited, no feedback is provided by N_1 and N_2, and oscillations cease. Other modes of operation are also possible. Care must be taken to provide the correct base current (which is dependent on transistor current gain) so that loading does not excessively shift the frequency. The amount of this shift is also dependent on the "rounding" of the B-H loop.

In the center-tap inverter circuit, each transistor must withstand a voltage equal to or greater than twice the supply potential. Transistors having a sufficiently high rating to withstand a 48-volt source are more expensive. Usually, above 24 volts it is less expensive to use the bridge circuit shown in Figure 4.23x.

The bridge circuit operates in a manner similar to that described for the center-tap circuit. Two starting resistors, R_{s1} and R_{s2}, are necessary. The diodes CR 1, 2, 3, 4 provide transient voltage suppression for unsymmetrically wound transformers.

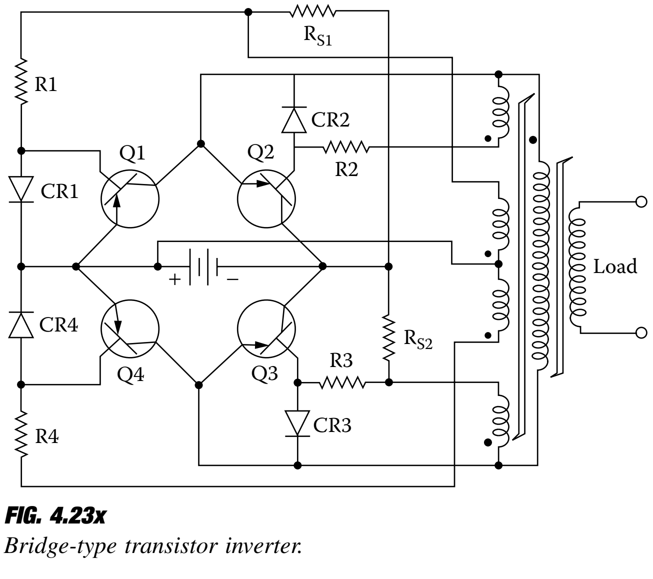

FIG. 4.23x
Bridge-type transistor inverter.

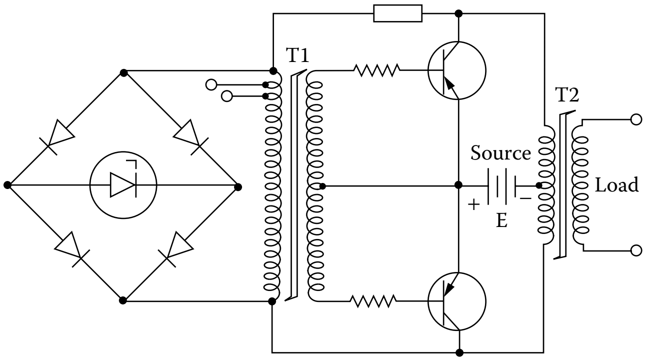

FIG. 4.23y
Typical means of stabilizing inverter frequency.

A typical means of stabilizing frequency is shown in Figure 4.23y. Since the saturation flux density and turns are relatively constant, frequency is controlled by the supply voltage *E*. Use of a "zener" diode stabilizes the voltage and therefore, frequency.

Silicon-controlled rectifier-inverters are the "work horse" of static inverters. They operate efficiently and reliably at high input voltage (130 to 600 direct volts) and high output capacities (500 volt-amperes and larger). Proper specification of the equipment is essential to obtaining reliable operation.

The operation of a static inverter may be stimulated by switches as shown, in Figure 4.23z. Switches 1 and 1′ are operated in unison, as are switches 2 and 2′. When 1 and 1′ are closed and 2 and 2′ are open, load current flows in a direction shown by the arrow in Figure 4.23z. With 2 and 2′ closed and 1 and 1′ open, load current flows in the reverse direction. Thus, whereas the source current i_s flows in the same direction when either set of switches is closed, the load current i_l reverses polarity as each set is alternately closed and opened. Consequently, the current has been inverted by the circuit.

The switches used in Fig. 4.23z are not static since a switch contains moving parts. In Figure 4.23aa, the mechanical switches have been replaced with electrical switches (silicon-controlled rectifiers). Also shown are the commutating indicators L and communicating capacitor C. These components are necessary to turn the controlled rectifiers off. Turn-on is accomplished by the application of the voltage to the gate leads of the controlled rectifiers by the oscillator.

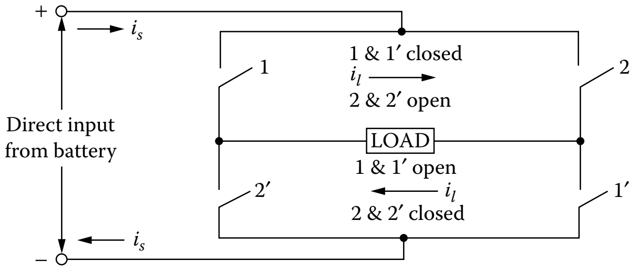

FIG. 4.23z
Simulated static inverter using mechanical switches.

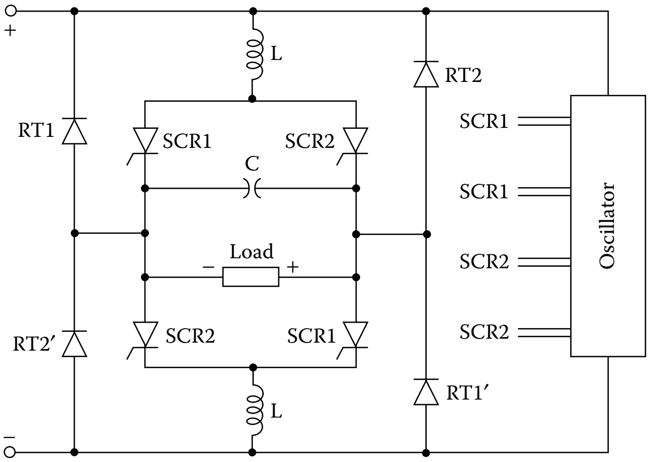

FIG. 4.23aa
Bridge-type SCR static inverter.

Rectifiers diodes RT_1, RT_1, RT_2, and RT_2 are *not* a part of the basic inverter switching circuit. They serve to clamp the amplitude of the load voltage to a value approximately equal to the magnitude of source voltage.

Figure 4.23aa shows the diagram of a bridge-connected static inverter. This arrangement is frequently used for source voltages of 130, 260, and 600 volts. For source potentials of 12, 24, and 48 volts, the circuit of Figure 4.23bb is frequently used. Its operation is seen to be similar to that of the bridge circuit. It differs in that half the number of controlled rectifiers is used, and each must hold off a voltage approximately equal to twice the supply voltage.

Various types of output waveforms may be obtained from the square wave, which is the basic output waveform of the static inverter. Sinusoidal waveforms are most common, but triangular, sawtooth, and many rectangular combinations are also possible. Voltage stabilization may be a welcome bonus provided by the output wave-shaping circuitry. Current limiting is also possible.

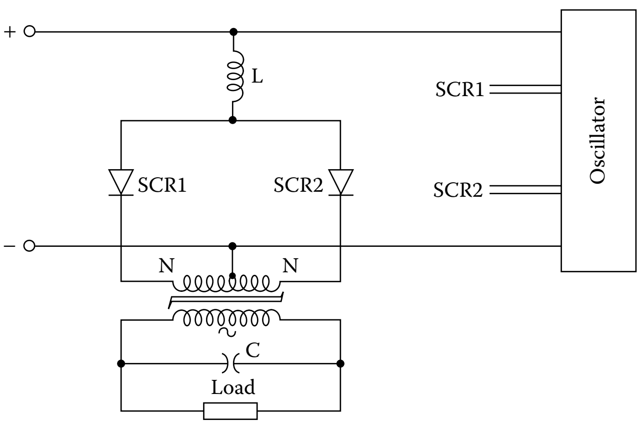

FIG. 4.23bb
Center-tap-type SCR static inverter.

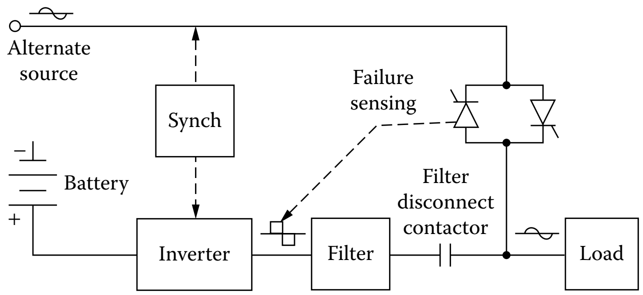

FIG. 4.23cc
No-break power system with hybrid transfer switch.

Bus Transfer Switches

Bus transfer switches have historically been of the electromechanical type. Various techniques have been used to speed the transfer from one source to the other. These techniques have included a pulsing arrangement on the coil of the electromechanical switch in order to overcome the inherent inertia. "Make-before-break" sequences have also been used.

A newer development has been the use of the static switch for more rapid transfers. Generally, thyristors have been used as the power-handling switching component. Figure 4.23cc represents a hybrid transfer switch on the output side of the inverter. Momentary paralleling of sources is achieved by the "drop out" time of the electromechanical contactor. Fast turn-on is achieved by the thyristors. Sensing is performed at the output of the inverter switch (prior to the filter) in order to anticipate output failure.

A static set that serves the same function is shown in Figure 4.23dd. In this case, momentary paralleling is achieved by the logic circuit that supplies the gating pluses.

Protective Components

It is essential to the proper operation of the emergency power supply system that adequate thought be given to the protective devices. Available as protective devices are fuses of various speeds and circuit breakers. The application of fuses to the load circuit was discussed earlier in this section.

Although it is not possible to provide a clear definition of the components to be used for the specific applications within a system, it is necessary to urge that one pay careful attention to the selection. In-rush current on start-up, transient variation of the input voltage, and transient load variation each present particular problems. A frequent experience is that the protective system may be the least reliable of the system components. This is not intended to mean that the component itself fails, but rather that the system fails through action of the protective device under normal operating conditions. Whenever the standby power supply system fails to provide output, whether the components are damaged or not, the resulting damage is the same.

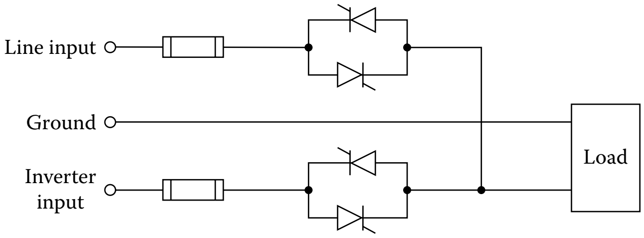

FIG. 4.23dd
Static no-break power system.

STANDBY POWER SUPPLY SYSTEMS

A number of standby power supply systems have been presented in the previous discussion. These have been categorized in terms of the type of power failure but not in terms of the class of system they represent. It was noted earlier that the systems themselves could be classified by virtue of the time it takes to transfer from the primary to the secondary power source. This grouping is more nearly akin to the thinking of the purchaser than is the classification by power failure noted previously.

Multicycle Transfer System

In general, multicycle transfer systems involve either electromechanical transfer switches or engine- or motor-driven equipment that must start up. Figures 4.23ee and 4.23ff show two composite systems using both rotating and static equipment. In Figure 4.23ee both a battery input and an engine-driven generating input are provided to the inverter.

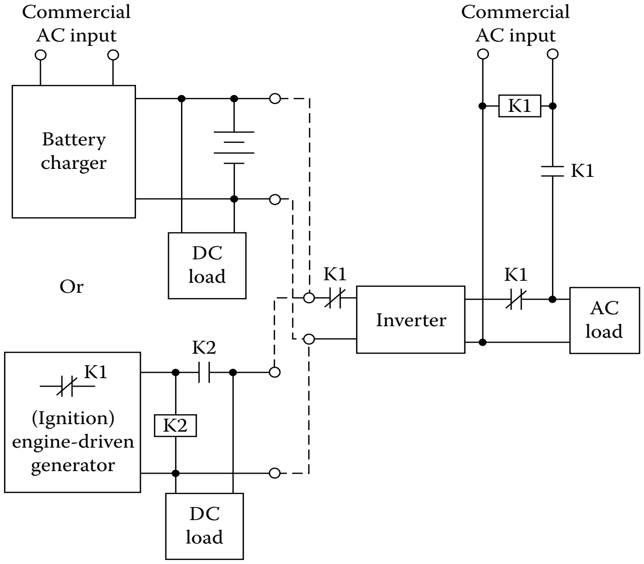

FIG. 4.23ee
Composite multicycle transfer system using both batteries and an engine-driven generator.

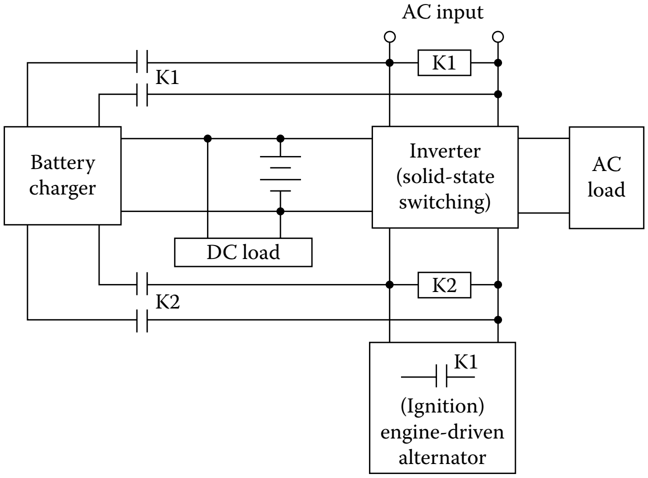

FIG. 4.23ff
Alternative arrangement of a multi-cycle transfer system.

If the engine-driven generator is started prior to the time the energy contained in the battery is completely used by the inverter and the load, *no* interrupt time occurs. Note that the commercial AC power input provides the load normally. On failure of the power lines, the contactor K_1 operates to insert the inverter. Since the inverter is started on the fallout of the contactor K_1, some start-up transient must occur in the inverter, requiring some time between the failure of the commercial AC input source and the inverter source. Note that the use of a static switch in position K_1 would increase the speed of operation of the electromechanical contactor but would *not* materially affect the start-up of the inverter.

Note that a rearrangement of the components of Figure 4.23ee results in the system shown in Figure 4.23ff. This system may not have a transfer time since the battery would normally be chosen to have a capacity sufficient to cover the energy required by the inverter and load during the time it takes to start the engine-driven alternator. Should that interval be long, multicycle startup will result. Note, however, that in this system there is no protection for inverter failure. The system of Figure 4.23ff does have a bypass to the AC commercial line, providing some protection in the event of component failure in the system.

Sub-Cycle Transfer System

Sub-cycle transfer systems are generated by the use of static switches on the output side of the inverter. Thus, the circuits of Figures 4.23j, k, l, m, dd and ee may be sub-cycle transfer systems depending entirely on the arrangement of the switch itself and, in the case of Figure 4.23ee, the start-up time of the inverter.

No-Break Transfer System

The so-called no-break transfer system may be no-break in the sense that if the AC commercial source fails, no cessation in output power results. No-break may also be applied to those systems having a redundant source on the output side of the inverter. Figures 4.23c, g, h, i, and 4.23ff are examples of no-break systems with redundant input sources so that no break occurs in the output power should the AC commercial source fail.

The switching systems shown in Figures 4.23cc and dd can be used in many of the previously defined circuits to provide no-break switching under the right sequence of operations. Figures 4.23j, k, l, and m are of this type.

SYSTEM REDUNDANCY

The subject of system redundancy has been frequently mentioned in the previous discussions. Two basic classifications of system redundancy are made on the basis of input and output. Redundancy in the input circuit to the inverter results from the use of multiple battery sources, multiple input lines coming from separate power feeders, or various types of rotating alternators and generators with either motor or engine drives. Figures 4.23c, h and i illustrate the various types of input redundancy.

Redundancy in the output circuit of the inverter is obtained by use of a switch that will provide a path to an alternate source. Output redundancy may involve switching from the inverter output to the power line. More complex schemes involve switching from one inverter standby system to another inverter standby system. Figures 4.23j, k, l, and m provide examples of output redundancy.

The previous examples have shown the wide number of choices available for component redundancy in standby power supply systems. In order to select the best system for a given application, it is necessary first to evaluate the degree of integrity required for the application. It is then essential that the standby system be evaluated to determine which component is most likely to fail. A decision can then be made, balancing the cost of redundancy versus the needs of the application.

SPECIFICATIONS

Considerable activity is underway to attempt to provide specifications for standby power supply systems and system components. It is essential that the user provide in the specifications certain types of information that are important in ensuring system reliability.

It is suggested that consideration be given not only to the immediate load requirements but also to future load requirements. It is generally less expensive to purchase additional capacity when the system is first acquired than to add capacity to that system at a later date.

In many cases, the characteristics of the loads are most important. Power factor as well as transient characteristics should be clearly defined. These definitions are particularly important if static equipment is involved.

Transient data on the input sources are important in proper design of the system. If a battery source is used, it is desirable to know the transients that can exist on the battery bus. These transients should be specified in terms of their maximum voltage as well as their energy content. If an existing battery installation is used, any loads that are switched will generally institute a transient voltage because of the inductance of the lines themselves. A knowledge of this transient voltage is particularly important in the proper design of static equipment.

Although it is difficult to obtain any meaningful data regarding the number and duration of outages of the utility power lines, it is necessary to provide information concerning the length of time the power supply must produce power for the loads without having the primary input source available. This evaluation can best be performed on the time required to "shut down" the load system rather than with reference to the input failure.

Particular note should be taken of the characteristics of static inverters. Three overload ratings are important. In order that sufficient commutating capacity can be designed into the inverter, it is necessary to know the maximum instantaneous current. It is also necessary to know the overload current for a one- to two- minute interval in order that ample cooling be provided to the semiconductor devices. The final overload rating of importance is the one- or -two hour overload necessary in order to provide ample thermal capacity in the magnetic components. This third overload rating is also of importance in defining rotating equipment.

In the event that the standby system includes a means of transferring the load of the inverter output to an alternate source, the characteristics during transfer and retransfer should be amply defined. Among those characteristics is the length of time, during which switching between the two sources, that zero voltage can be tolerated. Phase shift in voltage from one source to the other should also be stated, together with the transient voltage characteristics on transfer or retransfer. These characteristics can be defined by an evaluation of the sensitivity of the loads to varying phase angle, frequency, and transient voltage. If dynamic loads are included, the transient response and time constant of these loads should be stated.

CLASSIFICATION OF WORKSTATIONS

Operator stations can be divided into various categories, based on the hardware architecture and on the functions they perform.

Hardware Architecture

Those workstations classified based on the hardware architecture can be further divided into two categories: (1) diskless workstations or dumb terminals and (2) intelligent or stand-alone workstations.

Diskless Workstations This type of workstation does not have a hard disk. Its major task is to act as a dumb interface between the application program and the end user. This type of workstation was popular in the days of mainframe computers, where the main processor, which had enormous processing power, was centrally located, and the terminals were used as an interface for the end users.

Diskless workstations are defined by *webopedia* as: A workstation or PC on a local-area network (LAN) that does not have its own disk. Instead, it stores files on a network file server. Diskless workstations can reduce the overall cost of a LAN because one large-capacity disk drive is usually less expensive than several low-capacity drives. In addition, diskless workstations can simplify backups and security because all files are in one place—on the file server. Also, accessing data from a large, remote file server is often faster than accessing data from a small, local storage device. One disadvantage of diskless workstations, however, is that they are useless if the network fails (Figure 4.24a).

Intelligent Workstations Intelligent or stand-alone workstations are fully equipped with hard disks and application software (see Figure 4.6m). These operator stations may also have databases and may perform various critical operation and control functions. The advantage is that intelligence is distributed across the network, and each workstation can do its piece of a task, which helps reduce processing overhead

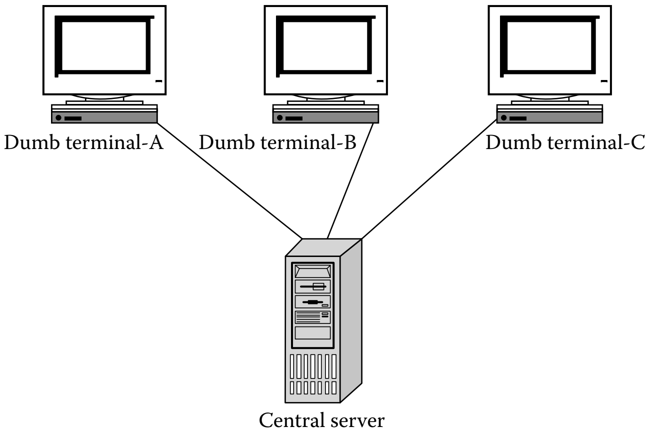

Fig. 4.24a
Diskless workstations.

on a single computer. Also, if one of the operator stations is down, only the functionality related to that workstation is affected and all other tasks remain unaffected. The disadvantage of this type of workstation is that it requires additional hardware and software. The licenses of each software (application or database) have to be purchased for each operator station wherever the particular software is loaded. Certain processes become redundant and are duplicated over various workstations. Client/server architecture is based on this philosophy (Figure 4.24b).

Function

The second category of classification is based on the functions workstations perform; in this grouping, workstations are known by the task to which they are primarily assigned:

- *Operator Workstations*: These workstations are used solely to operate, monitor, and control plant parameters.
- *Engineering Workstations*: The main task of engineering workstations is to perform engineering functions: creating new loops; adding various input and output points, modifying sequential and continuous control logic, simulating the logic offline, database engineering, and preparing such engineering documentation as input/output (I/O) lists and device summaries, etc.
- *Historian Workstations*: These workstations are specifically reserved for performing plantwide acquisition, storage, and retrieval of historical process and system information such as alarms, events, operator actions, and system diagnostics.
- *Application Workstations*: A hybrid of all the above-mentioned functions is performed at a single station, known as an application workstation. The workstation may be capable of database management, historical data management, plant and process control, third-party interface functions, etc. The application workstation performs operations such as online configuration and provides a broad range of configuration capabilities, including database, display, system definition, control strategy configuration, and system status monitoring.
- *X-Terminals/Application Processors/Gateways*: These workstations are dedicated servers. They are preassigned to perform a predefined task and normally they act as a black box for the users. Their wide functionality may include conversion of protocols to enable connection of various types of networks (token ring, token bus, Ethernet, etc.), DDE (dynamic data exchange), and OLE (object linking and embedding) servers, and X-terminals.
- *Gateways*: A gateway is a special host that interfaces with two or more distinct networks, to provide for extension of the address cover of each. Some gateway hosts provide protocol translation between the nets they connect. There are two fundamental types of gateways: a gateway that has the capability of performing routing functions when interconnected networks have a consistent message format, and a gateway that must translate services between interconnected networks when hosts use dissimilar message formats. In this case, the internetwork can only support services that can be mapped between the two dissimilar networks. End-to-end flow control is lost with this type of gateway.
- *Portable Workstations*: These are mobile workstations with a special wireless network interface card, which allows operation of the plant from anywhere in the plant (based on the distribution of the antennas). In contrast to the fixed type of workstation, these stations provide the convenience of remote access to ease operation and maintenance. This type of workstation is very useful in plant start-ups and troubleshooting. However, portable workstations are still not very popular in industrial mission-critical applications.

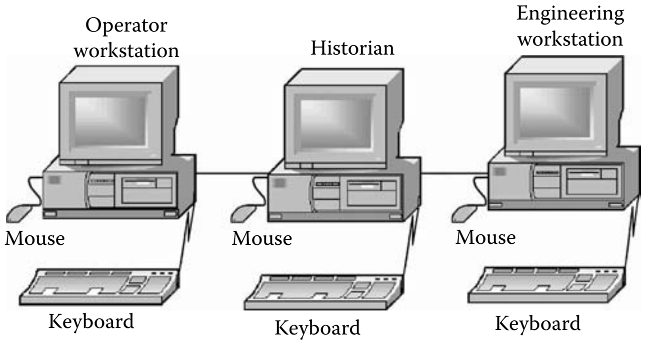

FIG. 4.24b
Intelligent workstations.

Photographs of diskless workstation-based DCS and intelligent workstation-based DCS are shown in Figures 4.24c and 4.24d, respectively.

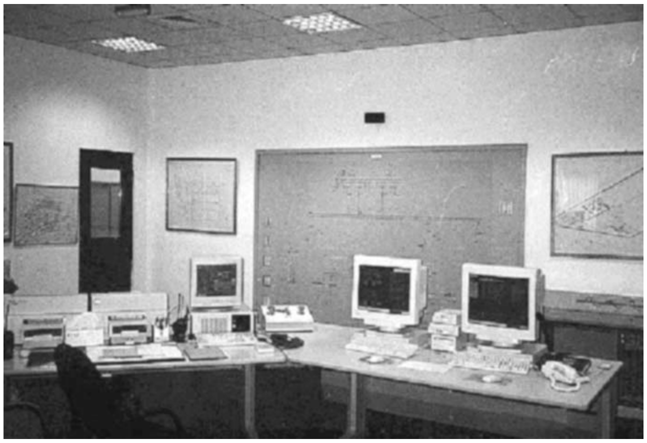

FIG. 4.24c
A diskless workstation-based DCS.

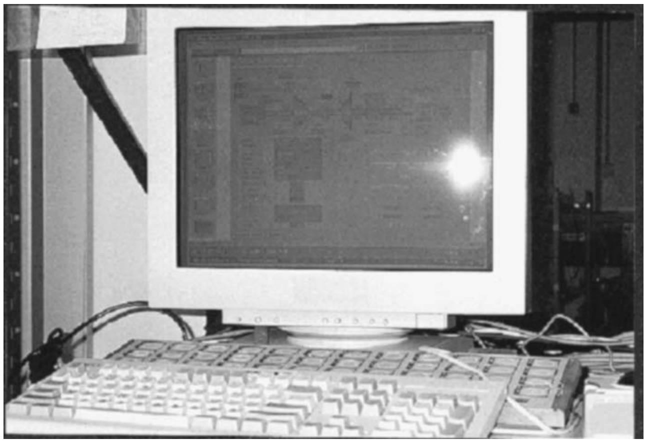

FIG. 4.24e
A workstation with an alarm annuciator panel and keyboard.

HARDWARE COMPONENTS

Any workstation may have the following components:

- Central processing unit (CPU)
- Workstation display (with/without touchscreen)
- Alphanumeric keyboard
- Annunciator and annunciator/numeric keyboards (Figure 4.24e)
- Mouse
- Trackball
- Permanent storage device (e.g., a hard disk)
- Temporary storage device (e.g., a floppy drive, CD-ROM drive, or tape drive)
- RAID (redundant array of inexpensive disks) for backups
- RAM

Several of these hardware components affect the performance of any workstation:

FIG. 4.24d
An intelligent workstation-based DCS.

CPU: The central processing unit is the main workhorse of the workstation. The higher the number of bits, the higher the processing power. RISC processors and 64-bit processors are popular in workstation applications.

RAM: This is a very critical component of any operator station. Because all operator stations will have a lot of graphic capabilities and software, it is critical that the size of the RAM be adequate to achieve a faster refresh rate for the graphics. Generally, the accepted refresh rate for switching between one graphic to another is 1 s or less, and apart from various software methods that can be used to reduce this time, the size of the RAM plays a very important role.

Monitor: The display resolution of the monitor is very important for the aesthetics of a workstation. CRTs (cathode ray tubes) have been the mainstay of computer technology. CRT monitors are measured diagonally from the outer corners of the glass tube as in 14, 17, 19, 20, or 21 in., but the viewable image size on a CRT is smaller because the corners of the glass have a radius, so they are not available as viewable area. Active matrix TFT (thin-film transistor) LCDs (liquid crystal displays) or flat-panel LCD monitors are popular in applications where CRTs have traditionally been used, thanks to their improved color and brightness, better appearance, higher resolution, lesser power consumption, and longer life. Stray magnetic fields generated by motors, high-power machinery, welders, buses, and transformers are common on the plant floor and can result in screen noise and degraded color purity, or can cause severe geometric distortions in CRT images. Flat-panel monitors are not affected by magnetic fields, and hence TFT screens are becoming more and more popular. Figure 4.24f shows a dual-screen workstation.

The RAM size of the video card also plays a crucial role. The optimum size must be selected based on the graphics and their orientation.

Workstations may also consist of special utilities, such as touchscreen utilities, speech synthesizer, etc. They must be correctly selected for the application, and additional software utilities must be matched to these applications.

FIG. 4.24f
Typical dual-screen workstation. (Courtesy of Foxboro Systems.)

SOFTWARE FEATURES

Most of the time the operator station acts as a gateway between the user and the plant. Thus, it must be robust enough to sustain crude handling by operators and be failproof to avoid catastrophe due to errors committed unknowingly.

There are a number of standard applications on any operator station:

- Provision of equipment information for the workstation and its associated I/O devices, buses, and printers
- Capability for change actions directed to the associated equipment
- Processing of station alarm conditions and messages and maintenance of the system date and time
- Database management, storage, retrieval, and manipulation of system data files
- Maintenance of a history of values for process-related measurements, which have been configured for retention by the historian
- Subsetting of the overall operating environment according to the type of user process engineers, process operators, and software engineers who have access to specialized functions and databases suited to their specific requirements and authorizations
- Dynamic and interactive process graphics

Following are the key features available in a Windows NT-based/Windows 2000/X-Windows/UNIX-based workstation:

- Operating system: The operating system (NT/UNIX/Linux/OS2, etc.) is the basic platform of operation of the workstation over which all other software is ported.
- System software: System management function software (data acquisition, control, and management) performs the real-time data collection, management, and storage of the process control messages and data, database management software, and its interface with the historian software.
- Graphical user interface: The graphical window interface to software applications, which is also known as display manager software, determines the user-friendliness and the aesthetics of the workstation.
- Application programming interface (API): API, used for interface with third-party devices, defines the capability of performing control and data acquisition functions for direct connection to a variety of I/O devices.
- Database management system: Database management systems such as DB/2, Informix, Access, Oracle, etc. are the workhorses where the raw data are stored. These database management systems provide front-end software such as SQL, Access, Developer 2000, and Visual Basic for manipulating the data.

Optional packages may include:

Historian package for viewing the history of various parameters
Sequence of event recording function
Trend display and troubleshooting functions
Special engineering software such as performance monitoring systems, efficiency calculators, maintenance management software, etc.

SELECTION OF CORRECT PLATFORM

With the advent of various operating systems such as Windows 95, Windows 98, Windows NT, Windows 2000, Windows XP, Linux, UNIX, OS/2, etc., the question arises: Which is the best?

NT can be considered a *de facto* open operating system because it is a widely used operating system and supports a wide variety of products; however, it is still a proprietary operating system, and most of the internal source code related to the system registry is not released to the public. This makes it cumbersome for administrators to secure NT positively because of the obscurity built into the operating system.

UNIX is an old but highly tested operating system. UNIX is an open operating system in which the source code is available and reviewable. A skilled team of administrators can secure UNIX systems more positively than NT.

Each of the operating systems has advantages and disadvantages. For example, a UNIX-based system comes with a very high level of security provisions, but it requires a great deal of effort and a special skill set to develop and maintain such a system. At the same time a system on Windows NT may not have the robustness of UNIX but may be easier to handle. UNIX has an advantage at the high end (enterprise-level automation) whereas for a small to medium level of enterprise automation this difference is negligible.

However, all these issues are very much debatable. Each operating system has certain advantages and disadvantages over others; the right question a system designer must ask is what is right for a particular application.

The following are questions that may help any control system engineer decide on the ideal choice:

Is a highly open system or a closed system required?
Need the system have a very high level of security provision?
Is the special type of skilled labor available to operate the system that is sought?
Is user-friendliness built into the system?
What support is available for a particular system in the marketplace?
What are the third-party interfaces supported by the system?
What is the proven track record of the system?
Is the system upgradable to the next version?
What is the history of the product under consideration?
Does the vendor support upgrading or will it be necessary to change to a new system altogether?

Technical superiority is not the only consideration in the choice of an operating system. Personal, economic, and environmental factors also play important roles in the decision-making process of platform selection for a particular system. A particular operating system may be ideal technically, but too expensive.

Often a particular feature may be absolutely essential to one company, important to another, trivial to a third, and an unacceptable impediment to a fourth.

Hardware and the interactions between hardware and software can be significant factors in both quantifiable and anecdotal results. Variations in software, even software that shares the same name and version number, can play a significant role.

Variations in the personnel creating, administering, and maintaining the computer system (the human factor) can be a significant factor in results. Many times considerable emphasis is placed on the selection of the platform, but how well the applications are designed and interwoven with the platform is equally important. Many times the platform may be very stable but the application program is unstable.

COMPARING VARIOUS OPERATING PLATFORMS

A brief comparison of the various attributes of each type of operating system follows (Table 4.24g).

TABLE 4.24g
Comparison of Architectural Features of Windows NT Server with SCO UNIX

Architecture	*Windows NT*	*SCO UNIX*
Multiuser operating system	Yes	Yes
Preemptive multitasking	Yes	Yes
Support to intel processor	Yes	Yes
Symmetric multiprocessing	Yes	Yes
Asymmetric multiprocessing	No	Yes
Paged virtual memory	Yes	Yes
Maximum number of user connections	Unlimited	Unlimited
Single login to network	Yes	No
Dynamic loading of services	Yes	Yes
Memory protection	Yes	Yes
Audit alerts	Yes	No
Structured exception handling	Yes	No
Installable file system	Yes	Yes
Hardware abstraction layer	Yes	No
Microkernel-based architecture	Yes	No

Cost

For any buying decision, the bottom line always is determining the cheapest solution available. However, choosing an operating system and evaluating its cost is a different ballgame, because one should consider not only the initial investment but also the maintenance cost over the long run. Normally, the major cost categories are hardware and software costs, but often there are also hidden costs, such as costs of after-sales support agreements, upgrades/service packs, hardware upgrades, profits lost due to downtime, and last, but not least, costs for systems engineers and supporting staff.

It is very important that when the costs of systems are compared the features that are standard in one system must be compared with those in the other systems. It should be determined if these features are also available as a standard package or if they must be purchased at additional cost. NT is often chosen for budget reasons because many customers are not willing to pay for the more expensive hardware required by most commercial versions of UNIX.

Reliability

Reliability is generally considered important by end users. Even if one operating system offers more functionality, is more scalable, and offers greater ease of system management, it would be of no use when a server processing real-time mission-critical process application is plagued by frequent crashes resulting in costly downtimes.

In addition, an operating system may be extremely reliable at one kind of task and extremely unreliable at another. UNIX has been operating in the server environment for more than 30 years and now has proved its mettle as far as reliability is concerned. However, Windows NT and Windows 2000 are still trying to prove their credentials. Many system integrators and manufacturers have shifted from OS/2 or UNIX to Windows NT over the past few years but still UNIX is considered a more reliable system than NT. Only the coming years will establish the reliability of Windows NT as compared with UNIX.

Manageability and Administration

This is a very important issue for system engineers who influence the buying decision of a system. For a distributed control system, manageability and administration are very important, and it is generally recognized that the Windows-based system provides easier manageability and administration because of its graphical user interface (GUI). NT has long enjoyed an intuitive user interface for managing single systems, largely benefiting from the exceptional familiarity of the Windows look-and-feel adopted by the NT GUI. For the administration of a control system, the administration functions are frequently much simplified by providing special administration programs with a user-friendly GUI. Such functions as backup, creating users, sharing resources, defining priorities in the execution of multiple tasks, defining access, and security are a few of the core management and administrative functions.

Scalability

Scalability is a measure of the ability of an operating system to *scale* from use on a very small personal computer to a very large network of computers. The existence of scalability allows for the smooth growth of a computer system: using the same operating system on the entire installed system base.

If the operating system is truly scalable, it is possible (but not always achievable) to reduce administrative, maintenance, and training costs by standardizing on a single operating system. For control system users, scalability is of prime importance because the ever-expanding nature of any business always demands the system to grow larger and larger. If this topic is discussed in the context of the commercial systems, then the issue of multiprocessing capability would arise. However, for a control system manufacturer, scalability is not only the power of the operating system to support multiple processors but also relates to the capability of the hardware that is used in the system, the network topology adopted, the media used for communication, etc. Both Windows NT– and UNIX-based systems are highly scalable. Another viewpoint of scalability is the capability of a system to support physical memory and processors. UNIX systems can, in general, support more physical memory and processors than can NT. This, in turn, leads to higher performance even though both systems can be supported on the same microprocessors.

Security

The *security* of a system is a very debatable subject. No system can claim perfect security. Normally, for a control system security is designed with the following aspects in mind:

1. Security features to avoid corruption or loss of data
2. Security features to avoid misuse (intentional or by operator error)

Regarding the first aspect, the major culprits are computer viruses, worms, or Trojan horses that may enter the system and corrupt the data of the system. To prevent this, *never* allow floppy disks or tape drives from unknown sources to be used in the system. Also, the system must be guarded with strong antivirus software, which must be upgraded regularly. Apart from this, the user rights for editing, copying, etc. must only be accessible to the system engineer. It is generally believed that UNIX-based systems are less prone to virus attacks as compared with Windows NT–based systems.

Regarding the second aspect, system programmers must strive to make the system failproof by anticipating the various combinations that a naive operator may perform on the system. Ideally, all the critical functions must be password-protected or at least they should not be activated by a single key press. There should always be an acknowledgment to each task. These issues may not be directly related to the operating system; however, they are definitely linked indirectly via the built-in security features of each operating system. For example, the Windows NT system has a built-in security feature such that, unless files are allowed to be shared, by default the files remain not shared.

Error Handling

Systems are prone to failures; therefore, some disaster management plan must always be in place. Many of the operating systems provide for annunciation of the failure of their hardware; however, if there are problems in the software/services they also need to be annunciated to the administrator. What is important for a control system engineer is that all the hardware- and software-related alarms and messages appear in the system alarms. A separate group of alarms called system alarms must always be created, and this group must be different from the process alarms. Once errors are reported, it is important to know how to recover from these errors, and here lies the real test of a system engineer. Error recoveries are predominantly governed by the hardware architecture that has been selected for the system and how the system administration tasks are done. If regular backups of the latest changes are kept, then it may be easier to restore the system to good health. Such hardware architecture as disk mirroring and RAID, normal standby configuration, etc. may be very helpful in handling the errors. Both Windows NT- and UNIX-based systems support various error recovery tools very well.

Integration of Software and Hardware

This is the crux of a computer system. A computer system consists of both hardware and software. A key recurring question is how well the software and hardware are integrated. The choice here is between close integration of hardware and software versus the availability of a wide number of choices of vendors, which forces purchase managers to collect the different parts from different parties and then ask system engineers to synchronize the system.

It takes more than a GUI to make a computer easy to use. It takes tight integration between software and hardware.

> The Mac is still more elegant and stylish, still more tightly integrated, with better links between software and hardware, because a single company makes both the computer and operating system.—*The Wall Street Journal*

Both Windows NT and UNIX support a large variety of hardware; however, performance may vary with each type of hardware used. Also, the same application can run quite differently on different platforms, even though the platforms have the same speeds and feeds on performance. This is because optimization levels differ, and sometimes hardware vendors assist software vendors in tuning applications for their particular environments.

The ideal solution is to have a total solution from a single system integrator; for example, buying branded hardware and software from SUN, IBM, HP, or the equivalent would be a better choice than collecting an operating system from one source, a workstation from another source, and other applications from a third source.

Openness

Distributed control systems are the central supervisory and monitoring system for the plant, and there may be many third-party interfaces required to connect with the system. Thus, openness is crucial to the system. Both UNIX and NT are highly open systems. The NT system is considered more open because of the possibility of connecting it to various subsystems available commercially. Normally, these interfaces are a major cause of downtime of the system and the compatability of these interfaces must always be checked before considering them. It must be kept in mind that many times these interfaces require special hardware (gateways, bridges, etc.) and software. Integration and management of these additional gateways is often very cumbersome. If these interfaces are redundant, then the overall redundancy of the system must be reviewed after considering the redundancy of these interfaces in tandem with system redundancy.

Another measure of connectivity is the ability to run programs from other operating systems in emulation. Emulated software runs more slowly than native software, but allows for easy trading of data and use of obscure programs available on a limited number of platforms. Hardware emulation can attain the same speed as the actual system being emulated. It also has the possible advantage of sharing some computer resources (sharing hard drives, sharing monitors, etc.) and perhaps even the ability to copy and paste between systems or other levels of direct sharing, as well as saving desk space by requiring only one computer setup to run multiple systems.

CONCLUSIONS

The bottom line is that there is little to distinguish between UNIX and Windows NT. This choice is much more dependent on the environment in which the operating system has to run, the industry and the application to be served, the technical support and programming staff, the client environment, and the existing infrastructure. Eventually many of the glaring technical differences between these operating systems will become nonissues because of the industry trend toward better integration of these two operating systems, with products such as OpenNT.

As process control tends to move away from single-loop control toward unit-operation control, the workstation designs will also reflect that trend (see Figure 4.6m).

GLOSSARY

CLIENT/SERVER ARCHITECTURE An architecture where processing is shared between client and server applications. The server accepts requests from the client, processes the requests, and sends information back to the client.

DATA A representation of facts, concepts, or instructions in a formalized manner suitable for communication, interpretation, or processing by people or automatic means; any representation, such as characters, to which meaning might be assigned.

DATA ACQUISITION The process of identifying, isolating, and gathering source data to be processed by some central agency into a usable form.

DRIVER A series of instructions the computer follows to reformat data for transfer to and from a particular network device. Software drivers standardize the data format between different kinds of devices. Multiplexing of messages through a driver, for example, is made possible by supervisor synchronizing commands, or primitives, that permit several sender processes to send messages to a single-receiver process port associated with the driver.

EMULATION The use of programming techniques and special machine features to permit a computing system to execute programs written for another system.

END USER A person, process, program, device, or system that functions as an information source or destination and/or employs a user–application network for the purpose of data processing and information exchange.

ETHERNET A baseband local-area network specification developed jointly by Xerox Corporation, Intel, and Digital Equipment Corporation to interconnect computer equipment using coaxial cable and transceivers.

HOST (1) In a network, a computer that primarily provides services such as computation, database access, special programs, or programming languages; the primary or controlling computer in a multiple-computer installation. (2) An abstraction of an operating environment wherein a set of processes interacts with a supervisor. The supervisor contains system processes and manages the operating environment, which includes input/output devices, directories, and file systems. A host is a convenient boundary for containing specific resources needed by other hosts. A host is virtual, and several hosts may reside on the same computer.

INTERFACE (1) A shared boundary. For example, the physical connection between two systems or two devices. (2) Generally, the point of interconnection of two components, and the means by which they must exchange signals according to some hardware or software protocol.

SERVER A processor that provides a specific service to the network, for example, a routing server, which connects nodes and networks of like architectures; a gateway server, which connects nodes and networks of different architectures by performing protocol conversions; and a terminal server, printer server, and file server, which provide an interface between compatible peripheral devices on a local-area network.

TERMINAL (1) A point at which information can enter or leave a communication network. (2) An input/output device to receive or send source data in an environment associated with the job to be performed, capable of transmitting entries to and obtaining output from the system of which it is a part.

TOPOLOGY (1) The physical arrangement of nodes and links on a network; description of the geometric arrangement of the nodes and links that make up a network, as determined by their physical connections. (2) The possible logical connections between nodes on a network, indicating which pairs of nodes are able to communicate, whether or not they have a direct physical connection. Examples of network topologies are bus, ring, star, and tree.

5.1 Binary Logic Diagrams for Process Operations

Standard formatted for publication in this handbook by:

J. E. JAMISON (2005)

Reprinted by permission. Copyright © 1976, Instrument Society of America. From *ANSI/ISA-S5.2-1976 (R 1992)*, "*Binary Logic Diagrams for Process Operations*," reaffirmed July 13, 1992. Also, permission was granted by ISA for inclusion of the latest thinking on binary logic, memory, and time functions from *Draft 4 of ISA Draft 5.01.01 Instrumentation Symbols and Identification, Copyright 2000 ISA,* which now includes the previous S5.2.[1]

1. PURPOSE

1.1 The purpose of this Standard is to provide a method of logic diagramming of binary interlock and sequencing systems for the start-up, operation, alarm, and shutdown of equipment and processes in the chemical, petroleum, power generation, air conditioning, metal refining, and numerous other industries.

1.2 The Standard is intended to facilitate the understanding of the operation of binary systems and to improve communications among technical, management, design, operating, and maintenance personnel concerned with the systems.

2. SCOPE

2.1 The Standard provides symbols, both basic and nonbasic, for binary operating functions. The use of symbols in typical systems is illustrated in the appendices.

2.2 The Standard is intended to symbolize the binary operating functions of a system in a manner that can be applied to any class of hardware, whether it be electronic, electrical, fluidic, pneumatic, hydraulic, mechanical, manual, optical, or other.

3. USE OF SYMBOLS

3.1 By using the symbols designated as "basic," logic systems may be described with the use of only the most fundamental logic building blocks. The remaining symbols, not basic, are more comprehensive and enable logic systems to be diagrammed more concisely. Use of the nonbasic symbols is optional.

3.2 A logic diagram may be more or less detailed depending on its intended use. The amount of detail in a logic diagram depends on the degree of refinement of the logic and on whether auxiliary, essentially nonlogic, information is included.

As an example of refinement of detail: A logic system may have two opposing inputs, e.g., a command to open and a command to close, which do not normally exist simultaneously; the logic diagram may or may not go so far as to specify the outcome if both the commands were to exist at the same time. In addition, explanatory notes may be added to the diagram to record the logic rationale.

Nonlogic information may also be added, if desired, e.g., reference document identification, tag numbers, terminal markings, and so on.

In these ways, the diagram may provide the level of detail appropriate, for example, for communication between a designer of pneumatic circuits and a designer of electric circuits, or may provide a broad-view system description for a plant manager.

3.3 The existence of a logic signal may correspond physically to either the existence or the nonexistence of an instrument signal, depending on the particular type of hardware system and the circuit design philosophy that are selected.[2] For example, a high-flow alarm may be chosen to be actuated by an electric switch whose contacts open on high flow; on the other hand, the high-flow alarm may be designed to be actuated by an electric switch whose contacts close on high flow. Thus, the high-flow condition may be represented physically by the absence of an electric signal or by the presence of the electric signal. The Standard does not attempt to relate the logic signal to an instrument signal of any specific kind.

3.4 A logic symbol that is shown in Section 4 with three inputs—A, B, and C—is typical for the logic function having any number of two or more inputs.

3.5 The flow of intelligence is represented by lines that interconnect logic statements. The normal direction of flow is from left to right, or top to bottom. Arrowheads may be added to the flow lines wherever needed for clarity and shall be added to lines whose flow is not in a normal direction.

---

[1] A disclaimer to any future ISA Standards documents is hereby stated. The reader is cautioned that the Draft ISA Document that provided Table 5.1a has not been approved as of the time of this writing. Therefore, it cannot be presumed to reflect the position of ISA or any other committee, society, or group.

[2] In process operations, binary instrument signals are commonly either *ON* or *OFF*. However, as a more general case, logic systems exist that make use of binary hardware having signals with two alternate real values, e.g., +5 V and –3 V. In *positive logic,* the more positive signal, +5 V, represents the existence of a logic condition, e.g., *pump stopped*. In *negative logic*, the less positive signal, –3 V, represents the existence of a logic condition of *pump stopped.*

3.6 A summary of the status of an operating system may be put in the diagram wherever it is deemed useful as a reference point or landmark in the sequence.

3.7 There may be misunderstanding of binary logic statements involving devices that are not recognizable as inherently having only two specific alternative states. For example, if it is stated that a valve is not closed, this could mean either (a) that the valve is open fully, or (b) that the valve is simply not closed, namely, that it may be in any position from almost closed to wide open. To aid accurate communication between writer and reader of the logic diagram, the diagram should be interpreted literally. Therefore, possibility (b) is the correct one.

If a valve is an open-close valve, then, to avoid misunderstanding, it is necessary to do one of the following:

1. Develop the logic diagram in such a way that it says exactly what is intended. If the valve is intended to be open, then it should be so stated and not be stated as being not closed.
2. Have a separate note specifying that the valve always assumes either the closed or the open position.

By contrast, a device such as a motor-driven pump is either operating or stopped, barring some special situations. To say that the pump is not operating usually clearly denotes that it has stopped.

The following definitions apply to devices that have open, closed, or intermediate positions. The positions stated are nominal to the extent that there are differential-gap and dead band in the instrument that senses the position of the device.

Open position: a position that is 100% open.
Not-open position: a position that is less than 100% open. A device that is not open may or may not be closed.
Closed position: a position that is 0% open.
Not-closed position: a position that is more than 0% open. A device that is not closed may or may not be open.
Intermediate position: a SPECIFIED position that is greater than 0% and less than 100% open.
Not-at-intermediate position: a position that is either above or below the SPECIFIED intermediate position.

For a logic system having an input statement that is derived inferentially or indirectly, a condition may arise that will lead to an erroneous conclusion. For example, an assumption that flow exists because a pump motor is energized may be false because of a closed valve, a broken shaft, or other mishap. Factual statements, that is, statements based on positive measurements that a certain condition specifically exists or does not exist, are generally more reliable.

3.8 A process operation may be affected by loss of the power supply[3] to memories and to other logic elements. In order to take such operating eventualities into account, it may therefore be necessary to consider the effect of loss of power to any logic component or to the entire logic system. In such cases, it may be necessary to enter power supply or loss of power supply as logic inputs to a system or to individual logic elements. For memories, the consideration of power supply may be handled in this manner or as shown in sections 10–12 in Table 5.1a.

By the same token, it may be necessary to consider the effect of restoration of power supply.

Logic diagrams do not necessarily have to cover the effect of logic power supplies on process systems but may do so for thoroughness.

3.9 It is recommended, for clarity, that a single time-function symbol, as appropriate, be used to represent each time function in its entirety. Though not incorrect, the representation of a complex or uncommon time function by using a time-function symbol in immediate sequence with a second time-function symbol or with a *NOT* symbol should be avoided (see Table 5.1a).

3.10 Process instrument symbols and designations follow ANSI/ISA Standard S5.1-1984 (formerly American National Standards Institute Standard Y32.20-1975), "Instrumentation Symbols and Designations." However, these symbols are included for illustrative purposes only, and are not part of Standard S5.2.

3.11 If a drawing, or set of drawings, uses graphic symbols that are similar or identical to one another in shape or configuration and that have different meanings because they are taken from different standards, then adequate steps shall be taken to avoid misinterpretation of the symbols used. These steps may be to use caution notes or reference notes, comparison charts that illustrate and define the conflicting symbols, or other suitable means. This requirement is especially critical if the graphic symbols used, being from different disciplines, represent devices, conductors, flow lines, or signals whose symbols, if misinterpreted, may result in danger to personnel or damage to equipment.

4. SYMBOLS

The symbols for diagramming binary logic are defined in Table 5.1a and are the latest thinking of the ISA SP5.1 subcommittee:

The symbols in Table 5.1a are never used in piping and instrument diagrams (P&IDs) and are used to help document and diagram logic control designs and narratives. The present Standard ISA S5.2 (ANSI/ISA-S5.2-1976(R1992) is now being revised and rolled into the new ANSI/ISA-5.01.01 standard as proposed in the current (as of this writing) Draft 4. Symbols, Truth Tables, Definitions, and Graphs used here in Section 5.1 are in accordance with Draft 4 and are very different from S5.2. These are given here to illustrate to the reader the latest thinking in this area, including expanded timing functions. Application information and examples on

---

[3] The term "power supply" covers the energizing medium, whether it be electric, pneumatic, or other.

the use of the binary symbols given in Appendices *A*, *B*, and *C* are direct extracts from and utilize the current Standard ANSI/ISA-S5.2-1976(R1992).

Binary logic switching and memory functions are used in analog or sequential control schemes. In truth tables and graphs, Logic One ("1") is "true" and Logic Zero ("0") is "false."

APPENDIX A: GENERAL APPLICATION EXAMPLE

A1. Introduction

This example uses a representative process whose instruments are denoted by the symbols of ANSI/ISA-S5.1-1984 (R 1992) (ANSI Y32.20-1975). The process equipment symbols are included only to illustrate applications of instrumentation symbol. The example is not a part of Standard S5.2.

A2. Simplified Flow Diagram

Figure 5.1b provides the flow sheet representation of the logic involved in a tank filling operation. A written explanation of the various symbols follows:

A3. Word Description

A3.1 Pump Start Feed is pumped into either tank A or tank B. The pump may be operated manually or automatically, selected manually on a local maintained output select switch, *HS-7*, which has three positions: *ON*, *OFF*, and *AUTO*. When the pump is operating, red pilot light *L-8A* is on; when not operating, green pilot light *L-8B* is on. Once started, the pump continues to operate until a stopping command exists or until the control power supply is lost.

The pump may be operated manually at any time provided that no trouble condition exists: The suction pressure must not be low; the seal water pressure must not be low; and the pump motor must not be overloaded and its starter must be reset.

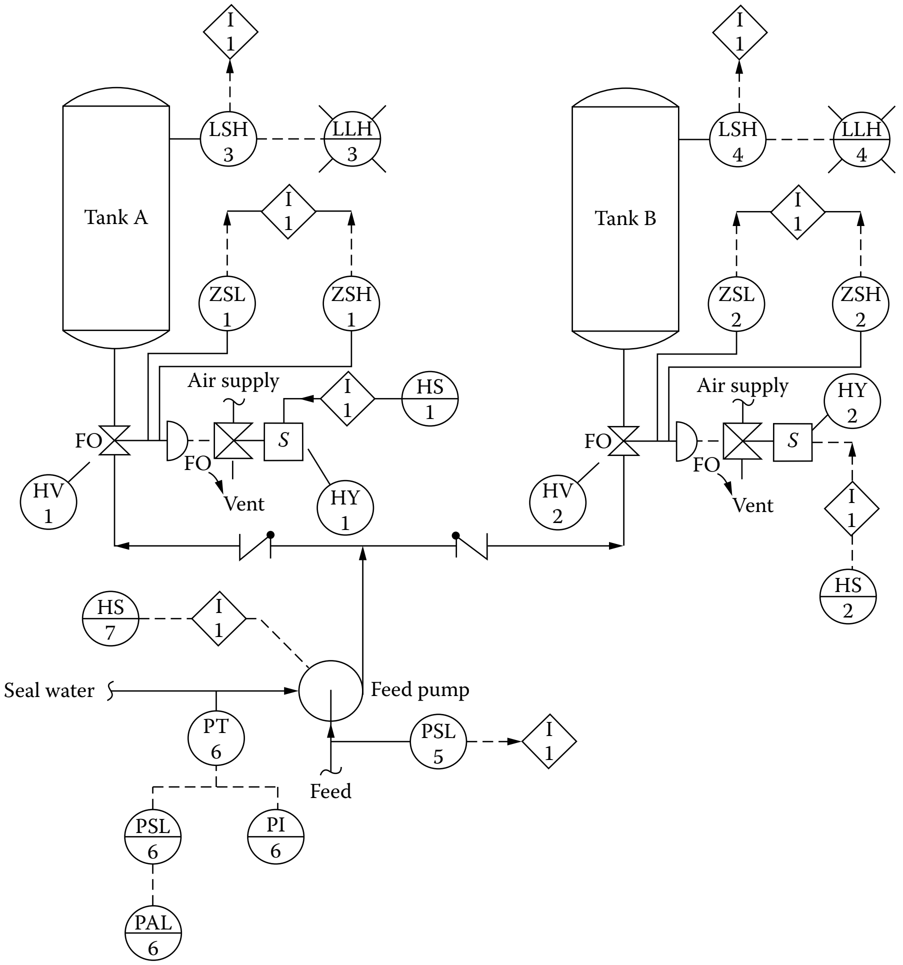

FIG. 5.1b
Tank filling operation-simplified flow diagram.

In order to operate the pump automatically, all the following conditions must be met:

A3.1.1 Board-mounted electric momentary-contact hand switches, *HS-1* and *HS-2*, start the filling operation for tanks *A* and *B*, respectively. Each switch has two positions, *START* and *STOP. START* de-energizes the associated solenoid valves, *HY-1* and *HY-2*. De-energizing a solenoid valve causes it to go to the fail-safe position, i.e., to vent. This depressurizes the pneumatic actuator of the associated control valves, *HV-1* and *HV-2*. Depressurizing a control valve causes it to go to the fail-safe position, i.e., to open. The control valves have associated open-position switches, *ZSH-1* and *ZSH–2*, and closed-position switches*, ZSL-1* and *ZSL-2*.

The *STOP* position of switches *HS-1* and *HS-2* causes the opposite actions to occur so that the solenoid valves are energized, the control valve actuators are pressurized, and the control valves close.

If starting circuit power is lost, the starting memory is lost and the filling operation stops. The command to stop filling can override the command to start filling.

To start the pump automatically, either control valve *HV-1* or *HV-2* must be open and the other control valve must be closed, depending on whether tank *A* or tank *B* is to be filled.

A.3.1.2 The pump suction pressure must be above a given value, as signaled by pressure switch *PSL-5*.

A.3.1.3 If valve *HV-1* is open to permit pumping into tank *A,* the tank level must be below a given value, as signaled by level switch *LSH-3*, which also actuates a board-mounted high-level pilot light, *LLH-3*. Similarly, high-level switch, *LSH-4*, permits pumping into tank *B,* if not actuated, and actuates pilot light *LLH-4*, if actuated.

A.3.1.4 Pump seal water pressure must be adequate, as indicated on board-mounted receiver gage, *PI-6*. This is a non-interlocked requirement that depends on the operator's attention before the operation starts. Pressure switch, *PSL-6*, behind the board, actuates the board-mounted low-pressure alarm, *PAL-6.*

A.3.1.5 The pump drive motor must not be overloaded and its starter must be reset.

A.3.2 Pump Stop The pump stops if any of the following conditions exists:

A.3.2.1 While pumping into a tank, its control valve leaves the fully open position, or the valve of the other tank leaves its fully closed position, provided that the pump is on automatic control.

A.3.2.2 The tank selected for filling becomes full, provided that the pump is on automatic control.

A.3.2.3 The pump suction pressure is continuously low for 5 seconds.

A.3.2.4 The pump drive motor is overloaded. It is immaterial to the process logic whether or not the memory of the pump motor overload is retained on loss of power in this system because the maintained memory that operates the pump is defined as losing memory on loss of power, and this by itself will cause the pump to stop. However, an existing motor-overload condition prevents the motor starter from being reset.

A.3.2.5 The sequence is stopped manually through *HS-1* or *HS-2*. If stop and start commands for pump operation exist simultaneously, then the stop command overrides the operate command.

A.3.2.6 The pump is stopped manually by *HS-7*.

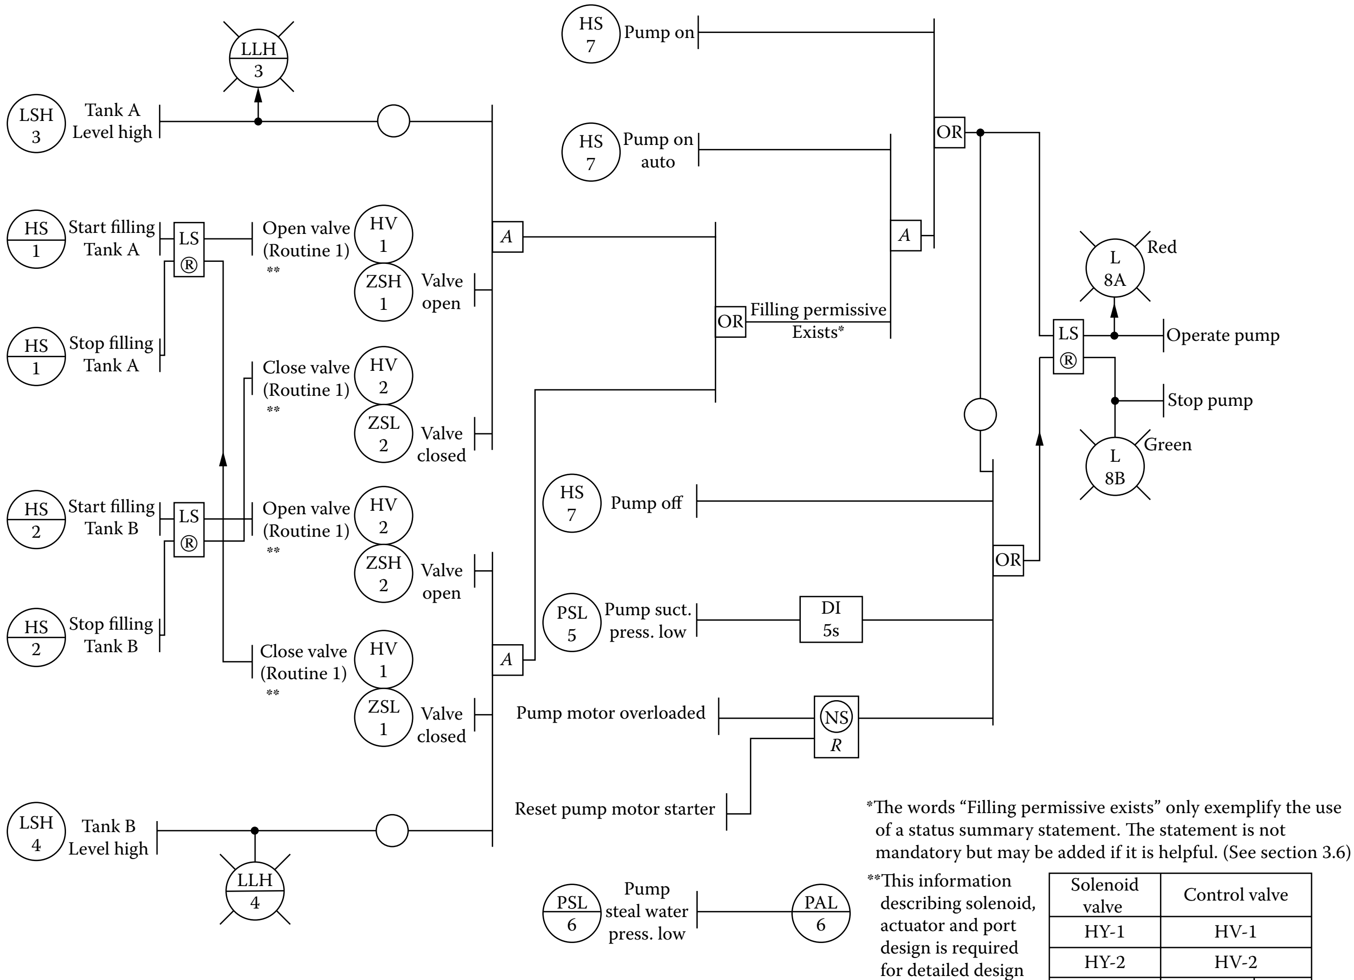
A.3.2.7 The pump seal water pressure is low. This condition is not interlocked and requires manual intervention to stop the pump.

A4. Logic Diagram

The equivalent of the flow sheet representation shown in Figure 5.1b is the logic diagram provided in Figure 5.1c.

Comments on the logic diagram for Interlock 1 described in Figure 5.1c:

1. The diagram may be simplified by using general notes (GN) for a project, especially for repetitive items. For example, the operating light for the pump may be omitted from the diagram by using a general note that states: “All pumps have red and green pilot lights to denote that the pump motors are operating or not operating, respectively.”

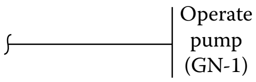


*The words “Filling permissive exists” only exemplify the use of a status summary statement. The statement is not mandatory but may be added if it is helpful. (See section 3.6)

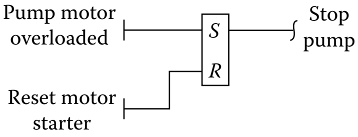
**This information describing solenoid, actuator and port design is required for detailed design work

		Solenoid valve	Control valve	
		HY-1	HV-1	
		HY-2	HV-2	
			Actuator	Port
Operation	Open valve	De-Energized	Vented	Open
	Close valve	Energized	Pressurized	Closed

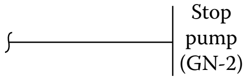
FIG. 5.1c
Tank filling operation-interlock 1 logic diagram.



As another example, the motor lockout detail



will commonly be simplified by referring to a general note that states: "The motor starter locks out when tripped,"
Thus:



2. The memory function that keeps the pumps in operation may be, but is not necessarily, provided by a circuit breaker for the pump motor. The other maintained-memory function in the diagram may be provided by pneumatic or electric latching relays or other types of hardware. This illustrates the essentially hardware-free nature of the operational logic portion of the diagram and the emphasis on logic function.

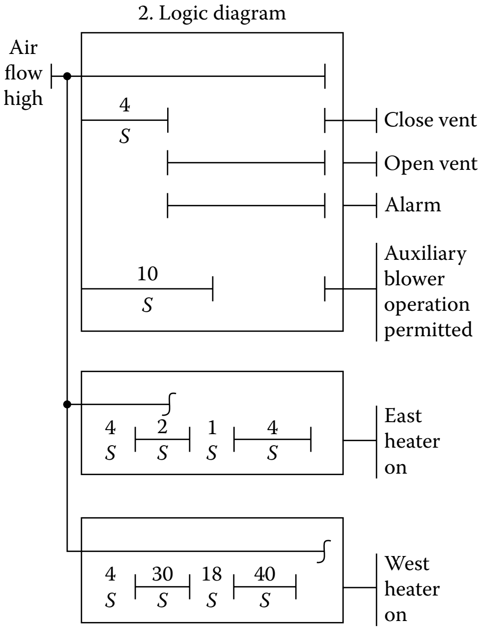


FIG. 5.1d
Logic diagram equivalent of the "word description."

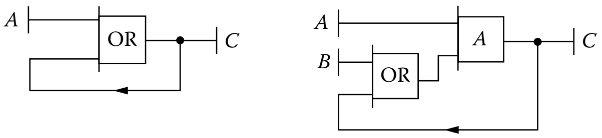

FIG. 5.1e
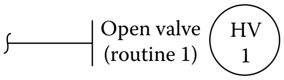
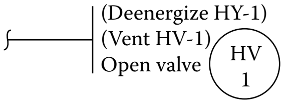
This symbology is not recommended to be used for depicting memory loss due to power supply failure.

3. The logic diagram emphasizes the operating logic of the process by not detailing the system mechanism for opening and closing the control valves. Thus, this information is provided by means of Routine 1, which may apply to similar hardware of an entire project as well as to Interlock 1. However, if it is desired to make the diagram more self-contained by including hardware functions, this can be done as follows, using an excerpt from the diagram as an example:



Alternative:



APPENDIX B: COMPLEX TIME-ELEMENT EXAMPLE

B.1 Word Description

For an illustration of the logic equivalent of the word description (Figure 5.1d), assume a process operation, as follows:

If air flow becomes high and is so sustained for 4 seconds, then open vent, actuate alarm, and initiate heating by east and west heaters. If heating by east heater is initiated, the heater goes on for 2 seconds, off for 1 second, and on again for 4 seconds, regardless of whether the air flow remains high while this is occurring. If heating by west heater is initiated, then heater goes on for 20 seconds, off for 18 seconds, and on for 40 seconds, but only if the air flow remains high while this is occurring.

If high flow of air is sustained for 10 seconds, stop the auxiliary blower if it is running.

When air flow is no longer high, close the vent and permit the auxiliary blower to be restarted and the alarm to be reset.

APPENDIX C: LOSS OF POWER SUPPLY FOR MEMORY

There are no symbols in the new Table 5.1a from Draft 4 of the new proposed Standard to indicate how to symbolize memories that are lost in the event of loss of power supply. The use of a logic feedback to symbolize a memory is deprecated. Thus, the symbolisms shown in Figure 5.1e shall not be used:

5.2 Ladder Diagrams

R. A. GILBERT (1985) **W. P. DURDEN** (1995, 2005)

INTRODUCTION

Ladder diagrams are one of the traditional methods for describing logic control circuits, whether they are electrical, pneumatic, or hydraulic. Ladder diagrams sometimes are referred to as elementary diagrams or schematics. They are called so because of the vertical power rails and the horizontal rungs that are individual parallel circuits between the common power rails.

For the purpose of this discussion electrical symbols will be used. Boolean logic is used in these diagrams to represent switch and relay contacts. The basic ladder diagram symbols that are used in electrical ladder diagrams are described in this section. Also presented are examples that illustrate the connection between the process and the ladder diagram and that indicate the procedure for analyzing a ladder diagram to determine its control functions.

For the standard that describes the binary logic symbols and diagrams recommended by the Instrument Society of America, refer to Section 5.1. The ISA standard compiled for ladder diagrams and other process logic depictions is ISA-5.2-1976 (R1992), "Binary Logic Diagrams for Process Operations."

LADDER DIAGRAM SYMBOLS

Figure 5.2a describes a few of the common symbols that are used in ladder diagrams and will be discussed in this section. The top row of the symbols in this figure include two manually operated pushbuttons (P.B.s) and a selector switch.

In the symbol for the three-position, two-pole selector switch, "X" represents the closed and "O" represents the open state. The "XOO" notation adjacent to the first level (top) of the selector switch represents the states of the switch contact in each of the three selector switch positions. The multiple lines from the top of the switch show the number of positions the switch can take, and the line that is drawn heavily represents the position that corresponds to the state drawn in the figure.

The second row in Figure 5.2a shows a coil, which can be that of a starter, a relay, or a solenoid coil (relays are discussed in Section 5.9). This symbol often includes a letter to describe the type of coil used. Also shown in the second row of the figure are the symbols for a Normally Open (NO) and a Normally Closed (NC) relay contact.

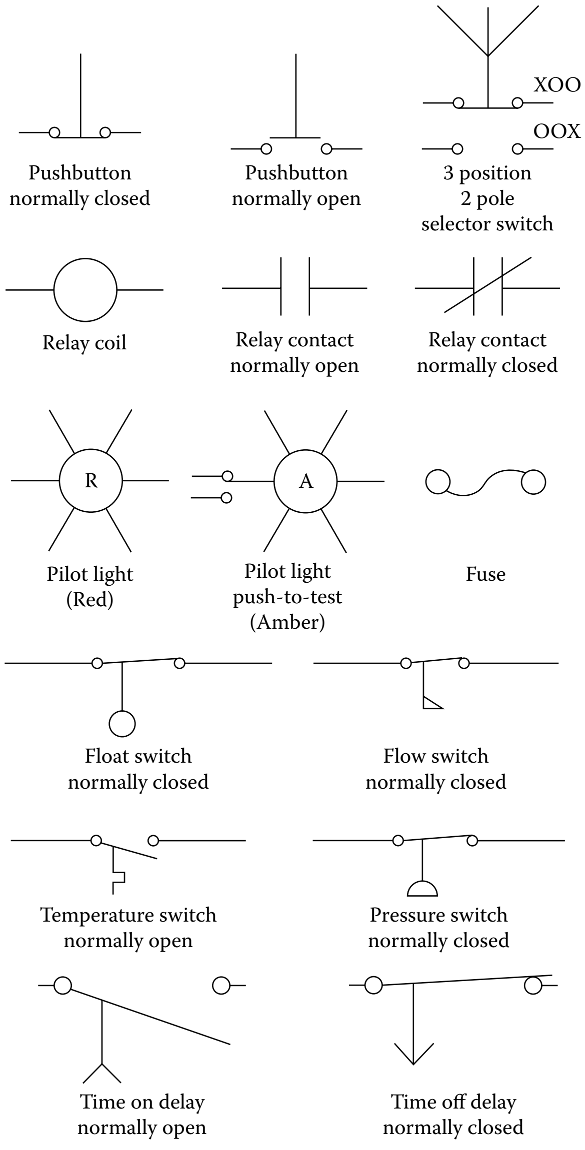

FIG. 5.2a
Sample of symbols used in ladder diagrams.

The third row shows two forms of a pilot or indicator light and a symbol for a fuse. The fourth and fifth rows describe switch contacts of level, flow, temperature, and pressure switches that are activated by the process. The last row depicts two time delay relay contacts, one normally open, the other normally closed. If the time delay is used to delay the turning on of a device, it has an arrow pointing into the contact (left), and if it serves to delay the turning off of a device, it has an arrow pointing away from the contact (right).

Although there are a great number of other ladder diagram symbols, the set presented here is sufficient to enable the reader to understand the drawings presented in this section.

The wires in the ladder diagram should be labeled with unique alphanumeric identifiers. The rule of labeling is that an electrically common point of a circuit that will never be switched or disconnected will carry the same label. A variation of the above rule is to have a single wire number for each continuous circuit, but added to this number is a "subnumber" (-#) that changes at each termination point. For example, in the wire labels *D*1-47-1 and *D*1-47-2, *D*1 is the loop or device number, 47 is the wire number, and 1 and 2 are electrically the same wire but are connected at a terminal block.

DEVELOPING A LADDER DIAGRAM

Figure 5.2b illustrates the automatic control of a pressurized water tank and the ladder diagram of its automatic control circuit. The figure shows a water storage tank, a pressurized water tank, a pump, and some level switches and other devices required to control the system.

The ladder diagram of the system illustrates a control circuit, which has both an automatic and a manual mode of operation. The stop P.B. is usually located near L_1 before any

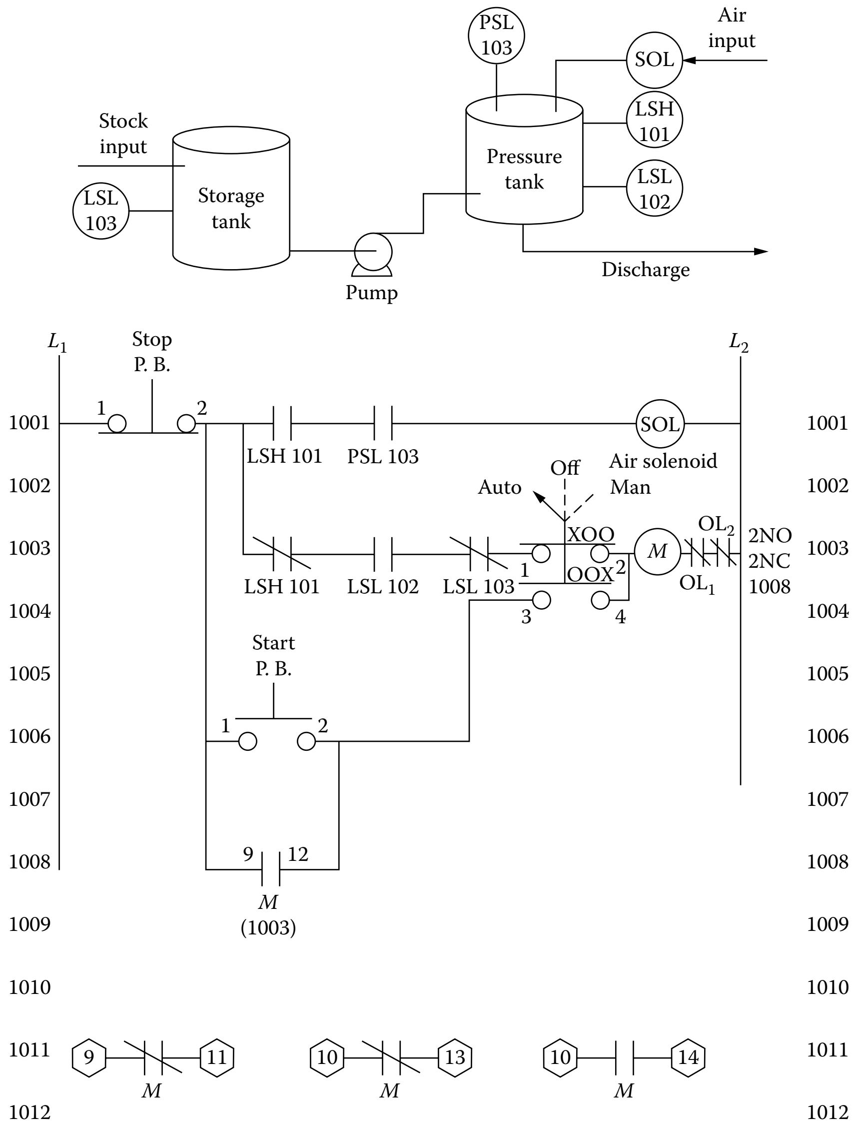

FIG. 5.2b
Automatic control of a pressurized water tank.

branches are added to the drawing. The manual control mode in this instance consists of only a start-and-stop pushbutton and the safety overload protection (OL_1 and OL_2) for the pump. These elements are shown in the ladder diagram and have been arranged so that the electrical connection from L_1 to L_2 will be made when the stop P.B. contact is closed, the start P.B. is pressed (contact closed), and the operating mode selector switch is in the "Auto" position.

L_1, on the left or power side of the ladder diagram, and L_2, on the right or neutral side, represent the power feed to the circuit. The normally open contacts (9 and 12), labeled "*M*," are activated (closed) when the pump relay is energized and keep the pump relay energized (engaged) even after the start P.B. has been released and therefore contacts 1 and 2 are open. This circuit is called a seal-in or latching circuit.

The common terminology for relay contacts is NO (Normally Open or Form *A*) and NC (Normally Closed or Form *B*). *A* Form *C* relay is one where the common power supply is connected to both an NO and an NC set of contacts. Refer to Section 5.9 for a more thorough description.

Automatic Mode of Operation

In the control system there is a high- and a low-level switch (LSH-101 and LSL-102) on the pressurized tank and a low-level switch (LSL-103) on the water storage tank. In addition there is a low-pressure switch (PSL-103) on the pressurized water tank. In preparing the ladder diagram for the corresponding control system, one should make sure that the water pump will be energized only when each of the control constraints have been satisfied and the electrical path from L_1 through the pump starter relay to L_2 has been completed.

The automatic portion of this water control circuit is presented in the top half of the ladder diagram in Figure 5.2b. In this control circuit, the electrical connection between L_1 and L_2 will only be made if the switch contacts shown in the figure are closed.

The high-level switch on the pressure tank (LSH-101) has two sets of contacts: a normally open set to control the operation of the air solenoid and a normally closed set to provide a limit condition for pump operation. The pump can only operate if, in addition to the level not being high (the NC LSH-101 contacts closed), the level is not low in the storage tank (the NC LSL-103 contact is closed) and the level is low in the pressurized tank (the NO LSL-102 contacts are closed). The pump starter coil will, therefore, be energized when the water level is low in the pressurized tank but will be deactivated (the pump will be stopped) when the water level is low in the storage tank.

This configuration will both protect the pump and maintain the pressure in the pressurized tank. To keep the water supply pump running, once the level in the pressurized tank drops to the low level switch (the NO contacts of LSL-102 are momentarily closed), an interlock with a set of pump relay contacts must be provided. The normally open contacts (9 and 12), labeled "M," are activated (closed) when the pump relay is energized, and they keep the pump relay energized (engaged) even after the level in the pressurized tank is no longer low (the NO contact of LSL-102 is open).

In Figure 5.2b the mode selection switch is placed near the starter relay and the normally closed contacts of LSL-103 and LSH-101 are placed in series with the normally open LSL-102 contacts. As it was the case in the manual mode of operation, a set of normally open starter relay contacts (9 and 12) ensure that the starter relay remains energized when the liquid level rises above the minimum set by LSL-102, but remains below the maximum set by LSH-101. Therefore, LSH 101 disengages (de-energizes) the relay when the level in the pressurized tank reaches its high set point.

When the NO contacts of this high water level switch (LSH-101) close, that will energize (open) the air solenoid, if the tank pressure is also below the setting of PSL-103 and therefore the NO contacts of that switch are closed.

SUMMARY

In summary, the steps required in developing a ladder diagram for a process control system include (1) to review the possible process conditions and the responses required, (2) to select the various switches and other control elements that can accomplish these required tasks, and (3) to arrange the system components in a sequential fashion between the voltage lines of the ladder diagram.

When the required response to a momentary condition is to latch in the state of operation, interlock contacts should be provided around start pushbuttons and other momentary contacts. Stop pushbuttons and other safety interlock contacts should be arranged so that they are electrically close to the source voltage line.

Each component of the drawing should be labeled by the same tag number that is used for the corresponding actual device in the process. Particular attention should be paid to identifying all of the contact sets of a specific relay coil. Finally, all automatic contacts of all switches and other actuating devices should be shown in a state (normally open or closed) that will exist when the device is in a de-energized (idle or inactive) state.

LADDER DIAGRAM ANALYSIS

The basic procedure for the analysis of a control circuit ladder diagram is to consider the diagram one component at a time and to decide what will happen if a pushbutton contact is closed or a switch contact is opened. If the ladder diagram is reviewed from this point of view, it will be noted that such contact activity usually closes or opens complete circuits and then a particular coil will be energized or de-energized, depending on the continuity of the circuit.

When the circuit is complete to any particular coil, that contactor, relay, or starter will be energized and the state of its contacts will be the opposite to its normal, de-energized position. If they are normally closed contacts, they will now be open, and if they are normally open, they will be closed.

When a time delay relay is used in the circuit, its contacts are opened or closed after some delay. If relays are used in the circuit, it is important to consider every contact that is operated by that relay whenever the coil is energized. Failure to consider all contact sets of a relay will result in a misconception of the function of the circuit. Finally, when analyzing a circuit, one should be certain that every component is considered in both its de-energized (normal) and energized position so that the whole operation of the complete circuit can be comprehended.

START-UP AND SHUTDOWN

In the design of a complex ladder logic it is very important to consider power-up and power-down sequences. In an electrical circuit the start-up and the shutdown are the times when strange and undesirable conditions can evolve. Typically, on power-up, if a circuit has a normally closed contact, this contact could cause a motor to start before it should, due to the dynamics of the circuit.

On the other hand, if there is a normally open circuit that prevents a device from running, this could prevent the device from ever starting unless manually started the first time. Also, when time delay relays are used, the circuit could be "locked out" until the time has elapsed and the relay has either energized or de-energized. This delay can be either intentional or unintentional.

Dynamic Breaking of a Motor

The ladder diagram of a motor's dynamic breaking circuit is shown in Figure 5.2c. This diagram can be reviewed by using the ladder diagram analysis procedures presented in this section. The example also provides insight into the concept of dynamic braking.

Dynamic braking can be applied to any equipment when a smooth, fast stop is required or when it is desired to prevent the manual rotation of the motor shaft when the power is disconnected. A dynamic braking system provides a stop without any tendency to reverse and it also produces less shock to motor drive components than does plug stop braking.

In a dynamic braking system, a DC voltage is applied to the rotating motor to provide a smooth but positive braking action and to bring the motor to a rapid stop. The DC signal is removed when the motor is almost stopped to prevent any motor winding damage caused by overheating as a result of excessive current flow in the low-resistance windings.

The diode rectifier element that produces the DC voltage is shown in the lower portion of the ladder diagram in Figure 5.2c. This part of the diagram also shows that the rectifier is isolated from motor terminals T_1 and T_3 by two sets of normally open brake coil contacts, *B*. There are also two sets of normally open brake contacts that isolate the primary side of the transformer from power lines L_1 and L_2. The fifth contact controlled by the brake coil is a normally closed set that is in series with the motor relay coil and the start pushbutton.

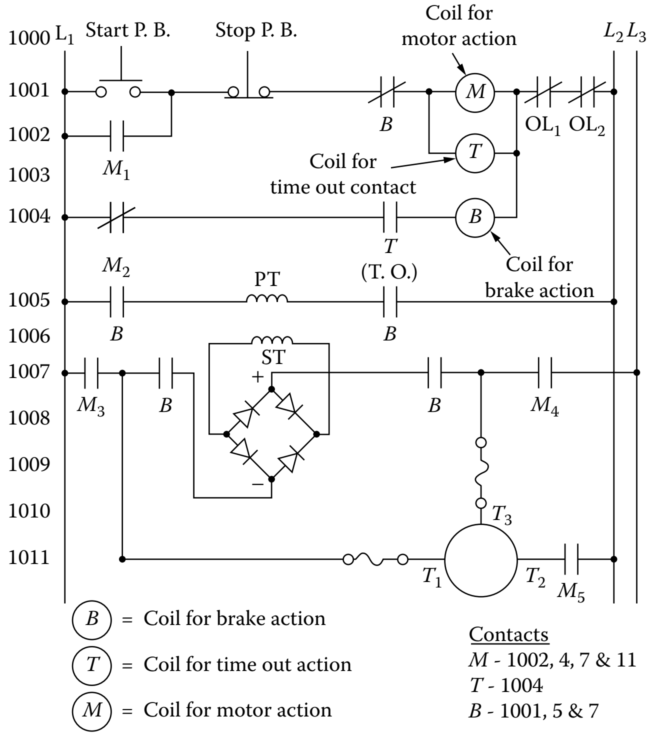

FIG. 5.2c
Ladder of a motor diagram for a dynamic braking circuit.

If the motor start P.B. is depressed (provided that the safety overload contacts are closed) and the stop P.B. is not also depressed, then the motor relay coil is engaged and the five sets of motor relay contacts are activated. The first of these motor relay contacts, M_1, is illustrated in the top horizontal line of the ladder diagram. This normally open contact closes when the coil is energized to guarantee that the coil remains hot even after the start P.B. is released.

The second motor contact set, M_2, which is located on the drawing just below the first, is normally closed but is opened on motor coil activation to prevent the brake coil from receiving the L_1 signal. It should be noted that the normally open time-out contact, *T*, is closed because the time-out relay is also energized when the motor coil is active. The last three normally open motor contact sets are connected to the motor terminals and, when closed, provide a connection from the power lines to the three motor terminals.

The braking portion of the ladder diagram includes symbols for the brake relay, the time-out relay, the rectifier, the primary and secondary transformer elements, and the five brake contact sets. Figure 5.2c indicates that motor terminals T_1 and T_3 are connected to the DC terminals of the rectifier when the stop P.B. is pressed. When the stop P.B. is engaged, the motor relay is deactivated, the motor is isolated from the

AC lines, the time-out relay is dropped from the circuit, and the brake contacts are all activated.

The brake relay is energized because M_2 has returned to its idle state and the time-out contact, *T*, remains closed for the time-out period. Thus, the activated brake coil keeps the four normally open *B* contacts associated with the transformer and the rectifier closed until the time delay relay has timed out to force *T* to its normally open position. The actual time-out period is determined as a function of the time needed to bring the motor to a near stop.

FAIL-SAFE DESIGN

Another consideration in ladder design is the "what-if" aspect. What if a wire breaks or vibrates loose? Will an alarm condition occur that will go unnoticed because the alarm indicator never receives power, or will the alarm indicator become energized as a "default"? This part of the ladder diagram design is one of the most difficult to grasp. It can become a tail chasing the dog problem.

The general guiding rule is this question, "Which situation is worse, more catastrophic, or potentially life treating?" If an alarm is initiated when either the process is in alarm or when the alarm circuit has failed, that would be better than having a pumps seal water flow switch go into alarm but not realizing it until the motor bearings overheat and seize. This may require an additional relay, or a time delay relay, but the protection of safety and capital equipment will normally far outweigh any cost increase.

DOCUMENTATION

As in any design, good documentation is important. Several things can be done to allow for easier troubleshooting and for thorough documenting of design. Simple ladder diagrams as shown in the examples do not require any additional steps, but complicated diagrams do. The first thing that can be done is to run a number string down the side of the neutral and power side of the diagram with a number corresponding to each line space, whether a rung exists there or not. In other words, if rung spacing is every 0.75 in., the spacing (placement) of the numbers would also be 0.75 in.

To use these numbers, make note of the location of the use of each contact of a relay beside the coil location. This allows easier analysis of the logical use of the coil's activation. Second, it is good practice to note how many normally open and normally closed contacts are available on all coils. This enables the designer to know if there are any spare contacts available for modifications to the design.

Third, mark the terminal numbers for each contact or coil as well as any unused contacts. The unused contacts should be shown at the bottom of the rung column where the coil is used. This completely documents the circuit and the use of the components in it. Uniquely label each electrically common point in the diagram. These labels will be used on the wires in the physical circuit.

CONCLUSIONS

In summary, the proper procedure for ladder diagram analysis is to consider the circuit one component at a time and to decide what happens to the component when a contact is closed. In this process, one should determine the function of each component in its de-energized (normal) and energized positions and, finally, one should review the role of each component in relation to the other elements in the system.

It is important to perform a complete analysis of the diagram without jumping to conclusions halfway through the analysis. A hurried analysis can be disastrous, because the action of just one additional contact set can easily change the response or the basic nature of the circuit.

5.3 Optimization of Logic Circuits

P. M. KINTNER (1970) **R. A. GILBERT** (1985, 1995, 2005)

Instrumentation and controls is an engineering discipline, expertise, and practice that relies heavily on information presented in P&ID function, and circuit diagrams. An interesting but challenging aspect of function and circuit diagrams is the fact that the logic circuits depicted have often been optimized. Process control loop element cost and assembly drive this optimization. Since logic simplification always means less hardware, circuits that are less expensive and more reliable, and simpler circuits for troubleshooting, new control scheme circuit designers are encouraged to expand their knowledge in this area beyond the introductory material presented here.

Extensive optimization accents the need for two skills. Today, most personnel involved in instrumentation and controls comprehend optimized function diagrams and, to some extent, create optimized logic circuits. This section presents the building blocks for the optimization of basic function diagrams. The section begins with a brief review of logic elements and the impact of the inversion operator on logic functions.

Classically, the design and optimization of logic circuits have centered on the synthesis of switching element (static or relay-type) interconnections that will satisfy the switching functions required by the process. With the development of computer control there is an increased need for instrument and control engineers who understand and can apply logic techniques for process control. In addition, new computer-aided design software produces function diagrams equivalent but not visually similar to the initial design idea. The ability to recognize this equivalency is essential to avoid lost time, energy, and money altering something that does not need to be altered. This awareness begins with a sound appreciation of the fundamental building blocks.

OPTIMIZATION BUILDING BLOCKS

The basic logic components and operations are straightforward and have their origins in ancient Greek philosophy. Modern engineering uses of logic expand the application of the AND, NAND, OR, and NOR operations to decision making—e.g., whether equipment is to be turned on or off, a voltage level is to be high or low, or a valve is to be opened or closed. Figure 5.3a illustrates these four cornerstone operations with respective truth tables.

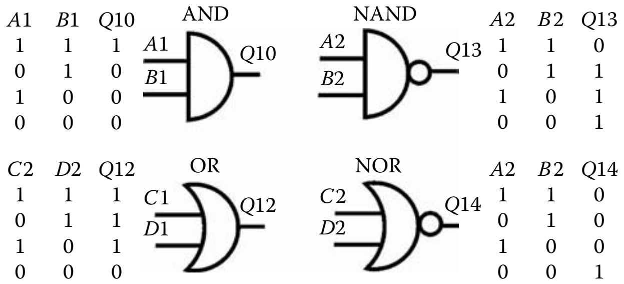

FIG. 5.3a
Summary of fundamental logic operations.

Equation 5.3(1) is a succinct statement of a control scheme that only permits a backup pump to engage if both the liquid level and tank pressure are below sensor alarm values.

$$Z0 = 1 \text{ only if LSL} = 1 \text{ and PSL} = 1 \qquad \textbf{5.3(1)}$$

This equation presents logic signals or logic variables, such as the ones into or out of logic switching elements, as alphanumeric characters with possible values of "1" or "0." In this example, *Z*0 represents the pump, and LSL and PSL stand for level sense low and pressure sense low, respectively, and symbolize the low-level and low-pressure alarm status within the tank. Thus, LSL = 1 indicates the liquid has dropped below the low-level limit while PSL = 0 indicates that the pressure within the tank is above an established minimal value.

The AND symbol with its truth table in the upper left side of the Figure 5.3a also summarizes the idea presented in Equation 5.3(1). The reader must be comfortable with that fact and also recognize the unique properties of the other symbols in the figure. For example, the NOR is the only logic operation that provides a logic "0" when any of its inputs are at logic "1." The unique output situation for the NAND, also logic "0," occurs when all of its inputs are high, while the OR only goes to logic "0" when all its inputs are at logic "0."

Figure 5.3b provides a nonoptimized function diagram for an application that involves a timing requirement. The diagram presents two AND devices, one NAND device, and a 555 pulse-generating device. The circuit also has two inverter devices, shown as triangles with circles attached. Although the discussion of this diagram is delayed, it does provide a segue to review the properties of the inverter.

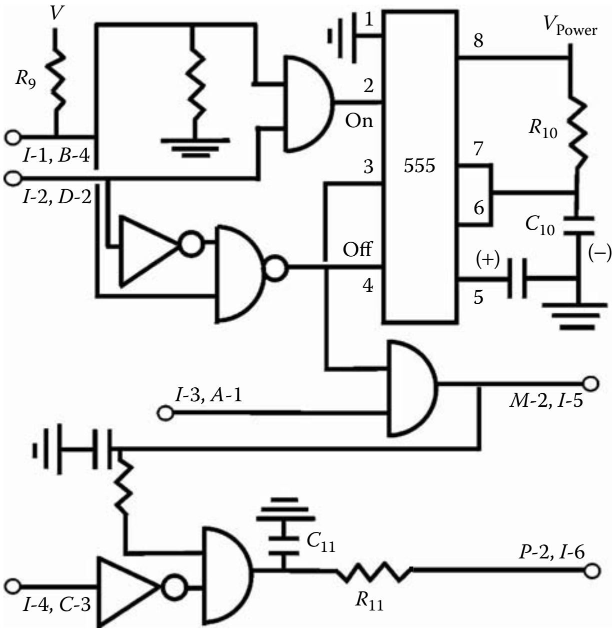

FIG. 5.3b
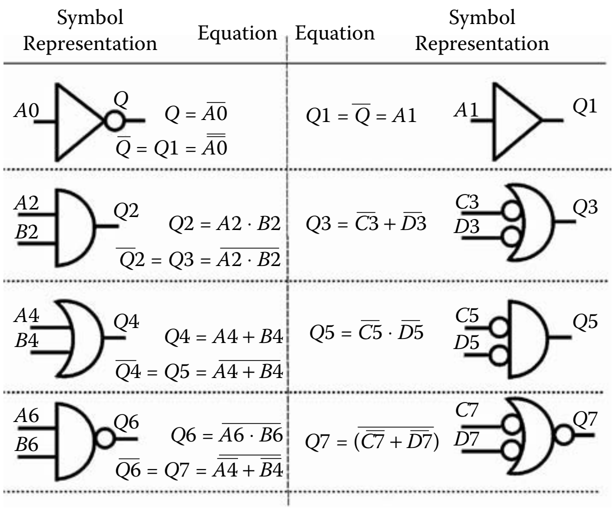
Nonoptimized logic circuit application.

The inverter is a circuit element that performs the inversion operation. This mathematical operator is often known as the NOT, and the top left section of Figure 5.3c provides its symbolic as well as mathematical representation. The value of the input variable, $A0$ in this case, is inverted and expressed as the variable Q. The line, or bar, over the $A0$ is a visual reminder that if $A0$ is at logic "1," then output Q will be at logic "0." Thus, the NOT operation is merely the inverse of the current value of the input variable; i.e., if $A0 = 0$, then Q will equal 1 after the NOT operation.



Q1 is the inverse of Q
Q5 is the inverse of Q4

Q3 is the inverse of Q2
Q7 is the inverse of Q6

FIG. 5.3c
Logic function negation examples.

The inversion operation can also be performed on sets or subsets of logic variables. For example,

$$Z1 = \overline{(A \cdot B) + (C \cdot D)} \qquad \textbf{5.3(2)}$$

is an extremely succinct method of stating that two outputs from two AND operations based on variables (A, B and C, D, respectively) are the inputs to an OR operation; the results of this are inverted to provide a value for the variable $Z1$. The reader should confirm that Equation 5.3(2) is fundamentally a NOR idea because the only way $Z1$ can be at logic "1" is when the results of both AND operations are "0."

The mathematics of logic circuit optimization involves the use of the inversion (negation) operation. Figure 5.3c summarizes the results when the negation (inversion) operation is performed on a set of basic logic operations. The figure is vertically divided, with the results of the negation shown to the right of the dashed line. For example, the symbol and equation for an inverter are presented as the top left entry in the diagram. If a negation is performed on output variable Q, the resulting symbol, a triangle without an attached circle, and the equality, $Q1 = A1$, are shown on the right. Now $Q1$ also equals $A0$ and $Q1$ is the inverse of Q. Although this is an obvious result, the other examples suggest why inversion can appear to be confusing.

The symbol and equation on the bottom left side of Figure 5.3c represent the NAND operator. A review of the AND and NAND truth tables in the top row of Figure 5.3a indicates that the inverse of the NAND is an AND. However, the symbol in the bottom right section of Figure 5.3c does not match the AND symbol in Figure 5.3a. This is not a mistake, discrepancy, or deception but recognition that even though there is more than one way to symbolize the results of an inversion, the truth table results are identical. The value of $Q7$ is the inverse of $Q6$. Likewise, the symbol to the right of the AND symbol in the second row of Figure 5.3c is equivalent to a NAND symbol, and the value of $Q3$ is always the inverse of $Q2$. The reader should develop the truth table for the equation for $Q5$ on the right side of the third row of the figure to confirm that the complex logic symbol associated with $Q5$ also represents a NOR, with its equivalent truth table presented in Figure 5.3a.

Figure 5.3d summarizes the results if an additional negation is performed.

The operational principle is the fact that two cascaded inversions cancel, because this amounts to a double negation. Stated in symbolic form

$$\overline{\overline{A}} = A \qquad \textbf{5.3(3)}$$

where it is indicated that the logic signal A has been inverted twice, returning it to its original value. The progression of

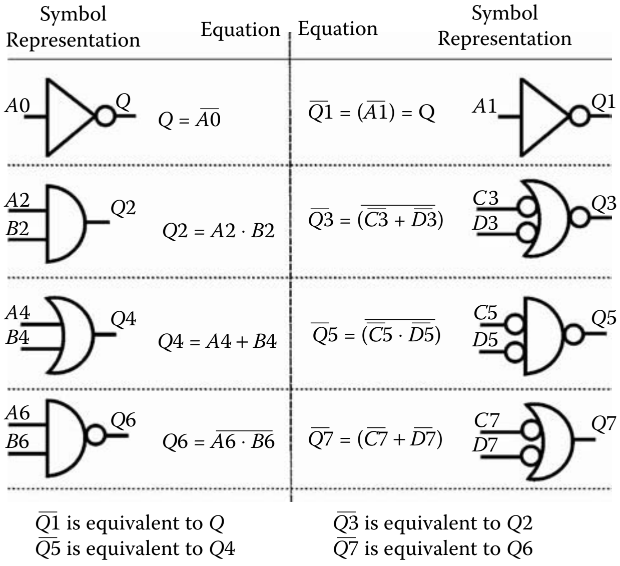


FIG. 5.3d

Examples of cascaded negation logic operations (DeMorgan equivalent circuits).

negations from left to right in the first row of Figure 5.3c and then in the right side of the first row of Figure 5.3d also illustrates this double negation effect. The inverter output variable, $Q1$, shown in Figure 5.3c is the inverse of Q, while the subsequent inversion of $Q1$ in Figure 5.3d returns the value of $Q1$ to the original Q value state. Following the same presentation pattern, the reader should confirm that the remaining three logic functions illustrated on the right side of Figure 5.3d are identical to the respective AND, OR, and NAND in the left portion of the corresponding row of Figures 5.3c and 5.3d.

As an instructional example of how a double inversion cascade is performed, consider Equation 5.3(4).

$$Z2 = (A \cdot B) + (C \cdot D) \qquad \textbf{5.3(4)}$$

A single inversion of Equation 5.3(4) can certainly be represented as Equation 5.3(2), where $Z1$ is the inverse of $Z2$. However, the expression on the right side of Equation 5.3(2) is not the only possible representation. To develop an addition equivalent logic statement, the inversion of every input signal and simultaneous interchange of the AND and OR operations (DeMorgan's theorem) is performed on Equation 5.3(2). Equation 5.3(5) summarizes these operations as

$$Z1 = \overline{Z2} = (\bar{A} + \bar{B}) \cdot (\bar{C} + \bar{D}) \qquad \textbf{5.3(5)}$$

Following this same set of rules, the second inversion is performed on $Z1$ to return to Equation 5.3(4). In this case, the individual inversion symbols above variables A, B, C, and D are removed, and the OR operation within each parenthesis becomes an AND operation, while the AND operation that separates the parentheses now becomes an OR operation.

This cascade inversion process can be used to obtain equivalent forms of both the NOR operation

$$\overline{A + B} = \bar{A} \cdot \bar{B} \qquad \textbf{5.3(6)}$$

and the NAND operation

$$\overline{A \cdot B} = \overline{\overline{\bar{A} + \bar{B}}} = \bar{A} + \bar{B} \qquad \textbf{5.3(7)}$$

The respective left and right sides of Equation 5.3(6) and Equation 5.3(7) are called DeMorgan equivalents. The right side of Figure 5.3d shows the DeMorgan equivalent symbols for the NAND as well as the OR, AND, and the inverter. Because the inverter only has a single input, the DeMorgan equivalent for the inverter is sometimes depicted as a triangle with the circle moved to its input side. Although the DeMorgan equivalent for the NOR is not included in Figure 5.3d, the reader, after re-examination of Figure 5.3c, should realize that the NOR equivalent symbol is associated with variable $Q5$.

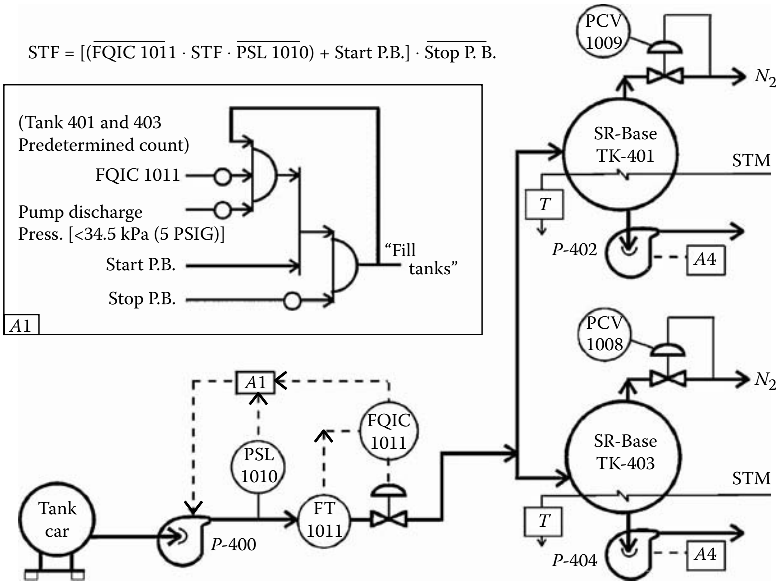
Graphic Logic Functions

Control logic schemes are mathematical relationships between input and output variables that can be represented graphically through logic diagrams. Figure 5.3e illustrates a chemical storage and filling station. The figure provides a description of the tank filling process from three distinct perspectives. The equation at the top of the diagram connects the storage tank fill (STF) operation to all of the variables affecting that filling step. The P&ID diagram provides the visual details of the interconnections among the equipment, sensors, and actuators. The panel in the center left portion of the figure presents the function diagram that emphasizes the seal-in action included in the control scheme.

A good way to appreciate the utility of logic diagrams and the complication optimization can create is to review Figure 5.3e. The example illustrates the tank section for a chemical process. The drawing shows three pumps (equipment 400, 402, and 404), a low-pressure sensor (PSL 1010), two pressure control valves (PCV 1008 and 1009), and a flow quantity indicator and controller (FQIC 1011). For simplicity, consider the filling operation for this system because it involves only one pump and two control elements, PSL 1010 and FQIC 1011. In this example it will be assumed that the logic function for this part of the operation is

$$\begin{aligned} STF = {} & ((\overline{FQIC\,1011} \cdot STF \cdot \overline{PSL\,1010}) \\ & + START\ P.B.) \cdot \overline{STOP\ P.B.} \end{aligned} \qquad \textbf{5.3(8)}$$

where START P.B. and STOP P.B. are the variables assigned to the start and stop pushbuttons in the system and STF is the variable associated with the operation of the pump. STF



$$STF = [(\overline{FQIC\ 1011} \cdot STF \cdot \overline{PSL\ 1010}) + Start\ P.B.] \cdot \overline{Stop\ P.\ B.}$$

FIG. 5.3e
Chemical storage and tank filling station.

equals "1" when the pump is on and has a value of "0" when the pump is off. Although Equation 5.3(8) is accurate, it is difficult to comprehend, particularly because the output variable, STF, appears on both sides of the equation. Such implicit logic functions are common and are best interpreted by use of a logic diagram.

The panel in Figure 5.3e is the logic diagram for the storage tank fill system. The drawing uses a second graphic symbol convention common to industrial applications. A three-input AND, a two-input AND, a two-input OR, and three inversion operations are illustrated in the figure. The inversions are represented by the three circles; the OR symbol is the short vertical line in the center of the drawing.

As suggested above, this logic diagram is not as complex looking as Equation 5.3(8). Variable STF is present twice in the equation because of the safety interlock for the stop pushbutton. In addition, the diagram clearly shows that for this specific example, once the pump is running, the pump will not continue to function if the pressure sensor is in alarm OR the predetermined count has been obtained OR the stop action has been initiated.

Ladder Diagrams from Logic Diagrams

Although some form of ladder logic language is often used to program a programmable logic controller (see Section 5.2), the logic diagram is still a very popular way to illustrate the target control scheme. Figure 5.3f presents a logic diagram and ladder program for the pump station illustrated in Figure 5.3e. A review of these two drawings illuminates the procedure for interchanging ladder diagram elements with logic diagram elements.

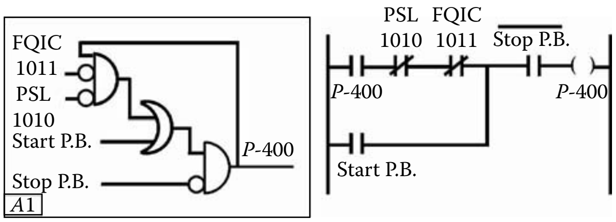


FIG. 5.3f
Function diagram and ladder logic program for tank filling station.

The three features of a ladder diagram to be considered are the serial, parallel, and interlock portions. The serially arranged elements in the ladder diagram are used as inputs to an AND operation in the logic diagram. The parallel components of ladder diagrams become inputs to OR operations in logic diagrams. Thus, for the present example, the serially arranged elements (FQIC 1011, PSL 1010, and P-400) in the ladder program reflect the three inputs to the AND operation shown in the top left section of plate *A*1, while the START P.B. in the parallel rung reflects the OR operation. Finally, the interlock or seal-in is accomplished by associating the ladder program output variable, P-400, with the AND operation.

OPTIMIZED LOGIC CIRCUIT CONSTRUCTION

In general, logic diagrams are useful tools for the instrument engineer to use in debugging logic functions and circuits. These function diagrams indicate the role of the digital variables and the priority each variable may have. In Figure 5.3g,

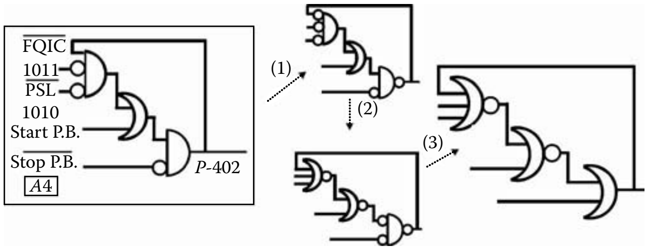

FIG. 5.3g
Visualization of circuit optimization process.

for example, it is clear that the stop action shown in plate A4 has the highest priority over the other three input variables depicted. This same message is shown in the ladder diagram as well. The stop action will occur no matter what the logic states of the other variables are. The confusion might develop when the function diagram reflects the optimized logic circuit instead of an original control scheme motivated diagram. The former diagram is accurate and useful from an electrical engineering standpoint but might not easily reflect the intended control function of the circuit.

This situation is demonstrated with two examples. In the first example, the function diagram on the side of Figure 5.3g reflects a control scheme for pump 402 that is graphically transformed into an optimized form, shown on the right side of the figure. The initial diagram includes two AND devices, an OR device, and three inverters, while the optimized version of the same control circuit is constructed from three OR devices and two inverters. The actual circuit would be easily constructed from the optimized function diagram but the recognition that the stop action overrides all the other variables is not immediately obvious. The second example returns to Figure 5.3b. The details for this circuit are provided in Section 5.10, and the optimized version of this circuit is presented in that section as Figure 5.10g. Again, the optimization focus was to reduce the number of devices needed to accomplish the task. In this case, the control circuit is TTL based (see Section 5.10), and it can be constructed with two TTL packages, 7400 and 7404, in its optimized form instead of three packages, 7408, 7400, and 7404, as dictated by the function diagram presented in Figure 5.3b.

Logic Circuit Synthesis

The optimization of a complex logic function demands mastery of logic circuit synthesis methods. Comfort level with and interpretation of these complex logic functions require knowledge and use of these same tools. Maxterm, minterm, Boolean algebra, and logic maps are popular examples of logic circuit synthesis tools.

The minterm and maxterm are two special functions used in logic circuit development and analysis. As a facilitating example, consider a complex logic function that has the truth table summarized as Equation 5.3(9). As this truth table suggests, logic "1" is the

LSH	*PSH*	*Z*3
1	1	0
0	1	0
0	0	0
1	0	1

5.3(9)

unique output for the logic function but this output is not the result of an AND or an OR logic function. It will be some combination of the AND, OR, and inverter logic operations such that when LSH and PSH are both active the output of the logic function is at logic "1."

The minterm for this system is developed from the row in the table in which there is a "1" in the output column. In general, a minterm is generated in a two-step fashion. First, an AND operation links the elements on the row where the output "1" appeared. Second, all of the inputs in this row that have "0" indicate the variables that have a NOT operation applied to them. For this example, the last row of the truth table is the only minterm; it is defined by Equation 5.3(10):

$$Z3 = \overline{PSH} \cdot LSH \qquad \textbf{5.3(10)}$$

Note that the NOT operation is applied to variable PSH and that this variable has a value of "0" in the last row of the table.

The synthesis of complex functions using the maxterm is a process that is the inverse of that for the minterm. An OR operation is used, and those inputs with a "1" in the row where the "0" output appears have the NOT operation applied to them. When more than one maxterm exists, the logic function is synthesized through AND connections among these maxterms. (If multiple minterms were present, the complex logic function would be created by OR connections among the minterm contributions.) Thus, Equation 5.3(9) can also be expressed by the following logic function:

$$Z3 = (\overline{LSH} + \overline{PSH}) \cdot (LSH + \overline{PSH}) \cdot (LSH + PSH) \qquad \textbf{5.3(11)}$$

There are three separate maxterms in this equation, and they correspond to the first three rows of the truth table shown as Equation (tabulation) 5.3(9).

The synthesis of a complex logic function can also be accomplished using NAND operations that are based on the minterm procedure explained earlier. The procedure is to construct the minterm function as before and then to replace both the OR and the AND operations by NAND operations. For logic function synthesis with NOR operations, the maxterms are used, then the NOR operation replaces both the OR and the AND operations.

As an example of function synthesis with NAND operations, consider an alternate control scheme that still uses the

LSH and PSH limit sensors. This modification is summarized as follows:

LSH	*PSH*	*Z5*
1	1	0
0	1	0
0	0	1
1	0	1

5.3(12)

where the third row of the table now reflects the modification in the desired operation of the final control element associated with Z5; i.e., this element is now also active when LSH = 0 and PSH = 0. The logic function for this new system is

$$Z5 = (\overline{LSH} \cdot \overline{PSH}) + (LSH \cdot \overline{PSH}) \qquad \textbf{5.3(13)}$$

where the first AND term represents the new minterm in the system. Now, following the procedures stated previously, the AND operations $(LSH \cdot PSH)$ and $(LSH \cdot PSH)$ are replaced by NAND operations. The OR operation is then also replaced by a NAND operation, to yield the final NAND synthesized function

$$Z5 = \overline{\overline{(\overline{LSH} \cdot \overline{PSH})} \cdot \overline{(LSH \cdot \overline{PSH})}} \qquad \textbf{5.3(14)}$$

Equation 5.3(14) can be manipulated further, with one option being an overall NAND of two OR functions, one of which is just $(LSH + PSH)$.

Logic Simplification with Boolean Algebra

Boolean algebra is the class of mathematics used to manipulate logic expressions. The maxterm and minterm circuit synthesis methods outlined above are based on Boolean algebra theorems. A few of these theorems are given below as examples. These particular theorems are easy to remember, because they parallel familiar arithmetic and conventional algebraic operations. They are also important to remember because they represent common algebra manipulations used to construct or comprehend optimized logic circuits.

The following are some examples of Boolean algebra equivalents:

$$1 \cdot A = A \qquad \textbf{5.3(15)}$$

$$0 \cdot A = 0 \qquad \textbf{5.3(16)}$$

$$1 + A = 1 \qquad \textbf{5.3(17)}$$

$$0 + A = A \qquad \textbf{5.3(18)}$$

$$\bar{A} + A = 1 \qquad \textbf{5.3(19)}$$

$$A + A = A \qquad \textbf{5.3(20)}$$

$$A \cdot B + A \cdot C = A \cdot (B + C) \qquad \textbf{5.3(21)}$$

To show the use of these relationships for logic simplification, consider the three input variables, $A4$, $B4$, C_4, and one output variable, $Z4$, expression defined by Equation (tabulation) 5.3(22):

$A4$	0101	0101
$B4$	0011	0011
C_4	0000	1111
$Z4$	0001	0001

5.3(22)

The numerical pattern arrangement of the possible input variable values in the table is by design. The numerical value for the column sum of the binary entries in each column of the table correspond to the numbers 0, 1, 2, 3, 4, 5, 6, and 7 when the top row, the $A4$ row, in the table is assigned the least significant bit place. Thus, the eight columns in the table clearly include all the possible three variable value patterns. Using the $Z4$ row of the table, the minterm expression for Equation 5.3(22) is

$$Z4 = A4 \cdot B4 \cdot \bar{C}_4 + A4 \cdot B4 \cdot C_4 \qquad \textbf{5.3(23)}$$

where the first and second logic functions are derived from column 4 and column 7, respectively. This term is examined to determine if it has an algebraic equivalent with fewer variables. For this illustrative example the sequence of steps is brief and to the point. If Equation 5.3(23) is "factored," Equation 5.3(24) results

$$Z4 = A4 \cdot B4(C + \bar{C}_4) \qquad \textbf{5.3(24)}$$

and Equation 5.3(24) then becomes

$$Z4 = A4 \cdot B4 \cdot 1 \qquad \textbf{5.3(25)}$$

It is clear that the expression for $Z4$ in Equation 5.3(25) is mathematically equivalent to the expression for $Z4$ in Equation 5.3(23) and that variable C is not needed.

Logic Simplification through Logic Maps

The synthesis of logic functions based on minterms or maxterms often produces functions that are unnecessarily complex. The comparison of the two equivalent expressions, Equation 5.3(10) and Equation 5.3(11), dramatically demonstrates this point. In this example, the minterm synthesis was more efficient, but in many cases the designer does not intuitively select the better synthesis route. Another problem common to Equation 5.3(11) and other complex functions is the possible presence of extra logic elements.

The existence of unnecessary inputs in a logic expression is called redundancy. Some cases of logic redundancy are easily seen by inspection of the logic function or logic table, as in the example just given. However, many cases of redundancy are difficult to recognize. A common tool used to find redundant terms is a method known as the logic map, or the Karnough map. The logic map consists of an array with entries corresponding to elements from a logic table.

As an example, consider the logic circuit described by Equation (tabulation) 5.3(22). For a three-input system, the table is first rearranged as presented in Equation (tabulation) 5.3(26):

$A4$	0011	0011
$B4$	0110	0110
C_4	0000	1111
$Z4$	0001	0001

5.3(26)

The numerical value for the column binary sums in Equation 5.3(26) are, from left to right, 0, 2, 3, 1, 4, 6, 7, and 5, respectively. The rules for the use of this pattern, or map, can be interpreted such that any detected square or rectangular pattern of logic "1" values indicates a possible logic variable redundancy. In this case, the redundancy can be removed if the variable C is removed from the set. Naturally, Karnough mapping has more table arrangement possibilities than shown above; however, computer programs are now available that will map all the possible column arrangements for any logic table size and identify the variables that are redundant candidates.

NEGATIVE VS. POSITIVE LOGIC USAGE

The graphic presentation of complex logic functions that describe the control of an industrial process is an essential aspect of a designer's responsibilities. Large process logic control schemes cannot be understood or maintained by the engineering support group unless a graphic version of the logic circuit is supplied. Once the designer has developed the logic circuit, removed the redundancies, and constructed the optimized circuit, a decision must be made to present the circuit graphically with positive or negative logic. The choice of logic is based on the purpose of the circuit and the general desire to explain the circuit graphically in a clear, concise fashion.

A positive logic circuit is one that illustrates logic elements that output "1"s as a result of the input of "1"s into the element. An AND is an example of a positive logic element. The only way an AND operation produces a "1" is when all of its input variables are "1." Logic functions described with AND as well as OR operations are considered positive logic functions. Conversely, negative logic circuits illustrate a logic function by using logic elements that require logic "0" values at inputs to produce logic "0" values at their outputs.

The distinction between and significance of positive and negative logic may be initially difficult to understand. The second row of Figure 5.3d presents one graphic example of positive and negative logic elements. As stated earlier, these two logic functions have the same logic table and illustrate the AND operation. It should also be clear from previous discussions that $Q2$ has the unique value of "1" only if $A2$ and $B2$ also have a value of "1." (All other combinations of values for $A2$ and $B2$ result in a value of "0.")

The values of $Q3$ do not seem as simple to understand when viewed from a positive logic perspective. The addition of the three inversion circles complicates our thought process when we attempt to determine the output logic of the drawing associated with $Q3$. However, this logic function is easily interpreted from a negative logic perspective; i.e., output variable $Q3$ has a value of "0" when either input C3 or input D3 has a value of "0." (The remaining combination of values for C3 and D3 results in a value of "1.")

The merit to negative logic is that it facilitates the creation of control circuits for many real systems. For example, many alarm sensors are classified as active low sensors because they provide a low electrical signal when they indicate an alarm situation. Under these circumstances, it is convenient to assign the logic value of "0" to the sensor output when it provides a low electrical signal. Stop pushbuttons are another example of an active low input. If a stop button is pushed it provides the low signal while the button is engaged. Plate $A4$ in Figure 5.3g reflects this negative logic point of view and uses a bar over the appropriate variables to indicate an active low characteristic of the sensor or contact set in question.

SUMMARY

In any process environment, a major fraction of instrumentation and control personnel time and energy is spent keeping the process running. The quality of the logic circuit documentation and the ease in which it is interpreted contribute significantly to the reduction of the time spent on this task. Most process engineers develop control schemes but do not necessarily design control circuits.

However, they must be able to comprehend the control logic circuits that are provided, especially if the circuit has been optimized. To this extent, knowledge of circuit optimization and the various logic functions available to do the same logic task must be appreciated. Although this section has presented the fundamental tools used to create or comprehend optimized logic circuits, it is anticipated that most readers will most often use the skills for logic circuit comprehension.

Virtual optimization is one example where optimization skill is required even though no circuit is physically constructed. In these situations large logic control schemes are to be installed in a programmable controller or process computer. The optimization is performed to reduce the number of instructions, improve scan time, and diminish "debugging" efforts. In these situations documentation is extremely important because the final virtual circuit seldom has the appearance of the original logic scheme. Thus, it is a very good practice to provide function diagrams of both the virtual and original versions of the logic scheme.

INTRODUCTION

A programmable logic controller (PLC) is an industrially hardened computer-based unit that performs discrete or continuous control functions in a variety of processing plant and factory environments. Originally intended as relay replacement equipment for the automotive industry, the PLC is now used in virtually every industry imaginable. Though they were commonly referred to as PCs before 1980, PLC became the accepted abbreviation for programmable logic controllers, as the term "PC" became synonymous with personal computers in recent decades.

PLCs are produced and sold worldwide as stand-alone equipment by several major control equipment manufacturers. In addition, a variety of more specialized companies produce PLCs for original equipment manufacturer (OEM) applications.

Typically, PLC vendors can supply large volumes of application notes for their products. Most major PLC vendors also publish detailed articles about applications in technical journals and prepare papers for engineering societies and industrial symposia on control, automation, and so forth. Each manufacturer's software package usually has its own application programming techniques. Vendors also are a valuable source of "how-to" information, providing training courses in their local office or at the factory as well as actual hands-on experience to help users gain familiarity with the PLC. Most vendors offer an applications or programming manual that provides insight on how to use available programming features. Of course, familiarity with one brand of PLC generally helps the engineer learn to use other brands quickly.

HISTORY

The automotive industry fostered the development of the PLC primarily because of the massive rewiring required each time a model change occurred. Solid-state logic is much easier to change than relay panels, and this advantage was reflected in the cost of installing and operating PLCs instead of traditional relay systems. Table 5.4a lists some of the milestones in the development of PLCs. Table 5.4b provides a summary of the differences among various technologies that perform logic control.

Bedford Associates, the forerunner of Modicon, designed the first PLC in 1968 for the Hydramatic Division of General Motors Corporation to eliminate costly scrapping of assembly-line relays during model changeovers and to replace unreliable electromechanical relays. The objectives of the program were to:

- Extend the advantages of static circuits to 90% of the machines in the plant
- Reduce machine downtime related to controls problems
- Provide for future expansion
- Include full logic capabilities, except for data reduction functions[1]

Richard Morley, a Bedford engineer, is credited with the original PLC design and the creation of ladder logic programming.[2] Morley says the diagrams on which ladder logic is based, however, probably originated in Germany years before to describe relay circuitry.[3] Describing the technology of the day, Morley explains, "Automatic control of industrial metalworking and assembly operations in 1969 were mostly by relays and clock-driven electromechanical devices. Relays ran hot and tended to beat themselves to death with their persistent 60-cycle hum and contact arcings. Electromechanical timers/sequencers were much like enlarged music box mechanisms and were maintenance headaches."[4] Describing the early years of the PLC, Morley recounts, "We had some real problems in the early days of convincing people that a box of software, albeit cased in cast iron, could do the same thing as 50 feet of cabinets, associated relays, and wiring."

Morley recounted that in 1969, "all computers required a clean, air-conditioned environment, yet were still prone to frequent malfunctions. … Thus, even though PLCs were and are special, dedicated computers, considerable effort was made to not identify PLCs as computers due to the poor reliability of computers and the fact that they were not things procured

TABLE 5.4a

History of Programmable Logic Controller (PLCs)

1968	PLC designed for General Motors Corporation to eliminate costly scrapping of assembly-line relays during model changeovers.
1969	First commercial PLCs manufactured for automotive industry as electronic equivalent of relays.
1971	First application of PLCs outside the automotive industry.
1972	Allen-Bradley (AB) adds the first computer interface to its PLC, read-write controller, and off-line software documentation package.
1973	Introduction of "smart" PLCs for arithmetic operations, printer control, data move, matrix operations, CRT interface, etc.
1974	First CRT-based program panel for PLC.
1975	Introduction of analog proportional, integral, derivative (PID) control, which made possible the accessing of thermocouples, pressure sensors, etc. Allen-Bradley coins the PLC acronym.
1976	First use of PLCs in hierarchical configurations as part of an integrated manufacturing system. AB introduces Remote I/O.
1977	Introduction of PLCs based on microprocessor technology.
1978	PLCs gain wide acceptance; sales approach $80 million. USDATA introduced REACT, the industry's first microprocessor-based, user-configurable, interactive color graphics workstation for use with PLCs.[2]
1979	Integration of plant operation through a PLC communications system with AB's DataHighway.
1980	Introduction of intelligent input and output modules to provide high-speed, accurate control in positioning applications.
1981	IBM introduces PC/XT using DOS. Data highways enable users to interconnect many PLCs up to 15,000 feet from each other. More 16-bit PLCs become available. Color graphics CRTs are available from several suppliers.
1982	Larger PLCs with up to 8192 I/O become available.
1983	"Third-party" peripherals, including graphics CRTs, operators' interfaces, "smart" I/O networks, panel displays, and documentation packages, become available from many sources.
1985	IBM-PC programming terminal introduced. AB PLC-5/15 introduced with built-in RIO and peer-to-peer DH+ directly on processor card.[6] Intellution introduces the FIX software, the first DOS-based process control system for IBM PCs.[2,5]
1986	Various other PC HMI software introduced.
1990	Wonderware introduces InTouch, the first MS Windows-based HMI application, and starts a major transition to Windows-based "open" technology.[2,5]
1991	Small (Brick) PLCs enter the market place.
1992	Networked block I/O developed. Moore Products manufactures APACS, the first control system using IEC 1131-3 standard allowing DCS function blocks, PLC ladder, sequential function chart, and structured text to be used and combined within a single controller.[2]
1993	Ethernet and TCP/IP connectivity appear on PLCs.
1994	AB launches DeviceNet, an open device-level network.

by manufacturing operations."[4] Unlike computers of that era, the programmable controller was designed to be reliable. Morley explains, "No fans were used, and outside air was not allowed to enter the system for fear of contamination and corrosion. Mentally, we had imagined the programmable controller being underneath a truck, in the open, and being driven around—driven around in Texas, driven around in Alaska. Under those circumstances, we wanted it to survive. The other requirement was that it stood on a pole, helping run a utility or a microwave station which was not climate controlled, and not serviced at all. Under those circumstances, would it work for the years that it was intended to be? Could it be walled in? Could it be bolted in a system that was expected to last 20 years?" Upon arriving for a client demonstration, the PLC was accidentally dropped on the floor. The client was surprised that not only did the PLC work perfectly, but that Modicon staff expected it to work after being dropped.[3]

Bedford Associates demonstrated the Modicon 084 solid-state sequential logic solver at GM in 1969.[5] The fundamental advantage that PLCs introduced was that they used programming rather than rewiring to configure for a new application. PLC programming could be done much quicker than the traditional rewiring methods. In addition, solid-state devices offered greater reliability, required less maintenance, and had a longer life than mechanical relays, all in a smaller footprint.[2,6]

The 1970s and 1980s were dominated by proprietary systems and software. Odo Struger, often called the father of Allen-Bradley's PLC, is credited with the PLC acronym.[5] The early

TABLE 5.4b
Cost Advantages over Relay

	Relays	*Solid-State Controls*	*Microprocessor*	*Minicomputer*	*PLCs*
Hardware cost	Low	Equal	Low	High	High to low, depending on number of controls
Versatility	Low	Low	Yes	Yes	Yes
Usability	Yes	Yes	No	No	Yes
Troubleshooting maintainability	Yes	No	No	No	Yes
Computer-compatible	No	No	Yes	Yes	Yes
Arithmetic capability	No	No	Yes	Yes	Yes
Information gathering	No	No	Yes	Yes	Yes
Industrial environment	Yes	No	No	No	Yes
Programming cost	(Wiring) High	(Wiring) High	Very high	High	Low
Reusable	No	No	Yes	Yes	Yes
Space required	Largest	Large	Small	OK	Small

1980s saw a cross pollination between PLCs and distributed control systems (DCSs). PLCs, for example, had already begun incorporating distributed control functions so they could be linked much in the way that DCSs were linked. Building on the trend, software companies sprang up in great numbers during this time.[2]

During the 90s, standardization and open systems were the main themes. Ethernet peer-to-peer networking became available from virtually all PLC manufacturers. EEPROM and Flash memories replaced the EPROMs of the 1980s. PCs and CRTs in general became accepted and started to replace switches and lights on control system panels. Small PLCs called “Bricks” were introduced to the marketplace. Redundancy for PLCs became a standard product. Many PLC systems were upgraded to address Y2K concerns. The first few years of the 21st century have seen a consolidation of PLC manufacturers. Very small nano or pico PLCs, some as small as industrial relays, have appeared. Safety PLCs featuring triple redundancy were introduced. LCD base operator interface panels have largely displaced CRTs, especially on the plant floor.

PLC SIZES

Today’s PLC is at best a distant relative of the first- and second-generation PLCs built during the 1970s and 1980s. There are now many PLC sizes to select from, ranging from nano- and micro-size devices with 12–30 I/O, to large supervisory control units with built-in PC and networking capabilities.[7]

The modern medium-sized PLC performs all the relay replacement functions expected of it but also adds many other functions—including counting, timing, and complex mathematical applications—to its repertoire. Most medium-sized PLCs can perform proportional, integral, derivative (PID), feedforward, and other control functions as well (see Chapter 2). In addition, medium-sized and large-scale PLCs have data highway capabilities and can function well in DCS environments.

Nano PLCs

In the 1990s, small PLCs were introduced with limited functionality. Today’s small PLCs generally contain all of the software and networking power that used to be confined to the larger units.[8] A small PLC can be amazingly inexpensive. This small, dedicated controller is enclosed in a single-mounted hardened case. It is intended to be a relay replacement unit and provide reliable control to a stand-alone section of a process. Small PLCs offer many of the same functions as larger models but with limited flexibility of adding I/O points. They are especially suited to limited applications with only basic communications requirements. “For instance, a $99 PLC with four PID loops and two serial ports, matched with a $79 four channel analog plug-in option card, is a cost-effective choice over traditional relays and a single-loop controllers.”[9]

BASIC PLC COMPONENTS

A PLC manufactured by virtually any company has several common functional parts. Figure 5.4c illustrates a generic PLC architecture. The diagram shows a central processor, memory, I/O, power supply, and programming and peripheral device subsections. Each is discussed below.

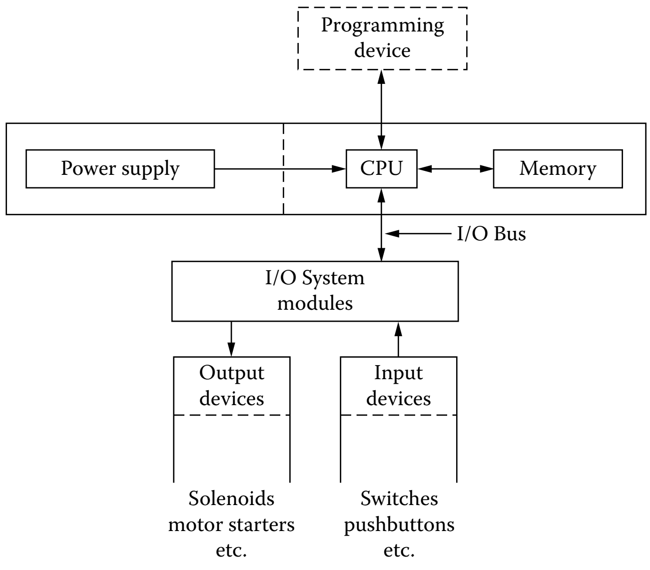

FIG. 5.4c
PLC architecture.

Central Processor Unit (Real Time)

The central processor unit (CPU) performs the tasks necessary to fulfill the PLC function. Among these tasks are scanning, I/O bus traffic control, program execution, peripheral and external device communications, special function or data handling execution (enhancements), and self-diagnostics. Central processing units that use microprocessor-based (VLSI) systems are both more powerful and more flexible than earlier technologies such as TTL or CMOS. It should be noted that the CPU and memory units are considered separate functions.

One common method for rating how a PLC performs these tasks is its scan time. Scan time is roughly defined as the time it takes for the PLC to interrogate the input devices, execute the application program, and provide updated signals to the output devices. Scan times can vary from 0.1 ms per 1 K (1024) words of logic to more than 50 ms per 1 K of logic. Although scan times are often given as performance measures, there are factors that make them misleading. Word size varies from 4 bits to 32 bits depending on the PLC model and manufacturer. Special features, which vary from preprogrammed drum times to full floating-point mathematics, have different processing times and may generate longer scan times. Because of these variables, other performance factors must be considered when selecting a PLC. The user should take into account the application as well as the speed of the controller. Generally speaking, process applications need to take advantage of microprocessor power, whereas machine control applications are usually more concerned with program execution speed.

Newer CPUs are equipped with communications ports such as ASCII (RS-232), remote I/O (RIO), and Ethernet built into the CPU module. Some CPUs now even support timed interrupts.

Redundancy The new breed of data highways can provide a process with a "hot" backup PLC to take over in the event of a PLC processor failure. Figure 5.4d depicts a PLC system with redundant CPUs and I/O.

Until recently, it was difficult or impossible to configure an ordinary PLC into a redundant hot backup system. Siemens was one of the first PLC makers to introduce redundant configurations for PLCs. For some people, redundancy is very important. Why is redundancy important? Safety in areas containing explosives or flammables, unattended operation, and environmental liabilities lead the list of concerns addressed in part by redundancy.[10]

Safety PLCs For several years, Triconex was one of a few manufacturers that offered a triplicate PLCs for use in safety systems. Fault tolerant systems called programmable safety systems (PSSs) are now offered by a number of PLC manufacturers. "The big difference between a regular PLC and a PSS is that all the triple redundant features needed in both hardware and software are built into the latter. That can be done with regular PLCs but it's a significant engineering challenge."[11] See Section 5.8 for further information on safety PLC systems.

It's important to acknowledge that having redundant CPUs doesn't necessarily provide system-wide redundancy. Nor does it protect against all types of errors. A programming error, such as divide by zero, or an infinite loop will stop a redundant CPU just as fast as a nonredundant CPU.

Memory Unit

The memory unit[12] of the PLC serves several functions. It is the library where the application program is stored. It is also where the PLC's executive program is stored. An executive program functions as the operating system of the PLC, which serves as the program that interprets, manages, and executes the user's application program. Finally, the memory unit is the part of the PLC where process data from the input modules and control data for the output modules are temporarily stored as data tables. This includes I/O status bits, counter values, timer preset and accumulated values, and other stored constants or variables. Typically, an image of these data tables is used by the CPU and, when appropriate, sent to the output modules.

The basic PLC memory element is the word. A word is a collection of 4, 8, 16, or 32 bits that is used to transfer data about the PLC. As word length increases, more information can be stored in a memory location. Even with the ambiguity associated with word length, PLCs that provide the equivalent of 32 K of 8-bit memory locations can execute application programs that are moderately complicated and interact with 50–100 discrete I/O points.

Memory can be volatile or nonvolatile. Volatile memory is erased if power is removed. Obviously, this is undesirable, and most units with volatile memory provide battery backup to ensure there will be no loss of program in the event of a power outage. This is often referred to as battery-backed

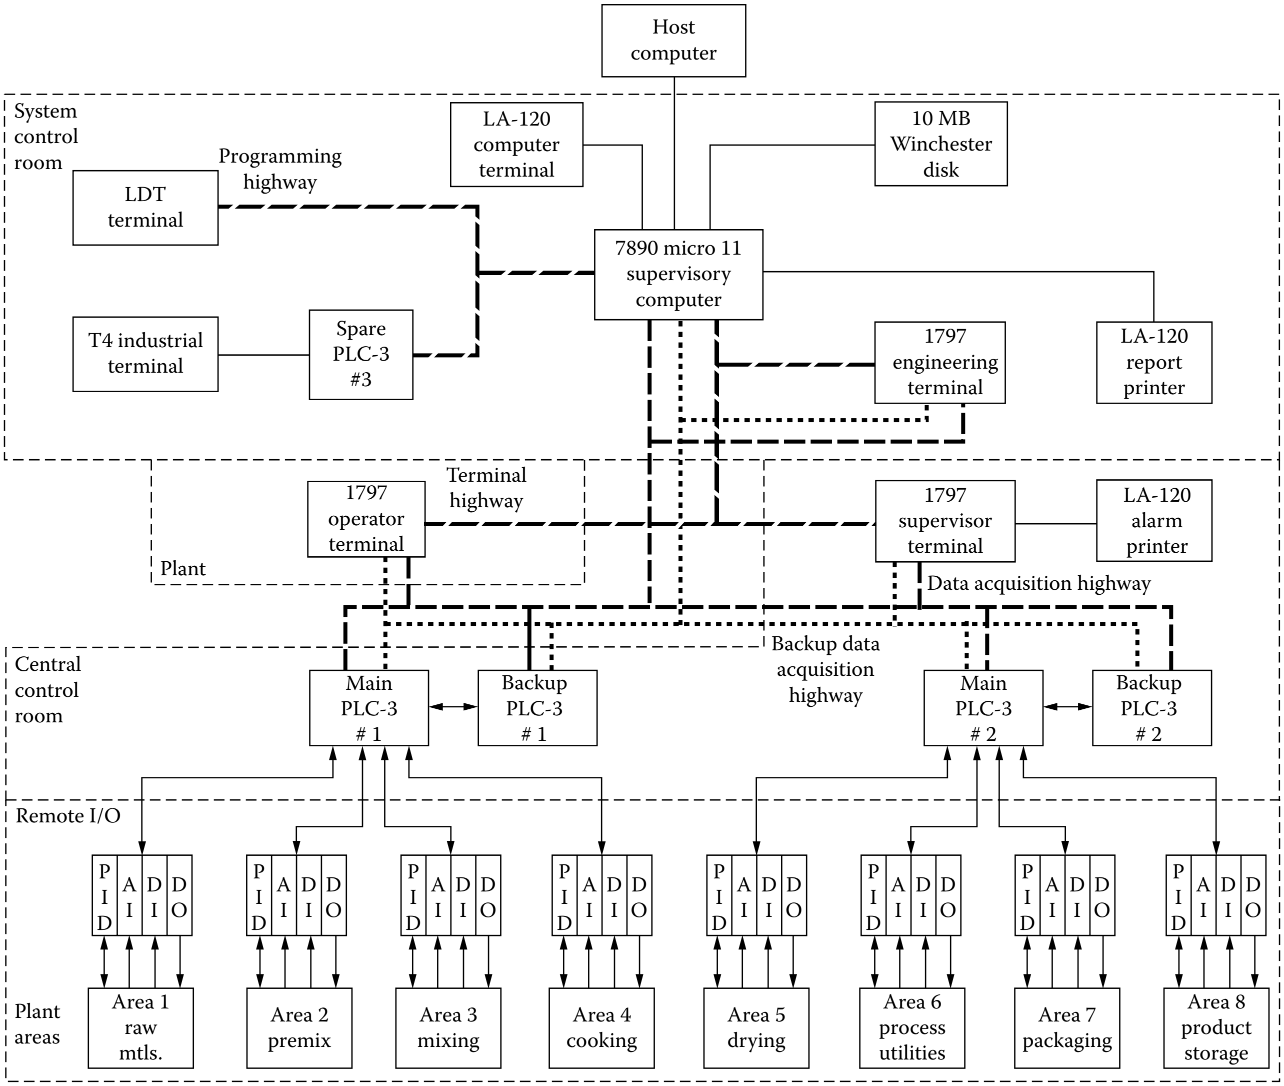

FIG. 5.4d
Hot backup PLC networking. (Courtesy of Allen-Bradley.)

RAM. When batteries are used, they must be replaced on a regular basis, typically 1–2 years. Some small PLCs use a large capacitor instead of a battery to avoid this maintenance issue.

Nonvolatile memory does not change state on loss of power and is used in cases in which extended power outages or long transportation times to job sites (after program entry) are anticipated. Core memory was widely used in the 60s and early 70s but is no longer used. In the late 70s a solid-state nonvolatile memory called programmable read-only memory (PROM) became popular. The user programmed the PROM by applying a high current pulse in order to fuse internal links to set individual bits to 1 or 0. This procedure was irreversible.[13] This required a separate piece of equipment called a PROM burner. Then erasable PROMs became available. Like the PROMs, EPROMs could be programmed by the user. The advantage was that EPROMs could be erased optically, through exposure to ultraviolet light through a quartz window on the chip, and then rewritten electrically. A drawback to EPROM devices was that they had to be removed from the equipment to be reprogrammed.

EEPROM and Flash Memory New memory technologies, electrically erasable (or Alterable) PROMs (EEPROMs, E^2PROMs, or EAPROMs) and Flash memories, became available in the 90s and have essentially replaced the earlier types. EEPROM and Flash memories can be electrically reprogrammed by the user, but without removal from the system, and without the use of exterior programming devices such as PROM programmers.[14] Flash is also used for the firmware used by PLCs and intelligent modules. Revision changes to the firmware can be “Flash upgraded” in the field, without equipment disassembly. EEPROM and Flash memory are the current choices for nonvolatile memory.

I/O Systems

The I/O group includes all types of modules, from dry contact modules to intelligent I/O to remote I/O capabilities. Inputs are defined as real-world electrical signals that give the controller real-time status of process variables such as level, pressure, flow, temperature, weight, analysis results, position, or status (hand switches, pushbuttons, alarm contacts, and so on). These signals can be analog or digital, low or high frequency, maintained or momentary. Typically, they are presented to the PLC as a varying voltage, current, or resistance value.[15,16] Based on the status sensed or values measured, the PLC controls various output modules to operate devices such as valves, motors, pumps, and alarms. PLC manufacturers are providing more and more types of input and output capabilities in their products. There are, however, many third-party peripherals that aid the PLC in interfacing to the field devices.

One of the most important functions of the I/O is its ability to filter, condition, and isolate real-world signals (0–120 VAC, 0–24 V DC, 4–20 mA, 0–10 V, and thermocouples) and convert these to the low signal levels (typically 0–5 V DC max) in the PLC I/O bus. This is accomplished by use of optical isolators. A light-emitting diode (LED) generates a light that optically turns on a phototransistor. Because the only thing normally connecting the input to the output is light, there is an excellent isolation between input and output voltages. Only the electrical breakdown of the isolator (typically over 1000 V) limits the voltage isolation achieved with these devices. Typical discrete I/O schematics are shown in Figures 5.4e, 5.4f, and 5.4g.

Most I/O systems are modular in nature; that is, a system can be arranged by use of modules that contain multiples of I/O points. These modules can be composed of 1, 4, 8, 16, or 32 points and plug into the existing bus structure. The bus structure is really a high-speed multiplexer that carries information back and forth between the I/O modules and the central processor unit. Higher point densities are possible, but their selection may involve a trade-off in wire size used, as well as the ease of wire harness installation to the module.

In small PLCs, the CPU and I/O are generally contained in a single enclosure and may or may not be expandable. These have been nicknamed “Bricks” because the size of the enclosure is similar to the size of a brick. In most medium and large PLCs, plug-in I/O modules are used to convert the I/O signal level to one that is compatible with the bus architecture. These modules can be composed of 1, 4, 8, 16, or 32 points, depending on the manufacturer’s standard design. For small projects (20–256 I/O), I/O requirements are usually easy to define and group. A systematic approach is required for medium-sized projects (256–1024 I/O), however, in order to avoid confusion of I/O allocation. Obviously, the organization of I/O for large systems (1024 I/O and above) requires careful planning.

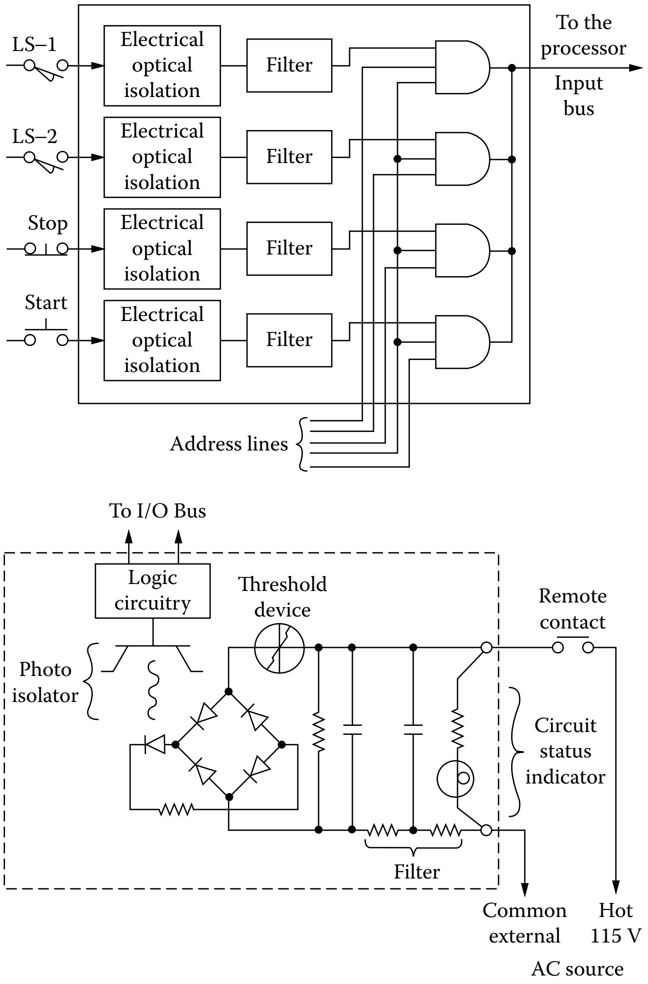

FIG. 5.4e
Typical input area; typical AC input unit.[4]

PLC manufacturers are typically very good at backward compatibility. When new models of CPUs are introduced,

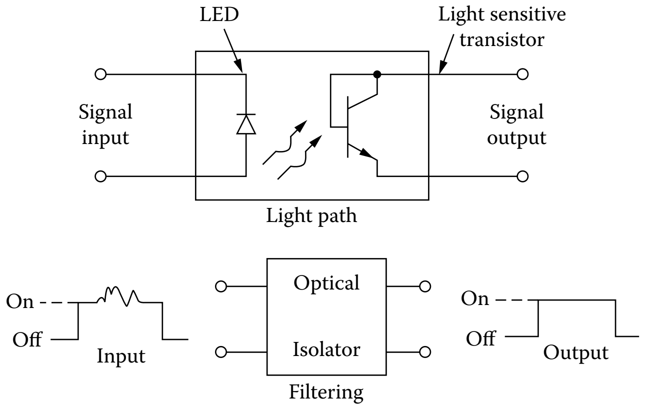

FIG. 5.4f
Electrical optical isolator.[4]

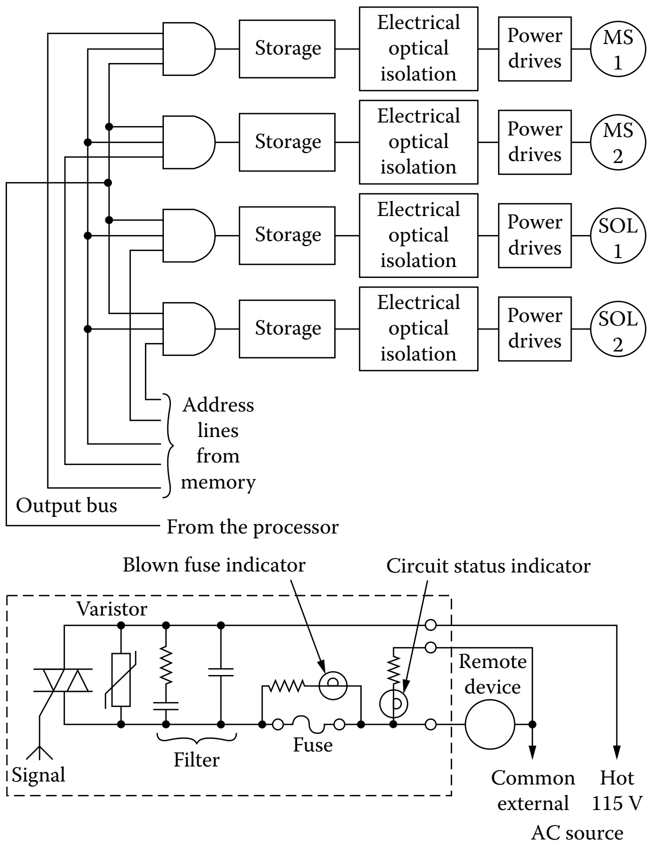

FIG. 5.4g
Typical output area; typical AC output unit.[4]

they are generally able to use the I/O modules made years before. For example, at least one PLC manufacturer's current PLC still works with I/O modules introduced nearly 30 years ago — an impressive feat considering the advances in technology during that time span. In other cases, when manufacturers have changed lines, other companies have stepped in to support and expand the older PLC equipment.

Some manufacturers assign I/O memory locations based on I/O type and position in the rack. Care must be taken in these systems when adding I/O to these systems, as it might cause an automatic readdressing of existing I/O modules. Because the program doesn't alter itself, it would need to be updated for it to function like it did before the I/O module addition.

Local I/O There are at least three different types of racks: local, expansion, and remote. A local I/O base can hold the CPU module, power supply, and optionally I/O modules. Expansion racks that are close by (usually within the same panel) are either plugged into the side of the local I/O base or connected by a short parallel cable. Standard cabling is provided for connection from the remote I/O base to the PLC processor. These cables are generally high-speed serial cables to simplify installation. The PLC processor generally plugs into a dedicated slot in the rack. Some manufacturers allow multiple processors in a single rack.

The I/O base (rack or housing) is used to hold the I/O module in place and to provide a termination point for the wiring. The bases may be mounted anywhere in the control enclosure; however, there are cable length and free space requirements that must be met. Some racks are sized to mount directly into a standard 19-in. rack enclosure. The majority of bases mount horizontally to allow proper module cooling. Some manufacturers define how much space must be reserved around the rack to permit proper circulation. A terminal strip is built into the mounting base for field connections so that no wiring need be disturbed in order to remove or replace a module. These bases typically hold various quantities of I/O — anywhere from 1 to 128 I/O points.

Some PLC vendors provide wire-way as part of the rack structure to "clean up" the panel design. As each new generation of I/O becomes increasingly dense, the systems become progressively harder to wire. Interposing terminal blocks between the field connections and the rack may become standard in the future. Some manufacturers already offer prewired field terminals that mount in a panel and are equipped with a cable that plugs directly onto the I/O module.

Digital Inputs Pushbuttons, limit switches, or even electromechanical relay contacts are familiar examples of digital, contact closure type signals. Input modules are typically transistor-triggered and have built-in time delays to protect against contact bounce. The input signal from a field device (limit switch) has to be energized for some amount of time in order for the module to notify the processor of a true "on" condition. The modules are available in a number of voltages including DC voltages (14, 15–30, 24, 120, 240), TTL (5 V DC), and AC voltages (24, 48, 120, 240). They come in 8, 16, or 32 points per module.

Discrete I/O modules come equipped with an LED indicator light to indicate the status of each I/O point in the module (on or off) for troubleshooting. The input module LED indicates field side status of the pushbutton.

Modules, especially high-density modules, often share a common neutral between multiple inputs. This means that the input voltages must be referenced to the same neutral. AC signals powered from different power sources cannot be mixed within the shared group. Using a different module for the different sources or using isolating relays solves the problem.

Digital Outputs Digital or discrete outputs (DOs) can be used to power pilot lights, solenoid valves, or annunciator windows (lamp box). The discrete output module uses a solid-state switch (triac) to power a field device, such as a motor starter, a valve, or lights. Outputs are available for voltage ranges of 5–240 V at currents up to 5 A, with typical 120 V outputs operating at 1–2 A maximum. Solid-state drivers of this type are not intended to drive large loads directly (e.g., a large motor starter). Highly inductive loads or those with a high surge current may also require an interposing dry contact relay in order to power the field device or a resistor-capacitor (RC) network to control transients.

Both manufacturers and third-party vendors offer dry contact modules. These modules solve the problems normally associated with triacs: low power and uncertainty of failure state. Triac outputs also "leak" some current when they are off. When attached to high impedance devices such as Sonalerts or LED pilot lights, this leakage current can cause continuous or intermittent operation. A voltage-dropping resistor can be added across the load to solve this, but the resistors are often large and run hot. Some designers simply add inexpensive isolation relays as needed to address this problem.

Manufacturers rate their equipment output current at different temperatures. All current ratings for solid-state outputs will vary with ambient temperatures. Therefore, one should be sure to check the PLC output rating for each application and manufacturer. Built-in fusing on output modules is becoming standard in the industry and provides good protection for overload conditions. The type of fuse depends on the module, and the way in which fuses are accessed varies from one PLC manufacturer to another. Some wiring arms have individual fuses for each output.

Discrete I/O modules come equipped with an LED indicator light to indicate the status of each output on the module (on or off) for troubleshooting. The output module LED generally indicates logic side status.

Analog Inputs Analog modules are sometimes referred to as A/D (analog-to-digital) modules. They provide optical isolation for electrical noise protection and are typically arranged in a quad module or an eight-point module. The analog I/O system is designed to interface with analog field devices such as flowmeters, pressure transmitters, and valve positioners. This system accepts inputs of 0–5 V DC, 0–10 V DC, –5 to +5 V DC, –10 to +10 V DC, 0–20 mA, or 4–20 mA. Precisions of 1 in 4,096 (12-bit), 1 in 32,768 (15-bit), or 1 in 65,536 (16-bit) are commonly available.

Direct thermocouple and RTD input modules typically accept eight to ten points each. On-board cold junction compensation is often included with thermocouple input modules, and many different types of thermocouples (B, C, E, J, K, N, R, S, T), RTD (100 Ω platinum, 120 Ω nickel, 10 Ω copper), and mV signals (0–50 mV, 0–100 mV) can be accommodated.

Analog Outputs Analog outputs can drive signals to variable-speed drives, control valves, and other analog devices. The output analog module can output a signal of 4–20 mA current loop as well as 0–10 V DC, 0–5 V DC, –5 to +5 V DC, and –10 to +10 V DC. Most source their power from the back plane. Some loops require external loop power supplies.

Register I/O Systems One additional type of input signal, the register input, reflects the computerized nature of the PLC. The register input is particularly useful when the process condition is represented by a collection of digital signals delivered to the PLC at the same time. A binary-coded decimal (BCD) thumbwheel is a good example of an input device that is compatible with a register input port. If the thumbwheel represents three and one-half digits of process data, then all 14 data output wires from the thumbwheel would provide their digital signal directly to the PLC register input unit, which would, in turn, signal the condition and transfer the data to the central processor unit.

The register I/O system provides direct interface to multibit data field devices, such as thumbwheel switches, position encoders, and digital readouts to the PLC. These devices are typically TTL level, which allows interface to other types of electronic hardware as well. Intelligent I/O and other special-purpose I/O requirements are becoming increasingly common.

Specialty Modules Specialty modules are designed to solve a single interface problem. X/Y positioner modules can be included in this category, as well as servo axis controllers, stepper motor outputs, and even maintenance access modules. These modules are a further extension of the distributed technology. Combination I/O modules combine either digital or analog inputs and outputs on a single module. They are particularly useful in small systems.

High-Speed Modules Fast-response I/O is currently offered in both discrete and analog versions. Discrete rapid response modules are facilitated by the PLC logic, but the output does not rely on ladder logic scan times to get updated. High-speed analog modules provide quicker analog-to-digital and digital-to-analog (D/A) conversions. This gives PLCs the ability to control faster PID loops and to make analog measurements of assembly-line parts (weight, for example). High-speed pulse counter modules provide the ability to interface with turbine meters, stepper motors, and optical encoders. High-speed pulses cannot normally be interfaced to PLC inputs because of the scan time of the ladder logic. These modules provide an interface that does not rely on the scan time, so the PLC is able to monitor fast pulses that indicate position or flow. They can often be configured as high-speed up counters, up/down counters for quadrature use, high-speed interrupts, pulse catchers for very fast pulses, and adjustable filter inputs. PID loop coprocessor and temperature controller modules are also available.

Intelligent I/O Modules Intelligent I/O modules include all modules that are able to perform processing functions. Because the tasks performed by the PLC are further distributed, greater speed and reliability for the overall system can be realized. Intelligent I/O modules give the PLC multiple additional capabilities, which may include memory storage and retrieval, computing tasks, and communications. Memory modules provide additional room to store data points, alarm messages, lookup tables, and the like. This approach leaves the main operating memory free for the control tasks. Computing modules give PLCs the ability to perform true computer functions using a language like Basic. Basic modules can be used for a variety of things, such as complex math abilities.

Because they usually come with two or more serial ports, they can be used for handling specialized ASCII protocols and they can demultiplex a multiplexer data stream. Of course they can be programmed as Modbus masters or slaves. Again, the real-time tasks are left in the main memory, but tasks such as setpoint calculation, formation of data, and some operator interface tasks may be placed in the computer module. Other in-rack modules include complete computers, state language coprocessors, and real-time interrupt modules.

Clock modules that fit into the I/O bus may be considered part of this group. These modules provide real-time and day/date functions upon interrogation from the PLC. Most are backed up by a battery to ensure time keeping during power outages.

I/O Simulators Some I/O simulators used to develop and debug programs can be categorized in the I/O enhancement group. These specific devices are typically hardware modules that can be plugged into the PLC. I/O simulators generally look like input cards except switches are built into the module for testing.

PLC Power Supply

The power supply may be integral or separately mounted. It always provides the isolation necessary to protect solid-state components from most high-voltage line spikes. The power supply converts power line voltages to those required by the solid-state components. All PLC manufacturers provide the option to specify line voltage conditions (typically 120 VAC, 240 VAC, or 12/24 V DC). In addition, the power supply is rated for heat dissipation requirements for plant floor operation. This dissipation capability allows PLCs to have high-ambient-temperature specifications and represents an important difference between PLCs and PCs for industrial applications.

The power supply drives the I/O logic signals, the central processor unit, the memory unit, and possibly some peripheral devices. As I/O is expanded, some PLCs may require additional power supplies in order to maintain proper power levels. The power supply generally does not provide power to field devices, though some manufacturers provide external terminals to permit this use. The additional power supplies may also be separate or part of the I/O structure. The power requirements of all the I/O modules and CPU or remote I/O adapters are added together for each voltage used to make sure that the power supply is large enough.

ADDITIONAL PLC COMPONENTS

Communications Modules

Communications modules can provide the PLC with a range of capabilities, from simple ASCII output strings to communications networking. The storage of ASCII messages for a printer or display can be contained outside the main memory of the PLC, and the data can be output when required. Full-system communications networking capabilities are provided with network modules, giving the designer the ability to multidrop PLCs off a single operator interface device or a supervisory computer. A wide variety of devices communicate using ASCII, including weight scales, bar code scanners, some operator interfaces, and modems. Modules included in this category also include telephone and radio modem modules. Remote I/O and peer-to-peer are specialized communications modules that are discussed below.

Remote I/O

Robust industrial networks make distributed I/O feasible. Networks enable I/O modules to be located close to field devices, resulting in labor and material savings for wiring.[8,11] Often manufacturers provide a remote I/O distribution panel or module to serve the efficient multiplexing of the modules on the remote I/O rack back to the CPU. A remote I/O base is similar to the local I/O base except it holds a remote I/O adapter (or has it built-in) instead of the CPU. Most medium-sized PLCs can support several remote racks, which in turn contain 4, 8, or 16 I/O modules. It may or may not be possible to mix various modules in a remote rack. Specific information about module compatibility and remote I/O multiplexing is available from the manufacturer. This information is required to facilitate PLC selection and sizing for specific applications.

Whereas in most systems the module has the intelligence to communicate with the CPU, some systems require the use of serial interface modules. In any case, some provision is made to accept register input data from the input modules and to send this data (on or off status of field device) in serial format to the PLC processor. Serial data are also converted into register data to be sent to the output module. This is normally a proprietary protocol.

Remote I/O adapters need to be configured for a particular drop, either by programming or a switch setting on the module itself. Remote I/O is very often an RS-485-based system. The end modules in the RIO network are usually terminated with a resistor that matches the impedance of the cable used. RIO communications speeds range from 56 K to 230 Kbps. Remote I/O is broken down into two distinct types: the integral type, which allows a limited transmission distance (up to 15,000 ft, or 4,500 m); and the transmitter/receiver type, which allows virtually unlimited transmission capability. Most PLC manufacturers and third-party peripherals manufacturers can provide some form of either type. Technology is advancing rapidly in this area, as systems change from fiber optics to microwave and radio transmission. Many manufacturers are now offering flexible remote I/O solutions. Often these are modular, plug-together systems instead of being rack based. Designed to be located next to the wireway, they incorporate built-in terminal blocks for direct wiring.

Open vs. Proprietary I/O Networks Proprietary networks have a compelling advantage: They are easy to put together. If you buy all your network components from one supplier, even if they're for an open network like DeviceNet, you avoid potential configuration problems. Even so, offering both open and proprietary systems is important to most manufacturers.[11]

Besides proprietary remote I/O networks, a variety of open protocols exist to enable I/O data interchange. These include Modbus, DeviceNet, Profibus, HART, and Fieldbus, among others. Because these are open, a number of different manufacturers offer products based on them. Ethernet is becoming a major factor by providing a backbone that can carry the diverse protocols of nonproprietary I/O communications.[17]

Peer-to-Peer Communications

Many PLC manufacturers have responded to the increasing industry demands for equipment that allows communications among multiple process areas.[18,19,20,21] The original master control layout shown in Figure 5.4h is adequate for PLC control of moderate-size applications of perhaps 100–500 I/O points, but as the application grows the PLC becomes overburdened under this arrangement. The hierarchical plan illustrated in Figure 5.4i provides a supervisory PLC controlling network that reduces this burden. The plan allows for a "master" PLC that oversees the process and controls a set of "slave" PLCs that control the actual process activities in the plant.

An alternate approach is illustrated in Figure 5.4j. This distributed control system allows dedicated PLCs to control sections of the process with an interface to management. As indicated in the figure, this interface could be to a human operator. This person would monitor selected data from the collection of PLCs. Any management decisions generated from this data are passed back to the PLCs by an input terminal. Under normal conditions it is expected that each dedicated PLC can monitor and control its section of the process.

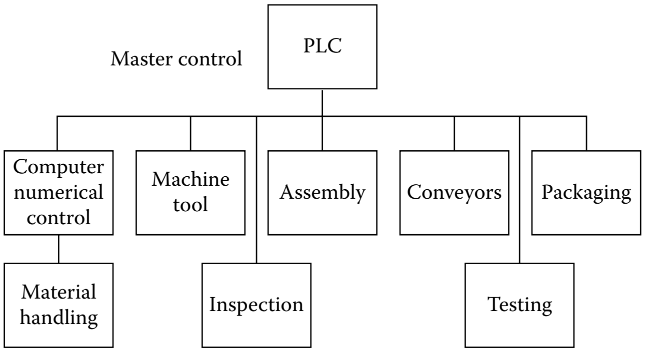

FIG. 5.4h
With master control, one PLC controls a number of related machines and processes. This system is simple but may require long runs of multiple-wire cables, and the entire system is vulnerable to the failure of the one PLC. (Courtesy of Allen-Bradley.)

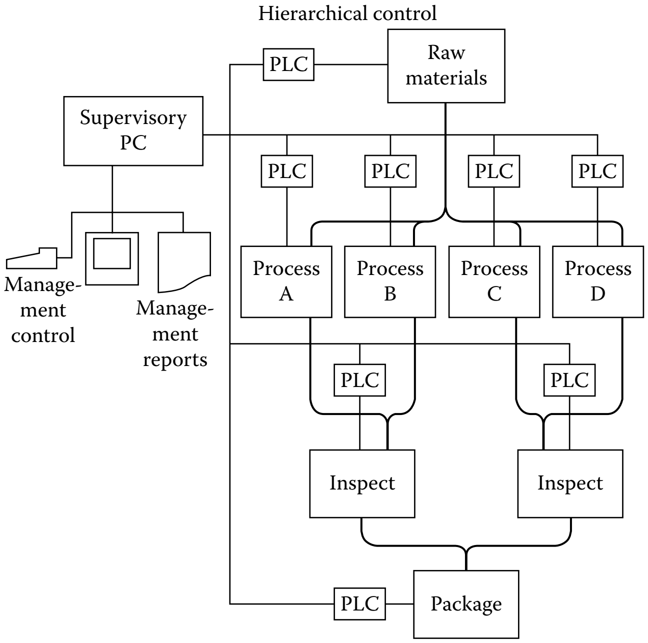

FIG. 5.4i
Hierarchical control. (Courtesy of Allen-Bradley.)

Most major PLC manufacturers currently offer their own network communications for their products (e.g., DataHighway+, ControlNet, Modbus+, and TI-WAY). Various network protocols exist and efforts to generate standards are gaining momentum. Instrument and control organizations such as the Instrumentation, Systems, and Automation (ISA) Society constantly exert pressure on the PLC industry to agree on one or at least a few communications standards. In any event, there are several communications philosophies of interest. Some of these are outlined below.

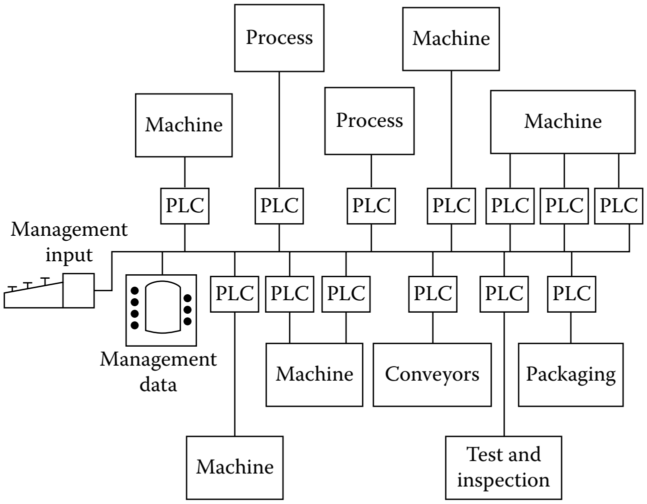

FIG. 5.4j
Distributed control. (Courtesy of Allen-Bradley.)

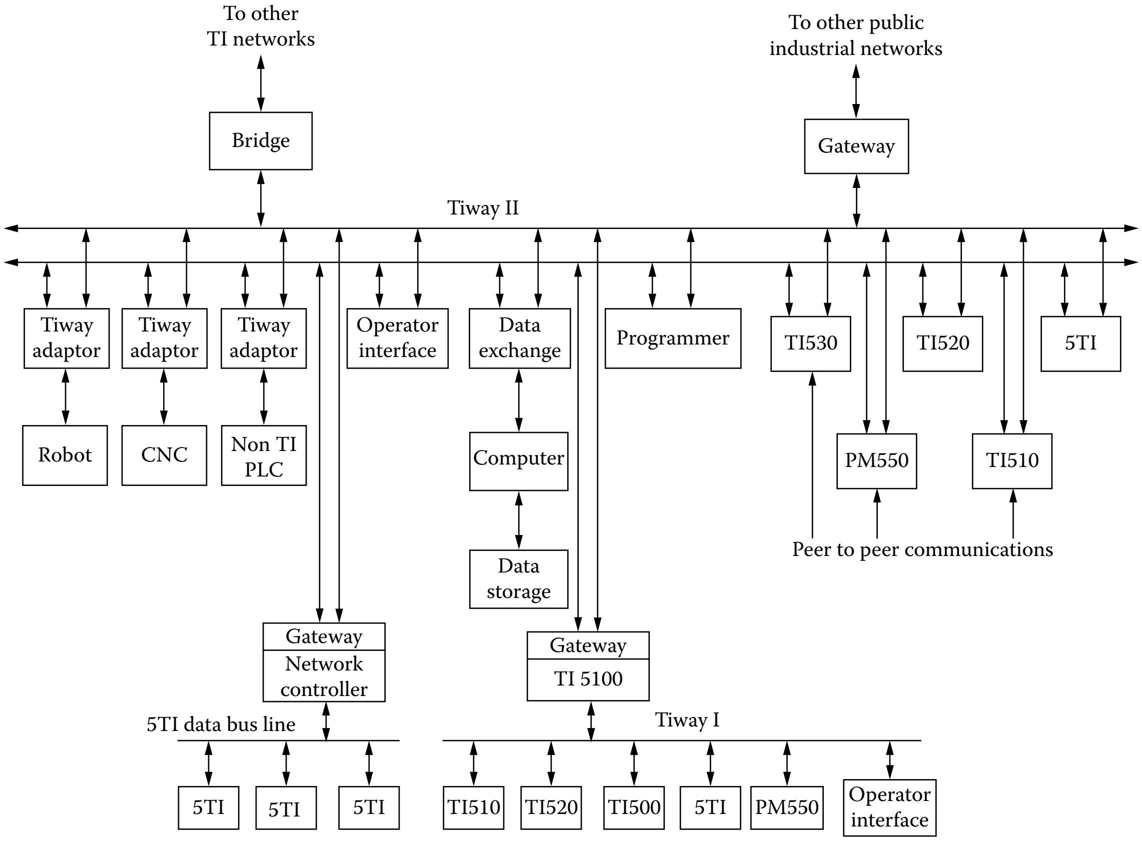

FIG. 5.4k
Peer-to-peer communications. (Courtesy of Texas Instruments.)

The computer interface device group is a rapidly expanding section of PLC peripheral devices. These devices allow peer-to-peer communications (i.e., one PLC connected directly to another), as well as network interaction with various computer systems. In fact, this group of devices will certainly expand in number as communications standards become commonly accepted and more and more products are provided to facilitate such network interactions.[22]

Most PLC manufacturers have already addressed the need for peer-to-peer communications among PLCs on a distributed network. Without this feature, every time one PLC needs to know the status of another part of the machine or plant, it must interrupt the activities of the supervisory computer in order to get the information (Figure 5.4k) or interface through status I/O points. The ability of one PLC to “talk” to another along the data highway greatly speeds the control activities of each machine and allows the supervisory computer to “concentrate” on its tasks.

Some PLC manufacturers and third parties are offering universal communications networking based on open protocols such as Modbus. This is likely to be the favored method in the future, because the need for networking different brands of PLCs together will increase.

More PLC vendors are adding Ethernet compatibility to their systems. Ethernet has become the open architecture of choice for a variety of industries. However, care must be taken to ensure that the PLC is never connected to the Internet. Doing so opens the door to all sorts of security issues, especially hackers.[11] Using a PC in combination with firewalls, encryption, and passwords helps address some of these issues.[23]

Peripheral Devices

The popularity of PLCs has led to the creation of a strong third-party peripheral manufacturing industry. These companies are always developing new products that assist the PLC user with interfacing a specific application to a PLC. Two categories of these products— operator stations and programming/documentation tools—are presented below. The operator stations facilitate operator interface with the PLC-controlled process to monitor process variables, to alter program parameters, to conduct on-line program alterations, and to conduct troubleshooting procedures. Programming and documentation tools include products supplied by the manufacturers or made available by third-party vendors.[24,25]

Local Operator Interface

Operational aids include a variety of resources that range from switches and lights, to color graphics CRTs, to equipment or support programs that can give the operator specific access to processor parameters. In this situation the operator is usually allowed to read and modify timer, counter, and loop parameters but not access the program itself. Some aids facilitate the interaction between the PLC and printers to deliver process information in a desired format. Some devices have the ability to set up an entire panel and plug into the PLC through external RS-232-C ports, saving enormous panel and wiring costs.

The most basic of operator interfaces is switches and lights. These are directly wired to the input and output cards and relay information back and forth to the PLC. Analog signals can also be used with potentiometers, panel meters, and chart recorders. Individual loop controllers can be wired to accept a remote set point from the PLC. Register I/O is used with BCD thumbwheels and BCD displays. Annunciator panels can also be used. Although just about all control panels have some switches and lights, the cost of using a display has fallen to such an extent that it is often not cost-effective to use switches and lights as the primary interface. PLC backup systems that are used if the PLC is being serviced still use these simple devices.

Annuniciator panels are still used in some industries. They are light boxes that have alarm descriptions illuminated when an output is activated. The PLC generally supplies one output point per alarm. The lamp test, silence, and acknowledge functions are built into the annunciator assembly. Text display units are also available in a number of sizes, which display a preprogrammed message when signaled by the PLC. Other message systems are available that can dial a preprogrammed phone number and deliver a page, a text message, or a verbal description of the triggering event. Some switches and light assemblies became available in standard arrangements that connected directly using remote I/O technology. Some are available that communicate using the Modbus protocol.

Operator stations include those provided by manufacturers intended to be used with their particular PLC and those offered by third parties for use with either a particular brand or anyone's PLC. These stations may include devices such as timer/counter access modules (TCAMs), loop access modules (LAMs), data terminals, color graphics consoles, computers, printers, and manual backup stations. Most PLC manufacturers provide an operator interface unit (OIU) designed specifically for their PLC. These are either part of the standard system or offered as an option. They are sometimes mounted directly on the PLC or can be panel-mounted and cabled back to the controller. Functions include access to read/write register data, simple programming, and diagnostics.

Some specialized devices, such as TCAMs, LAMs, and OIUs, provide operator interaction with PLC internal registers and loop tables. This gives the systems designer the ability to provide real-time changing of variables, loop tuning and inspection, manual control of analog outputs, and the ability to provide batch- or menu-type information at low cost. Communications with the PLC are multidropped over an RS-422 or a similar differential line. Unauthorized data entry is prevented with software locks, keylock protection, or both. TCAMs and LAMs have become less popular as the cost of graphic interface panels has dropped, because their functions are easily added to these newer interface panels. Some PLCs can support communications directly with dumb data terminals. However, dumb terminals have been replaced almost completely by PCs.

Many PLCs are able to provide communications directly to printers. A stand-alone PLC system can often provide performance reports, alarm logging, and the like without ever involving a computer. This feature is usually somewhat limited, because PLCs were designed primarily to control the process machine. Large amounts of data, sophisticated print logs, and multiple alarms are not really within the realm of a stand-alone PLC system. This type of data manipulation is too cumbersome and requires too much memory for most PLCs. In addition, many PLCs are located in the process floor, which is generally not a good environment for printers.

Small touch screen panels have become very popular in recent years. They provide basic reporting of status information and commands in a small format. Some also provide built-in alarm management functions. They are meant to replace the traditional switches, lights, and meters. The main disadvantage these small screens have is that they are fundamentally different from the computers in the control room. The screen graphics for the local panels must be developed separately. They generally are limited to the individual control panel they are associated with.

With the advent of plant floor Ethernet and relatively inexpensive computers, it has become practical to provide the same screens at the local control panel that are displayed in the control room. An industrial computer or a regular desktop computer in a sealed computer enclosure is used. The same software that is used in the control room is loaded onto the local computer, which uses the local area network (LAN) to communicate with the supervisory control and data acquivision (SCADA) server. This has many advantages. Because the screens are shown on the same type of hardware, they can be simply copied from the control room computers. Obviously, this helps reduce development and maintenance costs. Because these communicate with the entire plant, an alarm can be investigated at any control panel throughout the plant.

Human-Machine Interface

Intelligent human-machine interfaces (HMIs) can be networked into a total distributed system to give a redundant or local interface to the system (Figure 5.4l). This technique can be used to provide the control room interface, while the supervisory computer supports its own interfaces. Another powerful technique is to allow the networking of a few PLCs together solely for the purpose of providing a single human-machine interface to all parts of the system (Figure 5.4m). This solution is ideal for small PLC users because it is very economical yet allows expansion as the plant grows.

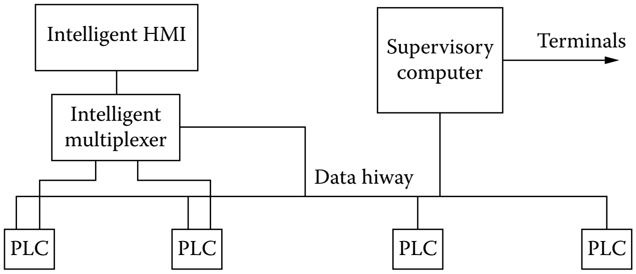

FIG. 5.4l
Local or redundant HMI in network.

Color graphics consoles offer process graphics and communications facilities simultaneously to many brands of PLCs. Because of this ability, HMIs are sometimes used to tie multiple PLC systems together. These systems range from those that can simply be purchased and put on-line with a minimum of engineering effort to those that require some programming. The basic differences are in flexibility. Those that do not require programming may not be able to provide the custom menus and graphics that are required. The ease of communications with different types of PLCs also varies according to manufacturer. Finally, the method of generating the graphics pages differs greatly. Most color graphics consoles offer multiple graphics pages that are animated by reading data tables in the PLCs. Operators enter the data by means of standard keyboards, user-configurable industrial keyboards, light pens, touch screens, and the like. Different graphics pages may be selected with preformatted menus or custom menus programmed by the user or the systems house. Development stations are often required to give the final user the ability to change graphics menus or key commands after the initial project is completed.

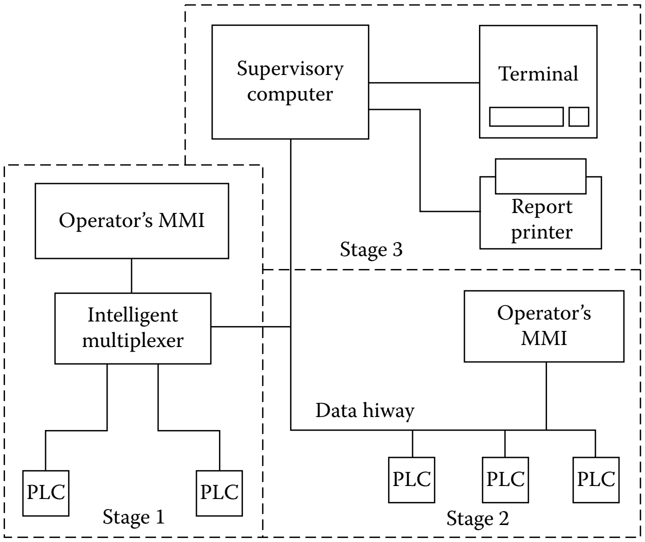

FIG. 5.4m
Entry-level networking grows with user's needs.

Computer systems can be made to perform human-machine interface functions. Indeed, the color graphics consoles described in the previous paragraph are simply computers with standard graphics and communications software packages. Most PLC manufacturers provide board-level additions or modules that give the PLC the ability to converse via the RS-232 or Ethernet with nearly any computer. Of course, both the communications software and the particular applications software must be generated to provide an interface. Many vendors and systems houses are providing communications packages for various PLCs to run on microcomputers and PCs. These small systems offer low-cost operator interfaces to PLCs, providing data handling capabilities and the ability to be networked into a true distributed architecture. Microcomputers that have the ability to multitask, access large amounts of both RAM and nonvolatile memory, have proper software support, and are able to be networked will provide a good investment in terms of operator interface functions as well as total system capability.

Printers

Printers have always been an important part of the PLC system both as a development tool and for handling some of the operator interface functions. Two types of printers are commonly found in control rooms: dot matrix printers and laser printers. The dot matrix printers are used to print alarms and events as they occur. They are unique because as soon as a line of text is sent to the printer, the operator can read it. This is not possible with most types of printers currently popular. The laser printers are used for reports or screen printout and are either color or black and white.

Programmers and Workstations

The programmer unit provides an interface between the PLC and the user during program development, start-up, and troubleshooting. The instructions to be performed during each scan are coded and inserted into memory with the programmer.

Programmers vary from small handheld units the size of a large calculator to desktop stand-alone intelligent CRT-based units. These units come complete with documentation, reproduction, I/O status, and on-line and off-line programming ability.[26,27] Most PLCs can use a PC as the programming tool. A program for the PC allows it to interface with a serial or Ethernet port in the PLC.

Programming units are the liaison between what the PLC understands (words) and what the engineer desires to occur during the control sequence. Some programmers have the ability to store programs on floppy disks or on a hard drive. Another desirable feature is automatic documentation of the existing program. This is accomplished by a printer attached to the programmer. With off-line programming, the user can write a control program on the programming unit, then take the unit to the PLC in the field and load the memory with the new program, all without removing the PLC. Selection of these features depends on user requirements and budget. On-line programming allows cautious modification of the program while the PLC is controlling the process or the machine.

Manufacturers of PLCs provide two basic programming tools. These are handheld programmers and programming software that runs on PCs. The programming software may not be an option if a small PLC is purchased. Dedicated CRT programmers, once manufactured for the sole purpose of programming PLCs, have been replaced with PCs running PLC programming software.

The handheld programmer enables the operator to enter a program one contact at a time. These units are widely used because they are rugged, portable, and easy to operate. They are very cost-effective and give an engineer the capability to enter a program and to diagnose trouble in logic and field devices.

The programming software on a PC provides the engineer with a visual picture of the program in the PLC. Ladder diagrams are drawn on the screen, just as they would be drawn on paper. Design and troubleshooting time is reduced. With menu-driven software, programming training time is decreased. Information is stored on either floppy disks or the hard drive. Programs can be copied from one disk to another and then verified without need for loading the PLC's memory. With stand-alone programming an engineer can develop a program on the PC and then load it into the PLC.

PLC programming software generally provides complete documentation capability, including ladder diagrams, cross-reference listing, I/O listing, user-defined contacts, and coil names along with commentary above each network or rung. All of this is can be sent to a printer for hard copy documentation. The screen typically shows eight rungs of ladder logic by 11 contacts across. The ladder diagrams can be placed into the real-time mode, which allows visual contact status. A whole screen of contacts and coils can be updated in as fast as a few seconds. Laptop PCs are often used for portability. With a modem connection, these programs can be used at remote locations for programming and troubleshooting.

PLC programming software may be restricted for use on only one PC. Security keys are one way to obtain this isolation. Security keys are devices that plug into the back of the computer or a special key disk. Without the key the software will not run. Some manufacturers use alternate security schemes such as providing extra keys at group prices or issuing site license agreements. In any case, it is unlikely that a PLC manufacturer will ever allow the use of programming software on an unlimited number of PCs.

Some PC-compatible software allows the PLC to be emulated by the PC. This software is sold by the PLC manufacturer or a licensee and is often model-specific. If the software also offers on-line programming and troubleshooting characteristics, it might be usable on only a single specific PLC. This restriction is achieved by means of software or hardware keys that come with each copy of the software purchased.

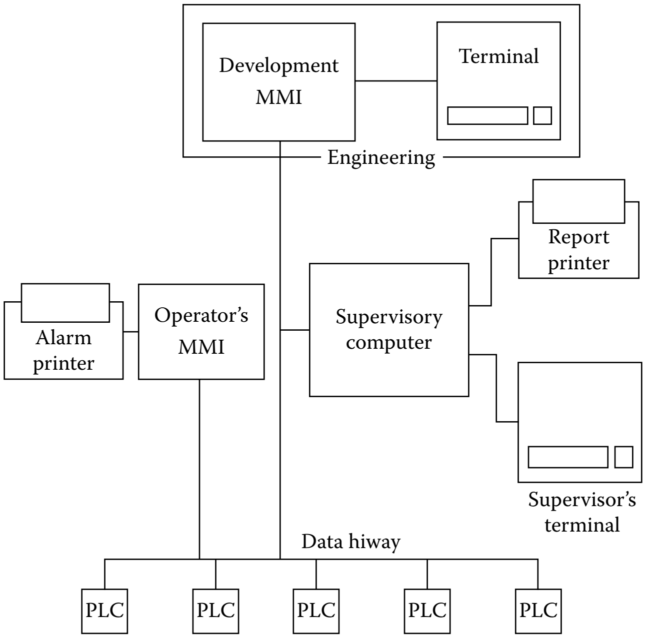

FIG. 5.4n
Networking with on-line engineering.

On-line engineering of PLC systems can be configured from a remote location like a control room with the combination of the programming/documentation tools and the distributed network. Systematic start-up and debugging of processes are available with this technique. Figure 5.4n depicts on-line engineering as part of a distributed system.

JUSTIFICATION FOR THE USE OF PLCs

For a given control problem, several technologies besides PLCs can be applied to achieve a solution: relays and stand-alone controllers, DCSs, and software running on PCs. PLCs differ from these technologies as described below.

PLCs vs. Relays and Stand-Alone Controllers

The main purpose of any control system is to get the process variable under control effectively and reliably. When control options are available, several factors can be taken into consideration in making an implementation decision. Some of these factors include the controller's cost, versatility, flexibility, and expandability.

Cost The ideas associated with cost are discussed first because this is usually the first issue users consider when selecting a control technology. In most cases, the two things initially known about a problem are the results desired and the budget available for fixing the problem. Unfortunately, at the beginning of a project the understanding of the problem is often limited. If the user's focus on the problem is too narrow, the solution might solve only the perceived symptoms of the problem while the problem itself may reappear in an alternate form at some other point in the process.

The budget assigned to solve a problem should be based not only on the initial investment required for the PLC hardware, but also on the costs associated with labor, maintenance, and downtime. Purchasing a larger and therefore more expensive PLC might in some situations be cost-effective when labor, maintenance, and downtime costs are also considered. Similarly, while PLCs may be more expensive than individual solid-state control units, if the indirect costs are also considered then the PLC becomes a cost-competitive alternative. As the cost of PLCs continues to drop, the cost of small PLCs may be equal to or even be less expensive than the cost of industrial relays.

Although significant, cost reductions alone are not the only reason that PLCs are the major replacement candidate for traditional relay logic. Compared with electromechanical relay systems, PLCs offer the following additional advantages:

- Ease of programming and reprogramming in the plant
- A programming language that is based on relay wiring symbols familiar to most plant electrical personnel
- High reliability and minimal maintenance
- Small physical size
- Ability to communicate with computer systems in the plant
- Moderate to low initial investment cost
- Rugged construction
- Modular design

Versatility The multifunction capability of a PLC allows control logic decision-making, enabling versatility rarely possible with other systems. The ability to combine discrete and analog logic is a powerful tool for the controls engineer. This is particularly evident in the control of batch processes. Entire start-up and shutdown sequences can be performed by the sequencer logic, and analog logic can be brought in during the batch run. Control of critical start-up parameters, such as temperature and pressure, can be precisely preprogrammed for each start-up step. Temperature stepping is easily programmed, as are the feedforward calculations that are used in some polymer reactors. All of these types of PLC applications are currently in use today and are well documented.[28,29,30,31]

Flexibility As a process goes on-line and is refined, the control equipment should be easily reconfigured to accommodate such modifications. The multifunction use of the PLC has already been discussed. In addition, digital blending applications, boiler control of either carbon monoxide or excess oxygen, and some other forms of optimizing control are also within the capabilities of PLCs. Because one common device performs multiple functions in a plant, fewer spare parts are needed, and the programming language is technician-friendly. In addition, the digital nature and self-diagnostic capabilities are strong additional justification for the PLC.

Expandability As a process matures, it is inevitable that enhancements will be added. These usually require more inputs and outputs. For hand-wired relay systems this usually necessitates extensive panel changes, which generally are problematic. A PLC easily accommodates the additional I/O without requiring changes in the existing wiring: The new points are merely placed in the system. If a PID loop or two is being added, no panel rework is necessary; only the wiring of the new points and some reprogramming to incorporate them are required. Conversely, if the initially selected PLC is "tight," additional I/O bases might be necessary. For this reason, most manufacturers recommend sizing the system to allow for 10 to 20% expansion.

Another advantage of the PLC is that it allows piecemeal implementation of projects. Systems can be brought on-line quickly and can be gradually converted to the PLC while on-line. The ability of the PLC to be reprogrammed while operating permits automation of processes that are too expensive to shut down. This technique is valuable to new as well as to retrofit projects (revamps).[32,33]

PLC vs. DCS

The capabilities of PLCs and DCSs have changed to the extent that today many applications that used to be the exclusive province of one or the other can be handled by both. The technology differences between PLCs and DCSs have evolved to be subtle or nonexistent. Manufacturers that had been making relays for logic and interlock applications developed PLCs, while DCS systems were developed by process control manufacturers with substantial experience in PID-type analog control. In the past it made good sense to use each type of controller in its area of superior experience. If the bulk of the I/O was digital (discrete), the logical choice was to use a PLC. If the I/O was mostly analog, a DCS system was selected. This logic is no longer universally true, and personal preference and end-user familiarity have become decisive factors in system selection. PLC and DCS comparisons have been taking place for as long as the two systems have existed. What's odd about this debate is that PLCs define only the controllers, whereas DCSs also include the software, operator interface, and network.[34]

In terms of pros and cons between the two designs, PLC I/O is likely to be more rugged and PLCs are likely to handle discrete logic faster than DCS systems. PLCs are also likely to be more desirable because their languages, such as ladder logic, are usually more familiar to plant personnel, and therefore there is less resistance to using them. On the other hand, ladder logic-type languages can be undesirable in some situations because they are not well suited to analog process control.

PLCs tend to be sold in a more piecemeal fashion as compared to the integrated systems approach common to DCSs. While PLCs are less expensive than DCSs, the end user often becomes more deeply involved with programming and systems integration issues. Nonetheless, many users find

PLCs to be a cost-effective solution for small to medium-sized process plants.[35]

Some users have overcome the limitations of PLCs by coupling them to PCs using custom-coded programming. The disadvantage of this approach is that such a nonstandardized system is usually understood fully only by its designer, and when that individual leaves the organization, the system can be ruined. When it comes to communications redundancy and data security, the DCS systems are superior. The DCS systems are also superior in their programming library, in advanced or optimizing control, in self-tuning algorithms, and, particularly, in their total plant architecture and information management capabilities.

PLC vs. Personal Computers

The PC is designed to be flexible and handle thousands of different types of applications, but PLCs are especially designed for control.[35] PCs started showing up on the factory floor in the mid-80s in programming and HMI applications. However, now the PC is migrating toward actual control. In response, PLC manufacturers have adapted PC technology, such as Ethernet. Some systems actually provide a “PC on a card” to plug into the PLC back plane.[11] PLCs are often thought of as computers. To a certain extent this is true; however, there are important differences between PLCs and computers.

Real-Time Operation/Orientation The PLC is designed to operate in a real-time control environment. The first priority of the CPU is to scan the I/O for status, make sequential control decisions (as defined by the program), implement those decisions, and repeat this procedure all within the allotted scan time. Most PLCs have internal clocks and “watchdog timers” built into their operations to ensure that a software error like “divide by zero” or an endless loop does not send the central processor into an undefined state. When the watchdog time is exceeded, the processor shuts down in a predetermined manner and usually turns off all outputs. In real-time systems, reliability is a big concern. PLC manufacturers' experience shows mean time between failures (MTBF) ranging from 20,000 to 400,000 hours. “This is far in excess of almost any other type of electronic or control equipment.”[3,6]

Environmental Considerations PLCs are designed to operate near the equipment they control. This means they function in hot, humid, dirty, noisy, and dusty industrial environments. Typical PLCs can operate in temperatures as high as 140°F (60°C) and as low as 32° F (0°C), with tolerable relative humidity ranging from 0 to 95% noncondensing. In addition, they have electrical noise immunities comparable with those required in military specifications.

Programming Languages and Techniques PLC languages are designed to emulate the popular relay ladder diagram format. This format is read and understood worldwide by maintenance technicians as well as engineers. Unlike computer programming, PLC programming does not require extensive special training. Applications know-how is much more important. Although certain special techniques are important for programming efficiency, they are easily learned. The major goal is the control program performance. Another difference between computers and PLCs is the sequential operation of the PLC. Program operations are performed by the PLC in the order they were programmed (Figure 5.4o). This is an extremely useful feature that allows easy programming of shift registers, ring counters, drum timers, and other useful indexing techniques for real-time control applications.

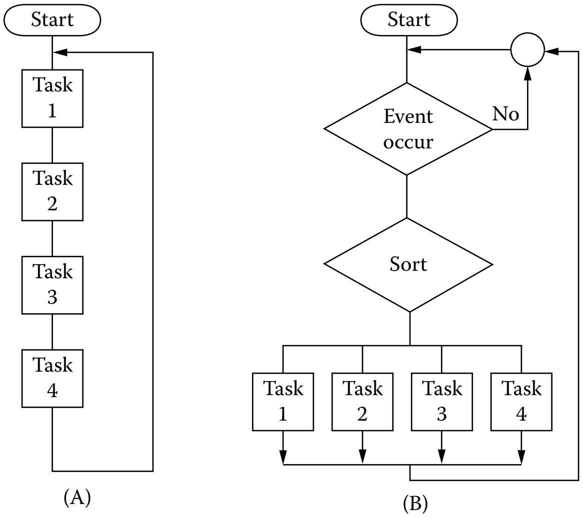

FIG. 5.4o

PLC versus computer. Program structure for a PLC (A) requires sequential execution with a scan, starting with task 1 and proceeding through task 4. The program structure for a general-purpose computer (B) permits task execution in any order.

Maintenance and Troubleshooting As a plant floor controller, the plant electrician or the instrument technician must maintain the PLC. It would be highly impractical to require computer-type maintenance service. To this end, PLC manufacturers build in self-diagnostics to allow for easy troubleshooting and repair of problems. Most PLC components are modular and simple to isolate; remove-and-replace (system modules) diagnostic techniques are usually implemented.

SUMMARY

Table 5.4p together with Figures 5.4q and 5.4r provide illustrative summaries of the PLC characteristics discussed thus far. Table 5.4p illustrates an I/O list for a milling application, while Figure 5.4q shows in some detail the PLC and all its key parts. The CPU is shown in the center of the figure as the PLC processor. Power for this unit is delivered by the

* Rung is a grouping of PLC instructions that controls one output or storage bit. This is represented as one section of a logic ladder diagram.

power supply shown to its right. The programming unit connected directly to it on the left is the way a ladder logic program line, like the one shown just above the CPU, is entered into the controller.

Representations of two I/O modules are shown in Figure 5.4r. The input module is on the left of the drawing and indicates a variety of contacts directly attached to seven of the eight points on the module. The point at address zero is shown as a spare for use as a replacement or future enhancement site. The output module shown has all eight of its output addresses (from address 140 through 147) in use.

Figure 5.4q shows an example of a remote I/O rack. Although the rack shown (rack No. 2) is powered by the main power supply, that is not a requirement. A remote I/O rack functions the same way as its direct I/O counterpart does. Various modules can be inserted in the rack to match the application's control needs.

PROJECT EXECUTION

Like any major enterprise, the PLC project must take into account the important considerations of schedule and budget. The PLC can facilitate the transition, however, by simultaneously pursuing several activities, thereby condensing the overall project schedule. A review of each major activity is presented in the following paragraphs.

Systems Analysis

The control system should be analyzed as a whole to determine plant control requirements. The PLC plays an integral part in these analyses, and its capabilities should be thoroughly understood by the controls engineer. Vital to systems analysis are the process and instrument diagram (P&ID), the descriptive operational sequence, and a logic diagram

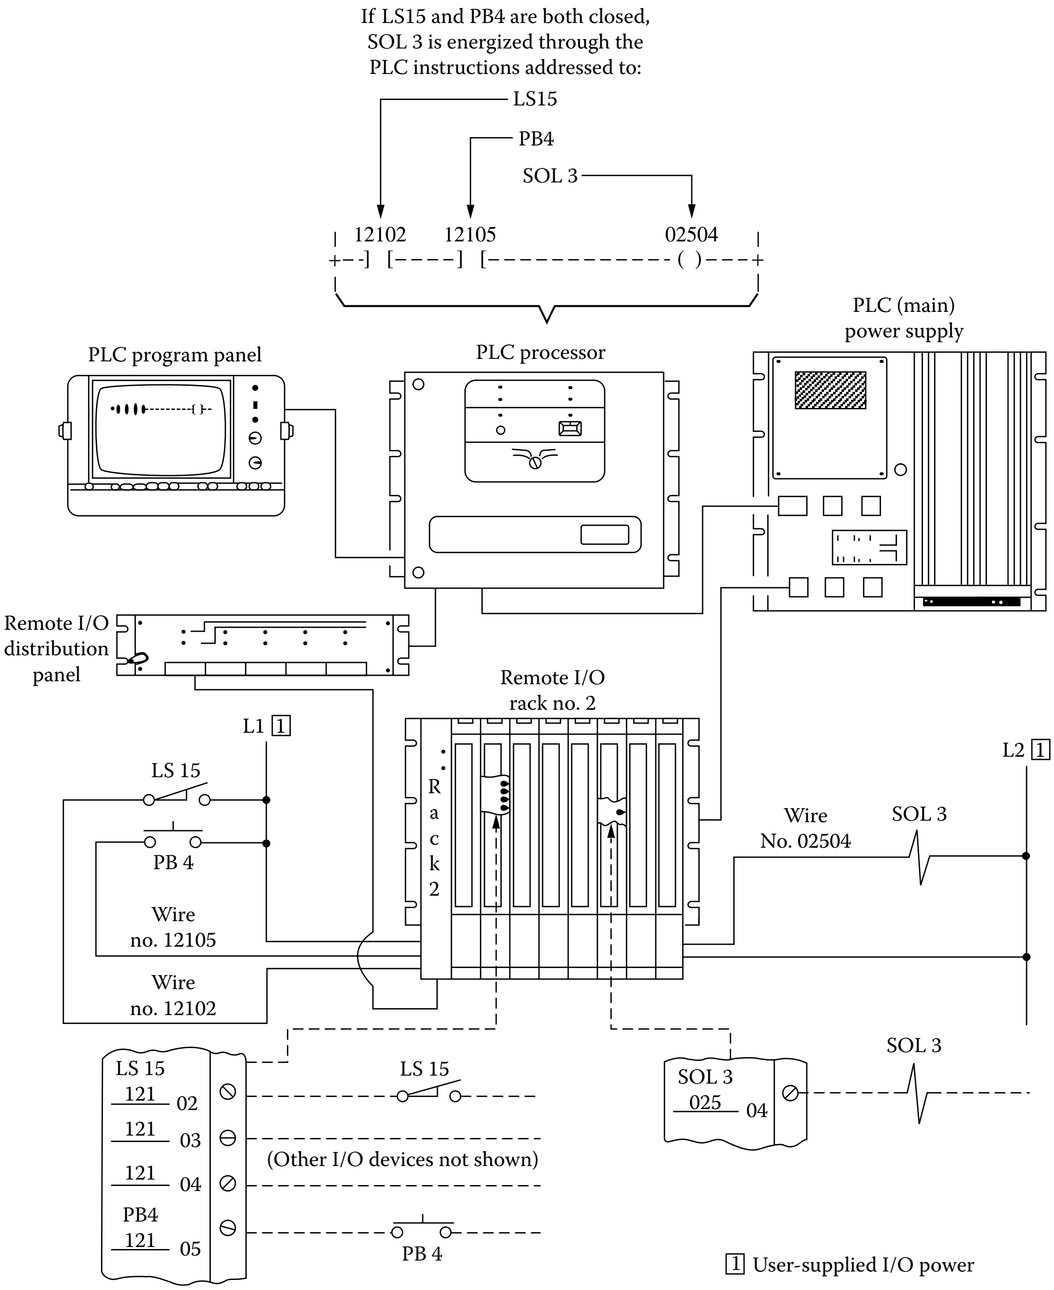

FIG. 5.4q
Configuration drawing. (Courtesy of Allen-Bradley.)

or electrical schematic. Part of this evaluation will be system sizing and selection. Once the appropriate PLC is selected and purchase orders are placed, two activities should begin immediately: engineering design and software development.

Systems Integrators One of the first decisions is whether to perform the work in-house or have a systems integrator do it. The general trend in the industry is that systems are more likely to be sold to OEMs and system integrators than to end users.[10] If an integrator will be used, it should be selected carefully. Some things to consider include:

- How well does the integrator know the PLC/HMI/reporting software?
- How well does it know your industry?
- How familiar is the integrator with your operations?
- How well can you define the operation of your project?
- How good is its training?
- Will it have time and budget to fine-tune the system?

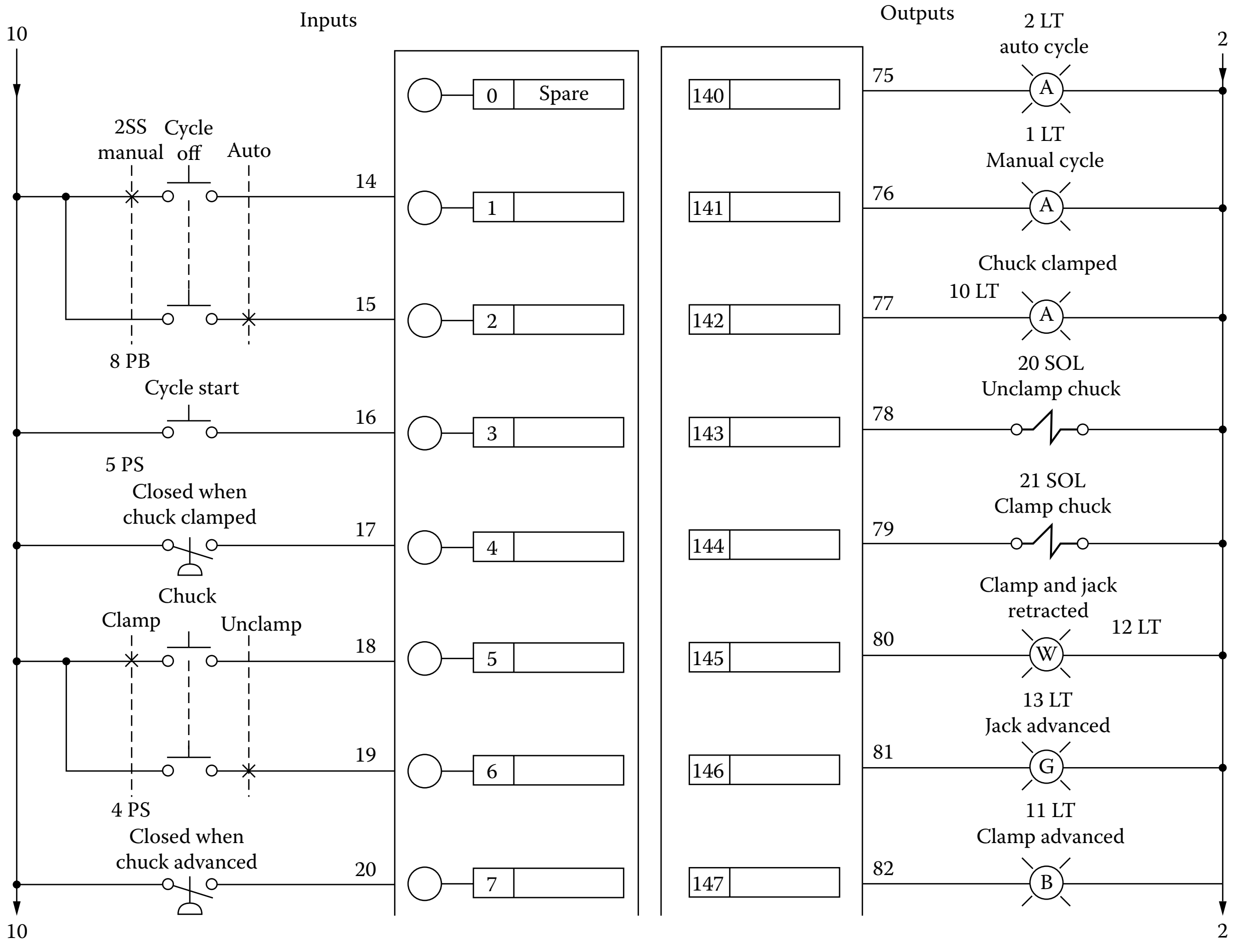

FIG. 5.4r
Point-to-point wiring diagram.[14]

- After warranty, will you be able to make changes without the integrator or will you have to pay for it to return?[36]

For budgeting, whether the work is done in-house or by an integrator, software costs range from 50 to 100% of the hardware cost. System engineering costs and documentation costs each range from 25 to 50% of hardware cost. Therefore, the total cost (without installation labor) is about twice (if not more) the hardware cost.

Open Systems

Another consideration is whether to use open systems or proprietary. A major benefit of using open systems is that a number of different manufacturers can supply equipment for the system. “The trend today is definitely towards open systems and open languages, but the bulk of the PLC market is still proprietary—about 75% proprietary and 25% open or standards-based. Even so, a large number of proprietary PLCs are shipped with Profibus, DeviceNet, or other open networking capabilities.”[7]

Distributed Control “One of the effects of better networks and intelligent devices is that control function no longer has to reside in a central controller. It can be scattered about, either in a network of small PLCs or in intelligent I/O bases.… Some distributed processing is good to have because you can divide an operation into logical pieces, but it becomes difficult to partition programs and logic and so forth into the machines.”[11] A potential benefit dividing a single large system into separate areas of control is that starting and troubleshooting a smaller piece of the system is more manageable.[37]

Redundancy Another issue is the amount of redundancy that will be built into the control system. Some areas to consider when evaluating the need for redundancy include preventing production impacts, equipment damage, business interruption and quality impacts, liability costs, public health and safety, site safety, and environmental impacts.[38] Redundant PLCs are available and I/O can be made redundant but it is often better to provide diversity in redundancy planning. Instead of using PLCs, manual controllers can be used. Manual control stations are important as backups in case of failure of the PLC controlling PID loops. Operator stations and HMI often provide manual control capabilities but still rely on the integrity of the PLC, so they are not truly manual in the hardwired sense. A manual control station is an important part of the distributed control system because it gives true manual control of the loops locally or in the control room, even when the local control systems are down. It is important to look at the overall system when evaluating redundancy. Unfortunately, the term "control-system redundancy" has come to refer to only the CPU, possibly the I/O but not the field devices. Even redundant PLCs can "fail" if they are powered from a single power source.

PLC Hardware, System Sizing, and Selection

Despite the variety of available PLC models, system sizing is relatively simple. Hardware and system size can be determined by an analysis of the following system characteristics:

1. I/O quantity and type
2. Remote I/O requirements
3. Memory quantity and type
4. Programming requirements
5. Programmers
6. Peripheral requirements

Although sizing is generally straightforward, selection of the right PLC requires considerable judgment regarding trade-offs between future requirements and present cost. The first three are examined below. The others are addressed elsewhere in this chapter.

I/O Quantity and Type (Example 1) For this simple system, the first step is development of the I/O list (Table 5.4p). This detailed document will be used extensively and should be developed with great care. (Once I/O numbers are assigned, it becomes very difficult to change all references to these numbers.) If switches and pilot lights are used to operate the controls, include I/O for them. Include any alarm outputs used for alarm annunciators. An intrusion switch on the panel door is useful for larger control panels. Also, consider allowing 20% spare I/O of each type used. The I/O list is followed by the configuration drawing.

The configuration drawing (Figure 5.4q) shows the arrangement of the I/O and support hardware. The point-to-point wiring diagram (Figure 5.4r) is used by the panel shop and the installation contractor to make the I/O device interconnect. Panel, or enclosure, design should now be coordinated with the addition of panel instrumentation, such as light switches, meters, and recorders. Once these steps are completed, panel fabrication and assembly can begin.

I/O Quantity and Type (Example 2) In this somewhat more complicated example, the user should arrange any special I/O types as well as the commonly available modules according to an I/O matrix by logical area, as shown in Table 5.4s. In this table, I/O types are listed across the first row and plant areas are listed down the first column. In this way, one can accurately reconstruct the decision-making process concerning I/O quantity and type. It is important to include at least 10 to 20% spare rack space in all I/O considerations.

For example, consider a typical process application. Assume a total I/O count of 764, broken down into 436 inputs and 328 outputs. This application falls into the *medium* PLC category. Because the majority of the field devices are located a good distance from the CPU, a PLC with remote I/O is desirable. The I/O requirements by locations are as follows:

Process Area: Total of 390 inputs and outputs, of which 230 are 24 V (discrete DC inputs), 24 are 4–20 mA analog inputs, and 136 are 24 V DC discrete outputs.

Tank Farm #1: Total of 98 I/O, of which 62 are 120 VAC discrete inputs (DIs) and 36 are 120 VAC discrete outputs.

Tank Farm #2: Total of 86 I/O, of which 52 are 120 VAC discrete inputs and 34 are 120 VAC discrete outputs.

Loading Station: Total of 190 I/O, of which 68 are 120 VAC discrete inputs and 122 are discrete outputs (of which 24 are 120 VAC and 98 are 240 VAC).

Let us assume that the PLC system being considered has the following features: (1) No constraints on input and output mixture; (2) the I/O modules are available in two formats, 16 points per module and 8 points per module; and (3) 10% spare I/O is required. For the sake of illustration, we will use the 16 points per module I/O structure in the process area and the 8 points per module structure in the tank farms and loading station. The I/O distribution (including spares) per location would now be as follows:

Process Area: Total of 390 I/O points, which require the following modules:
- 230 + 10% = 253 24 V DC inputs with 16 points/module = 15.8 modules; use 16 modules
- 24 + 10% = 26.4 4–20 mA analog inputs at 16 points per module = 1.6; use 2 modules
- 136 + 10% = 149.6 24 V DC discrete outputs at 16 points per module = 9.35; use 10 modules

Tank Farm #1: Total of 98 I/O points, which require the following modules:
- 62 + 10% = 68.2 are 120 VAC discrete inputs at 8 points per module = 8.5; use 9 modules
- 36 + 10% = 39.6 are 120 VAC discrete outputs at 8 points per module = 4.9; use 5 modules

Tank Farm #2: Total of 86 I/O points, which require the following modules:
- 52 + 10% = 57.2 are 120 VAC discrete inputs at 8 points per module = 7.2; use 8 modules
- 34 + 10% = 37.4 are 120 VAC discrete outputs at 8 points per module = 4.7; use 5 modules

TABLE 5.4s
I/O Matrix

Plant Area	*Analog*	*In*	*Model No.*[2]/*Qty*	*Analog Out*	*Model No.*[2]/*Qty*	*Discrete In*/*Voltage*	*Model No.*[2]/*Qty*	*Discrete Out*/*Voltage*	*Model No.*/*Qty*
Process area[1]	24	4–20 mA	—/2	0		230/24 VDC	—/16	136/24 VDC	—/10
Tank farm #1[3]	0			0		62/120 VAC	—/9	36/120 VAC	—/5
Tank farm #2[3]	0			0		52/120 VAC	—/8	34/120 VAC	—/5
Loading station[3]	0			0		68/120 VAC	—/10	24/120 VAC	—/4
								98/240 VAC	—/14

Notes: (1) Discrete in 16 pts/card
Discrete out 16 pts/card
Analog in 16 pts/card
Analog out
(2) Add model numbers after award of contract.
(3) DI and DO are 8 points per card

Loading Station: Total of 190 I/O points, which require the following modules:

- 68 + 10% = 74.8 are 120 VAC discrete inputs at 8 points per module = 9.4; use 10 modules
- 24 + 10% = 26.4 are 120 VAC discrete outputs at 8 points per module = 3.3; use 4 modules
- 98 + 10% = 107.8 are 240 VAC discrete outputs at 8 points per module = 13.5; use 14 modules

If we assume that one remote communications channel can service up to 128 I/O in groups of sixteen 8-point modules or eight 16-point modules, the system becomes:

- Process Area—390 I/O; 28 16-point modules; four remote channels
- Tank Farm #1—98 I/O; 14 8-point modules; one remote channel
- Tank Farm #2—86 I/O; 13 8-point modules; one remote channel
- Loading Station—190 I/O; 28 8-point modules; two remote channels

Remote I/O vs. Distributed Control A unique feature of the PLC is the multiplexed nature of the I/O bus. This can be used to great advantage to reduce overall wiring cost. If I/O racks are centralized in logical clusters, plant wiring requirements can be greatly reduced. Wiring between racks and the CPU can be reduced to a few twisted pairs of wires or a single cable. The tremendous cost savings that result can be realized without a compromise of control accuracy or capability.

A system configuration diagram (such as that shown in Figure 5.4q), when used in conjunction with the I/O matrix in Table 5.4s, aids in keeping track of the overall system configuration.

It is important to remember the major weakness of remote I/O systems. If the bus is cut or interrupted, the effects of I/O failure will be relatively unpredictable. One must consider the effect of a possible system failure on each step in the sequence. Some users install a redundant version of remote I/O communications to guard against the loss of remote I/O communications. For this reason, duplication of smaller CPUs at each remote location is often considered preferable to a large central CPU. This is actually an extension of distributed control within the network of the PLC itself. This approach can be very cost-effective, because requirements for the central unit size can be reduced. Serious consideration should be given to distributed versus centralized architecture in remote I/O systems in which control system integrity is important.

Memory Quantity and Type The type and quantity of PLC memory used depends on the controller's size and the company that manufactured it. Most small PLCs come with a fixed quantity of RAM. Although this is usually 2 K to 4 K of memory, the actual number of memory locations is not as important as the average size application program the PLC can be expected to handle. (In this case, size refers to the number of I/O points that are to be controlled and the average number of logic, timer, counter, and mathematics operations that are to be performed.) Some manufacturers may provide an extra-expense option of EEPROM or Flash memory with their small PLCs.

Midsize and large PLCs provide users an option for almost any type of memory desired. This includes various types of nonvolatile memory. Quantity limits imposed by the PLC will exceed most application demands. When this is not the case, it usually suggests that a more efficient control scheme is in order or that the application really does not belong on a PLC in the first place.

Total memory, as stated in the manufacturer's literature, does not necessarily mean the entire content is available to the user. Some manufacturers reserve large blocks for the PLC executive. A system with 4 K of 16-bit words of user memory may comfortably accommodate a program, whereas another system with 8 K of 8-bit words may have too little memory for the same program.

Special programming language features are an important aspect of memory sizing, especially in process control. The PID algorithm is a perfect example: One manufacturer requires 33 words of user-available memory, whereas another may need in excess of 1000 words. Obviously, the memory sizing for a loop control program would vary in these two systems. Another example is the use of special functions, such as shift registers. An alternative way of developing a shift register in ladder logic is to use a special function shift register or handling data to require less user memory. Word (or register) moves are also powerful in terms of memory efficiency. Programming languages, which can be binary- or octal-based or alphanumeric Boolean, affect memory use. The closer the language is to a machine code (binary-based), the more user memory is required to perform the more complex functions. The closer the language is to alphanumeric Boolean, the less memory will be required for complex functions.

The best way to determine program memory prerequisites is to write a representative sample program reflecting some actual project requirements and to request information about user memory size from the various manufacturers. If the manufacturer's suggestions are followed, the user can be reasonably assured that the memory will not be undersized.

The final area of caution about memory size concerns the consideration of data storage. Data tables, scratch pads, and historical data retrieval requirements can inflate the size of the PLC memory. It should be remembered that the primary task of a PLC is control of the process. If data requirements are large, connection to auxiliary devices, such as mini- and microcomputers, should be given serious consideration. Many of these devices are currently available and are of an industrial grade; furthermore, the price of these systems is coming down rapidly. It is not good engineering practice to degrade control capabilities by burdening the PLC with excessive data acquisition functions. As a plant goes online, operational requirements for data generally increase astronomically. These will be easily accommodated by a mini- or microcomputer but not by the PLC memory.

PLC Installation and Panel Design

Installation of PLC systems is not a difficult or mysterious procedure, but the following general rules will save time and trouble for the systems designer or installer. The basic principles of PLC installation are the same as those for the installation of relay or other control systems. Safety rules and practices governing proper use of electrical control equipment in general should be observed. These include correct grounding techniques, placement of disconnect devices, proper selection of wire gauge, fusing, and logical layout of the device. PLCs can often be retrofitted into existing hardwired relay enclosures because they are designed to withstand the typical plant environment. PLC vendors provide installation manuals upon request.

After the PLC equipment is selected, the support equipment will need to be identified. Some panel shops that build PLC panels can assist or perform this additional design. At the panel level this includes terminal blocks, wireway, wire type and size both for discrete and analog, loop power supply (usually 24 V DC), circuit breakers and fuses, isolation relays, intrinsic safety barriers (if I/O wiring enters flammable or explosive environments as defined by national electric code), main isolation transformer, pilot lights, pushbuttons and switches, internal panel work lights, and receptacle. Also included are any door-mounted equipment like chart recorders, digital panel meters, and operator interface panels. A UPS may be required. Separate isolated grounding is sometimes used for loop shields. Motor starters and small variable frequency drives may also be in the same enclosure.

After all the equipment in the panel is determined, a heat calculation should be done for the ambient extremes expected, particularly if the cabinet is outdoors, to verify the internal temperature is well below the maximum temperature of all components. Generally the PLC is not the limiting factor here, but other electronics and power supplies may limit the maximum allowable temperature. If the interior temperature is too high, a heat exchanger or air conditioner may be required. If the panel is installed in a cold area, a heater may be needed to prevent condensation, which can ruin electronic equipment.

Safety Considerations Perhaps the most important safety feature, which is often neglected in PLC system design, is emergency stop and master control relays. This feature must be included whenever a hardwired device is used in order to ensure operator protection against the unwanted application of power. Emergency stop functions should be completely hardwired (Figure 5.4t). In no way should any software functions

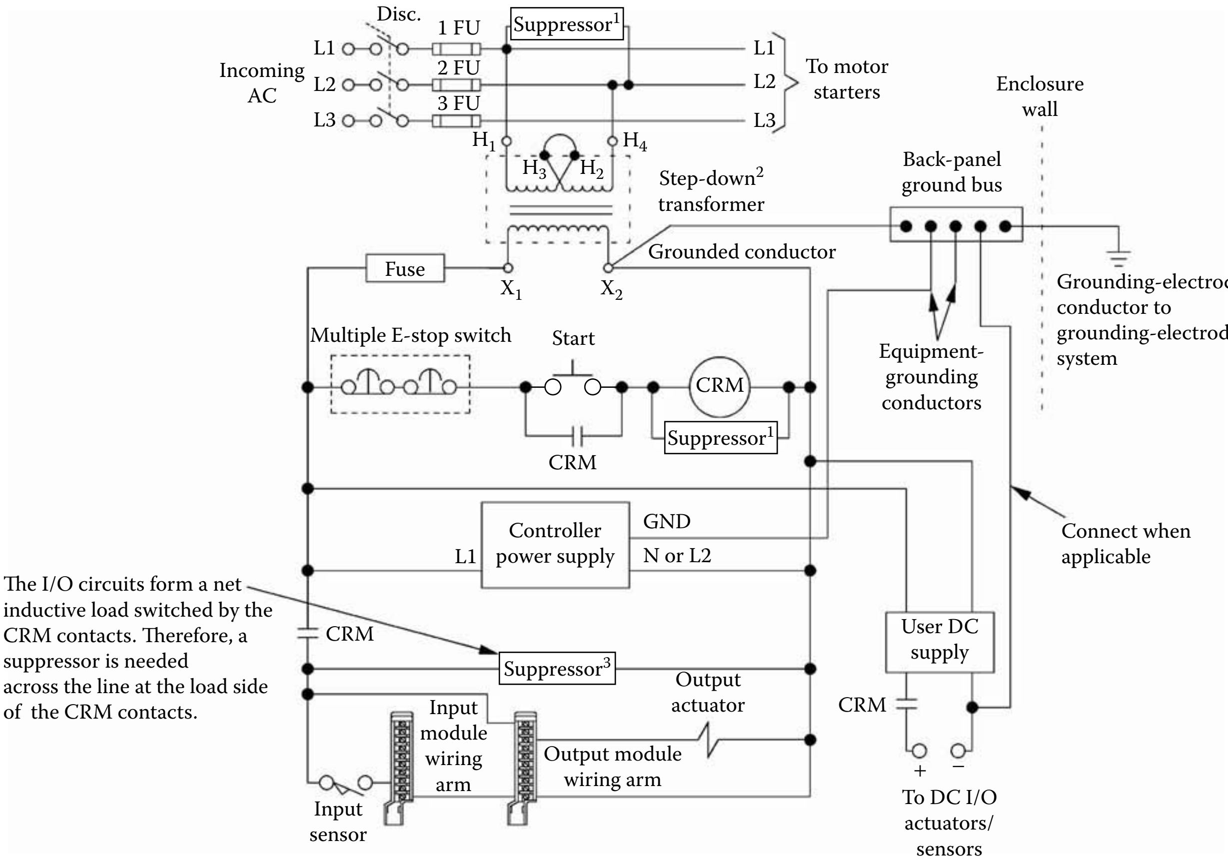

FIG. 5.4t

Grounded AC power-distribution system with master-control relay.

Notes:

1. To minimize EMI generation, connect a suppressor across an inductive load.
2. In many applications, a second transformer provides power to the input circuits and power supplies for isolation from the output circuits.
3. Connect a suppressor here to minimize EMI generation from the net inductive load switched by the CRM contacts. In some installations, a 1 µf 220 ohm suppressor or 2 µf 100 ohm suppressor has been effective. (Courtesy of Allen-Bradley)

be relied upon to shut off the process or the machine. Disconnect switches and master control relays should be hardwired to cut off power to the output supply of the PLC. This is necessary because most PLC manufacturers use triacs for their output switching devices, and triacs are just as likely to fail on as off. This feature is often required by local or national codes. In the United States, NFPA 79, "Electrical Standard for Industrial Machinery," covers this subject.[39,40,41,42]

Implementation Planning ahead is every bit as important in designing a complete PLC system as in laying out a relay logic panel. Care in counting I/O points in the beginning—and leaving a safety factor—will save headaches in the panel fabrication stage. Panels should always have plenty of expansion room left over, because I/O is invariably added as the job progresses and the operators see the advantages of PLCs. The designer should refer to the layout considerations provided by the manufacturer. Extra space should be left to provide access to the boards and connectors of the PLC. The diagnostic and status indicators should all be visible. The designer should leave room between I/O racks for wireways and large hands.

One good technique for ensuring efficient panel layouts is to involve maintenance personnel in the design procedure. This not only optimizes the layout but also introduces the staff to the hardware (Figure 5.4u).

In general, the best defense against creating a tangled mess when designing a PLC system is to follow proper documentation techniques. A little more time spent documenting panel layout, I/O counts, and wiring diagrams results in a lot less time spent starting up the system. PLCs can handle large amounts of I/O points with varying electrical characteristics, so things can get pretty confusing in a hurry. Cable requirements between hardware boxes vary from one type of PLC to another, so this is an important consideration in panel layout.

Enclosure Enclosures should nearly always be provided for the PLCs themselves. This protects the electronics from moisture, oil, dust particles, and unwanted tampering. Most

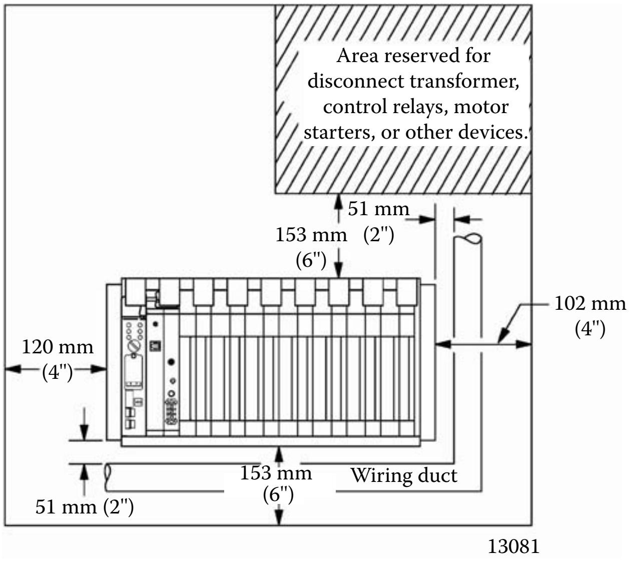

FIG. 5.4u
Typical enclosure layout. (Courtesy of Allen-Bradley.)

manufacturers recommend a NEMA 12 enclosure for the standard industrial environment or a NEMA 4X for outdoor or corrosive environments. A NEMA 3R is not recommended because it is not sealed against dust and moisture. This type of enclosure is readily available in a variety of sizes and, in fact, may be already included with a new system.

PLCs are designed to be located close to the machine or the process under control. This keeps the wiring runs short and aids in the troubleshooting procedure. At times, however, mounting the PLC directly on the machine or too close to the process is not advisable, such as in cases of vibration inherent in the machine, electrical noise interference, or excessive heat problems. In these situations, the PLC must be either moved away or successfully protected against these environmental conditions.

Temperature Considerations Installing any solid-state device requires paying attention to ambient temperatures, radiant heat bombardment, and the heat generated by the device itself. PLCs are typically designed for operation over a broad range

Ground connection details. (Courtesy of Allen-Bradley.)

of temperatures, usually from 0 to 60°C. When analyzing the proposed PLC environment, however, one should remember that enclosure temperatures usually run a few degrees higher than ambient temperatures. Radiant heat on an enclosure from surrounding tanks can raise the internal temperature beyond that specified by the manufacturer.

Heat generated by the PLC is a key issue when the device is placed in ambient temperatures close to the extreme mentioned in the specifications. The temperature rise caused by the power consumption of the PLC itself is not hard to estimate. In addition, most manufacturers will provide a notation of the power consumption of the triacs driving field loads. When designing the hardware layout within the panel, one should adhere to the manufacturer's suggestions regarding ways to minimize heating problems. Most PLCs use convection over fins to take heat away from particular areas within the hardware. Care must be taken to ensure that no obstruction to air flow over these fins is introduced by placement of the PLC in the enclosure. Wireways are typically provided with holes to allow air to pass through. Generally, one can avoid problems with PLC enclosures by simply leaving plenty of air space around the heat producers.

Should all of these factors combine to cause a temperature problem, the panel can be vented, air conditioned, or moved to another location. Usually, simply blowing filtered air through the enclosure will resolve minor difficulties. If air conditioning is required, small units that are designed for cooling electronic enclosures are readily available.

Noise Noise or unwanted electrical signals can generate problems for all solid-state circuits, particularly microprocessors. Each PLC manufacturer suggests methods for designing a noise-immune system. These guidelines should be strictly followed in the design and installation phases, because noise problems can be very difficult to isolate after the system is up and running. I/O systems are isolated from the field, but voltage spikes can still appear within the low-voltage environment of the PLC if proper grounding practices are not followed.

A well-grounded enclosure can provide a barrier to noise bombardment from outside. Metal-to-metal contact between the PLC and the panel is a must, as is a good connection from the panel to the ground (see Figure 5.4v). Noise producers within the panel should be noted during the panel design phase, and the PLC must not be located too close to these devices. Wiring within the panel should also be diverted around noise producers to avoid picking up any stray signals. Often, it is necessary to keep AC and DC wiring bundles apart, particularly when high-voltage AC is used at the same time that low-level analog signals are present. Refer to Tables 5.4w and 5.4x and Figure 5.4y for recommendations.

TABLE 5.4w
Follow These Guidelines for Grouping Conductors with Respect to Noise (Courtesy of Allen-Bradley)

Group Conductor Cables Fitting This Description	*Into This Category:*	*Examples:*
Control and AC power-High-power conductors that are more tolerant of electrical noise than category 2 conductors and may also cause more noise to be picked up by adjacent conductors Corresponds to IEEE levels 3 (low susceptibility) and 4 (power)	Category 1	AC power lines for power supplies and I/O circuits. High-power digital AC I/O lines—to connect AC I/O modules rated for high power and high noise immunity. High-power digital DC I/O lines — to connect DC I/O modules rated for high power or with input circuits with long time-constant filters for high noise rejection. They typically connect devices such as hard-contact switches, relays, and solenoids.
Signal and communications—Low-power conductors that are less tolerant of electrical noise than category 1 conductors and should also cause less noise to be picked up by adjacent conductors (they connect to sensors and actuators relatively close to the I/O modules) Corresponds to IEEE levels 1 (high susceptibility) and 2 (medium susceptibility)	Category 2	Analog I/O lines and DC power lines for analog circuits. Low-power digital AC/DC I/O lines — to connect to I/O modules that are rated for low power such as low-power contact-output modules. Low-power digital DC I/O lines — to connect to DC I/O modules that are rated for low power and have input circuits with short time-constant filters to detect short pulses. They typically connect to devices such as proximity switches, photo-electric sensors, TTL devices, and encoders. Communications cables (ControlNet, DeviceNet, Universal remote I/O, extended-local I/O, DH+, DH-485, RS-232-C, RS-422, RS-423 cables) — to connect between processors or to I/O adapter modules, programming terminals, computers, or data terminals.
Intra-enclosure — Interconnect the system components within an enclosure Corresponds to IEEE levels 1 (high susceptibility) and 2 (medium susceptibility)	Category 3	Low-voltage DC power cables — to provide backplane power to the system components. Communications cables — to connect between system components within the same enclosure.

TABLE 5.4x
Follow These Guidelines for Routing Cables to Guard against Noise (Courtesy of Allen-Bradley)

Route This Category of Conductor Cables:	*According to These Guidelines*
Category 1	These conductors can be routed in the same cable tray or raceway with machine power conductors of up to 600 VAC (feeding up to 100 hp devices).
Category 2	If it must cross power feed lines, it should do so at right angles. Route at least 5 ft from high-voltage enclosures, or sources of RF/microwave radiation. If the conductor is in a metal wireway or conduit, each segment of that wireway or conduit must be bonded to each adjacent segment so that it has electrical continuity along its entire length, and must be bonded to the enclosure at the entry point. Properly shield (where applicable) and route in a raceway separate from category 1 conductors. If in a contiguous metallic wireway or conduit, route at least 0.08 m (3 in) from category 1 conductors of less than 20 A; 0.15 m (6 in) from AC power lines of 20 A or more; but only up to 100 kVA; 0.3 m (1 ft) from AC power lines of greater than 100 kVA. If not in a contiguous metallic wireway or conduit, route at least 0.15 m (6 in) from category 1 conductors of less than 20 A; 0.3 m (1 ft) from AC power lines of 20 A or more; but only up to 100 kVA; 0.6 m (2 ft) from AC power lines of greater than 100 kVA.
Category 3	Route conductors external to all raceways in the enclosure or in a raceway separate from any category 1 conductors with the same spacing listed for category 2 conductors, where possible.

Line voltage variations can cause hard-to-trace problems in the operation of any computer-based system. PLCs are no exception, even though they are designed to operate over a much larger variation in supply voltage. Large spikes or brownout conditions can cause errors in program execution. Most manufacturers protect against this, enabling the controller to come up running after a brownout, but these measures may not be acceptable in all applications. The designer may wish to add an isolation transformer to a proposed PLC system, sized for twice the anticipated load. This is cheap insurance, and PLC manufacturers will help determine the required load.

Triac outputs require some special attention that will be new to relay users. Triacs used for AC loads typically leak a small amount of current. In the case of triac outputs from a PLC, this leakage may be enough to keep panel lamps glowing or small relays energized. When a triac is used to switch the input on a PLC, the leakage may be enough to make the PLCs "think" the input is on. A dummy load (shown in Figure 5.4z) can be used to drain this leakage when the input should be off. Whenever a mechanical contact is used in series with a load energized by a triac (as shown in Figure 5.4aa), a resistance-capacitance (RC) network should be used as shown to protect the triac from inductive kickback. A varistor should be provided in parallel with a load whenever the load can be "hot-wired" around the triac (Figure 5.4bb). The user should check with the PLC manufacturer for the suggested RC and metal oxide varistor (MOV) types for the particular application. Triacs cannot directly drive large motor starters and similar devices. PLC manufacturers provide surge specifications for the various I/O cards. Sometimes an interposing relay or dry contacts will be required for large loads.

PLCs are similar to most electrical control systems. To be sure, solid-state devices, microprocessors, and triacs require some special considerations during the design, installation, and start-up phases of a project, but these concepts are not too complex or difficult to assimilate. As always, good design habits in the beginning will ensure a safe and reliable control system.

Hookup PLC panels can be very neat and orderly if all the terminals are arranged in a logical fashion. The actual result is a direct function of the time spent during the design process. Interposing terminal blocks between the PLC I/O structure and the field is suggested, because the terminations provided by PLC manufacturers are shrinking in the race to provide higher-density I/O. This also gives the panel designer the ability to place the field termination points where they are easily accessed. Wiring ducts keep the panel neat and protect the wire from mishap.

Following good wiring practices can avert many noise problems. Low-voltage signal wiring should be kept away from noise sources. Analog signals should be shielded, with the shield terminated at an isolated ground in the panel only (to prevent shield ground loops). Again, these analog signals should be separated from power wiring.

Software (Program) Development

The I/O list mentioned previously will be used to begin the program development. Basic control philosophy decisions need to be made at this point. Should valves fail open or closed? What fail-safe provisions are necessary for analog control? These philosophical decisions should be documented and included with the process operational descriptions.[15] Often this document will be referred to as the software functional specification. Its purpose is to define, as precisely as possible, the operation of the controls.[43] It also has several other functions:

1. It communicates the functional requirements of the control system to those writing the PLC code.

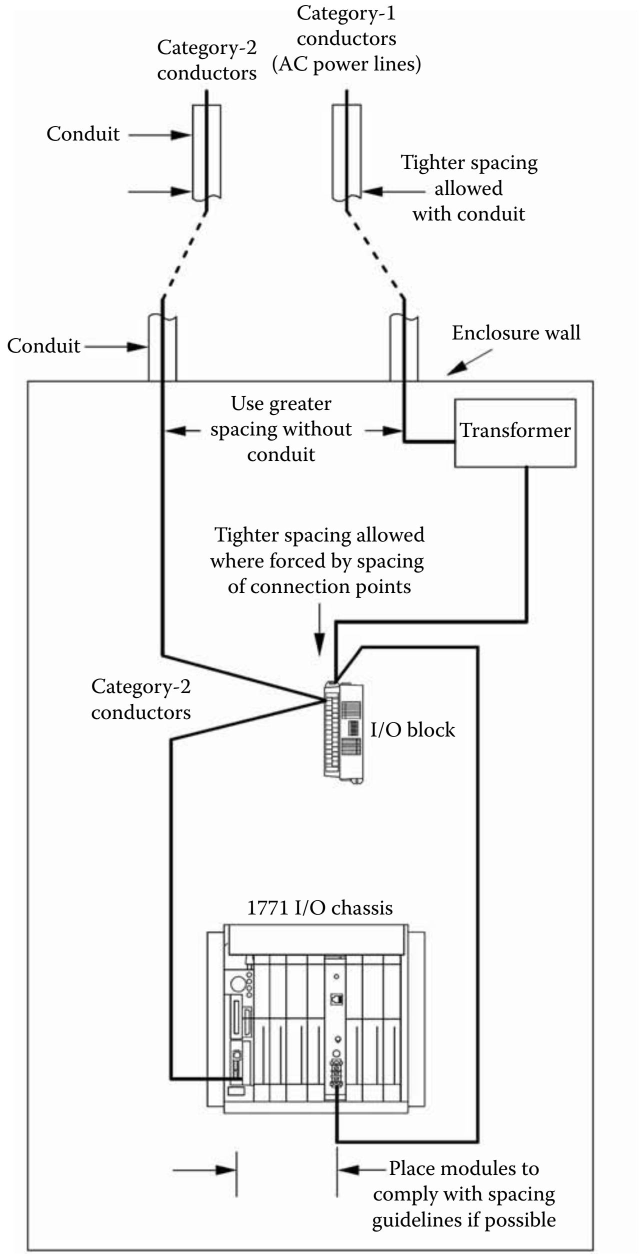

FIG. 5.4y
Mounting and wiring details. (Courtesy of Allen-Bradley.)

2. It records the thought process (regarding control) of the system designer to be used in the event of a personnel change. Such information can be invaluable.[44]
3. It provides a review document for personnel working in other capacities (mechanical, process, and project management) to ensure that they understand the operation of the controls.
4. It provides a guide for developing the operational description for the operator's manual.

After the functional specification has been reviewed and approved, a detailed operational sequence chart, timing

Dummy load for leakage. If a "leaky" triac, such as a proximity switch, is used to switch the hot side of the line, then a pull-down resistor (R) is required to counteract the leakage.

diagram, logic diagram, flowchart, or electrical schematic is developed from it. This schematic is translated or coded into the appropriate PLC language, cross-referencing I/O with PLC designator tags. The piping and instrument diagram is also cross-referenced with PLC designators. In this way, future cross-referencing of system drawings and PLC codes is facilitated.

As the code is entered, a memory map or register index is kept by the programmer (Table 5.4cc). This map is useful for organizing program data in logical arrangements and will prove invaluable during start-up, when the programmer may need to locate available blocks of memory quickly for program revisions. Most PLC programming software can generate a cross-reference; however, certain types of instructions are difficult for the program to cross-reference, so a list is still desirable.

The use and understanding of PLC programming depends on knowledge of the process to be controlled, an understanding of electrical schematics, and an appreciation for logic operations and for various types of logic and relay devices. Other sections of this chapter provide information on each of these topics. A review of those topics might be useful at this point.

Although the programming style and language used is, to some extent, dictated by the size of the PLC used, there are fundamental programming elements, including logic operations, timers, counters, and arithmetic capabilities, that are provided in all models. Some of the characteristics of these important elements are briefly discussed below (see Sections 5.5 and 5.6 for more information). Ladder logic continues to be popular because it was purposely created to look like hardwired relay logic drawings already in use. It is this similarity between ladder diagrams used for relays and the programming version that eased the change from using relays to using PLCs. In addition, ladder logic is relatively easy to learn.[9,45]

Boolean Logic Relay type instructions are the most basic of all PLC instructions. Boolean logic functions (AND, OR, and NOT) are diagrammed as combinations of normally open and normally closed contacts. A coil symbol represents the result of the logic function. In ladder logic, contacts can be shown in series or parallel to achieve the "AND" or "OR" functions, respectively. A normally closed contact represents a "NOT" function.[45]

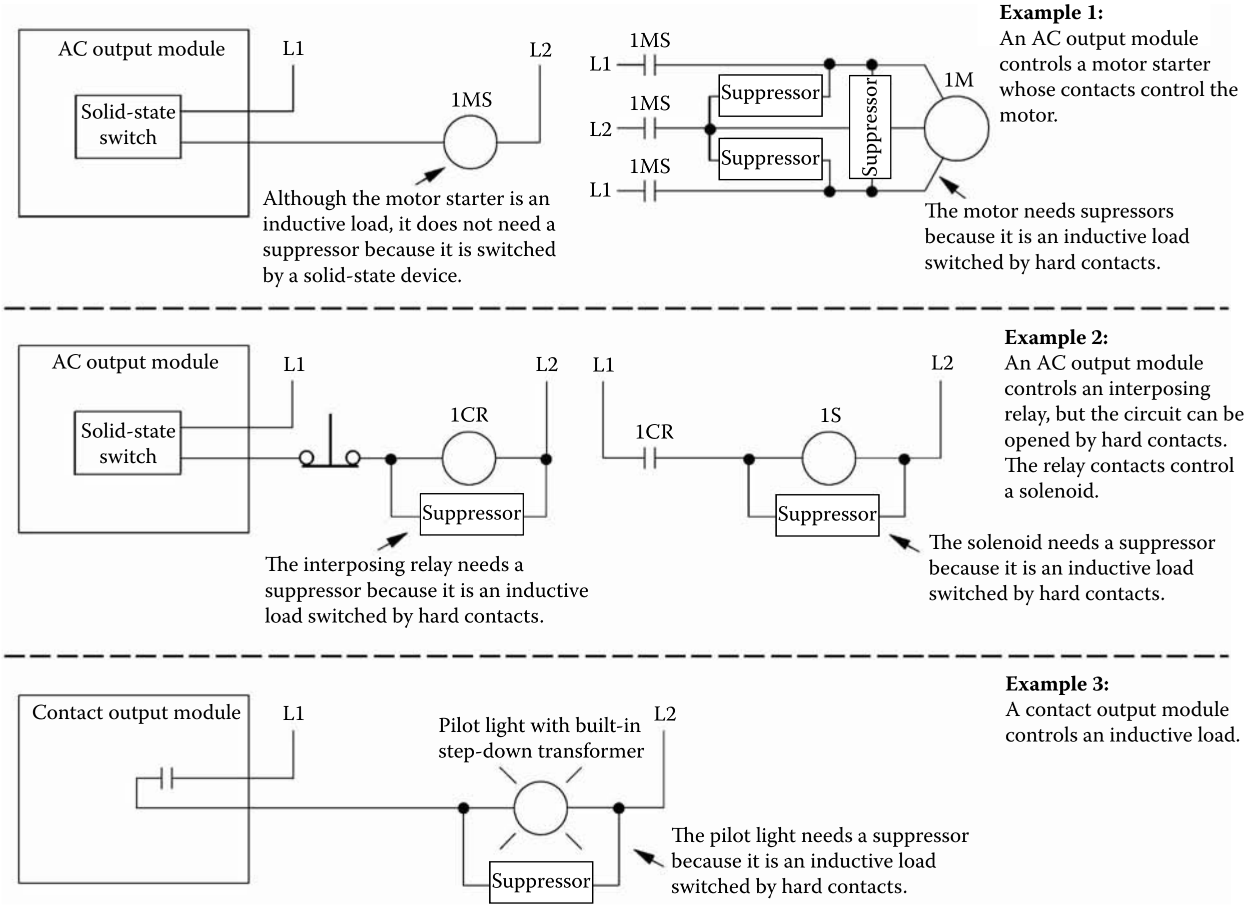

FIG. 5.4aa

Examples of where to use suppression. (Courtesy of Allen-Bradley.)

One popular programming technique involves defining the sequential logic in electrical schematic format, using actual tag numbers, and then translating this diagram into the appropriate programming language. Figure 5.4dd shows the translation of some examples of typical circuits to ladder diagrams, Boolean algebra, and mnemonics. Because this translation is relatively simple, maintenance and engineering personnel have accepted PLCs, although they have not accepted computers as readily. The unknown has been replaced with the familiar.

Timing and Counting Figure 5.4ee is a schematic representation of a timer and a counter. Although their formats differ, the principles are the same. The legs of the timer represent start/stop and reset. Timers can be on-delay or off-delay and can be cascaded (that is, linked together in series). Counters can be up or down and have a count leg (in which the number of switch closures is the count) and an up/down leg (in which the position of the switch determines up count or down count). A PLC with arithmetic capability can use a combination timer and counter as an integrator. Figure 5.4ff shows a turbine meter pulse counter turned into a low-cost integrator within the PLC. Obviously, the scan rate of the PLC (scans per second) must be twice the pulse rate of the turbine (pulses per second).

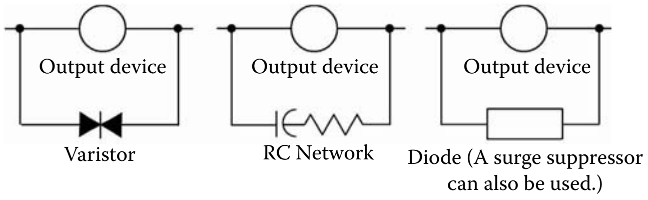

FIG. 5.4bb

Surge suppression for inductive AC load devices. (Courtesy of Allen-Bradley.)

Arithmetic Capabilities Figure 5.4ff shows an arithmetic program that permits the rapid addition of pulse counts from two counters hooked to two electric meters. The resulting sum is displayed through a panel meter. This logical addition is performed using integer mathematics (that is, no decimal calculations can be performed). Most PLCs use an approximation technique called “double-precision integer mathematics” to do calculations of greater complexity (such as PID). Some PLCs have true floating-point mathematics capability.

Floating-point mathematics is a powerful tool for process applications. For example, in the integrator example in

Figure 5.4gg, the division of pulses by elapsed time can be expressed as a decimal number rather than as a truncated integer. Feedforward calculations and PID can be performed in double-precision integer mathematics but are more memory-intense than in floating-point mathematics. Floating-point mathematics may require the use of a separate microprocessor within the CPU and usually involves two adjacent memory locations to store the mantissa and the abscissa in a form of scientific notation. The programmer automatically translates when the memory location is followed by a period (.), indicating a floating point number.

Programming Documentation The following technique can be used for PLC programming applications. There are many advantages to this approach.

1. Develop detailed I/O lists. Table 5.4p shows an I/O cross-reference relating tag numbers to I/O points. This list should be used extensively; starting without it will cause confusion and errors resulting from inevitable changes.
2. Develop a detailed descriptive operational sequence of events. Figure 5.4ii shows a sample sequence using a process batch application.

3. Develop electrical schematics or ladder diagrams for sequential control.
4. Develop piping and instrumentation drawings (or a logic diagram) for process control. Figure 5.4jj shows a diagram that will allow maintenance personnel to find important activities quickly. Note the I/O matrix index, showing what happens inside the PLC software, and the cross-referenced I/O memory locations and tag numbers.
5. Translate the drawings in steps 3 and 4 to the PLC language.
6. Enter the program code using a memory map (see Table 5.4cc).
7. Debug the program at the programmer's facility. Use a simulator to debug the program. Run through the operational sequence defined in step 2. If it has changed, be sure to ascertain how that change has affected other parts of the program. Rewrite the sequence description to reflect current operations, if necessary.
8. Save and document the program. Reproduce the program on transportable media, such as floppy disks. (Do this daily.) Document programming changes using printouts.
9. Enter and debug the program in the field. It is essential to note all changes made on the documentation. Some of the biggest problems with relay systems are undocumented field modifications.
10. Redocument and reproduce the final program.[14,21,46,47]

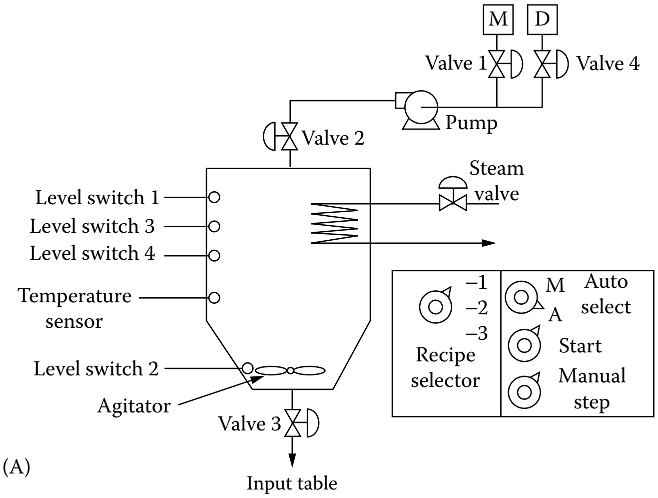
The final documentation package should include the following: I/O list and cross-reference, descriptive operational sequence, electrical schematics, process schematics, program listing (see Figure 5.4gg for annotated final document), memory maps (showing the memory areas that have been used and those that are available), and notes for future program changes or additions.

One important word about the documentation package: A major advantage of the PLC is its ability to be reprogrammed as plant requirements change. Without proper documentation, previous programming efforts will have to be reproduced in order to make the changes that are required. Poor documentation results in wasteful efforts at reconstruction. The PLC, like all engineering tools, requires good control systems engineering practices in order for its full potential to be realized. Good documentation is an essential element of any PLC project.[22,48]

Programming and Documentation Tools Both PLC and aftermarket parties offer programming and documentation tools for the system designer or user. Programming software is typically provided by the PLC manufacturer and is designed to program a specific machine or family of machines. Some third parties are offering universal programming software. These software packages vary greatly in price and capabilities but offer on- and off-line programming to many different types of PLCs, real-time status, and some very sophisticated annotation. Communications to different PLCs are usually supported by different software packages. Each vendor's product offers different types and amounts of ladder and contact comments. Again, many types of cross-references are available to be printed out. Often, other PLC design documentation problems may be solved, such as the generation of panel configuration drawings, point-to-point wiring diagrams, and I/O layout. One system even prints out the wire labels.

HMI Software (Program) Configuration The operator interface needs to be designed and implemented. Generally, the same process is followed whether the interface is a local panel or the SCADA server in the control room. Sketches of the displays should be made and reviewed with operations staff. These should emphasize operator-friendly graphics for the plant operators, who will spend the most time with them.[49] Most of the time, operators need to view an operations-oriented view of the process. Only when an abnormal event occurs will they go to the detail screens to find the cause.[50]

Once a consensus is reached on how the system should be operated, the screens can be configured on the interface equipment. "Linking" is the term used for defining how the screen will change based on the contents of PLC memory locations.



Output table

Step	Description	Input conditions to advance	Outputs Valve 1 300	Valve 2 301	Valve 3 302	Pump 303	Steam 304	Agitate 305	Valve 4 306

Batch sequence. (A) Graphic representation of a simple batch process reactor vessel, with inputs and outputs. (B) Outputs for each step in the process are described in the "Output Table." The advance conditions for each step are shown along with input interlocks (bottom), which affect certain outputs. (C) The "Input Table" correlates the connection terminal number with the word description of each input.[29]

Reports Configuration Some simple reports can be directly set up in the operator interface software. More extensive reports usually require separate reporting or database software. These reports should be set up early so that they can be checked before installation of the equipment.

Software/Hardware Integration

Once the program is entered, a simulation is recommended, and the program checkout process begins "on the bench." This process uses the functional specification to prove the software is acceptable. A large percentage of the program can be proved in this manner. Program debugging can be completed before field installation. Field corrections will then be minimized, and high-salaried electrical and installation personnel will not be standing around waiting. The savings that can be realized are quite significant.[51] In addition, it's important to keep in mind that there's no substitute for a bench-simulated program check. The software simulation proves the program and allows acceptance by the customer. The program should be reproduced and documented after it has been checked.

Once the panels are built, and all configuration and programming are complete, as much of the system as possible should be set up in a staging area for a complete checkout. Final control elements (valves, motor starters) function can be checked for proper outputs. Analog sensors (pressure, level, flow, and so on) are usually simulated with a 4–20 mA calibrator. Using the PLC and programming aids, the panel wiring can be "rung out" (that is, checked point by point) through the PLC. Each I/O point should be activated separately to the terminal block or from the panel controls (buttons, lights, switches). In this manner, the electrical integrity of the panel from the terminal blocks inward is ensured. If any continuity problems exist thereafter, they will be located in the field wiring. All remote I/O should be connected. The data highway or Ethernet networks should be temporarily connected. All displays should also be checked to make sure that the I/O points trigger the correct part of the screen or activate the correct alarm.

Some organizations prefer to perform a simulated operation checkout at this time. This is a highly useful approach and can be implemented if the simulators and the I/O point arrangement are organized to simulate the process outside the panel. Some I/O points may need to be jumpered for simulation. For instance, if run contacts are required to close a few seconds after the motor is called to run, they can often be temporarily connected to the output for the test. It is generally felt that each hour spent troubleshooting at this point will save two or three hours during system start-up. Occasionally, operations personnel are brought in

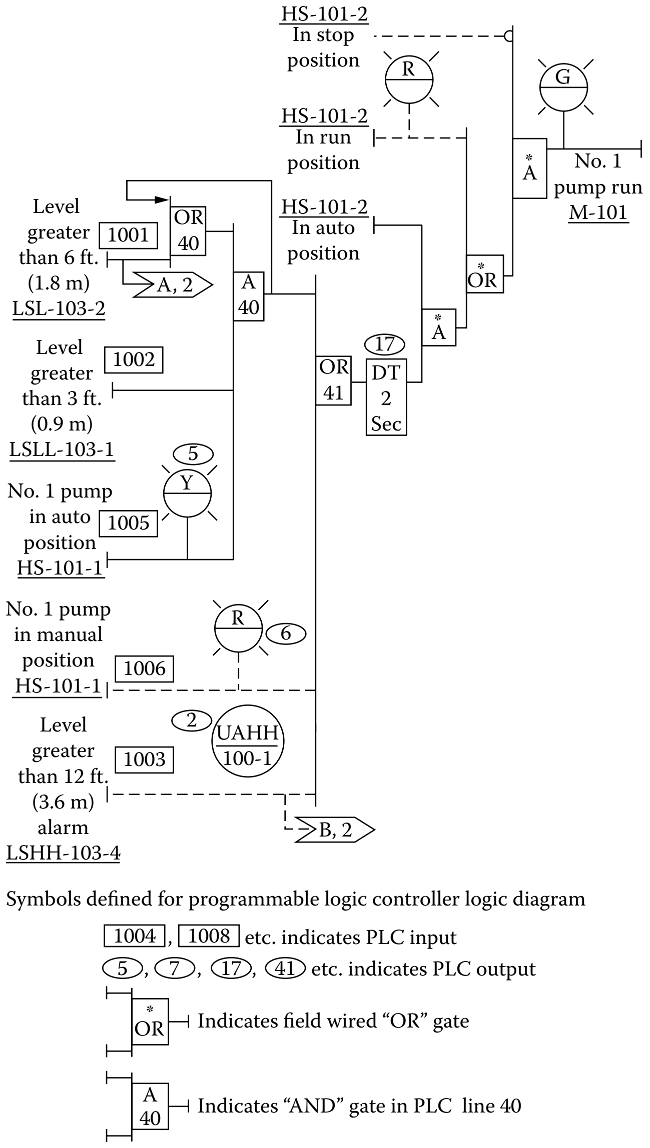

FIG. 5.4jj
Process and logic diagrams. This logic diagram is for a sump pump.[40]

to demonstrate this process. This is an effective way for the operations personnel to become familiar with the new system, especially in new automation projects in which there may be some "fear of the unknown" to overcome. Occasionally, operations personnel find operational flaws or make suggestions for improvements that can be easily implemented in the panel shop but would be difficult or impossible in the field.

Test software intelligently by trying to break it. Testing all aspects of the project during start-up will save time and money in the long run. Also it is recommended to wait until after major milestones in the project to perform software and hardware upgrades. This makes upgrade troubleshooting easier.[49] At the conclusion of this exercise the panel is accepted by the customer and is shipped to the job site.

System Checkout and Start-Up

After electrical interconnections are made and point-to-point wiring is completed (mechanical completion), the system is ready for start-up. The ability of the PLC to operate step by step through the start-up becomes very useful at this stage.

Experienced PLC personnel may provide temporary switches in the back of the panel in order to facilitate the start-up procedures. These switches can be key-locked, software-locked, or disconnected for normal operation. They are also very useful as future maintenance and troubleshooting tools to diagnose future problems.

Unanticipated circumstances are always a factor during start-up. Wiring errors, program errors, and mismatches between PLC and HMI databases are common problems at this stage. For this reason it is not uncommon to have electrical and programming personnel available at this time for implementation of any changes that might be necessary. Quite often, program changes can be accomplished over long-distance telephone lines using modems. These changes are not easily implemented without adequate documentation. After successful start-up, the plant is signed off.

After Start-Up

Once again, it is imperative for future successful plant operation that complete, current documentation be available. This documentation should include the items discussed previously. Especially useful for future changes or additions are the start-up notes and notes pertaining to future modifications.

Training of operations, maintenance, and engineering personnel should be timely and "hands-on." It is useful to videotape these training sessions for future reference (e.g., for training of new personnel). Suggested programs for PLC training can be obtained from the PLC vendor. This is an important function provided locally at the job site, at a nearby metropolitan area, or at the PLC vendor factory.

Troubleshooting When troubleshooting a PLC system it is good to remember that almost 80% of the time the problem is either outside the PLC entirely or in a broken I/O module. Program errors and wiring errors and mismatch of PLC/HMI databases can also cause these problems, but these are usually resolved during start-up. Some simple troubleshooting tips can be followed to decide if a problem is in PLC or elsewhere.

Discrete Inputs: Because DIs are usually high impedance, check the input voltages with a high impedance multimeter. Using a low impedance solenoid voltage checker on digital inputs can sometimes cause confusing results. For a discrete input, an indicator on the module shows the state of the input. This should match what is observed on the HMI screen or PLC programmer monitor. The commons for the DI card may be grouped or individual. Check the voltage between common for that point on the I/O card terminal block (or swing arm) and the point in question. If possible actuate the field device and verify that the PLC logic status and voltage change together. If the module shows the correct I/O status, but the PLC monitor or HMI does not, the I/O module or its configuration is suspect and may need replacing.

Discrete Outputs: Because triacs-type outputs "leak" a small amount of current, they may show a voltage on a multimeter if they are not connected to a load. For discrete outputs, an indicator on the module shows the state of the output. This should match what is observed on the HMI screen or PLC programmer monitor. The power to the DO card may be grouped or individual. Check the voltage for that point on the I/O card terminal block (or swing arm). Then check the voltage for the point in question. If possible cause the output to actuate and verify that the PLC logic status and output voltage change together. If the module shows the correct I/O status, but the measured output voltage does not, the I/O module or its configuration is suspect and may need replacing.

Analog 4–20 mA Inputs: For analog I/O, the input values are not displayed on the module. Temporarily remove field wiring and place a 4–20 mA calibrator directly on the point and select either passive or sourced as appropriate for the input configuration. Verify that 4 mA gives the minimum value, that 20 mA gives the maximum value, and that 12 mA produces the value exactly between the min and the max values at the HMI or the PLC. If this works, then the problem is outside the PLC hardware.

Analog 4–20 mA Outputs: For analog I/O, the output values are not displayed on the module. Some modules require an external loop power supply. Verify its operation. Put a multimeter in current mode in series with the point in question. Have an operator set the output to 0%, 100%, and 50%. This should produce readings of 4 mA, 20 mA, 12 mA, respectively. If this works, then the problem is outside of the PLC hardware.

Erratic Problems: To troubleshoot erratic PLC operations that affect more than a single I/O module, check PLC grounding, power to PLC power supply, DC power output of the power supply, and batteries. Electromagnetic interference (EMI) or radio frequency interference (RFI) generated by large motors starting, arc welding, lightning strikes, handheld radios, or transmitters (a common issue) can produce erratic operation. Improvements in power conditioning, grounding, and shielding can usually resolve these issues. If the program has been affected, it may need to be reloaded.[52]

CONCLUSION

PLCs are durable, delivering real-time control in a rugged and dependable package with no moving parts.[7] They can be installed on either the factory floor or outdoors, withstanding temperature swings up to 60°C PLCs have the critical ability to process sequential logic without experiencing faults in the operating system. Moreover, users continue to use PLCs because they know how to support them and understand the simple ladder logic language they use.[10]

The sheer number of PLC applications is enormous. According to a recent *Control Engineering* magazine poll, "The major applications for PLCs include machine control (87%), process control (58%), motion control (40%), batch control (26%), diagnostic (18%), and other (3%)."[53] The results don't add up to 100% because a single control system generally has multiple applications. Many sources documenting various PLC applications are listed in the Bibliography of this section.

5.5 PLC Programming

V. A. BHAVSAR (2005)

Costs of Programming:	PLC programming cost depends on the complexity and the length of the project. The hourly rate of programming is between \$40 and \$80. Typically, the programming cost is 50 to 100% or more of the hardware cost depending on the size and complexity of the PLC system.
Partial List of Suppliers:	Most PLC manufacturers also do programming for their clients or they have systems integrators who can do the programming for them. Listed below are some of the major PLC manufacturers:

ABB (www.abb.com)
Allen-Bradley (www.ab.com)
GE Fanuc (www.gefanuc.com)
Klockner-Moeller (www.km-medialab.com)
Mitsubishi (www.mitsubishielectric.com)
Modicon (www.modicon.com)
Omron (www.omron.com)
Siemens (www.siemens.com)
Triconex (www.triconex.com)

INTRODUCTION

This section covers the basics of PLC programming. It provides the readers with enough information about PLC system hardware and programming techniques to enable them to write simple programs and understand complex programs. It starts with a basic understanding of PLC, followed by an introduction to major hardware components and operation of PLC system, and various programming languages available.

The main focus of this section is on ladder logic, which is the most widely used PLC language. The rest of the section gives details about basic ladder logic instructions, programming devices used to write ladder logic, ladder logic structure, how to develop ladder logic and program a PLC, programming considerations, and documentation. The section concludes with a typical ladder logic program example and recent developments in PLC programming.

What Is a PLC?

PLC is an acronym for programmable logic controller. It is also known by such other names as programmable controller or logic controller. Basically, a PLC is an electronic device that was invented to replace the electro-mechanical relay logic circuits used for machine automation in the automobile industry. It was first introduced in late 1960s by Bedford Associates as Modular Digital Controller (MODICON) to a major U.S. car manufacturer. Modern definition of PLCs: They are small computers, dedicated to automation tasks in an industrial environment.

There are three major kinds of PLCs:

Compact PLC: Monolithic construction, monoprocessor, fixed number of I/Os
Modular PLC: Modular construction, one or multiprocessor, expandable I/Os
Soft-PLC: Windows NT- or CE-based, direct use of CPU or coprocessors

Today, PLCs are used in many industries including machining, packaging, material handling, automated assembly, and countless others. Usually PLC manufacturers provide their customers with various applications of their products. Other useful sources to learn more about existing and new PLC applications are technical journals, magazines, and papers published on control and automation.

SYSTEM HARDWARE AND OPERATION[1]

A modular PLC system consists of the following major components:

- Rack
- Power supply module

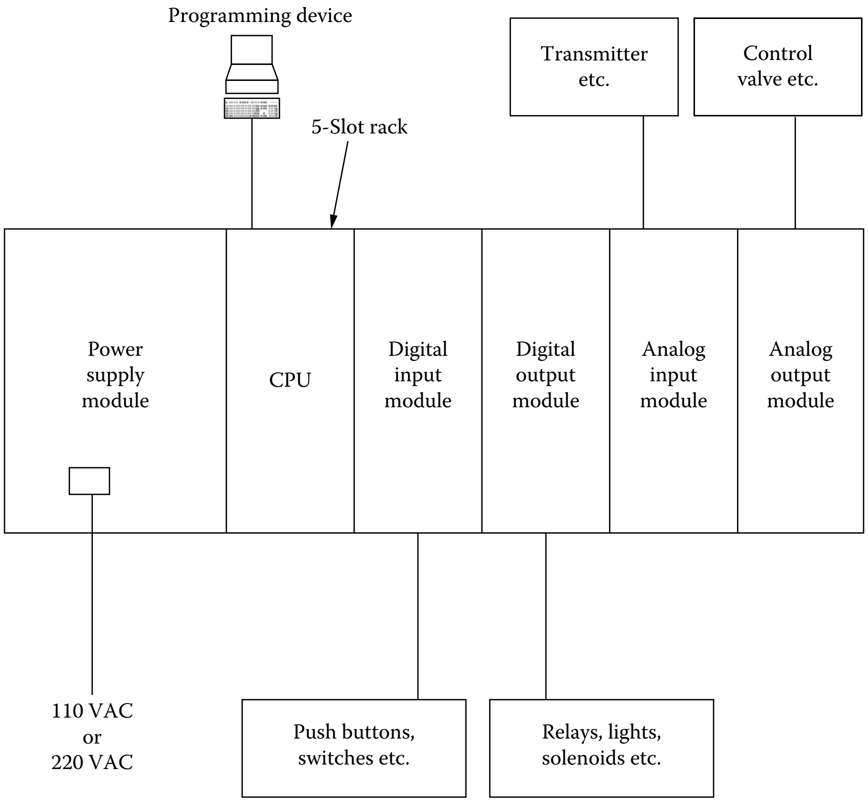

FIG. 5.5a
Modular PLC system.

- CPU (processor/memory)
- I/O modules
- Programming device

Figure 5.5a shows a typical modular PLC system.

A PLC is a sequential device; i.e., it performs one task after another. Figure 5.5b shows how a conventional PLC system operates. There are three major tasks that a PLC performs, in the following order:

- Task 1: Read inputs. PLC checks status of its inputs to see if they are on or off and updates its memory with their current value.
- Task 2: Program execution. PLC executes program instructions one by one sequentially and stores the results of program execution in the memory for use later in task 3.
- Task 3: Write outputs. PLC updates status of its outputs based on the results of program execution stored in task 2.

After PLC executes task 3 it goes back to execute task 1 again. The total time taken by a PLC to perform these three tasks is called the PLC scan time. Scan time depends on CPU clock speed, user program length, and number of I/Os. Typically scan time is in milliseconds. The smaller the scan time, the faster the updates of the I/O and the program execution.

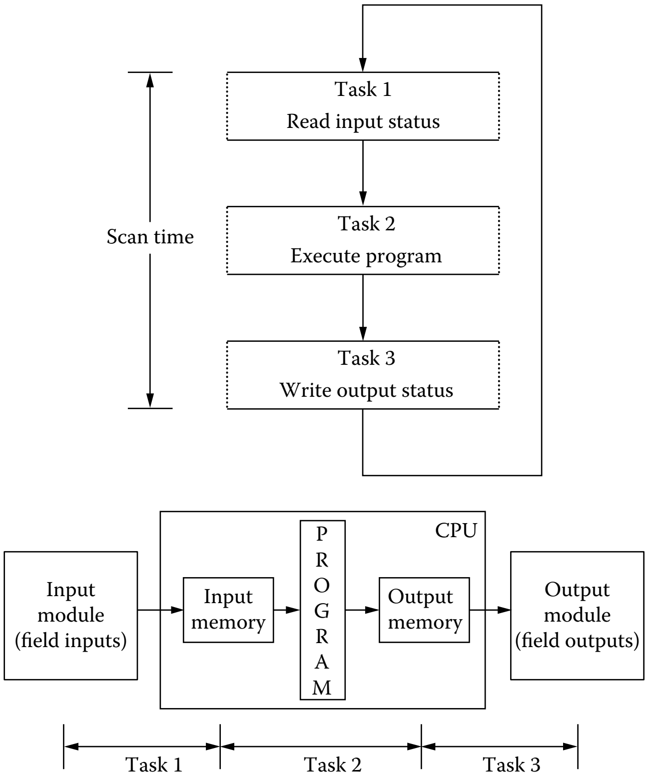

FIG. 5.5b
PLC operation.

As a general guide, PLC scan time should be less than half the time it takes the fastest changing input signal to change in the system.

The following are the functions of a PLC:

Measure: Measure process values, both discrete and continuous
Command: Execute logic and control programs
Regulation: Control field devices
Communication: Communicate with other PLCs, remote I/Os, MMIs, and other network peripherals

PROGRAMMING LANGUAGES

The two forms of PLC programming languages are text and graphic languages:

Text languages are the instruction list (IL) and the structured text (ST) types. The graphic languages are the sequential function charts (SFCs), function block diagrams (FBDs), and the ladder logic types.

Different PLCs support one or more of the above languages for programming. These languages have their advantages and limitations, and they complement one another to provide programmers with more programming power. A brief understanding of these languages is given below, followed by a detailed understanding of ladder logic.

Instruction List

Instruction list is a low-level language. It is mainly used for smaller applications or for optimizing parts of an application. IL is one of the languages for the description of the actions within the steps and conditions attached to the transitions of the SFC language (this is discussed in more detail later). Instructions always relate to the current result (or IL register value). The operator indicates the operation that must be performed on the current value of the IL register and the operand. The result of the operation is stored again in the IL register.

An IL program is a list of instructions. Each instruction must begin on a new line and must contain an operator and, if necessary, for the specific operation, one or more operands, separated with commas (,). A label followed by a colon (:) may precede the instruction. If a comment is attached to the instruction, it must be the last component of the line. Comments always begin with (* and end with *). Empty lines may be entered between instructions. Comments may be put on empty lines. Listed below are examples of instruction lines:

Label	*Operator*	*Operand*	*Comments*
Start:	LD	IN1	(* start pushbutton *)
	AND	MD1	(* mode is manual *)
	ST	Q2	(* start motor *)

LD-Load, ST-Stove

Structured Text

Structured text is a high-level structured language designed for automation processes. This language is mainly used to implement complex procedures that cannot be easily expressed with graphic languages. ST is one of the languages for the description of the actions within the steps and conditions attached to the transitions of the SFC language (this is discussed in more detail later). An ST program is a list of ST statements. Each statement ends with a semicolon (;) separator. Comments may be freely inserted into the text. A comment must begin with (* and end with *). The basic types of ST statements are

- Assignment statement (variable := expression;)
- Subprogram or function call
- Function block call
- Selection statements (IF, THEN, ELSE, CASE ...)
- Iteration statements (FOR, WHILE, REPEAT ...)
- Control statements (RETURN, EXIT ...)
- Special statements for links with other languages such as SFC

Sequential Function Charts

Sequential function chart is a language used to graphically describe sequential operations. The process is represented as a set of well-defined steps, linked by transitions. A sequence of steps is called a task, and many such tasks make up the whole process. Figure 5.5c shows basic components (graphic

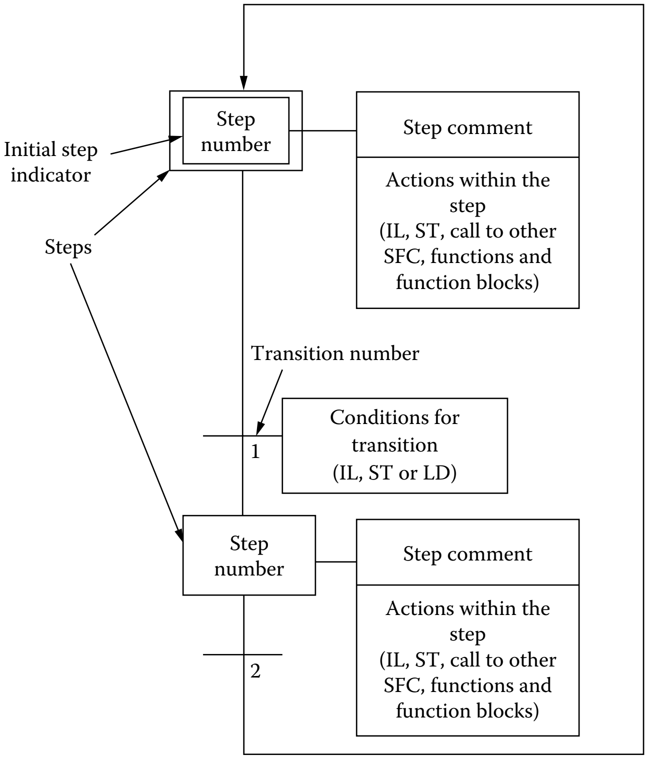

FIG. 5.5c
Basic components of SFC language.

symbols) of the SFC language: steps and initial steps, transitions, and links between steps and transitions.

An SFC program is activated by the system when the application starts. At run time, the step that is active is highlighted. When program execution starts, the initial step becomes the current step by default. When the conditions for transition become true, the sequence advances to the next step in the sequence. Actions within the step can be Boolean, ST or IL statements, calls to other SFCs, or function blocks or functions. A Boolean condition is attached to each transition using other languages, such as ST, IL, or ladder logic (LD).

Function Block Diagrams

The functional block diagram (FBD) is a language used to graphically build complex procedures by taking existing functions and wiring them together. Figure 5.5d shows basic components (graphic symbols) of the FBD language. An FBD diagram describes a function between input variables and output variables. A function is described as a set of elementary function blocks. Input and output variables are connected to blocks by connection lines. An output of a function block may also be connected to an input of another block.

Each function block has a fixed number of input connection points and a fixed number of output connection points. A function block is represented by a single rectangle. The inputs are connected on its left border. The outputs are connected on its right border. An elementary function block performs a single function between its inputs and its outputs. The name of the function to be performed by the block is written in its rectangle symbol. Each input or output of a block has a well-defined type. Input variables of an FBD program must be connected to input connection points of function blocks.

The type of each variable must be the same as the type expected for the associated input. An input for an FBD diagram can be a constant expression, any internal or input variable, or an output variable. Output variables of an FBD program must be connected to output connection points of function blocks. The type of each variable must be the same as the type expected for the associated block output. An output for an FBD diagram can be any internal or output variable, or the name of the program (for subprograms only). When an output is the name of the currently edited subprogram, it represents the assignment of the return value for the subprogram (returned to the calling program).

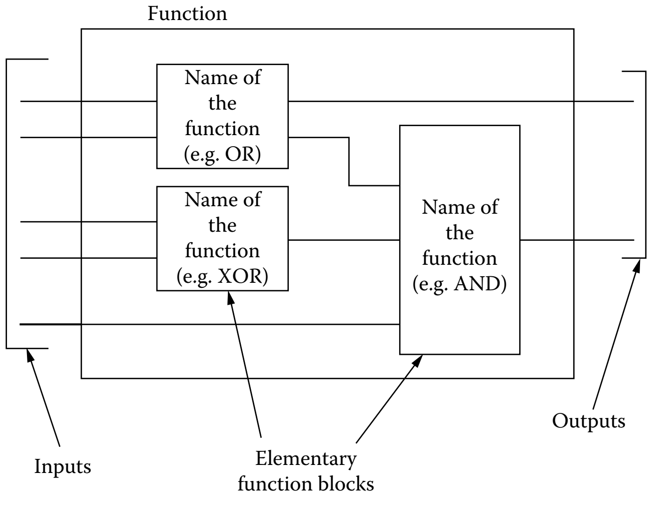

FIG. 5.5d
Basic components of FBD language.

LADDER LOGIC PROGRAMMING

Ladder logic is one of the most popular and widely used programming languages by electricians and programmers, since it emulates the old relay-based ladder logic structure. For this reason, the rest of this section discusses ladder logic programming in greater detail.

Ladder Logic Structure

As ladder logic is an extension of the relay logic, it makes sense to see how the ladder logic and relay logic structures are analogous to each other. Also, a basic understanding of Boolean logic will help in writing ladder logic, since many times a control scheme is first developed using Boolean logic and then converted into a ladder logic in PLC. Figure 5.5e shows three different representations of a simple logic for starting/stopping a motor.

In relay logic, the lines L1 and L2 represent the power applied to the relay circuit. Start pushbutton is normally open type and stop pushbutton is normally closed type. When the start pushbutton is pressed, the start pushbutton's contact closes, the current flows through start and stop pushbuttons' contacts to the relay coil, and it energizes the relay coil. The contact of the relay coil gets closed and provides an alternate current path to the relay coil, thus keeping it energized. When the stop pushbutton is pressed, the stop pushbutton's contact opens, the current path to the relay is opened, the relay gets de-energized, and the relay contact opens. The motor runs as long as the motor relay stays energized.

In Boolean logic, the start pushbutton and motor relay contact are represented as inputs to the OR logic block, output of the OR logic block and stop pushbutton are represented as inputs to the AND logic block, and motor relay coil is represented as output of the AND logic block. Normally closed stop pushbutton is shown by inverting the stop input (logical 1). When the start pushbutton is pressed (logical 1), output of the OR block becomes logical 1. With both inputs of the AND block being logical 1, output of the AND block becomes logical 1 and turns the motor relay on. Status of motor relay is fed back to the OR block to keep its output on. Motor relay turns off as soon as the stop button is pressed.

In PLC ladder logic, two vertical lines represent virtual power lines, and the actual electrical current is replaced by

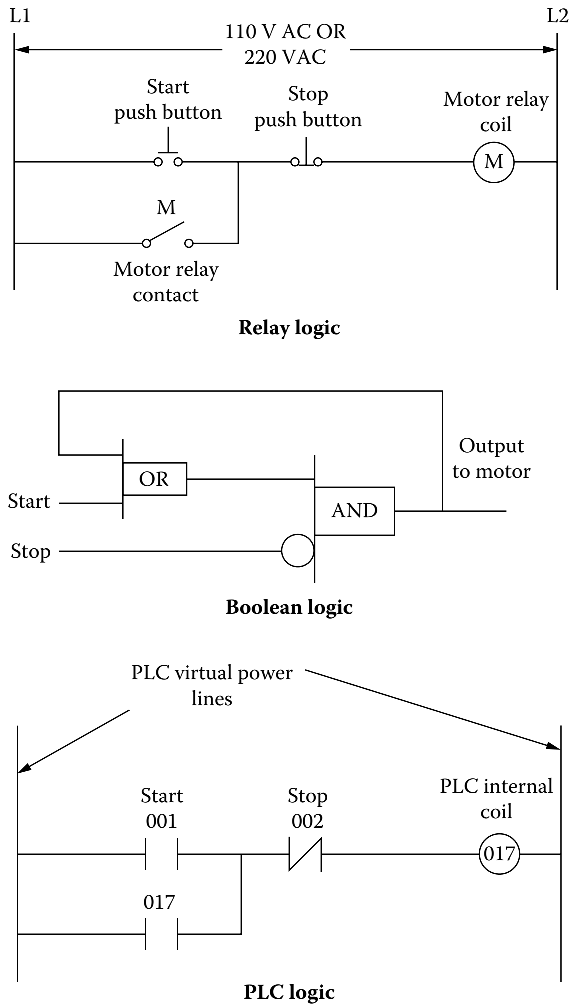

FIG. 5.5e
Three types of logic representation.

logical path. A horizontal line represents a logical rung. Inputs are shown near the left vertical line and outputs are shown near the right vertical line on a rung. When the inputs have logical 1 or TRUE state, logical path to the outputs completes, and outputs get logical 1 or TRUE state.

In this example, start and stop pushbutton contacts are shown as inputs that represent the physical pushbuttons connected to the PLC input module. Inputs have their PLC memory addresses where their current values are stored (here they are 001 and 002). As the pushbuttons are operated, the PLC memory is updated with their current status. An open contact represents logical 0 or FALSE, and a closed contact represents logical 1 or TRUE in PLC memory. In this example the relay coil is shown as an internal coil (PLC memory address 017) that represents a physical relay connected to the PLC output module. As the internal coil's status changes based on the pushbuttons status, PLC memory is updated with the internal coil's current status.

An energized internal coil represents logical 1 and a de-energized internal coil represents logical 0 in PLC memory. The physical relay coil gets energized when the PLC internal coil is energized (logical 1) and de-energized when the PLC internal coil is de-energized (logical 0). The internal coil has a large number of virtual contacts limited only by the PLC memory capacity.

Ladder Logic Programming Basic Instructions

Figure 5.5f and Figure 5.5g show graphical symbols of ladder logic basic instructions discussed below.

Contact This is an input instruction. It can be used to represent an external digital input or a contact of internal (soft) relay. There are two basic types of contacts:

1. Normally open contact (NO) is used to represent an input signal that is normally off and will become on when operated, e.g., a physically connected pushbutton with normally open contact. For an NO contact, logical 0 represents OFF or FALSE condition and logical 1 represents ON or TRUE condition.
2. Normally closed contact (NC) is used to represent an input signal that is normally on and will become off when operated, e.g. a normally closed contact of an internal (soft) relay coil. For an NC contact, logical 0 represents ON or TRUE condition and logical 1 represents OFF or FALSE condition.

Coil This is an output instruction. It can be used to represent an external digital output or an internal (soft) relay. There are two basic types of coils:

1. Normally de-energized coil is used to represent an output signal that is normally off or de-energized and will become on or energized when all inputs on a rung preceding this coil are TRUE.
2. Normally energized coil is used to represent an output signal that is normally on or energized and will become off or de-energized when all inputs on a rung preceding this coil are TRUE.

Timer This is a timing instruction. Timer is used to delay an event or to time an event. Generally, a timer instruction has enable input, preset time value, elapsed time value, and an output signal. Preset and elapsed times are stored in PLC memory registers. There are two basic types of timers. Figure 5.5h shows the timing diagram for these timers.

1. On-delay timer is used to delay turning on an output. When the enable condition becomes true, timer starts timing, its current time value starts to go up, and after its current time reaches the preset time value, output of the timer is turned on. Output stays on as long as the enable input signal is on. As soon as the enable signal becomes false or logical 0, the output goes off

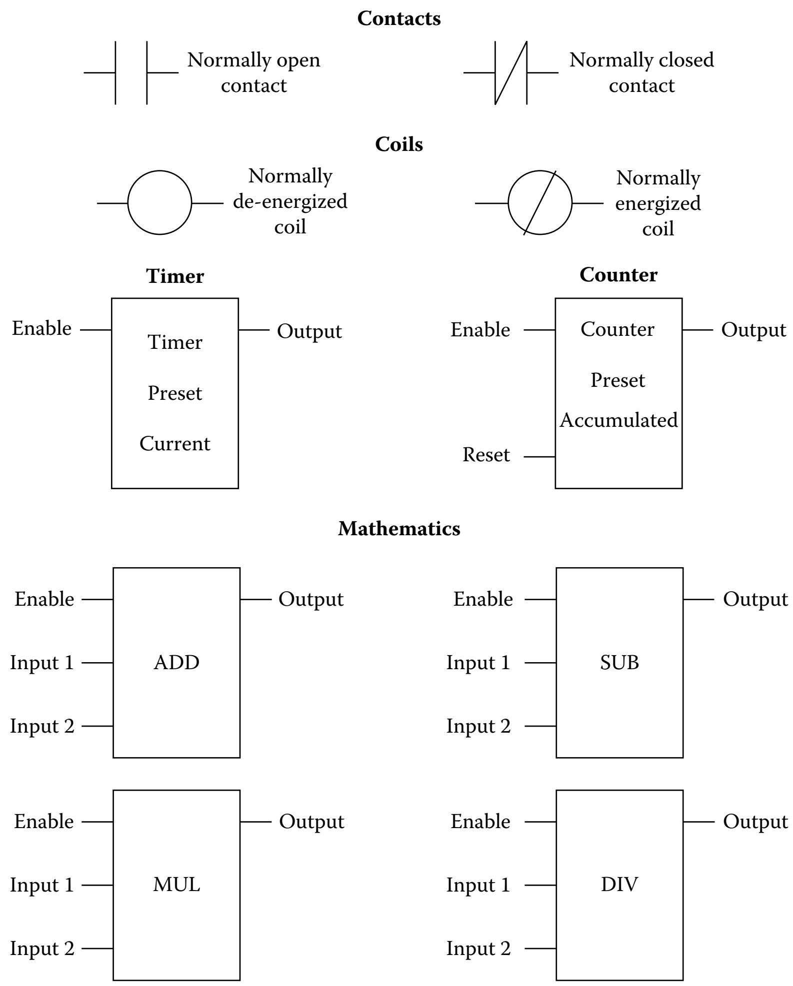

FIG. 5.5f
PLC ladder logic instruction symbols.

and the timer current value becomes 0. There are other variations of timers that have a reset input connection to reset the timer current value.

2. Off-delay timer is used to delay turning off an output. As soon as the enable condition becomes true, output of the timer turns on. When the enable condition becomes false or logical 0, timer starts timing and its current time value starts to go up. Timer output stays on until its current time reaches the preset time value. As soon as the timer current time reaches the preset time, its output goes off and the timer stops timing and its current value stops increasing. When enable input becomes true the next time, timer current value is reset to 0.

Counter This is a counting instruction. Counter is used to count the number of occurrences of an event. Generally, a counter instruction has enable input, preset count value, accumulated count value, reset input, and an output signal. Preset and accumulated counts are stored in PLC memory registers. There are two basic types of counters. Figure 5.5i shows a timing diagram for these counters.

1. Up-counter is used to count up. When the enable condition becomes true, i.e., transitions from logical 0 to logical 1, the counter accumulated value is incremented by 1. Every time this transition takes place, the counter accumulated value increases by 1. When the accumulated value reaches the preset value, the counter output turns on. Output stays on until the counter is reset.
2. Down-counter is used to count down. Counter accumulated is set at the preset value. When the enable condition becomes true, i.e., transitions from logical 0 to logical 1, the counter accumulated value is decremented by 1. Every time this transition takes place, the counter accumulated value decreases by 1. When the accumulated value reaches 0, counter output turns on. Output stays on until the counter is reset.

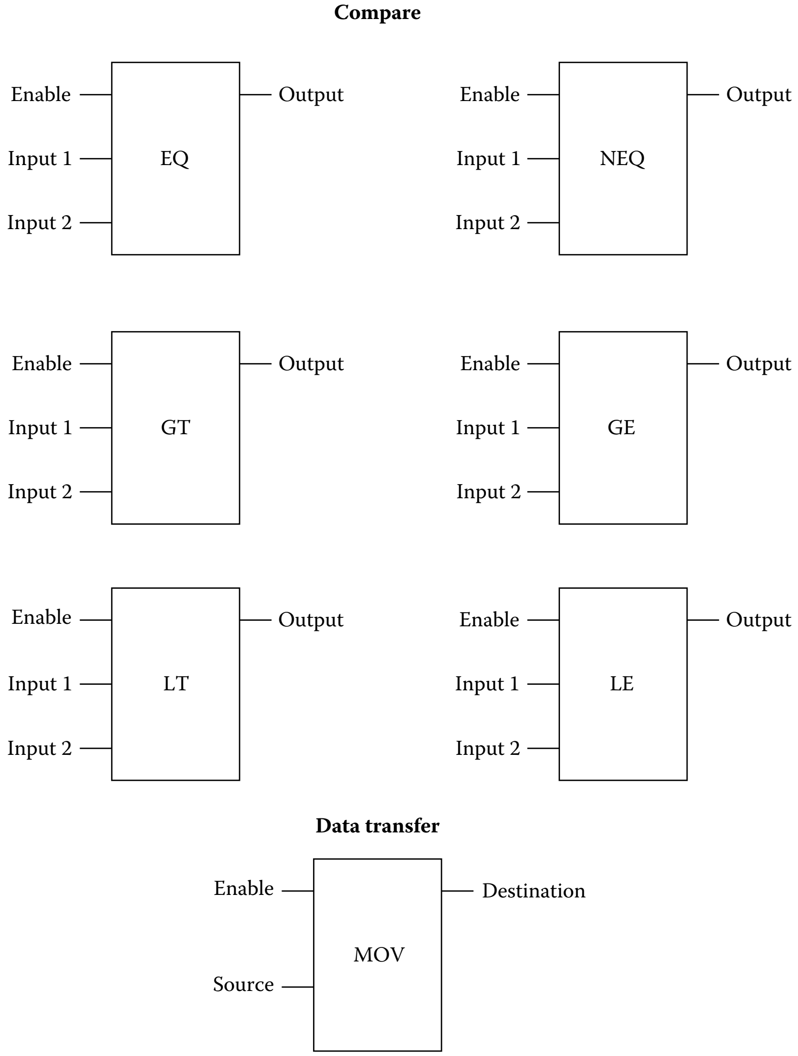

FIG. 5.5g
PLC ladder logic instruction symbols.

Mathematics Math instructions are used for data manipulations. Generally, a math instruction has enable input, two data inputs, and one output. Data inputs are register locations or constants and output is a register location where the result of the math operation is stored. There are four basic types of math instructions:

1. ADD is used to perform addition. When the enable condition becomes true, input 2 data are added to input 1 data and the result is stored in output.
2. SUB is used to perform subtraction. When the enable condition becomes true, input 2 data are subtracted from input 1 data and the result is stored in output.
3. MUL is used to perform multiplication. When the enable condition becomes true, input 1 data are multiplied with input 2 data and the result is stored in output.
4. DIV is used to perform division. When the enable condition becomes true, input 1 data are divided by input 2 data and the result is stored in output.

Although most advanced PLCs support real math, some PLCs only support integer math, i.e., math performed on integer numbers. Hence, when you perform division on integers, the result is an integer and loose remainder (fraction part of the result). To deal with this, you must first multiply the number being divided with 10 for one decimal digit accuracy and then perform the division in PLC. Thus, the result is an integer number with one implied decimal digit. To display this number on a man-machine interface (MMI), which has only one decimal digit, you have to read the integer value from PLC and display it after dividing it by 10 in the MMI.

Compare Compare instructions are used for comparing data. Generally, a compare instruction has enable input, two data inputs, and one output. Data inputs are register locations or constants. There are six basic types of compare instructions:

1. EQ is used to check if input 1 and input 2 are equal. When the enable condition becomes true, input 1 data

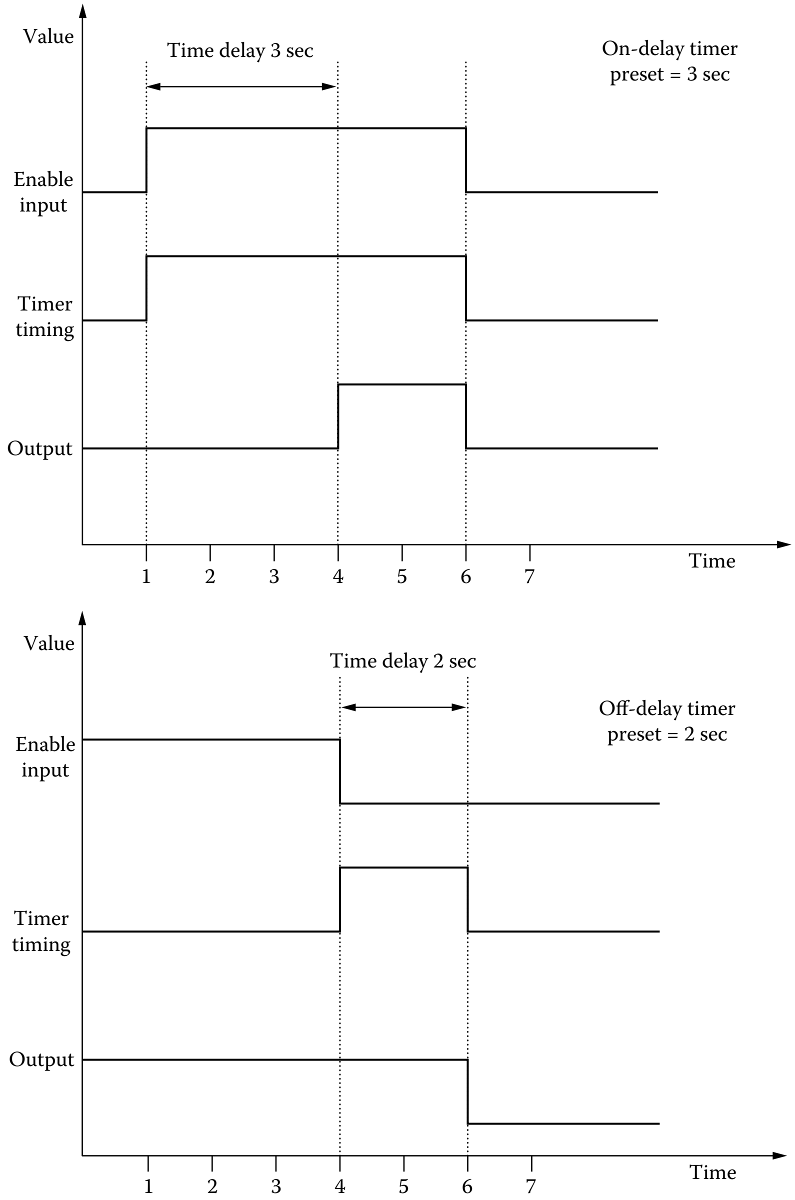

FIG. 5.5h
Timing diagram for PLC timers instruction.

are compared with input 2 data to see if they are equal and if so, output of EQ instruction becomes on.

2. NEQ is used to check if input 1 and input 2 are not equal. When the enable condition becomes true, input 1 data are compared with input 2 data to see if they are not equal and if so, output of NEQ instruction becomes on.
3. GT is used to check if input 1 is greater than input 2. When the enable condition becomes true, input 1 data are compared with input 2 data to see if input 1 is greater than input 2 and if so, output of GT instruction becomes on.
4. GE is used to check if input 1 is greater than or equal to input 2. When the enable condition becomes true, input 1 data are compared with input 2 data to see if input 1 is greater than or equal to input 2 and if so, output of GE instruction becomes on.
5. LT is used to check if input 1 is less than input 2. When the enable condition becomes true, input 1 data are compared with input 2 data to see if input 1 is less than input 2 and if so, output of LT instruction becomes on.
6. LE is used to check if input 1 is less than or equal to input 2. When the enable condition becomes true, input 1 data are compared with input 2 data to see if input 1 is less than or equal to input 2 and if so, output of LE instruction becomes on.

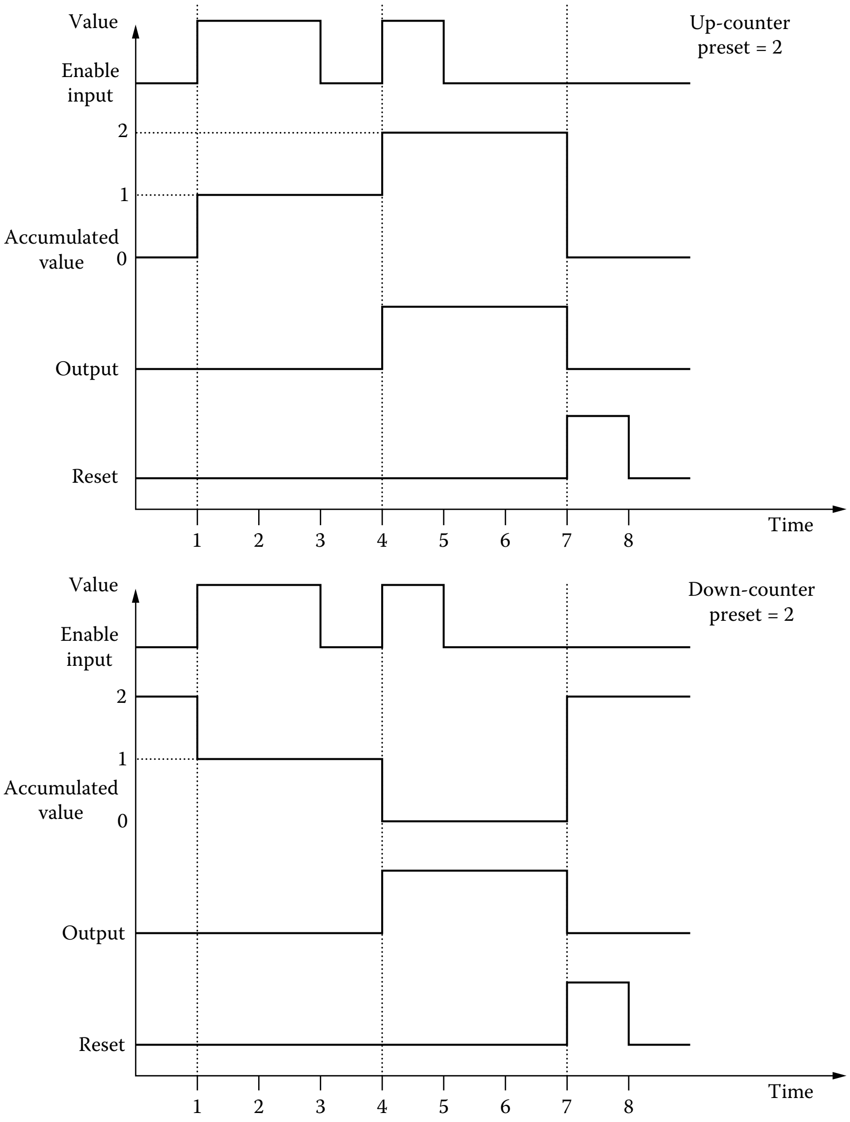

FIG. 5.5i
Timing diagram for PLC counters instruction.

Data Transfer This instruction is used for moving data. It has enable input, a source input, and a destination output. MOVE is a basic data transfer instruction. MOVE is used to transfer data from a source memory location to a destination memory location. When the enable condition becomes true, source data are transferred to destination.

Memory Structure

PLC memory is embedded in CPU. The following types of memory are used in CPU:

1. Read-only memory (ROM) is used to store the firmware or operating system of the PLC. It is not available to the user for data or user program storage.
2. Random access memory (RAM) is used to store user program, data, and results of various arithmetic and logical operations performed by the CPU. RAM is battery-backed to prevent data loss in the event of a power failure.
3. Erasable programmable read-only memory (EPROM) is similar to ROM, but can be erased with ultraviolet light and reprogrammed.
4. Electrically erasable programmable read-only memory (EEPROM) is similar to ROM, but can be erased with voltage and reprogrammed. Newer types of EEPROM, such as Flash memory, are becoming available.

When we refer to the PLC memory structure, we are talking about the user memory, i.e., RAM.

PLC user memory is specified in bytes. One byte represents 8 bits of data. One register represents two bytes or 16 bits of data. If a PLC has 1K memory, it means it has 1056 bytes or 528 registers of memory available for the user. PLC memory is divided in the following major areas and is referenced by register number/bit number in a register by user program:

1. User program memory: This memory stores user ladder logic or any other form of user program.
2. Input status memory: This memory stores the status of inputs physically connected to the PLC. Each digital field input takes 1 bit of input memory. Each analog field input takes 8, 12, or 16 bits of input memory depending on the resolution of analog input module.
3. Output status memory: This memory stores status of outputs physically connected to the PLC. Each digital field output takes 1 bit of output memory. Each analog field output takes 8, 12, or 16 bits of output memory depending on the resolution of analog output module.
4. Timer status memory: This memory stores the status, preset, and elapsed time values of timers in the PLC.
5. Counter status memory: This memory stores status, preset, and accumulated values of counters in the PLC.
6. Numeric data memory: This memory stores numeric data in the PLC. It is used to store data for manipulation by user program and the results of data manipulation.

Ladder Logic Programming Devices

Programming devices are required to write, edit, and monitor user programs, to download them into the PLC through the programming port on the CPU, and to monitor and force I/O status. It is also used for debugging PLC programs and to view PLC diagnostics. There are hand-held programmers and personal computer-based programmers available for PLC programming.

A hand-held programmer is a dedicated programming device manufactured and supplied by a PLC manufacturer for its PLCs. It has a keypad and an LCD display. You can connect the programmer to the PLC using the programming cable that comes with the programmer and do online programming or make program changes. You cannot store programs in this type of programmer.

A personal computer-based programmer needs the following to write PLC ladder logic:

1. PC with DOS or Windows operating system
2. Serial port or interface card
3. PLC programming software supplied by the PLC manufacturer
4. Programming cable supplied by the PLC manufacturer

Personal computer-based programmers are very popular for the following reasons.

1. Off-line programming can be done and programs can be stored on hard disk.
2. Program documentation becomes easier.
3. Big screen makes it easier to see large ladder rungs.
4. Program printouts can be easily made for permanent records.
5. Some programmers even allow logic simulation by executing the program in a PC as if it were being executed in the PLC.

In the industrial environment today, laptops are used for on-line programming and program changes.

Programming Considerations

The following are some of the major considerations while writing any PLC program:

1. Program scan time: This is a very important factor in any PLC program. As explained earlier, scan time is time taken by PLC to complete its three main tasks: read input status, execute PLC program, and write output status. PLC repeats these three tasks continuously. If the total scan time of a program is not less than half the time at which the fastest input changes in the system, there is a possibility that PLC will not be able to detect a change in that input and will fail to respond to the change. The following are ways to reduce the scan time in a PLC system:
   - Use faster CPU
   - Use interrupt routine
   - Make program compact by logic optimization (Reference 1) and simplification
   - Organize program in such a way so that for elements in parallel, the one most likely to be true is highest in the ladder and so on, and for elements in series, the one least likely to be true is leftmost in the ladder and so on. This way, when one of the parallel elements is found true, the rest of the parallel elements are not required to be solved and program execution progresses to the next rung. The same is true for elements in series.
2. Program scan direction: It is very important in PLC programming to know how the PLC program scan is done. Some PLCs, e.g., Allen-Bradley PLCs, scan programs left to right (called rung scanning), whereas others, e.g., Modicon PLCs, scan programs top to bottom (called column scanning). Both methods are appropriate; however, a programmer should be aware of the scan method used by the PLC because it has an impact on whether a coil gets energized or de-energized in the same scan or the next scan after input conditions become true.
3. Fail-safe programming: A program should be written in such a way that it always puts the process it is controlling in safe mode when any of the critical system components fails. This is called fail-safe programming. In the system, first define fail-safe conditions and then determine what outputs are required to be turned off or turned on to achieve those conditions. There are many components in a PLC system, like I/O modules, power supply module, and cables. The program

should be written in such a way that if there is a loss of input signal due to power loss or cabling problems or failure of the input module itself, then the outputs will go to a state that is safe. Also, programs should be designed so that they check for problems, and shut down in safe ways. Use modular well-designed predictable programs and PLC's built-in functions for error and failure detection.
4. Emergency shutdown: There should be a hardwired relay, called master control relay (MCR), and a normally closed (NC) emergency stop button wired in series in the system. MCR is normally kept energized through emergency stop button by the PLC system power. Power to the physical outputs is supplied through the contacts of this MCR. In case of emergency, the emergency stop button is activated and the power to all the outputs is removed.
5. PLC fault handling and diagnostics: A program should also have the ability to use various diagnostics available in the CPU and generate alarms for any fault condition in the system or failure of any hardware that might create unsafe operating conditions. There are status registers in the PLC that can be used to generate alarms or messages to help diagnose the problems and indicate prompt corrective actions.
6. Program structure and memory allocation: Program should be divided into smaller separate blocks by function. This will help in troubleshooting the code. Each functional block should be allocated its own block of memory so that there are no conflicts with shared memory.

Program Documentation

Program documentation is a very important aspect of PLC programming, though many times it is overlooked or given less importance. These days, programming software is available with good program documentation capabilities. Good program documentation has the following advantages:

- Helps in program debugging
- Helps program users understand and maintain/modify the logic
- Provides on-line information about field connections, thus in so many cases it eliminates the need to have the wiring diagrams handy in troubleshooting

Program documentation involves the following main areas:

- I/O names and descriptors: These are the short user-defined meaningful names given to field inputs and outputs with a more detailed description of the I/O signals. The name is usually a shortened field tag name, and the descriptor is a short explanation about the signal.
- Internal memory names and descriptors: These are the short user-defined meaningful names given to internal coils and registers with a more detailed description of their function. The name is usually a shortened identifier and the descriptor is a short explanation about the function.
- Program comments: Rung titles and comments are inserted between the logic rungs in the program to explain the purpose of a block of logic and how that piece of logic works.

Program documentation is a continuous process during PLC programming. The following are the commonly used steps for program documentation:

- Define all the I/O names and descriptors
- Define all the internal memory names and descriptors
- Write comments before writing a piece of logic
- Keep adding/editing comments and other descriptors/names as you write the program

There are utilities available in programming software to import/export names, descriptors, and comments from/to word processors and spreadsheets. Use of Excel spreadsheets in creating PLC documentation saves a lot of time.

A PLC program documentation printout consists of the following:

- List of I/O names and descriptors
- List of internal memory names and descriptors
- Cross-reference list for I/Os and internal memory
- Usage list of I/Os and internal memory
- Total PLC memory used and available
- PLC ladder logic listing
- PLC system configuration

PLC Hardware Configuration

PLC programming also involves hardware configuration. Hardware configuration lets the CPU know what components make up the whole PLC system and their addresses. PLC has to be configured first before it can be programmed with logic. PLC hardware configuration involves the following:

1. Select type of rack (chassis) used (5- or 10-slot)
2. Select type of card that is installed in each slot (digital input/output or analog input/output)
3. CPU configuration for memory allocation of various types of user memory
4. CPU configuration for communication ports (programming port and so on)
5. Address allocation for physical I/Os connected to I/O modules

PLC programming software is used to develop and download PLC configuration into CPU. A typical PLC system hardware and CPU configuration for GE Fanuc PLC is discussed next.

LADDER PROGRAM STRUCTURE

Typical GE Fanuc PLC

Figure 5.5j shows a typical GE Fanuc program structure. A program is contained in a folder and can be divided into various logic blocks. When you start to write a program, first you create a folder with an appropriate name, e.g., TEST. There is a main program block where you write ladder logic and also make calls to other logic blocks. These other logic blocks are declared in the main logic block and are called subroutines. In this example, the main program block is divided in three sections or subroutines (ANALOG, ALARMS, and OUTPUT) and makes calls to these

subroutines. These subroutines contain specific logic as explained below.

- ANALOG subroutine handles analog input signals and converts the raw analog value into engineering units for alarming purpose. This value in engineering units can also be displayed on any operator interface (MMI).
- ALARMS subroutine generates alarms with deadband.
- OUTPUT subroutine generates physical outputs for annunciator alarms.

This block structure makes it easier to understand and troubleshoot the program.

Typical Allen-Bradley PLCs

A program in Allen-Bradley PLC-5 is organized in a file structure. First, you create a project with an appropriate name. In the project, there are program files as explained below:

File #	*Name*	*Description*
0	System	PLC operating system, unavailable to programmers
1	Undefined	PLC operating system, unavailable to programmers
2	Main program	Main program code and subroutine calls
3–999	Subroutines	Subroutine code, called by main program

In a typical project, there are different types of data files, such as:

Data files O0 (output) and I1 (input) are physical I/O status files.
Data file S2 (status) is a general status file.
Data files B3 (binary), T4 (timers), C5 (counters), R6 (control word), N7 (integer), F8 (floating) are reserved for the main program file. Other data files can be designated for subroutines as needed.

Addressing is done in the following format:

XY:WW:ZZ

where
X is the file identifier such as I for input, O for output, S for status, B for binary, T for timers, C for counters, R for real, N for integer, and F for floating point
Y is the file number (in decimal) such as 0 for output, 1 for input
WW is the word number (in decimal) in file such as 00 for word #1
ZZ is the bit number (in octal) in a word such as 00 for bit #1

A program in Allen-Bradley's ControlLogix PLC is organized by tasks. First, you should identify a project with an appropriate name and controller type. In the project, there are a variety of tasks, programs, and routines. For example, the controller contains controller tags, controller fault handler, and power-up handler. The controller tags are global tags that can be used by all programs.

Controller supports 31 separate tasks. Each task can contain multiple programs, status information, and configuration information.

There is always a main task, which is created when you create the project and is by default a continuous task. Other (up to 30) tasks are user-defined and are periodic tasks. There

can be up to 32 programs in a task. The program contains program tags and routines. Program tags are local tags that can be used by routines within an individual program. There is a main routine, which gets executed first in each program. The main routine is used to make calls to other routines.

A program can be scheduled or unscheduled for execution. Scheduled programs are executed and unscheduled programs are not executed. Data types for tags can be user-defined or predefined. There are module-defined data types, as well. There are no physical or internal addresses assigned to tags. Tags are referenced in the programs by their names. Tags have various parameters depending on their data type. I/O configuration is used to configure the physical I/O modules.

FIG. 5.5n
GE Fanuc PLC logic for analog inputs.

Typical Modicon PLC 984

A program in Modicon PLC is organized in networks. First, you create a program file. In the program file, there are segments that are made up of logic networks. In PLC 984, there are 1–32 segments, and you can write logic networks in each of these segments. Network numbers start from 1 and are continuous for the program. Addressing is done in the following format for data tables:

XYYYY

where X is data type identifier such as 0 for discrete o/p or coil (used to drive real outputs through output module or to set internal coils), 1 for discrete input (used to drive contacts in the logic program, controlled by input module), 3 for input register (holds numeric input from external source like analog or high-speed counter input module), and 4 for output holding registers (used to store numeric data for internal use or analog output module).

YYYY is reference number in decimal such as 1, 2, etc., with upper limit as configured.

Total memory for all data types should not exceed processor user memory.

Access and Programming Modes

The following are a few ways of connecting a programming device with a PLC:

1. Serial connection
2. Ethernet
3. Data Highway Plus (DH+)

FIG. 5.5p
GE Fanuc PLC logic for annunciator outputs.

Once a programming device has been connected to the PLC, you can place the CPU in one of the following modes:

1. Run: In this mode CPU does all three tasks: read inputs, execute program logic, write to outputs.
2. I/O Scan Only: In this mode CPU does only one task: read inputs.
3. Stop/Program: In this mode CPU stops all three tasks: read inputs, execute program logic, write to outputs, and the PLC can be programmed in this mode.

The PLC programming and configuration can be done in the following two ways:

1. Off-Line Programming: In this mode, a PLC can be programmed on a PC-based programmer without connecting the programmer to the PLC. The program can be saved on computer hard disk or on a floppy disk for download to the PLC later.
2. On-Line Programming: In this mode, a PLC can be programmed on a PC-based programmer after connecting the programmer to the PLC on its programming port. The program can be saved on the computer hard disk or on a floppy disk and at the same time downloaded to the PLC. Some PLCs allow a program to be downloaded into the PLC only in stop/program mode. If PLC was in run mode prior to program download, a message is given to the programmer that PLC is in run mode and its mode needs to be changed to stop/program mode before the download can be done.

Developing the PLC Program Logic

There are no set rules or guidelines on how to develop PLC program logic. However, the following steps will help in developing PLC program logic:

1. Write a process description or obtain it from the process or operations engineer
2. Make a sketch of the process or obtain it from the process or operations engineer
3. Prepare control strategy narratives
4. Make a list of field devices and their inputs and outputs that will be connected to PLC
5. Assign addresses to inputs/outputs
6. Develop flowcharts (if required)
7. Develop Boolean logic diagrams
8. Develop PLC hardware configuration based on number and type of I/Os
9. Write PLC ladder logic, i.e., convert Boolean logic into actual ladder logic
10. Test PLC ladder logic

Level Control Example Figure 5.5q illustrates a tank level control application where a remotely operated pump is used as the final control element in the system. In this example, a ladder logic program will be developed, using a GE Fanuc PLC, using the steps that are listed above.

1. Process description: Water tank TK-001 is being filled continuously and its level is to be controlled by an on/off drain pump.

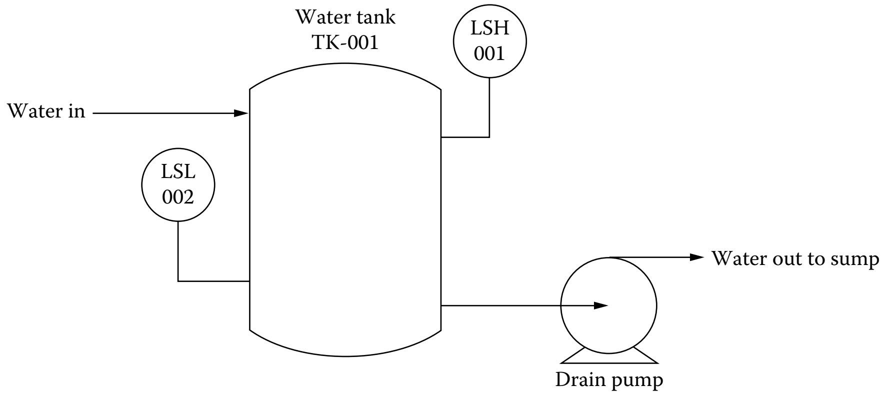

FIG. 5.5q
Tank level control.

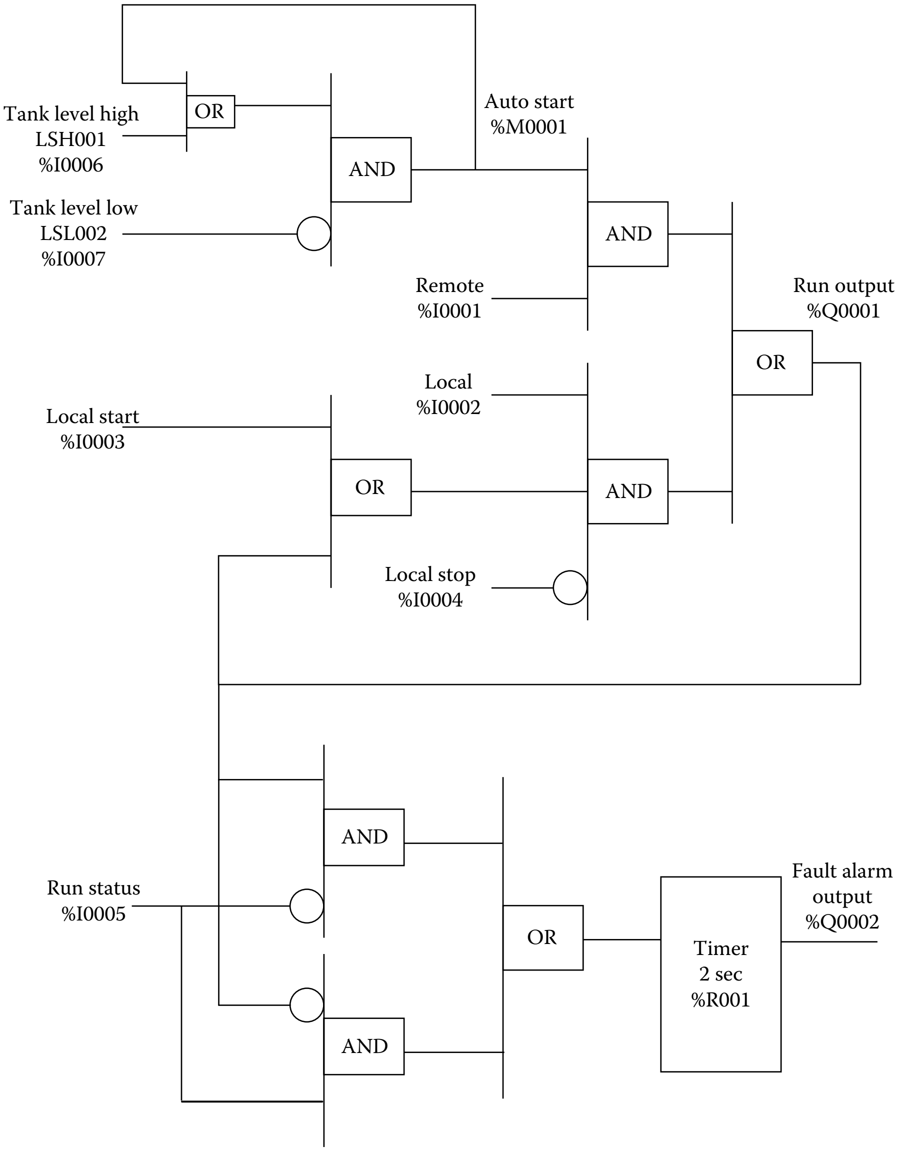

FIG. 5.5r
Boolean logic for tank level control example.

2. Make a sketch of the process: Make a sketch as shown in Figure 5.5q.
3. Prepare control strategy narrative for this pump, which has two modes of operation:
    - Remote mode: In this mode, its operation is controlled automatically by the level in the tank. When the level rises to its high limit (say 90%), the water pump should start to drain the water to the sump. Pump will continue to drain water until the level drops to its low limit (say 10%) in TK-001.
    - Local mode: In this mode, the pump operation is controlled by the operator out in the field, and the automatic level control logic is bypassed.
4. Make a list of field devices (sensors and so on) and their inputs and outputs that will be connected to the PLC.

Field Device	*Input*	*Output*	*Remarks*
Local/remote switch	02	—	For pump operation control
Local start pushbutton	01	—	To start pump in local mode
Local stop pushbutton	01	—	To stop pump in local mode
Water pump	01	01	Input = Run status, Output = Run command
Motor fault alarm	—	01	For annunciation
LSH001	01	—	High-level switch
LSL002	01	—	Low-level switch

5. Assign addresses to inputs/outputs.

Field Device	*Input*	*Output*	*PLC Address*
Local/remote switch	02	—	%I0001 (Remote), %10002 (Local)
Local start pushbutton	01	—	%I0003
Local stop pushbutton	01	—	%I0004
Water pump	01	01	%I0005 (Run status), %Q0001 (Run command)
Motor fault alarm	—	01	%Q0002
LSH001	01	—	%I0006
LSL002	01	—	%I0007

6. Develop Boolean logic diagram as shown in Figure 5.5r.
7. Develop PLC hardware configuration as shown in Figure 5.5m without the analog modules in slots 4 and 5.
8. Write PLC ladder logic, i.e., convert Boolean logic developed in previous step into ladder logic as shown in Figure 5.5s.
9. Download program in PLC and test the program as explained below.

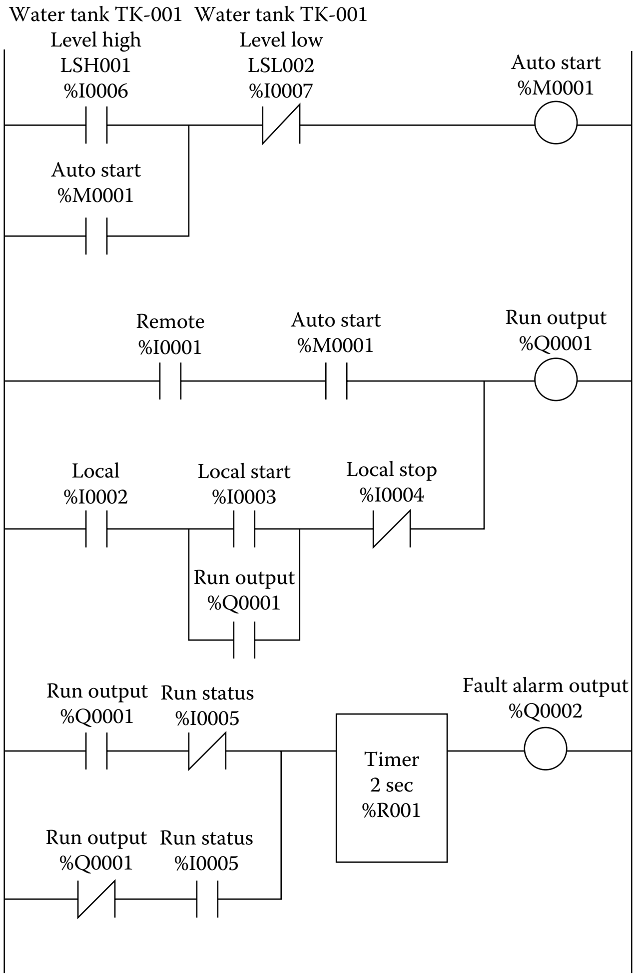

FIG. 5.5s
PLC logic for tank level control example.

TESTING AND SIMULATION

Once the logic is entered in the PLC, the next step is to debug the program to make sure that the logic works the way it is supposed to and to correct any errors made while developing and writing the PLC program.

Input modules with switches to simulate the input signals are used. Such a simulation module is installed to simulate the digital inputs to the PLC. The PLC is placed in the run mode, and its inputs are simulated by operating the corresponding switches. The logic outputs are checked to see if the program properly carries out the required logic. The status of the internal coils is determined by using the PLC data table.

Instead of using simulation modules, it is also possible to use the FORCE I/O function in the PLC to enable or disable inputs in order to simulate field inputs. FORCE ON can be used to turn input on and FORCE OFF can be used to turn input off. Once the inputs are forced on or off you would proceed to check if the program has turned the various

 60   INPUT # $(1)                                     -- inputs data from weigh scale (port #2)
 70   PRINT “WEIGH SCALE RESPONSE IS : “, $(1)         -- prints weigh scale data string on port #1
 80   $(2) = LEFT$ ($(1),1)                            -- assigns 1st character of data string to $(2)
 90   $(3) = MID$ ($(1),2,4)                           -- assigns crate weight data string to $(3)
100   $(4) = MID$ ($(1)7,4)                            -- assigns tare weight data string to $(4)
110   IF $(2) = CHR$ (02) THEN GOTO 160 ELSE GOTO 120  -- if 1st character is <STX> then valid data
120   OUT(2,0) = 1                                     -- sets bad value flag in PLC memory (bit 1 of AI011)
130   WEIGHT = 0                                       -- sets crate weight to 0
140   TWEIGHT = 0                                      -- sets tare weight to 0
150   GOTO 190
160   WEIGHT = VAL ($(3))                              -- sets crate weight to value read from weigh scale
170   TWEIGHT = VAL ($(4))                             -- sets tare weight to value read from weigh scale
180   OUT(2,0) = 0                                     -- resets bad value flag in PLC memory (bit 1 of AI011)
190   PRINT “WEIGHT IS : “, WEIGHT                     -- prints crate weight on port #1
200   PRINT “TARE WEIGHT IS : “, TWEIGHT               -- prints tare weight on port #1
210   OUT (0) = WEIGHT                                 -- stores crate weight in PLC memory (AI009)
220   OUT (1) = TWEIGHT                                -- stores tare weight in PLC memory (AI010)
230   GOTO 50
240   RETURN
```

FIG. 5.6v
Basic program for ASCII basic module.

outputs on or off per the logic. Again, the status of the internal coils is determined by using the PLC data table.

In case of large PLC systems with a lot of I/Os, you should use a graphical process simulator package, which can be developed by using MMI packages. As was discussed in Section 4.13 in Chapter 4, processes can be displayed graphically on the screen and respond to the PLC signals in the same manner as the actual process would. Equipment can be operated from the screen, and their status can be seen on the screen. Naturally, interface cards are needed to connect PLC to computer running simulator programs.

ADVANCES IN PROGRAMMING

Until recently, most of the PLC programming softwares available in the market were DOS-based for ladder logic programming. Recently, as Windows-based laptop computers are becoming inexpensive and popular, PLC manufacturers are coming out with Windows-based programming software.

The advantages of Windows-based programming software include ease of programming, the ability to use multiple windows to do both the programming and the troubleshooting, and an improvement in the on-line help available for programming.

Another significant advancement is the PLC's ability to communicate with intelligent devices using interface cards that are programmable in the Basic language. This interface module is called ASCII Basic module and is physically installed in the PLC rack like any other module; it is programmed using a serial port on the module.

One such system used for weigh scale interfacing is shown in Figure 5.5t. In this system, ASCII Basic module is programmed in Basic language to read the measured weight from the weigh scale using RS-232 serial communication.

Figure 5.5u shows the PLC configuration, and Figure 5.5v shows the Basic code for an ASCII module. This type of application can be used to connect the PLC to any intelligent device that supports ASCII serial communication. Some typical applications include RF tag readers and labeling stations.

As PC costs keep dropping, personal computers are used more and more in place of conventional PLCs. PCs can solve ladder logic, scan I/Os, and communicate with other network devices, if the appropriate software is loaded into them. However, there are safety considerations to be resolved if the PC is shared among several applications. Yet there already are a number of small-scale PC-based control systems in use today, in areas such as data acquisition, process monitoring, and batch control.

An alternative to relay ladder logic (RLL) is state logic. It is a language that forces the user to build the program with finite states. It uses a natural language, known as English Control Language Programming Software (ECLiPS), which allows the programmers to write their control commands in their own words. State logic was created to reduce the program development and modification time.

Program Development:	Sequence definition thru flowcharts, state diagrams, or sequential function charts
PLC Programming Languages:	Graphical—Ladder logic and function block Text based—Instruction list and structured text Flowchart like—Sequential function charts
Language Standards:	IEC 61131-3 and IEC 848
Suppliers:	PLC manufacturers are listed in Section 5.4

INTRODUCTION

Programmable controllers were originally introduced to replace large panels of relays used for running automobile assembly lines. Controller flexibility allowed reprogramming for year-to-year model changes. Early controllers were restricted to discrete (ON/OFF) control. Programs were represented by the use of ladder diagrams (Section 5.2), the same way that relay logic is represented.

Programmable controller capability has been extended to include mathematical functions, file manipulations, analog signal manipulations, and techniques for dealing with high-speed signals. Programmable controllers are now routinely linked together in networks, connected to general-purpose computer systems, and connected to specialized intelligent devices, as was shown in Section 5.4. These devices include displays, high-speed control cards, and interfaces to specialized sensors such as bar code readers and RF identifiers. Many programmable controller suppliers support computer software for program development, program annotation, and program storage/retrieval.

These added capabilities have allowed the application of programmable controllers in many areas outside of the traditional automobile assembly-type service. They are used for continuous process control high-speed packaging, energy distribution, and automated warehousing. Many of these applications strain the capability of ladder logic for program design and implementation.

The software available in many programmable controllers has extended ladder logic to serve these diverse applications. To engineer a software system correctly, the application's requirements must be well understood. A graphic representation of these requirements is described below. Among the ladder logic advances are indirect addressing, program flow modification, incorporation of mathematical or scientific instructions, communication with intelligent devices, and methods for working with high-speed signals. Ladder logic segments can be organized using sequential flow chart languages to produce a sequentially oriented program.

Productivity enhancements developed for computer programmers are appearing in PLC programming software. Many program editors emulate MS Visual Studio formats with multiple windows and tool bars, pull-down menus, and visible "tree" structure for the project. Wizards have appeared in programming editors to automate tasks. If fact, Siemens provides one wizard in its S7 (200) programming software that automatically programs a Master-Slave polling task.

PLC logic simulation, a powerful tool for programming and debugging even before the hardware is on hand, is becoming more widely available.[1] Most major PLC manufacturers now offer PC-based PLC simulation software. Even the hardware configuration is easier. PLCs used to be configured with switches and jumpers. Now PLCs can be programmed and configured remotely over the network.

GRAPHIC DESCRIPTION OF CONTROL REQUIREMENTS

There have been many studies of time and money investments in building computer systems.[2,3] One key conclusion of these studies is that spending more time on the planning, design, and study of systems can have several benefits. One benefit is that the risk of project failure is reduced. Another benefit is that the resulting system is more likely to meet real needs and to provide continuing returns.

One of the effective ways of representing program requirements is through the combined use of state diagrams

Symbol		*Explanation*
	Data flow	Represents data movement.
	Data transformation	Computes outputs from inputs.
	Terminator	Defines items outside of the context of the system.
	State	A user-identifiable system mode.
	State transition	A transition causes a state change while actions occur during a transition.
	Data store	Shows how data are archived.
	Control flow	Data triggering WHEN things happen.

FIG. 5.6a
Data flow diagram primitives (symbols).

and data flow diagrams.[4,5] These structured documents contain symbols for terminators, data transformations, data storage, triggers for control flows, and state diagrams. Figure 5.6a includes a list of these symbols (primitives). Control flows and transformations describe when actions occur. Data flows and data transformations describe what the system does. Either data transformations are further decomposed into other data transformations, or the input/output character of the transformation is specified.

The left side of Figure 5.6b shows a tank provided with a level transmitter. The sequence of tank filling and emptying are controlled by starting and stopping two pumps. If the level transmitter, pump motors, and display devices are connected to a programmable controller, the software shown on the right side of Figure 5.6b is needed to control the tank. This software must provide such actions as the automatic shutting off of the fill motor when the tank is full.

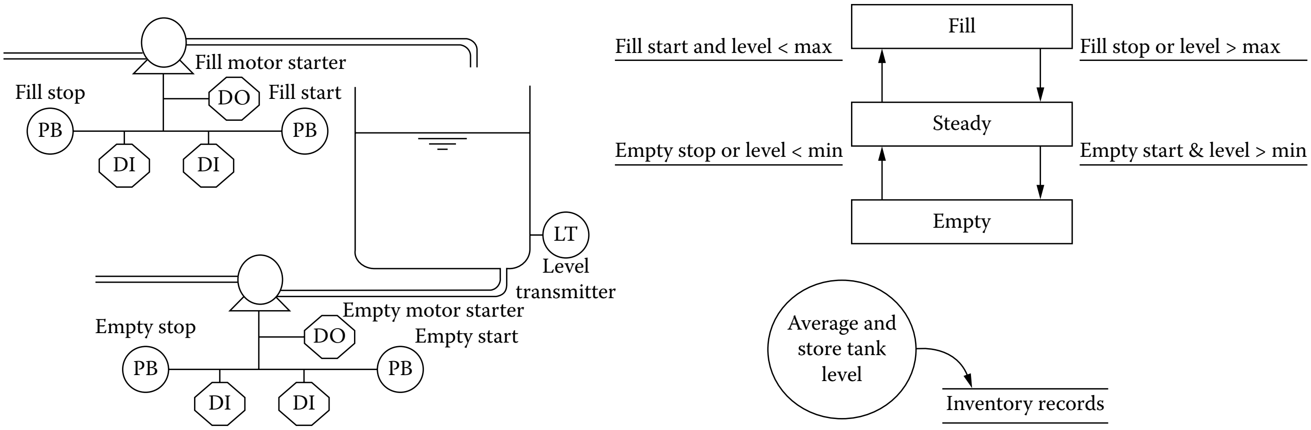

FIG. 5.6b
Tank level control example.

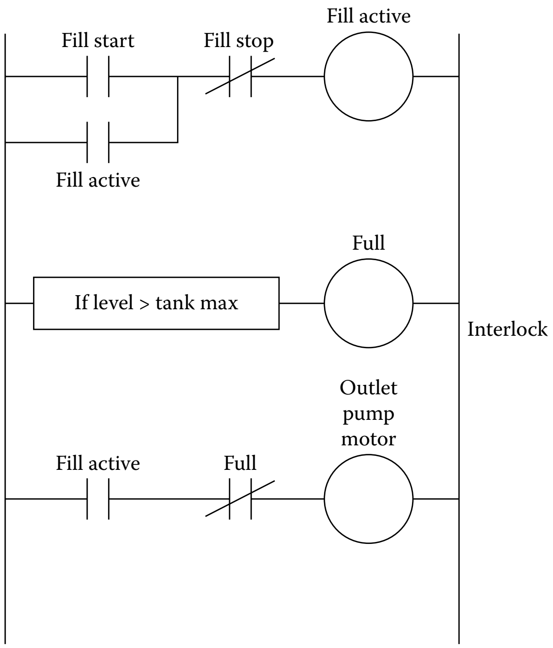

FIG. 5.6c
Portion of ladder logic code.

The programmable controller's ladder logic code for the fill motor starter controls is shown in Figure 5.6c. It shows how the start/stop station and the level interlock functions in order to guarantee that the tank does not overflow.

Some programmers advocate the use of state-machine representation as a planning tool and then implementing the program directly in ladder logic. Sequential function charts (SFCs) can be used the same way. The benefits are:

- Design decision are made before programming begins.
- Project engineers can review and make changes before programming.
- Stakeholders can more easily understand and review the state-machine representation.
- Once the diagram is finished, it is easy to program.
- The diagrams help document the ladder logic.[6]

Another programming technique is based on the cycles of a machine. The cycles for the machine are numbered in sequence and are called states. The set conditions of coils or a counter is used to indicate which step the machine is in. All the actions that take place in that particular step are executed and when completed, the condition is defined to move to the next state. In addition to the cycle states, an initial state and a default safe state should also be defined. If the machine gets stuck in a state because of a malfunction, this programming technique is easy to troubleshoot, because only the logic in that step needs to be examined.[7]

LADDER LOGIC ADVANCES

Section 5.2 discussed ladder diagrams and their generation of commands that energize, latch, and unlatch coils. Other ladder logic commands read live inputs, outputs, or internal bits and perform instructions based on their state. Timers and counters are other sources of ladder logic commands.

In most medium- and large-size controllers, these ladder logic-style commands are augmented by assembler-style instructions. Rather than working on bits alone, they operate on entire words. Some ladder logic extensions take on the character of high-level languages such as C or Basic.

The assembly language is a primitive computer language, which Bryan defines as "a symbolic programming language that can be directly translated into machine language instructions."[8] While a particular assembly language is dependent on the type of machine used, each of the ladder logic extensions has its basis in some type of assembler language. For a survey of the many ways of using assembler (and advanced ladder logic), see the books by Knuth.[9] Table 5.6d lists some typical assembler-style instructions along with their comparable ladder logic instructions.

Program Flow Modification

Some of the ladder logic extensions shown in Table 5.6d modify the program flow. Conventional relay logic commands execute sequentially. In this case there are no changes in program flow, because each instruction is executed in every program scan.

A GO TO command, when invoked, dictates that certain portions of the program will not be executed during the particular (current) scan. It allows the program flow to jump over the commands between the GO TO and the destination that is indicated in the GO TO.

While the GO TO instruction is frequently used in general programming practice, it can make programs difficult to understand and maintain. A better device that serves the same purpose is the subroutine. The subroutine has a beginning, usually marked by a subroutine number, and an end, noted by a RETURN. The subroutine is executed by a JSR (jump to subroutine) or similar command (GOSUB, for example). When this occurs, the program flow goes to the label indicated in the command and executes the instructions that follow.

Programs that consist of many subroutines are referred to as modular programs. After the RETURN is encountered at the end of the subroutine, program flow can return to the portion of the logic following the JSR.

The benefits of the subroutine are as follows:

1. The same code can be run for different purposes in different places of the program without recopying the code. Fewer lines of code mean less time to make modification and maintain the code.
2. The code can be run conditionally. This means that the scan time, or time it takes to run once through the system, can be lowered if portions of the code run conditionally.

TABLE 5.6d
Assembly Language

	Comparable Assembler-Style Instructions		
Instruction Category	*Instruction Name*	*Mnemonics in Allen-Bradley's PLC5 and Square D's 650*	*Definition*
Arithmetic Operators	Add	ADD	Add two registers
	Subtract	SUB	Subtract two registers
	Multiply	MUL	Multiply two registers
	Divide	DIV	Divide one register into another
	Average	AVE	Average contiguous registers
	Negate	NEG	Take opposite sign of source and store in destination
Compare	Equal	EQU	Set bit if source A equals source B
	Greater than or equal	GEQ	Set bit if source A is greater than or equal to source B
	Greater than	GRT	Set bit if source A is greater than source B
	Less than or equal	LEQ	Set bit if source A is less than or equal to source B
	Less than	LES	Set bit if source A is less than or equal to source B
	Not equal	NEQ	Set bit if source A is not equal to source B
	Clear	CLR	Set destination to zero
Logical Operators	And	AND	Set a bit only if two bits are TRUE
	Or	OR	Set a bit if either of two bits is TRUE
	Excusive Or	XOR	Clear a bit if two bits are the same, otherwise set the bit
	Not	NOT	Reverse state of bit
Register Assignment	Move	MOV	Place a bit from one register into another
	Masked move	MVM	Place a bit from one register into another if set in mask
	BCD convert	BCD* convert	Convert a register from BCD into integer
		Indirect read	Read a word, given its address
Shift Register	Bit shift left	BSL	Shift bits in work left
	Bit shift right	BSR	Shift bits in work right
	First in, first out load	FFL	Add an element to a waiting line
	First in, first out unload	FFU	Remove an element from a waiting line
Program Control	Jump	JMP	Skip rungs until the label is found
	Jump to subroutine	JSR	Execute subroutine
	Return from subroutine	RET	Exit subroutine and return to normal ladder execution

*BCD = binary-coded decimal.

3. Details can be hidden. Breaking up the overall program into modules affords the programmer an opportunity to hide details inside of subroutines. Thus, someone other than the original author can follow the overall program better by understanding what each module of code does, without examining module internals.[10]

As an example, it would be possible to code the previously described tank farm example in four separate subroutines. All of the tank logic for a single tank can be written in a single subroutine. The logic that sets up the tank logic by reading the appropriate signals can be written in another subroutine. A third subroutine might communicate with other equipment after the tank logic has run. An executive routine can be used to call on each individual subroutine when they need to be called. This configuration is shown schematically in Figure 5.6e. The executive, in this case, contains only calls to the individual subroutines.

Indirect Addressing

One way to extend the tank-filling example across a tank farm would be to physically add sections of code for each tank. With a large number of tanks in a tank farm, a large number of rungs (lines in a ladder diagram) would be needed.

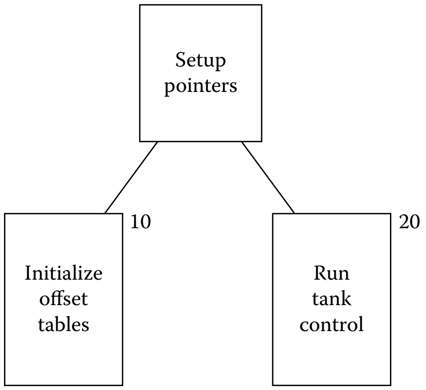

FIG. 5.6e
Tank farm structure.

The larger the number of rungs, the larger the chances are that one of them could contain an error.

Indirect addressing, which is new to most users of programmable controllers, is an effective way of simplifying and reducing the size of large programs. If, for instance, there are 200 tanks in a tank farm and to code one tank requires about 200 rungs, the resulting 40,000-rung program is difficult to maintain. With indirect addressing, if only one rung needs to be changed for each tank, there is only one rung to change in the total system. Without it, modifying the control would require modifications in 200 rungs.

While there are variations in the capabilities of programmable controllers in regard to indirect addressing, by using assembler commands, indirect addressing is usually possible. If one desires to extend the code developed for one tank to work for an entire tank farm, the resulting requirement might look like the diagram in Figure 5.6f.

The code reads the tank in progress, reads the offsets needed to run the code, reads the required information, triggers the code to operate on this information, and then writes out the result and increments to the next tank on the available tank list. Figure 5.6g shows a listing of the necessary codes. Note that this code is “data driven.” By making files larger (B9 in Figure 5.6g is a file) and modifying their contents, indirect addressing provides a means for using fewer instructions than physical coding would use.

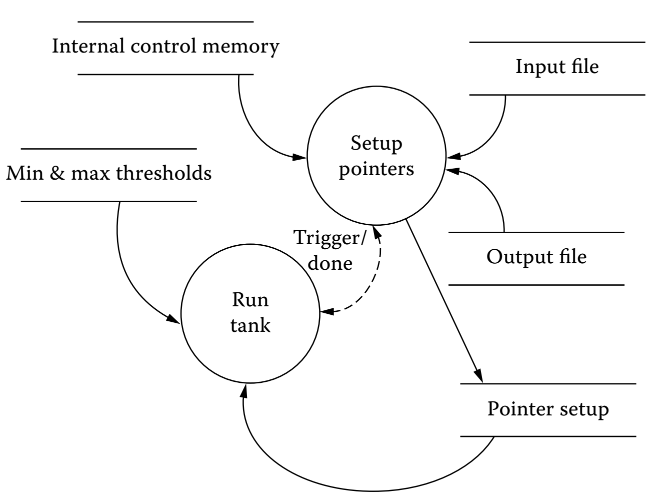

FIG. 5.6f
Partial tank farm requirement.

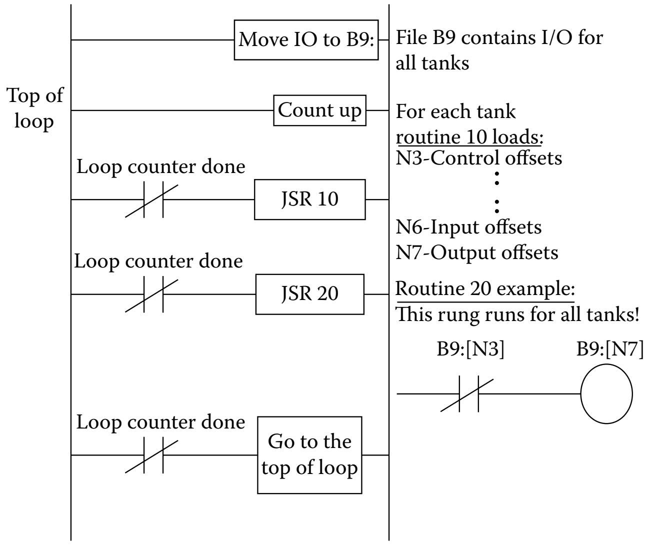

FIG. 5.6g
Pointer setup and indirect addressing.

Figure 5.6g shows the operation of indirect addressing. On the first pass, the value of the counter is 1. Then the code (JSR 10) runs, jumping to the subroutine 10. In this subroutine, integers are placed in registers N3, N4, N5, N6, and N7. Although the details of this subroutine are not shown, there could be a table for each of the registers, and the value of the counter would tell the program which element should be moved from the table to the register.

Since the counter is at 1, the values associated with tank 1 are loaded into the registers. When subroutine 20 is run, it operates the controls for tank 1. For example, if the register that contains tank 1’s inputs is B9:45, then B9:[N3] will resolve to B9:45. Therefore, the same rung can be used for different tanks. When the counter is 2, subroutine 20 will load a different value in register *N*3, so that the rung will inspect a different input.

Trade-Offs of Indirect Addressing Indirect addressing can help reduce the time involved in writing the ladder logic. However, it is more difficult to understand and maintain it than to maintain regular ladder logic. The benefits of indirect addressing must be weighed against some major trade-offs, including:

- Execution times are slower.
- Troubleshooting becomes more difficult.
- Accommodating differences in the group can be difficult.

In time-critical applications, indirect addressing will require more processor time than would physical addressing. Thus, if, for instance, one unit's code takes 20 ms to run, the indirect code for 100 units will take much more than the 2 seconds that would be required to run the code, if done physically. Instead of executing all the codes in a single scan, a counter can be set up to run one or more tanks per scan. In this case, it will still take more than 2 seconds to update all the tanks, but other parts of the system can run normally, and watchdog timeouts can be avoided.

The second trade-off is in using a programming terminal to view the operation of the logic. When using direct I/O, either the ladder logic displays or the display of the data table can be used. With indirect addressing, the state of the logic can only be determined by studying the data table display. This makes troubleshooting difficult.

A third trade-off is really an assumption that all the tanks are the same and will stay the same. It can become burdensome to write and troubleshoot the special logic to accommodate several small differences in the 100 tanks. In addition, other programming and documentation tools (like cross-referencing) may not work as expected, either.

Assembly Language-Like Extensions

Commands shown in Table 5.6d can perform data manipulation, including arithmetic operators, Boolean operations, and register assignment. One way that these are used is in a counting application. If, for instance, one needs to deliver a number of packages to an operator, a register can be assigned to contain the count.

When operators want the programmable controller to read a thumbwheel, they can depress a button. A high state on the button causes the programmable controller to read the thumbwheel setting in binary-coded decimal and place that setting in its count register. Sensors are used to detect when individual packages are delivered to the operator. A change in state in these sensors causes the count to decrement.

A ladder logic program performing these functions is shown in Figure 5.6h. The first rung moves information from the thumbwheel 10:1 to an internal word, $B1:1$. This word represents the required number of packages. The next decrements this number once for every FALSE to TRUE transition of the photoeye.

Commands is another group shown in Table 5.6d to perform queue management. Queue management commands include LIFO (last in, first out) and FIFO (first in, first out) commands, which load and unload the queue. A queue in a programmable controller is usually a series of words that are loaded into contiguous registers to form an array. A queue management command will insert or extract a word from the array.

One use for the FIFO queue is in tracking packages on a conveyor belt. Every package that enters the belt loads the FIFO and every one that exits unloads the FIFO. The word contains, for example, a package identification number. Package sensing can be accomplished with photoelectric devices.

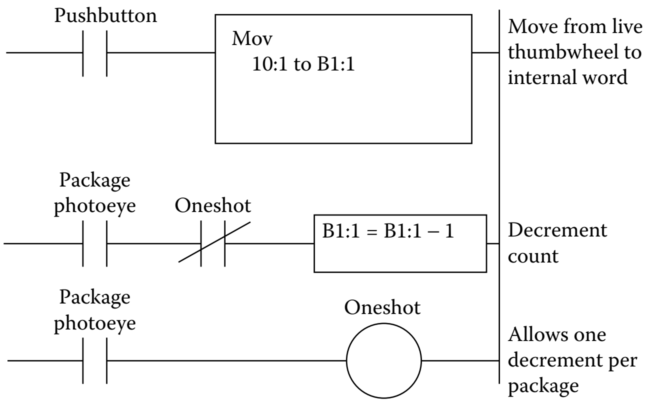

FIG. 5.6h
Ladder logic for package counting.

Communication with Intelligent Devices

Often, there are microprocessor devices that communicate with the programmable controller. Some newer devices do this by mimicking racks and by being scanned as a rack would be scanned. While this scheme affords a simple interface to these devices, it decreases the number of racks with which the programmable controller may connect.

Often these devices physically plug in like an I/O card and communicate using some type of serial communication. In fact, one common type of card is the ASCII card, a card that is able to communicate using RS-422 or RS-232. As long as the supplier is specific about the format of the serial communication, the user can program these cards with ladder logic and jumpers on the card to communicate with any device using this form of serial communication.

One common feature of these applications is that they require a ladder logic program that reads and writes a block of words, often performed continuously. One device that uses this type of programming and is common to many programmable controller vendors is the counter card. Counter cards count pulses that might occur too quickly for a programmable controller to handle. The words communicated to and from the counter cards might include a setpoint, an accumulated count, and a word containing information about the state of the communication itself. The way that this block of words is read from the external card and written to the external card is illustrated in Figure 5.6i.

In Figure 5.6i, "BTR" refers to the statement in Allen-Bradley's PLC-5 called a block transfer read. The rest of the items on this instruction indicate how the read will be done, including the PLC memory to be used, the location of the physical hardware, and the amount of data in the transmission. A similar statement is available in other programmable controllers that provide serial communication with intelligent devices.

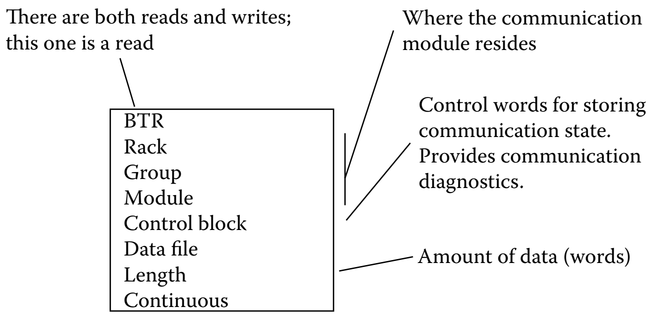

FIG. 5.6i
The block transfer statement.

Fast I/O Updating Methods

In many medium- to large-size programmable controllers there are numerous ways to read signals that occur faster than the scan time of the programmable controller. Conversely, outputs must sometimes be updated quickly, without the error associated with a variable scan time. The four most common methods for fast I/O updating are time-scheduled interrupts, programmable interrupts, latching hardware, and independent (dedicated) programmable controllers.

If, for instance, one desires to capture a pulse of 20 ms duration in a controller with a program scan time of 100 ms, there is a good chance that the program that serves to count the pulses is going to miss some.

One solution is the use of a concurrent time-scheduled routine. The routine contains a counter that reads the pulse input in question. By scheduling this counter to run once every 15 ms, the program would be guaranteed to read the 20 ms pulse, yet it would count each pulse only once, on the leading edge of the pulse. Several suppliers provide this type of routine. Code for such a routine is loaded in some special area of the memory, and the user must provide a time interval for running the concurrent routine.

In many programmable controllers, there is an immediate update input instruction, or a "programmable interrupt." When the instruction is encountered, the controller stops scanning the program, determines the current state of the particular (interrupting) input, and then continues on with the program. Several suppliers provide this type of interrupt on their inputs or outputs.

As another option for reading quick, discrete signals, suppliers provide a special-purpose card for reading pulses, usually called a latching card. It is a useful approach for counting pulses only if the time between pulses is longer than the maximum program scan time. After using the "latched" input, the program needs to rest the card, making it ready for the next pulse.

A final updating method is the use of another programmable controller. A small controller that is fast enough to detect quick pulses can be programmed to act like a counter or a latching card. Some manufacturers supply small controllers to act as cards for the programmable controller rack or with convenient serial communication for communication to other controllers.

GRAPHIC, FLOWCHART-LIKE LANGUAGES

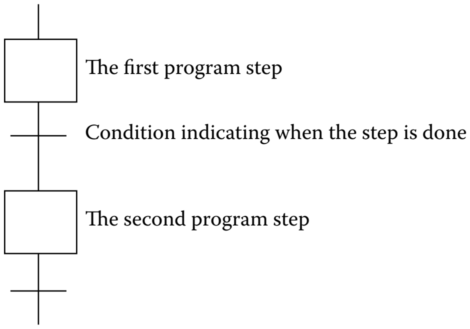
Graphic languages are natural in today's computer environments (e.g., Windows). Since the early 1980s, there have been several versions of graphic, flowchart-like languages, including sequential function charts.

Their goal is to provide a maintenance-related programming language for sequences of operations. Because of this, they are often not very adaptable to continuous process control. As the origin of ladder logic is in relays, it is a language well adapted to describing a large number of relays. By their nature, these devices operate in a nonsequential, highly concurrent manner. Only with great difficulty is a sequence of control possible. These sequences are usually tracked by a counter or by latching relays. The order of the sequence is usually difficult, if not impossible, to quickly determine from the program.

Several attempts have been made to build a language in which sequential control is easily coded. There is an international standard for a graphic programming language.[11] In this language, there are several basic symbol blocks (primitives). They are:

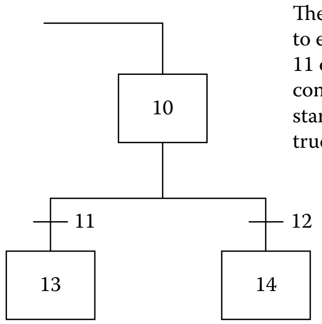
- Steps
- Transitions
- Directed links
- Branching sequences
- Simultaneous sequences

Steps are small programs. The programs might be written in any language, but many are ladder logic–driven. The transitions initiate a move from one step to another. When a step is connected to a transition, steps can be made to occur sequentially, as shown in Figure 5.6j. The direct sequential connection of steps with a transition is known as a directed link.



Note: The detailed description of each step and transfer condition is a separate program listing.

FIG. 5.6j
The use of directed links.

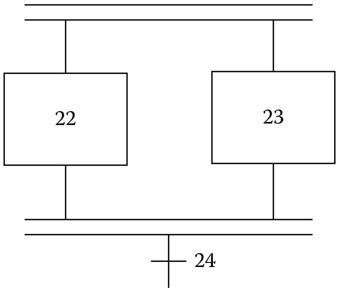


The process will branch from step 10 to either step 13 or step 14. If condition 11 comes true, step 13 will start. If condition 12 comes true, step 14 will start. Condition 11 and 12 cannot be true simultaneously.

FIG. 5.6k
Branching steps.

Steps can also branch, depending on some other condition, allowing alternate sequences to occur. In the example shown in Figure 5.6k, conditions 11 and 12 control the program flow, allowing execution of step 13 or 14. It is possible to program concurrent or simultaneous steps. This means that during a program scan, the code associated with both of the concurrent steps is executed.

In the example shown in Figure 5.6l, so long as exit condition 24 is not true, steps 22 and 23 will be executed during each program scan. If an exit condition becomes true, its associated step will no longer be executed.



In this instance, both steps 22 and 23 run until condition 24 indicates completion.

FIG. 5.6l
Concurrent steps.

An example of using concurrent steps is shown in Figure 5.6m. In this example, each assembled product needs to have a cover placed on it and four screws fastened on the cover. One solution is to design a program for each screw, to be run concurrently. Each program turns a screwdriver driving a screw. When a screw has been inserted completely, as indicated by screwdriver position, that screwdriver is retracted and its program is no longer executed. The flowchart for this example, Figure 5.6m, illustrates the application power of this type of controller programming.

IEC 61131-3 PLC LANGUAGE STANDARD

Programming a PLC is one of the most labor-intensive tasks in assembling a control system. It therefore makes good sense to try to reuse as much of the program as possible, once it is debugged.[12] A uniform programming environment for all manufacturers aids reusability, limits errors, and increases programmer efficiency. Developing the code only once and reusing it in many recurring control process scenarios is highly desirable, and attempts to standardize PLC language are in progress (see Table 5.6n).

The International Electrotechnical Commission (IEC) introduced IEC 1131-3 in 1992[13] and shortly thereafter renamed it IEC 61131-3. Since then, it has become widely accepted by the international user and vendor community. There are eight parts to the IEC 61131-3 standard for programmable controllers:

1. General information
2. Equipment requirements and tests

8. Guidelines for the application and implementation of programming languages

Programming languages (part 3) define, as a minimum set, the basic programming elements, syntactic and semantic rules for the most commonly used programming languages. It also defines major fields of application, applicable tests, and means by which manufacturers may expand or adapt those basic sets to their own programmable controller implementations.[14] The IEC 61131-3 standard defines the following languages:

- Sequential function chart
- Ladder logic diagram
- Function block diagram
- Instruction list
- Structured text

Sequential function chart is a flowchart-like organizational construct based on the French Graphcet (IEC 848). Actual programming for steps and transitions is programmed in the other four languages.

The two graphical languages are ladder logic and function block. Ladder logic was invented in the United States and is still the most widely used there. Function block is popular in Europe and is widely used in DCS systems. It is also well suited to controlling batch operations.

The two text languages are the instruction list and structured text languages. Instruction list is an assembler-type language that was widely used in Germany. Structured text is the only language that was invented for the standard. It has a high-level syntax that resembles Basic. It is unique in that it can combine the SFC in text form and incorporate the control in the same language.

In actual application, rifts exist between standardized versus proprietary versions. Each vendor's implementation of the standard is a little different. This inevitably causes some rewriting of code when moving programs between manufacturers. The degree that reuse is possible depends on how well each vendor complies with the standard.

Also, high-level functions like PIDs are not addressed within the standard, so each manufacturer puts together its own version.[15] To address this, PLC Open was formed in 1992 to promote the adaptation of IEC 61131-3 and to minimize the number of variant adaptations of the standard. It also provides independent certification of conformance.[16]

End users and system integrators want to be able to move easily between different brands and types of PLCs. Software that can configure all of the PLCs of at least one manufacturer and be similar to other manufacturers' programming software would be a step in the right direction.[17]

In the past, sequential and continuous processes were often addressed separately, with PLC used for the sequential and DCS for the continuous process and using their respective languages of ladder diagrams for PLCs and function blocks for DCS. One of the benefits of IEC 61131-3 is that PLC users can use ladders and DCS veterans can use function blocks in the same PLC.

CONCLUSION

Modern PLC software advances are increasing the productivity of PLC programmers. PLCs have matured from simple relay replacement to sophisticated controls involving interfacing to PCs and intelligent controllers. International standards like IEC 61131-3 have produced a unified, manufacturer-independent programming environment.

Graphical languages (ladder logic and function block), text languages (instruction list and structured text), and organizational constructs (sequential function charts) support a wide variety of applications. The ability to mix these languages within a single PLC has also fueled software development. Modern software productivity tools (including wizards) and simulation software have made PLC programming and testing considerably easier than it was just ten years ago.

5.7 Practical Logic Design

A. TUCK (2005)

EXAMPLE

> An operator notices a demineralized water-forwarding pump rapidly cycling on and off during the regeneration cycle of a demineralized water system. The plant has been in service for years. "Why," the operator wonders, "after all this time, has the pump logic stopped working properly? Who changed the logic?"

The logic has not changed at all but contains an error that appears only under a certain combination of conditions—in this case, when the supply tank level is hovering around the low-low set point and the demineralized water system requires the pump to run.

Many simple logic schemes that were tested and thought to work properly have subtle errors that are discovered only after they are placed in service. It is easy to test for the things the logic *should* do, but it is much harder to test for the things it *should not* do.

To help avoid such problems when designing logic, we have provided standard logic diagrams and solutions for control in this section. We have also provided information, compiled from years of correcting logic in various plants, that will help avoid the most common problems found in logic. This information will be especially useful while redesigning logic during commissioning.

For an explanation of the symbols used for the logic elements in this section, refer to Figure 5.7a

DESIGN PHILOSOPHY

Make It Simple. Somehow, the simplest and most direct way to solve a problem usually works best. When correcting logic that does not work properly, the best way to solve the problem often involves removing extraneous logic rather than adding more. Logic can be made to do almost everything anyone can dream up, provided there is enough input/output (I/O), but such lengths usually are not necessary. Find a simple way of solving the problem and do that instead.

The purpose of the logic is to keep systems controlled at steady state and to protect the equipment—it works best when it does not attempt to make all of the decisions for the operator. It is better for the operator to understand what the logic is doing and to stay involved in the operation of the plant. If too much is controlled *for* the operators, they will not be clear about where the logic stops and their jobs begin, and they are more likely to miss something that needs their attention. The only safe alternative would be to have the logic control everything and replace the operator entirely, and that usually is not practical.

Be Consistent. Writing logic that is consistent throughout the plant is fundamental to good design, and is important for safety as well. All valves and pumps of the same type should work the same way so that the operator knows what to expect when a button is pushed. Keep in mind all of the operators who will be hired in the years to come—they will not have the advantage of learning all the quirks of the plant during its start-up.

OPEN/CLOSE VALVES

> A valve opens automatically upon a steam turbine trip. While the turbine is down, the operator tries to close the valve; however, the steam turbine trip indication is still in place and locks the valve open. The operator then puts the valve in manual mode and closes it. The steam turbine is started again a few days later, and by this time the operator has forgotten about the valve and does not return it to auto mode. When the steam turbine trips again, the valve does not open.

Many would call this operator error, but it also is a design flaw that makes the plant hard to control. There are many different ways to design open/close valve logic, and it is not always clear how difficult it is to control until the plant is up and running.

Following are some tips for creating safe and easy-to-control logic, and some diagrams of standard logic for motor-operated valves (MOV) and solenoid valves.

Definitions

Input to the logic:

Open and close command: The commands from the graphic display, initiated by operator, to open and close the valve. Note that these are always momentary.

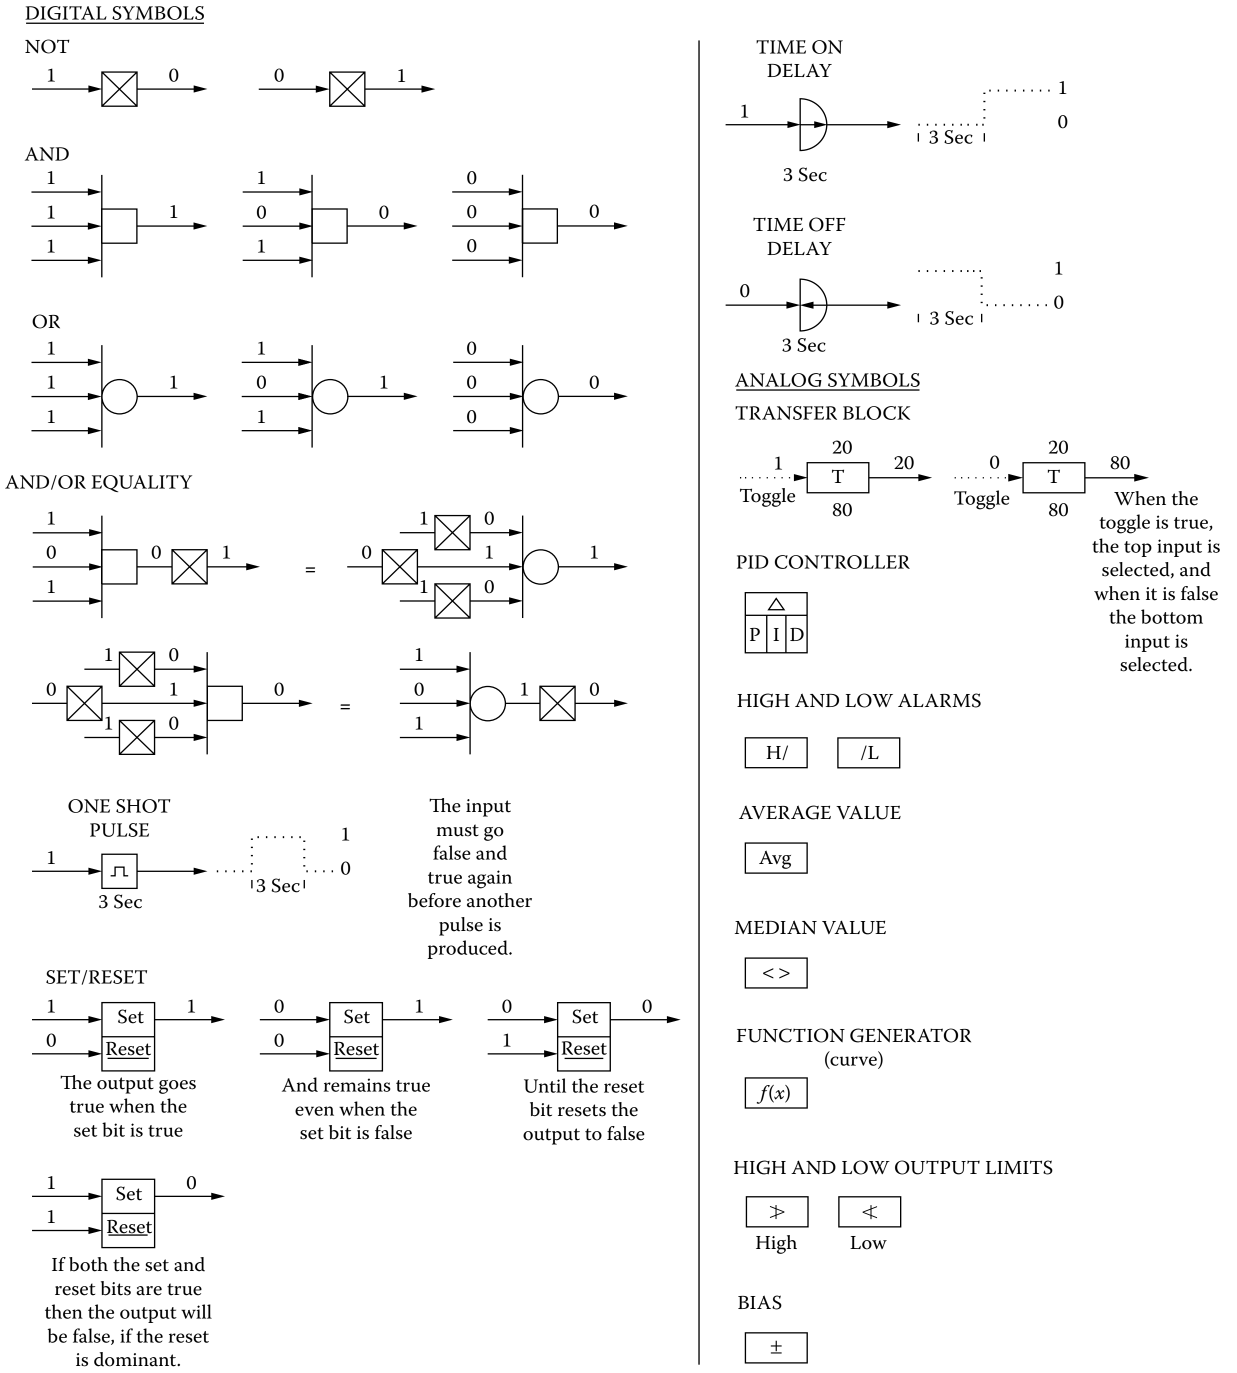

FIG. 5.7a
Logic design symbols.

Open and close limits: The indication from the valve limit switches that tells the operator and the logic when the valve is fully open or fully closed.

Open and close permissive: Process conditions that are required before the valve can be opened or closed.

Auto open or close: Conditions that open and close the valve automatically while the valve is in auto mode.

Output from the logic:

Open and close outputs: The output from the logic to the valve that strokes it open and closed.

Indications and alarms:

Auto mode: Shows that the valve is in auto mode and will be operated automatically by the **auto open** and **auto close** commands.

Failed to open/failed to close: An alarm that shows that the valve was given an **open** or **close** output, but the fully open or fully closed limit was not reached in a specified amount of time.

Mismatch: An alarm that shows that both the open and close limit are true at the same time.

Auto Mode

One common approach to designing auto/manual logic is to design the logic to automatically switch the valve to manual mode upon an open or close command from the operator. Unfortunately, that makes it even easier for the operator to forget to place the valve in auto mode, because it can go unnoticed that the valve switched to manual mode. Logic designers also often elect not to use an auto mode at all to avoid the risk of the operator's forgetting to put the valve into auto mode; however, this makes the operator's job quite difficult since he or she will need to stroke the valve for maintenance when the system is not in service and will have to force the auto commands to do that.

A better way to handle this is not to require that the valve be in manual for the operator to give a command and to reserve manual mode for locking out the auto commands when the system is not in service—this can be done by simply making all auto open and auto close commands momentary as shown in the standard logic for valves in Figures 5.7e, 5.7f, and 5.7g, later in this section.

The operator in the example above would need only to give the valve a close command; then, when the steam turbine trips again, the valve will open as it should.

By making the auto command momentary, one need not worry about conflicting auto open and auto close commands that are True at the same time or about having a valve that strokes in the direction of the auto command as soon as it is placed into auto mode (the operator should always know what to expect when placing a valve into auto mode). Also, if the auto commands are latched, then they will lock the reset of the fail alarm.

If an auto command should hold the valve in place while it is True, then the command should also be a permissive. For example, an auto open command that should hold a valve open should also be inverted and fed into the close permissive. This way, when the auto open condition is True, the valve will open and cannot be closed even when it is put into manual mode (Figure 5.7b).

If there is more than one auto open or auto close command, use a pulse for each individual auto command as shown in Figure 5.7c; otherwise, one of the commands may

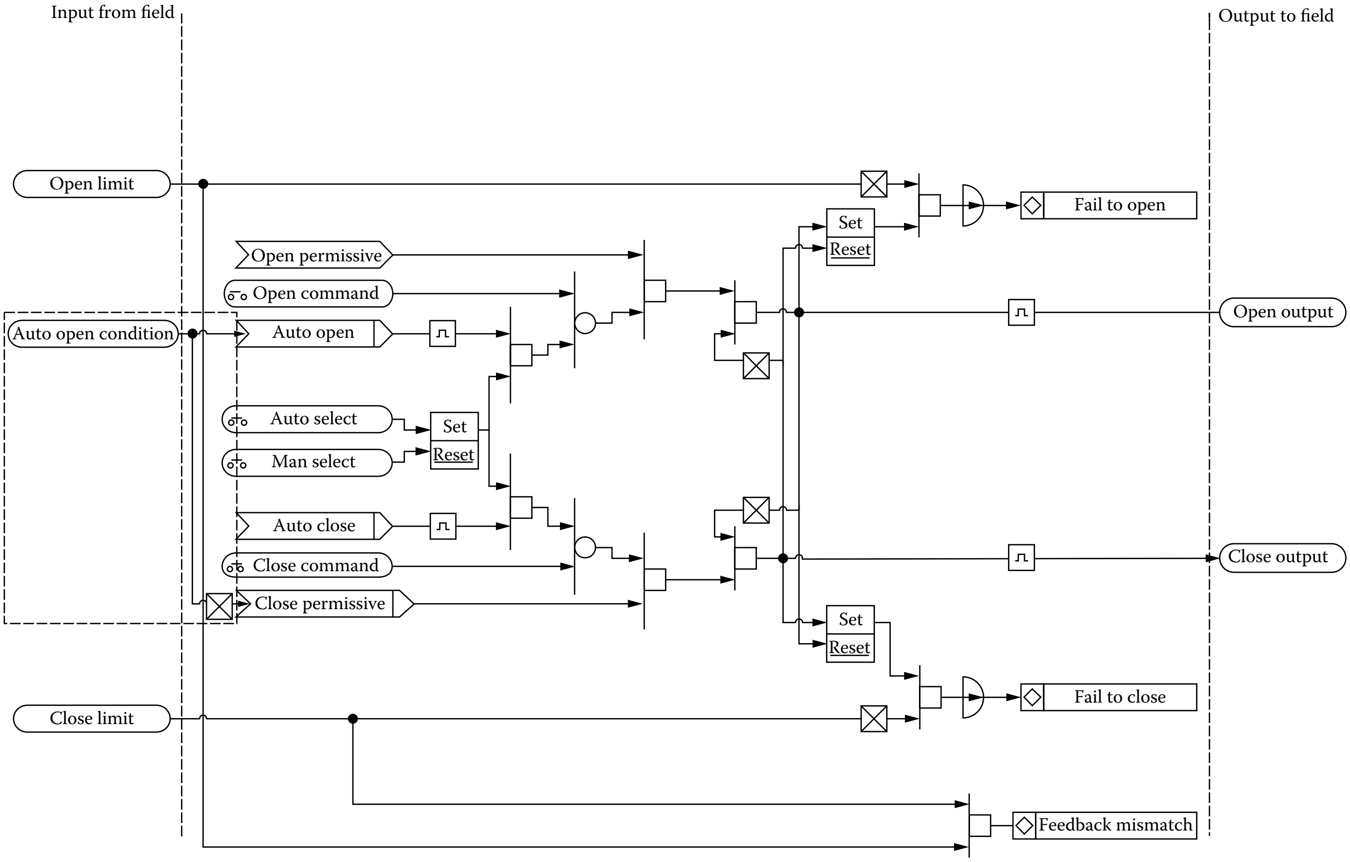

FIG. 5.7b
Open/close valve—use permissive to hold auto command.

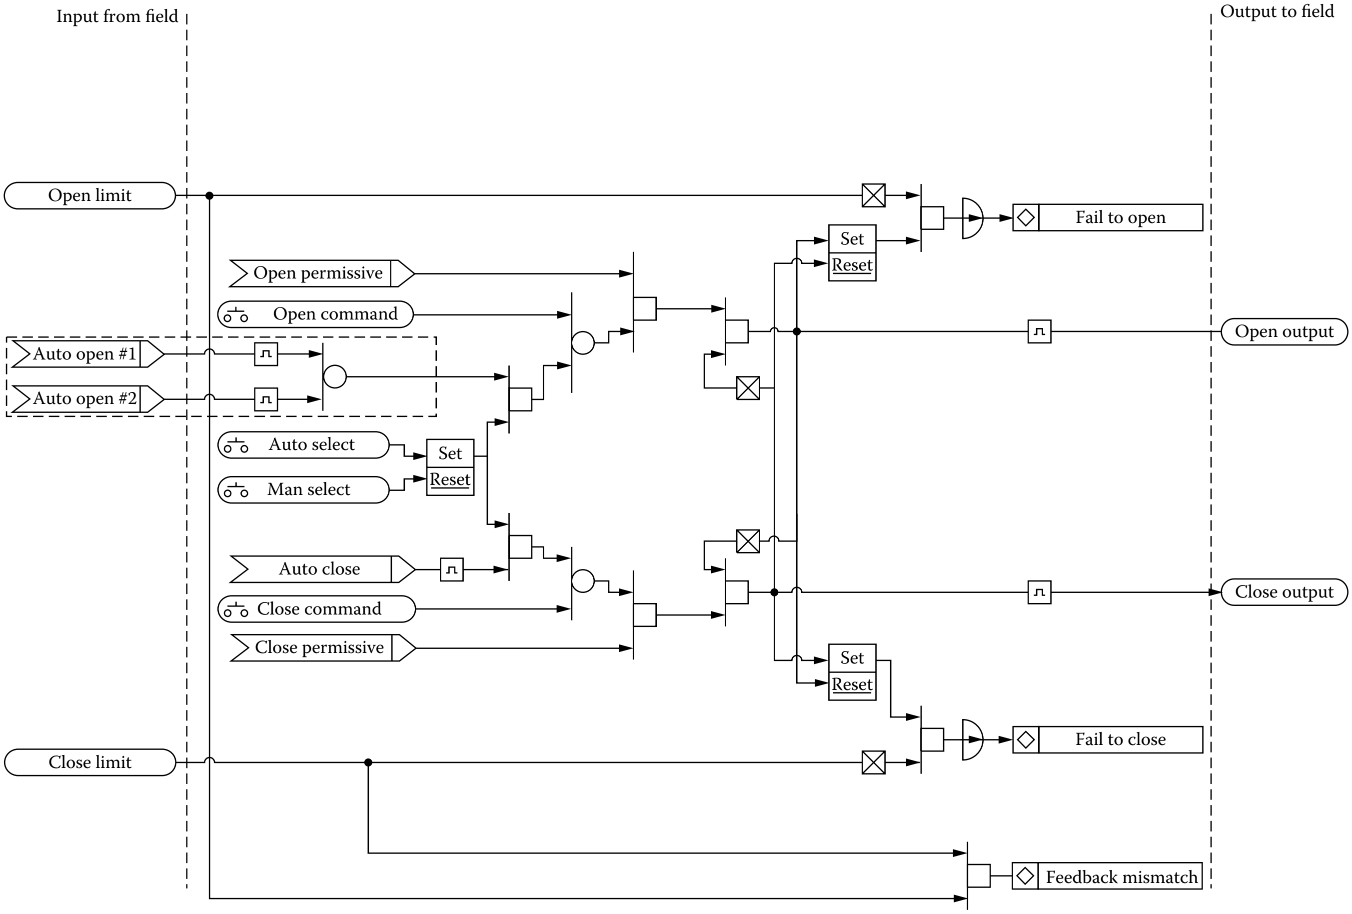

FIG. 5.7c
Open/close valve—more than one auto command.

be ignored. For example, if there are two auto open commands, and one of them opens the valve and remains True, and then an auto close command shuts the valve, when the other auto open command becomes True, the valve will not reopen because the pulse will not have occurred since the first auto open command is still True.

With motor-operated valves in particular, it is important not to write logic that will continually cycle the valve open and closed as this will eventually destroy the motor. Take the time to analyze the logic to make sure the auto open and auto close commands will not cause the valve to cycle.

For example, it is best not to use the same input for both the auto open and (inverted) auto close commands, which can cause the valve to cycle open and closed. If it is necessary, because of hardware restrictions, be sure to add a hefty time delay on either auto mode input, as shown in Figure 5.7d.

Motor-Operated Valves

The standard logic for two of the most common types of motor operated valve (MOV) logic is shown in Figures 5.7e and f. The logic in Figure 5.7e has momentary open and close outputs that will command the MOV to move. The circuit for the MOV will then take over and continue to stroke the valve and will stop stroking when the limit is reached. The logic in Figure 5.7f sends latched outputs to the field that stay True until the limits are reached.

Failure Logic

An operator gives an open command to an MOV on a main steam line. The valve opens, releasing steam to the system, but does not quite reach the open limit. The maintenance engineer who has been troubleshooting the valve thinks he has found the problem and asks the operator to give another open command to the valve to open it fully. Unfortunately, the operator can only give an open command after first closing the valve, which would bottle up the steam and cause the relief valves to open.

The operator should be able to issue a second command to attempt to move a valve that has failed. It is a common problem to leave this option out of the logic, which makes it very difficult to remedy the problem of a failed valve while a system is in service.

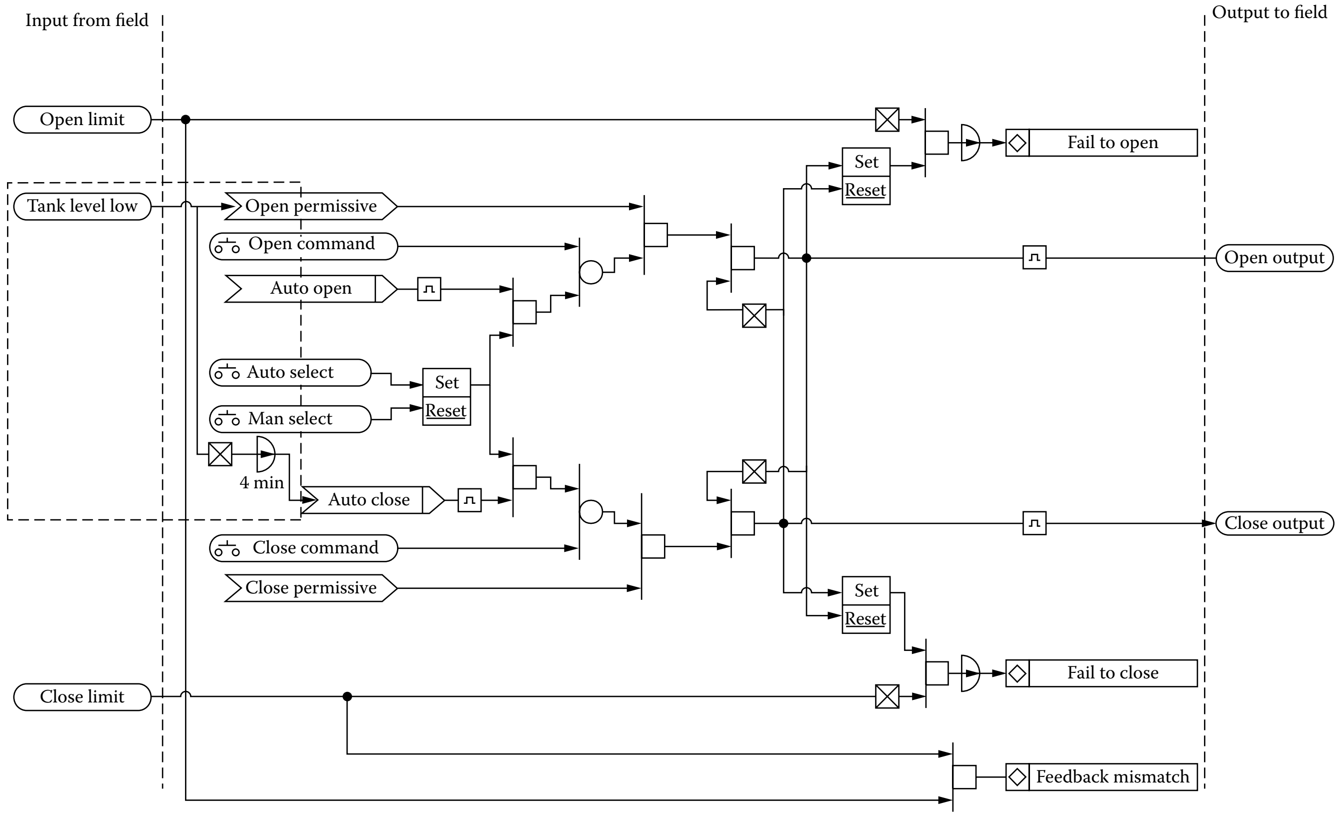

FIG. 5.7d
Open/close valves—auto open and close from the same input.

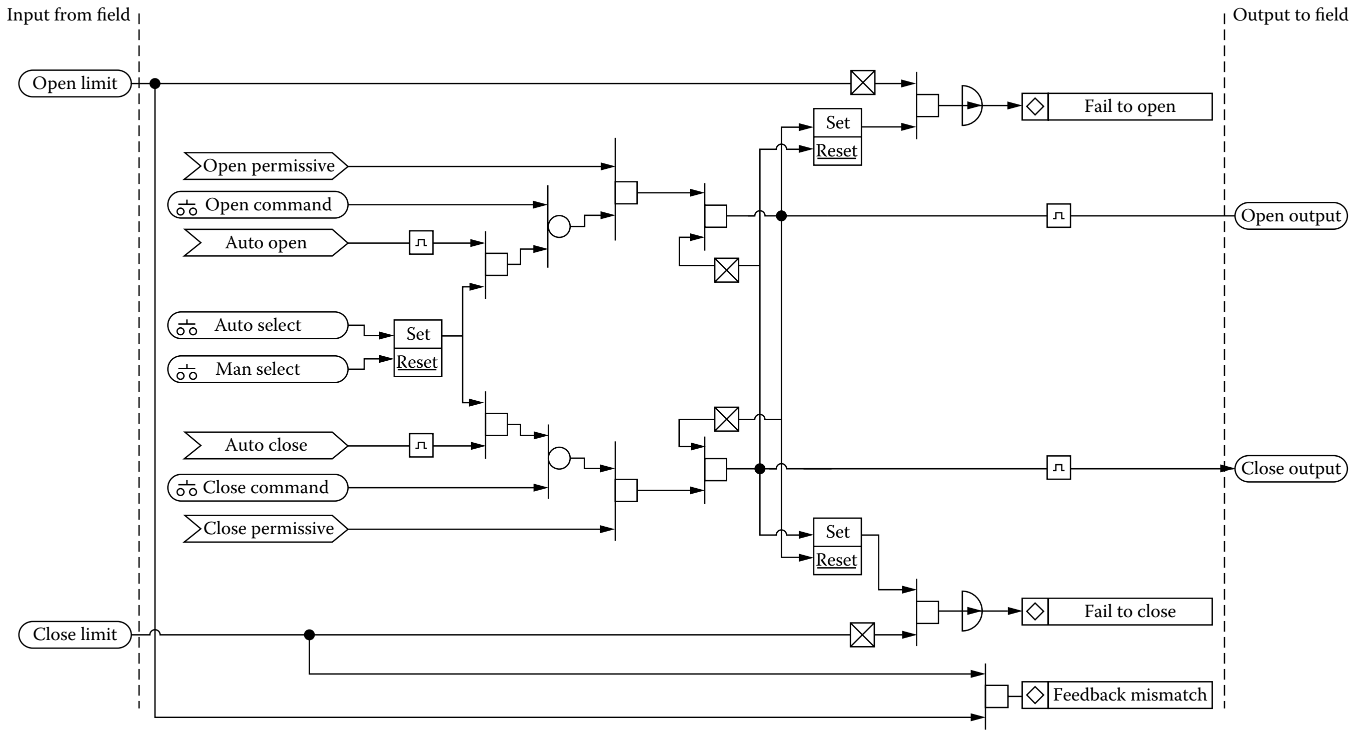

FIG. 5.7e
Standard MOV logic—momentary outputs.

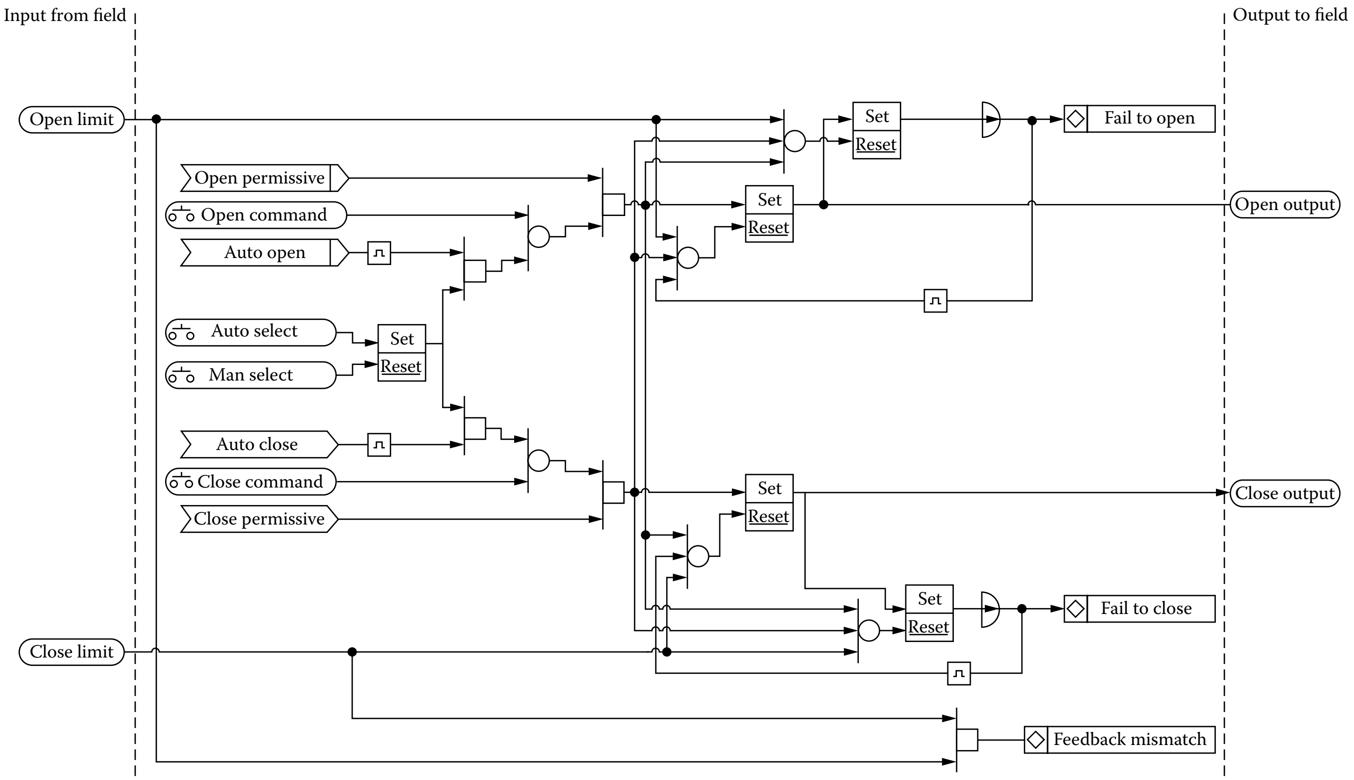

FIG. 5.7f
Standard MOV logic—maintained outputs.

Also, if the valve fails because process flow slows the stroke of the MOV past the stroke time limit of the fail timer, the fail alarm should reset automatically when the limit is eventually reached without requiring the operator to stroke the valve first.

If the MOV is opened (or closed) and later loses its open (or close) limit, then a fail alarm should appear. Often, logic is not written to do this, and many days can pass without the operator knowing that an MOV has failed.

For most MOVs the fail timer can be set to be the stroke time plus about 20 s. Make sure to time the stroke time for both open and close as they are often different. Also, it is wise to power the limit switches from the I/O cabinet instead of the breaker. This way, if the MOV breaker is open, the logic will still see the correct state of the valve and will not react to incorrect information.

For MOVs with latched outputs, as shown later in Figure 5.7l, the outputs must be cleared upon a fail to open or close; otherwise, there will be a chance of personal injury, since the output will remain True while someone is troubleshooting the valve.

Solenoid Valves

Figure 5.7g shows the logic for solenoid valves. Often, only one limit switch or none is used. In these cases, simply omit the failure logic for those limit switches that are missing.

PUMPS

Figures 5.7h and 5.7i show standard logic for the two most common types of pump motor. Figure 5.7h, the most common type of pump motor, has one maintained output for starting the pump (True = start and False = stop). The pump motor with two momentary outputs shown in Figure 5.7i is often used for very large pump motors.

Definitions

Input to the logic:

Start and stop command: The commands from the graphic display initiated by the operator to start and stop the motor. Note that these are always momentary.

Run contact: The indication from the pump motor that tells the logic that the pump is running.

Start permissive: A condition that is required before the pump can be started.

Process trip: Process conditions that shut down the pump motor (i.e., trip the pump when the tank level is too low).

Auto start: A condition that starts a pump automatically while the pump is in auto mode (example: Auto start the pump when another pump fails).

Auto stop: A condition that stops the pump automatically when the pump is in auto mode.

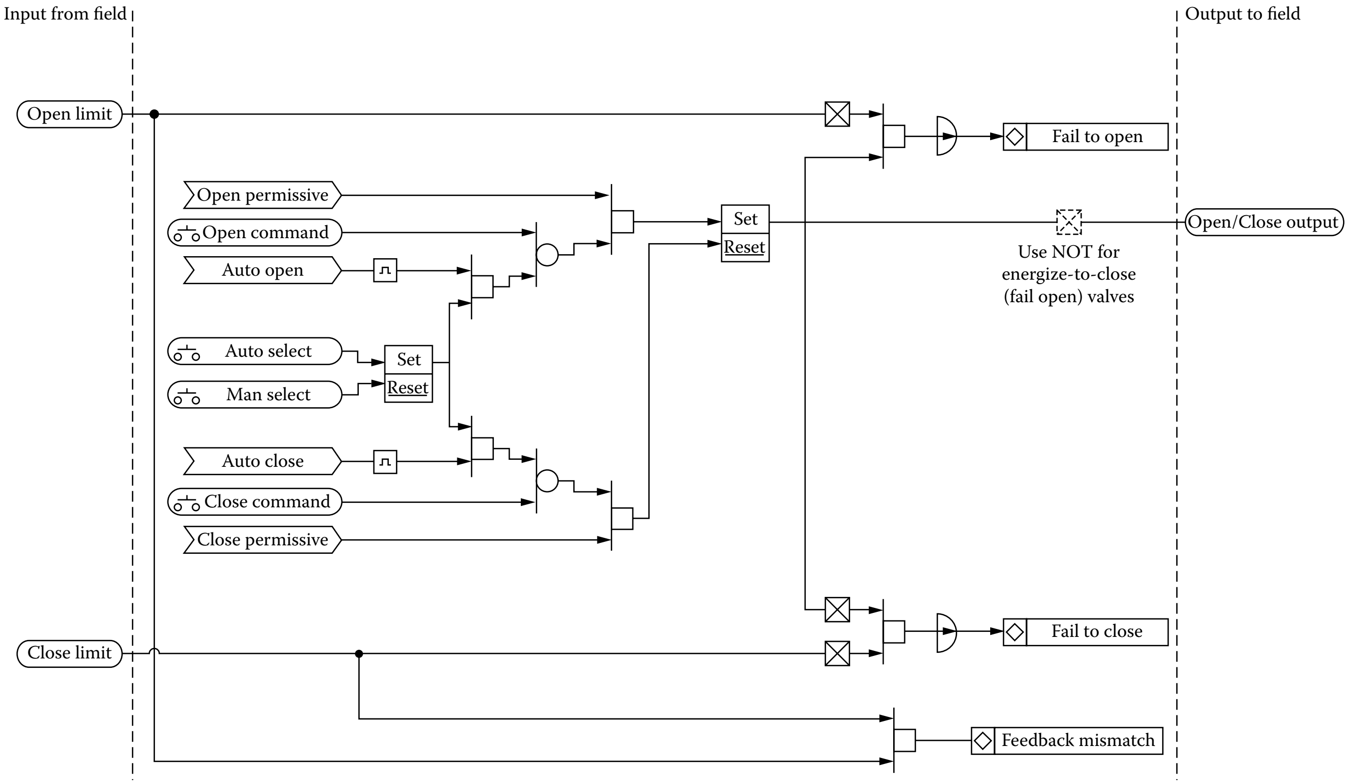

FIG. 5.7g
Standard solenoid valve logic.

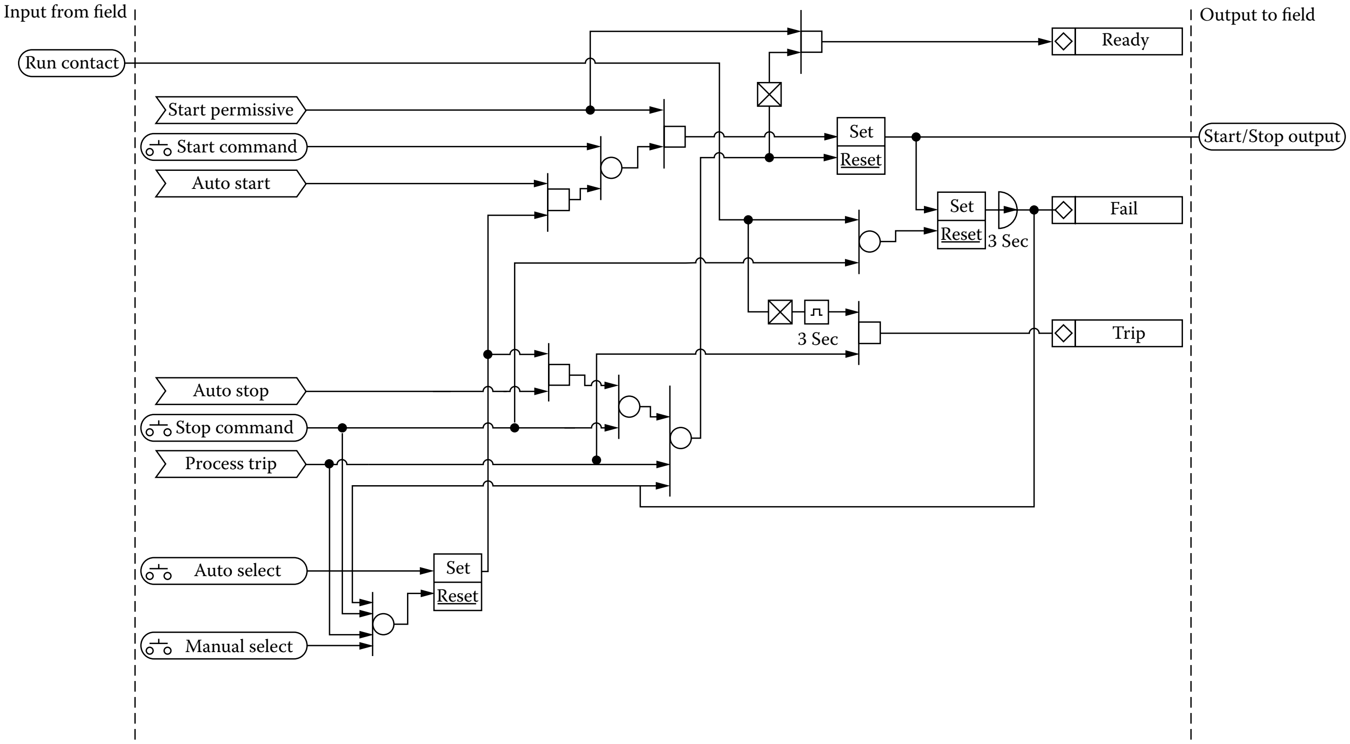

FIG. 5.7h
Standard pump logic—maintained output.

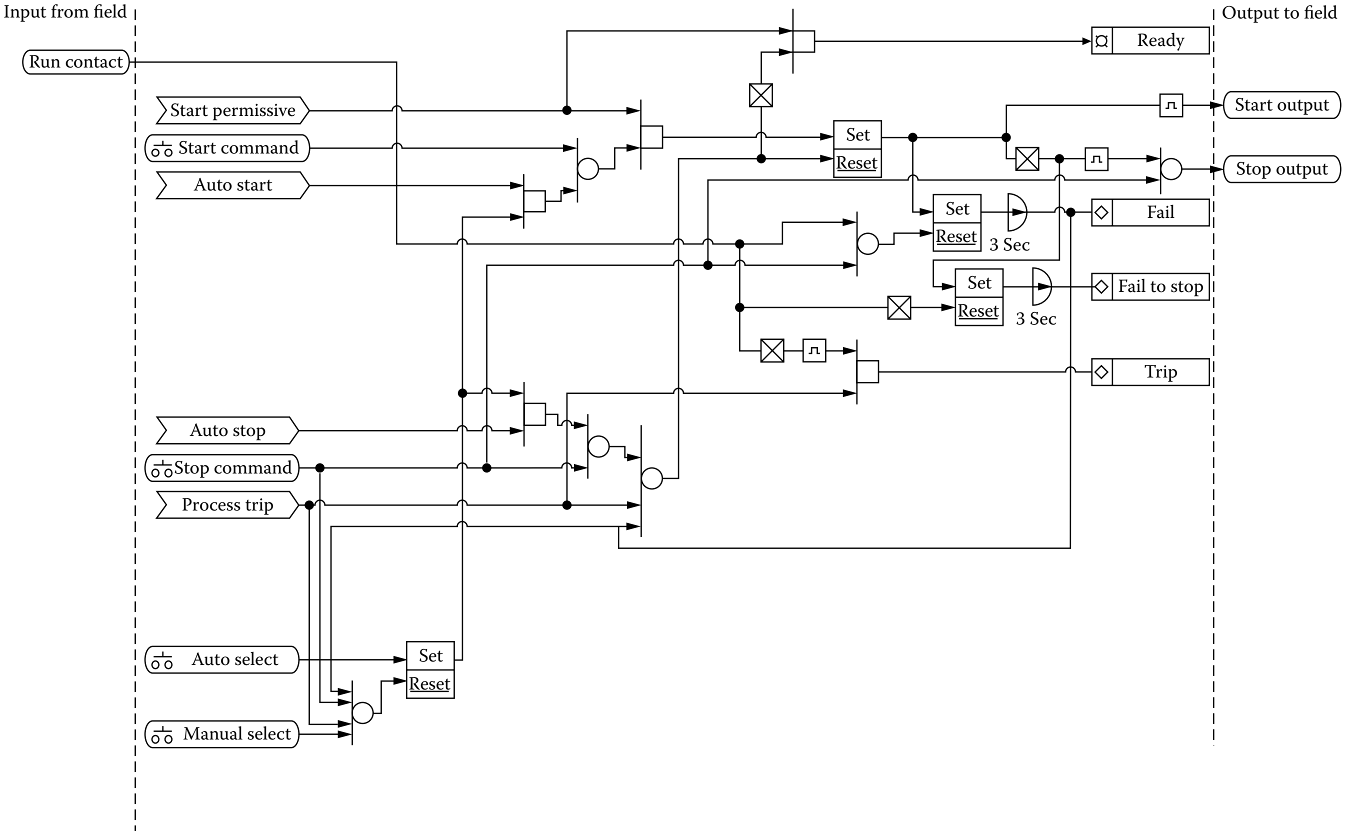

FIG. 5.7i
Standard pump logic—momentary output.

Output from the logic:

Start and stop output: The output from the logic to the pump motor that starts and stops the motor.

Indications and alarms:

Ready: Shows that all permissives have been met and the pump is ready to be started by the operator.

Auto mode: Shows that the pump is in auto mode and will be operated automatically by the auto start and auto stop commands.

Failed: An alarm that tells the operator that the pump was given a start output, but it is not running. This tells the operator that there is a problem with the pump itself and indicates that either the pump did not start when it was told to, or that it stopped after it had been running, *but it was not stopped by the logic*.

Tripped: An alarm that tells the operator that the pump was stopped by the logic via the process trip (not by the operator or an auto stop command). This alarm is not always included in pump logic.

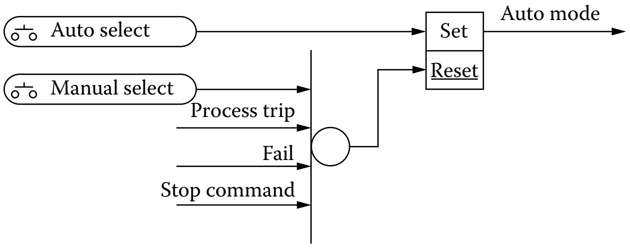

FIG. 5.7j
Typical pump auto mode.

Auto Mode

The “auto” and “manual” push buttons shown in Figure 5.7j set and reset the auto mode that allows the pump to start and stop automatically when the auto start and auto stop commands are True. The auto mode reset should also include pump fail, process trip, and the operator stop command. If the auto mode does not reset upon pump failure, the pump will restart as soon as the failure is reset while the auto start is True. Similarly if the operator stop does not reset the auto mode the pump will restart after the operator stops it if the auto condition is True.

If the process trip does not reset the auto mode, a problem like the demineralized water pump behavior described in the introduction will occur. If the trip condition cycles on and off (as a level trip may do while the level hovers around the set point) while the auto start condition is True, the pump will cycle on and off.

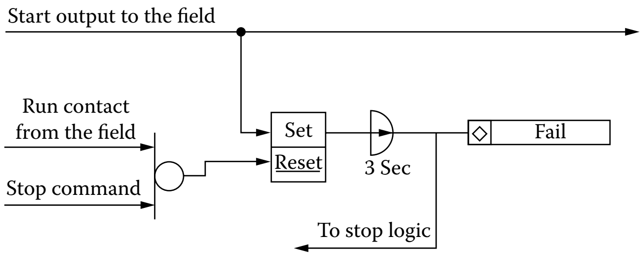

FIG. 5.7k
Typical pump failure logic.

Pump Fail

A pump failure occurs when a start output is sent to the motor and no run contact is detected (Figure 5.7k). This is different from a pump trip, which indicates that the pump was tripped by the logic upon a process condition. Making the distinction between fail and trip eliminates much confusion about what has shut down a motor—something that happened in the field or something caused by the logic. The "fail" alarm tells the operator that the problem is in the field and the "trip" alarm indicates that the motor was shut down by the logic.

For safety purposes, when a motor fails, the start output must be reset so that a person inspecting the failed pump will not be surprised by a sudden start. Although this is accepted as standard design practice for safety purposes, it is often erroneously omitted.

The failure indication will remain True and will inhibit the start of the motor until the operator manually resets it by giving a stop command. The start inhibit is performed by feeding the fail bit into the stop logic (as shown in Figures 5.7h and 5.7i) and should not be pulsed before it is fed to the stop circuit or the pump will be allowed to start again without first clearing the fail indication, and will not clear the start command after it has failed a second time.

Other Common Problems with Pump Logic Design

Quite often, motor logic is written so that when the run contact is seen by the logic, a start output is given to the motor. If, for example, the run contact is forced True during simulation, or if the run contact is accidentally made True when wiring is altered in the I/O cabinet, the pump will start unexpectedly. This is a safety hazard that must be removed from the logic.

The start and stop commands from the operator should always be momentary. Otherwise, the pump will start unexpectedly when the permissives are later satisfied if an earlier attempt was made to start the pump when the permissives were not satisfied. A maintained command will also cause the pump to start unexpectedly when the trip condition that caused the trip is cleared. The momentary pulse is usually executed by the graphic and not the programmed logic. For all of the diagrams given in this section, it is assumed that the command push buttons are momentary.

Problems often appear when permissives are overridden by another input from the logic such as an auto start. Make sure that the permissives are always used as they are intended. If in rare cases it is necessary to override a permissive, then design the logic so that the operator will have to make a conscious decision to perform the override.

Often a "red tag" or logic lockout system is used to show that a pump is undergoing maintenance and to lock out start commands from the operator. Surprisingly often, it is mistaken for a substitute for proper locking and tagging out of the motor breaker, and when used alone it does not provide adequate prevention against starting the motor. It is acceptable to put the motor in manual mode while using proper maintenance procedures for locking out the breaker instead.

After a pump trips upon a process trip, the operator should not be required to initiate a stop command before restarting the pump. This is another common design flaw that is not a safety hazard, but it is a nuisance to the operator and should be fixed.

Pumps with Two Outputs

Figure 5.7i shows standard logic that can be used for pumps with two outputs. When motors of this type fail, it is important to send a stop output to the motor even though it may already have stopped. If the motor fails after losing the run contact but is still running, then the motor will not trip when a process trip occurs because the logic "thinks" that the motor has already stopped.

The stop output for this type of motor can be made fail-safe by inverting it so that it is always True unless a stop command is given. If the stop output is not fail-safe, then it is necessary to include a "fail to stop" alarm in the motor logic. The logic in Figure 5.7b has been designed so that the operator can make a second attempt to stop the motor upon a fail to stop without having to give a start command first.

Controlling Two Pumps Together

Standby Pump Logic Figure 5.7l shows how to start a standby pump upon the failure of the running pump. The fail indication of one pump is simply fed to the auto start input of the standby pump so that when the standby pump is in auto mode, it will start when the running pump fails. When two pumps are required to run at the same time, for example, when the discharge pressure of the running pump is insufficient, a low pressure contact is fed into the auto start. In this case, a time delay is required after the first pump is started to allow time for pressure to build up; otherwise, the standby pump will start as soon as the main pump has started.

Some pump systems should start the standby pump on trip conditions that are not common to both pumps as well as on pump failure. For example, a standby boiler feed pump can start when the running pump trips on high vibration or bearing temperature, low lube oil pressure, and any other noncommon trips, as well as when it fails. Figure 5.7m shows how this is done.

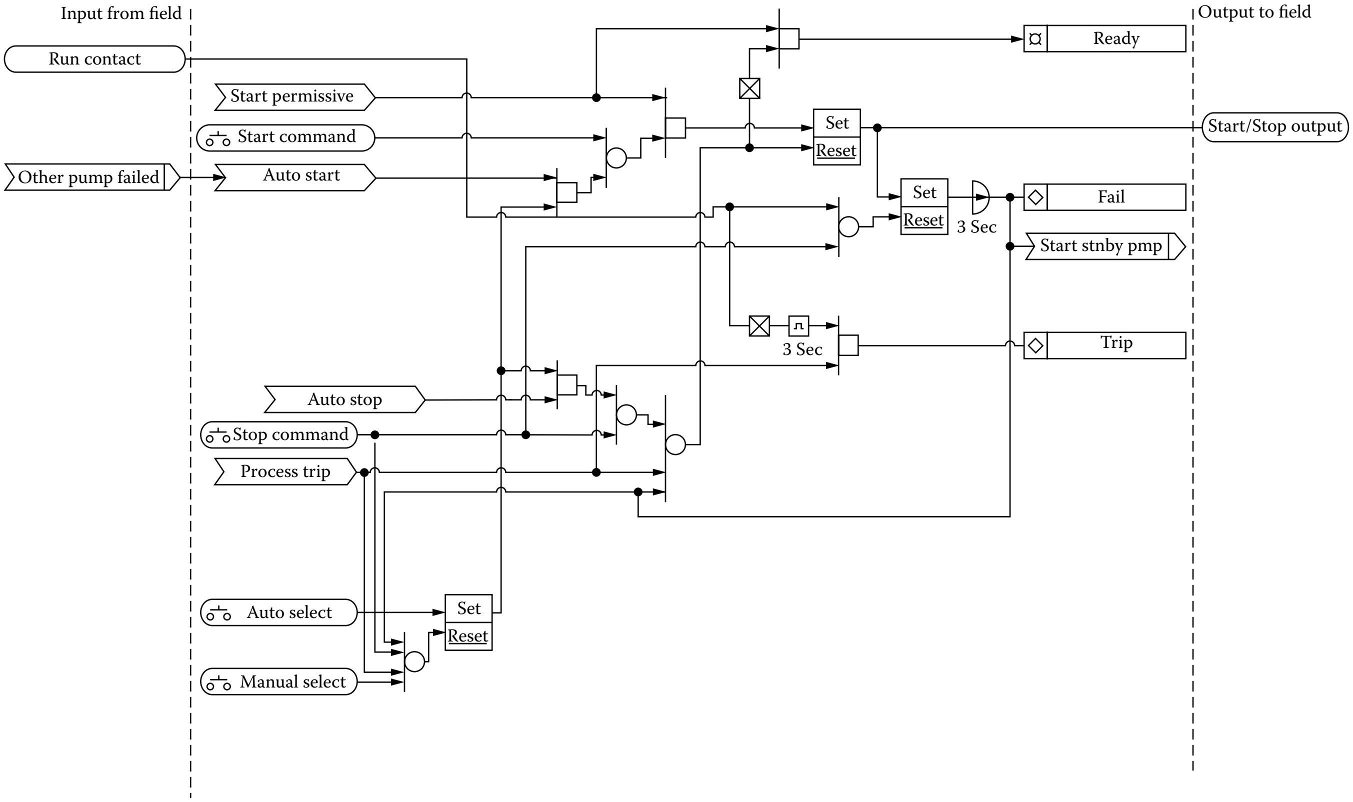

FIG. 5.7l
Pump—standby start.

Main and Auxiliary Pump Logic Figure 5.7n shows logic for starting an auxiliary pump upon the start command of the main pump (for example, a boiler feed pump with an auxiliary lube oil pump, or a vacuum pump with an auxiliary seal water pump). Upon the start command of the main pump, the auxiliary pump is started first, and after a specified condition (such as lube oil pressure sufficient, seal water flow sufficient, or a simple time delay) the main pump is started.

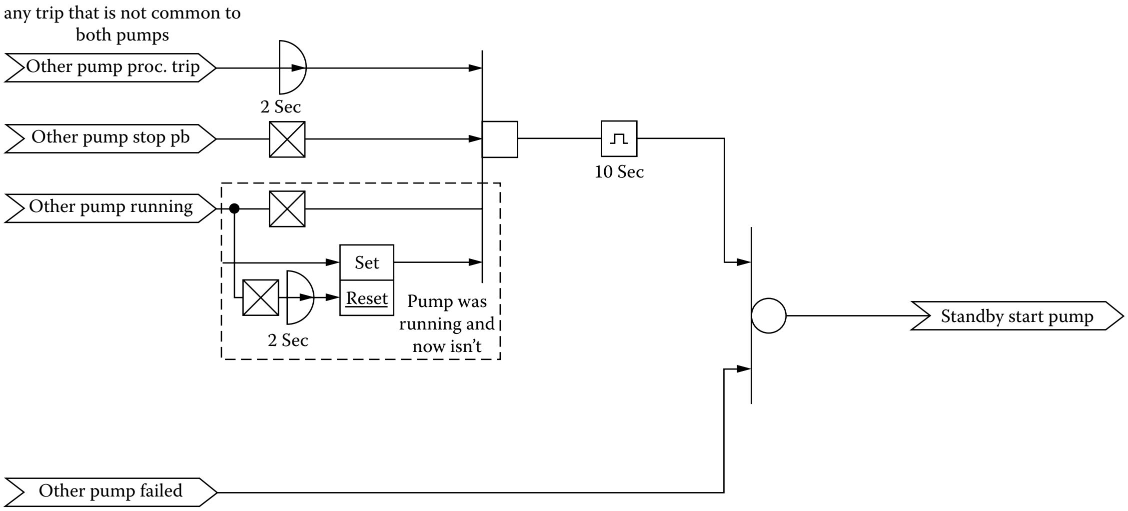

FIG. 5.7m
Standby start upon fail and noncommon trips.

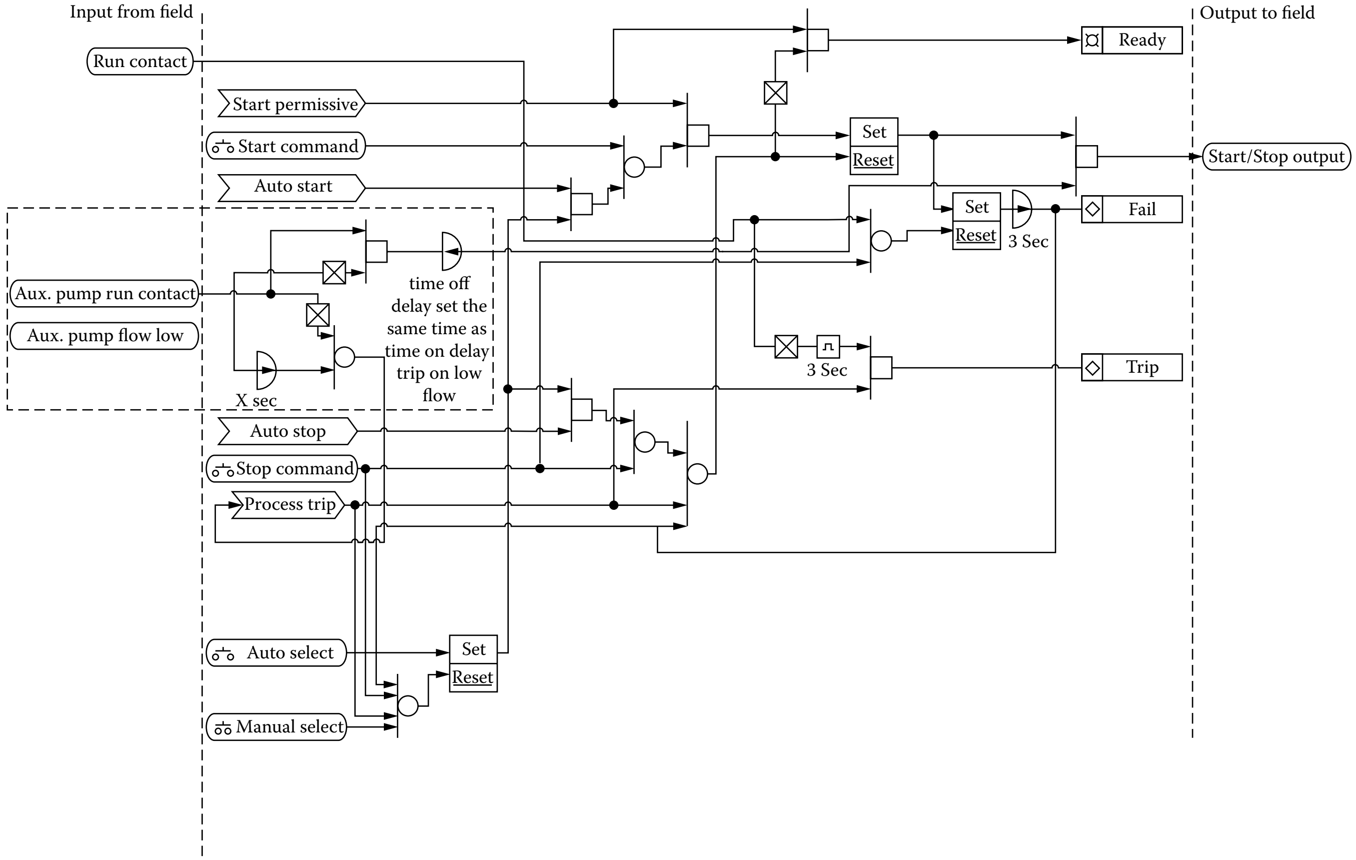

FIG. 5.7n
Main and auxiliary pump start.

BREAKERS

Figure 5.7o shows simple breaker logic. If both the field circuit and the control system logic are controlling the breaker, make sure that the two parts of logic do not interfere with each other. A remote/local switch is often used to remedy this and is fed into the permissive.

ANALOG CONTROLS

A feedwater controller is designed to switch from the start-up feedwater valve to the main valve when the start-up valve reaches 100%—immediately closing the start-up valve and popping the main valve open to 20% during the start-up of the power plant. The operator dreads the swap over to the main valve, because it upsets the drum level control, and it must be caught in manual mode to keep the plant from tripping.

Switchover

Switching over from one valve to another in a process is often a tricky thing to control. Often the logic is written with transfer blocks that immediately close one valve while opening the other. For a smoother transition, curves can be used instead and can be adjusted as needed during the tuning process to better control the way the valves open and close during switchover. For split ranged valves, if the first valve can be kept open after the second one starts to open, then logic as shown in Figure 5.7p can be used. If the first valve must close after the second opens, then the first valve must be ramped closed (not using the curve), while releasing the second valve to open on its own as it controls the process.

For switching between two valves that are controlled with separate controllers, the hold option in the controller can be used to freeze the controller that is not in use.

Pop Open/Clamp Closed

To pop a valve open or clamp it closed upon a specified condition, use the low and high output limit parameters of the controller that specify the range that the output of the controller is allowed—normally 0 to 100%. For example, all that is needed to clamp a valve closed (say, when a pump is not running) is simply to change the high output limit from 100 to 0% so that the range that the output of the controller is allowed will be 0 to 0%. This example, shown in Figure 5.7q, shows how the change from 100 to 0% is handled with a transfer block. The valve is clamped closed the

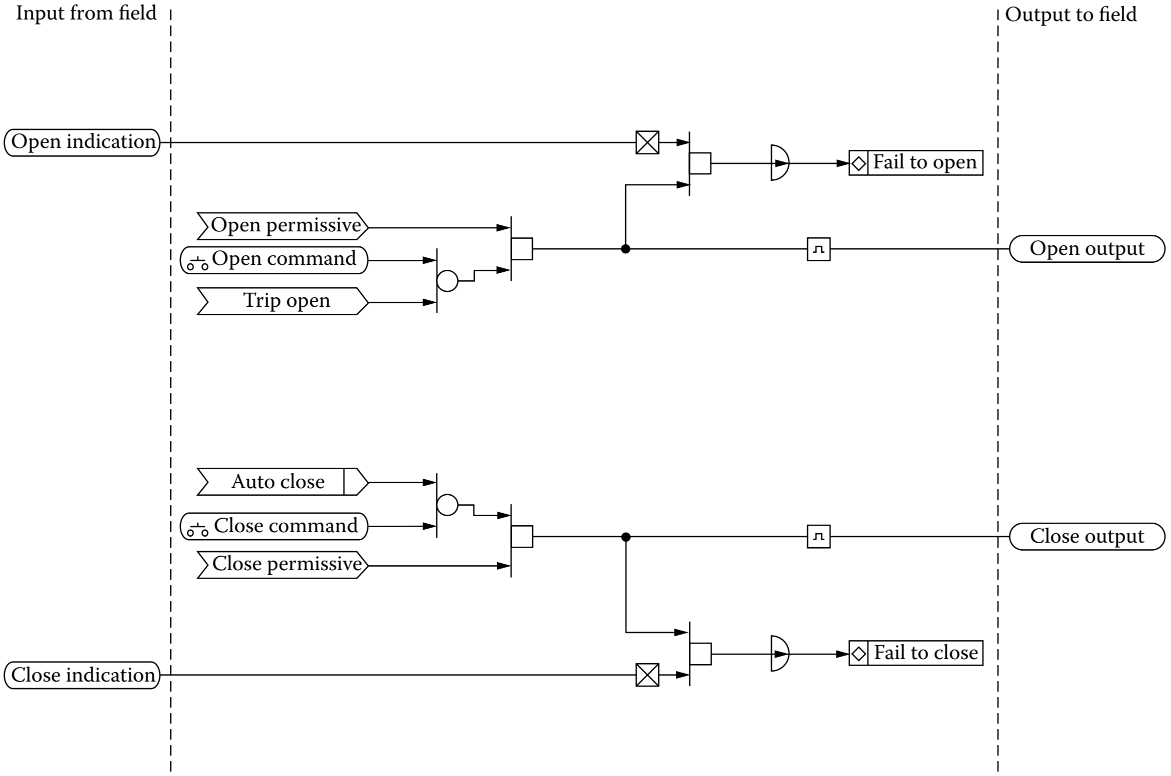

FIG. 5.7o
Standard breaker logic.

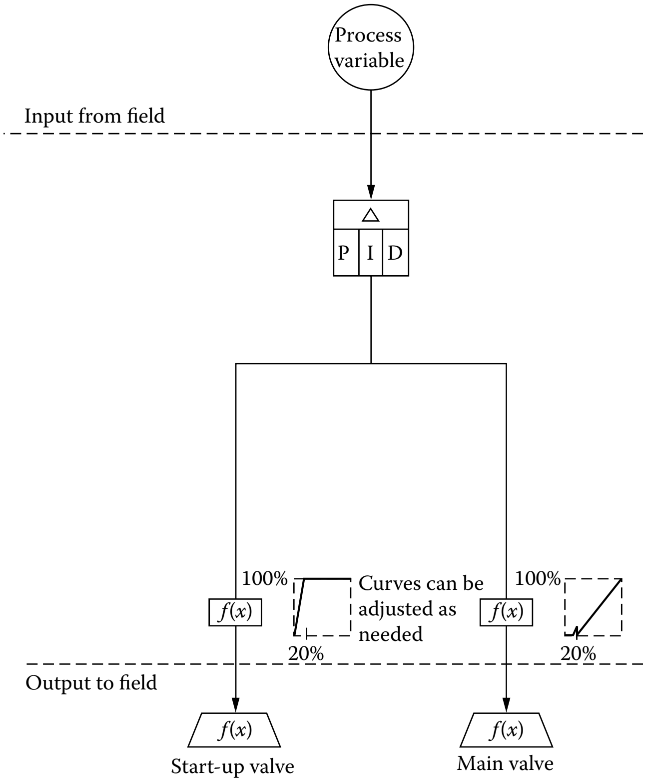

FIG. 5.7p
Analog—split range valves.

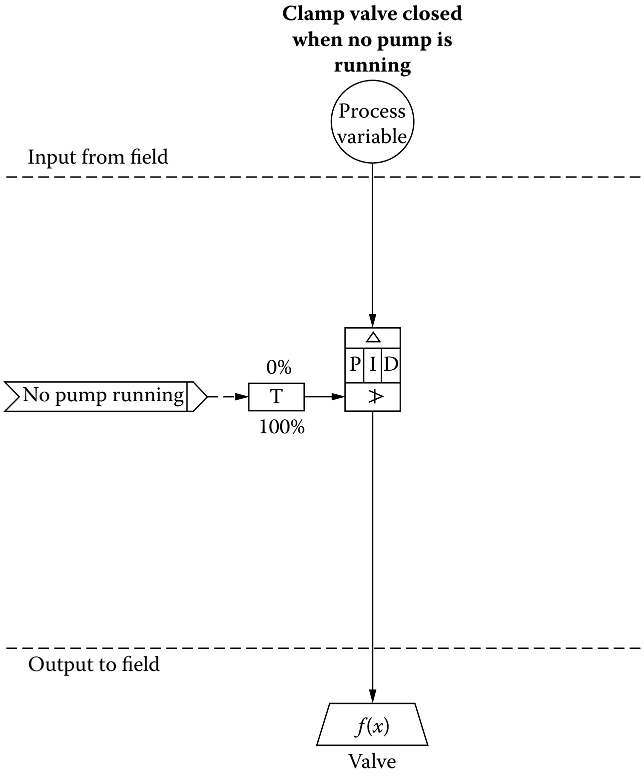

FIG. 5.7q
Analog—clamp valve closed when no pump is running.

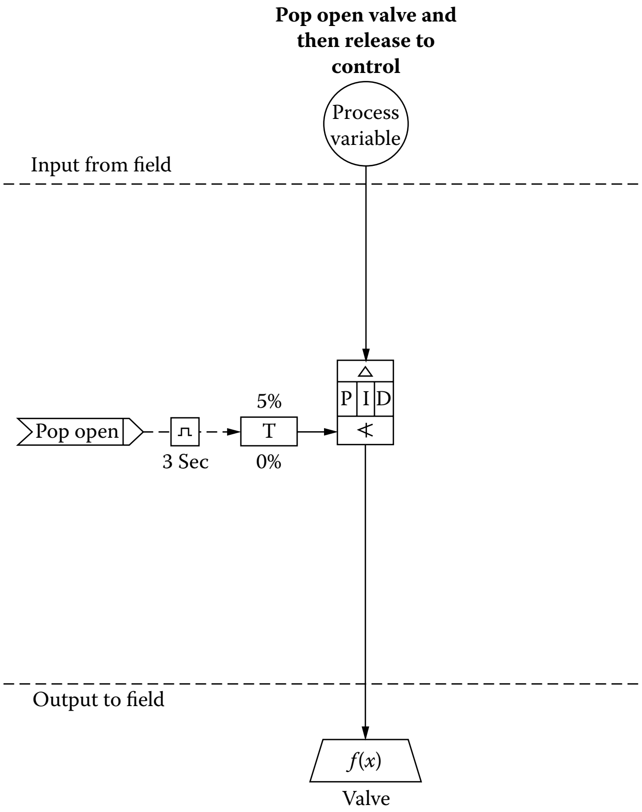

FIG. 5.7r
Analog—pop open valve and then release to control.

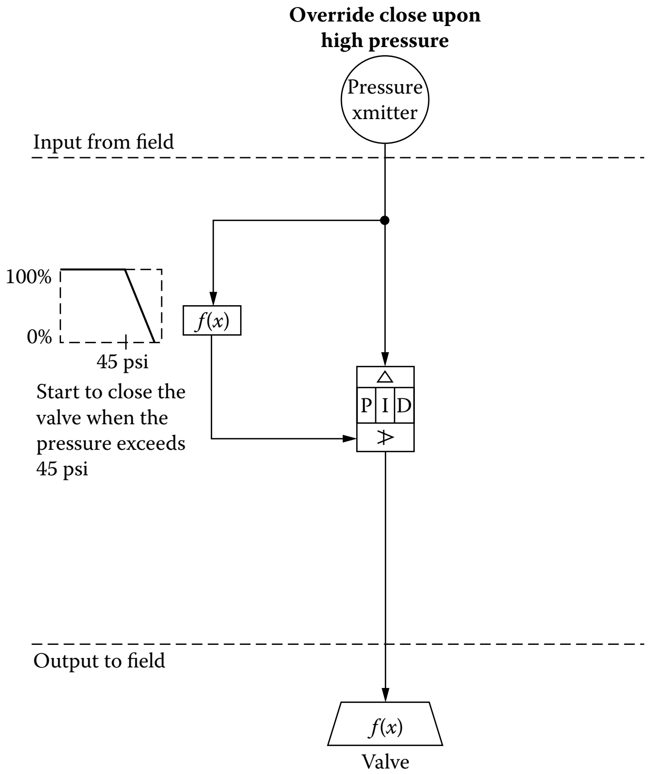

FIG. 5.7s
Analog—override close.

whole time that the pump is not running, so that there is no need also to switch the controller to manual mode, as is often done. When the pump runs again, the controller is automatically released and there is no need to have to remember to reset the controller to auto mode before starting the pump.

To pop open a controller, simply increase the low output limit. The controller will open to the specified position and start controlling from that point. In these cases, it is best to make the pop-open condition momentary so that the operator can manually close the valve if needed (Figure 5.7r). If a smoother transition is desired, a lagged transfer block can be used.

Override Open and Close

To override the controller to ensure that a limit on the process variable is maintained (for example, to push a level controller closed upon high water level in a drum), use a function block to generate a curve to feed the high output limit. As shown in Figure 5.7s, the input to the curve is the process variable to be controlled. When the limit is nearly reached, the output of the curve will start to decrease the high output limit from 100 to 0%, to close the valve until the process is normal. These curves can be adjusted during the tuning stage to best control the limit.

Similarly, one can use a controller to make sure that a limit is not reached on a process variable that one is not directly controlling and feed the controller output into the high or low limit of another related controller. This is different from cascade control (explained below), which controls two process variables at the same time, or feedforward control (explained below), which modifies the main controller as another process variable changes. In this case, one normally controls one process variable and uses the override to control only during the "out of spec" condition. For example, to control recirc flow in a system while making sure not to overpressurize the main discharge pipe, simply feed the overpressure controller output into the low output limit of the flow controller. This will push open the flow controller only when needed, as shown in Figure 5.7t.

Feedforward

If the change of one process affects another process under control, one can use the bias input of the controller to modify the controller output as the other process variable changes. This is especially handy for anticipating the need for more or less output before the controller sees the result of the change. The bias simply adds or subtracts a value from the output of a controller and is often added during the tuning process as needed (Figure 5.7u). The process variable should be passed through a multiplier so that the effect of the feedforward can be adjusted as needed. The feedforward adjustment can be made even more accurate by using a curve instead of a multiplier if

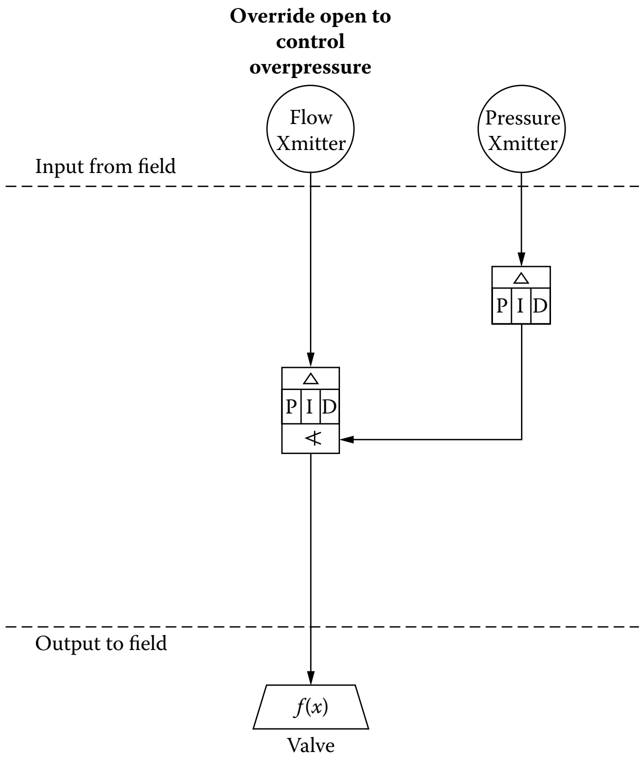

FIG. 5.7t
Analog—override open.

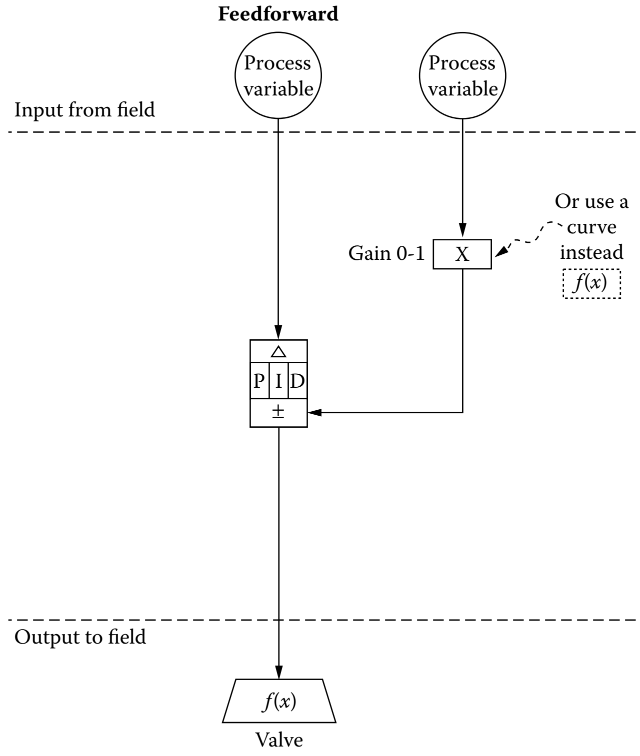

FIG. 5.7u
Analog—feedforward.

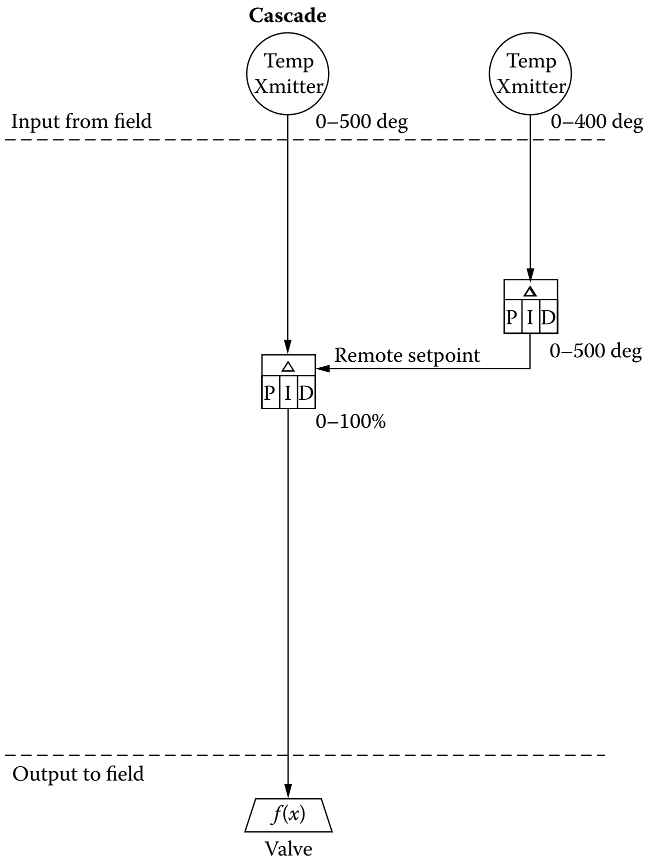

FIG. 5.7v
Analog—cascade.

it is known exactly how the controller should change with the change of the process variable.

Cascade

To control two process variables at once, use two controllers and feed the output of the first controller into the set point of the second controller. Then feed the output of the second controller to the valve (Figure 5.7v). Think of the controller that feeds the valve as the worker, because it is usually located at the point in the process where it can have the most effect or can see process changes sooner. The top controller adjusts that controller as necessary. Remember to adjust the high and low output limits of the controller so that the output is within range of the set point of the worker.

Three-Transmitter Select

When three redundant transmitters are used, a selection method as shown in Figure 5.7w is used to choose the median value, if the data from all three of the transmitters are of good quality, or to use the average of two if one transmitter has a faulty reading, or to select one transmitter. If the output of a transmitter has bad quality (usually specified as below 4 mA or above 20 mA), the logic automatically throws out its value.

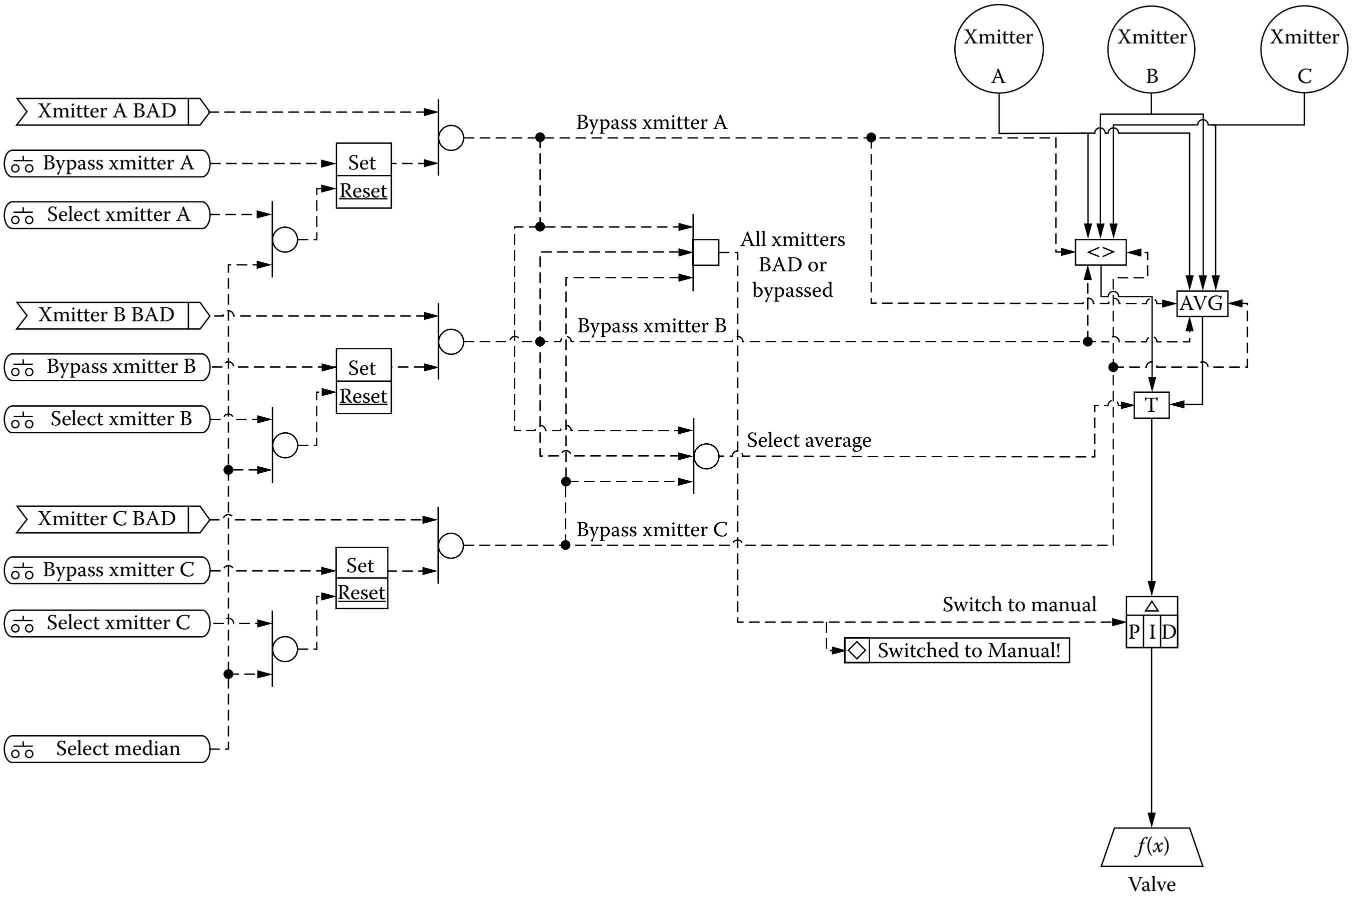

FIG. 5.7w
Analog—three transmitter selector.

The operator can also choose to bypass a transmitter that has a reading that does not "look right." If all of the transmitters are bad or bypassed, any controller that is using the selected value as a process variable may be set to manual mode.

Switch to Manual Mode

If a controller is automatically switched to manual mode by the logic, there should always be an alarm to the operator to show what has happened. Switch to manual mode only if absolutely necessary (for example, where there is no available process variable). Otherwise, it is best to leave the decision to switch to manual mode to the operator's discretion.

Changing the Set Point with Changes in the Number of Pumps Running

The set point of a controller such as a flow controller can be changed as the number of pumps running changes by using the logic shown in Figure 5.7x. If the pump is tripped when the flow is too high or low, one must make sure to add a hefty time delay in the trip logic to allow for the process to meet set point after the set point has been changed.

START-UP AND SHUTDOWN SEQUENCES

Automatic start-up sequences will start an entire plant with the touch of a button. Because they take a lot of control out of the operator's hands, they should be reserved only for those plants that are particularly complicated and would take more time to start manually, or those plants that are started and shut down frequently. Operators often have a difficult time following these fully automatic sequences, especially if the sequence graphics are not sufficiently detailed.

Think of the sequence logic as acting in place of the operator during the start-up sequence. It should not include any safety logic that is normally included in the logic for the pumps and valves themselves so that the safety logic will function even when the auto sequence is not used or is on hold. For example, logic that automatically closes boiler vent valves when the steam pressure reaches 25 psig should reside in the valve logic, not in the sequence, because the automatic start-up sequence could be on hold while the pressure passes the 25 psig set point.

Figure 5.7y shows the basic structure of a start-up sequence. The logic should include a hold button so that, if there is an equipment malfunction during the sequence, it

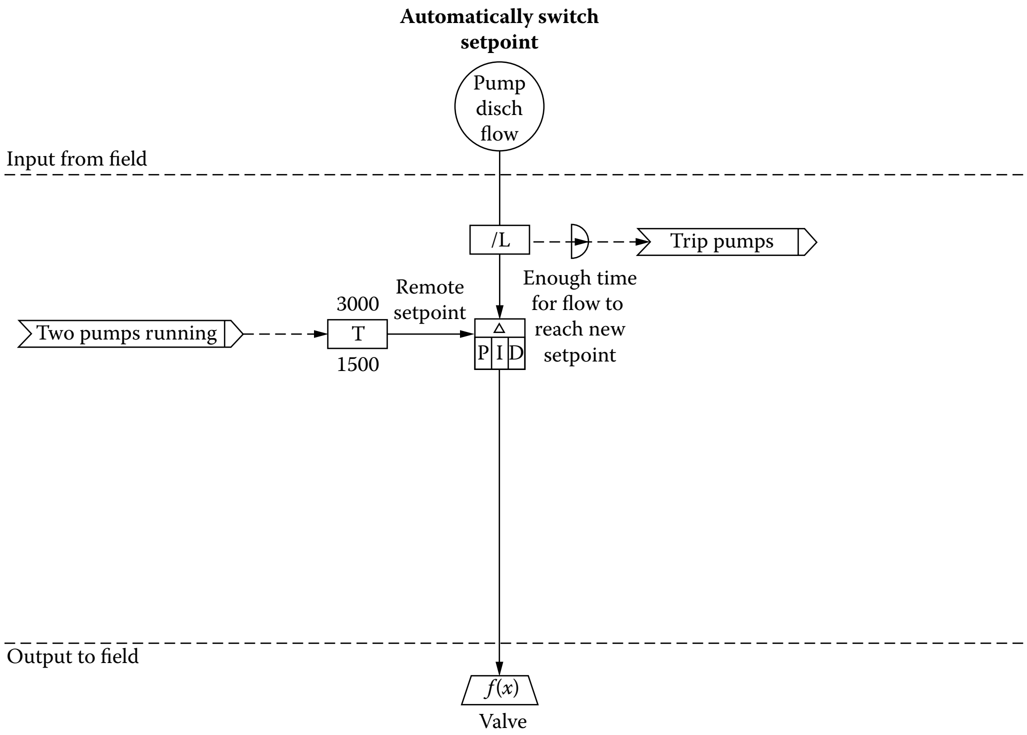

FIG. 5.7x
Analog—automatically switch set point.

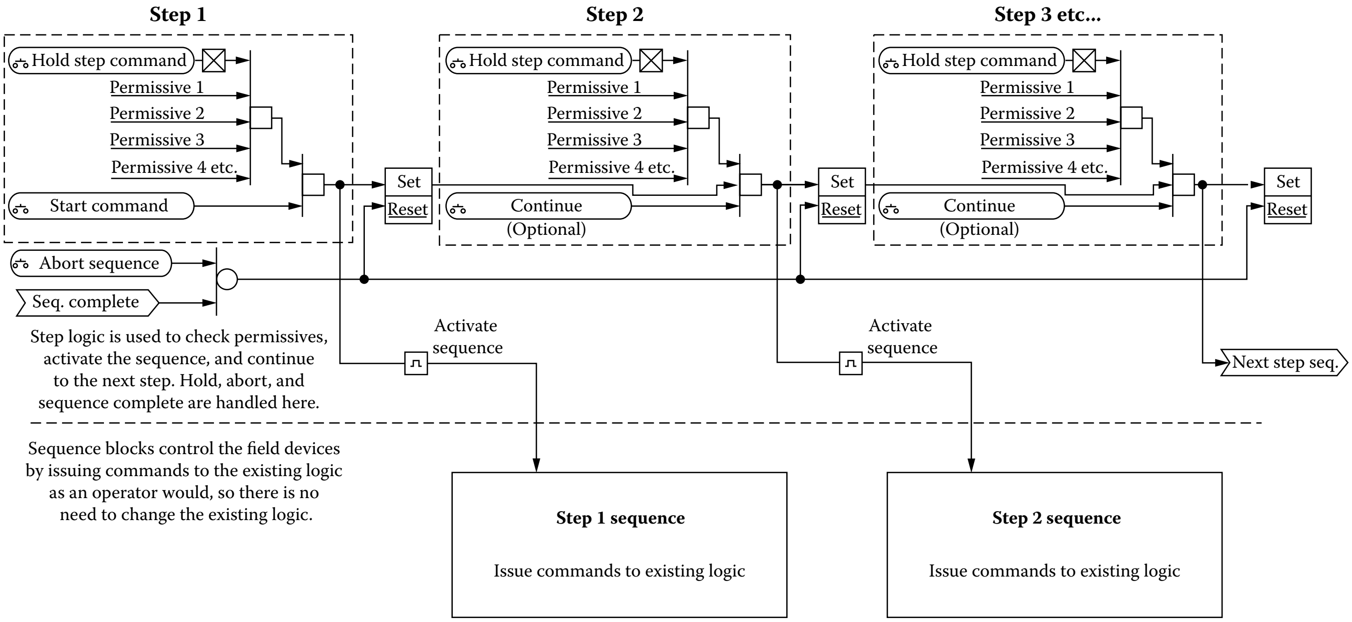

FIG. 5.7y
Auto start sequence logic structure.

will wait while the problem is remedied. In this way, the operator will not have to shut down the sequence and start over. A sequence abort should be included in case the problem cannot be fixed quickly.

OPERATION AND CUSTOMIZATION

Now is the time to operate the equipment with the logic the designer has written. By now the designer should have simulated the logic, independently of the system that it controls, to work out any bugs. This is very important, as it will take years to find all of the bugs as they occur during operation, and *it will actually save time to do all the testing beforehand.* Even logic that the designer has personally programmed, and most certainly logic that has already been tested in a factory acceptance test, should be retested.

Now that the equipment is running, the logic designer will soon find that the systems do not always behave exactly as expected. This stage of the job is a humbling experience because the designer inevitably finds problems with logic that was thought to be well designed for the system. Designers will produce a much better product if they are willing to make changes to the design, customizing it to fit the equipment in the field.

Listen to the operators. The logic designer must rely on operators for information on errors or upsets that have occurred while the designer was away. Operators can often offer important insights on the behavior of the equipment, as well.

A good historian system is a useful tool. If possible, make sure to collect data on all of the process variables and the outputs and set points for all of the controllers—it will make troubleshooting and tuning much easier. Keep all the changes simple. Before adding new logic or feedforward to controllers, make sure the system is well tuned first—additions may not be necessary. Go easy on the fancy stuff—tuning parameters that change automatically and controllers that switch make the whole process less stable.

A NOTE ON SAFETY

Not enough has been said in this section about safety. Fortunately, safety goes hand in hand with good logic design. Safety should be the first priority. When safe systems are designed, well-designed logic will follow.

A few simple points to remember: Ensure that the equipment does not start, open, close, etc. unexpectedly. Remove any outputs to the field when in the failed state. Make sure the logic is consistent throughout the plant so that the operator will know what to expect when a button is pushed.

Document your system well so that others can understand how it works. Design user-friendly graphics that show permissives and trips so the operators can easily determine what is going on. Fewer accidents happen when there is less confusion in the control room.

INTRODUCTION

Since the publication of the IEC 61508 safety standard[1] and more recently the IEC 61511 standard for process safety,[2] the interest in rigorous safety analysis and in certified safety instrumented systems (SISs) has increased considerably among the users. As users are becoming more knowledgeable about safety issues, they are increasingly focusing on the goal of overall safety.

Users want their safety systems to be cost-effective and to provide closer integration of the safety and control systems. They are looking for flexible architecture with more scalability. They are also looking for increased functionality for modifying alarm limits based on process conditions and on orderly shutdown procedures in case of an emergency. The major trends in safety systems are

- Increased focus on overall safety
- Closer integration with control systems
- Increased flexibility and scalability
- Increased function block capabilities

Both IEC 61508 and 61511 standards are performance-based; as such, they do not mandate any specific safety system architecture or risk assessment procedures. However, they do provide guidance on the analysis of safety life cycle, hazards, and risks, and on methods for determining safety requirements.

TABLE 5.8a
Factors that Increase Risk

- Operating plant and machinery closer to their limits
- Transient operation states
- Use of hazardous raw materials
- Manufacture of hazardous intermediates
- Presence of untrained personnel
- Absence of safety culture

Transient operations include startup, shutdown, shift change, and workforce transitions

Safety system certifications should objectively assess the reliability and availability of critical control and safety shutdown systems and related equipment. Technical Inspection Associations (in German, Technischer Uberwachungs Verin, or TUVs) in Germany have been in the forefront of inspection and certification of safety-related systems worldwide.

In choosing a safety system, users should take into account not only all the features of that system but also the specified restrictions, which are spelled out by the certification authority. This information is often found in the product safety manual. In choosing a system supplier, users should take into account the supplier's knowledge and experience in safety analysis, their application knowledge, and local support.

Risk Reduction

Risk is usually defined as a combination of the severity and probability of an unplanned event. Risk depends on how often that event can happen and how bad it will be when it does. In manufacturing operations, the type of events and their associated risks include loss of life or limb, environmental impact, loss of capital equipment, and loss of production. For many manufacturers, loss of company image can also be a significant risk factor. With increased environmental awareness, regulatory concerns, and threat of litigation, risk reduction is becoming more and more important to most manufacturers (Table 5.8a).

The best way to reduce risk in a manufacturing plant is to design inherently safe processes. However, inherent safety is rarely achievable in today's manufacturing environments. Risks prevail wherever there are hazardous or toxic materials stored, processed, or handled (Figure 5.8b).

Because it is impossible to eliminate all risks, a manufacturer must agree on a level of risk that is considered to be acceptable. After identifying the hazards, a study should therefore be performed to evaluate each risk situation by considering likelihood and severity. Site-specific conditions, such as population density, in-plant traffic patterns, and meteorological conditions, should also be taken into consideration during risk evaluation.

The risk levels that are determined by the safety studies can be used to decide if the risks are within acceptable levels. Basic process control systems, including process alarms and the means of manual intervention, provide the first level of risk reduction in a manufacturing facility. Additional protection measures are needed where a basic control system does not reduce the risk to an acceptable level. They include safety-instrumented systems along with hardware interlocks, relief valves, and containment dikes. To be effective, each protection subsystem should act independently of the others (Table 5.8c).

History

In the early days of process control, commonly used alarming and safety interlocking devices included pressure, flow, level,

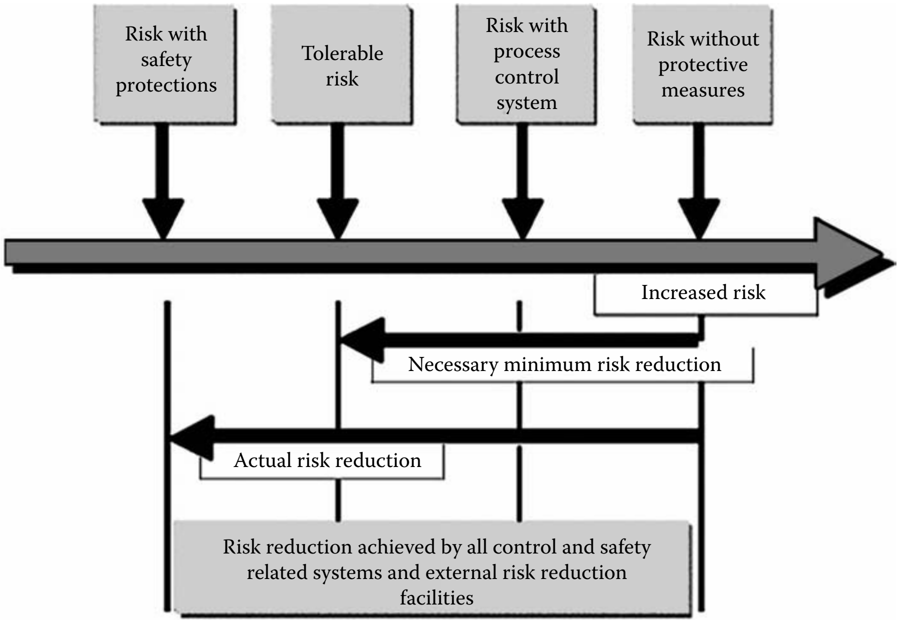

FIG. 5.8b
Reducing risk.

TABLE 5.8c
Driving Forces for Lowering Risks

- Higher environmental awareness
- Increased regulatory considerations
- Emergence of safety standards
- Maintaining company image

and temperature switches. These switches were simple mechanical or electromechanical devices that, upon detection of hazardous conditions, activated valves, motors, and other plant equipment to bring a process to a safe state. Other mechanical devices, which are also still used today, include such physical devices as electrical fuses, safety valves, and rupture disks.

While the electromechanical and solid-state relays could be used to design more sophisticated safety systems, they were difficult to program or to interface with digital computers. Hence, programmable safety systems were developed in the early 1970s. Programmable safety systems provide scalability, flexibility, and ease of configuration (Table 5.8d).

Duplex and Triplex Designs In the late 1970s, August Systems pioneered the development of the programmable safety system, which was followed by systems from Triconex and Triplex. These three suppliers developed the triple modular redundant (TMR) systems, in which three independent, parallel processors with extensive diagnostics are integrated into a single system (2oo3). At each decision point within the system, a two-out-of-three vote is taken to determine failures and guarantee correct operations. Other suppliers of TMR systems for process industries include GE Fanuc and Yokogawa (Figure 5.8e).

TABLE 5.8d
Typical Applications of Safety Systems

- Emergency shutdown (ESD)
- Fire and gas monitoring and protection
- Critical process control
- Burner management and control
- Turbine and compressor control
- Unmanned installations

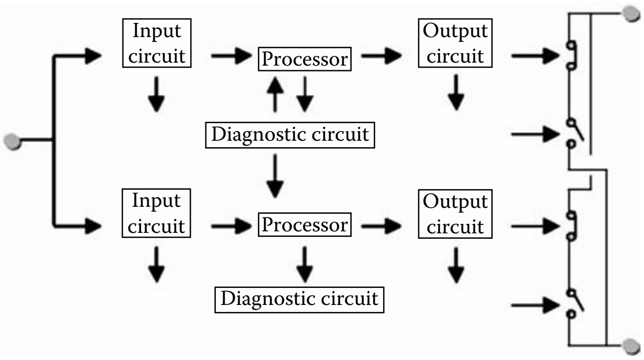

FIG. 5.8f
Typical duplex system.

A dual redundant system with extensive diagnostics (duplex) is another common safety system design. Here, two identical processors are configured as a married pair to check the health of the system (1oo2D). In this arrangement, two identical processors operate in parallel. They use the same inputs, while only one processor controls the output modules at any given time. The outputs of both processors are always compared to ensure that they are synchronized and identical. If they disagree, a diagnostic evaluation is initiated to determine which of the two is still reliable, and that the one used will continue the process in a safe state or shut it down. At the same time, messages are to fix the failed processor (Figure 5.8f). Major suppliers of duplex systems include ABB, Honeywell, Siemens, and Yokogawa.

Quadruple Redundant Systems Another safety system design is the quadruple modular redundant (quad) system. The quad architecture provides four processors — two per channel (2oo4) — which may be viewed as a pair of duplex

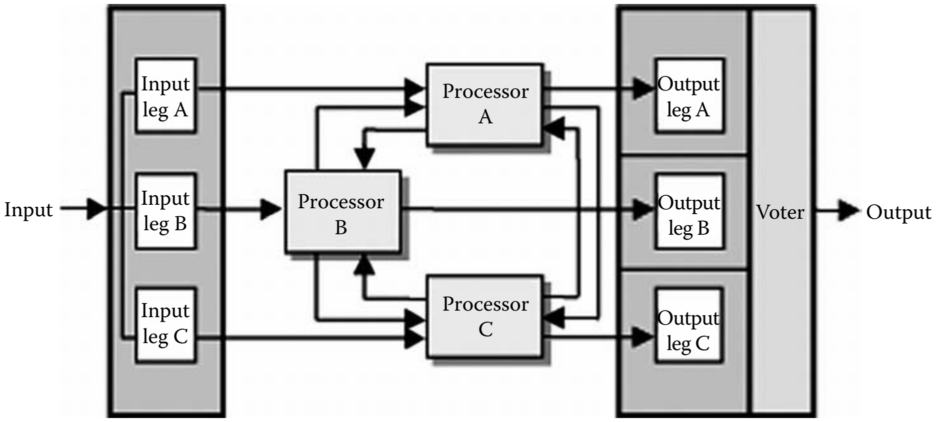

FIG. 5.8e
Typical TMR system.

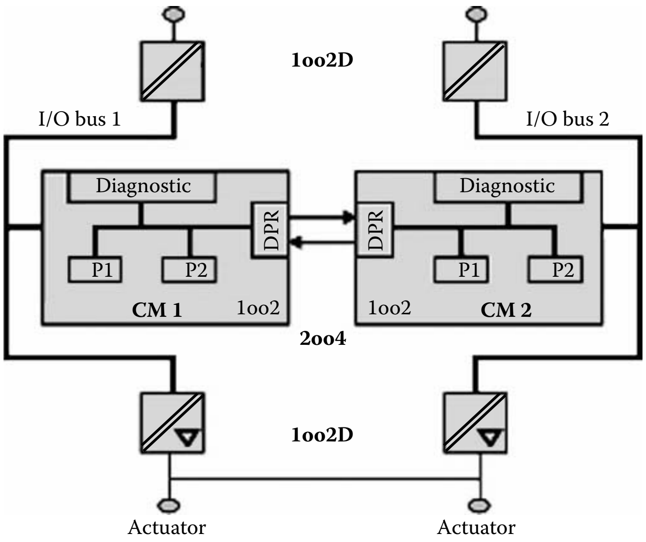

FIG. 5.8g
Typical quad system.

systems with diagnostics. Both pairs of active processors operate synchronously with the same user program. A hardware comparator and a separate fail-safe watchdog monitor the operation of each pair of processors to diagnose and resolve anomalies (Figure 5.8g).

At present HIMA and Honeywell are the two major suppliers of quad systems. The safety and availability of quad, TMR, and duplex systems are comparable. It is the quality of diagnostics and the system implementation that determines their relative performance.

In recent years, the increased awareness of safety, the impact of various regulatory agencies, and the publication of safety standards have led to the rapid growth in demand for safety systems. Many DCS- and PLC-based control system suppliers are competing for a share of this market.

SAFETY STANDARDS

The IEC 61508 safety standard published by the International Electrotechnical Commission (IEC) is applicable to a wide range of industries and applications. The standard is intended both as the basis for the preparation of more specific standards and for standalone use. A more specific international safety standard for process industries (IEC 61511) has also been published.

Since the publication of IEC 61508 and IEC 61511 standards, interest in rigorous safety analysis and in applying certified safety instrumented systems has increased. These standards give guidance on good practice and offer recommendations, but do not absolve its users of responsibility for safety. The standards not only deal with technical issues but also include planning, documentation, and assessment of all activities. Thus, the standards deal with the management of safety throughout the entire life of a system.

IEC 61508: General Safety Standard

The IEC 61508 standard is in seven parts:

- Part 1: General requirements
- Part 2: Requirements for safety-related systems
- Part 3: Software requirements
- Part 4: Definitions and abbreviations
- Part 5: Examples of methods for the determination of safety integrity levels (SILs)
- Part 6: Guidelines on the applications
- Part 7: Overview of techniques and measures

The standard is generic and can be used directly by industry, as a standalone standard, and by international standards organizations as a basis for the development of industry-specific standards, such as for the machinery sector, the process sector, or the nuclear sector. The IEC 61511 standard is more specific to the process industries.

IEC 61511: Safety Standard for Process Industries

While IEC 61508 has seven parts, the IEC 61511 standard has only three parts:

- Part 1: Framework, definitions, system, hardware, and software requirements
- Part 2: Guidelines on the application
- Part 3: Guidance for the determination of the required safety integrity levels

IEC 61511 Part 1 is primarily normative, while Parts 2 and 3 are informative. Part 1 is structured to adhere to a safety life cycle model similar to that in the IEC 61508 standard. The hazard and risk analysis utilizes the notion of protection layers and specifies the safety integrity level concept developed by the IEC 61508 standard. It also lists key issues that need to be addressed when developing a safety requirement specification. Issues like separation, common cause, response to fault detection, hardware reliability, and proven-in-use are also addressed in this part (Table 5.8h).

In this part of the standard, software safety requirement specifications are included, addressing such items as

TABLE 5.8h
Main Differences Between IEC 61508 and IEC 61511 Standards

IEC 61508	*IEC 61511*
Generic safety standard for broad range of applications	Sector-specific safety standard for the process industries
Applies to all safety-related systems and external risk reduction facilities	Applies only to safety-instrumented systems
Primarily for manufacturers and suppliers of safety systems and devices	Primarily for system designers, integrators, and users of safety systems

architecture, relationship to hardware, safety instrument functions, safety integrity level, software validation planning, support tools, testing, integration, and modification. In addition, a section is dedicated to factory acceptance testing requirements, and another section lists the installation and commissioning requirements.

Part 2 of the standard provides "how to" guidance on the specification, design, installation, operation, and maintenance of safety instrumented functions and related safety instrumented system as defined in Part 1 of the standard.

Part 3 of the standard provides guidance for development of process hazard and risk analysis. It provides information on:

- The underlying concepts of risk and the relationship of risk to safety integrity
- The determination of tolerable risk
- A number of different methods that enable the safety integrity levels for the safety instrumented functions to be determined

It also illustrates methods from different countries that have been proven-in-use. It further illustrates good engineering practices across cultural and technological differences, providing the end user with effective methods from which to select.

ANSI/ISA-84.01 Standard

The original ANSI/ISA-84.01 standard was published in 1966; as such, it predates the IEC 61508 safety standard. However, it is being abandoned in favor of the IEC 61511 international standard. A new ISA standard was released in 2004, which was nearly identical to the IEC 61511 safety standard. There is, however, a grandfather clause in the new version that allows the continued use of safety systems following the original version of the standard.

The safety standards give guidance on good practice and offer recommendations, but do not absolve its users of responsibility for safety. The standard recognizes that safety cannot be based on retrospective proof, but must be demonstrated in advance, and there cannot be a perfectly safe system. Therefore, the standards not only deal with technical issues, but also include planning, documentation, and assessment of all activities. Thus, the standard deals with the management of safety throughout the entire life of a system. The standards bring safety management to system management and safety engineering to software engineering.

Safety Integrity Levels Safety integrity is defined as the likelihood of a safety instrumented system satisfactorily performing the required safety functions under all stated conditions, within a stated period. A safety integrity level (SIL) is defined as a discrete level for specifying the safety integrity requirements of safety functions. Whereas a safety integrity level is derived from an assessment of risk, it is not a measure of risk. It is a measure of the intended reliability of a system or function (Table 5.8i).

TABLE 5.8i

Safety Integrity Levels (SIL)

Safety Integrity Level (SIL)	*Probability of Failure on Demand Mode of Operation*	*Probability of Failure on Continuous Mode of Operation*
1	$\geq 10^{-2}$ to $<10^{-1}$	$\geq 10^{-6}$ to $<10^{-5}$
2	$>10^{-3}$ to $<10^{-2}$	$>10^{-7}$ to $<10^{-6}$
3	$>10^{-4}$ to $<10^{-3}$	$>10^{-8}$ to $<10^{-7}$
4	$\geq 10^{-5}$ to $<10^{-4}$	$\geq 10^{-9}$ to $<10^{-8}$

Notes:

1. Demand Mode: Where actions are taken in response to process or other conditions (no more than once per year)
2. Continuous Mode: Functions, which implement continuous control to maintain functional safety

Safety Life Cycle Safety life cycle is a method or procedure that provides the way to specify, design, implement, and maintain safety systems in order to achieve overall safety in a documented and verified way. All major safety standards, such as ANSI/ISA-84-01-1996, IEC 61508, and IEC 61511, have specified safety life cycles, which show considerable similarities, differing only in the details. The safety life cycle specified by the IEC 61511 standard shows a systematic approach to safety starting from hazard and risk analysis to implementation of safety system and finally to its decommissioning (Figure 5.8j).

Perform Hazard and Risk Analysis: Determine hazards and hazardous events, the sequence of events leading to hazardous condition, the associated process risks, the requirements of risk reduction, and the safety functions required.

Allocate Safety Functions to Protection Layers: Allocate safety functions to protection layers and safety systems.

Specify Requirements for Safety System: Specify the requirements for each safety system and their safety integrity levels.

Design and Engineer Safety System: Design system to meet the safety requirements.

Design and Develop Other Means of Risk Reduction: Means of protection other than programmable safety systems include mechanical systems, process control systems, and manual systems. They are not specified in any detail in the standard (Figure 5.8k).

Install, Commission, and Validate the Safety Protections: Install and validate that the safety system meets all the safety requirements of the safety integrity levels.

Operate and Maintain: Ensure that the safety system functions are maintained during operation and maintenance.

Modify and Update: Make corrections, enhancements, and adaptations to the safety system to ensure that the safety requirements are maintained.

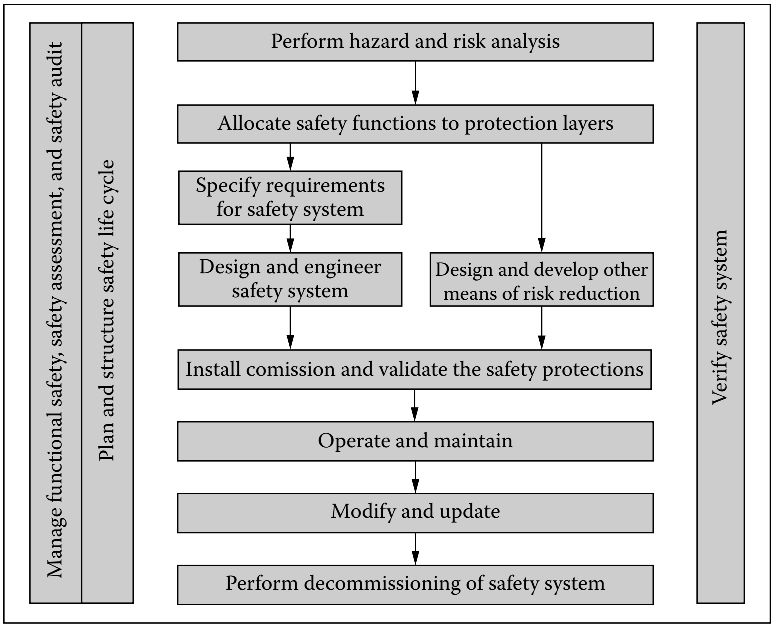

FIG. 5.8j
The safety life cycle.

Perform Decommissioning of Safety System: Conduct review and obtain required authorization before decommissioning of a safety system. Ensure that the required safety functions remain operational during decommissioning.

Manage Functional Safety, Safety Assessment, and Safety Audit: Identify the management activities that are required to ensure the functional safety objectives are met.

Plan and Structure Safety Life Cycle: Define safety life cycle in terms of inputs, outputs, and verification activities.

Verify Safety System: Demonstrate by review, analysis, or testing that the required outputs satisfy the defined requirements for each phase of the safety life cycle.

Like all models, the safety life cycle is also an approximation. While the life cycle phases are listed sequentially, in reality, there are significant iterations between these phases.

Requirements of some of the functions, such as hazard and risk analysis, allocation of safety functions to protection layers, and designing and developing other means of risk

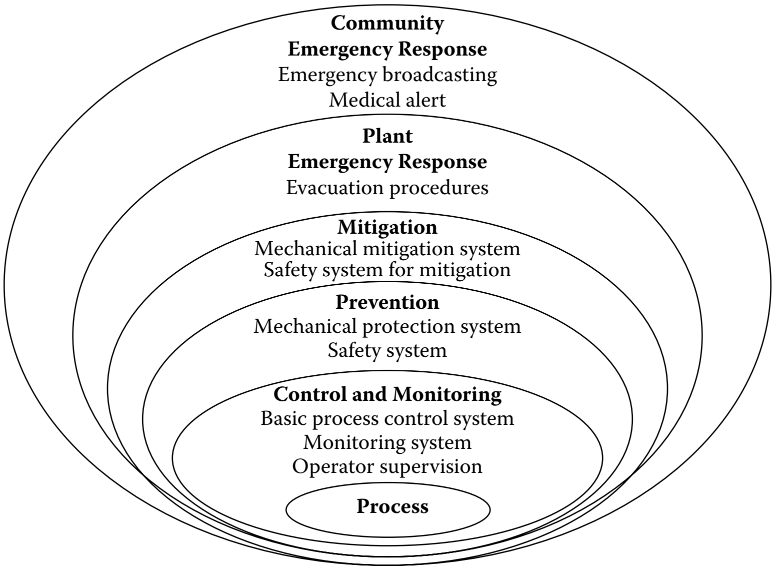

FIG. 5.8k
The protection layers.

reduction, are not specified in any detail in the standard. Certain functions, such as managing functional safety, planning and structuring safety life cycle, and verifying safety requirements at each phase, are carried out continuously during the whole life cycle and are shown as vertical boxes in the figure.

MANAGEMENT CONSIDERATIONS

The standards should be recognized as defining requirements for safety management rather than merely for system development. Not all safety life cycle phases will be relevant to every application, and it is the responsibility of management to define what requirements are applicable in each case. The standards do not prescribe exactly what should be done in any particular case, but only offer advice and guidance to the management. Therefore, management is still responsible for taking appropriate actions and for justifying them.

Management responsibilities include rigorous safety planning, which includes the choice of safety life cycle phases to be used and the activities to be carried out within those phases. However, the users should realize that safety systems by themselves do not achieve safety. People working within a strong safety culture achieve greater safety, and it is management's responsibility to foster and maintain such a culture (Table 5.8l).

TABLE 5.8l
Management Responsibilities

- Put organization structure with necessary authority
- Define applicable requirements
- Provide documentation infrastructure
- Foster safety culture

HAZARD AND RISK ANALYSIS

The standard requires that safety requirements should be determined by analyzing the risks posed by the totality of a manufacturing system and its control system. The analysis consists of three stages: hazard identification, hazard analysis, and risk assessment.

A hazard is defined as a potential source of harm. A manufacturing system and its control system may pose many hazards, each carrying its own risk. In determining the necessary overall risk reduction, the risk posed by each hazard must be considered. The importance of hazard identification cannot be overemphasized, because the risks associated with unidentified hazards cannot be reduced.

Hazard identification is unlikely to be effective if carried out by an individual; therefore, it is preferable to have a team whose members are chosen to bring complementary viewpoints to the process. A well-managed team with defined objectives is more effective in performing hazard analysis than a single individual.

IEC 61508 and 61511 are performance-based standards; as such, they do not mandate any specific safety system architecture or risk assessment procedures. However, they provide guidance in the areas of risk assessment and risk reduction. Following are some of the risk assessment and SIL determination concepts as outlined in the IEC 61511 standard Part 3. Detailed descriptions of these techniques are beyond the scope of this section. Readers are advised to refer to the IEC 61511 standard or the textbooks listed in the References section.

As Low as Reasonably Practicable (ALARP)

The ALARP principle may be applied during the determination of tolerable risk and safety integrity levels. However, it is not in itself a method for determining safety integrity levels. Tolerable risk implies that it is not possible to achieve absolute safety. A level of risk may be considered tolerable, in the light of the benefit gained in taking the risk, provided it is as low as reasonably practicable.

The ALARP triangle is divided into three regions with the width at any point indicating the magnitude of the risk (Figure 5.8m). Risk class I represent risks that cannot be justified except in extraordinary circumstances. Risk class III represents risk that is so low as to be negligible and is thus acceptable without any further risk avoidance measures. Risk class II in the middle represents risk that can only be tolerated if measures have been taken to reduce it to as low as reasonably practicable. This means that the cost of mitigating the risk is disproportionate to the benefits gained.

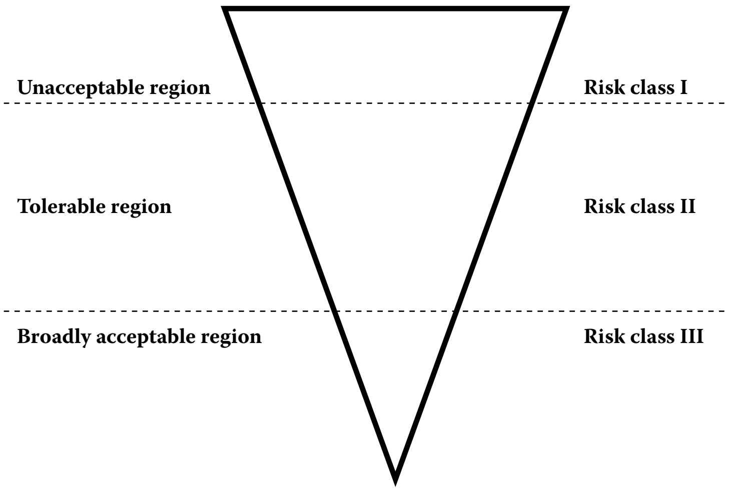
The concept of ALARP can be used when qualitative or quantitative risk targets are adopted. In order to apply the ALARP principle, it is necessary to define the three regions in terms of the probability and consequence of an incident. This definition would take place by discussion and agreement between the interested parties, such as those producing the risks, those exposed to the risks, and safety regulatory authorities.

Table 5.8n is an example of the three risk classes for a number of consequences and frequencies. After determining the tolerable risk target, it is then possible to determine the safety integrity levels of safety-instrumented functions.

Required Safety Integrity Level

The IEC 61511 standard Part 3 specifies a number of ways of establishing the required safety integrity levels for a specific application. The methods selected for a specific application depends on many factors, such as:

- Application complexity
- Guidelines from regulatory authorities
- Nature of the risk and the risk reduction requirements
- Experience and skills of the persons available to undertake the work
- Information available on the parameters relevant to the risk



Risk class I: Risk cannot be justified except in extraordinary circumstances

Risk class II: Risk is tolerable only if:
—Further risk reduction is impracticable or its cost is grossly disproportionate to the improvements gained
—Society desires the benefit of the activity given the associated risk

Risk class III: Level of residual risk regarded as negligible and further measures to reduce not usually required

Note: There is no relationship between risk class and SIL

FIG. 5.8m
Tolerable risk and ALARP.

More than one method may be used in an application. A qualitative method may be used first, followed by a more rigorous quantitative method, if needed. Qualitative methods outlined in the standard include:

- Safety reviews
- Checklists
- What if analysis
- Hazard and operability (HAZOP)
- Failure mode and effects analysis
- Cause-consequence analysis

Hazard and operability analysis is one of the more widely used techniques. It identifies and evaluates hazards in process plants and nonhazardous operability problems that compromise its ability to achieve design productivity. Table 5.8o is an example of the results of a HAZOP analysis.

TABLE 5.8n
Example of Risk Classification of Incidents

Probability	*Catastrophic*	*Critical*	*Marginal*	*Negligible*
Frequent	I	I	I	II
Probable	I	I	II	II
Occasional	I	II	II	II
Remote	II	II	II	III
Improbable	II	III	III	III
Incredible	II	III	III	III

The probability of occurrence are defined as:
Frequent: Many times in the system's lifetime
Probable: Several times in the system's lifetime
Occasional: Once in the system's lifetime
Remote: Unlikely during the system's lifetime
Improbable: Very unlikely
Incredible: Absolutely improbable

The consequences are defined as:
Catastrophic: Multiple loss of life
Critical: Loss of a single life
Marginal: Major injuries to one or more person
Negligible: Minor injuries

Note: The risk classes are application dependent

TABLE 5.8o
Example of a HAZOP Report

Item	*Deviation*	*Cause*	*Consequence*	*Safeguards*	*Recommendations*
Reactor	High level	Failure of control system	High pressure	Operator	
	High pressure	• High level • External fire	Release to environment	– Alarm, protection layer – Fire deluge system	Evaluate conditions for release to environment
	Low flow	Failure of control system	Excess pressure	Operator	Open pressure release valve manually

Semi-Quantitative Risk Analysis Techniques

An estimate of the process risk can be made by a semi-quantitative risk analysis procedure that identifies and quantifies the risks associated with potential process accidents or hazardous events. The results can be used to identify necessary safety functions and their associated SIL in order to reduce the process risk to an accepted level. Following are the main steps of this technique, where the first four steps can be performed during the HAZOP study:

- Identify process hazards
- Identify safety layer composition
- Identify initiating events
- Develop hazardous event scenarios for every initiating event
- Ascertain the frequency of occurrence of the initiating events and the reliability of existing safety systems
- Quantify the frequency of occurrence of significant hazardous events
- Integrate the results for risks associated with each hazardous event

The above exercise leads to a better understanding of hazards and risks associated with a process and leads to the identification of safety functions needed to reduce risks to acceptable levels.

Risk Graphs

The use of a risk graph is a method for evaluating safety integrity levels, which is illustrated in Figure 5.8p.

This method focuses on the evaluation of risk from the point of view of a person being exposed to the incident impact zone. In a risk graph there are four parameters to characterize a potential hazardous event: consequence, frequency of exposure, possibility of escape, and likelihood of events. In assessing the consequence severity, the following are considered:

- Potential for injury or fatality
- Possibility of the exposed person recovering and returning to normal activities
- The effects of injury: acute or chronic

The resulting safety integrity levels are shown in vertical columns.

SAFETY SYSTEM CERTIFICATION

Safety system certifications objectively assess the reliability and availability of critical control and safety shutdown systems and related products. Following are some of its advantages:

- Allows making informed decisions when choosing a product for a specific application
- Allows products and systems certified against standards
- Allows installing certified products and achieves recognized levels of process safety
- Gives the manufacturers of safety systems the opportunity to improve their products
- Gives suppliers of safety systems competitive advantage through documented product quality and reliability

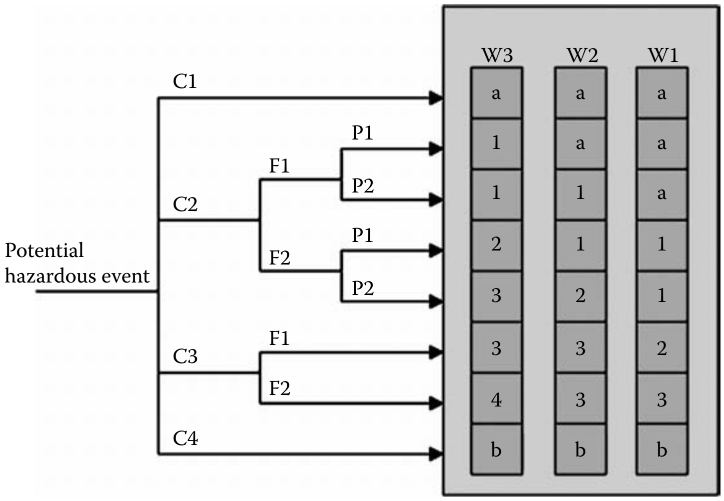
Safety regulations came after the start of industrialization when steam engines and boiler explosions caused many deaths. For over 127 years, TUVs have been in the forefront of inspection and certification of safety related systems in Germany.

The TUV certification process is very exhaustive and covers everything from the formulation and documentation of the original design concepts to the manufactured product and its suitability for a defined application. TUV is not a single entity, but consists of a number of independent regional organizations. Among them, TUV Rheinland, TUV Product Services (a part of TUV Suddeutschland), and TUVIT (part of RWTUV) are most active in certifying safety-related systems.

A research project started in the early 1980s by the TUVs on computer-based safety systems resulted in a document that led to the German safety standard DIN/VDE 0801. Until recently, the TUVs certified systems were based on the DIN standard (AK Class 1 to 7). They are now certifying systems based on IEC 61508 standards.

Every supplier that pursues this market has systems certified by one of the TUVs. This condition has been viewed favorably by both users and suppliers of safety systems, where users wanted reassurance of having a system certified by a qualified agency, and suppliers were willing to pay the necessary fees in order to differentiate themselves from competitors.

It should be emphasized, however, that some of the certified equipment has extensive restrictions. These restrictions effectively represent requirements not met by the manufacturer. When this happens, the user must compensate by adding externally wired equipment or user-programmed logic.



a = No special safety requirement
b = A single safety system is not sufficient
1, 2, 3, 4 = Safety integrity level

Consequence of event:
C1 = Minor injury
C2 = Serious permanent injury to one or more persons, death to one person
C3 = Death of several people
C4 = Very many people killed

Frequency of exposure:
F1 = Rare to more often exposure in the hazardous zone
F2 = Frequent to permanent exposure

Possibility of escape:
P1 = Possible under certain conditions
P2 = Almost impossible

Probability of occurrence:
W1 = Slight probability (less than 0.3 pa)
W2 = Medium probability (greater than 0.3 pa but below 3 pa)
W3 = High probability (3 pa or above)

FIG. 5.8p
Example of a risk graph.

This extra work and extra expense should be estimated before selecting the equipment.

Other organizations involved in safety system certification include INERIS, Factory Mutual, UL, BASEEFA, and many other national organizations. INERIS is a French research organization with close links with French Ministries of the Environment and Industry. It has been involved in safety system certification since its inception in 1992. INERIS has little presence outside France, and its clients are predominantly French manufacturers.

Factory Mutual, whose headquarters are in Norwood, MA, has a long history in product testing and approval. The company services its clients through offices around the globe and interlaboratory agreements with testing facilities in North America, Europe, Asia, Australia, and Latin America.

In late 1997, Factory Mutual and TUV Product Services signed a collaborative agreement enabling safety system manufacturers to obtain global certification of their products at either laboratory. The two labs are also working together to develop common interpretation and certification procedures for the IEC 61508 standard.

As the two organizations have name recognition in the different regions of the world, safety certification from either organization will be more widely accepted than before. The two organizations will be able to work in parallel, when required, to reduce the time required for the certification process and time to market. Users with manufacturing facilities around the world will be able to install safety systems in more countries without recertification.

It is essential that users consider only those systems that have been certified by a TUV or a similar organization for safety applications. To get full details of specific restrictions a user should demand a copy of the safety certification report and safety manual from its prospective supplier.

MAJOR TRENDS

As users are getting more knowledgeable about safety issues, they are performing more thorough safety analysis to determine their needs for each application more accurately. They are looking for reduction of risks by increasing their focus on overall safety. They would like their safety systems to satisfy their needs in a more cost-effective way by closer integration of safety with control systems. They are looking for a flexible architecture and with more scalability; increased functionality for modifying alarm limits based on process conditions; and orderly shutdown procedures in case of emergency.

Overall Safety

The main cause of an SIS failure is not the failure of logic, but the failure of field devices. There has been a significant advance in the development of the architecture of logic solvers with voting circuits and advanced diagnostics. However, they do not address over 90% of the causes for failure, which are due to the failure of field devices. What is needed is an integrated safety approach, where field devices are well integrated with the programmable safety systems.

Today, a protective system should be able to check the health of the process inputs and outputs (I/O). In fact, it needs to incorporate the I/O components in its overall design. They include:

- Sensor validation
- Environment condition monitoring, such as temperature and humidity that can cause sensor degradation
- Impulse line blockage monitoring

Failures of electronic components are frequently due to environmental conditions. Many electronic device failures are due to elevated humidity and temperature, which need to be monitored closely. Sensor calibration is also becoming an integral part of a safety system. Use of protocols, such as HART, Profibus, and Foundation Fieldbus, allows for remote monitoring, diagnostics, and validation.

Intelligent valves and digital valve positioners can also contribute to improved safety. With valves, the most frequent safety problems is when the valve does not respond to the trip demand, which is often caused by stem seizure or packing failure. The newer control valve designs, such as TUV certified valves, have reduced the probability of these and are available on the marketplace. The SIS-based valve design includes the feature of testing for limited valve movement during normal operation.

Separation from the Control System

It has long been the practice of many users to keep controllers used for safety completely independent of those used for control and optimization. In the past, controllers used for safety came from specialized manufacturers that added extensive diagnostics and received TUV safety certification. There was no choice but to use completely different systems for control and safety. Some users even mandated the purchase of control and safety systems from different manufacturers.

There are many other reasons to place the safety and control functions in different control systems. They include

- Independent failures: Minimizing the risk of simultaneous failure of a control system along with the SIS
- Security: Changes in a control system not causing any change or corruption in the associated SIS
- Special requirements for safety controllers: Special features, like diagnostics, certified fail-safe response, special software error checking, protected data storage, and fault tolerance

The IEC 61508 safety standard is somewhat ambiguous on this issue; it generally recommends separation but does not mandate it. In contrast, the IEC 61513 standard for the nuclear industries mandates physical separation of control and safety functions.

Today, a number of users in process industries are finding logical reasons for using the same systems for control and safety functions, because that will reduce the integration problems caused by the different programming procedures, languages, installation requirements, and maintenance. There is always the risk caused by communication problems resulting from integration of different software languages and procedures. It is preferred by the users to have the same service and support requirements for both the control and safety functions.

Control system and SIS suppliers now offer similar systems for both functions, including their HMI, configuration procedures, programming languages, and maintenance procedures. The systems may be physically separate but are similar and are provided with a common operator interface. They may communicate with each other, but are provided with adequate protection from corruption of one by the other (Table 5.8q).

Flexibility and Scalability

The installed base of systems for critical control or safety shutdown is largely either TMR (2oo3) or duplex (1oo2D) systems. However, other architectures, such as quad (2oo4D), hybrid 2oo4/1oo2, and other combinations, are also available. Increasingly, suppliers are offering configuration flexibility, where the user has the choice of combining two or more safety controllers to reduce failure rate and increase availability.

TABLE 5.8q
Advantages of Closer Integration with Control Systems

- Common data mapping
- Increased security
- Similar engineering tools
- Significant reduction in integration efforts

Safety controllers are also becoming more scalable. They are getting smaller, where one controller handles a limited number of I/O, but a number of these controllers working together can handle a much larger application. This is a saving for the users, as they no longer have to purchase large and expensive systems for their smaller applications.

Function Blocks

A state-of-the-art safety system provides facilities for simple sequencing (usually without looping) to allow orderly shutdown of a process on detection of a failure condition. Although orderly shutdown in case of some alarm conditions is often controlled by the basic control system, also incorporating it in the safety system reduces the risks.

Rich function blocks make it easier to configure functions, such as trip levels, deviation percentage, pretrip alarm, and degradation behavior. They make it easier to bypass specified alarms during start-up. Traditionally, cause-and-effect matrices (CEMs) are implemented in ladder logic. Rich functions blocks make their applications easier and support more intuitive presentations at run time.

SAFETY SYSTEM SELECTION

Before embarking on the selection procedure, a user should do a study to determine the safety protection requirements for the application. The requirements should conform to safety standards and meet the guidelines of regulatory agencies such as OSHA and EPA. Outside help from a third-party consultant or an established safety system supplier is strongly recommended if the necessary experience in safety study and risk reduction procedures does not exist in-house.

Conventional control systems provide the first line of defense against hazardous conditions. Incorporating alarming and effective shutdown procedures in the basic control systems can considerably reduce the risks. Further reduction or elimination of a number of risks is possible by adding protection measures such as hardware interlocks, relief valves, and improved operator access for manual intervention. In many situations, containment systems such as dikes and firewalls can considerably reduce the effects of an accident. Programmable safety systems are needed if these actions do not reduce the risks to an acceptable level.

Once the need for a programmable safety system is established, the user should also take into account the requirements of the certifying organization. These requirements specify the allowable operating conditions and requirements for redundant I/O and for initiating shutdowns in case of a processor failure.

TABLE 5.8r
System Selection Criteria

- TUV Certification and Restrictions
- Required Speed of Response
- Product Maturity and Installed Base
- Ease of Integration to Your Control System

TABLE 5.8s
Supplier Selection Criteria

- Knowledge & Experience in HAZOP Analysis
- Knowledge of Regulatory Requirements
- Industry Application Expertise
- Local Support

Speed of response can also be an important consideration for some applications, and it must be considered along with the response time of all the field instruments (Table 5.8r).

In making a safety system evaluation, the user should take into account its installed base and product maturity. The ease of integration of the safety system with the control system is also an important consideration. Providing the same interface and the same configuration software for the two systems is also recommended, because it will help reduce the learning efforts of engineers and operators. The control system should be able to monitor the status of the safety system and to monitor real-time data in order for the two systems to work in a unified fashion.

When selecting suppliers, their knowledge and experience in safety analysis and regulatory requirements should be considered, including experience in applying safety systems to similar applications. Finally, one should also consider the availability of local support and of spare parts (Table 5.8s).

5.9 Relays

H. C. ROBERTS (1970, 1985) **B. G. LIPTÁK** (1995) **W. P. DURDEN** (2005)

Available Capacities:	Relays can handle microvolts to kilovolts, microamperes to kiloamperes, with response speeds from milliseconds to any longer period
Power and Frequency:	Relays can be actuated by microwatts but usually use milliwatts. They will operate from DC to RF
Environmental Limits:	Some relays can operate from –50° to 400°F (–45° to 204°C), from vacuum to 400 PSIG (2.8 MPa), and to 100 G shock or vibration
Sizes:	From 0.03 in.^{3} (0.47 cc) up
Cost:	Depending on size and capability, from about $10 to $100

INTRODUCTION

An electrical relay is a device that changes the state of a circuit in response to it being energized or de-energized by that or another circuit. In addition to electrical relays, there are pneumatic, fluidic, and other varieties. The relays described here are electromechanical or solid-state designs. Solid-state relays are only briefly mentioned in this section, because they are discussed in detail in Section 5.10.

The function of a relay is to open or close an electrical contact or a group of contacts in response to a “signal,” which is a change in some electrical condition. The contact closures of the relay can be used to select other circuits or to turn on or off various devices or operations.

More generally, a relay may be considered as an amplifier and a controller. It has a power gain that is defined as the ratio of output power handled to input power required. Thus, a relay may require a coil current of 0.005 A at 50 V but can control 2500 W of power—a gain of 10,000. As it will be discussed in this section, among the many forms of relays a variety of specific functions are available.

RELAY TYPES AND FEATURES

Electromechanical and electrothermal relays are discussed in this section. They are available in a variety of forms, but the basic characteristics that are described here are common to all of them.

Relays control the flow of electric current by means of contacts, which may be open or closed. When these contacts are open, they create a very high resistance (megaohms), and when they are closed, their resistance is low (milliohms). They may have multiple contacts. As many as eight SPDT contact assemblies are available on relays that are in stock. Each contact assembly is electrically isolated from all the others, and the contacts are actuated in some definite sequence.

The actuating coil can be (and usually is) completely isolated from the controlled circuit. It may be actuated by an electric energy that is of an entirely different character from that of the controlled circuit; e.g., milliamperes of DC may control kilowatts of RF.

Each of the various mechanical relay structures has certain advantages and certain limitations. Some respond rapidly—in less than 1 ms—but cannot safely handle large amounts of power. Others handle large amounts of power but at a slower speed, and so forth. Nearly all forms can be obtained with open contacts, can be enclosed in dust covers, or can be hermetically sealed in glass tubes or in vacuum-degassed plastic. Some glass tubes are evacuated for handling extremely high voltages. Some have contact assemblies suited for handling radio frequency voltages and to protect against capacitive cross-coupling.

There are also “solid-state relays,” which use transistors, SCRs, triacs, and similar components as current-control elements. In these devices the controlled circuit is usually isolated from the controlling circuit by a transformer (DC only), by an optical element, or perhaps by an electromechanical relay. These devices are covered in Section 5.10.

Special Relays

Some special relays that might be of interest to instrument engineers include sequence counters with transmitting contacts, opto-electronic relays in which coupling between actuator and circuit closure is a light beam, permitting elaborate interlocking of functions. These are often part of solid-state relays.

Also of interest are meter relays with microwatt sensitivity, ultrasensitive polarized DC relays (20 μW sensitivity), sensitive meter relays with two or more actuating values, resonant-reed relays for remote-control switching, coaxial RF relays, vacuum relays for extremely high voltages, multipole relays that can actuate 50 or more circuits simultaneously, polarized telegraphic and pulse-forming relays, voltage-sensitive relays for power system protection, phase-monitoring relays for protection in polyphase systems, impulse-actuated relays, instrumentation relays with negligible capacity between circuits, and crossbar switches that can select any one of 100 or more circuits. Solid-state devices with many of the same features are also available.

Relay Characteristics

The available relay designs include DC relays with contact capacities from microamperes to kiloamperes and coil energies from a few microwatts to several watts. In case of meter relays and amplifier relays, the actuating energy can be a small fraction of a microwatt. There are also AC relays handling from a few watts of power to many kilowatts. Relays can control both AC and DC potentials in the thousands of volts and frequencies from DC to RF. They can be made to respond to specific frequencies only or indiscriminately to all frequencies.

Many of the relay designs are for special applications. This discussion will be limited to the forms most often used in typical instrumentation work—principally small DC and AC relays, sensitive relays, miniature and sealed relays, and some small power relays. In the accompanying References, information may be found describing a wide variety of relay applications.

In selecting relays for particular applications, it is convenient to first consider the actuating energy that is available or needed to operate a relay. A rough classification, associating coil requirement with power-handling ability, is given in Table 5.9a. The values in this table are only approximate.

Relays can also be classified by operating function. Available energy often dictates relay choice. Examples are given in the following paragraphs.

Rating, Size, and Other Selection Criteria

Meter relays and ultrasensitive relays are actuated by very small energies (perhaps as small as a fraction of a microwatt). They are used in applications where only a very weak signal is available, such as at the output of a transducer or bridge.

General-purpose, or small control, relays are used in cases in which no great amount of power need be handled but flexibility in application and reliability in operation are both essential. Depending on the number of contacts, they usually require coil power of 200 to 800 mW, which may be either AC or DC. Typically they will control perhaps 5 A at 120 V per contact.

TABLE 5.9a
The Range of Relay Characteristics

Type of Relay	*Coil Power Required (Approximate)*	*Contact Capacity (Typical)*
Meter relay	As low as 1 mW	Low energy only
Ultrasensitive relay	Less than 10 mW	0.5–1.0 A, noninductive
Sensitive relay	From 10–60 mW	1.0 A noninductive typical
Typical crystal-can relay	100 mW per form C contact	0.5–1.0 A, noninductive
Transistor-can (TO-5) or miniature relay	150 mW per form C contact	0.5 A, noninductive
Reed relay	200 mW per form C contact	0.5–1.0 A, noninductive
General-purpose relay	200 mW per form C contact, up to 3 VA AC	10 A, 120 VAC
Small power relay	Usually AC coils, from 1–10 VA	30 A, 240 VAC

Small power relays are used in cases in which more power must be controlled. These usually have coils operating on 120 or 240 VAC, which can be controlled by sensitive relays. These small power relays have contact capacities up to 30 A, at voltages up to 600 V. Much larger relays are of course available (often called magnetic contactors or controllers).

Relays can also be classified by size. Subminiature relays may be as small as 0.13 in.^{3} (2.03 cc), and TO-5-size relays are the size of a TO-5 transistor case. In contrast, miniature plug-in relays measure approximately 1 in.^{3} (16 cc), and general-purpose plug-in relays are about 2 in.^{3} (31 cc) in size.

The type of *mounting* may be important (screw-mount, plug-in, or printed-circuit mounts); or the number of poles available in a single unit (as many as 48) may be the determining factor. Alternatively, extremely low (or perhaps extremely constant) contact resistance may be needed—mercury relays, or mercury-wetted contacts, have this characteristic. Reed relays and other subminiature units are suitable when many relays must be mounted on a single circuit board.

Relays may have appliance-grade, general-purpose, aerospace, or military-standard applications. There may be little difference in their reliability when they are used for their prescribed purposes, but the more expensive types will operate more satisfactorily under adverse conditions. Relays also vary in terms of mode of construction: There are clapper-type relays, telephone relays, solenoid-actuated types, reed relays, and many other forms.

Contact Configurations

Common terminology to describe the status of relay contacts is NO (Normally Open) and NC (Normally Closed). These refer to the relay contacts, when the relay is de-energized, as it is on the shelf. Relay contacts are also referred to as SPDT (Single-Pole-Double-Throw) or SPST (Single-Pole-Single-Throw). The term SPST (A and B in Figure 5.9b) means that the relay is provided with a single pair of contacts, which can be open or closed, similarly to a light switch. A Single-Throw relay would have either a Form A, Normally Open, contact or a Form B, Normally Closed, contact.

The term SPDT (C in Figure 5.9b) means that a pair of contacts (one NO, the other NC) is sharing a common input contact and will reverse its state when the relay is energized and will return to “shelf” state when the relay is de-energized. A Double-Throw relay is also referred to as having a Form C contact consisting of a NO and a NC contact. DPDT (Double-Pole-Double-Throw) relays have a pair of isolated contacts.

Electromechanical relays are produced with a wide range of contact arrangements, in various combinations. A number of these have become standard forms, and the ones that are used most frequently are shown in Figure 5.9b with their

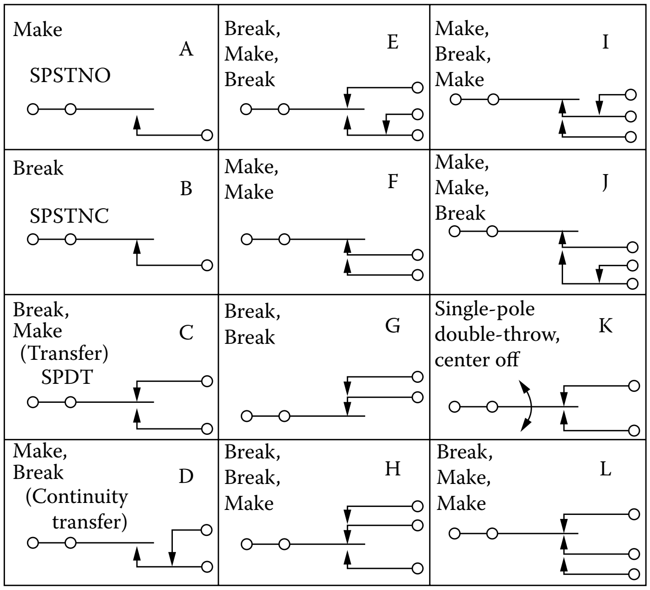

FIG. 5.9b
Standard relay contact configurations.

identifying code letters. The same relay contact assembly can be described as Single-Pole Double-Throw or SPDT; as make, break (continuity transfer); or has having form C contacts—all these terms mean the same thing. Four form C contacts means 4PDT, and so on.

Certain mechanical structures tolerate some contact pile-ups (the term for an assembly of leaf contacts) better than others. Small clapper-type relays seldom carry more than three form C contacts (although a modified clapper structure is used for high-density relays carrying as many as 48 contacts). Telephone-type relays may handle as many as eight form Cs, or perhaps four form Cs and one or two form Es or form Fs.

These contact assemblies permit the actuation of some circuits only after others have been actuated. This ensures the proper sequence of operation; there can be no "race of contacts." Solid-state relays seldom offer any wide selection of contact configurations; usually only form A or form B contacts are provided, unless the solid-state relay serves as a pilot for an electromechanical relay.

Electrical insulation between contacts can be very high, so that there is little leakage even at high voltages. Contact spacing can be wide, to protect from arc-over at high voltages. Capacity coupling can be kept low.

Mechanical Structures

Electromagnetic relays are actuated by magnetic forces that are produced by electric currents flowing through wire coils. In most relays of this type, the magnetic force moves an iron armature, while in a few other designs, especially in meter relays, a coil is moved in a magnetic field.

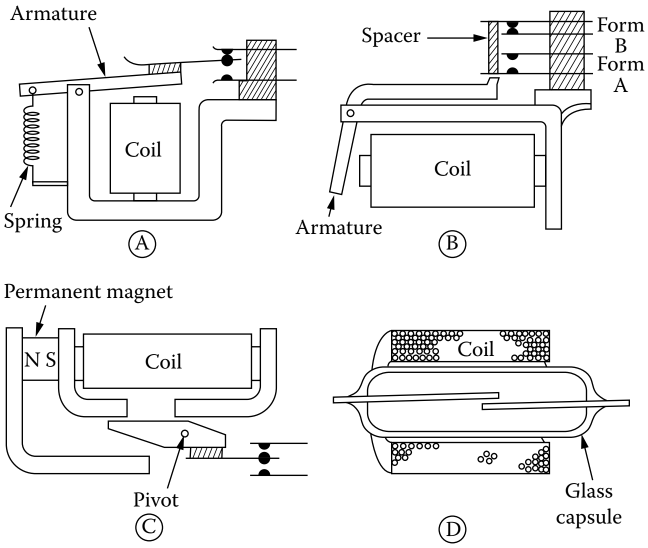

FIG. 5.9c
Typical relay structures.

The most widely used mechanical structures are shown in Figure 5.9c. The elements of a clapper-type relay are shown in part A of the figure, and the elements of a telephone-type relay are illustrated in part B. When there is no current flow in the coil, the relay armature is held away from the core by a spring. When current flows through the coil, the magnetic field that is produced pulls the armature toward the core, decreasing the air gap. As the air gap decreases, the pull usually increases, providing appreciably more contact pressure when the relay is energized than when the contact force is only that of the return spring.

Both the type depicted in part A and the type shown in part B can be used with either direct or alternating current. When AC is used, a shading coil is often added to smooth out the magnetic pull and to eliminate chattering. When AC current is used, the smaller air gap when the relay is actuated increases the impedance of the coil circuit and reduces the current flowing in that condition. Telephone-type relays are often fitted with shading coils (called "slugs") when used with DC current. This controls the speed of response of the relay.

Two other configurations in wide use are shown in Figure 5.9c, in parts C and D. The "balanced-force" mechanism is illustrated in part C. This structure has two mechanically stable positions. One of them is controlled by the permanent magnet, and the other is controlled by the magnetic force from the coil, which must be strong enough to overcome the pull of the permanent magnet. These relays can be made quite small in size, yet can be positive in action and affected only slightly by vibration.

Reed Relays The reed relay is shown in the partial sectional drawing of Figure 5.9c, in part D. Two reeds of magnetic metal are mounted in a glass capsule, which is itself installed within a coil. Current flowing through the coil produces a magnetic field, magnetizing the reeds and causing them to attract each other, to bend toward each other, and to make contact. The contacting surfaces are usually plated with precious metal contact alloy. The required spring action is provided by the reeds themselves.

Reed relays are among the fastest electromechanical relays. Some operate in less than 500 μsec. They are available in several contact configurations: They can be polarized, or they can be made into latching relays by the addition of small, permanent magnetic elements. Reed relays are available either with dry or with mercury-wetted contacts.

More than one reed assembly can be used in a single capsule, or several capsules can be operated by a single coil assembly. Reed relays are widely used in transistorized driver systems and in printed-circuit work, because of their small size, high reliability, and long life—a life of 100 million operations is not unusual.

Specialized Relay Structures The elementary magnetic structures described earlier can be combined to produce special-purpose relays.

If small permanent magnets are added to the relay, a relay armature may be forced in one direction for receiving a signal of one polarity and in the opposite direction when a signal of the opposite polarity is received. The elements of such a polarized relay are shown in Figure 5.9d, part A.

Mechanical or magnetic latching devices can be applied to produce a relay. This relay can permit either one of two circuits to be actuated, but not both at the same time. A simple form of this is shown in Figure 5.9d, part B. When one of the actuators is energized, its arm slides past the other arm, where it locks and is restrained from returning to its normal position even when de-energized. Energizing the other actuator reverses the procedure and latches the unit to the opposite side.

For certain applications, it is useful to be able to actuate one of two different circuits, depending on which of two signals is the larger—with little regard to the absolute magnitude of either signal. Two coils, with a single tilting armature, provide this ability (Figure 5.9d, part C). Usually, a weak spring is added to ensure that when no signal at all is present the relay will go to its neutral position.

Multiposition rotary switches can be driven by magnetic ratcheting devices, permitting the selection of any desired contact positions. Such stepping switches (or stepping relays, or “steppers”) are available in a wide range of positions and number of circuits. They can also be secured with electrical zero-reset or for continuous rotary operation. Stepping switches are used in many communications systems, in data-handling and materials-handling equipment, and in a large number of miscellaneous applications.

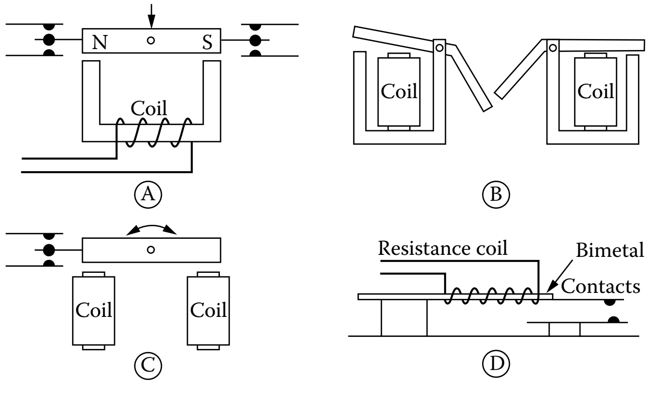

FIG. 5.9d
Some specific relay structures.

The lowest-current relays are the moving-coil meter-type relays. These utilize a d’Arsonval meter movement carrying delicate contacts. Sometimes the meter pointer is retained, and sometimes contact force is supplemented by magnetic contacts or by auxiliary coils. Such relays are susceptible to vibration and shock and to overloading. They are, however, capable of close adjustment for overvoltage or undervoltage applications and the like.

Time Delay Relays Thermal time delay relays can delay an action for a brief period after another action, in cases in which accuracy of timing is not critical. One form consists of a thermal bimetal strip wound with a resistance coil. The coil heats on the application of current, causing the bimetal strip to bend, which closes the electrical contacts (Figure 5.9d, part D).

In another popular form, the electric current flows through a stretched resistance wire, which expands and causes movement. These devices are somewhat affected by ambient temperature, and they cannot be recycled (returned to their initial cold position) instantly.

Another popular, low-cost time delay relay uses a small dashpot to delay the armature movement. Still another form (often called “slugged” relays) uses a heavy shading coil around a portion of the magnetic structure. This can produce a delay of a fraction of a second on opening or closing or on both actions. It is especially useful to protect against a “race-of-contacts.” These are typically low-cost, low-accuracy time delay devices. Thermal types can provide higher accuracy and repeatability, at a higher cost. Time delay relays are described in detail in Section 5.12.

Contact Materials

A variety of contact materials are available, with characteristics suitable for the various applications. For very low-current, low-voltage applications (dry circuit), it is essential to select contact materials that do not oxidize, develop insulating coatings, or erode mechanically. Some precious metals (such as gold and platinum) and some proprietary alloys satisfy these requirements. Such contacts are used in choppers and in meter relays, in which contact-sticking can be a serious problem.

Silver and silver-cadmium contacts withstand fairly high currents without overheating, but they tend to form coatings (oxide and sulfide coatings) that, while conductive, do have appreciable resistance. Tungsten-alloy contacts usually resist pitting and erosion when used at high voltages.

Mercury-wetted contacts can be expected to have higher current ratings and lower contact resistance than do dry metal contacts of the same size. Similarly to mercury-pool contacts, they are usually less noisy and display far less bounce. Dry metal contacts may fail by welding together; mercury contacts seldom do this. Relays with mercury contacts must usually be mounted in a nearly vertical position, and they are often vibration-sensitive.

Contact Shape and Mounting

The shapes of contacts depend on their use. Heavy-current contacts are usually dome-shaped. Low-resistance, small-current contacts are often crossed cylinders and are so placed that they wipe against each other. In wire-spring relays the round wires themselves, plated locally with contact material, form the contacts. They thus are long-lived and inexpensive. In reed relays, the flat strips, which are the reeds, also form the contacts. They may be shaped at the ends and usually are plated for good contact.

Contact mounting is an important part of relay design. In multicontact relays it is essential that all contacts be able to bear properly on their mating contacts, without interference. In low-voltage applications it is usually desirable that a wiping contact be provided. The higher voltages can break through thin surface films. In nearly all relays it is desirable that contact bounce and chatter be minimized. Some forms of reed relays, in particular, are very fast yet do not bounce.

SELECTION AND APPLICATION

Among the many factors affecting the selection of relays are cost, physical size, speed, and required energy. In addition, more restrictive parameters, such as mounting limitations and open or sealed contacts, are sometimes required for safety and for protection against unfavorable ambient conditions. The catalogs of relay manufacturers usually list dozens of types, forms, and sensitivities. Although relays have been in use for more than a century, new forms are still appearing. Tables 5.9e and 5.9f list the features of some representative designs of open-contact and sealed-contact relays, respectively.

TABLE 5.9e
Typical Open-Contact Relays

Relay Type	*Coil Description*	*Contact Description*	*Mounting*
Sensitive DC relay	1000–10,000 Ω, 20 mW per form C	Up to 4 form C, 1/2 A	Screw
Plate-circuit relay	2000–20,000 Ω, 50 mW per form C	Up to 2 form C, 2 A	Screw
Small utility relay	AC or DC, 6–120 V, about 250 mW	Up to 2 form C, 2 A, 120 V	Screw
General-purpose relay	AC or DC, about 200 mW per form C	Up to 3 form C, 10 A, 120 V	Screw or plug-in
Small power relay	Usually 120 VAC 2–10 VA	Up to 3 form C, 30 A, 600 V	Screw

Selection

In order for relays to be applied satisfactorily, the relay functions must be clearly understood and relay characteristics must be established. The relay must be selected to fit the need, and the circuitry must be designed to properly couple the relay with the rest of the system. Thus, it is usual to begin the selection process by determining how much energy must be controlled and how much energy is available in the signal that operates the relay.

One must also consider the number of contacts needed. It may be necessary to use two cascaded relays, if signal energy is too small, or two paralleled relays to provide enough contacts. Ambient conditions must also be considered. One must answer such questions as: Are sealed relays needed? Is there a space problem? Is there a vibration, shock, or temperature problem?

Relay Circuitry If a suitable relay has been selected and is available for the projected use, the circuit problem must be considered. In general, the same criteria may be used in designing relay circuits as in designing other circuits, yet because of some basic relay characteristics, relay circuitry involves some special problems of its own. Among the most important of these

TABLE 5.9f
Typical Hermetically Sealed Relays

Relay Type	*Contact Description*	*Mechanical Size (inches)*	*Speed of Action (milliseconds)*
Midget plug-in	1 form C, 0.5–1.0 A	$^3/_4 \times 2$	2
Mercury-wetted plug-in	1 form C, 2 A	$1^1/_2 \times 3^1/_2$	5
Mercury-wetted plug-in	4 form C, 2 A	$1^3/_4 \times 3^1/_2$	5
Balanced-armature DC, sensitive	2 form C, 2 A	1 × 1 × 2	3 (shock-resistant)
Crystal-can relay	2 form C, 1 A, noninductive	0.8 × 0.8 × 0.4	1.5 (shock-resistant)
Reed relay, dry contact	1 form C, 12 VA	0.5 × 0.5 × 3	1
Transistor-can relay	2 form C, 1 A, noninductive	0.3 × 0.3 × 0.3	1.5
Mercury-pool power relay	1 form A or B	2 × 2 × 6	Slow, vertical mount, affected by vibration

are the problems of transients across relay coils and the problem of protecting relay contacts from sparking, arcing, and welding.

In low-current, low-voltage relay circuit applications, as in most communication or logic circuits, serious problems with contacts usually do not arise, and often the most difficult problem is simply to keep the contact surfaces clean under low-current (dry-circuit) conditions. On the other hand, when larger currents must be handled (especially if the load is inductive or if it experiences an appreciable inrush for any reason), steps should be taken to protect the contacts from the effects of arcing, sparking, or welding. Under certain conditions, arcs tend to develop between contact and case or between contact and mounting. This can be prevented by proper circuit design.

One can minimize welding of contacts from high inrush currents by using sufficiently large contact areas that are made of suitable materials. Occasionally, more drastic measures—such as parallel contacts—must be considered. Lamp loads and the starting of single-phase motors—both drawing high inrush currents—are examples of troublesome conditions.

Sparking at contacts or arcing resulting from interruption of an inductive load can be minimized by use of spark suppressors (surge protectors, contact protectors, and so forth). These often are simple resistor-capacitor (RC) circuits but may be special devices—discharge tubes, diodes, or other solid-state instruments. Mercury-pool relay contacts are often used for heavy currents because the circulation of mercury provides a clean contact surface for each operation. Large power relays may use double-break contacts, blowout devices, or other means that are not within the scope of this discussion.

Transient Suppressors Most relay coils possess enough inductance to produce large transients when their currents are interrupted. A 28 V DC coil can produce a 1000 V transient, which can endanger insulation. Such transients can be reduced by use of semiconductor devices, neon lamps, or (on DC relays) a short-circuited winding as an absorption device. The problem can be a serious one and should not be ignored.

In many relay applications, it is advantageous to momentarily apply an overvoltage to ensure fast and positive action and then to reduce the coil current to a lower value to avoid overheating. There are many methods for doing this. Two of these methods are shown in Figure 5.9g. Shown in part A is a circuit useful only for DC relays. A 24 V relay is fed from a 50 V source; the capacitor (C) is initially charged to 50 V, so that when the controlling contacts are closed, the inrush current is nearly double the normal coil current. After the capacitor has discharged to its normal value, the resistor (R) limits the coil current. If R is equal to the coil resistance, only the normal coil current flows. In this diagram, a resistor-capacitor transient suppression circuit is connected in parallel with the coil. Other types of suppressors might be used with equally good results.

Circuit B in Figure 5.9g can be used with either AC or DC coil voltage. It involves a positive-coefficient resistor (often a small tungsten lamp, or a barretter) in series with the relay coil. When the barretter is cold, its resistance is rather low, but after current has passed through it for a few seconds, its temperature (and, hence, its resistance) increases, and the coil current is reduced to its normal value. This diagram shows two Zener diodes connected across the coil to serve as transient suppressors.

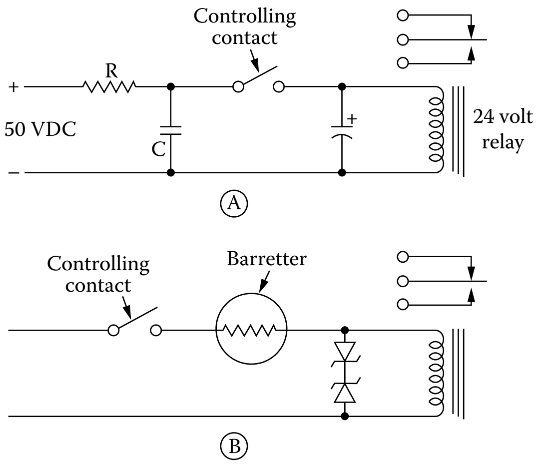

FIG. 5.9g
Typical coil circuits with transient suppressors.

Sometimes an unused relay contact is connected just to insert more resistance after a relay has been energized. It should be remembered that the inductance of an AC relay coil usually increases when the relay is closed, and this will reduce the coil current to some extent.

Relay users should not hesitate to consult the relay manufacturer for assistance in selecting and applying any of these devices. No catalog can possibly contain all the available data, and most manufacturers are happy to supply details on relay use.

RELATIVE COSTS

Small general-purpose relays can usually be purchased for about $10 each, with dust covers and simple contact configurations. More complicated contact assemblies, with hermetic seals, will cost more. If plug-in relays are used—and many general-purpose industrial relays are plug in—the socket will add several dollars to the cost and transient protection will cost a little more. The cost of high-sensitivity relays can reach $100. Installation charges are difficult to estimate, because they vary with locality, type of mounting, and type of base used.

Relays vs. Solid-State Devices

Relays compete primarily with silicon-controlled rectifiers, silicon switches, and transistors, which are discussed in more detail in Section 5.10.

Electromechanical Advantages

Electromechanical relays outperform such solid-state devices in some respects. They offer both extremely low resistances

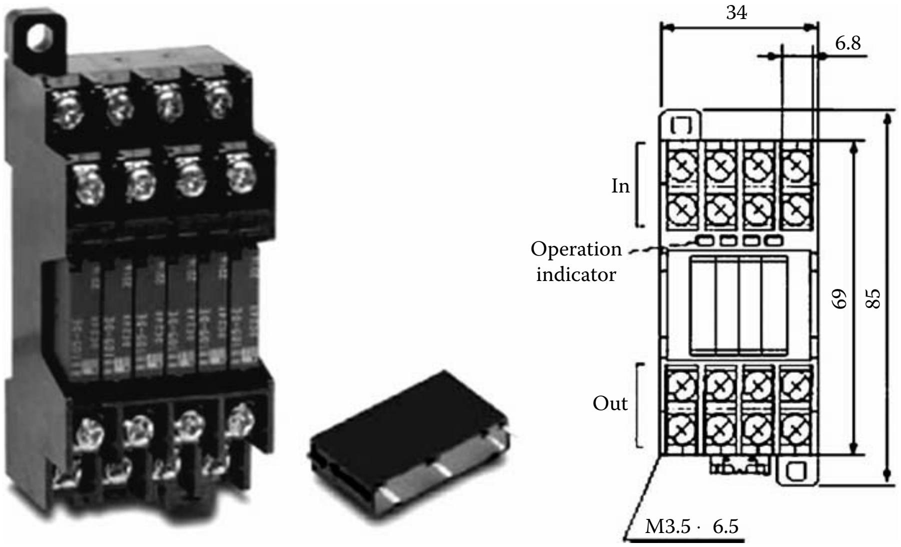

FIG. 5.9h
Card relay package and schematic. (Courtesy of KOYO Automation Direct.)

(and thus low voltage drop—about 1 μV with gold plated contacts) when closed and extremely high resistance when open.

They also provide essentially complete isolation of the controlled circuit from the controlling circuit without auxiliary links, and they can provide essentially simultaneous actuation of several circuits or actuation of several circuits at short intervals, without added cost. Some relays can handle extremely high voltages at a range of frequencies, and some can handle high currents in more compact form than can most solid-state devices. Relays provide positive circuit closures and can tolerate much abuse with only some shortening of life. Modern relays can also withstand the extremes of ambient conditions.

Some relays (in particular, high-density relays) are as small or nearly as small as the competing solid-state devices when installed. In some cases, they are cheaper to procure and to install than the competing solid state devices, and some—such as latching relays or steppers—can provide other advantages, such as a functional memory, which is not destroyed by power interruptions.

One form of high density design is the "card relay." This is a DIN rail-mounted package of four, six, or more individual relays. The relays are individually replaceable and can handle up to 5 A. An example of such a design is shown in Figure 5.9h.

Solid-State Advantages

For extremely high-speed operation, solid-state devices are superior to relays, because only a few relay forms will operate in less than a millisecond. Solid-state devices are more resistant to vibration than are relays but can be less resistant to some other environmental conditions. For the ultimate in compactness if cost is not a factor, and for logic rather than power-handling applications, integrated solid-state devices will usually be preferred.

Many relays operate on ordinary line power, in contrast with solid-state devices, which often require some other form—although this is frequently hidden in a packaged assembly. If only a few relays of different kinds and capacities are needed, electromechanical units may be more convenient for this reason alone.

CONCLUSIONS

Relay reliability depends upon their quality but even more on their correct selection. Relays carrying only small currents may be expected to operate millions of times before failure. Relays that control currents in the order of amperes necessarily wear faster. With proper contact protection, however, relay lives of 100,000–20,000,000 operations are common.

Reliability does depend upon selection of the proper relay; contact protection and transient suppression; the use of dust covers or hermetic seals when needed; proper circuit design; and observance of the usual rules of good practice as regards voltages, ambient conditions, and the like.

INTRODUCTION

With the advent of semiconductor technology and subsequent hybrid device fabrication techniques, solid-state logic devices have undergone dynamic application changes in the past 10 years. Today, it is common to have a sensing element directly coupled, if not integrated, to input logic operations and output logic process condition requirements. It is also now possible to employ "smart" solid-state logic elements that function as stand-alone control loops.

These integrated circuits (ICs) perform control switching operations without moving parts. Their advantages are: (1) high switching speeds, (2) life independent of the number of operations, (3) operation unaffected by dirt and certain corrosive atmospheres, (4) small size, and (5) low power consumption. They make the process variable measurement, examine that sensor data according to specific logic expectations, and then decide what, if any, alteration in the device output signal should be provided. Their disadvantages are: (1) sensitivity to electrical interference, (2) lack of input/output isolation, and (3) low power output driving capabilities.

These mini distributed control systems reduce the information noise that is forwarded to the process controller, provide an average or logic filtered response to a process variable disturbance, and greatly enhance the performance and speed of the entire process control loop. This section will briefly discuss the fundamental engineering science principles required to apply the analog, digital, and logic components of solid-state logic technology.

ANALOG CIRCUIT ELEMENTS

Although modern solid-state logic devices completely incorporate any required analog, digital, and logic circuits elements, instrumentation and controls personnel are still required to interpret circuit and function diagrams that contain isolated circuit elements as they relate to solid-state device implementation. These elements include resistors, capacitors, inductors, diodes, transistors, and operational amplifiers. Many common solid-state logic device control applications include external resistors, capacitors, and diodes. These elements as well as switching transistors are discussed below.

The resistor represents the simplest and most basic auxiliary component in a solid-state control circuit application. It is used for its ability to lower the potential, voltage, as electrons pass through it. Although the reader is encouraged to explore resistance, resistivity, and Ohm's law, from a digital circuit control's application perspective, an appreciation of the voltage drop concept is particularly useful. Figure 5.10c illustrates this point.

A P-N junction is formed by joining a small amount of *p*-type semiconductor material to a small amount of *n*-type material. Transistors (Figures 5.10a and 5.10b) are formed by the combination of two P-N diodes. PNP or NPN transistors differ from each other in the positions of the *p* and *n* layers and the polarity of the applied voltages and in the directions of the resulting current flows.

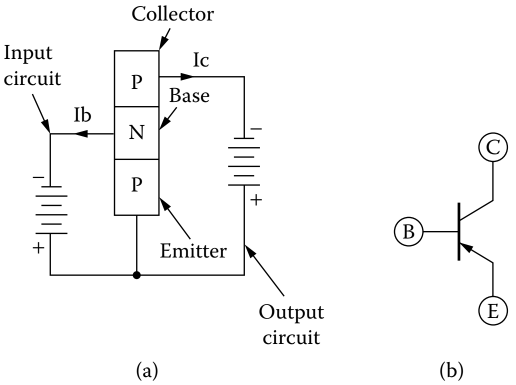

FIG. 5.10a
Combination of P-N junctions into a transistor. (a) Arrangement for the PNP transistor. (b) Commonly used circuit symbol for PNP transistor.

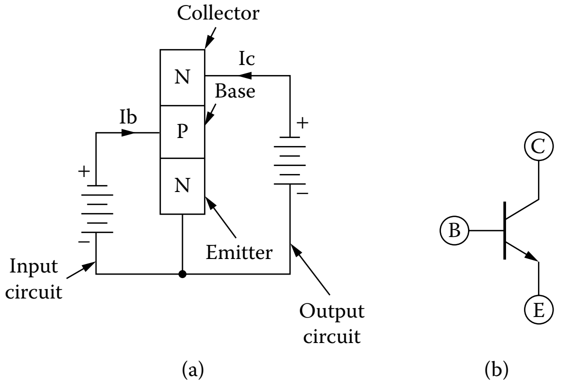

FIG. 5.10b
Combination of P-N junctions into a transistor. (a) Arrangement for the NPN transistor. (b) Commonly used circuit symbol for NPN transistor.

Transistor Switch

Figure 5.10c depicts the basic structure of a PNP transistor switch. The figure exemplifies several points to be presented in this section. However, initially the focus is on the voltage drop concept. The left side of the diagram shows a serial connection between two resistors, R_1 and R_2, and a parallel connection between R_2 and a set of normally open contacts, PSL 21. The figure indicates that there is a total voltage drop, V_T, when current flows between the node point above R_1 to the node point below R_2.

The discussion of this serial resistor and parallel contact often includes the terms voltage divide and pull up resistor. Both terms reflect the Ohm's law relationship that the sum of the voltage drops across R_1 and R_2 equals V_T but each term reflects a different perspective of the node point, (a), located between R_1 and R_2.

The term voltage divide brings the reader's attention to node point (a). The voltage at this point is determined using the voltage divide equation shown here as

$$V_{(a)} = V_T\,[R_1/(R_1 + R_2)] \qquad \mathbf{5.10(1)}$$

where the resistance ratio in the brackets is known as the voltage divide ratio. If, for example, the two resistors have the same value, then the voltage at the node point (a) would be one-half of the total voltage drop, V_T.

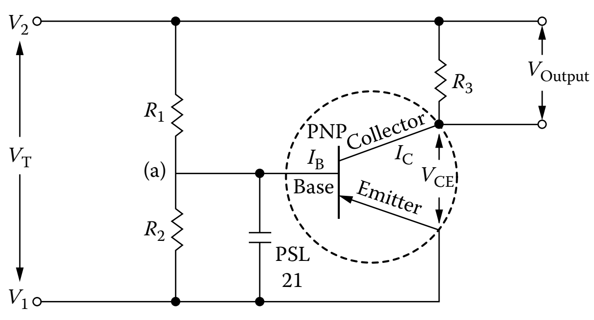

FIG. 5.10c
Voltage divide example in a PNP switching circuit.

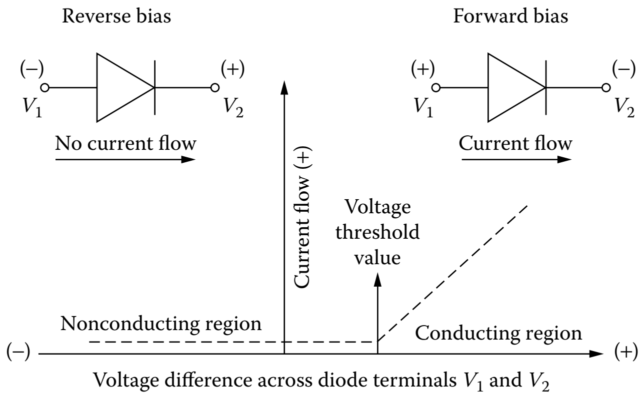

FIG. 5.10d
Diode voltage bias versus current characteristic curve.

The term pull up resistor draws attention to the fact that the voltage at node point (a) is higher than the voltage at the node point below R_2 as long as contact PSL 21 remains open. R_2 is now identified as a pull up resistor. The use of pull up resistors is very common in solid-state control circuit applications, and their role is to ensure a desired reference voltage at a specific input or output in the digital circuit.

Diodes and Their Switching

The diode represents the simplest semiconductor device digital control circuit element. It is formed when a small amount of *p*-type material and a similarly small amount of *n*-type material are joined to produce a single interface known as a P-N junction. Such a junction provides a comparatively low resistance for one direction of current flow and very high resistance for the flow of current in the reverse direction.

The diode circuit symbol representations are illustrated in Figure 5.10d. The figure shows the voltage assignments that define the reverse and forward bias conditions for a diode. If the voltage polarities depicted on the diode on the left side of the diagram are imposed, the diode is reverse biased and in a nonconduction mode. No current flows when a diode is reverse biased. The figure also presents the current versus voltage across the diode plot. This graph indicates that the current increases rapidly after a small threshold of voltage is exceeded.

A simplified diode switching application is presented in Figure 5.10e. The circuit translates the digital sensor voltage input signals to a control output voltage delivered across R_6. In this case, the voltage divide provided by R_4 and R_5 creates a reference voltage, V_{node}, that defines the bias on the two diodes. If a voltage lower than V_{node} is applied at Input *a* or Input *b*, the respective diode becomes forward biased, current flows, and a voltage drop across R_6, V_{output}, results. Thus, any control action generated by V_{output} occurs when either or both of the input sensors present the low signal to the circuit's respective input port.

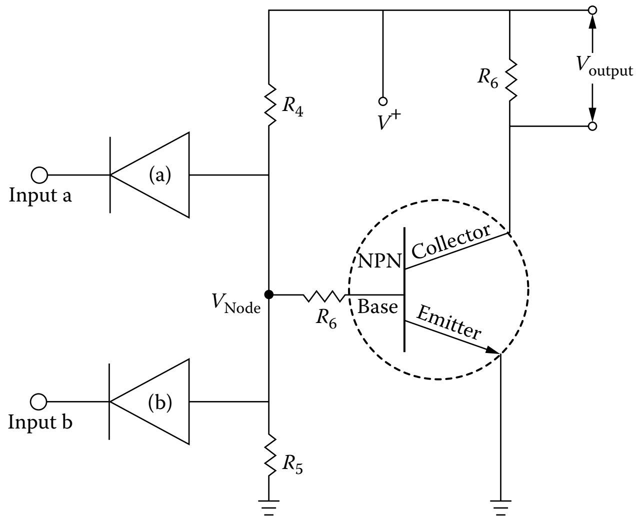

FIG. 5.10e
Circuit elements for a diode-transistor logic device.

Transistors

The transistor represents the simplest multiple junction semiconductor device employed in control logic element applications. Transistors are formed by the combination of two P-N junctions and contain two circuits: emitter-to-base and emitter-to-collector. The emitter-to-base circuit is generally referred to as the base circuit, and the emitter-to-collector circuit is known as the power, or output, circuit. The right section of Figure 5.10c shows a PNP transistor with its terminals appropriately labeled.

The manufacture and internal composition and action of the transistor is interesting but not of immediate value to the instrument engineer. However, three general characteristics (which can be observed by external measurements) are significant for logic applications or switching actions:

1. The emitter-to-base circuit controlling I_B in Figure 5.10c closely resembles a diode.
2. The emitter-to-collector circuit functions as an open/close switch.
3. The switch is open and the transistor is not conducting, I_C is zero, whenever the voltage difference between the emitter and the base is zero or whenever the emitter-to-base circuit is reverse biased.

Figure 5.10c illustrates a PNP transistor circuit as an interface to a low pressure-sensitive switch, PSL 21. Because of various design considerations it is usually desirable for the transistor to be conducting when no signal is applied and to stop conducting when a signal is applied.

Resistors R_1 and R_2 together with the normally open contact PSL 21 provide this function for the circuit. If properly selected, R_1 and R_2 generate the appropriate potential value at the base to yield full conduction in the emitter-to-collector circuit. In this state, I_C is at its maximum value.

The closing of contact PSL 21 alters the voltage at node point (a) enough to open the transistor, drastically reduce the value of I_C, and thus bring V_{output} to 0 V.

The proper selection of R_2 and R_3 depends on an understanding of the concept of saturation voltage. Examination of Figure 5.10c easily confirms that the voltage drop across the transistor, the collector voltage, V_{CE}, is defined as

$$V_{CE} = V_T - I_C R_3 \tag{5.10(2)}$$

where $I_C R_3$ is the voltage drop, V_{output}, generated when the PNP collector current, I_C, is not 0. Since I_C is related to the base current, I_B, by

$$I_C = \beta I_B \tag{5.10(3)}$$

with β defined as the amplification factor, V_{CE} can now be expressed as

$$V_{CE} = VT - \beta I_B R_1 \tag{5.10(4)}$$

The base current changes as a function of the voltage divide network that contains R_1 and R_2. As the potential at the transistor base is made more negative, I_B increases and V_C decreases to a minimum value. This minimum value, called the saturation voltage, is less than 0.2 V for typical switching transistors, and the effective resistance between collector and emitter at saturation is accordingly small (on the order of a few ohms).

By contrast, when I_B is reduced to 0, the collector-to-emitter resistance is that of a reverse-biased or nonconducting diode and is in the region of millions of ohms. The collector-to-emitter circuit operates to open and shut under the control of I_B with the output voltage, V_{output}, switching off and on accordingly.

Figure 5.10e also presents a transistor that interfaces input signals to a control output voltage. In this situation, the transistor is an NPN type that fundamentally operates the same way as the PNP transistor in Figure 5.10c. In both cases, the emitter-to-collector power circuit is turned on or off, and this maximum or minimum V_{output} value switching action depends on the flow of current in the emitter-to-base circuit within the transistor.

For the diode application in Figure 5.10e, the emitter-to-collector power circuit conducts and develops the desired V_{output} value when the process variable input signal forward biases either or both of the diodes. In this particular application, the process variable signal can be analog or digital, because the bias threshold voltage of the diodes determines the switching action. In fact, the diodes perform a rudimentary but effective analog-to-digital signal conditioning that allows an analog sensor to also operate as a limit alarm.

INTEGRATED CIRCUIT ELEMENTS

The term *integrated circuit* reflects the fabrication process that puts the functions of transistors, diodes, and resistors into a layer-constructed device. Before considering switching and logic applications for integrated circuits, the nature of the switching operations themselves will be defined. The general requirement for logic devices is that they generate on–off output control signals from on–off input signals in a way dictated by a logic operation. From a positive logic perspective, the five elementary and basic logic operations are:

1. AND: The output is on if all inputs are on.
2. OR: The output is on if one or more inputs are on.
3. NOT: The output is off if the input is on and vice versa.
4. NOR: The output is off if one or more inputs are on.
5. NAND: The output is off if all inputs are on.

Figure 5.10e represents a simple example of an individual component circuit that can be fabricated as an integrated circuit. For this specific example, the *IC* package would have five terminals available to the user with no access to the transistor or any of the individual resistors or diodes. Two of these terminal are reserved for the power and ground for the package, the third terminal provides access to V_{output}, while the remaining two terminals are assigned to Input *a* and Input *b*.

The reader is encouraged to review the overall function of the circuit in Figure 5.10e to confirm that it would perform an OR logic operation if the input signals were inverted before they were presented to the diodes.

Families of IC Switching

Although the fabrication of integrated circuits is not of immediate interest, it is important to appreciate that the technology options influence the applications. There are four main families of integrated circuit switching in common use for control:

1. RTL (resistance-transistor logic)
2. DTL (diode-transistor logic)
3. TTL (transistor-transistor logic)
4. HLL (high-level logic)

RTL was the first type of switching logic produced in integrated form. It basically replaced component circuits that were simple combinations of resistors and transistors. The primary advantage of this technology over its separate component equivalent is the size and reliability bonus that accompanies the integration process.

If the OR circuit in Figure 5.10e was manufactured as an *IC*, it would be an example of DTL technology. The major impact of integrated circuits accompanied the development of TTL technology. TTL devices have high switching speeds and are now common to most digital instrumentation and control applications. Table 5.10f is a summary of technology characteristics.

TABLE 5.10f
Integrated Circuit Characteristics

Type	*Resistance to Noise*	*Switching Speed*	*Cost*
RTL	Poor	Fair	Low
DTL	Fair	Good	Medium
TTL	Good	High	Medium
HLL	Excellent	Low	High

Some examples of TTL packages are provided in Figure 5.10g, which shows the pin configuration for the 7400, 7404, 7408, and the 7474 TTL packages. The 7400 and 7408 are know as 2 input quad NAND and 2 input quad AND packages, respectively. The 7404 is a hex inverter package while the 7474 is a dual D-type positive edge triggered flip-flop.

The four NAND devices in the 7400 and the four AND devices in the 7408 operate independently of each other. For example, if the proper operating voltages are applied to pins 14 and 7, a high input signal, logic "1," on pin 1 and pin 2 of the 7408 will generate the logic "1" signal on pin 3 independent of the signals that may be present on pins 4, 5, 9, 10, 12, or 13.

A similar statement is true for the 7400, with the exception that the logic "0" signal is generated on pin 3 of the 7400. Each inverter in the 7404 also operates independently. The logic "1" signal on pin 1 produces a logic "0" signal on pin 2 even though a logic "0" signal on pin 3 will simultaneously produce a logic "1" signal on pin 4.

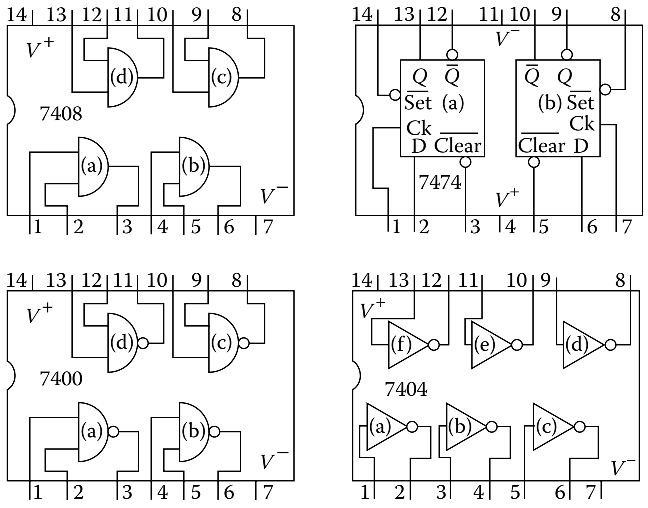

FIG. 5.10g
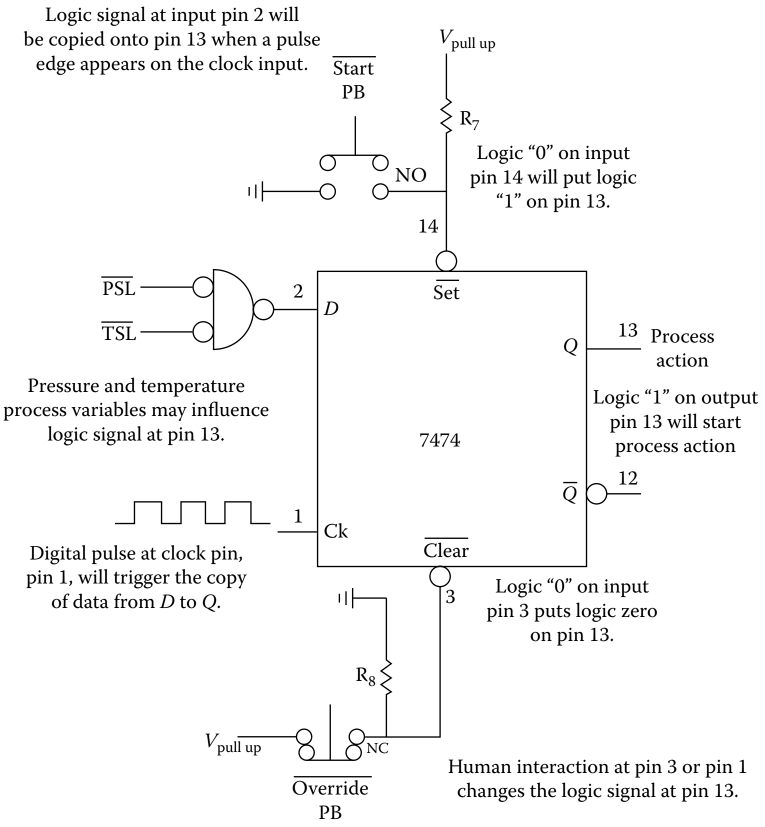
Pin configurations for the 7400, 7404, 7408, and 7474 TTL logic devices.



Logic signal at input pin 2 will be copied onto pin 13 when a pulse edge appears on the clock input.

Logic "0" on input pin 14 will put logic "1" on pin 13.

Pressure and temperature process variables may influence logic signal at pin 13.

Logic "1" on output pin 13 will start process action

Digital pulse at clock pin, pin 1, will trigger the copy of data from D to Q.

Logic "0" on input pin 3 puts logic zero on pin 13.

Human interaction at pin 3 or pin 1 changes the logic signal at pin 13.

FIG. 5.10h
Process variable sensors and pushbutton interface to a 7474 positive edge flip-flop.

APPLICATIONS

To illustrate the utility of integrated circuit devices, two simplified applications will be discussed.

Merging Human and Instrument Inputs

Figure 5.10h presents a function diagram that shows how logic devices can merge the human and instrument input requirements of a control scheme.

The 7474 solid-state logic flip-flop element shown is an integrated circuit that combines NAND and AND circuits to perform a specific switching operation at its outputs. The logic on pin 13, the *Q* output, will be at logic "1" or logic "0" depending on the signals at inputs 1, 2, 3, and 14. The logic signal on pin 12 is always the opposite of that presented to pin 13. The rules of operation for the 7474 are also provided in Figure 5.10h.

As suggested, the utility of the 7474 resides in its ability to combine the logic of human and process sensor inputs to direct a switching control action. The function diagram suggests an application that involves a process action that depends on the condition of two process variables, temperature and pressure, as well as human interaction with pushbutton inputs. The diagram indicates that a human override decision has priority over the process variable information. If the override pushbutton is engaged, a logic "0" is generated at the *Q* output and the process action will not be allowed to continue.

For this simple example, it is predicated that the temperature and pressure will not remain above their alarm values if the process action is discontinued. If that were not the case, an AND device could be added to the control scheme as a gate for the clock pin. The logic state at pin 13 would be fed back to serve as the gate pin signal on the AND. The AND rather than a NAND would be selected as the gate device, because a negative edge will be generated by the AND when the gate pin goes to logic "0."

The negative edge delivered to pin 1 ensures that the logic state at pin 2 will not be transferred to pin 13. This removes the possibility of a logic "1" signal on D immediately replacing the override generated logic "0" signal on *Q*.

The process action is started or restarted when the active low start pushbutton is engaged. At this point, the *Q* output is at logic "1" and will remain in that state when the start button is released. If the override pushbutton is not engaged, the process action will continue until both of the active low sensors detect that the respective process variables have dropped below their low-level limit values.

Again for simplicity, in this example, it is assumed that upon start-up the temperature and pressure immediately rise above alarm levels. In most applications this will not be the situation. For this example, one way to adjust to such a temperature or pressure lag is to use the AND gate discussed above and extend the time the gate pin detects the logic "0" signal.

Time Synchronization

Figure 5.10i presents an example of a data acquisition logic control circuit (sheet I) that deals with a designed time-dependent presentation of a logic signal for a control action. The simplified circuit depicts one of several sheets that describes the complete control scheme.

Sheet I suggests a complicated scheme that uses four sensor input signals to direct two output control signals, M-2,I-5 and P-2,I-6. The control scheme uses devices in single NAND and OR packages and a single 555. The 555 provides a pulse duration feature that is initiated by the proper combinations of the input signals. The 555 integrated circuit is a popular device (see Section 5.13) when adjusted pulse duration situations are required. The 555 is not a TTL device but is TTL compatible and is often used with TTL control circuits.

For this application, pin 3 provides, on demand, a logic "1" signal for a time determined by the R_{10} C_{10} circuit associated with pins 6 and 7. The output signal on M-2,I-5 is directed to sheet *M* as input 2, where it will activate an analog-to-digital conversion of a process variable measurement as shown in sheet *M*. The time needed to accomplish that conversion is provided by the extended logic "1" signal delivered to pin 12 on NAND device (d). To ensure proper transfer of the digitized variable value to its computer-based data logging system, a delayed signal to the data logger is provided to sheet P-2 via the R_{11} C_{11} circuit associated with output P-2,I-6.

The presentation of the data acquisition logic signal at pin 12 of NAND (d) depends on the signals that are delivered to the other 7400 NAND devices. All of these devices are operating as gates, with pins 2, 4, 13, and 9 serving as gate pins.

The reader may wish to review Figure 5.10i to confirm that the proper signals will not be presented to M-2,I-5 and P-2,I-6 unless input I-4,C-3 is at logic "1." In addition, inputs I-1,B-4 and I-2,D-2 as well as I-4,C-3 must be at logic "0." The diodes and inverter in line I-2,D-2 are needed to condition the signal arriving from an input circuit as documented in sheet D output 2, and the pull up resistor, R_9, together with the flip-flop action of AND device (a) and AND device (b) ensures that the output of the 555, pin 3, is off unless I-1,B-4 is really at logic "0."

The use of the 555 to control the duration of the logic signal presented to pin 12 of NAND device (d) emphasizes the range of skills instrumentation and controls personnel may have to master. In this specific situation, a 74121 is a TTL device that, on first glance, could be a substitute for the 555. However, the pulse duration requirement for this application is better suited when the 555 is used.

In general, Section 5.10 is presented from an application user perspective. The section provides information that introduces solid-state elements, reviews fundamental electronics concepts, and facilitates the interpretation of application circuits but does not cover the specific electrical and electronic considerations and details if the task is to actually design the circuit, as compared to designing or interpreting the control task.

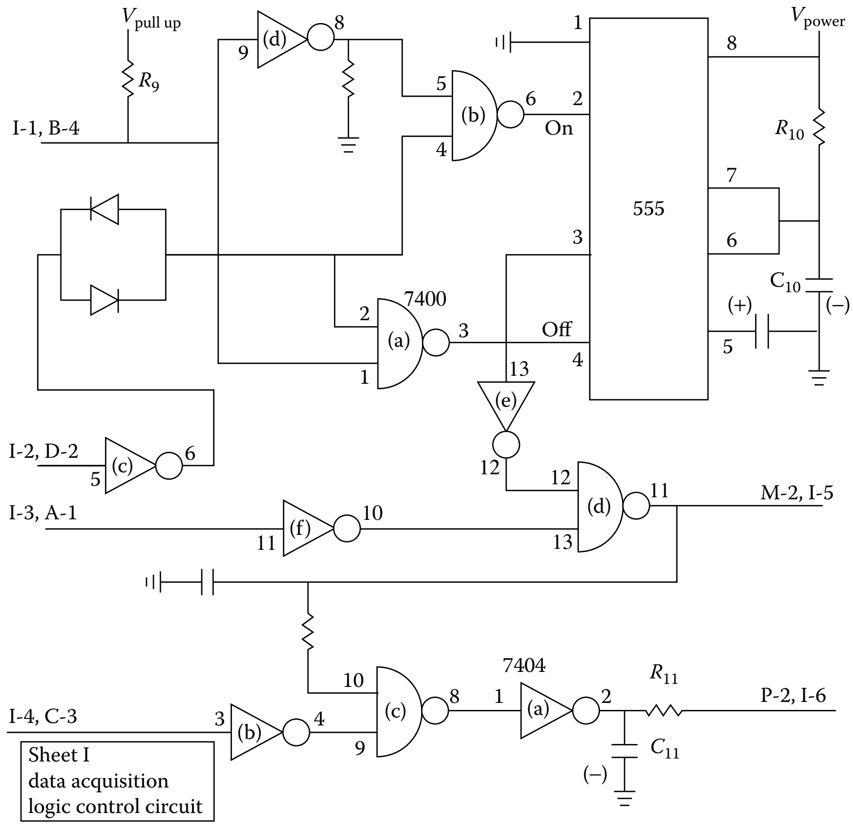


FIG. 5.10i
7400, 7404, and 555 interface for time synchronization for data acquisition.

For example, although the function diagram in Figure 5.10i does not violate any fan-in or fan-out device restrictions, voltage and current input and output characteristics are not provided, and the fan-in and fan-out requirements associated with the inclusion of the 555 into a TTL application are not discussed. There is no attempt to discuss the resistor and capacitor values needed to build the circuit for this application. Nor is there any focus beyond awareness of the specific diode signal conditioning requirements for this circuit.

IMPLEMENTATION OPTIONS

Although it is clear that integrated technology takes less space and is considerably faster than its original relay logic counterparts, there are several choices in implementing this relay replacement technology. The initial choice of solid-state logic elements over mechanical relay elements is a matter of economics and requirements. In general, solid-state elements are indicated when any of the following factors are important:

1. The switching speed requirements are high (above 100 per sec). At such speeds, the life of an ordinary relay is limited to a few hundred hours.
2. The system requirements are complex, involving a large number of elements for implementation.
3. The system receives or transmits signals from or to a digital computer.
4. Space is limited, such as in portable equipment.
5. Process downtime is costly and must be minimized.

If the amount of logic to be implemented is large and it involves a batch or continuous process application, the implementation selection is easy: The application should be installed on a programmable logic controller (see Section 5.4). However, for instrumentation applications or process applications similar to or smaller than the applications reviewed above, the use of dedicated solid-state circuits is a reasonable option.

Solid-State Logic Options

There are three popular methods of implementing dedicated solid-state logic control circuits. In the first option, the circuit is constructed on a plastic card, called a printed circuit board (PCB). The conducting connections shown between pins on the device packages are etched on the PCB, with the input and output leads brought to the edge of the board. The logic packages are attached to the appropriate places on the board, and the entire circuit board is plugged into a protective chassis. Circuit repair usually encompasses replacement of the entire board.

The second method of solid-state logic circuit implementation is the use of a plug-in module. This technique is popular because it closely mimics the construction philosophy in the relay logic circuits, which it is replacing. A rack is mounted near the application, and small, individual, often cubic solid-state packages are plugged into the rack. Wires are connected between cubes where necessary. This technique offers more versatility than the dedicated circuit board approach but also requires more space and is subject to more failures generated by human error during or after installation.

The third way to implement dedicated pure logic control involves using a single board controller card that is driven by programmable logic device (PLD). These cards allow the user to program various combinations of logic operations into the PLD. In operation, the inputs to this board generate output responses that are functions of the logic scenario currently resident in the PLD. These cards may or may not come with the appropriate industrial signal input/output interface. However, such interfaces are available and the entire setup, i.e., the PLD card and the interface cards, provides a compact stand-alone pure logic control.

5.11 System Integration: Computers with PLCs

S. VITTURI (2005)

Data Transfer Speeds:	9.6 to 38.4 Kbps via serial point-to-point links 9.6 Kbps to 12 Mbps depending on which fieldbus is used 100 Mbps to 1 Gbps or more if Ethernet LANs are employed
Transmission Distance:	*Serial links* are used to transfer small amounts of data over short (<100 m) distances. *Ethernet*: The maximum coverable distance between two stations connected to a switch is 100 m, but the use of rooters and bridges can extend that limit to several thousand meters. *Fieldbuses* can transmit over several hundred meters.
Costs:	*Serial links*: Port available free of charge on PC. The serial interface board for the PLC ranges from \$200 to \$800. Fieldbuses require one interface board at the PC and another one at the PLC, both with the same protocol and each costing about \$500. *Ethernet* connections also require two interface boards, the widespread board at the PC is about \$20, while the PLC Ethernet board is about \$500.

INTRODUCTION

The integration of DCS systems with various communication networks is discussed in Section 4.9, and the integration of DCS systems with programmable logic controllers (PLCs) or personal computers (PCs) is discussed in Section 4.10. In this section, the integration of PCs and PLCs is discussed, which can be achieved by the use of three types of connections: (1) serial links, (2) Ethernet connections, and (3) fieldbus-type communication networks. The transfer speeds and costs of each of these links been listed above.

The integration will only be successful if suitable communication protocols are adopted. When serial links are used, it is important to correctly match their electrical features; therefore, proprietary communication protocols have to be used. Conversely, communication networks and buses are equipped with their own protocols as defined in the international standards to which they belong.

The data transfer speed required by a PC–PLC connection is not only determined by the number of bits that have to be transferred through that link. The response time of the system is also influenced by factors such as the time required to acquire the data that is to be transmitted and the time required to execute the program in either the PC or the PLC.

The requirement for connecting computers with programmable logic controllers is becoming more and more frequent. In the past such connections could only be made with mainframes, workstations, and personal computers. Currently, due to both the improvement in PC performance and because of their increased use in industrial environments, the majority of PCs and PLCs can be connected. Therefore, in this section, the only computers that will be discussed will be PCs.

A PC can be connected to a PLC for two different purposes: programming and monitoring/supervision.

After a short description of the connection that serves programming, the rest of this section will be devoted to the discussion of the monitoring/supervision connection.

PCs FOR PROGRAMMING THE PLC

In this case, the PC is used to both implement and test the program of the PLC. Each PLC supplier provides software packages to implement and test their programs. In practice, these packages assist the programmers to completely develop their control systems. Thus, in general the software packages should include:

- Compiler/interpreter programs suited for the PLC programming languages
- Tools to transfer program blocks to/from the PLC
- Tools to force or observe the status of the internal variables of the PLC
- Tools to implement the cross-checking of variables throughout the PLC program

PCs FOR MONITORING AND SUPERVISING THE PLC

When the PC is connected to the PLC for purposes of monitoring and supervision, the PLC is usually designed to control the industrial plant or machine while communicating with a PC, which is an integral part of the plantwide automation system. Such a connection usually allows the PLC to handle the operation of process, while the PC is there as an overseer.

Usually, the control tasks (whose execution may be time critical) are completely implemented by the PLC, while the monitoring and supervisory tasks are resident in the PC. In this way there is a clear separation between the tasks, and the PC–PLC connection can be interrupted without any harmful consequences on the plant or machine that is being controlled.

In order to implement the monitoring and supervisory functions, the PC has to be equipped with a suitable software package. However, while the PLC suppliers provided the software for supporting the programming connection, they do not supply this software package. This software can be obtained by the user, either from the customization of a general-purpose Supervisory Control and Data Acquisition (SCADA) system or developed ad hoc for the application.

SCADA System

In a SCADA system, a group of tasks are running on the PC, each of them performing specific functions. The database stores the tag numbers of devices and loops, which are exchanged for the various tasks. Because many of these tags are mapped onto the corresponding PLC variables by one or more of the tasks, the handling of the plants or machines may be implemented by means of read/write actions on the relevant tags.

Figure 5.11a illustrates how the SCADA system notifies a human operator through a PC of an alarm condition that was detected by the PLC. The alarm condition is detected by a sensor, which is located in the field. The field device sends the alarm to the PLC through its input boards. This initiates a suitable alarm handling procedure in the PLC, which results in the transmission of an alarm event, via the PC–PLC connection, to the PC.

Such an event is handled by a PLC task (action) of the SCADA and results in associating the event with the tag number of the alarm, which resides in the SCADA database. Then, the alarm handling task of the SCADA notifies the human operator of the existence of the alarm condition by

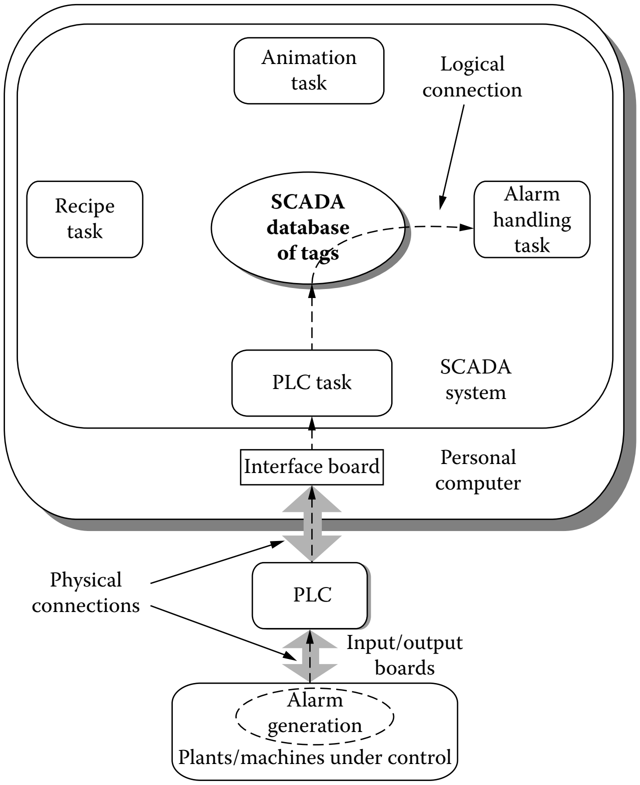

FIG. 5.11a
Example of transmitting an alarm event by SCADA.

sending a suitable text message to the screen of the PC. If necessary, an audible signal can also be initiated.

A software package that is developed to serve only the monitoring and supervision of a PLC is usually simpler than a complete SCADA system and can be implemented using one of the high-level programming languages.

Handling of Tasks

No matter what software implementation is used, the ability to handle some actions (tasks) is indispensable for the monitoring and supervision by the PC. In particular, it is necessary to support the direct data exchange between the PC and the PLC. In Figure 5.11a this data exchange operation is identified as "PLC task."

"Animation task" in Figure 5.11a refers to the capability of performing graphics and dynamic tasks. These provide the human operator with mimic diagrams, which can dynamically represent the status of the plant. The operator can also issue commands from these mimic diagrams to change set points or to make other changes in the control system of the process.

Other tasks that are also available relate to trend recording of process variables, process data logging, and recipe handling.

IMPLEMENTATION

The physical connection between the PC and the PLC can be implemented in one of two ways:

1. Via a serial point-to-point link
2. Using a communication network

Serial Link

Point-to-point serial link connections have been often used in the past, because of their simplicity and low cost. From a hardware point of view, such a connection can be made by using two interface boards and one connecting cable. In this configuration, because the PC is typically provided with at least one serial interface board, it is only necessary to equip the PLC with a corresponding board.

The serial point-to-point links are normally based on the RS-232[1] and RS-422[2] standards. With reference to the International Standards Organization (ISO) model for Open System Interconnection (OSI),[3] these standards are concerned only with the features of the physical layers used by the links; that is, the levels of electrical signals, their timing, and so on.

Consequently, in order to transfer process data over the connection, it is necessary to develop a suitable protocol, which has to be implemented on both the PC and the PLC sides. Since these protocols are often designed by the users, they tend to strictly reflect the particular application and are not flexible or general in their nature. As a consequence, these protocols are completely proprietary and are not recognized by any standard.
